Fig. 6. Emission and excitation spectrum of the photoproduct of $[Co(CN)_6]^{3-}$ in the aerated pyridine solution produced by the irradiation at 365 nm for 6 hr at 25 °C.
a) emission spectrum, b) excitation spectrum measured at room temperature, respectively.

measured in aqueous solution. Since $K_2[Co(CN)_5py]$ which is prepared has an absorption maximum at 352 nm in water and exhibits no fluorescence at room temperature, and since the excitation spectrum of the fluorescent solution does not coincide with the absorption spectrum of $[Co(CN)_5py]^{2-}$, we can consider that the fluorescent product is not $[Co(CN)_5py]^{2-}$ but perhaps some organic compound. Therefore the total reaction is written as

$$[Co(CN)_6]^{3-} + py \xrightarrow{h\nu} [Co(CN)_5py]^{2-} + \text{fluorescent compound} \quad (3)$$

The deaerated solution causes the same reaction also and there is no difference in the quantum yield. Interestingly, the preliminary experiments show that the benzonitrile solution of $[Co(CN)_6]^{3-}$ gives rise to the fluorescent compound also (in this case the isosbestic points cannot be seen from the initial stage), whereas the acetonitrile solution does not give any product other than $[Co(CN)_5(CH_3CN)]^{2-}$. It is therefore reasonable to consider that the aromatic ligand is required in order to form the fluorescent compound. A reaction analogous to Eq. (3) is found in the case of $[Cr(CN)_6]^{3-}$ in the aerated pyridine.[21] These types of reaction involving the formation of the fluorescent compound have not been known till now and though at this stage we have not been able to determine the structure of the fluorescent compound, we will report all the features of this interesting reaction in the near future.

The quantum yields obtained in several organic solvents are also summarized in Table 1. It can be seen from this Table that the quantum yields are almost the same in our experimental conditions except those in chloroform and ethylenediamine where no reaction occurred. Thus, in these coordinative solvents, the rate-determining step may be regarded as the elimination process of CN^-.

Sensitization Experiments. The donors used are pyrazine, $Rh(acac)_3$, triphenylamine, Michler's ketone,

and fluoranthene, and the concentration of $[Co(CN)_6]^{3-}$ varies from 1×10^{-3} M to 1×10^{-2} M. Higher concentrations than this cannot be obtained because of the solubility limitation. It is found that in both the cases of using as donors the first three sensitizers irradiated at 313 nm and the latter two sensitizers irradiated at 365 nm, no sensitized photosolvation reactions in ethanol occur.

The authors are grateful to Professors C. Sato and K. Uchida for helpful discussions. This work was partly supported by the scientific research fund from the Ministry of Education.

21) In the deaerated pyridine solution of $[Cr(CN)_6]^{3-}$, the irradiation at 365 nm causes predominantly the photosolvation. A little formation of the fluorescent compound can be seen also. It is clear that O_2 plays an important role in this system.

Apparent Molal Volumes of *n*-Alkylammonium Chlorides and Sodium *n*-Alkanecarboxylates in Dilute Aqueous Solutions

Masao SAKURAI, Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 2, 1975)

The densities of dilute aqueous solutions of two homologous organic salts, RNH_3Cl and RCOONa, where R varies from H to *n*-octyl, have been measured at 5, 25, and 45 °C using a buoyancy technique. The apparent molal volumes, ϕ_v, of the salts and the limiting partial molal volumes, $\bar{V}°$, of the individual ions have been evaluated. The contributions of a methylene group to the partial molal volume, $\bar{V}°(CH_2)$, as estimated from the $\bar{V}°$ data for longer-chain salts, are nearly the same for both series: approximately 15.3, 15.9, and 16.5 ml/mol at 5, 25, and 45 °C respectively. Compared to these values, on the other hand, the $\bar{V}°(CH_2)$ estimated for shorter-chain RNH_3Cl is larger and that for shorter-chain RCOONa is smaller. The second derivative of the $\bar{V}°$ with respect to the temperature, $\partial^2\bar{V}°/\partial T^2$, which is often regarded as a useful measure of structural effects, is almost independent of the chain length for longer-chain homologues. The concentration dependence of ϕ_v does not always vary in a regular manner with the chain length. The present results suggest that the volumetric behavior of aqueous organic electrolyte solutions is more complicated than has previously been believed.

A careful examination of the volumetric properties of aqueous solutions can provide useful information about the nature of solute–water and solute–solute interactions. Although the partial molal volumes of simple electrolytes and alkylammonium halides have been extensively investigated,[1] little attention has been paid to other organic salts.

It is known that the hydrogen-bonded structure of water is enhanced by the introduction of a nonpolar solute molecule. Such a solute–water interaction is often called "iceberg formation,"[2] "hydrophobic hydration,"[3] or "hydration of a second kind."[4] The nature of this interaction is, however, not yet clearly understood. Furthermore, little is known about the contributions of polar groups to the structural effect. Previously we reported that the effects of NH_3^+ and COO^- groups on the hydrophobic hydration are quite different from one another.[5,6] The purpose of this paper is to supplement the earlier study[5] by presenting data on the apparent molal volumes of the organic salts recently measured in our laboratory.

Experimental

The *n*-alkylammonium chlorides, $H(CH_2)_nNH_3Cl$, and sodium *n*-alkanecarboxylates, $H(CH_2)_nCOONa$, were prepared by the neutralization of the corresponding amines and carboxylic acids with hydrochloric acid and sodium hydroxide respectively. The salts were recrystallized twice from ethanol for shorter-chain homologues and from ethanol–benzene mixtures for longer-chain salts. Each sample was then dried under vacuum at room temperature. The water used in all the measurements was deionized and further distilled using a quartz still.

The float densitometer (with a precision of 2 ppm) and the experimental procedure were previously described.[5]

The apparent molal volume, ϕ_v, was calculated by means of this equation:

$$\phi_v = \frac{1000(d_0-d)}{mdd_0} + \frac{M}{d} \qquad (1)$$

where d and d_0 are the densities of the solutions and the water respectively, M is the molecular weight of the salts, and m is the molality.

Results and Discussion

The limiting partial molal volumes, $\bar{V}°(=\phi_v^\circ)$, were obtained from this equation:

$$\phi_v = \phi_v^\circ + S_v\sqrt{c} + b_v c \qquad (2)$$

where S_v is the Debye-Hückel limiting slope, b_v is a deviation constant, and c is the molarity calculated from the observed density. The S_v values for the 1–1 electrolyte at 5, 25, and 45 °C are 1.529, 1.868, and 2.234 respectively.[7]

A few typical examples of the plots of $\phi_v - S_v\sqrt{c}$ *vs.* c are shown in Fig. 1. Good linearities were obtained over the concentration range studied, except for the octylammonium and octanecarboxylate salts (Figs. 5 and 6), which will be discussed later. The $\bar{V}°$ values estimated from these figures are summarized in Table

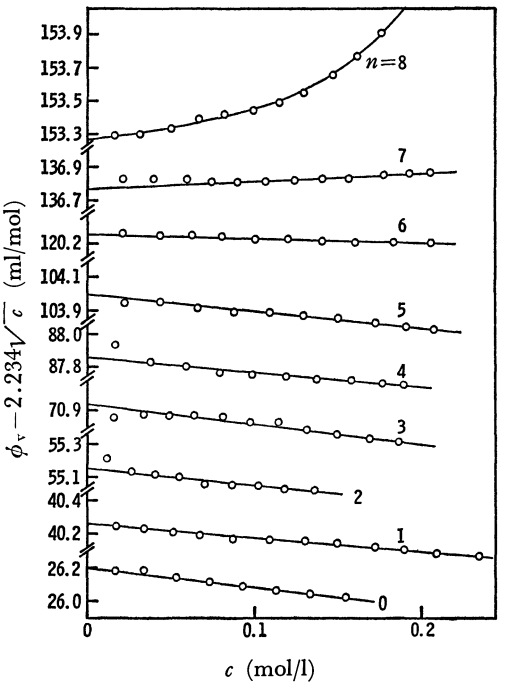

Fig. 1. Apparent molal volumes of sodium *n*-alkanecarboxylates, $H(CH_2)_nCOONa$, in water at 45 °C.

a) Ref. 5.

1. We could not obtain reasonable ϕ_v data for pentylammonium chloride; the value obtained by us was in disagreement with that calculated from the data of pentylammonium bromide[8] at 25 °C, and, furthermore, if the value was used in the calculation of $\bar{V}°(CH_2)$ described below, Fig. 2a gave an anomalous maximum and minimum. It was also found that our earlier ϕ_v values[5] for butane-, pentane-, and hexanecarboxylate salts were too small compared to the present results.

Partial Molal Volume of a Methylene Group. The $\bar{V}°$ increment per methylene group, $\bar{V}°(CH_2)$, was calculated as:

$$\bar{V}°(CH_2) = \frac{\bar{V}°(n_i) - \bar{V}°(n_j)}{n_i - n_j} \quad (3)$$

where n_i and n_j are the number of methylene groups in the homologous pairs considered. Figure 2 shows the $\bar{V}°(CH_2)$ as a function of $(n_i+n_j)/2$. It appears to converge toward a common $\bar{V}°(CH_2)$ value as the chain length increases; approximately 15.3, 15.9, and 16.5 ml/mol at 5, 25, and 45 °C respectively. These values are in good agreement with our previous results obtained with the *n*-alcohol series: 15.5, 15.9, and 16.4 ml/mol at the above temperatures.[9]* These values represent the limiting partial molal volumes of the methylene group free from the influences of the polar groups.

With shorter-chain homologues, on the contrary, deviations from the common $\bar{V}°(CH_2)$ value are apparent: a positive deviation was found for alkylammonium and a negative deviation for alkanecarboxylate salts. It seems likely that the deviations can be ascribed primarily to the influences of the polar groups on the hydrophobic hydration of the methylene group. This explanation may be supported by the fact that the $\bar{V}°$ of branched isomers of butylammonium and butanecarboxylate salts, in which polar groups exist very

near to the CH_2 groups, can be well predicted on the basis of the additivity of the $\bar{V}°(CH_2)$ values.[6] The good agreement between predicted and experimental values suggests that the distance between the nonpolar part and the polar group in a solute molecule is a significant factor in determining the volumetric behavior of the organic salts. The effects of polar groups on the hydrophobic hydration have been discussed by Krishnan and Friedman[10] on the basis of their studies of the solvation enthalpies of various solutes.

Particularly to be noted in Fig. 2a is the fact that the $\bar{V}°(CH_2)$ estimated from the $\bar{V}°$ data of $MeNH_3Cl$ and $EtNH_3Cl$ at 5 °C is larger than that estimated at 25 or 45 °C. A similar phenomenon was observed with the $\bar{V}°(CH_2)$ estimated from the data of HCOONa and MeCOONa (Fig. 2b). The former is closely related to the negative expansibility of the *tert*-butylammonium ion.[6] Quite similar behavior has been accounted for[6] in the case of the negative expansibilities of *tert*-butanol[11] and the methylene group estimated from methanol and ethanol.[9] These results suggest that the negative expansibility is mainly attributable to the influence of the polar group on the hydrophobic hydration; further details have been described in a previous paper.[6]

Temperature Dependence of Partial Molal Volume. For the study of ion–water interactions, it is necessary to divide the $\bar{V}°$ values of salts into those of ions. Using $\bar{V}°(H^+) = -5.1$, -5.4, and -5.8 ml/mol at 5, 25, and 45 °C respectively,[1] and also using the $\bar{V}°$ data for HCl[12] and NaCl,[13] we calculated the ionic partial molal volumes of the organic ions under consideration.

Since the structural effect is considered to show characteristic temperature behavior, it is very useful to examine the partial molal expansibility, $\partial\bar{V}°/\partial T$, and especially its temperature dependence, $\partial^2\bar{V}°/\partial T^2$.[5,9,14-16] Figure 3 shows the $\partial\bar{V}°/\partial T$ values at 15 and 35 °C as a function of the chain length. For both the homologous ions, the expansibilities seem to increase linearly with the increase in chain length when $n>3$ or 4. Therefore, it appears that the ionic

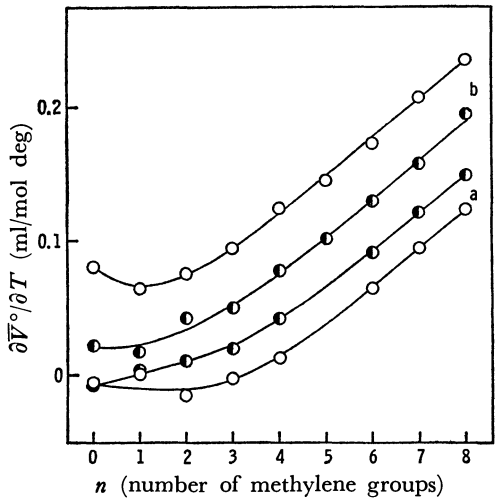

Fig. 3. Partial molal expansibilities of *n*-alkylammonium ions (a) and *n*-alkanecarboxylate ions (b). ○: 15°C, ◐: 35 °C.

hydration caused by NH_3^+ or COO^- ions affects the hydrophobic hydration up to the β- or γ-CH_2 groups. This is consistent with the results of the chain-length dependence of $\bar{V}°(CH_2)$ shown in Fig. 2.

On the basis of the thermodynamic relation, $\partial(\bar{C}_p°/\partial P)_T = -T(\partial^2\bar{V}°/\partial T^2)_p$, Hepler[14] proposed that structure-making solutes are accompanied by positive $\partial^2\bar{V}°/\partial T^2$ values, and structure-breaking solutes, by negative values. His proposal has been supported by the experimental results with tetraalkylammonium halides[15] and various nonelectrolytes.[16] Recently we have reported that, in the case of the homologous *n*-alcohol series, the $\partial^2\bar{V}°/\partial T^2$ values increase linearly with the chain length;[9] this may imply that the hydrophobic hydration becomes more significant with the increase in the chain length. It is apparent from Fig. 4 that, for the alkylammonium and alkanecarboxylate salts, on the other hand, the $\partial^2\bar{V}°/\partial T^2$ values are almost independent of the chain length, with the exception of the shorter-chain homologues. This fact may suggest either that the saturation of the hydrophobic hydration takes place with an increase in the chain length,[17] or that the $\partial^2\bar{V}°/\partial T^2$ value is governed primarily by the influence of the polar group on the hydrophobic hydration. At present, the second interpretation seems to us more likely, although the molecular aspect of the effect of the polar group is less understood. As was mentioned in the preceding section and in a previous paper,[6] we consider that the anomalous temperature behavior of the nonpolar groups, especially that of the *tert*-butyl group, which has been believed to be evidence of the hydrophobic hydration, can be mainly ascribed to the effect of the polar group.

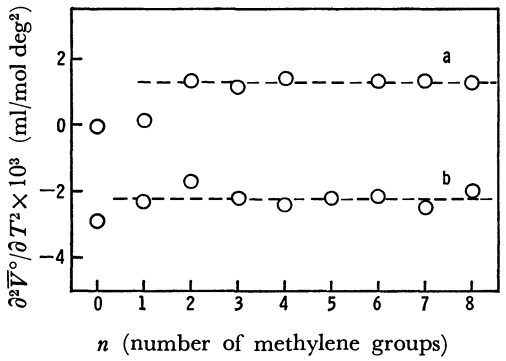

Fig. 4. The $\partial^2\bar{V}°/\partial T^2$ values of *n*-alkylammonium ions (a) and *n*-alkanecarboxylate ions (b).

It is interesting that the $\partial^2\bar{V}°/\partial T^2$ values for RNH_3^+ are positive, while those for $RCOO^-$ are negative. Based on the classification of the structural effect of solutes proposed by Hepler,[14] it may be concluded that the alkylammonium ion is a structure-maker, and the alkanecarboxylate ion, a breaker. In this connection we should note another classification of the solutes presented recently by Tamaki *et al.*[18] on the basis of viscosity measurements; the carboxylate ion is an "electrostrictive structure maker," while the ammonium ion is a "structure breaker." The apparent contradiction of the two classifications men-

tioned above may not be surprising, because it is known that the features of the structural effect vary from property to property.

Concentration Dependence of Apparent Molal Volume. We can obtain information on solute-solute interactions from a careful examination of the concentration dependence of the apparent molal volume. The b_v value in Eq. (2) reflects the solute–solute interactions other than the Coulombic force expected from the Debye-Hückel theory. A number of investigators have discussed the b_v values,[19] but, in our opinion, there still appears to be no satisfactory explanation. For the most of the alkylammonium salts,[8,20-23] the b_v values have been reported to be more or less negative; this is also the case in our study, as can be seen from Table 1. It has been known that the concentration dependence of the apparent molal volume, $\partial\phi_v/\partial m$, is negative for hydrophobic nonelectrolytes, such as alcohols[9,24] or amines,[24] and positive for hydrophilic solutes, such as glycol or urea.[16] Furthermore, it has been known that the b_v or $\partial\phi_v/\partial m$ value becomes more negative as the alkyl-chain length increases.[5,8,9,20,21] On the basis of these experimental results, the negative b_v value has been interpreted in terms of the overlap of the hydrophobic hydration accompanying the increase in concentration.

At present, however, there are two contradictory explanations for the overlapping effect: (1) the overlap results in a more efficient hydrophobic hydration because of co-operative stabilization,[5,25] and (2) the total increase in the hydrophobic hydration caused by the two solutes is less than twice that caused by the first solute alone.[8,9] The discrepancy in the above two explanations may be related in part to the model used for the explanation of the volume change associated with the mixing of water and organic solutes. Many authors believe that the hydrophobic hydration is accompanied by a net volume contraction.[8] On the other hand, some workers[9,26] have attributed the negative excess volume of mixing observed in aqueous systems to the ability of the small water molecules to fill in the free space between larger solute molecules. They have, therefore, concluded that the hydrophobic hydration results in an increase in the volume as a result of the increase in the bulky icelike structure of water.

In Table 1 we can find some interesting features of the variation of the b_v values with the solute species, with the chain length, and with the temperature. For both the homologous series, the b_v values decrease with the increase in the chain length. However, with longer-chain members, the opposite order was observed, especially in the cases of alkanecarboxylate salts and at higher temperatures. This unexpected trend for the salts with large alkyl residues has been also reported by Desnoyers *et al.*,[27,28] who proposed extra weak interactions between the solutes other than the hydrophobic hydration. Lindenbaum[29] pointed out that the positive b_v values for sodium carboxylates signify the structure-breaking effect of the salts and are, therefore, incompatible with the thermochemical results. Recently we reported that the b_v values are almost independent of the chain branching of alkyl residues,[6] although the chain branching causes some changes in the nature of the hydration layers, as can be expected from the $\bar{V}^\circ$ behavior. Considering these experimental results and the obscurity concerning the effect of the hydrophobic hydration on the volumetric behavior mentioned above, we cannot offer a plausible explanation of the concentration dependence of the apparent molal volume. Before we can do so it will be necessary to examine the b_v values as functions of various solute species, solvents, and temperatures.

Figures 5 and 6 show the concentration dependence of ϕ_v for the octylammonium and octanecarboxylate salts at 5, 25, and 45 °C. We can see upward deviations from the linearity of the $\phi_v - S_v\sqrt{c}$ *vs.* c plot. This is analogous to the sharp increase in ϕ_v at critical micelle concentration(CMC) in surfactant solutions.[28,30,31] Although the micellization is not sharp for the salts under consideration, the CMC seems to be about 0.15~0.2 mol/l for both the salts; this is in agreement with the literature value.[32] It should be

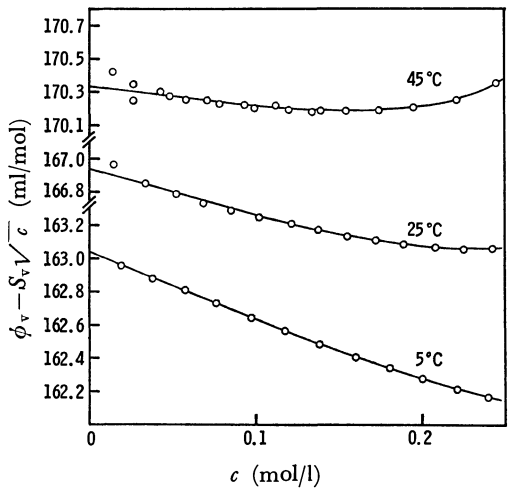

Fig. 5. Apparent molal volumes of *n*-octylammonium chloride.

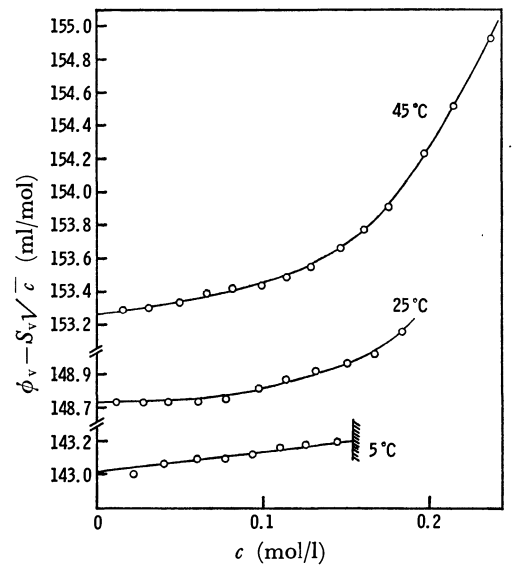

Fig. 6. Apparent molal volumes of sodium *n*-octanecarboxylate.

noted that the deviations are more remarkable at higher temperatures, whereas the CMC of typical surfactants goes through a minimum at room temperature.[28] The large increase in ϕ_v may be interpreted mainly in terms of the increase in free space associated with the micellization.[28,31]

We would like to thank Mr. Toshio Nakajima and Mr. Shigeharu Harada for their helpful discussions. The present work has been supported in part by a Grant for Scientific Research from the Ministry of Education.

The dissociation-association behavior of phycocyanin has been studied by sedimentation-equilibrium measurements under various pH and ionic-strength conditions. The weight-average molecular weight of phycocyanin changed according to the changes in concentration of the solute. From the concentration dependence of the molecular weight, it has been claimed that the dissociation-association equilibrium system of phycocyanin is trimer⇌monomer at pH 6.8 in the relatively low concentration region and hexamer⇌monomer at pH 5.4. However, the coexistence of the trimer⇌monomer and hexamer⇌monomer systems is in evidence in the concentration region larger than 0.06 g/dl. This dissociation-association behavior of phycocyanin is supported by the experimental results obtained from sedimentation-transportation[1] and osmotic-pressure measurements.[5]

In the course of our continuing study of the solution properties of phycocyanin, it was found, from an analysis of the sedimentation velocity data, that the dissociation-association reacting state for phycocyanin was a trimer⇌monomer system at pH 6.8 and a hexamer⇌monomer system at pH 5.4, and that the dissociation constants for the reacting systems were $0.13\sim0.15\times10^{-4}$ $(g/dl)^2$ for a trimer⇌monomer system at pH 6.8 and in the ionic-strength(μ) range of 0.1∼0.2, and $0.1\sim0.5\times10^{-13}$ $(g/dl)^5$ for a hexamer⇌monomer system at pH 5.4 and at an ionic strength of 0.1∼0.2. From the results, it was assumed that the predominant species of phycocyanin was a trimer at pH 6.8 and a hexamer at pH 5.4.[1] Since the dissociation constants described above were evaluated from the concentration dependence of the sedimentation coefficients, these constants should not considered to be thermodynamically the equillibrium values. Therefore, it is desirable to investigate the dissociation-association equilibrium of phycocyanin on the basis of sedimentation-equilibrium experiments.

The purpose of the work to be reported here is to determine the dissociation constant of phycocyanin under various conditions of pH and ionic strength by sedimentation-equilibrium measurements and to obtain information about the dissociation-association state of phycocyanin.

Experimental

Materials and Buffers. The crystalline phycocyanin used in this study was obtained from red algae *Porphyra tenera* by repeated precipitations with ammonium sulfate. The details of the purification of the protein were presented in an earlier paper.[1] Phosphate(pH 6.8, μ 0.1 and 0.2) and acetate (pH 5.4, μ 0.1 and 0.2) buffer solutions were used in this study.

Sedimentation-equilibrium Measurements. The sedimentation-equilibrium measurements were carried out using a magnetically suspended equilibrium-type ultracentrifuge with an interference optical system; a double sectorial cell was also used. The apparatus used here has been described in detail elsewhere.[2]** All the measurements were made at a given speed for approximately 24 hours so as to ensure that an equilibrium was established in an about 3-mm liquid column. The rotor speeds were set at approximately 6000∼9000 rpm, and the temperature was maintained at 25.00± 0.01 °C through all the measurements.

The apparent weight-average molecular weight, M_w^{app}, and the apparent z-average molecular weight, M_z^{app}, of phycocyanin were calculated from Eq. (1) and Eq. (2).

$$M_w^{app} = \frac{2RT}{(1-\bar{v}\rho)\omega^2}\frac{1}{(r_b^2-r_a^2)}\frac{\Delta c}{c_0} \quad (1)$$

$$M_z^{app} = \frac{RT}{(1-\bar{v}\rho)w^2}\frac{(dc/dr)_b-(dc/dr)_a}{\Delta c} \quad (2)$$

In these expressions, $\bar{v}$ is the partial specific volume of the solute; ρ, the density of the solvent; ω, the angular velocity of the rotor; r, the radial position from the center of rotation in the ultracentrifuge cell, and r_a and r_b, the position of the meniscus and the cell bottom respectively. The concentration difference, Δc, between r_a and r_b, was calculated by the use of this formula:

$$\Delta c = (\Delta N)\lambda/(dn/dc)L$$

where ΔN is the number of fringes counted from the standard fringe along the direction of the ultracentrifugal field; λ, the wavelength of light (546 nm), dn/dc, the refractive-index increment, and L, the thickness of the cell (12 mm). The refractive index increment of the protein was obtained from the schlieren pattern of a protein solution of a known concentration; the value of 0.18 ml/g was obtained at 546 nm. This value for dn/dc was used throughout this study irrespective of the aggregation state of phycocyanin. For the partial specific volume, $\bar{v}$, of phycocyanin, the literature value[3] of 0.744 ml/g was used in all the measurements. The solvent density, ρ, was determined with a pycnometer approximately 2 ml in volume.

Determination of the Dissociation Constant. The determination of the dissociation constants for each dissociation-association system with a computational method was performed by using the sedimentation-equilibrium data. The computational method used in this study is essentially an extension of the theory for a monomer-dimer self-association system published by Williams.[4] In this procedure, it is assumed that all of the systems considered here are ideal solutions. The thermodynamic ideality of phycocyanin was confirmed by the experimental results from the osmotic-pressure measurements.[5]

For the i-mer⇌monomer equilibrium system, the weight-average molecular weight, M_w, is expressed by the following formula;

$$M_w = \frac{c_1M_1+c_iM_i}{c} \quad (3)$$

* Some of the experimental results in this paper were presented at the 23rd Annual Meeting of The Socity of Polymer Science, Japan, Tokyo, June 6, 1974.

** This apparatus is in the possession of the Department of Chemistry, Tokyo Kyoiku University.

where c is the total weight concentration of the solute, c_1 and M_1 are the weight concentration and the molecular weight of the monomer, and c_i and M_i are the weight concentration and the molecular weight of i-mer respectively.

The dissociation constant for the trimer$\rightleftharpoons$monomer system, K_3, is defined as Eq. (4) by using the mass-action law;

$$K_3 = c_1^3/c_3 \tag{4}$$

$$M_3 = 3M_1$$

$$c = c_1 + c_3 \tag{5}$$

From Eqs. (3)$\sim$(4), the following expression can be derived:

$$\frac{M_1^2(M_w^{app}-M_1)}{(3M_1-M_w^{app})^3} = \left(\frac{1}{4K_3}\right)c^2 \tag{6}$$

where M_w^{app} is the apparent weight-average molecular weight at the initial concentration, c. Equation (6) may be rewritten as Eq. (7):

$$\frac{(X-1)}{(3-X)^3} = \left(\frac{1}{4K_3}\right)c^2 \tag{7}$$

where X is M_w^{app}/M_1. It is clear that the quantity, $(X-1)/(3-X)^3$, becomes zero when $c=0$. Therefore, the dissociation, constant, K_3, can be determined from the initial slope of the plot of $(X-1)/(3-X)^3$ *versus* c^2.

By a similar treatment, Eq. (8) can be derived for the hexamer$\rightleftharpoons$monomer system by the same procedure as that used for Eq. (7):

$$\frac{(X-1)}{(6-X)^6} = \left(\frac{1}{625K_6}\right)c^5 \tag{8}$$

where K_6 is the dissociation onstant.

When the apparent z-average molecular weight, M_z^{app}, is used in place of M_w^{app} in Eqs. (7) and (8), the following equations, (9) and (10), are obtained:

$$\frac{(X-1)(4-X)^2}{(3-X)^3} = \left(\frac{27}{4K_3}\right)c^2 \tag{9}$$

$$\frac{(X-1)(7-X)^5}{(6-X)^6} = \left(\frac{6^6}{5^5K_6}\right)c^5 \tag{10}$$

where X is M_z^{app}/M_1.

Results and Discussion

The apparent weight-average molecular weight and the apparent z-average molecular weight were obtained from sedimentation-equilibrium measurements performed at a number of initial concentrations of the solute. Figure 1 shows the concentration dependence of the apparent weight- or number-average molecular weight of phycocyanin and, in the inset, that dependence in the low concentration region. The lines in this figure represent the theoretical curves except for (e). The (a), (b), (c) and (d) lines were calculated by using the dissociation constant obtained from the subsequent analysis in this work. The (a) and (b) lines were computed by using the dissociation constants obtained from the weight-average and the z-average molecular weight respectively for the trimer$\rightleftharpoons$monomer system, and the (c) and (d) lines, by using those constants for the hexamer$\rightleftharpoons$monomer system. The (e) line was drawn based on the dissociation constant for the hexamer$\rightleftharpoons$monomer system which was obtained from the sedimentation coefficient.[1]

As is shown in Fig. 1, the values for the apparent weight-average molecular weight depend on the change

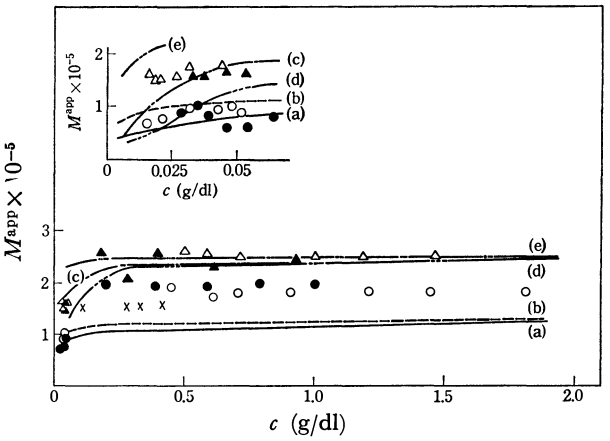

Fig. 1. Concentration dependence of apparent molecular weight of phycocyanin in various buffer solution over a wide concentration range; ○, pH 6.8 and $\mu=0.1$; ●, pH 6.8 and $\mu=0.2$; ×, pH 6.8 and $\mu=0.01$; △, pH 5.4 and $\mu=0.1$; ▲, pH 5.4 and $\mu=0.2$. Lines in this figure were obtained by using various K_3 and K_6 values; (a), $K_3=6.1\times10^{-4}$ (from M_w^{app}); (b), $K_3=1.4\times10^{-5}$ (from M_z^{app}); (c), $K_6=4.4\times10^{-10}$ (from M_w^{app}); (d), $K_6=2.4\times10^{-8}$ (from M_z^{app}); (e), $K_6=0.5\times10^{-13}$ (from s). These dissociation constants have units of $(g/dl)^2$ for K_3 and that of $(g/dl)^5$ for K_6.

in the pH of the solution. In addition, it is clear that the weight-average molecular weight in each system tends to decrease with a decrease in the concentration of the solute in the concentration region studied. The authors conclude from this evidence that phycocyanin undergoes a dissociation-association reaction in solution. The concentration dependencies of the apparent weight-average molecular weight under different pH values are independent of the ionic strength in the concentrations examined in this study. The mean values of the weight-average molecular weight were 78000 at pH 6.8 and 156000 at pH 5.4, while the values for the z-average molecular weight were 125000 at pH 6.8 and 181000 at pH 5.4.

It has been reported from the sedimentation-transportation experiment that the dissociation-association equilibrium system is trimer$\rightleftharpoons$monomer at pH 6.8 and hexamer$\rightleftharpoons$monomer at pH 5.4.[1] Therefore, these systems were assumed to be in a stable equilibrium state under each pH condition. The equilibrium constants were calculated from the experimental data by using Eqs. (7)$\sim$(10). The molecular weight of the monomeric species, M_1, is necessary for this calculation. As has been described in a previous paper[1], the phycocyanin molecule is stable in solution at pH 5.4, and the predominant species is the hexameric form under this pH condition. This conclusion receives support from the results of the osmotic-pressure measurement, which gives a value of 256000 as the number-average molecular weight of the protein.[5] It is, therefore, assumed that the molecular weight of the monomer is 42000.

Figure 2 shows the plot of the quantity, $(X-1)/(3-X)^2$, as a function of the square values of the concentration, c^2, where $X=M_w^{app}/M_1$. Since all of the

protein species in solution are expected to decompose to the monomer at an infinite dilution, the left-hand side of Eq. (7) approaches zero at an extremely low concentration. The dissociation constant, K_3, was calculated from the slope of the plot. Though there is some error in the z-average molecular weight as a result of the difficulty of making an accurate analysis of the experimental data, the dissociation constant, K_3, was calculated by using the M_z^{app} value as a trial (Fig. 3).

Figure 4 shows the plot of $\ln(6-X)^6/(X-1)$ *versus* $\ln c$. As is known from Eq. (8), the plot is a straight line with the value of slope −5. Although there are some scattering in the experimental data, the dissociation constant, K_6, was calculated from the interception of the ordinate for the straight line with the tangent value at $\ln c=0$, and was also calculated from M_z^{app} (Fig. 5).

The values for K_3 were given as 6.1×10^{-4} (g/dl)^2 from M_w^{app} and 1.4×10^{-5} (g/dl)^2 from M_z^{app}, while those for K_6 were 4.4×10^{-10} (g/dl)^5 from M_w^{app} and 2.4×10^{-8} (g/dl)^5 from M_z^{app}.

In order to ascertain the validity of the results obtained in this study, the concentration dependencies of M_w^{app} were recalculated from the K_3 and K_6 values obtained from the sedimentation-equilibrium measurement. There is another way to recalculate the concentration dependence of M_w^{app} by using the data obtained from the sedimentation-transportation method. The results obtained from these procedures are shown in Fig. 1. Although there is some difference between the numerical value for the dissociation constants obtained from the sedimentation equilibrium and those from the transportation measurements,[1] the concentration dependencies recalculated from the two procedures are essentially in accordance with the experimental results. In this figure, the molecular weights in the lower-concentration region are the weight-average values, while those at higher concentrations are the number-average values which were obtained from the osmotic-pressure experiments.[5]

As is shown in Fig. 1, the curves calculated by using the K_6 values at pH 5.4 agree with the experimental data over the whole range of concentrations. On the other hand, the curves calculated by using the K_3 values show a significant deviation from the experimental values in the concentration region larger than 0.06 g/dl. Therefore, it may be concluded from a comparison of the calculated and experimental values of M^{app} as functions of the concentration that the state of the dissociation-association equilibrium at pH 5.4 is hexamer⇌monomer over a wide concentration range. However, the equilibrium state at pH 6.8 depends on the concentration of the solute in the solution. The trimer⇌monomer system can be expected to be predominant in the concentration region less than 0.06 g/dl, and a higher-order aggregate, probably a hexamer, is formed in the concentration higher than 0.06 g/dl. It may be supposed both the trimer⇌monomer and hexamer⇌monomer systems exist in the higher-concentration region.

In the lower-concentration region, below 0.06 g/dl, the dissociation-association equilibrium is significantly shifted in one direction at both pH 6.8 and 5.4; that is, the predominant species at pH 6.8 are trimers, and those at pH 5.4, hexamers. Furthermore, the effect of the ionic strength on the equilibrium shift

in the higher-concentration region is almost negligible for the solution of pH 5.4. However, the effect of the ionic strength on the shift in the higher-concentration region is clear for the solution at pH 6.8.

The authors wish to express their gratitude to Professor Emeritus A. Kotera, of Tokyo Kyoiku University, for his interest and helpful discussion of the problem, and for permission to use the magnetically suspended equilibrium ultracentrifuge. They also wish to express their gratitude to Dr. K. Yoshizaki and Mr. K. Kanoo for their valuable assistance in the sedimentation-equilibrium measurements.

Long-range Interaction between a Hydrogen Atom and a Hydride Ion

Tokio YAMABE, Kazuyoshi TANAKA, Hiroshi UENO, and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received June 20, 1975)

The long-range force between a hydrogen atom and a hydride ion has been studied by means of the second-order perturbation theory. This H–H$^-$ system has been chosen as the simplest example of a system composed of a neutral atom and an anion. The results seem to suggest that the analytical closed form of the second-order energy is desirable for any discussion of the long-range interaction between H and H$^-$ in place of the usual multipole expansion. According to the multipole expansion until the R^{-12} term, the nature of the long-range interaction operating in this system seems to be dispersive, and it seems to become inductive at a much larger R because of the existence of the leading R^{-4} term.

Generally, long-range forces among atoms and molecules are conveniently classified into two categories: the induction force and the dispersion force. The former is due to the long-range interaction energy between a neutral system and a cationic one, and the latter, to that between two neutral systems. Numerous theoretical studies have been devoted to these forces, particularly the systems composed of combinations of H$^+$, H, and He; the perturbation theory or equivalent variational methods have been used.[1] As a matter of course, the long-range interaction between a cation and an anion is Coulombic. Now, then, what kind of interaction operates between a neutral system and an anionic one? In order to clarify the nature of the interaction energy between such systems, we will try, as the first step, to investigate the long-range force between H and H$^-$ as the simplest system.

The long-range force between H and H$^-$ actually has an important role in the dissociation process of the H_2^- molecule ion into H and H$^-$ in the solar corona[2] and is referred to as considerably strong in spite of its anionic nature.[3] Theoretical investigations of the H–H$^-$ long-range force have been done only by Dalgarno and Kingston[4] and by Davison[5] using the usual multipole expansion of the second-order perturbation energy. The latter has evaluated the coefficients of the R^{-4}, R^{-6}, and R^{-8} terms in the series expansion of the inverse powers of the internuclear distance, R, between H and H$^-$ (hereafter we will briefly representthe above quantities as C_4, C_6, C_8, *etc.* and will use the atomic units for energies and distances throughout this paper). The results, however, were too poor for us to get the interaction energy by means of the multipole expansion, since the convergency of the series was bad, even in the asymptotic sense:

$$\bar{E}_2(\text{Davison}) = -\left(\frac{2.25}{R^4}+\frac{93}{R^6}+\frac{7\cdot10^3}{R^8}\right) \tag{1}$$

For instance, the values of these terms are comparable at $R=10$; hence, we need to estimate the higher-order terms at least in the region of *ca.* $R=10$.

In view of this inherent defect in the series expansion, an analytical form is desirable instead. In preceding papers,[6a–6d] we have already investigated the analytical formulae for the second-order perturbation energies with respect to the H–H$^+$, H–H, and He–He systems, neglecting exchange in the framework of the Unsöld approximation. Similarly, in this paper, we will try to obtain a closed form of the second-order perturbation energy of the interaction between H and H$^-$, both in their ground states, and afterwards, will try to show an expansion form again derived from the closed one in order to discuss the nature of the force operating in this system.

Method of Calculation

As is well known, in the framework of the Unsöld approximation,[7] neglecting the exchange for a larger R, the second-order perturbation energy caused by a perturbation, H_1, can be represented by:

$$\bar{E}_2(\text{Unsöld}) = -\frac{\langle H_1^2\rangle_{00}-\langle H_1\rangle_{00}^2}{\langle \Delta E\rangle_{\text{AV}}}, \tag{2}$$

where 0 means the eigenfunction, Φ_0, in the ground state with respect to the unperturbed Hamiltonian, H_0; $\langle \Delta E\rangle_{\text{AV}}$ is called an 'average excitation energy,' after Unsöld. In the cases of the H–H$^-$ system, neglecting the exchange, Φ_0 appears as follows:

$$\Phi_0 = \Psi_a(1)\Psi_b(2,3), \tag{3}$$

where $\Psi_a(1)$ is the 1s-function of a hydrogen atom, a, and where $\Psi_b(2,3)$ is a wavefunction of a hydride ion, b. In order to get an analytical form of $\bar{E}_2$ (Unsöld), we need a wavefunction, $\Psi_b(2,3)$, simple enough to be used for Φ_0, but also accurate enough to show the stability of H$^-$. The simplest form is one for the $1s^2\ {}^1S$ state, but it gives no stabilization of H$^-$.[8] The form we employ here is a linear combination of the product of the 1s-like functions with different orbital exponents, z and z', for different spins:

$$\Psi_b(2,3) = \frac{1}{\sqrt{2(1+s^2)}}[\Psi_b(2)\Psi_b'(3)+\Psi_b(3)\Psi_b'(2)], \tag{4}$$

where:

$$\Psi_b(i) = \frac{z^{3/2}}{\sqrt{\pi}}\exp[-zr_i], \tag{5-a}$$

and

$$\Psi_b'(j) = \frac{z'^{3/2}}{\sqrt{\pi}}\exp[-z'r_j], \tag{5-b}$$

and where:

$$s = \left(\frac{2\sqrt{zz'}}{z+z'}\right)^3. \tag{6}$$

The notations in the H–H$^-$ system are shown in Fig. 1. This wavefunction, which was first obtained by Chandrasekhar[9] and was thereafter used by Dalgarno *et al.*[3] and Fischer-Hjalmars[10] for the calculation of

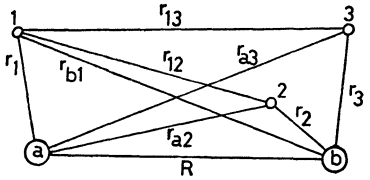

Fig. 1. Notation for distances among electrons 1, 2, and 3, and nuclei a and b in the H-H⁻ system.

the energy of H_2^-, predicts the stability of H^- when $z' \simeq z/3$; hence, we assume that this wavefunction is the correct one for H^-. Using this $\Psi_b(2,3)$, we construct an unperturbed wavefunction as follows:

$$\Phi_0 = \left(\frac{zz'}{\pi}\right)^{3/2} \cdot \frac{1}{\sqrt{2(1+s^2)}} \exp[-r_1]\{\exp[-zr_2] \times \exp[-z'r_3] + \exp[-zr_3]\exp[-z'r_2]\}. \quad (7)$$

The perturbation, H_1, between H and H^- at an internuclear distance, R, is written by:

$$H_1 = \frac{1}{R} - \frac{1}{r_{a2}} - \frac{1}{r_{a3}} - \frac{1}{r_{b1}} + \frac{1}{r_{12}} + \frac{1}{r_{13}}, \quad (8)$$

which is then rearranged into three parts:

$$H_1 = \left[\frac{1}{r_{12}} + \frac{1}{R} - \frac{1}{r_{b1}} - \frac{1}{r_{a2}}\right] + \left[\frac{1}{r_{13}} + \frac{1}{R} - \frac{1}{r_{b1}} - \frac{1}{r_{a3}}\right] - \left[\frac{1}{R} - \frac{1}{r_{b1}}\right] \equiv H_1(1,2) + H_1(1,3) - H_1(1). \quad (9)$$

It can easily be seen that the first two terms and the last term furthest to the right correspond to the interactions between H–H and that between H–H^+ respectively. Using the wavefunction in Eq. (7), $\langle H_1\rangle_{00}$ and $\langle H_1^2\rangle_{00}$ may be rewritten as:

$$\langle H_1\rangle_{00} = \langle H_1(1,2)\rangle_{00} + \langle H_1(1,3)\rangle_{00} - \langle H_1(1)\rangle_{00} = 2\langle H_1(1,2)\rangle_{00} - \langle H_1(1)\rangle_{00}, \quad (10)$$

and:

$$\langle H_1^2\rangle_{00} = \langle H_1^2(1,2)\rangle_{00} + \langle H_1^2(1,3)\rangle_{00} + \langle H_1^2(1)\rangle_{00} + 2\langle H_1(1,2)H_1(1,3)\rangle_{00} - 2\langle H_1(1,2)H_1(1)\rangle_{00} - 2\langle H_1(1,3)H_1(1)\rangle_{00} = 2\langle H_1^2(1,2)\rangle_{00} + \langle H_1^2(1)\rangle_{00} + 2\langle H_1(1,2)H_1(1,3)\rangle_{00} - 4\langle H_1(1,2)H_1(1)\rangle_{00}. \quad (11)$$

It should be noticed that only the first two terms furthest to the right in Eq. (11) contain non-exponentially decreasing terms and therefore contribute to the origin of the long-range interaction. That is, the first term, $\langle H_1^2(1,2)\rangle_{00}$, corresponds to the second-order interaction energy of H–H with the well-known R^{-6} decay, while the second term, $\langle H_1^2(1)\rangle_{00}$, corresponds to that of H–H^+ giving the first leading term of R^{-4} in the Unsöld approximation except for the factors of the 'average excitation energy.'

Using Eqs. (10) and (11), Eq. (2) can be rewritten as:

$$\bar{E}_2(\text{Unsöld}) = -\frac{1}{\langle \Delta E\rangle_{AV}}\left[-\frac{2}{R^2} + \frac{4}{R}\langle H_1(2)\rangle_{00} - \langle H_1^2(1)\rangle_{00} - 2\langle H_1^2(2)\rangle_{00} + 4\left\langle \frac{1}{r_{a2}} W(2,1)\right\rangle_{00} + 2\left\langle \frac{1}{r_{12}^2}\right\rangle_{00} + 2\langle H_1(2)H_1(3)\rangle_{00} - 2\langle H_1(2)W(1,3)\rangle_{00} - 2\langle H_1(3)W(1,2)\rangle_{00} + 2W\langle (1,2)W(1,3)\rangle_{00} - 4\langle H_1(1,2)\rangle_{00}^2 - \langle H_1(1)\rangle_{00}^2 + 4\langle H_1(1,2)\rangle_{00}\langle H_1(1)\rangle_{00}\right], \quad (12)$$

where:

$$W(1,i) = \frac{1}{r_{b1}} - \frac{1}{r_{1i}} \quad (i=2,3), \qquad W(i,1) = \frac{1}{r_{ai}} - \frac{1}{r_{1i}} \quad (i=2,3), \quad (13)$$

In order to avoid complexity arising from the presence of many terms, we will introduce some further notations. For any hermitian operator, F, the expectation value, $\langle F\rangle_{00}$, in which 0 stands for the function defined as in Eq. (7), is decomposed into three parts:

$$\langle F\rangle_{00} = \frac{1}{2(1+s^2)}[\{F|R,z,z'\} + \{F|R,z',z\} + 2s^2\{F|R,z'',z''\}], \quad (14)$$

where s is defined as in Eq. (6), where $z''=(z+z')/2$, and where:

$$\{F|R,z,z'\} = \langle \Psi_a^*(1)\Psi_b^*(2)\Psi_b'^*(3)|F|\Psi_a(1)\Psi_b(2)\Psi_b'(3)\rangle,$$
$$\{F|R,z',z\} = \langle \Psi_a^*(1)\Psi_b'^*(2)\Psi_b^*(3)|F|\Psi_a(1)\Psi_b'(2)\Psi_b(3)\rangle, \quad (15)$$

and

$$\{F|R,z'',z''\} = \langle \Psi_a^*(1)\Psi_b''^*(2)\Psi_b''^*(3)|F|\Psi_a(1)\Psi_b''(2)\Psi_b''(3)\rangle.$$

In Eq. (15), the asterisk indicates the hermitian conjugate, $\Psi_b(i)$ and $\Psi_b'(j)$ are defined by Eqs. (5-a) and (5-b), and

$$\Psi_b''(k) = \frac{z''^{3/2}}{\sqrt{\pi}} \exp[-z''r_k]. \quad (5\text{-c})$$

All the integrals used in Eq. (12) are shown in the Appendix. Thus, Eq. (12) may be evaluated exactly without resorting to a series expansion and can be given in a closed analytical form applicable to an arbitrary internuclear distance, R, and orbital exponents, z and z'.

Results and Discussion

In the calculation of $\bar{E}_2$ (Unsöld), we adopt the values of the orbital exponents following Fischer-Hjalmars[10] that is, $z=1.00$, $z'=0.30$, and hence $z''=(z+z')/2=0.65$. As to $\langle \Delta E\rangle_{AV}$, we can consider three kinds of values: 1) the sum of the first ionization potentials of H and H^-, 0.52775*, which is

* Pekeris has obtained, by concentrated numerical efforts, the ground state energy of H^- as −0.52775 (*Phys. Rev.*, **126**, 1470 (1962)). He has also thought that H^- has no more than one bound state; that is, the first ionization potential of H^- is 0.02775 to make the H+e⁻ system. Power and Somorjai have tried to prove the above fact (*ibid.*, **A5**, 2401 (1972)), but in vain (*ibid.*, **A6**, 1996 (1972)). It is very likely, however, that H^- has no more than one bound state (Ref. 2-b); hence, we assume that the first ionization potential is 0.02775.

a) $\langle\Delta E\rangle_{AV}=1.02775$, 0.52775, and 0.402775 in the cases (A), (B), and (C), respectively. b) Ref. 11. c) At $R=\infty$, $E=-1.02775$.

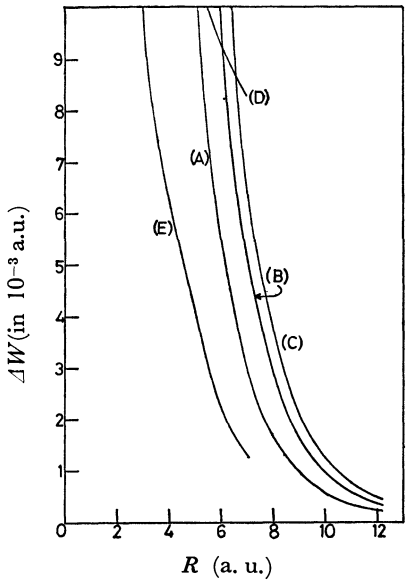

Fig. 2. Long-range interaction energy ΔW between H and H^-.

reasonable and which is usually adopted, 2) the sum of the first excitation energies, 0.40275, which gives an approximate lower bound of $\bar{E}_2$ (Unsöld), and 3) the sum of the ground state energies of H and H^-, -1.02775, which gives an approximate upper bound.[6c,6d] By substituting these values into Eq. (12), three kinds of $\bar{E}_2$ (Unsöld) values for various R values are obtained, as is shown in Table 1. The first-order perturbation energy, E_1, is equal to the expectation value, $\langle H_1\rangle_{00}$; it is also shown in Table 1 for each R.

On the other hand, Taylor and Harris have previously obtained a potential curve for the $^2\Sigma_u^+$ state of the H_2^- system using a CI method until $R=7.0$;[11] this seems to be the most reliable value at present. In Fig. 2, three kinds of total interaction energy curves, (A), (B), and (C) taken as far as the second-order between the H and H^- obtained by means of the above criterion, are compared with the results of the variational calculation done by Taylor and Harris and also with the version modified here using the exact sum of the ground state energies of H and H^-, -1.02775, as the standard of the separated system. This modified version can afford a strict lower bound of the total interaction energy.** The potential curve (A) represents almost the lower bound of the interaction energy taken up to the second-order term, and (C), almost the upper bound. The exact one would lie in the zone between (A) and (C). The result of the original variational calculation, (D), lies above the zone obtained here. However, the modified version, (E), lies below.

Now, discarding the terms attenuating exponentially with an increase in R in Eq. (12), we obtain this reduced formula:

$$\bar{E}_2(\text{Unsöld}) \simeq -\frac{1}{\langle\Delta E\rangle_{AV}}\cdot\frac{1}{2(1+s^2)}[V(R,z)+V(R,z')+2s^2V(R,z'')], \quad (16)$$

where:

$$\begin{aligned}V(R,z) &= \exp[-2R]\widetilde{Ei}[2R]\times\left\{-1+\frac{2z^4}{(1-z^2)^2}+\left(-\frac{1}{2}+\frac{z^4(5-z^2)}{(1-z^2)^3}\right)\frac{1}{R}\right\}\\ &+\exp[2R]Ei[-2R]\times\left\{-1+\frac{2z^4}{(1-z^2)^2}+\left(\frac{1}{2}-\frac{z^4(5-z^2)}{(1-z^2)^3}\right)\frac{1}{R}\right\}\\ &+\exp[-2zR]\widetilde{Ei}[2zR]\times\left\{-2z^2+\frac{2z^2}{(1-z^2)^2}+\left(-z+\frac{z(1-5z^2)}{(1-z^2)^3}\right)\frac{1}{R}\right\}\\ &+\exp[2zR]Ei[-2zR]\times\left\{-2z^2+\frac{2z^2}{(1-z^2)^2}+\left(z-\frac{z(1-5z^2)}{(1-z^2)^3}\right)\frac{1}{R}\right\}. \quad (17)\end{aligned}$$

In Eq. (17), $\widetilde{Ei}[x]$ is the usual exponential integral, defined as:

$$\widetilde{Ei}[x] = -\int_{-x}^{\infty}\frac{\exp[-t]}{t}dt,$$

and

$$Ei[-x] = -\int_{x}^{\infty}\frac{\exp[-t]}{t}dt.$$

** It should be noticed that the lower and the upper bound alternate in the case of the interaction energy, since it is defined as a positive quantity.

Using the well-known asymptotic expansion,

$$\exp[-x]\widetilde{Ei}[x] \simeq \sum_{n=1}^{\infty} \frac{(n-1)!}{x^n},$$

and

$$\exp[x]Ei[-x] \simeq \sum_{n=1}^{\infty} \frac{(-1)^n(n-1)!}{x^n},$$

we obtain:

$$V(R,z) = \frac{1}{R^4} + \frac{3(8+3z^2)}{2z^2}\cdot\frac{1}{R^6} + \frac{45(3+3z^2+z^4)}{z^4}\cdot\frac{1}{R^8} + \frac{315(16+18z^2+16z^4+5z^6)}{2z^6}\cdot\frac{1}{R^{10}} + \frac{14175(3z^8+10z^6+12z^4+12z^2+10)}{2z^8}\cdot\frac{1}{R^{12}}\cdots\cdots \quad (18)$$

Using Eqs. (16) and (18), and substituting $z=1.00$, $z'=0.30$, and $z''=0.65$, we obtain a form of series expansion with respect to the inverse powers of R, which can be compared with Davison's result using Eq. (1), as follows:

$$\bar{E}_2(\text{Unsöld}) = -\frac{1}{\langle \Delta E\rangle_{\text{AV}}}\left(\frac{1}{R^4} + \frac{65.497}{R^6} + \frac{7116.8}{R^8} + \frac{1.4302\cdot 10^6}{R^{10}} + \frac{4.4604\cdot 10^8}{R^{12}} + \cdots\cdots\right). \quad (19)$$

In this series, at $R=18$, 14, and 10, the R^{-12} term is comparable with the R^{-10} term, the R^{-10} term with the R^{-8} term, and the R^{-8} term with the R^{-6} term. Adopting $\langle \Delta E\rangle_{\text{AV}}=0.52775$, which gives the potential (B) in Fig. 2, we obtain:

$$\bar{E}_2(\text{Unsöld}) = -\left(\frac{1.8948}{R^4} + \frac{1.2411\cdot 10^2}{R^6} + \frac{1.3485\cdot 10^4}{R^8} + \frac{2.7100\cdot 10^6}{R^{10}} + \frac{8.4517\cdot 10^8}{R^{12}} + \cdots\cdots\right). \quad (20)$$

The results definitely show the divergent nature of the sequence C_{2n} ($n=2$, 3, 4, 5, 6, and so on). On the contrary, the use of the closed form obtained in this paper easily affords the value of $\bar{E}_2$ (Unsöld) at any given R. It can easily be seen that the R^{-4} term comes from the first term of the induction force in the H–H⁺ system:[12]

$$\bar{E}_2 = -\left(\frac{2.25}{R^4} + \frac{7.50}{R^6} + \frac{65.625}{R^8} + \frac{1063.125}{R^{10}} + \frac{27286.875}{R^{12}} + \cdots\cdots\right). \quad (21)$$

The other terms in Eq. (21) contribute little to Eq. (20). In order to clarify this, we have calculated another series expansion with regard to the perturbation H_1:

$$H_1 = H_1(1,2) + H_1(1,3), \quad (22)$$

which involves no H–H⁺ interaction, in contrast with Eq. (9). The results of expansion are as follows:

$$\bar{E}_2(\text{Unsöld}) = -\frac{1}{\langle \Delta E\rangle_{\text{AV}}}\left(\frac{60.998}{R^6} + \frac{7071.8}{R^8} + \frac{1.4294\cdot 10^6}{R^{10}} + \frac{4.4601\cdot 10^8}{R^{12}} + \cdots\cdots\right). \quad (23)$$

In this case, $V(R, z)$ as defined in Eq. (16) becomes:

$$V(R,z) = \frac{12}{z^2}\cdot\frac{1}{R^6} + \frac{135(1+z^2)}{z^4}\cdot\frac{1}{R^8} + \frac{2520(1+z^4)+2835z^2}{z^6}\cdot\frac{1}{R^{10}} + \frac{70875(1+z^6)+85050(z^4+z^2)}{z^8}\cdot\frac{1}{R^{12}} + \cdots\cdots. \quad (24)$$

If we subsitute unity into z, this $V(R, z)$ is clearly reduced to twice the values of the well-known H–H long-range interaction previously obtained by Dalgarno and Lewis.[13] When we compare Eq. (19) with Eq. (23), the terms of higher-order than R^{-4}, therefore, prove to be mainly due to the dispersion force.

In Fig. 3, we show some $\bar{E}_2$ (Unsöld) curves obtained by the partial summation of the series in Eq. (20), along with Davison's series expansion in Eq. (1). It should be noticed that his expansion may be rather near to our closed form at R values less than 6.0, while at larger R values there appears an underestimating tendency. On the other hand, the series expansion until the R^{-10} or R^{-12} term leads to an overestimation of the interaction energy at R values less than *ca.* 9.0.

In conclusion, it turns out that the closed form obtained above is effective for describing the long-range interaction for the H–H⁻ system. Although the values of the second-order interaction energy predicted here have some ambiguousness because of the arbitrariness of the 'average excitation energy,' the upper and lower bounds obtained are reliable to a considerable extent. The series expansion described here shows that the dispersion force contributes to the nature of the interaction: when R is much larger, the R^{-4} term comes to be dominant, and hence

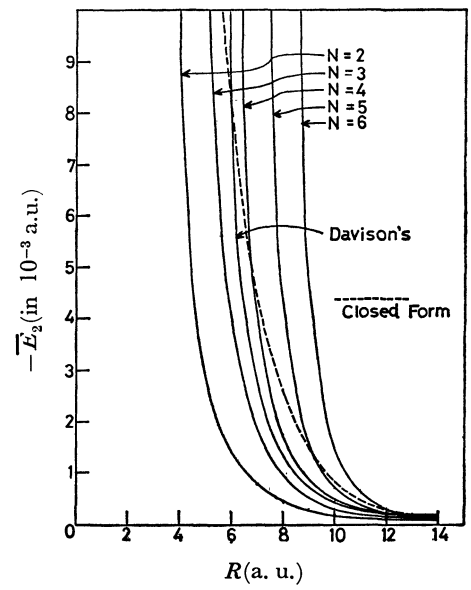

Fig. 3. Various curves of the second-order perturbation energy in the H–H⁻ system obtained by partial summations, $-\bar{E}_2(\text{Unsöld}) = \sum_{n=2}^{N} \frac{C_{2n}}{R^{2n}}$ in Eq. (20). The closed form curve corresponds to (B) in Table 1, and Davison's curve is based on the result in Ref. 5.

the induction force begins to prevail over the dispersion. The former extraordinary large magnitude of the dispersion force mainly comes from the quantity of z' in Eq. (7)—namely, the orbital exponent of the outer orbital in H^-. In other words, the weakly bound electron plays an important role in the origin of the large dispersion force in the system. Generally speaking, a weakly bound electron, which exists also in such anions as F^- or Cl^-, or the electron in frontier orbital with a similar physical nature, will maintain its importance when the system interacts with other distant species.

Appendix

The miscellaneous integrals used in Eq. (12) are shown in the form of $\{F|R,z,z'\}$ in Eq. (15).

$$\{H_1(1)\,|\,R,z,z'\} = \int_{-\infty}^{\infty}\frac{1}{\pi}\exp[-2r_1]\left(\frac{1}{R}-\frac{1}{r_{b1}}\right)d\tau(1)$$
$$= \left(1+\frac{1}{R}\right)\exp[-2R]. \quad \text{(A-1)}$$

$$\{H_1(2)\,|\,R,z,z'\} = \int_{-\infty}^{\infty}\frac{z^3}{\pi}\exp[-2zr_2]\left(\frac{1}{R}-\frac{1}{r_{a2}}\right)d\tau(2)$$
$$= \left(z+\frac{1}{R}\right)\exp[-2zR]. \quad \text{(A-2)}$$

$$\{H_1(1,2)\,|\,R,z,z'\} = \int_{-\infty}^{\infty}\frac{z^3}{\pi^2}\exp[-2(r_1+zr_2)]$$
$$\times\left(\frac{1}{R}+\frac{1}{r_{12}}-\frac{1}{r_{b1}}-\frac{1}{r_{a2}}\right)d\tau(1)d\tau(2)$$
$$= \frac{1}{(1-z^2)^3}\exp[-2R]$$
$$\times\left\{(2z^4-3z^2+1)+\frac{1}{R}(-3z^2+1)\right\}$$
$$+\frac{z^3}{(1-z^2)^3}\exp[-2zR]$$
$$\times\left\{(-z^4+3z^2-2)+\frac{z}{R}(-z^2+3)\right\}, \quad (z\neq 1) \quad \text{(A-3)}$$

if $z=1$,

$$\{H_1(1,2)\,|\,R,1,z'\} = \exp[-2R]\left(\frac{1}{R}+\frac{5}{8}-\frac{3R}{4}-\frac{R^2}{6}\right). \quad \text{(A-3')}$$

$$\{H_1^2(1)\,|\,R,z,z'\} = \int_{-\infty}^{\infty}\frac{1}{\pi}\exp[-2r_1]$$
$$\times\left(\frac{1}{R^2}-\frac{2}{r_{b1}R}+\frac{1}{r_{b1}^2}\right)d\tau(1)$$
$$= -\frac{1}{R^2}+\frac{2}{R}\left(1+\frac{1}{R}\right)\exp[-2R]$$
$$+\left(1+\frac{1}{2R}\right)\exp[-2R]\widetilde{Ei}[2R]$$
$$+\left(1-\frac{1}{2R}\right)\exp[2R]Ei[-2R]. \quad \text{(A-4)}$$

$$\{H_1^2(2)\,|\,R,z,z'\} = \int_{-\infty}^{\infty}\frac{z^3}{\pi}\exp[-2zr_2]$$
$$\times\left(\frac{1}{R^2}-\frac{2}{r_{a2}R}+\frac{1}{r_{a2}^2}\right)d\tau(2)$$
$$= -\frac{1}{R^2}+\frac{2}{R}\left(z+\frac{1}{R}\right)\exp[-2zR]$$
$$+\left(z^2+\frac{z}{2R}\right)\exp[-2zR]\widetilde{Ei}[2zR]$$
$$+\left(z^2-\frac{z}{2R}\right)\exp[2zR]Ei[-2zR]. \quad \text{(A-5)}$$

$$\left\{\frac{1}{r_{a2}}W(2,1)\,|\,R,z,z'\right\} = \int_{-\infty}^{\infty}\frac{z^3}{\pi^2}\exp[-2(r_1+zr_2)]$$
$$\times\left(\frac{1}{r_{a2}^2}-\frac{1}{r_{a2}r_{12}}\right)d\tau(1)d\tau(2)$$
$$= \exp[-2zR]\left[-z^2\log\left|\frac{z-1}{z+1}\right|+\frac{z^3}{1-z^2}\right.$$

Studies of Phase Transitions in Cholesteryl Myristate by Means of Simultaneous Measurements of Polarizing Microscopy and Thermal Analyses*

Kazuko SASAKI KUNIHISA and Takako SHINODA
National Chemical Laboratory for Industry, Shibuya-ku, Tokyo 151
(Received June 7, 1975)

An improved DTA furnace and sample cell have been used for accurate DTA measurements and clear polarizing microscopic photographs. The photographs, DTA and TTA curves were obtained simultaneously at different heating or cooling rates for solid-smectic, smectic-cholesteric and cholesteric-isotropic liquid phase transitions in cholesteryl myristate.

Polarizing microscopy has been used for observing the static state of the substance microscopically, and differential thermal analysis (DTA) and total thermal analysis (TTA) for studying the thermal behavior of a substance dynamically. With simultaneous use of the two methods, it is possible to observe the process of transition more in detail.

We have studied the solid-smectic, the smectic-cholesteric and the cholesteric-isotropic liquid phase transitions in cholesteryl $CH_3(CH_2)_{12}COOC_{27}H_{45}$.

Experimental

Apparatus. A DTA furnace and a cell were constructed for increasing the accuracy of DTA measurements and for obtaining clear polarizing microscopic photographs. The furnace is illustrated in Fig. 1. A heater ($\phi=0.3$ mm, manganin) and all the electrical lead wires are wound around A. A sectional view of the sample or reference cell, made of pyrex glass (0.6 mm thick) and a quartz plate, with an internal volume *ca.* 0.07 ml, is shown in Fig. 2. The thermocouple, a chromel *p*-constantan type, is used for the absolute or difference temperature measurements. Measurements for the calibration of the absolute temperature scale were reported previously.[1] For increasing the accuracy of DTA measurements, two differential thermocouples were connected in series. Operations for polarizing microscopy and DTA were the same as those described previously.[2]

Material. Cholesteryl myristate (Tokyo Kasei Kogyo Co., Ltd.) was recrystallized from *n*-pentanol twice, pumping being carried out for 22.5 h with a rotary pump in order to remove any trace of solvent. Cholesteryl benzoate (Tokyo Kasei Kogyo Co., Ltd.) was used as a refernce substance.

Microscopic observations were carried out through crossed nicols and a color-sensitive plate, magnification being 200. A tungsten lamp (30 W) was used as a light source. The position for taking a photograph is marked on the recording paper for the DTA and TTA.

Results and Discussion

Annealing Effects. Polymorphic behavior of solid phases of substances forming liquid crystals has been reported for PAA,[3] MBBA[4] and OH-MBBA.[5] In the course of annealing the solid specimen, polymorphic behavior for cholesteryl myristate has also been observed. The results are shown in Figs. 3 and 4. The solid state established by cooling the specimen of isotropic liquid state with an average cooling rate of

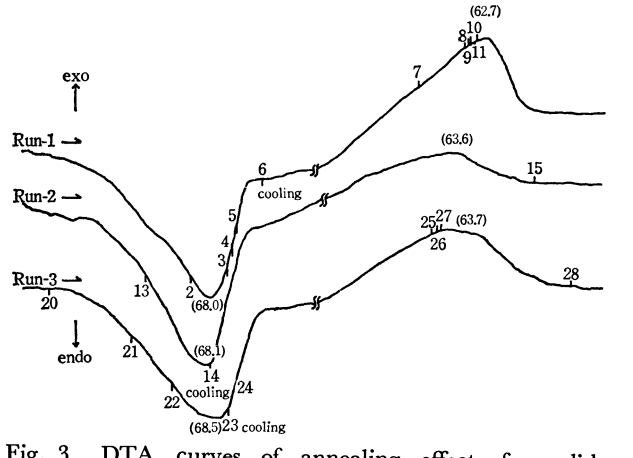

Fig. 3. DTA curves of annealing effects for solid cholesteryl myristate. Numerals in parentheses indicate T_{max} (°C).

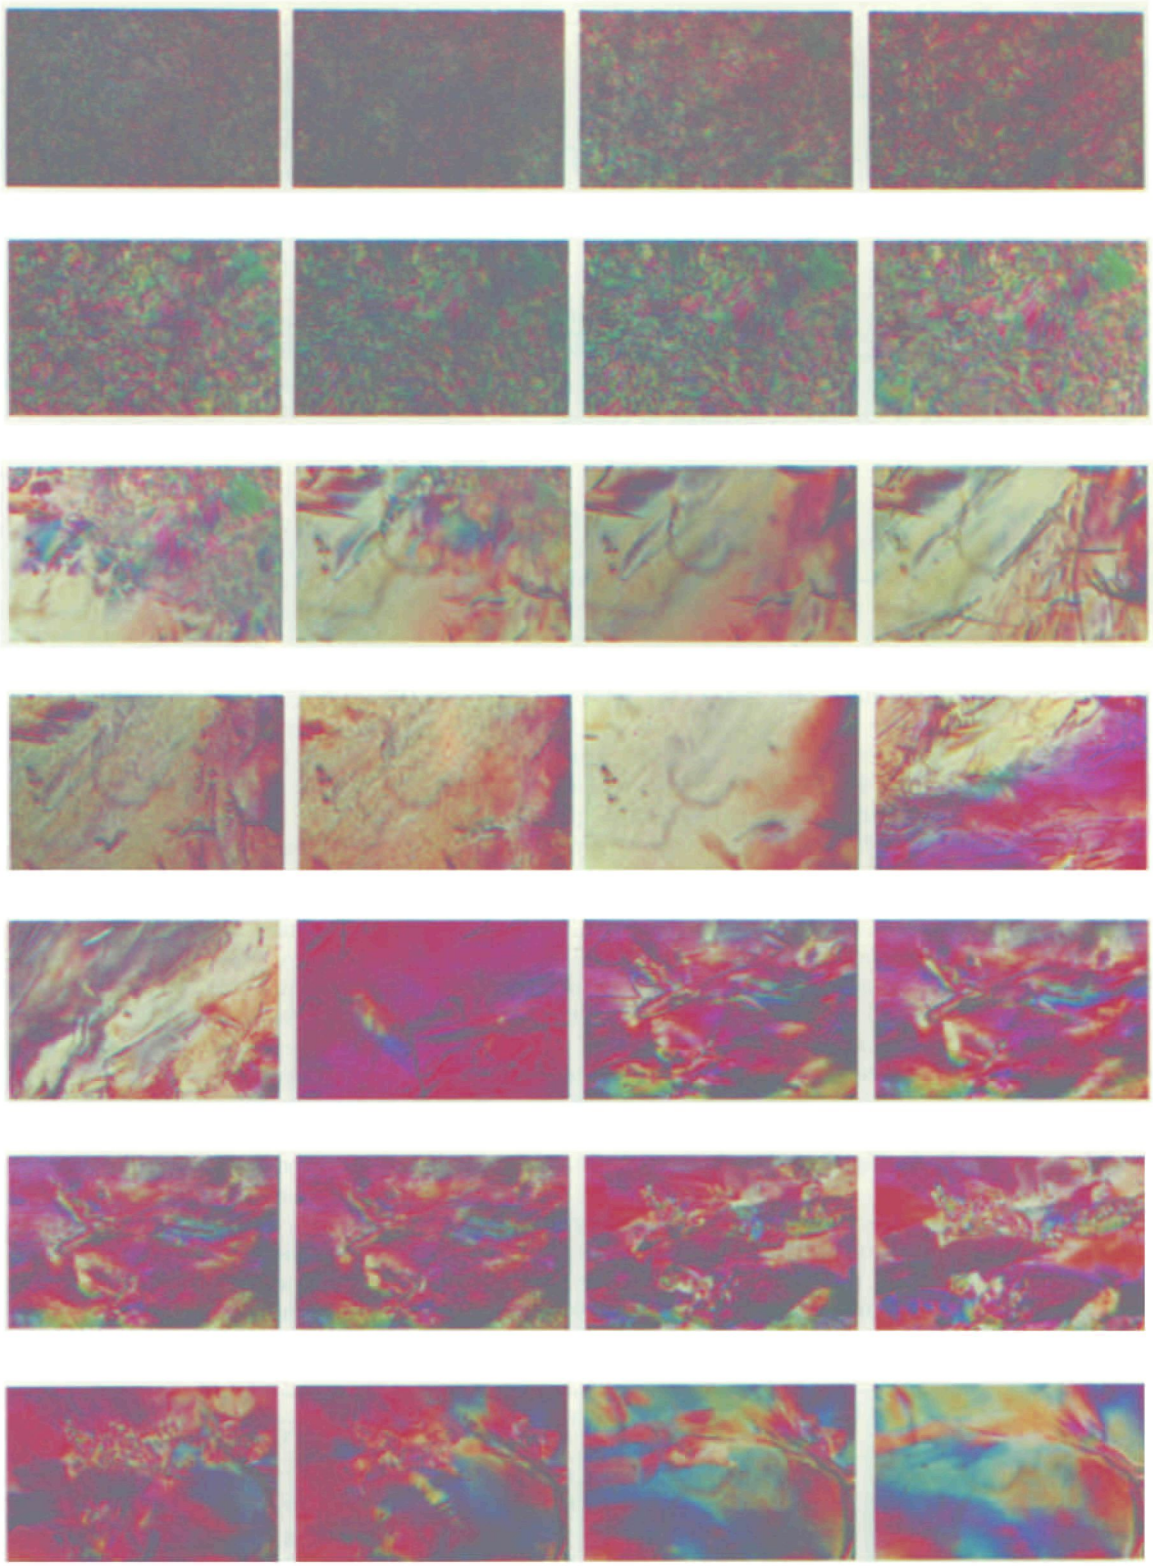

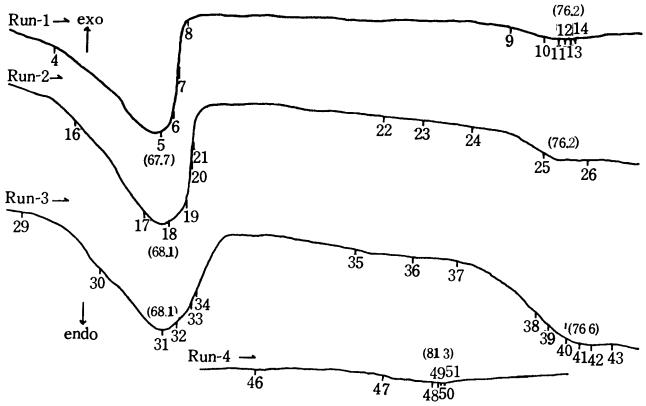

Fig. 5. DTA curves of cholesteryl myristate at heating condition. Numerals in parentheses indicate T_{max} (°C).

ca. 1.79 °C min^{-1} to room temperature, is denoted by solid-I. In Fig. 3, Run-1 represents a DTA curve obtained by heating solid-I at the rate 0.22°C min^{-1} from room temperature to point 6, and then by cooling at the rate 0.23 °C min^{-1} to room temperature. Figure 4-12 gives a photograph of the solid obtained at 32 °C after 18.5 hr. The annealing effects for this solid are shown by the DTA curve at the heating rate 0.23 °C min^{-1} and the cooling rate 0.22 °C min^{-1} for Run-2. Figs. 4-16, 4-17, 4-18 and 4-19 show the annealed solid states at room temperature after 19 hr. Run-3 gives a DTA curve obtained by annealing the specimen (Fig. 4-19) at the heating rate 0.24 °C min^{-1} and the cooling rate 0.22 °C min^{-1}. The last established solid is denoted by solid-III.

Heating Process. Another solid state denoted by solid-II (Fig. 6-15) was obtained by cooling the specimen of isotropic liquid state to 49.4 °C at the cooling rate *ca.* 0.22 °C min^{-1}. We found that the situation of the transitions from solid to smectic and then to cholesteric depends upon the starting solid-state. The DTA curves for solids-I, II and III are shown by Runs-1, 2, and 3, respectively, in Fig. 5, at heating rates of 0.21, 0.21 and 0.23 °C min^{-1}, respectively. Figs. 6-1 to 6-43 show the microscopic photographs taken during the course of transformation.

Figure 6-1 shows the microscopic photograph of solid-I at room temperature, Figs. 6-2 and 6-3 being those of partial solid-I states. Figs. 6-4 to 6-14 show photographs corresponding to the points indicated by the numbers in the DTA curve for Run-1 in Fig. 5, Fig. 6-8 giving the smectic-state obtained from solid-I state. The smectic-to-cholesteric transition takes place directly from the openings of the rod (or bunch) shaped smectic-liquid crystals, as shown in Figs. 6-12 and 6-13. Figure 6-14 shows the established cholesteric state.

Figures 6-15 to 6-26 show microscopic photographs of solid-II corresponding to the DTA curve of Run-2 in Fig. 5. Figure 6-22 shows the smectic-state obtained by heating the specimen of solid-II. The upper part on the left is similar to the smectic-state obtained from solid-III. The lower part on the right shows the rod shaped smectic-state found in solid-I. Figure 6-26 gives the cholesteric-state obtained and resembles Fig. 6-14.

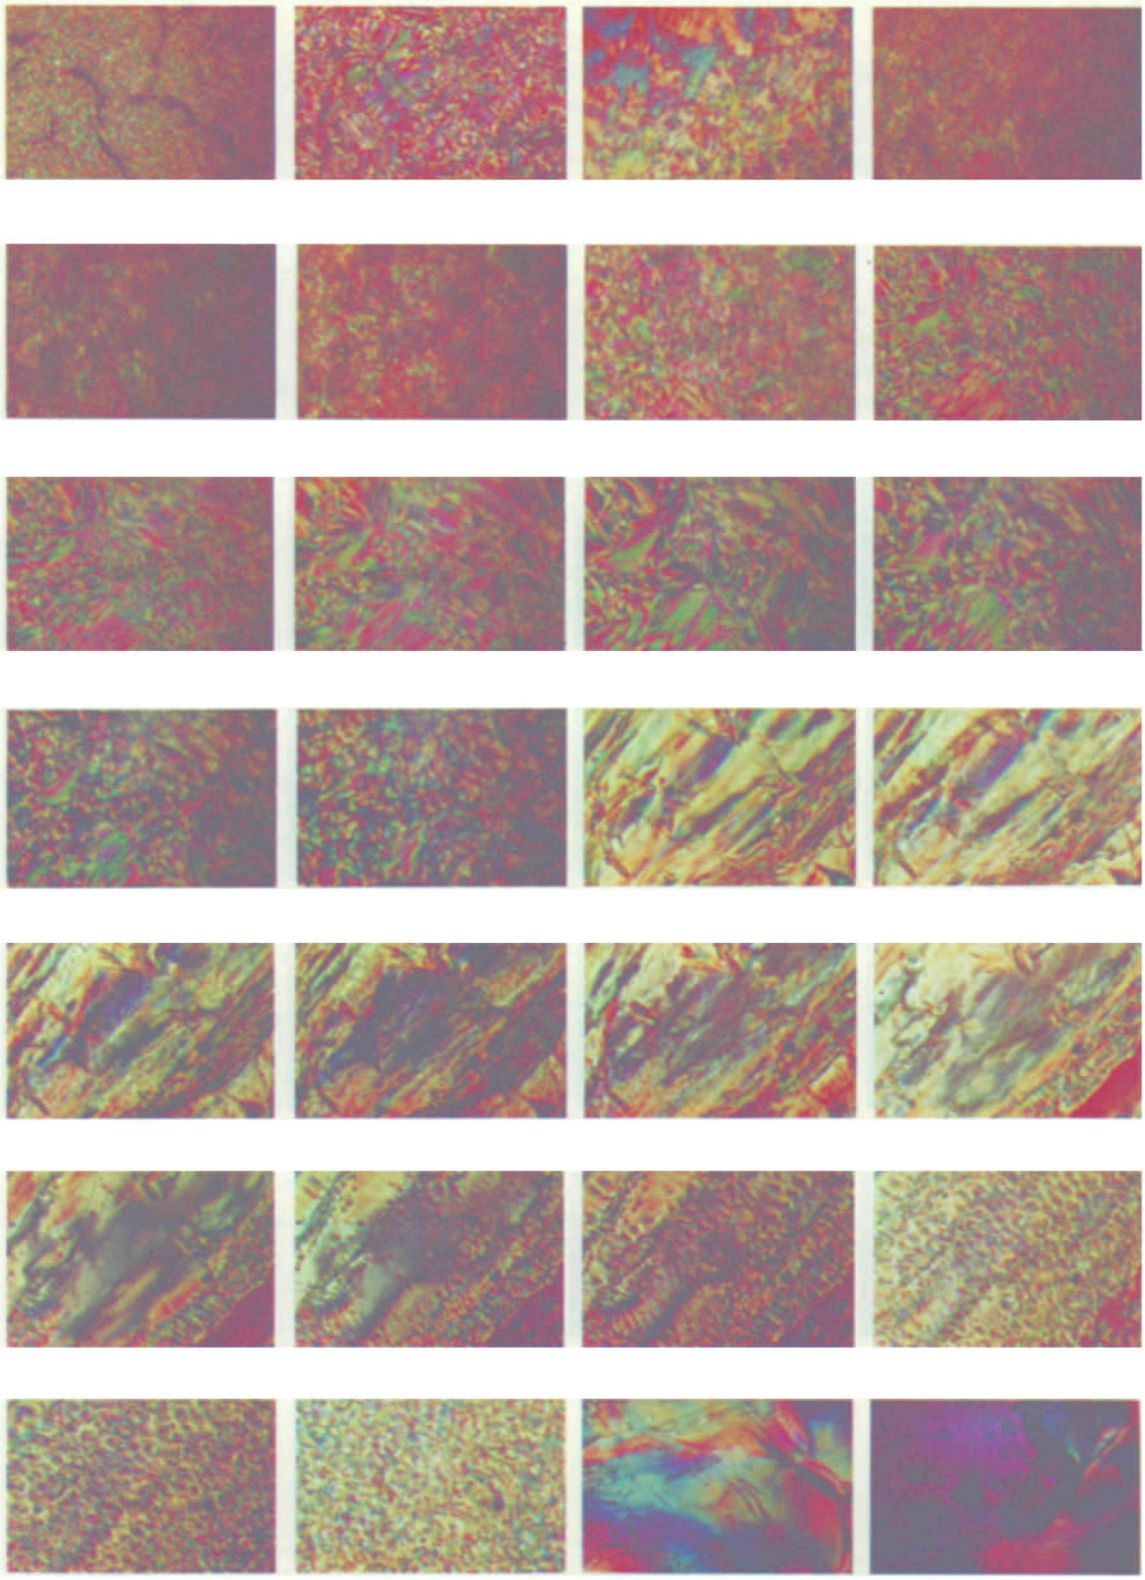
We found locally the state of solid-III at room temperature as shown in Fig. 6-28. It might be a glassy solid-state. Figures 6-29 to 6-43 show the microscopic photographs for solid-III (Fig. 6-27) corresponding to the DTA curve of Run-3 in Fig. 5. The established smectic-state(Fig. 6-35) was transformed into the cholesteric-state by way of establishing the spherical-state (Figs. 6-36 to 6-40). The thermal behavior was also observed on the DTA curve in Fig. 5 (compare with Runs-1 and 3). The obtained cholesteric-state (Fig. 6-43) is much the same as shown in Figs. 6-14 and 6-26.

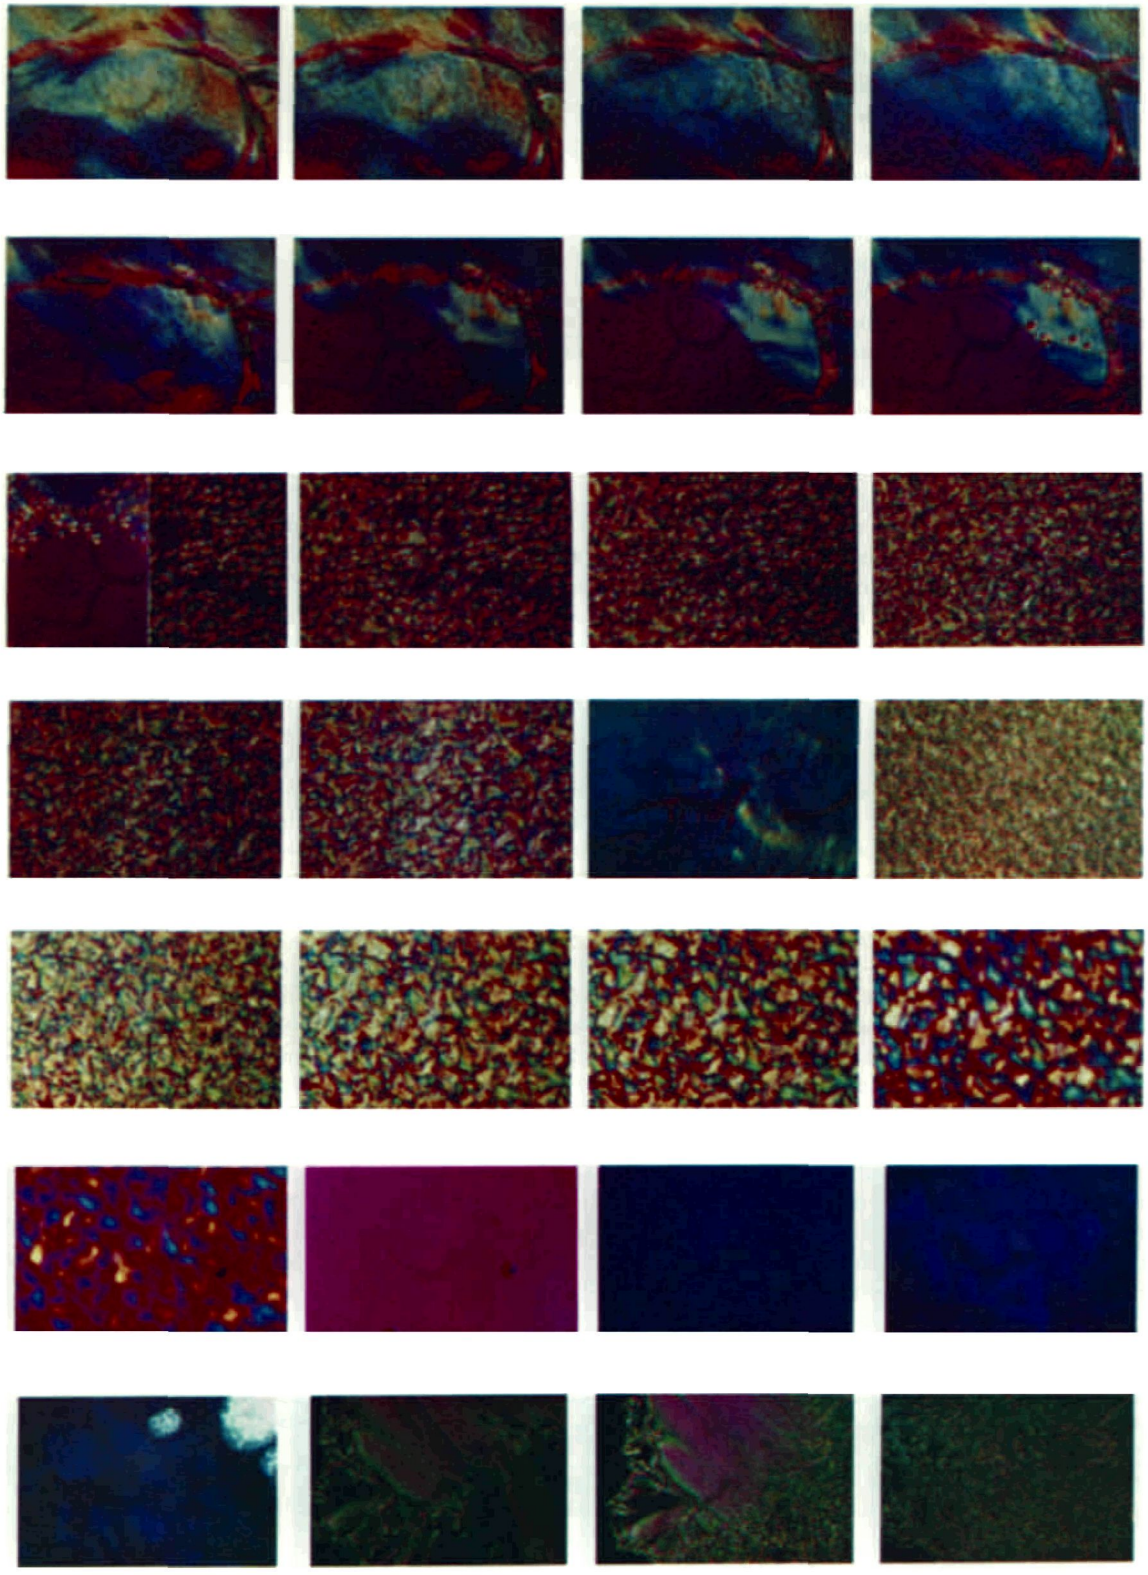
We see from Figs. 5 and 6 that there is some difference between the thermal behavior of solids-I, II and III not only in the solid-to-smectic transition but also in the smectic-to-cholesteric one. However, no difference was observed in the cholesteric-to-isotropic liquid transition between solids-I, II and III. The transition for solid-II is shown by the DTA curve for Run-4 in Fig. 5 and by the microscopic photographs (Figs. 6-46 to 6-51). The cholesteric-state of cholesteryl myristate (Fig. 6-46) is a state in which spherical-liqud crystals (Figs. 6-37 to 6-39) stick to each other. It might be assumed that the difference in color between the yellow part and the blue part corresponds to the molecular orientation of the block, the red part being similar to the isotropic liquid state. The red part spreads with the progress of cholesteric-to-isotropic liquid transition.

