while a far smaller maximum of $F=30\%$ is obtained for the system of pH controlled using ammonia in the same pH region. The difference may be caused by the reduction of the formation of polynuclear cadmium hydroxide due to ammine complex formation in the latter system mentioned above. In order to see the effect of the pH on the flotation rate, the flotation was carried out for a solution containing 1.78×10^{-5} mol/l Cd^{2+} ions, 1.78×10^{-4} mol/l surfactant, and 0.01% bentonite. No difference in the nature of the cationic surfactant on the flotation rate was observed for the surfactants used in the present study. The flotation rate remains zero up to pH 5, above which it increases gradually up to pH 8.5 and rapidly thereafter. The maximum F of 97% was observed above pH 11.3. As a whole, the F *vs.* pH curve of Cd^{2+} shifts towards a pH higher by two units than that for Cu^{2+} ions. The shift may be due to the stronger basic nature of the former. In the case of Cd^{2+} ion flotation by bentonite and cationic surfactants, Cd^{2+} ions, polynuclear cations, and complex anions such as $Cd(OH)_4^{2-}$ combined with the cationic surfactants adsorb on the bentonite particles in this order as the pH of the solution increases, and the bentonite is subsequently coagulated and floated by bubbles. Thus, the flotation may be classified as an adsorbing particle (bubble) flotation. At pH values lower than 8, the flotation rate is largely reduced by the absence of polynuclear Cd^{2+} ions and the suppression of Cd^{2+} ion adsorption of bentonite by H^+ ions.

Effect of Bentonite. To study the effect of bentonite, the F *vs.* bentonite concentration was plotted for DPC, DTAC, and HTAC. Some of the results are shown in Fig. 7 for DTAC. The flotation rates increase and the regions of the flotation range extend up to a certain point with an increase in the amount of bentonite for all the systems studied. For the cationic surfactant with the 1.78×10^{-4} mol/l concentration, the maximum F value of 97% was obtained with the addition of 0.01% bentonite and at pH 11.3, as adjusted by sodium hydroxide. Here, the addition of bentonite also favored the bubble production, without any foam

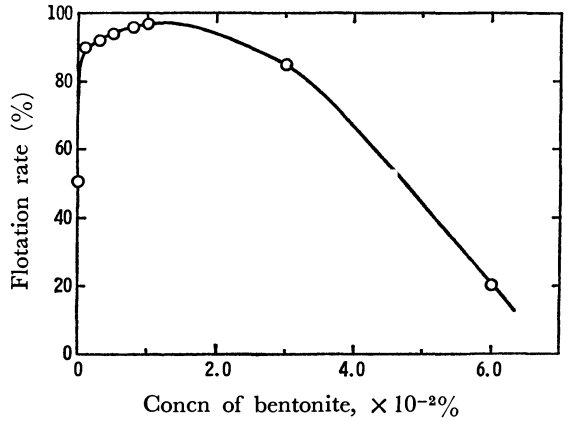

Fig. 8. Flotation rate *vs.* concn of bentonite for Cd^{2+}-bentonite-HTAC system.
Cd^{2+}: 1.78×10^{-5} mol/l, HTAC: 1.78×10^{-4} mol/l, pH adjusted by NaOH.

formation. Thus, bentonite acts not only as a bridge between Cd^{2+} ions and bubbles, but also as an inhibitor of foaming due to the surfactant, thus resulting in effective bubble flotation. The flotation was carried out further for a solution containing 1.78×10^{-4} mol/l Cd^{2+}, 2×10^{-4} mol/l HTAC, and varying amounts of bentonite at a gas-flow time of 7 min and a gas-flow rate of 10 ml/min at pH 11. The results are shown in Fig. 8. It was further confirmed that a stable foam layer was produced for the solution containing less than 0.008% bentonite. As may be seen in the figure, the flotation rate increases sharply and then decreases to zero after showing a distinct maximum. The concentration of bentonite favorable for the bubble flotation of Cd^{2+} ions is found to be 0.008—0.015%. The decrease in the flotation rate above 0.015% bentonite may be explained by the surfactant being insufficient to float the bentonite adsorbing Cd^{2+} ions evenly. About 50% of the Cd^{2+} ions are floated even in the absence of bentonite. This may be due to some Cd^{2+} ions being entrapped in or adsorbed on the cationic foam by nonspecific interaction between the cationic surfactant and polynuclear Cd^{2+} or cadmium

hydroxide.

Effect of the Concentration of the Surfactant. To study the effect of the concentration of the cationic surfactant, a *F vs.* pH_1 curve for varying concentrations of DPC, and DTAC was obtained; it is not shown in the figure, however. The flotation rate decreases from 95 to 73% with a decrease in the DPC concentration from 1.78×10^{-4} to 1.78×10^{-5} mol/l in the case of Cd^{2+} ion flotation by DPC, whereas in the case of Cd^{2+} ion flotation by DTAC the flotation rate did not change with an increase in the concentration of DTAC from 3.56×10^{-5} to 1.78×10^{-4} mol/l above pH 9. Figure 9 shows the *F vs.* surfactant concentration for HTAC at pH 11.3. As may be seen in Fig. 9, the optimum rate of bubble flotation (about 97%) was observed in the region of the HTAC concentration from 8×10^{-5} to 3.56×10^{-4} mol/l. The decrease in the flotation rate for the concentrations of HTAC larger than 3.56×10^{-4} mol/l is caused by both the excessive surfactant repelling Cd^{2+} ions from the surface of bentonite and the bimolecular layer of surfactant adsorption producing hydrophilic bentonite of a poor flotability. The decrease in the flotation rate in the low-surfactant-concentration region may be explained as resulting from the surfactant being insufficient to float the bentonite.

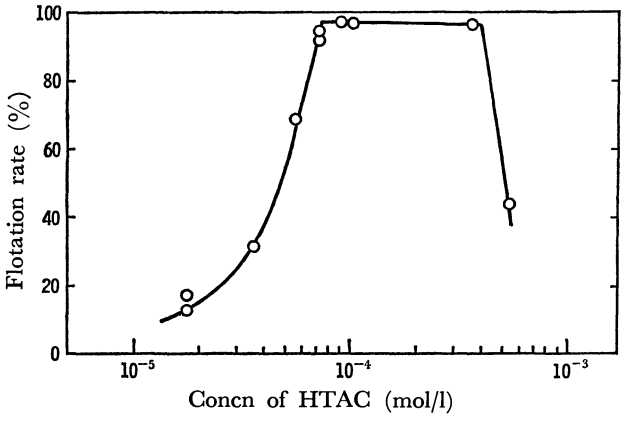

Fig. 9. Flotation rate *vs.* concn of HTAC for Cd^{2+}-bentonite-HTAC system.
Cd^{2+}: 1.78×10^{-5} mol/l, bentonite: 0.01%, pH_1: 11.2, pH adjusted by NaOH.

In conclusion, Cd^{2+} ions could be efficiently floated by using an anionic surfactant or a cationic surfactant with bentonite, and the ion-flotation method can be effectively used under such conditions for the removal of Cd^{2+} ions from sewage and waste water.

The author wishes to thank Professor Tsunetaka Sasaki of the Tokai University for his valuable discussion and suggestions.

Studies of the Removal of Cd^{2+} Ions by Adsorbing Particle Flotation

Koichi KOBAYASHI*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received December 20, 1974)

The conditions for the removal of Cd^{2+} ions from an aqueous solution by adsorbing particle flotation using bentonite and a cationic surfactant has been investigated. It has been found that the most suitable method was to conduct flotation in the region of the coagulation flotation of bentonite. The addition of polyacrylamide (PAA) extended not only the region of coagulation flotation towards lower and higher hexadecyltrimethylammonium chloride (HTAC) concentrations tested, but also increased the flotation efficiency (expressed as the percentage of ions removed from the total solution). The selective flotation from an aqueous solution containing two kinds of metal ions was also investigated. Each metal ion could be floated from the solution with the pH of the metal hydroxide formation. By selecting proper conditions, it was possible to remove each metal ion separately from a mixed solution.

It has been well-known that the suspended particles in an aqueous solution are coagulated and precipitated by the addition of coagulating agents.[1-5] On the other hand, the suspended particles in an aqueous solution can be floated by adhering them on bubbles by the addition of collectors or foaming agents.[6-10] It is also known that the surfactant changes the state of suspension of the particles, from coagulation precipitation through coagulation flotation to redispersion, with an increase in the amount of surfactant added.[11,14]

Since ions in solution are adsorbed on bentonite as an ion-exchanger, the flotation of bentonite is considered to have a close relation to the removal of ions. Such an ion flotation is called "adsorbing particle flotation."[11] Adsorbing particle flotation is perhaps one of the most effective methods for the ion flotation. The method consists of a simple adsorption or exchange adsorption of ions from a solution onto adsorbent particles like bentonite, which are subsequently floated by the addition of a suitable surfactant.[12]

The present paper will describe a study of the phenomena of the coagulation flotation of bentonite suspensions and the adsorbing particle flotation of Cd^{2+} ions and a Cd^{2+}–Cu^{2+} ion mixture by the addition of bentonite. The explanation of the mechanism of such an ion flotation will also be attempted.

Experimental

Materials. The bentonite powder (Bt) used as an ion-exchanger was obtained from the Wako Pure Chemical Co., Ltd.; the fraction passing through a 350-mesh sieve was collected and dried under reduced pressure. The pure-grade hexadecyltrimethylammonium chloride used as a cationic surfactant, obtained from the Kao Soap Co., Ltd., was used without further purification. A stock solution containing 1.78×10^{-4} mol/l cadmium ions (Cd^{2+}) was prepared by dissolving Cd metal of a 99.999% purity, kindly supplied by the Laboratory of General Chemistry of our department, in nitric acid. The pH of the solution was 2.7. The cupric sulfate used was a reagent-grade $CuSO_4\cdot5H_2O$, which had been recrystallized from distilled water, a stock solution of 1×10^{-3} mol/l concentration was prepared. A stock solution containing 9.3×10^{-4} mol/l ferric ions was prepared from reagent-grade ferric chloride dissolved in triply distilled water. The polyacrylamide (PAA) with an amide content of 87% used as a coagulating agent was the product of the Nitto Chemical Co., Ltd.; it was dried under reduced pressure. Special-grade sodium hydroxide and sulfuric acid supplied by the Wako Pure Chemical Co., Ltd., were used to adjust the pH.

The water used was obtained by first refluxing ordinary distilled water with an acid permanganate solution; then it was distilled from an alkaline permanganate solution and finally distilled twice with a Hysil flask.

Apparatus and Procedure. The apparatus and method used for flotation measurements were the same as have been described.[13] Nitrogen gas humidified with water vapor and controlled to a constant rate of gas flow was bubbled through a glass filter (No. 4) into a flotation cell containing 10 ml of the sample solution. The gas-flow rate and time were kept at 10 ml/min and 7 min respectively. For the measurement of the effect of HTAC on the state of Bt suspension, a 10-ml portion of a suspension containing varying amounts of Bt and HTAC was introduced into a ground test tube 1.0 cm in inner diameter and 20.0 cm in length. The tube was then shaken, and the coagulation-dispersion and precipitation-flotation behavior was judged by the naked eye.[14] The centrifugation was applied when necessary for 20 min at 3500 rpm. The concentrations of Cu^{2+} ions, Fe^{3+} ions, and Cd^{2+} ions were measured by using an atomic absorption spectrometer (Techtron Pty., Ltd., Model-AA-100). The absorbance was measured at 3248 Å for Cu^{2+} ions, 2483 Å for Fe^{3+} ions, and 2288 Å for Cd^{2+} ions. The measurements were carried out at room temperature (about 25 °C).

The flotation efficiency of Cd^{2+}, Fe^{3+}, and Cu^{2+} ions is conventionally expressed by:

$$F = (1-C_f/C_i)\times100\ \%$$

where C_i and C_f are the concentrations of ions before and after the flotation.

All the experiments were run under the conditions of bubble flotation, that is, flotation using only ascending bubbles, without the aid of foam formation. Since most of the solution after flotation was used for the measurement of C_f, the flotation efficiencies calculated substantially express the percentages of these ions removed from the total solution.

Results and Discussion

Change in the Dispersion State of Bentonite upon the Addition of HTAC. Figure 1 shows the various regions of the state of bentonite after shaking as a function of the bentonite and HTAC concentrations. As may be seen, the bentonite in an aqueous HTAC solution shows the regions of dispersion, coagulation flotation, coagulation precipitation, and redispersion, as has been reported

* Present address: Department of Chemistry, Musashi Institute of Technology, 1-28-1 Tamatsutsumi, Setagaya, Tokyo 158.

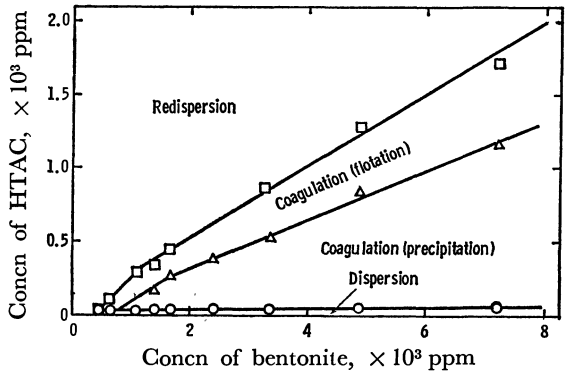

Fig. 1. Effect of HTAC on dispersion state of bentonite suspension.

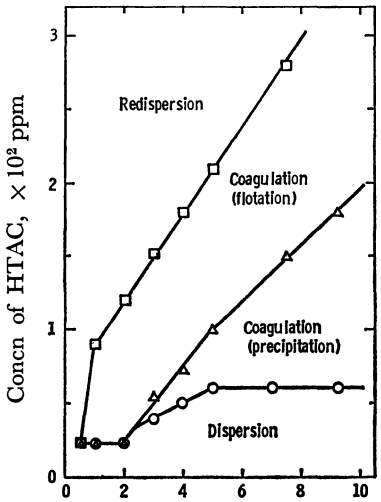

Fig. 2. Effect of HTAC on dispersion state of bentonite suspension at low concentration region.

previously.[14] In the regions of dispersion, coagulation flotation, and coagulation precipitation of Fig. 1, the layer scarecely forms on a solution, but in the region of redispersion, the stable foam layer forms with an increase in the HTAC concentration. Further, the regions of dispersion and coagulation precipitation give an opaque solution, while the region of coagulation flotation is transparent as a whole. Thus, the region of coagulation flotation seems to offer optimum conditions for bubble flotation. Also, it is noticeable that the change from coagulation precipitation to coagulation flotation is sensitive to a slight change in the HTAC concentration. Figure 2 shows the coagulation flotation region for low concentrations of Bt and HTAC especially measured in detail, which is useful for the adsorbing particle flotation.

A similar experiments was done with the addition of 10 ppm PAA as a coagulating agent. The results are shown in Fig. 3. As can be seen, the region of coagulation flotation in the Bt–HTAC–PAA system is broader with respect to the HTAC concentration and shifts towards lower concentrations with respect to the Bt concentration, compared with the Bt–HTAC system shown in Fig. 2. Therefore, the former system is more favorable for adsorbing-particle flotation than the latter.

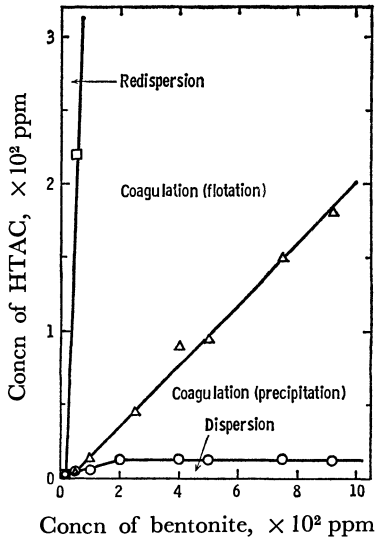

Fig. 3. Effect of HTAC on dispersion state of bentonite suspension in the presence of 10 ppm PAA.

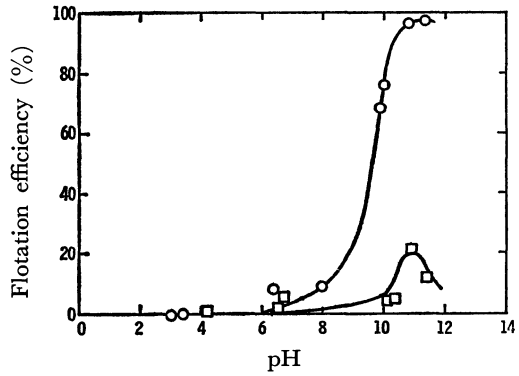

Fig. 4. Flotation rate *vs.* pH for the Cd^{2+}-Bt-HTAC system.
Cd^{2+}: 1.78×10^{-5} mol/l, HTAC: 56.8 ppm, Bt: 600 ppm (□), 100 ppm (○).

Flotation of Cd^{2+} Ions by HTAC. The adsorbing-particle flotation of Cd^{2+} was carried out under the conditions of coagulation flotation described above. The flotation was carried out for a solution containing 1.78×10^{-5} mol/l Cd^{2+}, 56.8 ppm HTAC, and 100 ppm Bt (belonging to the coagulation-flotation region) or 600 ppm bentonite (belonging to the dispersion region) under a gas flow of 7 min and a gas-flow rate of 10 ml/min. The results are shown in Fig. 4. In the case of Cd^{2+} ion flotation by 100 ppm bentonite, the flotation efficiency begins to increase at about pH 8 and a maximum F of 98% is obtained at about pH 11.3, but in the case of Cd^{2+} ion flotation by 600 ppm bentonite, the flotation efficiency is extremely low, showing a maximum of about 20% of F. In the former case, the Cd^{2+} ions are considered to float by HTAC through the bridge of bentonite, while in the latter case, the decrease in flotation efficiency may be due to the surfactants being insufficient to float the bentonite, though Cd^{2+} ions are adsorbed on the particles.

Figure 5 shows the flotation efficiency *vs.* surfactant concentration curve at an optimum pH of 11.2. The optimum efficiency of flotation was observed in the

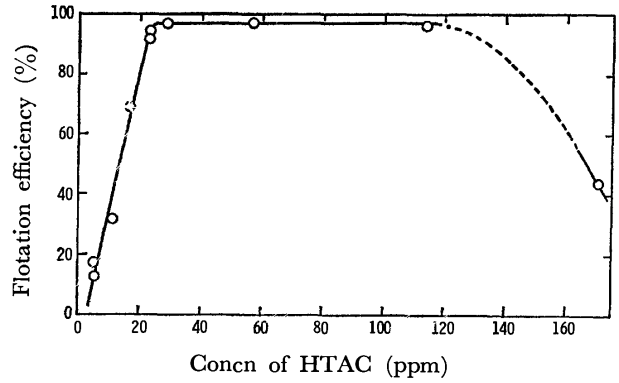

Fig. 5. Flotation rate *vs.* concentration of HTAC for the Cd^{2+}-Bt-HTAC system.
Cd^{2+}: 1.78×10^{-5} mol/l, Bt: 100 ppm, pH: 11.2.

region of HTAC concentrations from about 25 to 110 ppm. It can be seen from Fig. 2 that these ranges of the HTAC concentration coincide with those of coagulation flotation. Thus, the optimum conditions for adsorbing-particle flotation are confirmed to be the region of the optimum coagulation flotation.

Flotation of Cd^{2+} Ions by HTAC and PAA. In order to study the effect of PAA, the flotation was carried out for solutions containing 1.78×10^{-5} mol/l Cd^{2+}, 100 ppm Bt, 56.8 ppm HTAC, and 10 ppm PAA under the condition of a gas-flow time of 7 min. The results are shown in Fig. 6. A comparison of Fig. 6 with Fig. 4 shows no effect of PAA addition at the optimum Cd^{2+}-Bt-HTAC composition. Then the flotation was carried out with varying concentrations of HTAC, the other conditions being kept constant at the values mentioned above. The results are shown in Fig. 7. As may be seen, the flotation efficiency remains constant down to a lower HTAC concentration than that for the system without PAA shown in Fig. 5. Above 110 ppm HTAC, the flotation efficiency sharply decreases in the case of the system without PAA, while in the case of the system with PAA, the flotation efficiency gradually decreases with an increase in the HTAC concentration above 110 ppm. Thus, the addition of PAA increases the optimum region of Cd^{2+} ion flotation towards both the lower and higher

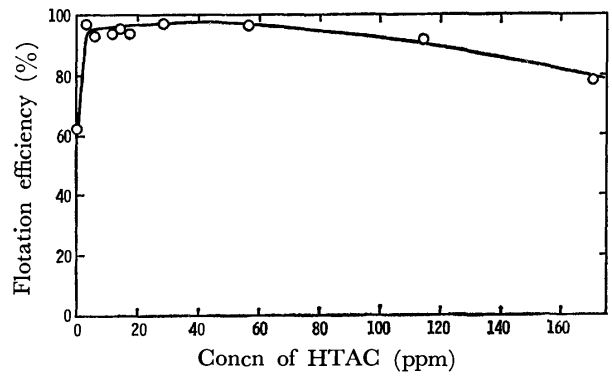

Fig. 7. Flotation rate *vs.* concentration of HTAC for the Cd^{2+}-Bt-HTAC-PAA system.
Cd^{2+}: 1.78×10^{-5} mol/l, Bt: 100 ppm, PAA: 10 ppm, pH: 11.2.

concentrations of HTAC. This increase in the region just corresponds to the increase in the region of coagulation flotation of Fig. 3 compared with that of Fig. 2. The reduction of minimum amount of 26 ppm HTAC required for the optimum flotation in the Bt-HTAC system to 3 ppm by the addition of 10 ppm PAA is particularly noticeable.

Removal of Cd^{2+} Ions by Centrifugation. To study the effects of the pH and additives on the adsorption of Cd^{2+} ions, a Bt suspension containing Cd^{2+} ions in the state of equilibrium adsorption was centrifuged and the concentration of Cd^{2+} was determined. The amount of Cd^{2+} adsorbed on Bt or the amount centrifuged was expressed by $R=(1-C_f/C_i)\times100$, which is plotted against the pH in Fig. 8. The centrifugation of Cd^{2+} ions was performed for 20 min at 3500 rpm for the Cd^{2+}-Bt-HTAC-PAA (A), Cd^{2+}-Bt-HTAC (B) and Cd^{2+}-Bt (C) systems with the compositions shown in Fig. 8. In the cases of A and B, the efficiency of the centrifugation of Cd^{2+} ions begins to increase rapidly at about pH 8 and a maximum of $R=98\%$ was obtained. In the case of C, the value of R stays rather high in the low pH region and begins to increase at pH 8, but the maximum is only 79%, attained at pH 11.3.

These facts confirm that, at an optimum pH of 11.3, the adsorption of Cd^{2+} is complete in A, B, and C, but

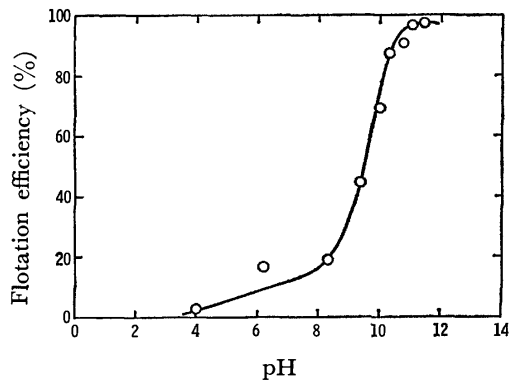

Fig. 6. Flotation rate *vs.* pH for the Cd^{2+}-Bt-HTAC-PAA system.
Cd^{2+}: 1.78×10^{-5} mol/l, Bt: 100 ppm, HTAC: 56.8 ppm, PAA: 10 ppm.

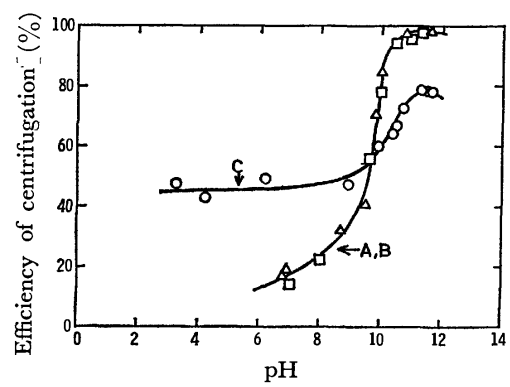

Fig. 8. Effect of pH on rate of Cd^{2+} adsorption on Bt.
Cd^{2+}: 1.78×10^{-5} mol/l, A: 100 ppm Bt, 56.8 ppm HTAC, 10 ppm PAA, B: 100 ppm Bt, 56.8 ppm HTAC, C: 100 ppm Bt.

the aggregates do not grow sufficiently large in the case of C to be centrifuged completely during 20 min, as is the case in A and B, while the removal of rather large amounts of Cd^{2+} in the pH region for C is due to a certain amount of Bt being centrifuged, upon which some Cd^{2+} ions are adsorbed, not hindered by the adsorption of HTAC which may occur in the cases of A and B. At any rate, it is confirmed that, in the cases of A and B, Cd^{2+} ion flotation is realized by the ions being adsorbed on Bt particles, which are subsequently coagulated and floated by bubbles.

Selective Ion Flotation from a Mixed System. The flotation of Cd^{2+} and Cu^{2+} ions from a solution containing 1.78×10^{-5} mol/l Cd^{2+} ions, 1×10^{-4} mol/l Cu^{2+} ions, 100 ppm Bt, and 56.8 ppm HTAC under the condition of a gas-flow rate of 10 ml/min was carried out while varying the pH. The results are shown in Fig. 9. In the mixed system, Cd^{2+} and Cu^{2+} ions are floated above pH 6 and 8 respectively, much as in the flotation of the separate system.[13] Thus, even in the mixed system the flotation begins from the point of the formation of insoluble cadmium and copper hydroxide. According to this finding, Cu^{2+} ions are exclusively floated between pH 6 and 8 and it is possible to separate Cu^{2+} ions from the mixed system by the control of the pH. From the color of the scum, it is clear that copper hydroxide has formed.

Figure 10 shows the results of the flotation of Cd^{2+}

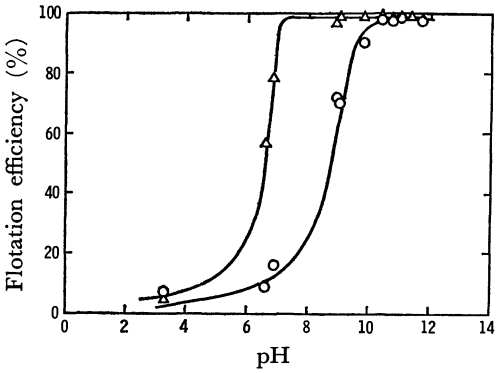

Fig. 9. Selective flotation of Cd^{2+} and Cu^{2+} ions.

Bt: 100 ppm, HTAC: 56.8 ppm.

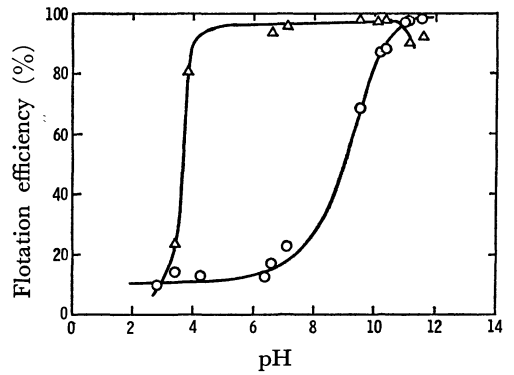

Fig. 10. Selective flotation of Cd^{2+} and Fe^{3+} ions.
Cd^{2+}: 1.78×10^{-5} mol/l (○), Fe^{3+}: 4.65×10^{-5} mol/l (△), Bt: 100 ppm, HTAC: 56.8 ppm.

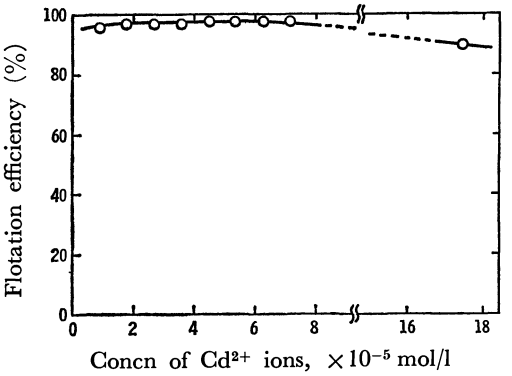

Fig. 11. Flotation rate *vs.* concentration of Cd^{2+} ions for the Cd^{2+}-Bt-HTAC system.
Bt: 100 ppm, HTAC: 56.8 ppm, pH: 11.4.

and Fe^{3+} ions from a solution containing 1.78×10^{-5} mol/l Cd^{2+} ions, 4.65×10^{-5} mol/l Fe^{3+} ions, 100 ppm Bt, and 56.8 ppm HTAC. Beyond pH 10, the complete flotation of both Cd^{2+} and Cu^{2+} is possible, showing about a 98% of flotation efficiency for both ions. In this system, as in the Cd^{2+} and Cu^{2+} systems, Fe^{3+} and Cd^{2+} ions are floated from the respective pH of the insoluble hydroxide formation, and selective flotation is possible by the method of a starvation dose, [15] although about 10% of the Cd^{2+} ions are floated even in the pH region of less than 8, which is not the case for the system containing Cd^{2+} ions alone, as is shown in Fig. 4. This may be due to some Cd^{2+} ions being adsorbed together with Fe^{3+} ions on the Bt particles. The phenomenon is preferably called coadsorption. In the case of limited amounts of cationic surfactant and Bt, it may be expected that, as the flotation of Cd^{2+} ions begins to occur above pH 8, the flotation efficiency of Fe^{3+} ions will gradually decrease with an increase in the pH above pH 10.7.

Effect of the Cd^{2+} Ion Concentration on the Flotation Efficiency. Under the optimum conditions of 100 ppm Bt, 56.8 ppm HTAC, and pH 11.5, the effect of the concentration of Cd^{2+} ions on the flotation efficiency was studied. The results are shown in Fig. 11. As may be seen, in the Cd^{2+} concentration region from about 1×10^{-5} to 7×10^{-5} mol/l, the optimum flotation efficiency of $F=98\%$ was obtained. In the more concentrated solution of 1.78×10^{-4} mol/l, the flotation efficiency decreases to about $F=90\%$. The optimum concentration of the order of magnitude of 10^{-5} mol/l is in agreement with the conditions under which ion flotation is usually carried out.

The author wishes to thank Professor Tsunetaka Sasaki of the Tokai University for his valuable discussion and suggestions.

Effects of the Tension and Viscosity on the Rate of Growth of Black Soap Films

Teruko YAMANAKA

Laboratory of Chemistry, Faculty of Education, Chiba University, Yayoi-cho, Chiba 280

(Received September 19, 1974)

The additional tension and the rate of growth of black films formed from aqueous solutions of polyoxyethylated nonionic surfactants and sodium dodecylsulfate, which contain inorganic electrolytes in high concentrations, were measured for the large vertical films drawn from these solutions. It was found that the rate of growth of black films was proportional to the additional tension in both systems. The reciprocal of the slope of each line was concluded to be a viscosity parameter, since the additional tension acted as the driving force for the growth of black films, and the viscosity parameter, as the resistance. The effect of added glycerol on the rate of growth of black films was compared with that of electrolytes for the films of nonionic surfactants. The former affected both the viscosity parameter and the additional tension, while the latter showed an effect on only the additional tension.

The thinning of mobile films is considered to be caused mainly by gravity and capillary suction at the border when the films are thick. As the films become thinner, they exhibit a third type of thinning behavior, namely, the spontaneous appearance and growth of a thin black film from a much thicker silver film.[1] It is generally accepted that this thinning is due to van der Waals attraction acting between the molecules in the film.[2] In such a state, additional intermolecular forces come into action and give rise to a disjoining pressure, which results in additional film tension and a macroscopic contact angle between the thin film and the bulk liquid in contact with it.[3–5]

A previous paper has dealt with the thinning of large vertical films stabilized with nonionic surfactants.[6] The addition of the inorganic electrolytes did not show any appreciable effects on the rate of movement of the position of a definite thickness in the region of interference fringes, but the specific effects of anions did appear on the blackening time, namely, the time necessary for converting the total film area completely to the black film; these effects were explained in terms of lyotropy. Such a growth of black films plays an important role in the thinning of some soap films and is, therefore, of interest in connection with foam stability, for instance.[7,8]

In this paper, studies of the additional tension and the rate of growth of black films will be reported for large vertical films drawn from aqueous solutions of anionic and of nonionic surfactants containing varying amounts of inorganic electrolytes and glycerol.

Experimental

Materials. Heptaoxyethylene dodecyl ether (N7) of the Nikko Chemicals Co., Ltd., was used. Gas chromatography proved it to be homologously pure. The polyoxyethylene nonylphenyl ether (PNE) was obtained from commercially available PNE by molecular distillation. The average number of ethylene oxide groups was 11.4 per molecule.[6] The sodium dodecylsulfate (SDS) was synthesized by the usual method and was purified by recrystallization before use. Inorganic electrolytes commercially obtained were degreased with ether in a Soxhlet extractor. The sodium sulfate used for the viscosity measurements was also purified by recrystallization from water. Pure-grade glycerol was used without further purification. The surface tension of the 39.2 wt% aqueous glycerol solution was 69.1 dyn/cm; this value did not change with time. The water used was first distilled from an alkaline potassium permanganate solution and then distilled using a fused quartz vessel. All the solutions used were freshly prepared before use.

Measurement of the Rate of Growth of Black Films. The rate of growth of black films was measured for vertical large films supported on a rectangular glass frame. The apparatus was similar to that previously reported,[6] except for the following points. The frame used was made of a glass rod about 0.6 mm in diameter and 1 cm in width. It was supported vertically from the top of the vessel through a water seal and was withdrawn in 5 s from the surfactant solution by a motor operation so that the top of the film rose 3 cm above the solution surface. All the experiments were carried out by using film of the same size except for the study of the effects of film size on the rate of growth. The cell was submerged in a thermostated water bath of 30±0.1 °C, and the whole apparatus was set in a chamber of 30±0.5 °C for about 17 hr before measurement.

The border between the black and the thicker films was photographed to plot the displacement of it against the time, from which the rate was determined. The rate gradually changed in the case of a relatively long blackening time. In such cases, the constant rate appearing in the later stage (shown in Fig. 2) was taken in PNE systems, and the overall rate, in SDS systems.

Measurement of the Additional Tension of Black Films. The additional tension, $\overline{\Delta}$, is defined by:

$$\overline{\Delta} = 2\gamma - \sigma_f \qquad (1)$$

where σ_f is the film tension, and γ, the surface tension of a solution.[9] It was measured by the microbalance technique[10,11] based on the Wilhelmy plate method. A rectangular vertical glass frame 4 cm in width was made of a glass rod about 0.4 mm in diameter. A thinner glass wire about 0.15 mm in diameter was attached horizontally across the frame at a position 1 cm below the top of frame; the wire limited the upper edge of the film formed on the frame. The frame was suspended from one arm of a recording microbalance (Cahn RG Electrobalance). The cell containing the solution and the frame were put in a glass jacket with double walls between which thermostated water was circulated to keep the temperature at 30±0.1 °C. All the apparatus was then placed in an air-thermostated chamber kept at 30± 0.5 °C.

To measure $\overline{\Delta}$, the frame was manually withdrawn from the solution up to a fixed height of 1 or 2 cm. When the

black/thicker film boundary reached the bulk liquid surface, a sudden decrease in the force exerted on the frame corresponding to the difference in tension between the black and the thicker films was recorded on a chart. The decrease divided by the width of the frame gives $\bar{A}$.

The viscosity of the solutions was measured by an Ostwald viscometer at 30±0.1 °C.

Results and Discussion

The rate of growth of black films was measured for the films formed from 0.1 wt% aqueous PNE solutions containing varying amounts of Na_2SO_4, NaF, NaCl, and NaSCN. The same measurement was made for the films formed from 0.05 wt% (1.7×10^{-3} M) aqueous SDS solutions containing varying amounts of NaCl.

Figure 1 shows the effect of the concentration of Na_2SO_4 on the growth of the black films formed from 0.1 wt% PNE solutions. The vertical length of black film is plotted against the elapsed time. The plots in Fig. 1 give the straight lines except for the final stage of the boundary approaching the bulk liquid surface. The black film formed from a 0.1 wt% aqueous PNE solution containing 0.8 N NaF gave a similar linearity and a relatively short blackening time, as in the case of Na_2SO_4. The dependence of the total height and width of the films on the growth of black films of a short blackening time drawn from aqueous solutions of 0.1 wt% PNE containing 0.7 N Na_2SO_4 was studied by using films 1.5 and 3.0 cm in height and ranging from 1 to 4 cm in width. The effects of the size were found to be negligible.

Figure 2 shows the time dependence of the vertical length of the black film formed from a 0.1 wt% aqueous PNE solution containing 0.8 N NaCl. Plots a and b show the results for the films withdrawn 3.0 cm and 1.5 cm respectively above the liquid surface. As may be seen in Fig. 2, the b plot is linear, whereas the a plot exhibits a curve with a linear portion in the later stage which is nearly parallel to the b plot.[12] It is evident that the difference between the a and b plots is mainly due to the longer blackening time or the larger total height in the former film than in the latter. In the films 3 cm in total height, the black films formed from 0.1 wt% aqueous PNE solutions containing 0.5 N NaF, 0.5 N NaCl, 0.8 N NaCl, and 0.5 N NaSCN gave plots of the type of the a plot in Fig. 2. In the case of these films with a long blackening time, both the rate of film growth of the linear portion and the overall rate decreased to about four-tenths when the width of the film was changed from 1 to 4 cm, while the height was held constant at 3 cm.

Figure 3 shows the effect of the concentration of NaCl on the growth of the black films formed from 0.05 wt% SDS solutions. For the film formed from the solution containing 0.3 N NaCl, a transition from the first to the second black film was visually observed by the reflected light. A nucleation of the second black film appeared in the first black film already formed, and the former film grew rapidly at the ex-

pense of the latter and any remaining thicker films. The second black film was easily distinguished from the first one because the former was darker than the latter and a sharp boundary could be observed between the two films.[13] From another study[14] it may be deduced that the first black film is exclusively formed at concentrations lower than 0.3 N, whereas above 0.3 N the second black film is exclusively formed. As is shown in Fig. 3, the second black film of SDS grows at a constant rate and faster than the first black film, which shows a gradual decrease in the rate of growth.

The values of $\overline{\Delta}$ were measured for the black films formed from the same solutions as those used for the measurements of the growth rate of black films. First, to check the reliability of the measurement, the contact angle, θ, between the black film and the bulk liquid was calculated for a 0.05 wt% aqueous SDS solution containing 0.5 N NaCl. For the calculation, the following relation was used:[5,9]

$$\overline{\Delta} = 2\gamma(1-\cos\theta) \qquad (2)$$

using the additional tension, $\overline{\Delta}$, and the surface tension, γ, separately obtained. The calculated value of 9°25′ (30.0 °C) is considered to be reasonable in comparison with the reported values of 9°54′ (28.5 °C),[11] 10°52′ (25.0 °C),[10] and 11°28′ (24.3 °C),[15] considering the temperatures.

Figures 4 and 5 show the plots of the rate of growth of black films, dl/dt, against $\overline{\Delta}$ for the black films formed from aqueous PNE and SDS solutions containing varying amounts of electrolytes. The values of $\overline{\Delta}$ and dl/dt depend strongly on the kind of surfactant, on the added electrolytes, and on the kind or the thickness of the black films. However, dl/dt is proportional to $\overline{\Delta}$, regardless of the kind and the amount

of added electrolytes as well as the kind of surfactants. The reciprocals of the slope of the lines in these figures, $\overline{\Delta}/(dl/dt)$, considered as a viscosity parameter, are about 8.6 and 8.3 g/(cm·s) for PNE and SDS films respectively.

Figure 6 shows the effects of the change in bulk viscosity upon the addition of glycerol on the relationship between dl/dt and the $\overline{\Delta}$ of the black films, which is formed from aqueous solutions of 5×10^{-4} M (2.5×10^{-2} wt%) N7 containing varying amounts of Na_2SO_4. The solid lines indicate the systems containing varying amounts of Na_2SO_4 while keeping the amounts of N7 and glycerol constant, and the broken lines indicate the systems in which the amounts

of glycerol are varied while N7 and Na_2SO_4 are kept constant.

The values of the bulk viscosity of 5×10^{-4} M aqueous N7 solutions containing 0.8 N Na_2SO_4 and glycerol of different concentrations, that is, 0, 10, and 15 wt%, were 0.89, 1.13, and 1.29 centipoise respectively; also, the bulk viscosity of a 5×10^{-4} M N7 solution containing 0.7 N Na_2SO_4 and 30 wt% glycerol was 1.98 centipoise. On the other hand, the bulk viscosity increased only slightly with the concentration of Na_2SO_4; that is, the bulk viscosity of the aqueous N7 solutions varying from 0.5 N to 0.8 N Na_2SO_4 increased from 0.86 to 0.89 centipoise. All the films formed from these solutions were found to be simple mobile films.[16] The reciprocals of the slope of the straight lines, $\overline{\Delta}/(dl/dt)$, shown in Fig. 6 are 8.7, 11.6, 12.4, and 21.9 g/(cm·s) for solutions of 0, 10, 15, and 30 wt% glycerol respectively. It was also found, when $\overline{\Delta}/(dl/dt)$ was plotted against the bulk viscosity from the results in Fig. 6, that $\overline{\Delta}/(dl/dt)$ was proportional to the bulk viscosity of the solution used.

As is shown in Figs. 1—3, the growth rate of the black film becomes nearly constant after arriving at the stationary state. Since the values of dl/dt in Figs. 4—6 are those in the stationary state, and since a proportionality is observed between $\overline{\Delta}$ and dl/dt, the following relation is obtained by using a proportionality constant, a_f:

$$\overline{\Delta} = a_f(dl/dt) \tag{3}$$

In this equation, it may be inferred that a_f gives a friction coefficient and that $\overline{\Delta}$ is a dominant factor in the driving force in the growing process of the black film, considering that the friction force is equal to the external force.

As Scheludko indicated,[9] $\overline{\Delta}$ is related to the disjoining pressure, π, in the expression:

$$\overline{\Delta} = -\int_h^\infty \pi dh - \pi h \tag{4}$$

where h is the film thickness. Furthermore, at a sufficiently high concentration of added electrolytes, the diffuse electrical double layer is highly compressed and $\overline{\Delta}$ is almost entirely determined by the van der Waals component of the disjoining pressure, expressed by:

$$\overline{\Delta} \approx -\int_{h_e}^\infty \pi_{vw} dh \tag{5}$$

where π_{vw} is the van der Waals component of the disjoining pressure, and h_e, the equilibrium thickness of the film. Kolarov *et al.* observed the same relationship as in this report between the growth rate of black film in the initial stage and $\overline{\Delta}$ for the micro-horizontal circular films; that is, $(dr/dt)_{t_0}=a_{t_0}\overline{\Delta}$, where r represents the radius of the black film.[17]

Here, as a_f is considered to be the friction coefficient for the growing process of black film, various kinds of factors affecting the rate of drainage, such as the bulk viscosity and the surface dilational or shear viscosity, must be included in this coefficient. However, since a_f is proportional to the bulk viscosity of the solution, as has been described above, it may be inferred that the growth rate of the black film is predominantly determined by a flow controlled by the bulk viscosity, and that the contribution of the other factors to the growth rate is negligibly small.

From this point of view, if the black film grows at an invariable thickness, its growth will be determined by the outflow of the excess liquid in the silver film. In most cases in this experiment, however, dl/dt is nearly constant, regardless of the length of the thicker film between the black/thicker film boundary and the solution surface. Therefore, if $\overline{\Delta}$ is invariable, a_f must be constant, irrespective of the length of the thicker film. It thus seems reasonable to assume that the flow of bulk solution in the whole thicker film does not determine the growth rate of the black film, but that only a certain local flow in the thicker film dominates this. It is considered that the flow of liquid between surface layers in the vicinity of the black/thicker film boundary has a high resistance to the film growth. In addition to this, the contribution of dilational surface viscosity must also be considered to some extent, but it must be small, because the relationship between a_f and the bulk viscosity of solution passes near the point of origin. In this context, it is concluded that the flow resistance resulting from the bulk viscosity in the thin film regulates the growth rate of the black film, though the precise mechanism of the growth of black films based on hydrodynamics has not yet been made clear because of its complexity.

As may be seen in Figs. 4 and 5, the effects of added electrolytes on the rate of growth of black films are mainly due to the increase in the additional tension operating as a driving force, and the magnitude of the increase of this tension depends on the nature and amounts of electrolytes, whereas glycerol is found to show the two effects shown in Fig. 6. Glycerol, as far as has been observed in the presence of the electrolytes, decreases the additional tension, as seen in the broken lines in this figure, and simultaneously reduces the slope of the straight lines. For the former, further study is still awaited.

The author wishes to express her hearty thanks to Professor Tsunetaka Sasaki of Tokyo Metropolitan University for his encouragement and guidance throughout the experiments.

Effects of Electrolytes on Properties on Black Films and Foam Stability of Aqueous Nonionic Surfactant Solutions

Teruko YAMANAKA

Laboratory of Chemistry, Faculty of Education, Chiba University, Yayoi-cho, Chiba 280

(Received December 27, 1974)

The properties of black film, the surface tension of solution and the foam stability in the aqueous solutions of polyoxyethylene-type nonionic surfactants containing various electrolytes were studied. The additional tension $\overline{\Delta}$ of black films showed a maximum and a minimum in the concentration range of electrolytes of 1×10^{-5}—1 N. The concentration at this minimum shifted in accordance with the lyotropic series of anions. The surface tension was unaffected by the electrolyte of the concentration less than about 1×10^{-2} N, whereas $\overline{\Delta}$ exhibited a maximum in this range. The overall rate of growth of the black film was found to be proportional to $\overline{\Delta}$ over a wide range of electrolyte concentration. The effects of electrolytes on the foam stability were discussed being based upon the properties of the black films.

Single liquid film is easily formed on a frame and provides a geometrically well-defined model system for investigating the stability of foams consisting of thin liquid films. Most studies of such films have been made for ionic surfactants, while studies using nonionic surfactants have been rather few.[1,2] The films stabilized with nonionic surfactants are of particular interest in discussing the repulsive forces acting between two surfaces of the thin films consisting of non-ionic molecules.

In the previous papers, [3,4] the dependence of the rate of growth of black films formed from aqueous nonionic surfactant solutions on the added electrolytes was reported, and the phenomena were interpreted in terms of the lyotropic effect of anions. Further, a proportionality was observed between the rate of growth of the black film and the additional tension, regardless of the electrolytes used.

In the present paper, the effects of added electrolytes on the properties of black films, on the surface tension of the solutions, and on the foam stability are studied for the aqueous solutions of the polyoxyethylene-type nonionic surfactants. The effects of electrolytes on the foam stability are discussed on the basis of the properties of the black films.

Experimental

Materials. Heptaoxyethylene dodecyl ether (N7) of Nikko Chemicals Co., Ltd. was used without purification, while polyoxyethylene nonylphenyl ether (PNE) of Kao Soap Co., Ltd. was used after being purified by molecular distillation.[3,4] Inorganic reagents were recrystallized twice from water, and it was confirmed that they showed no time dependence in the surface tension of 1 M aqueous solutions. Water was first distilled from alkaline potassium permanganate solution and then distilled using fused quartz vessel. All the solutions were freshly prepared before the experiment.

Properties of Thin Liquid Films and Surface of Solutions. The additional tension, $\overline{\Delta}$, is defined by the formula:

$$\overline{\Delta} = 2\gamma - \sigma_f = 2\gamma(1-\cos\theta) \qquad (1)$$

where σ_f is the film tension, γ the surface tension of the bulk solution, and θ the contact angle formed by the black film and the bulk liquid surface.[5] The method used for $\overline{\Delta}$ measurements consists essentially of the Wilhelmy plate method, and the liquid film was formed on a rectangular vertical glass frame 4 cm in width. The difference in tension between the black and the thicker films was measured by using a electro-microbalance, details of which were described in the previous papers.[4,6] The surface tension was measured by the Wilhelmy plate method using the electro-microbalance. The contact angle was calculated from the experimental results of $\overline{\Delta}$ and γ according to Eq. (1). The overall rate, v, of growth of the black film was obtained as the reciprocal of blackening time recorded on the chart of $\overline{\Delta}$ measurement. Here the blackening time was taken as the time required for converting total film area into the black film. All the measurements were performed at 30±0.1 °C.

Foam Stability. In a cylinder of 2 cm in diameter, a foam column 30 cm in height was produced by passing nitrogen gas saturated with water vapor through the solution from a single orifice under a constant pressure. After the gas flow was cut off, the height, H, of the foam column was measured as a function of time for about an hour.

Results and Discussion

The additional tension, $\overline{\Delta}$, is of importance for the studies of thin films, since it expresses the difference of free energies, ΔF_e, between the black film and the bulk liquid, and is associated with a disjoining pressure, π, by the formula:

$$\overline{\Delta} = -\int_h^\infty \pi dh - \pi h \qquad (2)$$

where h is the film thickness.[5] Figure 1 shows $\overline{\Delta}$ of the N7 stabilized films over a wide range of concentration of the added electrolytes. It is seen that each curve gives a maximum and a minimum in $\overline{\Delta}$. The concentrations at the minimum are found to be about 2×10^{-1}, 1×10^{-1}, 5×10^{-2}, and 1×10^{-2} N for Na_2SO_4, NaCl, NaBr, and NaSCN respectively.

Recently, Clunie *et al.* and Ingram measured the thickness and the additional tension of the black films formed from aqueous solutions of nonionic surfactant *n*-decyl methyl sulfoxide (DMS) as a function of the concentration of NaCl and NaBr.[7,8] They reported that the thickness of the films formed in the lower concentrations of electrolytes was not changed, but when increased the concentration it abruptly increased, where the films were transformed from the second

black film to the first one. They also reported that the curve of the additional tension *vs.* electrolyte concentration showed a minimum at this transition concentration. Although the thickness of the films was not measured in the present experiment, the respective minima appeared in the curves of Fig. 1 are considered to reveal the same kind of transition in the films, because of the similarity in the shape of the curves to that of DMS, despite the difference in hydrophilic groups between both systems.

The transition from the second to the first black films with increasing concentration of electrolytes was interpreted to be due to the formation of diffuse electrical double layer resulting from a specific adsorption of the respective anions at the film surfaces.[7,8] This effect is more marked for weakly hydrated ions than strongly hydrated ones. The concentrations at the minimum in the curves of Fig. 1 increase in the order of

$$NaSCN < NaBr < NaCl < 1/2Na_2SO_4.$$

Thus, the present results obtained with various anions having different adsorption tendency are in agreement with those reported[7,8] and the anions also follow the lyotropic series.

As seen in Fig. 1, the additional tensions of first black films formed from N7–Na_2SO_4 solutions remarkably increase with increasing concentration of Na_2SO_4, whereas in the other electrolytes they are all smaller than the former even at 1 M solutions. In the concentration range above the minima, that is, in the first black films, the order of $\bar{\Delta}$ for different electrolytes still obeys the lyotropic series though not so distinct. This fact is further stressed in the systems including F^- as seen in Fig. 2. It was reported that the variation of additional tension of the first black films with electrolyte concentration was in excellent agreement with the predictions of DLVO theory of colloid stability.[8] The contribution of electrical double layer to the additional tension must become much smaller than that of dispersion force, as the concentration of electrolytes increases. This effect together with the dehydration effect of electrolytes causes the formation of the thinner first black film, which leads to the significant increase of the additional tension of N7 and PNE films at high concentrations of Na_2SO_4.

It is interesting to compare the effects of electrolytes upon $\bar{\Delta}$ of the black film with those upon the surface tension of the solution. The effects of electrolytes upon the surface tension were studied for the same series of solutions used for the measurements of $\bar{\Delta}$. The results are shown in Fig. 3. The surface tension decreases with the increase in concentration of electrolytes, except for NaSCN in the concentration range above 10^{-2} N. Observed change of surface tension is in accordance with the lyotropic series of anions. This effect is analogous to that appearing on the cloud points of surfactant solutions.[9] On the other hand, in the range of electrolyte concentration less than about 1×10^{-2} N, the surface tension is unaffected by

1×10^{-1}	1 17	1 6	46	38
5×10^{-1}		1 6	57	54
8×10^{-1}	3 24	1 6	1 7	1 4
1	4 39	1 7	1 4	1 5

the electrolytes and is equal to that of pure nonionic surfactant solution. The corresponding contact angles were calculated from the experimental results of $\bar{\Delta}$ and γ according to Eq. (1), a part of which are shown in Table 1.

As shown in Fig. 1, $\bar{\Delta}$ shows a maximum in the range of second black film for all electrolytes added, which is also observed in the DMS system.[7,8] The concentrations at maximum are 1×10^{-3}, 1×10^{-3}, 5×10^{-4}, and 1×10^{-5} N for Na_2SO_4, NaCl, NaBr, and NaSCN respectively, the values of which depend upon the kinds of anions. Since the surface tensions of the solutions are nearly constant at low electrolyte concentrations, the increase of $\bar{\Delta}$ in such a dilute electrolyte range may indicate the decrease of tension of the second black film involving a minimum. Such a behavior could be explained by the additional intermolecular forces arising from the change in the orientation of the solvent molecules and specific adsorption of ions and so on, besides the van der Waals attraction and a steric repulsion acting within the films, as appeared in the literature.[7,8]

Figure 4 shows the dependence of the blackening time on the concentration of added electrolyte, and Fig. 5 gives a plot of the overall rate of growth of the black film as a function of $\bar{\Delta}$. As seen in Fig. 5, the overall rate of growth of the black film is proportional to $\bar{\Delta}$, regardless of the amounts and kinds of added electrolytes.

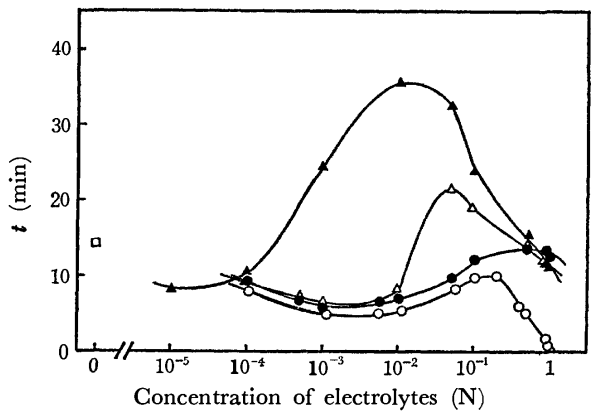

Fig. 4. Effect of electrolytes on blackening time (t) of liquid films formed from aqueous N7 solutions at 30 °C.
Concentration of N7 and added electrolytes: The same as in Fig. 1

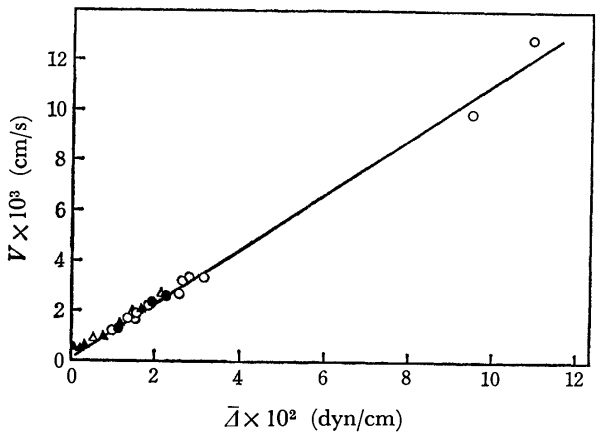

Fig. 5. Dependence of additional tension ($\bar{\Delta}$) on overall rate (v) of growth of black films formed from aqueous N7 solutions containing varying amounts of electrolytes at 30 °C.
Concentration of N7 and added electrolytes: The same as in Fig. 1

The rate of growth of the black film was previously found to be proportional to $\bar{\Delta}$ in the systems of sodium dodecylsulfate (SDS), PNE, and N7 at high concentrations of added electrolytes, and it is mentioned that a_f in the equation $\bar{\Delta}=a_f\cdot v$ may be taken as a viscosity parameter which is found to be proportional to the bulk viscosity.[4] The straight lines showing the proportionality in our preceding paper[4] fall on the same straight line together with the line of Fig. 5, except for the systems containing glycerol, irrespective of the types of the surfactants as well as the amounts and kinds of the electrolytes. This may indicate that the viscosity parameter a_f is independent of the amounts and kinds of added electrolytes, and of the types of the surfactants used at least.

Figure 6 shows the effect of electrolytes on the decay constant, k, of foams formed from 0.1 wt% aqueous PNE solutions containing varying amounts of electro-

lytes.[9] Foam stability was conventionally expressed by a decay constant $k=-\mathrm{d}\log H/\mathrm{d}t$, since H was found to decrease as a whole exponentially with time. Foam stability decreases with increasing concentration of electrolyte. The values of k are in the following order; $HCl \simeq 1/2\ CaCl_2 \simeq NaSCN \simeq NaCl < 1/3\ AlCl_3 < NaOH < 1/3\ Na_3PO_4 < 1/2\ Na_2SO_4 \simeq 1/2\ Na_2CO_3$.
The order for sodium salts is in agreement with the lyotropic series of anions excepting minor detail.

Figure 7 shows the plot of $\overline{\Delta}$ *vs.* k for varying concentrations of inorganic electrolytes added. It is seen that k is proportional to $\overline{\Delta}$, which indicates that the rate of collapse of foam is proportional to the additional tension and therefore to the rate of growth of the black film as seen in Fig. 5. Thus, the stability of foam is mainly determined by the rate of growth of the black film, that is, the rate of thinning or the thickness of black film, because $\overline{\Delta}$ is reported to vary with the reciprocal of the square of film thickness in the first black film.[8] This is consistent with the view proposed by de Vries.[10] No appreciable influence of the electrolytes on the thinning of films in the range of colored film was observed,[3] which indicates less influence of the drainage in the thick films on the stability of foams. Eventually, it may be concluded that the rupture of the foams under consideration does not occur until the colored foam film has given way to the black film, and the thickness and the expansion of the black of film dominates the rupture.

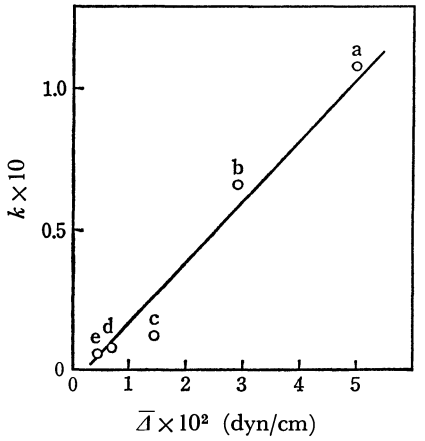

Fig. 7. Dependence of additional tension ($\overline{\Delta}$) on decay constant (k) of foams formed from aqueous PNE solutions containing varying amounts of electrolytes at 30 °C.
Composition of solutions: 0.1 wt% PNE + (a) 0.6 N Na_2SO_4, (b) 0.4 N Na_2SO_4, (c) 0.2 N Na_2SO_4, (d) 0.5 N NaSCN, (e) 0.1 N NaCl.

The author wishes to express her hearty thanks to Professor Tsunetaka Sasaki of Tokyo Metropolitan University for his encouragement and guidance throughout the experiments.

Dielectric Behavior of Water Molecules Adsorbed on Iron(III) Oxide Hydroxides

Katsumi KANEKO, Mamoru SERIZAWA, Tatsuo ISHIKAWA, and Katsuya INOUYE

Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba 280

(Received June 28, 1974)

The change in the dielectric constant of α-FeOOH, β-FeOOH, and γ-FeOOH with the amount of adsorbed water was examined at 30.0 °C in the frequency range 200 Hz—100 kHz for the purpose of clarifying the mechanism of water adsorption. The adsorption isotherms belong to the BET II type. The sample with the adsorbed water shows a particular dispersion of the dielectric constant with frequency in the low frequency range. The dispersion was ascribed to the transition between different orientational directions of the dipole moment of the adsorbed water. The change in the dielectric constant with the amount of adsorbed water for each iron(III) oxide hydroxide was interpreted in relation to the surface structure of predominant faces of crystals, in particular the number and position of hydroxyls on crystal surfaces. The following adsorption process was suggested below the monolayer adsorption coverage for each iron(III) oxide hydroxide. For α-FeOOH, water molecules are adsorbed on the (100) planes in three successive steps. For β-FeOOH, water molecules are primarily bound in the tunnels existing in the crystal along a direction parallel to the c-axis and then are adsorbed on the cracked tunnels exposing to the outer surface. For γ-FeOOH, water molecules are adsorbed on the (010) planes in two steps.

Of the four polymorphs of iron(III) oxide hydroxide (the so-called ferric oxyhydroxide) so far known, α-FeOOH, β-FeOOH, and γ-FeOOH occur naturally as minerals and as the corrosion products of iron. Each iron(III) oxide hydroxide exhibits characteristic properties, on which the authors have examined in several cases, such as the effect of Cu(II) on the crystal formation,[1-3] the activity to sulfur dioxide,[4] and the electrical conductivity.[5]

A study on the interaction between water molecules and iron(III) oxide hydroxide crystals is expected to clarify the corrosion process of iron surface in the atmospheric environments, since iron(III) oxide hydroxides are the main components in corrosion products. The dielectric measurement is used for the study of water adsorption because of the large dipole moment of the water molecule. Many dielectric studies on the water adsorption onto solids have been attempted. McCafferty *et al.*[6] reported the dielectric behavior of adsorbed water on α-Fe_2O_3. The correlation between the change in capacitance caused by applying electric field and the amount of adsorbed water appears significant to discuss the adsorption mechanism based on a structural view-point, because polar molecules adsorbed in a monolayer are too tightly connected with surface so as to orientate, whereas the molecules adsorbed in the second or higher layers are relatively free to orientate under the influence of the applied field.[7,8]

In this paper, the relationship between the dielectric behavior of water adsorbed on iron(III) oxide hydroxides and the surface structure of the oxyhydroxides is examined.

Experimental

Sample. Both α-FeOOH and β-FeOOH were synthesized by the methods described.[5] γ-FeOOH was prepared by the following procedure. After 3.6 g of $FeSO_4 \cdot 7H_2O$ was dissolved in 600 ml of oxygen-free water, air was blown for 3 hr into the solution adjusted to pH 4.3—6.5 with 10% NH_4OH solution. γ-FeOOH suspension thus obtained was aged at 30 °C for 5 days at pH 4.5. The crystals were filtered, washed with 2.5 l distilled water, and dried at 60 °C for 9 hr.

Examination of Samples. The X-ray diffraction patterns were obtained by the powder method with an automatic diffractometer (Geigerflex 2001, Rigaku Denki Co.) by use of Mn-filtered Fe*Kα* at 30 kV and 10 mA. Electron-microscopic observations were carried out by JEM 50B (Japan Electron Optics Co.). The predominant face of α-FeOOH crystals was identified by the selected-area electron diffraction with Hitachi HU-11D. The BET surface-area was determined by Shibata surface-area meter using N_2 adsorption at liquid nitrogen temperature for the samples dried at 110 °C for 1 hr in a stream of nitrogen.

The iron content in β-FeOOH crystals was determined, after the sample had been dissolved in hydrochloric acid by titration with 0.1 M $K_2Cr_2O_7$ standard solution, and the chlorine content in β-FeOOH by the Volhard method with 0.1 M $AgNO_3$ standard solution.

Adsorption of Water. The adsorption of water vapor was measured at 30.0 °C with a conventional volumetric apparatus. The water vapor was produced from $BaCl_2 \cdot 2H_2O$. Samples were outgassed at 110 °C under 10^{-5} Torr for 15 hr prior to the adsorption measurement. The adsorption reached an equilibrium within 1 hr.

Dielectric Measurements. The dielectric constant was measured in the frequency range 200 Hz—100 kHz by a substitution-type Schering bridge. The resistance-ratio bridge used consists of a precise variable air-capacitor (Yokogawa Hewlett-Packard Co., CDS-500), a low frequency oscillator and an oscilloscope in connection with a pre-amplifier as the detector. The sample cell is made of brass coaxial cylinders 5 cm long and 2 mm apart, insulated mutually by Teflon. This cell is fitted into the annular glass receptacle which can be connected with the above-mentioned adsorption apparatus. The capacitance of the cell C_0, a constant capacitance C' in parallel with C_0, and the accuracy of the apparatus, were determined and checked by the measurements with air, benzene, cyclohexane, and dichloroethane. These solvents were dried with Na wires and distilled just before the measurements. The values of C_0 and C' were 17.0 and 10.1 pF, respectively. The accuracy of the capacitance determination was ±1% in the range 40—200 pF; the capacitance was determined mostly in this range. The apparent dielectric constant is given by $(C—C')/C_0$, where C is the capacitance of the cell filled with the water-adsorbed sample.

Results

Properties of Samples. Each sample prepared gave X-ray diffraction patterns of well crystallized

Table 1. Properties of samples

	α-FeOOH	β-FeOOH	γ-FeOOH
Crystallite size by X-ray (Å)	280	550	110
Crystal length by EM (Å)	3000	2600	900
Crystal shape	Thin rectangular plate	Long square rod	Very thin rectangular plate
Predominant face	(100)	(100), (110) or (310)[9]	(010)[10]
S_{N_2} (m^2/g)	64	30	100

α-, β-, and γ-FeOOH, respectively. Table 1 gives the crystallite size calculated by the Scherrer formula from the half-value width of the principal X-ray diffraction lines, the mean crystal length by the electron microscopy (EM), the shape of crystals, and the predominant face of crystals. The predominant face of β-FeOOH crystals is cited from Mackay's results[9] and that of γ-FeOOH crystals from Oosterhout's results.[10] The specific surface area S_{N_2} by the adsorption of nitrogen is also given in Table 1. The ratio of chlorine to iron for β-FeOOH was found to be 8.2 atomic %.

Adsorption Isotherms. The adsorption isotherms at 30.0 °C for each sample are shown in Fig. 1, and are the BET II type. The monolayer-adsorption volume was determined by use of the BET plot of the adsorption data. Table 2 gives the monolayer volume V_m in milliliter of water per gram of the oxyhydroxide, the monolayer volume A_m in milliliter per S_{N_2}, and the area occupied by an adsorbed water molecule σ_w.

Dielectric Properties. Figure 2 shows the variations of apparent dielectric constant with frequency at different degrees of water adsorption for β-FeOOH. The dielectric constant of the dry sample did not exhibit any recognizable dispersion with respect to

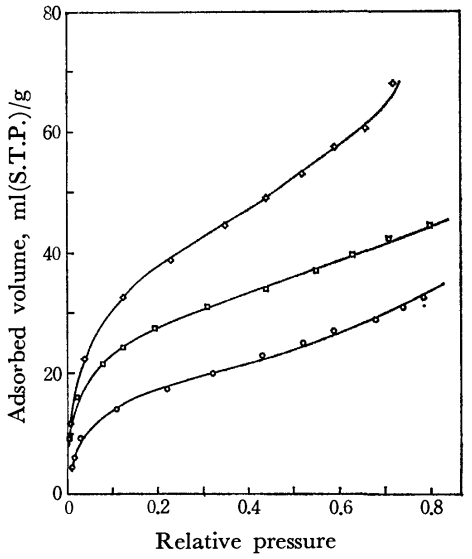

Fig. 1. Adsorption isotherms of water on α-FeOOH (□), β-FeOOH (○), and γ-FeOOH (◇).

Table 2. Monolayer volume and σ_w

	V_m (ml/g)	A_m (ml/m^2)	σ_w (Å^2)
α-FeOOH	24	0.37	10
β-FeOOH	12	0.38	9.7
γ-FeOOH	32	0.32	12

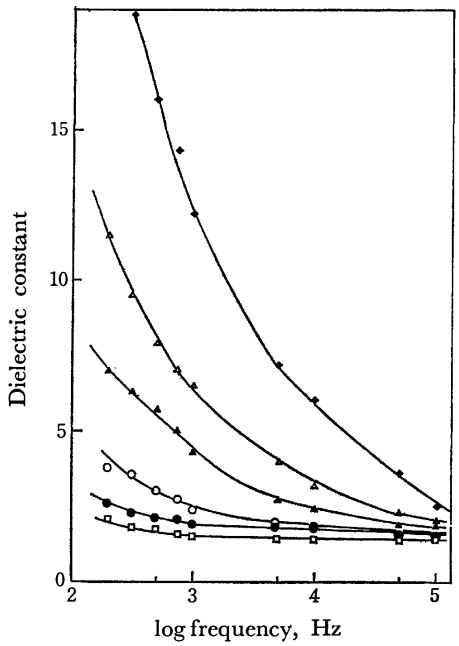

Fig. 2. Variations of dielectric constant with frequency at different degrees of water adsorption for β-FeOOH. The relative pressures are 0 for (□), 0.034 for (●), 0.067 for (○), 0.163 for (▲), 0.288 for (△), and 0.583 for (◆).

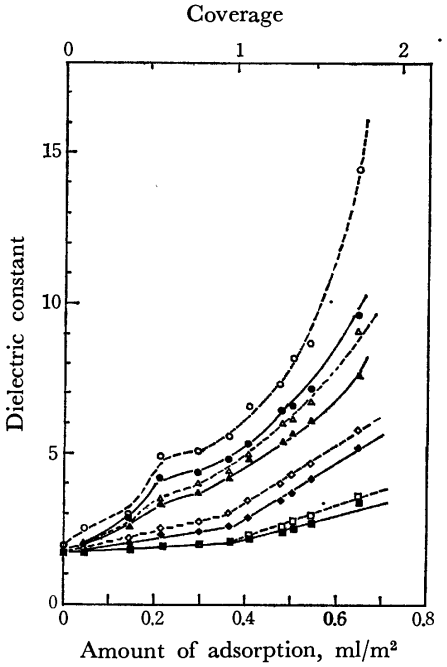

Fig. 3. Variations of dielectric constant with the amount of adsorption at various frequencies for α-FeOOH. ○: 200 Hz, ●: 500 Hz, △: 700 Hz, ▲: 1 kHz, ◇: 5 kHz, ◆: 10 kHz, □: 50 kHz, ■: 100 kHz.

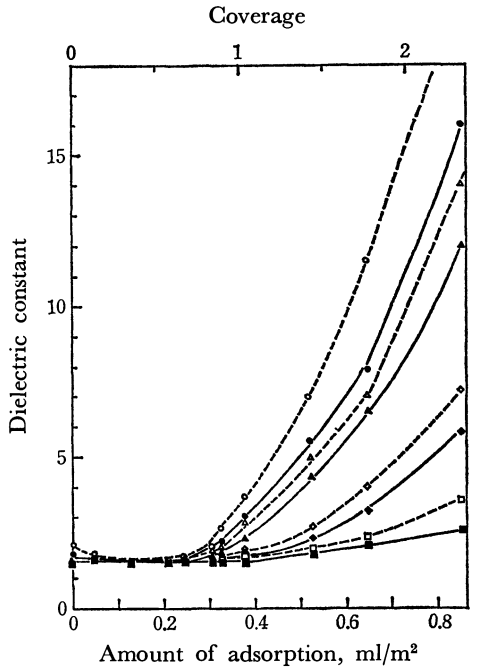

Fig. 4. Variations of dielectric constant with the amount of adsorption at various frequencies for β-FeOOH. Each symbol denotes the same frequency as that used in Fig. 3.

frequency. The dielectric constant in lower frequency range increased considerably with the amount of adsorption, whereas that in higher frequency range increased only slightly. In Figs. 3—5, the relationship between the dielectric constant and the amount of adsorbed water in milliliter per S_{N_2} is presented at different frequencies for α-, β-, and γ-FeOOH, respectively. The coverage which indicates the number of layers of adsorbed molecules is also shown on the top abscissa of the figures. The curve at lower frequencies for α-FeOOH (Fig. 3) has a shoulder in the neighborhood of 0.6 coverage and rises steeply with adsorption at the coverage over unity. Figure 3 illustrates the fact that the dielectric constant at higher frequencies (5—100 kHz) increases with adsorption linearly and that each linear relation has a clear bend at unity of the coverage. The dielectric constant for β-FeOOH (Fig. 4) does not vary with adsorption up to 0.7 coverage (adsorbed water 0.25 ml/m²) irrespective of frequency, but it increases remarkably with adsorption above 0.7 coverage. No change in dielectric constant with the adsorption for γ-FeOOH (Fig. 5) is noticeable up to 0.5 coverage. The dielectric constant at lower frequencies with adsorption rises remarkably in the 0.5—1 range of coverage, but it increases only slightly with adsorption over unity. On the other hand, the dielectric constant at higher frequencies increases linearly with adsorption above 0.8 coverage though only slightly.

Discussion

Frequency Dependence. The dispersion of dielectric constant with frequency for the solid with adsorbed water has been explained both by the heterogeneous sturcture of the system consisting of adsorbed film, solid, and intergranular gap,[11] and by the orientation of adsorbed water under the influence of electrical field.[8] In the case of the solid with monolayer or bilayer adsorption film as in the present experiment, the dc conductance in the adsorbed film is not influenced by the dissolution of surface ions into the water film, but by the hopping of the protons in the absorbed water molecules on the solid surface. The dispersion by the latter influence may be regarded as an orientation mechanism, since the hopping of protons causes a variation in the direction of the dipole moment.

Thus the dielectric dispersion observed in the low frequency range seems to be ascribed to the transition between some different orientational directions of the dipole of adsorbed water. It is anticipated that the adsorbed water forms a structure analogous to that of ice which shows the low frequency dielectric dispersion explained by the molecular reorientaiton.[12,13] The transition of molecular orientation depends on the force on the solid surface. The low frequency dielectric constant shows sensitively the adsorption state of water molecules. On the other hand, the dielectric constant in the high frequency range, where the dipole lags behind the field, depends to a lesser extent on the adsorption state.

Dielectric Behavior and Surface Structure. Electron microscopic observation showed that the predominant face of crystals occupies more than 90% of the total surface (Table 1). The adsorption occurs therefore mainly on the predominant surfaces of each crystal. The surface structures of α-, β-, and γ-FeOOH shown in Figs. 6, 7, and 8, respectively, were illustrated from available crystallographic data (α-FeOOH,[14,15] β-

Table 3. Data on the two-dimensional unit cell of the predominant face

	Area of *TD*-unit s_u, (Å^2)	Number of H_2O per s_u, n_w	Number of OH per s_u, n_{OH}
α-FeOOH	30.3	3	2
β-FeOOH	31.7	3	2
γ-FeOOH	11.8	1	1

FeOOH,[9,16,17] and γ-FeOOH[18]). The ionic radius values of 1.40 and 1.53 Å were employed for oxygen and hydroxyl ions, respectively, in the drawing of Figs. 6—8.[19] Table 3 gives the area of the two-dimensional unit cell (TD-unit) s_u calculated from the lattice constant, the number of hydroxyls n_{OH} per s_u estimated from the structure of the predominant surfaces, and the number of water molecules n_w in the monolayer per s_u. n_w is the integer nearest to the ratio of s_u to σ_w. It is assumed that adsorption sites on α- and γ-FeOOH crystals are hydroxyls, whereas those on β-FeOOH are hydroxyls and tunnels. The dissociative adsorption of water may be ignored, since it was demonstrated that the heat of immersion in water for α- and γ-FeOOH is much less than that for α-Fe_2O_3, immersion of which in water is apparently accompanied by rehydration.[20]

The dielectric behavior of α-FeOOH with respect to the amount of adsorbed water may be explained by assuming the presence of two kinds of hydroxyl (hydroxyl-I and II) on the surface ($n_{OH}=2$). A water molecule denoted by W(I) is localized on hydroxyl-I by the triple hydrogen bonding with one OH^- and with the nearest two O^{2-}. Another water molecule W(II) is adsorbed on hydroxyl-II by the single hydrogen bond. A third water molecule W(III) assumes a position between W(I) and W(II). Figure 6 shows the state of water adsorption, where n_w equals 3. The immobile water molecules W(I) result in a slight increase in the dielectric constant up to 0.3 coverage. The freely orientating molecules W(II) exhibit a considerable increase in the dielectric constant in the 0.3—0.6 coverage range. W(III) molecules hinder the orientation of W(II); W(III) brings about a further slight increase in the dielectric constant in the 0.6—1 coverage range. Molecules in the second adsorption layer with greater freedom of movement cause a considerable increase in dielectric constant at lower frequencies.

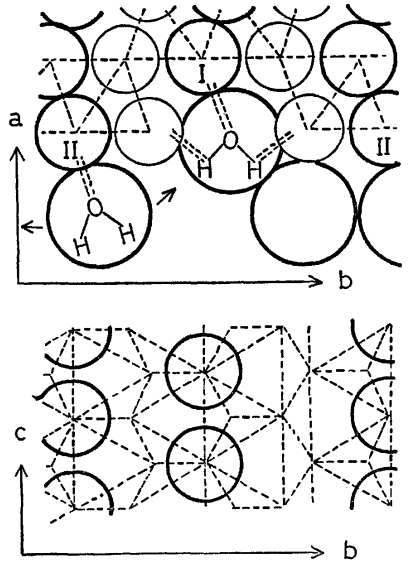

Fig. 6. Adsorption process of water molecules on the (100) plane of α-FeOOH. The smallest circle, the intermediate circle, and the largest circle denote oxygen ion, hydroxyl ion, and water molecule, respectively. The single broken line denotes the edge of the octahedron including an iron ion. The double broken line denotes hydrogen bond binding the adsorbed water molecule.

β-FeOOH is stable in the presence of F or Cl ions.[9] The Cl content in β-FeOOH can not be easily reduced below 12% by washing.[21] Mackay[9] reported that β-FeOOH has a hollandite ($BaMn_8O_{16}$) structure having tunnels parallel to the c-axis, in which Cl^- and H_2O can be occluded (Fig. 7); the extra negative charge due to Cl^- in β-FeOOH crystals must be compensated by the replacement of O^{2-} by OH^-. According to the results by Byström and Byström,[22] it is considered that in the case of hollandite a half the volume of tunnels is filled with Ba ions and the other half with water molecules; the ratio of Ba to Mn is 1/8, *viz.*, 12.5%. The chlorine in β-FeOOH plays the role of Ba ion in hollandite. The most stable composition of β-FeOOH is assumed to be $FeO_{1-1/8}(OH)_{1+1/8}Cl(t)_{1/8}H_2O(t)_{1/8}$, where (t) indicates the state bound to the tunnel. The electron-micrographs of β-FeOOH crystals obtained by several authors[9,16,23] clearly show the presence of holes, indicating that the tunnels are broken up midway. Cl ions in the neighborhood of the exits of tunnels and holes are supposedly replaced by water molecules in the course of washing. The washing process may be expressed as follows.

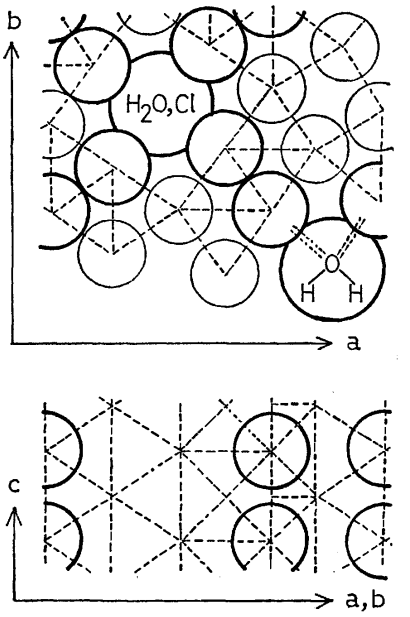

Fig. 7. Adsorption process of water molecules in the tunnels and on the cracked tunnels of β-FeOOH.

$FeO_{1-1/8}(OH)_{1+1/8}Cl(t)_{1/8}H_2O(t)_{1/8} \rightarrow FeO_{1-1/8+x}(OH)_{1+1/8-x}Cl(t)_{1/8-x}H_2O(t)_{1/8+x}$, where $1/8-x$ is equal to 8.2%. Accordingly x is equal to 4.3%. The replaced water xH_2O could be removed in the course of pretreatment. The 4.3% vacant sites thus produced can be used as the adsorption sites for water. The possible amount of water adsorbed to these sites is calculated to be 0.25 ml/m². Assuming that this amount of water is bound tightly in the tunnel, the fact that the dielectric constant is almost constant up to 0.25 ml/m² of adsorption (Fig. 4) is quite conceivable. After the tunnel is choked up, approximately 0.11 ml/m² water molecules are bound to the two hydroxyls at outer surfaces by the bifurcated hydrogen bonding (Fig. 7). The second step of adsorption corresponds to a slight increase in the dielectric constant in the range of the amount of adsorption from 0.25 to 0.4 ml/m² (A_m) (Fig. 4). The water molecules in the second layer are bound to the surface by weak forces and are mobile to orientate, when the dielectric constant increases markedly.

The dielectric behavior of γ-FeOOH with respect to the amount of adsorbed water may be explained by assuming the presence of only a kind of hydroxyl on the surface ($n_{OH}=1$). It is supposed that each water molecule is localized on two hydroxyls by the bifurcated hydrogen bonding up to the half coverage adsorption, so that only a slight increase in dielectric constant is observed in the region of coverage up to 0.5 (Fig. 5). Water molecules loosely bound to hydroxyls by single hydrogen bonds ($n_{OH}=n_w$) above the half coverage are relatively free to orientate, when the dielectric constant increases sharply. Figure 8 shows the adsorption process of water on γ-FeOOH. From the fact that the calculated density of hydroxyls on γ-FeOOH is the highest (8.4×10^{14} cm^{-2}) in comparison with 6.6×10^{14} cm^{-2} on α-FeOOH and 6.3×10^{14} cm^{-2} on β-FeOOH, it follows that even the second layer of the adsorbed water on γ-FeOOH will be comparatively ordered. The ordered adsorbed water molecule in the second layer withholds the dielectric constant from an abrupt increase in the range of coverage over unity as shown in Fig. 5.

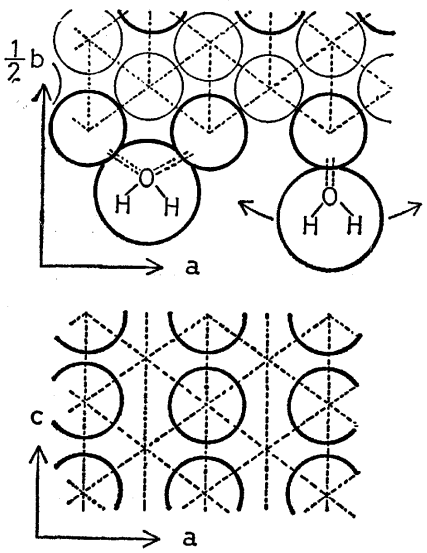

Fig. 8. Adsorption process of water molecules on the (010) plane of γ-FeOOH.

The increase in dielectric constant in a higher frequency range is due to the change in the atomic polarization, which depends on the product of the atomic polarizability and the number of molecules of adsorbed water. The atomic polarizability of the water molecule in the adsorption layer is identical, so that the dielectric constant in a higher frequency range is proportional to the number of water molecules. Therefore, the dielectric constant in higher frequency range increases linearly with the amount of adsorption. The variation in the slope of linear plots in the contiguity of monolayer capacity seems to be caused by the difference between the atomic polarizability of adsorbed water in the first layer and that in the second layer.

Conclusion

The adsorption isotherm of water on iron(III) oxide hydroxides (α-, β-, and γ-FeOOH) was found to be of the BET II type. The change in dielectric constant with the amount of adsorption of water was measured. The adsorption mechanism was discussed on a structural view-point that the relationship between the dielectric constant and the amount of adsorbed water reflects the adsorption process of coverage below unity. The structure of the predominant surface of crystals, in particular the number and position of hydroxyls, is the main determining factor in the adsorption of water; two kinds of hydroxyl on (100) plane for α-FeOOH crystal, the tunnels parallel to the c-axis and the hydroxyls on the outer surface for β-FeOOH crystal, and a kind of hydroxyls on (010) plane for γ-FeOOH crystal are the sites of adsorption. Water molecules are adsorbed on surfaces in two or three steps, which is characteristic of the surface structure of each iron(III) oxide hydroxide.

A Theory of Ion Association as a Complement of the Debye-Hückel Theory*

Haruhiko YOKOYAMA and Hideo YAMATERA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received December 23, 1974)

The classical Debye-Hückel theory of strong electrolyte solutions was re-examined in order to explain ion association. Regarding a symmetrical electrolyte in very dilute solutions, a more precise expression was derived for excess chemical potential due to electrostatic ion-ion interactions. This expression has, in addition to the Debye-Hückel term, a supplementary term resulting from a more proper account of the energy of the interactions of ions existing near each other. If the concept of ion association is taken as a complement of the Debye-Hückel theory, the contribution to the chemical potential of the electrolyte from ion association should correspond to the supplementary term. The following equation was thus obtained for the ion-association constant:

$$K=(8\pi Na^3/1000)\sum_{n=1}^{\infty} b^{2n+2}/[(2n+2)!\ (2n-1)]$$

This equation is in agreement with that derived by Ebeling on the basis of the cluster theory and has an asymptotic representation (at $b\to\infty$) in common with Bjerrum's. For practical b values, the present equation has the merit that it gives moderate K values, decreasing monotonously with an increase in the a value, and eliminates the disadvantages of Fuoss's result, giving a minimum K value at $b=3$, and of Bjerrum's, giving $K=0$ at $b\leqq 2$.

Debye and Hückel[1] have been successful in explaining the behavior of ions in dilute solutions of strong 1 : 1 electrolytes. For polyvalent ions, however, their theory was not satisfying, and the theoretical prediction evidently deviates from the experimental results even for dilute solutions.

Gronwall, LaMer, and Sandved[2] made an attempt to improve the Debye-Hückel theory by solving the Poisson-Boltzmann equation more accurately. However, the accurate solutions obtained by them and by other authors[3] were found to lack self-consistency.[4,5]

On the other hand, Bjerrum[6] introduced the concept of so-called ion association to explain the deviation of the experimental results from the Debye-Hückel theory. Thereafter, many other theories of ion association have been proposed by Denison and Ramsey,[7] Gilkerson,[8] Fuoss,[9] Ebeling,[10] and other authors.[11] These theories of ion association, with the probable exception of Ebeling's theory, have been based on specific models of the ion-pair.

Although evidence can be given for the formation of ion-pairs in solution, the geometrical configurations of the ion-pairs can hardly be specified. There may be solvent-separated ion-pairs in addition to contact ion-pairs.[12] If, as in Bjerrum's theory, all pairs of oppositely charged ions within a certain critical distance of each other are regarded as ion-pairs, some arbitrariness will be involved in the choice of the critical distance. Moreover, there seems to be a chance that fast-moving unassociated ions momentarily exist within the critical distance of each other. Thus, no geometrical models of the ion-pairs can be free from arbitrariness.

In our opinion, a theory of ion-association dealing with ion-pairs must be complementary to the theory describing the behavior of free ions (usually, the Debye-Hückel theory). We therefore re-examined the Debye-Hückel theory to see what correction could be made to improve the theory. Then, relating the correction to ion association, we obtained a theoretical expression for the ion-association constant of symmetrical electrolytes. The expression includes no arbitrary parameters except for the one representing the closest distance of approach of ions, and incidentally, it is in agreement with the expression derived by Ebeling on the basis of the cluster theory.

We shall describe the derivation of the expression for ion-association constants and compare the results with those deduced by other authors.[6,7,9,10]

Symbols

a	closest distance of approach of ions
b	Bjerrum's parameter [Eq. (14)]
c	concentration of electrolyte
e	elementary charge
k	Boltzmann's constant
n_i	number of i-type ions in V cm^3 of solution
q	$=z^2s/2$
r	distance from central ion
s	$=e^2/\varepsilon kT$
y	activity coefficient
z_i	charge number of i-type ion
z_j	charge number of central j-ion
z	absolute value of charge number of ions of symmetrical electrolytes
A	constant to be determined from condition of electrical neutrality [Eqs. (11) and (13)]
G^{el}	Gibbs free energy of electrostatic interactions between ions
K	ion-association constant
N	Avogadro's number
R	gas constant
T	absolute temperature
V	volume of solution
α	degree of association
γ	Euler's constant ($\gamma=0.5772\cdots$)
ε	dielectric constant of solvent
κ	reciprocal thickness of ionic atmosphere [Eq. (4)]
λ	charging parameter
μ	chemical potential per mole of electrolyte
μ^{el}	contribution of ion-ion interactions to μ
μ_i^{el}	contribution of ion-ion interactions to chemical potential of one i-type ion

* Presented in part at the 27th Annual Meeting of the Chemical Society of Japan, Nagoya, October, 1972, and at the 15th International Conference on Coordination Chemistry, Moscow, USSR, June, 1973. A preliminary report has been published: H. Yokoyama and H. Yamatera, *Chem. Lett.*, **1973**, 337.

ρ charge density
ψ electrostatic potential due to all the ions
ψ^{cloud} electrostatic potential due to all the ions except central j-ion
A_{DH}, ρ_{DH}, ψ_{DH}, and $\psi_{\text{DH}}^{\text{cloud}}$ approximate expressions for A, ρ, ψ, and ψ^{cloud} respectively, under Debye-Hückel conditions

Boltzmann Distribution and Poisson Equation. In the following discussions, the solvent is considered to be a continueous medium of a dielectric constant, ε, and the ions to be rigid spheres. The ion-ion interactions are assumed to be purely electrostatic.

If a particular ion is selected as the center of a coordinate system, the Boltzmann distribution law gives the charge density, ρ, as a function of the radial coordinate, r:

$$\rho(r) = \sum_i \frac{n_i z_i e}{V} \exp\left(-\frac{z_i e\psi(r)}{kT}\right) \tag{1}$$

where n_i is the number of i-type ions in V cm^3 of the solution, $z_i e$ the charge of the i-type ions, and $\psi(r)$ the electrostatic potential. We shall use in the following the subscripts 1 and 2 to denote, respectively, the cation and the anion of a single electrolyte. For a symmetrical electrolyte:

$$n_1 = n_2 \quad \text{and} \quad z_1 = -z_2 = z(z>0)$$

With n_1 and z, Eq. (1) can be rewritten as follows:

$$\rho(r) = \frac{n_1 ze}{V}\left[\exp\left(-\frac{ze\psi(r)}{kT}\right) - \exp\left(\frac{ze\psi(r)}{kT}\right)\right] \tag{2}$$

By expanding the exponential functions in Eq. (2) and introducing the parameter κ (the reciprocal thickness of the ionic atmosphere), one obtains:

$$\rho(r) = -\frac{\varepsilon\kappa^2}{4\pi}\sum_{n=0}^{\infty}\frac{1}{(2n+1)!}\left(\frac{ze}{kT}\right)^{2n}[\psi(r)]^{2n+1} \tag{3}$$

The parameter κ is defined by the expression:

$$\kappa^2 = \frac{8\pi n_1 z^2 s}{V} \tag{4}$$

or by the general expression:

$$\kappa^2 = \frac{4\pi\sum_i n_i z_i^2 e^2}{V\varepsilon kT} = \frac{4\pi s\sum_i n_i z_i^2}{V} \tag{5}$$

where s is a parameter with the dimension of length** and is defined by:

$$s = \frac{e^2}{\varepsilon kT}$$

The potential, $\psi(r)$, and the charge density, $\rho(r)$, are related to each other by the Poisson equation:

$$\frac{1}{r^2}\cdot\frac{\mathrm{d}}{\mathrm{d}r}\left(r^2\frac{\mathrm{d}\psi(r)}{\mathrm{d}r}\right) = -\frac{4\pi\rho(r)}{\varepsilon}$$

Debye-Hückel Approximation. For a very dilute solution, Debye and Hückel[1] simplified Eq. (3), ignoring the terms with $n \geqq 1$ under the condition of $|ze\psi(r)/kT| \ll 1$:

$$\rho(r) \simeq \rho_{\text{DH}}(r) = -\frac{\varepsilon\kappa^2}{4\pi}\psi_{\text{DH}}(r) \tag{6}$$

** In an aqueous solution at 25.0 °C with $\varepsilon = 78.30_3$, s has a value of 7.157 Å.

where the subscript DH indicates that the Debye-Hückel condition is assumed to be satisfied. Then they solved the Poisson equation and derived the expression:

$$\psi_{\text{DH}}(r) = A_{\text{DH}}\frac{\exp(-\kappa r)}{r} \tag{7}$$

The constant, A_{DH}, can be determined by means of the condition of electrical neutrality:

$$\int_a^{\infty} 4\pi r^2\rho(r)\mathrm{d}r = -z_j e \tag{8}$$

where $z_j e$ is the charge of the central j-ion and a is the closest distance of approach of ions. Equation (8) was solved with Eqs. (6) and (7) to give:

$$A_{\text{DH}} = \frac{z_j e\exp(\kappa a)}{\varepsilon(1+\kappa a)} \tag{9}$$

The potential, $\psi(r)$, is in general represented by the sum of the potential due to the j-ion, $z_j e/\varepsilon r$, and the potential due to all the other ions, $\psi^{\text{cloud}}(r)$. With the Debye-Hückel approximation,

$$\psi^{\text{cloud}}(r) \simeq \psi_{\text{DH}}^{\text{cloud}}(r)\left(=\psi_{\text{DH}}(r) - \frac{z_j e}{\varepsilon r}\right)$$
$$= \frac{z_j e}{\varepsilon r}\left[\frac{\exp(\kappa a - \kappa r)}{1+\kappa a} - 1\right]$$

Since the j-ion is present inside a cavity with a radius of a surrounded by an ionic cloud, the potential, $\psi^{\text{cloud}}(r)$, at the j-ion is given by the potential, $\psi^{\text{cloud}}(r)$, at $r=a$:

$$\psi^{\text{cloud}}(a) \simeq \psi_{\text{DH}}^{\text{cloud}}(a) = -\frac{z_j e\kappa}{\varepsilon(1+\kappa a)} \tag{10}$$

Contribution of the Ions Existing in the Vicinity of the j-ion to the Potential, $\psi^{\text{cloud}}(a)$. The contribution of the ions existing in the vicinity of the j-ion to the potentials, $\psi(r)$, $\psi^{\text{cloud}}(r)$, and $\psi^{\text{cloud}}(a)$, was ignored in the Debye-Hückel approximation. More exact expressions for these potentials including the ignored contribution can be derived by using a closer approximation to the original equation [Eq. (3)] for the charge distribution. In Eq. (3), the Debye-Hückel-type expression [a modification of Eq. (7)]:

$$\psi(r) = A\frac{\exp(-\kappa r)}{r} \tag{11}$$

can be used as an approximation to $\psi(r)$. A is a constant to be determined from the conditions of electrical neutrality. Since, for our purposes in this paper, we are primarily interested in the potential, $\psi^{\text{cloud}}(a)$, we shall describe below only the derivation of the potential, $\psi^{\text{cloud}}(a)$, of a closer approximation.

The time-averaged number of i-type ions in a unit volume at a certain distance, r, from the j-ion is given by the Boltzmann distribution law. Thus, their contribution to the potential at the j-ion can be expressed by:

$$\frac{1}{\varepsilon r}\cdot\frac{n_i z_i e}{V}\exp\left(-\frac{z_i e\psi(r)}{kT}\right)$$

The superposition of the contributions of the ions (except the j-ion) of all types in the whole space gives the potential at any one place within the distance

$r \leqq a$ due to the ionic cloud, $\psi^{\text{cloud}}(a)$:

$$\psi^{\text{colud}}(a) = \int_a^\infty \frac{1}{\varepsilon r} \sum_i \left[\frac{n_i z_i e}{V} \exp\left(-\frac{z_i e \psi(r)}{kT} \right) \right] 4\pi r^2 \mathrm{d}r$$

or

$$\psi^{\text{colud}}(a) = \frac{4\pi}{\varepsilon} \int_a^\infty r\rho(r)\mathrm{d}r$$

Using Eq. (11) for $\psi(r)$, one obtains:

$$\begin{aligned}\psi^{\text{cloud}}(a) &= -\kappa^2 \sum_{n=0}^{\infty} \frac{1}{(2n+1)!} \left(\frac{ze}{kT} \right)^{2n} A^{2n+1} \\ &\quad \times \int_a^\infty \frac{\exp[-(2n+1)\kappa r]}{r^{2n}} \mathrm{d}r \\ &= -\kappa A \exp(-\kappa a) \\ &\quad - (\kappa a)^2 \sum_{n=1}^{\infty} \frac{\exp[-(2n+1)\kappa a]}{(2n+1)!(2n-1)a^{2n+1}} \left(\frac{ze}{kT} \right)^{2n} A^{2n+1} \\ &\quad + (\kappa a)^3 (\cdots\cdots) + \cdots\cdots \end{aligned} \tag{12}$$

(For details of the calculation of the integral, see the footnote.***) The constant A in Eq. (12) is determined by the condition of electrical neutrality [Eq. (8)] as follows. The whole charge in all the volume outside the sphere of radius a is given by:

$$\begin{aligned}&\int_a^\infty 4\pi r^2 \rho(r)\mathrm{d}r \\ &= -\varepsilon\kappa^2 \sum_{n=0}^{\infty} \frac{1}{(2n+1)!} \left(\frac{ze}{kT} \right)^{2n} A^{2n+1} \int_a^\infty \frac{\exp[-(2n+1)\kappa r]}{r^{2n-1}} \mathrm{d}r \\ &= -\varepsilon(1+\kappa a) A \exp(-\kappa a) \\ &\quad - \varepsilon(\kappa a)^2 \left\{ -\frac{\ln(3\kappa a)+\gamma}{6a^2} \left(\frac{ze}{kT} \right)^2 A^3 \right. \\ &\quad \left. + \sum_{n=2}^{\infty} \frac{\exp[-(2n+1)\kappa a]}{(2n+1)!\,(2n-2)a^{2n}} \left(\frac{ze}{kT} \right)^{2n} A^{2n+1} \right\} \\ &\quad + (\kappa a)^3 (\cdots\cdots) + \cdots\cdots \end{aligned}$$

where γ is Euler's constant ($\gamma = 0.5772\cdots$.) Since this charge must be equal to $-z_j e$, the constant A becomes:

$$\begin{aligned}A = \frac{z_j e \exp(\kappa a)}{\varepsilon(1+\kappa a)} &\left\{ 1 - (\kappa a)^2 \left[-\frac{\ln(3\kappa a)+\gamma}{6} b^2 \left(\frac{z_j}{z} \right)^2 \right. \right. \\ &\left. \left. + \sum_{n=2}^{\infty} \frac{b^{2n} (z_j/z)^{2n}}{(2n+2)!\,(2n-1)} \right] \right\} \end{aligned} \tag{13}$$

where the $(\kappa a)^3$ and higher-order terms are disregarded. b is Bjerrum's parameter and is defined by:

$$b = \frac{|z_1 z_2| s}{a} = \frac{|z_1 z_2| e^2}{\varepsilon k T a} \tag{14}$$

or, for a symmetrical electrolyte,

$$b = \frac{z^2 s}{a} \tag{15}$$

By substituting Eq. (13) into Eq. (12) and by disregarding the $(\kappa a)^3$ and higher-order terms, one obtains:

$$\psi^{\text{Cloud}}(a) = -\frac{z_j e \kappa}{\varepsilon(1+\kappa a)} - (\kappa a)^2 \frac{z_j e}{\varepsilon a} \sum_{n=1}^{\infty} \frac{b^{2n} (z_j/z)^{2n}}{(2n+1)!\,(2n-1)} \tag{16}$$†

The second term on the right-hand side has been added as the first correction term to the Debye-Hückel expression [Eq. (10)].

The Gibbs Free Energy of the Electrostatic Interactions between Ions, G^{el}. According to the Debye charging process,[1] G^{el} can be evaluated as the electric work of charging up all the ions simultaneously from zero to their actual values at the same relative rate:[4,5]

$$G^{\text{el}} = \int_0^1 \sum_j z_j e \psi^{\text{cloud}}(a, \lambda z, \lambda\kappa) \mathrm{d}\lambda \tag{17}$$

where the summation is made over all the ions in V cm^3 of the solution, λ denotes the fraction of their final charges which the ions have at any stage of the integration, and $\psi^{\text{cloud}}(a, \lambda z, \lambda\kappa)$ is given by:

$$\begin{aligned}\psi^{\text{cloud}}(a, \lambda z, \lambda\kappa) &= -\frac{\lambda z_j e \lambda\kappa}{\varepsilon(1+\lambda\kappa a)} \\ &\quad - (\lambda\kappa a)^2 \frac{\lambda z_j e}{\varepsilon a} \sum_{n=1}^{\infty} \frac{(\lambda^2 b)^{2n}}{(2n+1)!\,(2n-1)} \end{aligned}$$

This expression is obtained by substituting $\lambda z_j e$ and $\lambda z e$ for $z_j e$ and ze respectively in Eq. (16). Then the right-hand side of Eq. (17) can be calculated as follows:

$$\begin{aligned}G^{\text{el}} &= -\frac{\sum_j z_j^2 e^2 \kappa}{\varepsilon} \int_0^1 \frac{\lambda^2}{1+\lambda\kappa a} \mathrm{d}\lambda \\ &\quad - \frac{\sum_j z_j^2 e^2}{\varepsilon a} (\kappa a)^2 \sum_{n=1}^{\infty} \frac{b^{2n}}{(2n+1)!\,(2n-1)} \int_0^1 \lambda^{4n+3} \mathrm{d}\lambda \\ &= -\frac{\sum_i n_i z_i^2 e^2}{3\varepsilon} \kappa\tau(\kappa a) \\ &\quad - \frac{\sum_i n_i z_i^2 e^2}{2\varepsilon a} (\kappa a)^2 \sum_{n=1}^{\infty} \frac{b^{2n}}{(2n+2)!\,(2n-1)} \end{aligned} \tag{18}$$

where

$$\tau(x) = \frac{3}{x^3} \left[\ln(1+x) - x + \frac{1}{2} x^2 \right]$$

The relation, $\sum_j z_j^2 e^2 = \sum_i n_i z_i^2 e^2$ (where i denotes the type of ion), is used in the last step of the calculation.

Contribution of Ion-Ion Interactions to the Chemical Potential of an Ion of Type i, μ_i^{el}. We have two ways for the derivation of μ_i^{el} as follows:

A) Derivation of μ_i^{el} from G^{el} (According to the Debye Charging Process). μ_i^{el} can be defined by the equation:

$$\mu_i^{\text{el}} = \frac{\partial G^{\text{el}}}{\partial n_i} \tag{19}$$

***

$$-\int_a^\infty \frac{\exp[-(2n+1)\kappa r]}{r} \mathrm{d}r = \ln[(2n+1)\kappa a] + \gamma - (2n+1)\kappa a + \frac{[(2n+1)\kappa a]^2}{2\cdot 2!} - \cdots\cdots + \frac{[-(2n+1)\kappa a]^p}{p\cdot p!} + \cdots\cdots$$

$$\int_a^\infty \frac{\exp[-(2n+1)\kappa r]}{r^m} \mathrm{d}r = \frac{\exp[-(2n+1)\kappa a]}{(m-1)a^{m-1}} \times \left\{ 1 + \frac{-(2n+1)\kappa a}{(m-2)} + \frac{[-(2n+1)\kappa a]^{m-2}}{(m-2)!} \right\} + \frac{[-(2n+1)\kappa a]^{m-1}}{(m-1)!\,a^{m-1}} \int_a^\infty \frac{\exp[-(2n+1)\kappa r]}{r} \mathrm{d}r$$

(when $m \geqq 2$)

† The $(\kappa a)^2$ term in Eq. (13) contributes only to the $(\kappa a)^3$ and higher-order terms, which are ignored in Eq. (16); therefore, the use of A_{DH} [Eq. (9)] instead of A [Eq. (13)] leads to the same result.

Using Eq. (18) and Eq. (5), Eq. (19) becomes:

$$\mu_i^{el} = -\frac{z_i^2e^2\kappa}{2\varepsilon(1+\kappa a)} - kT(\kappa a)^2\sum_{n=1}^{\infty}\frac{b^{2n+1}}{(2n+2)!\,(2n-1)} + \frac{kT(\partial V/\partial n_i)}{24\pi a^3}(\kappa a)^3\sigma(\kappa a) + \frac{kT(\partial V/\partial n_i)}{8\pi a^3}(\kappa a)^4\sum_{n=1}^{\infty}\frac{b^{2n}}{(2n+2)!\,(2n-1)} \quad (20)$$

where

$$\sigma(x) = \frac{3}{x^3}\left[-2\ln(1+x) + (1+x) - \frac{1}{1+x}\right] = 1 - 3\cdot\frac{2}{4}x + 3\cdot\frac{3}{5}x^2 - 3\cdot\frac{4}{6}x^3 + 3\cdot\frac{5}{7}x^4 - \cdots$$

The Debye-Hückel approximation corresponds to the first and third terms on the right-hand side of Eq. (20).[4,5] For a very dilute solution, the second term is more important than the third term.

B) Direct Derivation of μ_i^{el} (According to the Güntelberg Charging Process). μ_i^{el} is the electrostatic work done when a single ion of the i type is added to an assembly consisting of the rest of the ions and the solvent. If we disregard the work due to the volume change $(\partial V/\partial n_i)$, which is negligibly small compared with the other electric work in dilute solutions, μ_i^{el} can be evaluated as the electric work of increasing the charge of the particular ion from zero to z_ie in the solution.[4,5] Thus, according to Güntelberg, one has:

$$\mu_i^{el} = \int_0^1 z_ie\psi^{cloud}(a, \lambda z_i)\mathrm{d}\lambda \quad (21)$$

where $\psi^{cloud}(a, \lambda z_i)$ is given by Eq. (16), with the substitution of λz_i for z_j:

$$\psi^{cloud}(a, \lambda z_i) = -\frac{\lambda z_ie\kappa}{\varepsilon(1+\kappa a)} - (\kappa a)^2\frac{\lambda z_ie}{\varepsilon a}\sum_{n=1}^{\infty}\frac{\lambda^{2n}b^{2n}}{(2n+1)!\,(2n-1)}$$

By integration, Eq. (21) becomes:

$$\mu_i^{el} = -\frac{z_i^2e^2\kappa}{2\varepsilon(1+\kappa a)} - kT(\kappa a)^2\sum_{n=1}^{\infty}\frac{b^{2n+1}}{(2n+2)!\,(2n-1)} \quad (22)$$

This equation can also be derived from the Debye charging process, if $(\partial V/\partial n_i)$ is so small or if the solution is so dilute that the $(\kappa a)^3$ and $(\kappa a)^4$ terms can be ignored [see Eq. (20)].

A more involved expression for μ_i^{el} was derived by Gronwall *et al.*[2] from a more accurate solution of the Poisson-Boltzmann equation. However, these authors' expression has disadvantages in that it is too complicated to be applied to actual systems and involves the inconsistency that the two charging processes give different expressions for μ_i^{el}.[4,5] This inconcistency can be avoided only for very dilute solutions, where the correction terms derived by these authors can in practice be expressed by the first two terms of the progression in Eq. (22). Kaneko[3] made another correction to the Debye-Hückel theory. Although his expression for μ_i^{el} involves the same kind of problem as mentioned above, his expression is consistent with Eq. (22) for very dilute solutions. By advancing the approximation, we might obtain a more accurate result for solutions of moderate concentration, but the difficulties encountered by Gronwall *et al.* and Kaneko will remain. Therefore, no further efforts will be made to derive an expression for the μ_i^{el} of a closer approximation than Eq. (22). Although Eq. (22) in itself is valid only for solutions of sufficiently low concentrations, an attempt will be made to extend the application of Eq. (22) up to higher concentrations by connecting it with the concept of ion association.

Concept of Ion Association and the Derivation of the Ion-Association Constant. It is a common practice to attribute deviations from the Debye-Hückel theory to ion association. The ion-association equilibrium for a symmetrical electrolyte is expressed by:

	M	+	A	$\rightleftharpoons$	MA
concentration	$c(1-\alpha)$		$c(1-\alpha)$		$c\alpha$

(23)

where c denotes the concentration of the electrolyte and α the degree of association. When the ion-association equilibrium is assumed, the cation, M, and the anion, A, are usually considered to be free ions in the sense that they behave as predicted by the Debye-Hückel theory. The activity coefficients, y_M and y_A, of the ions, M and A, respectively are given by:

$$\ln y_M = \ln y_A = -\frac{z^2e^2\kappa}{2\varepsilon kT(1+\kappa a)} \quad (24)$$

Now, the chemical potential μ of the electrolyte is:

$$\mu = \mu_M^0 + \mu_A^0 + 2RT\ln c + RT\ln(y_My_A) + 2RT\ln(1-\alpha) \quad (25)$$

where μ_M^0 and μ_A^0 represent the chemical potentials of the two ionic species, M and A, respectively in the standard state. The contribution of ion-ion interactions to the chemical potential of the electrolyte, μ^{el}, is equal to the last two terms of Eq. (25). Using Eq. (24) and considering $\alpha \ll 1$ in very dilute solutions, one obtains:

$$\mu^{el} = RT\ln(y_My_A) + 2RT\ln(1-\alpha) \simeq -\frac{Nz^2e^2\kappa}{\varepsilon(1+\kappa a)} - 2RT\alpha \quad (26)$$

where N is the Avogadro number.

Since μ_i^{el} given by Eq. (22) is the contribution of ion-ion interactions to the chemical potential of an ion of the i type, μ_i^{el} multiplied by the total number of ions, $2N$, gives μ^{el}:

$$\mu^{el} = 2N\mu_i^{el} = -\frac{Nz^2e^2\kappa}{\varepsilon(1+\kappa a)} - 2RT(\kappa a)^2\sum_{n=1}^{\infty}\frac{b^{2n+1}}{(2n+2)!\,(2n-1)} \quad (27)$$

A comparison of Eqs. (26) and (27) leads to:

$$\alpha = (\kappa a)^2\sum_{n=1}^{\infty}\frac{b^{2n+1}}{(2n+2)!\,(2n-1)} \quad (28)$$

The equilibrium constant, K, of the ion-association reaction [Eq. (23)] is given by:

$$K = \frac{\alpha y_{MA}}{c(1-\alpha)^2y_My_A} \quad (29)$$

where y_{MA} is the activity coefficient of the ion-pair MA. In very dilute solutions, Eq. (29) can be written as:

$$K \simeq \frac{\alpha}{c} \tag{30}$$

By noticing that $c=1000n_1/NV$, $\kappa^2=8\pi n_1 z^2 s/V$ [Eq. (4)], and $b=z^2 s/a$ [Eq. (15)], Eqs. (30) and (28) give:

$$K = \frac{8\pi N a^3}{1000}\cdot\frac{b^{2n+2}}{(2n+2)!\,(2n-1)} \quad \text{when } b\to\infty \tag{31}$$

The sum of the progression terms is shown in Table 1 for a variety of b values and is compared with the corresponding value of $\exp(b)/2b$. Obviously, it approaches $\exp(b)/2b$ with an increase in the b value, so that the ion-association constant becomes:

$$K \simeq \frac{4\pi N a^3}{1000}\frac{\exp(b)}{b} \quad \text{when } b\to\infty \tag{32}$$

This is in agreement with the limiting case ($b\to\infty$) of the Bjerrum theory.[6,13]

Comparison of This Theory with Other Theories of Ion Association. In this work the Debye-Hückel treatment was extended and correction terms were derived on the assumption that the solution is very dilute. By using these results and by assuming the ion-association equilibrium, we obtained an expression for the ion-association constant [Eq. (31)] which includes no arbitrary parameters except for a. (The other parameter, b, is a function of a.) Although the same expression for K was previously derived by Ebeling[10] from the cluster theory, the much simpler method of derivation given above will make the thermodynamical understanding of the ion association easier and clearer.

We shall now compare our results with those of the Bjerrum theory,[6] in which the ion-association constant is given by:

$$K = \frac{4\pi N}{1000}(z^2 s)^3 Q(b) \tag{33}$$

$$Q(b) = \int_2^b \frac{\exp(x)}{x^4}\mathrm{d}x$$

In the derivation of this equation, Bjerrum assumed a so-called "critical distance of ion association,"

Table 2. Thermodynamic parameters for ion-pair formation

Parameter	Yokoyama-Yamatera, Ebeling, and Bjerrum ($b\to\infty$)	Fuoss	Denison-Ramsey
K	$\frac{4\pi Na^3}{1000}\cdot\frac{\exp(b)}{b}$	$\frac{4\pi Na^3}{3000}\exp(b)$	$\exp(b)$
$\Delta G°$	$-RT\left(\ln\frac{4\pi Na^3}{1000b}+b\right)$	$-RT\left(\ln\frac{4\pi Na^3}{3000}+b\right)$	$-bRT$
$\Delta S°$	$R\ln\frac{4\pi Na^3}{1000b}-bRT\frac{\partial\ln\varepsilon}{\partial T}$	$R\ln\frac{4\pi Na^3}{3000}-bRT\frac{\partial\ln\varepsilon}{\partial T}$	$-bRT\frac{\partial\ln\varepsilon}{\partial T}$
$\Delta H°$	$-bRT^2\left(\frac{\partial\ln\varepsilon}{\partial T}+\frac{1}{T}\right)$	$-bRT^2\left(\frac{\partial\ln\varepsilon}{\partial T}+\frac{1}{T}\right)$	$-bRT^2\left(\frac{\partial\ln\varepsilon}{\partial T}+\frac{1}{T}\right)$

$q(=z^2s/2)$, and regarded a pair of oppositely charged ions within the cririca distance of each other as an ion-pair, and an ion with no other ions within the critical distance, as a free ion.†† In the present theory, an ion-pair is treated as a chemical species of unknown geometrical configuration, and the ion-association constant is derived from a thermodynamical consideration of the ion-ion interaction. A comparison between $\rho(r)$, the time-averaged charge distribution around an ion due to the Boltzmann distribution law [Eq. (1)], and $\rho_{DH}(r)$, the charge distribution assumed by the Debye-Hückel theory, shows that the latter underestimates the charge distribution in the vicinity of an ion. The excess (negative) free energy arising from the interaction of the ion with the additional opposite charge in excess of $\rho_{DH}(r)$ is regarded as resulting from the ion-pair formation, assuming that a free ion is such an ion as is described by the Debye-Hückel theory [Eq. (24)].

For very large values of b ($b\to\infty$), both expressions, (31) and (33), can be approximated by Eq. (32). This probably results from the fact that an approximate classification of ions into free ions and contact ion-pairs can be made at large b values. With a decrease in the value of b, the discrepancy between the ion-association constants predicted by Eqs. (31) and (33) gradually increases. The greatest discrepancy is found at $b\leqq 2$ (*i.e.*, $a\geqq q$), where the Bjerrum theory gives $K=0$, while the present theory predicts a definite value for K. This situation is illustrated by Fig. 1, where log K for 2 : 2 electrolytes in aqueous solutions at 25.0 °C is plotted against a in accordance with Eqs. (31) and (33). According to our opinion that the ion association is a working hypothesis for interpreting the deviation of the behavior of actual electrolyte solutions from that predicted by the Debye-Hückel theory, the ion-association constants should have finite values even at $b\leqq 2$, corresponding to non-zero values of the second term on the right-hand side of Eq. (22).

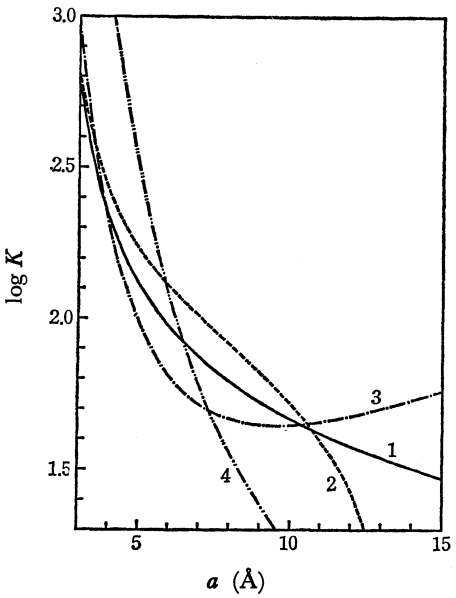

Fig. 1. Theoretical log K values for 2 : 2 electrolytes in aqueous solutions at 25.0 °C.
1: Present theory and Ebeling's theory (——)
2: Bjerrum's theory (— —)
3: Fuoss's theory (— · —)
4: Denison-Ramsey's theory (— · · —)

The Fuoss 1958 theory[9] is different from the Bjerrum theory in that a pair of ions in physical contact is meant by ion-pair. Although it gives a clearer idea of ion-pairs, it seems to be less adequate for complementing the Debye-Hückel theory. Fuoss's expression for the ion-association constant (Table 2) gives a minimum value of K at a certain value of a and then increasingly large values with an increase in a, as is shown in Fig. 1. For usual values of a, however, it gives K values not very much different from those predicted by the present theory. This seems to be a reason why the Fuoss theory gives a good explanation of the experimental results.

Denison and Ramsey[7] proposed the expression for the ion-association constant:

$$K=\exp(b)$$

†† Guggenheim[5,14] and other authors[15] introduced another parameter, d, as a variable critical distance or the distance defining the association, and made a generalization of Bjerrum's expression [Eq. (33)] using:

$$Q(b)=\int_{d/s}^{b}\frac{\exp(x)}{x^4}dx$$

Thus, they introduced flexibility in the critical distance of the Bjerrum theory. In addition, the parameter d can be considered to be the closest distance of approach of free ions and can be used in place of a in the Debye-Hückel expression (24).

in preference to the Fuoss theory. Their theory is based on the assumption of the Born thermodynamic cycle for the dissociation of an ion-pair, and is similar to the Fuoss theory[9] in that the contact ion-pair is assumed. However, the ion-association constants predicted by Denison-Ramsey's expression decrease with an increase in a, similarly to those predicted by the present theory.

The Gibbs free-energy change, $\Delta G°$, the enthalpy change, $\Delta H°$, and the entropy change, $\Delta S°$, for ion-pair formation were derived from the theoretical expressions for the ion-association constant; they are shown in Table 2, where Eq. (31) for the present and Ebeling's theories[10] and Eq. (33) for the Bjerrum theory[6] are approximated by the limiting equation (32). The thermodynamic parameters derived from Eq. (32) are not very different from those from Fuoss's and Denison-Ramsey's expressions; indeed, the formulas for $\Delta H°$ are identical with each other. (It should be noted that this remark is concerned with the limiting case of a large value of b.)†††

In a subsequent paper,[16] the ion-association constants predicted by the theories will be compared with the experimental results obtained from measurements of the electric conductivity and the osmotic coefficient.

The authors wish to thank the Ministry of Education for the financial support granted for this research. Thanks are also due to Nagoya University Computation Center for the use of a FACOM 230–60 computer.

††† At a large value of b, contact ion-pairs predominate over other kinds of ion-pairs in contributing to the chemical potential arising from ion-ion interactions. This seems to be the reason why all the theories give similar results in the limiting case.

Theoretical Calculations of the Raman Intensities by the Vibronic Method

Hiroyuki SHINODA

Department of Applied Chemistry, Faculty of Science and Engineering, Waseda University, Nishi-Ohkubo, Shinjuku-ku, Tokyo 160

(Received September 30, 1974)

The values of the transition moment of Raman scattering have been calculated according to the formula derived from the vibronic expansion approach. The calculations have been performed for the symmetry coordinates of several small molecules and for the normal vibrations of methane. The electronic wave functions were calculated by the CNDO/2-CI method. The calculated results are large in comparison with the experimental ones. The calculated Raman intensities for the symmetric stretching vibrations were almost all contributed by the term *A* in the vibronic expansion theory. From the calculated results for the normal vibrations of methane, it was found that the vibronic method used in this work leads to more appropriate values than those obtained from the polarizability theory which was used in the previous paper.

The development of the research technique using the laser Raman instrument has aided the discussion of the problem of the Raman intensity. Therefore there is now enhanced interest in the theoretical calculation of the Raman intensity. The theory of the Raman intensity has been discussed on the basis of the Kramers-Heisenberg dispersion formula.[1] Placzek[2] approximated the term of the transition moment of Raman scattering in this formula by the term of the polarizability derivative of the ground state in the nuclear coordinate, provided that the incident light is far away from the resonance region and the ground state of the molecule is not degenerate. There have since been several reports[3] in which the Raman intensities of H_2 and H_2^+ have been calculated according to Placzek's polarizability theory. Recently the calculations of the polarizability derivatives for small polyatomic molecules have been performed by several investigators, the electronic wave functions being evaluated by the LCAO-ASMO-SCF method.[4] By the use of the wave functions obtained from the finite perturbation method within the CNDO version, Hush and Williams[5] calculated the polarizabilities for some diatomic molecules and estimated their polarizability derivatives. They concluded that these polarizability derivatives are suitable for interpreting the factors determining the Raman transition probabilities within a valence orbital scheme. Yamada[6] calculated the polarizability derivatives with the symmetric stretching vibrations of four hydrocarbons, CH_4, C_2H_2, C_2H_4, and C_2H_6, the polarizabilities being calculated according to the expression derived from the second-order perturbation theory. She concluded that the CNDO calculations might useful in understanding the Raman intensities, although the calculated results were small in comparison with the experimental ones. Moreover the present author and Miyazaki[7] calculated the polarizability derivatives for several small molecules by the use of the formula derived from the time-dependent perturbation theory. The calculations described above were performed on the basis of Placzek's polarizability theory. On the other hand, there have been several reports[8–12] in which the theory of the Raman intensity has been discussed. In this work, then, the values of the Raman intensity have been calculated according to the formula derived from the vibronic expansion approach.[8–10] The electronic wave functions were evaluated by the CNDO/2-CI method. For the symmetric stretching vibrations of small molecules, the transition moments of Raman scattering were calculated in the approximation of the symmetry coordinate. Moreover, the intensities and the depolarization ratios of the Raman scattering for the normal vibrations of methane were calculated. The calculated results were discussed in comparison with the experimental ones and with the results obtained from the polarizability method, based on Placzek's theory, which was used in the previous work.[7]

Methods of Calculations

Raman Intensity. The vibronic expansion approach for the Raman intensity used in these calculations has been discussed in detail in Ref. 13. The total intensity of a Raman line after averaging all the molecular orientations is given as follows:

$$I_{mn} = \frac{2^3\pi}{3^2c^4} I_0\omega^4 \sum_{\rho,\sigma} |(\alpha_{\rho\sigma})_{mn}|^2, \tag{1}$$

where c is the velocity of light; I_0 is the intensity of the incident light; ω is the frequency of the scattered light; m is the initial state; n is the final state and $(\alpha_{\rho\sigma})_{mn}$ is the $\rho\sigma$-th component of the polarizability tensor for the $m\rightarrow n$ transition; the sum goes over $\rho=x,y,z$, and $\sigma=x,y,z$, which independently refer to the molecule fixed coordinate system. As has been described in Ref. 13, the general vibronic representation of $(\alpha_{\rho\sigma})_{mn}$ has been given as following equation, involving the terms A, B, and C:

$$(\alpha_{\rho\sigma})_{mn} = A + B + C, \tag{2}$$

$$A = \sum_{r\neq g}\sum_{i}\left[\frac{1}{E_{ri}-E_{gm}-E_0}+\frac{1}{E_{ri}-E_{gn}+E_0}\right] \times \langle g^0|R_\rho|r^0\rangle\langle r^0|R_\sigma|g^0\rangle\langle\psi_m^g|\psi_i^r\rangle\langle\psi_i^r|\psi_n^g\rangle, \tag{3}$$

$$B = \sum_{a}\sum_{r\neq g}\sum_{i}\sum_{s\neq r}\left[\left\{\frac{\langle g^0|R_\rho|r^0\rangle\langle r^0|h_a|s^0\rangle\langle s^0|R_\sigma|g^0\rangle}{(E_{ri}-E_{gm}-E_0)(\varepsilon_r^0-\varepsilon_s^0)} + \frac{\langle g^0|R_\sigma|r^0\rangle\langle r^0|h_a|s^0\rangle\langle s^0|R_\rho|g^0\rangle}{(E_{ri}-E_{gn}+E_0)(\varepsilon_r^0-\varepsilon_s^0)}\right\} \times\langle\psi_m^g|\psi_i^r\rangle\langle\psi_i^r|Q_a|\psi_n^g\rangle + \left\{\frac{\langle g^0|R_\rho|s^0\rangle\langle s^0|h_a|r^0\rangle\langle r^0|R_\sigma|g^0\rangle}{(E_{ri}-E_{gm}-E_0)(\varepsilon_r^0-\varepsilon_s^0)}\right.$$

$$+\frac{\langle g^0|R_\rho|s^0\rangle\langle s^0|h_a|r^0\rangle\langle r^0|R_\tau|g^0\rangle}{(E_{ri}-E_{gn}+E_0)(\varepsilon_r^0-\varepsilon_s^0)}\Big\}$$
$$\times\langle\psi_m^g|Q_a|\psi_i^r\rangle\langle\psi_i^r|\psi_n^g\rangle\Big], \quad (4)$$

and

$$C=\sum_a\sum_{r\neq g}\sum_i\sum_{s\neq g}\Big[\Big\{\frac{\langle g^0|h_a|s^0\rangle\langle s^0|R_\tau|r^0\rangle\langle r^0|R_\rho|g^0\rangle}{(E_{ri}-E_{gm}-E_0)(\varepsilon_g^0-\varepsilon_s^0)}+\frac{\langle g^0|h_a|s^0\rangle\langle s^0|R_\tau|r^0\rangle\langle r^0|R_\rho|g^0\rangle}{(E_{ri}-E_{gn}+E_0)(\varepsilon_g^0-\varepsilon_s^0)}\Big\}\times\langle\psi_m^g|Q_a|\psi_i^r\rangle\langle\psi_i^r|\psi_n^g\rangle$$
$$+\Big\{\frac{\langle g^0|R_\tau|r^0\rangle\langle r^0|R_\rho|s^0\rangle\langle s^0|h_a|g^0\rangle}{(E_{ri}-E_{gm}-E_0)(\varepsilon_g^0-\varepsilon_s^0)}+\frac{\langle g^0|R_\tau|r^0\rangle\langle r^0|R_\sigma|s^0\rangle\langle s^0|h_a|g^0\rangle}{(E_{ri}-E_{gn}+E_0)(\varepsilon_g^0-\varepsilon_s^0)}\Big\}\times\langle\psi_m^g|\psi_i^r\rangle\langle\psi_i^r|Q_a|\psi_n^g\rangle\Big], \quad (5)$$

where E_{gm} and E_{gn} are the energies of the initial vibronic state, $|g\rangle|\psi_m^g\rangle$, and the final vibronic state, $|g\rangle|\psi_n^g\rangle$, respectively; here $|g\rangle$ is the wave function of the electronic ground state, and $|\psi_m^g\rangle$ and $|\psi_n^g\rangle$ are the wave functions of the m-th and n-th vibrational states respectively in the electronic ground state; E_{ri} is the energy of the intermediate vibronic state, $|r\rangle|\psi_i^r\rangle$; here $|r\rangle$ is the wave function of the electronic excited state and $|\psi_i^r\rangle$ is the wave function of the i-th vibrational state in the $|r\rangle$ electronic state; E_0 is the energy of the incident light; ε_g^0 is the energy of the $|g^0\rangle$ electronic ground state; ε_r^0 and ε_s^0 are the energies of the $|r^0\rangle$ and $|s^0\rangle$ electronic states respectively; here the superscript 0 denotes the equilibrium nuclear position in the ground state; R_ρ and R_σ are the operators of the ρ- and σ-components respectively of the electronic dipole moment; Q_a is the normal coordinate of the a vibrational mode, and $h_a=(\partial H/\partial Q_a)$, the first-order vibronic coupling operator introduced initially by Herzberg and Teller.[14] Equations (3)—(5) can not be used directly in the calculation of $(\alpha_{\rho\sigma})_{mn}$ because we have meager knowledge of the vibrational wave function of a molecule in the electronic excited state. Therefore, we have to rearrange the equations in order to express $(\alpha_{\rho\sigma})_{mn}$ in a form without the vibrational wave functions. The expression of the term A is rearranged by Verlan's technique,[10] an expansion of the energy denominators around a fixed energy in a power series. When only the first-order terms in the expansion are retained, and when E_{gn} and E_{gm} are put approximately equal to ε_g^0, the term A is given by:

$$A=-\sum_a\sum_{r\neq g}\Big[\frac{\langle g^0|R_\sigma|r^0\rangle\langle r^0|h_a|r^0\rangle\langle r^0|R_\rho|g_0\rangle}{(\varepsilon_r^0-\varepsilon_g^0-E_0)^2}+\frac{\langle g^0|R_\sigma|r^0\rangle\langle r^0|h_a|r^0\rangle\langle r^0|R_\rho|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0+E_0)^2}\Big]\langle\psi_m^g|Q_a|\psi_n^g\rangle. \quad (6)$$

The terms B and C are simplified as follows by the use of the approximation that the energy, E_{ri}, is regarded as constant over i and put equl to ε_r^0:

$$B=-\sum_a\sum_r\sum_{s\neq r}\Big[\frac{\langle g^0|R_\sigma|r^0\rangle\langle r^0|h_a|s^0\rangle\langle s^0|R_\tau|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0-E_0)(\varepsilon_s^0-\varepsilon_g^0-E_0)}+\frac{\langle g^0|R_\rho|s^0\rangle\langle s^0|h_a|r^0\rangle\langle r^0|R_\sigma|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0+E_0)(\varepsilon_s^0-\varepsilon_g^0+E_0)}\Big]\langle\psi_m^g|Q_a|\psi_n^g\rangle \quad (7)$$

and

$$C=-\sum_a\sum_{r\neq g}\sum_{s\neq g}\Big[\frac{\langle g^0|h_a|s^0\rangle\langle s^0|R_\sigma|r^0\rangle\langle r^0|R_\rho|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0-E_0)(\varepsilon_s^0-\varepsilon_g^0)}+\frac{\langle g^0|h_a|s^0\rangle\langle s^0|R_\rho|r^0\rangle\langle r^0|R_\sigma|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0+E_0)(\varepsilon_s^0-\varepsilon_g^0)}+\frac{\langle g^0|R_\tau|r^0\rangle\langle r^0|R_\rho|s^0\rangle\langle s^0|h_a|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0-E_0)(\varepsilon_s^0-\varepsilon_g^0)}+\frac{\langle g^0|R_\rho|r^0\rangle\langle r^0|R_\sigma|s^0\rangle\langle s^0|h_a|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0+E_0)(\varepsilon_s^0-\varepsilon_g^0)}\Big]\langle\psi_m^g|Q_a|\psi_n^g\rangle. \quad (8)$$

By using the expressions in Eqs. (6)—(8), the equation for $(\alpha_{\rho\sigma})_{mn}$ can be written as:

$$(\alpha_{\rho\sigma})_{mn}=\sum_a(\alpha_{\rho\sigma}^a)'\langle\psi_m^g|Q_a|\psi_n^g\rangle, \quad (9)$$

where:

$$(\alpha_{\rho\sigma}^a)'=\sum_{r\neq g}\sum_{s\neq g}\Big[\frac{\langle g^0|R_\sigma|r^0\rangle\langle r^0|h_a|s^0\rangle\langle s^0|R_\rho|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0+E_0)(\varepsilon_s^0-\varepsilon_g^0-E_0)}+\frac{\langle g^0|R_\sigma|r^0\rangle\langle r^0|h_a|s^0\rangle\langle s^0|R_\rho|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0+E_0)(\varepsilon_s^0-\varepsilon_g^0+E_0)}+\frac{\langle g^0|h_a|s^0\rangle\langle s^0|R_\tau|r^0\rangle\langle r^0|R_\rho|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0-E_0)(\varepsilon_s^0-\varepsilon_g^0)}+\frac{\langle g^0|h_a|s^0\rangle\langle s^0|R_\rho|r^0\rangle\langle r^0|R_\sigma|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0+E_0)(\varepsilon_s^0-\varepsilon_g^0)}+\frac{\langle g^0|R_\sigma|r^0\rangle\langle r^0|R_\rho|s^0\rangle\langle s^0|h_a|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0-E_0)(\varepsilon_s^0-\varepsilon_g^0)}+\frac{\langle g^0|R_\rho|r^0\rangle\langle r^0|R_\sigma|s^0\rangle\langle s^0|h_a|g^0\rangle}{(\varepsilon_r^0-\varepsilon_g^0+E_0)(\varepsilon_s^0-\varepsilon_g^0)}\Big]$$
$$-2\sum_{r\neq g}\frac{1}{(\varepsilon_r^0-\varepsilon_g^0-E_0)(\varepsilon_r^0-\varepsilon_g^0-E_0)}\times[\langle g^0|R_\tau|r^0\rangle\langle r^0|h_a|g^0\rangle\langle g^0|R_\rho|g^0\rangle+\langle g^0|R_\tau|g^0\rangle\langle g^0|h_a|r^0\rangle\langle r^0|R_\rho|g^0\rangle]. \quad (10)$$

In the above expression, all the terms have been multiplied by (-1). $(\alpha_{\rho\sigma}^a)'$ corresponds to the polarizability derivative $(\partial\alpha_{\rho\sigma}/\partial Q_a)_0$ in Placzek's theory and will hereafter be called the $\rho\sigma$-component of the Raman tensor for a normal vibration, a.

Electronic Wave Functions. One-electron wave functions, φ_n's, were obtained by the CNDO/2 method, an approximate self-consistent molecular orbital theory, proposed by Pople *et al.*[4] The wave function of the ground state, $|g^0\rangle$, was given by an antisymmetrized product with a closed-shell structure, Φ_0. The wave functions of the excited states, $|r^0\rangle$ and $|s^0\rangle$, in Eq. (10) were described by a linear combination of singly-excited configurations, $\Phi_{(i-k)}$'s.[15] By the use of the coefficients, $C_{(i-k)}^r$'s, of the configurations, the integrals in Eq. (10) could be rewritten as follows:

$$\langle g^0|H'|g^0\rangle=\langle\Phi_0|H'|\Phi_0\rangle, \quad (11)$$

$$\langle g^0|H'|r^0\rangle=\sum_i^{\text{occ}}\sum_k^{\text{unocc}}C_{(i-k)}^r\langle\Phi_0|H'|\Phi_{(i-k)}\rangle, \quad (12)$$

and

$$\langle r^0|H'|s^0\rangle = \sum_{i,j}^{occ}\sum_{k,l}^{unocc} C^r_{(i-k)}C^s_{(j-l)}\langle\Phi_{(i-k)}|H'|\Phi_{(j-l)}\rangle, \quad (13)$$

where H' denotes R_ρ, R_σ, or h_a. Since H' is defined as the sum of one-electron operators, $H'=\sum f$; the integrals on the right-hand sides of Eqs. (11)—(13) can thus be described by the integral terms with the one-electron wave functions:

$$\langle\Phi_0|H'|\Phi_0\rangle = 2\sum_{n}^{occ}\langle\varphi_n|f|\varphi_n\rangle, \quad (14)$$

$$\langle\Phi_0|H'|\Phi_{(i-k)}\rangle = \sqrt{2}\langle\varphi_i|f|\varphi_k\rangle, \quad (15)$$

and

$$\langle\Phi_{(i-k)}|H'|\Phi_{(j-l)}\rangle = \delta_{ij}\delta_{kl}\,2\sum_{n}^{occ}\langle\varphi_n|f|\varphi_n\rangle + \delta_{ij}\langle\varphi_k|f|\varphi_l\rangle - \delta_{kl}\langle\varphi_i|f|\varphi_j\rangle, \quad (16)$$

where the sums in the above equations go over the occupied orbitals in the ground state. When H' is R_ρ or R_σ, the integrals, $\langle\varphi_i|f|\varphi_k\rangle$'s, are calculated by the method described in a previous report.[16] When H' is h_a, the integrals are expressed as follows:[17]

$$\langle\varphi_i|f|\varphi_k\rangle = \sum_{\beta}\sum_{\mu}\sum_{\nu} e^2Z_\beta d_{i\mu}d_{k\nu}\left(\frac{\partial \boldsymbol{r}_\beta}{\partial Q_a}\right)\cdot\left\langle\chi_\mu\left|\frac{\boldsymbol{r}_{i\beta}}{r^3_{i\beta}}\right|\chi_\nu\right\rangle, \quad (17)$$

where e is the charge of the electron; Z_β is the core charge of the β atom; $\boldsymbol{r}_{i\beta}$ is the distance vector of the electron, i, from the β atom; $r_{i\beta}$ is the norm of the vector; $\boldsymbol{r}_\beta$ is the position vector of the β atom, and $d_{k\nu}$ is the coefficient of the atomic orbital, χ_ν, in the molecular orbital, φ_k. $(\partial\boldsymbol{r}_\beta/\partial Q_a)$ in Eq. (17) indicates the elements of the L_x matrix obtained by the usual **GF** method. In this work, the integrals on the right-hand side of Eq. (17) were calculated with the approximation that the integrals were neglected unless the atomic orbitals, χ_μ and χ_ν, belong to the same atom. This is consistent with the CNDO version used to obtain electronic wave functions. When χ_μ and χ_ν belong to an A atom which differs from the β atom, the integral is approximated by the following expression:

$$\left\langle\chi_\mu\left|\frac{\boldsymbol{r}_{i\beta}}{r^3_{i\beta}}\right|\chi_\nu\right\rangle = \delta_{\mu\nu}\frac{\boldsymbol{r}_{A\beta}}{r^3_{A\beta}}, \quad (18)$$

where $r_{A\beta}$ is the norm of the distance vector, $\boldsymbol{r}_{A\beta}$. When χ_μ and χ_ν belong to the β atom, the integration is performed rigorously.

Polarizability Method. According to Method I, described in a previous paper,[16] the polarizabilities were calculated for the molecule distorted in the manner dictated by the normal coordinate. The values of the Raman tensor were obtained by fitting the calculated polarizabilities to a cubic function with respect to the normal coordinate and by taking the first derivative at the equilibrium position.

Results and Discussions

In the calculations according to the vibronic method, the wavelength of the incident light was fixed at 5145 Å, which is the wavelength of an Ar^+ laser line, but in the calculation of the polarizabilities in the polarizability method, the energy of the incident light was taken to be zero.

Symmetric Stretching Vibrations: The symmetric stretching coordinates discussed in this work were the C–H and C–C vibrations of acetylene, ethylene, and ethane, the C–H vibration of methane, and the N–H vibration of ammonia. Since the Raman tensor with respect to symmetry coordinate, S_a's, were calculated with reference to the symmetric stretching modes, $(\partial\boldsymbol{r}_\beta/\partial Q_a)$ in Eq. (17) had to be replaced by $(\partial\boldsymbol{r}_\beta/\partial S_a)$, which was approximated as will be described below. For the C–H and N–H stretching modes, $(\partial\boldsymbol{r}_\beta/\partial S_a)$ was zero unless β denoted the hydrogen atom, while for C–C stretching modes $(\partial\boldsymbol{r}_\beta/\partial S_a)$ was zero unless β denoted the carbon atom. The vector $(\partial\boldsymbol{r}_\beta/\partial S_a)$ had a direction along the bond referring to the symmetry coordinate involving the displacement of the β atom.

The calculated results of $\bar{\alpha}_a'$ and $(\gamma_a')^2$ are listed in Table 1, where $\bar{\alpha}_a'=[(\partial\alpha_{xx}/\partial S_a)+(\partial\alpha_{yy}/\partial S_a)+(\partial\alpha_{zz}/\partial S_a)]/3$ and $(\gamma_a')^2=[\{(\partial\alpha_{xx}/\partial S_a)-(\partial\alpha_{yy}/\partial S_a)\}^2+\{(\partial\alpha_{yy}/\partial S_a)-(\partial\alpha_{zz}/\partial S_a)\}^2+\{(\partial\alpha_{zz}/\partial S_a)-(\partial\alpha_{xx}/\partial S_a)\}^2+6\{(\partial\alpha_{xy}/\partial S_a)^2+(\partial\alpha_{yz}/\partial S_a)^2+(\partial\alpha_{zx}/\partial S_a)^2\}]/2$. In the table, the calculated results in the polarizability method and the experimental results are also given. It is found that the values of $\bar{\alpha}'$ calculated by the vibronic method are 2—6 times larger than the experimental ones. The values in the parentheses in Table 1 are those obtained by the calculation using only the term A in Eq. (6). It is indicated that the Raman tensor for the symmetric stretching vibration is almost entirely explained by the term A. This fact supports the conclusion suggested by Verlan.[10] Practically,

the calculated values of the terms B and C were very small.

The anisotropy term $(\gamma_a')^2$ is an effective factor for the theoretical calculation of a Raman intensity and is closely related to the depolarization ratio, ρ_n; $\rho_n = 6(\gamma_a')^2/[45(\bar{\alpha}_a')^2+7(\gamma_a')^2]$. In comparing the values of ρ_n calculated from the Raman tensor with respect to the symmetry coordinates, it is found that the values of ρ_n obtained from the vibronic method are smaller than those obtained from the polarizability method, with the exception of the C–H stretching in ethylene. In order to discuss the magnitude of $(\gamma_a')^2$ relative to the values of $\bar{\alpha}_a'$ in the calculated results, these values were compared with the experimental results. From the measurement by Schrötter and Bernstein,[18] the depolarization ratios of the Raman spectrum of acetylene are 0.27 and 0.06 for the C–H and C–C stretching vibrations respectively. The corresponding values are 0.310 and 0.308 in the vibronic method, and 0.445 and 0.383 in the polarizability method. It may be said that the theoretical calculations lead to an overestimation of the anisotropy terms in comparison with the magnitudes of $\bar{\alpha}'$.

Normal Vibrations of Methane: The normal modes were obtained by the usual **GF** method, using the **F** matrix reported by Shimanouchi *et al.*[19] The L_x matrix elements used in the calculations are given in Table 2. The calculated results of the Raman intensities, I/I_0, and the depolarization ratios, ρ_n, are listed in Table 3. In the table, the results calculated by the polarizability method and the experimental results are also listed. At a glance it may be seen that the results of the vibronic method show an entirely different tendency with respect to the relative intensities in comparison with the results calculated from the polarizability method. In the results of the vibronic method, the Raman intensity of the ν_1 vibration is strong, while those of the other vibrations are

nearly equal to zero. In the results of the polarizability method, however, the Raman intensity of the ν_2 vibration is larger than that of the ν_1 vibration. In the experiments[20-22] a ν_1 vibration with a very strong intensity and ν_2 and ν_3 vibrations with weak intensities are observed. Moreover, for the depolarization ratio of the ν_2 vibration the two methods give different values. The values of the elements of the Raman tensors calculated in the vibronic method are listed in Table 4. The values for the ν_2 vibration are very small; they may be regarded as zero in comparison with those for the other vibrations. For the ν_3 and ν_4 vibrations, the values of the diagonal elements are zero. However the values from the terms A and B are not zero, and the absolute value of one element, for example $(\alpha_{xx})'$, from the term A is equal to that of the corresponding element from the term B, and their signs are opposite. The values of the $\bar{\alpha}'$ calculated by the use of only the term A or the term B are zero. Then, the depolarization ratio calculated by the use of one term, A, B, or C, is the same value, 0.857, as that calculated with the total values of the elements. This is not the case for the ν_2 vibration. The Raman tensors calculated in the polarizability method are shown in Table 5. The values of the three diagonal elements of the Raman tensor for the

ν_2 vibration are different from one another. This contradicts the conclusion obtained from the group-theoretical consideration, as indicated in the review by Loudon.[23]

In comparison with the experimental results, the results of methane calculated by the vibronic method will now be discussed in detail. Schrötter and Bernstein[18] determined the Raman intensity by the use of the rotational Raman line, $J=1\rightarrow3$, of hydrogen as the standard. From their experimental results, the Raman intensity of the ν_1 vibration is 23.6×10^{-30} cm^2, this value being, in magnitude, about one-fourth of the calculated result. Furthermore, the Raman line from the ν_2 and ν_3 vibrations are also observed to have weak intensities. However, Dickinson *et al.*[21] reported, from the experimental results, that the relative intensity of the ν_3 vibration is 5 in comparison with the value of 20 for the intensity of the ν_1 vibration. On the other hand, this calculation showed that the Raman intensity of ν_4 is stronger than those of the ν_2 and ν_3 vibrations, although their intensities are so small as to be unobserved. The experimental results for the ν_2 and ν_3 vibrations may be explained by a theoretical calculation involving factors which are not considered in this work.

Conclusions

For the symmetric stretching vibrations of several small molecules and the normal vibrations of methane, the theoretical calculations of Raman tensors were performed in the vibronic method. From the results, the following conclusions can be drawn:

(a) Verlan's conclusion that the intensity for symmetric stretching vibration is almost entirely contributed by the term A is confirmed.

(b) The calculated intensities for the symmetric stretching vibrations are large in comparison with the experimental values.

From a comparison of the results for the normal coordinates of methane in the vibronic method with those in the polarizability method:

(c) The vibronic method is more suitable for theoretical calculations of the Raman intensity than is the polarizability method.

I would like to thank Professor Tomoo Miyazaki for his helpful advice and for his critical reading of the manuscript.

(Received January 16, 1975)

Solubility of tris(1,10-phenanthroline)iron(II) perchlorate was determined at 25 °C by spectrophotometry in aqueous solutions of sodium halides, sulfate, acetate, and trichloroacetate up to ionic strength of 0.5. It was found that the solubility is higher in the presence of water-structure breaking anions but is lower in the presence of water-structure making anions than is expected from the change in activity coefficients with ionic strength. This was interpreted in terms of compatibility and incompatibility of the influence of the complex cation on the water structure with that of added anions, and the hydrophobic nature of the complex cation was noted.

According to Gurney[1] or Frank,[2] ions in aqueous solution are classified into three groups on the basis of their interaction with water.[1-4] The first group consists of so-called electrostrictive water-structure makers, which attract surrounding water molecules so tightly through ion-dipole interaction that their co-spheres[1] cause a local increase in the viscosity. Typical examples are provided by Li^+, F^-, SO_4^{2-}, and other highly charged ions. The second group consists of water-structure breakers, which render the motion of water molecules more vivid around them than that of bulk ones (so-called negative hydration[5]). K^+, Rb^+, I^-, and other ions with low charge-to-radius ratio belong to this group and lead to a decrease in the viscosity of the solution. The last one consists of hydrophobic water-structure makers and is quite unique in that, when they are dissolved in water, though hardly soluble in general, water-water interaction is strengthened, *i.e.*, "iceberg" is formed in the vicinity of their hydrophobic parts (hydration of the second kind[6] or hydrophobic hydration) and sometimes so-called hydrophobic bonding[7] may take place. This behavior is characteristic of aqueous solutions and has attracted the attention of biochemists in recent years. Tetraalkylammonium homologues[8] and some organic ions including surfactants belong to this group.

As for coordination compounds, however, the above classification has not been well established,[3] though they can be permitted to have a variety of physical and chemical properties by substituting metal ions or coordinated ligands. In a series of our study on the solubility of transition metal complexes, we intend to focus our attention on the nature of their interaction with water and also with coexisting ions and to try to classify them into some groups.

Recently Steigman and Dobrow,[9] and Desnoyers *et al.*[4,10] succeeded in interpreting most excess thermodynamic functions of aqueous electrolyte solutions on the following assumptions: ions belonging to the first group are antagonistic with those belonging to the second and third groups with respect to their influence on the water structure, while those belonging to the second and third groups are cooperative with each other. On the basis of the above assumptions, it follows that electrolytes composed of cooperative ion pairs tend to have lower activity coefficients in water and the reverse holds for antagonistic pairs.[2,11] This phenomenon is often called a mutual or structural salting-in and -out, respectively and has been recently discussed quantitatively by Friedman *et al.*[12]

In our recent study on the Pfeiffer effect,[13] it was proposed that $[Zn(phen)_3]^{2+}$ (phen=1,10-phenanthroline) is classified into the third group in spite of its relatively high charge. However, the complex is so labile that it is not easy to examine its hydrophobic nature by usual techniques such as electrolytic conductance or viscosity measurements.[14] Since $[Zn(phen)_3]^{2+}$ and $[Fe(phen)_3]^{2+}$ are closely matched in many respects, particularly with regard to their interaction with water in which we are interested and the latter is extremely stable, the solubility of $[Fe(phen)_3](ClO_4)_2$ was measured in place of $[Zn(phen)_3](ClO_4)_2$ in various aqueous salt solutions as a function of the total ionic strength of these solutions. These data are expected to provide a valuable information on the hydrophobic nature of $[Fe(phen)_3]^{2+}$ as well as $[Zn(phen)_3]^{2+}$ if the concept of compatibility and incompatibility of the water structure influenced by ions,[9,10] is suitably applied.

Experimental

Preparation. Tris(1,10-phenanthroline)iron(II) perchlorate monohydrate was prepared by dissolving Mohr's salt, $FeSO_4(NH_4)_2SO_4 \cdot 6H_2O$ and 1,10-phenanthroline monohydrate in a mole ratio of 1 : 3 in hot water containing *ca.* 10% of methanol, followed by adding sodium perchlorate monohydrate. The resulting crystal was washed with water and recrystallized from water. Its purity was checked by elemental analysis.

Reagents. Added salts were sodium halides, sulfate, acetate, and trichloroacetate, all of which were of reagent grade and used without further purification.

Procedure. Solution equilibration was attained in a small glass bottle (100 ml) dipped in a water bath kept at 25±0.1 °C with a mercury-in-glass thermoregulator. The salt solution to which solid $[Fe(phen)_3](ClO_4)_2$ had been added, was continuously stirred in the water bath by a magnetic stirrer for 5 to 6 hours. Then an aliquot of the solution was pippetted out through a glass filter and was diluted appropriately in a volumetric flask with water. After 1 or 2 hours, an aliquot of the same solution was again pippetted out and diluted as before. $[Fe(phen)_3]^{2+}$ in the two diluted solutions was determined with a Shimadzu UV-200 spectrophotometer by use of its charge-transfer band with the maximum absorption at 510 nm. When the solution equilibration proved incomplete within experimental error, a similar procedure was done again after 1 to 2 hours. The time taken to reach solution equilibrium was usually from 5 to 6 hours. The molar absorption coefficient of $[Fe(phen)_3]^{2+}$

at 510 nm was 11100 and was not affected at all by added salts.

Results and Discussion

If K is defined as a thermodynamic solubility product[15] for $[Fe(phen)_3](ClO_4)_2$, K in water is expressed as

$$K = [[Fe(phen)_3]^{2+}][ClO_4^-]^2 f_{\pm(0)}{}^3 = 4S_{(0)}{}^3 f_{\pm(0)}{}^3 \quad (1)$$

where S and $f_\pm$ denote the solubility in mol/l and the mean activity coefficient of the complex salt, respectively, and the subscript (0) refers to water. In salt solutions, on the other hand, K is given by

$$K = 4S^3 f_\pm{}^3 \quad (2)$$

In the above two equations, ion association is ignored on the ground that $S_{(0)}$ is so small (8.99×10^{-4} mol/l) that there is little contribution from ion association to the solubility when the amount of added salts is small and if any, it does not differ greatly as long as halide ions are concerned[16] (the Bjerrum's critical distance[17] amounts to 7.1 Å for halides). From the identity of Eq. (1) with Eq. (2), it follows that

$$S/S_{(0)} = f_{\pm(0)}/f_\pm \quad (3)$$

If the Debye-Hückel approximation[18] for activity coefficients is employed, Eq. (3) is rearranged to

$$\log S/S_{(0)} = 1.018[I^{1/2}/(1+0.329aI^{1/2}) - I_{(0)}^{1/2}/(1+0.329aI_{(0)}^{1/2})] \quad (4)$$

at 25 °C, where I denotes the total ionic strength of the salt solution in which $[Fe(phen)_3](ClO_4)_2$ is dissolved and a the distance of closest approach in Å. Equation (4) suggests that $S/S_{(0)}$ should be greater than unity, increase with I, and should not be dependent on the kind of added salts.

Figure 1 shows the ratios $S/S_{(0)}$ as a function of square root of I and clearly indicates that they are in fact greater than unity but differ considerably from salt to salt added when they are compared at the same ionic strength. Since the cation (sodium ion) is common to all salt solutions and the concentration of ClO_4^- is much lower than that of added salts, the differences in $S/S_{(0)}$ are attributed to these added anions and the co-sphere of $[Fe(phen)_3]^{2+}$ overlaps predominantly with those of added anions rather than that of ClO_4^-. As a result, it can be concluded to a good approximation that the increase in $S/S_{(0)}$ with I depends on whether the complex cation is co-operative or antagonistic with added anions with regard to their influence on the water structure. In Fig. 1 are also drawn the two curves estimated by Eq. (4) with a=8 and 9 Å, which are chosen because the radius of $[Fe(phen)_3]^{2+}$ in water has been determined to be 6.5 and 5.3 Å by viscosity[19] and conductance[16] measurements, respectively and that of ClO_4^- to be 2.92 Å.[20]

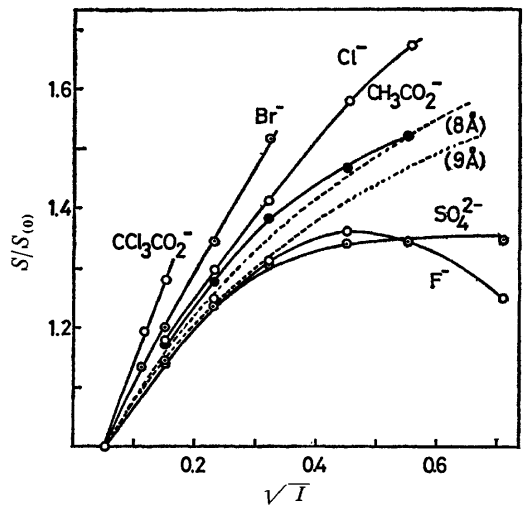

Fig. 1. Dependence of the solubility ratio $S/S_{(0)}$ on square root of ionic strength I. Dotted lines represent the theoretical values estimated by Eq. (4).

A close inspection of Fig. 1 indicates that the deviations of $S/S_{(0)}$ from theoretically estimated values are observed even at low salt concentrations at which the Debye-Hückel approximation is taken valid[18] and that the order of increasing ratio $S/S_{(0)}$ is $CCl_3COO^- > Br^- > Cl^- > CH_3COO^- > F^- \sim SO_4^{2-}$, which is in good agreement with the order of increasing water-structure breaking power of anions[9] (NaI could not be examined because of the precipitation of $[Fe(phen)_3]I_2$). Therefore, it is certain that $[Fe(phen)_3]^{2+}$ is cooperative with structure breakers, *i.e.*, it belongs to the third group. It is probably due to the ion association between $[Fe(phen)_3]^{2+}$ and SO_4^{2-} that the curve for sulfate tends to level off at high salt concentration, since the Bjerrum's critical distance amounts to 14.3 Å in this case (the association constant of $[Ru(phen)_3]SO_4$ in water has been reported to be 47 by Yokoyama and Yamatera[21]). Otherwise, the ratio should begin to decrease like that for fluoride at high salt concentrations.

The authors would like to express their deep gratitude to Prof. Y. Yamamoto, Hiroshima University, for helpful discussions.

The Solvent Extraction-Polarographic Determination of Cadmium(II) as the Tris(2,2′-bipyridine)iron(II) Tetraiodocadmate(II) Complex*

Kiyoshi Hasebe, Tsukasa Ohtsuki, and Tomihito Kambara

Department of Chemistry, Faculty of Science, Hokkaido University, Kita-ku, Sapporo 060

(Received March 18, 1974)

A new method for the solvent extraction-polarographic determination of cadmium has been proposed. The quaternary complex formed by the tris(2,2′-bipyridine)iron(II) cation and the tetraiodocadmate(II) anion can be readily extracted into benzyl alcohol. The extracted complex shows a well-defined reduction wave in the ternary electrolyte-solvent mixture, composed of benzyl alcohol, an aqueous electrolyte solution, and methyl cellosolve. The available range of the present method covers from 5.7×10^{-6} to 91.4×10^{-6} M of cadmium(II) in the aqueous phase. The optimum pH range for extraction is 3—9, and the extracted species is stable in the ternary solvent mixture for 5 hr. Zinc (II), bromide, and chloride ions do not interfere, but copper (II), mercury(II), and iron(III) do interfere.

Among the several methods devised for the determination of cadmium, especially the spectrophotometric method using dithizone[1] and the polarographic method,[2] are the most useful. 2,2′-Bipyridine (bpy) and related compounds are well known as remarkably useful colorimetric reagents for analytical use.[3] As to the determination of cadmium, for example, a spectrophotometric determination employing the ion-pair formation of the tetraiodocadmate(II) anion with the tris(2,2′-bipyridine)iron(II) cation has been reported.[4] However, this method makes it necessary to pay careful attention to the absorbance of the reagent blank solution. Fujinaga *et al.*[5] and the present authors[6,7] have already reported a polarography in a ternary solvent mixture consisting of chloroform, water, and methyl cellosolve (MCS). Recently, Kitagawa and Ichimura[8] have reported an interesting extraction-polarography of an extracted complex of tris(acetylacetonato)iron(III) and similar complexes in the methyl iso-butyl ketone. These methods are very useful since the concentration and separation can be achieved simultaneously. In the present paper, the solvent extraction-polarographic method is applied to the quaternary complex of tris(2,2′-bipyridine)iron(II) tetraiodocadmate(II) $[Fe(bpy)_3][CdI_4]$.

Experimental

Reagents. *2,2′-Bipyridine solution*: An aqueous 2×10^{-2} M solution was prepared.

Standard Iron(II) Solution: Mohr's salt was dissolved in water containing a small amount of sulfuric acid to give a 2×10^{-2} M solution. This was then standardized by EDTA titration.

Standard Cadmium(II) Solution: Guaranteed cadmium nitrate (Wako Chemicals) was dissolved in water containing sufficient nitric acid to give a 2×10^{-3} M solution. This was then standardized by EDTA titration with Eriochrome Black T as the indicator. This stock solution was used after accurate dilution.

Buffer Solutions: The pH was adjusted with the following solutions: hydrochloric acid (pH 1—3), acetic acid-sodium acetate (pH 3—6), and potassium dihydrogen phosphate-sodium borate (pH 9—10).

All the reagents used were of an analytical reagent grade.

Apparatus. A Yanagimoto polarograph, model PA-102, was used for recording the DC and AC polarograms. The DME had these characteristics: $m=1.88$ mg s^{-1} in pure water and $t=4.96$ s in the electrolysis solution at open circuit at $h=39$ cm. The experiments were carried out by using a cell with a mercury pool or a modified H-type cell with an SCE in a water bath thermostated at (20+0.1) °C. Before each polarographic measurement, all the solutions were deaerated by bubbling through for 15 min nitrogen gas which has been presaturated with the same solution as that used in the measurements.

A Hitachi-Horiba glass electrode pH meter, model F-5, was used. An Iwaki shaker, model KM, was used for the shaking.

Results and Discussion

Established Procedure. Twenty millilitres of a 2×10^{-2} M 2,2′-bipyridine solution was pipetted into a 100-ml separatory funnel. Five millilitres of a 3 M iron(II) solution, 3 ml of a 3 M sodium acetate solution, 1 ml of a 3 M potassium iodide solution and the sample solution containing the cadmium ion were pipetted into the funnel in that sequence. After adjusting the volume to 35 ml with water, the solution was let stand for about 2 min. It was then shaken with 10 ml of benzyl alcohol for 3 min. After the separation of the two phases, a 6-ml portion of the extract was pipetted into a 20-ml volumetric flask, and then 6 ml of aqueous 1 M potassium iodide was added as a supporting electrolyte. The flask was filled up to the mark with MCS. After deaeration with nitrogen gas, a polarogram was recorded.

Choice of Extracting Solvent. Five of the extracting solvents examined—namely, nitrobenzene, methyl *iso*-butyl ketone, 1, 2-dichloroethane, cyclohexanone, and chloroform, all of which have a relatively large dielectric constant,—extracted only a small amount of cadmium (II) in the form of the quaternary complex of $[Fe(bpy)_3CdI_4]$, and some of the above-mentioned solvents also caused a film at the interface between the two phases. Therefore, the above solvents were not suitable. When benzyl alcohol was used, however, tetraiodocadmate (II) was extracted quantitatively as the quaternary complex with the tris(2, 2′-bipyridine)iron(II) complex. Benzyl alcohol was, therefore, used in the present work.

Extractability. In order to confirm that tetraiodocadmate(II) anions were quantitatively extracted into benzyl alcohol as a quaternary complex, hydrogen

* Presented at the 19th Annual Meeting of the Polarographic Society of Japan, Sapporo, October, 1973.

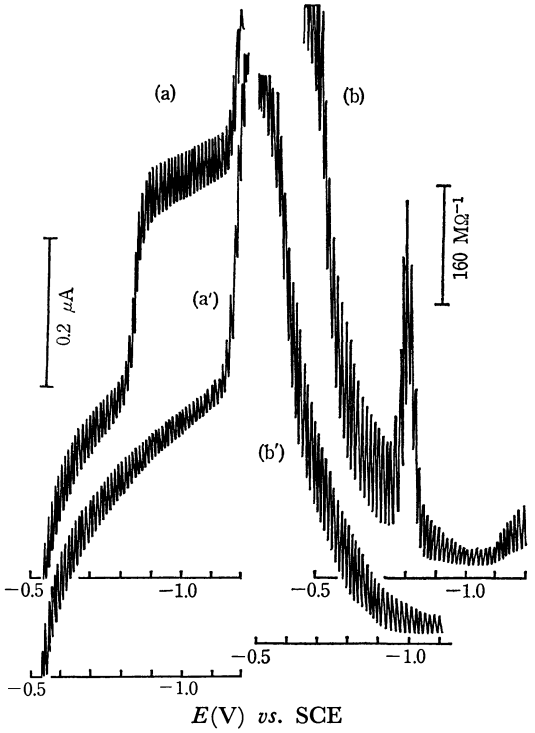

Fig. 1. The polarograms of the quaternary complex composed of tetraiodocadmate(II) anion with tris(2,2'-bipyridine)iron(II) cation into the ternary solvent mixture.
Concentration of iodide ion in aq. phase: $[I^-]_w = 8.58 \times 10^{-2}$ M, Concentration of bpy in aq phase: $[bpy]_w = 1.14 \times 10^{-2}$ M, Concentration of iron(II) in aq. phase: $[Fe(II)]_w = 2.86 \times 10^{-3}$ M, pH 7.5, Volume of aq. phase $V_w = 35$ ml, Volume of org. phase $V_0 = 10$ ml, (a) and (b): 6.86×10^{-5} M of Cadmium(II) in aq. phase, (a') and (b'): Without cadmium(II), (a) and (a'): DC polarogram, (b) and (b'): AC Polarogram.

sulfide was bubbled into the aqueous phase after the extraction. No yellow precipitate was formed. Upon carrying out a second extraction, cadmium could not be found in the aqueous phase; *i.e.*, the cadmium has been removed completely from the aqueous phase by a single extraction.

Polarograms of the Extracted Quaternary Complex in the Ternary Solvent Mixture. The polarograms obtained by the use of the established procedure are shown in Fig. 1. The half-wave potential of the complex was about −0.80 V *vs.* SCE. As may be seen from Fig. 1, no DC polarographic wave and no AC peak appeared in the absence of cadmium.

Effect of pH. The effect of the pH on the extraction of the quaternary complex was studied with several buffer solutions and sodium acetate. An approximately constant DC wave height and AC peak height were obtained between pH 3.72 and 9.39. Thus, the pH of the aqueous solution was adjusted to about 7 by adding sodium acetate solution, according to the Kotsuji method.[4]

Effect of Shaking Time and Standing Time. A constant DC wave height, or the corresponding AC peak height, was obtained by shaking for more than

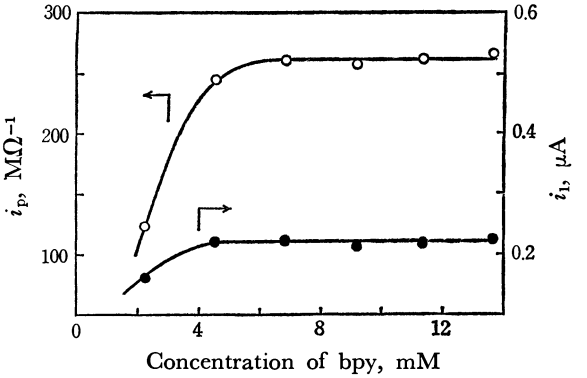

Fig. 2. Effect of 2,2'-bipyridine concentration on the extraction of the quaternary complex, $[Fe(bpy)_3CdI_4]$. ○: AC peak height, ●: DC wave height, $[Cd(II)]_w = 5.72 \times 10^{-5}$ M. Other conditions are the same as in Fig. 1.

1 min; we chose the shaking time of 3 min. The extracted species was very stable, its polarographic DC wave height in the ternary solvent mixture showed no change for 5 hours, and the corresponding AC peak height also remained unchanged.

Effect of the 2,2'-Bipyridine Concentration. With the concentrations of cadmium(II), iodide ion, and iron(II) kept constant, various amounts of 2,2'-bipyridine were added, after which the extraction was carried out according to the above procedure. The DC wave height, or the corresponding AC peak height of the ternary mixture, was found to be constant and at its maximum when the mole ratio of bipyridine to cadmium(II) was in the range from 100 to 250, as is shown in Fig. 2.

Effect of the Iodide and Iron(II) Concentrations. The DC wave height and the corresponding AC peak height in the ternary solvent mixture consisting of the extract, aqueous electrolyte, and MCS were found to be constant when the concentrations of iodide and iron(II) ions in the aqueous phase were higher than 4×10^{-2} M and 3×10^{-3} M respectively. Figure 3 shows the effect of the iron(II) concentration on the DC polarographic wave height, and the corresponding AC peak height. When the concentration of iron(II) was lower than

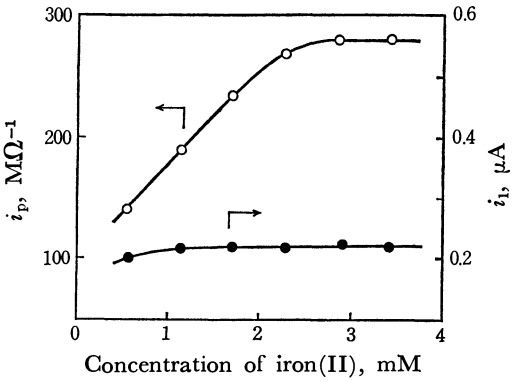

Fig. 3. Effect of iron(II) concentration on the extraction of the quaternary complex.
○: AC peak height, ●: DC wave height, $[Cd(II)]_w = 5.72 \times 10^{-5}$ M. Other conditions are the same as in Fig. 1.

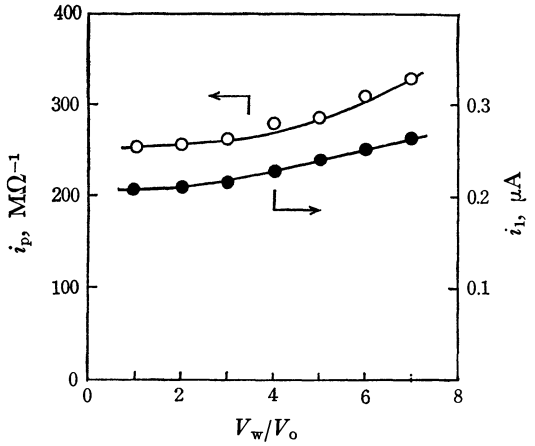

Fig. 4. Effect of aqueous-to-organic volume ratio (V_w/V_o) on DC wave height, or the corresponding AC peak height.
$V_o = 10$ ml, $V_w = 10$—70 ml, $[Cd(II)]_w = 5.72 \times 10^{-5}$ M.
Other conditions are the same as in Fig. 1.

3×10^{-3} M in the aqueous phase, a decrease of the AC peak height was observed. It can be seen that the excess of bpy reacts with cadmium(II) and produces a non-reducible complex, which is more stable than the tetraiodocadmate(II) complex.[9] Therefore, it is desirable that the excess of bpy be changed into the tris(2,2′-bipyridine)iron(II) chelate,[9,10] by the addition of an excess amount of iron(II).

Effect of the Aqueous-to-Organic Volume Ratio on the Polarogram. While keeping other conditions constant, the effect of the aqueous-to-organic volume ratio on the polarogram was studied by the polarographic method. The results are shown in Fig. 4, from which it is found that an increase in the volume ratio produced an increase in the DC wave height and also in the corresponding AC peak height. This is caused by the decrease in the volume of the organic phase by the mutual dissolution. Consequently, the aqueous-to-organic volume ratio should be adjusted to an approximately constant value.

Choice of Supporting Electrolyte. Several supporting electrolytes were investigated; the results are summarized in Table 1. As the supporting electrolyte, potassium iodide was the most suitable for the polarographic measurement.

Miscible Organic Solvent. As possible miscible solvents, methanol, ethanol, dioxane, and MCS were selected and investigated. Methanol and ethanol were found not to be suited for being miscible solvents, however, because these solvents were easily evaporated by bubbling nitrogen gas and did not mix well. The other two solvents were found to be very miscible. However, a better-defined polarogram was obtained by using MCS rather than dioxane.

Effect of Diverse Ions. The interference of diverse ions was examined; the results are given in Table 2. According to the familiar *t*-tests, not even a 100 : 1 mole ratio of zinc and bromide ions, or a 50 : 1 mole ratio of the chloride ions to cadmium(II) ions interfered with the solvent extraction-polarographic measurement. Copper(II), iron(II), and mercury(II) ions interfered seriously, however.

Calibration Curve. According to the established procedure described above, the calibration curve was drawn; the results are given in Fig. 5. It was found that the difference between the two averages of the two days was not found to be significant at the 95% level by the familiar *t*-test, using the data obtained

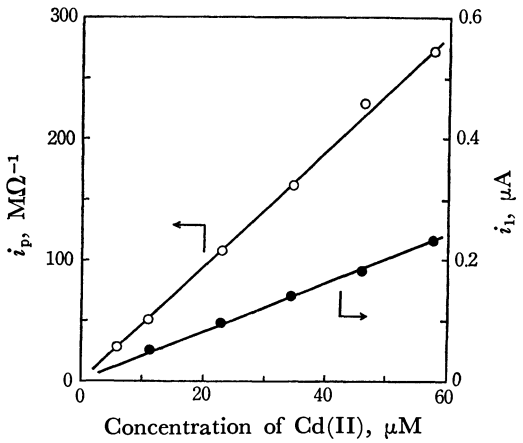

Fig. 5. Calibration curve of cadmium(II) in aqueous phase.
Data obtained under the same conditions as in Fig. 1.

with the 4.75×10^{-5} M cadmium(II) ion in the aqueous phase.

Characteristics of Limiting Current. The tetraiodocadmate(II) ion undergoes a two-electron reduction to the cadmium amalgam in a single step. An analysis of the log plot indicated the quasi-reversible nature of the process, the value of the slope being 45 mV at 20 °C, as is shown in Fig. 6. The reduction was diffusion-controlled as is evident from the linear plot of i_l against $h^{1/2}$, shown in Fig. 7. The relative temperature coefficient of the limiting current was 1.83% K^{-1} at 20 °C.

The Rapid Determination of Heavy Metals in Sediment by Means of X-ray Fluorescence Analysis* Modification of the X-ray Intensity Using Scattered Radiation

Hideki TANAKA** and Genzo HASHIZUME***

Environmental Science Institute of Hyogo Prefecture, Hyogo-ku, Kobe 652

(Received June 25, 1974)

The present method was developed as a way of modifying intensity using the mass-absorption coefficient of the matrix, which is itself obtained from the measurement of the intensity at an arbitrary scattered wavelength. This modification, derived from the simplified equation by the utilization of the known matrix composition, has been empirically demonstrated, and it has been applied to various river-sediment samples. Repeated analyses on copper and zinc in representative sediments were carried out, and the average ($\bar{x}$) and the coefficient of the variation (*c.v.*) obtained by the present method and by the atomic-absorption method were compared. In the former method, $\bar{x}$=1,550 μg/g, *c.v.*=4.25% on copper, $\bar{x}$=4,400 μg/g, and *c.v.*=7.11% on zinc; in the latter method, $\bar{x}$=1,500 μg/g, *c.v.*=9.87% on copper, $\bar{x}$=4,330 μg/g, and *c.v.*=13.03% on zinc.

The X-ray fluorescence method, the atomic-absorption method, and the colorimetric method have all been used to determine the elements in a samples with a homogeneous composition of samples. Of these analytical methods, the X-ray fluorescence method has these advantages compared with the others;

(1) many elements can be analyzed rapidly, (2) the samples need not be destroyed, and (3) the X-ray spectro-chemical analysis of heavy metals does not generally depend on any of the chemical properties of the elements in which they are present.

There is, however, a problem related to the analysis of sediments by the X-ray fluorescence method-the matrix effect. Therefore, many investigators have reported modifications.

There have been modifications derived from the theoretical equation on the basis of the absorption and excitation effects of X-ray emission,[1-3] and experimental modifications derived by assuming a definite relation between the X-ray intensities and constituent elements of a sample.[4-6]

Taylor and Andermann[7-8] adopted a technique which involves the utilization of a modification using the value of the ratio of the $K\alpha$- or $L\alpha$-ray intensity to the scattered radiation at an empirically selected wavelength. With this method, the variation in the X-ray intensity with the matrix effect could be modified at lower concentrations (less than 500 μg/g content of copper).[9] However, at higher concentrations, differences in the mass-absorption coefficients at the constituent elements of the substructure for both wavelengths appeared in the intensity ratio, an example is shown in Fig. 1.

The present modification was developed by using the modification factor of the variation in the fluorescence intensity, which was determined from the measurement of the scattered radiation at an arbitrary wavelength.

This paper will deal with the modification and with the analytical results on metals in the river- and sea-sediments.

Experimental

Sample Treatment and Analytical Conditions of the X-ray Measurements. The sediment was sufficiently separated from water and then displaced on the evaporating dish. After dehydration for three hr at 110 °C in a drying oven, the sample was moderately crushed by a pestle, sieved to obtain a fine fraction, and finally crushed by means of a mixer-mill until the particle size became smaller than 100 μ. The specimen was molded at a pressure of 15 t/cm² and then analyzed by using a X-ray spectrometer.

A Rigaku Denki Geigerflex X-ray spectrometer equipped with a D9C-type constant-potential X-ray generator and a KG-X-type goniometer was used for the X-ray emission measurements.

The analytical conditions of the X-ray spectra are shown in Table 1.

Path	About 10^{-2} Torr
Counting time	10 s (Fix time)
Measuring method	To detect by using the pulse height analyzer and the differential method

Results and Discussion

The Intensity of the Scattered Radiation and the Mass-absorption Coefficient. The background of the X-ray fluorescence analysis is composed of the coherent scattering of photons of the given wavelength by the sample, the Compton scattering of the photons of the given wavelength by the sample, the scatter of radiation by the analyzing crystal, and fluorescence by the crystal. The intensity of the scattered radiation is approximately equal to that of the background, therefore, it can be expressed by the following equation.[10]

$$I_B = K_1[\{J_{(\lambda k)}\Sigma(C_iF_i^2/A_i)\}/\{\mu_{m(\ k)}(\sec\theta_1+\sec\theta_2)\} + \{J_{(\lambda k)}\Sigma C_i(Z_i-f_i^2)r\}/\{\mu_{m(\lambda c)}(\sec\theta_1+\sec\theta_2)\}] \quad (1)$$

where J is the photon flux which is the intensity distribution of the exciting source; λ_k is the $K\alpha$ wavelength for the i element; μ is the mass-absorption coefficient; m is the matrix; θ_1 and θ_2 are the angles of incidence and excitation (from the normal state to the sample surface); λ_c is the Compton scattering of the photons of the given wavelength; K is a factor which is decided by the k element and the geometrical conditions of the instrument; C is the concentration; A is the atomic number; F is the atomic scattering power, f is the incoherent scattering power, and r is a recoil factor. Equation(1) is expressed as the background intensity underneath a peak.

Now, if the k element to be analyzed is rarely present in the sample, this intensity can be regarded as that of the radiation scattered at the same arbitrary wavelength. Therefore, λ_k was experimentally selected to be 0.906 Å of the scattered radiation at an arbitrary wavelength which was not influenced by the coexisting elements and which was obtained with a relatively high intensity.

Equation (1) can be simplified by noting that, since $\lambda_k-\lambda_c=0.03$ Å$\doteqdot 0$, $\mu_{(\lambda c)}=\mu_{(\lambda k)}$.
Thus,

$$I_B = K_2\cdot K_s/\mu_{m(0.906\text{Å})} \quad (2)$$

where:

$$K_s = \Sigma\{C_i(K_s)_i\} \text{ and } (K_s)_i=\{F_i^2+(Z_i-f_i^2)r\}/A_i$$

$$K_2 = K_1\cdot J_{(\lambda k)}/(\sec\theta_1+\sec\theta_2) = \text{const.}$$

The values of $(K_s)_i$ for each element can be calculated from the values of F and f^2, which are available in the standard text by Lonsdal.[11]

Equation (3) can be obtained by the conversion of the logarithms with regard to two variables, I_B and μ_m (0.906 Å), on both sides of Eq. (2):

$$\log I_B + \log \mu_{m(0.906\text{Å})} = K_3 \quad (3)$$

The mass-absorption coefficient of the X-ray is expressed as a function of the wavelength, containing the photoelectric absorption coefficient (τ) and the scattering coefficient (δ). The photoelectric absorption coefficient increases in proportion to the third power of the wavelength in the region from a remote absorption edge. On the other hand, however, the scattering coefficient is constant and independent of the wavelength in the first approximation.[12] Therefore, the mass-absorption coefficient of the X-ray is generally expressed as $\mu=\delta+\tau$. Then, $\tau=CZ^m\lambda^3$; thus, $\mu=\delta+n\lambda^3$.

The mass-absorption coefficient of the scattered radiation at the arbitrary wavelength is

$$\mu_{m(0.906\text{Å})} = \delta + n(0.906)^3, \quad (4)$$

while that of the $K\alpha$-line to be analyzed is expressed as

$$\mu_{m(\lambda s)} = \delta + n\cdot\lambda_s^3, \quad (5)$$

where λ_s is the wavelength of the $K\alpha$-line to be analyzed.

The relation between $\mu_{m(\lambda s)}$ and $\mu_{m(0.906\text{Å})}$ can be expressed as follows from Eqs. (4) and (5):

$$\log \mu_{m(0.906\text{Å})} = \log \mu_{m(\lambda s)} + K_4 \quad (6)$$

When Eq. (6) is substituted in Eq. (3), Eq. (7) is obtained:

$$\log I_B + \log \mu_{m(\lambda s)} = K_5 \quad (7)$$

Thus, Eq. (7) shows that the mass-absorption coefficient for the given wavelength, λ_s, can be determined by the measurement of I_B.

The relation between the background intensity at 0.906 Å and the mass-absorption coefficient for the $K\alpha$-line to be analyzed on various model matrices was examined. Copper oxide, zinc carbonate, chromium oxide, arsenic trioxide, cadmium oxide, and stannous chloride were used as the standards. The concentrations of copper, zinc, chromium, arsenic, cadmium, and tin were adjusted to 1000 μg/g for each portion of boric acid, anhydrous aluminium sulfate, potassium sulfate, sodium sulfate, and sodium carbonate respectively used as the model materices.

The calculated results of the mass-absorption coefficients with the Cu$K\alpha$-, Zn$K\alpha$-, Cr$K\alpha$-, Cd$K\alpha$-, As$K\alpha$, and Sn$K\alpha$-emission spectra for the matrices are shown in Table 2.

The relation between the background intensity at 0.906 Å and the mass-absorption coefficient for Cu$K\alpha$-

Table 2. Values of mass absorption coefficient of K-emission spectra for various matrices

K-Emission spectrum	Matrix				
	H_3BO_3	Na_2CO_3	Na_2SO_4	$Al_2(SO_4)_3$	K_2SO_4
Cu$K\alpha$	10.56	17.15	28.53	31.43	63.30
Zn$K\alpha$	8.60	13.97	23.27	25.64	51.76

As$K\alpha$	4.24	6.58	10.74	11.81	23.76
Cd$K\alpha$	0.74	1.02	1.55	1.69	3.27
Sn$K\alpha$	0.60	0.84	1.25	1.34	2.56

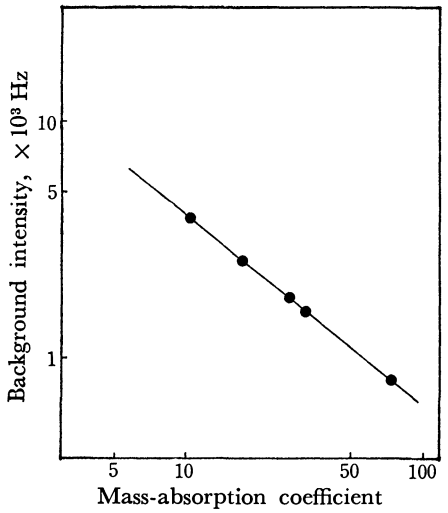

Fig. 2. Relationship between mass-absorption coefficient for Cu$K\alpha$-line and background intensity at 0.906 Å.

line is shown in Fig. 2 as representative of the standard elements.

A satisfactory reciprocity was obtained between I_B and $\mu_m(\mathrm{Cu}K\alpha)$.

Fluorescence X-Ray Intensity and Mass-absorption Coefficient. Kalman and Heller[13] have shown that the intensity of the fluorescence X-ray can be represented by:

$$I_S = K_6 C_s / \{\mu_{m(\bar{\lambda})} \sec\theta_1 + \mu_{(\lambda s)} \sec\theta_2\} \quad (8)$$

where I_S is the intensity of the fluorescence peak of the s element, $\bar{\lambda}$ is the effective exciting wavelength, and K_6 is a factor which is decided by the s element and the geometrical conditions of the instrument. The constancy of $\bar{\lambda}$ in the case of a measurable $K\alpha$-line excited by operating an X-ray tube continuously with a constant power input has been verified.[11]

Equation (8) can be simplified as follows:

$$I_S = K_6 C_s / N \cdot \mu_{m(\lambda s)} \quad (9)$$

where:

$$N = \mu_{m(\bar{\lambda})} / \mu_{m(\lambda s)} + \sec\theta_2 / \sec\theta_1 \quad (10)$$

Compton has proved that N can be considered a constant if, for all the matrices, $\mu_{(\lambda)} \propto \lambda^n$ (where n is independent of the matrix) over the range from $\bar{\lambda}$ to λ_s.[10]

As is shown Eq. (9), the intensity of the fluorescence is a function of the concentration and the mass-absorption coefficient. The relation between I_S and C_s can be represented as the calibration curve on an identical matrix; however, the relation between the $\mu_{m(\lambda s)}$ obtained from Eq. (8) and I_S should be examined further.

The result obtained by taking a intensity ratio on any matrix (m_i) and the standard model matrix (m_1) of the element to be analyzed at a constant concentration is shown in Eq. (11):

$$I_{S_1}/I_{S_i} = K_7 \mu_{m_1(\lambda s)} / \mu_{m_i(\lambda s)} \quad (11)$$

Equation (12) is obtained by the conversion of the logarithms on both sides Eq. (11), when the value of $\mu_{m_1(\lambda s)}$ is a unit:

$$\log I_{S_1}/I_{S_i} + \log \mu_{m_i(\lambda s)} = K_8 + \log \mu_{m_1(\lambda s)} \quad (12)$$

The main components in river- and sea-sediments are light elements, such as silicon and aluminium; the heavy metals to be analyzed in these samples usually comprize less than 0.2—0.3% of the total (by weight). Therefore,

$$C_s \ll C_1 + C_2 + C_3 + \cdots\cdots + C_n \text{ and } \mu_s \lesssim \mu_i$$
$$i = 1, 2, 3, \cdots\cdots, n$$

Then,

$$\mu_m = \mu_1 C_1 + \mu_2 C_2 + \mu_3 C_3 + \cdots\cdots + \mu_n C_n + \mu_s C_s$$
$$\fallingdotseq \mu_1 C_1 + \mu_2 C_2 + \mu_3 C_3 + \cdots\cdots + \mu_n C_n$$

If it should happen that the metal content in the standard model sample varies, the value of the mass-absorption coefficient for the measurable metal can be regarded as approximately constant in the range of lower concentrations.

The relation between I_{S1}/I_{Si} and $\mu_{m(\lambda s)}$ was examined on various matrices. Boric acid, sodium sulfate, anhydrous alminium sulfate, potassium sulfate, and sodium carbonate were used as the model matrices. The standard model matrix selected was anhydrous alminium sulfate, which had a mass-absorption coefficient close to that of the usual sediments. The samples containing 1000 μg/g copper in each matrix were used; the results are shown in Fig. 3.

The technique for the quantitative determination of elements in unknown samples is as follows: first, I_{S1}/I_{Si} is calculated from the value of $\mu_{mi(\lambda s)}$ (Fig. 3), which can be obtained by measuring the background intensity at 0.906 Å (Fig. 2); the peak intensity (I_{Si}) of an element in the sample is determined subsequently. Then, I_{Si} multiplied by I_{S1}/I_{Si} is transformed into I_{S1} for the matrix based on $\mu_{m_1(\lambda s)}$, and the concentration of the element with the transformed I_{S1} is determined from the calibration curve between C_s and I_{S1} on the standard model matrix.

Calibration Curves for Copper on Various Matrices. The calibration curves for copper in the concentration range

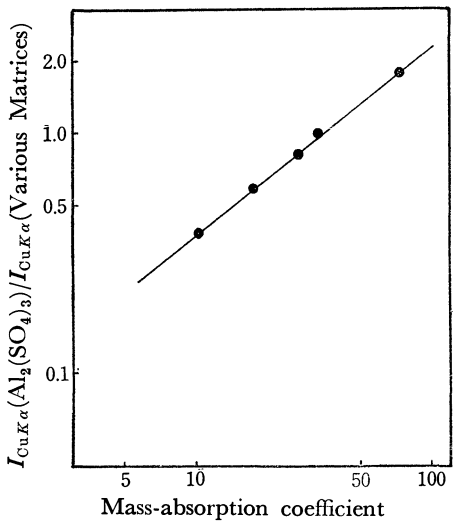

Fig. 3. Relationship between mass-absorption coefficient and intensity ratio of Cu$K\alpha$-line.

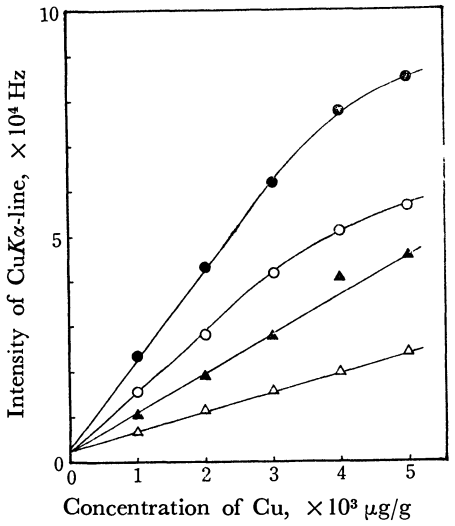

Fig. 4. Calibration curves for Cu on various matrices.
○: H_3BO_3, ●: Na_2CO_3, △: $Al_2(SO_4)_3$, ▲: K_2SO_4

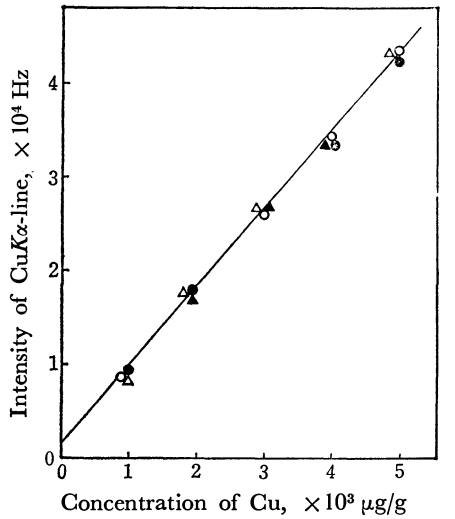

Fig. 5. Calibration curve for Cu converted into $Al_2(SO_4)_3$ matrix.
○: H_3BO_3, ●: Na_2CO_3, △: $Al_2(SO_4)_3$ ▲: K_2SO_4

of 500—5000 μg/g prepared in the various matrices described above are shown in Fig. 4. Each calibration curve for copper shows that the intensities become weak and become very different with an increase in the mass-absorption coefficient of the matrix for the $K\alpha$-emission spectrum. Therefore, each calibration curve agreed very closely with that of the standard model matrix ($Al_2(SO_4)_3$ matrix) when this modification technique was used. The results are shown in Fig. 5.

Theoretically, this relation can be applied to any element except for an element in the vicinity of the absorption edges with the constituent element of the matrix. On the other hand, it is unnecessary to consider the excitation effect of measurable X-rays by the coexisting elements on the measurement of heavy metals in the sediments, because the elements forming the matrices of the sediments are mainly silicate and organic compounds.

The modification technique for the fluorescence intensities of other metals may be examined similarly.

Precision of Analytical Values. The results of the measurement of the copper and zinc contents by the present method and by the atomic-adsorption method on 10 specimens drawn as 1-lot sediment specimens are shown in Table 3.

The pretreatment of a sediment for the atomic-absorption method was carried out as follows: the metals to be analyzed, consisting of 10 g of portions the dried sediment, were extracted with 50 ml of 2 M-HNO_3 for 2 hr and then filtered. The extracted solution was heated and concentrated in a Kjeldahl flask, and the organic compounds in the sample were decomposed with 10 ml of 98% sulfuric acid and 10—20 ml

a) X-Ray fluorescence method. b) Atomic absorption method.

of 60% nitric acid. Then, the sample was analyzed by using the standard addition method.

The averages ($\bar{x}$) of the series of values obtained by the two analytical methods were approximately similar, but the coefficient of variation (*c.v.*) by the atomic-absorption method was larger than that by the X-ray fluorescence method.

Analysis of Several Metals in Sediments. The analytical values of copper, zinc, chromium, and tin in sediments obtained by the X-ray fluorescence method and the atomic-absorption method were compared. The results are listed in Table 4.

The standard addition technique was used for the atomic-absorption analysis. The values obtained by the two analytical methods agreed approximately.

The time required from pretreatment to the measurement of the sediments is shortened to about 30 min per sample, while 3 hr is needed for the atomic-absorption method. The present method is thus suitable for the rapid analysis of a number of samples, and good results are obtained for the concentration of each element in the range of 50—5000 μg/g.

The Solubility of Elemental Mercury Vapor in Water

Isao SANEMASA

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami-machi, Kumamoto 860

(Received September 17, 1974)

The solubility of mercury vapor in water has been measured by means of atomic absorption spectrophotometry over the temperature range of 5—60 °C under atmospheric pressure. The aqueous solubility obeys Henry's law at each temperature. The solubilities and the Henry coefficients are reported. From the solubility data, the heat of the solution of mercury vapor in water is found to be −5.3 kcal/mol. The relationship between the Henry coefficient, k, and the solution temperature, T, is expressed by $\log k = -1078 \times 1/T + 6.250$. From this equation, the solubilities at 70—100 °C are estimated. The solubility of the mercury vapor in sea water has also been measured over the temperature range of 5—30 °C. A salting-out effect on the solubility is observed. The practical application of the aqueous solubility of the mercury vapor is discussed from the analytical point of view.

Bonhoeffer and Reichart[1] showed that the absorption spectrum of an aqueous solution of mercury was essentially the same as that of mercury vapor. At about the same time, Stock *et al.*[2] reported the solubilities of the metallic mercury in water. Since then, the solubilities of mercury have been studied by many workers. There is, however, a considerable disagreement among the literature values. This may be ascribed to the different experimental techniques used. The conventional techniques for the measurement of the mercury solubilities are as follows: colorimetric analysis, Pariaud and Archinard;[3] radioactive-tracer technique, Moser and Voigt;[4] neutron-activation method, Choi and Tuck;[5] atomic absorption spectrophotometry, Glew and Hames.[6] The most recent work is that by Onat,[7] who studied the dissolved mercury by means of ultraviolet spectrophotometry. The principle of measuring the dissolved mercury employed by Moser and Voigt and by Onat is different from that of other workers; it is based on the disproportionation reaction of the mercurous dimer into mercuric ions and free mercury. However, the procedures to attain the solubility equiliblium are essentially similar to those employed by other workers: they brought water into contact with metallic mercury. In the present work, mercury is treated as a vapor, and the solubility is determined based on Henry's law. The present study is different in this respect from those of the other workers.

Mercury, because of its high vapor pressure at room temperature, is introduced into the atmosphere through the impingement of the vapor and the fallout of particulate matters derived from the industrial process. During the past few years, considerable attention has been directed toward the potential hazards of mercury and its compounds in our environment. There have also been several articles[8-11] dealing specifically with the presence of mercury in air.

The generally accepted procedure for the determination of trace amounts of mercury is the cold-vapor atomic absorption technique, because it exhibits a high sensitivity. It is essentially based on a reduction-aeration method found by Kimura and Miller;[12] mercury present in solution as Hg(II) is reduced with Sn(II), and the resulting mercury vapor is separated by aeration. The most commonly utilized method at present was originally described by Hatch and Ott,[13] who combined the closed system reduction-aeration principle with atomic absorption spectrophotometry. The aqueous solubility of mercury vapor is, therefore, a common topic in analytical laboratories.

There are various forms of mercury found in nature, such as metal, inorganic, and organic compounds. Although most of the mercury reported in fish tissue is in the methyl form,[14] very little metylmercury has been discovered in sediments or river waters. Spangler *et al.*[15] demonstrated that demethylation processes by microbes in sediments probably reduce some or all of the methyl form to metallic mercury. It is also of interest, from this aspect, to study the aqueous solubility of elemental mercury.

Experimental

Reagents. All the chemicals were of an analytical reagent grade unless otherwise specified. The solutions used were: stannous chloride, 10% solution in 1 M HCl; sulphuric acid, 50% solution; potassium permanganate, 6% solution. The standard mercury stock solution of 0.5 mg/ml was prepared by dissolving the required amount of mercury (II) chloride in water. This solution was used to prepare a working standard containing 0.5 mg/l by dilution before each use. The metallic mercury was purified by distilation under reduced pressure after the air oxidation of the contaminated metal through successive aeration in water and by passing it through a column filled with a diluted HNO_3 solution.

Apparatus. The atomic absorption measurements were made with a Hitachi Model 508 atomic absorption spectrophotometer equipped with a mercury hollow-cathode lamp. A 10-cm-long gas cell with a 9.1-cm^2 cross-section and quartz windows was used. The instrumental settings were as follows: hollow-cathode lamp current, 6 mA; wavelength, 253.7 nm; band width, 0.32 nm. The solubility apparatus used was a simple closed system, as is shown in Fig. 1. It was composed of four glass flasks, a circulating pump (P) the metallic part of which was covered with plastic, and polyethylene tubes to connect them. Flask A is a 300 ml three-necked flask; the center neck is stoppered, while the other two are connected to a condenser and a gas inlet-type adapter with a stopcock. Flask B is a 1-l three-necked flask; the center neck is stoppered, while the other two are connected to a gas inlet-type adapter and an adapter, each with a stopcock. Flasks C and D, used as traps for the water vapor, are gas-washing-type, long-necked bottles with capacities of 500 ml and 2 l respectively. Flask A and Flasks B, C, and D were immersed in separate thermostats controlled within ±0.05 °C. The inlet of the circulating pump was connected

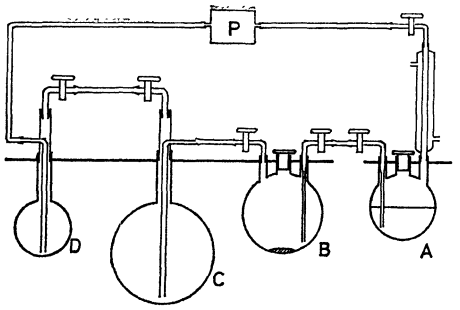

Fig. 1. Mercury vapor solubility apparatus.

to Flask A through the condenser, which was maintained at the same temperature as Flask B by circulating the water of the thermostat. The outlet of the pump was connected to Flask B, before which Flasks C and D were placed. The temperature of the room was always maintained higher than that of Flask B. The pressure in the closed system was always kept under atmospheric pressure.

Procedure. About a 20-g portion of metallic mercury is dropped into Flask B. A water sample (100 to 200 ml) is then poured into Flask A. After the mercury and the solution reach the desired temperatures, mercury vapor is introduced, bubbled into Flask A, and circulated by means of the pump. The circulation rate is adjusted to 100 to 200 ml/min. by using a Variac. After solubility equiliblium is attained, a suitable aliquot (1 to 20 ml) of the solution is withdrawn from Flask A and immediately added to a reduction-aeration bottle in the atomic absorption spectrophotometer. Measurements were made at least three times.

Measurement. The analytical procedure for determining the dissolved mercury by the flameless atomic absorption method is essentially similar to that reported by Omang.[16] Introduce a 100 ml portion of distilled water, 2 ml of 9 M sulphuric acid, and 2 ml of 10% tin(II) chloride solution into a 300-ml reduction-aeration bottle. Connect the bottle to an aeration apparatus equipped with a circulating pump and exhaust any mercury arising from contaminated reagents. When the recorder pen has returned to the base line, add the sample solution to the bottle and turn on the circulating pump at a constant flow rate of 1.5 l/min. Record the absorption peak of the mercury vapor. Carry the mercury working standard (0.05 to 0.5 μg) in the same manner as in the sample. In this case, care must be taken to adjust the total volume and the salt concentration in the bottle to make them constant. Determine the mercury concentration in the sample solution by means of a calibration curve.

Results and Discussion

The Time Required for the Attainment of the Solubility Equilibrium. The attainment of an equilibrium is important for solubility determinations and is checked in the following manner. A part of the solubility apparatus is disconnected and combined directly to the gas cell of the atomic absorption spectrophotometer. Drop metallic mercury into Flask B in the same manner as has been described in the Experimental section in the absence of water in Flask A, and then turn on the circulating pump and the recorder. The absorbance reading then begins to rise, reaches a maximum within 5 to 30 min. in accordance with the surface area of the mercury, and thereafter remains constant. Add an aqueous solution of about 100 ml to Flask A and monitor the absorbance reading. This monitoring shows that the reading, after a temporary sinking, returns slowly to the former constant line within 10 to 30 min. From the practical point of view, the liquid phase will reach equilibrium with the circulating mercury vapor within an hour.

The Effect of Oxygen on the Solubility. It has been said that mercury is readily oxidized in humid air.[2] In order to clarify this, experiments were made under conditions of both sufficiently aerating and bubbling nitrogen gas through the water. As a result, no appreciable differences in the solubility of mercury vapor were observed under the present experimental conditions.

The State of Mercury Gas Dissolved in Aqueous Solutions. In order to obtain information about the state of the mercury gas dissolved in pure and sea water, atomic absorption measurements were made with and without the addition of a reductant, Sn(II)-H_2SO_4 solution, to sample solutions in a reduction-aeration bottle. In the absence of the reductant, the readings of the absorption peaks were lowered by 1 to 2%. This is probably because of the relatively high salt concentrations in the liquid phase upon the addition of the reductant-that is, the salting-out effect. Indeed, the absorption peak increased gradually with an increase in the additional reductant. The same situation was also found in the case of the standard mercury solution. From the facts mentioned above and from the fact that the solubility obeys Henry's law, it may be concluded that the mercury gasses dissolved in pure and sea waters are in the elemental form.

Solubility of the Mercury Vapor in Water. In Figs. 2 and 3, the solubilities of mercury vapor in water in the temperature range from 5 to 60 °C are plotted against its vapor pressure; they are in equilibrium with the metallic mercury at the desired temperatures. The solubility at 5 °C may be less reliable. Figures 2 and 3 show that the aqueous solubility of mercury vapor obeys Henry's law at each solution temperature except at 5 °C. When the temperatures

of mercury are higher than those of solutions, the solubility values become lower than those expected from Henry's law because of the condensation of the vapor. The solubility data are summarized in Table 1, together with the Henry coefficients. The Henry coefficients are determined by dividing the partial pressures of mercury vapor (atm) by the mole fractions of the mercury dissolved.

The Temperature Dependence of the Solubility. The Henry coefficients are plotted in Fig. 4 according to the van't Hoff equation:

$$d\ln k/dT = \Delta H/RT^2 \quad (1)$$

where k is the Henry coefficient. The heat of solution, ΔH, is calculated from the slopes of the log k *vs.* $1/T$ plots to be −5.3 kcal/mol. The relationship between the Henry coefficient and the solution temperature is expressed in the following empirical equation:

$$\log k = -1078\times 1/T + 6.250 \quad (2)$$

The solubility data and the Henry coefficients at 70—100 °C listed in Table 1 are calculated from Eq. (2) and the mercury-vapor pressures at the corresponding solution temperatures on the assumption that Henry's law holds up to those pressures.

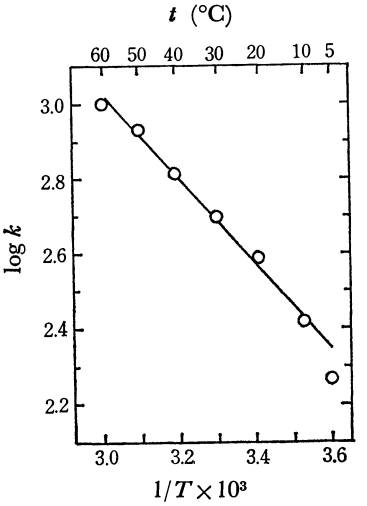

Fig. 4. log k *vs.* $1/T$ plot. The temperature dependence of solubility of mercury vapor in water.

Comparison of the Present Results with the Literature. This paper has presented the solubility results of mercury vapor in water. The aqueous solubility of mer-

cury in the metallic and gaseous states shoud be identical, provided that the dissolved metal mercury is in the elemental form. The results reported in the literature are illustrated in Fig. 5, together with those of the present work. The solubility data at 25 °C, summarized in Table 2, are in good agreement except for the earlier measurements by Stock *et al.* and Pariaud and Archinard. Above 50 °C, however, the present results are higher than those reported by other workers. Below 20 °C, the present results are considerably lower than those by Glew and Hames. However, their results are definitely too high, in view of the temperature dependences of the other two studies. The discrepancies in the present results at moderately higher temperatures may be caused by the different procedures used to attain the solubility equilibrium.

The Solubility in Sea Water. The solubility of mercury vapor in sea water was measured in the interest of practicality. The total mercury contained in the sample was analyzed prior to the solubility measurements. The blank concentration was found to be less than 0.1 μg/l. For this low content, the solubility data obtained were uncorrected. As is shown in Fig. 2, it is also confirmed that the solubility of mercury vapor in sea water at 30 °C obeys Henry's law. The solubility data at 5—30 °C are given in Table 1. It can be said, from Fig. 2 and Table 1, that the salting-out effect is observed on the aqueous solubility of mercury vapor, just as is observed in atomic absorption measurements. "Salting-out" is the decrease in the solubility of a non-electrolyte in ionic solutions.[17]

The Practical Application of the Aqueous Solubility of Mercury Vapor. According to the literature, the concentrations of mercury vapor in several laboratory atmospheres were determined to be 2—8,[8] 0.012,[9] or 1—30 μg/m³.[11] Based on the emission standard for mercury (1 μg/m³) promulgated by the U. S. Environmental Protection Agency,[10] the estimation of the aqueous solubility of the mercury vapor has been attempted. As a result, it has been found to be 0.0034 μg/l at 20 °C. In general, the concentration range of mercury in natural waters is from 0.5 to 364 ng/l.[18] Because of its low abundance, care must be taken in the discussion of the results when analytical experiments are made in the laboratory of the several μg/m³ level.

The author is indebted to Professor Hideo Nagai and Mr. Toshio Deguchi of Kumamoto University for their encouragement and discussions. Thanks are also due to the members of the Marine Biological Station of Kumamoto University for sampling the sea water.

The Chemical Behavior of Low Valence Sulfur Compounds. IX.[1] Photometric Determination of Thiosulfate, Trithionate and Tetrathionate in Mixture

Tadaaki MIZOGUCHI* and Taijiro OKABE

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Sendai 980

(Received September 26, 1974)

The cyanolysis and photometric determination of thiosulfate, trithionate and tetrathionate have been investigated under the various conditions. The cyanolysis of thiosulfate catalyzed by cupric ions proceeded quantitatively in the presence of acetate buffer solution of pH 4.5, while the degree of cyanolysis of trithionate and that of tetrathionate were 0.3 and 0.6%, respectively. The degree of cyanolysis of trithionate was not so depressed as to a negligible extent by the methods previously proposed, but was depressed to 0.7% or less by the addition of such organic solvents as acetone, methanol, *etc.* The determination of thiosulfate, trithionate and tetrathionate in the concomitant presence of them could be made with a high accuracy.

A simple analytical method for 0—10 μmol of thiosulfate and polythionates has been a subject in the study on the chemical behavior of low valence sulfur compounds in biological systems. The classical iodometric method for the determination of these compounds,[2] which was used in our previous studies, has been found inapplicable to the analysis of systems in which reducing organic compounds are contained.

A colorimetric method depending on the photometric determination of thiocyanate formed in the reaction with cyanide seems superior in the possibility of fractional determination of these compounds, to many other methods proposed previously.[3,4] This method was proposed by Nietzel *et al.*[5] to determine tetrathionate, and was then extended to the colorimetric determination of thiosulfate by Sörbo.[6] Urban has described the cyanolysis of thiosulfate[7] and polythionates,[8,9] obtaining only the mean value *n* in the formula $S_nO_6^{2-}$.[10] Koh *et al.* have fully investigated the cyanolysis and photometric determination of trithionate,[11] tetrathionate,[12] pentathionate[13] and hexathionate,[14] and also have reported a highly sensitive analytical method for thiosulfate[15] and polythionates[16] by means of solvent extraction. The application, however, has been restricted to the determination of two-component mixtures excluding trithionate.[17] Kelly *et al.*[18] have proposed a fractional determination method for thiosulfate, trithionate and tetrathionate, but the measured values fluctuate within 10 to 20%, requiring a more accurate analytical method to investigate the reaction mechanism of low valence sulfur compounds.

The reactions of thiosulfate and polythionates with cyanide are given by Eqs. (1)—(4). As the velocity of the reactions largely depends on the conditions applied,

$$S_2O_3^{2-} + CN^- \overset{Cu^{2+}}{=} SCN^- + SO_3^{2-} \quad (1)$$

$$S_3O_6^{2-} + CN^- + 2OH^- = SCN^- + SO_3^{2-} + SO_4^{2-} + H_2O \quad (2)$$

$$S_4O_6^{2-} + CN^- + 2OH^- = SCN^- + S_2O_3^{2-} + SO_4^{2-} + H_2O \quad (3)$$

$$S_4O_6^{2-} + 2CN^- + 2OH^- \overset{Cu^{2+}}{=} 2SCN^- + SO_3^{2-} + SO_4^{2-} + H_2O \quad (4)$$

it may be expected that special reactions proceed exclusively under the suitable conditions. However, it has not been shown systematically to what degree the side reactions can be depressed.

From a result of investigation of the respective reaction under the various conditions, it has become clear that three sorts of procedures shown in Table 1 can be employed with satisfactory accuracy, and that the determination of thiosulfate, trithionate and tetrathionate in mixtures can be made by those procedures. The present paper is concerned with the result of this investigation.

thionate were prepared by Stamm's method[19] and Martin's method[20], respectively, and were found to be free from thiosulfate as well as other polythionates by paper chromatography.[21] The results of analyses of the polythionates are shown in Table 2, indicating that these polythionate samples are pure enough for the purpose of this study.

Standard Trithionate Solution (0.01 M): Dissolve 0.5407 g of potassium trithionate in distilled water, and dilute to 200 ml. Prepare working solutions by suitable dilution.

Standard Tetrathionate Solution (0.01 M): Dissolve 0.6049 g of potassium tetrathionate in distilled water, and dilute to 200 ml. Prepare working solutions by suitable dilution.

Standard Thiocyanate Solution (0.05 M): Dissolve potassium thiocyanate in distilled water, and standardize by Volhard's method. Prepare working solutions by suitable dilution.

Standard Thiosulfate Solution (0.01 M): Dissolve sodium thiosulfate pentahydrate in distilled water, and standardize by iodometry. Prepare working solutions by suitable dilution.

Potassium Cyanide Solution (0.5 M): Dissolve 17.2 g of potassium cyanide in distilled water and dilute to 500 ml.

Cupric Chloride Solution (0.2 M): Dissolve 17.6 g of cupric chloride dihydrate in distilled water, dilute to 500 ml, and add a drop of concentrated hydrochloric acid to prevent the hydrolysis of cupric ions.

Buffer Solutions: Buffer solutions of desired pH values are obtained by mixing the following two solutions in a suitable ratio.

2 M acetate buffer solution: 2 M acetic acid with 2 M ammonium acetate,

0.2 M phosphate buffer solution: 0.2 M sodium dihydrogen phosphate with 5 M sodium hydroxide.

Ferric Nitrate-Perchloric Acid Solution:[13] Dissolve 303 g of ferric nitrate, $Fe(NO_3)_3 \cdot 9H_2O$, in a small volume of distilled water containing 217 ml of concentrated perchloric acid (60 wt%), and then dilute to 500 ml with distilled water.

Recommended Procedures. Procedure A. Cupric Ion-Catalyzed Cyanolysis of Thiosulfate at pH 4.5: Transfer an aliquot of the sample solution to a 50-ml volumetric flask. To this, add 10 ml of acetate buffer of pH 4.5, 1 ml of 0.5 M potassium cyanide solution, and 1.5 ml of 0.2 M cupric chloride solution, in this order, with mixing. Finally, add 5 ml of ferric nitrate-perchloric acid solution with continuous mixing, and make up to 50 ml with distilled water. Measure the absorbance of the solution against reagent blank at 460 nm in a glass cell of 10 mm thick. The content must be kept at 20 °C or lower to prevent the cyanolysis of higher polythionates. The thiocyanate equivalent can be obtained from the calibration curve prepared by using standard thiosulfate or thiocyanate solutions.

Procedure B. Cyanolysis of Tetrathionate in the Presence of Acetone Followed by Cupric Ion-Catalyzed Cyanolysis of Thiosulfate: Transfer an aliquot of the sample solution to a 50-ml volumetric flask, and add water to give a total volume of about 15 ml. Neutralize with 1 M ammonia water to thymolphtalein, add 10 ml of acetone, and cool to 20 °C. Add 2 ml of 0.5 M potassium cyanide solution and maintain at 20 °C for 20 min. Add 1.5 ml of 0.2 M cupric chloride solution, and apply the same ensuing manipulation as that in Procedure A.

Procedure C. Cyanolysis of Trithionate and Tetrathionate in Boiling Water Bath Followed by Cupric Ion-Catalyzed Cyanolysis of Thiosulfate: Transfer an aliquot of the sample solution to a 50-ml volumetric flask. Add a few drops of 0.1% thymolphtalein as well as 2 ml of 0.5 M potassium cyanide solution, and also 1 M ammonia water until a blue color comes out. Keep the flask in a boiling water for 30 min, and then cool to room temperature. Add 1.5 ml of 0.2 M cupric chloride solution and apply the same ensuing manipulation as that in Procedure A.

Unless otherwise stated, the concentrations mentioned in this report are values presented when the solutions are made up to 50 ml. The term of "cyanolysis" denotes "cyanolysis in the absence of cupric ions", and is distinct from "cupric ion-catalyzed cyanolysis". The degree of cyanolysis in each procedure is expressed as the ratio of equivalents of thiocyanate obtained to those expected to be obtained which are shown in Table 1. The concentrations of the stock solution of trithionate and of tetrathionate were determined on the assumption that the purities of both samples were 100%, since the impurities are not correctly determined by any of the methods previously reported. A Hitachi spectrophotometer model 101 was used to measure the absorbance.

Results and Discussion

Procedure A. Cupric Ion-Catalyzed Cyanolysis of Thiosulfate at pH 4.5. In Procedure A, the reaction shown by Eq. (1) is expected to proceed exclusively.

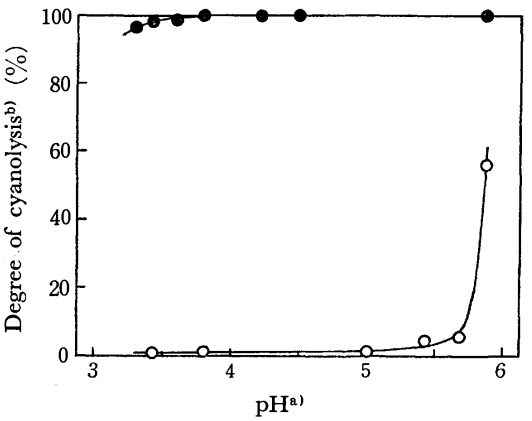

Fig. 1. Effect of pH on the cyanolysis of thiosulfate and tetrathionate.
Concn of KCN: 10 mM, concn. of $CuCl_2$: 6 mM, $S_2O_3^{2-}$(●) and $S_4O_6^{2-}$(○) taken: 5.00 μmol/50 ml.
a) pH values are those shown after $CuCl_2$ addition, which differed from those of the buffer solutions used by less than 0.2.
b) The degree of cyanolysis at each pH value was calculated by [(the absorbance obtained when such solutions as sample, buffer, KCN, $CuCl_2$ and $Fe(NO_3)_3$-$HClO_4$ were mixed in this order)/(the absorbance obtained when such solutions as sample, KCN, $CuCl_2$, $Fe(NO_3)_3$-$HClO_4$ and buffer were mixed in this order)] × 100. In the cyanolysis of tetrathionate, the reaction mixtures were maintained at the room temperature for 5 min before an addition of $CuCl_2$ solution.

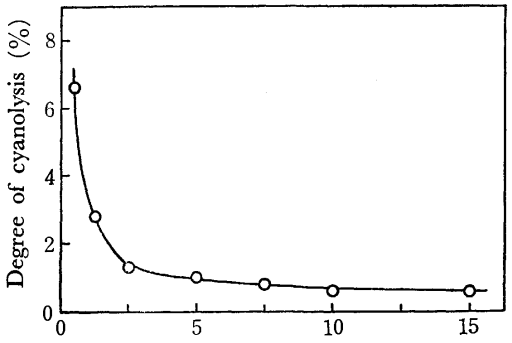

Fig. 2. Effect of the amount of acetate buffer solution of pH 4.5 on the cyanolysis of tetrathionate.
Concn. of KCN: 10 mM, concn. of $CuCl_2$: 6 mM, $S_4O_6^{2-}$ taken: 5.00 μmol/50 ml.

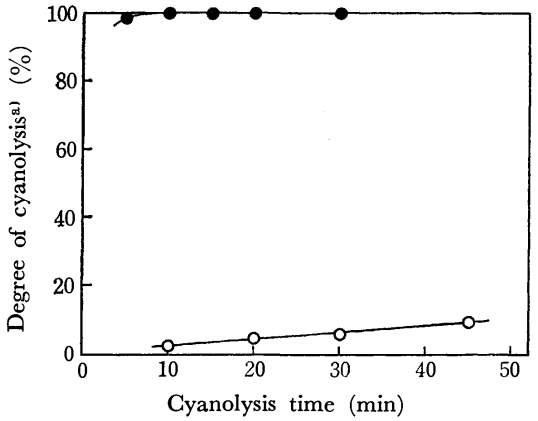

Fig. 3. Cyanolysis of trithionate and tetrathionate by Kelly's method.
○: trithionate, ●: tetrathionate.
Temp.: 5 °C, concn. of KCN: 20 mM, cyanolysis pH: 9.7, $S_3O_6^{2-}$ taken: 10.13 μmol/50 ml, $S_4O_6^{2-}$ taken: 5.00 μmol/50 ml.
a) Determined by using a calibration curve prepared from a standard thiocyanate solution. See Table 1 for the theoretical equivalents of thiocyanate.

It has been cleared by Urban[7] that the reaction shown by Eq. (1), catalyzed by cupric ions, proceeds selectively if the pH is carefully controlled, but the procedure is complicated. Figure 1 shows the results of the cyanolysis of thiosulfate and tetrathionate in the presence of acetate buffer solutions of various pH values. It is clear that the reaction shown by Eq. (1) takes place quantitatively above the pH value of 4, while the cyanolysis of tetrathionate hardly proceeds below the pH value of 5. These results are almost consistent with those by Urban.[7] Koh *et al.*[17] have reported that thiosulfate is not converted quantitatively to thiocyanate below the pH value of 5. This discrepancy may be attributed to their determination of pH values after an addition of cyanide solution. Figure 2 shows the effect of the amount of buffer solution added on the degree of cyanolysis of tetrathionate. It is clear that the addition of more than 5 ml has little effect. The amount added in the recommended procedure has been decided to be 10 ml per 50 ml so as to depress the fluctuation of pH in the analysis of practical samples.

The cyanolysis degree of 10 μmol of trithionate and that of 5 μmol of tetrathionate were 0.3 and 0.6%, respectively, showing that the cyanolysis of thiosulfate shown by Eq. (1) proceeds exclusively in the presence of acetate buffer of pH 4.5.

Procedure B. Cyanolysis of Tetrathionate in the Presence of Acetone Followed by Cupric Ion-Catalyzed Cyanolysis of Thiosulfate. In Procedure B, the reactions shown by Eqs. (1) and (4) are expected to proceed, while the cyanolysis of trithionate shown by Eq. (2) must be depressed. Kelly *et al.*[18] have described that the cyanolysis of trithionate can be depressed under the conditions of reaction temperature 5 °C and pH 9.65, but the actual degree of cyanolysis of trithionate is not shown.

The procedure proposed by Kelly *et al.* (Treatment I) was applied to analyses of trithionate and tetrathionate. The results in Fig. 3 show that tetrathionate undergoes a quantitative conversion according to Eq. (3), while the degree of cyanolysis of trithionate cannot be ignored. One of the reasons why recoveries of tetrathionate in the analysis of mixtures tend to be high, and those of thiosulfate correspondingly low by their method, may be that the cyanolysis of trithionate is not depressed quantitatively.

Several sorts of organic solvents were added to lower the dielectric constant of the solution, so as to prevent the cyanolysis of trithionate. Organic solvents were added after the regulation of pH. As is evident from the results shown in Table 3, the degree of cyanolysis of trithionate is depressed greatly by the addition of organic solvents, which, however, cannot be related simply to the dielectric constant of the solution. The cyanolysis in the presence of methanol and acetone was

Table 3. Effect of organic solvents on the cyanolysis of trithionate and tetrathionate in the absence of cupric ions

Organic solvent added (vol.%)	Degree of cyanolysis[a] (%)

investigated in detail, results of which being shown in Tables 4 and 5, respectively. Under each table are described the optimum conditions, where at as near as 20 °C, in a short time, the cyanolysis of tetrathionate is saturated, and that of trithionate shows its minimum.

In the case when methanol was added, ferric nitrate–nitric acid solution[6] was used instead of ferric nitrate–perchloric acid solution, so as potassium perchlorate not to precipitate. As is evident from Table 6, the conditions shown under Table 5 seem to be superior to those shown under Table 4, in respect that the ab-

Amount of sample taken (μmol/50 ml): $S_2O_3^{2-}$ 10.00, $S_3O_6^{2-}$ 9.90, $S_4O_6^{2-}$ 5.04.

sorbance is not affected so much by co-existing ions. Accordingly, the authors have concluded that acetone is superior to methanol as a solvent to be added for depressing the cyanolysis of trithionate. Nietzel *et al.*[5] have reported that the sensitivity of analysis is increased by the addition of acetone in the cyanolysis of tetrathionate. However, it may be a new finding that the degree of cyanolysis of trithionate is depressed by the addition of organic solvents.

The degrees of cyanolysis of thiosulfate, trithionate and tetrathionate under the recommended conditions are given in Table 7. It is clear that the degree of cyanolysis of trithionate is extremely low, compared with the value of 4.7% under the conditions proposed by Kelly *et al.* (see Ref. 18, Treatment I). On the other hand, the degree of cyanolysis of tetrathionate was almost 100%. However, it may be well considered that 1% of thiosulfate formed as shown by Eq. (3) is converted to thiocyanate, since the purity of tetrathionate sample is not necessarily pure, and the cyanolysis of thiosulfate proceeds by 0.8% under these above-mentioned conditions. The reason why the discrepancy between expected value and obtained value in Treatment I is much larger than the discrepancies obtained in Treatments II and III proposed by Kelly *et al.*, may be also related to the phenomena of partial cyanolysis of thiosulfate as described above. On the other hand, the error due to the partial cyanolysis of thiosulfate may be eliminated, if all of the thiosulfate are converted to thiocyanate in the presence of cupric ions.

Now Procedure B′ will be discussed below. This procedure denotes the cyanolysis procedure for only tetrathionate in the absence of cupric ions and is identical, in principle, with Treatment I proposed by Kelly *et al.* As a relation of $S_B=S_A+2S_{B'}$ exists between the thiocyanate equivalents(S) of three sorts of procedures, one of the three procedures can be omitted for the determination of thiosulfate, trithionate and tetrathionate. It seems that Procedure B′ is most apt to produce error among the three procedures, so the authors have not adopted this procedure as one of the recommended procedures. Procedure B′, however, is useful for judging if higher polythionates are present or not in the sample solutions.

In Table 8, the thiosulfate concentration obtained in the presence of acetone is compared with that obtained in the absence of acetone, showing that the cyanolysis of thiosulfate proceeds quantitatively in

Table 8. Effect of acetone on the cupric ion-catalyzed cyanolysis of thiosulfate[a]

Addition (vol.%)	$S_2O_3^{2-}$ obtained (mM)
None	1.042

Concn. of KCN: 20 mM, concn. of $CuCl_2$: 6 mM, $S_2O_3^{2-}$ concn. determined by iodometry: 1.035 mM.
a) The calibration curves were prepared by using a standard thiocyanate solution. The figures are the means of three measurements.

Procedure B. The purity of potassium tetrathionate sample used in the present study was found to be 99.0% by means of Procedure B.

Procedure C. Cyanolysis of Trithionate and Tetrathionate in Boiling Water Bath Followed by Cupric Ion-Catalyzed Cyanolysis of Thiosulfate. In Procedure C, not only thiosulfate and tetrathionate but also trithionate must be converted to thiocyanate. Urban[8] has reported the conditions under which the cyanolysis of trithionate proceeds quantitatively. These conditions, however, are not practical due to the extremely long reaction time. Kelly *et al.*[18] have proposed a procedure for the determination of trithionate by means of its cyanolysis at 100 °C and pH 9.6, followed by cupric ion-catalyzed cyanolysis of thiosulfate formed by the side reaction shown by Eq. (5).

$$S_3O_6^{2-} + H_2O = S_2O_3^{2-} + SO_4^{2-} + 2H^+ \quad (5)$$

The principle of Procedure C in the present study is wholly identical with that proposed by Kelly *et al.* The addition of a large amount of phosphate, however, decreased the absorbance, as in the case of Procedure B, so the present authors decided to adopt the recommended procedure as shown above. There seems to be sufficient probability that thiosulfate and tetrathionate undergo the quantitative cyanolysis under the conditions of Procedure C.

The cyanolysis of trithionate without cupric ions was investigated at various temperatures, the results of which are shown in Fig. 4. It is obvious that the maximum

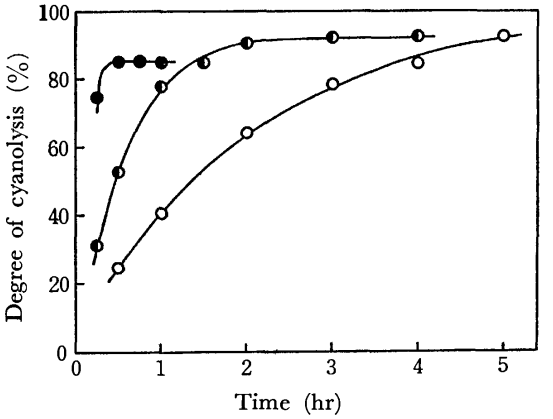

Fig. 4. Cyanolysis of trithionate at various temperatures.
Temp. (°C): ○ 50, ◐ 70, ● 90—95.
Concn. of KCN: 20 mM, $S_3O_6^{2-}$ taken: 4.95 μmol/50 ml.

recovery of trithionate decreases gradually with the increase of the cyanolysis temperature. On the other hand, the recoveries of trithionate under the following two sorts of cyanolysis conditions for 3 hr at 50 °C and 30 min at 95 °C, were the same and amounted to 97.6%, in the case when cupric ions were added after the cyanolysis. A difference of 2.4% between the expected value and the found value may be attributed to the impurities of the sample. Accordingly, it seems that trithionate undergoes the side reaction as shown by Eq. (5) during the cyanolysis at high temperature, and that Procedure C can be performed with a satisfactory accuracy for trithionate as well as thiosulfate and tetrathionate, as having been shown by Kelly *et al.* The purity of potassium tetrathionate sample used in the present study was found to be 99.3% by means of Procedure C.

Precision and Range of Determination. The precisions of Procedures A, B and C were evaluated by determining the concentrations of thiosulfate, tetrathionate and trithionate solutions, respectively, the results of which are shown in Table 9. An absorbance of 1.0 was obtained, when Procedures A, B and C were carried out, taking 12, 11 and 12 μ equivalents of thiocyanate in a 50-ml volumetric flask, respectively.

TABLE 9. REPLICATE DETERMINATION OF THE CONCENTRATIONS OF THIOSULFATE, TETRATHIONATE AND TRITHIONATE SOLUTIONS

Sample solution / Procedure applied		$S_2O_3^{2-}$ A	$S_4O_6^{2-}$ B	$S_3O_6^{2-}$ C
Analysis	1	0.495 mM	0.495 mM	0.489 mM
	2	0.496	0.495	0.488
	3	0.496	0.496	0.487
	4	0.495	0.495	0.487
	5	0.495	0.495	0.488
	6	0.495	0.494	0.488
Average		0.4953	0.4950	0.4878
CV (%)		0.23	0.28	0.34

TABLE 10. APPLICATION TO THE ANALYSIS OF MIXTURES OF THIOSULFATE, TRITHIONATE AND TETRATHIONATE (unit: mM)

		$S_2O_3^{2-}$	$S_3O_6^{2-}$	$S_4O_6^{2-}$	Procedures
Expt. 1	Expected	0	0	0.494	
	Found	0.002	0.004	0.486	A, B, C
2	Expected	0.364	0	0.368	
	Found	0.371	0.008	0.358	A, B, C
3	Expected	0.414	0.393	0.401	
	Found	0.418	0.382	0.395	A, B, C
		0.418	0.358	0.407	A, B', C
		0.394	0.382	0.407	B', B, C

The sample solutions were prepared by mixing the individual stock solutions. Procedure B' is identical with Procedure B; the only difference is that cupric chloride is not added in Procedure B'. In the case when Procedure B' is adopted, the amount of thiosulfate, trithionate and tetrathionate are given as follows: $(S_2O_3^{2-}) = S_B - 2S_{B'}$, $(S_3O_6^{2-}) = S_C - S_A - 2S_{B'}$, $(S_4O_6^{2-}) = S_{B'}$.

Absorbance and concentration showed a good linear relation between them within this concentration range.

Application to the Analyses of Mixtures. From the results described above, it is concluded that Procedures A, B and C can be performed without any noticeable side reactions. The following equivalents of thiocyanate(S) are formed by the three procedures (see Table 1):

$$S_A = (S_2O_3^{2-})$$
$$S_B = (S_2O_3^{2-}) + 2(S_4O_6^{2-})$$
$$S_C = (S_2O_3^{2-}) + (S_3O_6^{2-}) + 2(S_4O_6^{2-}).$$

Then, the amount of the species are given as follows:

$$(S_2O_3^{2-}) = S_A$$
$$(S_3O_6^{2-}) = S_C - S_B$$
$$(S_4O_6^{2-}) = \frac{1}{2}(S_B - S_A).$$

Table 10 shows the results of analyses of the mixtures consisting of thiosulfate, trithionate and tetrathionate. The values determined by Procedures A, B and C agree well with the expected values with a maximum discrepancy of 3%. This discrepancy seems to arise mainly by assuming that the polythionate samples are pure. On the other hand, it is noted that in the case when Procedure B' is adopted, recoveries of tetrathionate tend to be high, while those of thiosulfate or trithionate tend to be correspondingly low. This phenomena may be explained by the fact that the cyanolysis of thiosulfate and trithionate cannot be depressed completely in Procedure B'.

In the analytical method described here, polythionates above tetrathionate were not considered. Investigation on the photometric determination method for thiosulfate, trithionate, tetrathionate and pentathionate are currently under way. If polythionates above tetrathionate react with cyanide quantitatively in Procedure B as shown in Eq. (6), the value of $1/2(S_B - S_A)$

$$S_nO_6^{2-} + (n-2)CN^- + 2OH^- = (n-2)SCN^- + SO_3^{2-} + SO_4^{2-} + H_2O \quad (6)$$

would be as follows: $((S_4O_6^{2-}) + 3/2(S_5O_6^{2-}) + 2(S_6O_6^{2-}) + \cdots\cdots)$. Paper chromatography[21] may be useful for judging the presence of such higher polythionates.

In the reaction of low valence sulfur compounds, a few sorts of polythionates often appear together with the familiar compounds such as thiosulfate, sulfite and sulfate. However, the analysis of sulfite and sulfate is not a serious problem. Accordingly, the present analytical method, by which the determination of thiosulfate, trithionate and tetrathionate in the concomitant presence of them can be made with a great simplicity and a high accuracy, may be used widely in various fields.

Phase Equilibria in the $Fe-Fe_2O_3-Eu_2O_3$ System at 1200 °C

Tadashi SUGIHARA, Noboru KIMIZUKA,* and Takashi KATSURA

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

**National Institute for Researches in Inorganic Materials, Sakuramura, Niiharigun, Ibaragi 300-31*

(Received October 9, 1974)

The standard Gibbs energies of the reaction of $EuFeO_3$ and $Fu_3Fe_5O_{12}$ were determined to be -63300 ± 200 cal and -297800 ± 600 cal respectively at 1200 °C by means of following reactions: $Fe+1/2\ Eu_2O_3+3/4\ O_2=EuFeO_3$ and $5\ Fe+3/2\ Eu_2O_3+15/4\ O_2=Eu_3Fe_5O_{12}$, based on the phase equilibria in the $Fe-Fe_2O_3-Eu_2O_3$ system.