Figures 6-44 and 6-45 give microscopic photographs

Table 1. Transition temperatures and enthalpy ratios of transition for cholesteryl myristate

	Heating rate (°C min^{-1})	$t_{solid\text{-}to\text{-}smectic}$ (°C)	$t_{smectic\text{-}to\text{-}cholesteric}$ (°C)	$t_{cholesteric\text{-}to\text{-}isotropic}$ (°C)
Solid-I	1.73	68.8	77.3	82.8
	0.89	68.4	76.8	82.1
Annealed solid	1.79	70.3	78.5	83.7
	0.90	68.7	77.0	82.0
	Heating rate (°C min^{-1})	ΔH-ratio (solid-to-smectic)	ΔH-ratio (smectic-to-cholesteric)	ΔH-ratio (cholesteric-to-isotropic)
Solid-I	1.73	47.0 (95.6%)	1.2 (2.4%)	1.0 (2.0%)
	0.89	43.5 (95.1%)	1.2 (2.7%)	1.0 (2.2%)
Annealed solid	1.79	39.4 (93.7%)	1.7 (3.9%)	1.0 (2.4%)
	0.90	34.2 (91.2%)	2.3 (6.1%)	1.0 (2.7%)
Griffen and Porter[7]	—	45.4 (95.0%)	1.4 (2.9%)	1.0 (2.1%)





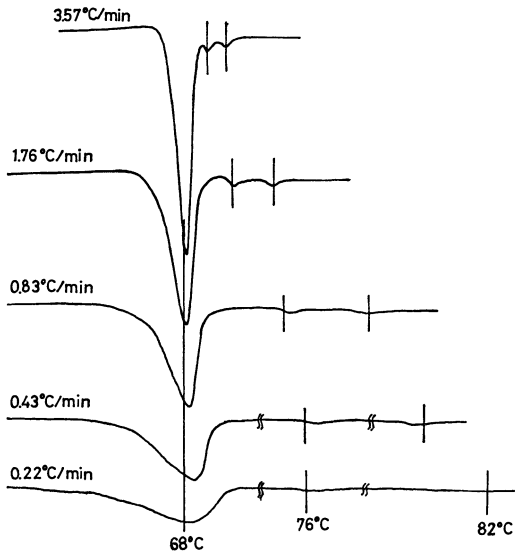


Fig. 7. DTA curves obtained at various heating rate of solid-I.

of the smectic and cholesteric states established by heating the specimen of the solid-state obtained by heating solid-I from room temperature to the maximum point of the solid-to-smectic transition and by cooling to 42.5 °C at a rate of *ca.* 0.22 °C min^{-1}. It is suggested that on the basis of molecular configuration solid-I is a frozen-in solid state of cholesteric-state(compare Figs. 4-1 and 6-45), the annealed solid (Fig. 4-12) is a frozen-in solid state of smectic-state (Fig. 6-44), and solid-II is a mixed state of these solids (compare Figs. 6-8, 6-22 and 6-44).

Cooling Process. All states obtained during the course of heating were also observed in the course of cooling the specimen from isotropic liquid-state to solid-state.

Figures 6-52 to 6-54 show the process of isotropic-to-cholesteric transition at such a slow cooling rate that no DTA curve can be observed. The blue color turns light with the thickness of the specimen, probably because of high optical-rotatory power[6] of the cholesteric state. Figures 6-52 to 6-57 were taken without color sensitive plate but with crossed nicols. Figures 6-55 to 6-57 show the microscopic photographs during the course of smectic-to-solid transition. The solid-state became wrinkled horizontally with the width of the rod shaped smectic-block.

Differential Thermal Analysis (DTA). DTA measurements at several heating rates were made for the specimen of solid-I. Figure 7 shows the DTA curves obtained. The changes in the transition temperature due to the discrepancy of heating rate were found to be considerably small. Two measurements of solid-I and annealed-solid were also made at different heating rates. The transition temperature and the enthalpy ratio* of transition are summarized in Table 1.

The transition temperatures from solid to smectic and to cholesteric for the annealed-solid are higher than those for solid-I. The transition temperature from cholesteric to isotropic liquid for the annealed-solid is much the same as that for solid-I. The enthalpy of the solid-to-smectic transition for the annealed-solid is smaller than that for solid-I, the enthalpy of the smectic-to-cholesteric transition for the annealed-solid being larger than that for solid-I.

Topological Index as Applied to π-Electronic Systems. II. Topological Bond Order*

Haruo HOSOYA and Miyuki MURAKAMI

Department of Chemistry, Ochanomizu University, Bunkyo-ku, Tokyo 112

(Received June 24, 1975)

Topological bond order p_l^T is proposed to be defined for a bond l in the graph corresponding to the carbon atom skeleton of a hydrocarbon. This quantity is obtained by hand calculation of the topological indices of the graph and its subgraphs. The p_l^T value is linearly correlated well with the Coulson bond order p_l^C for both the chain and cyclic compounds. If the bonds with the same Pauling bond order p_l^P are compared this linear relationship is greatly improved and one gets an empirical relation as

$$p_l^C = A\,p_l^T + B\,p_l^P .$$

In order to describe the π-electronic distribution on the carbon atom skeleton of a given unsaturated hydrocarbon several bond orders have been proposed, *e.g.*, by Paluing,[1] Coulson,[2] Mulliken,[3] Ham and Ruedenberg,[4] and so on. The Coulson bond order, p_{rs}^C, is obtained from the molecular orbitals of LCAO form as

$$p_{rs}^C = 2\sum_n^m C_{nr}C_{ns} \tag{1}$$

in terms of the notations currently adopted. Because of mathematical neatness let us confine ourselves to the ground state of neutral unsaturated hydrocarbon molecules with even number $[N=2m]$ of π-electrons without any NBMO and let the term "molecular orbital" be meant by the Hückel molecular orbital. The Pauling bond order, p_l^P, is defined in the valence bond method as

$$p_l^P = \frac{K(G\ominus l)}{K(G)}, \tag{2}$$

where $K(G)$ is the number of the Kekulé structures for graph $\boldsymbol{G}$ (composed of points and lines corresponding to the carbon atom skeleton of a hydrocarbon) and the notation $\boldsymbol{G}\ominus l$ stands for the subgraph of $\boldsymbol{G}$ obtained by deleting a bond, say $l(\overline{rs})$, together with all the bonds adjacent to l. The value $K(G\ominus l)$ is equal to the number of the Kekulé structures for $\boldsymbol{G}$ such that a double bond is assigned to l. This means that the Pauling bond order is the weight of a bond in the graph with respect to a set of the Kekulé structures.

Ham has given an ingenious proof[5] that the molecular orbital (MO) and valence bond (VB) methods are rigorously connected to each other through the bond order p_{rs}^{HR} as defined by

$$p_{rs}^{HR} = 2\sum_n^m \frac{C_{nr}C_{ns}}{X_n},^{4)} \tag{3}$$

where X_n is the eigenvalue of the secular equation, or the root of the characteristic polynomial

$$P_G(X) = (-1)^N \det|\boldsymbol{A}-X\boldsymbol{E}| = \sum_{k=0}^N a_k X^{N-k}. \tag{4}$$

Here $\boldsymbol{A}$ and $\boldsymbol{E}$ are respectively the adjacency and unit matrices of graph $\boldsymbol{G}$. It was shown that for alternant hydrocarbons without any $4n$-membered ring the MO expression p_{rs}^{HR} is identical to the VB expression p_l^P,

$$p_{rs}^{HR} = p_l^P \qquad (l=\overline{rs}).^{5)} \tag{5}$$

Aside from the two main streams (MO and VB) of the electronic theory the topological or graph-theoretical approach is now being realized as a powerful and perspective tool for understanding the nature of the several properties of molecules.[6,7] In this paper a topological bond order, p_l^T, is proposed to be defined as

$$p_l^T = \frac{Z_{G\ominus l}}{Z_G}, \tag{6}$$

where Z_G is the topological index for graph $\boldsymbol{G}$. The topological index is an integer assigned to a graph for characterizing the topological nature of the graph and will be explained later in detail. It will be shown that p_l^T is correlated well with all the bond orders described above. One can roughly estimate the relative magnitudes of the bond orders quite easily with a "paper and pencil" manipulation for the graph.

Topological Index

Consider a graph ($\boldsymbol{G}$) composed of linearly connected six points, which may be the carbon atom skeleton of *n*-hexane or 1,3,5-hexatriene (I) (See Table 1). A non-adjacent number $p(G, k)$ is defined as the number of ways in which k disconnected lines are chosen from G, $p(G, 0)$ being defined as unity for all the graphs. It has been shown that for a tree graph, *i.e.*, a graph without any ring, the coefficients of the characteristic polynomial is equal to $p(G, k)$ numbers as

$$P_G(X) = \sum_{k=0}^m (-1)^k p(G,k) X^{N-2k} \quad (\boldsymbol{G}\in\text{Tree}).^{6)} \tag{7}$$

Especially for linear graph $\overline{N}$ composed of consecutive N points we have

$$P_{\overline{N}}(X) = \sum_{k=0}^m (-1)^k \binom{N-k}{k} X^{N-2k}. \tag{8}$$

These are special cases of a more general relation for non-tree graphs between the $p(G, k)$ and $P_G(X)$,

$$P_G(X) = \sum_{R_i\in G}\sum_{k=0}^{m_i} (-2)^{r_i}(-1)^k p(G\ominus R_i, k) X^{N-n_i-2k} \tag{9}$$

where R_i runs over all the sets of $r_i(\geq 0)$ disjoint rings with a total of $n_i(\geq 0)$ points.[7,8] This relation is

* The first paper of this series is, H. Hosoya, K. Hosoi, and I. Gutman, "A Topological Index for the Total π-Electron Energy. Proof of a Generalised Hückel Rule for an Arbitrary Network," *Theor. Chim. Acta*, **38**, 37 (1975).

Table 1. Physical meaning of the topological index as exemplified by graph $\bar{6}$.

k	l 1 2 3 4 5	p(G,k)	p(G-1,k)
0	x x x x x	1	1
1	o x x x x	5	4
	x o x x x		
	x x o x x		
	x x x o x		
	x x x x o		
2	o x o x x	6	3
	o x x o x		
	o x x x o		
	x o x o x

	x x o x o		
3	o x o x o	1	0
	5 3 4 3 5 $Z_{G\ominus l}$	13 Z_G	8 Z_{G-1}

equivalent to the more compact one derived independently by Sachs

$$P_G(X) = \sum_{n=0}^{N} \sum_{s\in S_n} (-1)^{c(s)}\, 2^{r(s)}\, X^{N-n} \tag{10}$$

where s runs over all the Sachs graph composed of n points, $c(s)$ components and $r(s)$ rings.[9-11] However, Eq. (9) has more advantage over and is more practical than Eq. (10) in that useful recursive relations which will be described later are known to get the $p(G,k)$ numbers for larger graphs.

The value $p(G, 1)$ is nothing else but the number of lines in $\boldsymbol{G}$. As illustrated in Table 1 for I ($=\bar{6}$) there are six different ways in which two disconnected lines are chosen and we have $p(G, 2)=6$. There is only a unique choice of three disconnected lines for $\boldsymbol{G}$ and one gets $p(G, 3)=1$, the maximum number m of k for I being three. This means graph I has only one Kekulé structure.

The topological index is the sum of the $p(G, k)$ numbers of a given graph as

$$Z_G = \sum_{k=0}^{m} p(G,k). \tag{11}$$

For tree graphs Z_G is the sum of the absolute values of the coefficients of the characteristic polynomial.

$$Z_G = \sum_{k=0}^{N} |a_k| = \sum_{k=0}^{m} |a_{2k}| \qquad (\boldsymbol{G}\in\text{tree}). \tag{12}$$

For later discussions it is convenient to define the Z-counting polynomial $Q_G(Y)$ as

$$Q_G(Y) = \sum_{k=0}^{m} p(G,k)\, Y^k. \tag{13}$$

With this polynomial the topological index is expressed as

$$Z_G = Q_G(1). \tag{14}$$

For graph I in Table 1 we have

$$Q_{\bar{6}}(Y) = 1 + 5Y + 6Y^2 + Y^3 \tag{15}$$

and $Z_{\bar{6}}=13$. Extensive tabulation on the quantities $p(G, k)$, Z_G, and $P_G(X)$ are given elsewhere.[12-14]

Let such a subgraph of $\boldsymbol{G}$ be denoted as $\boldsymbol{G}$-l that is derived by deleting bond l. The polynomial $Q_G(Y)$ is expressed as

$$Q_G(Y) = Q_{G-l}(Y) + Y\cdot Q_{G\ominus l}(Y). \tag{16}$$

If graph $\boldsymbol{G}$ is decomposed into fragments $\boldsymbol{L}$, $\boldsymbol{M}$, ... by the deletion of l,

$$\boldsymbol{G} - l = \boldsymbol{L} \cup \boldsymbol{M} \cup \cdots \tag{17}$$

$$\boldsymbol{L} \cap \boldsymbol{M} \cap \cdots = 0, \tag{18}$$

the polynomial $Q_{G-l}(Y)$ reduces to their product

$$Q_{G-l}(Y) = Q_L(Y)\cdot Q_M(Y)\cdots \tag{19}$$

and so does $Q_{G\ominus l}(Y)$.

For the topological index we have

$$Z_G = Z_{G-l} + Z_{G\ominus l} \tag{20}$$

$$Z_{G-l} = Z_L\cdot Z_M \cdots \tag{21}$$

Note that Eqs. (16) and (20) hold true irrespective of the choice of l.

As a special case the Z-counting polynomials $Q_G(Y)$'s of a series of graphs $\bar{N}$ recurse as

$$Q_{\bar{N}}(Y) = Q_{\bar{N-1}}(Y) + Y\cdot Q_{\bar{N-2}}(Y) \qquad (N\geq 2) \tag{22}$$

$$Q_{\bar{0}}(Y) = Q_{\bar{1}}(Y) = 1, \tag{23}$$

and their topological indices $Z_{\bar{N}}$'s form the well-known Fibonacci numbers (1,1,2,3,5,8,13 ...) as

$$Z_{\bar{N}} = Z_{\bar{N-1}} + Z_{\bar{N-2}} \qquad (N\geq 2) \tag{24}$$

$$Z_{\bar{0}} = Z_{\bar{1}} = 1. \tag{25}$$

A number of interesting mathematical relations are derived for $Q_G(Y)$ and Z_G.[6,15]

Topological Bond Order

The value Z_G may be regarded as the total number of ways in which disconnected double bonds are assigned onto the single bond skeleton of $\boldsymbol{G}$ as in Table 1, where a 13×5 matrix is constructed with elements o and x corresponding respectively to double and single bonds. Each row forms a set of disconnected double bonds and the number of rows gives the topological index Z_G. Then this number is thought to represent the degree of choice for distributing π-electrons over the molecular skeleton $\boldsymbol{G}$. The mode of π-electron population will then be dependent on the topology of molecules.

Choose any bond l from $\boldsymbol{G}$, say bond 1 from this graph. Then the Z_G sets of disconnected double bonds are divided into two groups, according to such a criterion that bond l is chosen as double (l-inclusive) or not (l-exclusive). The numbers of these two groups are denoted respectively as Z_G (l-inclusive) and Z_G (l-exclusive) and we have

$$Z_G = Z_G(l\text{-inclusive}) + Z_G(l\text{-exclusive}). \tag{26}$$

They are obtained respectively as the numbers of o and x's in the given column l. In this case ($l=1$) one gets $Z_G(l\text{-inclusive})=5$ and $Z_G(l\text{-exclusive})=8$. It is to be noted that each set of disconnected double bonds in the latter group appears once and only once in counting the value of Z_{G-l} (See the double rectangles in

Table 2. Comparison of the topological and Coulson bond orders for an isomer II of tetradecaheptaene[a)]

Bond type	Bond[a)] l	$Z_{G\ominus l}$[b)]	p_l^c approx.[c)]	p_l^c exact
Single bond	f	70	0.387	0.389
	b	75	0.400	0.400

	a	200	0.915	0.913

a) See Fig. 1. b) $p_l^\tau = Z_{G\ominus l}/Z_G$, $Z_G = 475$ for this graph. c) For single bonds: $0.002636\ Z_{G\ominus l} + 0.2020$, for double bonds: $0.002697\ Z_{G\ominus l} + 0.3757$.

Table 1). It means

$$Z_{G-l} = Z_G(l\text{-exclusive}). \tag{27}$$

Now by combining Eqs. (20), (26), and (27) one gets

$$\begin{aligned} Z_G(l\text{-inclusive}) &= Z_G - Z_{G-l} \\ &= Z_{G\ominus l}\,. \end{aligned} \tag{28}$$

The quantity Z_G (l-inclusive), or $Z_{G\ominus l}$, can then be considered as the weight of bond l in distributing π-electrons over G, and the topological bond order for l in G may be defined as Eq. (6).

In what follows a number of examples will be given of the good correlation between p_l^c and p_l^τ or $Z_{G\ominus l}$. In Table 2 and Fig. 1 the values of p_l^c and $Z_{G\ominus l}$ for an unsaturated hydrocarbon isomer II with 14 electrons

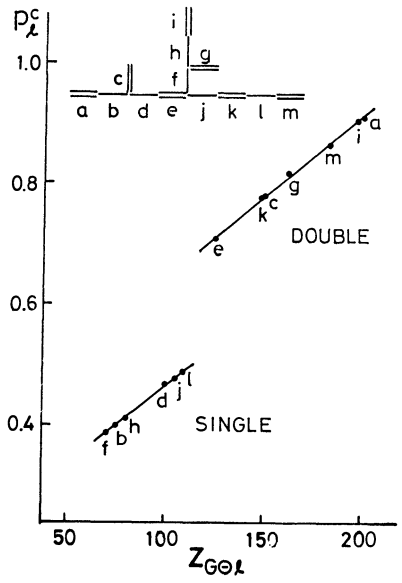

Fig. 1. Linear relationships between the Coulson bond order p_l^c and the topological bond order $p_l^\tau = Z_{G\ominus l}/Z_G$. The Z_G value for this graph (II) is 475. See also Table 2.

are compared. Note that two different sets of linear relationships are observed respectively for the bonds marked with "single" and "double" in the Kekulé structure. A procedure for obtaining the $Z_{G\ominus l}$ values with the recursive relations (20) and (21) is exempli-

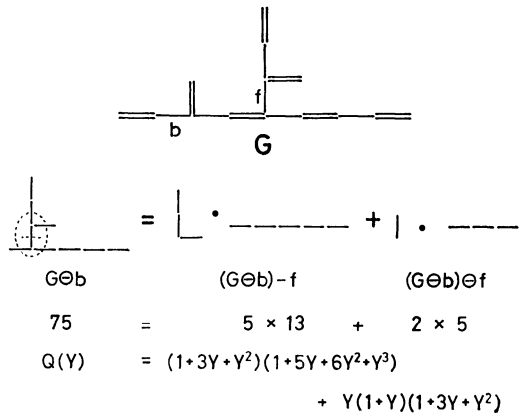

Fig. 2. The procedure for obtaining the topological index Z_G and the Z-counting polynomial $Q_G(Y)$ as exemplified by the subgraph $G\ominus b$ of the graph given in Fig. 1. Bond f is chosen to decompose the graph into fragments.

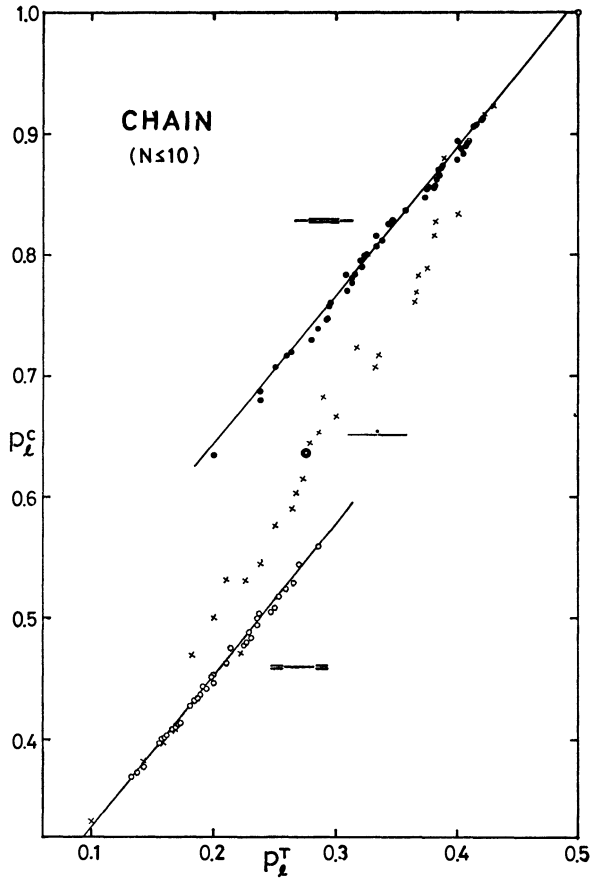

Fig. 3. Plots of p_l^c and p_l^τ values for all the possible isomers of polyenes not larger than decapentaene. ○: single bond, ●: double bond, x: bond in a radical, ◎: limiting bond order ($p_l^c = 0.6366$ and $p_l^\tau = 0.2764$) of an infinite polyene (See Eqs. (29)—(31), (40), (43)).

fied in Fig. 2 for bond b in the graph concerned, where bond f is chosen to decompose the graph into fragments. The topological indices of the fragmental graphs are given as the Fibonacci numbers or their combinations. The procedure is simple and easy enough for hand calculation but the result is surprizingly predictable.

Figure 3 gives the plots of p_l^c and p_l^τ for all the possible isomers of chain polyenes with not more than ten carbon atoms. The circles for the "single" (open) and "double" (filled) bonds in even-numbered polyenes with singlet ground states lie respectively on the two parallel lines, while for radicals (marked with crosses) the points lie on a line spanning from the "single bond line" over to the "double bond line" in Fig. 3. Two different classes of radicals are involved in this category, *i.e.*, even-numbered polyenes with a triplet ground state as III and odd-numbered polyenes with a doublet or higher multiplet ground state as IV. Thus for

III IV

chain polyenes or hydrocarbon radicals the Coulson bond order p_l^c can be estimated fairly accurately by hand calculation of p_l^τ value and bond type (single, double, or radical) classification. Tentatively from the set of points in Fig. 3 the following relations were obtained for the three classes of bonds.

$$p_l^c = 1.24\,p_l^\tau + 0.392 \quad (l=\text{double bond}) \tag{29}$$

$$p_l^c = 1.24\,p_l^\tau + 0.200 \quad (l=\text{single bond}) \tag{30}$$

$$p_l^c = 1.67\,p_l^\tau + 0.164 \quad (l=\text{bond in a radical}). \tag{31}$$

It is interesting to note that the topological bond orders of a linear polyene oscillate by going from the terminal to the center and converge to a limit as predicted by the p_l^c value. This is demonstrated in Fig. 4 for 1,3,5,7,9,11,13-tetradecaheptaene. For an infinite polyene p_l^τ and p_l^c values converge to $(5-\sqrt{5})/10=0.2764$ and $2/\pi=0.6366$ respectively (See Appendix), the speed of convergence of the former being much faster. Thus it is expected that for higher members of chain polyenes the relations (29)—(31) are getting worse as shown in Fig. 5, where p_l^τ and p_l^c values for linear polyenes larger than decapentaene are plotted. This is the limitation of the topological bond order for chain compounds.

For cyclic compounds there is no rigorous one-to-one correspondence between the coefficients of $P_G(X)$ (Eq. (7)) and $Q_G(Y)$ (Eq. (13)) polynomials as inferred from Eq. (9). Then correlation between p_l^c and p_l^τ values is not expected as good as what is

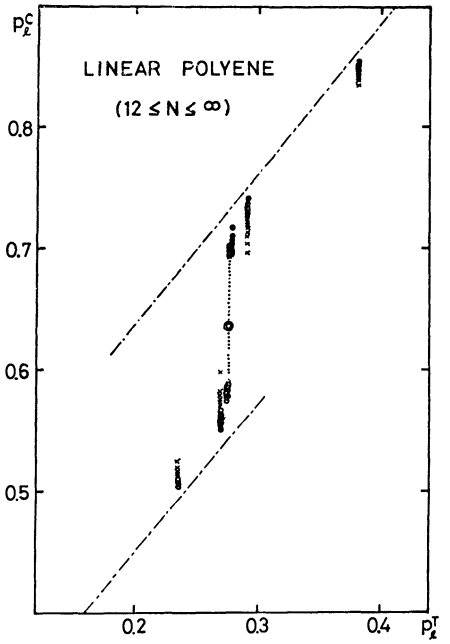

Fig. 5. Plots of p_l^c and p_l^τ values for larger linear polyenes ($N>10$). In the dotted line region a number of circles and crosses are crowded. The two parallel lines are the "single" and "double bond lines" in Fig. 3. Other marks are the same as used in Fig. 3.

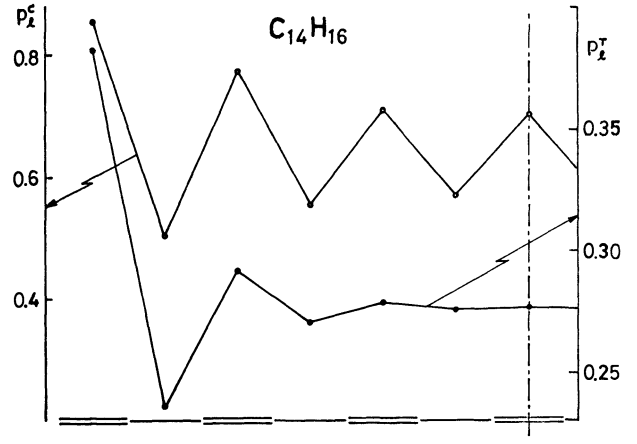

Fig. 4. Zig-zag nature of the Coulson and topological bond orders for a linear polyene (1,3,5,7,9,11,13-tetradecaheptaene).

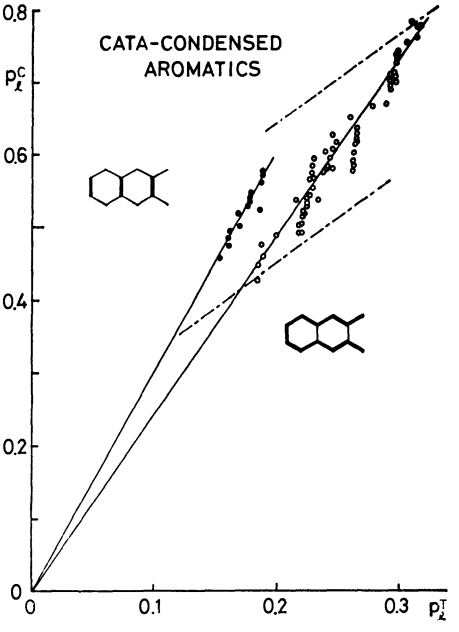

Fig. 6. Plots of p_l^c and p_l^τ values for cata-condensed aromatic hydrocarbons not larger than pentacene. ●: bridge bond, ○: peri-bond.

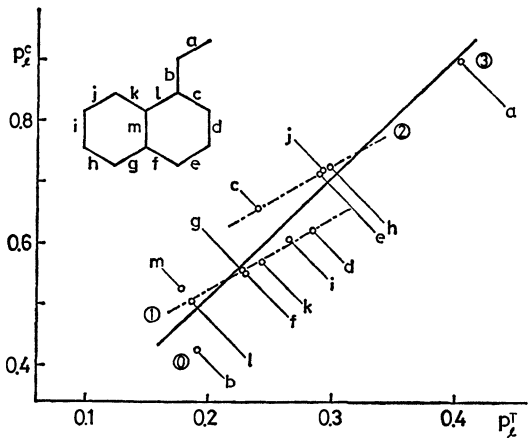

Fig. 7. Correlation between the p_l^C and p_l^T values of 1-vinylnaphthalene. The number in the circle indicates the $K(G\ominus l)$

shown in Figs. 1 and 3. In Fig. 6 are plotted the p_l^C and p_l^T values for cata-condensed aromatic hydrocarbons not larger than pentacene. Almost all the points lie within the region between the two parallel lines for single and double bonds in Fig. 3 and are grouped into two parts. The filled and open circles respectively correspond to the "bridge" and "peri-bonds". Both the classes of points lie on the respective lines passing through the origin. The linearity of these two classes of points is not so good as that of small polyenes (Fig. 3) but is unexpectedly good if one thinks of a simple procedure for getting the p_l^T values. Further, on the contrary to the chain compounds, the larger the cyclic graphs the better the correlation between p_l^C and p_l^T values as shown in Fig. 7 for 1-vinylnaphthalene. The thirteen points lie around a straight bold line. Inspection of this figure reveals an interesting feature of the correlation between p_l^C and p_l^T values. That is, the "corner bonds" (c, e, h, and j) lie perfectly on a straight line, while the "side bonds" (d, f, g, i, k, and l) lie on another line parallel to the former. The point for the "bridge bond" m is located nearby the latter line. Note that the unnormalized Pauling bond orders p_l^P's, *i.e.*, $K(G\ominus l)$ defined in Eq. (2), of these two groups of bonds are respectively two and one. The $K(G\ominus l)$ values of bonds a and b are respectively three and zero. Similar relations have been found in Eqs. (29)—(31).

Now it is empirically induced that for a certain group of molecules or for a group of bonds in a certain molecule the following relation is generally observed,

$$p_l^C = A\,p_l^T + B\,p_l^P. \tag{32}$$

This will be mathematically proved in a forthcoming paper by the use of an integration over the complex plane.[7,16]

Recently it is discussed which of the bond orders p_l^C and p_l^P is correlated better with the bond length.[17,18] However, as the aim of the present paper is to show the relation between these bond orders, much will not be discussed on this problem. Table 3 gives the comparison of the bond lengths and various bond orders for coronene. This is one of the cases where the topological bond order shows the best correlation

Table 3. Comparison of the bond lengths and various bond orders for coronene

with the experimentally obtained bond lengths.

Appendix

The Limiting Values of the Topological Bond Order p_l^T.

Consider a polyene $\overline{N}$ with N consecutive points linearly connected. The topological bond order p_l^T of the l-th bond from one of the terminals is given by Eq. (6) as

$$p_l^T = \frac{Z_{\overline{N}\ominus l}}{Z_{\overline{N}}}. \tag{33}$$

Note that graph $\overline{N}\ominus l$ has two component graphs $\overline{l-1}$ and $\overline{N-l-1}$.

Then we have

$$Z_{\overline{N}\ominus l} = Z_{\overline{l-1}} \times Z_{\overline{N-l-1}}. \tag{34}$$

The $Z_{\overline{N}}$ series form the Fibonacci numbers and is expressed by the Binét's formula as

$$Z_N = (\alpha^{N+1} - \beta^{N+1})/\sqrt{5} \tag{35}$$

where

$$\alpha = (1+\sqrt{5})/2$$

and

$$\beta = (1-\sqrt{5})/2.^{6)} \tag{36}$$

From Eqs. (33)—(36) one gets

$$p_l^T = \frac{1}{\sqrt{5}\,\alpha}\,\frac{1-X^l+X^N(1-X^{-l})}{1-X^{N+1}} \tag{37}$$

where

$$X = \beta/\alpha = (\sqrt{5}-3)/2 = -0.38197. \tag{38}$$

For larger N Eq. (37) reduces to

$$p_l^T \to (1-X^l)/(\sqrt{5}\,\alpha) \tag{39}$$

which oscillates by going from the terminal ($l=1$) to the center ($l\to\infty$) and finally reaches

$$p_l^T \to 1/(\sqrt{5}\,\alpha) = (5-\sqrt{5})/10 = 0.27639. \tag{40}$$

This behavior of p_l^T corresponds to that of p_l^C as expressed by

$$p_l^C = \frac{1}{N+1}\left\{\operatorname{cosec}\frac{\pi}{2N+2} + (-1)^{l-1}\operatorname{cosec}\frac{(2l+1)\pi}{2N+2}\right\} \quad (N=\text{even}) \tag{41}$$

$$p_l^c = \frac{1}{N+1}\left\{\cot\frac{\pi}{2N+2} + (-1)^{l-1}\cot\frac{(2l+1)\pi}{2N+2}\right\}$$

$$(N=\text{odd}).^{19)} \quad (42)$$

Namely, since for larger N $\operatorname{cosec}\theta$ and $\cot\theta$ converge to θ^{-1}, one gets

$$p_l^c \to \frac{2}{\pi}\left\{1+(-1)^{l-1}\frac{1}{2l+1}\right\} \to 2/\pi = 0.63662. \quad (43)$$

Competition of the Two Reaction Mechanisms of Maleic Anhydride Formation in Vapor-Phase Oxidation of Butadiene over Supported Molybdena Catalysts

Masamichi Akimoto and Etsuro Echigoya

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 25, 1975)

Vapor-phase oxidation of butadiene, 2,5-dihydrofuran and furan over supported molybdena catalysts has been investigated with reference to the reaction mechanism and the rate-determining step of maleic anhydride formation from butadiene. Formation of maleic anhydride during the oxidation of butadiene was found to follow two reaction mechanisms, (a) *via* 2,5-dihydrofuran and furan, and (b) *via* 2,5-dihydrofuran but not *via* furan. The energy barrier for the addition of oxygen species to adsorbed butadiene or furan is very high, *i.e.*, 28.9 or 21.9 kcal/g-mol, respectively, as compared to that for the oxidative dehydrogenation of the intermediate compounds such as 2,5-dihydrofuran. Formation of 2,5-dihydrofuran is rate-determining in these mechanisms during the oxidation of butadiene to maleic anhydride. The second mechanism plays a more important role in maleic anhydride formation at low temperatures, the role of the first mechanism increasing with a rise in the reaction temperature.

The increasing technical importance of maleic anhydride has strongly stimulated interest in its production by the direct oxidation of C_4-fraction obtained from petroleum. Many attempts to oxidize butane, butenes, and butadiene with gaseous oxygen, forming maleic anhydride, have been made, but most of them have been mainly devoted to the development of new catalysts.[1] In contrast, there are only a few studies on the mechanism and the rate-determining step for anhydride formation.[2] Ai, Harada, and Suzuki[3] studied extensively the vapor-phase oxidation of *n*-butenes to maleic anhydride over P_2O_5–V_2O_5 catalyst and concluded that the anhydride is formed *via* butadiene and furan. However, the exact mechanism and the rate-determining step have not yet been clarified.

In previous studies on the vapor-phase oxidation of butadiene over supported molybdena catalysts, it was shown that the selectivity for maleic anhydride formation is strongly affected not only by the kind of oxygen species formed on molybdenum ion but also by the nature of adsorbed butadiene species and that 2,5-dihydrofuran is the first intermediate compound for the anhydride formation from butadiene.[4,5] Thus, it is meaningful to study the oxidation of butadiene, 2,5-dihydrofuran, and furan over supported molybdena catalyst with reference to the reaction path for maleic anhydride formation in the oxidation of butadiene. Detailed investigation of these oxidation reactions has been made over various molybdena catalysts followed by the prediction of the reaction mechanism for anhydride formation. The reaction step for maleic anhydride formation at which the energy barrier is highest was also determined.

Experimental

The apparatus and procedure used for the oxidations were the same as those reported,[5] except that 2,5-dihydrofuran and furan were evaporated by bubbling air through the liquids cooled with ice-water followed by dilution with a large amount of air and then by introduction of the mixtures into the reactor. As reactants, very pure butadiene, reagent grade 2,5-dihydrofuran and furan were used.

Various supported molybdena catalysts and molybdena-titania modified with 5B group element were prepared by the method reported.[5,6]

The gaseous effluent from the reactor was analyzed by gas chromatography. PEG 20 M 20 wt% on Neopak 1 A (80 °C, 2,5-dihydrofuran, furan, acrolein), propylene carbonate 40 wt% on Celite 545 (room temp, butadiene, carbon dioxide) and molecular sieve 13X (room temp, carbon monoxide, nitrogen, oxygen) were used as separating columns. Since maleic anhydride was the only acid obtained, the product was absorbed into water followed by titration with an aqueous solution of sodium hydroxide using a pH meter, after boiling off carbon dioxide.

Results and Discussion

Reaction Mechanism for Maleic Anhydride Formation. Anatase-type titania is a very good carrier for molybdena catalyst in vapor-phase oxidation of butadiene to maleic anhydride, in contrast with alumina and magnesia and a maximum activity and selectivity is obtained at a molybdena content of 25 mole%.[4] In order to predict the intermediate compound for anhydride formation, the effects of the contact time on the selectivity to maleic anhydride formation and on the distribution of the reaction products were

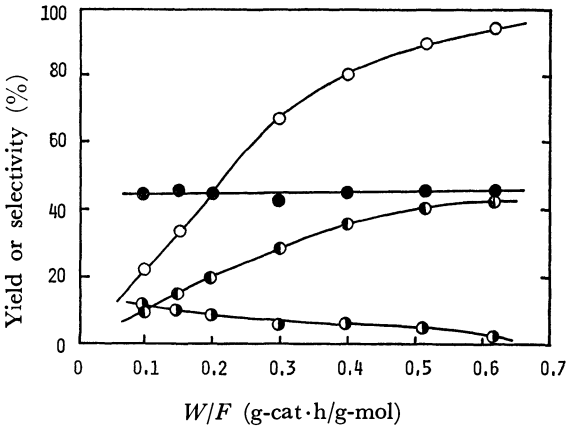

Fig. 1. Effect of the contact time on the distribution of the products in the oxidation of butadiene. Cat.: MoO_3–TiO_2–Sb_2O_3 [MoO_3/TiO_2=1/3, Sb/Mo=15 atom%], reaction temp: 380 °C, butadiene: 1.50 vol% in air, ○: conversion of butadiene, ◐: yield of (CO_2+CO), ●: selectivity to maleic anhydride, ◑: selectivity to furan

investigated with MoO_3–TiO_2 (1 : 3 mole ratio) catalyst modified with a small amount of antimony oxide at 380 °C and butadiene 1.50 vol% in air. The result obtained is graphically represented in Fig. 1. 2,5-Dihydrofuran is hardly obtained in the oxidation. Formation of a small amount of furan is observed in the reaction product. Increase in the contact time results in a decrease of selectivity for furan formation in contrast with conversion of butadiene and yield of (CO_2+CO), but the selectivity for maleic anhydride remains almost unchanged. For the sake of comparison, the oxidation of furan over MoO_3–TiO_2 (1 : 3) catalyst was carried out. The results obtained are summarized in Table 1. It seems that furan is easily converted into the anhydride at 380 °C. Thus, furan formed is possibly oxidized consecutively to the anhydride during the course of oxidation of butadiene at this temperature. However, if furan is an intermediate compound for the anhydride formation, it is expected that the selectivity for maleic anhydride is enhanced with decrease in the slectivity for furan formation. This is not in line with the results shown in Fig. 1. They suggest that furan is an intermediate compound for maleic anhydride formation from butadiene (denoted by mechanism A) in accordance with the result of earlier workers[3)] and also the presence of a reaction path through which the anhydride is formed not *via* furan (denoted by mechanism B).

As 2,5-dihydrofuran was already assumed to be the first intermediate for the anhydride formation from butadiene, it is very likely that furan is formed as a result of oxidative dehydrogenation of 2,5-dihydrofuran produced during the course of oxidation of butadiene over the molybdena catalyst. For the purpose of confirming this assumption, oxidation of 2,5-dihydrofuran was carried out over unsupported Bi_2O_3–MoO_3 (1 : 2) catalyst, *i.e.*, a typical catalyst for oxidative dehydrogenation of butenes to butadiene, and MoO_3–TiO_2 (1 : 3) catalyst with reference to the formation of furan (Table 2). The selectivity for furan formation over the Bi_2O_3–MoO_3 catalyst is very high, in contrast with that over the MoO_3–TiO_2. This can be attributed to the different nature of the catalysts, *viz.*, the latter catalyst has the ability of oxidizing 2,5-dihydrofuran to maleic anhydride in addition to oxidative dehydrogenation even at low temperatures. The results show definitely the formation of furan by oxidative dehydrogenation of 2,5-dihydrofuran produced during the oxidation of butadiene.

For the sake of clarifying the difference between mechanisms A and B, vapor-phase oxidation of 2,5-dihydrofuran was studied in detail using MoO_3–TiO_2 (1 : 3) catalyst. Figures 2 and 3 show the effect of the contact time and that of the reaction temperature on the distribution of the reaction products in the oxidation of 2,5-dihydrofuran. The selectivity for maleic anhydride formation at 320 °C is found to be

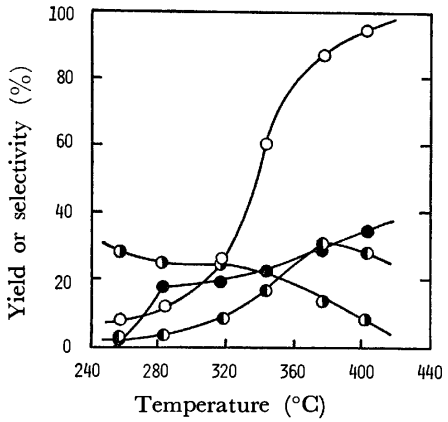

Fig. 3. Effect of the reaction temperature in the oxidation of 2,5-dihydrofuran.
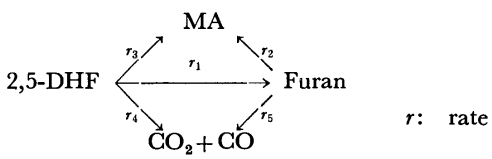
Cat.: MoO_3-TiO_2 (1 : 3), 2,5-dihydrofuran: 1.49 vol% in air, contact time: $W/F=0.377$ [g-cat·h/g-mol], ○: conversion of 2,5-dihydrofuran, ◐: yield of (CO_2+CO), ●: selectivity to maleic anhydride, ◑: selectivity to furan

gradually enhanced with increase in the contact time in contrast with that to furan, which together with the results given in Table 1 give good evidence for the formation of maleic anhydride from 2,5-dihydrofuran *via* furan. A sudden enhancement of selectivity for maleic anhydride formation is observable without a large decrease in the selectivity for furan when the reaction temperature varies from 258 °C to 284 °C, though formation of maleic anhydride in the oxidation of furan is thought to be negligible at these temperatures (Table 1). Mechanism B seems to play an important role in maleic anhydride formation especially at these low temperatures, where furan is not an intermediate compound for the anhydride, being formed immediately from 2,5-dihydrofuran. Selectivity for both maleic anhydride- and furan-formations is almost unchanged at 284—320 °C though an increase in anhydride formation from furan with the rise in temperature is remarkable. This suggests formation of maleic anhydride *via* furan and at the same time not *via* furan as discussed below.



In the reaction path, the selectivities are defined by the following equations.

$$\text{select. to MA}=\frac{r_2+r_3}{r_1+r_3+r_4},\quad \text{select. to furan}=\frac{r_1-r_2-r_5}{r_1+r_3+r_4}$$

Assuming that these rates are independent of the concentration of 2,5-dihydrofuran and furan, if $r_2\fallingdotseq 0$, the overall activation energies in r_1, r_3, r_4, and r_5 are expected to be equal in order to obtain these constant selectivities. However, this condition can not be satisfied. In the case where $r_3\fallingdotseq 0$, the constant selectivities can be obtained so long as the activation energies in r_1, r_2, r_4, and r_5 are equal. The latter condition seems also not to be attained. Thus, it is impossible to deny that maleic anhydride is formed through

Table 3. Kinetic parameters for maleic anhydride formation[a)]

Reactant	Temp range (°C)	α	β	E_{all} (kcal/g-mol)
Butadiene	340—390	−0.17	0.65	28.9
Furan	340—370	0.00	0.49	21.9
2,5-Dihydrofuran	258—320	—	—	17.2

a) Cat.: MoO_3-TiO_2 (1 : 3), α,β: reaction order with respect to the reactant or oxygen, reactant: 1—2.5 vol%, oxygen: 7—20 vol%.

mechanisms A and B at these temperatures. Therefore, the anhydride appears to be formed *via* furan (mechanism A) above 284 °C in addition to the mechanism B, and the role of mechanism A seems to become important with rise in the reaction temperature.

Rate-Determining Step for Maleic Anhydride Formation

For the purpose of determining the reaction step for maleic anhydride formation from butadiene at which the energy barrier is the highest, butadiene, furan and 2,5-dihydrofuran were oxidized over the MoO_3–TiO_2 catalyst by means of a differential method. The kinetic parameters obtained are summarized in Table 3. Yield of furan is larger than that of maleic anhydride in the oxidation of 2,5-dihydrofuran (Fig. 3). It is likely because of the low reaction temperatures that the anhydride is formed mainly from 2,5-dihydrofuran and not *via* furan. Unlike the reaction orders of maleic anhydride formation, a striking difference appears between the overall activation energies for the anhydride formation from butadiene, furan, and 2,5-dihydrofuran. This suggests that the real activation energy for maleic anhydride formation from butadiene is also larger than that from furan and 2,5-dihydrofuran, the energy barrier from 2,5-dihydrofuran being the lowest.

The rates of furan formation in the oxidative dehydrogenation of 2,5-dihydrofuran over the Bi_2O_3–MoO_3 and the MoO_3–TiO_2 catalyst are included with the overall activation energy required for this reaction step in Table 2. The energy barrier for the oxidative dehydrogenation step is very low, *i.e.*, only 6.0—9.5 kcal/g-mol, as compared to that for maleic anhydride formation in the oxidation of butadiene and furan. This is presumably attributed to the larger delocalization of π-electrons even over oxygen atom in the intermediate compound formed by the abstraction of α-hydrogen from 2,5-dihydrofuran. Thus, the energy barrier for hydrogen abstraction from various oxygenated intermediate compounds is expected to be very low. The activation energy 28.9 or 21.9 kcal/g-mol is possibly required for the addition of the selective oxygen species to adsorbed butadiene or furan forming 2,5-dihydrofuran or maybe 5,6-dioxabicyclo[2.1.1]-hex-2-ene, respectively. Hence, it can be said that oxidative dehydrogenation of 2,5-dihydrofuran to furan is not rate-determining because of the very low energy barrier. This is also valid in oxidative dehydrogenation of the bicyclo-compound and other intermediate compounds. This is strongly supported by the absence of 2,5-dihydrofuran and the bicyclo-compound in the reaction product in contrast with furan during the

oxidation of butadiene. Therefore, it can be concluded that the reaction step for maleic anhydride formation from butadiene, at which the energy barrier is the highest, is an addition of the selective oxygen species to adsorbed butadiene followed by 2,5-dihydrofuran formation.

Double bond type lattice oxygen $Mo^{6+}=O$ is selective for maleic anhydride formation and its reactivity as a radical oxygen decreases with the electronegativity of molybdenum ion on which the lattice oxygen is bonded.[4,6] When the molybdena catalyst is modified with a relatively small amount of oxide of 5B group element, the reactivity of the double bond oxygen can be expected to be $Bi_2O_3>Sb_2O_3>As_2O_3>P_2O_5$ as a sequence of modifiers. The oxidation of butadiene was thus studied over MoO_3–TiO_2 (1 : 3) catalysts modified with various 5B group elements by a differential method, and the rate of maleic anhydride formation per unit surface area was carefully measured (Fig. 4). We see that the order of the activities of the catalysts for the anhydride formation is $Bi_2O_3>Sb_2O_3>P_2O_5>As_2O_3$, in line with that of the reactivities of the double bond oxygen in these modified catalysts. This provides further evidence for the above conclusion. Butadiene, furan, and 2,5-dihydrofuran were oxidized over the MoO_3–TiO_2 catalyst by means of a differential method with respect to the reaction temperature at which formation of the anhydride becomes remarkable (Fig. 5). The order in the rate of maleic anhydride formation is 2,5-dihydrofuran>furan>butadiene at 250—320 °C, in line with the sequence of the rate as judged from the height of the energy barrier. A relatively large rate of the anhydride formation is observed even at 258 °C in the oxidation of 2,5-dihydrofuran as compared to furan and butadiene oxidations. Thus, the results strongly suggest the presence of mechanism B through which maleic anhydride is produced not *via* furan.

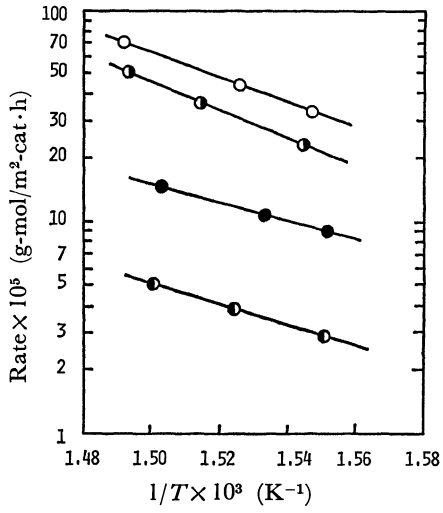


Fig. 4. Rate of maleic anhydride formation in the oxidation of butadiene over modified MoO_3–TiO_2 catalysts.
Cat.: X_mO_n–MoO_3–TiO_2 [$MoO_3/TiO_2=1/3$, X/Mo =30 atom%, X=Bi, Sb, As, or P], butadiene: 1.50 vol% in air, ○: Bi, ◑: Sb, ◐: As, ●: P

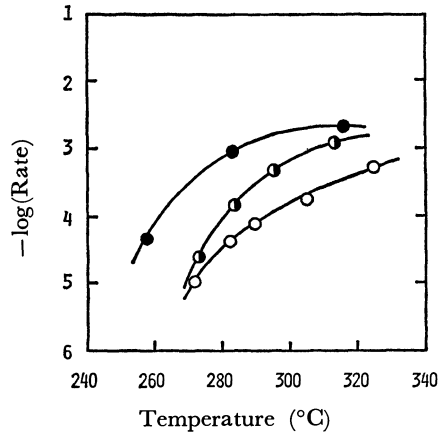

Fig. 5. Oxidation of butadiene, furan, and 2,5-dihydrofuran over MoO_3–TiO_2 catalyst.
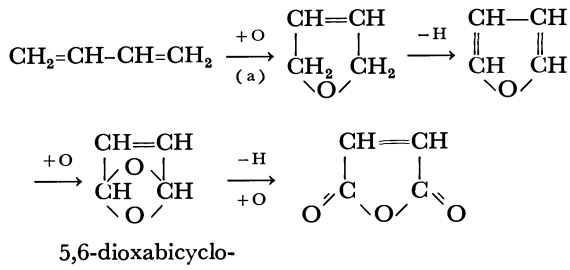
Cat.: MoO_3–TiO_2 (1 : 3), feed: 1.50 vol% in air, rate: [g-mol MA/g-cat·h], ●: 2,5-dihydrofuran, ◑: furan, ○: butadiene

In general, the rate of catalytic reaction is proportional to the rate constant of surface reaction and the concentration of adsorbed reactant species. Determination of the surface concentration of the intermediate compounds such as 2,5-dihydrofuran, furan, and 5,6-dioxabicyclo[2.1.1]hex-2-ene during the oxidation of butadiene was not carried out. However, it is apparent that addition of the selective oxygen species to adsorbed butadiene or furan species forming 2,5-dihydrofuran or 5,6-dioxabicyclo[2.1.1]hex-2-ene is the rate-determining step for maleic anhydride formation from butadiene. Conversion of butadiene and the selectivity to furan formation are 44% and 8.5%, respectively, at $W/F=0.200$ g-cat·h/g-mol and 380 °C (Fig. 1). From this, the average concentrations of butadiene and furan in the vapor-phase along the catalyst bed are calculated to be 1.17 vol% and 0.028 vol%, respectively. The concentration of butadiene is very high relative to that of furan, but rate (butadiene→2,5-dihydrofuran), rate (2,5-dihydrofuran→furan), and rate (furan→maleic anhydride) through mechanism A are the same. This suggests the lowest reactivity of butadiene for anhydride formation. Formation of 2,5-dihydrofuran seems to be rate-determining, as previously presumed, as regards the activation energy. The reaction mechanisms are assumed as follows.

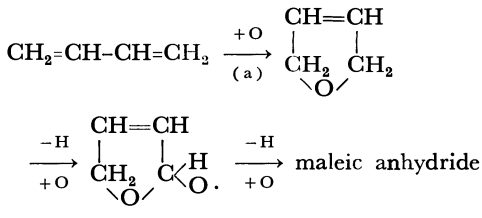
Mechanism A



5,6-dioxabicyclo-[2.1.1]hex-2-ene

where step (a) is rate-determining.

Mechanism B



where step (a) is rate-determining.

In the case of mechanism B, since the intermediate compound formed from 2,5-dihydrofuran by the hydrogen abstraction is a radical, addition of the double bond oxygen to this compound seems to proceed more easily than that to adsorbed furan species. Thus, this path is energetically advantageous, as is evident from the oxidation of 2,5-dihydrofuran to maleic anhydride (Table 3). Consequently, it is natural that mechanism B plays the main role in anhydride formation especially at low temperatures. However, with a rise in temperature, rate of furan formation from 2,5-dihydrofuran becomes very large and thus the role of mechanism A seems to increase. It is, therefore, not unlikely that the selectivity for maleic anhydride formation is almost independent of that for furan formation (Fig. 1).

There is no direct evidence for the formation of 5,6-dioxabicyclo[2.1.1]hex-2-ene. As formation of an intermediate such as the bicyclo-compound was proposed in the vapor-phase oxidation of furfral to maleic anhydride,[7] it is probable that the anhydride is formed from butadiene *via* the bicyclo-compound in mechanism A. With the exception of 2,5-dihydrofuran and furan, formation of 5,6-dioxabicyclo[2.1.1]hex-2-ene is not really confirmed.

In conclusion, two mechanisms A and B have been found to participate in the selective oxidation of butadiene to maleic anhydride over supported molybdena catalyst. Mechanism B seems to play the main role of anhydride formation at low temperatures. Addition of the double bond oxygen to adsorbed butadiene species leading to 2,5-dihydrofuran formation is rate-determining in these mechanisms.

Non-empirical Calculation of the *G*-Values for the Ionization and Excitations in Diatomic Molecules Irradiated by 100 keV Electrons

Kiyoshi OKAZAKI and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received June 26, 1975)

The binary-encounter collision theory has been applied to the calculation of the *G*-values for the ionization and excitations of diatomic molecules irradiated by 100 keV electrons. The obtained *G*-values of electrons are as follows, in the order of H_2, N_2, CO, NO, and O_2: 2.83, 2.55, 2.68, 3.61, and 2.98. These values are in fair agreement with the experimental ones. The present non-empirical method is compared with the semi-empirical ones proposed by other investigators. The *G*-values of some other products were also calculated: the excited hydrogen atoms in the radiolysis of H_2 (0.9) and the ozone formation in the radiolysis of O_2 (12.6). These *G*-values are also in fair agreement with the experimental ones.

Many investigators have measured the *W*-values ($=100/G_e$; G_e is the *G*-value of electrons) of diatomic molecules by the saturation-ion-current-method.[1-4] In the experiments of the radiolysis of carbon monoxide, nitric oxide, oxygen, and nitrogen, some of the information about the yields of the charged and excited species produced in the primary process has been obtained by measuring the final products and by considering the reaction mechanisms.[5-10] However, scarcely no theoretical treatment of the primary process in the radiolysis of these molecules has been carried out.

Recently, we have developed the non-empirical method for the estimation of the initial *G*-values by combining the binary-encounter collision theory with the theory of the degradation spectrum.[11,12] We have thus far calculated the cases of noble gases from helium to xenon and of such molecules as methane, ammonia, and water, and have shown that our calculation can provide much information for use in considering the primary processes of the radiolyses of these atoms and molecules.[13,14]

In this paper, we will apply this method to estimating the initial *G*-values of products from five diatomic molecules: H_2, N_2, CO, NO, and O_2. The most striking aspect of the present results is that the *W*-values calculated from this comparatively simple method are in reasonable agreement with the experimental values. In the discussion, we will compare the present method with the semi-empirical ones proposed by other investigators.[15-18]

Method of Calculation

The procedure for the present calculation is the same as that shown in the previous paper,[11-14] except for the treatment of the highly excited states of hydrogen to be described below; this treatment was special because the energies of these highly excited states are now available.

When the modes of the excitations of hydrogen are considered in further detail, two channels of the energy loss of electrons have to be introduced at the energy above the ionization potential. These channels are the dissociative excitation and the dissociative ionization. In the present treatment, their threshold energies are denoted by E^* and $E^\dagger$ respectively. When high-energy-electrons lose the energies between E^* and $E^\dagger$, we assume that one half of the energy gives rise to the ordinary ionization ($H_2^+ + e^-$), while the other half of this energy gives rise to the dissociative excitation ($H + H^*$). Therefore, the cross section for the dissociative excitation producing an excited hydrogen atom may be expressed in this form:

$$Q_{de}(T) = \frac{1}{2}\int_{E^*}^{E\dagger}[\sigma_{E,dir}+\sigma_{E,exc}]dE \qquad (1)$$

for $T \geq E^\dagger$. Here $\sigma_{E,dir}$ and $\sigma_{E,exc}$ denote, respectively, the differential cross sections for direct and exchange excitations.[11,12] When $E^* \leq T < E^\dagger$, the upper limit of the integral in Eq. (1) has to be replaced by T. When $T < E^*$, $Q_{di}(T)$ is set equal to zero.

Similarly, the total cross section for the dissociative ionization ($H + H^+ + e^-$) may be expressed by:

$$Q_{di}(T) = \frac{1}{4}\int_{E\dagger}^{E^{**}}[\sigma_{E,dir}+\sigma_{E,exc}]dE \qquad (2)$$

for $T \geq E^{**}$. Here E^{**} is the threshold energy for the double excitation ($H^* + H^*$). When $E^\dagger \leq T < E^{**}$, the upper limit of Eq. (2) has to be replaced by T. When $T < E^\dagger$, $Q_{di}(T)$ is set equal to zero. The factor of 1/4 in Eq. (2) has to be introduced because there are two energy-loss-processes (the ordinary ionization and dissociative ionization); also, we cannot distinguish the origin of the scattered electron and so do not know whether it is originally the incident electron or the molecular electron.

Therefore, the total cross section for the ordinary ionization can be expressed by:

$$Q_i(T) = \frac{1}{2}\int_{I_i}^{T}[\sigma_{E,dir}+\sigma_{E,exc}]dE - \frac{1}{2}Q_{de}(T) - Q_{di}(T) \qquad (3)$$

Constants Used for Calculation

The binding energies (I_i), the kinetic energies (E_i), and the lowest energies of the allowed and forbidden excitations (E_s and E_t) used in the present calculation are summarized in Table 1. Here, the I_i values are those obtained by the technique of ESCA[19] and the E_i values are those calculated from the SCF wave functions.[20-23] The E_s and E_t values in the outermost shell were those experimentally obtained,[24] and the values in the inner shells were calculated using the following equations: $E_s(\text{inner shell}) = I_i(\text{inner}) - (I_i - E_s)_{outermost}$, $E_t(\text{inner shell}) = I_i(\text{inner}) - (I_i - E_t)_{outermost}$.

Table 2 shows the constants used for the calculation

respectively, double ionization, double excitation, ionization and successive excitation, and excitation and successive ionization.

Discussion

W-Value. The calculated G-values of electrons and W-values are summarized in Table 6, along with the W-values obtained both experimentally[1-4] and theoretically.[15-18] Obviously, our W-values are in fair agreement with the experimental ones. Similar

results have been obtained previously with noble gases from He to Xe, methane, ammonia, and water.[11-14] Therefore, it may be concluded that our method is useful for estimating the G-values of the electrons for all atoms and molecules.

Recently, Green and his associates have calculated the W-values for N_2.[15] O_2,[15] H_2,[16] and CO[17] out of aeronomic interest. In order to perform the calculation, they accumulated experimental data concerning

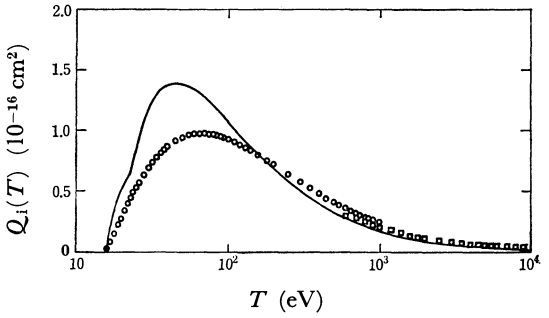

Fig. 9. The total cross section of ionization in H_2. ——, Calculated; ○, Ref. 25; □, Ref. 26.

the total cross section, the energy distribution of the secondary electrons, and the stopping power. They then determined the parameters of one equation to fit the experimental data, and finally they calculated the W-values under the assumption of a continuous slowing down. They did not use the concept of the degradation spectrum. On the other hand, Jones calculated the W-value and the yield of excitations in a hydrogen molecule out of radiation-chemical interest.[18] He did not use the assumption of a continuous slowing down either, but calculated the Fowler equation; the parameters were obtained semi-empirically. These two semi-empirical methods used to estimate the W-value both have the demerits that the method of calculation is very complex and that, if a complete set of the experimental data is not available, the estimation of any value is impossible.

On the other hand, the treatment of our non-empirical calculation is much simpler, and no experimental data on the cross sections are needed. Moreover, once the degradation spectrum of the electrons is constructed, we can estimate the G-values of any process by combining the degradation spectrum with the cross sections if they are available either theoretically or experimentally. However, since the cross sections used in our calculation are formulated only from the Coulomb interaction between two encountering species, the theoretical total cross section does not agree exactly with the experimental one. Nevertheless, the G-values calculated by our non-empirical method are in good agreement with the experimental values.

Figure 9 shows the total cross section for ionization in a hydrogen molecule as a function of ln T. The calculated cross sections at the electron energies from 10^2 to 10^4 eV are in good accordance with the experimental ones, but between the threshold energy and 10^2 eV the calculated ones are about 1.4 times the experimental ones.[25,26] Similarly, the calculated cross sections for N_2, CO, NO, and O_2 under the electron energy of 10^3 eV are much larger than the experimental ones.[25-27]

Since the calculated cross sections in N_2 is about three times the experimental one at its maximum, we tried to calculate the G-values by assuming that the differential and total cross sections were one-third of the cross sections used above; *i.e.*, the stopping power, $S(T)$, is one-third of that used above. However, the G-values thus obtained were the same as those obtained

above. This is because, when the degradation spectrum, $y(T)$, is calculated, the stopping power comes to the denominator. That is, the factor of three is cancelled during the course of the calculation. Consequently, we may conclude that, in order to estimate the G-values, it is not necessary to use the absolute cross sections, but only the relative values at each electron energy.

The Ratio of the G-Values of Excited Species to Those of Ionic Ones. We calculated the G-values for the total excitations, G_{ex}, the total loss of molecules, $G(-M)$, and the ratios of the G_{ex} to G_e. The results are shown in Table 7. Since the G_{ex}/G_e ratios of diatomic molecules are much larger than those of noble gases (0.4—0.6)[12], the excited species may play a more important role in the successive reaction than those in noble gases. This is similar to the finding in the molecules consisting of ten electrons.[14] Therefore, when we analyze the radiolyses of molecules, we must consider not only the charged species but also the excited ones. Especially, the G_{ex}/G_e of the oxygen molecule is very large because the energy of the lowest excited state ($^1\Delta$) is small.

The G-Value of Emissions. From the present calculations using the $y(T)$, the G-values for the emission of the light from highly excited species can be estimated by the use of the experimental cross sections described in the previous paper.[14] These cross sections in the hydrogen molecule and the nitrogen molecule have been reported by Vroom and de Heer[28] and by Aarts and de Heer[29] respectively. The results are shown in Tables 9 and 10. Especially, the G-value of the emission from excited hydrogen atoms (0.81) accords fairly well with the $G(H^*)$ in Table 8 (0.94). These G-values of the products of the charged and excited species in Table 8 are calculated from Table 3. The G-value of the excited nitrogen atoms in N_2 is the same amount as that of the excited hydrogen atoms in methane, ammonia, and water. However, since the G-value of the excited hydrogen atoms in H_2 is very large, the G-value of the hot hydrogen atoms in H_2 may be produced in a large amount. The G-value of the hot hydrogen atoms was estimated to be about 2.

The Radiolysis of Nitric Oxide. Hochanadel *et al.* proposed the following reaction mechanism and estimated the G-values of the products in the radiolysis at 25°C of NO irradiated by a 2 MeV electron beam:[6]

$$24.8\,NO \rightarrow 5.3\,N_2 + 7.0\,NO_2 + 3.6\,N_2O_3$$

$$NO \rightsquigarrow NO^+ + e^-$$

$$\rightarrow NO^* \rightarrow N + O$$

$$NO^+ + e^- \rightarrow NO^* \rightarrow N + O$$

$$NO + e^- \rightarrow NO^-$$

$$NO^+ + NO^- \rightarrow N + O + NO$$

$$N + NO \rightarrow N_2 + O$$

$$O + NO \rightleftarrows NO_2^*$$

$$NO_2^* + M \rightarrow NO_2 + M$$

$$NO_2 + NO \rightleftarrows N_2O_3$$

If the excited state of the outermost shell in our calculation cannot dissociate into nitrogen and oxygen atoms, the G-values of the nitrogen and oxygen atoms can be estimated to be 5.50. Therefore, the G-values of these atoms are in fair accordance with the experimental values (5.3).

The Formation of Ozone. The radiolysis of an oxygen molecule at a high dose rate has been experi-

mented with by Willis *et al.*[7,8] They reported that the *G*-value of ozone is 12.8; this value is used as a chemical dosimeter. If we assume as follows, we can estimate the *G*-value of ozone from the present results: all the nuetralization reactions give two oxygen atoms per ion pair, and all the excited oxygen molecules, except for the lowest excited one ($^1\Delta$), dissociate into two oxygen atoms. That is, one oxygen atom produces one ozone. Then, the calculated *G*-value of ozone is 12.6. This value is in reasonable agreement with the experimental one.

Microwave Spectrum of Ethylene Oxide in Excited Vibrational States

Nobuaki YOSHIMIZU, Chiaki HIROSE, and Shiro MAEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, O-okayama, Meguro-ku, Tokyo 152

(Received June 26, 1975)

In the rotational spectrum of ethylene oxide, the five lowest-lying vibrational states are assigned and the vibration-rotation constants and the centrifugal distortion constants are derived. The vibrational frequencies are estimated from relative intensity measurements at $\nu_a=803\pm18$ cm^{-1} and $\nu_b=814\pm23$ cm^{-1} for the antisymmetric species (with respect to the C_2 operation) and at $\nu_c=872\pm34$ cm^{-1}, $\nu_d=1020\pm33$ cm^{-1}, and $\nu_e=1109\pm42$ cm^{-1} for the symmetric species. The intensity measurements of the remaining spectral lines showed that these lines belong to vibrational states at frequencies above about 1000 cm^{-1}. The ν_a, ν_b, and ν_c states are tentatively assigned to ν_{15}, ν_{12}, and ν_5, respectively, by taking into account the Coriolis interactions.

With a considerable number of infrared and Raman investigations carried out so far,[1-13] the assignments of certain fundamental frequencies of ethylene oxide are still subject to controversy. Namely, as shown by some examples in Table 1, different authors have proposed considerably different frequencies for ν_7 (A_2, CH_2-twisting), ν_8 (A_2, CH_2-rocking), and ν_{12} (B_1, ring deformation), for which no direct spectral evidence has been obtained. Under these circumstances, further infrared and Raman studies would seem to be ineffective in improving the situation significantly, and rather somewhat different approach is required.

Now, it is known that the intensity measurements of microwave absorption in vibrationally-excited states[14] and the analysis of the vibration-rotation interaction[15-18] provide useful information about the energy and symmetry of these vibrational states. In fact, these methods may certainly be advantageous when the vibrational transition is extremely weak or forbidden as in those described above. Thus, the present work was carried to out examine the frequencies and the assignments of the lower fundamental frequencies of ethylene oxide using microwave spectroscopy.

TABLE 1. VIBRATIONAL ASSIGNMENT OF ETHYLENE OXIDE (in cm^{-1})

Symmetry	Type of vibration	Lord and Nolin[a]	Potts[b]	Hirokawa *et al.*[c]	Cant *et al.*[d]

Experimental

Ethylene oxide was purchased from the Matheson Co. and was used without further purification. The rotational spectrum was observed with a conventional spectrometer at 300 K mainly in the frequency region from 9 to 42 GHz. Previous results[19-21] were referred to in eliminating the spectral lines of isotopic species. A double resonance experiment was performed on the $2_{11}\leftarrow2_{02}$ and $2_{20}\leftarrow2_{11}$ transitions in order to confirm the assignment of the Q-branch transitions. Spectral line intensities were measured from a chart recorded using a Hewlett-Packard MRR8460A-607 R-band spectrometer.[24] The accuracy of the measurements was checked by measuring the natural abundance ratio of $^{12}C^{13}CH_4O$ to $^{12}C_2H_4O$.

Results and Discussion

The microwave spectra of ethylene oxide and its isotopic species have been investigated in the ground state by a number of authors,[19-23] resulting in the determination of the r_0, r_s, and r_m structures,[19-21] the dipole moment,[19] the centrifugal distortion constants,[21-23] and the ^{17}O quadrupole coupling constants.[23] On the basis of these results, the rotational spectrum of the vibrationally-excited states was identified and frequencies were assigned to the transitions in five low-lying vibrational states, ν_a, ν_b, ν_c, ν_d, and ν_e in increasing order of frequency, as listed in Table 2. Since the molecular dipole moment lies along the b-axis, a rotational transition $J_{K_{-1}K_1}\leftrightarrow J_{K_{-1}'K_1'}$ is allowed only for such $K_{-1}K_1\leftrightarrow K_{-1}'K_1'$ combinations as ee↔oo and eo↔oe, where e and o signify even and odd. The calculated transition frequencies for the three lower vibrational states, ν_a, ν_b, and ν_c, were obtained using the parameters given in Table 3, which were determined by a least-squares fit including the centrifugal distortion effect to the first order.[25] For ν_d and ν_e states no R-branch transitions were identified, so that their calculated transition frequencies were derived from the observed values of $1_{10}\leftarrow1_{01}$ and $2_{20}\leftarrow2_{11}$ *via* Q-branch plots without taking account of the centrifugal distortion.

In Table 4, the intensities of the excited state lines

t_2[c]	−0.1021±0.0144	−0.91±0.49	0.65±0.37	−0.29±0.31

	Ground state[b]	ν_d	ν_e
$2B_s-A_s-C_s$	4659.90	4799.59	5404.57
A_s-C_s	11386.10	11206.23	10749.00

a) Error limits for the rotational constants and the vibration-rotation constants (α_s^x) for ν_a, ν_b, and ν_c were estimated from 2.5 times the standard deviations to be less than ±0.5 MHz. For the ν_d and ν_e states the values of $2B_s-A_s-C_s$ and A_s-C_s were derived using Q-branch plots of the observed values of the $1_{10}\leftarrow 1_{01}$ and $2_{20}\leftarrow 2_{11}$ transitions, and the reliability intervals were estimated to be ±0.5 MHz and ±2 MHz or more, respectively, for ν_d and ν_e. The large ambiguity in ν_e is due to the Coriolis interaction. b) The values for the ground state were calculated from the observed transitions reported in Ref. 22. c) $t_1=\tau_{aabb}'+\tau_{ccaa}'(A-B)/(A-C)$, $t_2=\tau_{bbcc}'+\tau_{ccaa}'(B-C)/(A-C)$.

are given by the ratios to those of the corresponding ground state lines. The table is limited within the frequency range covered by the MRR8460A-607 R-band spectrometer, and leaves quite a few lines unlisted because of the uncertainty due to overlapping. It can be noticed, however, that in the ν_a and ν_b states the relative intensity I of eo↔oe type transitions is about three times that of ee↔oo type values, while the I is approximately equal for both types of transitions in the ν_c, ν_d, and ν_e states.

a) $g^{0}(J_{K_{-1}K_1})$ and $g^{v}(J_{K_{-1}K_1})$ denote the spin weights of the $J_{K_{-1}K_1}$ rotational level for the ground and excited vibrational states, respectively. b) Since Stark components were not fully resolved, the value was not used in the subsequent analysis. c) 2.5 times the standard deviations introduced by $\exp(-h\nu/kT)\cdot g^{v}/g^{0}$ are indicated.

Now, this fact can be understood as arising from the degeneracy of the hydrogen nuclear spin states. Namely, the symmetry requirement for the composite wave functions formed by the vibrational, rotational, and nuclear spin parts leads to the following statement for the present C_{2v} case:[26] in the vibrational states of the A_1 and A_2 species, ee and oo type rotational levels are associated with a 10-fold nuclear spin weight, while eo and oe levels are associated with a 6-fold weight, with the situation in the B_1 and B_2 vibrational states, however, being inverted, *i.e.*, ee and oo are 6-fold while eo and oe are 10-fold. Then, since the ground state is necessarily an A_1 species, the Γ of the A_1 and A_2 states should be equal to the vibrational Boltzmann factor irrespective of the type of rotational transition. In B_1 and B_2 states, however, the Γ of ee$\leftrightarrow$oo type and eo$\leftrightarrow$oe type transitions prove to be equal to 6/10 and 10/6 times the Boltzmann factor, respectively. Thus, it is evident from Table 4 that ν_a and ν_b are of the B-type species and the rest are of the A-type. The energy of each vibrational state is calculated from the Boltzmann factor obtained as is given in Table 4. Slight changes in the dipole moment, rotational energies, and line widths in different vibrational states were ignored in the above discussion, as they are not expected to influence the conclusion significantly.

Referring to Table 3, it is noted that the rotational constant C and the centrifugal distortion constant τ'_{cccc} of the ν_b and ν_c states show unusually large deviations from those of the ground state in opposite directions. This observation indicates the presence of a c-type Coriolis interaction between the ν_b and ν_c states. It can be shown that the Coriolis terms in α^c and τ'_{cccc} are approximately given by $\mp 4C^2(\zeta_{b,c}^{(c)})^2/(E_b-E_c)$ and $\mp 64C^4(\zeta_{b,c}^{(c)})^4/(E_b-E_c)^3$, where the upper and lower signs refer to the ν_b and ν_c states at the vibrational energies E_b and E_c respectively.[16,18,27] Taking the conclusion of the preceding paragraph into consideration, the Coriolis coupling constant $\zeta_{b,c}^{(c)}$ proves to vanish except when the ν_b and ν_c states belong to either B_1 and A_1 or B_2 and A_2 species. Accordingly, after comparing the ν_b and ν_c energies in Table 4 with those in Table 1, their possible assignments are reduced to the following two cases: (i) ν_b to ν_{12} (B_1, ring deform) and ν_c to ν_5 (A_1, ring deform), or (ii) ν_b to ν_{15} (B_2, CH_2 rock) and ν_c to ν_8 (A_2, CH_2 rock). A tentative calculation using the force field fitted to the assignment of Lord and Nolin gives $\zeta_{12,5}^{(c)}=0.9965$ and $\zeta_{15,8}^{(c)}=0.3689$.[28] Then, the Coriolis parts of α^c and τ'_{cccc} are calculated to be ± 454 MHz and ± 0.473 MHz in case (i), and ± 62 MHz and ± 0.009 MHz in case (ii), respectively. Comparing these results with Table 3, the assignment of case (i) appears to be more probable, though not definite because of the uncertainty in E_b-E_c value used above. Assuming case (i) above to be correct, ν_a, ν_d, and ν_e may be reasonably assigned to ν_{15} (B_2, CH_2 rock), ν_7 (A_2, CH_2 twist) and ν_4 (A_1, CH_2 wag), respectively, in view of their frequencies and symmetries (see Table 1). Then the situation arises that the present microwave results lack an assignment for the vibrational state ν_8 (A_2, CH_2 rock). As it is very unlikely that the present study should have missed a vibrational state as low as about 800 cm^{-1},[29] this means that the frequency of ν_8 should be higher than those proposed by other authors, as listed in Table 1. In fact, we observed several spectral lines in addition to those

listed in Table 4 in the same frequency region, but their intensities gave little indication of the sixth vibrational state below 1000 cm^{-1}.

This conclusion is in fair agreement with the assignments of Hirokawa *et al.*[12] and the very recent one by Cant *et al.*[13] except for the location of ν_8 (A_2). The frequency of the last mode has, so far, always been based on solid spectra obtained at low temperature,[7,10,13] for which the infrared prohibition of A_2 modes may perhaps be lifted. In solid spectra, however, the appearance of crystal field splittings has always to be taken into account in dealing with such closely lying lines as 825 and 818 cm^{-1}, which have been assigned to ν_8 and ν_{12} by Cant *et al.* The present result suggests that they are not separate fundamental frequencies but are the split components of ν_{12}, contrary to the conclusions in Ref. 13. Incidentally, Cant *et al.* assigned the corresponding C_2D_4O frequencies at 587 and 779 cm^{-1}, but the former was also very close to the 595 cm^{-1} line which they assigned to ν_{15}. In view of their observation on a dilute C_2D_4O/C_2H_4O mixture, which gave only a single evident line near 590 cm^{-1}, it seems that the lines at 587 and 595 cm^{-1} are more likely to be the crystal field doublet of ν_{15}.

Finally, the possibility for case (ii) is mentioned, though it was previously discarded on the basis of Coriolis interaction behavior. Assuming the choice of case (ii), we can conclude that the ν_5 (A_1) state is missing in the present result, instead of ν_8. Such a case is very improbable, however, because the ν_5 frequency given in Table 1 has been established quite convincingly.

The authors are grateful to Professor Robert F. Curl, Jr., for allowing them to use the spectrometer in his laboratory at the initial stage of the present study. The authors wish to express their appreciation also to Dr. Shuji Saito of Sagami Chemical Research Center for his loan of the millimeter-wave klystrons and spectrometer for observation of some of the $J=2\leftarrow1$ transitions, and to Professor Kunio Kozima for encouragement throughout the work. They also wish to thank Professors Kozo Kuchitsu and Yonezo Morino, and Drs. Charles D. LeCroix and Harold Jones for reading the draft of this paper and making critical comments.

29) There are two possible causes of missing the rotational lines of a vibrational state as low as about 800 cm^{-1}: (1) overlapping of the lines with those of the ground state, or (2) extremely strong Coriolis interaction which shifts all the transitions outside of the frequency region of the present observation. For the former case, all the three rotational constants of the vibrational state have to be equal to those of the ground state to within a few megahertz, thus, case (1) is unlikely though not impossible. Although, for the latter case, such a strong Coriolis interaction requires a fifth vibrational state located very close to the fourth state, none of the ν_a, ν_b, and ν_c states is perturbed as strongly and no rotational spectra that can be assigned to the fourth and fifth vibrational states were observed in this region. Furthermore, infrared and Raman spectra do not indicate the existence of the fifth state around 800 cm^{-1}. Therefore, this case can be ruled out.

Studies of the Coagulation Flotation of Bentonite and Its Application to the Removal of Co^{2+} Ions and Fission Products, Ce and Eu

(Received July 11, 1975)

The regions of dispersion, coagulation precipitation, coagulation flotation, and redispersion were determined for aqueous bentonite-cationic surfactant and bentonite-cationic surfactant-polyacrylamide(PAA) systems. The region of coagulation flotation was markedly extended by the addition of PAA to both the lower and higher concentration regions of the cationic surfactant, hexadecyldimethylbenzylammonium chloride(HDBAC), and to the lower concentration region of bentonite. The phenomenon of coagulation flotation was investigated in detail and was applied to the removal of Co^{2+} ions and nuclear fission products, ^{144}Ce and ^{155}Eu, from an aqueous solution. The composition of the reagents for the maximum efficiency of bentonite flotation corresponded to that of the maximum efficiency of Co^{2+}-ion flotation. The effect of the pH on the flotation efficiency was studied in particular. The maximum flotation efficiency of 96% was obtained at pH 11 for Co^{2+} ions, 86% at pH 9.7 for ^{144}Ce, and 93% at pH 10.5 for ^{155}Eu. These radioactive elements were almost completely adsorbed on the surface of bentonite particles and were floated with them in the pH region of the maximum flotation efficiency. It was confirmed that Co^{2+} ions could be floated also from an extremely low concentration (10^{-9} mol/l) of Co^{2+} ions with nearly the same efficiency of flotation and with the additives in the same condition. Co^{2+} ions could also be effectively removed by using the step-by-step flotation, showing as high a flotation efficiency as 99.8%.

The importance of coagulation flotation is well known, as has already been discussed in a previous paper.[1] Coagulation flotation is of interest as a means for the rapid removal or separation of suspended particles from suspensions, since the velocity of flotation is faster than that of coagulation precipitation. Also, coagulation flotation is an effective means for the removal of coexisting ions from the solution when the coagulating particles have an ion-exchange capacity, like bentonite; this process is called adsorbing particle flotation,[2] or "piggy-back" flotation.[3] As has been pointed out in a previous paper,[4] the region of coagulation flotation is extended by the addition of PAA towards the higher and lower concentrations of the cationic surfactant and toward the lower-concentration region of bentonite. Therefore, the addition of PAA is considered to be effective for the removal of bentonite or radioactive cations.

Recently, the removal of substances from an aqueous solution has drawn increasing attention in connection with the problem of water pollution. The radioactive decontamination or the removal of radioactive elements is one of the most important problems involved in the processing of radioactive elements; it is also concerned with public health. Various methods for the removal of these contaminating elements have been employed —for instance, adsorption including ion exchange, coagulation precipitation, evaporation concentration, foam separation, and flotation.[5] Among these methods, the flotation method is considered to be the most effective and the least expensive. However, a comparatively limited number of works have reported on the ion flotation of radioactive elements.[6] For these reasons, it is of importance to investigate the basic parameters to be considered in the flotation process.

In the present study, the coagulation flotation of bentonite, the effect of PAA upon the flotation, and its application to the separation of Co^{2+} ions and some fission products were investigated in detail. The amount of bentonite, the cationic surfactant, PAA, and the effect of the pH on the flotation efficiency were studied in particular.

Experimental

Materials. The cobalt chloride used was a reagent-grade $CoCl_2 \cdot 6H_2O$, which was used without further purification. The stock solution of Co^{2+} ions (1×10^{-4} mol/l) was prepared by dissolving cobalt chloride in triply distilled water, with the addition of a small amount of ^{60}Co as a radiotracer. The ^{144}Ce and ^{155}Eu, which had been obtained by processing fission products, were supplied by the Japan Atomic Energy Research Institute. The initial activities of the aqueous ^{144}Ce and ^{155}Eu solutions were 2×10^{-2} and 1.5×10^{-2} μCi/ml respectively. The bentonite powder(Bt) used as an ion exchanger was supplied by the Wako Pure Chemical Co., Ltd.; the fraction passing through a 350-mesh sieve was collected and dried under reduced pressure. A suspension of the desired Bt content was made before each experiment and was used after shaking.

The hexadecyldimethylbenzylammonium chloride (HDBAC, 95% purity) was supplied by the Nippon Oils and Fats Co., Ltd., recrystallized from acetone, and dried under reduced pressure. The critical micelle concentration of HDBAC in an aqueous solution was found from surface-tension measurements to be about 8×10^{-5} mol/l. Polyacrylamide (PAA) with an 87% amide content was used as a coagulating agent; it was the product of the Nitto Chemical Co., Ltd., and had been dried under reduced pressure. The Bt, HDBAC, and PAA were all kept in a desiccator. The water was triply

distilled using a borosilicate glass apparatus after it had been refluxed overnight with a sulfuric acid-potassium permanganate solution.

Apparatus and Procedure. The procedure used for the measurements of the dispersion state of Bt by HDBAC was the same as that described in the previous paper.[1] The apparatus and method used for flotation were likewise the same as those described previously.[7] A humidified nitrogen gas was introduced through a sintered glass plate of No. 4 into a 10-ml sample solution held in a glass tube (1.0 cm in inner diameter and 32.0 cm in length) for 1 or 2 min at a gas-flow rate of 10 ml/min, unless otherwise specified. Experiments were run under the condition of bubble flotation—namely, flotation using only ascending bubbles, without the aid of foam formation. The concentration of Bt was determined by turbidity measurements using a photoelectric colorimeter, Spectronic 20, of Bausch and Lomb, Inc. The light absorbance was measured at 440 mμ. The concentration of the stock solution of Co^{2+} ions was determined by the chelate titration method with EDTA[8], using murexide as an indicator. For the measurement of the flotation efficiency, a constant amount of the sample was pipetted out of the solution and dried in a stainless steel planchet, and the radioactivities of ^{60}Co, ^{144}Ce, and ^{155}Eu were measured by using the Geiger-Muller counter tube. From the radioactivity of the solution before and after the flotation, the flotation efficiency was calculated.

The flotation efficiency, F, was calculated according to this equation:

$$F = (1 - C_f/C_i) \times 100\%$$

where C_i and C_f are the concentrations or radioactivities of the solution before and after the flotation respectively.

The centrifugation was carried out in a 15-ml cell at 3000 rpm for 10 min; the concentration or radioactivity of the supernatant solution was similarly determined. The efficiency of centrifugation, R, was calculated as follows:

$$R = (1 - A_f/A_i) \times 100\%$$

where A_i and A_f are the radioactivities of the solution before and after the centrifugation respectively.