Many works on the double oxides involving rare earth sesquioxide and iron oxide have been investigated from the standpoint of crystal chemistry and the magnetic properties of perovskite and garnet structures.[1] Recently, Bedford and Catalano[2] have confirmed the existence of EuO, Eu_3O_4, and Eu_2O_3 at 1500 °C; they were first found by Bärnighausen.[3] McCarthy and Fischer[4] have also studied the Eu–Fe–O system at 1200 °C in a flowing argon atmosphere; they have also confirmed these compounds in addition to $EuFeO_3$ and $Eu_3Fe_5O_{12}$. However, very few studies have been done on the Gibbs energy of the reaction of lanthanoid-iron -perovskite or -garnet.

Recently, Kimizuka and Katsura[5] have determined the standard Gibbs energy of the reaction of $LaFeO_3$ from metallic iron, La_2O_3, and oxygen on the basis of the phase equilibria in the $Fe-Fe_2O_3-La_2O_3$ system at 1204 °C. They[6] have also established the phase equilibria in the $Fe-Fe_2O_3-Y_2O_3$ system at 1200 °C and determined the Gibbs energy of the reactions of $YFeO_3$, $Y_3Fe_5O_{12}$, and YFe_2O_4.

In the present study, we have determined the standard Gibbs energy of the reaction of $EuFeO_3$ and $Eu_3Fe_5O_{12}$ at 1200 °C on the basis of the phase equilibria in the $Fe-Fe_2O_3-Eu_2O_3$ system.

Experimental

Materials. High-purity-grade (99.9%) Eu_2O_3 and guaranteed-reagent-grade Fe_2O_3 were employed as the starting substances. Eu_2O_3 was heated at 1200 °C in air for 2 days to obtain B-type Eu_2O_3.[7] Fe_2O_3 was heated at 900 °C in air for 1 day. The subsequent procedures to obtain the sintered mixtures were the same as those described in a previous paper.[5]

Apparatus and Procedures. The quenching and thermogravimetric methods were adopted in the present study; the details of the procedures have been described by Kimizuka and Katsura.[5,6] The weight of the sample in oxygen was chosen as the reference for thermogravimetry. The equilibrium composition was determined by means of two side reactions. The quenching method employed in the present study is the same as that described in a previous paper,[6] the phases in quenched samples were identified by the powder X-ray diffraction method, with Mn-filtered Fe-$K\alpha$ radiation. The Fe^{2+}/Fe^{3+} ratio in the quenched nonstoichiometric $EuFeO_3$ was determined by the wet chemical method.[8]

Results and Discussion

Phase Equilibria. The equilibrium data at 1200 °C are summarized in Table 1 and are illustrated in Fig. 1. The following phases were stable under the present ex-

Abbreviations have the following meaning: E=Eu_2O_3, Pv=$EuFeO_3$, G=$Eu_3Fe_5O_{12}$, H=Fe_2O_3, M=Fe_3O_4, W=FeO, Fe=metallic iron.

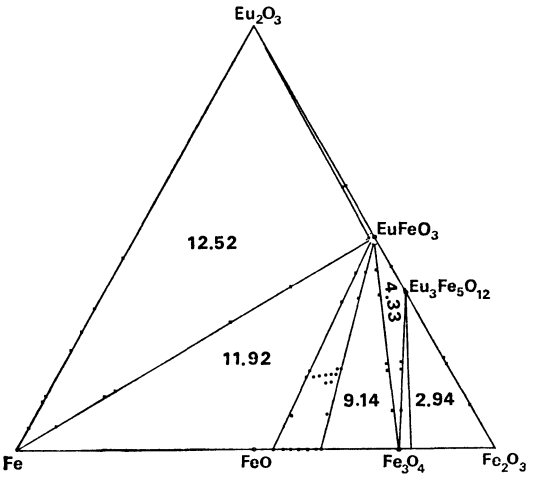

Fig. 1. Phase equilibria in the Fe-Fe_2O_3-Eu_2O_3 system at 1200 °C.
Numbers in the Figure mean values of $-\log P_{O_2}$ at which three crystalline phases are in equilibrium state. Small dots show the experimental results given in Table 1.

perimental conditions: Europium sesquioxide (Eu_2O_3), hematite (Fe_2O_3), magnetite (Fe_3O_4), wüstite (FeO), metallic iron (γ-Fe), europium-iron-perovskite ($EuFeO_3$), and europium-iron-garnet ($Eu_3Fe_5O_{12}$). The equilibria among the three condensed phases are as follows: (1) $EuFeO_3$, Eu_2O_3, and metallic iron, (2) $EuFeO_3$, wüstite, and metallic iron, (3) $EuFeO_3$, magnetite, and wüstite, (4) $EuFeO_3$ $Eu_3Fe_5O_{12}$, and magnetite, and (5) $Eu_3Fe_5O_{12}$, magnetite, and hematite. The following phases were characterized with respect to the stoichiometry: (a) Pure Eu_2O_3 was stable down to an oxygen partial pressure of $10^{-15.80}$ atm. However, it showed a small degree of non-stoichiometry at $10^{-15.80}$ atm. McCarthy and White[9] have reported the approximate phase relation of the Eu–Eu_2O_3 system at elevated temperatures up to 2200 °C; they showed the non-stoichiometry for Eu_2O_3 at 1200 °C and about 10^{-15} atm P_{O_2}, but they did not ascertain the extent of this non-stoichiometry. In the present study, by means of the thermogravimetric method, we determined the composition of the non-stoichiometric Eu_2O_3 phase to be $Eu_2O_{2.98\pm0.02}$ at $10^{-15.80}$ atm P_{O_2}: The lattice constants of both stoichiometric and non-stoichiometric Eu_2O_3 are given in Table 2. It is supposed that the non-stoichiometric Eu_2O_3 has a larger unit cell volume than the stoichiometric Eu_2O_3; this may be caused by the substitution of Eu^{2+} for Eu^{3+}. (b) The deviation from the stoichiometric composition of $Eu_3Fe_5O_{12}$ was not observed, and the lattice constants of the respective $Eu_3Fe_5O_{12}$ compounds equilibrated with Fe_2O_3, $EuFeO_3$ and with Fe_3O_4 were identical with each other. The values of stoichiometric $Eu_3Fe_5O_{12}$ are identical with those obtained by Espinosa.[10] (c) $EuFeO_3$ showed a significant deviation from the stoichiometry at relatively low oxygen partial pressures. The degree of non-stoichiometry was determined by both thermogravimetry and wet chemical analysis. These results were consistent with each other. The maximum deviation was

Table 2. Lattice constants of Eu_2O_3 and $EuFeO_3$

a) Eu_2O_3 (monoclinic B-type)

Deviations in *a*, *b*, and *c* are ±0.001 by the least squares method, and those of *V* ±0.1.

determined to be $EuFeO_{2.976}$ at an oxygen partial pressure of $10^{-12.52}$ atm; at this point the non-stoichiometric $EuFeO_3$ was in equilibrium with both metallic iron and stoichiometric Eu_2O_3. $EuFeO_3$ shows a small but equivocal solubility of the three components. Since we could not determine the exact boundary of the $EuFeO_3$ field, the $EuFeO_3$ field was approximately bounded by the dotted line shown in Fig. 1. The lattice constants of $EuFeO_3$ in equilibrium with Eu_2O_3 and $Eu_3Fe_5O_{12}$, and of non-stoichiometric $EuFeO_3$ with the composition of $EuFeO_{2.976}$, were compared with those of stoichiometric $EuFeO_3$ given in Table 2.

(2) Calculation of the Standard Gibbs Energy of the Reaction of $EuFeO_3$ and $Eu_3Fe_5O_{12}$. On the basis of the phase equilibria, we may determine the following two standard Gibbs energies of the reaction of $EuFeO_3$ and $Eu_3Fe_5O_{12}$ from metallic iron, Eu_2O_3, and oxygen:

$$Fe + 1/2\,Eu_2O_3 + 3/4\,O_2 = EuFeO_3 \quad (1)$$

$$5\,Fe + 3/2\,Eu_2O_3 + 15/4\,O_2 = Eu_3Fe_5O_{12} \quad (2)$$

Since the $EuFeO_3$ component in equilibrium with metallic iron and Eu_2O_3 has the composition of $EuFeO_{2.976}$, it is convenient to choose the reference activity of the $EuFeO_3$ component as unity at this composition. As has been described before, the Eu_2O_3 component had a small compositional variation at lower oxygen partial pressures. However, the composition of Eu_2O_3 was nearly stoichiometric at an oxygen partial pressure of $10^{-12.52}$ atm, at which Reaction (1) was in the equilibrium state. Thus, with reference to Eq. (1), we may determine the standard Gibbs energy of the reaction of $EuFeO_3$ as follows

$$\Delta G^0(1) = 3/4\,RT \ln P_{O_2} = -63300\pm200\ \text{cal}\cdot\text{mol}^{-1},$$

where R and T indicate the gas constant and the absolute temperature respectively. The experimental error was estimated on the basis of the fluctuations of both temperature and the oxygen partial pressure.

Because the stoichiometric $Eu_3Fe_5O_{12}$ was in equilibrium with both stoichiometric $EuFeO_3$ and Fe_3O_4 at an oxygen partial pressure of $10^{-4.33}$ atm, the standard Gibbs energy change, referred to the following equation (3), may be calculated to be -4900 ± 200 cal:

$$3\,EuFeO_3 + 2/3\,Fe_3O_4 + 1/6\,O_2 = Eu_3Fe_5O_{12} \quad (3)$$

According to Darken and Gurry,[11] the activity of metallic iron in stoichiometric magnetite in equilibrium with wüstite is $10^{-1.545}$ at 1200 °C, while the oxygen partial pressure related to the wüstite-magnetite equilibrium in $10^{-9.14}$ atm. Thus, the standard Gibbs energy of the formation of Fe_3O_4, $\Delta G^0(4)$, referred to the following equation (4) may be calculated to be -154500 ± 300 cal at 1200 °C:

$$3\,Fe + 2\,O_2 = Fe_3O_4 \quad (4)$$

By adding $\Delta G^0(3)$, $2/3\Delta G^0(4)$, and $3\Delta G^0(1)$, we obtain the standard Gibbs energy of the reaction of $Eu_3Fe_5O_{12}$, $\Delta G^0(2)$, referred to Equation (2), as -297800 ± 600 cal.

It is interesting to compare the present Gibbs energy data with those of $LaFeO_3$, $YFeO_3$, and $Y_3Fe_5O_{12}$ which have been determined by Kimizuka and Katsura.[5,6] Comparing these data, we may observe that the standard Gibbs energy of the reaction of lanthanoid-iron perovskite from metallic iron, lanthanoid sesquioxide, and oxygen increases with decrease in the ionic radii of lanthanoid ions. The relationship between the ionic radii and the Gibbs energy will be discussed in more detail in the near future.

The authors wish to express their thanks to Dr. Kenzo Kitayama and Mr. Toshimori Sekine, Tokyo Institute of Technology.

Thermochemical Properties of Lanthanoid-Iron-Perovskite at High Temperatures

Takashi KATSURA, Kenzo KITAYAMA, Tadashi SUGIHARA, and Noboru KIMIZUKA*

Department of Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

**National Institute for Researches in Inorganic Materials, Kurakake, Sakuramura, Niihari-gun, Ibaragi 300-31*

(Received October 9, 1974)

The standard Gibbs energy of formation of $\bar{C}FeO_3$($\bar{C}$=La, Nd, Sm, Eu, Gd, Tb, and Dy) from metallic iron, $\bar{C}_2O_3$, and oxygen has been determined at temperatures from 1473 to 1673 K. Based on the free-energy data, the heat of reaction and the entropy change resulting from the reaction have been calculated. The values of the heat of reaction of $LaFeO_3$, $NdFeO_3$, $SmFeO_3$, $EuFeO_3$, and $GdFeO_3$ (the first group) were identical, -107 kcal/mol, at the present temperature interval. However, the values of the heat of reaction of $TbFeO_3$ and $DyFeO_3$ (the second group) decreased with an increase in the temperature. The entropy change of each reaction in the first group was constant, independent of the temperature, and each value decreased in the sequence from $LaFeO_3$ to $GdFeO_3$. The entropy change of the second group decreased with an increase in the temperature. The change of the standard Gibbs energy was intimately related to the ionic radii of $\bar{C}$-ions, and the relationship between the Gibbs energy and the tolerance factor has been clarified.

Recently, Kimizuka and Katsura[1,2] and Sugihara *et al.*[3] have determined the standard Gibbs energy of the formation of $LaFeO_3$, $YFeO_3$, $Y_3Fe_5O_{12}$, $EuFeO_3$, and $Eu_3Fe_5O_{12}$ at 1200 °C on the basis of the phase equilibria in the Fe–Fe_2O_3–La_2O_3, Fe–Fe_2O_3–Y_2O_3, and Fe–Fe_2O_3–Eu_2O_3 systems. Sugihara *et al.*[3] suggested that the standard Gibbs energy of formation of lanthanoid-iron-perovskite from metallic iron, lanthanoid sesquioxides and oxygen would decrease in negative value with a decrease in the ionic radii of lanthanoid ions with 12 coordination number. Kimizuka and Katsura[2] and Kimizuka *et al.*[4,5] have found two series of new compounds, $\bar{A}Fe_2O_4$ ($\bar{A}$=Y, Ho, Er, Tm, Yb, and Lu) and $\bar{B}_2Fe_3O_7$ ($\bar{B}$=Yb and Lu), and determined the standard Gibbs energy of formation of YFe_2O_4. Tannieres *et al.*[6] and Evrard *et al.*[7] have also found the $\bar{A}Fe_2O_4$ and $Lu_2Fe_3O_7$ compounds, but they did not show any equilibrium relation in the Fe–Fe_2O_3–$\bar{A}_2O_3$ systems which could be used for calculating the standard Gibbs energy. It would be expected from the present knowledge about lanthanoid-iron-complex oxides that the $\bar{C}FeO_3$($\bar{C}$= La, Nd, Sm, EU, Gd, Tb, and Dy) would decompose straightforwardly to form metallic iron and $\bar{C}_2O_3$ at any definite oxygen partial pressure. On the other hand, the situation with $\bar{A}FeO_3$ is somewhat complicated because of the presence of the $\bar{A}Fe_2O_4$ and $\bar{B}_2Fe_3O_7$ compounds, and we can determine the standard Gibbs energy of formation of $\bar{A}FeO_3$ only after determining the standard Gibbs energy of formation of $\bar{A}Fe_2O_4$ and $\bar{B}_2Fe_3O_7$.

In the present study, we determine the standard Gibbs energy of formation of $\bar{C}FeO_3$ from metallic iron, $\bar{C}_2O_3$, and oxygen by the method of controlling the oxygen partial pressure by using a mixed gas of CO_2 and H_2. Temperatures were changed from 1473 to 1673 K. Based on the standard Gibbs energy data, we calculate the heat of reaction and entropy change resulting from the reaction, Fe+1/2 $\bar{C}_2O_3$+ 3/4 O_2=$\bar{C}FeO_3$. The relationship between the tolerance factor of the $\bar{C}FeO_3$ compounds and the standard Gibbs energy will also be presented.

Experimental

The experimental methods and apparatus adopted in this study are the same as those described by Kimizuka and Katsura.[1] Every equilibrium value of p_{O_2} was measured by means of a solid electrolyte cell composed of $(ZrO_2)_{0.85}(CaO)_{0.15}$. The values of P_{O_2} calculated from the thermochemical data[8] were in good agreement with those measured, and the differences were within ± 0.02 at most in terms of log P_{O_2} over the temperature and P_{O_2} ranges studied. The temperature was kept constant within ± 1 °C and was calibrated against the gold point.

A guaranteed reagent-grade Fe_2O_3 and a 99.9% pure-grade of each lanthanoid sesquioxide were used as the starting substances. The mixture of $Fe_2O_3/\bar{C}_2O_3=1$ was thoroughly mixed under ethyl alcohol and calcined at 1200 °C for from 20 to 30 hr in air. The subsequent procedures were the same as those described by Kimizuka and Katsura.[1] The weight change accompanying the reaction was followed by the thermogravimetric method within an error of ± 0.5 mg per about 3 g of every sample. The equilibrated sample was quenched rapidly, and the phases present were identified by an X-ray powder method.

Results and Discussion

The $\bar{C}FeO_3$ compounds decomposed straightforwardly to form metallic iron and $\bar{C}_2O_3$ at any definite oxygen partial pressure, and the reverse reaction occurred at the same P_{O_2} value.

We may write the general reaction scheme as follows:

$$Fe(s) + 1/2\bar{C}_2O_3(s) + 3/4O_2(g) = \bar{C}FeO_3(s) \quad (1)$$

In Equation (1), Fe(s) is in the form of γ-iron at temperatures from 910 to 1390 °C, while it is in the form of δ-iron from 1390 to 1534 °C.[9] Thus, in the present study, metallic iron is almost in the form of γ-iron except for $LaFeO_3$ at 1673 K. A recent study by Roth and Schneider[10] showed that La_2O_3 and Nd_2O_3 belong to the A-type with the hexagonal crystal system, Sm_2O_3, Eu_2O_3, and Gd_2O_3 to the B-type with the monoclinic crystal system, and Tb_2O_3 and Dy_2O_3, to the C-type with the cubic crystal system at the temperatures covered by the present study. The $\bar{C}FeO_3$ compounds are all perovskite-like compounds and all

belong to the orthorhombic crystal system. McCarthy and White[11] have studied the lower oxides of the Sm, Eu, Yb, Bedford anf Catalano[12] have also studied the Eu–Eu_2O_3, Sm–Sm_2O_3, and Yb–Yb_2O_3 systems at 1500 °C. As verified by them, $\bar{C}_2O_3$ is so stable at very low oxygen partial pressures that we cannot reduce them to lower oxidation states by the present techniques.

The most interesting fact in Equation (1) is that all the Fe^{3+} ions with the coordination numbers of 6 in the perovskite structure are reduced to metallic iron without passing through the state of Fe^{2+} ions.

Non-stoichiometry in $\bar{C}FeO_3$. It has been pointed out by Sugihara *et al.*[3] that $EuFeO_3$ has a non-stoichiometric composition, represented by $EuFeO_{3-x}$. This is also found in $\bar{C}FeO_3$, when the $\bar{C}$'s are Gd, Tb, and Dy. The deviated compositions of these compounds were determined to be approximately $\bar{C}FeO_{2.98}$ when the compounds were in equilibrium with metallic iron and Gd_2O_3, Tb_2O_3, or Dy_2O_3. We ascertained in addition no significant solubility of other components in the $\bar{C}_2O_3$ phases. The lattice constants of these non-stoichiometric compounds, synthesized at various temperatures and oxygen partial pressures, were obtained by the least-squares method. The results were almost identical with those for stoichiometric compounds. The lattice constants of stoichiometric $\bar{C}FeO_3$ were identical with those reported by Geller and Wood[13] and by Eibschütz.[14]

The Standard Gibbs Energy of Formation of $\bar{C}FeO_3$ from Metallic Iron, $\bar{C}_2O_3$, and Oxygen. In the present study, we define the activity of each $\bar{C}FeO_3$ component as being unity at the composition where each $\bar{C}FeO_3$ component is in equilibrium with both metallic iron and $\bar{C}_2O_3$ at the respective definite oxygen partial pressure. Thus, the standard Gibbs energy of formation $\bar{C}FeO_3$ from metallic iron, $\bar{C}_2O_3$, and oxygen can readily be calculated by measuring the equilibrium oxygen partial pressure in each assembly. Here, the $\bar{C}_2O_3$ phases are all in the stoichiometric composition, as has been mentioned before. The results are given in Table 1. The errors due to the fluctuations of both temperature and oxygen partial pressure may be estimated to be ±200 cal at most.

Figure 1 shows the relationship between $\Delta G^0/T$ and $1/T$, where T is the absolute temperature. As may be seen in Fig. 1, the slope for each $\bar{C}FeO_3$ except for $TbFeO_3$ and $DyFeO_3$ is straight and identical with all others. This means that the heat of reaction of each compounds except for $TbFeO_3$ and $DyFeO_3$ is constant, with an identical value of −107 kcal per mol. In the cases of $TbFeO_3$ and $DyFeO_3$, the heats of reaction change with temperature. The calculated heats of reaction at various temperatures are given in Table 1.

The Entropy Change. The entropy change, ΔS^0, is determined either by $(\Delta H^0-\Delta G^0)/T$ or $d\Delta G^0/dT$. The results are given in Table 1. As may be seen in Table 1, the entropy value of each compounds except for $TbFeO_3$ and $DyFeO_3$ is independent of the temperature and is constant with a good accuracy when we adopt the values of $(\Delta H^0-\Delta G^0)/T$.

Table 1. Values of standard Gibbs energy, heat of reaction, and entropy change

	1548	11.04	58.7	147	57	(65±5)

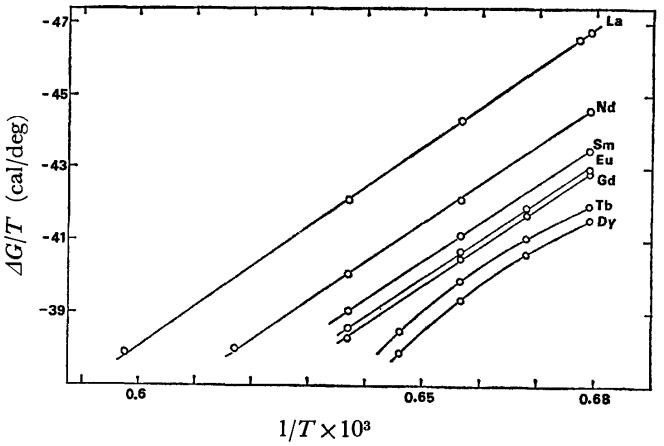

Fig. 1. The relationship between $\Delta G^0/T$ and $1/T$. The value at 1204 °C was cited from the paper by Kimizuka and Katsura.[1]

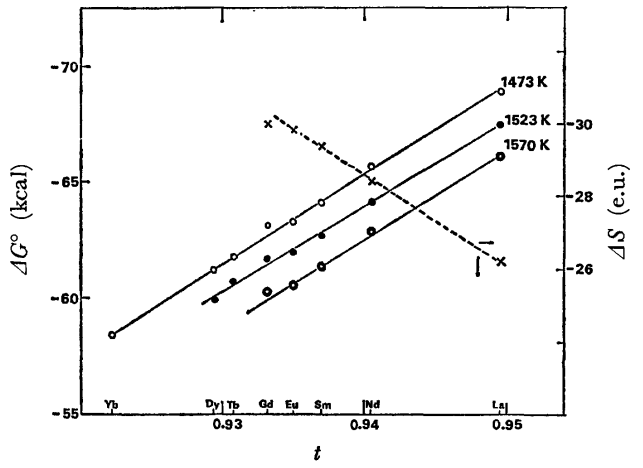

Fig. 2. The relationship between ΔG^0 and the tolerance factor t.

The values from $d\Delta G^0/dT$ seem to have some larger errors than those from $(\Delta H^0-\Delta G^0)/T$. On the other hand, the entropy change of $TbFeO_3$ and $DyFeO_3$ increases in negative value with an increases in the temperature.

It should be emphasized here that there are two groups of compounds in $\bar{C}FeO_3$ in respect to thermochemistry; the first includes $LaFeO_3$, $NdFeO_3$, $SmFeO_3$, $EuFeO_3$, and $GdFeO_3$, and the second, $TbFeO_3$ and $DyFeO_3$. This trend should be investigated furthermore with reference to the $\bar{A}FeO_3$ compounds.

The Relationship between the Tolerance Factor and the Standard Gibbs Energy of Formation of $\bar{C}FeO_3$. Figure 2 shows the relationship between the tolerance factor defined by Goldschmidt,[15] $[r_a+r_o=t\sqrt{2}(r_b+r_o)]$, and the standard Gibbs energy of formation of $\bar{C}FeO_3$ from metallic iron, $\bar{C}_2O_3$, and oxygen. In the tolerance-factor equation, r_a, r_b, and r_o mean the ionic radii of $\bar{C}$, Fe, and O ions in the perovskite structure respectively, and t is the tolerance factor. Here, we adopt the values reported by Espinosa[16] for ions of $\bar{C}$ with the coordination number of 12 in the perovskite structure. The ionic radii of Fe^{3+} and O^{2-} are 0.645 Å and 1.40 Å respectively; these values are given by Shannon and Prewitt.[17] The ΔG^0 value of $YbFeO_3$[18] is also given in Fig. 2. As may be seen in Fig. 2, the ΔG^0 value is proportional to the tolerance factor except for the case of $GdFeO_3$. The deviation in $GdFeO_3$ from the general trend is significant though within the range of experimental error; we cannot explain the reason for this deviation.

The entropy change resulting from the reaction is also plotted in Fig. 2. As is illustrated in Fig. 2, the entropy change decreases with a decrease in the tolerance factor.

The Fluorometric Determination of Gallium in Aluminum Metal with 8-Quinolinethiol[1]

Kunihiro WATANABE and Kyōzō KAWAGAKI

Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda-shi, Chiba 278

(Received December 18, 1974)

A method for the fluorometric determination of gallium in aluminum metal is presented which involves extraction with the methyl isobutyl ketone (MIBK) of the gallium 8-quinolinethiolate complex. The extracted complex has a greenish-yellow fluorescence, with an emission maximum at 505 nm. The maximum fluorescence intensity is obtained at a pH of the initial aqueous phase of around 3.3; the fluorescence remains stable for at least 2 hr. When 50 ml of a sample aqueous solution containing gallium and 0.2 ml of a 0.2% 8-quinolinethiol solution is subjected to extraction with 10 ml of MIBK, the quantity of gallium which can be present for determination in the sample solution amounts to 1 to 30 μg. For the removal of the interfering effects of zinc, cadmium, copper, and nickel on the fluorometric determination, gallium was extracted with isopropyl ether from a 7 M HCl solution. The relative error of this method was 5% for 0.019% gallium in aluminum metal.

The fluorometric determination of gallium with such reagents as oxine and rhodamine B has been proposed, and the application to gallium in aluminum metal has also been tested.[2,3]

A benzene-extraction method for the fluorometric determination of gallium with 8-quinolinethiol was investigated by Korenman *et al.*[4] and chloroform extraction, by Davis.[5] However, in these studies no metal of any practical use was tested. Details on the analytical conditions are not available, and there exists disagreement between these studies as to the optimum conditions. 8-quinolinethiol does not react with aluminum and magnesium, but forms a stable complex with gallium. In view of these facts, the present authors examined the conditions in the determination of gallium in aluminum metal. MIBK was used as the extraction solvent.

Experimental

Reagents. Standard solution of gallium: A stock solution of gallium was prepared by dissolving 0.1819 g of 99.999% gallium metal (Mitsubishi Kinzoku Kogyo) in 6 M hydrochloric acid. The standard solution was prepared by diluting the stock solution. 0.2% 8-quinolinethiol solution: 0.1 g of 8-quinolinethiol hydrochloride (Dojin Yakka) was dissolved in 50 ml of 6 M hydrochloric acid.

10% L-ascorbic acid solution: 10 g of L-ascorbic acid was dissolved in water, and the mixture was diluted to 100 ml. This solution was freshly prepared for every experiment. 0.1% *O*-phenanthroline solution: 0.25 g of *O*-phenanthroline was dissolved in 10 ml of ethyl alcohol, and the mixture was diluted to 250 ml with water.

0.2 μg/ml uranine solution: 0.10 g of uranine was dissolved in water and diluted to 100 ml. The solution was then further diluted with water to make a solution containing 0.20 μg uranine per ml. The resultant solution was used as a reference standard to adjust the sensitivity of the fluorescence spectrophotometer.

Other reagents: The MIBK used as an extraction solvent and all the other chemicals were of an analytical grade. Under some conditions, ammonia was washed with an 8-quinolinethiol solution and MIBK.

Apparatus. The fluorometric measurements were carried out using a Hitachi fluorescence spectrophotometer, Model 203, with a mercury lamp. A 120 W Xenon lamp was used as the exciting source for the measurements of the fluorescence and excitation spectra. A 1 cm × 1 cm quartz cell was used. A Toa Denpa Model HM-5 A glass electrode pH meter was used for the pH measurements. An Iwaki KM shaker was used.

Procedure. A sample solution containing less than about 10 μg of gallium was transferred into a beaker. Then, 0.2 ml of the 0.2% 8-quinolinethiol solution and 5 ml of the 10% ascorbic acid solution were added to the solution. After the solution has been diluted to 50 ml with water, the pH of the solution was adjusted to 3.3 with dilute hydrochloric acid or ammonia. The resultant aqueous solution was then transferred into a separatory funnel. The gallium complex was extracted for 5 min with 10 ml of MIBK. After the separation of the aqueous phase, the fluorescence intensity of the organic phase was measured using a uranine solution as a reference standard. The amount of gallium was evaluated from the calibration curve. The excitation and fluorescence wavelengths used were 365 and 505 nm (exciting source: a mercury lamp) respectively.

Results and Discussion

Excitation and Fluorescence Spectra. 8-Quinolinethiol reacts with gallium to form a complex of a yellowish-green fluorescence. The complex showed an excitation maximum at 395 nm and a fluorescence maximum at

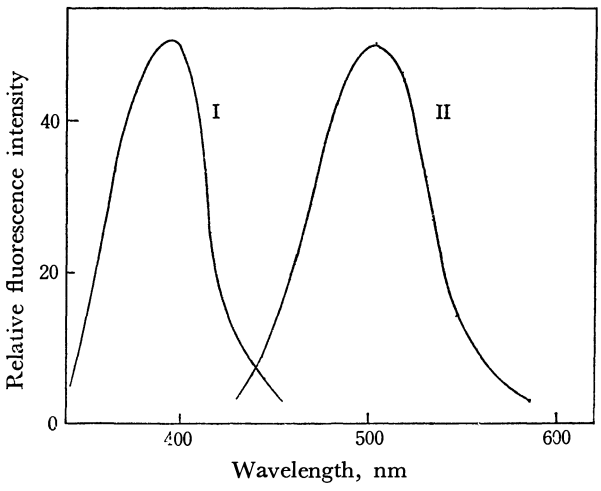

Fig. 1. Excitation and fluorescence spectra.
Excitation spectrum(I): Excited with xenon lamp and analyzed at wavelength for maximum fluorescence intensity.
Emission spectrum(II): Excited at 395 nm.

505 nm (exciting source: Xenon lamp). The apparent spectra are shown in Fig. 1.

Effect of the Amount of 8-quinolinethiol. The effect of the concentration of 8-quinolinethiol was investigated by adding various amounts of the reagent to a solution containing 5.8 μg of gallium. As is shown in Fig. 2, the maximum fluorescence intensity was obtained by the use of 0.1—0.2 ml of the 0.2% 8-quinolinethiol solution; above 0.2 ml of 8-quinolinethiol the fluorescence intensity decreased gradually in direct proportion to the amount of the reagent added. The fluorescence intensity of the reagent blank was found to be constant.

Effect of pH. The effect of the pH of the aqueous phase on the extraction was also studied. The results are shown in Fig. 3. The fluorescence intensity showed a maximum at pH 3.2—3.4. When the pH was higher than 3.5, the intensity decreased and became negligibly low at pH 11. Therefore, all the extractions were carried out at pH 3.3. According to Korenman, the optimum pH in a benzene extraction was 5, but Davis found that it was 3. The present result is in agreement with that of Davis.

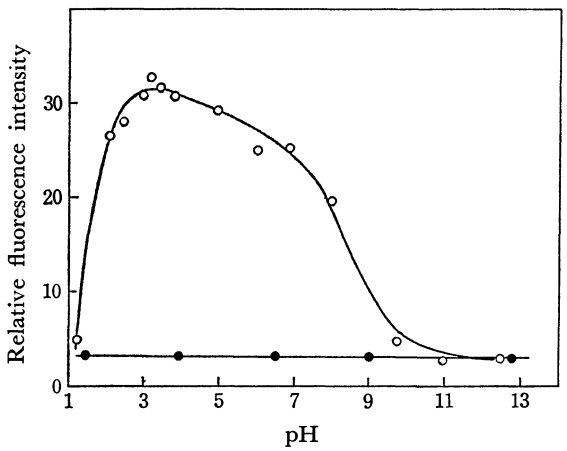

Fig. 3. Effect of pH on fluorescence intensity.
—○— Ga: 5.8 μg 0.2% 8-quinolinethiol: 0.2 ml
—●— Reagent blank

The pH was adjusted by adding hydrochloric acid or ammonia. The buffer solution used was a L-ascorbic acid solution. As the old ascorbic acid solution reduced the fluorescence intensity of the gallium complex, the solution was freshly prepared for each experiment.

Effect of the Shaking Time. The effect of the shaking time was tested in the range from 0.5 to 10 min. It was found that a 3-min shaking was sufficient. 5 min was chosen for shaking in the present experiments, though. The fluorescence intensity of an extracted complex was stable for at least 2 hr at room temperature.

Effect of the Volume of Aqueous Solution. When MIBK was used for the extraction of the chelate in water, a small amount of MIBK dissolved in the aqueous layer. For the investigation of the effect of the aqueous solution, the volume of the organic phase of MIBK was kept at 10 ml, while that of the aqueous phase was varied from 40 ml to 140 ml. As is shown in Fig. 4, the fluorescence intensity gradually increased in proportion to the volume of the aqueous phase, although no great effect of the volume of the aqueous solution on the intensity was observed.

Effect of Foreign Ions. The effect of 25 kinds of ions coexistent with 5.8 μg gallium was studied. The results are summarized in Table 1. The following ions did not interfere: aluminum, magnesium, calcium, chromium, scandium, lanthanum, titanium, zirconium, manganese, barium, and strontium ions. Zinc ions gave a positive error. A small amount of cobalt, nickel, copper, bismuth, iron, and silver ions reduced the fluorescence intensity. One milligram of vanadium ions (VO_3^-) reduced by ascorbic acid did not interfere. To remove some interfering ions in the above ions contained in aluminum metals, an isopropyl ether extraction method[6] was used.

The gallium chloride complex is extracted from the 7 M hydrochloric acid solution with isopropyl ether; then the organic phase is washed with 7 M hydrochloric acid, so that some interfering ions are completely removed from the gallium in the organic layer. In this separating method, zinc (up to 5 mg), cadmium (1.7 mg), copper (5 mg), nickel (1 mg), and cobalt (1 mg) do not interfere. Iron (III) is reduced to iron (II), masked with *O*-phenanthroline. However, the

iron *O*-phenanthroline complex increases the blank value slightly; therefore, a large amount of iron ions interferes.

Calibration Curves. The calibration curves for the determination of gallium were prepared under optimum conditions. The results are shown in Fig. 5. The I calibration curve was obtained by setting up the fluorometer at 50 using the standard uranine solution. The II curve was set at 25.

A linear relationship between the fluorescence intensity and the concentration of gallium was obtained over the concentration range of 0−10 μg of gallium per 10 ml of MIBK. The possible range for the accurate determination of gallium was 1—30 μg.

Synthetic Samples. The determination of gallium in some synthetic samples was done. For a synthetic sample containing copper, cobalt, nickel, and iron, which interfere significantly when present in even small amounts, both the gallium and the iron (III) were extracted with isopropyl ether from a 7 M hydrochloric acid solution. Then the iron (III) was reduced by an ascorbic acid solution, masked with *O*-phenanthroline. Table 2—4 shows the results of the determination of gallium. The samples containing zinc were

treated in the same way as above (Tables 2-2, 3, 5). For a sample containing aluminum, magnesium, iron, and vanadium, the ether extraction was omitted and the gallium 8-quinolinethiolate was directly extracted with MIBK. The results are shown in Table 2-1.

In all of the cases studied in these synthetic samples, the gallium could be determined with an average error of 3 percent.

Determination of Gallium in Aluminum Metal. From the experimental results described above, a recommendable procedure is as follows: Dissolve 0.1—0.3 g of a sample in 50 ml of hot 7 M hydrochloric acid. Transfer the resultant solution to a 100-ml volumetric flask. Bring up to the mark with a 7 M hydrochloric acid solution. Pipet a 10 ml aliquot into a 100-ml beaker, and add 20 ml of 7 M hydrochloric acid. Transfer the solution to a separatory funnel and shake for 5 min with 20 ml of isopropyl ether. After this extraction has been repeated twice using 10 ml of isopropyl ether, discard the aqueous phase. Wash the resultant ether solution two times, with 20-ml and 10-ml portions of 7 M hydrochloric acid. Then add 20 ml of water to the ether phase. Evaporate only the ether phase on a sand bath, and then cool the water phase. Add 5 ml of 5% ascorbic acid solution and 2 ml of a 0.1% *O*-phenanthroline solution to the

Table 3. Analytical results for standard sample NBS 85 B

	5.1	0.019	5.3	0.020
	5.3	0.020	5.2	0.020
20 ml	11.2	0.021		
	10.9	0.021		

Relative error: 5% for 0.019% gallium (standard sample NBS 85 B).

aqueous solution remaining in the beaker. After the dilution of the solution to 50 ml, add 0.2 ml of 0.2% 8-quinolinethiol and adjust the pH of the solution to 3.3. Transfer the solution to a separatory funnel, and then extract the gallium 8-quinolinethiolate complex by shaking for 5 min with 10 ml of MIBK. Then filter out the organic phase through a cotton plug. Transfer the extract to a quartz cell. The fluorescence intensity at 505 nm is measured at an excitation wavelength of 365 nm with reference to a 0.2 μg/ml uranine solution.

The accuracies of the amount of gallium in a sample as determined by the present method and by the conventional 2-methyl-8-quinolinol method[3,7] are shown in Table 3. The present method is shown to be accurate enough for the determination of gallium in the aluminum metal.

The authors would like to thank Mr. Hideto Kasagi for his assistance to experiments in the initial stage.

The Mechanism of Thermal Reactions in Apatites–Silica–Water Vapor Systems[1)]

Hideki MONMA and Takafumi KANAZAWA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received December 18, 1974)

The reactions of fluor-, hydroxy-, and chlorapatites with silica in the presence of water vapor have been studied under various conditions—*i.e.*, various amounts of added silica, various temperatures (up to 1300 °C), and various heating times and water-vapor pressures (0.6—760 mmHg). As the pressure increased, the decomposition rate of hydroxyapatite with silica decreased considerably. Fluorapatite and chlorapatite were found to be decomposed with silica after being partially defluorinated or dechlorinated. In the case of fluorapatite, no effect of silica addition was recognized under a low water-vapor pressure (0.6 mmHg). This effect was observed under a high water-vapor pressure (760 mmHg), accompanied by rapid increases in the fluorine volatility and the destruction rate of the apatite in their time-dependence plots. In the reaction using chlorapatite, a similar effect was found under both low and high pressures. The results for the defluorination and dechlorination could mostly be interpreted by assuming the following changes: (1) halogen-oxyapatite formation, (2) the substitution of hydroxyl ions for halogen ions, and (3) the decomposition of apatite with silica.

Fluorine volatilization during the heat-treatment of rock phosphate in the presence of water vapor is accelerated by adding silica. In fact, thermal treatments above 1300 °C can be carried out by applying this reaction process to produce a defluorinated phosphate. Some thermodynamic considerations and a preliminary experiment on the fluorapatite (FAp)–silica–water vapor system were described in previous papers by the present authors.[2,3)] On the basis of these studies, it was estimated that silica can react with partially or completely hydroxylated FAp, but not stoichiometric FAp. A similar estimation may also hold for chlorapatite (CAp).

The purpose of the present investigation is to obtain some information concerning the mechanisms of the destruction, defluorination, and dechlorination of apatites in the presence of both silica and water vapor.

Experimental

Materials. The FAp was prepared by heating a stoichiometric mixture of $Ca_3(PO_4)_2$ (thermally synthesized material) and CaF_2 (special-grade reagent) at 1150 °C for 2.5 hr in a N_2 gas flow. Another substance, CaF_2, was placed upstream near the mixture to minimize volatilization of fluorine from the reactant. This synthetic FAp contained 3.76% F. The hydroxyapatite (HAp) was synthesized by heating a mixture of $Ca_2P_2O_7$ and CaO (added as $CaCO_3$) in the molar ratio of 1 : 2.7 at 1200 °C for 3 hr in water vapor (p_{H_2O}=150—230 mmHg), and was then purified by washing it with an aqueous solution of NH_4Cl to remove the excess CaO. The CAp was prepared by heating a mixture of $Ca_2P_2O_7$, $CaCO_3$ and $CaCl_2$ in the molar ratio of 1 : 1 : 2.5 at 1200 °C for 3 hr, followed by air quenching and by washing with a NH_4Cl aqueous solution to remove the calcium salts other than apatite. The chlorine content in this synthetic CAp was 6.72%. Apatite–silica mixtures with molar ratios in silica/apatite of from 1/1 to 18/1 were prepared by manual mixing in an agate-mortar. As the SiO_2 sample, silica sand (α-quartz) for optical glass making was adopted after it had been purified with hydrochloric acid. All the samples thus prepared were ground to 200 mesh and then used.

Heat-treatment and Analyses. The reaction runs were carried out by heating the samples at various temperatures (up to 1300 °C) and times (up to 9 hr) in a Na–H_2O mixed gas flow of 150 ml/min (p_{H_2O}=0.6—760 mmHg). The partial water-vapor pressure in the flow of the N_2 gas used here was determined to be 0.6 mmHg from a comparison of the data shown in Fig. 2 with the thermal stability curve of HAp reported by Riboud.[4)]

The decomposition rate of FAp or HAp was determined from a calibration curve of the apatite content *vs.* the relative X-ray diffraction intensity. This intensity means $I_{AP}/(I_{AP}+I_{\alpha-T}+I_{\beta-T})$, where the I's are the diffraction intensities obtained by using CuKα radiation at 31.8 °, 30.6 °, and 31.0 ° in 2 θ for apatite, α-, and β- tricalcium phosphates respectively.[5,6)] The procedure described above was, however, inapplicable to the measurement of the CAp decomposition because of a considerable change in the diffraction pattern of CAp itself upon heating.[7)] In this case, we investigated qualitatively whether or not the decomposition occurred.

The fluorine and chlorine contents were determined by thorium-nitrate and potassium-thiocyanate titrarions respectively. DTA was conducted in air from room temperature to 1350 °C at a rate of 10 °C/min. The sample weight was 400—600 mg, and the reference material used was α-Al_2O_3.

Results and Discussion

Thermodynamic Considerations. FAp and CAp are considered to be thermally stable up to their melting temperatures, whereas the thermal stability of HAp is strongly dependent on the pressure of the coexisting water vapor.[4,5)] The reactivities of apatites with silica were determined by the calculation of the standard free-energy changes (ΔG°_r) in these reactions, assuming $Ca_3(PO_4)_2$, Ca_2SiO_4, $CaSiO_3$, CaO, H_2O, HF, HCl, SiF_4, and $SiCl_4$ as reaction products. On the basis of these calculations, the following results were obtained: the ΔG°_r values for a reaction of HAp–SiO_2 system became negative above 600—700 °C, and even above 760 mmHg of coexisting water vapor it was considered possible for the decomposition of HAp to occur. On the other hand, the ΔG°_r values for the reactions of FAp–SiO_2 and CAp–SiO_2 systems were always positive in the range of 25—1300 °C. However, silica possibly reacts with FAp or CAp during heat-treatment in the presence of water vapor. The reason for this is that the standard free energies of formation of these apatites become close to the value of HAp with an increase in the substitution

degree of OH^- for F^- or Cl^-.[8]

DTA. Each apatite and apatite–silica mixture was examined by DTA (Fig. 1). The broad endothermic peak at 1000—1300 °C was due to a decomposition reaction of HAp with silica, and the peak above 1300 °C suggested a thermal change due to the formation of different phosphates, such as $4CaO \cdot P_2O_5$, $Ca_7P_2Si_2O_{16}$, and $Ca_5P_2SiO_{12}$. HAp to which silica was added was completely decomposed to produce α-tricalcium phosphate after the heating test. On the other hand, the apatitic structures of all the samples except for the HAp–SiO_2 mixtures were maintained even after the heating.

Effect of the Addition of Silica to HAp. HAp and a HAp–SiO_2 mixture were heated at various temperatures for 3 hr in a flow of N_2 gas, and the decomposition rate (α) of HAp was measured (Fig. 2). The only product detected by X-ray powder diffraction was tricalcium phosphate. The decomposition apparently started from 1200—1250 °C for HAp and from 850—900 °C for the HAp–SiO_2 mixture. The former and the latter were due to the self-decomposition of HAp and the reaction of HAp with silica respectively.

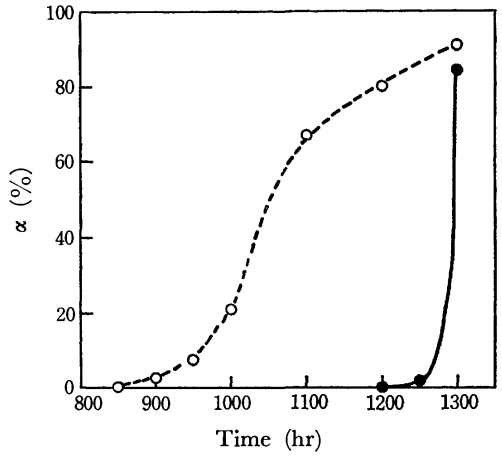

Fig. 2. Effect of added silica on decomposition (α) of HAp.
Heat-treatment: for 3 hr in N_2.
—●—: HAp, --○--: HAp-SiO_2 mixture (1 : 3).

Figure 3 shows the effects of the amount of added silica and the heating condition on α. The values of α were largely influenced by the heating temperature and the water-vapor pressure (p_{H_2O}) in the atmosphere.

In order to find further quantitative relations between α and p_{H_2O}, α was plotted against p_{H_2O} and its logarithm (Fig. 4). From these plots, nearly linear relations were obtained as follows:

$$\alpha = K p_{H_2O} + C \quad \text{(at 1200 °C)}$$
$$\alpha = K \log p_{H_2O} + C \quad \text{(at 1000—1100 °C)}$$

where α is a value after an apparent steady state had been reached, both K and C are constants depending on the heating temperature.

Effect of the Addition of Silica to FAp. The FAp and FAp–SiO_2 mixtures were heated at 1000—1300 °C for 3 hr under various water-vapor pressures. Their heating weight losses were 0.1—0.7%. Table 1 represents the volatilities of fluorine upon the reactions. The difference in the volatilities between the samples with and without silica was negligible at 1000—1200 °C, while it was clear at 1300 °C under a high water-vapor pressure. On the other hand, the decomposition rates of FAp were less than 1% at 1100—1300 °C in a N_2 gas flow, regardless of the presence or absence of silica. Under a pressure of 760 mmHg of water vapor, however, the rate at 1300 °C was 45% for a 1 : 18 mixture of FAp and SiO_2, compared with the value of less than 1% for FAp without silica.

Figure 5 indicates the changes in the fluorine volatility and the decomposition rate with the heating time at 1300 °C under a pressure of 760 mmHg. No

effect of silica addition on the volatility was observed up to 2 hr. The effect, however, was clearly observed after 2 hr; this time agreed approximately with the beginning of a rapid increase in the decomposition. The fluorine volatilization within 0—2 hr is based on

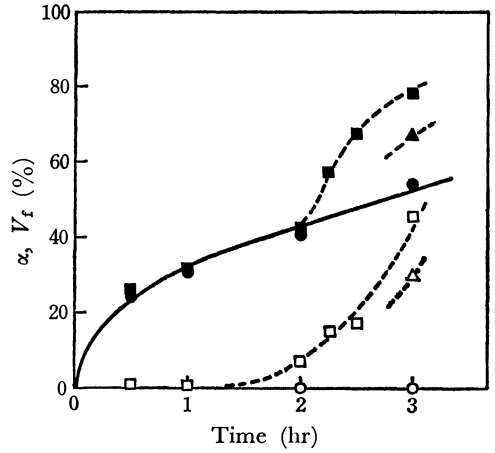

Fig. 5. Effects of added silica on decomposition (α) of FAp and fluorine volatility (V_f).
Heat-treatment: at 1300 °C in H_2O (760 mmHg).

the substitution of OH^- for F^-. Hence, the substitution degree required to decompose the apatite with silica was estimated to be about 40% under those heating conditions. In other words, no effect of silica addition is due to a low degree of substitution, which can rise upon further heating. For example, the defluorination is observed even at 1200 °C in a similar test using rock phosphate.[9]

Effect of the Addition of Silica to CAp. The effect of added silica on the chlorine volatility in the N_2 gas flow was also tested (Fig. 6). The chlorine volatilization was generally greater than the fluorine volatilization. The dechlorination due to silica addition was observed at all times; an especially rapid increase in the volatility appeared in the heating at 1300 °C. The starting point of this rapid increase was found to be about a 2-hr heating time and a 30% volatility; this agreed with the point at which tricalcium phosphate was first detected. On the other hand, the values of the volatility under a water-vapor pressure of 760 mmHg were unexpectedly decreased by adding silica at all times (Fig. 7). However, when the decom-

position of a partially dechlorinated CAp began, its decreasing rate seemed to be reduced.

Figure 8 shows the relation between the chlorine volatilities and the heating losses. The fact that the extrapolated values are 0.3—0.4% in the loss may be ascribed to the evaporation of the water adsorbed on the samples. The changes in the slope from the (C) line to the (C') line, and from the (D) to the (D') line, in Fig. 8 were considered to be accompanied by the destruction of the apatite. The slopes of the (A), (B), (C), and (D) lines suggested the existence of some dechlorination processes, with a retention of the apatitic structure. Table 2 shows a comparison of the slopes calculated from the assumed reactions given in the footnote with the slopes determined from Fig. 8. The slopes of (A) and (C) agreed with that of chlor-oxyapatite formation.[10] The slopes of (B) and (D) agreed approximately with that of chlor-hydroxyapatite formation.

Table 2. Slopes for chlorine volatility-heating loss plots with linear relation

Method of calculation		Slope (Volatility (%)/Loss (%)) CAp	CAp-SiO_2 (1 : 18)
From reactions assumed			
Chlor-oxyapatite formation[a]		19.0	38.6
Chlor-hydroxyapatite formation[b]		28.2	57.4
From straight lines in Fig. 8	(A)	19.5	—
	(B)	26.0	—
	(C)	—	38.0
	(D)	—	57.5

a) $Ca_{10}(PO_4)_6Cl_2 \rightarrow Ca_{10}(PO_4)_6Cl_{2(1-x)}(OH)_{2x} \rightarrow Ca_{10}(PO_4)_6Cl_{2(1-x)}O_x\square_x$, where □ shows vacancy. b) $Ca_{10}(PO_4)_6Cl_2 \rightarrow Ca_{10}(PO_4)_6Cl_{2(1-x)}(OH)_{2x}$.

Summarizing the above results, the following interpretation may be given concerning the dechlorination processes: (1) Under low water-vapor pressures, chlor-oxyapatite is produced by the dehydration of the chlor-hydroxyapatite formed intermediately. (2) The substitution of OH^- for Cl^- proceeds under high water-vapor pressures. (3) In the presence of silica, a partially dechlorinated CAp is decomposed with silica.

Studies on the Hexagonal Hydrate of Molybdenum Trioxide. The Physical Properties of the Hydrate and Its Changes on Heat Treatments in Air, in Hydrogen, and in a Hydrogen–thiophene Mixture

Noriyuki SOTANI

College of Liberal Arts, Kobe University, Tsurukabuto, Nada, Kobe 657

(Received December 20, 1974)

The hexagonal hydrate(I) of molybdenum trioxide, which has been newly found and reported, was studied by X-ray diffraction analysis, IR and NMR spectroscopies, and by other methods. Also studied was the change in (I) on heat treatments in air, in hydrogen, and in a hydrogen–thiophene mixture. The crystal was found to belong to a hexagonal system. The air-dried sample has about 0.46 mol of water. This water is included as a water molecule, not as hydroxyl. By the dehydration of (I), anhydrous molybdenum trioxide (I′), which has the same crystal structure as (I), is obtained. Another new form of (I′) is the hexagonal trioxide, which is hygroscopic and which easily absorbs water when standing in air. This (I′) is metastable and is irreversibly transformed to rhombic molybdenum trioxide(II) at 420—430 °C. In hydrogen and in a hydrogen–thiophene mixture, reduction and sulfurization occur in addition to transformation, which can be shown schematically as: (I)→(I′)→(II)$\begin{cases}\nearrow MoO_2\\ \searrow MoS_2\end{cases}$. Transformation in hydrogen and in the hydrogen–thiophene mixture proceeds faster than in air. Reduction occurs more quickly in the hydrogen–thiophene mixture than in hydrogen.

Molybdenum trioxide is usually prepared by the calcination of hydrate, the so-called molybdic acid or ammonium salt. Many works have been reported on the hydrates of molybdenum trioxide[1–4] and hydrates.[5–10] Among the hydrates of molybdenum trioxide, though only a rhombic MoO_3 is well known.[4] In addition to the rhombic MoO_3, there are several oxides the composition of which are very close to MoO_3, such as Mo_4O_{11},[11] Mo_8O_{23},[12] and Mo_9O_{26}.[12] All of these oxides show specific deep colours. As for the hydrate, the yellow dihydrate has been studied by many workers[5–10] and its precise structure was recently determined by Krebs.[13] Besides, yellow monohydrate and white monohydrate were found, but their precise natures have not yet been reported.

In a previous paper,[14] the present author reexamined in detail the nature of these hydrates of molybdenum trioxide. In these studies, a new form of hydrate, with a hexagonal structure, was found. By heat treatment, this new hydrate was transformed to anhydrous trioxide, which has the same structure as the initial hydrate. This anhydrous trioxide has never been reported, either. This hydrate and this oxide have smaller densities than other oxides and show interesting properties.

In the present paper, the author will report on his research into the precise physical properties of the hexagonal hydrate by X-ray diffraction analysis, IR and NMR spectroscopies, and by other methods. Also reported on will be research into their changes on heat treatments in air, in hydrogen, and in a hydrogen–thiophene mixture, this research was undertaken with a view to revealing the natures of the hydrate when used as a catalyst.

Experimental

Preparation of the Hexagonal Hydrate. The new hydrate of molybdenum trioxide was prepared by precipitation from a saturated ammonium paramolybdate solution by the addition of conc. HNO_3, to give an acidity of 2—3 M at about 70 °C. (HCl can be also used instead of HNO_3.) The sample (denoted as 'Sample A') was dried in air at room temperature.

To obtain an ammonia-free sample (denoted as 'Sample B'), the precipitate was prepared from a saturated sodium molybdate solution under the same conditions as the sample A. It probably contains a small amount of sodium ions, unlike Sample A, which contains ammonium ions.

X-Ray Diffraction, IR, and NMR Studies. The precise methods of the X-ray diffraction analysis, and IR and NMR spectroscopies were described previously.[14] Electron microscopic observation was carried out with a scanning-electron microscope (JAPAN ELECTRONICS LAB.-JSM U3 Type).

Measurements on Heat Treatments. Diffrential thermal analysis (DTA) and thermogravimetric analysis (TGA) were performed in air. The rate of weight decrease was measured by means of a quartz spring balance[15] with helices 15 mm in diameter and with 135 turns, with a capacity of 2 g and with a sensitivity of 0.1 mg/div. After heat treatment at each temperature, the sample was subjected to X-ray diffraction analysis, IR spectroscopy, and chemical analysis.

The behavior of the sample upon heat treatment in atmospheric hydrogen and in the hydrogen–thiophene mixture was studied in the same way. The purified hydrogen flowed at a rate accurately controlled to 0.1 mol/hr by means of a needle valve and an auxiliary regulator. The thiophene was fed into a stream of hydrogen by means of a calibrated hypodermic pump, at the feed rate of 1.4×10^{-2} mol/hr.[16]

Analysis of Ammonia and Sulfur. The ammonia was analyzed by the Kjeldahl method[17] and the sulfur, gravimetrically by the $BaSO_4$ method.[18]

Results

Air-dried Sample A. The X-ray pattern of the sample A, as shown in Fig. 1 (this pattern is not seen on the ASTM cards), belongs to a hexagonal system with a lattice constant of $a=6.09$Å and $c=9.14$Å. The indecies and the calculated spacings of lattice planes are listed in Table 1. Observation by the scanning-electron microscope also shows that the crystal belongs to the hexagonal system, as is shown in the photo.

The amount of ammonia in the air-dried sample A was about 1.6%, according to chemical analysis, this value corresponds to 0.15 mol of NH_3 per mol of MoO_3. According to thermogravimetric analysis, the sample has 0.54 mol of water per MoO_3, therefore, the

composition can be represented as $(NH_3)_{0.15}\cdot MoO_3\cdot 0.54\,H_2O$ or $(NH_4)_{0.15}\cdot MoO_{3.08}\cdot 0.46\,H_2O$. However, the amounts of ammonia and water are indefinite and vary slightly with the conditions of preparation.

As can be seen from Fig. 2, which shows the IR spectrum of the A sample, the intensities of the bands at 3478 and 1610 cm^{-1} decrease when heated at a temperature below 300 °C, the bands can be attributed to the OH stretching and deformation vibrations of hydrated water respectively. The band at 1610 cm^{-1} shows that the water is present as water molecules, not as hydroxyl. The bands at 3170 and 1409 cm^{-1} agree exactly with the frequencies of the stretching and deformation vibrations of the ammonium ion.[19,20]

In the range below 1000 cm^{-1} of Mo-O-bond stretching and bending vibrations and of the librational motion of H_2O, the sample has a relatively sharp band at 976 cm^{-1}, a broad band at 916 cm^{-1}, a shoulder at 869 cm^{-1}, and a broad absorption in the range from 750 cm^{-1} to 450 cm^{-1}.

The NMR absorption was measured at room temperature and at that of liquid nitrogen. The peak-to-

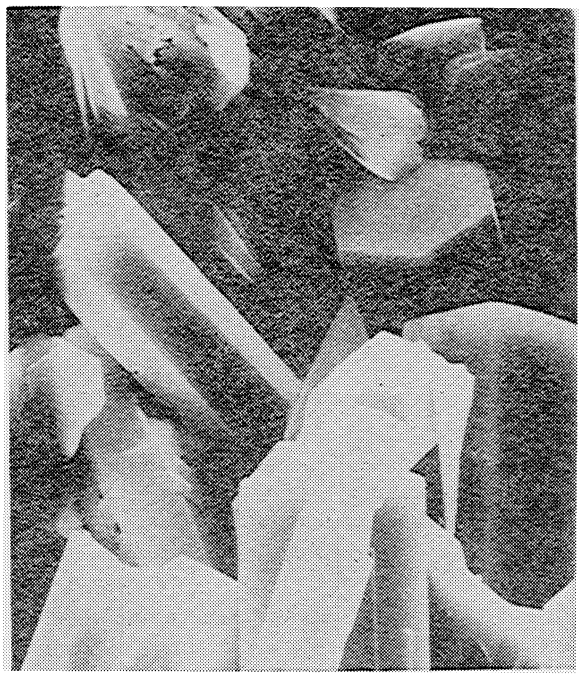

Photo. The sample A observed by the scanning electron microscope (×6000).

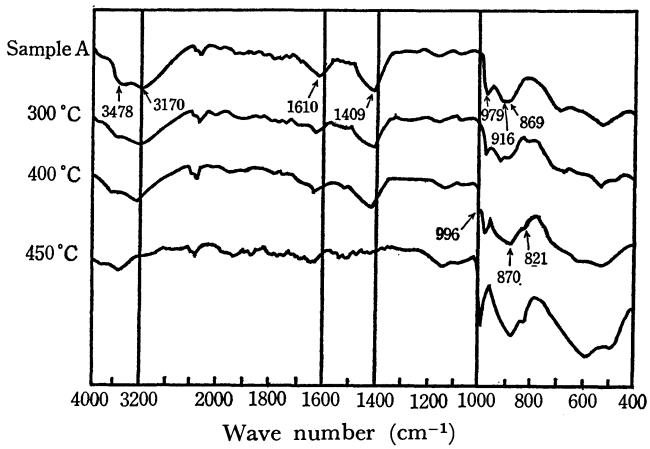

Fig. 2. IR spectra of the sample A.

peak values of the A sample at the temperature of liquid nitrogen, as shown in Fig. 3, are 1.4 G (I) and 11.7 G (II) respectively. (The values are the mean of at least five measurements.) As has been reported in a previous paper,[14] the peak-to-peak value of the II band may be attributed to absorption by the water molecule. The I band is attributed to the ammonium ion, which is mobile at the temperature of liquid nitrogen (probably in flip-flop motion).

The number of protons contained as water molecules was determined by free induction decay after a 90° pulse at 10 MHz; it agreed well with the value obtained by chemical and thermal analyses.

The density of the sample A was determined pycnometrically with cyclohexane at 25 °C. The density of the sample A is 3.73 g/cm^3, and that of the anhydrous hexagonal trioxide is 3.58 g/cm^3. These values are smaller than the 4.175 g/cm^3 of rhombic MoO_3[21] and the 6.47 g/cm^3 of MoO_2,[4] and are closer to the 3.117 g/cm^3 of the yellow dihydrate.[13]

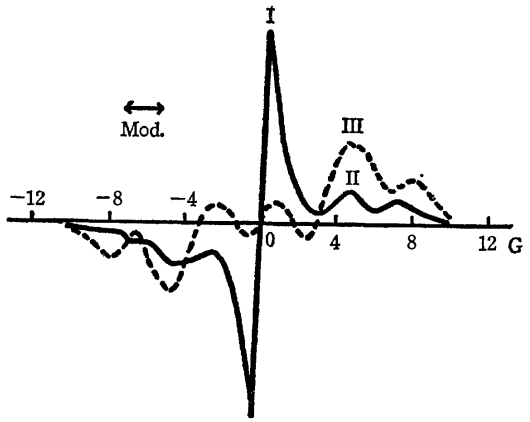

Fig. 3. NMR spectra of the samples A and B at liquid nitrogen temperature.
——: sample A, ----: sample B.

Air-dried Sample B. The B sample from sodium salt gives an X-ray diffraction pattern identical with that of the sample A except for a small difference in intensity.

The IR spectrum of the B sample is identical with that of the A sample except for the disappearance of the bands due to the ammonium ion.

The peak-to-peak value (III) of the NMR derivative curve of the B sample at the temperature of liquid nitrogen, which is also shown in Fig. 3, is nearly equal to that of the II band of the A sample and is due to the water molecule. In the case of the B sample, no band due to the ammonium ion was observed.

The X-ray and IR spectra show that the B sample is exactly the same compound as the A sample. The B sample probably contains a small amount of the sodium ion, unlike the A sample, which contains the ammonium ion, but the fact that the crystal structures are identical seems to show that these ions are contained as impurities in the crystal.

Behavior on Heat Treatment in Air. The DTA-TGA measurement of the A sample was done up to 500 °C. As can be seen from the typical DTA-TGA curve shown in Fig. 4, the weight of the sample decreases continuously up to 300 °C, without any definite

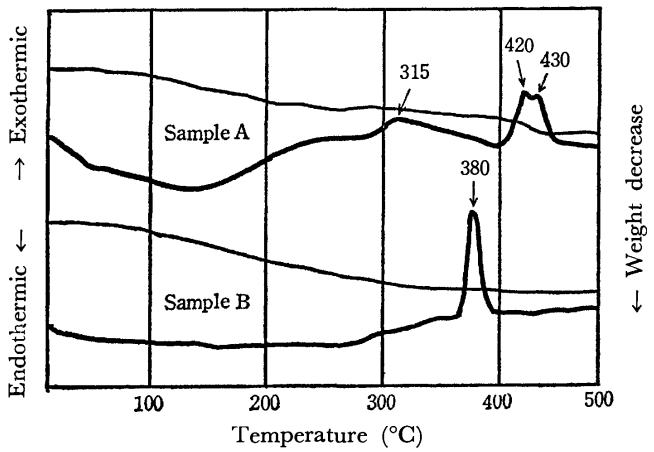

Fig. 4. DTA-TGA curves of the samples A and B.

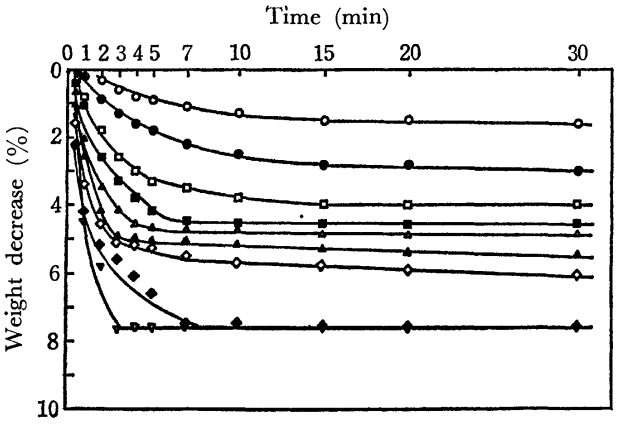

Fig. 5. Isothermal curves of weight decrease of the sample A by heat treatment in air.
○: 100 °C, ●: 150 °C, □: 200 °C, ■: 250 °C, △: 300 °C, ▲: 350 °C, ◇: 400 °C, ◆: 450 °C, ▽: 500 °C.

decomposition temperature, which corresponds to 0.46 mol of H_2O per mol of MoO_3. At 315 ° and 420—430 °C, an exothermal transformation, accompanied by a small weight loss, is observed. The transformation temperature, however, was not reproducible, because, for samples from different lots, one to three exothermal peaks appeared in the range from about 300 to 430 °C.

Figure 5 shows the rate of the weight loss measured in air at various temperatures by means of a quartz spring balance. At every temperature below 300 °C, the rate of weight loss rapidly decreases for several minutes, while the weight is kept nearly constant by further heating. The weight loss is about 5% at 300 °C. By heating at a temperature above 300 °C, after an initial rapid weight loss of about 5%, the weight exponentially approaches a certain minimum value, which is quickly attained by 450 and 500 °C heating. Thus, these curves seem to show weight decreases by two different processes—one below 300 °C and the other above 300 °C. These two processes correspond exactly to the endothermal change at the temperature below 300 °C and the exothermal transformation above 300 °C, observed on the DTA-TGA curve, respectively.

The quantities of ammonia included in the A sample heated for 30 min at various temperatures, as determined

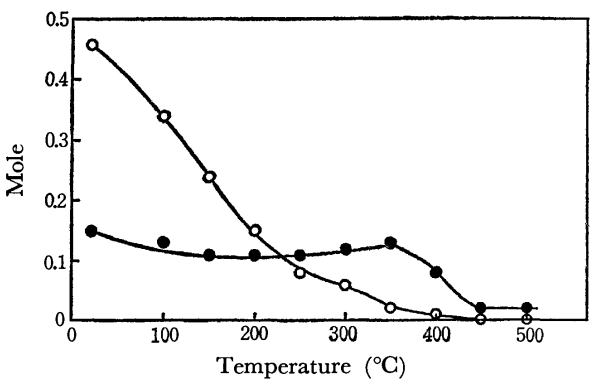

Fig. 6. Amounts of ammonia and water in the sample A after 30 min heating.
●: ammonia, ○: water.

Table 2. The results of X-ray diffraction analysis of the sample A after heat treatments, in air, in hydrogen and in a hydrogen-thiophene mixture

Time (min)		5	10	20	30	40	60	100	180	360
Air	350 °C	I	I	I	I	I	I	I	I	I+II

Hydrogen	350 °C	I	I			I	I*+II+III	II+III		
	400 °C		I*+II+III			II+III				
Hydrogen + thiophene	350 °C	I+II	I+II	II+III		III				
	375 °C	I+II	II+III	III						
	400 °C	II+III	III							

I(I'); hexagonal oxide, II; rhombic MoO_3, III; MoO_2, *; trace

by chemical analysis, are plotted against the heating temperature in Fig. 6. The amount of ammonia content decreases slightly at below 150 °C, probably because of the desorption of the absorbed ammonia, is kept nearly constant up to 350 °C, and begins to decrease above 350 °C. The amount of residual water in the heated sample, as calculated from the total weight loss and the weight loss due to the deammoniation, is also shown in Fig. 6, on the assumption that the ammonia was contained as ammonium ions.

According to the above results, the weight loss below 300 °C is mainly to the liberation of the hydrated water, and the small weight decrease accompanied by the exothermal transformation at 420—430 °C in the DTA-TGA measurement is due to deammoniation. However, as the deammoniation must be endothermic, the transformation at 420—430 °C is essentially a solid-phase transformation. The small deammoniation is, therefore, considered to be an evolution of an ammonia impurity induced by the crystal rearrangement.

In the case of the B sample also, it evolves water as does the A sample below 300 °C and undergoes an exothermal transformation at about 380 °C, as is shown in Fig. 4, but no detectable weight loss is observed.

The results of the X-ray diffraction analysis of the A sample treated in air are summarized in Table 2. No change is observable in the diffraction pattern on heating at 350 °C for 360 min, even though most of the hydrated water is liberated in several minutes at that temperature, showing the conversion of the hydrated sample A (I) to anhydrous hexagonal oxide (I'). After 360 mins' heating at the same temperature, a weak pattern of rhombic MoO_3(II) is detectable. At 400 °C, II appears in 30 min; the X-ray pattern gradually increases in intensity as the duration of heating increases.

In the previous paper,[14] the present author reported that the transformation of I' to II was observed at 420—430 °C. However, a small exothermal peak appears at 315 °C on the DTA curve. The X-ray studies show that a small amount of II is observed when I' is heated in air at 350 °C for 360 min. It may, therefore, be assumed that the small peak at 315 °C can be the transformation of I' to II.

I' below the transformation temperature is highly hygroscopic, as is clearly shown by the fact that it absorbs easily about half of the water in heating. On the other hand, the sample heated above the transformation temperature absorbs water only slightly.

The IR spectra of the sample after heat treatment are shown in Fig. 2. The IR absorption bands at 3478 and 1610 cm^{-1} due to H_2O sharply decrease in intensity below 300 °C. The bands at 3170 and 1409 cm^{-1} due to the ammonium ion are retained up to near 350 °C, the intensities begin to decrease temperatures above 400 °C, as is to be expected from the results of thermal analysis, while the bands below 1000 cm^{-1} do not show any appreciable change at 300 °C. Above 400 °C, new bands at 996, 876, and 821 cm^{-1} due to II appear, and at 450 °C the spectrum changes completely to that of II.

Heat Treatment in Hydrogen (Reduction). The A sample was treated in hydrogen under an atmospheric pressure at 350 °C and 400 °C, and the structural changes were observed by X-ray diffraction (see Table 2). At 350 °C, no change is observable for 40 min, but at 60 min the intensity of the original hexagonal pattern is markedly reduced and patterns due to II and MoO_2(III) appear. At 100 min, most of the sample is reduced to III. A similar change is observable at 400 °C, though the rate is steep.

According to the X-ray results, II always coexists with the III phase. This suggests that no abrupt reduction of I' to III occurs; rather, the reduction passes through II—that is, I'→II→III.

Heat Treatment in the Hydrogen-thiophene Mixture. The changes in the A sample in the hydrogen–thiophene mixture were studied at 350, 375, and 400 °C. In this case, the hydrodesulfurization of thiophene also takes place, and the sample acts as a catalyst for the reaction. The results of the X-ray diffraction analysis of the A sample are listed in Table 2.

As in hydrogen, the transformation to II and the reduction to III also occur. II appears before III is detected. This fact suggests, as in the case of hydrogen, that the reaction proceeds in this sequence: I'→II→III. In the hydrogen–thiophene mixture, however, the transformation and reduction proceed far more quickly than in hydrogen. II, for example, appears in 5 min at 350 °C, and III, in 20 min. The change is even faster at higher temperatures.

The sulfur contents of the A sample when treated in the hydrogen–thiophene mixture were analyzed by the $BaSO_4$ method. Though MoS_2 was not detected by X-ray diffraction analysis, the sulfur contents increased with the time of treatment, as is shown in Fig. 7. The sulfurization did not exceed 5%, however, the rate of sulfurization was slower than those of transformation and reduction. As III was not easily sulfurized

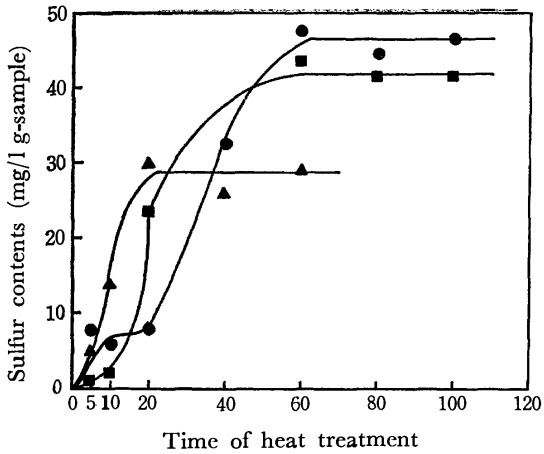

Fig. 7. Sulfur contents in the sample A after heat treatment for 30 min in a hydrogen-thiophene mixture.
●: 350 °C, ■: 375 °C, ▲: 400 °C.

under the same conditions,[16] II was assumed to selectively sulfurized in this experiment.

Discussion

As has been described above, I′, with the same hexagonal crystal structure as I, is obtained by dehydration. Neither I nor I′ have ever been reported previously; they may, then, be regarded as a new form.

The results of IR and NMR spectroscopies show that the water included in I is contained as water molecules, not as hydroxyl. The fact that I′ has the same crystal structure as I means that I′ has a structure with vacancies, in which the water molecule can be occluded.

The postulation of this structure is supported by the following facts: (i) I has no definite decomposition temperature upon dehydration. (ii) I′ is highly hygroscopic, in contrast with the nonhygroscopic nature of II. (iii) The density, when the substance A treated in air, changes from 3.75 g/cm^3 of I to 3.58 g/cm^3 of I′, without any change in the crystal structure.

I′ is surely transformed to II at 420—430 °C. II is not, on the other hand, transformed to I′ on cooling, and, so is regarded as a stable phase at low temperatures. I′ is, therefore, a metastable phase, and the transformation at 420—430 °C is from a metastable to a stable phase. The variation in the transformation temperature is probably due to the above fact. As has previously been described, the transformation is always accompanied by the decomposition of a small amount of ammonium ions. At the same time, the endothermal deammoniation overlaps the exothermal change. The exothermal change in the DTA curve is, therefore, somewhat compensated for by the endothermal deammoniation. This is another reason for the irreproducibility of the DTA curve. In the case of the B sample, which is free from ammonium ions, the transformation shows a simple single exothermal peak, with no endothermal change. Such impurities as the ammonium ion or the Na^+ ion, which may be contained in the vacancies of the oxide, are assumed to stabilize the hexagonal phase; therefore, the transformation temperature may have something to do with the amount of such impurities.

In addition to dehydration, the reduction and sulfurization of I′ occur in hydrogen and in the hydrogen-thiophene mixture. It is clear from Fig. 5 that the dehydration proceeds more quickly than the reduction and the sulfurization. Thus, it may be concluded that the reduction and the sulfurization occur after dehydration.

On the other hand, the X-ray results suggest, as has been described previously, that the reduction occurs consecutively as I′→II→III.

Sulfurization also occurs along with reduction in the hydrogen-thiophene mixture. As has been described previously, it is assumed that II is preferentially sulfurized. Consequently, in the hydrogen-thiophene mixture I changes as is shown in Fig. 8. The X-ray diffraction analysis confirms that the I′→II transformation in hydrogen proceeds faster than in air, and that, in the hydrogen-thiophene mixture, the transformation proceeds much faster still. An interesting fact is that the existence of hydrogen or thiophene accelerates the I′→II transformation. The precise mechanism is not known, but it seems to be certain that these gases have some catalytic function in the transformation.

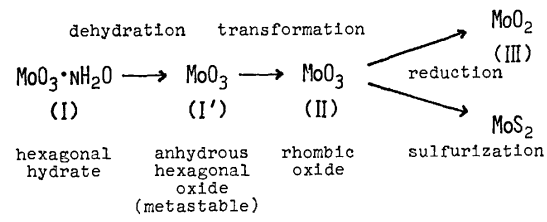

Fig. 8. Changes of the state of the hydrate by heat treatment, in air, in hydrogen and in a hydrogen-thiophene mixture.

The author is grateful to Professor Masatomo Hasegawa for his encouragement and helpful advice. He is also indebted to Professor Yushiro Saito for his NMR measurements and inspiring suggestions, and to Dr. Itaru Moto-oka for his DTA-TGA measurements and useful discussions. Also, the author is grateful to Mr. Yoshihiro Nishimitsu for his kind suggestions with respect to the format of this manuscript.

Preparation and Reaction of Some Di-*tert*-butylnitroxidopalladium(II) Complexes, $PdX(Bu^t_2NO)L$ ($L=PPh_3$, $AsPh_3$, $P(OPh)_3$; $X=Cl$, Br, I)

Masaaki OKUNAKA, Gen-etsu MATSUBAYASHI, and Toshio TANAKA

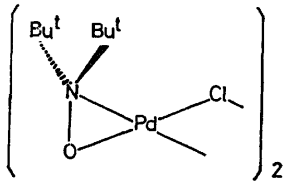
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

(Received January 23, 1975)

$PdX(Bu^t_2NO)L$ ($L=PPh_3$, $AsPh_3$, $P(OPh)_3$; $X=Cl$, Br, I) was isolated by the reactions of $[PdCl(Bu^t_2NO)]_2$ with L and by the halogen exchange reactions of the chloro complexes with $LiBr\cdot H_2O$ or NaI. PMR and IR spectra revealed that $PdX(Bu^t_2NO)(PPh_3)$ and $PdX(Bu^t_2NO)(AsPh_3)$ exist as only one geometrical isomer with the halogen atom *trans* to the oxygen atom of the nitroxide ligand, while two isomers of $PdX(Bu^t_2NO)[P(OPh)_3]$ coexist in solution. The reaction of $PdX(Bu^t_2NO)(PPh_3)$ ($X=Cl$, I) with triphenylphosphine was found to give $Pd(PPh_3)_4$ together with $Pd X_2(PPh_3)_2$ and $Bu_2NO\cdot$. A similar reaction proceeded between $PdCl(Bu^t_2NO)$-$[P(OPh)_3]$ and triphenylphosphite to yield $Pd[P(OPh)_3]_3$, while a not well-defined complex $[PdCl(AsPh_3)_2]_n$ was obtained in the reaction of $PdCl(Bu^t_2NO)(AsPh_3)$ with triphenylarsine.

The interactions between stable nitroxide radicals and metal halides have been studied by several workers.[1-8]

Some time ago, Beck and Schmidtner[2] reported that di-*tert*-butyl nitroxide reacts with palladium chloride to give a diamagnetic chloro-bridged complex $[PdCl(Bu^t_2NO)]_2$ (I), in which $Bu^t_2NO^-$ coordinates to the palladium through both the nitrogen and oxygen atoms to form a three-membered ring. The chloro-bridge is expected to undergo a cleavage reaction by nucleophiles. In addition, the unique three-membered



I

ring moiety is supposed to be reactive.

In these respects, it is of interest to investigate the reaction of I with some nucleophiles. This paper reports the preparation of $PdX(Bu^t_2NO)L$ ($L=PPh_3$, $AsPh_3$, $P(OPh)_3$; $X=Cl$, Br, I), and the reactions of $PdX(Bu^t_2NO)L$ with L to give low-valent palladium complexes.

Experimental

Di-*tert*-butyl nitroxide radical was prepared as described by Hoffmann *et al.*[9] $[PdCl(Bu^t_2NO)]_2$ was prepared according to the literature.[2] All the manipulations in the reaction of $PdX(Bu^t_2NO)L$ with L ($L=PPh_3$, $AsPh_3$, $P(OPh)_3$; $X=Cl$, I) were carried out under dry nitrogen.

Preparation of $PdX(Bu^t_2NO)L$ ($L=PPh_3$, $AsPh_3$, $P(OPh)_3$; $X=Cl$, Br, I). To a benzene solution of $[PdCl(Bu^t_2NO)]_2$ (0.57 g, 1.0 mmol) was added dropwise a benzene solution of triphenylphosphine (0.53 g, 2.0 mmol) with stirring for 30 min at room temperature. The solvent was evaporated to dryness under reduced pressure. The product obtained was dissolved in diethyl ether to give a suspension. It was filtered, and the filtrate was evaporated to dryness again under reduced pressure. The resulting solid was recrystallized from a benzene solution by adding petroleum ether to afford orange crystals of $PdCl(Bu^t_2NO)(PPh_3)$ (0.74 g, yield 68%).

$PdCl(Bu^t_2NO)(PPh_3)$ and a large excess amount of $LiBr\cdot H_2O$ were mixed in ethanol. After stirring for 30 min, the solution was evaporated to dryness and the product was recrystallized from ligroin to give dark red needles of $PdBr(Bu^t_2NO)(PPh_3)$. $PdI(Bu^t_2NO)(PPh_3)$ was synthesized by

the reaction of the chloro complex with excess NaI in a similar manner. Six other complexes were similarly prepared. The melting points and analytical data are summarized in Table 1.

Reaction of $PdCl(Bu^t_2NO)(PPh_3)$ with Triphenylphosphine. To a benzene solution of $PdCl(Bu^t_2NO)(PPh_3)$ (0.55 g, 1.0 mmol) was added dropwise a benzene solution of triphenylphosphine (1.57 g, 6.0 mmol) with stirring at room temperature. The solution changed from orange to yellow *via* red, and finally a light yellow precipitate was obtained. Stirring was continued for 6 hr to force the reaction to completion. Then the solution was evaporated under reduced pressure, and the resulting solid was washed with diethyl ether to remove unreacted triphenylphosphine and liberated di-*tert*-butyl nitroxide. The product was recrystallized from ethanol to give pale yellow crystals of $Pd(PPh_3)_4$ (0.13 g, 0.11 mmol), mp 103—105 °C (decomp.) [lit,[10] 100—105 °C (decomp.)]. Found: C, 72.97; H, 5.56%. Calcd for $Pd(PPh_3)_4$: C, 74.83; H, 5.24%. From the component insoluble in ethanol $PdCl_2(PPh_3)_2$ (0.33 g, 0.47 mmol) was obtained, mp above 220 °C. Found: C, 61.36; H, 4.38%. Calcd for $PdCl_2(PPh_3)_2$: C, 61.60; H, 4.32%. ν(Pd–Cl) 360 cm^{-1}.

An equimolar amounts of $PdCl(Bu^t_2NO)(PPh_3)$ and triphenylphosphine were mixed in benzene and stirred for 42 hr at room temperature. The solution was concentrated under reduced pressure to give a yellow precipitate, which was washed with diethyl ether and collected by filtration. The IR spectrum of this product showed ν(Pd–Cl) band at 303 and 360 cm^{-1} arising from $PdCl(Bu^t_2NO)(PPh_3)$ and $PdCl_2(PPh_3)_2$, respectively.

Reaction of $PdI(Bu^t_2NO)(PPh_3)$ with Triphenylphosphine. A benzene solution containing $PdI(Bu^t_2NO)(PPh_3)$ (0.30 g, 0.47 mmol) and triphenylphosphine (0.74 g, 2.82 mmol) was allowed to react overnight at room temperature to form pale yellow crystals of $Pd(PPh_3)_4$ (0.18 g, 0.16 mmol) and red brown crystals of $PdI_2(PPh_3)_2$ (0.20 g, 0.23 mmol). They were identified by IR spectra and decomposition points.

Reaction of $PdCl(Bu^t_2NO)[P(OPh)_3]$ with Triphenylphosphite. To a benzene solution of $PdCl(Bu^t_2NO)[P(OPh)_3]$ (0.45 g, 0.76 mmol) was added dropwise a benzene solution of triphenylphosphite (1.40 g, 4.53 mmol) with stirring at room temperature. Immediately, the yellow color of the solution faded away. The solution was concentrated under reduced pressure to give an oily product, which was dissolved in petroleum ether. The resulting white precipitate was collected by filtration and recrystallized from ethanol to give colorless crystals of $Pd[P(OPh)_3]_3$ (0.14 g, 0.14 mmol), mp 128—130 °C (decomp.) under dry nitrogen [lit,[11] 118—129 °C (decomp.) under argon]. Found: C, 62.02; H, 4.35%. Calcd for $Pd[P(OPh)_3]_3$: C, 62.52; H, 4.38%. $PdCl_2[P(OPh)_3]_2$ (0.12 g, 0.14 mmol) was obtained from the petroleum ether solution, mp 177—179 °C (lit,[12] 175—180 °C).

Reaction of $PdCl(Bu^t_2NO)(AsPh_3)$ with Triphenylarsine. $PdCl(Bu^t_2NO)(AsPh_3)$ (0.95 g, 1.60 mmol) and tripenylarsine (2.95 g, 9.63 mmol) were mixed in benzene and stirred for 7 days at room temperature to form a yellow precipitate, which was filtered, washed with diethyl ether and dried *in vacuo* (0.92 g), mp 154—156 °C (decomp.). Found: C, 57.14; H, 4.65%. Calcd for $[PdCl(AsPh_3)_2]_n$: C, 57.32; H, 4.02%. ν(Pd–Cl), 318 cm^{-1}.

Physical Measurements. IR spectra were recorded in Nujol mulls or in chloroform on a Hitachi EPI-L (700—200 cm^{-1}) spectrophotometer. PMR spectra were recorded on a JOEL JNM-PS-100 spectrometer, using tetramethylsilane as the internal reference. ESR spectra were recorded on a JOEL JES-ME-3X spectrometer. Molecular weights were determined in chloroform using a Mechrolab vapor pressure osmometer.

Results and Discussion

Preparation and Configuration of $PdX(Bu^t_2NO)L$ ($L=PPh_3$, $AsPh_3$, $P(OPh)_3$; $X=Cl$, Br, I). The reaction of $[PdCl(Bu^t_2NO)]_2$ with L ($L=PPh_3$, $AsPh_3$, $P(OPh)_3$) gave $PdCl(Bu^t_2NO)L$ (Eq. 1), which underwent halogen exchange reactions to yield the corresponding bromo and iodo complexes (Eq. 2). Molecular

$$[PdCl(Bu^t_2NO)]_2 + 2L \longrightarrow 2PdCl(Bu^t_2NO)L \quad (1)$$
($L=PPh_3$, $AsPh_3$, $P(OPh)_3$)

$$PdCl(Bu^t_2NO)L + \text{excess } LiBr\cdot H_2O \text{ or } NaI \longrightarrow PdX(Bu^t_2NO)L \quad (X=Br, I) \quad (2)$$

weight determination indicates that these complexes are essentially monomeric in chloroform (Table 1), which is consistent with the fact that the IR spectra of $PdCl(Bu^t_2NO)L$ show an intense band at 303—316 cm^{-1} assigned to the terminal Pd–Cl stretch as shown in Table 2. These facts reveal that the cleavage reaction took place at the bridging moiety.

In these complexes obtained two geometrical isomers, *A* and *B*, are possible. PMR spectra of $PdX(Bu^t_2NO)(PPh_3)$ and $PdX(Bu^t_2NO)(AsPh_3)$ show only one *tert*-butyl signal (Table 2). In view of a large steric repulsion between *tert*-butyl and phenyl groups in *B*, but the insignificant one in *A*, this signal would be assigned to the isomer *A*. On the other hand, $PdX(Bu^t_2NO)[P(OPh)_3]$ exhibits another weak *tert*-butyl signal, which is probably arising from the isomer *B*. This is

Table 2. PMR and IR data of the complexes

Complex	δ (Bu^t) in $CDCl_3$ at 23 °C	ν(Pd-Cl), cm^{-1}

A *B*

supported from the smaller steric hindrance of triphenylphosphite than triphenylphosphine[13] (and probably triphenylarsine, too). In accordance with the PMR observations, IR spectra of $PdCl(Bu^t_2NO)(PPh_3)$ and $PdCl(Bu^t_2NO)(AsPh_3)$ in chloroform show only one ν(Pd–Cl) band, while two ν(Pd–Cl) bands appear in $PdCl(Bu^t_2NO)[P(OPh)_3]$ (Table 2).

ESR Spectra. The ESR spectrum of $PdCl(Bu^t_2NO)(PPh_3)$ in dichloromethane at room temperature shows a weak triplet with a spacing of 16.5 gauss (Fig. 1), which indicates a little dissociation of the complex in solution to produce di-*tert*-butyl nitroxide radical. The intensity of this signal is enourmously enhanced by the addition of triphenylphosphine as depicted in Fig. 1. These observations confirm that a redox reaction of the complex took place in the presence of triphenylphosphine. That is to say, $Bu^t_2NO^-$ which had coordinated as an anion was oxidized to $Bu^t_2NO\cdot$ radical, and, as an inevitable consequence, some reduced palladium species must be formed in solution. Thus, we

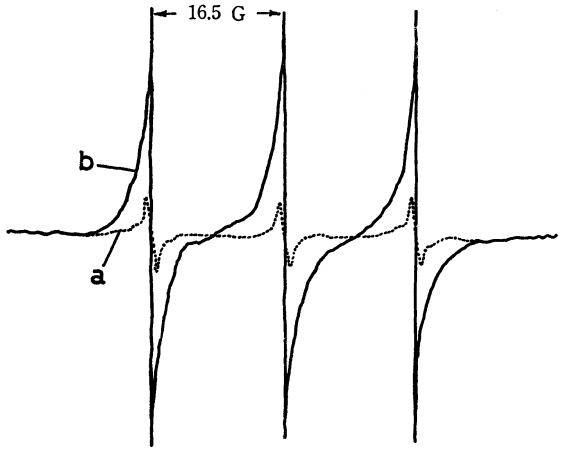

Fig. 1. ESR spectra of (a) $PdCl(Bu^t_2NO)(PPh_3)$ and (b) $PdCl(Bu^t_2NO)(PPh_3)+2PPh_3$, both in CH_2Cl_2 at 25 °C.
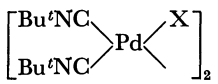
The concn. of the complex: 1.3×10^{-2} M; the signal is considered to be caused by $Bu^t_2NO\cdot$ produced by decomposition.

investigated the reaction of $PdX(Bu^t_2NO)L$ with L in order to clarify the reduced palladium complex.

Reaction of $PdX(Bu^t_2NO)L$ with L. $PdX(Bu^t_2NO)(PPh_3)$ (X=Cl, I) reacted readily with triphenylphosphine to give $Pd(PPh_3)_4$ and $PdX_2(PPh_3)_2$. Since $Bu^t_2NO^-$ works clearly as a one electron reducing agent, a monovalent palladium complex must be formed as an intermediate in the course of the reaction (Path 3 in Scheme 1). Recently, Otsuka *et al*[14] reported the preparation of monovalent palladium complexes $[PdX(Bu^tNC)_2]_2$, for which they proposed a dimeric halide-bridged structure (II). Thus, an



(X=Cl, Br, I)

II

equilibrium 4 between monomer and dimer will be most probable in solution. Further, the dimeric complex may disproportionate to $Pd(PPh_3)_4$ and $PdCl_2(PPh_3)_2$ by assist of another triphenylphosphine molecule (Path 5). However, the assumed intermediate involving monovalent palladium could not be isolated even in the equimolar reaction of $PdCl(Bu^t_2NO)(PPh_3)$ with triphenylphosphine (see Experimental).

Similarly, $Pd[P(OPh)_3]_3$ and $PdCl_2[P(OPh)_3]_2$ were obtained by the reaction of $PdCl(Bu^t_2NO)[P(OPh)_3]$ with excess triphenylphosphite. This reaction is thought to proceed through a similar way to Scheme 1.

In contrast to the results obtained for triphenylphosphine and triphenylphosphite complexes, no zerovalent complex could be isolated in the reaction of $PdCl(Bu^t_2NO)(AsPh_3)$ with excess triphenylarsine. Instead, a yellow complex whose IR spectrum shows a ν(Pd–Cl) band at 318 cm^{-1} was obtained. This complex is suggested to be $[PdCl(AsPh_3)_2]_n$ from analytical data. This complex is stable in air so far as it is in solid state. It is almost insoluble in common organic solvents, and at elevated temperatures decomposes in suspension in benzene even under dry nitrogen. The detailed structure of this complex has to await further studies in the solid state.

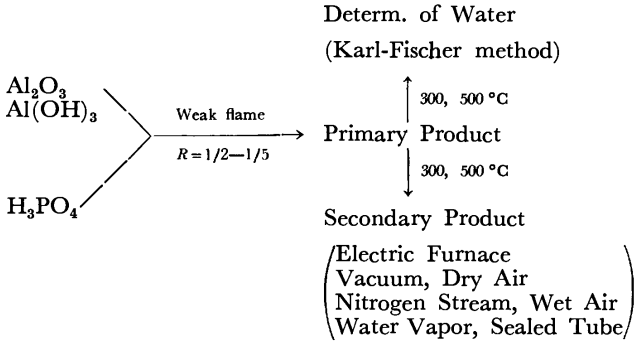
(Received February 3, 1975)

In the reaction of Al_2O_3 or $Al(OH)_3$ with phosphoric acid, the conditions of the formation of the I and II types of aluminum dihydrogen tripolyphosphate, $AlH_2P_3O_{10}$, and the A and B types of aluminum tetrametaphosphate, $Al_4(P_4O_{12})_3$, were established. The I and II types of $AlH_2P_3O_{10}$ were chiefly obtained at 300 °C; the formation of the I type predominated when the water content of the primary product was 15—30%, while the II type was more readily formed at a water content of 10—15%. Also, the I and II types were easily formed at vapor pressures of 1—5 atm. $Al_4(P_4O_{12})_3$ was produced when the water content was less than 10% or more than 30%. On the other hand, the A and B types of $Al_4(P_4O_{12})_3$ were easily formed at 500 °C; the A type was chiefly formed when the water content was below 10% or above 25%, while the B type was produced at the water content of 10—25%. The water content of the primary product is presumably due to the dehydration caused by the condensation of the P–OH. Thus water, effective for the formation of aluminum phosphates, is the structural water (P–OH). Further, the B type was liable to be formed on rapid dehydration, while the A type was more readily produced on slow dehydration. Accordingly, the formation of aluminum phosphate has been confirmed to be greatly dependent on the water content of the primary product and on the vapor pressure in the secondary heat treatment.

Although many kinds of aluminum phosphates have been discovered as minerals[2-4] and synthesized by many investigators,[5-9] their structures, methods of preparation, and physical properties are not yet well known. The existence of the A, B, C, D and E types of aluminum tetrametaphosphate, $Al_4(P_4O_{12})_3$,[10,11] and the I and II types of aluminum dihydrogen tripolyphosphate, $AlH_2P_3O_{10}$,[12-14] has already been reported by d'Yvoire, but he isolated each phosphate from its mixture by dissolution with an alkaline solution or by decantation. Therefore, their formation conditions have not yet been established. Especially, the difference between the conditions of the formation of the I and II types or those of the A and B types is not clear. According to the authors' experience, it is very difficult to establish a preparation method of aluminum phosphates, because various phosphates are formed depending on the kind of aluminum and phosphorus starting material employed, their mixing ratio, and the heating temperature.[16-19] Therefore, in this study the relationship between the water content or the dehydration velocity and the yields of aluminum phosphates was studied; the formation of phosphates in various heating atmospheres was also examined in order to investigate the influence of the vapor pressure.

Experimental

Preparation of Aluminum Phosphate. Al_2O_3 or $Al(OH)_3$ and phosphoric acid were mixed in a gold or porcelain crucible in the molar ratios Al_2O_3/P_2O_5 (R) of 1/2, 1/3, 1/4, and 1/5; the mixture was then dehydrated by heating over a weak flame with vigorous agitation to obtain a white, highly viscous product in each case. (This is designated as the primary heat treatment, giving the primary products.) A small amount (0.5—0.6 g) of the product was accurately weighed, and the content of water liberated upon heating at 300 or 500 °C was determined by the Karl-Fischer method; meanwhile, another portion was heated for 5 or 20 hr in a thermostated electric furnace, in a vacuum (0.01 mmHg), in a nitrogen stream (50 ml N_2/min, vapor pressure (vp) 0—1 mmHg), in dry air (50 ml/min, vp 0—1 mmHg), in wet air (15—20 mg H_2O/hr, vp 20—25 mmHg), in water vapor (500 g H_2O/hr, vp 760 mmHg), and in a sealed tube[20] (vp 1.5—5 atm). (This is designated as the secondary heat treatment, giving the secondary products.) The experimental method may be shown schematically as follows:



The temperature of the primary heat treatment is dependent on the aluminum materials used, their amounts, and the molar ratio R, it generally being 250—270 °C in the α-Al_2O_3—H_3PO_4 system, 140—160 °C in the γ-Al_2O_3 system, and 130—150 °C in the $Al(OH)_3$ system.

Measurement of the Dehydration Velocity. About 0.5 g of the primary product was weighed and elevated from room temperature to 500 °C at heating rates of 20, 6—7, and 0.8—1.0 °C/min, while the water content was continuously measured by the Karl-Fischer method.

Reaction of $Al(OH)_3$ or Al_2O_3 with P_2O_5. $Al(OH)_3$ or Al_2O_3 and P_2O_5 was rapidly mixed to give a molar ratio of $R=1/3$ in a dry box; the mixture was then heated in an electric furnace at 300 or 500 °C for 20 hr to form aluminum phosphates.

The aluminum phosphates thus obtained were relatively hard, but those obtained at 300 °C absorbed moisture when left in air; the phosphates were taken off the crucible as thin

plates. Especially, the I type of $AlH_2P_3O_{10}$ readily absorbed moisture to form dihydrate $AlH_2P_3O_{10}\cdot 2H_2O$ and separated from the crucible easily.

Apparatus and Methods. The X-ray analysis was carried out with a Rigaku Denki Geigerflex X-ray diffractometer, using Ni filtered Cu$K\alpha$ radiation. A Kyoto Denshi Karl-Fischer Titrator was used for the determination of water. A Rigaku Denki Diffrential Thermogravimetric Analyzer, 8002 HD, was used for the DTA and TG. The X-ray analysis, differential thermal analysis, and thermogravimetry (DTA, TG) of aluminum phosphate were carried out by the methods described in the previous papers.[18,19] The amounts of $AlH_2P_3O_{10}\cdot 2H_2O$, the II type of $AlH_2P_3O_{10}$, and the A and B types of $Al_4(P_4O_{12})_3$ formed in the secondary heat treatment were determined from the integrated intensities of their characteristic X-ray diffraction peaks; *i.e.*, $AlH_2P_3O_{10}\cdot 2H_2O$ was determined by the peak at $2\theta=11.2°$; the II type, by that at 26.4°; the A type, by that at 20.4°; and the B type, by that at 16.2°.

Results and Discussion

Relationship Between the Yield of Aluminum Dihydrogen Tripolyphosphate and the Water Content. It is very difficult to produce the I and II types of $AlH_2P_3O_{10}$ purely, because any attempts give a mixture of $AlH_2P_3O_{10}$ and $Al_4(P_4O_{12})_3$. Therefore, for the purpose of establishing the formation conditions of the I and II types, we studied the relationship between the yields of the I and II types and the water content of the primary product. The results are shown in Fig. 1. As can be seen, the II type was obtained in a good yield when the water content of the primary product was 10—15%, while the I type was obtained at the water content of 15—30%. Also, the water content of the primary product is 8—30% in the α-Al_2O_3–H_3PO_4 system, 15—28% in the γ-Al_2O_3 system, and 15—35% in the $Al(OH)_3$ system. Therefore, the I type is most readily formed, irrespective of the aluminum materials employed, but the II type is easily produced in the α-Al_2O_3–H_3PO_4 system. The water in the primary product is considered to be composed of the structural water (P–OH), the loose water, and coordinated water, though it is found from the results of DTA and TG (Fig. 2) that the amount of the loose and coordinated water is much less than that of the

structural water. This may be because the primary heat treatment was carried out at high temperatures (over 130—150 °C). In Fig. 2, the endothermic peaks with weight loss at 250—300, 360—390, and 620—630 °C are due to the dehydration caused by the condensation of the P–OH. Therefore, the formation of aluminum phosphates is confirmed to be greatly dependent on the amount of the structural water. On the other hand, $Al_4(P_4O_{12})_3$ was chiefly formed when the water content of the primary product was below 10% or above 30%, but the formation region of the A and B types was not clear at 300 °C. This may be because $Al_4(P_4O_{12})_3$ was generally formed under such special conditions as a large molar ratio and a low or high water content. $AlH_2P_3O_{10}\cdot 2H_2O$ can not be directly obtained by the secondary heat treatment at 300 °C, but when the I type of $AlH_2P_3O_{10}$ was allowed to stand in air, it readily absorbed moisture and was completely transformed into dihydrate $AlH_2P_3O_{10}\cdot 2H_2O$. Thus, the amount of the I type formed corresponds to the amount of $AlH_2P_3O_{10}\cdot 2H_2O$; accordingly, the amount of the latter is expressed as that of the former in Fig. 1. From the mixture of the composition of $R=1/2$, $AlPO_4$ (Berlinite) was found to be formed in addition to $AlH_2P_3O_{10}$ and $Al_4(P_4O_{12})_3$, though the amount of $AlPO_4$ is omitted in Fig. 1.

types of $Al_4(P_4O_{12})_3$ and the water content liberated upon heating the primary product at 500 °C. The A type can be readily formed when the water content of the primary product is below 10% or above 25%, while the B type is obtained at a water content of 10—25%. The results show that the region of formation of the B type is more limited than that of the A type, it consequently being very difficult to prepare the pure B type. The authors repeated the experiment by this procedure 500—600 times, but only in 2—3% of the experiments could the pure B type be obtained, the product in most cases being a mixture of the A and B types. The A type was more likely to be obtained when the molar ratio, R, was low ($R=1/4$—$1/5$), that is, at larger amounts of phosphoric acid. The I and II types of $AlH_2P_3O_{10}$ were not formed at all at 500 °C, possibly because of the thermal transformation of the I and II types into $Al_4(P_4O_{12})_3$ at this temperature. The thermal transformation of the I and II types will be considered in detail latter.

Relationship Between the Formation of Aluminum Tetrametaphosphate and the Dehydration Velocity. As has been described above, the formation of $Al_4(P_4O_{12})_3$ was greatly affected by the water content of the primary product. The rate of dehydration of the primary product was examined in order to investigate the influence of dehydration in the preparation of the A and B types of $Al_4(P_4O_{12})_3$, using several samples with equal water contents. Figure 4 shows the relationship between the heating temperature and the weight loss (the degree of dehydration) at the heating rate of 6—7 °C/min. The ultimate weight loss of each sample was about 24—25%. Naturally, the amount of product may differ with the water content of the primary product, but in the primary product containing same water content it is also seen that the higher the dehydration velocity, the more readily the B type is formed, whereas the slower the dehydration velocity, the more A type is produced. Almost the same results were obtained at heating rates of 0.8—1.0 and 20 °C/min. About 70 to 75% of the

$Al_4(P_4O_{12})_3$ prepared in this experiment gave the A or B types or a mixture of the A and B types, according to dehydration velocity.

Preparation of Aluminum Phosphate in Various Heating Atmospheres. The relationship between the heating atmosphere and the products obtained at 300 °C is shown in Table 1. On heating in an electric furnace, the I type of $AlH_2P_3O_{10}$ was the product chiefly formed when the water content was 15—30%, while the II type was obtained at a water content of 10—15%. This is in good agreement with the above-mentioned results. A comparison of the products obtained in dry air, a nitrogen stream, wet air, water vapor, and in a sealed tube shows that both the I and II types are readily formed by heating the primary product in atmospheres containing much water, while neither of them is produced at all in dry air. In particular, it was proved that the type of product obtained in a sealed tube is dependent entirely on the water content of the primary product. Thus, it is clear that a high vapor pressure is required for the formation of the I and II types. On the contrary, on heating in a vacuum, no $AlH_2P_3O_{10}$ was obtained at all, and only the B type was formed. This shows that the B type is readily formed by rapid dehydration, as has been described above. The product becomes hygroscopic as the molar ratio R decreases ($R=1/4$—$1/5$), that is, with an increase in the amount of phosphoric acid. The relationship between the heating atmosphere and the products formed at 500 °C is given in Table 2. In both the α-Al_2O_3–H_3PO_4 and $Al(OH)_3$–H_3PO_4 systems at $R=1/3$, although some difference in products was observed according to the water content of the primary product, a mixture of the A and B types of $Al_4(P_4O_{12})_3$ was the product chiefly formed, regardless of the heating atmosphere; this shows that the kind of atmosphere had very little influence here. On the contrary, only the A type was obtained in a sealed tube, irrespective of the aluminum materials used, the molar ratio, and the water content. This may be because of the difficulty of the evaporation of water, *i. e.*, by the very low dehydration velocity. The formation of a mixture of the A type and $AlPO_4$ (berlinite and cristobalite type) in an atmosphere of water vapor can be interpreted in terms of the evaporation of the white P_2O_5 fumes caused by the flow of water vapor. The complete absence of the formation of the B type may also be due to the low dehydration velocity in water vapor, such as in a sealed tube. On the other hand, only the B type was obtained in a vacuum, *i. e.*, under conditions of rapid dehydration. The formation of the A type became dominant with a decrease in the molar ratio ($R\leqq 1/5$), regardless of the heating atmosphere, except in a vacuum, where the B type was still the product chiefly formed. The conditions for the formation of the A and B types could not be determined at 300 °C, but were clearly distinguished at 500 °C. No I or II type was formed at all at 500 °C. At $R=1/2$, a mixture of $Al_4(P_4O_{12})_3$ and $AlPO_4$ (berlinite and cristobalite type) was formed in any heating atmosphere. $AlPO_4$ (berlinite) was formed more readily in the $Al(OH)_3$–H_3PO_4 system than in the α-Al_2O_3–H_3PO_4 system. This may be

explained in terms of the higher reactivity of $Al(OH)_3$ than that of α-Al_2O_3 with phosphoric acid.

Reaction of α-Al_2O_3 or $Al(OH)_3$ with P_2O_5. Reactions in the systems of α-Al_2O_3–P_2O_5 and $Al(OH)_3$–P_2O_5 were carried out in order to investigate the preparation of aluminum phosphate in a much lower water content. At 500 °C, almost only the A type was formed in the α-Al_2O_3–P_2O_5 system, but the A type was contaminated by the B type in the $Al(OH)_3$–P_2O_5 system. This may be because of the water contained in $Al(OH)_3$. Thus, these experimental results show that the A type is liable to be produced in the absence of water.

Thermal Transformation of Aluminum Dihydrogen Tripolyphosphate. Although the present authors have already reported data on the thermal transformation of $Al_4(P_4O_{12})_3$,[21] little is yet known about that of $AlH_2P_3O_{10}$. The results of the DTA and TG of $AlH_2P_3O_{10}\cdot 2H_2O$ and the II type are shown in Fig. 5. For $AlH_2P_3O_{10}\cdot 2H_2O$, an endothermic reaction with a weight loss of $2H_2O$ was observed at about 150—160 °C; further, another endothermic reaction with a weight loss of the structural water occurred at about 520—530 °C, and the B type was formed. For the II type, an endothermic reaction occurred at 560—570 °C, and losing its structural water, the II type was transformed into a mixture of the A and B types of $Al_4(P_4O_{12})_3$. The determination of the water by the Karl-Fischer method proved that the weight loss seen in the TG curve was caused only by the loss of water. Figures 6 and 7 show the results obtained on heating the I and II types in air at 400—1200 °C for 5 hr. The I type was transformed into the D type of $Al_4(P_4O_{12})_3$ when heated at 450—500 °C; into the B type, at 500—800 °C, and into the A type, above 900 °C. The thermal transformation from the D type to the B type or from the B type to the A type could not be confirmed by the DTA method. On the other hand, the thermal transformation of the II type was quite different from that of the I type, a mixture of the A and B types being directly obtained

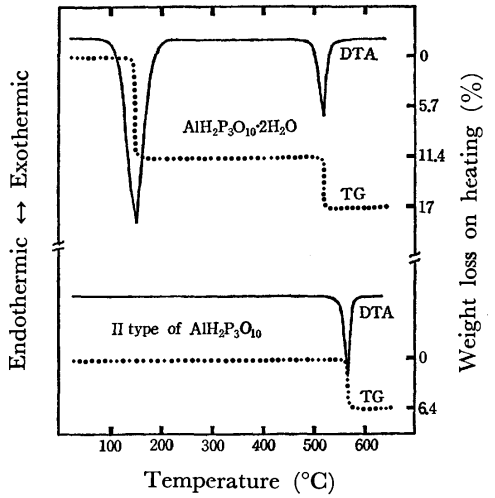

Fig. 5. DTA and TG of aluminum dihydrogen tripolyphosphate.

—●—: A type.

with no intermediate D type. The B type was readily obtained at 500 to 800 °C, but it was always contaminated by the A type; while only the A type was formed above 900 °C. Further, both the I and II types were vitrified by heating at 1200 °C for 5 hr. From these results, it may be concluded that the thermal transformation of the I and II types and of $AlH_2P_3O_{10}\cdot 2H_2O$ heated in air occurs as follows:

$$AlH_2P_3O_{10}\cdot 2H_2O \underset{}{\overset{150-160\,^\circ C}{\rightleftharpoons}} AlH_2P_3O_{10}\ \text{I type}$$

$$\xrightarrow{450-500\,^\circ C} Al_4(P_4O_{12})_3\ \text{D type} \xrightarrow{500\,^\circ C} \text{B type} \xrightarrow{900\,^\circ C}$$

$$\text{A type} \xrightarrow{1200\,^\circ C} \text{Metaphosphate glass}$$

$$AlH_2P_3O_{10}\ \text{II type} \xrightarrow{560-570\,^\circ C} \text{A + B type} \xrightarrow{900\,^\circ C}$$

$$\text{A type} \xrightarrow{1200\,^\circ C} \text{Metaphosphate glass}$$

Conclusions

The experimental results can be summarized as follows:

1) The formation of aluminum phosphates is greatly dependent on the water content of the primary product and on the vapor pressure in the secondary heat treatment.

2) The water effective in the formation of phosphates is that resulting from the dehydration caused by the condensation of the P-OH.

3) The I and II types of $AlH_2P_3O_{10}$ are produced

by heating the primary product at 300 °C; the I type can be most readily obtained when the water content of the primary product is 15—30%.

4) The II type is readily formed when the water content is 10—15%. Both the I and II types are formed under the conditions of a high vapor pressure.

5) $Al_4(P_4O_{12})_3$ is chiefly formed at a heating temperature above 500 °C. The A type is easily obtained when the water content is below 10% or above 25%.

6) The B type is formed at a water content of 10—25%.

7) $AlH_2P_3O_{10}\cdot 2H_2O$ undergoes the following thermal transformation in air: $AlH_2P_3O_{10}\cdot 2H_2O \rightleftarrows$ I type $\rightarrow$D type$\rightarrow$B type$\rightarrow$A type$\rightarrow$Metaphosphate glass.

Cobalt(III) Complexes Containing Large Chelate Rings. I. Syntheses and Properties of Bis(ethylenediamine)-1,ω-diaminoalkanecobalt(III) Complexes[1)]

Hiroshi OGINO and Junnosuke FUJITA*

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Sendai, 980

(Received February 24, 1975)

New cobalt (III) complexes, $[Co(en)_2(H_2N(CH_2)_nNH_2)]X_3$ (n=4, 10, 12 and 14), $[Co_2(en)_4(H_2N(CH_2)_n-NH_2)_2]X_6$ (n=4, 5, 6, 8, 10 and 12), $[Co(en)_2(H_2N(CH_2)_4NH_3)_2]X_5$ and $[CoCl(en)_2(H_2N(CH_2)_{12}NH_3)]X_3$ were isolated from the products of reactions between $[CoCl_2(en)_2]Cl$ and 1,ω-diaminoalkane in dimethylsulfoxide, with the aid of SP-Sephadex column chromatography. For n=5, 6 and 8, no monomeric $[Co(en)_2(H_2N(CH_2)_nNH_2)]^{3+}$ was observed. This result is compatible with instability of the medium size rings in organic compounds. The elution behaviors on Sephadex column and the visible and ultraviolet absorption spectra of the new complexes were also described.

Although several reports on the isolation of metal complexes containing large chelate rings have been presented, no conclusive evidence for the ring formation has ever been obtained.[2)] Attempts to prepare metal complexes with 1,ω-diaminoalkanes, $H_2N(CH_2)_nNH_2$ (n>3) have also been made extensively.[3-10)] However, only Pfeiffer[11)] succeeded in isolating copper(II) complexes of bis(1,4-diaminobutane) and of bis- and tris-(1,6-diaminohexane), although his brief report did not give any evidence for the formation of seven- or nine-membered chelate rings. As shown later, these diamines tend to coordinate to a metal ion as a unidentate ligand or to two metal ions as a bridging ligand.

This paper will present the syntheses and properties of cobalt(III) complexes containing various 1,ω-diaminoalkanes. The diamines, $H_2N(CH_2)_nNH_2$, used in this work are as follows; n=2(en), 3(tn), 4(tmd), 5(pmd), 6(hxn), 8(ocn), 10(den), 12(don) and 14(tden). Some part of this work have been reported briefly in two communications.[12,13)] Very recently, Pryde *et al.*[14)] obtained platinum(II) and iridium(I) complexes containing $Bu^t_2P(CH_2)_nPBu^t_2$ (n=9 or 10).

Experimental

Materials. Guaranteed reagent grade dimethyl sulfoxide (DMSO) and 1,ω-diaminoalkanes (N-N) were obtained from Tokyo Kasei Co. and used without further purification. Column chromatography was carried out by use of SP-Sephadex C-25 (Pharmacia, Sweden).

Preparation of Cobalt(III) Complexes. All bis(ethylenediamine)-1,ω-diaminoalkanecobalt(III) complexes were obtained from the products of reactions of *cis*- or *trans*-$[CoCl_2(en)_2]Cl$ with N-N in DMSO. The *cis*-isomer of $[CoCl_2(en)_2]Cl$ seems to be a better starting material than the *trans*-isomer, because the *cis*-isomer is more soluble in DMSO.

The analytical data for the complexes prepared in this work are summarized in Table 1.

1) *$[Co(en)_2(tmd)]Br_3$ and $[Co_2(en)_4(tmd)_2]Br_6\cdot 6H_2O$*: To 550 ml of DMSO containing 4.3 g of *cis*- or *trans*-$[CoCl_2(en)_2]Cl$ (0.015 mol) was added 1.4 g of tmd (0.016 mol). The solution was kept at 50 °C for 20 hr and then cooled to room temperature. The reddish orange solution resulted was neutralized with concd HCl and diluted to 3 l with water. This was poured on a Sephadex ion exchange column (ϕ 5×40 cm). After washing the column with water, 1 l of an 0.1 M KBr solution was passed through the column. At this stage, the column showed four bands; pink (very small amount), red (small amount), yellow and yellowish orange bands from bottom to top of the column. After the first and second bands had been eluted with an 0.2 M KBr solution, the third yellow band was eluted with an 0.4 M KBr solution. The eluate was concentrated with a rotary evaporator to a small volume. A mixture of yellowish orange crystals of $[Co(en)_2(tmd)]Br_3$ and solid KBr was collected on a glass filter and washed with a small amount of water to remove KBr. The crude product thus obtained was recrystallized from water by the addition of solid NaBr. Pure crystals were filtered off and washed with ethanol and then with ether. Yield: 5.4 g (70%).

The last yellowish orange band was eluted with a warm 1 M KBr solution. Yellowish orange crystals of $[Co_2(en)_4(tmd)_2]Br_6\cdot 6H_2O$ were obtained from the eluate by a procedure similar to the above. Yield: 0.3 g.

2) *$[Co(en)_2(tmdH)_2]Br_5\cdot 4H_2O$*: To 100 ml of DMSO containing 2.9 g of *cis*-$[CoCl_2(en)_2]Cl$ (0.01 mol) was added 1.9 g of tmd (0.02 mol). The solution was stirred for 3 hr at room temperature. The reddish orange solution resulted was treated by a method similar to 1). When 2 l of an 0.2 M NaBr solution and then 4 l of an 0.25 M NaBr solution were passed through the column, five bands were observed on the column; red, yellow, reddish orange, yellow and orange bands from bottom to top of the column. They were eluted with 0.3—1 M NaBr solutions successively. The second yellow band gave $[Co(en)_2(tmd)]Br_3$ (0.15 g) and the fourth yellow band, $[Co(en)_2(tmdH)_2]Br_5\cdot 4H_2O$ (1.5 g). When the fourth band was eluted from the column, the fifth band was found to be separated into several bands, from one of which $[Co_2(en)_4(tmd)_2]Br_6\cdot 6H_2O$ (0.6 g) was obtained. Species in eluates obtained from other bands were not characterized.

3) *$[Co_2(en)_4(pmd)_2]Br_6\cdot 2H_2O$, $[Co_2(en)_4(hxn)_2]Br_6\cdot 4H_2O$, $[Co_2(en)_4(ocn)_2]Br_6\cdot 4H_2O$, $[Co(en)_2(den)]Br_3\cdot 2H_2O$ and $[Co_2(en)_4(den)_2]Br_6\cdot 3H_2O$*: To 550 ml of DMSO containing 4.3 g of *cis*-$[CoCl_2(en)_2]Cl$ (0.015 mol) was added 0.015 mol of N-N (1.5 g for pmd, 1.7 g for hxn, 2.2 g for ocn and 2.6 g for den). The solution was kept at 65 °C for 30 hr and then treated in a similar way to 1). By developing the adsorbed band with an 0.3 M KBr solution, the column gave the following eight bands regardless of the kind of N-N used; pale pink (very small amount, characterized as Co^{2+} species), reddish violet, yellow (this band is refered to as A band), reddish orange, yellowish orange, reddish orange, yellowish orange (B band) and orange from bottom to top of the column. The last orange band seems to be a mixture of highly charged species, because the band was separated into several bands with progression of the elution.

After the pale pink and reddish violet bands had been

* Present address: Department of Chemistry, Faculty of Science, Nagoya University, Nagoya, 464.

TABLE 1. SUMMARY OF ANALYTICAL DATA FOR THE COMPLEXES PREPARED IN THIS WORK

Complex	Formula	C, %		H, %		N, %	
		Calcd	Found	Calcd	Found	Calcd	Found
$[Co(en)_2(tn)]Br_3$	$[CoC_7H_{26}N_6]Br_3$	17.06	16.81	5.32	5.46	17.05	16.80
$[Co(en)(tn)_2]Br_3\cdot 4H_2O$	$[CoC_8H_{28}N_6]Br_3\cdot 4H_2O$	16.59	16.66	6.27	6.97	14.51	14.71
$[Co(en)_2(tmd)]Br_3$	$[CoC_8H_{28}N_6]Br_3$	18.95	18.71	5.57	5.76	16.58	16.58
$[Co(en)_2(den)]Br_3\cdot 2H_2O$	$[CoC_{14}H_{40}N_6]Br_3\cdot 2H_2O$	26.81	26.72	7.07	6.88	13.40	13.73
$[Co(en)_2(don)]Br_3\cdot H_2O$	$[CoC_{16}H_{44}N_6]Br_3\cdot H_2O$	30.16	29.91	7.28	7.31	13.19	13.04
$[Co(en)_2(tden)]Br_3\cdot 2.5H_2O$	$[CoC_{18}H_{48}N_6]Br_3\cdot 2.5H_2O$	31.23	31.35	7.72	7.61	12.14	12.37
$[CoCl(en)_2(donH)]Br_3\cdot 2.5H_2O$	$[CoClC_{16}H_{45}N_6]Br_3\cdot 2.5H_2O$	27.43	26.91	7.19	6.78	11.99	12.16
$[Co(en)_2(tmdH)_2]Br_5\cdot 4H_2O$	$[CoC_{12}H_{42}N_8]Br_5\cdot 4H_2O$	17.39	17.43	6.08	6.06	13.52	13.50

$[Co_2(en)_4(pmd)_2]Br_6\cdot 2H_2O$	$[Co_2C_{18}H_{60}N_{12}]Br_6\cdot 2H_2O$	20.05	19.92	5.98	5.96	15.59	15.68
$[Co_2(en)_4(hxn)_2]Br_6\cdot 4H_2O$	$[Co_2C_{20}H_{64}N_{12}]Br_6\cdot 4H_2O$	21.03	20.95	6.35	6.35	14.72	14.30
$[Co_2(en)_4(ocn)_2]Br_6\cdot 4H_2O$	$[Co_2C_{24}H_{72}N_{12}]Br_6\cdot 4H_2O$	24.06	23.68	6.73	6.35	14.03	14.03
$[Co_2(en)_4(den)_2]Br_6\cdot 3H_2O$	$[Co_2C_{28}H_{80}N_{12}]Br_6\cdot 3H_2O$	27.20	26.92	7.01	6.74	13.59	13.83
$[Co_2(en)_4(don)_2]Cl_6\cdot 6.5H_2O$	$[Co_2C_{32}H_{88}N_{12}]Cl_6\cdot 6.5H_2O$	35.30	35.52	9.35	9.25	15.44	15.09

eluted with an 0.3 M KBr solution, the A band was eluted with an 0.4 M KBr solution and its yellow eluate was concentrated. A small amount of yellow crystals of $[Co(en)_3]Br_3\cdot 3H_2O$ was obtained and no formation of $[Co(en)_2(N\text{–}N)]^{3+}$ was observed for all the diamines except the den. In the case of den, the eluate gave yellowish orange crystals of $[Co(en)_2(den)]Br_3\cdot 2H_2O$. They were recrystallized similarly from water by the addition of solid KBr. Yield: 0.24 g (2.5 %).

After the A band had been eluted from the column, the concentration of eluent was increased to 0.6 M and then 1 M or more with progression of the elution. However, the use of such KBr solutions caused sometimes crystallization of $[Co_2(en)_4(N\text{–}N)_2]Br_6\cdot nH_2O$ in the column, so that a warm KBr solution (40—70 °C) was used. In the case of the den system, it was still difficult to avoid the crystallization. Therefore, the layer of B band was transfered to a beaker and a colored species was extracted with a hot 0.6 M KBr solution repeatedly. Yellowish orange crystals which were obtained from each eluate or extract by concentration were $[Co_2(en)_4(pmd)_2]Br_6\cdot 2H_2O$, $[Co_2(en)_4(hxn)_2]Br_6\cdot 4H_2O$, $[Co_2(en)_4(ocn)_2]Br_6\cdot 4H_2O$ and $[Co_2(en)_4(den)_2]Br_6\cdot 3H_2O$. The yields of $[Co_2(en)_4(N\text{–}N)_2]^{6+}$ ranged from 30% (pmd) to 12% (den) depending on the length of the methylenic chain of the N–N.

4) *$[CoCl(en)_2(donH)]Br_3\cdot 2.5H_2O$, $[Co(en)_2(don)]Br_3\cdot H_2O$ and $[Co_2(en)_4(don)_2]Cl_6\cdot 6.5H_2O$*: These complexes were obtained from 4.3 g of *cis-* or *trans-*$[CoCl_2(en)_2]Cl$ (0.015 mol) and 3.0 g of don (0.015 mol) by a method similar to 3). By developing the reaction product on a Sephadex column with an 0.2 M NaBr solution, eight bands were observed; pink (small amount), red (A band), yellow (B band), yellowish orange, reddish orange, yellowish orange, yellowish orange (C band) and orange from bottom to top of the column. The last band seems also to be a mixture of several highly charged species. After the first pink band had been eluted with an 0.2 M NaBr solution, the red A band was eluted with an 0.3 M NaBr solution. By evaporating the eluate, reddish violet crystals of $[CoCl(en)_2(donH)]Br_3\cdot 2.5\,H_2O$ were obtained and recrystallized from water by the addition of NaBr. The eluate of the A band contained a small amount of $[Co(en)_3]^{3+}$, but it was separated easily from the desired complex by the recrystallization.

The B band was eluted with an 0.4 M NaBr solution and the eluate was concentrated. Yellowish orange crystals of $[Co(en)_2(don)]Br_3\cdot H_2O$ were obtained and recrystallized from water by the addition of solid NaBr. Yield: 0.87 g (9%).

Then the column was washed with water. The layer of C band was transfered to a beaker and a colored species was extracted with a hot 1 M NaCl solution repeatedly. Upon cooling the extract to room temperature, fine crystals of $[Co_2(en)_4(don)_2]Cl_6\cdot 6.5H_2O$ were precipitated, filtered off and recrystallized from water.

5) *$[Co(en)_2(tden)]Br_3\cdot 2.5H_2O$*: This complex was prepared similarly by warming a DMSO (500 ml) solution containing 2.9 g of *cis-*$[CoCl_2(en_2)]Cl$ (0.01 mol) and 2.3 g of tden (0.01 mol) at 60 °C for 20 hr. The Sephadex column gave six bands on developing the product with an 0.2 M KBr; pale pink (small amount), yellow (small amount of $[Co(en)_3]^{3+}$), reddish violet, yellowish orange, reddish orange and brownish orange from bottom to top of the column. After the first three bands had been eluted with an 0.3 M KBr solution, the fourth yellowish orange band was eluted with a warm 0.6 M KBr solution. A gummy oil was separated from the solution by concentrating the eluate. The oil was dissolved into a small amount of warm water and the solution was cooled gradually to room temperature. Yellowish orange crystals of $[Co(en)_2(tden)]Br_3\cdot 2.5H_2O$ were precipitated, filtered off and recrystallized from water. Yield: 0.38 g (6%).

6) *$[Co(en)_2(tn)]Br_3$*: This complex was prepared by the procedure reported by Bailar and Work.[10] The product contained a considerable amount of $[Co(en)_3]Cl_3\cdot 3H_2O$. Pure crystals of $[Co(en)_2(tn)]Br_3$ were obtained by recrystallizing the product several times from water by the addition of a KBr solution.

Alternatively, a method similar to 1) was employed; to 100 ml of DMSO containing 2.9 g of *cis-*$[CoCl_2(en)_2]Cl$ (0.01 mol) was added 0.74 g of tn (0.01 mol). The solution was allowed to stand overnight at room temperature, neutralized with conc. HCl and subjected to Sephadex column chromatography. The fastest moving band seemed to be Co^{2+} species. The second band was pink and was followed by a yellow band. The yellow band was eluted with an 0.2 M KBr solution. Some bands remained on the column after elution of the yellow band. Evaporation of the yellow eluate gave crystals of $[Co(en)_2(tn)]Br_3$ which also contained $[Co(en)_3]Br_3\cdot 3H_2O$. They were recrystallized similarly from water by the addition of a KBr solution to give pure $[Co(en)_2(tn)]Br_3$. Yield: 1.2 g.

7) *$[Co(en)(tn)_2]Br_3\cdot 4H_2O$*: To 40 ml of an aqueous solution containing 12 g of $CoCl_2\cdot 6H_2O$ (0.05 mol) were added 11 g of tn (0.15 mol), 3 g of en (0.05 mol), 8.3 ml of 6 M HCl (0.05 mol) and 1 g of active carbon. Air was passed through the solution for 12 hr at room temperature. After removal of active carbon by filtration, solid KBr was added to the filtrate. A mixture of $[Co(en)_2(tn)]Br_3$ and $[Co(en)(tn)_2]Br_3\cdot 4H_2O$ was obtained. The latter was more soluble than the former and the desired complex was obtained by the fractional crystallization.

When solid $[CoCl_2(tn)_2]Cl$ was added in small portions to a DMSO solution containing equimolar amount of en, the desired complex was also formed together with $[Co(en)_3]^{3+}$ and $[Co(en)_2(tn)]^{3+}$

Apparatus. Visible and ultraviolet absorption spectra of aqueous solutions of the complexes were recorded on a Hitachi EPS-3 recording spectrophotometer.

Results and Discussion

Chromatographic Properties and Characterization of the Complexes. Both yellowish orange complexes of the monomeric $[Co(en)_2(N\text{–}N)]X_3$ and the dimeric $[Co_2(en)_4(N\text{–}N)_2]X_6$ obtained here have the same chemical composition, but their complex cations have different charges. The difference in the charge of the complex ion may be reflected on the chromatographic properties.

Sephadex resin charged with two kinds of complex ion was placed carefully on the top of a Sephadex column (ϕ 1.6×20 cm) by 1 mm thickness. The adsorbed complex ions were eluted with an 0.25 M KBr solution adjusted to pH 3 with HBr at a rate of about 1.6 ml/min. The relative R_f values to that of $[Co(en)_3]^{3+}$ are summarized in Table 2 where those of the authentic samples of the known charge are given for comparison. Table 2 shows that the R_f value increases by four to ten times as the charge of the complex ion decreases by one and that the complexes, $[Co(en)_2(N\text{–}N)]^{3+}$ give values expected for a monomeric tripositive ion, although a slight deviation from unity is observed for the complexes containing larger diamine chelate.

Table 2. The relative R_f values of various complexes
(Eluent: 0.25 M KBr solution adjusted to pH 3 with HBr.)

Complex ion	Relative R_f value
$[CoCl(NH_3)_5]^{2+}$	7.6[a]
$[Co(en)_3]^{3+}$	1[b]
$[Co(NH_3)_6]^{3+}$	0.65
$[CoCl(en)_2(donH)]^{3+}$	~1
$[Co(en)_2(tn)]^{3+}$	1.0
$[Co(en)_2(tmd)]^{3+}$	1.0
$[Co(en)_2(den)]^{3+}$	0.87
$[Co(en)_2(don)]^{3+}$	0.54
$[Co(en)_2(tden)]^{3+}$	0.43
$[Co(en)_2(tmdH)_2]^{5+}$	0.16
$[Co_2(en)_4(tmd)_2]^{6+}$	0.01_8
$[Co_2(en)_4(hxn)_2]^{6+}$	<0.02
$[Co_2(en)_4(don)_2]^{6+}$	<0.01
$[Cr\{(OH)_2Cr(en)_2\}_3]^{6+}$	~0.008

a) This value was determined by the elution of resins charged with $[CoCl(NH_3)_5]^{2+}$ and $[Co(en)_3]^{3+}$. (Eluent: 0.1 M KBr solution adjusted to pH 3 with HBr.) b) The R_f value of this complex ion is taken as unity.

Under the same elution condition, other yellowish orange complexes assignable to $[Co_2(en)_4(N\text{–}N)_2]^{6+}$ show such slow flow rates that their R_f values are determined with difficulty. However, these ions flow with an 0.5 M KBr solution at rates similar to that of $[Cr\{(OH)_2Cr(en)_2\}_3]^{6+}$, indicating that they are dimeric with hexapositive charge.

The R_f value of the yellowish orange complex whose elemental analysis gives correct value for $[Co(en)_2(tmdH)_2]Br_5\cdot 4H_2O$ is 0.16 and the complex ion can be concluded to be pentapositive. This complex will be the first example of cobalt(III) complex containing two unidentate diamines.

For the $[Co(en)_2(N\text{–}N)]^{3+}$, two nitrogen atoms of the N–N can occupy *cis* or *trans* positions as shown in Fig. 1A, if the methylenic chain of the N–N is long enough. However, all the N–N used in this work will occupy only *cis* positions. Molecular models reveal that the non-bonding interaction between the en and the N–N chelates make *trans* spanning difficult even in the case of tden with 14 methylenes. This will be supported by the fact that $[Co(en)_2(tmd)]^{3+}$ and $[Co(en)_2(don)]^{3+}$ were resolved into optical isomers by SP-Sephadex column chromatography using an 0.15 M potassium tartratoantimonate(III) solution as an eluent.[12,15]

Many isomers are possible for the dimeric complexes, $[Co_2(en)_4(N\text{–}N)_2]^{6+}$. As shown later, the formation of $[Co_2(en)_6]^{6+}$ was never observed, indicating that en will be unfavorable as a bridging ligand. Molecular models suggest that the structures in Fig. 1B are most probable. The catenane structures of which one example is shown in Fig. 1C are also possible, if the methylenic chain of

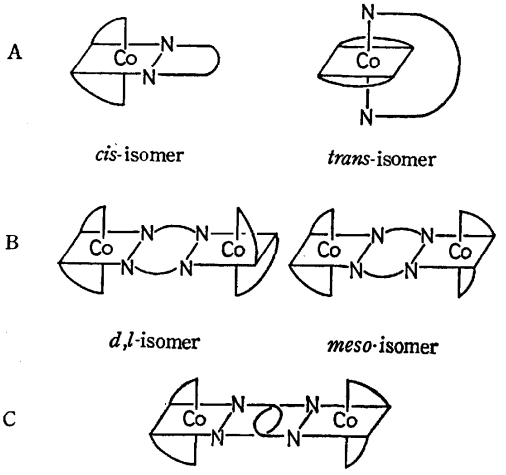

Fig. 1. Possible structures for the monomer ($[Co(en)_2(N\text{–}N)]^{3+}$) and the dimer ($[Co_2(en)_4(N\text{–}N)_2]^{6+}$). ⌒ and N⌒N denote en and N–N, respectively.
A: Possible structure of the monomer.
B: Most probable structures of the dimer.
C: One example of the catenane structures for the dimer.

the N–N becomes long enough.

The red complex assigned to $[CoCl(en)_2(donH)]Br_3 \cdot 2.5H_2O$[16] gives the R_f value almost the same as that of $[Co(en)_3]^{3+}$. This complex shows the first and the second absorption band at 18900 cm^{-1} with a shoulder at 21300 cm^{-1}, and at 27400 cm^{-1}, respectively. This spectral pattern is characteristic of a $[CoClN_5]$ type.[17,18] The complex is converted into aqua complex $[Co(H_2O)(en)_2(donH)]^{4+}$ when treated with silver nitrate in an acidic aqueous solution. The aqua complex exhibits a symmetrical first absorption band at 20400 cm^{-1}. Alexander and Spillert[19] prepared $[CoCl(en)_2(enH)]Cl_3 \cdot H_2O$ and assigned it to *cis* configuration. The present chloro complex may have the same *cis* structure.

Mechanism of the Reaction of $[CoCl_2(en)_2]Cl$ with N–N in DMSO. In order to elucidate the mechanism of the reaction of $[CoCl_2(en)_2]Cl$ with N–N, the preparations have been carried out under various conditions. The change of concentration of the reactants affects the distribution of products considerably. The yield of $[Co(en)_2(tmd)]^{3+}$ amounts to 70%, when 0.015 mol of tmd is allowed to react with an equivalent amount of $[CoCl_2(en)_2]Cl$ in 550 ml of DMSO. However, when the solvent DMSO is reduced to 50 ml, the yield of this monomer decreases to a few percent and that of the $[Co_2(en)_4(tmd)_2]^{6+}$ increases. In this case, formation of $[Co(en)_2(tmdH)_2]^{5+}$ and other very highly charged species than the hexapositive dimer is observed, some of the latter species remaining on the Sephadex column even after washed with a 1 M KBr solution. The mole ratio of $[CoCl_2(en)_2]Cl$ to N–N also affects the distribution of the products. As stated in the experimental section, the reaction of 0.01 mol of $[CoCl_2(en)_2]Cl$ with 0.02 mol of tmd in 100 ml of DMSO gives a small amount of $[Co(en)_2(tmd)]^{3+}$ and a large amount of $[Co(en)_2(tmdH)_2]^{5+}$ and $[Co_2(en)_4(tmd)_2]^{6+}$.

From these experimental results, the following mechanism can be deduced for the reaction of $[CoCl_2(en)_2]Cl$ with N–N:

cis- or *trans*-$[CoCl_2(en)_2]^+ + N\text{-}N \xrightarrow{\text{fast}}$

cis- or *trans*-  Intermediate(Int) (1)

Int— Intramolecular reaction →  (2)

Int— Intermolecular reaction → dimer and higher polymers (3)

The reaction of $[CoCl_2(en)_2]Cl$ with N–N gives an intermediate species (Int) rapidly. The formation of the Int will be supported by the isolation of $[CoCl(en)_2(donH)]Br_3 \cdot 2.5H_2O$. An intramolecular ring closure of the Int leads to the formation of the monomer, while an intermolecular reaction of the Int results in the formation of the dimer and higher polymers. The former reaction is of the first-order and the half-time of the reaction should be independent of the concentration of the Int. On the other hand, the intermolecular reaction is bimolecular, so that the half-time of this reaction should decrease with increase of the concentration of the Int. Therefore, the reaction in a dilute solution favors the formation of the monomer in agreement with the experimental results.

The formation of $[Co(en)_2(tmdH)_2]^{5+}$ in a concentrated solution can be interpreted by a mechanistic consideration similar to that mentioned above; the bimolecular reaction of the Int with tmd would yield $[Co(en)_2(tmd)_2]^{3+}$ containing two unidentate tmd. The half-time of this reaction in a concentrated solution will be shorter than that in a dilute solution and hence the yield of $[Co(en)_2(tmdH)_2]Br_5 \cdot 4H_2O$ would increase with increase of the concentration of reactants.

A partial reduction of cobalt(III) to cobalt(II) were found for almost all the reactions in DMSO. The formation of a small amount of $[Co(en)_3]^{3+}$ may be related to this reduction reaction.

Relation between the Yield of $[Co(en)_2(N\text{–}N)]^{3+}$ and the Size of the Chelate Ring formed by N–N. The yields of monomeric complexes, $[Co(en)_2(N\text{–}N)]^{3+}$ are markedly dependent on the methylenic chain length of the N–N. In Fig. 2 is plotted the yield of $[Co(en)_2(N\text{–}N)]^{3+}$ obtained from $[CoCl_2(en)_2]Cl$ (0.015 mol), N–N (0.015 mol) and 550 ml of DMSO, against the number of ring members of the N–N in the complex ion. The reaction of $[CoCl_2(en)_2]Cl$ with en gives $[Co(en)_3]^{3+}$ almost quantitatively and no dimeric complex is detected even under the reaction in a highly concentrated solution. The yield of the monomer decreases sharply at pmd, which should form an eight membered chelate ring. The formation of the monomer is virtually zero for pmd, hxn and ocn. However, the monomer is again formed when the number of methylene groups becomes more than nine. The yield increases with increase of the number of methylene groups and seems to show a maximum at don, forming a fifteen membered chelate ring. This tendency is strikingly similar to that observed in the syntheses of organic ring

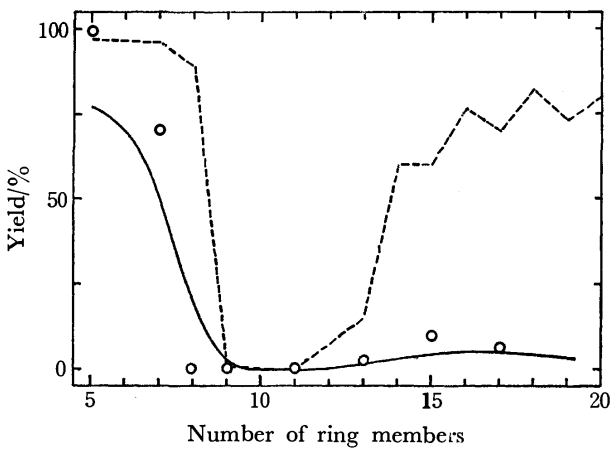

Fig. 2. Relation between the yield of compounds and the number of ring members. Open circles indicate the yields of $[Co(en)_2(N\text{–}N)]^{3+}$. Solid line and dashed line indicate the yield of ring ketones[22] obtained by Ruzicka and Ziegler, respectively.

Table 3. Absorption spectral data for the complexes prepared in this work and the related complexes
Wave numbers are in 10^3 cm^{-1} and the intensities given by log ε in parentheses.

Complex	I Band	II Band	Charge Transfer Band
$[Co(en)_3](ClO_4)_3$	21.3 (1.94)	29.6 (1.89)	47.5 (4.36)

ketones from bifunctional aliphatic molecules.

Ruzicka[20] succeeded in preparing large ring ketones by pyrolysis of metal salts of dicarboxylates. Ziegler *et al.*[21,22] improved Ruzicka's method and obtained the same compounds from dinitriles by employing the high dilution method. The relations between the yields of ring ketones prepared by both methods and the ring size are also given in Fig. 2. In organic chemistry, medium size ring compounds which correspond to eight to eleven membered ring systems are known to be less stable owing to such strains as bond angle deformations, bond opposition forces and trans-annular interactions.[23,24] Larger ring compounds than eleven members will be released from such strains sterically and becomes more stable than the medium size compounds. Existence of a minimum in the yields of the ring ketones in Fig. 2 has been interpreted in terms of such strains and entropy factor in the ring closure process.[23-26] Similar situation must exsist in the present complexes containing N–N. Molecular models reveal that the complexes containing pmd, hxn or ocn are seriously strained. With more increase of the ring members, the complex is formed but its yield decreases again over fifteen ring members. This second decrease can be understood by a concept similar to that widely accepted for the ring closure process of bifunctional organic compounds; the longer the chain the smaller probability of encounter between the cobalt(III) center and the terminal nitrogen atom of diamine in the Int. Parallelism between the chelate ring complexes and the ring ketones provides an additional support for the formulation of the present monomeric complexes containing a large chelate ring.

Spectral Properties of the Complexes. Numerical data for visible and ultraviolet absorption spectra of the complexes are summarized in Table 3.

The successive substitution of en in $[Co(en)_3]^{3+}$ with tn or tmd causes shifts in the first and second absorption bands to longer wave length. In Fig. 3 are plotted the

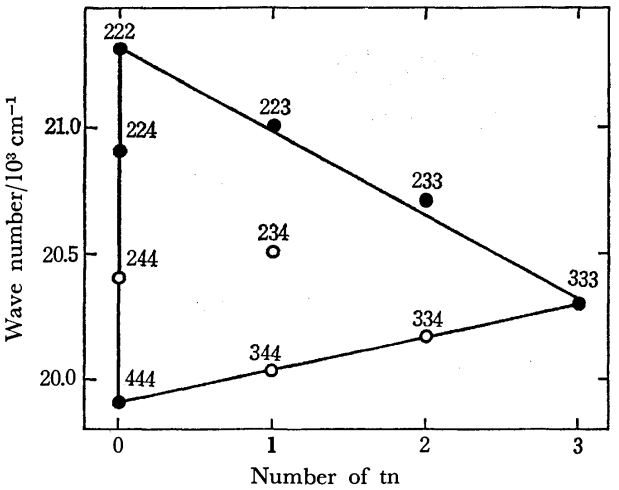

Fig. 3. Positions of the first absorption bands of $[Co(en)_a(tn)_b(tmd)_{3-a-b}]^{3+}$.
In the figure, 2, 3 and 4 indicate en, tn and tmd in the complex, respectively. For example, 234 denotes $[Co(en)(tn)(tmd)]^{3+}$. Open circles are the estimated values.

positions of the first absorption band maxima of $[Co(en)_a(tn)_b(tmd)_{3-a-b}]^{3+}$ against the number of tn in the complexes. The magnitude of the shifts is additive. Hence, the positions of the first absorption maxima of unknown complexes consisting of en, tn or tmd can be estimated from Fig. 3.

Figure 4 compares the maximum positions of the first absorption bands of various tris(diamine)cobalt(III) complexes. The absorption bands of $[Co(en)_2(N–N)]^{3+}$ shift to longer wave-length as the methylenic chain of the N–N becomes longer. However, the magnitude of the shifts becomes smaller with increase of the number of methylenic chain. A similar trend is observed for $[Co(en)(N–N)_2]^{3+}$ and $[Co(N–N)_3]^{3+}$.

Table 3 shows that the $[Co_2(en)_4(N–N)_2]^{6+}$ give the

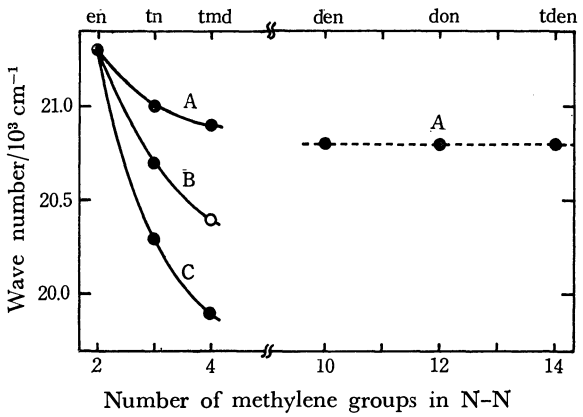

Fig. 4. Relation between the maximum potitions of the first absorption bands and the methylenic chain length of the N-N in $[Co(en)_2(N\text{-}N)]^{3+}$ (A), $[Co(en)(N\text{-}N)_2]^{3+}$ (B) and $[Co(N\text{-}N)_3]^{3+}$ (C). Absorption maximum of $[Co(en)(tmd)_2]^{3+}$ is taken from Fig. 3 (open circle).

absorption bands at almost the same positions as those of $[Co(en)_2(N\text{-}N)]^{3+}$. Their molar extinction coefficients are approximately 2 times larger than those of the monomeric complexes, the intensities of the dimeric complexes per one cobalt(III) ion being almost the same as those of the monomeric complexes.

The authors wish to thank Prof. Nobuyuki Tanaka and Prof. Kazuo Saito, Tohoku University, for their encouragement and support.

The ^{13}C Magnetic Resonance Study on the Effects of Divalent Paramagnetic Metal Acetylacetonates on Pyridine, Quinoline, and Isoquinoline. Specific Interactions with $Mn(AA)_2$

Kikuko HAYAMIZU, Makoto MURATA,* and Osamu YAMAMOTO

National Chemical Laboratory for Industry, 1-1-5 Honmachi, Shibuya-ku, Tokyo 151

(Received October 24, 1974)

^{13}C nuclear magnetic resonance studies of pyridine solutions containing paramagnetic Ni(II), Co(II), Cu(II), or Mn(II) acetylacetonate are made by observing the induced chemical shift, the line width, and the spin-lattice relaxation time due to the paramagnetism of these metals. The origin of the paramagnetic effects on the ^{13}C spectra induced by Ni, Co, or Cu acetylacetonate is mainly the contact interaction, while the ^{13}C spectra of the pyridine–$Mn(AA)_2$ system can not be interpreted by the same interaction. The ^{13}C spectra of quinoline and isoquinoline containing $Mn(AA)_2$ are also studied; the results indicate that the predominant mechanism is the dipole-dipole interaction.

Up to now, the influences of paramagnetic metals on the ^{13}C nuclear magnetic resonance (NMR) spectra have been studied mainly from two different viewpoints. The ^{13}C spectra of *N*-heterocyclic compounds with addition of Ni(II) acetylacetonate, $Ni(AA)_2$, were investigated in order to observe the ^{13}C contact shift, where the molecule under study interacts with the paramagnetic $Ni(AA)_2$ at the position of the nitrogen atom.[1-4] In magnetic resonances of nuclei other than ^{13}C, especially in the ^1H NMR, the contact shifts induced by paramagnetic metals have been studied for many molecules and metals, and the nature of the interaction between them have been elucidated.[5] From the studies of the induced ^{13}C shift, much information has been obtained about the electronic structure of the carbon skelton of the molecules.[1-4]

Another study is the observation of the quenching of the nuclear Overhauser effect (NOE), which is characteristic of the ^{13}C resonance.[6-11] In this case, the molecule under study does not have any special interacting site with the paramagnetic metals in solution. The roles of the paramagnetic metals are to accelerate the slow ^{13}C relaxation and to reduce the NOE enhancement. An attempt has been made to use various paramagnetic metals as "paramagnetic relaxation agents" for this purpose, but clearly the utility of the paramagnetic metals is limited since many molecules are known to associate with metals.

Morishima and his co-workers[1-4] have studied the ^{13}C contact shifts induced by $Ni(AA)_2$ and indicated that the induced ^{13}C contact shifts show an alternation in sign and an attenuation in magnitude, depending on the distance from the nitrogen atom of the interacting site. They interpreted this phenomenon in terms of the electron spin densities on the carbon s atomic orbitals. The line broadening of the ^{13}C spectra of *N*-heterocyclic compounds due to $Ni(AA)_2$ is in the order of the β, α, and γ-carbons to the nitrogen atom attached by $Ni(AA)_2$; this order is the same as that of the absolute magnitude of the ^{13}C contact shift induced by $Ni(AA)_2$.

On the other hand, Kotowycz and Hayamizu first observed that when the paramagnetic Mn^{2+} ion was added to the aqueous adenosine monophosphate (AMP) solution, the ^{13}C line broadening was observed from the nearest position of the metal-binding site.[12] This trend has been shown to be the same for pyrimidine nucleoside and nucleotide in the presence of the Mn^{2+} ion,[13] while a different trend was observed upon the addition of the Cu^{2+} ion in similar aqueous solutions.[14] Clearly these results suggest that different paramagnetic metals affect the ^{13}C spectra in different manners.

Although many studies have been made to observe the ^{13}C contact shifts induced by $Ni(AA)_2$ for various *N*-heterocyclic compounds or to quench the NOE enhancement using various paramagnetic metals, only a few observations have been reported for the effects due to various paramagnetic metals on the ^{13}C parameters of *N*-heterocyclic compounds. In this paper we wish to report on the influences of four kinds of divalent paramagnetic metals, *i.e.*, Ni, Co, Cu, and Mn on the ^{13}C spectra of pyridine by observing the ^{13}C chemical shift, the line width, and the spin-lattice relaxation time, T_1. The behavior of these parameters upon the addition of $Ni(AA)_2$, $Co(AA)_2$, and $Cu(AA)_2$ is approximately similar, but $Mn(AA)_2$ gives quite different effects on the induced ^{13}C shifts and the line broadening. To confirm whether or not this is a general trend, the ^{13}C spectra of quinoline and isoquinoline were also studied upon the addition of $Mn(AA)_2$.

Experimental

The ^1H-decoupled ^{13}C spectra were obtained by an NV-14 spectrometer, NEVA Ltd., Tokyo, operating at 15.1 MHz with a Fourier transform mode. The deuterium signal from the solvent, $CDCl_3$, was used for the heteronuclear lock. The FID signals were accumulated in 8192 data points of a Varian 620 l computer, and the spectral width was 800 Hz. To obtain reliable values, 16 to 1000 accumulations were made, depending on the line width, the tip angle being about 30°. The sample temperature was maintained at about 28°C by blowing in compressed air. As the chemical shift reference, internal benzene was used for pyridine and quinoline, while external benzene was used for isoquinoline in order to prevent overlapping of the signals. The chemical shift accuracy was within ± 0.2 Hz. T_1 was measured by the usual 180°—90° pulse method. The rms errors of the semi-logarithmic plot of $(M_0 - M(\tau))/M_0$ *vs.* τ were within 5%.

All the substances were obtained from commercial sources. The materials were used without further purification except for pyridine, which was distilled. The concentrations

* Present address: Nippon Electric Varian Ltd., 5-8-1 Yotsuya, Fuchu-shi, Tokyo 183.

of the $CDCl_3$ solutions were 62, 41, and 41 mole % for pyridine, quinoline, and isoquinoline, respectively. The stock solution of various metal acetylacetonates, $M(AA)_2$, in $CDCl_3$ or in pyridine was added successively by means of a microsyringe to obtain 5 to 7 different concentration of $M(AA)_2$.

Results and Discussion

Effects of Paramagnetic Metals on the ^{13}C Chemical Shift, the Line Width, and the Spin-Lattice Relaxation Time. The chemical shift induced by paramagnetic species in solution, $\Delta\delta_M$, consists of two terms, *i.e.*, the pseudocontact and contact terms.[15]

$$\Delta\delta_M = -\left[f(g)\frac{\beta^2}{kT}\frac{3\cos^2\theta-1}{r^3}+A\frac{\gamma_e}{\gamma_N}\frac{g\beta}{3kT}\right]S(S+1) \quad (1)$$

where $f(g)$ is the function of g component of the electron spin and other notations have the usual meanings. It has been reported that the pseudocontact term may be negligible for the ^{13}C shift induced by $Ni(AA)_2$ and that the contact term plays the main role.[1-4]

In a solution containing the paramagnetic species, the nuclear spin-lattice relaxation time, T_{1M}, and the nuclear spin-spin relaxation time, T_{2M}, due to the metal are written by [15]

$$\frac{1}{T_{1M}} = \frac{Nn_h}{N_p}S(S+1)\left[\frac{2}{15}\frac{g^2\beta^2\gamma_I^2}{r^6}\left(3\tau_c+\frac{7\tau_c}{1+\omega_s^2\tau_c^2}\right)+\frac{2}{3}\frac{A^2}{\hbar^2}\left(1+\frac{\tau_e}{1+\omega_s^2\tau_e^2}\right)\right] \quad (2)$$

$$\frac{1}{T_{2M}} = \frac{Nn_h}{N_p}S(S+1)\left[\frac{1}{15}\frac{g^2\beta^2\gamma_I^2}{r^6}\left(7\tau_c+\frac{13\tau_c}{1+\omega_s^2\tau_c^2}\right)+\frac{1}{3}\frac{A^2}{\hbar^2}\left(\tau_e+\frac{\tau_e}{1+\omega_s^2\tau_e^2}\right)\right] \quad (3)$$

where

$$\frac{1}{\tau_c} = \frac{1}{\tau_r} + \frac{1}{\tau_s}$$

and

$$\frac{1}{\tau_e} = \frac{1}{\tau_h} + \frac{1}{\tau_s}$$

τ_s is the electron spin relaxation time, τ_r is the characteristic time for the tumbling motion of the paramagnetic complex, and τ_h is the chemical exchange time for the ligand molecule between the coordination sphere and the bulk medium. n_h is the number of the ligand molecule in the solvation sphere, N_p is the molar concentration of the ligand molecule, and N is the molar concentration of paramagnetic metals.

The line broadening, $\Delta\nu_M$, induced by the paramagnetic metals is obtained from the difference between the full line width, $\Delta\nu_{obs}$, with the metal and $\Delta\nu_0$ without the metal:

$$\Delta\nu_M = \Delta\nu_{obs} - \Delta\nu_0$$

In a rough approximation, T_{2M} may be obtained from $\Delta\nu_M$ by the following relation:

$$1/T_{2M} = \pi\Delta\nu_M \quad (4)$$

Equations (2) and (3) show that T_{1M} and T_{2M} are functions of the contact correlation time, τ_e, and the dipolar correlation time, τ_c, and at the same time, they depend upon the magnitude of the isotropic coupling constant, A, and the distance between the metal and the nuclei.

Table 1. The effects of various metal acetylacetonates on the ^{13}C resonance of pyridine[a]

	S		α	β	γ
$Cu(AA_2)$	1/2	$1/T_{1M}(s^{-1})$	0.32	0.13	0.11

a) These values are obtained from the linear plots of the parameters *vs.* the metal concentration at 5×10^{-3} M and normalized by $S(S+1)$.

In this paper, $\Delta\delta_M$, T_{1M}, and $\Delta\nu_M$ of the ^{13}C NMR spectra are measured in order to observe the influences of the four paramagnetic metals and to discuss the different effects according to Eqs. (1) to (4).

Interactions between Pyridine and Ni(AA)$_2$, Co(AA)$_2$, Cu(AA)$_2$, and Mn(AA)$_2$. To observe the paramagnetic effects due to $M(AA)_2$ (M=Ni, Co, Cu, and Mn) on the ^{13}C spectra, a pyridine solution was used with $M(AA)_2$ added successively. In Table 1 the values observed for $\Delta\delta_M$, $\Delta\nu_M$, and T_{1M} of each carbon of pyridine due to the four kinds of $M(AA)_2$ are summarized. These values are obtained from the plots of these parameters *vs.* the concentrations of $M(AA)_2$ at the point of 5×10^{-3} M, the mole ratio of pyridine to $M(AA)_2$ being approximately 1500 : 1. All the parameters, P_M, are calculated by means of

$$P_M = (P_{Mobs}-P_0)\frac{1}{S(S+1)}$$

where P_{Mobs} and P_O are the values with and without paramagnetic metals, and S is the electron-spin quantum number for each metal. In order to discuss the nature of the metal–pyridine interaction, all the parameters due to the presence of the metal must be normalized by $S(S+1)$, as is indicated by Eqs. (1) to (3).

Figure 1 shows the effects of various amounts of $M(AA)_2$ on the induced ^{13}C shifts of pyridine in $CDCl_3$, where the $\Delta\delta_M$'s are not normalized by $S(S+1)$. When the metals are Ni and Co, the $\Delta\delta_M$ values show a similar trend, *i.e.*, an increased concentration of the metals brings a larger shift. The singals of α and γ-carbons move to the higher field and that of β-carbons moves to the lower field, and the absolute magnitudes of $\Delta\delta_M$ are ordered as: $|\Delta\delta_M(\beta)|>|\Delta\delta_M(\alpha)|>|\Delta\delta_M(\gamma)|$. This trend was interpreted for the $Ni(AA)_2$–pyridine system in terms of the electron-spin densities on the carbon orbitals by Morishima and his co-workers.[1]

When $Cu(AA)_2$ was added to the pyridine solution (Figure 1(C)), each carbon signal behaves in a different manner from those of the $Ni(AA)_2$ and $Co(AA)_2$ systems, and the magnitudes of $\Delta\delta_M$ are rather small and not

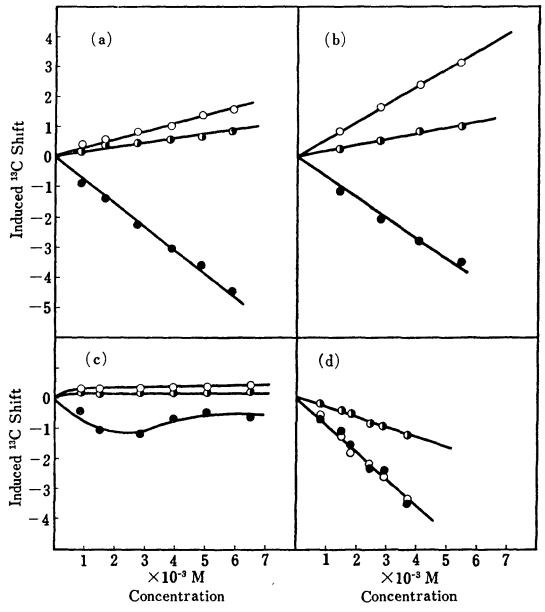

Fig. 1. The linear plots of the induced ^{13}C shifts for α(○), β(●), and γ(◑)-carbons of pyridine *vs.* the concentration of (a) $Ni(AA)_2$, (b) $Co(AA)_2$, (c) $Cu(AA)_2$, and (d) $Mn(AA)_2$.

linear to the concentration of $Cu(AA)_2$. However, the direction of the induced ^{13}C shifts for each carbon upon the addition of $Cu(AA)_2$ shows a trend similar to that in the addition of $Ni(AA)_2$ or $Co(AA)_2$.

The line broadening due to $Ni(AA)_2$, $Co(AA)_2$, and $Cu(AA)_2$ for each carbon resonance of pyridine arises in the same order as the magnitude of $\Delta\delta_M$, *i.e.*, $\Delta\nu_M(\beta) > \Delta\nu_M(\alpha) > \Delta\nu_M(\gamma)$. However, when $Cu(AA)_2$ was added, the line width of the β-carbon of pyridine was broadened to a large extent. It is known that $Cu(AA)_2$ takes a dimer structure in a pyridine solution; the non-linearity of $\Delta\delta_M$ *vs.* the concentration of $Cu(AA)_2$ and the particularly large line broadening of the β-carbon resonance line may be related to this fact.

Surprisingly, upon the addition of $Mn(AA)_2$ the carbon signals behave in a very different way, as is shown in Fig. 1(d); all the carbon signals move to a lower field, and the magnitudes of $\Delta\delta_M$ are ordered as: $|\Delta\delta_M(\alpha)| > |\Delta\delta_M(\beta)| > |\Delta\delta_M(\gamma)|$. The line broadening, $\Delta\nu_M$, due to $Mn(AA)_2$ occurs in the same way as the magnitude of $\Delta\delta_M$. This remarkable differences in the $\Delta\delta_M$ and $\Delta\nu_M$ may imply different mechanisms of the interactions between the metal and pyridine in the case of $Mn(AA)_2$.

To make clearer the pyridine–metal interaction mechanism, the T_{1M} values were measured; the results are shown in Table 1. The magnitude of $1/T_{1M}$ decreases in the order of the α, β, and γ-carbons of pyridine for all the $M(AA)_2$ systems, which suggests that $1/T_{1M}$ is mainly governed by the distance between the metal and each carbon of pyridine. Equation (2) shows that both the dipolar and scalar terms contribute to $1/T_{1M}$, but in this case the dipolar contribution is considered to be predominant, since this term is a function of $1/r^6$.

It is clear from Eq. (2) that, if $\omega_s\tau_e \gg 1$, the scalar term can be neglected. At the field of 15 MHz of the carbon resonance, the electron-spin resonance frequency, $\omega_s \approx 2.4\times10^{10}\ s^{-1}$,[16] and τ_s is known to be 3×10^{-9} and $4\sim7\times10^{-10}$ s for Mn^{2+} and Cu^{2+} respectively;[17] therefore, $\omega_s\tau_e \gg 1$ is valid for these two $M(AA)_2$ systems, and the scalar contribution to $1/T_{1M}$ can be neglected.

The τ_s of Co^{2+} is known to be rather short,[17] so that τ_e and τ_c are considered to be short also. The small values of $1/T_{1M}$ and $\Delta\nu_M$ upon the addition of $Co(AA)_2$ (see Table 1) may be due to the short correlation times. Here, the main mechanism for the spin-lattic relaxation is thought to be also a dipolar interaction.

For the system containing $Ni(AA)_2$, it is not obvious that the contribution of the scalar term to $1/T_{1M}$ of each carbon is negligible, although the $1/T_{1M}$ of the α-carbon is larger than that of the β-carbons. The ratio of the $1/T_{1M}$ of the α to the β-carbons in the $Ni(AA)_2$ system is a little smaller (1.2 : 1) than the other $M(AA)_2$ systems (about 3 : 1). However, the discussion of the $\Delta\delta_M$ values has indicated $|A_{\alpha\text{-carbon}}| < |A_{\beta\text{-carbon}}|$, and a remarkable line broadening is observed at the β-carbon resonance, but not at the α-carbon resonance. Therefore, as far as $1/T_{1M}(\alpha)$ is concerned, the contribution of the contact term may also be small and negligible in this system.

As has been discussed above, the values of the $1/T_{1M}$ of the α-carbons of pyridine containing these $M(AA)_2$ may be determined by the dipolar term. Actually assuming the distance between the metal and nitrogen atom of pyridine to be 3 Å, and using the observed values of $1/T_{1M}$ and Eq. (2), the τ_c values are calculated to be 4, 2.5, 0.76, and 0.23×10^{-11} s for the Cu-, Ni-, Mn-, and $Co(AA)_2$-pyridine complexes respectively. From these values, $\omega_s\tau_c \ll 1$ is shown to hold; therefore,

$$\frac{1}{T_{1M}} = \frac{Nn_h}{N_p} S(S+1)\frac{4}{5}\frac{g^2\beta^2\gamma_I^2}{r^6}\tau_c \qquad (5)$$

The stability constants of metal-pyridine systems have been obtained by various methods.[18] Although the stability constants for the $M(AA)_2$–pyridine systems in $CDCl_3$ solution are not known, the order of the stability of the complexes of $M(AA)_2$ may be estimated to be Cu>Ni>Mn>Co from similar systems. This order agrees with that of the $1/T_{1M}$ values of the α-carbons in Table 1, and at the same time with the τ_c value of each $M(AA)_2$–pyridine complex. Since the τ_c is a measure of the duration time for the dipolar coupling between the ligand and the paramagnetic metal, it is reasonable that the stability constants of the complexes are proportional to τ_c. Therefore, T_1 measurement is shown to give useful information about the stability constants of paramagnetic metal–ligand complexes.

Unlike the mechanism of the spin-lattice relaxation due to the paramagnetic metals, both the scalar and the dipolar relaxation mechanisms are effective in the spin-spin relaxation, as is shown in Eq. (3), even if the two assumptions $\omega_s\tau_c \ll 1$ and $\omega_s\tau_e \gg 1$ (in the case of Cu and Mn), or $\omega_s\tau_e \ll 1$ (in the case of Co), are used. From equation (4), $\Delta\nu_M$ may be used as a measure of $1/T_{2M}$. In the system containing $Cu(AA)_2$ and $Ni(AA)_2$, the values of $1/T_{2M}$ as well as $\Delta\delta_M$ of the β-carbons are the largest, indicating that the scalar coupling is one of the most important mechanisms of

the spin-spin relaxation. However, in the $Mn(AA)_2$–pyridine system, the $\Delta\nu_M$ values of the β-carbons are not the largest and takes place in the order of α, β, and γ-carbons, the same as the absolute magnitude of $\Delta\delta_M$. The different trends in both the $\Delta\delta_M$ and $\Delta\nu_M$ values of pyridine containing $Mn(AA)_2$ from the other $M(AA)_2$ suggest that the interaction between pyridine and $Mn(AA)_2$ seems to be quite different from the other metal systems.

Since pyridine is soluble in water, the ^{13}C spectra were observed for aqueous pyridine solutions containing the divalent metal ions. To D_2O solution of pyridine, Ni^{2+}, Co^{2+}, Cu^{2+}, or Mn^{2+} was added. The $\Delta\delta_M$ and $\Delta\nu_M$ due to these ions showed trends similar to those in the systems of pyridine–$CDCl_3$ solutions containing the corresponding $M(AA)_2$. In the D_2O system also, Mn^{2+} brings all the ^{13}C signals to a lower field, and the absolute magnitudes of $\Delta\delta_M$ are in the order of $|\Delta\delta_M(\alpha)| > |\Delta\delta_M(\beta)| > |\Delta\delta_M(\gamma)|$ and $\Delta\nu_M$ arises in the same way, *i.e.*, $|\Delta\nu_M(\alpha)| > |\Delta\nu_M(\beta)| > |\Delta\nu_M(\gamma)|$, while the paramagnetic effects due to the other ions are the largest in the β-carbon resonance line in both the induced shift and the line broadening.

Since the same trends are observed in $CDCl_3$ and the aqueous solutions containing Mn, the origin of the characteristic effects on the ^{13}C resonance due to Mn may come from the nature of the Mn–nitrogen bond. Thus, we extended our work to the systems of quinoline and isoquinoline interacting with $Mn(AA)_2$ in $CDCl_3$, in order to observe the paramagnetic effects on the ^{13}C resonance lines of nine carbons of these compounds.

The Interactions of Quinoline and Isoquinoline with Mn(AA)$_2$. When $Mn(AA)_2$ is added to quinoline or isoquinoline in $CDCl_3$ solutions, the $\Delta\delta_M$, $\Delta\nu_M$, and $1/T_{1M}$ of each carbon resonance increase linearly as the concentration of the metal increases, just as in the pyridine–$CDCl_3$ solution. Table 2 shows the effects of $Mn(AA)_2$ on the ^{13}C resonance parameters of pyridine, quinoline, and isoquinoline. These values were obtained from the slopes of the linear plots of the observed parameters *vs.* the concentration of $Mn(AA)_2$, and were calculated as the values relative to the corresponding parameters of a particular carbon of the γ-position to the nitrogen atom, *i.e.*, C-4 of pyridine and quinoline and C-10 of isoquinoline, which are set at unity. In the systems of quinoline and isoquinoline, the effect of $Mn(AA)_2$ on T_{1M} decreases in magnitude according to α, β, γ, $\cdots$ carbons, which is the same trend as that observed in the system of pyridine containing $Mn(AA)_2$ discussed above. All the $\Delta\delta_M$ values of quinoline and isoquinoline as well as those of pyridine due to $Mn(AA)_2$ shift to a lower field, and their magnitudes decrease in the order of the α, β, γ, $\cdots$ carbons. The $\Delta\nu_M$ value also shows the same trend, quite unlike the systems containing other $M(AA)_2$.

The facts described above suggest that the magnitudes of the paramagnetic effects on the ^{13}C resonance induced by $Mn(AA)_2$ mainly depend upon the distance between Mn and the carbon atoms. Equation (5) indicates that $1/T_{1M}$ is proportional to $1/r^6$; if the scalar interaction were neglected, $\Delta\delta_M$ and $1/T_{2M}$ would also become only a function of the geometric factor, as shown in Eqs. (1) and (3). Actually, the values of $1/T_{1M}$ and $\Delta\nu_M$ are plotted against $1/r^6$, together with the plot of $\Delta\delta_M$ against $(1-3\cos^2\theta)/r^3$, in Fig. 2. The molecular structures of quinoline and isoquinoline were assumed from those of pyridine and benzene. The metal–nitrogen distances in the crystal structures of the pyridine complexes have been reported to range from 2.0 to 2.3 Å,[19] but in solutions it is considered to become larger. Furthermore, the distance in a solution is assumed to be the averaged distance when the ligand molecule exchanges in the coordination sphere and in the bulk medium. The best fit of $1/T_{1M}$ as a function of $1/r^6$ was obtained for the metal–N distances at 3.3, 3.4, and 2.8 Å in pyridine, quinoline, and isoquinoline respectively. However, when the experimental errors are considered, it may be adequate to estimate 3 Å as

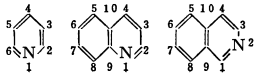
Table 2. The effects of $Mn(AA)_2$ on the ^{13}C spectra of pyridine, quinoline, and isoquinoline[a]

Pyridine	α(2,6)-positions	β(3,5)-positions	γ(4)-position
$1/T_{1M}$	10.0	2.3	1.0
$\Delta\delta_M$[b]	3.7	3.7	1.0
$\Delta\nu_M$	7.9	5.9	1.0

Quinoline	α-positions		β-positions			γ-positions			δ-position
	2	9	8	3	10	4	5	7	6
$1/T_{1M}$	9.4	7.7	5.5	2.0	1.9	1.0	0.9	1.2	1.2
$\Delta\delta_M$[b]	1.9	1.8	1.4	1.3	1.1	1.0	1.1	0.6	0.0
$\Delta\nu_M$	11.3	12.7	6.7	3.3	2.7	1.0	0.0	0.6	0.0

Isoquinoline	α-positions		β-positions		γ-positions		δ-positions		ε-position
	1	3	4	9	10	8	7	5	6
$1/T_{1M}$	11.8	13.1	2.0	2.4	1.0	0.5	0.5	0.4	0.4
$\Delta\delta_M$[b]	2.9	2.2	2.0	2.0	1.0	1.0	0.5	0.0	0.8
$\Delta\nu_M$	18.1	11.9	6.4	5.9	1.0	0.9	0.0	0.0	0.0

a) These values are obtained from the slopes of the linear plots of the parameters *vs.* $Mn(AA)_2$ concentration and normalized to those of C_4-carbon of pyridine and quinoline, and C_{10}-carbon of isoquinoline, which are set to unity. b) All the induced ^{13}C chemical shifts move to the lower field.



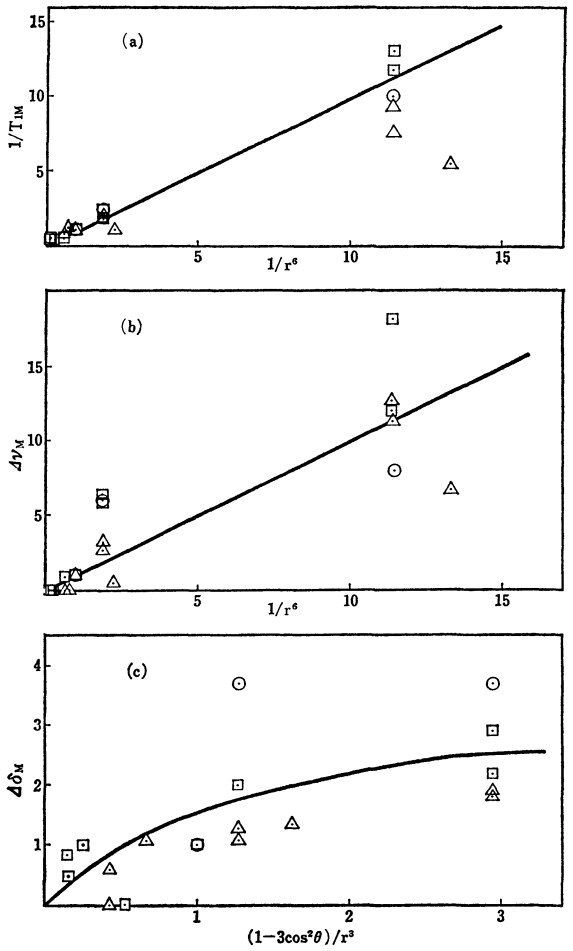


Fig. 2. The plots of (a) $1/T_{1M}$ and (b) $\Delta\nu_M$ against $1/r^6$, and (c) $\Delta\delta_M$ against $(1-3\cos^2\theta)/r^3$, where r is the distance between Mn and each carbon of pyridine (⊙), quinoline (△), and isoquinoline (⊡). All the values including the geometric factors are referred to C_4 of pyridine and quinoline, and C_{10} of isoquinoline.

the approximate averaged metal–N distance for these compounds; this value is used in Fig. 2. Since the parameter values relative to a particular γ-carbon resonance are used, the geometric parameters are also normalized to the same carbon. In other words, both the ^{13}C resonance parameters and the geometric values of the γ-carbon are set at unity.

As is shown in Fig. 2, although the linearity is not very good, there are apparent correlations between $1/T_{1M}$ and $1/T_{2M}$ and $1/r^6$, and between $\Delta\delta_M$ and $(1-3\cos^2\theta)/r^3$. This indicates that the ^{13}C resonance parameters induced by $Mn(AA)_2$ are mainly governed by the geometric factors. The scalar interaction is very small, and its extent may be the order of the deviation from the observed correlation between the induced parameters and the geometric factors. This conclusion seems a little surprising when we consider the results of the many studies of the interactions between $Ni(AA)_2$ and various *N*-heterocyclic compounds,[1-4] which clearly show that the induced ^{13}C shift can be interpreted in terms of the scalar interaction, with the complete neglect of the dipolar term.

The lanthanide shift reagents are also paramagnetic and induce large pseudocontact shifts without any significant line broadening in most cases. The unpaired electrons of the lanthanide metals, which induce the paramagnetic shift, occupy the inner shell. This may be one of the most important reasons why the contact term is negligible.[5]

On the other hand, Mn is a d-transition metal such as Cu, Co, and Ni; therefore we can expect that the paramagnetic effects on the NMR parameters would be induced in a similar way by these metals. However, the present study indicates that the contact interaction is very small in the manganese complexes in the ^{13}C resonance, quite unlike the cases of Cu, Co, and Ni complexes, where the contact interaction is predominant. The negligible contact interaction in the ^{13}C resonance of Mn complexes implies that the unpaired electron spin density does not exist on the carbon atoms of the ligand molecules. From the discussion of $1/T_{1M}$ and $1/T_{2M}$, the Mn metal approaches the nitrogen atom of the ligand molecule and forms the Mn–N bond, which persists for the duration of the dipolar correlation time. In that period the unpaired electron from Mn does not transfer into the ligand molecule through the Mn–N bond. It is not certain why the Mn-complexes are different from other paramagnetic metal complexes, but the difference is evident in the ^{13}C NMR spectra shown in the present study.

This fact is very valuable for the studies of metal binding in biological systems. When a manganous ion is added to an aqueous solution in biological systems, the effects of the paramagnetism on the ^{13}C NMR will appear in the chemical shift, the line width as well as the spin-lattice relaxation time, and their magnitudes will depend upon the distance between the carbon atom and the Mn metal. In other words, Mn is a very useful paramagnetic metal for studying the binding site, and in a favorable case, the averaged distance between the metal and the molecule under study may be estimated.

Thermal Bleaching of the Colored Form in the Photochromism of 2-Hydroxy-2′,4,4′-trimethoxytriphenylmethanol in Acetonitrile

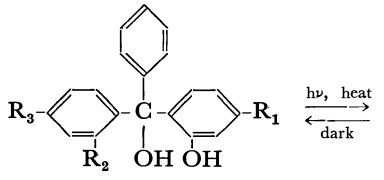
Sanyo HAMAI and Hiroshi KOKUBUN

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

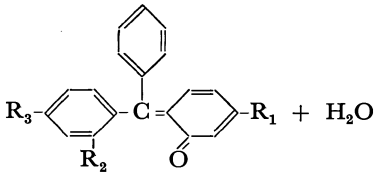
(Received November 1, 1974)

The photochromism of 2-hydroxy-2′,4,4′-trimethoxytriphenylmethanol (HTMM) in acetonitrile differs from that of other 2-hydroxytriphenylmethanol derivatives in some aspects. The colored form, 2′,4,4′-trimethoxy-*o*-fuchsone (TMF), of HTMM partly converts to 2-hydroxy-2′,4,4′-trimethoxytriphenylmethyl cation (Cat) at an early stage of the bleaching reaction. At a later stage a slow bleaching of TMF to HTMM becomes the main decay process. Bleaching of the produced Cat is so slow that Cat remains even after complete disappearance of TMF. The formation of Cat was concluded to be a reaction between adsorbed TMF and water on the cell surface. The rate determining step is not a diffusion process since the activation energy found is much larger than that of viscosity. Cat decays by the reaction with water, not with hydroxide ion.

2-Hydroxytriphenylmethanol derivatives show photochromism[1] as well as thermochromism.[2] The reaction scheme is as follows:



I



II

Ia $R_1=R_2=R_3=H$, 2-hydroxytriphenylmethanol (HM)
Ib $R_1=OCH_3$, $R_2=R_3=H$, 2-hydroxy-4-methoxytriphenylmethanol (HMM)
Ic $R_1=R_2=R_3=OCH_3$, 2-hydroxy-2′,4,4′-trimethoxytriphenylmethanol (HTMM)
IIa $R_1=R_2=R_3=H$, *o*-fuchson (F)
IIb $R_1=OCH_3$, $R_2=R_3=H$, 4-methoxy-*o*-fuchson (MF)
IIc $R_1=R_2=R_3=OCH_3$, 2′,4,4′-trimethoxyfuchson (TMF)

The colored form of HM, F, decays according to pseudo-first order kinetics.[1] However, MF, the colored form of HMM, shows an unusual bleaching pattern in saturated hydrocarbons such as *n*-hexane, but in polar solvents the bleaching reaction becomes the pseudo-first order.[3] Both substituents and solvent polarity have a critical effect on the bleaching mechanism. TMF which has three electron donating methoxy groups shows no unusual bleaching pattern in *n*-hexane as in the case of MF. However, in acetonitrile it was found to decay in a different pattern. We have investigated the thermal bleaching of TMF in acetonitrile in detail, the reuslts being given in the following.

Experimental

HTMM was synthesized from 2-hydroxy-2′,4,4′-trimethoxybenzophenone by the Grignard reaction with phenylmagnesium bromide and recrystallized several times from ether-*n*-hexane and ethanol-water mixtures. 2-Hydroxy-2′,4,4′-trimethoxybenzophenone was synthesized from 3-methoxyphenol and 2,4-dimethoxybenzoic acid in the presence of boron trifuoride-ethyl ether complex.[4] HTMM; mp 129—131 °C. Found: C, 72.34; H, 6.29%. Calcd for $C_{22}H_{22}O_5$: C, 72.10; H, 6.06%.

Acetonitrile was distilled over phosphorous pentoxide. A 6 W germicidal mercury lamp was used as a light source for 253.7 nm illumination. Absorption spectra were measured with a Hitachi EPS-3T spectrophotometer. A Haake FJ regulater was employed for temperature control.

The initial concentrations of HTMM were chosen to be *ca.* 2×10^{-4} M in all the experiments. The illuminated sample solutions were shaken before the measurements in order to make the concentration of TMF in the cell uniform.

Results and Discussion

The absorption spectral change with time for the solution of HTMM in acetonitrile after illumination for 20 s is shown in Fig. 1. Beside the absorption of TMF there is an absorption band due to other species at 438 nm. This band increases rapidly at the expense of the TMF band with isosbestic points at 420 and 456 nm at an early stage of bleaching. After the absorbance at 438 nm attains maximum, the absorption band due to TMF decreases slowly. The 438 nm band reamins even after TMF has disappeared completely. This absorption spectrum is iden-

tical with that of 2-hydroxy-2′,4,4′-trimethoxytriphenylmethyl cation (Cat) prepared by adding sulfuric acid or an oxidizing agent to the HTMM acetonitrile solution. Only TMF is produced photochemically, since the absorption band of Cat does not appear by illumination of HTMM at 77 K.

Since the absorption spectra of TMF and Cat are superposed immediately after illumination, we should know the shapes of individual absorption spectra in order to analyze the growth and the decay of individual species. The absorption spectrum of Cat is known. The absorption spectrum of TMF was obtained by addition of triethylamine to the illuminated solution. Triethylamine forms a colorless complex with Cat selectively. Similar complexing phenomena are reported between crystal violet and primary amines and other triphenylmethyl cation derivatives and amines.[5] The resulting absorption spectrum of THF is given in Fig. 2.

Simultaneous measurement of absorbances at two different wavelengths discriminates the contribution of individual species to the measured absorbances. The wavelengths at 350 nm and 438 nm were chosen which correspond respectively to the absorption maxima of TMF and Cat. The absorbances of TMF and

●: TMF, ○: Cat.

Cat as functions of time are plotted in the logarithmic scale in Fig. 3. The rapid growth of Cat corresponds to the initial decrease of TMF. Mechanical shaking of a sample cell at the stage where Cat is growing causes an increase in the absorbance of Cat and a slight decrease in the absorbance of TMF (Fig. 4). A similar phenomenon was also observed at 35 °C.

In the later stage both TMF and Cat show the first order decay (Fig. 3). In acetonitrile containing water less than 0.3 M, the type of concentration change of TMF and Cat is similar to that in neat acetonitrile. The first order decay rate constants for TMF and Cat at the later stage are proportional to the concentration of water added (Fig. 5).

With increasing water concentration, the concentration of Cat immediately after illumination becomes so high that the growth of Cat can not be followed. Moreover, the concentrations of TMF and Cat change in a complicated way.

In the solution containing a small amount of water, Cat seems to react with water yielding a starting material HTMM. This differs from other triphenylmethane cation dyes which react with anion to give their leuco forms.[6,7] The formation of Cat occurs only in the initial stage of the TMF decay. This suggests that the reaction is a kind of an inhibited reaction.

The molar absorption coefficient of TMF is not known. It seems to be of the order of 10000 at 350 nm, since that of an analogous compound F is 7830 at the absorption maximum at 77 K in methanol–ethanol (1 : 1). The molar absorption coefficient of Cat was found from the chemically prepared Cat solution to be 62200, being more than six times larger than that of TMF. Since the amounts of the decrease and increase in the absorbances, respectively, of TMF and Cat do not differ significantly from each other at the initial stage, it is probable that a part of TMF converts to Cat and another portion to HTMM.

An effect of mechanical stirring indicates that TMF reacts with water on a cell surface to give Cat. When TMF and Cat occupy the same adsorption sites, the adsorbed amount are given by $[\mathrm{Cat}]_{ads}=\alpha_1[\mathrm{Cat}]/(1+\beta_1[\mathrm{Cat}]+\beta_2[\mathrm{TMF}])$ for Cat and $[\mathrm{TMF}]_{ads}=\alpha_2[\mathrm{TMF}]/(1+\beta_1[\mathrm{Cat}]+\beta_2[\mathrm{TMF}])$ for TMF, respectively, where α's and β's are constants. If Cat is adsorbed much more strongly than TMF, the adsorbed amount of TMF can be given by $[\mathrm{TMF}]_{ads}=C[\mathrm{TMF}]/[\mathrm{Cat}]$, where C is a constant. Hence, the reaction rate is given for TMF by Eq. 1 and for Cat by Eq. 2.

$$-\frac{\mathrm{d[TMF]}}{\mathrm{d}t}=k_1\frac{[\mathrm{TMF}][\mathrm{H_2O}]}{\mathrm{Cat}}+k_1'[\mathrm{TMF}][\mathrm{H_2O}] \quad (1)$$

$$\frac{\mathrm{d[Cat]}}{\mathrm{d}t}=k_2\frac{[\mathrm{TMF}][\mathrm{H_2O}]}{[\mathrm{Cat}]}-k_2'[\mathrm{Cat}][\mathrm{H_2O}] \quad (2)$$

At the initial stage of reaction, the second terms of the right hand of Eqs. 1 and 2 can be neglected as compared with the first terms. The concentration of water is expected to be practically unchanged. Thus we obtain

$$\ln([\mathrm{TMF}]/[\mathrm{TMF}]_0)=-k_{\mathrm{TMF}}\int \mathrm{d}t/[\mathrm{Cat}] \quad (3)$$

$$[\mathrm{Cat}]^2-[\mathrm{Cat}]_0^2=k_{\mathrm{Cat}}\int[\mathrm{TMF}]\mathrm{d}t \quad (4)$$

Plots according to Eqs. 3 and 4 are linear (Figs. 6 and 7, respectively), indicating that the proposed mechanism is highly probable. The activation energies for k_{TMF} and k_{Cat} were found to be 17.8 and 25.6 kcal/mol, respectively, considerably larger than that of viscosity for acetonitrile, 0.8 kcal/mol. The rate determining step is, therefore, not diffusion process unlike the bleaching reaction of MF in *n*-hexane. A mechanical stirring may cause a forced convection which accelerates the reaction between TMF and water on a cell surface. Thus, the absorbance of TMF decreases in smaller amount than the corresponding increase in the absorbance of Cat, being consistent with the larger molar absorption coefficient of Cat.

Equations similar in form to Eqs. 3 and 4 can be derived from another mechanism in which dissociated proton from water reacts with TMF to give Cat in acetonitrile instead of on the cell surface. However, this is not the case, since the presence of sulfuric acid affects neither the growth rate now the initial yield of Cat when the acid concentration is lower than 2×10^{-5} M. A feature differing from the neat acetonitrile solution is that the growth of Cat is not monotonic but stepwise. The reason for the stepwise growth is not clear at all. In the solution containing acid

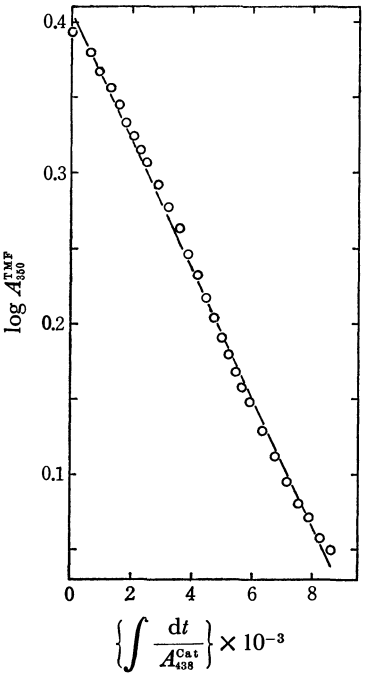

Fig. 6. Reaction analysis of TMF at the initial period at 23 °C.

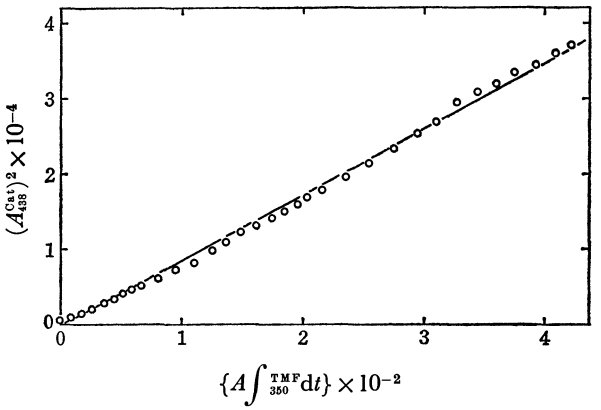

Fig. 7. Reaction analysis of Cat at the formation period at 23 °C.

of higher concentration, a considerable amount of Cat is produced immediately by the addition of acid.

The decay rate of TMF at the later stage is faster in solutions containing aqueous sulfuric acid as compared with solutions containing the same amount of water. The effect of added acid is not the simple protonation of TMF to give Cat, since Cat also decays. The following may be a possible reaction:

$$\mathrm{TMF}+(\mathrm{H_3O^+})_{solv}\rightarrow \mathrm{HTMM}+(\mathrm{H^+})_{solv}.$$

The decay rate of Cat, however, is slower in acidic solutions. The slower decay of Cat may be due to the slow production of Cat from the reaction between acid and HTMM. An enhanced stability of Cat in acidic solution may also be responsible.

In solutions containing triethylamine, the absorption due to Cat does not appear, although the bleaching pattern of TMF is the same as in neat acetonitrile. Cat once produced, therefore, is complexed with

triethylamine quickly. The resulting complex cation would be adsorbed on the cell surface as in the case of Cat. Consequently, the bleaching pattern of TMF is the same as in solution without triethylamine. The decay rate of TMF at the later stage is proportional to the triethylamine concentration. The reaction $TMF+(Et)_3N\cdot H_2O \rightarrow HTMM+(Et)_3N$ is plausible.

Photoelectron Spectra of Substituted Naphthalenes

Chikatoshi UTSUNOMIYA, Tsunetoshi KOBAYASHI, and Saburo NAGAKURA
The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106
(Received December 27, 1974)

The photoelectron spectra (PES) of 1- and 2-substituted naphthalenes (naphthols, aminonaphthalenes, *N,N*-dimethylaminonaphthalenes, acetylnaphthalenes, and cyanonaphthalenes) were measured in the region from 6 to 20 eV. The observed PES were assigned with the aid of the CNDO/2 calculations and the substituent effect. The lower energy bands of the compounds with the electron-donating group were found to be due to the ionization from the orbitals caused by the interaction of the highest three occupied π orbitals of the naphthalene ring with the nonbonding orbital of the substituent group. The second bands of the 1-substituted naphthalenes are commonly assigned to π orbitals almost completely localized on the naphthalene ring. The dimethylamino group of 1-dimethylaminonaphthalene was found to be twisted to a great extent from the ring plane.

Photoelectron spectroscopy is effective in getting information concerning electronic structures, especially concerning occupied orbitals, of molecules. In the preceding papers,[1-4] we have studied the PES of substituted benzenes. In this paper we extend the study to substituted naphthalenes. The PES of substituted naphthalenes have scarcely been studied and a few papers have hitherto been published. For example, Bock and his co-workers[5] studied the PES of 1- and 2-methoxy- and 1- and 2-methylthionaphthalenes. Maier[6] reported quite recently on the PES of aminonaphthalenes.

Experimental and Calculations

Naphthols, aminonaphthalenes, dimethylaminonaphthalenes, acetylnaphthalenes, and cyanonaphthalenes used in the present study were purified in usual ways and their purities were checked with the aid of NMR spectra. The PES of these compounds were measured as described previously,[3] the He I 584 Å resonance line being used as the excitation source and Xe gas as the internal standard for the energy-scale calibration. The CNDO/2[7] calculations of these compounds were carried out by a FACOM 230-60 computer at the Institute of Physical and Chemical Research. The geometrical structures of these compounds were assumed on the basis of the data for naphthalene and the corresponding benzene derivatives given in Refs. 8 and 9.

Results and Discussion

Naphthols. The PES of 1-naphthol and 2-naphthol are shown in Fig. 1. The vertical ionization potentials, I_v, of these compounds derived from the observed PES are summarized in Table 1.

As is seen in Fig. 1, naphthols show three lower-energy bands in the region from 7 eV to 10.1 eV. This is the region for the highest three occupied π orbital I_v's of naphthalene.[10] Therefore, these bands are reasonably due to the naphthalene π orbitals mixed with the hydroxyl n orbital, the energy of which is -10.96 eV for methanol.[11]

As is seen in Fig. 1 and Table 1, the I_v's of the first and third bands of 1-naphthol are smaller than the corresponding ones of naphthalene, but the second band I_v's agree with each other for both compounds. This fact demonstrates that the highest occupied π orbital of naphthalene (a_u) and the third one (b_{3g}) interact with the n orbital of the hydroxyl group, while

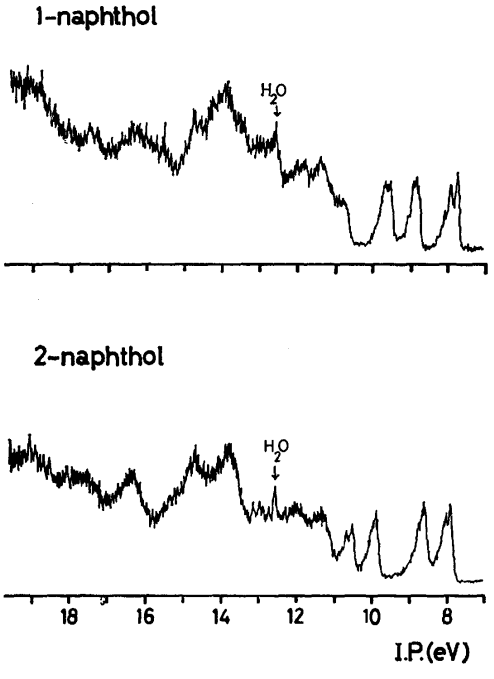

Fig. 1. Photoelectron spectra of naphthols.

the second one does not because the b_{1g} π orbital of naphthalene has nodes at the α-positions. On the other hand, the first three highest occupied orbital I_v's of 2-naphthol are smaller than the corresponding ones of naphthalene. This is because all the highest three occupied π orbitals of naphthalene have no node at the β-positions and can interact with the n orbital of the hydroxyl group. The CNDO/2 calculations (Fig. 2(b)) also support this conclusion. The orbital energy diagram given by the CNDO/2 method (Fig. 2(b)) qualitatively agrees with the observed one obtained on the assumption of Koopmans' theorem,[12] $\varepsilon = -I_v$, (Fig. 2(a)).

Aminonaphthalenes and Dimethylaminonaphthalenes. The PES of 1-aminonaphthalene, 2-aminonaphthalene, 1-dimethylaminonaphthalene, and 2-dimethylaminonaphthalene are shown in Figs. 3 and 4, the I_v's of these compounds being summarized in Table 1. These compounds show four lower-energy bands in the region from 7 eV to 10.5 eV except for 1-dimethylaminonaphthalene; the latter apparently shows only three bands in this region, but the second band consists

of two overlapping bands, judging from its integrated intensity. After all, all of these compounds show four bands in this region. This region includes the first three π bands of naphthalene, the methylamine n band,[13] and the trimethylamine n band.[13] Therefore, these bands are regarded as due to the four π orbitals constructed by the interaction between the highest three occupied π orbitals of naphthalene and the n orbital of the amino or dimethylamino group.

The observed orbital energy diagram estimated according to Koopmans' theorem and the calculated

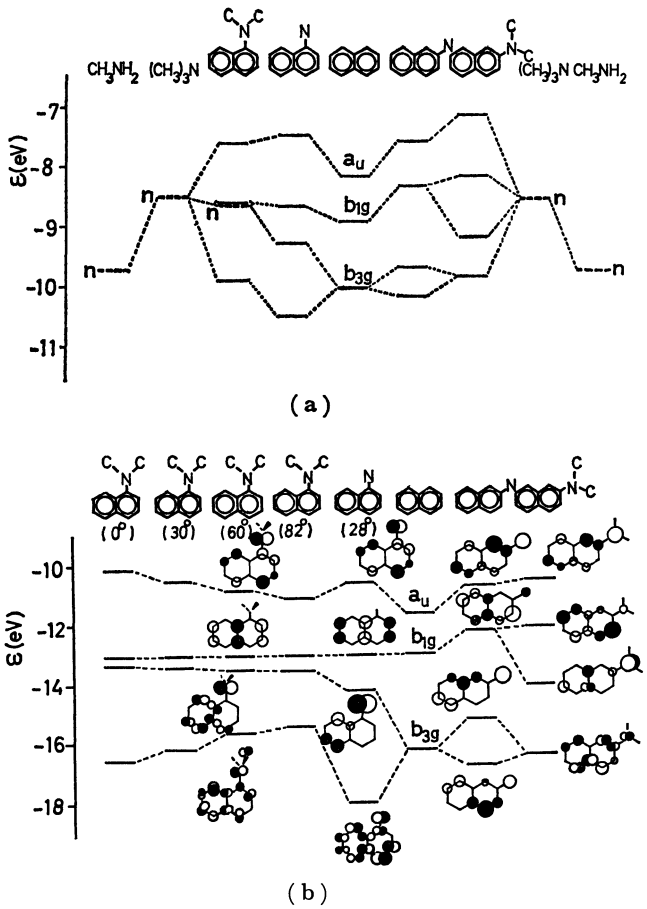

Fig. 5. Orbital energy diagrams for the higher occupied orbitals of aminonaphthalenes and dimethylaminonaphthalenes; (a) experimental, (b) calculated.

orbital energy diagram are shown in Figs. 5(a) and 5(b), respectively. In the calculations, the twist angle of the amino group from the naphthalene ring plane was assumed to be 28° for 1-aminonaphthalene on the basis of the molecular polarizability data.[14] The angle was assumed to be 0° for 2-aminonaphthalene and 2-dimethylaminonaphthalene. As for 1-dimethylaminonaphthalene, the calculations were carried out for the following twist angles of the dimethylamino group: 0°, 30°, 60°, and 82°. The last value, 82°, was estimated from van der Waals' radii.

As is seen in Fig. 5(a), the highest and second highest occupied orbitals of 1-aminonaphthalene and 2-aminonaphthalene are higher in energy than the corresponding first and second ones of naphthalene, respectively, but their fourth orbitals are lower in energy than the third highest π orbital of naphthalene. This indicates that the n orbital of the amino group is located between the second and third highest occupied π orbitals of the naphthalene ring. This is supported by the fact that the methylamine n I_v is 9.7 eV.[13] From the location of the methylamine n orbital, the third bands of 1-aminonaphthalene and 2-aminonaphthalene are due to the ionization from the orbitals which mainly consist of the nitrogen n orbital. This is supported by the fact that the band of 2-aminonaphthalene is more sensitive to *N,N*-dimethylation than the other lower-energy bands and also by the CNDO/2 calculations.

Judging from the fact that the energy of the second highest occupied orbital of 1-aminonaphthalene is scarcely changed by *N,N*-dimethylation, it is concluded that the second highest occupied π orbitals of 1-aminonaphthalene and 1-dimethylaminonaphthalene are almost completely localized on the naphthalene ring. This is supported by the sharpness of these bands and by the CNDO/2 calculations.

The first I_v of 1-aminonaphthalene can be expected to be reduced by *N,N*-dimethylation because of the electronic effect of methyl groups so long as the twist angle of the amino group from the naphthalene plane is not changed by *N,N*-dimethylation. In reality, however, the first I_v of 1-aminonaphthalene is increased by *N,N*-dimethylation. This indicates that the amino group of 1-aminonaphthalene is twisted further by the *N,N*-dimethylation because of the increment in steric hindrance. As is seen in Figs. 5(a) and 5(b), the overall pattern of the observed orbital energy diagram for the higher occupied orbitals of 1-aminonaphthalene, 1-dimethylaminonaphthalene, and naphthalene is qualitatively well reproduced by the result calculated for the 1-dimethylaminonaphthalene model with a twist angle at least of 60°. The total energy calculated by the CNDO/2 method also indicates that the 60° model is more stable than the others. These results suggest that the dimethylamino group of 1-dimethylaminonaphthalene is twisted by about 60°. This is consistent with Maier's result obtained with HMO level model calculations.[6]

According to the CNDO/2 calculations, the third highest occupied orbital of 1-dimethylaminonaphthalene consists mainly of the n orbital of the dimethylamino group. The band due to the ionization from this orbital is expected to appear around 8.5 eV, in view of the fact that the n orbital energy of trimethylamine is 8.5 eV.[13] Therefore, the band corresponds to one of the overlapping bands around 8.59 eV of 1-dimethylaminonaphthalene.

The observed I_v's of 2-aminonaphthalene and 1-dimethylaminonaphthalene agree with those reported by Maier.[6] As for 1-aminonaphthalene, however, our results are rather different from the values reported by him. We repeated the measurements carefully and confirmed our results.

Cyanonaphthalenes. The PES of 1-cyanonaphthalene and 2-cyanonaphthalene are shown in Fig. 6, the I_v's of these compounds being summarized in Table 1. We can see that cyanonaphthalenes show three lower-energy bands in the region from 8 eV to 10.6 eV. The highest three occupied π orbital bands of naphthalene fall in this region, and the first band of acetonitrile appears at 12.21 eV.[15] Therefore, the three lower-energy bands may be ascribed to the highest three occupied π orbitals of naphthalene mixed with the cyano group π orbital. According to Koopmans' theorem, the correlation diagram for these orbitals may be drawn as is shown in Fig. 7(a).

As is seen in Fig. 7(a), the third highest occupied orbital of 2-cyanonaphthalene is lower in energy than the corresponding one of 1-cyanonaphthalene. Since the third highest occupied π orbital of naphthalene has

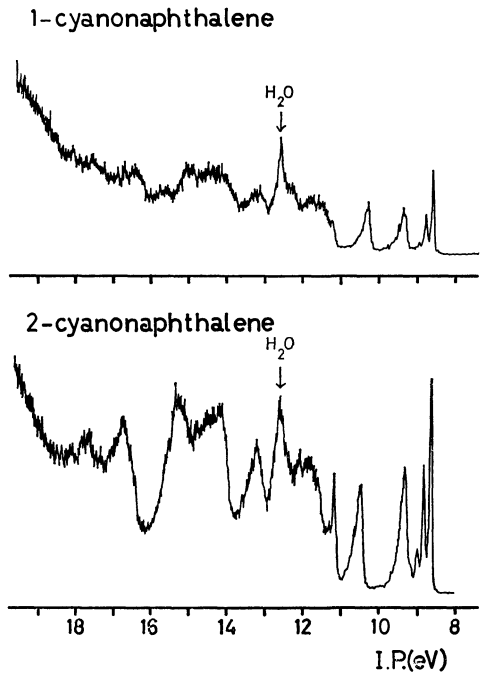

Fig. 6. Photoelectron spectra of cyanonaphthalenes.

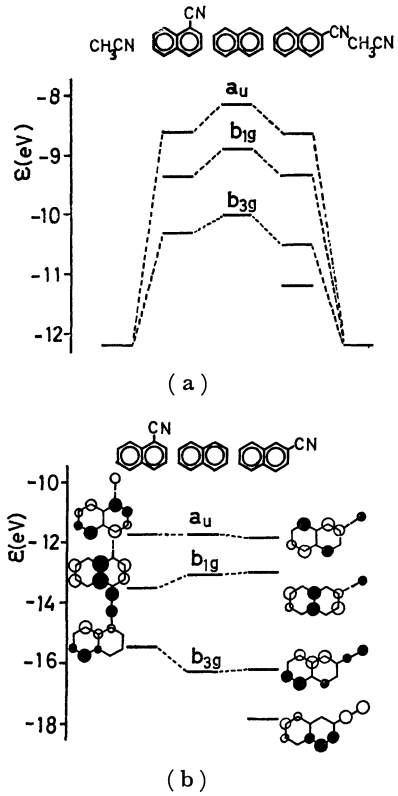

Fig. 7. Orbital energy diagrams for the higher occupied orbitals of cyanonaphthalenes; (a) experimental, (b) calculated.

a larger AO coefficient on carbon atom 1 than on carbon atom 2, this finding can be explained by considering the interaction of the orbital with the occupied π orbital of the cyano group located below. The same tendency was observed for the highest occupied π orbitals of these cyanonaphthalenes. However, the difference between the first I_v's of these compounds is considerably smaller than that between their third I_v's. This may be explained by considering the following two factors. 1) The third highest occupied π orbital of the naphthalene ring interacts more strongly with the occupied π orbital of the cyano group than the highest occupied one does. 2) The energy lowering due to the interaction with the vacant π orbital of the cyano group is more effective in the highest occupied π orbitals of the cyanonaphthalenes than in the third highest occupied ones.

In contrast with the first and third bands, the second band I_v of 2-cyanonaphthalene is smaller, though only slightly, than that of 1-cyanonaphthalene. This is because the second highest occupied π orbital of 1-cyanonaphthalene is almost completely localized on the naphthalene ring, while that of 2-cyanonaphthalene is composed of the naphthalene second highest occupied π orbital mixed with the occupied π orbital of the cyano group, as suggested by the CNDO/2 calculations (Fig. 7(b)).

As is seen in Fig. 7(a), the highest three occupied orbitals of these cyanonaphthalenes are much lower in energy than the corresponding ones of naphthalene. This indicates that the electron-withdrawing effect of the cyano group is very effective.

The fourth sharp band of 2-cyanonaphthalene at 11.18 eV may be ascribed to the fourth highest occupied π orbital constructed by the interaction of the naphthalene ring fourth highest occupied π orbital with the cyano group π orbital.

Acetylnaphthalenes. The PES of 1-acetylnaphthalene and 2-acetylnaphthalene are shown in Fig. 8, and the I_v's of these compounds are summarized in Table 1. Both compounds show three lower-energy bands in the region from 8 eV to 10.2 eV. Their

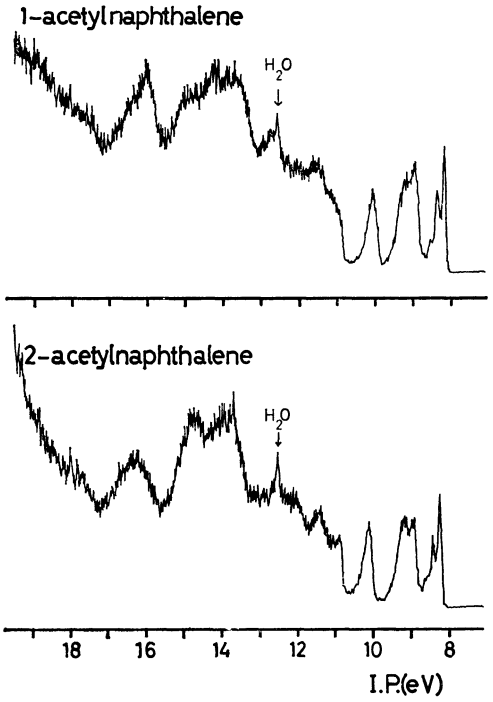

Fig. 8. Photoelectron spectra of acetylnaphthalenes.

second bands seem to consist of two overlapping bands, judging from the integrated intensities. Thus, there are four bands in the region from 8 eV to 10.2 eV for the acetylnaphthalenes. This region is for the first three π bands of naphthalene and the acetyl n orbital band (for example, acetophenone: 9.37 eV[4]). Therefore, the four observed bands may be ascribed to three orbitals caused by the interaction of the highest three occupied π orbitals of the naphthalene ring with the occupied π orbital of the acetyl group and to the acetyl n orbital.

According to the CNDO/2 calculations (Fig. 9(b)), in which the twist angle of the acetyl group was estimated to be 42° for 1-acetylnaphthalene from the polarizability data[16] and was assumed to be 0° for 2-acetylnaphthalene, the occupied orbitals of these compounds are located in the following order, from the top: π, n, π, π, $\cdots$.

First, let us consider the overlapping bands around 9.2 eV of each compound. One of them is assigned to the ionization from the n orbital of the acetyl group in view of the fact that the n orbital I_v of acetophenone is 9.37 eV.[4] According to the CNDO/2 calculations, the second highest occupied π orbital of 1-acetylnaphthalene is the orbital localized mainly on the naphthalene ring; its energy scarcely changes compared with that of naphthalene (−13.04 eV for naphthalene; −13.17 eV for 1-acetylnaphthalene). Therefore, the lower-energy band of the overlapping bands of 1-acetylnaphthalene is assigned to the ionization from this orbital. The second band at 9.00 eV of 2-acetylnaphthalene may also safely be assigned to the second highest occupied π orbital.

The remaining first and fourth bands of acetylnaphthalenes are assigned to the ionization from the orbitals constructed by the interaction mainly between the first and third highest occupied π orbitals of naphthalene and the π orbital of the acetyl group, respectively.

The observed correlation diagram for the orbital energies obtained on the assumption of Koopmans' theorem is shown in Fig. 9(a). The calculated relative ordering of the n and π orbitals of acetylnaphthalenes (Fig. 9(b)) is different from the experimental one (Fig. 9(a)). This discrepancy is often found in the CNDO/2 calculation of closely located n and π orbitals.

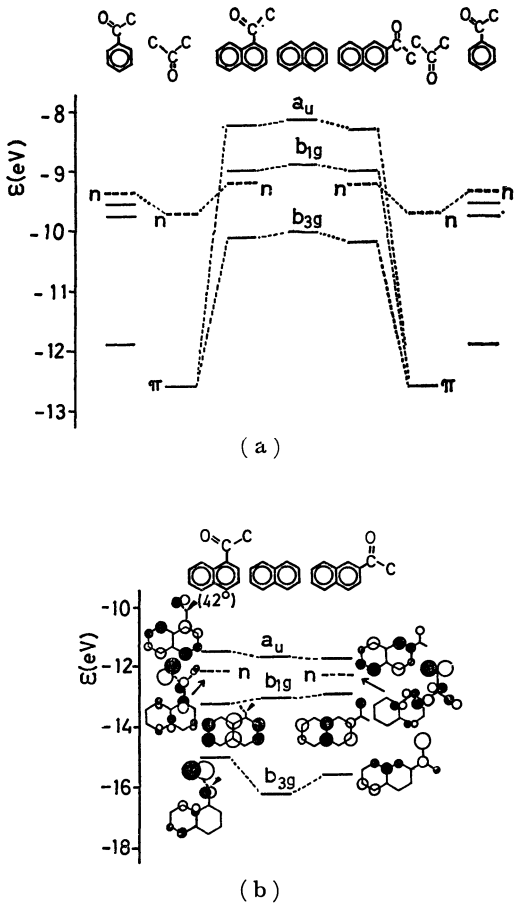

Fig. 9. Orbital energy diagrams for the higher occupied orbitals of acetylnaphthalenes; (a) experimental, (b) calculated.

Dry Grinding on a Pigment Mixture. I. The Effect of α-Copper Phthalocyanine as a Lubricant on the Mechanochemical Transformation of Calcium Carbonate

Norimichi KAWASHIMA and Kenjiro MEGURO

Department of Chemistry, Faculty of Science, Science University of Tokyo, 1-3 Kagurazaka, Shinjuku-ku, Tokyo 162

(Received January 24, 1975)

α-Copper phthalocyanine and calcium carbonate were mixed and ground with a grinder, and then the surface properties of the mixtures were investigated in comparison with the grinding time by means of X-ray diffraction analysis, electron-micrograph observation, and the specific surface area as obtained by the B.E.T. method. In the grinding process, the crystal decays of both α-copper phthalocyanine and calcium carbonate were observed. Particularly, the calcite-aragonite transformation occurred in the case of calcium carbonate. However, the addition of some α-copper phthalocyanine to calcium carbonate interfered with the transformation of calcium carbonate. As a conclusion, it was evident that the surface of calcium carbonate was covered with α-copper phthalocyanine and that the grinding of calcium carbonate was interfered with by the lubricating action of α-copper phthalocyanine.

In some cases, not only are changes in the particle shape and size found in mechanical treatments such as crushing, grinding, and rolling, but also the physical and chemical properties of the particles become different from the original intrinsic properties.[1-5]

Many reports have been published on the mechanochemical changes in inorganic single material[6-8] and in inorganic–inorganic material mixed systems.[9-11] In the field of the paint industry, mixed-type pigments are used to obtain various color pigments. However, few studies have dealt with the grinding of mixtures of an organic pigment and an inorganic one.

In a previous work, we ourselves examined the mechanochemical change in the surface properties of α-copper phthalocyanine–titania, γ-quinacridone–titania mixed systems[12] and α-copper phthalocyanine–alumina mixed systems.[13] In this paper, the grinding process of a mixture of an organic pigment and an inorganic one was investigated by means of X-ray diffraction analysis, the observation of electron micrographs, and also surface-area measurements.

Experimental

The α-copper phthalocyanine (abbrev. α-CuPc) used here was supplied by Dainippon Ink Chemical, Ltd. The calcium carbonate was supplied by the Kokusan Kagaku Co., Ltd. The specific surface areas of α-CuPc and calcium carbonate, as measured by the B.E.T. method, were about 50 m^2/g and 2 m^2/g respectively. These pigments were ground with an Ishikawa-type grinder in a closed chamber at room temperature at the following mixed ratios of weight: α-CuPc *vs.* $CaCO_3$: (1 : 1), (1 : 9) and (1 : 19); these mixtures were abbreviated as follows;

Sample A: a (1 : 1) mixture of α-CuPc and $CaCO_3$
Sample B: a (1 : 9) mixture of α-Cupc and $CaCO_3$
Sample C: a (1 : 19) mixture of α-CuPc and $CaCO_3$

The grinding was done after; 2, 4, 6, 8, and 10 hr.

The X-ray diffractions were measured by using a nickel-filtered copper radiation at 35 kV and 10 mA as the X-ray diffraction source, with a scanning speed of 1/2° per min., a time constant of 2 s, a divergence slit of 1°, and a receiving slit of 0.2 mm. The X-ray diffraction diagrams were recorded by means of an X-ray diffractometer (Geigerflex).

The electron micrographs were taken by means of a Hitachi HU-200-type electron microscope.

The specific surface areas were measured by the B.E.T. method from the nitrogen-gas adsorption at the temperature of liquid nitrogen. The specimens were pretreated under a pressure of 10^{-5} Torr at room temperature for about one hour.

Results and Discussion

The Results for Calcium Carbonate and α-CuPc Alone. Calcium carbonate is well known to have two crystal forms, such as a stable type (calcite) and a metastable type (aragonite) as morphisms at an ordinary temperature and pressure.[14] The X-ray diffraction traces in the grinding process of calcium carbonate are given in Fig. 1. The intensities of all the reflections in the X-ray diffraction diagrams decrease and become weaker during the grinding process. The prominent peak of calcite corresponding to the (104) crystal face decreases more than those of the others. The aragonite peaks are detected for the first time in the specimen ground for 6 hr. After 10 hr grinding, aragonite become the main component of the mixture.

The X-ray diffraction traces of α-CuPc at various stages of the mechanical treatment are given in Fig. 2.

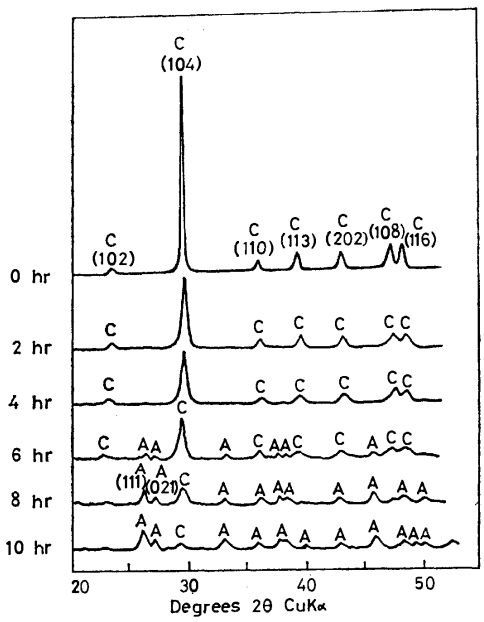

Fig. 1. X-ray diffraction patterns of $CaCO_3$ at different grinding times.

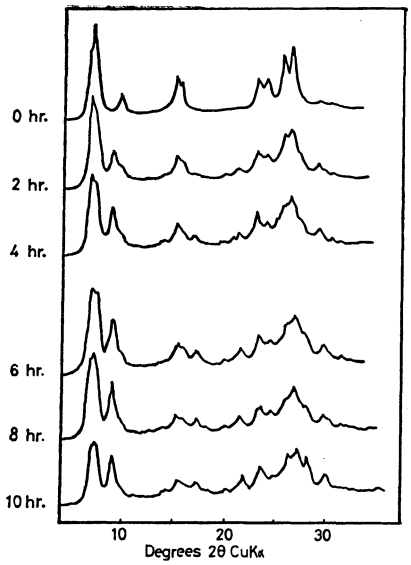

Fig. 2. X-ray diffraction patterns of α-CuPc at different grinding times.

The reflections characteristic of α-CuPc at the (200) and (002) crystal faces near 5°—8° in 2θ and four succesive medium reflections are observed to become broad with the grinding; they become hard to resolve in the specimen ground for 10 hr, much unlike the original situation. The reflection characteristic of β-CuPc corresponding to the $(20\bar{1})$ crystal face is observed in the specimen ground for 2 hr. In general, β-CuPc is known to be transformed to α-CuPc when comminution media are used.[15] However, α-CuPc may be considered to be transformed partially to the β-CuPc by absorbing the grinding energy.

The electron micrographs of the nongrinding specimens and the specimens ground for 10 hr of both calcium carbonate and α-CuPc alone are shown in Fig. 3. The micrograph of the calcium carbonate ground for 10 hr shows it to be finely divided particles. On the other hand, the particles of α-CuPc, compared with the case of calcium carbonate alone, aggregate considerably in the specimen ground for 10 hr. These facts are also confirmed by the specific-surface-area measurements.

The specific surface areas of both calcium carbonate and α-CuPc alone are plotted against the time of grinding in Fig. 4. It can be seen from this figure that the specific surface area of calcium carbonate gradually increases with the treatment, while that of α-CuPc decreases. Two factors may be considered to be the causes of the change in the specific surface area which take place in the process of grinding. One is associated with changes in the crystallite or particle size, the shapes of the particles, an dthe growth of cracks—that is, with primary structural changes. The other factor is related to the formation of secondary particles, which grow as a result of the aggregation or agglomeration of primary particles.[16] In the case of calcium carbonate alone, as has been described above, the particles are divided finely and no formation of secondary particles is observable. On the other hand, the specific surface area of α-CuPc may be considered to decrease with the grinding because of the aggregation.

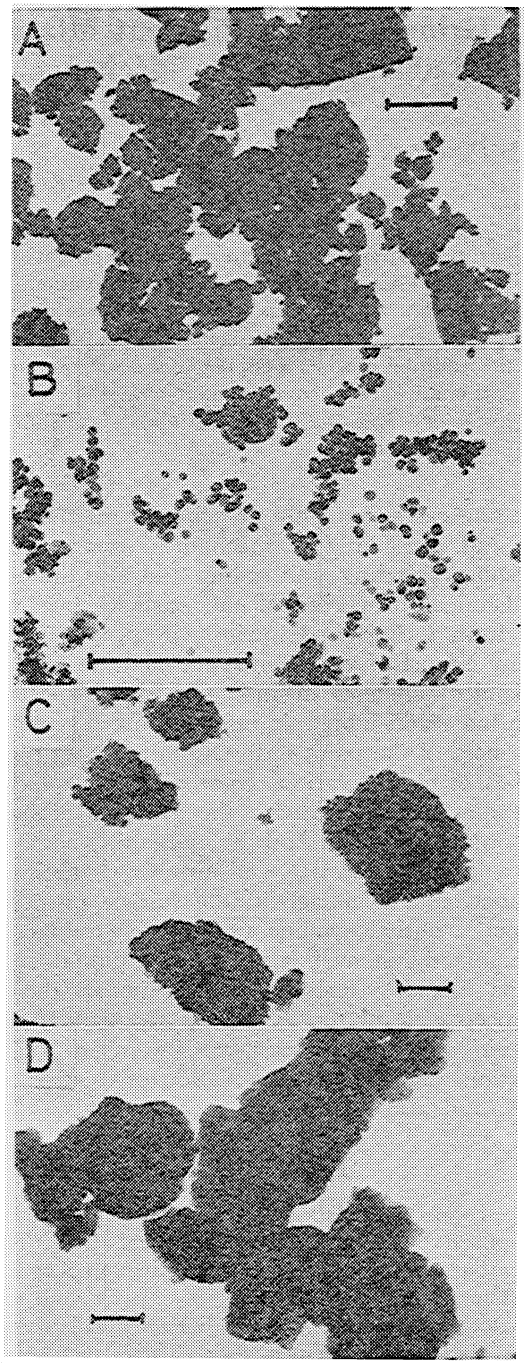

Fig. 3. Electron micrographs of $CaCO_3$ and α-CuPc. The linear dimension on the micrograph represents 1 μ.
A: original $CaCO_3$, B: $CaCO_3$ ground for 10 hr, C: original α-CuPc, D: α-CuPc ground for 10 hr.

The Results for Mixtures of Calcium Carbonate and α-CuPc. As with α-CuPc and calcium carbonate alone, the change in the surface properties of mixtures of several weight ratios of α-CuPc and calcium carbonate during the grinding process are estimated by a method similar to that used above.

The X-ray diffraction patterns of the mixtures (Samples A, B, and C) in the grinding process are given in Fig. 5. The reflections characteristic of α-CuPc in Sample A corresponding to the (200) and (002) crystal

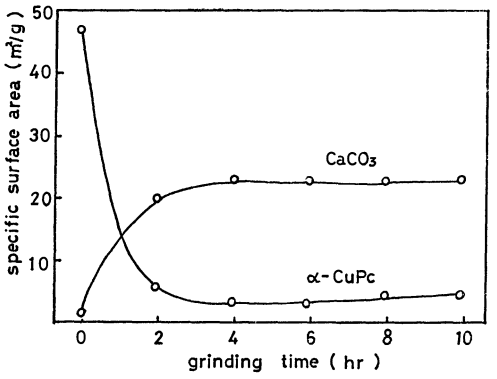

Fig. 4. The change of specific surface areas of α-CuPc and $CaCO_3$ with the time of grinding.

faces become broad, and the medium reflections at higher range become hard to resolve as the grinding proceeds. On the other hand, the (104) reflection of calcium carbonate in the mixtures does not decrease during the treatment more than in the case of calcium carbonate alone.

The calcite-aragonite transition is not observed in the specimen ground for 10 hr in Samples A and B; it is detected only in Sample C. The fact that the calcite-aragonite transition does not occur when the calcium carbonate is mixed with α-CuPc suggests that the calcium carbonate may be considered to be covered with α-CuPc; that is, the grinding of calcium carbonate may be interfered with by the lubricating action of α-CuPc. The strength of the lubricating action is also observed to increase with the amount of α-CuPc in the mixture system.

The electron micrographs of the specimens ground for 10 hr are shown in Fig. 6. In the case of Sample A, the particles of the mixture aggregate with each other, and the growth of secondary particles take place in the specimen ground for 10 hr, as in the case of α-CuPc alone. As is to be expected from Fig. 5-a, the calcium carbonate is also observed to be covered with α-CuPc and the grinding of calcium carbonate may be interfered with by the lubricating action of α-CuPc. In the case of Sample B, however, the ground particles of α-CuPc adhere around calcium carbonate particles. As is to be expected from the X-ray diffraction traces, the calcium carbonate in Sample C is ground considerably more than that of the other mixture systems. The electron micrograph of this specimen ground for 10 hr is similar to that of calcium carbonate alone in Fig. 3.

The calcium carbonate in the mixture is hardly ground more than calcium carbonate alone by the lubricating action of α-CuPc, judging from the results of the X-ray diffraction analysis and the observation of the electron micrographs. Consequently, though the specific surface area of calcium carbonate alone increases with grinding, the lubricating action of α-CuPc is expected to prevent an increase in the specific surface area of a mixture. Therefore, it is possible to determine the extent that the lubricating action of α-CuPc prevents the grinding of calcium carbonate by comparing the experimental curve with the theoretical one obtained by evaluating the specific surface areas of both α-CuPc and calcium carbonate alone, as based on the assumption of additivity.

The specific surface areas of mixtures are plotted against the time of grinding in Figs. 7, 8, and 9. It is interesting that the specific surface areas of Sample C gradually increase with the treatment, as with that of calcium carbonate alone, and those of Sample B decrease in the early stage of grinding and afterward gradually increase, while those of Sample A decrease, as with that of α-CuPc alone.

The experimental curves are observed to become lower than the theoretical one. This fact can be explained as follows. As has been described above, if the lubricating action of α-CuPc prevents the grinding of calcium carbonate, the specific surface area of calcium carbonate will not increase as the grinding continuos; that is, as the particle surfaces of calcium carbonate are covered with α-CuPc particles, aggregation is considered to occur. These facts agree with the results of the X-ray diffraction analysis and the elcctron-micrograph study.

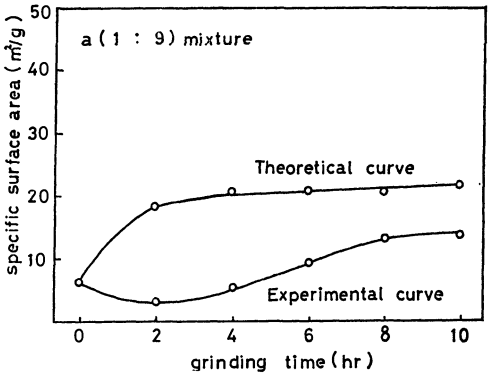

Fig. 8. The change of specific surface areas of sample B with the time of grinding.

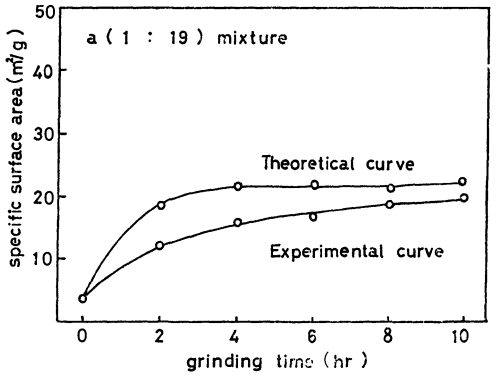

Fig. 9. The change of specific surface areas of sample C with the time of grinding.

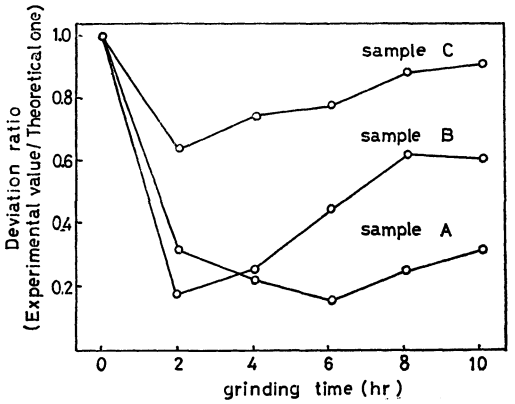

Fig. 10. The change in deviation ratio (Experimental value/Theoretical one) of pigment mixtures with the time of grinding.

The change in the deviation ratios (experimental value/theoretical one) for the mixtures with the time of grinding are shown in Fig. 10. The point at which the deviation ratio equals 1.0 coincides with the value at which the experimental value equals the theoretical one. That is, the lubricating action of α-CuPc is observed in the region in which the deviation ratio becomes lower than 1.0. The lubricating action of α-CuPc is observed in every mixture system, the order of the strength is as follows; Sample A > Sample B > Sample C.

The main conclusions obtained from these results are

as follows: when α-CuPc is mixed with calcium carbonate, the surface of the calcium carbonate is covered with that of α-CuPc, and the grinding of calcium carbonate is interfered with by the lubricating action of α-CuPc.

The Reaction of *N*-Substituted Carbonimidic Dihalides with Grignard Reagents. The Generation of Alkyl or Aryl Halides from Grignard Reagents

Sakuya TANAKA, Masaya OKANO*, and Shigeo TANIMOTO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received July 1, 1974)

The reaction of *N*-alkyl- or *N*-aryl-carbonimidic dihalides with Grignard reagents afforded α-elimination products, isocyanides, rather than substitution ones. Two kinds of alkyl or aryl halides were produced concomitantly in this reaction: one kind consisted of halides generated from the Grignard reagents used, and the other, of halides the halogens of which had been derived from the dihalides. The ease of formation of these halides was found to decrease in the order: iodide> bromide> chloride, regardless of which substrate served as the source of a halogen atom. A probable reaction mechanism is proposed.

The Grignard reactions of various carbonate derivatives (*e.g.*, phosgene,[1] chloroformates, and carbonates), as well as acyl chlorides and esters, which involve the replacement of one or two chlorine or alkoxy groups by alkyl or aryl groups of Grignard reagents have been well-established.[2] A very similar replacement has been reported for iminocarbonates,[3a] imidoyl chlorides,[3b] and imidates;[3a] and we have also observed that a chloroformimidate behaved similarly.[4] In contrast to these results, we found that *N*-alkyl- or *N*-aryl-carbonimidic dihalides reacted with Grignard reagents to afford α-elimination products, isocyanides, and that two kinds of alkyl or aryl halides were formed concomitantly. One of the latter products consisted of halides generated from the Grignard reagents used. A closely related observation has been reported for (dichloroiodo)-benzene by Melnikov.[6] This compound reacted with phenylmagnesium bromide to afford diphenyliodonium chloride (a substitution product), iodobenzene, chlorobenzene, bromobenzene (products corresponding to the present elimination), and biphenyl. The formations of all these products, except for that of bromobenzene, may be explained by either an ionic or radical mechanism; the pathway to afford bromobenzene has not yet been explored. The present paper will describe our results regarding the Grignard reaction of carbonimidic dihalides, which involves a novel generation of alkyl or aryl halides from the Grignard reagents.

Results and Discussion

When *N*-alkyl- or *N*-aryl-carbonimidic dihalides were treated in ether with Grignard reagents with a different halogen atom, the reaction occurred exothermally to afford isocyanides (**1**), two kinds of alkyl or aryl halides (**2** and **3**), magnesium halides, and a tarry product. Since the reaction of **1** with Grignard reagents is known, we adopted an inverse addition procedure (*i.e.*, the addition of a Grignard reagent to the dihalide) for the present reaction. Some typical data are shown in Table 1. Though the recorded yields of **1**, **2**, and **3** were not always those obtained under the optimum conditions for each reaction, their yields appeared to depend on the structures of both substrates.

$$\underset{}{R\text{-}N{=}CX_2} + R'MgX' \rightarrow \underset{\mathbf{1}}{R\text{-}N{\equiv}C} + \underset{\mathbf{2}}{R'X'} + \underset{\mathbf{3}}{R'X}$$

No liberation of isocyanides from *N*-substituted carbonimidic dihalides was observed, at least under the reaction conditions without Grignard reagents; therefore, it is obvious that the elimination reaction is promoted by the use of Grignard reagents. The halides **2** are produced only by the present reaction, since the absence of the remaining halides in the Grignard reagents was confirmed in each case before their use.

The preference for elimination over substitution in the present reaction appears to arise from the structual characteristics of *N*-substituted carbonimidic dihalides. It is well-known that the Grignard reactions of carboxylic acid derivatives, such as acid chlorides and esters, proceed by means of an addition-elimination mechanism, in which the initial coordination of the carbonyl O with the Mg atom of the Grignard reagent is involved. Thus, in the present reaction, the failure of the substitution of X in the dihalides may be attributed to a considerable decrease in the electron density on the imino N, which is caused by the presence of two electron-withdrawing groups (X) on the carbonimidoyl C. Further, it may be considered that the formation of stabilized products, isocyanides, may favor the elimination process.

It is worthwhile to present some information regarding the formation of **2** from Grignard reagents, because only one such transformation has been known.[6] The reactions of *N*-alkyl- or *N*-aryl-carbonimidic dichlorides with aryl magnesium bromides or iodides gave only **2**, while reactions with alkylmagnesium bromides or iodides yielded both **2** and **3**, the former being predominant. When *N*-phenylcarbonimidic dibromide was used as the substrate,[7] both halides were generally formed; **2** predominated over **3** when the halogen atom in the Grignard reagents was iodine, and the reverse was true when the halogen was chlorine. Further, the yields of **1** were roughly equal to the combined yields of **2** and **3** in general, except for some cases in which alkyl- or aryl-magnesium iodides were used.[8] To explain all these results, we tentatively proposed a mechanism involving the formation of a coordinated complex, **4**, followed by its synchronous decomposition to give **1** and either **2** or **3**.

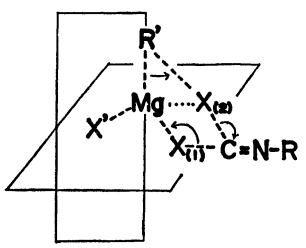
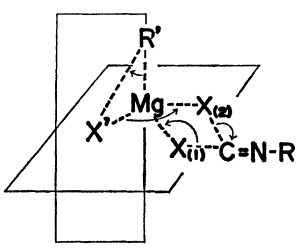
a) Based on carbonimidic dihalide charged (determined by glc). b) Not determined. c) Both substrates, 0.02 mol each; solvent, 30 ml. d) THF was used as solvent. e) Benzene (10 ml) was used as solvent.

yields of the reaction products shows that their reactivity toward a fixed Grignard reagent decreases in this order: cyclohexyl>*n*-butyl>phenyl. We also observed a similar substituent effect on the reaction of the dichlorides with SCN^- in ethanol,[9] suggesting an S_N1 character for the fission of the C–Cl bond. Thus, it may be anticipated that the decomposition of **4** will be started by the loosening of the C–$X_{(1)}$ bond and that this will result in bond formation between $X_{(1)}$ and Mg atoms. If the induced nucleophilic attack of the R' group on $X_{(2)}$ or X' and the subsequent electron-transfer from the C–$X_{(2)}$ bond to the C atom (when the attack of R' occurred on X', an additional electron-transfer from Mg–X' to Mg–$X_{(2)}$ should be involved) take place before the complete fission of the C–$X_{(1)}$ bond, the transition state affording **1** and **3**, and that affording **1** and **2**, can be pictured as **5** and **6** respectively. Here the assumption that a geometrically and electronically approximate equivalence can be attained in the transition states appears not unreasonable. The reason will be given below. If this is true, the relative ease of the halide formation can be expected to decrease in this order: iodide>bromide>chloride, whichever participates X or X', because the susceptibilities of X and X' toward R' are considered to correlate with their electronegativities. The selectivity data in the halide formation from the reactions with *N*-phenylcarbonimidic dibromide were in qualitative agreement with this expectation. In the reaction with *N*-cyclohexylcarbonimidic dichloride, aromatic Grignard reagents showed a higher selectivity for the halide formation (*i.e.*, only **2** is formed), than that from aliphatic Grignard reagents. This may be because aryl carbanions are generally less reactive than alkyl ones.



5



6

An extension of this reaction to other organometallic reagents was also attempted. When phenylzinc bromide was treated with *N*-cyclohexylcarbonimidic dichloride, a similar reaction occurred, though the yields of the products were unsatisfactory as expected. The reaction with much less reactive phenylmercuric bromide, however, did not afford any products; rather, most of the starting materials were recovered. Phenyllithium reacted with the dichloride to give the corresponding isocyanide and chlorobenzene.

Experimental

Materials. All the carbonimidic dihalides were prepared by the method of Kühle *et al.*[10] R=*cyclo*-C_6H_{11} in RN=CCl_2, bp 88—91 °C/23 mmHg (lit,[10] 79—82 °C/13 mmHg); R=*n*-C_4H_9, bp 40—42 °C/11 mmHg (lit,[10] 45—45.5 °C/14 mmHg); R=C_6H_5, bp 79—80 °C/8 mmHg (lit,[10] 83—85 °C/11 mmHg); R=C_6H_5 in RN=CBr_2, bp 104 °C/10 mmHg (lit,[10] 76.5—77.5 °C/0.15 mmHg). In the preparation of Grignard reagents, the complete conversion of the halides was confirmed by glc analyses. Phenylzinc bromide was prepared *in situ* by the exchange reaction[11] of phenylmagnesium bromide with zink chloride in ether. Phenylmercuric bromide was prepared from tetraphenyltin and mercuric bromide as has been described by Seyferth *et al.*[12] (mp 274—280 °C, lit,[12] 280 °C).

Reaction of Carbonimidic Dihalides with Grignard Reagents. Several examples are given below.

a) Reaction of Cyclohexylcarbonimidic Dichloride with Phenylmagnesium Bromide. An ethereal solution of the Grignard

reagent, prepared from 7.9 g (0.05 mol) of bromobenzene and 1.2 g (0.05 mol) of magnesium turnings in 50 ml of ether in the usual way[13] except that the solution was refluxed for an additional 30 min after the addition of all the bromobenzene, was gradually added to 9.0 g (0.05 mol) of cyclohexylcarbonimidic dichloride, the temperature being kept below 10 °C. After the mixture had then been allowed to stand at room temperature, the reaction started spontaneously and a white precipitate began to come out; then the mixture was refluxed for 30 min. The brown reaction mixture, with a characteristic odor of isocyanide, was poured into ice-water; the ethereal layer was separated, and then it was combined with a chloroform extract of the aqueous phase. The organic layer was dried, and the solvents were removed. The subsequent distillation of the residue gave 7.9 g of the distillate (bp 40—78 °C/23 mmHg), which was revealed to contain bromobenzene (46% yield), cyclohexyl isocyanide (40%), and the recovered dichloride (16%), leaving 2.1 g of a tarry product. No chlorobenzene was formed in this reaction.

b) Reaction of Cyclohexylcarbonimidic Dichloride with n-Hexylmagnesium Bromide. The Grignard reagent prepared from 8.3 g (0.05 mol) of *n*-hexyl bromide and 1.2 g (0.05 mol) of Mg in 50 ml ether was added to 9.0 g (0.05 mol) of the dichloride, after which the mixture was treated as has been described above. Distillation afforded 7.9 g of the distillate (bp 57—82 °C/55 mmHg) and left a tarry residue (2.7 g). The yields of the products were as follows: *n*-hexyl chloride, 7%; *n*-hexyl bromide, 46%; cyclohexyl isocyanide, 66%; and a trace amount of recovered dichloride.

c) Reaction of Phenylcarbonimidic Dibromide with Phenylmagnesium Iodide. A solution of the Grignard reagent obtained from 4.1 g (0.02 mol) of iodobenzene and 0.5 g (0.02 mol) of Mg in 20 ml of ether was slowly added to 5.3 g (0.02 mol) of the dibromide in 10 ml of ether at 0 °C. During the addition, the reaction occurred spontaneously and the temperature of the reaction mixture rose to *ca.* 30 °C, even under external cooling with an ice-salt mixture. After the reaction had subsided, the brown reaction mixture was refluxed for 15 min and then worked-up as has been described above. Distillation gave 2.6 g of the distillate (bp 40—74 °C/23.5 mmHg), leaving a tarry residue (1.5 g). The yields of the products were as follows: bromobenzene, 9%; iodobenzene, 27%; and phenyl isocyanide, 59%. Neither benzophenone anil nor benzanilide (the expected substitution products) could be detected in the tarry residue.

Reaction of Cyclohexylcarbonimidic Dichloride with Phenyllithium. An ethereal solution of phenyllithium, prepared from 7.9 g (0.05 mol) of bromobenzene and 0.8 g (0.12 mol) of lithium, was treated with 9.0 g (0.05 mol) of the dichloride at 0 °C. Glc analysis showed that the reaction products were chlorobenzene (35% yield) and cyclohexyl isocyanide (40%).

Authentic Samples for Glc. All the isocyanides were prepared from the corresponding formamides by the method of Ugi *et al.*[14]

Glc Analysis. The analysis was carried out on a Shimadzu GC-5A apparatus, using Apiezon L (25%)-Shimalite (3 m) and PEG 6000 (25%)-Chromosorb W (3 m) columns (carrier gas, N_2).

The Birch Reduction of Heterocyclic Carboxylic Acids. I. The Birch Reduction of 3-Furoic Acid

Takamasa KINOSHITA, Kouichi MIYANO, and Toshio MIWA
Faculty of Science, Osaka City University, Sumiyoshiku, Osaka 558

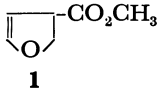
(Received July 26, 1974; in revised form, March 4, 1975)

The reduction of 3-furoic acid with sodium and 2-propanol in liquid ammonia gave 2,3-dihydro-3-furoic acid, which was isolated as a methyl ester (**1**) in 85% yield. The acid-catalyzed addition of methanol, ethanol, or 2-propanol to the ester **1** yielded 5-alkoxytetrahydro-3-furoate ester, **2**, **3**, or **4**, respectively, in a quantitative yield. When methanol or ethanol was used as a proton source in the reduction, work-up of the reaction mixture gave 5-alkoxytetrahydro-3-furoic acid, which was isolated as the methyl ester, **2** or **3**, in 87 or 92% yield, respectively. A mechanism for the Birch reduction of aromatic carboxylic acids is proposed.

The Birch reduction of the aromatic molecules has been extensively studied and widely applied to synthetic reactions.[1] Nevertheless, only few papers concerned with the Birch reduction of furan derivatives. Furan and its alkyl derivatives resist the Birch reduction.[2] Recently, Bedenbaugh *et al.* reduced simple furans with lithium in methylamine.[3] 2-Furoic acid has been reduced under the condition of the Birch reduction,[4] as expected from a facile reduction of benzoic acid.[5] The Birch reduction of 3-furoic acid into 2,3-dihydro-3-furoic acid and its application to a one-step synthesis of 5-alkoxytetrahydro-3-furoic acids will be described in this paper. The Birch reduction of 3-furoic acid provides a useful entry into the total synthesis of the branched-chain sugars.[6]

Results and Discussions

The Birch Reduction of 3-Furoic Acid. The reduction of 3-furoic acid with sodium and 2-propanol in liquid ammonia gave an acid, which, after esterification with diazomethane, was isolated as a methyl ester in 85% yield. The molecular formula, $C_6H_8O_3$, was determined by the elemental analysis and mass spectrometry ($M^+=128$). The IR spectrum of the ester showed the presence of a saturated ester function (1735 cm^{-1}) and an enol ether (3120 and 1620 cm^{-1}),[7] suggesting the product to be methyl 2,3-dihydro-3-furoate (**1**). The NMR spectrum of this compound shows a pattern characteristic of 3-substituted 2,3-dihydrofurans[8] as indicated in the experimental part.



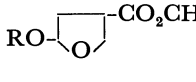
1

Syntheses of Methyl 5-Alkoxytetrahydro-3-furoates. Treatment of the ester **1** in methanol with acid catalyst gave methyl tetrahydro-5-methoxy-3-furoate (**2**) in a quantitative yield. The fact that the acid-catalyzed addition of alcohols to the α,β-unsaturated ether is a well-established reaction[9] may suffice to assign the structure **2** to the ether. Disappearance of the C=C stretching band due to enol ether function of **1** in its IR spectrum supports the structure.

Although the methyl peaks of **2** show sharp singlets in the NMR spectrum, the signal for H-5 is rather complex, inferring that the product is a mixture of stereoisomers. Actually, the gas chromatography of **2** gave two peaks in a ratio of 2 : 1. The major fraction was assumed to have a *trans* configuration from a stereochemical consideration of the addition of methanol. This was further confirmed by the downfield shift of the proton H-3 (δ 3.16) deshielded by the 5-methoxy group compared to that of the *cis* isomer (δ 3.04).[10]

Treatment of the ester **1** with ethanol or 2-propanol in the presence of acid gave an ethyl ether **3** or an isopropyl ether **4** corresponding to **2**, respectively, in a quantitative yield. They also were mixtures of stereoisomers, showing a signal for H-5 similar to that of the methyl ether **2**; however, no attempts were made to separate the isomers.

The reduction of 3-furoic acid with sodium and methanol or ethanol in liquid ammonia produced the methyl ether **2** or the ethyl ether **3** in 87 or 92% yield, respectively, after the methylation with diazomethane. Apparently, these ethers, **2** and **3**, were formed by the addition of alcohols to 2,3-dihydro-3-furoic acid in the course of work-up of the reaction mixture.[11]



2: R=CH_3
3: R=C_2H_5
4: R=$CH(CH_3)_2$

Reaction Mechanism for the Birch Reduction of Aromatic Carboxylic Acids. The Birch reduction is initiated with the addition of an electron to the substrate molecule to form a radical anion, followed by the rapid protonation at the position with the highest electron density. The addition of another electron produces an anion, which is kinetically protonated to give an unconjugated cyclohexadiene.[12] According to the molecular orbital theory,[13] the extra electron in the first step of the Birch reduction will be introduced to the lowest unoccupied molecular orbital of symmetric or anti-symmetric character depending upon whether the substituent is electron-withdrawing or electron-releasing. Protonation at the highest electron density will occur at the 1- or 4-position in the former case and at the *o*- or *m*-position in the latter. The Birch reduction of benzoic acid gave 1,4-dihydrobenzoic acid,[14] indicating the carboxylate group is sufficiently electron-withdrawing in the Birch reduction. The highest spin density at the para position of the radical dianion derived from benzoate anion was also verified by the ESR study.[15] Apart from the MO argument, the products of the Birch reduction of the aromatic carboxylic acids may be rationalized as follows. All the aromatic carbonyl compounds, including benzoate anion, are assumed to add the electron not to the

aromatic nucleus but to the carbonyl group.[16] In the case of benzoate anion, the negative charge of the carboxylate anion will repel the charge of the resulting radical dianion **5a** as far as possible, favoring the contributing structure **5b** with the highest electron density at the carbon-4. As a corollary, benzamides may be well reduced on their aromatic nucleus only when the amide proton can be removed by a base to form amide anion. Thus, more acid benzamide substituted by methoxy groups at the meta positions can be reduced in good yield.[14]

The same argument may be valid for the Birch reduction of furoic acids. The addition of an electron to 2-furoate anion will produce a radical dianion with the highest electron density at the carbon-5 in its most favorite contributing structure **6**, followed by protonation at the position. The kinetic protonation of the dianion formed by the addition of another electron should occur at the carbon-2, forming the unconjugated acid, 2,5-dihydro-2-furoic acid. On the other hand, the radical dianion formed by the addition of an electron to 3-furoate anion will have the highest electron density at the carbon-2 in the most important contributing structure **7**; thus, the product of the Birch reduction of 3-furoic acid is 2,3-dihydro-3-furoic acid.

6 **7**

Experimental

General. IR spectra were taken neat on a JASCO Model IR-E IR spectrometer and were calibrated against the 1600 cm^{-1} band of polystyrene. NMR spectra were recorded in deuteriochloroform solution at 100 MHz with a JEOL Co PS-100 spectrometer using tetramethylsilane as an internal reference. Mass spectra were recorded with a Hitachi RMU-6 mass spectrometer.

The Birch Reduction of 3-Furoic Acid. All the Birch reductions were carried out as follows: To a mixture of 3-furoic acid and *ca.* 8 molar equivalents of alcohol in liquid ammonia (*ca.* 10 ml per mole of acid) was added 3 equivalent atoms of sodium little by little with constant stirring under reflux. The mixture was stirred for an additional hour and excess of ammonium chloride was added. After evaporation of liquid ammonia at room temperature, the residue was dissolved in water. The aqueous solution was washed with several portions of ether to remove alcohol, acidified and immediately extracted continuously with ether for 24—48 h. The ether extract was esterified with excess of diazomethane and, after evaporation of the solvent, the residue distilled under reduced pressure.

With 2-Propanol: Methyl 2,3-dihydro-3-furoate (**1**), bp 83—84 °C/30 mmHg, was obtained in 85% yield. MS: (80 eV) *m/e* (rel intensity) 128 (20), 69 (100), 41 (26), 39 (16). NMR: δ 3.72 (s, 3, ester CH_3), 3.75 (m, 1, H-3), 4.44 (q, 1, $J_{2,3}=11$, $J_{2,2'}=-9.5$ Hz, H-2), 4.69 (q, 1, $J_{2',3}=7$ Hz, H-2'), 5.03 (t, 1, $J_{3,4}=3$, $J_{4,5}=3$ Hz, H-4), 6.42 ppm (t, 1, $J_{3,5}=2$ Hz, H-5).

Found: C, 56.08; H, 6.41%. Calcd for $C_6H_8O_3$: C, 56.24; H, 6.29%.

With Methanol: Methyl tetrahydro-5-methoxy-3-furoate (**2**), bp 90—92 °C/10 mmHg, n_D^{25} 1.4325, was isolated in 87% yield. IR: 1735 cm^{-1}. MS: (80 eV) *m/e* (rel intensity) M^+ absent[17], 159 (1.3), 145 (1.8), 129 (55), 115 (12), 103 (29), 99 (28), 87 (14), 71 (18), 69 (100), 59 (25), 58 (35), 55 (14), 45 (15), 41 (41), 39 (12). NMR: δ 2.00—2.45 (m, 2, H-4), 3.00—3.25 (m, 1, H-3), 3.27 (s, 3, ether CH_3), 3.65 (s, 3, ester CH_3), 4.05 (d, 2, H-2), 5.0 ppm (m, 1, H-5).

Found: C, 52.31; H, 7.44%. Calcd for $C_7H_{12}O_4$: C, 52.49; H, 7.55%.

Preparative gas chromatography of **2** was performed on a Varian Aerograph Model 90-P instrument equipped with a 4 mm × 2 m column of 20% Carbowax 20M at 150 °C with a flow rate of 40 ml/min. Two peaks of retention times of 9.1 and 10.8 min appeared in a ratio of 2 : 1. The faster-moving fraction showed the following NMR spectrum: δ 2.0—2.45 (m, 2, H-4), 3.16 (quintet, 1, H-3), 3.27 (s, 3, ether CH_2), 3.65 (s, 3, ester CH_3), 4.05 (d, 2, H-2), 5.02 ppm (q, 1, H-5). The slower-moving fraction showed the following NMR spectrum: δ 2.20—2.35 (m, 2, H-2), 3.04 (quintet, 1, H-3), 3.27 (s, 3, ether CH_3), 3.65 (ester CH_3), 4.05 (d, 2, H-2), 5.00 ppm (t, 1, H-5).

With Ethanol: Methyl 5-ethoxytetrahydro-3-furoate (**3**), bp 106—110 °C/15 mmHg, was obtained in 92% yield.[18] IR: 1735 cm^{-1}. MS: (80 eV) *m/e* (rel intensity) M^+ absent, 173 (0.7), 159 (2.7), 143 (12), 129 (47), 115 (10), 100 (24), 99 (13), 87 (15), 85 (17), 72 (19), 69 (100), 59 (17), 57 (12), 55 (15), 45 (11), 41 (28), 32 (22). NMR: δ 1.16 (t, 3, C–CH_3), 1.95—2.45 (m, 2, H-4), 2.90—3.40 (m, 1, H-3), 3.49 (q, 2, OCH_2), 3.64 (s, 3, OCH_3), 4.08 (d, 2, H-2), 5.18 ppm (m, 1, H-5).

Found: C, 55.05; H, 8.10%. Calcd for $C_8H_{14}O_4$: C, 55.16; H, 8.10%.

Acid-catalyzed Addition of Alcohols to Ester **1**. A solution of the ester **1** in appropriate amount of alcohol containing Dowex 50 (W-X8, H^+) ion-exchange resin (200—400 mesh) was stirred at room temperature overnight. After filtration of the resin followed by evaporation of the solvent, the residue was distilled under reduced pressure. The yields were quantitative. The esters, **2** and **3**, obtained by the Birch reduction were identified with the compounds produced by the acid-catalyzed addition of methanol and ethanol, respectively, by NMR spectrometry. The addition of 2-propanol gave methyl tetrahydro-5-isopropyloxy-3-furoate (**4**), bp 120—121 °C/30 mmHg. IR: 1735 cm^{-1}. MS: (80 eV) *m/e* (rel intensity) M^+ absent, 189[19] (0.6), 187 (0.4), 173 (3.1), 145 (13), 129 (89), 128 (11), 115 (16), 100 (40), 87 (37), 85 (10), 69 (100), 59 (13), 55 (11), 45 (10), 43 (22), 41 (26), 39 (13). NMR: δ 1.16 (d, 3, C–CH_3), 1.18 (d, 3, C–CH_3), 1.95—2.45 (m, 2, H-4), 2.90—3.45 (m, 1, H-3), 3.65 (s, 3, OCH_3), 3.84 (m, 1, O–CH), 4.00—4.15 (m, 2, H-2), 5.3 ppm (m, 1, H-5).

Found: C, 57.03; H, 8.46%. Calcd for $C_9H_{16}O_4$: C, 57.43; H, 8.57%.

The authors are greatly indebted to Dr. Yoshio Hirose and Mr. Kazuo Yoshihara of the Institute of Food Chemistry, Osaka, for the recording and analyses of the mass spectra and to Mr. Jun'ichi Gōda for the elemental analyses.

Studies of Polyphenyls and Polyphenylenes. I. The Syntheses and Infrared and Electronic Spectra of Several Sexiphenyls

Eiichi IBUKI, Shigeru OZASA, and Kazue MURAI

Department of Organic Chemistry, Kyoto College of Pharmacy, Yamashina, Higashiyama-ku, Kyoto 607

(Received July 26, 1974)

Seven linear sexiphenyls were synthesized by the Ullmann reaction of iodobiphenyl and diiodobiphenyl. Infrared studies indicated that the fine structure in the 780—810 cm^{-1} region suggests the presence of consecutive *m*-phenylene units, and that the positions of the strong or medium bands in the 820—840 cm^{-1} region indicate approximately the number of continuous *p*-phenylene units. The electronic spectra commonly displayed a prominent E-band in the narrow region of 192—207 nm. The intense K-band above 260 nm was considered to be an indication of the presence of one or more *p*-phenylene units.

It has been known that a twist of the pivot bond in a conjugated system of polyphenyls influences the interaction of π-electrons across the pivot bond and also the conjugation of the system, and consequently affects the spectral features.[1-3] In order to investigate the relationship between the number and arrangement of the benzene rings and the physical properties of polyphenyls and polyphenylenes, a series of symmetrical linear sexiphenyls, with closely related structures, have been prepared and their infrared and electronic spectra have been measured.

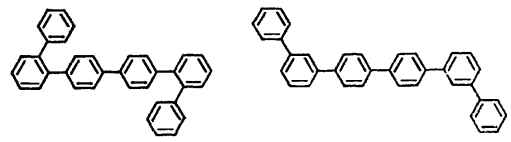
XVIII XX



XXI XXII

The convenient route generally used for the preparation of polyphenyls is based on the reaction of arylcyclohexenone or arylcyclohexanone with an appropriate Grignard reagent or a corresponding lithium compound, followed by dehydration and dehydrogenation.[4,5] The resultant polyphenyl, however, is liable to be contaminated with a partially hydrogenated product.[6]

To avoid this disadvantage, the Ullmann coupling of aryl halides has been used in the present work. There are two forms of coupling in the syntheses of a series of symmetrical sexiphenyls: a) the coupling of iodoterphenyl, and b) the coupling of iodobiphenyl and diiodobiphenyl. In this work, the b method has been adopted in spite of the troublesome separation of polyphenyl from the reaction products, because the b method has the advantage of synthesizing both iodo compounds with ease from commercially available materials. Thus, iodobiphenyls (2- [I], 3- [II], and 4-iodobiphenyl[III]) and diiodobiphenyls (2,2'- [IV], 3,3'- [V], and 4,4'-diiodobiphenyl[VI]) were prepared from commercial aminonitrobenzene, chloronitrobenzene, aminobiphenyls, and benzidine. Then a mixture of mono- and diiodo compounds in the molar ratio of 2 to 1 was subjected to the Ullmann reaction at 260—270 °C with copper powder. The sexiphenyls and by-products thus obtained are shown in Table 1.

Table 1. Ullmann syntheses oe sexiphenyls

Iodides	Sexiphenyls (Yield, %)	By-products
I+IV	X (5.4)	VII VIII IX XI
II+IV	—	VII VIII XI XIV XVII
III+IV	XIII (1.6)	VII VIII XII XIV XV
I+V	XVI (5.5)	VII IX
II+V	XVIII (8.6)	VII XVII
III+V	XX (9.7)	VII XV XIX
I+VI	XXI (9.0)	VII IX XV
II+VI	XXII (14.0)	VII XVII XIX

Four sexiphenyls, X, XIII, XVI, and XXI, were found by the mixed-melting-point method and the IR spectra to be identical with authentic samples synthesized by the Ullmann coupling of the corresponding iodoterphenyls. An alternative synthesis of six sexiphenyls (X, XIII, XVIII, XX, XXI, XXII) has been reported earlier by other workers. Whereas the melting points of XIII and XX[7] do not coincide with those of the previous authors, those of the four remaining sexiphenyls fall within 1—2 °C of those of the other authors (X, XVIII,[8] XXI,[9] XXII[10,11]).

In all of the Ullmann coupling experiments, biphenyl and one or two kinds of quaterphenyls were isolated as by-products. Beside these substances, biphenylene and 1-phenyltriphenylene were separated from the product of I+IV, and biphenylene and 2-phenyltriphenylene, from III+IV.[12]

The yields of all the pure sexiphenyls except XIII were 5—14%. In the coupling reactions using IV

a) v: very, s: strong, m: medium, w: weak, sh: shoulder. γ_{C-C} and γ_{C-H} refer to vibrations which are primarily out-of-plane C-C, and out-of-plane C-H bending motions. M, *o*, *m*, *p* in parentheses refer to mono-, *ortho*-, *meta*-, and *para*-substituted rings.

as one of the iodo compounds (I+IV, and III+IV), the sexiphenyls were obtained only in low yields; furthermore, in the case of II+IV, no corresponding sexiphenyl was isolated, but biphenylene, 1- and 2-phenyltriphenylene were obtained. Hence, the Ullmann coupling of appropriate iodoterphenyl is preferable for these three sexiphenyls with an *o*-quaterphenyl unit in the middle of their structure.

For the separation of polyphenyl from a mixture of several products, liquid column chromatography, using alumina as the adsorbent and a cyclohexane or cyclohexane–benzene mixture as the eluent, was found to be a satisfactory technique.[13]

The IR spectra of the sexiphenyls were measured by the KBr-disk method. All the sexiphenyls commonly show the following absorptions: a group of prominent bands due to C–H out-of-plane deformation vibrations in the 675—910 cm^{-1} region; intense bands due to C–C out-of-plane deformation vibrations in the fairly narrow region of 685—710 cm^{-1};[14] medium bands due to C–C in-plane deformation vibrations near 1000 cm^{-1}, and weak bands due to C–H in-plane deformation vibrations in the 975—1350 cm^{-1} region. In addition, groups of medium bands due to C–C stretching vibrations and a weak band due to aromatic C–H stretching vibrations in the 1350—1600 cm^{-1} and 3000—3100 cm^{-1} regions respectively were observed.

The most characteristic bands of sexiphenyls in the 675—910 cm^{-1} region are shown in Table 2; the table indicates that these bands are consistent with the kinds of phenylene rings in each sexiphenyl.

Let us now discuss the assignment of the strong bands in the 734—761 cm^{-1} region of X, XIII, XVI, and XXI, in all of which one or more *o*-phenylene rings are present. Stewart and Hellman[16] have pointed out that the bands at 733—757 cm^{-1} of *o*-quaterphenyl must be due to C–H out-of-plane deformation vibrations of terminal rings; Sandroni and Geiss[17] have proposed a similar assignment for the intense bands in the 753±10 cm^{-1} region of polyphenyls. However, the strong bands near 745—755 cm^{-1} were also observed in the spectra of some polyphenylenes, which contain no terminal rings. Thus, tetraphenylene, *o*-hexaphenylene, *o*-octaphenylene,[20] and *o,p,o,p,o,p*-hexaphenylene[21] showed strong

bands at 745—755 cm^{-1}. Consequently, in the case of polyphenyls containing *o*-phenylene rings, the intense bands in the 734—761 cm^{-1} region should be assigned not only to the C–H out-of-plane bending bands of terminal rings, but also to those of *o*-phenylene rings.

Then the prominent bands observed commonly in the spectra of X, XIII, XVI, and XXI at 776—786 cm^{-1} should be assigned to the C–H out-of-plane bending vibrations of *o*-phenylene rings, as has been suggested by Stewart and Hellman[16] and Sandroni and Geiss,[17] because the medium or weak bands at 766—773 cm^{-1} were found commonly in the spectra of four polyphenylenes.

The four bands at 776, 786, 803, and 817 cm^{-1} in the spectra of XVIII were assigned to the C–H out-of-plane bending vibrations of *m*-phenylene rings. Stewart and Hellman[16] have pointed out that the characteristic C–H bands of some *m*-polyphenyls in the 780—810 cm^{-1} region are observed as a multiplet with an increase in the complexity, in accordance with the progression of *m*-phenylene rings, and have concluded that the fine structure can be attributed to the interaction bands between a ring and its nearest neighbors. The spectrum of XVIII supports strongly their opinion.

In the spectra of XIII, XX, XXI, and XXII, strong C–H out-of-plane bending vibration bands of two adjacent hydrogen atoms of *p*-phenylene rings were clearly observed at 842; at 839; at 832, and at 826, 833, and 837 cm^{-1} respectively. While XIII and XX have two *p*-linkages separated, respectively, by *o*- and *m*-phenylene groups, XXI and XXII have two consecutive *p*-linkages. A red shift of the characteristic bands was observed in the spectra of the latter two compounds. A similar red shift has been reported by Doss[19] and others[17] in the spectra of compounds with consecutive *p*-phenylene units.

These results show that the fine structure in the 780—810 cm^{-1} region suggests the presence of consecutive *m*-phenylene units, and that the positions of strong or medium bands in the 820—840 cm^{-1} region serve as an indication of the number of continuous *p*-phenylene units.

The electronic spectra of the seven sexiphenyls were measured in a cyclohexane solution. The absorption curves are shown in Figs. 1—4. The absorption maxima above 220 nm coincide within 1—2 nm for XIII, XVIII, XX, and XXI, and within 3—4 nm for X and XXII, with those of other workers.[8–10,22]

Gillam[1] has reported that the first intense band of the first four *p*-polyphenyls is shifted progressively toward a longer wavelength and increases in intensity with an increase in the number of rings. In the *m*-series, terphenyl and compounds containing 9—16 benzene rings absorb at substantially the same wavelength and with an intensity which is approximately proportional to the number of ring units.[1] In the case of *o*-polyphenyls, however, Dale[2] and others[20] have observed a blue shift and a weakening of the conjugate band as compared with those of the corresponding *m*-polyphenyls; these are results of reduced π-π interaction across the pivot bond.

In the present study, all seven sexiphenyls displayed two groups of intense bands: one in the fairly narrow region of 192—207 nm (ε=72800—98700) and another

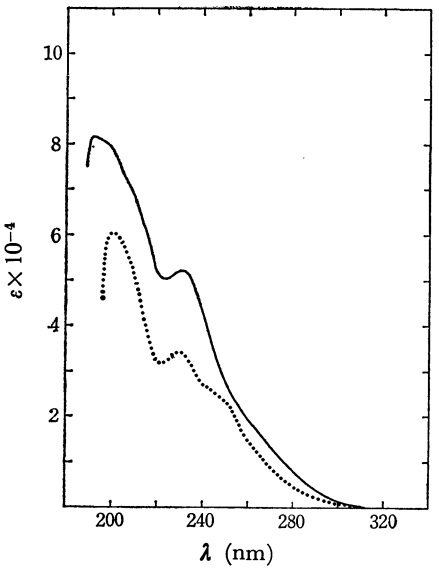

Fig. 1. Electronic spectra of quaterphenyl and sexiphenyl in cyclohexane.

in the broad region of 230—300 nm with a high intensity. While the band position for the former was found to be rather independent of the structure, that for the latter was substantially affected by the nature and number of linkages formed between benzene rings. The first one, corresponding to the band at 203 nm (ε=49600) of biphenyl, is considered to be the E-band (the notation is according to Braude[23]), which is presumably due to the transitions between localized π-orbitals within each benzene ring.[2,3] The other one, corresponding to the band at 248 nm (ε=18500) of biphenyl, is regarded as the K-band (Burawoy's notation[23]), which should originate from

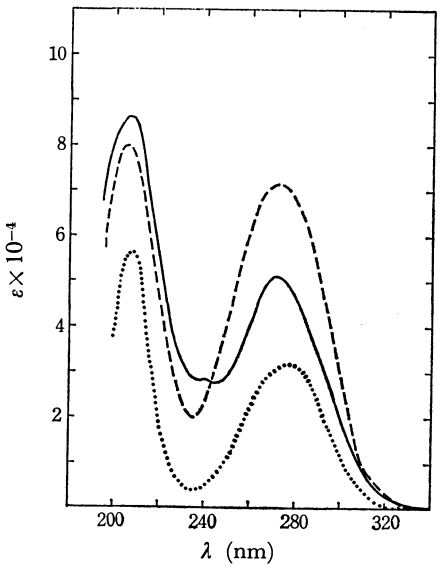

Fig. 3. Electronic spectra of terphenyl and sexiphenyls in cyclohexane.
·····: *p*-Terphenyl,
——: 2,2′-Di(4-biphenylyl)biphenyl (XIII),
----: 3,3′-Di(4-biphenylyl)biphenyl (XX).

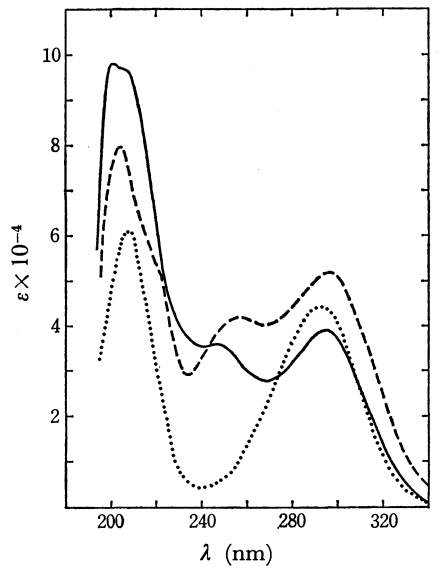

Fig. 4. Electronic spectra of quaterphenyl and sexiphenyls in cyclohexane.
·····: *p*-Quaterphenyl (XV),

----: 4,4′-Di(3-biphenylyl)biphenyl (XXII).

transitions between whole-molecular π-orbitals made up of ring orbitals with no longitudinal node.[2,3]

Thus, the spectrum of X has the K-band with λ_{max} at 231 nm and an ε_{max} value of 52200, slightly stronger in its intensity than, but very similar in its location to, *o*-quaterphenyl (230; 34100) (Fig. 1). The spectra of XVIII and XVII (*m*-quaterphenyl) revealed intense bands at substantially the same wavelength, 248± 1 nm, with intensities about five times and three times respectively those of the biphenyl band. Therefore, the intensity of the K-band in the *m*-series may be correlated with the maximum number of biphenyl units in each compound (Fig. 2). In the case of XVI, in which *o*- and *m*-linkages are present, the spectrum revealed a strong K-band at 237 nm (ε=74100) which may correspond to the band near 230 nm of *o*-polyphenyls, but the characteristic band of *m*-polyphenyls near 250 nm was observed only as a shoulder.

Then in the spectra of XIII, XX, XXI, and XXII, all of which have *p*-linkage, a remarkable red shift of the K-band as compared with that in biphenyl was distinctly observed, as is shown in Figs. 3 and 4. Thus, XIII and XX have two *p*-terphenyl units in each structure and show a distinct band at about 270 nm, while XXI and XXII each have one *p*-quaterphenyl unit and both reveal a strong band near 300 nm. It may be considered that the arrangement of the *p*-phenylene units in the four sexiphenyls, even in the presence of *o*- or *m*-phenylene units, has a tendency to maintain a coplanarity of the rings; a distinct bathochromic shift of K-band results because of the elongation of the conjugated system.

On the basis of these results, the intense K-band above 260 nm in the spectra of sexiphenyl may be considered to be an indication of the presence of one or more *p*-phenylene units.

Experimental

All the melting points and boiling points are uncorrected. The IR spectra were recorded with a Leitz IIIG spectrophotometer. The electronic spectra were measured on a Shimadzu QV-50 spectrometer and a Hitachi EPS-2 spectrophotometer, using spectral-grade cyclohexane as the solvent. In the measurement in the short-wavelength region, 2-mm silica cells were used. The molecular weights were determined with a Mechrolab 301A vapor-pressure osmometer unless otherwise noted.

2-Iodobiphenyl (I). Commercial 2-aminobiphenyl (20 g, 0.12 mol) dissolved in sulfuric acid was diazotized with sodium nitrite. The suspension of the diazonium salt thus formed was treated with a potassium iodide solution. The product was purified by distillation *in vacuo* to give a pale yellow liquid; bp 130—134 °C/4 mmHg (lit,[24] bp 158 °C/6 mmHg); yield, 26.3 g (79.8%). (Found: C, 51.51; H, 3.26%.)

3-Iodobiphenyl (II). 3-Nitroaniline (69 g, 0.50 mol) in sulfuric acid (33 ml) and water (500 ml) were treated with sodium nitrite (36 g) in water (76 ml) at 0—5 °C with stirring. To the cold suspension of diazonium salt thus formed, benzene (1000 ml) and sodium acetate (160 g) in water (330 ml) were added in portions, after which the mixture was stirred at an ambient temperature for 7 hr and then at 30—35 °C for 40 hr. The benzene layer was separated, washed with water, and then dried. After the removal of the benzene, the residue was distilled *in vacuo* to afford a pale yellow oil; bp 166—170 °C/8 mmHg. Recrystallization from methanol gave 3-nitrobiphenyl as pale yellow needles; mp 59—60 °C (lit,[25] mp 61 °C); yield, 50.0 g (50.3%).

3-Nitrobiphenyl (20 g, 0.10 mol) was dissolved in hot benzene (800 ml) and treated with activated iron by a method similar to that of Hazlet and Dornfeld.[26] After filtration, hydrogen chloride was passed into the filtrate. The precipitate was separated off, washed with benzene, and dried. Then the salt was treated in the usual manner with 20% aqueous alkali. The benzene extract was washed with water and dried. The evaporation of the solvent, followed by

distillation *in vacuo*, yielded 3-aminobiphenyl as a colorless oil; mp 30 °C; bp 175—177 °C/13 mmHg (lit,[27] mp 31—31.5 °C; bp 177—178 °C/18 mmHg); yield, 12.3 g (72.4%).

3-Iodobiphenyl was prepared by the method described for the preparation of I to give a pale yellow oil; mp 25—26 °C; bp 175—178 °C/15 mmHg (lit,[27] bp 149—152 °C/1 mmHg); yield, 78.6%. (Found: C, 51.58; H, 3.48%.)

4-Iodobiphenyl (III). 4-Iodobiphenyl was prepared from 4-aminobiphenyl in the manner described above. Colorless plates from ethanol; mp 112.5—113.5 °C (lit,[28] mp 112 °C); yield, 70.8%. (Found: C, 51.51; H, 3.41%.)

2,2′-Diiodobiphenyl (IV). 2-Chloronitrobenzene (40 g, 0.25 mol) was heated with copper powder (80 g, 1.26 g-atom) at 215—225 °C and then at 225 °C for 1 hr. The subsequent extraction of the cooled mass with hot benzene, followed by evaporation, and the recrystallization of the residue from ethanol gave 2,2′-dinitrobiphenyl as pale yellow prisms; mp 122.5—124.5 °C (lit,[29] mp 123.5—124.5 °C); yield, 18.8 g (60.7%).

2,2′-Dinitrobiphenyl was reduced with activated iron in hot benzene in a manner previously described. Recrystallization from petroleum benzine afforded colorless prisms; mp 79—80 °C; yield, 73.0%.

The 2,2′-diaminobiphenyl (10 g, 0.054 mol) thus obtained was subjected to tetrazotization, followed by treatment with potassium iodide. The product was purified by distillation *in vacuo*; the subsequent recrystallization of the distillate (bp 130—170 °C/4 mmHg) from methanol gave 2,2′-diiodobiphenyl as pale yellow needles; mp 107.5—108.5 °C; yield, 8.8 g (40.0%). (Found: C, 35.63; H, 2.28%.)

3,3′-Diiodobiphenyl (V). 3-Iodonitrobenzene was prepared from 3-aminonitrobenzene by a method similar to that of Daines and Eberly;[30] mp 35.5—36.5 °C; yield, 55.4%. 3,3′-Diiodobiphenyl was obtained by the Ullmann reaction of 3-iodonitrobenzene, followed by reduction with tin and hydrochloric acid, and the Gries reaction of the product. Colorless needles from petroleum benzine; mp 71—72 °C (lit,[31] mp 72 °C); yield, 23.2% (based on 3-iodonitrobenzene). (Found: C, 35.59; H, 2.09%.)

4,4′-Diiodobiphenyl (VI). Commercial benzidine (18.4 g, 0.10 mol) was tetrazotized and then treated with potassium iodide in the manner described above to give VI as colorless leaves from benzene; mp 202—203 °C (lit,[32] mp 202 °C); yield, 35.0 g (86.3%). (Found: C, 35.78; H, 2.19%.)

Preparation of o-Sexiphenyl (X). A mixture of I (5.6 g, 20.0 mmol) and IV (4.0 g, 9.9 mmol) in a test tube (ϕ 2.5×20 cm) was heated in an oil bath at 265—270 °C, and then copper powder (28 g, 440 mg-atom) was stirred in in portions over a 1.5-hr period, after which the mixture was heated at 270 °C for an additional 1.5 hr. After cooling, the mixture was extracted with hot benzene, and the solvent was distilled off. The resulting solid (4.98 g) was subjected to chromatography on alumina, with cyclohexane and then with a cyclohexane-benzene (5 : 1 v/v) mixture (C–B (5 : 1)) as the eluents. The cyclohexane eluted three fractions, which, upon the evaporation of the solvent and recrystallization from ethanol, afforded VII, VIII, and IX. The mixture eluted two fractions, which, upon treatment as above, yielded X and XI. The properties of these compounds are as follows.

i) Biphenyl (VII): colorless leaves; mp 70—71 °C; yield, 11 mg.

ii) Biphenylene (VIII): pale yellow needles; mp 110—111 °C (lit,[33] mp 111—112 °C); yield, 322 mg.

Found: C, 94.45; H, 5.56%. Calcd for $C_{12}H_8$: C, 94.70; H, 5.30%. Picrate: 121—122 °C. (Found: C, 56.67; H, 3.11; N, 10.83%.) Styphnate: 160—162 °C. (Found: C, 54.43; H, 3.01; N, 10.60%.)

iii) *o*-Quaterphenyl (IX): colorless cubes; mp 118—119 °C (lit,[15] mp 118 °C); yield, 1880 mg.

Found: C, 93.87; H, 6.18%; mol wt (Rast), 324. Calcd for $C_{24}H_{18}$: C, 94.08; H, 5.92%; mol wt, 306.

iv) *o*-Sexiphenyl (X): colorless cubes from ethanol; mp 217—217.5 °C (lit,[8] mp 216—217 °C); yield, 249 mg (5.4%). UV: λ_{max} (ε) 192(82100), 231 nm (52200).

Found: C, 94.14; H, 5.98%; mol wt, 451. Calcd for $C_{36}H_{26}$: C, 94.28; H, 5.72%; mol wt, 458.

v) 1-Phenyltriphenylene (XI): colorless needles from ethanol; mp 160—161 °C (lit,[34] mp 162 °C); yield, 245 mg.

Found: C, 94.46; H, 5.47%; mol wt, 298. Calcd for $C_{24}H_{16}$: C, 94.70; H, 5.30%; mol wt, 304.

Reaction of II and IV. A mixture of II (8.4 g, 30.0 mmol) and IV (6.0 g, 14.8 mmol) was treated with copper powder (27.0 g, 430 mg-atom) at 270—280 °C for 1 hr. The hot benzene extract of the mixture was then chromatographed on an alumina column in a manner previously described. The three fractions which were eluted with a C–B (5 : 1) mixture gave VII (876 mg), VIII (545 mg), and XVII; the one fraction which was eluted with C–B (5 : 2) afforded XI (158 mg), and a last fraction which was eluted with benzene yielded XIV.

i) *m*-Quaterphenyl (XVII): colorless needles from ethanol; mp 86—87 °C (lit,[6] mp 85.5—86 °C); yield, 1250 mg.

Found: C, 93.80; H, 6.06%; mol wt (Rast), 314. Calcd for $C_{24}H_{18}$: C, 94.08; H, 5.92%; mol wt, 306.

ii) 2-Phenyltriphenylene (XIV): colorless needles from the C–B (5 : 2) mixture; mp 183—183.5 °C (lit,[34] mp 185 °C); yield, 200 mg.

Found: C, 94.74; H, 5.53%; mol wt, 306. Calcd for $C_{24}H_{16}$: C, 94.70; H, 5.30%; mol wt, 304.

Preparation of 2,2′-Di(4-biphenylyl)biphenyl (XIII). A mixture of III (9.8 g, 35 mmol) and IV (7.0 g, 17.5 mmol) was treated with copper powder (32 g, 500 mg-atom) at 265—270 °C for 1 hr and then at 270—280 °C for 1.5 hr. The hot benzene extract of the mixture was treated with the C–B (5 : 2) mixture to separate it into soluble and insoluble parts. Filtration and several crystallizations of the latter from benzene provided XV. The former, after the removal of the solvent, was dissolved in cyclohexane and subjected to chromatography on alumina. The cyclohexane eluted two fractions, which, upon recrystallization from ethanol, afforded VII (406 mg) and VIII (1357 mg). A mixture of C–B (5 : 1) eluted three fractions, which, after recrystallization, provided XII, XIII, and XIV (640 mg).

i) 2,4′-Diphenylbiphenyl (XII): colorless prisms from cyclohexane; mp 116—118 °C (lit,[35] mp 119—119.5 °C); yield, 50 mg.

Found: C, 94.45; H, 5.76%; mol wt, 307. Calcd for $C_{24}H_{18}$: C, 94.08; H, 5.92%; mol wt, 306.

ii) 2,2′-Di(4-biphenylyl)biphenyl (XIII): colorless rhombs from benzene; mp 192—194 °C (lit,[8] mp 189—190 °C); yield, 125 mg (1.6%). UV: λ_{max} (ε) 207 (86700), 240 (sh) (28100), 272 nm (51200).

Found: C, 94.43; H, 5.60%; mol wt, 451. Calcd for $C_{36}H_{26}$: C, 94.28; H, 5.72%; mol wt, 458.

iii) *p*-Quaterphenyl (XV): colorless plates from benzene; mp 318—319 °C (lit,[36] mp 317.7—318.7 °C); yield, 2200 mg.

Found: C, 94.38; H, 6.02%. Calcd for $C_{24}H_{18}$: C, 94.08; H, 5.92%.

Preparation of 3,3′-Di(2-biphenylyl)biphenyl (XVI). A mixture of I (3.5 g, 12.5 mmol) and V (2.5 g, 6.2 mmol) was heated with copper powder (13 g, 204 mg-atom) at 260—265 °C for 2 hr and at 270 °C for 1 hr. The hot benzene extract of the mixture was separated into three fractions by chromatography on alumina. A C–B (5 : 3) mixture eluted

two fractions, which provided VII (17 mg) and IX (1950 mg). Benzene eluted the third fraction, which, upon recrystallization from methanol, gave XVI. The elution with benzene afforded a colorless oil which was unidentified (1210 mg).

3,3′-Di(2-biphenylyl)biphenyl (XVI): colorless needles; mp 151.5—152 °C; yield, 155 mg (5.5%). UV: λ_{max} (ε) 194 (86500), 237 (74100), 252 nm(sh)(45400).

Found: C, 94.43; H, 5.90%; mol wt, 458. Calcd for $C_{36}H_{26}$: C, 94.28; H, 5.72%; mol wt, 458.

Preparation of m-*Sexiphenyl (XVIII).* A mixture of II (2.8 g, 10 mmol) and V (2.0 g, 5 mmol) was treated with copper powder (10 g, 160 mg-atom) under conditions similar to those used in the preparation of XVI. The hot benzene extract of the reaction mixture was chromatographed on an alumina column in the manner previously described. The two fractions which were eluted with a C–B (5 : 2) mixture gave VII (159 mg) and XVII (440 mg) respectively, while the next fraction, which was eluted with C–B (5 : 3), afforded XVIII.

m-Sexiphenyl (XVIII): colorless needles from cyclohexane; mp 145—146 °C (lit,[8] mp 146—147 °C); yield, 195 mg (8.6%). UV: λ_{max} (ε) 196 (72800), 205 (72300), 249 nm (101700).

Found: C, 94.05; H, 5.78%; mol wt (Rast), 465. Calcd for $C_{36}H_{26}$: C, 94.28; H, 5.72%; mol wt, 458.

Preparation of 3,3′-Di(4-biphenylyl)biphenyl (XX). A mixture of III (3.7 g, 13 mmol) and V (2.7 g, 6.6 mmol) was treated with copper powder (9.5 g, 150 mg-atom) at 260 °C for 1 hr and then at 280 °C for an additional hour. The hot benzene extract of the reaction mixture was digested with 120 ml of the C–B (5 : 2) mixture to give soluble and insoluble parts. Upon filtration, the filtrate was chromatographed on alumina, with the same solvent as the eluent, to give VII (8 mg) and XIX. The insoluble part was dissolved in benzene and then subjected to chromatography on alumina with benzene. Several crystallizations of the eluate afforded XX and XV (57 mg).

i) 3,4′-Diphenylbiphenyl (XIX): colorless needles from ethanol; mp 164—165 °C (lit,[4] mp 166—167 °C); yield, 201 mg.

Found: C, 94.04; H, 6.12%; mol wt (Rast), 309. Calcd for $C_{24}H_{18}$: C, 94.08; H, 5.92%; mol wt, 306.

ii) 3,3′-Di(4-biphenylyl)biphenyl (XX): colorless small plates from benzene; mp 257—258 °C (lit,[8] mp 247.5 °C); yield, 295 mg (9.7%). UV: λ_{max} (ε) 206 (79800), 273 nm (71200).

Found: C, 94.34; H, 5.83%; mol wt (Rast), 461. Calcd for $C_{36}H_{26}$: C, 94.28; H, 5.72%; mol wt, 458.

Preparation of 4,4′-Di(2-biphenylyl)biphenyl (XXI). A mixture of I (4.2 g, 15 mmol) and VI (3.0 g, 7.4 mmol) was heated with copper powder (15 g, 236 mg-atom), as has been described in the preparation of XVIII. The benzene extract was chromatographed on alumina in a manner previously used. A C–B (5 : 2) mixture eluted three fractions, which, upon treatment as above, gave VII (47 mg), IX (1063 mg), and XXI. Benzene eluted one fraction, which, upon recrystallization from benzene, provided XV (164 mg).

4,4′-Di(2-biphenylyl)biphenyl (XXI): colorless plates from benzene; mp 233—236 °C (lit,[10] mp 237.9—238.1 °C); yield, 304 mg (9.0%). UV: λ_{max} (ε) 202 (98700), 205 (sh) (97000), 250 (35700), 297 nm (38900).

Found: C, 94.08; H, 5.70%; mol wt (Rast), 470. Calcd for $C_{36}H_{26}$: C, 94.28; H, 5.72%; mol wt, 458.

Preparation of 4,4′-Di(3-biphenylyl)biphenyl (XXII). A mixture of II (6.3 g, 22.5 mmol) and VI (4.5 g, 11 mmol) was treated with copper powder (22.5 g, 350 mg-atom) as has been described in the preparation of XX. The benzene extract of the mixture was digested with 150 ml of the C–B (5 : 2) mixture to separate it into soluble [A] and insoluble [B] parts. After filtration, the filtrate was chromatographed on alumina, with the same solvent as the eluent, to give VII (510 mg) and XVII (1470 mg); further elution with benzene gave XIX (410 mg) and XXII. The insoluble part [B] and the xylene extract of the reaction mixture also gave additional XXII after chromatography on alumina with benzene, followed by several recrystallizations.

4,4′-Di(3-biphenylyl)biphenyl (XXII): slender, colorless plates from benzene; mp 287—288 °C (lit,[9] mp 280—281 °C; lit,[10] mp 287—288 °C); yield, 710 mg (14.0%). UV: λ_{max} (ε) 204 (80000), 256 (41700), 296 nm (51900).

Found: C, 94.13; H, 5.84%; mol wt, 465. Calcd for $C_{36}H_{26}$: C, 94.28; H, 5.72%; mol wt, 458.

The authors are indebted to the members of the Center of Elemental Analysis, Faculty of Pharmacy, Kyoto University, for the elemental analyses. Thanks are also due to Nippon Shinyaku Co., Ltd., for the measurements of IR spectra.

The Reaction of Cycloalkanones with Copper(II) Halides. II.[1] The Reaction of Cyclohexanones with Copper(II) Bromide

Kyoko Nishizawa* and J. Yasuo Satoh

Department of Chemistry, St. Paul's (Rikkyo) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received August 9, 1974)

The reaction of cyclohexanones with copper(II) bromide gave polybrominated cyclohexanediones in all cases except for the case of 3,5-dimethylcyclohexanone. Moreover, in this reaction, a pyrocatechol and a phenol derivative were obtained from 4-methyl- and 3,5-dimethylcyclohexanone respectively. The mechanism of this reaction was discussed.

Previously, the present authors reported that cyclohexanones reacted with copper(II) chloride in 50% dioxane to give polychlorinated cyclohexanediones in fairly good yields.[1,2] In this reaction, mono-, di-, and trichlorinated cyclohexanediones were obtained in good yields by controlling the quantity of copper(II) chloride and the reaction times. However, chlorocyclohexanone, which seems to be an intermediate from cyclohexanone to the cyclohexanediones, could not be isolated. This seems to be because α- and α,α'-chloro ketones are not as easy to crystallize as bromo ketone. Consequently, in the present work, in order to confirm the reaction mechanism by isolating bromo intermediates, the reaction of cyclohexanones with copper(II) bromide instead of copper(II) chloride was carried out.

Experimental

All the melting points are uncorrected. Thin-layer chromatography was carried out on silica gel (Wakogel B-5), and detected by means of iodine or an *o*-phenylenediamine–ethanol solution. Column chromatography was carried out on silica gel (Wakogel C-100). The IR spectra were measured with a Hitachi 215 grating infrared spectrophotometer by the KBr disk method, and the UV spectra, with a JASCO ORD/UV-5 spectrometer and a Hitachi 323 recording spectrophotometer in an EtOH solution. The NMR spectra were recorded in $CDCl_3$, unless otherwise noted, with TMS as the internal standard, with a Hitachi R-20A nuclear magnetic resonance spectrometer. The chemical shifts are presented in terms of the δ value. The mass spectra were obtained with a Hitachi RMU-7M mass spectrometer at 70 eV.

Reaction of Cyclohexanones with Copper(II) Bromide. The typical procedure was in accordance with that used in the case of copper(II) chloride described previously[1] under reflux for 0.5—2.5 hr. The reaction mixture was extracted with ether, and the extracts, after being washed and dried over Na_2SO_4, were evaporated under reduced pressure. The residue was purified by column chromatography to give the pure product.

Results and Discussion

The results are summarized in Tables 1 and 2. The NMR and IR spectra of the product from cyclohexanone showed the absorptions due to α-hydroxy-α,β-unsaturated ketone similar to those of the reaction product from cyclohexanone with copper(II) chloride; the product was identified as 3,6,6-tribromo-2-hydroxycyclohex-2-en-1-one (**3**).

In the reaction of 2- and 3-methylcyclohexanone, a product was obtained which, from its spectroscopic data, was identified as 6,6-dibromo-2-hydroxy-3-methylcyclohex-2-en-1-one (**4**), corresponding to the chloro compound.

In the case of 4-methylcyclohexanone, two products were isolated by column chromatography. The first product was determined to be 3,6-dibromo-2-hydroxy-5-methycyclohex-2-en-1-one (6), since it showed the absorptions due to an α-hydroxy-α,β-unsaturated ketone in the NMR and IR spectra and also a peak at 4.43 ppm (doublet, $J=3$ Hz) attributable to –CH(Br)– in the NMR spectrum. The second product had a peak at 2.61 ppm (singlet) attributable to aromatic methyl protons and a peak at 5.76 ppm (broad) attributable to the phenolic hydroxyl group; the ratio of their protons was 3 : 2 in the NMR spectrum. However, no peak due to aromatic protons was observed in the NMR spectrum. Accordingly, the product was identified as a hexasubstituted benzene derivative (**10**). In order to confirm that **10** can be formed through **6**, the reaction with 4-methylcyclohexanone was carried out for a longer time (2.5 hr). As a result, **6** was not obtained, but the yield of Compound **10** doubled (18%).

In the case of 3,4-dimethylcyclohexanone, it was deduced from the spectroscopic data that the product was 6,6-dibromo-2-hydroxy-3,4-dimethylcyclohex-2-en-1-one (**18**).

From the reaction of 3,5-dimethylcyclohexanone, three products were isolated by column chromatography. In the NMR spectrum of the first product, peaks were observed at 2.60 ppm (singlet) attributable to aromatic methyl protons and at 5.82 ppm (singlet) attributable to a phenolic hydroxyl group, the ratio of their protons being 6 : 1. Just as in the case of **10**, the absorption due to aromatic protons was not observed. Thus, this product was identified as a hexasubstituted benzene derivative (**17**). This identification was further confirmed by comparing the product with the sample produced from 3,5-dimethylphenol in a previously described manner.[3] The second product showed the absorptions due to an α,β-unsaturated ketone (1683 and 1607 cm^{-1}) in the IR spectrum. There was a peak at 1.43 ppm (doublet, $J=6$ Hz) due to methyl protons and one at 2.20 ppm (singlet) due to allylic methyl protons, but there were no peaks attributable to –CH(Br)– or hydroxyl groups in the NMR

a) Analyzed by high resolution mass spectrometry.

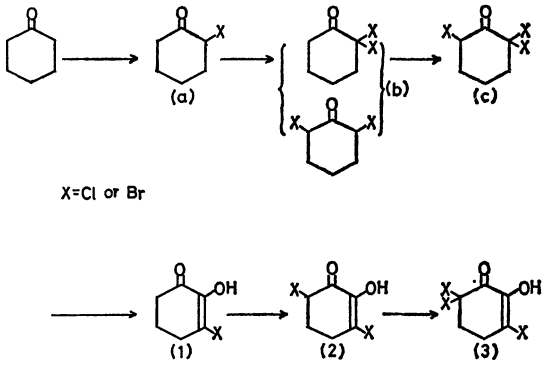
spectrum. From these data, the product was identified as 2,6,6-tribromo-3,5-dimethylcyclohex-2-en-1-one (**14**). The third product showed an absorption due to a saturated ketone (1725 cm^{-1}) in the IR spectrum, and no absorption due to unsaturated ketone in the UV spectrum. There was a peak at 1.25 ppm (doublet, J=6 Hz) attributable to methyl protons and one at 4.34 ppm (doublet, J=11.2 Hz) attributable to -CH(Br)-, the ratio of their protons being 3 : 1. Hence, the product was identified as a dibrominated cyclohexanone derivative (**11**).

In conclusion, the results of the present investigation of the reactions of cyclohexanones with copper(II) bromide can be summarized as follows: cyclohexanedione derivatives were obtained in all cases except in the case of 3,5-dimethylcyclohexanone; polysubstituted aromatic compounds were obtained in the cases of 4-methyl- and 3,5-dimethylcyclohexanone.

Now, the pathway for the formation of the polybrominated cyclohexanediones will be considered. The question of whether or not the liberated molecular bromine (Eq. 1) participates in the reaction of organic compounds with copper(II) bromide has been discussed in earlier reports:[4]

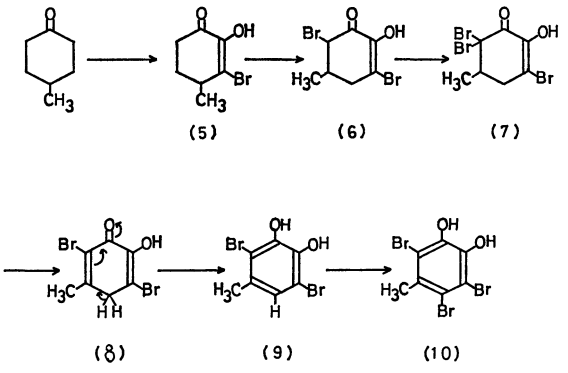
$$CuBr_2 \longrightarrow 1/2Br_2 + CuBr \quad (1)$$

Hence, the reaction of cyclohexanone with comparable amounts of bromine (15-fold molar) was carried out under the same conditions. 2,2,6,6-Tetrabromocyclohexanone [mp 118—120 °C (lit,[5] 122—123 °C)] was obtained in a quantitative yield, but neither **1**, **2**, nor **3** was obtained. Thus, it can be concluded that the reaction leading to cyclohexanedione derivatives is a specific reaction with copper(II) bromide. Considering this finding, together with previous results in the cases of reactions with copper(II) chloride,[1] a plausible mechanism for the formation of polyhalogenated cyclohexanediones is that shown in Scheme 1. **1** may be formed by the hydrolysis and dehydration of *gem*-dihalogen of Compound (**c**), followed by enolization.



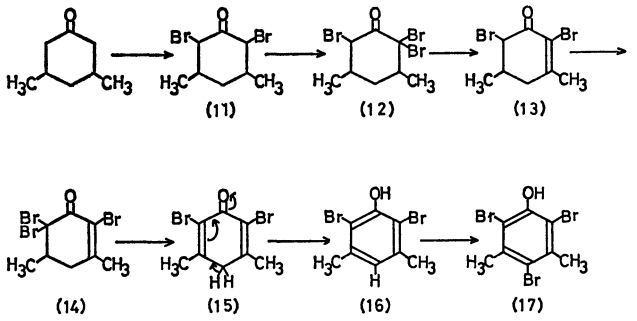
Scheme 1.

Next, the pathway to the pyrocatechol derivative will be considered. When the reaction with 4-methylcyclohexanone was stopped after only 30 min, the major product was **6**. In addition, the NMR spectrum indicated that Compound **7** [1.45 ppm (doublet, J= 6 Hz, $-CH_3$) and 2.05—2.88 ppm (multiplet, -CH- and $-CH_2-$)] exists in the filtrate as the minor product. From all the results in the case of 4-methylcyclohexanone, the following pathway was thus demonstrated (see Scheme 2). In the first stage of the reaction, **5** was produced through the pathway shown in Scheme 1, not affected by the methyl group because the methyl group in **5** was located in the γ-position with respect to the carbonyl group. The resulting **5** was further brominated to give **6** and then **7**. **7** was then led to **8** by dehydrobromination between the *gem*-bromine and the hydrogen on the adjacent tertiary carbon because of the larger steric hindrance due to the methyl group in **7** as compared with that in Compound **3**. **8** was subjected to enolization to give a more stable aromatic compound, **9** followed by bromination to the tetrasubstituted pyrocatechol derivative (**10**).



Scheme 2.

Lastly, the pathway to the phenol derivative will be considered. When the reaction with 3,5-dimethylcyclohexanone was stopped for 1 hr and the reaction mixture then treated in the usual way, the only resulting product was **11**. Hence, we propose the following pathway for the formation of **17** (see Scheme 3). The dehydrobromination and bromination of **12**, which is derived from **11**, gives **14**. The resulting **14** was subjected to dehydrobromination, followed by enolization to give a more stable aromatic compound, **16**. **16** was then brominated to give **17**. The last step is supported by a report[6] of halogenation at the *p*-position in the reaction of a phenol derivative with copper(II) halide.



Scheme 3.

We wish to express our appreciation to Professor A. Hagitani of Rikkyo University for his kind guidance and helpful suggestions in this work. Thanks are also due to Dr. S. Hishida, Naka Works, Hitachi Ltd., for his measurement of the high-resolution mass spectra.

NMR Studies of the Conformations of 3-Aryl-1,2,3-oxathiazolidine 2-Oxides

Fukiko YAMADA, Tomihiro NISHIYAMA, and Hiroshi SAMUKAWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Senriyama, Suita, Osaka 564

(Received October 30, 1974)

Proton magnetic resonance spectroscopy has been used to investigate the conformations of a series of 3-aryl-1,2,3-oxathiazolidine 2-oxides. Their conformations were assigned on the basis of the vicinal coupling constants between four methylene protons at the C-4 and C-5 positions. The oxathiazolidine 2-oxides prefer twist-envelope forms, and their conformations vary with both the situation and the nature of the ring substituent. Postulated collision complexes based on the data of the observed solvent-shifts can also be explained in terms of the differences in the conformations.

Recently, considerable attention has been directed to the elucidation of the conformations of heterocyclic compounds by NMR spectroscopy. However, only a few studies have been reported on the stereochemistry of the 1,2,3-oxathiazolidine 2-oxides. For example, Deyrup and Moyer reported that the sulfoxide bond was known to have an acetylenic-like anisotropy and that, therefore, the NMR spectra of the two isomeric 4- or 5-substituted 3-*t*-butyl-1,2,3-oxathiazolidine 2-oxides permitted the assignment of *cis* and *trans* geometry.[1] On the other hand, we ourselves have reported that twelve new 3-aryl-5-methyl- and 3-aryl-5-chloromethyl-1,2,3-oxathiazolidine 2-oxides have been prepared in good yields, and the configurations of their stereoisomers have been discussed on the basis of the NMR spectral data.[2] In continuation of our previous reports concerning the formation of 3-aryl-1,2,3-oxathiazolidine 2-oxides and their NMR and mass spectra,[3,4] this paper will report the results of NMR analyses of a series of 3-aryl-1,2,3-oxathiazolidine 2-oxides (**1**).

Experimental

Measurements. All the boiling and melting points are uncorrected. All the NMR spectra were determined at 100- and 60-MHz with Japan Electron Optics Model JNM-PS-100 and JNM-3H-60 spectrometers respectively. The chemical shifts were reported in ppm downfield from the internal TMS (δ). The coupling constants were determined from the spectra with a 270 Hz sweep width and a sweep time of 0.5—1.0 Hz/s. The IR spectra were recorded on a Shimadzu Model 27-G grating spectrophotometer on a KBr disk for the solid materials or a NaCl plate for the liquid materials. The glc analysis was carried out on a Shimadzu gas chromatograph, Model GC-5AP$_3$T, using a 2.15-m column packed with silicone SE-30 (10 wt%). The percentage composition of the product was estimated by means of the relative peak areas (uncorrected).

Compounds. A series of **1** was prepared by the reaction of the corresponding *N*-sulfinylanilines with ethylene oxide in the presence of lithium chloride as a catalyst, and was purified by distillation or recrystallization, as has been described in our previous papers.[2,3] The above reaction conditions and the properties of the compounds thereby obtained are listed in Table 1.

Results and Discussion

Sulfoxide Bond. The IR spectra of all the **1** compounds showed a characteristic band of the S=O group at 1155—1172 cm^{-1} (Table 1). In trimethylene sulfites, the S=O group prefers to be axial,[5] and the same conformational preference is found in six-membered ring sulfoxides.[6,7] The assignment of the axial and equatorial S=O groups has been made on the basis of the positions of the S=O stretching bands in trimethylene sulfites: 1190 cm^{-1} for an axial oxygen and 1230 cm^{-1} for an equatorial oxygen. In the case of ethylene sulfite, the position of the S=O stretching band 1193 cm^{-1} (neat) to 1214 cm^{-1} (cyclohexane) indicates a predominance of pseudoaxial conformers.[8] If this consideration can be extended to the **1** compounds, and assuming an equilibrium between pseudoaxial and pseudoequatorial conformers, the position of the S=O stretching bands of **1**, 1172 (neat) to 1182 cm^{-1} (carbon tetrachloride) would indicate a predominance of pseudoaxial conformers. An inspection of the molecular model also reveals that the **1** compounds exist in pseudoaxial conformers.

Methylene Protons. The NMR spectra of the methylene protons of the IIa, IIIc, IV, and VI compounds are shown in Fig. 1. All the **1** compounds displayed similar sets of methylene-proton multiplets of the representative ABCD pattern. That is, the two well-separated multiplets of an unequal height and width correspond to the two protons at the 5 position, while the other ones further upfield correspond to the protons at the 4 position.[2] Besides, according to S=O bond anisotropy, which exerts a stronger deshielding effect at the *cis*-position than at the *trans*-position,[1,2] the NMR signals of the H_a and H_c protons can be assigned multiplets in a lower field than those of H_b and H_d respectively.

The appearance of the NMR spectra of **1** gave well-defined patterns for the methylene-proton signals. We have, therefore, segregated the spectra into four types—A, B, C, and D, as can be seen in Fig. 1. The signals of Compounds I, IIb, IIc, IV, Vb, and Vc may all be

considered to belong to Type A. Similarly, those of Compounds IIa, IIIa, and Va appear to belong to Type B, and those of IIIb and IIIc, to Type C. Only the signal of VI belongs to a different Type, D.

The NMR spectra of **1** are of an almost pure first-order type, and all the coupling constants can be obtained by inspection. Small second-order effects can be observed on the basis of a comparison of the peak pattern at 100 MHz with that of 60 MHz. Theoretically, one of these methylene protons is individually split to octet lines because of coupling with the three other protons. Computor simulations of the observed signals were carried out using the five-spin system (No. 396) of the Japan Electron Opt. Co., Ltd., program.

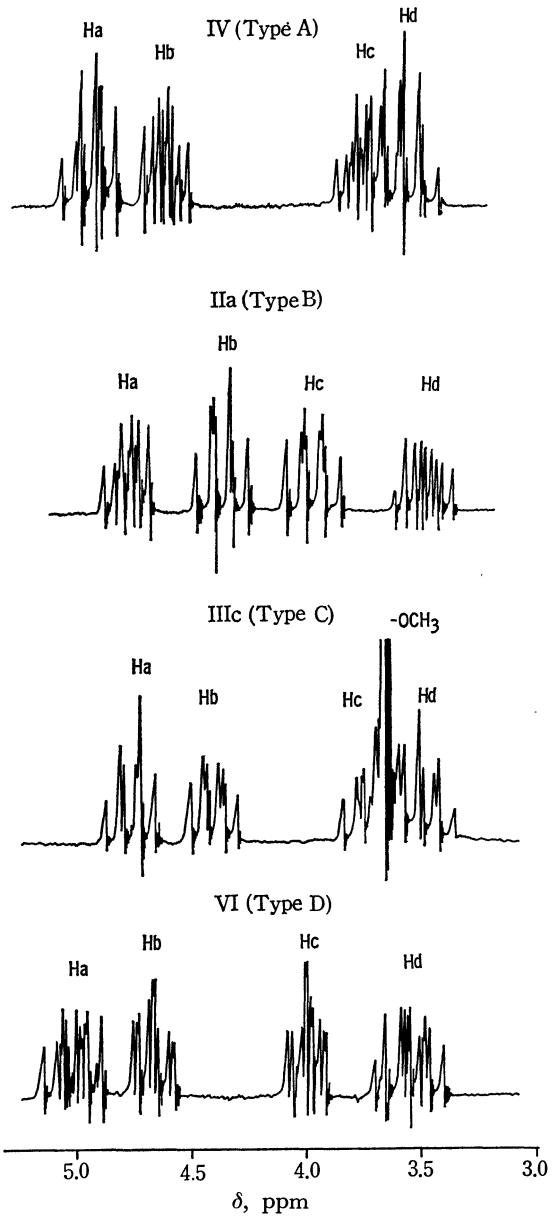

Fig. 1. 100 MHz NMR spectra of the methylene protons of **1** in CCl_4.

The agreement between the observed and calculated spectra was excellent. The NMR spectral data are listed in Table 2, while their coupling constants are summarized in Table 3.

As can be seen in Table 2, the differences between the chemical shift values for the geminal protons (H_a-H_b and H_c-H_d, δ ppm) may be due to the conformation of the oxathiazolidine ring. In the case of the compounds of Types A and C, the values of H_a-H_b and H_c-H_d are 0.34—0.37 and 0.22—0.26 ppm respectively. On the other hand, in the compounds of Types B and D, the above values are 0.36—0.41 and 0.27—0.51 ppm respectively. From the above results, it may be thought that the conformations of **1** vary with both the situation and the nature of the ring substituent, and that it is possible to distinguish them by the appearances of their methylene-proton signals.

Geminal Coupling. Two geminal coupling have been determined in this study (in Table 3); they were found to be in agreement with the values obtained for the other 3-aryl-5-methyl-1,2,3-oxathiazolidine 2-oxides (J_{cd}=8.3—8.8 Hz).[2]

Vicinal Coupling and Stereochemistry. In view of the results of the present investigation, the relevant distortions from the idealized stereochemistry of the **1** system, in which H_a is completely eclipsed by H_c and in which H_b is also eclipsed by H_d, involve torsional changes about the C-4 and C-5 bonds. These changes are most likely to be of two kinds, represented by the projections of **2** and **3** in Fig. 2.

A comparison of the pairs of entries in Table 3, where the electronegativities of the substituents are the same or similar, but where the substituents differ in position, leads to some suggestions. Thus, the much greater J_{ad} constants for Compounds IIb, IIc, IIIb, IIIc, Vb, and Vc than those of IIa, IIIa, and Va suggest that the distortions of the compounds with an *m*- or *p*-substituent are in the direction of the **2** projection, while those with *o*-substituents cause a distortion toward the **3** projection.

Williamson[9] and Laszlo and Schleyer[10] reported that the magnitudes of coupling constants between protons on adjacent saturated carbon atoms vary significantly with

changes in the electronegativity (ER) of the adjacent substituent and that the internal chemical shifts for the same protons also depend on the ER of the substituent. From this literature, values of approximately 1—2 ppm/ER unit for the chemical shift and 1—1.5 Hz/ER for the coupling constant are given. Such values, which can be obtained from Tables 2 and 3, are quite small in comparison with the values mentioned above. Besides, the plots of J vicinal *vs.* ER of **1** showed a considerable scatter. There seems to be no unequivocal correlation between the ER and the coupling constant. These facts indicate that the chemical shifts and the coupling constants in the series of **1** do not depend on the ER of the ring substituent. Furthermore, the nature of our system assures the constancy of other variables, for example, the C–C bond length and the H–C–C angle. It is, therefore, probable that the vicinal coupling constants of **1** depend only on each dihedral angle.

Assuming, as is mentioned above, that the most important factor determining the magnitude of the vicinal coupling constant is the dihedral angle, one may conclude that the J_{trans}(J_{ad} or J_{bc}) in **1** is more sensitive to distortions from perfect eclipsing than J_{cis} (J_{ac} or J_{bd}) because of the shape of the Karplus function. In this series of 12 compounds, J_{ad} varies from 4.5 to 10.3 Hz, and J_{ac} varies from 6.0 to 7.2 Hz (Table 3).

When the envelope conformation and various other conformational extremes are considered, there is found to be a wide range of variability in the stereochemical relationships between methylene protons of **1**. For the molecule existing in the ideal envelope conformation, the coupling constants, J_{ad} and J_{bc}, correspond to the dihedral angles of approximately 120 and 120° respectively. In this case, the ratio (r) of J_{ad} to J_{bc} in the five-membered ring of **1** is close to 1.0. On the other hand, Lambert[11] reported that the ratio (R) of the average $^3J_{trans}$ to the average $^3J_{cis}$ in the six-membered ring compounds is nearly independent of the ER of the substituents and become a direct measure of the conformational effects, and that the ratio was close to 2.0 for the molecules in the perfect-chair conformation. In our system, a further inspection of molecular model reveals that a decrease in θ will decrease J_{ad} (Projection **2** in Fig. 2) or J_{bc} (Projection **3**), whereas it will increase J_{bc} (Projection **2**) or J_{ad} (Projection **3**). Thus, the coupling constant caused by each torsion angle, θ, is given by the following Karplus eq.:[12]

$$r = (J_{ad}/J_{bc}) \text{ or } (J_{bc}/J_{ad}) = \frac{A - B\cos(120+\theta) + C\cos 2(120+\theta)}{A - B\cos(120-\theta) + C\cos 2(120-\theta)} \quad (1)$$

For the above eq. (1), a reasonable set of empirical parameters, $A=+7$, $B=+1$, and $C=+5$,[12] was employed. Then we attempted to use the $A=+8$ parameter in eq. (1) in order to get good results. The changes in θ caused by the distortions and the corresponding changes in J and r are listed in Tables 4 and 5 ($+30° \geq \theta \geq -30°$).

The tortion angles corresponding to the calculated r values (in Table 5) with the best agreement with the observed r values (Table 3) were found out to be as is shown in Table 3. Figure 3 shows the plots of the observed vicinal coupling constants *vs.* the dihedral angles with the calculated Karplus curves for both of the parameters, $A=+7$ and $A=+8$. In the case of the $A=+8$ parameter, the data clearly fall on the Karplus curve.

Calculated Karplus curves {—— in $A=8$ ---- in $A=7$

From these results, the conformations of **1** may be divided roughly into the following four groups:

Group 1. $\theta=10$—$15°$, $r=1.8$—2.2. The compounds of Type A, —that is, I, IIb, IIc, IV, Vb, and Vc, and IIIb—show this type of conformation.

Group 2. $\theta=-5$——$11°$, $r=1.3$—1.8. The compounds of Type B, IIa, IIIa, and Va, all with an *o*-substituent, show this type of conformation.

Group 3. $\theta=-5$—$+4°$, $r=1.2$—1.3. In IIIa and IIIc (Types B and C respectively), the two methylene groups are nearly eclipsed.

Group 4. $\theta\geq30°$, $r=4.7$. Compound VI, Type D, shows this conformation.

In Group 1, r is approximately 2.0 ± 0.2 (within 10—15%). In Group 3, both the r values are close to 1.0. The r of Group 4 shows an extremely large value; this indicates the presence of severe distortion in VI. Thus, deviations from $r=1$ indicate distortions from the envelope conformation.

It is interesting to compare these conformations with their chemical stabilities. Group 1 and Group 4 compounds are stable at room temperature. On the contrary, Group 2 and Group 3 compounds are unstable even at room temperature and are easily decomposed by water to the corresponding *N*-(β-hydroxyethyl)-anilines, as can be seen in Table 1.

Solvent-shift Studies. The NMR spectral data of **1** in a deuterobenzene solution exhibit benzene-induced shifts, as can be seen in Table 6. The proposed geometry of a benzene–solute collision complex of **1** is shown in Fig. 4. The results furnish considerable information on the stereochemical structure of the collision complex. (1a) In the case of Compounds I, IIb, IIc, and IIIb the solvent-shifts, $\Delta\delta_H$ ppm, for the different protons are in this order: $H_d>H_b>H_c>H_a$.

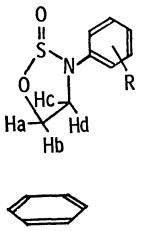

Fig. 4. Proposed geometry of benzene-solute collision complex of the oxathiazolidines.

This fact confirms the finding that the torsion angles in these compounds (Group 1) are found in the 10—15° range. In each compound, the $\Delta\delta_{Ha}$ value is smaller than the other three values; they are approximately 1.5 times H_a. This means that the co-ordinated benzene molecule exists rather closer to the C-4 atom than to the C-5 atom. (1b) On the other hand, Compounds IV, Vb, and Vc, all with a halogen substituent in Group 1, show this order of $\Delta\delta_H$ values; $H_d>H_c>H_b>H_a$. The values of the different four protons are somewhat greater than those of the corresponding protons in (1a) (*e.g.* $\Delta\delta_{Ha}$ in 1b$>\Delta\delta_{Ha}$ in 1a). These facts suggest that the co-ordinated benzene molecule in these compounds (1b) comes closer to the oxathiazolidine ring than with that of the compounds of (1a). (2) In the compounds with an *o*-substituent, IIa, IIIa, and Va, the $\Delta\delta_{Hc}$ values are somewhat smaller than the other three values. This indicates that the sign of the torsion angle of this group is negative compared with that of the compounds in Group 1.

TABLE 6. BENZENE-INDUCED SOLVENT SHIFTS $\Delta=[\delta(CCl_4)-\delta(C_6D_6)]$ FOR THE DIFFERENT PROTONS IN **1**

Compd. No.	Resonance					$(\Delta\delta_{Hc}-\Delta\delta_{Ha})/(\Delta\delta_{max}-\Delta\delta_{min})$
	H_a	H_b	H_c	H_d	CH_3 or OCH_3	
I	0.515	0.780	0.745	0.820	—	0.75
IIa	0.552	0.759	0.481	0.741	0.170	−0.26
IIb	0.475	0.725	0.675	0.760	0.240	0.70
IIc	0.445	0.680	0.605	0.715	0.215	0.59
IIIa	0.510	0.655	0.487	0.701	0.560	−0.11
IIIb	0.461	0.727	0.697	0.772	0.355	0.76
IIIc	0.485	0.770	0.580	0.725	0.390	0.39
IV[a)]	0.720	0.955	1.025	1.105	—	0.79
Va	0.620	0.705	0.520	0.805	—	−0.35
Vb[a)]	0.710	0.940	1.070	1.140	—	0.84
Vc	0.575	0.805	0.900	0.985	—	0.79
VI[a)]	0.590	0.820	0.745	0.730	—	—

a) $\Delta=\delta(CDCl_3(30\%)\text{-}CCl_4)-\delta(C_6D_6)$.

In IIa, the $\Delta\delta_H$ values show the order of $H_b > H_d > H_a > H_c$, and while in IIIa and Va the values show the order of $H_d > H_b > H_a > H_c$. (3) Compounds IIIa and IIIc, with a methoxy substituent, are considered to belong to this section. The $\Delta\delta_{Hb}$ value of IIIa is the smallest of all those of **1**; the value of $\Delta\delta_{Ha} - \Delta\delta_{Hc}$ is also the smallest of those of the compounds with an *o*-substituent,—that is, IIa, IIIa, and Va. In IIIc the $\Delta\delta_{Hd}$ value is relatively small and the value of $\Delta\delta_{Hc} - \Delta\delta_{Ha}$ is the smallest of the compounds in Group 1 and VI. In IIIa, the $\Delta\delta_H$ values show the order of $H_a > H_c$ and $H_d > H_b$, while in IIIc the order is $H_c > H_a$ and $H_b > H_d$. These facts indicate that the torsion angles of IIIa and IIIc are small and have either a positive or a negative sign. This result is quite consistent with the near-ideal envelope conformation of Group 3. (4) Compound VI, with tri-chloro substituents, shows the following effects. (a) The value of $\Delta\delta_{max} - \Delta\delta_{min}$, that is, $\Delta\delta_{Hb} - \Delta\delta_{Ha}$, is 0.230 ppm, the smallest of all those of **1**. (b) $\Delta\delta_{Hc}$ and $\Delta\delta_{Hd}$ are almost the same. From the above facts, we suggest that the co-ordinated benzene molecule exists at almost the same distance from both the H_c atom and the H_d atom.

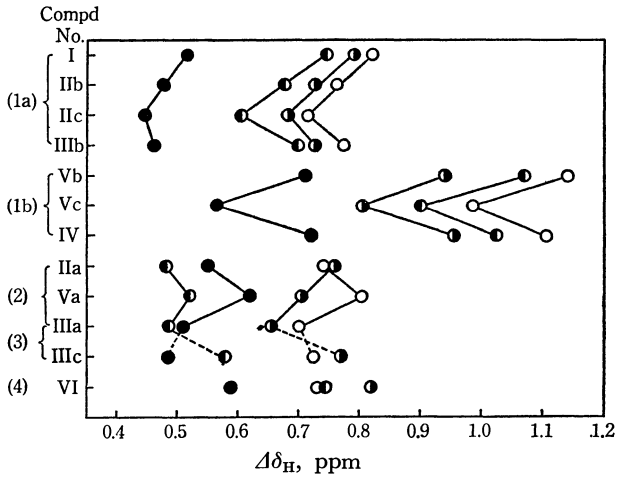

Fig. 5. Solvent-shift changes ($\Delta\delta_H$ obsd) of the methylene protons of **1**.
—●— H_a, —◑— H_b, —◐— H_c, —○— H_d

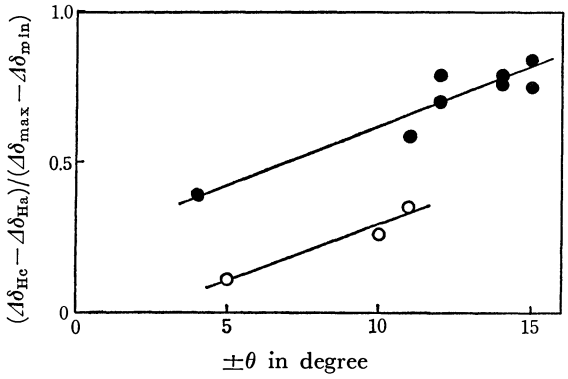

Fig. 6. Relationships between the values of $(\Delta\delta_{Hc} - \Delta\delta_{Ha})/(\Delta\delta_{max} - \Delta\delta_{min})$ and torsion angles θ.
●: I, IIb, IIc, IIIb, IIIc, IV, Vb, and Vc.
○: IIa, IIIa, and Va.

All the above phenomena are easily recognizable in Fig. 5. All the values of $(\Delta\delta_{Hc} - \Delta\delta_{Ha})/(\Delta\delta_{max} - \Delta\delta_{min})$ in **1**, except for VI, gave the proportional relationship with the θ angle, as can be seen in Fig. 6.

We are greatly indebted to Dr. Tadao Kamikawa of Osaka City University for recording the 100 MHz NMR spectra.

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

**Application Laboratory, Naka Works, Hitachi Ltd., Ichige, Katsuta-shi, Ibaragi 312*

(Received November 8, 1974)

High resolution mass spectra of shionane and friedelane derivatives were measured and characteristic fragmentation patterns were described.

In the course of structure study of shionone (**1**),[1] a triterpene ketone, $C_{30}H_{50}O$, isolated from roots of *Aster tataricus* L., low resolution mass spectra of shionone (**1**) and several derivatives were measured.[2] We now wish to describe studies on the characteristic fragmentation patterns of a shionane-type skeleton (**2a**) as well as those of a friedelane-type skeleton (**3a**) by high resolution mass spectrometry. These two frameworks bear a common partial structure in respect to A/B/C/D rings.

Courtney *et al.* examined the mass spectra of several friedelin derivatives and described fission patterns as shown in **A**. The cleavages **c**, **e**, and **f** were described to be characteristic for friedelin derivatives with a hydroxyl, an acetoxyl or a carbonyl group in ring E, **a** and **d** for compounds with a carbonyl group at C_3, and **b** and **g** for a friedelane skeleton.[3]

Later, Budzikiewicz *et al.* reported cleavages **b** and **g** as well as the subsequent fragmentations for friedel-18-ene (**4a**) and friedel-18-en-3-one (**4b**)[4].

In the high resolution mass spectra of methyl tri-, tetra-, and pentanorshionanoates (**5**, **6**, and **7**), obtained by degradation reactions of the side chain of shion-24-ene (**8**), prominent peaks are classified into two groups: one group consists of peaks which vary with the side chain length, and the other is composed of peaks which are independent of the side chain (Table 1).

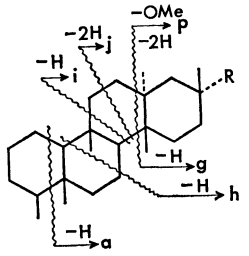
The peaks due to $(M-15)^+$, $(M-31)^+$, $(M-71)^+$, $(M-139)^+$, $(M-179)^+$, $(M-194)^+$, $(M-207)^+$, and $(M-239)^+$ showed characteristic shifts by 14 mass units for **5** and **6**, and for **6** and **7**. It is obvious that these peaks are due to the species including the side chain. These compounds exhibit the molecular ions and the $(M-15)^+$ ions with high intensities, as well as the $(M-31)^+$ ions due to a fission between the acyl group and the oxygen atom with weak intensities.

Species $(M-71)^+$, $(M-139)^+$, $(M-179)^+$, and $(M-207)^+$ due to fissions **a**, **h**, **i**, and **g**, respectively, are derived from the two-bond fission between a quarternary and a tertiary carbon atoms and between a tertiary or a quarternary and a secondary carbon atoms, followed by loss of an additional hydrogen from the charged species.

The species due to $(M-194)^+$ is originated by rupture of bonds C_8–C_{14} and C_{11}–C_{12}. Although the latter is a bond between two secondary carbon atoms, the fission **j** occurred with relative ease (relative intensities: 20, 10, and 36% for **5**, **6**, and **7**, respectively).

The (M–239) peaks, observed in the spectra of **5** and

6, are considered to be due to species **p** which could be derived by the fission **g** followed by loss of a methoxyl group and two hydrogen atoms. These fissions are shown as in **B**.



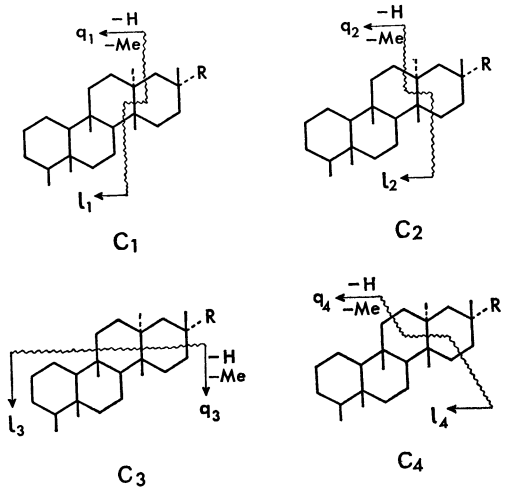
B

On the other hand, the peaks at *m/e* 329, *m/e* 259, *m/e* 233, *m/e* 217, *m/e* 205, *m/e* 193, *m/e* 191, *m/e* 179, *m/e* 177, *m/e* 149, *m/e* 137, *m/e* 135, *m/e* 123, *m/e* 109, *m/e* 95, *m/e* 81, *m/e* 69, and *m/e* 55 are independent of the side chain length.

The fragment **k** at *m/e* 329 ($C_{24}H_{41}$) is derived from the scission of the side chain of **5**, **6**, and **7**.

It has been reported that fission **b** due to two-bond fission between C_{13} and C_{18} and between C_{14} and C_{15} in friedelin (**3b**)[3,4] and friedel-18-ene (**4a**)[4] followed by loss of one hydrogen atom gives species at *m/e* 273 and 259, respectively. Although intense peaks due to fission **b** were observed in the spectra of friedelane derivatives (**3a**, **14**, and **15**), these peaks due to fission **b** in the spectra of **6** and **7** were rather weak. Friedelane derivatives and a few shionane derivatives were accompanied by species **b'**, derived from the two-bond fission **b** without loss of one hydrogen atom.

Peaks at *m/e* 233 ($C_{17}H_{29}$) were observed in the spectra of **5**, **6**, and **7**. The fragmentation process has remained obscure, because four alternative scissions such **1**$_1$, **1**$_2$, **1**$_3$, or **1**$_4$ including three-bond fission in ring C and D could be considered (**C**$_1$—**C**$_4$). The fragment **q** at *m/e* 217 ($C_{16}H_{25}$) observed for **2a**, **5**, **6**, and **8** is seemed to be due to scission **l** accompanied by loss of one hydrogen atom and a methyl group (**C**$_1$—**C**$_4$).



In a friedelane series, the corresponding scission **q** gives the peak at *m/e* 217 for **3a**, **4a**, and **15**, and a peak at *m/e* 233 for **14**.

By the two-bond fission of C_{12}—C_{13} and C_8—C_{14}, a charged species **m** (*m/e* 206) containing rings A and B was formed, which was followed by loss of a hydrogen atom to give species **m'** (*m/e* 205) for **5** and **6**. The counterpart to give a species **g** was discussed above.

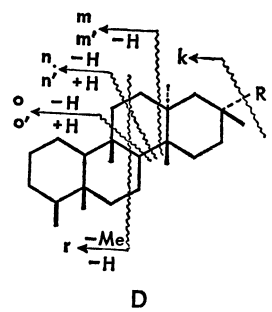
The two-bond fission of C_{11}—C_{12} and C_8—C_{14} could produce either a charged species containing rings A and B or ring D. The latter charged species gives a species **j**, mentioned above. The former charged species, on removal of a hydrogen atom, affords a species **n** (*m/e* 191) for **5**, **6**, and **7**, whereas by abstraction of an additional hydrogen atom from the leaving moiety gives species **n'** (*m/e* 193).

The species at *m/e* 177 due to fragmentation **o** is formed by cleavage of two bonds (C_8–C_{14} and C_9–C_{11}) followed by loss of an additional hydrogen atom from the charged species. This fission is visualized by the rupture involving the quarternary C_9 and C_{14} centers. In the case of **5**, the species **o** ($C_{13}H_{21}$, *m/e* 177.1642, obs. 177.1637) was accompanied by $C_{12}H_{17}O$ (*m/e* 177.1279, obs. 177.1280) with weak intensity, which was likely due to a species **p** derived from the two-bond fission of C_{12}–C_{13} and C_8–C_{14} accompanied by loss of two hydrogen atoms and a methoxyl group (*cf.* **B**). This was supported by the appearance of the corresponding peak at *m/e* 163.1106 ($C_{11}H_{15}O$) in the mass spectrum of **6**. The fragment ion **o** constitutes the counterpart of ion **i**.

The above mentioned fission of the two bonds (C_8–C_{14} and C_9–C_{11}) and a subsequent hydrogen abstraction gave species **o'**, which were observed with nearly the same intensities as those due to the species **o**.

Peaks **r** were observed at *m/e* 149 for **2a**, **5**, **6**, **7**, and **8** with considerably high intensities. It is considered that this peak is produced from the three-bond fission of C_6–C_7, C_8–C_9, and C_{11}–C_{12} followed by loss of one methyl group and one hydrogen atom. In friedelane derivatives, the corresponding rupture **r** gives peaks at *m/e* 149 for **15**, at *m/e* 163 for **3b**, and at *m/e* 165 for **9** and **14**.

Fragmentation patterns independent of the side chain length can be depicted as in **D**.



D

Although we can find other common peaks at *m/e* 263 ($C_{17}H_{27}O_2$ for **5** and **6**) and *m/e* 249 ($C_{16}H_{25}O_2$ for **5**, **6**, and **7**) for these compounds, it is likely that each fragment may be produced by a different mode of scission in each compound. These fragmentation patterns are therefore left undetermined.

than *m/e* 137 were examined by high resolution mass spectrometry. Since these species would be formed through multi-step fissions, their fragmentation patterns are not discussed here.

The high resolution mass spectra of shionone (**1**), shionane (**2a**), shionanone (**2b**), shion-24-ene (**8**), and shion-24-en-3β-ol (**9**) and the low resolution mass spectra of shion-3-ene (**10**), shion-25-ene (**11**), norshionan-25-one (**12**), and shionan-3β,29-olide (**13**) are well interpreted by the fragmentation patterns above mentioned (Tables 1 and 2).

The $C_{14}H_{23}^+$ (*m/e* 191) peaks in the mass spectra of shionone (**1**), shionanone (**2b**), and friedelin (**3b**) are considered to be derived from the fragment **m′** and subsequent loss of a carbon monoxide molecule.

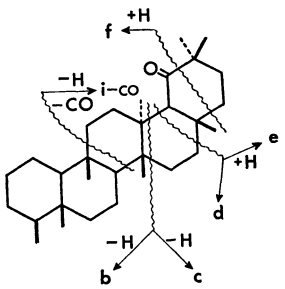
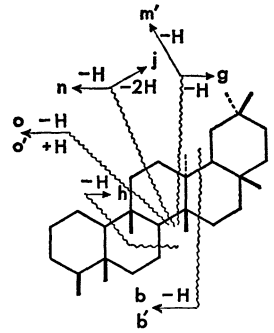
siderable changes in the fragmentation pattern of the friedelane skeleton. Among the fissions **b**, **c**, **d**, **e**, and **f** which are characteristic of a friedelane skeleton[3], two prominent peaks due to fissions **e** and **b** were observed in the mass spectrum of friedelan-19-one (**15**). The cleavage **f** seems to be not so important in the fragmentation of **15** (Figure **E**). A peak at *m/e* 219 was also observed. This ion could be explicable by the fragmentation (**i**—CO).



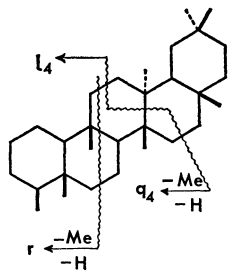
E

In conclusion, the cleavages **a**, **g**, **h**, **j**, **k**, **l**, **m** (**m**′), **n** (**n**′), **o** (**o**′), **q**, and **r** were shown to be characteristic of a shionane-type skeleton (**B**, **C**, and **D**).

The high resolution mass spectra of friedelin (**3b**), friedelane (**3a**), friedel-18-ene (**4a**), friedelan-3β-ol (**14**), and friedelan-19-one (**15**) confirmed the characteristic scissions **b**′ (or **b**) and **g** described earlier.[3,4] The fissions **h**, **j**, **l**,† **m** (**m**′), **n**, **o** (**o**′), **q**,† and **r** were also considered to be characteristic of a friedelane-type skeleton (**F** and **F**′).



F



F′

Peaks due to the species **a** appeared for all shionane derivatives. The cleavages **b** and/or **b**′ were observed constantly for friedelane derivatives, while peaks due to these scissions were absent in the spectra of some shionane derivatives (Tables 1 and 2). These observations are considered to be due to structure differences between the two skeletons of shionane and friedelane.

Experimental

The high and low resolution mass spectra were determined with a Hitachi RMU-7M double-focusing and a Hitachi RMU-6-Tokugata mass spectrometers, respectively, operating at 70 eV. The samples were introduced by direct inlet system at 100 to 180 °C. Shionane and friedelane derivatives were available from earlier studies.[1,2,5]

The Reaction of Aroyl Alkyl Carbonates with Isocyanates

Yuzuru UCHIDA and Seizi KOZUKA*

Department of Applied Chemistry, Osaka Institute of Technology, Asahi-ku, Osaka 535

**Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558*

(Received November 25, 1974)

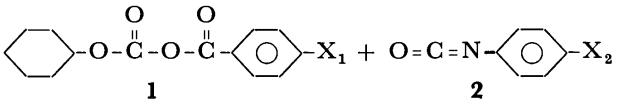
Aroyl alkyl carbonates were treated with isocyanates with or without addition of sodium methoxide and alkyl *N*-aroylcarbanilates were obtained as the major products. Based on ^{18}O tracer study and catalytic effect of alkoxide ion, a base catalyzed ionic reaction process was confirmed for the mechanism of the carbanilate formation.

Thermal decomposition of acyl alkyl carbonates giving esters has been known to proceed through two different mechanisms.[1] The one is a cyclic unimolecular process and the second one is an ionic mechanism involving alkoxide ion as a chain carrying agent. The structure of the starting material and the nature of the solvent are considered to have important roles in making a choice between the two mechanisms. These results suggest that if the reaction carried out with a second reactant, such as isocyanate which reacts facilely with alkoxide ion, the formation of the product through alkoxide ion as an intermediate would be interrupted.

Acyl alkyl carbonates, on the other hand, are also known as acylating reagents.[2] Thus, alkoxy-acylation of isocyanates giving *N*-acylcarbanilates can be expected by the reaction with acyl alkyl carbonates. We have now tried the reaction and wish to report our results focusing our attention mainly to the synthesis of *N*-aroylcarbanilate and the formation mechanism.

Results and Discussion

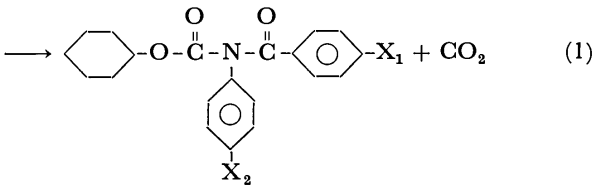
Cyclohexyl benzoyl carbonate (**1**) was heated with phenyl isocyanate (**2**) in *o*-dichlorobenzene as a solvent at 150—160 °C. As expected, the product obtained was cyclohexyl *N*-benzoylcarbanilate (**3**), along with the products apparently formed by thermal decomposition of the carbonate[3] such as esters, acid anhydrides and symmetrical carbonates.



1 **2**

X_1: NO_2, CN, Br, H, OCH_3

X_2: NO_2, H, CH_3



3 (1)

At the biginning of this study, the reaction was carried out without base. In the meantime, however, addition of a small amount of methoxide ion in the solution was found to complete the reaction much faster and with better result. Accordingly, the reaction was carried out with a small amount (*ca.* 15 mol%) of sodium methoxide. The results are given in Table 1.

The structure of the product was determined by the following observations. Namely, aroyl hydrazides (**4**)

Table 1. Reaction of aroyl alkyl carbonate and isocyanate

Reactant					Producct	
1	X_1	**2**	X_2	$NaOCH_3$	**3**	Yield %[a]
1a	CN	**2a**	H	none[b]	**3a**	36

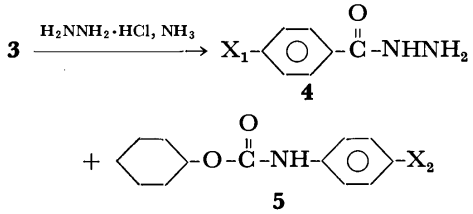
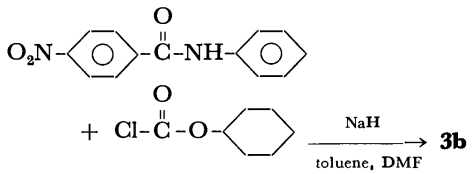
a) Yields of **3** were calculated based on **1**. b), c) See Experimental.

and cyclohexyl carbanilates (**5**) were obtained on treating **3** with hydrazine hydrochloride and ammonia in ether.



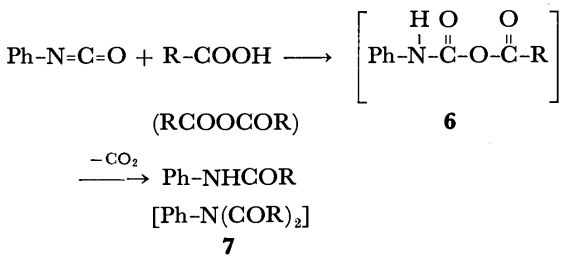
4 **5** (2)

Spectroscopic evidences and elemental analysis also confirmed this structure. The carbanilate **3b** was also prepared by the reaction of *p*-nitrobenzanilide, sodium hydride and cyclohexyl chloroformate.



(3)

The reaction of phenyl isocyanate with a carboxylic acid or anhydride, which appears to be an analogous reaction to the present reaction, was studied by Ötvös *et al.*[4] An unstable mixed anhydride **6** was suggested as an intermediate which led to an amide or imide **7** on decarboxylation.



(RCOOCOR) **6**

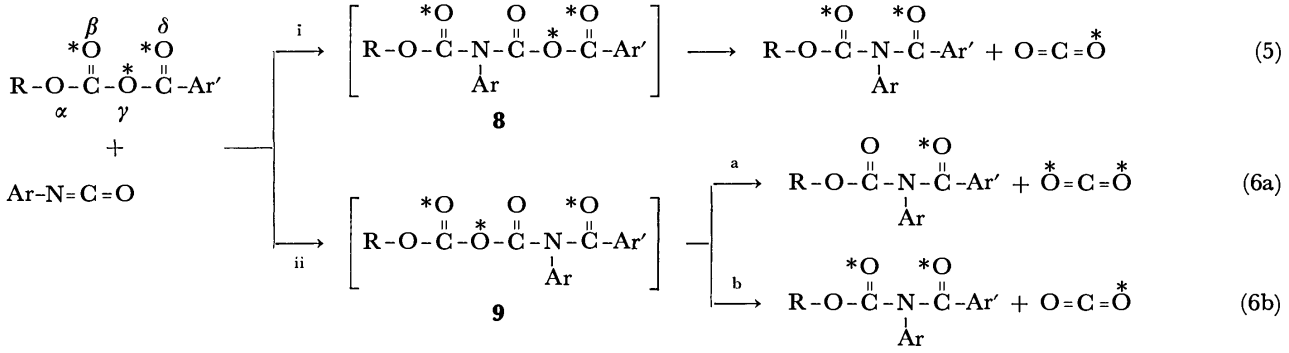
$-CO_2$

Ph-NHCOR

$[Ph\text{-}N(COR)_2]$

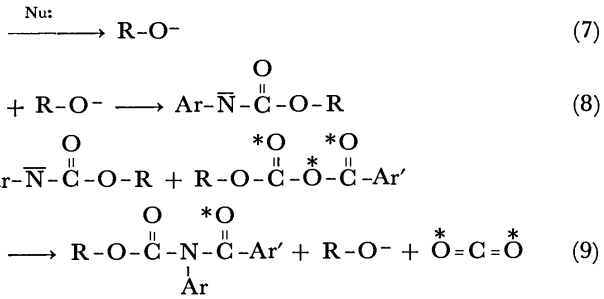
7 (4)

By analogy with this mechanism, there are two possible processes that can be shown for the present reaction as shown below.

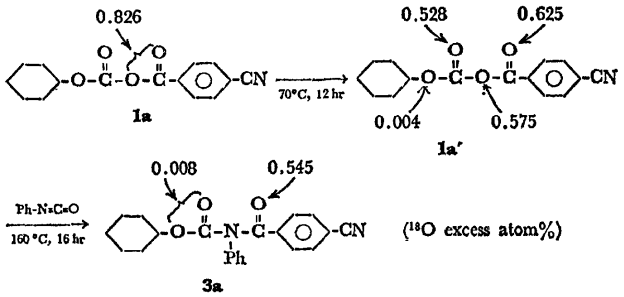


Nucleophilic attack of the aroyloxy group on the isocyanate results in formation of **8**. Attack of the γ-oxygen atom on the isocyanate with acyl-oxygen bond fission forms **9** as an intermediate. Decarboxylation of those intermediates lead to the product **3**.

The other possible process to give **3** is a base catalyzed reaction involving alkoxide ion as a catalyst. These processes can be distinguished by using ^{18}O labeled **1** at β, γ and δ oxygens as shown as asterisk in the equations, although the processes (6a) and (9) give the same results.



^{18}O Labeled **1a'** was prepared as follows:[5] The reaction of *p*-cyanobenzoic acid-^{18}O (0.826 excess atom%) with cyclohexyl chloroformate gave the carbonate **1a** which was then allowed to scramble ^{18}O by heating at 70 °C in CCl_4 for 12 hr. The ^{18}O distribution in **1a'** after heating was analyzed obtaining nearly complete ^{18}O scramblings among β, γ and δ oxygens. The reaction of the labeled **1a'** with phenyl isocyanate (**2a**) was carried out in *o*-dichlorobenzene without addition of sodium methoxide. After heating for 16 hr at 160 °C, **3a** was obtained in 36% yield. ^{18}O Content and distribution in **3a** were measured after the cleavage reaction shown in Eq. (2). The result is given in Scheme 1.



Scheme 1.

The ^{18}O in **3a** was found only at the benzoyl oxygen and the incorporation (0.545 excess atom%) concurred well to that of mean value of β, γ and δ oxygens of the starting **1a** (0.551 excess atom%). The result indicates that the starting **1a** scrambled ^{18}O completely among the three oxygens before reacting with the isocyanate. This was quite reasonable since the reaction with the isocyanate required a higher temperature (160 °C) than the oxygen scrambling reaction of the carbonate (70 °C).[5]

These results clearly ruled out the processes shown in Eqs. (5) and (6b) because only a negligible amount of ^{18}O was found in the carbanilate moiety in **3a**. The very small amount of ^{18}O seems to have originated from the ^{18}O in the alkoxide oxygen (α) of the starting material.

The base catalyzed reaction process shown in Eqs. (7)—(9) is the most probable mechanism between the two remaining possibilities because the reaction was catalyzed markedly by the addition of alkoxide ion.[6]

Experimental

Preparation of Aroyl Alkyl Carbonates. ^{18}O Labeled **1a** and **1d** were prepared in a similar manner reported in the previous paper. **1a**: mp 54.5—55.0 °C (lit,[5] mp 54.5—55.0 °C). **1d**: mp 21.0—22.0 °C (lit,[5] mp 21.0—21.5 °C). Carbonate **1b** was prepared as follows: An ether (50 ml) solution of triethylamine (15.0 g) was added dropwise into an ether (500 ml) suspension of *p*-nitrobenzoic acid (24.7 g) and cyclohexyl chloroformate (25.5 g) cooled in an ice bath. After stirring the mixture for additional 4 hr, water (200 ml) was added. The ether layer separated, was washed with dil. HCl, dil. aqueous $NaHCO_3$ and water then dried over Na_2SO_4. The solvent was evaporated under reduced pressure to give **1b** in 57% yield. mp 49.0—50.0 °C (from ether). Found: C, 57.31; H, 5.11; N, 4.77%. Calcd for $C_{14}H_{15}O_6N$: C, 57.33; H, 5.16; N, 4.78%. Carbonates **1c** and **1e** were obtained similarly in 79 and 87% yields, respectively. **1c**: mp 19.5—20.5 °C. Found: C, 51.41; H, 4.50%. Calcd for $C_{14}H_{15}O_4Br$: C, 51.39; H, 4.62%. **1e**: mp 59.5—60.5 °C. Found: C, 65.03; H, 6.34%. Calcd for $C_{15}H_{18}O_5$: C, 64.73; H, 6.52%.

Reaction of Aroyl Alkyl Carbonates with Isocyanates. A typical run was as follows: A mixture of **1b** (5.96 g), phenyl isocyanate (3.10 g) and sodium methoxide (0.15 g) in *o*-dichlorobenzene (25 ml) was heated at 160 °C for 1.5 hr. After evaporation of the solvent under reduced pressure, the residual

oily material was dissolved in ether (50 ml) and washed with water, dil. HCl, dil. aqueous $NaHCO_3$ and water then dried over Na_2SO_4. The crude product was purified through a colum chromatography on silica gel with benzene as an eluent then recrystallized from methanol obtaining **3b** (4.60 g). mp 103—104 °C. IR: 1735 and 1690 cm^{-1} ($\nu_{C=O}$). Found: C, 65.34; H, 5.48; N, 7.53%. Calcd for $C_{20}H_{20}O_3N_2$: C, 65.21; H, 5.47; N, 7.61%. Physical propaties and analytical results of other carbonates are as follows: **3a**: mp 105.0—105.5 °C. Found: C, 72.69; H, 5.66; N, 7.98%. Calcd for $C_{21}H_{20}O_3N_2$: C, 72.39; H, 5.79; N, 8.04%. **3c**: mp 90—91 °C. Found: C, 60.05; H, 4.93; N, 3.41%. Calcd for $C_{20}H_{20}O_3NBr$: C, 59.71; H, 5.01; N, 3.48%. **3d**: mp 77—78 °C. Found: C, 74.54; H, 6.59; N, 4.31%. Calcd for $C_{20}H_{21}O_3N$: C, 74.28; H, 6.55; N, 4.33%. **3e**: bp 228—233 °C/3 mmHg. **3f**: mp 97—98 °C. Found: C, 65.23; H, 5.42; N, 7.54%. Calcd for $C_{20}H_{20}O_5N_2$: C, 65.21; H, 5.47; N, 7.61%. **3g**: mp 81.5—82.5 °C. Found: C, 75.84; H, 6.96; N, 4.14%. Calcd for $C_{21}H_{23}O_3N$: C, 74.75; H, 6.87; N, 4.15%.

^{18}O Tracer Experiment. A solution of ^{18}O labeled **1a** (6.0 g) in CCl_4 (50 ml) was heated at 70 °C for 12 hr. The solvent was removed under reduced pressure and the residue was used for the reaction with **2a**. The same procedure described in the previous paper[5] was used for the determination of ^{18}O distribution in **1a** and **1a'**.

*Reaction of **3** with Hydrazine.* Anhydrous ammonia was bubbled into a mixture of **3a** (0.80 g) and hydrazine hydrochloride (0.80 g) in dry ether (50 ml) for 20 min with stirring at room temperature. The mixture was stirred for additional 7 hr. Cyclohexyl carbanilate (**5**) (0.50 g) was obtained from the ether solution by filtration. mp 83.5—84.5 °C (from $CHCl_3$-pet. ether) (lit,[7] mp 81—82 °C). The residue of the filtration gave *p*-cyanobenzhydrazide (0.20 g) on recrystallization. mp 197—198 °C (from methanol-CCl_4) (lit,[8] mp 198—199 °C).

^{18}O-Analysis was done by the same way as reported previously.[5]

*Preparation of Cyclohexyl N-(p-Nitrobenzoyl)carbanilate (**3b**).* A mixture of *p*-nitrobenzanilide (6.7 g) and NaH (1.5 g as 50% paste) in dry toluene (100 ml) was refluxed for 1 hr with stirring. Into the mixture, cyclohexyl chloroformate (4.5 g) in DMF (20 ml) was added with stirring at 70 °C. After stirring for additional 30 min, the mixture was then washed with dil. HCl, dil. aqueous $NaHCO_3$ and water then dried over Na_2SO_4. Removal of the solvent gave crude **3b** (7.2 g) which was recrystallized from methanol. mp 103—104 °C.

(Received December 13, 1974)

A new synthesis of 2-hydroxy-3-methyl-2-cyclohexen-1-one (**1**) is described. The Mannich reaction of cyclohexane-1,2-dione (**2**) or 2-morpholino-2-cyclohexen-1-one (**3**) with morpholine and formalin gave a Mannich base (**4**), which was then hydrogenolized to afford **1**. However, the Mannich reaction of **1** merely gave a bis-Mannich base (**22**), which was then similarly hydrogenolized to afford 3,6-dimethyl-2-hydroxy-2-cyclohexen-1-one (**7**) along with 3,6-dimethyl-2-hydroxy-6-morpholinomethyl-2-cyclohexen-1-one (**26**); 2-hydroxy-3,6,6-trimethyl-2-cyclohexen-1-one could not be obtained under these conditions. The Mannich reaction of other alicyclic α-diketones and the hydrogenolysis of their Mannich bases are also described.

2-Hydroxy-3-methyl-2-cyclohexen-1-one (**1**) has been known as a flavor constituent in coffee aroma.[2] Previous papers have described several routes to synthesize **1** from 2-ethoxycarbonyl-2-methylcyclohexanone.[3]

In this paper, we will investigate the orientation and reactivities of several alicyclic α-diketones in the Mannich reaction for the synthesis of **1**.

The Mannich reaction of cyclohexane-1,2-dione (**2**),[4] which exists almost entirely in the enolic form[5] with 1 equivalent of both morpholine and formalin in dioxane, afforded 2-hydroxy-3-morpholinomethyl-2-cyclohexen-1-one (**4**) in a good yield.

Furthermore, 2-hydroxy-3,6-bismorpholinomethyl-2-cyclohexen-1-one (**5**) was easily obtained by the treatment of **2** with two equivalents of both morpholine and formalin. On the other hand, the Mannich reaction of cyclopentane-1,2-dione with excess morpholine and formalin in dioxane have been shown to give 2-hydroxy-3-morpholinomethyl-2-cyclopenten-1-one (**6**) as the sole product. This is supposed to be attributable to the significant difference in the solubility of the mono-Mannich bases, **4** and **6**.

The Mannich base **4** was hydrogenolized with zinc powder in glacial acetic acid to give **1** in a 51% yield. Similarly, the Mannich base **5** afforded 3,6-dimethyl-2-hydroxy-2-cyclohexen-1-one (**7**) by a similar hydrogenolysis.

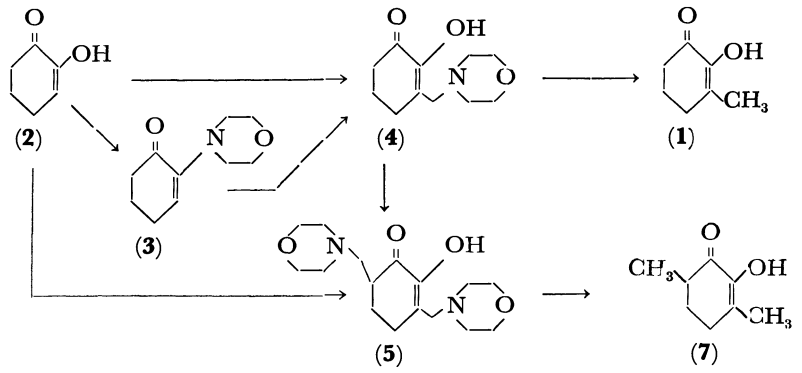
Then we examined the Mannich reaction of 2-morpholino-2-cyclohexen-1-one (**3**). Enaminoketone (**3**) could be obtained by refluxing **1** with morpholine in benzene.

The Mannich reaction of **3** with morpholine and formalin in various solvents, for example, dioxane, ethanol, and isopropyl ether, resulted in recovery of only the starting material. However, **4** was successfully attained in a good yield by the refluxing of **3** with morpholine hydrochloride and with paraformaldehyde in dioxane–ethanol, while no bis-Mannich base (**5**) could be isolated even when **3** was treated with two molar equiv. of both morpholine hydrochloride and paraformaldehyde.

Although no 2-morpholino-3-morpholinomethyl-2-cyclohexen-1-one could be obtained, the above results suggest that the substrate underwent morpholinomethylation in the form of enaminoketone. On the other hand, the Mannich reaction of 2-morpholino-2-cyclopenten-1-one with morpholine and formalin did not afford the corresponding mono-Mannich adduct, but it did readily give the bis-Mannich base.[6]

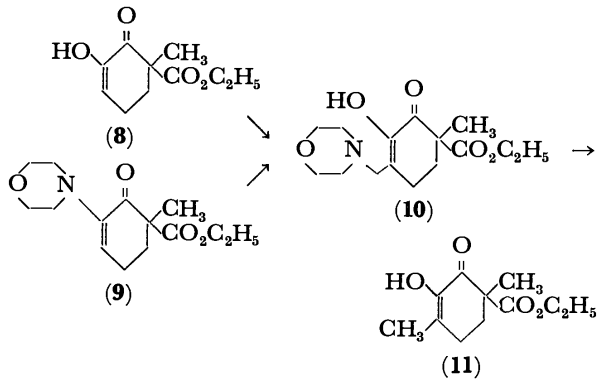
Enaminoketone may be represented by three principally contributing resonance structures.[7] The Mannich reactions of enaminoketones have revealed an interesting relationship between the product and the ring size, but the detail are uncertain. Cycloalkanones have been shown to give the corresponding Mannich bases by treatment with paraformaldehyde and with secondary amine hydrochloride.[8]

Since **3** is enolizable, it can not easily be determined whether the morpholinomethylation occurs at the enol site or at the enamine site. Therefore, we studied the Mannich reactions of nonenolizable ketons such as 6-ethoxycarbonyl-6-methyl-2-cyclohexen-1-one (**9**).[3]



** To whom all correspondence should be addressed.

6-Ethoxycarbonyl-2-hydroxy-6-methyl-2-cyclohexen-1-one (**8**) easily reacted with morpholine and formalin in dioxane at room temperature to give a Mannich base (**10**); this base was then hydrogenolized to afford 6-ethoxycarbonyl-2-hydroxy-3,6-dimethyl-2-cyclohexen-1-one (**11**).



(**8**) (**9**) (**10**) (**11**)

Under the same conditions, **9** did not react even when warmed at 55 °C. However, **9** reacted with morpholine hydrochloride and with formalin in dioxane-water at room temperature to form **10**. In this case, however, it is not clear whether the substrate undergoes morpholinomethylation in the form of **9** or **8**, which is formed after the hydrolysis of **9** under the present reaction conditions.[3] At least these results imply that α-diketone is more subject to morpholinomethylation than is enaminoketone.

On the basis of these results, it may be supposed that the Mannich reactions of enolizable enaminoketons proceed *via* electrophilic substitution by morpholinomethylation through the hydrogen-bonded complex between enol and amino nitrogen.[9]

Then we examined the Mannich reactions of 2-hydroxy-3-methyl-2-cycloalken-1-ones. Tonari and his co-workers[10] reported the Mannich reaction of 2-hydroxy-3-methyl-2-cyclopenten-1-one (**12**) to give a mono-Mannich adduct (**14**) in a 30% yield and obtained 2-hydroxy-3,5-dimethyl-2-cyclopenten-1-one by subsequent hydrogenolysis. However, their characterization of the mono-Mannich base was inadequate. Therefore, we reexamined the Mannich reaction of **12** with various secondary amines.

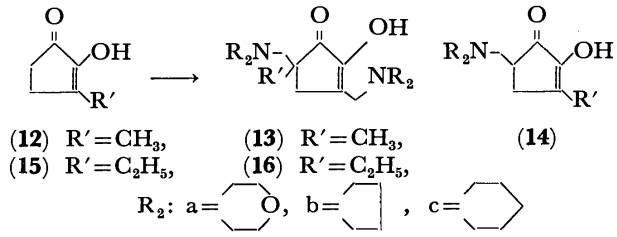
The Mannich reaction of **12** under the conditions previously reported[10] afforded 2-hydroxy-5-methyl-3,5-bismorpholinomethyl-2-cyclopenten-1-one (**13a**) in a 34% yield. The melting point of this crude crystals was compatible with the reported[10] mp of 115—6°C. The structure of **13a** was confirmed by analytical and spectral data, and no mono-adduct (**14**) could be obtained. This reaction was examined with various ratios of reagents; these ratios are shown in Table 1. Moreover, we examined the Mannich reaction of 3-ethyl-2-hydroxy-2-cyclopenten-1-one (**15**) under the various conditions listed in Table 1.

When diketone (**15**) was treated with equimolar amounts of formalin and morpholine in dioxane at room temperature, 5-ethyl-3,5-bis-morpholinomethyl-2-cyclopenten-1-one (**16**) was obtained as the sole product; the best yield was attained with two molar equivalents of both formalin and morpholine,

Table 1. The Mannich reaction of **12** and **15** under various conditions

Formalin (equiv.)	Amine	(equiv.)	Mannich base	Yield[a] (%)
1.0	Morpholine hydrochloride	1.0	**13a**	34.8[b]
1.0	Morpholine	1.0	**13a**	38.4
2.0	Morpholine	2.0	**13a**	70.3
1.0	Pyrrolidine	1.0	**13b**	34.5
2.0	Pyrrolidine	2.0	**13b**	53.6
2.0	Piperidine	2.0	**13c**	90.0
1.0	Morpholine	1.0	**16a**	30.9
2.0	Morpholine	2.0	**16a**	85.3
2.0	Pyrrolidine	2.0	**16b**	40.8
2.0	Piperidine	2.0	**16c**	80.6

a) Yields are based on diketone. b) Procedure by Tonari and coworkers.[10]

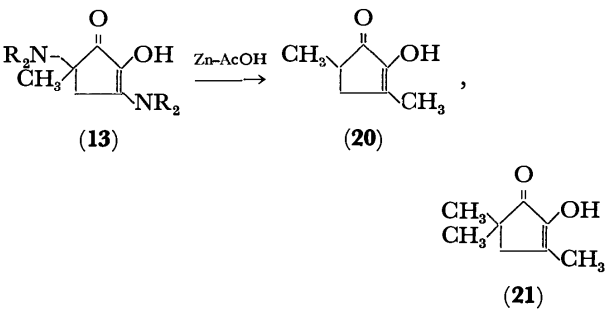


(**12**) R′=CH_3, (**13**) R′=CH_3, (**14**)
(**15**) R′=C_2H_5, (**16**) R′=C_2H_5,
R_2: a=O, b=, c=

The chemical properties and analytical characterization of **13** and **16** are summarized in Table **2**.

Then we studied the Mannich reactions of 2-cyclopentnones derived from **12**. The Mannich reaction of 2-pyrrolidino-5-methyl-2-cyclopenten-1-one (**17**)[11] with both formalin and pyrrolidine at −10 °C provided the bis-Mannich base (**13b**). However, efforts to introduce an aminomethyl group into such 2-cyclopenteneones with an electron-withdrawing group as 2-acetoxy-3-methyl-2-cyclopenten-1-one (**18**)[12] or 1-methyl-3-oxo-1-cyclopenten-2-yl *p*-toluene sulfonate (**19**) failed.

The hydrogenolysis of the Mannich bases **13a—c** with zinc powder in glacial acetic acid at 80 °C for 5 hr was accompanied by deaminomethylation to afford 3,5-dimethyl-2-hydroxy-2-cyclopenten-1-one (**20**); no trimethyl derivative (**21**) could be obtained under these conditions.



(**13**) (**20**) (**21**)

Then we examined the Mannich reaction of **1**. When **1** was treated with equimolar amounts of both morpholine and formalin, 2-hydroxy-6-methyl-3,6-bis-morpholinomethyl-2-cyclohexen-1-one (**22**) was obtained along with the recovered **1**.

The analytical data of **22** agreed with the $C_{17}H_{28}N_2O_4$

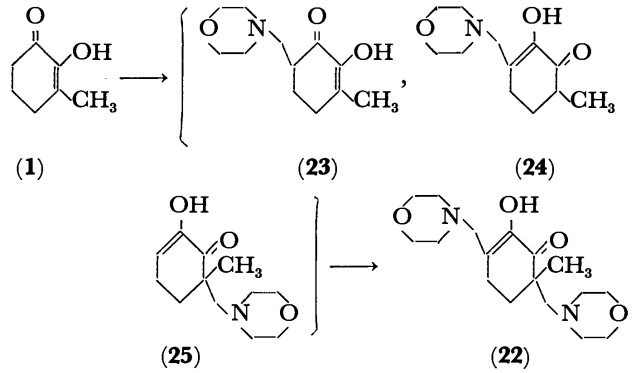
a) Recrystallization from ethanol. b) TMS was used as an internal standard. c) Hydrogen-bonded O-H. d) Recrystallization from petroleum ether-ethanol.

formula, and the structure was assigned on the basis of its IR, NMR, and UV spectra. This reaction was run with the various ratios of reagents listed in Table 3; the best yield was obtained with 2 molar equivalents of both morpholine and formaline.



(1) (23) (24)

(25) (22)

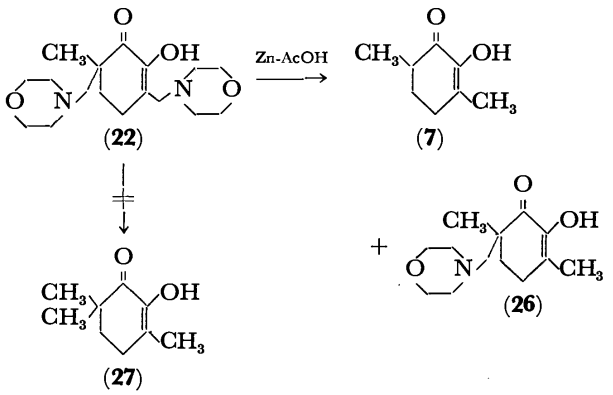
Table 3. The Mannich reaction of **1** under various conditions in dioxane

Morpholine (equiv.)	Formalin (equiv.)	Reaction Temp. (°C)	Reaction Time (hr)	Yield (**22**)[a] (%)
1.0	1.0	27—28 and 55—56	2.5 5.0	40[b]
1.6	1.6	34—35 and 55—56	22.0 3.0	67[b]
2.0	2.0	25—27	60.0	79.2

a) Isolated yield based on diketone. b) Diketone 1 was recovered.

In no case, could any mono Mannich adducts (**23**, **24**, or **25**) be isolated. These results imply that the second morpholinomethylation is faster than the first.

The hydrogenolysis of **22** with zinc powder in acetic acid at 73—76 °C for 6 hr also afforded a demorpholinomethylation product (**7**) (60%) and 2-hydroxy-3,6-dimethyl-6-morpholinomethyl-2-cyclohexen-1-one (**26**) (6.8%). Under these conditions, no trimethyl diketone (**27**) could be isolated.



(22) (7) (26) (27)

On the basis of these facts, it was supposed that the Mannich bases with a tertiary aminomethyl group could easily undergo deaminomethylation[13] in the hydrogenolyses described above.

The NMR spectra of 6-substituted-2-cyclohexenones (**7**, **11**, and **26**) indicate that the allylic methyl protons appear as a doublet (J=0.6 Hz) at 1.83—1.89 ppm. Further work is under way to elucidate the reason for the splitting of these allylic methyl protons.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Hitachi Model 215 spectrophotometer, and the UV spectra, with a Hitachi Model EPS-3T spectrophotometer. The NMR spectra were obtained on a JEOL Model C-60H spectrometer, with tetramethylsilane as the internal reference. The mass spectra were determined on a Hitachi RMU-6E spectrometer.

*2-Morpholino-2-cyclohexen-1-one (**3**).* A mixture of 4.6 g (41 mmol) of cyclohexane-1,2-dione, 4.5 g (51 mmol) of morpholine, and 100 ml of benzene was refluxed, while the water was removed, for 5 hr. After the removal of the benzene and the surplus morpholine, the residue was solidified. Recrystallization from isopropyl ether-ethanol gave 6.7 g (90.4%) of **3** as colorless crystals; mp 52.5—53 °C (lit,[14] mp 53—54 °C); IR(KBr) 3050 (=C-H), 1667 (C=O), 1605 cm^{-1} (C=C); NMR (CCl_4) δ *ca.* 1.95 (m, 2H), *ca.* 2.30 (m, 4H), *ca.* 2.70 (m, 4H), *ca.* 3.60 (m, 4H), 5.69 (t, 1H, J=3.9 Hz); UVmax (95% EtOH) 294 nm (ε=2450). Found: C, 66.24; H, 8.24; N, 7.58%. Calcd for $C_{10}H_{15}NO_2$; C, 66.27; H, 8.38; N, 7.73%.

*2-Hydroxy-3-morpholinomethyl-2-cyclohexen-1-one (**4**). A):* To a mixture of 2.80 g (25 mmol) of cyclohexane-1,2-dione in 3 ml of dioxane and 2.18 g (25 mmol) of morpholine, formalin (2.0 g, (25 mmol)) was added drop by drop, at room temperature and the mixture was then stirred for 3 hr. After the removal of the dioxane *in vacuo*, the residue was solidified. Recrystallization from isopropyl ether-ethanol gave 4.6 g (87.1%) of colorless crystals of **4**; mp 72—73 °C; IR(KBr) 3400 (O-H), 1665 (C=O), 1643 cm^{-1} (C=C); NMR (CCl_4) δ *ca.* 1.96 (m, 2H), *ca.* 2.38 (m, 8H), 3.08 (s, 2H), *ca.* 3.55 (m, 4H), *ca.* 5.73 (s, 1H); UVmax (95% EtOH) 274 nm (ε=8670). Found: C, 62.52; H, 8.06; N, 6.55%. Calcd for $C_{11}H_{17}NO_3$: C, 62.54; H, 8.11; N, 6.63%.

B): A mixture of 18.1 g (10 mmol) of **3**, 1.48 g (12 mmol) of morpholine hydrochloride, 0.36 g (4 mmol) of paraformaldehyde in 10 ml of dioxane, and 5 ml of ethanol was stirred for 6 hr under reflux. After cooling, the precipitated morpholine hydrochloride was separated, and the resulting mixture was diluted with ether, washed with water, and dried. After the evaporation of the solvent, trituration with isopropyl ether gave 1.75 g (83%) of **4**.

*2-Hydroxy-3,6-bismorpholinomethyl-2-cyclohexen-1-one (**5**).* To a mixture of 2.80 g (25 mmol) of **2** in 3 ml of dioxane and 5.22 g (60 mmol) of morpholine, formalin (4.8 g, (60 mmol)) in 1 ml of dioxane was added, drop by drop, at room temperature and the mixture was then stirred for 4.5 hr. After the removal of the dioxane *in vacuo*, the residual solid was recrystallized from isopropyl ether-ethanol to afford 6.28 g (85.2%) of **5**: mp 126.5—7.5 °C; IR (KBr) 3320 (O-H), 1672 (C=O), 1641 cm^{-1} (C=C); NMR (CCl_4) δ *ca.* 2.0 (m, 3H), 2.20—2.55 (m, 12H), 2.76 (s, 1H), 3.10 (s, 2H), *ca.* 3.45 (m, 8H); UVmax (95% EtOH) 277 nm (ε=6680). Found: C, 61.83; H, 8.53; N, 9.19%. Calcd for $C_{16}H_{26}N_2O_4$: C, 61.91; H, 8.44; N, 9.03%.

*2-Hydroxy-3-methyl-2-cyclohexen-1-one (**1**).* A mixture of 2.32 g (11 mmol) of **4**, 18.5 ml of glacial acetic acid, and 4.8 g (73 mg-atom) of zinc powder was stirred at 78—80 °C for 5 hr. After the zinc had then been filtered off and the acetic acid had been removed under reduced pressure, a small amount of water was added. The solution was subsequently extracted with chloroform. After drying, the chloroform was removed and the residue was chromatographed on a silica gel column. Elution with benzene-ethyl acetate (10 : 1) yielded 0.71 g (51.4%) of **1**; mp 60.5—61.5 °C (lit, [5] mp 63 °C). The spectral data were identical with those of an authentic sample.[3]

*2-Hydroxy-3,6-dimethyl-2-cyclohexen-1-one (**7**).* A mixture of 3.83 g (13 mmol) of **5**, 30 ml of acetic acid, and 8.45 g (0.13 g-atom) of zinc powder was stirred at 75—76 °C for 5 hr. After the zinc had then been filtered off and the acetic acid had been removed under reduced pressure, a small amount of water was added and the solution was extracted with chloroform. After drying, the solvent was evaporated and the residue was chromatographed on a silica gel column using benzene-ethyl acetate (10 : 1) to give 0.36 g (20%) of **7**; mp 61.5—62.5 °C; IR (KBr) 3420 (O-H), 1675 (C=O), 1650 cm^{-1} (C=C): NMR (CCl_4) δ 1.13 (d, 3H, J=7.0 Hz), 1.83 (d, 3H, J=0.6 Hz), 1.6—2.7 (m, 5H), 5.90 (s, 1H); UVmax (95% EtOH) 273 nm (ε=11900); mass *m/e* (%) 140 (41), 111 (80), 70 (83), 41 (100). Found: C, 68.08; H, 8.91%. Calcd for $C_8H_{12}O_2$: C, 68.55; H, 8.63%.

*6-Ethoxycarbonyl-2-hydroxy-3,6-dimethyl-2-cyclohexen-1-one (**11**). A):* To a mixture of 1.0 g (5 mmol) of **8** in 5 ml of dioxane and 0.40 g (5 mmol) of morpholine, formalin (0.4 g, (5 mmol)) in 1 ml of dioxane was added, at 14—15 °C and the mixture was then stirred for 3 hr. After removal of the dioxane *in vacuo*, we obtained a crude Mannich base (**10**) which was used without further purification for the next step. A mixture of the crude **10**, 18 ml of acetic acid, and 1.64 g (25 mg-atom) of zinc powder was stirred at 72—74 °C for 7 hr. After the zinc had then been filtered off and the acetic acid had been removed under reduced pressure, a small amount of water was added. After extraction with chloroform and drying with magnesium sulfate, the solvent was evaporated and the residue was chromatographed on a silica gel column. Subsequent elution with benzene-ethyl acetate (10 : 1) yielded 0.28 g (26%) of **11**; mp 46—48 °C; IR(KBr) 3440 (O-H), 1715, 1670 (C=O), 1640 cm^{-1} (C=C); NMR ($CDCl_3$) δ 1.22 (t, 3H, J=7.0 Hz), 1.40 (s, 3H), 1.89 (d, 3H, J=0.6 Hz), *ca.* 2.36 (m, 3H), 4.13 (q, 2H, J=7.0 Hz), 5.99 (s, 1H). Found: C, 61.87; H, 7.30%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%.

B): A mixture of 1.34 g (5 mmol) of **9**, 5 ml of dioxane, 0.62 g (5 mmol) of morpholine hydrochloride, and 0.40 g (5 mmol) of formalin was stirred at 50—55 °C for 4 hr. After having been worked up, the resulting mixture gave 1.20 g of crude **10**. To this Mannich base, 18 ml of acetic acid and 1.64 g (25 mg-atom) of zinc powder was added, the mixture was then stirred for 7 hr at 75 °C. A subsequent work-up in a manner similar to that described above afforded 266 mg (25%) of **11**.

*The Mannich Reaction of **12** with Secondary Amines: 2-Hydroxy-5-methyl-3,5-bismorpholinomethyl-2-cyclopenten-1-one (**13a**).* To 5.6 g (0.05 mol) of **12** in 50 ml of dioxane and 8.7 g (0.1 mol) of morpholine, a 8.1 g portion (0.1 mol) of formalin was added, drop by drop, at 0 °C. The mixture was then stirred at room temperature for several hours and allowed to stand overnight. After the subsequent removal of the dioxane under reduced pressure, the residue was solidified. Recrystallization from ethanol afforded 10.9 g (70.3%) of **13a**: mp 123—123.5 °C. The results with individual compounds under various conditions are shown in Table 1. The analytical data for **13a—c** are presented in Table 2.

*The Mannich Reaction of **15** with Secondary Amines: 5-Ethyl-2-hydroxy-3,5-bismorpholinomethyl-2-cyclopenten-1-one (**16**).* To 2.6 g (21 mmol) of **15** in 20 ml of dioxane and 3.7 g (42 mmol) of morpholine, formalin (3.4 g, (42 mmol)) was added at O °C. The mixture was then stirred at room temperature for several hours and kept overnight. The precipitated solid was recrystallized from ethanol to give 5.8 g (85.3%) of **16a**; mp 157—158 °C. The other results under various conditions are

shown in Table 1, while individual analytical data for **16a—c** are presented in Table 2.

*The Mannich Reaction of **17**: 2-Hydroxy-5-methyl-3,5-bispyrrolidinomethyl-2-cyclopenten-1-one (**13b**).* To 10.0 g (60 mmol) of **17** in 30 ml of dioxane and 8.6 g (0.12 mol) of pyrrolidine, a 9.8 g portion (0.12 mol) of formalin was slowly added, drop by drop at −10 °C, after while the mixture was stirred for 6 hr. The mixture was then stirred for 30 min at room temperature. After the subsequent removal of the solvent *in vacuo*, the resulting solid was recrystallized from petroleum ether-ethanol (10 : 1) to give 7.8 g (45.9%) of **13b**; mp 110.5—111.5 °C.

*1-Methyl-3-oxo-1-cyclopenten-2-yl p-Toluene Sulfonate (**19**).* To a stirred solution of 13.7 g (0.072 mol) of *p*-toluensulfonyl chloride in 4.7 g of pyridine, 6.7 g (0.06 mol) of **12** in 2.4 g of pyridine was added, drop by drop, with ice-water-bath cooling. The mixture was then stirred for 5 hr at 14—15 °C and the resulting mixture was poured into 60 ml of ice water. The precipitated crystals were filtered and recrystallized from petroleum ether-ethanol to afford 8.0 g (50.3%) of **19**; IR (KBr) 1710 (C=O), 1640 (C=C), 1585 cm^{-1} (aromatic (C=C); UVmax (99% EtOH) 229.5 nm (ε=24500); NMR ($CDCl_3$) δ 2.06 (s, 3H), 2.19—2.81 (m, 4H), 7.40 (m, 4H). Found: C, 58.97; H, 5.43%. Calcd for $C_{13}H_{14}O_4S$: C, 58.63; H, 5.30%.

*3,5-Dimethyl-2-hydroxy-2-cyclopenten-1-one (**20**). A)*: A mixture of 31.0 g (0.1 mol) of **13a**, 250 ml of glacial acetic acid, and 65.4 g (1 g-atom) of zinc powder was stirred at 80 °C for 5 hr. After the zinc had then been filtered off and the acetic acid removed *in vacuo*, 30 ml of water was added. The solution was then extracted with chloroform. After drying, the chloroform was evaporated and the residue was recrystallized from water to afford 5.1 g (40.5%) of **20**; mp 91—92.5 °C (lit,[6] mp 91—92 °C); IR (KBr) 3250 (O–H), 1690 (C=O), 1640 cm^{-1} (C=C); NMR ($CDCl_3$) δ 1.14 (d, 3H, J=7.5 Hz), 1.97 (t, 3H, J=0.6 Hz), 2.50 (m, 3H), 6.79 (s, 1H): UV max (99% EtOH) 261 nm (ε=12100). mass *m/e* (%) 126 (100), 111 (42), 83 (38), 79 (44), 56 (51). Found: C, 66.61; H, 8.10%. Calcd for $C_7H_{10}O_2$: C, 66.65; H, 7.99%.

B): Similarly, from 3.5 g (12.6 mmol) of **13b**, 35 ml of acetic acid, and 8.2 g (0.126 g-atom) of zinc powder, 0.50 g (31.4%) of **20** was obtained.

C): Similarly, from 3.10 g (10 mmol) of **13c**, 40 ml of acetic acid, and 6.5 g (0.1 g-atom) of zinc powder, 0.70 g (55.6 %) of **20** was obtained.

*2-Hydroxy-6-methyl-3,6-bismorpholinomethyl-2-cylohexen-1-one (**22**).* To a mixture of 0.60 g (4.75 mmol) of **1** in 3 ml of dioxane and 0.825 g (9.5 mmol) of morpholine, formalin (0.78 g, (9.5 mmol)) in 1 ml of dioxane was added slowly drop by drop at room temperature, and the mixture was stirred for 60 hr. After the removal of the dioxane *in vacuo*, the residue was diluted with a small amount of isopropyl ether to give white crystals. Recrystallization from isopropyl ether-ethanol afforded 1.22 g (79.8%) of **22**; mp 112—113 °C; IR (KBr) 3300 (O–H), 1674 (C=O), 1648 (C=C); NMR ($CDCl_3$) δ 1.05 (s, 3H), 1.6—2.3 (m, 4H), *ca.* 2.45 (m, 10H), 2.77 (s, 1H), *ca.* 3.69 (m, 8H); UVmax (99% EtOH) 274.5 nm (ε=8800). Found: C, 62.96; H, 8.68; N, 9.00%. Calcd for $C_{17}H_{28}N_2O_4$: C, 62.94; H, 8.70; N, 8.63%.

*Hydrogenolysis of **22** in Glacial Acetic Acid with Zinc Powder.* A mixture of 1.20 g (3.7 mmol) of **22**, 9 ml of glacial acetic acid, and 2.0 g (30.6 mg-arom) of zinc powder was stirred at 73—76 °C for 6 hr. After the zinc had then been filtered off and the acetic acid removed *in vacuo*, a small amount of water was added. The solution was then extracted with chloroform. After drying, the solvent was evaporated and the residue was chromatographed on 12 g of silica gel, using a 10 : 1 mixture of benzene-ethyl acetate as the eluent. An early fraction afforded 0.31 g (59.8%) of **7**: mp 61.5—62.5 °C. This compound was identical with the **7** derived from **4** as has been described above.

A later fraction gave 60 mg (6.8%) of **26**; mp 70—72 °C; IR (KBr) 3420 (O–H), 1670 (C=O), 1640 cm^{-1} (C=C); NMR (CCl_4) δ 1.00 (s, 3H), 1.83 (d, 3H, J=0.6 Hz), 1.90—3.0 (m, 10 H), *ca.* 3.49 (m, 4H), *ca.* 5.70 (broad s, 1H); UV_{max} (95% EtOH) 275 nm (ε=11800). Found: C, 65.58; H, 9.13; N, 5.88%. Calcd for $C_{13}H_{21}NO_3$: C, 65.25; H, 8.84; N, 5.85%.

A Study of the Kinetic Resolution of DL-Propylene Oxide with Optically Active Co(I)(salen) Type Complexes

Haruhiko Aoi, Michihiro Ishimori, and Teiji Tsuruta

Department of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Bunkyo-ku, Tokyo 113

(Received December 18, 1974)

An optically active Co(I)(salen) type complex, lithium *N,N'*-bis-(salicylaldehyde)-1(*R*),2(*R*)-1,2-*trans*-cyclohexanediiminatocobaltate (I), was prepared by reducing the Co(II) complex, *N,N'*-bis-(salicylaldehyde)-1(*R*),2(*R*)-1,2-*trans*-cyclohexanediiminatocobalt(II), with butyllithium. The structure of the Co(I) complex was determined by means of its absorption and circular dichroism (CD) spectra. D-Propylene oxide was found to react preferentially (*e.g.*, $\ll D/D+L \gg = 68\%$ in a dioxane solution) in a kinetic resolution of DL-propylene oxide using the above Co(I) complex as a catalyst. On the contrary, L-propylene oxide reacted selectively when Lewis acids were added to the system of the lithium Co(I) complex. The Lewis acids were demonstrated to interact with the Co(I) complex and to play a significant role in the asymmetric selectivity of the Co(I) species.

The square-planar tetradentate Schiff-base complexes of cobalt, such as cobaloxime[1] and Co(salen),[2] have been studied in relation to the coenzyme B_{12}. Few studies, however, have been done to explore the possibilities of an optically active Co(salen) type complex as a catalyst for any of the asymmetric reactions.

We reported in one of our previous papers[3] the kinetic resolution of DL-propylene oxide using an optically active Co(I) complex prepared by reducing an optically active Co(II)(salen) type complex, *N,N'*-bis(salicylaldehyde)-1(*R*),2(*R*)-1,2-*trans*-cyclohexanediiminatocobalt(II), Co(II)(sal)$_2$(*R*-CHXDA), with $LiAlH_4$; L-propylene oxide* was reacted in 95% selectivity.

In the course of further studies, it was found that D-propylene oxide, instead of the L-isomer, reacted preferentially when the Co(I) complex, prepared by reducing Co(II)(sal)$_2$(*R*-CHXDA) with butyllithium (BuLi), was used as a catalyst. This paper will describe the features of the kinetic resolution of DL-propylene oxide by use of the Co(I) complex prepared with BuLi. The effects of several metal alkyls and solvents on the asymmetric selectivity of the Co(I) complex will also be discussed in comparison with the case of the Co(II)(sal)$_2$(*R*-CHXDA)/$LiAlH_4$ system.

Experimental

Measurements. The absorption spectra were measured using a Shimadzu automatic recording spectrophotometer, Model MPS-50L. The CD spectra were taken on a Jasco Model J-20 spectrometer. The optical rotations were observed using a Perkin-Elmer Polarimeter Model 241. The glc analyses were carried out with a Hitachi Model K-53 Gas Chromatograph equipped with a column containing PEG.

Preparation of Cobalt Complexes. The reagents used were purified by the usual methods, as described elsewhere.[4] BuLi was prepared from *n*-butyl chloride and lithium metal; a cyclohexane solution of BuLi at the concentration of 1.42 mol/l was used. The Co(II)(sal)$_2$(*R*-CHXDA) was prepared by the method described in the previous paper.[3]

The Co(I) complex, Li$^+$[Co(I)(sal)$_2$(*R*-CHXDA)]$^-$, was prepared as follows: 0.05 mmol of Co(II)(sal)$_2$(*R*-CHXDA) was suspended in 50 ml of THF; then an equimolar amount of BuLi in cyclohexane added, and the solution was stirred for 1 hr at room temperature under a dry nitrogen atmosphere. A blue-green solution of the Co(I) complex was thus obtained. The evolved gases were analyzed by glc and calculated based on the amount of BuLi used. The Li$^+$[Co(I)(sal)$_2$(*R*-CHXDA)]$^-$/Lewis acid system was prepared by addition of an equimolar amount of a Lewis acid to the above solution of Li$^+$[Co(I)(sal)$_2$(*R*-CHXDA)]$^-$.

Reaction of the Co(I) Complex with DL-Propylene Oxide. 0.36 mmol of the Co(II) complex was suspended in a benzene (10 ml)/dioxane (5 ml) solvent (Tables 1 and 2) or an appropriate solvent (Tables 1 and 3); to which a cyclohexane solution of BuLi was added at the Co(II)/BuLi ratio of 1.0 or 2.0, after which the mixture was stirred for 2 hr at room temperature under a dry nitrogen atmosphere. In the case of the Co(I)/Lewis acid system (Table 2), a Lewis acid was added to the above solution at the ratio BuLi/Lewis acid=1.0 or 2.0, after which the mixture was stirred for 1 hr. Then 70 mmol of DL-propylene oxide was added to the above Co(I) solution. The mixture was sealed in an ampule under dry nitrogen and allowed to stand at 25 °C. After an appropriate reaction time, the non-reacted epoxide and acetone formed were analyzed by gas chromatography. The optical rotation of the recovered propylene oxide was measured.

The reaction of DL-propylene oxide with the Co(I) species prepared from the Co(II)/$LiAlH_4$ system was carried out similarly.

Results and Discussion

Preparation of Li$^+$[Co(I)(sal)$_2$(R-CHXDA)]$^-$. It has been reported that Co(II)(sal)$_2$(*R*-CHXDA) is a low-spin square-planar cobalt(II) complex with a λ conformation of the central chelate ring.[3] The absorption and CD spectra of the Co(I) species prepared by reducing Co(II)(sal)$_2$(*R*-CHXDA) with an equimolar amount of BuLi are shown in Figs. 1 and 2. The absorption spectrum in Fig. 1 is very similar to those of the reported Co(I) species[3] prepared by reducing Co(II)(sal)$_2$(*R*-CHXDA) with $LiAlH_4$ and with Na sand. The spectrum is also similar to that of Na$^+$[Co(I)(salen)]$^-$ observed by Calderazzo and Floriani.[5] Furthermore, by comparing the CD spectrum of the Co(I) species obtained from the Co(II) complex/BuLi system with that[3] of the Co(II) complex/$LiAlH_4$ system, these two Co(I) complexes are considered to have almost the same structure as to the co-planar ligand.

When the reaction of Co(II)(sal)$_2$(*R*-CHXDA) with

* L-propylene oxide: (*S*)-L-(−)-propylene oxide, D-propylene oxide: (*R*)-D-(+)-propylene oxide.

(c) Co(II)(sal)$_2$(*R*-CHXDA)/Na

BuLi was carried out in a benzene or toluene solvent, butane and 1- and 2-butene were evolved, while butane was evolved quantitatively in a dioxane solution. It is thus concluded that the Co(I) species, Li$^+$[Co(I)(sal)$_2$(*R*-CHXDA)]$^-$ was prepared with simultaneous formation of the butyl radical by the reaction between Co(II)(sal)$_2$(*R*-CHXDA) and BuLi.

Resolution of DL-*Propylene Oxide with Li$^+$[Co(I)(sal)$_2$(R-CHXDA)]$^-$.* According to a previous study,[3] L-propylene oxide was reacted selectively in a kinetic resolution of DL-propylene oxide using an optically active Co(I) complex prepared by the reaction of Co(II)(sal)$_2$(*R*-CHXDA) with LiAlH$_4$. The reacted propylene oxide was isomerized to acetone quantitatively in the system at the ratio Co(II)/LiAlH$_4$=3.0, where the asymmetric selectivity** was very high, $\ll$L/D+L$\gg$ = 95%. On the other hand, at the ratios Co(II)/LiAlH$_4$ =1.5 and 1.0 the apparent percentage of acetone formed** and the asymmetric selectivity had lower values. This phenomenon was ascribed to side reactions involving the LiAlH$_4$ which remained in the system because of the incomplete reaction between LiAlH$_4$ and the Co(II) complex.

On the other hand, the reaction of BuLi with the Co(II) complex proceeds almost completely, resulting in the formation of a simple system of the Co(I) complex, which may be anticipated from the spectral similarity to behave as a catalyst similar to the Co(II)(sal)$_2$(*R*-CHXDA)/LiAlH$_4$ system.

In a typical experiment carried out in a benzene/dioxane mixed solvent, the reacted propylene oxide was found to be isomerized to acetone quantitatively even at the Co(II)/BuLi ratio of 1.0, the Co(I) species being recycled as shown by the recycling number of the catalyst, given in Table 1. Contrary to the anticipation from the spectral similarity between the Co(II) complex/LiAlH$_4$ system and the Co(II) complex/BuLi system, D-propylene oxide was preferentially reacted in the reaction with the latter catalyst. Resolution reactions with the Co(II)/BuLi system were carried out in various solvents, as summarized in Table 1. A group of solvents, such as dioxane, tetrahydrofuran, toluene, and cyclohexane, was found to favor the reaction with D-propylene oxide over the L-isomer, whereas benzene exhibited the opposite effect. For comparison, the solvent effect on the reaction with the

Co(II)/LiAlH$_4$ system was next examined. The Co(II)/LiAlH$_4$ system was found to attack L-propylene oxide selectively, regardless of the nature of the solvents used, as shown in Table 2. The selectivity is much higher than that of the Co(II)/BuLi system.

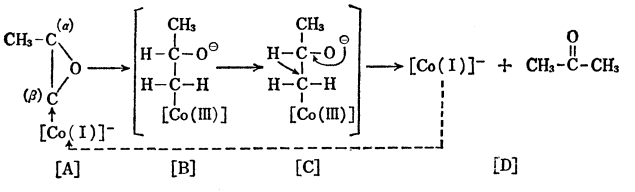
The remarkable difference in asymmetric selectivity between the Co(II)/BuLi and Co(II)/LiAlH$_4$ systems is of particular interest. It might be suspected that the AlH$_3$ moiety in the Co(II)/LiAlH$_4$ system interacts, as a Lewis acid, with the Co(I) species and plays a significant role in the asymmetric selectivity. Thus, the effect of a Lewis acid on the selectivity of the Co(I) species obtained from the Co(II) complex and BuLi was studied in the dioxane/benzene solvent. The results are summarized in Table 3. As expected, L-propylene oxide was preferentially consumed in a series of reactions involving triisobutylborane, triisobutylaluminum, dibutylzinc, and triethylindium as a Lewis acid, respectively. The results strongly suggest that the Lewis acids interact with the Co(I) species to form a "complex," for instance, Li$^+$[Co(I)]$^-$·Lewis acid. The selection for L-propylene oxide was observed even at the ratio Co(II)/BuLi/Lewis acid=2/2/1, where comparable amounts of Li$^+$[Co(I)]$^-$ and Li$^+$-[Co(I)]$^-$·Lewis acid are considered to co-exist, the apparent selectivity ≪L/D+L≫ being lowered by the presence of the Li$^+$[Co(I)]$^-$, which prefers D-propylene oxide. The low selectivity for L-propylene oxide at the ratio Co(II)/BuLi/InEt$_3$=2/1/1 and the selection of D-propylene oxide at the 2/2/1 ratio can be explained by the weak interaction between the Co(I) complex and InEt$_3$ because of the weak Lewis acidity of InEt$_3$.[8]

It has been reported that a Lewis acid such as trialkylaluminum reacts with acetone.[9] In the series of reactions in Table 3, however, the reacted propylene oxide was converted to acetone almost quantitatively, and no further reaction was observed. The Lewis acids may be stabilized by complexation with the Co(I) species, as has been described.

It is considered that the Co(I) species of the Co(II)/LiAlH$_4$ system is present as a complex, Li$^+$[Co(I)(sal)$_2$-(*R*-CHXDA)]$^-$·AlH$_3$, in accordance with the asymmetric selectivity being similar to that of the Co(II)/BuLi/Lewis acid system.

Mechanism for the Kinetic Resolution of DL-*Propylene Oxide.* A probable mechanism for the resolution of DL-propylene oxide and the isomerization of propylene oxide to acetone was previously discussed.[3] As shown in Scheme 1, the Co(I) species attacks the β-carbon of propylene oxide by an S_N2 mechanism, thus forming Co–C bonding; this is followed by isomerization of the propylene oxide moiety to acetone, the Co(I) species regenerated being recycled as a nucleophilic reagent.

The kinetic resolution is considered to take place at



Scheme 1.

Table 4. The CD spectra of $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-$, $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-\cdot Al(i\text{-Bu})_3$ and $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-\cdot AlH_3$ in THF

	$\tilde{\nu}\times10^{-3}$ cm^{-1} and $\Delta\varepsilon$ in parentheses			
$Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-$	28.3	23.0	19.8	16.1
	(+2.15)	(+1.21)	(−0.95)	(−3.03)
$Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-\cdot Al(i\text{-Bu})_3$	28.2	22.7	19.4	16.1
	(+1.84)	(+1.21)	(−0.97)	(−2.93)
$Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-\cdot AlH_3$	—	22.4	19.9	16.3
		(+2.08)	(−2.06)	(−5.39)

the stage [A] in Scheme 1. The Co(I) species reacts with either D- or L-propylene oxides preferentially, leaving unreacted propylene oxides containing a higher ratio of the other enantiomer. The CD spectra were measured in order to clarify the difference in asymmetric selectivity between the Co(II)/BuLi system and the Co(II)/BuLi/Lewis acid system. The CD spectra of the Co(II)/$LiAlH_4$ system and the Co(II)/BuLi/Lewis acid systems exhibit shapes similar to, but with slight band shifts† compared to, that of the Co(II)/BuLi system, as is shown in Table 4; this indicates that these Co(I) complexes have almost the same structure as to the inplane ligand, with a λ conformation of the central chelate ring similar to that of $Co(II)(sal)_2$-(*R*-CHXDA). In the light of the structure of trialkyltin-cobaloxime(I), Ph_3Sn–$Co(Dmg)_2$·Base, with a bond nature of Sn^+–$Co(I)^-$ reported by Schrauzer and Kralel,[10] it may be considered that the lithium cation is situated above the square plane of the Co(I) complex. Some information has been previously presented as to the site of Lewis acids in Co(salen) complexes. In Co(II)(salen)·$CHCl_3$,[11] Co(II)(salen)·InX_3,[12] Co(II)(salen)·SnX_4[13](X: halogen), and CH_3·Co(III)(salen)·H_2O-metal salt complexes,[14] it has been reported that $CHCl_3$ is combined with a phenolic oxygen by hydrogen bonding and that the metal atoms of Lewis acids form bonding with two phenolic oxygens.

On the basis of the above discussions, a possible structure for $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-$·Lewis acid including $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-\cdot AlH_3$ is depict-

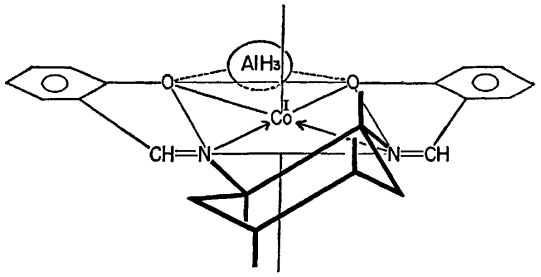


Fig. 3. A possible structure for $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-\cdot AlH_3$.
The structure without AlH_3 moiety corresponds to that for $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-$.

† The shifts are considered to reflect the interaction between the Co(I) species and Lewis acid.

†† The selectivities of the Co(II)/BuLi/Lewis acid systems can be interpreted in terms of those of mixed species, $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-$·Lewis acid and $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-$.

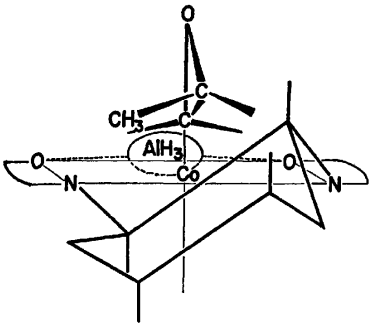

Fig. 4. Probable stereochemistry in the selection of a propylene oxide molecule by $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-\cdot AlH_3$.

ed in Fig. 3. It should be easier for an incoming propylene oxide molecule to assume an orientation onto the active site as shown in Fig. 4; the bulky methyl group of propylene oxide and the Schiff-base ligand are far apart, because the left part of the diamine chelate is fixed below the square N_2O_2-plane due to the λ conformation. The chiral steric circumstance around the active site is established by the λ conformation of the central chelate ring, in co-operation with the Lewis acid moiety combined with pehnolic oxygens, which restricts the modes of orientation of the propylene oxide molecule. As shown in Fig. 4, L-propylene oxide would much more easily come to the Co(I) species, resulting in the high selectivity of the Co(II)/$LiAlH_4$ system to the L-isomer. Any orientation of D-propylene oxide could not be so easy as that of L-propylene oxide in Fig. 4 because of the steric hindrance caused by the right part of the diamine chelate fixed above the N_2O_2-plane and by the phenyl-azomethine parts and the AlH_3 placed on the same N_2O_2-plane, which were shown by the molecular-model consideration. In the absence of the Lewis acid moiety, the much smaller steric requirement around the active center would allow an incoming monomer to assume the orientation in a less specific way. According to our observation, D-propylene oxide exhibited a preference to the L-isomer in the reaction with $Li^+[Co(I)(sal)_2(R\text{-CHXDA})]^-$, though strong steric interaction between the Co(I) complex and the monomer may not be expected.†† The selection of L-propylene oxide by the Co(II)/BuLi system in benzene seems to be rather strange. Of interest, however, are the results of the X-ray analysis of the Co(II)(BAE)·benzene complex reported by Brückner *et al.*,[15] where benzene is fixed to the two phenolic oxygen atoms by the van der Waals distances. If such a specific fixation of benzene around phenolic

oxygens is also present in the Co(II)/BuLi system, a chiral structure similar to that of the $Li^+[Co(I)(sal)_2$-(*R*-CHXDA)]$^-$·Lewis acid system might be established around the active site.

Component Amino Acids of the Antibiotic Longicatenamycin. Isolation of 5-Chloro-D-tryptophan[1]

Tetsuo SHIBA, Yasuo MUKUNOKI, and Hitoshi AKIYAMA

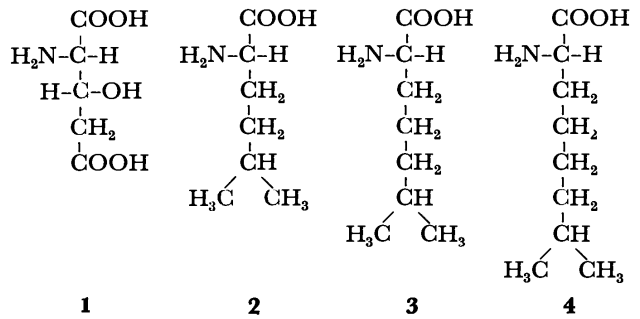
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received January 6, 1975)

An amino acid composition of the peptide antibiotic longicatenamycin was investigated. Four new amino acids, *i.e.*, *threo*-β-hydroxy-L-glutamic acid, L-2-amino-5-methylhexanoic acid, L-2-amino-6-methylheptanoic acid, and L-2-amino-7-methyloctanoic acid, which were reported by Shoji *et al.*, were reconfirmed by comparison with the synthetic specimens. Racemic forms of the latter three amino acids were synthesized through acetaminomalonate method. Furthermore, 5-chloro-D-tryptophan was newly isolated from the hydrolyzate of the antibiotic. This structure was assigned by NMR, MS and ORD. A steric configuration of this amino acid was certified by degradation to D-aspartic acid through ozonization. 5-Chloro-DL-tryptophan was synthesized from 3-cyanopropionaldehyde and *p*-chlorophenylhydrazine by Fischer's indole synthesis.

Longicatenamycin is an antibiotic isolated from the strain S-520 of *Streptomyces diastaticus* by Shoji and his collaborators in 1970 and tentatively named S-520.[2] This antibiotic is active against Gram-positive bacteria including *Diplococcus pneumoniae*. The hydrochloride of the antibiotic has extremely poor solubilities in water and almost all organic solvents except lower alcohol or dimethyl sulfoxide. Longicatenamycin showed the positive Ehrlich reaction and the characteristic UV absorptions at 299 nm, 290, 283 and 227.[2] According to the preliminary investigation by Shoji *et al.*, longicatenamycin is a peptide containing several unusual amino acids. They also suggested that the antibiotic is a complex mixture composed of several closely related peptides which have three exchangeable positions for amino acid residues in their molecules.[3] This feature seems to be rather common in many peptide antibiotics.[4-7] Among the component amino acids they reported, two kinds of new amino acids are involved. The one is *threo*-β-hydroxy-L-glutamic acid (**1**)[8] and the other is a group of three homologous amino acids with long carbon chains, *i.e.*, L-2-amino-5-methylhexanoic acid (**2**), L-2-amino-6-methylheptanoic acid (**3**) and L-2-amino-7-methyloctanoic acid (**4**).[9] They assigned the structures of those four amino acids mainly by NMR studies.[8,9]

Since Dakin had pointed out a possibility of an existence of β-hydroxyglutamic acid in the hydrolyzate of casein in 1918,[10] much efforts have been made in vain for isolation of this amino acid. However, at the present time, an occurrence of the amino acid was denied after all negative results by many workers.[11,12] If Shoji's presumption is right,[8] this will be a first presentation for an occurrence of β-hydroxyglutamic acid in nature. In the present study, a sample of the acid **1** obtained from the hydrolyzate of longicatenamycin was compared with the authentic *threo* and *erythro*-β-hydroxy-DL-glutamic acids which had been early synthesized by Kaneko *et al.*[13] The natural L-amino acid **1** was completely identical with synthetic *threo* isomer in NMR, amino acid analysis and thin-layer chromatography.



1 **2** **3** **4**

Fig. 1.

Three other new amino acids **2**, **3** and **4** exceed, in their carbon chain lengths, leucine which is known as the longest naturally occurring amino acid of $(CH_3)_2CH(CH_2)_nCH(NH_2)COOH$ type. We synthesized these amino acids by means of acetaminomalonate method. Thus, diethyl acetaminomalonate was coupled with isoamyl bromide, isohexyl bromide and isoheptyl bromide respectively and each coupling product was hydrolyzed to yield the corresponding DL-α-amino acids. Three natural L-amino acids **2**, **3** and **4**, were identified with the synthetic 2-amino-5-methylhexanoic acid, 2-amino-6-methylheptanoic acid and 2-amino-7-methyloctanoic acid respectively in NMR, amino acid analysis and thin-layer chromatography.

The amino acid composition of the acid hydrolyzate of longicatenamycin was reinvestigated in our study by amino acid analysis. Our result as shown in Table 1 coincides with that of Shoji *et al.*[2] within the experimental errors.

The molar ratio of amino acid composition indicates that there are three groups each comprising the homologous amino acids and corresponding to one mole respectively, *i.e.*, i) Val, Ile ii) **2**, **3**, **4** iii) Orn, Lys. The low value of **1** may be ascribed to the possible degradation *via* retroaldol condensation during the acid hydrolysis. The loss due to such decomposition was confirmed in the reference experiment with the authentic β-hydroxyglutamic acid.

At the stage of this investigation, the characteristic UV absorption and positive Ehrlich reaction of longicatenamycin cannot be explained by the component amino acids isolated so far. In addition, a difference between an apparent molecular weight (566) calculated based on a cyclic pentapeptide consisting of each one mole of Gly, **1**, Val (Ile), **2** (**3**, **4**) and Orn (Lys)[14] and the measured values of molecular weight of 2,4-dinitrophenyl (969) and acetyl (*ca.* 900) derivatives of longicatenamycin from extinction coefficients of the absorption spectra at 350 and 289 nm respectively, sug-

Table 1. The molar ratio of component amino acids of longicatenamycin[a)]

Gly[b)]	1	Val	Ile	2	3	4	Orn	Lys	Amm
1.00	0.45	0.77	0.17	0.20	0.36	0.38	0.76	0.28	0.68

a) The ratio of 5-chloro-D-trypophan is not included. b) Gly: glycine; Val: D-valine; Ile: D-isoleucine; Orn: D-ornithine; Lys: D-lysine; Amm: ammonia; **1**: *threo*-β-hydroxy-L-glutamic acid; **2**: L-2-amino-5-methylhexanoic acid; **3**: L-2-amino-6-methylheptanoic acid; **4**: L-α-2-amino-7-methyloctanoic acid.

gests strongly a presence of a tryptophan-like substance which might escape from the amino acid analysis because of a possible decomposition in the acid hydrolysis.

An experiment to trace such a predicted amino acid was done first by an alkaline hydrolysis of the antibiotic.[15] Thus, longicatenamycin was hydrolyzed with 10% barium hydroxide. From isobutyl alcohol extract of the hydrolyzate, a neutral amino acid with a molecular formula of $C_{11}H_{11}O_2N_2Cl$ was isolated in a crystalline state. This amino acid was positive to both ninhydrin and Ehrlich reactions, and showed UV absorptions at λ_{max}^{EtOH} 298 nm (ε 3800), 289 (5300), 282 (5200) and 226 (36700). From its NMR spectrum in C_5D_5N–D_2O as shown in Fig. 2 and mass spectrum, a structure of this new amino acid was assumed to be 5-chlorotryptophan. A position of chlorine atom on the indole nucleus was determined by the fact that a signal (Ha) in the lowest magnetic field can be assigned as H-4 in comparison with the spectrum of tryptophan itself and it shows only long range coupling of J=2 Hz with Hb.

A steric configuration of α-carbon atom cannot be clarified on this sample which was completely racemized during the alkaline hydrolysis. Therefore, the hydrolysis of longicatenamycin was carried out newly with 6 M hydrochloric acid in a sealed, evacuated tube. An optically active 5-chlorotryptophan thus obtained showed a positive ORD curve: $[\phi]_{320}$+3410° (peak), $[\alpha]_D^{25}$ +40° (methanol). Since L-tryptophan gave the negative ORD curve in methanolic solution, we assigned D-form for this amino acid. On the contrary, a configuration of α-carbon atom of *N*-carbethoxyacetyl-4-chlorotryptophan which was isolated as a hypocotyl swelling factor from immature seeds of *Pisum sativum* was assumed to be D-form by Marumo and Hattori only from the negative ORD curve.[16] Both conclusions seem to be controversy though there are differences in substitution groups. Since any contribution of acyl or chlorine substituent on tryptophan molecule to the sign of Cotton effect is not known well, a suspection of the configuration of tryptophan derivative from the sign of ORD curve must be very prudent.

Therefore, we now oxidized (+)-5-chlorotryptophan with ozone to lead to an optically active aspartic acid[17] which was purified as 2,4-dinitrophenyl (DNP) derivative. This DNP aspartic acid showed the negative value of the specific rotation: $[\alpha]_D^{20}$ −45° ($NaHCO_3$), indicating D-form of the amino acid unambiguously. Conclusively it is determined that (+)-5-chlorotryptophan in longicatenamycin has D-configuration at α-carbon atom.

For confirmation of the supposed structure of 5-chlorotryptophan, it was synthesized through the following novel method where the tryptophan synthesis by Komachiya *et al.*[18] was applied (Scheme 1). 3-Cyanopropionaldehyde (**5**)[19] was changed to 5-(2-cyanoethyl)-hydantoin (**6**) by Bücherer's method. A nitrile group in compound **6** was reduced to aldehyde using poisoned nickel catalyst according to the procedure by Komachiya *et al.*[18] The hydantoin aldehyde (**7**)

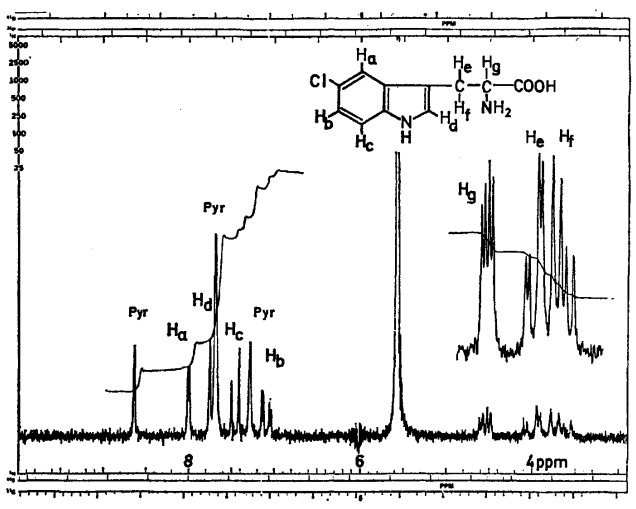


Fig. 2. NMR spectrum of 5-chlorotryptophan from longicatenamycin in C_5D_5N–D_2O (1 : 1) at 100 MHz.

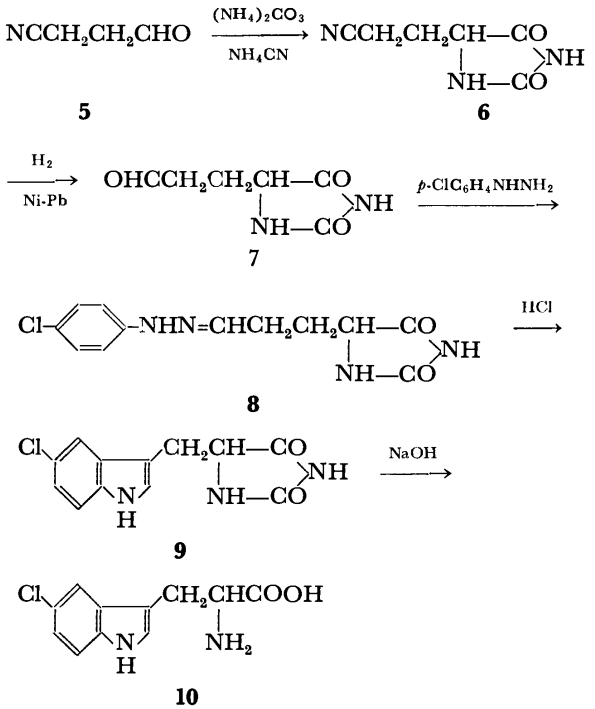

Scheme 1.

thus obtained was converted to *p*-chlorophenylhydrazone (**8**) which was then cyclized to indole hydantoin (**9**) through Fischer's indole synthesis using dilute hydrochloric acid. Alkaline hydrolysis of the product **9** gave 5-chloro-DL-tryptophan. The synthetic amino acid was completely identical with the natural compound in IR, NMR, amino acid analysis and mass spectrum. This is the first occurrence of 5-chlorotryptophan in nature.

This amino acid had been already synthesized by Rydon and his collaborators but through tedious long path.[20,21] One of the advantage in our synthetic method is that a single product of 5-chloroindole compound is obtained in principle even if the indole ring is formed at either *ortho* position of the compound **8** in Fischer's indole synthesis. Moreover, the overall yield from 3-cyanopropionaldehyde dimethyl acetal in this synthesis was as good as about 40%.

Now, the experimental formula of longicatenamycin becomes $C_{36.6}H_{54.3}O_{9.0}N_{8.0}Cl_{1.0}$ (MW 786) on the basis of the molar ratio of the component amino acids mentioned before added with one mole of 5-chlorotryptophan.[22] Apparent molecular weights of mono-DNP (953) and diacetyl (871) derivatives calculated from this formula are consistent with the observed values mentioned before. This indicated that there is no more amino acid unidentified in the molecule of longicatenamycin.

Other than these amino acids, Shoji *et al.* reported one spot of a-II in the acidic area of two-dimensional paper chromatogram of the hydrolyzate of longicatenamycin, although they could neither isolate nor detect it in amino acid analysis.[3] In our experiment where the antibiotic was hydrolyzed with hydrochloric acid in the evacuated tube, no such spot appeared on paper-chromatogram. Therefore, this spot would be due to some degradation of 5-chlorotryptophan during the acid hydrolysis in the presence of air.

From all of the above results, it can be now concluded that longicatenamycin is composed of each one mole of glycine, *threo*-β-hydroxy-L-glutamic acid, 5-chloro-D-tryptophan, D-valine (D-isoleucine), L-2-amino-5-methylhexanoic acid (L-2-amino-6-methylheptanoic acid, L-2-amino-7-methyloctanoic acid) and D-ornithine (D-lysine).[14]

Experimental

All melting points are uncorrected. The following apparatuses were employed: Jasco Model IR-S Infrared Spectrophotometer, Hitachi 124 Spectrophotometer, Jasco Model ORD/UV-5-Optical Rotatory Dispersion Recorder, Varian T-60 Spectrometer, Varian XL-100 Spectrometer and Hitachi Amino Acid Analyzer KLA-3. For NMR measurement, tetramethylsilane was used as an internal reference substance. Paper electrophoresis was carried out in a pyridine-acetic acid-water (30 : 4 : 966) buffer solution using Toyo filter paper No. 51. For thin-layer chromatography on silica gel G, the solvent systems of *n*-butanol–acetic acid–water (4 : 1 : 2) and methyl ethyl ketone–pyridine–water–acetic acid (35 : 5 : 5 : 1) were employed mainly.

DL-2-Amino-5-methylhexanoic Acid (2). To a solution of diethyl acetaminomalonate (13.0 g, 0.06 mol) and sodium metal (1.38 g, 0.06 mol) in absolute ethanol (100 ml), there was added isoamyl bromide (8.72 g, 0.06 mol) and the mixture was heated under reflux for 36 hr. To an oily residue obtained after evaporation of the solvent, water (100 ml) was added and the product was extracted with ether (500 ml). Extract was washed with water and dried with magnesium sulfate. Oily substance obtained after evaporation of ether was crystallized on addition of *n*-hexane. The product was recrystallized from ether to give needles, yield, 5.5 g. These were hydrolyzed by refluxing with 47% hydrobromic acid (100 ml) for 18 hr. The amino acid obtained was purified by Dowex 50×8 (H^+ form) column. From the eluate with M ammonium hydroxide, crystals of DL-2-amino-5-methylhexanoic acid were obtained and recrystallized from hot water, yield, 2.2 g (25%); mp 273—275 °C (decomp.). R_f value on thin-layer chromatogram: 0.38 (methyl ethyl ketone–pyridine–water–acetic acid, 35 : 5 : 5 : 1).

Found: C, 57.86; H, 10.41; N, 9.67%. Calcd for $C_7H_{15}O_2N$: C, 57.90; H, 10.41; N, 9.65%.

DL-2-Amino-6-methylheptanoic Acid (3). Isohexyl bromide was prepared by bromination of isohexyl alcohol with mixed acid of 47% hydrobromic acid and concentrated hydrochloric acid.[23] Isohexyl alcohol was obtained by reduction of 4-methylpentanoic acid with lithium aluminum hydride.[24] The latter compound was synthesized from isoamylbromide by Grignard reaction with carbon dioxide.[25] A coupling reaction of isohexyl bromide (5.0 g, 30 mmol) with diethyl acetaminomalonate (6.5 g, 30 mmol) was carried out in a similar manner to that for **2**. Elution of the amino acid from Dowex-50 column was done using a mixed solvent of 1 M ammonium hydroxide and methanol (1 : 1), yield, 1.6 g (33%); mp 286—290 °C (decomp.). R_f value on thin-layer chromatogram: 0.50 (methyl ethyl ketone–pyridine–water–acetic acid, 35 : 5 : 5 : 1).

Found: C, 60.24; H, 10.70; N, 8.77%. Calcd for $C_8H_{17}O_2N$: C, 60.34; H, 10.76; N, 8.80%.

DL-2-Amino-7-methyloctanoic Acid (4). Isoheptyl bromide was prepared from isohexylbromide through Grignard reaction, lithium aluminum hydride reduction and bromination successively. Coupling of isoheptyl bromide (4.60 g, 26 mmol) and diethyl acetaminomalonate (5.56 g, 26 mmol) was carried out in a similar way to that mentioned above, yield, 1.57 g (35%); mp 271—273 °C (decomp.). R_f value on thin-layer chromatogram: 0.54 (methyl ethyl ketone–pyridine–water–acetic acid, 35 : 5 : 5 : 1).

Found: C, 62.16; H, 10.99; N, 8.07%. Calcd for $C_9H_{19}O_2N$: C, 62.39; H, 11.05; N, 8.09%.

Isolation of 5-Chloro-DL-tryptophan (Alkaline Hydrolysis). Longicatenamycin (1.0 g) was refluxed with 10% aqueous barium hydroxide (50 ml) for 48 hr. The reaction mixture was diluted with water (50 ml) and then neutralized with 2 M sulfuric acid. Precipitate of barium sulfate was filtered, and the filtrate was extracted with isobutyl alcohol (100 ml) three times. After evaporation of the solvent, the brown powder was obtained. This was purified by repeated crystallization with aqueous methanol and ether to obtain colorless crystals, yield, 50 mg; mp 250—255 °C (decomp.). UV: λ_{max}^{MeOH} 298 nm (ε 3800), 289 (5300), 282 (5200), 226 (36700). NMR (100 MHz, C_5D_5N–D_2O (1 : 1): H-4: δ 8.03 (1H, d, J=2.0 Hz), H-6: 7.11 (1H, dd, J=2.0, 9.0), H-7: 7.49 (1H, d, J=9.0), H-2: 7.78 (1H, s), H-β: 3.66 (1H, dd, J=4.0, 16.0), H-β′: 4.00 (1H, dd, J=10.0, 16.0), H-α: 4.55 (1H, dd, J=4.0, 10.0), MS: *m/e*, 238, 193, 164, 127.

Found: C, 55.04; H, 4.89; N, 11.74; Cl, 14.68%. Calcd for $C_{11}H_{11}O_2N_2Cl$: C, 55.35; H, 4.65; N, 11.74; Cl, 14.86%.

Isolation of 5-Chloro-D-tryptophan (Acid Hydrolysis). A suspension of longicatenamycin (250 mg) in 6 M hydrochloric acid (10 ml) was heated at 110 °C for 1 hr in a sealed, evacu-

ated tube. After dilution with water (20 ml), the hydrolyzate was neutralized with 2 M sodium hydroxide and extracted with isobutyl alcohol (300 ml). The residue obtained after evaporation of the solvent from the extract was dissolved in a mixture of methanol–acetic acid–water (1 : 1 : 1) and subjected to Dowex 50×2 column (1.5×30 cm) bufferized with 0.2 M pyridine–acetic acid buffer of pH 3.1. Elution was carried out gradiently with 0.2 M pyridine buffer of pH 3.1 (200 ml) and 2 M pyridine buffer of pH 5.0 (200 ml) successively. From fractions No. 32—40 of each 8 g, colorless crystals were obtained, yield, 10 mg; mp 238—245 °C (decomp.); ORD, $[\phi]_{320}+3410°$ (peak) (*c* 0.58, methanol), $[\alpha]_D^{25}$ +40° (*c* 0.58, methanol). This compound was identified with DL-isomer obtained by the alkaline hydrolysis in UV spectrum, thin-layer chromatography and amino acid analysis.

Ozonization of 5-Chloro-D-tryptophan. Optically active 5-chlorotryptophan (5 mg) obtained above was dissolved in 0.5 M hydrochloric acid (2 ml) and ozone was passed through the solution on ice-cooling for 2 hr. After addition of 30% aqueous hydroperoxide (0.3 ml), the reaction mixture was heated on boiling water bath for 10 min. Crystals obtained after evaporation were dissolved in a small amount of water and subjected to Dowex 50×2 column (0.5×10 cm) bufferized with 0.2 M pyridine–acetic acid of pH 3.1. Elution was carried out with the same buffer solution and fractions of each 4 g were collected fractionally. From fractions No. 11 and 12, colorless crystals of aspartic acid were obtained. This amino acid was 2,4-dinitrophenylated using sodium hydrogencarbonate in the usual manner. Crystals of DNP-aspartic acid were obtained from ether extract after acidification. These were purified by silica gel column (0.5×15 cm) using a mixed solvent of *n*-hexane–ether (9 : 1). $[\alpha]_D^{18}$ −8.0° (c 0.03, methanol), $[\alpha]_D^{30}$ −45° (*c* 0.11, 1% $NaHCO_3$).

5-[2-(4-Chlorophenylhydrazonoformyl)-ethyl]-hydantion (8). i) 5-(2-Cyanoethyl)-hydantoin (**6**) was prepared from 3-cyanopropionaldehyde (**5**)[26] through Bücherer's reaction.[18] According to the method by Komachiya *et al.*,[18] nitrile group in the hydantoin **6** was reduced to aldehyde using Raney nickel catalyst poisoned with lead acetate in acetic acid to yield 5-(2-formylethyl)-hydantoin (**7**). The reaction mixture starting from 15.3 g (0.10 mol) of **6** was filtered to remove the catalyst, and a solution of *p*-chlorophenylhydrazine (14.3 g, 0.10 M) in 100 ml of 1 M hydrochloric acid was added with stirring. Crystals deposited were collected by filtration and recrystallized from ethanol–water, to give the hydrazone **8**, yield, 15.4 g (55%); mp 147—149 °C (decomp.).

Found: C, 51.25; H, 4.70; N, 19.80; Cl, 12.56%. Calcd for $C_{12}H_{13}O_2N_4Cl$: C, 51.34; H, 4.67; N, 19.96; Cl, 12.63%.

ii) The same hydrazone **8** was obtained from semicarbazone of **7** (9.98 g, 47 mmol) and *p*-chlorophenylhydrazine 6.70 g (47 mM) in a similar way, yield, 12.3 g (94%), mp 147—148 °C (decomp.).

5-(5-Chloroindolyl-3-methyl)-hydantoin (9). The hydrazone **8** (1.40 g, 5.0 mmol) was dissolved in hot water (80 ml) containing 3 M hydrochloric acid (3.72 ml) on heating at 100 °C. After keeping at this temperature for 80 min, the reaction mixture was evaporated *in vacuo*. The residue was crystallized in addition of a small amount of water. The crystals were filtered off, washed with water and dried to give the crude product, yield, 1.15 g (85%). A pure sample was obtained by purification on silica gel column chromatography using chloroform–methanol (95 : 5) as an elution solvent, mp 127—132 °C (decomp.).

Found: C, 53.10; H, 4.18; N, 15.74%. Calcd for $C_{12}H_{10}O_2N_3Cl\cdot 1/2H_2O$: C, 52.85; H, 4.07; N, 15.41%.

5-Chloro-DL-tryptophan (10). The chloroindole derivative **9** (540 mg, 2.0 mM) was dissolved in M sodium hydroxide and heated at 150—155 °C for 1 hr in a sealed tube in which air was displaced with nitrogen. After neutralization to pH 5.9 with 3 M hydrochloric acid, the reaction mixture was extracted with isobutyl alcohol (80 ml). Extract was washed with water and evaporated *in vacuo*. A small amount of undissolved material in ethanol was removed, and the filtrate was again evaporated. The residue thus obtained was crystallized from methanol–ether, yield, 260 mg (55%). A pure sample was obtained by Dowex 50×2 column chromatography using a gradient buffer of 0.2 M pyridine–acetic acid of pH 3.1 and 2.0 M buffer of pH 5.0, mp 254—256 °C (decomp.).[27] R_f values on thin-layer chromatogram: 0.71 (*n*-butanol–acetic acid–water, 4 : 1 : 2); 0.10 (chloroform–methanol–water, 45 : 12 : 1).

Found: C, 55.14; H, 4.83; N, 11.79; Cl, 14.40%. Calcd for $C_{11}H_{11}O_2N_2Cl$: C, 55.35; H, 4.65; N, 11.74; Cl, 14.86%.

The authors are deeply indebted to Dr. Hideo Otsuka and Dr. Junichi Shoji of Shionogi Co., Ltd. for their kind supply of longicatenamycin and encouragement throughout this work.

Absolute Configurations and Chiroptical Properties of Optically Active Derivatives of Tricyclo[4.3.0.0^{3,8}]nonane ("Twist-brendane")

Masao NAKAZAKI, Koichiro NAEMURA, and Sigeyuki HARITA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received January 13, 1975)

(+)-Tricyclo[4.3.0.0^{3,8}]nonane ("twist-brendane") was synthesized *via* (+)-tricyclo[4.3.0.0^{3,8}]nonan-9-one from (+)-*endo*-2-carboxybicyclo[2.2.2]oct-5-ene. Optically active derivatives of twist-brendane with two functional groups such as (−)-2,9-twist-brendanedione and (−)-9-methylenetwist-brendan-2-one were synthesized from (−)-*endo*-2-carboxybicyclo[2.2.2]oct-5-ene. Absolute configurations of the compounds were established and their chiroptical properties were discussed.

Tricyclo[4.4.0.0^{3,8}]decane ("twistane")[1] belongs to point group D_2 and is one of the representatives of tricyclodecanes whose carbon frameworks are inherently chiral. We were the first to obtain twistane in optically active form, and assigned to configuration (**1a**) to (+)-twistane on the basis of the chiroptical property of the intermediate, (+)-2-twistanone.[2] In recent years, Tichý reinvestigated this problem and assigned the opposite configuration (**1b**) to the same dextrorotatory enantiomer.[3]

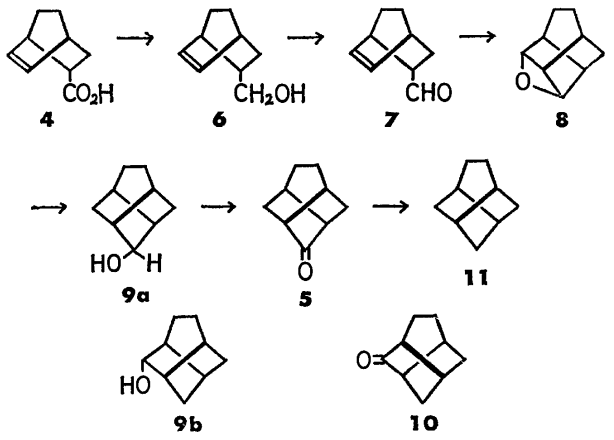
1a **1b**

In the preceeding paper, we reported the preparation of (−)-twist-brendane[4] from (−)-*endo*-2-carboxybicyclo[2.2.1]hept-5-ene (**3**) with known absolute configuration[5], and assignment of the absolute configuration (**2**) to (−)-twist-brendane.

2 **3**

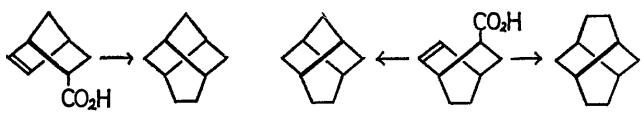
In this paper, we wish to report an alternative synthesis of optically active twist-brendane from bicyclo[2.2.2]octane derivative (**4**) which eventually correlates the configuration of (−)-twist-brendane with that of twistane. Since twist-brandane derivatives have rigid structures with well-defined molecular geometry and may afford a suitable model to study intramolecular interactions between the functional groups held in these fixed relative orientations, the syntheses and chiroptical properties of various twist-brendane derivatives will be also described in this paper.

Our first task was the preparation of optically active 9-twist-brendanone (**5**)[6] from *endo*-2-carboxybicyclo-[2.2.2]oct-5-ene (**4**) $[\alpha]_D^{26}$ +31.8°[7] which was obtained through the optical resolution of racemic acid with the aid of (+)-2-(1-aminoethyl)naphthalene. Reduction of the (+)-carboxylic acid with lithium aluminum hydride followed by oxidation with Collins' reagent gave (+)-unsaturated aldehyde (**7**) which was smoothly converted into the (+)-oxetane (**8**) upon intramolecular Paterno-Büchi photoreaction.[8] Reductive cleavage of (+)-oxetane (**8**) with lithium aluminum hydride in *N*-methylmorpholine[9] afforded (+)-tricyclic alcohol (**9a**), which was oxidized with Jones' reagent to give (+)-ketone. Among two possible courses of the reductive ring fission of the (+)-oxetane (**8**), apparently the one leading to 2-hydroxytwist-brendane (**9b**) was not followed, because the (+)-ketone obtained showed a carbonyl absorption at 1765 cm^{-1} in its IR spectrum and was found to be different from 2-twist-brendanone (**10**) whose structure had been established by unambigous synthesis. These facts indicated that our (+)-ketone was the desired (+)-9-twist-brendanone (**5**). Wolff-Kishner reduction of this (+)-9-twist-brendanone gave a dextrorotatory hydrocarbon (11) $[\alpha]_D^{21}$ +177°, which was purified by chromatography and sublimation. Comparison of its NMR, IR, mass spectrum and vpc retention time with those of (−)-twist-brendane (**2**) confirmed that they are enantiomeric. This result gave us a clear information about the configurational relationship between (+)-twist-brendane (**11**) and our starting material (+)-*endo*-2-carboxybicyclo[2.2.2]oct-5-ene (**4**)[10] as shown below.



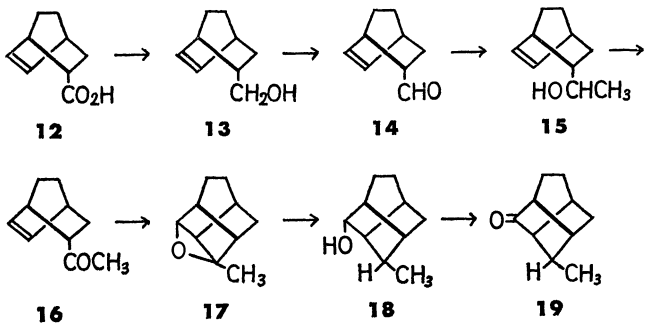
4 **6** **7** **8** **9a** **5** **11** **9b** **10**

Since (+)-twistane was derived from this bicyclo-[2.2.2]octane derivative (**4**), our previous assignment of the absolute configuration to (+)-twistane by chiroptical method has to be reversed confirming Tichý's new result.

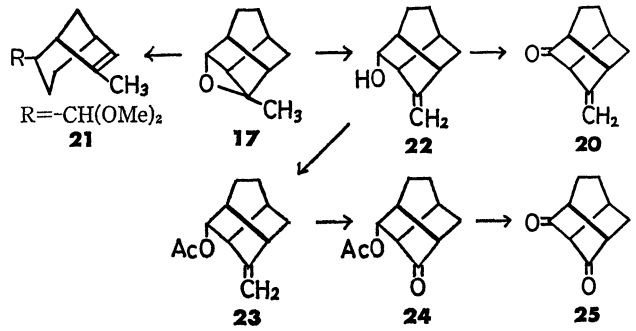


3 **2** **11** **4** **1b**

Next our attention was turned to prepare optically active twist-brendane derivatives with two functional groups and investigate their intramolecular interaction in their rigid molecular frameworks. (−)-Aldehyde (**14**) prepared *via* (−)-alcohol (**13**) from (−)-*endo*-2-carboxybicyclo[2.2.2]oct-5-ene (**12**) $[\alpha]_D^{24}$ −27.8° was treated with methylmagnesium iodide to give (−)-alcohol (**15**), which was oxidized with Collins' reagent to yield (−)-ketone (**16**). The ring closure leading to twist-brendane framework was again achieved by the Paterno-Büchi reaction. Irradiation of a solution of (−)-ketone (**16**) in benzene with mercury lamp gave a liquid product which was purified by distillation to give (−)-oxetane (**17**). Reductive cleavage of (−)-oxetane (**17**) with lithium aluminum hydride in *N*-methylmorpholine yielded alcohol (**18**), which, without purification, was treated with Collins' reagent to give (−)-ketone (**19**). The structural evidence was obtained on the basis of its following spectral data. The NMR spectrum exhibited sharp doublet signals centered at δ 1.11 (J=7 Hz) for the methyl group and the IR spectrum showed a carbonyl absorption at 1753 cm^{-1}.

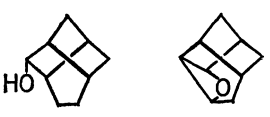


For the preparation of olefinic ketone (**20**), (−)-oxetane (**17**) was treated with perchloric acid in methanol and the product was chromatographed on alumina to give two products. To the minor product (22% yield) eluted with pentane was assigned the structure (**21**) on the basis of its IR spectrum which showed characteristic absorptions at 2839 cm^{-1} due to methoxy group and 3020 and 805 cm^{-1} due to trisubstituted olefin. Elution with ether–pentane afforded the major product (28% yield) whose IR spectrum (3450 cm^{-1} for hydroxyl group and 3050, 1675, 890 and 870 cm^{-1} for terminal methylene group) indicated the structure (**22**) for this olefinic alcohol. Upon Collins' oxidation, (−)-alcohol (**22**) gave (−)-ketone (**20**) whose structure was confirmed by the NMR spectrum data; δ 4.80 and 4.65 (olefinic protons) and 2.95 and 2.70 (two bridge head protons at C_1 and C_3). The olefinic alcohol (**22**) in hand, we diverted our effort to preparation of the twist-brendane with two oxo groups at C_2 and C_4 positions. After protection of hydroxyl group by acetylation, the resulted acetate (**23**) was ozonolyzed in chloroform (at −78 °C) to provide the ketoacetate (**24**) which was purified by chromatography followed by vaccum distillation. Failure in removing the acetyl group by hydrolysis with methanolic potassium hydroxide forced us to take a detour. Reduction of the ketoacetate (**24**) with lithium aluminum hydride followed by Collins' oxidation afforded a solid and the product was purified by sublimation to give diketone (**25**) which showed two carbonyl absorptions at 1785 and 1740 cm^{-1}. The specific rotation of the diketone (**25**) observed in chloroform solution was $[\alpha]_D$ −225° at 17 °C. When the substance was dissolved in methanol and the specific rotation of the solution was observed, there was a gradual change in the rotation from initial value $[\alpha]_D^{17}$ −153° to an equilibrium value $[\alpha]_D^{17}$ +32.0° during 4 hr.



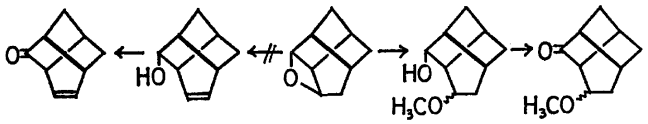
Since inspection of a molecular model of the olefinic ketone (**26**) reveals an interesting feature about the interaction of the double bond and carbonyl group in this unique twist-brendane framework, our final effort was directed to the preparation of this twist-brend-4-en-2-one (**26**). The key intermediate selected for the ketone (**26**) was a new oxetane (**27a**) which was obtained from 2-formylmethylbicyclo[2.2.1]hept-5-ene (**33**) by the Paterno-Büchi reaction. The Diels-Alder reaction of cyclopentadiene with allyl alcohol gave an *endo* and *exo* mixture of 2-hydroxymethylbicyclo[2.2.1]hept-5-ene (**28**) which was converted into the nitrile (**30**) *via* the tosylate (**29**). Upon hydrolysis with alkaline, the nitrile (**30**) afforded carboxylic acid (**31**) which was reduced with lithium aluminum hydride to yield alcohol (**32**). Oxidation of the alcohol (**32**) with Collins' reagent gave a mixture of *endo* and *exo*-2-formylmethylbicyclo[2.2.1]hept-5-ene (**33**). Irradiation was carried out on *endo* and *exo*-mixture of aldehydes (**33**) in benzene. Oxetane (**27a**) was smoothly produced and purified by sublimation to give a solid. Although there are two alternative ways of ring closure leading to (**27a**) and (**27b**), we assigned the structure (**27a**) to the oxetane since this compound could be transformed into 2-twist-brendanone (**10**) *via* 2-twist-brendanol (**34**) by reductive cleavage followed by Collins' oxidation.

28: R=OH, **31**: R=CO_2H **27a**
29: R=OTs, **32**: R=CH_2OH
30: R=CN, **33**: R=CHO



34 **27b**

Oxetane (**27a**) was treated with perchloric acid in methanol to give an alcoholic product. The product was oxidized with Collins' reagent to yield ketone which was chromatographed on silica gel. A fraction eluted with ether–pentane was distilled to give a ketone, to which the structure (**36**) was assigned to the basis of the following facts. The NMR spectrum exhibited signals at δ 3.75—3.55 due to a proton at C_4 and did not exhibit any signal at the region for olefinic proton. The IR spectrum showed a carbonyl absorption at 1750 cm^{-1} and absorptions for methoxy group at 2830 and 1105 cm^{-1}. The elementary analysis and mass spectrum (*m/e* 166 M^+) were in agreement with the calculated value for $C_{10}H_{14}O_2$. An expected alcohol (**37**) could not be obtained from the oxetane (**27a**) by the method.



26 **37** **27** **35** **36**

Chiroptical Properties

(−)-*endo*-2-Methylbicyclo[2.2.1]heptan-7-one (**38**) is a bicyclic ketone being compared with (+)-9-twist-brendanone (**5**) and shows a positive Cotton effect at about 295 nm in its CD.[11] But (+)-9-twist-brendanone (**5**) exhibited a negative Cotton effect at 285 nm (Fig. 1). An ethano bridge of the tricyclic ketone twisted a center six-membered ring, hached in the formula (**39**) and a projection formula (**40**), where the C=O lies in the "point" of the twist,[12] is drawn for (+)-9-twist-brendanone (**5**). Then the octant rule is applied to both "outer" five-membered rings in this projection formula (**40**). It is obvious that negative contributions coming from the two "outer" rings determine the sign of the Cotton effect.

The chirality of carbon framework of (−)-9-methyltwist-brendan-2-one (**19**) is the opposite sense in contrast to that of (+)-9-twist-brendanone (**5**). However,

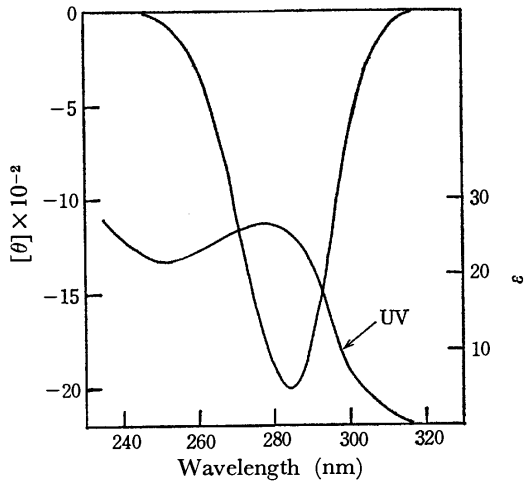


Fig. 1. CD and UV spectra of (+)-9-twist-brendanone (**5**).

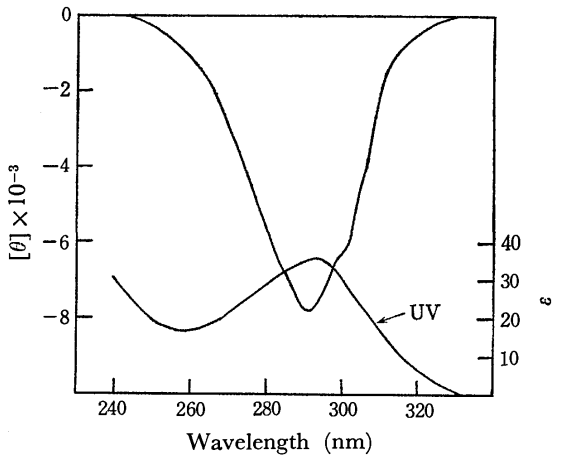

Fig. 2. CD and UV spectra of (−)-9-methyltwist-brendan-2-one (**19**).

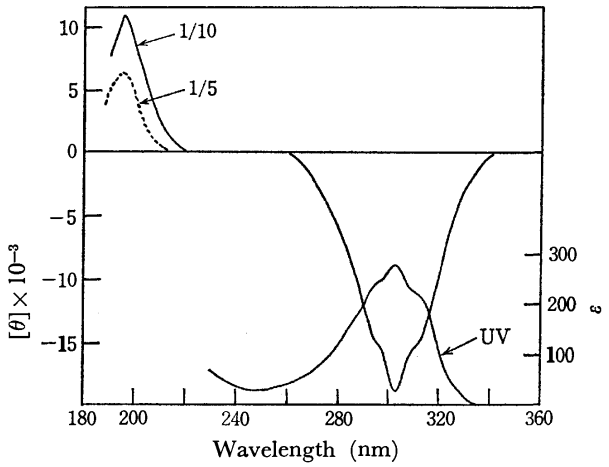

Fig. 3. CD (----) spectrum of (−)-9-methylenetwist-brendan-2-ol (**22**) and CD (——) and UV (——) spectra of (−)-9-methylenetwist-brendan-2-one (**20**).

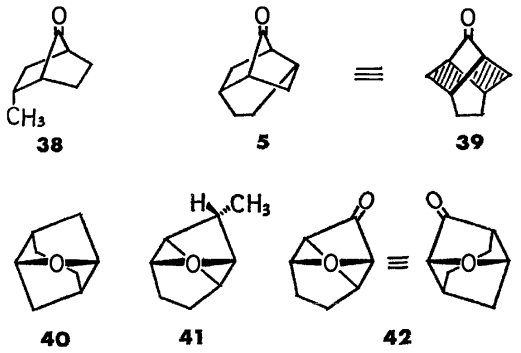
(−)-9-methyltwist-brendan-2-one (**19**) exhibited also a negative Cotton effect at 292 nm (Fig. 2). The fact is explained by the same rule as mentioned above. Negative contributions coming from the two "outer" rings of the projection formula (**41**) determine the sign of the Cotton effect. (−)-9-Methylenetwist-brendan-2-ol (**22**) exhibited a strong positive Cotton effect at 195 nm (Fig. 3). (−)-9-Methylenetwist-brendan-2-one (**20**) exhibited a positive Cotton effect at 195 nm and a negative one at 302.5 nm and the intensities of both maximum were increased in contrast to those of the alcohol (**22**) and the saturated ketone (**19**). The negative Cotton effect at around 300 nm is also predictable from the same rule. These facts showed us that the sign of the Cotton effect at around 300 nm exhibited by twist-brendanones was essentially predictable from application of the octant rule to "outer" rings in the projection formula. In other word, the sign of the Cotton effect exhibited twist-brendanones is unequivocally related to a chirality of a middle ring of the projection formula and the concept is adopted for twistanones.[12] For the ketones exhibited a negative Cotton effect, the middle ring adopts P-helicity.



There are P-helicity six-membered ring and M-helicity seven-membered ring in (+)-2,9-twist-brendandione (**25**) as shown in the projection formula (**42**) and the diketone exhibited complicating maxima in its CD (Fig. 4). We have never offered a pertinent explanation for the fact.

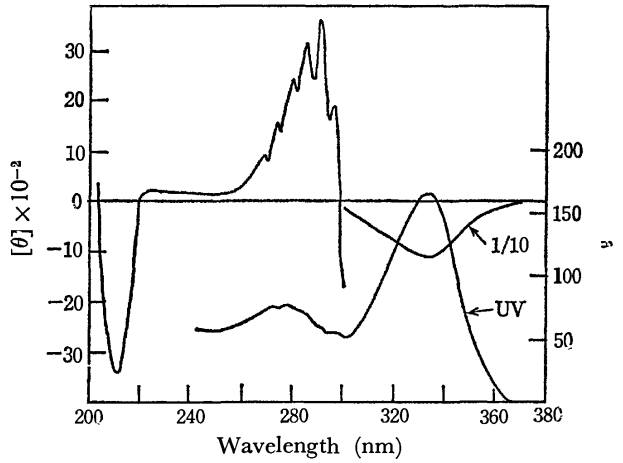


Fig. 4. CD and UV spectra of (+)-2,9-twist-brendandione (**25**).

Experimental

All the melting points and the boiling points are not corrected. The IR spectra were measured with Hitachi EPI-S2 spectrophotometer. The NMR spectra were obtained on LNM-C-60HL and JNM-MH-100 spectrometers. The UV spectra were measured with Beckman DB spectrometer. The optical rotations were measured with JASCO DIP-SL automatic polarimeter. The CD spectra were obtained on JASCO J-20 spectropolarimeter with CD attachment.

(+)-endo-*2-Carboxybicyclo[2.2.2]oct-5-ene (4).* A salt of *endo*-2-carboxybicyclo[2.2.2]oct-5-ene with (+)-2-(1-aminoethyl)naphthalene was recrystallized from ethanol and then a dextrorotatory salt was treated with hydrochloric acid to give (+)-carboxylic acid (**4**) mp 42—43 °C, $[\alpha]_D^{26}$ +31.8° (*c* 0.54, methanol).

Found: C, 71.21; H, 8.02%. Calcd for $C_9H_{12}O_2$: C, 71.02; H, 7.95%.

(+)-endo-*2-Hydroxymethylbicyclo[2.2.2]oct-5-ene (6).* Reduction of 10.9 g of (+)-carboxylic acid (**4**) with lithium aluminum hydride in ether gave 8.49 g of alcohol (**6**) bp 95 °C at 5 Torr, $[\alpha]_D^{25}$ +4.5° (c 1.1, methanol).

IR (neat film): 3350(s), 3050(w), 2950(s), 2880(m), 1055(m), 1035(m), 1015(m), and 710(s) cm^{-1}.

Found: C, 78.03; H, 10.35%. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.21%.

(+)-endo-*2-Formylbicyclo[2.2.2]oct-5-ene (7).* To a solution of 59 ml of dry pyridine in 1.34 l of dry methylenechloride was added 36.4 g of chromium trioxide and the mixture was stirred at room temperature for 15 min. Then a solution of 8.4 g of (+)-alcohol (**6**) in 10 ml of dry methylenechloride was added to the mixture and it was stirred at room temperature for further 15 min. An organic layer was separated and a residue was rinsed with the same solvent. Combined organic solutions were washed with dilute hydrochloric acid, satd. aqueous sodium bicarbonate, water and dried over magnesium sulfate. After evaporation of the solvent a residue was distilled to give 6.53 g of (+)-aldehyde (**7**) bp 58 °C at 2 Torr, $[\alpha]_D^{26}$ +5.1° (*c* 1.2, methanol).

IR(neat film): 3050(w), 2950(s), 2880(m), 2820(w), 2750(w), 1720(s), 930(w) and 715(s) cm^{-1}.

Since the aldehyde was very sensitive to air, a correct elementary analysis datum was not obtained.

Photoreaction of (+)-Aldehyde (7). A solution of 6.08 g of (+)-aldehyde (**7**) in 500 ml of benzene was irradiated for 20 hr with mercury lamp (SHL-100 UV, Toshiba) under nitrogen atmosphere. After evaporation of the solvent, a residue was chromatographed on neutral alumina (Woelm Activity III) and a solid eluted with pentane was sublimed to give 2.85 g of (+)-oxetane (**8**) mp 167—170 °C (in sealed tube), $[\alpha]_D^{23}$ +148° (*c* 0.78, methanol).

IR(KBr): 2950(s), 2880(m), 1025(m), 935(m), 915(m), 895(m), 870(m), 840(m), 830(m) and 808(w) cm^{-1}.

NMR($CDCl_3$): δ 0.9—1.9(m, 7H), 2.1—2.5(m, 2H), 3.1—3.2(m, 1H), 4.3—4.5(m, 1H) and 4.6—4.8(m, 1H).

Found: C, 79.24; H, 8.86%. Calcd for $C_9H_{12}O$: C, 79.37; H, 8.88%.

(+)-Tricyclo[4.3.0.0^{3,8}]nonan-9-ol (9a). To a solution of 2.78 g of (+)-oxetane (**8**) in 170 ml of *N*-methylmorpholine was added 5.7 g of lithium aluminum hydride and the mixture was heated at reflux for 60 hr. After cooling, a few ml of methanol was added to the reaction mixture and then it was acidified with dilute hydrochloric acid. The mixture was extracted with ether. The extract was washed with satd. aqueous sodium bicarbonate, water and dried over magnesium sulfate. After evaporation of the solvent, a residue was chromatographed on neutral alumina (Woelm, activity III) and a solid eluted with ether-pentane was sublimed to give 1.22 g of (+)-tricyclic alcohol (**10**) mp 162—165 °C (in sealed tube), $[\alpha]_D^{23}$ +164° (*c* 0.66, methanol).

IR(KBr): 3350(s), 2930(s), 2880(m), 1090(s), 1075(m), 1030(m), 1010(m) and 875(w) cm^{-1}.

NMR($CDCl_3$): δ 1.2—2.2(m, 12H), 2.34(s, 1H) and 4.12(m, 1H).

Found: C, 78.09; H, 10.43%. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.21%.

(+)-Tricyclo[4.3.0.0^{3,8}]nonan-9-one (5). A solution of 1.38 g of (+)-alcohol (**9a**) in 20 ml of acetone was treated with excess of 8 N Jones' reagent for 2 hr with ice cooling. The reaction mixture was poured into water and it was extracted with ether. The extract was washed with satd. aqueous sodium bicarbonate, water and dried over sodium sulfate. After evaporation of the solvent, a residue was chromatographed on neutral alumina (Woelm, Activity III) and a solid eluted with pentane was sublimed to give 711 mg of ketone (**5**) mp 159—161 °C (in sealed tube) (lit,[9] racemic: mp 141—143 °C), $[\alpha]_D^{19}$ +176° (*c* 0.57, methanol).

IR(KBr): 2900(s), 2830(m), 1765(s), 1470(m), 1190(m), 1140(m), 1115(m), 1070(w), 880(m), 840(m), 790(w) and 735(w) cm^{-1}.

NMR(CCl_4): δ 1.4—2.1 (m, 12H).

UV: $\lambda_{max}^{isooctane}$ (ε) 379 (27) nm.

CD (c 4.03×10^{-2}, isooctane): $[\theta]_{245}$ 0, $[\theta]_{285}$ −2020, $[\theta]_{320}$ 0.

(+)-Tricyclo[4.3.0.0^{3,8}]nonane (**11**). A solution of 400 mg of 9-twist-brendanone (**5**), 219 mg of potassium hydroxide and 0.38 ml of 80% hydrazine hydrate in 3.5 ml of triethylene glycol was heated at reflux for 2 hr. Then water was allowed to boil out of the solution and the resulting solution was heated at 210 °C for further 5 hr. The reaction mixture was diluted with water and it was extracted with pentane. The extract was washed with water and dried over magnesium sulfate. After evaporation of the solvent, a residue was sublimed to give 134 mg of twist-brendane (**11**) mp 154—157 °C (in sealed tube), $[\alpha]_D^{21}$ +177° (c 0.46, ethanol). The NMR, IR, mass spectra and vpc retention time (10% SE-30 2m at 110 °C) were identical with those of (−)-enantiomer.[4]

(−)-endo-*2-Formylbicyclo[2.2.2]oct-5-ene* (**14**). Reduction of 34.0 g of (−)-*endo*-2-carboxybicyclo[2.2.2]oct-5-ene (**12**) $[\alpha]_D^{20}$ −27.8° with lithium aluminum hydride gave 27.7 g of (−)-*endo*-2-hydroxymethylbicyclo[2.2.2]oct-5-ene (**13**) $[\alpha]_D^{18}$ −4.0° (c 0.12, methanol). Upon oxidation with chromium trioxide, pyridine in dry methylene chloride, 13.8 g of (−)-alcohol (**13**) yielded 9.9 g of (−)-*endo*-2-formylbicyclo[2.2.2]oct-5-ene (**14**) bp 90—4 °C at 18 Torr, $[\alpha]_D^{18}$ −4.5° (c 1.86, methanol).

(−)-2-(1-Hydroxyethyl)bicyclo[2.2.2]oct-5-ene (**15**). A solution of 41.1 g of methyl iodide in 150 ml of dry ether was slowly added to a mixture of 6.4 g of magnesium with 100 ml of dry ether at room temperature and then the mixture was gently refluxed for 1 hr. After cooling to room temperature, a solution of 19.8 g of (−)-aldehyde (**14**) in 150 ml of dry ether was added to the Grignard reagent and the reaction mixture was boiled for 4 hr. It was cooled with ice and satd. aqueous ammonium chloride solution was added to the chilled mixture. A separated solid was filtered off and washed with ether. Combined ether solutions were washed with water and dried over magnesium sulfate. After evaporation of the solvent, a residue was distilled to give 20.2 g of (−)-alcohol (**15**) bp 108—110 °C at 20 Torr, $[\alpha]_D^{20}$ −0.23° (c 1.20, methanol).

IR(neat film): 3350(s), 3030(w), 2930(s), 2880(m), 1135(m), 1085(s), 1030(m), 925(m), 880(m) and 710(s) cm^{-1}.

Found: C, 78.62; H, 10.59%. Calcd for $C_{10}H_{16}O$: C, 78.89; H, 10.59%.

(−)-2-Acetylbicyclo[2.2.2]*oct-5-ene* (**16**). A solution of 9.60 g of (−)-alcohol (**15**) in 10 ml of dry methylene chloride was added to a mixture which was prepared from 42.0 g of chromium trioxide, 67.0 g of dry pryidine and 1000 ml of dry methylene chloride by the usual manner. The mixture was stirred for 15 min at room temperature. After working up as usual, a product was distilled to give 8.14 g of (−)-ketone (**16**) bp 102 °C at 20 Torr, $[\alpha]_D^{18}$ −8.1° (c 2.90, methanol).

IR (neat film): 3050(w), 2950(s), 2880(m), 1710(s), 1355(m), 1170(m) and 710(m) cm^{-1}.

Found: C, 79.97; H, 9.42%. Calcd for $C_{10}H_{14}O$: C, 79.95; H, 9.39%.

Photoreaction of (−)-2-acetylbicyclo[2.2.2]oct-5-ene (**16**). A solution of 7.00 g of (−)-ketone (**16**) in 600 ml of benzene was irradiated with mercury lamp (SHL-100UV, Toshiba) for 35 hr. After evaporation of the solvent, a residue was distilled to give 6.03 g of (−)-oxetane (**17**) bp 83—85 °C at 20 Torr $[\alpha]_D^{17}$ −177° (c 1.32, methanol).

IR (neat film): 2950(s), 2880(m), 1390(m), 1155(m), 1105(m), 1025(m), 955(m), 905(m), 890(m), 860(m) and 835(m) cm^{-1}.

Found: C, 79.50; H, 9.53%. Calcd for $C_{10}H_{14}O$: C, 79.95; H, 9.35%.

(−)-9-Methyltricyclo[4.3.0.0^{3,8}]nonan-2-one (**19**). To a solution of 2.78 g of (−)-oxetane (**17**) in 280 ml of *N*-methylmorpholine was added 6.9 g of lithium aluminum hydride at room temperature and the mixture was heated at reflux for 65 hr at which time it was cooled and added carefully with methanol, water and hydrochloric acid. The mixture was extracted with ether. The extract was washed with satd. aqueous sodium bicarbonate, water and dried over magnesium sulfate. After evaporation of the solvent, a residue was distilled to yield 1.62 g of the recovered oxetane (**17**) and a residual liquid was used to the following reaction. A solution of the residue in 5 ml of dry methylene chloride was added to a mixture of 1.58 g of chromium trioxide, 2.5 g of dry pryidine and 50 ml of dry methylene chloride and then the reaction mixture was stirred at room emperature for 15 min. After working up as usual, a crude product was chromatographed on neutral alumina (Woelm, activity III) and an elute with pentane was distilled to give 240 mg of (−)-ketone (**19**) bp 95—100 °C at 20 Torr, $[\alpha]_D^{15}$ −139° (c 0.38, methanol).

IR (neat film): 2950(s), 2870(m), 1753(s), 1455(m), 1380(w), 1300(w), 1180(w) and 1075(w) cm^{-1}.

NMR (CCl_4): δ 1.02(d, J=7 Hz, 3H), 1.4—2.2(m, 9H) and 2.3—2.5 (m, 2H).

UV: $\lambda_{max}^{isooctane}$ (ε) 292.5 (37) nm.

CD (c 5.00×10^{-2}, isooctane): $[\theta]_{240}$ 0, $[\theta]_{292}$ −7792, $[\theta]_{299}$ −6433, $[\theta]_{330}$ 0.

(−)-9-Methylenetricyclo[4.3.0.0^{3,8}]nonan-2-ol (**22**). To a solution of 2.99 g of (−)-oxetane (**17**) in 200 ml of methanol was added 100 μl of 70% perchloric acid and then the mixture was kept at 18—20 °C for 20 hr. After dilution with 200 ml of water and saturation with sodium chloride, it was extracted with ether and the extract was washed with water. After drying over magnesium sulfate and evaporation of the solvent, a residue was chromatographed on neutral alumina (Woelm, activity III). First elution with pentane gave a bicyclic compound which was further purified by distillation to give 0.86 g of **21** bp 127—130 °C at 20 Torr, $[\alpha]_D^{18}$ +26.7° (c 1.22, methanol). Followed fraction eluted with pentane gave 1.10 g of the recovered oxetane (**17**). Fractions eluted with ether-pentane (2 : 8 volume) gave an alcoholic product which was distilled to yield 845 mg of **22** bp 135 °C at 20 Torr, $[\alpha]_D^{15}$ −319° (c 1.16, methanol).

A Mixture of endo *and* exo*-2-Cyanomethylbicyclo[2.2.1]hept-5-ene (**30**).* A solution of 26.9 g of a mixture of *endo* and *exo*-2-hydroxymethylbicyclo[2.2.1]hept-5-ene (**28**) which was prepared by the Diels-Alder reaction of allyl alcohol with cyclopentadiene in 95 ml of pyridine was added with 50.0 g of *p*-toluenesulfonyl chloride. The reaction mixture was stirred for 5 hr at 0—5 °C and then kept for further 24 hr at room temperature. It was poured into ice-water and acidified with hydrochloric acid. The mixture was extracted with ether. The extract was washed with saturated aqueous sodium bicarbonate, water and dried over magnesium sulfate. Removal of the solvent gave 56.4 g of tosylate (**29**), which, without purification, was used to the next reaction. A mixture of 56.4 g of tosylate (**29**), 32.5 g of sodium cyanide and 300 ml of dimethylformamide was heated for 12 hr at 120—140 °C. After cooling to room temperature, a solid was filtered off and a filtrate was concentrated under reduced pressure. A residue was added into ice-water and it was extracted with ether. The extract was washed with dilute hydrochloric acid, saturated aqueous sodium bicarbonate and water, and dried over magnesium sulfate. After evaporation of the solvent, a residue was distilled to give 20.5 g of a mixture of *endo* and *exo*-nitrile (**30**) bp 108—110 °C at 17 Torr.

IR (neat film): 3030(w), 2950(s), 2850(m), 2260(w), 1420(w), 1345(w), 1330(w) and 720(s) cm^{-1}.

Found: C, 81.27; H, 8.34; N, 10.31%. Calcd for $C_9H_{11}N$: C, 81.16; H, 8.33; N, 10.52%.

A Mixture of endo *and* exo*-2-(2-Hydroxyethyl)bicyclo[2.2.1]-hept-5-ene (**32**).* A mixture of 20.2 g of nitrile (**30**), 26.0 g of potassium hydroxide and 200 ml of ethylene glycol was heated for 7 hr at 140—160 °C. After cooling to room temperature, 300 ml of water was added to the reaction mixture and it was washed with ether to remove neutral compounds. Then the aqueous solution was acidified with hydrochloric acid and it was extracted with ether. The extract was washed with water and dried over magnesium sulfate. After evaporation of the solvent, a residue was distilled to give 20.1 g of carboxylic acid (**31**) bp 103—110 °C at 3 Torr. A solution of 19.8 g of carboxylic acid (**31**) in 150 ml of dry ether was slowly added to a suspension of 5.5 g of lithium aluminum hydride in 150 ml of dry ether and the reaction mixture was gently refluxed for 4 hr. After cooling with ice, saturated aqueous ammonium chloride solution was added to the chilled reaction mixture. A separated solid was filtered off and a filtrate was washed with water and dried over magnesium sulfate. After evaporation of the solvent, a residue was distilled to yield 17.1 g of a mixture of *endo* and *exo*-2-(2-hydroxyethyl)bicyclo[2.2.1]hept-5-ene (**32**) bp 77—79 °C at 4 Torr.

Found: C, 78.08; H, 10.23%. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.21%.

A Mixture of endo *and* exo-*2-Formylmethylbicyclo[2.2.1]hept-5-ene (**33**).* To a mixture of 24.0 g of chromium trioxide, 38.0 g of dry pyridine and 580 ml of dry methylene chloride was added a solution of 5.52 g of alcohol (**32**) in 10 ml of dry methylene chloride. The reaction mixture was stirred for 15 min at room temperature. An organic layer was separated and a residue was rinsed with the same solvent. Combined organic solutions were worked up the usual manner. After evaporation of the solvent, a residue was distilled to yield 3.67 g of aldehyde (**33**) bp 89—91 °C at 20 Torr.

IR (neat film): 3050(w), 2950(s), 2860(m), 2730(w), 1720(s), 903(w), 830(w) and 725(m) cm^{-1}.

Found: C, 79.24; H, 8.98%. Calcd for $C_9H_{12}O$: C, 79.37; H, 8.88%.

*Photoreaction of Aldehyde (**33**).* A solution of 3.47 g of aldehyde (**33**) in 300 ml of benzene was irradiated for 15 hr with mercury lamp (SHL-100 UV, Toshiba) under nitrogen atmosphere. After evaporation of the solvent, a residue was chromatographed on neutral alumina (Woelm, acitivity III). An elution with pentane gave a solid which was sublimed to give 1.13 g of oxetane (**27a**) mp 161—163 °C (in sealed tube).

IR (KBr): 2950(s), 2880(m), 1330(s), 1050(s), 985(s), 955(m), 885(m), 840(m) and 800(m) cm^{-1}.

NMR ($CDCl_3$): δ 1.1—2.6 (m, 9H), 3.32—3.50 (m, 1H) and 4.50—4.80 (m, 2H).

*Tricyclo[4.3.0.0^{3,8}]nonan-2-ol (**34**).* A solution of 848 mg of oxetane (**27a**) in 60 ml of *N*-methylmorpholine was added with 2.0 g of lithium aluminum hydride and the reaction mixture was heated at reflux for 68 hr. After cooling with ice, methanol was carefully added to the chilled reaction mixture and then it was acidified with dilute hydrochloric acid. The mixture was extracted with ether. The extract was washed with saturated aqueous sodium bicarbonate, water and dried over magnesium sulfate. After evaporation of the solvent, a residue was sublimed to yield 655 mg of alcohol (**34**) mp 188—191 °C (in sealed tube).

IR (KBr): 3400(s), 2950(s), 1305(w), 1280(w), 1160(w), 1130(w), 1095(m), 1065(m), 1025(m) and 810(w) cm^{-1}.

NMR ($CDCl_3$): δ 1.1—2.4 (m, 12H) and 3.9—4.1 (m, 1H).

Found: C, 77.72 H, 10.35%. Calcd for $C_9H_{14}O$: C, 78.21; H, 10.21%.

*Tricyclo[4.3.0.0^{3,8}]nonan-2-one (**10**).* A solution of 522 mg of alcohol (**34**) in 3 ml of dry methylene chloride was added to a mixture of 3.8 g of dry pyridine, 2.4 g of chromium trioxide and 58 ml of dry methylene chloride and then the reaction mixture was stirred for 15 min at room temperature. After working up as the usual manner, the solvent was evaporated and a residue was chromatographed on neutral alumina (Woelm, activity III). A fraction eluted with pentane gave a solid, which was sublimed to yield 329 mg of tricyclo-[4.3.0.0^{3,8}]nonan-2-one (**10**) mp 173—174 °C (in sealed tube). The IR, NMR and mass spectra were in complete agreement with those of authentic sample.[4]

*4-Methoxytricyclo[4.3.0.0^{3,8}]nonan-2-one (**36**).* A solution of 340 mg of oxetane (**27a**) in 20 ml of methanol was added with 20 μl of 70% perchloric acid and the reaction mixture was kept for 24 hr at room temperature. After dilution with water, it was extracted with ether. The extract was washed with water and dried over magnesium sulfate. After evaporation of the solvent, a residue was chromatographed on silica gel and fractions eluted with pentane-ether (8 : 2 volume) gave 290 mg of an oily product, which was used for the next reaction. To a solution of 290 mg of the product in 5 ml of acetone was added excess of 8 N Jones' reagent with ice cooling. After stirring for 15 min at room temperature, it was diluted with water and extracted with pentane. The extract was washed with saturated aqueous sodium bicarbonate and water, and dried over magnesium sulfate. After evaporation of the solvent, a residue was chromatographed on silica gel and fractions eluted with pentane gave an oily product which was distilled to yield 218 mg of 4-methoxytricyclo[4.3.0.0^{3,8}]-nonan-2-one (**36**) bp 125 °C (bath temperature) at 18 Torr.

IR (neat film): 2950(s), 2880(m), 2820(m), 1750(s), 1365(m), 1240(m), 1210(m), 1170(m), 1105(s), 1085(m), 1075(m), 1065(m), 1025(m) and 930(m) cm^{-1}.

NMR (CCl_4): δ 1.6—1.8 (m, 4H), 1.9—2.2 (m, 2H), 2.3—2.6 (m, 4H), 3.24 (s, 3H) and 3.5—3.7 (m, 1H).

Found: C, 71.90; H, 8.36%. Calcd for $C_{10}H_{14}O_2$: C, 72.26; H, 8.49%.

The authors are grateful to Dr. H. Ogura for measurement of the CD spectra.

Coenzyme Models. II. Effect of Micellar Environments on the Acid-Catalyzed Hydration of 1,4-Dihydropyridine Derivatives[1]

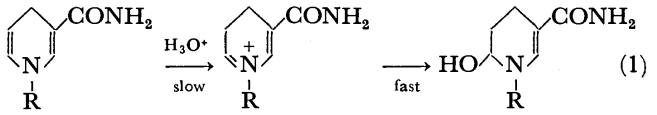
Seiji SHINKAI, Reiko ANDO, and Toyoki KUNITAKE

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received February 8, 1975)

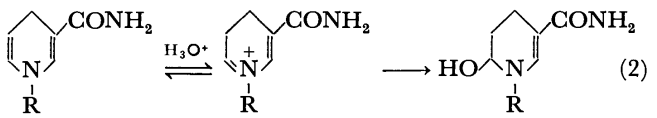
An effect of micelles on the acid-catalyzed modification reaction of two dihydropyridines is reported in connection with the NADH function bound to alcohol dehydrogenase, and the hydration equilibrium of dihydronicotinamides was found to be quite susceptible to the ionic environment. The absorption maximum at 357 nm of 1-benzyl-1,4-dihydronicotinamide(NBzNH) was not affected by the presence of cationic micelles, while that of 1-lauryl-1,4-dihydronicotinamide(NLaNH) shifted by 5—6 nm to shorter wavelengths, probably due to the neighboring cationic charge. The hydration rates for dihydronicotinamides were prompted by NaLS micelle and retarded by CTAB micelle. The rate augmentation in the NaLS micelle, compared with the non-micellar system, was 1.7-fold for NBzNH and 33-fold for NLaNH. On the other hand, CTAB micelle pronouncedly depressed the hydration rate of NLaNH, which is 414-fold slower than in NaLS. The micelle of 1-lauryl-3-carbamoylpyridinium(NLaN), which forms the charge transfer complex with NLaNH, was found to inhibit the acid-catalyzed hydration more efficiently(1400-fold slower). Thus, it is suggested that the ammonium ion adjacent to the dihydronicotinamide group in alcohol dehydrogenase-NADH complex performs some biological functions.

NADH and its model compounds, 1,4-dihydronicotinamide derivatives, undergo rapid structural alternations in acidic solutions, and their UV spectra result in a shift of the characteristic absorption band in the 340—360 nm region downward to around 290 nm with tight isosbestic points.[2] Metzler and co-workers have studied the acid transformation of NADH and NPrNH[3] in the presence of a series of acids, and established that the observed spectral shift of NPrNH is completely reversible until the much slower secondary decay takes place.[4] They claimed acid-catalyzed hydration for the initial acid modification reaction (Eq. 1 or 2).