The pH of the solution was adjusted by means of a sodium hydroxide solution, which had been prepared by the dilution of a saturated NaOH solution. All the experiments were carried out at room temperature (about 25 °C).

Results and Discussion

Change of Dispersion State of Bt by HDBAC and/or PAA. The coagulation-dispersion and precipitation-flotation behavior is shown in Fig. 1 as a function of the amount of HDBAC and Bt added. The regions of dispersion, coagulation precipitation, coagulation flotation, and redispersion may be seen distinctly. Especially the change from coagulation precipitation to coagulation flotation is very sensitive to the slight addition of HDBAC under a constant Bt concentration.

Figure 2 shows the effect of HDBAC on the Bt suspension in the presence of 10 ppm PAA. As may be seen in Fig. 2, the region of coagulation flotation extended towards lower and higher concentrations of HDBAC and a lower concentration of Bt compared with the case of the Bt–HDBAC system. Also, the addition of PAA markedly clarifies the turbid solution and markedly increases the floating velocity of the coagulum by increasing the size of the aggregates. The transition from the region of dispersion to that of coagulation flotation is more distinct in the presence of PAA than in the system without PAA. In Fig. 2 a second region of coagulation precipitation appears, though it is somewhat indistinct at the low-concentration regions of Bt and HDBAC.

Figure 3 shows the change in the dispersion state in the PAA–Bt system in the absence of HDBAC.

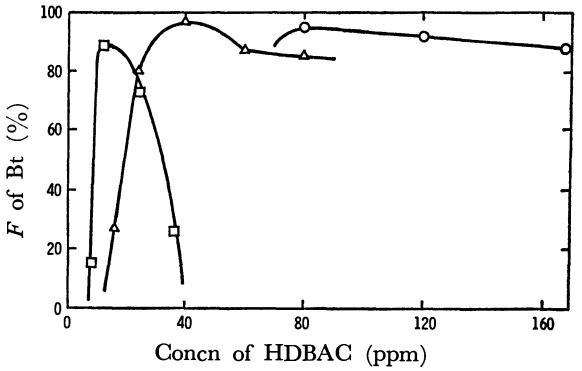

Fig. 4. Effect of HDBAC on flotation efficiency of Bt in the presence of PAA. PAA: 10 ppm, pH: 5—7, gas-flow time: 1 min, Bt: 100 ppm(□), 300 ppm(△), 600 ppm(○).

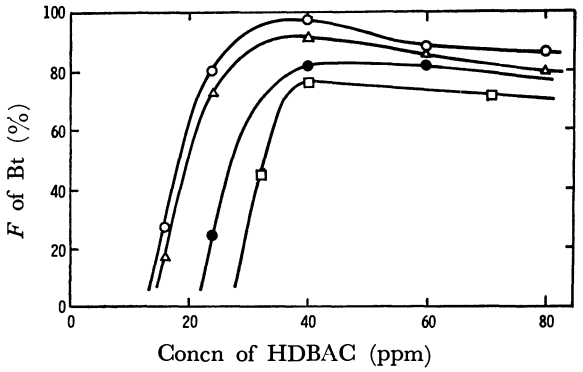

Fig. 5. Effect of PAA on flotation of Bt by HDBAC. Bt: 300 ppm, pH: 7, gas-flow time: 1 min, PAA: 0 ppm(□), 5 ppm(●), 10 ppm(○), 26 ppm(△).

As expected, the region of coagulation flotation disappears in Fig. 3. The fact that the lines separating each region are nearly linear and pass through the point of origin may suggest that the coagulation-dispersion change occurs at constant compositions of the Bt–PAA complex.

Effect of HDBAC on the Efficiency of Coagulation Flotation. In order to study the behavior of the Bt suspension in the region of coagulation flotation in detail, the efficiency of the flotation of Bt at various concentration levels of HDBAC was studied in the presence of 10 ppm of PAA. The results are shown in Fig. 4. It may be seen that the maximum efficiency of flotation appears and that the maximum becomes flatter with the increase in the concentration of Bt. The concentration ratio of Bt/HDBAC at the maximum flotation is nearly constant, as may be seen from the plots shown by filled circles in Fig. 2. This constancy may also indicate the constancy of the aggregate composition at the maximum flotation efficiency. Values of more than 90% were observed at the maximum of flotation. Beyond the maximum points of the flotation efficiency, redispersion began to occur and the supernatant become opaque or turbid. Although the composition of the floated Bt-surfactant aggregates was not determined, it must be similar to what has been reported for Bt–HTAC.[1] In the case of the low concentration of Bt, the flotation efficiency of Bt rapidly decreased beyond a sharp maximum and the region of coagulation flotation became narrow.

Effect of PAA on Efficiency of Coagulation Flotation. Figure 5 shows the effect of PAA on the relation between the coagulation-flotation efficiency and the HDBAC concentration in the system of 300 ppm Bt. As may be seen in the figure, the HDBAC concentration at the maximum efficiency of Bt flotation is nearly independent of the PAA concentration, but the flotation efficiency itself is markedly influenced by the concentration of PAA. From Fig. 5, the concentration of 10 ppm PAA was found to be optimum in the case of 300 ppm Bt. From this result, together with the results obtained from Fig. 4, it may be concluded that an optimum concentration ratio of Bt : HDBAC : PAA, and therefore an optimum composition of the aggregate, exists which gives a maximum efficiency of flotation. The concentration ratio is estimated to be 300 : 40 : 10 (in the case of 300 ppm Bt).

Effect of the Heat Treatment on the Flotation Efficiency of Bt. In Fig. 6, the flotation efficiencies of Bt are compared between two samples; one was heated at 110 °C for 48 h, while the other had no heat treatment. In the case of pH 7 (solid curves), a flat maximum appeared in the *F vs.* HDBAC concentration curve for the system of untreated Bt, while a distinct maximum of a larger value was observed for the heat-treated Bt. In the case of pH 11 (dashed curves), both curves show a flat maximum and the effect of heat treatment disappears.

Effect of the Coexistence of PAA and HDBAC on the Flotation Efficiency of Bt and Co^{2+} Ions. From the enhancement of the flotation efficiency of Bt by the simultaneous addition of HDBAC and PAA, it may be presumed that the Co^{2+} ions can also be effectively floated under such conditions. To confirm this, the flotation efficiencies of Bt and Co^{2+} ions were investigated for the Co^{2+}–Bt–HDBAC–PAA, Co^{2+}–Bt–HDBAC, and Co^{2+}–HDBAC–PAA systems. The results are shown in Table 1. As may be seen in Table 1, both Bt and Co^{2+} ions are best floated by the simultaneous addition of PAA and HDBAC, while the

flotation efficiencies markedly fall for the system lacking either PAA or Bt. In particular, the flotation efficiency of Co^{2+} ions in the absence of Bt is quite poor. The decrease in flotation efficiency due to the lack of PAA does not completely recover even if the concentration of HDBAC is increased. Further, the comparision of the flotation efficiencies of the Co^{2+} ions and Bt shows that the Co^{2+} ions may be considered to float by combining with Bt at the optimum flotation, as will be shown in Table 2, while some Co^{2+} ions can float without the aid of Bt in other systems.

Relation between the Coagulation Flotation and the Concentration of Bt. The relation between the Bt concentration and the flotation efficiency was investigated under the conditions of 3 ppm PAA and 20 ppm HDBAC at pH 9. The results are shown in Table 2. It may be seen that the flotation efficiencies of 99.2% for the Co^{2+} ions and 96% for Bt are obtained at Bt : PAA= 130 : 3 (wt). Thus, the optimum conditions of Co^{2+}-ion flotation were found to be 130 ppm Bt, 20 ppm HDBAC, and 3 ppm PAA for Co^{2+} of a 1×10^{-5} mol/l concentration; these conditions are in agreement with the ratio listed in the former section.

Effect of the Time of the Gas-Flow on the Flotation Efficiency of Co^{2+} Ions and Bt. Figure 7 shows the floatation of Co^{2+} ions and Bt from the Co^{2+}–Bt–HDBAC–PAA system of the composition listed in each figure as a function of the time. The effect of the gas-flow time on the flotation efficiency of Bt closely resembles that of Co^{2+} ions, as is shown by Curve A in Fig. 7. In this case, the flotation efficiencies of both Co^{2+} and Bt increase with the gas-flow time. About 95.5% of the flotation efficiency was attained after 2—3 min. When the amount of additives is doubled, as is shown by Curve B, a maximum of F=

Co^{2+}: 1×10^{-5} mol/l, pH: 10—11, gas-flow time: 2 min. Amount of Bt, HDBAC, and PAA are variable for the first and second flotations, but the total amount of each of these additives must sum up to 260 ppm, 40 ppm, and 6 ppm, respectively.
●: first flotation efficiency, ○: first plus second flotation efficiencies. △, ▲: results of one step flotation process under the condition of 260 ppm Bt, 40 ppm HDBAC, and 6 ppm PAA(△ is for gas-flow time of 2 min, ▲ is for gas-flow time of 4 min)

98.2% also appears after 2 min, but this gradually decreases on a further increase in the gas-flow time. The decrease is perhaps due to the partial redispersion of a scum once floated by continued bubbling. A similar curve was obtained for Bt, as is shown by Curve C. Therefore, the gas-flow time of 2 min was used as the optimum condition for all subsequent investigations.

Effect of the Step-by-step Flotation of Co^{2+} Ions. In the practice of flotation, a step-by-step method is often adopted.[9] Here, the effect of such a method will also be discussed. First, the flotation of Co^{2+} ions from a solution containing 1×10^{-5} mol/l Co^{2+}

ions, 260x ppm Bt, 40x ppm HDBAC, and 6x ppm PAA was run at pH 10—11, where $x(\leqq 1)$ is a variable. After the underlying liquid had been removed from the flotation cell as completely as possible, the second flotation of the solution was carried out with the further addition of $260(1-x)$ ppm Bt, $40(1-x)$ ppm HDBAC, and $6(1-x)$ ppm PAA. The F value for the first flotation and the sum of the F-values for the first and second flotations are plotted against the initial Bt concentration of 260x ppm in Fig. 8, together with the flotation efficiency obtained for the one-step flotation process of 260 ppm Bt with the gas-flow times of 2 and 4 min, for comparison. It is evident in Fig. 8 that the step-by-step flotation is far more effective than the simple flotation; it is especially so when we compare the open circles with the filled triangle, which indicates the F-value of the simple flotation with a total gas-flow time of 4 min. In the case of the step-by-step flotation, a flotation efficiency as high as 99.6—99.8% was obtained at pH 10—11.

Effect of the pH on the Flotation Efficiencies of Co^{2+} Ions and Bt. According to Table 2, the optimum conditions of Co^{2+} ion flotation are presumed to occur at the composition of 130 ppm Bt, 20 ppm HDBAC, and 3 ppm PAA. The subsequent flotations were carried out under these conditions and under varying pH values. Figure 9 shows the results concerning the flotation efficiencies of Co^{2+} ions and Bt from a solution containing 1×10^{-5} mol/l Co^{2+} ions. It may be seen that the flotation efficiency of Co^{2+} ions begins to increase sharply at around pH 8 and that the maximum F of 95% is recorded in the pH range from 9 to about 11. The flotation efficiency is seen to decrease gradually with a further increase in pH. The flotation efficiency of Bt shows a curve with a flat maximum which coincides with that of Co^{2+} ions in the pH region of 9—11. As the cobalt hydroxide begins to form in the vicinity of pH 9, Co^{2+} ions are considered to float as polynuclear species,[10] similar to the flotation of Cu^{2+},[7] and Cd^{2+} ions.[7] In this pH region, Co^{2+} ions are considered to combine almost completely with Bt and are floated together with Bt with the aid of a surfactant, while in other pH regions, especially in the acid region, a large amount of Bt is floated without adsorbing Co^{2+} ions. The effect of Bt is clearly shown by comparing the flotation efficiencies of Co^{2+} ions for the system containing HDBAC with and without Bt, as is shown in Figs. 9 and 10, where Fig. 10 shows the flotation efficiency of Co^{2+} ions from solutions each containing 1×10^{-5} and 7.4×10^{-9} mol/l of Co^{2+} ions and 20 ppm of HDBAC. It is evident that the flotation efficiency of Co^{2+} ions decreases from about 95% for the system with Bt to 5% for the system without Bt, although the latter system also lacks PAA. This decrease in flotation efficiency is more remarkable than in the case of Cu^{2+}-ion flotation.[7] Further, we can observe a remarkable foam formation in the case of the system lacking Bt; this renders the bubble flotation impossible.[7] From these facts, it may be concluded that the addition of Bt acts both to bridge Co^{2+} ions and HDBAC and to suppress foam, thus ensuring bubble flotation.

A similar flotation experiment was carried out for such a dilute solution of Co^{2+} as 7.4×10^{-9} mol/l. The system was studied since the behavior of Co^{2+} ions in such a dilute solution may give information concerning that of the carrier-free state or of radioactive contamination. The measurements of the flotation efficiency of the Co^{2+} ions and Bt were made for the systems with the same conditions as those listed in

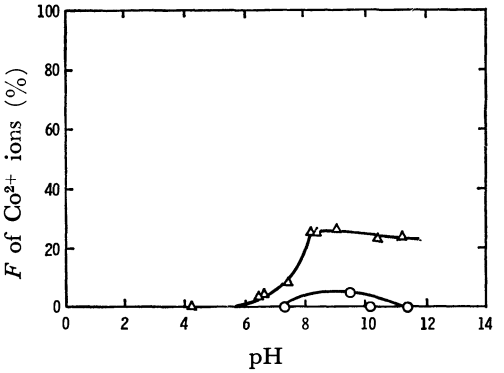

Fig. 10. Foam flotation of Co^{2+} ions.

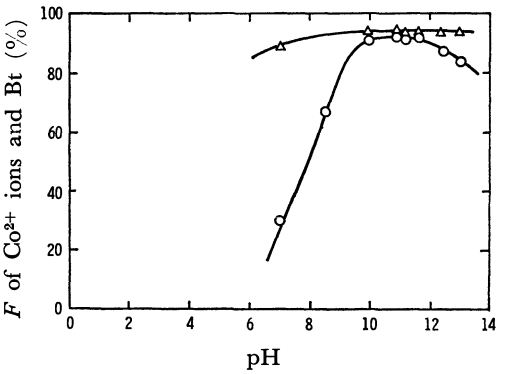

Fig. 11. Effect of pH on flotation efficiency of Co^{2+} ions and Bt.
Co^{2+}: 7.4×10^{-9} mol/l, Bt: 130 ppm, HDBAC: 20 ppm, PAA: 3 ppm, gas-flow time: 2 min.
○: F of Co^{2+} ions, △: F of Bt.

Fig. 9 except that the concentration of the Co^{2+} ions was 7.4×10^{-9} mol/l. The results are shown in Fig. 11. It may be seen that the plots are similar as a whole to those of Fig. 9, though somewhat lower maxima. Also, in this case, the coincidence of the maxima of the flotation efficiency of the Co^{2+} ions and Bt indicates that the Co^{2+} ions are adsorbed on Bt particles and are removed with them.

Removal of Co^{2+} Ions by Centrifugation. It may be considered likely, on the basis of the above observations, that Co^{2+} ions combine with Bt particles under the optimum conditions of flotation. To further confirm this mechanism, the centrifugation of the Co^{2+} ions was carried out at 3000 rpm for 10 min at varying pH values, and the efficiency of the centrifugation or efficiency of the adsorption of Co^{2+} ions on Bt was measured and was plotted against the pH (*cf.* Fig. 12).

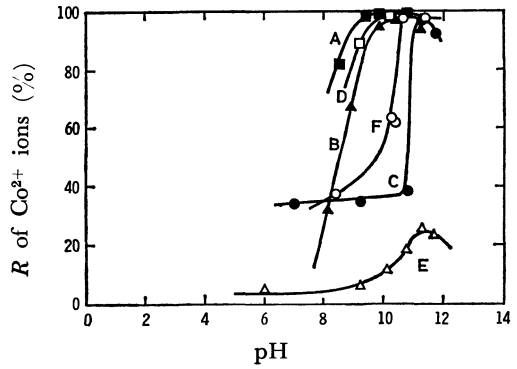

Fig. 12. Effect of pH on R or adsorption of Co^{2+} ions.
Co^{2+}: 1×10^{-5} mol/l, Bt: 130 ppm, HDBAC: 20 ppm, PAA: 3 ppm, centrifugation: 3000 rpm for 10 min.
A: Co^{2+}-Bt-HDBAC-PAA system,
B: Co^{2+}-Bt-HDBAC system,
C: Co^{2+}-Bt-PAA system,
D: Co^{2+}-Bt system,
E: Co^{2+}-PAA system,
F: Co^{2+} system.

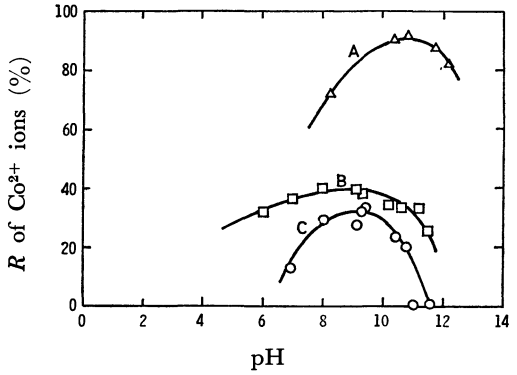

Fig. 13. Effect of pH on efficiency of centrifugation of Co^{2+} ions.
Bt: 130 ppm, HDBAC: 20 ppm, PAA: 3 ppm, centrifugation: 3000 rpm for 10 min.
A: Co^{2+}-Bt-HDBAC-PAA system, Co^{2+}: 3.1×10^{-9} mol/l,
B: Co^{2+}-Bt-PAA system, Co^{2+}: 7.4×10^{-9} mol/l,
C: Co^{2+}-PAA system, Co^{2+}: 7.4×10^{-9} mol/l.

As may be seen in Fig. 12, high R values were obtained for the Co^{2+}-Bt-HDBAC-PAA system(A), the Co^{2+}-Bt-HDBAC system(B), and the Co^{2+}-Bt system-(D). It is confirmed that the R value of the system containing PAA but lacking HDBAC is very low up to high pH values, while the system containing Co^{2+} ions alone still shows a large R value in a sufficiently high alkaline region. It seems likely that, in the absence of HDBAC, the Co^{2+} ions are protected by PAA against adsorption on Bt and hydroxide formation. The centrifugation was carried out further for solutions containing 7.4×10^{-9} mol/l of Co^{2+} ions or 3.1×10^{-9} mol/l of Co^{2+} ions, with other constituents similar to those of Systems (A), (B), and (E), shown in Fig. 12. The results are shown in Fig. 13. The tendencies are similar to those of Fig. 12, and the Co^{2+}-Bt-HDBAC-PAA system is seen to be most effective in removing the Co^{2+} ions from this dilute solution.

Application of Adsorbing Particle Flotation to the Fission Product. Figure 14 shows the results of the flotation of ^{155}Eu from a solution containing 2×10^{-2} μCi/ml of ^{155}Eu ions, 130 ppm of Bt, 20 ppm of HDBAC, and 3 ppm of PAA. The flotation efficiency of ^{155}Eu ions is plotted against the pH. As may be seen in Fig. 14, the flotation efficiency increases from pH 3 with an increase in the pH and two maxima of 85% and 93% flotation efficiencies are observed, at

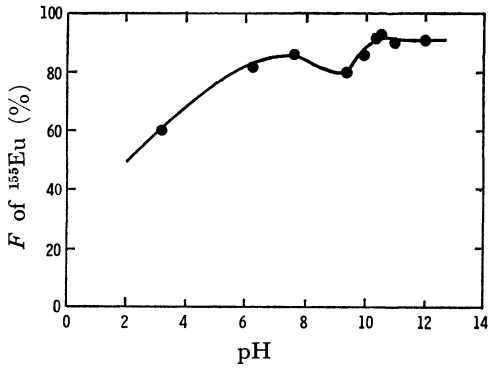

Fig. 14. Effect of pH on flotation efficiency of ^{155}Eu.
^{155}Eu: 2×10^{-2} μCi/ml, Bt: 130 ppm, HDBAC: 20 ppm, PAA: 3 ppm, gas-flow time: 2 min.

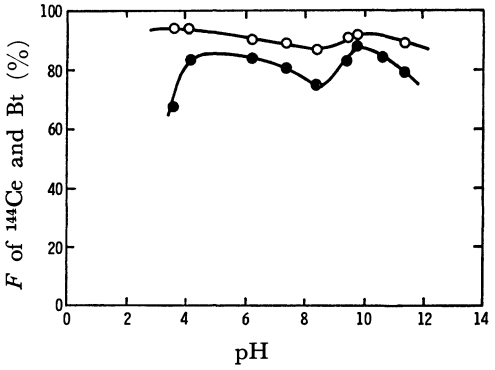

Fig. 15. Effect of pH on flotation efficiency of ^{144}Ce and Bt.
^{144}Ce: 1.5×10^{-2} μCi/ml, Bt: 130 ppm, HDBAC: 20 ppm, PAA: 3 ppm, gas-flow time: 2 min,
●: F of ^{144}Ce, ○: F of Bt.

pH 7.5 and 10.5 respectively. The former and the latter maxima may be explained by the formation of the radiocolloid of ^{155}Eu and of insoluble europium hydroxide respectively, but this requires further study.[11] Figure 15 shows the flotation efficiency of ^{144}Ce and Bt from a solution of 1.5×10^{-2} μCi/ml of ^{144}Ce ions, 130 ppm of Bt, 20 ppm of HDBAC, and 3 ppm of PAA as a function of the pH. In this case, the similar maxima of 85% at pH 5 and 80% at pH 9.7 are observed. The flotation efficiency of ^{144}Ce ions parallels that of Bt. Likewise, this may suggest that there is a relationship between the combining ratio of Bt and the cerium ion under its optimum flotation conditions.

The authors wish to thank Dr. Fujio Ichikawa of the Japan Atomic Energy Research Institute for the supply of fission products.

Interfacial Layer between a Mercury Electrode and Dilute Aqueous Solutions of Alkali-Metal Chloride at Potentials of the Cathodic Limiting Current Plateau

Katsuo TAKAHASHI and Reita TAMAMUSHI

The Institute of Physical and Chemical Research, Hirosawa, Wako, Saitama 351

(Received June 27, 1975)

The electrochemical properties of the interfacial layer between a DME and dilute aqueous solutions of MCl (M: alkali-metal) at the cathodic limiting current plateau were studied by means of impedance measurements at relatively low frequencies ($\leq$250 Hz). From the frequency and potential dependence of the capacitive and the resistive components of the electrode impedance, the following conclusions were obtained concerning the properties of the interfacial layer under the above condition: (i) when the concentration of cations is extremely low in the vicinity of the electrode surface, the impedance behaves as if the conventional double-layer were absent: (ii) the impedance behavior of the present system can be explained by assuming an equivalent circuit which is given by a series combination of the Warburg impedance for the reduction of M^+ and the resistance of solution; and (iii) such an interfacial layer is conventionally called "the Nernst double-layer" and its formation is determined by the mass-transport of the reacting species M^+.

A conventional double-layer of the Helmholtz-Gouy-Chapman type is formed at a polarizable electrode/solution interface by some nonfaradaic interaction between the electrode and ionic species in the solution. The structure of such a double-layer has been extensively studied.[1,2] However, only a limited amount of information is available on the properties of an electrode/solution interface where the concentration of electrochemically-inactive ions is extremely low.[3-5]

The capacitance behavior of the interface between mercury and dilute electrolyte solutions was reported in previous papers.[6,7] Contrary to Grahame's model of the double-layer, the capacitance of a compact double-layer at highly negative electrode potentials was found to decrease with a decrease in the concentration of electrolytes.[6] It was observed that the capacitance of a dropping mercury electrode (DME)/TlOH system decreased markedly at electrode potentials in the region of the cathodic limiting current plateau.[7] Such a decrease in the double-layer capacitance was explained in terms of the deficiency of electrochemically-inactive cations forming the conventional double-layer.

This study deals with the impedance behavior of a DME/MCl (M: alkali-metal) system in the potential region of the cathodic limiting-current plateau. Sluyters-Rehbach *et al.*[8,9] measured the impedance of similar systems and discussed the electrode reaction of alkali-metal cations at a DME; in contrast to their study, our measurements were carried out with dilute aqueous solutions (less than a few mM) of alkali-metal chlorides in order to obtain detailed information on the structure of the interfacial layer where the concentration of cations is extremely low. From the frequency dependence of the electrode impedance, a possible equivalent circuit is proposed, and the characteristics of such an interfacial layer are discussed.

Experimental

The conductive and the susceptive components of the admittance of an electrode/solution system were measured as a function of the electrode potential by means of a phase-sensitive AC polarograph consisting of a conventional AC polarographic unit and two phase-sensitive detectors. In order to make accurate measurements with high-impedance systems, the phase-sensitive detectors were carefully adjusted and calibrated by using appropriate dummy-cells of known resistors and capacitors. The details of the measuring circuits and procedures have been reported elsewhare.[10]

The cell employed was a glass beaker of 100 cm^3 capacity with a silicon-rubber stopper. The working electrode was a conventional DME; in most cases, the rate of flow of mercury was 0.526 mg s^{-1}, and the drop-time was mechanically controlled at 4.1 s. Admittance measurements were made on a surface area of 0.0142 cm^2. A platinized-platinum spiral of large surface area was used as a counter electrode. The reference electrode was a silver-silver chloride electrode placed in the cell as shown in Fig. 1; this location of the reference electrode is not desirable from the standpoint of eliminating the ohmic *IR*-drop, but is essential for the stable performance of the potentiostat when a high-impedance system is to be measured. The correction of the electrode potential for the ohmic drop was made by calculating the *IR*-values assuming an appropriate value of the solution resistance.

The measurements were made with deaerated solutions at 25.0$\pm$0.1 °C. All solutions were prepared from analytical reagent grade chemicals and redistilled water.

Results and Discussion

Frequency Dependence of the Electrode Impedance and a Possible Equivalent Circuit. A typical DC-polarogram of a DME/1 mM KCl system is presented in Fig. 2; the potential regions F_1, P, and F_2 correspond to the reduction wave of K^+, the limiting current plateau, and the reduction of water, respectively. In this paper, the impedance behavior in the potential region P ($E=-2.7$ to -0.3 V *vs.* Ag-AgCl) will be discussed.

Figure 3 shows the potential dependence of the series capacitance C_s and the series resistance R_s of the impedance observed with a DME/1 mM KCl system at several frequencies. A remarkable frequency dispersion of C_s and R_s is observed at each electrode potential of the cathodic limiting current plateau. The value of C_s is clearly lower than that of the conventional double layer (about 16 $\mu F\ cm^{-2}$), and R_s is much higher than that corresponding to the resistance of the bulk solution.

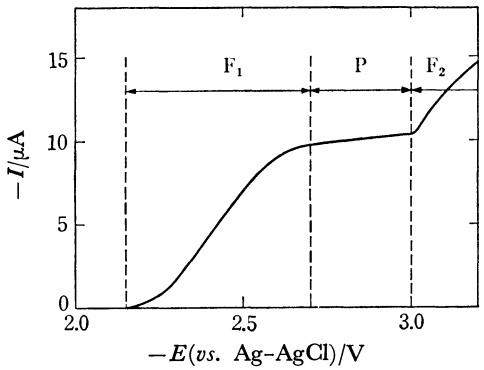

Fig. 2. Current-potential curve obtained with a DME/1 mM KCl system at 25 °C: F_1, the potential region of the reduction step of K^+; P, the limiting current plateau; F_2, the potential region of the reduction of water.

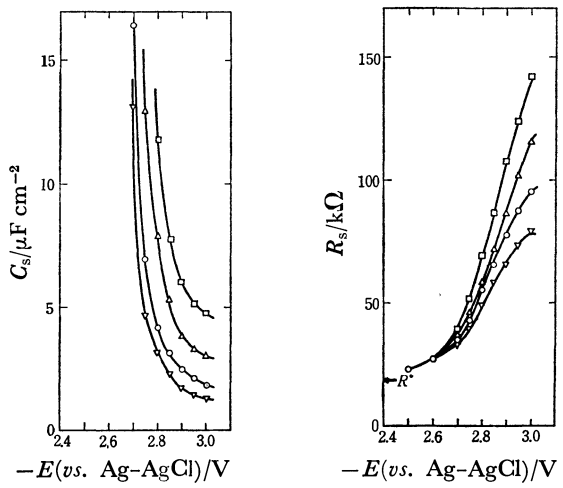

Fig. 3. Potential dependence of the series capacitance C_s and resistance R_s of a DME/1 mM KCl system (25 °C) at different frequencies: -□- 32 Hz, -△- 64 Hz, -○- 120 Hz, -▽- 250 Hz. $R°$ is the resistance of solution as defined by Eq. (12).

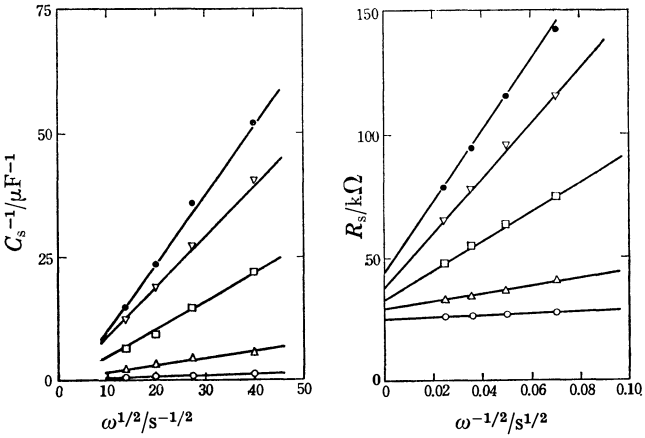

Fig. 4. Frequency dependence of the C_s- and R_s-components of a DME/1 mM KCl system (25 °C) at various electrode potentials: E(*vs.* Ag-AgCl)/V= −2.6(-○-), −2.7(-△-), −2.8(-□-), −2.9(-▽-), and −3.0(-●-).

Table 1. The intercepts and the slopes of Eqs. (1) and (2), obtained with a DME/1 mM KCl system at 25.0 °C

$-E$ (*vs.* Ag-AgCl)/V	$(C_s°)^{-1}$ / μF^{-1}	S_c / $\Omega s^{-1/2}$	$R_s°$ / kΩ	S_r / $\Omega s^{-1/2}$
2.6	~0	3.5×10^4	25	4.0×10^4
2.7	~0	1.4×10^5	29	1.6×10^5
2.8	−1	5.7×10^5	33	6.0×10^5
2.9	−1	1.04×10^6	38	1.12×10^6
3.0	−4	1.41×10^6	44	1.46×10^6

In Fig. 4, the C_s and R_s at each electrode potential are plotted as a function of the angular frequency ω. From the linear relationship observed with the C_s^{-1} *vs.* $\omega^{1/2}$ and the R_s *vs.* $\omega^{-1/2}$ plots, the frequency dependence of C_s and R_s can be represented by the following equations:

$$C_s^{-1} = (C_s°)^{-1} + S_c\omega^{1/2} \quad (1)$$

$$R_s = R_s° + S_r\omega^{-1/2} \quad (2)$$

The intercepts ($(C_s°)^{-1}$ and $R_s°$) and the slopes (S_c and S_r) as given by Eqs. (1) and (2) are summarized in Table 1. It can be assumed from this result that, at each potential, $S_c=S_r=S$ and $(C_s°)^{-1}=0$ within the limit of experimental accuracy. With this approximation, Eqs. (1) and (2) can be reduced to

$$C_s^{-1} = S\omega^{1/2} \quad (3)$$

$$R_s = R_s° + S\omega^{-1/2} \quad (4)$$

Figure 5(a) shows the simplest electrical equivalent circuit which satisfies the impedance behavior represented by Eqs. (3) and (4). The impedance Z_w is a Warburg-type impedance given by

$$Z_w = R_w + jX_w \quad (5)$$

with

$$R_w = -X_w = S\omega^{-1/2} \quad (6)$$

The magnitude of Z_w is equal to $\sqrt{2}S\omega^{-1/2}$, and the phase angle between R_w and X_w is equal to $\pi/4$.

Consider a simple electrode reaction,

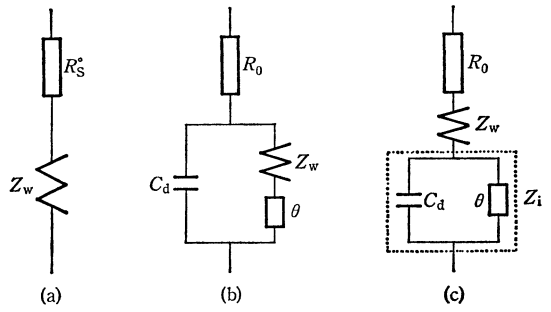

Fig. 5. Electrical equivalent circuits of the electrode impedance.

$$M^+ + e(Hg) \rightleftharpoons M\text{-}Hg \quad (M: \text{alkali-metal}) \qquad (7)$$

in which the mass-transport of M^+ and M in mercury is controlled by diffusion. According to the theory of electrode processes,[11,12] the equivalent circuit for the electrode reaction (7) in solutions containing an excess of supporting electrolytes is represented by Fig. 5(b), where C_d is the conventional double-layer capacitance; θ, the polarization resistance; and R_0, the resistance of solution. This equivalent circuit implicitly involves the assumption that different kinds of ions are responsible for the faradaic and the double-layer charging processes, *i.e.*, the faradaic process is controlled by the depolarizer flux, while the charging process is controlled by the supporting electrolyte flux.

In solutions containing no supporting electrolytes, however, both the faradaic and charging processes may be controlled by the flux of the same ionic species—alkali-metal cations, in the present systems. When alkali-metal cations reach the electrode surface by mass-transport, they will contribute to both faradaic and charging currents. In such cases, the equivalent circuit is considered to be represented by Fig. 5(c), where the Warburg impedance of the depolarizer is in series with the impedance of electrode interface, Z_I, which involves θ and C_d. If the flux of the depolarizer contributes mainly to the charging process, the impedance Z_I should be capacitive, while, if the flux contributes mainly to the faradaic process, Z_I should be resistive.

The equivalent circuit (Fig. 5(a)) determined by the impedance measurements shows that the impedance Z_I in Fig. 5(c) should be resistive, *i.e.*, the condition

$$\theta \ll 1/\omega C_d \qquad (8)$$

is satisfied at the frequencies used in the present study. This relationship is reasonable, because the electrode reaction (7) is known to be polarographically reversible and the polarization resistance θ is very small. In this case, the Warburg-type impedance in Fig. 5(a) can be considered to be due to the mass-transport of the depolarizer, and the resistance R_s° is assumed to be practically equal to the resistance, R_0, of the solution.

Resistance Component R_s°. It should be mentioned that the resistance component R_s° observed with the DME/KCl system depends on the electrode potential as shown in Fig. 6. Such a potential-dependence

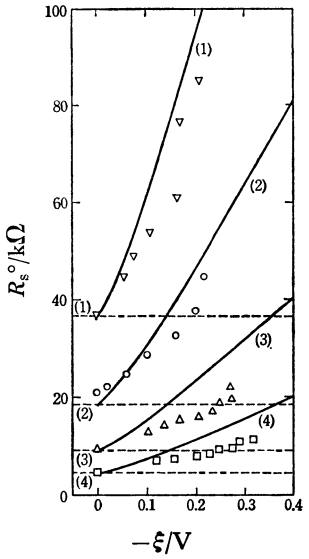

Fig. 6. Potential dependence of resistance R_s° of a DME/x mM KCl system (25 °C): x=0.5(1, ▽), 1.0 (2, ○), 2.0(3, △), and 4.0(4, □). Solid lines are theoretical curves, and broken lines represent the R°-values for each concentration. Potential axis $\xi = E_{cor} - E_{1/2}{}^r$ (see text).

of R_s° can be explained by taking into account the contribution from the resistance R_m of a mass-transport layer where the concentration of depolarizer changes with the distance from the electrode surface. The resistance component R_s° is then given by

$$R_s^\circ \simeq R_o = R_m + R_b \qquad (9)$$

R_b being the resistance of the bulk solution where the composition of the solution is uniform.

In the present systems containing no supporting electrolytes, the resistance R_m is expected to increase with an increase in the negative electrode potential because of the decrease in the concentration of depolarizer at the electrode surface. In the following calculation, we assume that the concentration change of the depolarizer is linear in the mass-transport layer (the Nernst-type layer) as shown in Fig. 7 and that the ionic mobilities are constant throughout the solution phase.

With these approximations, the resistance of the mass-transport layer R_m and that of the bulk solution R_b are given by the following equations:

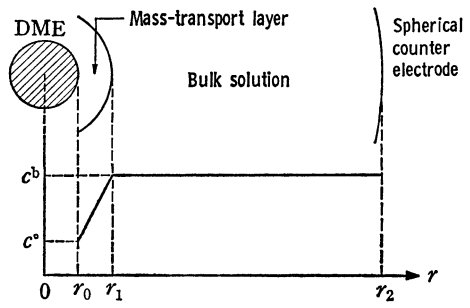

Fig. 7. A model of the mass-transport layer.

$$R_m = R^\circ c_M^b\left(\frac{1}{r_0}-\frac{1}{r_2}\right)^{-1}\frac{r_1-r_0}{r_1c_M^\circ - r_0c_b^M} \times\left[\left(\frac{1}{r_0}-\frac{1}{r_1}\right)+\frac{c_M^b-c_M^\circ}{r_1c_M^\circ-r_0c_M^b}\ln\frac{r_0c_M^b}{r_1c_M^\circ}\right] \quad (10)$$

and

$$R_b = R^\circ\left(\frac{1}{r_0}-\frac{1}{r_2}\right)^{-1}\left(\frac{1}{r_1}-\frac{1}{r_2}\right) \quad (11)$$

with

$$R^\circ = \frac{1000}{4\pi\Lambda c_M^b}\left(\frac{1}{r_0}-\frac{1}{r_2}\right) \quad (12)$$

where c_M^b and c_M° are the concentrations of M^+ in the bulk solution ($r_1 \leq r \leq r_2$) and at the electrode surface ($r=r_0$), respectively, and Λ is the molar conductivity of the solution. The value of R° corresponds to the resistance of the solution phase when the composition of the solution is uniform from r_0 to r_2; R° can be determined from the measurement at potentials where no electrode reaction occurs.

In the calculation of R_s° using Eqs. (9)—(12) as a function of the electrode potential, the following two assumptions are introduced:

$$\delta = r_1 - r_0 = \left(\frac{3}{7}\pi D_M t\right)^{1/2} \quad (13)$$

and

$$\frac{c_M^b - c_M^\circ}{c_M^\circ} = \exp\left(\frac{-F}{RT}\xi\right) \quad (14)$$

with

$$\xi = E_{cor} - E_{1/2}{}^r \quad (15)$$

where δ is the thickness of the mass-transport layer, D_M the diffusion coefficient of the depolarizer M^+, t the time of electrolysis, $E_{1/2}{}^r$ the reversible half-wave potential, and E_{cor} the electrode potential corrected for the ohmic IR-drop. Relation (13) is obtained from the theory of the polarographic limiting current, and relation (14) is based upon the Nernstian behavior of the electrode reaction.[13]

In Fig. 6, the experimental relationship between R_s° and ξ is compared with the theoretical curves (solid lines) obtained with the numerical values: $r_0=0.0339$ cm, $r_2=0.5$ cm, $t=4.0$ s, and $D_M=1\times10^{-5}$ cm^2 s^{-1}. The agreement between the experimental and the theoretical curve is sufficiently good to support the assumption that R_s° is the resistance of the solution phase from r_0 to r_2 as represented by the simplified model shown in Fig. 7.

Warburg-type Impedance Z_w. Let us assume that the Warburg-type impedance in our present system is given by an expression[12] similar to that derived for the electrode reaction in the supporting electrolyte solutions. Then, the coefficient σ of the Warburg impedance for electrode reaction (7) may be given by the equation,

$$\sigma = SA = \frac{RT}{\sqrt{2}F^2}\left[\frac{1}{\sqrt{D_A^*}}\exp\left(\frac{\alpha_aF}{RT}\xi\right)+\frac{1}{\sqrt{D_M^*}}\times\exp\left(-\frac{\alpha_cF}{RT}\xi\right)\right]\left[\alpha_ac_a^\circ\exp\left(\frac{\alpha_aF}{RT}\xi\right)+\alpha_cc_M^\circ\exp\left(-\frac{\alpha_cF}{RT}\xi\right)\right]^{-1} \quad (16)$$

where A is the surface area of the electrode, $\alpha_{a(c)}$ the anodic (cathodic) transfer coefficient, $D_{a(M)}^*$ the apparent diffusion coefficient of M-Hg (M^+), $c_{a(M)}^\circ$ the concentration of M-Hg (M^+) at the electrode surface, and other symbols have their usual meanings.

At sufficiently negative potentials where the cathodic limiting current is observed, the following conditions can be satisfied:

$$c_a^\circ \simeq c_M^b \quad (17)$$

and

$$\exp\left(\frac{\alpha_aF}{RT}\xi\right) \ll \exp\left(-\frac{\alpha_cF}{RT}\xi\right) \quad (18)$$

Then, assuming the relation, $\alpha_a+\alpha_c=1$, we obtain the expression:

$$\sigma = \frac{RT}{(2D_M^*)^{1/2}F^2}\left[\alpha_ac_M^b\exp\left(\frac{F}{RT}\xi\right)+\alpha_cc_M^\circ\right]^{-1} \quad (19)$$

Equation (19) shows that the experimental values of σ provide information on the surface concentration c_M° of the depolarizer at each potential ξ. If the surface concentration is determined by the Nernstian relation, expression (20) can be obtained from Eqs. (14) and (19):

$$\sigma = \frac{RT}{(2D_M^*)^{1/2}F^2c_M^b}\exp\left(-\frac{F}{RT}\xi\right) \quad (20)$$

In Fig. 8, the experimental values of σc_M^b obtained with several alkali-metal chlorides are plotted against the electrode potential ξ; the theoretical line with the slope given by Eq. (20) is also shown. Considering the accuracy of the measurements and the rough approximations involved in the theoretical calculation, we can conclude that the agreement between the

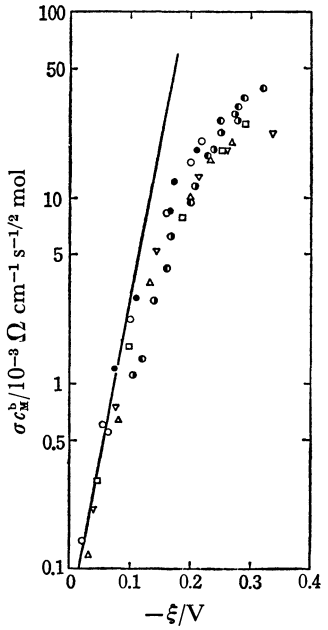

Fig. 8. Potential dependence of the Warburg-parameter σc_M^b of DME/alkali-metal chloride systems (25 °C): 0.5 mM KCl(-●-); 1.0 mM KCl(-○-); 2.0 mM KCl(-◑-); 4.0 mM KCl(-◐-); 1.0 mM NaCl (-□-); 1.0 mM RbCl(-△-); 1.0 mM CsCl(-▽-). Solid line shows the theoretical curve as calculated with $D_M^*=1\times10^{-5}$ cm^2 s^{-1} by means of Eq. (20).

experiments and the theory is satisfactory unless $|\xi|$ exceeds 150 mV.

Conclusion

The present results show that the impedance behavior of the DME/MCl (M: alkali-metal) system at the potentials of the limiting current plateau (region P in Fig. 2) can be represented by the equivalent circuit as shown in Fig. 5(a); the Warburg impedance Z_w for electrode reaction (7) is in series with resistance $R_s°$ of the solution from the surface of the working electrode to the counter electrode. It is interesting that, at relatively low frequencies ($\leq$250 Hz), the impedance in the potential region P behaves as if the conventional double-layer were absent. For this situation, the interfacial layer between the electrode and the solution phase may be called "the Nernst double-layer"; the potential difference across the Nernst double-layer is determined by the electrode reaction, and the formation of the layer is controlled by the mass-transport of the reacting species.

The Inductive Susceptance Observed with Electrode Reaction of Water at Far Negative Potentials

Katsuo TAKAHASHI, Kiyoshi MATSUDA, and Reita TAMAMUSHI
The Institute of Physical and Chemical Research, Hirosawa, Wako, Saitama 351

(Received July 16, 1975)

The admittance of various electrodes/dilute aqueous electrolyte solution systems was measured at far negative potentials in the frequency range of 22—500 Hz, and the experimental results were discussed in terms of the mechanism of the electrochemical reduction of water molecules. The frequency dependence of the conductance- and susceptance-components was analyzed by assuming possible equivalent circuits. It was concluded that, in the systems which give inductive susceptances at low frequencies, the reduction of water proceeds according to the electrochemical mechanisms;

$$H_2O + e \longrightarrow H_{ad} + OH^-, \quad H_{ad} + H_2O + e \longrightarrow H_2 + OH^-$$

where the current density due to the second reaction path is proportional to the product of θ and $(1-\theta)$, θ being the coverage of the electrode surface by adsorbed hydrogen atoms, H_{ad}. At some metal electrodes in solutions of alkali-metal cations, no inductive susceptance was observed; this suggests that the hydrogen evolution proceeds according to other mechanisms.

The faradaic admittance of usual electrode reactions involves a positive conductance and a capacitive susceptance. In some electrode reactions, however, unusual faradaic admittances with negative conductances and/or inductive susceptances have been observed under certain experimental conditions. A typical example with a negative conductance is the reduction of In(III) at a dropping mercury electrode (DME) in thiocyanate solutions,[1] while an example with an inductive susceptance is the electrochemical dissolution of iron and nickel in alkaline solutions.[2] The theoretical interpretation of these unusual faradaic admittances has been made by several authors[1-6] in connexion with the mechanisms of electrode reactions; in particular, a recent study of Smith and Sobel[5] clearly demonstrates the possibility of some ECE mechanisms giving inductive susceptances.

In the cathodic evolution of hydrogen, the appearance of an inductive susceptance was suggested on a theoretical basis by Gerischer and Mehl,[3] by Batrakov and Iofa,[7] and by Novosel'skii and Gudina.[8] In a previous paper,[9] the present authors reported the experimental observation that the susceptance components of DME/dilute aqueous electrolyte solutions become inductive at far negative potentials, where the reduction of water molecules is supposed to proceed. This paper will present the details of the admittance behavior of the above-mentioned systems and will discuss the possible mechanism of the electrochemical reduction of water molecules.

Experimental

The electrolytic currents (DC-components), conductances, and susceptances due to the electrode process were measured as functions of the electrode potential by using an apparatus whose block diagram is shown in Fig. 1; the instrumental details of the apparatus were reported previously.[10] The readings of each output-signal of the instrument were carefully calibrated by using appropriate dummy cells consisting of known resistors and capacitors. The output-signal of the 90°-phase-sensitive-detector at the stage before a low-pass filter, when observed with a cathode-ray oscilloscope, gives the patterns shown in Fig. 2 according to the nature of the admittance to be measured; this difference in the oscilloscopic patterns was used to determine whether the susceptance component was capacitive or inductive.

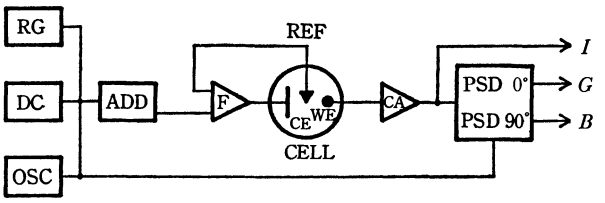

Fig. 1. Block diagram of the measuring instrument. RG: ramp-generator; DC: DC-voltage source; OSC: oscillator; ADD: adder; F: follower-type potentiostat; CA: current amplifier; PSD: phase-sensitive detector.

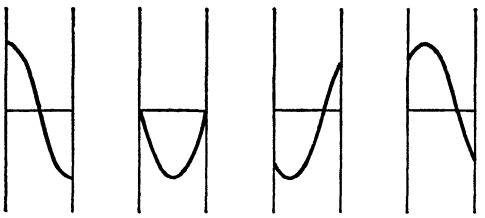

Fig. 2. Typical oscilloscopic patterns observed at the output of the 90°-PSD (before the low-pass filter) when the admittance to be measured (a) pure resistance, (b) pure capacitance, (c) capacitive admittance, (d) inductive admittance.

The arrangement of electrodes (working, counter, and reference electrodes) in a cell was the same as that described in a previous paper.[11] Conventional DME and microelectrodes (both rotating and stationary) of various metals were used as the working electrodes; in the case of the DME, the rate of the flow of the mercury was 0.526 mg s^{-1}, the drop time was mechanically controlled at 4.1 s, and admittance measurements were made at a surface area of 0.0142 cm^2. The counter electrode was a Pt–Pt spiral with large dimensions. In most solutions a Pt–Pt spiral was employed as the reference electrode; in chloride solutions, however, a Ag–AgCl electrode was also used as the reference. In this paper, the electrode potential is not corrected for the ohmic *IR*-drop.

All the solutions were prepared from analytical reagent-

grade chemicals by using redistilled water. The measurements were carried out with deaerated solutions at 25.0± 0.1 °C.

Results

The direct current (I)-potential (E), conductance (G)-E, and susceptance (B)-E curves observed with a DME/0.5 mM $Cd(NO_3)_2$ system were given in a previous paper;[9] the B-E curve clearly shows the inductive susceptance ($B<0$) at very negative potentials, where the cathodic current, which is considered to be due to the reduction of water molecules,[12] increases almost linearly with the electrode potential. Similar inductive susceptances were also observed at the DME in solutions containing various cations and at many solid electrodes in dilute aqueous solutions of strong acids; the systems examined in this work are summarized in Table 1.

Figures 3, 4, and 5 present typical examples of the I-E, G-E, and B-E curves obtained with the DME/1 mM KNO_3, Pt/2 mM HCl, and Pt/1 mM NaCl systems

respectively. In the systems which give inductive susceptances at far negative potentials, the cathodic limiting-current plateau due to the reduction of the cations in the solution is clearly observed on the I-E curve, and the final rise in the cathodic current is well separated from the previous reduction step of the cation (see Figs. 3 and 4). On the other hand, no inductive susceptances could be observed at many solid electrodes in aqueous solutions containing alkali-metal cations; in these systems, the cathodic current increases monotonously without reaching a limiting-current plateau (see Fig. 5). The following part of this paper will be concerned mainly with the inductive susceptances observed with the DME systems.

The electrode potentials, $E_{B=0}$, where the susceptance, B, changes from capacitive ($B>0$) to inductive ($B<0$),

a) Approximate values. b) In a perchlorate solution.

are summarized in Table 2. As may be seen from this table, the cations can be classified into two groups according to the correlation between their $E_{B=0}$ and their polarographic half-wave potentials, $E_{1/2}$: Group (A) includes the cations (Pb^{2+}, Cd^{2+}, Zn^{2+}, Ni^{2+}, Ag^+, Hg_2^{2+}, and In^{3+}), whose half-wave potentials are less negative than that of H^+; Group (B) includes the cations (Li^+, Na^+, K^+, Ca^{2+}, and Al^{3+}), whose half-wave potentials are more negative than that of H^+. The $E_{B=0}$ values for the cations in Group (A) do not show any particular correlation with the half-wave potentials, while the $E_{B=0}$ values for the cations in Group (B) become more negative in the same order as their half-wave potentials.

The effect of the frequency on the inductive susceptance was studied mainly with DME/KNO_3 (or KCl) solutions. The electrode potential, $E_{B=0}$, for a DME/1 mM KNO_3 system shifted to more negative potentials almost linearly with the increasing frequency, as is shown in Fig. 6. The $E_{B=0}$ value extrapolated to zero frequency was found to be equal to the electrode potential, E_D, where the polarographic cathodic current begins to increase linearly with the electrode potential (see Fig. 6).

The frequency dependence of the admittance measured with a DME/1 mM KNO_3 system at several electrode potentials is shown in Fig. 7 by plotting B against G on a complex admittance plane. Similar diagrams were also obtained with DME/KCl solutions of different concentrations at $E=-3.2$ V (*vs.* SCE) (see Fig. 8). The *B-G* plots for these systems suggest that the electric properties of the systems can be represented by assuming some resonance circuits which involve capacitive and inductive elements.

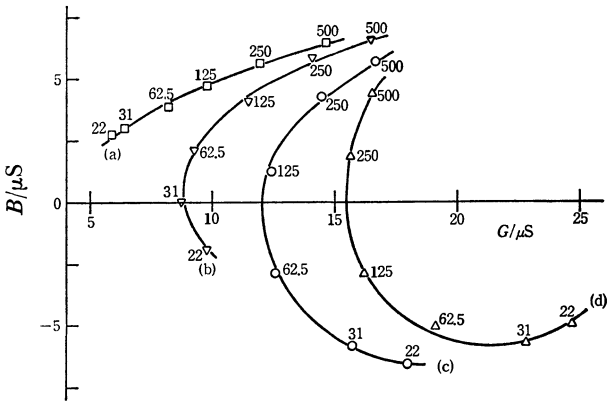

Fig. 7. Frequency dependence of the admittance measured with a DME/1 mM KNO_3 system at different electrode potentials; E/V(*vs.* SCE) = −2.8(a), −3.0 (b), −3.2(c), and −3.4(d). The figure beside each experimental point represents the frequency in Hz.

Discussion

The experimental results presented in the previous section suggest that the appearance of the inductive susceptance is related to the mechanism of the reduction process of water molecules at the electrodes.

In analogy with the mechanisms proposed for the hydrogen overvoltage,[13] water molecules are considered to be reduced electrochemically through either one of the following reaction schemes: the recombination (EC) mechanism (I):

$$H_2O + e \rightarrow H_{ad} + OH^- \quad \text{(I-1)}$$

$$H_{ad} + H_{ad} \rightarrow H_2 \quad \text{(I-2)}$$

or the electrochemical (EE′ or ECE′) mechanism (II):

$$H_2O + e \rightarrow H_{ad} + OH^- \quad \text{(II-1)}$$

$$H_{ad} + H_2O + e \rightarrow H_2 + OH^- \quad \text{(II-2)}$$

where H_{ad} indicates the hydrogen atom adsorbed on the electrode surface. In solutions containing alkali-metal cations, a third (catalytic) mechanism (III) can be considered, in which the reduction of water molecules proceeds *via* an intermediate discharge of alkali-metal cations:

$$M^+ + e(Me) \rightarrow M(Me) \quad \text{(III-1)}$$

$$M(Me) + H_2O \rightarrow M^+ + H_{ad} + OH^- + (Me) \quad \text{(III-2)}$$

$$H_{ad} + H_{ad} \rightarrow H_2 \quad \text{(III-3)}$$

where M^+ is an alkali-metal cation and Me represents a metal of the electrode.

According to the theoretical analysis of the faradaic admittance by Smith and Sobel,[5] no faradaic susceptance of the inductive nature can be expected for the electrode reactions with the following mechanisms: a simple charge-transfer process, the CE and EC mechanisms, and a catalytic mechanism, unless negative transfer-coefficients are assumed. In the cases of the ECE′ and $(EC)_nE'$ mechanisms, however, the theory shows that inductive susceptances can be observed under certain conditions. This theoretical result suggests that the inductive susceptance in our present systems can be explained more reasonably by assuming the electrochemical mechanism (II) than by assuming the recombination mechanism (I) or the mechanism (III) for the reduction of water molecules.

Theoretical Expressions for the Faradaic Admittance. In this paper, the theoretical expressions of the faradaic admittance for the reaction mechanism (II) are derived on the basis of the following assumptions*:

(a) In the negative potential region where the cathodic current due to the reduction of water molecules is observed, the partial anodic current can be neglected in comparison with the partial cathodic current. Thus, the overall faradaic current density (c.d.), j, due to the reaction (II) is given by:

$$j = j_{c1} + j_{c2} \quad (1)$$

where j_{c1} and j_{c2} are the partial cathodic c.d. for the reaction steps (II-1) and (II-2) respectively.

(b) The partial cathodic c.d., j_{c1}, is represented by:

$$j_{c1}/F = -k_1(1-\theta)\exp(-\beta_1 E) \quad (2)$$

with

$$\beta_1 = \frac{\alpha_{c1}F}{RT} \quad (3)$$

where θ is that fraction of the electrode surface which is covered with H_{ad}; E, the electrode potential referred to a given reference electrode; α_{c1}, the cathodic transfer-coefficient for the step (II-1); k_1, a positive constant which is independent of E, and θ but a function of the concentration of H_2O at the electrode surface. The other symbols have their usual meanings. In this paper, the sign of the cathodic current is taken as negative.

(c) The partial cathodic c.d., j_{c2}, is given by:

$$j_{c2}/F = -k_2\,\theta(1-\theta)\exp(-\beta_2 E) \quad (4)$$

with

$$\beta_2 = \frac{\alpha_{c2}F}{RT} \quad (5)$$

where α_{c2} is the cathodic transfer-coefficient for the step (II-2), and k_2, a positive constant similar to k_1.

Some authors[2,7,8] have used the expression:

$$j_{c2}/F = -k_2\,\theta\exp(-\beta_2 E) \quad (4')$$

As will be discussed later, however, Eq. (4′) cannot explain the present experimental results. Therefore, the following analysis will be made primarily on the basis of Eq. (4).

(d) Under the experimental conditions of the admittance measurement, the electrode potential, E, is equal to the sum of a DC-component, $\bar{E}$, and an AC-component, $\tilde{E}$:

$$E = \bar{E} + \tilde{E} \quad (6)$$

The AC-component is assumed to be sufficiently small, so that the condition:

$$\exp(-\beta_{1(2)}\tilde{E}) = 1-\beta_{1(2)}\tilde{E} \quad (7)$$

is satisfied.

For the faradaic c.d. and for the coverage, we assume the following relations, respectively:

$$j = \bar{j} + \tilde{j} = (\bar{j}_{c1}+\bar{j}_{c2}) + (\tilde{j}_{c1}+\tilde{j}_{c2}) \quad (8)$$

and

$$\theta = \bar{\theta} + \tilde{\theta} \quad (9)$$

where $\bar{j}$ and $\bar{\theta}$ are the DC-components, and $\tilde{j}$ and $\tilde{\theta}$, the AC-components.

(e) When $\tilde{E}$ is given by

$$\tilde{E} = \Delta E\exp(j\omega t) \quad (10)$$

$\tilde{\theta}$ is represented by

$$\tilde{\theta} = \Delta\theta\exp(j\omega t+\phi) \quad (11)$$

where ΔE and $\Delta\theta$ are the amplitudes; ω, the angular frequency; ϕ, the phase-angle between $\tilde{E}$ and $\tilde{\theta}$, and t, the time.

(f) The contribution of the time-dependence of the H_2O-concentration at the electrode surface to the

* Similar treatments of the faradaic admittance have been reported by Batrakov and Iofa,[7] by Novosel'skii and Gudina,[8] and by Epelboin *et al.*[2]

faradaic admittance can be ignored, because a large amount of H_2O is available for the reaction.

By using these assumptions and by neglecting the terms involving a product of the AC-components (*e.g.*, $\tilde{\theta}\tilde{E}$), we obtain the following expressions for $\bar{j}$ and $\tilde{j}$:

$$-\bar{j}/F = (1-\bar{\theta})(\bar{k}_1+\bar{k}_2\bar{\theta}) \tag{12}$$

and

$$\tilde{j}/F = \{\bar{k}_1+\bar{k}_2(2\bar{\theta}-1)\}\tilde{\theta} + (1-\bar{v})(k_1\beta_1+k_2\bar{\theta}\beta_2)\tilde{E} \tag{13}$$

where

$$\bar{k}_1 = k_1\exp(-\beta_1\bar{E}) \text{ and } \bar{k}_2 = k_2\exp(-\beta_2\bar{E}) \tag{14}$$

The faradaic admittance, Y_F, is then given by the equation:

$$Y_F = G_F + jB_F = \frac{d\bar{j}}{d\tilde{E}} = F(1-\bar{\theta})(\bar{k}_1\beta_1+\bar{k}_2\bar{\theta}\beta_2) + F\{\bar{k}_1+\bar{k}_2(2\bar{\theta}-1)\}\frac{d\tilde{\theta}}{d\tilde{E}} \tag{15}$$

where G_F is the faradaic conductance, and B_F, the faradaic susceptance.

The time-dependence of the coverage, θ, follows the relation:

$$[H_{ad}]_s\frac{d\theta}{dt} = k_1(1-\theta)\exp(-\beta_1E) - k_2\theta(1-\theta)\exp(-\beta_2E) \tag{16}$$

where $[H_{ad}]_s$ is the maximum amount of H_{ad} divided by the surface area of the electrode when the surface is saturated with H_{ad}. Similarly to the faradaic c.d., $d\theta/dt$ can be divided into the DC- and AC-components:

$$[H_{ad}]_s\frac{d\bar{\theta}}{dt} = (1-\bar{\theta})(\bar{k}_1-\bar{k}_2\bar{\theta}) \tag{17}$$

and

$$[H_{ad}]_s\frac{d\tilde{\theta}}{dt} = -\{\bar{k}_1+\bar{k}_2(1-2\bar{\theta})\}\tilde{\theta} - (1-\bar{\theta})(\bar{k}_1\beta_1-\bar{k}_2\bar{\theta}\beta_2)\tilde{E} \tag{18}$$

The introduction of Eq. (11) into Eq. (18) gives the equation for $d\tilde{\theta}/d\tilde{E}$:

$$\frac{d\tilde{\theta}}{d\tilde{E}} = -\frac{(1-\bar{\theta})(\bar{k}_1\beta_1-\bar{k}_2\bar{\theta}\beta_2)}{\bar{k}_1+\bar{k}_2(1-2\bar{\theta})+j\omega[H_{ad}]_s} \tag{19}$$

From Eqs. (15) and (19), the following expressions are derived for the faradaic conductance and susceptance respectively:

$$G_F = G_F' + G_F'' \tag{20}$$

$$G_F' = F(1-\bar{\theta})(\bar{k}_1\beta_1+\bar{k}_2\bar{\theta}\beta_2) \tag{21}$$

$$G_F'' = \frac{q}{1+\omega^2p^2} \tag{22}$$

$$B_F = \frac{-\omega pq}{1+\omega^2p^2} \tag{23}$$

where

$$p = \frac{[H_{ad}]_s}{\bar{k}_1+\bar{k}_2(1-2\bar{\theta})} \tag{24}$$

and

$$q = -F\frac{\bar{k}_1-\bar{k}_2(1-2\bar{\theta})}{\bar{k}_1+\bar{k}_2(1-2\bar{\theta})}(1-\bar{\theta})(\bar{k}_1\beta_1-\bar{k}_2\bar{\theta}\beta_2) \tag{25}$$

The conductance, G_F', being independent of the frequency, is equivalent to the reciprocal of the charge-transfer resistance, while the conductance, G_F'', and the susceptance, B_F, both being dependent on the frequency, are due to the concentration polarization.

Equation (21) shows that G_F' is always positive if both the transfer-coefficients, α_{c1} and α_{c2}, are positive (*i.e.*, $\beta_1>0$ and $\beta_2>0$). In our present systems, the possibility of negative transfer-coefficients may be excluded because of the normal behavior of the DC *I-E* curves (if the transfer-coefficient were negative, some abnormal decrease in the cathodic current could be observed with the increase in the negative potentials).

In order to discuss the conditions under which the faradaic susceptance becomes inductive ($B_F<0$), the stationary-state assumption is introduced with respect to the DC-component of the coverage: $d\bar{\theta}/dt=0$. By using this assumption, we obtain the relation:

$$\bar{k}_1 = \bar{k}_2\bar{\theta} \tag{26}$$

from Eq. (17) unless $(1-\bar{\theta})=0$.

From Eqs. (21), (24), (25), and (26), the following expressions are derived for p and a dimensionless parameter, r, which is the ratio of q to G_F':

$$p = \frac{[H_{ad}]_s}{\bar{k}_2(1-\bar{\theta})} \tag{27}$$

and

$$r \equiv \frac{q}{G_F'} = \frac{(3\bar{\theta}-1)(1-b)}{(1-\bar{\theta})(1+b)} \tag{28}$$

where b is a dimensionless quantity as defined by

$$b \equiv \frac{\beta_1}{\beta_2} = \frac{\alpha_{c1}}{\alpha_{c2}} \tag{29}$$

When $r>0$, q must be positive and the faradaic susceptance, B_F, becomes inductive ($B_F<0$), because p should be positive according to Eq. (27). On the other hand, if $r<0$, q must be negative and the faradaic susceptance becomes capacitive ($B_F>0$). By means of Eq. (28), the relationship between b and $\bar{\theta}$ can be drawn for different values of r, as is shown in Fig. 9; (a) represents the b-$\bar{\theta}$ diagram for $r>0$ (inductive susceptance), and (b), the b-$\bar{\theta}$ diagram for $r<0$ (capacitive susceptance). In Fig. 9(a), the combination of b and $\bar{\theta}$ which will result in an inductive susceptance under the condition, $b>0$, is shown by solid lines.

The above theoretical treatment of the faradaic admittance, although not very rigorous, clearly demonstrates that the susceptance, B_F, for the electrochemical mechanism (II) can be either capacitive or inductive according to the conditions determined by the r, b, and $\bar{\theta}$ parameters (see Fig. 9(a) and (b)).

Complex Admittance Plane Diagram and the Equivalent Circuit. Equations (20)—(23) for the faradaic conductance and susceptance show that, when $q>0$,

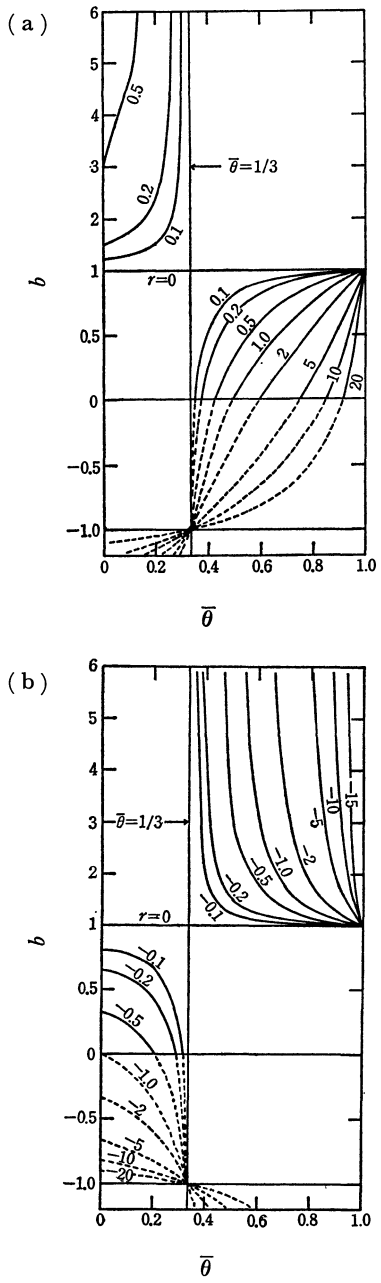

Fig. 9. Theoretical b-$\bar{\theta}$ curves for various values of the parameter, r, as calculated by means of Eq. (28): (a), b-$\bar{\theta}$ curves for $r>0$ (inductive susceptance); (b), b-$\bar{\theta}$ curves for $r<0$ (capacitive susceptance). Solid lines correspond to the condition, $b>0$, and broken lines to the condition, $b<0$.
The figure beside each curve represents the r-value.

a plot of B_F against G_F on a complex admittance plane gives a semi-circle with its center at $[(G_F')+(q/2)]$ and a radius of $q/2$, as is shown in Fig. 10. This admittance behavior can be represented by assuming an equivalent circuit which consists of two resistances, R_1 and R_2, and an inductance, L, as is presented in Fig. 10(a), where $R_1=(G_F')^{-1}$, $R_2=q^{-1}$, $r=R_1/R_2$, $L=p/q$, and the time-constant of the circuit is equal to L/R_2 $(=p)$.

The conductance and the susceptance of an electrode/solution system, which can be measured experimentally,

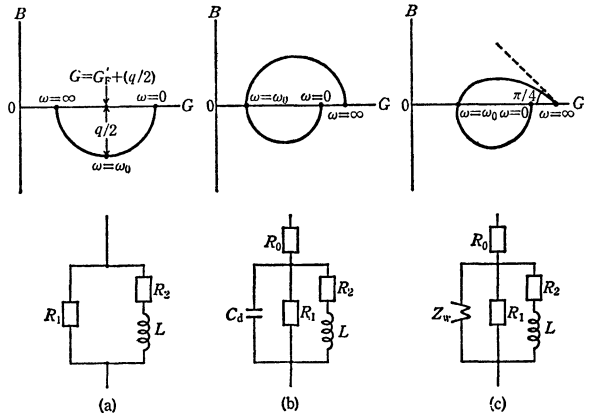

Fig. 10. Theoretical B-G plots (schematic) on a complex admittance plane and the corresponding equivalent circuits.

involve not only the faradaic components, but also the solution resistance, R_0, and the double-layer capacity, C_d. It has been shown by our previous studies[11,14] that, in the far negative potential region where the reduction of all the cations present in the solution gives the cathodic limiting-current plateau, the double-layer capacity of the Helmholtz-Gouy-Chapmann type becomes very small and the admittance behavior of the electrode surface is practically determined by the Warburg-type impedance, Z_w, due to the mass-transport of the depolarizable cations. Consequently, the actual equivalent circuit for the system which gives inductive susceptances may be considered to be represented either by (b) or (c) in Fig. 10; the schematical B-G plots corresponding to the equivalent circuits are presented in the same figure. The expressions for the characteristic points on the complex admittance plane are summarized in Table 3.

Both the equivalent circuits, (b) and (c), can reproduce the experimental observation that the B-G plot starts from the fourth quadrant of the complex admittance plane at lower frequencies and then passes into the first quadrant with the increase in the frequency (see Figs. 7 and 8). In Fig. 11, one of the best experimental results is compared with the B-G diagrams obtained by means of simulation using the equivalent circuits (b) and (c) in Fig. 10; the values of each element, as determined by simulation, are summarized in Table 4. The values of r thus obtained are relatively large, suggesting that the possible values of $\bar{\theta}$ should be in the range of $0.8<\bar{\theta}<1$ (see Fig. 9(a)); in other words, $\bar{k}_2$ is close to $\bar{k}_1$, according to relation (26).

Finally, let us discuss the possibility that the current density due to the reaction path (II-2) is given by Eq. (4'). In this case, too, inductive susceptances can be expected when $r>0$; by following a similar treatment, we obtain the b-$\bar{\theta}$ diagram shown in Fig. 12 for various positive values of r. Figure 12 suggests that the values of r cannot be larger than unity $(r<1)$ for the appearance of inductive susceptances. This result is not in agreement with the r-values ($r=15$ or 25) evaluated by means of simulation (see Table 4).

Conclusion

The discussion above has been made on the basis of the assumption that the inductive susceptance is related to the mechanism of the faradaic processes. There may exist some other mechanisms of the non-faradaic nature which also give inductive susceptances at an electrode/solution interface. However, so long as we accept the above assumption, we can conclude that, in the electrode systems which show the inductive susceptance at far negative potentials, water molecules are reduced through the electrochemical mechanism (II), in which the rate of reaction path (II-2) is proportional to the product of θ and $(1-\theta)$.

The experimental fact that no inductive susceptance is observed at some metal electrodes in solutions containing alkali-metal cations (see Table 1) suggests the possibility that the hydrogen evolution proceeds according to the other mechanisms, such as (I) or (III), in such systems.

(Received July 19, 1975)

The partition coefficients of normal alkanols (R_mOH, m=2 to 6) and a number of polyoxyethylene normal alkyl ethers (R_mE_nOH, n=1,2 m=2 to 5; n=3,4 m=4,5) in the dodecane–water system have been determined at a high dilution at 25 °C. From the finding that the standard free energies of the transfer of the solutes from water to the dodecane phase show a linear relation with the number of methylene and oxyethylene groups, the contribution of the groups to the free energy was obtained as −0.858 for alkanols and −0.808 kcal/mol methylene group for ethers, and 0.655 kcal/mol oxyethylene group respectively. Extrapolation to zero oxyethylene in the linear relationship for the normal alkylethers gave standard free energies of transfer less than those for normal alkanols with the same alkyl chain length. Thus, the alkanol is more hydrophilic than the hypothetical "ether" with no oxyethylene group. The difference in the free energies is discussed from the viewpoint of intramolecular hydrogen-bond formation in the polyoxyethylene chain in the dodecane phase.

In spite of the importance and usefulness of the data of the partition coefficient for amphiphiles between water and the nonpolar phase for the study of colloid chemistry, only a few systematic investigations[1,2] have ever been made. The process of the transfer of amphiphiles from an aqueous to a nonpolar phase seems of much interest in many respects. Davies[3] proposed a relation of the hydrophile-lipophile balance (HLB) with the partition coefficenet, and further estimated the "group number". The solubilization and micelle formation are regarded as a partition process, especially in the treatment by the phase-separation model for micell formation.[4] The solubilities of alkanols[5] and hydrocarbons[6] in water are also a measure of a similar process of transfer.

The standard free energy of transfer obtained from the partition coefficients can be applied to such transfer processes in colloid chemistry, and the comparison of the free energies for different processes yields useful information about the environment around a solute molecule. It is well known that the physicochemical properties of the alkyl[7] or polyoxyethylene derivatives[8] show a linear dependence on the number of methylene or oxyethylene groups. In the present investigation, the contribution of each group contained in the solute molecules to the standard free-energy changes of transfer was tentatively estimated. Dodecane is chosen as the nonpolar phase because of its low mutual solubility with water as well as because of the possibility of disregarding a specific interaction with solute molecules. Normal alkanols and polyoxyethylene alkyl ethers are chosen for the solutes; the former are simple amphiphilic compounds, and the later, model compounds for nonionic surfactants.

Experimental

Materials. The normal alkanols (R_mOH, m=2 to 6) and some (m=2 to 4, n=1,2) of the polyoxyethylene normal alkyl ethers (R_mE_nOH) used as solutes were commercially available (Tolyo Kasei, G.R. and E.P. grade). They were dehydrated and distilled prior to use. The other ethers (m=4, n=3, 4; m=5, n=1 to 4) were prepared by the Williamson reaction of the corresponding glycol and alkyl bromide.[9] Their purification was carried out by the following procedure. After the addition of a large amount of water to the reaction mixture, the ether was repeatedly extracted with a small amount of hexane. Each hexane fraction was analyzed by g-l chromatography, whereupon diether was found to be rich in the earlier fractions, and glycol, in the later ones. The middle fractions, being rich in monoether, were collected and evaporated. The extract was distilled to obtain monoether under reduced pressure. The purities of the compounds were confirmed to be above 98% by g-l chromatography. The dodecane (Tokyo Kasei, G. R. grade) was first distilled and used once as a nonpolar phase for the measurement of the partition coefficient; it was then repeatedly washed with an amount of water sufficiently large to remove a solute, and used in the next run.

Procedure. Aqueous solutions of a desired solute were prepared at concentration of *ca.* 10^{-3} to 10^{-2} mol/kg. A sample prepared from a known weight of the aqueous solution and of dodecane was maintained for a day at room temperature; then the sample was stirred in a thermostat and kept at 25±0.05 °C for about seven hours. This operation was performed for at least six aqueous solutions with different concentrations of a given solute. Then the sample was allowed to stand and a quantity of the aqueous phase was pipetted out. The solute concentration of the aqueous phase in equilibrium was determined at 25±0.005 °C by using a Ostwald-type viscometer the flow time of which was *ca.* 9 min. The solute concentration in the dodecane phase was obtained from the material balance relation.

Results and Discussion

Figure 1 shows the logarithmic relations between the solute concentrations in the dodecane and water phases for R_mE_nOH (m=5, n=2 to 4) as illustrative examples. All the plots dropped on a straight line, with a unity slope for each solute; therefore, we can conclude that the solute is dissolved in the monomeric state in each phase, as may be seen from the spectroscopic data for alkanols,[1] and the partition coefficient does not depend on the concentration within the region studied.

The partition coefficient is expressed as:

$$K_x = x_o/x_w \quad (1)$$

where x_o and x_w are the mole fractions of solute in

TABLE 1. PARTITION COEFFICIENTS IN *n* DODECANE-WATER SYSTEM AT 25 °C

dodecan and in the water phase, respectively. The partition coefficients for each solute were determined for at least six samples with different concentrations of the solute; the mean values for a given solute are listed in Table 1, along with their standard deviations. The expression of the partition coefficient in the mole fraction is convenient not only for the thermodynamic discussion of the transfer phenomena between different phases, but also for indicating the independence of the kind of nonpolar-phase substances (normal hydrocarbons containing different chain lengths), although the partition coefficient in molarity depends on the kind of nonpolar-phase substance, as may be supposed from the results for alkanols reported by Aveyard and Mitchell.[1]

The standard free energy of the transfer of a solute from the water to the dodecane phase can be calculated from the K_x value assuming ideality, because it is a value at a high dilution;

$$\Delta G^\circ = -RT\ln K_x \qquad (2)$$

The ΔG° value is plotted against the chain length in the alkyl group in Fig. 2, and the plot for a homologous series shows a linear relation except for R_mE_nOH with $m=2$. We can now assume that ΔG° is divisible into independent additive contributions from each group constituting the solute molecule:

$$\Delta G^\circ = \Delta G^\circ_{CH_2}(m-1) + \Delta G^\circ_{CH_3} + \Delta G^\circ_g \qquad (3)$$

where $\Delta G^\circ_{CH_2}$, $\Delta G^\circ_{CH_3}$, and ΔG°_g are the contributions from the methylene, terminal methyl, and polar groups respectively. A least-squares treatment gives the $\Delta G^\circ_{CH_2}$ and $(\Delta G^\circ_{CH_3}+\Delta G^\circ_g)$, as may be seen for $\Delta G^\circ_{CH_2}$ in Table 2. The $\Delta G^\circ_{CH_2}$ values are −0.858 and −0.808 kcal/mol for R_mOH and R_mE_nOH respectively in the table; they are numerically comparable with the corresponding values for alkyl derivatives in the related processes.[5-7] The standard free energy of the transfer of one mole of the methylene group from water to micelle or to an air-water interface is about −0.65 kcal/mol, a little less negative than the present value.

The estimation of ΔG°_g in Eq. (3) requires $\Delta G^\circ_{CH_3}$;

Compound	m[a]	$-\Delta G^\circ_{CH_2}$ (kcal/mol)	ΔG°_g (kcal/mol)
R_mOH	2—6	0.858	4.39
R_mE_1OH	3—5	0.818	4.05
R_mE_2OH	3—5	0.837	4.75
R_mE_3OH	4—5	0.781	5.19
R_mE_4OH	4—5	0.799	5.89
		0.808[b]	

a) Range of alkyl chain length for least-squres treatment. b) Mean value of $\Delta G^\circ_{CH_2}$ for ethers alone.

therefore, the value is estimated as −2.10 kcal/mol from the available data for the solubility[6] of liquid alkanes (m=5 to 8) in water at 25 °C, from the assumption of an additive contribution[11] such as:

$$\Delta G^\circ = \Delta G^\circ_{CH_2}(m-2) + 2\Delta G^\circ_{CH_3} \quad (4)$$

Assuming that, in the present solutes, the terminal methyl group in the alkyl group makes the same contribution to ΔG° as that in the normal alkanes, the ΔG°_g values can be calculated by means of Eq. (3); they are tabulated in Table 2. Those are not an intrinsic value for the polar group itself, but an apparent value (extrapolated value) of the standard free energy of the transfer of the polar group from water to dodecane, for the property of the methylene group proximal to the polar group may differ from that of the separate one, as may be seen from Fig. 2. The value is, however, useful, considering the hydrophilic properties of whole of the solute molecule, which consists of a long alkyl chain and a polar group. The ΔG°_g value for R_mOH, *i.e.*, for the OH group (denoted by ΔG°_{OH}), is 4.39 kcal/mol; this value is comparable to the standard free energy of transfer, about 4 kcal/mol, of water from liquid water into hydrocarbons obtained from the data for solubility of water in hydrocarbons.[12] This implies that the most important factor govering ΔG°_{OH} is the dehydration of the group.

The relation between ΔG° for R_mE_nOH and the number of the oxyethylene group in the ethers is shown in Fig. 3, together with ΔG°_g; the ΔG° value for R_mOH is also plotted at n=0 for comparison. It is evident from the linear relation for each ether containing the same alkyl-chain length that the contribution of an oxyethylene group to ΔG°, denoted by ΔG°_E, is additive. A similar relation is also seen for ΔG°_g in Fig. 3. Therefore, Eq. (3) may be rewritten as follows for R_mE_nOH:

$$\Delta G^\circ = \Delta G^\circ_{CH_2}(m-1) + \Delta G^\circ_{CH_3} + \Delta G^\circ_E n + \Delta G^\circ_{\langle OH\rangle} \quad (5)$$

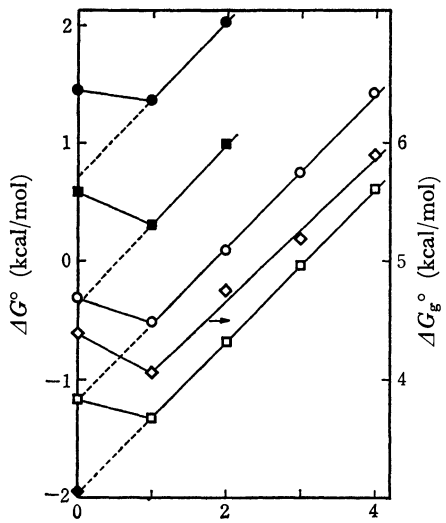

Fig. 3. The dependence of ΔG° and ΔG_g° on the number of oxyethylene groups (n), ΔG° for R_mOH is plotted at n=0.

mean value		0.655		0.835
polar group[b]	1—4	0.596	3.48	0.91

a) Range the number of oxyethylene groups for least-squares treatment. b) Obtained from ΔG°_g.

where $\Delta G^\circ_{\langle OH\rangle}$ is the apparent contribution of the OH group in the ether molecule to the ΔG°, distinct from the contribution of that in R_mOH. The ΔG°_E listed in Table 3 can be obtained by the least-squares treatment of R_mE_nOH. The mean value for all of the ethers studied is 0.655 kcal/mol, which is comparable with the value of 0.60 kcal/mol obtained from the partition coefficients of homogeneous octylphenoxypolyethoxyethanols in the *iso*-octane–water system investigated by Crook *et al.*[2] The positive value of ΔG°_E may result from a positive change in the enthalpy of dehydration exceeding a positive change in entropy; this shows that the oxyethylene group behaves as a hydrophilic group, as is usual for nonionic surfactants, *e.g.*, the CMC of a surfactant, polyoxyethylene alkyl ether, increases with the increase in the number of the groups.[8]

The infercept of the line for R_mE_nOH in Fig. 3 is more negative than the ΔG° for R_mOH with the same alkyl-chain length. This means that the OH group situated in the terminal portion of the polyoxyethylene chain is not in the same state as that in R_mOH; *i.e.*, the former is less hydrophilic than the latter. Yamaguchi *et al.*[13] deduced, from their calorimetric study, that, for polyoxyethylene dodecylethers in dodecane, intramolecular hydrogen-bond formation occurs between the terminal OH group and an oxygen atom in the polyoxyethylene chain; this is unlike the results for normal dodecanol. The ΔG° at n=0 in Eq. (5) is expressed as $\Delta G^\circ_{\langle ROH\rangle}$, which is distinct from the value for R_mOH (denoted by ΔG°_{ROH}). If the OH group in R_mE_nOH in the monomeric and non-hydrogen bonding state behaves thermodynamically in the same way as that in R_mOH in dodecane, it may be considered that the difference between $\Delta G^\circ_{\langle ROH\rangle}$ and ΔG°_{ROH} is a standard free energy change (ΔG°_{HB}) for hydrogen-bond formation in the dodecane phase, *i.e.*:

$$\Delta G^\circ_{HB} = \Delta G^\circ_{\langle ROH\rangle} - \Delta G^\circ_{ROH} \quad (6)$$

The calculated ΔG°_{HB} values for the present ethers containing different alkyl-chain lengths are in good agreement with each other; their mean value is −0.835 kcal/mol, as is shown in Table 3. A similar value corresponding to ΔG°_{HB} can be obtained as the difference between $\Delta G^\circ_{\langle OH\rangle}$ and ΔG°_{OH}, −0.91 kcal/mol, but this value is less reliable because of the scattering of the ΔG°_g values, as may be seen from Fig. 3. It happens that this value is numerically coincident with

$\Delta G^{\circ}_{CH_2}$; ΔG° for R_mE_nOH becomes equal to that for $R_{m+1}OH$, as may be seen from Fig. 3. From the ΔG°_{HB} obtained here and the enthalpy of hydrogen-bond formation, -5.19 kcal/mol, for alkanol in alkanes, as was established in the calorimetric study by Aveyard and Mitchell,[1] we can evaluate the corresponding entropy, -14.5 eu., by assuming that the enthalpy for the intermolecular hydrogen-bond formation of alkanol is the same as for the intramolecular one in the polyoxyethylene chain. These thermodynamic parameters for hydrogen-bond formation seem reasonable compared with the published values.[14,15]

We would like to thank Professor Ryohei Matsuura and Assistant Professor Shoji Kaneshina of Kyushu University for their helpful suggestions and observations.

Infrared and Raman Spectra and Rotational Isomerism of 1,4-Pentadiene

Fuyuhiko INAGAKI, Masaaki SAKAKIBARA, Issei HARADA, and Takehiko SHIMANOUCHI
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received July 23, 1975)

Rotational isomerism of 1,4-pentadiene has been studied. Normal frequencies have been calculated for the low frequency vibrations of four possible rotational isomers. From the change in the spectra in the gaseous, liquid, glassy, and solid states, it has been concluded that the two skew-skew forms (SS and SS′) and the *cis*-skew form (CS) are stable in the liquid and gaseous states, the SS and SS′ forms coexist in the glassy state, and only the SS form remains in the solid state. It has also been found that the energy difference among the three isomers in liquid state is not appreciably large.

The rotational isomerism about the C–C bond adjacent to the C=C double bond has been studied by several authors. Harrah and Mayo suggested the existence of rotational isomers of 1-olefins from the infrared spectra.[1] Kondo, Hirota, and Morino analyzed the rotational spectra of 1-butene and determined the structures of the *cis* and skew isomers, the latter being obtained from the *cis* form by an internal rotation of about 120°.[2] Shimanouchi, Abe, and Alaki studied the skeletal deformation vibrations of 1-olefins in relation to the stable conformations of 1,4-polybutadiene chains. They concluded that the *cis* and skew conformations are stable for the C–C bond neighbouring the *trans* C=C bond, whereas only the skew conformation is stable for the C–C bond adjacent to the *cis* C=C bond.[3]

As an extension of such a work, we have studied the molecular conformations of 1,4-pentadiene in the gaseous, liquid, and solid states by analyzing the infrared and Raman spectra. After our work had been completed, we found a paper by Gallinella and Cadioli, which treated the same subject by means of Raman spectroscopy and *ab initio* MO calculations.[4] Although their conclusion about the conformations of the stable isomers in liquid is consistent with ours, there seems to be significant differences regarding the assignments of bands to each isomer. In this paper we will describe the band assignments based on our experimental results and normal vibration calculations.