(1)

or



(2)

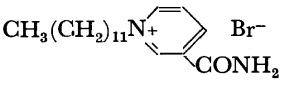
The 290 nm-absorbing compound was referred to as the "primary acid modification compound," and was later identified as 6-hydroxy-1,4,5,6-tetrahydronicotinamide by X-ray crystallography.[5] This compound is also unstable in acid, and the absorption at 290 nm disappears through the much slower, so-called "secondary acid reaction."

This reaction may be biologically important in connection with the fact that NADH bound to glyceraldehyde-3-phosphate dehydrogenase is characterized by a change in the UV spectrum similar to that which accompanies the primary acid reaction.[6,7] Reaction schemes (1) and (2) involve the formation of a cationic intermediate that is established to be a rate-determining step in aqueous media.[5] One would anticipate that the anionic environment would result in the acceleration of the apparent hydration rate as seen in acetal hydrolyses.[8,9] On the other hand, the cationic environment would retard the hydration rate. If this expectation is correct, it is conceivable that the lysine residue of the alcohol dehydrogenase which is postulated to exist very close to the bound NADH[10] performs some biological function by affecting the NADH reactivity.

In this paper we describe the effect of ionic micelles on the apparent hydration rate of acid-modifications of a few 1,4-dihydropyridines. Sodium laurylsulfate (NaLS), cetyltrimethylammonium bromide (CTAB) and 1-lauryl-3-carbamoylpyridinium bromide (NLaN) were used as surfactants. In order to study the micellar effect we chose 1-lauryl-1,4-dihydronicotinamide (NLaNH) in addition to 1-benzyl-1,4-dihydronicotinamide (NBzNH).

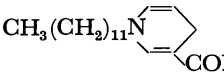
Surfactants: $CH_3(CH_2)_{11}SO_4Na$ (NaLS)

$CH_3(CH_2)_{15}N(CH_3)_3Br$ (CTAB)

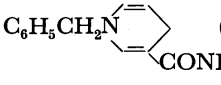


(NLaN)

Dihydropyridines:



(NLaNH)



(NBzNH)

Experimental

Materials. Surfactants were products of Wako Pure Chemical Ind., NaLS(biochemical use) was used without further purification, and CTAB was recrystallized from ethanol before use.

NBzNH was prepared according to the method of Kim and Chaykin,[5] and recrystallized from ethanol-water, yellow needles, mp 110—112 °C (lit,[5] mp 110—112 °C). NLaN was obtained from lauryl bromide and nicotinamide[11], and reduced to NLaNH with sodium dithionite by the procedure used to prepare NPrNH.[12] The yellow precipitates were collected and recrystallized twice from petroleum ether-ether, mp 45—48 °C. An NMR spectrum taken in $CDCl_3$ was identical to that of NPrNH except for the resonance of the 1-alkyl group: $CH_3(CH_2)_{10}$–, 0.8—1.6 ppm, 23.1H; N–CH_2- and C_4–H_2, 3.0—3.2 ppm, 4.2H; C_5–H, 4.5—4.8 ppm, 1.0H; C_6–H and NH_2, 5.4—5.8 ppm, 2.8H; C_2–H, 7.0 ppm, 1.0H. This dihydropyridine was unstable to heat and slowly decomposed to the orange-colored oil even at room tempera-

ture. The crystals were preserved in a refrigerator, and stock solutions for kinetic measurements were prepared on the day of use.

Kinetics. The kinetic and spectroscopic measurements were carried out at 30±0.1 °C at a calculated ionic strength (with KCl) using a Hitachi 124 spectrophotometer. Reaction rates of hydration (NBzNH and NLaNH) were estimated by following the increase of absorbance at 292 nm or the decrease of absorbance at 357 nm, and both methods provided the identical result. The pseudo first-order rate constants were determined from the time-course of reaction thus obtained.

Results

Electronic Spectra. In order to assess the environmental effect of micelles on the absorption maxima of dihydronicotinamides, spectra of NLaNH and NBzNH were taken in various solvents (Table 1). The absorption maximum of NLaNH could not be determined in water because of the sparing solubility. If the hypothetical λ_{max} value of NLaNH in water is assumed to be the same as that of NPrNH in water, λ_{max} of NLaNH in cationic micelles is estimated to shift to the shorter wavelength by 5—6 nm by transferring from the aqueous to micellar phase. A similar hypsochromic shift was observed in ethanol.

Table 1. Electronic spectra of dihydropyridines in various media.[a]

Medium	λ_{max} (nm)		
	NLaNH	NPrNH	NBzNH
Diethyl ether			340[c]
Methanol		354[b]	
Ethanol	355		354[c]
52wt% Methanol-water		362[b]	
Water		362[b]	357[c]
CTAB micelle	356		357
NLaN micelle	357		357

a) 30 °C. b) S. Shinkai and T. C. Bruice, *Biochemistry*, **12**, 1750 (1973). c) From Ref. 10.

The λ_{max} value of NBzNH in water was not affected by the addition of cationic surfactants. Presumably, the equilibrium constant for the association of NBzNH with surfactants is rather small, resulting in the smaller micellar effect.

Hydration of 1-Benzyl-1,4-dihydronicotinamide (NBzNH). The absorption spectrum of the acid modification product of NBzNH are essentially the same as that of reference 4 with tight isosbestic points. In Fig. 1, pseudo first-order rate constants (k_{obsd}) for the hydration of NBzNH in the phosphate buffer were plotted against the concentration of surfactants, CTAB and NaLS. The concentration-rate profile is multiphasic. The rate constants are independent of the surfactant concentration below cmc, while they rapidly rise or descent with increasing concentration of surfactants above cmc. From Fig. 1 the cmc is estimated to be 4×10^{-4} M for CTAB and 3×10^{-3} M for NaLS under the reaction condition employed (lit,[13] cmc at 25 °C for CTAB, 9.2×10^{-4} M; for NaLS, 8.1×10^{-3} M).

The existence of the NaLS micelle raises the reaction

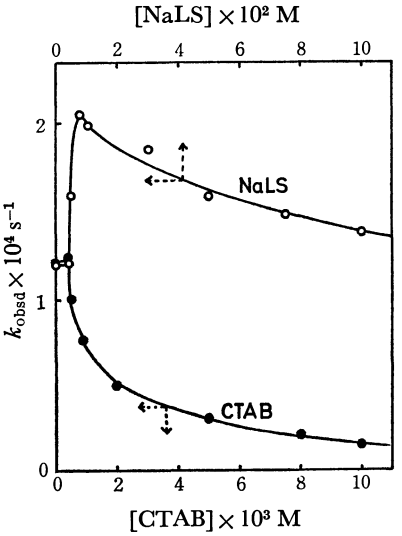


Fig. 1. Pseudo first-order rate constants for the acid-catalyzed hydration of NBzNH in aqueous solution. 30 °C, pH 6.30 with 0.01 M phosphate.

rate, and a rate augmentation of 1.7-fold is observed at the optimal surfactant concentration. Since the rate enhancement is slight, it is presumed that most of NBzNH is dissolved in the bulk phase and that the small amount of NBzNH bound to the micelle contributes to the rise of the total reaction rate.

On the contrary, CTAB depressed the hydration rate above the cmc, and the rate constant is 8.4-fold smaller at [CTAB]$=10^{-2}$ M, compared with that obtained without surfactant.

Hydration of 1-Lauryl-1,4-dihydronicotinamide (NLaNH). NBzNH is moderately soluble in aqueous solution (solubility: *ca.* 10^{-2} M), while NLaNH is sparingly soluble in water. In fact, precipitation of NLaNH (1.67×10^{-4} M) was recognized with less than 3.0×10^{-3} M of NaLS. Therefore, it would be reasonable to infer that the acid-catalyzed hydration reaction of this dihydronicotinamide entirely proceeds in the micelle. The surfactant concentration-rate profile for NLaNH is shown in Fig. 2. In the CTAB micelle the decay of NLaNH was extremely inhibited, so that

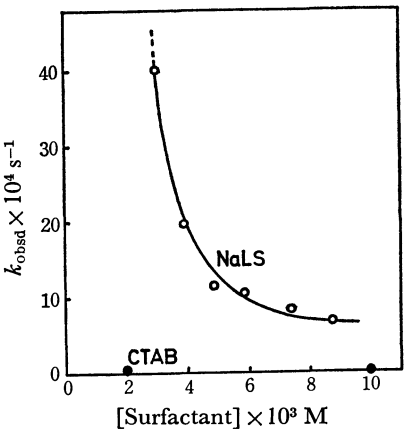

Fig. 2. Pseudo first-order rate constants for the acid-catalyzed hydration of NLaNH in aqueous solution. 30 °C, pH 6.30 with 0.01 M phosphate, [NLaNH]$=1.67\times10^{-4}$ M.

the first-order rate constant was calculated by means of the Guggenheim's equation: $k_{obsd}=9.7\times10^{-6}$ s^{-1} ($t_1/_2=$ *ca.* 20 hr) at [CTAB]$=1.0\times10^{-2}$ M. This reaction rate is about 12-fold slower than that of NBzNH in the non-micellar system. Since the NADH- or 1,4-dihydronicotinamide-mediated reduction reaction is generally much faster,[2] it may be said that dihydronicotinamides in the CTAB cationic micelle are almost completely stabilized in weakly acidic solutions.

In the accompanying paper we showed that NLaNH forms the charge transfer complex with NLaN in micellar systems (association constant, $K=22$—45 M^{-1}).[14] The hydration reaction in NLaN micelle is of much interest from the biological standpoint because the glyceraldehyde-3-phosphate dehydrogenase-NAD complex involves the charge transfer interaction between the 3-carbamoylpyridinium group of NAD and the enzyme residue, probably an indole nucleus.[15] The pseudo first-order rate constant for the hydration reaction of NLaNH was estimated to be 2.8×10^{-6} s^{-1} at [NLaN]$=1.56\times10^{-2}$ M, which is 3.5 times slower than in CTAB micelle. It seems, therefore, that the charge transfer interaction inhibits the acid-catalyzed hydration reaction more efficiently.

In NaLS micelle the hydration rates were conspicuously accelerated (Fig. 2). Shiny crystals of NLaNH were recognized in the presence of NaLS below 3.0×10^{-3} M. The rate rapidly increases as the surfactant concentration approaches the cmc, and, at [NaLS]$=3.0\times10^{-3}$ M, a remarkable rate augmentation of 414-fold (relative to that in the CTAB micelle) was observed. This enhanced rate is 33-fold greater than the hydration rate of NBzNH in non-micellar solution. The protonated intermediate (or the transition state) of the hydration reaction should be significantly stabilized by the anionic environment consisting of the NaLS micelle.

Discussion

Absorption Maxima of Dihydronicotinamides. The absorption maximum of dihydropyridines is known to shift depending on the environment. This phenomenon is of particular interest in connection with the observation that the complex of alcohol dehydrogenase and NADH has an absorption maximum at 325 nm in contrast to that of NADH at 340 nm.[16] This observation has been repeated and extended to NADH analogs and NAD-addition products.[17,18] Although the shift to shorter wavelengths is also brought forth by non-polar environments, Kosower rather claimed that a positively-charged nitrogen(probably ammonium ion of a lysine residue) which is located 3 Å apart from the nitrogen of the dihydropyridine ring produces the shift by destabilization of the polar excited state of the dihydropyridine.[10]

In the present study λ_{max} of NLaNH shifted by 6 nm to shorter wavelengths in the CTAB micelle compared with NPrNH in water (Table 1). NLaN efficiently forms the charge transfer complex with NLaNH in micellar systems,[14] and the complex probably possesses the face-to-face orientation. Despite the expectation that the remarkable hypsochromic shift may occur, the observed shift was only 5 nm in the micelle of NLaN. Therefore, the ring nitrogen of NLaNH may not be located very close to the cationic charge of surfactant molecules enough to perturb the spectrum.

Hydration Rates of Dihydronicotinamides. Although the hypsochromic shift of dihydronicotinamides caused by the adjacent cationic charge of the surfactant is only 5—6 nm, it is interesting to assess the acid-catalyzed hydration rates in reference to the shifts.

The experimentally observed first-order rate constants for the hydration of a dihydronicotinamide can be satisfactorily described by a general acid catalysis equation (3), in which k_0 is the reaction rate with water and k_H and k_{HA} are the catalytic constants of hydronium ion and buffer acid, respectively.[4]

$$k_{obsd} = k_0 + k_H[H_3O^+] + k_{HA}[HA]$$

Since the k_0 term is negligible in comparison with other terms,[4] one can consider that hydronium ion and buffer acid catalyze the hydration reaction. Under the condition employed, the hydration reaction is mainly catalyzed by $H_2PO_4^-$ ion,[4] that is, k_{HA} [HA]$>$ k_H [H_3O^+]. The CTAB micelle would localize $H_2PO_4^-$ ion around the Stern layer, while H_3O^+ ion would be expelled out of the micellar surface. Thus, one may expect that the hydration rates would be accelerated by concentrated $H_2PO_4^-$ ion. On the contrary, the presence of CTAB micelle depressed the reaction rates, so that the retardation should be caused by the cationic micelle itself. It is concluded, therefore, that a cationic micelle destabilizes a positively-charged intermediate (or the transition state to form the intermediate; Eqs. 1 and 2). A similar discussion would be possible to account for the acceleration effect by an anionic micelle. Thus, the effect of the cationic and anionic micelles on the hydration reaction is consistent with the previous proposition by Kim and Chaykin[5] that the protonation of dihydronicotinamides is involved in the rate-determining step.

The micellar effect on the hydration rate was most pronounced in the case of NLaNH. Though the decay of NLaNH is extremely depressed in CTAB micelle, it would not mean the dihydronicotinamide portion of NLaNH to be in the apolar core of the micelle. The hydration reaction is accelerated by the presence of NaLS micelle, and the acceleration phenomenon could not be expected for the functional group sinking in the micelle core. The dihydronicotinamide group probably exists in the Stern layer or at the vicinity. Our recent observation that NLaNH efficiently forms the charge transfer complex with the 3-carbamoylpyridinium group of NLaN in CTAB-micelle[14] would support this inference.

The relative rate augmentation and depression, compared with NBzNH in non-micellar system, are listed in Table 2. The surfactant concentration, where the rate difference is the greatest, was employed to demonstrate the susceptibility of the hydration reaction to the ionic environment. The conspicuous micellar effect is seen in the case of NLaNH. The NaLS micelle accelerates the hydration rate of NLaNH by 33-fold. This augementation corresponds to 414-fold of that in CTAB micelle, and, in fact, 1400-fold of that in NLaN micelle.

The cationic charge of CTAB and NLaN micelles is not located close to the nitrogen of the nicotinadmie

Table 2. Relative hydration rate[a)]

Dihydronicotinamide	Non-micelle	Micelle		
		LaLS	CTAB	NLaN
NBzNH	1.0	1.7	1/ 8.4	
NLaNH		33	1/12.6	1/44

a) 30 °C, pH 6.30 with 0.01 M phosphate. Surfactant concentrations which provide the greatest difference are as follows: for NBzNH, $[NaLS]=8.00\times10^{-3}$ M, $[CTAB]=1.00\times10^{-2}$ M; for NLaNH, $[NaLS]=3.00\times10^{-3}$ M, $[CTAB]=1.00\times10^{-2}$ M, $[NLaN]=1.56\times10^{-2}$ M.

group enough to cause the significant spectral shift. However, it exerts the remarkable inhibitory effect on the hydration. In the complex between NADH and alcohol dehydrogenase, a positively-charged nitrogen in the form of an ammonium ion is located at the distance of 3 Å from the nitrogen of the dihydropyridine ring, which does generate the spectral shift.[10] It is conceivable from the present results that the hydration reaction of the bound NADH to alcohol dehydrogenase would be greatly affected by the presence of such a closely neighboring ammonium ion. At present, however, it is uncertain if any biological function is associated with the presence of such a positive charge. The present work suggests that the positive charge protects the bound NADH from the hydration decay, and that it would enable the dihydronicotinamide group to act as a reducing function over a wide pH range.

Concluding Remark. As described above, the acid-catalyzed hydration of 1,4-dihydronicotinamide is quite susceptible to the influence of the ionic environment. This finding in a model system may be of importance bearing to an attempt to understand the function of the bound NADH to alcohol dehydrogenase. Micelles would be a typical model system such that the dihydronicotinamide group is located close to the ionic group. A similar system is possible in polyelectrolytes containing the dihydronicotinamide function (Eq. 4).[19]

Coenzyme Models. III. Enhanced Charge Transfer Interaction between the Oxidized and Reduced Forms of Nicotinamide in Micellar and Polymeric Systems. NAD Coenzyme Model[1]

Seiji SHINKAI, Kiyoshi TAMAKI, and Toyoki KUNITAKE

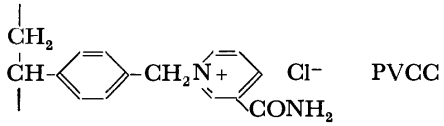
Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received February 8, 1975)

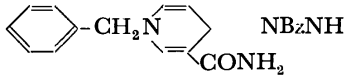
The micelle of 1-lauryl-3-carbamoylpyridinium bromide(NLaN) and poly-1-(*p*-vinylbenzyl)-3-carbamoylpyridinium chloride (PVCC) were shown to form charge transfer complexes with dihydronicotinamides and several aromatic compounds in aqueous media. A broad charge transfer absorption at longer wavelengths was easily detected, and the association constant of 1 : 1 complexes which was estimated from the CT band was enhanced by 6.2—220 times in the NLaN micelle and by 14—66 times in the polymeric system, compared with non-micellar, monomeric system. The enhancement of the interaction between NLaN and its reduced from (NLaNH) was similar in the CTAB micelle and in a nonionic micelle. The increased electron-acceptabilities of the pyridinium group in micellar and polymeric systems were discussed in reference to NAD coenzyme.

The oxidized and reduced forms of flavin mononucleotide produce a charge transfer complex which is a precursor of the semiquinone-type free radical.[2] The charge transfer interaction is similarly expected to exist in NAD coenzyme, and, in fact, a new broad absorption which appears to be due to a 1 : 1 charge transfer complex between NAD and NADH was observed at the longer wavelength.[3] In the nonenzymatic system the charge transfer interaction could be recognized only at abnormally high concentrations (0.14—1.5 M),[3] in the intramolecular charge transfer systems,[4,5] and in the frozen system at −78 °C.[6] Though it is quite important to prove the existence of the charge transfer interaction in connection with the hydrogen transfer reaction involving NAD coenzyme, the conditions employed in the previous model systems seem to be far from the original milieu where the enzymic reaction proceeds. Thus, it occurs to us that the charge transfer interaction may be more easily detected in microheterogeneous systems such as micelles and water-soluble polyelectrolytes. This paper describes charge transfer interactions of poly-1-(*p*-vinylbenzyl)-3-carbamoylpyridinium chloride(PVCC) and 1-lauryl-3-carbamoylpyridinium bromide (NLaN) with dihydronicotinamides (NBzNH, NLaNH) and several aromatic compounds, and the results obtained were compared with the corresponding monomeric compound.

Acceptor: $CH_3(CH_2)_{11}N^+$ (pyridinium, $CONH_2$) Br^- NLaN



Donor: $CH_3(CH_2)_{11}N$ (dihydropyridine, $CONH_2$) NLaNH



Experimental

Materials. *p*-Chloromethylstyrene was prepared according to the method of Miyake and Tanimoto,[7] bp 58—61 °C/0.13 mmHg (lit,[7] 58—62 °C/0.4 mmHg).

1-(*p*-Vinylbenzyl)-3-carbamoylpyridinium chloride (VCC) was prepared by quaternization of nicotinamide by *p*-chloromethylstyrene in methanol. Recrystallization of the resulting precipitates from methanol gave colorless needles; yield 86—92%, mp 235—238 °C. Found: C, 64.16; H, 6.21; N, 10.16%. Calcd for $C_{15}H_{15}N_2OCl \cdot 0.33\ H_2O$: C, 64.16; H, 6.35; N, 9.88%.

Polymerizations of VCC were conducted using potassium persulfate as initiator at 65 °C in water solvent. After 24 hr viscous polymer solutions were poured into acetone, and the recovered polymers were purified by dialysis to give white powders, yield 90%.

The syntheses of NLaN and NLaNH were described in the accompanying paper.[8] Other materials used in this paper were products of Wako Pure Chemical Ind.

Electronic Spectra. Absorption spectra were taken on a Hitachi 124 spectrophotometer at a slow scan speed to permit accurate determination of extinction coefficients. Spectra were recorded at 30 °C in aqueous solutions adjusted to pH 9.30 with 0.02 M borate buffer.

Association Constants. Association constants (K) in polymeric systems were determined by varying the concentration of PVCC while maintaining the concentration of donor compounds(D) constant. Data thus obtained were plotted according to Eq. 1 which holds for formation of a 1 : 1 complex,[9]

$$\frac{\Delta OD}{[PVCC]} = K \cdot \varepsilon [D] - K \Delta OD \qquad (1)$$

where [PVCC] represents the concentration of the VCC unit in the polymer, ε is the apparent molar absorption coefficient of the complex, and ΔOD represents the difference of optical density between the observed value and the sum of the individual absorptions. From the least-squares procedure of ΔOD *vs.* $\Delta OD/[PVCC]$ plots, slopes and intercepts were evaluated, and K and ε values are determined according to Eq. 1.

In micellar systems it was experimentally difficult to attain the conditions mentioned above, so that Eq. 1 was modified to Eq. 2 and ΔOD values were measured at two different NLaN concentrations.

$$\Delta OD = \frac{\varepsilon K}{\left(K + \frac{1}{[NLaN]}\right)} \cdot [D] = A \cdot [D] \qquad (2)$$

From the slope of [D] *vs.* ΔOD plots at different NLaN concentrations were determined two A values, the simultaneous equation of which gave K and ε values.

Results and Discussion

Charge Transfer Absorption Spectra. The absorption spectrum of NLaNH obtained in a micellar solution of cetyltrimethylammonium bromide (CTAB: 2.50×10^{-2} M) was essentially the same as that in absolute ethanol. On the other hand, the addition of NLaNH to a NLaN-micellar solution provided a colored solution (yellow-light orange). A new, diffused absorption appeared at 430—550 nm (Fig. 1) as previously reported for NAD[3] and for 1-benzyl-3-carbamoylpyridinium[9] in non-micellar systems at higher concentrations. In the NLaN-micelle, addition of 10^{-3}—10^{-4} M of NLaNH was found to be sufficient to detect the charge transfer absorption. According to Ludowieg and Levy,[3] the charge transfer absorption between 1-propyl-3-carbamoylpyridinium chloride (NPrN) and its reduced form (NPrNH) is very susceptible to the dilution effect. Although mixing of a 10^{-2} M colorless solution of NPrN with a 10^{-2} M light-yellow solution of NPrNH gave a solution with little increase in color intensity, an instantaneous orange color was observed at higher concentrations (0.7—1.5 M).[3] Therefore, the enhanced charge transfer interaction observed in the present micellar system may be associated with increased concentrations of the nicotinamide groups of NLaN and NLaNH in the thin Stern layer. The intensity of the charge transfer absorption was proportional to the concentration of NLaNH, when the concentration of NLaN was maintained constant under the condition of [NLaN] $\gg$ [NLaNH]. Thus, Eq. 2 is applicable to the present system, *i.e.*, the 1 : 1 complex is formed between NLaN and NLaNH even in a micellar system.

The interaction between NLaN and NLaNH was enhanced to a similar extent in a nonionic micelle of polyoxyethylene (10) oleyl alcohol as well as in CTAB micelle, and the spectra observed were almost the same as that observed in NLaN micelle (Fig. 1). Evidently, the ionic environment, characteristic of ionic micelles, is not obligatory to enhanced interaction. The concentration effect must play a decisive role for the enhancement of the charge transfer interaction in micellar systems.

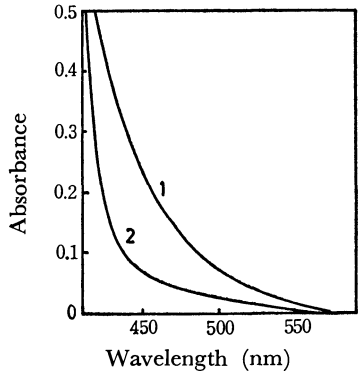


Fig. 1. Absorption spectra of NLaNH in micellar systems.
[NLaNH] $=4.0\times10^{-3}$ M, 30 °C, pH 9.30 with 0.02 M borate, 8 vol % ethanol.
1: [NLaN] $=1.56\times10^{-2}$ M, 2: [CTAB] $=2.50\times10^{-2}$ M.

Enhanced charge transfer interactions with NLaN and with PVCC were also observed for naphthalene, acenaphthene, adenosine and indole derivatives. Complexes with indole derivatives showed strong charge transfer absorptions at 320—450 nm and a difference spectrum indicated absorption maxima at 303—324 nm (ε=2600—900, Fig. 2).[10] These spectra are of particular interest because of their similarity to the spectrum of the NAD-glyceraldehyde-3-phosphate dehydrogenase complex (λ_{max} 360 nm).[11] This enzyme is the only one which is known to form a charge transfer complex between NAD and the enzyme residue, probably an indole nucleus. Velick[12] suggested that the NAD coenzyme is bound at the top or bottom of a tryptophan stack in the enzyme. A similar spectrum is observed in a model compound, 1-(β-indolylethyl)-3-carbamoylpyridinium chloride, which possesses the intra-

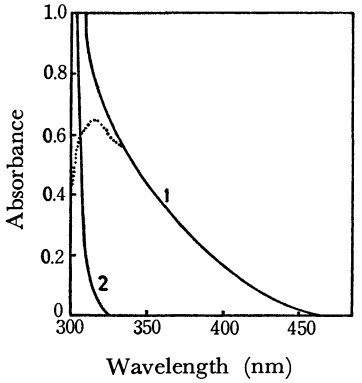

Fig. 2. Absorption spectra of (3-indolyl)acetic acid in micellar systems. The dotted curve indicates a difference spectrum (λ_{max} 317 nm).
[(3-Indolyl)acetic acid] $=1.0\times10^{-3}$ M. Other conditions are the same as a note of Fig. 1.

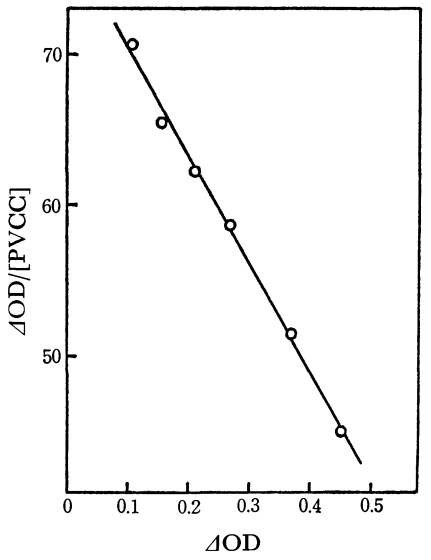

Fig. 3. Spectrophotometric determination of the association constant for the complex of indole with PVCC in water.
30 °C, pH 9.30 with 0.02 M borate, [indole] $=3.0\times10^{-3}$ M. See text (Experimental, Eq. 1) for details of the method.

molecular interaction between 3-carbamoylpyridinium and indole moieties (λ_{max} 325 nm, $\varepsilon=1000$).[4,5]

Association Constants. Association constants were determined according to the method of Cilento *et al.*[9,13,14] as described in the experimental section. The wavelengths employed are the same as in their system. The plots of ΔOD *vs.* ΔOD/[PVCC] in the polymeric systems gave good linear relationships and the correlation coefficients were better than 99% (Fig. 3). Association constants (K) and molar absorption coefficient (ε) determined using the least squares method are recorded in Table 1. It is seen that ε values are one half to two thirds of those of monomeric 3-carbamoylpyridinium.[9,13,14] On the other hand, the association constant was enhanced by 14—66 times. These results indicate that PVCC provides a better environment in forming the charge transfer complex compared to the monomeric compound and that a 1 : 1 complex is formed between a donor molecule and a VCC unit in the polymer. In the polymeric system two VCC units could interact with a donor molecule from both sides. However, this is not the case. And the better acceptor property observed may suggest that adjacent VCC units function to increase the electron-acceptability of the complex-forming VCC unit. As expected, the association constant of (3-indolyl)acetic acid was the greatest.

The plots of [D] *vs.* ΔOD for micellar systems gave linear relationships (Fig. 4), and association constants and molar absorption coefficients were computed from Eq. 2. The result is summarized in Table 2. Association constants for indole derivatives were enhanced by only 6—10 times in NLaN micelle, compared with non-micellar system. The enhancement was greater in the polymeric system than in the micellar system. On the other hand, association constants for naphthalene and acenaphthene were enhanced by 129—220 times in NLaN micelle. This large augmentation would be associated with solubilization by micellar systems, that is, water-insoluble aromatics like naphthalene and acenaphthene should be fixed in and/or near the Stern layer of NLaN micelle, resulting in strong charge transfer interactions. These aromatic compounds are insoluble in the aqueous solution of PVCC.

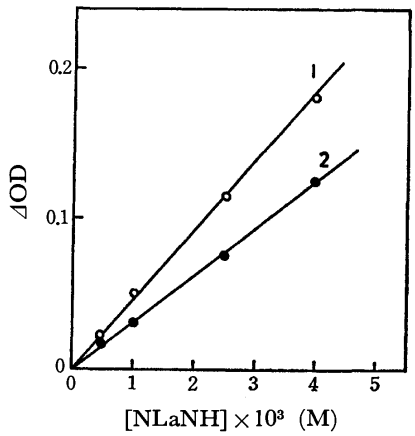

Fig. 4. Spectophotometric determination of the association constant for the complex of NLaNH with NLaN.
30 °C, pH 9.30 with 0.02 M borate, 8 vol % ethanol. 1: [NLaN] = 1.56×10^{-2} M, 2: [NLaN] = 1.00×10^{-2} M. See test (Experimental, Eq. 2) for details of the method.

Table 1. Association constants of PVCC[a]

Indole	380	890	2.21	360	72
(3-Indolyl)acetic acid	380	1060	4.09	440	271

a) 30 °C, pH 9.30 with 0.02 M borate buffer. b) Wavelength employed to evaluate ΔOD values of Eq. 1. c) Determined by Cilento *et al.*[9,13,14]

Association constants of aromatic compounds with NLaN decreased in CTAB and nonionic micelles. On the other hand, those of NLaNH with NLaN increased, or were unaffected in these micelles (Table 2). Presumably, the formation of a charge transfer complex between NLaNH and NLaN is favored because both of them possess the surfactant structure.

NAD Coenzyme Model. The foregoing observations establish that micellar and polymeric systems provide favorable environmentals in forming the 1 : 1 charge transfer complex between NLaN and donors including NLaNH, indole derivatives, and other aromatic compounds. These findings imply that these systems would act as a proper NAD coenzyme model, since it has been known that the interaction between pyridine

and adenine rings produced by the folded conformation plays an important role to adjust the oxidation-reduction reactivity in the enzymic system.[15,16] It would be interesting to assess the effect of such an interaction on the oxidation-reduction reaction in a model system.

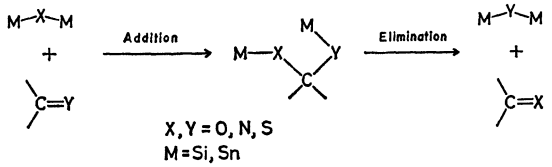
(Received February 28, 1975)

N,N'-Bis(trimethylsilyl)-1,2-diamines gave imidazolidine derivatives accompanied with the elimination of hexamethyldisiloxane in excellent yields by condensation reactions with carbonyl compounds under mild conditions. These reactions are regarded as the typical addition-elimination reaction of group IV organometallics.

Imidazolidine derivatives have been synthesized by a dehydration condensation reaction between diamine and carbonyl compounds. This preparative reaction, however, is reversible, and removal of generated water is required to complete the reaction. This operation takes generally long time and is inadequate to prepare water-sensitive homologues.

In this paper we describe a modified preparation of imidazolidine skeleton by means of *N,N'*-bis(trimethylsilyl)ethylene- and -*o*-phenylenediamines. Elimination of unreactive hexamethyldisiloxane should favor an irreversible generation of imidazolidine under mild reaction conditions. In addition, the present manipulation is easy to carry out simple separation of hexamethyldisiloxane *in vacuo*. These condensation reactions constitute an extension of addition-elimination reactions of main group organometallics from the standpoint of organometallic chemistry.



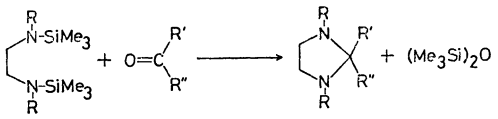
(1)

The most important driving force in either β-addition-β-elimination of heptamethyldimetallazane (M=Me_3Si,[2,3] Me_3Ge,[4] and Me_3Sn[2,5] X=NMe), or β-addition-ω-elimination (M=$^nBu_3Sn$; Y=$O(CH_2)_nO$,[6] $NR(CH_2)_2O$,[7] $NR(CH_2)_2NR$[7]) was the organometallic affinity differences between product (with stable M–Y bonds) and starting materials (with labile M–X bonds).[8]

This work is devoted to examine the possibility of utilization of the strong silicon-oxygen bond formation (a hard-hard interaction) in the imidazolidine cyclizations, because we previously elucidated that an inverse soft-soft interaction of tin-sulfur bond formation had substantial synthetic potential in iminocarbonylation or cyclization to thione-carbonate and spiro-orthoesters.

Results and Discussion

Reactions of electronically and sterically different various *N,N'*-bis(trimethylsilyl)-1,2,-diamines with aldehyde or ketones gave corresponding imidazolidine derivatives in excellent yields.



(2)

Hexamethyldisiloxane generated as a sole by-product could be removed completely by evaporation *in vacuo* at room temperature. When dimethylformamide was used as a reactant with *N,N'*-bis(trimethylsilyl)ethylenediamine and -*o*-phenylenediamine, subsequent elimination of dimethylamine induced the generation of 2-imidazoline and 2-benzimidazole, respectively. Preparative results are summarized in Table 1. Analytical and spectroscopic results are shown in Table 2.

Reaction of N,N'-*Bis(trimethylsilyl)ethylenediamine (**1**).* *N,N'*-Bis(trimethylsilyl)ethylenediamine (**1**) reacted with diethyl ketone and cyclohexanone to give the expected imidazolidines (**4b**) and (**4a**), which were readily purified by distillation. Analytical and spectral informations are in consistent with the depicted structures.

Dimethylformamide reacted with **1** at 120 °C to give imidazoline (**4c**) by way of further elimination of dimethylamine. Although 2-substituted imidazolines have been prepared by dehydration condensation under highly drastic conditions (200—220 °C), parent skeleton of 2-imidazoline has not been obtained. This method is extremely useful to prepare simplest 2-imidazoline (**4c**). The mechanism of this reaction was discussed later. Benzaldehyde did not give expected imidazolidine by ω-elimination of hexamethyldisiloxane but afforded *N,N'*-dibenzylideneethylenediamine (**4d**), which was definitely identified by analysis, IR ($\nu_{C=N}$ 1640 cm^{-1}), and NMR [τ_{CH} 1.80 (2H, s), τ_{CH_2} 6.16 (4H, s)].

Reaction of N,N'-*Bis(trimethylsilyl)*-N,N'-*dimethylethylenediamine (**2**).* Introduction of methyl groups on each nitrogen atom of **2** increased both electron density and steric hindrance around the nitrogen atom. The reaction of **2** with diethyl ketone, cyclohexanone, and even benzaldehyde, however, gave quantitatively the corresponding imidazolidines, **5b**, **5a**, and **5c**, which were unambiguously identified by analytical and spectral informations. Dimethylformamide did not react with **2** even at 120 °C for 6 hr indicative of the participation of steric effect to some extent.

Reaction of N,N'-*Bis(trimethylsilyl)*-o-*phenylenediamine (**3**).* Benzimidazoline derivatives (**6b** and **6a**) were obtained successfully by the reaction of **3** with benzaldehyde or cyclohexanone in excellent yields,

a) See experimental section. b) Yield is isolated yield and that in parentheses is determined by NMR.

whereas diethyl ketone did not react with **3** even at 180 °C.

When **3** was reacted with benzaldehyde and with dimethylformamide at elevated temperature (120 °C), 2-phenylbenzimidazole (29%) and benzimidazole (97%) were generated respectively by way of the successive β-elimination of hydrogen and dimethylamine. In fact, 2-phenylbenzimidazoline (**6b**), prepared from **3** and benzaldehyde at room temperature, caused smooth elimination reaction of hydrogen to aromatize to benzimidazole at 120 °C.

Mechanism. Above-mentioned preparative reactions are reasonably explained by a β-addition-ω-elimination reaction controlled by the affinity difference between labile Si–N and stable Si–O bonds. The primary step is the nucleophilic attack of either nitrogen atom in *N,N'*-bis(trimethylsilyl)-1,2-diamines to the carbonyl carbon atom, followed by the rapid migration of trimethylsilyl group to oxy anion to give intermediate insertion product [A]. Formation of extremely stable hexamethyldisiloxane is the driving force of the ω-elimination reaction to give imidazolidine [B] as cyclization product. The reaction between **1** and benzaldehyde belongs to an exceptional case and facile β-elimination of trimethylsilanol is induced to give [C] which captures the second benzaldehyde at

the another end to generate *N,N'*-dibenzylideneethylenediamine [D].

Experimental

IR spectra were recorded with a Japan Spectroscopic Co., Ltd. IR-S instrument. ^{1}H NMR spectra were measured with a Japan Electron Optics Lab. Co., Ltd. C-60 HL instrument. *N,N'*-Bis(trimethylsilyl)diamines were prepared according to Birkofer, Kühlthau, and Ritter.[9] Carbonyl compounds were freshly distilled before use.

Synthesis of Imidazolidines. To the *N,N'*-bis(trimethylsilyl)diamine (3.5—13.5 mmol) were added dropwise equimolar amounts of carbonyl compounds under an atmosphere of nitrogen at 0 °C.

In *Method* **A** the reaction mixture was warmed to room temperature. In *Method* **B** the mixture was heated in a sealed tube. In both methods formed hexamethyldisiloxane was removed from the reaction mixture to leave imidazolidine under reduced pressure (*ca.* 30 mmHg). For the purpose of elemental analysis, imidazolidines were distilled under reduced pressure. The elemental analyses, ^{1}H NMR spectra, IR spectra and other properties provided an adequate support for the structure assigned.

Reaction of N,N'-*Bis(trimethylsilyl)ethylenediamine with Benzaldehyde. Synthesis of* N,N'-*Dibenzylideneethylenediamine (**4d**).* To *N,N'*-bis(trimethylsilyl)ethylenediamine (2.75 g, 13.5 mmol) was added benzaldehyde (1.36 g, 12.8 mmol) dropwise under nitrogen at −78 °C. When the reaction mixture was warmed gradually to room temperature, exothermic reaction occurred to give transparent liquid separated into two layers. The reaction mixture was then distilled under reduced pressure (152 °C/0.8 mmHg) to yield colorless needles (1.48 g, 98% yield based on benzaldehyde used). Mp 52.0—54.0 °C. Found: C, 81.54; H, 7.06; N, 11.40%. Calcd for $C_{16}H_{16}N_2$: C, 81.34; H, 6.83; N, 11.85%. IR (in KBr) 1640 cm^{-1} ($\nu_{C=N}$). ^{1}H NMR (in CCl_4) τ 6.16 (4H, s), 2.25 (10H), and 1.80 (2H, s).

*Conversion of 2-Phenylbenzimidazoline (**6b**) to 2-Phenylbenzimidazole (**6c**).* By the heating of the benzene solution of 2-phenylbenzimidazoline (1.00 g, 5.11 mmol) in sealed tube at 120 °C for 12 hr, colorless precipitates sparingly soluble in benzene separated out. Upon recrystallization from acetone 2-phenylbenzimidazole precipitated as colorless prisms (0.291 g) in a 29% yield. The mp and spectroscopic data of the product were in good agreement with those of authentic sample.

Selenocyanatodethallation in Organothallium(III) Compounds

Sakae UEMURA,* Akio TOSHIMITSU, Masaya OKANO, and Katsuhiko ICHIKAWA**

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

***Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606*

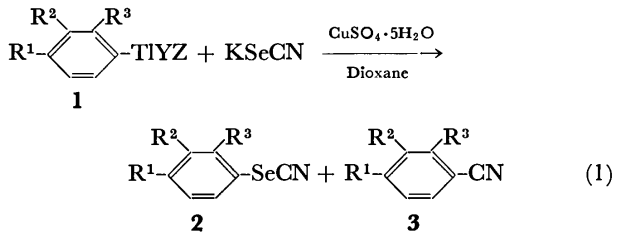
(Received March 3, 1975)

Substitution of thallium moiety in organothallium(III) compounds by selenocyanate is reported. Arylthallium (III) compounds react with KSeCN and $CuSO_4 \cdot 5H_2O$ or with $Cu(SeCN)_2$ in dioxane to give aryl selenocyanates in good yields. Alkoxythallates of styrene react smoothly with KSeCN in methanol to afford 1-alkoxy-1-phenyl-2-selenocyanatoethanes almost quantitatively. The oxyselenocyanation of terminal olefins is conducted by the *in situ* oxythallation of olefins, followed by the reaction with KSeCN.

Substitution of thallium moiety in organothallium-(III) compounds, such as aryl-,[1] vinyl-,[2] and alkylthallium(III) compounds,[3,4] by halogen (I, Br, and Cl) or pseudohalogen (CN and SCN) by use of copper and/or potassium salts has been reported. As another example of such substitution reactions we now wish to report the result of selenocyanatodethallation in aryl- and alkyl-thallium(III) compounds. This reaction would be a convenient method for the preparation of aryl and alkyl selenocyanates.

Results and Discussion

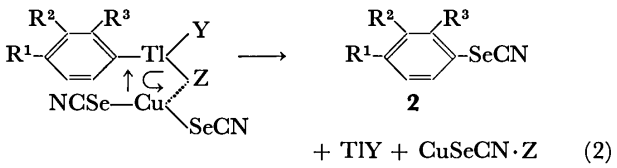
Reaction of Arylthallium(III) Compounds with Copper and/or Potassium Selenocyanates. When a mixture of arylthallium(III) compound (**1**), potassium selenocyanate and copper(II) sulfate hydrate was stirred in such solvents as dioxane, acetonitrile, methanol, and pyridine under reflux for 0.5 hr, aryl selenocyanate (**2**) was obtained in a good yield together with a small amount of aryl cyanide (**3**) (Scheme 1). Dioxane was revealed to be a solvent of choice for the preparation of **2**.



(1)

As in the case of the previously reported halogeno- and pseudohalogeno-dethallation,[1] the replacement of thallium moiety by SeCN occurred at the position where thallium was attached previously to aromatic ring. In contrast to thiocyanatodethallation which was accompanied by protodethallation forming aromatic hydrocarbon,[1d] almost no protodethallation occurred in this case. Sandmeyer reaction for preparing **2** has been known to be accompanied by the formation of diaryl selenide,[5] while none of such product was detected in the reaction products in this case. Typical results are summarized in Table 1.

The reaction proceeded even in the absence of copper-(II) sulfate, but the yield of **2** was low. Since the preparation of copper(II) thiocyanate from copper-(II) sulfate and potassium thiocyanate has been known,[6] it seems to be reasonable to assume that **2** was mainly formed by the interaction of **1** with copper(II) selenocyanate which may be formed in a reaction mixture. In order to ascertain this possibility, we prepared copper-(II) selenocyanate separately and examined the reaction of some arylthallium(III) compounds with this salt in dioxane. As a result, **2** was obtained in a good yield irrespective of the presence or absence of KSeCN, the formation of **3** being minimized (Table 1). Thus it is highly probable that the reaction affording **2** essentially involves the attack of $Cu(SeCN)_2$, formed *in situ*, on **1**. The reaction is ionic in nature since no effect was observed by the introduction of oxygen into the reaction mixture and no acrylonitrile polymer or phenylated acrylonitrile was obtained from the reaction in the presence of acrylonitrile.[1b] Reaction scheme seems to be a concerted nucleophilic substitution after coordination of copper to a ligand on thallium as proposed in the cases of halogeno- and pseudohalogeno-dethallation (Scheme 2).[1b-d]



(2)

As to the formation of a side-product **3**, we confirmed in separate experiments that **3** was not derived from **2** under the present reaction conditions; *i.e.*, no deselenation from **2** occurred by heating **2** in the presence of KSeCN, $CuSO_4 \cdot 5H_2O$ or $Cu(SeCN)_2$ in dioxane. Although the exact pathway for **3** is not yet clear, one possibility is that commercial KSeCN may contain KCN, since the former is prepared by heating Se and KCN, which reacts with copper salt to form CuCN or $Cu(CN)_2$ in the reaction mixture. Cyanodethallation of arylthallium(III) compounds by these salts has been reported.[1d]

Reaction of the Alkoxythallate of Styrene with KSeCN. When a mixture of the alkoxythallate of styrene and KSeCN was stirred in methanol under reflux for 15—30 min, 1-alkoxy-1-phenyl-2-selenocyanatoethane (**5**) was obtained almost quantitatively (100% yield when R = CH_3, C_2H_5, and n-C_3H_7; 80—83% yield when R = i-C_3H_7, n-C_4H_9, and i-C_4H_9) (Scheme 3). The reaction did not occur at 25 °C for 2 hr. An elongation of the reaction time at refluxing temperature decreased the yield of **5**, because of the secondary reaction of **5** giving unidentified resinous products. When the reaction was applied to the alkoxythallate of α-methylstyrene and the acetoxythallate of norbornene, the compounds corresponding to **5** were scarcely obtained

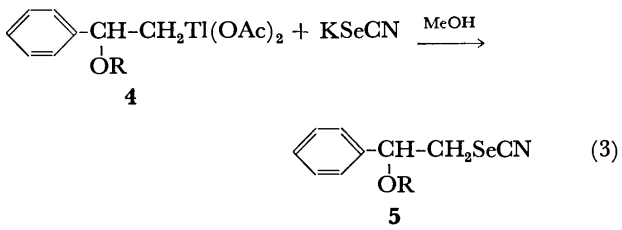
a) $Tl(OAc)_3$ 8 mmol, KSeCN 20 mmol. b) Time for oxythallation. c) Time for Tl-SeCN replacement. d) Based on olefin charged.



under room or refluxing temperature for 0.5 hr, and the oxidation products of olefins and/or the deoxythallation products were obtained. For example, benzyl methyl ketone and α-methylstyrene were obtained in 50% and 32% yields respectively in the former case, while norbornene was mainly formed in the latter.

The in situ Oxyselenocyanation of Olefins. The result of the reaction of the alkoxythallate of styrene with KSeCN described above and the report[3] of the *in situ* oxythiocyanation of olefins by $Tl(OAc)_3$ and KSCN prompt us to examine the *in situ* oxyselenocyanation of olefins. After a mixture of olefin and thallium(III) acetate was stirred in alcohol at 15—20 °C for 1—2 hr (oxythallation), an alcoholic solution of KSeCN was added and the mixture was then heated under reflux for 15—30 min to afford oxyselenocyanated compound, **6** (Scheme 4). Typical results are summarized in

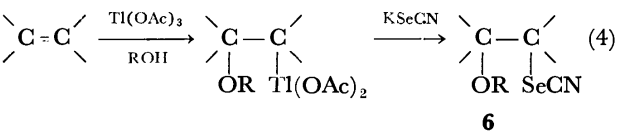


Table 2. Terminal olefins reacted smoothly to give **6**, while internal olefins such as cyclohexene and 2-octene gave only the oxidation products. This may be due to the difference of the stability between the intermediate alkoxythallates of olefins. From isoprene, two oxyselenocyanated compounds which seem to be 1,2- and 3,4-addition products were obtained, but the yield was very low (<10% yield) compared to the case of butadiene. Application of the reaction to isopropenyl acetate and α-methylstyrene resulted in only a slight formation of **6**, while methyl vinyl ketone and β-methylstyrene did not react at all under the conditions described above. The reaction with allyl chloride as a substrate afforded only allyl selenocyanate (bp 80 °C/20 mmHg; lit,[7] bp 75 °C/12 mmHg) quantitatively, irrespective of the presence or absence of thallium(III) acetate. The reaction of alkyl halide with KSeCN affording alkyl selenocyanate is well-known.[8]

Experimental

The IR spectra were taken with a Hitachi EPI-S2 spectrometer in paraffin mull and KBr disc. The NMR spectra were recorded with a Varian A-60 spectrometer in CCl_4, using TMS as an internal standard. Glc analyses were carried out on a Shimadzu 5APTF apparatus, using DEGS (25%)-Shimalite(1m) column (N_2 as carrier gas).

Materials. Arylthallium (III) acetate perchlorate monohydrate[9] and ditrifluoroacetates,[10] and the alkoxythallates of styrene and α-methylstyrene[4] were prepared by the reported methods. Arylthallium(III) nitrate hydroxide was prepared by heating aromatics with $Tl(NO_3)_3 \cdot 3H_2O$ in CCl_4.[11] Commercial butadiene, $CuSO_4 \cdot 5H_2O$, and KSeCN were used without purification. Other organic materials were purified before use by distillation.

Cu(SeCN)$_2$: An aqueous (20 ml) solution of KSeCN (10.8 g, 70 mmol) was added to an aqueous (50 ml) solution of $CuSO_4 \cdot 5H_2O$ (12.5 g, 50 mmol) at room temperature to afford the black precipitates immediately. After the mixture was stirred vigorously for 0.5 hr, the black precipitates were filtered off and washed with water and methanol to afford pure $Cu(SeCN)_2$. Yield, 9 g (94% yield based on KSeCN). It turns to pale brown at 200—210 °C and decomposes at about 260—280 °C. Found: C, 8.69; N, 9.77%. Calcd for $C_2CuN_2Se_2$: C, 8.79; N, 10.25%. IR 2150 cm^{-1}.

Reaction of Arylthallium(III) Compounds with KSeCN in the Presence of $CuSO_4 \cdot 5H_2O$. The following preparation of **2** ($R^1=CH_3$, $R^2=R^3=H$), *p*-tolyl selenocyanate, shows a typical procedure. To a brown heterogeneous solution of KSeCN (5.76 g, 40 mmol) and $CuSO_4 \cdot 5H_2O$ (2.50 g, 10 mmol) in dioxane (15 ml) was added a dioxane (10 ml) solution of **1**($R^1=CH_3$, $R^2=R^3=H$, X=OAc, $Y=ClO_4 \cdot H_2O$) (2.36 g, 5 mmol) at 15—20 °C. The mixture was then refluxed for 30 min under stirring to give a black heterogeneous solution. The solution was cooled down and filtered from the dark-grey precipitates. The filtrate was added by water (150 ml) and extracted with benzene. The extract was washed with aqueous $NaHCO_3$ and dried over Na_2SO_4. Glc analysis with dibenzyl as an internal standard showed the presence of 3.4 mmol of **2** ($R^1=CH_3$, $R^2=R^3=H$) (68% yield) and 0.2 mmol of *p*-tolunitrile (4% yield). Distillation gave pure *p*-tolyl selenocyanate; bp 86 °C/2 mmHg, mp 52—53 °C (lit,[12] mp 55—56 °C). IR 2140 (ν_{SeCN}) and 804(1,4-substituted phenyl) cm^{-1}. NMR δ 2.38 (s. 3H), 7.17 (d. 2H, J=8.5 Hz), and 7.50 (d. 2H, J=8.5 Hz).

Characterization of other aryl selenocyanates is as follows. **2**($R^1=R^2=R^3=H$); bp 111 °C/8 mmHg (lit,[13] 134 °C/10 mmHg). **2**(R^1=MeO, $R^2=R^3=H$); bp 115 °C/3 mmHg, mp 61—63 °C (lit,[14] mp 65 °C). IR 2140 (ν_{SeCN}) and 823 (4-substituted phenyl cm^{-1}. NMR δ 3.77 (s. 3H), 6.85 (d. 2H, J=9 Hz), and 7.53 (d. 2H, J=9 Hz). **2** (R^1 or R^3=Cl, $R^2=H$), chlorophenyl selenocyanate (*o*-/*p*-=3/7); bp 92 °C/2 mmHg (lit,[15] *o*-isomer; bp 152–153 °C/20 mmHg, *p*-isomer; mp 55 °C). **2** ($R^1=R^2$=Me, $R^3=H$); bp 105 °C/4 mmHg. IR 2150 (ν_{SeCN}) and 802 (phenyl)cm^{-1}. NMR δ 2.24 (s. 6H) and 7.0—7.35 (m. 3H). Found: C, 51.92; H, 4.49; N, 6.67%. Calcd for C_9H_9NSe: C, 51.47; H, 4.32; N, 6.67%. **2** ($R^1=R^3$=Me, $R^2=H$); bp 96—100 °C/3.5 mmHg (lit,[16] bp 138—139 °C/5 mmHg).

Reaction of the Alkoxythallates of Styrene with KSeCN. A methanol solution (25 ml) of KSeCN (2.88 g, 20 mmol) was added to **4**($R^1=CH_3$) (2.28 g, 5 mmol) and the mixture was heated under reflux for 30 min during which period the yellow solids formed at first turned to white precipitates. The solution was cooled down and filtered from white precipitates (1.51 g, TlSeCN). The filtrate was treated as described above. Glc analysis with benzophenone as an internal standard showed the presence of 5 mmol of **5** ($R^1=CH_3$), 1-methoxy-1-phenyl-2-selenocyanatoethane (100% yield). Distillation gave pure compound; bp 150—151 °C/6.5 mmHg. IR 2150(ν_{SeCN}), 1103(ν_{C-O}), 761(phenyl), and 698(phenyl)cm^{-1}. NMR δ 3.25 (s. 3H, methoxy), 3.27 (d. 1H, J=5.5 Hz, methylene), 3.29 (d. 1H, J=7.5 Hz, methylene), 4.42 (q. 1H, J=5.5 and 7.5 Hz, methine), and 7.30 (s. 5H, phenyl). Found: C, 50.04; H, 4.76; N, 5.52%. Clacd for $C_{10}H_{11}NOSe$: C, 50.02; H, 4.62; N, 5.83%.

Characterization of the products obtained by a similar treatment with other oxythallates is as follows. **5**(R^1=Et): bp 133 °C/5 mmHg. IR 2150 (ν_{SeCN}), 1095 (ν_{C-O}), 760

(phenyl), and 700 (phenyl) cm^{-1}. NMR δ 1.17 (t. 3H, J= 7 Hz), 3.31—3.45 (m. 4H), 4.53 (q. 1H, J=5.5 and 7.5 Hz), 7.28 (s. 5H). Found: C, 52.20; H, 5.26; N, 5.38%. Calcd for $C_{11}H_{13}NOSe$; C, 52.00; H, 5.16; N, 5.51%. **5**(R^1=*n*-Pr): bp 120 °C/3 mmHg. IR 2150 (ν_{SeCN}), 1097 (ν_{C-O}), 762 (phenyl) and 700 (phenyl) cm^{-1}. NMR δ 0.92 (t. 3H, J= 7 Hz), 1.57 (sex. 2H, J=7 Hz), 3.2—3.4 (m. 4H), 4.52 (q. 1H, J=5.5 and 8 Hz), and 7.30 (s. 5H). Found: C, 53.46; H, 5.86; N, 5.05%. Calcd for $C_{12}H_{15}NOSe$: C, 53.75; H, 5.64; N, 5.22%. **5** (R^1=*i*-Pr): bp 115 °C/2.5 mmHg. IR 2150 (ν_{SeCN}), 1120 (ν_{C-O}), 1088 (ν_{C-O}), 762 (phenyl) and 700(phenyl) cm^{-1}. NMR δ 1.07 (d. 3H, J=6 Hz), 1.20(d. 3H, J=6 Hz), 3.25(d. 1H, J=5.5 Hz), 3.27 (d. 1H, J=8 Hz), 3.55 (sep. 1H, J=6 Hz), 4.66 (q. 1H, J=5.5 and 8 Hz), and 7.30 (s. 5H). Found: C, 53.72; H, 5.75; N, 5.18%. **5** (R^1=*n*-Bu): bp 121 °C/3 mmHg. IR 2150 (ν_{SeCN}), 1100 (ν_{C-O}), 762 (phenyl), and 701(phenyl) cm^{-1}. Calcd for $C_{13}H_{17}NOSe$: C, 55.33; H, 6.07; N, 4.96%. **5**(R^1=*i*-Bu): bp 128 °C/3 mmHg. IR 2150(ν_{SeCN}), 1100(ν_{C-O}), 762(phenyl), and 700(phenyl) cm^{-1}. NMR δ 0.90 (d. 6H, J=6.5 Hz), 1.4—2.2 (m. 1H), 3.10 (d. 1H, J=5.5 Hz), 3.11 (d. 1H, J=6.5 Hz), 3.29 (d. 1H, J=5.5 Hz), 3.32 (d. 1H, J=8 Hz), 4.50 (q. 1H, J=5.5 and 8 Hz), and 7.29 (s. 5H). Found: C, 55.33; H, 6.21; N, 4.97%.

The in situ *Oxyselenocyanation of Olefins.* The following preparation of α-selenocyanatomethylcoumaran shows a typical procedure. To a suspension of $Tl(OAc)_3$ (3.05 g, 8 mmol) in methanol (10 ml) was added *o*-allylphenol (0.67 g, 5 mmol) at 15—20 °C to give a pale yellow homogeneous solution. After the solution was kept at 15—20 °C for 2 hr under stirring, a methanolic solution (15 ml) of KSeCN (2.88 g, 20 mmol) was added to give the voluminous yellow precipitates. The mixture was then rapidly heated to refluxing temperature and kept for 15 min to give the white precipitates of TlSeCN (2.2 g, 7 mmol). The reaction mixture was cooled down and treated as described above. Glc analysis with benzyl phenyl ketone as an internal standard showed the presence of 2.5 mmol of α-selenocyanatomethylcoumaran (50% yield). Distillation gave pure compound; bp 132 °C/ 2 mmHg. IR 2150 (ν_{SeCN}), 1480 (δ_{CH_2}), 1229 (ν_{C-O}), and 751(phenyl) cm^{-1}. NMR δ 2.7—3.6 (m. 2H, CH_2Se–), 3.24 (d. 2H, J=5.5 Hz, $ArCH_2$), 4.75—5.2 (m. 1H, methine), and 6.6—7.2 (m. 4H, aryl). Found: C, 50.51; H, 3.92; N, 5.79%. Calcd for $C_{10}H_9NOSe$: C, 50.45; H, 3.81; N, 5.88%.

Characterization of other oxyselenocyanatoalkanes in Table 2 is as follows. 1-Selenocyanato-2-methoxyoctane: bp 131 °C/ 6 mmHg. IR 2150 (ν_{SeCN}) and 1093 (ν_{C-O}) cm^{-1}. NMR δ 0.7—1.7 (m. 13H), 3.15—3.35 [m. 3H, –CH(OR)–CH_2Se–], and 3.35 (s. 3H, methoxy). Found: C, 48.63; H, 8.16; N, 5.60%. Calcd for $C_{10}H_{19}NOSe$: C, 48.40; H, 7.72; N, 5.64%. 1-Selenocyanato-2-methoxyhexane: bp 90 °C/4 mmHg. IR 2150 (ν_{SeCN}) and 1090 (ν_{C-O}) cm^{-1}. NMR δ 0.8—1.7 (m. 9H), 3.1—3.5 [m. 3H, –CH(OR)–CH_2Se–], and 3.36 (s. 3H, methoxy). Found: C, 43.69; H, 7.19; N, 6.38%. Calcd for $C_8H_{15}NOSe$: C, 43.65; H, 6.87; N, 6.36%. 1,1-Diethoxy-2-selenocyanatoethane: bp 81 °C/2.5 mmHg. IR 2150 (ν_{SeCN}), 1120 (ν_{C-O}), and 1060 (ν_{C-O}) cm^{-1}. NMR δ 1.21 (t. 6H, J=7 Hz, methyl), 3.21 (d. 2H, J= 5.5 Hz, $-CH_2Se$-), 3.58 (q. 2H, J=7 Hz, $-OCH_2$–), 3.62 (q. 2H, J=7 Hz, $-OCH_2$–), and 4.70 (t. 1H, J=5.5 Hz, methine). Behaviour of Some Selenium Bases in Disulphuric Acid. Conductometric and Cryoscopic Studies of Selenides, Selenoxides and Selenones in Disulphuric Acid

Ashok BALI and K. C. MALHOTRA

Department of Chemistry, Himachal Pradesh University, Simla 171001, India

(Received August 23, 1974)

Dimethylselenoxide is fully ionized in disulphuric acid whereas diphenyl selenoxide and its nitro derivatives behave as weak bases. In the case of selenones, alkyl selenones are completely ionized in disulphuric acid, diphenyl selenone and its nitro derivatives behave as weak electrolytes. From the extent of protonation it is observed that selenones are stronger bases than the corresponding sulphones. Amongst the selenides, diphenyl selenide is sulphonated whereas its nitro derivatives behave as weak bases in it.

In a continuation of our investigations,[1-5] we report here a study on the behaviour of selenides and compounds containing selenium–oxygen bonds in disulphuric acid. These data may be helpful in determining their relative basic strengths and also in determining their basicity with respect to sulphones. Szmant and Lapinski[6] and Szmant and Brost,[7] from their cryoscopic and spectroscopic studies on diphenyl sulphoxide in sulphuric acid concluded that it formed diphenyl sulphedium ion. This conclusion has been refuted by various workers.[8-9] Most alkyl sulphones behave as non electrolytes in sulphuric acid[9] and are protonated in disulphuric acid,[10] consequently their relative strengths have been differentiated in fluorosulphuric acid.[11] In the present study, the behaviors of selenides, selenoxides and selenones have been investigated and comparative studies with the analogous sulphur compounds have been made.

Results and Discussion

Disulphuric acid is a molecularly dissociated and slightly self ionized solvent. Its mode of dissociation and ionization may be represented[12] as in Eq. (1).

$$2H_2S_2O_7 \longrightarrow H_2SO_4 + H_2S_3O_{10} \rightleftharpoons H_3SO_4^+ + HS_3O_{10}^- \quad (1)$$

Because of its high acidic nature, most of the solutes behave as bases in it. The behaviour of a base in disulphuric acid may be represented by the general Eq. (2).

$$\text{Solute} + sH_2S_2O_7 \longrightarrow aX^+ + aHS_3O_{10}^- + bY + cH_2SO_4 \quad (2)$$

where Y represents uncharged species. Sulphuric acid formed in the reaction does not contribute significantly to the value of γ, the number of $HS_3O_{10}^-$ ions, or to ν, the number of particles or ions produced per mole of solute as it is one of the products of self dissociation of the acid. Methods of determining the values of γ, ν and c have been discussed in detail in the experimental section.[10,11,13-15] In the case of the compounds which are not fully protonated in disulphuric acid, dissociation constants have been determined by a method, already used by various workers.[16,17]

Interpolated values of the specific conductance and the depression in freezing points of various solutes at different concentrations are given in Tables 1 and 2 respectively. The dissociation constants for solutes which are not fully ionised have been determined and are reported in Table 4. In order to compare the relative basic strength of selenium compounds with those of sulphur compounds, dissociation constants previously reported for sulphur compounds are also included in Table 4.

Like dimethyl sulphoxide, dimethyl selenoxide is stable in disulphuric acid and forms a highly conducting stable solution. From the values of γ, ν, and c, it is evident that it is completely protonated as:

$$(CH_3)_2SeO + 2H_2S_2O_7 \longrightarrow (CH_3)_2SeOH^+ + HS_3O_{10}^- + H_2SO_4 \quad (3)$$

The solutions are colourless which suggests that there is no disproportionation to form elemental selenium which would have produced a green or yellow solution.[18] But in the case of diphenyl selenoxide, conductances of the solutions are quite low and increase

TABLE 1. SPECIFIC CONDUCTANCES OF SOLUTIONS OF VARIOUS SOLUTES IN DISULPHURIC ACID AT 25 °C

Specific Conductance $\times 10^3$ (ohm^{-1} cm^{-1})

Solute	Molality $\times 10^2$								
	2	4	6	8	12	14	16	18	20

Diethyl selenone	34.81	34.76	34.62	34.56	34.44	34.30	34.26	34.12	34.04	33.88
Diphenyl selenone	35.06	35.03	34.96	33.84	34.76	34.66	34.58	34.46	34.32	33.92
4-Nitrodiphenyl selenone	35.02	34.96	34.84	34.80	34.72	34.64	34.52	34.42	34.36	34.24
4,4′-Dinitrodiphenyl selenone	34.98	34.88	34.78	34.70	34.64	34.56	34.48	34.39	34.29	34.18

with time. Simultaneously the solutions develop a dirty brown color but when the solutions are poured onto crushed ice, nothing separates out. This suggests that diphenyl selenoxide is sulphonated and the sulphonated product behaves as a weak base. A slight increase in the conductance of the solution is due to the formation of sulphuric acid which is known to behave as a weak base in disulphuric acid (*loc. cit.*). There has been no indication of the existence of dipositive selenidium ions as was proposed by Szmant and Lapanski for sulphoxide (*loc. cit.*) since that would have produced highly conducting solutions.

Table 3. Summary of the values of γ, ν and c for various selenium compounds in $H_2S_2O_7$

Compound	γ	ν	c		
			Conductivity	Cryoscopy	Titration
Dimethyl selenoxide	1	2	1	1.1	1
Diphenyl selenoxide	—	1	1	—	1
Dimethyl selenone	1	2	1	1.1	1.1
Diethyl selenone	1	2	1	1.1	1.1
Diphenyl selenone	1	2.1	1	1.1	1.1
p-Nitrophenyl selenide	1	2	—	—	—
Selenyl chloride	—	1	—	—	—
Selenyl fluoride	—	1	—	—	—

Table 4. Dissociation constants of various compounds containing sulphur–oxygen and selenium–oxygen bond in disulphuric acid

Compound	$K_b \times 10^2$
4-Nitrodiphenyl sulphoxide	86.42
4-Nitrodiphenyl selenoxide	92.38
4,4′-Dinitrodiphenyl sulphoxide	49.56
4,4′-Dinitrodiphenyl selenoxide	63.74
4-Nitrodiphenyl sulphone	78.46
4-Nitrodiphenyl selenone	82.58
4,4′-Dinitrodiphenyl sulphone	60.92
4,4′-Dinitrodiphenyl selenone	72.54

The introduction of an electron withdrawing group in one of the rings deactivates both of the rings towards sulphonation as 4-nitrodiphenyl selenoxide gives a stable pink solution in disulphuric acid. The conductance and the freezing point of the solution do not change with time. From the cryoscopic and conductance studies, it is evident that it behaves as a weak base. The dissociation constant is reported in Table 4. The introduction of a nitro group in the other ring further reduces the basicity of the Se–O group as is evident from the behavior of 4,4′-dinitrodiphenyl selenoxide, which in disulphuric acid forms an orange colored solution that becomes darker with time. However, there is no significant change with time in the values of γ, ν and c indicating that the solutions are fairly stable. From the experimental data it is evident that 4,4′-dinitrodiphenyl selenoxide behaves as a weak base. When solutions of both the mono- and di-nitro compounds are poured onto crushed ice, both the compounds are recovered quantitatively suggesting that in these compounds there is no sulphonation of the ring. From the cryoscopic and conductance data only, we do not feel qualified to specify the site of the protonation in these compounds. However, it may be reasonable to believe that the π electrons in the Se=O group are more labile and therefore the Se=O group will be protonated in preference to the ring NO_2 group. From the extent of the protonation of selenoxides, it is evident that selenoxides are more basic than sulphoxide *i.e.* the extent of the $d\pi$-$p\pi$ overlap between sulphur and oxygen is more than that between selenium and oxygen and consequently sulphoxide are less basic.

Alkyl sulphones are known to behave as weak electrolytes in sulphuric acid[9] but behave as strong bases in both fluorosulphuric[11] and disulphuric acids.[10] Dimethyl and diethyl selenones are monoprotonated and completely ionized in disulphuric acid. Becasue of the higher acid strength of the medium, the basicity of all these alkyl selenones is leveled to that of $HS_3O_{10}^-$ and it does not seem to be possible to differentiate their relative basicity. It is also observed that as compared to diphenyl selenoxide, diphenyl selenone is more stable towards sulphonation by the solvent as the conductance and the freezing point of the solutions do not change with time. It may be that unlike selenone, the deactivating inductive effect of the selenoxide group is counter balanced by the conjugation of the shared pairs of electrons on the selenium atom with the aromatic ring. Conjugation of the Se=O with the aromatic ring may be negligible and therefore diphenyl selenoxide undergoes sulphonation whereas the selenones are comparatively stable.

From the conductance and cryoscopic studies, it is evident that diphenyl selenone bahaves as a strong base

and the introduction of a deactivating group in one or both of the rings decreases the basicity of the Se=O group to a large extent as 4-nitro- and 4,4′-dinitrodiphenyl selenones behave as weak bases in disulphuric acid. Their dissociation constants have been determined and are included in Table 4. Our observations are at varience with those of Szmant and Lapinski (*loc. cit.*) who observed that the introduction of a nitro group in the *para* position of the ring increases the basicity of the SO group in sulphones and are in agreement with our earlier observations in fluorosulphuric acid. These observations are supported by the results of a theoretical molecular orbital treatment of sulphones by Koch and Moffitt[19] who have shown that there is only a slight conjugation between the double bond of S=O and the aromatic ring in diphenyl sulphone. This conclusion is supported by IR and UV spectroscopic measurements. By analogy similar arguments can be put forward for selenones.

In order to compare the basicity of compounds containing the selenium–oxygen bond and to determine the effects of substitution on their basicity, investigations have been extented to the behavior of SeO_2Cl_2, SeO_2F_2 and diethyl selenate in disulphuric acid. It is interesting to observe that the value of ν for these electrolytes is one, but there is a decrease in the conductance of the solution. This suggests that these compounds behave as non-electrolytes in disulphuric acid. This behaviour of non-electrolytes is similar to the one observed in the solvo-system sulphuric acid.[20] This decrease in the conductance of the solution may be attributed to a decrease in the mobilities of $H_3SO_4^+$ or $HS_3O_{10}^-$ ions caused by the non-electrolyte or to a reduction in the concentration of the autoprotolysis ion. A decrease in the mobilities of the characteristic solvent ions could be attributed to strong hydrogen bonding interactions between these solutes and the solvent molecules which would hinder the orientation of the latter and decrease their effectiveness in the proton-transfer conduction process. Diethyl selenate behaves as a weak base. The increase in the conductance is so insignificant that it is not possible to determine its dissociation constant.

It has been of interest to investigate the behaviour of selenides in disulphuric acid. Sulphides undergo sulphonation and oxidation in both sulphuric and disulphuric acids but in fluorosulphuric acid they are strong bases. The solutions of diphenyl selenides in disulphuric acid are not very stable as the solutions are green and the conductance of the solution changes with time. Even *p*-nitrophenyl selenide does not form stable solutions when dissolved in disulphuric acid. However, initial conductance and freezing point data indicate that it may be singly protonated. For each addition of the solute the changes in the conductance and freezing point have been observed with time and then extrapolated to zero time to get the initial conductance and freezing point. The introduction of a nitro group to each of the rings decreases the basicity of the selenide group to the extent that 4,4′-dinitrodiphenyl selenide behaves as a weak electrolyte. The solutions become intensely coloured. The intensity of the colour increases very much after 24 hr although there is no significant change in the conductance of the solution. The properties may be due to the presence of a quinonoid structure for the protonated species.

It may thus be concluded that compounds containing selenium–oxygen bonds are more basic than the corresponding compounds containing sulphur–oxygen bonds. Thus suggesting that the extent of $d\pi$-$p\pi$ overlap is greater in the sulphur–oxygen compounds than in the selenium–oxygen compounds.

Experimental

The design of the conductivity cell and the cryoscopic set up has been described earlier. Conductance measurements were made in an oil thermostat regulated at 25.00 ± 0.02 °C using a precision measuring bridge WBR No. 108 with logarithmic indicator amplifier type TAV, IKC No. 034 (Wissenchaftlich Technische Werkstatten) Wielheim Oby/ Germany. The composition of disulphuric acid was determined from its conductance in conductometric studies and from its freezing point in the cryoscopic studies. Addition of powdered solids was made with a weight burette having a wide bore tap while liquids were added with a weight dropper which was fitted with quickfit joints to avoid contact with moisture.

The conductometric factors γ ($HS_3O_{10}^-$) were obtained by comparison of the conductance at various concentrations of the solute with that of nitromethane in disulphuric acid. The temperature at which all conductance measurements were made (25 °C) was below the freezing point of all the solutions studied but since disulphuric acid super cools readily no problems were encountered with spontaneous crystallization of the solutions during the measurements.

In the case of the cryoscopic measurements, the observed freezing points were corrected for the super cooling by adding the correction ($\delta=0.014S\theta$) where S is the amount of super cooling and θ is the depression of the freezing point. The value of ν (the number of particles or ions produced per mole of the solute) has been calculated by equation:

$$\nu = \frac{\theta(1-0.178mS)}{5.9m}$$

where m is the molality, S is the number of the solvent molecules used and θ is the depression of the freezing point obtained by subtracting the observed freezing points from 35.82° which is the freezing point of a hypothetical solvent containing zero concentration of ionic self dissociation products. The factor c, the amount of sulphuric acid produced per mole of the solute has been found out by titrating these solutions against sulphur trioxide. Freezing point rises because of the reaction $H_2SO_4+SO_3\rightarrow H_2S_2O_7$, passes through a maximum and then decreases. The maximum in the freezing point represents the number of moles of sulphuric acid produced in a particular reaction. This technique has already been used by Wyatt and Dacre.

Dimethyl selenoxide was purified by fractional distillation under reduced pressure. Diphenyl selenoxide was prepared by the oxidation of diphenyl selenide with an equimolar amount of a 30% solution of hydrogen peroxide in glacial acetic acid. 4-Nitro- and 4, 4′-dinitro-diphenyl selenoxide were prepared by the oxidation of the corresponding selenides which in turn were prepared by refluxing ethanol solution of 1-chloro-4 nitrobenzene with freshly prepared concentrated solution of sodium selenide. The compounds were recrystallized from acetic acid. Diethyl selenone (Aldrich) was

purified by several recrystallization from absolute alcohol. 4-Nitro- and 4,4′-dinitro-diphenyl selenones were prepared by the oxidation of the corresponding selenoxides with an excess of 30% H_2O_2 in acetic acid. Alkyl selenates were purified by distillation under reduced pressure.

(Received October 28, 1974)

The oxo-bridged binuclear iron(III) complexes $[L_2(NCS)Fe–O–Fe(NCS)L_2]^{2+}$ (L=1,10-phenanthroline or 2,2′-bipyridine) were prepared recently in spite of the earlier report that they could not be prepared. The unperturbed and perturbed Mössbauer spectral and magnetic susceptibility data on these compounds are reported here and compared with those for the well characterized oxo-bridged compounds $[L_2XFe–O–FeXL_2]^{2+}$ (X= Cl^-, Br^-, $SO_4^{2-}/2$ or NO_3^-). The effect of Fe–X bond (X=Cl^-, Br^-, $SO_4^{2-}/2$, NO_3^-, or NCS^-) on the Mössbauer parameters was investigated, and the results are discussed in terms of the bonding properties of these anionic ligands. The data indicate that the electronegativity of the X ligands has no significant effect on the Mössbauer parameters. Another system, the mononuclear iron(III) complexes $[FeL_2(NCS)_2](NCS)$, investigated in this work showed no Mössbauer resonance at or above 223 K and below this temperature the unperturbed spectra exhibited a broad asymmetric singlet. Magnetic susceptibilities and magnetically perturbed Mössbauer spectra indicated that iron(III) ion in these mononuclear complexes was paramagnetic with $S=5/2$.

The Mössbauer parameters of isomer shift (*I.S.*) and quadrupole splitting (*Q.S.*) have been utilized in elucidating the structure and bonding in a large series of organometallic and coordination compounds.[1–6] Mössbauer studies have indicated that *I.S.* values are an approximate additive property of the type and number of ligands, and Erickson[7] has suggested a relative covalency scale. The *Q.S.* values provide complementary information on the nature of σ- and π-bonding in low-spin and high-spin compounds.

Binuclear complex of iron(III) with 1,10-phenanthroline (phen) or 2,2′-bipyridine (bipy), $[Fe_2L_4OCl_2]Cl_2$ (L=phen or bipy) has been of considerable interest since its first isolation by Gains *et al.*[8] It is now established that these complexes contain a linear Fe–O–Fe bridge[9–12]. Mössbauer studies on binuclear complexes $[Fe_2(phen)_4OX_2]X_2\cdot YH_2O$ (X=Cl^-, Br^- or $SO_4^{2-}/2$; $Y=2$—7) have been reported[4,10,12] while only one bipy complex, $Fe_2(bipy)_4O(SO_4)_2\cdot 9H_2O$ has received attention[4,10].

The exchange of Cl^- ligands in $[Fe_2L_4OCl_2]^{2+}$ by SO_4^{2-}, ClO_4^-, and Br^- to form $[Fe_2L_4X_2]^{2+}$ (where X=$SO_4^{2-}/2$, ClO_4^-, or Br^-) has been described.[9,13a,14] But it was reported by Driver and Walker[14] that an attempt to prepare $[Fe_2(phen)_4O(NCS)_2]^{2+}$ by analogous procedure resulted in the reduction product $Fe(II)(phen)_2(NCS)_2$. David[13] recently investigated in detail the reaction between $[Fe_2L_4OCl_2]^{2+}$ and NCS^- and reported that the observations of Driver and Walker were incorrect. David[13] prepared the binuclear complexes $[Fe_2L_4O(NCS)_2](NCS)_2$. We report here the Mössbauer spectral and magnetic susceptibility data on these compounds. The present data are in firm support of the conclusions reached earlier by David[13] based on electronic and infrared spectral data, and conductivity studies. Further, the Mössbauer spectral and magnetic susceptibility data for these compounds are in fair agreement with those reported for similar oxo-bridged binuclear compounds.

The effect of the anionic ligand X^- on the Mössbauer spectra of the binuclear complexes $[Fe_2L_4OX_2]X_2$ (where X=Cl^-, Br^-, $SO_4^{2-}/2$, NO_3^-, or NCS^-) are also presented here. Preparations of these anhydrous compounds have been reported recently. Even though Mössbauer investigation on a few of these complexes has been carried out,[4,10,12] there has been no systematic study to decide on the effect of the bonding properties of these anionic ligands on the Mössbauer parameters.

Yet another purpose of this article is to present data on Mössbauer spectra and magnetic susceptibility on the mononuclear iron(III) complexes $[FeL_2(NCS)_2]NCS$. The preparations of these compounds were reported recently by David and were characterized to be iron(III) compounds based on electronic and infrared spectral data and conductivity studies. Our Mössbauer and magnetic susceptibility data confirmed the conclusions of David while proving to be incorrect the earlier report of Driver and Walker that reduction of iron(III) to iron(II) occured during the attempted preparation of $[FeL_2(NCS)_2]^+$.

Experimental

Preparations. The following binuclear and mononuclear complexes were prepared by literature procedures: $Fe_2(phen)_4OCl_4$,[8] $Fe_2(phen)_4OBr_4$,[14] $Fe_2(phen)_4O(SO_4)_2$,[14] $Fe_2(phen)_4O(NO_3)_4$,[9] $Fe_2(phen)_4O(NCS)_4$,[13] $Fe_2(bipy)_4OCl_4$,[13] $Fe_2(bipy)_4OBr_4$,[13] $Fe_2(bipy)_4O(SO_4)_2$,[14] $Fe_2(bipy)_4O(NCS)_4$,[13] $Fe(phen)_2(NCS)_3$,[13] and $Fe(bipy)_2(NCS)_3$.[13] All these complexes were dried at room temperature in a vacuum desiccator for 3—5 days to effect complete removal of water of hydration.

The compound $Fe_2(bipy)_4O(NO_3)_4$ was prepared by a modification of the method used for the corresponding phen complex. In this procedure 2.34 g (0.015 mol) of 2,2′-bipyridine was added to a solution containing 3.03 g of $Fe(NO_3)_3\cdot 9H_2O$ (0.0075 mol) in 20 ml of water. The resulting dark brown solution was nearly saturated with sodium nitrate. The solution was filtered and the filtrate cooled in a refrigerator for 2—3 days, during which time dark brown crystals of $Fe_2(bipy)_4O(NO_3)_4$ separated out. The crystals were collected by filtration, washed with small quantities of ice-cold water

followed by *n*-hexane, and dried at room temperature in a vacuum desiccator.

Found: C, 47.40; H, 3.22; N, 16.60; Fe, 10.88%. Calcd for $Fe_2O(C_{40}N_8H_{32})(NO_3)_4$: C, 47.27; H, 3.17; N, 16.53; Fe, 10.98%.

Methods. The Mössbauer spectra were recorded in the standard transmission geometry with a constant acceleration Doppler velocity transducer, ^{57}Co in copper, and Ar–CH_4 filled proportional counter, and a 400 channel analyser. The data were least square fitted. To avoid possible corrections of solid angle, fairly small distance of detector-to-absorber, and large distance of source-to-absorber of the order of four times the window for detection were used. The velocity scale of the spectrometer was calibrated using an enriched iron foil. For calibration of temperature a copper-constantan thermocouple was used. For low temperature spectra in external magnetic field a Westinghouse superconducting solenoid with a stainless steel cryostat was used.

Magnetic susceptibility measurements were made with a torsion balance type magnetometer, Shimadzu MB-2, equipped with cryostatic arrangements for low temperature measurements.

Infrared spectra were recorded using a Perkin-Elmer 237 grating spectrophotometer. The samples were in the form of Nujol mulls. The potassium bromide disk method was considered but rejected owing to the possibility of exchange of the anionic ligands with Br^- which may lead to ambiguous results.

Results and Discussion

Binuclear Complexes. The binuclear oxygen-bridged complexes I—X (Table 1) are octahedral, the oxygen sharing the two octahedra. The presence of an oxygen bridge has been supported by infrared spectra.[10,15] It is known that in the solid phase $Fe_2L_4OX_4$ (X=Cl^-, NO_3^-, or $SO_4^{2-}/2$) exhibits an effective paramagnetic moment of the order of 1.5 B.M. per iron indicating the ground state multiplicities of iron(III) ions to be either $S=5/2$ corresponding to the d^5 high-spin configuration in the octahedral symmetry or $S=3/2$ corresponding to an electronic configuration $t_{2g}^4 e_g^1$ in octahedral symmetry.[9,10] Simple magnetic data do not clearly indicate the spin state $S=3/2$ or

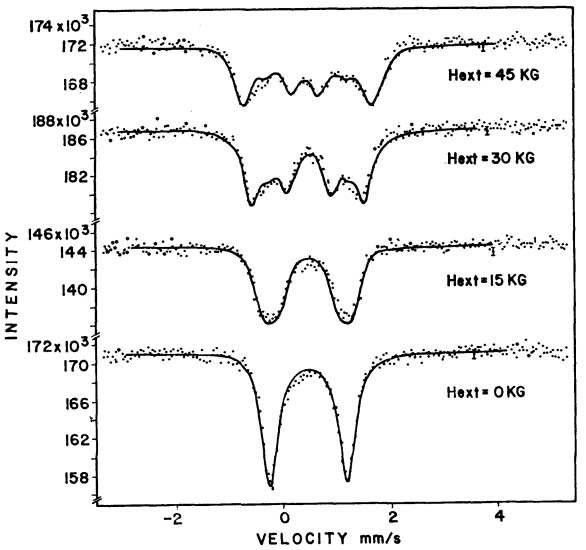

Fig. 1. Mössbauer spectra of $Fe_2(bipy)_4O(NCS)_4$ in externally applied magnetic fields at 4.2 K. The solid lines are the theoretical best fit curve for $\eta=1.0$ and $H_{ext}=H_{int}$.

$S=5/2$. But recent NMR contact shift,[13] Mössbauer,[10,16,17] and ESR[18] data have been interpreted to support that both iron(III) ions in the binuclear complexes are high-spin ($S=5/2$). The two $S=5/2$ ground state ions couple, through the intramolecular π-bonding interaction of the two oxygen p-orbitals and the metal d_{xz} and d_{yz} orbitals, to form a singlet ground state ($S=0$) for the complex as a whole. Our Mössbauer results in external magnetic field give further support to this singlet ground state (see below).

The effect of an external magnetic field on the Mössbauer spectra of the binuclear complex VI is shown in Fig. 1. All other binuclear complexes investigated in the present study shows similar effects in an external magnetic field. Similar study on $[Fe_2(salen)_2O]$, a compound similar to those investigated in our work, was carried out by Okamura *et al.*[19] They assigned a positive electric field gradient to their compound conforming to the observation that the quadrupole split lines underwent further splitting in the external field, one at the low velocity into a triplet and the other at the higher velocity into a doublet. In our oxo-bridged compounds the low velocity and the high velocity peaks split further into doublets in the external magnetic fields (Fig. 1) giving rise to a nearly symmetrical spectrum. Hence, the assignment of the sign to the electric field is not feasible. The nearly symmetrical spectrum may arise from the large asymmetry parameter.[20] The least square fit curves assuming $\eta=1.0$ and $H_{ext}=H_{int}$ closely approximate the experimental points, thus conforming to the asymmetry parameter close to 1.0.

The observed field in all our binuclear complexes is equal to the externally applied one within the experimental error of ±5.0 KG. Even if the moment for each iron(III) ion is 1 B.M., the internal field would be observable when the external field is close to 45 KG at 4.2 K. Hence, this is a clear evidence for the singlet ground state in these binuclear complexes, in agreement with the previous studies.[9,10,12]

In the solid phase the binuclear complexes have the structure $[L_2XFe\text{–}O\text{–}FeXL_2]^{2+}$ ($X=Cl^-$, NO_3^-, SO_4^{2-}/2, or NCS^-). The evidence for the coordination of these X ligands to iron(III) is obtained from the infrared spectral data. Khedekar *et al.*[9] observed the Fe–Cl stretching vibrations at 253 cm^{-1} in the infrared spectrum of $Fe_2(phen)_4OCl_4$, while our results in Table 2 prove the existence of coordination between iron(III) and the anionic ligands NO_3^-, SO_4^{2-}, and NCS^-. Our results are in fair agreement with the literature results for compounds containing coordinated NO_3^-, SO_4^{2-}, or NCS^- to metal.[21–24] There is no experimental evidence for the coordination of Br^- to iron(III) in the binuclear compound $Fe_2L_4OBr_4$. But considering the coordination of weak ligands like NO_3^- to iron(III) we tend to believe that Br^- is also coordinated.

Table 2. Infrared vibrartional frequencies of the anionic ligands

Compound	Anionic Ligand	$\bar{\nu}$, cm^{-1}
$Fe_2(phen)_4O(SO_4)_2$	SO_4^{2-}	1173(s), 1035(s), 975(s)[a]
$Fe_2(bipy)_4O(SO_4)_2$	SO_4^{2-}	1160(s), 1039(s), 930(s)[a]
$Fe_2(phen)_4O(NO_3)_4$	NO_3^-	1280(s, b), 1030(v, s)[a]
$Fe_2(bipy)_4O(NO_3)_4$	NO_3^-	1500(s),[a,b] 1282(s, b), 1010(v, s)[a]
$Fe_2(phen)_4O(NCS)_4$	NCS^-	2080(s, sh),[a] 2040(s)
$Fe_2(bipy)_4O(NCS)_4$	NCS^-	2080(s, sh),[a] 2040(s)

s=strong, v=very, b=broad, sh=shoulder
a) These peaks clearly indicate the presence of coordination of these anionic ligands to iron(III). b) This peak was partially obscured by the Nujol peaks.

The Mössbauer parameters for the binuclear complexes in which the anionic ligands are Cl^-, Br^-, NO_3^-, SO_4^{2-}, or NCS^- are depicted in Table 1. Within the experimental uncertainty the *I.S.* values do not show any appreciable change with the variation of the anionic ligands. By virtue of the strong antiferromagnetic coupling through the π-bonding interaction of the metal d-orbitals and the p-orbitals of O^{2-} the change in bonding properties, if any, of the X ligands may not have any significant effect on the Mössbauer parameters. The bonding is influenced by the combined effects of the electronegativity and the resonance of the X ligands concerned. While the electronegativity may fall in the order $Cl^->Br^->SO_4^{2-}>NO_3^->NCS^-$, the last named three ligands can withdraw electrons away from the coordination site by virtue of the resonance effects. The failure of these ligands to influence the *I.S.* values to any appreciable extent suggests that the electron density at the metal due to the (L→M) σ-donation is essentially identical.

The replacement of phen by bipy does not change the *I.S.* values and the π-back bonding of iron to both O^{2-} and bipy ligands (Table 1). Comparing the phen complex to the corresponding bipy complex, the *Q.S.* value is always greater for the phen complex although the same value of *I.S.* is obtained. This points out that the phen ligand is a better π-acceptor and/or a poorer σ-donor while the total σ-donor+π-acceptor ability is similar for both. In view of the lack of detailed information of the sign of *Q.S.* and the contribution from the lattice charge one cannot specifically refer to the d-orbitals which participate in the π-back

Table 3. Magnetic susceptibilities and magnetic moments

	Compound	Temperature (K)	$\chi\cdot10^6$/Fe (cgs)[a]	μ_{eff}/Fe (B.M.)[b]
I	$Fe_2(phen)_4O(NCS)_4$	294	5413	1.79[c]

a) The molar susceptibility after correction for diamagnetism. The diamagnetic corrections ($\times10^6$ cgs/mol): Fe^{3+}, 13; bipy, 105; phen, 128; Cl^-, 23; NCS^-, 35; O^{2-}, 6 (Ref. 10). b) all ±0.05 B.M. c) These are in fair agreement with the literature results for similar binuclear compounds (Refs. 8—10).

bonding.

The effect of temperature on the Mössbauer parameters (Table 1) is insignificant. The compounds $Fe_2L_4O(NCS)_4$ are remarkable for the absence of any detectable Mössbauer resonance at room temperature and slight absorption around 223 K, the absorption increasing as the temperature is decreased. It is considered that the absence of any resonance at temperatures above 223 K is a consequence of low Debye temperature for iron in these compounds.

Mononuclear Iron(III) Complexes. The magnetic susceptibility data indicate that iron(III) ion in $[FeL_2(NCS)_2]NCS$ is in the high-spin state with $S=5/2$ at room temperature and temperatures to about 8 K (Table 3). The Mössbauer parameters for these complexes are given in Table 1. Without any external magnetic field at temperatures below 223 K the spectrum has a broad asymmetric line, and no resonance at room temperature or down to around 223 K. This lack of absorption at temperatures above 223 K may be the result of low Debye temperature. The comparable results for the corresponding binuclear complexes $Fe_2L_4O(NCS)_4$ show the significant influence of NCS^- ligands on the Mössbauer spectra of these complexes. Very broad peaks for the compounds $[FeL_2(NCS)_2]NCS$ (compounds XI and XII) could possibly be due to spin-spin relaxation.

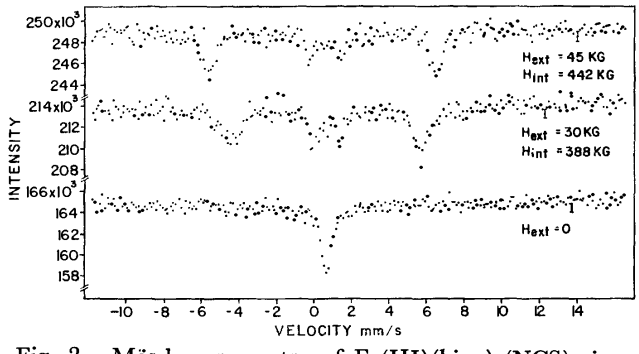

Fig. 2. Mössbauer spectra of $Fe(III)(bipy)_2(NCS)_3$ in externally applied magnetic fields at 4.2 K.

The Mössbauer spectra of $[Fe(bipy)_2(NCS)_2]NCS$ with the external magnetic fields are shown in Fig. 2. The compound $[Fe(phen)_2(NCS)_2]NCS$ shows identical effects. The results indicate that iron(III) ions in these complexes are in the high-spin state ($S=5/2$), in agreement with the magnetic susceptibility results. When the external field of 45 kG is applied the observed effective field is of the order of 442 kG. Because the sign of the internal field is negative, the induced field should be $442+45=487$ kG. Assuming purely paramagnetic case, the hyperfine field for $T\rightarrow 0$ and $H_{ext}\rightarrow\infty$ can be calculated for a d^5 system using a Brillouin function, the calculated value being -550 kG.[25] This is the limiting value arising from the exchange polarization of 1s and 2s electron cores with the d-shell electrons. Since the iron(III) complexes have 3s as well as 4s electrons which are expected to produce a positive electric field, the actual internal field will be the difference between these negative and positive contributions. This may at least partially account for the low experimental value. Saturation core polarization fields of the order of 500 kG are common in iron(III) compounds.[26,27] Hence, this further supports the $S=5/2$ spin state for iron(III) in our mononuclear complexes.

The authors are grateful to BNDE and CNPq (contract No. VKG–TC 17–174) of Brasil for partial support to this work and to Professor S. P. Puri for helpful suggestions.

Changes in the Catalytic Activity of Cold-worked Platinum during the Oxidation of Carbon Monoxide

Shozo KISHIMOTO

Department of Chemistry, Faculty of Science, Kobe University, Rokkodai, Nada, Kobe 657

(Received June 29, 1974)

Synopsis. The rate of the oxidation of carbon monoxide was measured on cold-worked platinum to study the influence of annealing on the catalytic behavior. It was found that the presence of lattice defects (dislocations) in the crystal plays a role in initiating the reaction and serves to create new active sites during an acceleration period of the reaction.

Many experiments have been shown that the presence of lattice defects in a metal for various reactions plays an important role in governing the catalytic activity.[1-16] The reactions used in these experiments, in most cases, were hydrogenations and dehydrogenations. There are very few reports about the nature of active sites of metals for oxidation reactions effected by molecular oxygen. Very important contributions to this problem have been carried out by Gwathmey and his colleagues.[17,19] They found that the morphological changes of crystal faces of copper occur during the catalytic oxidation of hydrogen and suggested that these changes are initiated at the special sites of emergence of imperfections in the crystal. The purpose of the present study is to investigate the effects of lattice defects in platinum produced by cold-working on the rate of the catalytic activity change during the oxidation of carbon monoxide. This reaction was chosen as a typical reaction because of the simplicity of the reacting system. The reason for selecting platinum is that this metal is one of the most commonly used catalyst for oxidation reactions and is resistant to bulk oxidation at effective temperatures.

In order to introduce lattice defects, well annealed Pt wire (99.97% purity) with a diamer 0.5 mm was rolled to a thickness of 0.1 mm at room temperature. After being washed with acetone and distilled water, these specimens were annealed again at different temperatures between 300 and 800 °C in hydrogen and under vacuum for 1 hr. The catalytic activity was determined in a static system by measuring the decrease in the total pressure. A stoichiometric mixture of CO and O_2 was used for all experiments at a total pressure of 100 Torr. The product, CO_2, was continuously condensed by a liquid nitrogen trap connected to the reaction vessel. The apparent surface area of specimens used as the catalyst was about 15 cm^2. The gases, obtained from Takachiho Co., Ltd., were carefully purified by passing through adsorbent traps and fractionating *in vacuo*.

Some typical results at a reaction temperature of 295 °C are given in Fig. 1. Curve (A) shows the course of reaction as a function of time on the fresh specimen

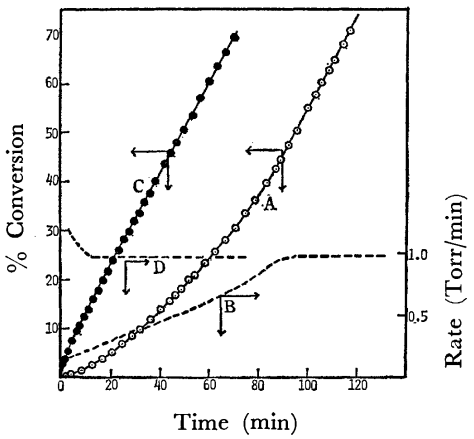

Fig. 1. Oxidation of CO on Pt annealed at 350 °C (reaction temperature 295 °C).
(A) and (B), first run: (C) and (D), second run.

annealed at 350 °C (first run). The change in the rate during the reaction is shown as curve (B) obtained from each point in curve (A). It is found that the rate increases at first with the progress of the reaction and attains to a steady limiting value. That is, two periods in the course of reaction can be defined: an acceleration period, and a steady state period, during which the rate of reaction is constant. These two periods are always observed under the conditions of present experiments when the freshly annealed specimens are used as the catalysts. The steady state rate is independent of the annealing temperatures (300—800 °C), however, the length of the acceleration period is strongly dependent on both the annealing temperatures and the reaction temperatures. Curves (C) and (D) are the results of the second run which is obtained with a new dose of the reacting gases after the first run. After an initial decrease, the rate becomes equal to the stationary value and no acceleration period is observed. Such a constant activity is found to remain unchanged even after several reaction runs. These results may suggest that the acceleration period is the process of the production of new active sites by the reaction itself. It is probable that the initial decrease in the rate (curve D) is due to CO poisoning on special active sites which are revealed by the evacuation after the first run. Figure 2(A) indicates the effect of annealing temperature on the catalytic activities in the range of the acceleration process at a reaction temperature of 295 °C. (The activities are expressed as a per cent conversion to CO_2 at a fixed reaction time, 50 min.) The change in the activity is considerable in the range 500—600 °C. According to

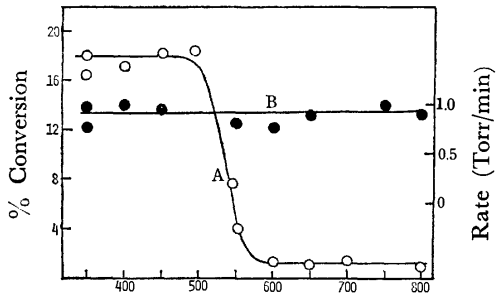

Fig. 2. Dependence of the catalytic activity in the acceleration period (A) and the steady period (B) on the annealing temperatures.
(A) Per cent conversion at a fixed reaction time, 50 min.
(B) Steady state rate, (Torr/min)

(B) Catalysts annealed at 600 °C.

our previous results, this range approximately corresponds to the recovery temperature range involving the disappearance of dislocations produced by cold-working.[8] Figure 2(B) indicates that the catalytic activities in the stationary state is independent of the annealing temperatures. The dependence of the length of the acceleration period on the reaction temperature is given in Fig. 3. The length of the acceleration period increases with decreasing the reaction temperature, and the Arrhenius plots give the slopes equivalent to the activation energies of 35 and 79 kcal over the range 280—360 °C for the catalysts annealed at 350 and 600 °C, respectively. These results indicate that the activation of the surface by the reaction is very difficult when the catalyst is well annealed. Further, it can be concluded that under the conditions of the present experiments, the surface terminations of dislocations play an important role in initiating the oxidation reaction and serve greatly to create new active sites during the acceleration period. For the nature of these active sites, we have no complete explanation but it seems likely that these sites can be related to a kind of surface defects created by the cyclic oxidation-reduction process of the surface involved in the catalytic reaction. On the other hand, it may be considered that the possible reasons for affecting the catalytic activity on annealing are the decrease in surface area and active lattice planes at the surface, however, these factors do not seem to explain the sudden decrease in the activity in a limiting annealing range (500—600 °C) as discussed in previous papers.[6,7,15,16] Furthermore, it is clear that the annealing at temperatures above 600 °C has direct effects on a length of crystallite boundaries, crystal edges, and angular points at the surface. However, the results also indicate that these factors have no influence on the activity.

A few experiments were also carried out on cold-worked gold at a reaction temperature of 390 °C. It was found that no acceleration period is observed and the activity is not influenced by annealing in the range 400—800 °C. According to the previous paper, the recovery temperature range of cold-worked Au is in the range of 100—200 °C.[15] Accordingly, in this case, dislocations produced by cold-working cannot be responsible for the catalytic activity, since the catalysts are already annealed out at 400 °C before the measurements are made.

The author wishes to express his gratitude to Professor I. Uhara for reading the manuscript and for helpful discussions.

Studies on the Catalytic Properties of Synthetic Zeolite A. V.[1] Site Selectivity of Silver Ion in (Ag^{ex}, Ca^{ex})-A

Masahiro NITTA, Kiyoshi OGAWA, and Kazuo AOMURA

Faculty of Engineering, Hokkaido University, Sapporo 060

(Received September 25, 1974)

Synopsis. The X-ray diffraction pattern and the propane-adsorption capacity of (Ag^{ex}, Ca^{ex})-A zeolites were determined as a function of the degree of ion exchange. From the change in diffraction intensity and the molecular sieving effect, it was deduced that Ag^+ ion prefers site I to site II.

It is well-known that synthetic zeolites A replaced by various cations are very useful as catalyst and adsorbent. The physicochemical property of zeolite A has been investigated in detail by many workers, but many points concerning the cation positions and the exchange scheme remain unclarified. We reported that Ag^+ ions were introduced into Na-A in an order of exchanging cations differing from that known for K^+ ions,[2] though both cations have a similar ionic radius larger than Na^+ ion. In this paper the site selectivity of Ag^+ ion in the (Ag^{ex}, Ca^{ex})-A* system is discussed.

The unit cell composition of $Ca^{ex}_{1.00}$-A is denoted by Ca_6 ($12AlO_2$ $12SiO_2$) nH_2O (M_{12} instead of Ca_6 for the monovalent cation form). From X-ray crystallography[3] and sorption study[4,5] of (Ca^{ex}, Na)-A, it was shown that all the $6Ca^{2+}$ ions occupy positions near the centers of the six-oxygen rings (site I) corresponding to the (111) plane. Other positions occupied by monovalent cations are sites near the centers of the eight-oxygen rings (site II) corresponding to the (100) plane, and site near a four-oxygen ring (site III) corresponding to the (110) plane.[6] In the hydrated Na-A, there are $4Na^+$ ions in site II and $8Na^+$ ions in site I. No X-ray structural data for (Ag^{ex}, Ca^{ex})-A seem to have been published. A recent study[7] suggests that Ag^+ ions occupy similar positions to those of Na^+ and K^+ ions.

The scattering power of silver for X-ray is much greater than that of calcium. Thus, when $Ca^{ex}_{1.00}$-A is replaced by Ag^+ ions, the intensity change in the X-ray diffraction of the above planes of (Ag^{ex}, Ca^{ex})-A should indicate the sites replaced by Ag^+ ions. As is shown in Fig. 1, the peak intensity of the (111) plane of hydrated samples decreased sharply with an increase in the degree of exchange, and reduced to zero at *ca.* 60%, while the intensity of the (100) plane did not decrease until 40% and then decreased gradually. This suggests that Ag^+ ions first occupy site I ($\leqq 8/12=66\%$), and then site II ($\geqq 5/12=41\%$). That is, Ag^+ ion prefers site I to site II. This is supported by the results of molecular sieving properties of (Ag^{ex}, Ca^{ex})-A and (K^{ex}, Ca^{ex})-A as given in the following.

Figure 2 shows the adsorption isobars of propane on (Ag^{ex}, Ca^{ex})-A and (K^{ex}, Ca^{ex})-A as a function of the degree of exchange. Since site II of $Ca^{ex}_{1.00}$-A is vacant, propane is rapidly diffused into the zeolite cavity and is adsorbed. In the case of K^+-exchange, propane was excluded by a $K^{ex}_{0.41}$, $Ca^{ex}_{0.69}$-A ($=5/12$). As is well known,[4] this is due to the siting of the initial K^+ ions into site II, which diminishes the apparent pore size. Takaishi *et al.*[5] have also confirmed from molecular sieving effects of (Ca^{ex}, K)-A with various adsorbates that K^+ ion prefers site II to site I. On the other hand, the replacement by Ag^+ ions permitted propane-sorption up to 70% ($\approx 8/12$) exchange, and then suddenly interfered with the sorption to *ca.* one fifth. This clearly indicates that the filling-up of site II by Ag^+ ions is completed after site I is completely filled

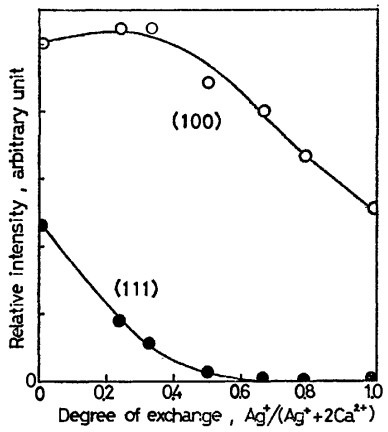

Fig. 1. Relationship between X-ray powder diffraction intensity and the degree of ion exchange.

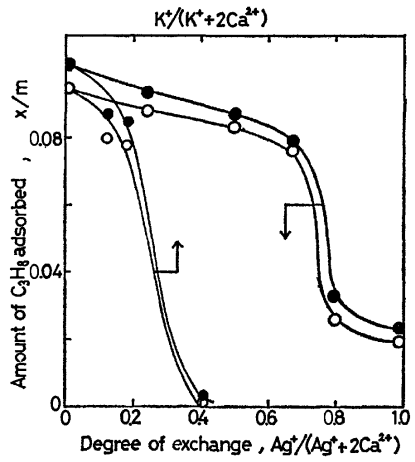

Fig. 2. Effects of silver and potassium exchanges for calcium on the sieving property.
○: 100 Torr, ●: 250 Torr, x/m: amount adsorbed in grams per gram of adsorbent.

* The nomenclature of cation-exchanged zeolite A obeyed Barrer's rule.[1] Superscript ex of M^{ex} indicates that M^{n+} ion was indroduced by ion-exchange.

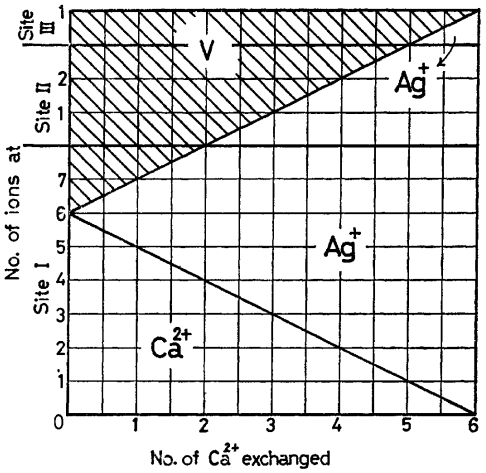

Fig. 3. Distribution of cations in (Ag^{ex}, Ca^{ex})-A.
V: Vacancies.

with $8Ag^+$ ions. That is to say, Ag^+ ion prefers site I to site II, in contrast with K^+ ion. This can be well interpreted by X-ray observation, and is consistent with the result of the (Ag^{ex}, Na)-A system.[2] The incomplete hindrance of $Ag^{ex}_{0.70-1.00}Ca^{ex}_{0.30-0}$-A for propane-sorption is due to the small ionic radius of Ag^+ (1.26 Å) compared to K^+ (1.33 Å).

From these results, the following diagram can be given to the dehydrated (Ag^{ex}, Ca^{ex})-A (Fig. 3). Such a diagram may be used as a guide line to future structural studies, and the true locations of Ag^+ ions should be determined only by X-ray structural analysis.

This work was supported by a Grant in Aid for Research from the Hokkaido Government.

Experimental

$Ca^{ex}_{1.00}$-A was prepared first from the original sodium-form zeolite A (Na-A) (Linde Molecular Sieve 4A powder). (Ag^{ex}, Ca^{ex})-A and (K^{ex}, Ca^{ex})-A were then prepared. The ion-exchange was carried out at 85±1 °C for 10 hr as already described.[1] Precaution was taken to shield the sample from light during ion-exchange and operations. The crystallinity of the samples was confirmed from the specific surface area to be unchanged by ion-exchange.

The X-ray powder diffraction pattern of the hydrated sample was obtained on a scintillation counter spectrometer using filtered Cu K_α radiation. The samples were exposed to air at room temperature while their spectra were measured.

The propane-adsorption was measured volumetrically at 0 °C on the sample activated at 250 °C in a vacuum at 10^{-3} Torr. Commercial propane (purity>99.5%) was subjected to two freeze-pump-thaw cycles before use.

Fluorescence Polarization of Intramolecular EDA Complexes in (9,10-Dicyanoanthracene)-$(CH_2)_n$-(Naphthalene)

Tsutomu MIMURA, Michiya ITOH,* and Toshihiko OKAMOTO

Faculty of Pharmaceutical Sciences, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received September 26, 1974)

Synopsis. Fluorescence of the intramolecular EDA complex was observed below ~140 K in the nonpolar solution of (9,10-dicyanoanthracene)-$(CH_2)_n$-(naphthalene), $n=2$. The fluorescence and excitation polarizations of these EDA ($n=2$ and 3) complexes at 77 K were determined.

During the course of investigations of EDA complexes at low temperatures in the nonpolar solution of EDA system exhibiting exciplex fluorescence at room temperature, Itoh *et al.* reported on the intramolecular exciplex (above ~200 K) and fluorescence of the EDA complex (below ~160 K) in (9, 10-dicyanoanthracene)-$(CH_2)_n$-(naphthalene) (abbreviated as $\beta\alpha$(III) and $\beta\beta$(III), $n=3$), fluorescent states of which were found to be quite different from each other.[1,2] Recently, Itoh and Mimura reported on experimental evidence of an identical fluorescent state of the intermolecular exciplex and EDA complex between 9,10-dicyanoanthracene (DCA) and various naphthalenes;[3] CT absorption bands in these EDA systems lie in the region of the ^1L_a band of the electron acceptor with the aid of photoselection studies in 3-methylpentane (MP) solutions at 77 K.[4,5]

We have observed fluorescence of the intramolecular EDA complex in the MP solution of $\beta\alpha$(II) below ~140 K, but no exciplex formation at temperatures from room temperature to ~140 K. The fluorescence and excitation polarizations of intramolecular EDA complexes of $\beta\alpha$(II), $\beta\alpha$(III) and $\beta\beta$(III) were determined in MP solutions at 77 K.[6] The sample $\beta\alpha$(II) was synthesized and purified by preparative thin layer chromatography and recrystallized before use.

Synthesis of 1-(9,10-Dicyano-2-anthryl)-2-(1-naphthyl)-ethane. *N-(2-Anthrylmethylene)aniline (anile):* 2-Anthraldehyde (1 mol) and aniline (1 mol) were refluxed in benzene for several hours; yellow crystals separated out from a cooled solution. Recrystallized from benzene; mp 246 °C; yield 84%; IR(KBr) 1590, 1615, 1419, 900 and 750 $cm.^{-1}$

1-(2-Anthryl)-2-(1-naphthyl)ethylene: 1-Methylnaphthalene (180 mg) and potassium *tert*-butoxide (300 mg) were dissolved in DMF, and then the anile (350 mg) was added. The mixture was stirred for 3 hr at 95 °C, and poured into water and extracted with benzene. The solvent was evaporated and extracted with warm hexane. Yellow green product was purified through silica gel chromatography (benzene–hexane); mp 235 °C; yield 12%;

Found: C, 94.36; H, 5.45%. Calcd for $C_{26}H_{18}$: C, 94.55; H, 5.45%. IR(KBr) 745, 772, 795, 895 and 957 cm^{-1}.

1-(2-Anthryl)-2-(1-naphthyl)ethane: The ethylene derivative (92 mg) was hydrogenated over 5% Pd/C for 6 hr in THF and ethanol (1 : 1). Colorless crystals were obtained. Recrystallized from benzene–hexane; mp 157 °C; yield 95%.

Found: C, 94.21; H, 6.16%. Calcd for $C_{26}H_{20}$: C, 93.98; H, 6.02%. IR (KBr) 745, 778 and 900 cm^{-1}.

The substituted ethane was brominated and cyanogenated as described previously.[1]

1-(9,10-Dibromo-2-anthryl)-2-(1-naphthyl)ethane: Recrystallized from benzene; mp 155 °C.

Found: C, 63.94; H, 3.63%. Calcd for $C_{26}H_{18}Br_2$: C, 63.67; H, 3.67%. IR(KBr) 1255, 925, 745 and 768 cm^{-1}.

1-(9,10-Dicyano-2-anthryl)-2-(1-naphthyl)ethane: Recrystallized from benzene; mp 230 °C.

Found: C, 87.92; H, 4.73; N, 7.30%. Calcd for $C_{28}H_{18}N_2$: C, 87.96; H, 4.71; N, 7.33%. IR(KBr) 2220, 772 and 760 $cm.^{-1}$

Results and Discussion

An MP solution of $\beta\alpha$(II) at room temperature shows fluorescence due to the DCA moiety alone in $\beta\alpha$(II) (quantum yield; 0.92)[7] and no fluorescence in the 500-nm region. Exciplex fluorescence in MP or 2-methyltetrahydrofuran (MTHF) solutions of $\beta\alpha$(III) and $\beta\beta$(III) was observed.[1] The electronic absorption spectrum was the sum of the each component moiety. Although a remarkable fluorescence quenching of DCA moiety and a weak structureless fluorescence in the 450—550 nm region were observed in an MTHF solution of $\beta\alpha$(II) at room temperature, no distinct exciplex fluorescence was observed in either the polar or nonpolar solutions.

The fluorescence intensity due to the DCA moiety of an MP solution of $\beta\alpha$(II) decreased markedly at 77 K, a new broad fluorescence spectrum (λ_{max} 540 nm) being observed as shown in Fig. 1. The fluorescence excitation spectrum (monitored at 560 nm) and the absorption spectrum of an MP solution of $\beta\alpha$(II) differ from those of the DCA moiety at room temperature, and are very similar to the fluorescence excitation spectra and also the absorption spectra of MP solutions of $\beta\alpha$(III) and $\beta\beta$(III).[1] Fluorescence maximum and lifetime (540 nm, 100 ns) of an MP solution of $\beta\alpha$(II) at 77 K show similar values to those of $\beta\alpha$(III) (540 nm, 125 ns) and $\beta\beta$(III) (540 nm, 150 ns). The intramolecular EDA complex might be formed in an MP solution of $\beta\alpha$(II) below ~140 K, while no exciplex was detected at room temperature.

In intermediate temperatures, ~140—240 K, an MP solution of $\beta\alpha$(II) shows also a long wavelength fluorescence spectrum (500—600 nm), its excitation spectrum differing somewhat from that of the DCA

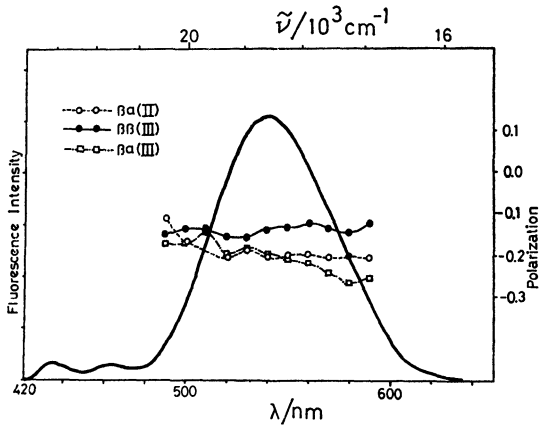

Fig. 1. The fluorescence spectrum of $\beta\alpha$(II) and the fluorescence polarizations of $\beta\alpha$(II), $\beta\alpha$(III) and $\beta\beta$(III) in MP at 77 K (excited at 360 nm; concentration: $\sim 10^{-6}$ M) The fluorescence intensity is in an arbitrary unit.

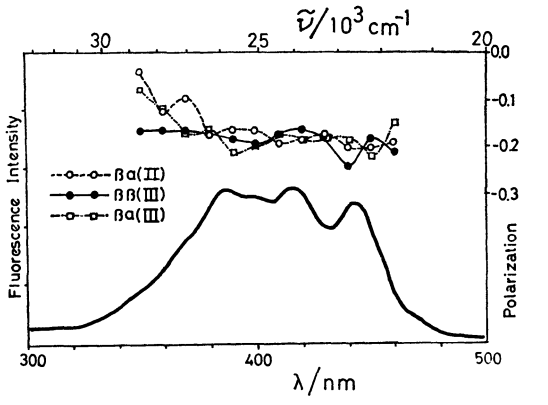

Fig. 2. The excitation spectrum of $\beta\alpha$(II) and the excitation polarizations of $\beta\alpha$(II), $\beta\alpha$(III) and $\beta\beta$(III) in MP at 77 K (monitored at 550 nm; concentration: $\sim 10^{-6}$ M) The fluorescence intensity is in an arbitrary unit. The excitation spectrum is not corrected for the intensity.

moiety (room temperature) and the EDA complex (77 K). An absorption spectrum corresponding to the excitation spectrum was also detected at almost the same intermediate temperature. These fluorescence and absorption spectra at ~140—240 K suggest an intramolecular electronic interaction in the ground state, geometrical and electronic structures of which seem to differ from those of the EDA complex at 77 K.

The fluorescence and excitation polarizations of MP solutions of $\beta\alpha$(III), $\beta\beta$(III) and $\beta\alpha$(II) were determined at 77 K by the photoselection method. Figure 1 shows negative polarization of these three compounds with excitation at 360 nm. Excitation polarization monitored at 550 nm exhibits negative values almost flat in the 440—360 nm range, as shown in Fig. 2. It is therefore unlikely that CT absorption bands in these intramolecular EDA complexes lie in this region. CT absorption bands in the EDA complexes between DCA and various naphthalenes lie in the wavelength region.[4,5] Since the electronic absorption band in the range 350—440 nm was ascribed to a local excitation (mostly ^1L_a transition) in the EDA complex, the negative fluorescence polarization by the excitation at 360 nm suggests that the long wavelength fluorescence (λ_{max} 540 nm) in these compounds is the CT fluorescence between DCA and naphthalene moieties,[8] if it is mixed with local excitations.

The average distance between the electron donor and acceptor seems to be larger in the intramolecular interaction than in the intermolecular interaction of DCA and naphthalene by a steric factor of the trimethylene chain in $\beta\alpha$(III) and $\beta\beta$(III). This is consistent with the results of the dipole moments in the fluorescent state of the exciplex, which are larger in $\beta\alpha$(III) and $\beta\beta$(III) (8.7—9.5 D)[1] than in the intermolecular systems of DCA and naphthalenes (5.9—8.6 D).[5] Thus, the CT state in the EDA complex may be higher in the former, and the CT band seems to shift to the shorter wavelength region than the first excited state of DCA by mixing with local excitations.

On the Phase Transition of Cyclic Tris(ethylene terephthalate)

Yukishige KITANO,* Michio KASHIWAGI,** and Yasuyuki EBATA
Basic Research Laboratories, Toray Industries, Inc., Tebiro, Kamakura 248
(Received October 31, 1974)

Synopsis. The crystal data of the Type B modification of the cyclic tris(ethylene terephthalate) showed it to be hexagonal, with the unit-cell dimensions of $a=15.42\pm0.03$ and $c=20.78\pm0.05$ Å (space group, $P6_1$ or $P6_5$). The effects of some organic reagents on the stability of Type B were studied qualitatively, and some information about the phase changes was obtained by the X-ray-diffraction and thermal-analysis techniques.

Because of their industrial importance and structural interest, the oligomers of poly(ethylene terephthalate), especially the cyclic trimer, have been investigated by many workers. The existence of two different forms, Type A and Type B,*** of the cyclic trimer was first found by Binns *et al.*,[1] and the discrepancies among the data previously reported[2-5] have been adjusted. Further observations were made by Ito and Okajima.[6] However, the Type B structure has not yet been unequivocally described. In this study we prepared stable Type B single crystals at room temperature and obtained crystal data on this material and some information concerning the effects of several organic reagents on the stability of the material.

The samples of the Type A cyclic trimer were extracted from a piece of poly(ethylene terephthalate) film with chloroform and were recrystallized repeatedly from a DMF solution. The samples of Type B were prepared by heating the Type A powder above 200 °C and by subsequently cooling it to room temperature. The X-ray diffraction data taken on the Type A samples were generally in agreement with those of Farrow *et al.*[7] and of Ito and Okajima.[6] The data for the Type B samples were similar to those of Binns *et al.*[1] and of Ito and Okajima,[6] but the X-ray pattern contained a number of reflections other than those previously reported. Single crystals of the Type B cyclic trimer were also prepared by the sublimation of the Type A powder. They are white platelet crystals of a size between 3 and 5 mm. The single-crystal X-ray pattern was identical to that of the Type B sample prepared by heating Type A and was completely indexed on the basis of the computer-refined hexagonal lattice parameters of $a=15.42\pm0.03$ and $c=20.78\pm0.05$ Å. The results are shown in Table 1. On the basis of six cyclic tris(ethylene terephthalate) per unit cell, the theoretical density is calculated to be 1.342 g·cm^{-3}; this should be compared with the observed density of 1.351 g·cm^{-3} obtained by floatation in a $ZnCl_2$ solution. Systematic absences are observed on the Weissenberg photographs for the $(00l)$ reflections with $l=6n$, where n is any integer. These data, combined with the Laue symmetry, 6/m, indicated the space group to be $P6_1$ or $P6_5$. Moreover, it is quite remarkable that the $(00l)$ reflections with $l=6n$ show a diffuse scattering elongated in the direction perpendicular to [001]. Such diffuse scattering is undoubtedly due to some disordering in the packing of molecules in the crystal.

Next, the stability of Type B at room temperature was investigated. The endothermic transition peaks from Type A to B in the differential thermal analysis of

a) $d=_{obsd}$, From diffractometer pattern calibrated by silicon powder; d_{calcd}, based on hexagonal lattice parameters, $a=15.42$ and $c=20.78$ Å; I_{obsd}, peak intensities from diffractometer pattern (Cu$K\alpha$ radiation).

the samples were found to vary when Type B was exposed to the vapor of such reagents as methanol, ethanol, acetone, DMF, benzene, and chloroform. Figure 1 shows the DTA diagrams of a sample treated with ethanol. After the sample had been treated for one hour, a small peak appeared at 187 °C. This peak grew larger and sharper, and, moreover, it shifted to high temperatures with time. After 24 hr of treatment, the peak reached 204 °C. In the course of this treatment, structural changes occurred, as assessed by X-ray diffraction. As is shown in Fig. 2, initial Type B structure gradually changed with time; finally it was almost entirely transformed into the Type A structure. Similar phenomena were observed when the samples were treated with other organic reagents.

X-Ray diffraction diagrams taken after the samples had been kept in air with a relative humidity of 30 to 50% for different lengths of time are given in Fig. 3. The peaks gradually broadened, showing that the samples became amorphous with time; one month later the Type B structure completely changed into Type A. On the other hand, when the Type B samples were kept in a desiccator over silica gel, no such phenomena were observed. This means that the Type B cyclic trimer is stable at room temperature in dry air.

A Fluorometric Determination of Zinc in Portland Cement with 8-Quinolinethiol

Kunihiro WATANABE and Kyōzō KAWAGAKI

Faculty of Science and Technology, Science University of Tokyo, Yamazaki, Noda-shi, Chiba 278

(Received September 20, 1974)

Synopsis. A method for the fluorometric determination of zinc in cement with 8-quinolinethiol is presented. *o*-Phenanthroline and sodium thiosulfate have been found to be useful as masking reagents of interfering ions.

Atomic absorption[1] and polarographic[2] methods, among others, have been proposed in the literature for the determination of the zinc contained in a cement. In the fluorometric determination method of zinc[3] with 8-quinolinethiol previously reported by the present authors in connection with the removal of interfering ions, it was found that 8-quinolinethiol forms a stable complex with zinc and that most of the main constituent elements of a cement except iron do not interfere. In view of these findings, a fluorometric method has been developed for the determination of zinc in cement.

Good agreements were obtained between the results of the present method and those of conventional atomic absorption method.[1] The relative error of this method was from 1 to 5%.

Experimental

Reagents and Apparatus. A stock solution of zinc was prepared by dissolving 1.5286 g of zinc metal (Wako Junyaku Co.) in dilute hydrochloric acid. A 0.2% 8-quinolinethiol solution was prepared by dissolving 0.1 g of 8-quinolinethiol hydrochloride (Dojin Yakka Co.) in 50 ml of 6 M hydrochloric acid. The other reagents used were of an analytical reagent grade. The 8-quinolinethiol solution and chloroform were used for washing some of the reagents.

A Hitachi fluorescence spectrophotometer, Model 203, with a mercury lamp, was used for the fluorometric measurements. A Toa Denpa, Model HM5A, glass electrode pH meter was used for the pH measurements. An Iwaki KM shaker was also used.

Standard Procedure. Put 10 ml of a sample solution containing less than 30 μg of zinc into a beaker. Add 5 ml of a 10% ascorbic acid solution as well as 0.2 ml of a 0.2% 8-quinolinethiol solution (6 M HCl solution).

Dilute to about 50 ml with water, and adjust the pH of the solution to 4.0. Then transfer the solution to a separatory funnel and extract the zinc chelate with 10 ml of chloroform by shaking the funnel for 2 min. Measure the fluorescence intensity of the extract with reference to a 0.2 μg/ml uranine solution.

Results and Discussion

Effect of Diverse Ions. The effects of the main components of a cement on the fluorometric dermination of zinc have been intensively studied. The results are shown in Table 1. Calcium, aluminum, magnesium, sodium, potassium, and silicate ions do not interfere. However a large amount of aluminum forms hydroxides in an aqueous solution of pH 4; therefore, this element must be masked by ascorbic acid. Titanium and chromium do not interfere. Manganese does not interfere when zinc chelate is extracted at pH 4. Iron interferes strongly. Among the minor elements[4] in a cement, nickel, cobalt, copper, lead, and cadmium interfere.

Table 1. Effect of diverse ions

Ions	(mg)	Added	Zn found (μg)
Ca^{2+}	340	$Ca(NO_3)_2 \cdot 4H_2O$	7.6
Mg^{2+}	25	$Mg(NO_3)_2 \cdot 6H_2O$	7.6
Al^{3+}	36	$Al(NO_3)_3 \cdot 9H_2O$	7.6
Na^{+}	1000	NaCl	7.6
K^{+}	1000	KCl	7.6
Mn^{2+}	0.25	$MnSO_4 \cdot 6H_2O$	7.6
Fe^{2+}	0.1	$Fe+HNO_3+0.1\%$ *o*-phen 3 ml + ascorbic acid	7.5
Cd^{2+}	0.007	$Cd+HNO_3+Na_2S_2O_3 \cdot 5H_2O$ 1 g	7.9
Pb^{2+}	0.1	$Pb(NO_3)_2+Na_2S_2O_3 \cdot 5H_2O$ 1 g	7.6
Ti^{4+}	0.46	$TiO_2+H_2SO_4$	7.6
Hg^{2+}	0.1	$Hg(NO_3)_2$	5.2
SO_4^{2-}	2000	$(NH_4)_2SO_4$	7.6
VO_3^{-}	2	NH_4VO_3	7.4
PO_4^{3-}	1	$(NH_4)_2HPO_4$	7.6
SiO_3^{2-}	20	Na_2SiO_3	7.6

Zn taken: 7.6 μg; pH: 4.0; *o*-phen: *o*-phenanthroline

Masking and Removal of Interfering Ions. The uses of potassium cyanide and *o*-phenanthroline as masking reagents of iron ions were examined. The amount of potassium cyanide has little effect on the fluorescence intensity of zinc chelate. However, because of the use of the masking reagent in an alkaline solution, some ions from hydroxides, thus interfering with the fluorescence intensity. Potassium cyanide was less effective in masking than *o*-phenanthroline. In view of these results, *o*-phenanthroline was chosen as the masking reagent.

The effect of the concentration of *o*-phenanthroline is shown in Fig. 1. The extractability of chelate decreases upon the addition of more than 5 ml of a 0.1% *o*-phenanthroline solution. However, less than 5 ml of *o*-phenanthroline has very little effect on the fluorescence intensity.

The amount of iron ions to be masked by *o*-phenanthroline was also examined. As is shown in Fig. 2, a 5-ml portion of 0.1% *o*-phenanthroline is required to mask 0.3 mg of iron ions.

The procedure used to remove some interfering ions is as follows: Add *o*-phenanthroline and 8-quinolinethiol to the sample solution to form the zinc chelate. Then extract the zinc chelate with chloroform. Repeat the extraction. Combine the organic extracts. To

separate the zinc from the organic phase, shake with a 0.1 M hydrochloric acid solution. In this back-extraction, copper (up to 0.1 mg) and cobalt (up to 0.1 mg) ions remain in the organic phase, but the zinc, lead, cadmium, and nickel are transferred into the aqueous phase. Lead and cadmium react with sodium thiosulfate to form thiosulfate complex ions; therefore, lead (up to 1 mg) and cadmium (up to 10 μg) are masked with sodium thiosulfate. In the case of the coexistence of *o*-phenanthroline, nickel does not interfere up to 50 μg.

Synthetic Sample. For the synthetic sample of cement shown in Table 2, the separation of the chloroform layer from the aqueous layer after the extraction of the zinc chelate was difficult. For quick separation into two layers, a 10-ml portion ethyl alcohol was added to the sample solution.

Determination of Zinc in Cement Samples. In view of the experimental results described above, the recommended procedure for the determination of zinc in cement samples is: Take about 0.25 g of a cement sample, and 0.5 g of ammonium chloride, and add 5 ml of hydrochloric acid to the mixture. Then heat on a steam bath for 30 min, and add 20 ml of hot water to the solution for the complete dissolution of the soluble components of the cement sample. Filter the solution, and wash the precipitate with hot water. Cool the filtrate, and dilute the solution to 250 ml in a volumetric flask.

0.1% *o*-phenanthroline (I: 5 ml; II: 10 ml; III: 20 ml; IV: 20 ml)
Zn: 7.6 μg (I, II, III); Zn: 0 μg (IV); Wavelength: 365 nm/520 nm

Table 2. Analytical results of synthetic samples

Sample No.	Zn taken (μg)	Diverse ions (mg)	Zn found (μg)
I	7.6	Al^{3+} 6, Mg^{2+} 3, Ca^{2+} 120, Fe^{3+} 1, Cr^{3+} 0.1, Mn^{2+} 0.1, Ti^{4+} 0.08, Ni^{2+} 0.04, Cu^{2+} 0.04, Pb^{2+} 0.04, SiO_3^{2-} 1, PO_4^{3-} 0.1	7.5, 7.6, 7.5
	3.8		3.8, 4.0, 3.9
II	7.6	Ca^{2+} 240, Mg^{2+} 6, Mn^{2+} 0.1, Al^{3+} 12, SiO_3^{2-} 1, PO_4^{3-} 0.1, Cr^{3+} 0.1	7.6, 7.6, 7.5

Table 3. Analytical results of portland cements

Portland cement	Sample taken (g)	Zn found (%)	
		Proposed method	Atomic absorption method
I	0.2706	0.06_4	0.06_1
II	0.2171	0.04_0	0.04_4
III	0.2143	0.05_8	0.05_8

Pipet a 10- or 20-ml aliquot into a 100-ml beaker, add 5 ml of a 10% ascorbic acid solution, and 5 ml of a 0.1% *o*-phenanthroline solution to each 10 ml of the sample solution and 10 ml of ethyl alcohol. Then dilute the solution to 50 ml, add 0.3 ml of a 0.2% 8-quinolinethiol solution, and adjust the pH to 4. Extract the zinc chelate with 10 ml of chloroform by shaking for 2 min. Put the aqueous phase into a beaker, add 0.2 ml of 0.2% 8-quinolinethiol, adjust the pH to 4, and repeat this extraction twice. Combine the organic extracts. To back-extract zinc chelate from the organic phase, shake with 40 ml of 0.1 M hydrochloric acid for 2 min. Separate the aqueous phase, neutralize with a sodium hydroxide solution, and add 1 g of sodium thiosulfate to the solution. After the complete dissolution of the sodium thiosulfate, add 0.2 ml of 0.2% 8-quinolinethiol, adjust the pH to 4, and extract the zinc chelate with 10 ml of chloroform. Measure the fluorescence intensity with respect to a uranine solution. The zinc content (0— 30 μg) can then be calculated from the calibration curve.

The zinc in synthetic and Portland cement samples was determined by the proposed method. The results are shown in Tables 2 and 3. The present method is rapid and accurate enough for the determination of zinc in cement. The relative error of this method was from 1 to 5% for from 0.01 to 0.1% of zinc.

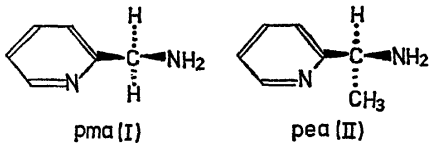
Synthesis of *trans*-Dibromo-bis{(2-pyridyl)methylamine} and -bis{*S*-1-(2-pyridyl)ethylamine} cobalt(III) Complexes

Toshishige M. SUZUKI,* Yoshiko WATANABE, Junnosuke FUJITA,** and Kazuo SAITO
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Sendai 980

(Received January 8, 1975)

Synopsis. Light green crystals of *trans*-dibromo-bis{(2-pyridyl)-methylamine} and -bis{*S*-1-(2-pyridyl)-ethylamine}cobalt(III) bromide have been prepared. The latter complex shows a circular dichroism (CD) spectrum enantiomeric with that of the corresponding *S*-propylenediamine complex in the first absorption band region.

Several cobalt (III) complexes with (2-pyridyl)-methylamine (pma)[1,2,3] (I) and optically active 1-(2-pyridyl)ethylamine (pea)[4] (II) have been prepared. However, these complexes are limited to tris- and *cis*-bis-diamine types, and no *trans*-bis type complex has been reported. Michelsen[3] claimed that the *trans* type



complexes were not formed in the preparation of bis type complexes. In the course of our preparative work on cobalt (III) complexes with the same ligands, we have obtained *trans*-dibromo-bis(pma) and -bis(pea) cobalt (III) complexes for the first time. This paper reports the preparation of these complexes as well as circular dichroism spectrum of the pea complex.

Experimental

Ligands: (2-Pyridyl)methylamine (pma) was purchased from Aldrich Chemical Co., and used without further purification. 1-(2-Pyridyl)ethylamine (pea) was prepared according to the method described in the literature[5] and resolved with (−)$_D$-tartaric acid by a method similar to that given by Michelsen.[4] (−)$_D$-Isomer of pea is known to have *S*-configuration.[6,7] *trans*-Dibromo-bis{*S*-1-(2-pyridyl)ethylamine}-cobalt(III) hydrogen dibromide, *trans*-[$CoBr_2$(*S*-pea)$_2$]-Br·HBr: A mixture of $NH_4[Co(SO_3)_2(NH_3)_4]$[8] (3.0 g, 0.01 mol) and *S*-pea (2.44 g, 0.02 mol) in 20 ml of water was heated at 60 °C for 2 hr with stirring. The brownish yellow solution was evaporated to dryness under reduced pressure at 60 °C and the residue dissolved in 20 ml of 48% hydrobromic acid. The solution was warmed at 60 °C for 2 hr to give light green crystals, which were filtered off, washed with a small amount of ethanol and then with ether. Found: C, 26.95; H, 3.39; N, 8.98%. Calcd for $C_{14}H_{20}N_4CoBr_4$: C, 26.50; H, 3.78; N, 9.13%. *trans*-Dibromo-bis{(2-pyridyl)-methylamine}cobalt(III) bromide monohydrate, *trans*-[$CoBr_2$(pma)$_2$]Br·H_2O: This complex was prepared by a similar method by use of pma instead of *S*-pea. Found: C, 27.39; H, 3.18; N, 10.54%. Calcd for $C_{12}H_{18}N_4OCoBr_3$: C, 27.07; H, 3.40; N, 10.51%.

Absorption and CD spectra were recorded with a Shimadzu Double 40-R spectrophotometer and a Jasco J-20 spectropolarimeter, respectively, at room temperature.

Results and Discussion

The two dibromo complexes have light green color, characteristic of *trans*-dibromo-diamine complexes. Figure 1 shows that their absorption spectra are very similar to that of the corresponding *S*-propylenediamine (*S*-pn) complex. The present *trans*-dibromo complexes with two unsymmetrical bidentate ligands have further geometrical isomers, *cis* and *trans* with respect to the configuration of the pyridyl groups (py). However, the *cis* isomer involves a big steric hindrance between the hydrogen atoms of the two pyridyl groups and the present complex can be assigned to *trans*(Br-Br)*trans*(py-py) configuration. This assignment may be supported by the *trans*(py-py) configuration of $[Cu(S\text{-pea})_2]Cl_2\cdot 2H_2O$.[7]

Isolation of the corresponding dichloro complexes was not successful because of their high solubility.

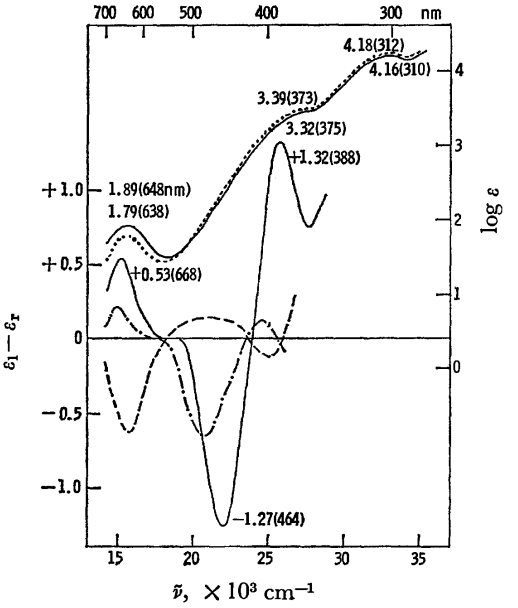


Fig. 1. Absorption spectra of (·····) *trans*-[$CoBr_2$(pma)$_2$]$^+$ and (——) *trans*-[$CoBr_2$(*S*-pea)$_2$]$^+$ in methanol. CD spectra of (——) *trans*-[$CoBr_2$(*S*-pea)$_2$]$^+$ (----) *trans*-[$CoBr_2$(*S*-pn)$_2$]$^+$ [9] and (—·—) *trans*-[$CoCl_2$(*N*-Me(*R*)-en)$_2$]$^+$ [11] in methanol.

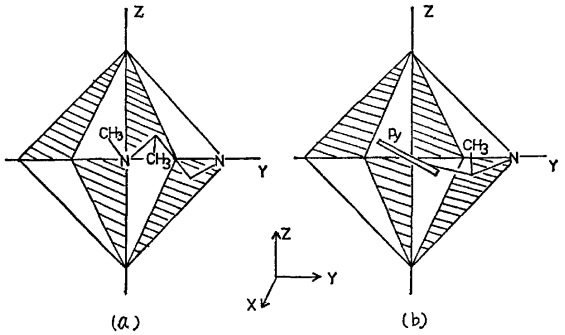

Fig. 2. The hexadecadal regional rule proposed by Mason.[13]

The CD spectrum of *trans*-$[CoBr_2(S\text{-pea})_2]^+$ gives a positive and a negative CD band in the region of the Ia($A_{1g}\rightarrow E_g$) and Ib ($A_{1g}\rightarrow A_{2g}$) absorption component (D_{4h} approximation), respectively (Fig. 1). This spectrum is virtually enantiomeric with that of *trans*-$[CoX_2(S\text{-pn})_2]^+$ (X = Cl^-, Br^-),[9] but very similar to those of *trans*(Cl,Cl) *trans*(*N*-CH_3, *N*-CH_3)-$[CoCl_2(N\text{-}CH_3(R)\text{-}S\text{-pn})_2]^{+}$[10] (*N*-$CH_3$(*R*)-*S*-pn = *N*-methyl(*R*)-*S*-propylenediamine) and -$[CoCl_2(N\text{-}CH_3(R)\text{-en})_2]^{+}$[11] (*N*-$CH_3$(*R*)-en = *N*-methyl(*R*)-ethylenediamine). X-Ray diffraction method[12] showed that three complexes have a similar conformational structure to one another.

Mason[13] proposed a hexadecadal regional rule (Fig. 2(a)) to account for the CD sign of a *trans*-dihalogeno-diamine complex. The *N*-methyl group in an unhatched region gives contribution to a negative CD for the $A_{1g}\rightarrow A_{2g}(D_{4h})$ component, while the *S*-pn has no such *N*-methyl group and its chain alkyl group lies in a hatched region where contribution to the sign is reversed. The CD sign of the $A_{1g}\rightarrow E_g(D_{4h})$ component is usually opposite to that of the $A_{1g}\rightarrow A_{2g}(D_{4h})$ owing to the partial sum-rule.[12] Detailed structure of the present dibromo complex is unknown. However, the *S*-pea chelates in $[Cu(S\text{-pea})_2]Cl_2\cdot H_2O$[7] have slightly puckered structures and the chelates and the pyridyl rings are not co-planar. On the analogy of this X-ray analysis, the *S*-pea chelate ring in the bromo complex is depicted in Fig. 2(b). Such a twisted structure can be expected whenever the methyl group tends to take an equatorial orientation to the chelate ring. Hence most atoms in the pyridyl group seem to occupy the unhatched region and will give a CD with negative sign for the $A_{1g}\rightarrow A_{2g}(D_{4h})$ component. The *N*-methyl-*S*-pn(en) complex has asymmetric nitrogen atom but the *S*-pea complex does not. The similarity in the CD spectra between the *S*-pea and the *N*-methyl(*R*)-*S*-pn(en) complexes will thus be understood by the hexadecadal rule.

The *trans*-$[CoBr_2(S\text{-pea})_2]^+$ react readily with *S*-pea in DMSO at room temperature to give $[Co(S\text{-pea})_3]^{3+}$ consisting of all possible four diastereomers. Of these, *fac*-*Δ*, *fac*-*Λ* and *mer*-*Λ* were separated and isolated by SP-Sephadex column chromatography, but *mer*-*Δ* isomer was too little to be isolated. Michelsen[4] obtained also the first three isomers from $[CoCl_2\,py_4]Cl\cdot 6H_2O$ and *S*-pea in pyridine using a similar column chromatography. The origin of such a stereoselective complex formation remains unknown.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(6), 1949—1950 (1975)

The Regioselective Addition of Alcohols to Isoprene with Rhodium Trichloride Hydrates

Hiroshi KAWAZURA,* Toshihisa TAKAGAKI, and Yoshio ISHII

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464

(Received October 7, 1974)

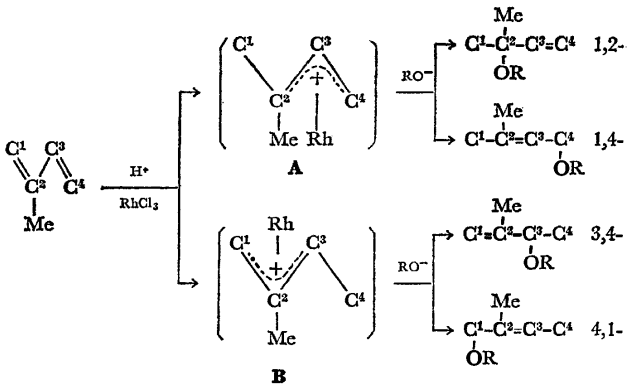
Synopsis. Rhodium trichloride hydrates gave predominantly the 1,2-addition product, 2-alkoxy-2-methylbut-3-ene, in the addition reaction of alcohols to isoprene. The regioselective path was established by assuming the formation of the π-(2-methylbut-3-en-2-yl)rhodium complex.

The almost exclusive formation of 2-alkoxybut-3-ene in the addition reaction of alcohols to 1,3-butadiene with rhodium trichloride hydrates[1] prompted us to examine the same reaction with isoprene, with special attention, paid to its regioselectivity, which was not noticed in the pioneering work.[2]

Table 1 summarizes the results of the addition reactions of various alcohols to isoprene carried out at 50 °C for 96 hr under nitrogen in the presence of a catalytic amount of $RhCl_3 \cdot 3H_2O$. The addition products were fractionated by preparative glc, and all the structures, as described in the table, were unambiguously determined by IR and PMR. The predominant formation of 2-alkoxy-2-methylbut-3-ene, a 1,2-addition product, accounting for more than 70% of the total products, proved the regioselectivity of the reaction.

The ionic nature of the reaction is evident, since the total yields of the addition products hold a parallel correlation with the intensities of the OH stretching vibrations of the alcohols, as in the case of butadiene.[1]

The regioselective path of the reaction may be understood if one assumes the formation of π-allylic rhodium complexes originating from an alcoholic proton attack on isoprene, as is delineated in the following scheme. The overwhelming formation of the **A** complex can be understood in view of the higher electron density of the C^1 carbon in comparison with the C^4 carbon in isoprene. Consequently, the predominant formation of the 1,2-addition product may be well explained as an attack



of alkoxy nucleophile on the electron-deficiently stabilized C^2 tertiary carbon in the **A** complex. The nil to minor formations of 3-alkoxy-2-methylbut-1-ene, the 3,4-addition product and the total absences of 1-alkoxy-2-methylbut-2-ene, the 4,1-addition product may be reflections of the electronically unfavored formation of the **B** complex.

Eventually the regioselectivity to the 1,2-addition may be ascribed to the predominant formation of the π-(2-methylbut-3-en-2-yl)rhodium complex, to whose tertiary carbenium carbon occurs the highly directive addition of the alkoxy nucleophile.

Experimental

Reaction of n-*BuOH to Isoprene.* A mixture of *n*-BuOH (25.0 ml) containing $RhCl_3 \cdot 3H_2O$ (62.0 mg, 0.24 mmol) and isoprene (15.0 ml, 150 mmol) was heated at 50 °C for 96 hr with stirring under nitrogen. The reaction mixture was then filtered, and the filtrate was subjected to preparative glpc (PEG 6000, 3 m, 60 °C, H_2 50 ml/min) to give three

addition products. Isolated were 2-*n*-butoxy-2-methylbut-3-ene (1,2-addition product) (4.77 g (33.0 mmol); bp 12—13 °C/2 mmHg; IR (liquid, cm^{-1}) 1650 ($\nu_{C=C}$), 1093 (ν_{C-O}), 1000 and 920 (δ_{CH} in $-CH=CH_2$); PMR (CCl_4 with TMS, τ) 4.21 (1H, dd, $J=18$ and $J=10$ Hz, proton at C^3), 5.01 (1H, dd, $J=18$ and $J=2$ Hz, *trans* proton at C^4), 5.04 (1H, dd, $J=10$ and $J=2$ Hz, *cis* proton at C^4), 6.75 (2H, t, $J=6.0$ Hz, $-CH_2O-$), 8.58 (4H, m, $-(CH_2)_2-$), 8.75 (6H, s, protons of two methyls at C^2), and 9.08 (3H, t, $J=6.2$ Hz, methyl protons in butoxy)), 3-*n*-butoxy-2-methylbut-1-ene (3,4-addition product) (1.07 g (8.1 mmol); bp 12—13 °C/2 mmHg; IR (liquid, cm^{-1}) 1650 ($\nu_{C=C}$), 1090 ($\nu_{C=C}$), and 920 (δ_{CH} in $>C=CH_2$); PMR (CCl_4 with TMS, τ) 5.16 (2H, m, protons at C^1), 6.21 (1H, q, $J=6.0$ Hz, proton at C^3), 6.75 (2H, t, $J=6.0$ Hz, $-CH_2O-$), 8.35 (3H, s, methyl protons at C^2), 8.58 (4H, m, $-(CH_2)_2-$), 8.77 (3H, d, $J=6.0$ Hz, protons at C^4-methyl), and 9.08 (3H, t, $J=6.2$ Hz, methyl protons in butoxy)), and 4-*n*-butoxy-2-methylbut-2-ene (1,4-addition product) (0.81 g (5.7 mmol); bp 23—25°C/2 mmHg; IR (liquid, cm^{-1}) 1650 ($\nu_{C=C}$), 1095 (ν_{C-O}), and 1000 (δ_{CH} in $>C=CH-$); PMR (CCl_4 with TMS, τ) 4.78 (1H, t, $J=6.0$ Hz, proton at C^3), 6.21 (2H, d, $J=6.2$ Hz, protons at C^4), 6.73 (2H, t, $J=6.0$ Hz, $-CH_2O-$), 8.30 (3H, s, C^1-methyl protons), 8.38 (3H, s, methyl protons at C^2), 8.56 (4H, m, $-(CH_2)_2-$), and 9.10 (3H, t, $J=6.3$ Hz, methyl protons in butoxy).

Reaction of the Other Alcohols to Isoprene. According to the procedure described above, the addition reaction and the products analysis were carried out for the other alcohols to give the glpc fractions, which were determined, as is shown in the table, by their IR and PMR, in which were found a characteristic pattern attributable to the 1,2-, 3,4-, or 1,4-addition product.

The Photolysis of Dimethyl Diazomalonate in Alcohols. The Detection of Triplet Carbene

Wataru ANDO, Tsuneo HAGIWARA, and Toshihiko MIGITA
Department of Chemistry, Gunma University, Kiryu, Gunma 376

(Received November 7, 1974)

Synopsis. The photolysis of dimethyl diazomalonate n alcohols gave the O–H insertion product of biscarbomethoxycarbene and dimethyl malonate as the major products. The dimethyl malonate might be formed by the hydrogen abstraction of a triplet carbene.

There have been a few reports which show the occurrence of a triplet carbene in the direct photolysis of diazo compounds, whereas its benzophenone-sensitized photolysis is generally accepted to produce a triplet carbene.[1,2]

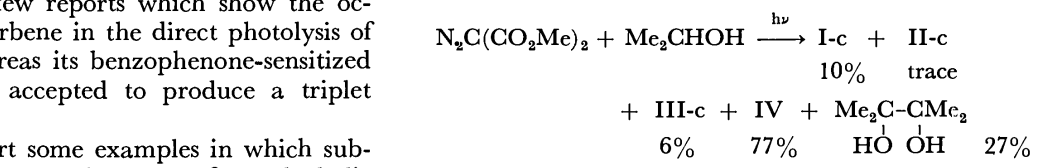
This paper will report some examples in which substantial amounts of hydrogen abstraction from alcoholic solvents and of non-stereospecific addition to olefin result from the biscarbomethoxycarbene produced through the photolysis of dimethyl diazomalonate in alcoholic media.

The direct irradiation of a methanol solution of dimethyl diazomalonate (0.16 g in 2.5 ml) was carried out with a high-pressure mercury lamp until the disappearance of the diazo compound. A gas chromatographic analysis of the reaction mixture gave dimethyl methoxymalonate and dimethyl malonate in 78 and 10% yields respectively; the structures of the products were established by NMR, IR, and elemental analyses. Appropriate control experiments showed that the products are stable under the present reaction conditions.

The photolysis in ethanol gave four products; dimethyl ethoxymalonate (I-b), ethyl methyl ethoxymalonate (II-b), ethyl methyl methoxymalonate (III-b), and dimethyl malonate (IV). From the photolysis of the diazomalonate in 2-propanol, the Wolff rearrangement product (III) was obtained together with the O–H insertion (I) and ester exchange (II) products, as minor products, while dimethyl malonate became the major product.

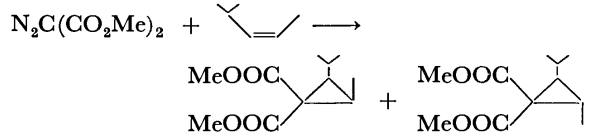
		I	II	III	IV
a	R=Me	78%	—	—	10%
b	R=Et	33	2%	13%	34
c	R=*iso*-Pr	21	4	12	41
d	R=*tert*-Bu	40	5	12	0

It is noteworthy that the photolysis of diazomalonate produced substantial amounts of dimethyl malonate, which increased with an increase of the H-donor abilities of the alcohols. Furthermore, a change of the concentration of the diazomalonate from 1 mmol to 0.2 mmol in 5 ml 2-propanol resulted in an increase in the yield of dimethyl malonate from 41 to 77%, with the formation of pinacol (27%) and the O–H insertion product (10%).



Although I and III are quite familiar products of the reaction of the singlet carbene derived from the diazo compound in alcohols,[3,4] the formation of malonate and pinacol can be though to be rather characteristic for the triplet carbene, which can abstract the α-hydrogen atom from alcohol. Indeed, the benzophenone-sensitized photodecomposition of dimethyl diazomalonate in ethanol and 2-propanol gave dimethyl malonate in 74—80% yields.

It is also worth noting that the photolysis of diazomalonate in mixtures of *cis*-4-methyl-2-pentene and alcohols gave cyclopropane derivatives in a non-stereospecific manner, but rather similar to the case of the photosensitized reaction,[5] especially in the presence of methanol, although the total yields of the adducts were quite low.



hν	92%	8%
hν + Ph_2C=O	14%	86%
hν + MeOH[a]	18%	82%
hν + EtOH[a]	66%	34%
hν + *iso*-PrOH[a]	75%	25%

a) The mole ratio of *cis*-4-methyl-2-pentene and alcohol is 1 : 10.

These findings strongly support the idea that the triplet species are involved in the direct photolysis of diazomalonate in alcohols. Singlet carbene reacts with alcohols to give either O–H insertion or Wolff-rearrangement products, while the residual carbene, which contains the triplet, abundantly reacts with olefin to give non-stereospecific adducts.

At present, the occurrence of the triplet carbene in the direct photolysis of diazomalonate in alcohols is thought to be brought about through some intersystem crossing processes. The small amounts of triplet carbene thus formed abstract a hydrogen atom from

Table 1. Reaction of dimethyl diazomalonate with *cis*-4-methyl-2-pentene in methanol

4	38	62
10	18	82

alcohol, and the α-hydroxalkyl radical may induce the decomposition of diazomalonate by chain processes, giving substantial amounts of dimethyl malonate, since the thermal decomposition of diazomalonate in the presence of benzoyl peroxide in alcohol has been known to give dimethyl malonate in a good yield.[6]

Experimental

General. Solutions of dimethyl diazomalonate were placed in clean 10×100 mm Pyrex tubes. The tubes were corked (non-degassed), placed in a water-cooled bath, and then irradiated by means of a Rikosha 400-W high-pressure mercury lamp, with a maximum output at 3650—3660 Å. Photolyses were carried out until the diazo band in the infrared region disappeared. The solutions were analyzed on an Ohkura gas chromatograph with a calibrated 2 m×4 mm stainless steel column of 15% silicon SF-96 on Celite 545. The products were characterized by NMR (see the table shown below), IR and elemental analyses.

Reaction of Dimethyl Diazomalonate with Methanol. A solution of 187 mg of dimethyl diazomalonate in 1 ml of methanol was cooled with running water and irradiated through Pyrex with a high-pressure mercury lamp for 5 hr. After the distillation of the solvent, the residue was fractionated by gas chromatography. The major product was then collected. I-a: Found: C, 44.15; H, 6.02%. Calcd for $C_6H_{10}O_5$: C, 44.44; H, 6.22%.

Reaction of Dimethyl Diazomalonate with Ethanol. A solution of 155 mg of dimethyl diazomalonate in 1 ml of ethanol was similarly irradiated for 3 hr. Subsequent gas chromatography gave 34% of dimethyl malonate and 33% of a major product identified as dimethyl ethoxymalonate(I-b). The minor products were collected in 2% (II-b) and 13% (III-b) yields. I-b: Found: C, 47.58; H, 6.93%. Calcd for $C_7H_{12}O_5$: C, 47.72; H, 6.87%. II-b: Found: C, 50.29; H, 7.18%. Calcd for $C_8H_{14}O_5$: C, 50.52; H, 7.42%. III-b: Found: C, 47.86; H, 6.75%. Calcd for $C_7H_{12}O_5$: C, 47.72; H, 6.87%.

Reaction of Dimethyl Diazomalonate with 2-Propanol. Irradiation of a solution of 160 mg of dimethyl diazomalonate in 1 ml of 2-propanol gave I-c and IV as major products, and II-c and III-c as minor products. When a solution of 160 mg of dimethyl diazomalonate in 5 ml of 2-propanol was irradiated, the five products were isolated by gas chromatography at 160 °C. The two major products were pinacol (47% yield) and dimethyl malonate (64% yield). The minor products were found to to be I-c (8%), II-c (trace), and III-c (5%). I-c: Found: C, 50.43; H, 7.32%. Calcd for $C_8H_{14}O_5$: C, 50.52; H, 7.42%. II-c: Found: C, 54.93; H, 8.12%. Calcd for $C_{10}H_{18}O_5$: C, 55.03; H, 8.21%. III-c: Found: C, 50.16; H, 7.39%. Calcd for $C_8H_{14}O_5$: C, 50.52; H, 7.42%.

Reaction of Dimethyl Diazomalonate with tert*-Butyl Alcohol.* A solution of 152 mg of dimethyl diazomalonate in 1 ml of *tert*-butyl alcohol was irradiated for 5 hr through Pyrex tubes. The products were analyzed by gas chromatography at 170 °C. The major product was identified as I-d by spectral analysis. The minor products were collected in 5% (II-d) and 12% (III-d) yields. I-d: Found: C, 52.45; H, 7.95%. Calcd for $C_9H_{16}O_5$: C, 52.93; H, 7.90%. II-d: Found: C, 58.37; H, 8.95%. Calcd for $C_{12}H_{22}O_5$: C, 58.51; H, 9.00%. III-d: Found: C, 52.78; H, 8.12%. Calcd for $C_9H_{16}O_5$: C, 52.93; H, 7.90%.

Sensitized Decomposition of Diazomalonate in Alcohols. A solution of 170 mg of dimethyl diazomalonate and 0.95 g of benzophenone in 2.5 ml of alcohol was placed in a Pyrex tube under a nitrogen atmosphere and irradiated with the high-pressure mercury lamp for 5 hr. Gas-chromatographic analysis gave only dimethyl malonate as a major product.

Decomposition of Dimethyl Diazomalonate in cis*-4-Methyl-2-pentene and Alcohols.* All the samples, in Pyrex tubes, were irradiated under nitrogen with the same light source for the same long time. The products were analyzed by gas chromatography. The results of a typical run, in which dimethyl diazomalonate and *cis*-4-methyl-2-pentene were dissolved in methanol, are shown in Table 1.

NMR Data of the Products

Sucrose Chemistry. 6. Synthesis of Amino Derivatives of Sucrose

Tetsuo SUAMI, Toshihide IKEDA, Shigeru NISHIYAMA, and Ryoichi ADACHI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received December 6, 1974)

Synopsis. 6'-Amino-6'-deoxy- and 1',6'-diamino-1',6'-dideoxysucrose have been prepared by azidolysis of the corresponding tosylates, followed by catalytic hydrogenation.

In connection with the preceding papers on sucrose chemistry,[1a-e] we have attempted to prepare amino derivatives of sucrose. Two triamino-trideoxysucroses[2,3] and 6-amino-6-deoxysucrose[4] have been described in the literature. In the present paper, we wish to report the synthesis of 6'-amino-6'-deoxy- (**3**) and 1',6'-diamino-1,'-6'dideoxysucrose (**9**).

	R	R'
3:	OH	NH_2
9:	NH_2	NH_2

2,3,4,6,1',3',4'-Hepta-*O*-acetylsucrose[5-7] was treated with tosyl chloride in pyridine to give 2,3,4,6,1',3',4'-hepta-*O*-acetyl-6'-*O*-tosylsucrose (**1**). Nucleophilic replacement of **1** with an azide ion gave 6'-azido-6'-deoxysucrose heptaacetate (**2**). Catalytic hydrogenation of **2**, followed by de-*O*-acetylation afforded **3**.

2,3,4,6,3',4'-Hexa-*O*-acetyl-1',6'-di-*O*-tosylsucrose (**7**) was prepared by tosylation of 2,3,4,6,3',4'-hexa-*O*-acetylsucrose (**6**).[8] 1',6'-Diazido-1',6'-dideoxysucrose hexaacetate (**8**) was obtained by azidolysis of **7**. Compound **8** was de-*O*-acetylated and subsequently hydrogenated to afford **9**. Compounds **3** and **9** showed faint astringent taste.

PMR spectra of the acetyl derivatives of **3** and **9** were determined and the methyl group signals at highest field (δ 2.00 and 2.02) were assigned definitively to those of the acetamido methyl groups on C-6' and C-1' by the specific deuteration technique.[11-13]

Experimental

General. Melting points were determined in capillary tubes, and are uncorrected. Solutions were evaporated under diminished pressure below 40 °C. Optical rotations were measured on a Japan Spectroscopic DIP-SL polarimeter. PMR spectra were determined at 60 MHz on a Varian A-60D spectrometer in chloroform-*d* or deuterium oxide with tetramethylsilane or sodium 4,4-dimethyl-4-silapentane-1-sulfonate as an internal standard. The peak position is given in δ-value. Tlc was performed on a silica gel (Wakogel B-10) plate, and silica gel (Wakogel C-200) was used for column chromatography.

*2,3,4,6,1',3',4'-Hepta-*O*-acetyl-6'-*O*-tosylsucrose (**1**).* To a solution of 2,3,4,6,1',3',4'-hepta-*O*-acetylsucrose[5-7] (790 mg, 1.2 mmol) in dry pyridine (20 ml), tosyl chloride (1.22 g, 6.4 mmol) was added and the mixture was agitated for 72 hr. The mixture was poured into ice cold water and extracted with chloroform repeatedly. The combined extracts were evaporated and the residue was crystallized from aqueous methanol to give **1** (780 mg, 80%), mp 120—122 °C. $[\alpha]_D^{24}$ +62.0° (*c* 1.0, chloroform). PMR data ($CDCl_3$): δ 1.99 (s, 3H, OAc), 2.02 (s, 3H, OAc), 2.06 (s, 12H, 4 OAc), 2.12 (s, 3H, OAc) and 2.45 (s, 3H, aryl-CH_3).

Found: C, 50.37; H, 5.27; S, 3.67%. Calcd for $C_{33}H_{42}O_{20}S$: C, 50.13; H, 5.35; S, 4.06%.

*2,3,4,6,1',3',4'-Hepta-*O*-acetyl-6'-azido-6'-deoxysucrose (**2**).* A mixture of **1** (696 mg, 0.9 mmol) and sodium azide (350 mg, 5.4 mmol) in *N*,*N*-dimethylformamide (14 ml) was heated at 130—133 °C for 24 hr under agitation. The mixture was filtered and the filtrate was evaporated. The residue was acetylated with acetic anhydride in pyridine in the usual manner to a product (515 mg). The product was subjected to chromatography on a silica gel column and the fractions which showed a single spot at R_f 0.58 in butanone–toluene(2 : 5, v/v) were collected. The solution was evaporated to give **2** (411 mg, 71%) as a glassy solid. $[\alpha]_D^{21}$ +52.4° (*c* 8.6, chloroform). PMR data ($CDCl_3$): δ 2.03 (s, 3H, OAc), 2.06 (s, 3H, OAc), 211 (s, 12H, 4 OAc), 2.18 (s, 3H, OAc) and 5.64 (d, 1H, $J_{1,2}$ 3.4 Hz, H-1).

Found: C, 47.43; H, 5.49; N, 6.35%. Calcd for $C_{26}H_{35}N_3O_{17}$: C, 47.20; H, 5.33; N, 6.35%.

*6'-Amino-6'-deoxysucrose (**3**).* Compound **2** (401 mg) was hydrogenated in ethanol (60 ml) in the presence of platinum catalyst (85 mg) at 3.4 kg/cm² of hydrogen atmosphere at 40 °C for 20 hr. After the catalyst was removed, the solution was concentrated. The residue was de-*O*-acetylated in 0.1 M sodium methoxide in methanol (13 ml) for 2 hr and the solution was neutralized with Amberlite IR-120 (H^+). The solution was evaporated and the residue was crystallized from ethanol–methanol–water (3 : 3 : 4, v/v) in a refrigerator for two weeks to give **3** (110 mg, 53%), mp 132—135 °C (dec). $[\alpha]_D^{24}$ +57.5° (*c* 1.8, water). PMR data (D_2O): δ 5.46 (d, 1H, $J_{1,2}$ 2.9 Hz, H-1).

Found: C, 42.47; H, 6.54; N, 3.93%. Calcd for $C_{12}H_{23}NO_{10}$: C, 42.22; H, 6.79; N, 4.10%.

*2,3,4,6,1',3',4'-Hepta-*O*-acetyl-6'-acetamido-6'-deoxysucrose (**4**).* Compound **3** (92 mg) was acetylated in the usual manner to give **4** (138 mg, 76%) as an amorphous solid. $[\alpha]_D^{25}$ +56.0° (*c* 0.54, chloroform). PMR data ($CDCl_3$): δ 2.00 (s, 6H, OAc and NAc), 2.04 (s, 3H, OAc), 2.09 (s, 6H, 2 OAc), 2.10 (s, 6H, 2 OAc), 2.17 (s, 3H, OAc) and 5.60 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1).

Found: C, 49.33; H, 5.90; N, 2.27%. Calcd for $C_{28}H_{39}NO_{18}$: C, 49.63; H, 5.80; N, 2.07%.

*2,3,4,6,1',3',4'-Hepta-*O*-trideuterioacetyl-6'-acetamido-6'-deoxysucrose (**5**).* Compound **4** (96 mg) was dissolved in methanol (20 ml) previously saturated with ammonia. After settled overnight, the solution was evaporated and the residue was acylated with acetic anhydride-d_6 in pyridine. The product was purified on a silica gel column in acetone–chloroform (1 : 4, v/v) to give **5** (92 mg, 93%). $[\alpha]_D^{14}$ +55.1° (*c* 1.4, chloroform). PMR data ($CDCl_3$): δ 2.00 (s, 3H, NAc) and 5.62 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1).

*2,3,4,6,3',4'-Hexa-*O*-acetylsucrose (**6**).* This compound

was prepared from 2,3,4,6,3′,4′-hexa-*O*-acetyl-1′,6′-di-*O*-tritylsucrose[8,9] by detritylation with hydrogen bromide in glacial acetic acid[10] in a yield of 75%. Mp 131—132 °C. $[\alpha]_D^{18}$ +40.4° (*c* 2.24, chloroform). Found: C, 48.88; H, 5.94%. Lit,[9] mp 132 °C, $[\alpha]_D$+40.1° (*c* 2.07, chloroform). PMR data ($CDCl_3$): δ 2.00 (s, 3H, OAc), 2.04 (s, 3H, OAc), 2.07 (s, 3H, OAc), 2.08 (s, 6H, 2 OAc), 2.19 (s, 3H, OAc), 2.56 (s, 2H, 2 OH) and 5.66 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1).

*2,3,4,6,3′,4′-Hexa-*O*-acetyl-1′,6′-di-*O*-tosylsucrose (**7**).* Compound **6** (830 mg, 1.4 mmol) was treated with tosyl chloride (1.33 g, 7.0 mmol) in pyridine (10 ml) for 44 hr. The reaction mixture was poured into ice cold water (100 ml) to give the crude product (1.22 g, 97%), mp 62—67 °C. $[\alpha]_D^{21}$ +57° (*c* 1.0, chloroform). PMR data ($CDCl_3$): δ 2.02 (s, 3H, OAc), 2.03 (s, 6H, 2 OAc), 2.08 (s, 6H, 2 OAc), 2.13 (s, 3H, OAc) and 2.50 (s, 6H, 2 CH_3).

Found: C, 50.64; H, 5.07; S, 6.80%. Calcd for $C_{38}H_{46}O_{21}S_2$: C, 50.55; H, 5.14; S, 7.10%.

*2,3,4,6,3′,4′-Hexa-*O*-acetyl-1′,6′-diazido-1′,6′-dideoxysucrose (**8**).* A mixture of **7** (1.22 g, 1.4 mmol) and sodium azide (0.7 g, 10.8 mmol) in DMF (30 ml) was heated and subsequently treated as described in the preparation of **2** to give **8** (0.51 g, 59%) as a glassy solid. $[\alpha]_D^{24}$ +53.7° (*c* 1.42, chloroform). PMR data ($CDCl_3$): δ 2.01 (s, 3H, OAc), 2.02 (s, 3H, OAc), 2.08 (s, 9H, 3 OAc), 2.15 (s, 3H, OAc) and 5.60 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1).

Found: C, 44.61; H, 5.03; N, 12.62%. Calcd for $C_{24}H_{32}N_6O_{15}$: C, 44.72; H, 5.01; N, 13.04%.

*1′,6′-Diamino-1′,6′-dideoxysucrose (**9**).* Compound **8** (356 mg) was dissolved in 0.1 M sodium methoxide in methanol (10 ml). After settled for 2 hr, the solution was neutralized with Amberlite IR-120 (H^+), and the solution was hydrogenated as described in the preparation of **3**. The crude product was dissolved in aqueous methanol and precipitated by adding acetone to give **9** (113 mg, 60%), mp 119—124 °C (dec). $[\alpha]_D^{20}$ +77.3° (*c* 0.97, water).

*2,3,4,6,3′,4′-Hexa-*O*-acetyl-1′,6′-diacetamido-1′,6′-dideoxysucrose (**10**).* Compound **9** (157 mg) was acetylated in the usual manner and the crude product was purified by column chromatography to give an amorphous solid (119 mg, 38%). $[\alpha]_D^{21}$ +51.8° (*c* 0.74, chloroform). PMR data ($CDCl_3$): δ 2.00 (s, 3H, NAc), 2.02 (s, 6H, OAc and NAc), 2.04 (s, 3H, OAc), 2.08 (s, 6H, 2 OAc), 2.12 (s, 3H, OAc), 2.17 (s, 3H, OAc) and 5.64 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1).

Found: C, 49.78; H, 6.01; N, 3.92%. Calcd for $C_{28}H_{40}N_2O_{17}$: C, 49.70; H, 5.96; N, 4.14%.

*2,3,4,6,3′,4′-Hexa-*O*-trideuterioacetyl-1′,6′-diacetamido-1′,6′-dideoxysucrose (**11**).* Compound **10** (70 mg) was de-*O*-acetylated and subsequently acylated as described in the preparation of **5** to give **11** (70 mg, 97%). $[\alpha]_D^{20}$ +51.2° (*c* 3.7, chloroform). PMR data ($CDCl_3$): δ 1.99 (s, 3H, NAc), 2.01 (s, 3H, NAc) and 5.62 (d, 1H, $J_{1,2}$ 3.5 Hz, H-1).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(6), 1955—1956 (1975)

The Formation of 1,1′-Oligomeric Ferrocenes from Chloromercuriferrocene and Bis(chloromercuri)ferrocene

Taeko IZUMI and Akira KASAHARA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992

(Received December 18, 1974)

Synopsis. A series of 1,1′-oligomeric ferrocenes, including biferrocene, 1,1′-biferrocenylene, 1,1′-terferrocene, 1,1′-quaterferrocene, 1,1′-quinqueferrocene, and 1,1′-sexiferrocene, was formed by the reaction between chloromercuriferrocene and 1,1′-bis(chloromercuri)ferrocene in the presence of palladium(II) salt.

The increasing interest in systems containing directly bonding ferrocene nuclei has been focused on the study of the synthesis of oligomeric ferrocene.[1] Nesmeyanov *et al.*[2] reported a mixed Ullmann reaction with bromoferrocene and 1,1′-dibromoferrocene to give a series of 1,1′-oligomeric ferrocenes. Watanabe *et al.*[3] also described the formation of the 1,1′-oligomeric ferrocenes from the reaction of a mixture of mono- and dilithioferrocenes with cobalt chloride. More recently, Roling and Rausch[4] reported a mixed Ullmann reaction between haloferrocene and 1,1′-diiodoferrocene.

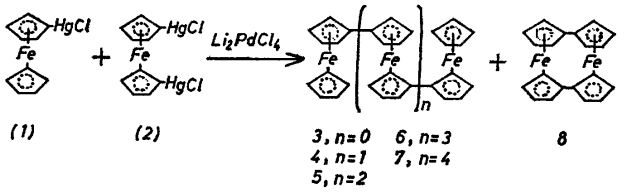

Fig. 1.

In this report, we wish to describe the synthesis of ferrocene oligomers from the reaction between a palladium(II) salt and a mixture of chloromercuriferrocene (**1**) and 1,1′-bis(chloromercuri)ferrocene (**2**).

In the presence of lithium chloropalladite, the reaction between **1** and **2** was accomplished in a polar solvent, such as ethanol or acetonitrile, under an atmosphere of nitrogen. The reaction products were separated by a combination of crystallization and chromatography on alumina and were found to be biferrocene (**3**), 1,1′-terferrocene (**4**), 1,1′-quaterferrocene (**5**), 1,1′-quinqueferrocene (**6**), 1,1′-sexiferrocene (**7**), and 1,1′-biferrocenylene (**8**). As may be seen in Table 1, different product ratios were obtained depending on the ratio of **1** to **2**. Roling and Rausch[4] reported that **8** could not be detected in a mixed Ullmann reaction; however, the **8** prepared in this study agreed in its properties with the 1,1′-biferrocenylene obtained by Hedberg and Rosenberg.[5]

Table 1. Reaction of chloromercuriferrocene (**1**) and 1,1′-bis(chloromercuri)ferrocene (**2**) with palladium(II) salt

Run	Ratio of **1** to **2**	Solvent	Percentage yields[a] of products						
			3	**4**	**5**	**6**	**7**	**8**	total
1	2 : 1[b]	EtOH	44	9	2			3	58
2	2 : 1[b]	CH_3CN	48	10	2	1		4	65
3	1 : 1[c]	EtOH	31	16	4	1	1	4	57
4	1 : 1[c]	CH_3CN	30	18	6	2	1	3	59
5	1 : 2[d]	EtOH	16	24	6	3	1	6	56
6	1 : 2[d]	CH_3CN	20	18	5	3	1	4	51

a) Yields are based on the limiting reagent in each reaction. b) Six mmol of **1** and 3 mmol of **2** were used. c) Four mmol of **1** and 4 mmol of **2** were used. d) Two point four mmol of **1** and 4.8 mmol of **2** were used.

Heck[6] previously reported that the reaction of olefins with arylmercuric chloride and palladium(II) salt produces the arylated olefinic compounds, accompanied by biaryl; he suggested that the mechanism of the formation of biaryl as a by-product involves a coupling reaction of arylpalladium chloride or a reaction of arylpalladium chloride and arylmercuric chloride. The formation of ferrocene oligomers may, therefore, be accounted for as follows:

$$FcHgCl + Li_2PdCl_4 \rightarrow [FcPdCl] + HgCl_2 + 2LiCl$$

$$Fcl(HgCl)_2 + 2Li_2PdCl_4 \rightarrow [Fcl(PdCl)_2] + 2HgCl_2 + 4LiCl$$

$$2[FcPdCl] \rightarrow Fc\text{-}Fc + PdCl_2 + Pd$$

or

$$[FcPdCl] + FcHgCl \rightarrow Fc\text{-}Fc + HgCl_2 + Pd$$

$$2[FcPdCl] + Fcl(HgCl)_2 \rightarrow Fc\text{-}Fc\text{-}Fc + 2HgCl_2 + 2Pd$$

$$2[FcPdCl] + [Fcl(PdCl)_2] \rightarrow Fc\text{-}Fc\text{-}Fc + 2PdCl_2 + 2Pd$$

$$[FcPdCl] + [Fcl(PdCl)_2] \rightarrow [Fc\text{-}FcPdCl] + PdCl_2 + Pd$$

$$2[Fc\text{-}FcPdCl] \rightarrow Fc\text{-}Fc\text{-}Fc\text{-}Fc + PdCl_2 + 2Pd$$

$$2[Fc\text{-}FcPdCl] + [Fcl(PdCl)_2] \rightarrow Fc\text{-}Fc\text{-}Fc\text{-}Fc\text{-}Fc + 2PdCl_2 + 2Pd$$

$$[Fc\text{-}FcPdCl] + [Fcl(PdCl)_2] \rightarrow [Fc\text{-}Fc\text{-}FcPdCl] + PdCl_2 + Pd$$

$$2[Fc\text{-}Fc\text{-}FcPdCl] \rightarrow Fc\text{-}Fc\text{-}Fc\text{-}Fc\text{-}Fc\text{-}Fc + PdCl_2 + Pd$$

$$2[Fcl(PdCl)_2] \rightarrow Fcl\text{-}Fcl + 2PdCl_2 + 2Pd$$

$$[Fcl(PdCl)_2] + Fcl(HgCl)_2 \rightarrow Fcl\text{-}Fcl + 2HgCl_2 + 2Pd$$

Fc=ferrocenyl, $FeC_{10}H_9$; Fcl=1,1′-ferrocenylene, $Fe(C_5H_4)_2$.

Experimental

Materials. All the melting points are uncorrected. The chloromercuriferrocene[7] (**1**) and 1,1′-bis(chloromercuri)-ferrocene[7] (**2**) were prepared by the standard literature method. The IR spectra were measured using a Hitachi 215 spectrometer. The NMR spectra were measured using a Hitachi R-22 (90 MHz) spectrometer. The chemical shifts were expressed in downfield from TMS as an internal standard. The mass spectra were recorded on a Hitachi RMU-6E mass spectrometer at 70 eV.

General Procedure for the Preparation of Oligomeric Ferrocenes. The lithium chloropalladite solutions were prepared by stirring 1.01 g (24 mmol) of anhydrous lithium chloride and 2.12 g (12 mmol) of anhydrous palladium chloride overnight at room temperature in 100 ml of ethanol. On the other hand, in the case of acetonitrile, a 12-mmol portion instead of a 24-mmol portion of lithium chloride was used.

To this lithium chloropalladite solution, a mixture of **1** and **2** was added, after which the mixture was stirred at room temperature for 48 hr under nitrogen. After the separation of the precipitated palladium, the solvent was evaporated under reduced pressure to yield Substance A. The precipitated palladium was further extracted with boiling toluene until the toluene extracts were colorless; the toluene was then evaporated to yield Substance B. Finally, the precipitated palladium was extracted with boiling bromobenzene, the extracts were allowed to cool, and the resulting precipitate was collected to give Substance C.

Substance A was dissolved in 30 ml of benzene, and 30 ml of hexane was added. The precipitate, thus formed was collected to yield a yellow product, which was crystallized from benzene and identified as 1,1′-quinqueferrocene (**6**); mp 258—260 °C (lit, 240—245 °C,[3] 262—264 °C[4]). IR (KBr) 1105, 1100, 1020, 998, 805 cm^{-1}. The NMR spectrum of **6** is not available, for **6** is insoluble in the solvent necessary for the observation of the NMR spectrum.

Found: C, 64.88; H, 4.47%; mol wt, 922 (mass spectrometry). Calcd for $C_{50}H_{42}Fe_5$: C, 65.13; H, 4.59%; mol wt, 922.

The filtrate was chromatographed on neutral alumina. The first elution with hexane-benzene (4 : 1) afforded orange-yellow crystals; they were identified as biferrocene (**3**) (mp 236—238 °C) by a mixed-melting-point determination with an authentic sample (mp 238—239 °C[8]). IR (KBr) 1105, 1100, 1028, 1000, 818 cm^{-1}. NMR ($CDCl_3$) δ 3.95 (s, 10H, unsubstituted cyclopentadienyl ring protons), 4.17 (m, 4H, β protons on the substituted ring), 4.31 ppm (m, 4H, α protons on the substituted ring). Found: mol wt, 370 (mass spectrometry). Calcd for $C_{20}H_{18}Fe_2$: mol wt, 370.

The second band was eluted with hexane-benzene (1 : 1) to yield a yellow material, which was then cryatallized from a mixture of hexane-benzene. This material was 1,1′-terferrocene (**4**); mp 223—224 °C (dec.) (lit,[3] 226.5—227.2 °C (dec.)). IR (KBr) 1105, 1100, 1020, 1000, 815 cm^{-1}. NMR ($CDCl_3$) δ 3.94 (s, 10H, unsubstituted cyclopentadienyl ring protons), 4.06—4.28 ppm (m, 16H, α and β protons on the substituted ring).

Found: C, 64.92; H, 4.61%; mol wt 554 (mass spectrometry). Calcd for $C_{30}H_{26}Fe_3$: C, 65.03; H, 4.73%; mol wt, 554.

The third band was eluted with benzene to give a orange-yellow compound, which was then crystallized from benzene to yield 1,1′-quaterferrocene (**5**); mp 275—280 °C (dec.) (lit,[3] mp 280 °C). IR (KBr) 1105, 1100, 1025, 1000, 810 cm^{-1}. The NMR spectrum of **5** is not available, for **5** is insoluble in the solvent necessary for the observation of the NMR spectrum.

Found: C, 64.89; H, 4.60%; mol wt, 738 (mass spectrometry). Calcd for $C_{40}H_{34}Fe_4$: C, 65.09; H, 4.64%; mol wt 738.

The last band was eluted with benzene-chloroform (1 : 1) to give reddish-orange crystals, which were then crystallized from benzene to yield 1,1′-biferrocenylene (**8**) (mp 370 °C (dec) (lit,[5] mp 380 °C (dec))). IR (KBr) 1110, 1105, 1027, 1005, 824 cm^{-1}. NMR (C_6D_6) δ 3.79 (t, 8H), 5.25 ppm (t, 8H).

Found: C, 65.48; H, 4.31%; mol wt 368 (mass spectrometry). Calcd for $C_{20}H_{16}Fe_2$: C, 65.54; H, 4.39%; mol wt, 368.

Substance B was purified in a similar manner to yield **3**, **4**, **5**, **6**, and **8**.

Substance C was extracted with boiling benzene until the extracts were colorless. The benzene was then allowed to cool to yield a yellow-brown material, 1,1′-sexiferrocene (**7**) (mp 265—268 °C (dec.), (lit, mp 252—256 °C,[3] mp 270—272 °C[4])). IR (KBr) 1105, 1100, 1020, 995, 802 cm^{-1}. The NMR spectrum of **7** is not available, for **7** is insoluble in the solvent necessary for the observation of the NMR spectrum.

Found: C, 65.01, H, 4.46%; mol wt, 1106 (mass spectrometry). Calcd for $C_{60}H_{50}Fe_6$: C, 65.15; H, 4.56%; mol wt, 1106.

The results are summarized in Table 1.

The Preparation of Biferrocene (3) and 1,1′-Biferrocenylene (8). To a solution of 10 mmol of lithium chloropalladite in acetonitrile, a 5-mmol portion of **1** was added, after which the mixture was stirred at room temperature for 24 hr under nitrogen. The product was isolated by filtration to remove a precipitated palladium and by distillation under reduced pressure to remove the solvent. The residue was dissolved in hexane-benzene (1 : 1); subsequent chromatography on alumina afforded yellow crystals (mp 236—238 °C, 66% yield), which were identical as biferrocene (**3**) by a comparison of the IR and NMR spectra and by a mixed-melting-point determination with an authentic sample.[8]

1,1′-Biferrocenylene (**8**) (mp 370 °C, 48% yield) was also obtained from the reaction of 10 mmol of lithium chloropalladite and 2.5 mmol of **2** in a manner similar to that used for **3**.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(6), 1957—1958 (1975)

The C–O Bond Cleavage of Allyl Ethers by Rhodium Compounds

Masami WAYAKU, Kiyotomi KANEDA, Toshinobu IMANAKA, and Shiichiro TERANISHI
Department of Chemical Engineering, Faculty of Engineeing Science, Osaka University, Toyonaka, Osaka 560
(Received January 6, 1975)

Synopsis. Allyl ethers were cleaved by rhodium compounds under mild conditions to give aldehydes and hydrocarbons. This reaction can be extended to allyl esters.

The cleavage of allyl or benzyl ethers has hitherto been known—*e.g.*, i) by hydrogenolysis over Raney-nickel,[1] ii) by treatment with strong bases or rhodium compounds to generate an enol ether followed by acid hydrolysis or oxidation,[2] and iii) by oxidation with SeO_2 in acetic acid.[3] The reaction products were usually alcohols and aldehydes. Also, the reactions of allyl ethers with transition metals are known to give a metal hydride or π-allyl complex.[4]

In this paper, we wish to report that the C–O bonds of cinnamy and benzyl ethers have been easily cleaved to the corresponding aldehydes and hydrocarbons in

TABLE 1. THE CLEAVAGE OF CINNAMYL AND BENZYL ETHERS

	Catalyst	Solvent	Reaction time, hr	Reaction temp, °C	Products and yields, %[a]
Cinnamyl ethers					
Dicinnamyl ether 1.2 mmol	$RhCl_3$-PPh_3-EtOH	Dioxane	2	100	(II), 97 (III), 96
p-Methylcinnamyl hydrocinnamyl ether 1.2 mmol	$RhCl_3$-PPh_3-EtOH	Dioxane	2	100	*p*,*β*-Dimethylstyrene, 48 *β*-Phenylpropionaldehyde, 41 *p*-Methylcinnamaldehyde, 27 *n*-Propylbenzene, 21 Allylbenzene, 14
Cinnamyl *n*-propyl ether 3.0 mmol	$RhCl_3$-PPh_3-EtOH	Dioxane	2	100	(II), 40 (III), 37 Cinnamyl alcohol, 3.3 Propionaldehyde, Propane Propylene
Cinnamyl isopropyl ether 3.0 mmol	$RhCl_3$-PPh_3-EtOH	Dioxane	2	100	(II), 33 (III), 17 Acetone, Propane, Propylene
Cinnamyl allyl ether 5.0 mmol	$RhCl_3$-PPh_3-EtOH	Tetrahydrofuran	2	60	(II), 44 (III), 34 Acrolein, Propylene
	$RhCl(PPh_3)_3$	Tetrahydrofuran	2	60	(II), 12 (III), 9.5
	$RhCl(CO)(PPh_3)_2$	Tetrahydrofuran	2	60	(II), 19 (III), 18
Benzyl ethers					
Dibenzyl ether[c] 1.2 mmol	$RhCl_3$-PPh_3-EtOH	Dioxane	8	100	Toluene, 3.0 Benzaldehyde, 2.4
p-Anisyl benzyl ether 1.2 mmol	$RhCl_3$-PPh_3-EtOH	Dioxane	8	100	*p*-Methylanisole, 17 Benzaldehyde, 16 *p*-Anisaldehyde, 4.5 Toluene, 3.6
p-Nitrobenzyl benzyl ether 1.2 mmol	$RhCl_3$-PPh_3-EtOH	Dioxane	8	100	*p*-Nitrobenzaldehyde, 16 Toluene, 15 Benzaldehyde, 0.6 *p*-Nitrotoluene, 0.5
Benzyl allyl ether 5.0 mmol	$RhCl_3$-PPh_3-EtOH	Tetrahydrofuran	16	60	Toluene, 24 Benzaldehyde, 17 Propylene, Acrolein
Cyclic ethers[b]					
2,5-Dihydrofuran 5.0 mmol	$RhCl_3$-PPh_3-MeOH	Tetrahydrofuran	16	60	Crotonaldehyde, 21
	$RhCl(PPh_3)_3$	Tetrahydrofuran	16	60	Crotonaldehyde, 15
Cinnamyl esters					
Cinnamyl *n*-butyrate 5.0 mmol	$RhCl(CO)(PPh_3)_2$	——	6	150	(II), 34 (III), 22 Styrene, 2.5 Cinnamyl *n*-propyl ether, trace
Cinnamyl isobutyrate 5.0 mmol	$RhCl(CO)(PPh_3)_2$	——	6	150	(II), 37 (III), 15 Styrene, 1.1 Cinnamyl isopropyl ether, trace
Cinnamyl acetate 5.0 mmol	$RhCl(CO)(PPh_3)_2$	——	6	150	(II), 23 (III), 16 Cinnamyl methyl ether, trace
Benzyl ester					
Benzyl acetate[c] 5.0 mmol	$RhCl(CO)(PPh_3)_2$	——	24	150	Benzyl methyl ether, 4.0 Toluene, 1.2 Benzaldehyde, 0.9

a) Yields are based on the reactants. b) Cyclic ethers such as tetrahydrofuran, tetrahydropyran, and 3,4-dihydro-α-pyran were not cleaved under these conditions. c) Unreacted ether and ester were recovered.

the presence of rhodium compounds under mild conditions.

The reaction of cinnamyl alcohol with $RhCl_3$ and PPh_3 in dioxane gave dicinnamyl ether (I), β-methylstyrene (II), and cinnamaldehyde (III). In an early stage of the reaction, the ether formation was remarkable. Therefore, the reaction of ether (I) with $RhCl_3$ and PPh_3 was carried out. As expected, C–O bond cleavage products (II) and (III) were obtained in high yields.[5]

$$PhCH{=}CHCH_2OH \longrightarrow \underset{(I)}{(PhCH{=}CHCH_2)_2O}$$
$$\longrightarrow \underset{(II)}{PhCH{=}CHCH_3} + \underset{(III)}{PhCH{=}CHCHO}$$

$RhCl(PPh_3)_3$ and $RhCl(CO)(PPh_3)_2$ were also active as catalysts, but $PdCl_2$, $RuCl_3$, and $IrCl_3$ were not good catalysts.

The generality of this cleavage reaction was demonstrated for cinnamyl alkyl, cinnamyl allyl, dibenzyl, and benzyl allyl ethers. In the case of *p*-substituted benzyl ethers, the bonds between the carbon of a benzyl group containing a more electron-donating substituent and oxygen were selectively cleaved. However, non-allylic ethers, such as hydrocinnamyl isopropyl and dihydrocinnamyl ether, did not react. The cleavage of cyclic allyl ether to unsaturated aldehyde was also observed.

In addition, this reaction could also be applied to allyl esters. Cinnamyl *n*-butyrate afforded (II), (III), propionaldehyde, propylene, and cinnamyl propyl ether. The reaction was accompanied by a decarbonylation of the ester to ether. These results are summarized in Table 1.

This C–O bond cleavage reaction is characteristic of allyl and benzyl ethers. Presumably the allyl rhodium complex might play an important role as an intermediate species.

Experimental

Materials. The dibenzyl ether, 2,5-dihydrofuran, and benzyl acetate were purchased from Nakarai Kagaku. The other ethers and esters were prepared by the methods of the literature.[6]

Cleavage of Cinnamyl or Benzyl Ethers. To a solution of $RhCl_3 \cdot 3H_2O$ (0.25 mmol) and PPh_3 (0.25 mmol) in ethanol (2.5 mmol) and dioxane or tetrahydrofuran (5 ml), we added cinnamyl or benzyl ether (1.2—5.0 mmol). After 2 hr (or 8 hr) of refluxing under a nitrogen stream, the solvent was removed and the residue was treated by gas chromatography (25% Apiezon grease L on Neopak) to isolate the products. The structures of the products were determined by means of the IR and NMR spectra. From cinnamyl allyl ether, β-methylstyrene (II) (2.30 mmol), cinnamaldehyde (III) (1.72 mmol), acrolein, and propylene were obtained.

Decarbonylation of Cinnamyl or Benzyl Esters. A mixture of the ester (5 mmol) and $RhCl(CO)(PPh_3)_2$ was heated at 150 °C for 6 hr. The resulting solution was treated as has been mentioned above. $RhCl(CO)(PPh_3)_2$ was recovered quantitatively.

The Optical Rotatory Dispersion and Circular Dichroism of Levoglucosenone

Akio OHNISHI, Eriko TAKAGI, and Kunio KATŌ

Central Research Institute, The Japan Tobacco & Salt Public Corporation, 6-2 Umegaoka, Midori-ku, Yokohama 227

(Received December 27, 1974)

Synopsis. The ORD and CD of levoglucosenone were measured in order to elucidate its abnormally large $[\alpha]_D$ value of $-524°$.[1] The complicated pattern observed was considered to contain three Cotton effects—at 357, 231 and 207 nm; the first one at 357 nm seems to be responsible for the large $[\alpha]_D$ value.

In our previous paper,[1] anhydro sugar homologues, such as levoglucosan (1,6-anhydro-β-D-glucopyranose) (II), 1,6-anhydro-3-deoxy-β-D-glucopyranosen (III),[1,2] and levoglucosenone (1,6-anhydro-3,4-dideoxy-β-D-glucopyranosen-2-one) (IV),[1,3] were determined to be the primary pyrolysis products of cellulose using Curie-point pyrolysis-gas liquid chromatography. Compound IV was first identified by Halpern *et al.*[3] in 1973; its abnormally large $[\alpha]_D$ value has been reported to be $-460°$ ($CHCl_3$, *c* 1.0)[3] and $-524°$ (C_2H_5OH, *c* 1.0),[1] while those of D-glucose (I), II and III are of the usual magnitude, as Table 1 shows. To elucidate this abnormality, the optical rotatory dispersions (ORDs) and circular dichroisms (CDs) of IV and its related compounds were measured in the wavelength region of 600—190 nm using a JASCO model J-20 spectropolarimeter. The results are shown in Figs. 1 and 2.

Compounds I and III showed a simple positive dispersion of the ORD curves, whereas Compound II showed a simple negative dispersion, as may be seen in Fig. 1. On the contrary, IV showed a complicated ORD curve with peaks at 328 ($[\phi]=+6500°$), 246 ($+15000°$), and 195 ($+31500°$) nm and troughs at 390 ($-6000°$), 293 ($+4500°$), and 217 ($-66500°$) nm, as may be seen in Fig. 2. From the CD curves of IV, the first negative Cotton effect, involving the 390 nm

TABLE 1. THE OPTICAL ROTATION AT 589 nm

Compound	Formula	$[\alpha]_D$	Solvent	Reference
I		+52.7°	H_2O	4)
II		−66.5°	H_2O	5)
III		+86°	C_2H_5OH	2)
IV		−460° −524°	$CHCl_3$ C_2H_5OH	3) 1)

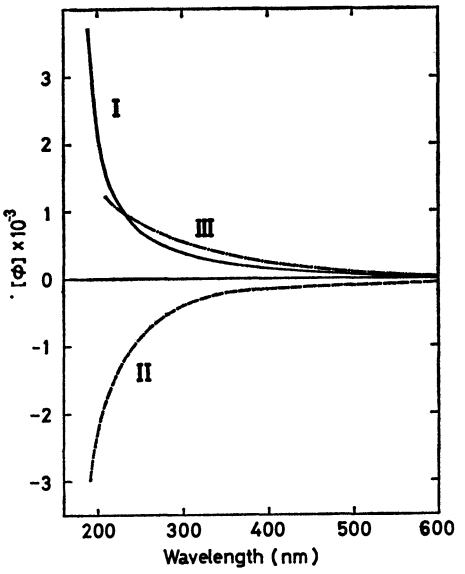

Fig. 1. The ORD curves of D-glucose (I), levoglucosan (II) and 1,6-anhydro-3-deoxy-β-D-glucopyranosen (III) measured in H_2O (I, II) or in C_2H_5OH (III) at 20 °C.
The ordinate is expressed in terms of molar rotation, $[\phi]$.

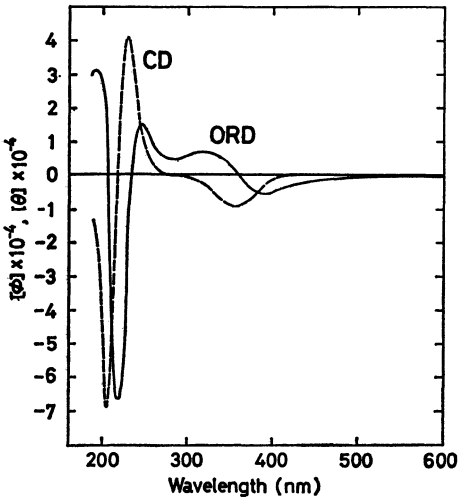

Fig. 2. The ORD and CD curves of levoglucosenone measured in C_2H_5OH at 20 °C.
The ordinate is expressed in terms of molar rotation, $[\phi]$, or molar ellipticity, $[\theta]$.

trough and the 328 nm peak of the ORD curve, was observed at 357 nm. The second positive Cotton effect, involving the 246 nm peak and the 217 nm trough of the ORD curve, was observed at 231 nm. The third negative Cotton effect, involving the 217 nm trough and the 195 nm peak of the ORD curve, was observed at 207 nm. The negative Cotton effect at 357 nm seems to correspond to the absorption band at 355 nm (ε 85, n–π^*)[1] of the carbonyl group while the other two Cotton effects may correspond to the absorption band at 217 nm (ε 6000, π–π^*).[1]

The abnormally large $[\alpha]_D$ value of IV seems to be due to the negative Cotton effect at 357 nm.

Temperature-Dependent Infrared Study on L- and DL-α-Alanine

Norio KANEKO, Hiroaki TAKAHASHI, and Keniti HIGASI

Department of Chemistry, School of Science and Engineering, Waseda University, Tokyo 160

(Received November 21, 1974)

Infrared spectra from 4000 to 30 cm^{-1} of L- and DL-α-alanine and their *N*-deuterated analogues were measured at temperatures ranging from 295 to 100 K. Highly temperature-dependent bands were observed at 972 cm^{-1} (at 100 K) for L-α-alanine and 975 cm^{-1} for DL-α-alanine. The temperature dependence of the half-widths of these bands indicates that above 200 K the vibrational modes are considerably modulated by some motions, possibly arising from breaking of hydrogen bonds. These bands are thus assigned to the first overtone of the NH_3^+ torsional mode.

Temperature studies of vibrational spectra of amino acids would provide valuable information on the nature of hydrogen bonding as well as molecular motions in these biologically important substances. Although numerous studies have been published on amino acids, temperature studies of the infrared and Raman spectra are very scarce.[1-5]

It is the purpose of this paper to report on the changes due to the temperature variation observed in the infrared spectra of L- and DL-α-alanine and their *N*-deuterated analogues.

Experimental

L-Alanine and DL-α-alanine were recrystallized several times from aqueous solution. *N*-Deuterated analogues were prepared by successive exchanges with D_2O.

Infrared spectra were recorded on a Hitachi EPI-G3 spectrophotometer for the 4000 to 400 cm^{-1} range and a Hitachi FIS-3 spectrophotometer for the 400 to 30 cm^{-1} range. The spectra were obtained from Nujol mulls between KRS-5 or polyethylene plates (depending on the frequency range). A Dewar-type low temperature cell with a copper-constantan thermocouple was used. The frequencies are estimated to be accurate within ± 2 cm^{-1}.

Results

L-α-Alanine. Infrared spectra from 1800 to 30 cm^{-1} of L-α-alanine at both room and liquid nitrogen temperatures are given in Fig. 1. A band appears at 972 cm^{-1} which does not seem to have been reported

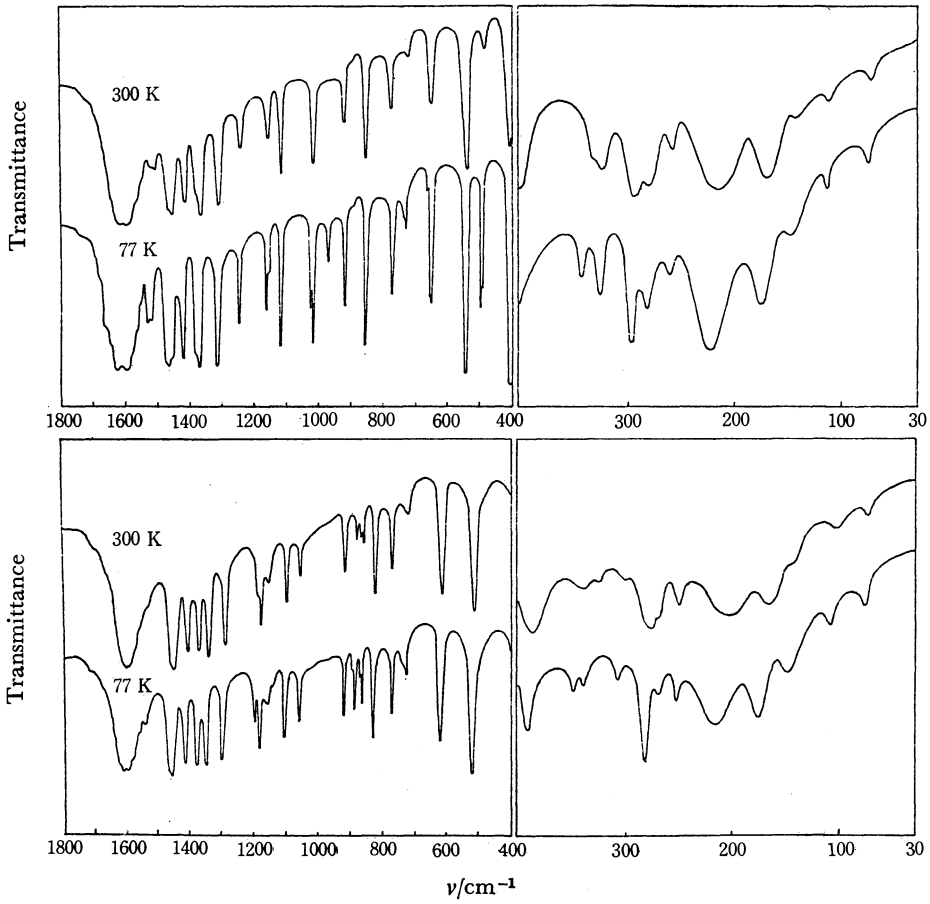

Fig. 1. Infrared spectra of L-α-alanine (upper) and its *N*-deuterated powder (bottom) suspended in Nujol, observed at room temperature and liquid nitrogen temperature.

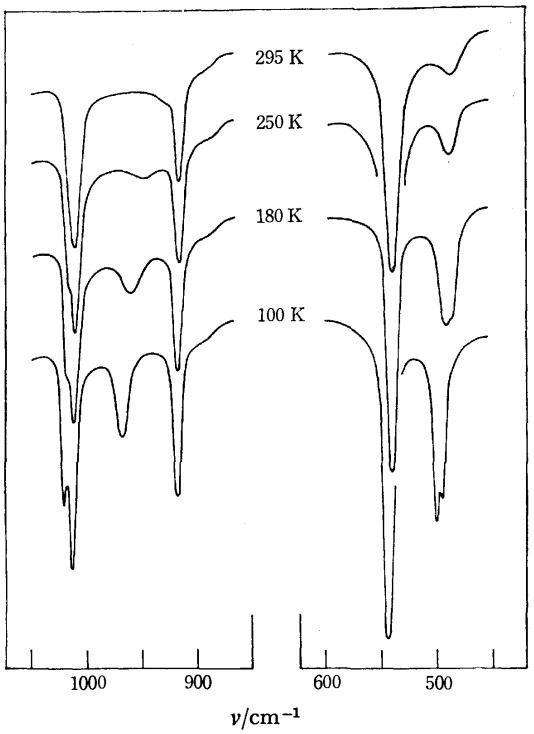

Fig. 2. Temperature dependence of the bands at 972 and 487 cm^{-1} for L-α-alanine.

before—this is the most interesting feature of the liquid nitrogen temperature spectrum. This band disappears by deuteration of the NH_3^+ group as shown in Fig. 1.

The temperature variation of the band is shown in Fig. 2 together with that of the band at 487 cm^{-1}. At room temperature the band is recognizable as a very weak and rather broad shoulder on the 920 cm^{-1}. With a fall in temperature the shoulder becomes sharper, the intensity increasing and shifting towards higher frequency. A similar behavior is observed for the band at 487 cm^{-1}, except that it exhibits splitting as well. This band has been assigned to the NH_3^+ torsional vibration.[2]

DL-α-*alanine.* The liquid nitrogen temperature spectrum from 1800 to 30 cm^{-1} of DL-α-alanine is shown in Fig. 3 along with the room temperature spectrum. The very weak and broad band at 975 cm^{-1} and the band at 497 cm^{-1} show a similar temperature effect to that of the bands at 972 cm^{-1} (at 100 K) and 487 cm^{-1} of L-α-alanine. See Fig. 4 for its detailed feature. The 497 cm^{-1} band has been assigned to the NH_3^+ torsional vibration.[6] The 975 cm^{-1} band, not previously reported, is absent from the spectrum of the *N*-deuterated analogue as shown in Fig. 3.

Infrared spectra of α- and γ-glycine, L- and DL-valine and DL-leucine were also measured at various low temperatures. Although NH_3^+ torsional frequencies were

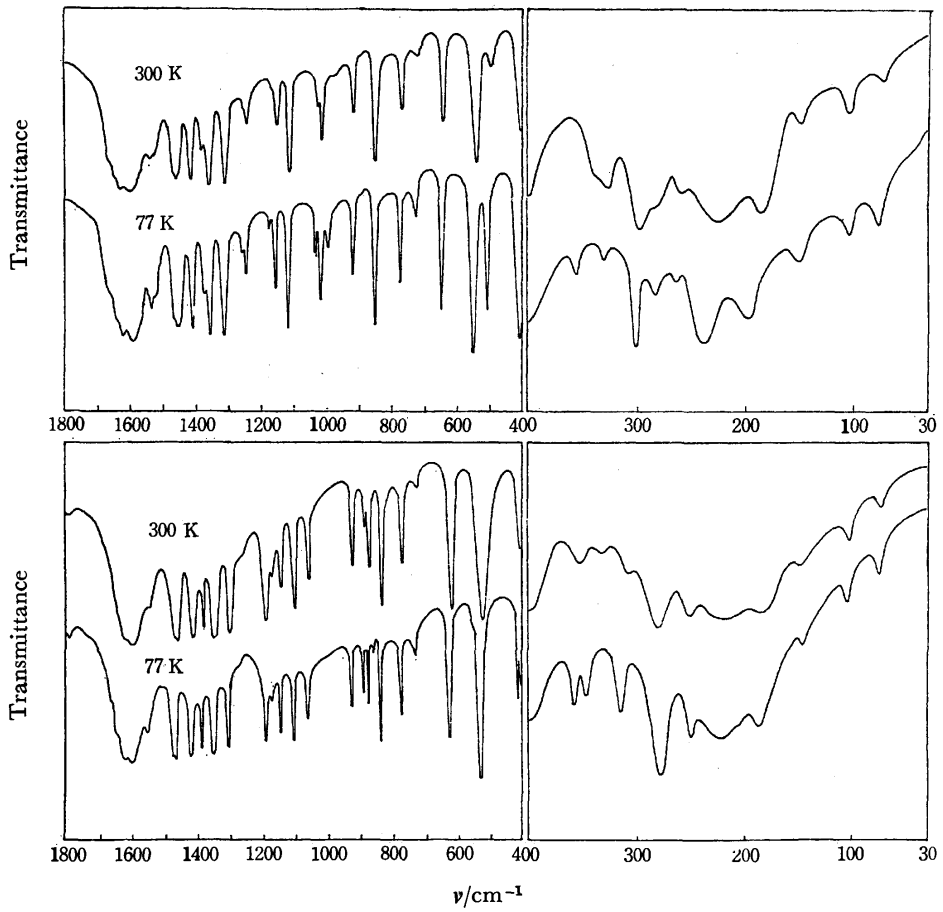

Fig. 3. Infrared spectra of DL-α-alanine (upper) and its *N*-deuterated powder (bottom) suspended in Nujol, observed at room temperature and liquid nitrogen temperature.

observed respectively at 525, 560, 575, 565, and 580 cm^{-1} for α-, γ-glycine, L-, DL-valine, and DL-leucine, no temperature-dependent band was detected between 1200 and 900 cm^{-1}.

Discussion

Since the bands at 972 cm^{-1} (at 100 K) for L-α-alanine and at 975 cm^{-1} for DL-α-alanine are both far (over 40 cm^{-1}) from adjacent bands, it is unlikely that they arise from crystal-field splitting.

We find that the temperature effect of the bands at 972 and 975 cm^{-1} is very similar to that of the NH_3^+ torsional vibrations at 487 and 497 cm^{-1} and that the frequencies are about twice as high as the corresponding torsional frequencies. We may infer that the temperature dependence of overtone vibrations is analogous to that of the fundamental vibrations, and, hence, the newly observed bands at 972 cm^{-1} for L-α-alanine and at 975 cm^{-1} for DL-α-alanine should be assigned to the first overtone of the NH_3^+ torsional vibration.

The above assignment can be substantiated by the spectra of *N*-deuterated analogues. Disappearance of the bands at 972 and 975 cm^{-1} by deuteration of the NH_3^+ group indicates that they originate from the motion of the NH_3^+ group. However, the location of the first overtone of the ND_3^+ torsional vibration is not clear. We see from Figs. 1 and 3 that the ND_3^+ torsional fundamental is observed at 346 cm^{-1} for L-α-alanine and at 354 cm^{-1} for DL-α-alanine at room temperature. The first overtone is thus expected to appear around 700 cm^{-1} at liquid nitrogen temperature. However, no new band is detected around this frequency. It is possible that the overtone bands are hidden under the Nujol band at 720 cm^{-1} or the intensities are too low to be observed.

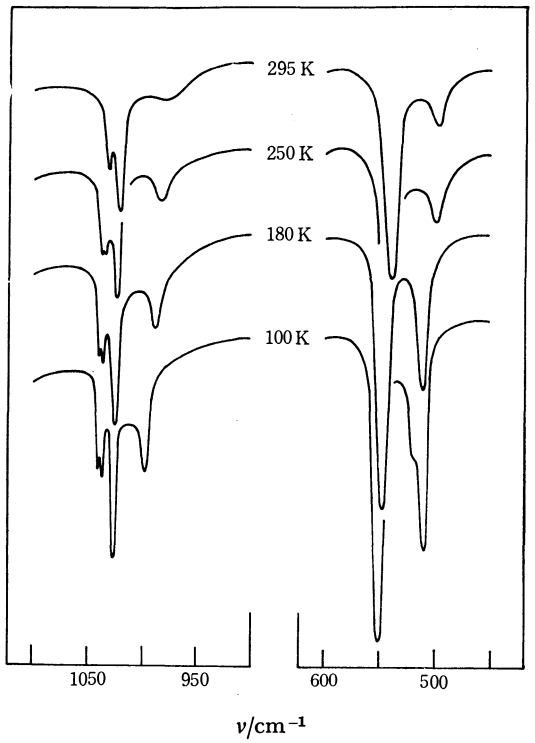

Fig. 4. Temperature dependence of the bands at 975 and 497 cm^{-1} for DL-α-alanine.

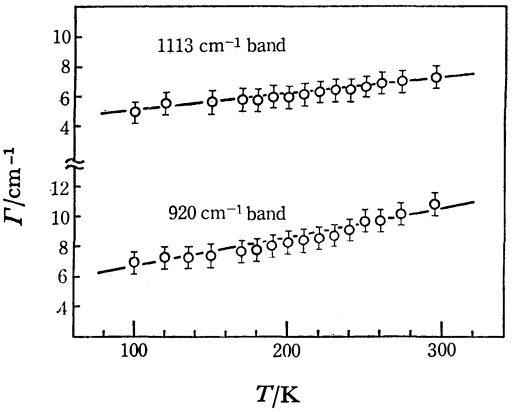

Fig. 5. The half-width of the band at 1113 cm^{-1} (CH_3 rock[4]) and that of the band at 920 cm^{-1} (CCN sym. stretch[4]) for L-α-alanine *versus* absolute temperature. The spectral slit-width is 3 cm^{-1}.

The appearance of the first overtone of the NH_3^+ torsional vibrations in the infrared spectra can be explained if we assume that the NH_3^+ torsions in L-α-alanine and DL-α-alanine are very anharmonic, as one would expect from any vibration associated with hydrogen bonds.

The theory given by Maradudin and Fein[7] predicts that the phonon width due to anharmonicity increases linearly with increasing temperature when the temperature is sufficiently high and is proportional to the square of the cubic force constant. The half-width of the band at 1113 cm^{-1} (CH_3 rock[4]) and that of the

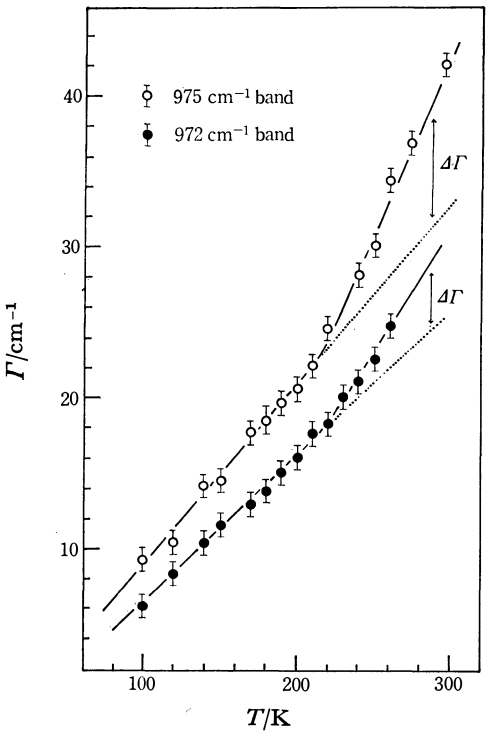

Fig. 6. The half-width of the band at 972 cm^{-1} for L-α-alanine and that of the band at 975 cm^{-1} for DL-α-alanine *versus* absolute temperature. The spectral slit-width is 3 cm^{-1}.

band at 920 cm^{-1} (CCN sym. stretch[4]) of L-α-alanine are plotted against temperature as shown in Fig. 5. They show a gradual temperature dependence, varying linearly with temperature, which indicates that the anharmonicity is small. In Fig. 6, the half-width of the 972 cm^{-1} band for L-α-alanine as well as that of the 975 cm^{-1} band for DL-α-alanine are plotted as a function of temperature. In the temperature range from 100 to 200 K, the half-widths of both bands also increase linearly with increasing temperature. However, the slopes are much steeper in this case, indicating considerable anharmonicity. An interesting feature in this figure is that the deviation from the linearity starts at about 200 K.

Wang and Storms[2,3] reported that a similar deviation was observed above 220 K for the half-width of the NH_3^+ torsional Raman band at 484 cm^{-1} for L-α-alanine. They explained the deviation as due to the modification of the NH_3^+ torsional mode by breaking of a –NH···O– hydrogen bond above 220 K.

If the extra broadening of the 972 and 975 cm^{-1} bands is also caused by relaxation induced by the rupture of a –NH···O– hydrogen bond, it is reasonable to assume that the extra broadening $\Delta\Gamma$ can be expressed as

$$\Delta\Gamma = \Delta\Gamma_0 \exp(-\Delta E/RT)$$

where ΔE is the activation energy of the hydrogen breaking process. In fact, a straight line was obtained when the observed values of $\ln(\Delta\Gamma)$ were plotted against $1/T$. From the slope of this straight line, ΔE was calculated to be 3.6 ± 0.6 kcal/mol for L-α-alanine and 3.7 ± 0.7 kcal/mol for DL-α-alanine.

These values are quite reasonable for the energy of a –NH···O– hydrogen bonding, being in good agreement with the hydrogen bonding energy of 3.5 ± 0.6 kcal/mol calculated by Wang and Storms from the half-width of the torsional Raman band at 484 cm^{-1} for L-α-alanine This may be regarded as additional evidence that the newly observed infrared bands at 972 cm^{-1} for L-α-alanine and at 975 cm^{-1} for DL-α-alanine are due to the first overtone of the NH_3^+ torsional mode.

The half-widths of the NH_3^+ torsional infrared bands at 487 cm^{-1} for L-α-alanine and at 497 cm^{-1} for DL-α-alanine were also measured at various temperatures. However, the splitting of these bands at low temperatures (Figs. 2 and 4) made it almost impossible to evaluate half-width accurately and ΔE was not calculated for these bands.

The Photovoltaic Effect in Naphthacene-Gold Layers

Michio MATSUMURA, Hiromichi UOHASHI,* Masaki FURUSAWA,**
Naoto YAMAMOTO, and Hiroshi TSUBOMURA
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received November 25, 1974)

The photovoltaic effect in gold–naphthacene thin layers has been studied. By excitation in the region of the visible absorption band of naphthacene (2.4—3.0 eV), it was found that the photovoltage consists of two components; one with a short response time, caused by the electron transfer across the boundary between gold and naphthacene, and the other with a long response time, attributable to a diffusion process in the naphthacene film. The lifetime of carriers produced by the former process was estimated to be 0.08 s at least, decaying by the recombination of trapped holes in naphthacene with electrons in gold. Photovoltage was also observed in a region of wavelengths greater than the visible absorption band of naphthacene.

Photovoltaic effects of organic compounds have been investigated by many authors.[1] It is known that the photovoltage for a semiconductor is produced by the transport of charge carriers across contact barriers.[2] Other processes such as the Dember effect[3] are also known. However, in the case of organic compounds such as anthracene and naphthacene, analysis of the phenomena is more difficult because of complicated features and poor reproducibility.

In order to clarify the mechanism of photovoltage by illumination in the region of the absorption band of naphthacene, we have made a detailed study of the photovoltaic effect across the gold-naphthacene interface. The photovoltage for a similar system was reported by Reucroft *et al.*[4] Ghosh and Feng investigated the photovoltage for a gold-naphthacene–aluminum system, attributing the photovoltage to the difference in the work function of the two electrode materials.[5]

Experimental

The specimens are made in the form of successive thin layers of gold(Au^1), naphthacene, inositol[$C_6H_6(OH)_6$], and gold (Au^2), obtained by evaporation onto a quartz substrate at less than 10^{-5} Torr (Fig. 1). The gold layers at the two ends, serving as electrodes, are semi-transparent. The deposition rate of naphthacene was about 2 nm/s. The thickness of the naphthacene layer was determined, by measurements of the optical density, to be in the range 0.05—1.0 μ. The area covered by both electrodes was about 0.2 cm^2. The photovoltage was measured by two methods, (a) with exciting light chopped at 30 Hz and a lock-in amplifier(NF circuit design block, LI-573), and (b) with a steady light and vibrating reed electrometer (Takeda Riken, TR-84M). Throughout this paper, the photovoltage is defined as the voltage at the Au^1 electrode taking that at the other electrode (Au^2) as zero. An Ushio 500 W xenon lamp and an Ushio 500 W halogen lamp were used as light sources. A Japan Jarrel-Ash, 0.25 m Ebert-type monochromator was used. The light intensity was measured with a thermopile (Eppley, Bismus-silver type). Most measurements were made under ordinary atmosphere.

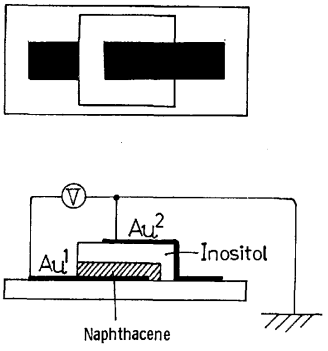

Fig. 1. A diagrammatic picture of a specimen used for photovoltaic measutements.

Results

The photovoltage of the Au^1–naphthacene–inositol–Au^2 system measured with the aid of a vibrating reed electrometer by exciting the visible absorption band of naphthacene is shown in Fig. 2. When the light was turned on, the photovoltage showed a quick negative response, followed by a slow rise toward the positive direction. When the light was turned off, it became more positive for an instant and then degraded slowly. It is obvious from this behavior that there are two components in the photovoltage (shown by broken lines): One has a negative polarity and a fast response and the other a positive polarity and a slow response. This photovoltaic behavior did not change with the direction of illumination, *i.e.*, illumination from either side of the Au electrodes. The response time and the intensity of

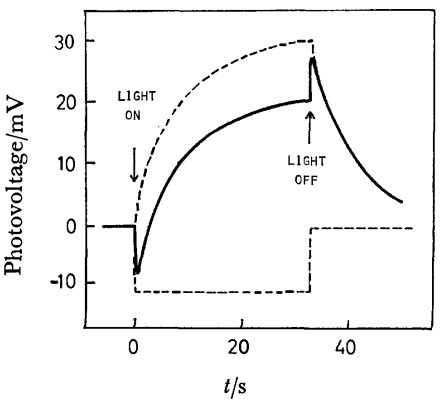

Fig. 2. The photovoltage measured as a function of time with steady illumination (λ=500 nm) by use of a vibrating reed electrometer.

** Present address: Sony Corp., Osaki, Tokyo.

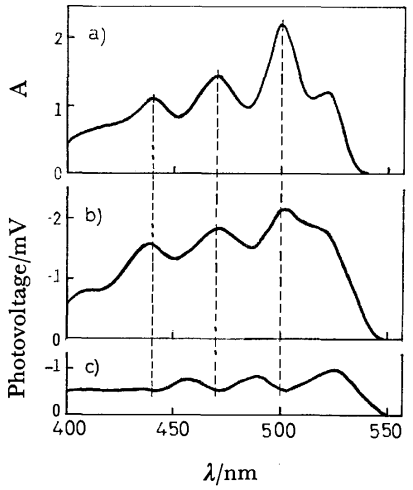

Fig. 3. (a) The absorption spectrum of a naphthacene film. (b) The photovoltage action spectrum, illuminated from the side of Au[1]. (c) The photovoltage action spectrum, illuminated from the side of Au[2]. The thickness of naphthacene layer is about 0.6 μ throughout. The photovoltage was measured by using a lock-in amplifier. The curves (b) and (c) are corrected so as to give photovoltages at the illumination intensity of 5.4×10^{13} photons/cm^2·s throughout the spectral region.

the slow component differed to some degree with specimen.

The visible absorption spectrum of a naphthacene layer deposited on a quartz glass plate is shown in Fig. 3a. The spectrum nearly coincides with the absorption spectrum of the single crystal of naphthacene assigned to a ^{1}La transition.[6]

The action spectra for the photovoltages measured with a lock-in amplifier are shown in Figs. 3b and c. It should be noted that only the component of photovoltage alternating at 30 Hz is given by this method and the resulting action spectra correspond to the fast-response component of the photovoltage shown in Fig. 2. Curve b, the action spectrum for illumination from the Au[1] side, closely resembles the absorption spectrum of curve a, while curve c, the action spectrum for illumination from the Au[2] side, is entirely different.

One of the action spectra for the photovoltage measured with the vibrating reed electrometer is shown in Fig. 4, with illumination from the Au[1] side and the wavelength scanned from short to long wavelengths at the speed of 25 nm/min. Contrary to the case shown in Fig. 3b, the action spectrum has a shape quite different from the absorption spectrum. The position of the minima indicated by arrows correspond well with the absorption peaks. Since there are two components in the photovoltage, the action spectrum should contain spectra for the positive and negative components. The fast-response, negative component should have a structure similar to the absorption spectrum, and therefore the action spectrum can be regarded as the difference between the slow-response, positive component, shown by the broken line, and the fast-response, negative component (hatched part).

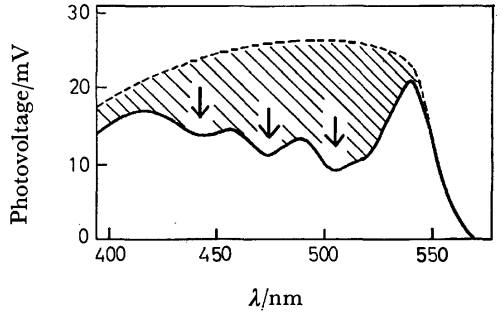

Fig. 4. The photovoltage action spectrum observed by using a vibrating reed electrometer under steady illumination.

The dependence of photovoltage on the exciting light intensity for each of the components is shown in Fig. 5. The photovoltage of the slow-response component (Fig. 5a) was measured with light at 535 nm and a vibrating reed electrometer. In the region where the light is weak, the photovoltage is proportional to light intensity,

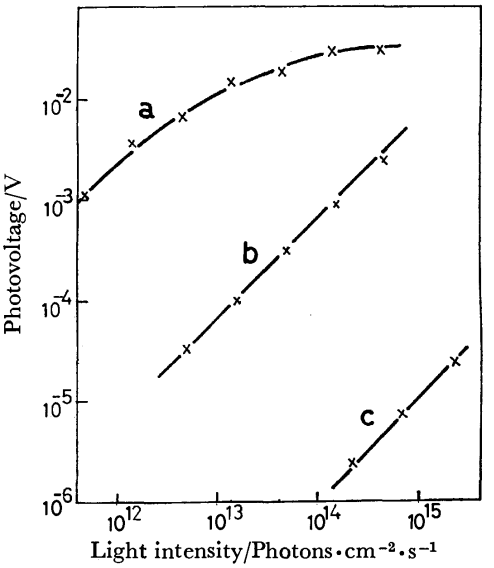

Fig. 5. The dependence of the photovoltages on light intensity. (a) Slow-response component, measured with a vibrating reed electrometer, λ 535 nm. (b) Fast-response component, measured with a lock-in amplifier, λ 500 nm. (c) Photovoltage in the long wavelength region, measured with a lock-in amplifier, λ 820 nm.

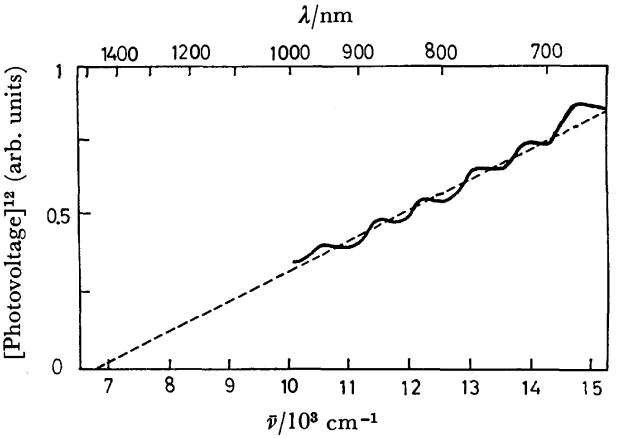

Fig. 6. Photovoltage action spectrum measured with the aid of a lock-in amplifier in the region of wavelength longer than the absorption band of naphthacene.

but shows saturation in the strong light region. The light intensity at which saturation began differed a little with specimen. It also shifted to the weaker intensity side day by day. The fast-response component of the photovoltage, measured with light at 500 nm and the lock-in amplifier, was proportional to the light intensity (Fig. 5b).

Weak photovoltages were also observed even with light at wavelengths longer than the absorption band of naphthacene. The action spectrum measured by using the lock-in amplifier is shown in Fig. 6. The dependence on light intensity is shown in Fig. 5c. The polarity was the same as that of the fast-response component observed for the excitation in the region of the absorption band.

Discussion

Mechanism for the Photovoltaic Effect. *a. The Fast-response Component*: The fast-response component makes the Au^1 electrode negative, and can be selectively measured by means of the chopped light method. When the light comes from the Au^1 side, the action spectrum agrees with the absorption spectrum of the naphthacene layer (Fig. 3b). When the light comes from the other side, the maxima of the action spectrum do not agree with the absorption peaks, but agree in wavelength with those of the absorption bottoms. In the case where the layer of naphthacene was thinner than 0.2 μ, the action spectra did not change with the direction of the illumination and agreed with the absorption spectra. These results suggest that the fast-response component of the photovoltaic effect takes place near the interface between gold (Au^1) and naphthacene, because the light coming from the side of Au^2 is absorbed more strongly at the absorption peaks in the naphthacene layer before reaching the naphthacene-Au^1 boundary than at the bottoms. The charge transfer process caused by the exciton at the interface may be suitable for explaining the results. The negative polarity shows electron trasfer from the naphthacene exciton to Au^1. A similar mechanism was proposed by Killesreiter and Baessler for an aluminum electrode-anthracene crystal system.[7,8] They attributed the photocurrent to a charge carrier generated by the exciton-metal interaction, and concluded that the electron transfer from the exciton takes place mainly within 20 Å from the boundary.

The depths of light absorption (the distance at which the light intensity becomes 1/e) of the naphthacene layer can be approximately estimated from the absorbances to be 0.12 μ at λ 500 nm (at the absorption maximum) and about 0.3 μ at the minima. When illuminated from the side of Au^2 into the naphthacene layer 0.6 μ or more in thickness, the exciting light hardly reaches the interface. The fact that we obtained photovoltage to a considerable magnitude under these conditions (Fig. 3c) shows that some species with long diffusion length (>0.1 μ) participate in the electron transfer process at the boundary. The diffusion length of the singlet exciton in naphthacene single crystal is determined to be 120 Å[9] by fluorescence studies, and that of triplet exciton to be 0.4 μ[10] by photocurrent studies. For a thin film made by evaporation, the values should be smaller. It might be concluded that the participation of triplet excitons formed from singlet excitons is predominant in the charge carrier generation for the case of excitation from the Au^2 side. When illuminated from the Au^1 side, both singlet and triplet excitons can participate in the electron transfer process.

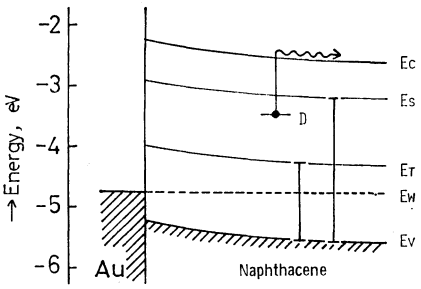

Fig. 7. A band model for the gold-naphthacene interface. E_C, E_V, and E_W designate the energies of the conduction band, the valence band and the work function of gold, respectively. E_S and E_T are the energies of the singlet and triplet excitons of naphthacene. *D* indicates a hypothetical donor level.

The work function of gold (E_w) is about 4.8 eV,[11] the ionization potential of naphthacene (I_p) is about 5.25 eV[12] and the band gap of naphthacene (E_g) is 3.0 eV.[13] If one takes the position of the valence band of naphthacene (E_v) to be 5.25 eV, then, that of the conduction band (E_c) is 2.25 eV. The energies of the singlet exciton (E_s) and the triplet exciton (E_T) from the valence band are 2.4 eV[13] and 1.25 eV,[14] respectively (Fig. 7). The electron transfer from naphthacene to gold requires an energy higher than $E_v - E_w$, *viz.*, 0.45 eV. For the case of the electron transfer from gold to naphthacene, the energy of $E_w - E_c$, *viz.*, 2.55 eV or more, is required. The energies of both singlet and triplet excitons are therefore large enough to cause an electron transfer from naphthacene to gold, but not to cause an electron transfer from gold to naphthacene. This conclusion is compatible with the polarity of photovoltage observed.

b. The Slow-response Component: The photovoltage curve in Fig. 4 can be interpreted to be the superposition of a slow-response, positive component and a fast-response, negative one. When the light is not very strong, the two components of the photovoltage are nearly proportional to the light intensity, as shown in Figs. 5a and b. One can therefore conclude that the action spectrum when illuminated from the Au^1 side should have the same fine structure as that of the absorption spectrum. But the slow-response component is strong in the region of the tails of absorption band of naphthacene (Fig. 4), which implies that the slow component of the photovoltaic effect takes place, not at the interface but inside the naphthacene layer.

Jortner proposed an exciton-exciton interaction mechanism for free carrier generation in the bulk.[15] This mechanism, however, does not explain the dependence on light intensity we obtained. The exciton-impurity (electron donor or electron acceptor) interaction or exciton-trapped carrier interaction, leading to carrier

formation as indicated in Fig. 7, seems to be a plausible mechanism for the slow response component.