Experimental

1,4-Pentadiene(Tokyo Chemical Industry Co.) was used without further purification for the measurement of the infrared spectra. The sample was distilled *in vacuo* prior to measurement of the Raman spectra. The infrared spectra were recorded on a Hitachi EPI-L double beam grating spectrometer in the region 700—300 cm^{-1}, and on a Hitachi FIS-1 double beam vacuum grating spectrometer in the region 500—200 cm^{-1}. The spectra in the gaseous state were taken with a 10 cm cell in the region 700—200 cm^{-1} and a 4.9 m multireflection cell with polyethylene windows in the region 400—200 cm^{-1}. We measured the spectrum in the liquid state for the thin film obtained by warming up the solid film deposited on a cooled KRS-5 plate just above the melting point. The glassy solid was obtained by the deposition of the sample on a cooled window of KRS-5 or silicon. For the spectrum in the crystalline state, the sample was repeatedly annealed until no further spectral change was observed. The Raman spectra were measured on a JRS-400D spectrophotometer with a Coherent Radiation CR-3 argon ion laser as the light source. A multireflection accessary was used for the measurement of the spectrum of gaseous state.

Results and Discussion

Infrared and Raman Spectra and Rotational Isomerism. The infrared and Raman spectra of 1,4-pentadiene in the gaseous, liquid, and solid states are shown in Figs. 1 and 2. The Raman spectra in the liquid and solid states are just the same as those reported by Gallinella and Cadioli.[4] The results so far obtained for the rotational isomerism about the C–C axis adjacent to the C=C bond show that the stable conformations are always *cis* and skew.[2,3] Since 1,4-pentadiene has two C–C axes, four isomers, SS, SS′, CS, and CC (Fig. 3) are considered to exist. Because of the steric repulsion between the terminal CH_2 groups in the CC form, the existence of this isomer is unlikely. Thus, the SS, SS′, and CS forms are the possible stable isomers. For each isomer, two CH out-of-plane vibrations and three skeletal deformation vibrations are expected in the regions 700—500 cm^{-1} and 500—200 cm^{-1}, respectively.[3] Thus the five Raman lines observed at 672, 618, 457, 376, and 318 cm^{-1} in the crystalline state (Fig. 2d) are reasonably assigned to one isomer. In the infrared spectra, the bands at 444 and 306 cm^{-1}

in the glassy state (Fig. 1c) which disappear in the spectrum in the crystalline state (Fig. 1d) are evidently assigned to another isomer. A third isomer is clearly identified by the bands at 555 and 268 cm^{-1} newly appearing in the spectra in the gaseous and liquid states (Figs. 1a and 1b). Gallinella and Cadioli misassigned these two bands to two different isomers.[4]

Normal Vibration Calculations. Normal frequencies were calculated for the purpose of the assignment of the observed bands to the rotational isomers. For the calculation of normal frequencies and normal modes, a Hitachi 5020E computer at the Computer Centre of the University of Tokyo and the programs BGLZ and LSMB prepared in our laboratory were used.[5] The values of the bond lengths and angles were taken from the corresponding values of 1-butene and are listed in Table 1.[2] The torsion angles were assumed as 0° for the *cis* form and 120° for the skew form.

The wagging constants, the torsional constants, wagging-torsion interaction constants and the *cis* C· · ·C repulsive constant were introduced in addition to the simple Urey Bradley force field. The values of the force constants were transferred from those of olefins[3] and used without further modification (Table 2). The calculated frequencies below 700 cm^{-1} are compared with the observed in Table 3 and Fig. 4. Assignments based on the potential energy distribution are also given in Table 3.

Shimanouchi, Abe, and Alaki showed that the CH out-of-plane vibration consisting of the C=C torsion and CH wagging modes is a good key band for the study of the rotational isomerism of 1-olefins.[3] When CH_2=CH–CH_2–C group takes the skew conformation, the CH out-of-plane vibration couples with the skeletal

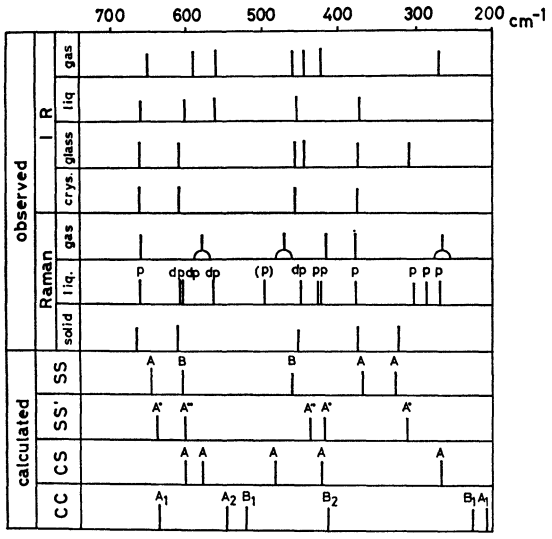

Fig. 4. Observed and calculated frequency patterns of 1,4-pentadiene.

deformation vibrations and gives a frequency near 640 cm^{-1}, while this coupling does not occur for the *cis* conformation the former giving a frequency near 580 cm^{-1}. There are two such vibrations for each isomer in the case of 1,4-pentadiene. These vibrations of the CC form do not couple with the skeletal deformation by symmetry requirement and give frequencies, 550 and 522 cm^{-1}. For the SS and SS′ forms, the symmetric CH out-of-plane vibration couples with C–C–C deformation and gives a frequency near 640 cm^{-1} and the antisymmetric CH out-of-plane vibration gives a frequency of about 610 cm^{-1}. The skew and *cis* parts of the CS form have the frequencies 603 and 585 cm^{-1}, respectively. Therefore, the frequency of the CH out-of-plane vibration can also be a clue to the assignment of rotational isomers in the case of 1,4-pentadiene. The difference in frequency of C–C–C deformations may be useful for the discrimination of the SS form from the SS′ form.

Stable Conformations. From the results given in Table 3 and Fig. 4, it can be concluded that the conformation in the crystalline state is the SS form. The frequencies calculated for this form are 643, 609, 470, 367, and 325 cm^{-1}. They correspond to the five Raman lines at 672, 618, 457, 376, and 318 cm^{-1}. The calculated values for the CC and CS forms differ greatly from the observed in the crystalline state. There is a possibility that the SS′ form exists in the crystalline state. However, it is not probable since the frequencies 437 and 419 cm^{-1} calculated for the SS′ form do not correspond to the observed.

The appearance of two frequencies at 444 and 306 cm^{-1} in the spectrum of glassy state in addition to the bands observed in the crystalline state is explained by the coexistence of the SS and SS′ forms. These two bands are assigned to the calculated frequencies, 437 and 310 cm^{-1}, of the SS′ form. Moreover, the change of the relative intensities of the infrared bands at 664 and 610 cm^{-1} on going from the crystalline state to the glassy state can be explained by the overlap of the two CH out-of-plane vibrations of the SS′ form with those of the SS form. Thus, the third isomer corresponds to the CS form. Actually, the Raman lines (infrared bands) at 560 (555), 494, ~420 (425),

and 265 (268) cm^{-1} are in good agreement with the frequencies calculated for the CS form, 585, 486, 425, and 264 cm^{-1}. No corresponding bands to the calculated frequencies of the CC form were found in the spectra.

Now, the stable isomers of 1,4-pentadiene are proved to be the SS, SS′, and CS forms. It is noteworthy that these forms are in accord with those of the stable isomers predicted by *ab initio* MO calculations.[4] It is to be noted that the band broadening and the frequency shifts are distinctly observed by the change in the temperature in the liquid state. This tendency is also observed in the spectrum in the gaseous state. The spectral changes are far more pronounced than in the case of 1,2-dichloroethane[6] and other molecules[7] with the usual C–C torsion axis. This suggests that the barrier to internal rotation is low except for the *cis-cis* barrier and the anharmonicity in the potential function causes the band broadening and frequency shifts.

Conclusion

It is shown that 1,4-pentadiene exists in the SS form in the crystalline state. The SS and SS′ forms coexist in the glassy state while three forms, the SS, SS′, and CS, are found in the liquid and gaseous states. Although the intensities of the Raman lines at 560 and 494 cm^{-1} decreased slightly and the line at 305 cm^{-1} broadened and shifted toward lower frequency at a higher temperature (Figs. 2b and 2c), no significant intensity change due to the temperature change was observed. This shows that the energy difference among the three isomers is not very large and the stability of the SS form in the crystal can be ascribed to the possible close packing of the molecules.

(Received August 4, 1975)

The object of this paper is to investigate the effect of the ratio of the viscosities of dispersed and continuous phases, μ_d/μ_c, on the particle-size distribution in o/w-type emulsions. The viscosity ratios (μ_d/μ_c) used were 0.836 : 1, 0.271 : 1, 0.0992 : 1, 0.0280 : 1, and 0.00133 : 1. The size of the dispersed liquid droplets was measured by the microphotographic method. The mean diameter and the particle-size distribution were determined, and, further, the specific interfacial energy was evaluated. When the viscosity ratio was much smaller than unity, the particle-size distribution showed a skewed curve. On the contrary, the specific interfacial energy increased remarkably as the viscosity ratio approached unity.

Emulsion formation has, in general, been discussed from two different points of view[1] from the point of view of surface chemical[2] and from that of chemical engineering.[3] There are many factors which affect emulsion formation; the combination of two liquids, the mode of mixing two liquid phases, the concentration of the dispersed phase, the kind of emulsifying agent, the viscosity ratio of the two phases, the temperature, the equipment, the method of agitation, the impeller velocity, the agitation time, and so on.

In our previous papers,[4-6] statistical considerations of the experimental results were presented in connection with emulsion formation under various conditions. In those considerations, attempts were made to obtain the effects on emulsion formation of the kind and concentration of emulsifying agents, the energy efficiency of agitation,[5] and the agitation time. However, these studies were all undertaken without taking the viscosity factor into account.

In this paper, therefore, the effect of the ratio of the viscosities of the dispersed and continuous phases, μ_d/μ_c, on emulsion formation will be examined in relation to the particle-size distribution, the mean diameter of the dispersed phase, and the specific interfacial energy.

Experimental

Equipment. A sketch of the apparatus employed is shown in Fig. 1. The clear acrylate resin agitation tank with 4-baffles was 150 mmϕ in diameter and 210 mm deep. A stainless-steel agitation impeller of 49.00 mmϕ was of the standard Rushton type with 6-blades.[7] The tank was surrounded by a water jacket in order to keep the temperature of the liquid within it at 20.0 °C.

Measurement of Physical Properties. Mixtures of sodium silicate (Kishida Chemical Co.) and distilled water in varying ratios were used as the continuous phase. The total concentration of sodium silicate in the mixtures was varied from 17.0 to 88.0% (w/w). The dispersed phase was made up by mixing *n*-C_7H_{16} and CCl_4 in various volume ratios; the density was adjusted so as to be the same as that of the continuous phase (1.000—1.567 g/cm^3).

Tween-20 (Tōhō Chemical Industry Co.) was employed as the emulsifying agent; its concentration was 0.1% (w/w). The interfacial tensions were measured by the ring method,[8] and the viscosities of liquids, by the rotating viscometer[9] at

Impeller diameter: 49.0 mm, Tank diameter: 150 mm, Revolution number: 330, 400, and 660 rpm.

20.0±0.1 °C.

The viscosity ratio, μ_d/μ_c, was widely varied from 0.836 : 1 to 0.00133 : 1. The concentration of sodium silicate, the density of the continuous phase, the density ratio, the viscosity of the continuous phase, the viscosity ratio, and the interfacial tension are summarized in Table 1.

Experimental Procedure. The experiments were carried out under the following conditions:

(1) The viscosity ratios, μ_d/μ_c, used were 0.836 : 1, 0.271 : 1, 0.0992 : 1, 0.0280 : 1, and 0.00133 : 1.

(2) The revolution rates were 330, 400, and 660 rpm.

(3) Samplings were made 5, 10, 20, 35, and 60 min after agitation has started.

The agitation tank was filled with 1960 ml of an aqueous sodium silicate solution, a continuous phase, containing Tween-20 as an emulsifying agent. The impeller was set in the center of the tank. On the middle of the impeller was gently placed 40 ml of a mixed solvent, a dispersed phase, as an almost perfect globule. The concentration of the dispersed phase was kept at 2.0% (v/v). The total liquid volume was, therefore, 2000 ml. After agitation has started, the liquid was sampled with a glass tube (5 mmϕ) at regular time intervals. Each sample was photographed with a Nikon AFM camera under a microscope. The diameters of the droplets were measured by a micrometer scale which has been photographed and enlarged under the same conditions. The number of droplets measured was one thousand[10] in all cases. The mean length diameter, the mean surface diameter, the mean volume diameter, the standard deviation, and the particle-size distribution were calculated by means of a SEIKO-301 computer.

Results and Discussion

Effect of the Viscosity Ratio, μ_d/μ_c, on the Particle-size Distribution. The particle-size distributions, calculated based on the length diameters measured at different revolution number and after 60 min of agitation, are shown in Fig. 2. In these cases, the viscosity ratio was 0.271 : 1, and the revolution rates were 330, 400, and 660 rpm. Although sufficient agitation was undertaken, the size distribution was broad and had two peaks at the revolution number of 330 and 400 rpm. The size distribution at 660 rpm, however, was normal and had only one peak.

Changes in the particle-size distribution, calculated using the length diameter measured in the course of agitation, are shown in Fig. 3. The viscosity ratio and the revolution number were 0.271 and 400 rpm respectively. The size distribution at an agitation time of 5 min spread over a wide range of particle-sizes and had three peaks. After 20 min of agitation, the size distribution had two peaks, because large particles were subdivided into small ones. The size distribution at an agitation time of 60 min was narrower than that at a shorter agitation time, but it still had two peaks.

○: 0—30 μm, △: 30—60 μm, □: 60 μm.

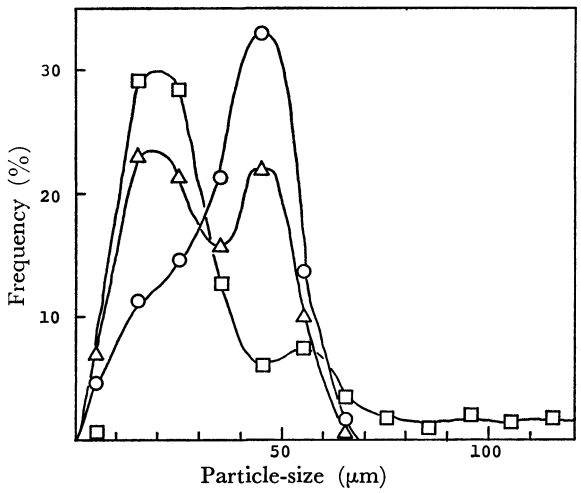

Fig. 5. Particle-size distributions at various viscosity ratios.
D_I: 49.0 mm, D_T: 150 mm, θ: 60 min, N': 400 rpm, T-20: 0.1% (w/w).
○: μ_d/μ_c=0.836, △: μ_d/μ_c=0.271, □: μ_d/μ_c= 0.00133.

In order to analyze the above results, we divided the observed particle-size range of droplets into the following three subranges: 60 μm and larger, 60 μm to 30 μm, and 30 μm and smaller. Variations in the frequency of the three subranges in the course of agitation are plotted in Fig. 4. It can clearly be observed that the frequency of droplets larger than 60 μm decreased slowly with an increase in the agitation time. On the contrary, the frequency in the middle and low subranges increased with an increase in the agitation time. However, in the middle subrange, it showed a maximum value at an agitation time of about 35 min, and then decreased.

Particle-size distributions calculated using the length diameters measured at three different viscosity ratios are shown in Fig. 5. The revolution number and the agitation time were 400 rpm and 60 μm respectively. When the continuous phase consisted of distilled water (μ_d/μ_c=0.836 : 1) alone, the size-distribution curve had only one peak. When the continuous phase consisted of a mixture of distilled water and sodium silicate (μ_d/μ_c=0.271 : 1 or 0.0133 : 1), however, the size distribution showed two peaks. On the other hand, as the viscosity ratio got smaller than unity, a broadening tendency of the size distribution was obtained. In particular, when the viscosity ratio was 0.00133 : 1, there appeared a very broad size distribution extending to the range from 70 μm to 150 μm.

Effect of the Viscosity Ratio, μ_d/μ_c, on the Mean Length Diameter. As has already been described in the section on the experimental procedure, 40 ml of an aqueous solution, a dispersed phase, was gently placed on the middle of the impeller as a globule (d_1=4.4 cm) before agitation. As soon as the agitation started, the globule was subjected to a strong shear stress in and around the impeller. Then, the globule was broken up into a number of droplets of some hundreds of microns within a few seconds. The mean length diameter of the broken-down droplets in the course of agitation at each of four different viscosity ratios was found to decrease linearly on a log-log plot, as is shown in Fig. 6. The mean length diameter was found to have the smallest value when the viscosity ratio was 0.271 : 1. In Fig. 6, the straight lines are drawn by the least-squares method. From these results, the relation between the average diameter, d_1, and the agitation time, θ, may be experimentally formulated as:

$$\log d_1 = \log \beta + \alpha \log \theta \quad (1)$$

Furthermore, the effect of the viscosity ratio on the mean length diameter at three revolution number after 60 min of agitation is given in Fig. 7. At each revolution number, the plot of the data gave a concave curve with a minimum at a viscosity ratio of 0.271 : 1. Consequently, the optimum condition for preparing an emulsion of the minimum mean length diameter would be when the viscosity of the continuous phase is slightly higher than that of water, as in Table 1. Table 3 summarizes the results of the calculations of the standard deviation, σ, of the mean length diameter and the maximum diameter of the droplets, d_m, under various conditions. As the viscosity ratio at each revolution number decreased, both σ and d_m increased. However, this trend was not observed when the continuous phase consisted of distilled water (μ_d/μ_c= 0.836 : 1) alone.

0.00133	660	60	21.4	246.0

The Relation between the Specific Interfacial Energy and the Viscosity Ratio. The mean surface-volume diameter of droplets is generally represented by;

$$d_{sv} = \frac{\sum d_i^3}{\sum d_i^2} = \frac{\sum d_i^3/n}{\sum d_i^2/n} = \frac{d_v^3}{d_s^2} \quad (2)$$

where d_i is the length diameter; n, the number of droplets measured; d_s, the mean surface diameter (cm), and d_v, the mean volume diameter (cm). The specific interfacial area per 1 cm³ of the dispersed phase is given by;

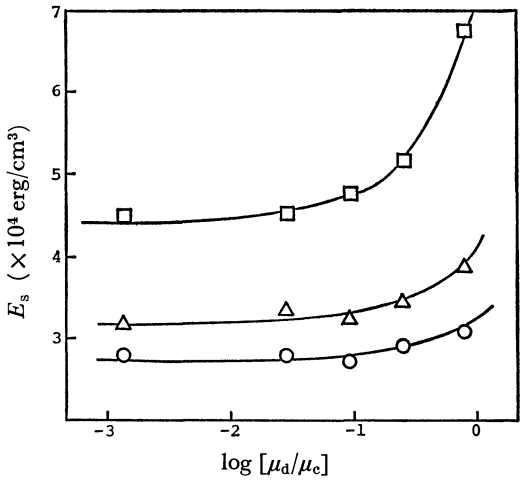

Fig. 8. Relation between the specific interfacial energy and the viscosity ratio.
D_I: 49.0 mm, D_T: 150 mm, θ: 60 min, T-20: 0.1% (w/w).
○: 330 rpm, △: 400 rpm, □: 660 rpm.

$$S = \frac{\pi \sum d_i^2}{\pi/6 \cdot \sum d_i^3} = \frac{6 d_s^2}{d_v^3} = \frac{6}{d_{sv}} \quad (3)$$

Further, the specific interfacial energy is defined as:

$$E_s = \gamma \cdot S = 6 \cdot \gamma / d_{sv} \quad (4)$$

where E_s is the specific interfacial energy (erg/cm³) and where γ is the interfacial tension (dyn/cm).

The relation between the specific interfacial energy and the viscosity ratio is shown in Fig. 8. At each revolution number, the specific interfacial energy increases remarkably as the viscosity ratio approached unity. This trend was especially notable at a high revolution number (660 rpm). Accordingly, the probability of the droplets breaking-up during agitation will increase as the viscosity ratio approaches unity.

Anharmonic Potential Functions of Simple Molecules. II. Direct Numerical Diagonalization of Vibratinal Hamiltonian Matrix and Its Application to CO_2 and CS_2

Isao SUZUKI

Educational Computer Centre, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 9, 1975)

A general formalism is presented for the calculation of the vibration-rotation energy levels of linear symmetrical XY_2 type molecules through direct numerical diagonalization of the vibrational hamiltonian matrix. This method is applied to the CO_2 and CS_2 molecules, of which the general quartic force fields have been known accurately. The results are compared with those obtained by an ordinary perturbation treatment, and the truncation effects of the matrix sizes as well as of the expansions of the potential functions are discussed. Special attention is paid to the peculiarities in the potential function of CO_2 for which very strong mixings of the basis harmonic oscillator wave functions are observed. The general formula for evaluating the matrix elements of the transition moment are also discussed and its applicability to the problems of vibrational intensities and the dipole moment functions is discussed.

In Part I,[1] a method was presented in which the vibration or vibration-rotation energy levels of a diatomic molecule are calculated from the harmonic and anharmonic force constants by solving the vibrational hamiltonian numerically. This method has an advantage over the conventional contact transformation approach,[2] since a true (perturbed) orthonormal wave function is readily obtained for a given vibrational level through numerical diagonalization. Two basic physical properties of a molecule, *i.e.* the potential and dipole moment functions may be handled simultaneously by this method.[3]

As pointed out in I, the numerical diagonalization method is very attractive in handling the polyatomic molecules, since no special treatment is required for the anharmonic resonances. Efforts have been made to extend this method to a linear symmetrical triatomic molecule. This extension is not altogether simple, since the vibration-rotation hamiltonians of polyatomic molecules are complex and possess extra terms which are not present in diatomic molecules. The basic algorithms to compute vibration and vibration-rotation energy levels have been established for this type of molecule, and they are applied to the cases of the CO_2 and CS_2 molecules. The results are reported in the present paper.

Hamiltonian

The general form of vibration-rotation hamiltonian of a polyatomic molecule is given by Goldsmith, Amat, and Nielsen.[4] The form is greatly simplified in the specific case of a linear symmetrical molecule XY_2.[5] The vibration-rotation hamiltonian may be expressed as the sum of vibrational, rotational, and Coriolis hamiltonians. With replacement of a degenerate pair of bending coordinates q_{2x} and q_{2y} by cylindrical coordinates r_2 and χ_2, it has the following form.[6]

$$\mathbf{H} = \mathbf{H}_{\mathrm{vib}} + \mathbf{H}_{\mathrm{rot}} + \mathbf{H}_{\mathrm{Cor}}, \tag{1}$$

$$\begin{aligned}\mathbf{H}_{\mathrm{vib}} = {} & (1/2)\sum_{s=1,3}\omega_s(q_s^2+p_s^2)+(\omega_2/2)(r_2^2+p_{r_2}^2) \\ & + (k_{111}q_1^2+k_{122}r_2^2+k_{133}q_3^2)q_1 \\ & + k_{1111}q_1^4+k_{1133}q_1^2q_3^2+k_{3333}q_3^4 \\ & + (k_{1122}q_1^2+k_{2222}r_2^2+k_{2233}q_3^2)r_2^2 \\ & + \mathbf{H}_{\mathrm{vib}'},\end{aligned} \tag{2}$$

$$\mathbf{H}_{\mathrm{vib}'} = B_e(j_x^2+j_y^2)\sum_{k=0} R_k q_1^k, \tag{3}$$

$$\mathbf{H}_{\mathrm{rot}} = B_e(J_x^2+J_y^2)\sum_{k=0} R_k q_1^k, \tag{4}$$

$$\mathbf{H}_{\mathrm{Cor}} = -2B_e(j_xJ_x+j_yJ_y)\sum_{k=0} R_k q_1^k, \tag{5}$$

where $R_k=(-1)^k(k+1)\gamma_1^{(k/2)}$, $\gamma_1=(2B_e/\omega_1)$, j_x and j_y are the dimensionless vibrational angular momenta ($j_x=p_x/\hbar$ and $j_y=p_y/\hbar$). The totally symmetric q_1 normal coordinate plays essentially the same role as q in diatomic molecules, and each hamiltonian is expressed as a power series expansion of q_1. This is suited for numerical treatment and the hamiltonians may be truncated at a desired order of approximation. The normal coordinates q_{2x}, q_{2y}, and q_3 do not appear in the expressions in Eqs. (3)—(5). The molecular vibrations affect the moments of inertia through the shift of the average nuclear positions as well as by the anisotropy of the mean square amplitude of vibration. The former effect is linear in normal coordinates and vanishes unless $\langle\bar{q}_r\rangle\neq 0$, which holds only for $r=1$ in linear XY_2. The latter effect is quadratic in normal coordinates, and there are, indeed, non-vanishing terms for q_{2x}^2, q_{2y}^2, and q_3^2, but they are all cancelled out when the Eckart condition is imposed to separate vibration and rotation. This problem has been discussed by Oka[6a] in greater detail.

The term designated $\mathbf{H}_{\mathrm{vib}}'$ arises from the squared vibrational angular momentum and contributes only to the vibrational energies of a molecule, it is treated as a part of vibrational hamiltonian. The general quartic potential function is used in Eq. (2). If higher-order force constants are included, another term,

$$(B_e/2)\sum_{k=1}\gamma^{(k/2)}q_1^k, \tag{6}$$

which is originated from pseudo-potential $U(q's)$[2,7] must also be considered in $\mathbf{H}_{\mathrm{vib}}'$.

Energy Levels

Vibrational Energy Levels. As diatomic molecules, the vibrational hamiltonian matrix elements may be evaluated from the harmonic oscillator basis functions,

$$\langle n|\mathbf{H}_{\mathrm{vib}}|n'\rangle$$

where $|n>$ represents $|n_1, n_2, l_2, n_3>$.[8] The vibrational energy levels are calculated by diagonalizing the vibrational hamiltonian matrix numerically. For a given vibrational level v, the corresponding wave function is evaluated as a linear combination of the basis harmonic oscillator wave functions, and may be expressed as

$$|v> = \sum_n a_{vn}|n>, \tag{7}$$

where the coefficients a_{vn}'s are the corresponding elements of eigen vectors. The basis functions may be arranged according to their symmetry so that the resultant vibrational hamiltonian matrix is divided into symmetry blocks, each of which may be treated separately. Therefore, Eq. (7) holds in each symmetry block. It is readily seen that the wave functions $|v>$ also form an orthonormal set.

Vibration-Rotation Energy Levels. The rotational energy levels in a given vibrational state v are given as

$$E_v(J) = B_v[J(J+1)-l_2^2]-D_v[J(J+1)-l_2^2]^2 \tag{8}$$

Both $\mathbf{H}_{\rm rot}$ and $\mathbf{H}_{\rm Cor}$ must be considered to obtain the rotational constants B_v. The contribution from $\mathbf{H}_{\rm rot}$ is simpler to evaluate, and the procedure is essentially similar to the evaluation of B_v in diatomic molecules. By applying the first order perturbation treatment, the contribution from $\mathbf{H}_{\rm rot}$ to $E_v(J)$ is given as

$$\begin{aligned} E_v(J)^r &= \langle v,J|\mathbf{H}_{\rm rot}|v,J\rangle \\ &= B_e[J(J+1)-l_2^2]\sum_{k=0} R_k\langle v|q_1^k|v\rangle, \end{aligned} \tag{9}$$

which is further reduced to

$$\begin{aligned} E_v(J)^r &= B_e[J(J+1)-l_2^2]\sum_{k=0}\sum_n\sum_{n'} a_{vn}a_{vn'}R_k\langle n|q_1^k|n'\rangle \\ &= B_e[J(J+1)-l_2^2] \\ &\quad\times[1+\sum_{k=1}\sum_n\sum_{n'} a_{vn}a_{vn'}R_k\langle n|q_1^k|n'\rangle]. \end{aligned} \tag{10}$$

TABLE 1. NON-VANISHING MATRIX ELEMENTS FOR J_+, J_-, j_+, AND j_-

(a) J_+ and J_-

$$\langle J, l_2|J_+|J, l_2+1\rangle = \langle J, l_2+1|J_-|J, l_2\rangle = [J(J+1)-l_2(l_2+1)]^{1/2}$$
$$\langle J, l_2|J_-|J, l_2-1\rangle = \langle J, l_2-1|J_+|J, l_2\rangle = [J(J+1)-l_2(l_2-1)]^{1/2}$$

(b) j_+ and j_-

$\langle n_2, l_2, n_3|j_+|n_2', l_2', n_3'\rangle = \langle n_2', l_2', n_3'|j_-|n_2, l_2, n_3\rangle$

	n_2'	l_2'	n_3'	Matrix element
j_+	n_2-1	l_2-1	n_3+1	$\Omega_{23}[(n_2+l_2)(n_3+1)]^{1/2}$
	n_2+1	l_2-1	n_3-1	$\Omega_{23}[(n_2-l_2+2)n_3]^{1/2}$
	n_2-1	l_2-1	n_3-1	$\Phi_{23}[(n_2+l_2)n_3]^{1/2}$
	n_2+1	l_2-1	n_3+1	$\Phi_{23}[(n_2-l_2+2)(n_3+1)]^{1/2}$
j_-	n_2+1	l_2+1	n_3-1	$\Omega_{23}[(n_2+l_2+2)n_3]^{1/2}$
	n_2-1	l_2+1	n_3+1	$\Omega_{23}[(n_2-l_2)(n_3+1)]^{1/2}$
	n_2+1	l_2+1	n_3+1	$\Phi_{23}[(n_2+l_2+2)(n_3+1)]^{1/2}$
	n_2-1	l_2+1	n_3-1	$\Phi_{23}[(n_2-l_2)n_3]^{1/2}$

$\Omega_{23}=(1/2)[(\omega_2/\omega_3)^{1/2}+(\omega_3/\omega_2)^{1/2}]$
$\Phi_{23}=[(\omega_2/\omega_3)^{1/2}-(\omega_3/\omega_2)^{1/2}]$

R_k, a_{vn}, and the matrix element $\langle n|q_1^k|n'\rangle$ are all known. The contribution from $\mathbf{H}_{\rm Cor}$ to the rotational energy is more complex. Obviously, the diagonal matrix element $\langle v, J|\mathbf{H}_{\rm Cor}|v, J\rangle$ vanishes, and the second-order contribution must be considered,

$$E_v(J)^C = \sum H_{vv'}{}^{(1)}H_{v'v}{}^{(1)}/(E_v^\circ - E_{v'}^\circ) \tag{11}$$

$\mathbf{H}_{\rm Cor}$ may be expressed in more convenient form by using ladder operators $J_\pm = J_x \pm iJ_y$ and $j_\pm = j_y \pm ij_x$,

$$\mathbf{H}_{\rm Cor} = -B_e(j_+J_- + j_-J_+)\sum_{k=0} R_k q_1^k. \tag{12}$$

The relevant non-vanishing matrix elements are listed in Table 1. Again, $|v>$ and $|v'>$ may be expressed in terms of the harmonic oscillator wave functions, $|v>=\sum_n a_{vn}|n>$ and $|v'>=\sum_m a_{v'm}|m>$. As expected from the nature of Coriolis force, $H_{vv'}$ vanishes unless the direct product of v and v' contains the π_g representation to which the rotations around the x- and y- axes (R_x, R_y) belong. For example, if v belongs to the σ_g^+ species, v' should be the π_g state, and if v belongs to the π_u state, v' should be either in the σ_u^+ or Δ_u state. $H_{vv'}{}^{(1)}$ is given as

$$\begin{aligned} H_{vv'}{}^{(1)} &= \sum_n\sum_m a_{vn}a_{v'm}\langle n,J|\mathbf{H}_{\rm Cor}|m,J\rangle \\ &= -B_e[J(J+1)-l_2(l_2-1)]^{1/2}\sum_n\sum_m a_{vn}a_{v'm}\langle n|j_+|m\rangle \\ &\quad -B_e[J(J+1)-l_2(l_2+1)]^{1/2}\sum_n\sum_m a_{vn}a_{v'm}\langle n|j_-|m\rangle. \end{aligned} \tag{13}$$

It is readily seen from Table 1 that $H_{vv'}{}^{(1)}=H_{v'v}{}^{(1)}$ holds and that either $\langle n|j_+|m\rangle$ or $\langle n|j_-|m\rangle$ vanishes.[9] In the latter case, the leading term of $E_v(J)^C$ is given as

$$\begin{aligned} E_v(J)^C &= B_e^2[J(J+1)-l_2(l_2-1)] \\ &\quad\times\sum_{v'}[\sum_n\sum_m a_{vn}a_{v'm}\langle n|j_+|m\rangle]^2/(E_v^\circ - E_{v'}^\circ)] \end{aligned} \tag{14}$$

The final expression for B_v is, therefore,

$$\begin{aligned} B_v &= B_e\sum_{k=0}[R_k\sum_n\sum_m a_{vn}a_{vn'}\langle n|q_1^k|n'\rangle \\ &\quad + B_eR_k\sum_{v'}\{\sum_n\sum_m a_{vn}a_{v'm}\langle n|q_1^k\cdot j_+|m\rangle\}^2/(E_v^\circ - E_{v'}^\circ)]. \end{aligned} \tag{15}$$

The higher-order term in $\mathbf{H}_{\rm Cor}$ is included in Eq. (15). The wave functions designated with n and n' belong to the same symmetry species, while those with n and m do not. The last integral Eq. (15) may be rewritten as $\langle n|q_1^k\cdot j_+|m\rangle = \langle n_2, l_2, n_3|j_+|m_2, l_2', m_3\rangle\cdot\langle n_1|q_1^k|m_1\rangle$, since j_+ (or j_-) does not involve q_1. When the σ_g^+ or σ_u^+ state ($l_2=0$) is considered, the Coriolis contributions from the $l_2=-1$ states as well as those from the $l_2=+1$ states must be considered, and this doubles the value given in Eq. (15). Since $E_v(J)^C$ is derived by the ordinary second-order perturbation method, it breaks down for a case of accidental degeneracy in which a (v,J) level locates close to another (v', J') level with proper symmetry. Such a case must be handled separately.

l-Type Doubling in XY_2. So far it is implicitly assumed that the levels with the positive and negative l_2 values have identical energy. This holds for rotationless case. There is also no vibration-rotation hamiltonian which directly connects, for example, the 01^10 and $01^{-1}0$ states. However, these levels couple with each

other through the third states (001 or 02^01 in the above example) by $\mathbf{H}_{Cor}$. For illustration, the 01^10, 001, and $01^{-1}0$ levels are chosen and the vibration-rotation hamiltonian matrix for a given J is expressed,

$$\begin{matrix}\phi(01^1\ 0,J)\\ \phi(00\ \ 1,J)\\ \phi(01^{-1}0,J)\end{matrix}\begin{bmatrix}E_{vJ}^{\circ} & a & 0\\ a & E_{v'J}^{\circ} & a\\ 0 & a & E_{vJ}^{\circ}\end{bmatrix}$$

with $a=[J(J+1)]^{1/2}\langle 1^10|j_+|01\rangle=[J(J+1)]^{1/2}\langle 01|j_-|1^{-1}0\rangle=\sqrt{2}\,\Omega_{23}[J(J+1)]^{1/2}$. By using the linear combinations ϕ_c and ϕ_d given below, the matrix is reduced to

$$\begin{matrix}\phi_c=(1/\sqrt{2})[\phi(01^10,J)+\phi(01^{-1}0,J)]\\ \phi(001,J)\\ \phi_d=(1/\sqrt{2})[\phi(01^10,J)-\phi(01^{-1}0,J)]\end{matrix}\begin{bmatrix}E_{vJ}^{\circ} & \sqrt{2}\,a & 0\\ \sqrt{2}\,a & E_{v'J}^{\circ} & 0\\ 0 & 0 & E_{vJ}^{\circ}\end{bmatrix}$$

This indicates that in calculating the rotational constants of the c and 001 levels, the contributions from H_{vv}[2] must be doubled, while the d state is free from Coriolis type interaction. This causes the well-known l-type doubling: A given J level of the 010 state splits into two sub-levels with slightly different energies. Since ν_3 is larger than ν_2, the rotational constant of the c sub-level is expected to be smaller than that of the d sub-level. It must be noted, however, the Eq. (15) still holds for evaluating the average rotational constant of the c and d levels. In the present calculation this average rotational constant is usually computed, and calculation of the l-type doubling constants is installed as option.

Higher Order Force Constants. The present method is not limited to the treatment of the general quartic force field, and any higher order terms may be included without disturbing the general procedure. This is an advantage of the direct diagonalization method over the contact transformation approach, since the latter requires at least the twice transformed hamiltonians to go beyond the quartic force field. It has already been pointed out[10,11] that some third-order parameters λ_1, λ_2, λ_3, and δ, which appear in Fermi resonance off-diagonal matrix elements are necessary to elucidate the vibration and vibration-rotation levels of most linear triatomic molecules, particularly those in CO_2. In the present treatment this is equivalent to including the quintic force constants k_{11112}, k_{12222}, and k_{12233}, and this has been done very easily.

Computational Methods

Most of numerical computations have been carried out on a MELCOM 7700 system in Educational Computer Centre in the University of Tokyo. A HITAC 8800/8700 system in Computer Centre in the University of Tokyo has also been used for eigenvalue problems of large matrices. Programs written in FORTRAN IV are compatible in both systems: only the sizes of a certain arrays are changed.

Generation of Basis Functions and Matrix Elements. In actual calculations, the harmonic oscillator basis functions are specified by a set of four integers corresponding to n_1, n_2, l_2, and n_3 ($l_2=n_2, n_2-2, \ldots,$ 1 or 0). A desired number of the basis functions are systematically generated with the condition of $n_1+n_2+n_3<n$, where n is a suitable interger. The following simple rule has been applied to identify the symmetry species of a given basis function:

(i) n_2+n_3 (even, odd) $\leftrightarrow$ (g, u)

(ii) l_2 $(0, 1, 2, 3, \cdots) \leftrightarrow (\sigma^+, \pi, \delta, \phi, \cdots)$

The matrix elements of the vibrational hamiltonian are generated by using the subroutines OPERQ and OPERR. The former was described in I, and the latter is written to evaluate the radial part matrix elements $\langle n,l|r^m|n',l'\rangle$. The diagonal part of vibrational hamiltonian matrix has a familiar form of

$$\langle n|\mathbf{H}_{v1b}|n\rangle=\sum_i \omega_i(n_i+d_i/2)+\sum_{i,j} x^*_{ij}(n_i+d_i/2)(n_j+d_j/2)+x^*_{l_2l_2}l_2^2 \qquad (16)$$

where $d_1=d_3=1$ and $d_2=2$. The asterisks indicate that they differ from the x_{ij}'s defined by Nielsen,[2] and if the general quartic force field is employed, $x^*_{ii}=(3/2)k_{iiii}$, $x^*_{l_2l_2}=k_{2222}/2$, and $x_{ij}{}^*=k_{iijj}$ with an exception of $x^*_{23}=k_{2233}+B_e[(\omega_2/\omega_3)+(\omega_3/\omega_2)]$. The last term in x^*_{23} arises from $\mathbf{H}_{v1b}{}'$. The contributions from $\mathbf{H}_{v1b}{}'$ are also considered for the evaluation of off-diagonal matrix elements which involve $\langle n_2,\ l_2,\ n_3|n_2\pm 2,\ l_2,\ n_3\rangle$, $\langle n_2,\ l_2,\ n_3|n_2,\ l_2,\ n_3\pm 2\rangle$, $\langle n_2,\ l_2,\ n_3|n_2\pm 2,\ l_2,\ n_3\pm 2\rangle$, and $\langle n_2,\ l_2,\ n_3|n_2\pm 2,\ l_2,\ n_3\mp 2\rangle$. The resultant vibrational hamiltonian matrix is divided into symmetry blocks, which can be treated separately. The correction of the zero-point energy, however, should be done to each level.

Just as in the case of diatomic molecules, the vibrational hamiltonian matrix is obtained as the form of matrix sum:

$$\mathbf{H}_{v1b}=\sum k^{(i)}\mathbf{A}^{(i)} \qquad (17)$$

The harmonic and anharmonic force constants are numbered consecutively; $i=1,2\ldots,f$. $\mathbf{A}^{(1)}$ represents the contribution of the i-th force constant to the vibrational hamiltonian matrix, the elements of which may be evaluated once for all if the set of basis functions has been determined. Non-vanishing matrix elements $a_{ij}^{(k)}$ may be stored in magnetic tapes or discs. The contribution from the $\mathbf{H}_{v1b}{}'$ term may also be included in Eq. (17) by formally setting $k^{(0)}\equiv 1$. The elements of $\mathbf{A}^{(0)}$ are easily obtained from Eq. (3). Also time-consuming is the process to calculate the second term in Eq. (15). The computing time is considerably abridged, however, by storing the non-vanishing elements of $\langle n|q_1^k\cdot j_+|m\rangle$ and $\langle n|q_1^k\cdot j_-|m\rangle$ for $k=0$ to 4.

Eigenvalue Problems. In the present calculations it is necessary to solve real $n\times n$ symmetric matrices, where n ranges from 30 to 200. Usually 30 lowest eigenvalues and eigenvectors are obtained for each symmetry block. The Givens-Householder method for symmetric matrices[12] is satisfactory in most cases. In HITAC 8700/8800 system it takes eight seconds to solve 100×100 matrix (30 seconds for a 200×200 matrix). Double precision arithmetics are used to retain the desired accuracy.

As seen from Eq. (2), the present calculation is primarily based on the force constants in dimensionless normal coordinates. However, the force constants

in curvilinear internal coordinates are more convenient for the systematic handling of various isotopic molecules, since the latters are independent to isotopic substitutions. Therefore, a subprogram is implemented which handles the transformation from the internal to the normal coordinate systems. Either the general valence force constants or the force constants in dimensionless normal coordinates are allowed as input.

Results and Discussion

Application to CO_2 and CS_2. The present method has been applied to two XY_2 type linear molecules, *i.e.* CO_2 and CS_2. They are probably only molecules of this type, of which the general quartic force fields have been studied extensively.[10,13-16] The force constants of CO_2 and CS_2 used in the present calculations have been taken from Refs. 10 and 16, respectively, they are listed in Table 2. It is clearly seen in Table 2 that the both sets of force constants show markedly similar trend. In terms of the Nielsen-Amat's perturbation scheme,[2,4] however, these molecules differ considerably in Fermi resonance of the $v_1 \simeq 2v_2$ type. It is known that the unperturbed v_1° and $2v_2^\circ$ levels are almost coincident in CO_2, while they are apart by about 130 cm^{-1} in CS_2.[16] It is, therefore, interesting to see how they differ in the numerical diagonalization method.

Table 2. General quartic force constants of CO_2 and CS_2

	General valence[a] representation			Dimensionless normal representation (cm^{-1})	
	CO_2[b]	CS_2[c]		CO_2	CS_2

a) $R_1=\Delta r_{CX}$, $R_2=\Delta\phi$, and $R_3=\Delta r_{CX'}$. b) Set (iv) of Table 2 in Ref. 10. c) Set (i) of Table 2 in Ref. 1.

Truncation Effect. Presicion of the present calculations is determined, at least in part, from the number of basis functions taken for a symmetry block: the more basis functions are used, the more accurate results are usually expected. In the treatment of diatomic CO and HCl in I, 20 to 30 harmonic oscillator wave functions must be taken as basis to elucidate the vibrational levels up to $v=6$. As mentioned earlier, a set of three quantum numbers must be considered in XY_2,[17] and the sum of these quantum numbers $n=\sum n_s$ may be regarded as the measure corresponding to n in diatomic molecules. The value of n is in the ranges of 13—14 and 18—20 in the respective cases of 100 and 200 basis functions, the latter may be a practical limit in the present treatment. Therefore, the truncation effect of the matrix sizes has first been examined by varying the number of basis functions from 30 to 200 for each of eight symmetry blocks ($l_2=0$, 1, 2, 3). Parts of the results are given in Tables 3—6. In each table the results for the Σ_g^+, Σ_u^+, and Π_g blocks are given, the latter two blocks are chosen because relatively large number of corresponding experimental data is available. The calculated values for the 200×200 problem are given in the first column in each table and the differences from the 200×200 case are entered in the remaining columns. The entry of zero or small numbers indicates that the convergence is completed at that stage. For the lowest two or three levels 100 basis functions are sufficient, but 200 basis functions are needed to account for the lowest six to ten levels in a given symmetry block. The convergence in CS_2 is somewhat faster than that in CO_2, which is in accordance with our results in diatomic molecules (I). The off-diagonal matrix elements of CS_2 are relatively smaller than those of CO_2.

In order to calculate the rotational constants, the terms up to $k=4$ in Eqs. (4) and (5) have been retained just as in the case of diatomic molecules. Fewer terms may be used, since the values for $\gamma_1=(2B_e/\omega_1)$, which represent 'order of smallness', are 5.8×10^{-4} and 3.2×10^{-4} for CO_2 and CS_2, respectively, which are considerably smaller than the corresponding values of $(2B_e/\omega_e)$ in CO and HCl (1.7×10^{-3} and 7.0×10^{-3}) we have adopted the following values: $B_e=0.391600$ cm^{-1} for CO_2 and $B_e=0.108859$ cm^{-1} for CS_2.

Comparison with Contact Transformation Method. One of the primary purposes of the present study is to compare the results of the numerical diagonalization method with those in Refs. 10 and 18 which utilized the 2nd-order perturbation treatment with 3rd-order Fermi resonance corrections. The differences between the two calculated quantities are given in the columns designated as δ_{cal} in Tables 3—6. The differences are much larger than expected particularly for the higher levels of CO_2 which are involved in strong Fermi resonance. The general quartic force field is used in the both methods, the only difference is the inclusion of the third-order parameters λ's and δ in the treatment of Fermi resonances. These third-order parameters are rather complicated functions of force constants and geometrical parameters.[18] However, the contributions of force constants quadratic through quartic terms are considered to infinite order of approximation in the numerical diagonalization method, and the only extra terms which have to be considered are three quintic force constants, k_{11122}, k_{12222}, and k_{12233}. These quintic force constants may be evaluated from the values of the three λ's as well as those of the lower order force constants, but this requires the rather lengthy calculations. Fortunately, the sextic potential function of CO_2 has been explored by Cihla and Chedin[19] who reported the values of 0.665, −1.052, and 5.4 cm^{-1} respectively for k_{11122}, k_{12222}, and

Table 3. Calculated vibrational levels of CO_2 and their variations with the number of basis functions[a,b]

k_{12233}. Another calculation has been proceeded by including the matrix elements originated from these three quintic force constants. In the last columns designated as δ_{cal}' in Tables 3 and 5, the corresponding differences are entered. Significant changes (most of them are improvements) are observed upon the inclusion of the three quintic force constants.

As mentioned earlier, the numerical diagonalization method has an advantage that in that process anharmonic resonances are automatically taken care of. As shown in I, however, this method is not free from the truncation effects of the potential functions. This effect is magnified in the special case of CO_2 in which an ordinary separation of higher-order force constants from the general quartic force constants does not work properly. Since a number of smaller anharmonic resonances are considered in the present process, the discrepancies in calculated vibrational levels and rotational constants are still expected, and the fit to the experimental data may be improved by slightly adjusting the 15 force constants including the three quintic force constants.

The inclusion of other quintic as well as sextic force constants has also been tested, the changes of calculated vibrational levels and rotational constants are far smaller than those induced by the three quintic force constants above, but they are not negligible. This encourages us to proceed the least-squares fit of higher-order force constants to experimental data. This will be our project in near future.

l-Type Doubling Constants. The l-type doubling constants for a given pair of the $l_2=\pm1$ states may be evaluated through the procedure given earlier. In harmonic approximation the separation of the levels is expressed as

$$\Delta\nu = q^e_{harm}(v_2+1)J(J+1), \tag{18}$$

where

$$q^e_{harm} = (B_e^2/\omega_2)[1+4\omega_2^2/(\omega_3^2-\omega_2^2)]. \tag{19}$$

From the harmonic frequencies listed in Table 1 as well as the equilibrium rotational constants, the following values are obtained: q^e_{harm} $(CO_2)=5.27\times10^{-4}$ cm^{-1} and q^e_{harm} $(CS_2)=7.63\times10^{-5}$ cm^{-1}. Deviations from the above values may be regarded as anharmonic effects. For a few vibrational levels of CO_2 and CS_2 the l-type doubling constants have been measured accurately[20-22]. In Table 7 the observed l-type doubling constants are listed along with the corresponding calculated values. The isotopically consistent set of force constants is used to evaluate the constants of $^{13}CS_2$ species. The agreements between the calculated and observed values are quite satisfactory.

Vibrational Wave Functions and Their Application to Intensity Problem. Another useful feature in the numerical diagonalization method is its readiness to obtain an orthonormal set of perturbed vibrational wave functions, $|v\rangle=\sum_n a_{vn}|n\rangle$. The six lowest levels in the Σ_u^+-block are chosen as examples for both CO_2 and CS_2, and the coefficients which make major contributions to the above levels are listed in Table 8. The mixings of the basis harmonic oscillator wave functions are so complete in CO_2, it is senseless to label a certain level in terms of a single basis function. The mixings are not so strong in CS_2 for which the labeling is much simpler. There also exists a considerable mixing between the wave functions $|n_1, n_2, l_2, n_3\rangle$ and $|n_1\pm1, n_2, l_2, n_3\rangle$ probably through the cubic force constant k_{111}.

The usefulness of the coefficient a_{vn} may be demonstrated in its application to the calculation of the transition moment from v to v' states, $R_v^{v'}$, the square of which is related to the total integrated intensity of the band:

$$R_v^{v'} = \langle v'|M|v\rangle, \tag{20}$$

where M is the dipole moment function $M=M(q_1, q_2, q_3)$, which may be expressed as the sum of the $M_{/\!/}$ and $M_\perp$ components for linear symmetrical XY_2 molecule. The former is parallel to the molecular axis (z-axis) and has the same symmetry property as $T_z(\sigma_u^+)$, whereas the latter is perpendicular to the z-axis and has the Π_u symmetry to which T_x and T_y belong. The both components are expanded as

$$M_{/\!/} = \mu_3 q_3 + \mu_{13}q_1q_3 + \sum_{i=1}^{3}\mu_{ii3}q_i^2q_3 + \cdots \tag{21}$$

and

$$M_\perp = \mu_2 q_2 + \mu_{12}q_1q_2 + \sum_{i=1}^{3}\mu_{ii2}q_i^2q_2 + \cdots \tag{22}$$

For simplicity q_2 is used instead of r_2. The zeroth order term vanishes because of the molecular symmetry ($D_{\infty h}$). If $v\times v'\ni\sigma_u^+$, Eq. (20) is rewritten as

$$R_v^{v'} = \langle v'|M|v\rangle = \mu_3\sum_n\sum_m a_{vn}a_{v'm}\langle n|q_3|m\rangle + \mu_{13}\sum_n\sum_m a_{vn}a_{v'm}\langle n|q_1q_3|m\rangle + \cdots \tag{23}$$

Similar expression may be written for the case of $v\times v'\ni\Pi_u$. In Eq. (23), the first term vanishes unless $m_1=n_1$, $m_2=n_2$ $(l'_2=l_2)$ and $m_3=n_3\pm1$, while the second term vanishes unless $m_1=n_1\pm1$, $m_2=n_2(l'_2=l_2)$, and $m_3=n_3\pm1$. Such requirements considerably simplify the practical calculations.

a) Asterisks indicate negative coefficients.

It is emphasized here that Eq. (23) is valid for any transitions satisfying the relation $v \times v' \ni \sigma_u^+$. This contrasts with the expressions derived from the perturbation method[23)] or those derived from the contact transformation method as has been applied to the intensity problem of the bent XY_2 molecules.[24)] Actually the numerical diagonalization method was used by Foord and Whiffen[25)] for the treatment of the dipole moment function of OCS. They obtained the vibrational wave functions by solving a 30×30 vibrational hamiltonian matrix.

Conclusions. In the present paper it has been shown that the direct diagonalization method is applicable to the treatment of vibration and vibration-rotation problem of linear symmetrical XY_2 molecules. This method has a certain merits over the conventional perturbation method: Exact solutions are usually secured if the number of basis functions is taken large enough, the quintic and higher-order force constants are easily accomodated and the method may be extended to handle with the general sextic potential function. A set of orthonormal vibrational wave functions may be obtained regardless of the potential functions employed. Eq. (23) holds whatever potential functions may be used. The obvious demerit of the present method is that it involves the eigenvalue problem for large martices to avoid the truncation effect of the vibrational hamiltonian matrix. In addition, the calculation of vibration-rotation constants is not simple and rather time consuming. However, the rapid progress of existing computers as well as of computational technique has made the above calculations quite manageable, and its application to the determination of more precise force field or to the intensity problem through dipole moment functions seems very promising.

This research has been supported by the grant from the Ministry of Education.

The Raman spectra of the liquid, unannealed solid and annealed solid, and the infrared spectra of the gas, liquid, and annealed solid of ethyl methyl sulfide were measured. Normal vibrations were treated of the *trans* and *gauche* isomers. C–S stretching, CH_2 rocking and skeletal deformation vibrations were discussed in relation with molecular structures. Only the *gauche* isomer was found to exist in the annealed solid. In the liquid state, the *gauche* isomer was found to be more stable, by 0.14±0.05 kcal/mol, than the *trans* isomer. The vibrational assignment made of ethyl methyl sulfide is consistent with those of related sulfides and disulfides.

The vibrational spectra and molecular structure of ethyl methyl sulfide have been extensively studied,[2)] and it has been concluded that the *trans* isomer exists in the crystalline state. In our previous studies, however, the molecules of dialkyl sulfides[3,4)] and dialkyl disulfides[5,6)] were taken up as models of methionine and cystine groups of protein side-chains. The Raman spectra of ethyl methyl sulfide, methyl propyl sulfide, and isobutyl methyl sulfide were analyzed in the region 800—600 cm^{-1}. A systematic assignment was made of the normal vibrations of these three molecules, and the Raman lines of the annealed solid of ethyl methyl sulfide were assigned to the *gauche* isomer rather than the *trans* isomer.[3)]

In the present study, a normal coordinate treatment was made of the *trans* and *gauche* isomers of ethyl methyl sulfide and the vibrational spectra (C–S stretching, CH_2 rocking, and skeletal deformation vibrations) were analyzed for establishing the molecular conformation of ethyl methyl sulfide in the crystalline state.

Experimental

The sample of ethyl methyl sulfide was obtained from commercial sources and was purified by fractional distillation. Raman spectra were recorded with a JEOL Raman Spectrometer (Model JRS-02AS) with an argon-ion laser. Infrared spectra were recorded with a Hitachi EPI-G3 Infrared Spectrophotometer.

Normal Coordinate Treatment

As an aid for analyzing the vibrational spectra in the low frequency region, normal vibrations were treated for the *trans* (C_s) and *gauche* (C_1) isomers of ethyl methyl sulfide. The structural parameters used in the calculations were the bond lengths of r(C–S)=1.81 Å, r(C–C)=1.54 Å, and r(C–H)=1.09 Å, bond angles of ϕ(C–S–C)=98.67° and the tetrahedral angles for carbon atoms. The internal-rotation angles were taken as 180° and 60° for the *trans* and *gauche* forms, respectively. The force constants of the Urey-Bradley type were mostly transferred from dialkyl disulfides,[7)] except that the bending constant H(C–S–C) [=0.244 mdyn/Å·rad²] and repulsion constant F(C–S–C) [=0.210 mdyn/Å] were transferred from dimethyl sulfide.[8)]

C–S Stretching Vibrations

The Raman spectra of ethyl methyl sulfide in the 800~200 cm^{-1} region are shown in Fig. 1. The top spectrum (a) was observed for the liquid at room temperature. The second spectrum (b) was observed after freezing the sample rapidly. Then the frozen solid sample was readily annealed and the third spectrum (c) was observed. The infrared spectra of the liquid and annealed solid of ethyl methyl sulfide are shown in Figs. 2(b) and (c).

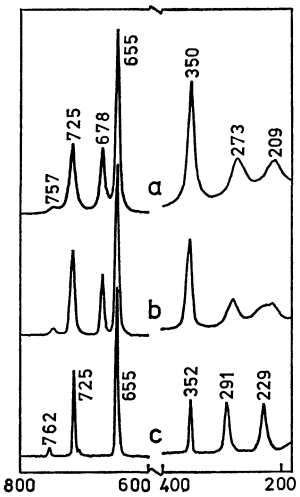

Fig. 1. The Raman spectra of ethyl methyl sulfide; (a) liquid at 300 K, (b) unannealed solid at 150 K, and (c) annealed solid at 130 K.

For each of the *trans* and *gauche* isomers of ethyl methyl sulfide, three fundamental vibrations are expected to lie in the 800—600 cm^{-1} region, including two C–S stretching and one CH_2 rocking vibrations. In fact, the Raman [Fig. 1(c)] and infrared [Fig. 2(c)] spectra of the annealed solid exhibit only three bands, indicating the presence of only one isomer. The band observed at 762 cm^{-1} (weak in Raman scattering but strong in infrared absorption) is assigned to the CH_2 rocking vibration while the bands at 725 and 655 cm^{-1} are assigned to the CH_3–S and CH_2–S stretching vibrations, respectively. For the liquid or unannealed solid, an additional band is observed at 678 cm^{-1} and is assigned to the CH_2–S stretching vibration of the other isomer. From the comparison of these C–S stretching frequencies with those of methyl propyl sulfide and isobutyl methyl sulfide,[3,4)] the Raman lines of ethyl methyl sulfide at 725 and 655 cm^{-1} are assigned to the *gauche* isomer and the Raman line at 678 cm^{-1} is assigned to the *trans* isomer.

Energy Difference between Rotational Isomers. Relative intensities of the Raman lines at 678 cm^{-1} (*trans*) and 655 cm^{-1} (*gauche*) were measured over the temperature range from 290 K to 180 K. Thus, the *gauche* isomer was found to be slightly more stable than the *trans* isomer, with the energy difference of 0.14±0.05 kcal/mol.

The temperature dependence of the relative intensities of the Raman lines at 725 and 655 cm^{-1} was also measured. The apparent energy difference of 0.05±0.05 kcal/mol is consistent with the assignment of the liquid Raman line at 725 cm^{-1} to the overlap of the CH_3–S stretching vibrations of the *trans* and *gauche* isomers.[4]

Skeletal Deformation Vibrations

For each isomer of ethyl methyl sulfide, two skeletal deformation vibrations and one CH_3–CH_2 torsional vibration are expected to lie in the 400—200 cm^{-1} region. Generally in the Raman scattering, skeletal vibrations are strongly observed but CH_3–CH_2 torsional vibrations are hardly observed. However, if the CH_3–CH_2 torsional mode is extensively hybridized with skeletal deformation modes, "CH_3–CH_2 torsional" vibration may well be observed in Raman spectra.

Such hybridization was found to be the case for the *gauche* isomer of ethyl methyl sulfide. The potential energy distribution calculated for the *gauche* isomer indicates that the skeletal deformation modes and CH_3–CH_2 torsional mode are appreciably hybridized to yield the normal vibrations at 291 and 229 cm^{-1}. Indeed, three well-defined Raman lines were observed for the annealed solid [Fig. 1(c)]. This observation is consistent with the presence of the *gauche* isomer in the annealed solid, since such hybridization is not expected to occur for the *trans* isomer belonging to the point group C_s.

CH_2 Rocking Vibrations

In our previous studies on dialkyl disulfides, the correlations were found between the CH_2 rocking frequencies and internal rotation about the CH_2–S bond of CH_3–CH_2–S–S group.[6] For the case of ethyl methyl disulfide [Fig. 2(d)], the infrared bands of the liquid at 781 and 761 cm^{-1} were assigned to the *trans* and *gauche* forms, respectively, of the CH_3–CH_2–S–S group. Similarly for diethyl disulfide, the infrared bands at 781 and 762 cm^{-1} were found to be due to the *trans* and *gauche* forms, respectively. Thus, the CH_2 rocking frequency of the *trans* form is higher, by about 20 cm^{-1}, than that of the *gauche* form. This correlation may now be applied to the case of ethyl methyl sulfide. The infrared bands of the liquid at 785 and 760 cm^{-1} are assigned to the *trans* and *gauche* isomers respectively. The observation of the infrared band at 764 cm^{-1} indicates that the *gauche* isomer exists in the annealed solid.

CH_2 rocking frequencies were also observed for the rotational isomers of isobutyl methyl sulfide, $(CH_3)_2$-CH–CH_2–S–CH_3. The infrared bands of the liquid at 813 and 803 cm^{-1} are due to the P_C-T and P_C-G

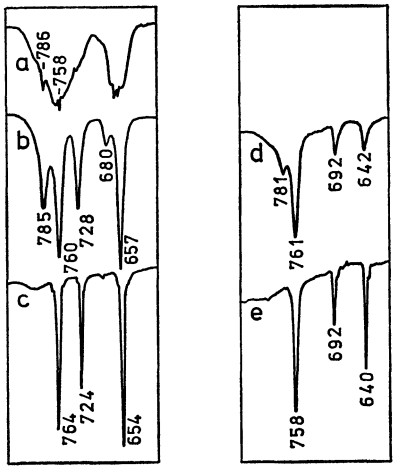

Fig. 2. Left: the infrared spectra of ethyl methyl sulfide; (a) vapor at 130 Torr and 300 K, (b) liquid at 300 K, and (c) annealed solid at 80 K. Right: the infrared spectra of ethyl methyl disulfide; (d) liquid at 300 K and (e) annealed solid at 80 K.[6]

forms, where the second symbol (T or G) refers to the internal rotation about the CH_2–S bond.[4] In the case of methyl propyl sulfide CH_3CH_2–CH_2–S–CH_3, there are two CH_2 rocking vibrations for each isomer and the lower frequency vibration lies in the 800—700 cm^{-1} region. The infrared bands (see Fig. 1 of Ref. 3) observed at 751 and 731 cm^{-1} are assigned to the P_C-T and P_C-G forms and those at 793 and 785 cm^{-1} to the P_H-T and P_H-G forms, respectively.[3] In all these cases, the CH_2 rocking frequency of the *trans* form (P_C-T or P_H-T) is higher, by 8∼25 cm^{-1}, than that of the *gauche* form (P_C-G or P_H-G).

Gas Phase. The electron diffraction of ethyl methyl sulfide was studied by Oyanagi *et al.*,[9] and the *gauche* isomer was found to be more abundant than the *trans* isomer in the gas phase. In our present study, the infrared spectrum of the gas phase was measured at the gas pressure of 130 Torr and room temperature [Fig. 2(a)]. The infrared bands due to CH_2 rocking vibrations were observed at 786 cm^{-1} (*trans*) and 758 cm^{-1} (*gauche*). The absorption band of the *gauche* isomer is stronger than that of the *trans* isomer. This observation is consistent with the result of the electron diffraction study.

To summarize, the present analyses of the Raman and infrared spectra (C–S stretching, CH_2 rocking and skeletal deformation vibrations) indicate that the *gauche* isomer of ethyl methyl sulfide exists in the annealed solid.

The authors wish to thank Prof. K. Kuchitsu, Dr. T. Fukuyama and Miss K. Oyanagi of the University of Tokyo for making available the results of the gas electron diffraction studies prior to publication.

(Received October 23, 1973)

The differential heat of adsorption of ammonia on synthetic zeolites was calorimetrically measured and the distribution of the surface acidity was discussed in relation to the catalytic activity for cumene-cracking as a function of zeolite compositions. A newly designed apparatus, a twin-conduction-type calorimeter equipped with a semiconductor thermoelement and an adsorption apparatus, was used for the direct measurement of the differential heat of adsorption. The differential heat of adsorption of ammonia decreased with the increase in surface coverage, the acid site on the surface becoming stronger up to 27 kcal/mol for ammonia-adsorption when the ratio of silica to alumina was higher and the content of exchanged ammonium ions was higher. The cumene-cracking reaction was effectively catalyzed by zeolites having such sites with heat of adsorption of ammonia exceeding 25 kcal/mol.

Calorimetric studies on the interaction between solids and gases or liquids provide significant information on the surface state of the solids. For this purpose, the heats of adsorption of gas and the heats of immersion of solid into liquids are the important quantities to be measured. The heat of immersion of solids into liquids has been extensively measured calorimetrically for the past two decades.[1] It is difficult, however, to measure the heat of adsorption calorimetrically and it was usually calculated from the isotherm of adsorption[2] or from the temperature dependence of the retention volume in gas-chromatography.[3] The calculation of heat of adsorption is based on the assumptions that a reversible adsorption mechanism holds and the surface state is invariable during measurement. However, these assumptions are not necessarily applicable to the practical systems.

The difficulty in the calorimetric measurement of the interaction energy between solids and gases lies in the accurate measurement of the heat evolved. A few authors reported the results on evaporated metal films using metallic thermometers[4-6] and some other dealt with Dewar-type calorimeters.[7-11] Recently, Gravelle measured the heat of adsorption on heterogeneous catalysts by means of a heat-flow calorimeter.[12] Several other studies have also appeared.[13-16]

This paper reports a newly designed calorimeter for the measurements of the interaction energy between solids and gases, and the measurements of differential heat of adsorption of ammonia on zeolites, the results being discussed in relation to the cracking of cumene catalyzed by the zeolites.

Experimental

The calorimeter used is of a twin-conduction-type, the main cell of which is illustrated in Fig. 1. The cell is made of stainless steel and Pyrex glass which are joined by Kovar glass. The calorimeter has a second cell as a reference, which is of the same structure as that of the sample cell and serves to eliminate the effect of external disturbance. The two cells and the gas storage tank are connected to each other by a Pyrex glass tube having a stopcock connected to a vacuum line and a manometer. The sample in the cell was pretreated at various temperatures and pressures. The two cells and the gas storage tank were set in a thermostated

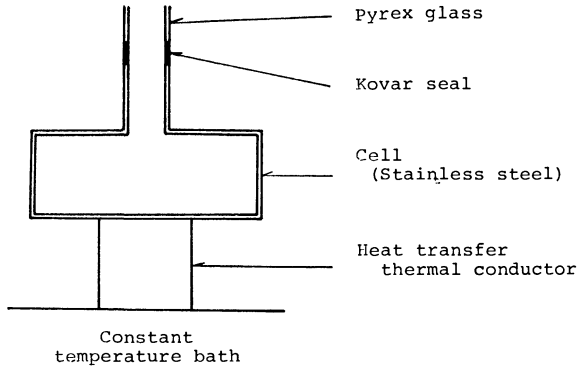

Fig. 1. Calorimetric cell.

bath. After the whole system reached thermal equilibrium, the gas storage tank was opened and the gas was led to the cell. The heat evolved in the sample cell caused the thermoelectromotive force in the thermoelement, which was amplified and recorded as shown in Fig. 2. When the thermal equilibrium was again established after completion of adsorption, the amount of heat was calibrated by flowing a given amount of electrical energy through a standard electric heater which was set in contact to the cell. An example of the cooling curve and the calibration curve is shown in Fig. 2. The ordinate, ΔT, indicates the temperature difference between the sample cell and the thermostated bath. When the heat, q, is generated in a unit of time within the cell, the following equation can be derived for the

NH_4-$Y_{3.47}$	$0.70(NH_4)_2O \cdot 0.10Na_2O \cdot 3.47SiO_2 \cdot Al_2O_3$	87.5
NH_4-$X_{2.5}$	$0.41(NH_4)_2O \cdot 0.36Na_2O \cdot 2.5SiO_2 \cdot Al_2O_3$	53.3
La-$Y_{4.71}$	$0.66La_2O_3 \cdot 0.27Na_2O \cdot 4.71SiO_2 \cdot Al_2O_3$	71.0
Ca-$Y_{5.0}$	$0.80CaO \cdot 0.10Na_2O \cdot 5.0SiO_2 \cdot Al_2O_3$	88.9

relation between the amount of q and the temperature change of the cell by assuming a uniform temperature distribution in the cell.

$$q = C \cdot d(\Delta T)/dt + \sigma \Delta T \quad (1)$$

where C is the heat capacity of the cell with the sample and the thermoelement, and σ the heat transfer coefficient. The total heat released, Q, can be obtained by integrating q with respect to time t:

$$Q = \int_{-\infty}^{+\infty} q \cdot dt = C(\Delta T)_{-\infty}^{+\infty} + \sigma \int_{-\infty}^{+\infty} \Delta T \cdot dt \quad (2)$$

Since the thermal equilibrium is established in the cell before and after the adsorption, the first term on the right side of Eq. 2 is reduced to zero. Thus the total heat should be proportional to the area under the ΔT–t curve.

The amount of adsorbed gas was determined as the difference between the amount introduced to the adsorption vessel and that of the residual gas. In most initial doses, no gas remained in the gas phase. In these runs, the relation between the heat of adsorption and the adsorbed amount of gas gave the differential heat of adsorption. After the adsorption of the first dose had been accomplished, the second dose of gas was introduced; the same procedure was repeated until the differential heat of adsorption became constant.

The heat of adsorption of ammonia was measured at 25 °C. Ammonia was condensed in a liquid nitrogen trap and then allowed to evaporate into the vacuum system. The pretreatment of zeolites was carried out at 400 °C and 10^{-5} Torr for 8 hr. The catalytic activity for the cumene-cracking reaction was measured in a microreactor, the details of which were described in a previous paper.[17]

Materials. The original zeolites were the commercial Linde Molecular Sieve 13X, SX-40 and Na-$Y_{3.47}$ synthesized from silica-alumina gel and sodium hydroxide. The calcium-, lanthanum- and ammonium-form zeolites were prepared by treating Na-form zeolite with an 0.1 M solution of the corresponding chloride (guaranteed-grade reagents of Wako Pure Chemicals Industries, Ltd.). The treatment was repeated several times in order to obtain a high extent of exchange. The remaining salts were removed by washing the samples with distilled water until no chloride ions detected in washing solutions with silver nitrate. The samples were then dried and stored over the saturated sodium chloride solution. Zeolites with silica-to-alumina ratios greater than 5 were prepared by extracting aluminum atoms in NH_4-$Y_{4.8}$ zeolite with EDTA.[18] Decationated zeolites were obtained by heat treatment of the ammonium-form zeolite at 400 °C. The compositions of zeolites were measured by chemical analysis and flame photometry. The results are summarized in Table 1.

Results and Discussion

The accuracy of the calorimeter was confirmed by comparing the areas under the ΔT–t curve for the standard electric heater. The constant current supplied to the heater buried in the solid yielded a typical ΔT–t curve as shown in Fig. 2A. The ΔT–t curve for the calibration heat is also shown in Fig. 2B The ratio of the integrated area of the former ($S_{samp.}$) to that of the latter ($S_{calib.}$) is given in Table 2. We see that the ratio is equal to unity. The integrated area changes linearly with the amount of the supplied heat, the lower limit of the detected heat being a few milli-calories. The results on the heat of adsorption of ammonia on the ammonium-form zeolites with various ratios of silica-to-alumina (H-$Y_{10.29}$, H-$Y_{7.38}$, H-$Y_{4.8}$, H-$Y_{3.47}$ and H-$X_{2.5}$) are shown in Fig. 3. Since the initial stages of adsorption below 2 mmol/g are considered to be important for the catalytic activity, the results in these ranges are shown in Fig. 4 in a larger scale. Except the case of H-$X_{2.5}$, the initial heats of adsorption of ammonia on the

zeolites were larger than 24 kcal/mol in the coverage range less than 3×10^{-2} mmol/g. The heats, then, decrease sharply to about 21.5 kcal/mol, where the four curves intersect at 1.75 mmol/g. The abrupt decrease of the heat of adsorption at the coverage of 3×10^{-2} mmol/g suggests that the selective adsorption of ammonia molecules on the strongest acid sites takes place at a lower coverage.

It is interesting to note that the number of sites with the heat of adsorption of ammonia above 23 kcal/mol on the surface of H-$Y_{10.29}$ is larger than those of other specimens (Fig. 4). As the adsorbed amount increases to about 1.7 mmol/g, the heats of adsorption H-$Y_{10.29}$ and on H-$Y_{7.38}$ fall off steeply to about 15 kcal/mol, whereas the heats of adsorption on H-$Y_{4.8}$ and H-$Y_{3.47}$ decrease gradually to about 19.5 kcal/mol in the coverage range up to 4.5 and 5.0 mmol/g, respectively.

It is known that the thermal treatment of ammonium-form zeolites at 400 °C generates Brönsted acid sites. The initial heats of adsorption of ammonia on H-$Y_{7.38}$ and H-$Y_{10.29}$ are larger than those on H-$Y_{4.8}$ and H-$Y_{3.47}$ (Fig. 3 and 4). However, the total number of acidic sites with heats of adsorption larger than 20 kcal/mol on H-$Y_{4.8}$ and H-$Y_{3.47}$ is greater than those on H-$Y_{10.29}$ and H-$Y_{7.38}$. Since H-$Y_{10.29}$ and H-$Y_{7.38}$ were prepared by extracting aluminum atoms from the alumino-silicate frame-work with EDTA, the treatment would bring about a decrease in the total number of sites to which protons could combine. On the other hand a decrease in the aluminum content reduces the number of negative sites and lowers the electric shielding for the cations in the zeolitic cavity. Thus, the protons with weaker electrostatic shielding should be more mobile and form stronger acidic sites.

The total number of protons contained in the zeolites could be calculated by assuming that ammonium ions were converted into protons during the course of heat treatment at 400 °C. The numbers of protons thus calculated for H-$Y_{10.29}$, H-$Y_{7.38}$, H-$Y_{4.8}$ and H-$Y_{3.47}$ are 1.76, 2.26, 3.79 and 4.76 mmol/g, respectively. If one ammonia molecule is chemisorbed on one acidic site, the chemisorption of ammonia on H-$Y_{10.29}$ would amount to 1.76 mmol/g. The heat of adsorption of ammonia on H-$Y_{10.29}$ falls steeply from 22 kcal/mol to 14 kcal/mol at the coverage of 1.76 mmol/g, in accordance with the prediction (Fig. 3). A similar coincidence occurs also in the other cases. The heats of adsorption of ammonia on H-$Y_{7.38}$, H-$Y_{4.8}$ and H-$Y_{3.47}$ steeply decrease at the adsorbed amounts of 2.3, 3.4, 4.5 mmol/g, respectively, which are also consistent with the values calculated above. The heat values at these amounts are about 19.5 kcal/mol in all three cases. We can conclude that the minimum value of the chemical interaction energy between ammonia molecules and Brönsted acid sites is greater than 19.5 kcal/mol. It is likely that the acidic sites of H-$Y_{10.29}$ and H-$Y_{7.38}$ are more homogeneous in energetic character than those of H-$Y_{4.8}$ and H-$Y_{3.47}$.

By comparing with the results of infrared spectroscopy, pyridine molecules are supposed to be chemisorbed on the acidic sites of zeolites, where the heat of adsorption is greater than 20 kcal/mol.[18] Since ammonia is chemisorbed on both Brönsted and Lewis acid sites and the steric factor in adsorption of ammonia differs from that of pyridine, no quantitative coincidence was found between the adsorption of pyridine and that of ammonia.

After stepwise decrease, the heats of adsorption attain the nearly plateau region of *ca.* 10 kcal/mol and then decrease to *ca.* 5 kcal/mol. In the cases where the molecules adsorbed exceed the monolayer, the interaction between ammonia molecules and ammonium ions should be considered. According to Hsiesh[14], newly adsorbed ammonia molecules interact with the ammonium ions formed by ammonia molecules adsorbed on Brönsted acid sites. The ammonium ions polarize the ammonia molecule; the ammonia molecules also interact with the catalyst surface by the van der Waals force. In these regions, the differential heat of adsorption continues to decrease gradually until four ammonia molecules "co-ordinate" with each ammonium ion on the surface, which is in accordance with the present observations. The differential heat of adsorption finally drops to *ca.* 6 kcal/mol, which is quite close to the value of the heat of liquefaction of ammonia, 5.2 kcal/mol.

The initial heat of adsorption of H-$X_{2.5}$ is *ca.* 20.5 kcal/mol. The differential heat of adsorption gradually decreases to *ca.* 12 kcal/mol at 4 mmol/g, and then becomes constant at about 11 kcal/mol. The number of the acid sites with heats of adsorption over 19.5 kcal/mol is *ca.* 0.4 mmol/g. The value is very low as compared with that of the zeolites with higher silica-to-alumina molar ratios. Some authors[19,20] reported that the faujasite zeolite with the silica-to-alumina molar ratio of 2.5 is unstable under heat treatment. The remarkable decrease in the heat of adsorption of ammonia on H-$X_{2.5}$ might be due to the destruction of the crystalline structure by the pretreatment at 400 °C.

Figure 5 shows the plots of the heat of adsorption of ammonia *vs.* the adsorbed amount on faujasite Y with various exchange ions (Na-, Ca-, La-, and H-). The heat of adsorption of ammonia on both Ca-$Y_{5.0}$

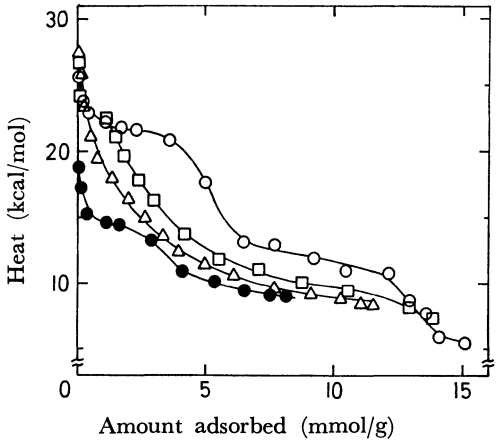

Fig. 5. Variation of differential heat of adsorption of ammonia with amount adsorbed on zeolites.
●: $Na\text{-}Y_{5.0}$ □: $Ca\text{-}Y_{5.0}$ △: $La\text{-}Y_{4.71}$ ○: $H\text{-}Y_{4.8}$

Table 3. Conversion of cumene-cracking on zeolite catalysts

Zeolite	Conversion %
$H\text{-}Y_{10.29}$	91
$H\text{-}Y_{7.38}$	95
$H\text{-}Y_{4.8}$	62
$H\text{-}Y_{3.47}$	44
$H\text{-}X_{2.5}$	0
$La\text{-}Y_{4.71}$	89
$Ca\text{-}Y_{5.0}$	71
$Na\text{-}Y_{4.8}$	0

and $La\text{-}Y_{4.71}$ falls sharply at first from a high initial value and then gradually to *ca.* 6 kcal/mol, which is nearly equal to the heat of liquefaction of ammonia. As compared with the case of the multi-valent ion-exchange zeolites, the initial heat of adsorption on the original $Na\text{-}Y_{4.8}$ is very low (about 19 kcal/mol), and decreases slowly. This indicates that the $Na\text{-}Y_{4.8}$ has a rather homogeneous surface. The conversion of the cumene-cracking on the zeolites is listed in Table 3. We see that the conversion of the cumene-cracking on ammonium-form zeolites increases in the order $H\text{-}X_{2.5}<H\text{-}Y_{3.85}<H\text{-}Y_{4.8}<H\text{-}Y_{7.38}$; it increases with the increase in the silica-to-alumina molar ratio. The conversion activity of $H\text{-}Y_{10.29}$ is somewhat lower than that of $H\text{-}Y_{7.38}$. $La\text{-}Y_{4.71}$ has a higher activity than $Ca\text{-}Y_{5.0}$, while $Na\text{-}Y_{4.8}$ has no cracking ability. In the cracking reaction of cumene, the carbonium ion is formed on the Brönsted acid site of the catalyst.[21] A site having stronger acidity will show larger activity of the formation of carbonium ions and consequently a larger cracking ability. Decrease in aluminum content makes the proton active, and increases the catalytic activity.

Morita *et al.*[22] reported that the sites effective for the cracking of cumene have the acid strengths of $H_0 \leq -3.0$, as measured by the butylamine titration with Hammett indicators. By using the same method, we found that the amount of acid sites of $H\text{-}Y_{4.8}$ with an acid strength of $H_0 \leq -3.0$ is *ca.* 2 mmol/g.[23] The heat of adsorption of ammonia at this surface coverage is found to be *ca.* 22 kcal/mol (Fig. 4). If sites on which the heat of adsorption is more than 22 kcal/mol were available for the cracking reaction of cumene, the activities of $H\text{-}Y_{3.47}$, $H\text{-}Y_{4.8}$ and $H\text{-}Y_{7.38}$ should be nearly equal to each other and lower than that of $H\text{-}Y_{10.38}$. But this is apparently not the case.

The $H\text{-}Y_{10.29}$ sample has a higher heat of adsorption of ammonia than other samples in the region of coverage 0.2—1.7 mmol/g. However, the cumene-cracking activity of $H\text{-}Y_{10.29}$ is lower than that of $H\text{-}Y_{7.38}$. Beaumont and Barthomeuf[19] reported that the crystalline structure of zeolite was partially destroyed if the content of aluminum was below 28 atoms per unit cell. The zeolite with 28 atoms per unit cell corresponds to that with a silica-to-alumina molar ratio of 9.8. In fact, the X-ray diffraction pattern of $H\text{-}Y_{10.29}$ shows a decrease in intensity.[18] The decrease in activity of cumene-cracking and the high initial heat of adsorption of $H\text{-}Y_{10.29}$ might be attributed to the partial destruction of the lattice structure.

The $H\text{-}Y_{4.8}$ and $H\text{-}Y_{3.47}$ samples, which have the same values of the initial heat of adsorption, show a remarkable difference in the activity of cumene-cracking. This is probably owing to the difference in the number of strong sites. The initial heat of adsorption on $H\text{-}Y_{3.47}$ is larger than 25.5 kcal/mol. On the other hand, the number of adsorption sites for this energy region on $H\text{-}Y_{4.8}$ is three times as much as that of $H\text{-}Y_{3.47}$. A possible reason for the difference in the activity of cumene-cracking between the two zeolites may lie in the difference in the degree of change of the Brönsted acid site to the Lewis one. Since the catalyst was treated at 550 °C before activity measurement, its number of Brönsted acid sites should be smaller than that of the sample treated at 400 °C. Dehydration occurs easily at higher temperatures on $H\text{-}Y_{3.47}$, since it possesses a larger amount of hydroxyl groups.

The present evidence is not yet conclusive as to which sites are effective in cumene-cracking reaction. However, all the data about the heat of adsorption and the cracking activity seem to be compatible with the suggestion that the sites with the heat of adsorption of ammonia of more than 25 kcal/mol are effective in cumene-cracking reaction and that the sites of stronger acidity show a greater activity. The total number of such strong acid sites also affects the activity.

Multidentate Ligand Kinetics. I. The Ligand Substitution Reaction between Ethylenediaminetetraacetatocuprate(II) and Triethylenetetraminezinc(II)

Tetsuo KATSUYAMA and Toshihiko KUMAI

Department of Basic Technology, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992

(Received January 24, 1975)

The kinetics and the mechanism of the ligand substitution reaction between ethylenediaminetetraacetatocuprate(II)(CuY^{2-}) and triethylenetetraminezinc(II)(ZnT^{2+}) were studied spectrophotometrically in the pH range 7.0—10.5 at I=0.2($NaClO_4$) and 25.0 °C. The exchange reaction was accelerated by traces of either EDTA or triethylenetetramine(Trien). The exchange reaction was shown to proceed by the chain reaction mechanism where the chain-propagating steps are the reaction of CuY^{2-} with Trien and the reaction of ZnT^{2+} with EDTA. Each chain-propagating step was investigated. The apparent rate constant of the reaction of CuY^{2-} with Trien increases with pH, while that of ZnT^{2+} with EDTA decreases with pH.

Ligand substitution reactions between two multidentate ligand complexes have been studied by Margerum *et al.*[1-4] The exchange reactions were found to be accelerated by the addition of small numbers of free ligands and to be inhibited by the addition of small numbers of metal ions. A coordination chain reaction mechanism was proposed for the exchange reactions, where the chain-propagating steps are the reactions of metal complexes with free ligands.

These catalytic exchange reactions are useful for analysis.[5-7] In analytical applications, rapid coordination chain reactions are of interest for several reasons. (1) In coordination chain reactions, a metal impurity reacts very rapidly with ligands and the resulting complexes may influence the chain reaction. In rapid coordination chain reactions, this influence may be eliminated if the main chain reaction takes place rapidly. (2) In rapid coordination chain reactions, kinetic measurements can be easily repeated using the stopped-flow technique. Therefore, rapid analysis may be achieved by handling the results statistically with an on-line computer.

It seemed worthwhile to find rapid coordination chain reaction systems. In the present study, the kinetics and mechanism of the ligand substitution reaction between ethylenediaminetetraacetatocuprate(II)(CuY^{2-}) and triethylenetetraminezinc(II)(ZnT^{2+}) were studied.

$$CuY^{2-} + ZnT^{2+} \rightleftharpoons CuT^{2+} + ZnY^{2-} \quad (1)$$

The reaction of this system was greatly accelerated by the addition of free ligands.

Experimental

Reagents. Reagent grade zinc(II) and copper(II) perchlorates, and guaranteed reagent grade sodium perchlorate were recrystallized from their aqueous solutions. Guaranteed reagent grade triethylenetetramine(Trien) was purified by distillation at reduced pressure. EDTA used was a Dotite reagent. Water used was distilled with an all quartz distillation apparatus after passing through a column of mixed-bed ion exchange resin. A standard copper nitrate solution was prepared from copper plate, and used to standardize the Trien and EDTA solutions.

Solutions of CuY^{2-} and ZnT^{2+} were prepared by the following procedure. The ligand was dissolved in water and standardized. Metal perchlorate was added stoichiometrically to the ligand solution and also a slight excess of the metal perchlorate was added to the solution. The excess metal was precipitated as hydroxide at about pH 9. The resulting precipitate was filtered off and the solution prepared was adjusted to about pH 7 for storage. The concentrations of the solutions prepared were standardized by the following procedure. CuY^{2-}: a large excess of Trien was added to the CuY^{2-} solution and the concentration of the CuT^{2+} formed was measured spectrophotometrically. ZnT^{2+} : a slight excess of the copper(II) ion was added to the ZnT^{2+} solution. The zinc(II) ion liberated and the excess of copper(II) ion were precipitated at pH 9, because the reaction of ZnT^{2+} with the copper(II) ion proceeds essentially to completion. Then the concentration of the CuT^{2+} formed was measured spectrophotometrically.

Other reagents were of guaranteed reagent grade.

Kinetic Measurements and Apparatus. The kinetics of the double ligand-exchange reaction between CuY^{2-} and ZnT^{2+} was studied in the presence of a large excess of CuY^{2-} and small amounts of EDTA over a pH range 7.0—10.5. In the kinetic measurements, a stopped-flow technique was employed with a Hitachi Model RSP2 Rapid Scanning Spectrophotometer which was equipped with two syringes used as reactant containers. One of the syringes was filled with a CuY^{2-} solution containing small amounts of EDTA, and the other, with a ZnT^{2+} solution containing a buffer and sodium perchlorate. After the two reactant solutions were mixed, the change in the transmittance at 550 nm was recorded on a storage-type oscilloscope as a function of time. Molar absorption coefficients of CuT^{2+} and CuY^{2-} at 550 nm are 138 and 5, respectively, which were measured with a Hitachi 139 spectrophotometer. ZnT^{2+} and ZnY^{2-} do not absorb light at 550 nm.