As is usual in the band theory for semiconductors, we assume that the naphthacene energy bands are bent near the boundary due to the difference of work functions between gold and naphthacene. Since the work function of naphthacene is reported to be 4.51 eV,[16] we can assume that the bands for naphthacene are bent downwards toward the interior as shown in Fig. 7 by an amount of (4.87—4.51) eV. When free carriers are produced in the naphthacene, the electrons move to the interior of the naphthacene layer and the holes move to the gold electrode according to the energy gradient. It is therefore expected that the polarity of the photovoltaic effect becomes positive at the electrode, regardless of the species of the mobile carrier. Thus we can conclude that the slow-response component arises from the charge carrier generation in the interior of naphthacene layer.

Some of the carriers might be captured by shallow traps. The trapped carriers can be thermally excited and recombine slowly with the counter charge carriers. The decay of the slow-response component can be interpreted by such a thermal recombination process.

c. Photovoltaic Effect in the Region of Long Wavelength: A very weak photovoltage was observed in the region of wavelength longer than the absorption band of naphthacene with a lock-in amplifier. The polarity and the light intensity dependence are the same as those of the fast-response component caused by light in the region of the absorption band. The action spectrum is shown in Fig. 6, where the square root of the photovoltage is plotted against wave number. The photovoltage could be observed even with light at 1000 nm. The small humps in the spectrum are due to the interference of light in the sample. No peak can be observed which corresponds to S–T absorption band of naphthacene. It is seen that the plot lies roughly on a straight line (dotted line). From the intersection of the straight line with abscissa, the threshold energy for the photovoltage is found to be about 6800 cm^{-1} (0.84 eV). Williams and Dresner reported the threshold value of photoemission of holes from gold to anthracene crystal to be 1.17 eV[17] from the photocurrent measurement. Based on their result, 0.77 eV is estimated as the threshold of photoemission of holes from gold to naphthacene, since naphthacene has an ionization potential 0.40 eV smaller than anthracene. This nearly coincides with the value derived experimentally by us. Our result also shows that the photoemission occurs for an organics-metal system without external electric field.

A slow-response, positive component of the photovoltage was observed with the light at wavelengths greater than the absorption edge of naphthacene, in addition to the fast-response, negative one. The former component might be caused by the direct excitation of the trapped carriers.

Since the photovoltage measured with the aid of a lock-in amplifier gives only the alternating part of the voltage caused by chopped light, there should be no effect by an additional steady illumination, if the photovoltage is proportional to light intensity. Contrary to expectation, the photovoltage remarkably increased by steady illumination in the region of the absorption band of naphthacene in addition to the chopped light at wavelengths greater than that of absorption band. It was also observed that this enhancement grew slowly on application of the steady light, as in the case of the slow-response component. It is plausible that the long wavelength light stimulates the detrapping of the trapped carriers produced by the steady light in naphthacene layer.

Carrier Formation and Recombination at the Boundary. The excitons at the boundary between gold and naphthacene inject holes into the naphthacene layer.

The rate of transfer is formulated as

$$dN/dt = I\Phi\eta - kN, \quad (1)$$

where N is the density of holes in the naphthacene layer [holes·m^{-2}], I the light intensity [phtons·m^{-2}·s^{-1}], Φ the quantum yield of the excitons which can reach the boundary per photon, η the efficiency that the exciton causes electron transfer, and k is the rate constant for the recombination of holes with the electrons in the gold electrode [s^{-1}].

In the stationary state, N is given by Eq. 2 taking $dN/dt=0$

$$N = I\Phi\eta/k, \quad (2)$$

For the sake of simplicity we assume that the holes lie on a plane parallel to the boundary with a distance d. Then the photovoltage (V_{ph}) can be given by

$$V_{ph} = Ned/\varepsilon\varepsilon_0, \quad (3)$$

where e is the elementary electronic charge, ε the dielectric constant of naphthacene, and ε_0 the vacuum permittivity. From Eqs. 2 and 3, we find that V_{ph} is proportional to the light intensity, in agreement with the experimental result (Fig. 5b). The experimental value of V_{ph} was obtained to be 20 mV, at $I=10^{18}$ photons·m^{-2}·s^{-1}, at $\lambda=500$ nm, measured with the aid of a vibrating reed electrometer and using the specimen whose slow-response component was weak. η and ε can be taken to be 0.2[7] and 3.8,[18] respectively, according to Baessler *et al.* d can be reasonably assumed to be 5 Å, and Φ 0.5 at most. We can then get k to be 12 s^{-1} or less. This corresponds to a lower limit of the lifetime of the holes produced at the boundary of 0.08 s. The lifetime thus obtained is much longer than the value of 1.2—2.0 μs[19] reported by Bogus. Bogus derived the lifetime of the hole produced at the boundary between an anthracene crystal and silver from measurement of the photocurrent, where free carriers only participate. It should be noted that the photovoltage is caused not only by free carriers but also by trapped carriers. Thus it is concluded that the holes produced in our experiment are trapped within a few microseconds, and the trapped holes then recombine with electrons in the metal within some hundreds of milliseconds. Although no detailes on the state of trapped holes are known, they might either be localized on naphthacene cation or impurity cation stabilized near the boundary. Our studies on the photovoltaic effect have thus revealed the existence of trapped holes with a long lifetime at the boundary between an organic substance and a metal.

Hydrogen Bonding Interactions of Carboxylic Acids with *N,N*-Dimethylacetamide and Pyrazine as Studied by Means of NMR Dilution Shifts

Hideaki FUJIWARA, Nobuyuki YOSHIDA, and Tsuneo IKENOUE

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira 2-1-1, Sendai 980

(Received December 9, 1974)

The NMR dilution shifts of OH proton in several carboxylic acids have been studied for mixtures with *N,N*-dimethylacetamide (DMA) or pyrazine. The acids treated were acetic, propionic isobutyric, and trifluoroacetic acids. The dilution shifts curve of OH proton in each acid–DMA system showed a characteristic *v*-type curve with the minimum value at 0.65—0.75 mol fraction of the acid. The curve for the isobutyric acid–pyrazine system was linear below 0.45 mol fraction of the acid, taking the minimum at 0.75 mol fraction. These curves were explained by assuming the formation of both 1: 1 and 2 (acids): 1(base) complexes in the chemical equilibrium. The formation constants of the complexes and the shifts of OH proton in the 2: 1 complex were estimated for each system. Liability of the complex formation and the structure possible for the 2: 1 complex were discussed.

The amide-acid interaction has been of interest to many NMR investigators.[1-6] Gillespie and Birchall[1] studied the proton NMR spectra of several amides in FSO_3H at low temperatures and concluded that amides were protonated at the oxygen atom. It was found that the addition of trifluoroacetic acid (TFA)[3] or dichloroacetic acid[4] to an amide leads to the unrestricted internal rotation around the C–N bond, which was interpreted as resulting from the occurrence of *N*-protonation in the amide. The examination of the absorption spectra of amides in sulfuric acid by Goldfarb *et al.*[7] indicates the presence of two equilibria in the mixture, one corresponding to the protonation of the amide and the other to the hydrogen bonding of the protonated amide with the solvent. Edward and Wang,[8] however, explained the spectral data only in terms of a protonation equilibrium of the amide considering the difference in the hydration number between a protonated amide and a protonated Hammett indicator which was used to establish the H_0 scale. Thus the simultaneous interaction of the amide with two acidic protons has not been corroborated yet.

The interaction of *N,N*-dimethylacetamide (DMA) with some carboxylic acids has been studied also by measuring the density, viscosity, electric conductivity, melting point, and infrared and Raman spectra.[3,9-11] For the acetic acid–DMA system, the formation of 1: 1 and 2 (acids): 1(DMSO) complexes has been suggested, the former from the fact that the glass formation occurred in the range 0.4—0.6 mol fraction of the acid,[10] and the latter from the fact that the viscosity and electric conductivity became maximum in the range 0.6—0.7 mol fraction.[11] The presence of the 1: 1 and 2: 1 complexes in the acetic acid–DMA system was also suggested by Khazova and Chesnokov[11] as a result of the measurements of their infrared and Raman spectra, though the importance of the Fermi resonance to interpret the spectra had been pointed out by Haurie and Novak.[9]

In a previous paper,[12] the NMR dilution shifts for the binary systems of some carboxylic acids and dimethyl sulfoxide (DMSO) were examined and the shift curves were explained assuming the formation of both 1: 1 and 2 (acids): 1 (DMSO) complexes in the chemical equilibrium. A similar examination for the systems of some carboxylic acids in DMA has been carried out. To ascertain the participation of 2: 1 complex in such acid-base interaction, pyrazine was also chosen as a base which possesses two equivalent basic sites in a molecule. Acetic, propionic, isobutyric, and trifluoroacetic acids were used as the acid.

Experimental

All the procedures for the purification of carboxylic acids and the preparation of solutions are the same as reported previously.[12] Commercial DMA was dried by returning the forerun through barium oxide into a still pot after the addition of toluene by 30 volume %. After drying had been accomplished, toluene was removed by distillation under reduced pressure. When methanol was mixed with the purified DMA, the NMR fine structure of OH proton was clearly observed, in particular below 0.5 mol fraction of the alcohol,[13] showing the marked efficiency of DMA to retard the exchange rate of the OH proton.

Pyrazine was handled in a liquid state with use of a constant temperature box at about 65°C. Commercial pyrazine was purified in a similar way to that for DMA.

NMR spectra were obtained with a Hitachi R-20B high resolution NMR spectrometer (60 MHz, at 34.5 °C). The chemical shift was measured with a frequency counter, the error being within $\pm$0.1 Hz. NMR measurements at high temperatures were carried out with a Hitachi R-20VTP prove. The sample temperatures were determined with a ethylene glycol "chemical shift thermometer". The NMR spectra for the isobutyric acid–pyrazine system at ordinary temperature were measured with a Varian V-4300B NMR spectrometer (60 MHz). The shift was determined by the side band technique with accuracy of $\pm$0.15 Hz. The probe temperature was 33 °C.

Results

The shifts of OH proton (δ_{OH}) in the carboxylic acid–DMA systems plotted against acid mol fraction (X) are shown in Figs. 1 and 2. The dilution shift curves for isobutyric and propionic acids exhibit the *v*-type pattern (Fig. 1), the curve for TFA being linear below 0.45 mol fraction of the acid (Fig. 2). These curves are similar to those obtained for the carboxylic acid–DMSO systems.[12] The curve for acetic acid (Fig. 1) exceptionally shows no minimum in the intermediate con-

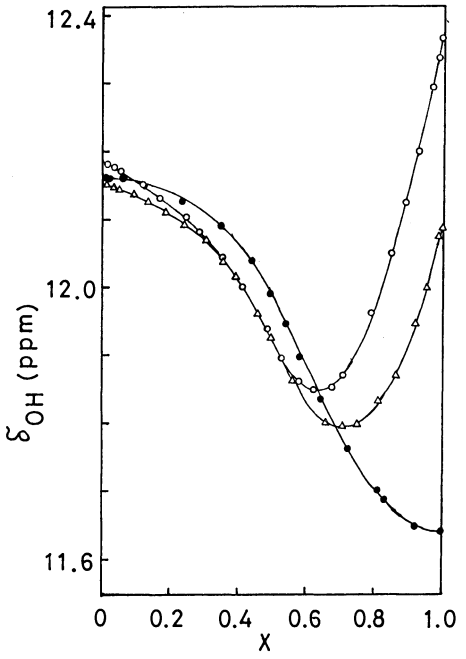

Fig. 1. Dilution shift curves observed for the acid–DMA systems.
○: Isobutyric acid. △: Propionic acid. ●: Acetic acid.

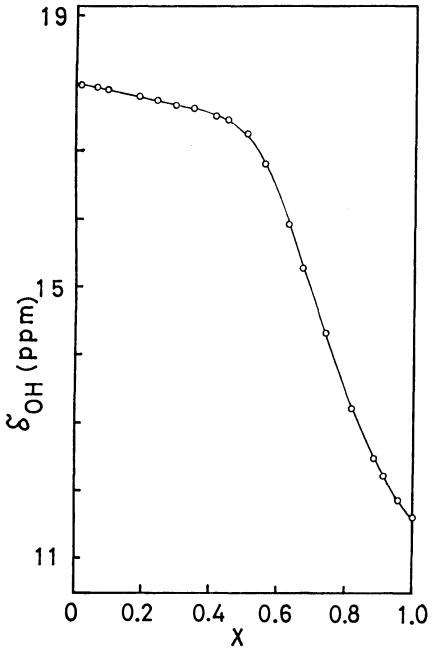

Fig. 2. A dilution shift curve observed for the TFA –DMA system.

centration. This is understandable from the following facts: (1) the difference between the minimum shift and the shift for the neat solution decreases in the order of isobutyric, propionic, and acetic acids for the acid-DMSO systems, (2) the difference is smaller in the acid-DMA systems than that in the acid-DMSO systems for isobutyric and propionic acids.

The dilution shift curve for the isobutyric acid-pyrazine system at ordinary temperature (curve a,

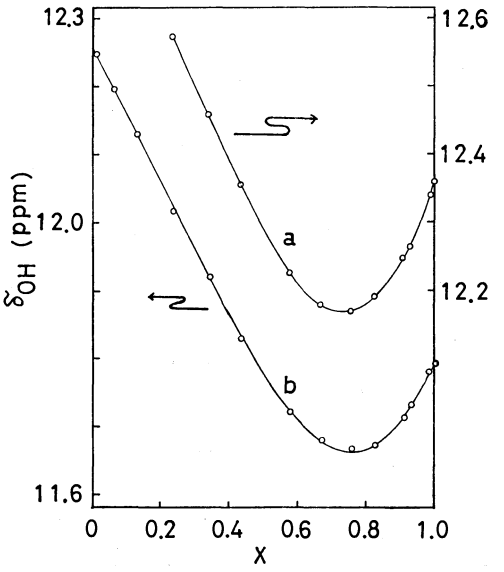

Fig. 3. Dilution shift curves observed for the isobutyric acid-pyrazine system.
a: At 33 °C. b: At 80.5 °C.

Fig. 3) also goes through the minimum at 0.75 mol fraction of the acid. The measurements for this system at two high temperatures of 80.5 °C (curve b) and 127 °C (not shown but similar to curve b in Fig. 3) revealed that the concentration corresponding to the minimum shift does not vary with temperature and the curves are practically linear below 0.45 mol fraction of the acid.

The dilution shift curve of the TFA-pyrazine system at 60 °C was similar to the curves for the TFA-DMA (Fig. 2) and TFA-DMSO[12] systems.

Two proton signals due to the two *N*-methyl groups of DMA in the TFA-DMA system coalesced into a singlet above 0.55 mol fraction of the acid.[3] The acid concentration where the coalescence occurred was temperature dependent; it decreased from 0.55 mol fraction at 34.5 °C to 0.35 mol fraction at 40.0 °C. No such coalescence was observed for the systems containing isobutyric, propionic, or acetic acid instead of TFA at 34.5 °C.

The shift of CH proton in the acid and base changed monotonously with the acid concentration. The variation of the shift was less than 1/5 of that for the OH proton.

Discussion

An acid-base interaction in solution generally produces either the ionic species such as the conjugate acid or base of the initial species, or the hydrogen bonded complex. The former is important in the case of a strong acid against a strong base, and the latter in the case of a weak acid against a weak base. Measurements of the infrared spectra on the systems of acetic acid-DMA,[14] formic acid-DMA,[15] and formic acid-DMSO[15] revealed no ionic species. Examination of the absorption spectra of pyrazine in the mixture of isobutyric acid and *n*-hexane did not show any evidence of the presence of ionic species,[16] though the dissolu-

tion of pyrazine in aqueous sulfuric acid clearly produces the ionic species such as pyrazinium ions.[17-19]

It can thus be assured that only the hydrogen bond formation is important in interpreting the NMR data for the OH protons of acetic, propionic, and isobutyric acids in DMSO, DMA, and pyrazine. Since the presence of ionic species has been reported for the systems containing TFA with DMSO,[3] DMA,[14] or pyrazine,[20] the contribution of ionic species may be unavoidable in interpreting the data for these systems.

The characteristic ν-type shift curves (Figs. 1 and 3) are interpreted by assuming that the carboxylic acid dimer produces the 2: 1 and 1: 1 complexes with a base[12] as follows:

$$A_2 + B \rightleftarrows A_2 \cdot B \qquad K_1$$

$$A_2 \cdot B + B \rightleftarrows 2(A \cdot B) \qquad K_2$$

where A_2 and B denote the carboxylic acid cyclic dimer and the base, respectively, and $A_2 \cdot B$ and $A \cdot B$ the 2: 1 and 1: 1 complexes, respectively. The procedure for analysis of the ν-type shift curve is summarized below, the detailes having been given previously.[12] Under the above conditions, the shift of OH proton can be calculated in terms of the following six parameters:

δ_D=the shift of OH proton in the cyclic dimer of the acid. The value was evaluated by extrapolating the straight part of the dilution shift curve in cyclohexane to infinite dilution of the acid,

$\delta_{C\beta}$=the shift of OH proton in the 1: 1 complex. The value was substituted by the value of δ_{OH} (the shift observed) at infinite dilution of the acid in DMA or pyrazine,

$\delta_{C\alpha}$=the shift of OH proton in the 2: 1 complex,

K_1=the formation constant of the 2: 1 complex,

K_2=the formation constant of the 1: 1 complex, and

X=initial mol fraction of the acid in monomer unit.

Of these, $\delta_{C\alpha}$, K_1, and K_2 remain to be determined. δ_D, $\delta_{C\beta}$, and X were obtained experimentally. These three parameters can be determined by calculation so as to give the best fit between the calculated and observed dilution shift curves. This process of the least squares was achieved by the trial and error method, only one set of parameters being obtained for each system within an acceracy of the measurement of shifts and concentrations. Parameters obtained experimentally or by calculation for each system are summarized in Table 1, together with those for the acid-DMSO systems.[12] The shift data above 0.6 mol fraction of the acid were omitted in the calculation, since the deviation between the calculated and observed shifts never diminished in that region.

Table 1. Parameters obtained experimentally or by calculation[a] for carboxylic acid–DMSO, DMA, and pyrazine systenms (34.5 °C)

Base	Acid	δ_D	$\delta_{c\beta}$	K_1	K_2	$\delta_{c\alpha}$
DMSO	Acetic	13.36	11.88	100	9	11.13
	Propionic	12.49	11.89	60	9	11.00
	Isobutyric	12.64	11.92	40	9	10.87
	TFA	12.03	16.44	c	c	c
DMA	Acetic	12.36	12.162	220	10	11.70
	Propionic	12.49	12.155	60	8	11.52
	Isobutyric	12.64	12.185	90	5	11.59
	TFA	12.03	18.00	c	c	c
Pyrazine[b]	Isobutyric	12.19	12.257	20	1.7	11.353

a) δ_D and $\delta_{c\beta}$ are obtained experimentally and K_1, K_2, and $\delta_{c\beta}$ by calculation. The accuracy of calculation is $\pm 20\%$ for K_1 and K_2 and ± 0.05 ppm for $\delta_{c\alpha}$. b) The isobutyric acid–pyrazine system is investigated at 80.5 °C. c: Not fully analyzed.

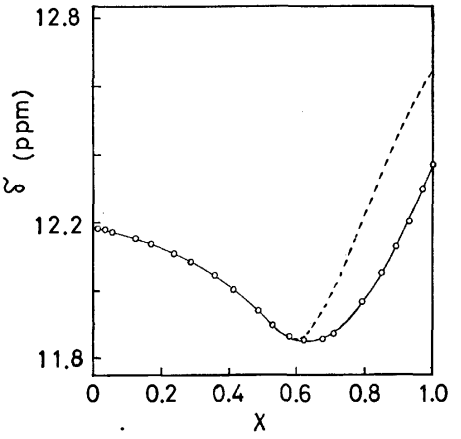

Fig. 4. A comparison of the observed and the calculated dilution shift curves for the isobutyric acid-DMA system.
——: Observed. ----: Calculated. ○: Experimental points.

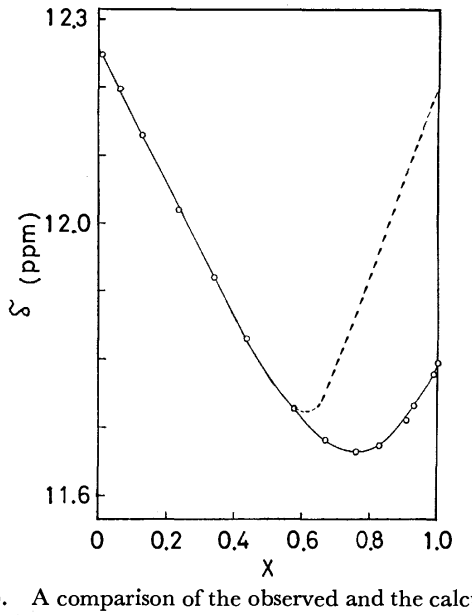

Fig. 5. A comparison of the observed and the calculated dilution shift curves for the isobutyric acid-pyrazine system (at 80.5 °C).
——: Observed. ----: Calculated. ○: Experimental points.

The deviation of δ_{calcd} (shift value calculated) from δ_{OH} (shift value observed) above 0.6 mol fraction of the acid is shown in Figs. 4 and 5. It is larger in the isobutyric acid-pyrazine system than in the isobutyric acid-DMA system. The larger deviation for the pyrazine system is presumably due to the fact that the measurement temperature was higher. Since a rise in

temperature usually causes a larger contribution of the monomer and/or chain oligomer of carboxylic acid,[21] higher temperature may be responsible for the larger deviation of δ_{calcd} from δ_{OH}.

The K_1 values are always more than five times larger than the K_2 values (Table 1). The large K_1 value implies the low concentration of the cyclic dimer in solution and a remarkable tendency of the acid molecule to form complexes with the base. The Raman spectral data[9] also show a negligibly small amount of the cyclic dimer for the solutions of about 0.5 mol fraction of acetic acid in DMSO or DMA.

Although pyrazine is known to be more basic than DMSO and DMA,[22] K_1 in pyrazine is smaller than that in either DMSO or DMA. This is partly ascribed to the higher measurement temperature of pyrazine system than that of DMSO and DMA systems. The polarity of each species in a solution may also explain the small K_1 in pyrazine. Pyrazine is a non-polar solvent, while DMSO and DMA are dipolar solvents. While the cyclic dimer of carboxylic acid will be less polar, the complexes of the acid with these basic solvents may be well supposed to be polar. The polar species is stabilized in a polar medium to a larger extent than the less polar species such as the cyclic dimer, leading to the large K_1 value in a polar medium.

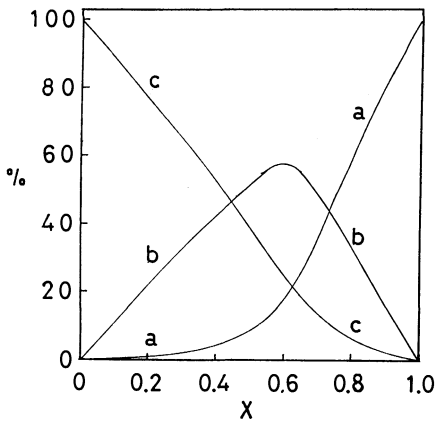

Fig. 6. A distribution curve of the acid molecule to each species in the isobutyric acid-pyrazine system.
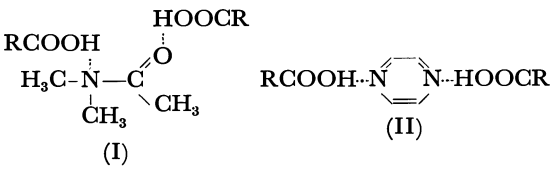
a: Cyclic dimer. b: 2: 1 Complex. c: 1: 1 Complex.

For the isobutyric acid-pyrazine system, the dilution shift curve is linear below 0.45 mol fraction of the acid, an apparent difference from the curves for the acid-DMA systems. As seen from Fig. 6, the 1: 1 and 2: 1 complexes predominate below 0.45 mol fraction of the acid, and the shift depends almost on the K_2 value which is decisive to the ratio of 1: 1 complex to 2: 1 complex. Thus, the linearity in the dilution shift curve of the isobutyric acid-pyrazine system may be due to the smallness of the K_2 value.

It is noteworthy that $\delta_{C\alpha}$ lies in a higher field side than $\delta_{C\beta}$ and δ_D (Table 1). This is closely related to an appearance of the minimum in the shift curve at a higher acid concentration. The structure possible for the 2: 1 complex of the acid with DMA and pyrazine are readily given as I and II, respectively, in which two basic sites of the base interact simultaneously with the acids.



The authors are grateful to Professor Y. Ikegami and Mr. M. Kumano for their helpful discussions. They are also indebted to Mr. K. Fujieda for discussing the accuracy of NMR measurements.

Photolysis of Cyclopropane at 1470 and 1634 Å

Kazuhiko SHIBUYA, Kin-ichi OBI, and Ikuzo TANAKA

Department of Chemistry, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received December 18, 1974)

The vacuum-ultraviolet photolysis of cyclopropane in the gas phase has been investigated at room temperature at excitation wavelengths 1470 and 1634 Å. Primary processes are discussed in terms of variations of product yield as a function of conversion and in the presence of additives such as NO, C_2D_4, and H_2. The relative yields of decomposition are determined at both wavelengths. The main primary process is cyclo-$C_3H_6+h\nu\rightarrow C_2H_4+CH_2$, the yield being 67% at 1470 Å (69% at 1634 Å). The observed product yield responsible for methylene is much less than that for ethylene. However, the yields become equal in the photolysis of cyclopropane with excess hydrogen. The other primary processes are as follows in order of decreasing importance; cyclo-$C_3H_6+h\nu\rightarrow C_2H_3+CH_3$, 19% (18%), cyclo-$C_3H_6+h\nu\rightarrow C_3H_4+2H$, 9% (7%), cyclo-$C_3H_6+h\nu\rightarrow C_2H_2+CH_3+H$, 3% (4%), cyclo-$C_3H_6+h\nu\rightarrow C_2H_2+CH_4$, 1% (1%).

Numerous studies have been carried out on the vacuum ultraviolet photolysis of simple hydrocarbons.[1,2] However, less attention has been paid to the photolysis of cycloalkanes than to typical alkanes and alkenes.

Photolysis of the simplest cycloalkane, cyclopropane, was first carried out at 1470 Å by Currie, Okabe, and McNesby.[3] Using an isotopic technique, they postulated the following primary processes in order of decreasing importance:

$$\text{cyclo-}C_3H_6 + h\nu \begin{cases} \longrightarrow CH_2 + C_2H_4 \\ \longrightarrow H_2 + C_3H_4 \\ \longrightarrow H + C_3H_5 \end{cases}$$

Scala and Ausloos[4] proposed the following reaction as the major primary process in the photolysis at 1470 and 1236 Å:

$$\text{cyclo-}C_3H_6 + h\nu \longrightarrow CH_2CH_2CH_2^*$$

The highly excited trimethylene intermediate, formed by the primary act of the photoexcited cyclopropane molecule, undergoes two kinds of decomposition,

$$CH_2CH_2CH_2^* \begin{cases} \longrightarrow C_2H_4 + CH_2 \\ \longrightarrow C_3H_4 + 2H \end{cases}$$

or isomerization to excited propylene which is always followed by fragmentation.

Dhingra and Koob[5] suggested, on the basis of two kinds of experimental evidence, that there is no need to postulate the trimethylene formation in the primary process, at least as a source of methylene and ethylene. First, no collisional conversion of singlet to triplet trimethylene is observed, and secondly, *cis*- and *trans*-1,2-dimethylcyclopropane yield only *cis*- and *trans*-2-butene, respectively. Since no direct method was available to detect the proposed trimethylene intermediate chemically, they concluded that if it exists it must be very short lived.

In the present work, the photolysis of cyclopropane at 1470 and 1634 Å has been studied with and without additives. Nitric oxide was used to suppress the radical reactions, and hydrogen was employed to scavenge methylene formed in the primary act. Major attention is focused upon quantitative features of the primary processes; the relative yields of the primary processes have been determined.

Experimental

Most of the experimental procedures used in the present study have been described previously.[6] The xenon lamp was equipped with a sidearm containing zeolite as a gettering agent and activated by a microwave generator. The bromine lamp was provided with a quartz window and a cold finger. The vapor pressure of bromine was maintained constant by cooling the cold finger with dry-ice.

Cyclopropane, hydrogen, methane, and nitric oxide were obtained from Takachiho Chem. Ind. Co., and ethylene-d_4 from Merck, Sharp, & Dohme, Ltd. Cyclopropane was purified by gas chromatography of a 9 m long squalane column at room temperature and subsequently distilled at dry-ice temperature. The resulting cyclopropane contained about 0.002% propylene. Nitric oxide was distilled at -160 °C and degassed at -196 °C. The other materials were used without further purification.

After irradiation, the products and the remaining reactants were collected in a sample tube with a Teopler pump and analyzed by gas chromatography; products of C_1 and C_2 were analyzed with a 2 m long silica gel column with 5% squalane or 3 m long activated charcoal column, and those of C_3 and C_4 were analyzed with a 9 m long squalane column. All products were identified by authentic gas samples. Mass spectrometric analyses of hydrogen and methane were carried out in the experiments of isotopic mixture of cyclopropane and ethylene-d_4.

Results and Discussion

Primary Processes. The products observed in the photolysis at both wavelengths were identical but somewhat different in proportions. The measured products were methane, acetylene, ethylene, ethane, propylene, propane, methylacetylene, allene, *n*-butane, butene isomers, and methylcyclopropane. Of these products, ethane, propylene, propane, and *n*-butane completely disappeared with the addition of 10% nitric oxide.

Ethylene, the most abundant product in the photolysis of cyclopropane at 1470 and 1634 Å, was hardly suppressed by added nitric oxide, so that the major primary process would be

$$\text{cyclo-}C_3H_6 + h\nu \longrightarrow C_2H_4 + CH_2, \quad \Delta H = 92 \text{ kcal/mol.} \qquad (1)$$

If ethylene formed has sufficient energy to decompose into acetylene and hydrogen competing with the collisional deactivation, the ratio of acetylene to ethylene

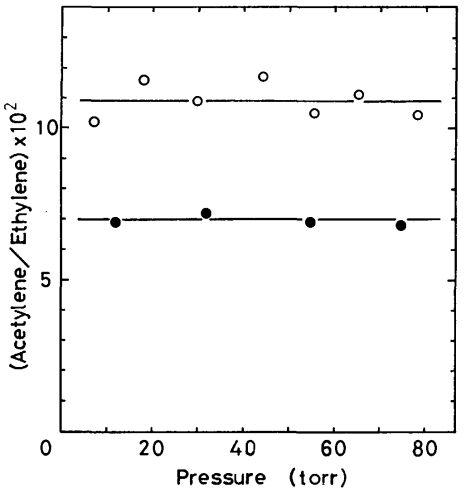

Fig. 1. Ratio of acetylene to ethylene as a function of total pressure in the photolysis of cyclopropane at 1470 Å:
○, *without NO;* ●, *with 10% NO.*

would decrease with the pressure of cyclopropane. Formation of such an energized ethylene has been confirmed in the photolysis of ethane, propane, *n*-butane, and cyclobutane at 1470 Å,[7,8] where the maximum available energy for ethylene is in the range of 160—175 kcal/mol. In order to examine whether energized ethylene is produced in our system, cyclopropane was photolysed in the pressure region of 7—77 Torr. The results are shown in Fig. 1. Since the ratio is evidently independent of pressure, it might be concluded that ethylene produced in the photolysis of cyclopropane at 1470 Å hardly decomposes. Considering the lower available energy of 102 kcal/mol for the 1470 Å photolysis of cyclopropane than that for other paraffins, the result seems reasonable. This would also be the case for the 1634 Å photolysis, in which the maximum energy carried by ethylene formed in the process (1) is 82 kcal/mol.

Yields of the products at both wavelengths are expressed relative to the yield of allene (allene=10) and plotted as a function of the allene/cyclopropane ratio in Figs. 2a—3b. Under the conditions of our experiments, the allene/cyclopropane ratio can be used as a scale proportional to conversion for the following reasons. 1) Within experimental error, the yield of allene was almost proportional to the irradiation time and equal both with and without nitric oxide in the photolysis of cyclopropane. Allene is therefore considered to be produced molecularly by the primary step and its yield never varies with occurrence of the secondary reactions. 2) The relative yield of ethylene, the most abundant product at the both wavelengths, changes during the period of the photolysis without nitric oxide (Figs. 2a and 3a). However, if the secondary reactions with regard to ethylene are taken into account, the amount of ethylene produced by the primary step remains constant relative to that of allene throughout the irradiation period.

The existence of vinyl radicals in this system is confirmed by the following experimental results. 1) Propylene, disappearing entirely with the addition of 10% nitric oxide, is formed *via* radical reactions,[9] namely the recombination reaction of C_3H_5 and H, or C_2H_3 and CH_3. If the association of C_3H_5 with H yields propylene, the formation rate of propylene should be depressed with increasing conversion since the concentration of hydrogen atom is lowered with the increasing amount of ethylene formed. The results show, however, that the rate of propylene formation is constant as a function of conversion. Thus, the following reaction is plausible for the formation of propylene:

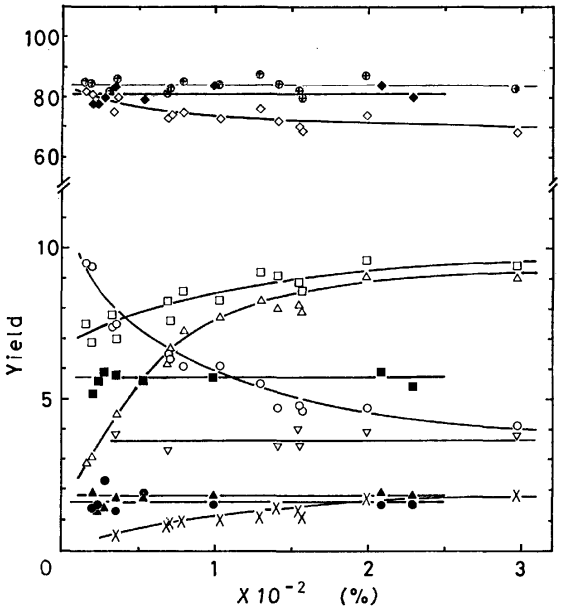

Fig. 2a. Relative yield of product as a function of ratio of allene to cyclopropane in the photolysis of cyclopropane at 1470 Å:

$$C_2H_3 + CH_3 \longrightarrow C_3H_6. \quad (2)$$

2) Since some part of acetylene formation is depressed by addition of nitric oxide, it is formed *via* radical reactions. The following processes might be possible for the acetylene formation:

$$2C_2H_3 \longrightarrow C_2H_2 + C_2H_4, \quad (3)$$
$$\longrightarrow CH_2{=}CH{-}CH{=}CH_2 \quad (4)$$

Although the reported values[10,11] of k_3/k_4 lie between 0.02 and 3, only a trace amount of 1,3-butadiene was observed in our experiments. Therefore, Reaction (3) would contribute little to the formation of acetylene. Another possible reaction sequence forming acetylene through radical reactions is as follows:

$$C_2H_4 + H \longrightarrow C_2H_5, \quad (5)$$
$$C_2H_5 + C_2H_3 \longrightarrow 1\text{-}C_4H_8, \quad (6)$$
$$\longrightarrow 2C_2H_4, \quad (7)$$
$$\longrightarrow C_2H_2 + C_2H_6, \quad (8)$$

where ethylene is the reaction product formed by primary process (1).

In order to examine whether the reaction sequence (5) to (8) occurs, the photolysis of cyclopropane at 1470 Å was carried out with the same irradiation time with and without 10% nitric oxide. The results are given in Table 1. The relative yields are normalized to the yield of allene because it is independent of the addition of nitric oxide. In the presence of nitric oxide the yields of the other products were reduced but not suppressed completely. The portions of the remaining C_4 products, which are not scavenged by 10% nitric oxide, seem to be formed by the insertion reaction of methylene into cyclopropane. The behavior of chemically activated methylcyclopropane has been studied by several researchers[12,13] who suggested the following reaction sequence for the formation of C_4H_8 isomers;

Table 1. Relative yields with the same irradiation time in the photolysis of cyclopropane at 1470 Å[a]

Products	without NO	with 10% NO
C_2H_2	7.7	5.8
$CH_2{=}C{=}CH_2$	10.0	9.9
1-C_4H_8	6.6	1.7
iso-C_4H_8	0.9	0.9
trans-2-C_4H_8	2.6	2.0
cis-2-C_4H_8+cyclo-$C_3H_5CH_3$	3.3	2.6

a) The total pressure was kept at 21 Torr in all the experiments with and without 10% NO. The yield of allene in the photolysis of cyclopropane without NO is taken to be ten. The two kinds of experiments were alternately repeated with the same irradiation time, the values listed being the averages over the five runs.

$$CH_2 + \text{cyclo-}C_3H_6 \longrightarrow CH_3 + C_3H_5, \quad (9)$$
$$\longrightarrow \text{cyclo-}C_3H_5CH_3{*}, \quad (10)$$
$$\text{cyclo-}C_3H_5CH_3{*} \xrightarrow{+M} \text{cyclo-}C_3H_5CH_3, \quad (11a)$$
$$\longrightarrow \text{butene isomers}, \quad (11b)$$
$$CH_3 + C_3H_5 \xrightarrow{+M} \text{cyclo-}C_3H_5CH_3, \quad (12a)$$
$$\longrightarrow \text{butene isomers}. \quad (12b)$$

If these reactions occur even in the photolysis of cyclopropane, then the C_4H_8 isomers would be formed not only by Reaction (11a, 11b) but also by Reaction (12a, 12b). In the presence of 10% nitric oxide the latter reaction would be suppressed, while the former is opera-

tive both with and without nitric oxide. As seen from the yields of *iso*-C_4H_8, *trans*-2-C_4H_8, and *cis*-2-C_4H_8 plus cyclo-$C_3H_5CH_3$ in Table 1, the amount of each C_4H_8 isomer formed by Reaction (12a, 12b) was equal to 0.3 times of that formed by Reaction (11a, 11b), respectively. Applying this value to the case of 1-C_4H_8, the fraction of 2.2 ($=1.7\times1.3$) should be expected to be formed by Reactions (11a, 11b) and (12a, 12b) in the experiment without nitric oxide, and the remainder of 1-C_4H_8 (the fraction of 4.4) should be ascribed to Reaction (6). Moreover, since the yield of acetylene in the presence of nitric oxide is attributed to the molecular detachment, the fraction of 1.9 results from Reaction (8). We can finally obtain the value 2.3 for k_6/k_8 which is almost equal to the value 2.1 reported by Ibuki and Takezaki.[11] We thus conclude that the reaction sequence (6) to (8) surely occurs, and vinyl radical plays an important role as an intermediate. Occurrence of these reactions might be suggested by the fact that the increments of acetylene, ethane, and 1-butene *vs.* conversion show a similar trend and correspond to the increase of ethyl radical formation (Figs. 2a—3b). The following primary process would be the proper mode forming vinyl radicals,

$$\text{cyclo-}C_3H_6 + h\nu \longrightarrow C_2H_3 + CH_3. \quad (13)$$

Figures 2a and 3a show that the yield of methane decreases with increasing conversion without nitric oxide. This would reflect the variation of ethylene concentration. Since ethylene formed in the main primary process (1) scavenges hydrogen atom, Reaction (5), the stationary state concentration of hydrogen atom would decrease as a greater amount of ethylene is produced, which turns out that the association of methyl radical with hydrogen atom,

$$CH_3 + H \xrightarrow{+M} CH_4, \quad (14)$$

is suppressed, while the formation of propane and *n*-butane,[3]

$$CH_3 + C_2H_5 \longrightarrow C_3H_8, \quad (15)$$

$$2C_2H_5 \longrightarrow n\text{-}C_4H_{10}, \quad (16)$$

is promoted. Although the yield of methane is in opposite variation to that of propane, their sum remained constant, which implies that the decrement of methane is virtually compensated by the increment of propane. Reaction (8) was presented as a mechanism of ethane formation. The recombination of methyl radicals should be added as another step:

$$2CH_3 \xrightarrow{+M} C_2H_6. \quad (17)$$

Methane would also be formed in a primary process, because it was found even with nitric oxide. The molecular production of methane should be accompanied by formation of acetylene:

$$\text{cyclo-}C_3H_6 + h\nu \longrightarrow C_2H_2 + CH_4. \quad (18)$$

However, there was several times as much acetylene as methane in the photolysis with the radical scavenger and it is concluded that the following step is another mode of acetylene formation.

$$\text{cyclo-}C_3H_6 + h\nu \longrightarrow C_2H_2 + CH_3 + H. \quad (19)$$

The alternative explanation of acetylene formation from energized ethylene for an excess of acetylene over methane has been rejected since there exists no energized ethylene in our system.

Currie *et al.*[3] proposed that allene and methylacetylene are formed by the molecular elimination of hydrogen,

$$\text{cyclo-}C_3H_6 + h\nu \longrightarrow C_3H_4 + H_2, \quad (20)$$

from the isotopic composition of hydrogen molecule formed in the photolysis of the mixture of cyclopropane-d_0 and -d_6. On the other hand, Scala and Ausloos[4] demonstrated that they are formed substantially by the following reaction sequence,

$$\text{cyclo-}C_3H_6 + h\nu \longrightarrow C_3H_5^* + H, \quad (21)$$

$$C_3H_5^* \longrightarrow C_3H_4 + H, \quad (22)$$

on the basis of the isotopic composition of hydrogen molecule formed from the mixture of cyclopropane-d_6 and H_2S. They concluded that the majority of the allyl and/or cyclopropyl radicals formed in the primary process (21) dissociate further to form C_3H_4. We carried out the photolysis of the mixture of cyclopropane-d_0 and ethylene-d_4 ([cyclo-C_3H_6]/[C_2D_4]$\simeq$30). If the molecular elimination of hydrogen is the dominant process for the C_3H_4 formation, the ratio H_2/C_3H_4 should be close to unity. It was obtained as 0.18 and 0.15 by mass spectrometry and gas chromatography for the 1470 and 1634 Å photolysis, respectively. Thus, it may be concluded that the majority of C_3H_4 are produced by the atomic elimination of hydrogen:

$$\text{cyclo-}C_3H_6 + h\nu \longrightarrow CH_2{=}C{=}CH_2 + 2H, \quad (23)$$

$$\text{cyclo-}C_3H_6 + h\nu \longrightarrow CH_3{-}C{\equiv}CH + 2H. \quad (24)$$

Relative Yields of the Primary Processes. We can determine the relative weights of the primary processes according to the foregoing discussion. To facilitate comparison, weight of the primary process (23) is taken as ten at both wavelengths ($\phi_{23}=10$) and the yields of the other primary processes (ϕ_1, ϕ_{13}, ϕ_{18}, ϕ_{19}, and ϕ_{24}) are expressed relative to ϕ_{23}.

We have noted that the most abundant product, ethylene, scavenges hydrogen atoms and the resultant ethyl radicals undergo the association or disproportionation reactions with themselves or the other radicals. The stationary state assumption leads to the relation,

$$\phi_1 = (C_2H_4) + (C_3H_8) + 2(n\text{-}C_4H_{10}) + \left(\frac{k_6}{k_8} - \frac{k_7}{k_8} + 1\right)(C_2H_2)_r, \quad (I)$$

where $(C_2H_2)_r$ represents the yield of acetylene formed by Reaction (8); *viz.*, that reduced by adding nitric oxide. The value of $(C_2H_2)_r$ was attributed to the difference between the acetylene yields with and without nitric oxide in Fig. 2a at 1470 Å and Fig. 3a at 1634 Å. By means of Eq. (I) and the values[11] of $k_6/k_7=0.89$ and $k_8/k_7=0.43$, the values of ϕ_1 *vs.* conversion at 1470 and 1634 Å are illustrated in Figs. 2a and 3a, respectively. We obtain 83 at 1470 Å and 113 at 1634 Å as the constant values of ϕ_1. The relative weight of the primary process (13) is estimated from the amount of vinyl radical. Since vinyl radicals react with methyl or ethyl radicals, Reaction (2) or Reactions (6)—

(8), the yield of vinyl radical is nearly equal to the sum of propylene and $(C_2H_2)_r \times (k_6+k_7+k_8)/k_8$ at high conversion. Thus, the relative weights of the primary process (13), ϕ_{13}, are 24 and 30 at 1470 and 1634 Å, respectively. Primary process (18) is the only molecular mechanism forming methane and therefore methane formed in the presence of nitric oxide should be attributed to Reaction (18); *viz.*, its relative weights (ϕ_{18}) are equal to 1.6 and 1.8 at 1470 and 1634 Å, respectively. Although Reaction (18) yields molecularly the same amounts of acetylene and methane, the former is obtained in much larger quantities (Figs. 2a and 3a). The difference should be attributed to another step forming acetylene molecularly, or Reaction (19). Thus, we obtain $\phi_{19}=4.0$ at 1470 Å and 6.0 at 1634 Å. Since methylacetylene is formed only by Reaction (24), the yield should be equal to the relative weight of this process, $\phi_{24}=1.7$ and 1.8 at 1470 and 1634 Å, respectively. The total value of ϕ's is normalized to 100, the resulting values (ϕ) being summarized in Table 2.

TABLE 2. RELATIVE YIELDS OF PRIMARY PROCESSES IN THE PHOTOLYSIS OF CYCLOPROPANE AT 1470 AND 1634 Å[a)]

Primary process		Relative yield	
		1470 Å	1634 Å
$C_2H_4+CH_2$	(ϕ_1)	67	69
$C_2H_3+CH_3$	(ϕ_{13})	19	18
$CH_2=C=CH_2+2H$	(ϕ_{23})	8	6
$C_2H_2+H+CH_3$	(ϕ_{19})	3	4
$C_2H_2+CH_4$	(ϕ_{18})	1	1
$CH_3-C\equiv CH+2H$	(ϕ_{24})	1	1

a) The relative yields are noramlized to $\phi_1+\phi_{13}+\phi_{18}+\phi_{19}+\phi_{23}+\phi_{24}=100$.

Although the same amounts of ethylene and methylene are formed in Reaction (1), the observed yield of the products resulting from methylene is much less than that from ethylene.[4)]

A polymer is a major product in the mercury photosensitized reaction of cyclopropane. Strausz *et al.*[14)] stressed that hexyl and allyl radicals are most likely to be precursors of polymer formation. We supposed that C_3H_5 radicals obtained according to Reaction (9) do act as a precursor of polymerization and hence the yield of methylene estimated from the products becomes much smaller than expected. We therefore added a large amount of hydrogen as methylene scavenger to the pure cyclopropane system. Methylene obtained by primary process (1) is converted into methyl radical or methane by the following reaction sequence[15)]:

$$^1CH_2 + H_2 \longrightarrow CH_4^* \begin{cases} \longrightarrow CH_3 + H, & (25) \\ \xrightarrow{+M} CH_4, & (26) \end{cases}$$

$$^1CH_2 \xrightarrow{+M} {}^3CH_2, \quad (27)$$

$$^3CH_2 + H_2 \longrightarrow CH_3 + H. \quad (28)$$

In the presence of excess hydrogen, the reaction of methylene with hydrogen has an advantage over that with cyclopropane. When the $[H_2]/[\text{cyclo-}C_3H_6]$ ratio exceeded four, methylcyclopropane and butene isomers except 1-butene almost disappeared while the yields of methane, ethane, and propane increased to a great extent. This means that Reactions (9) and (10) become unimportant while Reactions (25) to (28) become the ruling steps as regards methylene. In the photolytic system without hydrogen where polymerization occurs, methyl radicals would make a large contribution to polymer formation process. Consequently, the total yield of products resulting from methylene becomes apparently small. The yields of products responsible for ethylene and methylene, $Y(C_2H_4)$ and $Y(CH_2)$, are given by

$$Y(C_2H_4) = \phi_1, \quad (II)$$

and

$$Y(CH_2) = (CH_4) + 2\{(C_2H_6) - (C_2H_6)_r\} + C_3H_6 + (C_3H_8) - (\phi_{13}+\phi_{18}+\phi_{19}), \quad (III)$$

respectively, when cyclopropane is photolysed with no additives. On the other hand, with excess hydrogen, we have

$$Y(C_2H_4) = (C_2H_4) + (C_3H_8) + 2(n\text{-}C_4H_{10}) + 0.36(1\text{-}C_4H_8), \quad (IV)$$

and

$$Y(CH_2) = (CH_4) + 2\{(C_2H_6) - 0.48(1\text{-}C_4H_8)\} + (C_3H_6) + (C_3H_8) - (\phi_{13}+\phi_{18}+\phi_{19}). \quad (V)$$

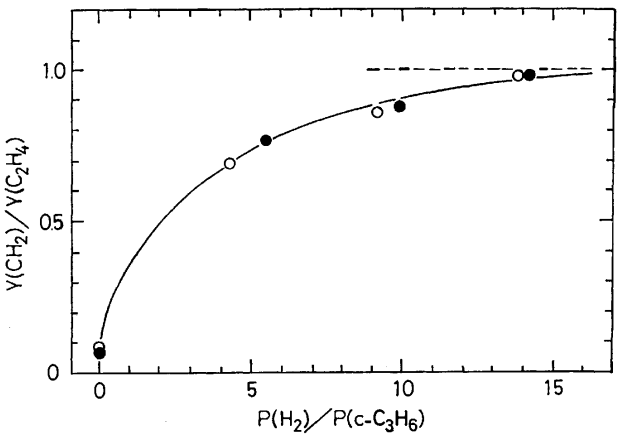

Fig. 4. $Y(CH_2)/Y(C_2H_4)$ as a function of $P(H_2)/P$ (cyclo-C_3H_6) in the photolysis of cyclopropane with an excess of hydrogen:
●, 1470 Å photolysis; ○, 1634 Å photolysis. The pressure of cyclopropane, P(cyclo-C_3H_6), was kept at 21 Torr.

The ratios of $Y(CH_2)$ to $Y(C_2H_4)$ are plotted *vs.* the ratio of $P(H_2)$ to P(cyclo-C_3H_6) in Fig. 4, where $P(H_2)$ and P(cyclo-C_3H_6) are the pressure of hydrogen and cyclopropane, respectively. We see that the ratio of $Y(CH_2)$ to $Y(C_2H_4)$ is asymptotic to unity at high pressure of hydrogen. This implies that the yield of products resulting from methylene becomes almost equal to that from ethylene in the presence of excess hydrogen. Thus, it can be shown that Reaction (1) is the main primary process and that the same amounts of methylene and ethylene are surely produced.

The Crystal and Molecular Structure of the *p*-Bromobenzoate of Sterigmatocystin

Keiichi FUKUYAMA, Tomitake TSUKIHARA, Yukiteru KATSUBE, Nobuo TANAKA,*
Takashi HAMASAKI,** and Yuichi HATSUDA**
Faculty of Engineering, Tottori University, Koyama, Tottori 680
(Received December 23, 1974)

The crystals of the *p*-bromobenzoate of sterigmatocystin, $C_{25}H_{15}O_7Br$, are monoclinic, with the space group of $P2_1$, and with two molecules per unit cell with the dimensions of $a=13.062(7)$, $b=9.029(4)$, $c=8.942(4)$ Å, and $\beta=102.25(5)°$. The structure was refined by a least-squares method to $R=0.055$ for 1292 non-zero reflections. The absolute configuration of the molecule was determined by using the anomalous dispersion effect of the bromine atom. The absolute configuration of the bisdihydrofuran ring agrees with that in aflatoxin B_1.

Sterigmatocystin is one of the carcinogenic metabolites of the mold *Aspergillus versicolor* (Vuillemin) Tiraboschi. A preliminary report on the X-ray structural analysis of the *p*-bromobenzoate of sterigmatocystin has already been published.[1] In the series of studies of the structures of the metabolites of this mold,[1-3] the refinement of the structure and the determination of the absolute configuration of the *p*-bromobenzoate of sterigmatocystin have been undertaken.

Refinement of the Structure

The title compound, $C_{25}H_{15}O_7Br$, was prepared by the method described in the previous paper.[1] The unit-cell constants were remeasured on a Toshiba four-circle diffractometer with Ni-filtered Cu$K\alpha$ radiation ($\lambda=1.5418$ Å). The crystal data are: monoclinic, space group $P2_1$, $a=13.062$ (7), $b=9.029$ (4), $c=8.942$ (4) Å, $\beta=102.25$ (5)°, $V=1030.6$ Å^3, $Z=2$, $M=507.3$, $D_m=1.640$ g·cm^{-3}, $D_x=1.635$ g·cm^{-3}, $\mu=34.4$ cm^{-1}. The structure found in the previous paper[1] was refined by the block-diagonal least-squares procedure using the three-dimensional intensity data obtained by the Weissenberg method. Out of 1580 measured reflections,*** 1292 non-zero reflections were used for the refinement. After several cycles of refinement with individual anisotropic temperature factors, the discrepancy factor (R value) was reduced to 0.065. The difference electron density map at this stage revealed peaks corresponding to fifteen hydrogen atoms. Three cycles of refinement, including hydrogen atoms, brought the R value down to 0.057.

Determination of the Absolute Configuration

In the final stage of the analysis, the absolute configuration of the molecule was determined by using the anomalous scattering of Cu$K\alpha$ radiation by the bromine atom.[4] The structure factors were calculated for the two enantiomorphs with a scattering factor for bromine of the $f_{Br}=f^{\circ}_{Br}+\Delta f_{Br}'+i\Delta f_{Br}''$ form, where $\Delta f_{Br}'=-0.9$ and $\Delta f_{Br}''=1.5$. Sixteen Friedel pairs of reflections strongly affected by the anomalous dispersion effect were selected for accurate intensity measurements. The intensities were obtained by the $\omega-2\theta$ scan technique using Ni-filtered Cu$K\alpha$ radiation on the four-circle diffractometer with a specimen with dimensions of *ca.* $0.07\times0.04\times0.30$ mm^3. The absolute configuration was established by a comparison of the observed and calculated intensities shown in Table 1. Three further cycles of refinement including the anomalous dispersion effect reduced the R value to 0.055 for 1292 non-zero reflections. The unit weight was applied for all the non-zero reflections. The final atomic parameters are shown in Table 2. The absolute configuration is correctly represented by the atomic parameters of Table 2 if a right-handed coordinate system is adopted.

TABLE 1. FRIEDEL PAIRS OF REFLECTIONS USED IN DETERMINING THE ABSOLUTE CONFIGURATION
The right-handed coordinate system is adopted.

k	h	l	$F_c(hkl)$	$F_c(\bar{h}\bar{k}\bar{l})$	$I_o(hkl)$ $I_o(\bar{h}\bar{k}\bar{l})$
5	3	0	108	92	$>$

Description of the Structure and Discussion

The present X-ray analysis has established the absolute configuration of the *p*-bromobenzoate of sterigmatocystin. Figure 1 shows a view of the packing of the molecules in the crystal and the numbering of atoms, while Fig. 2 shows the stereoscopic view of the molecule. Both figures are illustrated with the correct absolute configuration. As has been shown by Holker *et al.*,[7]

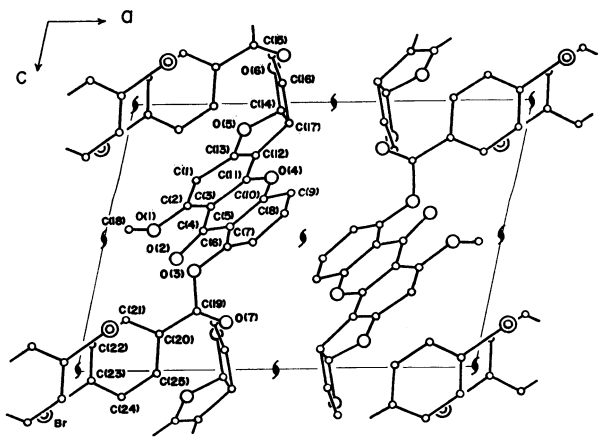

Fig. 1. The crystal structure viewed along the *b* axis and the numbering of atoms. Hydrogen atoms are omitted in the figure.

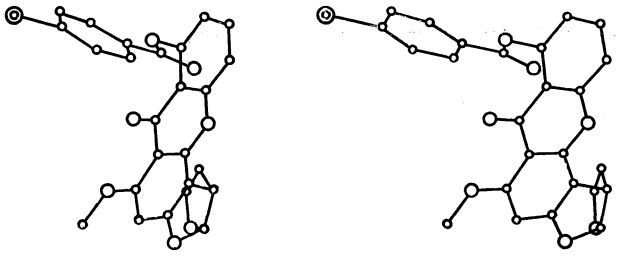

Fig. 2. Stereoscopic view of the molecule.

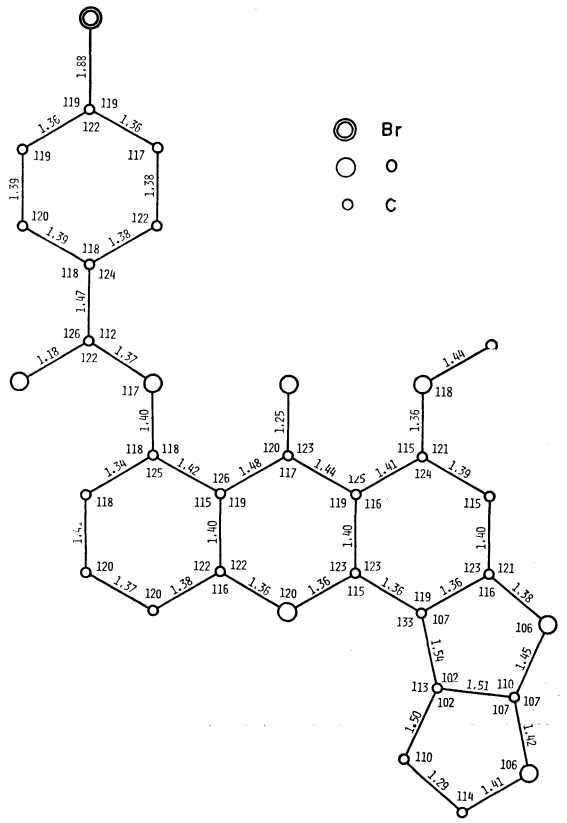

Fig. 3. The bond lengths (Å) and angles (°). The e.s.d.'s of the bond lengths and angles are about 0.02 Å and 1.2 °, respectively.

the absolute configuration of the bisdihydrofuran ring in this compound agrees with that found in aflatoxin B_1.[6] The bond lengths and angles for non-hydrogen atoms are illustrated in Fig. 3. The e.s.d.'s of the bond lengths and the angles for non-hydrogen atoms are about 0.02 Å and 1.2 ° respectively. The bond angles of C(3)–C(4)–C(5), C(9)–C(10)–O(4), and O(4)–C(11)–C(12) are 117 °, 116 °, and 115 ° respectively; these values are smaller than the trigonal sp^2 hybrid angle. On the other hand, the bond angles of C(2)–C(3)–C(4) and C(4)–C(5)–C(6) are larger than 120 °. This structural situation has also been found in the xanthone skeleton in sterigmatin.[3] The dimensions of the bisdihydrofuran ring are close to those in the compounds, such as aflatoxin B_1[6] and sterigmatin,[3] within the limit of experimental error.

The least-squares planes through the xanthone skeleton with O(1) and O(3) atoms, through the terminal five-membered ring, through the benzene ring, and through the C(19), C(20), O(3), and O(7) atoms are represented by the equations;

$$0.580X - 0.370Y + 0.726Z = 4.592 \quad \text{(I)}$$

$$0.973X - 0.055Y - 0.225Z = 4.956 \quad \text{(II)}$$

$$0.405X + 0.831Y + 0.383Z = 4.533 \quad \text{(III)}$$

and

$$0.345X + 0.880Y + 0.325Z = 4.135 \quad \text{(IV)}$$

respectively, where $X=ax+cz\cos\beta$, $Y=by$, and $Z=$

C(20)	O(5)[c]	3.30	C(20)	O(6)[c]	3.49
C(24)	O(5)[c]	3.53	C(25)	O(5)[c]	3.24
O(3)	O(6)[c]	3.39	C(25)	C(10)[d]	3.54
C(25)	O(4)[d]	3.50	O(1)	C(15)[d]	3.59
O(2)	C(15)[d]	3.43	O(7)	C(16)[d]	3.32
C(7)	C(1)[e]	3.52	C(8)	C(13)[e]	3.58
C(8)	O(5)[e]	3.42	C(7)	O(4)[f]	3.43
C(8)	C(10)[f]	3.58	C(8)	O(4)[f]	3.40
C(17)	O(7)[g]	3.25	C(18)	O(2)[h]	3.37
O(1)	C(21)[h]	3.48			

The superscripts refer to the following positions relative to the reference molecule at x,y,z; a) $-x,1/2+y,1-z$. b) $-x,1/2+y,2-z$. c) $x,1+y,1+z$. d) $x,y,1+z$. e) $x,1+y,z$. f) $1-x,1/2+y,1-z$. g) $1-x,-1/2+y,1-z$. h) $-x,-1/2+y,1-z$.

$cz \sin\beta$. Table 3 shows the deviations of the atoms from these planes and the dihedral angles between these planes. The dihedral angle between the I and II planes is 65.1 °; this value is close to the corresponding angle found in aflatoxin B_1.[6] The deviations of the atoms from the plane of the xanthone skeleton in this compound are large in comparison with those in sterigmatin;[3] the xanthone skeleton bends slightly about the O(2)–O(4) axis. The intermolecular distances for non-hydrogen atoms of less than 3.6 Å are listed in Table 4, which indicates that there is no abnormally short contact.

The authors wish to thank Professor Tamaichi Ashida of Nagoya University for his permission to use the block-diagonal least-squares program.

Molecular Structure of 2-Fluoropropane as Determined By Gas Electron Diffraction

Hironobu KAKUBARI,* Takao IIJIMA, and Masao KIMURA**
Department of Chemistry, Faculty of Sciences, Hokkaido University, Sapporo 060
(Received December 23, 1974)

The skeletal parameters, C–C, C–F, and C···F distances, of 2-fluoropropane have been determined by means of gas electron diffraction. The r_g-values obtained are: C–C 1.514±0.004 Å, C–F 1.405±0.005 Å and C···F 2.366 ±0.006 Å.*** By a joint analysis of the diffraction data and the spectroscopic moments of inertia, determination of the remaining structural parameters has also been attempted, and the ϕ_z value of the CCC angle being found to be 114.6±1.5 °.

It is well-known that systematic elongations of both C–C and C–Cl distances are observed in the series of chloroalkanes, *viz.*, from methyl to ethyl to isopropyl to *t*-butyl chlorides.[1-3] In the corresponding series of fluorides,[4] however, the structure of isopropyl fluoride, or 2-fluoropropane, was not determined until recently. The microwave spectrum of this molecule was observed by Griffiths, Owen, and Sheridan, and the rotational constants were obtained.[5] However, they did not determine the structural parameters since their spectrum was only for the normal species. Saito and co-workers measured the microwave spectra of the normal and six isotopic species and found a reasonable set of the r_0-structure.[6]

The molecule is unfavorable for determining the structure from spectroscopic data, because the central carbon is close to the center of gravity and there is no stable isotope for fluorine. The C–C and C–F distances are especially difficult to determine accurately. Such being the case, it is desirable to obtain information on the skeletal structure by means of gas electron diffraction to complement the spectroscopic r_0-structure.

In the present diffraction study, the C–C and C–F bonded distances and the C···F non-bonded distance were determined. Furthermore, by a joint analysis of the diffraction and spectroscopic data, determination of the complete structure of this molecule was attempted.

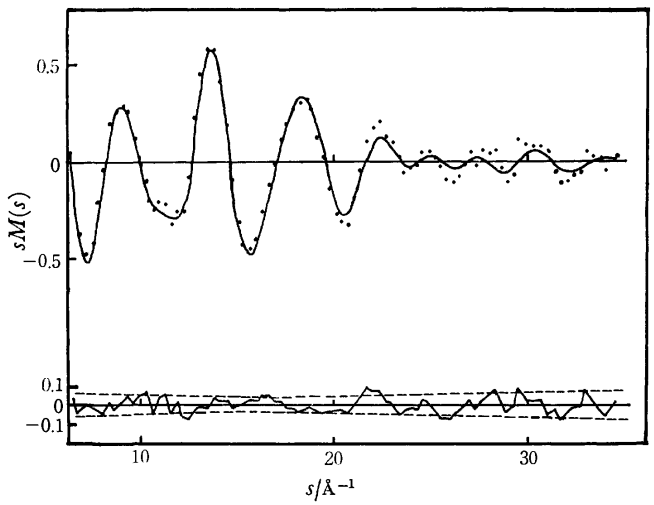

Fig. 1. Molecular intensity curve of 2-fluoropropane. Experimental values (dots) are compared with the best-fit theoretical (solid curve). The residuals are shown below, where the broken curves represent the estimated uncertainty in the intensity measurement.

Experimental

The sample was synthesized by Dr. Shuji Saito, Sagami Chemical Research Center, the purity being checked by him to be about 99.5% by gas-chromatography. The diffraction photographs were taken at room temperature by a unit with an r^3-sector[7] under the following conditions: camera length, 109.3 mm; accelerating voltage, 40 kV; beam current, 0.2 μA; exposure time, 2—4 min; sample pressure, 50—20 Torr. The scale factor was calibrated by the diffraction pattern of carbon disulfide. The total range of s covered was from 7 to 36 Å^{-1}. Five plates were selected for the least square analysis. The observed reduced molecular intensity is shown in Fig. 1, together with the calculated intensity for the best-fit model.[8]

Analysis of the Diffraction Data

The skeletal parameters, C–C, C–F, and C···F distances, were determined by a least square adjustment for molecular intensity. Routine procedure[9,10] was followed for scattering factors, anharmonicity constants and other details of the analytical processes. The final results obtained from the analysis of five plates are given in Table 1. Other structural parameters were fixed

Table 1. Results of the least square analysis of the diffraction data for 2-fluoropropane[a]

Adjusted parameters		Fixed parameters[b]	
r_g(C–F)	1.405(5)	r_a(C···C)	2.535
r_g(C–C)	1.514(4)	r_a(C–H_{Methyl})	1.091
r_g(C···F)	2.366(6)	r_a(C–H_{sec})	1.096
index of resolution	0.97—1.05	ϕ_α(CCH_{sec})	109.2
		ϕ_α(HCH_{Methyl})	107.7

a) Distances in Å and angles in degrees. The numbers in parentheses indicate the limits of error attached to the last significant digit. For the definitions of r_g, r_a and ϕ_α see Ref. 11. b) Those non-bonded distances not shown in the Table were computed by use of the parameters listed here. The local C_{3v} symmetry of the methyl groups is assumed. The C–H bonds which lie on the CCC plane are in the *trans* position to the C–C bond.

*** 1 Å=100 pm is used throughout this paper.

to appropriately assumed values, also listed in Table 1. Most of the assumed values were taken from the r_s-structure of propane.[12] These values were eventually replaced by those obtained by a joint analysis of the diffraction results and the spectroscopic moments of inertia, given in Table 4, and the least square calculation was repeated for the molecular intensity of a plate or two. The most probable values of the adjusted parameters did not vary significantly.

The mean amplitudes of vibration were also fixed to the calculated values. The force constants were adjusted by the method of Cyvin and Cyvin[13] so as to reproduce the fundamental frequencies observed by Griffiths, Owen and Sheridan[5] and Crowder and Koger.[14] The method is an iterative process based on the relation, $\boldsymbol{F}=\tilde{\boldsymbol{L}}_0^{-1}\boldsymbol{\Lambda}\boldsymbol{L}_0^{-1}$, where $\boldsymbol{L}_0$ is the transformation matrix obtained from a trial set of the force constants, $\boldsymbol{\Lambda}$ is the eigenvalue matrix of the observed values and $\boldsymbol{F}$ is the improved force-constant matrix. The calculation is iteratively repeated until the calculated eigenvalues converge exactly to the observed values. The force constants thus obtained are still approximate, since the set can only be one of the many possible sets which could reproduce the observed vibrational frequencies. However, it is considered to be sufficient for evaluating mean amplitudes as long as the initial trial set is properly chosen.

Table 2. Calculated values of the mean amplitudes of vibration at 298 K (in Å units)

C–F	0.0540	H···H	0.13—0.26[a]
C–C	0.0562	C···H	0.11—0.16
C···F	0.0814	F···H	0.11—0.16
C–H	0.0784		

a) The range indicates the distribution of the calculated values among the non-equivalent non-bonded distances.

The set of force constants of 2-chloropropane determined by Cyvin and Cyvin[13] was used as the initial trial, where the diagonal constant for the C–F stretching of CH_3F,[15] 3.135 mdyn/Å, was used. The mean amplitudes at 298 K thus calculated are listed in Table 2.

Joint Analysis of the Diffraction Results and the Spectroscopic Rotational Constants

Determination of the structural parameters which were not obtained by analysis of the diffraction data was carried out by means of a joint analysis of the diffraction intensity and the rotational constants on the basis of the zero-point average structure. The vibrational corrections for both r_g-distances and rotational constants were carried out by the ordinary method.[16] All the normal modes including the torsional motion of the methyl tops were treated as small-amplitude motions, since the barrier to internal rotation as high as 3.0—3.5 kcal/mol[5] makes it unnecessary to rely on the large-amplitude theory for the vibrational correction.[17,18] The moments of inertia and the calculated values of the vibrational correction are listed in Table 3. The values of r_g—r_α^0 are 0.0029 Å, 0.0024 Å, and 0.0007 Å for C–F, C–C, and C···F distances, respectively.

Table 3. Moments of inertia of 2-fluoropropane[a] (in amu Å² units)

	$I^{(0)}$	ΔI	$I^{(z)}$
a	58.131	0.065	58.196(7)[b]
b	62.373	0.091	62.464(9)
c	105.533	0.064	105.597(7)

a) $I^{(0)}$; Observed effective values for the ground vibrational state (Refs. 5 and 6). Conversion factor 505376 MHz amu Å² was used. ΔI; Calculated values of the vibrational correction. $I^{(z)}$; Moments of inertia for the zero-point average structure.
b) Estimated uncertainties to be attached to the last significant digit.

Table 4. Structure parameters of 2-fluoropropane compatible with both the diffraction data and the spectroscopic moments of inertia[a]

C–F	r_g	1.405±0.005
C–C	r_g	1.514±0.004
C···F	r_g	2.366±0.006
∠CCC	ϕ_z	114.6±1.5
$C–H_{Methyl}$ $C–H_{sec}$	r_g	1.13±0.03[b]
$\angle HCH_{Methyl}$	ϕ_z	110±3
$\angle CCH_{sec}$	ϕ_z	109.0 (assumed)

a) Distances in Å and angles in degrees. b) The values of $r_g-r_\alpha^0$ for $C–H_{Methyl}$ and $C–H_{sec}$ are 0.020 Å and 0.016 Å, respectively.

For a complete description of the structure of this molecule, eight independent parameters given in Table 4 are necessary. Three distances from electron diffraction and three moments of inertia from microwave spectroscopy are therefore insufficient. Although the rotational constants of ^{13}C-species and singly deuterated species are available,[6] none of them effectively provide independent additional information. The following two assumptions were then made: (1) The $C–H_{Methyl}$ and $C–H_{sec}$ are equivalent in their r_g-values. (2) The CCH_{sec} angle is within the range of 109±2 °. The implication of the first assumption is essentially the same as the equivalence of C-H distances in r_e-values. As for the second assumption, it was found that the moments of inertia $I^{(z)}$ are very insensitive to the CCH_{sec} angle. A variation of CCH_{sec} as much as 2 ° produces changes in $I^{(z)}$ of only about 0.01 amu Å².

Since there remain six parameters for the six independent observables, they can be determined uniquely for each combination of the six observed values which are allowed to vary within their stated uncertainties. Therefore, for the three distances from electron diffraction, the uncertainties can not be reduced by the joint analysis as in other more favorable cases.[17,19] The other three parameters can only be determined with large uncertainties, since they are strongly correlated with the three distances from diffraction. Numerical results are summarized in Table 4. The uncertainties for ∠CCC, C–H, and ∠HCH represent the maxima and minima of the ranges of these parameters in which the values compatible with the moments of inertia are

found, as the C–F, C–C, and C···F distances are varied within the stated limits of error. The uncertainties associated with the limits of error of $I^{(z)}$ are much smaller. The CCC angle is determined with a reasonable range of uncertainty. The C–H distance and the HCH angle shown in Table 4 are larger than the commonly accepted range of methyl structure. Nevertheless, both C–H and HCH would decrease if the C···F distance decreases. This seems to suggest that the anharmonicity of the non-bonded C···F distances, which was assumed negligible in the present study, is substantially nonzero.

Discussion

The C–C and C–F distances of 2-fluoropropane are compared with those of other fluoroalkanes in Table 5. Although the comparison is somewhat obscured by lack of the r_g-distances for some of the compounds concerned, the trends that both C–C and C–F distances increase from methyl to ethyl, isopropyl, and *t*-butyl are observed in the same way as in the chlorides. The C–C distances of fluorides are smaller than those of *n*-alkanes, *e.g.*, propane.[10] The shortening seems to be similar in nature to that often encountered in fluorine substitution.[23]

TABLE 5. COMPARISON OF THE STRUCTURAL PARAMETERS OF FLUORO-ALKANES (IN Å UNITS)

		C–C	C–F	Ref.
CH_3F	r_0		1.3852(1)	20
CH_3CH_2F	r_0	1.505(3)	1.398(5)	4
$(CH_3)_2CHF$	r_0	1.515(1)	1.407(2)	6
	r_g	1.514(4)	1.405(5)	a)
$(CH_3)_3CF$	r_0	1.516(5)	1.43(2)	21
	r_g	1.522(8)	1.427(8)	22[b]
$(CH_3)_2CH_2$	r_g	1.532(3)		10

a) The present study. b) Estimated from the reported r_a-values, 1.520 and 1.425, respectively.

The r_0-structure reported by Saito and co-workers[6] is consistent with the r_g-structure determined in the present study. However, since the difference between r_0 and r_g values is often as large as 0.01 Å, the closeness of r_0 and r_g seen in Table 5 can be fortuitous.

The authors wish to thank Dr. Shuji Saito, Sagami Chemical Research Center, for the sample and for his helpful discussions. Numerical computation was performed on a FACOM 230-60 of the Hokkaido University Computing Center and also on a FACOM 270-20 in the laboratory of Professor Kimio Ohno, to whom the authors' thanks are due.

Theoretical Determination of the Principal Axes of ^{13}C Chemical Shielding Tensors and their Relationship to the Anisotropies in Some Organic Compounds

Isao ANDO, Atsuo NISHIOKA, and Masahiro KONDO

Department of Polymer Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received January 27, 1975)

The principal axes and values for the ^{13}C chemical shielding tensors of carbonyl compounds (formaldehyde, acetaldehyde, acetone, and formic acid), methanol, and *n*-paraffins (propane and *n*-butane) have been determined theoretically by the LCGI-MO theory using the MINDO/2 method. Further, their anisotropies have been estimated. These results have then been discussed by comparing them with the observation of Pines *et al.* and in part compared with the anisotropies in the literature calculated by using other theoretical methods.

The chemical shielding constant of a molecule in NMR is a symmetric second-rank tensor quantity with nine components. In gases and liquids one can observe only the isotropic value of the chemical shielding tensor, that is, the average of the three diagonal components resulting from the rapid molecular reorientation. On the other hand, in solid states the molecular motion is greatly reduced. Thus, in principle, it is possible to determine the six independent components of the tensor; in practice, however, it is normally difficult. To know the full tensor would be extremely valuable for, especially, the theoretical study of the chemical shielding constant. In the last several years significant progress has been achieved in experimental techniques and also in the calculation of the ^{13}C chemical shift.[1] The present authors[2] recently concerned themselves with a theoretical study of the anisotropy of the ^{13}C chemical shielding constant in several organic compounds in order to interpret the experimental data measured by Pines *et al.*[3] Although it is very important to know the exact directions of the principal axes of the ^{13}C shielding tensor for each carbon atom in any molecule, we have not enough information about them at present.

Recently Waugh *et al.*[4] and others[5] have determined experimentally the relative orientation of the principal axes of the ^{13}C shielding tensors using single crystals of several organic compounds, and have shown that such information is more easily obtained from NMR than from X-ray diffraction. In this work we will be concerned with the theoretical determination of the principal axes of the ^{13}C shielding tensors and their relations to the shielding tensor in several compounds, such as formaldehyde, acetaldehyde, acetone, formic acid, methanol, propane, and *n*-butane(*n*-paraffins are known to be planar in the solid state).

There are two theoretical approaches to the determination of the principal axes and values. In one, the six independent shielding elements of the tensor are calculated, the principal values are obtained by diagonalizing the complete tensor, and then, from these, the corresponding axes are determined. In the other, the dependence of the diagonal elements of the tensor on the rotation of the coordinate system chosen is calculated, and then, from this, the principal axes and the principal values are determined. In this work the latter method was used because of its simplicity and its applicability to our case.

Theoretical

The shielding tensor, $\boldsymbol{\sigma}'$, is expressed as follows:

$$\sigma' = \begin{pmatrix} \sigma'_{xx} & \sigma'_{yx} & \sigma'_{zx} \\ \sigma'_{xy} & \sigma'_{yy} & \sigma'_{zy} \\ \sigma'_{xz} & \sigma'_{yz} & \sigma'_{zz} \end{pmatrix} \quad (1)$$

The value of each element in the shielding tensor depends upon the coordinate system chosen in any specific molecule. Therefore, in order to determine the principal axes and values, the dependence of the values of the diagonal terms upon the rotation of the coordinate system chosen must be known.

Now, a coordinate system, $\mathbf{X}$ (x,y,z) for the inherent principal axes is defined for $\boldsymbol{\sigma}$ (diagonalized shielding tensor). The transformation of an arbitrary coordinate system, $\mathbf{X}'$ (x',y',z'), into the coordinate system, $\mathbf{X}$-(x,y,z), by rotation is as follows:

$$\mathbf{X} = \mathbf{T}\cdot\mathbf{X}' \quad (2)$$

where $\mathbf{T}$ is the transformation matrix. All the molecules concerned are planar. Thus, one of the three principal axes is along the direction perpendicular to the molecular plane due to their symmetry; this axis is defined as the z axis. The rotation of the right-handed coordinate system is about the z axis. Thus, $\mathbf{T}$ is defined as:

$$\mathbf{T} = \begin{pmatrix} \cos\theta & -\sin\theta & 0 \\ \sin\theta & \cos\theta & 0 \\ 0 & 0 & 1 \end{pmatrix} \quad (3)$$

The coordinate system rotates counterclockwise about the z axis. As $\mathbf{T}$ is an unitary matrix, the inverse matrix, $\mathbf{T}^{-1}$, is identical to the transposed matrix, $\tilde{\mathbf{T}}$. From the character of a tensor, we can write the following relation by choosing an appropriate value of θ:

$$\begin{aligned} \sigma &= \mathbf{T}^{-1}\cdot\sigma'\cdot\mathbf{T} \\ &= \tilde{\mathbf{T}}\cdot\sigma'\cdot\mathbf{T} \end{aligned} \quad (4)$$

Then, as $\tilde{\mathbf{T}}\cdot\mathbf{T}=\mathbf{E}$ ($\mathbf{E}$: unit matrix),

$$\sigma' = \mathbf{T}\cdot\sigma\cdot\tilde{\mathbf{T}} \quad (5)$$

As has been described above, one of the three principal axes is the z axis perpendicular to the molecular plane. In obtaining the remaining principal axes, we first calculate the angle (relative to the principal axes) at which the value of σ'_{xx} and σ'_{yy} are equal to each other:

$$\sigma'_{xx} = \sigma'_{yy} \quad (6\text{-}1)$$

then

$$\sigma_{xx} + (\sigma_{yy}-\sigma_{xx})\sin^2\theta = \sigma_{yy} - (\sigma_{yy}-\sigma_{xx})\sin^2\theta \quad (6\text{-}2)$$

$$(\sigma_{yy}-\sigma_{xx})(2\sin^2\theta-1) = 0 \quad (6\text{-}3)$$

From this equation, the value of θ is found to be 45 degrees when $\sigma_{yy}\neq\sigma_{xx}$. This result may be true only in this case. Therefore, the position where $\sigma'_{xx}=\sigma'_{yy}$ is found to deviate by 45 degrees from the principal axis. This shows that, in the principal axis systems, the values of σ'_{xx} and σ'_{yy} take the maximum or minimum value. Thus, we can find the principal axes and values by calculating the dependence of the values of σ'_{xx}, σ'_{yy} and σ'_{zz} upon the rotation of the coordinate system chosen.

The paramagnetic term governing predominatly the ^{13}C chemical shielding constant is estimated using the LCGI-MO theory of Pople[6] according to a previous paper[2] as follows (*e.g.*, σ'^{p}_{xx}):

$$\sigma'^{p}_{xx} = -(2e^2\hbar^2/m^2c^2)\langle r^{-3}\rangle_{2p}\sum_{i}^{occ}\sum_{k(\neq i)}^{unocc}\Delta E_{k-i}^{-1} \times (C_{iy_A}C_{kz_A}-C_{iz_A}C_{ky_A})\sum_{B}(C_{iy_B}C_{kz_B}-C_{iz_B}C_{ky_B}) \quad (7)$$

where C_{ix_A} is the coefficient of the $2p_x$ atomic orbital on the A atom of the i-th molecular orbital in the LCAO MO theory, where $\sum_{i}^{occ}$ and $\sum_{k(\neq i)}^{unocc}$ are the summations over occupied and unoccupied orbitals, respectively, where $\sum_{B}$ runs over all the atoms in the molecule, and where ΔE_{k-i} is the singlet-singlet excitation energy between the i-th occupied and the k-th unoccupied orbitals. $\langle r^{-3}\rangle_{2p}$ represents the atomic 2p orbital dimension given by:[7]

$$\langle r^{-3}\rangle_{2p} = 34.33a_0^{-3}(1-0.323q_A')/24 \quad (8)$$

where a_0 is the Bohr radius and where $-q_A'e$ is the net charge. The MINDO/2 method[8] was used as the molecular orbital method.

The bond lengths and bond angles used were as follows:[9] Bond length (the notation of Xn is used for an atom, X, with an elemental symbol being bonded to n neighbours. For example, the carbon atoms in propane and formaldehyde will be described as C4 and C3, respectively):

$l_{C4-H}=1.09$, $l_{C3-H}=1.08$, $l_{C4-C4}=1.54$,
$l_{C4-C3}=1.52$, $l_{C3-O1}=1.22$, $l_{C4-O2}=1.43$,
$l_{C3-O2}=1.36$, $l_{O2-H}=0.96$ (Å)

Bond angle:

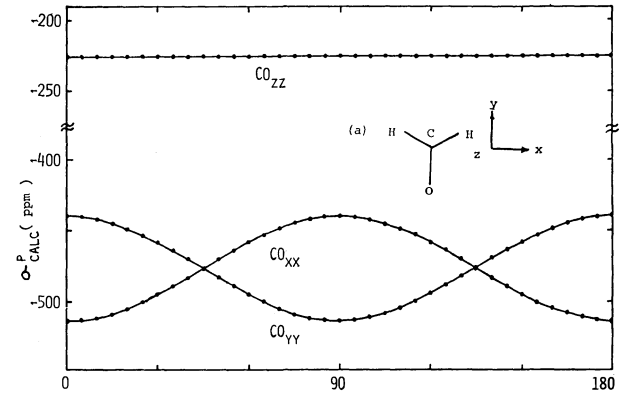
$$\angle C\text{-}C\text{-}C=\angle C\text{-}C\text{-}H=\angle H\text{-}C\text{-}H=\angle H\text{-}O\text{-}C=\angle O\text{-}C\text{-}H=109°28'$$

$$\angle C\text{-}C\text{=}O=\angle H\text{-}C\text{=}O=\angle O\text{-}C\text{=}O=120°$$

All the calculations were carried out by means of the HITAC-8800 computer of the Computer Center of the University of Tokyo.

Results and Discussion

The calculated dependences of the σ'^{p}_{xx}, σ'^{p}_{yy}, and σ'^{p}_{zz} of the molecules concerned here upon the rotation of the coordinate system chosen are shown in Fig. 1, where the coordinate system of each carbon rotates



Angle of rotation about z axis (Degrees)

Fig. 1. Dependence of the calculated ^{13}C shielding tensor components σ^P_{calc} upon the rotation of the coordinate system for (a) formaldehyde, (b) acetaldehyde, (c) acetone, (d) formic acid, (e) methanol, (f) propane, (g) *n*-butane. For example, CH_{3xx} denotes the xx component of the shielding tensor for the methyl carbon.

counterclockwise from the position shown in the figure; the interval of the plots of the calculated value is 5 degrees, and the conformations of *n*-paraffins are taken as of the *trans* zig-zag form.

Let us first discuss the position of the principal axes by dividing the compounds concerned into two groups, carbonyl compounds and methanol, and *n*-paraffins. In the former group, if the carbonyl carbon is involved, we can expect that one of the principal axes in formaldehyde and acetone is along the C=O bond axis, as is predicted by the molecular symmetry, but the axes for acetaldehyde and formic acid are not always along the C=O bond axis (*cf.* Fig. 1). As for acetaldehyde and formic acid, the corresponding axes deviate by 20 degrees clockwise and by 8 degrees counterclockwise from the C=O bond axis, as is shown in the figure. Therefore, the axis of the former is oriented approximately along the direction bisecting the O–C–C angle, and the deviation of the latter from the C=O bond axis is very slight, contrary to expectations. These results show that the influence of the OH group neighbouring the carbonyl carbon on the position of the principal axes concerned is smaller than that of the CH_3 group. As for the methyl groups of acetaldehyde, acetone, and methanol, it is found that the principal axis corresponding to the C_{3v} axis of the CH_3 group is oriented at the positions of 25 degrees counterclockwise, 30 degrees counterclockwise, and 6 degrees clockwise respectively from the fixed coordinate system defined in the figure; therefore, these corresponding principal axes are found to deviate by 5 degrees clockwise, and about 0 degree and 6 degrees clockwise respectively from the C_{3v} axis of the CH_3 group. In these compounds, one of the principal axes is found to be oriented approximately along the C_{3v} axis, although this axis, speaking strictly, deviates slightly from the C_{3v} axis.

Next, let us discuss the *n*-paraffins. As for the methyl carbons of propane and *n*-butane, it is found that their principal axes corresponding to the above-mentioned axis deviate by 35 and 30 degrees counterclockwise respectively from the fixed coordinate system; therefore, these principal axes are found to deviate by 16 and 10.5 degrees respectively from the C_{3v} axis of the CH_3 group. The deviation of the former is slightly larger than that of the latter. This may be due to the difference between the CH_3 and CH_2 groups in its next nearest-neighbour group. However, it may still be said that these axes are oriented approximately along the C_{3v} axis. As for the CH_3 groups of these molecules, one of the principal axes is found to deviate by 54.7 and 62 degrees counterclockwise respectively from the fixed coordinate system; therefore, in propane this axis bisects the angle formed by the directions of the CH_3–CH_2 and CH_2–CH_3 bonds, and in *n*-butane it deviates slightly by 7.3 degrees

counterclockwise from the corresponding axis, probably because of the symmetry.

Next, let us discuss the principal values and the anisotropies of the shielding constants of the compounds concerned. Here, for convenience, we will define the principal values in terms of σ_{11}, σ_{22}, and σ_{33} (the magnitude of shielding is $\sigma_{11} \lesssim \sigma_{22} \lesssim \sigma_{33}$) instead of σ^{p}_{xx}, σ^{p}_{yy}, and

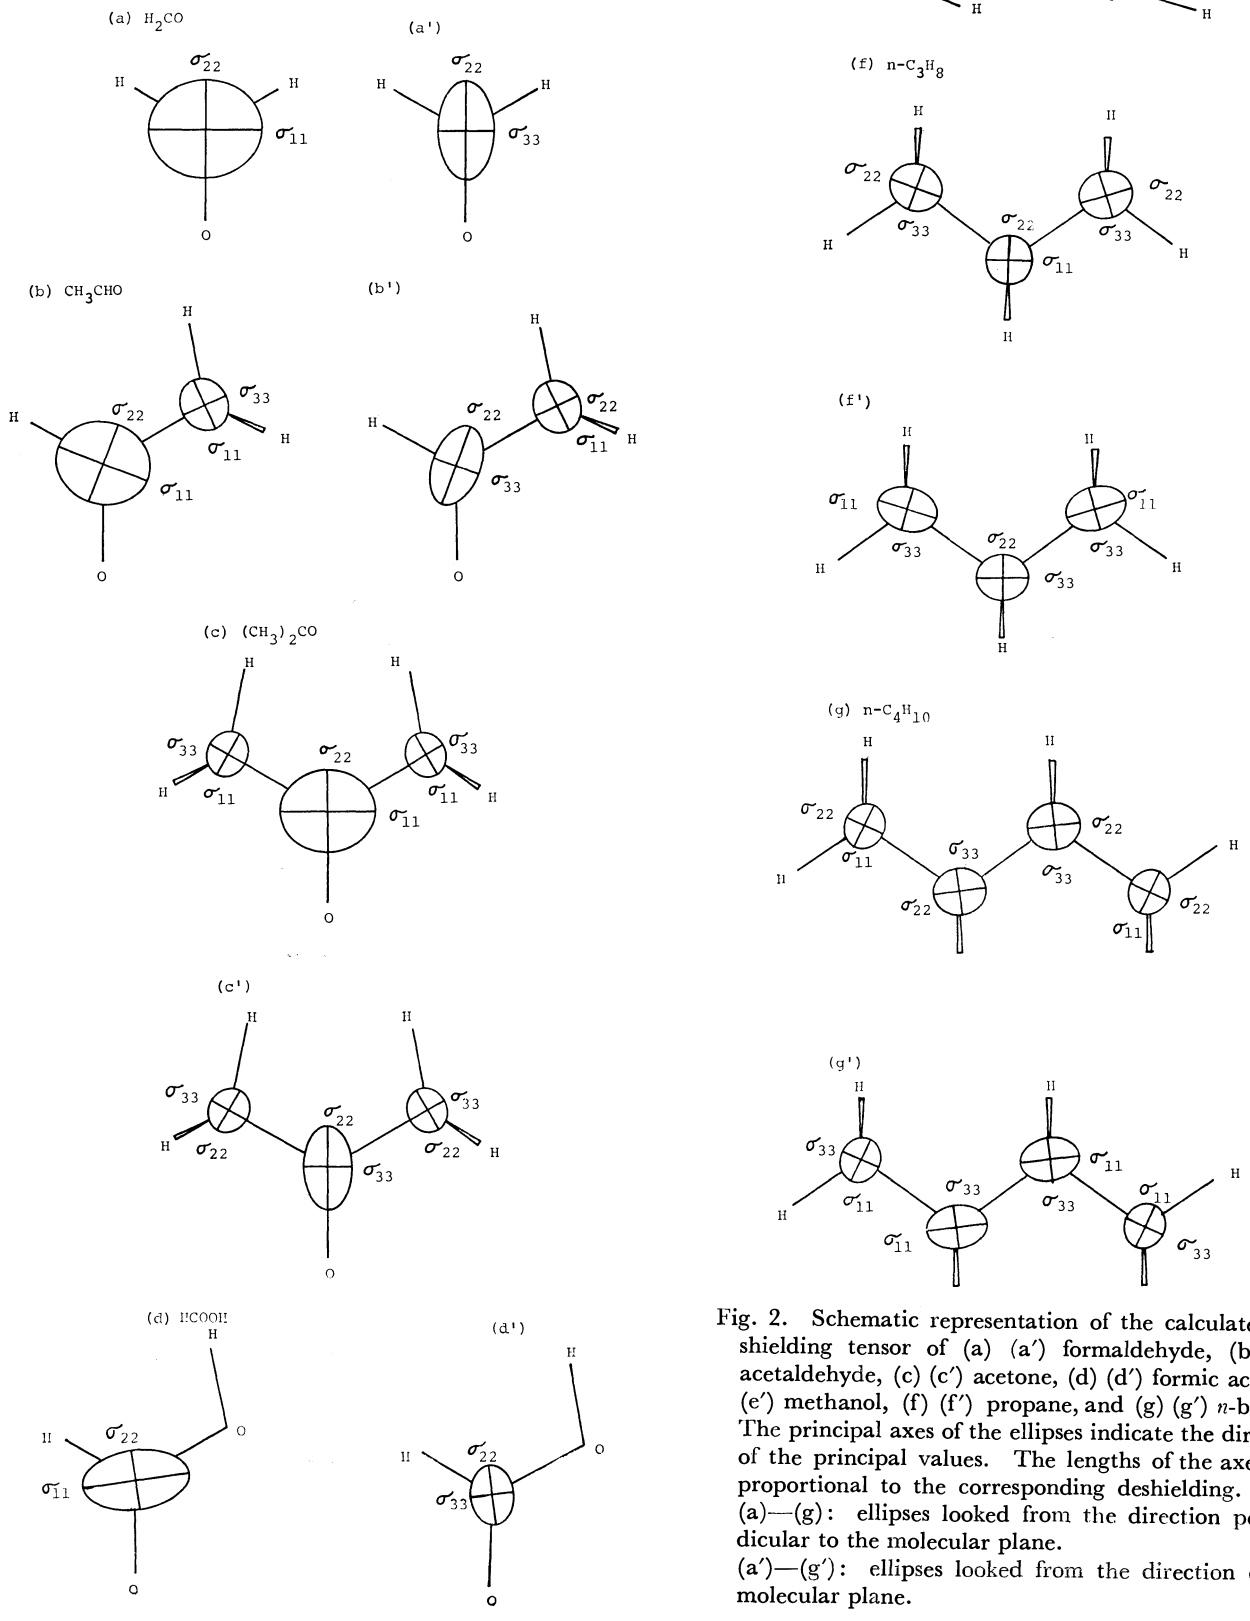

Fig. 2. Schematic representation of the calculated ^{13}C shielding tensor of (a) (a′) formaldehyde, (b) (b′) acetaldehyde, (c) (c′) acetone, (d) (d′) formic acid, (e) (e′) methanol, (f) (f′) propane, and (g) (g′) *n*-butane. The principal axes of the ellipses indicate the direction of the principal values. The lengths of the axes are proportional to the corresponding deshielding.
(a)—(g): ellipses looked from the direction perpendicular to the molecular plane.

a) $\Delta\sigma=\sigma_{33}-(\sigma_{11}+\sigma_{22})/2$ b) Shifts are in ppm relative to benzene liquid.

σ^{p}_{zz}, because the physical meaning for the xx, yy, and zz suffixes sometimes becomes obscure in this case. The calculated results of the principal values and the anisotropies for the compounds concerned are tabulated in Table 1, together with the experimental data in the literature. For further clarification, the principal axes and values are shown by a schematic representation in Fig. 2. In the carbonyl carbons it is found that the principal value of the shielding tensor perpendicular to the molecular plane is the largest one, that the order of the magnitude of their anisotropies ($\Delta\sigma=\sigma_{33}-(\sigma_{11}+\sigma_{22})/2$) is $\overset{H}{H}\!>\!C{=}O > \overset{CH_3}{H}\!>\!C{=}O > \overset{CH_3}{CH_3}\!>\!C{=}O > \overset{H}{HO}\!>\!C{=}O$, and that the magnitude of $\Delta\sigma$ is sensitive to the substituents. As for the methyl carbons in all the compounds concerned the axis of the most shielding component is found to be oriented approximately along the C_{3v} axis except for CH_3OH (*cf.* Fig. 2).

Next, we will discuss the individual compounds separately. As for the anisotropy of formaldehyde, Appleman *et al.*[1] and Tokuhiro *et al.*[10] have reported values of 250.8 and 294.9 ppm respectively, calculated using the *ab initio* method. Our results agree well with the former. For acetaldehyde, the value of the carbonyl carbon in this work increases slightly compared with the previous case[2b] ($\Delta\sigma=192.8$ ppm); one of the principal axes is assumed to lie on the C=O bond and is very much smaller than the value of 280 ppm calculated by Appleman *et al.*[1] On the other hand, for the methyl carbon our value is larger than their value of 2.9 ppm. The experimental values of Pines *et al.*[3] are found to agree with our results. As for acetone, the value of the methyl carbon in this work increases compared to the previous case;[2a] one of the principal axes is assumed to lie on the C=O bond.[11] The value in this work is found to be consistent with the experimental value.[3] As for formic acid, the value in this work is smaller than that of 198.4 ppm calculated by Appleman *et al.*[1] In general, their calculated results are larger than our results for carbonyl carbons. As for methanol, the calculated value is somewhat smaller than the experimental data. One of the reasons for this discrepancy may be that it partly arises from the neglect of the hydrogen bonding among the molecules. Further, it should be noted that the most shielded component is not along the C_{3v} axis, but along the direction perpendicular to the fixed molecular plane, contrary to the results for the other methyl groups. As for *n*-paraffins, the value of $\Delta\sigma$ for the methylene carbon in propane is found to be larger than that in *n*-butane. This may be because in the former the neighbouring groups are the methyl groups, while in the latter they are the methyl and methylene groups. The value of $\Delta\sigma$ is found to be very sensitive to the environment of the specified carbon. As for the methyl carbons, it is found that there is a slight difference between the values of $\Delta\sigma$ in the two paraffins; this must also be due to the above-mentioned reason. The observation of these molecules has not yet been done; after it has, we hope to measure $\Delta\sigma$ to get important information for the study of the molecular motion in a solid.

(Received May 8, 1974)

The present work was conducted to investigate the electroreduction of anions (typically $S_2O_8^{2-}$ and BrO_3^-) under the influence of the adsorption of polymers (polyethyleneglycol, alkylphenoxy polyethoxy ethanols and polyvinylpyrrolidone) on the electrode surface. The limiting current of $S_2O_8^{2-}$ reduction was depressed by the polymers in the region from nearly the zero-charge potential to the more negative potential. The half-wave potential of BrO_3^- reduction shifted towards more negative potential by adding the polymers. In the potential range where the cathodic current was mainly controlled by mass transfer of the anions, the time (t_m) needed to complete the formation of a monolayer was obtainable conveniently from the instantaneous current *vs.* time ($I-t$) curve as reported previously for the inhibited reduction of Cd^{2+} or Cu^{2+}.[2,3,8] In the potential range where the current was mainly controlled by charge transfer, an exact determination of t_m, by which the maximum surface concentration of polymer was given, was possible only when the instantaneous current density (i) was plotted against $t^{1/2}$. In such a potential range, i was expressed as follows.

$$i = i_0 - (i_0 - i_1)(t/t_m)^{1/2} \quad \text{for } t \leqslant t_m$$

or

$$i = i_1 \quad \text{for } t > t_m$$

Moreover,

$$\bar{I}_{ads}/\bar{I}_0 = 1 - \frac{10}{13}\frac{i_0 - i_1}{i_0}(t_d/t_m)^{1/2} \quad \text{for } t_d \leqslant t_m$$

$$\bar{I}_{ads}/\bar{I}_0 = 1 - \frac{10}{13}\frac{i_0 - i_1}{i_0} - \frac{3}{13}\frac{i_0 - i_1}{i_0}\{1 - (t_d/t_m)^{-5/3}\} \quad \text{for } t_d > t_m$$

where i_0 and i_1 are the instantaneous current densities at $\theta=0$ and 1, $\bar{I}_{ads}$ and $\bar{I}_0$ the polarographic currents with and without polymers, t_d the drop time, t_m the time required to attain the saturated adsorption. The relationship between the shift of half-wave potential and $(t_d/t_m)^{1/2}$ (for $t_d \leqslant t_m$) or $(t_d/t_m)^{-5/3}$ (for $t_d > t_m$), was introduced and the results were verified for the inhibition effects of polymer on the electroreduction of BrO_3^- as well as for that on VO^{2+} reduction.

The adsorption of polymers at the mercury/solution interface has been investigated by differential capacity measurements,[1] and it was found that the adsorption is mainly controlled by diffusion process at the initial stage. The inhibition due to an adsorbed polymer on the electroreduction of Cd^{2+} or Cu^{2+} scarcely took place until the attainment of a certain high coverage when the sharp increase of inhibition occured. Such inhibition effects might be characterized by the diffusion process of depolarizer.[2,3]

The present paper is mainly concerned with the inhibition effects of polymer on the electroreduction of some anions, which will be compared with those on Cd^{2+} reduction. The process of electroreduction of anion is characterized by the interference owing to the influence of electric field in the double layer on the reacting entities, and the interference arises markedly in a dilute supporting electrolyte solution.[4] In consideration of polyvalent anions including $S_2O_8^{2-}$, $Fe(CN)_6^{3-}$, and $PtCl_4^{2-}$ or monovalent anions such as BrO_3^-, NO_3^-, and IO_3^- under the double layer effects,[5] the electroreduction of $S_2O_8^{2-}$ [4,6] and BrO_3^- [7] will be investigated typically.

Experimental

A DME (dropping mercury electrode) was used as the test electrode. All the potentials were referred to a saturated calomel electrode (SCE). A Yanagimoto P-8 Type Polarograph with three electrodes system was used for the measurements of current-potential curves. The instantaneous current *vs.* time curves were determined from the iR drop observed with a recorder or an oscilloscope in parallel with 2 kΩ resistance which was connected in series with the DME and the polarization circuit. Water-soluble polymers PVP (BASF), PEG (Sanyo Chemical Industry), and Triton X (Rohm and Haas) were used without further purification. The depolarizers were reagent-grade $CdSO_4$, $K_2S_2O_8$, $KBrO_3$, and $VOSO_4$. Observation was carried out in the atmosphere of purified nitrogen at 25 °C.

Results and Discussion

Inhibition Effects of Polymer on the Electroreduction of $S_2O_8^{2-}$. For the Case Where the Current Is Mainly Controlled by Mass Transfer: Figure 1 shows the polarograms of $S_2O_8^{2-}$ reduction inhibited by the adsorption of PVP. It was confirmed by the differential capacity measurements[1] that the adsorption of PVP occurs within the potential range in Fig. 1. The polarographic currents were inhibited in the range from the vicinity of zero-charge potential to *ca.* −1.5 V. Similarly, PEG or Triton X inhibited the reduction of $S_2O_8^{2-}$. The decrease of inhibition effects in the range from *ca.* −1.2 to −1.8 V may be ascribed to sufficient polarization. It is interesting that the inhibition effects of polymers on $S_2O_8^{2-}$ reduction are similar to the "supporting electrolyte effect"[5] which results from the double layer effects on anion reduction in the absence of adsorbates.

(b) 0.5 M sodium sulfate+1.0 mM $K_2S_2O_8$+various contents of PVP $\bar{M}=750000$.

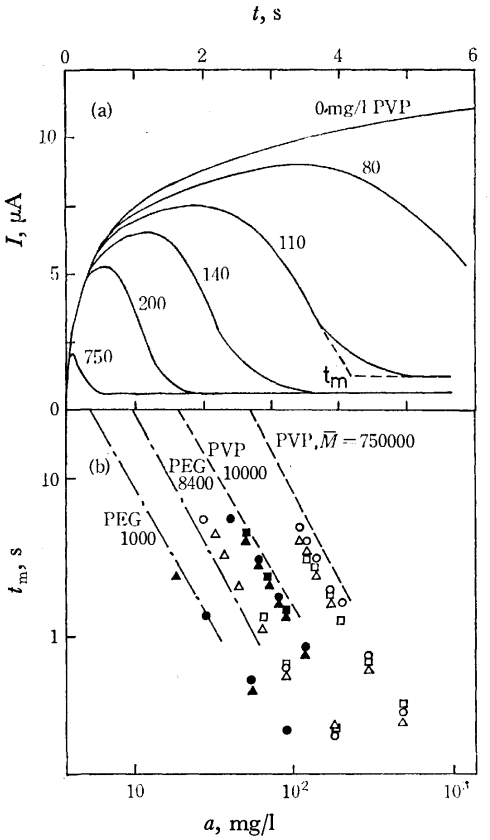

Fig. 2. Instantaneous current measurements for $K_2S_2O_8$ reduction.
(a) $I-t$ curves: 0.5 M sodium sulfate+1.0 mM $K_2S_2O_8$+various contents of PVP $\bar{M}=750000$, $E=-0.8$ V.
(b) log t_m *vs.* log a plots: 0.5 M sodium sulfate+1.0 mM $K_2S_2O_8$+various adsorbates, PVP $\bar{M}=750000$ observed at potentials (○: −0.4 V, △: −0.8 V, □: −1.2 V), PVP $\bar{M}=10000$ (●: −0.5 V, ▲: −1.0 V, ■: −1.5 V), PEG $\bar{M}=8400$ (○: −0.5 V, △: −0.9 V, □: −1.5 V), PEG $\bar{M}=1000$ (●: −0.5 V, ▲: −1.0 V), dashed lines for PVP observed at −0.5 V and one-dotted lines for PEG observed at −0.6 V are derived from differential capacity measurements in 0.5 M sulfuric acid.

In the case of diffusion-controlled adsorption in a dilute PVP solution, PVP of low $\bar{M}$ was more effective on the inhibition than that of high $\bar{M}$ as shown by the results for 50 mg/l of $\bar{M}=10000$ and 100 mg/l of $\bar{M}=750000$ in Fig. 1. Such results may be due to the diffusion coefficient which decreases with $\bar{M}$. On the contrary, PVP of high $\bar{M}$ took more the effect on the inhibitive action as compared with that of low $\bar{M}$ when the adsorption attained the saturation in concentrated PVP solution. The tendency similar to the cases of PVP was also revealed by PEG in the inhibition effects. However, the inhibition of Triton X became more effective with the decreases of $\bar{M}$ in each case of diffusion-controlled or saturated adsorption, which might be due to the increase of adsorbability of Triton X with the decrease of $\bar{M}$ in contrast with the cases of PVP and PEG.

We have investigated the determination of the maximum surface concentration (Γ_m) of polymer at the interface, and it was derived from the time t_m, at which the formation of a monolayer of polymer was achieved. The time t_m required to attain the saturated adsorption of polymer was obtained previously by the differential capacity measurements,[1] while it was also determined from the time dependence of instantaneous limiting current.[2,3] Such time dependence was observed at the potential where the polarogram was most depressed. Figure 2(a) shows the instantaneous limiting current *vs.* time ($I-t$) curves for $S_2O_8^{2-}$ at $E=-0.8$ V in the solution containing PVP of $\bar{M}=750000$. These curves are similar to those in Refs. 2, 3, and 8 where the limiting current is inhibited by diffusion-controlled film formation of polymer. The time t_m can be obtained conveniently by extrapolating the sharply decreasing region in $I-t$ curve to the minimum one. The plots of log t_m *vs.* log a (a: bulk concentration of adsorbates) obtained from $I-t$ curves are shown in Fig. 2(b) in comparison with those derived from the differential capacity measurements. In Fig. 2(b), the broken and one-dotted lines are derived from the capacity method,[1-3] and their slopes of *ca.* −2 are in approximate agreement with those plotted with t_m values obtained from $I-t$ curves, which supports the Koryta equation[9] as described in the previous papers.[1-3] Therefore, in the case as shown in Fig. 2, t_m can be conveniently determined by the instantaneous limiting current, which makes the estimation of Γ_m (maximum surface concentration of adsorbates) easy.

For the Case Where the Current Is Mainly Controlled by Charge Transfer: Figure 3(a) shows the polarograms of $S_2O_8^{2-}$ in 0.005 M sodium sulfate, where the limiting

current without adsorbates is depressed by the double layer effects in the range from *ca.* −0.6 V to −1.4 V. In the above range, the current is mainly controlled by charge transfer rather than mass transfer.[4,5] The inhibition effects of polymer in a dilute supporting electrolyte are larger than those in a concentrated electrolyte, as shown by the results for 50 mg/l PVP in Fig. 3(a) and Fig. 1(a). The $I-t$ curves in Fig. 3(b) were observed at $E=-1.0$ V where the maximum inhibition by polymer was shown. In the $I-t$ curve without adsorbates, I becomes the function of $t^{2/3}$ instead of $t^{1/6}$ which means limiting current. Further, the $I-t$ curves with adsorbates always show the ambiguous transition range from diffusion-controlled to saturated adsorption, which makes the graphical determination of t_m difficult.

For the purpose of determining the time t_m, $I-t$ curves in Fig. 3(b) were rewritten as i *vs.* $t^{1/2}$ plots in Fig. 4(a) in view of diffusion-controlled film formation. In the absence of adsorbates, the instantaneous current density somewhat decreases with time owing to the influence of diffusion process of depolarizer, though the value is expected to be constant independently of time. In the presence of adsorbates, the instantaneous current density decreases linearly with $t^{1/2}$ in the range of diffusion-controlled adsorption of polymer, whereas i becomes nearly constant after the attainment of saturated adsorption. Then, the inhibition effects of polymer on the instantaneous current density in the potential range where the current is mainly controlled by charge transfer of depolarizer can be given by Eqs. (1) and (2) shown later. This tendency is similar to that of C (differential capacity) *vs.* $t^{1/2}$ curves, and the time t_m can be easily determined by the graphical extrapolation in the same manner as described previously for $C-t^{1/2}$ curves.[1]

Relationship between Polarographic Current and Instantaneous Current Density. When the current is mainly controlled by charge transfer, the inhibition is assumed to be ascribed mainly to the blocking effect of adsorbates by considering the behavior of Fig. 4(a). The instantaneous current density before the attainment of saturated adsorption can be regarded as the sum of the instantaneous current densities on the covered (i_1) and the "clean" areas (i_0) as follows.

$$i = i_0(1-\theta) + i_1\theta = i_0 - (i_0-i_1)(t/t_m)^{1/2} * \quad \text{for } t \leqslant t_m \qquad (1)$$

* $\theta = \dfrac{\Gamma}{\Gamma_m} = \dfrac{0.736D^{1/2}at^{1/2}}{0.736D^{1/2}at_m^{1/2}} = (t/t_m)^{1/2}$, where D and a are the diffusion coefficient and bulk concentration of adsorbates.

When the saturated adsorption is achieved,

$$i = i_1 \qquad \text{for } t > t_m \qquad (2)$$

where i_0 and i_1 are the instantaneous current densities at θ (coverage)=0 and 1. These equations are supported by three conditions for $i-t^{1/2}$ curves: (i) instantaneous current density at $t=0$ (i_0) becomes constant regardless of polymer concentration, (ii) instantaneous current density in the presence of adsorbates decreases linearly with $t^{1/2}$, and (iii) instantaneous current density in the case of saturated adsorption becomes constant value i_1.

The relation between polarographic current and instantaneous current density can be derived from Eq. (1) or (2).

For $t_d \leq t_m$

$$I = A\{i_0-(i_0-i_1)(t/t_m)^{1/2}\}$$

Then,

$$\bar{I}_{ads}/\bar{I}_0 = \frac{\frac{1}{t_d}\int_0^{t_d} 0.85(mt)^{2/3}\{i_0-(i_0-i_1)(t/t_m)^{1/2}\}dt}{\frac{1}{t_d}\int_0^{t_d} 0.85(mt)^{2/3}i_0 dt}$$

$$= 1 - \frac{10}{13}\frac{i_0-i_1}{i_0}(t_d/t_m)^{1/2} \qquad (3)$$

where $\bar{I}_{ads}$ and $\bar{I}_0$ are the polarographic currents with and without adsorbates, and A, t_d, and m are the surface area ($=0.85\ m^{2/3}\ t^{2/3}$), the drop time, and the mercury flow rate, respectively.

For the purpose of investigating Eq. (3), the relation of $\bar{I}_{ads}/\bar{I}_0$ *vs.* $(t_d/t_m)^{1/2}$ was plotted in Fig. 4(b). $\bar{I}_{ads}/\bar{I}_0$ *vs.* $(t_d/t_m)^{1/2}$ curve becomes linear at -1.0V where the current is mainly controlled by charge transfer, whereas at -0.5 V it deviates from the linearity because of the mass transfer becoming predominant at -0.5 V.[4,5] Then, Eq. (3) holds for the system where the current being mainly controlled by charge transfer, is inhibited by polymer.

For $t_d > t_m$,

$$\bar{I}_{ads}/\bar{I}_0 = \frac{\frac{1}{t_d}\int_0^{t_m} A\{i_0-(i_0-i_1)(t/t_m)^{1/2}\}dt + \frac{1}{t_d}\int_{t_m}^{t_d} Ai_1 dt}{\frac{1}{t_d}\int_0^{t_d} Ai_0 dt}$$

$$= 1 - \frac{10}{13}\frac{i_0-i_1}{i_0} - \frac{3}{13}\frac{i_0-i_1}{i_0}\{1-(t_d/t_m)^{-5/3}\} \qquad (4)$$

Eq. (4) is expected to hold as well as Eq. (3) within the potential range where the current is mainly controlled by charge transfer.

Inhibition Effects of Polymer on the Electroreduction of BrO_3^-. Figure 5 shows the polarograms of BrO_3^- reduction in 0.05 M sulfuric acid where the half-wave potential shifts from -0.4 V to more negative side by adding PEG, and this tendency differs from that of polarograms for $S_2O_8^{2-}$ reduction in 0.5 M sodium sulfate. The shift of half-wave potential is relatively large in a dilute polymer solution where the adsorption is controlled by the diffusion of polymer, while the shift tends to be saturated in the polymer solution so concentrated as to attain rapidly the saturated adsorption. PVP and PEG of small $\bar{M}$ have greater influence on polarograms as compared with those of large $\bar{M}$ in the range of diffusion-controlled adsorption, however, the reverse is the case in the range of saturated adsorption.

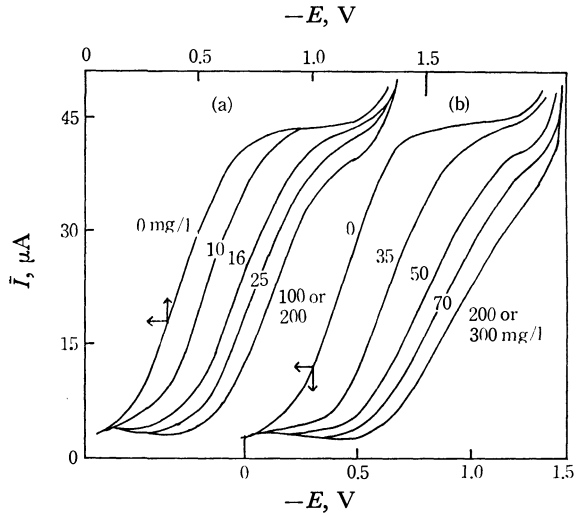

Fig. 5. Polarograms of $KBrO_3$ inhibited by PEG.
0.05 M sulfuric acid+1.0 mM $KBrO_3$+various contents of PEG,
(a) PEG $\bar{M}$=1000, (b) PEG $\bar{M}$=8400.

In the case of Triton X, the smaller the mean molecular weight ($\bar{M}$), the larger the influence on polarograms in each case of diffusion-controlled and saturated adsorption.

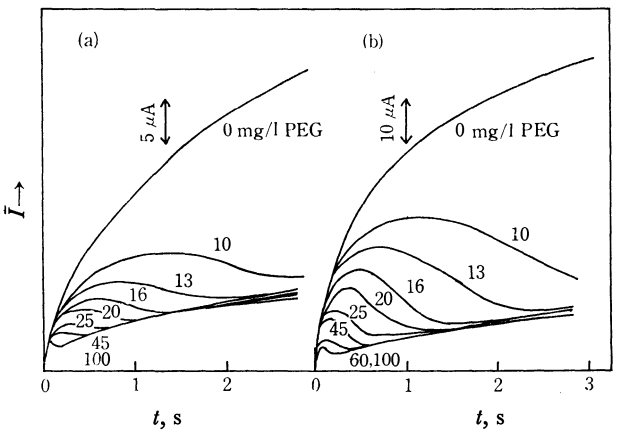

Fig. 6. Instantaneous current *vs.* time curves for $KBrO_3$ reduction inhibited by PEG.
0.05 M sulfuric acid+1.0 mM $KBrO_3$+various contents of PEG $\bar{M}$=1000,
(a) $E=-0.3$ V, (b) $E=-0.5$ V.

For the BrO_3^- reduction inhibited by PEG in 0.05 M sulfuric acid, $I-t$ curves were observed at two potentials along the waves in Fig. 5; -0.3 V is a typical potential at the foot of polarograms (Fig. 6(a)), and -0.5 V is that in the neighborhood of limiting current (Fig. 6(b)). The time t_m can be easily determined from $I-t$ curves at -0.5 V shown in Fig. 6(b) in the same way as described in Fig. 2(a). However, from the $I-t$ curves at -0.3 V in Fig. 6(a) the determination of t_m is difficult because of the indistinct transition range from the diffusion-controlled to the saturated adsorption.

The inhibition effects of polymers on BrO_3^- reduction are examined in detail at the foot of polarographic wave where the current is predominantly controlled by charge transfer (Fig. 7). Figures 7(a) and (b) are the results

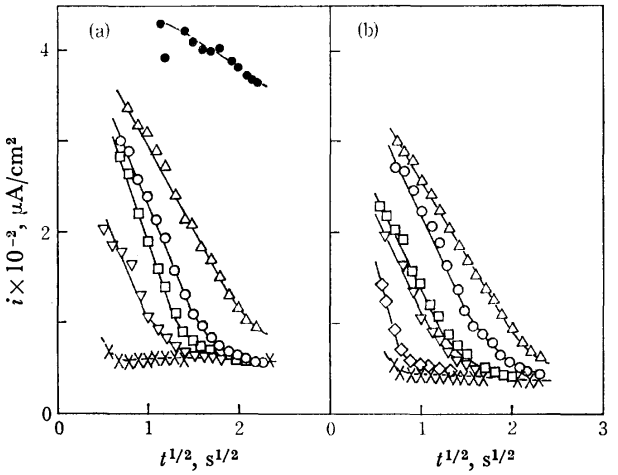

Fig. 7. Instantaneous current density *vs.* square root of time curves for $KBrO_3$ reduction inhibited by polymers. 0.05 M sulfuric acid+1.0 mM $KBrO_3$+polymers, $E=-0.3$ V,

(a) 0.05 M sulfuric acid+1.0 mM $KBrO_3$+PVP (○: $\bar{M}=10000$, △: $\bar{M}=750000$), $E=-0.3$ V,
(b) 0.05 M sulfuric acid+1.0 mM $KBrO_3$+Triton X-205 $\bar{M}=1100$, (○: observed at -0.2 V, △: -0.3 V, □: -0.4 V).

with PEG of $\bar{M}=8400$ and Triton X-405 of $\bar{M}=2000$. In the solution containing adsorbates, i decreases linearly with $t^{1/2}$ in the range of the diffusion-controlled adsorption prior to the saturated adsorption where nearly constant i of *ca.* 60 μA/cm² is obtained, while roughly constant i of *ca.* 400 μA/cm² is observed for the solution without polymer. These phenomena can be explained well by Eqs. (1) and (2).

On the relationships introduced in the foregoing paragraph, $\bar{I}_{ads}/\bar{I}_0$ *vs.* $(t_d/t_m)^{1/2}$ plots are shown in Fig. 8. For $t_d \leqslant t_m$, these plots result in a linear relation having the intercept of *ca.* 1, while for $t_d > t_m$, they approach to the asymptotic value of i_1/i_0, as expected from Eq. (3) or (4), respectively. The slopes of Eq. (3) and the asymptotic values of Eq. (4) for $t \to \infty$ obtained from $\bar{I}_{ads}/\bar{I}_0$ *vs.* $(t_d/t_m)^{1/2}$ plots are shown in Table 1, in comparison with those calculated from the instantaneous current densities at -0.3 V. The intercepts of Eq. (3) obtained by $\bar{I}_{ads}/\bar{I}_0$ *vs.* $(t_d/t_m)^{1/2}$ plots are also listed in Table 1. The slopes and the asymptotic values obtained from the figures like Fig. 8 agree approximately with those calculated with the instantaneous current densities except for the slopes with PVP. The intercept values at $t=0$ obtained from $\bar{I}_{ads}/\bar{I}_0$ *vs.* $(t_d/t_m)^{1/2}$ plots are somewhat larger than the theoretical values of unity expected from Eq. (3). Then, it follows that the current density (i_0) on free surface in the solution containing adsorbates is somewhat higher than that (i_0') in the solution without adsorbates, though Eq. (3) holds on the assumption of $i_0=i_0'$ (*cf.* the derivation of Eq. (3)). Such results might be attributed to the interaction between adsorbates and depolarizer on the surface or to the characteristics of capillary.[10]

a) Absolute values. b) The values observed directly from $\bar{I}_{ads}/\bar{I}_0$ *vs.* $(t_d/t_m)^{1/2}$ plots. c) The values calculated from instantaneous current densities (slope=$\frac{10}{13}\frac{i_0-i_1}{i_0}$, asymptotic value=$i_1/i_0$).

Table 2 shows the values of αn and $E''_{1/2}$ (half-wave potential at the saturated adsorption) for the inhibition effects of polymer on BrO_3^- reduction. The values of αn were obtained from the potential dependence of log $(\bar{I}_d-\bar{I}_{ads})/\bar{I}_{ads}$, where α, n, and $\bar{I}_d$ were the transfer coefficient, the number of electrons involved in the reduction, and the polarographic limiting current. From the results of $E_{1/2}''$ and αn in Table 2, Triton X is found to be most effective on the inhibition of BrO_3^- reduction. The shift of half-wave potential in the presence of

TABLE 2. HALF-WAVE POTENTIAL AT MAXIMUM SHIFT $E''_{1/2}$ AND αn FOR BrO_3^- ELECTROREDUCTION UNDER SATURATED ADSORPTION OF POLYMERS

	X-405	300	0.88	0.16

In the solution without adsorbates, half-wave potential and αn for BrO_3^- reduction are -0.40 V and 0.23.
a) The values of αn are calculated from the relation of $\log\{(\bar{I}_d-\bar{I}_{ads})/\bar{I}_{ads}\}$ *vs.* E.

polymer will be derived from the change of the apparent rate constant (k_{app}) with polymer and its potential dependence. The instantaneous current in the absence of polymer is given by,

$$I_0 = nFAk_0a^* \tag{5}$$

where k_0 and a^* are the rate constant at $\theta=0$ and the concentration at electrode surface.

For the case with polymer,

$$I_{ads} = nFAk_{app}a^* \tag{6}$$

The apparent rate constant can be assumed as the sum of rate constants on covered (k_1) and uncovered surface (k_0) as follows,[11]

$$k_{app} = k_0(1-\theta) + k_1\theta = k_0 - (k_0-k_1)(t/t_m)^{1/2} \quad \text{for } t \leqslant t_m \tag{7}$$

$$k_{app} = k_1 \quad \text{for } t > t_m \tag{8}$$

Then,

$$(I_{ads})_A = nFAa^*\{k_0-(k_0-k_1)(t/t_m)^{1/2}\} \quad \text{for } t \leqslant t_m \tag{9}$$

or $$I_{(ads)_B} = nFAk_1a^* \quad \text{for } t > t_m \tag{10}$$

The potential dependence of k_0 or k_1 is expressed as follows,

$$k_0 = k_0^s \exp\left\{-\frac{\alpha nF}{RT}(E-E_0)\right\} \tag{11}$$

$$k_1 = k_1^s \exp\left\{-\frac{\alpha nF}{RT}(E-E_0)\right\} \tag{12}$$

where k_0^s and k_1^s are the standard rate constants for $\theta=0$ and 1, and E_0 the standard potential of the system in question. The concentration at the electrode surface can be expressed by the instantaneous current, that is,

$$a^* = \frac{\delta}{D}(I_d-I_0) \tag{13}$$

where D and δ are the diffusion coefficient and the thickness of diffusion layer.

(a) Potential *vs.* polarographic current relation in the absence of adsorbates; Substituting Eqs. (11) and (13) into the expression for the polarographic current $\bar{I}_0$ which is given by integrating Eq. (5) and dividing its results by the drop life, we can obtain the potential *vs.* polarographic current relation.

$$E = E_0 + \frac{RT}{\alpha nF}\ln(0.85m^{2/3}nF\bar{\delta}D^{-1}) + \frac{RT}{\alpha nF}\ln\frac{\bar{I}_d-\bar{I}_0}{\bar{I}_0} + \frac{RT}{\alpha nF}\ln\frac{3}{5}k_0^s t_d^{2/3} \tag{14}$$

(b) Potential *vs.* polarographic current relation in the presence of adsorbates; When $t_d \leqslant t_m$, the $E-\bar{I}$ relation is given by substituting Eqs. (11), (12), and (13) into the polarographic current of $\bar{I}_{ads}$ obtained from Eq. (9),

$$E = E_0 + \frac{RT}{\alpha nF}\ln(0.85m^{2/3}nF\bar{\delta}D^{-1}) + \frac{RT}{\alpha nF}\ln\frac{\bar{I}_d-\bar{I}_{ads}}{\bar{I}_{ads}} + \frac{RT}{\alpha nF}\ln\left\{\frac{3}{5}k_0^s t_d^{2/3} - \frac{6}{13}(k_0^s-k_1^s)t_m^{-1/2}t_d^{7/6}\right\} \quad \text{for } t_d \leqslant t_m \tag{15}$$

When $t_d > t_m$, the polarographic current of $\bar{I}_{ads}$ is the sum of $(\bar{I}_{ads})_A = \frac{1}{t_d}\int_0^{t_m}(I_{ads})_A\,dt$ and $(\bar{I}_{ads})_B = \frac{1}{t_d}\int_{t_m}^{t_d}(I_{ads})_B\,dt$. Substituting Eqs. (11), (12), and (13) into $\bar{I}_{ads}$ above mentioned, we obtain

$$E = E_0 + \frac{RT}{\alpha nF}\ln(0.85m^{2/3}nF\bar{\delta}D^{-1}) + \frac{RT}{\alpha nF}\ln\frac{\bar{I}_d-\bar{I}_{ads}}{\bar{I}_{ads}} + \frac{RT}{\alpha nF}\ln\left\{\frac{9}{65}(k_0^s-k_1^s)t_m^{5/3}t_d^{-1} + \frac{3}{5}k_1^s t_d^{2/3}\right\} \quad \text{for } t_d > t_m \tag{16}**$$

The half-wave potentials $E_{1/2}$ without polymer and $E'_{1/2}$ with polymer can be derived from Eqs. (14), (15), and (16) by putting $\bar{I}_0 = 1/2\bar{I}_d$ and $\bar{I}_{ads} = 1/2\bar{I}_d$, respectively. Thus, the shift of half-wave potential ($\Delta E_{1/2} = E'_{1/2} - E_{1/2}$) is shown as follows,

$$\Delta E_{1/2} = \frac{RT}{\alpha nF}\ln\left\{1-\frac{10}{13}\left(1-\frac{k_1^s}{k_0^s}\right)\left(\frac{t_d}{t_m}\right)^{1/2}\right\} \quad \text{for } t_d \leqslant t_m \tag{17}$$

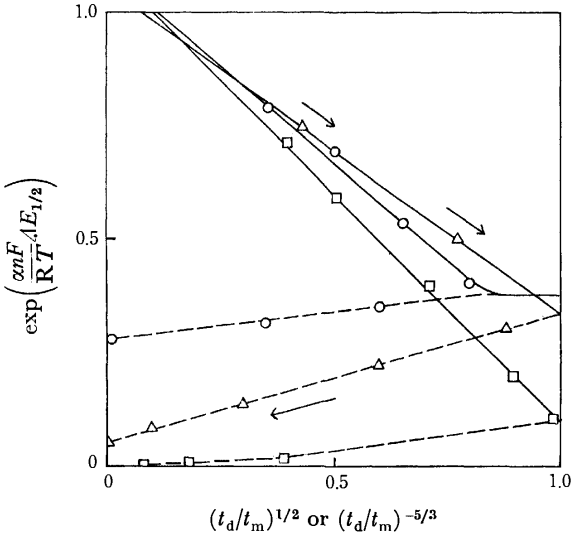

Fig. 9. Shifts of half-wave potential for $KBrO_3$ reduction in the presence of polymers.
0.05 M sulfuric acid+$KBrO_3$+polymers (○: 1.5 mM $KBrO_3$ with various content of PVP $\bar{M}=10000$, △: 1.0 mM $KBrO_3$ with PEG $\bar{M}=8400$, □: 1.0 mM $KBrO_3$ with TritonX-205 $\bar{M}=1100$),
solid lines: $\exp\left(\frac{\alpha nF}{RT}\Delta E_{1/2}\right)$ *vs.* $(t_d/t_m)^{1/2}$ plots, dashed lines: $\exp\left(\frac{\alpha nF}{RT}\Delta E_{1/2}\right)$ *vs.* $(t_d/t_m)^{-5/3}$ plots.

** $t_d\bar{I}_{ads} = \int_0^{t_m}(I_{ads})_A dt + \int_{t_m}^{t_d}(I_{ads})_B dt$

or

$$\Delta E_{1/2} = \frac{RT}{\alpha nF} \ln\left[\frac{k_1^s}{k_0^s} + \left\{1 - \frac{k_1^s}{k_0^s} - \frac{10}{13}\left(1 - \frac{k_1^s}{k_0^s}\right)\right\}\left(\frac{t_d}{t_m}\right)^{-5/3}\right] \quad \text{for } t_d > t_m \qquad (18)$$

On the basis of these relationships, the plots of $\exp\left(\frac{\alpha nF}{RT}\Delta E_{1/2}\right)$ *vs.* $(t_d/t_m)^{1/2}$ or $(t_d/t_m)^{-5/3}$ are shown in Fig. 9, where the arrows indicate the increase of adsorbates contents.

Since $\exp\left(\frac{\alpha nF}{RT}\Delta E_{1/2}\right)$ decreases linearly with $(t_d/t_m)^{1/2}$ for $t_d \leqslant t_m$ and increases with $(t_d/t_m)^{-5/3}$ for $t_d > t_m$, the shift of $E_{1/2}$ is explained by Eq. (17) or (18).

Examination of Eq. (17) or (18) for the Inhibition Effects of Polymers on Cation Reduction. The characteristics for the inhibition effects of polymer on the electroreduction are assumed to be independent of the ionic charge of depolarizer except for the double layer effects within the potential range where the current is predominantly controlled by charge transfer. In the irreversible reduction of VO^{2+}, the polarogram in the acetate

(b) 1 N sulfuric acid+1.0 mM $CdSO_4$+PVP $\bar{M}$=750000, $E=-0.9$ V, contents of PVP (○: 0 mg/l, △: 80 mg/l, ●: 100 mg/l, □: 150 mg/l, ▲: 400 mg/l, ×: 800 mg/l).

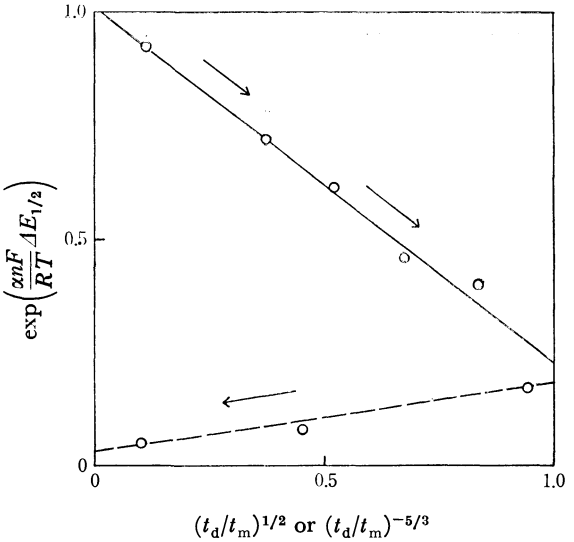

Fig. 11. Shift of half-wave potential for $VOSO_4$ reduction in the presence of polymers.
(0.5 M CH_3COOH+0.5 M CH_3COONa)+1.0 mM $VOSO_4$+various contents of PVP $\bar{M}$=750000, Solid line: $\exp\left(\frac{\alpha nF}{RT}\Delta E_{1/2}\right)$ *vs.* $(t_d/t_m)^{1/2}$ plot, dashed line: $\exp\left(\frac{\alpha nF}{RT}\Delta E_{1/2}\right)$ *vs.* $(t_d/t_m)^{-5/3}$ plots.

buffer of pH 4.7 was inhibited by the polymer in the same way as that for BrO_3^-, that is, the half-wave potential became more negative with the addition of the polymers. In this case, the exact determination of t_m was possible by the $i-t^{1/2}$ plot shown in Fig. 10(a) in the potential range where the charge transfer was predominant. The results in Fig. 10(a) show that Eqs.(1) and (2) hold well for the inhibited reduction of VO^{2+} where the current is mainly controlled by charge transfer. Then, it follows that Eq. (17) or (18) based on Eq. (1) or (2) is applicable to the above case. In Fig. 11, the plot of $\exp\left(\frac{\alpha nF}{RT}\Delta E_{1/2}\right)$ *vs.* $(t_d/t_m)^{1/2}$ or $(t_d/t_m)^{-5/3}$ becomes linear as expected from Eq. (17) or (18), respectively. The arrows in the figure indicate the increase of adsorbate contents. Meantime, typical results in contrast with $i-t^{1/2}$ plots in Fig. 10(a) are shown in Fig. 10(b), which reveals the inhibition effects of polymer on the instantaneous limiting current density of Cd^{2+} reduction. In the absence of adsorbates, the results reveal the process mainly controlled by linear diffusion of depolarizer, since the instantaneous current density decreases with the function of $1/t^{1/2}$ which is expected from the Ilković equation.[12] In the presence of adsorbates, the depression of instantaneous current density is not expressed as a linear relation of i *vs.* $t^{1/2}$ which implies the blocking effect of polymer, but shows the sharp change after a certain adsorption time. Such results may be due to the inhibition which is dependent not only on the blocking effect of adsorbates but also on the variation of diffusion path of depolarizer having fast reaction rate.[3]

Summary. So far as the present research is concerned, the inhibition effects of polymer on reduction current may be classified into two typical cases regard-

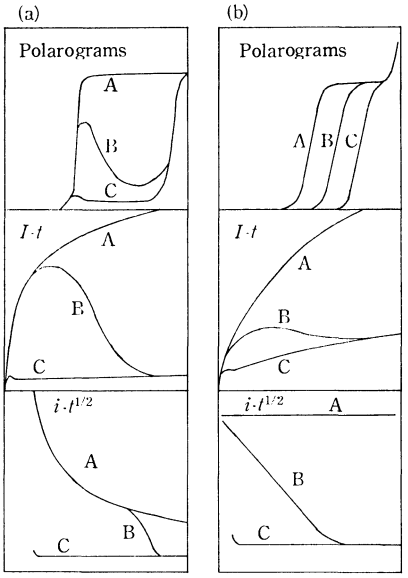

Fig. 12. Models for inhibition effects of polymer on electroreduction current.
A: with no polymer, B: with polymer in the case of diffusion-controlled adsorption, C: with polymer in the case of saturated adsorption,
(a) inhibition effects on reaction in the potential ranges of limiting current,
(b) inhibition effects on reaction in the potential ranges where the current is mainly controlled by charge transfer.

less of the ionic charge of depolarizer. Fig. 12(a) shows the typical inhibition effects of polymer when the current is predominantly controlled by mass transfer of ions. In such a case, the time t_m needed to complete a monolayer of polymer can be obtained directly from $I-t$ curve, which results in a convenient determination of Γ_m of polymer. In these cases, $i-t^{1/2}$ plots differ markedly from those in Fig. 12(b) for the process mainly controlled by charge transfer. Meanwhile, Fig. 12(b) shows the other type of inhibition effects of polymer when the current is mainly controlled by charge transfer. In such cases, the time t_m can be obtained exactly from $i-t^{1/2}$ relation instead of $I-t$ curve.

Moreover, Eqs. (17) and (18) for the shift of half-wave potential in the presence of adsorbates were verified with regard to the system of Fig. 12(b), *i.e.*, the inhibition effects of polymer on the electroreduction of BrO_3^- or VO^{2+}.

Studies on Bond Character in Phosphorus Ylides by Combustion Heat and X-Ray Photoelectron Spectroscopy

Manabu SENŌ, Shinji TSUCHIYA, Hideo KISE, and Teruzo ASAHARA

Institute of Industrial Science, The University of Tokyo, 7-22, Roppongi, Minato-ku, Tokyo 106

(Received October 24, 1974)

In order to clarify the electron structure of carbonyl-stabilized phosphorus ylides, measurements of X-ray photoelectron spectroscopy (XPS) and combustion heat were performed. NMR and IR spectra were also measured as complementary methods. The results suggest that carbomethoxymethylenetriphenylphosphorane has a major contribution of polar bond ($\overset{+}{P}$–$\bar{C}$) structure, whereas benzoylmethylenetriphenylphosphoranes have a larger contribution of covalent bond (P=C). A dπ—pπ interaction in the P–C bond was interpreted for XPS and NMR. The data for heat of combustion suggest that a large contribution of the polar bond structure brings about stabilization of the ylide molecule. These results show that XPS and combustion heat measurements are useful means for the analysis of ylide bonding.

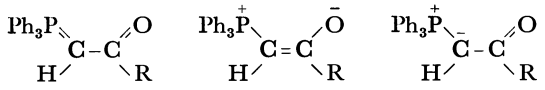
It has been considered that the phosphorus atom in phosphorus ylides has an oxidation number between P(IV) and P(V) and forms a multiple bond with an adjacent atom possessing lone-pair electrons *via* a dπ-pπ bonding. The nature of the P–C bonding in phosphorus ylides has been discussed mainly on the basis of their chemical properties. Recently, IR, NMR, dipole moment, and X-ray diffraction techniques have also been used for the elucidation of the bond character, but an uncertainty still seems to remain especially on the variation of the character with the substituents on the carbon atom.

It has been reported that X-ray photoelectron spectroscopy (XPS) is especially useful in the investigation of the bonding or the formal oxidation state of atoms in a variety of compounds.[1] This induced us to use XPS as a tool for probing the bond character of the phosphorus ylides, expecting the direct elucidation of the electronic environment of the phosphorus atom.

In the present work, we have analyzed the bonding mainly by means of XPS, and the ambiguities in electronic structure have been clarified through the examination of the binding energies. The measurement of combustion heat is also considered to give useful pieces of information on the bond energy in thermodynamic sense, and the results on the phosphorus ylides will be described as well as the data of IR, and NMR spectroscopy.

Results and Discussion

The compounds used for the present investigation are the carbonyl-stabilized phosphorus ylides, which have been already studied by IR,[2] NMR,[3] dipole moment,[4] and X-ray diffraction.[5] Measurement of p*K*a value and chemical reactivities[6] have also been carried out in order to clarify the effect of substituent on the carbonyl carbon. By these investigations, three resonance structures shown below have been presented:



Ia **Ib** **Ic**

The contribution of each structure is considered to vary with the substituents R through their inductive, mesomeric and steric effects. In the present investigation, we tried to clarify the degree of contribution of each resonance structure in differently substituted ylides.

IR Studies. The C=O stretching bands in phosphorus compounds are summarized in Table 1. The bands of the phosphonium salts appear at higher frequencies by 135—189 cm^{-1} than those of the ylides. This suggests that the contribution of the structure **Ib** is large in the ylides, whereas the phosphonium salts have not the contribution of this type of resonance structure.

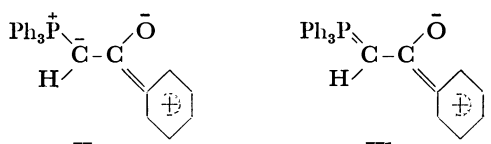
TABLE 1. STRETCHING BANDS OF C=O GROUPS IN THE YLIDES AND THEIR SALTS

Compounds	C=O band (cm^{-1})
1 Ph_3P=CHCO–C$_6$H$_4$–NO_2	1540—1500
2 Ph_3P=CHCO–C$_6$H$_5$	1527
3 Ph_3P=CHCO–C$_6$H$_4$–OMe	1503
4 Ph_3P=CHCO–OMe	1620
5 [$Ph_3\overset{+}{P}$–CH_2CO–C$_6$H$_4$–NO_2]Br^-	1689
6 [$Ph_3\overset{+}{P}$–CH_2CO–C$_6$H$_5$]Br^-	1662
7 [$Ph_3\overset{+}{P}$–CH_2CO–C$_6$H$_4$–OMe]Cl^-	1652
8 [$Ph_3\overset{+}{P}$–CH_2CO–OMe]Br^-	1725

In the salts (**5**), (**6**), and (**7**) an electron donating substituent on phenyl ring yields a low frequency shift by the conjugation of the carbonyl group with the phenyl ring.

In the ylides (**1**), (**2**), and (**3**), we also find the same aspect of the effect of substituents on phenyl ring with that mentioned above in the salts (**5**), (**6**), and (**7**).

Thus, we should consider not only the resonance structure **Ib**, but also **IIa** and **IIb**:



IIa **IIb**

The ylide (**4**) exhibits a C=O band at higher frequency by as much as about 100 cm^{-1} than those of other ylides. Furthermore, the difference of the C=O frequency between the salt (**8**) and the ylide (**4**) is the smallest (105 cm^{-1}) among the pairs of the salt and the ylide listed in Table 1. These results indicate that the contribution of the resonance structure **Ia** and/or **Ic** is significant in the ylide (**4**).

NMR Studies. The chemical shift and coupling constant of methylene and methine protons are summarized in Table 2.

Table 2. NMR data of the ylides and their salts

Compounds	^1H (methylene or methine) Shift (ppm)	^1H (methylene or methine) J_{P-C-H} (Hz)	^{31}P (ppm)	^{13}C[a] Shift (ppm)	^{13}C[a] J_{P-C} (Hz)
1	4.46	21.6	−16.8	52.5	108
2	4.40	24.3	−16.3	49.7	108
3	4.34	24.3	−16.7	48.4	107
4	2.82	—	−17.4	28.9	131
5	6.60	13.5	−20.5	—	—
6	6.40	13.5	−20.6	—	—
7	6.36	13.5	−20.4	—	—
8	5.25	15.8	−20.5	32.6	57

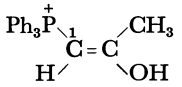
a) Methylene or methine carbons.

Comparison of the salts with ylides shows that the methylene signals of the salts appear in lower magnetic field than methine signals of the ylides. This may be attributed to higher electron densities on methine carbon atoms in the ylides than those on methylene carbon atoms in the salts, although, as generally observed, the partially olefinic character of the methine proton in the ylides would compensate the high field shift. Moreover, the difference in coupling constants between the ylides and the salts shows the existence of $d\pi$-$p\pi$ interaction in P–C bond of the ylides.

The methylene protons in the salts (**5**), (**6**), and (**7**) give signals at lower field by 1.11—1.35 ppm than that of the salt (**8**). The same tendency is observed between the ylides (**1**), (**2**), (**3**), and (**4**), and this may be attributed to the electron releasing character of the phenyl ring. The ylide (**4**) is distinct from others also in that the shift of the signal in going from the salt (**8**) to the ylide (**4**) is large (2.43 ppm) compared to the shift in other pairs of the salts and the ylides (2.00—2.14 ppm). It was supposed from the IR measurement that the ylides (**1**), (**2**), and (**3**) have a larger contribution of the resonance structure **Ib**, whereas the ylide (**4**) is considered to have the major resonance structure **Ia** or **Ic**. The present results of NMR suggest a high degree of negative charge on the methine carbon and this seem to support the structure **Ic** rather than **Ia** for the ylide (**4**).

The signals of ^{31}P NMR of the salts appear at lower magnetic field than those of the ylides as shown in Table 2; this may be attributed to less positive charge on phosphorus atoms in the ylides. The substituent effect is not found for the phosphonium salts. In the case of the ylides, the substituents on carbonyl carbon have a clear effect on phosphorus atom through $d\pi$-$p\pi$ bonding. The ^{31}P NMR peak of the ylide (**4**) appears at the lowest magnetic field among the ylides, probably because of the more positive charge on the phosphorus atom of the ylide. These results are consistent with those of IR and ^1H NMR, indicating the large contribution of resonance structure **Ic** in the ylide (**4**). The shift of the ylides (**1**), (**2**), and (**3**) suggests that the nature of P–C bonding in these ylides is of more double bond character. Hence, it is likely that the ylides (**1**), (**2**), and (**3**) have a larger contribution of resonance structure **IIb**.

The ^{13}C chemical shift and ^{13}C–^{31}P nuclear spin coupling constant are especially useful in the investigation of the bondings of phosphorus ylides. The shifts in Table 2 were assigned on the basis of previous studies.[3k,31] Gray showed that the ylides such as $Ph_3P(CR)CO_2R'$ should not be considered to have primarily **Ib** type electron structure, on the basis of comparison with value, $\delta_{13C}=70.92$ ppm and $J_{C-P}=99.2$ Hz, for C-1 of enol form **III**.

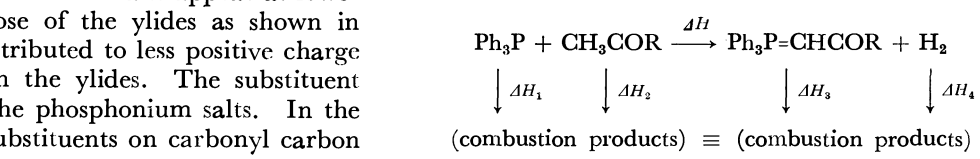


III

The results in Table 2 suggest a considerable carbanion character of P–C carbons especially for ylide (**4**), whereas the ylides (**1**), (**2**), and (**3**) seem to have considerable olefinic character by comparison with data for **III**. Especially, the values of the ^{13}C–^{31}P coupling constant are close to that of **III**. That is, since the ^{13}C–^{31}P coupling constant reflects the s character of the ylide bond,[31] the ylide bond in (**1**), (**2**), and (**3**) is considered to have the character of sp^2.

The substituent effect on ^{13}C NMR is consistent with IR and other NMR data shown above, and the order of ^{13}C NMR chemical shift is parallel with p*K*a values.[6]

Combustion Heat Studies. Two main factors have been suggested to account for bond strengthening in covalent bonds. The first reflects a certain amount of polar character of the bond. This ionic-covalent resonance causes lowering of energy of the molecule and a strengthening of the bonds. Another factor of bond strengthening has been attributed to some additional π-bonding. Pi-bonding involving d-orbital is often found in phosphorus compounds. It is of interest to see whether this type of bonding makes an important contribution to the overall energy content of the molecule. For phosphorus compounds there are much thermochemical data available and the effects of $d\pi$-$p\pi$ bonding are much more apparent.[7] Thus, the measurement of combustion heat may be useful for the studies of bonding of phosphorus ylides. The data of combustion heat of the ylides $Ph_3P{=}CHCOR$ and related compounds are summarized in Table 3. Now we consider the thermochemical cycle shown below:



Thus, the enthalpy change ΔH of the P–C bond formation is derived from the combustion heats, ΔH_1, ΔH_2, ΔH_3, and ΔH_4

$$\Delta H = (\Delta H_1 + \Delta H_2) - (\Delta H_3 + \Delta H_4) \quad (1)$$

where $\Delta H_4 = -68$ kcal·mol^{-1}. The results calculated by the above equation are given in Table 3.

Table 3. Combustion heats (ΔH_{comb}) and enthalpy changes of the P–C bond formation (ΔH) of ylides

R	ΔH_2 of CH_3COR (kcal·mol^{-1})	ΔH_3 of Ph_3P=CHCOR (kcal·mol^{-1})	ΔH (kcal·mol^{-1})
p-$NO_2C_6H_4$	−940.0	−3398.1	−0.9
Ph	−989.6	−3420.9	−27.7
p-$MeOC_6H_4$	−1116.1	−3535.4	−39.7
OMe	−378.3	−2701.7	−135.6

Ph_3P; $\Delta H_1 = -2527.0$ kcal·mol^{-1}

The value for the ylide with substituent R=OMe shows that this substituent brings about a large decrease in ΔH, compared to the other substituents R=p-NO_2-C_6H_4, Ph, and p-$MeOC_6H_4$. Since the decrease in ΔH indicates the stabilization of the P–C bond, the bond of the ylide (**4**) is thought to be most stable among four ylides.

According to NMR data, the ylide (**4**) is considered to have the smaller contribution of the covalent bond through dπ–pπ interaction, and the results obtained from the combustion heat measurement seem to show that a large contribution of **Ic** brings about stabilization of the ylide molecule. We also found a substituent effect in the combustion heat of the ylides (**1**), (**2**), and (**3**), and the change in these values is consistent with that of NMR data. Furthermore, Jolly *et al.* have shown that XPS shifts do correlate well with thermochemical data.[8] It is expected that a relation is established between XPS shifts and combustion heat data for phosphorus ylides.

XPS Studies. A survey of the literature reveals the utility of X-ray photoelectron spectroscopy (XPS) on the investigation of the electronic environment of anomalous covalent atom and this induced us to use XPS as a tool for probing the ylide bonds. Most recently, Mixan *et al.* reported the XPS measurement on sulfur-nitrogen ylides and related compounds attempting to probe the nature of the S–N polar bonds.[1f]

Table 4. P-2p electron binding energies in phosphorus ylides and their salts, the rate constants of Wittig reaction and basicities, pK_a[a]

Compounds	Binding energies (eV)	log k of Wittig reaction (k; l·mol^{-1}·s^{-1})	pK_a
Ph_3P=O	131.5

1	130.8	−5.19	4.2
2	131.2	−3.92	6.0
3	131.3	−3.39	6.7
4	131.7	−1.84	8.8
5	131.8		
6	132.0		
7	132.0		
8	132.5		

a) Reaction with benzaldehyde.[6]

The electron binding energies in phosphorus atom measured in the present work are summarized in Table 4.

The phosphorus 2p binding energies were recorded with reference to the C ls line at 284 eV. Distinct differences are found between the spectra of the ylides and those of their salts; the binding energies of the salts are higher than those of the corresponding ylides. It is also found that P-2p electron binding energies in the ylides decrease in the order (**4**)>(**3**)>(**2**)>(**1**), reflecting the substituent effect. It is likely that the large binding energy of the ylide (**4**) is due to a large contribution of resonance structure **Ic** rather than **Ia** and **Ib**, as revealed already by the measurements of IR, NMR, and combustion heat. Aryl substituents seem to bring about an increase in the electron density on phosphorus atom, compared to the methoxy group in the ylide (**4**). By considering the results of IR and NMR, the increase of electron density is thought to be the result of a large contribution of the structure **IIb** rather than that of **Ib**.

The binding energy of the ylide (**4**) is almost the same with those of Ph_3P=O and Ph_3P=S, and this implies that the polarity of P–C bond in (**4**) is comparable to those of P–O and P–S bonds in the phosphine oxide and sulfide. For the salts (**5**), (**6**), and (**7**), the substituent effect on the binding energies is not found; a distinct difference in chemical shift of the salt (**8**) has not been explained yet.

Siegbahn *et al.* demonstrated[9] that the chemical shift in the total screening constant can be written as

$$\Delta\sigma_A = \frac{-\Delta E_A}{3mc^2} + \frac{\pi e}{3mc\mu_0 g_A}\Delta\sum_\alpha C_{A,\alpha\alpha} I_{\alpha\alpha} \quad (2)$$

where ΔE_A: XPS shift, $C_{A,\alpha\alpha}$: spin-rotation constant for nucleus A along the αth molecular inertial axis, $I_{\alpha\alpha}$: corresponding principal moment of inertia of the molecule, μ_0: nuclear magneton, g_A: g-factor for nucleus A. From this relation, they concluded that the first term in equation (2) is the part of the shift in the diamagnetic constant and is proportional to the XPS shift. This term is only of the size of a few ppm. The second term is the part of the shift in the paramagnetic constant and is one or two orders of magnitude larger than the first term. Thus, no linear correlation between XPS and NMR shift can be expected even for the same kind of compounds.

In the present work, the shifts in the compounds having different kind of bondings vary largely as seen among Ph_3P=O, Ph_3P=S, and phosphorus ylides, and the correlation between XPS and NMR shift is not observed. However, in the series of phosphorus ylides and their salts, a correlation between XPS and ^{31}P NMR is found. The results seem to indicate that both the phosphorus ylides and salts used for the present investigation have almost the same contribution of paramagnetic term, and the diamagnetic term contributes mainly to the change in the shift of these spectra. For quaternary phosphonium compounds, Swartz *et al.* also reported that a linear relationship was established between the P-2p binding energies and the ^{31}P NMR

chemical shifts.[1c]

It has been elucidated that the overall rate of the Wittig reaction depends on the rate of electrophilic reaction of ketones or aldehydes onto the α-carbon of ylide compounds.[10] This step would be affected by the electronic character as well as the steric one. With respect to a series of ylides used here, a linear relationship between the basicity of the ylides and the reaction rate with benzaldehyde has been established.[6] This indicates that the rate determining step mentioned above is affected only by the electronic effect. Thus, more positive charge on phosphorus atom would favor the reaction. Since the binding energy of XPS is proportional to the positive charge, a relationship between the binding energy and the reactivity is expected, and this is actually the case as shown in Table 4.

Conclusion

1) In the present investigation it was concluded that the electronic structure of carbomethoxymethylenetriphenylphosphorane (**4**) has a major contribution of resonance structure **Ic**. Measurements of ^{31}P NMR and XPS support localization of positive charge on phosphorus atom, and combustion heat data also convince us of the large contribution of resonance structure **Ic**.

2) With respect to ylides (**1**), (**2**), and (**3**), the large lower shift of C=O stretching bands show that the carbonyl groups in the ylides are polar ($>\overset{\delta+}{C}-\overset{\delta-}{O}$), and it was clarified by ^{13}C NMR that the hybrid orbital of the methine carbon is close to sp^2 hybrid. These results indicate that these ylides have a large contribution of resonance structure **Ib**, **IIa**, and **IIb**. However, ^{31}P NMR and XPS measurements show that these ylides have less positive charge on phosphorus atom than ylide (**4**). Thus, the resonance structure **IIb** is considered to have a primary contribution.

3) In the ylides (**1**), (**2**), and (**3**), the substituent effect is found on both the methine proton and the phosphorus atom, whereas in the salts (**5**), (**6**), and (**7**), the substituent effect is observed only on methylene protons. This observation indicates that P–C bonds in the ylides are semipolar with $d\pi$-$p\pi$ interaction. P–C–H Coupling constant in Table 2 also support the above discussion. Thus, these results experimentally clarify $d\pi$-$p\pi$ interaction in phosphorus ylides.

4) The result of the analysis by XPS is consistent with those by IR and NMR, and gives additional informations on polar bondings. A correlation between P-2p binding energies of XPS and ^{31}P NMR shifts was observed in phosphorus ylides and phosphonium salts, and a relation was also established between the binding energies and combustion heat of ylides. These suggest that XPS may be a useful tool for the elucidation of the electronic structure of some organic compounds.

Experimental

The compounds used in this study were prepared, purified and characterized according published methods.[4,6,11] All the ylides were prepared by dehydrohalogenation of corresponding phosphonium salts. The results of elemental analyses are as follows.

	Calcd			Found		
	C	H	N	C	H	N
(**1**)	73.30	4.95	3.28	73.11	4.75	3.35
(**2**)	82.08	5.58	—	82.09	5.61	—
(**3**)	79.10	5.64	—	79.03	5.68	—
(**4**)	75.41	5.74	—	75.65	5.74	—

IR Spectroscopy. All the infrared spectra were obtained as mulls with Nujol on a JASCO IRA-2 infrared spectrometer. All the spectra have sharp absorption bands of C=O stretching except that of ylide (**1**) which has a broad peak due to the overlap with the absorption peak of the nitro group.

NMR Spectroscopy. ^1H NMR spectra were recorded on a Hitachi R-22 spectrometer (90 MHz) using deuteriochloroform as a solvent and TMS as an internal standard.

The measurement of ^{31}P NMR were made using a Hitachi R-20A NMR spectrometer at 24.3 MHz using 85% phosphoric acid as an external reference. The spectra were taken in chloroform; the concentration 1.0—0.5 M was needed for detection of the signals.

^{13}C NMR spectra were obtained using a Hitachi R-26 NMR spectrometer in Fourier transform mode, and was operated at 10 MHz. ^{13}C–H Couplings were eliminated using broad band ^1H-noise-modulated decoupling. The ylides and salts were run in saturated deuteriochloroform solutions in 10 mm sample tubes, and TMS was used as an internal standard.

X-Ray Photoelectron Spectroscopy. The measurements were performed with a JASCO ESCA-1 or a McPherson ESCA-36 electron spectrometer with Mg$K\alpha$ radiation. The spectra were obtained on powdered samples mounted on an aluminum plate. In order to compensate for the charging of the insulating samples during the phtoelectron ejection process, all the spectra were referenced to the photoelectron line of C ls; E_b=284 eV. An attempt was also made to reference the spectra to the Au $4f_{7/2}$; E_b=83 eV by vacuum deposition of gold onto the samples, and the results from the two methods were consistent with each other. The binding energies were read at the midway point of the full peak at half height.

Combustion Heat. Combustion heat data were obtained using a Shimadzu automatic bomb calorimeter CA-3. Powdered samples were wrapped in Gampi paper, and liquid samples were placed in gelatin capsule. The given data were averaged values of ten measurements.

The Free Energy of Transfer from a Binary to a Ternary Solution by the Isopiestic Measurements

Hatsuho UEDAIRA

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

(Received January 11, 1975)

A new method of calculating the free energy of transfer of a solute from a binary to a ternary solution on the mole fraction scale from isopiestic measurements is reported. It was proved that only the new method is consistent.

A knoledge of thermodynamic properties of aqueous ternary solutions is necessary for clear understanding of the interactions in many aqueous ternary systems containing two electrolytes, an electrolyte and a nonelectrolyte, and two nonelectrolytes. The knowledge is also fundamental to a comprehension of the mechanism of the denaturation of proteins and the interactions in complex biological systems.

It is shown that the chemical potential of each component in ternary solution can be calculated at various concentrations by the isopiestic vapor pressure method. The free energy of transfer of a solute from a binary to a ternary solution is obtained at various concentrations from the chemical potentials in these solutions.

In actual biological systems, the concentrations of some solutes are very low, while, for instance, the average local concentrations of amino acids and peptides within the protein molecule are very high.[1] Further, the free energy of transfer is found to alter even its sign at some concentration range.[2] Consequently, not only the interactions at the standard state but also the concentration dependence of the interactions are very important.

Unfortunately, contradiction is found in the calculation of the transfer free energy on the mole fraction scale in recent papers.[3,4]

Here we report a new consistent expression for the free energy of transfer from isopiestic measurements.

The Free Energy of Transfer on Molality Scale

Since the concentration of the solute is measured on molality scale in the isopiestic method, we start with the free energy of transfer on the molality scale. The chemical potentials of solute 1 in a binary and in a ternary (solute 2 and water) solution on the molality scale, $\mu_{10}(m)$ and $\mu_1(m)$, are expressed as follows,

$$\mu_{10}(m) = \mu_{10}^0(m) + \nu_1 RT \ln m_{10}\gamma_{10} \quad (1)$$

$$\mu_1(m) = \mu_1^0(m) + \nu_1 RT \ln m_1\gamma_1 \quad (2)$$

where $\mu_{10}{}^0(m)$ and $\mu_1{}^0(m)$ are the standard states in a binary and in a ternary solution, respectively. m_{10} and γ_{10} are the molality and the activity coefficient of solute 1 in a binary solution, and m_1 and γ_1 are the corresponding quantities in a ternary solution. γ_1 is the number of moles of ions formed from 1 mole of solute 1.

The immediate result of isopiestic vapor pressure measurements is the chemical potential of the volatile solvent (water) in the ternary solution. The chemical potentials of the solutes are calculated by Gibbs-Duhem equation,

$$n_w d\mu_w = -n_1 d\mu_1 - n_2 d\mu_2 \quad (3)$$

where

$$d\mu_i = \nu_i RT d\ln m_i\gamma_i \quad (i = 1 \text{ or } 2) \quad (4)$$

Equation (4) implies the assumption that $d\mu_j{}^0 = 0$. In other words, the activity coefficient of solute 1 is unity in the standard state in water and not in the standard state in a water-solute 2 solvent,[5]

$$\mu_{10}^0(m) = \mu_1^0(m) \quad (4a)$$

Consequently, the free energy of transfer of solute 1 from a given molality in water to the same molality in water-solute 2 solution is given by,

$$\Delta G_t(m) = \mu_1 - \mu_{10} = \nu_1 RT \ln (\gamma_1/\gamma_{10}) \quad (5)$$

The $\Delta G_t(m)$ in Eq. (5) has the same value as that of $\Delta G_t(m)$ which is defined by the change in excess free energy,

$$\Delta G_t(m) = \mu_1^{ex} - \mu_{10}^{ex}$$

where μ_1^{ex} and μ_{10}^{ex} are the excess free energy (or non-ideal free energy) defined by Friedman.[6]

The values of $\Delta G_t(m)$ of glycylglycine (solute 1) from water to urea-water solutions at various concentrations of glycylglycine (m_1) and urea (m_2) are shown in Table 1.

TABLE 1. FREE ENERGY OF TRANSFER ON MOLALITY SCALE (in J/mol) OF GLYCYLGLYCINE FROM WATER TO UREA SOLUTIONS

1.0	−102	−202	−289	−358	−411	−455
1.5	−82.8	−167	−238	−288	−317	−327

The Free Energy of Transfer on Mole Fraction Scale

The Examination of Previous Experessions.[4] When solute 2 is treated as a component of the mixed solvent, the appropriate concentration scale for solute 1 is the mole fraction. According to the definition in the previous paper,[4]

$$\Delta G_t(N) = \nu_1 RT \ln (f_1/f_{10}) \quad (6)$$

where $\Delta G_t(N)$ is the free energy of transfer of solute 1 from water to water-species 2 solution at constant mole fraction. f_{10} and f_1 are the activity coefficients of solute 1 in mole fraction scale in a binary and in a ternary solution, respectively. The activity coefficient of the

solute in molality scale is converted into the rational activity coefficient as usual by

$$f_{10} = \gamma_{10}(1+0.001 W_{A0}\nu_1 m_{10}) \tag{7}$$

where W_{A0} is the molecular weight of pure solvent. Let m_1' denote the molality of solute 1 in the ternary solution when the mole fraction of solute 1 in the ternary solution is the same as in a binary solution, then we have,

$$m_1' = (1+0.001 W_{A0}\nu_2 m_2)m_{10} \tag{8}$$

In the ternary solution, f_1 is related to γ_1' by

$$f_1 = \gamma_1'(1+0.001 W_A \nu_1 m_1') \tag{9}$$

where γ_1' is the activity coefficient of solute 1 at m_1' and W_A is the molecular weight of mixed solvent (water-species 2) defined by[3,4]

$$W_A = \frac{55.51 W_{A0} + W_2 m_2}{55.51 + m_2} \tag{10}$$

where W_2 and m_2 are the molecular weight and molality of species 2 in the mixed solvent, respectively.

To examine whether these definitions are consistent or not, we subtract $\Delta G_t(m)$ from $\Delta G_t(N)$. Then, at any concentration, using Eqs. (5) to (10), we obtain

$$\frac{\Delta G_t(N)-\Delta G_t(m)}{\nu_1 RT} = \ln\left\{\frac{1+0.001 W_A \nu_1 m_1'}{1+0.001 W_{A0}\nu_1 m_{10}}\right\} + \ln(\gamma_1'/\gamma_1) \tag{11}$$

At infinite dilution, $\gamma'_1=\gamma_1$, then,

$$\frac{\Delta G_t(N)-\Delta G_t(m)}{\gamma_1 RT} = 0 \tag{12}$$

On the other hand, since the chemical potential of solute 1 in a binary solution on mole fraction scale is,

$$\mu_{10}(N) = \mu_{10}^0(N) + \nu_1 RT \ln N_{10} f_{10} \tag{13}$$

Combining Eqs. (1) and (13), in a binary solution we have,

$$\ln f_{10} = \ln \gamma_{10} + \ln(m_{10}/N_{10}) + \frac{\mu_{10}^0(m)-\mu_{10}^0(N)}{\nu_1 RT} \tag{14}$$

Similarly in a ternary solution,

$$\ln f_1 = \ln \gamma_1' + \ln(m_1'/N_1) + \frac{\mu_1^0(m)-\mu_1^0(N)}{\nu_1 RT} \tag{15}$$

Substituting Eqs. (14) and (15) into Eq. (6) and combining Eqs. (5) and (6), we obtain

$$\frac{\Delta G_t(N)-\Delta G_t(m)}{\nu_1 RT} = \frac{\mu_1^0(m)-\mu_{10}^0(m)}{\nu_1 RT} - \frac{\mu_1^0(N)-\mu_{10}^0(N)}{\nu_1 RT} + \ln(m_1' N_{10}/N_1 m_{10}) + \ln(\gamma_1'/\gamma_1) \tag{16}$$

where $N_1=N_{10}$. Substituting Eqs. (4a) and (8) into (16), we have

$$\frac{\Delta G_t(N)-\Delta G_t(m)}{\nu_1 RT} = -\frac{\mu_1^0(N)-\mu_{10}^0(N)}{\nu_1 RT} + \ln(1+0.001 W_{A0}\nu_2 m_2) + \ln(\gamma_1'/\gamma_1) \tag{16a}$$

Combining Eqs. (11) and (16a), we obtain,

$$\frac{\mu_1^0(N)-\mu_{10}^0(N)}{\nu_1 RT} = \ln(1+0.001 W_{A0}\nu_2 m_2) - \ln\left\{\frac{1+0.001 W_A \nu_1 m_1'}{1+0.001 W_{A0}\nu_1 m_{10}}\right\}$$

which becomes at infinite dilution of solute 1,

$$\frac{\mu_1^0(N)-\mu_{10}^0(N)}{\nu_1 RT} = \ln(1+0.001 W_{A0}\nu_2 m_2) \tag{17}$$

Equation (17) shows that the difference between standard states on mole fraction scale in a binary and in a ternary solution depends on the concentration of solute 2. The free energy of transfer, defined by Eqs. (6), (7), (9), and (10) does not mean the difference in chemical potentials in the two states, but it means,

$$\Delta G_t(N) = \mu_1(N) - \mu_{10}(N) - \nu_1 RT \ln(1+0.001 W_{A0}\nu_2 m_2) \tag{17a}$$

Furthermore, using Eq. (17), we can examine Eq. (9). The usual relation between $\mu_{10}^0(m)$ and $\mu_{10}^0(N)$ is obtained from Eq. (14),

$$\frac{\mu_{10}^0(m)-\mu_{10}^0(N)}{\nu_1 RT} = -\ln\left(\frac{1000}{W_{A0}}\right) \tag{14a}$$

Then, using Eqs. (4a), (14a), and (17),

$$\frac{\mu_1^0(m)-\mu_1^0(N)}{\nu_1 RT} = \frac{\mu_1^0(m)-\mu_{10}^0(m)}{\nu_1 RT} - \frac{\mu_1^0(N)-\mu_{10}^0(N)}{\nu_1 RT} - \frac{\mu_{10}^0(N)-\mu_{10}^0(m)}{\nu_1 RT} = -\ln\left(\frac{1000}{W_{A0}}+\nu_2 m_2\right) \tag{18}$$

Equation (18) is substituted in Eq. (15), we obtain

$$f_1 = \gamma_1'\left(1+\frac{\nu_1 m_1'}{\frac{1000}{W_{A0}}+\nu_2 m_2}\right) = \gamma_1'\left(1+0.001\frac{1000}{\frac{1000}{W_{A0}}+\nu_2 m_2}\nu_1 m_1'\right) \tag{19}$$

Equation (19) differs from Eq. (9). For consistency, 1000 in the numerator in the second term in parenthesis of Eq. (19) should be $(1000+W_2 m_2)$. That is, the definition of f_1 by Eqs. (9) and (10) is not right.

The Consistent Expression for ΔG_t(N). Here $\Delta G_t(N)$ is defined by Eq. (6), and Eqs. (7) and (8) hold too. The difference between this and previous section is only in the definition of f_1. f_1 is defined by

$$f_1 = \gamma_1'\{1+0.001 W_{A0}(\nu_1 m_1' + \nu_2 m_2)\} \tag{20}$$

Now, at any concentration, from Eqs. (5), (6), (7), (8), and (20), we obtain

$$\frac{\Delta G_t(N)-\Delta G_t(m)}{\nu_1 RT} = \ln\left\{\frac{1+0.001 W_{A0}(\nu_1 m_1'+\nu_2 m_2)}{1+0.001 W_{A0}\nu_1 m_{10}}\right\} + \ln(\gamma_1'/\gamma_1) \tag{21}$$

At infinite dilution of solute 1, $\gamma'_1=\gamma_1$, so, Eq. (21) gives

$$\frac{\Delta G_t(N)-\Delta G_t(m)}{\nu_1 RT} = \ln(1+0.001 W_{A0}\nu_2 m_2) \tag{22}$$

which differs from Eq. (12) in previous section.

On the other hand, Eq. (16a) also holds here, consequently, combining Eqs. (16a) and (21), we obtain

$$\frac{\mu_1^0(N)-\mu_{10}^0(N)}{\nu_1 RT} = \ln(1+0.001 W_{A0}\nu_2 m_2) - \ln\left\{\frac{1+0.001 W_{A0}(\nu_1 m_1'+\nu_2 m_2)}{1+0.001 W_{A0}\nu_1 m_{10}}\right\}$$

which becomes at infinite dilution of solute 1,

TABLE 2. FREE ENERGY OF TRANSFER ON MOLE FRACTION SCALE (in J/mol) OF GLYCYLGLYCINE FROM WATER TO UREA SOLUTIONS

m_{10}	N_1	m_2					
		1.0	2.0	3.0	4.0	5.0	6.0
0	0	−189	−342	−456	−533	−579	−611
0.5	0.008927	−108	−201	−272	−319	−348	−369
1.0	0.017696	−64.0	−126	−174	−204	−216	−218
1.5	0.026311	−44.8	−90.4	−122	−129	−110	−82.4

$$\frac{\mu_1^0(N)-\mu_{10}^0(N)}{\nu_1 RT}=0 \tag{23}$$

That is, the standard states in a binary and in a ternary solution are the same on mole fraction scale too, and $\Delta G_t(N)$ means the difference in chemical potentials of the solute in a ternary and binary solution, as in the case of $\Delta G_t(m)$. The difference between the standard states in the ternary solution on molality and on mole fraction scale is obtained by combining Eqs. (4a), (14a), and (23),

$$\frac{\mu_1^0(m)-\mu_1^0(N)}{\nu_1 RT}=-\ln(1000/W_{A0}) \tag{24}$$

By substituting Eq. (24) into Eq. (15), we obtain the same equation for f_1 as Eq. (20). Consequently, the definition of $\Delta G_t(N)$ by Eq. (6) and f_1 by Eq. (20), results in the consistent relation.

The value of $\Delta G_t(N)$ at infinite dilution which is expressed by Eq. (22) has the same value as the quantity defined by Bower and Robinson as a measure of the medium effect.[7]

The values of $\Delta G_t(N)$ of glycylglycine from water to urea-water mixture are tabulated in Table 2. $\Delta G_t(N)$ has less negative values than $\Delta G_t(m)$.

Microwave Spectrum of 2-Pyridinecarbaldehyde

Yoshiyuki KAWASHIMA, Masao SUZUKI, and Kunio KOZIMA*

Laboratory of Molecular Spectroscopy, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received January 29, 1975)

The microwave spectrum of 2-pyridinecarbaldehyde has been observed in the region 8—22 GHz. The rotational constants of the ground state are $A=5362.52\pm2.19$ MHz, $B=1620.07\pm0.03$ MHz, and $C=1244.42\pm0.03$ MHz and the inertia defect is -0.075 amu·Å^2. This value demonstrates that the molecule is planar in its equilibrium position. The total dipole moment is 3.56 ± 0.07 D, the components of which are $\mu_a=3.48\pm0.05$ D and $\mu_b=0.76\pm0.08$ D. From these facts it is concluded that the conformation of the molecule is of the O–N *s-trans* form. The rotational constants of the five vibrationally-excited states have also been determined.

Several studies of the microwave spectra have been done to determine the structural isomerism of conjugated aldehyde compounds. While two isomers, *i.e.*, the *s-trans* and the *s-cis* isomer, have been observed for furfural,[1,2] only the *s-trans* isomer has been found for 2-thiophenecarbaldehyde,[1] acrolein,[3] and crotonaldehyde.[4,5] By means of the microwave spectrum it is also known that only one isomer exists in the vapor of methacrolein and the structure of this isomer is quite similar to that of crotonaldehyde, except for the methyl group.[6]

By measuring the NMR spectrum of 2-pyridinecarbaldehyde in solution it has been suggested that the molecules are of the O–N *s-trans* form to the extent of 70—80 per cent.[7] However, in the study of the far infrared spectrum only one torsional frequency has been observed.[8] In order to know whether or not the two isomers exsist for this compound and to ascertain the stable conformation, this investigation was carried out.

Experimental

The sample of 2-pyridinecarbaldehyde, obtained from a commercial source, was purified by distillation at 53 °C/7 Torr before use. The microwave spectrum was measured over the frequency range from 8- to 22-GHz with a conventional 100-kHz square-wave Stark modulation spectrometer. The measurements were made by using a 6-m absorption cell cooled by ice.

Results and Discussion

Microwave Spectrum and its Assignments. By assuming that the stable conformation is of the O–N *s-trans* form and the form is planar in its equilibrium configuration and by using the normal values of the structural parameters, the rotational constants were roughly calculated. The low-J R-branch transitions of the a-type for the vibrationally-ground state could be found near the frequencies calculated from the preliminary rotational constants by using the rigid rotor approximation. The splittings caused by the nuclear quadrupole of the nitrogen atom were not observed. The $J=4\leftarrow3$ transitions were ascertained by their characteristic features in the Stark effect. By using the least-squares method the rotational constants were determined so as to get the best fit between the observed and the calculated frequencies. The transition frequencies thus assigned are listed in Table 1, together with the differences between the observed and the calculated frequencies. A search was made for b-type transitions at the expected frequencies, but none could be detected unambiguously. As can be seen from Table 1, the agreement is such that the effect of centrifugal distortion can be said to be negligible in the range studied. The rotational constants determined are shown in

Table 1. Assigned transition frequencies of 2-pyridinecarbaldehyde in the vibrationally-ground state (in MHz)

Transition	ν_{obsd}[a]	$\Delta\nu$[b]	Transition	ν_{obsd}[a]	$\Delta\nu$[b]

Table 2. The small negative value of the inertia defect demonstrates that the molecule is planar in its equilibrium configuration.

By assuming the molecular parameters of the r_s structure of pyridine[9] for the ring and the parameters of furfural[1] for the aldehyde group, the distance, C_2–C, between the C_2 atom and the carbon atom of the CHO group and the angle of $\angle$N–C_2–C were determined so as to get a good fit between the observed and the calculated rotational constants, where the ring carbons are numbered from the nitrogen starting with C_2. The results obtained for the *s-trans* isomer are shown in Table 3, where the hydrogen atom attached to C_n is designated as H_n. The rotational constants thus calculated from these parameters were A=5362.5 MHz, B=1620.1 MHz, and C=1244.2 MHz, in good agreement with the observed values. By using these parameters the molecular configurations calculated for the *s-trans* and the *s-cis* isomer are schematically shown in Fig. 1. When the *s-cis* form is assumed for this compound, it seems hard to adjust the parameters to fit the calculated rotational constants with those observed, unless the parameters of the CHO group, for instance, are varied beyond the reasonable values. Therefore, it is probable that the molecule is of the O–N *s-trans* isomer. Some evidence for this is given by the data of the dipole moments.

TABLE 3. MOLECULAR PARAMETERS OF 2-PYRIDINECARBALDEHYDE

Assumed structural parameters[a]	
Distances	Angles
N–C_2: 1.340 Å	$\angle C_6$–N–C_2: 116°50′

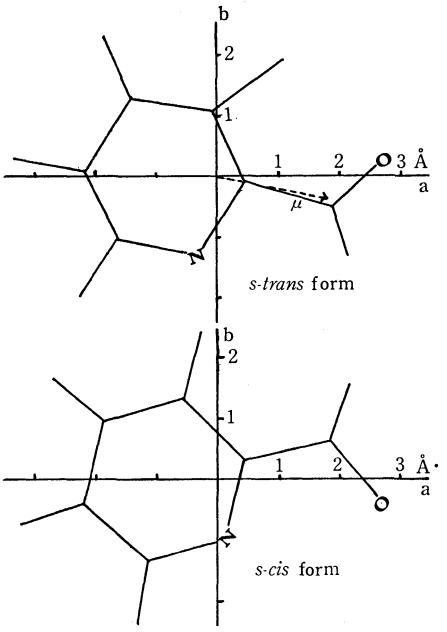

Fig. 1. Two isomers of 2-pyridinecarbaldehyde.

Dipole Moment. In order to determine the electric dipole moment, the Stark displacements of the six transitions, shown in Table 4 were measured. These lines fit the quadratic Stark displacements nicely. The absorption cell was calibrated using the J=1←0 transition of OCS, taking the dipole moment of OCS as 0.7152 D.[10] The observed and calculated Stark coefficients are given in Table 4, together with the value of the total dipole moment, μ, and those of its components along the a and b principal axes, μ_a and μ_b.

TABLE 4. (a) STARK EFFECT AND OBSERVED VALUES OF DIPOLE MOMEMNTS OF 2-PYRIDINECARBALDEHYDE

	μ_a	μ_b	$\tan^{-1}(\mu_a/\mu_b)$
s-trans form	3.83 D	0.78 D	11.5°
s-cis form	4.47	2.84	32.4°

It is reasonable to consider that the dipole moment of this compound is approximately given by the vector sum of the moment of benzaldehyde and that of pyridine.

Our recent study of the microwave spectrum of benzaldehyde has elucidated that the value of the component of the dipole moment parallel to the C=O bond is 2.95 D, pointing the negative end toward the oxygen atom, and that perpendicular to the C=O bond is 1.28 D, pointing the negative end toward the hydrogen atom of the aldehyde group.[11] By using the microwave spectrum the value of the dipole moment of pyridine is found to be 2.15 D.[12] There is no doubt that the C_2 axis of the pyridine molecule coincides with the orientation of the moment vector, the negative end of which points to the nitrogen atom. By considering that the molecular parameters of the *s-cis* form are not so different from those of the *s-trans* form, it can be calculated from the parameters that for the *s-trans* or the *s-cis* form the C_2 axis of the pyridine ring makes an angle of 66.7 ° or 43.5 ° with the a principal axis, and the C=O bond makes an angle of 43.3 ° or 48.5 ° with the same axis, respectively.

By adding the vectors mentioned above, the a and b components of the moment were calculated for the *s-trans* and the *s-cis* isomer. The results obtained are

shown in Table 4(b). From the table it can be concluded that the compound in the vapor exists mainly as the O–N *s-trans* isomer, in agreement with the preliminary result described above. Of the four possible directions of the dipole moment, the direction supported by the calculation is shown by an arrow in Fig. 1.

From the dielectric constant measurements, the value of the dipole moment has been reported as 3.35D in the benzene solution at 25 °C,[13,14] and the values of the moments for the *s-trans* and the *s-cis* form have been estimated as 3.51 D and 5.05 D, respectively.[13] These values estimated in the benzene solution seem almost to agree with the values of 3.91 D and 5.30 D estimated in the vapor, respectively, as can be calculated from the values shown in Table 4(b).

In the case where two isomers of a compound exist in equilibrium, it is well known that the abundance ratio of the molecules of the more polar isomer to those of the less polar isomer generally increases when the state changes from vapor to a benzene solution. Therefore, as the barrier to internal rotation of the CHO group of this molecule is considered to be comparable to that of benzaldehyde,[15] from the fact that the value of the moment obtained in the vapor is larger than that obtained in the benzene solution it can be said that no considerable amount of the molecules of the *s-cis* isomer exists even in the benzene solution.

Vibrationally-excited states. As the spectrum is very rich, an attempt should be made to find the lines due to the *s-cis* form. Therefore, the measurements were carefully made near the frequencies estimated by using the rotational constants of the *s-cis* form, which were tentatively calculated from the molecular parameters listed in Table 3. However, we could not observe

any lines which might be assigned to the *s-cis* form, while we could find the five sets of the spectra due to the vibrationally-excited states near the spectrum of the ground state. The excited states will be designated hereafter by the symbol of v_i, the suffix, i, being numbered from one upward in the order of decreasing intensity. By using the least-squares procedure, the five sets of the rotational constants were determined so as to get the best fit between the observed and the calculated frequencies. Of the observed frequencies for each set, several values, which do not seem to be precise, were omitted in this calculations. The assigned transition frequencies for the excited states are listed in Table 5, together with the differences between the observed and the calculated frequencies. The rotational constants thus obtained are shown in Table 6.

From the values of the inertia defects shown in Table 6, it is concluded that the v_1, v_2, and v_5 states are the excited ones for the out-of-plane deformation vibrations.

Table 6. ROTATIONAL CONSTANTS AND INERTIA DEFECTS OF 2-PYRIDINECARBALDEHYDE IN VIBRATIONALLY-EXCITED STATES

	Rotational constants (MHz)			Inertia defect (amu·Å²)
	A	B	C	
v_1	5342.21 ±2.71	1620.65 ±0.04	1246.31 ±0.04	−0.937 ±0.048
v_2	5256.60 ±4.22	1615.70 ±0.07	1245.49 ±0.05	−3.167 ±0.077
v_3	5432.22 ±4.66	1621.67 ±0.06	1246.67 ±0.04	0.709 ±0.076
v_4	5374.64 ±2.94	1622.03 ±0.03	1245.65 ±0.03	0.112 ±0.051
v_5	5342.23 ±2.92	1622.79 ±0.04	1247.91 ±0.04	−1.047 ±0.051

It should be noted that the values of the inertia defects for the v_1 and v_2 states are almost the same as those of the $v=1$ and $v=2$ states of benzaldehyde obtained by Kakar *et al.*,[15] respectively.

v_4	239±13		
v_5	312±35	—	—

a) This value is quoted from Ref. 8.

By measureing the relative intensities of the satellite lines with respect to the ground state transitions, the vibrational energy separations were estimated from the Boltzmann factor. The results are shown in Table 7, together with the corresponding wave numbers obtained from the far-infrared and the laser Raman spectrum of the liquid state for comparison. The broad infrared band near 225 cm⁻¹ may be a doublet.

Ligand-Ligand Interaction in Tris(2,2'-bipyridyl) and Tris (1,10-phenanthroline) Complexes of Nickel(II)

Takeshi OHNO and Shunji KATO

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

(Received February 1, 1975)

UV spectra of $[Ni(2,2'\text{-bipyridyl})_3]Cl_2$ and $[Ni(2,2'\text{-bipyridyl})(H_2O)_4]Cl_2$ in the mixed solvent of methanol and water (4: 1) were measured at 4.2 K. No difference between the spectra indicates a small splitting (<90 cm^{-1}) between the exciton states extending through the three 2,2'-bipyridyls. Since the UV spectrum of $[Ni(1,10\text{-phenanthroline})_3]Cl_2$ has a band with the progression as that of $[Ni(1,10\text{-phenanthroline})(H_2O)_4]SO_4$, a molecular exciton interaction between the three 1,10-phenanthrolines is not strong.

When some aromatic molecules coordinate to a metal ion through hetero atom(s) of the group(s) such as >C=O >O$^-$, and >N, they suffer from such ligand-ligand interactions as a molecular exciton interaction and a Coulomb exchange interaction between the neighbouring ligands.[1-3] We have investigated the ligand-ligand interactions by comparing the excited states of the bis- or the tris-bidentate complexes with those of the corresponding mono-bidentate complexes in the cases of β-diketones, 2,2'-bipyridyl,* 1,10-phenanthroline,** and *N*-alkylsalicylideneimine[4] at 77 K, and have obtained some remarks as follows; (a) the higher intensity of 0–0' band (absorption) and 0'-0 band (fluorescence) compared to those of the mono-bidentate complex suggests a delocalization of the excited singlet state through the two or three chelating ligands, (b) the increase in the yield of the triplet state formation is attributed to the overlap between the ligands nearly perpendicular with each other, (c) there was no distinct splitting of the absorption band, indicating a weak ligand-ligand interaction, (d) the depolarized fluorescence of $[Zn(bipy)_3]^{2+}$ at 77 K suggests that the energy splitting due to ligand-ligand interaction is so small (<70 cm^{-1}) that the upper state fluoresces as the lower does.

In contrast to the small splitting of the molecular exciton states, Mason *et al.* had concluded on the assumption of the strong coupling scheme that the molecular exciton splittings were nearly equal to differences (1200—2000 cm^{-1}) between the peaks of the positive and the negative bands of the circular dichroism observed at room temperature in the cases of trisacetylacetonato,[5] tris-phen[6] and tris-bipy[6] complexes. Recently, however, it was demonstrated[7] that either a medium or a weak coupling scheme was a suitable one, because the absorption and the circular dichroism spectra with a fine structure were observed in the case of $[Ni(bipy)_3]^{2+}$ below 0 °C: a small splitting value (<70 cm^{-1}) was inferred on the basis of the vibronic coupling theory proposed by Perrin and Gouterman.

In order to obtain the splitting in $[Ni(bipy)_3]^{2+}$, we tried to measure the well resolved absorption spectrum in a mixed solvent at 4.2 K, where the compound is free from a (crystal) exciton.

* 2,2'-Bipyridyl will be hereafter abbreviated to "bipy."

** 1,10-Phenanthroline will be hereafter abbreviated to "phen."

Experimental

Materials $[Ni(bipy)_3]Cl_2$, $[Ni(phen)_3]Cl_2$, and $[Ni(bipy)(H_2O)_4]SO_4$ were prepared from appropriate nickel (II) salts and the ligands and purified by recrystallization. G.R. methanol of Wako Chemical Co., and twice distilled water were used for the mixed solvent.

Procedure All the sample solutions except for $[Ni(phen)(H_2O)_4]^{2+}$ solution were prepared by dissolving a com plex in the mixed solvent of the methanol and the water (4:1 by volume). The sample solution of $[Ni(phen)(H_2O)_4]^{2+}$ is obtained by dissolving $NiSO_4 \cdot H_2O$ of $\sim 2 \times 10^{-4}$ M and the phenanthroline of 2×10^{-5} M in the solvent. It is assumed on the basis of the large formation constant (log $K_1 = 8.60$[8]) that the free phen was reduced to 0.1% at most. The absorption spectra at 4.2 K were measured by using a thin cell (0.1×10 mm) plunged in the liq. He in a Dewar vessel, which was kindly offered by prof. N. Mataga. Although the sample solutions had a great number of fine cracks at 4.2 K, the cracks did not interfere with the measurement of the absorption spectrum owing to the following reasons. One is that the fine cracks running perpendicular to the window of the cell do not seriously scatter the light beam. The other is that a head-on-type photomultiplier with a wide aperture (A=12 cm^2) can catch the most of the scattered light. Though a polyvinylalcohol film (PVA) and a rod of polymethylmethacrylate (PMM) containing a complex, had no crack at 4.2 K, the doped complex has a broader spectrum, which is probably attributed to many kinds of doping cite in PVA or a thermal decomposition of the complex during the thermal polymerization.

Results

Absorption spectra of $[Ni(bipy)_3]^{2+}$ and $[Ni(bipy)(H_2O)_4]^{2+}$ in the region of the UV are shown in Figs. 1 and 2, respectively. The absorption bands at 4.2 K (solid line in Figs. 1 and 2) have well resolved structure which are almost common to the two ions. Figure 3 shows the absorption spectra of $[Ni(phen)_3]^{2+}$, $[Ni(phen)(H_2O)_4]^{2+}$ and the free phen in the region of the UV at 77 K. The three compounds have similar and weakly resolved spectra at 77 K.

Discussion

$[Ni(bipy)_3]Cl_2$. Since $[Ni(bipy)(H_2O)_4]^{2+}$ has a similar absorption spectrum to that of $[Zn(bipy)(H_2O)_4]^{2+}$ in the region of the UV, the well resolved spectrum is mainly attributed to the coordinating bipy with *cis*-conformation (not to d-d transition). The

coordinating bipy in the nickel complex is assumed to have practically one kind of transition ($A_1 \rightarrow B_1$) with the moment which is a several tens times as large as the other one ($A_1 \rightarrow A_1$),[9] as in the case of $[Zn(bipy)(H_2O)_4]^{2+}$ whose strong fluorescence at 77 K has a good mirror image relation to the absorption spectrum. Therefore, several sub-bands of $[Ni(bipy)(H_2O)_4]^{2+}$ are assigned to vibronic ones of the transition, $A_1 \rightarrow B_1$.

It is easily seen that the tris-bipy complex of nickel (II) keeps the vibronic band system of the mono-bipy complex and has neither new band nor splitting of the vibronic bands, which should be observed if there are any strong or intermediate coupling between the three ligands. The common width (460 cm^{-1}) of the 0–0′ bands to the two complexes, offers a contradictory proof to the inter-ligand interaction.

It is assumed that in the weak interaction scheme, a splitting of the vibronic band is produced by the interaction between the same vibronic states, the one of the splitted bands of the lower frequency is assigned to the transition to the E state and the other of the higher frequency to the A_2 state of $[Ni(bipy)_3]^{2+}$ with D_3 symmetry. And the spacing between the two 0–0′ bands may be equal to the splitting between the E and the A_2 states. When the splitting is much smaller than a spacing between the adjacent progression bands, the bands do not split but become broader. On assuming a Gaussian band shape and a moment ratio, 1 : 2, of $A_1 \rightarrow E$ to $A_1 \rightarrow A_2$, it is obtained that a greater bandwidth (473 cm^{-1}) than that (460 cm^{-1}) of the mono-bipy complex may be observed for $[Ni(bipy)_3]^{2+}$ when the splitting is 90 cm^{-1}. Therefore, the common band width (460 cm^{-1}) to the complexes implies a splitting less than 90 cm^{-1} between the two states. This possible largest value is supported by the fact that the splitting of $[Zn(bipy)_3]^{2+}$ is less than 70 cm^{-1}, which had been obtained by a measurement of the fluorescence polarization. Assuming that the total coupling energy is four times as great as the splitting of the 0–0′ band, of which the intensity is one-fourth of the total intensity, the possible maximum value of the coupling energy (360 cm^{-1}) is consistent with 210 cm^{-1} which Hawkins *et al.*[7] have obtained by the spectrum simulation of the circular dichroism on the basis of Perrin-Goutermans' vibronic coupling theory.

On the other hand, Mason has obtained a larger coupling energy (1050 cm^{-1}) by fitting the observed intensity of the circular dichroism with the calculated one on the Hückel M.O.[10] However, the reconstituted circular dichroism was so complex as to contain some extra shoulders (as Fig. 2 in the reference 10 shows). Because a surplus of shoulders or bands is originated from a larger coupling, the phantom shoulders of the reconstituted spectrum may be explained by an overestimation of the coupling energy.

$[Ni(phen)_3]^{2+}$. As in the case of the bipy complexes, all the absorption bands of the tris-phen and the mono-phen complexes in the region of $30—40 \times 10^3$

Table 1. The fine structure of the highest band

$[Ni(phen)(H_2O_4)]^{2+}$		$[Ni(phen)_3]^{2+}$

(37740)[a]	700	37450	690
(38460)	720	(38170)	720

a) Parenthesis shows shoulder.

cm^{-1} are assigned to the transition localized in the ligand(s). The mono-phen complex holds a weakly resolved structure for the transition of the largest wave number (^1B_a in the free phen). The structure may be caused by a metal effect, because the ^1B_a band of the free phen has no structure (but a great band width). Since the structure has a common spacing between the adjacent sub-bands (700 cm^{-1}) as Table 1 shows, the sub-bands are assigned to the vibronic bands. In the tris-phen complex, the less clear progression with the spacing of 700 cm^{-1} was observed and the feature of the band was similar to that of the free phen. It is probable that the less clear structure is caused by a sharing of the metal effect with the three ligands. A similar situation has been observed in the case of $[Zn(phen)_2(H_2O)_2]^{2+}$.[3]

Hawkins *et al.* has offered another explanation to the less stronger 0–0′ band of $[Ni(phen)_3]^{2+}$ than the 0–0′ band of $[Ni(phen)(H_2O)_4]^{2+}$; this explanation was that a molecular exciton interaction in $[Ni(phen)_3]^{2+}$ produced a broading of the 0–0′ band.[7] However, it must be noticed that $[Ni(phen)_3]^{2+}$ has a common spacing between the sub-bands as $[Ni(phen)(H_2O)_4]^{2+}$ has.

Core-electron Spectra of Mono-substituted Benzenes Obtained by the Gas-phase X-Ray Photoelectron Spectroscopy

Toshiaki OHTA, Takashi FUJIKAWA, and Haruo KURODA

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received February 7, 1975)

The gas-phase X-ray photoelectron spectra were observed on benzene and its eight mono-substituted derivatives; C_6H_5X, X=H, CH_3, NH_2, OH, F, Cl, Br, NO_2 and CN. Binding energies of core levels were determined from the observed spectra by using the spectrum simulation technique, and they were compared with the chemical shift predicted from the CNDO/2 charge densities on the basis of the electrostatic potential model. It is shown that the C1s binding energies of benzene derivatives can be generally correlated with atomic charges, q_j, by the following equation;

$$E_i(\text{C 1s}) = 290.2 + 22.67q_i + \sum_{j\neq i}(q_j/R_{ij}) \quad \text{eV.}$$

By using this relation and the observed C1s binding energies, the atomic charge analysis is carried out. Satellite bands were observed in the C1s spectra as well as in some other core-electron spectra of benzene derivatives. Theoretical calculations are carried out on the energies and probabilities of shake-up transitions. It is concluded that the observed satellites are mainly due to the shake-up processes associated with the excitations of π electrons.

The effects of substituent groups on the charge distributions in benzene derivatives are of great interest from chemical point of view, and have been studied by means of various theoretical methods. However, hitherto, there has been no experimental method which directly gives the atomic charges of a molecule. The core electron binding energies of atoms in a molecule can be determined by means of X-ray photoelectron spectroscopy. It has been well established that the core electron binding energy varies more or less depending on the chemical bonds in the ground state of molecule, and this effect, called "chemical shift," is directly reflecting the charge distribution in the molecule. Thus X-ray photoelectron spectroscopy provides a way to investigate the atomic charges of a molecule.

On several benzene derivatives, Clark *et al.*[1] observed the X-ray photoelectron spectra of their frozen solid states, and discussed the correlation between CNDO/2 charge densities and observed binding energies. In particular, detailed investigations were carried out on fluorobenzenes.[2] In a previous paper,[3] we studied the charge distributions of *p*-benzoquinone, hydroquinone and their halogen-substituted derivatives from the X-ray photoelectron spectra of the solid states of these compounds.

However, the X-ray photoelectron spectrum of a solid sample is unavoidally affected by the so-called solid state effects, so that there always remain some ambiguities in the analyses of chemical-shift data obtained from the solid-state X-ray photoelectron spectroscopy. It is desirable to use the gas-phase X-ray photoelectron spectra in order to study molecular properties. The atomic charges of fluorobenzenes were investigated by Thomas[4] by this technique.

In the present paper, we report the gas-phase X-ray photoelectron spectra of monosubstituted benzenes and the results of the analyses of the observed spectra by means of the electrostatic potential model. We will also report the natures of the satellite bands accompanying the core electron peaks.

Experimental

The gas-phase X-ray photoelectron spectra were measured with a McPherson ESCA 36 electron spectrometer, by employing Mg$K\alpha$ radiation (1253.6 eV), on benzene and its monosubstituted derivatives: C_6H_5X (X=H, OH, NH_2, CH_3, CN, NO_2, F, Cl and Br). Each sample, purified by distillation in advance, was repeatedly out-gassed by the freezing and pumping technique, and then its vapor was introduced into gas-handling system of the spectrometer through a needle valve. In most of the present experiments, the pressure of sample vapor read at the position just after the needle valve, was maintained at about 0.2 Torr. Since this position is considerably separated with fine tubing from the gas-ionization cell of the spectrometer, the actual vapor pressure within the ionization cell must be very much lower, possibly one order less, than the above value.

The binding energies of core electron peaks, referred to the vacuum level, were calibrated by using the N1s peak of nitrogen gas, mixed in the sample vapor, as the reference; the binding energy of the N1s level of nitrogen molecule was taken as 409.9 eV. The energy calibration was repeated at least twice for each sample by independent experiments, and confirmed to be reproducible within 0.2 eV.

Results and Discussion

Binding Energies of Core Electron Levels. In the case of monosubstituted benzenes, there are four inequivalent positions of carbon atom in their benzene rings; we will label these positions as C_1, C_2, C_3, and C_4 as illustrated in Fig. 1. Thus we should expect that C1s levels of a monosubstituted benzene will split into four because of the chemical shifts. In the cases of toluene

a) X means halogen atoms

and benzonitrile, there will be another Cls level associated with the carbon atom of substituent group. However, the splittings of Cls levels are not large enough to give well resolved peaks in the observed Cls spectra. In effect, the Cls spectra of monosubstituted benzenes were observed only as a broad and asymmetrical peak with or without a shoulder. Therefore, we used the spectrum simulation technique to determine the binding energy of each Cls level. In applying this technique, we must first determine the peak shape of a single component. The Cls peak of benzene can be used for this purpose since there should be no splitting of Cls level in the case of benzene. In effect, the observed Cls spectrum of benzene gave a sharp symmetrical peak, its width (FWHM) being 1.05 eV under the present experimental condition. We tried to fit the observed peak with a modified Lorentz function described as follows;

$$f(E-E_0) = I\cdot\left[\frac{1-s}{1+\left(\frac{E-E_0}{w/2}\right)^2}+\frac{s}{1+\left(\frac{E-E_0}{w/2}\right)^4}\right] \quad (1)$$

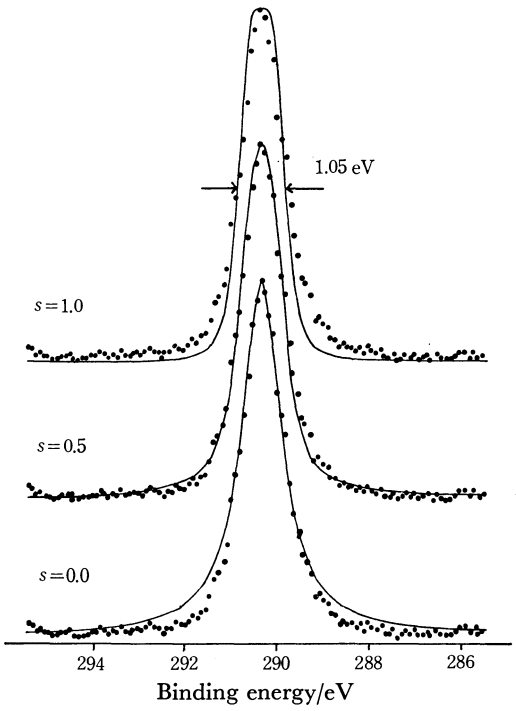

Fig. 2. X-Ray photoelectron spectrum of Cls electrons of benzene. The calculated curve (see text) are shown by solid lines.

where I, E_0 and w are the height, position and width of the peak, respectively, and s is a parameter determining the peak shape. In Fig. 2, the peak shapes calculated for $s=0.0$, 0.5, and 1.0 are compared with the observed Cls peak of benzene. The best agreement was obtained when $s=0.5$. Thus we decided to set $w=1.05$ eV and $s=0.5$ in the following process. Next, we examined the expected order of different Cls levels of each monosubstituted benzene. This information is desirable to have, though not indispensable, in order to carry out the spectrum simulation procedures. For this purpose, we estimated the relative chemical shift, ΔE_i, from the CNDO/2 charge densities by the following equation given by the electrostatic potential model;[5)]

$$\Delta E_i = k_c q_i + \sum_{j\neq i}(1/R_{ij})\cdot q_j \quad (2)$$

where q_i and q_j are the charge densities of the i-th and j-th atoms, respectively, R_{ij} is the interatomic distance (in atomic units), and k_c is a constant which we tentatively assumed as 22.1 eV/unit charge. The charge densities obtained by CNDO/2 calculations are given in Table 1. In the case of bromobenzene, we did not carry out the CNDO/2 calculation, but assumed that the order of the C ls levels is the same as in fluorobenzene.

Taking the intensity ratio of the peaks corresponding to C_1, C_2, C_3, and C_4 as 1 : 2 : 2 : 1, we adjusted the peak positions until the best agreement was obtained between the calculated and observed C ls spectra. The final

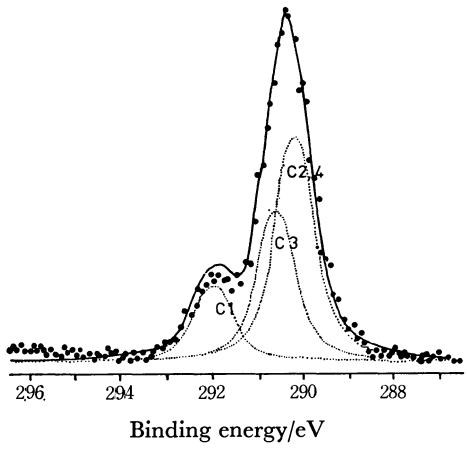

Fig. 3. Decomposition of the Cls spectrum of phenol into the constituent bands. The results of decomposition are shown with broken lines.

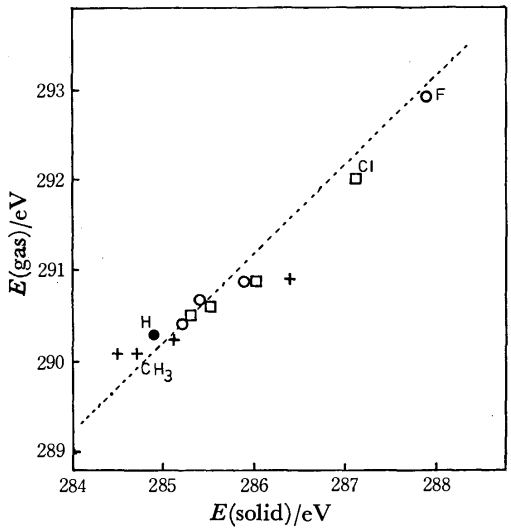

Fig. 4. Comparison of the C 1s binding energies obtained by the gas phase experiments with those reported from the studies of frozen solids.[1]

result of such a procedure is illustrated in Fig. 3, which is the one obtained of phenol. By the above technique, we were able to determine the binding energy of each C 1s level with an accuracy of ± 0.1 eV. The values thus obtained are given in Table 2 together with the binding energies of other core electron levels.

Clark *et al.*[1] reported the C 1s binding energies of benzene, toluene, chlorobenzene and fluorobenzene, obtained from the similar analyses of the shapes of the C 1s spectra of the frozen solid states. In Fig. 4, their values are compared with our gas-phase values. We can conclude that there is a nearly constant energy difference, 5.2 eV, between the solid and gas-phase values. It should be noted first that the solid-state values are the ones referred to the Fermi levels of the samples whereas our gas-phase values are referred to the vacuum level, and second that the binding energy obtained of a solid sample is necessarily affected by the fact that the core-hole ion state is stabilized by polarizing its surroudings. In other words, the binding energies determined from the X-ray photoelectron spectra of solid samples are dependent on the work function and polarization energy of the solid state, both of which should, in principle, vary from sample to sample. Therefore, it is rather surprising to find that the difference between the solid and gas-phase values is almost the same for a variety of monosubstituted benzenes.

Effects of Substituent Group on C 1s Levels. The binding energies of the C 1s levels of monosubstituted benzenes are compared in Fig. 5. We note that, in all cases, the C 1s level of the carbon atom at the substituted position is considerably shifted to higher binding energy as the result of substitution, while those of other carbon atoms of benzene ring show much smaller shifts except in the cases of nitrobenzene and benzonitrile.

As we compare the four molecules, C_6H_5X with X= H, Br, Cl, and F, the shifts of the C 1s level of the atom at the substituted position is the larger as the electronegativity of the substituent atom is the higher. The four substituents, CH_3, NH_2, OH, and F, are mutually

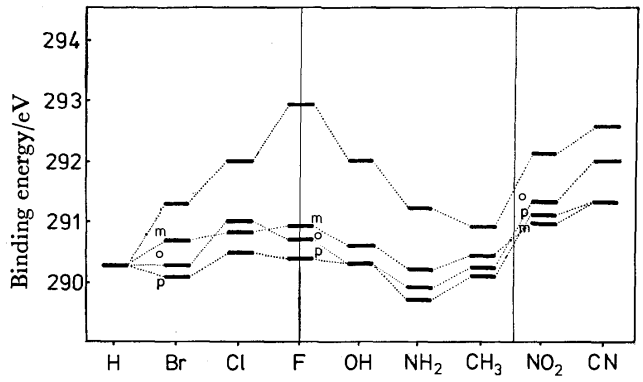

Fig. 5. C 1s Binding energies of benzene derivatives.

isoelectronic, and the electronegativity increases in the order, C<N<O<F. Here again, the core electron level of the carbon atom at the substituted position increases with the increase of electronegativity of the substituent.

In the cases of the six substituents mentioned above, the core electron binding energies of the carbon atoms at *ortho*-, *meta*-, and *para*-positions are in the order, *para*< *ortho*<*meta*, except for chlorobenzene.[6]

The CN and NO_2 groups are known to be electron attractive substituents, whose π-electron systems can interact strongly with those of benzene ring. These can be clearly distinguished from other substituents by looking their effects on the C 1s levels; In benzonitrile and nitrobenzene, all C 1s levels are considerably shifted to higher binding energy as compared with the C 1s level of benzene.

Charge Distribution and Chemical Shift. According to the electrostatic potential model, the binding energy E_i of a core electron level of the i-th atom in a molecule is given by the following equation,

$$E_i = E_0^{\mathrm{A}} + k_{\mathrm{A}} q_i + \sum_{j \neq i} (q_j / R_{ij}) \qquad (3)$$

where E_0^{A} and k_{A} are constants dependent on the kind of atom. Strictly speaking, the value of E_0^{A} must be slightly different for different molecules since it is affected by the molecular reorganization energy, but we could reasonably assume that it remains the same among benzene derivatives.[7]

We can rewrite Eq. (3) in the following form;

$$E_i - \sum_{j \neq i} (q_j / R_{ij}) = E_0^{\mathrm{A}} + k_{\mathrm{A}} q_i \qquad (4)$$

This means that one should obtain a straight line when $E_i - \sum_{j \neq i} (q_j / R_{ij})$ is plotted against q_i. Using the CNDO/2 charge densities and observed C 1s binding energies E_i(obsd), we calculated $E_i(\mathrm{obsd}) - \sum_{j \neq i} (q_j / R_{ij})$ and plotted it against q_i. The result is shown in Fig. 6. We see that the plots are, in effect, well on a straight line except a few points concerned with benzonitrile and chlorobenzene. The inclination of the above straight line gives the value of k_{C} as 22.67 eV/unit charge, which is in good agreement with the value, 22.0 eV/unit charge, calculated from Slater orbitals for the carbon atom by Siegbahn, *et al.*[5] The intercept of the line at $q_i=0$ gives the E_0^{A} value. This found to be 290.2 eV. Thus we obtain the following equation;

TABLE 2. BINDING ENERGIES OF CORE LEVELS (unit: eV)

	C_1	C_2	C_3	C_4	C	N	O	X

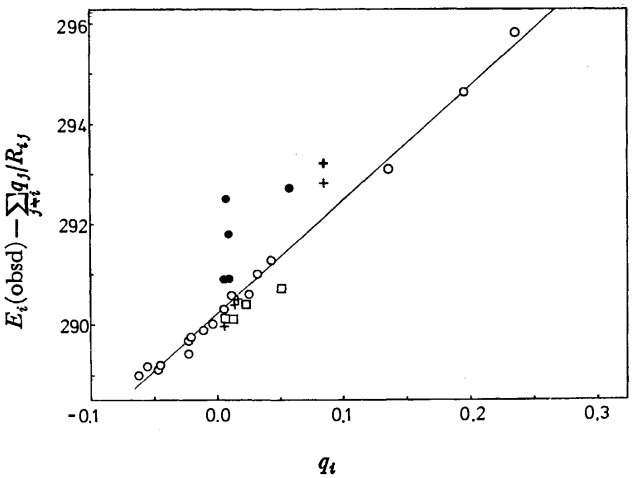

Fig. 6. Correlation of between $E_i(\text{obsd})-\sum_{j\neq i}q_j/R_{ij}$ and q_i. The data points shown by filled circles, open squares and crosses are those of benzonitrile, nitrobenzene and chlorobenzene, respectively. The data points related with other compounds are shown by open circles.

$$E_i(\text{Cls}) = 290.2 + 22.67q_i + \sum_{j\neq i}(q_j/R_{ij}) \qquad (5)$$

We propose the above equation as the one generally applicable for the analyses of Cls binding energies of benzene derivatives.

By Eq. (5) we calculated the binding energies of Cls levels of monosubstituted benzenes from the CNDO/2 charge densities listed in Table 1, and calculated the Cls spectrum of each compound. The results are compared in Fig. 7. The calculated spectra almost completely agree with the observed ones in the cases of toluene, aniline, phenol and fluorobenzene. In comparison with the above cases, the agreement is less satisfactory in the cases of chlorobenzene, nitrobenzene and benzonitrile. We think that this is reflecting the poor reliabilities of the charge densities estimated for these compounds by CNDO/2 calculations.

Atomic Charge Analysis. According to Eq. (3), the relative chemical shift, $\Delta E_i=E_i-E_0^{\text{A}}$, of each core level can be expressed by a linear combination of charge densities. Thus we have a series of linear equation of the following form;

$$\Delta E_i = \sum_j a_{ij}q_j \qquad (6)$$

In a matrix presentation, they can be summarized as follows

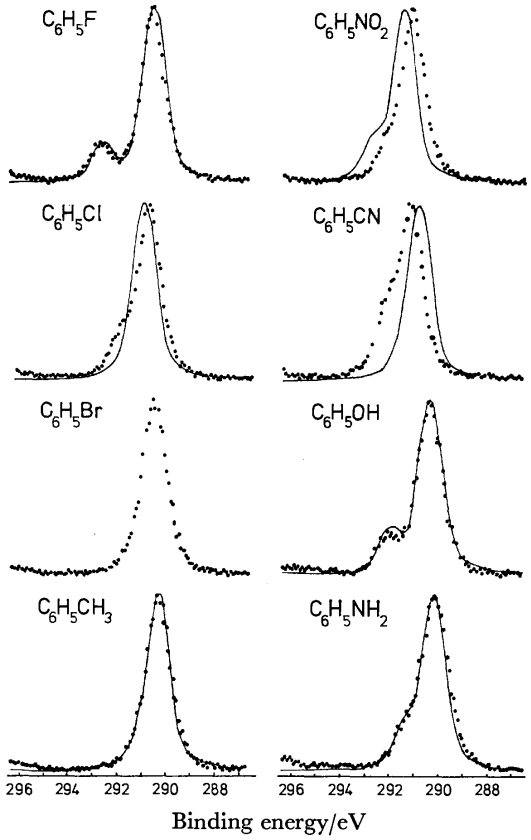

Fig. 7. Cls Spectra of benzene derivatives. The observed data are shown by points. The spectra calculated from the CNDO/2 charge densities are shown by lines.

$$\boldsymbol{\delta} = \mathbf{Aq} \qquad (7)$$

where $\boldsymbol{\delta}$ and $\mathbf{q}$ are vectors whose components are the ordered sets $\{\Delta E_i\}$ and $\{q_j\}$, respectively, and $\mathbf{A}$ is the matrix whose elements are a_{ij}. By comparing Eq. (6) with Eq. (3), one can easily see that an off-diagonal element a_{ij} of $\mathbf{A}$ matrix is equal to $1/R_{ij}$ which can be known from the molecular geometry, and a diagonal element a_{ii} is equal to k_{A}. Thus, if we know the $\boldsymbol{\delta}$ vector, we can, in principle, calculate the $\mathbf{q}$ vector. In other words, the charge densities can be estimated from the observed chemical shifts of core electron levels. This method has been used by several authors[3,4,8] and named "atomic charge analysis" (ACHARGE analysis).

In the preceeding section, we have determined the E_0^{A} and k_{A} values for Cls level, but not for other core levels. Furthermore, the components of $\boldsymbol{\delta}$ vector,

Table 3. Charge densities determined by ACHARGE analysis

C_6H_5CN	0.087	0.004	0.008	0.066	0.181	−0.364		

associated with hydrogen atoms are not experimentally available. Thus we have to reduce the dimension of δ vector by introducing a few assumptions. First, we used the condition of electrical neutrality of molecule, which is expressed as;

$$\sum_j q_j = 0 \tag{8}$$

Second, we assumed that the charge densities of hydrogen atoms are the same as the values obtained by the CNDO/2 calculations, and excluded from the unknown quantities which should be obtained by solving the equation. This assumption may not be legitimate, but seems allowable, since hydrogen atoms of benzene ring are likely to have small charges as indicated by the CNDO/2 calculations (see Table 1), so that the above assumption should not significantly affect the results of ACHARGE analysis. When we use the two assumptions described above, the dimension of $\mathbf{q}$ vector can be reduced to four for aniline, phenol, chlorobenzene, bromobenzene and fluorobenzene, and five for toluene, benzonitrile, and nitrobenzene. Thus we were able to carry out ACHARGE analysis using only the binding energies of C 1s levels in all cases except nitrobenzene. In the case of nitrobenzene, the analysis is possible if we use the N 1s or O 1s binding energy, but we did not carry out the analysis since reliable values of E_0^A and k_A are not available at present for nitrogen and oxygen atoms of benzene derivatives.

The charge densities thus obtained from the analyses of the C 1s spectra of benzene derivatives are listed in Table 3. In most compounds studied here, we found a good agreement between the charge densities derived from the ACHARGE analyses and those by the CNDO/2 calculations. It should be noted that ACHARGE analysis can be carried out without the aid of molecular orbital calculation once the values of E_0^A and k_A have been established. In this sence, we could regard its results as "experimental charge densities."

In Table 4, the results of the ACHARGE analysis of fluorobenzene reported by different authors are compared with those of the present study. They are in satisfactory agreement although the actual procedures of analysis differ a little between different authors.

Table 4. Atomic charges of fluorobenzene

Atom	CNDO/2	ACHARGE analysis		
		Thomas[4]	Clark *et al.*[2]	present work

F	−0.199	−0.19	−0.203	−0.270

We note in Table 3 that the net charge on the substituent group (CN) of benzonitrile is negative in agreement with the chemical intuition that CN group is an electron attractive substituent. The situation seems to be not so simple in the case of aniline where the substituent is an electron donative one. As shown in Table 3, the nitrogen atom of the NH_2 group has a considerably large negative charge, so that the net charge on the NH_2 group becomes negative even if we took into account the positive charges on the hydrogen atoms. The same conclusion is derived also from the CNDO/2 charge densities. However, if we examine the π-electron population predicted from the CNDO/2 molecular orbitals, we see that the amount of π electron transferred from NH_2 group to benzene ring amounts to 0.278 *e*. Thus we can conclude that the nitrogen atom of the NH_2 group is donating its π electron to the benzene ring, but attracting σ electron primarily from the carbon atom which is directly bonded to the nitrogen atom, so that the net charge of NH_2 group becomes negative. The situation seems to be more or less similar in the cases of other electron donative substituents.

Satellite Bands of Core Electron Peaks. Core electron peaks of X-ray photoelectron spectra are often accompanied by satellites associated with the two-electron process where an ejection (shake-off) or excitation (shake-up) of an outer-shell electron occurs simultaneously with the photoionization of a core level.[9,10] Figure 8 shows the satellite of the C 1s peak of benzene.

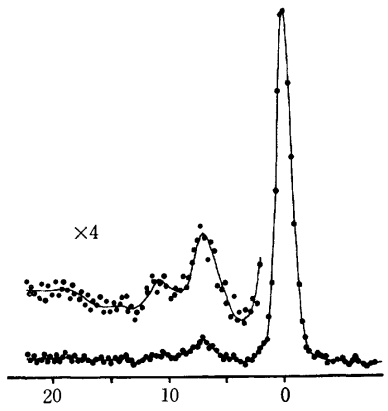

Fig. 8. C 1s Spectrum of benzene. The high-energy region of the spectrum is also shown by expanding the intensity scale to show the satellites. The energy difference from the main peak is given in the abscissa.

We can see two bands in the high binding-energy side of the C 1s peak, their maxima being at 7.0 and 11.0 eV, respectively, from the main peak. The intensity relative to the main peak is 10.5 and 2.5 percent for the 7.0 and 11.0 eV bands, respectively. We examined the pressure dependences of these bands, and confirmed that their energies and intensities relative to the C 1s peak are practically unaffected by the change of the vapor pressure of benzene. This fact indicates that the above bands are not due to the inelastic scattering of photoelectron, but due to the shake-up or shake-off process. Beside the above two bands, we observed several very weak bands at much higher binding energies. For these bands, however, we were not able to confirm whether they are really due to two-electron process or not.

Satellites by two-electron processes were also observed in the C 1s spectra of the monosubstituted benzenes. Their shapes and intensities were found to vary more or less depending on the substituent group. In the case of nitrobenzene, satellite appeared in the O 1s region as well as in the C 1s region, but not in the N 1s region. The O 1s satellite was composed of three bands located at 3.0, 10.0, and 13.0 eV, respectively, from the main peak. A considerably sharp satellite band was observed in the N 1s region of the spectrum of benzonitrile at 5.0 eV from the main peak. No satellite definitely attributable to two-electron process was found in the regions other than C 1s in the cases of other monosubstituted benzenes studied here.

According to the theory based on the sudden approximation, the probability of a shake-up process which yields the final state Ψ_k where a secondary excitation (or ejection) of a valence electron has occurred simultaneously with the photoionization of a core level, can be given as follows;[11]

$$P_k = |\langle\Phi_0|\Psi_k\rangle|^2 \tag{9}$$

where Φ_0 is the wave function in which the valence-electron orbitals are the same as in the ground state of the molecule without a core hole.

We calculated the molecular orbitals of valence electrons by means of the CNDO/2 method. In order to calculate the molecular orbitals of the core-hole ion, we assumed the localized-core-hole model[12] and used the equivalent-core approximation.[13] The wave functions Φ_0 and Ψ_k were then expressed in the form of a Slater determinant constructed from the above orbitals, and the shake-up probability was calculated by use of Eq. (9). A part of the results thus obtained of benzene are shown in Table 5 in order to illustrate the general trend of the predicted shake-up probabilities. It should be noted that the shake-up probability is predicted to be quite small for σ—σ^* transitions. This was also the case for other σ—σ^* transitions which we have omitted in Table 5. On the other hand, a π—π^* transition ($2b_1 \rightarrow 3b_1$) is predicted to have a considerably large shake-up probability. We carried out similar calculations on monosubstituted benzenes, and found that, like in benzene, the shake-up probability is generally quite small (less than 0.5 percent) in the case of σ—σ^* transition, and the transitions of significant shake-up probability can be found only among π—π^* transitions. Seemingly, the above results are reasonable since we can generally expect that, in a π-conjugated system, π electrons would play the most important role in the relaxation process accompanying the ejection of a core electron because of the labile nature of π electrons.

TABLE 5. SHAKE-UP PROBABILITIES(%) OF C 1s FOR BENZENE OBTAINED BY CNDO/2 CALCULATION

Occupied orbital	Vacant orbital							
	$3b_1(\pi)$	$2a_2(\pi)$	$8a_1$	$9a_1$	$6b_2$	$10a_1$	$11a_1$	$4b_1(\pi)$
$1b_1(\pi)$	0.51	—	—	—	—	—	—	0.06
$3b_2$	—	—	—	—	0.25	—	—	—
$5a_1$	—	—	0.08	0.16	—	0.32	0.0	—
$6a_1$	—	—	0.50	0.17	—	0.08	0.0	—
$4b_2$	—	—	—	—	0.06	—	—	—
$2b_1(\pi)$	5.26	—	—	—	—	—	—	0.09
$5b_2$	—	—	—	—	0.39	—	—	—
$7a_1$	—	—	0.0	0.09	—	0.03	0.08	—
$1a_2(\pi)$	—	0.04	—	—	—	—	—	—

The energy separation of a satellite band from the main core electron peak must be equal to the excitation energy of the core-hole ion. This will be given as follows;

$$\Delta E_k = \langle\Psi_k|H|\Psi_k\rangle - \langle\Psi_0|H|\Psi_0\rangle \tag{10}$$

where Ψ_k and Ψ_0 are the wave function of the excited state and that of the ground state of the core-hole ion, respectively. Unfortunately, however, the CNDO/2 method generally provides only poor predictions as regards the energies of π—π^* transitions which are most important to understand the satellites of benzene derivatives. As we have already pointed out, there is a good reason to suppose that, in π-conjugated molecules, the contributions of π electrons are of primary importance in the relaxation process accompanying the ionization of a core level. Therefore, it would be allowable, at least as a first approximation, to attribute the relaxation entirely to π electrons by freezing the states of σ electrons the same as in the initial state without a core hole, and estimate the energies of π—π^* transitions of the core hole ion by means of a semi-empirical SCF-MO-CI method within the framework of π electron approximation. Here again, we took the localized-core-hole model. This means that, for a monosubstituted benzene, we have to consider four different core-hole states corresponding to four inequivatent locations of C 1s hole in benzene ring. We carried out the calculation on each of these core hole state. The semiempirical parameters related to the core-hole atoms C($1s \cdot tr \cdot tr \cdot tr \cdot \pi$), N($1s \cdot tr^2 \cdot tr \cdot tr \cdot \pi$)| and O($1s \cdot tr^2 \cdot tr^2 \cdot tr \cdot \pi$) were assumed to be the same as those of $N^+(1s^2 \cdot tr \cdot tr \cdot tr \cdot \pi)$, $O^+(1s^2 \cdot tr^2 \cdot tr \cdot tr \cdot \pi)$ and $F^+(1s^2 \cdot 2s^2 \cdot 2p^2 \cdot 2p^2)$, respectively, according to the equivalent-core approximation. We used the Katagiri-Sandrofy's formula[14] for resonance integral and the Nishimoto-Mataga's formula[15] for two-center repulsion integral, and took into account not only the nearest-neighbor resonance integrals, but also the non-nearest-neighbor ones.[16] In the calculations of configuration interactions, we took into account all singly-excited con-

TABLE 6. SHAKE-UP ENERGIES(eV) AND PROBABILITIES(%) OF PHENOL OBTAINED BY π-ELECTRON APPROXIMATION

figurations. By means of the above method, we estimated the energies of π—π^* transitions of the core-hole state. The shake-up probability was then calculated by Eq. (9) by using the CI wave functions obtained by the above calculations.

The results obtained of phenol are listed in Table 6.

It should be noted that the location of C 1s hole does significantly affect not only the transition energies but also the shake-up probabilities. The observed satellite is to correspond to the superposition of the satellites associated with each C 1s peak. Unfortunately, however, the resolution of the observed spectrum is not high enough to discuss the fine structures of satellite. Thus, we tentatively took the weighted average of predicted satellites for the purpose to compare with the observed spectra. We see that the predicted satellites are in reasonable agreement with the observation (see Table 6).

Similar calculations were carried out on other monosubstituted benzenes, the results of which are compared in Fig. 9 with the observed satellites. The agreement between the prediction and observation is generally satisfactory. We also performed the calculations on the shake-up satellites of N ls peak of benzonitrile and O ls peak of nitrobenzene. The results are shown in Fig. 10. Here again, we see that the general features of the observed satellites are satisfactorily explained by the calculations.

From the results described above, we can conclude that the prominent satellites accompanying the core electron peaks of the X-ray photoelectron spectra of monosubstituted benzenes are mainly due to the shake-up of π electrons.

Electron Pair Concept and an Extension of the Penney-Dirac Bond Order

Takashi OKADA and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received March 24, 1975)

The density functions representing electron pairs are extracted from two-electron density matrices by operating irreducible tensor operators in a two-electron spin space. Properties of these functions are examined, and the generalized Penney-Dirac bond orders are defined between atomic orbitals. Significance of the bond orders in chemical valence problems is discussed.

The concept of electron pair first introduced by Lewis[1] has long been accepted as the concisest and most fundamental notion of chemical valence. Ever since Heitler and London[2] and Sugiura[3] unveiled the nature of chemical binding of the hydrogen molecule, quantum theory has gained a great deal of success in the description of bondings in molecules as well as electron pairs. Thus, in valence bond theory, the electron pair concept is cast into the premise that an electron pair bond is associated with perfect singlet pairing of spins of electrons in the valence orbitals of the atoms concerned. The picture of electron pair bond was further extended by the introduction of the resonance concept.[4] On the other hand, molecular orbital theory in its simplest form explains the electron pair concept from the viewpoint that for each chemical bond there exists a bonding orbital which is occupied by two electrons in a singlet spin coupling. The methods of equivalent orbitals[5] and localized orbitals[6] are considered to be a reformulation of Lewis' concept in the molecular orbital formalism.

The recent development of computers has made more exact and complicated wavefunctions available, and more sophisticated types of wavefunctions which preserve the electron pair concept have been examined by several authors.[7] However, all these attempts to interpret the electron pair concept are still liable to depend upon the forms of the wavefunctions adopted. It is desirable to reformulate Lewis' concept in terms of fundamental quantities that may be applicable to general types of wavefunctions.

For this purpose, the reduced density matrices, which were introduced by Hushimi[8] and developed by Löwdin[9] and McWeeny,[10] would be the most adequate tool. The first- and second-order reduced density matrices (hereafter referred to as 1- and 2-matrices, respectively) are defined, in the Löwdin normalization,[9] for an N-electron wavefunction $\Psi(x_1, x_2\, x_3, \cdots x_N)$ by the expressions

$$\rho^{(1)}(x_1; x_1') = N\int \Psi(x_1, x_2, \cdots x_N) \times \Psi^*(x_1', x_2, \cdots x_N)\mathrm{d}x_2 \cdots \mathrm{d}x_N \quad (1)$$

$$\rho^{(2)}(x_1, x_2; x_1', x_2') = \binom{N}{2}\int \Psi(x_1, x_2, x_3, \cdots x_N) \times \Psi^*(x_1', x_2', x_3, \cdots, x_N)\mathrm{d}x_3 \cdots \mathrm{d}x_N \quad (2)$$

The diagonal elements of 1-matrix, $\rho^{(1)}(x_1; x_1)$, are interpreted as the electron density at point x_1. A number of useful valence concepts such as various types of populations,[11-14] valence atomic orbitals[10,15] and force concept,[16] have emerged from 1-matrix. By contrast, 2-matrix has hitherto been scarcely employed in electronic structure interpretations despite its fundamental importance.[17]

In this article, we consider Lewis' electron pairs as singlet coupled pairs of electrons possible in an N-electron system and intend to extract these pairs from the total $N(N-1)/2$ pairs represented by 2-matrix. First, we will obtain the distribution of these pairs in an N-electron singlet state by applying to 2-matrix the operator, $-(4/3)\boldsymbol{S}(1)\cdot\boldsymbol{S}(2)$, which was used to define the Penney-Dirac bond order.[18] Then, we will define generalized bond orders from this distribution, which will prove to give spinless 1-matrix on integration. The characteristics of the pair distribution and the bond order will be examined. Finally, we will extend the formulation to nonsinglet states by introducing spin density as well as triplet coupled electron pairs.

I. Definitions of the Spin Coupling Matrix Q^0 and the Bond Order P^0_{ab} in a Singlet State

In the Dirac vector model,[19,20] the problem of permutation degeneracy is replaced by vector couplings between spin angular momenta. The Hamiltonian is equivalent to

$$H = \text{const.} - \frac{1}{2}\sum_{a>b}(1+4\boldsymbol{s}_a\cdot\boldsymbol{s}_b)J_{ab} \quad (3)$$

the summation being over all pairs. Here, J_{ab} is the exchange integral between orbitals a and b, and $\boldsymbol{s}_a$ is the spin vector of an electron in orbital a.

If the spins in orbitals a and b are antiparallel, as in the hydrogen molecule, $\boldsymbol{s}_a\cdot\boldsymbol{s}_b=-3/4$. However, if the spins are mutually random, $\boldsymbol{s}_a\cdot\boldsymbol{s}_b=0$. Penney defined the fractional bond order P_{ab} by a linear interpolation between the two limits. Thus,

$$P_{ab} = -(4/3)\overline{\boldsymbol{s}_a\cdot\boldsymbol{s}_b} \quad (4)$$

$$= (1+2\partial E/\partial J_{ab})/3 \quad (5)$$

Equation (5) shows that, once the energy has been obtained as a function of exchange integrals, the Penney-Dirac bond orders are easy to compute.[21] This definition of P_{ab} may be extended to general types of wavefunctions.[17]

Alternatively, we may think of a bonding electron pair as a pair of electrons with singlet coupled spins and generalize the original idea of Penney by operating $-(4/3)\boldsymbol{S}(1)\cdot\boldsymbol{S}(2)$ to 2-matrix for an N-electron singlet system. We define a matrix Q^0 with space variables

alone such that[22-24]

$$Q^0(r_1, r_2; r_1', r_2') = \int_{s_1=s_1', s_2=s_2'} -(4/3)\boldsymbol{S}(s_1)\cdot\boldsymbol{S}(s_2) \times \rho^{(2)}(x_1, x_2; x_1', x_2')ds_1ds_2 \quad (6)$$

where r_i and s_i are the space and spin variables, respectively. The spinless matrix Q^0 may be termed the spin coupling matrix.

For an eigenstate of $\boldsymbol{S}^2$ and $\boldsymbol{S}_z$ (with $M_s=0$), 2-matrix can always be decomposed into four components:[24]

$$\begin{aligned}\rho^{(2)}(x_1, x_2; x_1', x_2') &= P_2^{\tau_1\tau_1}\tau_1(s_1, s_2)\tau_1^*(s_1', s_2') \\ &+ P_2^{\tau_2\tau_2}\tau_2(s_1, s_2)\tau_2^*(s_1', s_2') + P_2^{\tau_3\tau_3}\tau_3(s_1, s_2)\tau_3^*(s_1', s_2') \\ &+ P_2^{\sigma\sigma}\sigma(s_1, s_2)\sigma^*(s_1', s_2') \end{aligned} \quad (7)$$

where $P_2^{\tau_1\tau_1}$, *etc.*, are the space functions that depend on r_1, r_2, r_1', r_2'. The four possible spin functions are abbreviated as τ_1, τ_2, τ_3 and σ:

$$\begin{aligned}\tau_1 &= \alpha(1)\alpha(2) \\ \tau_2 &= \beta(1)\beta(2) \\ \tau_3 &= [\alpha(1)\beta(2)+\beta(1)\alpha(2)]/\sqrt{2} \\ \sigma &= [\alpha(1)\beta(2)-\beta(1)\alpha(2)]/\sqrt{2}\end{aligned} \quad (8)$$

For a singlet state, three functions $P_2^{\tau_1\tau_1}$, $P_2^{\tau_2\tau_2}$ and $P_2^{\tau_3\tau_3}$ are identical,[24] so that they can be written as $P_2^{\tau\tau}$. Considering $\overline{\boldsymbol{S}(1)\cdot\boldsymbol{S}(2)}=-3/4$ and $1/4$ for singlet and triplet pairs, respectively, the Q^0 matrix is represented by

$$Q^0(r_1, r_2; r_1', r_2') = P_2^{\sigma\sigma} - P_2^{\tau\tau} \quad (9)$$

When we operate $-4\boldsymbol{S}_z(1)\cdot\boldsymbol{S}_z(2)$ on 2-matrix and integrate over spin variables, we obtain a quantity equal to

$$P_2^{zz} = P_2^{\sigma\sigma} + P_2^{\tau_3\tau_3} - P_2^{\tau_1\tau_1} - P_2^{\tau_2\tau_2} \quad (10)$$

For a singlet state, this quantity coincides with that of the Q^0 matrix (Eq. (9)). $\boldsymbol{S}_z(1)\cdot\boldsymbol{S}_z(2)$ givens an expectation value $1/4$ for parallel spins and $-1/4$ for antiparallel spins. Thus, we may interpret the Q^0 matrix of a singlet state as indicating the difference in the probabilities of two electrons at r_1 and r_2 being with antiparallel and parallel spins. Note that the terms *antiparallel* and *parallel* are used strictly as an attribute of $\boldsymbol{S}_z(1)\cdot\boldsymbol{S}_z(2)$, whereas the *singlet* and *triplet* pairs are defined on the basis of $\boldsymbol{S}(1)\cdot\boldsymbol{S}(2)$.

On the other hand, the following trace conditions hold[24]:

$$\mathrm{Tr}P_2^{\sigma\sigma} = N(N+2)/8 - S(S+1)/2 \quad (11)$$

$$\frac{1}{3}\mathrm{Tr}(P_2^{\tau_1\tau_1}+P_2^{\tau_2\tau_2}+P_2^{\tau_3\tau_3}) = N(N-2)/8+S(S+1)/6 \quad (12)$$

Therefore, the trace for our Q^0 matrix is given by:

$$\mathrm{Tr}Q^0(r_1, r_2; r_1', r_2') = N/2 - 2S(S+1)/3 \quad (13)$$

We regard the $N/2$ pairs represented by the Q^0 matrix in a singlet state ($S=0$) as electron pairs in the chemical sense.

It seems natural to base bond orders on the Q^0 matrix. To this end, we use a normalized atomic orbital basis set (a, b, c,$\cdots$) and introduce spatial "Heitler-London-like" geminals among these atomic orbitals:

$$\begin{aligned}S_{aa}(r_1, r_2) &= a(r_1)a(r_2) \\ S_{ab}(r_1, r_2) &= [a(r_1)b(r_2)+b(r_1)a(r_2)]/\sqrt{2} \\ T_{ab}(r_1, r_2) &= [a(r_1)b(r_2)-b(r_1)a(r_2)]/\sqrt{2}\end{aligned} \quad (14)$$

S_{ab} and T_{ab} are not necessarily normalized; the overlaps between atomic orbitals are generally nonzero. Using Eq. (14), we define the bond orders P_{aa}^0 and P_{ab}^0 as

$$\begin{aligned}P_{aa}^0 &= \int S_{aa}^*(r_1, r_2)Q^0(r_1, r_2; r_1', r_2')S_{aa}(r_1', r_2')dr_1dr_2dr_1'dr_2' \\ &= \int a^*(r_1)a^*(r_2)Q^0(r_1, r_2; r_1', r_2')a(r_1')a(r_2')dr_1dr_2dr_1'dr_2' \\ P_{ab}^0 &= \int S_{ab}^*(r_1, r_2)Q^0(r_1, r_2; r_1', r_2')S_{ab}(r_1', r_2')dr_1dr_2dr_1'dr_2' \\ &+ \int T_{ab}^*(r_1, r_2)Q^0(r_1, r_2; r_1', r_2')T_{ab}(r_1', r_2')dr_1dr_2dr_1'dr_2' \\ &= 2\int a^*(r_1)b^*(r_2)Q^0(r_1, r_2; r_1', r_2')a(r_1')b(r_2')dr_1dr_2dr_1'dr_2'\end{aligned} \quad (15)$$

By definition of Eq. (15), we may assign the bond order P_{aa}^0 and P_{ab}^0 to ionic and covalent terms, respectively. It should be noted that the bond orders proposed in this paper are not directly related to bond strength but are some topological indices concerning the electron spin coupling.

II. Characteristics of the Bond Order

Our bond orders and Q^0 matrix have been derived from 2-matrix, and so it is useful to investigate their relations with 1-matrix. By integrating the Q^0 matrix of a singlet state with respect to the second electron, we obtain the following relation:

$$P_1(r_1; r_1') = 2\int Q^0(r_1, r_2; r_1', r_2)dr_2 \quad (16)$$

where $P_1(r_1; r_1')$ is the ordinary spinless 1-matrix defined by

$$P_1(r_1; r_1') = \int_{s_1=s_1'} \rho^{(1)}(x_1; x_1')ds_1 \quad (17)$$

The proof of Eq. (16) will be given in the Appendix.

Equation (16) means that the spatial distribution of N electrons in $N/2$ paris as represented by the Q^0 matrix is identical to the charge density distribution, which has been accepted as a fundamental quantity in usual theories of molecular electronic structure.

The physical meaning of Eq. (16) becomes apparent when this relation is considered on the atomic orbital basis. The spinless 1-matrix is expanded by atomic orbital basis set (a, b,$\cdots$) in the following way:

$$P_1(r_1; r_1') = \sum_{a,b}\gamma_{ab}^0 a(r_1)b^*(r_1') \quad (18)$$

If we assume an orthogonalized atomic orbital basis set (OAO set), the integration over the one-electron Hilbert space can be divided into subspaces of the atomic orbitals involved. Then, from Eqs. (15), (16) and (18), we obtain

$$\begin{aligned}\gamma_{aa}^0 &= \int a^*(r_1)P_1(r_1; r_1')a(r_1')dr_1dr_1' \\ &= 2\sum_b\int a^*(r_1)b^*(r_2)Q^0(r_1, r_2; r_1', r_2')a(r_1')b(r_2')dr_1dr_2dr_1'dr_2' \\ &= 2P_{aa}^0 + \sum_{b\neq a}P_{ab}^0\end{aligned} \quad (19)$$

Once we have calculated bond orders on OAO basis, the electron population of each AO is easily computed according to Eq. (19). The contribution is two electrons from the ionic term and one electron from the covalent terms, in agreement with usual chemical concepts.

A similiar relation obtains for γ^0_{ab}, if we define $P^0_{\substack{ac\\bc}}$ as follows:

$$P^0_{\substack{ac\\bc}} = \int S^*_{ac}(r_1, r_2)Q^0(r_1, r_2; r_1', r_2')S_{bc}(r_1', r_2')dr_1dr_2dr_1'dr_2' + \int T^*_{ac}(r_1, r_2)Q^0(r_1, r_2; r_1', r_2')T_{bc}(r_1', r_2')dr_1dr_2dr_1'dr_2' \quad (20)$$

The resulting γ^0_{ab} is

$$\gamma^0_{ab} = \sqrt{2}(P^0_{\substack{aa\\ba}} + P^0_{\substack{ab\\bb}}) + \sum_{c\neq a,b} P^0_{\substack{ac\\bc}} \quad (21)$$

The meaning of Eq. (21) is to be discussed in a later section.

For single-determinant wavefunctions, 2-matrix can be expressed in terms of the products of 1-matrix.

$$\rho^{(2)}(x_1, x_2; x_1', x_2') = \frac{1}{2}\left\{\rho^{(1)}(x_1; x_1')\rho^{(1)}(x_2; x_2') - \rho^{(1)}(x_2; x_1')\rho^{(1)}(x_1; x_2')\right\} \quad (22)$$

By a straight manipulation using Eq. (18) we obtain the following expression for Q^0 matrix:

$$Q^0(r_1, r_2; r_1', r_2') = \frac{1}{4}\sum_{a,b,c,d}\gamma^0_{ad}\gamma^0_{bc}a(r_1)b(r_2)c^*(r_1')d^*(r_2') \quad (23)$$

The corresponding expressions for bond orders are

$$P^0_{aa} = {n^0_{aa}}^2/4,\ P^0_{ab} = {n^0_{ab}}^2/2 \quad (24)$$

where n^0_{aa} and n^0_{ab} are the diagonal and the off-diagonal elements of $\boldsymbol{n}^0$ matrix,

$$\boldsymbol{n}^0 = \boldsymbol{s}\boldsymbol{\gamma}^0\boldsymbol{s} \quad (25)$$

which was first defined by Davidson[13] and further discussed by Roby[14] in electronic population analysis. Here $\boldsymbol{s}$ is the ordinary overlap matrix between atomic orbitals and γ^0 is the matrix whose elements are γ^0_{ab} given in Eq. (18). On an OAO basis set, $\boldsymbol{n}^0$ simply reduces to γ^0.

We immediately see that Wiberg's bond indices[25]

$$W_{aa} = {\gamma^0_{aa}}^2,\ W_{ab} = {\gamma^0_{ab}}^2 \quad (26)$$

are simply related to our bond orders. Further, the bond index partitioning of atomic charge proposed by Trindle[26] may be regarded as a special case of Eq. (19), and the localization procedure by bond index maximization[27] has a clear physical meaning that each localized orbital contributes most to covalent electron pairing between the atomic orbitals concerned.

More generally, molecular wavefunctions are expressed as a linear combination of determinants made up of orthonormal spin orbitals. It will be convenient, therefore, to evaluate the Q^0 matrix elements and bond orders explicitly for these wavefunctions.

We consider a many-determinant wavefunction,

$$\Psi = \sum_\kappa a_\kappa\Phi_\kappa \quad (27)$$

The density matrix for the case of the present concern is a simple weighted sum of the transition density matrices connecting all different pairs of determinants which arise from the expansion.

$$Q^0(\kappa\lambda|r_1, r_2; r_1', r_2') = \binom{N}{2}\int_{s_1=s_1', s_2=s_2'}\Phi_\kappa(x_1, x_2, \cdots x_N) \times\left(-\frac{4}{3}\boldsymbol{S}(s_1)\cdot\boldsymbol{S}(s_2)\right)\Phi_\lambda^*(x_1', x_2', \cdots x_N)ds_1ds_2dx_3\cdots dx_N \quad (28)$$

$$Q^0(r_1, r_2; r_1', r_2') = \sum_{\kappa,\lambda}a_\kappa a_\lambda^*Q^0(\kappa\lambda|r_1, r_2; r_1', r_2') \quad (29)$$

We denote by $P^0_{aa}(\kappa\lambda)$ and $P^0_{ab}(\kappa\lambda)$ the bond orders pertaining to $Q^0(\kappa\lambda|r_1, r_2; r_1', r_2')$. Thus

$$P^0_{aa} = \sum_{\kappa,\lambda}a_\kappa a_\lambda^*P^0_{aa}(\kappa\lambda) \text{ and } P^0_{ab} = \sum_{\kappa,\lambda}a_\kappa a_\lambda^*P^0_{ab}(\kappa\lambda) \quad (30)$$

The transition densities and bond orders for determinants representing spin orbital configurations,

$$\kappa = (\phi_1\theta_1, \phi_2\theta_2, \cdots, \phi_i\theta_i, \cdots) \text{ and}$$
$$\kappa' = (\phi_1'\theta_1', \phi_2'\theta_2', \cdots, \phi_i'\theta_i', \cdots)$$

follow at once from Slater's rules:

(i) $\kappa = \kappa' = (\phi_1\theta_1, \phi_2\theta_2, \cdots, \phi_i\theta_i, \cdots)$

$$Q^0(\kappa\kappa|r_1, r_2; r_1', r_2') = \frac{1}{2}\sum_{i,j}\{\varepsilon_1\phi_i(r_1)\phi_j(r_2)\phi_i^*(r_1')\phi_j^*(r_2') - \varepsilon_2\phi_j(r_1)\phi_i(r_2)\phi_i^*(r_1')\phi_j^*(r_2')\}$$

$$P^0_{aa}(\kappa\kappa) = \frac{1}{2}\sum_{i,j}(\varepsilon_1-\varepsilon_2)c_{ia}{}^2c_{ja}{}^2$$

$$P^0_{ab}(\kappa\kappa) = \frac{1}{2}\sum_{i,j}\{\varepsilon_1(c_{ia}{}^2c_{jb}{}^2+c_{ja}{}^2c_{ib}{}^2)-2\varepsilon_2c_{ia}c_{ib}c_{ja}c_{jb}\}$$

(ii) $\kappa = (\phi_1\theta_1, \phi_2\theta_2, \cdots, \phi_i\theta_i, \cdots, \phi_j\theta_j \cdots)$
$\kappa' = (\phi_1\theta_1, \phi_2\theta_2, \cdots, \phi_i'\theta_i, \cdots, \phi_j\theta_j, \cdots)$

$$Q^0(\kappa\kappa'|r_1, r_2; r_1', r_2') = \frac{1}{2}\sum_{j\neq i}\{\varepsilon_1\phi_i(r_1)\phi_j(r_2)\phi_i'^*(r_1')\phi_j^*(r_2') + \varepsilon_1\phi_j(r_1)\phi_i(r_2)\phi_j^*(r_1')\phi_i'^*(r_2') - \varepsilon_2\phi_j(r_1)\phi_i(r_2)\phi_i'^*(r_1')\phi_j^*(r_2') - \varepsilon_2\phi_i(r_1)\phi_j(r_2)\phi_j^*(r_1')\phi_i'^*(r_2')\}$$

$$P^0_{aa}(\kappa\kappa') = \sum_{j\neq i}(\varepsilon_1-\varepsilon_2)c_{ja}{}^2c_{ia}c_{i'a}$$

$$P^0_{ab}(\kappa\kappa') = \sum_{j\neq i}\{\varepsilon_1(c_{jb}{}^2c_{ia}c_{i'a}+c_{ja}{}^2c_{ib}c_{i'b}) - \varepsilon_2c_{ja}c_{jb}(c_{ia}c_{i'b}+c_{ib}c_{i'a})\}$$

(iii) $\kappa = (\phi_1\theta_1, \phi_2\theta_2, \cdots, \phi_i\theta_i, \cdots, \phi_j\theta_j, \cdots)$
$\kappa' = (\phi_1\theta_1, \phi_2\theta_2, \cdots, \phi_i'\theta_i, \cdots, \phi_j'\theta_j, \cdots)$

$$Q^0(\kappa\kappa'|r_1, r_2; r_1', r_2') = \frac{1}{2}\{\varepsilon_1\phi_i(r_1)\phi_j(r_2)\phi_i'^*(r_1')\phi_j'^*(r_2') + \varepsilon_1\phi_j(r_1)\phi_i(r_2)\phi_j'^*(r_1')\phi_i'^*(r_2') - \varepsilon_2\phi_i(r_1)\phi_j(r_2)\phi_j'^*(r_1')\phi_i'^*(r_2') - \varepsilon_2\phi_j(r_1)\phi_i(r_2)\phi_i'^*(r_1')\phi_j'^*(r_2')\}$$

$$P^0_{aa}(\kappa\kappa') = (\varepsilon_1-\varepsilon_2)c_{ia}c_{ja}c_{i'a}c_{j'a}$$

$$P^0_{ab}(\kappa\kappa') = \varepsilon_1(c_{ia}c_{jb}c_{i'a}c_{j'b}+c_{ib}c_{ja}c_{i'b}c_{j'a}) - \varepsilon_2(c_{ia}c_{jb}c_{i'b}c_{j'a}+c_{ib}c_{ja}c_{i'a}c_{j'b})$$

In all the above equations, ε_1 and ε_2 are defined as follows:

If ϕ_i and ϕ_j have the same spin,

$$\varepsilon_1 = \varepsilon_2 = -1/3;$$

If ϕ_i and ϕ_j have different spins,

$$\varepsilon_1 = 1/3 \text{ and } \varepsilon_2 = -2/3.$$

c_{ia}, *etc.*, are the overlap between orbital ϕ_i and atomic orbital a

$$c_{ia} = \langle\phi_i|a\rangle = \sum_b d_{ib}s_{ab} \tag{31}$$

d_{ib} being the usual LCAO coefficients.

For a special case in which $\kappa=\kappa'=(\phi_1\alpha,\ \phi_1\beta,\cdots\phi_i\alpha,\ \phi_i\beta\cdots)$, the bond orders $P^0_{aa}(\kappa\kappa)$ and $P^0_{ab}(\kappa\kappa)$ reduce to

$$P^0_{aa}(\kappa\kappa) = (\sum_i c_{ia}{}^2)^2 \tag{32}$$

$$P^0_{ab}(\kappa\kappa) = 2(\sum_i c_{ia}c_{ib})^2 \tag{33}.$$

Noting that

$$\gamma^0_{\mu\nu} = 2\sum_i d_{i\mu}d_{i\nu}, \tag{34}$$

Eqs. (32) and (33) can readily be verified to be identical with Eq. (24) for a single determinant case.

Incidentally, it will be appropriate to define an atom-atom bond order, P^0_{AB}, as a simple sum of the bond orders between the atomic orbitals on atoms A and B

$$P^0_{AB} = \sum_a^{\text{on A}} \sum_b^{\text{on B}} P^0_{ab} \tag{35}.$$

If atomic orbitals on a given atom are assumed to be orthogonal, as is usually the case, the atom-atom bond order remains invariant under a unitary transformation of AO basis within each atom. This invariance is easily derived from the fact that the one-electron Hilbert space for each atom is constant under the transformation.

III. Bond Order and Molecular Binding

As has already been stated, the bond order defined in the present paper has no bearing with energy derivatives but is a topological index of spin coupling. Thus, the bond order of dissociated hydrogen molecule is 1 but there exists no energy stabilization. None the less, it is expected that one may gain some insight into molecular binding, using the present bond order concept.

In molecular orbital theory the binding energy is ascribed to resonance integrals, β_{ab}. Slater[28] and McWeeny[29] pointed out that this integral is also responsible for molecular binding in valence bond theory. Generally, the expression of total electronic energy contains a term $\sum_{a,b}\gamma^0_{ab}\beta_{ab}$, and γ^0_{ab} is considered to be some measure of binding. Fortunately, the electronic structure of stable molecules can well be represented by a single-determinant wavefunction. In this case the bond order, P^0_{ab}, simply reduces to $\gamma^0_{ab}{}^2/2$. Therefore, P^0_{ab} might also be a measure of binding, which varies more sharply than γ^0_{ab}.

In this connection, use of an effective one-electron Hamiltonian

$$h(1) = T(1) + V_a(1) + V_b(1) \tag{36}$$

is suggestive. The expectation values of this hamiltonian between "Heitler-London-like" geminals are

$$\langle S_{ab}|h(1)|S_{ab}\rangle = (E_a+E_b+2s_{ab}\beta_{ab})/2 \tag{37}$$

and

$$\langle T_{ab}|h(1)|T_{ab}\rangle = (E_a+E_b-2s_{ab}\beta_{ab})/2 \tag{38}$$

which show that the energy stabilization, $s_{ab}\beta_{ab}$, results if electrons in a and b couple into a singlet pair, whereas there appears a repulsive interaction of $-s_{ab}\beta_{ab}$ in triplet coupling. It can be concluded that the bond order, P^0_{ab}, which assures a net stabilization roughly proportional to s^2_{ab}, is a certain measure of the latent capability with which an electron pair can enter into covalent binding when the overlap between the relevant atomic orbitals becomes sufficiently large.

On the OAO basis set, we must turn to Eq. (21). $P^0_{\substack{aa\\ba}}$, $P^0_{\substack{ab\\bb}}$ and $P^0_{\substack{ac\\bc}}$ are interpreted as an intensity of resonance between the corresponding structures of electron pairing. Because γ^0_{ab} is a sum of many such terms, examination of its significance in chemical binding is somewhat boring to make. However, in single-determinant wavefunctions each term in Eq. (21) takes a simple form:

$$P^0_{\substack{aa\\ba}} = \gamma^0_{aa}\gamma^0_{ab}/2\sqrt{2},\quad P^0_{\substack{ab\\bb}} = \gamma^0_{bb}\gamma^0_{ab}/2\sqrt{2},$$
$$P^0_{\substack{ac\\bc}} = \gamma^0_{ac}\gamma^0_{bc}/2 \tag{39}$$

Substituting these expressions into Eq. (21), we obtain

$$\gamma^0_{ab} = (\gamma^0_{aa}+\gamma^0_{bb})\gamma^0_{ab}/2 + \sum_{c\neq a,b}\gamma^0_{ac}\gamma^0_{bc}/2 \tag{40}.$$

When the sum of populations on a and b equals 2, as is generally expected in electron pair bonds, γ^0_{ab} can in effect be imparted to $P^0_{\substack{aa\\ba}}$ and $P^0_{\substack{ab\\bb}}$ only. This result verifies the picture that the resonance between covalent and ionic structures is responsible for chemical binding depicted on the OAO basis.

IV. Extension to a Doublet State

It is desired to extend the analysis of electron pairs in previous sections to nonsinglet states. As can be seen from Eq. (13), the trace of the Q^0 matrix for these states is no longer equal to the number of singlet pairs. Obviously, we must add a certain quantity to make up the difference.

In this section we consider doublet states with N electrons which would be interpreted as $(N-1)/2$ pairs plus one odd electron. Integration of the Q^0 matrix over the second electron yields

$$P_1(r_1;r_1') - D_s(r_1;r_1') = 2\int Q^0(r_1,r_2;r_1',r_2)\mathrm{d}r_2 \tag{41}$$

where $D_s(r_1;r_1')$ is a normalized spin density matrix[30,31] defined by

$$D_s(r_1;r_1') = \frac{1}{M_s}\int_{s_1=s_1'} \mathbf{S}_z(s_1)\rho^{(1)}(x_1;x_1')\mathrm{d}s_1 \tag{42}$$

The relationship (41) will be proved in the Appendix.

Equation (41) can be interpreted as an indication that the electron distribution may be decomposed to $(N-1)/2$ pairs and an odd electron. The former distribution is represented by the same Q^0 matrix as in singlet states while the latter comes from the spin density matrix.

For an electron distribution represented by Eq. (41) the electron population on each atomic orbital is expressed by bond orders and spin density as follows:

$$\gamma^0_{aa} = 2P^0_{aa} + \sum_{b\neq a}P^0_{ab} + \gamma^s_{aa} \tag{43}$$

where γ^s_{aa} is an expansion coefficient of the spin density matrix

$$D_S(r_1; r_1') = \frac{1}{2S}\sum_{a,b}\gamma^s_{ab}a(r_1)b^*(r_1'). \quad (44)$$

As an example, we consider a linear H_3 system and show the distributions of one electron pair and one odd electron obtained from the HMO solution. Two configurations were considered: (a) an H_2 molecule plus an H radical; and (b) the linear symmetrical H_3 radical. The various bond quantities are as shown in Fig. 1.

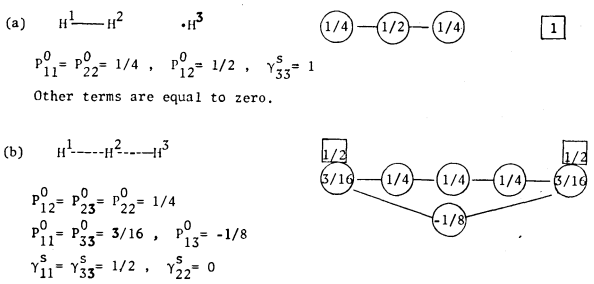

Fig. 1. Distribution of bond quantities in the linear H_n molecule. The quantities pertaining to electron pairs and odd electrons are shown in circles and squares, respectively.

V. States with Higher Spin Multiplicities

We may interpret the electronic structure of an N-electron system having a resultant spin $S \geq 1$ in the following two fashions. One is a system comprising $(N/2-S)$ electron pairs and $2S$ odd electrons while the other is $N/2$ pairs in which $(N/2-S)$ pairs are singlet type and the remaining S pairs are triplet type. Here we proceed along the latter line.

We now must seek for a density function which represents the distribution of triplet type pairs. The triplet type pairs of the present concern should be anisotropic ones which give the total spin angular momentum S, and are the origin of spin-spin dipolar interactions.[23,31,32] Further, it is preferred that this density function does not depend on the axis of spin quantization.

To meet these requirements, it seems appropriate to introduce the normalized spin-spin coupling function, $D_{ss}(r_1,r_2; r_1',r_2')$, defined by McWeeny.[31] This function is obtained by operating an irreducible tensor operator of rank 2, $3\boldsymbol{S}_z\cdot\boldsymbol{S}_z-\boldsymbol{S}\cdot\boldsymbol{S}$, to 2-matrix:

$$D_{ss}(r_1, r_2; r_1', r_2') = \frac{2}{S(2S-1)}\int_{s_1=s_1',s_2=s_2'}(3\boldsymbol{S}_z(s_1)\cdot\boldsymbol{S}_z(s_2) - \boldsymbol{S}(s_1)\cdot\boldsymbol{S}(s_2))\rho^{(2)}_{st}(x_1, x_2; x_1', x_2')ds_1ds_2 \quad (45)$$

where the subscript st on 2-matrix denotes that a standard state with $\langle \boldsymbol{S}_z\rangle = S$ is assumed. It has been shown that the function is invariant against different $\langle \boldsymbol{S}_z\rangle$values. The four spin functions in Eq. (8) are eigenfunctions of this operator.

$$3\boldsymbol{S}_z(s_1)\cdot\boldsymbol{S}_z(s_2)-\boldsymbol{S}(s_1)\cdot\boldsymbol{S}(s_2) \quad \begin{cases} \tau_1(s_1, s_2) = \frac{1}{2}\tau_1(s_1, s_2) \\ \tau_2(s_1, s_2) = \frac{1}{2}\tau_2(s_1, s_2) \\ \tau_3(s_1, s_2) = -\tau_3(s_1, s_2) \\ \sigma(s_1, s_2) = 0\ \sigma(s_1, s_2) \end{cases} \quad (46).$$

Obviously, neither of the electron pairs in singlet and random couplings contributes to D_{ss}.

We obtain $D_S(r_1; r_1')$ by integrating $D_{ss}(r_1,r_2; r_1',r_2')$ over the second electron.

$$D_S(r_1; r_1') = \int D_{ss}(r_1, r_2; r_1', r_2)dr_2 \quad (47)$$

On the other hand, the Q^0 matrix, upon integration, gives the following relation,

$$P_1(r_1; r_1') - \frac{4}{3}S(S+1)D_S(r_1; r_1') = 2\int Q^0(r_1, r_2; r_1', r_2)dr_2 \quad (48).$$

Equations (47) and (48) will be proved in the Appendix.

We are now at the position to define a matrix, Q^2, representing the distribution of triplet type pairs. It is most advantageous to define it by

$$Q^2(r_1, r_2; r_1', r_2') = \frac{2}{3}S(S+1)D_{ss}(r_1, r_2; r_1', r_2') \quad (49)$$

which leads to a simple relation

$$P_1(r_1; r_1') = 2\int\{Q^0(r_1, r_2; r_1', r_2) + Q^2(r_1, r_2; r_1', r_2)\}dr_2 \quad (50).$$

We define the corresponding bond order, P^2_{ab}, from Q^2 matrix as in Eq. (15).

$$P^2_{ab} = 2\int a^*(r_1)b^*(r_2)Q^2(r_1, r_2; r_1', r_2')a(r_1')b(r_2')dr_1dr_2dr_1'dr_2' \quad (51).$$

On the OAO basis, the electron population on each atomic orbital is expressed by P^0_{aa}, P^0_{ab} and P^2_{ab}:

$$\gamma^0_{aa} = 2P^0_{aa} + \sum_{b\neq a}(P^0_{ab}+P^2_{ab}) \quad (52).$$

Alternatively, in chemical interpretations, it is preferred that negative values are assigned to triplet coupled electron pairs. When we regard $N/2$ pairs as comprising $(N/2-S)$ singlet pairs and S triplet pairs, it is appropriate to use the following density function

$$Q^T = Q^0(r_1, r_2; r_1', r_2') + [(S-2)/(S+1)]Q^2(r_1, r_2; r_1', r_2') \quad (53)$$

and the bond order

$$P^T_{ab} = P^0_{ab} + [(S-2)/(S+1)]P^2_{ab} \quad (54).$$

On the OAO basis set, the sum of these bond orders is equal to $(N/2-2S)$, which is the difference in number between the singlet and triplet pairs.

In single-determinant wavefunctions with a definite spin angular momentum S, Q^0 and Q^2 matrices take the following forms:

$$Q^0(r_1, r_2; r_1', r_2') = \frac{1}{12}\sum_{a.b.c.d}(3\gamma^0_{ad}\gamma^0_{bc}-\gamma^s_{ad}\gamma^s_{bc}-2\gamma^s_{ac}\gamma^s_{bd}) \times a(r_1)b(r_2)c^*(r_1')d^*(r_2') \quad (55)$$

$$Q^2(r_1, r_2; r_1', r_2') = \frac{S+1}{3(2S-1)}\sum_{a.b.c.d}(\gamma^s_{ac}\gamma^s_{bd}-\gamma^s_{ad}\gamma^s_{bc}) \times a(r_1)b(r_2)c^*(r_1')d^*(r_2') \quad (56).$$

If we define $\boldsymbol{n}^s$ matrix by $\boldsymbol{n}^s = \boldsymbol{s}\gamma^s\boldsymbol{s}$ as in Eq. (25), the bond orders resulting from Eqs. (55) and (56) are

$$P^0_{aa} = (n^{0\,2}_{aa} - n^{s\,2}_{aa})/4 \quad (57)$$

$$P^0_{ab} = (3n^{0\,2}_{ab} - n^{s\,2}_{ab} - 2n^s_{aa}n^s_{bb})/6 \quad (58)$$

$$P^2_{ab} = [2(S+1)/3(2S-1)](n^s_{aa}n^s_{bb} - n^{s\,2}_{ab}) \quad (59).$$

These generalized bond orders can be applied to singlet

and doublet states as well.

We conclude the context by considering the H_4 system in a triplet state as an example. Three possible configurations are examined: (a) an H_2 molecule plus two H atoms; (b) an H_3 linear symmetrical doublet radical plus one H atom; and (c) an H_4 square planar configuration. The bond orders defined by Eq. (54) were calculated in the simple HMO approximation. The results are collected in Fig. 2.

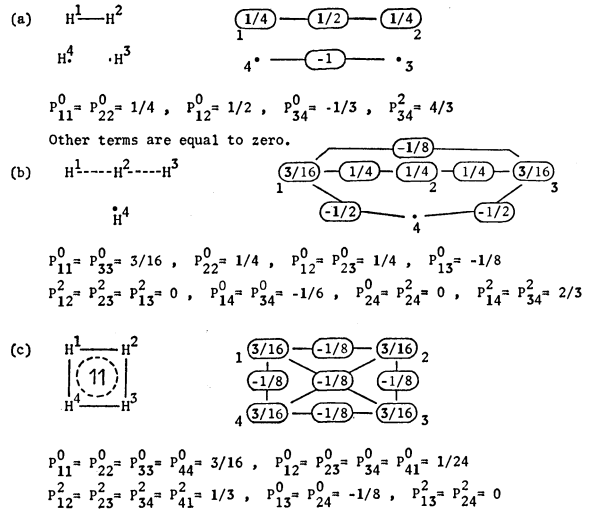

Fig. 2. Distribution of bond quantities in the triplet H_4 molecule. The bond orders defined by Eq. (54) are depicted.

VI. Concluding Remarks

We have shown in this introductory study that the electron pair concept as used in chemistry can be characterized adequately by the spin coupling matrices Q^0 and Q^2. These matrices in turn permit definitions of the generalized Penney-Dirac bond orders, from which the covalent and ionic characters of chemical binding can immediately be understood.

On the other hand, the contact nuclear spin-spin coupling constants are known to be a measure of the covalent bonding character.[33-35] Also, it has been shown implicitly that the bond order P^0_{ab} can be related to nuclear spin-spin coupling constants, provided a mean excitation energy approximation is adopted.[23,36-38] The situation endorses the usefulness of the bond order here defined.

The allowed and forbidden characters of chemical reactions are also a problem of current interest. Continuity of the bond order along reaction path has successfully been used for this purpose in connection with the space and spin symmetry conservations.[39,25] It was particularly with such uses for reactivity problems in mind that we decided to undertake the present analytical study. The concept of electron pair shift as was put forth by Robinson and Ingold[40] will be treated in a succeeding paper.

The authors would like to thank Dr. K. Yamaguchi for his helpful discussions.

Appendix

Our purpose is to prove Eqs. (47) and (48).

$$D_S(r_1; r_1') = \int D_{SS}(r_1, r_2; r_1', r_2)\mathrm{d}r_2 \tag{47}$$

$$P_1(r_1; r_1') - \frac{4}{3}S(S+1)D_S(r_1; r_1') = 2\int Q^0(r_1, r_2; r_1', r_2)\mathrm{d}r_2 \tag{48}$$

Both Eqs. (16) and (41) are special cases of Eq. (48).

To derive these relations it is convenient to use the results obtained by Cooper and McWeeny,[41,42] who expressed a wavefunction of configuration interaction type in the form

$$\Psi = \sum_\kappa a_\kappa \Psi_\kappa \tag{60}$$

where the Ψ_κ are general spin-coupled functions of valence bond type arising from arbitrary orbital configurations. They derived the general expressions of various transition density functions for any pair of standard states κ and λ. From Eq. (4.2) in reference (41) we can easily write Q^0 and Q^2 matrices in the following form:

$$Q(\kappa\lambda|r_1, r_2; r_1', r_2') = M_{\kappa\lambda}\Delta_{\kappa\lambda}\sum_{i,j}^{(\text{pairs})}\xi_{ij}\Phi_{ij}(r_1, r_2; r_1', r_2') \tag{61}$$

where Φ_{ij} is expressed in terms of the "Heitler-London-like" geminals as used in Eq. (14). The Φ_{ij}'s relevant to Q^0 and Q^2 matrices are listed in Table 1. For other symbols, original papers by Cooper and McWeeny are to be referred.

On the other hand, the P_1 and D_S matrices are written in the forms

$$P_1(\kappa\lambda|r_1; r_1') = M_{\kappa\lambda}\Delta_{\kappa\lambda}\sum_{i=1}^{N}\xi_i\phi_i(r_1)\phi_i^*(r_1') \tag{62}$$

$$D_S(\kappa\lambda|r_1; r_1') = (1/S)M_{\kappa\lambda}\Delta_{\kappa\lambda}\sum_{i=1}^{N}\xi_i x_i\phi_{i1}(r_1)\phi_i^*(r_1') \tag{63}$$

where
$$x_i = \frac{1}{2}p_i \quad \text{if } i \text{ is in an } O\text{-chain}$$
$$= 0 \quad \text{otherwise.}$$

It should be noted that no contribution occurs in this category if there are two or more orbital differences, or if any E-chain occurs.

The relations (47) and (48) are replaced by similar relations among the transition densities for each pair of standard states κ and λ. The two-body terms expressed by "Heitler-London-like" geminals give the following one-body terms by integrating over the second electron.

$$\int S_{ij}(r_1, r_2)S_{ij}'^*(r_1', r_2)\mathrm{d}r_2 =$$
$$\varepsilon\{\phi_i(r_1)\phi_i^*(r_1')\delta_{\phi_j\phi_{j'}} + \phi_j(r_1)\phi_{j'}^*(r_1')\delta_{\phi_i\phi_{i'}}\} \tag{64}$$

where

$\varepsilon = 1/2$ for $\phi_i \neq \phi_j$; $\phi_{i'} \neq \phi_{j'}$ or $\phi_i = \phi_j$; $\phi_{i'} = \phi_{j'}$

$\varepsilon = 1/\sqrt{2}$ for $\phi_i \neq \phi_j$; $\phi_{i'} = \phi_{j'}$ or $\phi_i = \phi_j$; $\phi_{i'} \neq \phi_{j'}$

$$\int T_{ij}(r_1, r_2)T_{ij}'^*(r_1', r_2)\mathrm{d}r_2 =$$
$$\frac{1}{2}\{\phi_i(r_1)\phi_i^*(r_1')\delta_{\phi_j\phi_{j'}} + \phi_j(r_1)\phi_{j'}^*(r_1')\delta_{\phi_i\phi_{i'}}\} \tag{65}.$$

It is verified from the above equations that Q^0 and Q^2 densities between standard states with more than two orbital differences do not contribute to the P_1 and D_S densities.

The proof is given for a case with no orbital difference. The contributions to $\phi_i(r_1)\phi_i^*(r_1')$ from Q^0 densities are obtained from Table 1 as follows.

[i in island]

(i), (xiii) $\rightarrow \frac{1}{2}\phi_i\phi_i^*$
(ii) $\rightarrow -\frac{1}{2}\phi_i\phi_i^*$
(iii), (iv) $\rightarrow 0$
$\Big\}$ — $\frac{1}{2}\phi_i\phi_i^*$

The number of pairs with $p_{ij} = -1$ is always more than that with $p_{ij} = +1$ by one, so that the sum of the above terms is $\phi_i\phi_i^*/2$.

[i in O-chain]

		$p_i=1$	$p_i=-1$
(iv)	$\rightarrow 0$		
(v)	$\rightarrow \frac{1}{2}\phi_i\phi_i^*$	0	$\phi_i\phi_i^*$
(vi)	$\rightarrow -\frac{1}{2}\phi_i\phi_i^*$		
(vii)	$\rightarrow -\frac{1}{6}\phi_i\phi_i^*$	$-\frac{1}{6}\phi_i\phi_i^*$	$\frac{1}{6}\phi_i\phi_i^*$
(viii)	$\rightarrow \frac{1}{6}\phi_i\phi_i^*$		

The results of summation are obtained by counting the number of pairs with $p_{ij} = +1$ and $p_{ij} = -1$. Further, the number of O-chains is equal to $2S$, where $S(S+1)$ is the eigenvalue of the S^2 operator. We get the expression of one-body terms in the following forms:

$$p_i = +1 \qquad \frac{1-2S}{6}\phi_i\phi_i^*$$
$$p_i = -1 \qquad \frac{2S+5}{6}\phi_i\phi_i^*$$

[i in E-chain]

(ix) $\rightarrow -\frac{1}{3}\phi_i\phi_i^*$
(x) $\rightarrow \frac{1}{3}\phi_i\phi_i^*$
$\Big\}$ — 0

The one-body terms from (ix) and (x) always cancel each other, so we can disregard the transition densities if any E-chain occurs.

On the other hand, the left-hand side of Eq. (48) is expressed by

$$M_{\kappa\lambda}\Delta_{\kappa\lambda}\sum_{i=1}^{N}\{1 - \frac{4}{3}(S+1)\times\frac{1}{2}p_i\}\phi_i(r_1)\phi_i^*(r_1') \tag{66}$$

where the second term in blackets is counted only if i is in O-chains. The expression (66) completely agrees with twice the sum of the various terms derived above.

We may obtain the contributions to $\phi_i(r_1)\phi_i^*(r_1')$ from Q^2 densities similarly.

[i in O-chain]

		$p_i=1$	$p_i=-1$
(vii)	$\rightarrow \frac{1}{4}\phi_i\phi_i^*$	$\frac{1}{4}\phi_i\phi_i^*$	$-\frac{1}{4}\phi_i\phi_i^*$
(viii)	$\rightarrow -\frac{1}{4}\phi_i\phi_i^*$		

[i in E-chain]

(ix) $\rightarrow -\frac{1}{4}\phi_i\phi_i^*$
(x) $\rightarrow \frac{1}{4}\phi_i\phi_i^*$
$\Big\}$ — 0

Then $[(2S-1)p_i/4]\phi_i(r_1)\phi_i^*(r_1')$ is the result of summation among all O-chains. Then, from Eq. (49) we obtain

$$\int D_{SS}(\kappa\lambda|r_1, r_2; r_1', r_2)dr_2 = M_{\kappa\lambda}\Delta_{\kappa\lambda}\sum_i^{\text{in } O\text{-chain}}(1/2S)p_i\phi_i(r_1)\phi_i^*(r_1')$$
$$= D_S(\kappa\lambda|r_1; r_1')$$

The proof for the case with one orbital difference can be obtained in a similar way and hence omitted.

Stereoisomers of the Bis(L-hydrogenaspartato)-trimethylenediaminecobalt(III) Complex

Yoshihiro KOJIMA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received October 14, 1974)

The bis(L-hydrogenaspartato)trimethylenediaminecobalt(III) complex has been prepared by the reaction of the *trans*-$[CoCl_2(tn)_2]^+$ complex with L-aspartic acid, and its eight stereoisomers have been separated by an ion-exchange chromatographic method. The six isomers are *trans*(*O*)-*Λ* and -*Δ*, *cis*(*O*)*cis*(*N*)-*Λ* and -*Δ* and *trans*(*N*)-*Λ* and -*Δ* isomers, in which either aspartate ion forms the five-membered chelate ring through an N atom of the amino group and an O atom of the α-carboxylate group. The remaining isomers are *Λ*- and *Δ*-*trans*(*O*) ones containing a five-membered chelate ring and a six-membered ring of L-aspartate ions. On the other hand, stereoselective formations have been found in the *Λ*, *Δ*, and *Λ* isomers for the *trans*(*O*), *cis*(*O*)*cis*(*N*), and *trans*(*N*) isomers respectively. It has become apparent that these stereoselectivities agree with those found for the corresponding *l*-pn and en complexes, while the orders of the formation amounts for the three geometrical isomers disagree.

In order to study stereochemistry and stereoselectivity, we previously examined the mixed L-aspartato complexes with *l*-propylenediamine[1] and ethylenediamine;[2] all of the stereoisomers isolated were characterized by their electronic absorption, circular dichroism (CD), and proton magnetic resonance (PMR) spectra. It was also found that the order of the formation amounts of the isomers agrees well between the *l*-propylenediamine and the ethylenediamine complexes.

In the present work, the stereoisomers of a mixed bis(L-hydrogenaspartato)trimethylenediamine complex ion were chosen in order to examine the influence of the six-membered chelate ring of the γ-diamine on the stereochemistry and stereoselectivity. Through this work, all the diastereoisomers corresponding to the six isomers which had been obtained in the previous work[2] were isolated. In addition, a novel pair of diastereoisomers containing an usual five-membered ring of a chelating L-aspartate ion and a six-membered ring formed by NH_2 and β-COO^- of another aspartate ion have been isolated.

Experimental

Preparation. 1) *Carbonatobis(trimethylenediamine)cobalt(III) Chloride*, $[Co(CO_3)(tn)_2]Cl \cdot 1.5H_2O$: Boyle and Harris[3] synthesized this complex by allowing silver carbonate to react on an aqueous solution of the *trans*-dichlorotrimethylenediamine complex. We prepared this complex easily by allowing trimethylenediamine(tn) to react on a solution of potassium tricarbonatocobaltate(III).[4] Trimethylenediamine (8.8 g, 0.12 mol) was added to a cold solution of tricarbonatocobaltate(III) ($CoCl_2 \cdot 6H_2O$, 10 g (0.042 mol) scale), and the mixture was stirred continuously at about 50 °C for 1.5 hr; the solution turned red-violet. After that, the resulting solution was concentrated on a water-bath until its surface was covered with crystals. The concentrated solution was then kept in a refrigerator overnight. The yield of the crude crystals was 13 g. This was subsequently dissolved in the least possible amount of water. After ethanol had been added to the solution until fine crystals began to deposit, the solution was kept in a refrigerator. The desired complex thus obtained was washed successively with ethanol and ether, and then dried in air.

2) trans-*dichlorobis(trimethylenediamine)cobalt(III) Chloride*, trans-$[CoCl_2(tn)_2]Cl$: Bailar and Work[5] synthesized this complex by allowing trimethylenediamine to react on anhydrous cobalt(II) chloride in ethanol with bubbling air. We prepared the complex easily by allowing concd HCl to react on the $[Co(CO_3)(tn)_2]^+$ complex. The complex obtained in 1) (5 g, 0.016 mol) was dissolved in a small amount of water, and then concd HCl (100 ml) was stirred in, little by little. Then the mixture was evaporated to a small volume (~30 ml) on a water-bath at about 60 °C and allowed to stand for a day to give bright green crystals. They were collected, washed successively with cold concd HCl and ethanol, and finally dried in air. The yield was 3.5 g. The crude crystals were dissolved in the minimum amount of hot concd HCl and then an ethanol–ether mixture (1: 1) was added to the solution. By keeping the whole in a refrigerator, pure crystals of the desired complex were deposited.

3) *Bis(L-hydrogenaspartato)trimethylenediaminecobalt(III) Perchlorate*, $[Co(L\text{-}Hasp)_2(tn)]ClO_4$: The preparative reaction for this complex and the procedure for the chromatographic separation of the stereoisomers were essentially the same as those in the previous work:[1] The complex obtained in 2) (3.1 g, 0.01 mol) and L-aspartic acid (2.7 g, 0.02 mol) were allowed to react at 50 °C for 1 hr in the presence of active charcoal (1 g) and under alkaline conditions (pH~10). For the chromatographic separation, a cation-exchange column containing 100—200 mesh Dowex 50W-X8 resin in the H-form (5.5×35 cm) was used. By eluting a red-violet band at the top of the column with a 0.05 M $NaClO_4$ aqueous solution, five bands colored red or red-violet were completely separated. After the first band had been collected in a fraction, the remaining bands were again eluted with a 0.1 M $NaClO_4$ solution. The fractions collected from the bands were numbered according to the order of elution (No. 1—5). The red-brown band remaining at the top of the column was of the bis(trimethylenediamine) complex. The chromatographic separation was repeated in order to store the same fractions.

The first eluted band actually consisted of two overlapping bands differing in their sign of the main CD peak; the first band showed (+), and the second band, (−). As to the remaining bands, no such phenomenon was observed.

The isolation of the isomeric compounds from the fractions was carried out as follows. Fraction No. 1 was concentrated at 35 °C until red-violet crystals began to deposit, and then it was allowed to stand in a refrigerator for a day. The less soluble isomer thus obtained was recrystallized from water until the $\Delta\varepsilon$ of the main CD peak with the (+) sign reached a constant value. For the sake of convenience, this isomer was labeled E-1. The filtrate obtained after isolating the E-1 isomer was stored in order to isolate the other isomers.

The No. 2 fraction was evaporated to a small volume at 35

°C along with the simultaneous removal of the perchlorate used for the elution, and then a large amount of an ethanol–ether mixture (1:3) was added to the solution in order to precipitate the red material. After the solution had stood in a refrigerator for a day, the precipitated material was collected by means of a centrifuge and then dissolved in a small amount of water. After ethanol had been added to the solution, the whole was kept in a refrigerator for several days. The red isomer (E-2) thus obtained was recrystallized from water by adding ethanol.

The No. 3 fraction was first evaporated to near dryness at 35 °C, and simultaneously the perchlorate was removed. The residue was dissolved in the minimum amount of water, and to the solution a large amount of an ethanol–ether mixture (1:5) was added. After the solution had been allowed to stand for some time, the desired isomer was separated as an oil. After the solvent had been eliminated, a large amount of ethanol was added to the oil to precipitate the isomer. The precipitates were then collected by means of the centrifuge and washed with ethanol. They were again dissolved in the minimum amount of water, and then ethanol was added until the solution began to cloud over. The turbid solution was clarified by warming and then the solution was kept in a refrigerator for several days. The red isomer (E-3) thus obtained was recrystallized from water by adding ethanol.

The No. 4 fraction was concentrated to a small volume at 35 °C and then kept in a refrigerator for a day to give red crystals. This isomer (E-4) was recrystallized from water.

The No. 5 fraction was treated in the same way as the No. 3. The desired red isomer (E-5) was recrystallized from water by adding ethanol.

The filtrate preserved after the E-1 had been isolated was rechromatographed using a small column (Dowex 50W-X8, 100—200 mesh, 2×40 cm, H-form) and 0.05 M $NaClO_4$. Three bands were separated and collected in fractions. Judging from the sign of the main CD peak, it was recognized that the first band was formed by overlapping two bands: the band showing (+) was first eluted, and then the band showing (−) was eluted, overlapping the (+) band. The second band uniformly showed the (+) sign, and the third band, the (−) sign. The first fraction was treated in the same fashion as No. 3. The crude material thus obtained was dissolved in the minimum amount of water, and ethanol (a 3-fold volume) was then added to the solution. By keeping the solution in a refrigerator, red-violet crystals exhibiting the (−) sign of the main CD peak were deposited. The recrystallization was repeated until the $\Delta\varepsilon$ of the CD peak became constant. This isomer was labeled E-1′. The other isomer, with the (+) sign, was isolated from the filtrate of E-1′. Judging from the spectral data and the chromatographic behavior, this isomer was exactly the same as E-1. The second fraction, containing a very small amount of isomeric species, was concentrated to a small volume at 35 °C and then kept in a refrigerator. The red-violet isomer thus obtained was labeled S-1. Its CD spectrum exhibited the (+) sign at the main peak. The third fraction was treated in the same fashion as No. 3. The crude material thus obtained was dissolved in the minimum amount of water. After alcohol had been added, the solution was kept in a refrigerator for several days. The red-violet isomer thus obtained was recrystallized from water by adding ethanol and was labeled S-2.

Formation Ratios of the Isomers. The relative concentrations of the isomers in the fractions were spectrophotometrically estimated by the method described in previous papers,[1,2] and the formation ratios among the isomers were calculated from the results.

Measurements. The electronic absorption spectra were measured with a Hitachi Recording spectrophotometer, Model 323. The circular dichroism spectra were recorded on JASCO Model ORD/UV-5 spectrophotometer with a CD attachment. The proton magnetic resonance (PMR) spectra were recorded on JEOL Model JNM-PS-100 spectrometer (100 MHz) at 23 °C. The values of the chemical shifts were measured in relation to sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as the internal reference. All the spectra were run in deuterium oxide. The E-1, E-1′, and E-4 isomers for the PMR samples were converted into chloride using an anion-exchange resin (Dowex 1-X8, 100—200 mesh) because of the poor solubility of the perchlorates.

Results and Discussion

From the results of elemental analysis (Table 1), it is obvious that all the compounds isolated are stereoisomers of the bis(L-hydrogenaspartato)trimethylenediaminecobalt(III) complex. However, elemental analysis was not performed for S-1 and S-2 because of their poor yields.

TABLE 1. ELEMENTAL ANALYSES OF THE COMPLEXES PREPARED

Label	Complex	C%	H%	N%
E-1	(+)-[Co(L-Hasp)$_2$-(tn)]ClO_4	26.70 (26.62	4.72 4.47	11.32 11.29)

Characterization of Isomers. Some representative absorption spectra are shown in Fig. 1, while the numerical data are summarized in Table 2. The spectra of E-1, E-1′, S-1, and S-2 are essentially the same and showed a characteristic splitting in their first absorption bands. This fact indicates that these four isomers have *trans*(*O*)*cis*(*N*) geometry, because it is well known that the first band of a *trans*(*O*)-Co^{III}-

a) mol^{-1} cm^{-1}. b) The ε and $\Delta\varepsilon$ values of S-1 and S-2 were estimated using the ε values of E-1 and E-1′, respectively, because the lack of the elemental analyses.

$(O)_2(N)_4$ type of complex shows a remarkable splitting.[1,2,6] On the other hand, the spectra of E-2, E-3, E-4, and E-5 reveal symmetrical patterns in their first bands. In addition, the values of $\varepsilon_{II}/\varepsilon_I$ for E-2, E-5, E-3, and E-4 have been calculated as 1.67, 1.62, 1.30, and 1.29 respectively. It has been found experimentally that the value of $\varepsilon_{II}/\varepsilon_I$ for the *cis*(*O*)*trans*(*N*) isomer is larger than that for the *cis*(*O*)*cis*(*N*) isomer.[2,6] These facts suggest that E-2 and E-5 have the *cis*(*O*)*trans*(*N*) geometry, while E-3 and E-4 have the *cis*(*O*)*cis*(*N*) structure. These absorption spectral assignments agree with those made by means of the PMR spectra, which will be discussed later.

The CD spectra are shown in Figs. 2—4, while the numerical data are summarized in Table 2. The spectrum of E-1 (*trans*(*O*)) shows a dominant (+) peak on the lower-energy-side in the first absorption band

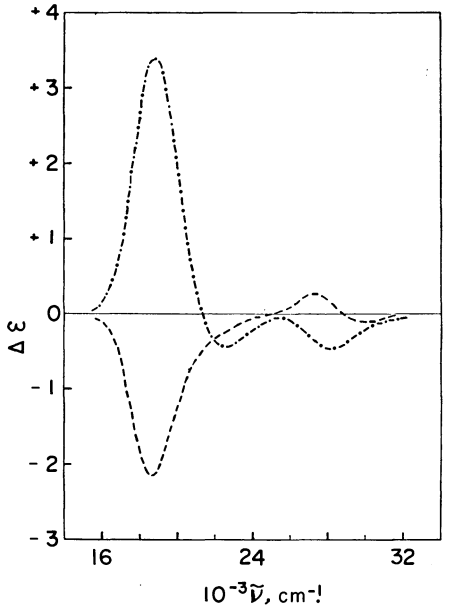

Fig. 2. The CD spectra for *trans*(*O*)*cis*(*N*)-*Λ*-(+)-[Co(L-Hasp)$_2$(tn)]ClO$_4$ (E-1) (·····) and *trans*(*O*)*cis*(*N*)-*Λ*-(−)-[Co(L-Hasp)$_2$(tn)]ClO$_4$ (E-1′) (——).

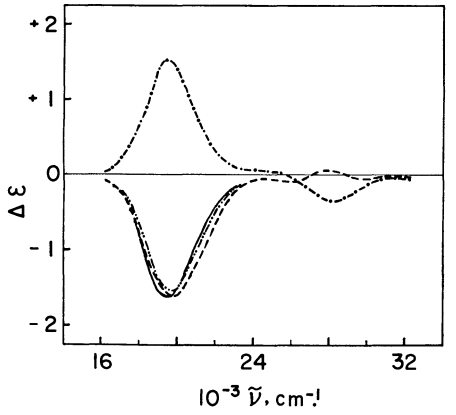

Fig. 4. The CD spectra for *cis*(*O*)*cis*(*N*)-*Λ*-(+)-[Co(L-Hasp)$_2$(tn)]ClO$_4$ (E-4) (·····) and *cis*(*O*)*cis*(*N*)-*Λ*-(−)-[Co(L-Hasp)$_2$(tn)]ClO$_4$ (E-3) (——), and the configurational effect curves of *cis*(*O*)*cis*(*N*)-*Λ*-(−)-[Co(L-Hasp)$_2$(tn)]$^+$ (·····) and *cis*(*O*)*cis*(*N*)-*Λ*-(−)-[Co(L-ala)$_2$(tn)]$^+$ (——).

region, while only one (−) peak is observed in the spectrum of E-1′ (*trans*(*O*)). E-2 and E-5 have a dominant (+) peak and only one (−) peak respectively in their CD spectra. E-3 shows a spectrum with a (−) peak, and E-4 shows a spectrum with a form nearly symmetrical to that of E-3.

The CD spectrum of the $(-)_{589}$-$[Co(tn)_3]^{3+}$ complex shows a minor (+) peak (E component) at a longer wave length and a major (−) peak (A_2 component) at a shorter wave length in the first band region.[7] The absolute configuration of this complex is determined to be *Λ*,[8,9] which is the same as that of the $(+)_{589}$-$[Co(en)_3]^{3+}$ complex.[10] As to the bis(diamine)-type complexes, the absolute configuration of the $(-)_{589}$-$[Co(acac)(tn)_2]^{2+}$ complex has been determined;[11] its CD spectrum shows only one (−) peak, and the *Λ* configuration is assigned to the complex. The corresponding ethylenediamine complex, $(-)_{589}$-$[Co(acac)(en)_2]^{2+}$, shows a similar spectrum.[12] This similarity suggests that, in the bis(diamine)-type complexes, the difference in tn and en has little influence upon the CD spectra. Accordingly, the absolute configuration of each isomer of the present complex, a bis(aminoacidato)diamine-type complex, was confidently determined by relating the sign of the dominant CD peak in the first absorption band region to that for the $[Co(L\text{-}Hasp)_2(en)]^+$ complex.[2] That is, the E-1, E-2, and E-4 isomers have the *Λ* configuration, and the E-1′, E-3, and E-5 isomers have the *Δ* configuration.

Applying Douglas' relationship,[13] the vicinal curves due to two L-aspartate chelates are calculated for the $[Co(L\text{-}Hasp)_2(tn)]^+$ and $[Co(L\text{-}Hasp)_2(en)]^+$ complexes. The results are shown in Fig. 5. The curves of the complexes resemble each other. This lends support

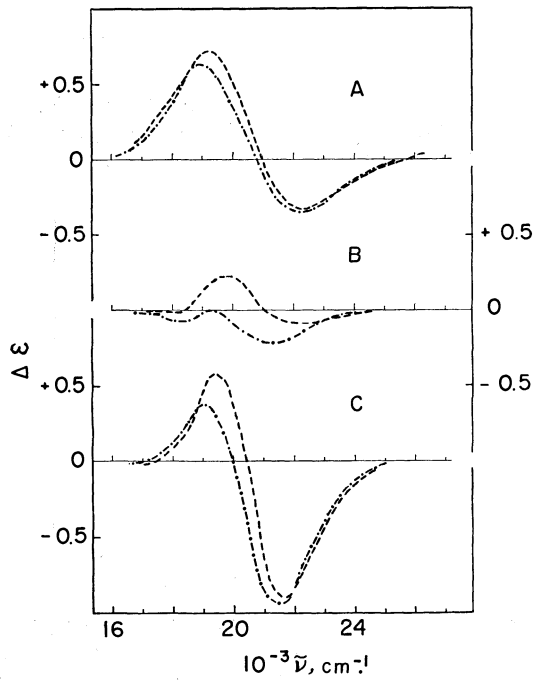

Fig. 5. The vicinal curves of $[Co(L\text{-}Hasp)_2(tn)]^+$ (-·-·-) and $[Co(L\text{-}Hasp)_2(en)]^+$ (——) complexes, A; *trans*(*O*)-*cis*(*N*), B; *cis*(*O*)*cis*(*N*), and C; *cis*(*O*)*trans*(*N*) isomers.

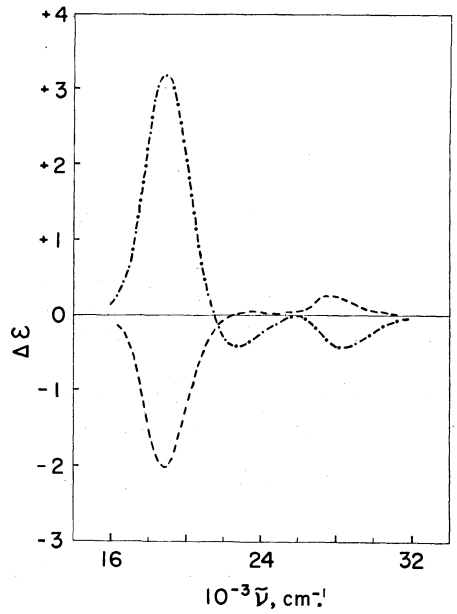

Fig. 6. The CD spectra for *trans*(*O*)*cis*(*N*)-*Λ*-(+)-$[Co(L\text{-}Hasp)_2(tn)]^+$ (S-1) (-·-·-) and *trans*(*O*)*cis*(*N*)-*Δ*-(−) $[Co(L\text{-}Hasp)_2(tn)]^+$ (S-2) (——).

to the previous assignment.

Figure 6 shows the CD curves of S-1 and S-2 drawn by assuming their ε values to be the same as those of E-1 and E-1′ respectively. The curve of S-1 is similar to that of E-1, while the curve of S-2 differs a little from that of E-1′. The absolute configurations of these isomers can also be determined tentatively from the sign of the main CD peak, similarly to the E isomers; S-1 has the *Λ* configuration, and S-2 has the *Δ* configuration. Accordingly, it may be concluded that the E-1 and S-1 isomers are of *trans*(*O*)*cis*(*N*)-*Λ*, while E-1′ and S-2 are *trans*(*O*)*cis*(*N*)-*Δ*.

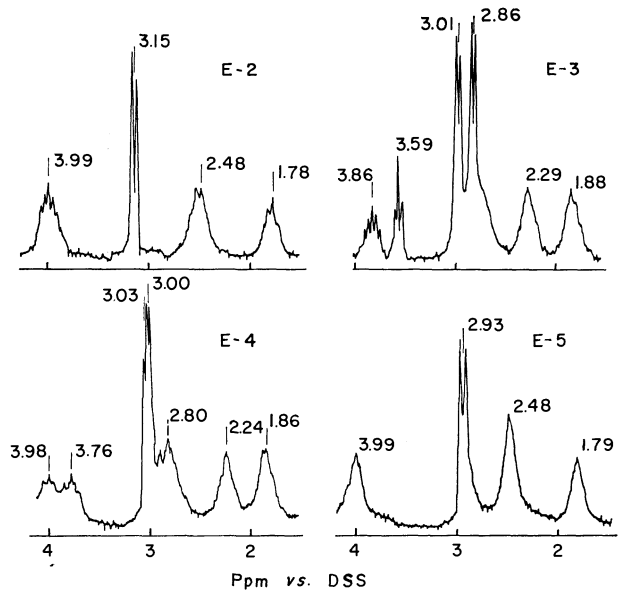

Fig. 7. The PMR spectra for *cis*(*O*)*trans*(*N*)-*Λ*-(+)-$[Co(L\text{-}Hasp)_2(tn)]^+$ (E-2), *cis*(*O*)*cis*(*N*)-*Δ*-(−)-$[Co(L\text{-}Hasp)_2(tn)]^+$ (E-3), *cis*(*O*)*cis*(*N*)-*Λ*-(+)-$[Co(L\text{-}Hasp)_2(tn)]^+$ (E-4), and *cis*(*O*)*trans*(*N*)-*Δ*-(−)-$[Co(L\text{-}Hasp)_2(tn)]^+$ (E-5).

The PMR spectra of the E-2, E-3, E-4, and E-5 isomers are shown in Fig. 7, with the signals of the NH_2 group and HDO eliminated. The resonance signals could be assigned on the basis of the signals of the $[Co(L\text{-Hasp})_2(en)]^+$ [2] and $[Co(CO_3)(tn)_2]^+$ complexes. The signal of the CH_2 protons (AB of ABX) of the β-carbon of the chelated aspartate ion was detected as a doublet, and its chemical shift is given as the center of the doublet. The signals due to the CH_2 and CH groups of the two aspartate ions are observed at 3.15 and 3.99 for E-2, and at 2.93 and 3.99 ppm for E-5. On the other hand, E-3 shows the CH_2 signals at 2.86 and 3.01 ppm and the CH signals at 3.59 and 3.86 ppm. Similarly, E-4 shows the CH_2 signals at 3.00 and 3.03 ppm and the CH signals at 3.76 and 3.98 ppm. Moreover, the signals of three CH_2 groups of the chelated diamine were observed as two peaks in the intensity ratio of 1 : 2 for E-2 and E-5, while the corresponding signals were observed as three peaks of equal intensities for the E-3 and E-4 isomers (a peak at the lowest-magnetic-field for E-3 overlaps with a CH_2 peak of the L-aspartate ion). These results indicate that the E-2 and E-5 isomers have a chemical environment of C_2 symmetry, while E-3 and E-4 have one of C_1 symmetry. Accordingly, it may be concluded that E-2 and E-5 are a pair of diastereoisomers of *cis(O)trans(N)*, while E-3 and E-4 are one of *cis(O)cis(N)*.

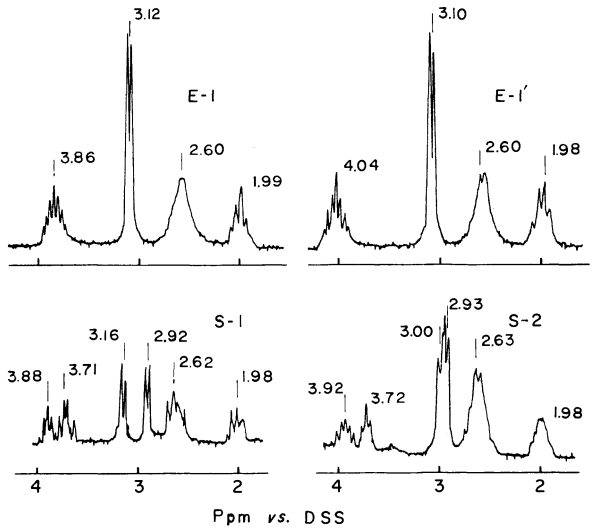

Fig. 8. The PMR spectra for *trans(O)cis(N)*-Λ-(+)-$[Co(L\text{-Hasp})_2(tn)]^+$ (E-1), *trans(O)cis(N)*-Λ-(−)-$[Co(L\text{-Hasp})_2(tn)]^+$ (E-1'), *trans(O)cis(N)*-Λ-(+)-$[Co(L\text{-Hasp})_2(tn)]^+$ (S-1), and *trans(O)cis(N)*-Λ-(−)-$[Co(L\text{-Hasp})_2(tn)]^+$ (S-2).

Figure 8 shows the PMR spectra for the E-1, E-1', S-1, and S-2 isomers, whose structure has been determined as *trans(O)cis(N)*. The CH and CH_2 protons of the chelated L-aspartate ions resonate at 3.86 and 3.12 ppm for E-1 and at 4.04 and 3.10 ppm for E-1'. These values are almost equal to those for a pair of diastereoisomers of the corresponding *l*-propylenediamine complex[1] and of the ethylenediamine complex[2] (Table 3). From these correspondences it may be assumed that the E-1 and E-1' isomers are a pair of diastereoisomers with *trans*(O_α)*cis(N)* geometry in respect

a) Values in ppm from DSS. b) Ratio of the integrated intensities of peaks.

to the donor O_α and N atoms of the glycinate backbone. As an alternative configuration of C_2 symmetry, the *trans*(O_β)*cis(N)* geometry due to the β-carboxylate ions of the chelated aspartate ions is possible. As may be seen in Fig. 3, the configurational effect curve of the E-3 (or *cis(O)cis(N)*-Λ) isomer is in close agreement with the curve of the *cis(O)cis(N)*-Λ-$[Co(L\text{-ala})_2(tn)]^+$ complex.[14] An agreement of the same kind is also observed for the other isomers labeled E. From these comparisons, it can be concluded that in every isomer labeled E two L-aspartate ions chelate to the central cobalt(III) ion, thus forming the five-membered rings.

Now let us characterize the S-1 and S-2 isomers. As compared with E-1 and E-1', the yields of these isomers were extremely poor. The ratios of the integrated intensities of all the signals for these isomers (Table 3) support the idea that both are complexes of the bis(L-aspartato)-type. Moreover, from the facts that the absorption spectra of the isomers show remarkable splittings of the first absorption band and that the $\Delta\varepsilon$ in the CD spectra estimated for S-1 and S-2 are almost equal to those for E-1 and E-1' respectively, it may be concluded that the S-1 and S-2 isomers are the stereoisomers of the *trans(O)cis(N)*-$[Co(L\text{-Hasp})_2(tn)]^+$ complex. The PMR spectra of these *trans(O)cis*(N) isomers differ from those of the other *trans(O)cis(N)* isomers (E-1 and E-1'); the CH protons of the two aspartate ions for S-1 resonate at 3.71 and 3.88 ppm, while those for S-2 resonate at 3.72 and 3.92 ppm. The splittings of the signals due to the CH_2 protons are also observed for the isomers labeled S. The chemical shifts of the CH signals and that of the CH_2 signals at the lower magnetic field for S-1 are in close agreement with the corresponding chemical shifts for E-1. The same relation helds for S-2 and E-1'. These

agreements in chemical shifts suggest that S-1 (or S-2) also has a chelate ring such as the E-1 (or E-1′) isomer. Since the actual spectra differ between S-1 and E-1 (or S-2 and E-1′), the alternative coordination mode of the L-aspartate ion must be taken into consideration. The pK values of the S-1 and E-1 isomers, which have been calculated from the concentration of the solution and its pH value, were roughly 11.0 and 7.0 respectively. These facts suggest that the S-1 isomer differs in its dangling carboxylate group from the E-1 isomer. Thus, the S-1 and S-2 isomers can now be characterized as a pair of diastereoisomers containing a five-membered ring and a six-membered ring, the latter due to the β-carboxylate of the L-aspartate ion. As far as we know, this is the first time that a complex with a six-membered chelate ring of the aspartate ion has been isolated.

Table 4. Formation ratios of $[Co(L\text{-}Hasp)_2(tn)]^+$ isomers

trans(O)cis(N)		*cis(O)cis(N)*		*cis(O)trans(N)*	
Λ	Δ	Λ	Δ	Λ	Δ
13	2.2	5.1	20	12	1
$\Lambda:\Delta=5.9:1$		$\Lambda:\Delta=1:3.9$		$\Lambda:\Delta=12:1$	

Stereoselectivity. The formation ratios among three geometrical isomers are summarized in Table 4. The stereoselective formations are found in the Λ, Δ, and Λ isomers for the *trans(O)cis(N)*, *cis(O)cis(N)*, and *cis(O)trans(N)* isomers respectively. This tendency agrees with those for the corresponding *l*-propylenediamine[1] and ethylenediamine complexes.[2] The amount formed in the present reaction decreased in this order: *cis(O)-cis(N)-*Δ > *trans(O)cis(N)-*$\Lambda \cong$ *cis(O)trans(N)-*Λ > *cis(O)-cis(N)-*Λ > *trans(O)cis(N)-*Δ > *cis(O)trans(N)-*Δ; this order differs from those of the *l*-pn and the en complexes.[2] The formation ratio of the *trans(O)cis(N)*: *cis(O)cis(N)*: *cis(O)trans(N)* isomer is about 29: 47: 24. On the other hand, the ratio of these three geometrical isomers in the *l*-pn complex is 61: 34: 5, and that in the en complex is 55: 34: 11. These facts show that the *trans(O)* isomer in the present complex is harder to form than the *cis(O)* isomers, compared with the *trans(O)* isomer in the *l*-pn and the en complexes. The orders in the *l*-pn and the en complexes have been explained on the basis of the consideration of the formation of hydrogen bonding between the β-carboxylate group and the amino group.[1,2] However, the order in the present complex can not be understood from the hydrogen bonding alone.

The author wishes to thank Professor M. Shibata for his kind instruction and continuous encouragement during this work.

The Steric Requirements of *N,N'*-Bis(salicylidene)-2-aminobenzylamines on Metal Chelate Formation

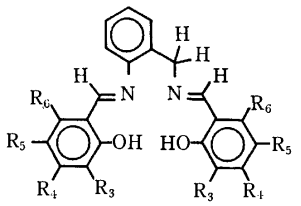
Hajime KANATOMI, Yoichi DEMURA, and Ichiro MURASE

Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810

(Received December 27, 1974)

Copper(II), Ni(II), Co(II), Zn(II), and Be(II) chelates of *N,N'*-bis(salicylidene)-2-aminobenzylamine and its methyl and dimethyl salicylidene derivatives have been prepared and characterized. According to the molecular models, the ligands are favorable to tetrahedral arrangement on complex formation. The spectral and magnetic properties revealed that all the Co(II) and some of the Cu(II) chelates were pseudo-tetrahedral, while the Ni(II) and other Cu(II) chelates were square-planar, with a considerable angle strain. This ligand property is somewhat inconsistent with the conclusion derived from *N,N'*-bis(salicylidene)polymethylenediamine chelates, in which the trimethylene analogue could not take a pseudotetrahedral arrangement around a metal ion. The difference in stereochemistry between the two ligands with the same number of bridging carbon atoms will be discussed on the basis of the flexibility and the steric requirement of the central chelate ring.

Several reports have revealed that metal chelates of *N,N'*-bis(salicylidene)polymethylenediamine change in their stereochemistry with an expansion of the central chelate ring size.[1-7] *N,N'*-Bis(salicylidene)ethylenediamine imposes a square-planar structure for transition-metal chelates due to the steric requirement of the ligand in which the central chelate ring was five-membered. On the other hand, *N,N'*-bis(salicylidene)trimethylenediamine forms a high-spin Co(II) chelate with a structure of a very flattened tetrahedron,[5] and in the square-planar Cu(II) and Ni(II) chelates a significant decrease of the apparent ligand field strength is observed relative to the corresponding ethylenic chelates.[1] The fact that the Co(II) chelate could not take a pseudotetrahedral geometry was explained by the insufficient flexibility of the six-membered central chelate ring consisting of a trimethylene chain.



LH_2

LaH_2: $R_3=R_4=R_5=R_6=H$
LbH_2: $R_5=CH_3, R_3=R_4=R_6=H$
LcH_2: $R_3=R_5=CH_3$, $R_4=R_6=H$
LdH_2: $R_4=R_6=CH_3$, $R_3=R_5=H$

In this report, *N,N'*-bis(salicylidene)-2-aminobenzylamine (abbreviated LaH_2 hereafter) and its 5-methyl, 3,5-dimethyl, and 4,6-dimethylsalicylidene derivatives (LbH_2, LcH_2, and LdH_2 respectively) are chosen as quadridentate ligands in order to study the stereochemistry of the metal chelates with regard to the effect of the central chelate ring flexibility. When these ligands combine with metal ions to form three condensed chelate rings, the central ring is six-membered, as is the trimethylene analogue. The flexibility of the ring is, however, suppressed much more than that of the trimethylene analogue because the two carbon atoms of the benzene ring are constituents of the central chelate ring. Molecular models suggest that a square-planar configuration around a metal ion is difficult without a deformation of bond angles; otherwise, the two phenolic oxygen may overlap on the same plane. A favorable arrangement is one which is distorted from square-planar bending at the flexible methylenic linkage of the central chelate ring. In the derivatives, the methyl groups will exert an electronic influence on the ligand-field strength through the donor atoms; this may affect the chelating tendencies or the metal chelate configuration.

Experimental

The infrared spectra were determined in potassium bromide disks by means of a Hitachi EPI-S2 spectrophotometer, while the electronic spectra were measured with a Hitachi EPS-3T spectrophotometer. The PMR spectra were recorded at 60 MHz in $CDCl_3$ with a Hitachi Model R-24 NMR spectrometer, and the chemical shifts are quoted as ppm values relative to tetramethylsilane. The magnetic moments were measured at room temperature by means of a recording magnetometer specially designed by Hirakawa.[14]

Preparation of the Schiff Bases (LaH_2, LbH_2, LcH_2, and LdH_2). A mixture of 0.02 mol of salicylaldehyde (for LaH_2) and 0.01 mol of 2-aminobenzylamine in 30 ml of methanol was refluxed for 20 min. The yellow crystals which resulted from cooling the reaction mixture in an ice bath were recrystallized from methanol. For LbH_2, LcH_2, and LdH_2, 5-methylsalicylaldehyde, 3,5-dimethylsalicylaldehyde, and 4,6-dimethylsalicylaldehyde were reacted respectively in place of salicylaldehyde. The melting points were: LaH_2, 82—83.5 °C; LbH_2, 118—120 °C; LcH_2, 105—106.5 °C; LdH_2, 123—125.5 °C.

Preparation of the 1: 1 Chelates. A warm methanol solution of the Schiff base was mixed with an equimolar amount of a metal acetate[Cu(II), Ni(II), Co(II), and Zn(II)] or beryllium nitrate in a minimum amount of warm methanol, after which the mixture was refluxed for 20 min. The crystals of the desired chelates were deposited on refluxing or after cooling the reaction mixture. They were collected by filtration, recrystallized from an ethanol-chloroform mixture if necessary, and dried at 90 °C for 8 hr *in vacuo*. The yield was 70—80% for every chelate. The Cu(II) chelate of Lb prepared in this procedure consisted of brown crystals carrying 1/2 mol of water.

Preparation of the Green Cu(II) Chelate(LbCu). To each mol of *o*-aminobenzylamine and Cu(II)-acetate in a minimum amount of hot methanol, we added a slight excess of double

molar 5-methylsalicylaldehyde in methanol, after which the mixture was heated on a water bath for 30 min. After the solution had stood overnight at room temperature, the dark green crystals which resulted were filtered off, washed with a small amount of methanol, and dried at 90 °C *in vacuo*.

Preparation of the 1: 2 Ni(II) Chelates. Although the reaction of LaH_2 or LdH_2 with the Ni(II) ion under the conditions described above inevitably afforded the 1: 2 chelates, they were best prepared by reacting the ligands with a double amount of the metal ion. The reaction was carried out with Ni(II)-acetylacetonate in benzene for LaH_2 and with Ni(II)-acetate in dimethylformamide for LdH_2. The chelates were crystallized out by heating the reaction mixture; they were filtered after cooling, washed with methanol, and dried at 90°C *in vacuo*.

The results of the elemental analyses of the free ligands and the metal chelates are summarized in Table 1.

TABLE 1. ELEMENTAL ANALYSES OF THE SCHIFF BASES AND THEIR METAL CHELATES

Compound	Formula	Found (Calcd) C%	H%	N%
LaH_2	$C_{21}H_{18}N_2O_2$	76.40 (76.34	5.45 5.49	8.49 8.48)

Results and Discussion

The infrared spectra of the free ligands reveal a difference between the two azomethine bondings. Each ligand shows two absorption bands in the 1600 cm^{-1} region, as is illustrated in Table 2. The higher one can be assigned to the double bond of the CH=N-(CH_2) stretching vibration, and the lower one, to the CH=N-(phenyl) stretching vibration, by analogy with the azomethine frequencies of salicylidenebenzylamine (1634 cm^{-1})[8] and salicylideneaniline (1625 cm^{-1})[9] respectively. In the case of LdH_2, only one band appeared, at 1625 cm^{-1}; this is because the bond order of the CH=N-(CH_2) was lowered by the electronic effect of the substituted methyl groups and the absorption overlapped with the CH=N-(phenyl) band.

TABLE 2. C=N STRETCHING FREQUENCIES OF *N,N'*-BIS-(SALICYLIDENE)-2-AMINOBENZYLAMINES AND THEIR 1: 1 METAL CHELATES (cm^{-1})

Ligand	Metal H_2	Cu(II)	Ni(II)	Co(II)	Zn(II)	Be(II)
La	1636	*	*	1608	1625	1632
	1625				1613	1618
Lb	1641	1627[a]	1628	1624	——	——
	1630					
Lc	1633	1627	1627	*	1624	——
	1629				1611	——
Ld	1625	1607	*	1604	1610	——

*: no chelate was isolated. —: no reaction was examined. a): anhydrous green chelate.

TABLE 3. PMR DATA RECORDED AT 60 MHz IN $CDCl_3$ (ppm VALUES RELATIVE TO INTERNAL TMS)

Compound	CH=N–(CH_2)	CH=N–(phenyl)	OH
LaH_2	8.63	8.49	13.10
LbH_2	8.50	8.36	12.82
LcH_2	8.48	8.33	13.05
LdH_2	8.86	8.72	13.41

The PMR spectra exhibit two peaks arising from different azomethine protons. The chemical shifts of the two pairs are about 0.15 ppm different, as may be seen in Table 3; the one at the higher magnetic field belongs to the CH=N–(CH_2) proton, while the lower one is due to the CH=N–(phenyl) proton. This assignment is supported by analogy with the azomethine PMR of salicylidenebenzylamine (8.23 ppm)[8] and of salicylideneaniline (8.50 ppm).[9] The methyl groups *ortho* and *para* to the azomethine groups increase, and the *meta* methyls decrease, the deshielding effect of the phenyl ring current. The OH proton resonance appears as a broad band; the band broadening is attributed to the proton exchange which is taking place at a high rate between the two OH bondings. The chemical shifts shown in Table 3 indicate the mean value due to the two OH protons. Judging from these values, the *para* and/or *ortho* methyl derivatives (LbH_2 and LcH_2) have more shielded OH protons than the nonsubstituted one (LaH_2), while that of the *meta* derivative (LdH_2) is less shielded.

Metal chelates isolated as pure crystals with the 1: 1 metal-ligand composition are listed in Table 2, which

shows the CH=N stretching frequencies. It may be seen that the two CH=N absorptions shift to lower frequencies on complex formation and that many of them are overlapped into one band. As is to be expected from the molecular model and from the fact that Cu(II) and Ni(II) chelates could not be isolated with La, the ligand is not likely to have a square-planar arrangement. Furthermore, the tetrahedrally distorted arrangement seems most likely for La because the ligand affords chelates with Zn(II) and Be(II) ions, which are believed to prefer to form tetrahedral complexes. It was shown that, in the case of *N,N'*-bis(salicylidene)-polymethylenediamine, the tetramethylene bridge was the smallest chain which would allow the four donor atoms to occupy truly tetrahedral sites around a metal ion. Since beryllium would not tolerate even a slight departure from tetrahedral stereochemistry, the trimethylene derivative did not form a 1:1 complex with the Be(II) ion, but instead gave a 1:2 complex in which the ligand functioned as a bidentate chelate.[3] This explanation is, however, inconsistent with the present finding, where La could form a 1:1 Be(II) chelate despite having a less flexible three-carbon bridge.

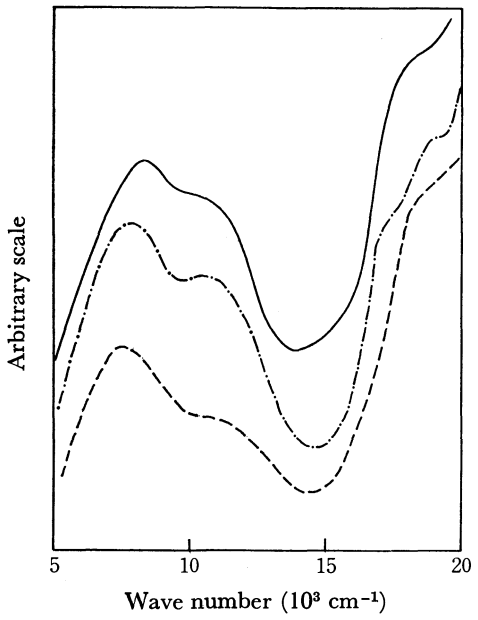

Fig. 1. Electronic reflectance spectra of La-Co(II), ----; Lb-Co(II), ——; Ld-Co(II), ——.

With La, Lb, and Ld, 1:1 Co(II) chelates were isolated as orange-red crystals. The spectral patterns of these chelates, shown in Fig. 1, are quite similar to that obtained for bis(*N*-phenylsalicylaldiminato)cobalt-(II), which exhibited absorption bands at 7600, 10700, 16700 (shoulder), and 19300 cm^{-1} in the near-infrared and visible region[10] and which has been shown by crystallographycal evidence to have a pseudotetrahedral geometry.[11] The magnetic moment of the Co(II) chelate with La was $\mu_{eff}=4.2$ B.M. ($\chi=18.69\times10^{-6}$ $egsu^{-1}$) at room temperature; this is in agreement with those expected for tetrahedral Co(II) complexes.[12] On the bases of these similarities in spectral and magnetic properties with complexes of a known structure, it may be concluded that these Co(II) chelates adopt the pseudotetrahedral geometry around the metal ion. In *N,N'*-bis(salicylidene)polymethylenediaminatocobalt-(II), those with four to six bridging methylene groups were found to be pseudotetrahedral; however, the trimethylene derivative showed an anomalous electronic spectrum and was assumed to be a highly flattened tetrahedron on the basis of the magnetic high-spin character (4.56 B.M.).[5]

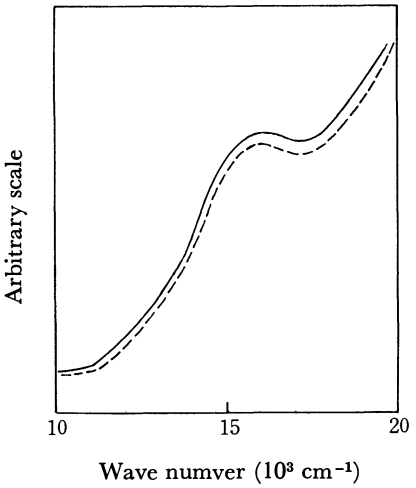

Fig. 2. Electronic reflectance spectra of Lb-Ni(II), ----; Lc-Ni(II), ——.

Nickel(II) chelates with a 1:1 metal-ligand composition were isolated with Lb and Lc. It is seen the presence of *para* and/or *ortho* methyl groups, which increase the electron density of the phenolic oxygens, is necessary for the chelate formation. These chelates were diamagnetic and exhibited *d-d* bands at 15900 cm^{-1} for the Lb-chelate and at 16000 cm^{-1} for the Lc-chelate in their reflectance spectra; the patterns are shown in Fig. 2. It thus appears that these chelates have a basically planar configuration, though it is not necessarily strictly planar. In *N,N'*-bis(salicylidene)polymethylenediaminatonickel(II), the planar structures were retained even when the bridging methylene groups increased to 3, 4, or 5, while a significant decrease in the apparent ligand-field strength was observed with an increase in the number of methylene groups.[1,7] The bands for the present Ni(II) chelates were in lower energy region than those of the tetra- and pentamethylene complexes; this may be attributed to the distortion of the bond angles produced when the ligand molecules are forced to adopt the square-planar configuration on the metal-chelate formation.

The PMR spectra of Ni(II) and Zn(II) chelates with Lc are shown in Fig. 3. It is interesting that the separate PMR peaks of the CH=N–(CH_2) and the CH=N–(phenyl) protons in the free ligand become a single peak in the Ni(II) chelate and shift to a higher magnetic field (7.34 ppm). Therefore, the two azomethine linkages are equivalent in the metal chelate rings; this agrees with the fact that the azomethine stretching vibration appears as a single band. On the contrary, the two PMR peaks in the corresponding Zn(II) chelate are merely shifted to the respective

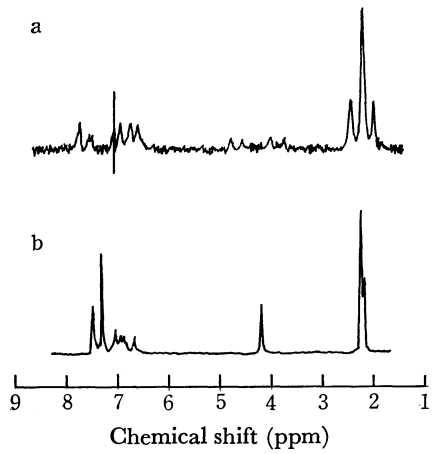

Fig. 3. PMR spectra of Lc-Zn(II) (a) and Lc-Ni(II) (b).

higher magnetic fields (7.87 and 7.77 ppm), indicating that each azomethine retains a different character in this case. Furthermore, the bridging methylene protons, which appear as a single peak at 4.76 ppm in the free ligand, shift to 4.28 ppm in the Ni(II) chelate, while it splits into an AB pattern centered at 4.30 ppm (J_{AB}=8 Hz) in the Zn(II) chelate. The different features; in the methylene PMR can be explained in terms of the central chelate ring flexibility when it is retained at the methylenic linkage in the Ni(II) chelate and fixed in the Zn(II) chelate. The characteristics of the ring flexibility probably arise from the difference in the configuration that is, the Ni(II) chelate is square-planar, while the Zn(II) chelate is tetrahedral.

La and Ld do not form 1:1 Ni(II)-chelates, but instead form 1:2 complexes in which these ligands function as a bidentate chelate. The presence of the uncoordinated salicylaldimino moiety in each ligand molecule is evidenced by the presence of a free OH group which exhibits a broad and weak infrared absorption around 2700 cm^{-1}. To distinguish the coordination site of the molecule, the CH=N stretching vibration were compared with the corresponding free ligand; however, they appeared as one rather broad band at 1618 cm^{-1} in $(LaH)_2Ni$ and at 1608 cm^{-1} in $(LdH)_2Ni$. Therefore, it was not clear that either CH=N–(CH_2) or CH=N–(phenyl) nitrogen coordinated to the metal ion. The reflectance spectral patterns are typical for a square-planar Ni(II) complex exhibiting one *d-d* band at 16000 cm^{-1} in the La-complex and at 16400 cm^{-1} in the Ld-complex.

Copper(II) chelates were isolated with Lb, Lc, and Ld. La could not be a chelate ligand; they must be due to an insufficient electron density of the donor atoms in the same sense as are the Ni(II) chelates. It should be noted that the chelate with Ld was brown and that with Lc was green, while Lb gave chelates of both color types, of which the brown one contained 1/2 mol of water. The difference in color was apparent in their reflectance spectral patterns, as may be seen in Fig. 4. The green chelates show a distinct absorption maximum at 16200 cm^{-1} in Lb-Cu(II) and 16400 cm^{-1} in Lc-Cu(II), with a shoulder both around 13500 cm^{-1}, while the brown chelates exhibit absorption only as a shoulder or broad band around 15000 cm^{-1}. According

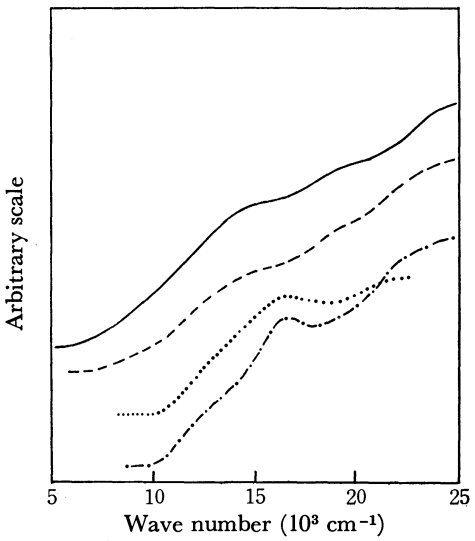

Fig. 4. Electronic reflectance spectra of Lb-Cu(II) (green), ·····; Lb-Cu(II) (brown), ——; Lc-Cu(II), -·-·-; Ld-Cu(II), ——.

to the criteria established by several investigators with regard to the Cu(II) chelates of bissalicylaldimines,[13] these types of absorptions are a result of tetrahedral distortion. The difference in the spectral patterns between the green and the brown chelates depends on the degree of distortion from a square-planar configuration; the green chelates are essentially square-planar, while the brown chelates are pseudotetrahedral.

In the present Cu(II) chelates, the degree of distortion may be attributed to the degree of the ligand-field strength, because the only structural difference in these ligands is in the presence of the methyl groups at the salicylidene moieties, which exert no steric effect on the chelate configuration. A relatively high electron density at the oxgen atoms, which is achieved by the electronic effect of *ortho* and *para* methyl groups, seems to be necessary to enforce the planar configuration on the chelate, as in the case of Lc. The ligand-field strength of Lb is likely to be intermediate in taking a planar or pseudotetrahedral arrangement, because it can from chelates of either type, depending upon the reaction conditions. However, this argument is partly hypothetical, since the role of the 1/2 mol of water has not been made clear.

Conclusion

In *N,N'*-carbon-bridging bissalicylaldimine derivatives, the three carbon-chain compounds are not necessarily unfavorable for tetrahedral arrangement around a particular metal ion. The stereochemistry of the metal chelates is governed not only by the steric requirement of the metal ion, but also by the steric preference of the bridging carbon linkages in addition to the chain flexibility. This has been evidenced by the present investigation, where *N,N'*-bis(salicylidene)-2-aminobenzylamines formed tetrahedral 1:1 chelates with Be(II) and Co(II) ions which were impossible with the trimethylene analogue. Since a Ni(II) ion enforced a square-planar coordination on the ligands, a

decrease in the ligand-field strength was observed and the derivatives with insufficient donor powder could not form a 1 : 1 chelate. In the Cu(II) chelates, the degree of tetrahedral distortion depended upon the donor power in each ligand. It may tentatively be considered that Lb is in a boundary condition in taking a planar or pseudotetrahedral arrangement around a Cu(II) ion.

Iminophosphorane Complexes of Palladium(II)

Mitsuyo FUKUI, Kenji ITOH, and Yoshio ISHII

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chikusa-ku, Nagoya 464

(Received January 28, 1975)

Iminophosphorane complexes of palladium $[(C_6H_5)_3P{=}N{-}C_6H_4{-}X{-}p]PdCl_2(CH_3CN)$ (X=NO_2, **1A**; $COOC_2H_5$, **2A**; Cl, **3A**; H, **4A**; CH_3, **5A**) have been prepared by ligand-substitution reaction between $(C_6H_5CN)_2PdCl_2$ and the parent iminophosphoranes, followed by recrystallization from acetonitrile–ethyl acetate. Other iminophosphoranes (X=OCH_3, and $(C_6H_5)_2(CH_3)P{=}N{-}Si(CH_3)_3$), however, gave only dimeric complexes with the $[(\text{Iminophosphorane})PdCl_2]_2$ composition. Complexes **1A—5A** and $\{[(C_6H_5)_3P{=}N{-}C_6H_4{-}X{-}p]PdCl_2\}_2$ (X=NO_2, **1B**; $COOC_2H_5$, **2B**; Cl, **3B**; H, **4B**; CH_3, **5B**) are also discussed. The ligand-exchange reaction of **2B** and **5B** with α,α'-bipyridine, $(C_6H_5)_3P$, and $(CH_3O)_3P$ took place, liberating the parent iminophosphorane.

Iminophosphoranes represented as two resonance hybrides, $R_3\overset{+}{P}{-}\overset{-}{N}R' \leftrightarrow R_3P{=}NR'$, are isoelectronic with phosphorus ylides. Numerous transition metal complexes of phosphorus,[1–10] nitrogen,[11–13] and sulfur[14–16] ylides have recently been prepared. Information on iminophosphorane complexes has, however, been limited to those of V(0),[19] Co(II),[17,18] Cu(II),[17] Mo(0),[20] and W(0),[20] there is no known palladium complex. In this paper, the quantitative preparation of palladium(II) complexes with aryliminotriphenylphosphoranes and *N*-trimethylsilyliminodiphenylmethylphosphorane will be described, and the IR spectra of these complexes will be discussed.

Experimental

All the preparations of the iminophosphorane complexes were carried out under an atmosphere of nitrogen or argon. The IR spectra were recorded on a JASCO Model DS-403G spectrometer calibrated with polystyrene. The proton NMR spectra were recorded on a JEOL C60-HL instrument, with TMS as the internal reference. The analyses were carried out by the Microanalytical Center of Kyoto University, Japan.

Starting Materials. The dichlorobis(benzonitrile)palladium(II) was prepared according to the method of Kharasch *et al.*[21] The *p*-substituted phenyliminotriphenylphosphoranes were obtained by the interaction of dibromotriphenylphosphine with *p*-substituted anilines in the presence of triethylamine.[22] The *N*-trimethylsilyliminodiphenylmethylphosphorane was prepared by a method reported previously.[23]

Preparation of $[(C_6H_5)_3P{=}N{-}C_6H_4{-}X\text{-p}]PdCl_2(CH_3CN)$ *(X=NO_2, 1A; $COOC_2H_5$, 2A; Cl, 3A; H, 4A; CH_3, 5A).* The preparation of the phenyliminotriphenylphosphorane complex (**4A**) will be described as a representative example. A benzene suspension (10 ml) of dichlorobis(benzonitrile)palladium(II) (0.1046 g, 2.730 mmol) and phenyliminotriphenylphosphorane (0.0964 g, 2.730 mmol) was stirred overnight under an inert atmosphere. Dark brown precipitates (**4B**) were thus obtained quantitatively (0.1437 g). When **4B** was recrystallized from the mixed solvent of acetonitrile–ethyl acetate (1:2) at 0 °C for few days, a black violet microcrystalline complex (**4A**) was obtained. The time required for the recrystallization increased upon substitution of an electron-releasing group on the phenyl ring; it was overnight for *p*-NO_2(**1A**) and *p*-$COOC_2H_5$(**2A**), a few days for *p*-Cl(**3A**) and *p*-H(**4A**), and three months for *p*-CH_3(**5A**). The analytical data and melting points of the complexes are shown in Table 1. The dark brown precipitates, which must be dinuclear complexes **1B-4B**, could not be isolated in an analytical pure form except for **5B**. Consequently, a definitive determination was achieved by means of the monomeric complexes, **1A-5A**, which were obtained by a cleavage of dichlorobridging in the crude **1B-5B** by means of a large volume of acetonitrile.

Preparation of $\{[(C_6H_5)_3P{=}N{-}C_6H_4{-}OCH_3\text{-p}]PdCl_2\}_2$ *(6B).* A benzene suspension (10 ml) of dichlorobis(benzonitrile)palladium(II) (0.2763 g, 7.204 mmol) and anisyliminotriphenylphosphorane (0.2763 g, 7.204 mmol) was stirred under an inert atmosphere overnight. Dark brown precipitates (**6B**) were thus obtained quantitatively (0.4010 g); they were recrystallized from an acetonitrile–ethyl acetate (1:2) mixed solvent. The resulting crystals were dichlorodi-μ-chlorobis(*p*-anisyliminotriphenylphosphorane)dichloropalladium(II) with one molecule of acetonitrile as the solvent of crystallization; mp 143—145 °C. Found: C, 52.83; H, 4.04; N, 3.37%. Calcd for $C_{52}H_{37}Cl_4N_3O_2P_2Pd_2$: C, 53.73; H, 4.08; N, 3.61%. PMR ($CDCl_3$): τ 8.70 (s, CH_3), τ 6.30 (s, OCH_3), τ 2.16—2.76 (m, C_6H_5 and C_6H_4). IR (KBr disk): 1238 cm^{-1} [ν(P=N)], (free 1334 cm^{-1}; $\Delta\nu$ 96 cm^{-1}); 302, 310, 332, and 348 cm^{-1} [ν(Pd-Cl)].

Reaction of α,α′-Bipyridine and Triphenylphosphine with Dichlorodi-μ-chlorobis(p-ethoxycarbonyliminotriphenylphosphorane)dipalladium-(II) (2B). A benzene (11 ml) solution of 2B (0.1610 g, 1.335 mmol) and α,α′-bipyridine (0.0417 g, 2.671 mmol) was stirred for one day. Dichloro(α,α′-bipyridine)palladium(II) was precipitated (0.0825 g, 96%) and the parent iminophosphorane was quantitatively liberated in a benzene solution. They were identified by comparison with authentic samples. A similar procedure was used in the reaction of 7B with four equimolar amounts of triphenylphosphine; the reaction gave quantitatively dichlorobis(triphenylphosphine)palladium(II) and the parent iminophosphorane. In the case of two equimolar amounts of triphenylphosphine, the reaction proceeded with one half mole of dichlorobis(triphenylphosphine)palladium(II); one half mol of **7B** was recovered.

Reaction of Trimethylphosphite with Dichlorodi-μ-chlorobis-(p-tolyliminotriphenylphosphorane)dipalladium(II) (5B). To a benzene (7 ml) solution of 5B (0.1627 g, 1.497 mmol), trimethylphosphite (0.0276 g, 5.990 mmol) was added under nitrogen. After the mixture had been stirred at room temperature for 3 hr, the solvent was evacuated. The white residue was recrystallized from chloroform–ether. Dichlorobis(trimethylphosphite)palladium(II) was thus obtained (0.1053 g, 81%).

Results and Discussion

The reaction between dichlorobis(benzonitrile)palladium(II) and aryliminotriphenylphosphorane in benzene took place at room temperature overnight under an inert atmosphere to give dark brown precipitates with the composition of $\{[(C_6H_5)_3P{=}N{-}C_6H_4{-}X\text{-}p]PdCl_2\}_2$ (X=NO_2, **1B**; $COOC_2H_5$, **2B**; Cl, **3B**; H, **4B**; CH_3, **5B**) in a quantitative yield. When these precipitates, **1B—5B**, were recrystallized from an acetonitrile–ethyl acetate (1: 2) mixed solvent, the palladium-chloride bridge of **1B—5B** was cleaved with acetonitrile to give $[(C_6H_5)_3P{=}N{-}C_6H_4{-}X\text{-}p]PdCl_2(CH_3CN)$ (X=NO_2, **1A**; $COOC_2H_5$, **2A**; Cl, **3A**; H, **4A**; CH_3, **5A**). The IR absorptions of the ν(P=N) stretching frequencies of free and complexed aryliminotriphenylphosphoranes, those of the ν(Pd–Cl) region, and those of the ν(C≡N) region are summarized in Table 2.

The difference in stretching frequencies, $\Delta\nu$(P=N), between free and complexed aryliminotriphenylphosphoranes shows that the electron-releasing substituent strengthens the bonding of the Pd–N bond except in the case of the *p*-methyl substituent, as is shown in Fig. 1.

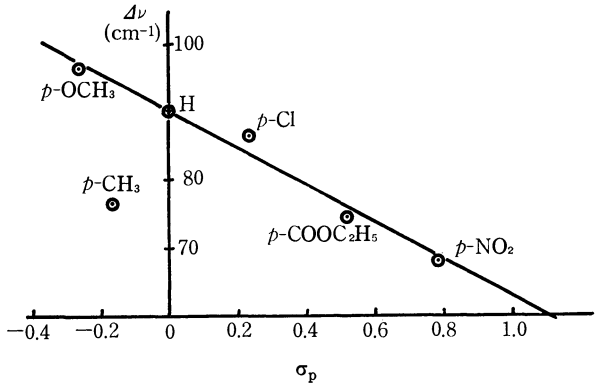

Fig. 1. A correlation between $\Delta\nu$(P=N) and Hammett constants (σ_p) in aryliminotriphenylphosphorane complexes.

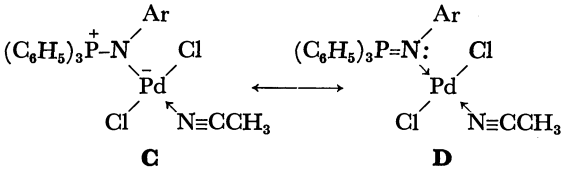
There are four ν(Pd–Cl) absorptions in the initially formed dimeric complexes (B); they became a simple band after recrystallization from acetonitrile–ethyl acetate. This fact supports the view that readily coordinating acetonitrile cleaved the dichlorobridging to afford the monomeric complex (A). The PMR spectrum of **5A** also indicates the presence of coordinated acetonitrile at τ 8.00 as a sharp singlet.

Monomeric aryliminotriphenylphosphorane complexes containing acetonitrile as a coordinated ligand can be represented by two resonance structures, the zwitter-ionic form (**C**) and the coordinated form (**D**):



The *trans* configuration of acetonitrile and aryliminotriphenylphosphorane is favorable, since the ν(C≡N) band of the complex was at the higher frequencies [2311—2329 cm^{-1}; each value is closer in order to the complexed ν(P=N) and ν(Pd–Cl) bands] than is that of free acetonitrile (2255 cm^{-1}), as is shown in Table 2. Aryliminotriphenylphosphorane, which has an electron-attracting substituent, displays a weak

		free	complexed **A** and **B**		**B**				**A**	**A**
1	NO_2	1364	1296	68	308	319	329	349	334	2311
2	$COOC_2H_5$	1356	1282	74	303	322	330	341	330	2313
3	Cl	1339	1253	86	295	310	333	361	330	2313
4	H	1338	1248	90	303	312	323	345	322	2315
5	CH_3	1325	1249	76	302	314	327	349	319	2329

trans effect on acetonitrile, which coordinates at the lone pair of the nitrogen atom. Alternatively, the monomeric complex (**A**) exhibits one distinct ν(Pd-Cl) frequency in the region of 319—334 cm^{-1}. This also suggests a *trans*-configuration structure with a higher symmetry.

When a strongly electron-releasing *p*-methoxy substituent was introduced, acetonitrile could not cleave the dichlorobridging and gave only the dimeric complexes (**B**), in contrast to the above complexes (**1**—**5**).

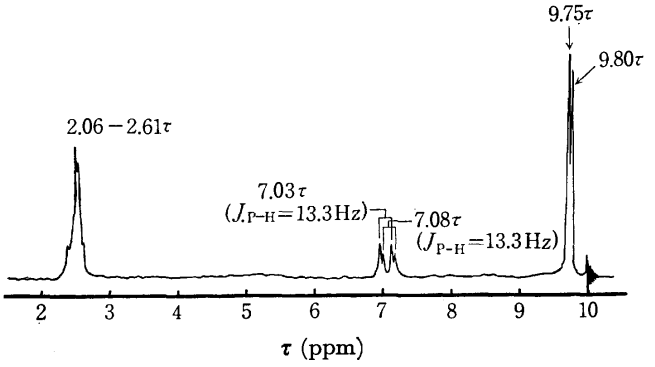

Fig. 2. Proton magnetic resonance spectrum of $\{[(C_6H_5)_2(CH_3)P{=}N{-}Si(CH_3)_3]PdCl_2\}_2$, **7B** in $CDCl_3$. Proton ratio at τ 7.03: 7.07=2: 1, and τ 9.75: 9.08 =2: 1.

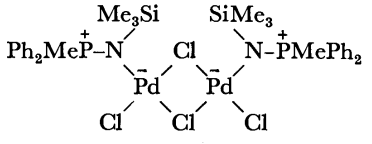
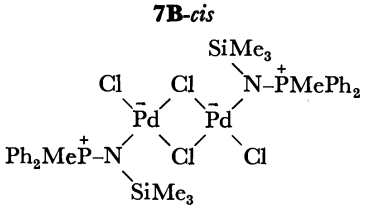
When *N*-trimethylsilyliminodiphenylmethylphosphorane was used instead of *N*-aryliminotriphenylphosphoranes as a ligand, a stable dimeric complex (**7B**) was obtained. The PMR spectrum, shown in Fig. 2, suggests the presence of two isomers. Four ν(Pd-Cl) bands were observed at 306, 328, 350, and 361 cm^{-1}, indicative of a dimeric structure. The ν(P=N) in benzene was observed at 1070 cm^{-1}, 227 cm^{-1} lower than the free ligand (at 1307 cm^{-1} in benzene). Such a large absorption difference compared with the aryliminotriphenylphosphorane complexes may be ascribed to the exclusive contribution of the zwitter-ionic structure to **7B**. From the PMR spectrum, we concluded that **7B** is present as a mixture of *cis* and *trans* (1 : 2) isomers.



7B-*cis*



7B-*trans*

Ph=C_6H_5, Me=CH_3

Such a zwitter-ionic structure had previously been established by an X-ray analysis of the nickl-phosphorus ylide complex.[24] It is interesting that the Si–N bond in **7B** is quite stable to hydrolysis. Such a stabilization can be explained in terms of the enhanced (2p-3d)π interaction, which is induced by the transmission of the negative charge on the anionic palladium to vacant 3d orbitals on the silicon atom through rehybridized 2p orbitals on the central nitrogen atom.

Finally, the ligand substitution of aryliminotriphenylphosphorane complexes was attempted with **2B**. The coordinated *p*-ethoxycarbonylphenyliminotriphenylphosphorane was selectively liberated by α,α′-bipyridine or triphenylphosphine to give the dichloro(α,α′-bipyridine)palladium(II) or the dichlorobis(triphenylphosphine)palladium(II) complex. A similar result was obtained by the reaction of **5B** with trimethylphosphite. These results suggest that aryliminotriphenylphosphoranes are weaker ligands than α,α′-bipyridine, triphenylphosphine, and trimethylphosphite.

Effect of Various Additives on Color Center Formation and Brightness Depreciation of Calcium Halophosphate Phosphors

Kazuo NARITA and Nobuyuki TSUDA

Toshiba Research and Development Center, 1 Komukai-Toshibacho, Saiwaiku, Kawasaki 210

(Received February 14, 1975)

Color center formation and brightness depreciation by 185 nm radiation were studied in calcium halophosphates containing various additives. Partial bleaching experiments show that the depreciation of plaque brightness is due to the absorption of 254 nm radiation by color centers, the reabsorption of luminescence by color centers being unimportant. In unactivated Ca halophosphates, the stronger the 185 nm absorption of additives, the weaker the color center formation. In Sb- and Mn-activated Ca halophosphates, however, no clear relation is found between the 185 nm absorption of additives and the brightness depreciation. The effect of cesium on improving lamp performance is described.

A great deal of information has been accumulated on the color centers of calcium halophosphate.[1-17] In fluorescent lamps, color centers are formed in halophosphate phosphors by exposure to 185 nm Hg radiation. It has been established that the decrease of lumen output in the first several minutes of lamp operation is closely related to the formation of color centers.[6,8] These centers are assumed to absorb a part of 254 nm exciting radiation and/or emitted luminescence energy in the visible region. It would be of great practical meaning to suppress, if not to prevent, the formation of color centers in halophosphate phosphors.

Aia and Poss[18] found that the initial light output of a fluorescent lamp is increased when a few percent of Cd is incorporated in halophosphate phosphors. Apple[6] explained the effect of Cd as follows. By introducing Cd, a strong absorption band appears in the wavelength region shorter than 200 nm in Ca halophosphate, which, in its pure state, is transparent down to 150 nm. In this manner, Cd provides a new process by which a considerable part of the deleterious 185 nm radiation is absorbed and dissipated without creating color centers. The major part of color centers is created in the first several minutes of lamp operation. It is, therefore, understandable why the "initial" lamp efficiency, which is usually measured after several tens of minutes of stabilization, appears to be increased.

If one follows Apple's explanation, other elements which would equal or surpass Cd in improving lamp efficiency might be found by examining whether the elements in question fulfill the following two conditions.

(I) In order to suppress the formation of color centers, such elements that give rise to strong absorption in the 185 nm region in the halophosphate matrix would be effective.

(II) The elements mentioned above should have little or no absorption at 254 nm and in the visible region, so that they absorb neither 254 nm exciting radiation nor the emitted fluorescence.

In this work, diffuse reflection spectra of Ca halophosphates with various metal additives were measured between 180 and 650 nm. Then it was checked whether any additive exists which satisfies the above conditions, and whether the element selected in this manner really brings about the expected decrease of depreciation.

Experimental

Materials. Samples prepared were: (1) Sb- and Mn-activated halophosphate $Ca_{9.5}Sb_{0.1}Mn_{0.2}(PO_4)_6(F_{0.9}Cl_{0.1})_2$, which has a composition close to that of commercial 4200 K phosphor (hereafter referred to as "Standard"), (2) unactivated halophosphate $Ca_{9.8}(PO_4)_6(F_{0.9}Cl_{0.1})_2$ ("Matrix"), (3) unactivated halophosphates with additives $Ca_{9.7}M_{0.1}(PO_4)_6(F_{0.9}Cl_{0.1})_2$ where M represents metal additives ("Series A" samples), and (4) $Ca_{9.4}M_{0.1}Sb_{0.1}Mn_{0.2}(PO_4)_6(F_{0.9}Cl_{0.1})_2$ ("Series B" samples). The raw materials ($CaHPO_4$, $CaCO_3$, CaF_2, $CaCl_2$, Sb_2O_3, $MnCO_3$ and a suitable compound of the desired metal M) were dry-mixed, ignited at 1150 °C for 30 min in air, ground thoroughly and ignited again under the same conditions.

Formation and Bleaching of Color Centers. Color centers were formed by 185 nm radiation from a 10 W, low pressure mercury lamp with a quartz envelope. Phosphor plaques were placed about 1 cm below the lamp. All the irradiation experiments were carried out in a vacuum. In order to bleach the color centers, samples were irradiated with a germicidal lamp or a 500 W Xenon arc lamp coupled with appropriate filters.

Measurements. Reflection spectra were measured with a Jarrel-Ash vacuum monochromator of Seya-Namioka type (model 78—660) in vacuum ultraviolet, and with a Perkin-Elmer monochromator (model E1) in the UV and visible regions.

Brightness of phosphor plaques was obtained by integrating the emission spectra. For this purpose, a ZV-1 spectroradiometer[19] equipped with a Perkin-Elmer printing integrator was used. The 254 nm exciting radiation was made as weak as possible to prevent the bleaching of color centers during the course of brightness measurements. It was confirmed that the emission spectra of investigated samples change little with the 185 nm irradiation.

Results and Discussion

Correlation between Plaque Brightness and 254 nm Absorption by Additives. Wachtel investigated thoroughly the relation between the concentration of various impurities and plaque brightness of a 3000 K Ca halophosphate phosphor.[20] In order to examine the above-mentioned condition II more quantitatively, an attempt was made to correlate the plaque brightness of Series B phosphors with the 254 nm absorption due to additives.

In the calculations described below, the following

assumptions are made:

(1) Additives absorb the exciting 254 nm light and dissipate it nonradiatively.

(2) They do not sensitize nor quench the luminescence of the activators.

(3) They do not absorb the visible emission.

The plaque brightness of Series B samples, I, is given by

$$I = cE_e(1-R_B(\lambda_e))\frac{k_{ac}(\lambda_e)}{k_{ac}(\lambda_e)+k_m(\lambda_e)+k_{ad}(\lambda_e)}, \quad (1)$$

where c is a constant, E_e the energy of 254 nm exciting radiation and $R_B(\lambda_e)$ the diffuse reflectance at 254 nm, while $k_{ac}(\lambda_e)$, $k_m(\lambda_e)$ and $k_{ad}(\lambda_e)$ are the 254nm absorption coefficients of activators, pure halophosphate matrix, and metal additives, respectively.

The plaque brightness of Standard, I_0, is given by

$$I_0 = cE_e(1-R_0(\lambda_e))\frac{k_{ac}(\lambda_e)}{k_{ac}(\lambda_e)+k_m(\lambda_e)}, \quad (2)$$

where $R_0(\lambda_e)$ is the diffuse reflectance of Standard at 254 nm.

The absorption coefficients are correlated with diffuse reflectance by the Kubelka-Munk formula[21]

$$\frac{k}{s} = \frac{(1-R)^2}{2R}, \quad (3)$$

where s is scattering coefficient. The ratio k/s is called remission function. It is assumed that s is constant for all the samples. The ratio $(1-R_B(\lambda_e))/(1-R_0(\lambda_e))$ is close to unity in the presence of strong absorption of activators. Thus, the relative plaque brightness of Series B phosphors compared to Standard, I/I_0, is given by

$$\frac{I}{I_0} \fallingdotseq \frac{k_{ac}(\lambda_e)+k_m(\lambda_e)}{k_{ac}(\lambda_e)+k_m(\lambda_e)+k_{ad}(\lambda_e)} = \frac{(1-R_0(\lambda_e))^2/2R_0(\lambda_e)}{\{(1-R_0(\lambda_e))^2/2R_0(\lambda_e)+(1-R_A(\lambda_e))^2/2R_A(\lambda_e) - (1-R_m(\lambda_e))^2/2R_m(\lambda_e)\}} \quad (4)$$

where $R_A(\lambda_e)$ and $R_m(\lambda_e)$ are diffuse reflectance of Series A samples and Matrix at 254 nm, respectively.

Figure 1 shows diffuse reflection spectra of Matrix,

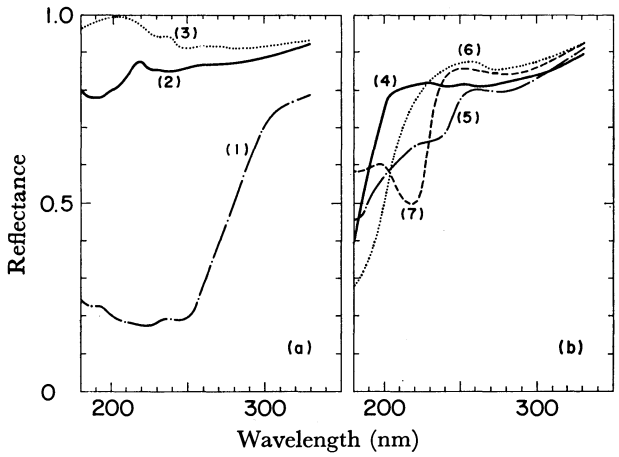

Fig. 1. Diffuse reflection spectra of Standard, Matrix and selected Series A samples (Additives are specified below).
(1) Standard. (2) Matrix. (3) Cs. (4) Cd. (5) Zr. (6) Ge. (7) Tb.

Standard and selected Series A samples. The $R_A(\lambda_e)$ values of all of Series A samples and the I/I_0 values of the corresponding Series B phosphors are given in Table 1. The same data are plotted also in Fig. 2. Using the observed values of $R_0(\lambda_e)=0.228$ and $R_m(\lambda_e)=0.865$, the dependence of I/I_0 on $R_A(\lambda_e)$ was calculated by Eq. (4) (solid line curve, Fig. 2).

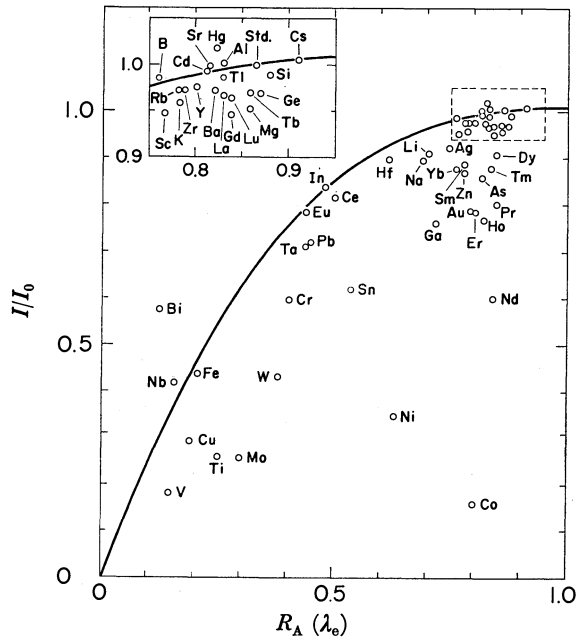

Fig. 2. Relation between 254 nm reflectance of Series A samples ($R_A(\lambda_e)$) and relative plaque brightness of corresponding Series B samples (I/I_0). Names of additives are indicated in the figure.

We see that the experimental I/I_0 values of such Series B samples as those containing K, Rb, Cs, Mg, Sr, Ba, Cd, Hg, Sc, Y, B, Al, Tl, Zr, Si, Ge, La, Gd, Tb, Lu, In, Eu, Fe and Nb are close to the calculated values. Of these, the first twenty additives might be of practical value, since their I/I_0 values are high. For the additives not mentioned above, I/I_0 is much lower than expected from Eq. (4), indicating that assumptions (2) and (3) are more or less invalid.

Change of Plaque Brightness due to Color Center Bleaching. As the absorption due to the color centers of Ca halophosphate extends from UV to visible region, both the 254 nm exciting radiation and the emission in the visible region may be absorbed by the color centers. In order to determine which of these two absorption processes is dominant in brightness depreciation, the effect of partial bleaching on plaque brightness was investigated.

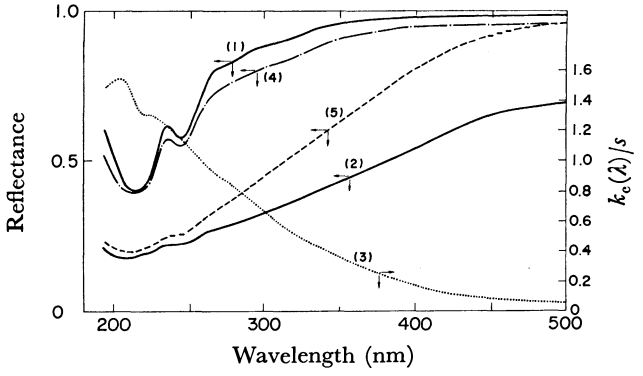

Fig. 3. Change of diffuse reflection spectrum of $Ca_{9.7}Sb_{0.03}(PO_4)_6(F_{0.9}Cl_{0.1})_2$ by 185 nm irradiation and by subsequent bleaching. (1) Before irradiation. (2) After 185 nm irradiation (6 hr in vacuum). (3) Spectrum of $k_c(\lambda)/s$ calculated from (1) and (2). (4) After bleaching by 254 nm light (1 hr). (5) After bleaching by blue light through UV 39+V-V 40 filters (10 hr).

Figure 3 shows the change of diffuse reflection spectra of a $Ca_{9.7}Sb_{0.03}(PO_4)_6(F_{0.9}Cl_{0.1})_2$ phosphor during the course of bleaching of color centers. The sample containing only a small amount of Sb was chosen because of ease of reflectance measurements. This sample has a weak absorption due to Sb in the UV region (curve (1)). The reflection spectrum after 185 nm irradiation (6 hr in a vacuum) is shown by curve (2). The remission function of the induced color centers, $k_c(\lambda)/s$, was calculated by

$$\frac{k_c(\lambda)}{s} = \frac{(1-R_i(\lambda))^2}{2R_i(\lambda)} - \frac{(1-R(\lambda))^2}{2R(\lambda)}, \qquad (5)$$

where $R(\lambda)$ and $R_i(\lambda)$ are diffuse reflectance before and after irradiation, respectively. The result is shown by curve (3). The color centers were then bleached, either by 254 nm light from a germicidal lamp or by blue light from a xenon lamp coupled with Toshiba UV-39 (sharp cut-off at 390 nm) and V-V 40 (band pass with peak at 400 nm) filters. The results are shown by curves (4) and (5), respectively. Note that 254 nm irradiation bleaches the color centers almost completely, while the blue light bleaches the color centers in the visible, with little change in the 254 nm region.

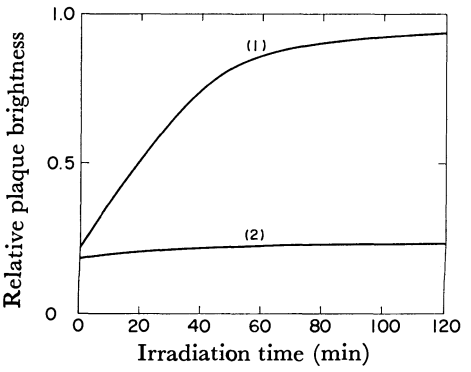

Fig. 4. Change of plaque brightness during bleaching. The sample was first irradiated by 185 nm light and then (1) by 254 nm light, (2) by blue light through UV 39+V-V 40 filters.

Figure 4 shows the change of plaque brightness of the same phosphor by bleaching. It is seen that the brightness, which has decreased to about 20% of the initial value due to 6 hr 185 nm irradiation, is almost completely restored by exposition to 254 nm light. On the other hand, little restoration of brightness is observed by blue light irradiation. It is thus concluded that the brightness depreciation is caused by the absorption of 254 nm light by color centers, the self-absorption of the emission in the visible region being unimportant. This might be due to the fact that the absorption of the color centers is very weak for the visible luminescence as compared with the absorption for the 254 nm radiation (Fig. 3, curve (3)). The same results as those shown in Figs. 3 and 4 were obtained for Standard phosphor.[22]

The nonradiative energy transfer from Sb to color

centers, proposed recently by Parodi,[17] does not seem to play a significant role in this case, since, in his concept, bleaching of color centers in the visible region should result in the recovery of brightness.

Relation between 185 nm Absorption and Color Center Formation. The next step is to investigate whether condition I can be used as a criterion to find other additives which are effective in suppressing the formation of color centers.

As a measure of the concentration of color centers, the remission function of the color centers at 254 nm, $k_c(\lambda_e)/s$, is used, since this value determines the extent of brightness depreciation.

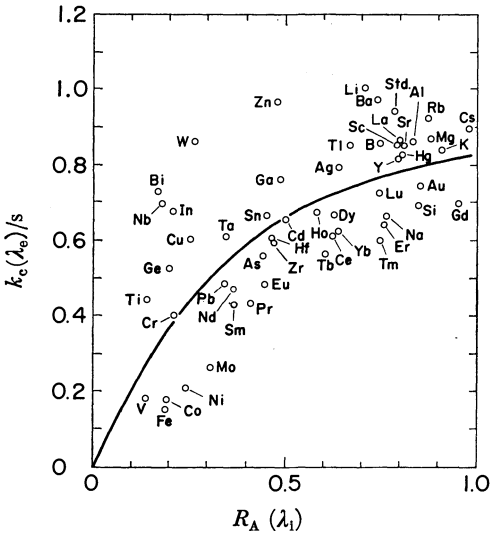

Fig. 5. Relation between 185 nm reflectance ($R_A(\lambda_i)$) and the extent of 254 nm absorption due to induced color centers ($k_c(\lambda_e)/s$) in Series A samples. Irradiation by 185 nm light was carried out for 6 hr in vacuum.

Figure 5 shows the relation between the reflectance at 185 nm ($R_A(\lambda_i)$) and the $k_c(\lambda_e)/s$ values induced by 6 hr of 185 nm irradiation in Series A samples. As expected, the stronger the 185 nm absorption due to additives, the weaker the color center formation. Of the twenty additives selected in accordance with condition II, Cd, Zr, Ge and Tb give rise to strong absorptions at 185 nm. Out of these additives, Cd, Zr and Tb suppress the formation of color centers to the extent expected for their $R_A(\lambda_i)$ values. Germanium also has such an effect, but less than expected for its strong absorption at 185 nm.

Relation between Color Center Formation and Brightness Depreciation. In order to calculate the relative brightness depreciation by color center formation, the view deduced from partial bleaching experiments is adopted. That is, a part of 254 nm light is absorbed and dissipated by color centers, the reabsorption of the emitted light being negligible. In a similar way to Eq. (4), the relative brightness in the presence of color centers, I_i/I, is given by

$$\frac{I_i}{I}=\frac{1-R_{Bi}(\lambda_e)}{1-R_B(\lambda_e)}\cdot\frac{k_{ac}(\lambda_e)+k_m(\lambda_e)+k_{ad}(\lambda_e)}{k_{ac}(\lambda_e)+k_m(\lambda_e)+k_{ad}(\lambda_e)+k_c(\lambda_e)}, \quad (6)$$

where I and I_i are the plaque brightness of Series B samples before and after 185 nm irradiation, respectively, and $R_{Bi}(\lambda_e)$ is 254 nm reflectance of Series B phosphors after irradiation.

In the first approximation, the term $k_{ad}(\lambda_e)$ is neglected, which in most cases is much smaller than the absorption coefficient of activators. Moreover, it is assumed that $k_c(\lambda_e)/s$ is related to $R_A(\lambda_i)$ by the solid line curve of Fig. 5. The values of I_i/I can then be calculated numerically as a function of $R_A(\lambda_i)$.

Figure 6 shows the result of this calculation (solid line curve) as well as experimental brightness depreciation data under 6 hr of 185 nm irradiation. The individual $R_A(\lambda_i)$ and I_i/I values are given in Table 1.

The calculation predicts that the brightness depreciation of Series B phosphors under this irradiation condition will be 15—25%. Another prediction is that the brightness would decrease, for example, by *ca.* 6% as compared to Standard, if one could find such an additive with $R_A(\lambda_i)=0.20$ with no absorption at 254 nm.

The experimental I_i/I_0 values are, as a whole, in rough agreement with the calculated one (Fig. 6). The dependence of I_i/I_0 on $R_A(\lambda_i)$ is, however, not so explicit as predicted by calculation. Some particular cases are discussed below.

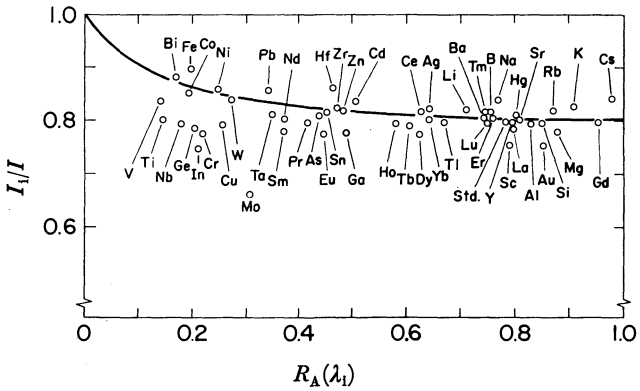

Fig. 6. Relation between 185 nm reflectance of Series A samples ($R_A(\lambda_i)$) and relative brightness after depreciation (I_i/I). Irradiation by 185 nm light was carried out for 6 hr in vacuum. Solid line curve was calculated by Eq. (6).

Considering the results mentioned in the previous section, particular attention was paid to Series B phosphors containing Cd, Zr, Ge and Tb. Cd- and Zr-containing phosphors show better performance than Standard under 185 nm radiation (Table 1 and Fig. 6). It was found, however, that Zr-containing phosphor has some disadvantages. Its initial brightness is inferior to that of Cd-containing phosphors. It tends to sinter slightly during lamp baking, thus giving an inhomogeneous phosphor layer.

Additives Ge and Tb were found, for unknown reasons, to be ineffective in improving performance. It seems that the absorption spectra of color centers in the presence of the activators differ considerably from those in the absence of activators. In short, application of conditions I and II did not lead to the finding of another additive having an advantage over Cd.

It was found unexpectedly that the addition of Cs improves not only the initial brightness, but also the maintenance. The increase of initial brightness can be understood in terms of the decreased absorption at 254 nm (Fig. 1, curve (3)). However, the reason for the brightness depreciation of the Cs-containing phosphor being even smaller than the Cd-containing phosphor (Table 1 and Fig. 6) is inexplicable, since Cs does not suppress color center formation at all (Fig. 5). Microscopic observation revealed that the Cs-containing phosphor is much more transparent or "porosity-free" than Standard. The optimum amount of Cs to be added depends strongly on the ignition conditions. In routine production, the best result was obtained when 0.03—0.1 g atom Cs was added to 1 mol phosphor. By chemical analysis, only a very small portion of the added Cs (<100 ppm) was found in the ignited phosphor. Moreover, the particle size of the Cs-containing phosphor was slightly greater than Standard. It is thus postulated that the added Cs compound (usually Cs_2CO_3) acts as a flux in the ignition process.

The promising outcome on the Cs-containing phosphor powder prompted a large scale lamp test using this phosphor. These lamps have 1—1.5% more initial lumen output than the reference lamps coated with Standard phosphor, and the decrease of the output after 1000 hr of operation is about 1% less than that of the reference. This result compares favorably with the Cd-containing phosphor, which gives 2% more initial lumens than the reference lamps, but no advantage in performance for long-term operation.

The authors wish to express their gratitude to Dr. Y. Uehara, presently at St. Marianna University, for suggesting this work. Thanks are also due to Dr. M. Tamatani for valuable discussions, A. Taya for sample preparation and M. Inoue and his group for lamp data.

ESR Studies of the Structures and Spin-exchange Interactions of the Dimers of Nitro-substituted Salicylaldehyde Schiff-base Complexes of Copper(II) in Frozen Solutions*

Makoto CHIKIRA and Taro ISOBE

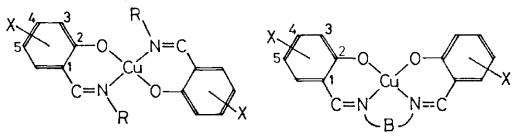
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received March 3, 1975)

The computer simulations of the ESR spectra for the triplet-state dimers of the title complexes in frozen solutions revealed that the dimeric structures change markedly upon nitro-substitutions at the positions of 3 or 5 in the phenyl-rings of the Schiff bases. It was also found that some of these nitro-substituted copper(II) complexes form 1 : 1 molecular complexes with bis(*N*-salicylideneisopropylaminato)copper(II) in toluene. The dependence of the ESR spectral intensities for the $\Delta M=2$ transitions upon the temperature in the range of 1.57—4.2 K indicated that the intra-dimer spin-exchange interactions are weakly anti-ferromagnetic (0.7—2.2 cm^{-1}).

Recently, many mononuclear copper(II) complexes have been found to be dimerized in solutions.[1-10] In our previous paper, it has been revealed that the angle (ξ) between the $g_{//}$ axis and the copper-copper axis for the dimers of various quadridentate salicylaldehyde Schiff-base complexes of copper(II) in frozen toluene solutions is considerably smaller than that for the bidentate ones.[6] However, we have now obtained a new experimental result that the dimeric structures of the Schiff-base complexes of copper(II) in frozen solutions change markedly upon the introduction of nitro-groups into the phenyl-rings of the Schiff bases at the 3 or 5 position. Moreover, it has been found that the nitro-substituted bidentate Schiff-base complexes of copper(II) form 1 : 1 molecular complexes in toluene with bis(*N*-salicylideneisopropylaminato)copper(II), which has no ability to be dimerized in toluene.

The purpose of this paper is to estimate the dimeric structures and intra-dimer spin-exchange interaction energies for these dimers and to investigate the nature of these dimerizations in solutions.



Cu(nX-RSal) Cu(nX-SalB)

Fig. 1. Schematic illustrations of salicylaldehyde Schiff-base complexes of copper(II). Following abbreviations were made.
Me=CH_3, Et=C_2H_5, *n*-Pr=C_3H_5, *iso*-Pr=$(CH_3)_2CH$, *t*-Bu=$C(CH_3)_3$, MeO=CH_3O, en=C_2H_4, pn=(CH_3)-$CHCH_2$, ibn=$(CH_3)_2CCH_2$, tren=$(CH_2)_3$.

Experimental

Materials. The copper(II) complexes generally represented as Cu($n$$NO_2$-RSal) and Cu($n$$NO_2$-SalB) (see Fig. 1) were prepared according to the method of Sacconi and Ciampolini.[11] Commercial toluene and nitroalkanes were purified by the usual methods.[12]

Measurements. The ESR spectra were measured at 77 K and in the range of 1.57—4.2 K. An improved insertion-type liquid helium Dewar in conjunction with a room-temperature cavity of a HITACHI 771 X-band ESR spectrometer was used for the measurements in the low-temperature range. The temperature below 4.2 K was obtained by pumping on liquid helium by means of a vacuum pump (150 l/min) and a manostat.

The sample solutions were transferred into thin quartz tubes (o. d. 2.0 mm). In order to secure thermal contact between the sample and liquid helium, the upper parts of the tubes were made open so that the tubes could be filled with the liquid helium. The relation between the microwave power and the intensity was examined at the lowest temperature of the measurement in every case in order to remove the effect of saturation in the measurement of the ESR spectral intensity.

Results and Discussion

Figure 2 shows the observed ESR spectra of Cu(5NO_2-EtSal) in toluene at 77 K. In general, the introduction of nitro-groups into the phenyl-rings of the Schiff base resulted in a decrease in the solubility of the copper(II) complexes in toluene. On the other hand, the ratio of dimers to monomers considerably increased with the nitro-substitutions. We have previously reported that, in the case of bidentate Schiff-base complexes of copper-(II) in toluene, the dimer formations are seriously inhibited by methyl or methoxy groups at the 3 positions in the phenyl-rings of the Schiff bases.[6] However, 3-nitro-groups did not hinder the dimerization at all. Moreover, the ratio of the triplet-state spectral intensity to the doublet-state one for Cu(3NO_2-EtSal) in toluene was larger than that for Cu(EtSal) at the same concentration. A similar correlation between the solubility and the ratio of dimers to monomers in solutions has been reported by Yokoi for bis(*t*-butylacetoacetato)-copper(II) in hydrocarbon solvents.[3]

The magnetic parameters for triplet-state dimers were defined in the manner previously described;[5,6] they are listed in Table 1, together with the data previously obtained for unsubstituted complexes.[5] In contrast to the parameters for the doublet-state monomers, those for the triplet-state dimers changed markedly with the nitro-substitutions. The triplet-state dimers of Cu-(3NO_2-EtSal) and Cu(5NO_2-EtSal) have the magnetic parameters characteristic of coaxial g and fine-structure tensors, that is, $g_2 \approx g_{M//}$ and $|A_{M//}/2| \approx A_1 \approx A_h$. In order to estimate the distance between the two copper ions and the ξ angle for theses dimers, the simulation

* Part of this report was preliminarily published in *Chem. Lett.*, **1974**, 865.

of the triplet ESR spectra was performed as has previously been described[5,10] on the basis of the spin-Hamiltonian expressed as:

$$\mathcal{H} = \beta g_{\perp}(S_xH_x+S_yH_y) + \beta g_{//}S_zH_z + A_{\perp}(S_xI_x+S_yI_y) + A_{//}S_zI_z+H_{dd}-JS_1\cdot S_2 \quad (1)$$

where H_{dd} is the point-spin-dipole interaction tensor; the other symbols have their usual meanings. The resonance magnetic fields were calculated by means of the perturbation calculations to the second order for both H_{dd} and hyperfine terms. The angular dependence of the transition probability was calculated by the use of the spin functions obtained from the first-order perturbation calculations only for H_{dd}.

As Fig. 2 shows, the observed spectra for Cu(5NO_2-EtSal) in toluene can be well simulated with the following spin-Hamiltonian parameters: $g_{//}=2.225$, $g_{\perp}=2.05$, $|A_{//}|=0.0095$ cm^{-1}, $|A_{\perp}|=0.0010$ cm^{-1}, r(copper–copper distance)=4.02 Å, and $\xi=15°$. The estimated values of r and ξ are very close to those for the dimers of Cu(EtSal) in methylcyclohexane[9] and for various quadridentate Schiff-base complexes of copper(II) in toluene.[6]

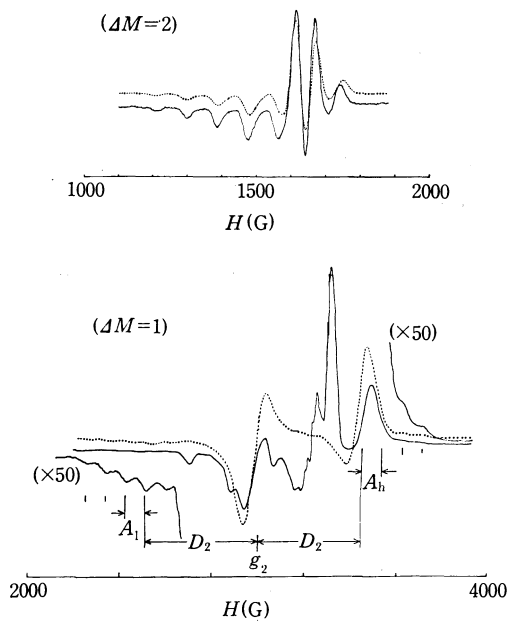


Fig. 2. ESR spectra of Cu(5NO_2-EtSal) in toluene at 77 K.
Broken lines: calculated spectra with the parameters, $g_{//}=2.225$, $g_{\perp}=2.050$, $|A_{//}|=0.0095$ cm^{-1}, $|A_{\perp}|=0.0010$ cm^{-1}, $r=4.02$ Å, $\xi=15°$, ΔH (Gaussian)=30 G ($\Delta M=1$) and 15 G ($\Delta M=2$). Microwave frequency; $\nu=9.2576$ GHz.

The triplet ESR spectra of Cu($n$$NO_2$-RSal) in toluene markedly changed in their line-shape upon the addition of a large excess of Cu(*iso*-PrSal). Figures 3 and 4 show the ESR spectra of Cu(5NO_2-EtSal) and Cu(5NO_2-*iso*-PrSal) respectively with a large excess of Cu(*iso*-PrSal) in toluene. The A_1 values (70 G) for these spectra are considerably smaller than those (87 G) for the dimers of Cu(5NO_2-EtSal) in toluene. The peaks near 3500 G are markedly broadened. It should be noted that neither Cu(*iso*-PrSal) nor Cu(5NO_2-*iso*-PrSal) in toluene exhibited triplet-sate ESR signals. Therefore, these triplet signals may be due to 1:1 molecular complexes of Cu(5NO_2-RSal) with Cu(*iso*-PrSal), although it remains uncertain whether these 1:1 complexes are the dimers of mixed-ligand complexes or the associated complexes of Cu($n$$NO_2$-RSal) and Cu(RSal).

Since the magnetic parameters for the monomers of Cu(5NO_2-*iso*-PrSal) are almost equal to those of Cu(*iso*-PrSal), Eq. (1) may still be a good approximated spin-Hamiltonian for the analysis of the triplet ESR

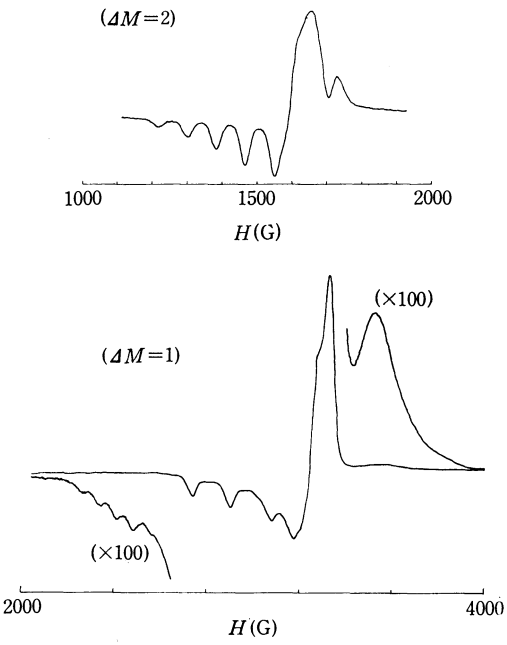

Fig. 3. ESR spectra of Cu(5NO_2-EtSal) with a large excess of Cu(*iso*-PrSal) in toluene at 77 K. $\nu=9.258$ GHz.

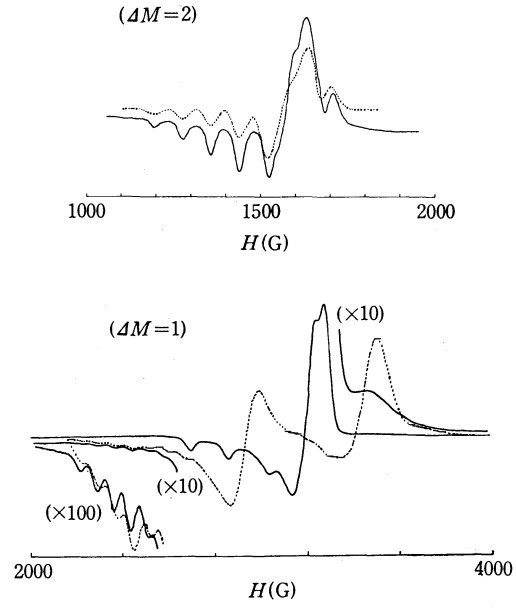

Fig. 4. ESR spectra of Cu(5NO_2-*iso*-PrSal) with a large excess of Cu(*iso*-PrSal) in toluene at 77 K. Broken lines: calculated spectra with the parameters, $g_{//}=2.230$, $g_{\perp}=2.040$, $|A_{//}|=0.0085$ cm^{-1}, $|A_{\perp}|=0.0015$ cm^{-1}, $r=3.75$ Å, $\xi=35°$, ΔH(Gaussian)=30 G ($\Delta M=1$) and 20 G ($\Delta M=2$).

spectra of the 1:1 molecular complexes. The best fit between observed and calculated spectra could be obtained with the following parameters: $g_{//}=2.23$, $g_{\perp}=2.04$, $|A_{//}|=0.0087$ cm^{-1}, $|A_{\perp}|=0.0015$ cm^{-1}, $r=3.75$ Å, and $\xi=35°$. These parameters are close to those of the dimers of Cu(*iso*-PrSal) in methylcyclohexane.[9]

In contrast with Cu(*iso*-PrSal), Cu(*t*-BuSal) did not form such 1:1 complexes with Cu(nNO$_2$-RSal) in toluene; the excess of Cu(*t*-BuSal) in the toluene solutions of Cu(5NO$_2$-RSal) did not alter the observed parameters of the triplet ESR spectra due to the dimers of Cu(5NO$_2$-RSal). In this case, only the broadenings of the spectra were observed. It has been reported by Yokoi that two species with different degrees of tetrahedral deformation exist for Cu(*iso*-PrSal) in toluene, while only one species with a high degree of that deformation exists for Cu(*t*-BuSal) in toluene.[14] It is of interest that the $g_{//}$ and $|A_{//}|$ values for the 1:1 complexes of Cu(5NO$_2$-RSal) with Cu(*iso*-PrSal) are closer to those for the species of Cu(*iso*-PrSal) with a lower degree of tetrahedral deformation. The difference between Cu(*t*-BuSal) and Cu(*iso*-PrSal) in the ability to form 1:1 complexes with Cu(nNO$_2$-RSal) is probably due to the differences in the tetrahedral deformation of the ligand coordination. A similar tendency in the dimer formation has been observed for Cu(RSal) in methylcyclohexane.[9]

The copper(II) complexes generally represented as Cu(nNO$_2$-SalB) are scarcely soluble in toluene, while Cu(3NO$_2$-Salpn) and Cu(3NO$_2$-Salibn) are considerably soluble in various nitroalkanes and exhibit intense ESR signals due to triplet dimers. The nitroalkane solutions of many other Cu(nX-SalB) complexes (X= H, Me, Br, and MeO) which were soluble in toluene did not exhibit the triplet ESR signals. The effect of the bridges between the iminoic nitrogens on the dimer formations of the 3-nitro-substituted Schiff-base complexes in nitroalkanes was quite analogous to that of the unsubstituted complexes in toluene:[6] Cu(3NO$_2$-Salen) is insoluble in nitroalkanes, and the amount of the dimers of Cu(3NO$_2$-Salpn) in nitroalkanes is larger than that of Cu(3NO$_2$-Salibn), while Cu(3NO$_2$-Saltren) is scarcely dimerized in nitroalkanes.

The ESR spectra of Cu(3NO$_2$-Salibn) in nitroethane at 77 K are shown in Fig. 5. In contrast with the dimers of Cu(nNO$_2$-RSal) in toluene, those for Cu-(3NO$_2$-SalB) in nitroalkanes have the parameters characteristic of the non-coaxial spin-Hamiltonian

TABLE 1. MAGNETIC PARAMETERS FOR COPPER(II) DIMERS (X-BAND)

Ligand	g_2	D_2 (G)	A_1 (G)	A_h (G)	$g_{M//}$	$A_{M//}$ (G)

Broken lines: calculated spectra with the parameters, $g_{//}=2.20$, $g_{\perp}=2.045$, $|A_{//}|=0.0100$ cm^{-1}, $|A_{\perp}|=0.0010$ cm^{-1}, $r=3.80$ Å, $\xi=35°$, ΔH (Gaussian) $=25$ G ($\Delta M=1$) and 22 G ($\Delta M=2$). $\nu=9.297$ GHz.

tensors- that is, $g_{M//}>g_2$ and $|A_{M//}/2|>A_1>A_h$. In addition, the D_2 values of Cu(3NO$_2$-SalB) is considerably larger than that of Cu(SalB) in toluene.[6] As Fig. 5 shows, the observed spectra could be simulated with those parameters: $g_{//}=2.20$, $g_{\perp}=2.045$, $|A_{//}|=0.0100$ cm^{-1}, $|A_{\perp}|=0.0010$ cm^{-1}, $r=3.80$ Å, and $\xi=35°$. These r and ξ values are closer to those of Cu(RSal) in toluene than to those of Cu(SalB) in toluene.[6] However, it is still uncertain whether the phenolic oxygen atoms in the Schiff base coordinate to the adjacent copper ions in the dimer at their apical positions, because we simulated the observed spectra with axially symmetric g and A tensors.

Intra-dimer Spin-exchange Interactions. When an ESR spectrum due to triplet-state dimers is not saturated, the spectral intensity (I) is proportional to the paramagnetic susceptibility of the dimer system; it can be expressed as:

$$I = c/T(3+\exp(-J/kT)) \qquad (2)$$

where c is an appropriate proportionality constant. Since the $\Delta M=2$ spectra for the present dimers are quite different in position from the allowed spectra due to both dimers and monomers, the I in Eq. (2) can be estimated from the intensity of the $\Delta M=2$ spectra alone.

Figure 6 shows the $\Delta M=2$ spectra of Cu(3NO$_2$-Salibn) in frozen nitroethane at 1.6 and 4.2 K. Since the line-shapes or linewidths of these spectra did not vary over this temperature range, the relative intensity of the triplet ESR spectra is equal to the relative peak height of a certain line (H) in the first derivative $\Delta M=2$ spectra. On the other hand, the shape of the $\Delta M=2$ spectra for Cu(5NO$_2$-EtSal) in toluene changed

with the temperature even at the minimum level of microwave power (0.48 mW) at which the $\Delta M=2$ spectra can be obtained with a satisfactory signal-to-noise ratio on our spectrometer. The examination of the relation between the spectral intensity and the microwave power revealed that the $\Delta M=2$ spectra at 4.2 K were saturated to some extent even at this microwave power. A similar change in the line-shape at 4.2 K could be observed at a stronger microwave power. These phenomena suggest that the modulations of the intradimer spin-exchange or spin-dipole interaction by thermal vibrations in this temperature range are not sufficient to make the spin-lattice relaxation time short enough to remove the saturation of the ESR signals. Because of the low solubility of Cu(5NO_2-EtSal) in toluene, the concentration of the sample cannot be made so high as that of Cu(3NO_2-Salibn) in nitroethane. Therefore, the modulation of the interdimer or dimer-monomer spin-dipole interaction in the toluene solutions of only Cu(5NO_2-EtSal) may be too weak to recover the spin-lattice relaxation.

This problem, however, could be solved by the addition of a large excess of Cu(*t*-BuSal) to the toluene solutions of Cu(5NO_2-EtSal). When an excess of Cu(*t*-BuSal), which does not combine with Cu(5NO_2-EtSal), coexists in the solution, the shape of the $\Delta M=2$ spectra no longer depends on the temperature and the intensity increases linearly with the square root of the microwave power over the range of 0.48—4.8 mW (see Fig. 7). This phenomenon indicates that the thermal contact between the spin system of Cu(5NO_2-EtSal) and that of Cu(*t*-BuSal) could recover the spin-lattice relaxations. Consequently, the J value for the dimers of Cu(5NO_2-EtSal) in toluene could be estimated in the way described above by the addition of excess Cu(*t*-BuSal) to the solutions.

In the case of the 1 : 1 complexes of Cu(5NO_2-RSal) with Cu(*iso*-PrSal) in toluene, the line shapes of the $\Delta M=2$ spectra depend on the temperature in a more complicated manner. Figure 8 shows the $\Delta M=2$ spectra for the 1 : 1 complexes of Cu(5NO_2-EtSal) with Cu(*iso*-PrSal) in toluene at 4.2 and 1.57 K. The linewidth at 1.57 K is quite broad compared to that at 4.2 K. In this case, the broadening of the spectrum is not due to the saturation effect, because the intensity

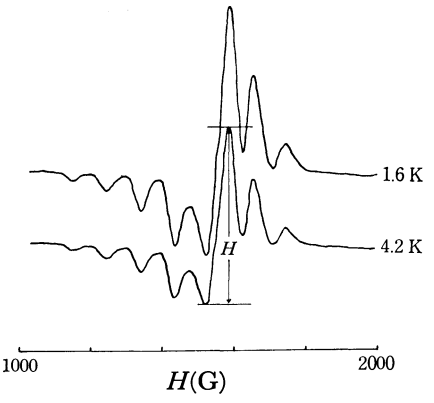

Fig. 6. $\Delta M=2$ spectra of Cu(5NO_2-Salibn) in nitroethane at 4.2 and 1.6 K.

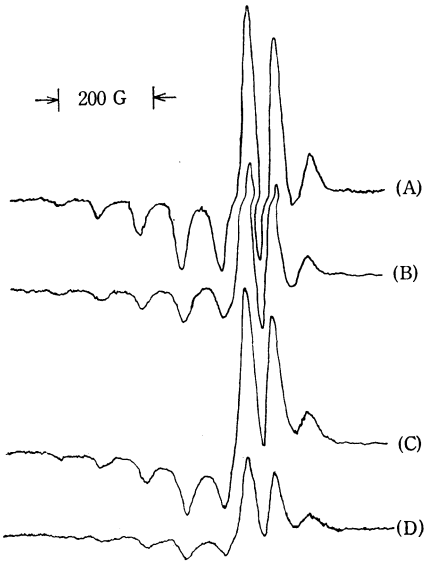

Fig. 7. $\Delta M=2$ spectra of Cu(5NO_2-EtSal) in toluene. (A): 1.57 K, (B): 4.2 K without Cu(*t*-BuSal). (C): 1.57 K, (D): 4.2 K with a large excess of Cu(*t*-BuSal).

of the $\Delta M=2$ spectra at 1.57 K increased linearly with the microwave power over the range of 0.48—4.8 mW. A similar change in the line-shape was observed for the 1 : 1 complexes of Cu(5NO_2-*iso*-PrSal) with Cu(*iso*-PrSal). These changes in the line-shape may be attributed to a considerable decrease in the T_2 (spin-spin relaxation time) and/or in the degree of the structural homogeniety of the 1 : 1 complexes, including their surroundings. Since the line-shape varied in a complicated manner, we did not attempt to estimate the J values for these complexes.

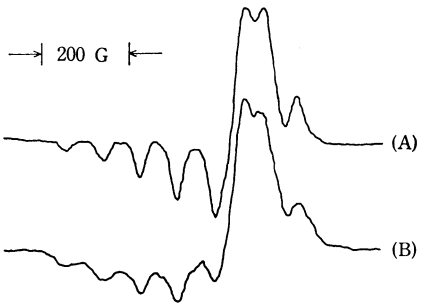

Fig. 8. $\Delta M=2$ spectra of Cu(5NO_2-EtSal) with a large excess of Cu(*iso*-PrSal) in toluene. (A): 4.2 K, (B): 1.57 K.

Figure 9 shows the calculated and experimentally determined relative intensity changes of the triplet ESR spectra for the dimers of Cu(5NO_2-EtSal) in toluene and of Cu(3NO_2-Salibn) in nitroethane, in units of the intensity at 4.2 K. The J values estimated from this figure are listed in Table 2, together with the r and ξ values determined by computer simulations. In this table, the corresponding parameters for the dimers of Cu(MeSal) and Cu(3Me-Salpn) in toluene are also listed. The J values for the dimers of Cu(5NO_2-EtSal) and Cu(3NO_2-Salibn) were antifer-

a) Refs. 7 and 10.

romagnetic, as in the case of the other Schiff-base complexes of copper(II) in frozen solutions.[7,9,10]

We have previously reported that many Cu(*n*X-RSal) and Cu(*n*X-SalB) complexes (X=H, Me, MeO, Br; R=Me, Et, *n*-Pr; B=pn, ibn) in toluene are similar in dimeric structure to Cu(MeSal) and Cu(Salpn) in toluene respectively.[6] Corresponding to the changes in the r and ξ values with the nitro-substitutions, marked changes in the J values were observed. Since the nitro-groups in phenyl-rings have a strong electron-attracting power, the π-electron distribution over the copper(II) chelates will be severely modified with these groups. In particular, the affinity of the phenolic oxygen for the adjacent copper(II) ions at their apical positions may be reduced because of a decrease in the π-electron density on the oxygen atoms. Therefore, the contribution of such apical coordinations of the phenolic oxygen atoms to the spin-exchange interactions may decrease upon the nitro-substitutions. However, this is merely one possible explanation for the changes in the dimeric structure and in the J values with the nitro-substitutions. The fact that the dimer formation was markedly promoted by the nitro-groups suggests that the change in the dispersion or polarization forces between the ligands may play an important role in determining the dimeric structure and spin-exchange interactions.

Since the dimeric structures have still not been revealed in detail, it is impossible to discuss the mechanisms of the intradimer spin-exchange interactions further. However, the results obtained above support the previous conclusion that dimeric structures for copper(II) chelates in frozen solutions are determined by the subtle balance of many kinds of interactions between monomeric halves in the dimers and between the dimers and solvents.[3,6,9,10]

The authors wish to express their thanks to Dr. Hiroshi Yokoi for his valuable discussions and suggestions during this work.

Ketyl Radicals Formed in Grignard Reaction. III.[1] Steric Effects on the Formation of Radicals

Masao ŌKUBO

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honshō-chō, Saga 840

(Received February 20, 1974)

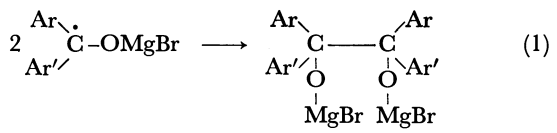
In the reaction of benzophenone with phenylmagnesium bromide, the concentration and life-time of the ketyl radical were influenced greatly by the substitution of *ortho*-hydrogen atoms of both the two reactants by methyl group. From the results of visible absorption and ESR measurements and also of product-analysis, the ketyl radical was considered to be a common intermediate towards normal and abnormal reaction products. The existence of an equilibrium between monomeric and dimeric states of the ketyl radical was also proposed.

The peculiarity of the ketyl radical observed in the Grignard reaction of *o*-methylbenzophenone was discussed in comparison with that of potassium-ketyl of the same ketone,[1] but the reason for the ketyl radical having a long "life time" remained ambiguous. The effects of the *o*-methyl group of benzophenone as well as those of the phenyl-Grignard reagent on the formation of ketyl radicals have been studied more precisely.

Results and Discussion

The formation of ketyl radicals was followed by observation of the characteristic coloration of the reaction solution by means of visible absorption spectroscopy and ESR spectroscopy. Results obtained by use of these techniques will be discussed separately.

"Life Time" of Ketyl Radicals. When *o*-methyl-substituted benzophenones were treated with arylmagnesium bromide (ArMgBr) in tetrahydrofuran (THF) under N_2-atmosphere or in vacuum and at room temperature, the colorless solution turned to purple or wine-red. The coloration, which is due to the formation of ketyl radicals,[1] lasted in most cases for as long as several months. Benzopinacol, as a minor product, has often been isolated from the reaction mixture of benzophenone and Grignard reagents, being considered to be the product formed by dimerization of the ketyl radical (Scheme 1).[2]



(1)

The time during which the characteristic coloration was observed is tentatively denoted in this paper as the "life time" of a ketyl radical. The "life time" at 50 °C was greatly influenced by the number of *o*-methyl groups. The "life times" of radicals and the yields of carbinols and pinacols are given in Table 1. The increasing number of *o*-methyl groups on the ketone prolongs the "life time" exceedingly (experiments 1, 2 and 3). That of *o*-methyl groups on ArMgBr also prolongs it, but the effect is smaller (experiments 1, 4 and 5). The fair yield of benzopinacol in experiment 5 can be attributed to the steric hindrance effect of *o*-methyl groups of mesityl-MgBr. However, the absence of the pinacol, despite the appearance of the characteristic color, in experiment 4 must be noted. This fact shows that the ketyl radical formed does not necessarily dimerize to the pinacol. When the velocity of the formation of *o*-methyltriphenylcarbinol in experiment 4 was compared with that of the same product in experiment 2, the unsubstituted benzophenone was

found to yield the carbinol rapidly and quantitatively (Fig. 1). The short "life time" of the ketyl radical in experiment 4 can thus be attributed to the rapidity of the normal addition reaction.

These facts make it possible to assume that the ketyl radical is a common intermediate in Grignard reaction. If the ketyl radical is pictured tentatively as shown in

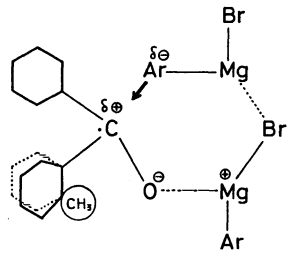

Fig. 2. Attempted depiction of ketyl-type radical intermediate.
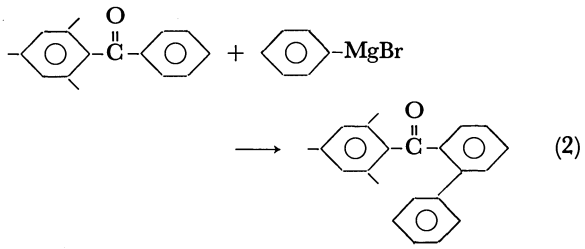
At present, it cannot be decided on which of the two (or more) Ar groups delocalizes the other free electron.

Fig. 2, the normal addition product and the dimerization product can be explained in terms of steric hindrance, effects of which can be classified as (i) the effect caused by the Grignard moiety, and (ii) that caused by the ketone moiety. When (i) is large and (ii) small, the Grignard-aryl group cannot come close to the carbonyl-carbon atom and the radical would tend towards the sterically less-hindered dimerization process,[2] this being the case in experiment 5. The dimerization process is retarded by effect (ii), which is shown in experiment 3. In this case (i) is small and (ii) very large, and the Grignard reagent attacks the unsubstituted phenyl group of the ketone as reported by Fuson *et al.*[3] (Scheme 2). This nuclear phenylation has been explained recently on the basis of an electron-transfer mechanism.[4]



(2)

The rapidity of the formation of the carbinol in experiment 4 is explained in terms of the energy level of the reaction intermediate, ketyl radical. The delocalization of the free electron spin is favored owing to the small twisting angle of the two phenyl groups of benzophenone out of plane of its carbonyl group, thus lowering the energy level. The same effect can be expected also in experiment 5, but the enhanced effect of steric hindrance of the Grignard-mesityl group makes it impossible to produce the carbinol.

A considerable amount of mesitylene was found in experiment 5. When a larger scale reaction was carried out using 28% excess molar mesityl-MgBr and the reaction mixture was decomposed by D_2O-D_2SO_4, the content of monodeuteriomesitylene in the recovered sample of mesitylene was about 30% on the basis of NMR absorption. Thus the mesityl radical, produced as a result of the electron-transfer from the Grignard reagent to the ketone (Scheme 3), would abstract hydrogen from the THF molecule (Scheme 4).

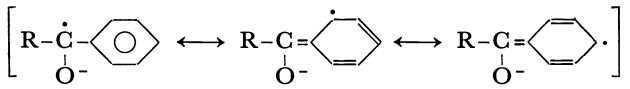
Table 2. Visible absorption bands of radical species
Ketone: 3.3×10^{-4}M, ArMgBr: 5.0×10^{-4}M
s: strong, m: medium, w: weak.

No.	Ketone	-MgBr λ_{max}(nm)	temp. (°C)	ε	-MgBr λ_{max} (nm)	temp. (°C)	Mg(Hg) λ_{max} (nm)
I	-CO-	553 s 610m	25	>8500	553 s, 610m	25	60—610 s (broad)
II	-CO-	434, 540 s, 580m	25	>8000	383, 530m, 570w	50	434, 540 s, 580w
III	-CO-	380, 534 s, 565m	25	>4000	380, 555w	50	438, 534 s, 565w
IV	-CO-	564 s, 620m	25	~2000	564 s, 620w	50	620 s
V	-CO-	450, 560m, 615w	50	~150	not observed	50	438, 570 s, 610w
VI	-CO-	430, 580w, 610w	50	~30	not observed	50	———

Thus, all the results are explained by considering the formation of a ketyl radical to be an essential process in the Grignard reaction.

Visible Absorption Spectra. Evacuated optical cells were used for the measurements of visible absorption spectra of ketyl radicals. Main absorption bands appear at 530—580 nm. They are accompanied by weaker bands at longer wavelength side (570—620 nm) in all cases. Absorption spectra of Mg-ketyls of respective ketones were also measured (Table 2).

The values of absorbance give a rough estimate obtained when the absorbance of main band becomes almost maximum after a certain time of reaction of each ketone with phenyl-MgBr. High absorbances observed in the cases of ketones bearing at least one unsubstituted phenyl group can be attributed to the spin delocalization given by:



Though the nearly planar structure of unsubstituted benzophenone favors spin delocalization, the ketyl of this least-hindered ketone favors, at the same time, normal addition and/or dimerization (Table 1, experiments 1, 4 and 5). For this reason, any high absorbance cannot be realized in the Grignard reaction of benzophenone itself.

The temperatures listed in Table 2 are those necessary to realize a velocity of color development suitable for ordinary measurements under the conditions of the described molar concentrations. In reactions with phenyl-MgBr, ketones I—IV easily reveal colors at room temperature but V and VI need higher temperatures. In reactions with *o*-tolyl-MgBr, only ketone I reveals color at room temperature, II—IV need higher temperatures, and V and VI do not reveal color after warming for several hours. Thus the initial electron-transfer process is affected by two kinds of steric hindrance; one due to ketones, and the other to Grignard reagents.

The absorption bands at 380—450 nm appear when at least one of the two aryl groups of ketone twists almost perpendicularly out of plane of the carbonyl group, but these bands were not assigned in this work. The following discussion is concerned mainly with *o*-methyl- and *o,o'*-dimethylbenzophenone. The variation of the relative absorbance $\varepsilon_{564}/\varepsilon_{620}$ in the time-course of the reaction of *o,o'*-dimethylbenzophenone with phenyl-MgBr is interesting. For convenience, the relative height at λ_{max}'s of the respective band was taken as the value of $\varepsilon_{564}/\varepsilon_{620}$. The relative absorbance is small in the initial stage, and becomes larger as the reaction proceeds under each molar concentration (Fig. 3). It becomes smaller when the solution is diluted. The convergence of the relative absorbance to the value of 1.65—1.70 after 24 hr suggests the existence of an equilibrium. As the 620 nm band of the Grignard ketyl can be assigned to its monomeric state on the basis of the fact that the Mg-ketyl has a simple band at the same wavelength, the 564 nm band could be assigned to its dimeric state. This assignment is supported by the following results. When

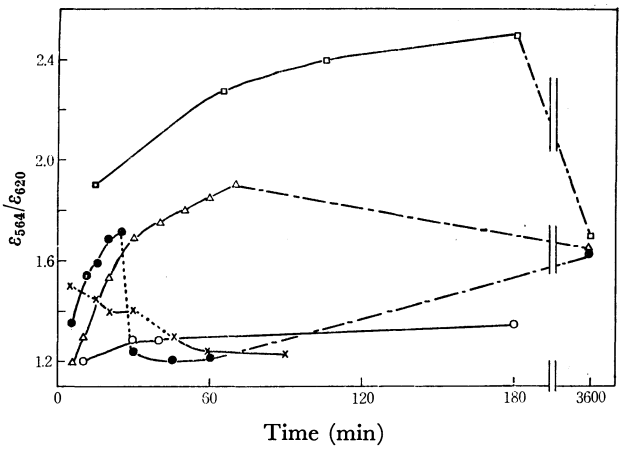


Fig. 3. Variation of relative absorbance $\varepsilon_{564}/\varepsilon_{620}$ with respect to time.

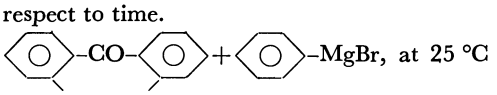

at 25 °C

·····: Diluted before the subsequent measurement.

v) □, 1.0/0.66=1.5

the concentration of ketone is low (experiments iii, iv and v), the relative absorbance is larger as the molar ratio of ketone is higher (experiments iv and v). The higher relative absorbances in the initial stage of experiment iii than that of iv can be explained as follows: a much higher amount of the monomeric ketyl initially formed by the action of the much higher amount of Grignard reagent in experiment iii affords a higher amount of the dimeric aggregate than in experiment iv.[6] This is reasonable since the velocity of the initial developement of absorbance decreases in the order: ii>iii>i~iv>v (not represented in Fig. 3).

In the reaction of *o*-methylbenzophenone with *o*-tolyl-MgBr, a similar phenomenon was observed (Table 3). The absorption band of Mg-ketyl of this ketone broadened from 560 to 610 nm probably owing

Table 3. Variation of relative absorbance $\varepsilon_{553}/\varepsilon_{610}$ with respect to time

to the unsymmetrical molecular structure. The twisting vibration of *o*-tolyl group out of plane of the benzoyl group is considered to be easier in Mg-ketyl than in Grignard-ketyl.[1] The mixing of the electronic transition corresponding to the benzoyl group with that corresponding to the *o*-tolyl group could be expected. In contrast to the Mg-ketyl, the Grignard-ketyl has bands at 553 and 610 nm, resembling the Grignard-ketyl of *o,o'*-dimethylbenzophenone. Taking into account the previous observation of the very high spin density on the unsubstituted phenyl group of the Grignard-ketyl of *o*-methylbenzophenone,[1] one could ascribe the absorption bands of this ketyl mainly to the electronic transition corresponding to the unsubstituted benzoyl group. A discussion on the relative absorbance is thus significant in this case. It becomes larger as the reaction proceeds, smaller when the solution is diluted, and again larger when the temperature is lowered.

The existence of another equilibrium between the original ketone and the monomeric ketyl is suggested from the effect of temperature and that of the steric hindrance caused by the Grignard reagent (Table 2). The existence of this equilibrium is also suggested from the relative velocity of the initial developement of absorbance found in the experiments (Fig. 3). A higher velocity was realized by the higher molar ratio of the Grignard reagent and also by the higher concentrations of the two reactants. The two equilibrium processes can be represented as follows (Scheme 5).

$$2G + 2B \overset{K_1}{\rightleftarrows} 2G^{\ddagger} + 2B^{\dashv} \overset{K_2}{\rightleftarrows} [B^{\dashv} \cdots G^{\ddagger} \cdots B^{\dashv}] + G^{\ddagger} \qquad (5)$$

G: Grignard reagents
B: Benzophenones

The ketyl radical in Fig. 2 depicts the monomeric state "$2G^{\ddagger}+2B^{\dashv}$," a part of which is the precursor of carbinol. The dimeric species $[B^{\dashv}\cdots G^{\ddagger}\cdots B^{\dashv}]$ is considered to be the precursor of pinacol. The Grignard reagent represented tentatively as monomeric in this scheme may exist as more aggregated state.[6,7]

Radical Concentration. The radical concentration, determined by ESR technique, was also affected by the structure of ketone and that of the Grignard reagent. A single sample tube was used throughout the measurement, and conditions of the ESR spectrometer were kept constant as far as possible. The results for the respective combinations of reactants differ considerably (Fig. 4), and thus it is feasible to discuss the relative effect of substituent.

The maximum concentration of the ketyl radicals formed in reactions with phenyl-MgBr decreases in the order:

2-*t*-Butyl- (C) > 2,6-Dimethyl- (D) > 2,2'-Dimethyl- (A) >
2-Methyl- (B) > 2,6,2'-Trimethylbenzophenone (F)

A different order, A>B>C>D>F, is found for the velocity of electron-transfer in the initial stage of the reaction. The two orders can be explained in terms

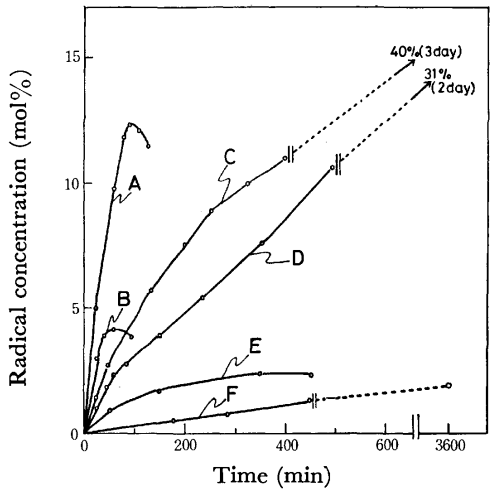

Fig. 4. Variation of radical concentration based on original ketones at 20 °C.
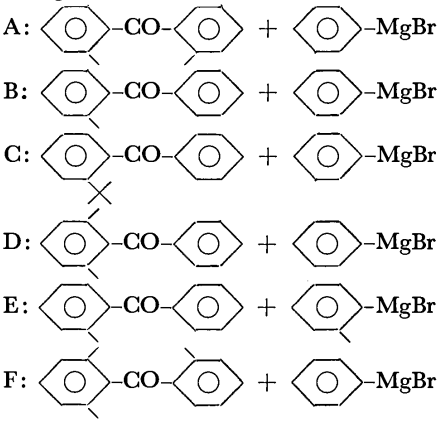
ArMgBr: 7.0×10^{-4}, Ketone: 3.3×10^{-4}.



of steric hindrance. In cases A and B, the initial electron-transfer is relatively rapid owing to the small steric hindrance which in turn favors the subsequent normal addition and dimerization, and thus the concentration of the ketyl radicals begin to come down in short times. In cases C and D, the large steric hindrance retards the initial electron-transfer as well as the subsequent processes,[4] and thus the remarkably high radical concentrations are realized after long times of reaction. The high radical concentrations in these cases are ascribed to the small equilibrium constant K_2 of Scheme 5. The low concentration in case F would be due mainly to the largest (of cases A—F) steric hindrance against the initial electron-transfer. If case E is compared with B, the effect of *o*-methyl group of Grignard reagent can be discussed. The velocity of the initial electron-transfer from *o*-tolyl-MgBr, being lower than that from phenyl-MgBr, becomes comparable to that of subsequent processes, thus depressing the radical concentration.

ESR measurement provides further evidence for the existence of the monomer-dimer equilibrium. The effect of temperature in the case of mesityl phenyl ketone and phenyl-MgBr is as follows: the radical concentration decreased to 89—91% at −30 °C and to 69—73% at −50 °C based on a concentration observed at +20 °C, and the variation was reproducible.

Another evidence obtained from the effect of dilution is as follows: when a volume of the solvent twice as much as that of the reaction solution was added just after the radical concentration reached the maximum (reaction A, Fig. 4), the resulting concentration was 21% higher than that expected from the extent of dilution.

Conclusion. The characteristics of the Grignard reaction are considered by a large number of investigators to be ionic, and the contribution of radical processes has been recognized only in a few cases.[2] Ashby and his co-workers[8] proposed that heavy metal impurities in magnesium initiate the formation of benzopinacol in the reaction of benzophenone with methyl-MgBr. However, they later observed the formation of the ketyl radical in the reaction of *o*-methylbenzophenone with the same Grignard reagent.[9] The reason for the long "life time" of the Grignard–ketyl of *o*-methylbenzophenone[1] can now be given: (a) the steric hindrance of the ketyl radical against the normal addition and dimerization, or (b) the enhanced delocalization of the free spin on the phenyl group.[1] The latter may cause a trend towards a slow nuclear phenylation similar to that observed in the reaction of mesityl phenyl ketone, though the detection of such a minor product was difficult.[4]

The effect of steric hindrance on the formation of the ketyl radical due to the initial electron-transfer is evidently consistent with the same effect on the decay of the radicals due to the subsequent processes.

Experimental

Materials and Reaction. *ortho*-Methyl-substituted benzophenones were prepared according to the method previously reported.[10] Grignard reagents in THF were prepared as usual and transferred to storage bottles under N_2-atmosphere. A definite aliquot of Grignard solution was pipetted out under N_2-stream, and transferred to a reaction flask. Benzophenone and its derivatives dissolved in THF were added at once. The reaction mixture was stirred at 50 °C for a certain time as long as the characteristic color was observed, and hydrolyzed with aqueous ammonium chloride. The products were analyzed by means of glc and tlc.

Visible Absorption Measurements. The apparatus for measurements was constructed from an optical cell and a reaction vessel equipped with a container for ketone connected with a breakable seal. An aliquot of ArMgBr solution was transferred under N_2-stream to the reaction vessel, frozen with liquid N_2, evacuated by means of a vacuum line, and diluted to an appropriate volume by vacuum distillation of THF. The apparatus was sealed off. Immediately after the breakable seal was broken, the optical measurement was begun. A Hitachi EPS-3T model spectrophotometer was used.

ESR Measurements. The apparatus for measurements was constructed as described previously.[11] Preparation of samples was similar to that for the optical measurements. Radical concentration was determined by the over-modulation technique. JEOL ME-3X model and PE-1X model spectrometers were used.

The author is grateful to Professor Kazuhiro Maruyama, Kyoto University, for his stimulating discussions. He thanks Professor Yasuo Deguchi and Mr. Hideo Fujita, Kyoto University, for use of the ESR spectrometer in their laboratory.

Photochemistry of *peri*-Substituted Naphthalenes. I. Photochemistry of Dimethyl 1,8-Naphthalenediacrylate

Koichi HONDA, Akira YABE, and Hideaki TANAKA

National Chemical Laboratory for Industry, 7th Division, 85 Shinshuku, Hiratsuka, Kanagawa 254

(Received October 29, 1974)

The photochemical reactions of dimethyl 1,8-naphthalene diacrylate (I) in solution are found to be *cis,trans* isomerization and concomitant intramolecular cycloaddition through a triplet state (E_T is *ca.* 40 kcal/mol). Cyclization reaction gives naphtho[1′,8′]bicyclo[3.1.1]hept-2-ene-6-*exo*,7-*endo*-dimethyl dicarboxylate (VI), its 6-*endo*, 7-*endo* substituted isomer (VII) and *cis-anti*-naphtho[1′,8′]bicyclo[3.2.0]hept-2-ene-6,7-dimethyl carboxylate (II) in a ratio of *ca.* 85: 10: 5. Predominant formation of crossed adducts is discussed, taking into consideration the ground-state conformations of (I). Biradical mechanism is proposed for the cyclization to explain the stereochemistry of the crossed products.

It is well-known that cinnamic acid derivatives photodimerize to yield stereospecific cyclobutane compounds in solid state, but isomerize to their geometrical isomers by irradiation in solution or in liquid state. The photochemical behavior differing according to state is attributable to the fixed distance and orientation between two olefin molecules in crystalline state. Schmidt[1] concluded in his topochemical studies that the photodimerization in crystalline state can take place only when the intermolecular distance between two olefin molecules is less than *ca.* 4 Å. Since the distance between 1 and 8 positions of naphthalene molecules is 2.57 Å, 1,8-naphthalene diacrylic acid derivatives are expected to undergo intramolecular photodimerization even in solution. As a part of photochemical studies of *peri*-substituted naphthalenes, we studied the photochemistry of *trans, trans*-dimethyl 1,8-naphthalenediacrylate (I) in solution.

Experimental

Spectral data of compounds I, II, III and VI are given in Table 1.

Preparation of I. Compound I was prepared by the Wittig condensation of naphthalaldehyde hydrate[2] with carbomethoxymethylene-triphenyl-phosphorane.[3] A solution of 5.0 g (25 mmol) of dialdehyde in 100 ml of benzene was heated at reflux temperature for 30 min. This hot benzene solution was then added dropwise to 200 ml of a refluxing benzene solution of 25 g (75 mmol) of the Wittig reagent over a period of 15 min. The solution was heated at reflux temperature for 5 hr with stirring in N_2 atmosphere and then filtered, the solvent being removed under reduced pressure. The residue was extracted with 300 ml of ether and the solvent of extract was evaporated off. The yellow residue enriched in I was chromatographed on a column of silica gel with ether to give, after recrystallization from ether, 2.8 g of pure product (I), mp 117—118 °C.

Preparation of II and III. Compound II was prepared from the photoproduct of maleic anhydride with acenaphthylene[4] by usual hydrolysis and esterification, mp 150—151 °C. Compound III was synthesized by base-catalysed epimerization of II. A solution of 0.5 g of II and 0.3 g of sodium methoxide in 5 ml dry methanol in a sealed tube was heated at 70 °C for 8 hr. Recrystallization of the product from methanol gave an equilibrated mixture of II and III in a 5: 95 ratio. Pure III was separated from the mixture by tlc (silica gel, elution

with chloroform), mp 125—128 °C.

Photocyclization of I in a Preparative Scale. An immersion-well type photoreactor with a 100 W high pressure Hg arc lamp was used for the irradiation of I in a preparative scale. Ethanol solution of naphthalene was circulated as a filter solution to prevent light absorption by the cyclized products. The reaction temperature was maintained at 25 °C.

A solution of 400 mg of I in 1.1 *l* of cyclohexane (0.0013 M) was irradiated with the reactor with bubbling N_2 gas. The reaction was monitored by following the disappearance of the absorption peak at 332 nm in the UV spectrum of I, and the starting material was entirely consumed after 5 hr. The solvent was completely evaporated under reduced pressure, and the residual crystal was dissolved in ether and treated with activated charcoal. The recrystallization of the ether solution yielded 320 mg of VI, mp 98—99 °C.

Photocyclization of I in an Analytical Scale. A solution of I (0.0013 M) in a quartz cubic (1 cm in length, 4 ml in volume) was irradiated at room temperature with use of a 500 W high pressure Hg arc lamp. Toshiba UV D25 and UV 35 filters were used for direct irradiation. Toshiba filters VY 42, VY 43, VY 48 and VY 49 were used for benzil, benzanthraquinone, erythrosine and rose bengal sensitization, respectively. The reaction was also monitored by the change of UV spectrum except for some sensitized experiments, the irradiation time required to reach the complete disappearance of I being used as a measure of the reaction rate. After the reaction was complete, the solvent was removed under reduced pressure and 0.5 ml of benzene was added. The concentrated benzene solution was used for product analysis. Quantitative analysis was performed by glc (Carbowax 20 M on Chromosorb W, 80—100 mesh, 2 m, 240 °C). In almost all experiments, only intramolecular cyclization products were obtained, but in the case of benzil sensitization and piperylene addition, some by-products from the sensitizer or the quencher were formed. In the dye sensitized experiments, the sensitizers themselves were slightly photo-bleached.

Results and Discussion

Photocyclization Reaction. We found that the direct and sensitized photochemical reaction of I in solution underwent *cis, trans* isomerization with concomitant cyclization and ultimately led exclusively to the formation of cyclized products. Glc analysis of the final products showed the formation of three intramolecular cyclized products, and no intermolecular adducts were formed. Six structures II—VII were considered for the cyclized products. The main product was identified to be VI by comparing its spectral data with those of II and III which were obtained from the photoadduct of maleic anhydride and acenaphthylene.[4] One of the two minor products was identified to be II by comparing its glc retention time with that of an authentic sample of II. The other minor product, the first eluent in glc, was presumed to be V or VII, since the crossed adducts (intramolecular head-to-tail adducts, V—VII) were expected to be eluted more rapidly than the straight adducts (intramolecular head-to-head adducts, II—IV). Photoproducts mixture obtained from the methanol solution, in which this minor product was involved in *ca.* 20% yield, gave almost the same NMR spectrum as that of pure VI, but the peak ratio of *exo-* and *endo*-carbomethoxy protons at δ 3.79 and 3.14 respectively (Table 1) was about 1 : 1.4. The NMR spectrum suggested the inclusion of the crossed adduct having *endo*-carbomethoxy group except VI. Hence, the minor product unidentified was determined to be VII, which has two *endo*-carbomethoxy groups.

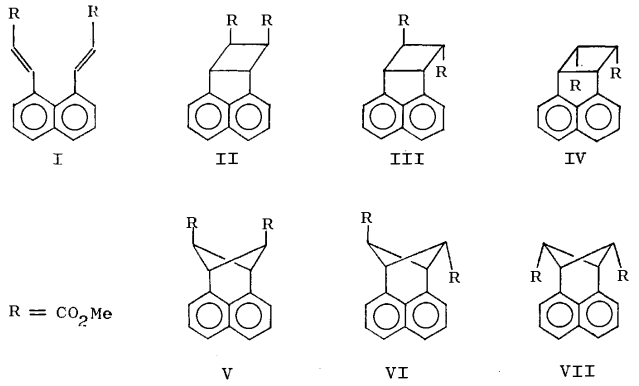

Table 2. Results of product analysis[a]

Solvent	Condition	Yields of products (%) VII	VI	II
Cyclohexane	Degassed	9	86	5
	N_2 Saturated	11	81	8
	Aerated	10	75	15
	O_2 Saturated	8	77	16

	N_2 Saturated	14	84	2

a) Sensitized or quenching experiments were performed in degassed or N_2 saturated solutions.

The results of the photochemical reaction in an analytical scale are summarized in Table 2. The product ratio in direct irradiation was almost the same as that of sensitized reaction. It is seen that benzil (the triplet energy, E_T=54 kcal/mol),[5] benz[*a*]anthraquinone (E_T=47 kcal/mol)[6] and erythrosine (E_T 42 kcal/mol)[7] are efficient sensitizers, while rose bengal (E_T=39 kcal/mol)[7] is a very inefficient one, acting rather as an effective quencher, whereas piperylene (E_T=47—49 kcal/mol)[8] shows no quenching action. The triplet energy of I was thus estimated to be *ca.* 40 kcal/mol, though the phosphorescence of I was not observed in the measurement in EPA solution at 77 K. In the presence of oxygen, II slightly increased and VI decreased complementarily, the reaction rate being suppressed at the same time. Decrease in the rate may be caused by triplet quenching since the fluorescence of I was scarcely quenched by oxygen. Dependence of product ratio on solvents was slightly seen. A larger amount of VII seemed to be produced in the more polar solvents. In addition, in *n*-propyl bromide

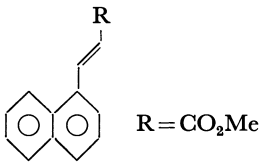
solution, the reaction rate was greatly accelerated probably by an external heavy atom effect.

The results suggest that the cyclization reaction proceeds predominantly through the triplet state of I, although from the oxygen addition experiments, II is considered to be formed from the singlet state to some extent.

Our results for the cyclization of I, in addition to those of Meinwald and Young[9] for 1,8-divinylnaphthalene (R=H in I) and 1,8-distyrylnaphthalene (R=Ph in I) seem to suggest that the intramolecular photocyclization of naphthalene-1,8-diolefins generally leads to crossed adducts. Interestingly, the photochemical tendency of naphthalene-1,8-diolefins to give predominantly crossed adducts differs from the well-known property of 1,6-dienes but is similar to that of 1,5-dienes,[10] although the present diolefins are 1,6-dienes.

We did not detect V in the photochemical reaction of I, but Meinwald and Young[9] found the product corresponding to V to be one of the main products in the photocyclization of distyrylnaphthalene. Since the reactive conformation should be common to the two diolefins, the difference in stereoselectivity might be due to different excited states or different intermediates, although they have not discussed what kind of excited state contributes to the reaction of distyrylnaphthalene.

Quantum Yields of Geometrical Isomerization, Cyclization and Fluorescence. Since attempts to isolate the geometrical isomers of I (*cis, trans* isomer, I′; *cis, cis* isomer, I″) were unsuccessful, an accurate quantum yield for the isomerization could not be determined. However, as a measure of photoreactivity under various conditions, we estimated the quantum yields for isomerization and cyclization from the disappearance rate of I followed by the UV spectral changes. The absorption spectrum changed with irradiation time on exciting with 365 nm light as follows. At first, the peak at 332 nm rapidly decreased and the shoulder peak at 265 nm disappeared, the cycloadducts even at this stage being detected by glc. Decrease of the 332 nm peak then became slow with concomitant appearance of adduct peaks (Table 1), and finally I was completely converted into adducts by prolonged irradiation. The change of spectrum with irradiation time is shown in Fig. 1. The spectral behavior of I would be explained by considering that the rapid decrease in the first stage is due to the superposition of rapid isomerization and considerably slow cyclization of I, and the slow decrease in the second stage is due only to cyclization of the *pseudo*-photostationary mixture of I and I′ (and I″)



VIII

formed at first. In fact, *trans*-methyl-1-naphthaleneacrylate (VIII), where only geometrical isomerization is possible, showed a spectral change similar to that of I in the first stage. Namely, on exciting with 350 nm light, the peak of VIII at 318 nm decreased rapidly with irradiation time and reached a photostationary state, as shown in Fig. 2.

The plot of the optical density of I at λ_{max} (332 nm) against irradiation time (Fig. 3) showed two approximately linear parts corresponding to the two stages of

(1); initial spectrum, (2); intermediate spectrum (*pseudo*-photostationary state between I and I′ (and I″), (3); final spectrum (intramolecular cycloadducts).

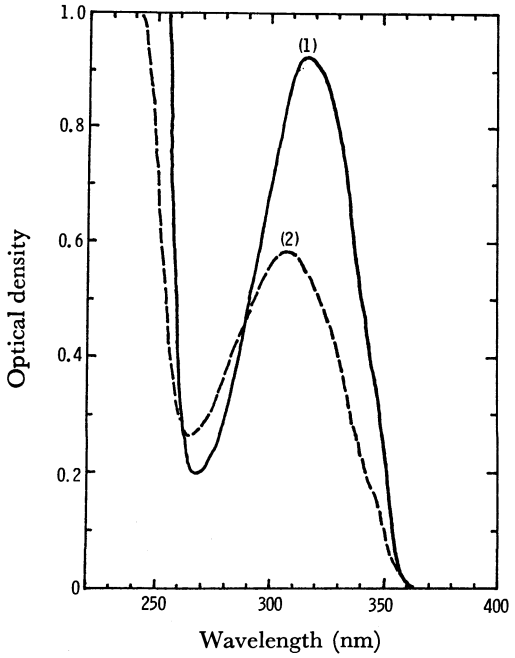

Fig. 2. UV absorption spectra change of VIII in cyclohexane solution with irradiation time on exciting 350 nm light.
(1); initial spectrum, (2); final spectrum (photostationary state between *trans*- and *cis*-isomer of VIII).

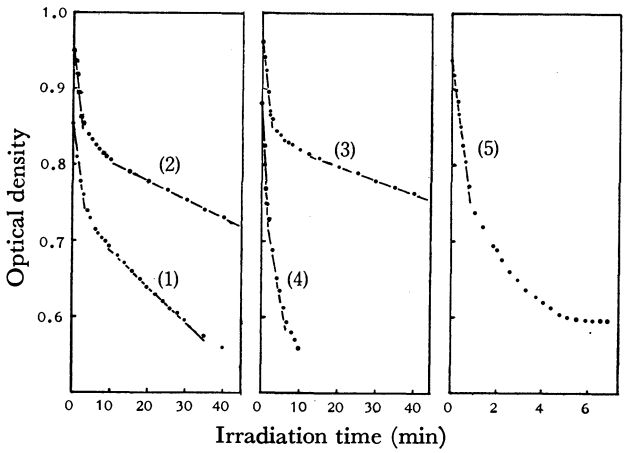

Fig. 3. The change of optical density of I and VIII at λ_{max} with irradiation time.
(1), (2), (3), and (4) denote respectively the conditions: degassed, N_2 saturated, O_2 saturated cyclohexane solution and N_2 saturated *n*-propyl bromide solution, in the change of (I) at 322 nm on exciting 365 nm light.
(5) denotes the change of VIII in N_2 saturated cyclohexane solution at 318 nm on exciting 350 nm light, when the intensity of the exciting light is normalized to that of 365 nm light.

the spectral change in small conversions. From the slope of the plot, we determined the quantum yields for isomerization and cyclization* without any corrections, since the absorptivity of I at 365 nm (exciting light) was almost constant in small conversions and the cyclized products did not absorb the exciting light. The results are given in Table 3 together with those of VIII. Both quantum yields for isomerization and cyclization decrease slightly with the addition of oxygen and increase remarkably on using *n*-propyl bromide as a heavy atom solvent. The quantum yield of fluorescence of I under various conditions is also summarized in Table 3. Anthracene was used as a fluorescence standard (the quantum yield is 0.30),[11] since the fluorescence peak of I is at about 410 nm. The yield of fluorescence in the heavy atom solvent is reduced to about one-half the yield in cyclohexane, although it is not affected by oxygen. The results on the quantum

Table 3. Quantum yields of reactions and fluorescence[a)]

		φ_i	φ_c	φ_f
I/Cyclohexane	Degassed	4.6×10^{-2}	0.57×10^{-2}	—
	N_2 saturated	4.5×10^{-2}	0.28×10^{-2}	3.5×10^{-2}
	O_2 saturated	4.3×10^{-2}	0.20×10^{-2}	3.5×10^{-2}
VIII/Cyclohexane	N_2 saturated	28×10^{-2}	—	—
I/*n*-PrBr	N_2 saturated	5.9×10^{-2}	2.5×10^{-2}	1.9×10^{-2}

a) φ_i, φ_c and φ_f denote the quantum yields of isomerization, cyclization and fluorescence, respectively. Potassium ferrioxalate is used as a chemical actinometer.

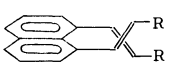
* Since the contribution of I″ is negligible, at least in small conversions, isomerization is that from I to I′, and cyclization is that of a *pseudo*-photostationary mixture of I and I′ (and I″).

yield measurement also suggest that the photochemical reaction of I proceeds mainly through the triplet state of I.

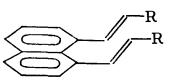
Photochemical reaction of a fairly concentrated solution of I (*ca.* 0.1 M $CDCl_3$ solution) was studied by following NMR spectral change with irradiation time (irradiated with 365 nm light). Rapid isomerization of I to I′ was confirmed by an appearance of NMR peaks based on *cis*-olefinic group (δ 6.16, doublet, J= 12.6 Hz, *cis*-vinyl H, another doublet peak is hidden in the peaks of aromatic protons; 3.59, methoxy H). Simultaneous appearance of peaks based on *trans*-vinyl protons (δ 6.24, 8.62, pair of doublet, J=15.4 Hz) differing from those of I (δ 6.29, 8.37, J=15.4 Hz) and lack of the peaks of intramolecular cyclization products on irradiating for a long time suggest that photochemical reaction of concentrated solution of I would be geometrical isomerization and intermolecular dimerization. Detailed analysis of dimerized products was not performed.

Since the predominant formation of VI is almost independent of irradiation time, namely independent of whether the *pseudo*-photostationary state between I and I′ (and I″) is attained or not, the main product from I′ is expected to be the same VI as that from I. The photocyclization of I and I′ greatly resembles that of 1,5-dienes. Scheffer and Wostradowski[12] reported that acetone sensitized photochemical reaction of *trans, trans*- and *trans,cis*-isomers of dimethyl octa-2,6-diene-1,8-dioate, $(-CH_2-CH{=}CH-CO_2Me)_2$, leads to *cis, trans* isomerization with concomitant formation of the cyclized products corresponding to VI and VII in the same 65: 35 ratio.

Reaction Mechanism. The predominant formation of crossed adducts in photochemical reaction of naphthalene-1,8-diolefins irrespective of their substituents (H, Ph or CO_2Me) suggests that ground-state conformations contribute strongly to the course of cyclization. Examination of molecular models suggests that two ground-state conformers, I-A and I-S, are stable sterically, where two olefinic groups rotate to a considerable extent from naphthalene plane due to their steric inhibition.



I-A



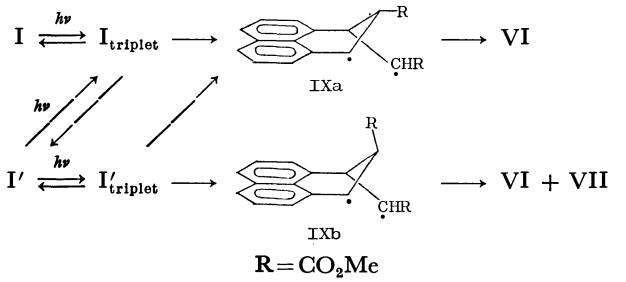
I-S

R=CO_2Me

From *anti* conformer I-A, only crossed adducts formation would be possible, and both crossed and straight adducts could be produced from *syn* conformer I-S. However, I-S is less favorable than I-A due to larger nonbonding interactions between two olefinic groups. Hence, the contribution of I-S to the crossed adducts formation is considered to be less important.

From the observations that (1) stereochemistry of crossed products VI and VII cannot be explained by the concerted mechanism, (2) isomerization and cyclization take place concomitantly through the triplet state and (3) both geometrical isomers I and I′ yield the same main product VI, we propose the reaction mechanism for the formation of crossed adducts as

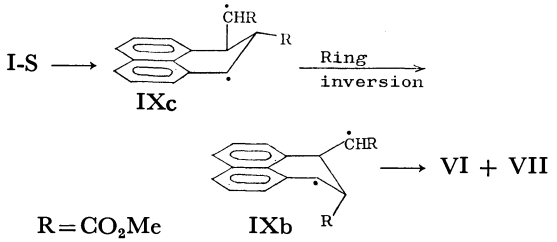
follows, assuming intermediate 1,4-biradicals from *anti* conformers, I-A and I'-A.



The back reactions of the biradicals to the ground state or the triplet state of I or I' are omitted to avoid complexity of the scheme.

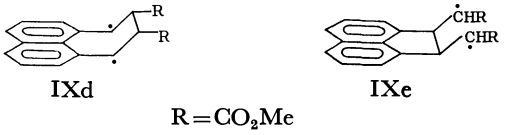
Sole biradical IXa could be formed from I-A, but formation of two biradicals IXa and IXb would be possible from I'-A. Since the spin of the biradicals is expected still to be parallel, spin inversion is necessary for ring closure. The biradicals would be long-lived enough to change into the most stable conformation. For ring closure of biradical IXa, rapid rotation of the terminal carbomethoxy methine site into the satble conformation, where the interaction with an *equatrial* carbomethoxy group is minimized, would lead to preferential formation of main product VI. If the lifetime of the biradical is comparable to the rotational rate of terminal site, V and VI would be produced from the biradical. Cyclization of distyrylnaphthalene would be the case, if the reaction proceeds through the biradical corresponding to IXa. Biradical IXb would yield VI and minor product VII for ring closure.

Formation of VII from less-favored conformer I-S would be possible, if ring inversion of biradical IXc is considered as follows.



However, considering the reduced importance of I-S and the formation of most products from *pseudo*-photostationary mixture of I and I' (and I''), most of minor product VII would be formed from I' through the biradical IXb. Although details are not available since neither I' nor I'' is isolated, the observed solvent effect (increase of VII in polar solvents) could be interpreted, if the portion of I' in the *pseudo*-stationary mixture increases in polar solvents.

Formation of straight adduct II would be related to less-favored conformer I-S. In fact, this is supported by the predominant formation of straight adducts in the photochemical reaction of the compound fixed to *syn* conformer, 1,7-(1',8'-naphthalene)-1,6-heptadienes (RR=$(-CH_2-)_3$ in I and I''). However, a biradical mechanism would be unreasonable for the formation of II, since straight adducts other than II are not detected. Two possible biradicals, IXd and IXe, from the conformer I-S are expected to give at least two straight adducts for ring closure with nearly equivalent probability.[14]



R=CO_2Me

If the observed oxygen effect (increase of II in the presence of oxygen) is considered, a concerted mechanism from singlet state would be more reasonable than a biradical one for the formation of another minor product II, although the formation of a small amount of II by triplet sensitization cannot be explained in a satisfactory manner.

Increase in cyclization efficiency by *n*-propyl bromide is much greater than that in isomerization efficiency (Table 3), even if experimental errors are considered. This suggests that the intermediate biradicals formed from the triplet state of I must be again affected by the heavy atom solvent, since the enhancement of triplet yield by heavy atom effect should increase the quantum yields of cyclization and isomerization at the same ratio. The additional heavy atom effect should cause an acceleration of spin-inversion rate of biradicals, resulting in an increase in the rate of their ring-closure to cyclized products.

Irradiation in Rigid Matrix and in Solid State. Prolonged irradiation of I in EPA rigid glassy solution at 77 K did not bring about any UV spectral changes. The unreactivity would be attributed to the reduced triplet-yield of I, since the fluorescence yield increases remarkably under these conditions (φ_f=*ca.* 0.5).

When I is irradiated in a crystalline state, the IR absorption peaks based on the olefinic groups of I disappear completely but the amount of cyclization products is negligible. Although further detailed analysis of the products was not performed, polymeric substances could be produced.

The authors are grateful to Prof. Makoto Takahasi, the University of Tokyo, for his valuable discussions, and to Mr. Kazuo Sato for his assistance in experiments.

Photoreduction and Photoaddition of *N*-Acetyldiphenylmethyleneamine in Alkylbenzenes

Shuichiro Asao, Naoki Toshima, and Hidefumi Hirai

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received December 19, 1974)

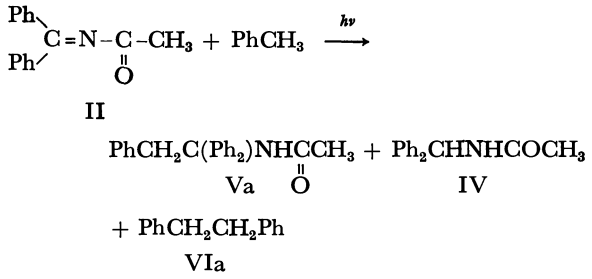
Irradiation of *N*-acetyldiphenylmethyleneamine (II) in toluene solution gave *N*-(1,1,2-triphenylethyl)acetamide and *N*-(1,1-diphenylmethyl)acetamide in 11% and 4.4% yields, respectively. The former is an addition product of toluene to the C=N bond of imine II, and the latter a hydrogenation product of II. The same kind of addition and hydrogenation products as those in toluene were obtained on irradiation of imine II in ethylbenzene, cumene, *o*-, *m*-, and *p*-xylene, mesitylene, *p*-methoxytoluene, and *p*-cyanotoluene, respectively. Two kinds of competitive reaction processes are proposed from the results of the substituent effects for the phenyl ring of toluene, the effect of the additives such as sensitizers and quenchers, and the dependence of the photoreaction yields on the concentration of the additive. The photoreaction proceeds not only by the "chemical sensitization" mechanism derived from the ketyl radical of benzophenone, a hydrolyzed product of II, but also by the mechanism through the excited state of II itself.

The photochemical behavior of acyclic imines is not very clear,[1-12] although it is well-known that heteroaromatic compounds containing nitrogen actively undergo photochemical reactions.[13] The photoreduction of benzophenone imine derivatives in particular has been investigated in detail.[1,3,4] On irradiation of diphenylmethyleneamine (I) in 2-propanol, benzhydrylamine and *N*-benzhydrylidenebenzhydrylamine were produced instead of a dihydro dimer of I corresponding to benzpinacol given by the photoreduction of benzophenone.[3] *N*-Alkyldiphenylmethyleneamine was also reduced photochemically on its C=N bond, the reaction mechanism being proposed by Fischer and Padwa as a "chemical sensitization" process.[1,4,14-18] "Chemical sensitization" means that the ketyl radical, derived photochemically from the carbonyl compound present in the starting materials as an impurity, transfers a hydrogen atom to the imine without any energy transfer. On the other hand, high photochemical reactivity of α,β-unsaturated ketones suggests that the imino ketone, the N-analogue of an enone, would undergo the photochemical reaction expected to be brought about *via* the excited state of itself.

In a previous paper,[19] the photoreduction of *N*-acetyldiphenylmethyleneamine (II) (*N*-acetyldiphenylketimine) in 2-propanol was reported to give *N*-diphenylmethylacetamide (IV). We now wish to report that the addition product and the hydrogenation product on the C=N bond were obtained on irradiation of imine II in several alkylbenzenes, indicating that the excited state of imine II has the character of hydrogen abstraction though it was generally proposed that the C=N group should scarcely abstract a hydrogen.[20]

Results

Photoreaction of N-*Acetyldiphenylketimine (II) with Toluene.* The toluene solution of *N*-acetyldiphenylketimine (II) in a quartz tube was irradiated under nitrogen atmosphere with a 500 W high pressure mercury lamp for 100 hr. After irradiation toluene was distilled off and three products were separated by column chromatography on silica gel: *N*-diphenylmethylacetamide (IV), *N*-(1,1,2-triphenylethyl)acetamide (Va), and dibenzyl (VIa) in 4.4%, 11%, and 3.4% yields, respectively.



The remainder was the starting material. Compound IV was the same as that given on irradiation of II in 2-propanol: *i.e.*, it was identified by spectral data which included infrared absorption (3245, 1646, 1544 cm^{-1}) for the amide group, and the NMR spectrum at δ 7.07—7.46 (10H, m) for aromatic protons, δ 6.00—6.51 (m) for an amide proton, δ 1.97 (3H, s) for acetyl protons, and δ 1.77 (m) for a methine proton. Structure IV was further confirmed by comparing the spectral data with those of the authentic sample. Compound VIa was the coupling product of benzyl radicals brought about on hydrogen abstraction. Amide Va was the adduct of toluene to II. This kind of adduct was obtained on the photoreaction of II in cyclohexene[8] but not in 2-propanol. Structure Va was inferred from its composition ($C_{22}H_{21}NO$) and spectral data which included the infrared absorption bands for an amide group (3326, 1657, 1546 cm^{-1}), and confirmed by the NMR spectrum showing acetyl protons (3H, δ 1.94, s), aromatic protons (15H, δ 6.40—7.42), an amide proton (δ 6.17, m), and methylene protons (2H, δ 3.92) originating from toluene.

Photoreaction of N-*Acetylketimine II with Alkylbenzenes and Relative Reactivities of Alkylbenzenes.* On irradiation of II in substituted toluenes, the reactions proceeded *via* hydrogen atom abstraction from alkylbenzenes, the adducts, hydrogenation products and dimeric hydrocarbons being obtained. Irradiation of II in *p*-methyltoluene (*p*-xylene) gave Vb (37%) and IV (14%). Structure Vb was determined as *N*-[1,1-diphenyl-2-(*p*-tolyl)ethyl]acetamide by its NMR spectrum data. It showed signals for methyl protons (δ 2.22) derived from *p*-xylene, and fourteen aromatic protons, four

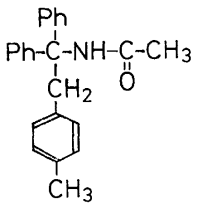
e	Cumene	16	40	2.3

a) Irradiation was carried out in a quartz tube with an Eikōsha 500 W high pressure mercury lamp for 100 hr. Concentration of II was 0.14 mol/l and volume of III was 30 ml. b) Yields refer to the conversion in this paper, *i.e.*, the remainder is the starting imine. c) See Ref. 21.



Vb

of which showed the typical A_2B_2 signal pattern of *p*-disubstituted benzene. Only one methyl group of *p*-xylene was concerned with the addition reaction. In ethylbenzene *N*-(1,1,2-triphenyl-*n*-propyl)acetamide (Vc, yield 25%), *d,l*- and *meso*-2,3-diphenylbutane, and IV (yield 11%) were obtained. The reaction occurred *via* hydrogen atom abstraction in a benzylic position, not in a methyl group. These results and the yields of the reaction in other alkylbenzenes are summarized in Table I. Product yields were determined by glpc (Apiezon greese L on Chromosorb W(HP)). As the adduct of ethylbenzene was not detectable by glpc, the yield of Vd was given by the remainder after subtracting the yield of IV in glpc from that of the mixtures of Vd and IV obtained by column chromatography on silica gel. The same method was applied to the yield of the adduct of cumene.

TABLE 2. DEPENDENCE OF THE PHOTOREACTION YIELD OF *N*-ACETYLKETIMINE II WITH TOLUENE IN THE PRESENCE OF SEVERAL ADDITIVES[a]

Additive	E_T[b] (kJ/mol)	Yield (%)	
		Adduct	Hydrogenation product
None		2.5	0.94
Xanthone	310	10	28
Triphenylamine	295	1.2	1.1
Benzophenone	290	12	12
Triphenylene	280	1.1	1.2
Diacetyl	235	6.6	1.4
Benzil[c]	220	5.2	1.7
Fluorenone	220	0.40	0.27
1-Methylnaphthalene	250	0.36	0.20

a) Irradiation was carried out in toluene (10 ml) solution with 0.23 mol/l of II and 4.3×10^{-2} mol/l of additives in a pyrex tube for 30 hr unless otherwise stated. b) See Ref. 22. c) Irradiation with light of wave lengths greater than 390 nm for 60 hr.

Effect of Additives on the Photoreaction of N-*Acetylketimine II with Toluene upon Additives.* The photoreaction of II with toluene was carried out in the presence of several additives (Table 2). The toluene (10 ml) solution of II (0.23 mol/l) with benzophenone (0.043 mol/l) in a pyrex tube under nitrogen was irradiated with a 500 W high pressure mercury lamp at 25 °C. After 30 hr irradiation IV (yield 12%) and Va (yield 12%) were obtained.

When 1-methylnaphthalene was used in this photoreaction instead of toluene, no photoreaction of II was observed. This can be explained by quenching of the photoreaction of II with 1-methylnaphthalene. On the basis of this result, quenching studies were carried out with naphthalene. The results indicate a Stern-Volmer relationship for product appearance (Fig. 1). The slope for Va is 2.46×10^2 l/mol and that for IV is 1.00×10^2 l/mol.

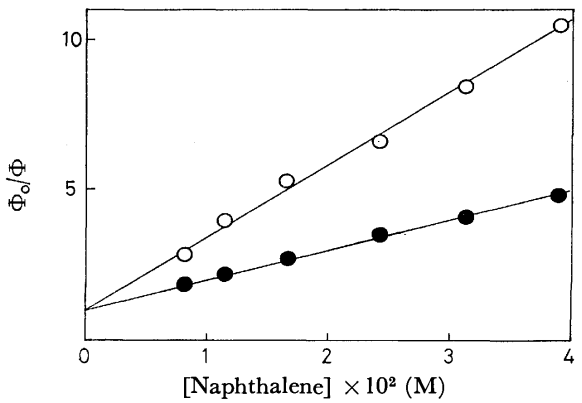


Fig. 1. Quenching of the photoreaction of *N*-acetylketimine II with toluene by naphthalene: Adduct (○), Hydrogenation product (●); [*N*-Acetylketimine] 0.23 mol/l, [Toluene] 10 ml; Irradiation was carried out with above 300 nm for 30 hr at 25 °C.

Dependence of the Photoreaction of N-*Acetylketimine II with Toluene upon the Concentration of Benzil.* The reaction yield increased in the presence of benzil (Table 2). The influence of benzil in the photoreaction was investigated on irradiation of II (0.23 mol/l) in toluene (10 ml) at wavelengths greater than 390 nm with various concentration of benzil. Benzil exhibits its absorption at 370 nm (ε_{max} 78) due to an n-π^* transition, the shoulder of the absorption appearing in the region of wavelengths greater than 390 nm. On the other hand,

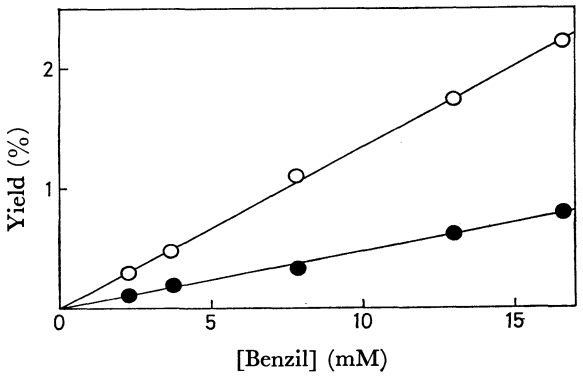

Fig. 2. Dependence of the yields of the photoreaction of *N*-acetylketimine II with toluene on the concentration of benzil: Adduct (○), Hydrogenation product (●); [*N*-Acetylketimine] 0.23 mol/l, [Toluene] 10 ml; Irradiation was carried out above 390 nm for 60 hr at 25 °C.

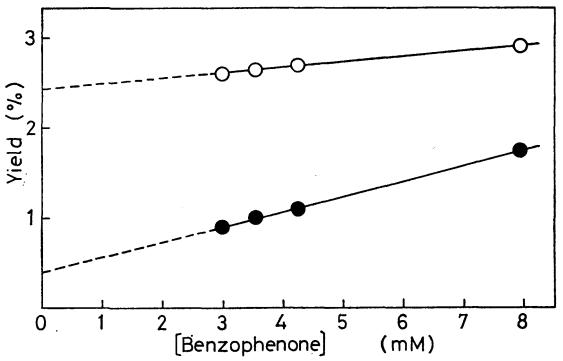

Fig. 3. Dependence of the yields of the photoreaction of *N*-acetylketimine II with toluene on the concentration of benzophenone: Adduct (○), Hydrogenation product (●); [*N*-Acetylketimine] 0.23 mol/l, [Toluene] 10 ml; Irradiation was carried out above 300 nm for 30 hr at 25 °C.

II shows no absorption in the region above 390 nm (Fig. 4, Experimental). No products were obtained at a light above 390 nm without sensitizers, the same results being obtained even with benzophenone under these conditions.[23] Figure 2 shows the results of the sensitization experiments with II using benzil, the reaction yields increasing linearly with added benzil. The same kind of dependence was observed on the reaction of II with diacetyl. Thus benzil and diacetyl were found to be effective to the reaction as additives.

Dependence of the Photoreaction of N-*Acetylketimine II with Toluene on the Concentration of Benzophenone.* The starting sample II contains a small amount of benzophenone, hydrolysis product of II which is easily hydrolyzed. Benzophenone was added as a chemical sensitizer and was recovered without any change after irradiation. Figure 3 shows the relations of the photoreaction yields *vs.* the total amount of benzophenone which should be the sum of an added amount and a hydrolyzed amount determined by glpc. The full lines indicate the experimental data and the dotted lines the extrapolation of the results. Both products increase in yields linearly with the concentration of benzophenone.

Photoreaction of N-*Acetylketimine II with Substituted Toluenes.* The results of the photoreaction of II with various substituted toluenes are summarized in Table 3. The total yields of the adducts and the hydrogenation products are shown in relative values using the value in toluene as a standard. For the sake of comparison, the relative reactivity of substituted toluenes toward benzophenone triplet is cited.[21] It is apparent that the reactivity of II differs a great deal from that of benzophenone, in the case of *p*-methoxytoluene. On the reaction of II with three isomers of methyltoluenes (xylenes), the yields decreased in the order $p\text{-}CH_3 > m\text{-}CH_3 > o\text{-}CH_3$.

Discussion

Effect of Additives. The mechanism of the photoreaction of II with alkylbenzenes appears to be complicated, since the energy of the excited triplet state of sensitizers is not concerned directly with the sensitization of the reaction of II (Table 2). As an example, benzophenone (E_T=290 kJ/mol) was effective in the reaction as a sensitizer, but not triphenylene (E_T=280 kJ/mol) with nearly the same triplet energy as that of benzophenone. Padwa and co-workers[1] suggested that benzophenone works as a so-called "chemical sensitizer" in the photoreduction of *N*-benzoyldiphenylketimine (VIII) in 2-propanol. Benzophenone was regarded as not transferring its triplet energy to VIII because of the fact that phosphorescence of benzophenone was not appreciably quenched by VIII. If the photoreduction and photoaddition reaction of II with toluene occurs by "chemical sensitization," the species with a hydrogen abstracting character can play the role of a chemical

Table 3. Photoreaction of *N*-acetylketimine II with substituted toluene (III)[a]

Substituted toluene (III)	Yields (%)			Relative reactivity	
	Hydrogenation product (IV)	Adduct (V)	Total (IV+V)	Imine II	$^3Ph_2CO$[b]
Toluene	1.2	4.2	5.4	1.00[c]	1.00[c]
p-Xylene	10	14	24	4.4	4.3
m-Xylene	3.4	8.8	12.2	2.3	2.9
o-Xylene	4.1	6.8	10.9	2.0	—
p-Methoxytoluene	2.0	3.7	5.7	1.1	10.6
p-Cyanotoluene	2.9	2.5	5.4	1.0	—

a) Photoreactions were carried out in a solution of substituted toluene (5 ml), benzene (5 ml), and II (0.23 mol/l) in a pyrex tube with light above 300 nm for 30 hr. b) See Ref. 21. c) Standard.

sensitizer to increase the product yields, regardless of the excitation energy. In fact, triphenylamine with triplet energy higher than that of benzophenone did not sensitize the reaction, but xanthone with a hydrogen atom abstracting character was effective. On irradiation of II above 390 nm, no reaction occurred with or without benzophenone.[23,24] Irradiation of II above 390 nm in toluene in the presence of benzil or diacetyl gave IV and Va. Benzil (E_T=220 kJ/mol) and diacetyl (E_T=235 kJ/mol) with a hydrogen abstracting character exhibit maxima at 370 nm (ε_{max} 78) with tailing and at 422 nm (ε_{max} 22), respectively,[24,25] indicating n-π^* absorption. Benzil or diacetyl is considered to abstract a hydrogen atom of the triplet state after excitation with light above 390 nm and to transfer it to II. In contrast, fluorenone, whose lowest triplet state is (π, π^*) with E_T=220 kJ/mol, retarded the reaction above 300 nm. Fluorenone is not able to abstract a hydrogen atom from toluene on irradiation,[26] and probably acts as a quencher on irradiation of II in toluene.

Chemical Sensitization of the Reaction of II by Benzil. Benzil is effective as a sensitizer (Table 2) and the photochemical reaction yields of both the adduct and the hydrogenation product increased linearly with benzil added at the wavelengths above 390 nm (Fig. 2). The reaction scheme is proposed as follows (Scheme 1).

$$\mathrm{Ph{-}\underset{\underset{O}{\|}}{C}{-}\underset{\underset{O}{\|}}{C}{-}Ph} \xrightarrow{h\nu} \mathrm{Bz^*(S_1)} \longrightarrow \mathrm{Bz^*(T_1)}$$

(Bz)

$$\mathrm{Bz^*(T_1)} \xrightarrow{k_d} \mathrm{Bz}$$

$$\mathrm{Bz^*(T_1) + PhCH_3} \xrightarrow{k_r} \mathrm{Ph{-}\underset{\underset{HO}{|}}{\dot{C}}{-}\underset{\underset{O}{\|}}{C}{-}Ph + Ph\dot{C}H_2}$$

(RH) (BzH) (R)

$$\mathrm{BzH + Ph_2C{=}NAc} \xrightarrow{k_H} \mathrm{Ph_2\dot{C}{-}NHAc + Bz}$$

(D) (DH)

$$\mathrm{DH + Ph\dot{C}H_2} \xrightarrow{k_{cc}} \mathrm{PhCH_2C(Ph_2)NHAc}$$

(R) (Ad)

$$\mathrm{2DH} \xrightarrow{k_D} \mathrm{Ph_2CHNHAc + D}$$

(DH_2)

$$\mathrm{2Ph\dot{C}H_2} \xrightarrow{k_c} \mathrm{PhCH_2CH_2Ph}$$

Scheme 1.

Only benzil (Bz) can absorb light above 390 nm to cause excitation, since imine II (D) and benzophenone cannot absorb light in that region. The excited triplet state of benzil [Bz* (T_1)] abstracts a hydrogen atom from toluene (RH) and α-amino radical (DH) is formed by hydrogen atom transfer from BzH to II. An adduct (Ad) is obtained by cross-coupling between DH and R. A hydrogenation product (DH_2) is produced by disproportionation.

The usual steady-state treatment of Scheme 1 gives the following two equations for the adduct (Ad) and the hydrogenation product (DH_2).

$$\frac{d[DH_2]}{dt} = k_D[DH]^2 = \frac{k_r[Bz^*(T_1)][RH]}{1+k_{cc}(k_Dk_c)^{-1/2}}$$

$$\frac{d[Ad]}{dt} = k_{cc}[DH][R] = \frac{k_r[Bz^*(T_1)][RH]}{1+(k_Dk_c)^{1/2}(k_{cc})^{-1}}$$

These equations show that yields of the adduct and the hydrogenation product should be proportional to the concentration of benzil, since [Bz*(T_1)] is proportional to [Bz]. The results in Fig. 2 indicate that Scheme 1 is valid. Consequently, the reaction *via* "chemical sensitization" is promoted linearly with the quantity of chemical sensitizer.

Quenching of the Photoreaction of N-*Acetylketimine II in Toluene.* Padwa and co-workers reported on the photoreduction of *N*-(diphenylmethylene)methylamine (IX) in 2-propanol[1] and suggested that the photoreduction of IX occurs *via* "chemical sensitization" due to the fact that a quantum yield of the photoreduction of IX was very low ($\Phi<10^{-3}$) and that only such the sensitizers with a hydrogen abstracting power as benzophenone (Φ=0.66) are effective.

If the photoreaction of II with toluene proceeds only *via* "chemical sensitization," the reaction does not involve the excited state of II as an intermediate and II serves as a hydrogen atom capture. The reaction path on the basis of "chemical sensitization" mechanism in the presence of a quencher can be considered to be that outlined in Scheme 2.

$$\mathrm{Ph_2CO} \xrightarrow{h\nu} \mathrm{Ph_2CO^*(S_1)} \longrightarrow \mathrm{Ph_2CO^*(T_1)}$$

$$\mathrm{Ph_2CO^*(T_1)} \xrightarrow{k_d} \mathrm{Ph_2CO}$$

$$\mathrm{Ph_2CO^*(T_1) + PhCH_3} \xrightarrow{k_r} \mathrm{Ph_2\dot{C}OH + Ph\dot{C}H_2}$$

$$\mathrm{Ph_2\dot{C}OH + Ph_2C{=}NAc} \xrightarrow{k_H} \mathrm{Ph_2\dot{C}NHAc + Ph_2CO}$$

$$\mathrm{Ph_2\dot{C}NHAc + Ph\dot{C}H_2} \xrightarrow{k_{cc}} \mathrm{PhCH_2C(Ph_2)NHAc}$$

$$\mathrm{2Ph_2\dot{C}NHAc} \xrightarrow{k_D} \mathrm{Ph_2CHNHAc + Ph_2C{=}NAc}$$

$$\mathrm{2Ph\dot{C}H_2} \xrightarrow{k_c} \mathrm{PhCH_2CH_2Ph}$$

$$\mathrm{Ph_2CO^*(T_1) + Q} \xrightarrow{k_q} \mathrm{Ph_2CO + Q^*}$$

Scheme 2.

The usual steady-state treatment of Scheme 2 gives the Stern–Volmer equation:

$$\frac{\Phi_A^\circ}{\Phi_A} = \frac{\Phi_R^\circ}{\Phi_R} = 1 + \frac{k_q[Q]}{k_r[RH]+k_d}$$

where Φ is the quantum yield of the reaction in the presence of a quencher, Φ^0 is that without a quencher, and subscripts A and R denote the adduct and the reduction product, respectively.

This equation being exactly the same as that for benzophenone, the Stern-Volmer plot should coincide with that of benzophenone. In the plot for Φ_A°/Φ_A *vs.* [Q], the slope for the adduct was 2.46×10^2 l/mol. But the slope of the Stern-Volmer plots on the photoreaction of benzophenone in toluene was reported to be *ca.* 10^3 l/mol[27–32] differing from that for the reaction of II. This difference cannot be explained by the difference of viscosity of the solution between benzo-

phenone and II. In fact, the viscosity of the solution of II in the experiment is 0.573 cp and does not influence the assumption of diffusion control. On the other hand, the slope of the plot for the adduct differs from that of the hydrogenation product. These results suggest that the photoreaction of II with toluene is not explicable by "chemical sensitization" of benzophenon , and that the excited state of II should influence the reaction.

Mechanistic Consideration on the Sensitization Effect of Benzophenone. The photoreaction yields increase linearly with the amount of a chemical sensitizer, and additives such as benzil and benzophenone act as chemical sensitizers.

The photoreaction of II with toluene in the presence of various amounts of benzophenone equal to the sum of an impurity in II and the added compound was investigated to see if the excited state of II could abstract a hydrogen atom from toluene. The linear dependence of the reaction yields on the total concentration of benzophenone (Fig. 3) agrees with the result of the reaction in the presence of benzil (Fig. 2). From the linearity, the plot of the experimental data can be extrapolated to the zero concentration of benzophenone. If the excited state of II cannot abstract a hydrogen atom, the reaction yields should converge on 0% at the point of no benzophenone. Actually, however, Fig. 3 indicates clearly the formation of the adduct and the hydrogenation product in about 2.5% and 0.4% yields, respectively, without benzophenone. These figures indicate exactly the yields of the reactions through the excited state of II.

Consequently, the present photoreaction is explained by the competition reactions between *via* "chemical sensitization" and *via* the excited state of II (Scheme 3).

$$Ph_2C{=}NAc \xrightarrow{h\nu} Ph_2C{=}NAc^*(S_1) \longrightarrow Ph_2C{=}NAc^*(T_1)$$
$$Ph_2C{=}NAc^*(T_1) + PhCH_3 \longrightarrow Ph_2\dot{C}{-}NHAc + Ph\dot{C}H_2$$
$$Ph_2\dot{C}{-}NHAc + Ph\dot{C}H_2 \longrightarrow PhCH_2C(Ph_2)NHAc$$
$$2Ph_2\dot{C}{-}NHAc \longrightarrow Ph_2CHNHAc + Ph_2C{=}NAc$$
$$2Ph\dot{C}H_2 \longrightarrow PhCH_2CH_2Ph$$
$$Ph_2CO \xrightarrow{h\nu} Ph_2CO^*(S_1) \longrightarrow Ph_2CO^*(T_1)$$
$$Ph_2CO^*(T_1) + PhCH_3 \longrightarrow Ph_2\dot{C}OH + Ph\dot{C}H_2$$
$$Ph_2\dot{C}OH + Ph_2C{=}NAc \longrightarrow Ph_2\dot{C}{-}NHAc + Ph_2CO$$

Scheme 3.

Comparison of the Photoreactivity between N-*Acetylketimine II and Benzophenone.* The ability of hydrogen abstraction by the excited state of II is further emphasized by comparison of the photoreactivity of II with that of benzophenone. Walling and Gibian reported on the photoreduction of benzophenone in substituted toluenes.[21] The rate-determining step of the photoreduction was the process of a hydrogen abstraction,[27-32] the rate constant of formation of benzpinacol by radical reaction of benzophenone ketyl radicals being $3.6\times10^9\ M^{-1}\ s^{-1}$.[32] In the case of the reaction of II (0.15 mol/l) with large excess of alkylbenzenes in the presence of 0.25 molar equivalent of benzophenone, benzpinacol was not obtained, at least below 50% conversion, and added benzophenone was recovered without any change. If the reaction proceeds *via* "chemical sensitization" by benzophenone in II as an impurity, the rate for hydrogen atom transfer from a ketyl radical to II should be greater than that of disproportionation of the ketyl radicals. That is, if the situation were contrary, benzpinacol should have been formed on irradiation. In order to explain the photoreaction of II with toluene by "chemical sensitization," the rate-determining step should be the process of hydrogen atom abstraction by benzophenone. The photoreactivity of II with substituted toluenes should then coincide with that of benzophenone. However, the relative reactivity of II with *p*-methoxytoluene differs greatly from that of benzophenone. Furthermore, on irradiation of II with *p*-halotoluenes the adduct and the hydrogenation product increased in yields in the order *p*-F<*p*-Cl<*p*-Br.[33] The order is reverse to that in the photoreduction of benzophenone in *p*-halotoluenes. These findings support existence of the reactive excited state of II.

Hammond and co-workers reported on the photoreaction of benzophenone with alkylbenzenes which gives rise to the formation of benzpinacol, a reduction product, and a cross coupling product of benzophenone ketyl radical with benzyl radical.[34] Their results are shown in Table 4 with the present data of II.

Table 4. Comparison of the photoreactivity of *N*-acetylketimine II and benzophenone

Ketone or imine	Alkylbenzene	Yield (%)[a]		
		Benzpinacol	Hydrogenation product	Adduct
Ph_2CO[b]	$PhCH_3$	51	—	43
Ph_2CO[b]	$PhCH(CH_3)_2$	24	—	48—60
II	$PhCH_3$	—	29	71
II	$PhCH(CH_3)_2$	—	29	71

a) Yield based on the consumed benzophenone or II.
b) See Ref. 34.

The proportion of a cross coupling product in the photoproducts of *N*-acetylketimine II with alkylbenzenes is higher than that of benzophenone. This can be interpreted by the difference between the reaction mechanism of II and that of benzophenone. Although there is no band indicating an intermolecular interaction in the electronic spectra of II with toluene, the differences mentioned above suggest that II interacts with alkylbenzenes weakly in some way.

Experimental

Materials. Alkylbenzene such as toluene, ethylbenzene, *p*-xylene, cumene, and mesitylene (Yoneyama Chemical Industry), and *o*-, *m*-xylene, and, *p*-methylanisole (Tokyo Chemical Industry) were dried over sodium by refluxing and then distilled. Benzophenone (Yoneyama Chemical Industry), xanthone, fluorenone, and benzil (Tokyo Chemical Industry) were recrystallized from ethanol. Triphenylene and triphenylamine (Tokyo Chemical Industry) were used without further purification. Eluting solvents for column chromatography such as cyclohexane, benzene, methylene chloride, chloroform, and ethanol were used in the state they were received.

Instrumentations. Irradiation was performed with a 500

W Halos high pressure mercury lamp (Eikōsha Ltd.). Most comparative runs were carried out on a merry-go-round type reactor (Rikōkagaku Ltd.) with a turntable device holding the rotating pyrex tubes. This turntable also rotated around the lamp in a water cooled quartz immersion well. The turntable and tubes were held in a constant temperature water bath maintained at 25 °C. Glpc analysis was performed with a Ohkura Rikagaku gaschromatograph with a flame ionization detector, equipped with a 2 m × 3 mm ϕ stainless steel column packed with 10% Apiezon Grease L on 60—80 mesh Diasolid A or on 60—80 mesh Chromosorb W(HP). Infrared spectra were obtained using a JASCO IR-E spectrometer. Ultraviolet measurements were carried out on a Shimadzu MPS-50L spectrophotometer. The NMR spectra were recorded on a JEOL PS-100 or a Hitachi Perkin-Elmer R-20B spectrometer. A Hitachi RMS-4 mass spectrometer was used for mass spectrometry. Melting points were determined with a Yanagimoto micro melting point apparatus. Vapor pressure osmometer analyses were carried out on a Mechrolab Inc. Model 301A osmometer.

Preparation of N-*Acetyldiphenylmethyleneamine(II) (*N-*Acetyldiphenylketimine).*[6,35,36] An ethereal solution of the Grignard reagent from bromobenzene was treated with a stoichiometric amount of benzonitrile. Completion of the decomposition of the Grignard-nitrile complex by addition of methanol gave a pale yellow slurry. The slurry was filtered, and the filtrate was distilled a few times. The fraction of bp 125 °C (1.0 mmHg) was diphenylketimine [lit,[36] bp 127 °C (3.5 mmHg)]. *N*-acetyldiphenylketimine (II) was prepared by refluxing diphenylketimine in twice the number of moles of acetic anhydride for six hr. bp 168—170 °C (1.0 mmHg)] [lit,[35] bp 168—171 °C (1 mmHg)]. UV spectrum of II is shown in Fig. 4.

Preparative Irradiation Procedure. The solution of *N*-acetylketimine II (0.14 mol/l) in toluene (30 ml) in a quartz tube was degassed in three succesive freeze-thaw cycles and irradiated under nitrogen with a 500 W high pressure mercury lamp for 100 hr. The photoreaction mixtures were worked up by evaporation of the solvent at a reduced pressure and separated by column chromatography on silica gel. The reaction mixtures were eluted in succession with 500 ml of cyclohexane, benzene, methylene chloride, chloroform, and ethanol. The coupling products of benzyl radicals were eluted with cyclohexane, and *N*-acetylketimine II and benzophenone, almost the entire amount of which is a hydrolysis product in the silica gel column, were eluted with benzene. The fractions eluted by chloroform contained both the adduct and the reduction product separately. Both products were purified by repeated recrystallization from the mixed solvent of cyclohexane and ethanol, or that of *n*-hexane and ethanol. The structure of the adducts and the coupling products were determined from their spectral data and elemental analyses. The analytical and spectral data are show in Tables 5 and 6. The hydrogenation product [*N*-(1,1-diphenylmethyl)acetamide, IV] was identi-

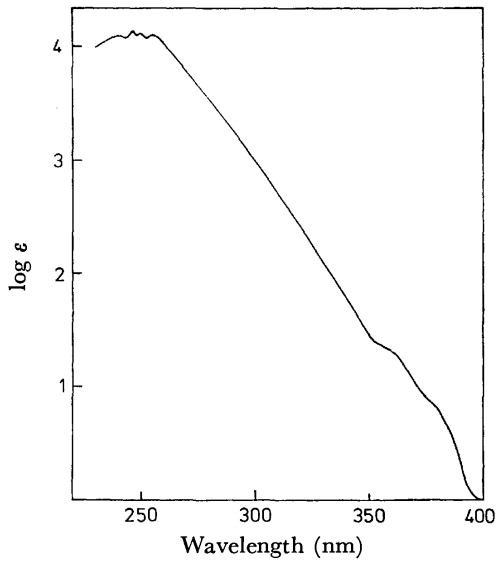

Fig. 4. UV spectrum of *N*-acetyldiphenylmethyleneamine (II) in *n*-hexane.

fied by comparing its spectral data with those of an authentic sample prepared otherwise, and by its inability to depress the melting point.