A mannitol—boric acid—sodium borate or sodium borate—sodium hydroxide buffer system was used to control the pH of the solutions. All pH values were measured with a Toa-Electronics Model HM-15A digital pH-meter. The temperature was controlled at 25.0 °C and the ionic strength was adjusted to 0.2 with sodium perchlorate. In this study, several calculations were performed with the aid of an electronic computer (TOSBAC 40).

Results

Equilibrium reaction (1) is highly favored to proceed to the right so that the ligand exchange reaction between CuY^{2-} and ZnT^{2+} goes to completion and the reverse reaction can be neglected in the kinetic study.

At high pH(9.5—10.5), the rate equation can be expressed as

$$-\frac{d[ZnT^{2+}]}{dt} = k_1'[ZnT^{2+}] \quad (2)$$

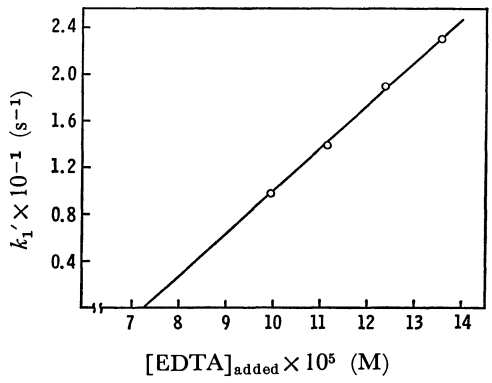

Fig. 1. Dependence of the conditional rate constant k_1' on concentration of added EDTA.
Conditions: $[CuY^{2-}]=2.40\times10^{-2}$ mol/l, $[ZnT^{2+}]=1.60\times10^{-3}$ mol/l, pH=10.12, $I=0.2(NaClO_4)$, 25.0 °C.

where k_1' is the conditional rate constant involving the added EDTA and hydrogen ion concentrations. The rate plots of $\log(A_\infty - A)$ *vs.* t were linear for over 80% of the reaction. The conditional rate constant k'_1 was determined from the slope of the straight line. In Fig. 1, the values of k_1' determined at pH 10.12 are plotted against the added EDTA concentration. It is evident from Fig. 1 that k_1' is linearly related to the added EDTA concentration [Ya] in the region above a threshold value b, and thus, the following relation is obtained:

$$k_1' = k_1([Ya]-b) \tag{3}$$

where k_1 is the slope of the straight line. The values of k_1 were obtained at various pH values.

On the other hand, for low pH (7.0—8.5), reaction (1) was of pseudo-zero-order with respect to ZnT^{2+}. Thus, the rate equation is given by

$$-\frac{d[ZnT^{2+}]}{dt} = k_0' \tag{4}$$

where k_0' is the conditional zero-order rate constant involving the CuY^{2-}, added EDTA and hydrogen ion concentrations. Integration of Eq. (4) yields

$$A = \Delta\varepsilon k_0' t + A_\infty - a\Delta\varepsilon \tag{5}$$

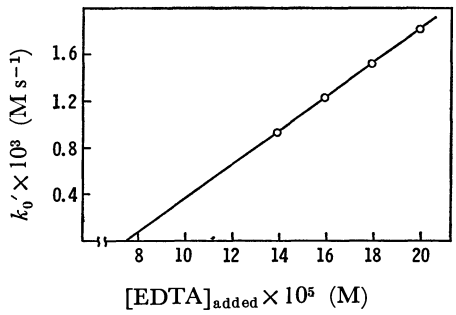

Fig. 2. Dependence of the conditional rate constant k_0' on concentration of added EDTA.
Conditions: $[CuY^{2-}]=2.40\times10^{-2}$ mol/l, $[ZnT^{2+}]=1.60\times10^{-3}$ mol/l, pH=7.55, $I=0.2(NaClO_4)$, 25.0 °C.

where A_∞ and A are the absorbance of the reaction system at $t=\infty$ and t, respectively, $\Delta\varepsilon$ is the difference in molar absorption coefficient between CuT^{2+} and CuY^{2-}, and a is the initial concentration of ZnT^{2+}. The plots of A *vs* t are linear for over 80% of the reaction. The conditional zero-order rate constant k_0' was calculated from the slope of the straight line. In Fig. 2, the values of k_0' determined at pH 7.55 are plotted against the added EDTA concentration. k_0' is linearly related to the added EDTA concentration, thus

$$k_0' = k_0([Ya]-b') \tag{6}$$

The values of the slope k_0 were obtained at various pH values.

Discussion

Reaction Mechanism. The ligand-exchange reaction between CuY^{2-} and ZnT^{2+} can be shown to proceed by the chain reaction mechanism:

$$CuY^{2-} + T' \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} CuT^{2+} + Y' \tag{7}$$

$$ZnT^{2+} + Y' \underset{k_{-3}}{\overset{k_3}{\rightleftharpoons}} ZnY^{2-} + T' \tag{8}$$

where Y′ and T′ represent the sum of the uncomplexed species of EDTA and Trien, respectively. The equilibrium constants of reactions (1), (7) and (8) at an ionic strength $I=0.2$ were calculated from the stability constants of the related complexes and the protonation constants of the related ligands. The stability constants and the protonation constants at an ionic strength $I=0.2$ were estimated from the constants[8] at $I=0.1$ on the basis of the diagram of Ringbom.[9] The equilibrium constants calculated are plotted against pH in Fig. 3.

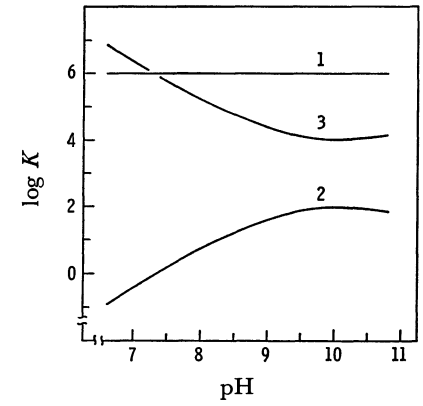

Fig. 3. Dependence of the conditional equilibrium constants of Eqs. (1), (7) and (8) on pH at 25 °C and $I=0.2$.
1: Eq. (1), 2: Eq. (7), 3: Eq. (8).

Steady-State Treatment. The rate expression derived from a steady-state treatment with the assumptions that all of the exchange is carried by reactions (7) and (8), and that the concentration of the free ligand remains constant throughout the exchange is

$$-\frac{d[ZnT^{2+}]}{dt} = \frac{(k_2k_3[CuY^{2-}][ZnT^{2+}]-k_{-2}k_{-3}[ZnY^{2-}][CuT^{2+}])[L]}{k_2[CuY^{2-}]+k_{-2}[CuT^{2+}]+k_3[ZnT^{2+}]+k_{-3}[ZnY^{2-}]} \quad (9)$$

where [L] is the total concentration of free ligands, EDTA and Trien. Because the value of the equilibrium constant of reaction (8) shows $k_3 \gg k_{-3}$, Eq. (9) can be simplified to

$$-\frac{d[ZnT^{2+}]}{dt} = \frac{(k_2k_3[CuY^{2-}][ZnT^{2+}])[L]}{k_2[CuY^{2-}]+k_{-2}[CuT^{2+}]+k_3[ZnT^{2+}]} \quad (10)$$

In the denominator of Eq. (10), term $k_2[CuY^{2-}]$ becomes predominant and the other terms may be neglected at pH 9.5—10.5, which will be shown later. Equation (10) then becomes

$$-\frac{d[ZnT^{2+}]}{dt} = k_3[L][ZnT^{2+}] \quad (11)$$

Since the metal impurity reacts very rapidly with added EDTA, the total concentration of free ligands in the solution is written as

$$[L] = [Ya] - [M] \quad (12)$$

where [Ya] and [M] are the concentrations of the added EDTA and metal impurity, respectively. Thus Eq. (11) becomes

$$-\frac{d[ZnT^{2+}]}{dt} = k_3([Ya]-[M])[ZnT^{2+}] \quad (13)$$

Equation (3) can be rewritten as

$$k_1' = k_1([Ya]-b) = k_1([Ya]-[M]) \quad (14)$$

where b equals [M]. Therefore, Eq. (13) agrees with the rate equation derived experimentally at high pH. Thus k_3 is equal to k_1.

On the other hand, in the denominator of Eq. (10), term $k_3[ZnT^{2+}]$ becomes predominant and the other terms may be neglected for pH 7.0—8.5, which will also be shown later. Equation (10) then becomes

$$-\frac{d[ZnT^{2+}]}{dt} = k_2[L][CuY^{2-}] \quad (15)$$

For a large excess of CuY^{2-}, $k_2[CuY^{2-}]$ can be constant during the reaction so that Eq. (15) becomes

$$-\frac{d[ZnT^{2+}]}{dt} = (\text{const.})[L] = (\text{const.})([Ya]-[M]) \quad (16)$$

Therefore, Eq. (16) agrees with the rate equation derived experimentally at low pH, because Eq. (6) can be rewritten as

$$k_0' = k_0([Ya]-[M]) \quad (17)$$

Thus k_2 can be calculated from the value of k_0. The values of k_2 and k_3 obtained are plotted against pH in Fig. 4. The approximations used in this discussion can be shown to be valid from Figs. 3 and 4, and the experimental conditions.

Several possible reactions excepting the chain-propagating steps may be eliminated from the exchange reaction mechanism by adding either EDTA or Trien to the reaction system, because the chain reaction pathway becomes predominant with the addition of the ligand.

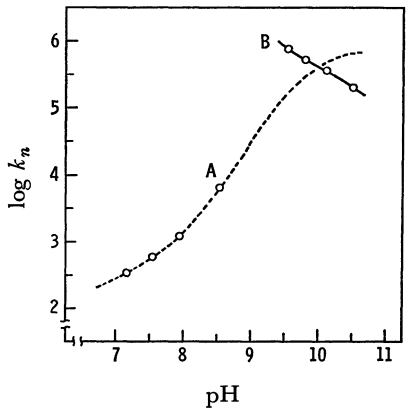

Fig. 4. Dependence of the apparent rate constants k_2 and k_3 on pH at 25.0 °C and $I=0.2$($NaClO_4$).
A: k_2, B: k_3. The dotted line(A) is the theoretical curve calculated with the aid of the individual rate constants.

Resolution of the Apparent Rate Constant k_2. From a steady-state consideration of reactions (7) and (8) with the assumption that the concentration of the free ligand remains constant, the following relation is derived

$$\frac{[Y']}{[T']} = \frac{k_2[CuY^{2-}]+k_{-3}[ZnY^{2-}]}{k_{-2}[CuT^{2+}]+k_3[ZnT^{2+}]} \approx \frac{k_2[CuY^{2-}]}{k_3[ZnT^{2+}]} \quad (18)$$

At low pH, the form k_3 $[ZnT^{2+}] \gg k_2[CuY^{2-}]$ holds, as mentioned above, so that the total free ligand concentration in the solution becomes equal to the Trien concentration.

At low pH (7.0—8.5), the total uncomplexed Trien concentration is expressed as

$$[T'] = [T] + [HT^+] + [H_2T^{2+}] + [H_3T^{3+}] \quad (19)$$

Thus, the following relationship can be derived:

$$\begin{aligned} k_2[L][CuY^{2-}] &= k_2[T'][CuY^{2-}] \\ &= k_T[T][CuY^{2-}] + k_{HT}[HT^+][CuY^{2-}] \\ &\quad + k_{H_2T}[H_2T^{2+}][CuY^{2-}] + k_{H_3T}[H_3T^{3+}][CuY^{2-}] \end{aligned} \quad (20)$$

where k_T, k_{HT}, k_{H_2T} and k_{H_3T} are the resolved rate constants. With the protonation constants of Trien species, Eq. (20) is written as

$$\begin{aligned} k_2(1+K_1[H^+]+K_1K_2[H^+]^2+K_1K_2K_3[H^+]^3) &= k_T + K_1[H^+]k_{HT} + K_1K_2[H^+]^2k_{H_2T} \\ &\quad + K_1K_2K_3[H^+]^3k_{H_3T} \end{aligned} \quad (21)$$

where K_1, K_2 and K_3 are the successive protonation constants of HT^+, H_2T^{2+} and H_3T^{3+}, respectively. The apparent rate constant k_2 was resolved into the individual proton dependent terms, k_T, k_{HT}, k_{H_2T} and k_{H_3T}, satisfying Eq. (21) with the aid of a computer. The rate constants k_T, k_{HT}, k_{H_2T} and k_{H_3T} determined in this investigation are 9.1×10^5, 1.8×10^4, 3.6×10^2 and 4.4×10 $M^{-1}s^{-1}$, respectively.

The resolved rate constants at $I=0.1$, which were estimated from those of this investigation ($I=0.2$) by evaluating the influence of the primary salt effect, agree approximately with the rate constants of the reaction of CuY^{2-} with Trien at $I=0.1$ which were determined by Margerum *et al.*[10] Using the resolved

rate constants, the apparent rate constant k_2 can be calculated. The calculated values are shown in Fig. 4.

Characteristics of the Present System. The coordination chain reactions studied by Margerum *et al.* are slow. In analytical applications, their customary reaction time is about 10 min or longer. However, the reaction of the present system takes place rapidly. The reaction time is about 1 s at low pH and about 0.2 s at high pH.

The ligand substitution reaction of ZnT^{2+} with EDTA cannot be investigated by the usual spectrophotometric method as the spectral data of ZnT^{2+} and ZnY^{2-} are essentially identical. In this paper it was shown that the coordination chain reaction of the present system provides a useful method for the study of the ligand substitution reaction of ZnT^{2+} with EDTA.

Presumptive Structures of Activated Complexes of Polarographic Redox Reactions of Unsaturated Organic Compounds. I.[1] Polarographic Reductions of Aromatic Hydrocarbons, Aromatic Aldehydes, and Quinones

Yo UEDA and Yukio ONO

Faculty of Pharmaceutical Sciences, Kyushu University, Maedashi, Higashi-ku, Fukuoka 812

(Received February 10, 1975)

Activated complexes of the polarographic reductions of unsaturated organic compounds were assumed to be formed by the interaction of the π-molecular orbital of each compound with a hypothetical atomic orbital of the electrode employed. Linear correlations were obtained between the mutual differences in the polarographic half-wave reduction potentials of a series of unsaturated organic compounds and the respective differences in the π-stabilization energies calculated on the basis of the presumed structures of activated complexes. These linear relationships were considered to lend experimental support to the propriety of the presumed structures of the activated complexes of the polarographic reductions of unsaturated organic compounds.

The electron-transfer phenomenon in electrochemical reactions has become rather clearer as a result of several theoretical investigations. However, the structures of the activated complexes in the electrochemical reaction are still ambiguous. For example, Marcus[2] developed a unified theory of homogeneous and electrochemical electron-transfer rates; he also gave a basis for the quantitative correlations among the chemical and electrochemical rate constants. There have been several papers[3] describing satisfactory results obtained by the application of Marcus's theory to each subject. Hush[4] also developed a theory accounting for the activation process in electrochemical reactions.

With regard to the structures of activated complexes in electrochemical reactions, it may be said that no concrete figure of an activated complex has yet been presented. For example, Vlček[5] reported that an initial activated complex ($*D \cdot E^-$) is formed by the contact of a depolarizer, *D, having an excited electronic state with the electrode, E^-, in the polarographic reduction reaction. However, this structure may not be considered to be concrete, because no definite explanation of either the mechanism of the contact of *D with E^- or the mechanism of electronic excitation was given.

By the way, it is known that mutual reactivity differences in the chemical reactions of a homologous series of organic compounds with the same reagent and under the same reaction conditions must be explained in terms of the differences in the potential energy changes of their possible reaction paths calculated theoretically. However, this kind of calculation is almost impossible except for simple reactions of small molecules. Therefore, such differences are usually explained in terms of the differences in the activation energies of the reactions. If a profile of the potential energy surface of an electrochemical reaction is very similar to that of the homogeneous chemical reaction, as in Marcus's theory, the mutual differences in the electrode potentials required for polarographic reactions of organic compounds having analogous chemical structures with the same electrode in the same solvent to proceed may also have to be explained in terms of the differences in their activation energies.

It is known that the stabilization energy of an activated complex of a chemical reaction can be estimated by a simple quantum-chemical method.[6] It has also been known that the mutual reactivity differences of a homologous series of organic compounds in the same kind of chemical reaction can be correlated rather roughly with the differences in their stabilization energies. This roughness may be assumed to be due to the complex reaction mechanisms involved and to the consequent difficulty of making presumptions as to the structures of the activated complexes.

However, in the case of polarographic reactions, many reactions proceed by means of rather simple reaction mechanisms. Moreover, the reagent in a usual chemical reaction is nothing else than the electron(s) on the electrode.[7] Therefore, the presumption of the structures of activated complexes is expected to be rather easy. If this presumption can be made a mutual difference in the energies necessary for the reversible electrochemical oxidation-reduction reactions of two analogous compounds with the same electrode under the same condition to proceed, it may be expected to be correlated linearly with the difference in the stabilization energies of their activated complexes.

In this paper, the structures of activated complexes of the diffusion-controlled reversible polarographic reductions, employing a dropping mercury electrode, of unsaturated organic compounds are presumed. Moreover, an expected linear correlation between the mutual differences in the half-wave reduction potentials of a series of compounds and the differences in their stabilization energies calculated on the basis of the presumed structures of activated complexes is derived. Lastly, the proprieties of the presumed structures of activated complexes are examined on the basis of the experimental results.

Results and Discussion

Presumption of the Structure of Activated Complexes. The comparisons of the half-wave potentials ($E_{1/2}$) of a series of diffusion-controlled reversible polarographic one-electron reactions, employing a dropping mercury electrode, of a homologous series of unsaturated organic

compounds (R) in the same solvent are considered. If these reactions are assumed to proceed *via* the respective activated complexes (Eq. (1)), the standard free-energy change (ΔG°) of the reaction of a compound, R, is equal to the difference in the free energies of the activation of its forward and reverse reactions ($\vec{\Delta G}^{\neq} - \overleftarrow{\Delta G}^{\neq}$):

$$R + e^-(Hg) \rightleftharpoons [\text{activated complex}] \rightleftharpoons R^- + (Hg) \quad (1)$$

Moreover, the difference in the standard free-energy changes of two analogous compounds, R_A and R_B, is expressed by Eq. (2). The polarographic half-wave reduction potential of a reversible

$$\begin{aligned}\Delta G^\circ_A - \Delta G^\circ_B &= (\vec{\Delta G}^{\neq}_A - \overleftarrow{\Delta G}^{\neq}_A) - (\vec{\Delta G}^{\neq}_B - \overleftarrow{\Delta G}^{\neq}_B) \\ &= (\vec{\Delta G}^{\neq}_A - \vec{\Delta G}^{\neq}_B) - (\overleftarrow{\Delta G}^{\neq}_A - \overleftarrow{\Delta G}^{\neq}_B) \quad (2)\end{aligned}$$

reaction system such as Eq. (1) is known to be a linear function of the free-energy change (Eq. (3)).[8] Moreover, according to the law of linear free-energy relation, ($\Delta G^\circ_A - \Delta G^\circ_B$) can be considered to be proportional to ($\vec{\Delta G}^{\neq}_A - \vec{\Delta G}^{\neq}_B$) (Eq. (4)). Here, a is the proportional constant determined by the nature of the reaction. Therefore, the difference in the polarographic half-wave potentials of two compounds can be correlated with the difference in their free energies of activation (Eq. (5)).

$$E_{1/2} = -\frac{\Delta G^\circ}{F} + \frac{RT}{F}\ln\left(\frac{D_{R^-}}{D_R}\right)^{1/2}\left(\frac{f_R}{f_{R^-}}\right) \quad (3)$$

D: diffusion coefficient; R: gas const.;
F: Faradays const.; f: activity coefficient; T: K

$$\vec{\Delta G}^{\neq}_A - \vec{\Delta G}^{\neq}_B = a(\Delta G^\circ_A - \Delta G^\circ_B) \quad (4)$$

$$\begin{aligned}E^A_{1/2} - E^B_{1/2} &= -\frac{(\Delta G^\circ_A - \Delta G^\circ_B)}{F} \\ &\quad + \frac{RT}{F}\ln\left(\frac{D_{R_A}\text{-}D_{R_B}}{D_{R_A}D_{R_B^-}}\right)^{1/2}\left(\frac{f_{R_A}f_{R_B^-}}{f_{R_A^-}f_{R_B}}\right) \\ &= -\frac{(\vec{\Delta G}^{\neq}_A - \vec{\Delta G}^{\neq}_B)}{aF} \\ &\quad + \frac{RT}{F}\ln\left(\frac{D_{R_A}\text{-}D_{R_B}}{D_{R_A}D_{R_B^-}}\right)^{1/2}\left(\frac{f_{R_A}f_{R_B^-}}{f_{R_A^-}f_{R_B}}\right) \quad (5)\end{aligned}$$

$$E^A_{1/2} - E^B_{1/2} \simeq -\frac{(\vec{\Delta G}^{\neq}_A - \vec{\Delta G}^{\neq}_B)}{aF} \quad (6)$$

Because R_A and R_B were supposed to have similar chemical structures, the contribution of the second term on the right-hand side of Eq. (5) to the left-hand side seems insignificant. Therefore, Eq. (5) is simplified to Eq. (6).

In order to estimate the free energy of activation of R, a presumption as to the structure of its activated complex is necessary. In the forward reaction of Eq. (1), the electron (e^-) on a dropping mercury electrode [(Hg)] may be considered to be supplied from the Fermi level of liquid mercury, whose energy is known to be -6.84 eV.[9] Since only one electron participates in the reaction, while innumerable electrons on (Hg) do not, it might be thought that the electron is the true reagent of the forward reaction, while (Hg) is its carrier. Therefore, the electron is assumed to occupy a hypothetical atomic orbital of liquid mercury [$\chi_{(Hg)}$][10] with the orbital energy of -6.84 eV. The magnitude of the energy of this hypothetical atomic orbital is not much different from that of the Coulomb integral (α) of a carbon atom forming part of a π-electronic system of organic compounds, because the Coulomb integral is generally considered to be about -7 to -9 eV. Therefore, the hypothetical atomic orbital of the electrode is considered to be able to interact with the π-molecular orbital of a compound, R. Therefore, when the compound is going to collide with the electrode, the hypothetical atomic orbital of the electrode and the π-molecular orbital of R may begin to overlap each other; at the moment of collision, this overlap may become complete. In this state, of course, it cannot be considered that the electron and R are bound rigidly, but it may be considered that the π-electronic cloud of R spreads not only over the molecule, but also over the hypothetical atom of the electrode. In other words, the electron localized initially on the hypothetical atomic orbital of the electrode is considered to be delocalized on the π-electronic system newly formed. Therefore, the transference of an electron from the electrode to R may occur. This state may be presumed to be the activated complex, and its structure may be expressed by $[R\cdots e^-\cdots(Hg)]^{\neq}$. Just after the collision, the electron may be localized on the original π-electronic system of R, and an activated complex of the reaction may begin to decompose. This decomposition may produce the products (an anion radical and the electrode with a vacant hypothetical atomic orbital).

In the reverse reaction of Eq. (1), a vacant hypothetical atomic orbital of the electrode of the same kind as that of the forward reaction may be assumed. Much as in the case of the forward reaction, the formation of an activated complex, $[R\cdots e^-\cdots(Hg)]^{\neq}$, may be considered.

Therefore, the process of the reversible one-electron polarographic reductions of a series of unsaturated organic compounds may be assumed to be as follows (Eq. (7)):

$$R + e^-(Hg) \rightleftharpoons [R\cdots e^-\cdots(Hg)]^{\neq} \rightleftharpoons R^- + (Hg) \quad (7)$$

The presumed structure of the activated complexes of one-electron reactions may be applicable, with a slight modification, to the structure of the activated complexes of two-electron reactions. That is, in a reversible reaction of an unsaturated organic compound, R(Eq. (8)), a hypothetical atomic orbital of the electrode occupied by two electrons may be assumed. These two electrons may then be assumed to be transferred to the π-molecular orbital of R. The formation of an activated complex, $[R\cdots 2e^-\cdots(Hg)]^{\neq}$, may also be assumed:

$$R + 2e^-(Hg) \rightleftharpoons [R\cdots 2e^-\cdots(Hg)]^{\neq} \rightleftharpoons R^{2-} + (Hg) \quad (8)$$

π-Stabilization Energy of the Presumed Activated Complex. According to the transition-state theory, the $\vec{\Delta G}^{\neq}$ of a forward reaction of Eq. (7) can be correlated with its equilibrium constant $K^{\neq}$ (Eq. (9)), and $K^{\neq}$ can be expressed by Eq. (10). Here, Q is the parti-

tion function, and $\vec{E}_0$ is the activation energy, defined by the difference between the zero-point energy of the reactant and that of the activated complex.

$$\vec{\Delta G}^{\neq} = -RT\ln K^{\neq} \tag{9}$$

$$K^{\neq} = \frac{Q_{[R\cdots e^-\cdots(Hg)]^{\neq}}}{Q_R Q_{e^-(Hg)}} \exp\left(-\frac{\vec{E}_0}{RT}\right) \tag{10}$$

$$\vec{\Delta G}^{\neq} = -RT\ln\left(\frac{Q_{[R\cdots e^-\cdots(Hg)]^{\neq}}}{Q_R Q_{e^-(Hg)}}\right) + \vec{E}_0 \tag{11}$$

$$\vec{\Delta G}^{\neq}_A - \vec{\Delta G}^{\neq}_B = -RT\ln\left(\frac{Q_{R_B}}{Q_{R_A}}\right) + (\vec{E}^A_0 - \vec{E}^B_0) \tag{12}$$

$$\vec{\Delta G}^{\neq}_A - \vec{\Delta G}^{\neq}_B \simeq (\vec{E}^A_0 - \vec{E}^B_0) \tag{13}$$

$$E^A_{1/2} - E^B_{1/2} \simeq -\frac{(\vec{E}^A_0 - \vec{E}^B_0)}{aF} \tag{14}$$

Because the partition functions of two activated complexes, $[R_A\cdots e^-\cdots(Hg)]^{\neq}$ and $[R_B\cdots e^-\cdots(Hg)]^{\neq}$, formed from two compounds, R_A and R_B, with analogous chemical structures and the same electrode can be assumed to be very similar, the difference in their free energies of activation, $\vec{\Delta G}^{\neq}_A - \vec{\Delta G}^{\neq}_B$, can be correlated with the difference in their activation energies, $\vec{E}^A_0 - \vec{E}^B_0$ (Eq. (12)). Moreover, Q_{R_A} and Q_{R_B} may also be regarded as very similar. Equations (13) and (14) can thus be obtained.

The activation energy of a molecule is considered to be contributed by five energy changes[11]: the vibrational energy change ($\Delta\varepsilon^{\neq}_v$), the energy change of localized bonds ($\Delta\varepsilon^{\neq}_l$), the energy change of delocalized system ($\Delta\varepsilon^{\neq}_d$), the energy change of interaction between nonbonded atoms ($\Delta\varepsilon^{\neq}_{n,t}$) and the energy change of solvation ($\Delta\varepsilon^{\neq}_s(T)$) (Eq. (15)). When the differences $(\vec{E}^A_0 - \vec{E}^B_0)$ between two unsaturated organic

$$\vec{E}_0 = \Delta\varepsilon^{\neq}_v + \Delta\varepsilon^{\neq}_l + \Delta\varepsilon^{\neq}_d + \Delta\varepsilon^{\neq}_{n,t} + \Delta\varepsilon^{\neq}_s(T) \tag{15}$$

compounds with analogous chemical structures in the same solvent is considered, the following approximations may be considered to be reasonable. The vibrational energies of their activated complexes may not be much different each other. Not only the magnitude of $\Delta\varepsilon^{\neq}_l$ itself, but also the difference in $\Delta\varepsilon^{\neq}_l$ between two compounds may be insignificant, because the formation of an activated complex is presumed to be based on the interaction of the π-electronic system of a compound and a hypothetical atomic orbital of the electrode. For the same reason, both $\Delta\varepsilon^{\neq}_{n,t}$, and its difference between two compounds may also be insignificant. Because the overlap of two orbitals is considered to occur very rapidly, the value of $\Delta\varepsilon^{\neq}_s(T)$ may be rather small and its difference between two compounds may be insignificant. If these approximations are made, the difference $(\vec{E}^A_0 - \vec{E}^B_0)$ may become a function of the difference in $(\Delta\varepsilon^{\neq}_d)_A$ and $(\Delta\varepsilon^{\neq}_d)_B$ (Eq. (16)).

In the activated complex, the original π-electronic system of R is considered to be perturbed slightly by the interaction with a hypothetical atomic orbital of the electrode. The energy change of the π-electronic system of R due to this kind of perturbation is called the π-stabilization energy (ΔE_{rs}). Here, r and s denote the atoms of the two reactants where the interaction occurs. In the present case, one of the reactants is the electron on the electrode, so it may be expressed as $\Delta E_{r(Hg)}$. It is known that the larger the ΔE_{rs}, the smaller the π-activation energy. Therefore, it may be said that the larger the $\Delta E_{r(Hg)}$, the smaller the $(\Delta\varepsilon^{\neq}_d)$ (Eq. (17)).

$$(\vec{E}^A_0 - \vec{E}^B_0) \simeq (\Delta\varepsilon^{\neq}_d)_A - (\Delta\varepsilon^{\neq}_d)_B \tag{16}$$

$$\Delta\varepsilon^{\neq}_d = b - c\cdot\Delta E_{r(Hg)} \tag{17}$$

Equation (17) is known to be useful not only in predicting the specific position, r, of a molecule where a reaction is expected to occur preferentially, but also in predicting the difference in the reactivities of the molecules of a series of compounds with analogous chemical structures in the same kind of chemical reaction. Therefore, both b and c can be assumed to keep nearly constant throughout a series of reactions employing analogous compounds. Therefore, it might be possible to expect that the difference in the activation energies of the reversible polarographic reactions of R_A and R_B can be correlated linearly with the difference in their maximum π-stabilization energies (Eq. (18)):

$$\vec{E}^A_0 - \vec{E}^B_0 \simeq (\Delta\varepsilon^{\neq}_d)^A_{min} - (\varepsilon^{\neq}_d)^B_{min} \simeq -c[(\Delta E_{r(Hg)})^A_{max} - (\Delta E_{r(Hg)})^B_{max}] \tag{18}$$

From the viewpoint of chemical reactions, a polarographic reduction may be considered to fall in the category of addition reactions. Also, it is known that the π-stabilization energy of the addition reaction of a neutral molecule (R_m) with a radical molecule (R_n) or with an ionic molecule (R_t) at their rth and sth atom can be calculated by means of Eq. (19) or Eq. (20) respectively:

$$\Delta E_{rs} = 2\left(\sum_m^{occ}\sum_n^{unocc} - \sum_n^{occ\text{-}N}\sum_m^{unocc}\right)\frac{(C^m_r)^2(d^n_s)^2}{\lambda_n - \eta_m}(\gamma^2\beta) + \left(\sum_m^{occ} - \sum_m^{unocc}\right)\frac{(C^m_r)^2(d^N_s)^2}{\lambda_N - \eta_m}(\gamma^2\beta) \tag{19}$$

$$\Delta E_{rs} = 2\left(\sum_m^{occ}\sum_i^{unocc} - \sum_m^{unocc}\sum_i^{occ}\right)\frac{(C^m_r)^2(d^t_s)^2}{\lambda_t - \eta_m}(\gamma^2\beta) \tag{20}$$

Here, C^m_r, d^n_s, and d^t_s denote the coefficient of the rth atomic orbital of the mth molecular orbital of R_m and the coefficient of the sth atomic orbital of nth (or ith) molecular orbital of R_n (or R_t) as calculated by the HMO method, respectively. γ_n, γ_t, and η_m denote the coefficients of the resonance-energy parts of the energy levels of R_n, R_t, and R_m respectively. N denotes the half-occupied orbital of R_n. $\gamma\beta$ denotes the resonance integral of the π-electronic system newly formed between R_m and R_n (or R_t).

In the case of the calculation of the $\Delta E_{r(Hg)}$ of a one-electron reduction, R_n has only one half-occupied orbital and d^N_s is unity. Moreover, λ_n has already been assumed to be approximately equal to 0. Equa-

tion (19) is, therefore, simplified to Eq. (21),* and, in the case of two-electron reductions, Eq. (22)* is derived:

$$\Delta E_{rs} = \left(\sum_{m}^{occ} - \sum_{m}^{unocc}\right) \frac{(C_r^m)^2}{-\eta_m} (\gamma^2\beta) \tag{21}$$

$$\Delta E_{rs} = \sum_{m}^{unocc} \frac{(C_r^m)^2}{\eta_m} (\gamma^2\beta) \tag{22}$$

Now, the difference in the half-wave reduction potentials of two analogous compounds, R_A and R_B, can be correlated with the difference in their π-stabilization energies (Eq. (23)):

$$F(E_{1/2}^A - E_{1/2}^B) \simeq \frac{c}{a}[(\Delta E_{r(Hg)})_{max}^A - (\Delta E_{r(Hg)})_{max}^B] \tag{23}$$

If the presumption of the structures of activated complexes is proper, the linear relationship expressed by Eq. (23) can be expected to hold. Therefore, the validity of this equation was examined by using the values of both the diffusion-controlled reversible polarographic half-wave reduction potentials and the calculated π-stabilization energies of several types of organic compounds.

Examination of the Validity of Eq. (23). Maccoll[8] indicated that the polarographic half-wave potentials of the reversible one-electron reductions of eight unsaturated hydrocarbons can be linearly correlated with the magnitudes of the energies of the lowest vacant π-molecular orbitals (E_{LVMO}^{π}) of these compounds, as calculated by the HMO method. This indication has also been recognized to hold in many hydrocarbons by several groups of researchers, such as Hoijtink *et al.*[12] and Pullman *et al.*[13] Since this kind of quantum chemical approach to the interpretation of the $E_{1/2}$'s of organic compounds has been widely accepted as relevant, parallel examinations of the validity of Maccoll's indication and that of Eq. (23) by means of the same experimental results were thought to be significant.

a) Aromatic Hydrocarbons: According to the conclusion of Wawzonek *et al.*,[14] the first reduction waves of these compounds, determined in 75% dioxane–water, correspond to the addition of either one or two electrons to the compounds. Later, Hoijtink *et al.*[15] clarified the reduction mechanism of unsaturated hydrocarbons in a protic solvent (75% and 96% dioxane–water) as follows: (i) At first, an anion radical (R^-) is formed by the reversible addition of one electron to the compound, regardless of the solvent employed, and (ii) the number of electrons corresponding to the first wave is decided according to whether the rate of the proton addition to R^- is lower or higher than the rate of the diffusion of R^- from the electrode surface layer to the bulk of the solution. The latter mechanism means that, if the former rate is lower than the latter one, as it is so in many unsaturated hydrocarbons, the first wave corresponds to the addition of one electron.

The first wave of the polarographic reduction of unsaturated hydrocarbons, such as stilbene, styrene, and 1,1-diphenylethylene, as determined in an aprotic solvent, has also been reported[16] to correspond to the addition of either one or two electrons to the compounds. However, Bergman[17] concluded that the first reduction wave of many aromatic hydrocarbons, as determined in ethylene glycol monomethyl ether, corresponds to the addition of one electron. Bergman's investigation not only included seventy-two aromatic polynuclear hydrocarbons of a variety of chemical structures, but also all of the $E_{1/2}$ of these compounds were determined in the same solvent. Therefore, the $E_{1/2}$ values of the present study were taken from this literature. He classified these compounds into several classes with respect to the similarities in their chemical structures. In this study, at first sixty-nine compounds were classified into four classes (a, b, c, and d) in accordance with Bergman's classification, as is shown below. However, the three compounds which form the class e in Bergman's report were omitted, because one of them, diindeno[1,2,3-*fg*: 1′,2′,3′-*op*]naphthacene, has a nonbonding orbital which makes the calculation of $\Delta E_{r(Hg)}$ impossible. Consequently, the remainder was insufficient for the investigation. Also, it was considered that four compounds (No. 42, 43, 57, and 58) should be classified into a new class, c′, because they are related not only to both perylene and pyrene, but also to *p*-terphenyl.

a) the *cata*-condensed aromatic hydrocarbons (No. 1—31)

b) the *peri*-condensed aromatic hydrocarbons related to perylene (No. 32—41)

c) the *peri*-condensed aromatic hydrocarbons related to pyrene (No. 44—61(except 57 and 58))

c′) the *peri*-condensed aromatic hydrocarbons related to perylene, pyrene, and *p*-terphenyl(No. 42, 43, 57, and 58)

d) the non-alternant hydrocarbons related to fluoranthene (No. 62—69)

Unlike the case of the aromatic carbonyl compounds to be discussed later, each aromatic hydrocarbon can be expected to be reduced simply at the position bearing the maximum π-stabilization energy. Then, the π-stabilization energies at all positions of all compounds were calculated.

The differences in both $E_{1/2}$ and $(\Delta E_{r(Hg)})_{max}$, and the values of both $E_{1/2}$ and E_{LVMO}^{π}, are shown in Tables 1—4. The standard deviations and correlation coefficients are also shown in these tables. The correlation between the differences in the values of $(\Delta E_{r(Hg)})_{max}$ and the differences in the $E_{1/2}$ values of compounds of Group a is shown in Fig. 1. This figure indicates that the linear relationship given by Eq. (23) is satisfactorily fullfilled.

b) Aromatic Aldehydes: Schmidt *et al.*[18] described how, in a strong alkaline solution, the polarographic half-wave reduction potential of aromatic aldehydes is independent of the pH value of the solution employed, and how the diffusion current corresponds to the addition of one electron to the oxygen atom of a molecule (Eq. (24)). They also showed that the $E_{1/2}$ of six aromatic aldehydes determined in a strong alkaline solution are linearly correlated with the E_{LVMO}^{π}'s expressed by the unit of γ. Streitwieser[19] confirmed the

* These equations are also known to be equations giving the superdelocalizabilities of a radical substitution and a nucleophilic substitution reaction respectively.

same linear relationship between the very same value of every one of the $E_{1/2}$ values determined by Schmidt *et al.* and the E^{π}_{LVMO} value expressed by the unit of β.

$$R\text{-}CHO + e^- \rightleftharpoons R\text{-}\dot{C}HO^- \quad (24)$$

In this case, the activated complex $[(R\text{-}C(H)=O\cdots e^-\cdots(Hg))^{\neq}]$ is assumed to be formed by the interaction of a hypothetical atomic orbital occupied by one electron of the electrode with the π-molecular orbital of a molecule at the oxygen atom of the carbonyl group. Then the linear relationship between the differences in $E_{1/2}$ values and the differences in the π-stabilization energies $(\Delta E_{O(Hg)})$ of the same series of six aromatic aldehydes was investigated.

Although neither Schmidt *et al.* nor Streitwieser described anything about the influence of the change in the hetero-atomic parameters of the carbonyl group on the linearity between $E_{1/2}$ and E^{π}_{LVMO}, this influence ought not to be ignored. Also, the $\Delta E_{O(Hg)}$ values should be dependent on the same change. Therefore, the $\Delta E_{O(Hg)}$ values were calculated repeatedly by the HMO method with the employment of three sets of parameters proposed in the literature.[18-20] The results, the differences in the two $E_{1/2}$ values determined by Schmidt *et al.*, and the $\Delta E_{O(Hg)}$ values calculated by three kinds of parameters are listed in Table 5. The $E_{1/2}$ values and three kinds of E^{π}_{LVMO} values are shown in Table 6. The standard deviations and correlation coefficients of each set of parameters are also listed in these tables. These tables indicate that all three sets of hetero-atomic parameters gave the comparable linear relationships expected by Eq. (23).

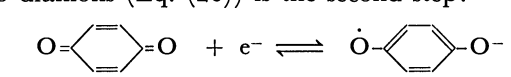
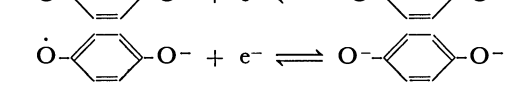
c) Quinones: With regard to the polarographic reduction of quinones in an aprotic solvent, Wawzonek *et al.*[21] made it clear that the first wave corresponds to the formation of semiquinone anion radicals (Eq. (25)), while the succeeding reduction of these anions to dianions (Eq. (26)) is the second step:



(25)



(26)

Then the linear relationship between the differences between the $E_{1/2}$ values taken from the literature[22] and the differences between the $\Delta E_{O(Hg)}$ values corresponding to the structure $\left[\left(O=\bigcirc=O\cdots e^-\cdots(Hg)\right)^{\neq}\right]$ of the four *p*-quinones was investigated. *p*-Quinones with substituents in their molecule and *o*-quinones were omitted from this investigation, because it was considered that the usefulness of the hetero-atomic parameters employed in this work has not yet been examined for the calculation of compounds with an *ortho* di-substituted structure.

In the preceding example it was clarified that all three sets of hetero-atomic parameters gave comparable

Table 7. Values of $E_{1/2}(V)$, $\Delta E_{1/2}(V)$, $\Delta(\Delta E_{o(Hg)})$-$(-\gamma^2\beta)$ and $E^{\pi}_{LVMO}(\alpha-m\beta)$ of quinones

Compound	$-\Delta E_{1/2}$ [a]	$-\Delta(\Delta E_{o(Hg)})$ [b]	$-E_{1/2}$	m
76	0.0	0.0	0.51	0.4827

a) $\Delta E_{1/2}=(E_{1/2})^{1,4\text{-Benzoquinone}}-(E_{1/2})^{\text{Compound}}$.
b) $\Delta(\Delta E_{o(Hg)})=\Delta(\Delta E_{o(Hg)})^{1,4\text{-Benzoquinone}}-(\Delta E_{o(Hg)})^{\text{Compound}}$.
$(\Delta E_{o(Hg)})^{1,4\text{-Benzoquinone}}=0.6524$.

results. Therefore, only one set of the hetero-atomic parameters, one which had previously been proposed by us,[20] was employed.

The differences between the two $E_{1/2}$ values taken from the literature[22] and $\Delta E_{O(Hg)}$, and the values of both $E_{1/2}$ and E^{π}_{LVMO} are shown in Table 7. The standard deviations and correlation coefficients obtained are also listed in the same table.

The standard deviations and correlation coefficients shown in Tables 1—7 indicate that, in all the cases examined, the differences in the $E_{1/2}$'s can be correlated linearly with the differences in the π-stabilization energies as satisfactorily as the linear relationship observed between $E_{1/2}$'s and E^{π}_{LVMO}'s. Since no investigation of the systematic polarographic reduction reaction of unsaturated organic compounds with no substituent other than that of these three groups of compounds has yet been reported in the literature, this examination can be considered to include all of the cases. Therefore, the results of these examinations may be considered to be experimental support to the presumed structures of the activated complexes of the reversible polarographic reductions of unsaturated organic compounds are proper.

Experimental

The molecular orbital calculations were carried out on a FACOM 230-60 computer at the Computation Center of Kyushu University.

(Received March 3, 1975)

The hydrolysis of sodium trimeta- and tetrametaphosphates was run in water, dioxane–water, and formic acid–water solvents with an initial concentration of 0.025 mol/l at various pH values and temperatures. The hydrolysis of both the metaphosphates followed first-order kinetics with respect to the concentration of the phosphate under all the conditions studied and was an acid- and base-catalyzed reaction. In acidic solutions, the rate of hydrolysis of both the metaphosphates in water is faster than that in formic acid–water and slower than that in dioxane–water. Therefore, it is concluded that, in the formic acid–water solvent, the nucleophilicity of the water molecule may decrease on account of the solvation of the water molecule with the acid, while, in the dioxane–water solvent, since the scission of the hydrogen bond between water molecules may occur by the interaction of dioxane and water molecules, the nucleophilicity of the water molecule may increase. The hydrolysis of both metaphosphates in acidic solutions is considered to be an S_N2 reaction, because the overall-reaction rate is highly dependent upon the nucleophilicity of the water molecule. In basic solutions, the rate of hydrolysis of sodium trimeta- and tetrametaphosphates in water is faster than or almost the same as that in dioxane–water. Consequently, the mechanism of the hydrolysis of both the metaphosphates in basic solutions seems to differ from that in acidic solutions. The increase in the rate of hydrolysis of small-ring phosphates in acidic solutions depends upon the activation energy and frequency factor, while that in basic solutions depends significantly upon the frequency factor. This may cause the difference in the solvent effect on the rate of hydrolysis of small-ring phosphates between acidic and basic solutions. The activation energy of the hydrolysis of both ring phosphates was 20—40 kcal/mol in the pH range of 1.0—12.5. The rate of hydrolysis of the metaphosphates in an aqueous sodium hydroxide solution is faster than that in an aqueous tetramethyl ammonium hydroxide solution and this can be attributed to catalysis by a sodium ion. The hydrolysis of sodium tripolyphosphate was also carried out in basic water and dioxane–water solvents. The solvent effect on the rate of hydrolysis of tripolyphosphate in basic solutions was the same as that in acidic solutions.

The solvent effect on organic reactions has been studied by many investigators.[1,2] An S_N1 reaction is generally accelerated in an ionizing solvent, while the solvent effect on an S_N2 reaction is complex. The hydrolysis of condensed phosphates has never been considered from the viewpoint of the exact interaction between a phosphate and a water molecule. In previous works[3,4] by the present authors, the hydrolysis of sodium pyro-, tripoly-, and long-chain polyphosphates was carried out in water, formic acid–water, acetic acid–water, and dioxane–water solvents. Formic acid and acetic acid are so-called protic solvents and dioxane is a dipolar aprotic solvent.[5] It was concluded from the kinetic data that the nucleophilic attack of a water molecule on a phosphorus atom of pyro-, tripoly- (in acidic solution), and long-chain polyphosphates (in basic solution) plays an important role in the hydrolytic degradation of the phosphates. It is well known that the hydrolysis of short-chain phosphates is an acid-catalyzed reaction and that of small-ring phosphates is an acid- and base-catalyzed reaction.[6] The reason for the different hydrolytic reactivity between the short-chain and small-ring phosphates has never been discussed. In the present paper, the hydrolysis of sodium trimeta- and tetrametaphosphates will be accomplished in the same types of solvent mentioned above in order to obtain some information about the hydrolytic mechanism of the small-ring phosphates.

Experimental

Materials and Procedure. All the materials used other than the sodium trimeta-, tetrameta-, and tripolyphosphates were of commercial grade. Sodium trimetaphosphate hexahydrate, sodium tripolyphosphate hexahydrate, and sodium tetrametaphosphate tetrahydrate were prepared by the method described in Refs. 7 and 8. The solvents used in this experiment are listed in Table 1. The pH's of the phosphate solutions with water and dioxane–water solvents were controlled with nitric acid and/or aqueous tetramethyl ammonium hydroxide at reaction temperature by using a Hitachi-Horiba pH meter, F-5. The pH of the phosphate solution with formic acid–water did not change at any time, while those of the solutions with water and dioxane–water changed with the reaction time elapsed. Therefore, aqueous tetramethyl ammonium hydroxide or nitric acid was added to restore them to the proper pH. The pH adjustment was made to within ±0.1 unit of the desired pH value. For the hydrolysis of sodium trimeta- and tetrametaphosphates in basic water and dioxane–water solvents, aqueous sodium hydroxide was also used to obtain the required pH value in order to compare the hydrolysis of the phosphates with that in an aqueous tetramethyl ammonium hydroxide solution. Since a sodium ion is considered to act as a catalyzer for the hydrolysis of polyphosphates,[9-11] an equal volume of aqueous sodium hydroxide was added to each solvent in all conditions studied and the pH adjustment was made by using nitric acid; the concentration of the sodium ion was

TABLE 1. SOLVENTS USED FOR THE HYDROLYSIS OF TRIMETA- AND TETRAMETAPHOSPHATES

Solvent	Symbol
35 vol% aqueous dioxane	S_1
21 vol% aqueous dioxane	S_2
Water	S_3
Formic acid–water	S_4

Table 2. Composition of the solvents used for paper-chromatography[12]

Acidic solvent		Basic solvent	
isopropyl alcohol	70 ml	isopropyl alcohol	20 ml
25% aqueous trichroloacetic acid	20 ml	dimethylfolmamide	20 ml
water	10 ml	methyl ethyl ketone	20 ml
28% aqueous ammonia	0.3 ml	water	39.1 ml
		28% aqueous ammonia	0.9 ml

1.11 mol/l. The initial concentration of the phosphates was 0.025 mol/l. This concentration is suitable for analysis. The 0.025 mol/l concentration of the phosphates in the acidic S_1 solvent having pH values smaller than 2 and that in the basic S_2 solvent produced nearly saturated concentration. After the pH adjustment of a sample solution was completed at the reaction temperature, 10 μl of the sample solution was spotted on Toyo No. 51A filter paper (2×50 cm) for the paper-chromatographic separation of the phosphates. At measured time intervals, further samples were similarly taken for quantitative chromatographic analysis. When the pH of the sample solution was larger than 11, the separation of each phosphate on the chromatagram is not complete. Therefore, after the basic sample solution was acidified with nitric acid, the acidified solution was spotted on the filter paper. Development was made by using an acidic (for the separation of polyphosphates) and basic (for the separation of metaphosphates) solvents[12] at 3 °C. The composition of the solvents is listed in Table 2. Each band of the phosphates on the filter paper was identified by the same treatment of a reference solution of known phosphates. The colorimetric determination of each band on the filter paper was carried out by using the method of a previous paper.[3]

Results and Discussion

Order of Reaction and the pH Dependence of the Reaction Rate. The rate of the hydrolysis of sodium tri-

meta-, tetrameta-, and tripolyphosphates follows first-order kinetics with respect to the concentration of the phosphates under all conditions studied. The pH dependences of the rate constant for trimeta- and tetrametaphosphates are shown in Figs. 1 and 2, respectively. In all solvents, the rates of hydrolysis of both the metaphosphates decreases in acidic solutions and increases in basic solutions with an increase in the pH value. The rate is slowest in a neutral solution. Therefore, the hydrolysis of both the metaphosphates is an acid- and base-catalyzed reaction. The results agree well with those reported in previous papers.[6] To obtain information concerning the mechanism of the hydrolysis of trimeta- and tetrametaphosphates, the activation energy and log A (A: frequency factor) of the hydrolysis of both the phosphates were calculated by means of an Arrhenius plot and are listed in Table 3. In all acidic solutions, the activation energy of the hydrolysis of both the metaphosphates increases and the log A of the hydrolysis of both the metaphosphates decreases with an increase in the pH value. Accordingly, the increase in the rate of hydrolysis of both the metaphosphates in acidic solutions depends on the

activation energy and frequency factor. In basic solutions, as the pH rises, the rate and activation energy of the hydrolysis of both the metaphosphates increase. Therefore, the increase in the rate of hydrolysis of both the metaphosphates in basic solutions is strongly dependent on the frequency factor.

The Stability of Tetrametaphosphate. The rate of hydrolysis of trimetaphosphate is about 4—30 times faster than that of tetrametaphosphate under all the conditions studied. The results agree well with those obtained by other investigators.[6] In the case of the hydrolysis of short-chain polyphosphates, generally, the longer the chain of the phosphate, the faster is the reaction rate. The stability of tetrametaphosphate against hydrolysis is explained by Van Wazer as follows; a tetrametaphosphate ring exhibits a greater number of possible atomic configurations and modes of internal motion than does a trimetaphosphate ion, so that the latter is essentially more rigid and hence more subject to scission.[6] According to Griffith and Rutt,[13] a trimetaphosphate ion has a D_{3h} symmetry (planer form) and a tetrametaphosphate ion has a C_{2h} symmetry (chair form) in an aqueous solution. The former may be more rigid than the latter. By quantum-chemical consideration, the stability of a system generally proceeds with an increase in the number of obtainable states of the system. It can reasonably be concluded from the data in Table 3 that the stability of tetrametaphosphate against hydrolytic scission depends mainly on the activation energy.

The Solvent Effect on the Rate of Hydrolysis. As is shown in Figs. 1 and 2, in acidic solutions, the rate of hydrolysis of trimeta- and tetrametaphosphates in water is slower than that in dioxane–water and faster than that in formic acid–water at the same pH value. In an acidic dioxane–water solvent, as the content of dioxane increases, the rate constants of both the phosphates increase for all pH values. The rates of hydrolysis of both the metaphosphates in the acidic S_1 and S_2 solvents are about 2.1—2.6 and 1.6—2.0 times faster, respectively, than that in the acidic S_3 solvent for all pH values. While the rates of hydrolysis of both the metaphosphates in the S_4 solvent are about 3.3—3.6 and 1.3—1.6 times slower, respectively, than that in the S_3 solvent at respective pH values of 0.9 and 1.5 (the concentrations of formic acid at the pH values of 0.9 and 1.5 are about 30 and 10%, respectively), that is, the difference in the rate constants for the S_3 and S_4 solvents is larger at smaller pH values. This can reasonably be explained in terms of the difference in the nucleophilicity of the water molecule in each solution as follows; since formic acid (protic solvent) combines with a water molecule by means of a hydrogen bond (solvation), the nucleophilicity of the water molecule for the phosphorus atom of the phosphates may decrease, and since the oxygen atom of dioxane forms a hydrogen bond with the hydrogen atom of the water molecule and since, consequently, the hydrogen bond between water molecules may be broken, the nucleophilicity of the water molecule for the phosphorus atom of the phosphates may increase in the S_1 and S_2 solvents. When the nucleophilicity of the water molecule decreases through the hydrogen bond with the acid, the hydrolysis of the phosphate may become energetically disadvantageous and the approach of the water molecule to the phosphorus atom of the phosphates may also be prevented. The results given in Table 3 seem to support this contention, because the activation energy of hydrolysis of both the metaphosphates in the S_3 solvent is larger than those in the S_1 and S_2 solvents and is smaller than that in the S_4 solvent at pH 1 and 2. These results are in good agreement with those for the hydrolysis of pyro- and tripolyphosphates.[3] Since the overall-reaction rate of the hydrolysis of both the metaphosphates is highly dependent upon the nucleophilicity of a water molecule in the acidic solution, the rate-determining step of the hydrolysis of both the metaphosphates in an acidic solution may be the nucleophilic attack of a water molecule on the phosphorus atom of the phosphates and the reaction may be of the S_N2 type.[3,4]

In basic solutions, as is seen in Figs. 1 and 2, the rate of hydrolysis of both the metaphosphates in the S_3 solvent is faster than that in the S_2 solvent at all temperatures and pH values, and the activation energy of hydrolysis of both the metaphosphates in the S_3 solvent is smaller than or the same as that in the S_2 solvent at pH 11 and 12. This tendency is completely contrary to that in an acidic solution. The hydrolysis of sodium tripolyphosphate was also studied at 50 °C in the S_2 and S_3 solvents at pH 11.0, in order to compare the behavior of polyphosphate with that of trimeta- and tetrametaphosphates in basic solutions. The pH ad-

justment of the tripolyphosphate solutions was made by using nitric acid and aqueous tetramethyl ammonium hydroxide. The rate constants of the hydrolysis of tripolyphosphate in the S_2 and S_3 solvents at pH 11.0 are 3.27×10^{-6} and 1.54×10^{-6} min^{-1}, respectively. This tendency of the solvent effect on the rate of the hydrolysis of tripolyphosphate is the same as that in acidic solutions[3] and it can be concluded that the mechanism of the hydrolysis of short chain polyphosphates in basic solutions is analogous to that in acidic solutions. However, according to the above results, the mechanism of the hydrolysis of trimeta- and tetrametaphosphates in basic solutions differs from that in acidic solutions. The difference in the rates of hydrolysis of both the metaphosphates in the basic S_2 and S_3 solvents cannot be reduced to the difference in the nucleophilicities of the water molecule in each solvent. Therefore, it can hardly be considered that the nucleophilic attack of a water molecule on the phosphorus atom of the metaphosphates has the most important influence on the overall-reaction rate of the hydrolysis of trimeta- and tetrametaphosphates in basic solutions. As mentioned above, the acceleration of the rate of hydrolysis of both the metaphosphates in basic solutions depends very much upon the entropy term (as is clearly seen by comparing the results in Tables 3 and 4, the increase in the rate of hydrolysis of both the metaphosphates by a sodium ion is also highly dependent upon the frequency factor), while the increase in the rate of hydrolysis of both the metaphosphates in acidic solutions depends upon both the activation energy and frequency factor. This may be the reason for the difference in the solvent effects on the rate of hydrolysis of both the metaphosphates in acidic and basic solutions.

The Effect of the Sodium Ion. The hydrolysis of sodium trimeta- and tetrametaphosphates was also carried out in the S_2 and S_3 solvents at pH 12.5 and at 30, 40, 50, and 60 °C by adjusting the pH of the solutions with aqueous sodium hydroxide and nitric acid. The kinetic data are listed in Table 4. As is seen by comparing the data in Table 4 and those in Figs. 1 and 2, the rate of hydrolysis of both the metaphosphates in aqueous sodium hydroxide is very much faster than that in aqueous tetramethyl ammonium hydroxide in any solvent, and at all temperatures, and pH values. This can be attributed to catalysis by a sodium ion, because, excluding the concentration of sodium ions, the other conditions of the trimeta- and tetrametaphosphate solutions of aqueous sodium hydroxide are the same as those of aqueous tetramethyl ammonium hydroxide. The activation energies of the hydrolysis of both the metaphosphates in aqueous tetramethyl ammonium hydroxide at pH 12.5 were calculated by using an Arrhenius plot on the basis of the data obtained by extrapolating the lines in Figs. 1 and 2. The activation energy of the hydrolysis of trimetaphosphate was 34 kcal/mol in the S_2 solvent and 33 kcal/mol in the S_3 solvent, and that of tetrametaphosphate was 30 kcal/mol in the S_2 solvent and 27 kcal/mol in the S_3 solvent. The rate of hydrolysis of both the metaphosphates in all aqueous sodium hydroxide solutions is nevertheless very much faster than that in any aqueous tetramethyl ammonium hydroxide solution, the activation energy of the hydrolysis in the faster solutions being larger than in the latter solutions. Therefore, the increase in the rate of the hydrolysis of both trimeta- and tetrametaphosphates in basic solutions by a sodium ion depends entirely upon the frequency factor. As Table 4 shows, the rate of hydrolysis of trimetaphosphate in the S_3 solvent is about 1.5—1.7 times faster than that in the S_2 solvent, and the rate of hydrolysis of tetrametaphosphate in the S_3 solvent is the same as that in the S_2 solvent. The solvent effect on the rate of hydrolysis of both the metaphosphates in alkaline solutions differs from that in acidic solutions. Therefore, the nucleophilic attack of a water molecule on the phosphorus atom of the metaphosphates has little influence on the overall-reaction rate of the hydrolysis of both the phosphates in alkaline solutions. As stated above, the increase in the rate of hydrolysis of both the metaphosphates in alkaline solutions depends significantly upon the entropy term, and this may cause the solvent effect on the rate of hydrolysis of both the small-ring metaphosphates in alkaline solutions.

The Amperometric Titration of Metal(II) Ions with *trans*-1,2-Cyclohexanediamine-*N*,*N*,*N*′,*N*′-tetraacetate (CyDTA)

Mutsuo KODAMA

Department of Chemistry, College of General Education, Hirosaki University, Bunkyo, Hirosaki 036

(Received March 22, 1975)

The use of CyDTA in the amperometric determination of metal-ion mixtures was studied systematically. Because of the sluggishness of the nickel(II)-EDMA~CyDTA substitution reaction, the nickel(II) ion in the EDMA solution could be masked completely in respect to the CyDTA. Therefore, even in the presence of an excess of nickel(II)ions, the copper(II), lead(II), cobalt(II), cadmium(II), and zinc(II) ions in the EDMA solution at about pH=6.50 could be determined accurately with CyDTA. In the amperometric titration of binary mixture of copper(II) and zinc(II), lead(II), cadmium(II), or cobalt(II) ions in the EDMA solution, titration curves with two sharp breaks could be obtained by following the change in the diffusion current due to the reduction of the copper(II)-EDMA complex. The first and second breaks correspond, respectively, to the equivalence point of zinc(II), lead(II), cadmium(II), or cobalt(II) and to that of copper(II).

Chelatometric titrations play an increasingly important role in the analysis of metal-ion mixtures. To widen the scope of these applications, a great number of methods of selective titrations have been proposed. However, the selectivity in the chelatometric titration of a mixture of metal ions has very often been discussed only from the thermodynamic point of view,[1] and the reaction rate effect on the titration has been disregarded. Therefore, it seems worthwhile to discuss this phenomenon from both thermodynamic and kinetic points of view in predicting the optimum conditions necessary for selective titrations. In this paper, the amperometric titration of metal-ion mixtures in an EDMA solution will be studied by using CyDTA as a titrant and will be discussed from both thermodynamic and kinetic points of view.

Experimental

Reagents. The CyDTA and diethylenetriaminepentaacetate (DTPA) used in this study were recrystallized from their aqueous solutions as their acids. The preparation and purification of the acid form of ethylenediaminemonoacetate (EDMA) were described in a previous paper.[2] All the other chemicals used were of an analytical-reagent grade and were used without further purification.

Apparatus and Experimental Procedures. All the DC current-voltage curves were measured with a Yanagimoto pen-recording polarograph P-8 or with a manual polarograph similar to Kolthof and Lingane's. The characteristic features of the dropping mercury electrode used were described previously.[3] All the other apparatus and the experimental procedures were the same as those in that paper. In this study, no buffer reagent was used, because the sample solutions contained a large excess of uncomplexed EDMA and had a sufficient buffer capacity in its pH ranges ($5.80<$ pH <7.70 and $8.50<$pH<10.50).

Results and Discussion

Let us consider the amperometric titration of the complexed metal ion, M, existing in the forms of MX and MX_2, with the chelon Z. If the reaction is rapid enough so that the equilibrium with respect to the formation reaction of MZ is practically maintained at every stage of the titration, the successful determination of M with Z is possible only when the conditional formation constant of MZ, K'_{MZ}, defined as $K'_{MZ}=[MZ]/([MX]+[MX_2])\cdot[Z]_f=K_{MZ}/(\alpha_H)_Z\cdot(K'_1\cdot[X]_f+K'_1\cdot K'_2\cdot[X]_f^2)$, is larger than $1\times10^4/C$, where C means the total concentration of the metal ion; $[X]_f$, the concentration of the uncomplexed X; K'_i, the i-th conditional successive formation constant of the M–X complex, and $(\alpha_H)_Z$, the (α_H) value of Z $(=1+[H^+]/K_n+\cdots+[H^+]^n/K_n\cdots K_1)$. Here, the charges are omitted for the sake of simplicity. Table 1 lists the K'_{MZ} values calculated for the reaction of CyDTA with metal ions in a 20 mM EDMA solution using the related equilibrium constants previously reported.[4,5] The K'_{MZ} values given in Table 1 show that if the reactions of CyDTA with metal ions in the EDMA solution are sufficiently rapid, 1.0 mM copper(II), nickel(II), cobalt(II), zinc(II), lead(II), and cadmium(II) ions in the 20 mM EDMA solution of pH=6.00 can be titrated successfully with CyDTA. In all cases other than the cobalt(II) system, the equivalence point was determined by following the change in the diffusion current of the metal(II)–EDMA complex, because the negative shift in the reduction potential at DME due to the complexation with CyDTA is sufficient. In the case of the cobalt(II) system, the course of the titration was followed by measuring the change in the oxidation wave-height of the cobalt(II)–EDMA complex at the DME. Typical titration curves obtained for the copper(II) and lead(II) ions are reproduced in Fig. 1. All the metal ions other than nickel(II) ion could be titrated accurately with CyDTA. In the case of the nickel(II) system, no end point could

be obtained. This can be ascribed to the slow reaction of CyDTA with the nickel(II)-EDMA complex in the EDMA solution. Some typical results are given in Table 2.

In the titration of a binary metal-ion mixture solution of M and M′ containing an excess of X and using Z as a titrant, when the equilibria with respect to the formation reactions of metal-Z complexes are always maintained, the optimum conditions for the selective titration can be easily predicted only from a theoretical consideration of the chemical equilibria involved. In this case, if the K'_{MZ} value for the M system is 1×10^4 times larger than that of the M′ system, M in the solution containing an equal amount of M′ will react preferentially with Z, hence, a titration curve with two sharp breaks, the first and second of which correspond to the equivalence points of M and M′ respectively, can be obtained by following the change in the concentration of M′. On the other hand, in cases where the reactions of Z with the metal complexes of X are rapid, while those of the metal-Z complexes formed during the course of the titration are very slow, the situation is complicated, because M, with a larger K'_{MZ} value, does not always react with Z at a rate larger than M′, which has a smaller K'_{MZ} value; hence, the formation of MZ may proceed not only through the direct reaction of the M-X complex with Z, but also through the exchange reaction of M′Z with the M-X complex. Therefore, if M′Z, with a smaller K'_{MZ} value, is substitution-inert, M can be titrated preferentially with Z only when the reaction of Z with M in the solution containing X proceeds much faster than that with M′. However, when the reaction of Z with M in the solution of X is much slower than that with M′, M′ will react first and can be titrated first with Z, irrespective of its smaller K'_{MZ} value. Thus, in the amperometric titration of the above binary mixture, when the course of titration is followed by determining the change in the limiting current of M′, the shape of the titration curve will depend on the relative rate constants of the reactions of Z with M and M′. The amperometric titration curves for such system can be calculated by using the following relation (1) for various reaction rates, assuming that the reaction of M′Z is completely substitution-inert:

$$r_{M'}=\frac{k_{M'}\cdot[M']_f}{k_{M'}\cdot[M']_f+k_M\cdot[M]_f}\times f_t \qquad (1)$$

where f_t is the total fraction titrated ($=C_Z/(C_M+C_{M'})$); $r_{M'}$, the fraction of M′ reacted with Z; k_M and $k_{M'}$, the relative apparent rate constants, and $[M]_f$ and $[M']_f$, the metal-ion concentration at a given f_t value. The titration curves calculated for the equimolar mixture of M and M′ are reproduced in Fig. 2. The results shown in Fig. 2 clearly indicate that, if the rate constant ratio, $k_M/k_{M'}$, is smaller than 0.02, the

titration curve shows only one break, corresponding to the equivalence point of M′, whereas if the $k_M/k_{M'}$ value is larger than 50, two break points occur, the former corresponding to the equivalence point of M, and the latter, to that of M′. Furthermore, if the $k_M/k_{M'}$ ratio is nearly identical to unity, the titration with Z will give only one break point, corresponding to the sum of M and M′.

The K'_{Mz} values in Table 1 show that all the EDMA complexes studied in this paper other than the copper(II) complex can replace the CyDTA anion thermodynamically from the copper(II)–CyDTA complex in the EDMA solution of pH=6.00 to 6.50. The kinetics of the reaction of the copper(II)–CyDTA complex with the EDMA complexes of zinc(II), lead(II), cadmium(II), cobalt(II), and nickel(II) ions in the EDMA solution was studied by observing the increase in the reduction wave-height of the copper(II)–EDMA complex in the pH range from 5.60 to 7.00. The reaction proceeds so slowly that the rate could not be determined accurately. However, the following results could be obtained in the preliminary experiments. In all the reactions studied except in the nickel(II) system, the rates 1) were independent of the concentrations of the zinc(II), lead(II), cadmium(II), and cobalt(II) ions and 2) were exactly proportional to the concentration of the copper(II)–CyDTA complex and that of the uncomplexed EDMA. Furthermore, 3) the plot of the product of the initial rate and $(\alpha_H)_{edma}/[H^+]$ against the hydrogen-ion concentration, $[H^+]$, gave a linear relation passing through the point of origin, provided that the other experimental conditions were kept constant (Fig. 3). In the nickel(II) system, no reduction step due to the copper(II)–EDMA complex could be observed. The above findings suggest the following reaction mechanism for the reaction of the copper(II)–CyDTA complex with the EDMA complexes of zinc(II), lead(II), cadmium(II), and cobalt(II) ions in the EDMA solution:

$$Cucydta^{2-} + H_2edma^+ \overset{k_{2H}}{\rightleftharpoons} Cu(edma)^+ + H_2cydta^{2-} \quad \text{rds} \qquad (2a)$$

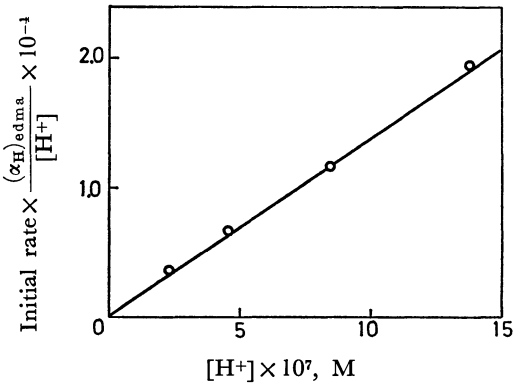

Fig. 3. The effect of the solution pH on the rate of the substitution reaction of copper(II)–CyDTA complex with zinc(II) ion in the EDMA solution.

pH ranged from 5.80 to 6.80

$$M(edma)^+ + H_2cydta^{2-} \rightleftharpoons Mcydta^{2-} + H_2edma^+ \qquad (2b)$$
$$\downarrow\uparrow \quad \text{in a rapid equilibrium}$$
$$M(edma)_2^0$$

corresponding to the following relation:

$$\text{initial rate} = \frac{k_{2H}\cdot[Cucydta^{2-}]\cdot[edma]_f}{(\alpha_H)_{edma}\cdot K_3\cdot K_2}\times[H^+]^2 \qquad (3)$$

where K_i denotes the i-th deprotonation constant of H_3edma^{2+}. The k_{2H} value was determined to be $6.7\times10^{-3}\ M^{-1}\cdot s^{-1}$ from the slope of the above linear relation. The k_{2H} value thus determined suggests that only the 0.5% of the CyDTA anion coordinated to the copper(II) (1 mM) can be replaced by the 1 mM metal(II) ion in the 10 mM EDMA solution within an hour. As is clear from the above kinetic consideration of the titration of a binary mixture, this fact obviously suggests that the conditions for the titration of a binary mixture involving the copper(II) ion with CyDTA using the EDMA solution should be discussed from the kinetic point of view. As has been mentioned by Olson and Margerum,[6] the exchange reaction of two metal complexes generally proceeds by means of a chain-reaction mechanism. Therefore, the above reaction mechanism proposed for the reaction of the copper(II)–CyDTA complex with the metal–EDMA complex in the EDMA solution must be reasonable. Since the reactions of CyDTA with the EDMA complexes of metal(II) ions other than the nickel(II) ion in the EDMA solution proceed very rapidly, one cannot determine their reaction rates by a conventional method. Previously, the present author studied the kinetics of the substitution reaction of the nickel(II)–EDMA complex with the aminopolycarboxylate anion,[7,5b] and proposed the following reaction mechanism:

$$Ni(edma)_2^0 \rightleftharpoons Ni(edma)^+ + edma^- \qquad (4a)\ \text{rapid}$$

$$Ni(edma)^+ + H_nZ^{n-m} \underset{k_{b'}}{\overset{k_{f'}}{\rightleftharpoons}} NiZ^{2-m} + H_iedma^{i-1} + (n-i)H^+ \qquad (4b)$$

He also studied the kinetics of the dissociation reaction of the nickel(II)–EDMA complex.[8] From the magnitude of their reaction rates, it was concluded that the rates of the substition and formation reactions of the nickel(II)–EDMA complex can be understood by assuming the ethylenediamine reaction mechanism[9] and the water-exchange mechanism[10,11] respectively. Furthermore, there are several features which support the conclusion that the reactions of the cadmium(II), lead(II), zinc(II), and cobalt(II) complexes also have a reaction mechanism similar to that of the corresponding reaction of the nickel(II) complex.[11,12] Therefore, it is not unreasonable to assume the ethylenediamine reaction mechanism for the CyDTA reactions of the EDMA complexes of the zinc(II), lead(II), cadmium(II), and cobalt(II) ions and the water-exchange mechanism for the formation reactions of these EDMA complexes. Thus, the relative rates for the CyDTA reactions with the EDMA complexes were calculated by assuming the ethylenediamine-reaction mechanism for the CyDTA reactions and the water-exchange mechanism for the formation reactions

of the EDMA complexes, with the aid of Eq. (5):

$$k_M = \frac{k_f'}{(1+K_2'\cdot[X]_f)} = \frac{k_M^{-H_2O}\cdot K_{os}\cdot K_{M-gly}}{K_1\cdot(1+K_2'\cdot[X]_f)} \quad (5)$$

where all the symbols have their usual meanings.[5,11] The estimated relative k_M values for the EDMA concentration of 20 mM and the solution pH of 6.50 are listed in Table 3. Here, the steric effects of the CyDTA anion on the reaction rates are all assumed to be the same. As is shown in Table 3, the k_M values calculated for the zinc(II), cadmium(II), and lead(II) systems are much larger than that of the copper(II) system. This suggests that the equilibrium for the formation reaction of the zinc(II)-, cadmium(II)-, or lead(II)-CyDTA complex will be ensured even in the presence of the copper(II) ion. Therefore, the titration of a mixture of copper(II) and zinc(II), cadmim(II), or lead(II) can safely be discussed from the thermodynamic point of view.

* Rate = $k_M\cdot$[Metal(II)-EDMA]$_t\cdot$[CyDTA]

Thus, the amperometric titration (the course of which is followed by measuring the change in the concentration of the copper(II)-EDMA complex) of a mixture of copper(II) and zinc(II), cadmium(II), or lead(II) in the EDMA solution with CyDTA can be expected to give two sharp breaks. The first break corresponds to the equivalence point of zinc(II), cadmium(II), or lead(II), and the second, to that of the copper(II) ion. On the other hand, in the light of the above kinetic consideration, the k_M values for the copper(II) and nickel(II) systems evidently show that the titration of a mixture of copper(II) and nickel(II) ions in the EDMA solution will give only one end-point break, corresponding to the equivalence point of the copper(II) even when the concentration of the nickel(II) ion is 20 times higher than that of the copper(II) ion. Furthermore, as is shown by the titration curve (3) in Fig. 2, the titration of cobalt(II) in the presence of the copper(II) ion will probably give a positive error for the cobalt(II) and a negative error for the copper(II). Since the copper(II)-EDMA complex is reduced at much less negative potentials than its CyDTA complex and the EDMA and CyDTA complexes of other metal(II) ions, the above prediction was examined experimentally by following the change in the reduction wave-height of the copper(II)-EDMA complex. Some typical titration curves obtained for the Cu(II)~Zn(II) and Cu(II)~Ni(II) systems are reproduced in Fig. 4. In full accordance with the theoretical prediction, the equimolar mixture of copper(II) and zinc(II), cadmium(II), or lead(II) ions in the EDMA solution could be titrated successfully with CyDTA, and the

nickel(II) ion had no effect on the amperometric determination of copper(II) (Table 4). The amperometric titration of a binary mixture of the nickel(II) ion and the lead(II), cadmium(II), or cobalt(II) ion with CyDTA was also carried out in the EDMA solution. The nickel(II) had no effect on the determination of lead(II), cadmium(II), or cobalt(II) with CyDTA. This can be also be ascribable to the inertness of the CyDTA reaction of the nickel(II)–EDMA complex. As is shown by the data in Table 4, the CyDTA titration of a mixture of copper(II) and cobalt(II) ions, especially when the concentration of copper(II) ions is high, gave a positive error for the cobalt(II) determination. This is in good accordance with the theoretical prediction made from the kinetic point of view. The K'_{MZ} values in Table 1 evidently show that, thermodynamically, the successful determination of cobalt(II) in the presence of copper(II) is possible.

The present author also investigated the amperometric titration of a mixture of copper(II) and nickel(II) ions in the EDMA solution, using DTPA as a titrant. As in the case of the CyDTA system, the K'_{MZ} value for the nickel(II) ion is much larger than that of the copper(II) ion, but the k_M value for the copper(II)–EDMA∼DTPA reaction can be expected to be much larger than that of the nickel(II)–EDMA∼DTPA reaction, suggesting the possibility of the successful performance of the selective titration of copper(II). However, no distinct end break could be obtained. This can probably be ascribed to the fact that the reaction of the copper(II)–DTPA complex with the nickel(II)–EDMA complex in the EDMA solution proceeds to an appreciable extent.

This paper has been concerned only with the amperometric titration of binary metal-ion mixtures in an EDMA solution with CyDTA, because the kinetics of this system could be fully investigated. However, many other systems can probably be submitted to the titration of multicomponent mixtures.

Analysis of the Elution Curve in Eluting Lutetium from Cation-Exchanger with α-Hydroxyisobutyric Acid

Masumitsu KUBOTA

Japan Atomic Energy Research Institute, Tokai, Naka, Ibaraki 319-11

(Received April 28, 1975)

The elution behavior of lutetium from a cation-exchange column with α-hydroxyisobutyric acid solution (pH 3.77) was studied as a function of column distribution ratio of lutetium, flow rate, temperature and amount of lutetium. The elution curve fitted the normal distribution when the flow rate was smaller than 40 cm hr^{-1} for 0.14 M of the eluant, 60 cm h^{-1} for 0.12 M and 120 cm h^{-1} for 0.10 M. However, the normal distribution and constancy of the peak position could not be maintained when the amount of lutetium exceeded 200 μg cm^{-2}. Within the range 15—35 °C, the peak position appeared late and the elution curve became sharper with temperature rise, but the diffusion coefficients remained constant. The value of the height equivalent to the theoretical plate was determined from the position and width of the elution peak which varied as a function of the flow rate. The diffusion coefficients of lutetium ions in the ion-exchange resin and the solution were calculated to be 2.6×10^{-7}—$6.4\times10^{-9}\ \lambda''$ cm^2s^{-1} and $4.2\times10^{-5}\ \lambda''$ $cm^2\,s^{-1}$, respectively, according to Glueckauf's theoretical equation, where λ'' is the column distribution ratio of lutetium ions. The experimental results make it possible to construct an elution curve for any column distribution ratio of lutetium in the range 2—20, temperature and flow rate.

In the cation-exchange separation of trace amounts of rare earths, α-hydroxyisobutyric acid has been used as the most prominent eluant. However, there are few reports on quantitative discussion of the elution behavior in connection with such factors as compositions of the eluant, operating temperatures, amounts of rare earths, *etc.* Only Seyb,[1] Massart and Hoste[2] have reported that yttrium and terbium can be separated successfully only by using eluant solutions containing sufficient amounts of undissociated hydroxy acid, and that the operating temperature and the amount of lutetium absorbed on the resin bed affect the appearance and shape of the elution peak. Although the flow rate of the eluant is an important factor influencing the separation, no one has ever discussed quantitatively the effect of flow rate on elution behavior of rare earths.

According to Glueckauf,[3] the elution curve can be expressed as follows with the assumption that the ion-exchange reaction is reversible:

$$C_i(V) = C_{i\max}\exp\left[-\frac{N(V_i-V)^2}{2V_iV}\right] \qquad (1)$$

where C_i=concentration of species i in the effluent
N=plate number
V=effluent volume—dead volume of the column
V_i=effluent volume at which the concentration of the given ion reaches its maximum—dead volume of the column.

The shape of the elution curve apparently depends on V_i and N obtained by dividing the bed length (L) by the height equivalent to the theoretical plate (HETP). The value of HETP can be calculated by the theoretical formula:[3]

$$\mathrm{HETP} = 1.64\,r_0 + \frac{\lambda_i''0.14r_0^2u}{(\lambda_i''+\beta)^2\overline{D}} + \left(\frac{\lambda_i''}{\lambda_i''+\beta}\right)^2\frac{0.266\,r_0^2u}{D(1+70\,r_0u)} + \frac{D\beta\sqrt{2}}{u} \qquad (2)$$

where r_0=radius of spherical ion-exchange resin particle
λ_i''=column distribution ratio of species i
$$=\frac{\text{amount of species } i \text{ per ml of the resin bed}}{\text{amount of species } i \text{ per ml of the solution}}$$
β=fractional void volume of the resin bed
u=linear flow rate of the eluant
$\overline{D}$=interdiffusion coefficient in the ion-exchange resin
D=diffusion coefficient in the solution

Of the right hand terms of the equation, the first is due to finite particle size, the second to slow particle diffusion, the third to slow film diffusion, and the last to longitudinal diffusion. This equation indicates that the HETP varies with the flow rate of the eluant. If Eq. (2) is applicable to the elution of lutetium with α-hydroxyisobutyric acid, and the diffusion coefficients are known, the equation enables us, in combination with Eq. (1), to construct an elution curve for any flow rate at a given column distribution ratio.

This paper deals with the effect of the flow rate as the main subject in the study of the elution behavior of lutetium from cation-exchange resin bed with α-hydroxyisobutyric acid solution having pH 3.77, the most suitable for the separation of thulium and lutetium at a lutetium distribution coefficient of around 10 $ml\cdot g^{-1}$. The temperature dependence of the diffusion coefficients as well as the column distribution ratio and the variation of elution curve with the amount of lutetium were also studied.

The elution curves obtained under various conditions were analyzed to get HETP, and the diffusion coefficients $\overline{D}$ and D were determined as a function of λ'' so as to satisfy Eq. (2). The results enabled us to construct an elution curve under arbitrary conditions.

Experimental

Reagent and Apparatus. Ion-exchange Resin: Cation-exchange resin (Diaion SK-1, 100~200 mesh) was digested with a mixture of 30% hydrogen peroxide, ethylendiaminetetraacetic acid and ammonium hydroxide, and washed with distilled water. This ion-exchange resin was successively treated in a glass column with a large excess of 3 M hydrochloric acid and 3 M ammonium chloride. After being washed with distilled water, the resin was suspended in distilled water in a large glass column to collect particles

of uniform size. Over 95% of the particles thus obtained had a diameter between 100~150 μm in 0.10 M α-hydroxyisobutyric acid solution, as confirmed by microscopic examination. The resin was stored in distilled water.

Column: A glass column of 0.8 cm in diameter and 25.0 cm in length with a water jacket was used. Water was circulated through the jacket to keep the column temperature at 15.0± 0.1 °C unless otherwise stated.

Eluant: α-Hydroxyisobutyric acid (HB), supplied by Wako Chem. Co., was dissolved in redistilled water to give a 2.5 M solution, and in redistilled water and concentrated ammonia solution to give a 2.5 M solution having pH 6.97. The acid solution (2.5 M) was mixed with a salt solution (2.5 M NH_4B) in a volume ratio of 3 : 2. Finally, eluants were prepared simply by diluting this mixed solution with redistilled water.

Lutetium Tracer: Lutetium-177 was produced by neutron irradiation of "spec pure" lutetium oxide, which had been spectrographically guaranteed by Johnson Matthey Co., in the JRR-2 reactor with a thermal neutron flux of 3×10^{13}n $cm^{-2}s^{-1}$. The irradiated oxide (5 mg Lu_2O_3) was dissolved in concentrated hydrochloric acid, dried under an infrared lamp and finally dissolved in 50 ml of 0.1 M hydrochloric acid.

Procedure. A resin slurry was poured into the column to make a resin bed of 21.9 cm long. Before each experiment, the bed was washed with eluant until the pH of the effiuent became the same as that of the eluant. The lutetium tracer solution was introduced into the column. The column was then washed successively with 2 ml of distilled water, 0.5 ml of 0.5 M ammonium chloride solution and 1.5 ml of distilled water. Lutetium absorbed was eluted with the α-hydroxyisobutyric acid solution. The effluent from the column was passed through a thin polyethylene tube connected to the column and wound into a spiral to record its radioactivity counting rate continuously with an end-window GM counter. The flow rate was controlled by varying the height of the exit of the tube. One drop was taken from every one ml of the effluent onto a glass plate and evaporated to dryness with an infrared lamp. The radioactivity was counted with a GM counter to make an elution curve. The fractional void volume of the resin bed was determined with $^{131}I^-$ by the eqution

$$\beta = \frac{V_{^{131}I^-}}{V_b} \tag{3}$$

where V_b=bed volume of the column and $V_{^{131}I^-}$=effluent volume at which the first appearance of $^{131}I^-$ is confirmed in the effluent solution−dead volume of the column. The column distribution ratio of lutetium was determined from the peak position of lutetium activity by the equation

$$\frac{V_i}{V_b} = \lambda_i'' + \beta \tag{4}$$

Results and Discussion

Effect of Flow Rate on Elution Curve. Elution curves are shown in Figs. 1, 2 and 3 as a function of the flow rate and concentration of the eluant. At the elution with 0.10 M solution with a flow rate up to 120 cm h^{-1}, elution curves were symmetrical within 5% with respect to the vertical line passing the maximum of the peak. However, as the eluant concentration increases, the maximum flow rate at which a symmetrical elution curve is obtained, becomes small, *i.e.*, up to 60 cm h^{-1} for 0.12 M and 40 cm h^{-1} for

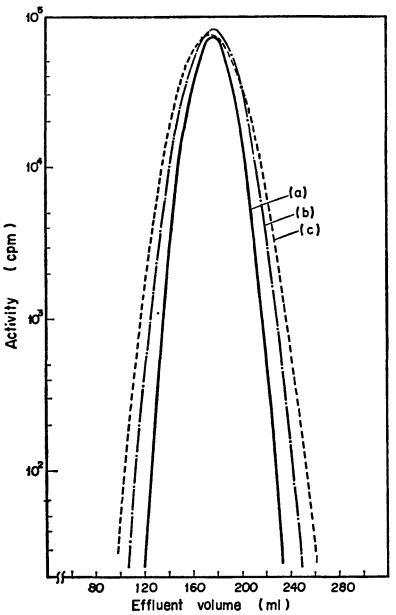

Fig. 1. Effect of the flow rate on the elution curve at the eluant concentration of 0.10 M.
(a): 21.9 cm h^{-1}, (b): 69.0 cm h^{-1}, (c): 116 cm h^{-1}.

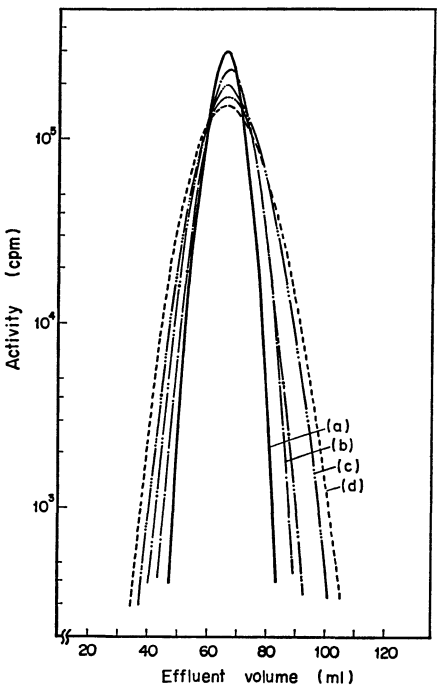

Fig. 2. Effect of the flow rate on the elution curve at the eluant concentration of 0.12 M.