Irradiation for Mechanistic Study. A degassed solution of *N*-acetylketimine II (0.23 mol/l), substituted toluene (5 ml), and benzene (5 ml) in a pyrex tube under nitrogen was irradiated with a 500 W high pressure mercury lamp at 25±1 °C for 30 hr using a merry-go-round type reactor. The reaction mixtures were worked up by evaporation of the solvent at reduced pressure, and analysed by glpc. Column was a 2 m×3 mm ϕ in 10% Apiezon Grease L on 60—80 mesh Diasolid A or on 60—80 mesh Chromosorb W (HP). The results are summarized in Tables 1 and 3 in the case of alkylbenzenes and *p*-substituted toluenes, respectively. Yields are given in percentage of the starting imine II. No other products of the imine II except those in Table 3 could be obtained, and the remaining imine was recovered after the reaction.

Mechanistic Study in the Presence of Additives. A degassed solution of II (0.23 mol/l) in toluene (10 ml) in the presence of additives in a pyrex tube under nitrogen was irradiated with a 500 W high pressure mercury lamp at 25±1 °C for 30 hr with a merry-go-round type reactor described above. After irradiation, toluene was distilled off in a reduced pressure, and yields of both products, the adduct (Va) and the hydrogenation product (IV), were determined by glpc equipped with a 2 m× 3 mm ϕ column packed with 10% Apiezon Grease L on 60—80 mesh Chromosorb W (HP) at 222 °C at a nitrogen flow rate of 55 ml/min. The results are summarized in Table 2. Yields are shown in percentage with respect to the starting imine II. The remainder of imine was recovered in each case.

Carboxymethylation of Organic Halides by Palladium Complexes under Mild Conditions[1)]

Masanobu HIDAI, Tomoji HIKITA, Yoshimasa WADA, Yuzo FUJIKURA, and Yasuzo UCHIDA
Department of Industrial Chemistry, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received January 8, 1975)

Palladium complexes, $Pd(CO)(PPh_3)_3$, $Pd_3(CO)_3(PPh_3)_4$, $Pd_3(CO)_3(PPh_3)_3$, and $PdCl_2(PPh_3)_2$ were found to be excellent catalysts for the carboxymethylation of various organic halides under very mild conditions. The carboxymethylation reaction is considered to proceed *via* acyl complexes as the intermediates.

In previous papers we reported syntheses of palladium(0) carbonyl complexes, $Pd(CO)(PPh_3)_3$ (**1**), $Pd_3(CO)_3(PPh_3)_4$ (**2**), and $Pd_3(CO)_3(PPh_3)_3$ (**3**),[2)] and the oxidative addition of various organic halides to **1** affording acyl complexes of palladium.[3)] In the present paper is described carboxymethylation of various organic halides under ambient conditions catalyzed by **1**, **2**, **3**, and also $PdCl_2(PPh_3)_2$ (**4**).

A number of papers on the carbonylation of organic halides by transition metal complexes have been reported, but the reactions required high temperature and pressure. Recently there appeared several reports on the carbonylation of organic halides under ambient conditions, in which $Ni(CO)_4$,[4-7)] $NaCo(CO)_4$,[8)] or a nickel-thiourea complex[9)] was used as the catalyst in combination with base. However, the yields of carbonylated products were below one mole or at best a few mole per mole of the transition metal complex used, and reaction temperatures of *ca.* 100° were sometimes required. In contrast, the palladium complexes **1**—**4** show remarkable catalytic activities in the carboxymethylation of various organic halides under very mild conditions.

Results and Discussion

When carbon monoxide is bubbled through a mixture of iodobenzene, methanol, diethylamine, and the palladium(0) complex (**1**, **2**, or **3**) at room temperature, methyl benzoate is produced with the formation of diethylammonium iodide. The yield of the ester was determined by means of gas chromatography and observed to increase linearly with the reaction time. Table 1 shows the yields exceeding far 100% based on palladium atom, along with other results which will be described hereinafter. As shown in Table 1, catalytic activities of **2** and **3** are comparable and higher than that of **1**.

Since **1** and **2** are formed by the treatment of **4** with methanol, diethylamine, and carbon monoxide,[10)] **4** can be conveniently used as the catalyst for the carboxymethylation instead of **1**, **2**, or **3**. Complex **4** is a stable compound and easy to handle compared with **1**, **2**, and **3** which are appreciably air-sensitive. Therefore carboxymethylation of various organic halides was carried out by employing **4** as the catalyst, and the

a) Molar ratio of the complex: iodobenzene: diethylamine: methanol is 0.01: 1: 1: 5. In case of **2** or **3**, the molecular weight is reduced to a mononuclear basis. b) Molar ratio of the complex: halide: diethylamine is 0.01 to 0.02 : 1: 1. c) Calcium oxide is used as the base in place of diethylamine. Molar ratio of **1**: halide: CaO: methanol is 0.01: 0.8: 0.2: 10. d) One molar equivalent of PPh_3 is added.

results are listed also in Table 1. The reaction procedure is essentially the same as in the case of **1**, **2**, or **3**. The methyl esters are formed after an induction period of about 30 min, and the yields increase linearly with the reaction time even after 22 hr. As shown in Table 1, iodobenzene, *p*-iodotoluene, bromobenzene, *p*-dibromobenzene, *β*-bromostyrene, and 1-bromo-2-ethoxyethylene are converted catalytically by **4** to corresponding esters in high yields under mild conditions. Organic halides such as vinyl chloride, vinyl bromide, 1,2-dichloroethylene, 1,2-dibromoethylene, and chlorobenzene did not afford corresponding esters under the same conditions.

Amines other than diethylamine, *e.g.* dicyclohexylamine, can be used as the base. Organic halides that readily form ammonium salts with amines cannot be used as the substrate. But the use of calcium oxide as the base in place of amines enables carboxymethylation of benzyl bromide as well as iodobenzene at room temperature and under 1 atm carbon monoxide. As indicated in the lowest lines of Table 1, benzyl bromide was converted catalytically to methyl phenylacetate by **1**, while methyl iodide gave only a trace amount of methyl acetate.

In order to elucidate the reaction mechanism, two kinds of benzoyl complexes of palladium were also employed as the catalyst for the carboxymethylation of iodobenzene. One is $PdI(COPh)(PPh_3)_2$ (**5**), which is obtained by the reaction of **1** with iodobenzene in toluene under carbon monoxide at room temperature, and has an IR absorption at 1634 cm^{-1} assignable to $\nu_{O=O}$.[3] The other one is [$PdI(COPh)(PPh_3)$·toluene] (**6**), which is obtained by the reaction of **2** or **3** with iodobenzene in toluene (in the reaction of **2**, **6** is obtained together with **5**), and has an absorption at 1660 cm^{-1} also assignable to $\nu_{C=O}$. Both of **5** and **6** give molar equivalent of methyl benzoate by the treatment with methanol and diethylamine under nitrogen at room temperature. Moreover, they show similar catalytic activities in the carboxymethylation of iodobenzene as shown in Table 1. These results suggest that the benzoyl complexes **5** and **6** are the reaction intermediates of the carboxymethylation, and the following scheme is proposed.[11]

$$Pd(CO)(PPh_3)_n \xrightarrow{RX} PdX(COR)(PPh_3)_n \quad (n=1 \text{ or } 2)$$

MeOH, CO, base

RCOOMe, base·HX

In the absence of base, the palladium complexes show no catalytic activities. That is, when carbon monoxide is bubbled through a mixture of **1**, iodobenzene, and methanol for several hours, no ester formation is observed. And when diethylamine is added to the mixture after carbon monoxide is expelled by nitrogen bubbling, stoichiometric amount of benzoate is obtained. This indicates the reductive elimination of benzoyl iodide hardly occurs in the absence of base. Therefore the base is considered to rather enhance the direct attack of methoxide anion on the Pd-COPh moiety than neutralize the acidity being formed during the reaction. The acidity constant of methanol is 10^{-16}, while the equilibrium constant of $MeOH+R_2NH \leftrightarrows MeO^- + R_2NH_2^+$ is about 10^{-6}.[12]

As shown in Table 1, the yield of methyl benzoate from iodobenzene depends on the palladium complexes used and increases in the order **1**<**4**<**2**—**3**. When one molar equivalent of triphenylphosphine is added to the reaction mixture catalyzed by **4**, the yield observed is similar to that with **1**. This is compatible with the fact that **1** is prepared by treatment of **4** with diethylamine and methanol in the presence of one molar equivalent of triphenylphosphine under carbon monoxide. The addition of triphenylphosphine to **1** lowers the yield of ester formation since the ligand added shifts the equilibrium $\mathbf{1} \leftrightarrows Pd(CO)(PPh_3)_2 + PPh_3$ to the left-hand side and prevents the oxidative addition of iodobenzene.[3]

Experimental

Syntheses of complexes **1**, **2**, **3**, and **5** were already described in previous papers.[2,3,10] The complex **1** was also prepared by treatment of **4** with diethylamine and methanol in the presence of one molar equivalent of triphenylphosphine under carbon monoxide (yield, 60%). These complexes are air-sensitive and their handling must be conducted in oxygen-free, dry atmosphere. Complex **4** was prepared according to the published method.[14] Methanol, toluene, and diethylamine were purified according to the usual methods and distilled under nitrogen atmosphere. Organic halides were commercially obtained and were degassed and saturated with carbon monoxide before use. 1-Bromo-2-ethoxyethylene was prepared according to the published method.[15] Esters used as the standard material in gas chromatography analyses were commercially obtained.

Carboxymethylation Reaction under 1 atm Carbon Monoxide. When carbon monoxide was bubbled at room temperature (18°C) through a stirred mixture of **1** (0.100 g, 0.109 mmol), iodo benzene (2.22 g, 10.9 mmol), methanol (1.76 g, 55.0 mmol), and diethylamine (0.80 g, 11.0 mmol), the mixture became a yellow, homogeneous solution and then white powder of ammonium salt precipitated gradually with the formation of benzoate. After 5 hr the amount of benzoate determined by gas chromatography was 0.65 mmole (6.0 times molar equivalent of **1**). The above procedure was applied to all other similar reactions.

Another reaction system containing **4** (0.100 g, 0.285 mmole), iodobenzene (5.50 g, 27.0 mmole), dicyclohexylamine (3 ml), and methanol (5 ml) afforded methyl benzoate of 15.7 times molar equivalent of **4** for 6.5 hr, and 48.6 times for 22 hr at room temperature. Still other system containing **1** (0.100 g, 0.109 mmol), benzyl bromide (1.44 g, 8.42 mmol), calcium oxide (0.100 g, 1.78 mmol), and methanol (3.95 g, 123 mmol) gave methyl phenylacetate of 1.47 mmol (13.5 times molar equivalent of **1**) for 3 hr at 19 °.

Carboxymethylation under Elevated Pressures. In a 50 ml stainless-steel autoclave were placed **4** (0.200 g, 0.285 mmol), *p*-dibromobenzene (6.37 g, 27.0 mmol), methanol (20 ml), and diethylamine (3 ml). The reaction mixture was magnetically stirred at 80 °C under carbon monoxide pressure of 10 kg/cm^2, and 1 hr after the pressure dropped to zero. The mixture was extracted by 100 ml of toluene, in which methyl *p*-bromobenzoate (5.13 mmol), dimethyl terephthalate (3.46 mmol), and unreacted *p*-dibromobenzene (18.4 mmol) were analyzed.

Preparation of [PdI (COPh) (PPh_3)·toluene] (6). When carbon monoxide was bubbled through a toluene solution (10 ml) of **2** (0.173 g, 0.126 mmol) and iodobenzene (3 ml), the original red color of the solution turned into yellow in 15 min. After the solution was allowed to stand overnight, yellow crystals of **6** precipitated (0.148 g (55% based on Pd), $\nu_{C=O}$ at 1660 cm^{-1}). Cryoscopic molecular weight measurement could not be conducted because of the insufficient solubility of the complex. Found: C, 54.99; H, 4.00; P, 4.88%. Calcd for $C_{32}H_{28}OPIPd$: C, 55.50; H, 4.04; P, 4.48%. By adding *n*-hexane to the filtrate of the above solution, yellow crystals of **5** precipitated (0.050 g (16% based on Pd), $\nu_{C=O}$ at 1634 cm^{-1}). When the reaction was carried out in methanol in place of toluene, was obtained yellow powder which was a mixture of **5** and **6**.

Stoichiometric Ester Formation from 5 or 6. When the benzoyl complex **5** (0.119 g) was treated with methanol (2.5 ml) and diethylamine (1.5 ml) under nitrogen at room temperature, the original yellow color turned into brown, and 99.9% molar equivalent of methyl benzoate resulted. As for **6**, the procedure was almost the same.

The Sesquiterpenes of Ginseng

Kazuo YOSHIHARA and Yoshio HIROSE

The Institute of Food Chemistry, 475 Shimamotocho, Mishimagun, Osaka 618

(Received January 21, 1975)

The sesquiterpenes of ginseng have been studied. From the volatile oil, fifteen compounds were characterized. Three of those compounds, α-panasinsene, β-panasinsene and β-neoclovene, were new compounds and were characterized in this paper. Panasinsenes are considered as intermedial compounds in isomerization of caryophyllene to neoclovene.

The root and rootlet of ginseng (*Panax ginseng* C.A. Meyer) have long been used as Chinese medicine. A large number of reports on saponines and triterpenes have been published,[1] but no study of the volatile oil of ginseng has yet been made. Here we have investigated the volatile oil in detail and have isolated several interesting hydrocarbons.

The ginseng used in this investigation consisted of commercial dried rootlets gathered in Korea and in Japan, and fresh roots and rootlets gathered in Japan. There is little difference between the gas chromatograms of the volatile oils of dried Korean rootlets and dried Japanese rootlets. There is also little difference between the fresh root and fresh roots. The characterized compounds are listed in Table 1. As Japanese

TABLE 1. THE LIST OF COMPOUNDS FROM GINSENG

Compound	Ratio in the voltatile oil	
	Fresh ginseng	Dried ginseng
β-Gurjunene	2%	3%
β-Panasinsene	8	20
α-Panasinsene	5	4
Caryophyllene	8	6
β-Farnesene	3	4
α-Neoclovene	7	15
α-Humulene, β-Humulene	5	6
γ-Selinene	—	4
β-Neoclovene	3	5
β-Selinene	—	3
α-Selinene	—	5
Selina-4(14), 7(11)-diene	—	2
Caryophyllene alcohol	—	2
Bicyclogermacrene	36	—

fresh roots obtained from another source showed a similar composition, we regarded the difference in the volatile oils is due to the different treatment of the roots and the rootlets. It is remarkable that bicyclogermacrene is a main component in the volatile oil of fresh ginseng root. This compound has been found only in *Citrus Junos* Sieb. ex Miquel,[2] yet it is expected to be of wide distribution as a precursor of bicyclogerelemene, aromadendrene, ledol, maaliene, *etc.*

The acidity of fresh root homogenate is pH 4.8—4.6, on standing for one week, the homogenate showed a change in its volatile constituents, whereby the amount of bicyclogermacrene decreased markedly and three selinene type compounds, α-selinene, β-selinene, and selina-4(14),7(11)-diene, appeared.

We will describe below the four hydrocarbons, α-neoclovene, β-neoclovene, α-panasinsene, and β-panasinsene, which were isolated for the first time from a natural source.

α-Neoclovene (I) was identified by comparing its spectral data with those of authentic neoclovene, which had been known as the product of the concd H_2SO_4-catalyzed isomerization of caryophyllene.[3]

β-Neoclovene (II) was isolated as a minor component in the oil of dried rootlets. From the spectral data, it was supposed that there were three tertiary methyl groups and an exocyclic methylene group in II, and that two of the tertiary methyl groups occupied geminal positions. II gave two dihydroderivatives on catalytic hydrogenation. Those two dihydroderivatives were identical with two dihydro-neoclovenes obtained by the hydrogenation of α-neoclovene. Therefore, II must be an isomer of α-neoclovene in respect to the position of the double bond, and represented by the structure II in Fig. 1. In order to distinguish those two isomers, we named I, which had previously been called by the name of neoclovene, and II α-neoclovene and β-neoclovene, respectively.

The spectral data of α-panasinsene (III) exhibits the existence of three tertiary methyl groups, an olefinic methyl group, and a trisubstituted double bond in III. The fact that the hydrogenation of III resulted in two dihydroderivatives and the molecular ion peak of III at *m/e* 204 showed III is tricyclic hydrocarbon.

β-Panasinsene (IV) is also a sesquiterpene hydrocarbon (molecular weight, 204). The NMR spectrum shows the existence of three tertiary methyl groups and an exocyclic methylene group. The IR spectrum shows that two tertiary methyl groups are geminal. The catalytic hydrogenation of IV gave two dihydroderivatives, which were identified with two dihydroderivatives of III. Therefore, III and IV are isomers of the same carbon skeleton, differing only in the position of the double bond. On isomerization with concd H_2SO_4 in ether, IV was transformed to three hydrocarbons, α-neoclovene, β-neoclovene, and α-panasinsene. On the basis of the results mentioned above and the spectral data, we supposed that α-panasinsene and β-panasinsene had to be assigned the structure III and IV, respectively. The framework of III and IV appeared in Parker's report[4] in connection with his explanation of the pathway leading from caryophyllene to neoclovene in the presence of H_2SO_4. Furthermore, the ozonolysis of IV gave a ketone (V).[5] Therefore, we have elucidated the structure III and IV

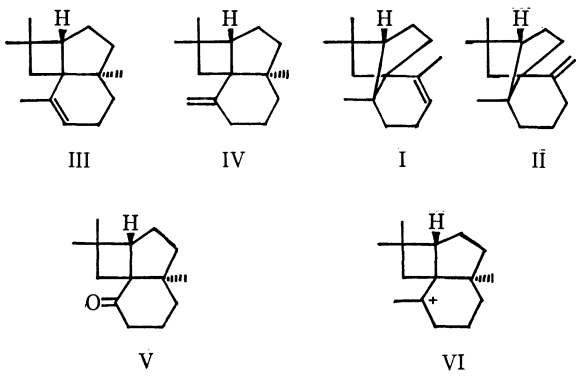

Fig. 1.

as mentioned above.

The discovery of intermediate tricyclic hydrocarbon, β-panasinsene, strongly supports Parker's explanation that caryophyllene rearranges through the panasinsene type cation (VI) to neoclovene with acid.

Most araliacean plants in Japan show a rather simple and common feature on their volatile constitutions, which contain β-farnesene, caryophyllene, and humulene as the main components. However, we found a few remarkable instance in Araliaceae. Two example are *Panax japonicum* C.A. meyer and *Acanthopanax sciadophylloides* Franch et Sav., which contain germacrene-D as the sole component,[6] and the third one is *Panax ginseng*. In the latter, caryophyllene is transformed to neoclovenes through panasinsenes, and a novel hydrocarbon, bicyclogermacrene, is accumulated.

Experimental

Analytical Instruments. As an analytical gas chromatograph, Hitachi-Perkin F6-D-type apparatus fitted with a HB-2000 capillary column (45 m by 0.25 mm) was used. N_2 gas was flowed through as the carrier gas. For the measurement of the physical data, a Hitachi EPI-G2-type infrared absorption spectrometer with NaCl cell, a JEOL-JNM-C-60-type nuclear magnetic resonance spectrometer, a Hitachi RMU-6-type mass spectrometer (operated at an accelerating voltage of 2 kV, an ionization voltage of 80 eV, and an ion source temperature of 250 °C), and a Perkin-Elmer's 141-type polarimeter were used.

Extraction and Isolation. Commercial dried rootlets of ginseng (5 kg) were extracted with ethanol, and the extract was concentrated and steam-distilled. About a 5 g portion of a volatile oil was thus obtained. The volatile oil dissolved in ethyl ether was washed with an aqueous $NaHCO_3$ solution, and a 4.3 g portion of the neutral fraction was obtained from the ethyl ether layer. The neutral oil obtained thus was subjected to column chromatography on Merck's Al_2O_3 column (activity II-III), and then separated into 3.5 g of the hydrocarbon fraction (eluted with n-hexane) and 0.5 g of the oxygenated compound fraction (eluted with ethyl ether). The former was further subjected to column chromatography on Al_2O_3 impregnated with 15 wt% $AgNO_3$ and was eluted with *n*-hexane and ethyl ether. Each eluted fraction was separated into pure compounds by means of a Varian MODEL 90-P-type gaschromatograph fitted with an aluminum column (20 ft by 3/8 in) packed with Carbowax 20 M on Diasolid L. The gas chromatograph was operated at a bath temperature of 180—200 °C, He gas was used as the carrier gas.

Fresh root (4 kg) was mashed, filtered, and then washed with acetone. The acetone in the filtrate was then evaporated, and the residue was extracted with *n*-hexane. When this extract was concentrated and distilled under diminished pressure, 500 mg of oil were obtained. The same procedure was carried out for the fresh rootlets. The oil from the fresh rootlets was used for comparison. Another 500 g portion of fresh ginseng was homogenized, and the pH of this homogenate was measured using B.T.B. and B.C.G. After standing for one week at room temperature covered with benzene, the homogenate was treated by the procedure described above. The oil of the homogenate was then examined by mean of analytical gas chromatography.

Physical Properties and Chemical Reactions. α-Neoclovene (1), $[\alpha]_D^{25}$ −56° (in MeOH), NMR: τ 8.99(s, 6H), 8.81 (s, 3H), 8.41 (m, 3H), and 4.91 (m, 1H), IR: 1650, 1140, 980, 840, 815, 790, and 775 cm^{-1}, MS: *m/e* 204 (M^+, $C_{15}H_{24}$), 189 (base peak), 175, 161, 147 and 105.

β-Neoclovene (II), $[\alpha]_D^{25}$ −30° (in MeOH), NMR: τ 9.16 (s, 3H), 8.98 (s, 3H), 8.81 (s, 3H), 5.37 (t, J=2 Hz 1H), and 5.62 (t, J=2 Hz 1H), IR: 3050, 1625, 1365, 1355 and 890 cm^{-1}, MS: *m/e* 204 (M^+, $C_{15}H_{24}$), 189, 176, 161 (base peak), 147, 148, 133, 119, and 91, (Found; C, 88.14; H, 11.82%. $C_{15}H_{24}$ requires C, 88.16; H, 11.84%).

α-Panasinsene (III), NMR: τ 9.12 (s, 3H), 9.05 (s, 3H), 8.77 (s, 3H), 8.05 (allyl coupled m, 3H) and 4.60 (m, 1H), IR: 1640, 1370, 1360, 1200, 1110, 1070, 1000, 940 and 800 cm^{-1}, MS: *m/e* 204 (M^+, $C_{15}H_{24}$), 189, 161, 122 (base peak) and 107, (Found; C, 88.13; H, 11.83%. $C_{15}H_{24}$ requires C, 88.16; H, 11.84%).

β-Panasinsene (IV), $[\alpha]_D^{25}$ −3° (in MeOH), NMR: τ 9.26 (s, 3H), 9.14 (s, 3H), 8.92 (s, 3H), 5.22 (d, J=2 Hz 1H) and 5.16 (d, J=2 Hz 1H), IR: 3080, 1620, 1365, 1360, 1260, 1080, 930, and 885 cm^{-1}, MS: *m/e* 204 (M^+, $C_{15}H_{24}$), 189, 175, 161 (base peak), 146, 133, 122, 109 and 107.

The Hydrogenation of I and II. I and II were hydrogenated in methanol over platinum oxide. Both gave the same products in analytical gas chromatography, and by preparative gas chromatography two isomeric compounds, neoclovane-A and neoclovane-B, were isolated.

Neoclovane-A, NMR: τ 9.07 (d, J=6 Hz 3H), 8.97 (s, 3H), and 8.80 (s, 6H), IR: 1370, 1360, 1305, 1165, 1135, 970, and 945 cm^{-1}, MS: *m/e* 206 (M^+, $C_{15}H_{26}$), 191, 178, 163, 150, 135, 123, 109, 81 (base peak), 82, 69 and 55, (Found; C, 87.28; H, 12.70%. $C_{15}H_{26}$ requires C, 87.30; H, 12.70%).

Neoclovane-B, NMR: τ 9.25 (d, J=6 Hz 3H), 8.98 (s, 3H), 8.93 (s, 3H) and 8.80 (s, 3H), IR: 1380, 1365, 1315, 1295, 1155, 1140 and 965 cm^{-1}, MS: *m/e* 206 (M^+, $C_{15}H_{26}$), 191, 178, 163, 150, 135, 123, 109, 81 (base peak), 82, 69 and 55, (Found; C, 87.27; H, 12.70%. $C_{15}H_{24}$ requires C, 87.30; H, 12.70%).

The Hydrogenation of III and IV. III and IV were hydrogenated in methanol using platinum oxide as the catalyst. The products were subjected to preparative gas chromatography, and two dihydroderivatives, panasinsane-A and panasinsane-B, were isolated from both hydrogenation products.

Panasinsane-A, NMR: τ 9.15 (s, 3H), 9.11 (s, 3H), 9.05 (d, J=6 Hz 3H) and 8.85 (s, 3H), IR: 1370, 1365, 1265, 1110 and 1050 cm^{-1}, MS: *m/e* 206 (M^+, $C_{15}H_{26}$), 191, 178, 163, 150, 135 (base peak), 123, 122, 109, 93 and 81, (Found; C, 78.27; H, 12.69%. $C_{15}H_{26}$ requires C, 87.30; H, 12.70%).

Panasinsane-B, NMR: τ 9.12 (s, 3H), 9.08 (s, 3H), 8.86 (s, 3H) and 8.84 (d, J=3 Hz 3H), IR: 1375, 1360, 1160, 1140, 1010 and 985 cm^{-1}, MS: *m/e* 206 (M^+, $C_{15}H_{26}$), 191, 177, 163, 150, 135 (base peak), 124, 109, 93 and 81, (Found; C, 87.28; H, 12.69%. $C_{15}H_{26}$ requires C, 87.30; H, 12.70%).

Isomerization of IV. IV (150 mg) was dissolved in 20 ml

of ethyl ether, and then 2 ml of concd H_2SO_4 were added. After 10 min, the resultant solution was poured into a saturated $NaHCO_3$ solution and extracted with ethyl ether. After drying with Na_2SO_4, the solvent was removed; about 130 mg of oil were thus obtained. The oil was examined by means of gas chromatography. Three new peaks in ratio of 3: 1: trace; they were identified with α-neoclovene, β-neoclovene, and α-panasinsene respectively.

The Ozonolysis of IV. The *n*-hexane solution of IV was subjected to ozonization, and the reaction mixture was shaked with water. After drying with Na_2SO_4, the solvent was removed. The product was purified by mean of gas chromatography.

Tricyclic ketone (V), NMR: τ 9.13 (s, 6H) and 9.02 (s, 3H), IR: 1695, 1470, 1430, 1385, 1375, 1325 and 1920, MS: *m/e* 206 (M^+, $C_{13}H_{22}O$), 191, 178, 173, 163, 151 (base peak), 135 and 107.

The authors wish to express their hearty thanks to Mr. Minoru Shiga of the Shiono Koryo Kaisha, Ltd., for providing the caryophyllene and to Mr. Katsumasa Okamura of Nagano Nogyo Shikensho for provinding the fresh ginseng.

Synthesis of (2*R*, 3*S*, 4*S*)-4-Amino-3-hydroxy-2-methyl-5-(3-pyridyl)-pentanoic Acid Present in Antibiotic Pyridomycin

Mitsuhiro KINOSHITA and Satoshi MARIYAMA

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Kohoku-ku, Yokohama 223

(Received April 12, 1975)

Natural (2*R*,3*S*,4*S*)-4-amino-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoic acid (**1**) present in antibiotic pyridomycin was synthesized. The 5,6-anhydro-1,2-*O*-isopropylidene-3-*C*-methyl-α-D-allofuranose (**4**) was prepared from (the known) 3-deoxy-1,2;5,6-di-*O*-isopropylidene-3-*C*-methyl-α-D-allofuranose (**2**). Regiospecific introduction of 3-pyridyl group to the C-6 of **4** was effected by 3-pyridyllithium. The product (**5**) was converted to the 5-azido derivative (**7**) by the S_N2 substitution reaction of the 5-mesylate (**6**) of **5**. Hydrolysis of **7** followed by two-stage oxidation with periodate-bromine in aqueous acetic acid afforded (2*R*,3*S*,4*S*)-4-azido-3-formyloxy-2-methyl-5-(3-pyridyl)pentanoic acid (**9**), which was transformed to the dihydrochloride of **1**.

A novel amino acid, 4-amino-3-hydroxy-2-methyl-5-(3-pyridyl)pentanoic acid (**1**) present in antimycobacterial antibiotic pyridomycin[1,2] was isolated as a degradation product of pyridomycin by Ogawara, *et al.*[3] Its absolute configuration was established as "2*R*,3*S*,4*S*" (structure **1**) based on the complete structure of the parent antibiotic determined by X-ray crystallographic analysis.[4] This paper presents a synthesis of **1** with the natural configuration from an appropriate sugar derivative through regiospecific and stereospecific routes as shown in the Chart.

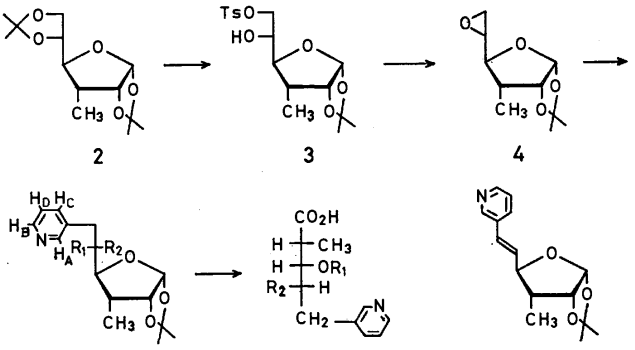

Chart.

Removal of 5,6-*O*-isopropylidene group of (the known) 3-deoxy-1,2; 5,6-di-*O*-isopropylidene-3-*C*-methyl-α-D-allofuranose[5] (**2**) with a warm 91% aqueous acetic acid followed by selective *O*-tosylation in the usual way afforded the 6-tosylate (**3**) in a 65% yield. Treatment of **3** with sodium methoxide in chloroform gave 5,6-anhydro-3-deoxy-1,2-*O*-isopropylidene-3-*C*-methyl-α-D-allofuranose (**4**) in a 76% yield. The epoxide ring of **4** was regiospecifically opened with 3-pyridyllithium[6] in ether at −10 °C to afford 3,6-dideoxy-1,2-*O*-isopropylidene-3-*C*-methyl-6-*C*-(3-pyridyl)-α-D-allofuranose (**5**) in an 88% yield, whose structure was confirmed by PMR spectroscopy. Mesylation of **5** with mesyl chloride in pyridine gave crystalline 5-mesylate (**6**) in a 75% yield. Substitution reaction of **6** with sodium azide in dimethylsulfoxide at 85 °C afforded two kinds of products, which were separated from each other by silica gel column chromatography in homogeneous states. Structural elucidations of the reaction products isolated on the basis of elemental and spectroscopic analyses revealed that the reaction produced one substitution reaction product and one elimination reaction product in 70 and 23% yield, respectively, none of the rearrangement reaction product being formed. Since this substitution reaction seemed to be very characteristic of the S_N2 reaction which should theoretically have only one alternation (*E*2 reaction),[7] the major product above-obtained was considered the expected S_N2 substitution reaction product, 5-azido-3,5,6-trideoxy-1,2-*O*-isopropylidene-3-*C*-methyl-6-*C*-(3-pyridyl)-β-L-talofuranose (**7**), the C-5 configuration of which was opposite to that of **6**. The structure of the minor product assigned to the elimination reaction product was determined as 3,5,6-trideoxy-1,2-*O*-isopropylidene-3-*C*-methyl-6-*C*-(3-pyridyl)-α-D-*ribohex-trans*-5-enofuranose (**8**) by PMR analysis. When the mesylate (**6**) was kept without the nucleophile (azide ion) in dimethyl sulfoxide at ~85 °C, the formation of **8** was never observed. This fact indicated that the compound (**8**) should be formed in the *E*2 reaction of **6** under S_N2 condition. Moreover, the fact that in the case of **6**, such an *E*2 reaction practically occured to some extent, may demonstrate that the 3-pyridylmethyl hydrogens at C-6 of **6** are so active that they are removed by the weakly basic azide ion.

Hydrolysis of **7** in a boiling 20% aqueous acetic acid, followed by successive oxidations of the resultant free sugar with sodium periodate and with bromine in the same aqueous acetic acid at room temperature afforded (2*R*,3*S*,4*S*)-4-azido-3-formyloxy-2-methyl-5-(3-pyridyl)pentanoic acid (**9**) as needles in a 59% yield. It should be noted that the two-stage oxidation of the free sugar must be carried out in the acidic condition at pH≤2, in order to prevent the complicated side reactions including the β-elimination of the formyloxy group which may probably be catalysed by the free pyridyl residue present in its own molecule at heigher pH values than 2.

De-*O*-formylation of **9** with dilute hydrogen chloride in aqueous dioxane at room temperature gave the corresponding azido hydroxy acid (**10**) as a crystalline hydrochloride in an 81% yield. The hydrochloride of **10** was hydrogenolyzed on palladium black in methanol to afford the title compound (**1**) as a monohydrochloride in a 97% yield, from which the dihydrochloride of **1**

was obtained as a colorless hygroscopic powder with a negative rotation ($[\alpha]_D$ −2° in 5 M hydrochloric acid). The synthetic dihydrochloride of **1** proved to be identical with the natural amino acid dihydrochloride derived from pyridomycin according to Ogawara, *et al.*[3] in all respects.

Experimental

Melting points were determined on a Mitamura Riken micro hot-stage and are uncorrected. IR spectra were taken on a Hitachi 225 spectrophotometer, PMR spectra were recorded on a Varian A-60D spectrometer using TMS as an internal standard. Specific rotations were determined with a Zeiss Photoelectric Precision Polarimeter. Tlc was performed on WAKO-GEL B-5 and silica gel column chromatography on WAKO-GEL C-200 which was activated at 110 °C for 1 hr. Paper chromatography was conducted on Toyoroshi No. 525 with butanol–acetic acid–water (3: 1: 1). Paper electrophoresis was carried out with a Savant 1V-5000A in formic acid–acetic acid–water (1: 3: 36). pK_a values were measured with a Metrohm Herisau Potentiograph E436. In general, all concentration were carried out under reduced pressure below 40 °C.

3-Deoxy-1,2-O-isopropylidene-3-C-methyl-6-O-tosyl-α-D-allofuranose (3). Treatment of **2** (7.00 g) prepared according to Rosenthal, *et al.*[5] with a 91% aqueous acetic acid (38.8 ml) at 60 °C for 30 min followed by evaporation afforded a syrup, which was chromatographed through silica gel (140 g) with benzene–ethyl acetate (1: 1) to give a practically pure sample of the de-5,6-*O*-isopyridenation product (5.36 g, 90.5% yield). The product (4.15 g, 18.9 mmol) was tosylated with tosyl chloride (3.99 g, 20.9 mmol) in pyridine by the usual way to afford **3** (5.06 g, 72%) as a colorless syrup: $[\alpha]_D^{28}$ +23° (*c* 1.15, chloroform); $\nu_{max}^{CCl_4}$ 3550 (OH) and 1175 cm^{-1} (sulfonate); $\delta(CDCl_3)$, 1.15 (d, 3-CH_3, J_{3,CH_3}=6.8 Hz), 1.32 and 1.48 [each s, $(CH_3)_2C$], 3.33—4.08 (m, OH and H-3), 4.13 (s, Ar–CH_3), 3.62—4.33 (m, H-4, H-5, and H-6), 4.57 (dd, H-2, $J_{2,3}$=4.9 Hz), 5.77 (d, H-1, $J_{1,2}$=3.9 Hz), and 7.33—7.97 (m, Ar).

Found: C, 55.09; H, 6.53; S, 8.30%. Calcd for $C_{17}H_{24}O_7S$: C, 54.83; H, 6.50; S, 8.60%.

5,6-Anhydro-3-deoxy-1,2-O-isopropylidene-3-C-methyl-α-D-allofuranose (4). A 2.12M solution of sodium methoxide in methanol (6.5 ml) was added dropwise with stirring to a solution of **3** (5.06 g, 13.6 mmol) in dry chloroform (20 ml) under ice-cooling. After the cooled mixture was vigorously stirred, it was allowed to stand at room temperature for 2 hr. The resultant solution was poured into cold water (20 ml) and the mixture was extracted with chloroform. The chloroform layer was washed with satd. aq. NaCl, dried, and evaporated. The syrupy residue (2.69 g) was chromatographed through silica gel (150 g) with benzene–ethyl acetate (5: 1) to afford **4** (2.06 g, 76%) as a colorless syrup: $[\alpha]_D^{25}$ +12° (*c* 0.85, chloroform); $\nu_{max}^{CCl_4}$ 1250 and 870 cm^{-1} (epoxide); $\delta(CDCl_3)$, 1.18 (d, 3-CH_3, J_{3,CH_3}=6.8 Hz), 1.35 and 1.52 [each s, $(CH_3)_2C$], 1.75—2.42 (m, H-3), 2.58—3.17 (m, H-5 and H-6), 3.58 (dd, H-4, $J_{3,4}$= 10.0 Hz and $J_{4,5}$=5.9 Hz), 4.63 (dd, H-2, $J_{2,3}$=4.9 Hz), and 5.88 (d, H-1, $J_{1,2}$=3.9 Hz).

Found: C, 59.84; H, 7.88%. Calcd for $C_{10}H_{16}O_4$: C, 59.98; H, 8.05%.

3,6-Dideoxy-1,2-O-isopropylidene-3-C-methyl-6-C-(3-pyridyl)-α-D-allofuranose (5). The reaction was carried out under nitrogen. An ethereal solution (16.6 ml) of butyllithium (8.61 mmol) was cooled to −35 °C in a dry ice-methanol bath and there was added dropwise with stirring, a solution of 3-bromopyridine (1.82 g, 11.5 mmol) in ether (8 ml) during a period of 30 min. After 15 min, to the bright yellow colored suspension was added dropwise with stirring, a solution of **4** (573 mg, 2.87 mmol) in ether (7 ml), the mixture being maintained at −10 °C for 1.5 hr. The resultant brown mixture was then poured into cold water and extracted with ether twelve times. The ether extracts were washed with satd. aq. NaCl, dried and evaporated to afford a brown syrup (1.24 g). The syrup was chromatographed through silica gel (80 g) with benzene–acetone (1: 1) to give pale yellow crystals of **5** (700 mg, 88%). Recrystallization from ethyl acetate–petroleum ether afforded an analytical sample as a colorless needle: mp 114.0—115.0 °C; $[\alpha]_D^{14}$ +39° (*c* 0.74, chloroform); ν_{max}^{KBr} 3460 (OH), 1585, 1430, 795 and 710 cm^{-1} (pyridine); $\delta(CDCl_3)$, 1.23 (d, 3-CH_3, J_{3,CH_3}=6.8 Hz), 1.38 and 1.55 [each s, $(CH_3)_2C$], 1.83—2.50 (m, H-3), 2.75—3.01 (m, H-6 and OH), 3.75—4.17 (m, H-4 and H-5), 4.65 (dd, H-2, $J_{2,3}$=4.9 Hz), 5.87 (d, H-1, $J_{1,2}$= 3.9 Hz), 7.30 (m, H_D, $J_{A,D}$=1.0 Hz, $J_{B,D}$=5.0 Hz and $J_{D,C}$= 8.3 Hz), 7.73 (m, H_C, $J_{A,C}$=2.6 Hz and $J_{B,C}$=2.0 Hz), 8.40 (m, H_B, $J_{A,B}$=0.5 Hz), and 8.55 (m, H_A).

Found: C, 64.73; H, 7.59; N, 4.91%. Calcd for $C_{15}H_{21}O_4N$: C, 64.49; H, 7.58; N, 5.01%.

3,5,6-Trideoxy-1,2-O-isopropylidene-5-O-mesyl-3-C-methyl-6-C-(3-pyridyl)-α-D-allofuranose (6). Mesylation of **5** (1.20 mmol) with mesyl chloride (1.44 mmol) in dry pyridine (3.4 ml) at room temperature followed by work up in the usual manner afforded a crystalline solid of **6**(540 mg), which was recrystallized from ethyl acetate–petroleum ether to give a pure sample of **6** (333 mg, 75%): mp 111.5—112.0 °C; $[\alpha]_D^{18}$ +31° (*c* 0.89, chloroform); ν_{max}^{KBr} 1360 and 1175 cm^{-1} (sulfonate); $\delta(CDCl_3)$, 1.23 (d, 3-CH_3, J_{3,CH_3}=6.8 Hz), 1.37 and 1.51 [each s, $(CH_3)_2C$], 4.47 (s, $-SO_3CH_3$), 1.83—2.33 (m, H-3), 3.17 (d, H-6, $J_{5,6}$=6.0 Hz), 3.98 (dd, H-4, $J_{3,4}$=10.0 Hz and $J_{4,5}$=4.5 Hz), 4.65 (dd, H-2, $J_{2,3}$=4.8 Hz), 5.01 (dt, H-5), 5.88 (d, H-1, $J_{1,2}$=3.8 Hz), 7.3—7.9 and 8.5—8.9 (each m, 3-pyridyl).

Found: C, 53.67; H, 6.47; N, 3.77; S, 9.02%. Calcd for $C_{16}H_{23}O_6NS$: C, 53.77; H, 6.49; N, 3.92; S, 8.96%.

5-Azido-3,5,6-trideoxy-1,2-O-isopropylidene-3-C-methyl-6-C-(3-pyridyl)-β-L-talofuranose (7) and 3,5,6-Trideoxy-1,2-O-isopropylidene-3-C-methyl-6-C-(3-pyridyl)-α-D-ribohex-trans-5-enofuranose (8). A solution of **6** (331 mg, 0.925 mmol) in dimethylsulfoxide (1.7 ml) was heated with sodium azide (181 mg, 2.78 mmol) at 85 °C for 2 hr: tlc [benzene–acetone (3: 1)] revealed the absence of **6** (R_f 0.37) and the presences of the two products (R_f 0.60 and 0.52). The cooled solution was diluted with water (2 ml) and extracted with ethyl acetate seven times. The extracts were washed with satd. aq. NaCl, dried and evaporated to afford a yellow syrup (295 mg). Column chromatography [silica gel 45 g, benzene–acetone (10: 1)] of the syrup afforded the substitution product (**7**) [R_f 0.60, colorless syrup, 196 mg (70%)] and the elimination product (**8**) [R_f 0.52, colorless needle, 54 mg (23%)].

7: $[\alpha]_D^{15}$ +11° (*c* 1.40, chloroform); $\nu_{max}^{CCl_4}$ 2105 cm^{-1} (N_3); $\delta(CDCl_3)$, 1.02 (d, 3-CH_3, J_{3,CH_3}=6.8 Hz), 1.36 and 1.46 [each s, $(CH_3)_2C$], 2.0—2.6 (m, H-3), 3.0—3.5 (m, H-5 and H-6), 3.80 (dd, H-4, $J_{3,4}$=10.2 Hz and $J_{4,5}$=1.3 Hz), 4.66 (dd, H-2, $J_{2,3}$=4.0 Hz), 5.93 (d, H-1, $J_{1,2}$=3.6 Hz), 7.2—7.9 and 8.5—8.8 (each m, 3-pyridyl).

Found: C, 68.80; H, 7.33; N, 5.31%. Calcd for $C_{15}H_{19}O_3N$: C, 68.94, H, 7.33; N, 5.36%.

(2R,3S,4S)-4-Azido-3-formyloxy-2-methyl-5-(3-pyridyl)-pentanoic Acid (9). A solution of **7** (506 mg, 0.172 mmol) in a 20% aqueous acetic acid (25 ml) was refluxed for 5 hr. After evaporation, the residual syrup (free sugar) was dissolved in a 33% aqueous acetic acid (15 ml) and then cooled at 5 °C, there was added dropwise under stirring a solution of $NaIO_4$ (716 mg) in water (7.2 ml). After 20 min, bromine (0.45 ml) was added to the reaction mixture (pH 2) and allowed to stand at room temperature overnight. The resultant solution was aerated to remove an excess of bromine and evaporated. The residual solid mass was extracted with ethanol (*ca.* 5 ml) and the extract was evaporated to give a yellow syrup (958 mg). Column chromatography [silica gel 50 g, chloroform–methanol–acetic acid (80:5:1)] of the syrup afforded a yellow solid, which was recrystallized twice from acetone to give a pure sample of **9** (275 mg, 59%) as colorless needles: mp 127.5—129.5 °C (decomp.); $[\alpha]_D^{26}$ −114° (*c* 0.57, methanol); ν_{max}^{KBr} 2100 (N_3) and 1725 cm^{-1} (OCHO and COOH); $\delta(CDCl_3)$, 1.34 (d, 2-CH_3, J_{2,CH_3}=7.1 Hz), 2.73 (dd, H-5, $J_{4,5}$=11.0 Hz, $J_{5,5'}$=14.5 Hz), 3.16 (dq, H-2, $J_{2,3}$=4.5 Hz), 3.54 (dd, H-5′, $J_{4,5'}$=3.6 Hz), 4.13 (dq, H-4, $J_{3,4}$=8.0 Hz), 5.53 (dd, H-3), 7.4—8.2 and 8.7—9.1 (each m, 3-pyridyl), 8.47 (s, OCHO), and 12.0—12.3 (broad s, COOH).

The Facile Synthesis of 5′-Nucleotides by the Selective Phosphorylation of a Primary Hydroxyl Group of Nucleosides with Phosphoryl Chloride*

Tsuneo Sowa and Shunji Ouchi

Research Section, Foodstuff Plants, Asahi Chemical Industry Co., Ltd., Nobeoka, Miyazaki 882

(Received June 6, 1974)

5′-Nucleotides were directly prepared by selective phosphorylation with phosphoryl chloride in the presence of water and pyridine in acetonitrile. The rate of phosphorylation with phosphoryl chloride was markedly improved by the addition of suitable amounts of water and pyridine; the maximal formation of 5′-nucleotides was obtained by mixing these three reactants phosphoryl chloride, water, and pyridine in a molar ratio of 2:1:2 at a low temperature, followed by adding nucleosides corresponding to a one-fourth or one-fifth of the phosphoryl chloride. By mixing phosphoryl chloride, water, and pyridine in acetonitrile under controlled conditions, a hygroscopic complex (Complex 1), an active phosphorylating agent in the present phosphorylation of nucleosides, was isolated. It was identified as an adduct composed of tetrachloropyrophosphate and pyridinium chloride by means of its infrared spectra and by its chromatographic behavior. One of the proposed structures of the adduct is trichloropyrophosphopyridinium chloride. Both the selectivity in the 5′-hydroxyl group of the nucleosides and the yield of 5′-nucleotides increase upon the addition of pyridinium chloride in the phosphorylation of the unprotected nucleosides with tetrachloropyrophosphate. In the phosphorylation with tetrachloropyrophosphate, the H^+ derived from pyridinium chloride in acetonitrile is considered to increase the selectivity for the 5′-hydroxyl group by decreasing the reactivity of the hydroxyl groups in the ribose moiety of the nucleosides with the adduct. Similar results were obtained in the phosphorylation with phosphoryl chloride in the presence of pyridinium chloride in acetonitrile. Thus, several procedures for the selective phosphorylation of unprotected nucleosides to 5′-nucleotides are available.

Several attempts at the direct and selective phosphorylation of the 5′-hydroxyl group of nucleosides in the unprotected form have been made. Along those lines, 5′-nucleotides have been prepared from the corresponding nucleosides by direct phosphorylation with phosphoryl chloride in pyridine.[1,2] However, all of these methods are far from practical either in the laboratory or for commercial application because of the low conversion of nucleosides into nucleotides and because of the low selectivity in the formation of 5′-nucleotides.

Recently, Yoshikawa *et al.*[3] reported the preparation of 5′-nucleotides in good yields from the corresponding nucleosides by direct phosphorylation with phosphoryl chloride in trialkylphosphates; they also reported that, by the addition of an adequate amount of water to the reaction mixture, the competitive phosphorylation of the 2′ (or 3′)-hydroxyl group was strongly inhibited.

In the present paper, the authors will describe the methods of preparing the 5′-nucleotides by direct phosphorylation, with a complete selectivity for the primary hydroxyl group of nucleosides in acetonitrile, and will discuss the possible reaction mechanisms.

The nucleosides used in this experiment are adenosine (An-R), guanosine (Gn-R), inosine (Hx-R), xanthosine (Xn-R), uridine (Un-R), cytidine (Cn-R), 1-β-D-arabinofuranosyl uracil (Ara–Un), 1-β-D-arabinofuranosyl cytosine (Ara-Cn), 9-β-D-arabinofuranosyl adenine (Ara-An), 2′-deoxycytidine (Cn-dR), 2′-deoxyuridine (Un-dR), 8-bromoadenosine (Br-AnR), 8-hydroxyadenosine (8-OH-AnR), 8-mercaptoadenosine (8-SH-AnR), 8-bromoguanosine (8-Br-GnR), N^6-*n*-butyladenosine (N^6-Bu-AnR), 8,2′-*S*-anhydro(9-β-D-arabinofuranosyl) 8-mercaptoadenine (*S*-Anhyd-An), 2,2′-*O*-anhydro(1-β-D-arabinofuranosyl) cytosine hydrochloride (Anhyd-Cn), 2,2′-*O*-anhydro(1-β-D-arabinofuranosyl) uracil (Anhyd-Un), and 5-amino-1-β-D-ribofuranosylimidazole-4-carboxamide (AICAR).

Results and Discussion

Phosphorylation of Unprotected Nucleosides. When inosine was subjected to the addition of phosphoryl chloride in the presence of water and pyridine in acetonitrile, inosine-5′-phosphate (5′-IMP) was exclusively obtained; the yield reached 92.4%. 5′-Nucleotides with the other base components listed in Table 1 could similarly be obtained with an almost complete selectivity in the 5′-hydroxyl group, but the nucleoside containing 8-bromoguanine was resistant to direct phosphorylation by phosphoryl chloride.

One of the advantages of the present phosphorylation method was distinctly demonstrated in the preparation of 5′-arabinonucleotides. Since the arabinonucleoside has no 2′,3′-*cis*-diol group, which could be easily protected with the isopropylidene or the benzylidene group, it has been difficult to prepare 5′-arabinonucleotides by a conventional phosphorylation method. For example, when Schreckel *et al.*[4] prepared 1-β-D-arabinofuranosyl cytosine 5′-monophosphate by the phosphorylation of 2′,3′-*O*-benzylidene cytidine with polyphosphoric acid, the yield amounted to only 10%. It was found that the present method was much superior to Schreckel's method for preparing 5′-arabinonucleotides because the phosphorylation of the arabinonucleosides could be accomplished directly without the introduction of any protecting groups to the secondary hydroxyl groups in the sugar moiety.

Similarly, 2′-deoxyuridine, 2′-deoxycytidine, 2,2′-*O*-

* Most of this study was presented at the 22nd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1969.

Table 1. Direct phosphorylation of nucleosides

AICAR[b]	27	1	76.9	—

Experimental conditions:
CH_3CN 10 ml, $POCl_3$ 44 mmol, C_5H_5N 48 mmol
H_2O listed in above Table, nucleoside 10 mmol at 2 °C.

a) Adenine was produced in almost quantitative yield.
b) AICNR-5′MP was produced as a by-product.

anhydro(1-β-D-arabinofuranosyl) uracil, and 8,2′-*S*-anhydro(1-β-D-arabinofuranosyl)-8-mercaptoadenine, all with no 2′,3′-*cis*-diol group, could be easily phosphorylated to prepare the corresponding 5′-nucleotides in good yields. All attempts at the phosphorylation of 2′-deoxyadenosine and 2′-deoxyguanosine failed because of the lability of their glycosidic linkage and their low solubilities.

The phosphorylation of 5-amino-1-β-D-arabinofuranosylimidazole-4-carboxamide (AICAR) under the present conditions gave 5-amino-1-β-D-arabinofuranosylimidazole-4-carboxamide 5′-phosphate (AICAR-5′-MP).[5] In addition to the expected 5′-phosphomonoester, its dehydrated derivative, 1-β-D-arabinofuranosyl-4-cyano-5-aminoimidazole 5′-phosphate (AICNR-5′-MP, λ_{max} at pH 2.0, 240—242 nm),[6] was detected on the paper electrophoresis of the phosphorylation mixture. AICAR-5′MP was readily isolable from AICNR-5′MP by precipitating the former as its free acid from an acidic aqueous solution at pH 2.5.

In the present phosphorylation, the amounts of the three reagents were held to a definite value. That is, phosphoryl chloride, water, and pyridine were mixed in the molar ratio of 2: 1: 2 at a low temperature, and then nucleosides corresponding to one-fourth or one-fifth of the phosphoryl chloride was added. No reaction was observed without water, and the amount of water was thought to be critical. As is shown in Fig. 1, the formation of inosine 5′-phosphate obviously depended on the amount of water in the reaction

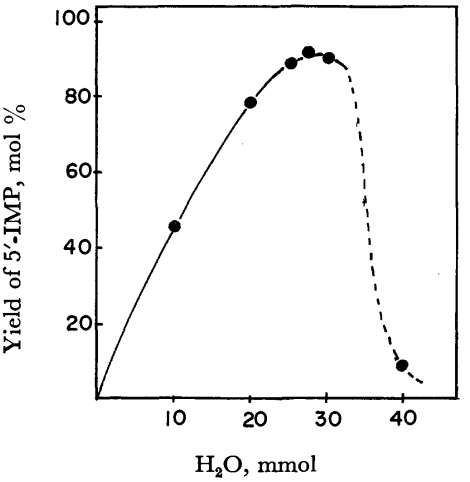

Fig. 1. Effect of water.
Experimental conditions: CH_3CN 10 ml, $POCl_3$ 44 mmol, C_5H_5N 48 mmol, H_2O: figured above, inosine 10 mmol at 2 °C.

media. When about 0.6 mol of water per mole of phosphoryl chloride was added, the yield of inosine 5′-phosphate rose to 90%. Either an increase or a decrease in the amount of water remarkably decreased the formation of inosine 5′-phosphate.

Yoshikawa *et al.*[3] reported that 5′-nucleotides were selectively obtained by treating the unprotected nucleosides with phosphoryl chloride in trialkylphosphates in the presence of a half amount of water per mole of phosphoryl chloride. In the present phosphorylation, however, there was no reaction without pyridine, the amount of pyridine was thus thought to be critical, too. When an amount of pyridine equimolar to phosphoryl chloride was added, the best result was obtained, as is shown in Fig. 2. The reaction temperature also influenced the phosphorylation yield and selectivity toward the 5′-hydroxyl group. In the present phosphorylation, the maximal formation of 5′-nucleotides was obtained in the reaction at a temperature between 0 and 2 °C (Fig. 3). A reaction at a higher temperature brought about an unfavorable formation of inosine 2′ (or 3′), 5′-diphosphate, and of hypoxanthine

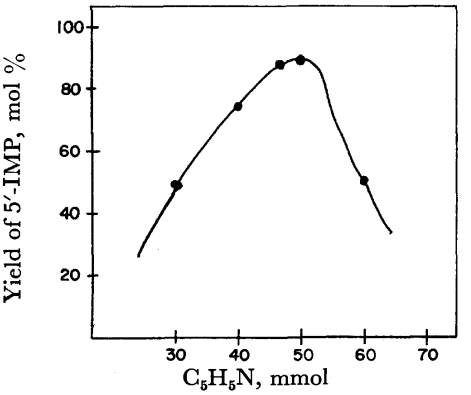

Fig. 2. Effect of pyridine on the direct phosphorylation of nucleosides.
Experimental conditions: CH_3CN 10 ml, $POCl_3$ 44 mmol, H_2O 28 mmol; C_5H_5N: figured above, inosine 10 mmol at 2 °C.

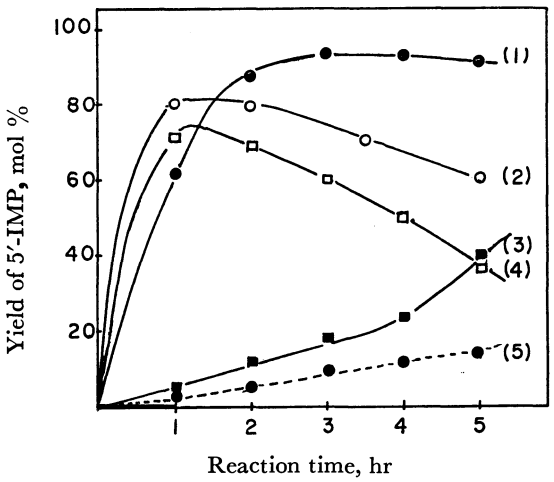

Fig. 3. Effect of reaction temperature.

reaction temp.: (1) at 2 °C, (2) at 10 °C, (3) at 20 °C, (4) inosine 2′ (or 3′),5′-diphosphate produced at 20 °C, (5) hypoxanthine produced at 20 °C.

due to the cleavage of the glycosidic linkage.

Possible Mechanisms of the Selective Phosphorylation of the Unprotected Nucleoside. In the present phosphorylation described above, it was requisite to maintain the molar ratio of phosphoryl chloride, water, and pyridine at 2: 1: 2. On the basis of the evidence obtained so far, the real phosphorylating agent was assumed to be a species different from phosphoryl chloride. Phosphoryl chloride was partially hydrolyzed to dichlorophosphoric acid,[7] which was then further hydrolyzed provided an excess of water was present:

$$POCl_3 + H_2O + C_5H_5N \longrightarrow POCl_2(OH) + C_5H_5NHCl$$

In the present phosphorylation, the amount of water was strictly controlled, and only one-half of phosphoryl chloride was hydrolyzed to dichlorophosphoric acid. Moreover, in this hydrolysis only one mole of water and of pyridine was utilized; the stoichiometry of these reactants effected a phosphomonoester formation shown to have a molar ratio of phosphoryl chloride, water, and pyridine not of 1: 1: 1 but of 2: 1: 2. This seems to show that dichlorophosphoric acid might not be a phosphorylating agent. It is known that dichlorophosphoric acid is capable of reacting with phosphoryl chloride to give tetrachloropyrophosphate:[13]

$$HOPOCl_2 + POCl_3 + C_5H_5N \longrightarrow P_2O_3Cl_4 + C_5H_5NHCl$$

In this formation of tetrachloropyrophosphate from dichlorophosphoric acid, one mole of phosphoryl chloride and of pyridine were utilized, and the amounts of phosphoryl chloride, water, and pyridine were in the molar ratio of 2: 1: 2. Thus, the real species acting for the phosphorylation was considered to be tetrachloropyrophosphate, which dichlorophosphorylated the 5′-hydroxyl group in the reaction with the nucleoside. The pyrophosphate linkage in the tetrachloro-derivative of pyrophosphoric acid is extremely sensitive to hydrolysis with a base. The necessity to keep the amount of water limited and to keep the temperature low during the phosphorylation has been explained by the above discussion.

If tetrachloropyrophosphate is the species causing the selective phosphorylation at the 5′-hydroxyl group, dichlorophosphoric acid should be produced as an intermediate during the reaction. The transient formation of dichlorophosphoric acid is further indicated by the following evidence. The reaction of *t*-butanol with phosphoryl chloride is known to give dichlorophosphoric acid:[3,7]

$$POCl_3 + t\text{-}C_4H_9OH \longrightarrow POCl_2(OH) + t\text{-}C_4H_9Cl$$

If water provides a hydroxyl group to substitute for a chlorine atom in phosphoryl chloride, and if dichlorophosphoric acid is then actually formed, *t*-butanol might be utilized in place of water. Since *t*-butanol acts as an acceptor of the chlorine atom (as in the above equation), the molar ratio of phosphoryl chloride, *t*-butanol, and pyridine for the preparation of tetrachloropyrophosphate should be kept at 2: 1: 1. In the present study, in fact, under these conditions, 5′-nucleotides were similarly obtained by the direct phosphorylation of common nucleosides, in good agreement with the results obtained in the phosphorylation with phosphoryl chloride in the presence of water and pyridine, as is shown in Table 2. Though it was shown

that *t*-butanol could be replaced by methanol or ethanol without affecting the reaction yield and selectivity** in the phosphorylation, its isomeric *n*-butanol gave poor results. *n*-Butanol was shown not to produce dichlorophosphoric acid, but to provide its phosphomonoester by reacting with phosphoryl chloride; it was not considered to be suitable for the preparation of tetrachloropyrophosphate in the presence of pyridine.

However, when the unprotected nucleosides were subjected to a reaction with tetrachloropyrophosphate in acetonitrile, it was found that the reaction went

** Selectivity of 5′-nucleotides is defined as the molar ratio (%) of 5′-nucleotides to all of the phosphorylated product.

a) nucleoside 2′ (or 3′), 5′-diphosphate

essentially to completion within half an hour, that the 5′-nucleotides, except for uridine 5′-phosphate and xanthosine 5′-phosphate, were obtained in yields between 60 and 80%, and that considerable amounts of the phosphorylated by-products, nucleoside 2′ (or 3′), 5′-diphosphate, were formed (Table 3). Similar results had been obtained by the direct phosphorylation of nucleosides with tetrachloropyrophosphate in trialkylphosphate.[3] Therefore, it can not be concluded that tetrachloropyrophosphate acts alone in the efficient selective phosphorylation of the 5′-hydroxyl group of nucleosides.

When phosphoryl chloride, water, and pyridine were mixed in acetonitrile at a low temperature and when the reaction mixture was then treated with dry ether, hygroscopic crystals (Complex 1) were obtained; they began to soften at 40 °C and were completely molten at 50—51 °C. The thin-layer chromatography of this hygroscopic product showed a different behavior from tetrachloropyrophosphate (Fig. 4). The infrared spectra of the product was not the same as that of tetrachloropyrophosphate. Moreover, a crystalline product (Complex 2) which has been prepared by reacting tetrachloropyrophosphate with pyridinium chloride in the molar ratio of 1:2 showed the same hygroscopic

properties, and its chromatographic behavior was quite similar to that of Complex 1. The identity of Complex 1 with Complex 2 was further confirmed by a comparison of their infrared spectra (Fig. 5). The infrared spectra of Complex 1 and Complex 2 both included a broad strong band due to P=O stretching at 1280 cm^{-1}, a broad band associated with the P–O–P group at 980 cm^{-1} and three fairly sharp bands at 2500, 2200, and 1680 cm^{-1} (–C=N$^+$–stretching). The fact that both Complex 1 and Complex 2 absorb ultraviolet light strongly suggests the presence of pyridine as a constituent of both these complexes.

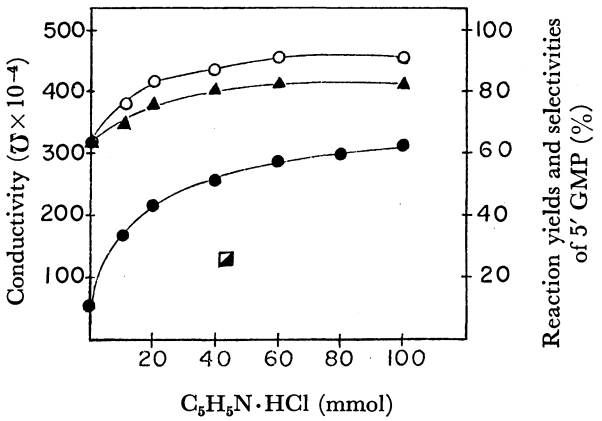

Fig. 6. Effect of pyridinium chloride.

○: selectivity of 5′-guanylic acid (5′ GMP), ●: reaction yield of 5′ GMP, ▲: conductivity, ◪: conductivity in the absence of $P_2O_3Cl_4$.

Figure 6 shows the conductivity of mixtures of tetrachloropyrophosphate with varying amounts of pyridinium chloride in acetonitrile. The conductivity increases with the addition of pyridinium chloride to four times the initial value when pyridinium chloride equivalent to twice the molar amount of tetrachloropyrophosphate is present. Similar results were obtained on the addition of water after the mixing of phosphoryl chloride and pyridine in acetonitrile, and the same conductivity was obtained when water was

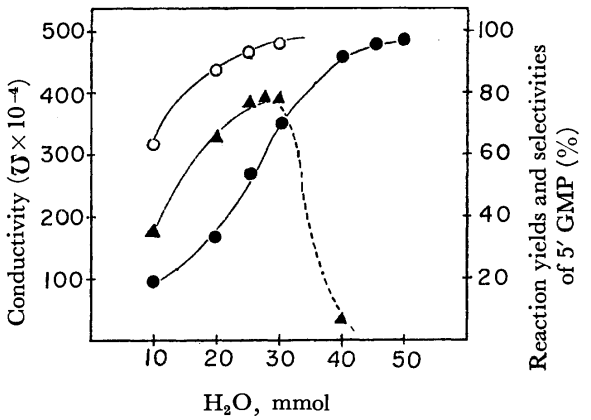

Fig. 7. Effect of water on conductivity, the reaction yield and selectivity of 5′ GMP.

added in half the molar amount of phosphorus oxychloride (Fig. 7). On the other hand, the conductivity of pyridinium chloride was only 105×10^{-4} ℧ at the same concentration in anhydrous acetonitrile, as is plotted in Fig. 6. The results obtained suggest that the active phosphorylating agent formed by the reaction of phosphoryl chloride with pyridine containing water is an adduct of tetrachloropyrophosphate with pyridinium chloride, which is readily dissociated into charged species in solution.

In order to test the potency of the adduct for selective phosphorylation, a common nucleoside was reacted with tetrachloropyrophosphate in the presence of varying amounts of pyridinium chloride. A typical example is shown in Fig. 6. Both the reaction yield and the selectivity of phosphorylation were obviously influenced by the amount of pyridinium chloride. The results presented in Table 4 showed a good agreement with those obtained in the mixture of phosphoryl chloride, water, and pyridine.

Although, at the present stage of the investigation, no definite determination of the structure of the adduct of tetrachloropyrophosphate with pyridinium chloride has been made, one proposed structure is trichloropyrophosphopyridinium chloride, which would be formed as in the following equations:

$$C_5H_5NHCl \rightleftharpoons C_5H_5N^+H + Cl^- \quad (1)$$

$$C_5H_5N^+H \rightleftharpoons C_5H_5N + H^+ \quad (2)$$

$$Cl_2P(O)-O-P(O)Cl_2 + C_5H_5N \longrightarrow \left[Cl_2P(O)-O-P(O)(Cl)-N^+C_5H_5\right] Cl^- \quad (3)$$

One possible hypothesis is that H^+ derived as indicated in the above equations increases the conductivity of the mixture in acetonitrile, and also increases the selectivity for the 5′-hydroxyl group by decreasing the reactivity of the hydroxyl groups in the ribose moiety of nucleosides with the adduct.

5′-Nucleotides could not be obtained by reacting nucleosides with phosphoryl chloride in the presence of water and strong bases, such as triethylamine, morpholine, or pyrolidine, in acetonitrile (Table 5). In the phosphoylation with tetrachloropyrophosphate,

however, interesting evidence was obtained that the above organic amine hydrochloride could replace pyridinium chloride (Table 6). The reaction of morpholine with phosphoryl chloride is knwon to give morpholinophosphorodichloridate or dimorpholinophosphorochloridate.[8,9] This means that, in the reaction of the free base with phosphoryl chloride, no adducts were derived because the strong base is too reactive to permit the substitution of a chlorine atom by a hydroxyl group; thus, no formation of dichlorophosphoric acid as an intermediate occurs.

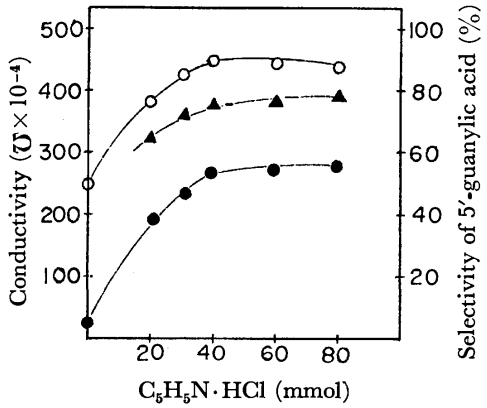

Fig. 8. Effect of pyridinium chloride on conductivity and selectivity of 5′-guanylic acid.

●: conductivity.

The addition of pyridinium chloride to phosphoryl chloride in acetonitrile also increased the conductivity of the mixture (Fig. 8). This shows that a dissociable adduct, dichlorophosphopyridinium chloride, similar to trichloropyrophosphopyridinium chloride was probably present in this mixture, suggesting the selective formation of 5′-nucleotides by directly reacting nucleosides with phosphoryl chloride in the presence of pyridinium chloride. As expected, 5′-nucleotides were formed in yields between 85 and 98% from the corresponding nucleosides under the above conditions, as is shown in Table 7.

the 5′-hydroxyl group (Table 8). Nitromethane and methylene chloride, which dissolve nucleosides completely, are useful as reaction solvents in place of acetonitrile. However, no 5′-nucleotides were formed in dimethylformamide (DMF) or *n*-butanol, presumably because both the amide and alcohol were so reactive to phosphoryl chloride. In acetone, the isopropylidenation reaction took place in inosine at the same time to give 2′,3′-*O*-isopropylidene inosine 5′-phosphate in a 38% yield.

The methods described here simple, direct ways to effect phosphorylation with a complete selectivity to the primary hydroxyl group of nucleosides under mild conditions; they have been adapted to produce the 5′-nucleotides economically.

Experimental

The ultraviolet spectra were recorded on a Hitachi EPS-2T spectrophotometer, and the infrared spectra, on a Hitachi EPI-G2. The conductivity experiments were run on a Shimadzu conduction meter. The paper chromatography was carried out by the ascending technique on Toyo-Roshi No. 51 paper (40×40 cm), using the following solvent systems: Solvent A, isopropyl alcohol–saturated ammonium sulfate–1M-sodium acetate, 2: 79: 19, Solvent B, *n*-butanol–acetic acid–water 4: 1: 5. The paper electrophoresis of the product was performed on the same paper with a 0.05M-borate buffer (pH 8.8) and a 0.05M-citrate buffer (pH 2.5) at a potential gradient of 1.5 kV/cm, for 1 hr. The structure of 5′-nucleotides was confirmed by both a sodium periodate–benzidine test[10] and a 5′-nucleotidase of bull-seminal-plasma treatment.[11] Thin-layer chromatography was used for the identification of the reaction product obtained by mixing phosphoryl chloride, water and pyridine; it was carried out on Wakogel B-5F with Solvent C, ethyleneglycohol dimethyl ether, in a dry box. The location of the products on the layer was determined by the Allen method[12] and by ultraviolet absorption. The nucleotides were identified by a comparison of the R_f-values with those of the authentic samples, as summarized in Table 9.

Preparation of Tetrachloropyrophosphate. Tetrachloropyrophosphate was readily obtained by the method of Craft.[8] A mixture of phosphoric oxide (42.6 g, 0.15 mol) and phosphorus pentachloride (97.8 g, 0.47 mol) was heated at 105 °C for 8 hr, and then cooled and filtered. The solid was washed with carbon tetrachloride, and the combined filtrate and washings were distilled, giving tetrachloropyrophosphate (18.3 g, 31.3 %). Bp 101—103 °C/10 mmHg, d_4^{20}, 1.81.

Preparation of Complex 1. Into a mixture of freshly distilled phosphoryl chloride (20.2 g), water (1.18 g) pyridine (10.4 g), and acetonitrile (23 g) were vigorously stirred at a temperature of 2 °C. Dry ether (100 ml) was then added to the reaction mixture; the precipitate was separated by filtration, washed with ether, and then dried. The hygroscopic crystals (25.8 g) began to soften at 40 °C and was completely molten at 50—51 °C.

Preparation of Complex 2. The hygroscopic crystal (22.3 g) were prepared by mixing tetrachloropyrophosphate (15 g) and pyridinium chloride (13.8 g) in acetonitrile, followed by adding ethyl ether (300 ml) in essentially the same manner as has been described above. Mp 82—88 °C.

Phosphorylation of Nucleosides in the Unprotected Form.

Method A: To a mixture of freshly distilled phosphoryl chloride (44 mmol), water (28 mmol), pyridine (48 mmol), and acetonitrile (189 mmol), which was maintained at 2 °C with stirring, we added a nucleoside (10 mmol, dried at 120 °C for 4 hr), after which the mixture was maintained for 4 hr. The reaction mixture was poured into ice water and stirred further for 1 hr at 5 °C. The resulting solution was analyzed by the paper electrophoretic method described above. The results obtained are listed in Table 1.

Method B: A nucleoside (10 mmol) was dissolved in a mixture of tetrachloropyrophosphate (22 mmol) and acetonitrile (190 mmol), after which the resulting mixture was poured into ice water and analyzed by the paper-electrophoretic method. The results obtained are listed in Table 3.

Method C: A solution which contained a 5′-nucleotide was obtained by reacting the nucleoside (10 mmol) with a mixture of phosphoryl chloride (44 mmol), alcohol (24 mmol), and pyridine (24 mmol) in acetonitrile (190 mmol) in essentially the same manner as that described for Method A. The results obtained are listed in Table 2.

Method D: A solution which contained a 5′-nucleotide was obtained by reacting the nucleoside (10 mmol) with phosphoryl chloride (24 mmol) or tetrachloropyrophosphate (24 mmol) in the presence of pyridinium chloride (44 mmol) in acetonitrile (190 mmol) in the same way as in Method A. The results obtained are listed in Table 4 and Table 7.

Effect of Base on Palladium-Black Catalyzed Carbonylation of Iodobenzene

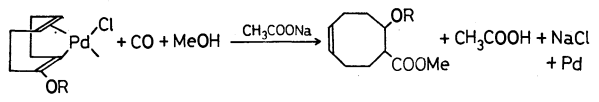
Takeshi Ito, Kunio Mori, Tsutomu Mizoroki, and Atsumu Ozaki

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received October 22, 1974)

It was found that palladium-black is a highly active catalyst for the carbonylation of iodobenzene with carbon monoxide and methanol in the presence of potassium acetate, triethylamine, or tributylamine to give methyl benzoate. The kinetic study of the carbonylation showed that the oxidative addition of iodobenzene to a palladium(0) complex is rate-determining, and that the bases affect considerably the rate-determining step.

It is known that relatively stable alkoxy-enyl complexes such as **1** are quantitatively carbonylated in the presence of sodium acetate in methanol[1] and that a complex containing Pd–C sigma-bond reacts extremely rapidly with carbon monoxide in the presence of sodium methoxide in methanol–benzene to give the corresponding ester almost quantitatively.[2] Maitlis, *et al.* demonstrated that an acyl–Pd bond is much less readily cleaved by acid than by base.[2] The styrene-palladium complex can be carbonylated with carbon monoxide and alcohol in the presence of tertiary amines to give cinnamate and phenylsuccinate *via* carbomethoxy palladium as an intermediate.[3,4] Hidai, *et al.* obtained $Pd(CO)(P\phi_3)_3$ and $Pd_3(CO)_3(P\phi_3)_3$ by the reaction of $PdCl_2(P\phi_3)_2$ with carbon monoxide in methanol-amine systems by use of primary or secondary amines, while a carbomethoxy complex, $(P\phi_3)_2PdCl(COOCH_3)$, was isolated by use of tertiary amines.[5]



1

The present work was undertaken to examine whether these stoichiometric reactions in a basic medium is reflected in a palladium-catalyzed carbonylation. Palladium(0) complexes is readily oxidized by aryl iodide and bromide to give σ-arylpalladium(II) complexes.[6,7] This reaction was successfully utilized for the palladium-black catalyzed phenylation of olefin with iodobenzene in the presence of potassium acetate in methanol.[8] In a basic medium, palladium-black is also highly active for the carbonylation of iodobenzene. Thus, the effect of bases on the carbonylation was kinetically investigated.

Experimental

Procedure. All the carbonylations were carried out using a Ti–Mn alloy autoclave (100 ml) equipped with a magnetic stirrer. The experimental procedure is illustrated by the carbonylation of iodobenzene with carbon monoxide and methanol to give methyl benzoate. Iodobenzene (40 mmol), methanol (1—30 ml), palladium-black (0.01—1.0 mmol), and a base selected from potassium acetate, triethylamine, and tributylamine were placed in the autoclave. Benzene or toluene (30 ml) was used as the solvent, if necessary. The autoclave was heated up to a desired temperature (60—130 °C) within 20 min, and carbon monoxide (purity 98%) was then introduced up to 5—70 kg/cm². The pressure was kept constant during the reaction by supplying carbon monoxide from a high pressure vessel. After the reaction, the autoclave was rapidly cooled by water, and then carbon monoxide was purged out.

Analysis. Liquid products were quantitatively determined by gas chromatography. A DC-550 columun (3 m) with hydrogen carrier was used at 130 °C for the determination of methyl benzoate, iodobenzene, benzaldehyde, and propiophenone by use of bromobenzene as an internal standard. The amounts of benzal acetophenone and benzanilide were determined using the same columun at 190—230 °C with benzophenone or 1-bromonaphthalene as an internal standard. All the materials were obtained from commercial sources, and utilized without purification.

Results and Discussion

Formation of Methyl Benzoate. As shown in Table 1, the yield of methyl benzoate increased with increase in the amount of potassium acetate. Most of iodobenzene is consumed for the carbonylation when the amount (mmol) of potassium acetate exceeds that of iodobenzene used. Benzoic acid was always found as a product, although its amount was not determined. Accordingly the selectivity based on the amount of iodobenzene consumed is higher than that described in Table 1. The reaction mixtures were always colourless, and most of the catalyst was present in the form of palladium-black. Triethylamine and tributhylamine were also effective, while pyridine was much less

effective giving a reddish reaction mixture, from which a palladium(II) compound, $Pd(C_5H_5N)_2I_2$, was isolated. In any case, neither diphenyl nor anisole was detected in the products. The effect of the amount of palladium-black is also represented in Table 1. Palladium-black is so active that it was difficult to examine the effect of the amount of palladium-black in detail.

The effects of the amount of methanol and the pressure of carbon monoxide on the yield of methyl benzoate using triethylamine ($C_6H_5I/N(C_2H_5)_3=1/1.25$ in mol) and benzene as the solvent, are shown in Figs. 1 and 2 respectively. The yield of methyl benzoate is independent of the amount of methanol when the molar ratio of methanol to iodobenzene is more than 3 (Fig. 1). The carbonylation is slightly retarded under higher pressures of carbon monoxide (Fig. 2). The rate of carbonylation was determined under a constant pressure of carbon monoxide (20 kg/cm²) in the presence of enough amounts of methanol ($MeOH/C_6H_5I=7/1$ in mol) and triethylamine or tributhylamine (amine/$C_6H_5I=1.25/1$ in mol) as the base. The results are shown in Fig. 3, where C_t is the conversion of iodobenzene. The yield of methyl benzoate significantly

depends not only on the base used, but also its amount as described in Table 1. It was confirmed, however, that in the presence of an enough amount of a base (base/$C_6H_5I\geq1$), the carbonylation rate was almost independent of its amount. Potassium acetate was not used for this kinetic study because of its low solubility in benzene. Admitting that the concentration of an active palladium species is constant during the reaction with an equilibrium apparently established among the enough amount of amine, carbon monoxide, and palladium-black, the rate is proportional to the amount of iodobenzene. The rate constants are obtained from the gradients of these linear plots, and the Arrehenius plot is shown in Fig. 4. Tributhylamine needs higher reaction temperature than triethylamine does, while the apparent activation energy in the former case (14 kcal/mol) is smaller than that in the latter case (25 kcal/mol).

In the arylation of olefin with iodobenzene catalyzed by palladium-black, it was considered that the palla-

dium-black supplied an active palladium complex of low oxidation state during the reaction, and that the arylation proceeded *via* σ-arylpalladium intermediate.[8] Four processes were proposed as essential for the arylation of olefin. The kinetics of carbonylation of iodobenzene with carbon monoxide and methanol can also be understood by the following scheme similar to that of the arylation. The fact that the rate of car-

$$\underset{\mathbf{2}}{PdL_n} + C_6H_5I \longrightarrow \underset{\mathbf{3}}{C_6H_5PdIL_{n-2}} + 2L \quad (1)$$

$$C_6H_5PdIL_{n-2} + CO \longrightarrow \underset{\mathbf{4}}{C_6H_5COPdIL_{n-2}} \quad (2)$$

$$C_6H_5COPdIL_{n-2} + CH_3OH \longrightarrow C_6H_5COOCH_3 + \underset{\mathbf{5}}{HPdIL_{n-2}} \quad (3)$$

$$HPdIL_{n-2} + 2L + \text{base} \longrightarrow PdL_n + (\text{H-base})^+ I^- \quad (4)$$

(L=CO, base, or solvent)

bonylation is proportional to the amount of iodobenzene as shown in Fig. 3, indicates the oxidative addition of iodobenzene to the palladium complex 2, where n is probably 4 as seen in $Pd(CO)(P\phi_3)_3$ and $Pd(P\phi_3)_4$, to be rate-determining. The acylpalladium intermediate 4 must be formed rapidly, because of no increase in the yield of methyl benzoate with increasing the pressure of carbon monoxide as shown in Fig. 2. This is consistent with the fact that neither diphenyl nor anisole was detected in the product. Methyl benzoate must be also formed rapidly by the attack of methanol to the acylpalladium 4, because the yield of methyl benzoate is almost independent of the amount of methanol as shown in Fig. 1. This is consistent with the result of stoichiometric reaction that acylpalladium sigma-bond is readily cleaved in a basic medium.[1,2] No detection of palladium(II) compound in the products obtained on using potassium acetate, triethylamine, or tributylamine as the base, suggests that the equilibrium of the reaction (4) is much inclined to the right.

It is worthy of notice that the rate of carbonylation depends significantly on the base used. The difference in the rate and the apparent activation energy shown in Fig. 4 demonstrates that the amines work as ligand to control the concentration of palladium complex **2** and its reactivity for the oxidative addition of iodobenzene. This difference can be explained by assuming that less crowded triethylamine coordinates to the complex **2** more tightly than tributhylamine. That is, triethylamine will keep the concentration of complex **2** higher than tributhylamine during the course of carbonylation, resulting in increasing the rate of reaction (1). Triethylamine, however, needs higher activation energy, since the oxidative addition of iodobenzene to the complex **2** must be accompanied by dissociation of the ligand (amine, CO, and solvent) coordinate to the complex **2**. Pyridine is less effective. It probably stabilizes the intermediate **3**, **4**, or **5**, and retards the regeneration of the active complex **2**.

The other possible scheme, *via* carbomethoxy palladium intermediate, is worthy of metnion here, since carbomethoxy palladium was suggested as an intermediate in the carbonylation of olefin or acetylene.[3,4] Neither of carbomethoxy nor the other palladium(II) complexes, however, were detected in the carbonylation products of iodobenzene. Hidai, *et al.* reported that the stoichiometric reaction of carbomethoxy palladium, $(P\phi_3)_2PdCl(COOCH_3)$, with methyl iodide at 90 °C or with benzyl bromide at 140 °C gave quantitatively methyl acetate or methyl phenylacetate respectively,[5] while the reaction with iodobenzene gave no methyl benzoate even at higher temperature.[9] These facts positively eliminate the scheme *via* carbomethoxy palladium intermediate in the carbonylation of iodobenzene catalyzed by palladium-black.*

Formation of Benzoyl Derivatives. The carbonylation of iodobenzene with carbon monoxide and aniline or hydrogen was examined in benzene or toluene. As summarized in Table 2, the carbonylation in aniline–benzene gives benzanilide selectively. The rate is almost proportional to the amount of iodobenzene. The carbonylation with carbon monoxide and hydrogen also gives benzaldehyde selectively, although it needs an enforced reaction condition. In the absence of carbon monoxide, iodobenzene was hydrogenated quantitatively to benzene under the condition specified in

* Yoshida *et al.* independently reported on the carbonylation of C_6H_5I with CO and methanol catalyzed by $PdCl_2$–Py system (*Nippon Kagaku Kaishi*, **1974**, 1386), where Py seemed to be most effective as the base, and they postulated kinetically the scheme *via* carbomethoxy palladium(II) intermediate. The present carbonylation using palladium-black, however, was strongly retarded by the addition of Py as shown in Table 1, and the catalyst was mostly converted into $Pd(Py)_2I_2$ after the carbonylation. This fact also eliminates the carbomethoxy palladium(II) intermediate.

Table 2, while only a trace amount of benzene was detected in the carbonylation product. The carbonylation with carbon monoxide and ethylene gives a considerable amount of propiophenone and a polymer, contrary to our expectation that acrylophenone would be formed. The sources of hydrogen to give propiophenone remains unclarified. The carbonylation with styrene gives a small amount of benzal acetophenone as determined by retention time of gas chromatograph. The arylation of ethylene or styrene was observed only in the absence of carbon monoxide. The formation of these benzoyl derivatives can also be explained by an acylpalladium intermediate.

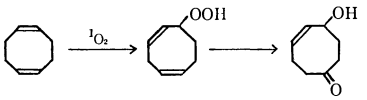
Photosensitized Oxygenation of Unconjugated Cyclic Dienes[1]

Akio HORINAKA, Ruka NAKASHIMA, Masaharu YOSHIKAWA, and Teruo MATSUURA
Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto **606**
(Received December 21, 1974)

The present investigation was undertaken in order to see whether singlet oxygen-oxidation of unconjugated cyclic dienes having spatially close double bonds causes a particular transannular reaction as previously observed with 1,5-cyclooctadiene which gave 4-hydroxy-5-cyclooctenone. Most cyclic dienes tested underwent normal "ene" reaction to give allylic hydroperoxides. Thus, on dye-sensitized photooxygenation followed by reduction with sulfite, dicyclopentadiene, *cis,trans*-1,5-cyclodecadiene, *trans,trans,trans*-1,5,9-cyclododecatriene, 1,4-cyclooctadiene, 1,3-cyclooctadiene, and germacrone yielded a stereoisomeric mixture of tricyclo[5.2.1.$0^{2,6}$]decan-4,8-diene-3-ols, *cis,cis*-2,7-cyclodecadienol, a stereoisomeric mixture of two 2,5,9-cyclododecatrienols, 2,4-cyclooctadienol, *endo*-3,8-peroxide of cyclooctene, and germacra-3,7(11),10(14)-trien-9-ol-6-one(*E*), respectively. Under similar conditions, norbornadiene, and *cis,cis*-1,6-cyclodecadiene remained virtually unchanged.

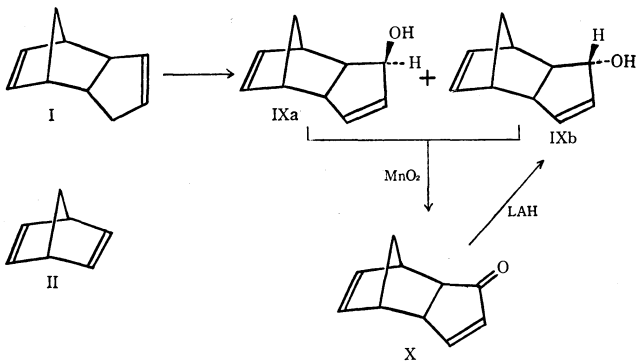
It was reported[2] that the rose bengal-sensitized photooxygenation of 1,5-cyclooctadiene gives 6-hydroperoxy-1,4-cyclooctadiene, a normal "ene" reaction product by singlet oxygen,[3] and 4-hydroxy-5-cyclooctenone which resulted from an unusual transannular reaction of the hydroperoxide, possibly due to the proximity of the reacting groups. As an extension of this type of transannular reaction, the photosensitized oxygenation of various unconjugated cyclic dienes and a triene, some of which are known to often undergo transannular reactions,[4] was investigated.

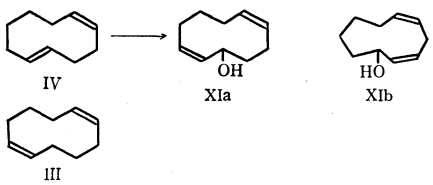


The photosensitized oxygenation of cyclic polyenes I—VIII was carried out in methanol or methylene chloride containing rose bengal or methylene blue as a sensitizer under irradiation with visible light. The reaction mixture was treated with aqueous sodium sulfite in order to reduce the initially formed peroxides. Contrary to our expectation, in most cases the main products were allylic alcohols resulting from a normal "ene" reaction, no particular transannular reaction product being obtained.

Photosensitized oxygenation of dicyclopentadiene (I) followed by reduction gave a 9: 1 mixture of *exo*- (IXa) and *endo*- (IXb) allylic alcohols in 72% yield, which was converted into a single α,β-unsaturated ketone X[5] by treating with active manganese dioxide. On reduction with lithium aluminum hydride X underwent a less-hindered side attack of hydride ion to give exclusively IXb. The structure of the *exo* isomer IXa was confirmed by its synthesis by the oxidation of I with selenium dioxide.[5] The results indicate that I undergoes "ene" reaction with predominant attack of singlet oxygen to the less hindered side of the molecule to give isomeric allylic hydroperoxides corresponding to IXa and IXb.

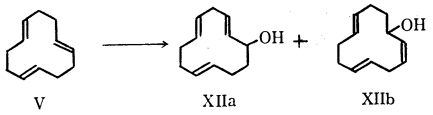
Under similar conditions, norbornadiene (II), and *cis,cis*-1,6-cyclodecadiene (III) remained virtually unchanged, although the former gave a complex mixture of products in a small yield on prolonged photooxygenation. However, *cis,trans*-1,5-cyclodecadiene (IV) suffered photosensitized oxygenation to give, after reduction, a single crystalline cyclodecadienol in 44% yield, for which one of two structures XIa and XIb is possible because of the absence of IR band around 970 cm^{-1} characteristic of a *trans* double bond.[6] Structure XIb was excluded by the fact that the MNR spectrum showed no signal of diallylic methylene protons (C=C–CH_2–C=C) usually appearing at δ 2.78.[7] Predominant formation of XIa from IV indicates that the *trans* double bond of IV is more susceptible to the attack of singlet oxygen than the *cis* double bond, probably due to the more strained nature of the *trans* double bond or to the more axial-like conformation of hydrogens allylic to the *trans* double bond.[8]





Litt and Nickon reported the photosensitized oxygenation of *trans,trans,trans*-1,5,9-cyclododecatriene (V).[9] They pointed out that no *cis-trans* isomerization occurred during photooxygenation but did not describe the reaction products. Photooxygenation of V under the usual conditions gave an about 1: 1.3 mixture of two 2,5,9-cyclododecatrienols in 41% yield and crystalline products in 3% yield. The structures of these two cyclododecatrienols were tentatively assigned as XIIa and XIIb on the basis of the following facts. The NMR spectrum of the mixture was in accord with these structures (see Experimental), and on catalytic hydrogenation the mixture gave cyclodecanol as the sole single product. The crystalline product appeared

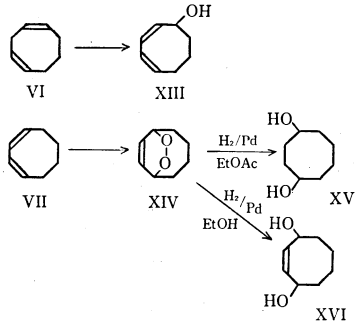
to be a mixture of cyclododecatrienediols but was not further examined.



V XIIa XIIb

Similar sensitized photooxygenation of 1,4-cyclooctadiene (VI) gave a single product for which structure XIII was deduced from its spectral data (see Experimental).

The photosensitized oxygenation of a conjugated cyclic diene, 1,3-cyclooctadiene (VII) was also examined. Both sensitized[10] and unsensitized[11] photooxygenations of VII have been reported. By sensitized photooxygenation, VII is known to give an *endo*-peroxide XIV formed by the 1,4-addition of singlet oxygens to a conjugated diene system.[10] We observed also that methylene blue-sensitized photooxygenation of VII in methylene chloride gave XIV in 53% yield, and that rose bengal-sensitized photooxygenation in methanol gave a complex mixture of products, probably due to participation of the solvent methanol. Peroxide XIV was converted into *cis*-cyclooctane-1,4-diol (XV)[11] and *cis*-2-cyclooctene-1,4-diol (XVI) by controlled hydrogenation.



VI XIII VII XIV XV XVI

Germacra-3,9-diene derivatives have been considered to be important precursors of various types of bicyclic sesquiterpenes, which may be formed by transannular cyclisation *in vivo*.[12] Such types of biogenetic-type syntheses have drawn considerable attention.[13] In an attempt to obtain such a germacradiene precursor having an alcoholic oxygen function, the photosensitized oxygenation of germacrone (VIII) was carried out. Rose bengal-sensitized oxygenation of VIII in methanol yielded a complex mixture of products, from which a crystalline substance was obtained in a low yield. Its IR spectrum showed bands at 3400 (hydroxyl), 1660 (α,β-enone), and 895 cm^{-1} (end methylene). In the NMR spectrum new signals due to vinyl protons at δ 4.86 (singlet) and 5.05 (singlet) and a triplet signal due to a $-\underline{C}H-OH$ proton at δ 3.78 (J=6 Hz) appeared, instead of one of the two methyl signals, δ 1.45 and 1.62, and one of the two di-π-methylene signals at δ 3.16 in VIII. These data suggest two possible structures XVIIa and XVIIb for the product. However, assignment of the NMR spectrum of the photooxygenation product in comparison with those of germacrone (VIII)[14] and of germacrone epoxides XVIII and XIX[15] reveals that the correct structure must be XVIIa, since a doublet signal at δ 2.6 (J=6 Hz), which couples with the $-\underline{C}H-OH$ proton, is not assignable to structure XVIIb. It should be noted that in the photosensitized oxygenation of germacrene (1(10),4,7(11)-germacratriene(E,E)) singlet oxygen attacks predominantly the exocyclic double bond at 7 position but the triphenylphosphite–ozone adduct attacks the most strained double bond at 5 position.[16]

XVIII XIX

Experimental

Materials. Commercial olefins, dicyclopentadiene (I), norbornadiene (II), *trans, trans, trans*-1,5,9-cyclododecatriene (V), and 1,3-cyclooctadiene (VII) were used. The preparation of 1,4-cyclooctadiene (VI) was carried out according to the method of Moon and Gang.[7] *cis, cis*-1,6-Cyclodecadiene (III) and *cis,trans*-1,5-cyclodecadiene (IV) were supplied by Dr. P. Heinbach, Max-Planck-Institut für Kohlenforschung, Mülheim/Ruhr, and germacrone (VIII) by Dr. Y. Hirose, Institute of Food Chemistry, Osaka, and Dr. Y. Tomita, Shionogi Research Laboratories, Osaka.*

Photosensitized Oxygenation of Dicyclopentadiene (I). A solution of I (10 g) and rose bengal (200 mg) in methanol (230 ml) was irradiated with a tungsten–bromine lamp under bubbling oxygen until 0.45 mol equivalent of oxygen (810 ml) was consumed. The reaction mixture was diluted with methanol to 250 ml. In order to determine the peroxide content, an aliquot was analyzed by iodometry which showed that the mixture contained 91 mol % of peroxide based on the consumed oxygen. The reaction mixture was treated with sodium sulfite (7 g) in water (300 ml) under ice-cooling and vigorously stirring for 1 hr. The mixture was concentrated and the aqueous residue was extracted with light petroleum and then with ether. Evaporation of the extracts followed by vacuum distillation gave a mixture of tricyclo[5.2.1.$0^{2,6}$]deca-4,8-diene-3-ols (IXa and IXb) as an oil (3.17 g; 72% yield based on the consumed oxygen); bp 95 °C (bath temperature)/2 mmHg; Mass: m/e 148 (M^+); IR (neat): 3300 (OH), 2940, and 1035 cm^{-1}; NMR (CCl_4): δ 5.4—6.0 (m, 4H), 4.0 (br. s, 1H), 3.8 (br. s, 1H, OH), 3.4 (m, 1H), 3.02 (br. s, 1H), 2.8 (m, 1H), 2.6 (m, 1H), and 1.2—1.7 (m, 2H). Vpc analysis (Silicon DC 550; 180 °C; carrier gas, hydrogen; 1 kg/cm^2) of the oil revealed that it consisted of a 9: 1 mixture of IXa (retention time, 5.0 min) and IXb (4.2 min). The identity of IXa and IXb was confirmed by comparison of their vpc retention times with those of authentic samples, and also by their conversion into X (see below). The authentic samples of IXa and IXb were prepared by selenium dioxide oxidation of I[5] and lithium aluminum hydride reduction of X.[17] The IR spectrum of the oil was almost identical with that of IXa prepared as above.

Oxidation of IXa and IXb into Tricyclo[*5.2.1.*$0^{2,6}$]*decan-4,8-*

* The authors are grateful for the generous supply of these samples.

diene-3-one (X). A 9:1 mixture of IXa and IXb (865 mg) in light petroleum (100 ml) was stirred vigorously with active manganese dioxide (9 g) for 5 hr. After filtration the mixture was concentrated and the residue was purified by sublimation followed by recrystallization from *n*-hexane to give X (582 mg) as colorless prisms; mp 61—63 °C (lit, mp 65.3—65.6 °C[5]); 59—59.5 °C[17]); λ_{max}^{EtOH} 225 nm (ε 8600); NMR (CCl_4) δ 7.3 (dd, 1H, J=2.2 and 6 Hz) and 5.6—6.1 (m, 3H). (Found: C, 81.97; H, 7.14%. Calcd for $C_{10}H_{10}O$: C, 82.11; H, 6.90%).

Photosensitized Oxygenation of cis,trans-*1,5-Cyclodecadiene (IV).* A solution of IV (1.5 g) and rose bengal (200 mg) in methanol (230 ml) was photooxygenated. After being treated with sodium sulfite, the mixture was worked up in a similar manner to the case of I to give XIa (660 mg, 44%) as crystals; mp 96—96.5 °C (from light petroleum); Mass: *m/e* 152 (M^+); NMR (CCl_4): δ 5.3 (m, 4H), 4.32 (m, 1H), 2.34 (s, 1H, OH), 2.22 (m, 2H), 1.85 (m, 4H), and 1.62 (m, 4H).

Found: C, 78.61; H, 10.82%. Calcd for $C_{10}H_{16}O$: C, 78.89; H, 10.59%.

Photosensitized Oxygenation of trans,trans,trans-*1,5,9-Cyclododecatriene.* A solution of V (16.2 g) and rose bengal (300 mg) in methanol (310 ml) was photooxygenated for 25 hr, consuming 0.22 mole equivalent of oxygen (490 ml). After treatment with sodium sulfite, the mixture was worked up as above. Evaporation of the light petroleum extract followed by vacuum distillation gave an oil (1.49 g; 41% based on the consumed oxygen); bp 103 °C/2 mmHg; Mass: *m/e* 178 (M^+); IR (neat): 3300, 2900, 1650, 1440, and 970 cm^{-1}. Vpc analysis revealed that it consisted of 1:1.3 mixture of XIIa and XIIb. A solution of the oil (0.21 g) in ethyl acetate (10 ml) was hydrogenated in the presence of platinum black (25 mg). After filtration, the mixture was evaporated. Recrystallization of the residue from *n*-hexane gave cyclododecanol as crystals, mp 79—80 °C, which were identified by comparison of IR, glc and tlc with those of a commercial sample.

Ether extraction of the original aqueous layer followed by evaporation gave a solid, which on recrystallization from ethyl acetate yielded crystals (110 mg; 3% yield); mp 131—139 °C; IR (Nujol) 3150, 2850, 1660, 1440, 1025, 1010, and 970 cm^{-1}. (Found: C, 74.19; H, 9.44%. Calcd for $C_{12}H_{18}O_2$: C, 74.19; H, 9.34%). These crystals appear to be a mixture of cyclododecatrienediols but were not further examined.

*Photosensitized Oxygenation of 1,4-Cyccloctadiene (VI).*** A solution of VI (1.64 g) and rose bengal (100 mg) in methanol (130 ml) was photooxygenated for 13 hr, consuming 0.81 mol equivalent of oxygen (275 ml). After treatment with sodium sulfite, the mixture was worked up as above to give an oil (806 mg) which on vacuum distillation afforded 2,4-cyclooctadienol (XIII) as an oil (530 mg; 39% based on the consumed oxygen); bp 105 °C (bath temperature)/3 mmHg; Mass: *m/e* 124 (M^+); IR (neat) 3330, 3005, 2925, 2850, 1690, 1445, and 1040 cm^{-1}; NMR (CCl_4): δ 5.9—5.4 (m, 4H), 4.6—4.2 (m, 1H), 2.32 (s, 1H, OH), and 2.7—1.2 (m, 6H); λ_{max}^{EtOH} 210 nm (ε 5600).

Found: C, 77.13; H, 9.70%. Calcd for $C_8H_{12}O$: C, 77.37; H, 9.74%.

Photooxygenation of 1,3-Cyclooctadiene (VII). A solution of VII (5.40 g) and methylene blue (100 mg) in methylene chloride (240 ml) was photooxygenated for 23 hr, consuming 0.6 mol equivalent of oxygen (875 ml). The mixture was washed with water and dried over anhydrous sodium sulfate. Evaporation of the solvent followed by vacuum distillation gave *endo*-3,8-peroxide of cyclooctene (XIV) as crystals (2.58 g; 53% based on the consumed oxygen); bp 80—97 °C/2 mmHg; mp 60—65 °C (lit, mp 50.5—55.5 °C[10]); IR (Nujol,): 1000, 975, 920, and 760 cm^{-1}; NMR (CCl_4): δ 6.23—6.07 (q) 2H), 4.76 (m, 2H), and 2.3—1.3 (m, 8H).

Catalytic Hydrogenation of XIV. Palladium Black: A solution of XIV (100 mg) in ethyl acetate (10 ml) was hydrogenated in the presence of palladium black (30 mg). After removal of the catalyst, the mixture was evaporated to give an oil which was chromatographed on a neutral alumina column (30 g). Elution with 1:1 benzene-acetone yielded 1,4-cyclooctanediol (XV) (54 mg; 55%). Recrystallization from ethyl acetate gave crystals, mp 84—87 °C (lit, mp for *cis*-diol 85—86.5 °C[11]). (Found: C, 66.06; H, 11.42%. Calcd for $C_8H_{16}O_2$: C, 66.63; H, 11.18%).

Palladium Charcoal: A solution of crude XIV prepared by the methylene blue-sensitized photooxygenation of VII (2.7 g) in ethanol (20 ml) was hydrogenated in the presence of palladium charcoal (200 mg) and treated in the same manner as above to give *cis*-2-cyclooctene-1,4-diol (XVI) (105 mg; 38% based on the consumed oxygen in the photooxygenation). Recrystallization from ethyl acetate gave crystals; mp 143—151 °C; IR (Nujol) 3200, 1050, 1030, 960, and 750 cm^{-1}; Mass: *m/e* 142 (M^+).

Found: C, 67.57; H, 9.93%. Calcd for $C_8H_{14}O_2$: C, 68.00; H, 9.95%.

Photosensitized Oxygenation of Germacrone (VIII). A solution of VIII (6 g) and rose bengal (200 mg) in methanol (350 ml) was photooxygenated for 4 hr until VIII was completely consumed. The mixture was found by iodometry to contain 0.75 mol equivalent of peroxide on the basis of the consumed oxygen (1.1 l). The mixture was treated with sodium sulfite (4.8 g) in water (200 ml) under ice cooling, concentrated under reduced pressure and then extracted with light petroleum and ether successively. The organic layers were dried over anhydrous sodium sulfate and evaporated. The residue from the light petroleum extract was recrystallized from carbon terachloride to give germacra-3,7(11),10(14)-trien-9-ol-6-one(*E*) (XVIIa) as crystals (153 mg; 2.5%); mp 91.5—92.5 °C; IR (KBr): 3400, 1660, 1015, and 895 cm^{-1}; NMR (CCl_4): δ 1.60 (d, 3H, J=1 Hz), 1.78 (s, 3H), 1.81 (s, 3H), 2.2 (m, 4H), 2.3 (s, 1H, OH), 2.60 (d, 2H, J=6 Hz, $-CH(OH)-CH_2-$), 3.15 (s, 2H, $=C-CH_2-CO-$), 3.78 (t, 1H, J=6 Hz), 4.86 (s, 1H), 5.05 (s, 1H), and 5.35 (m, 1H).

Found: C, 76.79; H, 9.69%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%.

The mother liquor from XVIIa and the ether extract (1.91 g) were found to be complex mixtures, from which isolation of pure products was unsuccessful.

Potentiometric Analysis and Fundamental Technique

Yoshihiro SHIGEMASA, Masayuki SHIMAO, Chikahiro SAKAZAWA, and Teruo MATSUURA*

(Received January 13, 1975)

The formose reaction, the calcium hydroxide-catalyzed condensation of formaldehyde to monosaccharides, was potentiometrically analyzed. The oxidation-reduction potential varied in a characteristic way and gave information of considerable importance. Some appreciable transition points in the oxidation-reduction potential curve showed satisfactorily the occurrence of a phase change such as an induction period and saccharide-forming and saccharide-decomposing stages. With regard to the fundamental operating conditions, vigorous stirring and an increase in the dissolved oxygen elongated the induction period. Furthermore, the latter diminished the yield of saccharide under the lower limit of the critical range of the calcium hydroxide concentration.

The formose reaction, in which monosaccharides result from formaldehyde in the presence of an alkaline catalyst in an aqueous medium, was first reported by Butlerow.[1] Thereafter, much attention has been directed to studies of catalysts for saccharide-forming reactions. Of these, some alkali earth- and alkali-hydroxides and organic bases, such as pyridine and picoline, have been recognized as active catalysts.[2,3] Especially, $Ca(OH)_2$ is widely used for the investigation of the above reaction. From their experiments using a dilatometer, Belezin and Surykina[4] observed the existence of a time lag prior to the saccharide condensation; this period was shortened by adding glucose or fructose.

Pfeil and Schroth[5] prepared saccharides using TlOH as a catalyst, and recognized the formation of substances which accelerate the formose reaction during the induction time by pursuing the consumption of formaldehyde or products, followed by the Cannizzaro reaction. Subsequently, they supposed that the substances would form a calcium complex and contributed to the saccharide formation. Furthermore, they demonstrated that the extent of formose reaction is greatly affected by the kind of alkaline cations used.

Recently, in their series of studies of the formose reaction, Weiss *et al.*[6-9] followed the reaction in a continuously stirred tank reactor. They derived a kinetic expression for the formose condensation, and pointed out the instabilities observed in both the Cannizzaro reaction and the formose reaction were obviously attributable to changes in the $Ca(OH)_2$ concentration. Fujino *et al.*[10] have obtained evidence for the formation of soluble complexes consisting of alkali earth-saccharides or alkali earth-formaldehyde and recognized the presence of a relationship between their catalytic activity and their complex-forming ability.

In certain situations, the oxidation-reduction potential (ORP) has often been employed to estimate a state or a mechanism of reaction systems.[11,12] As has been mentioned above, with regard to the formose synthesis, much information concerning the activity of catalysts and the reaction mechanism has been accumulated. However, there have been few attempts to elucidate the nature of this reaction by employing ORP estimation. In an earlier paper[13] dealing with the potentiometric analysis of the formose reaction, it was shown that the changes in ORP show a good correlation with the characteristic reaction phases. The object of this paper is to present more details of the previous work and to describe some additional experiments concerning the fundamental techniques in the reaction.

Experimental

Procedure. Under N_2 an aqueous formaldehyde was treated with $Ca(OH)_2$ in an apparatus attached to a potentiometer.

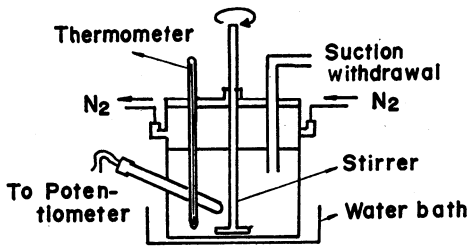

Fig. 1. Apparatus.

These are shown in Fig. 1. The bath temperature was kept in the range of 60±1 °C, and the rate of stirring remained at 320 rpm through the experiment. A representative method of the reaction was as follows. The reactor, which contained 90 ml of 37% formalin (commercial) and 790 ml of water, was pre-equilibrated at 60±1 °C in a thermostat; the reaction was then initiated, followed by the addition of 8.5 g of $Ca(OH)_2$. At convenient intervals, *ca.* a 10-ml aliquot was withdrawn into a 50 ml flask and immediately acidified with 1M HCl; these aliquots were analyzed for formaldehyde, the total saccharides, and organic acids as follows.

The formaldehyde was determined by the method of Bricker *et al.*,[14] only the optical density being measured at 579 nm.

The calculation of the formaldehyde concentration was done by means of a previously prepared calibration curve.

The total saccharides were determined using the phenol-sulfuric acid method,[15] the concentration being calculated as glucose from a calibration curve. The organic acids was determined by back titration with 1M KOH after the aliquot had been acidified. When A ml of 1M HCl was added to the solution and subsequently B ml of 0.1M KOH was consumed to neutralize the solution, the organic acid concentration, x M, was given by the following equation:

$$x = 2 \times 8.5 \times 1000/74 \times 880 + 0.01B - 0.1A$$

The dissolved oxygen was estimated by following a modification of the Winkler method,[16] while the stirring speed was measured using a stroboscope.

The UV spectra were measured using a Shimadzu Spectro-

photometer, MPS-50L. A sample solution withdrawn from the reaction mixture was cooled immediately in a dry ice–acetone bath to about 0 °C, at which the reaction would virtually not proceed at all. Next, the solution was centrifuged under a high speed to remove the turbidity of the medium. Even when the sample was simply cooled and not acidified, it was stable enough for the determination of the UV spectra so long as it was stored in a refrigerator.

Results and Discussion

As is shown in Fig. 2, a representative ORP curve for the formose reaction apparently has four characteristic steps. The first step: Almost no change in ORP is observed, and no production of saccharides can be detected with a little consumption of formaldehyde. This step may be an induction period, after which only a small amount of organic acids (mainly formic acid) is detected. The period of this step varies depending upon the reaction conditions. For example, it is shortened when a known promoter, such as glucose,[5] fructose,[17] xylose, or glycolaldehyde,[18] is added. The second step: After the induction period, the ORP curve begins to turn downward and reaches to a minimum point (the time up to this point is termed T_{min}). At this point, the yield of saccharides is only approximately 3% (as glucose based on formaldehyde), and the formaldehyde condensation to saccharides is initiated slowly, whereas as much as 20—30% of the formaldehyde is consumed. The rate of organic acid production is similar to that in the previous step. The third step: The ORP curve turns upwards from the minimum point and reaches a small maximum (the time up to this point is termed T_{max}), whereupon a little drop is observed, while the color of the solution simultaneously turns to pale yellow (the so-called yellowing point). As the ORP of the solution increases, the reaction proceeds rapidly with a rise in the temperature up to the maximum, 70—75 °C. At the termination of this step, the formaldehyde consumption is raised to 95% and the yield of the saccharides amounts to 50—70%. The fourth step: A steady state appears again in ORP, while the saccharides formed begin to decompose and the total amount of saccharides decreases successively as time passes. The temperature of the mixture slowly becomes lower, on the other hand, the color of the mixture changes from light yellow to light brown or brown.

In order to ascertain the optimum conditions for the saccharide formation, some basic experimental conditions, such as the influences of the stirring speed and the dissolved oxygen, were investigated. The stirring speed has a negligible influence on the saccharide yield within the rage of 200—1200 rpm. However, vigorous stirring causes the ΔORP (the ORP difference between T_{max} and T_{min}) to decrease (Fig. 3) and results in an increase in the period up to both T_{min} and T_{max} (Fig. 4). The results indicate that the stirring speed need not necessarily be high; hence, 320 rpm would seem an adequate speed for usual experiments.

[HCHO]=2.0 M; [Ca(OH)$_2$]=0.2 M.

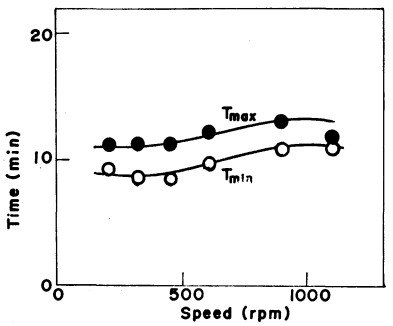

Fig. 4. Effect of agitation on T_{min} and T_{max}.
Reaction condition; Same as Fig. 3.

Concerning the influence of dissolved oxygen, a set of experiments were carried out in which the periods up to T_{min} and T_{max} were determined with an increase in the concentration of dissolved oxygen (Fig. 5). The oxygen concentrations were adjusted by introducing limited amounts of oxygen and nitrogen into the reactor. As may be seen in Fig. 5, slight elongation in the time up to both T_{min} and T_{max} is observed with an increase in the oxygen concentration. On the other hand, at a comparatively lower level of the Ca(OH)$_2$ concentration (0.17 M), the dissolved oxygen at a high concentration diminishes the sugar yield, while at a little higher concentration (0.20 M), the sugar yield remains unchanged within this range of oxygen concentration (Fig. 6). The results show that oxygen acts as a weak inhibitor of the formose reaction. Therefore, the progress of the reaction under a nitrogen atmosphere seems to be favorable for obtaining saccharides in a high yield.

The ORP measurements of the formose reaction were carried out under various conditions. Whenever the

Reaction conditions; Same as Fig. 5. [$Ca(OH)_2$]: ○, 0.17 M; □, 0.20 M.

conditions under which the formose reaction took place smoothly to give saccharides were employed, the minimum (2nd step) and maximum (3rd step) points necessarily appeared. On the contrary, under such conditions where the formose reaction would not take place, when, for example, the reaction was initiated under the lower limit of the critical of the $Ca(OH)_2$ concentration, the ORP did not show significant change but, rather, rose slowly. In these cases, the pH of the mixture was gradually lowered because of the organic acids resulting from the Cannizzaro reaction.

With regard to the saccharide formation, trioses may be produced at the early stage of the second step, followed by the additional formation of tetroses at the minimum ORP point, and then higher saccharides are accumulated up to the maximum ORP point, as may be seen from the paperchromatographic analysis of aliquots.[13]

The UV spectra data with samples withdrawn intermittently during the course of the reaction are shown in Table 1. Some absorption maximum at 290 nm is first observed at T_{min}, and the amount of optical absorption continues to increase until T_{max}. Immediately after the yellowing point (T_{max}), λ_{max} is shifted beyond the wavelength of 300 nm. The substance with the λ_{max} value of 290 nm may be considered to be an intermediate produced during the induction period and may play some role in the subsequent step of sugar formation. However, the substance has not yet been successfully isolated, and its nature remains to be elucidated. In view of the above facts, emphasis may be placed on the utility of ORP measurements in the formose reaction. Although there may not be completely satisfactory arguments for the observed ORP changes, it should be noted that some important features of the formose reaction, such as the initiation and the end of the reaction, can be characterized by means of the ORP curve; this is worthy of future investigation. For example, the visual method (yellowing point), which has been employed for obtaining the highest yield of saccharides, might better be placed by ORP measurements because of some disadvantages with the operation and accuracy of the former method.

In conclusion, the ORP-determination method might make some contributions to future studies of the formose reaction in searching for the optimum reaction conditions and for active catalysts; moreover, it might well be used in technological development.

A Novel Preparation of Enamine Phosphonates from Ketene *O,N*-, *S,N*-, and *N,N*-Acetals with Diethyl Phosphite

Masahiro FUKUDA, Kazuhito KAN, Yoshiki OKAMOTO, and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita-shi, Osaka **565**

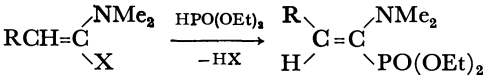
(Received January 22, 1975)

1-Dimethylamino-1-methoxy-1-alkenes (ketene *O,N*-acetals), 1-dimethylamino-1-ethylthio-1-alkenes (ketene *S,N*-acetals) and 1,1-bis(dimethylamino)ethylene (ketene *N,N*-acetal) reacted with diethyl phosphite to give the corresponding (*E*)-diethyl 1-dimethylamino-1-alkenylphosphonates. Although ketene diethylacetal (ketene *O,O*-acetal) reacted with diethyl phosphite to give diethyl 1,1-diethoxy-1-ethylphosphonate, 1,1-bis(ethylthio)-1-alkenes (ketene *S,S*-acetals) did not react with diethyl phosphite.

Enamine phosphonates have been synthesized by Horner's olefination method of tetraethyl dimethylaminomethylenediphosphonate with aldehydes,[1] and also by addition of diethyl phosphite to ynamines.[2] In this paper we wish to report a new method of preparation of enamine phosphonates by the reaction of ketene *O,N*-, *S,N*-, and *N,N*-acetals with diethyl phosphite. The method has the following adventages over the methods described above. The reaction proceeds smoothly under mild conditions, and the procedure is quite simple.

Results and Discussion

Ketene *O,N*- (Ia—c), *S,N*- (IIa—c), and *N,N*-acetals (III) reacted exothermally with diethyl phosphite at room temperature to give the corresponding enamine phosphonates (Va—c) in 50—80% yields (Table 1), according to the following scheme.



(1)

Ia R=H X=OMe
b R=Me X=OMe
c R=Et X=OMe
IIa R=H X=SEt
b R=Me X=SEt
c R=Et X=SEt
III R=H X=NMe_2

Va R=H
b R=Me
c R=Et

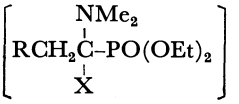
The structures of Va—c were identified by elemental analysis and NMR, mass, and IR spectral data. NMR spectra indicate that the enamine phosphonates obtained by this method are only *E*-isomer. The PCCH coupling constant of Vb and Vc was observed to be 13.5 Hz, which is the same as that reported by Schindler and Plöger.[2a]

TABLE 1. ENAMINE PHOSPHONATES FROM KETENE O,N-, S,N-, AND N,N- ACETALS WITH DIETHYL PHOSPHITE

Ketene Acetal	Product	Bp (°C)/ mmHg	Yield (%)
Ia(R=H, X=OMe)	Va(R=H)	92—94/1	75
Ib(R=Me, X=OMe)	Vb(R=Me)	114—115/5	58
Ic(R=Et, X=OMe)	Vc(R=Et)	116—123/6	47
IIa(R=H, X=SEt)	Va(R=H)		54
IIb(R=Me, X=SEt)	Vb(R=Me)		77
IIc(R=Et, X=SEt)	Vc(R=Et)		81
III(R=H, X=NMe_2)	Va(R=H)		55

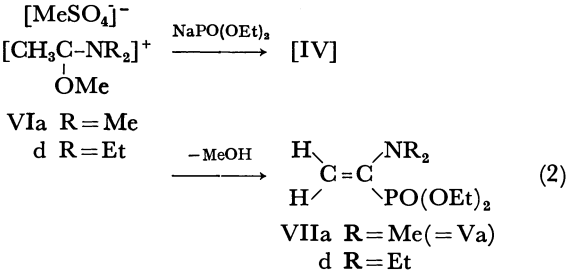
The reaction was carried out without solvent at 60—80 °C for 0.5—1 hr.

Since the compounds (I, II, and III) are the analog of enamine or ketene acetal, it is expected that β-carbon of I, II, and III would exhibit a strong nucleophilic character due to the conjugation of the double bond with electron donor groups.[3] Thus, it seems reasonable to speculate that an intermediate(IV) was formed by addition of diethyl phosphite to the C=C double bond of I, II, or III, although our attempt to isolate IV was unsuccessful. Enamine phosphonate (V) would be produced immediately by the elimination of HX from IV.



(IV)

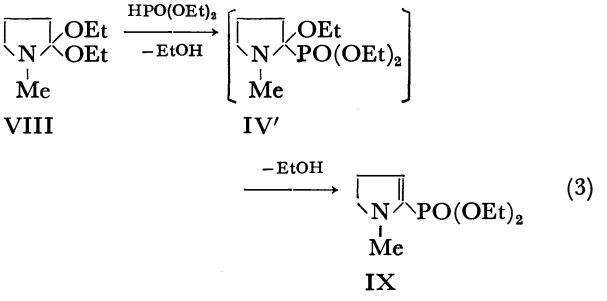
It was found that the adduct (VI) derived from *N,N*-dialkylacetamide and dimethyl sulfate reacted with diethyl phosphite to give VII in 30—40% yields. In this case also, the intermediate (IV) would be formed and undergo elimination of methanol *in situ* to give VII.



(2)

VIIa R=Me(=Va)
d R=Et

It is noteworthy that *N*-methylpyrrolidone diethylacetal (VIII) reacted with an excess diethyl phosphite to give the corresponding enamine phosphonate (IX).



(3)

The reaction process can be explained by considering the intermediate (IV') which will rapidly loose ethanol *in*

situ and give IX in 60% yield. The product (IX) obtained did not react with another diethyl phosphite, and the excess diethyl phosphite was recovered by distillation *in vacuo*.

In the case of ketene *O,O*-acetal (X), an addition reaction occurred at room temperature. One mole of diethyl phosphite reacted with one mole of X to give diethyl 1,1-diethoxy-1-ethylphosphonate (XI). The structure of XI was confirmed by its NMR spectrum.

$$\underset{\text{X}}{CH_2{=}C(OEt)_2} \xrightarrow{HPO(OEt)_2} \underset{\text{XI}}{CH_3C(OEt)_2PO(OEt)_2} \quad (4)$$

This seems to be the first example of diethyl phosphite being added to the activated unsaturated system in the absence of a base or free radical initiator.[4] The compound (XI) remained unchanged by refluxing over metallic sodium for 3 hr.

The contribution of dialkylamino group to the β-elimination of HX from the intermediate (IV) might be of great importance.

$$[RCH_2\text{-}\overset{\overset{\delta+}{\curvearrowleft}NR_2}{\underset{\underset{\delta-}{\curvearrowleft}X}{C}}\text{-}PO(OEt)_2] \qquad \text{IV}$$

Vinyl ethers reacted with diethyl phosphite to give aldehydes, no addition products of vinyl ether and diethyl phosphite being obtained.[5]

Thus, ketene *N,N*-, *O,N*-, and *S,N*-acetals react with diethyl phosphite to form the intermediate (IV, IV') and loose HX from IV or IV'. Ketene *O,O*-acetal is led only to the formation of 1:1 adduct (XI). Ketene *S,S*-acetals did not react with diethyl phosphite even under base-catalyzed conditions.

The nucleophilicity of β-carbon of ketene *N,N*-, *O,N*-, *S,N*-, and *O,O*-acetals, vinyl ethers, and ketene *S,S*-acetals decreases in the order given in literature.[3] The order is essentially the same as that obtained for this experiment on the reactivities of these compounds toward diethyl phosphite.

These enamine phosphonates (V, VII, and IX) have good thermal stabilities, but readily react with moisture to decompose to acylphosphonates. The acylphosphonates are further hydrolyzed to acids and diethyl phosphite.[1]

Experimental

All the boiling points are uncorrected. The NMR spectra were obtained at 100 MHz on a JNM-TS-100 spectrometer, with TMS as an internal reference in deuteriochloroform. The mass spectra were obtained on a Hitachi RMU-6 or RMU-7 spectrometer with an indirect inlet. The gas chromatographic analysis were carried out using a Shimadzu GC-3AF on a 1 m×3 mmϕ column packed with 5% SE-30 on Cellite.

Preparation of N,N-*Dialkylacetamide–Dimethyl Sulfate-Adduct (VI).* *N,N*-Dimethylacetamide and dimethyl sulfate-adduct (VIa) was prepared from *N,N*-dimethylacetamide and dimethyl sulfate according to the method of Bredereck *et al.*[6] Unreacted starting material was removed by extraction with dry ether. *N,N*-Diethylacetamide–dimethyl sulfate-adduct (VId) was prepared from the corresponding amide and dimethyl sulfate, in a similar manner.

Preparation of Ketene O,N-*Acetals (I).* 1-Dimethylamino-1-methoxyethylene (Ia) was prepared from IVa and sodium methoxide in methanol by the method of Bredereck *et al.*,[7] except that the mixture of Ia and *N,N*-dimethylacetamide dimethyl acetal was refluxed over sodium instead of calcium in order to purify the product (Ia). Yield 81%, bp 104 °C. (lit,[7] bp 104—105 °C). 1-Dimethylamino-1-methoxy-1-propylene (Ib) was prepared from *N,N*-dimethylpropionamide-dimethyl sulfate-adduct and sodium methoxide. The product, bp 117—118 °C, was obtained in 34% yield. (lit,[7] bp 117—120 °C). In a similar manner, 1-dimethylamino-1-methoxy-1-butene (Ic) was obtained in 30% yield, bp 128—136 °C.

Preparation of Ketene S,N-*Acetals (II).* 1-Dimethylamino-1-ethylthioethylene (IIa) was prepared from *N,N*-dimethyl-*S*-ethylthioacetamidium iodide and sodium ethylmercaptide in dry ether by the method of Mukaiyama *et al.*[8] The product was obtained in 72% yield, bp 58—59 °C/20 mmHg. (lit,[8] bp 58—59 °C/21 mmHg). In a similar manner, compounds IIb and IIc were obtained, respectively. 1-Dimethylamino-1-ethylthio-1-propylene (IIb); yield 58%, bp 68—71 °C/24 mmHg. 1-Dimethylamino-1-ethylthio-1-butene (IIc); yield 85%, bp 70—71 °C/17 mmHg. The purity of these compounds was confirmed by gas chromatography.

Preparation of Ketene N,N-*Acetal (III).* This was prepared from tetramethylacetamidinium methyl sulfate and sodium hydride by the method of Bredereck *et al.*[7] Yield 11%, bp 115—118 °C. (lit,[7] bp 115 °C).

Preparation of N-*Methylpyrrolidone Diethylacetal (VIII).* This acetal was prepared from *N*-methylpyrrolidone–dimethyl sulfate-adduct and sodium ethoxide by the method described above.[7] Yield 46%, bp 67 °C/12 mmHg. (lit,[7] bp 57—58 °C/10 mmHg). This acetal did not loose one mole of ethanol, even under reflux over metallic sodium for several hours.

Preparation of Ketene S,S-*Acetals.* These were prepared by pyrolysis of ethyl orthothioester in the presence of potassium bisulfate by the method of Volger and Arens.[9] 1,1-Bis(ethylthio)ethylene was obtained in 43% yield, bp 75 °C/12 mmHg. (lit,[9] bp 80—81 °C/17 mmHg). 1,1-Bis(ethylthio)-1-propylene was obtained in 70% yield, bp 79 °C/12 mmHg. (lit,[9] bp 60—60.2 °C/4 mmHg).

Preparation of Ketene O,O-*Acetal (X).* This was obtained from α-bromoacetaldehyde diethyl acetal by treatment with potassium *t*-butoxide.[10] Yield 40%, bp 82—84 °C/200 mmHg. (lit,[10] bp 83—86 °C/200 mmHg).

Reaction of Ketene O,N-*Acetals (I) with Diethyl Phosphite.* To 30 g (217 mmol) of diethyl phosphite in a flask equipped with a reflux condenser was added 22 g (106 mmol) of Ia at room temperature. An exothermic reaction took place and the temperature was raised to 60—80 °C. The methanol produced as the by-product was refluxed. The mixture was kept at 60—80 °C for 0.5 hr. After removal of the alcohol by means of an aspirator, the residue was distilled and purified by redistillation *in vacuo*. This was confirmed to be (*E*)-diethyl 1-dimethylaminovinylphosphonate (Va). Yield 34 g (75.4%), bp 92—94 °C/1 mmHg. IR; 1250 cm^{-1} (P=O). Mass; *m/e* (relative intensity) 207 (M^+, 17.5) 178 (16.3) 150 (17.5) 71 (93.8) 70 (100). NMR; δ 1.32 (t, 6H, $-OCH_2\underline{CH_3}$) 2.72 (s, 6H, $-NMe_2$) 3.65 (d, 1H, $^{H=}{}_P$, J_{PCCH}=11.2 Hz) 4.03 (d-q, 4H, $-O\underline{CH_2}CH_3$) 4.75 (d, 1H, $^{H=}{}_P$, J_{PCCH}=15.8 Hz). Found: C, 46.42; H, 8.66; N, 6.67%. Calcd for $C_8H_{18}NPO_3$: C, 46.33; H, 8.76; N, 6.78%.

In a similar manner, Ib and Ic reacted with diethyl phos-

Restricted Rotation Involving the Tetrahedral Carbon. XV. Restricted Rotation about a C_{sp^3}–C_{sp^2} Bond in 9-Aryltriptycene Derivatives[1)]

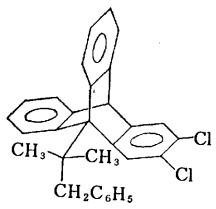
Mikio NAKAMURA and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113

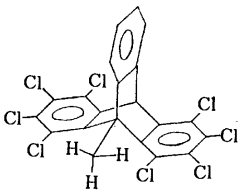
(Received January 25, 1975)

A series of 9-aryltriptycene derivatives have been prepared and their internal rotation about the C_{Ar}–C_9 bond has been examined by DNMR technique. The PMR behavior of these compounds is best interpreted by assuming a back and forth rotation rather than a full rotation. The barriers to rotation of compounds with one substituted benzo group have been found to be in the range 13—15 kcal/mol, whereas those with two substituted benzo bridges are lower than 9 kcal/mol. The low barrier of these compounds relative to 9-alkyltriptycenes is attributed to the rise in energy of the ground state. The stable conformation of the 9-aryltriptycenes is also discussed.

Barriers to rotation of alkyl groups are extraordinarily high when the alkyl group is bonded to the bridge head carbon of the triptycene skeleton. The barrier to rotation of the *t*-alkyl group in compound **1** is so high that the rotational isomers can be isolated as stable entities at room temperature.[2)] Even the methyl group in compound **2** has a high barrier to rotation showing clear AB_2 type signals below −70 °C.[3)]



1



2

These findings have stimulated us to study whether the rotational barriers are also high when an aryl group is bonded to the bridge head carbon of the triptycene molecule. Several 9-*o*-tolyl- and 9-*o*-anisyl-triptycene derivatives (**3**—**10**) were synthesized. The methyl or the methoxy group in the aryl ring is introduced to identify the isomers, if possible, by the NMR technique, because the methyl should show signals at different chemical shift when it is located at different environments and the life time is long enogh to be detected.

The purpose of this paper is to describe the results of the study on the barrier of these compounds and to discuss the possible rate process. Various factors which govern the barrier heights to rotation are also discussed.

Results and Discussion

Rate Process and Conformation. The PMR spectrum of compound **4** at room temperature shows two methyl signals with an interval of 1.5 Hz at 60 MHz. The same interval was also observed for these signals at 100 MHz which indicates that the signal is split by coupling. Irradiation at the aromatic region produced no collapse of the signals. The coupling between the methyl protons and fluorine nucleus takes place in this compound at room temperature. PMR spectra of **4** at low temperature show little change from the spectrum obtained at room temperature except for the aromatic region (Fig. 1), both the chemical shift and coupling constant remaining almost constant. On the other hand, two distinct signals are found at low tem-

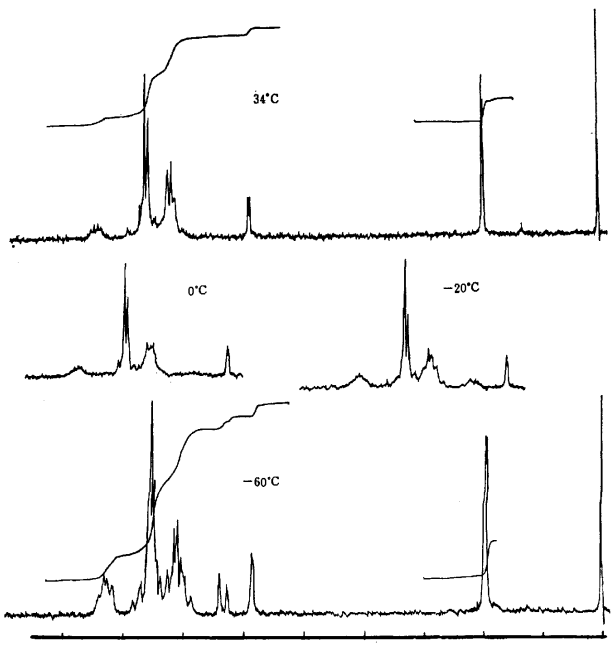

Fig. 1. Temperature dependent PMR spectra of compound **4**.

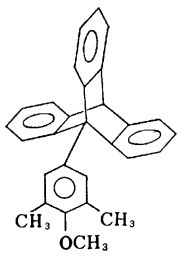
perature apart from the main aromatic signals, two peaks at δ 6.17 and a multiplet at δ *ca.* 8.1, each corresponding to 1 proton. Since there is a multiplet peak at δ *ca.* 8.1 at room temperature, the latter signal now corresponds to 2 protons. The former two peaks seem to be the A (or B) part of an AB quartet from the shape of the signals and coalescence behavior. The coupling constant is 7.5 Hz.

The peak at δ *ca.* 8.1 present in the spectrum at room temperature is assigned to the 6′-H for the following reasons. The PMR spectrum of **11** shows a broad singlet with the intensity of 2 protons at δ 7.77. This signal is most reasonably assigned to the protons at 2′ and 6′ positions. The assignment is confirmed by the strong intensification of the signal upon irradiation of the methyl signal. Jackman and Sternhell[4] stated that, in benzene derivatives, a methyl group causes a 0.17, 0.09 and 0.17 ppm upfield shift of the *ortho*, *meta* and *para* protons respectively, and a methoxy group causes a 0.1 ppm upfield shift of the *meta* protons. Taking these substituent effect into consideration, we can calculate the chemical shift of the 6′-H of compound **4** to be δ 8.1, which is in good agreement with the observed chemical shift.

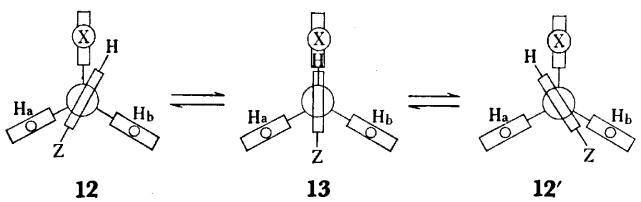


11

The PMR spectrum of compound **4** was examined at 136 °C, but no change was observed from that at room temperature. Thus the rate process which occurs in this molecule should conform to the fact that the methyl signals are not affected by temperature although the rotation in question is fast on the NMR time scale at room temperature and is slow at low temperatures.

We assume that the ground state is the conformation in which the aryl group does not eclipse the benzo group, although there are some examples that the ground state is the conformation in which one of the substituents in the alkyl group eclipses the phenyl ring.[5] We believe this assumption is reasonable because the benzo is a large group. Two mechanisms may be considered to account for the above findings.

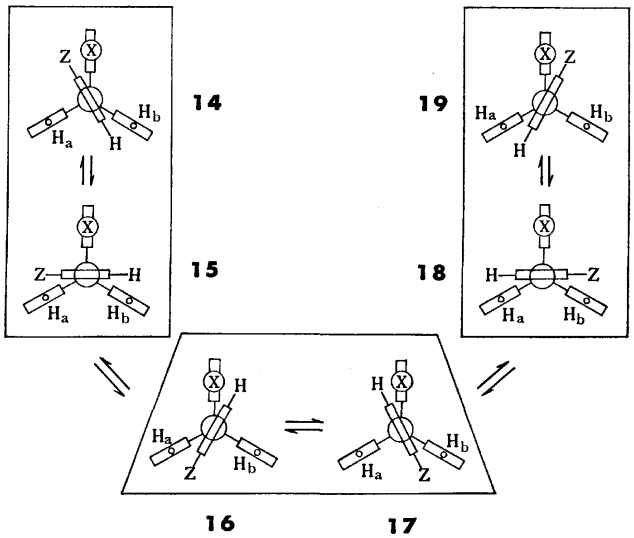
The first mechanism comprises a partial rotation shown in Scheme 1. In this process, the transition state of rotation is conformation (**13**) in which 6′-H passes over the substituent X. The ground state shown by **12** and **12′** are mirror images of each other and the



12 **13** **12′**

Scheme 1.

energy level should be the same. The locations of the Z group (methyl or methoxy) in **12** and **12′** are identical and the average of the chemical shifts of **12** and **12′** is the same as that of either **12** or **12′**. On the other hand, the *peri*-protons (H_a and H_b) experience different chemical shifts when the rotation is slow: in **12**, H_b must give a signal at a high magnetic field and H_a at a low field due to the anisotropy of the 9-aryl group while in **12′** the reverse is the case. When the rotation is fast, the chemical shifts of these protons are averaged out. In this mechanism, the barrier for the Z group to pass over the benzo group (H_a or H_b) must be very high, since otherwise it would be impossible to account for the small spectral change of the methyl group at various temperatures. This mechanism is called mechanism A in the later discussion.



Scheme 2.

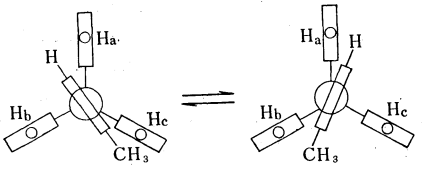
Another possible mechanism is shown in scheme 2. The barrier by which the 6′-H group passes over the unsubstituted benzo group is assumed to be so low that the corresponding motion is not detected by the present technique. Thus we assume that conformations **14** and **15** are not distinguishable even at low temperatures. A combination of **14** and **19** and that of **15** and **18** constitute pairs of *dl*-isomers. The averaged spectrum of **14** and **15** and that of **18** and **19** should then be identical. For an exchange of **14**—**15** and **18**—**19**, two possible ways may be considered, one which has a conformation in which Z eclipses the substituted benzo group as a transition state, and the other which occurs *via* **16** and **17**. Since the transition state of the former process, formed by eclipsing Z with the substituted benzo bridge, would be of too high an energy to pass over, it is reasonable to assume that the latter way is more plausible.

The substituent Z in a conformation of **14** and **15** will be in an identical magnetic environment with that in **18**—**19**, whereas the magnetic environment of Z in **16** and **17** is different. Thus in order to explain the small change in the methyl region of the PMR spectra, it is necessary to assume that conformations **16** and **17** are so unstable that their populations can be neglected or that the chemical shifts of the methyl protons in **16** and

17 coincide with those in **14**—**15** and **18**—**19**. These assumptions are referred to as mechanisms B and B′ respectively in the following discussions.

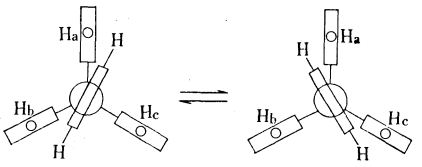
The possibility of these three cases can be discussed on experimental evidence. The first is the coupling of the methyl protons with the fluorine atom at a benzo bridge in compound **4**. If the coupling occurs through bonds, the number of the intervening bonds is seven including an sp^3-hybridized carbon. No such example has been found, though there are some examples of coupling through more than seven bonds in some conjugated systems.[6] On the other hand, the through space coupling of protons with a fluorine atom is well-known,[7] if they are close to each other in space. Thus the methyl-fluorine coupling is more easily explained by assuming mechanism B or B′.

The low temperature PMR spectra of compound **5** showed almost the same change as those of **4**. New signals appeared at δ 6.18 and 8.2 at low temperature, each corresponding to 1 proton, whereas the methyl signal at δ 1.77 showed little change. The free energy of activation for rotation was roughly estimated to be 14.5 kcal/mol, that of compound **4** being 13.2 kcal/mol. This small rise in the free energy of activation by going from the fluoro compound **4** to the chloro compound **5** again favors mechanism B or B′. If mechanism A were the case, the barrier would have been raised to a considerable extent by the substituent change. The PMR spectrum of **3** at low temperature shows one proton at a low field (δ 7.9) but no signal at a high field of the aromatic region. If mechanism A is assumed in which the barrier is the eclipsing of 6′-H with one of the benzo bridges, conformations **20** and **21** correspond to the ground state. H_a will give a signal at a low field, whereas H_b and H_c become non-equivalent, when the rotation is frozen. Thus there is no reason for a signal not to appear at a high field in mechanism A. On the other hand, mechanism B and B′ can explain the absence of a signal at a high field. Since mechanism B and B′ postulate that the barrier is the eclipsing of Z with one of the benzo groups and the exchange between **20** and **21** is fast, the signal of H_a at low temperature should appear at a low field, whereas those of H_b and H_c should appear at an average field. The averaged signal will be hidden by other aromatic signals.



20 **21**

The PMR spectra of **11**, wflich has no methyl group at 2′ and 6′ positions, should be temperature dependent if mechanism A were the case, since the magnetic environment of H_b differs from that of H_c when the rotation is frozen. On the other hand, mechanism B and B′ predict that the signals of compound **11** will not be temperature dependent down to −90 °C because the transition state where the Ar-H eclipses the unsubstituted benzo group is of low energy. An experimental

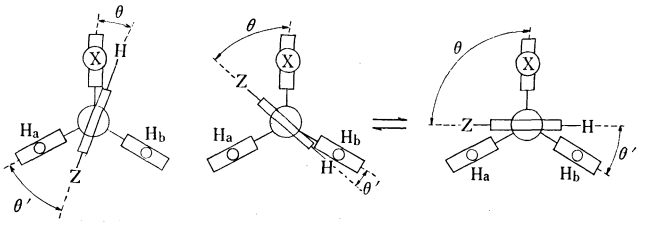


Compound **11** (Mechanism A).

fact that the spectra are independent on temperature down to −95 °C clearly supports mechanism B and B′.

All the experimental results favor mechanism B and B′, but a problem remains as to which of the two is more plausible. As regard this the fact that signals corresponding to one proton each appear at a low and a high field is of importance. Since the chemical shifts of *peri*-protons are mainly determined by the anisotropy effects of the aromatic ring, we must consider the stable conformation of the molecule.

In conformation **16**, the repulsive interaction between the substituent X and the Ar-H tends to widen the dihedral angle θ at the expense of the dihedral angle θ' in **16′**. The decrease in θ', however, necessarily increases the repulsive interaction between Z and the benzo bridge. Consequently, there will be a tendency that θ becomes small and θ' large. The result is that neither H_a nor H_b gives a signal at a high or a low field, even though the rotation is frozen. In the case where

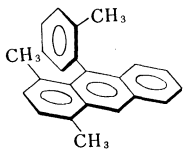


16′ **14′** **15′**

this barrier is small, the chemical shifts of H_a and H_b are averaged even at a low temperature. Thus the conformation **16** contradicts the experimental results. On the other hand, in conformation **14** the repulsive interaction between Z and X will tend to enlarge the dihedral angle θ and minimize the dihedral angle θ' in **14′**. In this conformation, H_a will give a signal at a high field and H_b at a low field. With the aid of conformation **15**, the large difference in the chemical shift between H_a and H_b cannot be explained, since these protons are located in almost the same magnetic environment with respect to aryl ring (see **15′**). Thus the appearance of signals at a low and a high field, each corresponding to one proton, is consistent with conformation **14** only. The above discusssion favors mechanism B over B′. Absence of conformations **16** and **17** seems strange, but the instability arises because of the repulsive force between X and Ar-H and that between Z and the benzo bridge.

Information on the dihedral angle θ is obtained from the large chemical shift difference between two *peri* protons, H_a and H_b (*ca.* 2.0 ppm for compounds **4**—**8**). Using the Johnson-Bovey diagram, we can calculate the difference to be *ca.* 1.8 ppm when the dihedral angle θ in **14′** is 60 °. Increasing the dihedral angle gives much smaller values.

Further evidence for the value of the dihedral angle is obtained from the rather large difference in chemical shifts (0.6 ppm) of two methyl groups at positions 1 and 4 in compounds **6** and **8**. Since it can be assumed that the methyl group at position 4 is not influenced by the 9-aryl group, signals at δ *ca.* 2.5* can be assigned to the 4-methyl group. This means that the anisotropy of the benzene ring causes a high field shift of the 1-methyl protons by *ca.* 0.5 ppm. Such a shift is possible only when θ is almost 60 °. When θ is below this, the chemical shift of 1-methyl protons becomes lower. When θ is almost 90 °, the chemical shift difference increases to the same extent as that of the methyl groups in compound **12**. In this compound the dihedral angle is predicted to be almost 90 ° from the dihedral angles of analogous biphenyls and the chemical shift difference amounts to as great as 0.9 ppm.

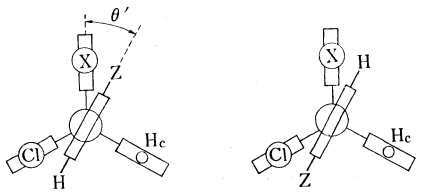


12

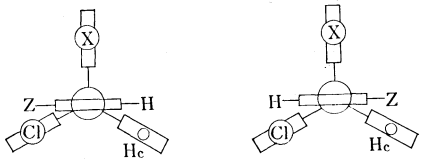
Conformation **14'** is also consistent with the through space coupling between 1-methyl and fluoro groups. Since the distance between these groups becomes large in other conformations, the coupling will be very small, if any.

The rationale for the stability of conformation **14** may be either or both of the following: a) there is attractive interaction between the methyl group and a halogen atom at a *peri* position, b) the repulsive interaction between the Ar-H and the substituent X and that between the methyl and the benzo bridge is large as was the case in conformations **16** and **17**. If the attractive interaction between the methyl and the halogen atom stabilizes conformation **14**, then the introduction of a repulsive group may cause the appearance of unstable conformations such as **16** and **17**. Thus compound **6** was prepared. However, the aromatic region of its PMR spectra is almost the same as that of other compounds at low temperatures: one proton at δ 6.20 and another at δ 8.1. Neither of the PMR spectra of **7** and **8** gave any sign of presence of conformations **16** and **17**. Thus the origin of instability of conformations **16** and **17** seems to be the steric effect.

Having found the unexpectedly low barrier to rotation in compounds **3**—**8**, we were interested in increasing the steric effect. Thus triptycene derivatives **9** and **10**, which have two benzo bridges with substituents, were prepared. Two points in the PMR spectra of these compounds at room temperature were found to differ from those with one substituted benzo group **4**—**8**. Namely, there is a proton which gives a signal at a considerably high field (δ 5.8), and the 6'-H does not give a signal at a low field. These characteristics are best interpreted by assuming conformations **22** and **23**, since H_c in these conformations should give signals at a high field. An alternative form **24** or **25** cannot explain the high field shift of H_c. The shift of 6'-H to the higher field should be attributed to the chloro group at *peri*-position. Since compound **9** has two benzo bridges with chloro groups, appearance of 6'-H of this compound at a high field supports this discussion. Although the chloro group has been known to shift the signals to lower field in alkyltriptycenes,[2] a different steric situation could cause the different effect. Absence of a signal due to 6'-H of compound **10** at a low field may be taken as an indication that the stable conformation of **10** is **22** which has 6'-H close to the chloro group.



22 **23**



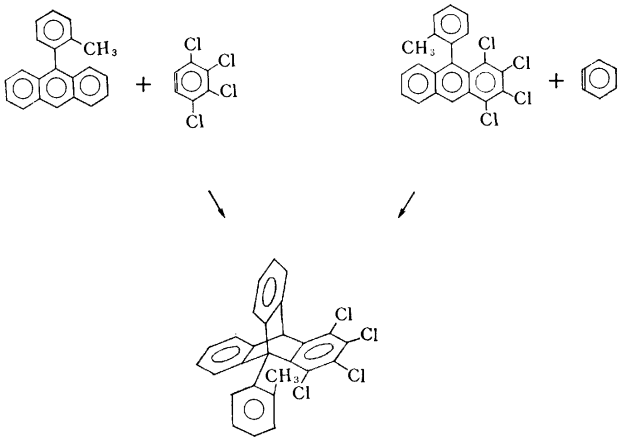
24 **25**

The chemical shifts of H_c in **9** and **10** are higher than those in **4**—**8** by *ca.* 0.3—0.4 ppm. If it is assumed that the main group which gives shielding to the H_c nucleus is the benzene ring, then H_c should be located just above the benzene ring of the 9-aryl group. This indicates that the dihedral angle θ' given in conformation **22** is close to 30 °. The small difference (0.07 ppm) in chemical shifts of 1- and 4-methyls of compound **10** also supports this conformation.

Barriers to Rotation. The temperature dependent behavior of the PMR spectra of 9-aryltriptycenes was a striking contrast to that of 9-alkyltriptycenes. The insensitiveness of the spectra at higher temperatures is possibly an indication of the frozen rotation of the aryl group and the temperature dependence of the spectra might be caused by freezing the motion of other parts of the molecule. In order to rule out this possibility, we undertook another experiment. The idea arose from the fact that the Diels-Alder reaction in making the triptycene skeleton is highly stereoselective and in the case of 9-*t*-alkyltriptycenes, it was possible to synthesize *dl* and *meso* forms separately.[2] If this technique is applied to the present case, the reaction of 9-*o*-tolylanthracene with tetrachlorobenzyne should give a different product from that obtained by the reaction between 1,2,3,4-tetrachloro-9-*o*-tolylanthracene and benzyne. An identical product, however, was obtained. Thus it is concluded that the rotation about C_{Ar}–C_9 bond in these compounds is fast at room temperature.

It was difficult to obtain the accurate values of rotational barriers, since the exchanging system contains 8

*) If compounds **6** and **8** only are taken into consideration, it is difficult to assign the signals since the other pair of signals appears also at δ 1.9. However, the data of compound **10** clearly suggest that the signal at δ 2.5 should be assigned to the methyl at position 4.



spins in these compounds. Fortunately, however, the signals of two protons at *peri*-positions, H_a and H_b, appear at a high and a low field. A rough estimation of the free energy of activation for internal rotation is possible by the usual method of coalescence temperature.[9] In Tables 1 and 2 chemical shift differences of H_a and H_b, coalescence temperatures and free energies of activation are listed.

TABLE 1. CHEMICAL SHIFT

	H_a	H_b	H_c	Z	X	6'-H
3	6.8—6.9	7.90	—	1.72	—	8.48

TABLE 2. ACTIVATION FREE ENERGY

	$\Delta\nu$ (Hz)	T_c (°C)	ΔG_c^* (kcal/mol)
3	60—66	—	—
4	113	5	13.2
5	120	34	14.6
6	116	10	13.4
7	121	40	14.8
8	116	0	12.9
9	—	—	—
10	—	−90>	9>

The free energy of activation is between 13 and 15 kcal/mol. However, we see that replacing a chloro group with a methyl group decreases the free energy of activation by more than 1 kcal/mol. Although the error involved in estimation of the energy may be large, it is evident that the coalescence temperatures of the methyl compounds **6** and **8** are lower than those of the chloro compounds **5** and **7**, whereas the chemical shift differences of H_a and H_b are almost the same. We have pointed out that the main factor governing the energy of the transition state for the rotation is the repulsive interaction between the aryl-substituent and the *peri*-proton. Thus the energy of the transition state should not vary too much from compound to compound. The reduction of the barrier height should be attributed to the raise of the ground state. In the ground state conformations **14** or **19**, the repulsive interaction between Z and X increases when X becomes larger, whereas this strain cannot be relieved by changing the dihedral angle, since the change results in increase of the interaction between Ar-H and H_a or H_b. Thus the ground state of the methyl compounds should be higher than that of the chloro compounds. This type of rise in ground state levels is also observed in compounds **9** and **10**. Since they have two *peri*-substituents, the ground state should be raised considerably. This is reflected in the low coalescence temperature of the PMR spectra. PMR spectra of **9** showed little change whereas that of **10** showed a little temperature dependence when the temperature is lowered to −90 °C. The methoxy signal broadened to show a half band width of 6 Hz at −90 °C. If we assume that the chemical shift difference of the methoxy group in conformations **22** and **23** is 10 Hz and the coalescence temperature is −100 °C, the barrier becomes 8.8 kcal/mol. We believe this is the maximum value for the barrier, since it is not likely that the chemical shift difference is less.

In conclusion, the 9-aryltriptycene studied here shows a lower barrier relative to 9-alkyltriptycenes. The highest barrier obtained corresponds to that of a 9-methyltriptycene derivative. Since the energy level of the transition state should be very high in 9-aryltriptycenes, this striking decrease in barrier height must be attributed to the rise of the ground state energy. Because of the required geometry of the 9-aryl group and the triptycene skeleton, the repulsive interaction between these groups seems to be severe in these compounds, raising the ground state.

Experimental

Syntheses. *9-o-Tolylanthracene*: To a vigorously stirred tetrahydrofuran solution of *o*-tolylmagnesium iodide, prepared from 21.8 g. (0.1 mol) of *o*-iodotoluene and 2.4 g (0.1 mol) of magnesium, was added 16.0 g (0.08 mol) of anthrone at 0 °C. The reaction mixture was stirred for 3 hr at room temperature and was then heated with stirring for 1 hr, cooled, and treated with concentrated hydrochloric acid. The organic layer was washed with aqueous sodium bicarbonate and dried over sodium sulfate. After evaporation of the solvent, the product was purified by chromatography on alumina. Elution with hexane gave a pure product, mp 126 °C (lit,[10] 125—126 °C), in 85% yield based on anthrone.

9-o-Anisylanthracene, mp 177—178 °C, was similarly prepared by treating *o*-anisylmagnesium iodide in tetrahydrofuran with anthrone. The yield was 82% based on anthrone. Found: C, 88.89; H, 5.50%. Calcd for $C_{21}H_{16}O$: C, 88.70; H, 5.67%. NMR ($CDCl_3$, δ) 3.52 (3H, s), 6.9—7.7 (12H, m), 8.38 (1H, s).

9-(4-methoxy-3,5-xylyl)anthracene, mp 178 °C, was similarly prepared by treating 4-methoxy-3,5-xylylmagnesium bromide in tetrahydrofuran with anthrone. The yield was 80% based on anthrone. Found: C, 88.54; H, 6.63%. Calcd for $C_{23}H_{20}O$: C, 88.42; H, 6.45%. NMR ($CDCl_3$, δ): 2.35 (6H, s), 3.82 (3H, s), 6.9—8.1 (10H, m), 8.43 (1H, s).

1,2,3,4-Tetrachloro-9-o-tolylanthracene. To a vigorously

stirred tetrahydrofuran solution of *o*-tolylmagnesium iodide, prepared from 21.8 g. (0.1 mol) of *o*-iodotoluene and 2.4 g (0.1 mol) of magnesium, was added a solution of 3 g (0.09 mol) of 1,2,3,4-tetrachloroanthrone[11] in 200 ml of benzene at room temperature over a period of 2 hr. The reaction mixture was heated for 1 hr and then cooled to 0 °C. About 10 ml (0.22 mol) of condensed chlorine was trapped at −70 °C and then introduced into the reaction vessel.** After stirring for 1 hr concentrated hydrochloric acid was added. Treatment of the product as above gave yellow crystals, mp 170—171 °C. The yield was 45% based on the anthrone. Found: C, 62.27; H, 2.91; Cl, 34.73%. Calcd for $C_{21}H_{12}Cl_4$: C, 62.10; H, 2.98; Cl, 34.92%. NMR ($CDCl_3$, δ): 1.86 (3H, s), 6.9—8.2 (8H, m), 9.0 (1H, s).

1,4-Dimethyl-9-o-tolylanthracene (**12**) was prepared by treating *o*-tolylmagnesium iodide with 1,4-dimethylanthrone[12] in tetrahydrofuran. This compound was obtained as a liquid after chromatography on alumina. The yield was 75%. Found: C, 93.40; H, 6.50%. Calcd for $C_{23}H_{20}$: C, 93.20; H, 6.80%. NMR ($CDCl_3$, δ): 1.89 (3H, s), 1.92 (3H, s), 2.80 (3H, s), 6.8—7.6 (9H, m), 7.8—8.1 (1H, m), 8.50 (1H, s).

1,4-Dimethyl-9-o-anisylanthracene, mp 135—136 °C, was prepared by treating *o*-anisylmagnesium iodide with 1,4-dimethylanthrone in tetrahydrofuran. The yield was 72%. Found: C, 88.72; H, 6.48%. Calcd for $C_{23}H_{20}O$: C, 88.42; H, 6.45%. NMR ($CDCl_3$, δ): 2.02 (3H, s), 2.79 (3H, s), 3.62 (3H, s), 6.9—7.7 (9H, m), 7.9—8.1 (1H, m), 8.58 (1H, s).

9-o-Tolyltriptycene (3). To a vigorously stirred refluxing solution of 1 g (0.0037 mol) of 9-*o*-tolylanthracene and 1 ml (0.009 mol) of butyl nitrite in 20 ml of methylene chloride was added 0.7 g (0.005 mol) of anthranilic acid in 5 ml of tetrahydrofuran over a period of 2 hr. The reaction mixture was refluxed for 2 hr, and evaporated *in vacuo* after cooling. The residue was taken up in ether, washed with aqueous sodium bicarbonate and dried over sodium sulfate. After evaporation, the product was purified by chromatography on alumina. Elution with hexane followed by recrystallization from benzene–hexane gave pure product, mp 249.5—250.5 °C, in 57% yield. Found: C, 94.29; H, 5.84%. Calcd for $C_{27}H_{20}$: C, 94.15; H, 5.85%. NMR ($CDCl_3$, δ): 1.72 (3H, s), 5.37 (1H, s), 6.7—7.6 (15H, m), 8.48 (1H, m).

1,2,3,4-Tetrafluoro-9-o-tolyltriptycene (**4**) was similarly prepared by treating 9-*o*-tolylanthracene and butyl nitrite in methylene chloride with tetrafluoroanthranilic acid[13] in purified acetone. The reaction mixture was purified by chromatography on alumina. Recrystallization from ethanol gave pure material, mp 163—164 °C. The yield was 48%. Found: C, 77.49; H, 4.22; F, 18.41%. Calcd for $C_{27}H_{16}F_4$: C, 77.28; H, 3.84; F, 18.88%. NMR ($CDCl_3$, δ): 1.90 (3H, d), 5.80 (1H, d), 6.8—7.7 (11H, m), 8.15 (1H, m).

1,2,3,4-Tetrachloro-9-o-tolyltriptycene (**5**), mp 288.5—289.0 °C, was prepared similarly by treating 9-*o*-tolylanthracene and butyl nitrite in methylene chloride with tetrachloroanthranilic acid[14] in purified acetone. The yield was 65%. Found: C, 67.13; H, 3 .08;Cl, 29.51%. Calcd for $C_{27}H_{16}Cl_4$; C, 67.25: H, 3.34; Cl, 29.41%. NMR ($CDCl_3$, δ): 1.77 (3H, s), 5.97 (1H, s), 6.7—7.7 (11H, m), 8.23 (1H, m).

1,4-Dimethyl-9-o-tolyltriptycene (**6**), mp 208—209 °C, was prepared by treating 1,4-dimethyl-9-*o*-tolylanthracene and butyl nitrite in methylene chloride with anthranilic acid in purified acetone. The yield was 72%. Found: C, 93.69; H, 6.26%. Calcd for $C_{29}H_{24}$: C, 93.51; H, 6.49%. NMR ($CDCl_3$, δ): 1.73 (3H, s), 1.85 (3H, s), 2.51 (3H, s), 5.57 (1H, s), 6.55, 6.64 (2H, AB quartet, J=8 Hz), 6.8—7.6 (11H, m), 8.40 (1H, m).

1,2,3,4-Tetrachloro-9-o-anisyltriptycene (**7**), mp 210—211 °C, was prepared similarly by treating 9-*o*-anisylanthracene with tetrachloroanthranilic acid in purified acetone. The yield was 57%. Found: C, 64.80; H, 3.31; Cl, 28.72%. Calcd for $C_{27}H_{16}Cl_4O$: C, 65.09; H, 3.24; Cl, 28.46%. NMR ($CDCl_3$, δ): 3.50 (3H, s), 5.95 (1H, s), 6.6—7.8 (11H, m), 8.14 (1H, m).

1,4-Dimethyl-9-o-anisyltriptycene (**8**): mp 216—217 °C, was similarly prepared by treating 1,4-dimethyl-9-*o*-anisylanthracene and butyl nitrite in dimethoxyethane with anthranilic acid in purified acetone. The yield was 23%. Found: C, 89.99; H, 6.20%. Calcd for $C_{29}H_{24}O$: C, 89.65; H, 6.23%. NMR ($CDCl_3$, δ): 1.90 (3H, s); 2.42 (3H, s), 3.50 (3H, s), 5.59 (1H, s), 6.53, 6.60 (2H, AB quartet, J=8 Hz), 6.8—7.7 (11H, m) 8.26 (1H, m).

1,2,3,4,5,6,7,8-Octachloro-9-o-tolyltriptycene (**9**), mp>300 °C, was prepared by treating 1,2,3,4-tetrachloro-9-*o*-tolylanthracene and butyl nitrite in methylene chloride with tetrachloroanthranilic acid in purified acetone. The yield was 35%. NMR ($CDCl_3$, δ): 1.87 (3H, s), 5.80 (1H, d, J=8 Hz), 6.71 (1H, s), 6.8—7.7 (7H, m).

1,4-Dimethyl-5,6,7,8-tetrachloro-9-o-anisyltriptycene (**10**), mp >300 °C, was prepared from 1,4-dimethyl-9-*o*-anisylanthracene, butyl nitrite, and tetrachlorothranilic acid. The yield was 44%. Found: C, 66.45; H, 3.90; Cl, 26.99%. Calcd for $C_{29}H_{20}Cl_4O$: C, 66.18; H, 3.83; Cl, 26.95%. NMR ($CDCl_3$, δ): 2.42 (3H, s), 2.49 (3H, s), 3.53 (3H, s), 5.75 (1H, d, J= 8 Hz), 6.27 (1H, s), 6.6—7.7 (9H, m).

9-(4-Methoxy-3,5-xylyl)triptycene (**11**), mp 255—256 °C, was similarly prepared from 9-(4-methoxy-3,5-xylyl)anthracene, butyl nitrite, and anthranilic acid. The yield was 82%. Found: C, 89.86; H, 6.02%. Calcd for $C_{29}H_{24}O$: C, 89.65; H, 6.23%. NMR ($CDCl_3$, δ): 2.42 (6H, s), 3.84 (3H, s), 5.37 (1H, s), 6.8—7.5 (12H, m), 7.75 (2H, broad s).

NMR Measurement. The PMR spectra at various temperatures were recorded as described previously.

**) This treatment is necessary because one of the chloro groups seems to undergo exchange. Without this treatment addition of water causes the formation of products with less chlorine content.

Reaction of Tetrachloroxylenes with Fuming Nitric Acid.[1] Side-chain Nitrooxylation and Quinol Nitrate Formation

Hitomi SUZUKI, Katsuro ISHIZAKI, Shigeru MARUYAMA, and Terukiyo HANAFUSA
Department of Chemistry, Faculty of Science, Hiroshima Uninersity, Higashi-sendamachi, Hiroshima 730
(Received February 18, 1975)

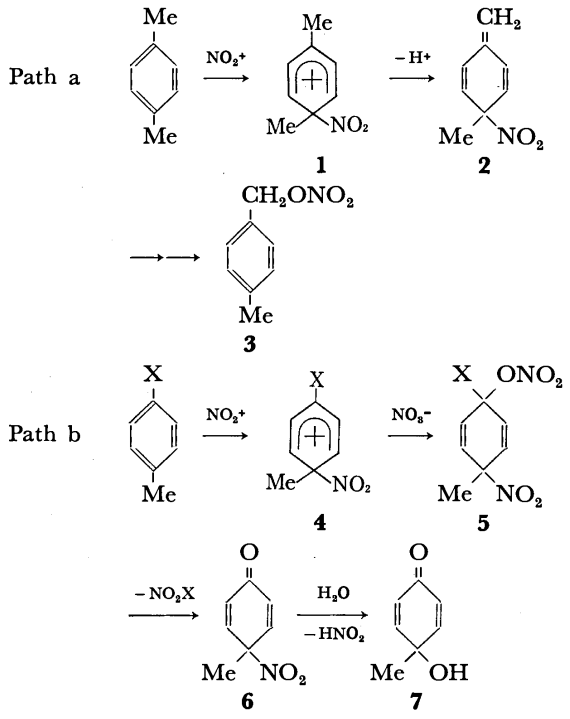
Direct action of fuming nitric acid upon tetrachloro-*o*- and -*m*-xylenes at room temperatur led to the formation of 3,5,6-trichloro-1,2-dimethyl-4-oxocyclohexa-2,5-dienyl nitrate and 2,5,6-trichloro-1,3-dimethyl-4-oxocyclohexa-2,5-dienyl nitrate, respectively, as the major products. In contrast, tetrachloro-*p*-xylene was simply converted into 2,3,5,6-tetrachloro-4-methylbenzyl nitrate. Plausible reaction sequences as well as criteria as a basis for predicting the propensity of polysubstituted alkylaromatics towards unusual nitration have been discussed.

Action of nitrating agent upon lightly substituted alkylbenzenes usually results in the replacement of one of the ring hydrogen atoms by nitro group. The increase in number of alkyl groups, however, tends to divert the reaction from the normal course into branch pathways leading to the production of unexpected products.[2] The most typical of these anomalous nitrations are the side-chain nitrooxylation (path a) and oxidation to unsaturated cyclic ketones (path b).

With substituted polymethylbenzenes these two processes are often in competition and as far as the substrate contains two methyl groups in *para* relationship, preference for the side-chain substitution dominates. We have previously suggested that the dichotomy of the reaction would presumably be determined by the structure of a benzenium ion intermediate;[3]

i) If the ion has the structure **1** in which the nitro group is attached to the nuclear carbon atom bearing a methyl group which is *para* to another methyl group, proton release would occur from the latter group to give a nitromethylene cyclohexadiene (**2**) which could be transformed into benzyl nitrate (**3**) (path a).

ii) If the ion has the structure **4** in which the nitro group is attached to the ring carbon atom bearing a methyl group which is *para* to a halogen atom, capture of the nitrate ion by the halogen-bearing carbon would occur to give an addition product (**5**), which will then be converted to the unsaturated carbonyl compound (**6**), usually isolated as *p*-quinol (**7**) (path b).



Scheme 1.

In order to test the reliability of the above criteria as a basis for predicting the propensity of polysubstituted alkylaromatics towards unusual nitration, as well as to obtain further insight into factors involved in the competition between side-chain substitution and nuclear oxidation, our studies were extended to the reaction of tetrachloroxylenes with fuming nitric acid.

A suspension of tetrachloro-*o*-xylene (**8**) in cold fuming nitric acid (d=1.50) was set aside with stirring overnight. **8** disappeared slowly to give a clear light brown solution which, on pouring into excess of water, gave a good yield of a pale yellow solid. Chromatography of the product on deactivated alumina resulted in the separation of some unchanged material and two new crystalline compounds melting at 166—167 °C and 145—146 °C, respectively. The high-melting compound had the formula $C_8H_7Cl_3O_2$ and showed mass peaks at m/e 240 (M^+), 225 (M^+—Me), and 205 (M^+—Cl). Proton NMR spectrum showed two methyl singlets at δ 1.68 and 2.32 and one hydroxyl peak at *ca.* 2.6 ppm (broad, exchangeable with D_2O). Its infrared spectrum contained carbonyl absorption at 1680 cm^{-1}, carbon-carbon double bond absorptions at 1637 and 1600 cm^{-1}, and hydroxyl absorption at 3400—3200 cm^{-1}, suggesting a cross-conjugated hydroxyketone. Its ultraviolet spectrum exhibited absorption maxima at 251—252 (log ε=4.08) and 291—292 nm (log ε=3.33) characteristic of a 2,5-cyclohexadienone system. Thus, the structure of dienone could be either 3,5,6-trichloro-1,2-dimethyl-4-oxocyclohexa-2,5-dienol (**12**) or 2,5,6-trichloro-1,3-dimethyl-4-oxocyclohexa-2,5-dienol (**19**). An unequivocal structure assignment to **12** was obtained by the zinc-acetic acid reduction of the ketone, which resulted in the isolation of a good yield of 2,5,6-trichloro-3,4-xylenol (**15**). The identity of the latter was confirmed by the independent synthesis starting with 3,4-xylenol according to the sequence shown in Scheme 2.[4]

The low-melting product had the formula $C_8H_6Cl_3NO_4$ and showed mass peaks at m/e 285 (M^+), 239 (M^+—NO_2), 223 (M^+—NO_3), and 221 (M^+—NO_2—CO). Its infrared spectrum showed prominent bands at 1683 (CO), 1646 (ONO_2), 1600 (C=C), 1292 (ONO_2), 1188,

1140, and 1042 cm^{-1}. The proton NMR spectrum displayed two methyl singlets at δ 1.71 and 2.27 ppm. The ultraviolet spectral pattern with maxima at 254—255 (log ε=4.05) and 286—290 nm (log ε=3.44) was typical of a 2,5-cyclohexadienone system. Given the presence of a cross-conjugated cyclohexadienone skeleton, two methyl groups, three chlorine atoms, and a nitrooxyl group, we could write twenty possible structures, nineteen of which, however, could readily be eliminated on the following chemical and spectral grounds:

1) Two methyl groups are magnetically non-equivalent.

2) Ring carbon atom bearing geminal chlorine atom and nitrooxyl group would be converted into carbonyl group.

3) Chlorine atoms are unable to undergo the intramolecular migration during the course of nitration.

4) Nitrooxyl group placed on a double bond would be subject to a facile nitrogen-oxygen single bond fission in protic acid medium.

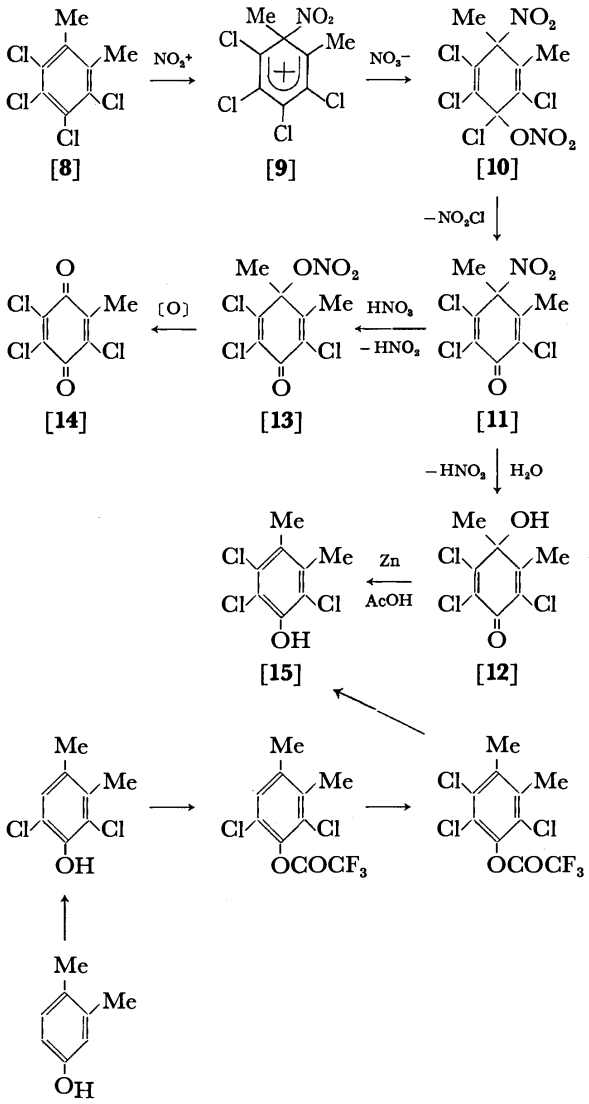
5) When dissolved into nitric acid, **12** was converted into this nitrooxyl compound, which on prolonged contact with the nitrating agent was further converted into trichloro-*p*-toluquinone (**14**). These leave the structure 3,5,6-trichloro-1,2-dimethyl-4-oxocyclohexa-2,5-dienyl nitrate (**13**).

When the reaction mixture was quenched immediately after the dissolution of **8** in cold nitric acid, a yellow crystalline solid was obtained. Since this product showed infrared bands at 1690, 1610, and 1570 cm^{-1} and proton NMR peaks at δ 2.10 and 2.19 ppm, and since it gradually converted to **12** and other unidentified substances on standing, it was assigned the structure 2,5,6-trichloro-3,4-dimethyl-4-nitrocyclohexa-2,5-dienone (**11**).

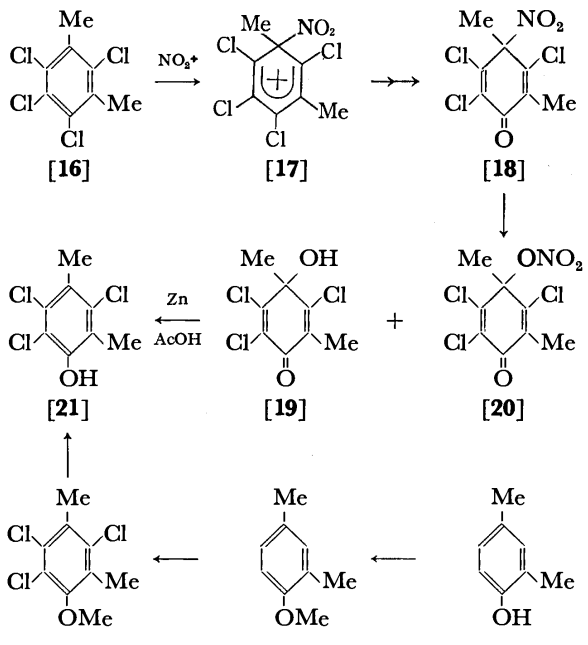
A plausible mechanism to account for the formation of **12** and **13** is outlined in Scheme 2. In this mechanism an electrophilic attack on the methyl-bearing carbon by nitronium ion results in the formation of benzenium ion (**9**) which would take up nitrate anion to form addition product (**10**), from which nitryl chloride is eliminated to yield ketone **11**. The nitro group on the doubly activated allylic carbon atom undergoes a facile solvolytic replacement, yielding **13** as the major product. Minor amount of **12** would arise from the hydrolysis of **11** during aqueous work-up. The possibility of some secondary reactions occurring on the alumina column during elution is excluded since **12** and **13** are also obtained directly from the reaction product by fractional crystallization from ethanol.

A similar treatment of tetrachloro-*m*-xylene (**16**) with nitric acid resulted in the formation of a mixture of two carbonyl compounds **19** and **20** melting at 151—152 °C and 135—136 °C, respectively. Elemental analysis and molecular weight determination revealed that **19** is isomeric with **12** and **20** is isomeric with **13**. The high-melting ketone was uniquely established as 2,5,6-trichloro-1,3-dimethyl-4-oxocyclohexa-2,5-dienol (**19**), since the alternative structure **12** had been assigned to the isomeric product from **8**.

The low-melting ketone with a formula $C_8H_6Cl_3NO_4$ (*m/e*, 285 (M^+)) exhibited two methyl singlet peaks



Scheme 2.

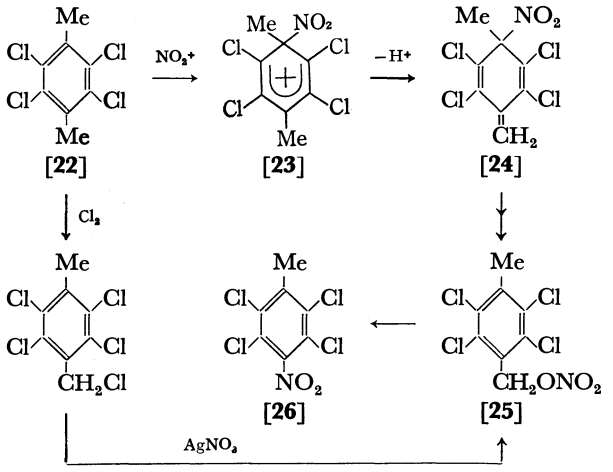


Scheme 3.

at δ 1.66 and 2.16 ppm. Its infrared spectrum showed absorptions at 1650, 1604, 1296, 1169, and 1051 cm^{-1}, and its ultraviolet spectrum with maxima at 255 (log ε=4.15) and 289—290 nm (log ε=3.46) indicated the presence of a 2,5-cyclohexadienone structure. Thus, the ketone is presumed to be a trichlorodimethyl-4-oxocyclohexa-2,5-dienyl nitrate and a similar consideration made for **13** allowed for **20** the structure 2,5,6-trichloro-1,3-dimethyl-4-oxocyclohexa-2,5-dienyl nitrate possible. Conclusive proof that the low-melting ketone has structure **20** was obtained through its transformation into 3,5,6-trichloro-2,4-xylenol (**21**) and comparing melting point, infrared spectrum and proton NMR spectrum of the latter with those of the authentic specimen prepared from 2,4-xylenol according to the sequence shown in Scheme 3.[4]

When the reaction mixture was worked up several minutes after mixing the reactants at room temperature, the predominant constituent of the product was an unstable nitroketone (**18**) which, however, could not be separated in pure form.

Tetrachloro-*p*-xylene (**22**) was treated with excess of nitric acid at room temperature to give a single clean product, which was isolated in 82% yield and identified as 4-methyl-2,3,5,6-tetrachlorobenzyl nitrate (**25**) by comparison with the authentic specimen. When the reaction mixture was allowed to stand for several weeks, initial product **25** was completely converted into 4-nitro-2,3,5,6-tetrachlorotoluene (**26**). Scheme 4 outlines the pathway from **22** to **26**. Attack on **22** by nitronium would result in the formation of a benzenium ion **23**, which would be converted to the expected nitrate **25** *via* diene **24**.



Scheme 4.

The presence of a pair of methyl group in *para* relationship is critical for the facile formation of benzyl nitrates. **22** with a pair of *para* methyl groups undergoes side-chain nitrooxylation to form benzyl nitarte **25**, whereas **8** and **16** both bearing no paired methyl groups in *para* positions undergo only nuclear oxidation to give unsaturated cyclic carbonyl compounds **12** and **13**, or **19** and **20**, respectively. No side-chain substitution was observed with the latter two substrates. Thus, the present results serve to reinforce the previous suggestion and augment the applicability of the above-mentioned guides *i* and *ii* as a basis for foreseeing the predisposition of substituted polyalkylaromatics towards the unusual nitration: electrophilic attack of the nitronium ion on three isomeric tetrachloroxylenes **8**, **16**, and **22** will lead to the formation of benzenium ions **9**, **17**, and **23**, respectively. Ion **23** satisfies the requirement *i* to follow the path a, giving the side-chain substitution product, while ions **9** and **17** comply with the requirement *ii* to follow the addition-elimination sequence (path b), resulting in the formation of unsaturated cyclic ketones. Our result, in addition to its mechanistic interest, provides a novel method for the synthesis of quinol nitrates. Further works to extend the method as an easy entry to quinols and related compounds are now in progress.

Experimental

All melting points were determined on a hot-stage apparatus and are uncorrected. Infrared spectra were obtained in Nujol mulls with a Jasco 402G spectrophotometer. Ultraviolet spectra were recorded in methanol on a Shimadzu QV-50 spectrophotometer. Proton NMR spectra were taken using a Varian T-60 instrument. All measurements were made on 5—10% deuteriochloroform solutions using TMS as an internal reference at probe temperature. Mass spectra were obtained on a Hitachi RMS-4 spectrometer.

Three tetrachloroxylene isomers were prepared by the chlorination of the corresponding hydrocarbons and purified through alumina chromatography.

Procedure for the Nitration of Tetrachloroxylenes. The procedures used for tetrachloro-*o*-xylene (**8**) and tetrachloro-*m*-xylene (**16**) were essentially the same and the only one experiment shall be reported here.

A suspension of **8** (10.0 g, 0.41 mol) in nitric acid (d=1.5, 130 g) was stirred at room temperature for 10 hr. The solid gradually dissolved giving a clear dark brown solution, which was then quenched by pouring into a large excess of ice water. The pale yellow solid precipitate (7.46 g) was collected by filtration, washed with dilute aqueous sodium hydrogen carbonate, and sucked as dry as possible. Aqueous washings were combined and extracted three times with ether and the extract was evaporated to give crude **12** (0.96 g) as pale yellow solid. A part of the product (1.0 g) was placed on the top of alumina column (deactivated by 10% acetic acid) and eluted with light petroleum to give **13** (0.33 g, 33%) as white needles, mp 145—146 °C with decomposition.

Found: C, 33.73; H, 2.05; N, 4.92; O, 22.14; Cl, 36.91%. Calcd for $C_8H_6Cl_3NO_4$: C, 33.54; H, 2.11; N, 4.89; O, 22.34; Cl, 37.12%.

Further elution with light petroleum containing benzene yielded **12** (0.39 g, 33%), which was recrystallized from ethanol to give white prisms, mp 166—167 °C.

Found: C, 40.07; H, 2.91%. Calcd for $C_8H_7Cl_3O_2$: C, 39.79; H, 2.92%.

Direct crystallization of the crude product mixture (3.25 g; air-dried for several weeks) from ethanol gave pure **13** (0.84 g). When a solution of **8** (0.63 g) in cold nitric acid (20 ml) was diluted with water immediately after complete dissolution, nitroketone **11** was obtained as pale yellow precipitate (0.34 g), mp 64—66 °C, which gradually decomposed to **12** and other unidentified substances. Its elemental analysis was not satisfactory.

Found: C, 33.07; H, 2.09; N, 4.90%. Calcd for $C_8H_6Cl_3NO_3$: C, 35.52; H, 2.24; N, 5.18%.

Similar treatment of **16** gave a mixture of several carbonyl compounds, the major components being **19** and **20**, although yields were lower under comparable conditions (20—30 and 15—24%, respectively).

19: mp 151—152 °C. ^{1}H NMR: δ 1.63 (s, 3H), 2.12 (s, 3H), and *ca.* 2.8 ppm (broad, 1H, exchangeable with D_2O); IR: 3400—3200, 1673, 1643, 1606, 1168, and 1070 cm^{-1}; UV: 249—251 (log ε=4.36) and 286—287 nm (log ε=3.75); Mass: *m/e* 240 (M^+), 225 (M^+-Me), and 205 (M^+-Cl).

Found: C, 39.62; H, 2.83%. Calcd for $C_8H_7Cl_3O_2$: C, 39.79; H, 2.92%.

20: mp 135—136 °C. Mass: *m/e* 285 (M^+), 239 (M^+-NO_2), and 223 (M^+-ONO_2).

Found: C, 33.84; H, 2.20; N, 4.59%. Calcd for $C_8H_6Cl_3NO_4$: C, 33.54; H, 2.11; N, 4.89%.

When the reaction mixture was diluted with water several minutes after mixing the reactants, there resulted a precipitate, mp 69—71 °C, which showed infrared bands at 1670, 1605, and 1570 cm^{-1} and proton NMR peaks at δ 2.15 and 2.19 ppm. These features are in line with the structure **18**, but attempt to obtain the ketone in pure form failed. On standing **18** gradually decomposed to **19** and other unidentified substances.

A suspension of tetrachloro-*p*-xylene (**22**; 0.51 g, 0.0021 mol) in nitric acid (13 g) was allowed to stand with stirring overnight. The dark mixture was poured into ice water and the precipitated solid was filtered off, washed with aqueous sodium hydrogen carbonate, and dried. The crude product (0.64 g; mp 69—72 °C) was recrystallized from ethanol to give **25** as white leaflets, mp 80—82 °C. Yield, 0.523 g (82%). IR: 1649, 1620, and 1276 cm^{-1}; ^{1}H NMR; δ 2.67 (s, 3H) and 5.85 ppm (s, 2H).

Found: C, 31.72; H, 1.63; N, 4.65%. Calcd for $C_8H_5Cl_4NO_3$: C, 31.51; H, 1.65; N, 4.59%.

When the reaction mixture was left to stand at room temperature for several weeks, the usual work-up followed by crystallization of the solid precipitate from ethanol gave 4-nitro-2,3,5,6-tetrachlorotoluene as the sole significant product. Mp 156—159 °C. The product was identical with an authentic specimen.[5]

Financial supports for this work from the Ministry of Education and the Saneyoshi Scientific Foundation are gratefully acknowledged.

Nitration of 9,10-Dialkylphenanthrenes. Side-chain Nitrooxylation in Competition with Side-chain Nitration[1]

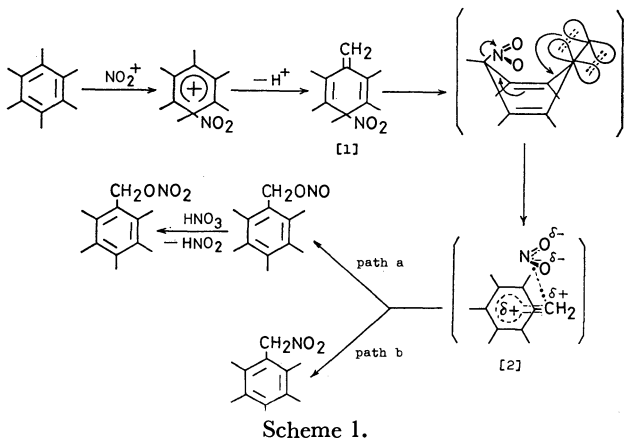
Hitomi SUZUKI, Hajime YONEDA, and Terukiyo HANAFUSA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashi-sendamachi, Hiroshima 730

(Received March 12, 1975)

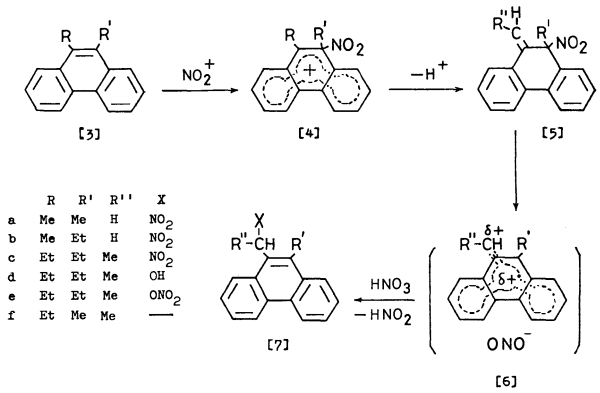
9,10-Dimethylphenanthrene and 9-methyl-10-ethylphenanthrene gave 9-methyl-10-nitromethylphenanthrene and 9-ethyl-10-nitromethylphenanthrene, respectively, as major product, when treated with fuming nitric acid in dichloromethane at low temperatures. In contrast, 9,10-diethylphenanthrene yielded a comparable mixture of products arising from side-chain nitration and side-chain nitrooxylation, which on chromatography over deactivated alumina gave 9-ethyl-10-(α-nitroethyl)phenanthrene and 9-ethyl-10-(α-hydroxyethyl)phenanthrene as main isolable products. 9-Methylphenanthrene and 9-ethylphenanthrene were both simply nitrated at the ring position to give the corresponding 9-alkyl-10-nitrophenanthrenes in good yields. No side-chain attack was observed. Factors responsible for determining which one of the competitive pathways will be followed have been discussed.

Reaction of polymethylbenzenes with fuming nitric acid often leads to the formation of products resulting from side-chain nitrooxylation (path a). In contrast, polymethylnaphthalenes and polymethylanthracenes can be attacked at the side-chain to yield naphthylnitromethanes and anthrylnitromethanes, respectively (path b). Both substitution processes have been suggested to involve nitromethylene cyclohexadiene intermediate with *para*-quinoid structure (**1**),[2] and a marked change in the modes of reaction towards the nitrating agent, observed on going from the benzenes to naphthalenes and anthracenes, has been related to the change in the development of carbonium ion character on the methylene carbon atom of intermediate ion pair (**2**) (Scheme 1).[3] In order to learn more about the mechanism of side-chain substitution and also to gain further insight into factors which determine whether path a or path b is followed, we have investigated the reaction of several alkylphenanthrenes with fuming nitric acid.



Scheme 1.

A dilute solution of 9,10-dimethylphenanthrene (**3a**) in purified dichloromethane was treated with an equivalent amount of nitric acid (d=1.5) at −10 °C and the dark brown mixture was allowed to stand in the refrigerator until the color had lightened. Quenching with water followed by chromatography of the crude product on deactivated alumina and recrystallization from chloroform–light petroleum resulted in the isolation of a new crystalline compound (**7a**), mp 175—176 °C, as principal product. **7a** had a molecular formula $C_{16}H_{13}NO_2$ and exhibited infrared bands due to nitro group at 1550 and 1361 cm^{-1}; proton NMR resonances at δ 2.81 (s, 3H), 6.09 (s, 2H), and 7.55—8.85 ppm (m, 8H). The mass spectrum showed the expected peaks at m/e 251 (M^+) and 205 (M^+-NO_2). These data are consistent with its formulation as 9-methyl-10-nitromethylphenanthrene (**7a**). This compound is unique in that it presents the first clear example of side-chain substitution which has occurred *via* nitromethylene cyclohexadiene with *ortho* quinoid structure (**5**). The overall reaction sequence is depicted in Scheme 2.



Scheme 2.

A similar reaction with 9-methyl-10-ethylphenanthrene (**3b**) yielded a yellow solid, the predominant component of which was readily separated by crystallization from ethanol and identified as 9-ethyl-10-nitromethylphenanthrene (**7b**) by its analysis and the usual spectroscopic measurements. Spectral inspection on a yellow syrupy residue from the mother liquor obtained in the recrystallization of the crude product indicated no appreciable formation of nitrate ester, which was not further sought for.

When 9,10-diethylphenanthrene (**3c**) was similarly allowed to react with nitric acid, a thick dark red liquid was obtained. It showed strong infrared bands at 1631—1635, 1278, and 860 cm^{-1}, indicating that the nitrate ester formation was a distinctly important process here. Proton NMR spectrum exhibited the characteristic

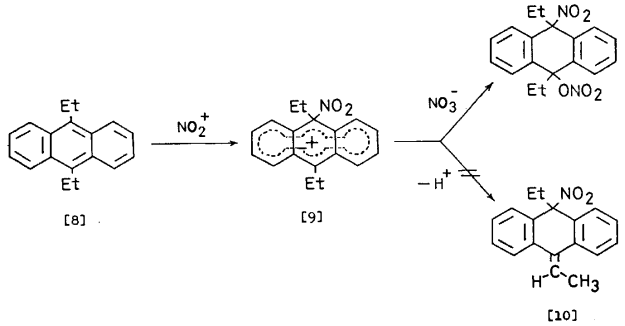
methyl and methylene splittings of two α-substituted ethyl groups, suggesting the presence of two major products arising from the attack in the α-position of ethyl groups. The signal integration revealed that these products were formed in almost equal amounts. When the product mixture was chromatographed over silica gel, slightly yellow needles melting at 107—110 °C was obtained from cyclohexane containing benzene eluates, and a low-melting glassy substance eluted from a mixture of benzene and methanol. The former compound with an elemental composition of $C_{18}H_{13}NO_2$ showed infrared bands for nitro group at 1548 cm^{-1}; proton NMR peaks due to ethyl group at 1.39 (t, 3H) and 3.23 (q, 2H), one methyl group at 2.16 (d, 3H), one methine proton at 6.33 (q, 1H), and aromatic protons at 7.36—8.89 ppm (m, 8H). On the basis of these evidences structure 9-ethyl-10-(α-nitroethyl)phenanthrene (**7c**) was assigned to the compound. The latter product with an approximate composition $C_{18}H_{18}O$ had the strong, broad infrared band due to hydroxyl group at 3540 cm^{-1}; proton NMR peaks at δ 1.38, 1.80, 3.26, 5.95, and *ca.* 7.5—9.2 ppm with the respective integrated peak area ratio of 3:3:2:1:8. These data support the assignment of structure 9-ethyl-10-(α-hydroxyethyl)phenanthrene (**7d**) to the product, characterization of which then allowed identification of a second major component in the original product mixture as 9-ethyl-10-(α-nitrooxymethyl)phenanthrene (**7e**). This would be the first case reported of the extensive nitrooxylation which occurs on an alkyl group of polycyclic aromatics and is contrasted with the reaction of 9,10-diethylanthracene (**8**) in which the only reaction that proceeds is the addition reaction.[3]

Under comparable conditions both 9-methylphenanthrene and 9-ethylphenanthrene were simply nitrated at the ring position and gave a good yield of 9-methyl-10-nitrophenanthrene and 9-ethyl-10-nitrophenanthrene, respectively. No side-chain attack was observed.

So far little work has been made of the nitration of alkyl derivatives of phenanthrene, but it is clear that 9- and 10-positions would maintain their reactivity.[4] Thus, nitronium ion attaches to the position carrying alkyl group to form arenium ion (**4**), which loses proton from the activated alkyl group on the adjacent carbon atom to give nitromethylene cyclohexadiene intermediate (**5**). **5** could collapse by heterolytic C-N bond fission to give a phenantrylmethylium-nitrite ion pair (**6**), the cationic component of which can dissipate its positive charge from the *exo*-cyclic carbon atom into two intact benzene nuclei. In a nitrite ion the the nitrogen atom has a much less electron density than oxygen atoms. A preferential bonding of 9-phenantrylmethylium ions (**6a** and **6b**) to the nitrogen atom of the ambident anion would then yield the observed nitro compound (**7a** and **7b**) (Scheme 2).

In contrast to **5a** and **5b**, diene **5c** affords a carbonium ion with branched structure (**6c**). This would mean the increase in the development of carbonium ion character in the cationic component of the ion pair **6c**. The greater the carbonium contribution, the greater would be the tendency for nitrite ion to form a covalent linkage at the atom having the higher electron density. Thus in recombining with the cationic center, oxygen atoms can effectively compete with the nitrogen atom, leading to the concurrent formation of nitro compound and nitrite ester. The latter compound is not stable in the presence of nitric acid and rapidly converted into the corresponding nitrate **7e**. The order of nitrate-forming tendencies as derived from the present work is **3c**≫**3b**>**3a**, which suggests that the mode of reaction is determined by the same factors that govern selectivity in the alkylation of the ambident anions.[5] The results are just what would have been predicted on the basis of the concept of "hard and soft acids and bases."[6]

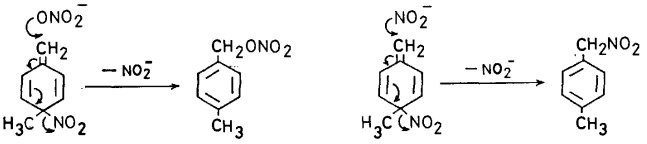
One may ask why the nitrate formation is prominent in the nitration of **3c**, but is not in the nitration of 9,10-diethylanthracene (**8**). The answer would appear to be related to a lesser degree of steric hindrance involved when arenium ion (**4**) comes in to form a nitromethylene cyclohexadiene **5c** than when ion **9** comes in to form diene **10**. Consequently, with **8** the addition product formation wins out over the side-chain substitution (Scheme 3).[3]



Scheme 3.

Spectral inspectrion of a product mixture from **3b** revealed that methyl group is much more reactive than ethyl group towards side-chain substitution. This result would be expected if one takes into account: 1) the greater contribution of intermediate ion **4b** relative to **4f** due to the partial relief of steric strain and the favorable inductive effect of ethyl group, 2) the relative ease of hyperconjugative proton release from the activated alkyl groups, and 3) the increase in steric interference with *peri*-hydrogen atom when the cyclohexadiene **5f** is formed.

An alternative possible route, which we have previously suggested for side-chain nitrooxylation of polymethylbenzenes[7] and could equally well explain the results, involves a nucleophilic attack of nitrate or nitrite anions at the *exo*-methylene group of **5** with simultaneous loss of the nitro group as nitrite anion (Scheme 4). The increase in nitrate-formation on going from **3a** to **3c** to polymethylbenzenes could con-



Scheme 4.

ceivably derive from difference in the proportion of S_N1' and S_N2' character in the transition state. Unfortunately, this pathway lacks good formal analogies in the literature as far as the authors are aware. In a recent paper,[8] some detailed discussion in favor of this mechanism has been made by Fischer and Ramsay in connection with their work on the adduct formation in the nitration of polymethylbenzenes. We do not feel, however, that sufficient data are yet available to be able to dismiss in a definite manner either of the two mechanisms proposed.

Experimental

All melting points are uncorrected. Infrared spectra were run in Nujol mulls on a Jasco DS-402G spectrophotometer. Proton NMR spectra were taken for deuteriochloroform solutions on a Varian T-60 spectrometer using TMS as internal standard. Mass spectra were obtained on a Hitachi RMS-4 spectrometer. Thin-layer chromatography on silica gel G was used for monitoring reactions and chromatographic separations. Indication was effected with iodine vapor or ultraviolet light.

9,10-Dialkylphenanthrenes were prepared by the reaction of 10-lithio derivatives of related 9-alkylphenanthrenes[9] with methyl and ethyl iodides, and purified by chromatography over alumina followed by recrystallization from benzene–light petroleum. Physical properties of some phenanthrene derivatives obtained in connection with the present work are summarized in Table 1. To our knowledge, compounds **7a** to **7e** are not previously described in the literature.

Dichloromethane used as solvent for the nitration was purified according to our procedure described in a previous paper of this series.[3] Yields are based on product isolation.

Procedure for the Nitration of 9,10-Dialkylphenanthrenes. 9,10-Dialkylphenanthrene (0.002 mol; 0.41 g for **3a**; 0.44 g for **3b**, and 0.47 g for **3c**) was dissolved in dichloromethane (5 ml) and vigorously stirred with external cooling at −10 °C. After slow addition of nitric acid ($d=1.5$; 0.002 mol, 0.86 ml) in the same solvent (5 ml) through a syringe over a period of 30 min, the mixture was kept in the dark at 0 °C for 2 hr and at room temperature for 30 min, and then quenched by the addition of water. The organic layer was separated, washed with dilute aqueous sodium hydrogen carbonate, and dried over anhydrous magnesium sulfate. The light yellow crystalline residue or syrupy liquid obtained after removal of the solvent was examined by infrared and proton NMR spectroscopy as well as thin-layer chromatography.

1) A crude product from **3a** was crystallized from a mixture of benzene and cyclohexane to give **7a** as faintly yellow needles, mp 175—176 °C. Yield, 0.43 g (86%).

Found: C, 76.57; H, 5.21; N, 5.53%. Calcd for $C_{16}H_{13}NO_2$: C, 76.48; H, 5.21; N, 5.57%.

2) A crude product from **3b** was crystallized from chloroform–pentane to give **7b** as white, fine needles, mp 172—174 °C. Yield, 0.34 g (64%). IR: 1548, 1328, 756, and 717 cm^{-1}; Mass: *m/e* 265 (M^+) and 219 (M^+-NO_2).

Found: C, 77.32; H, 5.84; N, 5.02%. Calcd for $C_{17}H_{15}NO_2$: C, 76.96; H, 5.70; N, 5.28%.

A syrupy residue obtained from the mother liquor showed infrared bands at 1632, 1276, and 853 cm^{-1}, indicating the presence of slight amounts of nitrate ester.

3) An oily product from **3c** failed to produce a solid on standing in refrigerator. It was then placed on a column of silica gel developed with cyclohexane. Elution with cyclohexane followed by a mixture of cyclohexane and benzene yielded unchanged hydrocarbon and **7c**. The latter recrystallized from benzene–chloroform appeared as slightly yellow needles, mp 107—110 °C. Mass: *m/e* 279 (M^+) and 233 (M^+-NO_2).

Found: C, 77.40; H, 6.07; N, 4.98%. Calcd for $C_{18}H_{17}NO_2$: C, 77.40; H, 6.14; N, 5.01%.

Further elution with benzene followed by 10%-methanol in benzene yielded a sticky glass, which we were unable to obtain in pure form but identified as **7d** by its NMR and IR spectra.

Found: C, 85.86; H, 7.15%. Calcd for $C_{18}H_{18}O$: C, 86.36; H, 7.25%.

Finally, elution of the column with methanol produced a trace of red-brown oil that was not further characterized.

Products from 9-methylphenanthrene and 9-ethylphenanthrene were recrystallized from a mixture of light petroleum and ether, and melted at 171—172 °C and 101—103 °C, respectively. Structural assignments were made on the basis of the analyses, NMR, and IR, spectra. Minor isomeric

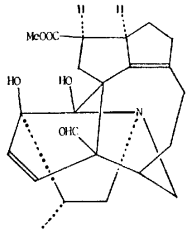
(Received April 1, 1975)

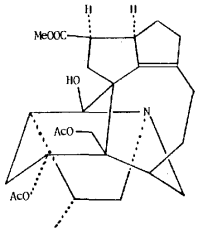
The structure of yuzurimine-C, one of the yuzurimine-type alkaloids, was unambiguously determined on the basis of chemical evidences coupled with its spectral data. Particularly, application of the ^{13}C NMR spectra plays an important role in the structural elucidation.

As described in the previous paper,[1] yuzurimine-C was isolated, as one of the minor components, from the plant *Daphniphyllum macropodum* Miquel (Japanese name "Yuzuriha"). In the present paper, we wish to describe the structure of yuzurimine-C on the basis of chemical evidences coupled with comparison of its ^{13}C NMR spectrum with those of yuzurimine and its derivatives.

Yuzurimine-C (**1**, mp 186—187 °C; $C_{23}H_{29}O_5N$) is one of the minor alkaloids, that has a secondary methyl group [δ 1.04 ppm (2H, d, J=6 Hz)] and a carbomethoxyl group [ν_{max} 1736 cm^{-1} and δ 3.58 ppm (2H, s)] analogous to those of yuzurimine (**2**).[2] The IR spectrum of **1** indicates the presence of two different carbonyl groups (ν_{max} 1736 and 1723 cm^{-1}), one of which can be due to an aldehyde group [ν_{max} 1723 cm^{-1} and δ 9.99 ppm (1H, s)], instead of a tertiary acetoxymethyl group in yuzurimine (**2**). Furthermore, two sharp doublets at δ 5.61 (1H, d, J=10 Hz) and 6.20 ppm (1H, d, J=10 Hz) in the NMR spectrum must be due to two olefinic protons  . From a biogenetic point of view, the above spectral data suggests that yuzurimine-C, which co-occurs with yuzurimine (**2**) in the plant, may have a tentative structure (**1**). In fact, this tentative structure (**1**) can be confirmed, as follows.



(**1**)



(**2**)

When heated with methyl iodide in acetone under reflux for 6 hr,* yuzurimine-C was converted into the corresponding methiodide (**3**, mp 209—210 °C; $C_{24}H_{32}O_5NI$) in almost quantitative yield. In the mass spectra of the methiodides corresponding to daphniphylline[3] and daphnilactone-B,[4] usually, they have the fragment peaks resulting from the loss of MeI from each molecular ion. In the case of **3**, however, the strong peak can be observed at m/e 413 resulting from the loss of HI, indicating that the original alkaloid (**1**) must have a HO-C-N< grouping. In fact, yuzurimine-C methiodide (**3**) was readily converted into a keto-amine (**4**, mp 199—200 °C; $C_{24}H_{31}O_5N$) only by contact with aqueous alkaline solution, as seen in the case of yuzurimine methiodide.[2] In the IR spectrum of **4**, extraordinary low C=O frequency (ν_{max} 1640 cm^{-1}) assigned to the newly formed keto-group must result from proximity of the nitrogen atom with a lone pair of electrons.

The presence of a vicinal glycol [HO-C-C(OH)-N<] can be confirmed on the basis of the following experiments. When treated with $NaIO_4$ in aqueous MeOH-THF (room temp., 16 hr), yuzurimine-C was converted into a keto-lactam [**5**, mp 179—181 °C; $C_{23}H_{27}O_5N$ (m/e 397 (M^+))], in good yield. In the IR spectrum of **5** [ν_{max} 1737, 1705 br. and 1660 cm^{-1}; no OH band], the absorption band at 1660 cm^{-1} is attributable to the newly formed lactam carbonyl. Furthermore, it is clear from the molecular model of **5** that the other newly formed keto-group can not conjugate well with the disubstituted double bond [ν_{max} 1705 br. cm^{-1} and λ_{max} 215 nm (ε, 6590)] which is readily reduced on catalytic hydrogenation leading to the formation of a dihydro-compound [**6**, mp 168—169 °C; $C_{23}H_{29}O_5N$ (m/e 399 (M^+))]. Further information of the disubstituted double bond can be obtained from the NMR spectrum of the keto-lactam (**5**), which has two doublets assigned to the grouping [δ 5.61 (1H, d, J=14 Hz) and 6.01 ppm (1H, d, J=14 Hz)]. Clearly, this disubstituted double bond in **5** (J=14 Hz) must be included in a medium ring, and not in the original six-membered ring (J=10 Hz in **1**, **3**, and **4**).[5]

As mentioned earlier, yuzurimine-C (**1**) seems to have an aldehyde group (-C-CHO) instead of the acetoxymethyl group in yuzurimine (**2**). This is also supported by the following chemical evidences: when treated with limited amounts of $LiAlH_4$ in THF (room temp., 5 hr), yuzurimine-C (**1**) was converted into the corresponding hydroxy-compound [**7**, mp 168—170 °C; $C_{23}H_{31}O_4N$ (m/e 385 (M^+) ν_{max} 3470, 3420, and 1715 cm^{-1}]. The NMR spectrum of **7** indicates two doublets at δ 3.75 and 4.06 ppm (each one proton, J=12 Hz) due to the newly formed hydroxymethyl group instead of the aldehyde group in yuzurimine-C (**1**). These doublets in **7** are further shifted to δ 4.48 ppm (2H, br. s) on acetylation with Ac_2O-pyridine (room temp., overnight) leading to the formation of the corresponding mono-acetate [**8**, mp 171—173 °C; $C_{25}H_{33}O_5N$ (m/e 427 (M^+)); ν_{max} 3440,

* The starting material was recovered under milder conditions (room temp., overnight).

1745, and 1735 cm^{-1}]. In the course of reduction, an anti-Bredt's rule imine (**9**) as an unstable intermediate must be produced,[6] as found in the case of yuzurimine (**2**).[2] Finally, the structure (**1**) for yuzurimine-C is supported by comparison of its ^{13}C NMR spectrum with those of yuzurimine (**2**) and its derivatives (**10**—**13**).[2]

Generally, partially relaxed Fourier transform (PRFT) ^{13}C NMR technique[7] is known to be very useful in the structural study on complex natural products, because methyl, methylene, methine and quaternary carbon signals are easily differentiated.

Thus, proton noise decoupled (PND) and partially relaxed FT ^{13}C NMR spectra of yuzurimine-C were measured, as shown in Fig. 1, in which the PRFT spectrum was obtained by using the pulse sequence (180 °–τ–90 °–T).

In the PRFT spectrum at τ=0.6 s, methylene and disubstituted olefin peaks appear as positive signals, while methine and secondary methyl peaks are nulled. Quaternary carbon and tetrasubstituted olefin peaks remain negative. The results of ^{13}C NMR experiments of yuzurimine-C (**1**), yuzurimine (**2**), and several derivatives (**10**—**13**) are summarized in Table 1.

In the Table 1, the signals of the quaternary carbon C-1 connected to the hydroxyl group and the nitrogen atom are seen in the spectra of **1** (δ 91.6 ppm), **2** (δ 96.8 ppm), and **10** (δ 97.3 ppm), whereas the spectra of **11**, **12**, and **13** lack the signal attributed to the above quaternary carbon. Nine methylene and six methine signals are observed in the spectra of **4** and **10**, whereas seven methylene, four methine, and one carbonyl (δ 207.0 ppm) signals are found in the case of yuzurimine-C (**1**). Furthermore, four olefinic signals are seen in the

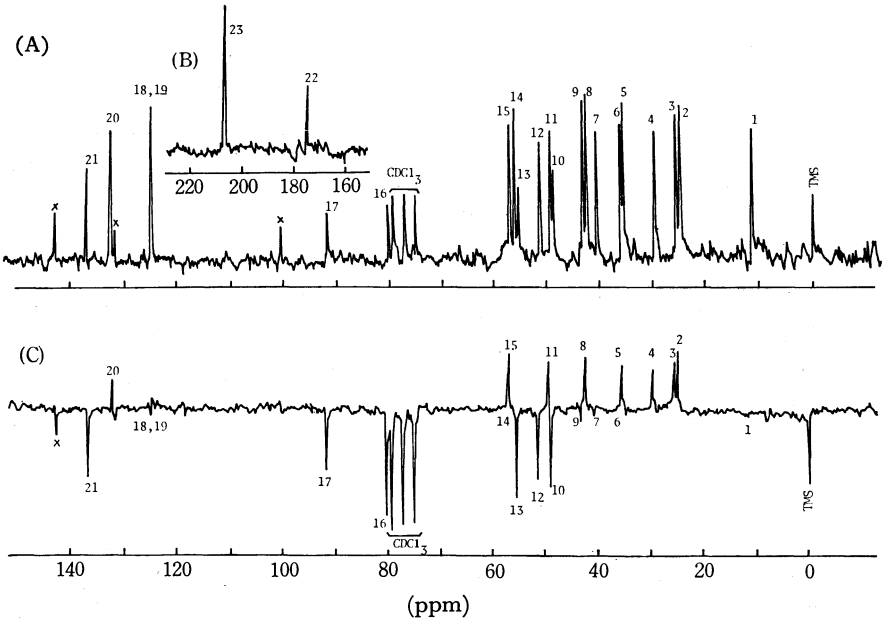

Fig. 1. (A, B) Proton noise decoupled (PND) natural abundance FT ^{13}C NMR spectra of yuzurimine-C (1) in $CDCl_3$ (100 mg/1.7 ml) at 15.04 MHz; (A): recycle time=1 s, number of scans=3600, sweep width=2500 Hz; (B): low field part, recycle time=1 s, number of scans=5400, sweep width=5000 Hz. (C): PRFT ^{13}C NMR spectrum of yuzurimine-C (1); interval time τ=0.6 s, recycle time T=10 s, number of scans=5000, sweep width=2500 Hz.

TABLE 1. ^{13}C CHEMICAL SHIFTS OF YUZURIMINE-C (**1**), YUZURIMINE (**2**), AND ITS DERIVATIVES (**10**—**13**)

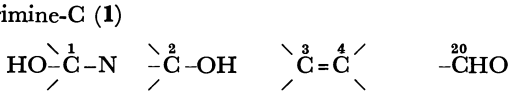
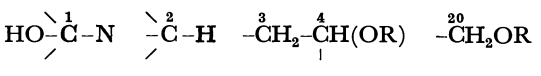
1) Chemical shifts are given in ppm relative to TMS. 2) Assignment of chemical shifts for close-lying peaks marked with asterisk may be reversed. 3) The ketonic ^{13}C NMR signal in **12** is observed at extraordinary high field (δ 189.3 ppm), indicating the presence of a strong interaction between the keto-group and the nitrogen atom, as suggested by the IR spectrum (ν_{max} 1633 cm^{-1})[2].

spectra of **1** and **13**. These facts are in good agreement with the partial structures, as shown below. The

Yuzurimine-C (**1**)



2 and **10**



presence of the hydroxyl group on C-2 in yuzurimine-C (**1**) rationalized the upfield shift of C-19 and C-22 signals and the down field shift of C-18 signal. The PRFT spectrum of **1** which lacks the signal at δ 125.0 ppm clearly indicates that the signal of one disubstituted olefinic carbon overlaps with that of one of the two tetra-substituted olefinic carbon atoms. The other signals show the one to one correspondence to each carbon atom.

The present study indicates that partially relaxed Fourier transform ^{13}C NMR technique must be very useful in the structural study on the daphniphyllum alkaloids of undetermined complex structure.[8,9]

From a structural point of view,[8] yuzurimine-C (**1**) belongs to be yuzurimine group of alkaloids as suggested in the previous paper,[1] and is the most highly oxygenated product among them.

Experimental

All mps were uncorrected. The IR and UV spectra were recorded on a JASCO Model IR-S and on a Perkin-Elmer 202 spectrophotometer, respectively. The ^1H and ^{13}C NMR spectra were obtained on a Nihondenshi JNM-PS 100 (100 MHz) and on a Nihondenshi JNM-PFT 60 (15.04 MHz), respectively. Chemical shifts for all NMR spectra are given in ppm from TMS as an internal standard using $CDCl_3$ as

solvent, unless otherwise stated. Only prominent peaks are cited. (d, doublet; m, multiplet; q, quartet; s, singlet; t, triplet). The mass spectra were recorded on a Hitachi RMU-6C mass spectrometer with an ionization energy of 70 eV. Column chromatography was carried out on basic alumina (Nakarai Chemical Co. Ltd., *ca.* 200 mesh). Thin layer chromatography (tlc) was performed on Kieselgel 60 PF_{254} using *n*-hexane–ether–diethylamine (10: 10: 1), unless otherwise stated.

Physical Properties of Yuzurimine-C (1). Mp 186—187 °C (from *n*-hexane–acetone); $[\alpha]_D^{25} = +28°$ ($c=1.33$ in $CHCl_3$); ν_{max} (KBr) 3450 br. s, 1736, 1722, and 1660 cm^{-1}; λ(EtOH) 210 nm (ε, 8410), end absorption; δ 1.04 (3H, d, $J=6.0$ Hz), 3.58 (3H, s), 5.61 (1H, d, $J=10.0$ Hz), 6.20 (1H, d, $J=10.0$ Hz), and 9.99 ppm (1H, s); *m/e* 399 (M^+), 381, 353, 352, and 324 (Found: C, 69.01; H, 7.22; N, 3.57%. Calcd for $C_{23}H_{29}O_5N$: C, 69.15; H, 7.32; N, 3.51%).

Formation of Yuzurimine-C methiodide (3). A solution of yuzurimine-C (20 mg) and MeI (2 ml) in acetone (5 ml) was heated under reflux for 6 hr, and then concentrated under reduced press to leave pale yellow crystals in quantitative yield, which were recrystallized from acetone–Et_2O to give needles of the corresponding methiodide (**3**), mp (decomp.) 209—210 °C; ν_{max} (Nujol) 3280, 1745, and 1720 cm^{-1}; δ($CDCl_3$–CD_3OD) 1.17 (3H, d, $J=6.0$ Hz), 3.20 (3H, s), 3.65 (3H, s), 3.56—4.60 (4-5H, complex), 5.88 (1H, d, $J=10$ Hz), 6.45 (1H, d, $J=10$ Hz) and 9.99 ppm (1H, s); *m/e* 413 (M^+—HI), 398, 384, 370, 356, and 327 (Found: C, 53.15; H, 6.04; N, 2.09%. Calcd for $C_{24}H_{32}O_5NI$: C, 53.24; H, 5.96; N, 2.59%).

Formation of the Keto-amine (4). A solution of **3** (30 mg) in $CHCl_3$ (20 ml) was shaken well with water (15 ml) containing Na_2CO_3 (30 mg). The chloroform solution was washed with sat. NaCl aq. solution, and then dried over anhydrous Na_2SO_4. Removal of the solvent afforded white crystals of **4** in almost quantitative yield, mp 199—200 °C (from acetone–*n*-hexane); ν_{max} (Nujol) 3400, 1725, 1715 sh., and 1640 cm^{-1}; δ 0.92 (3H, d, $J=7.0$ Hz), 2.17 (3H, s), 3.63 (3H, s), 4.08 (2H, br.), 5.83 (1H, d, $J=10$ Hz), 6.34 (1H, d, $J=10$ Hz), and 10.1 ppm (1H, s); *m/e* 413 (M^+), 398, 384, 370, 356, and 327 (Found: C, 69.27; H, 7.52; N, 3.20%. Calcd for $C_{24}H_{31}O_5N$: C, 69.70; H, 7.51; N, 3.39%).

Oxidation of Yuzurimine-C (1) with $NaIO_4$. To a solution of yuzurimine-C (100 mg) in MeOH–THF (4: 1; 8 ml) was added a solution of $NaIO_4$ (150 mg) in 50% aq. MeOH (3 ml) with stirring. The resulting solution was further stirred at room temperature for 16 hr, and then concentrated under reduced press. The remaining reaction mixture was dissolved in water and extracted with $CHCl_3$. The extract was washed with sat. NaCl aq. solution and then dried over anhydrous Na_2SO_4. Removal of the solvent gave an amorphous solid (*ca.* 107 mg), which was chromatographed on alumina (0.5 g) and eluted with Et_2O to give colorless needles of the keto-lactam (**5**), mp 179—181 °C (from Et_2O); ν_{max} (Nujol) 1737, 1705 br., and 1660 cm^{-1} (no OH absorption band); λ_{max} (MeOH) 215 nm (ε, 6590); δ 1.01 (3H, d, $J=7.0$ Hz), 3.06—3.50 (3H, complex), 3.64 (3H, s), 3,85 (1H, q, $J=13$, 8 Hz), 4.40 (1H, q, $J=12$, 8 Hz), 5.61 (1H, d, $J=14$ Hz), 6.01 (1H, d, $J=14$ Hz), and 9.95 ppm (1H, s); *m/e* 397 (M^+), 383, 369, 355, 350, 337, 311, and 310 (Found: C, 69.83; H, 7.02; N, 3.56%. Calcd for $C_{23}H_{27}O_5N$: C, 69.50; H, 6.85; N, 3.52%).

Catalytic hydrogenation of the Keto-lactam (5). Catalytic hydrogenation of **5** (15 mg) in EtOAc (2 ml) was carried out over 10% Pd–C (5 mg) at room temp. overnight, and then the catalysts were filtered. The filtrates were evaporated under reduced press. to give an almost colorless oil, which was chromatographed on alumina. Elution with Et_2O afforded white crystals (13 mg) which were recrystallized from Et_2O–*n*-hexane to give colorless plates of **6**, mp 168—169 °C; ν_{max} (Nujol) 1735, 1710, 1695, and 1623 cm^{-1}; δ 1.02 (3H, d, $J=7.0$ Hz), 3.05—3.50 (3H, complex), 3.64 (3H, s), 3.66 (1H, q, $J=13$, 8 Hz), 4.56 (1H, q, $J=12.5$, 8 Hz), and 10.01 ppm (1H, s); *m/e* 399 (M^+), 371, 339, 313, 312, 311, and 301 (Found: C, 69.12; H, 7.32; N, 3.35%. Calcd for $C_{23}H_{29}O_5N$: C, 69.15; H, 7.32; N, 3.51%).

$LiAlH_4$ Reduction of Yuzurimine-C (1). To a solution of yuzurimine-C (69 mg) in THF (3 ml) was added $LiAlH_4$ (14 mg) with stirring, and then the heterogeneous solution was continuously stirred at room temperature for 5 hr. After excess $LiAlH_4$ was decomposed with EtOH, the reaction mixture was poured into sat. potassium sodium tartarate aq. solution and extracted with $CHCl_3$. The extract was washed with sat. NaCl aq. solution and then dried over anhydrous Na_2SO_4. Removal of the solvent gave a white solid (56 mg) which was recrystallized from Et_2O–acetone to afford white crystals of **7**, mp 168—170 °C; ν_{max}(Nujol) 3470, 3420, and 1715 cm^{-1}; δ 1.16 (3H, d, $J=7.0$ Hz), 3.62 (3H, s), 3.75 (1H, d, $J=12$ Hz), 4.06 (1H, d, $J=12$ Hz), 5.69 (1H, d, $J=10$ Hz) and 5.83 ppm (1H, d, $J=10$ Hz); *m/e* 385 (M^+ for $C_{23}H_{31}O_4N$), 368, 354, and 326.

Acetylation of 7. A solution of **7** (15 mg) in dry pyridine (1 ml) and acetic anhydride (1 ml) was allowed to stand at room temperature overnight, and then concentrated under reduced press. to give a pale brown oil, which was chromatographed on alumina and eluted with EtOAc to give colorless needles of **8** (12 mg), mp 171—173 °C (from *n*-hexane–acetone); ν_{max} (Nujol) 3440, 1745, and 1735 cm^{-1}; δ 1.12 (3H, d, $J=7.0$ Hz), 2.09 (3H, s), 3.66 (3H, s), 4.48 (2H, br. s) and 5.72 ppm (2H, br. s); *m/e* 427 (M^+), 387, 368, 345, and 300 (Found: *m/e* 427.2336. Calcd for $C_{25}H_{33}O_5N$: *m/e* 427.2359).

Synthesis of 1-*N*-[(*S*)-4-Amino-2-hydroxybutyryl]lividomycin A[1]

Isamu WATANABE, Tsutomu TSUCHIYA, Sumio UMEZAWA, and Hamao UMEZAWA*

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

**Institute of Microbial Chemistry, Kamiosaki, Shinagawa-ku, Tokyo 141*

(Received April 16, 1975)

The title compound (**7**), which is active against resistant bacteria producing phosphotransferase I, was synthesized from lividomycin A through a cyclic carbamate derivative (**3**). Selective hydrolysis of the carbamate ring followed by acylation of the free C-1-amino group with (*S*)-2-hydroxy-4-aminobutyric acid by the active ester method led to **7**.

As already described,[2] (*S*)-4-amino-2-hydroxybutyrylation of 1-NH_2 of ribostamycin gives butirosin B which is active against kanamycin-resistant strains such as *E. coli* K–12 ML 1629 and ML 1630 producing neomycin-kanamycin phosphotransferase I[3] (P-ase I). The 5″-hydroxy group of lividomycins,[4] and ribostamycin undergoes this enzyme reaction and these antibiotics do not inhibit growth of these resistant organisms. We designed, therefore, to attach the above-mentioned side chain to the 1-NH_2 of lividomycin A, hoping that this antibiotic could be converted to a derivative with the activity against resistant strains.

Lividomycin A was treated with benzyl chloroformate to give penta-*N*-benzyloxycarbonyl derivative (**1**), which was treated with benzaldehyde dimethyl acetal in the presence of acidic catalyst according to the method described by Bissett, Evans, and Parrish.[5] Chromatographic separation of the products gave the tri-*O*-benzylidene derivative (**2**) in a yield of 48%. It should be noted that cyclohexylidenation of tetra-*N*-benzyloxycarbonylribostamycin with cyclohexanone dimethyl ketal gave a 5″-*O*-(1-methoxycyclohexyl) derivative.[6]

Selective removal of the protecting group at 1-NH_2 was successful through the cyclic carbamate method.[2] Treatment of **2** with sodium hydride in DMF afforded the 1,6-cyclic carbamate (**3**) in a yield of 52%. The presence of the cyclic carbamate was confirmed by the absorption peak[7] at 1765 cm^{-1}. Another cyclic carbamate formation between 2-NH_2 and 3-OH groups in the L-idose moiety was not recognized, suggesting that the 2,6-diamino-2,6-dideoxyidose moiety may be in 1C-like conformation which hinders the carbamate formation.

In order to determine the positions of the benzylidene and cyclic carbamate groups, **3** was mesylated in pyridine and the tri-*O*-mesyl derivative (**4**) was subjected to acidic hydrolysis in methanol. On examination of the hydrolyzate by thin-layer chromatography, the formation of 3′-deoxyparomamine[8] and methyl mannoside was clearly discerned, but formation of methyl riboside and methyl 2,6-diamino-2,6-dideoxyidoside was not observed. Since *O*-mesyl group is generally resistant to acid hydrolysis,[9] the above result indicates that the benzylidene groups are attached to 4′,6′-*O*, 2″″,3″″-*O*, and 4″″,6″″-*O*, and the cyclic carbamate is formed between 1-NH_2 and 6-OH groups. Observation of no OMe group of hemiacetal in the NMR spectrum of **3** also supported the structure **3**.

Protection of the hydroxyl groups with benzylidene groups is not required for the formation of 1,6-cyclic carbamate[7]; treatment of **1** with sodium hydride in DMF gave the corresponding cyclic carbamate in a yield of 45%. However, benzylidenation increased the solubility in organic solvents and facilitated later 1-*N*-acylation.

Selective hydrolysis of the cylic carbamate by gradual addition of barium hydroxide in a manner as already described[2] gave the aminol (**5**), which was then condensed with (*S*)-2-hydroxy-4-phthalimidobutyric acid[10] (HPBA) by the active ester method, using *N*-hydroxysuccinimide and dicyclohexylcarbodiimide (DCC) in tetrahydrofurane. The condensation product (**6**) was then treated with hydrazine to remove the phthaloyl group and with palladium black and hydrogen to remove the benzyloxycarbonyl and benzylidene groups to give the titled compound (**7**).

A mild acid hydrolysis of **7** gave 1-*N*-((*S*)-4-amino-2-hydroxybutyryl)-3′-deoxyparomamine (**8**), and this fact confirmed the structure of **7**.

The synthetic 1-*N*-((*S*)-4-amino-2-hydroxybutyryl)-lividomycin A showed antibacterial activity[1] against organisms producing P-ase I.

Thin layer chromatography (tlc) was carried out on silica gel (Silica Rider 5B, Daiichi Pure Chemicals Co., Ltd.)unless otherwise stated. Paper chromatography (ppc) was carried out on Toyo-Roshi paper No. 50, developed with 1-butanol-pyridine–water–acetic acid (6: 4: 3: 1) and detected by ninhydrin.

1,3,2′,2‴,6‴-Penta-N-*benzyloxycarbonyllividomycin A (1).* To a mixture of lividomycin A sulfate (21.4 g, approximately 20 mmol of lividomycin A base) and anhydrous sodium carbonate (16 g) in aqueous methanol (1: 4, 500 ml, ice-salt cooled), benzyl chloroformate (22.8 g) was added dropwise under stirring and stirring was continued for 3 hr at −5∼0 °C. The reaction mixture was evaporated to dryness and the residue was extracted with hot acetone (170 ml×3). The combined solution was evaporated to ∼100 ml. Addition of ether (300 ml) gave colorless precipitates, 30 g. On tlc with chloroform–methanol (6: 1), it gave a single spot at R_f 0.57. Purification by column chromatography on silica gel with chloroform–methanol (10: 1) as a solvent gave **1**, 26.07 g (91%); $[\alpha]_D^{22}$ +40 ° (*c* 1, MeOH). Found: C, 57.73; H, 6.14; N, 4.60 %. Calcd for $C_{69}H_{85}N_5O_{28}$: C, 57.86; H, 5.98; N, 4.89%.

4′,6′; 2‴,3‴; 4‴,6‴-Tri-O-*benzylidene-1,3,2′,2‴,6‴-penta*-N-*benzyloxycarbonyllividomycin A (2).* To a solution of **1** (5.5 g) in dry DMF (80 ml), anhydrous *p*-toluenesulfonic acid (140 mg) and benzaldehyde dimethyl acetal (8 g) were added and the solution was heated at 30 °C for 6 hr under reduced pressure (10—15 Torr). On tlc with chloroform–methanol (20: 1), the solution showed a major spot (R_f 0.68) and other several minor spots. Methanol (100 ml) was added and the solution was allowed to stand for 30 min. After addition of saturated sodium hydrogen carbonate solution (3 ml), the mixture was evaporated with the aid of toluene. The residue was extracted with chloroform (150 ml×2). The organic layer was washed with water, dried over sodium sulfate and the solvent was removed by evaporation. The residue (7 g) was chromatographed on a column of silica gel with chloroform–ethanol–triethylamine (25: 1: 0.05). The fractions containing **2** was evaporated to give a solid of **2**, 3.14 g (48%); $[\alpha]_D^{25}$ +32.5 °(*c* 1, $CHCl_3$). Found: C, 63.92; H, 5.92; N, 4.11%. Calcd for $C_{90}H_{97}N_5O_{28}$: C, 63.71; H, 5.76; N, 4.13%. Mono and di-*O*-benzylidene derivatives were also obtained (2.1 g).

4′,6′;2‴,3‴;4‴,6‴-Tri-O-*benzylidene-3,2′,2‴,6‴-tetra*-N-*benzyloxycarbonyllividomycin A 1,6-Carbamate (3).* To an ice-cold solution of **2** (550 mg) in dry DMF (5 ml) under nitrogen, 50% oily sodium hydride (70 mg) was added and the mixture was stirred for 3 hr under cooling. After addition of acetic acid (0.2 ml), the resulting viscous, pale-brown solution was poured into a mixture of chloroform (70 ml) and saturated sodium chloride solution (70 ml) under vigorous stirring. The organic layer was separated, washed with sodium chloride solution, dried over sodium sulfate and evaporated. The residue was chromatographed on a short column of silica gel with chloroform–methanol–triethylamine (20: 1: 0.1) to give a solid of **3**, 270 mg (52%); $[\alpha]_D^{25}$ +34° (*c* 1, $CHCl_3$); IR (KBr): 1765 cm^{-1} (*trans*-fused cyclic carbamate[7]). R_f 0.36 on tlc with chloroform–methanol (20: 1). Found: C, 62.49; H, 5.53; N, 4.21%. Calcd for $C_{83}H_{89}N_5O_{27}$: C, 62.75; H, 5.65; N, 4.41%.

4′,6′;2‴,3‴;4‴,6‴-Tri-O-*benzylidene-3,2′,2‴,6‴-tetra*-N-*benzyloxycarbonyl-2″,5″,3‴-tri*-O-*mesyllividomycin A 1,6-Carbamate (4).* To a solution of **3** (95 mg) in pyridine (2 ml), mesyl chloride (0.1 ml) was added and the solution was allowed to stand at room temperature overnight. Isolation of the product in a usual manner gave a solid of **4**, 105 mg (96%); $[\alpha]_D^{24}$ +28.5° (*c* 1, $CHCl_3$); IR (KBr): 1175 (ν_s SO_2), 1350 (ν_{as} SO_2) ,1770 cm^{-1}; NMR (in $CDCl_3$): δ 2.93 (3H s, SO_2CH_3), 3.06 (6H s, SO_2CH_3). Found: C, 56.39; H, 5.23; N, 3.99; S, 5.54%. Calcd for $C_{86}H_{95}N_5O_{33}S_3$: C, 56.67; H, 5.25; N, 3.84; S, 5.28%.

Acidic Methanolysis of 3 and 4. Procedure 1. A suspension of **3** or **4** in 1 M methanolic hydrogen chloride was heated at 80 °C and the reaction mixture was examined by ppc and ninhydrin coloration. After overnight heating, the reaction mixture of **3** gave a spot of 3′-deoxyparomamine[8] (the R_f-value was taken as 1) and a spot of R_f 3.5. The reaction mixture of **4** gave spots of R_f 4.75 and 3.31 (slight) and 1 (very slight). After 3 days heating, the chromatographic pattern of the reaction mixture of **3** did not changed but that of **4** changed to give a clear spot of 3′-deoxyparomamine. Other spots did not changed.

Procedure 2. A suspension of **3** or **4** in 0.5 M methanolic hydrogen chloride was heated at 80 °C for 2 days and the reaction mixture was examined by tlc (Kieselgel 60 F-254 from E. Merck in Germany) with benzene–methanol (1: 1) and detected by 5% anisaldehyde in ethanolic sulfuric acid. Each of the reaction mixtures gave a spot of methyl mannoside (R_f 0.28).

4′,6′;2‴,3‴; 4‴,6‴-Tri-O-*benzylidene-3,2′,2‴,6‴-tetra*-N-*benzyloxycarbonyllividomycin A (5).* To a solution of **3** (600 mg) in dioxane (35 ml), 0.025 M barium hydroxide solution (6 ml) was added and the mixture was stirred at 60 °C for 30 min to the completeness of neutralization. Additional aliquots (6 ml×2) of the barium hydroxide solution were added and treated similarly. Carbon dioxide was introduced and the mixture was filtrated. After evaporation of the filtrate, the residue was taken up in chloroform, washed with water, dried over sodium sulfate and freed of solvent. The crude product (620 mg) was chromatographed on a short column of silica gel with chloroform–methanol–triethylamine (10: 1: 0.03) to give a solid of **5**, 320 mg (54%); $[\alpha]_D^{20}$ +28° (*c* 1, $CHCl_3$). Found: C, 62.75; H, 6.00; N, 4.26%. Calcd for $C_{82}H_{91}N_5O_{26}$: C, 63.03; H, 5.87; N, 4.48%.

4′,6′; 2‴,3‴;4‴,6‴-Tri-O-*benzylidene-3,2′,2‴,6‴-tetra*-N-*benzyloxycarbonyl-1*-N-[*(S)-2-hydroxy-4-phthalimidobutyryl*]-*lividomycin A (6).* To an ice-cold solution of HPBA (42 mg) and *N*-hydroxysuccinimide (19 mg) in THF (1 ml), DCC (37 mg) was added and the mixture was stirred for 1 hr under cooling. To the resulting suspension, a solution of **5** (205 mg) and triethylamine (30 mg) in THF (2 ml) was added and the mixture was stirred for 2 hr under cooling. After filtration, the solution was evaporated and the residue was extracted with acetone. The solvent was removed and the residue (240 mg) was chromatographed on a short column of silica gel with chloroform–ethanol–triethylamine (20: 1: 0.05) to give a solid of **6**, 172 mg (73%); $[\alpha]_D^{22}$ +37° (*c* 1, $CHCl_3$); IR (KBr): 1713, 1655 (sh), 1525 cm^{-1}. Found: C, 62.73; H, 5.62; N, 4.60%. Calcd for $C_{94}H_{100}N_6O_{30}$: C, 62.94; H, 5.62; N, 4.68%.

1-N-[*(S)-4-Amino-2-hydroxybutyryl*]*lividomycin A (7).* To a suspension of **6** (185 mg) in aqueous ethanol (7: 1, 5 ml), hydrazine hydrate (200 mg) was added and the solution was heated at 60°C for 1.5 hr. After evaporation of the solvent, the residue was washed with water and extracted with chloroform. The solvent was removed and the residue was extracted with dioxane. To the solution (4 ml), water (1 ml) and acetic acid (0.3 ml) were added and the mixture was hydrogenated over palladium black at room temperature overnight. The mixture was filtered and evaporated. The residue was extracted with water and, after addition of a few drops of acetic acid, the aqueous solution was again treated with palladium black and hydrogen likewise. The hydrogenation was repeated once again. After filtration, the filtrate was evaporated and the residue was chromatographed on a column of CM-Sephadex C-25 (NH_4 form). Elution with a linear gradient of am-

monia (0—0.2 M) gave a single peak of chromatographically homogeneous **7**, 63 mg (69%); $[\alpha]_D^{22}$ +68° (*c* 1, H_2O); ppc, $R_{\text{flividonycin A}}$ 0.52; IR (KBr): 1660, 1575 cm^{-1}. Found: C, 44.81; H, 7.13; N, 9.30%. Calcd for $C_{33}H_{62}N_6O_{20}\cdot H_2O$: C, 45.00; H, 7.32; N, 9.54%.

1-N-((S)-4-Amino-2-hydroxybutyryl)-3'-deoxyparomamine (8). A suspension of **7** (100 mg) in 0.4 M methanolic hydrogen chloride (5 ml) in a sealed tube was shaken at 70 °C for 15 hr. Powdered sodium hydrogen carbonate was added and the neutral mixture was filtered and the filtrate was evaporated. The residue was chromatographed on a column of CM-Sephadex C-25 (NH_4 form). Elution with a linear gradient of ammonia (0—0.15 M) gave a single peak of chromatographically homogeneous **8**, 25 mg (47%); $[\alpha]_D^{19}$ +19° (*c* 0.7, H_2O); ppc, $R_{f\ 3'\text{-deoxyparomamine}}$ 0.45; IR (KBr): 1640, 1550 cm^{-1}. Found: C, 43.62; H, 7.41; N, 11.72%. Calcd for $C_{16}H_{32}N_4O_8\cdot H_2CO_3$: C, 43.40; H, 7.28; N, 11.90%.

(Received December 10, 1974)

The chemical shifts of the hydrogen bonded OH proton of *m*- and *p*-substituted phenols, and 4-substituted 2-cresols, 3-cresols, and 2,6-xylenols were determined in DMSO. The effects of substituents on the hydroxyl chemical shift of these series were correlated linearly with each other (correlation coefficient$>$0.999), except for the bulky planar substituents in the 3-cresol series which may be subject to the steric loss of their coplanarity with the benzene ring. The substituent effects were treated successfully with the equation, $\Delta\delta=\rho(\sigma^0+r^-\Delta\bar{\sigma}_R^-)$. The phenol series gave $r^-=0.673$ and $\rho=1.530$. The same r^- value appeared to be applicable to all the other series with negligible changes in the ρ value. Deviations from the correlation of particular substituents, in particular those having acidic hydrogen, were attributed to the modification of the electronic nature of substituents arising from the strong substituent-DMSO interaction.

Concerning the substituent effects, we discussed in detail the application of the LArSR Eq. (1) and LSFE Eq. (2)[2)] to the correlational analysis of the hydroxyl proton chemical shifts of *m*- and *p*-substituted phenols in DMF.[3)]

$$\log(k/k_0) \text{ or } P-P_0=\rho\bar{\sigma}=\rho(\sigma^0+r^+\Delta\bar{\sigma}_R^++r^-\Delta\bar{\sigma}_R^-) \quad (1)$$

$$\log(k/k_0)_p=\rho\bar{\sigma}_p=\rho(\sigma_i+q_r^+\sigma_\pi^++q_r^-\sigma_\pi^-) \quad (2)$$

$$\log(k/k_0)_m=\rho\bar{\sigma}_m=\rho(1.17\sigma_i+0.50\sigma_\pi^\pm) \quad (2')$$

The substituent chemical shifts of the hydrogen bonded hydroxyl proton were described in terms of inductive and resonance parameters derived from the chemical reactivity. This might be due to the fact that the hydrogen-bonding of phenols resembles the dissociation of phenols in the electronic situation. The results indicated that the electronic nature of substituents in DMF solution was effectively modified, in reference to those in aqueous solutions, by the particular substituent-solvent interactions. We tentatively derived a set of inductive and resonance substituent constants for such DMF-modified substituent groups. The validity of such a treatment should be verified for systems other than the substituted phenols in DMF solution. Further, the consistency of solvent-modified parameters therefrom should be verified in various systems whose resonance requirements with substituents differ; the constancy of parameters independent of the systems of different combinations of inductive-resonance effects should be examined. Since the chemical shifts of ordinary protons of substituted benzene derivatives are usually determined in non-aqueous aprotic solvents, similar modification of the substituent effect may be involved in these chemical shift data. In order to shed further light on these problems, we have studied substituent effects on the hydrogen-bonded proton NMR chemical shifts of various series of phenols, naphthols,[4)] anilines,[4)] and acetanilides[5)] in several aprotic solvents.

The proton resonance spectra of NH groups generally have a broadened line due to quadrupole of nitrogen, which hinders the ultimate accuracy of the chemical shift measurement of substituted anilines and acetanilides in DMF. However, such a difficulty due to broadening was found to be much reduced in measurements in DMSO solution. A similar improvement was also observed in the determination of OH chemical shifts of some hindered phenol systems such as substituted cresols and xylenols. DMSO is now being extensively used as a solvent and the substituent chemical shift data in DMSO solution have recently become available from our studies which include not only proton NMR but ^{13}C and ^{19}F NMR chemical shift data.[4)] Determination of the set of substituent parameters from the phenol substituent chemical shifts in the particular solvent thus becomes necessary as a reference for this series of studies. The phenol-hydroxyl chemical shifts in DMSO have been studied by several investigators[6-8)] and treated with σ^- constants. Our treatment stands on a different basis and appears to be more consistent.

The present paper gives brief discussions on our LArSR analysis of substituent effects on the chemical shifts of phenols in DMSO solution. A similar treatment of substituent chemical shifts of series of hindered phenols is included for comparison. A forthcoming paper[9)] will give the LSFE analysis and a comparison with relevant treatments of the same material by means of Taft[10)] and Swain and Lupton[11)] equations.

Experimental

The chemical shifts were measured from the low field ^{13}C–H satellite of dimethyl sulfoxide as an internal standard with a Hitachi-Perkin Elmer R-20 Spectrometer operating at 60 MHz.

Dimethyl sulfoxide was fractionally distilled from calcium hydride under reduced pressure and stored over molecular sieves.

All the phenols, cresols and xylenols were thoroughly purified by repeated fractionation or recrystallization from appropriate solvents, and for some phenols purification was effected by further sublimation of purified samples. Melting points and other physical constants agreed well with established values. The preparation of most *m*- and *p*-substituted phenols was previously described.[3)]

m- *and* p-*Hydroxyphenyltrimethylammonium Iodides* were prepared from corresponding aminophenols by exhaustive meth-

ylation with methyl iodide in aqueous sodium carbonate solution; *m*-$(Me)_3N^+I^-$ derivative, mp 198.5 °C, recrystallized from ethanol, lit,[12] mp 179 °C, and *p*-$(Me)_3N^+I^-$ derivative, mp 210.5 °C, recrystallized from ethanol, lit,[12] mp 195 °C.

m-*and* p-*Hydroxyphenyldimethylsulfonium Iodides* were prepared from methylmercaptophenols by methylation on heating with methyl iodide in a sealed tube at 110 °C for 12 hr; *m*-isomer, mp 79—80 °C, from methanol-ether, lit,[13] mp 97—98 °C; *p*-isomer, mp 127—128 °C, from ethanol-ether, lit,[14] mp 123—124 °C.

m-Methylmercaptophenol afforded m-*hydroxyphenyl methyl sulfoxide* on oxidation. The phenol was allowed to react with methanesulfonyl chloride in acetic anhydride for 24 hr at 0—−5 °C, to give the methanesulfonate (mp 36—37 °C, lit,[15] mp 38—39 °C). Oxidation of the sulfonate on standing the mixture with fuming nitric acid ($d=1.52$) in acetic anhydride for 24 hr at below 0 °C, yielded *m*-methylsulfinylphenyl methanesulfonate (mp 89—90 °C, lit,[15] mp 89—90 °C), which was hydrolyzed with 10% aq. sodium hydroxide solution at 50 °C for 24 hr to give the final product; mp 55—55.5 °C; from benzene-chloroform, lit,[15] mp 61—62 °C.

Several 3-cresols, available from commercial sources, were purified by appropriate methods; 3-*cresol*, bp 101 °C/20 mmHg, lit,[16] mp 202 °C; 3,4-*dimethylphenol*, mp 62—63 °C, from benzene-petroleum ether, lit,[16] mp 62.5 °C; 4-*chloro*-3-*cresol*, mp 63—63.5 °C, from *n*-hexane, lit,[17] mp 66 °C; 4-*nitro*-3-*cresol*, mp 133—133.5 °C, from ethanol-benzene, lit,[18] mp 129 °C; 4-*methylthio*-3-*cresol*, mp 56.8—57.2 °C, from benzene-*n*-hexane, lit,[12] mp 55—56 °C.

4-*Amino*-3-*cresol* was prepared from 4-nitro-3-cresol by reduction with stannous chloride in alcoholic hydrochloric acid and purified by sublimation under 1 mmHg at 120 °C (mp 180—181 °C, lit,[16] mp 179 °C), which was converted by acetylation with acetic anhydride-water into 4-*acetamino*-3-*cresol* (mp 132—133 °C, from aq. ethanol, lit,[16] mp 130 °C) and by methylation with methyl iodide into 2-*methyl*-4-*hydroxyphenyltrimethylammonium iodide*, mp 216—217 °C, from ethanol, lit,[12] mp 194.8—195 °C.

4-Dimethylamino-3-cresol was also derived from 4-amino-3-cresol. The aminocresol was converted into the methyl ether with diazomethane and then into *N,N,N*-trimethyl-4-methoxy-2-methylanilinium iodide with methyl iodide. The anilinium iodide was converted by the method given by Cope *et al.*,[19] reductive fission with lithium aluminum hydride in boiling THF, into 4-dimethylamino-3-methylanisole (bp 163 °C/26 mmHg), which yielded 4-*dimethylamino*-3-*cresol* (mp 89—89.2 °C, from ligroin. Found: C, 71.37; H, 8.57; N, 9.17%. Calcd for $C_9H_{13}NO$: C, 71.49; H, 8.67; N, 9.26%.) by the ether-fission with boiling hydroiodic acid.

4-Methoxy-3-cresol and 3-methylhydroquinone were prepared from 4-amino-2-cresol. 4-Amino-2-cresol was allowed to react with diazomethane to give 4-amino-2-methylanisole, which was diazotized in dil. sulfuric acid at 0 °C and decomposed at elevated temperature. The phenolic product gave two distillates, bp 120 °C/18 mmHg and bp 160 °C/18 mmHg, on fractionation. 4-*Methoxy*-3-*cresol*, mp 43.5—45.2 °C (lit,[20] mp 46 °C), was obtained from the former fraction by recrystallization from petroleum ether, and 3-*methylhydroquinone*, mp 131.5—132 °C, lit,[21] mp 124—125 °C, from the latter, by recrystallization from benzene.

Oxidation of 4-methylthio-3-cresyl acetate with hydrogen peroxide in acetic acid according to the method given by Bordwell and Boutan[15] gave 4-methylsulfonyl-3-cresyl acetate, which was hydrolyzed with 10% aq. potassium hydroxide solution to give 4-*methylsulfonyl*-3-*cresol* in good yield (mp 105.5—106.5 °C, from chloroform. Found: C, 51.38; H, 5.21; S, 17.28%. Calcd for $C_8H_{10}SO_3$: C, 51.60; H, 5.41; S, 17.22%.). 4-Methylthio-3-cresol was converted into 4-*methylsulfinyl*-3-*cresol* (mp 120.8—121 °C, from benzene-chloroform; Found: C, 56.28; H, 5.82; S, 18.70%. Calcd for $C_8H_{10}SO_2$: C, 56.44; H, 5.92; S, 18.84%.) *via* 4-methylthio-3-cresyl methanesulfonate, by the same oxidation procedure for *m*-hydroxyphenyl methyl sulfoxide. 4-*Hydroxy*-2-*tolyldimethylsulfonium iodide* (mp 113.5—114 °C, from ethanol-ether, lit,[12] mp 110—111 °C) was obtained by the same method as that for hydroxyphenyldimethylsulfonium iodide. 4-*Thiocyano*-3-*cresol* was prepared by the procedure given by Bordwell and Boutan[22] and was purified by recrystallization from benzene-ligroin; mp 79 °C, lit,[23] mp 76 °C.

4-*Acetyl*-3-*cresol* (mp 134 °C, from benzene, lit,[24] mp 128 °C) was obtained by the Fries rearrangement of 3-cresyl acetate with $AlCl_3$, being allowed to stand at room temperature for 24 hr in nitrobenzene.

4-*Bromo*-3-*cresol* was given by the bromination of *m*-cresol according to the reported method.[25] The bromination product obtained by the dropwise addition of bromine to *m*-cresol in chloroform was carefully fractionated to remove the 6-bromo derivative. The fraction, bp 140—145 °C at 20 mmHg, gave 4-bromo-3-cresol and purification was further effected by repeated recrystallization from petroleum ether; mp 59 °C, lit,[26] mp 58.5—59.2 °C and[25] 60—61 °C. 4-Bromo-3-cresol was converted into 4-*cyano*-3-*cresol* (mp 140—140.2 °C, from benzene. Found: C, 72.06; H, 5.21; N, 10.32%. Calcd for C_8H_7NO: C, 72.16; H, 5.30; N, 10.52%.) by the method given by Friedman and Shechter.[27] The 4-cyano derivative was hydrolyzed and esterified with methanol to give 4-*carbomethoxy*-3-*cresol*; mp 115.5—116 °C recrystallized from benzene (lit,[28] mp 109 °C).

2-*Cresol* (bp 128—129 °C/110 mmHg, lit,[16] bp 130 °C/112 mmHg) and 2,4-*xylenol* were obtained by purification of commercial products.

By the usual diazonium method, 4-chloro-2-toluidine was converted into 4-*chloro*-2-*cresol* (mp 48.5—49 °C, from petroleum ether, lit,[17] mp 49 °C), and 4-nitro-2-toluidine into 4-*nitro*-2-*cresol* (mp 95—95.5 °C, from benzene-ligroin, lit,[29] mp 94.4—95 °C).

4-Nitro-2-cresol was reduced with stannous chloride in alcoholic hydrochloric acid into 4-*amino*-2-*cresol* (mp 178 °C subl. at 100 °C/3.5 mmHg, lit,[16] mp 175 °C) which was followed by acetylation with aq. acetic acid and acetic anhydride into 4-*acetylamino*-2-*cresol* (mp 185—185.5 °C from aq. ethanol, lit,[16] mp 179 °C), and also by exhaustive methylation with methyl iodide into 4-*hydroxy*-3-*methyl phenyltrimethylammonium iodide* (mp 226.8—227 °C, from ethanol. Found: C, 40.84; H, 5.60; N, 4.70; I, 42.99%. Calcd for $C_{10}H_{16}ONI$: C, 40.97; H, 5.50; N, 4.78; I, 43.29%.).

4-*Dimethylamino*-2-*cresol* was prepared from 4-amino-2-methylanisole by same procedure as that for 3-cresol derivative, mp 84—85 °C, recrystallized from benzene-ligroin. Found: C, 71.20; H, 8.67; N, 8.98%. Calcd for $C_9H_{13}NO$: C, 71.49; H, 8.67; N, 9.26%.

4-Bromo-2-methylacetanilide was saponified to give 4-bromo-2-methylaniline, which was converted by the diazonium method into 4-*bromo*-2-*cresol*; mp 65—65.5 °C, from ligroin, lit,[16] mp 64 °C. Similarly, 4-*cyano*-2-*cresol* (mp 97.5—97.8 °C, from benzene-ligroin, lit,[16] mp 93 °C) was prepared from 4-cyano-2-methylaniline, and was converted by saponification and esterification into 4-*carbomethoxy*-2-*cresol*; mp125.8—126 °C, from ligroin-benzene. Found: C, 64.87; H, 5.98%. Calcd for $C_9H_{10}O_3$: C, 65.05; H, 6.07%.

4-*Acetyl*-2-*cresol* (mp 112—112.2 °C, from benzene, lit,[30] mp 104 °C) was obtained by the same method as that for 3-cresol.

4-*Methoxy*-2-*cresol* was synthesized according to the reported meth od[31]; 4-methoxyphenol was converted into 2-cresol by

direct introduction of 2-methyl group with dimethylamine and formaldehyde followed by hydrogenolysis (120 atom H_2, 200 °C, 16 hr) in the presence of CuCrO in dioxane; mp 72 °C, from benzene–ligroin, lit,[31] mp 70.5 °C.

4-*Thiocyano*-2-*cresol* was obtained by the same method as that for the 3-cresol derivative; mp 70.5—71 °C, from benzene–ligroin, lit,[23] mp 71 °C.

The following 4-substituted 2,6-xylenols were employed for measurements after repeated recrystallization of commercial products from appropriate solvents; 2,6-*xylenol*, mp 45—45.2 °C, from *n*-hexane, lit,[32] mp 46—47 °C; 2,4,6-*trimethylphenol*, mp 73.8—74.2 °C, from *n*-hexane, lit,[31] mp 70—71 °C; 4-*methylthio*-2,6-*xylenol*, mp 63 °C, from *n*-hexane, lit,[33] mp 62.5—64 °C.

4-*Nitro*-2,6-*xylenol* was prepared by the following procedure. 2,6-xylenol was converted into its methyl ether with dimethyl sulfate and then nitrated with nitric acid in acetic anhydride. 4-Nitro-2,6-xylenol methyl ether obtained was demethylated with hydrobromic acid–acetic acid mixture to give the final compound; mp 172.5—173 °C, from benzene, lit,[32] mp 170—172 °C. 4-*Hydroxy*-2,6-*xylenol* was obtained from the above 4-nitro-2,6-xylenyl methyl ether successively by reduction with tin in hydrochloric acid–ethanol, diazotization of the resulting aniline to give the phenol, and demethylation; mp 153—154 °C, sublimation 120 °C at 4 mmHg, lit,[16] mp 149—151 °C.

4-*Bromo*-2,6-*xylenol* was prepared[34,35] from 2,6-xylenol by bromination in acetic acid at 15°C and purified by recrystallization from *n*-hexane, mp 79—79.5 °C, lit,[35] mp 79 °C. The above 4-bromo compound was converted into 4-*cyano*-2,6-*xylenol* (mp 125 °C, from aq. ethanol, lit,[32] mp 124—125 °C) by the usual procedure[27] with cuprous cyanide in boiling DMF. 4-*Carbomethoxy*-2,6-*xylenol* was given by saponification of the 4-cyano compound and esterification of the 4-carboxylic acid with methanol–conc. sulfuric acid; mp 131.5—132 °C, from benzene, lit,[16] mp 130 °C.

4-*Acetyl*-2,6-*xylenol* was obtained by the Fries rearrangement of 2,6-xylenyl acetate and recrystallized from ethanol–benzene; mp 156—157 °C, lit,[32] mp 151—152 °C. 4-*Benzoyl*-2,6-*xylenol* was prepared by the same procedure from 2,6-xylenyl benzoate; mp 145 °C, from aq. ethanol, lit,[36] mp 142—142.5 °C.

4-*Methoxy*-2,6-*xylenol* was synthesized according to the procedure described for 4-methoxy-2-cresol; mp 78.2—78.5 °C, from ligroin, lit,[31] mp 77 °C.

4-*Hydroxy*-3,5-*dimethylphenyldimethylsulfonium iodide* was prepared from 4-methylthio-2,6-xylenol with methyl iodide by heating under reflux for 30 min; mp 130 °C, from methanol–ether. Found: C, 38.69; H, 5.10; S, 10.52; I, 40.51%. Calcd for $C_{10}H_{15}OSI$: C, 38.72; H, 4.87; S, 10.34; I, 40.91%.

4-*Methylsulfonyl*-2,6-*xylenol* was prepared from 4-methylthio-2,6-xylenol by oxidation by the same procedure as that for *p*-substituted cresol and recrystallized from chloroform–benzene–ethanol, mp 158—159 °C, lit,[37] mp 149—150 °C.

4-*Hydroxy*-3,5-*dimethylphenyl methyl sulfoxide* was prepared by the same procedure as that for *m*-hydroxyphenyl methyl sulfoxide; 4-methylthio-2,6-xylenol was converted into the corresponding methanesulfonate (mp 77—78.5 °C, from chloroform–*n*-hexane) which was oxidized with fuming nitric acid–acetic anhydride to 4-methanesulfoxy-3,5-dimethylphenyl methyl sulfoxide (mp 122.5—123.5 °C, from benzene–chloroform) and then followed by saponification to give the final compound, mp 76—77 °C, from benzene–chloroform–petroleum ether. Found: C, 58.56; H, 6.49; S, 17.23%. Calcd for $C_9H_{12}O_2S$: C, 58.67; H, 6.56; S, 17.40%.

4-*Acetamino*-2,6-*xylenol* was prepared by reduction of 4-nitro-2,6-xylenol with stannous chloride in ethanolic hydrochloric acid, followed by direct acetylation of the aniline obtained with aqueous acetic acid–acetic anhydride mixture and recrystallized from benzene, mp 142.5—143 °C; Found: C, 66.84; H, 7.44; N, 7.56%. Calcd for $C_{10}H_{13}NO_2$: C, 67.02; H, 7.31; N, 7.82%.

Results

In the hydroxyl chemical shift measurement in DMSO solution, relatively sharp and stable signals were obtained for various phenols even under conditions of highest possible dilution (about 0.065 M). The dilution shift was generally insignificant in this solvent, at most *ca.* 2 Hz on 4-fold dilution, and was practically negligible in the case of hindered phenols. Most phenols gave hydroxyl signals of half-height width within 1.5 Hz. Although Traynham[6] did not find the OH signal of *p*-aminophenol, we succeeded in observing a sharp signal of the OH proton with regular intensity by using the sample purified by repeated sublimation immediately before use. Fischer *et al.*[38] reported that 4-formyl- and 4-nitro-2,6-xylenols exhibited very broad peaks, especially the latter a peak of half-height width of 1.4 ppm. According to the present results, 2,6-xylenols generally gave slightly broader signals for the hydroxyl proton than unhindered phenols, but the nitro derivative gave a signal of width within 5 Hz, benzoyl and cyano derivatives 7 Hz, and at the worst, acetyl derivative 12—17 Hz.

The non-equivalent OH protons of 2-methyl- and 2,6-dimethyl-hydroquinones gave two separated signals of the ordinary half-height width in this solvent. This suggests that no rapid proton exchange occurs between the two OH groups. The assignment was made on the basis of correlations between substituent chemical shifts for different structural classes of phenols.

The hydroxyl proton chemical shifts extrapolated to the infinite dilution are summarized in Table 1. Since

the values for *m*- and *p*-substituted phenols were already reported,[3] the Table 1 includes only new data and those necessary for comparison with substituent shifts of other derivatives. The results for *m*- and *p*-substituted phenols are in good agreement with those reported by Traynham[6] and Ouellette[7] within ±0.01 ppm. The data for *p*-acetyl and *p*-trifluoromethyl derivatives are identical with Traynham's values but not with those of Ouellette. Socrates[8] also reported a set of data under the same conditions, differing from ours by more than ±0.1 ppm for 13 derivatives and more than ±0.3 ppm for 6 in 45 derivatives where comparisons are possible. The discrepancies appear to be out of the usual limit of conceivable errors when compared to the fact that the data of Tribble and Traynham differed from ours only at most by 0.03 ppm.

The chemical shifts of 4-substituted 2,6-xylenols are generally in good agreement with those reported by Fischer *et al.*[38]

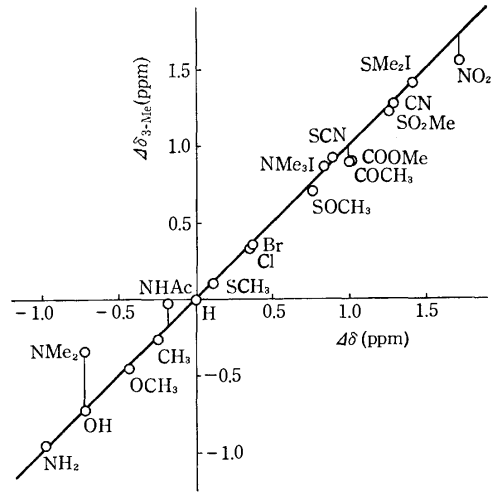

Fig. 1. The linear relation between the substituent chemical shifts of 3-cresols and phenols.

Discussion

In *m*- and *p*-substituted phenols, the electron attracting substituents gave a lower field shift and the releasing groups a higher field shift. This can be interpreted reasonably in terms of the stabilization or the dispersion of the acquired negative charge at the hydroxyl oxygen by the strong OH–DMSO hydrogen-bonding. The stronger hydrogen-bonding by the acid-strengthening substituents should bring about the greater shifts toward down field. Thus the substituent chemical shift may be in principle related to the Hammett-type substituent constants.

The substituent chemical shifts of 4-substituted 2-cresols correlate linearly to those of 4-substituted phenols with excellent precision (correlation coefficient 0.99995 and standard deviation ±0.009) by

$$\Delta\delta_{2\text{-Me}} = 1.047\Delta\delta - 0.008$$

Similarly 4-substituted 2,6-xylenols correlate with phenols by

$$\Delta\delta_{2,6\text{-Me}_2} = 0.999\Delta\delta - 0.009$$

with a correlation coefficient 0.9999 and a standard deviation ±0.013. Introduction of two methyl groups at both *ortho* positions to the phenol hydroxyl markedly shifts the correlation line to up field but does not affect the susceptibility of the hydroxyl chemical shift to changes in 4-substituent. 4-Substituted 3-cresols also give a good linear plot of the substituent chemical shifts against phenols, as shown in Fig. 1 with the slope= 1.000, except dimethylamino, acetamino, and nitro derivatives, deviations of which can of course be referred to the steric loss of coplanarity of substituents with the benzene ring.

Socrates[8] pointed out that the substituent chemical shifts of various phenols, including *ortho*-substituted derivatives, in DMSO solution were correlated linearly to the pK_a of corresponding phenols in water. Figure 2 shows a plot of the chemical shifts obtained in the present study against the corresponding pK_a values in water. Because of their leveling effect, strongly electron releasing substituents in the dissociation of

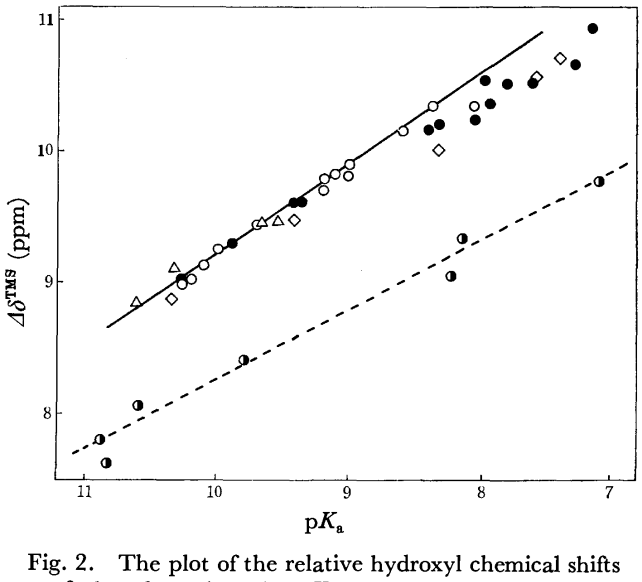

Fig. 2. The plot of the relative hydroxyl chemical shifts of phenols against the pK_a values: *m*-substituted ○, *p*-substituted ● phenols, 3-cresols ◇, 2-cresols△, and 2,6-xylenols ◑.

phenols could not be included in this comparison. *m*-Substituents appear to fall on a straight line and all +*R* class 4-substituted derivatives deviate substantially below the line. These systematic deviations should be significant in view of the excellent correlations of hydroxyl chemical shifts among different classes of phenols above. It is worthy to note that the 2,6-xylenols fall on a parallel line. Thus, Socrates' correlation does not seem to be an accurate description of the substituent effect on the hydroxyl chemical shift of various phenols in DMSO. The systematic deviations of *para* substituents evidently suggest that the resonance contribution (relative to the inductive contribution) of +*R* class *para* substituents is less important in the hydrogen-bonding hydroxyl chemical shifts with DMSO than in the dissociation of phenols in water.

The relative chemical shifts for 17 well-behaving *m*-substituents on phenol in DMSO give a linear Hammett correlation with the standard σ_m constants,[3]

$$\Delta\delta = 1.529\sigma_m - 0.004 \quad (3)$$

with standard deviation ± 0.022 and correlation coefficient 0.9987.[39] Fischer *et al.* applied a similar treatment to each of three sets of literature data[6,7] to give ρ values of 1.4—1.53.[38] In Eq. (3) of *meta* derivatives, deviations are obvious for amino, hydroxyl, and acetamino groups which were not included in the calculation. *m*-Acetyl, *m*-carboalkoxy, and *m*-methoxy groups exhibited slightly less electron-attracting effects than expected from the standard σ_m values and are fitted closer to the correlation line by employing the $\bar{\sigma}$ values, 0.291, 0.31, and 0.06, respectively, which were derived from pK_a of corresponding benzoic acids in aqueous organic solutions.[40] All the results suggest the importance of the solvent-substituent interaction. Amino, acetamino, and hydroxyl groups act as effective hydrogen-bond donors to DMSO. The negative charge acquired at hydroxyl oxygen or amino nitrogen due to hydrogen bonding with an acceptor solvent can make these groups more electron releasing. The loss of hydrogen-bond donation in non-aqueous aprotic solution can explain the deviations of *m*-methoxy, *m*-acetyl, and *m*-carboalkoxy groups. The substituent parameters of a given group should change due to the modification of its electronic nature by the solvent-substituent interaction.[3] Since the ordinary substituent parameters were derived from the data in aqueous solutions where donative hydrogen bonding to substituents is highly important, they may not correlate well with the data in aprotic solvents. We have denoted the overall effect as "the solvent-modification of substituent effects" or "the effect of solvent-modified substituents."[3] There should be a number of possible causes for the deviations, but we assume that the deviations observed in the above correlation can be referred primarily to the effect of the solvent-modification of substituents. Thus, all substituents would be modified more or less in the present system. However, most *meta* substituents except for the few groups mentioned above follow Eq. (3) and the range of fitting covers chemical shift changes over 1.2 ppm. Accordingly the ρ value obtained above appears to be sufficiently reliable.

We see from Socrates' correlation (Fig. 2) that the conjugatively electron attracting ($+R$) *para* substituents exhibit more enhanced resonance effects than those estimated from corresponding σ_p^0 values. Traynham applied σ_p^- values for correlating these substituents and gave slightly different ρ values for *para* and *meta* derivatives.[6] From the systematic deviations in Fig. 2 it is evident that neither σ_p^0 nor σ_p^- could represent appropriately the effects of $+R$ *para* substituents in this system with the same ρ value as *meta* substituents. In order to describe the effects of both *para* and *meta* substituents, an introduction of certain parameter weighting resonance contribution relative to the inductive or unexalted polar contribution appears to be necessary. The LArSR equation can be applied to this system as a useful approximation, giving a satisfactory correlation (for 30 *m*- and *p*-derivatives),

$$\Delta\delta = 1.530(\sigma^0 + 0.673\Delta\bar{\sigma}_R^-) - 0.004 \quad (4)$$

with standard derivation ± 0.024 and correlation coefficient 0.9990.[41] This confirms that the substituent effect on the hydrogen-bonded hydroxyl chemical shift can be treated in the same way as that on chemical reactivities in terms of the Hammett-type substituent parameters. The $-R$ *para* substituents appear to give a better fit to the σ_p than to σ_p^0 constants,[3,42] but the deviations due to the solvent-modification may also be expected for certain *para* substituents as observed in the *meta* correlation. When the $-R$ *para* groups are correlated with the standard σ_p^0 values, the *p*-amino, hydroxy, acetamino and some other groups deviate from the correlation to a comparative extent as the *meta* analogues do. The $+R$ groups generally satisfy Eq. (4), while carbonylamido and sulfonamido groups show significant derivations. Deviations of the trimethylammonium and dimethylsulfonium groups are remarkable. Nevertheless, it is evident from the satisfactory fit to Eq. (4) that modification of the electronic nature of substituents with DMSO is not significant at least as far as the ordinary $+R$ substituents are concerned.

The ρ values obtained by means of Eqs. (3) and (4) being identical, the apparent $\bar{\sigma}$ values of this system (Table 2) are calculated by using the ρ value of 1.529. The excellent linear correlations of the 4-substituent chemical shifts among phenols, 2- and 3-cresols, and xylenols indicate that these sets of data may give an identical set of apparent $\bar{\sigma}$ values for 4-substituents and that the degree of resonance exaltation of $+R$ 4-substituents, $r^-=0.673$ in Eq. (4), remains practically constant. The ρ value for each structural class is obtained by $1.529\,\lambda$, where λ is the slope of the plot of $\Delta\delta$ for a respective system aganist those of the phenol system. The sets of apparent $\bar{\sigma}$ values for all 4-substituents derived from 2-cresols and 2,6-xylenols are

identical within experimental uncertainty with the values from the parent phenols (Table 2). The same $\bar{\sigma}$ values are also given from the 3-cresol system for most 4-substituents, excluding the bulky planar groups which require the coplanarity with the benzene ring for resonance.

The agreement of these values suggests that the deviations from the calculated set of apparent substituent constants with standard parameters are not due to the experimental error but are inherent to substituents. Apparent $\bar{\sigma}$ values for most substituents are slightly more electron releasing than σ_p^0 for $-R$ groups and the calculated $\bar{\sigma}$ values for $+R$ groups. This can be attributed to the decrease in the electron-attracting effect of substituents in aprotic DMSO due to the absence of hydrogen-bonding from water in which the standard substituent parameters were determined. Significant deviations are observed for the substituents carrying an active hydrogen such as NH_2, OH, $NHCOCH_3$, $CONH_2$ and SO_2NH_2, whose particularly enhanced electron-releasing effects may be explained as to be due to the effect of the negative charge gained through the hydrogen-bonding with DMSO, in addition to the regular enhancement. The decreased electron attraction of charged groups NMe_3^+ and SMe_2^+ should not be unreasonable if the difference in solvation between the charged and dipolar substituents in aprotic and protic solvents is considered. The effect of solvent modification of respective substituents may thus be estimated at least qualitatively by the difference of apparent $\bar{\sigma}$ from the calculated values. However, since the $\bar{\sigma}$ values for $+R$ groups should only measure the apparent effects in reference to a given intermediate r value of 0.673, they cannot be taken as a proper set of substituent parameters for the solvent-modified substituents with DMSO, unless they can be in some way referred to the standard σ^0 scale ($r=0$) or σ^- scale ($r=1.00$).

The effect of the 3-methyl group in the 3-cresol system remains constant regardless of changes in 4-substituents, and the additivity of substituent effects holds giving an apparent $\bar{\sigma}$ of -0.07 for the 3-methyl group, except for the case where the steric loss of resonance of 4-substituents exists. In the 2-cresol system, the effect of the *o*-methyl group is represented similarly in an additive manner giving an apparent -0.075 effect in σ unit for the methyl group, even though the ρ value 1.579 is slightly higher than that for the parent phenol system. Introduction of another *o*-methyl group also exhibits a constant additive effect throughout the series, but the apparent -0.77 effect in σ unit appears too large for it to be referred to the electronic effect of two methyl groups. The effect of the 2,6-dimethyl group would not arise from electronic modification of the system but predominantly from a certain non-electronic effect due to its proximity to the phenol hydroxyl functionality.

The phenomenon was ascribed to the steric loss of coplanarity of the DMSO-hydrogen bonding OH function with the benzene ring and consequently to the enhanced shielding due to an acquired negative charge at the oxygen atom.[6] Deviation from the coplanarity of the detection function should produce a marked decrease in the resonance interaction with $+R$ *para* substituents and this is reflected in the apparent $\bar{\sigma}$ values. However, the difference between the $\bar{\sigma}_p$ values for the hindered and unhindered phenol series is hardly detectable. Further information is obtained from results of the 4-substituted 3-cresol system. 4-Dimethylamino and 4-acetamino groups exhibit a significant loss of electron-releasing effect (Fig. 1), while the 4-hydroxyl group which is effectively stabilized through hydrogen bonding with DMSO shows none. This is in line with the fact that the *o*-cresols exhibit an up-field shift no more significant than expected from the additivity of substituent effects, and does not conflict with the above argument. On the other hand, the chemical shift difference 0.618 of the unhindered hydroxyl proton of 3,5-dimethylhydroquinone relative to 3,5-dimethylphenol provides an apparent $\bar{\sigma}$ value of -0.40 for the sterically hindered hydrogen-bonding 4-OH substituent in the 3,5-xylenol system, on the assumption $\rho=1.53$. The decrease of the $\bar{\sigma}$ value from -0.46 for unhindered systems (Table 2) is insignificant in contrast to the marked reduction observed in the case of the methoxy group from the ordinary value of -0.27 to -0.12 for the hindered one. Thus, the coplanarity of the hydrogen-bonding OH is not lost effectively, even in the presence of two *ortho* methyl groups. The proximity of the DMSO molecule will be determined by the steric effects in the neighborhood of the phenol site and the steric restriction of approach of DMSO to the site should be sufficient to cause a minor loss (*ca.* 10%) in the electron releasing effect of the hydroxyl group. The data appear to be insufficient to draw any decisive conclusion, but it is conceivable that the up-field shift of the hindered hydroxyl proton is caused largely by the change in the extent of transfer of hydrogen-bonding proton between the donor and acceptor molecules.

Studies of the Fragment-ion Distribution and Reaction with a Charge Spectrometer. VI. A New Interpretation of the Fragmentation Mechanism in CH_3X Based on the Molecular Orbital Method. (2)*

Shigeru IKUTA, Kenji YOSHIHARA, and Takanobu SHIOKAWA

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received September 6, 1974)

We have proposed a new fragmentation mechanism and successfully applied it to various monosubstituted alkanes RX. The fragmentation mechanism can be described as follows: (1) The bond scission first occurs where the electrons exist densely in the particular occupied molecular orbital correlated to the particular ionization. (2) Process (1) competes with the electron redistribution. (3) In the higher-energy region, secondary scission also occurs. The breakdown curves of the $CH_3NH_2^+$, CH_3SH^+, and CH_3Br^+ produced by charge-exchange reactions have been obtained by the use of a perpendicular double-mass spectrometer. The experimental results can be satisfactorily explained by the proposed mechanism on the basis of the calculated eigenvectors of the various molecular orbitals.

The fragmentation mechanism of molecules by electron or photon impact has usually been interpreted by the quasiequilibrium theory (QET) first proposed by Rosenstock *et al.*[1] and later improved by other researchers.[2] Nevertheless, this theory does not have a wide applicability, especially in cases of very large and very small molecules.[3,4]

Hirota[5] and Lorquet[6] have suggested that the scission probability of the skeletal bonds is proportional to the electron densities of the highest occupied molecular orbital at the corresponding bond. However, this theory cannot completely explain the energy dependence of the mass spectra, as was pointed out in a previous paper.[7] Furthermore, in the cases of molecules with lone-pair electrons, the highest occupied MO is non-bonding, and the ionization caused by the loss of the non-bonding electron results in the formation of the stable molecular ion and does not result in the formation of the fragment ions. Therefore, in these molecules, Hirota's proposal is incomplete as an explanation of the production of the fragment ions.

In a previous paper[8] on the breakdown curves of various CH_3X substances (X=NH_2, OH, SH, Cl, Br, and I), we found that the C–X bond in methyl halides (Group A) easily dissociates, while that in methylamine, methanol, or methyl mercaptan (Group B) does not. This difference can be interpreted in terms of the main character of the various occupied MO's calculated by the Extended Hückel Molecular Orbital method,[9] on the assumption that fragmentation occurs at the bond at which an electron is ejected.

In this study we have improved our earlier proposal,[8] put forward a new theory based on the molecular orbital method for fragmentation mechanism, and succeeded in interpreting the fragmentation in several typical cases (CH_3NH_2, CH_3SH, and CH_3Br).

Experimental

The fragmentation of CH_3X^+ produced by charge-exchange reactions was studied using a perpendicular-type double-mass spectrometer. The details of the apparatus have already been described.[10] In this work, H_2S^+, $C_2H_2^+$, Xe^+, H^+, Kr^+, Ar^+, Xe^{++}, Ne^+, and He^+ ions were used as the primary incident ions; they were led into the reaction chamber, where the charge exchange between these ions and CH_3X occurred. The pressure in the reaction chamber was kept below 8×10^{-6} Torr in order to avoid consecutive ion-molecule reactions between the fragment ions and neutral molecules.

Calculation

The eigenvectors of the molecular orbitals of various CH_3X substances were calculated according to the Extended Hückel Molecular Orbital method.[9] The molecular orbitals to describe these molecules are represented by a linear combination of valence atomic orbitals. The Coulomb integrals of the atomic orbitals, H_{ii}, are shown in Table 1. The resonance integral between the i th and j th atomic orbitals, H_{ij}, was calculated by means of this equation: $H_{ij}=0.5\ K(H_{ii}+H_{jj})S_{ij}$, where S_{ij} was the overlap integral and where the value of K was taken to be 1.75, as in Hoffmann's paper.[9] For the calculation of the overlap integral, Slater μ-values for the valence-shell ns and np atomic orbitals were used as in Mulliken's paper,[11] and 4 was taken as the effective quantum number, n^* for bromine.[11] The calculation was performed at the Computer Center of Tohoku University.

Results and Discussion

Hirota[5] has proposed the molecular orbital theory to account for the mass spectra resulting from electron impact. According to his theory, the scission probability of the skeletal bonds is proportional to the electron densities of the highest occupied MO at the corresponding bond of the bombarded molecule. However, this theory cannot apply to the following fragmentation processes: (i) the fragmentation to produce the hydrogen-deficient ion from the molecular ion, and (ii) the fragmentation of the molecular ions involving lone-pair electrons. Also, his theory has difficulty in explaining the energy dependence of the fragmentation of the molecular ions as a function of an absorbed energy.[7]

Therefore, we considered the fragmentation mechanism to be as follows:

(1) The bond scission first occurs where the electrons exist densely in the particular occupied MO correlated to the particular ionization.

(2) Process (1) competes with the electron redistribution.

(3) In a higher-energy region, secondary scission also occurs.

Based on Process (1), the primary fragment ions from the molecular ions can be predicted by the main character of the particular MO which is correlated to the particular ionization. For example, if the occupied MO is non-bonding, the ionization caused by the loss of the non-bonding electron should result in the formation of the stable molecular ion. If the occupied MO is C-X bonding, the ionization caused by the loss of the electron in this orbital should result in the scission of the C-X bond. The absorbed-energy dependence of the fragmentation processes of the molecular ions can be explained by Processes (2) and (3) in addition to Process (1). Although we have obtained the breakdown curves of CH_3X (X=NH_2, OH, SH, Cl, Br, and I), this paper will deal with the typical fragmentation mechanism of methylamine (CH_3NH_2), methyl mercaptan (CH_3SH), and methyl bromide (CH_3Br).

Methylamine (CH_3NH_2). The electronic configuration and the model employed for this calculation on methylamine are shown in Table 2. The highest occupied MO(HOMO) is non-bonding (n(N)) and C–H bonding (σ(C–H)), because there is a larger population of the eigenvectors in the N(2pZ), C(2pZ), and H_1 atomic orbitals. The second occupied MO (SOMO) is C–H bonding (π(CH_2)), the third occupied MO (TOMO) is C–H bonding (π(CH_3)) and C–N bonding (σ(C–N)), and the fourth occupied MO(FOMO) is C–N bonding (σ(C–N)), N–H bonding (π(NH_2)), and C–H bonding (σ(C–H)).

According to Mechanism (1) the mechanism may be considered to be as follows. The ionization caused by the loss of the N(2pZ) non-bonding electron in HOMO results in the formation of the stable molecular ion, P^+, while the ionization caused by the loss of the C–H bonding electron in HOMO results in the formation of the $(P–H)^+$ ion, followed by the scission of the C–H bond. The ionization caused by the loss of the electron in SOMO results in the formation of the $(P–nH)^+$ ion, while the ionization caused by the loss of the electron in TOMO or FOMO results in the formation of the $(P–nH)^+$, and CH_3^+ or NH_2^+ ions, where $(P–nH)^+$ ion indicates a hydrogen-deficient species ($(P–H)^+$, $(P–2H)^+$, or $(P–3H)^+$) from the molecular ions. One hydrogen-deficient ion $(P–H)^+$ is considered to have the formula of $CH_2NH_2^+$ instead of CH_3NH^+, because the highest occupied MO is C–H bonding (and n(N)), while the second occupied MO is also

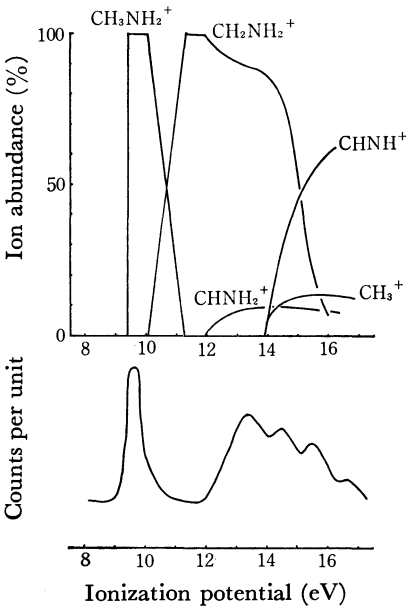

Fig. 1. Comparison of the observed breakdown curve with the photoelectron spectrum[13] for methylamine.

C–H bonding.

The photoelectron spectrum[13] and the breakdown curves of methylamine[14,15] are shown in Fig. 1. Although the bands (above the second one) of the photoelectron spectrum cannot be discriminated well because of the overlapping, there is an agreement between the appearance potentials of the fragment ions obtained by the charge-exchange and those of the bands in the photoelectron spectrum. That is, the appearance potential of $CHNH_2^+$ and that of $CHNH^+$ (or CH_3^+) correspond to the ionization potentials of the second and third bands respectively in the photoelectron spectrum. Although the appearance potential of CH_2-NH_2^+ does not seem to be equal to the ionization potential of the first band in the photoelectron spectrum, this discrepancy may be ascribed to the dissociation of the vibrationally excited ions. In the region of 10.5—12.0 eV, the cross section for photoelectron emission is small; this phenomenon is also observed in the charge-exchange reaction. The relative abundance of $CH_2NH_2^+$ obtained by the charge-exchange reactions is large in this region.

Methyl Mercaptan (CH_3SH). The electronic configuration and the model employed for this calculation of methyl mercaptan are shown in Table 3. The highest occupied MO is non-bonding (n(S)), and the ionization caused by the loss of the non-bonding electron results in the formation of only the stable molecular ion. The second occupied MO is S–H bonding (σ(S–H)), and the ionization caused by the loss of the S–H bonding electron results in the formation of the $(P–H)^+$ ion.[16] As the third occupied MO is C–S, C–H, and S–H bonding, the ionization caused by the loss of the electron in this orbital results in the formation of CH_3^+ or SH^+ and of hydrogen-deficient species from the molecular ions.

ions are equal to that of the third band. This means that the production of the fragment ions is correlated to the electronic configuration of the molecule. It is clearly shown in Fig. 2 that the stable molecular ion is obtained after the ionization caused by the loss of the electron in the highest occupied MO, the $(P-H)^+$ ion is obtained after that in the second occupied MO, and the $(P-3H)^+$ and CH_3^+ ions are obtained after that in the third occupied MO. These results are in good accordance with our theoretical consideration for the production of the fragment ions.

Methyl Bromide (CH_3Br). The electronic configuration and the model employed for this calculation of methyl bromide are shown in Table 4. As may clearly be seen from the table, the highest occupied MO (which is degenerate) is non-bonding (n(Br)), and the ionization caused by the loss of the non-bonding electron results in the formation of a stable molecular ion. The second occupied MO is C–Br bonding (σ(C–Br)), and the ionization caused by the loss of the C–Br bonding electron results in the formation of CH_3^+ or Br^+. The third occupied MO is C–H bonding, and the ionization of the C–H bonding electron results in the formation of the CH_2Br^+ ion.

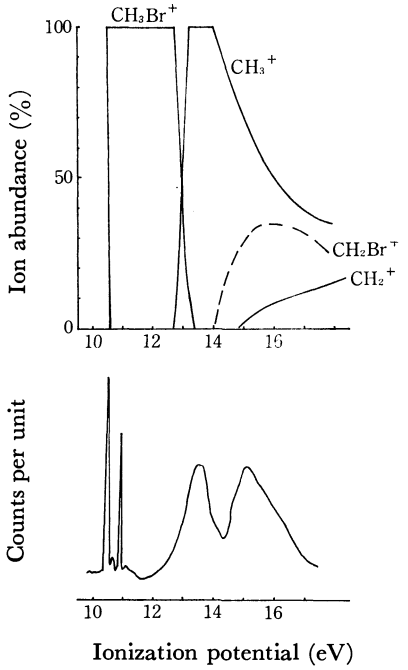

Fig. 3. Comparison of the observed breakdown curve with the photoelectron spectrum[18] for methyl bromide.

The photoelectron spectrum[19] and the breakdown curves of CH_3Br[20] are shown in Fig. 3. The appearance potential of CH_3^+ is equal to that of the second band of the photoelectron spectrum, while the appearance potential of CH_2Br^+ is equal to that of the third band. Accordingly, these results are also in good accordance with our theoretical consideration for the production of the fragment ions.

The energy dependence of the scission probability of the C–X bond in various CH_3X^+ substances (X=NH_2, OH, SH, Cl, Br, and I) obtained by the charge-exchange reactions is shown in Fig. 4. The sum of the abundance of the CH_3^+ and X^+ (produced by the ionization caused by the loss of the C–X bonding electron) was plotted as a function of the absorbed energy of CH_3X. The main characteristics of the highest, second, and third occupied MO's on various CH_3X are shown in Table 5. There are outstanding differences in the main characters in the second and third occupied MO's between Groups A and B. These differences are directly related to the fragmentation processes between the two groups (as is shown in Figs 1. (or 2) and 3, or 4). Moreover, it may be suggested that the order of the scission probability of the C–X bond shown in Fig. 4 corresponds to that of the bond population ($C_iC_jS_{ij}$, where C_i and C_j are the eigenvectors of the i th and j th atomic orbitals, and where S_{ij} is the overlap integral between them) in the second or third occupied MO.[21]

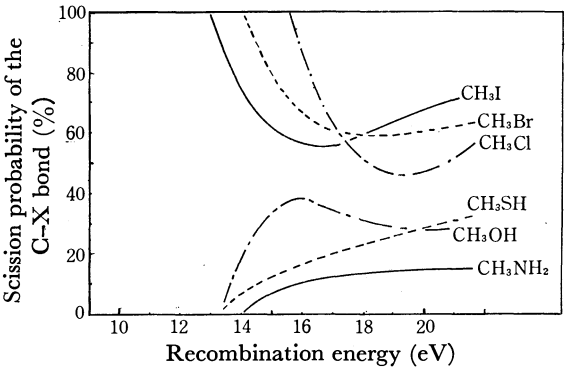

Fig. 4. The observed scission probabilities of the C–X bond in various CH_3X as a function of recombination energy.

Table 5. Main character in the highest, second, and third occupied molecular orbitals on various CH_3X

	Group A		
	Cl	Br	I
Highest	n(Cl)[a]	n(Br)[a]	n(I)[a]
Second	σ(C–Cl)	σ(C–Br)	σ(C–I)
Third	$\pi(CH_3)$[a]	$\pi(CH_3)$[a]	$\pi(CH_3)$[a]

	Group B		
	NH_2	OH	SH
Highest	n(N), $\pi(CH_3)$	n(O)	n(S)
Second	$\pi(CH_2)$	$\pi(CH_3)$	σ(S–H)
Third	σ(C–N),$\pi(CH_3)$	σ(C–O),σ(C–H)	σ(C–S),σ(S–H)

a) Orbital is degenerate

From these results it is obvious that the bond scission first occurs where the electrons exist densely in the particular occupied MO correlated to the particular ionization [Mechanism (1)]. The scission probability can be well predicted by means of the main characteristics and the bond populations of various occupied MO's (which fit the ionization energy) in the cases of simple compounds of CH_3X. Considerations of Mechanism (2), the redistribution of electrons, may become more significant for the more complicated systems, such as C_2H_5X, C_3H_7X, and C_4H_9X.[22] This subject will be discussed in succeeding papers.

The Computation of the Thermodynamic Properties of Aqueous Electrolyte Solutions by Means of the Perturbation Theory of Fluids

Fumio HIRATA and Kiyoshi ARAKAWA
Research Institute of Applied Electricity, Hokkaido University, Sapporo 060
(Received November 13, 1974)

A useful method to investigate the thermodynamic properties of aqueous electrolyte solutions was presented on the basis of the perturbation theory of fluids, where a *primitive model* was used as a reference system. A perturbation potential of a square type was applied. An analytical solution of the mean spherical model (MSM) equation obtained by Waisman and Lebowitz was used as the thermodynamic functions of the reference system, and an ionic distribution function in electrolyte solutions was derived. The values of the energy parameters which represent the depth of the well were determined by a comparison of the observed values of the thermodynamic quantities with the calculated ones.

Some remarkable progress in the field of electrolyte solution theory has been made recently,[1–7] the most important example coming from the application of the methods developed in the theory of liquids.[8–10] In many of these studies a simple model ("primitive model"[5]) has been used, where each ion behaves as a charged hard sphere imbedded in a continuum with a macroscopic value of the dielectric constant.

An analytical solution of the drirect correlation function for the model was obtained from the mean spherical model (MSM)[9] equation by Waisman and Lebowitz.[5] It may be said to be the only analytical solution which has been obtained through the statistical thermodynamic treatment of electrolyte solutions since the proposition of the Debye-Hückel theory.

A way to improve the primitive model is to take into account the effect of ions upon the liquid structure of solvents. It is well-known that water molecules around ions are not always bound strictly about the ions in aqueous solutions.[11–13] At room temperature, water molecules around very small (Li^+) or polyvalent (Mg^{2+}, Ca^{2+}) ions are considered to be less mobile than those in bulk water due to ion-water interactions (*positive hydration*), while in the case of comparatively large ions, such as Cs^+ and I^-, water molecules around ions become more mobile than those in bulk water (*negative hydration*).[11–13] Such ion-water interaction produces very complicated effects upon ion-ion interactions. Gurney represented the additional interactions by a term of the overlapping of cospheres in which solvent molecules are in a different state from those in bulk water.[11] Rasaiah[6] and Ramanathan and Friedman[7] solved numerically the hypernetted chain (HNC) equation,[8] where the interaction potential of an ion pair cotains a contribution from the overlapping of the cospheres.

On the basis of a model similar to that mentioned above, an alternative method for the improvement of the "primitive model" will be presented in this paper using the perturbation method in the theory of liquids;[10,14] the primitive model is used as a reference system, and the contribution from the overlapping of cospheres is regarded as a perturbation.

Perturbation Method

The basic idea of the perturbation theory is to represent the potential energy of a system as a sum of two terms:

$$U = U^{(0)} + U^{(1)}, \tag{1}$$

where $U^{(0)}$ is the potential energy of the unperturbed system ("reference system"), and $U^{(1)}$, the perturbation energy. It is assumed that $U^{(0)}$ and $U^{(1)}$ are a sum of pair potentials. The equation for the Helmholtz free energy of a multicomponent system is expressed straightforwardly by the perturbation theory as follows:

$$\beta A/N = \beta A^{(0)}/N + (2\pi\beta/\rho)\sum_{i,j=1}^{\sigma}\rho_i\rho_j\int_0^\infty g_{ij}^{(0)}(r)u_{ij}^{(1)}(r)r^2\mathrm{d}r. \tag{2}$$

Here, the subscripts i and j are used to distinguish the species in the system; $A^{(0)}$ and $g_{ij}^{(0)}(r)$, the Helmholtz free energy and the radial distibution function of the reference system, respectively; $u_{ij}^{(1)}(r)$, the perturbation potential of a pair of molecules; ρ_i, the number density of i-th component; N, the total number of molecules; ρ, the total number density ($=\sum_i^\sigma \rho_i$) and $\beta=(kT)^{-1}$.

In the present case, the pair potential, $u_{ij}^{(0)}(r)$, of the reference system is givn by:

$$\begin{aligned} u_{ij}^{(0)}(r) &= \infty, & r \leq R_{ij}, \\ &= e_ie_j/\varepsilon r, & r > R_{ij}, \end{aligned} \tag{3}$$

where e_i is the charge of the i-th type of ions; R_{ij}, the distance of the closest approach between ions of the i and j types, $R_{ij}=(R_{ii}+R_{ij})/2$, and ε, the macroscopic dielectric constant of the solvent. The interaction attributed to the effect of the overlap of cospheres, which is regarded as a perturbation, must have a very complicated form. Here, we will represent the potential by a simple form,[6,15] that is, a square well or a square mound potential, as follows:

$$\begin{aligned} u_{ij}^{(1)}(r) &= 0, & r \leq R_{ij}, \\ &= d_{ij}, & R_{ij} < r < R_{ij} + b_{ij}, \\ &= 0, & R_{ij} + b_{ij} \leq r. \end{aligned} \tag{4}$$

Here, d_{ij} is the depth (the height) of the well (mound), and b_{ij}, the width of the well (mound). Since the $u_{ij}^{(1)}(r)$ used here is the potential of the mean force averaged over the coordinate of the solvent molecules, which means the free energy of pair interaction between ions, the thermodynamic quantities derived are "osmotic quantities." For instance, the derivative of the free energy by the volume of solution is not the pressure

but the osmotic pressure.[16] From Eq. (2), we obtained this equation for the energy per unit volume:[2,6]

$$E = E^{(0)} + \frac{1}{2}\sum_{i,j=1}^{\sigma}\rho_i\rho_j\int_0^{\infty}\frac{\partial[\beta u_{ij}^{(1)}(r)]}{\partial\beta}g_{ij}^{(0)}(r)4\pi r^2\mathrm{d}r, \quad (5)$$

where $E^{(0)}$ is the energy per unit volume of the reference system given by:

$$E^{(0)} = \frac{1}{2}\sum_{i,j=1}^{\sigma}\rho_i\rho_j\int_0^{\infty}\frac{\partial[\beta u_{ij}^{(0)}(r)]}{\partial\beta}g_{ij}^{(0)}(r)4\pi r^2\mathrm{d}r. \quad (6)$$

By substituting Eq. (3) into Eq. (6), we obtained the following expression:

$$E^{(0)} = \left(1+\frac{\partial \ln \varepsilon}{\partial \ln T}\right)E^{el}. \quad (7)$$

E^{el} is given by:

$$E^{el} = (1/2)\sum_{i,j=1}^{\sigma}\rho_i\rho_j\int_0^{\infty}\frac{e_ie_j}{\varepsilon r}g_{ij}^{(0)}(r)4\pi r^2\mathrm{d}r. \quad (8)$$

Description of the Reference System

Analytical Solution of MSM Equation. We use the analytical solution of the MSM equation for the primitive model, which was derived by Waisman and Lebowitz,[5] as the reference system in the perturbation method.[6] According to MSM,

$$\begin{aligned} g_{ij}^{(0)}(r) &= 0, & r \le R_{ij} \quad (9)\\ C_{ij}^{(0)}(r) &= -\beta e_ie_j/\varepsilon r, & r > R_{ij} \end{aligned}$$

where $C_{ij}^{(0)}(r)$ is the direct correlation function of the reference system. Using the conditions in Eq. (9), Waisman and Lebowitz solved the Ornstein-Zernike equation by a method which was identical with Wertheim's[17] way of solving the Percus-Yevick (PY) equation[8] for a single-component fluid of hard spheres. The final solution was obtained only for the case in which the hard-sphere diameter of all the species were the same. The direct correlation function, $C_{ij}^{(0)}(r)$, derived was:

$$\begin{aligned} C_{ij}^{(0)}(r) &= \tilde{C}(r;\xi;\beta) - (\beta/\varepsilon R)e_ie_j(2B-B^2r/R), & r \le R\\ &= -\beta e_ie_j/\varepsilon r, & r > R \quad (10) \end{aligned}$$

where $\tilde{C}(r;\xi,\beta)$ is the Wertheim solution, and R, the distance of the closest approach of the ion pair which is common to all the pairs. ξ and B are the parameters given by:

$$\xi = \pi R^3\rho/6, \quad (11)$$

$$B = x^{-2}[x^2+x-x(1+2x)^{1/2}], \quad (12)$$

where x is the product of the Debye-Hückel parameter, κ, and the hard-sphere diameter, R,

$$x^2 = \kappa^2R^2 = [(4\pi\beta/\varepsilon)\sum_i^{\sigma}\rho_ie_i^2]R^2. \quad (13)$$

Thermodynamic Functions. The free energy and energy per unit volume were given by:

$$\beta a(x,\beta;\xi) = \beta\tilde{a}(\xi,\beta) - (12\pi R^3)^{-1}[3x^2+6x+2 - 2(1+2x)^{3/2}], \quad (14)$$

$$E^{el}(x,\beta) = (1/2)\sum_{i,j}^{\sigma}\rho_i\rho_j\int\frac{e_ie_j}{\varepsilon r}g_{ij}^{(0)}(r)4\pi r^2\mathrm{d}r = -\frac{x^2+x-x(1+2x)^{1/2}}{4\pi\beta R^3}. \quad (15)$$

Here, $\tilde{a}(\xi,\beta)$ is the free energy per unit volume of a hard-sphere fluid, which is derived by integrating the Wertheim's formula for the equation of state over the density.[17]

Radial Distribution Function. We have derived the radial distribution function, $g_{ij}^{(0)}(r)$, by an inverse Laplace transform from the function given by Waisman and Lebowitz.[5] The mathematical details are described in the Appendix. The resulting equation consists of the following two terms:

$$g_{ij}(y) = \tilde{g}_{ij}(y) + g_{ij}^{el}(y), \quad (16)$$

where y is the separation between an ion pair reduced by the distance of the closest approach, R. The first term of Eq. (16) is the radial distribution function obtained as the solution of the PY equation for the hard-sphere fluid, which was calculated by Bearman and his coworkers in the range of $1 \le y \le 6$.[18,19] The second term is the part related to the charge distribution, which is given by (see Appendix):

$$\begin{aligned} g^{el}(y) &= g_1^{el}(y), & \text{for } 1 \le y \le 2,\\ &= g_1^{el}(y) + g_2^{el}(y), & \text{for } 2 \le y \le 3,\\ &= g_1^{el}(y) + g_2^{el}(y) + g_3^{el}(y), & \text{for } 3 \le y \le 4, \quad (17) \end{aligned}$$

where $g_1^{el}(y)$, $g_2^{el}(y)$, and $g_3^{el}(y)$ are:

$$\begin{aligned} g_1^{el}(y) &= (\pm 2q^2/12\xi y)\{\sin[q(y-1)] - \cos[q(y-1)]\}\exp[-q(y-1)], \quad (18a)\\ g_2^{el}(y) &= (\pm 1/12\xi y)[2(y-2)q^3\{\cos[q(y-2)] + \sin[q(y-2)]\} - 2q^2\sin[q(y-2)]] \times \exp[-q(y-2)], \quad (18b)\\ g_3^{el}(y) &= (\pm 1/12\xi y)[2q^4(y-3)^2\{\cos[q(y-3)] - \sin[q(y-3)]\} - 2q^3(y-3) \times \{3\cos[q(y-3)] + \sin[q(y-3)]\} + 6q^2\sin[q(y-3)]]\exp[-q(y-3)]. \quad (18c) \end{aligned}$$

Here, q is a parameter given by:

$$q = \{(1+2\kappa R)^{1/2}-1\}/2. \quad (19)$$

The form of $g_{ij}(y)$ calculated in the range of $1 \le y \le 4$ is shown in Figs. 1(a)—(c). Eq. (16) shows that the distribution law of ions in electrolyte solutions is influenced by two different factors: the distribution law characteristic of hard-sphere fluids, which originates from the short-range repulsion between molecules, and a distribution law similar to the Debye-Hückel type which is caused by the long-range Coulombic interaction. While the Debye-Hückel-like distribution is dominant at low concentrations, the total distribution approaches that of a hard-sphere fluid at high concentrations. The change in the shape of the distribution curves with the concentration (Fig. 1) appears to represent such a feature in the distribution of ions.

The curve of $g_{ij}(y)$ has an oscillation that becomes outstanding with an increase in the concentration. This property of $g_{ij}(y)$ in electrolyte solutions was first predicted by Kirkwood and Poirier;[20] it was later formulated by Stillinger and Lovett[21] as a "second moment condition." Recently, Card and his coworkers confirmed the property through a Monte Carlo calculation.[22]

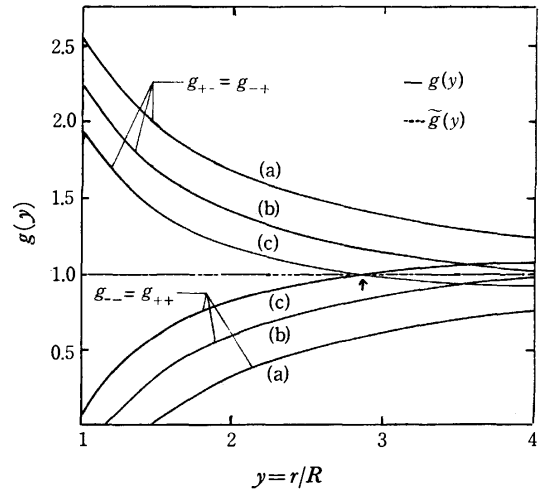

Fig. 1(a). The radial distribution functions computed from MSM equation for the primitive model at $\rho R^3=0.001$, 0.01, and 0.05 at 25 °C assuming that $R=4.0$ Å and $\tilde{g}(y)\simeq 1.0$ for $y>1$. (a) $\rho R^3=0.001$, (b) $\rho R^3=0.01$, (c) $\rho R^3=0.05$. In the curve (c), the inversion (oscillation) occurs at the point which is indicated by an arrow.

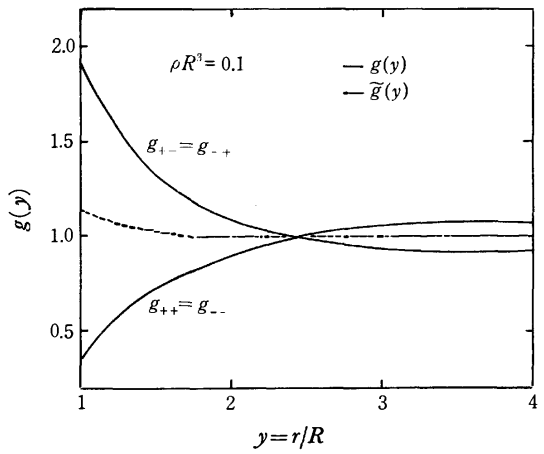

Fig. 1(b). The radical distribution function at $\rho R^3=0.1$. Values calculated by Throop and Bearman is used for $g(y)$ in this figure and the following.

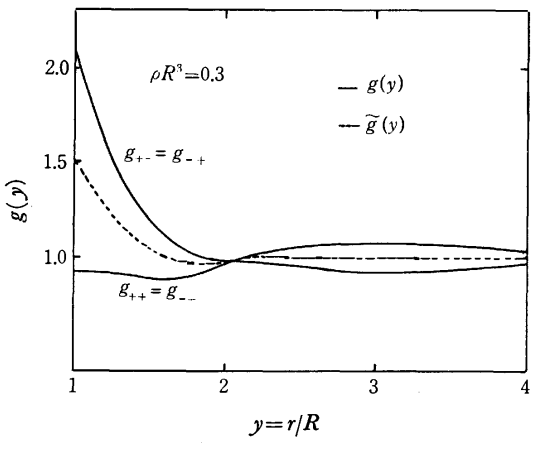

Fig. 1(c). The radial distribution functions at $\rho R^3=0.3$.

Computation of Thermodynamic Functions

Free Energy. After substituting Eq. (4) and changing the variable, r, to a reduced variable, y, we obtain from Eq. (2):

$$\beta(A-A^{(0)})/N = 3\xi J\beta d_{ij}, \tag{20}$$

$$J = \int_1^{1+a} g_{ij}(y)y^2 dy, \tag{21}$$

where a is b_{ij}/R. The contribution from like-like terms in Eq. (2) is ignored. Since the values of $\xi(=\pi R^3\rho/6)$ are smaller than 0.05 in this concentration range (smaller than 1.0 M in molarity),[23] we can safely suppose that $\tilde{g}_{ij}(y)=1$. Thus, Eq. (16) is written as:

$$g_{ij}(y) = 1 + g_{ij}^{el}(y). \tag{16'}$$

After substituting Eqs. (16'), (17), and (18) into Eq. (21), we get:

$$\begin{aligned} J &= (1/3)\{(1+a)^3-1\}+(1/12\xi)\{[(2q+2aq+1)\sin(aq) \\ &\quad +\cos(aq)]\exp(-aq)-1\}, \quad \text{for } R\geq b_{ij}, \\ &= (1/3)\{(1+a)^3-1\}+(1/12\xi)\{[(2q+2aq+1)\sin(aq) \\ &\quad +\cos(aq)]\exp(-aq)+[2(a^2-1)q^2+(3a+1)q-1] \\ &\quad \times\cos[q(a-1)]\exp[-q(a-1)]-[5(1+a)q-2q \\ &\quad +3]\sin[q(a-1)]\exp[-q(a-1)]-4q\}, \\ &\quad \text{for } R\leq b_{ij}\leq 2R. \end{aligned} \tag{24}$$

As the hard-sphere radii of ions, Pauling's crystal radii are used.[24] The width of the well, b_{ij}, is equal to the diameter of the water molecule, 2.76 A.[6] The parameter, d_{ij}, is dtermined by fitting the calculated values of A with the one observed at 0.5 M. In this paper, the experimental values of the thermodynamic quantities are transformed into the McMillan-Mayer system according to Friedman's procedure, and the comparison between the calculated and observed values is made in the McMillan-Mayer system.[25] The values of

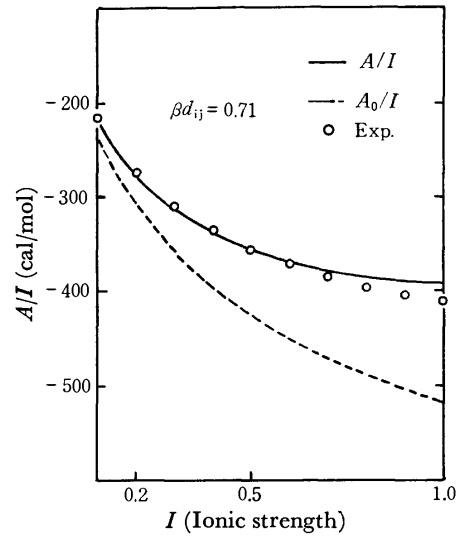

Fig. 2. Calculated and experimental Helmholtz free energy for aqueous solutions of NaCl at 25 °C. The broken line and the solid one are calculated values for the reference system and the system with a square well (or mound) potential as a perturbation, respectively and circles the experimental ones. It is assumed that $\beta d_{+-}=0.71$ and $\beta d_{++}=\beta d_{--}=0$.

TABLE 1. THE VALUES OF βd_{ij} WHICH GIVE THE BEST FIT BETWEEN OBSERVED AND CALCULATED VALUES OF FREE ENERGY

	Li^+	Na^+	K^+	Rb^+	Cs^+
F^-		0.72	0.65		
Cl^-	1.84	0.71	0.09	−0.16	−0.53
Br^-	1.74	0.72	0.07	−0.26	−0.61
I^-	2.02	0.73	0.08	−0.41	−0.76

d_{ij} are tabulated for some 1-1 electrolytes in Table 1. In Fig. 2, the agreement between the observed and calculated values of free energy in the concentration range up to 1.0 M is shown for NaCl as an example.

Energy. The second term of Eq. (5) becomes:

$$\frac{1}{2}\sum_{i,j=1}\rho_i\rho_j E_{ij}\int_R^{R+b_{ij}} g_{ij}^{(0)}(r)4\pi r^2 dr, \tag{25}$$

where E_{ij} is defined by:

$$E_{ij} = d_{ij} - T\frac{\partial d_{ij}}{\partial T}. \tag{26}$$

Eq. (5) is given by:

$$\frac{\beta(E-E^{(0)})}{\rho/2} = 6\xi J\beta E_{ij}. \tag{27}$$

The observed value with which the calculated value of E is compared is the relative apparent molal heat content.[6,7] The values of E_{ij} determined by a comparison of the observed values of E with the calculated ones are tabulated in Table 2, together with the values of $(-\partial d_{ij}/\partial T)$. The agreement between the observed and calculated values of E in the concentration range up to 1.0 M is very good, as is shown for NaCl in Fig. 3.

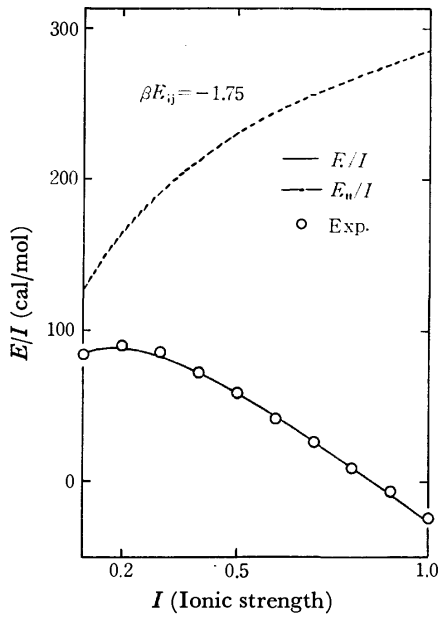

Fig. 3. Calculated and experimental excess energy for aqueous solution of NaCl at 25 °C. The broken line and the solid one are calculated values for the reference system and the system with a square well (or mound) potential as a perturbation, respectively. It is assumed that $\beta E_{+-} = -1.75$, $\beta E_{++} = \beta E_{--} = 0$.

TABLE 2. THE VALUES OF βE_{ij} (UPPER RIGHT HALF OF TABLE) AND $k^{-1}(-\partial d_{ij}/\partial T)$ (LOWER LEFT HALF)

	Li^+	Na^+	K^+	F^-	Cl^-	Br^-

Br^-	−1.77	−2.52	−1.81			

Discussion

Interpretation of the Parameter, d_{ij}. In the present computation, an energy parameter, d_{ij}, is used as an adjustable one. We will here discuss the physical meaning of the parameter. When two ions come close enough together so that their cospheres overlap each other, as is shown in Fig. (4), some of the water molecules in the cospheres are displaced. Thus, if the water molecules in the cospheres are in a state of lower free energy than those in bulk water, the overlap of the cospheres gives rise to an increase in the free energy of the water molecules which were in the cosphere before the overlap occurres, and the resulting contribution to the interaction between two ions is repulsive. When the water molecules in the cospheres are in a state of higher free energy than those in bulk water, the converse effect appears by the overlap of the cospheres, which is attractive. Thus, the plus and minus which appear in the sign of d_{ij} in Table 1 can be reasonably interpreted. This interpretation of the parameter, d_{ij}, coincides with that of Rasaiah.[6]

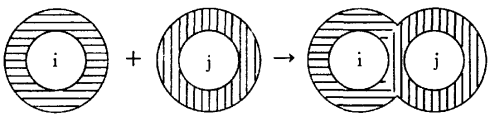

Fig. 4. Schematic representations of the process in which cospheres overlap.

Temperature Dependence of d_{ij}. As may be seen in Table 2, the signs of all the values of $(-\partial d_{ij}/\partial T)$ are minus. In the case of K^+, this sign is consistent with an intuitive picture, since the cospheres around the ions are considered to constitute a structure-breaking region, where water molecules are in a state of higher "entropy" than those in bulk water; the overlap of cospheres would thus lead to a net decrease in the "entropy." In the case of Li^+, it is difficult to interpret the sign of $(-\partial d_{ij}/\partial T)$, because the cospheres around the ions are expected to be in a state of lower "entropy." One possible explanation, which was given by Rasaiah,[6] is that $(-\partial d_{ij}/\partial T)$ is determined by the outer region far away from the nearest neighbor cosphere. This is plausible, since the structure-breaking region is considered to extend outside the cosphere in the case of very small ions, such as Li^+ and polyvalent ions (Mg^{2+}, Ca^{2+}, *etc.*).

Appendix

The Derivation of the Radial Distribution Function, $g_{ij}(y)$, from the Function Given by Waisman and Lebowitz. It is convinient

to start from Eq. (23) in Ref. (5a), which defines a function $\boldsymbol{L}(s)$.[5] That is:

$$\boldsymbol{L}(s) = \boldsymbol{G}(s)\boldsymbol{H}^T(-s). \tag{A,1}$$

Here, $\boldsymbol{G}(s)$ is a matrix whose (i,j)-element is a Laplace transform of the radial distribution function, $g_{ij}(y)$, of ions of the j type around an ion of i type:

$$G_{ij}(s) = 12(\eta_i\eta_j)^{1/2}\int_{R_{ij}}^{\infty} rg_{ij}(r)e^{-sr}dr, \tag{A,2}$$

where η_i is $\pi\rho_i/6$. $\boldsymbol{H}^T(-s)$ is a transpose of a matrix, $\boldsymbol{H}(-s)$, in which the sign of variables is changed to give this equation:

$$\boldsymbol{H}(s) = \boldsymbol{A} - s^2\boldsymbol{F}(s) - (\gamma^2/4)(s\boldsymbol{D}+2\boldsymbol{V}), \tag{A,3}$$

where γ and D_{ij}, the (i,j)-element of $\boldsymbol{D}$, are:

$$\gamma^2 = 8\pi\beta/\varepsilon \text{ and } D_{ij} = (\rho_i\rho_j)^{1/2}e_ie_j,$$

respectively. In Eq. (A, 3), $\boldsymbol{F}(s)$ is a matrix whose (i,j)-element is a Laplace transform of the direct correlation function.

$$F_{ij}(s) = -12(\eta_i\eta_j)^{1/2}\int_0^{R_{ij}} r\left(C_{ij}(r)+\frac{\beta e_ie_j}{\varepsilon r}\right)e^{-sr}dr. \tag{A,4}$$

The (i,j)-element of $\boldsymbol{L}(s)$ in Eq. (A,1) has been shown, on the basis of a consideration of the analyticity in the complex s-plane, to have this form:[5]

$$L_{ij}(s) - s^{-2}A'_{ij} = 2M_{ij}. \tag{A,5}$$

When the hard-sphere diameters of all species are equal, we get the following equalities:

$$A_{ij} = A_{ji} = A_{ii} = A_{jj} = A, \tag{A,6a}$$

$$A'_{ij} = A'_{ji} = A'_{ii} = A'_{jj} = A', \tag{A,6b}$$

$$V_{ij} = V_{ji} = -V_{ii} = -V_{jj} = -V, \tag{A,6c}$$

$$M_{ii} = M_{jj}, \quad M_{ij} = M_{ji} \tag{A,6d}$$

and $A' = 12\,\eta A$, where $\eta = \sum_i \eta_i$. By virtue of these equalities, the quadratic equations (28a)—(28e) in Ref. (5a) are reduced to a readily solvable form, and the solutions are:

$$A = 6\eta\frac{(2\xi+1)^2}{(1-\xi)^4}, \quad A' = 72\eta^2\frac{(2\xi+1)^2}{(1-\xi)^4},$$

$$M_{ij} = -\frac{6\eta}{R^2}\left\{\frac{6R\xi(1+\xi/2)^2}{(1-\xi)^4}+\frac{\beta e_ie_jB^2}{\varepsilon}\right\},$$

$$V_{ij} = -\frac{12\eta\beta e_ie_jB}{R(\gamma^2/2)\varepsilon},$$

$$M \equiv M_{ii} + M_{ij} = -\frac{72\eta R\xi(1+\xi/2)^2}{R^2(1-\xi)^4},$$

$$M' \equiv M_{ii} - M_{ij} = -\frac{12\eta\beta e^2B^2}{\varepsilon R^2}. \tag{A,7}$$

Now, multiplying the two sides of Eq. (A, 1) by an inverse of the matrix, $\boldsymbol{H}^T(-s)$, we get:

$$\boldsymbol{G}(s) = \boldsymbol{L}(s)\boldsymbol{H}^T(-s)^{-1} \tag{A,8}$$

Therefore, the (i,j)-element, $G_{ij}(s)$, of the matrix, $\boldsymbol{G}(s)$, is given by:

$$G_{ij}(s) = \{L_{ij}(s)H_{ii}(-s) - L_{ii}(s)H_{ji}(-s)\}D(s)^{-1}. \tag{A,9}$$

Here, $D(s)$ is a determinant of the matrix, $\boldsymbol{H}^T(-s)$; it is given by:

$$D(s) = \{A_{ii}-s^2F_{ii}(-s)-(\gamma^2/4)(-sD_{ii}+2V_{ii})\}^2 - \{A_{ij}-s^2F_{ji}(-s)-(\gamma^2/4)(-sD_{ji}+2V_{ji})\}^2. \tag{A,10}$$

Condisering the equalities in Eqs. (A, 7), the right-hand side of Eq. (A, 10) can be factores to give:

$$D(s) = \{-s^2[F_{ii}(-s)-F_{ji}(-s)]-2(\gamma^2/4)(-sD+2V)\} \times \{2A-s^2[F_{ii}(-s)+F_{ji}(-s)]\}. \tag{A,11}$$

By reference to Eqs. (A, 6) and (A, 7), the numerator of the right-hand side of Eq. (A, 9) is found to be given by:

$$\begin{aligned} &L_{ij}(s)H_{ii}(-s) - L_{ii}(s)H_{ji}(-s) \\ &= -(s^{-2}A'+2M_{ii})\{A-s^2F_{ji}(-s)-(\gamma^2/4)(sD-2V)\} \\ &\quad +(s^{-2}A'+2M_{ij})\{A-s^2F_{ii}(-s)-(\gamma^2/4)(-sD+2V)\} \\ &= (s^{-2}A'+M)\{-s^2[F_{ii}(-s)-F_{ji}(-s)] \\ &\quad -2(\gamma^2/4)(-sD+2V)\}-M'\{2A-s^2[F_{ii}(-s) \\ &\quad +F_{ji}(-s)]\}. \end{aligned} \tag{A,12}$$

Thus,

$$G_{ij}(s) = \frac{s^{-2}A'+M}{2A-s^2[F_{ii}(-s)+F_{ji}(-s)} - \frac{M'}{-s^2[F_{ii}(-s)-F_{ji}(-s)]-2(\gamma^2/4)(-sD+2V)}. \tag{A,13}$$

By the substitution of the expression for $F_{ij}(-s)$, which is obtained by combining Eq. (10) with Eq. (A, 4), Eq. (A,13) becomes:

$$G_{ij}(s) = \frac{1}{2}\frac{sL_1(s)}{L_1(s)+S_1(s)e^{Rs}} - \frac{1}{2}\frac{sL_2}{L_2+S_2(s)e^{Rs}}. \tag{A,14}$$

Here, $L_1(s)$, L_2, $S_1(s)$, and $S_2(s)$ are given by:

$$L_1(s) = 12\xi[(1+\xi/2)Rs+(2\xi+1)], \tag{A,15a}$$

$$S_1(s) = (1-\xi)^2(sR)^3 + 6\xi(1-\xi)(sR)^2 + 18\xi^2(sR) - 12\xi(1+2\xi), \tag{A,15b}$$

$$L_2 = -2p^2, \tag{A,15c}$$

$$S_2(s) = (s^2+2ps+2p^2)e^{sR} - 2p^2, \tag{A,15d}$$

where p is a parameter defined by:

$$p = \{(1+2\kappa R)^{1/2}-1\}/2R. \tag{A,16}$$

The expression for the radial distribution function is obtained by taking an inverse Laplace transform of Eq. (A, 14). Changing r and s to y and t respectively through the $r=Ry$ and $s=t/R$ relations, we get the final equation:

$$g_{ij}(y) = \tilde{g}_{ij}(y) + g^{01}_{ij}(y). \tag{A,17}$$

Here, $\tilde{g}_{ij}(y)$, $g_{ij}(y)$, and $g^{01}_{ji}(y)$ are given by:

$$g_{ij}(y) = \frac{1}{2\pi iy}\int_{\delta-i\infty}^{\delta+i\infty}\frac{1}{12\xi}G_{ij}(y)e^{ty}dt, \tag{A,18a}$$

$$g_{ij}(y) = \frac{1}{2\pi iy}\int_{\delta-i\infty}^{\delta+i\infty}\frac{tL_1(t)e^{yt}dt}{12\xi[L_1(t)+S_1(t)e^t]}, \tag{A,18b}$$

$$g^{01}_{ij}(y) = \frac{1}{2\pi iy}\int_{\delta-i\infty}^{\delta+i\infty}\frac{tL_2e^{yt}dt}{12\xi[L_2+S_2(t)e^t]}, \tag{A,18c}$$

where $L_1(t)$, $S_1(t)$, L_2, and $S_2(t)$ are:

$$L_1(t) = 12\xi[(1+\xi/2)t+(2\xi+1)], \tag{A,19a}$$

$$S_1(t) = (1-\xi)^2t^3 + 6\xi(1-\xi)t^2 + 18\xi^2t - 12\xi(1-2\xi), \tag{A,19b}$$

$$L_2(t) = -2q^2, \tag{A,19c}$$

$$S_2(t) = t^2 + 2qt + 2q^2, \tag{A,19d}$$

and

$$q = \{(1+2\kappa R)^{1/2}-1\}/2. \tag{A,20}$$

In Eq. (A, 17), the first term is Wertheim's solution of the PY equation for a hard-sphere fluid; the integral in Eq. (A, 18b) was evaluated by Bearman and his co-workers using the res-

idue theorem in the range of $1<y<6$.[18,19] The second term, which is characteristic of electrolyte solutions, can also be evaluated in a similar way. After the denominator of the integrand is expanded to the power series in $L_2/S_2(t)$, Eq. (A, 18c) is written by:

$$g_{ij}^{el}(y) = \frac{1}{12\xi y}\sum_{n=1}^{\infty}\frac{(-1)^{n+1}}{2\pi i}\int_{\delta-i\infty}^{\delta+i\infty}\exp[t(y-n)]\left[\frac{L_2}{S_2(t)}\right]^n t\,dt. \tag{A,21}$$

The path of integration is to be taken to the right of all the poles of $1/S_2(t)$. Thus, the integral for $y<n$ is zero and that for $y>n$ is evaluated by means of the residue theorem. The resulting equations in the range of $1\leq y\leq 4$ are:

$$\begin{aligned} g^{el}(y) &= g_1^{el}(y), \quad \text{for } 1\leq y\leq 2, \\ &= g_1^{el}(y) + g_2^{el}(y), \quad \text{for } 2\leq y\leq 3, \\ &= g_1^{el}(y) + g_2^{el}(y) + g_3^{el}(y), \quad \text{for } 3\leq y\leq 4, \end{aligned} \tag{A,22}$$

where $g_1^{el}(y)$, $g_2^{el}(y)$, and $g_3^{el}(y)$ are

$$\begin{aligned} g_1^{el}(y) &= (\pm 2q^2/12\xi y)\{\sin[q(y-1)] \\ &\quad - \cos[q(y-1)]\}\exp[-(y-1)], \end{aligned} \tag{A,23a}$$

$$\begin{aligned} g_2^{el}(y) &= (\pm 1/12\xi y)[2(y-2)q^3\{\cos[q(y-2)] \\ &\quad - \sin[q(y-2)]\} - 2q^2\sin[q(y-2)]] \\ &\quad \times \exp[-q(y-2)], \end{aligned} \tag{A,23b}$$

$$\begin{aligned} g_3^{el}(y) &= (\pm 1/12\xi y)[2q^4(y-3)^2\{\cos[q(y-3)] \\ &\quad + \sin[q(y-3)]\} - 2q^3(y-3) \\ &\quad \times \{3\cos[q(y-3)] + \sin[q(y-3)]\} \\ &\quad + 6q^2\sin[q(y-3)]]\exp[-q(y-3)]. \end{aligned} \tag{A,23c}$$

Studies of the $\pi \rightarrow \pi^*$ Absorption Bands of 9,10-Phenanthrenequinone

Akira KUBOYAMA, Fumio KOBAYASHI, and Satomi MOROKUMA
National Chemical Laboratory for Industry, Shibuya-ku, Tokyo 151
(Received November 13, 1974)

The $\pi \rightarrow \pi^*$ S–S absorption spectra of 9,10-phenanthrenequinone and 3-bromophenanthrenequinone in solutions up to the vacuum UV region were obtained. On the other hand, MO calculations of the π-electronic systems of these quinones were carried out by means of the P–P–P method. The $\pi \rightarrow \pi^*$ absorption bands of these quinones were assigned on the basis of the calculated results. The blue-shift of the longest-wavelength $\pi \rightarrow \pi^*$ band of phenanthrenequinone due to the bromine-atom substitution at its 3-position was observed. Similar facts are found in aromatic carbonyl compounds, fluorenone and acetophenone.

Previously, we have theoretically and experimentally studied the $\pi \rightarrow \pi^*$ singlet-singlet absorption bands of *p*-quinones (*p*-benzoquinone, α-naphthoquinone, and anthraquinone) and *o*-benzoquinone.[1] The $\pi \rightarrow \pi^*$ absorption bands of 9,10-phenanthrenequinone(PHQ) have been studied by few workers. We have obtained the electronic spectra of PHQ and 3-bromo-PHQ in solutions up to the vacuum UV (VUV) region, and carried out MO calculations of their π-electronic systems by means of the P-P-P method. Their $\pi \rightarrow \pi^*$ singlet-singlet bands have been assigned on the basis of the calculated results.

Experimental

Measurements. The absorption spectra were measured in the same manner as in the previous work.[1] *n*-Heptane, 1,1,1,3,3,3-hexafluoro-2-propanol (HFIP), and ethanol were used as solvents. The measurement of the absorption spectrum of PHQ in the gas phase was also carefully carried out at *ca.* 200 °C with a 5-cm-path cell wrapped with a ribbon heater, using a Cary 14M recording spectrophotometer.

Materials. Commercially-available PHQ was purified by vacuum sublimation (mp 209.5—210.5 °C). The 3-bromo-PHQ was prepared according to Schmidt *et al.*'s method[2] and recrystallized five times from acetic acid (mp 272.5—273.5 °C). The *n*-heptane was the same as that used in the previous work, while the ethanol was of the spectrograde from the Dozin Yakugaku Co. The HFIP of the Eastman Co. was used without further purification.

Results. The $\pi \rightarrow \pi^*$ absorption spectra obtained are shown in Figs. 1—3. The wavelengths and molar absorption coefficients of the absorption maxima in these spectra are shown in Table 1. The solubility of these quinones in *n*-heptane was too poor for us to determine their concentration. Especially, the absorption spectrum of 3-bromo-PHQ in the *n*-heptane solution in the VUV region could not be accurately measured because of its very poor solubility. The longer-wavelength $\pi \rightarrow \pi^*$ bands of PHQ in the gas phase could not be accurately measured because of their weak intensities.

Calculations

Method. As for the electronic integral values in the P-P-P method, various kinds of integral values were tentatively used, based on the results obtained in the previous calculations. The set of electronic integral values which brought about the best agreement between the calculated and the experimental results will now be described. The values of the one-center core integrals, the two-center core integral of the C–O bonds, and electron repulsion integrals are the same as those used in the previous calculations.[1] The two-center core integral values of the C–C bonds were obtained with the Pariser-Parr method.[3] In this calculation, the bromine atom substituted for PHQ is considered to participate in the π-electronic system of PHQ with a 3p lone electron-pair. The one-center

core integral value of the bromine atom (−20.00 eV) and the two-center core integral value of the carbon-bromine bond (−1.00 eV) were determined so that the results calculated with them might be reasonable.

In the calculation, the forty lowest singly-excited configurations were included. The calculations were carried out with a FACOM 270-30 computer. The dimensions of PHQ assumed are shown in Fig. 4. The molecular structure of PHQ has not yet been elucidated.[4] PHQ is considered to take the planar structure of C_{2v} The dimensions shown in Fig. 4 were assumed considering the reported dimensions of its related compounds[5] (fluorene, triphenylene, anthraquinone, and acenaphthenequinone). The lengths of all the bonds in the benzene rings in PHQ were assumed to be 1.40 Å. The bond length of the carbon-bromine bond in 3-bromo-PHQ was assumed to be 1.91 Å.[6]

Discussion

As may be seen in Fig. 1, PHQ in the n-heptane solution appears to have five distinct $\pi\rightarrow\pi^*$ bands–near 400, 315, 260, 210, and 180 nm. These five $\pi\rightarrow\pi^*$ bands are denoted as, respectively, the a-, b-, c-, d-, and e-bands. As for the very weak shoulder near 490 nm of the a-band in the HFIP solution, it may be assigned to the $n\rightarrow\pi^*$ band, since the $n\rightarrow\pi^*$ band is observed near 500 nm in the n-heptane solution.[8] The $n\rightarrow\pi^*$ band in the HFIP solution seems to be somewhat intensified, compared with that in the n-heptane solution, through a vibronic coupling of the two closely-situated excited states of the $n\rightarrow\pi^*$ band and the a-band. In the b- and c-bands, a shoulder is clearly found on the longer-wavelength side of the b-band in the n-heptane solution and of the c-band in the HFIP solution. These weak shoulders show that another $\pi\rightarrow\pi^*$ band may exist there. In the case of 3-bromo-PHQ, as may be seen in Fig. 2, a distinct shoulder is found on the longer-wavelength side of the b- and d-bands, and a new absorption peak is found on the longer-wavelength side of the c-band. These shoulders and peak on the longer-wavelength side of the b- and c-bands may correspond respectively to the above-mentioned shoulders of PHQ. As for the shoulder on the longer-wavelength side of the d-band, another $\pi\rightarrow\pi^*$ band may exist there. The corresponding band of PHQ may be hidden in its d-band. Therefore, eight $\pi\rightarrow\pi^*$ bands are noticeable in 3-bromo-PHQ, and PHQ may be supposed to have the corresponding eight $\pi\rightarrow\pi^*$ bands. These other $\pi\rightarrow\pi^*$ bands are denoted as b′-, c′-, and d′-bands respectively, as is shown in Table 1. The large energy changes of the $\pi\rightarrow\pi^*$ bands in HFIP solutions compared with those in n-heptane solution, as may be seen in Figs. 1 and 2, may be mainly due to a strong hydrogen-bond formation between the quinones and HFIP, because HFIP, containing six electronegative fluorine atoms in its molecule, is thought to be a strong proton-donor.

Since longer-wavelength $\pi\rightarrow\pi^*$ bands usually show a red-shift due to the substitution of such an electron-donating group as a bromine atom to a π-electronic system, it is noticeable that the a-band of PHQ shifts towards shorter wavelengths due to the bromine-atom substitution at its 3-position, as may be seen in Figs. 1 and 2. Similar facts are found in the longest-wavelength weak $\pi\rightarrow\pi^*$ band near 380 nm of fluorenone[9] and that near 280 nm of acetophenone,[10] using 3-bromo, 3-methyl, and 3-methoxyfluorenones[11] and p-methyl and p-chloroacetophenones respectively. In all these cases, the electron-donating groups are substituted at the para-position of benzene rings to carbonyl groups. Therefore, similar facts may be expected to be generally observed in other aromatic carbonyl compounds.

As for the assignments of the $\pi\rightarrow\pi^*$ bands of PHQ and 3-bromo-PHQ, the five bands, a-, b-, b′-, c-, and c′-bands, can be reasonably assigned on the basis of the calculated results, as may be seen in Table 2. The c′-band can be reasonably assigned on the basis of the relatively large decrease in its excitation energy with the bromine-atom substitution. As for the higher-energy bands, the d-, d′-, and e-bands, the assignments based on the calculated results are not clear.

As for the above-mentioned blue-shift of the a-band upon the bromine-atom substitution, the calculated energy changes of the a-band with the bromine-atom substitutions at the various positions are shown in Table 3. In addition, those with the alkyl-group

Table 3. The changes of the calculated excitation energies of the a-band of PHQ with the bromine-atom and the alkyl-group substitutions at its various positions

Position	ΔE (eV)[a]	
	Bromine atom	Alkyl group
1	−0.042	−0.006
2	−0.046	−0.035
3	−0.005	+0.011
4	−0.072	−0.033

a) ΔE denotes the remainders where the excitation energies of PHQ are subtracted from the corresponding ones of 3-bromo-PHQ.

substitutions are also shown in Table 3. The calculations of the alkyl-group substituted PHQ's were carried out taking the one-center core-integral value of the substituted carbon atoms as -9.00 eV, in consideration of the inductive effect of the alkyl group, but disregarding its resonance effect, as in the previous work.[1] As may be seen in Table 3, the calculated energy decrease of the a-band in 3-bromo-PHQ is far smaller than those in the other bromo-PHQ's. Therefore, the calculated results are not inconsistent with the observed results. On the basis of the calculated results shown in Table 3, a blue-shift of the a-band of 3-alkyl-PHQ compared with that of PHQ can also be expected.

As for the comparison of our theoretical assignment of the $\pi\rightarrow\pi^*$ bands of PHQ with the experimental facts[12-14] previously reported, our assignment of the a-, c-, and c'-bands is consistent with the dichroic absorption spectra of PHQ in the stretched PVA sheet, reported by Inoue *et al.*[12] but that of the b-band is inconsistent. The pattern of the calculated energies and f-values of the π, π^* excited states of PHQ are far more sensitive to the electronic integral values used than those in the quinones previously studied.[1] Therefore, further studies of the assignment of the $\pi\rightarrow\pi^*$ bands of PHQ are desirable.

As may be seen in Fig. 3, the shapes of the $\pi\rightarrow\pi^*$ bands of PHQ in the gas phase are similar to those in the *n*-heptane solution.[15] The broad shape of the $\pi\rightarrow\pi^*$ bands in the gas phase may be due to the measurement at a high temperature. It is noticeable that all the energies of the $\pi\rightarrow\pi^*$ bands in the gas phase are considerably larger than those in the *n*-heptane solution as may be seen in Table 1. The energy differences (in wave number) between the former and the latter are *ca.* 1760, *ca.* 1710, 1630, and 2140 cm^{-1} for the a-, b-, c-, and d-bands respectively. A similar fact is observed in anthraquinone.[16]

The authors are grateful to Mr. Toshihiro Kamada of this Laboratory and Mr. Yoshikuni Sato of the Tokyo Metropolitan Industrial Technology Center for their helpful cooperation in the experiments.

Some Properties of the Salt between Inosine and L-Lysine

Yoshihisa SUZUKI, Kentaro HARA, and Tsuneo HIRAHARA
Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210
(Received December 2, 1974)

Among several basic amino acids, only the L-lysine free base was found to form a crystalline salt with inosine. A specific stereochemical arrangement of these two molecules, inosine and L-lysine, is considered to be involved in such a crystalline salt-formation on the basis of the fact that D-lysine did not form a crystalline salt with inosine. Part of the equilibria were determined at 10 °C for the inosine–L-lysine–water and inosine–L-lysine–60 w/w % aqueous ethanol systems. The salt was unstable against water, while it was stable against aqueous ethanol (containing more than about 40% ethanol). The solubility of the salt in water was summarized as follows: $\log S$ (w/w %) $= 0.0219\,t + 0.624$. The X-ray powder diffraction data of the salt are given.

In the course of a study of the interactions between nucleic acid components and amino acids, L-lysine and L-(or D-)tryptophan have both been found to form 1 : 1 crystalline compounds with inosine.[1,2] It has also been demonstrated that the optical resolutions of these two amino acids are performed through these crystalline compounds with inosine.[2,3] Such a crystalline compound of inosine with L-lysine is considered to be a salt, while with tryptophan it is considered to be a molecular complex, on the basis of the facts that lysine is basic and tryptophan is neutral. This paper will describe some properties of the crystalline salt of inosine with L-lysine.

Results and Discussion

Inosine possesses a pK_a value of 8.8, due to the hydroxyl group at the 6 position, and can form salts with various inorganic basic substances.[4,5] However, among several basic amino acids tested, only L-lysine formed a crystalline salt with inosine. An equimolecular solution of inosine and one of the basic amino acids (free bases) including L-arginine, L-histidine, L-ornithine, L-citrulline, and L-creatine was evaporated to dryness. The powder X-ray diffraction data revealed that the residue was an equimolecular mixture of crystals of inosine and individual amino acid. (The L-ornithine free base was dried in the amorphous solid.) The characteristic X-ray diffraction patterns, shown in Table 1, were obtained only when the L-lysine free base was employed.

Such a specific ability of the salt-formation of L-lysine with inosine cannot be interpreted merely in terms of the basicity of amino acid. L-Arginine shows no salt-formation despite the fact that basicity is higher than that of L-lysine.

The solubilities of amino acids (free bases) may explain to a certain extent such a salt-formation. The L-arginine free base or the L-histidine free base is not so soluble in water, and it is easily precipitated independently before the precipitation of the salt. On the other hand, L-lysine is very soluble and it is not easily

precipitated alone, and so there is a large possibility for the crystallization of the salt. However, the explanation in terms of the solubilities is not yet enough for the salt-formation, since L-ornithine was not associated with inosine in spite of its high solubility, like that of L-lysine.

It is also confusing that D-lysine cannot easily form a crystalline salt with inosine. This fact is advantageous for the resolution of racemic lysine.[3] When an equimolecular aqueous solution of inosine and D-lysine was evaporated to dryness, it gave an amorphous solid, or an almost amorphous solid plus a small quantity of inosine crystals in the α-form.[6] A specific stereochemical arrangement of these two molecules, inosine and L-lysine, may be involved in such a crystalline salt-formation, as is a molecular complex.

However, there is no doubt that an ionic bond is involved in this interaction. The infrared spectrum of the crystalline salt (Fig. 1) showed a strong absorbance at 1600 cm^{-1}, like that of sodium salt of inosine. This fact indicates an anionic dissociation of the hydroxyl group at the 6 position of the inosine molecule. The absence of the absorption band at 1680—1700 cm^{-1} also indicates an absence of any carbonyl group in the inosine molecule.

A part of the equilibria for the inosine–L-lysine–water and inosine–L-lysine–60%(w/w) aqueous ethanol systems were determined at 10 °C. In order to attain to the equilibrium, the mixture of the crystals and the solution was shaken for 16 hr, 40 hr, or 48 hr; the different shaking times revealed no significant difference in the composition data of the solution phase with the shaking period.

Table 2 shows the composition data of a part of the equilibrium for the inosine–L-lysine–water system at 10 °C. Figure 2 illustrates the solution phase of this system. The solubility of inosine increases linearly with an increase in the amount of L-lysine until its L-lysine salt is precipitated (Point A in Fig. 2), and then it

○: The salt between inosine and L-lysine.

decreases with a further increase in L-lysine. The slope of the initial linear increase is, however, not unity in relation to the molar ratio of inosine to L-lysine, but is, instead, about 0.7. The molar ratio at Point A is, consequently, also about 0.7. Accordingly, the L-lysine salt of inosine is unstable in the solution in which the molar ratio is unity; in other words, the salt is incongruent and unstable against water. When an excess amount of the salt is added to water at 10 °C, the suspended salt is changed into inosine dihydrate. For the stable crystallization of the salt, it is desirable that the solution possesses an excess amount of L-lysine; the molar ratio of L-lysine to inosine must be more than 1.4 (a reciprocal of 0.7).

On the other hand, the salt is stable against about 60%(w/w) aqueous ethanol, as is shown in Table 3 and Fig. 3. Table 3 shows the composition data of a part of the equilibrium for the inosine–L-lysine–60% aqueous ethanol system at 10 °C, while Fig. 3 illustrates

Table 3. Composition data of the equilibrium for the inosine–L-lysine–60% (w/w) ethanol system at 10 °C

○: The salt between inosine and L-lysine.

the solution phase of this system. The solubility of inosine in 60% ethanol increases linearly with an increase in the amount of L-lysine until its L-lysine salt is precipitated (Point B in Fig. 3). However, the molar ratio of inosine to L-lysine at Point B is about 1.1. Accordingly, the salt is stable against a 60% ethanol solution, whereas it is unstable against water.

A stabilizing effect in the presence of ethanol was observed when the concentration of ethanol was more than 40 w/w%. Therefore, the stable crystallization of the salt is performed from an equimolar solution of inosine and L-lysine by means of the addition of ethanol to make the concentration more than 40%.

Table 4. The solubility of inosine, and the L-lysine salt of inosine in water

Temp. (°C)	Solubility (w/w %)		
	Inosine in the α-form[7]	The salt, inosine·L-lysine	(Inosine-content in the solution of the salt)
10	0.95	7.03	(4.56)
30	3.1	18.4	(11.9)
50	8.2	52.5	(34.0)

The precise determination of the solubility of the salt in water was difficult because of the instability of the salt against water. However, a brief determination was performed by the addition of the salt, a little at a time, to water at a constant temperature until no more salt was dissolved; we thus made clear solution. The results are summarized in Table 4, which also shows the solubility of inosine in the α-form for comparison of the inosine-content in the solution. The logarithm of the solubility is linear to the temperature; it is expressed as follows:

$$\log S\,(\%) = 0.0219\,t + 0.624$$

where S represents the weight of the salt contained in 100 g of the solution and where t is the temperature (°C). The inosine-content in the solution of the salt thus obtained is about four times as much as that in the saturated solution of inosine in the α-form.[7] An aqueous solution of a high concentration of inosine for medical use can be prepared by dissolving the salt of inosine with L-lysine into water.

Experimental

Materials. The crystals of inosine, the L-arginine free base and the L-histidine free base used were of a commercial grade of the Ajinomoto Co., Inc. The aqueous concentrated solutions of the free bases of L-ornithine, L-lysine, and D-lysine were prepared from their respective hydrochlorides through the ion-exchange method. The free bases of L-citrulline and L-creatine were commercially obtained. The salt between inosine and L-lysine was prepared according to Suzuki *et al.*[1]

Examination of the Salt-formation. Inosine (0.005 M) and one of the basic amino acids (0.005 M) were dissolved in water, after which the mixture was evaporated to dryness *in vacuo*. The resulting solids were examined by the X-ray powder diffraction method. The IR spectra (KBr) were measured with a Nippon Bunkoh Model IR-S instrument.

Analysis. The inosine was determined with the absorbance at 250 nm in 0.1 M HCl, using the molar extinction coefficient of 11800. The lysine was determined according to the ninhydrin method by Yamagishi *et al.*[8]

Determination of the Inosine–L-Lysine–Water System. An excess amount of the crystals collected from inosine and the L-lysine salt of inosine were added to water or an aqueous solution of the L-lysine free base to make a slurry in tightly-capped glass bottles at 10±0.2 °C. The equilibria were achieved by tumbling the bottles for 16 hr (Runs No. 2, 3, 5, 7, 8, and 11) or 40 hr (Runs No. 4, 6, 9, 10, 12, and 13) at a constant temperature. A tumbling period of at least 16 hr was employed so as to avoid any more significant variation in the composition data of the solution phase. The prolonged period of 40 hr was employed for the convenience of the experimental schedule. Then, the mixtures were quickly filtered by means of a glass filter. The clear solutions and wet residues were submitted to analysis. The residues were examined by means of the X-ray diffraction method (Cu$K\alpha$) in order to identify the crystal form.

Determination of the Inosine–L-Lysine–60% Ethanol System. The same method was used except that the solvent was not water but 60 w/w% ethanol containing a definite amount of L-lysine. The tumbling period for the equilibrium was 48 hr.

Stability of the Salt in Relation to Aqueous Ethanol. An excess amount of the salt between inosine and L-lysine was added to an aqueous ethanol which had a definite concentration of ethanol. After the mixture had been shaken overnight at 10 °C, the suspended solid was examined by means of the X-ray method in order to confirm whether or not the form of the crystals was changed.

The Solubility of the Salt in Water. The salt between inosine and L-lysine was added to water, little by little, with vigorous shaking in order to dissolve it at a constant temperature (10, 30, or 50 °C). When a very small amount of a suspended solid remained undissolved in the solution, the mixture was filtered; the clear supernatant was then submitted to the analysis of inosine. The amount of the salt dissolved was calculated from the stoichiometry of 1 : 1.

The authors wish to thank Mr. Takashi Sato for his technical assistance in a part of the present study.

The Calculation of the Primary Radiolysis Yield of Water Vapor Irradiated by 10-keV Electrons

Shin-ichi OHNO, Hisashi NAGAYAMA, Kiyoshi OKAZAKI,* and Shin SATO*

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki-ken 319-11

**Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received December 13, 1974)

The yields for the ionization and excitation from each molecular orbital of a water molecule irradiated by 10 keV electrons were calculated using the classical binary-encounter approximation. On further assuming fragmentation processes of the excited or ionized states consistent with the photochemical and mass spectrometrical results in the literature, we obtained, as the radiolysis yields of water vapor: G(electron)=2.96; $G(OH^-)=0.04$; $G(H_3O^+)=3.00$; G(H)=4.83—5.21, including G('hot' H-atoms)$\leq$0.87; $G(H_2)=0.28$—1.15; G(O)=0.83—1.21; G(OH)=6.70—7.08, and $G(-H_2O)=G$(ionized water)$+G$(excited water)$=2.91+4.96=7.87$.

The ideal study of radiation chemistry consists of (i) the experimental determination of the radiation-chemical products, and (ii) the interpretation of their formation by means of a detailed analysis, specifying the primary products in the physical stage[1] (chiefly molecules in the electronically excited or ionized state) and following their fate in temporal sequence until observable chemical changes appear. Thus, a knowledge of the nature and yields of the primary products is extremely important to radiation chemists.

The primary products are formed as a result of the interaction of molecules with electrons in an energy distribution given by the degradation spectrum.[2,3] Fast electrons in the degradation spectrum interact with molecules in an "optical" collision, for which the cross section is expressed by the Bethe-Born approximation. For slow electrons of the degradation spectrum ($T\lesssim100$ eV), however, this approximation loses its validity.[4]

We have chosen another possible approach to this problem of the calculation of the primary yields. Our method is a combination of the binary-encounter collision theory and a procedure for calculating the degradation spectrum. We previously applied it to the case of noble gases from He to Xe[5,6] and obtained results in reasonable agreement with the experimental ones.

The present paper is an extension of our work to a molecular system. The G-values of the ionization and excitation from each molecular orbital of the water molecule will be given. Then, we assume the mode with which the primary products decompose to give fragments on the basis of knowledge from photochemistry, mass spectrometry, and photoelectron spectroscopy. The yields of the fragments thus obtained may be compared with those estimated from the experimental work. The agreements are quite satisfactory, as will be shown later.

Method of Calculation

The "binary-encounter" collision theory, first presented by Thomas in 1927[7] and formulated and discussed in detail by Gryzinski,[8,9] Vriens,[10] and Burgess,[11] involves the following approximations:[10]

(i) the incident electron interacts with only one electron in the molecule.

(ii) the interaction between the molecular electrons and nucleus can be disregarded during the collision. In other wors, the collision takes place in a region small compared to the molecular dimensions. Thomas cosidered[7] the case of an electron with a kinetic energy of T moving through a cloud of free target electrons moving in random directions with kinetic energy of E_i. He gave this differential cross section per unit of energy interval for transferring an energy, E, to a target electron:

$$\sigma_{E,dir}=\frac{\pi e^4}{T+I_i+E_i}\left(\frac{1}{E^2}+\frac{4E_i}{3E^3}\right) \qquad (I)$$

for $T+I_i\geq E$. Here, I_i is the binding energy of the target electron in the i-th molecular orbital (M.O.). The target electron on receiving the energy, E, may jump to a higher M.O. with the excitation energy, E_n, if $E\geq E_n$. Ionization occurs if E is larger than I_i, the kinetic energy of the ejected electron being $E-I_i$. One may also apply the above formula to an excitation induced by the exchange between the incident electron and a molecular electron ($\sigma_{E,exc}$). In this case, E in Eq. I should be replaced by $T+I_i-E$.

The stopping power, the degradation spectrum, and the total number of the primary products were all calculated on the basis of Eq. I. The details of the formulation were the same as those presented previously,[6] except for a slight modification of the stopping power formula (Eq. IV in Ref. 6).

Stopping Power. In the present work we used the stopping power expressed as follows:

$$S(T)=N\sum_i S_i(T)$$

$$S_i(T)=n_i\left\{\int_{E_{si}}^{(T+I_i)/2}E(\sigma_{E,dir}+\sigma_{E,exc})dE+\frac{1}{2}\int_{E_{ti}}^{E_{si}}E\sigma_{E,exc}dE\right\} \qquad (II)$$

for $T\geq I_i$. Here, N is the number of molecules in a unit of volume, $S_i(T)$ is the stopping power due to the n_i-electrons in the i-th M.O., and E_{si} and E_{ti} are the excitation energies of the lowest singlet and triplet levels respectively for the electrons in the i-th M.O. When $T\leq I_i$, the upper limit of the first integral should be replaced by T. When $T<E_{si}$, the first term disappears and the E_{si} in the second integral should be replaced by T.

Double Collision. A molecule undergoing interac-

tion with an impacting electron may result in a simultaneous excitation and/or ionization of two electrons. Gryzinski formulated two such processes:[9] one in which two electrons in the molecule are excited and/or ionized by two successive collisions of the incident electron, and another in which the incident electron ejects the first electron, which in turn excites or ionizes the second electron in the same molecule. According to the treatment of Gryzinski,[9] and using Eq. I as the cross sections for transferring energy on collision, we derived the cross-section formulas[12] for double ionization (designated as $\sigma(H_2O^{++})$), double excitation $\sigma(H_2O^{ee})$, and simultaneous excitation and ionization $\sigma(H_2O^{e+})$ in order to estimate their yields with the help of the degradation spectrum obtained on the basis of single collisions alone.

Constants Used for Calculation

The ground-state electronic configuration of the H_2O molecule is:

$$(1a_1)^2(2a_1)^2(1b_2)^2(3a_1)^2(1b_1)^2, \quad {}^1A_1$$

For the present calculation, we must know the binding energies, I_i, of the electrons in each M.O., their average kinetic energies, E_i, and their lowest singlet and triplet excitation energies, E_{si} and E_{ti}. Table 1 summarizes the values used. The lowest excited states:

$$\cdots (1b_2)^2(3a_1)^2(1b_1)(4a_1), \quad {}^3B_1\ (5\text{ eV}), \quad {}^1B_1(7.5\text{ eV})$$

$$\cdots (1b_2)^2(3a_1)(1b_1)^2(4a_1), \quad {}^1A_1\ (9.6\text{ eV})$$

heve been identified by UV-absorption or electron-impact experiments.[14-16] The E_{si} values of the other M.O.'s given in Table 1 were estimated from the differences in the I_i-values. Selection rules for transitions were taken into account. All the E_{ti}-values, except for the lowest, were set equal to the respective E_{si} values; they are only provisional.

TABLE 1. THE BINDING ENERGY (I_i), THE KINETIC ENERGY (E_i), AND THE LOWEST SINGLET (E_{si}) AND TRIPLET (E_{ti}) LEVELS OF ELECTRONS IN THE WATER MOLECULE (IN eV)

M.O.	I_i	E_i	E_{si}	E_{ti}
$1b_1$	12.6	70.4	7.5	5.0
$3a_1$	14.7	42.0	9.6	9.6
$1b_2$	18.4	42.0	13.3	13.3
$2a_1$	32.2	70.4	27.1	27.1
$1a_1$	540	806	535	535

More difficult to ascertain are the average kinetic energies, E_i. Since the M.O. $1a_1$, $2a_1$, and $1b_1$ are composed mainly of the atomic orbitals of oxygen (1s, 2s+2pz, and 2px respectively), the E_i values of these M.O.'s may be calculated using Slater's rule.[17] The E_i values for $1b_2$ and $3a_1$ were set equal to the mean of the kinetic energies calculated for the corresponding atomic orbitals of oxygen and hydrogen.[18]

For the calculation of the double-collision cross-sections, we assumed, to simplify the computation, that double collisions occur only among the 6-electrons in the $1b_1$, $3a_1$, and $1b_2$ orbitals. The 6-electrons are situated uniformly on the surface of the sphere with a radius of 0.5 Å, so that the mean distance between two of these electrons is 0.8 Å. The first ionization energy, $\bar{I}(\mathrm{I})$, the first excitation energy, $\bar{E}_s(\mathrm{I})$, and the kinetic energy, $\bar{E}_i$, are taken to be the averages of the respective values of the $1b_1$, $3a_1$, and $1b_2$ electrons. The second ionization energy, $\bar{I}(\mathrm{II})$, and the second excitation energy, $\bar{E}_s(\mathrm{II})$, are tentatively taken to be $2\times\bar{I}(\mathrm{I})$ and $2\times\bar{E}_s(\mathrm{I})$ respectively.

Results

Figure 1 shows the $y(T)$ for a 10 keV electron in H_2O (1 atm, 0 °C). Once $y(T)$ is obtained, the calculation of the yields of the ionization and excitation is straightforward if we use the total cross-section, $Q_s(T)$, for each process.[6] Figures 2 and 3 show the $T\cdot y(T)\cdot Q_s(T)$ *vs.* $\ln T$ plots; according to Platzman[2] the area under the curve is proportional to the yield of the s process (Fig. 2 refers to ionizations, while Fig. 3 refers to excitations).

Tables 2—4 summarize the G-values of all the primary products obtained in the present calculation. All the integrations were carried out by means of a computer, HITAC 8700, with a mesh of $(0.5)^{1/40}$ for the energy.

Since the cross-sections for the dissociative-electron capture of the H_2O molecule have been previously reported,[19] we can estimate the order of magnitude of the yield of this process using the $y(T)$-curve obtained

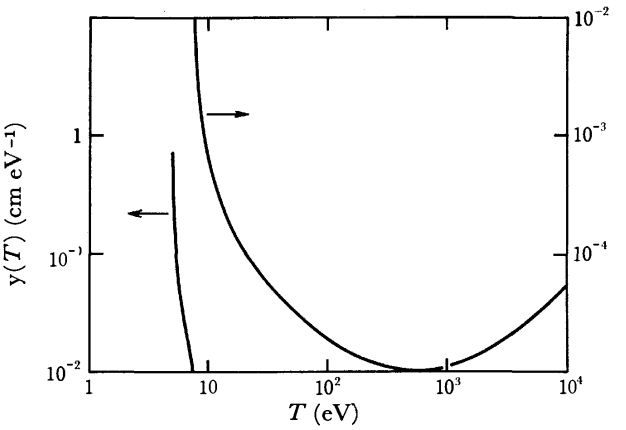

Fig. 1. The degradation spectrum for a 10 keV electron in water vapor (0 °C, 1 atm).

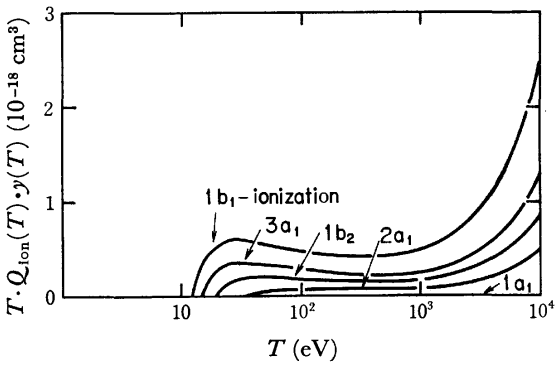

Fig. 2. Contribution of different portions of the electron degradation spectrum to ionizations from each M.O. in H_2O.

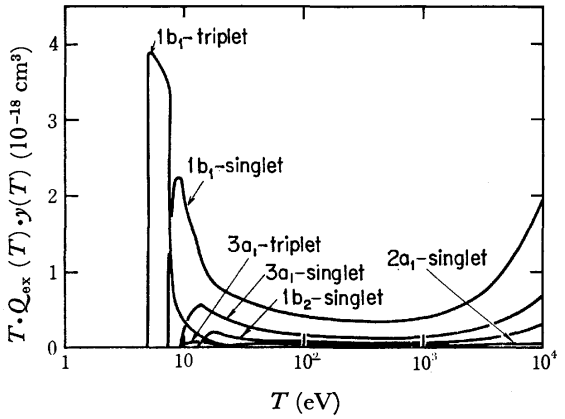

Fig. 3. Contribution of different portions of the electron degradation spectrum to excitations from each M.O. in H_2O.

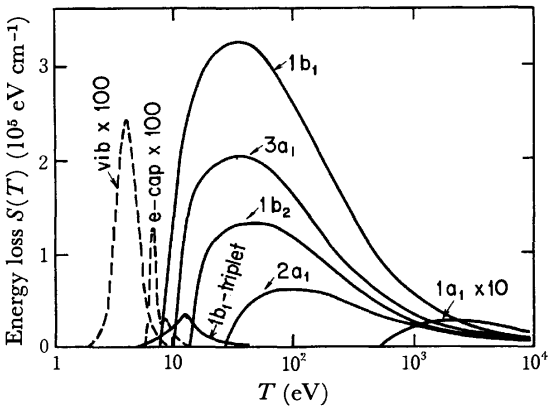

Fig. 4. The stopping power for electrons in water vapor. The contribution from electronic excitation and ionization of each M.O., dissociative electron capture (e-cap) and vibrational excitation (vib) of the H_2O molecule.

Table 2. The *G*-values of excitations in the H_2O molecule

M.O.	Singlet	Triplet	Mode of decomposition
$1b_1$	2.80	1.00	H+OH
$3a_1$	0.96	0.029	H+OH* (75%), H_2+O (25%)
$1b_2$	0.39	0.011	"hot H"+OH, or H_2+O*
$2a_1$	0.076	0.0016	Ion. frag.[a]
$1a_1$	0.000079	1.5×10^{-6}	Ion. frag.

a) Ionizing fragmentation.

Table 3. The *G*-values of ionizations in the H_2O molecule

M.O.	*G*	Mode of decomposition
$1b_1$	1.26	H_2O^++e
$3a_1$	0.68	H_2O^++e
$1b_2$	0.44	Ion. frag.
$2a_1$	0.21	Ion. frag.
$1a_1$	0.005	H^++OH^++2e *via* HO^{2+}

Table 4. The *G*-values for double collisions in the H_2O molecule

Primary product	Excitation energy (eV)	*G*	Mode of fragmentation
H_2O^{++}	45.6	0.09	H^++OH^++2e
H_2O^{ee}	30.6	0.12	H_2O^++e
H_2O^{+e}	35.6	0.31	Ion. frag.

in the present work. This gives $G\approx0.04$ for this reaction:

$$H_2O + e \longrightarrow H^- + OH \quad (1)$$

An alternative mode of dissociation:

$$H_2O + e \longrightarrow H_2 + O^- \quad (2)$$

has a much lower probability.[19]

Figure 4 shows the contribution from the electrons in each M.O. of the H_2O molecule to the stopping power for electrons in water vapor. Here are also shown, for convenience of comparison, the stopping power due to the dissociative-electron capture (Reaction 1) and the stopping power due to the vibrational excitations of water previously estimated by Mozumder.[20]

Yields of the Radiolytic Fragments

In order to obtain the radiolysis yields so as to compare them with the experimental results, we must know the fate or fragmentation process of the primary products listed in Tables 2 to 4.

The Ionized States. As to the ionized states, useful information is available from experimental photoelectron spectroscopy.[21] When an electron is removed from the $1b_1$ orbital, non-bonding in nature, the resulting ion is left practically unexcited. The loss of an electron from $3a_1$ will cause a bending vibration. If an electron is lost from a bonding $2a_1$ or $1b_2$ orbital, the O-H bond strength is weakened and its length is increased. In fact, the peaks of the band corresponding to the ionization from $1b_2$ in the P.E.S. spectrum are diffuse, suggesting a short lifetime prior to dissociation.[21]

The ejection of a $1a_1$-electron produces a doubly-charged ion by a well-known Auger process; the ion will then decompose.[22]

The Excited States. The UV absorption experiments threw light on the neutral excited states listed in Table 3. The continuous band ranging from 7 to 9 eV is due to the $\cdots\cdots(1b_1)^2$, $^1A_1\rightarrow\cdots\cdots(1b_1)(4a_1)$, $^1B_1$ transition, where the higher state is repulsive because of the anti-bonding nature of the $4a_1$ orbital.[23] The photochemical experiments have enabled us to conclude that the fragments are OH and H.[24] The excitation of an electron from $3a_1$, responsible for the bent shape of the molecule, to an anti-bonding $4a_1$ orbital will strain it towards its linear form and at the same time dissociate it. The photochemical experiments show that O, $OH(^2\Sigma^+)$, and $OH(^2\Pi)$ are formed simultaneously, their abundances being 25, 5, and 70% respectively.[24,25]

Nothing is known at present about the fate of the excited water molecules formed by promoting an electron from $1b_2$, $2a_1$, or $1a_1$ to $4a_1$ or a higher orbital. Since the excitation energy in these cases exceeds the lowest ionization energy of H_2O, both ionization and dissocia-

tion are possible. Therefore, we tentatively assume that the excitation of a $1b_2$-electron leads to dissociation to "hot H"+OH or H_2+O, while the excitation of a $2a_1$- or $1a_1$-electron leads to dissociative ionization. In the former case, the "hot H"-atoms might further react with water:

$$\text{"hot H"} + H_2O \longrightarrow H_2 + OH \quad (3)$$

as has been evidenced in the photochemical experiments.[24]

Double Collision. The doubly charged water and the excited water ion, designated as H_2O^{++} and H_2O^{+e} respectively in Table 4, would dissociate because of their large excitation energy. The doubly excited state, H_2O^{ee}, would lead to preionization.

The Ionizing Fragmentation. The yield of the primary products which will produce ionizing fragmentation amounts to $G\approx1$. Mass spectrometry provides information on the fragments. The mass spectrum of water obtained with an extremely high ion-extraction efficiency[26] shows that both H^+ and OH^+ are very abundant ions, about 25—30% of the parent ion, H_2O^+. The intensities of the other ions, O^+ and H_2^+, are low enough to be excluded from the present consideration. Thus, we may assume that the processes designated as Ion. frag. in Tables 2—4 are represented by:

$$H_2O \longrightarrow \begin{cases} H + OH^+ + e\ (50\%) & (4) \\ H^+ + OH + e\ (50\%) & (5) \end{cases}$$

It is possible that these fragments have a kinetic energy or an electronic excitation energy. Thus, the H-atoms formed in Reaction 4 can possibly react further according to Reaction 3.

Ion-molecule Reactions. The ionic fragments produced by the decomposition of the primary products of the water radiolysis may react with a water molecule to yield another ion. The following reactions are well known:[27]

$$H_2O^+ + H_2O \longrightarrow H_3O^+ + OH \quad (6)$$

$$OH^+ + H_2O \longrightarrow H_3O^+ + O \quad (7)$$

$$H^- + H_2O \longrightarrow H_2 + OH^- \quad (8)$$

The proton may react with several water molecules succesively to form a clustered state. We will represent this state as merely H_3O^+ for the sake of simplicity.

Final Results. We can now use the results shown in Tables 2 to 4 to estimate the G-values of the radiolytic fragments of water vapor in accordance with the above assumptions. The results are summarized in Table 5.

Table 5. The G-values of the fragments in the radiolysis of water vapor

Fragment	G
electron	2.96
OH^-	0.04
H_3O^+	3.00
H	4.83—5.21[a]
H_2[b]	0.28—1.15
O	0.83—1.21
OH	6.70—7.08

$G(-H_2O)=G$(ionized water)$+G$(excited water) $=2.91+4.96=7.87$

a) G("hot H")$\leq$0.87 is included. b) "molecular" H_2.

Discussion

The experimental W values which have been reported for water vapor lie around 30 eV.[27] Thus, G(ionization) $=3.3$. The values of G(electron) can be obtained experimentally from the difference in the radiolytic yields of water vapor with and without added electron scavengers; the values of 3.0 ± 0.4[28] and 2.7 ± 0.6[29] have been reported. The value for $G(-H_2O)$ was estimated by means of the total hydrogen yields from water vapor containing various organic additives. There is a reasonable agreement on $G(-H_2O)=8\pm1$.[27] Molecular hydrogen is also formed,[28,30] with a yield ($G\approx0.6$), not influenced by additives. More recently Boyd *et al.*[31] reported that the yields of hydrogen from the Febetron radiolysis of water vapor with HCl are $G(H_2)=7.9\pm0.2$ and $G(H_2)=4.6\pm0.2$ with 1 mol% SF_6. They combined their results, taking G("molecular" H_2)$=0.45$, with the relative primary ion yields of the radiolysis of water vapor as: G(e)$=3.3$, G(H)$=4.15$, G(OH)$=6.25$, and G(O)$=1.05$. It is of interest to compare all these results with the values compiled in Table 5. The agreement is satisfactory.

The important role of kinetically hot or electronically excited H-atoms has often been noticed.[32,33] According to the scheme discussed above, they are possibly formed either by the decomposition of the excited water molecule (itself formed by the promotion of a $1b_2$-electron) or by way of Reaction 4. Thus, the present results predict 0.9 as the maximum G-value of "hot" or excited H-atoms.

The yield of the doubly charged water, H_2O^{++}, amounting to $G=0.1$ should be noted in view of the radiolysis of frozen aqueous solutions. Molecular decomposition by Coulomb repulsion would bring about the atomic displacement in the solid phase,[34] the result of which may be the formation of trapped species.

The O-atoms, to which little attention has been paid, may be produced with a high yield ($G\approx1$) and may play an important role in the radiation chemistry of water.[35]

It is of some interest to know the mean energy, $\tilde{I}_1$, imparted to the molecule undergoing ionization. In an ionizing collision, the impacting electron loses the energy, E, which is the sum of the energy imparted to the molecule and the kinetic energy of the ejected electron. Using the results in Tables 2 to 4, one obtains:

$$\tilde{I}_i = \frac{\sum(I_i \times G_i)}{\sum G_i} = 19\,\text{eV}$$

which largely exceeds the lowest ionization energy, 12.6 eV. This is due to the electronic excitation of the ions formed or to excitation to repulsive ionic states, leading to the formation of fragments with a high kinetic energy.

We must further note that Santar and Bednar[4] calculated the yields of the excitation and ionization of valence electrons in the water molecule. They

treated separately the contributions to the yield from "fast" and "slow" electrons of the degradation spectrum. They used the available optical data for H_2O to calculate the yields due to "fast" electrons. They also utilized the optical data to ascertain the number and initial kinetic energy of the "slow" electrons, which are produced predominantly by "fast" collisions. They further used the experimental W value for water, considered the energy balance, and finally obtained results which are close to those found experimentally.

The present method is obviously more straightforward and simpler than that employed by Santer and Bednar. It requires neither the optical data nor the W value. Instead, it requires data on the binding energy, the excitation energy, and the kinetic energy of each electron in the molecule. In conclusion, we should mention that the "binary-encounter" approximation may be very useful, not only for getting a general idea about the primary process of radiolysis, but also for estimating non-empirically the radiation-chemical yields.

The authors wish to thank Dr. Kazuhiko Izui for his helpful discussions and Dr. Tsutomu Watanabe, University of Tokyo, for suggesting a procedure for the estimation of the E_i values.

The Radiation-induced Decoloration of Azo Dye in Aqueous Solutions

Nobutake Suzuki, Takeshi Nagai, Hiroshi Hotta, and Masamitsu Washino

Japan Atomic Energy Research Institute, Takasaki Radiation Chemistry Research Establishment, Takasaki 370-12

(Received December 25, 1974)

The decoloration yield of an Acid Red 265 neutral aqueous solution, G(-Dye), equaled 1.00 ± 0.04, regardless of the dose rate and the initial dye concentration in the early stage. The G(-Dye) increased to 1.46 in the presence of nitrous oxide, but was independent of the presence of oxygen and acetone. In nitrogen-saturated solutions, the G(-Dye) increased markedly upon the addition of alcohols—for example, up to 1.83 upon the addition of 2 mM *n*-butyl alcohol. On the other hand, in oxygen-saturated solutions, the G(-Dye) decreased markedly upon the addition of even a small amount of alcohols. The effects of alcohols, namely, the G(-Dye) in both the solutions were in the order of their reactivity with OH radicals. The decoloration is attributable to the attack of the OH radicals formed by the radiolysis of water to the dye. The increase in the G(-Dye) for the nitrogen-saturated solutions containing alcohols is attributable to the attack of the alcohol radicals ($R\dot{C}HOH$) formed by the reactions of alcohols with OH radicals. In the oxygen-saturated solutions, the $R\dot{C}HOH$ radicals are converted to the peroxides, which do not react with the dye. The rate constant for the reaction of the OH radical with Acid Red 265, obtained by using various additives from the competition reaction method, is $9.3\pm1.4\times10^9$ $M^{-1}s^{-1}$. The effects of CNS^-, glucose, and phenol were also examined.

The decoloration of organic dyes in aqueous solutions induced by ionizing radiation has recently been reviewed by Grossweiner.[1] However, the radiation chemistry of azo dyes in aqueous solutions has not been extensively studied. A few authors[2,3] have, though, reported on its radiation-induced decoloration of azo dye in aqueous solutions. Korgaonkar *et al.*[2] discussed the possibility that the color changes of azo dye solution induced by ionizing radiation might serve as convenient radiation dosimeters. Mytelka *et al.*[3] have studied the radiation-induced decoloration of azo dye waste water.

In this paper, the effects of alcohols and other additives on the radiation-induced decoloration of Acid Red 265 in aqueous solutions will mainly be discussed, and the rate of its decoloration reaction will be estimated.

Experimental

Reagents. The Acid Red 265 (Kayaku Acid Brilliant Red BL; see Fig. 1), obtained from the Nippon Kayaku Co., Ltd., was further purified by recrystallization from a methyl alcohol-ethyl alcohol mixture. The recrystallized Acid Red 265 was then dried overnight in a vacuum desiccator containing silica gel. A test by thin-layer chromatography showed only a single component in the sample. The nitrous oxide (99.0%) was used without further purification. The other reagents used were of a reagent grade.

Fig. 1. Schematic of the sodium salt of Acid Red 265.

Irradiation Procedure and Analysis. The dye solution was prepared by dissolving recrystallized Acid Red 265 in triply distilled water. The solution was bubbled with nitrogen for 40 min or with oxygen for 15 min prior to irradiation. In some experiments, a nitrous oxide-saturated solution was prepared by bubbling for about 20 min. The solutions were placed in Pyrex glass tubes (30 ml) with a stopper and then irradiated with cobalt-60 gamma rays at room temperature. The dose rate (1.1×10^5 rad/hr) was determined by Fricke dosimetry ($G(Fe^{3+})=15.6$).

The degree of decoloration was determined by the measurement of the optical density at 542 nm with a Shimadzu spectrophotometer UV-200.

Results

Decoloration of Acid Red 265 in Aqueous Solutions. The degrees of decoloration for the nitrogen- and oxygen-saturated 0.1 mM Acid Red 265 aqueous solutions are shown as a function of the dose in Fig. 2. The degree of decoloration increased linearly with the dose below 4.8×10^4 rad, following the first-order kinetics. The degree of decoloration was independent of the presence of oxygen, at least below 6.4×10^4 rad. The pH of the solution changed from 6.4 to 4.7 at 4.8×10^4 rad. When the initial pH of the solution was changed by the addition of sulfuric acid, the degree of decoloration was independent of the initial pH between 4.3 and 6.4.

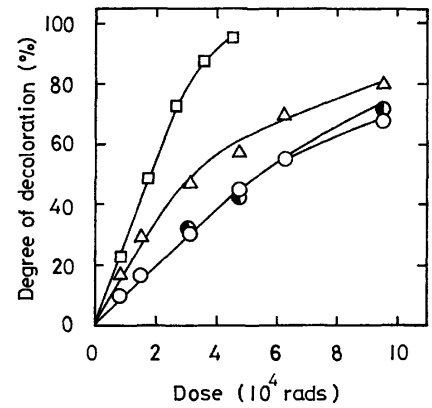

Fig. 2. Effects of additives on degree of decoloration. Dye concentration: 0.1 mM; ○: N_2 saturation, ◐: O_2 saturation, △: N_2O saturation, □: 2 mM *n*-butyl alcohol+N_2O.

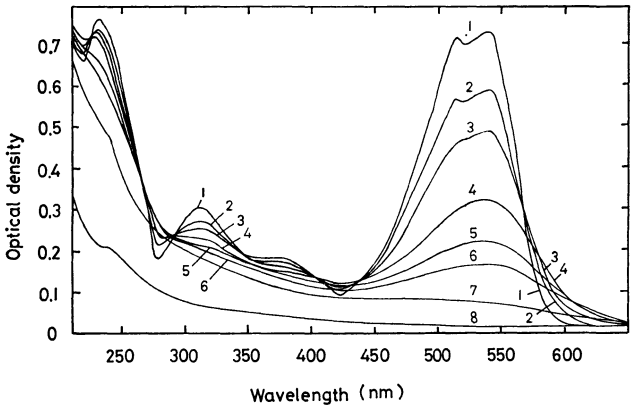

Fig. 3. Absorption spectra of unirradiated and irradiated oxygen-saturated Acid Red 265 aqueous solutions. Dye concentration: 0.1 mM; Curve 1 corresponds to the unirradiated sample. Curves 2—8 represented the spectra of solutions irradiated at the total doses of 1.6×10^4, 3.2×10^4, 6.4×10^4, 9.5×10^4, 1.3×10^5, 1.9×10^5, 2.8×10^5 rad, respectively.

The absorption spectra, shown in Fig. 3 as measured for the oxygen-saturated aqueous solution, indicate that the absorption band at 542 nm decreases with the dose, and that, below 6.4×10^4 rad (Curve 4), the isosbestic points appear at six different wavelengths, namely, 564, 439, 403, 290, 263, and 224 nm. Above 9.5×10^4 rad (Curve 5), the absorption band of the Acid Red 265 aqueous solution at 542 nm practically disappears and the isosbestic points disappear completely.

The results for the nitrous oxide-saturated similar solution are shown by open triangles in Fig. 2. The degree of decoloration for the nitrous oxide-saturated solution was higher than that for the nitrogen- and oxygen-saturated solutions. This suggests that nitrous oxide promotes the decoloration reaction.

When the decoloration yield, G(-Dye), was estimated as the number of dye molecules decolored per 100 eV of energy absorbed, from the concentration of the dye decolored, the G(-Dye) in the early stage equaled 1.00 ± 0.04, regardless of the dose rate in the range from 1×10^4 to 1.9×10^5 rad/hr and regardless of the initial dye concentration from 0.05 to 0.4 mM.

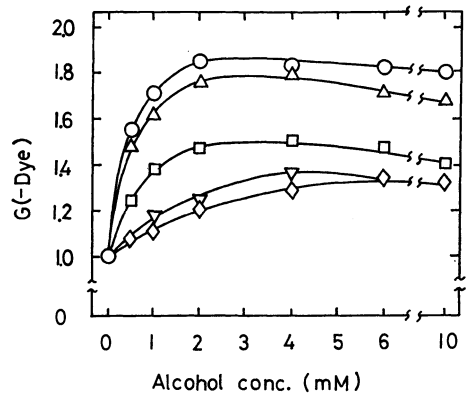

Fig. 4. Effect of alcohols on the G(-Dye) in the nitrogen-saturated solutions. Dose: 4.8×10^4 rad, Dye concentration: 0.1 mM, ◇: methyl alcohol, □: ethyl alcohol, △: *n*-propyl alcohol, ○: *n*-butyl alcohol, ▽: *tert*-butyl alcohol.

Effect of Alcohols. The degrees of decoloration for the nitrogen-saturated 0.1 mM Acid Red 265 aqueous solutions containing 4 mM alcohols increased linearly with the dose up to 4.8×10^4 rad in all cases. The values of the G(-Dye) for the nitrogen-saturated solutions containing *n*-alcohols and *tert*-butyl alcohol at 4.8×10^4 rad are shown as a function of the alcohol concentration in Fig. 4. Similar results for other isomers of butyl alcohol were also obtained. The G(-Dye) increased steeply with an increase in the concentration of alcohols up to 2 mM; then it decreased gradually except in the cases of methyl alcohol and *tert*-butyl alcohol.

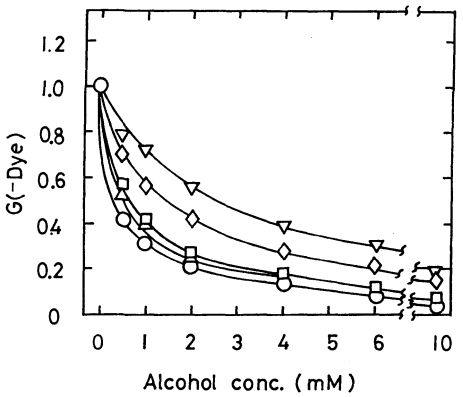

Fig. 5. Effect of alcohols on the G(-Dye) in the oxygen-saturated solutions. Dose: 4.8×10^4 rad, Dye concentration: 0.1 mM, ◇: methyl alcohol, □: ethyl alcohol, △: *n*-propyl alcohol, ○: *n*-butyl alcohol, ▽: *tert*-butyl alcohol.

On the other hand, the values of the G(-Dye) for the oxygen-saturated solutions containing *n*-alcohols and *tert*-butyl alcohol at 4.8×10^4 rad are shown as a function of the alcohol concentration in Fig. 5. Similar results for other isomers of butyl alcohol were also obtained. The G(-Dye) decreased with an increase in the concentration of alcohols.

Effect of Other Organic Additives. The values of the G(-Dye) for the nitrogen-saturated 0.1 mM Acid Red 265 aqueous solutions containing glucose and phenol are shown in Fig. 6 as a function of the organic additive concentration by open triangles and open squares respectively. The G(-Dye) increased up to 2 mM glucose, and thereafter decreased gradually with an increase in the concentration of glucose above 2 mM. The effect of phenol was in contrast to that of alcohols and glucose; that is, the G(-Dye) decreased upon the addition of phenol.

The results for the oxygen-saturated solutions containing glucose and phenol are shown in Fig. 7 as a function of the organic additive concentration by open triangles and open squares respectively. The G(-Dye) decreased steeply up to 2 mM glucose and phenol, and then decreased gradually above 2 mM. This tendency was almost the same as that for the solution containing alcohols.

The values of the G(-Dye) for the nitrogen- and oxygen-saturated solutions containing acetone are shown

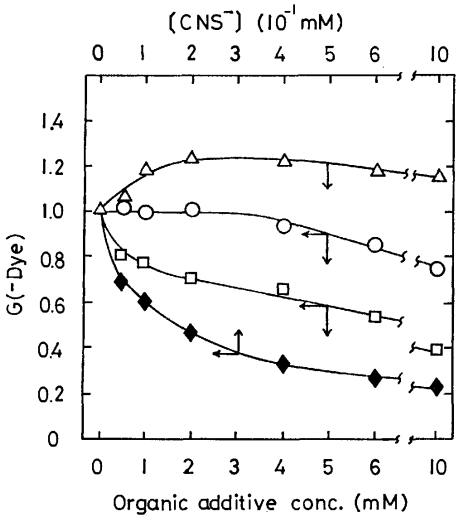

Fig. 6. Effect of organic additives and CNS^- on the G(–Dye) in the nitrogen-saturated solutions.
Dose: 4.8×10^4 rad, Dye concentration: 0.1 mM, △: glucose, □: phenol, ○: acetone, ◆: CNS^-.

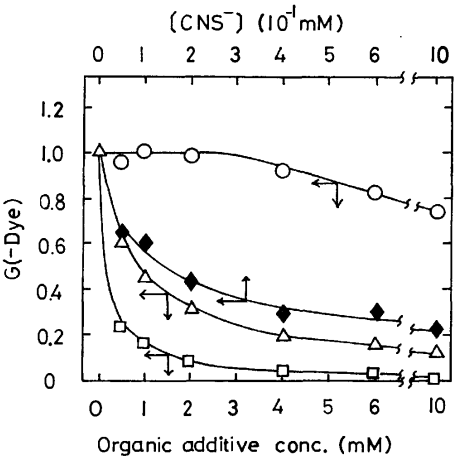

Fig. 7. Effect of organic additives and CNS^- on the G(-Dye) in the oxygen-saturated solutions.
Dose: 4.8×10^4 rad, Dye concentration: 0.1 mM, △: glucose, □: phenol, ○: acetone, ◆: CNS^-.

by open circles in Figs. 6 and 7 respectively. The G(-Dye) for neither solution was affected by the addition of acetone, at least not in the range from 0.5 to 2 mM. The effect of acetone for both the solutions is very different from those for the solutions containing alcohols and other organic additives.

Effect of CNS⁻. The G(-Dye) for the nitrogen- and oxygen-saturated 0.1 mM Acid Red 265 aqueous solutions containing CNS^- at 4.8×10^4 rad decreased markedly with an increase in the CNS^- concentration, as is shown in Figs. 6 and 7 respectively by solid lozenges. The two curves are almost the same. The effect of CNS^- for the nitrogen-saturated solution is, though, different from those for the solutions containing alcohols and other organic additives.

Effect of n-*Butyl Alcohol in N_2O-saturated System.* The degree of decoloration for the nitrous oxide-saturated 0.1 mM Acid Red 265 aqueous solution containing 2 mM *n*-butyl alcohol is shown by open squares in Fig. 2 as a function of the dose. The degree of decoloration increased linearly in the early stage. The G(-Dye) for the nitrous oxide-saturated aqueous solution containing 2 mM *n*-butyl alcohol was 2.56; this value was the highest of all the values for the nitrogen-saturated solutions.

Discussion

When a neutral aqueous solution is irradiated with cobalt-60 gamma rays, radicals and molecular products are formed from water:

$$H_2O \rightsquigarrow OH,\ H,\ e^-_{aq},\ H_2O_2,\ H_2, \qquad (1)$$

and in the presence of oxygen:

$$H + O_2 \longrightarrow HO_2 \qquad (2)$$

$$e^-_{aq} + O_2 \longrightarrow O_2^- \qquad (3)$$

As may be seen in Figs. 2, 6, and 7, the G(-Dye) was independent of the presence of oxygen; it was not even affected by the addition of 2 mM acetone. Acetone effectively scavenges hydrated electrons:[4,5]

$$e^-_{aq} + (CH_3)_2CO \longrightarrow (CH_3)_2CO^- \qquad (4)$$

and the rate of the reaction of acetone with the OH radical is slow.[6] This indicates that hydrated electrons do not contribute to the decoloration reaction. On the other hand, the G(-Dye) decreased markedly in the nitrogen- and oxygen-saturated solutions upon the addition of CNS^-, which is an efficient scavenger of OH radicals:[7]

$$OH + CNS^- \longrightarrow OH^- + CNS\cdot \qquad (5)$$

It is concluded from these findings that the decoloration of Acid Red 265 aqueous solutions is attributable to the attack of OH radicals formed from the radiolysis of water, and the species formed from water other than the OH radical contribute little to the decoloration reaction.

The G(-Dye) equals 1.00 ± 0.04 for the neutral aqueous solution. The primary yield of the OH radical, G(OH), formed from the radiolysis of water is 2.74 for neutral water.[8] This fact indicates that more than a half of the primary OH radicals are consumed by reactions other than the decoloration reaction.

On the basis of the results described above, the radiation-induced decoloration reaction of Acid Red 265 in aqueous solutions may be represented as follows:

$$A + OH \xrightarrow{k_6} AOH \text{ (decolored product)} \qquad (6)$$

$$A + OH \longrightarrow AOH' \text{ (colored product)} \qquad (7)$$

where A is Acid Red 265. The dye molecule has three kinds of sites for Reactions 6 and 7: (a) the azo group, (b) aromatic rings connecting directly to the azo group, (c) the benzene ring, not conjugated to the azo group. The attack of the OH radical on Site c would be independent of the decoloration reaction and would cause little change in the absorption spectra. This is represented as Reaction 7.

In Fig. 3, the absorption bands near 310 and 542 nm are attributable to the azo group and its auxochromic effect.[9,10] The absorption band near 230 nm is attri-

butable to substituted aromatic rings.[9,10] The optical density at 230 nm does not decrease with the dose so much as do those at 310 and 542 nm, and the isosbestic points at 224 and 263 nm appear below 6.4×10^4 rad (Curve 4). This suggests that the decoloration reaction is not necessarily accompanied by the destruction of substituted aromatic rings.

Azo group (Site a) is stabilized by hydrogen bonding with an adjacent OH group in a naphthalene ring.[11] Furthermore, the masking of the azo group can be expected because of the steric effect of the adjacent SO_3Na and CH_3 groups. Therefore, the direct attack on Site a would be minor. On the other hand, the attack of the OH radical on Site b clearly makes the dye decolor. This attack is, then, the main process for Reaction 6, as will be described later. Since the skeleton of the dye molecule is not necessarily destroyed by this reaction, the decrease in the optical density at 230 nm is small, as may be seen in Fig. 3.

When the attack of the OH radical on Site a occurs, this reaction may follow to scissor the C–N–N–C bridge. As aromatic rings after this scission may give a spectrum near 230 nm similar to that of the attack on Site b, the two attacks can not be distinguished by means of these spectra.

Nitrogen-saturated Solutions Containing Alcohols. Alcohols are also efficient scavengers of OH radicals.[12,13]

$$RCH_2OH + OH \xrightarrow{k_8} \dot{R}CHOH + H_2O \quad (8)$$

However, the addition of alcohols makes the G(-Dye) increase in the nitrogen-saturated solutions. This means that alcohol radicals ($R\dot{C}HOH$) contribute to the decoloration reaction in the nitrogen-saturated solutions, while some of alcohol radicals as well as OH radicals may be consumed by a reaction other than the decoloration reaction, like Reaction 7.

$$A + RCHOH \longrightarrow ARCHOH \text{ (decolored product)} \quad (9)$$

$$A + RCHOH \longrightarrow ARCHOH' \text{ (colored product)} \quad (10)$$

Ekstrom and Garnett have reported that, in the radiolysis of air-free binary mixture, that is, benzene–methyl alcohol[14] and polycyclic aromatic compounds–methyl alcohol,[15] $\cdot CH_2OH$ radicals add to benzene and the polycyclic aromatic compound. This supports the addition of alcohol radicals on aromatic rings (Reactions 9 and 10).

As may be seen in Fig. 4, the G(-Dye) increases steeply up to 2 mM alcohols and decreases gradually with an increase in the concentration of alcohols above 2 mM. The maximum values of the G(-Dye) and the concentration of alcohols for them are shown in Table 1. The increase in the G(-Dye) upon the addition of alcohols was in the order of *n*-butyl alcohol>*n*-propyl alcohol> *iso*-butyl alcohol, *sec*-butyl alcohol>ethyl alcohol>*tert*-butyl alcohol>methyl alcohol. The G(-Dye) increased up to 1.83 upon the addition of 2 mM *n*-butyl alcohol from 1.00 for the non-alcoholic aqueous solution. The order of the G(-Dye) in Table 1 almost corresponds to the order of the rate constants for the reaction of alcohols with OH radicals, as measured by the pulse-radiolysis technique; these rate constants are listed in Table 2.[6,7] The concentrations for the maximum G(-Dye) are high for methyl alcohol and *tert*-butyl alcohol, whose rate constants are low in comparison with others. The present findings indicate that the $R\dot{C}HOH$ radical destroys the dye chromophore more effectively than does the OH radical.

The small decrease in the G(-Dye) at 10 mM alcohol in Fig. 4 may be explained in terms of the following spur effect. Since alcohol molecules exist inside the spur of gamma rays at such a high concentration, they

Table 1. G(-DYE) FOR THE AQUEOUS SOLUTIONS CONTAINING VARIOUS ADDITIVES

a) Initial pH 6.4. b) Rate constants for reaction of OH radical with additives from references 6) and 7). c) See a text for the values of phenol.

react with a fraction of the OH radical larger than that predicted from the ratio of the concentration of alcohol to that of azo dye. The local concentration of the alcohol radicals produced is high in the spur or in the neighborhood of the spur, and the dye concentration is low. Therefore, some of the alcohol radicals are consumed through the following process,[16] that is, disproportionation or dimerization in advance of Reaction 9:

$$2RCHOH \longrightarrow RCHO + RCH_2OH \quad (11a)$$
$$\searrow (RCHOH)_2 \quad (11b)$$

According to Taub and Dorfman, the rate of the bimolecular reaction of two α-ethyl alcohol radicals in water is very fast and the absolute rate constant is $1.1\pm0.3\times10^9$ $M^{-1}s^{-1}$.[17]

Oxygen-saturated Solutions Containing Alcohols. In the oxygen-saturated solutions, the alcohol radicals ($R\dot{C}HOH$) react rapidly with oxygen, leading to the formation of peroxyradicals:

$$R\dot{C}HOH + O_2 \longrightarrow RC(O_2\cdot)HOH \quad (12)$$

As may be seen in Table 1, the G(-Dye) for the oxygen-saturated solutions decrease upon the addition of alcohols. This means that the peroxyradicals from Reaction 12 do not react with the dye. These peroxyradicals are easily converted to aldehydes (or ketones), glycols, and peroxide.[18,19]

The decrease in the G(-Dye) upon the addition of 2 mM alcohols for the oxygen-saturated solutions, as is shown in Table 1, was in the order of *n*-butyl alcohol> *iso*-butyl alcohol>*sec*-butyl alcohol>*n*-propyl alcohol> ethyl alcohol>methyl alcohol>*tert*-butyl alcohol. The order of the decrease in the G(-Dye) corresponds exactly to that of the rate constants for the reaction of alcohols with OH radicals in Table 2, because the role of alcohols in the above reaction scheme is simpler in the oxygen-saturated solutions than in the nitrogen-saturated solutions.

N_2O-saturated Solutions. As may be seen in Table 1, the $G(\text{-Dye})_{N_2O}$ for the nitrous oxide-saturated solution is 1.46; it increases to 2.56 upon the addition of 2 mM *n*-butyl alcohol. These values are remarkably larger than those for the nitrogen-saturated solutions. It is well known that nitrous oxide reacts rapidly with hydrated electrons, produced in an aqueous solution by ionizing radiations, thus leading to the formation of the OH radical:[20]

$$e^-_{aq} + N_2O \longrightarrow OH + OH^- + N_2 \quad (13)$$

Therefore, such a large G(-Dye) is attributable to an increase in the OH radical through Reaction 13 in addition to the primary radical.

Since the G(-Dye) for the nitrogen- and oxygen-saturated solutions equals 1.0 for $G(OH)=2.7$, the $G(\text{-Dye})_{N_2O}$ for the nitrous oxide-saturated solutions should be at least 2.0 for $G(OH)_{N_2O}=G(OH)+G(e^-_{aq})=5.6$, according to the scheme proposed above. The observed value of the $G(\text{-Dye})_{N_2O}$ indicates only a half of the expected increase, suggesting that OH radicals are consumed through another path, such as their recombination because of the high concentration.

Effects of Glucose and Phenol. The effect of glucose on the G(-Dye) is similar to that of alcohols in Table 1. The order of the decrease in the G(-Dye) for the oxygen-saturated solutions containing glucose in Table 1 corresponds exactly to that of the rate constant for the reactions of glucose with the OH radical shown in Table 2. However, in the nitrogen-saturated solution, glucose is less effective than methyl alcohol, even though the rate constant for glucose is larger than that for methyl alcohol (see Table 2). This may be due to the dependence of the rate constant of Reaction 9 on the structure of R- that is, a steric effect.

The effect of phenol on the G(-Dye) for the oxygen-saturated solution in Table 1 can be explained on the basis of the above reaction scheme; that is, phenol gives the smallest G(-Dye) in Table 1 and has the largest rate constants in Table 2. The G(-Dye) for the nitrogen-saturated solution also decreases upon the addition of phenol. This suggests that a $C_6H_5(OH)_2\cdot$ radical formed by the addition reaction of the OH radical to phenol hardly contributes to the decoloration reaction. According to Land and Ebert,[21] the $C_6H_5(OH)_2\cdot$ radical subsequently undergoes either the unimolecular elimination of water to form a more resonance-stabilized phenoxy radical($C_6H_5O\cdot$), or bimolecular radical-radical reactions.

Rate Constant for Reaction 6. The rate constant for Reaction 6 can be determined by using a competition reaction with additives. If G_r is the yield of the OH radicals consumed by Reactions 6 and 8, then:

$$\frac{1}{G(\text{-Dye})} = \frac{1}{G_r}\left(1+\frac{k_8[RCH_2OH]}{k_6[A]}\right) \quad (14)$$

where [A] and [RCH_2OH] are initial concentrations of Acid Red 265 and additives respectively. Since Reaction 9 is also attributable to the decoloration in the nitrogen-saturated solutions, the experiment of the competition reaction was carried out in the oxygen-saturated solution. The plots of $1/G$(-Dye) are linear against the additive concentration, in good agreement with Eq. 14. From Eq. 14, the slope of the curve gives the k_8/k_6 ratio and the intercept gives the G_r value by means of the least-squares method. The k_6 values listed in Table 2 were obtained from the observed k_8/k_6 ratio by using the corresponding k_8 values in Table 2. These k_6 values are in good agreement with each other. The average k_6 value is $9.3\pm1.4\times10^9$ $M^{-1}s^{-1}$. This value is near to the rate constants of the reactions of the OH radical with benzene (3.0×10^9 $M^{-1}s^{-1}$), toluene ($3.0\times10^9 M^{-1}s^{-1}$), and phenol ($4.2\times10^9$ and 1.06×10^{10} $M^{-1}s^{-1}$).[6] This fact supports the idea that the decoloration reaction is mainly attributable to the addition of the OH radical to aromatic rings adjacent to chromophore. The rate constants for the reactions of various dyes with the OH radical reported by some investigators are also of an order of about 10^9—10^{10} $M^{-1}s^{-1}$.[1,22]

Since the k_8 values for phenol in the reference are scattered, the k_6 value for phenol in Table 2 is calculated by using the two k_8 values, excluding the above average value.

The Crystal and Molecular Structure of *cis*-2,2-Diphenyl-3,4-dichlorothietane 1,1-Dioxide

Shigekazu KUMAKURA

Department of Chemistry, Saitama University, 255 Shimo-okubo, Urawa 338

(Received January 31, 1975)

The title compound crystallizes in the space group $C2/c$ with $a=18.85(2)$, $b=6.15(1)$, $c=27.94(2)$ Å, $\beta=111.3(1)°$, and $Z=8$. The structure was determined from the photographic X-ray data and was refined by the block-diagonal least-squares method to $R=0.10$ for 1006 observed reflections. Centrosymmetrically related molecules in the crystal form a dimer by means of weak intermolecular C-H···O hydrogen bonds. The thietane skeleton of the compound is bent with the dihedral angle, $C_\alpha SC_\alpha/C_\alpha C_\beta C_\alpha$, of 148.7°. The average distance of the C–S bonds is 1.87 Å, while that of the C–C's in the thietane ring is 1.58 Å. The conformation of the C–Cl bonds with respect to the thietane ring is (3a4e). The transannular S···Cl distance is 3.42 Å. The CNDO/2 calculation reveals that the 3*d*–3*p* bonding overlap is present between these atoms. The bond angles involving the ring substituents deviate greatly from those observed for *cis*-2,2-diphenyl-3,4-dichlorothietane. These deformations may be explained in terms of dipole-dipole interactions.

cis-2,2-Diphenyl-3,4-dichlorothietane 1,1-dioxide (abbreviated hereafter as *cis*-SO_2-DCTE) was prepared by the oxidation of *cis*-2,2-diphenyl-3,4-dichlorothietane (*cis*-DCTE) by using 30% H_2O_2 as an oxidizing agent.[1]

The crystal-structure analysis of *cis*-SO_2-DCTE was undertaken, and the molecular geometry was compared with that of *cis*-DCTE[2] in order to establish the geometry of the thietane ring and to know the effect of changing the ring substituents, which may alter the structure of the thietane ring.

Experimental

Single crystals of this compound grown from an ethanol solution are thin colorless plates with well-developed {001} planes and with a perfect {100} cleavage. The cell constants, determined from Weissenberg and oscillation photographs, are listed in Table 1, together with other crystal data.

TABLE 1. CRYSTAL DATA

Monoclinic	
$a=$	18.85 (2) Å
$b=$	6.15 (1) Å
$c=$	27.94 (2) Å
$\beta=$	111.3 (1)°
$V=$	3018 Å^3
Formula	$C_{15}H_{12}Cl_2SO_2$, F.W.=327.13
$D_m=$	1.44 g/cm^3
$D_x=$	1.440 g/cm^3
$Z=$	8
$\mu=$	51.20 cm^{-1} (Cu$K\alpha$)
Possible space group:	*Cc* or *C2/c*
(Absent spectra:	*hkl* when $h+k$ is odd, and *h0l* when *l* is odd.)

It was difficult to select a suitable crystal for the intensity measurements, because the crystals were thin, brittle plates. Specimens with dimensions of $0.05\times0.07\times0.2$ mm, $0.05\times0.1\times0.08$ mm and $0.1\times0.1\times0.05$ mm were used for the collection of the intensity data around the *b*, *a*, and *c* axes respectively. Equi-inclination Weissenberg photographs were taken for *h0l*—*h4l*, *0kl*, and *hk0* using byCu$K\alpha$ radiation ($\lambda=$ 1.542 Å). The intensities of 1006 reflections were estimated visually and were corrected for the Lorentz, polarization, and spot-shape factors by the usual procedures. Absorption and extinction corrections were not applied.

Structure Analysis

The positions of the sulfur and chlorine atoms were determined from a Patterson synthesis, sharpened by a factor $\exp(B\sin^2\theta/\lambda^2)$ ($B=3.0$ Å^2), while the positions of the remaining non-hydrogen atoms were determined from the subsequent Fourier syntheses of the electron density. The space group, $C2/c$, is consistent with this structure. A block-diagonal least-squares refinement using anisotropic temperature factors reduced the R value ($R=\sum||F_o|-|F_c||/\sum|F_o|$) to 0.10. In the final cycles of the refinement, all the hydrogen atoms located by assuming a suitable geometry were included in the structure-factor calculations. The temperature factors of hydrogen atoms were assumed to be isotropic; the values of 3.0 Å^2 and 4.0 Å^2 were given for those atoms in the thietane skeleton and in the phenyl groups respectively. At every stage of the refinement, the scale factor, S, for F_0 was calculated for each layer-line data according to the following relation:

$$S\times\sum|F_o(hkl)|=\sum|F_c(hkl)|,$$

where the summation is taken over all the values of h and l for each k. A weighting scheme for the least-squares procedure, $w=1$ when $|F_o|\geq5.0$ and 0.3 otherwise, was employed.

The final difference map is flat within the range of ±0.2 eÅ^{-3}. The final atomic and thermal parameters are listed in Table 2. A list of the observed and calculated structure factors has been deposited with the Chemical Society of Japan.[3]

The atomic scattering factors were taken from the International Tables for X-ray Crystallography, Vol. III.

The calculations were carried out on a HITAC 5020E computer at the Computer Center of the University of Tokyo and on a TOSBAC 3400 of Saitama University.

Description and Discussion of the Structure

Figure 1 shows the molecular conformation, the bond distances, the bond angles, and the atomic numbering scheme. The molecule is dissymmetric, but both

enantiomers are present in the crystal because the requirement of the space group.

The thietane ring is bent with a dihedral angle, C(2)SC(4)/C(2)C(3)C(4), of 148.7°. The average length of the C–S bonds is 1.87 Å, while that of the ring C–C's is 1.58 Å. The mean value of the S–C–C bond angles and the C–C–C in the ring are 88.8° and 95.3° respectively. The C–S–C of 77.6(8)° is much smaller than that of dimethyl sulfone (103.0°).[4] The average distance of the S=O bonds is 1.45 Å, and the

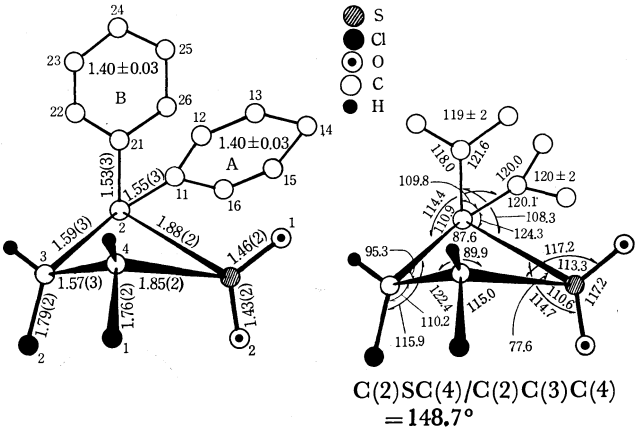

Fig. 1. Bond lengths (Å). E.s.d.'s are shown in parentheses. Bond angles (°). The e.s.d.'s of the bond angles involving Cl and S atoms are ±0.8 °∼1.3 ° and those of the others are ±1.4 °∼1.8 °.

O–S–O angle is 117.2°. These values agree with those observed for dimethyl sulfone (1.445(15) Å and 117.9(8)°). The C(3)–Cl(2) and C(4)–Cl(1) bond distances are 1.79(2) Å and 1.76(2) Å respectively. The directions of these bonds are axial and equatorial respectively, as is shown in Fig. 1, and differ from those, (3e4a), observed for *cis*-DCTE. This fact suggests an inversion of the thietane ring by the oxidation of *cis*-DCTE in the course of the preparation of *cis*-SO_2-DCTE. The non-bonded S·····Cl(2) distance in the *cis*-SO_2-DCTE molecule is 3.42 Å, significantly shorter than the usual van der Waals contact (3.65 Å). If the *cis*-SO_2-DCTE molecule could retain the conformation observed for *cis*-DCTE in its crystalline state, it would take the (3e4a) conformation, in which the transannular S····· Cl(2) distance would be 4.07 Å. Hence, the (3a4e) conformer seems not to be favored in view of the non-bonded repulsions between the Cl atom and the sulfonyl group. In order to explain the ring inversion, a molecular orbital calculation using the CNDO/2 method was carried out for the model molecules assumed for both the conformers.[5] It was found that the (3a4e) conformer may be more stable than the (3e4a) conformer. The electronic energy mainly participates in stabilizing the (3a4e) conformer. The ring inversion can be explained in terms of this contribution. It is noteworthy that the 3*d*-3*p* interaction between the S and Cl(2) atoms is bonding, while that in the (3e4a) conformer is approximately non-bonding.

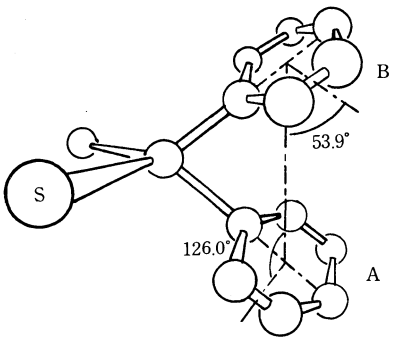

Fig. 2. Orientations of the phenyl groups.

The phenyl groups, A and B, are practically planar; their orientations are shown in Fig. 2. The non-bonded distances, O(1)·····C(26), S·····C(26), O(2)·····C(16), and S···C(16), are 3.21 Å, 3.41 Å, 3.13 Å, and 3.30 Å respectively. Non-bonded repulsions caused by these close contacts might play an important role in determining the phenyl orientations.

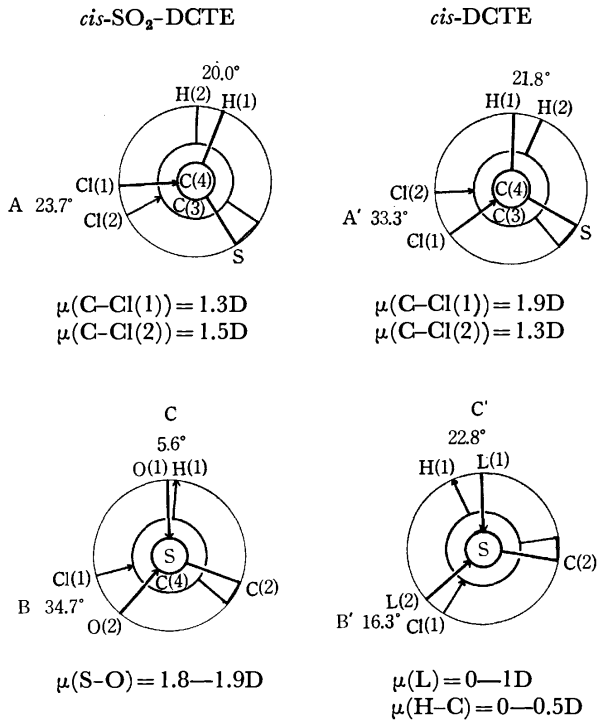

Fig. 3. Newman projections of the torsion angles involving the thietane-ring atoms in *cis*-SO_2-DCTE and in *cis*-DCTE. L(1) and L(2) represent the lone pairs in the axial and equatorial directions, respectively.

Figure 3 shows the torsion angles around the thietane rings observed for *cis*-SO_2-DCTE and *cis*-DCTE as Newman projections, where the arrows superposed on the projected bonds indicate the directions of the bond moments assigned to the respective bonds. The direction of the lone pairs of the sulfur atom in *cis*-DCTE is deduced by assuming a tetrahedral disposition around the sulfur atom. A comparison of the two molecules reveals that the bond angles in *cis*-SO_2-DCTE deviate greatly from the corresponding angles of *cis*-DCTE. The torsion angle, A, is smaller than A'; B is larger than B'; and C smaller than C'. These deformations can be explained qualitatively in terms of dipole-dipole interactions between the ring substituents by taking into account the values of the bond moments[6] given in Fig. 3.

The crystal structure viewed along the *b* axis is illustrated in Fig. 4. The relevant intermolecular contacts are listed in Table 3. These distances are all normal except for the C(4^{i})···O(2) of 3.26 Å, which is found in a pair of enantiomers. Using the calculated position of the hydrogen atom, H(1^{i}), attached to C(4^{i}), it is found that this atom is on a line connecting O(2) and C(4^{i}) and that the distance between O(2) and H(1^{i}) is 2.23 Å, much smaller than the usual van der Waals contact (2.6 Å). These facts suggest a weak C-H···O hyhrogen bond between O(2) and C(4^{i}). Similar hydrogen bonds have been found in the crystal of di-(*p*-chlorophenyl) sulfone.[7] The enantiomers in the crystal of *cis*-SO_2-DCTE form a dimer by this hydrogen bond, as is shown in Fig. 4.

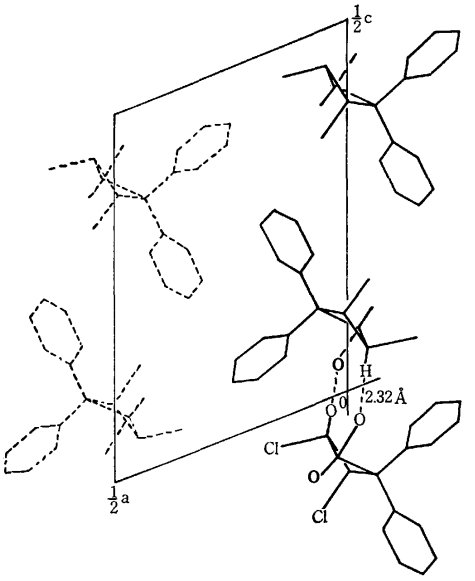

Fig. 4. Projection of the crystal structure viewed along the *b* axis.

ENDOR Studies in the Conformation of 3,3′- or 3,4′-Polymethylenebiphenyl Anion Radicals.

Kazuhiko ISHIZU, Fujito NEMOTO, Koji YAMAMOTO,* and Masao NAKAZAKI*

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

**Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560*

(Received February 3, 1975)

The ENDOR spectra have been observed for the anion radicals of 3,3′- and 3,4′-polymethylenebiphenyl with various chain lengths. The hyperfine coupling constants of the ring protons of the 3,3′-derivatives are comparable with those of the reference derivative, *m,m′*-bitolyl, and the biphenyl ring is considered to take the planar conformation. When the chain length is shortened and the polymethylene chain increases its probability of being held on the biphenyl aromatic plane, strong through-space interactions are observed between the aromatic π and the polymethylene pseudo-π orbital. In 3,4′-polymethylenebiphenyl with shorter chain lengths, the coplanar phenyl rings are twisted out by the polymethylene span and the magnitudes of the spin densities at the *ortho*-position are reduced by the resonance inhibition between two phenyls. McLachaln's MO calculations predict that the twisting angles between the two phenyls are similar to the value reported for 2,2′-bitolyl anion radical. In contrast to the case of the 2,2′-bitolyl anion radical, however, a conformational change in biphenyl resulting from the delocalization of the unpaired electron is suppressed by a tight lock of the rotation of the phenyl groups in the polymethylene derivatives.

Polymethylenebiphenyls bridged by a suitable polymethylene chain at the 3,3′- or 3,4′-positions were synthesized, and the conformation of the diamagnetic neutral molecule was investigated by means of UV and NMR absorption spectroscopies.[1,2] The UV absorption parameters of the 3,3′-polymethylenebiphenyls indicated that the biphenyl rings are coplanar.

On the other hand, in the cases of the 3,4′-polymethylenebiphenyls, the polymethylene span prevents the biphenyl ring from having the coplanar conformation and inhibition of the resonance between the two phenyls was observed in the conjugation band of the UV absorption. In the previous studies of hindered biphenyl anion radicals, one of the present authors, K.I., proposed that the coplanar character of the biphenyl ring is enhanced by delocalizations of the unpaired electron.[3–5]

In the cases of the polymethylenebiphenyls, the rotation of each phenyl ring is tightly locked in certain conformations, thus, little conformational change could be expected due to the presence of the unpaired electron.

A comparative study of the steric hindrance with the anion radical of the 2,2′-alkylbiphenyl and that of the polymethylenebiphenyl is of considerable interest, since the rotation of the phenyl group can be partially allowed and since interchange between the *trans*- and *cis*-conformations may be possible in 2,2′-dialkylbiphenyls.

However, the ESR technique is not suitable for this study, because the hyperfine multiplets may be very complicated as a result of the lower molecular symmetry. Furthermore, the possibility of the long-range interaction of the polymethylene may give an additional complexity to the ESR hyperfine structures, as may be expected from the anomalous NMR shift of the polymethylene protons observed in the neutral molecules.[1]

In the present work, ENDOR studies were made for 3,3′-polymethylenebiphenyl (n=8 and 10) and 3,4′-polymethylenebiphenyl (n=9, 10, 11), bridged by different chain lengths (n).

The spin densities of the *ortho*- and *para*-positions were determined, and the degrees of the steric hindrance were estimated from McLachlan's MO calculations carried out for the twisted biphenyls. In addition, it was clearly demonstrated that the long-range interaction of the polymethylene group varies with both the chain lengths and the bridging positions.

Experimental

The synthesis and physicochemical properties of the materials used here were reported in the previous paper.[1] The radical anions were prepared by reduction with a potassium metal in DME (Dimethoxyethane), letting the reaction mixtures stand in a dry ice–acetone bath. The stability of the anion radicals depends strongly on the polymethylene chain lengths. In paticular, the radical anions of the 3,4′-polymethylene derivative with n=9 are stable only at temperatures lower than −70 °C. The ENDOR spectra were recorded by a JEOL-type ES-EDX-1 spectrometer under operating conditions similar to those described elsewhere.[6] The ESR intensities began to saturate at a microwave output of about 2 mw on the dial scale of the JES-ME-3 ESR spectrometer, and the ENDOR spectra were successfully recorded in the vicinity of −80 °C.

Results and Discussion

3,3′-Polymethylenebiphenyl. The ESR spectra of 3,3′-bridged polymethylene derivatives showed merely the broadened nine-line hyperfine structures; these structures were not further resolved into any lines, as may be seen in Fig. 1. The ENDOR spectra shown in Fig. 2, however, were resolved to show the details of complicated hyperfine couplings. The hyperfine coupling constants of the *ortho*- and *para*-protons, (a_2^H, a_6^H, and a_4^H) were easily identified with reference to the ENDOR spectrum of the *m,m′*-bitolyl anion radical. The hyperfine coupling constants assumed in the ESR measurement of the *m,m′*-bitolyl anion radicals were reconfirmed by the present work; the absolute values of the hyperfine coupling constant determined by ENDOR also gave an excellent agreement with the

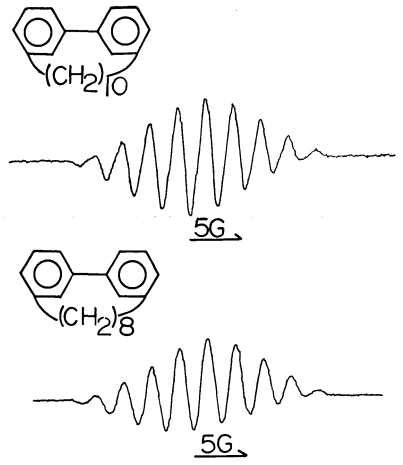

Fig. 1. ESR spectra of 3,3′-polymethylenebiphenyl anion radical recorded at −85 °C.

results of the recent NMR measurements.[7]

As compared with the ENDOR hyperfine structures of the *meta*-ring protons of the reference derivative, the polymethylene derivatives exhibited rather complicated structures around the free proton frequency.

Beside the β-proton splitting (0.15 gauss) and the ring-proton splitting (0.29 gauss) at the *meta*-position, the derivative with $n=10$ gave two extra splittings (0.58, 1.02 gauss); they probably resulted from the long-range interaction attributable to the polymethylene chain.

Similar long-range interactions attributable to long alkyls have already been demonstrated by the previous ENDOR study of the Banfield-Kenyon radical.[8] More substantial evidence of the long-range interactions can be seen in the derivative with $n=8$. The multiple hyperfine structures composed of six different splittings cannot be explained without taking into account the contribution from the long-range interactions.

It is quite intersting that the polymethylene derivatives bridged by the shorter chain length ($n=8$) give strong long-range interactions. In the 3,3′-polymethylene derivatives, the polymethylene strain may force the polymethylene chain to take a coplanar structure with the biphenyl aromatic plane. Thus, the through-space interaction between the aromatic-π and the polymethylene pseudo-π orbital must be effectively enhanced in the derivatives bridged by shorter chain lengths.

The hyperfine coupling constants of the 3,3′-polymethylenebiphenyl anion radicals are summarized in Table 1. It may be seen that the magnitude of the *ortho*(a_2^H, a_6^H)- and *para*(a_4^H)-splittings for the 3,3′-polymethylene derivatives resembles that for the *m,m*′-bitolyl and biphenyl anion radicals. This means that the biphenyl ring probably takes the planar conformation in 3,3′-polymethylene derivatives.

3,4′-Polymethylenebiphenyl. The ESR spectra of the 3,4′-polymethylenebiphenyl anion radical are shown in Fig. 3.

Since the molecule has no symmetry, the ESR spectra are very complicated as a result of the overlap of the unresolved hyperfine components. The resolution of the ESR spectrum is reduced with an increase in the chain length; thus, the undecamethylene derivative exhibits no resolvable hyperfine structures. As one may expect from the ESR observation, the ENDOR spectrum of the derivative with $n=11$ exhibits the most complicated structures. As is shown in Fig. 4, more than eight hyperfine splittings were detected in the frequency region of the *meta*-ring and β-methylene protons, indicating the possibility of a long-range interaction due to the polymethylene group.

Contrary to the cases of the 3,3′-polymethylene derivatives, the number of the hyperfine lines is reduced with a decrease in the polymethylene chain length. A molecular model suggests that a part of the polymethylene chain located around the 4′-position separates

from the aromatic plane and becomes perpendicular to the 4′-substituted phenyl ring as the twist of the phenyl group increases. In this situation, the probability of the orbital overlap between the polymethylene group and the aromatic ring may be considerably reduced.

The four lines appearing in the frequency range from 16 MHz to 18 MHz are assigned to the absorption due to the *ortho*-protons, while the two lines at 19 MHz and 21 MHz are attributed to the splittings of the β-methylene ($a_4^{R'}$) and the ring (a_4^H), respectively both at the *para*-positions.

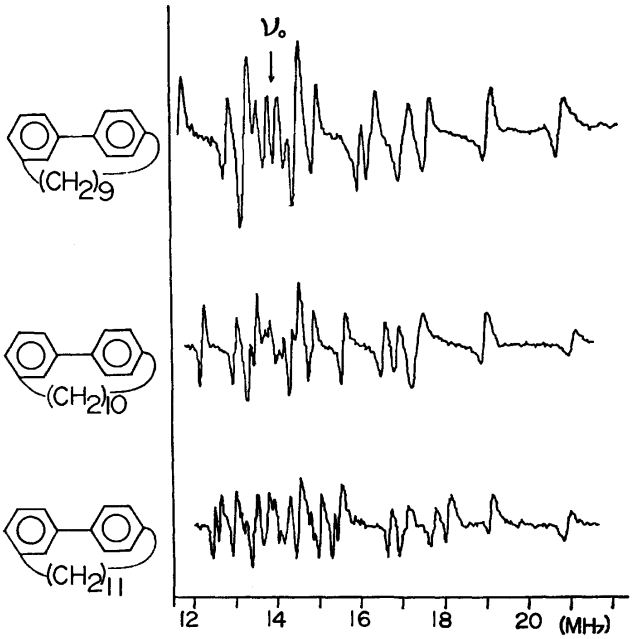

Fig. 4. Higher frequency halves of ENDOR spectra of 3,4′-polymethylenebiphenyl anion radicals.
ν_0: free proton frequency.

In the previous studies, an exceptionally hindered internal rotation of the alkyl chain was reported for the 4,4′-di-*n*-propylbiphenyl and 4,4′-polymethylenebiphenyl anion radicals, where a normal quintet splitting of the four methylene protons splits into two sets of triplet splittings.[9,10] A similar situation is probable for the present cases. Based on the observed methylene proton splitting ($a_4^{\beta'}$) and McLachlan's spin density ($\rho_4^{\pi'}$) at the 4′-position, the equilibrium dihedral angles, φ, of the β-methylene group were calculated tentatively, assuming McConnell-Heller's equation:[11]

$$a_{4'}^{\beta} = (B_0 + B_2 \cos^2 \varphi)\rho_{4'}^{\pi} \quad (1)$$

Taking the B_0/B_2 ratio to be +0.06 with B_2=50 gauss,[12] the dihedral angles were estimated to be 48°, 49°, and 53° for n=9, 10 and 11 respectively.

If the segment motion of the β-methylene group is tightly locked, one of the two β-methylene protons may give rise to the splitting ($a_4^{\beta'}$) in the range from 16 MHz to 17 MHz, as one would expect from a similar calculation using $\varphi' = 70°$. In the present case, however, it is difficult to identify this splitting because of the overlap of the absorption with those of the *ortho*-protons observed in the same frequency region.

The experimental spin densities of the ring carbon ρ_i^{π}, were calculated from the ring proton splitting (a_i^H) using Copla-Bolton's equation:[13]

$$a_i^H = Q_{CH}(0)\rho_i^{\pi} - K_{CH}^H[\rho_i^{\pi}]^2 \quad (2)$$

where $Q_{CH}^H(0) = -27$ and $K_{CH}^H = -12$ gauss. The Coulomb integrals of the ring carbons attached to the methylene were estimated to be $\alpha_i = \alpha - 0.2\beta$, and the resonance integral between the bridgehead carbons was taken to be $\beta_{11} = \beta\cos\theta$ as a function of the twisting angles (θ) of the phenyl groups. McLachlan's parameter, λ, is estimated to be 1.1 for any derivative. McLachlan's spin densities (ρ_2^{π}, $\rho_{2'}^{\pi}$, ρ_6^{π}, $\rho_{6'}^{\pi}$, and ρ_4^{π}) of the derivative with n=11 indeed show an excellent agreement with the experimental values when the biphenyl ring is assumed to take the planar conformation, that is, when θ=0. On the other hand, the MO calculation carried out on the twisted biphenyls taking θ=50° gives results which account for the observed spin densities of the derivatives with n=9 and 10, as may be seen in Table 3.

In the UV absorption maxima of the conjugation band observed for the neutral molecules, the derivatives bridged by shorter chains (n=9 and 10) display a blue shift as compared with the UV absorption parameters of the derivative with a longer chain (n=11); that is,

3,3′-Decamethylene	2.04	3,4′-Decamethylene	2.52
3,3′-Octamethylene	2.19	3,4′-Undecamethylene	1.97

a) $Q^{H}_{CH_2}$ is estimated to be 28 G. b) $\rho^{\pi}_{4'}$ -values are estimated from the McLachlan's MO calculations. c) ρ_p/ρ_o values are calculated to be $\frac{(\rho^{\pi}_4+\rho^{\pi}_{4'})/2}{(\rho^{\pi}_2+\rho^{\pi}_{2'}+\rho^{\pi}_6+\rho^{\pi}_{6'})/4}$.

3,4′-nonamethylenebiphenyl (λ_{max}=250 nm, ε=14500), 3,4′-decamethylenebiphenyl (λ_{max}=248 nm, ε=16700) and 3,4′-undecamethylenebiphenyl (λ_{max}=252 nm, ε=18800). The regular blue-shift of the absorption maxima from the undecamethylene to the nonamethylene derivative is accompanied by a decrease in the extinction coefficient. This can be understood in terms of the resonance inhibition resulting from the steric hindrance.

No detailed investigation of the structure of the neutral molecules has been reported, so the twisting angles, θ, of the two phenyls are assumed to be between the two values for biphenyls (θ=30°, λ_{max}=247 nm, ε=18050) and 2-methylbiphenyls (θ=58°, λ_{max}=235 nm, ε=10500).[14]

The present calculations of the twisting angles in the anion radicals are more or less qualitative. Therfore, the ratios of the averaged spin densities at the *para*- and the *ortho*-positions, $\rho_p{}^{\pi}/\rho_o{}^{\pi}$, which have often been used as parameters to estimate the degree of the steric hindrance, are tentatively compared with those for the usual alkyl derivatives in Table 4.

It is very interesting that the values for the 3,4′-nona- and decamethylene derivatives are close to that for *o,o*′-bitolyl, while the value for the 3,4′-undecamethylene derivative is rather akin to those of biphenyl and the 3,3′-polymethylene derivatives. Since the twisting angles of the 2,2′-dialkylbiphenyl anion radicals are assumed to be around 45°, one may see that the MO prediction of the steric hindrance is also valid for the present derivatives. In addition, it may be speculated that the same magnitude of the steric hindrance can be assumed for both the neutral molecules and the anion radicals of the hindered polymethylenebiphenyls.

In contrast to this situation, it has been known that the biphenyl rings of the 2,2′-dialkylbiphenyl anion radicals are likely to increase in planar character because of a delocalization of the unpaired electron.

In 2,2′-dialkylbiphenyl, the rotations of the two phenyl groups are partially allowed, and the extra delocalization energy of the unpaired electron may compenasate for the repulsion energy between the two phenyls so as to increase the coplanarity of the biphenyl ring. On the other hand, the rotation of each phenyl group is tightly locked in the hindered polymethylene derivatives and the conformation of the biphenyl ring may be fixed in a certain twisting angle by the strong polymethylene strain.

The Cadmium-photosensitized Reaction of Water, Alcohols, and Ethers. The Quenching of the Resonance Radiation at 326.1 nm and the Photosensitized Luminescence

Shunzo YAMAMOTO,* Kazuyuki TANAKA, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 5, 1975)

A luminescence similar to the photosensitized luminescence of ammonia was observed in the cadmium-photosensitized reaction of water, alcohols, and ethers. The quantum yields of the luminescence with these compounds were much smaller than that with ammonia. The rate constants for the formation of the excited complexes between the excited cadmium atoms and the substrates generally increased with a decrease in the ionization potentials of the substrates. This shows that the complex has the characteristics of a charge-transfer type. On the other hand, the efficiencies of the quenching of the resonance radiation at 326.1 nm by ethers were smaller than those of alcohols. It is concluded that the quenching through the formation of the complex is a minor process in the quenching of the resonance radiation by water, alcohols, and ethers.

By analogy with the mercury-photosensitization, it can be expected that such electron-donor molecules as ammonia and water react with excited cadmium atoms to form excited complexes, and that such complexes fluoresce.

In previous papers,[1-3] such luminescence was found in the cadmium-photosensitized reactions of ammonia and some aliphatic amines. The quantum yields of the luminescence, the wavelength at the peak, and the rate constants for the formation of excited complexes were measured. From the relationship between these values and the structure of the amines, it was concluded that the complexes are of the charge-transfer type. Further, we discussed a mechanism for the formation and the deactivation of the complexes on the basis of the pressure dependences of the intensities of the resonance line at 326.1 nm and of the luminescence.

It now seems valuable to observe the similar luminescence in the cadmium-photosensitized reactions of water, alcohols, and ether, to measure the rates of the quenching of the resonance radiation and of the formation of the complex, and to determine the effects of the structure of the alcohols and ethers on the quantum yields of the luminescence and the position of the emission band, in order to gain a further understanding of the cadmium-photosensitized luminescence.

Experimental

The apparatus and procedure were the same as those previously described.[1] The reaction cell and the cadmium resonance lamp were kept at 220 ± 1 °C. The vapor pressure of cadmium at this temperature is 1.04×10^{-3} Torr. The lamp was operated by an alternating current (50 Hz). As was described previously,[4] since the lifetimes of $Cd(5^3P_{1,0})$ are very short, the observed intensity of the light from the cell is not affected by the periodic change in the light intensity of the lamp.

The cadmium metal used was high-purity cadmium (99.9999%) manufactured by the Osaka Asahi Metal Co. Distilled water and 99.9% D_2O were freed of dissolved gases by alternate freezing and thawing under a vacuum. Spectro-grade methanol and ethanol were used after having been degassed. The dimethylether and ethylene oxide (G.R. grade) were used after having been degassed at the temperature of liquid nitrogen. The diethylether and tetrahydrofuran were used after having been dried by Na-K and repeated trap-to-trap distillations. In order to minimize the pressure dependence of the absorption intensity at 326.1 nm, the substrates were diluted with argon and the total pressure in the cell was kept constant.

Results

In Fig. 1 the emission bands obtained with water, methanol, and ethanol are shown, together with the analogous band with ammonia. The bands for ethers studied had the same basic shape and so are not given here. We could not detect an emission band with ethylene oxide. The band shapes are very similar to that observed with ammonia (the band widths for water and alcohols are slightly narrower than that for ammonia), but the intensities are much smaller than that for ammonia. The wavelengths at the peaks are listed in Table 1.

The quantum yields of the luminescence with water, alcohols, and ethers were determined by a comparison of the integrated intensity of the emission band for the compound in question that for ammonia under

8) ethylene oxide; 80(○), 67(◐), 56(◓), and 48(●).

the same conditions. The results are also listed in Table 1.

In order to estimate the efficiency of the quenching of the 326.1 nm resonance line, the emission intensity at 326.1 nm was measured as a function of the pressure

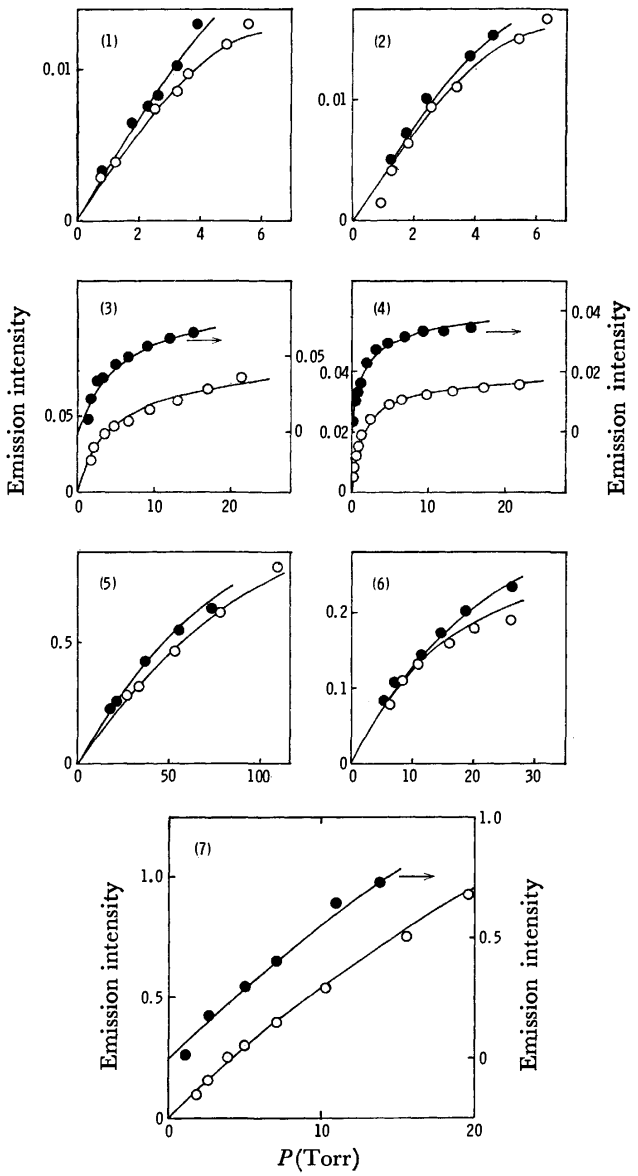

Fig. 3. The intensity at the peak of the emission band from the complex as a function of the partial pressure of substrates. The total pressures are 80(○) and 56(●) in Torr, except for dimethylether, and those for dimethylether are 210(○) and 148(●) in Torr. The plots for 48 Torr in the cases of methanol, ethanol, and tetrahydrofuran are displaced upwards for clearity.
1) H_2O; 2) D_2O; 3) methanol; 4) ethanol; 5) dimethylether; (6) diethylether; 7) tetrahydrofuran.

of the substrates. The Stern-Volmer plots are shown in Fig. 2, where I_0 and I are the intensities of the resonance lines in the absence and in the presence of the substrates respectively. As the intensity decreased with the increase in irradiation time, the I values shown in Fig. 2 were obtained by extrapolation to zero irradiation time. As is shown in Fig. 2, the plots for each substrate at various total pressures lie on one straight line; no total pressure dependence can be seen. The half-quenching pressure obtained from the slopes of the straight lines in Fig. 2 are listed in Table 2. The values for ethers are generally larger than those for alcohols.

The pressure dependence of the intensity at the peak of the emission band is shown in Fig. 3. The intensities were again obtained by extrapolation to zero irradiation time. As was shown in a previous paper,[3] the emission intensities for amines have maximum values, but those for water, alcohols, and ethers increase monotonously with an increase in the pressure.

Discussion

Let us first consider the effect of the structure of the substrates on the position of the emission band. In the mercury-photosensitized luminescence,[5,6] it was previously reported that the band given by the deuterated species is slightly shifted to longer wavelengths. In the present experiment, however, the bands obtained with H_2O and D_2O appeared at the same wavelength. As was described in the previous paper,[3] it would be expected that the decrease in the ionization potential of the substrate would cause the peak of the emission band to shift to a longer wavelength. In fact, as is shown in Table 1, the substitution of alkyl groups for hydrogen atoms in water, which increases the electron-donating ability of the oxygen atom, generally causes a red-shift of the emission band. An inspection of Table 1, however, shows that the peak for methanol is at a longer wavelength than that for dimethylether, while the peak for ethanol is at a longer wavelength than those for diethylether and tetrahydrofuran. It seems that the position of the emission band cannot be explained by the ionization potential alone. Freeman *et al.*[7] found a similar red-shift in Hg–alcohols system. However, they did not detect an emission band with ethers, so the effect of replacing both of the hydrogen atoms in water by alkyl groups remains an open question.

With respect to the quenching of the resonance line, the following reactions may be considered in a manner similar to that described in previous paper:[2,3]

$$Cd^*(^3P_1) \longrightarrow Cd(^1S_0) + h\nu \qquad k_0 \qquad (1)$$

$$Cd^* + M \rightleftarrows Cd^0(^3P_0) + M \qquad k_1, k_{-1} \qquad (2)\ (3)$$

$$Cd^* + A \longrightarrow \text{products} \qquad k_2 \qquad (4)$$

$$Cd^0 + A \longrightarrow \text{products} \qquad k_3 \qquad (5)$$

$$Cd^* + A \rightleftarrows CdA_v^* \qquad k_4, k_{-4} \qquad (6)\ (7)$$

where M stands for Ar or A and where A respesents the substrates. Since Reaction (2) and (3) are very fast in the presence of foreign gases, an equilibrium is established between $Cd(^3P_1)$ and $Cd(^3P_0)$. In the above mechanism, CdA_v^* is an unstabilized complex between the triplet cadmium atoms and the substrates. Reaction (7) was important in the case of ammonia,[2] but in the cases of water, alcohols, and ethers it does not seem to be important, since the Stern-Volmer plots lie on a straight line in the present experiment.[3] The overall rates of the quenching of the resonance line ($k_2+k_1k_3/k_{-1}+k_4$; $k_1/k_{-1}=1.68$ at 220 °C) were evaluated from the values of the half-quenching pressure in Table 2 by the method described in a previous paper;[2] they are listed in Table 3.

H_2O	3.9×10^{-12}	0.035
D_2O	6.7×10^{-13}	0.038
Methanol	7.2×10^{-12}	0.081
Ethanol	2.6×10^{-11}	0.091
Dimethylether	2.3×10^{-13}	0.044
Diethylether	1.9×10^{-12}	0.139
Ethylene oxide	1.6×10^{-10}	—
Tetrahydrofuran	7.8×10^{-13}	0.189

As was described previously,[3] the efficiency of the quenching by amines increases with an increase in the molecular complexity. However, as is shown in Table 3, the quenching by alcohols is generally more efficient than that by ethers.

From the pressure dependence of the intensity at the peak of the emission band, the relative values of k_4 can be estimated by a method described previously.[3] These values are also listed in Table 3. The values of k_4 increase in this order: $H_2O < D_2O <$ dimethylether $<$ methanol $<$ ethanol $<$ diethylether $<$ tetrahydrofuran. This order is in agreement with the order of the decrease in the ionization potential, except for the case of dimethylether. This tendency was also found in the cadmium-photosensitized reaction of amines; this indicates that the complex formed between the excited cadmium atoms and water, alcohols, and ethers is of the charge-transfer type.

The quantum yields of the luminescence for water, alcohols, and ethers given in Table 1 are much smaller than those for amines. As was mentioned in the previous paper,[3] the quenching of the resonance line by amines occurs mainly through the formation of the complex. However, it seems likely that the formation of the complex is not the predominant process in the quenching of the resonance line in the cases of water, alcohols, and ethers. In actuality, the k_4 values for water, alcohols, and ethers are about two or three orders of magnitude smaller than those for amines.

The ratio of the overall rates of the quenching of the resonance line for H_2O and D_2O is 5.9: 1. This value is considerably larger than the value of 1.91: 1 for the quenching of the Hg-253.7 nm resonance line by H_2O and D_2O. On the other hand, the ratio of the k_4 values for H_2O and D_2O is about unity. These findings also show that the quenching through the formation of the complex is not very important, as has been described

above. In the cadmium photosensitization, the available energy is only 87.7 kcal mol^{-1}. It is quite small compared with the O-H bond energy of H_2O (117 kcal mol^{-1}), even if the CdH formation is taken into account. The quenching of the excited cadmium atoms by water seems, then, to occur through the vibrational excitation of water. Therefore, the large isotope effect of H_2O and D_2O on the quenching rates may be due to the difference in the vibrational energies of O-H and O-D.

As was mentioned above, the quenching of the resonance line by alcohols is generally more efficient than that by ethers. Further, contrary to the expectation based on the ionization potential, the k_4 value for dimethylether is quite small. Thus, in the systems of Cd-alcohols and Cd-ethers, these values cannot be explained in terms of the electron-donating ability of the oxygen atom alone. In order to understand the effect of the higher substitution, we examined the effect of the replacement of the hydrogen atoms of ammonia by one, two, and three alkyl groups on the values of k_4 and $k_2+1.68k_3+k_4$. The results are shown in Table 4.

Table 4. The rate constants of the quenching of the resonance radiation and of the formation of the complex for primary-, secondary-, and tertiaryamines

Amines	$k_2+1.68k_3+k_4$ (cm^{3}molecule^{-1} s^{-1})	$k_4/k_4^{NH_3}$
Ammonia	2.4×10^{-12}	1.0
Methylamine	2.4×10^{-11}	10.7
Dimethylamine	2.9×10^{-11}	10.0
Trimethylamine	1.9×10^{-11}	5.1
Ethylamine	6.1×10^{-11}	15.8
Diethylamine	1.7×10^{-10}	43.1[a]
Triethylamine	1.1×10^{-10}	15.3[a]

a) These values were evaluated from the intensity at 450 nm (not at the peak) owing to the interference of the scattered light from the lamp, and therefore, they may be somewhat smaller than true values.

In both series of substitutions, methyl and ethyl, k_4 and $k_2+1.68k_3+k_4$ decrease on going from dialkyl amines to trialkyl amines. These tendencies are similar to those between methanol and dimethylether, and between ethanol and diethylether. As has been described in the previous paper,[3] in the series of primary amines a good relationship between k_4 and the ionization potential of amines was found. When secondary and tertiary amines are included, however, k_4 (and the efficiency of the quenching of the resonance line) cannot be explained in terms of the ionization potential (or the electron-donating ability of the nitrogen atom of amine) alone.

The relationship between k_4 and the ionization potential of substrates is shown in Fig. 4. The k_4 values for primary amines are quoted from Ref. (3). In general, k_4 increases with a decrease in the ionization potential. Especially for primary amines and alcohols, there is a good correlation between k_4 and the ionization potential. However, the k_4 values for secondary amines, tertiary amines, and ethers are somewhat smaller than the values predicted from the correlation mentioned above. In this manner, the reactivity of amines, alcohols, and ethers must be mainly governed by the electron-donating ability of the nitrogen and oxygen atoms, but partly by an other factor. This additional factor suppresses the formation of the excited complex in the cases of secondary amines, tertiary amines, and ethers. We tried to identify this factor, but we could not. Moreover, the origin of this factor remains an open question.

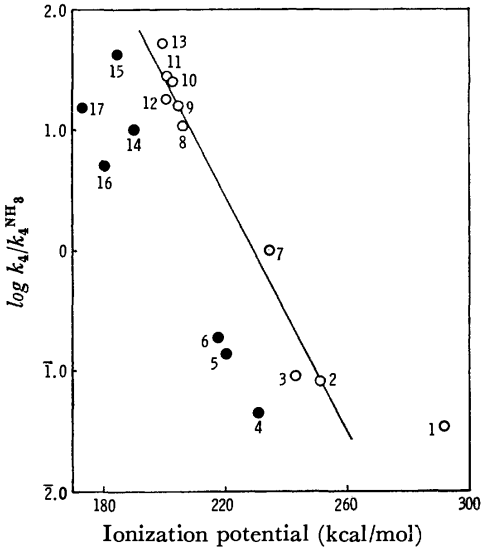

Fig. 4. Relationship between the relative rate constants for the formation of the excited complex and the ionization potential of substrates.

A Polarographic Cell for the Continuous Monitoring of Column Effluents and Its Application to the Determination of Nitropyridine Derivatives

Tamotsu WASA and Soichiro MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Sakai 591

(Received August 30, 1974)

The construction of a microdetector, based on the principle of polarography, for liquid chromatography and its application are described. The characteristics of the flow cells with a horizontal dropping mercury electrode (HDME), a vertical dropping mercury electrode (DME), and a mercury plated platinum electrode (Hg–Pt) are compared with each other. The flow cell has been applied to the analysis of a mixture of nitropyridine derivatives, such as 2-amino-3-nitropyridine (A3N), 2-amino-5-nitropyridine (A5N), 2-hydroxy-3-nitropyridine (O3N), 2-hydroxy-5-nitropyridine (O5N), and 2-nitroaminopyridine (NA), by means of a reversed-phase partition column or an ion-exchange column. In quantitative analysis, a standard deviation of better than 3% can be obtained.

Various physicochemical detectors, *e.g.*, refractometric,[1] colorimetric,[2] thermometric,[3] and ionization detector,[4] for the continuous analysis of column effluents are well established, and measurements have been made successfully in recent years. Some of these detectors are excellent in sensitivity and stability, but all add to the complexity and expense of the liquid chromatographic equipment.

On the other hand, the polarographic method was first used for the continuous monitoring of the column effluents by Drake;[5] the technique was later extensively developed with the powerful studies by Kemula.[6,7] Thereafter, various investigations of the apparatus[8–15] and its application[16–23] have been reported by several authors.

The present paper will describe a polarographic cell for the continuous measurement of a flowing solution, the characteristics of the flow cell, and its application to the determination of nitropyridine derivatives separated by either a reversed-phase partition column or an ion-exchange column.

Experimental

Apparatus. *Polarographic Flow Cell*: Three cells for a horizontal dropping mercury electrode (HDME),[24] a vertical dropping mercury electrode (DME), and a mercury plated platinum electrode (Hg–Pt) were designed and compared with each other. As is shown in Fig. 1, the cell for HDME was constructed of a Teflon plate (5) on which an effluent canal (2×2 mm) (1) and depressions for a mercury pool electrode (2), a detector electrode (3), and a thermostated water passageway (4) were caved. The Teflon plate was sandwiched between two plates of transparent acrylics (6). Polyethylene film (7) was used to prevent the swelling of acrylics with an organic solvent contained in the effluent. Though the cell for DME was constructed in the same way as for HDME, the cell was modified for DME. The capillary had the following characteristics in Britton-Robinson's buffer (pH 9.0) containing 0.2 M sodium sulfite at −0.9 V *vs.* SCE, at $h=35$ cm: $m=1.64$ mg/s for both electrodes, $t=1.51$ for HDME and 5.54 s/drop for DME. The cell for Hg–Pt was the same as for HDME. The Hg–Pt was a mercury plated platinum wire (0.3 mm in diameter×0.5 mm in length) which was plated electrolytically in a plating mixture containing 0.05 M mercuric chloride, 0.1 M EDTA, and 0.5 M sodium carbonate.

Voltage-applying and Current-measuring Equipment: The fundamental polarographic and chromato-polarographic measurements were carried out by using a Yanagimoto Automatic Recording Polarograph (PA-101) with a Toa Polyrecorder (EPR-2T). Simple equipment, as is shown in Fig. 2 (G and H), was also used for the practical chromato-polarography.

Chromatographic System: A schematic diagram of the apparatus used for liquid chromatography is shown in Fig. 2. The carrier liquid from an eluate reservoir (A) was conveyed into a saturator (C) by a Shibata micropump (SP-100; 0—120 ml/hr) (B). The saturator, made of glass (1 cm i.d. ×15 cm long) and filled with an organic solvent such as is used for the stationary phase in the column up to 10 cm from the bottom, ensures the proper equilibration of the moving phase with the stationary liquid. The carrier from the saturator passes through a sample injection device (D)[4] and is then delivered into the separation column (E) made of glass (0.5—0.9 cm i.d. × 5—30 cm long). The sample is introduced onto the top of the column by means of either a pipette or a calibrated syringe. Chromatographic peaks, leaving the column, pass through the flow cell (F) and are then presented on the recorder (H). The pulsing movement of the effluent due to the pump was damped by placing a nitrogen bubble (1—5 cm^3) on the top of the saturator and the column. The

Teflon tubing (0.9 mm i. d. and 1.7 mm o. d.) and various fittings were obtained from the Shibata Chemical Apparatus Mfg. Co., Ltd., Tokyo.

Preparation of the Column: The column packing was prepared as follows: after spherical polystyrene grains had been sufficiently swollen with an organic solvent (TCE or DCB), the excess solvent was removed by filtration with a small glass filter. The swollen polystyrene grains, which had been effectively washed with 10% ethanol, were suspended in 10% ethanol, and then the air bubbles cohesively attached to the grains were removed under reduced pressure. The suspension of the filler was quietly poured into the glass column plugged with a small wad of cotton and filled with 10% ethanol, while the filler liquid was quietly drained at the same rate. The column was then pressed under nitrogen pressure (about 2 atm) until the height of the carrier liquid above the packing was about 1 cm. These processes were repeated until the desired bed height was obtained. After filling the column, the top was then plugged with a small wad of cotton. The ion-exchange column was 0.5 cm i. d. × 5.6 cm long, and it was packed with Dowex 1×8 (100—200 mesh, nitrate form).

Materials and Reagents. The spherical polystyrene grains (7.1% cross-linked with divinylbenzene) employed as the support of the stationary phase were prepared by suspension polymerization according to the method of Winslow and Matreyek.[25] The polymer grains were sieved to five fractions of 100—115, 115—150, 150—200, 200—250, and above 250 mesh. The ion-exchange resin was Dowex 1×8 (100—200 mech), and the resin, supplied in the chloride form, was converted into the nitrate form by treating it with 1 M sodium hydroxyde and 1 M nitric acid. After having been washed with distilled water, the resin was stored in 1 M potassium nitrate. As for the stationary phase of the partition column, 1,1,2,2-tetrachloroethane (TCE) and *o*-dichlorobenzene (DCB) from Wako Pure Chemical Ind., Ltd., were used without further purification. The 2-amino-3-nitropyridine (A3N), 2-amino-5-nitropyridine (A5N), 2-hydroxy-3-nitropyridine (O3N), and 2-hydroxy-5-nitropyridine (O5N) were kindly donated by Professor Eiji Imoto of the University of Osaka Prefecture; their mp's were 164, 165—166, 226—228, and 192.5—193.5 °C respectively. The stock solutions (about 10^{-2} M) were prepared by dissolving the specimen in 10% ethanol. All the other chemicals were of a reagent grade or an equivalent. Britton-Robinson's buffer (BR) and 1 M potassium nitrate were used as the carrier liquid of the reversed partition and the ion-exchange chromatography respectively.

Procedures. After pre-conditioning the separation column under a fixed flow rate for 30—60 min at a constant temperature, an aliquot of the sample solution was introduced onto the top of the column and the current through the polarographic-flow cell at the constant applied voltage was recorded. The deaeration of the carrier liquid was carried out by means of either the addition of sodium sulfite (0.2 M) for neutral and alkaline solutions or a stream of nitrogen gas for an acidic solution.

Results and Discussion

Characteristics of the Flow Cell. To obtain some information concerning the characteristics of the three different flow cells described above, 2×10^{-4} M A3N in a BR buffer (pH 9.1) containing 0.2 M sodium sulfite was passed through the cell at a given flow rate and the polarographic current was recorded at an applied voltage of −0.9 V *vs.* Hg pool, which was sufficient for the reduction of A3N. The results obtained are presented in Fig. 3, where the current is plotted

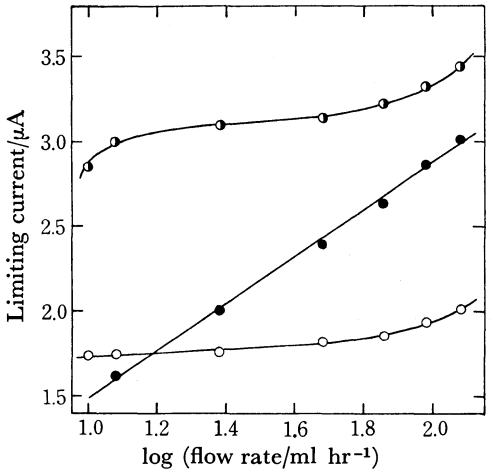

Fig. 3. Effect of flow rate on the polarographic current.
●: Hg–Pt, ◑: DME, ○: HDME.

against the logarithm of the flow rate. The effect of the flow rate on the current obtained with the HDME and DME is less pronounced than that on Hg–Pt. However, the slopes of the curves for both the dropping mercury electrodes exhibit a tendency to increase with the flow rate and to become similar to that for the stationary electrode[26] at a flow rate above 100 ml/hr. In the following experiments, the cell with HDME was used because the current oscillation, accompanied by the dropping of the mercury, can be easily reduced by the connection of a parallel capacitor (Fig. 2,c) and a good stability and reproducibility can be obtained.

The relationship between the limiting current in the flowing electrolyte and the height of the mercury reservoir is presented in Fig. 4; the change of the current with the mercury head was greater than that for the normal diffusion-controlled current, even in the

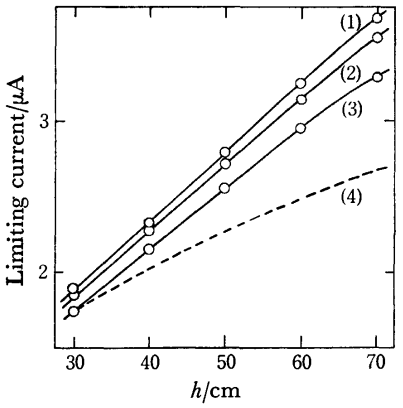

Fig. 4. Relationship between the limiting current (i) and the height (h) of Hg reservoir.
Flow rate of effluent: 1) 120, 2) 24, 3) 0 ml/hr, 4) diffusion current.

stationary solution. The steep increase in the current may be due to the stirring effect[27] of the rapidly dropping electrode in a narrow cavity. Takemori and Honda[15] found that the current through the particular cell designed as the detector of the liquid chromatography showed a constant value irrespective of the height of the mercury reservoir over a limited range. The discrepancy from the present observation seems to be caused by the difference in the flow rate in the electrode cavity and by the wall effect related to the electrode position.

Polarographic Behavior and Chromato-polarographic Separation of Nitropyridine Derivatives. Polarography: The course of the polarographic reduction was observed to be very similar in all the nitropyridines used (A3N, A5N, O3N, and O5N); they showed a diffusion-controlled and well-defined reduction wave (1st wave), followed by an ill-defined wave (2nd wave), at a potential, 0.8 V, more negative than that of first wave in an acidic buffered solution. The second wave became more ill-defined with an increase in the pH. The height of the first wave, except in the case of O5N, was observed to remain constant over the whole pH range studied and to be proportional to the concentration of the compounds in the range of $(0.5—20)\times10^{-4}$ M. On the other hand, at pH values heigher than 7 the splitting of the first wave for O5N into two waves was observed. The ratio of the two heights changed with the pH, the sum remaining constant.

As may be seen in Fig. 5, which presents the changes in the half-wave potentials of the nitropyridines with the pH, the polarographic separation of the mixtures in the normal manner seems to be difficult because the half-wave potentials are so close to each other.

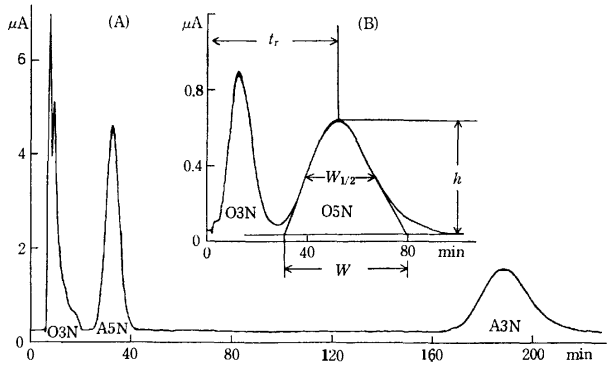

Fig. 6. Chromato-polarograms of nitropyridine mixtures at 30 °C.
A) Reversed-phase partition column (TCE), B) Ion-exchange column (Dowex 1×8, R-NO_3).

Chromato-polarography: Figure 6 (A) shows a typical chromato-polarogram obtained for a mixture of O3N, A5N, and A3N using a 0.9×10 cm column packed with spherical polystyrene grains (150—200 mesh) swollen by TCE, with a BR buffer (pH 9.1) containing 0.2 M sodium sulfite as a mobile phase, at a flow rate of 24 ml/hr. The current passing through the flow cell was recorded at an applied voltage of −0.8 V *vs.* Hg pool, which was sufficient for the reduction of all three compounds.

To examine the effect of the pH on the retention times of O3N, A5N, and A3N, such operating conditions as the sample size (1 μmol), the flow rate (24 ml/hr), and the column temperature (30 °C) were kept constant;

Table 1. The effect of pH on the retention times of niteopyridines
Column: 0.9×11.5 cm, polystyrene grains (150—200 mesh) swollen by TCE

pH	Retention time/min		
	O3N	A5N	A3N
1.82	8.3	8.3	23.5
3.02	8.3	14.1	79.0
5.02	6.0	19.5	110.0
7.02	7.1	21.3	117.2
9.16	7.0	22.7	111.7
11.0	5.0	22.7	110.0

only the pH of the mobile phase (BR buffer) was changed. The results obtained are listed in Table 1. From the table it can be seen that, whereas the retention times of A5N and A3N are practically unaffected by the pH in the pH range above 5, the retention time decreases steeply with the change in pH in the acidic range below 5 because of the protonation of pyridine derivatives, and that the retention time of O3N is smaller than that of the former in the whole pH range studied. In the following experiments, the BR buffer with a pH of 9 was mainly used as the mobile phase, since a good separation can be obtained and since the dissolving oxygen can be removed easily by adding sodium sulfite.

The effects of the size of the packing polystyrene particle, the column temperature, the flow rates of the mobile phase, and the concentration of methanol in the mobile phase on the height equivalent to a theoretical plate (HETP) and the resolving power (R) of the column were also investigated; the results obtained are summarized in Fig. 7.

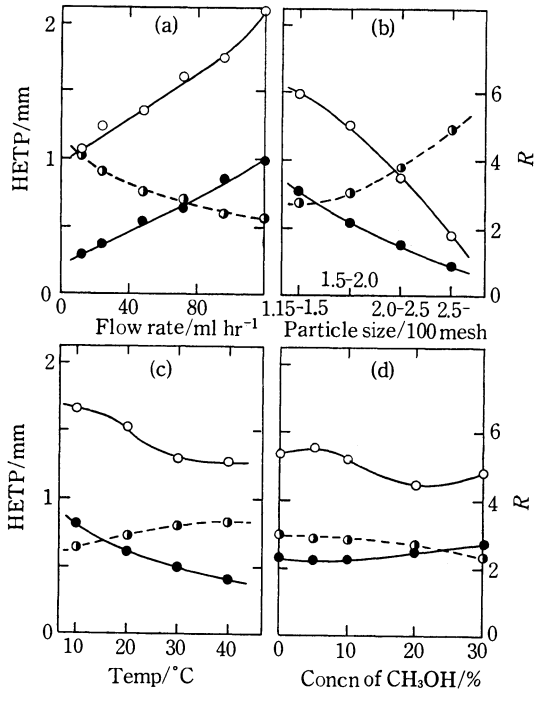

Fig. 7. Effect of flow rate (a), particle size (b), temperature (c), and methanol concentration (d) on the the HETP (——) and the resolving power (R,——) of the column.
Concn of nitropyridine: 1 μmol; ●: A3N, ○: A5N.

The efficiency of the column was calculated by means of Eq. (1) of the plate theory:[4,28]

$$n = 16(t_r/W)^2 \quad (1)$$

where n is the number of the theoretical plate in the column, t_r is the retention time (min), and W is the peak width in min at the base. HETP was calculated from:

$$\text{HETP} = \text{column length in mm}/n \quad (2)$$

The resolving power (R) for the separation of A5N and A3N was calculated from:

$$R = 2\Delta t_r/\sum W \quad (3)$$

where Δt_r is the difference in the retention times of the two peaks and $\sum W$ is the sum of the peak widths at the base.

From Figs. 7a, b, and c, it can be seen that both the efficiency and the resolving power of the column used under the controlled experimental conditions increase with a decrease in the flow rate and the particle sizes and with an increase in the column temperature. With an increase in the methanol concentration in the mobile phase, no significant changes in the efficiency or the resolving power could be observed (Fig. 7 d), but the operating time for the separation was shortened.

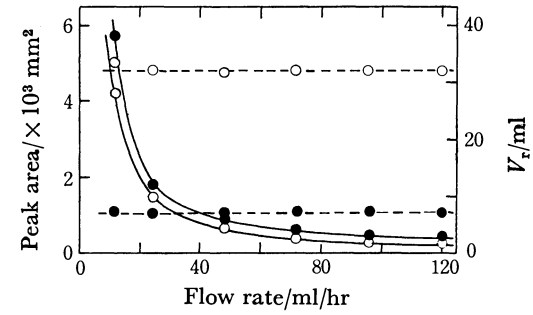

Fig. 8. Effect of flow rate on the peak area ($W_{1/2}\times h$, ——) and the retention volume (V_r,-----) at 30 °C.
Column: 0.9×5.7 cm, polystyrene grains (150—200 mesh) swollen by TCE; Elution: BR buffer (pH 9.2) contg. 0.2 M Na_2SO_3; Applied potential: −0.9 V *vs.* Hg pool; Sample: A5N (●, 1.29 μmol)+A3N (○, 1.26 μmol).

The changes in the peak areas corresponding to A5N and A3N with the flow rate are presented in Fig. 8, together with their retention volume, with the sample size and the experimental conditions being kept constant. With an increase in the flow rate, the peak areas for both A5N and A3N decreased hyperbolically, while their retention volumes showed fixed values independent of the flow rate. In determining components by means of chromato-polarography, therefore, the flow rate should be kept constant.

In order to obtain information concerning the reproducibility of the chromato-polarograms, the separation of a mixture of A5N (1.29 μmol) and A3N (1.26 μmol) was repeated five times under the same conditions; the results obtained are summarized in Table 2. The standard deviations of the peak heights and the peak areas (peak height×half-peak width) corresponding to each component were within 3.5 and 1.5% respectively; no appreciable change in the retention time was observed, even with ten runs of the separation.

The relationships between the chromato-polarographic responses obtained and the sample amounts added to the top of the column under the same operating conditions are presented in Table 3; linear relations were observed between the responses, the peak height, the peak areas (peak height×half-peak width and cutting-and-weighing method), and the amounts of A5N and A3N. In the analysis of the components in the sample by using the peak height, however, attention must be paid to keep the conditions strictly

controlled, since the height is markedly affected by even a small change in the operating conditions. The retention times for A5N and A3N were not pronouncedly affected by changes in the sample size, but the resolving power was observed to decrease slightly with an increase in the amounts.

Though all of the 2-hydroxy isomer could be easily separated from the mixture of 2-hydroxy and 2-amino nitropyridines by means of the reversed-phase partition column described above, as is shown in Fig. 6 (A), the separation of the mixture of 2-hydroxy isomers was not successful since they are sparingly soluble to such organic solvents as TCE and DCB. Thereupon, an ion-exchange column (5×56 mm) packed with Dowex 1×8 of 100—200 mesh was also used to separate the mixture of 2-hydroxy isomers. After adding the sample to the top of the column, the elution was carried out with 1 M potassium nitrate containing 0.2 M sodium sulfite at the flow rate of 24 ml/hr at 30 °C; a typical chromato-polarogram thus obtained is shown in Fig. 6 (B).

Application to the Determination of 2-Amino Nitropyridines in Nitrating Mixtures. The nitration was carried out by adding 5 ml of a nitrating reagent containing 1 ml of fuming nitric acid (d 1.52) in 20 ml of concentrated sulfuric acid to 100 ml of a concentrated sulfuric acid solution containing 0.5 g of 2-aminopyridine under continuous stirring at a temperature lower than 5 °C. One ml of the reaction mixture was pipetted out at a given time interval and transferred into a 25-ml volumetric flask. After having been neutralized with 5 M sodium hydroxyde under cooling by ice-water, the mixture was diluted to the desired volume with distilled water.

In a run, after a further tenfold dilution of the neutralized sample with a BR buffer (pH 7.1), the solution was polarographed in the usual way at 25 °C.

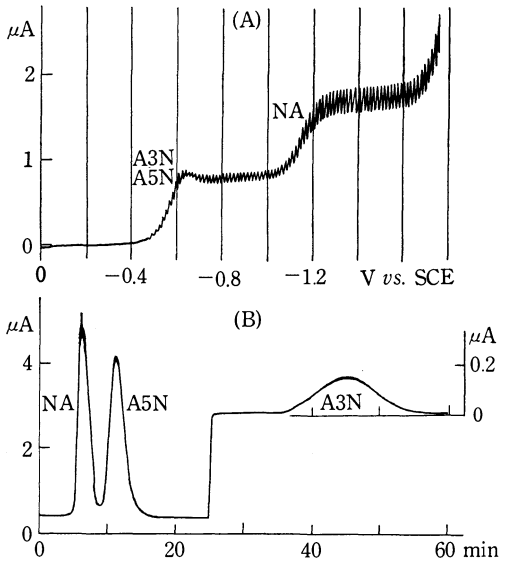

Fig. 9. Polarogram (A) and chromato-polarogram (B) of nitropyridines formed by nitration of 2-amino-pyridine.
Nitration: 5 °C, 30 min; Column: 0.5×10 cm, polystyrene grains swollen by DCB; Elution: 24 ml/hr; Applied potential: −1.5 V *vs.* Hg pool.

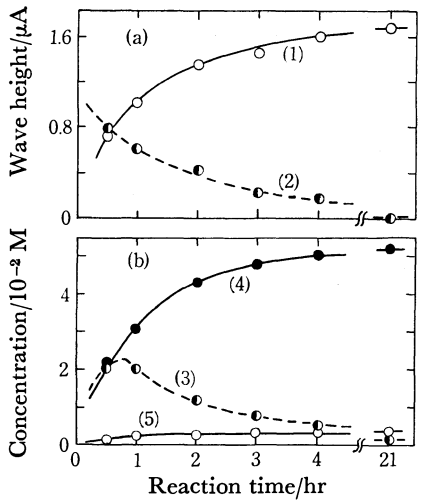

Fig. 10. Change of polarogram (a) and chromato-polarogram (b) during nitration.
1) 1st wave (A3N, A5N), 2) 2nd wave (NA), 3) 1st peak (NA), 4) 2nd peak (A5N), and 5) 3rd peak (A3N)

The polarogram thus obtained and the changes in the wave heights with the reaction times are shown in Figs. 9 (A) and 10 (a) respectively. From the latter figure, it can be seen that the second wave attains its maximum value rapidly after the addition of the nitrating reagent, while the first wave increases slowly at the expense of the second wave with the reaction time; the half-wave potential of the first wave coincides with that of A5N or A3N under the same conditions.

In another run, 0.5 ml of the neutralized sample was added to the top of the column described above and the column was eluted with BR buffer (pH 9) containing 0.2 M sodium sulfite at 30 °C. A typical chromato-polarogram is shown in Fig. 9 (B). The retention times of the second and the third peaks agreed with those for A5N and A3N respectively. The product corresponding to the second wave in Fig. 9 (A) and the first peak in Fig. 9 (B) may be concluded to be 2-nitroaminopyridine (NA).[29] Figure 10 (b) shows the changes in the concentration of the nitro compound formed in the reaction mixture with the reaction time, where the concentration of each substance was calculated by comparing the peak area obtained with that of a pure substance. From the findings described above, it may be deduced that 2-nitroaminopyridine forms rapidly at the first stage of the nitration and is then converted to A5N and A3N in the ratio of 14.5 to 1.

The authors wish to thank Professor Eiji Imoto for the gift of nitropyridine derivatives. They are also indebted to Mr. Hideo Oshima for his assistance in the experimental work.