0.14 M (Figs. 2 and 3). Variations of the widths at 1/2, 1/10, $1/10^2$, and $1/10^3$ peak height of the elution curves are shown in Fig. 4 as a function of the flow rate for 0.12 M eluant. Apparently a linear relation holds between the flow rate and the width of the elution peak within the symmetrical flow rate region (0~60 cm h^{-1}). This differs from the elution with citric acid,[4] where the width of the elution peak is

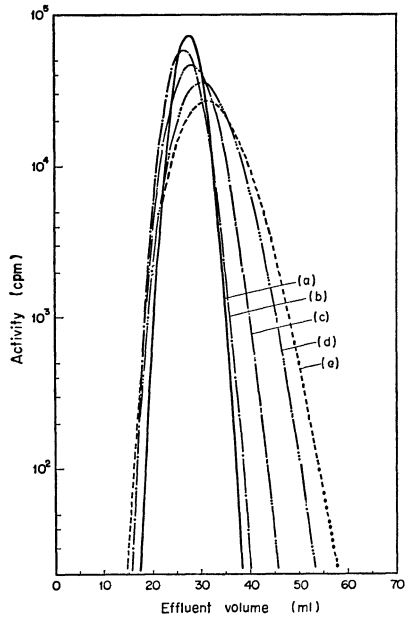

Fig. 3. Effect of the flow rate on the elution curve at the eluant concentration of 0.14 M.
(a): 15.9 cm h^{-1}, (b): 29.8 cm h^{-1}, (c): 47.2 cm h^{-1}, (d): 83.6 cm h^{-1}, (e): 109 cm h^{-1}.

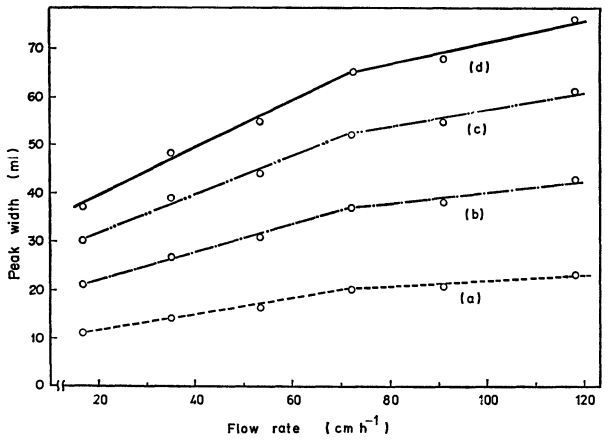

Fig. 4. Relation between the peak widths and the flow rate at the eluant concentration of 0.12 M.
(a): peak width at 1/2 peak height, (b): peak width at 1/10 peak height, (c): peak width at $1/10^2$ peak height, (d): peak width at $1/10^3$ peak height.

nearly independent of the flow rate below 30 cm h^{-1}. Ratios of the widths at 1/2, $1/10^2$ and $1/10^3$ peak height to that at 1/10 peak height do not vary with the flow rate and consist of those of the normal distribution curve.

For the symmetrical flow rate region in which the ion-exchange is considered to proceed reversibly, HETP can be calculated from the elution curve by the simplified equation[3]

$$\mathrm{HETP} = \frac{L}{16}\left(\frac{\Delta V_i}{V_i}\right)^2 \qquad (5)$$

where the bandwidth ΔV_i of species i is defined as the number of solution-volume units in the effluent between the intercepts of the tangents to the front and rear flanks of the peak with the abscissa.[3] The values of HETP calculated from Eq. (5) show linear increase with the flow rate (Fig. 5). The increase in the concentration of the eluant, or the decrease in the distribution coefficient makes the slope steeper. However, the change of the slope can not be explained only by the variation of the column distribution ratio λ_1'' in Eq. (2). The variation of the diffusion coefficients with the eluant concentration should be taken into consideration.

The diffusion coefficients $\overline{D}$ and D, which satisfy the relation of Eq. (2), were calculated by means of Eq. (2) and experimental values of $r_0 = 1.31 \times 10^{-2}$ cm, $\beta = 0.33$, and $\lambda_1'' = 17.3$ for 0.1 M α-hydroxyisobutyric acid solution, 6.26 for 0.12 M and 2.29 for 0.14 M. The results are shown in Fig. 6. The interdiffusion coefficient in the ion-exhcanger $\overline{D}$ increases with the concentration of the eluant, contrary to the view that the diffusion coefficient decreases with increase of salt concentration. The diffusion coefficient in solution D decreased as the concentration of the eluant increases.

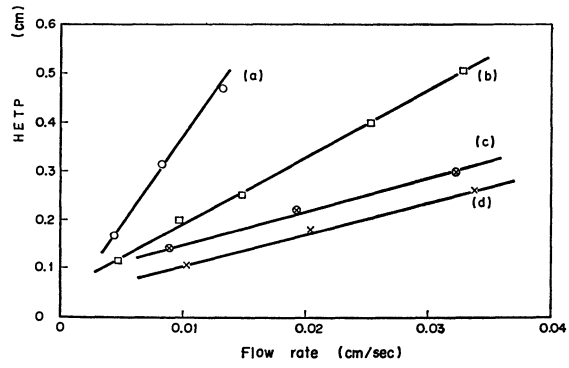

Fig. 5. Relation between HETP and the flow rate under the condition of various eluant concentrations and different column temperatures.

○: $\overline{D}$ at 15 °C, □: D at 15°C, ●: $\overline{D}$ at 33.8 °C, ■: D at 33.8 °C.

Brücher and Szarvas[5] recognized a similar phenomenon, *viz.*, the interdiffusion coefficients of cerium and promethium ions in the ion-exchanger increase with the concentration of ammonium lactate. They explained the phenomenon to be due to the decrease of the charge from 3 to a value around 2 of the rare earth ions diffusing in the resin phase owing to the formation of lactate complex above a certain ammonium lactate concentration. By applying their explanation to the present work, the increase of $\overline{D}$ with the eluant concentration can be connected to the increase in the contribution of LuB^{2+} ions to the ion-exchange reaction, where B is α-hydroxyisobutyrate ion. The assumption of the absorption of lutetium as LuB^{2+} ions is consistent with the view of Holm[6] and Powell.[7] However, the contribution of LuB^{2+} ions is thought to be smaller than that of Lu^{3+} ions, since the interdiffusion coefficient obtained in this work is almost consistent with that of Lu^{3+} ions.[8]

The linear relationships between $\overline{D}$ and D, and λ_1'' in Fig. 7 can be expressed as $\overline{D}=2.6\times10^{-7}-6.4\times10^{-9}\ \lambda_1''$ and $D=4.2\times10^{-5}\ \lambda_1''$, respectively. Consequently, in the case of separating lutetium with the eluant of pH 3.77, HETP at an arbitrary column distribution ratio and a flow rate can be calculated by substituting the above expressions for $\overline{D}$ and D into Eq. (2).

Effect of Temperature on Elution Curve. The elution curves of lutetium (Fig. 7) were obtained when the operating temperature varied within the range 15—35 °C. The peak position or the column distribution ratio varies greatly with temperature. There is a linear relationship between the column distribution ratio and the reciprocal of absolute temperature (Fig. 8). A similar linear relation was observed by Seyb[1] for terbium and yttrium except that his temperature dependence is rather small.

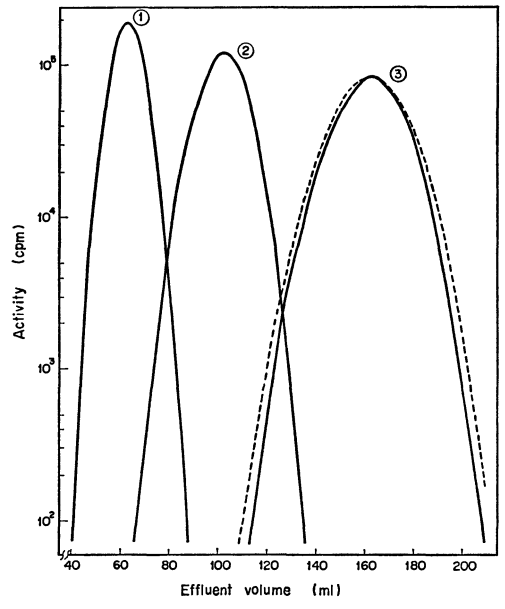

Fig. 7. Variation of the elution curve with column temperature at the eluant concentration of 0.12 M.
①: 15 °C, 33.6 cm h^{-1}, ②: 25 °C, 44.4 cm h^{-1}, ③: 34.8 °C, 50.1 cm h^{-1}.
The dotted line represents the calculated elution curve obtained at the column temperature of 15 °C by changing the eluant concentration so as to fit the peak position to that of case ③.

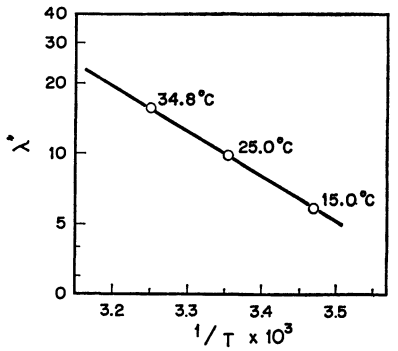

Fig. 8. Relation between the column distribution ratio and the reciprocal of absolute temperature (T).

From a direct comparision of the elution curves in Fig. 7, it is not clear whether a sharper elution peak can be obtained or not with temperature rise, since the peak position of lutetium is not kept constant. The effect of temperature on the shape of the elution peak can be analyzed by taking the variation of the diffusion coefficients due to the rise of temperature into consideration.

The values of HETP and the diffusion coefficients $\overline{D}$ and D at 33.8 °C were calculated in the same way as described above. The results are plotted in Figs. 5 and 6, respectively. The $\overline{D}$ and D values are equal to those obtained for the same concentration of the eluant at the operating temperature 15 °C (Fig. 6). The decrease of HETP with the increase of the column distribution ratio due to the rise of the operating temperature from 15 °C to 33.8 °C (compare b and d

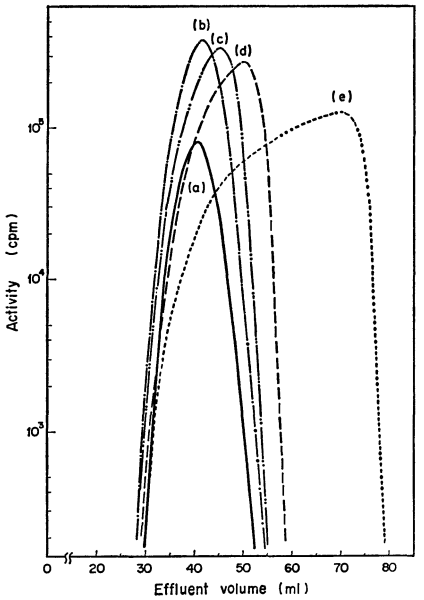

Fig. 9. Variation of the elution curve with the amounts of lutetium.
(a) 16 μg cm^{-2}, (b) 200 μg cm^{-2}, (c) 1.00 mg cm^{-2}, (d) 2.00 mg cm^{-2}, (e) 10.0 mg cm^{-2}.

in Fig. 5) exceeds the decrease of HETP by the increase of the column distribution ratio due to the decrease of the concentration of the eluant from 0.12 M to 0.10 M at 15 °C (compare b and c in Fig. 5), since the decrease of the concentration of the eluant results in the decrease of $\bar{D}$ and the increase of D as well as the increase of the column distribution ratio.

When the concentration of the eluant at 15 °C is selected so as to give the same column distribution ratio as obtained with 0.12 M of the eluant at 34.8 °C, the calculated elution curve of lutetium becomes as shown by the dotted line in Fig. 7. Obviously a sharper elution curve can be obtained by raising the operating temperature from 15 °C to 34.8 °C.

Effect of Lutetium Amount on Elution Curve. The shape of the elution curve of lutetium varies as shown in Fig. 9 as the amount of lutetium increases. The peak positions of the elution curves are the same in a deviation of 5% up to 200 μg cm^{-2} of lutetium. The result differs from that of Massart and Hoste.[2] Over 200 μg cm^{-2}, however, the symmetric elution curve is deformed rapidly with the increase of lutetium amount, simultaneously with the delay of the appearance of the position of the elution curve.

Mixed Complexes with Bulky Ligands. I. Cobalt(II) Complexes Containing *N,N*-Bis[2-(dimethylamino)ethyl]methylamine

Shunji UTSUNO

Department of Chemistry, Faculty of Science, Shizuoka University, Oya, Shizuoka 422

(Received May 12, 1975)

Nine new cobalt(II) complexes were prepared which contained *N,N*-bis[2-(dimethylamino)ethyl]methylamine (dienMe) and some unidentate or bidentate ligands, such as acetonitrile, ammonia, ethylenediamine (en), trimethylenediamine (tn), the acetylacetonate ion (acac), or the oxalate ion. The solid-reflectance spectra revealed that six complexes of the $[Co(XX)dienMe](ClO_4)_n$ formula ($XX=2CH_3CN$, $2NH_3$, en, tn, acac, or $1/2C_2O_4$; $n=1$ or 2) are five-coordinated, whereas three complexes, $[Co(C_2O_4)(H_2O)dienMe]$ and $Co(C_2O_4)_{1/2}(solv)(dienMe)ClO_4$ ($solv=CH_3CN$ or CH_3OH), are six-coordinated. On the basis of their electronic spectra, most of the five-coordinated complexes were supposed to have a trigonal-bipyramidal structure in the solid state and in solution. The IR spectra of three hemioxalato complexes revealed the presence of quadridentate oxalate-ion bridging between two cobalt ions, regardless of their coordination number.

In recent years, five-coordinated complexes have been extensively studied. From this laboratory, it has been reported that the bulky ligand, 6-methyl-2-aminomethylpyridine (mepic), reacts with the bivalent metal salts to form five-coordinated complexes $[MX(mepic)_2]ClO_4$ (M=Cu, Ni, or Co; X=Cl, Br, or I).[1] However, six-coordinated complexes were also obtained when the halo-ligand was replaced with relatively small ligands, such as two isothiocyanate ions, a bidentate nitrate ion, or two molecules of water.

N,N-Bis[2-(dimethylamino)ethyl]methylamine (dienMe) is also a bulky ligand reported to form high-spin complexes with the bivalent transition metals from manganese to zinc, these complexes have the general formula of $[MX_2dienMe]$ (X=Cl, Br, or I).[2] We have attempted to study the preparation and the properties of a mixed complex containing a simple bidentate ligand or unidentate ones in place of the two halo-ligands. This paper will report a study of the mixed complexes with cobalt(II).

Experimental

Reagents. *N,N*-Bis[2-(dimethylamino)ethyl]methylamine was prepared by the method in the literature.[3] Cobalt(II) perchlorate was obtained from perchloric acid and cobalt(III) hydroxide, which had itself been prepared by the reaction of chloropentaamminecobalt(III) chloride and sodium hydroxide. Nitromethane was purified by the fractional distillation of the water azeotrope, followed by dehydration with calcium chloride and by distillation under a nitrogen atmosphere using a 50-cm column packed with glass helices. All the other reagents were reagent-grade chemicals.

Preparation of the Complexes. Because of the unstability of the complexes toward moisture and carbon dioxide, all the complexes were prepared in a dry box in the presence of solid potassium hydroxide and silica gel. The ethylenediamine and the trimethylenediamine complexes were prepared under nitrogen.

$[Co(CH_3CN)_2dienMe](ClO_4)_2$. An acetonitrile solution of cobalt(II) perchlorate hexahydrate (18.3 g : 50 mmol in 100 dm^3 of the solvent) was evaporated with stirring almost to dryness. An additional 100 dm^3 of acetonitrile was then added to the residue, and the mixture was evaporated repeatedly to a volume of about 30 dm^3. After the solution had cooled to room temperature, 8.67 g (50 mmol) of dienMe was added. The crystals thus formed were collected on a sintered glass filter and washed with ethanol. The crude product was recrystallized by the addition of ethanol to the acetonitrile solution. In the open air, the complex turned from purple to green in only a few minutes.

$[Co(XX)dienMe](ClO_4)_2$ ($XX=2NH_3$, en, or tn). Into a filtered solution of 2 mmol of $[Co(CH_3CN)_2dienMe](ClO_4)_2$ in 30 dm^3 of methanol, an equimolar quantity of ammonia or diamine in methanol was stirred. The complex thus precipitated was collected on a filter, washed with ethanol, and dried over phosphorus pentoxide. It was then recrystallized from hot methanol.

$[Co(acac)dienMe]ClO_4$. In to a solution of 2 mmol of bis(acetylacetonato)cobalt(II) in ethanol, a drop of acetylacetone, 4 mmol of dienMe and 2 mmol of cobalt(II) perchlorate hexahydrate were stirred successively. The resulting solution was evaporated to dryness under a reduced pressure at room temperature. The residue was treated with chloroform, filtered, and evaporated to dryness. It was then recrystallized from small amount of hot ethanol and washed with 1 : 1 ethanol and diethyl ether.

$[Co(C_2O_4)(H_2O)dienMe]$. Freshly precipitated cobalt(II) oxalate was treated with equimolar quantities of dienMe in the presence of a small amount of water. The resulting solution was filtered and allowed to evaporate to dryness under a reduced pressure. The residue was dissolved in chloroform and was precipitated by the addition of diethyl ether to the filtrate.

$Co(C_2O_4)_{1/2}(dienMe)ClO_4$ and $Co(C_2O_4)_{1/2}(solv)(dienMe)ClO_4$ ($solv=CH_3CN$ or CH_3OH). To a slurry of 5.132 g (10 mmol) of $[Co(CH_3CN)_2dienMe](ClO_4)_2$ in 50 dm^3 of ethanol, 0.670 g (5 mmol) of sodium oxalate was added, after which the mixture was stirred overnight. The resulting crystals were collected on a glass filter and washed with hot ethanol. Recrystallization from hot methanol gave the methanol adduct, which yielded $Co(C_2O_4)_{1/2}(dienMe)ClO_4$ when washed with hot ethanol. The acetonitrile adduct was obtained by the addition of dry diethyl ether to the acetonitrile solution of the crude product.

Physical Measurements. The absorption spectra of the solutions were recorded at room temperature with a Shimadzu MPS-5000 recording spectrophotometer and silica cells with a path length of 1 cm. The reflectance spectra were obtained using the reflectance attachments and using potassium perchlorate as the reference. For the moisture-sensitive complexes, finely ground samples, prepared in a dry box, were covered with a glass plate. The IR spectra were measured over the range of 400—4000 cm^{-1} with a Hitachi EPI-G3 grating spectrophotometer. The samples were prepared as Nujol and hexachlorobutadiene mulls. The

magnetic moments were determined by the Gouy method at room temperature, using water as the standard. The molar susceptibility in each case was corrected for the diamagnetism of the ligands and perchlorate ions.

Analysis. The cobalt was determined volumetrically with an EDTA solution, using Xylenol Orange as the indicator. The sample solutions were prepared after decomposing the complexes with a mixture of sulfuric acid and perchloric acid. The organic elements were analyzed by Wako Pure Chemical Ind., Ltd., Osaka.

Results and Discussion

Table 1 shows the colors, the magnetic moments, and the analytical data for the complexes prepared. The analytical values of C, H, and N for $Co(C_2O_4)_{1/2}$(solv)-(dienMe)ClO_4 (solv=CH_3CN and CH_3OH) indicate that some of the solvent molecules were lost or displaced by water, however, the results of the metal analysis and the physical measurements, which were carried out in this laboratory with particular care taken to avoid moisture, show no signs of any loss of the solvent molecules or any adsorption of water.

The magnetic moments of $Co(C_2O_4)_{1/2}$(solv) (dienMe)ClO_4 (solv=CH_3CN and CH_3OH) and [$Co(C_2O_4)$(H_2O)dienMe] lie in the range of the six-coordinated cobalt(II) complexes (4.7—5.2 B.M.), whereas those of the others, which are identified from the electronic spectra as five-coordinated ones, are low, as Table 1 shows. The magnetic moments of most of the five-coordinated cobalt(II) complexes previously reported seem to lie in the range of the tetrahedral complexes (4.4—4.7 B.M.).[1b,2,4]

The IR spectra were measured for all the complexes studied. Because of their complex spectra, however, the assignment of each band was not possible. Thus, the configuration of the ligand was not determined. However, some information can be obtained from the characteristic bands due to anions or ligands: 1) The possibility of the coordination of a perchlorate ion can be rejected, because the bands at 1100 and 625 cm^{-1} are not appreciably split for any of the complexes containing the perchlorate ions. 2) As for the complexes with acetonitrile, *i.e.*, [$Co(CH_3CN)_2$dienMe]-(ClO_4)$_2$ and $Co(C_2O_4)_{1/2}(CH_3CN)$(dienMe)ClO_4, the sharp bands due to C≡N stretching were observed at 2280 and 2300 cm^{-1}, which are slightly higher than those of free acetonitrile, 2233 and 2282 cm^{-1}, in a neat solvent. No bands due to the presence of uncoordinated acetonitrile were observed in either complex. 3) In the 1600—1700 cm^{-1} region, the antisymmetric (O–C–O) stretching bands of the oxalato and the hemioxalato complexes are markedly different; *i.e.*, the former exhibits the splitted bands at 1614 and 1670 cm^{-1}, whereas the latter exhibit a sharp band at *ca.* 1660 cm^{-1}. The single peak found for the hemioxalato complexes seems to indicate that the four carbon-oxygen bonds of the oxalate ion are equivalent with each other. Thus, it may be inferred that the oxalate ion is bidentate in [$Co(C_2O_4)(H_2O)$-dienMe], whereas quadridentate in three hemioxalato complexes. It has been reported that an oxalate ion can bridge two metal ions, using all the oxygens as the ligand atoms.[5] This may also be the case for the present hemioxalato complexes.

The electronic spectra of these complexes were measured both in the solid state and in solution. Table 2 shows the positions and the molar absorptivities of the observed maxima.

The solid-reflectance spectra reveal that [$Co(C_2O_4)$-(H_2O)dienMe] and $Co(C_2O_4)_{1/2}$(solv) (dineMe)ClO_4 (solv=CH_3CN and CH_3OH) are six-coordinated, whereas the others are five-coordinated. The spectra of these five-coordinated complexes resemble that of [CoCl(trenMe)]Cl (trenMe=tris[2-(dimethylamino)-ethyl]amine) rather than that of [$CoCl_2$(dienMe)].[2,6] It has been reported that the former has essentially a trigonal-bipyramidal structure,[6,7] whereas the latter has a structure intermediate between a trigonal-bipyramidal one and a tetragonal-pyramidal one.[8] The similarlity of the spectra is the most remarkable in the acetylacetonato complex, the most probable structure of which is shown in Fig. 1. It may be supposed that the en, tn, and diammine complexes also take this structure.

In solution, most of the complex ions seem to maintain their structure in the solid state, because the absorption spectrum of the solution is essentially the same as the reflectance spectrum of the solid. An exception is the hemioxalato complex, $Co(C_2O_4)_{1/2}$-(dienMe)ClO_4. As Fig. 2 shows, the absorption spectra of this complex in nitromethane, in acetonitrile, and in methanol are different from each other,

a) All the species contained in the complex per one cobalt ion are indicated but a dienMe molecule. b) The chloroform, nitromethane, and the acetonitrile solutions give rise to practically the same spectra with each other.

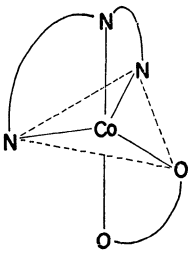

Fig. 1. The plausible coordination in $[Co(acac)dienMe]ClO_4$.

but are quite similar to the reflectance spectra of $Co(C_2O_4)_{1/2}(dienMe)ClO_4$, $Co(C_2O_4)_{1/2}(CH_3CN)(dienMe)ClO_4$, and $Co(C_2O_4)_{1/2}(CH_3OH)(dienMe)ClO_4$ respectively. The fact implies that solvolysis occurs both in acetonitrile and in methanol to form six-coordinated complexes. The coordination structure of this complex in a solid appears not to change only in nitromethane. No signs of the formation of six-coordinated complex were found in the nitromethane solution in the range of 9000—11000 cm^{-1}.

Both in the solid state and in solution, the ν_{max} values of the acac complex are slightly higher than those of the complexes containing en, tn, or ammonia. This is curious because the spectrochemical series of these ligands are generally in this order: en>tn> $NH_3 \gg$ acac. This fact may be ascribed to the stereochemical nature of the dienMe ligand, which has bulky methyl groups at the terminal nitrogen atoms. The steric repulsion between the methyl groups and the amine or ammine hydrogens may make the field around the cobalt(II) ion weaker than that in the acac complex.

The author is indepted to Miss Mitsue Futagi for her help in part of the measurements and the preparation of the complexes. This work was partly supported by the Scientific Research Grant from the Ministry of Education.

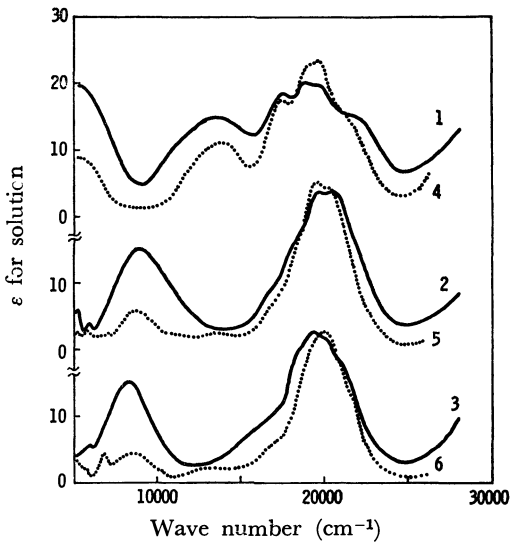

Fig. 2. The electronic spectra of the hemioxalato complexes in the solid state (——) and in solution (·····): the reflectance spectra of 1) $Co(C_2O_4)_{1/2}(dienMe)ClO_4$, 2) $Co(C_2O_4)_{1/2}(CH_3CN)(dienMe)ClO_4$, and 3) $Co(C_2O_4)_{1/2}(CH_3OH)(dienMe)ClO_4$; and the absorption spectra of $Co(C_2O_4)_{1/2}(dienMe)ClO_4$ in 4) nitromethane, 5) acetonitrile, and 6) methanol.

Circular Dichroism of Chromium(III) Complexes. V. Circular Dichroism of *trans*-Dihalogenobis(diamine) Complexes with Optically Active Diamines

Sumio KAIZAKI and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received June 19, 1975)

Nine chromium(III) complexes of *trans*-$[CrX_2(N)_4]$ type with three kinds of optically active diamines (*R*-propylenediamine, *S,S*-stilbenediamine and *S,S*-2,4-pentanediamine) were prepared and the absorption and circular dichroism spectra were measured in the region of their d–d transitions. The CD behaviors in the spin-allowed transitions were discussed in comparison with the corresponding cobalt(III) complexes and their bands were assigned to the tetragonal components. On the basis of the theoretical correlation between the rotational strengths for the spin-forbidden transitions and for the spin-allowed transitions, the CD peaks in the spin-forbidden transitions were discussed and assigned.

In the previous paper,[1] circular dichroism (CD) spectra of optically active tris-chelate chromium(III) complexes in the spin-forbidden transitions have been reported and analyzed in connection with the CD in the spin-allowed transitions in terms of the theoretical correlation between the rotational strengths in the spin-forbidden and the spin-allowed transitions. Since there have remained some ambiguities about the assignment of the trigonal splitting CD components in the spin-allowed transitions, alternative assignments may be possible. On the other hand, it has been well known that for so-called praseo type complexes the first spin-allowed bands of octahedral parantage split largely enough to resolve the tetragonal components in solution absorption spectra at room temperature and this allows to make the band assignment feasible. On the basis of analyses of absorption spectra as well as crystal field approximation treatments,[2–7] the assignments of spin-allowed d-d transitions of chromium(III) complexes in tetragonal field have been made rigorously, and the tetragonal crystal field parameters, *Dt* and *Ds*, and/or the angular overlap model (AOM) parameters, $\delta\sigma$ and $\delta\pi$,[8] have been derived and discussed.[2–7,9] By using these parameters, the positions and the splittings of the doublet states can also be estimated.[10] Thus, the observation of the spin-forbidden bands provides a criterion for testing the crystal field or AOM parameters. Some absorption and emission data in the spin-forbidden transitions have been reported[11–15] and their peaks have been assigned according to the crystal field theory. The CD in the spin-forbidden transitions will be expected to offer more detailed information, because the rotational strengths for these transitions are theoretically related to those for the spin-allowed transitions. Nevertheless, there has been no report on the CD spectra of tetragonal complexes with optically active diamines not only in the spin-allowed transitions but also in the spin-forbidden transitions, though optical activity of the corresponding Co(III) complexes has been intensively studied in the spin-allowed transitions.[16–19]

In this paper, nine *trans*-$[CrX_2(N)_4]$ type complexes with three kinds of optically active diamines (*R*-propylenediamine=*R*-pn, *S,S*-stilbenediamine=*S,S*-stien and *S,S*-2,4-pentanediamine=*S,S*-2,4-ptn) have been prepared and their absorption and CD spectra have been measured in their spin-allowed and spin-forbidden transition regions. The theoretical correlation between the rotational strengths for the spin-forbidden and spin-allowed transitions will be presented in a manner similar to the trigonal complexes, but in a more refined form including the configuration interaction and molecular orbital extension to the spin-orbit coupling effect on axial ligands.

Experimental

Preparation of Optically Active Diamines. *1)* R-*Propylenediamine*: This was resolved through its tartrate and isolated as free diamine.

2) S,S-*Stilbenediamine*: The racemic diamine was prepared by the method of Williams and Bailar,[20] and resolved into the enantiomer through its tartrate by the method of Lifschitz and Bos.[21]

3) R,R- *or* S,S-*2,4-Pentanediamine*: This was prepared and resolved by the method of Bosnich,[19] and isolated as its dihydrogen dichloride.

Preparation of the Complexes. The fluoro complexes were prepared by the method analogous to Glerup *et al.*'s.[22] The conversion of the fluoro complexes to the chloro and bromo complexes was carried out by the modified method of Fee *et al.*[23]

The R-*Propylenediamine Complexes.* *1)* trans-$[CrF_2(R\text{-}pn)_2]ClO_4\cdot H_2O$: This complex was obtained by the method of Glerup *et al.*[22] Found: C, 19.97; H, 6.35; N, 15.39%. Calcd for *trans*-$[CrF_2(R\text{-pn})_2]ClO_4\cdot H_2O$: C, 20.26; H,6.23; N, 15.75%.

2) trans-$[CrCl_2(R\text{-}pn)_2]ClO_4$: *trans*-$[CrF_2(R\text{-pn})_2]ClO_4\cdot H_2O$ (12 g) was dissolved in 15 cm³ of 40—44% hydrochloric acid, which was obtained by bubbling hydrogen chloride to concentrated hydrochloric acid at 0 °C. The dark red solution obtained was kept with stirring for a while at room temperature; then red crystals were precipitated. The color of the separated crystals was grayish green with a reddish tint. The yield was about 8 g. Recrystallization was carried out from methanol–ether. Found: C, 18.91; H, 5.66; N, 15.10%. Calcd for *trans*-$[CrCl_2(R\text{-pn})_2]ClO_4$: C, 19.45; H, 5.44; N, 15.12%.

3) trans-$[CrBr_2(R\text{-}pn)_2]Br\cdot H_2O$: One gram of *trans*-$[CrF_2(R\text{-pn})_2]ClO_4\cdot H_2O$ was dissolved in 3 cm³ of 48% hydrobromic acid, and the mixture was stirred for a while at room temperature. The complex was obtained as a green precipitate; the yield was about 0.3 g. This was recrystallized from methanol–ether. This complex was also obtained in good yield from the reaction in 3.5 M methanolic hydrogen bromide solution. Found: C, 15.70; H, 4.83; N, 11.98%. Calcd for *trans*-$[CrBr_2(R\text{-pn})_2]Br\cdot H_2O$: C, 15.74; H, 4.84; N, 12.23%.

The S,S-Stilbenediamine Complexes. *1)* trans-[CrF_2(S,S-*stien*)$_2$]$ClO_4 \cdot H_2O$: *trans*-[CrF_2(py)$_4$]ClO_4[22] (17.5 g) was dissolved in 100 cm^3 of hot 2-methoxyethanol. To the resulting violet solution was added 14 g *S,S*-stilbenediamine, and then the solution was refluxed for a while. The red solution obtained was condensed by a vacuum rotary evaporator. The red orange precipitate was obtained by adding the condensed solution to water. This was dissolved in methanol, filtered and the pinkish orange crystals were precipitated by adding ether. The color of the filtrate was red. The pinkish orange compound was insoluble in acetone, while the red one was soluble in acetone. The purification of this pinkish orange complex was performed by adding the methanolic solution to acetone. Found: C, 53.49; H, 5.49; N, 8.90%. Calcd for *trans*-[CrF_2(*S,S*-stien)$_2$]$ClO_4 \cdot H_2O$: C, 53.20; H, 5.42; N, 8.86%.

2) trans-[$CrCl_2$(S,S-*stien*)$_2$]$Cl \cdot 2H_2O$: To 47% methanolic hydrogen chloride solution was added 0.55 g of *trans*-[CrF_2(*S,S*-stien)$_2$]$ClO_4 \cdot H_2O$. The color of the solution changed to dark red. Then the reaction mixture was poured into water. The pale green powder was obtained. This was recrystallized from methanol–ether. Found: C, 54.27; H, 5.87; N, 9.03%. Calcd for *trans*-[$CrCl_2$(*S,S*-stien)$_2$]$Cl \cdot 2H_2O$: C, 54.33; H, 5.86; N, 9.05%.

3) trans-[$CrBr_2$(S,S-*stien*)$_2$]$Br \cdot CH_3OH$: *trans*-[CrF_2(*S,S*-stien)$_2$]$ClO_4 \cdot H_2O$ (1 g) was suspended in 20 cm^3 of 3.5 M methanolic hydrogen bromide solution. The starting complex was gradually dissolved during about one hour. After stirring for about two hours, the color of the solution turned to green. The resulting solution was poured into water. Then the desired complex was obtained as a green precipitate. This was recrystallized from methanol–ether. Found: C, 46.34; H, 4.83; N, 7.62%. Calcd for *trans*-[$CrBr_2$(*S,S*-stien)$_2$]$Br \cdot CH_3OH$: C, 46.55; H, 4.85; N, 7.49%.

The S,S-2,4-pentanediamine complexes. *1)* trans-[CrF_2(S,S-*2,4-ptn*)$_2$]ClO_4: Pure sodium (1.1 g) was dissolved in 30 cm^3 of 2-methoxyethanol. To this solution was added 4 g of *S,S*-2,4-ptn·2HCl by portions; then white powder of sodium chloride was precipitated. During this procedure, dry nitrogen gas was bubbled into the solution in order to protect from carbon dioxide and moisture. The sodium chloride was removed by filtration, and washed with a small amount of 2-methoxyethanol. To the combined filtrate and washings was added 5 g of *trans*-[CrF_2(py)$_4$]ClO_4. The mixture was heated on a steam bath and then orange crystals were precipitated. This product was contaminated by a small amount of impurities such as chromium(III) hydroxide. The recrystallization was carried out from the aqueous solution which was slightly acidified with a small amount of $HClO_4$. The yield was about 2.3 g. Found: C, 30.42; H, 7.24; N, 14.20%. Calcd for *trans*-[CrF_2(*S,S*-2,4-ptn)$_2$]ClO_4: C, 30.50; H, 7.17; N, 14.23%.

2) trans-[$CrCl_2$(S,S-*2,4-ptn*)$_2$]ClO_4: In a 5 cm^3 portion of concentrated hydrochloric acid was dissolved 0.7 g of *trans*-[CrF_2(*S,S*-2,4-ptn)$_2$]ClO_4, and the mixture was allowed to stand for 3—4 hr. Green needles were precipitated. They were recrystallized from methanol–ether. Found: C, 28.19; H, 6.67; N, 13.34%. Calcd for *trans*-[$CrCl_2$(*S,S*-2,4-ptn)$_2$]ClO_4: C, 28.21; H, 6.63; N, 13.16%.

3) trans-[$CrBr_2$(S,S-*2,4-ptn*)$_2$]Br: *trans*-[CrF_2(*S,S*-2,4-ptn)$_2$]ClO_4 (1 g) was dissolved in a small amount of 4 M ethanolic hydrogen bromide. The solution was allowed to stand over night in a refrigerator. Then light green leaflets were obtained. They were recrystallized from methanol–ether. Found: C, 24.03; H, 5.77; N, 11.30%. Calcd for *trans*-[$CrBr_2$(*S,S*-2,4-ptn)$_2$]Br: C, 24.21; H, 5.68; N, 11.29%.

Measurements. The electronic absorption spectra were measured by a Shimadzu spectrophotometer UV-200. The CD spectra were recorded with a Jasco MOE-1 spectropolarimeter. The CD measurements were carried out with the wavelength expansion of 4 nm/cm and 10 nm/cm in the spin-forbidden and spin-allowed transition regions, respectively. Therefore, four significant figures were used in expressing wave numbers in the spin-forbidden transition region, whereas three significant figures were used in the spin-allowed transition region. The concentrations of the complexes for the CD measurements in the spin-forbidden transition region were 10^{-1} to 10^{-2} mol dm^{-3}, and the cell lengths employed were 5 and 10 cm. The absorption and CD spectra of the fluoro complexes with *R*-pn and *S,S*-ptn were measured in water, while those of the other complexes in methanol.

Results and Discussion

1) Absorption Spectra. The ligand field absorption spectra of the nine complexes concerned are given in Figs. 1—3, and their characteristics are listed in Table 1. It is noted that their absorption patterns are similar, on the whole, to those of the corresponding *trans*-dihalogenobis(ethylenediamine)chromium(III) complexes, being independent of the optically active diamines and only dependent on the axial ligands. That is, for the fluoro complexes, two split components are observed in both the first $^4T_2 \leftarrow {}^4A_2$ and the second $^4T_1 \leftarrow {}^4A_2$ spin-allowed octahedral transition regions, whereas the other complexes show two largely split components in the first band region and only one in the second band region as in Figs. 1—3. The higher frequency component in the first band region shifts scarcely for any halogeno complexes and lies at about 22000 cm^{-1}, where the first absorption band of [Cr(N)$_6$] type complex is expected. While the lower frequency component shifts to the lower frequency side in the order of fluoro, chloro and bromo complexes. This order is in coincidence with spectrochemical series of the axial halogeno ligands.[21]

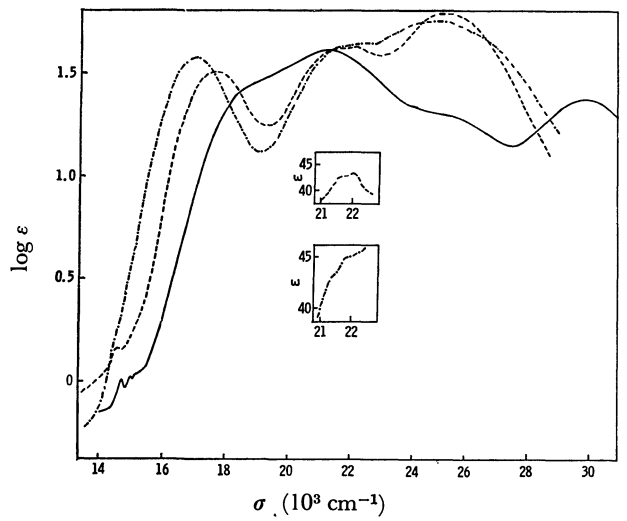

Fig. 2. Absorption curves of *trans*-$[CrX_2(S,S\text{-stien})_2]^+$ X=F (——); X=Cl (----); X=Br (—·—·—) in methanol.

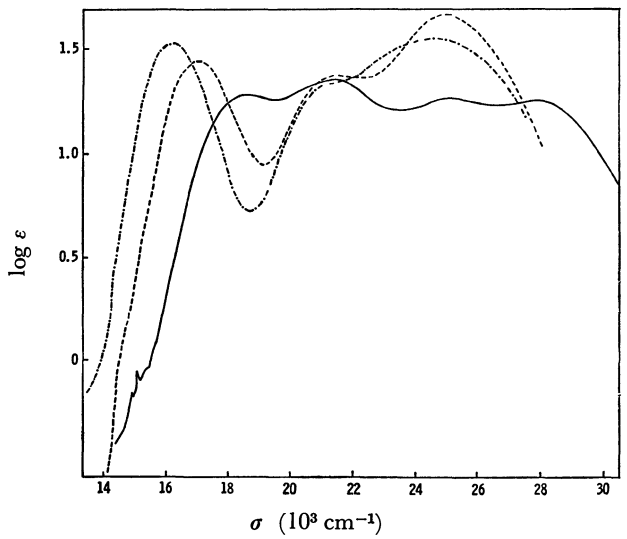

Fig. 3. Absorption curves of *trans*-$[CrX_2(S,S\text{-2,4-ptn})_2]^+$, X=F (——) in water; X=Cl (----) in methanol; X=Br (—·—·—) in methanol.

Since these absorption behavior agrees with the expectation from the ligand field theory[2] and the angular overlap model[6] for tetragonal chromium(III) complexes, the higher frequency and the lower frequency components in the first band region are due to the $^4E\leftarrow$ and $^4B_2\leftarrow{}^4B_1$ transition, respectively. This assignment has been unequivocally confirmed from single crystal polarized absorption spectra of *trans*-dihalogenobis(ethylenediamine)Cr(III) complexes.[4]

Both the split components, ^4E and $^4B_2$, in the first band region of the dichloro and dibromo complexes are found to shift to the lower frequency side in the order of *S,S*-stien, *R*-pn and *S,S*-2,4-ptn complexes. This fact suggests that the ligand field of the diamines decreases in this order as found in the case of the corresponding cobalt(III) complexes.[18,19]

The molar absorptivities of the $^4B_2$ components for the fluoro, chloro, and bromo complexes with a given diamine are close to each other, whereas those of the ^4E components increase in the order of the fluoro, chloro, and bromo complexes. This order is consistent with the hyperchromic series of the axial ligands.[25] The $^4B_2$ components of *trans*-$[CrCl]_2(R\text{-pn})_2]^+$ and *trans*-$[CrX_2(S,S\text{-stien})_2]^+$ (X=Cl, Br) split by some 500—800 cm^{-1}. This splitting may result from a strong spin-orbit coupling between the $^2\Gamma(^2T_2)$ and $^4B_2$ states as discussed later.

In the lower frequency region, where the doublet← quartet spin-forbidden transitions occur, some weak but sharp peaks or inflections are observed for the fluoro and chloro complexes, but none for the bromo complexes as shown in Figs. 1—3. The absorption intensities of spin-forbidden bands are found to be one twentieth to one fiftieth times as weak as those of the spin-allowed bands. The spin-forbidden transitions of the fluoro complexes are shifted to the lower frequency than those of the chloro complexes.

2) CD Spectra in the First Spin-allowed Transitions. Two CD components associated with the first $^4E\leftarrow$ and $^4B_2\leftarrow{}^4B_1$ spin-allowed transitions are observed for all the complexes concerned in Figs. 4—6. The CD patterns depend largely on the optically active diamines and independent of the axial ligands. That is, for the *R*-pn complexes, a large positive and a small negative CD component is observed in the region corresponding to the lower frequency ^4E and the higher frequency $^4B_2$ absorption band, respectively. For

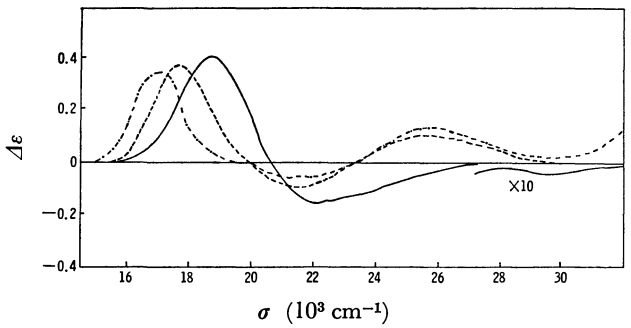

Fig. 4. CD curves in the spin-allowed transitions of *trans*-$[CrX_2(R\text{-pn})_2]^+$, X=F (——) in water; X=Cl (----) in methanol; X=Br (—·—·—) in methanol.

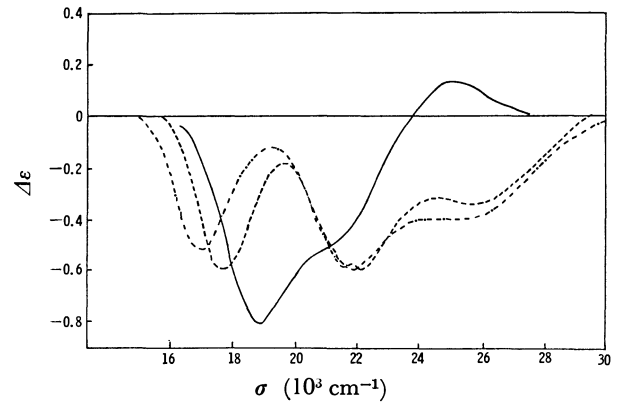

Fig. 5. CD curves in the spin-allowed transitions of *trans*-$[CrX_2(S,S\text{-stien})_2]^+$, X=F (——); X=Cl (----); X=Br (—·—·—) in methanol.

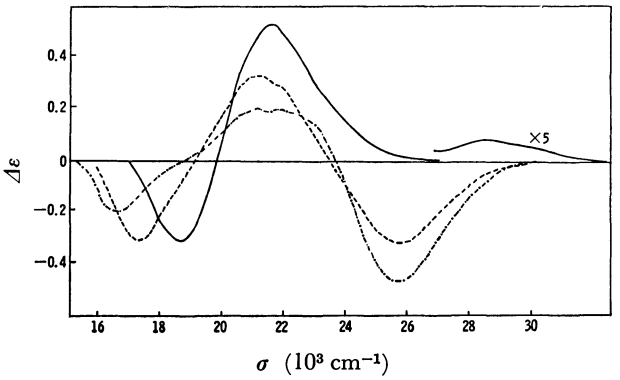

Fig. 6. CD curves in the spin-allowed transitions of *trans*-$[CrX_2(S,S\text{-2,4-ptn})_2]^+$, X=F (——) in water; X=Cl (----) in methanol; X=Br (—·—·—) in methanol.

the *S,S*-stien complexes, two negative CD bands are observed in this region. The *S,S*-2,4-ptn complexes show two CD components with opposite signs, (−) and (+) from the longer wavelength side, having nearly equal area. Such CD behavior of chromium(III) complexes is quite similar to the corresponding cobalt(III) complexes.[18,19,26] Therefore, it seems reasonable that the coordinated optically active diamines in the chromium(III) complexes take the same conformations as those in the cobalt(III) complexes. That is, the conformation of the *R*-pn, *S,S*-stien and *S,S*-2,4-ptn is assigned to *λ*-,[27] *δ-gauche*[26b] and *δ*-twist[18] form, respectively.

The CD intensities of the chromium(III) complexes are found to be about half as compared with those of the corresponding cobalt(III) complexes, as predicted by a general theory on CD of metal complexes.[28]

3) CD Spectra in the Second Spin-allowed Transitions. One CD component associated with the second $^4T_1 \leftarrow {}^4A_2$ octahedral transition of the chloro or bromo complex is observed at the higher frequency side than the absorption band, as in Figs. 4—6 and Table 1, indicating that the CD band is ascribed to the $^4E_b(^4T_1)$ component which lies at the higher frequency than the $^4A_2(^4T_1)$ component as is predicted theoretically and confirmed by single crystal polarized absorption spectra.[4] These CD bands are of the same signs as those of the $^4E_a(^4T_2)$ components. The CD band of the fluoro complexes with *R*-pn and *S,S*-2,4-ptn observed in the second band region lies rather closely to the $^4A_2$ absorption component, and therefore this band is assigned to the $^4A_2 \leftarrow {}^4B_1$ transition which may be vibronically allowed by lowering symmetry through the mixing with the $^4B_2$ component, as has been observed for *trans*-$[CoCl]_2(R\text{-pn})_2]^+$.[30] The CD intensities of these bands are found to be much weaker than those of the $^4E_b(^4T_1)$ components. The CD band of the fluoro complex with *S,S*-stien in the second band region corresponds to the ^4E_b absorption component, and is of opposite sign to the ^4E_a component. The fact that the ^4E_b CD component are not observed for the fluoro complexes with *R*-pn and *S,S*-2,4-ptn may be responsible for the overlapping with the $^4B_2$ component which may have the same sign as the ^4E_b one. Thus, it is seen that the CD sign of the ^4E_b component for the fluoro complexes in the second band region is opposite to those for the chloro and bromo complexes. This fact may be elucidated by taking into consideration of the configuration interaction between the ^4E_a and ^4E_b states. The magnetic dipole forbidden $^4E_b \leftarrow {}^4B_1$ transition borrows its magnetic transition dipole moment from that for the magnetic dipole allowed $^4E_a \leftarrow {}^4B_1$ transition through the configuration interaction between the ^4E_a and ^4E_b states in tetragonal field, of which the off-diagonal element, $\langle {}^4E_a | V(D_{4h}) | {}^4E_b \rangle$, is given as $(\sqrt{3}/2)\delta\sigma$.[30] The AOM parameter, $\delta\sigma$, is defined as the splitting of one electron level of the $e_g(d)$ orbital in tetragonal field and can be estimated from the observed splittings of the first and second octahedral bands. Thus, the rotational strength for the $^4E_b \leftarrow {}^4B_1$ transition is expressed as follows.

$$R(^4E_b) = (\sqrt{3}/2)\delta\sigma/\{E(^4E_b) - E(^4E_a)\} \cdot \mathrm{Im}\langle {}^4E_a | M | {}^4B_1 \rangle \cdot \langle {}^4B_1 | P | {}^4E_b \rangle$$

where M and P are magnetic and electric dipole operator, respectively, and Im means the "imaginary part of". Since the energy denominator, $E(^4E_b) - E(^4E_a) = 36B + \delta\sigma$, is usually positive, the sign of the $R(^4E_b)$ is governed by that of $\delta\sigma$. According to the measurements of single crystal polarized absorption spectra as well as theoretical crystal field calculations,[4] the $\delta\sigma$ value for *trans*-$[CrX_2(en)_2]^+$ complex has been estimated to be +600, −1240 and −1780 cm^{-1}, for the fluoro, chloro and bromo complex, respectively. The $\delta\sigma$ values for the present complexes do not seem to differ largely from those for the ethylenediamine complexes, for the ligand field strengths of these complexes are close to each other. Therefore, the sign inversion of the ^4E_b CD component from the fluoro to the chloro and bromo complexes is responsible for that of the $\delta\sigma$ parameter. A similar formulation can be also applied to the CD behaviors of the corresponding Co(III) complexes. It has been found that all the *trans*-difluoro, dichloro and dibromo(*l*-cyclohexanediamine)cobalt(III) complexes give the positive CD sign in the $^1E_b(^1T_2)$ component.[31] This finding is in accordance with the $\delta\sigma$ parameters for the three complexes having the same sign (negative).[31]

4) CD Spectra in the Spin-forbidden Transitions. a) General Considerations: The splitting of the doublet excited states in tetragonal field occurs as shown in Fig. 7. Although each the $^2E(^2T_1)$ and the ground $^4B_1(^4A_2)$ state is split into two Kramers doublets by a spin-orbit coupling, these splittings are estimated to be too small to be resolved spectroscopically at room temperature.[8b] Thus, in this case, these will be ignored and only four electronic spin-forbidden transitions, $^2A_1(^2E)$, $^2B_1(^2E)$, $^2E(^2T_1)$ and $^2A_2(^2T_1) \leftarrow {}^4B_1(^4A_2)$, will be taken into account throughout the following discussion. Contrary to the expectation, however, more than four sharp but weak CD peaks are observed for the present complexes. This fact indicates the appearance of vibronic structures as discussed later.

The Rotational Strengths for the Spin-forbidden Transitions. For tetragonal chromium(III) complexes,

TABLE 2. ROTATIONAL STRENGTHS FOR THE SPIN-FORBIDDEN $^2\Gamma \leftarrow {}^4B_1$ TRANSITIONS IN TETRAGONAL CHROMIUM(III) COMPLEXES

		in unit of $\zeta'^2/18\{\Delta E(^2\Gamma)\}^2$	
^2E	$^2A_1$	$24R(^4E)$	$(1/3)(3\zeta_3'^2+\zeta_4'^2)\varepsilon_1^{-2}\cdot R(^4E)$
	$^2B_1$	$8\{R(^4E)+4R(^4B_2)\}$	$(1/9)(3\zeta_3'^2+\zeta_4'^2)\varepsilon_1^{-2}\cdot R(^4E)+(16/9)\zeta_1'^2\varepsilon_2^{-2}\cdot R(^4B_2)$
$^2T_1$	^2E	$6\{R(^4E)+2R(^4B_2)\}$	$(1/12)(3\zeta_2'^2+\zeta_1'^2)\varepsilon_1^{-2}\cdot R(^4E)+(2/3)\zeta_4'^2\varepsilon_2^{-2}\cdot R(^4B_2)$
	$^2A_2$	$6R(^4E)$	$(1/12)(3\zeta_3'^2+\zeta_4'^2)\varepsilon_1^{-2}\cdot R(^4E)$

$\Delta E(^2\Gamma) = E(^2\Gamma)-E(^4\Gamma)$; ζ_1', ζ_2', ζ_3' and ζ_4' are the effective spin-orbit coupling constants as defined in the text. ε_1 and ε_2 are the energy interval between the $^2\Gamma$ and ^4E and between the $^2\Gamma$ and $^4B_2$, respectively.

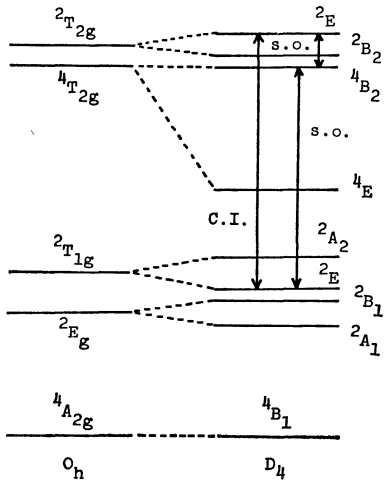

Fig. 7. Energy levels of a tetragonal chromium(III) ion. The vertical lines indicate the configuration interaction (C. I.) among the ^2E states or the spin-orbit coupling (s. o.) between the ^2E and the quartet state.

the spin-forbidden $^2\Gamma(t_2^3)\leftarrow{}^4B_1(t_2^3)$ transitions attain their rotational strengths by aquiring a small part, $(k\zeta'/\Delta E)^2$, of the rotational strengths for the nearby spin-allowed and magnetic dipole allowed $^4E(t_2^2e)$, $^4B_2(t_2^2e)\leftarrow{}^4B_1(t_2^3)$ transitions, as given by

$$R(^2\Gamma) = (k\zeta'/\Delta E)^2 R(^4\Gamma) \qquad (1)$$

where k is a numerical coefficient, and ζ' is a spin-orbit coupling constant, $\zeta'=(\sqrt{2}/6)i\langle t_2|H_{so}|e\rangle$, and ΔE refers to the energy interval between the $^2\Gamma$ and $^4\Gamma$, and $R(^4\Gamma)$ is the rotational strengths for the tetragonal splitting components of the $^4T_2$, $R(^4E)=2\mathrm{Im}\langle{}^4E|P|{}^4B_1\rangle\cdot\langle{}^4B_1|M|{}^4E\rangle$ and $R(^4B_2)=\mathrm{Im}\langle{}^4B_2|P|{}^4B_1\rangle\cdot\langle{}^4B_1|M|{}^4B_2\rangle$. The $k^2R(^4\Gamma)$ in the Eq. (1) are obtained by using the Wigner and Clebsh-Gordan coefficients with tetragonal field in the absence of vibronic contribution[32,33] as in the case of trigonal complexes[1] as shown in the third column of Table 2. This approximation seems to be valid, since it is inferred that CD intensity is static in origin for the corresponding tetragonal Co(III) complexes.[29] This Table shows that the $^2A_2\leftarrow{}^4B_1$ and $^2A_1\leftarrow{}^4B_1$ transitions borrow their rotational strengths only from the $R(^4E)$ and hence they should have the same sign. In the cases of the $R(^2B_1)$ and $R(^2E)$ to which both the $R(^4E)$ and $R(^4B_2)$ contribute, however, more exact examinations of $\zeta'/\Delta E$ are required. As seen in section *1)*, the energy separation between the $^4B_2$ and ^4E states is so large that the differencc between $\varepsilon_1=E(^2\Gamma)-E(^4E)$ and $\varepsilon_2=E(^2\Gamma)-E(^4B_2)$ needs to be taken into consideration. For the complexes concerned, ε_1 depends on axial ligands, increasing in the order of the fluoro, chloro and bromo complexes and ε_2 is almost constant. Assuming no spin-orbit effect on ligands, the terms involving the $R(^4E)$ give larger contribution to the $R(^2\Gamma)$ by a factor of $(\varepsilon_2/\varepsilon_1)^2$ than those involving the $R(^4B_2)$, for the $(\varepsilon_2/\varepsilon_1)^2$ is found to be ~3 for the fluoro, ~4—~5 for the chloro and ~7—~8 for the bromo complexes. In addition, the ratio between the contribution of the $R(^4E)$ to that of the $R(^4B_2)$ is governed by the kinds of optically active diamines. That is, it is found that the $|R(^4E)/R(^4B_2)|$ obtained from the observed CD spectra is about 3 to 6 for the *R*-pn complexes and about 1 for the *S,S*-stien and *S,S*-2,4-ptn complexes. Consequently, it is expected that the $R(^2\Gamma)$ increase in the order of the fluoro, chloro and bromo complexes and that the contribution from the terms involving the $R(^4E)$ is large in comparison with those involving the $R(^4B_2)$. These are contrary to the findings. That is, the CD intensities in the spin-forbidden transitions decrease in the order of the fluoro, chloro and bromo complexes and they do not always exhibit the same sign as that of the ^4E component, as in Figs. 8—10 and Table 1. These facts suggest the importance of a spin-orbit effect on the ligands.

According to a simple molecular orbital treatment, it has been shown that the spin-orbit effects on the halogeno ligands in $[CoX(NH_3)_5]^{2+}$ play an important role in gaining the spin-forbidden absorption band intensities.[34,35] The application of this MO treatment to the tetragonal Cr(III) complexes leads to four nonequivalent effective spin-orbit coupling constants. Assuming no π bonding between the metal and amine ligands, one electron antibonding LCAO-MO for the *trans*-$[CrX_2(N)_4]$ type complexes is given as follows.[4]

$$\left.\begin{aligned} a_1(e) &= N_{\sigma X}[a_1(d_{z^2})-\lambda_{\sigma X}\Sigma p_{zi}(X)] \\ b_1(e) &= N_{\sigma N}[b_1(d_{x^2-y^2})-\lambda_{\sigma N}\Sigma p_{zi}(N)] \\ a_2(t_2) &= a_2(d_{xy}) \\ e(t_2) &= N_{\pi X}[e(d_{xz})-\lambda_{\pi X}\Sigma\{p_{xi}(X)-p_{xj}(X)\}] \\ e(t_2) &= N_{\pi X}[e(d_{yz})-\lambda_{\pi X}\Sigma\{p_{yi}(X)-p_{yj}(X)\}] \end{aligned}\right\} \qquad (2)$$

where $N_{\sigma N}$, $N_{\sigma X}$, $N_{\pi X}$ and $\lambda_{\sigma N}$, $\lambda_{\sigma X}$, $\lambda_{\pi X}$ are normalizing and admixture coefficients, respectively, $\Sigma p(N)$ and $\Sigma p(X)$ stand for symmetry adapted linear combinations of p orbitals of nitrogens and halogens, respectively, and $a_1(d_{z^2})$ *etc.* are pure d orbitals. The

upper two e orbitals and lower two t_2 orbitals are σ- and π-antibonding MO's, respectively. By using these molecular orbitals, the molecular orbital matrix elements, $\langle t_2|H_{so}|e\rangle$, are evaluated as,[33]

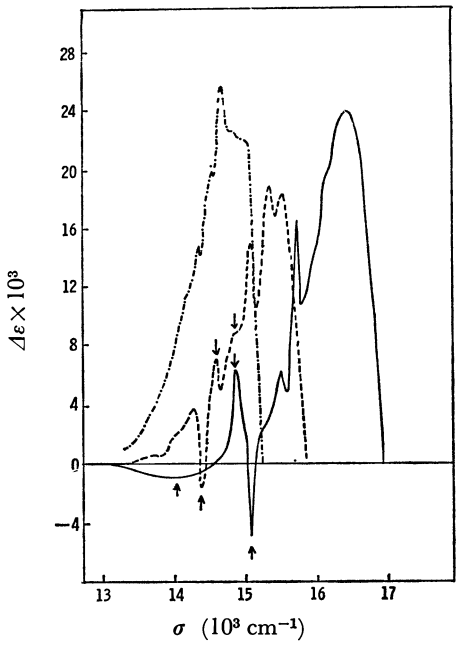

Fig. 10. CD curves in the spin-forbidden transitions of *trans*-$[CrX_2(S,S\text{-2,4-ptn})_2]^+$, X=F (——) in water; X=Cl (----) in methanol; X=Br (—·—·—) in methanol. The arrows as in Fig. 8.

$$\left.\begin{aligned}
\zeta_1' &= (\sqrt{2}/6)i\langle a_2(t_2)|H_{so}|b_1(e)\rangle = N_{\sigma N}\zeta_d' \\
\zeta_2' &= (\sqrt{2}/6)i\langle a_2(t_2)|H_{so}|a_1(e)\rangle = N_{\sigma X}\zeta_d' \\
\zeta_3' &= (\sqrt{2}/6)i\langle e(t_2)|H_{so}|a_1(e)\rangle \\
&= N_{\pi X}N_{\sigma X}\{\zeta_d' - (1/2)\lambda_{\pi X}\lambda_{\sigma X}\zeta_p\} \\
\zeta_4' &= (\sqrt{2}/6)i\langle e(t_2)|H_{so}|b_1(e)\rangle \\
&= N_{\pi X}N_{\sigma N}\zeta_d'
\end{aligned}\right\} \quad (3)$$

where ζ_d' and ζ_p are the spin-orbit coupling constants of pure 3d orbitals of Cr(III) ion and of p orbitals of halogen, respectively. It is noted that the ζ_1' and ζ_3' correspond to the effective spin orbit coupling constant for $Cr(N)_6^{3+}$ and $Cr(X)_6^{3-}$, respectively. Since the ζ_3' is given as a linear combination of ζ_d' and ζ_p, the value of ζ_3' varies with the halogen ligands. The Eq. (3) may be rewritten in terms of the relativistic nephelauxetic ratios, β^*(N) for the amine ligand and β^*(X) for the halogen ligands as follows. $\zeta_1'=\beta_{55}^*(N)\zeta_d'$, $\zeta_2'=\sqrt{\beta_{33}^*(X)\,\beta_{55}^*(N)}\,\zeta_d'$, $\zeta_3'=\beta_{55}^*(X)\,\zeta_d'$, $\zeta_4'=\sqrt{\beta_{33}^*(N)\,\beta_{55}^*(X)}\,\zeta_d'$, where ζ_p in ζ_3' is ignored. The $\beta_{55}^*(N)$ is mainly due to the relativistic nephelauxetic effect caused by the central field covalency.[36] Using these correlations, the ζ_2' and ζ_4' are connected with the ζ_3' and ζ_1' through the $\beta_{55}^*(N)$ and $\beta_{55}^*(X)$, as shown in the following. $\zeta_4'=\sqrt{\beta_{55}^*(X)/\beta_{55}^*(N)}\,\zeta_1'$; $\zeta_2'=\sqrt{\beta_{55}^*(N)/\beta_{55}^*(X)}\,\zeta_3'$, hence $\zeta_4'/\zeta_3'=\zeta_1'/\zeta_2'$, where it is assumed that $\beta_{55}^*=\sqrt{\beta_{33}^*\,\beta_{55}^*}$.[36] In this case, the values of the four constants seem close each other. In the case of the complexes having heavy ligands with large ζ_p, however, the substantial decrease in ζ_3' may be expected owing to the subtractive contribution of the terms involving the ζ_p to the ζ_3', assuming appropriate values of the ligand admixture coefficient, $\lambda_{\pi X}\lambda_{\sigma X}$.[37] Therefore, the difference between the ligand-dependent spin-orbit coupling constant ζ_3' and the other constants must be taken into consideration.

By introducing four different effective spin-orbit coupling constants in terms of the strong field wave functions of d^3 configurations in tetragonal field,[2] together with two kinds of the energy denominator, ε_1^{-1} and ε_2^{-1}, the refined rotational strengths for the spin-forbidden transitions can be represented as in the fourth column of Table 2. It is seen that most of the $R(^2\Gamma)$'s are rather sensitive to the ζ_3' and decrease with increasing ζ_p in the order of the fluoro, chloro and bromo complexes. This order is consistent with the observation.* As for the sign of the CD components, in either case of the complexes with vanishingly small ζ_3', or the complexes having $(\varepsilon_2/\varepsilon_1)^2<4$ and almost equal effective spin-orbit coupling constants, only the $R(^2B_1)$ among the four $R(^2\Gamma)$'s may be expected to exhibit the same sign as the $R(^4B_2)$, and the rotational strengths for the remaining spin-forbidden transitions are predicted to be of the same sign as the $R(^4E)$ for any axial ligands. It appears that this prediction holds for the *S,S*-stien complexes, though these complexes show two same signed CD bands in the first spin-allowed transition region. For the complexes with oppositely signed CD bands in the first spin-allowed transitions, some oppositely signed CD components are observed also in the spin-forbidden transitions as shown in Figs. 8 and 10. Such a CD behavior, however, was not elucidated by the spin-orbit coupling mechanism, only between the ^2E, $^2T_1$ and the $^4E(^4T_2)$, $^4B_2(^4T_2)$ states. Thus some additional contributions from the terms involvong the $R(^4B_2)$ become needed in terms of another mechanism.

More exact consideration including the configuration interaction accounts for the large mixing of the $^4B_2$ state into the doublet states. Of the doublet states, the $^2E(^2T_2)$ is strongly mixed with the $^4B_2$ state through a spin-orbit coupling, because these states lie very closely in the crystal field approximation. This strong coupling is substantiated from the fact that the $^4B_2$ component is split into double peaks in the absorption and CD spectra as in Figs. 1—2 and 4—6. In addition, the configuration interaction between the $^2E(^2T_2)$ and $^2E(^2T_1)$ occurs in tetragonal field. The off-diagonal matrix element is obtained as $3Ds-5Dt=2\delta\pi$, where Ds, Dt and $\delta\pi$ are the crystal field and AOM parameter, respectively.[2] The consequence of this configuration interaction has been discussed in photochemical implication for chromium(III) complexes[39] and in relation to the lower frequency shift of the $^2E(^2T_1)$ state.[14] The spin-orbit coupling gives rise to large admixture of the $^4B_2$ into the $^2E(^2T_2)$, and the $^4B_2$ mixes with the $^2E(^2T_1)$ through the configuration interaction with the $^2E(^2T_2)$ as in Fig. 7. The operation of these interactions gives additional rotational strengths for the $^2E(^2T_1)\leftarrow{}^4B_1(^4A_2)$ spin-forbidden transition by $(2/3)\varepsilon_4^{-2}\cdot\varepsilon_3^{-2}\cdot\zeta_4'^2\cdot4(\delta\pi)^2\cdot R(^4B_2)$, where ε_4 and ε_3 are the energy interval between the $^2E(^2T_2)$ and $^4B_2$ $(=10Dq-15B-5C)$ and between the $^2E(^2T_1)$ and $^2E(^2T_2)$ $(=6B+2C)$, respectively. Then the contribution of the terms involving the $R(^4B_2)$ to the $R(^2E(^2T_1))$ becomes $(2/3)\zeta_4'^2\varepsilon_3^{-2}\{1+4\varepsilon_4^{-2}(\delta\pi)^2\}\cdot R(^4B_2)$, assuming $\varepsilon_3\simeq\varepsilon_2$. The value of $\delta\pi$ is found to be of the order of 1000 cm^{-1} from the crystal field approximations and single crystal polarized absorption spectra of *trans*-$[CrX_2(en)_2]^+$. The ε_4 seems to be of the order of 1000 cm^{-1} or less. In the strong coupling case of $E(^4B_2)\simeq E(^2E(^2T_2))$ with zero spin-orbit coupling, the ε_4 is equal to $(\sqrt{3}/2)\zeta_4'$ and thus being estimated to be 100—200 cm^{-1}. Then the additional rotational strengths are sensitive to the ε_4 and in some cases, are expected to be so large that the term involving the $R(^4B_2)$ overwhelms that involving the $R(^4E)$.**

From these considerations, it may be summarized that the $R(^2A_1)$ should be the most intense and four times as large as the $R(^2A_2)$, and they should have the same sign as the $R(^4E)$. Further, the $R(^2E)$ and $R(^2B_1)$ are not always of the same sign as the $R(^4E)$.

b) The Assignments of the CD Components. The Fluoro Complexes with R-*pn and* S,S-*stien.* The crystal field theory predicts the positions and the splittings of the doublet states. In general, the ^2E cubic parent component lies at the lower frequency by about 700 cm^{-1} than the $^2T_1$ one. According to Macfarlane's approximation,[10a] the splitting of the ^2E cubic state into $^2A_1$ and $^2B_1$ in tetragonal field may be calculated in terms of the parameters, $\delta\sigma$, $\delta\pi$, $10Dq$, B and C; *i.e.*,

$$E(^2A_1)-E(^2B_1)=192B^2/(10Dq+14B+3C)\times\{\delta\pi/(10Dq+14B+3C)+\delta\sigma/(10Dq+5B)\} \quad (4)$$

On the other hand, owing to the configuration interaction between the $^2E(^2T_1)$ and $^2E(^2T_2)$ states, the $^2E(^2T_1)$ state is shifted by $4(\delta\pi)^2/\varepsilon_3$ to the lower frequency side. The former Eq. (4) leads to the expectation that the $^2B_1$ state for the fluoro complexes always locates at the lower frequency side than the $^2A_1$ because of positive sign of both the $\delta\pi$ and $\delta\sigma$.[3-6] The shift of the $^2E(^2T_1)$ state is sensitive to the value

* In the case of Co(III) complexes, the molecular spin-orbit coupling constants corresponding to the ζ_3', $\zeta=(-i/3)\langle t_2|H_{so}|t_2\rangle$, are given as an additive contribution of the terms involving ζ_p of halogeno ligands.[33] Thus, this constants increase with increasing ζ_p and in the order of the fluoro, chloro and bromo complexes. This order agrees with that obtained from the spin-forbidden absorption intensities.[38] On the other hand, for the Cr(III) complexes, the intensity order of the spin-forbidden absorption bands is contrary to that of CD intensities in the spin-forbidden transitions. This finding can not be interpreted in the course of the present discussion, since the sharp spin-forbidden bands are overlapped with the lower frequency envelope of the broad first spin-allowed bands to increasing extent in the order of the fluoro, chloro and bromo complexes.

** In the case of $[Cr(en)_3]^{3+}$, the similar configuration interaction between the $^2E(^2T_1)$ and $^2E(^2T_2)$ state and/or $^2E(^2E)$ and $^2E(^2T_2)$ state and the strong spin-orbit coupling between the $^2E(^2T_2)$ and $^4E(^4T_2)$ or $^4A_1(^4T_2)$ state can occur. The off-diagonal elements of these configuration interactions are proportional to the trigonal splitting parameter K. [S. Sugano and M. Peter, *Phys. Rev.*, **122**, 381 (1961).] In this case, however, the mixing of the $^2E(^2T_2)$ state with the $^2E(^2E)$ and $^2E(^2T_1)$ state seems to be negligible owing to small K value. [A. J. McCaffery, S. F. Mason, and B. J. Ballard, *J. Chem. Soc.*, **1965**, 5094.] In the trigonal case, therefore, these interactions may be ignored.

of $\delta\pi$, because ε_3 includes only the Racah electronic repulsion parameters, and hence almost independent on the ligand field. Thus, the $^2E(^2T_1)$ state for the fluoro complexes seems to be shifted to the lower frequency than that for the other aniono complexes, because the $\delta\pi$ value of the fluoro complexes is largest in the three halogeno complexes.[4] Then the $^2A_2(^2T_1)$ state locates at the highest frequency. In fact, from the luminescence and absorption spectra of *trans*-$[CrF_2(en)_2]ClO_4$ and its iodide, Flint *et al.*[14] have revealed that the lowest frequency phosphorescence band at 13098 cm^{-1} is assigned to the $^2E(^2T_1)$ state and the $^2B_1$, $^2A_1$ and $^2A_2$ states locate at 14860, 15052 and 15270 cm^{-1}, respectively, in spite of a number of observed vibronic structures. This assignment is also consistent with the prediction based on the crystal field theory. By collating this assignment with the CD components of the present fluoro complexes, the peaks are assigned on the assumption that the crystal field parameter values of the optically active diamine complexes are close to those of the ethylenediamine complex. For the *R*-pn complex, the lowest frequency positive CD peak at 13330 cm^{-1} is due to the $^2E(^2T_1)$ state, and the weak positive peak at 14730 cm^{-1} and the strongest positive peak at 15030 cm^{-1} are due to the $^2B_1$ and $^2A_1$ state, respectively, as in Fig. 8 a). The $^2A_2$ state may correspond to the shoulder near 15300 cm^{-1} of positive sign. The theoretical correlation between the rotational strengths in the spin-forbidden transitions and those in the spin-allowed transitions can account for the CD behaviors of these peaks semi-quantitatively. That is, the $^2A_1$ peak is the strongest and about four times as strong as the $^2A_2$ one as mentioned before. The weak intensities of the ^2E and $^2B_1$ peaks may be responsible for the increasing contribution of the terms involving the $R(^4B_2)$. That the ^2E peak of the fluoro complex is of the same sign as the ^4E one suggests a weak spin-orbit coupling between the $^2E(^2T_2)$ and $^4B_2$ state. In fact, no double peaks of the $^4B_2$ component is observed in absorption and CD spectra of the fluoro *R*-pn complex. Although a negative peak is observed at 15680 cm^{-1}, no negative sign is expected in this region. The vibronic CD theory for electric dipole forbidden and magnetic dipole allowed transitions which are spin-allowed either in zeroth order or in first order *via* a spin-orbit coupling expects the mixed signs of CD and that vibrational progressions of totally symmetric modes on electronic origins should contribute to CD spectra.[40] Therefore, this CD peak with negative sign together with other positive peaks unassigned may be due to the vibronic bands.*** The strong intensities of vibronic bands observed in CD are compatible with those in absorption spectra.[14]

For the *S,S*-stien complex (Fig. 9 a), the 12700 cm^{-1} peak with negative sign may be assigned to the $^2E(^2T_1)$ state. It appears that the $^2B_1$ and $^2A_1$ state correspond to a weak 14650 cm^{-1} and a strong 14950 cm^{-1} peak, respectively. The 15210 cm^{-1} peak is due to the $^2A_2(^2T_1)$ state, of which the CD intensity is about one fourth of that of the $^2A_1$ peak. The remaining peaks may be ascribed to the vibronic origins. It seems plausible that the CD signs of these peaks agree with those of the CD bands in the first spin-allowed transitions.

The Chloro Complexes with R-*pn and* S,S-*stien.* The luminescence spectrum of *trans*-$[CrCl_2(en)_2]^+$ has shown that the lowest frequency doublet state locates at 14380 cm^{-1}.[11] For the *S,S*-stien complex, the lowest frequency negative CD peak at 14270 cm^{-1} is the most intense and hence this peak is assigned to the $^2A_1$ state. The next-neighbouring peak at 14500 cm^{-1} may be due to the $^2B_1$ state. The CD peak at 15070 cm^{-1} may be assigned to the $^2A_2$ state, because the CD intensity of this peak is about one fourth of that of the $^2A_1$ component, as theoretically expected. Further, since the ^2E state is expected to lie at the lower frequency than the $^2A_2$ state, the CD peak at 14810 cm^{-1} may be assigned to the ^2E state.

The most intense CD peak of the *R*-pn complex at 14340 cm^{-1} may be due to the $^2A_1$, and it seems that the $^2B_1$, ^2E and $^2A_2$ state correspond to the 14580, 14700 and 15020 cm^{-1} peaks, respectively, although the lowest frequency peak at 14080 cm^{-1} can not be identified. In this complex also the $^2A_2$ peak is weaker than the $^2A_1$ one. It needs to be noted that the $^2E(^2T_1)$ component is negative and of the same sign as the $^4B_2$ one. This sign inversion may be attributed to that a spin-orbit coupling between the $^2E(^2T_2)$ and $^4B_2$ state is strong enough to cause the additional contribution of the term involving the $R(^4B_2)$, $(2/3)\zeta_4'^2\varepsilon_2^{-2}\{1+4\varepsilon_4^{-2}(\delta\pi)^2\}\cdot R(^4B_2)$, and to overcome the term involving the $R(^4E)$, $(1/12)(3\zeta_2'^2+\zeta_1'^2)\varepsilon_1^{-2}\cdot R(^4E)$, as discussed in the previous section. In fact, such a strong spin-orbit coupling gives rise to the splitting of the $^4B_2$ component in absorption spectra by about 400 cm^{-1} as in Fig. 1. The positions and the splitting of the doublet states of this complex is in accordance with the crystal field calculation for the corresponding ethylenediamine complex.[2,3] The remaining CD peaks may be due to the vibronic bands, though some negative peaks are observed.

The Bromo Complexes with R-*pn and* S,S-*stien.* The *R*-pn complex gives only two positive CD peaks at 14290 cm^{-1} and 14650 cm^{-1} (Fig. 8c). Thus, the lower frequency 14290 cm^{-1} peak and the higher frequency 14650 cm^{-1} peak are assigned to the $^2A_1$ and $^2A_2$ state, respectively, because their rotational strengths should have the same sign as the $R(^4E)$ and the $^2A_1$ state should lie at the lower frequency than the $^2A_2$ state from a theoretical point of view. Contrary to the other complexes mentioned before, however, the $^2A_2$ peak is more intense than the $^2A_1$ one. This may be due to the large mutual cancellation among the neighbouring CD peaks with alternate signs. For the bromo complexes, the crystal field approximation predicts the lowest frequency shift of the $^2E(^2T_1)$ state.[2,3] Therefore, a negative CD peak at 14080 cm^{-1} may be due to the ^2E state. The negative sign of this

*** The influences of the methyl group of *R*-pn in the present complex on the vibronic CD bands are disregarded, since the CD pattern in the spin-forbidden transitions of the fluoro complex with *R*-pn is found to be quite identical with that of the fluoro complex with *R,R*-cyclohexanediamine which was prepared by the method of Glerup *et al.*[22]

peak implies a strong spin-orbit coupling between the $^2E(^2T_2)$ and $^4B_2$ state, which may give rise to the splitting of the $^4B_2$ component in CD spectrum of this complex as in Fig. 4. The $^2B_1$ state may correspond to a negative peak at 14390 cm^{-1}. The negative sign of the $^2B_1$ state is caused by the vanishing decrease in ζ_3' owing to the large ζ_p of the axial ligand, in which case the term involving the $R(^4B_2)$ is $16(\zeta_1'/\zeta_4')^2$-$(\varepsilon_1/\varepsilon_2)^2$ times as large as that involving the $R(^4E)$ and, assuming $(\varepsilon_1/\varepsilon_2)^2 \simeq 1/8$ and $(\zeta_1'/\zeta_4')^2 = \beta^*_{55}(N)/\beta^*_{55}(Br) \gg 1$, thus overwhelming the $R(^4E)$.

From comparison with the *R*-pn complex, three CD peaks observed for the *S,S*-stien complex are assigned to the $^2A_1$, $^2B_1$ and $^2A_2$ state from the lower frequency side, respectively, though the ^2E component is missing.

The S,S-*2,4-ptn Complexes.* The *S,S*-2,4-ptn complexes show anomalous CD patterns in the spin-forbidden band region, compared with the *R*-pn and *S,S*-stien complexes as in Fig. 10. That is, relatively intense structural CD bands with positive sign are observed in the region of 16500—14500 cm^{-1}. Although the shift pattern with varying the axial ligands is similar to that of the ^4E component, suggesting that these bands seem to be associated with the spin-allowed transitions, they can not be assigned at the present. The spin-forbidden transitions may occur at the lower frequency side than these anomalous CD bands, but overlapping of some of them with the anomalous bands makes their assignments difficult. The tentative assignments are made as follows. For the fluoro complex, the lowest frequency CD peak at 13950 cm^{-1} with negative sign may be due to the ^2E state, and the 14850 cm^{-1} and 15080 cm^{-1} peaks to the $^2B_1$ and $^2A_1$ states, respectively, as in the case of the other fluoro complexes. It seems plausible that the $^2A_1$ peak exhibits the same sign as the ^4E one. The $^2B_1$ peak is of the same sign as the $^4B_2$ one. This is because of the $(\varepsilon_2/\varepsilon_1)^2 \simeq 3$ and $R(^4E)/R(^4B_2) \simeq -1$ and hence $R(^2B_1) = (4/9)\zeta_1'^2\varepsilon_1^{-2}\{R(^4E) + 4/3R(^4B_2)\} \simeq (4/27)\zeta_1'^2\varepsilon_1^{-2}$-$R(^4B_2)$ where $\zeta_1' \simeq \zeta_2' \simeq \zeta_3' \simeq \zeta_4'$ for the fluoro complex with *S,S*-2,4-ptn. The $^2A_2$ peak is obscured by the rather intense positive band. For the chloro complex, only one negative CD peak was observed at 14410 cm^{-1} and this may be due to the $^2A_1$ state. The 14590 cm^{-1} peak with positive sign may be assigned to the $^2B_1$ state, since the crystal field calculation predicts that the $^2B_1$ state lies at the higher frequency side of the $^2A_1$ state. The positive sign of the $^2B_1$ state may be caused by the considerable decrease in ζ_3' owing to the large ζ_p and the increasing contribution of the term involving the $R(^4B_2)$, as in the case of the bromo complex with *R*-pn. The $^2E(^2T_1)$ state may correspond to a positive peak observed at 14880 cm^{-1}. This positive sign may be attributed to a strong spin-orbit coupling as found for the chloro complex with *R*-pn. For the bromo complex, only in view of the transition energies, the 14330, 14510, and 14640 cm^{-1} CD peaks may be due to the $^2A_1$, $^2B_1$ and $^2A_2$ state, respectively, although their signs are all positive.

Conclusion. On the basis of the assignments thus obtained for the three series of complexes as in Table 1, it has been found that the positions of the $^2A_1$ state are shifted to the lower frequency in the order of the fluoro, chloro and bromo complexes, demonstrating the nephelauxetic effect.[37] The splitting of the ^2E cubic state, $E(^2A_1) - E(^2B_1)$, is found to be about +300 cm^{-1} for the fluoro, about −250 cm^{-1} for the chloro and −100 to −150 cm^{-1} for the bromo complexes, although the *S,S*-2,4-ptn complexes give somewhat smaller splittings. The splitting obtained for the chloro and bromo complexes is in an order of magnitude larger than the theoretical value estimated from Macfarlane's approximation on the crystal field calculation. That is, the theoretical splittings are obtained as +180, −41 and −11 cm^{-1} for the fluoro, chloro and bromo complexes, respectively, by using the parameter values estimated by Dubicki *et al.*[4] As observed[12,13] and discussed for the pentaammine aniono Cr(III) complexes by Flint and Matthews,[13] such a large splitting of the ^2E cubic state can not be elucidated by the crystal field theory. The positions of the $^2E(^2T_1)$ state vary with the coordinated diamines, *i.e.*, 13098 cm^{-1} for the en complex,[14] 13330 cm^{-1} for the *R*-pn complex, 12710 cm^{-1} for the *S,S*-stien complex, and 13950 cm^{-1} for the *S,S*-2,4-ptn complex. This is probably caused by variation of the parameters $\delta\pi$ and ε_3 for the diamines.

Transition-metal Complexes of Pyrrole Pigments. XII. Optical and Magnetic Resonance Spectra of the Cobalt(II) and Nickel(II) Complexes of 1,19-Disubstituted Tetradehydrocorrins†

Yukito MURAKAMI, Kazunori SAKATA, Yasuhiro TANAKA, and Tadashi MATSUO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received July 10, 1975)

The cobalt(II) and nickel(II) complexes of 1,19-dimethyl- and 1,19-diethoxycarbonyltetradehydrocorrins were prepared by the template reaction as functioned by metal ions from the corresponding 1,19-disubstituted 1,19-dideoxybiladiene-ac's. The absorption bands appearing in the energy region greater than 15000 cm^{-1} were attributed to the $\pi \rightarrow \pi^*$ transitions within a ligand molecule. The ligand-field bands were observed in the lower energy region ($<15000\ cm^{-1}$) for the cobalt(II) complexes in which cobalt(II) assumes the C_{2v} coordination symmetry: $^2A_1 \leftarrow {}^2A_1$, $^2A_2 \leftarrow {}^2A_1$, $^2B_2 \leftarrow {}^2A_1$, and $^2B_1 \leftarrow {}^2A_1$ in an increasing order of energy. The vibrational spectra provided evidences for the formation of the tetradehydrocorrin complexes with perchlorate ion as the counter ion. The angular methyl groups placed at the 1- and 19-positions of tetradehydrocorrins showed the abnormally large up-field shift (2.0 ppm) of their proton signal relative to the parent biladiene-ac's due to the magnetic anisotropy of the adjacent pyrrole rings A and D. For a 1,19-diethyoxycarbonyltetradehydrocorrin complex, the 1,19-substituents were also placed in the shielding zone of the neighboring pyrrole rings. In the case of the cyclized 2,8,12,18-tetra(2-ethoxycarbonylethyl) derivative, the ethyl ester groups of the 2,18-substituents were presumably placed in a conformational space different from that occupied by those of the 8,12-substituents according to the proton NMR behaviors. The parent biladiene-ac which carries ethoxycarbonyl groups at the 1,19-positions caused a up-field shift of its methine (at bridge positions) proton signal upon cyclization due to the loss of electronic conjugation of carbonyl groups with pyrrole rings, in consistent with the vibrational data. The ESR spectra were measured in chloroform–benzene (2 : 1) at 77 K in the presence and absence of pyridine. The cobalt(II) complexes were identified as of low-spin square-planar type with the unpaired electron in the cobalt d_{z^2} orbital. The coordination capability of 2-ethoxycarbonylethyl groups, which are directly bound to the pyrrole rings in the cyclized metal complex system, was also suggested.

Much work has been carried out on vitamin B_{12} model compounds of the cobaloxime type to obtain some information which may throw light on the chemistry of vitamin B_{12} itself.[1,2] On the other hand, 1,19-disubstituted tetradehydrocorrins have a ring structure which is closely related to the corrin ring of vitamin B_{12}. The cobalt complexes are of particular interest since these are the direct analogs of the vitamin B_{12} complexes. Hush and Woolsey studied the electronic and ESR spectra of the cobalt(II) and nickel(II) complexes of 1,19-diethoxycarbonyltetradehydrocorrins[3,4] without assignments of ligand-field bands observable in the electronic spectra.

On account of the increasing interest in the chemistry and structural feature of vitamin B_{12}, we report in this paper the results of electronic spectra of the cobalt(II) and nickel(II) complexes of 1,19-dimethyl- and 1,19-diethoxycarbonyltetradehydrocorrins with ligand-field interpretations as well as vibrational spectra of the complexes. The detailed NMR studies for the nickel(II) complexes and the ESR data for the cobalt(II) are also provided. The metal complexes of 1,19-disubstituted tetradehydrocorrins (**2**) were prepared by the template reaction as functioned by metal ions from the corresponding 1,19-disubstituted 1,19-dideoxybiladiene-ac's (**1**).

Experimental

1,19-Dideoxy-1,3,7,8,12,13,17,19-octamethylbiladiene-ac Dihydrobromide (3). Prepared after Johnson *et al.*[5] from 3,3′,4,4′-tetramethyl-5,5′-dicarboxydipyrromethane[6,7] (14.0 g) and 2-formyl-3,5-dimethylpyrrole[8] (11.5 g) in methanol (1150 ml) and aqueous ammonia (3.3 ml, 28%), the resulting solution being treated with aqueous hydrobromic acid (33 ml, 47%). The product was recrystallized from chloroform as red prisms with a green luster; yield 18.1 g (66%). UV($CHCl_3$): 19200(ε 2.05×10^5), 20400 sh(ε 3.58×10^4), 22100(ε 2.10×10^4), 23500 sh(ε 9.20×10^3), 27100(ε 1.37×10^4), and 34400 cm^{-1}(ε 2.73×10^3). IR(Nujol mull): 1611 cm^{-1}(biladiene skeletal str.). Found: C, 56.41; H, 6.05; N, 9.49%. Calcd for $C_{27}H_{34}Br_2N_4$: C, 56.46; H, 5.97; N, 9.75%.

1,19-Dideoxy-1,2,3,7,8,12,13,17,18,19-decamethylbiladiene-ac Dihydrobromide (4). Prepared as above[9] from 3,3′,4,4′-tetramethyl-5,5′-dicarboxydipyrromethane (1.5 g) and 2-

† Contribution No. 377 from this Department. Part XI: Y. Murakami and K. Sakata, This Bulletin, **47**, 3025 (1974).

formyl-3,4,5-trimethylpyrrole[10,11] (0.75 g) in methanol (150 ml) and aqueous ammonia (0.2 ml, 28%). The resulting solution was treated with aqueous hydrobromic acid (3 ml, 47%) and the product was recrystallized from chloroform–light petroleum as red prisms; yield 1.4 g (67%).

1,19-Dideoxy-8,12-di(2-ethoxycarbonylethyl)-1,2,3,7,13,17,18,19-octamethylbiladiene-ac Dihydrobromide (5). 3,3′-Di(2-ethoxycarbonylethyl)-4,4′-dimethyldipyrromethane-5,5′-dicarboxylic acid (**6**) was first prepared as follows. Dibenzyl 3,3′-di(2-ethoxycarbonylethyl)-4,4′-dimethyldipyrromethane-5,5′-dicarboxylate[12] (10 g) was hydrogenated in dry tetrahydrofuran (250 ml) and triethylamine (0.5 g) over 10% palladium–carbon (1.25 g) for 2 h. Saturated aqueous sodium hydrogen carbonate was added to the resulting mixture and tetrahydrofuran was removed *in vacuo* from the filtrate. The precipitates obtained by the addition of acetic acid were recovered and washed repeatedly with water; white powder, yield 6.1 g (85%), mp>300 °C. IR(KBr disk): 1710 (ester C=O str.), and 1656 cm^{-1} (carboxyl C=O str.). NMR (H_2O-KOH, tetramethylammonium chloride): δ 1.56 (2H, s, $-CH_2-$(bridge)), 0.64 (4H, q J=7.0 Hz, 3,3′-CH_3CH_2-$OCOCH_2CH_2-$), −0.18—−0.46 (8H, m, 3,3′-CH_3CH_2 $OCOCH_2CH_2-$), −0.75 (6H, s, 4,4′-CH_3), and −1.85 (6H, t J=7.0 Hz, 3,3′-$CH_3CH_2OCOCH_2CH_2-$).

The biladiene-ac dihydrobromide (**5**) was prepared[13] from **6** (1.51 g) and 2-formyl-3,4,5-trimethylpyrrole (0.68 g) in ethanol (7 ml) and aqueous hydrobromic acid (1 ml, 47%). The product was washed and recrystallized from chloroform–light petroleum (bp 80—100 °C) as red needles; yield 1.03 g (40%), mp>300 °C. IR(KBr disk): 1732 (ester C=O str.), 1616 (biladiene skeletal str.), and 1245 cm^{-1} (C–O–C str.). Found: C, 56.90; H, 6.41; N, 7.09%. Calcd for $C_{37}H_{50}Br_2N_4O_4$: C, 57.37; H, 6.51; N, 7.23%.

1,19-Dideoxy-2,8,12,18-tetra(2-ethoxycarbonylethyl)-1,3,7,13,17,19-hexamethylbiladiene-ac Dihydrobromide[13] (7). A mixture of 3,3′-di(2-ethoxycarbonylethyl)-4,4′-dimethyldipyrromethane-5,5′-dicarboxylic acid (2.31 g), aqueous ammonia (0.4 ml, 28%), and methanol (50 ml) was refluxed with stirring. After addition of 3-(2-ethoxycarbonylethyl)-5-formyl-2,4-dimethylpyrrole[13] (2.23 g) dissolved in methanol (20 ml) and aqueous hydrobromic acid (3.5 ml, 47%) subsequently, the reaction mixture was refluxed for another 15 min with stirring. Upon cooling the mixture in a refrigerator overnight, the crystalline solid was recrystallized from chloroform–acetone to give red needles; yield 2.8 g (59%), mp>300 °C. IR(KBr disk): 1728 (ester C=O str.), 1610 (biladiene skeletal str.), and 1237 cm^{-1} (C–O–C str.).

1,19-Dideoxy-1,19-diethoxycarbonyl-2,3,7,8,12,13,17,18-octamethylbiladiene-ac Dihydrobromide[14] (8). A mixture of phosphorus oxychloride (13 ml) and *N,N*-dimethylformamide (100 ml) was added dropwise into 3,4-dimethyl-2-ethoxycarbonylpyrrole[6] (20.8 g) which was dissolved in *N,N*-dimethylformamide (200 ml) and cooled with ice-water. An aqueous solution (700 ml) of anhydrous sodium acetate (44 g) was added into the reaction mixture, which was heated at 70—80 °C for 1 h subsequently. After being allowed to stand overnight in a refrigerator, the crystalline solid was recovered and recrystallized from *i*-octane to give colorless plates of 3,4-dimethyl-2-ethoxycarbonyl-5-formylpyrrole; yield 19.4 g (79.8%), mp 107.5—108.0 °C (lit,[15] mp 106—108 °C). IR(Nujol mull): 3320 (N–H str.), 1692, 1656 (C=O str.), and 1265 cm^{-1} (C–O–C str.). NMR(CCl_4, TMS): δ 1.39 (3H, t J=7.0 Hz, 2-CH_3CH_2OCO-), 2.23, 2.27 (6H, each s, 3-CH_3 and 4-CH_3), 4.38 (2H, q J=7.0 Hz, 2-CH_3CH_2-$OCO-$), 9.77 (1H, s, 5-CHO), and 10.03 (1H, s, 1-H).

Into a mixture of 3,4-dimethyl-2-ethoxycarbonyl-5-formylpyrrole (2.05 g), 3,3′,4,4′-tetramethyldipyrromethane-5,5′-dicarboxylic acid (1.3 g) and glacial acetic acid (25 ml) was added aqueous hydrobromic acid (5.5 ml, 47%) with stirring. The mixture was warmed at 40—43 °C for 40 min and allowed to stand in a refrigerator overnight. The crystalline solid was washed with acetic acid and ethyl ether subsequently to give reddish brown needles; yield 2.35 g (72.4%), mp>300 °C. IR(Nujol mull): 1705, 1712 (ester C=O str.), and 1604 cm^{-1} (biladiene skeletal str.).

1,3,7,8,12,13,17,19-Octamethyltetradehydrocorrinatocobalt(II) Perchlorate. Air was bubbled through a mixture of biladiene-ac dihydrobromide (**3**) (0.5 g), cobalt acetate tetrahydrate (0.5 g), and ethanol (30 ml) at room temperature for 6 h. The mixture was concentrated to *ca.* 10 ml *in vacuo*, and subsequently an aqueous solution (10 ml) of sodium perchlorate monohydrate (0.5 g) was added into it. The precipitates were separated and recrystallized from methanol–acetone to give dark brown needles; yield 0.29 g (59%), mp>300 °C. Found: C, 56.82; H, 5.12; N, 9.84%. Calcd for $C_{27}H_{29}ClCoN_4O_4$: C, 57.10; H, 5.15; N, 9.87%.

1,3,7,8,12,13,17,19-Octamethyltetradehydrocorrinatonickel(II) Perchlorate. A mixture of biladiene-ac dihydrobromide (**3**) (0.5 g), nickel acetate tetrahydrate (0.5 g), and ethanol (7 ml) was heated at 60 °C for 30 min. The stream of air was bubbled through the reaction mixture into which anhydrous sodium acetate (0.5 g) was added in advance. An aqueous solution (7.5 ml) of sodium perchlorate monohydrate (1 g) was added in the reaction mixture which was subsequently kept in a refrigerator overnight. The recovered crystalline solid was recrystallized from chloroform to give dark violet needles; yield 0.135 g (68%). Found: C, 56.90; H, 5.24; N, 10.00%. Calcd for $C_{27}H_{29}ClN_4NiO_4$; C, 57.12; H, 5.15; N, 9.87%.

1,2,3,7,8,12,13,17,18,19-Decamethyltetradehydrocorrinatocobalt-(II) Perchlorate. Prepared from biladiene-ac dihydrobromide (**4**) (2.3 g) and cobalt acetate tetrahydrate (2.3 g) in ethanol (200 ml) after Melent'eva *et al.*[9] The product was recrystallized from methanol–acetone to give dark brown prisms of golden luster; yield 1.42 g (62%). Found: C, 58.27; H, 5.62; N, 9.53%. Calcd for $C_{29}H_{33}ClCoN_4O_4$: C, 58.44; H, 5.58; N, 9.40%.

1,2,3,7,8,12,13,17,18,19-Decamethyltetradehydrocorrinatonickel-(II) Perchlorate. Prepared from biladiene-ac dihydrobromide (**4**) (1.4 g) and nickel acetate tetrahydrate (1.4 g) in the presence of anhydrous sodium acetate (1.4 g) and ethanol (200 ml) after Melent'eva *et al.*[9] The product was recrystallized from methanol–acetone to give dark brown needles; yield 0.83 g (60%). Found: C, 58.77; H, 5.73; N, 9.52%. Calcd for $C_{29}H_{33}ClN_4NiO_4$: C, 58.47; H, 5.58; N, 9.40%.

8,12-Di(2-ethoxycarbonylethyl)-1,2,3,7,13,17,18,19-octamethyltetradehydrocorrinatocobalt(II) Perchlorate. Prepared from biladiene-ac dihydrobromide (**5**) (0.287 g) and cobalt acetate tetrahydrate (0.30 g in 3 ml H_2O) in ethanol (100 ml) after Johnson *et al.*[13] The crystalline solid was washed with ethyl ether (100 ml) and *n*-hexane (40 ml) successively and recrystallized from dichloromethane–*n*-hexane to give reddish brown needles; yield 0.075 g (27%), mp 225.0—225.2 °C (lit.,[13] mp 181—183 °C). Found: C, 58.15; H, 5.96; N, 6.98%. Calcd for $C_{37}H_{45}ClCoN_4O_8$: C, 57.85; H, 5.91; N, 7.29%.

8,12-Di(2-ethoxycarbonylethyl)-1,2,3,7,13,17,18,19-octamethyltetradehydrocorrinatonickel(II) Perchlorate. Prepared from biladiene-ac dihydrobromide (**5**) (0.52 g) and nickel acetate tetrahydrate (0.60 g) in the presence of anhydrous sodium acetate (0.60 g) and ethanol (15 ml) after Johnson *et al.*[13] The product was recrystallized from ethanol–light petroleum

(bp 80—100 °C) to give violet needles; yield 0.37 g (71%), mp 243.2—244.3 °C (lit.,[13] mp 243—244 °C). Found: C, 58.08; H, 5.83; N, 7.21%. Calcd for $C_{37}H_{45}ClN_4NiO_8$: C, 57.87; H, 5.91; N, 7.30%.

2,8,12,18 - Tetra(2 - ethoxycarbonylethyl) - 1,3,7,13,17,19 - hexamethyltetradehydrocorrinatocobalt(II) Perchlorate. Prepared from biladiene-ac dihydrobromide (**7**) (1.0 g) and cobalt acetate tetrahydrate (1.0 g in 10 ml H_2O) in ethanol (200 ml) after Johnson *et al.*[13] The crystalline solid was washed with ethyl ether (100 ml) and recrystallized from ethanol–light petroleum (bp 80—100 °C) to give dark reddish needles; yield 0.50 g (48%), mp 139.9—141.7 °C (lit.,[13] mp 175 °C). Found: C, 56.85; H, 6.03; N, 5.89%. Calcd for $C_{45}H_{57}ClCON_4O_{12}$: C, 57.48; H, 6.11; N, 5.96%.

2,8,12,18 - Tetra(2 - ethoxycarbonylethyl) - 1,3,7,13,17,19 - hexamethyltetradehydrocorrinatonickel(II) Perchlorate. Prepared from biladiene-ac dihydrobromide (**7**) (1.0 g) and nickel acetate tetrahydrate (1.0 g) in the presence of anhydrous sodium acetate (1.0 g) and ethanol (50 ml) after Johnson *et al.*[13] The product was recrystallized from ethanol–light petroleum (bp 80—100 °C) to give reddish violet needles; yield 0.56 g (56%), mp 162.4—165.6 °C (lit.,[13] mp 169—170 °C). Found: C, 57.70; H, 5.97; N, 6.16%. Calcd for $C_{45}H_{57}ClN_4NiO_{12}$: C, 57.49; H, 6.11; N, 5.96%.

1,19 - Diethoxycarbonyl - 2,3,7,8,12,13,17,18 - octamethyltetradehydrocorrinatocobalt(II) Perchlorate.[14] An aqueous solution (25 ml) of cobalt acetate tetrahydrate (5.0 g) was added into an ethanol suspension (500 ml) of biladiene-ac dihydrobromide (**8**) (5.0 g). Air was introduced into the reaction mixture at room temperature for 2 hr with continuous stirring, which was subsequently concentrated to a half volume. After addition of an aqueous solution (30 ml) of sodium perchlorate monohydrate (5.0 g), the reaction mixture was allowed to stand in a refrigerator for 3 hr. The crystalline solid was washed with ethyl ether and recrystallized from acetone–*n*-hexane to give brown pillar-like crystals of golden luster; yield 4.2 g (85%), mp> 300 °C. Found: C, 55.89; H, 5.46; N, 7.92%. Calcd for $C_{33}H_{37}ClCoN_4O_8$: C, 55.67; H, 5.24; N, 7.87%.

1,19 - Diethoxycarbonyl - 2,3,7,8,12,13,17,18 - octamethyltetradehydrocorrinatonickel(II) Perchlorate.[14] A methanol solution (10 ml) of nickel acetate tetrahydrate (2.0 g) was added into a methanol suspension (200 ml) of biladiene-ac dihydrobromide (**8**) (2.0 g). The mixture was refluxed for 2 hr while air was continuously bubbled through it, and then concentrated to a half volume. After addition of an aqueous solution (100 ml) of sodium perchlorate monohydrate (2.0 g), the reaction mixture was allowed to stand overnight in a refrigerator. The crystalline product was recrystallized from acetone–*n*-hexane to give brown pillar-like crystals; yield 1.7 g (86%), mp> 300 °C. Found: C, 55.53; H, 5.20; N, 7.76%. Calcd for $C_{33}H_{37}ClN_4NiO_8$: C, 55.67; H, 5.24; N, 7.89%.

Spectral Measurements. Electronic spectra covering the 5000—40000 cm^{-1} region were recorded on a Hitachi EPS-2 spectrophotometer for chloroform solutions at room temperature. Vibrational spectra were measured with a JASCO DS-403G spectrophotometer by Nujol mull and KBr disk methods. A Varian A-60 spectrometer was used to obtain NMR spectra in trifluoroacetic acid at room temperature. Chemical shifts were reported in ppm from internal TMS and calibrated by the use of chloroform signal as the external reference. ESR spectra were recorded on a JEOL JES-ME-3 X-band spectrometer equipped with a 100K Hz field modulation unit. All samples were measured in chloroform–benzene (2 : 1) at 77 K, concentrations being maintained in the 10^{-2} M range. The manganese ion diffused into magnesium oxide was used to obtain the standard reference signals for measurements.

Results and Discussion

Electronic Spectra. The electronic spectra of the cobalt(II) and nickel(II) complexes are shown in Figs. 1 and 2, respectively, and the absorption bands appearing in the energy region greater than 15000 cm^{-1} are reasonably attributed to the $\pi\rightarrow\pi^*$ transitions within a ligand molecule. The general features of the spectra arising from the $\pi\rightarrow\pi^*$ transitions are similar to those observed for metal porphyrins[16,17] and corrins.[18] An extremely intense band is observed around 28000 cm^{-1} analogous to the Soret band of porphyrins, with a weaker series of bands in the 15000—25000 cm^{-1} region comparable with the α and β bands of metal porphyrins. Hush and his associates have established on the basis of PPP-SCF π-electron calculations [4,19] that the absorption bands of metal corroles appearing in the similar energy region arise from the $\pi\rightarrow\pi^*$ transitions of the corrole ligand. The $\pi\rightarrow\pi^*$ transition energies for the present cobalt(II) and nickel(II) complexes are summarized together in Table 1.

The nickel(II) complexes do not show any significant absorption in the region lying below 15000 cm^{-1}. This spectral behavior is consistent with the square planar coordination of nickel(II).[20] Due to the presence of intense $\pi\rightarrow\pi^*$ absorption bands in the higher energy region, we failed to assign ligand-field transition bands for the nickel(II) complexes.

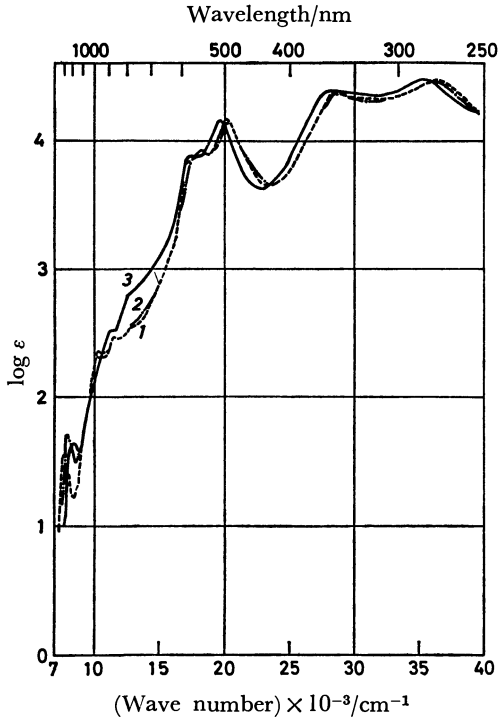

Fig. 1. Electronic absorption spectra of the tetradehydrocorrinatocobalt(II) perchlorates in chloroform at room temperature. Ligands: **1**, 1,2,3,7,8,12,13,17,18,19-decamethyltetradehydrocorrin; **2**, 8,12-di(2-ethoxycarbonylethyl) - 1,2,3,7,13,17,18,19 - octamethyltetradehydrocorrin; **3**, 1,19-diethoxycarbonyl-2,3,7,8,12,13,17,18-octamethyltetradehydrocorrin.

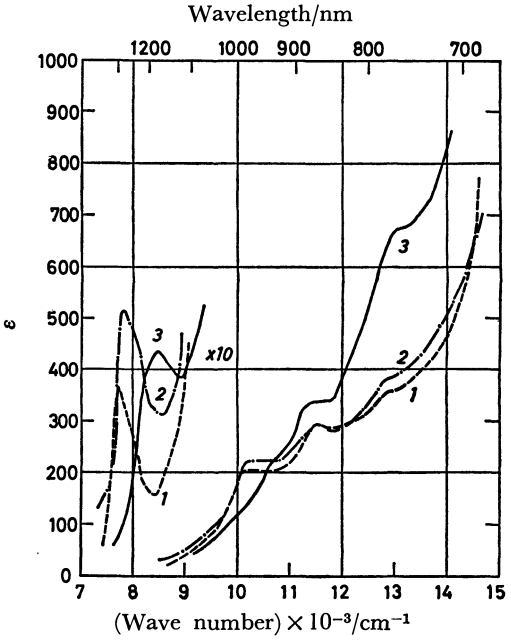

Fig. 3. Ligand-field spectra of the tetradehydrocorrinatocobalt(II) perchlorates in chloroform at room temperature. See Fig. 1 for numbering of the ligands.

The absorption spectra of the cobalt(II) complexes in the lower energy region (below 15000 cm^{-1}) are shown in Fig. 3. Nishikawa and Yamada pointed out that the ligand-field band appeared at around 8000 cm^{-1} is characteristic of the square planar low-spin cobalt(II) complexes.[21] The present cobalt(II) complexes show a distinct absorption band in the similar energy region. Meanwhile, Nishida and Kida[22] and Engelhardt and Green[23] as well have carried out ligand-field calculations for tetragonal low-spin d^7 complexes using a d^3 hole ligand-field model. We employed a energy level correlation different from these proposed by the former investigators on the basis of band-splitting behavior of the present spectra, and the ligand-field bands are assigned under the assumption of C_{2v} coordination

symmetry in consistent with the spectral feature shown in Fig. 3, as listed in Table 2.

Vibrational Spectra. The characteristic IR bands, which are meaningful for the present discussion, are summarized in Table 3 for metal-free biladiene-ac's and tetradehydrocorrin complexes. A strong absorption band observed at around 1600 cm^{-1} for a biladiene-ac dihydrobromide can be attributed to the stretching mode of the dipyrromethene skeleton. The similar spectral feature has been observed for dipyrromethenes,[24-29] tripyrrene-b, and bilene-b.[30] This characteristic band loses its intensity to a large extent as seen in Fig. 4 upon formation of the tetradehydrocorrin macrocycle in a manner as observed for the porphyrin system.[31] The change in absorption intensity may be due to the structural nature of the macrocycle which is nearly fixed in one plane. This structural effect would inhibit the independent skeletal vibration of each pyrrole ring and consequently diminish its IR activity.

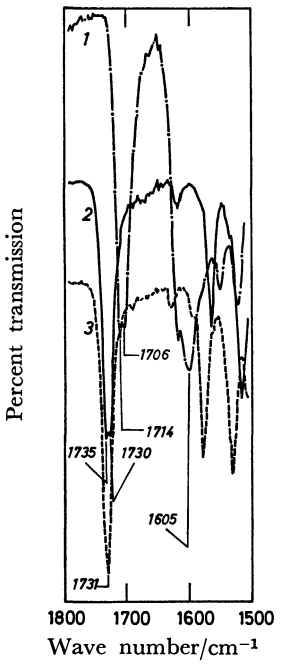

Fig. 4. Infrared spectra of biladiene-ac dihydrobromide and tetradehydrocorrin complexes by a Nujol mull technique: **1**, 1,9-dideoxy-1,19-diethoxycarbonyl-2,3,7,8,12,13,17,18-octamethylbiladiene-ac dihydrobromide; **2**, 1,19-diethoxycarbonyl-2,3,7,8,12,13,17,18-octamethyltetradehydrocorrinatocobalt(II) perchlorate; **3**, 1,19-diethoxycarbonyl-2,3,7,8,12,13,17,18-octamethyltetradehydrocorrinatonickel(II) perchlorate.

Since the carbonyl group of 2-ethoxycarbonylethyl in the biladiene-ac's does not have any electronic interaction with the pyrrole rings due to the structural reasons, the corresponding stretching mode is not affected by metal coordination as seen in spectra for the corresponding metal tetradehydrocorrins (III and IV in Table 3). On the other hand, the ethoxycarbonyl groups of 1,19-dideoxy-1,19-diethoxycarbonyl-2,3,7,8,12,13,17,18-octamethylbiladiene-ac lose their electronic conjugation with the pyrrole rings upon formation of the tetradehydrocorrin ring. Consequently, the C=O stretching band due to these carbonyl groups, which is observed in a relatively low frequency region for the biladiene-ac, is shifted to higher frequency upon metal coordination (V is Table 3).

A strong broad absorption at around 1080 cm^{-1} was observed for all the metal complexes and attributed to the stretching vibrational mode of perchlorate ion.[32] Since no splitting of this characteristic band was detected, the perchlorate group in the present metal complexes may be present not as a coordinated group but as a simple isolated ion.[33] Another peak due to the perchlorate group was observed at about 620 cm^{-1}, which may be attributed to its bending vibration.[33]

NMR Spectra. The NMR data for the 1,19-dideoxybiladiene-ac's and the corresponding tetradehydrocorrinatonickel(II) complexes are summarized in Table 4. The methyl-proton peak observed in the lowest field (2.72—2.77 ppm) for the biladiene-ac's is shifted to up-field by about 2.0 ppm upon cyclization along with nickel(II)-coordination (I—IV in Table 4). The abnormally large up-field shift is most likely associated with the angular methyl groups of the 1- and 19-positions.[15] The angular methyl groups placed at the 1- and 19-positions of tetradehydrocorrin are subjected to the shielding effect caused by the magnetic anisotropy of the adjacent pyrrole rings A and D. The proton signals for other methyl groups directly bound to the pyrrole rings show the down-field shift upon cyclization to form the tetradehydrocorrin macrocycle. These down-field shifts can be attributed to the deshielding effect due to positive charge provided by nickel(II) as well as to the additional anisotropy by the macrocyclic ring system. A similar behavior of methyl resonances has been observed for the zinc(II) chelates of dipyrromethenes.[29]

In the case of the cyclized 1,19-diethoxycarbonyl derivative, the 1,19-substituents are also placed in the shielding zone of the neighboring pyrrole rings as

observed for the angular methyl groups mentioned above. Thus, the methylene-proton peaks ($CH_3C\underline{H}_2$-OCO–) and the methyl-proton signals ($C\underline{H}_3CH_2OCO$–) show up-field shifts by 0.5 and 0.4 ppm, respectively, upon cyclization. The magnitude of up-field shifts for these ethyl groups is much smaller than those observed for the angular methyl groups. This is primarily due to the fact that the ethyl ester groups are placed further from the adjacent pyrrole rings, which provide magnetic anisotropy, relative to the angular methyls.

In the case of the cyclized 2,8,12,18-tetra(2-ethoxycarbonylethyl) derivative (IV in Table 4), the proton signals for ester-methylene ($CH_3C\underline{H}_2OCOCH_2CH_2$–) and ester-methyl ($C\underline{H}_3CH_2OCOCH_2CH_2$–) of the 2-ethoxycarbonylethyl group were observed as quintet and quartet, respectively. These peaks were analyzed as the overlaps of two quartet and of two triplet, respectively, for the quintet and quartet signals. This seems to indicate that the ethyl ester groups of the 2,18-substituents are placed in a conformational space different from that occupied by those of the 8,12-substituents. Consequently, one type of these ethyl ester groups secures the magnetic anisotropy effect due to the macrocyclic ring system in a manner different from the other.

The cyclization of biladiene-ac's, which do not carry any carbonyl group in conjugation with the pyrrole rings, causes a down-field shift of the proton signal due to the 5- and 15-methine groups. Another proton peak was observed in a lower field relative to the above one for the same tetradehydrocorrins along with the disappearance of the proton signal due to the 10-methylene group of the biladiene-ac precursors. Only exception is noticed in the case of tetradehydrocorrin complex II (see Table 4): the reversed relation of these proton signals is observed although the reason for this is not obvious at present. These down-field shifts may be attributed to the presence of aromaticity in the chelate rings as well as the electron-withdrawing effect of nickel(II) as observed previously for the zinc(II) complexes of dipyrromethenes[29] and bilene-b.[30] Meanwhile, the biladiene-ac precursor which carries ethoxycarbonyl groups at the 1,19-positions causes an up-field shift of its methine proton signal upon cyclization (V′ and V in Table 4) on the contrary. Since the strong electronic conjugation of carbonyl groups placed at the 1- and 19-positions is lost upon formation of the tetradehydrocorrin ring, the electron density at the 5- and 10-carbons is increased significantly as a whole. This result is consistent with the corresponding IR spectral behavior.

ESR Spectra. The ESR spectrum of 1,19-diethoxycarbonyl-2,3,7,8,12,13,17,18-octamethyltetradehydrocorrinatocobalt(II) perchlorate observed in chloroform–benzene at 77 K is shown in Fig. 5 as an example for those of the cobalt(II) complexes of 1,19-disubstituted tetradehydrocorrins. In this spectrum, a set of eight cobalt hyperfine lines on the parallel component of the g-tensor ($g_{\parallel}$), which lie at higher fields, with a g-value close to spin free. The low-field set of hyperfine lines that belongs to the perpendicular component of the g-tensor ($g_{\perp}$) is not clearly resolved. Thus, unambiguous analysis of these low-field lines is difficult and the evaluated $g_{\perp}$ values would involve some minor errors. In any case, the ESR spectra indicate that the present cobalt(II) complexes are of low-spin square-planar type with an unpaired electron in the cobalt d_{z^2} orbital. The similar spectral features have also been observed for the complexes derived from porphyrins,[34,35] phthalocyanin,[36] vitamin B_{12} and related compounds,[37–39] and Schiff bases.[40]

In the presence of a few drops of pyridine in the chloroform–benzene solution, the spectrum shown in Fig. 5 is transformed into that in Fig. 6. Since a triplet nitrogen superfine coupling due to axial coordination of a pyridine molecule is observed on the parallel cobalt hyperfine lines, it may be concluded that the unpaired electron of cobalt(II) is certainly in the d_{z^2}

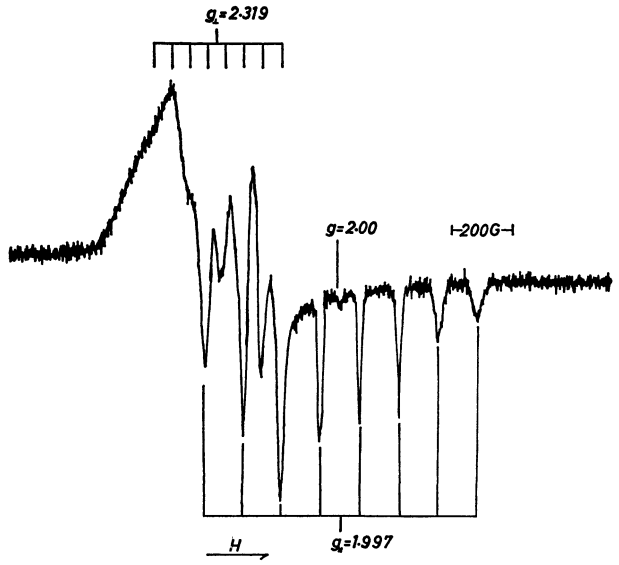

Fig. 5. ESR spectrum of 1,19-diethoxycarbonyl-2,3,7, 8,12,13,17,18-octamethyltetradehydrocorrinatocobalt-(II) perchlorate in chloroform-benzene(2 : 1) at 77 K.

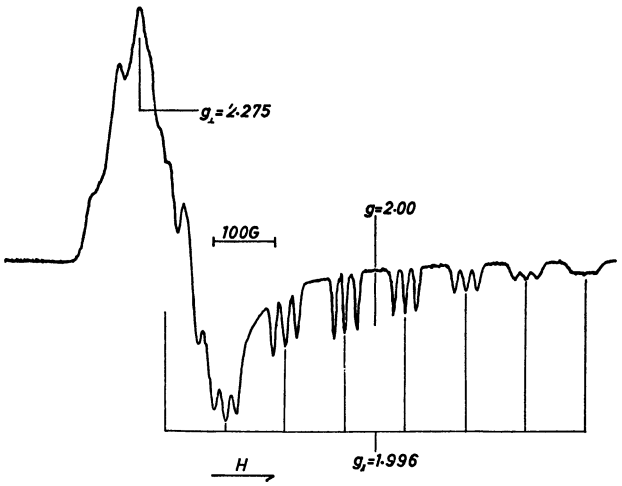

Fig. 6. ESR spectrum of 1,19-diethoxycarbonyl-2,3,7, 8,12,13,17,18 - octamethyltetradehydrocorrinatocobalt-(II) perchlorate in chloroform-benzene (2 : 1) at 77 K upon addition of pyridine.

orbital.

The ESR spectra were analyzed in terms of the spin Hamiltonian given by Eq. (1).

$$\mathscr{H}_s = \beta_e[g_{\parallel}H_zS_z + g_{\perp}(H_xS_x + H_yS_y)] + A_{\parallel}S_zI_z + A_{\perp}(S_xI_x + S_yI_y) \quad (1)$$

For the unpaired electron in the d_{z^2} orbital, the g factors of second-order calculations are[34]

$$g_{\parallel} = 2.0023 - 3(\lambda/\Delta)^2 \quad (2)$$

$$g_{\perp} = 2.0023 + 6(\lambda/\Delta) - 6(\lambda/\Delta)^2 \quad (3)$$

where λ is the spin-orbit coupling for Co(II), and Δ is the excitation energy from the degenerated d_{xz} and d_{yz} orbitals to the d_{z^2} orbital. The first-order $A_{\parallel}$ and $A_{\perp}$ components of hyperfine interaction are given as:[4]

$$A_{\parallel} = P[4/7 - K + 6/7(\lambda/\Delta)] \quad (4)$$

$$A_{\perp} = P[-2/7 - K + 45/7(\lambda/\Delta)] \quad (5)$$

where $P = g_e\beta_e g_n\beta_n\langle d_{z^2}|1/r^3|d_{z^2}\rangle$ and K is the Fermi contact interaction term. The spin Hamiltonian parameters evaluated according to Eqs. (2) through (5) are summarized in Table 5. The $g_{\parallel}$ values are quite similar in magnitude to those reported by Hush and Woolsey[3,4] for 1,19-diethoxycarbonyltetradehydrocorrinatocobalt(II) complexes, but the $g_{\perp}$ components are somewhat different from those evaluated by them and seem to be quite sensitive to the solvent environment. The decrease in A-tensor components along with the coordination of a pyridine molecule suggests that an unpaired electron in the d_{z^2} orbital of cobalt(II) is delocalized through the coordinate bond formed between cobalt(II) and pyridine nitrogen. The formation of similar penta-coordinated cobalt(II) complexes of square pyramidal structure with axial coordination of pyridine has been reported for the $\alpha,\beta,\gamma,\delta$-tetra($p$-methoxyphenyl)porphine complex, and the vitamine B_{12} and related complexes.[37-39] On the other hand, the cobalt(II) complexes derived from phthalocyanin,[36] and dimethylglyoxime[39] were found to take up two pyridine molecules at their axial positions. The reason for the difference in coordination

a) Measured in chloroform-benzene (2 : 1) at 77 K; concentration, 10^{-2}—10^{-3} M. b) Maximum possible errors: g, ±0.005; $A_{\parallel}^{Co}$, $\pm0.5\times10^{-4}$ cm^{-1}; $A_{\perp}^{C}$, $\pm5\times10^{-4}$ cm^{-1}, $A_{\parallel}^{N}$, $\pm0.05\times10^{-4}$ cm^{-1}. c) P_0 for the free cobalt(II) ion, 2.54×10^{-2} cm^{-1}. d) Estimated from line width.

behavior of pyridine molecule is not clear at present.

The P/P_0 values listed in Table 5 may be referred to as a measure for the degree of covalency of coordinate bonds, P_0 being as for the free cobalt(II) ion (254×10^{-4} cm^{-1} [41]). When the tetradehydrocorrin carries more than two groups of 2-ethoxycarbonylethyl (III and IV in Table 5), the P/P_0 value becomes relatively large compared to other analogous complexes given in Table 5. This seems to suggest that the 2-ethoxycarbonylethyl groups have a coordination interaction with cobalt(II) at the axial positions and can be replaced by a pyridine molecule along with the formation of the corresponding penta-coordinated complex.

Meanwhile, the present tetradehydrocorrinatocobalt(II) complexes which underwent reaction with $NaBH_4$ in dimethylformamide did not show any ESR signal, most likely due to the formation of the diamagnetic cobalt(I) complexes.

(Received July 31, 1975)

Three isomers of *trans*- and *cis*-$[Co(CN)_2\{(R,R)\text{-}1,2\text{-cyclohexanediamine}\}_2]^+$ and five isomers of the corresponding (*S*)-propylenediamine complexes have been isolated by chromatography with Dowex 50W-X8 and SP-Sephadex columns, their geometrical structures being assigned on the basis of the ligand field absorption and PMR spectra. Isomers of *cis*-$[Co(CN)_2\{(S)\text{-propylenediamine}\}_2]Cl$, which have different placement of methyl groups of (*S*)-propylenediamine, gave different methyl PMR resonances with different chemical shifts. The absolute configuration of the isomers was determined from the circular dichroism in the first spin-allowed d-d and the charge transfer band region. The configurational and the vicinal effect have been discussed.

Although several methods have been developed for the preparation of mixed cyano-diamine and cyano-ammine cobalt(III) complexes,[1-7] only a few studies[8,9] have been reported on the optically active complexes. The cyanide ion is the ligand which gives the strongest ligand field and a π-back donating character. It is interesting to compare the circular dichroism (CD) of the cyano-diamine complexes with those which have been extensively studied so far.[10] McCaffery *et al.*[8] showed that CD spectra of *cis*-$[CoL_2(en)_2]^{n+}$ have different patterns from the corresponding tris(diamine) complexes whenever the ligand L is well separated from neutral nitrogen donors in the spectrochemical series. When $L=CN^-$, two peaks with the same sign were observed in the region of the octahedral T_{1g} absorption.

The purpose of this study is to investigate the CD behavior more extensively for a variety of mixed cyano complexes of cobalt(III). We report preparation and characterization of the isomers of $[Co(CN)_2(R,R\text{-chxn})_2]^+$ and $[Co(CN)_2(S\text{-pn})_2]^+$ (chxn=1,2-cyclohexanediamine, pn=propylenediamine). Their visible and ultraviolet absorption, CD and PMR spectra are discussed for assigning the geometrical and optical isomers.

Experimental

Preparation and Separation of the Isomers of Dicyanobis[(R,R)-1,2-cyclohexanediamine]cobalt(III) Complexes. One gram of potassium cyanide was dissolved in 150 ml of dimethyl sulfoxide (DMSO) at 60 °C. To this solution was added 2 g of *trans*-$[CoCl_2(R,R\text{-chxn})_2]Cl\cdot 1/2H_2O$ in portions with stirring. The color of the solution turned from green to orange instantly. The solution was allowed to stand at 60 °C for 30 min., cooled to room temperature and poured into a column (120×4 cm) of an SP-Sephadex C-25 ion exchanger. The column was washed with water in order to remove DMSO. When the adsorbed band was eluted with a 0.05 M aqueous solution of sodium perchlorate at a rate 2 ml/min, one orange yellow and then two light yellow bands were eluted. The first orange yellow eluate was evaporated to dryness at 40 °C in a rotary evaporator under reduced pressure. Thirty ml of acetone was added to dissolve sodium perchlorate, leaving orange yellow residues which were then dissolved in a minimum amount of hot water and filtered. The filtrate was kept in a refrigerator overnight to obtain orange yellow crystals, C-1. Yield about 400 mg. Found: C, 37.53; H, 6.40; N, 18.89%. Calcd for $[Co(CN)_2\text{-}(R,R\text{-chxn})_2]ClO_4\cdot 1/2H_2O$: C, 37.56; H, 6.53; N, 18.77%.

The second and the third light yellow eluates were evaporated at 40 °C in rotary evaporators to dryness. Five ml portions of ethanol were added to extract the light yellow precipitates and the ethanol solutions were evaporated to dryness. The residues were dissolved in minimum amounts of hot water and the solutions were cooled in a refrigerator. Light yellow needlelike crystals were obtained from the two lots, C-2 and C-3. The yield was about 100 mg for both C-2 and C-3. These products were much more soluble than C-1. Found for C-2: C, 37.08; H, 6.60; N, 19.00%. Found for C-3: C, 37.41; H, 6.56; N, 18.79%. Calcd for $[Co(CN)_2(R,R\text{-chxn})_2]ClO_4\cdot 1/2H_2O$: C, 37.56; H, 6.53; N, 18.77%.

Preparation and Separation of the Isomers of Dicyanobis[(S)-propylenediamine]cobalt(III) Complexes. Method 1): To a cold solution (*ca.* 0 °C) of 10 g of $[Co(S\text{-pn})_3]Cl_3$[11] in 800 ml of water was added dropwise 2.5 g of potassium cyanide in 10 ml of cold water with stirring. Activated charcoal (2 g) was added and the solution was allowed to stand at room temperature for several days. The orange yellow solution was filtered and the filtrate was added at a rate 0.3 ml/min to a column (4×40 cm) of the ion exchanger (Dowex 50W-X8, 100—200 mesh) in the sodium form. After the column was washed with water the adsorbed band was eluted with a 0.2 M aqueous sodium chloride solution at a 0.15 ml/min rate. This procedure separated the adsorbed band into four bands. The first orange yellow band gave only one kind of crystal (P-1), which was assigned to *trans*-$[Co(CN)_2(S\text{-pn}_2)]Cl$ from the visible absorption spectrum (*vide infra*). The fourth band which remained at the top of the column consisted mainly of $[Co(S\text{-pn})_3]^{3+}$. During the progress of elution with the same eluent, both the second and the third band were separated into three bands. The six portions of eluates were individually concentrated under reduced pressure at 40 °C and treated with ethanol to precipitate sodium chloride, which was filtered off. Addition of ethanol, evaporation and filtration were repeated several times to remove sodium chloride as far as possible. Diethyl ether was added to the ethanol solutions to precipitate crude products, which were recrystallized by dissolving them in minimum amounts of water at 40 °C and keeping the solutions in a refrigerator. The six portions of light yellow crystals were named P-2, P-3, P-4, P-5, P-6 and P-7 in the order of elution and assigned to geometrical isomers of *cis*-$[Co(CN)_2(S\text{-pn})_2]Cl$ on the basis of the visible absorption spectra. P-2, P-3, P-4 and P-6 were in good crystalline state and gave satisfactory results

on elemental analysis. The yields of P-5 and P-7 were os poor that only spectral measurements were made and satisfactory elemental analysis was not carried out. Found for P-1: C, 29,77; H, 7.54; N, 26.66%. Calcd for $[Co(CN)_2(S\text{-pn})_2]Cl\cdot 3/2H_2O$: C, 29.96; H, 7.23; N, 26.21%. Found for P-2: C, 30.46; H, 7.32; N, 26.40%. Calcd for $[Co(CN)_2(S\text{-pn})_2]Cl\cdot H_2O$: C, 30.73; H, 7.09; N, 26.88%. Found for P-3: C, 31.57; H, 7.51; N, 27.27%. Calcd for $[Co(CN)_2(S\text{-pn})_2]Cl\cdot 1/2H_2O$: C, 31.75; H, 6.99; N, 27.77%. Found for P-4: C, 32.24; H, 7.43; N, 28.07%. Calcd for $[Co(CN)_2(S\text{-pn})_2]Cl$: C, 32.61; H, 6.84; N, 28.51%. Found for P-6: C, 30.06; H, 7.17: N, 26.46%. Calcd for $[Co(CN)_2(S\text{-pn})_2]Cl\cdot 3/2H_2O$: C, 29.96; H, 7.23; N, 26.21%.

Method 2) The same method as for the corresponding (*R,R*)-1,2-cyclohexanediamine complexes was applied, using *trans*-$[CoCl_2(R\text{-pn})_2]Cl$ in DMSO. One orange band and two light yellow bands were separated in an SP-Sephadex column. The orange one was assigned to the *trans* isomer of $[Co(CN)_2(R\text{-pn})_2]^+$, and the light yellow ones were to the *cis* isomers, on the basis of the visible absorption spectra. However, the two light yellow bands could not be separated further even on elution at a very small elution rate. The elemental analysis for these three isomers gave satisfactory results.

Measurement. The electronic absorption spectra were obtained with a Hitachi EPU-2A spectrophotometer and a Hitachi 323 recording spectrophotometer. The CD spectra were recorded on a JASCO Model ORD/UV-5 and J-20 spectropolarimeter. The PMR spectra were measured with a JEOL Model JNM MH 60 II spectrometer in deuterium oxide using sodium 2,2-dimethyl-2-silapentane-5-sulfonate (DSS) as an internal reference. Infrared spectra were measured as KBr disk with a DS 301 infrared spectrometer of Japan Spectroscopic Company.

Results and Discussion

Preparation, Separation and Characterization of the Isomers. The preparation of mixed cyano cobalt(III) complexes has been known to be difficult because of the strong tendency of cyanide ions to coordinate to a central cobalt(III) ion. In recent years, however, some preparative studies on the mixed complexes have been developed by several groups.[1-7] In the present work, two methods have been adopted to prepare the optically active dicyanobis(diamine)cobalt(III) complexes. One is the reaction of *trans*-$[CoCl_2(diamine)_2]^+$ with KCN in DMSO.[5] The other is based on the reaction of $[Co(diamine)_3]^{3+}$ with KCN in an aqueous solution in the presence of activated charcoal.[4] The former method is effective for preparing the *trans* dicyano isomers, the formation ratio *trans*/*cis* being about 2. In the latter method, the yields of the *trans* isomer were very poor as compared with those of the corresponding *cis* isomers. The yields for each isomer are very similar to those of the corresponding ethylenediamine complexes. The geometrical structure, *trans* or *cis*, was determined on the basis of the visible absorption spectra which are almost identical with those of the corresponding ethylenediamine complexes respectively; *i.e.* the *trans* isomer is well characterized by the splitting of its first absorption band, but the *cis* isomers show no splitting in the same region.

The bidentate ligand, propylenediamine, is unsymmetrical due to the placement of a methyl group on the chelate ring so that five geometrical isomers are possible for the $[Co(CN)_2(S\text{-pn})_2]^+$ complex as shown in Fig. 1. When the configuration (Δ and Λ) around the cobalt ion is considered, six isomers are possible for the *cis* dicyano complexes. The isomers would be expected to be nearly energetically equivalent because of the nearly symmetrical nature of pn. Several workers have studied such a geometrical isomerism. Most of them could observe no distinct differences in the chemical and spectroscopic properties.

For the tris(*R*-pn)cobalt(III) complexes, MacDermott[12] and Kojima *et al.*[13] separated the geometrical isomers (*facial* and *meridional*), although they could not observe any distinguishable differences in the visible and ultraviolet absorption, CD and PMR spectra. Sudmeier *et al.*[14] observed nonequivalent methyl resonances only in the 251 MHz PMR spectrum of *N*-deuterated Δ-$[Co(R\text{-pn})_3]^{3+}$ with Co-59 decoupling. Recently, the Co-59 NMR was successfully applied to this system.[15-17] For the bis(*R*-pn) complexes, MacDermott[18] tried to separate the isomers of $[Co(NO_2)_2(R\text{-pn})_2]^+$ and isolated three isomers. However, assignment of the structure only distinguished the *trans*(dinitro) and *cis*(dinitro) isomer. For the mono(*R*-pn) complexes, Lewis and Alexander[19] isolated the two isomers of $\Delta(C_3)$-*cis*β-$[Co(R\text{-pn})(2,3,2\text{-tet})]^{3+}$ (2,3,2-tet : 3,7-diaza-1,9-nonanediamine), which differ only in the placement of the methyl group of the *R*-pn. They could not observe, however, distinct differences in the visible absorption, CD and PMR spectra. On the other hand, Halloran and Legg[20] isolated the four isomers of *uns-cis*-$[Co(R\text{-pn})(edda)]^+$(edda : ethylenediamine-*N,N'*-diacetate) and observed a shift by 0.13 ppm for the methyl resonances between *cis*, *cis* (N–O) and *cis*,*trans*(N–O) isomers, which differ only in the placement of the methyl group of the *R*-pn.

In a previous paper,[21] some isomers of bis(L-hydrogenaspartato)(*R*-pn) and (L-aspartato)bis(*R*-pn)cobalt(III) complexes were isolated and characterized on the basis of the visible absorption, CD and PMR spectra. In the present work, we could separate all the isomers of *cis*-$[Co(CN)_2(S\text{-pn})_2]^+$ using a Dowex 50W-X8 ion exchange resin. This is useful for the separation of low charge complexes in contrast to an SP-Sephadex ion exchanger which is very good for high charge complexes.

Only one band was observed on the chromatographic separation of *trans*-$[Co(CN)_2(S\text{-pn})_2]^+$. The PMR spectrum of the isomer exhibits a doublet (J= 6 Hz) due to the CH_3 group of the coordinated *S*-pn at 1.23 ppm. Since the chemical environments of the methyl protons of the coordinated two *S*-pn are equivalent in the *trans* isomer, it is impossible to determine whether the obtained isomer is *trans-cis* or *trans-trans* isomer, or a mixture of the two (Fig. 1). However, the *trans-trans* isomer seems to be most predominant as in the corresponding dichloro complexes.[22]

For the *cis* dicyano complexes, P-2, P-3 and P-4 are assigned to Δ configuration around the cobalt ion and P-5, P-6 and P-7 to Λ on the basis of the CD spectra. Crystals P-5 and P-7 gave identical visible and ultraviolet absorption spectrum with those of P-2, P-3, P-4 and P-6, and the *cis* structure is verified although satisfactory elemental analysis was not obtained. The

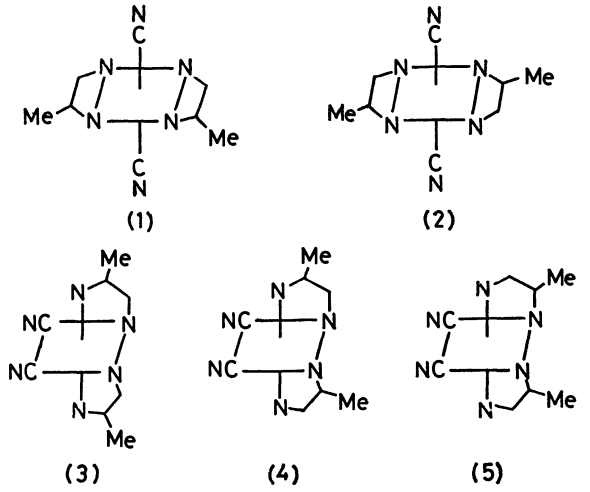

Fig. 1. Geometrical isomers of $[Co(CN)_2(S\text{-pn})_2]^+$. (1) *trans-cis*, (2) *trans-trans*, (3) *cis-trans*, (4) *cis*(C_1), (5) *cis-cis*.

cis-trans and *cis-cis* isomers (Fig. 1) have a C_2 symmetry axis and the *cis*(C_1) isomer has only a C_1 symmetry axis. The PMR spectra of P-2 and P-4 exhibit a doublet (J=6 Hz) due to the methyl groups of *S*-pn at 1.19 ppm and 1.34 ppm, respectively. P-3 showed two doublets at 1.19 ppm and 1.34 ppm and was assigned to the *cis*(C_1) isomer (Fig. 1). P-2 and P-4 isomers exhibit a significant difference in the methyl resonance. The absorption of P-4 isomer is shifted downfield relative to that of P-2. Assuming that the major environmental factor contributing to this shift is the relative position of the methyl group in the complex, such a difference in the chemical shift might arise from the intramolecular nonbonding interactions and the influence of ligating atoms, specifically the arrangement of ligating atoms in the other coordination sites. In a series of mixed en-pn and tris(pn) complexes of cobalt(III), the chemical shift hardly differs at all. The great chemical shift difference between P-2 and P-4 isomers seems to be due to the arrangement of cyanide ions. The chemical shift of the methyl group in $[Co(pn)_3]^{3+}$ is at about 1.37 ppm,[14] while in $[Co(CN)_4(R\text{-pn})]^-$ it is at about 1.25 ppm.[23] The methyl groups in the *cis-trans* isomer in Fig. 1 are nearer the cyanide ions than those in the *cis-cis* isomer. Thus we tentatively assigned P-2 isomer to *cis-trans* and P-4 to *cis-cis*. P-5, P-6 and P-7 showed a similar PMR behavior to P-2, P-3 and P-4, respectively. Hence we tentatively assigned P-5 to *cis-trans*, P-6 to *cis*(C_1) and P-7 to *cis-cis*.

The infrared absorption of these isomers was measured in the 4000—400 cm^{-1} region. Coordinated cyanide ions in each isomer showed a strong stretching $\nu(C{\equiv}N)$ band at *ca.* 2200 cm^{-1} which exhibited no splitting.

Circular Dichroism and Absolute Configuration. The observed absorption and CD spectral data for $[Co(CN)_2(R,R\text{-chxn})_2]^+$ and $[Co(CN)_2(S\text{-pn})_2]^+$ are summarized in Table 1.

Figure 2 shows the visible and ultraviolet absorption and CD spectra of *trans*-$[Co(CN)_2L_2]^+$ (L=*R*,*R*-chxn or *R*-pn) in water and of *trans*-$[CoCl_2(R,R\text{-chxn})_2]^+$ in methanol. The first absorption band, $^1T_{1g}{\leftarrow}^1A_{1g}$, of cobalt(III) complexes in an octahedral field splits into $^1A_{2g}+{}^1E_g{\leftarrow}^1A_{1g}$ in a tetragonal field. Yamatera[24] showed that the $^1A_{2g}$ band for *trans*-$CoN_4X_2^+$ should have roughly the same energy as the $^1T_{1g}$ band of CoN_6^{3+}. Furthermore, for axial ligand, X, which is lower than N in the spectrochemical series, ^1E_g should be lower in energy than $^1A_{2g}$. The first two peaks in the CD spectra of *trans*-dihalobis(diamine)cobalt(III) complexes are generally assigned to the ^1E_g and $^1A_{2g}$ levels in the order of increasing energy.[25,26] For the *trans*-$[Co(CN)_2(R,R\text{-chxn})_2]^+$ complexes, the axial ligands, CN^-, lie higher in the spectrochemical series than the basal cyclohexanediamine, so that the crystal field

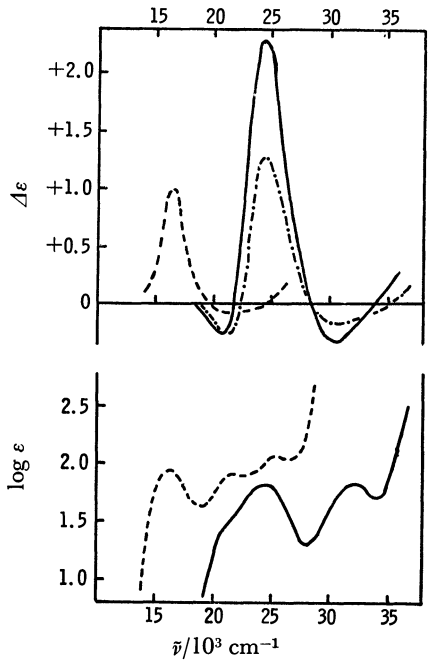

Fig. 2. Absorption and CD spectra of *trans*-$[Co(CN)_2(R,R\text{-chxn})_2]^+$ in H_2O (——), *trans*-$[Co(CN)_2(S\text{-pn})_2]^+$ in H_2O (—·—·—) and *trans*-$[CoCl_2(R,R\text{-chxn})_2]^+$ in methanol (— — —).

model expects the ^1E_g band to be at a higher energy than the $^1A_{2g}$ band. In the visible absorption spectra in Fig. 2, two components are observed in the first absorption band region. On the other hand, for the CD spectra two components, a small negative and a strong positive band, are observed in the first absorption band region, which we assign to $^1A_{2g}$ and ^1E_g component, respectively, in the order of increasing energy. The sign of the Cotton effect for each component is consistent for the dihalo and dicyano complexes, and related to the conformation of the chelate rings. The intensity of the Cotton effect for the dicyano complexes is much stronger than expected, as compared with the corresponding dihalo complexes. It seems that the conformation of the chelates is almost the same as for the dihalo and the dicyano complexes. A more complete molecular orbital treatment would be necessary to interpret the spectroscopic properties. However, quite recently similar differences in CD intensity were observed for *trans*-*R,R*-$[CoX_2(3,2,3\text{-tet})]^+$, *trans*-*S,S*-$[CoX_2(S,R,R,S\text{-}sk\text{-}3,2,3\text{-tet})]^+$ and *trans*-*S,S*-$[CoX_2(R,R\text{-}R,R\text{-}sk\text{-}3,2,3\text{-tet})]^+$ ($X=Cl^-$, CN^-).[27]

Figure 3 shows the CD spectra for the complexes obtained from the second(C-2) and the third (C-3) fraction of *cis*-$[Co(CN)_2(R,R\text{-chxn})_2]^+$ in H_2O. The CD spectrum of C-2 shows a very strong positive band in the first absorption band region which suggests a *Λ* configuration on the basis of an empirical rule.[10] C-3 shows two small negative bands and a strong positive band in the first absorption band region, which are rather complicated for the assignment of the absolute configuration. In the ultraviolet region, however, these two isomers gave very contrasting CD spectra; the CD spectrum of C-2 is similar to that of *cis*-*Λ*-$[Co(CN)_2(en)_2]Cl\cdot H_2O$, the absolute configuration of

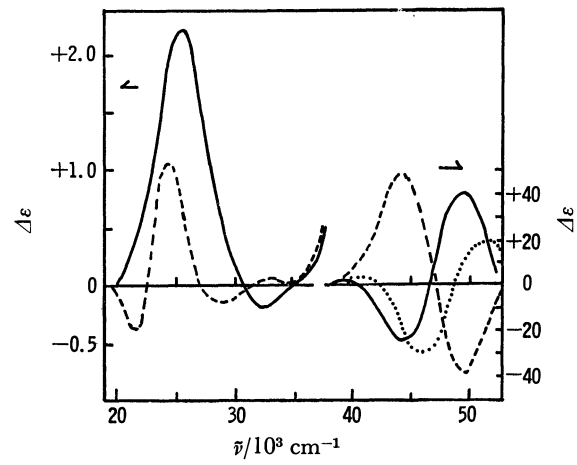

Fig. 3. CD spectra of *cis*-$[Co(CN)_2(R,R\text{-chxn})_2]^+$ in H_2O. C-2 (——), C-3 (— — —) and *cis*-*Λ*-$[Co(CN)_2(en)_2]Cl\cdot H_2O$ (·····).

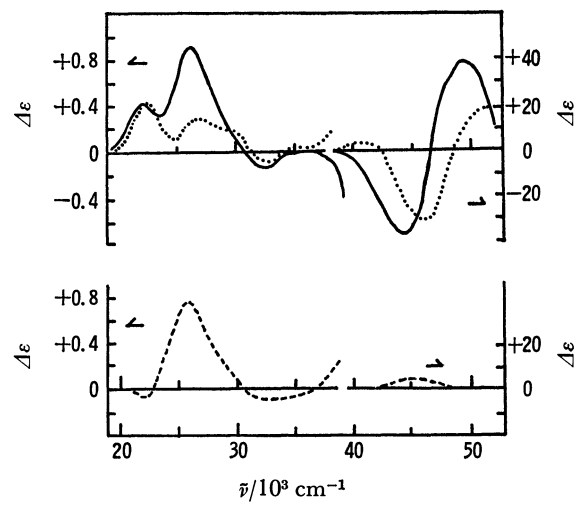

Fig. 4. Calculated configurational and vicinal CD curves of *cis*-$[Co(CN)_2(R,R\text{-chxn})_2]^+$. (C-2−C-3)/2 (——), (C-2+C-3)/4 (— — —) and *cis*-*Λ*-$[Co(CN)_2(en)_2]^+$ (·····).

which was determined by X-ray analysis.[28] Ogino *et al.*[29] suggested that in tris(diamine)cobalt(III) ions the configurational and the vicinal effect are also additive for the CD in the charge transfer region. This empirical rule would be useful for assigning the absolute configuration of dicyanobis(diamine) complexes. We have thus assigned the C-2 isomer to be *Λ* form.

The configurational and vicinal curves of *cis*-$[Co(CN)_2(R,R\text{-chxn})_2]^+$ are shown in Fig. 4. They were derived from the observed curves by use of the following relations.

$$\Delta\varepsilon(L) = 1/4\cdot[\Delta\varepsilon(\Lambda_{2L})+\Delta\varepsilon(\Delta_{2L})]$$
$$\Delta\varepsilon(\Delta) = 1/2\cdot[\Delta\varepsilon(\Delta_{2L})-\Delta\varepsilon(\Lambda_{2L})]$$
$$\Delta\varepsilon(\Lambda) = 1/2\cdot[\Delta\varepsilon(\Lambda_{2L})-\Delta\varepsilon(\Delta_{2L})]$$

where $\Delta\varepsilon(\Delta_{2L})$ and $\Delta\varepsilon(\Lambda_{2L})$ are the observed CD for the *Δ* and the *Λ* diastereoisomer, respectively, of *cis*-$[Co(CN)_2(R,R\text{-chxn})_2]^+$ complex and $\Delta\varepsilon(\Delta)$ and $\Delta\varepsilon(\Lambda)$ are the configurational CD, and $\Delta\varepsilon(L)$ is the vicinal CD for (*R,R*)-1,2-cyclohexanediamine ligand. The pattern of configurational CD curves agrees with the

observed CD of the corresponding ethylenediamine complex, except that the intensity of the peak at 2.62 $\times 10^4$ cm^{-1} (assigned to B_1 transition in C_{2v} symmetry by McCaffery *et al.*[8]) is strong in the cyclohexanediamine complex. The pattern of derived vicinal CD curves is similar to the observed CD spectrum of *trans*-$[Co(CN)_2(R,R\text{-chxn})_2]^+$.

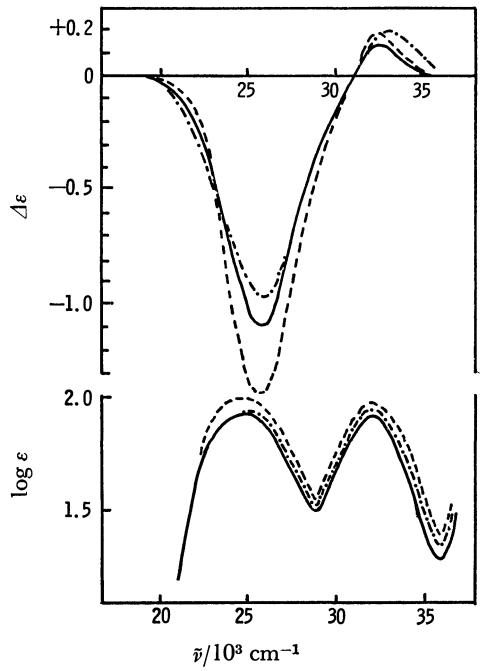

Fig. 5. Absorption and CD spectra of *cis*-$[Co(CN)_2(S\text{-pn})_2]^+$ in H_2O. P-2 (— — —), P-3 (——) and P-4 (—·—·—).

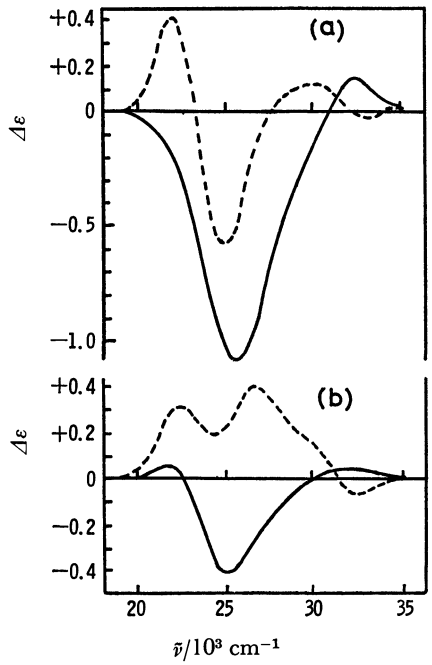

Fig. 6. (a) CD spectra of *cis*-$[Co(CN)_2(S\text{-pn})_2]^+$ in H_2O. P-3 (——) and P-6 (— — —). (b) Calculated configurational and vicinal CD curves of *cis*-$[Co(CN)_2(S\text{-pn})_2]^+$. (P-6−P-3)/2 (— — —) and (P-6+P-3)/4 (——).

Figure 5 shows the visible absorption and CD spectra of P-2, P-3 and P-4 isomer of $[Co(CN)_2(S\text{-pn})_2]^+$. The absorption and CD behavior are similar to those of the corresponding cyclohexanediamine complexes. The absorption maximum for each complex is slightly shifted, the intensity differing slightly from each other. However, the pattern is typical of *cis*-dicyanobis(diamine) complexes. The CD spectra of P-2, P-3 and P-4 are in contrast to that of *cis*-*Λ*-$[Co(CN)_2(R,R\text{-chxn})_2]^+$ in Fig. 3. When configurational and vicinal contribution are taken into consideration, these complexes are assigned to isomers of *cis*-*Λ*-$[Co(CN)_2(S\text{-pn})_2]^+$. Although the CD strength of these isomers in the first absorption band region differs somewhat from each other, geometrical isomers due to the placement of the methyl groups of propylenediamine give no difference in CD behavior.

Figure 6 shows the CD spectra of P-3 and P-6 isomer of $[Co(CN)_2(S\text{-pn})_2]^+$, the geometrical structure of which seems to be *cis*(C_1) (Fig. 1). The calculated configurational and vicinal curves are almost the same as those calculated for the cyclohexanediamine complexes. On the basis of these CD data, P-2, P-3 and P-4 are assigned to *Δ*-configuration and P-5, P-6 and P-7 to *Λ*-configuration.

The Resonance Energies of Polyacenes and Related Compounds

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 1, 1974)

The resonance energies of polyacenes were determined on the basis of the additive principle of π-bond energies in nonaromatic compounds. The additive components in the total π-energies for these compounds were reasonably estimated from the infinitely large polyacene. The calculated resonance energies appear to be much improved as compared with those calculated by Hess and Schaad.

In 1965, Dewar and Gleicher, using the semi-empirical SCF-MO method, found that the bond energies of acyclic polyenes are additive.[1-3] Therefore, we can readily calculate the total energy of any acyclic polyene by summing the energies of all its bonds. Using these additive bond energies, we can also calculate the reference energies of cyclic polyenes, and hence obtain their resonance energies. Here, the reference energy is defined as the energy which the compound in question would possess if it were absolutely olefinic in nature. These resonance energies were the first aromaticity indices which correlated very well with the experimental stability for a wide range of conjugated hydrocarbons.[4,5]

Subsequent HMO calculations, carried out by Hess and Schaad,[6-8] have produced results which nicely parallel the corresponding results of the SCF-MO approach. They classified the carbon-carbon bonds of acyclic polyenes into eight types, five types of double bonds and three types of single bonds, depending upon the number of attached hydrogens. The additive π-bond energies were then assigned to these types of π-bonds. These energies were used to calculate the reference energies of cyclic polyenes.

However, it must be noted that the additive bond energies have been, in all cases, somewhat arbitrarily determined from some groups of acyclic polyenes. Although the agreement between the calculated resonance energies and the experimental stabilities is generally good, the use of these fixed bond energies might sometimes cause a considerable ambiguity in the obtained resonance energies, especially for the larger conjugated systems.[9,10] With this in view, we reexamined the reference energies for the linear polyacenes within the framework of the HMO theory; we would now like to point out that the HMO resonance energies hitherto published for the polyacenes[6,7] appear to be considerably larger than what they should be. The classification of π-bonds made by Hess and Schaad[6] is assumed throughout this article.

Results and Discussion

It is widely known that the linear annellation of unsaturated six-membered rings yields a series of hydrocarbons (polyacenes) which show a decreasing stability as the number of rings is increased.[11,12] According to Clar,[11,12] every polyacene is stabilized primarily by a single aromatic sextet. One sextet is shared among all the rings by migrating from one ring to the other. This means a dilution of the sextet. The benzenoid character decreases with the length of polyacene. Such an aspect of polyacenes can be adequately visualized with the help of Herndon's resonance theory.[13,14]

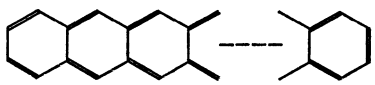
In 1973, Herndon succeeded in applying the resonance-theoretical approach to the evaluation of Dewar-type resonance energies. According to his theory, the resonance energy (E_R) for [N]acene, which contains N six-membered rings, is expressed as follows:

$$E_R([N]\text{acene}) = \frac{2[N\gamma_1 + (N-1)\gamma_2]}{N+1}\ , \qquad (1)$$

where γ_1 denotes the resonance interaction between two Kekulé structures related by a permutation of three double bonds within a six-membered ring, and where γ_2 denotes the resonance interaction related by a permutation of five double bonds within a periphery of two annellated rings.

On this basis, the resonance energy for an infinitely large polyacene (I) can readily be given as:

$$E_R(\text{I}) = 2(\gamma_1 + \gamma_2)\ . \qquad (2)$$



(I)

The limiting resonance energy of polyacene is thus a finite quantity, *i.e.*, twice the sum of the resonance energy of benzene and that of the ten-membered ring. It is, hence, assumed with little difficulty that the reference energy of any polyacene can be estimated from the infinitely large polyacene because the resonance energy per π-electron (REPE) is considered to be zero. The use of an infinitely large species as a reference compound has been successfully demonstrated for the monocyclic conjugated systems.[10,15]

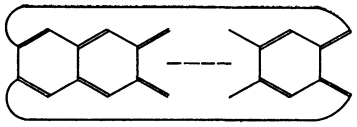
The unit energy (E_U) of polyacene is defined as the increment of the π-energy of the reference structure associated with every additional six-membered ring. All the energies will hereafter be given in units of β. The total π-energy (E_{HMO}) of [N]acene is analytically expressed in this form:[16,17]

$$E_{HMO}([N]\text{acene}) = 2 + 2\sum_{m=1}^{N}\sqrt{9+8\cos\frac{m\pi}{N+1}}\ . \qquad (3)$$

With the use of this expression, the unit energy of polyacene is given by the following expression:

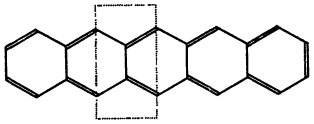
$$\begin{aligned} E_U(\text{polyacene}) &= \lim_{N\to\infty}\frac{2}{N}\sum_{m=1}^{N}\sqrt{9+8\cos\frac{m\pi}{N+1}} \\ &= 2\int_0^1\sqrt{9+8\cos\pi x}\ dx \\ &= 5.6113421\ \ldots\ldots\ . \end{aligned} \qquad (4)$$

In this connection, it is noteworthy that the unit



(II)

energy of polyacene does not necessarily depend upon the boundary conditions of the infinitely large polyacene. The hypothetical cyclic polyacene (II) has the same unit energy as that of the linear polyacene. It is clear that there is no aromatic sextet in any Kekulé structure of the cyclic polyacene. All six-membered rings in it are "empty" in Clar's sense.[11,12] According to Herndon's resonance theory,[13,14] the cyclic polyacene of any size must have zero resonance energy because neither γ_1-type nor γ_2-type interactions are present in it. This fact strongly suggests that the E_U(polyacene)-value, obtained in this manner, is free from aromaticity.



(III)

The unit structure corresponding to the unit energy of polyacene is illustrated in III as the portion of pentacene enclosed in the dotted line. As in the case of the cyclic polyacene, the unit structure of the infinitely large polyacene is considered to be a combination of two CH=C bonds, two CH–C bonds, and one C–C bond. In other words, the unit energy of polyacene is written as:

$$E_U(\text{polyacene}) = 2E_{CH=C} + 2E_{CH-C} + E_{C-C}, \quad (5)$$

where $E_{CH=C}$ is the additive π-bond energy of the CH=C bond, E_{CH-C} is that of the CH–C bond, and E_{C-C} is that of the C–C bond.

For this reason, the use of Kekulé structure of Type I is recommended for estimating the resonance energy for any polyacene. If it is employed as a reference structure, all the polyacene unit structures in it are structurally the same and are expressed by Eq. (5). Although there are N other Kekulé structures for [N]-acene, they are disregarded in the following calculations. It appears safe to arbitrarily adopt one Kekulé structure as a representative of all, as it has been reported that in no cases were the additive energies of the resonance structures of the same compound significantly different.[6]

The actual polyacene cannot, however, be constructed with the unit structures of the above type only. For example, pentacene is composed of four polyacene unit structures and the residual parts on both edges. If the residual parts are combined, they form a geometry of benzene. Therefore, the canonical structure of Type I for [N]acene corresponds to the sum of the $N-1$ polyacene unit structures and the reference structure of benzene. The π-energy of the reference structure (E_A) of benzene has already been calculated from the unit energy of the infinitely large annulene,[10] that is:

$$E_A(\text{benzene}) = 3(E_{CH=CH} + E_{CH-CH}) = 7.6394373\ldots\ldots, \quad (6)$$

where $E_{CH=CH}$ is the additive π-bond energy of the CH=CH bond and where E_{CH-CH} is that of the CH–CH bond. Accordingly, the additive energy, *i.e.*, the reference energy, of [N]acene is written in this form:

$$E_A([N]\text{acene}) = (N-1)E_U(\text{polyacene}) + E_A(\text{benzene}). \quad (7)$$

Using this expression for the reference energy, the resonance energy of [N]acene is given by:

$$E_R([N]\text{acene}) = E_{HMO}([N]\text{acene}) - E_A([N]\text{acene}). \quad (8)$$

The obtained resonance energies of polyacenes and related compounds are all listed in Table 1.

As may easily be seen, the total resonance energy of polyacene is a slowly varying function of N, and it appears to converge to some value near 0.460. These

TABLE 1. RESONANCE ENERGIES OF POLYACENES AND RELATED CONPOUNDS IN UNITS OF β

Total HMO π-energies marked with asterisks were taken from Ref. 19.

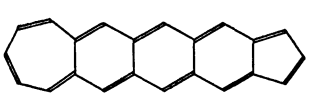
resonance energies are in marked contrast to those determined by Hess and Schaad,[6,7] which are placed in parentheses in Table 1. The latter resonance energies increase with an increase in the number of six-membered rings. This discrepancy between the two sets of resonance energies correspondingly expands on going to higher polyacenes. As a result, our resonance energy of pentacene (0.4592) is about a half of theirs (0.84), although the resonance energies of benzene are similar to each other.

This discrepancy in energy is mainly due to the difference between the π-energies of the polyacene unit structure as estimated by them and by us. The π-energy of the unit structure is calculated to be 5.5248 with the use of the π-bond energies determined by Hess and Schaad.[6] For reference, their additive π-bond energies are 2.1083 for the CH=C bond, 0.4362 for the CH–C bond, and 0.4358 for the C–C bond. Since the π-energy of the same unit structure is 5.6113 according to Eq. (4), the energy difference of 0.0865 is every time added to their resonance energy of polyacene. The most important point is that, if their π-bond energies are used, the limiting REPE amounts to as much as 0.0216; any higher polyacene must be as stable as azulene (REPE=0.023).

On the contrary, it is noticeable that the resonance energies determined by us are approximately constant from anthracene to decacene. Such a tendency of the resonance energies is in good accord with Clar's aromatic sextet theory.[11,12] The constancy of the total resonance energies apparently reflects the presence of a single aromatic sextet in every polyacene. The increment in the resonance energy from benzene to decacene is only 27.6 percent of the resonance energy of benzene. Such a small increment might be attributed to the resonance interactions among all possible Kekulé structures.

In this relation, it is interesting to see that the limiting resonance energy estimated by Herndon's method [Eq. (2)] is about twice as much as ours. Although we premised Herndon's resonance theory in evaluating the polyacene unit energy, the HMO resonance energies for the individual polyacenes are considerably different from the predictions of his theory. However, we might say that the two series of resonance energies of polyacenes are fairly consistent with each other in the sense that the REPE-values, which are closely associated with the stability of the compounds, rapidly converge to zero on going to higher polyacenes.

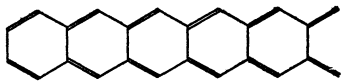
The validity of the polyacene unit energy, as estimated by us, is further supported by the plausible estimate of the resonance energies of some other polyacene analogues. Compound IV is one of the structural isomers of pentacene. This not-yet-isolated compound has been of theoretical interest, because its lowest energy state is supposedly a triplet.[18] As long as the spin states are disregarded, this compound possesses the same reference energy as pentacene. It can, then, be predicted to have the resonance energy of 0.3716 by using the π-bond energies of Hess and Schaad,[6] while it is much reduced to −0.0063 by using the present reference energy of pentacene. According to the PMO method,[3] when the essentially single bond is introduced between carbon atoms of a like parity in an alternant annulene, it leads to no first-order change in π-energy. In this sense, Compound IV should have the resonance energy similar to that of [22]annulene (0.0954).[10] In addition, there is no aromatic sextet in any of the resonance structures of this compound. These facts are evidently favorable to our resonance energy for this compound.



(IV)

The resonance energy ratio of azulene to benzene is 0.59 according to the calculations made by Hess and Schaad.[6] It is reduced by our treatment to 0.3127, which is in good agreement with Herndon's prediction (0.38).[13] The SCF-MO calculations performed by Dewar and de Llano[2] also favor our resonance energy of azulene. They showed azulene to have 19.4 percent of the resonance energy of benzene. Non-alternant hydrocarbons, such as Compound IV and azulene, are thus found to possess much less aromatic character than the isomeric benzenoid species. At the same time, it is suggested that the aromatic sextet in the classical resonance structure is the main origin of the aromaticity.

On the other hand, Gleicher *et al.* showed that the overall results of HMO calculations for quinododimethides with the use of the method and π-bond energies of Hess and Schaad are gratifying.[19] Nevertheless, the results concerning the series of polyacene-2,3-quinododimethides were disturbing. Although only a single classical structure can be written for each of these compounds, there is a steady increase in the REPE. Thus, pentacene-2,3-quinododimethide (V) is predicted to possess half the aromatic character associated with pentacene itself.



(V)

This problem can also be solved with the present unit energy of pentacene as follows. Note that there are $N-1$ polyacene unit structures in [N]acene-2,3-quinododimethide ([N]AQDM). Therefore, a correction must be made, at least, for the additive energy of this portion. As was mentioned above, the additive energy of the polyacene unit structure determined with the use of the π-bond energies of Hess and Schaad[6] differs by 0.0865 from that determined from Eq. (4). With this unit-energy difference, the reference energy of the entire compound can be approximately modified to this form:

$$E_A([N]\text{AQDM}) = E_{HS}([N]\text{AQDM}) - 0.0865(N-1). \quad (9)$$

Here, E_{HS} signifies the reference energy determined according to the method of Hess and Schaad. The resonance energies refined with Eq. (9) are much more acceptable, because the corresponding REPE values are all negligibly small. This is in good accord with

the fact that there is no aromatic sextet in the resonance structure of any polyacene-2,3-quinododimethide. Furthermore, the present resonance energies parallel fairly well the results of the SCF-MO calculations carried out by Gleicher *et al.*[19]

In conclusion, the well-established additivity of the π-bond energies of nonaromatic polyenes allowed us to take an infinitely large polyacene as a reference compound in estimating the aromatic character of a given polyacene. The present approach appears to be superior to the original method of Hess and Schaad when both are applied to polyacenes and related compounds. As has been pointed out in previous papers,[10,15] the discrepancy between the resonance energies of Hess and Schaad and ours is attributable to the differently determined π-bond energies. They determined the π-bond energies from acyclic polyenes of a medium size. Slight energy deviations from ours have been magnified in larger compounds, and have sometimes become comparable to the resonance energies themselves. The polyacene series is a good example of how small errors in the π-bond energies can easily produce spurious results by a cumulative effect. Our simplified model neglected all effects arising from bond alternation. It is hoped that the gross features of the aromatic character of these compounds are not changed by them.

We are grateful to the Hokkaido University Computing Center for the use of their FACOM 230-60, on which all the calculations were performed.

An Investigation of the *endo* Product Selectivity in the Diels-Alder Reaction[1]

Kazuyoshi SEGUCHI, Akira SERA, Yoshinobu OTSUKI, and Kazuhiro MARUYAMA
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received February 26, 1975)

The Diels-Alder reactions of cyclopentadienes with a variety of substituted ethylenes were carried out, and their reaction rates and the *endo* : *exo* isomer ratios of the products were determined. It was shown that the faster reaction is characterized by a higher *endo* isomer distribution and the existence of a linear correlation between the reaction rate and the *endo* isomer distribution. The results were interpreted in terms of the concept of secondary orbital interaction in the transition state.

Many investigators have been interested in the *endo* addition rule of the Diels-Alder reaction[2] since Alder expressed it as the "maximum accumulation of unsaturation."[3] The *endo* selectivity of the reaction has been discussed mainly in terms of dipole—dipole[4] or secondary orbital[5] interactions, steric[2a] and electronic[6] effects, dispersion force,[7] and favorable geometry for interacting orbitals[8] on both experimental and theoretical grounds. There have been a large number of studies of the *endo* selectivity of the reaction, but little has been done to investigate it from the viewpoint of the reactivity of dienophiles.

In the some Lewis acid-catalyzed Diels-Alder reactions, it has been reported that the dienophiles complexed with the catalysts show an enhanced *endo* selectivity in comparison with that of the uncomplexed ones in spite of the higher reactivities of the formers.[9,10] There seems to be a particular parallelism between the enhanced selectivity and the higher reactivity in the Diels-Alder reaction. In order to get a better insight into the mechanism of the Diels-Alder reaction, a detailed examination of this phenomenon is essential. Therefore, this work will be concerned with an investigation of the correlation between the *endo* selectivity and the reaction rate of the Diels-Alder reaction. For this purpose, the reactions of cyclopentadienes with various substituted ethylenes were examined (Scheme 1).

Results and Discussion

The following sets of Diels-Alder reactions were carried out: Dienes; cyclopentadiene (**1a**), diphenyl- and di-*p*-chlorophenylcyclopentadiene (**1b**, **1c**): Dienophiles; acrylic acid derivatives, vinyl ketones, acrolein, and maleic acid derivatives. All the reactions were carried out at 25° C and 35 °C. The second-order rate constants were determined by following the reaction by means of glpc and spectrophotometry. A competitive reaction method was employed for the estimation of the rate constants of **1a** with vinyl ketones and methyl 2-alkylacrylates. The results are tabulated in Tables 1 and 2. The isomer distributions of the reactions were analyzed by means of glpc and NMR. Control experiments showed that no *endo-exo* interconversion operated under the present reaction conditions and during the analytical procedure.

The isomeric adducts were isolated by means of glpc and tlc, and their configurations were confirmed by means of NMR analysis, taking into account the fact that the shielding effect of the double bond in 5-substituted 2-norbornene leads the signal of the *endo*-5-methyl proton to a higher field than that of the *exo*-5-methyl proton. The chemical shifts and the splitting patterns of the adducts were similar to those

TABLE 1. SECOND-ORDER RATE CONSTANTS FOR THE REACTIONS OF CYCLOPENTADIENES WITH VARIOUS DIENOPHILES AT 35 °C

No.	Diene	Dienophile	Solvent	k_2 (l mol^{-1} s^{-1})[a]
1	cyclopentadiene	*N*-phenylmaleimide	dioxane	1.30×10^{-1} [b]
2	cyclopentadiene	maleic anhydride	dioxane	1.22×10^{-1} [b]
3	cyclopentadiene	acryloyl bromide	benzene	3.09×10^{-2} [c]
4	cyclopentadiene	acryloyl chloride	benzene	2.00×10^{-2} [c]
10	cyclopentadiene	methyl acrylate	*n*-butyl chloride	5.30×10^{-5} [c]
11	1,4-diphenylcyclopentadiene	methyl acrylate	chloroform	6.94×10^{-6} [d]
12	1,4-di-*p*-chlorophenyl-cyclopentadiene	methyl acrylate	chloroform	2.55×10^{-6} [d]

a) Values are average of two or more runs. Estimated errors are about 10% for the reactions 3 and 4, and about 5% for the reactions 10—12. b) Calculated from the reported data, see ref. 21. c) Determined by means of glpc. d) Determined by spectrophotometry.

Table 2. Relative rates and *endo*-isomer distributions in the Diels-Alder reactions of cyclopentadienes with various dienophiles in benzene

No.	Diene[a] R^1	Dienophile[a] R^2	X	Relative rate[b]	*endo*-Adduct[c] (%)
1	H	*N*-phenylmaleimide		2.45×10^{3}	>99.5[d]
2	H	maleic anhydride		2.30×10^{3}	99.5
3	H	H	COBr	5.83×10^{2}	92.2
4	H	H	COCl	3.77×10^{2}	90.7
5	H	H	CO-*iso*-Pr	3.20	82.1
6	H	H	CO-*n*-Pr	2.40	80.5
7	H	H	COEt	2.28	82.8
8	H	H	COMe	2.28	82.3
9	H	H	CHO	2.00	75.0
10	H	H	CO_2Me	1.00	73.7

Analysis based on glpc. c) Determined by glpc. The values are accurate to within 0.2%. d) Determined by NMR. The values are accurate to within 1%. e) In methylene chloride.

reported for related compounds.[11]

Cyclopentadienes were employed as the diene components in order to avoid the uncertainty which is unavoidable in the reactions of acyclic dienes because of their *cis-trans* isomerization. The dienophiles employed were characterized by their carbonyl function so that the reactions to be compared would have similar character.

As may be seen in Table 2, a higher *endo* isomer distribution appeared when a more reactive dienophile was used. Although it is difficult to treat the reactivity of a dienophile in a quantitative sense, the logarithms of the apparent relative rate constants were employed as a provisional measure of the reactivity of the dienophile. In Fig. 1, the logarithms of the *endo* : *exo* isomer ratios, a measure of the *endo* selectivity, are plotted against the logarithms of the relative rates of the reactions. A fair correlation is found between the rates and the *endo* selectivity.

The fact that a more reactive addend has a higher *endo* selectivity seems to be contrary to the so-called selectivity-reactivity relationship in polar reactions.[12] Kojima and Inukai[13] have observed a similar phenomenon in the aluminum chloride-catalyzed Diels-Alder reactions. They have also pointed out the major role of the electrophilicity of dienophiles for the observed inter- and intramolecular selectivities.

Recently we ourselves reported on the pressure effect of the Diels-Alder reaction.[14] From an examination of the activation volumes of the reactions, it was deduced that a faster Diels-Alder reaction proceeds through a tighter transition state. The tighter transition state implies the existence of a stronger secondary orbital interaction as well as a closer proximity of the reacting species. The extent of stabilization due to secondary orbital interaction must be responsible

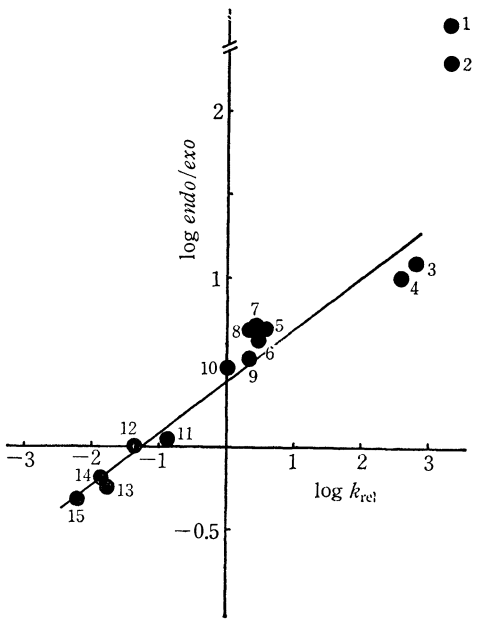

Fig. 1. A correlation of log (*endo*/*exo*) with log k_{rel}. The numerals correspond to the reaction number in Table 2.

for the determination of the *endo*: *exo* isomer ratio. The correlation shown in Fig. 1 indicates that the more reactive dienophile is characterized by the possibility of the stronger secondary orbital interaction.

The introduction of an alkyl group into the dienophile resulted in a decrease in the *endo* isomer distribution to less than 50%. However, even in these cases the correlation still holds, as is shown in Fig. 1.[15] Naturally, the alkyl group in the dienophile may depress its reactivity for electronic (inductive) and steric reasons.

A steric repulsion can operate between the alkyl group and the methylene group of cyclopentadiene in the *endo* transition state. These effects will make the *endo* transition state looser, and will result in a decrease in the amount of the *endo* isomer.

Thus, Fig. 1 substantiates the existence of a correlation between the *endo* selectivity and the relative rates in a given set of Diels-Alder reactions. Although it has been well-known in the field of synthetic organic chemistry that the faster Diels-Alder reactions preferentially yield a large amount of *endo* isomers, it should be emphasized that the linear correlation holds over a wide range of the reactivities of dienophiles.

Some anomalous deviation is seen in Fig. 1. That is, in the reactions of maleic anhydride or maleimide with cyclopentadiene, higher selectivities were observed than those expected from their relative rates. This possibly results from the two-fold interaction between the π-orbits of carbonyl groups and cyclopentadiene, as was pointed out in our previous report.[14] In the reaction of cyclopentadiene with maleic anhydride and maleimide, the transition-state geometry is quite favorable for secondary orbital interaction because of the cyclic feature of the dienophile. This must also be responsible for the observed higher *endo* selectivity in these two cases.

Experimental

All the NMR spectra were recorded on a JEOL PS-100 spectrometer, using TMS as the internal standard. The chemical shifts were expressed in δ-values. The analytical determination by glpc was performed by means of JEOL JGC-20K and Perkin-Elmer model 800 gas-chromatographs. The preparative glpc was performed by means of JEOL JGC-1100 gas-chromatograph. The UV spectra were recorded on a Shimadzu UV-200 spectrometer.

Materials. Methyl vinyl ketone[16] (bp 81 °C); ethyl vinyl ketone[17] (bp 102—103 °C); *n*-propyl vinyl ketone[17] (bp 35—36 °C/22 mmHg); isopropyl vinyl ketone[17] (33—35 °C/30 mmHg); acryloyl chloride[18] (bp 74—75 °C); acryloyl bromide[18] (bp 99—100 °C); methyl 2-*n*-butyl acrylate[19] (bp 69—70 °C/25 mmHg) and 1,4-diphenylcyclopentadiene-1,3 (**1b**)[20] (mp 161—162 °C) were prepared by the methods reported in the literature. 1,4-Di-(*p*-chlorophenyl)cyclopentadiene-1,3 (**1c**) was prepared from ethyl 3-(*p*-chlorophenyl)-propionate and *p*-chloroacetophenone[20]; mp 167—168 °C. Found: C, 71.37; H, 4.15%. Calcd for $C_{21}H_{12}O_2Cl_2$: C, 71.09; H, 4.21%. The other dienophiles were commercially available and were redistilled when necessary.

Product Analysis. In a typical run, a mixture of 2.5×10^{-3} M of a dienophile, 2.5×10^{-3} M of a diene, and 2 ml of a solvent was sealed in a glass ampoule and immersed in a thermostatted bath. The reaction time was changed from three hours to several days according to the reactivity of the addends and the temperature. The Diels-Alder adducts were analyzed by means of glpc and NMR. Stainless steel columns (2 m) packed with 5% PEG (column A), 5% TCPE (column B), 5% PEGS (column C), and 5% Silicon SE-30 (column D) on Diasolid L were used.

*Reactions of **1a** with Alkyl Vinyl Ketones.* The Diels-Alder adducts were separated by means of glpc (column A). All the adducts were colorless liquids. Retention times: 5-*endo*-acetylbicyclo[2.2.1]hept-2-ene (**3n**), 5.2 min; 5-*exo*-acetylbicyclo[2.2.1]hept-2-ene (**3x**), 4.0 min at 130 °C: 5-*endo*-propionylbicyclo[2.2.1]hept-2-ene (**4n**), 6.8 min; 5-*exo*-propionylbicyclo[2.2.1]hept-2-ene (**4x**), 5.2 min at 130 °C: 5-*endo*-*n*-butyrylcyclo[2.2.1]hept-2-ene (**5n**), 3.8 min; 5-*exo*-*n*-butyrylbicyclo[2.2.1]hept-2-ene (**5x**), 3.0 min at 160 °C: 5-*endo*-isobutyrylbicyclo[2.2.1]hept-2-ene (**6n**), 4.0 min; 5-*exo*-isobutyrylbicyclo[2.2.1]hept-2-ene (**6x**), 3.0 min at 160 °C.

NMR spectra (characteristic signals): **3n**, 2.00(CH_3); **3x**, 2.10 (CH_3); **4n**, 1.01 (CH_3CH_2-), 2.44(CH_3CH_2-); **4x**, 1.06(CH_3CH_2-), 2.50(CH_3CH_2-): **5n**, 0.88($CH_3CH_2CH_2$-), 2.30($CH_3CH_2CH_2$-); **5x**, 0.90 ($CH_3CH_2CH_2$-), 2.34($CH_3CH_2CH_2$-): **6n**, 0.98, 1.04 ((CH_3)$_2$CH-); **6x**, 1.06, 1.18 ((CH_3)$_2$CH-).

Elementary analysis: Found: **5n**, C, 80.24; H, 9.76%; **5x**, C, 80.24; H, 10.03%: **6n**, C, 80.38; H, 9.91%; **6x**, 80.18; H, 9.66%. Calcd for $C_{10}H_{16}O$: C, 80.44; H, 9.83%.

*Reactions of **1a** with Methyl Acrylate and Methyl 2-Alkylacrylates.* The Diels-Alder adducts were separated by means of glpc (columns A and B). All the adducts were colorless liquids. Retention times: 5-*endo*-carbomethoxybicyclo[2.2.1] hept-2-ene (**7n**), 3.1 min; 5-*exo*-carbomethoxybicyclo[2.2.1]hep -2-ene (**7x**), 2.7 min at 150 °C (column A): 5-*endo*-carbomethoxy-5-*exo*-methylbicyclo[2.2.1] hept-2-ene (**8n**), 2.9 min; 5-*exo*-carbomethoxy-5-*endo*-methylbicyclo-[2.2.1]hept-2-ene, (**8x**), 2.6 min at 110 °C (column B): 5-*endo*-carbomethoxy-5-*exo*-ethylbicyclo[2.2.1]hept-2-ene (**9n**), 3.2 min; 5-*exo*-carbomethoxy-5-*endo*-ethylbicyclo[2.2.1]-2-ene (**9x**), 2.7 min at 120 °C (column B): 5-*endo*-carbomethoxy-5-*exo*-*n*-butylbicyclo[2.2.1]hept-2-ene (**10n**), 4.3 min; 5-*exo*-carbomethoxy-5-*endo*-*n*-butylbicyclo[2.2.1]hept-2-ene (**10x**), 3.7 min at 126 °C (column B).

NMR spectra (characteristic signals): **7n**, 3.57 (CO_2CH_3); **7x**, 3.63 (CO_2CH_3): **8n**, 3.56 (CO_2CH_3), 1.38 (CH_3); **8x**, 3.65 (CO_2CH_3), 1.08 (CH_3): **9n**, 3.55 (CO_2CH_3), 0.82 (CH_3CH_2-); **9x**, 3.65 (CO_2CH_3), 0.72 (CH_3CH_2-): **10n**, 3.56 (CO_2CH_3), 0.90 ($CH_3(CH_2)_3$-); **10x**, 3.68 (CO_2CH_3), 0.88 ($CH_3(CH_2)_3$-).

Elementary analysis: Found: **10n**, C, 74.73; H, 9.72%; **10x**, C, 75.23; H, 9.77%. Calcd for $C_{13}H_{20}O_2$: C, 74.96; H, 9.68%.

*Reaction of **1a** with Acrolein.* The Diels-Alder adducts, 5-*endo*-formylbicyclo[2.2.1]hept-2-ene (**11n**) and 5-*exo*-formylbicyclo[2.2.1]hept-2-ene (**11x**), were separated by means of glpc (column A, at 125 °C; retention times: **11n**, 2.7 min; **11x**, 2.3 min). These are colorless liquids. NMR spectra (characteristic signals); **11n**, 9.32 (CHO): **11x**, 9.76 (CHO).

*Reactions of **1a** with Acryloyl Halides.* After the reactions were completed, the products were esterified with methanol containing lutidine in a sealed ampoule at room temperature, and subsequently analyzed by glpc (column A). The added litidine had no effect on the *endo* : *exo* isomer ratios. The esterified products were identified as **7n** and **7x** by comparing the retention time and the NMR spectra with those of authentic samples.

*Reactions of **1b** and **1c** with Methyl Acrylate.* The Diels-Alder adducts, 1,4-diphenyl-5-*endo*-carbomethoxybicyclo-[2.2.1]hept-2-ene (**12n**) and 1,4-diphenyl-5-*exo*-carbomethoxybicyclo[2.2.1]hept-2-ene (**12x**); 1,4-di(*p*-chlorophenyl)-5-*endo*-carbomethoxybicyclo[2.2.1]-hept-2-ene (**13n**) and 1,4-di-(*p*-chlorophenyl)-5-*exo*-carbomethoxybicyclo[2.2.1]hept-2-ene (**13x**) were separated by means of preparative tlc. The *endo* : *exo* isomer ratios were determined by integration on the NMR spectra. **12n**, oily liquid, NMR: 7.28 (Ph), 6.35 (CH=CH), 3.37(CO_2CH_3), 3.24(5-*exo*-H), 2.40(6-*endo*-H), 2.00(6-*exo*-H), 1.96(7-*anti*- and 7-*syn*-H): **12x**, mp 63—65 °C, NMR; 7.30(Ph), 6.35(CH=CH), 3.08(CO_2CH_3), 2.76(7-*anti*-H), 2.68(5-*endo*-H), 2.40(6-*exo*-H), 1.88(7-*syn*-H), 1.80(6-*endo*-H): **13n**, mp 88 °C, NMR; 7.28(Ph), 6.28(CH=CH), 3.48

(CO_2CH_3), 3.32(5-*exo*-H), 2.36(6-*exo*-H), 2.04—1.72 (other protons): **13x**, mp 96—97 °C, NMR; 7.30(Ph), 6.30(CH=CH), 3.20(CO_2CH_3), 2.75(7-*anti*-H), 2.72(5-*endo*-H), 2.38(6-*exo*-H), 1.96—1.70 (6-*endo*- and 7-*syn*-H).

Elementary analysis: Found: **12n**, C, 83.02; H, 6.69%: **12x**, C, 82.78; H, 6.62%. Calcd for $C_{21}H_{20}O_2$: C, 82.86; H, 6.62%. Found: **13n**, C, 67.41; H, 4.68%: **13x**, C, 67.38; H, 5.02%. Calcd for $C_{21}H_{18}Cl_2O_2$: C, 67.57; H, 4.86%.

Reactions of ***1a*** *with Maleic Anhydride and* N-*Phenylmaleimide.* The isomer distribution of the reaction of **1a** with maleic anhydride was determined by means of glpc (column D). Retention time: bicyclo[2.2.1]hept-5-ene-*endo*-2,3-dicarboxylic anhydride (**14n**), 3.9 min; bicyclo[2.2.1]hept-5-ene-*exo*-2,3-dicarboxylic anhydride (**14x**), 3.2 min at 150 °C. However, a small portion (0.15%) of **14n** was isomerized to **14x** in the glpc condition. Accordingly, the value of the isomer ratio was corrected by this figure. **14n**, mp 163—164 °C; NMR, 6.32(CH=CH), 3.40—3.70 (1—4-H's), 1.30—1.90 (other protons). **14x**; although no attempt to isolate **14x** was made, the structure of **14x** was confirmed by an isomerization experiment according to Craig's method.[22] NMR (including 70% of **14n**), 2.92 (2- and 3-H).

The adduct of **1a** with *N*-phenylmaleimide (**15n**), mp 144 °C; NMR, 7.10—7.64 (Ph), 6.28 (CH=CH), 3.28—3.64 (1—4-H's), 1.50—1.90 (other protons). The isomer distribution was determined by means of comparing the NMR data with those of **14**. An inspection of the NMR of the adduct with *N*-phenylmaleimide showed an *endo* isomer distribution of more than 99.5%.

Kinetic Experiments (a) The Reactions of ***1a*** *with Acryloyl Halides.* The initial concentrations were 0.0620—0.0842 M for the acryloyl halides, 0.0442 M for **1a**, and 0.0178 M for the internal standard (2,4-dichlorotoluene). The reaction mixture was maintained at 35±0.02 °C. Portions of the sample were withdrawn at appropriate time intervals and quenched with a large excess of methanol containing lutidine. After three hours, the solutions were analyzed by means of glpc. By following the amount of the esters, **7n** and **7x**, the second-order rate constants were calculated.

(b) The Reactions of ***1b*** *and* ***1c*** *with Methyl Acrylate.* The initial concentrations were $5.11—5.81\times10^{-4}$ M for the dienes and $7.07—10.1\times10^{-2}$ M for the dienophile. By following the disappearance of **1b** (or **1c**) spectrophotometrically, the pseudo-first-order rate constants were calculated (λ_{max}=353 nm for **1b** and 360 nm for **1c**).

The competitive reaction technique employed was the same as that used in the aromatic substitution reactions. The relative rates were calculated using the following formula:

$$k_1/k_2 = \{\log C_1^\circ - \log (C_1^\circ - X_1)\}/\{\log C_2^\circ - \log (C_2^\circ - X_2)\}$$

where C_1° and C_2° refer to the initial concentrations of dienophiles and where X_1 and X_2 refer to the final concentrations of the products. Analysis was performed by means of glpc, using appropriate internal standards. In most of the experiments, the competitive reaction of cyclopentadiene with the methyl acrylate—other dienophile pair was employed. However, the relative rate of methyl methacrylate was not obtained because of the coincidental overlap of the glpc peaks of the two reaction products. The relative rate of methyl methacrylate was calculated from the rate of methyl methacrylate relative to that of acrylonitrile and the rate of the latter relative to that of methyl acrylate. The results are shown in Table 3.

Table 3. Relative rates of the Diels-Alder reactions of cyclopentadiene with methyl acrylate (MeA), methyl methacrylate (MeMA), and acrylonitrile (AN)

Diene (mmol/l)	MeA (MeMA)[a] (mmol/l)	AN (mmol/l)	Relative rate
214	74.4	145	1.07[b]
325	46.9	136	1.02[b]
354	46.9	136	1.00[b]
627	(441)[a]	204	1.58×10^{-2}[c]
710	(430)[a]	192	1.63×10^{-2}[c]
720	(291)[a]	187	1.66×10^{-2}[c]

a) The values in parenthese are the concentration of MeMA. b) k_{AN}/k_{MeA}. c) k_{MeMA}/k_{AN}.

The authors wish to express their gratitude to Professor William J. leNoble for his valuable discussion. The financial support from the Ministry of Education is gratefully acknowledged.

The Retardation of the Benzidine Rearrangement of Hydrazobenzene by Cyclodextrins

Yoshihisa MATSUI, Kazuo MOCHIDA, Osamu FUKUMOTO, and Yoshio DATE

Department of Agricultural Chemistry, Shimane University, Nishikawazu, Matsue 690

(Received March 7, 1975)

The benzidine rearrangement of hydrazobenzene is retarded by the addition of α-, β-, and γ-cyclodextrins. The effects on the rate of the cyclodextrins are decreased by the addition of cyclohexanol. The deceleration of the reaction by the cyclodextrins was attributed to the equilibrium complexation of the substrate in the cavities of the cyclodextrins, which may either restrict the large conformational change of the substrate necessary for reaching a sandwich-type transition state or lower the concentration of the diprotonated hydrazobenzene by means of the space alkalinity of cyclodextrins.

Cyclodextrins form monomolecular inclusion complexes with a variety of substrates in aqueous solutions and affect the reactivity of the substrates. Griffiths and Bender[1] have explained the catalytic actions of cyclodextrins in terms of the nucleophilic catalysis, the microsolvent effect, and/or the conformational effect. However, there are relatively few examples in which the accelerations or decelerations of reactions are derived from the conformational effect of cyclodextrins. The present study will deal with the effects of cyclodextrins on the benzidine rearrangement of hydrazobenzene. It has been proven that the rearrangement requires a large conformational change to reach the transition state.

Experimental

Materials. The α-, β-, and γ-cyclodextrins were prepared by the method of Lane and Pirt.[2] They were separated and purified according to the directions of Cramer and Henglein.[3] The hydrazobenzene was prepared by the reduction of nitrobenzene with zinc dust and alkali in the presence of ethanol.[4] Mp 125.5—127.0 °C (lit, mp 125 °C[4]). Bindschedler's Green, used as an analytical reagent in following the rate of the rearrangement of hydrazobenzene, was prepared by the directions of Shine, Snell, and Trisler.[5] A solution of Bindschedler's Green was standardized against a standardized solution of titanium trichloride.[5] Reagent-grade cyclohexanol, methanol, citric acid, potassium citrate, and potassium sulfate were used without further purification.

Procedures. The reaction medium, generally 25 ml of a citrate buffer with a pH of 2.94 and with an ionic strength of 0.50 M adjusted by the use of potassium sulfate, was thermostated and degassed with N_2. To the solution we then added 3 ml of a 0.5 mM solution of hydrazobenzene in 60% methanol. Aliquots (2.0 ml) were pipetted out at regular time intervals and added to 10-ml standardized solutions of Bindschedler's Green. The residual amounts of Bindschedler's Green were colorimetrically determined at 712 nm with a Hitachi spectrophotometer, Model 124. The error in the determination of the hydrazobenzene concentration up to 1.00×10^{-4} M was about 0.01×10^{-4} M. The addition of cyclodextrins had virtually no effect either on the molar absorbance of Bindschedler's Green at 712 nm or on the determination of the hydrazobenzene contained in the solution. Therefore, the observed rate for the reaction of hydrazobenzene in the presence of cyclodextrins corresponds to the sum of the rate for the free hydrazobenzene and that for the complexed hydrazobenzene.

Results and Discussion

Hammond and Shine[6] have shown that the rate of the benzidine rearrangement of hydrazobenzene increases in proportion to the hydrazobenzene concentration and to the square of the hydrogen-ion concentration. Similar results were also obtained in the present study in both the absence and the presence of 8.97 mM β-cyclodextrin. Since the reaction rate is very sensitive to the pH of the medium, the effects of carbohydrates were examined at a constant pH. The first-order rate constants in the presence of methyl α-D-glucopyranoside or α-, β-, or γ-cyclodextrin are summarized in Table 1.

The reaction of hydrazobenzene was little influenced by the addition of methyl α-D-glucopyranoside, whereas it was markedly retarded by cyclodextrins, especially

TABLE 1. FIRST-ORDER RATE CONSTANTS FOR THE BENZIDINE REARRANGEMENT OF HYDRAZOBENZENE IN THE PRESENCE OF CARBOHYDRATES AT 25 °C

Table 2. Effect of cyclohexanol on the rate of the rearrangement of hydrazobenzene in the presence of 8.97 mM β-cyclodextrin at 25 °C and pH 2.91

[Cyclohexanol], mM	$k_{obsd} \times 10^2$, min^{-1}	k_{obsd}/k_{un} [a]
0	0.46±0.01	0.23
11	0.75±0.03	0.37
21	0.95±0.01	0.47
32	1.29±0.03	0.64
53	1.60±0.02	0.79
106	1.72±0.01	0.85

a) $k_{un} = (2.03 \pm 0.02) \times 10^{-2}$ min^{-1}.

by β-cyclodextrin. This fact suggests that the retardation of the reaction by cyclodextrins is not due to the action of the glucopyranose groups, but to the inclusion of the substrate in the cavities of cyclodextrins. This presumption was substantiated by the examination of the effect of cyclohexanol on the rate-constants in the presence of 8.97 mM β-cyclodextrin at pH 2.91 (Table 2). It has been known that cyclohexanol is included in the cyclodextrin cavity[7,8] and that it competitively retards the catalytic action of cyclodextrins on substrates. As anticipated, the effect of the cyclodextrin on the reaction rate decreased with an increase in the concentration of cyclohexanol.

In order to evaluate the dissociation constant (K_{diss}) and the rate constant (k_c) for the inclusion complex between cyclodextrin and hydrazobenzene, the effect of the cyclodextrin concentration on the rate constant was examined and analyzed in the standard way on the basis of the Michaelis-Menten kinetics.[9] On the assumption of the formation of the 1 : 1 cyclodextrin–hydrazobenzene complex, the observed first-order rate constant (k_{obsd}) may be represented by Eq. (1), if the concentration of the cyclodextrin is much higher than that of hydrazobenzene:

$$k_{obsd} = K_{diss}(k_{un} - k_{obsd})/[CD]_0 + k_c \quad (1)$$

where $[CD]_0$ is the total concentration of the cyclodextrin. Figure 1 shows the plot of k_{obsd} *vs.* $(k_{un} - k_{obsd})/[CD]_0$ for the reaction in the presence of β-cyclodextrin. The plot was virtually linear with a slope ($=K_{diss}$) of $(2.0 \pm 0.2) \times 10^{-3}$ M and with an

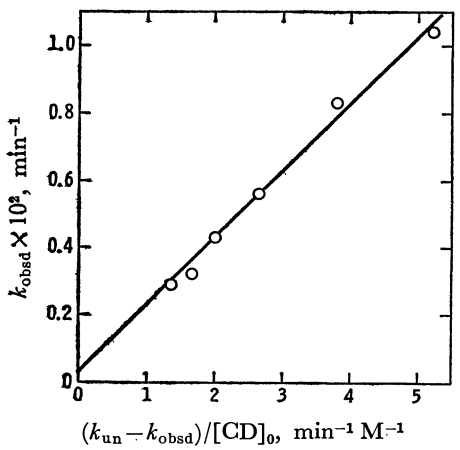

Fig. 1. The plot of k_{obsd} *vs.* $(k_{un} - k_{obsd})/[CD]_0$ for the reaction in the presence of β-cyclodextrin.

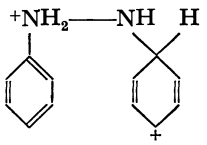
Table 3. The dissociation constant (K_{diss}) and the rate constant (k_c) of the cyclodextrin–hydrazobenzene complex at 25 °C

Cyclodextrin	pH	K_{diss}, mM	$k_c \times 10^2$ min^{-1}
α	2.94	30 ± 8	0.15±0.21
β	2.94	2.0± 0.2	0.02±0.03
γ	2.91	20 ±11	−0.10±0.84

intercept ($=k_c$) of $(0.02 \pm 0.03) \times 10^{-2}$ min^{-1}.[10] Although it might be possible that hydrazobenzene combines with two cyclodextrin molecules in a manner much like methyl orange,[11] the linearity of the above plot suggests that such complex formation, if present, is negligible. Similar linear plots were obtained for the reactions in the presence of α- and γ-cyclodextrins. The K_{diss} and k_c values determined are summarized in Table 3. It is apparent that the benzidine rearrangement of hydrazobenzene is virtually inhibited by the formation of the inclusion complexes with the cyclodextrins, although the K_{diss} values for α-, β-, and γ-cyclodextrins, were significantly different from one another.

It has been proven that the rearrangement is intramolecular, proceeding through a sandwich-type transition state in which the two benzene rings lie over each other. Recently, Olah *et al.*[12] has suggested that the folded structure, **1**, is the most likely diprotonated intermediate.



1

When hydrazobenzene is included in the cavity of cyclodextrin, this large conformational change, accompanied by the rearrangement, may be suppressed by the rigid structure of the cyclodextrin. That is, the cyclodextrin may restrict the conformation of the diprotonated hydrazobenzene to the unfolded one. The importance of the conformational restrictions of substrates has often been reported in enzymatic reactions, too.

Another explanation, which is less probable, of the effect of the cyclodextrins is that they depress the protonation of hydrazobenzene. Cramer[13] has shown that the acid-catalyzed hydrolysis of indican is depressed by the formation of the inclusion complex with β-cyclodextrin. The author explained the effect of the cyclodextrin in terms of the "space alkalinity" of the cavity of the cyclodextrin. However, cyclodextrin generally acts as a weak acid[14] rather than as a base, and the concept of space alkalinity is itself rather doubtful. Thus, Broser and Lautsch[15] have shown that, although cyclodextrins do facilitate the acid dissociation of various indicator molecules, they do not actually act as proton acceptors, but, rather, act as electrophiles on the dissociated indicator molecules to stabilize them.

In order to examine the driving force for the interaction of hydrazobenzene with cyclodextrin, the

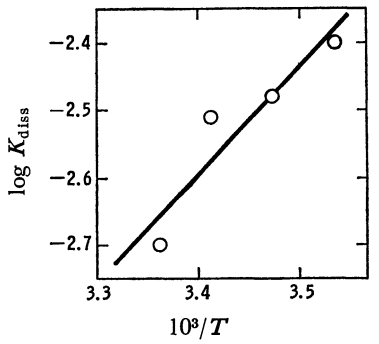


Fig. 2. The plot of log K_{diss} *vs.* the reciprocal of the temperature for the complex of hydrazobenzene with β-cyclodextrin.

thermodynamic parameters were determined for the complex formation. Figure 2 shows the plot of log K_{diss} *vs.* the reciprocal of the temperature for the complex of hydrazobenzene with β-cyclodextrin. The plot is approximately linear; the ΔH and ΔS for the dissociation of the complex were evaluated from the slope and the intercept to be -7.3 ± 6.0 kcal/mol and -36 ± 20 e.u. respectively.[10] It is evident that the driving force for the complex formation is entropic rather than enthalpic.

Hydrogenation and Hydrogenolysis. XV.[1] Hydrogenation of Isomeric Anisidines with Platinum Metal Catalysts in Acetic Acid

Shigeo NISHIMURA, Takeaki TAKAOKA, and Yoshihiro MAEKAWA

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

(Received March 31, 1975)

m-Anisidine was hydrogenolyzed to an extent of 92.5% in hydrogenation with a palladium catalyst in acetic acid at 60 °C and 90 kg/cm². The amount of hydrogenolysis in *o*- and *p*-anisidine was only 2.1 and 2.5%, respectively. This great difference in hydrogenolysis between the isomers was not observed with rhodium and platinum catalysts. With *m*- and *p*-anisidines, selectivity at the initiation of hydrogenation was studied for the formation of *N*-cyclohexylanisidine intermediates and for other products by an extrapolation method. Extensive hydrogenolysis of *m*-anisidine and slight hydrogenolysis of *o*- and *p*-anisidines over palladium result from a high selectivity in the formation of the enamine or imine intermediates. The hydrogenation pathways leading to hydrogenolysis and secondary amine formation over the three platinum metals are discussed.

In a previous paper,[2] it was shown that *m*-anisidine and *m*-phenetidine are hydrogenolyzed with a ruthenium catalyst to greater extents than the corresponding *ortho* and *para* isomers. With a rhodium catalyst, however, no appreciable difference in the amount of hydrogenolysis was observed among the isomers.[3] The ease of hydrogenolysis in the *meta* isomer over the *ortho* and *para* isomers was also observed in the hydrogenation of isomeric dimethoxybenzenes with platinum metal catalysts.[4] It has been suggested that the ready hydrogenolysis of methoxyl group in the *meta* isomers is due to the presence of electron releasing methoxy or amino group located *meta* to the methoxyl group to be hydrogenolyzed. The allyl-type ethers, formed as intermediates, have been assumed to hydrogenolyze readily, since the electron releasing groups would stabilize the transition states of carbonium ion character when the allyl ether intermediates are hydrogenolyzed. On the other hand, the electron releasing groups such as methoxy and amino might influence the distribution of various dihydro and tetrahydro intermediates in hydrogenation of aromatic compounds and thus cause differences in the amount of hydrogenolysis among the isomers.

In view of the pronounced effects of some electron releasing groups on the distribution of intermediates, as observed in the palladium-catalyzed hydrogenation of isomeric cresols[5] and ethyl tolyl ethers,[1,6] we have been interested in the hydrogenation of isomeric anisidines with a palladium catalyst. The presence of the amino group might lead to preferential formation of enamine or imine intermediate, which is expected to cause a great difference in the extent of hydrogenolysis among the isomers. In this investigation, acetic acid was chosen as the solvent, since anilines are hydrogenated most readily with palladium in this solvent,[7,8] and extensive formation of *N*-cyclohexylaniline as an intermediate allows to estimate the amount of the enamine or imine intermediate.[8] Anisidines were also hydrogenated using rhodium and platinum as catalysts under the same conditions in order to compare their selectivities with those of palladium.

The hydrogenation of anisidines with platinum metal catalysts was previously studied by Freifelder, Ng, and Helgren,[7] using ethanol–acetic acid and acetic acid as solvents. However, neither detailed analyses of high boiling products nor investigation of intermediates were made.

Results

Products of the hydrogenation of isomeric anisidines with 5% palladium-carbon, rhodium and 5% platinum-carbon catalysts in acetic acid at 60 °C under a hydro-

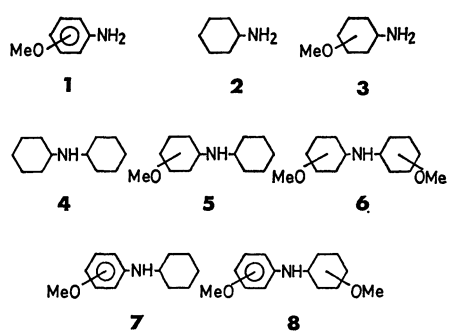
a) The anisidine (0.03 mol) was hydrogenated in 15 ml acetic acid at 60 °C under 90±10 kg/cm² hydrogen pressure. b) Values are based on mol% of anisidine consumed for the formation of each compound. **1**: anisidine; **2**: cyclohexylamine; **3**: methoxycyclohexylamine; **4**: dicyclohexylamine; **5**: methoxydicyclohexylamine; **6**: dimethoxydicyclohexylamine; **7**: *N*-cyclohexylanisidine; **8**: *N*-(methoxycyclohexyl)anisidine. Trace amounts of cyclohexane, cyclohexanol, methoxycyclohexane and methoxycyclohexanol were formed besides the compounds given in the table. c) 4.8% of 2-methoxycyclohexanol was found in the products.



[The letters **a**, **b** and **c** attached to the compound numbers refer to the products from *o*-, *m*- and *p*-anisidine, respectively]

gen pressure of 90±10 kg/cm² are summarized in Table 1. Acetylation of anisidines always occurs to 2—23% extent under these conditions, the hydrogenation of the acetylation products being very slow. It was confirmed that neither the acetylation of saturated amines nor the transformation of 2 mol of saturated primary amine into secondary amine occurs under these conditions. The acetylation products are excluded from the composition of the reaction mixture in Table 1.

The proportion of hydrogenolysis was calculated according to

$$\frac{\%\ \text{yield}\ (\mathbf{2}+\mathbf{4}+(1/2)\times\mathbf{5}+(1/2)\times\mathbf{7})}{\%\ \text{of}\ \mathbf{1}\ \text{hydrogenated}}\times 100 \qquad (1)$$

using the data in Table 1. The results are given in Table 2.

The proportion of secondary amines in the product was calculated according to:

Table 2. Proportion of hydrogenolysis in hydrogenation of isomeric anisidines (%)

Catalyst	Anisidine		
	Ortho	*Meta*	*Para*

Catalyst	Anisidine		
	Ortho	*Meta*	*Para*
Pd/C	52.9(36.0)	46.8(30.5)	64.2(47.3)
Rh	28.1(16.3)	17.5(9.60)	17.6(9.65)
Pt/C	—	59.5(42.3)[b)]	79.8(66.4)[c)]

a) Calculated according to Formula (2). Selectivity in mol% calculated according to Formula (3) is given in parentheses. b) At 66.6% conversion of *m*-anisidine. c) At 83.2% conversion of *p*-anisidine.

$$\frac{\%\ \text{yield}\ (\mathbf{4}+\mathbf{5}+\mathbf{6}+\mathbf{7}+\mathbf{8})}{\%\ \text{of}\ \mathbf{1}\ \text{converted}}\times 100 \qquad (2)$$

using the data in Table 1. The results are given in Table 3. The selectivity for secondary amine formation in mol% is given by

$$\frac{\%\ \text{yield}\ [(1/2)(\mathbf{4}+\mathbf{5}+\mathbf{6}+\mathbf{7}+\mathbf{8})]}{\%\ \text{yield}\ [\mathbf{2}+\mathbf{3}+(1/2)(\mathbf{4}+\mathbf{5}+\mathbf{6}+\mathbf{7}+\mathbf{8})]}\times 100 \qquad (3)$$

The effects of hydrogen pressure on hydrogenolysis and secondary amine formation in the hydrogenation with palladium and rhodium catalysts are shown in Figs. 1 and 2. In accord with the results obtained previously,[9)] the amount of hydrogenolysis always decreased with increasing hydrogen pressure. The effect of hydrogen pressure on secondary amine formation is not so straightforward. Formation of secondary amines increases with increasing pressure with a palladium catalyst, whereas a reverse trend was observed with a rhodium catalyst.

In order to obtain information on intermediates, the variation in the composition of reaction mixture with hydrogenation was studied with *m*- and *p*-anisidines. The results are shown in Figs. 3—8. By extrapolating the selectivity for saturated primary

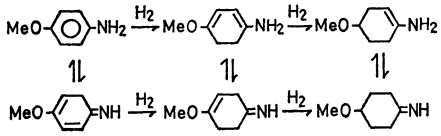
anisidines. Its presence may have considerable influence on the course of the hydrogenation of the *N*-cyclohexylanisidines.[8]

Discussion

We see from Table 2 that the ease of hydrogenolysis in the *meta* isomer over the *ortho* and *para* isomers is most pronounced in the palladium-catalyzed hydrogenation. The amount of hydrogenolysis is as large as 92.5% in the *meta* isomer, whereas in the *ortho* and *para* isomers it is only 2.1 and 2.5%, respectively. The same trend is also seen over rhodium and platinum catalysts, although the difference in the amount of hydrogenolysis between the isomers is much smaller.

an increase in primary amine formation as seen in Fig. 2.

Very slight hydrogenolyses in *o*- and *p*-anisidines over palladium are noteworthy and could be understood in terms of high selectivity for enamine or imine formation over this metal. As in the case of *m*-anisidine, the selectivity for formation of *N*-cyclohexyl-*p*-anisidine intermediate is very high (70.1 mol%) (Table 4). However, in sharp contrast to the hydrogenation of *m*-anisidine, no loss of the methoxyl group was observed in the formation of this intermediate. Hydrogenation of the intermediate **8c** also gave only a small amount of hydrogenolysis (2.6%) (Table 5). The hydrogenation of *o*-anisidine appears very similar to that of *p*-anisidine. The results indicate that hydrogenolysis scarcely occurs at all in the course of the formation of enamine or imine intermediates as well as in their further hydrogenation in the cases of *o*- and *p*-anisidines. A probable course of hydrogenation leading to selective formation of the enamine or imine intermediate over palladium is suggested to be as shown in Scheme 2 for the hydrogenation of *p*-anisidine.



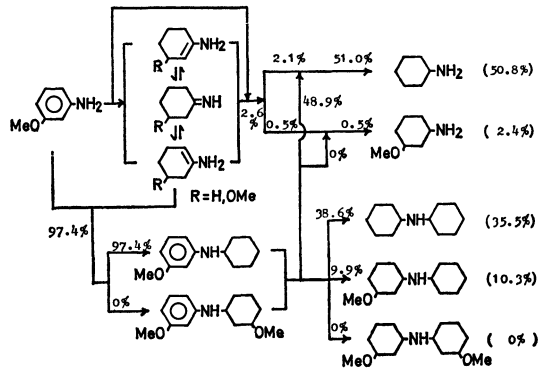
Scheme 2. Hydrogenation pathways leading to selective formation of the enamine or imine intermediate in *p*-anisidine.

The characteristic feature of the palladium-catalyzed hydrogenation of anisidines probably results from the selective hydrogenation of the enol ether moiety over the enamine moiety. This would lead to readily hydrogenolyzable enamines **9**, **11** or imine **10** in a high selectivity in the case of the *meta* isomer. Very poor tendency of palladium toward the hydrogenolysis of an enol ether,[1,11] might explain the occurrence of only slight hydrogenolysis in the course of the formation of enamines or imines in the case of *o*- and *p*-anisidines.

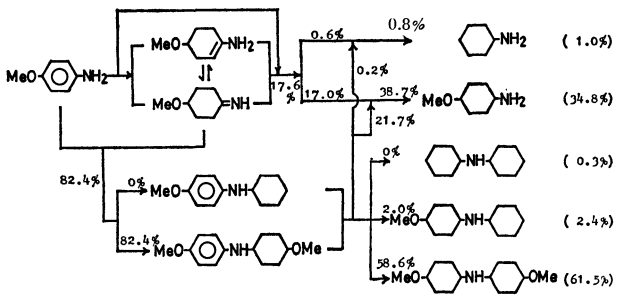
The primary amines formed at an initial stage of hydrogenation (Table 4) might arise through enamine or imine or through other unsaturated amines as intermediates. However, extensive hydrogenolysis at the primary amines from *m*-anisidine and slight hydrogenolysis at those from *p*-anisidine (Table 4) suggest that most of the primary amines is also formed through enamine or imine as an intermediate in the palladium-catalyzed hydrogenation.

On the basis of the results shown in Tables 4 and 5, the hydrogenation pathways of *m*- and *p*-anisidines over palladium are estimated to be those shown in Schemes 3 and 4. It is seen that the compositions of the products thus obtained are in good agreement with those in Table 1. They are also shown in parentheses theses in the Schemes.

In the rhodium-catalyzed hydrogenation, the formation of secondary amines is at low level and the formation of *N*-cyclohexylanisidines is not conspicuous. The selectivity for formation of secondary amines, however,



Scheme 3. Hydrogenation pathways of *m*-anisidine over a Pd-C catalyst in acetic acid (60 °C, 90±10 kg/cm² H_2).



Scheme 4. Hydrogenation pathways of *p*-anisidine over a Pd-C catalyst in acetic acid (60 °C, 90±10 kg/cm² H_2).

is larger at initiation than at complete hydrogenation, particularly in the case of *p*-anisidine. Since *N*-cyclohexylanisidines are mostly hydrogenated over rhodium catalyst to saturated secondary amines even in the presence of ammonium acetate (Table 5),[12] the result suggests that the selectivity for formation of *N*-cyclohexylanisidines decreases with decreasing concentration of anisidine in the course of hydrogenation. Accordingly the proportion of enamine or imine, formed from anisidine and hydrogenated directly to primary amine, might increase at a later stage of hydrogenation. This course of primary amine formation [step (2), Scheme 1] was suggested by Ikedate and Suzuki to be significant in the rhodium-catalyzed hydrogenation of aniline.[13] However, a great difference in the proportion of hydrogenolysis between the primary amines (9.6%) and *N*-cyclohexyl-*m*-anisidine (100%) found in the hydrogenation of *m*-anisidine (Table 4) suggests that most of the primary amines is formed in the rhodium-catalyzed hydrogenation through unsaturated amines as intermediates rather than through enamines or imines. A high degree of hydrogenolysis in the primary amines formed from the hydrogenation of **7b** (90%) (Table 5) might support the view, since it suggests that the formation of primary amines through enamines **9**, **11** or imine **10** would also result in extensive hydrogenolysis. It is of interest to note that, in line with the results with anisidines, 45—48% of cresol is hydrogenated to methylcyclohexanol through other intermediates

than methylcyclohexanone over a rhodium catalyst.[5] With palladium as a catalyst, however, all cresol is hydrogenated through the ketone as the intermediate.[5]

In the hydrogenation of anisidines with platinum, hydrogenolysis of the methoxy group as well as the formation of secondary amines occurred extensively. However, unlike the palladium-catalyzed hydrogenation, no great difference in the extent of hydrogenolysis was observed between *meta* and *para* isomers. An extensive loss of methoxyl group in *N*-cyclohexyl-*p*-anisidines (76%) (Table 4) indicates that hydrogenolysis has occurred extensively during the course of formation of enamine or imine intermediate. This result is plausible if we consider that platinum shows very high activity toward the hydrogenolysis of an enol ether.[1,11] The selectivity for formation of secondary amines does not differ much between the initiation and later stage of hydrogenation. With platinum considerable amounts of saturated secondary amines are formed together with *N*-cyclohexylanisidines (Figs. 7 and 8). However, when the selectivity for the formation of the saturated secondary amines is extrapolated to initiation, it is reduced to only a few percent (Table 4). Thus most of the secondary amines seems to be formed through *N*-cyclohexylanisidines as intermediates. Probably, in this case hydrogenation of the intermediates is fast as compared with that of anisidine. The same conclusion was also reached by Ikedate and Suzuki in the platinum-catalyzed hydrogenation of aniline.[13] Fairly large amounts of secondary amines formed over platinum indicate that the selectivity for the formation of enamine or imine intermediates is rather high over this metal.

Experimental

Materials. *o*-, *m*- and *p*-Anisidines (G. R. grade, Tokyo Kasei Kogyo) were used after distillation before use. *N*-cyclohexyl-*m*-anisidine (**7b**) and *N*-(4-methoxycyclohexyl)-*p*-anisidine (**8c**) were prepared by reductive condensation of the corresponding anisidine and cyclohexanone in isopropyl alcohol with 5% palladium-carbon at 35 °C and 3—7 kg/cm² pressure. **7b**: bp 175 °C/9 mmHg; **8c**: bp 175 °C/4 mmHg. The structures of **7b** and **8c** were confirmed by their NMR spectra (Table 6).

Catalysts. 5% Palladium-carbon and 5% platinum-carbon were obtained from Nippon Engelhard Co. Rhodium oxide was prepared by heating the rhodium hydroxide, precipitated from a hot rhodium chloride solution with an aqueous lithium hydroxide,[14] at 350 °C for 8 hr.

Solvent. The S. S. G. acetic acid (Wako Pure Chemical Ind.) was used without further purification.

Hydrogenations. All hydrogenations were carried out in a 40 ml stainless steel autoclave with a stirrer driven magnetically. The catalyst (0.2—3.2 g of the supported catalyst or 0.01—0.12 g of the oxide catalyst), the substrate (0.03 mol anisidine or 0.015 mol *N*-cyclohexylanisidine) and 15 ml acetic acid were put into the autoclave. After the air had been replaced by hydrogen, the autoclave was charged with hydrogen to the required pressure. The autoclave was then immersed in an oil bath maintained at 60±0.5 °C, hydrogenation being allowed to start after 20 min. The hydrogen pressure was kept constant within±10 kg/cm² during hydrogenation. The amount of catalyst used was adjusted to complete hydrogenation within a reasonable time (2—6 hr). Hydrogenation with the platinum catalyst became very

slow during the course of reaction and could not be completed by prolonging the reaction time (over 20 hr).

Analysis of Product. The reaction mixture was analyzed directly by gas chromatography. For low boiling products, a 3 mm×2.25 m column containing 10% PEG 6000—10% KOH on Chromosorb W was used in the temperature range 170—200 °C programmed at 4 °C/min. For high boiling products, a 3 mm×0.75 m column containing 30% PEG 20 M on Celite 545 was used at a temperature initially kept at 200 °C for 6 min and then programmed at 6 °C/min to 250 °C. For the separation of *N*-acetylanisidines and *N*-(methoxycyclohexyl)anisidines a combined column containing PEG 20M (3 mm×0.75 m) and OV-17 (3 mm×3 m) was used at 250 °C.

The secondary amines required for identification of the product peaks on gas chromatography were synthesized by the reductive condensation of the corresponding amines and cyclohexanones under the conditions described above for the preparation of **7b** and **8c**. Methoxycyclohexlamines for this condensation were prepared by hydrogenating the corresponding anisidines with ruthenium hydroxide as a catalyst in the presence of lithium hydroxide in isopropyl alcohol at 80 °C under 80—100 kg/cm².[2] The characteristics of the compounds synthesized are summarized in Table 6. The synthesis of 3,3'-dimethoxydicyclohexylamine (**6b**) and *N*-(3-methoxycyclohexyl)-*m*-anisidine (**8b**) was unsuccessful because of complete loss of the methoxyl group of the cyclohexanone component during the course of reductive condensation. Probable peaks of **6b** and **8b**, as inferred from the peaks of **6a**, **6c** and **8a**, **8c**, respectively, could not be found in the gas chromatograms of the products from hydrogenation of *m*-anisidine. A peak located around a probable peak region of **8b** was proved to be that of *N*-acetyl-*m*-anisidine by isolation with a gas chromatograph and measurement of its NMR spectrum. The gas chromatograms of the products at intermediate stages of hydrogenation often showed small peaks of *N*-cyclohexylideneanisidines in amounts less than 1%. They were added to the corresponding *N*-cyclohexylanisidines. *N*-Cyclohexylidenecyclohexylamines seem to undergo decomposition when subjected to gas chromatography in acetic acid solution. Their behavior on gas chromatography was not investigated further, but they can be neglected when we obtain the results in Table 4 by an extrapolation method. The peak areas were standardized by the mixtures of known compositions. This was done with *p*-anisidine and its hydrogenation products. The standardization for *o*- and *m*-anisidines and their hydrogenation products was approximated by applying that obtained with the *p*-anisidine series compounds.

The authors are indebted to Asst. Prof. Michiko Tsuchimoto for her helpful discussions concerning the NMR spectra and to Mr. Yoshiyuki Tomiyama for his assistance in glpc analyses.

Über die Feststellung der Wanderung des Äthoxycarbonyl-Restes bei der Dienon-Phenol-Umlagerung

Tadashi SUEHIRO und Shozo YAMAZAKI

Chemisches Institut der Gakushuin Universität, Toshima-ku, Mejiro, Tokyo 171

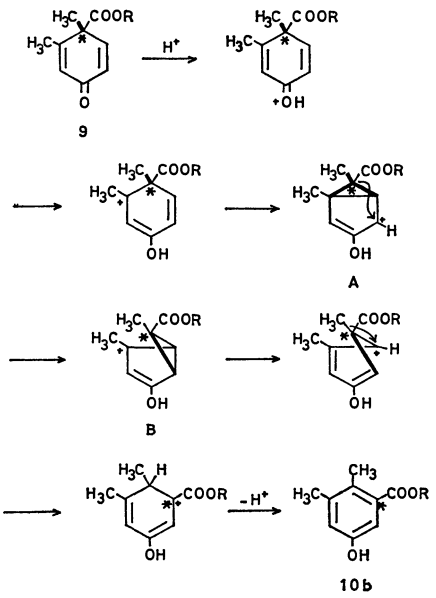
(Eingegangen am 11. 4. 1975)

3,4-Dimethyl-4-äthoxycarbonyl-cyclohexa-2,5-dienon-4-^{14}C (**9**) lagert sich bei 60—70 °C in 60% Schwefelsäure zu 2,3-Dimethyl-5-hydroxybenzoesäure-äthylester-2-^{14}C (**10**, 99.8%) und -1-^{14}C (**10b**, 0.2%) insgesammt in *ca.* 50% Ausbeute um, unter Nebenbildung von 3,4-Xylenol (**11**, 12%) und 2,3-Dimethyl-5-hydroxybenzoesäure (**12**, 5%). Dass **10** die Struktur von 2,3-Dimethylbenzoesäure-Derivat hat, wurde durch Mischprobe mit der authentischen Verbindung festgestellt.

Wir baben früher mitgeteilt, dass bei der durch Säure katalysierten Umlagerung von 3,4-Dimethyl-4-äthoxycarbonyl-cyclohexa-2,5-dienon (**9**) 2,3-Dimethyl-5-hydroxy-benzoesäure-äthylester (**10**) entsteht.[1,2] Die struktur des Ester **10** wurde unterstützt durch dessen chemische Eigenschaften, wie die schwierige Decarboxylierung der von **10** geleiteten Dimethyl-hydroxy-benzoesäure **12**[1] und auch durch die spektroskopischen Eigenschaften wie UV-Spektren von **12**, die der der *m*-Hydroxybenzoesäure ähnlich sind und wie die KMR-Spektren von **10**, die zwei Doubletts aromatischer Wasserstoffe und zwei Singuletts von Methyl-Wasserstoffen zeigen.[2] Wir haben diesmal die Struktur, die die nebeneinander stehenden CH_3-CH_3-COOR-Reste enthält, durch die Mischprobe von der aus **12** überführten 2,3-Dimethyl-cyclohexancarbonsäure (**14**) mit der aus *o*-Xylidin hergestellten Verbindung nachgewiesen, und weiter haben wir die Wanderung des Äthoxycarbonyl-Restes durch die ^{14}C-Markierungstechnik festgestellt, worüber wir hier berichten wollen.

Die Dienon-Phenol-Umlagerung ist viel untersucht worden, darunter findet man einige merkwürdige Ergebnisse, wie die 1,3-Wanderung des CCl_3-Restes[3] und die bevorzugte 1,2-Wanderung des Äthoxycarbonyl-Restes.[1] Weil der Rest COOR einen Elektronen anziehenden Charakter hat, ist die Wanderung von COOR zum Kation-Zentrum schneller als die der Elektronen liefernden Methyl-Gruppe schwierig zu verstehen.*

Es ist noch ein anderer Weg ohne die COOR-Wanderung denkbar, und zwar ein Weg von **9** zu **10** über die Bicyclo[3.1.0]hexen-Derivate **A** und **B** unter Umbau des aromatischen Ringes und mit anschliessender Umlagerung der Methyl-Gruppe zum Kation-Zentrum (Schema 1). Die Umlagerung unter Umbau des aromatischen Ringes dieser Art sieht man bei der photochemischen Dienon-Phenol-Umlagerung wie von 4-Methyl-4-dichlormethyl-cyclohexa-2,5-dienon in säurer Lösung.[4] Die kationische disrotatorische 5-Ring-Elektrocyclisierung und die kationische suprafaciale 1,4-sigmatropische Umlagerung sind nach der Woodward-Hoffmann-Regel** photochemisch erlaubt und die antarafaciale thermische Wanderung **A**→**B**



Schema 1.

müsste bei den Kleinring-Verbindungen schwierig sein, trotzdem ist es vom Wert, chemisch festzustellen, wie es bei **9** wirklich ist.

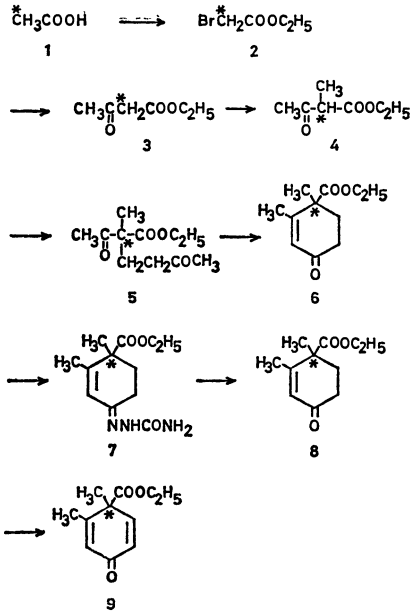
Ergebnisse und Diskussion

Wir haben 3,4-Dimethyl-4-äthoxycarbonyl-cyclohexa-2,5-dienon-4-^{14}C nach dem Schema 2 synthetisiert. Man führt Bromessigester-2-^{14}C (**2**) durch die Reformatsky-Reaktion mit Acetnitril nach der Methode von Dahn und Hauth[5] in mässiger Ausbeute in Acetessigester-^{14}C (**3**) über. α-Methyl-acetessigester-^{14}C (**4**) unterwirft man in Toluol der Michael-Addition bei −10 °C in Gegenwart katalytischer Mengen von Kalium *t*-Butoxid und cyclisiert das Produkt durch Erhitzen mit Piperidin-Acetat in 3,4-Dimethyl-4-äthoxycarbonyl-cyclohex-2-enon-4-^{14}C (**6**). Man verwandelt Cyclohexenon in festen Semicarbazon **7** zur Reinigung des flüssigen Ketons **6** und gewinnt das Keton durch säure Hydrolyse wieder. Dehydrierung von Cyclohexenon **8** zu Cyclohexadienon **9** gelang durch Kochen mit Selendioxid in *t*-Butanol. Die totale Ausbeute aus Eisessig in Cyclohexadienon **9** betrug 2.1% des theoretischen Wertes.

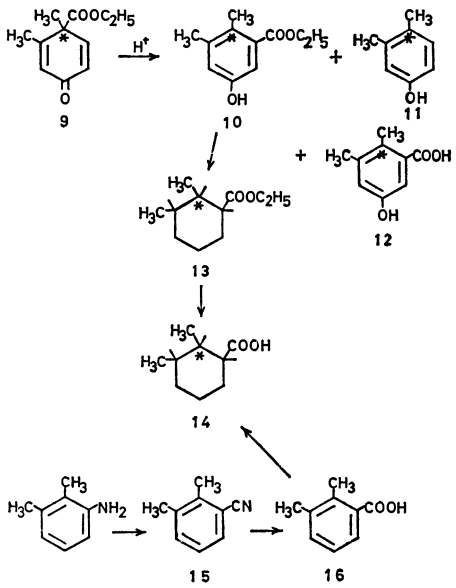
Bei der Behandlung von **9** mit 60% Schwefelsäure 30 Min. bei 60—70 °C erhält man 2,3-Dimethyl-5-hydroxy-benzoesäure-äthylester (**10**) vom Schmp.

* Siehe auch den Artikel von R. M. Acheson, *Accounts Chem. Res.* **4**, 177 (1971) über Umlagerung des COOR-Restes.

** R. B. Woodward und R. Hoffmann, "The Conservation of Orbital Symmetry" Verlag Chemie—Academic Press Inc (1970), Seite 45 und 118.



Schema 2.



Schema 3.

67.5—68.0 °C, 3,4-Xylenol (**11**) vom Schmp. 64—65 °C und 2,3-Dimethyl-5-hydroxy-benzoesäure (**12**) vom Schmp. 186—187 °C je in Ausbeute *ca.* 50, 12 und 5%. Die Umlagerung geschah also sehr sauber, und es war keine bemerkenswerte Nebenreaktion zu finden. Bei der Hydrierung von **10** bei Raumtemperatur in Eisessig auf Platinoxid nimmt **10** 4 Mole Wasserstoff auf und gibt in quantitativer Ausbeute 2,3-Dimethyl-cyclohexan-carbonsäure-ester-^{14}C (**13**) unter Hydroxyl-Abspaltung. Man erhält aus **13** durch Verseifen Dimethyl-cyclohexancarbonsäure-^{14}C (**14**) vom Schmp. 59—60 °C. Diese Carbonsäure kann man auch ausgehend von *o*-Xylidin über Dimethylbenzonitril **15**, Dimethylbenzoesäure **16** und durch anschliessende Hydrierung herstellen. Die Umsetzung von *o*-Xylidin in Nitril **15** geht sehr schlecht (18%), wahrscheinlich durch sterische Behinderung unter Nebenbildung von *o*-Xylenol vom Schmp. 75 °C. Die Hydrolyse von **15** gelang in mässiger Ausbeute erst durch Erhitzen von **15** mit Polyphosphorsäure auf 165 °C. Die Hydrierung von Dimethylbenzoesäure **16** verlief genau so gut wie bei **10** und man erhält Dimethylcyclohexancarbonsäure vom Schmp. 59—60.5 °C in 97% Ausbeute. Die beiden Dimethylcyclohexancarbonsäuren zeigten keine Schmelzpunkterniedrigung bei der Mischprobe, damit wurde klar, dass **10** die Struktur von 2,3-Dimethyl-benzoesäure-Derivat hat (Schema 3).

Wenn die Dienon-Phenol-Umlagerung von **9** nach dem Schema 1 verläuft, dann musste die 4-^{14}C-Markierung von **9** in die 1-Stellung von **10** wandern. Zur Bestimmung der Stellung der ^{14}C-Markierung in **10** haben wir **10** in Dimethyl-oxo-hexamethylenimin überführt und durch dessen Schmidt-Reaktion in Kohlendioxid und Dimethyl-pentamethylendiamin abgebaut. Um **14** in **19** oder **20** zu verwandeln, versetzt man **14** zuerst mit Thionylchlorid und das entstandene Säurechlorid **17** verwendet man direkt für die Friedel-Crafts-Reaktion in Benzol mit Aluminiumchlorid, wobei man in 62% Ausbeute Dimethylcyclohexyl-phenyl-keton **18** erhält. Wenn man das Keton **18** bei 65 °C in 90% Schwefelsäure-Natriumnitrit behandelt[6], so gewinnt man in 81% Ausbeute rohe Dimethyl-oxo-hexamethylenimine (**19**+**20**) vom Schmp. *ca.* 90 °C, woraus man nach mehrmaligem Umkristallisieren aus *n*-Hexan Nadeln vom Schmp. 123—125 °C (**19**, 28%) isoliert. Zur Analyse brachte man ein Produkt vom Schmp. 124.5—126 °C nach dem weiteren Umkristallisieren. Aufgrund der KMR-Spektren[7] von **19** in Tetrachlorkohlenstoff, δ 3.15 ppm (2H, m) und 2.7 ppm (1H, quartett) hat **19** wahrscheinlich die Struktur 3,4-Dimethyl-2-oxo-hexamethylenimin. Aus der Mutterlauge der Umkristallisierung vom Produkt Schmp. *ca.* 90 °C ohne ^{14}C-Markierung erhält man noch ein isomeres 2,3-Dimethyl-7-oxo-hexamethylenimin (**20**) vom Schmp. 65.5—67.5 °C mit KMR-Spektrum in Tetrachlorkohlenstoff, δ 2.3 ppm (2H, m) und 3.6 ppm (1H, quintett).

Die Schmidt-Reaktion von **19** mit anschliessender Benzoylierung gab glatt Dimethyl-pentamethylendiamin-dibenzamid vom Schmp. 151—153 °C (**21**, 69%) und Bariumcarbonat (**22**, 76%). Die Grignard-Reaktion mit dem aus **22** entwickelten Kohlendioxid und 3-fachen Mengen Phenylmagnesiumbromid in einem Einschlussrohr gab direkt Triphenylcarbinol (**23**) vom Schmp. 161—162.5 °C in 84% Ausbeute, dessen Struktur durch Mischprobe mit der authentischen Verbindung festgestellt wurde (Schema 4).

Die Ergebnisse der Radioaktivitäts-Bestimmung von **19**, **21** und **23** sind in Tabelle 1 aufgestellt, daraus ersieht man, dass das Ring-Gerüst von **10** während der Umlagerung 99.8% unverändert bleibt: Während der Umlagerung wandert der Äthoxycarbonyl-Rest schneller als der Methyl-Rest zum Kation-Zentrum. Dies stimmt genau mit den Ergebnissen der Blaise-Umlagerung überein[8]: Die Behandlung von α,α-Dimethyl-β-hydroxy-β-phenylpropionsäure-ester in Benzol mit Phosphorpentoxid ergab Dimethyl-atropasäure-ester unter COOR-Wanderung. Andere ähnliche Um-

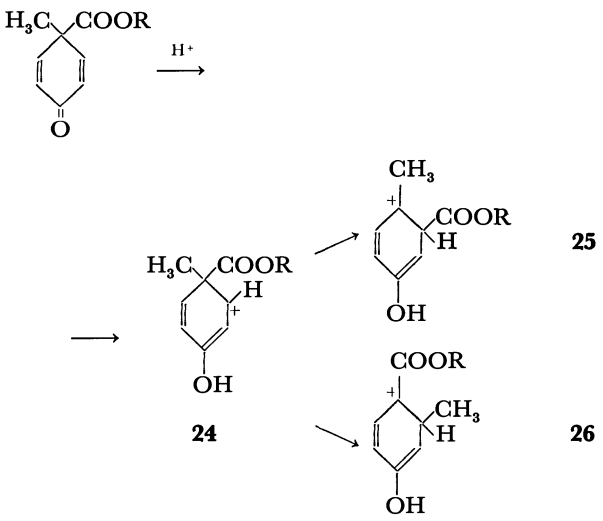
a) Die Bestimmung erfolgte mit dem Gerät Packard Tri-Carb Spektrophotometer mit einer Dioxan/PPO-DMPOPOP-Naphthalin Lösung.

lagerungen wurden auch bei den verwandten Verbindungen ausfindig gemacht.[9]

Wir finden zugleich eine kleine aber doch deutliche Radioaktivität (0.2%) in Kohlendioxid im Carbonat **22**: Thermische kationische 1,4-sigmatropische Umlagerung bei Kleinring-Verbindung findet anscheinend innerhalb 0.2% der ganzen Umlagerung statt und führt zur Bildung von **10b** (Schema 1).

Zum Mechanismus der Umlagerung haben Marx und andere[10] aufgrund ihrer kinetischen Untersuchung vorgeschlagen, dass die Geschwindigkeitsbestimmende Stufe der Umlagerung in der Stufe der Wanderung der Substituenten des protonisierten Dienons **24** liege und der Übergangszustand der Wanderung eher Produkt-ähnlich als Ausgangssubstanz-ähnlich sei: Die schnelle Wanderung des Äthoxycarbonyl-Restes werde durch die höhere Stabilität des Carboniumions **25** nach der COOR-Umlagerung als die des Ions **26** nach der Methyl-Umlagerung kontrolliert.

Es ist aber schlecht verständlich, warum sich 4,4-Dimethyl-cyclohexa-2,5-dienon mit nur ein Fünftel der Geschwindigkeit von 4-Methyl-4-äthoxycarbonyl-



cyclohexa-2,5-dienon umlagert[10]: Die beiden Dienone sollten eigentlich mit derselben Geschwindigkeit umgesetzt werden.

Wir wissen noch nicht genau, wie die Umlagerung des Äthoxycarbonyl-Restes vor sich geht. Eine ähnliche NO_2-Wanderung findet man bei der Säure-katalysierten Umlagerung von 1-Acetoxy-3,4-dimethyl-4-nitro-cyclohexa-2,5-dien[11] und von 1-Acetoxy-1-isopropyl-4-methyl-4-nitro-cyclohexa-2,5-dien.[12] Die Doppelbindung im COOR-Rest könnte für dessen bevorzugte Wanderung viel beitragen wie z. B. bei den homoallylischen Systemen der Bicyclo[2.2.1]hepten-Verbindungen[13]: Die C=O Gruppe könnte durch einfach Überschirmung auf dem Kation-Zentrum oder durch teilweise Verknüpfung an das Kation-Zentrum in der homoallylischen Stellung den Methyl-Rest vom Reaktionsbereich herausschliessen.

Herrn Dr. N. Morikawa an der Universität Tokyo danken wir herzlichst für die Bestimmung der Radioaktivität.

Beschreibung der Versuche

Die Synthese von 3,4-Dimethyl-4-äthoxycarbonyl-cyclohexa-2,5-dienon-4-^{14}C (**9**) wurde im Prinzip nach der Vorschrift von Plieninger und Suehiro[1] ausgehend von Eisessig-2-^{14}C durchgeführt, ausser der Überführung von Cyclohexenon **8** in Cyclohexadienon **9**.

3,4-Dimethyl-4-äthoxycarbonyl-cyclohexa-2,5-dienon-4-^{14}C (***9***): Nach der Method von Mystre und anderen[14] kocht man 25.31 g (0.128 Mol) **8** 7 Stunden lang mit 15 g (0.135 Mol) Selendioxid in 250 ml *t*-Butanol–2 ml Eisessig. Man dampft unter vermindertem Druck *t*-Butanol ab, nimmt den Rückstand in Dichlormethan auf, filtriert den Überschuss Selendioxid ab, lässt die Lösung durch eine Kolonne von Aluminiumoxid laufen, eluiert mit weiterem 800 ml Dichlormethan, dampft die Dichlormethan-Lösung ab und destilliert den Rückstand unter 2 Torr. Das Produkt geht bei 105—107 °C über. Ausbeute 7.51 g (38.4 mMol, 30%). KMR in Tetrachlorkohlenstoff, δ 6.83 ppm (1H, d, J=10 Hz, 6-C-H), 6.22 ppm (1H, doppelte d, J=10 Hz und 2 Hz, 5-C-H), 6.12 ppm (1H, breites s, 3-C-H).

Umlagerung von ***9***: Man erhitzt 7.51 g (38.4 mMol) von **9** in 100 ml 60% Schwefelsäure 25 Min. bei 60 °C. Die Mischung verdünnt man mit 300 ml Eiswasser und schüttelt mit Äther aus. Die äther. Lösung gibt nach dem Waschen

mit Natriumhydrogencarbonat und Abdampfen und Umkristallisieren aus Benzol–*n*-Hexan (1 : 5) **10** in Nadeln 3.64 g (18.5 mMol, 48%) vom Schmp. 66—68 °C (Schmp. in der Literatur[1] 69 °C). Gef. C 68.26, H. 7.30%. Ber. für $C_{11}H_{14}O_3$, C 68.02, H. 7.27%. KMR in Chloroform-*d*, δ 7.23 ppm (1H, d, J=3 Hz, 6-C-H), 7.07 ppm (breites s, O-H), 6.88 ppm (1H, d, J=3 Hz, 4-C-H), 2.25 ppm (3H, s, 2-CH_3), 2.10 ppm (3H, s, 3-CH_3).

Bei der Behandlung von nicht markiertem **9** isoliert man durch Schütteln mit Natriumcarbonat und fraktionierende Destillation ausser **10** noch 3,4-Xylenol vom Schmp. 64—65 °C in 12% Ausbeute, dessen Struktur durch Mischprobe mit der authentischen Verbindung und durch Schmp. von dem 3,5-Dinitrobenzoesäure-ester 180—181 °C festgestellt wurde, und auch 2,3-Dimethyl-5-hydroxybenzoesäure vom Schmp. 186—187 °C in 5% Ausbeute. Gef. C 64.87, H 6.09%. Ber. für $C_9H_{10}O_3$, C 65.05, H 6.07%. UV-Spektrum in Methanol, λ_{max} 301 nm (log ε=4.18), λ_{min} 267 nm.

2,3-Dimethyl-cyclohexancarbonsäure-äthylester-^{14}C ***(13)***: Man hydriert 3.64 g radioaktiven und 1.63 g nicht radioactiven Dimethyl-hydroxy-benzoesäure-ester (insgesammt 27.2 mMol) **10** in 30 ml Eisessig bei atmosphärem Druck und bei Raumtemp. über 0.4 g Platinoxid. Die Wasserstoff-Aufnahme betrug 2.75 Liter (25 °C, Th. 2.65 Liter). Nach dem Abtrennen vom Katalysator erhält man beim Destillieren unter 0.2 Torr. ein Produkt, das bei 48—50 °C überght. Ausbeute 4.67 g (25.4 mMol, 93%). KMR in Tetrachlorkohlenstoff, δ 0.93 ppm (3H, d, J=6.5 Hz, CH_3), 0.74 ppm (3H, J=6.5 Hz, CH_3).

2,3-Dimethyl-cyclohexancarbonsäure-^{14}C ***(14)***: Man kocht 4.67 g (25.4 mMol) von **13** 2 Stunden in 20 ml Äthanol—4 ml Wasser mit 4.0 g Natriumhydroxid. Man destilliert Äthanol ab, verdünnt den Rückstand mit Wasser, behandelt mit Teirkohle und säuert mit verd. Salzsäure an, dabei fallen Kristalle aus. Rohprodukt 2.84 g (18.2 mMol, 72%) vom Schmp. 52—57 °C. Umkristallisieren aus *n*-Hexan gibt ein Produkt vom Schmp. 59—60 °C. IR(KBr) 3300—2500 (breit), 1700 (breit), 1250 und 930 cm^{-1}. KMR in Tetrachlorkohlenstoff, δ 12.13 ppm (1H, s, COO-H), 2.5—1.0 ppm (breites m, 9H), 0.87 ppm (3H, d, J=7 Hz, CH_3), 0.76 ppm (3H, d, J=7 Hz, CH_3). Dieses Produkt zeigte keine Schmelzpunkterniedrigung bei der Mischprobe mit dem Produkt aus 2,3-Dimethylbenzoesäure durch Hydrierung vom Schmp. 60.5—61.5 °C. UV- und KMR-Spektren stimmten vollkommen mit denen des letzteren Pruduktes überein.

Hydrierung von 2,3-Dimethyl-benzoesäure zu 2,3-Dimethyl-cyclohexancarbosäure: Die aus *o*-Xylidin hergestellte 2,3-Dimethyl-benzoesäure vom Schmp. 144—145 °C (Literatur-Angabe, Schmp. 145 °C[15]) 8.90 g (59.3 mMol) hydriert man in 75 ml Eisessig bei atmosphärem Druck und Raumtemp. über 0.7 g Platinoxid. Die Hydrierung verläuft glatt und nimmt 4.94 Liter Wasserstoff auf (30 °C. Th. 4.47 Liter). Nach dem Trennen vom Katalysator erhält man bei Destillation unter 0.2 Torr. ein kristallines Produkt, das bei 91—96 °C übergeht. Umkristallisieren aus *n*-Hexan bei −5 °C gibt ein Produkt vom Schmp. 60.5—61.5 °C. Ausbeute 8.94 g (57.3 mMol. 97%). Gef. C 69.41, H 10.08%. Ber. für $C_9H_{16}O_2$, C 69.19, H 10.32%.

2,3-Dimethylcyclohexyl-phenyl-keton-^{14}C ***(18)***: Zu einer Lösung von 1.71 g radioaktiver und 2.61 g nicht radioaktiver 2,3-Dimethylcyclohexancarbonsäure **14** (insgesammt 27.7 mMol) in 15 ml Benzol gibt man 10.8 g (90 mMol) Thionylchlorid und kocht 2 Stunden unter Rückfluss. Man destilliert den Überschuss Thionylchlorid und Benzol ab und erhält bei der Destillation unter 25 Torr. ein Öl vom Siedep. 106—108 °C. Ausbeute 3.60 g (20.5 mMol, 74%). Zu einer Mischung von 3.60 g Säurechlorid **17** in 30 ml trocknem Benzol gibt man bei 20 °C unter Umrühren portionsweise 3.10 g (23 mMol) Aluminiumchlorid und erwärmt in einer Stunde bis auf 70 °C und lässt gleich danach die Mischung bis auf Raumtemp. abkühlen und über Nacht stehen. Man giesst die Mischung aufs Eis, schüttelt die Benzol-Lösung mit verd. Salzsäure, dann mit Natriumhydroxid. Aus der Benzol-Lösung erhält man bei Destillation under 0.05 Torr. ein Öl vom Siedep. 94—95 °C. Ausbeute 2.73 g (12.6 mMol, 62%). KMR in Tetrachlorkohlenstoff, δ 7.8 und 7.3 ppm (5H, m, aromatische H), 3.32 ppm (1H, m, cyclohexyl-1-C-H), 2.5—1.0 ppm (8H, m), 0.85 ppm (3H, d, J=6 Hz, CH_3), 0.56 ppm (3H, d, J=7 Hz, CH_3).

3,4-Dimethyl-2-oxo-hexamethylenimin-^{14}C ***(19)***: Nach der Methode von SNIA VISCOSA[6] löst man unter Umrühren 2.73 g (12.6 mMol) von **18** bei *ca.* 10 °C in 14 ml 90% Schwefelsäure, darauf gibt man bei 10—20 °C 1.05 g (15.1 mMol) Natriumnitrit in festem Zustand. Man erwärmt die Mischung allmählich bis auf 65 °C und hält 5 Stunden bei dieser Temp. Man giesst die Reaktionsmischung aufs Eis, zieht mit Äther die Carbonsäure und ebenso die schwerlösliche neutrale Substanz aus. Man neutralisiert die schwefelsäure-sauere wässer. Lösung mit Natriumhydroxid (*ca.* 18 g) bis zu pH 7.8 mit Kresolrot und gibt dazu ein Paar Tropfen 2 M Natriumcarbonat und schüttelt 6-mal mit je 30 ml Chloroform aus.

Der äther. Auszug gibt nach dem Waschen mit Soda-Lösung ein festes neutrales Produkt, ein rohes Laktam. Dieses rohes Produkt destilliert man zusammen mit dem aus der Chloroform-Lösung bei 0.2 Torr. und man bekommt ein Öl, das bei *ca.* 90 °C übergeht. Das Öl wird bald fest und schmilzt bei *ca.* 95 °C. Ausbeute 1.44 g (10.2 mMol, 81%). Nach mehrmaligem Umkristallisieren aus *n*-Hexan erhält man ein Produkt vom Schmp. 123—125 °C, 498 mg, wovon 463 mg zur weiteren Umsetzung gebracht wurde. Eine Analyse-Substanz gewinnt man nach weiterem Umkristallisieren, 19 mg vom Schmp. 124.5—126 °C. Gef. C 67.93, H 10.67, N 10.15%. Ber. für $C_8H_{15}ON$, C 68.04, H 10.71, N 9.92%. KMR in Tetrachlorkohlenstoff, δ 3.15 ppm (2H, m, CONHC-H_2), 2.7 ppm (1H, quartett, NHCOC-H).

2,3-Dimethyl-7-oxo-hexamethylenimin ***(20)***: Beim Umsetzen mit 3.61 g (16.8 mMol) von nicht radioaktivem Keton **18** wie oben beschrieben isoliert man 1.45 g rohes Produkt vom Schmp. 93—105 °C (**19**+**20**). Aus der Mutterlauge des Produktes erhält man nach mehrmaligem Umkristallisieren aus *n*-Hexan ein isomers Laktam vom Schmp. 65—67 °C, 57 mg. Gef. C 68.27, H 10.93, N 9.71%. Ber. für $C_8H_{15}ON$, C 68.04, H 10.71, N 9.92%. KMR in Tetrachlorkohlenstoff, δ 3.6 ppm (1H, quintett, CONHC-H), 2.3 ppm (2H, m, NHCOC-H_2).

1,2-Dimethyl-pentamethylendiamin-dibenzamid-^{14}C ***(21)*** *und Bariumcarbonat-*^{14}C ***(22)***: Man kocht 463 mg (3.27 mMol) von **19** mit 10 ml 5 M Salzsäure 7 Stunden unter Rückfluss (Dünnschicht-Chromatographie an Aluminiumoxid mit Essigester zeigte freie Aminosäure und deren HCl-Salz, aber kein Laktam). Nach dem Abdampfen unter vermindertem Druck versetzt man den Rückstand mit 3.2 g (32 mMol) Schwefelsäure und vertreibt Chlorwasserstoff bei 60 °C in Vak.

Man stellt eine Stickstoffwasserstoffsäure-Lösung in 10 ml Chloroform–5 ml Benzol her, durch Zutropfen von 1.00 g konz. Schwefelsäure (10 mMol) auf 1.3 g (20 mMol) Natriumazid–1.5 ml Wasser in Chloroform–Benzol-Mischung unter Ümrühren bei −5—+3 °C innerhalb 15 Min. Der Gehalt an Stickstoffwasserstoffsäure betrug 16 mMol.

Die Stickstoffwasserstoffsäure-Lösung wird bei 30—44 °C unter Ümrühren im Laufe von 40 Min. auf die Aminosäure-Schwefelsäure zugetropft, und die Mischung wird über Nacht bei 44 °C erwärmt. Das entwickelte Kohlendioxid leitet man durch eine Lösung 0.5 g Kaliumpermanganat—10 ml 0.5 M Schwefelsäure in die Alkali aus 4 ml 50% Natriumhydroxid-16 ml Kohlendioxid-freiem Wasser. Aus der alkali schen Lösung fällt man durch Zugabe von 100 ml 0.5 M Bariumchlorid-1.5 M Ammoniumchlorid 487 mg (2.47 mMol, 76%) Bariumcarbonat (**22**).

Die saure Reaktionsmischung wird in Vak. abgedampft und mit Wasser verdünnt. Durch Versetzen mit 3.45 g (86 mMol) Natriumhydroxid in 5 ml Wasser macht man alkalisch. Bei der Zugabe von 1.98 g (14 mMol) Benzoylchlorid bei 50 °C erhält man 0.76 g (2.25 mMol, 69%) rohes Dibenzamid vom Schmp. 141—146 °C, nach dem Umkristallisieren aus 40 ml Benzol-Essigester (1 : 2). Durch mehrmaliges Umkristallisieren gewinnt man eine Analyse-Substanz vom Schmp. 151—153 °C. Gef. C 74.31, H 7.66, N 8.43%. Ber. für $C_{21}H_{26}O_2N_2$, C 74.52, H 7.74, N 8.24%.

Triphenylcarbinol-^{14}C (***23***): In eine am Vakuum-System angeschlossene Ampulle fügt man 5 ml Phenylmagnesiumbromid-Lösung (7.38 mMol), dazu destilliert man Kohlendioxide aus 487 mg von **22** (2.47 mMol) und 5 ml konz. Schwefelsäure unter 0.01 Torr. ein, und schliesst die Ampulle in Vak. ab. Nach Stehenlassen über Nacht bei Raumtemp. versetzt man die Mischung mit verd. Salzsäure. Aus dem Soda-Auszug beim Ansäuern erhält man nur wenig Benzoesäure, aber aus dem neutralen Produkt isoliert man 532 mg (2.05 mMol, 84%) Triphenylcarbinol vom Schmp. 159—161 °C. Umkristallisieren aus Methanol gibt eine Analyse-Substanz vom Schmp. 161—162.5 °C. Sie zeigt bei der Mischprobe mit dem authentischen Triphenylcarbinol keine Schmelzpunkterniedrigung.

Photochemical Reactions between Dibromomaleic Anhydride and *N*-Phenylpyrrole[1]

Taku MATSUO and Satoru MIHARA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Fukuoka 812

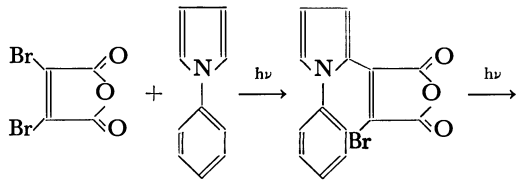
(Received April 28, 1975)

With the irradiation of dibromomaleic anhydride and *N*-phenylpyrrole, photosubstitution and photocyclization took place in succession to yield pyrrolo[1,2-a]quinoline-4,5-dicarboxylic anhydride as the final product. On the basis of energy-transfer experiments, both of the reactions were concluded to proceed *via* triplet species. Solvent effects were carefully examined and the presence of polar reaction intermediates was proposed to account for the solvent-dependent deactivation process.

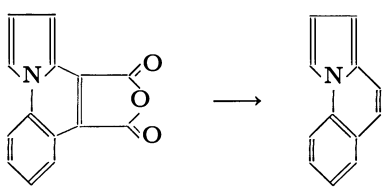
The photoinduced addition between maleic anhydride and benzene is a well known example where charge-transfer complexes determine the course of photochemical reactions.[2] In the case of dibromomaleic anhydride and benzene homologues closely related to the above system, the irradiation of charge-transfer bands induced successive substitution of the two bromine atoms with phenyl groups, and further irradiation afforded phenanthrene-9,10-dicarboxylic anhydride as the final product.[3] Since the photochemical characteristic of dibromomaleic anhydride has not been reported, the mechanistic details of the reaction were investigated here by the use of *N*-phenylpyrrole, whose ionization potential is much lower than other benzene homologues.[4]

Results

Identification of the Reaction Products. After irradiation of dibromomaleic anhydride (**1**) and *N*-phenylpyrrole (**2**) with a high-pressure mercury lamp, the reaction mixture was treated with silica-gel column chromatography, and a crystalline material was obtained. On the basis of the spectroscopic data, the crystalline material was suggested to be 3-bromo-4-(*N*-phenyl-2-pyrryl)-2,5-furandione (**3**). On further irradiation, **3** was quantitatively converted to pyrrolo-[1,2-a]quinoline-4,5-dicarboxylic anhydride (**4**). The structure of **4** was deduced from the spectroscopic data and was verified by the fact that 5,6-benzopyrocholine (**5**) was obtained after the thermal decarboxylation. The overall reactions are summarized as follows:



1 **2** **3**



4 **5**

Quantum Yields. The absolute quantum yields for the formation of **3** (called photosubstitution hereafter) in benzene solution on direct excitation were determined by irradiating the sample solution with a collimated beam of monochromatic light (334 nm). The light intensity was determined by the use of a potassium ferrioxalate actinometer. Relative quantum yields in the presence of various additives were determined by the use of a modified merry-go-round irradiation apparatus. The irradiating light from a high-pressure mercury lamp was filtered through two layers of solutions around the lamp. The growth of **3** was monitored in each case by the change in optical density at the characteristic absorption band in the electronic spectra. The total conversion was never allowed to exceed 5%. The results are summarized in Table 1, where the triplet energy of each additive is also included. Biacetyl (E_T=55 kcal/mol) also was found to sensitize the reaction, although the quantum yield was not accurately determined due to the small extinction coefficient of biacetyl. No sensitization was observed with either pyrene (E_T=49 kcal/mol) or anthracene (E_T=42 kcal/mol). In the absence of additives, the quantum yields (Φ_p) depend on the concentration of **2**. A linear correlation between the inverse of the two quantities was observed, as discussed later (Fig. 1). In the case of photocyclization from **3** to **4**, the quantum yield on the direct excitation of **3** was strongly affected by the change in solvents, as shown in Table 2. The effect of additives on the photocyclization was also investigated. The reaction was sensitized in the presence of xanthone (E_T=74), benzophenone (E_T=69), phenanthrene (E_T=62), and pyrene (E_T=49 kcal/mol). Quenching of the reaction was observed, on the other hand, when acridine (E_T=

TABLE 1. QUANTUM YIELDS OF THE PHOTOSUBSTITUTION (Φ_p) IN THE PRESENCE OF VARIOUS ADDITIVES[a]

Additive	Triplet energy (kcal/mol)	Φ_p

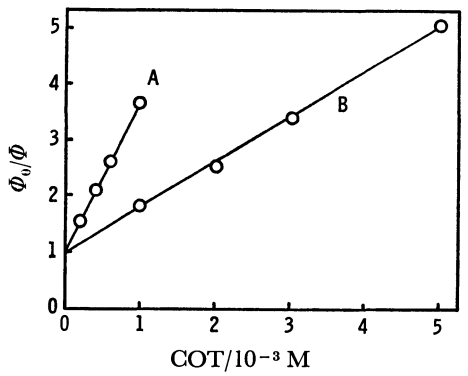

Fig. 2. Stern-Volmer plots of the reaction between **1** and **2** in dichloromethane. A: [**2**]$=2\times10^{-4}$ M. B: [**2**]$=1\times10^{-3}$ M.

45), anthracene ($E_T=42$), COT ($E_T<39$) and oxygen ($E_T=23$ kcal/mol) were present in the solution.

Quenching Studies. Since the photosubstitution reaction was quenched either by COT or oxygen as described above, the variation of the quantum yield was studied as a function of COT concentration. A typical example of a Stern-Volmer plot is shown in Fig. 2. The Stern-Volmer plot was invariably linear out to Φ_0/Φ values greater than 5. The quenching constant (K) was found to depend both on the concentration of **2** and also on the solvent, as summarized in Table 3. The photocyclization from **3** to **4** also gave nice Stern-Volmer plots, as shown in Fig. 3, for three different quenchers in benzene solutions. The lifetimes of the triplet state of **3** thus obtained in various solvents are summarized in Table 4.

Table 3. Quenching constants (K) for photosubstitution reaction under irradiation with 313 nm-light

Solvent	[**2**] (mM)	K (M^{-1})
Carbon tetrachloride	0.2	2600
	1.0	670
Diethyl ether	0.3	700
	3.0	220
Chlorobenzene	3.0	120
	10	60
Dichloromethane	0.2	2700
	1.0	620

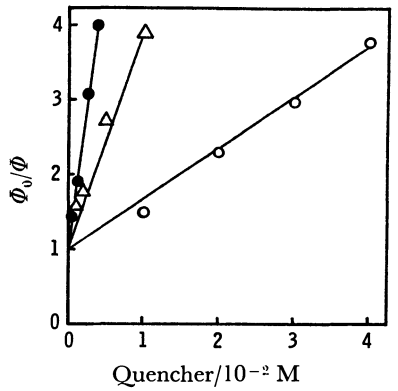

Fig. 3. Stern-Volmer plots of the photocyclization of **3** in the benzene solution (6×10^{-5} M). The reactions were quenched by the following additives (Q): COT (—●—), anthracene (—△—), and acridine (—○—).

Table 4. Quenching constants (K) and lifetimes (τ_0)[a] of the triplet species in the photocyclization of **3**[b] under irradiation with 436 nm light, when the reaction was quenched with COT

Solvent	K, M^{-1}	τ_0, s
Carbon tetrachloride	1.3×10^4	2.0×10^{-6}
Benzene	8.6×10^3	8.0×10^{-7}
Diethyl ether	5.2×10^3	9.0×10^{-8}
Dichloromethane	3.2×10^3	3.5×10^{-7}

a) The lifetime ($\tau_0=K/k_q$) is defined as the inverse of the sum of the rate constants for the radiationless decay and for the photocyclization of **3**. The k_q-value was estimated on the assumption that the quenching process is diffusion-controlled ($k_q=k_{diff}$), where the value for k_{diff} was obtained by the use of the following equation:

$$k_{diff}=\frac{8RT}{3000\,\eta}\ M^{-1}\,s^{-1}\ (20\ ^\circ C)$$

b) 6×10^{-5} M solutions.

Discussion

Photosubstitution Reaction. On the basis of both sensitization and quenching studies, the photosubstitution reaction is clearly concluded to proceed *via* a triplet state. Results of the sensitization experiment in Table 1 suggest that the energy of the triplet state lies between 49 and 55 kcal/mol. The triplet energy of **1**, on the other hand, has been estimated to be 53.5 kcal/mol by studying the phosphorescence spectra.[5] The experimental condition for the irradiation without any additive was adjusted so that **1** alone was selectively excited. Then, it is quite reasonable to suggest that the reactive species is the triplet state of **1**. One may suggest that a charge-transfer complex between **1** and **2** would be involved in the excitation. It is true that a charge-transfer band is observed on mixing **1** and **2**, and also irradiation of the charge-transfer band induces the same reaction as above.[9] On the basis of the equilibrium constant (0.1 m^{-1}), however, it is concluded that the concentration of the charge-transfer complex is too small to make any contribution to the excitation under the present experimental conditions. When the reaction was sensitized by benzophenone, the Φ_p-value is raised by 30% (Table 1). The experimental conditions were adjusted so that neither spontaneous decay or self-quenching of excited benzophenone effectively competed with the rate of quenching induced by **1**. In other words, the excitation energy of benzophenone is expected to be transferred to **1** without any loss. Then, the difference in Φ_p-values is taken to correspond to that in the intersystem-crossing efficiency between **1** and benzophenone. On the basis of these arguments, the intersystem-crossing efficiency in **1** is estimated to be close to 0.8. Then, the following reaction scheme is suggested to explain the above experimental observations. The presence of an associated species C is assumed here in order to take into consideration the deactivation process after the reactive triplet **1** encountered **2**. Essentially the same reaction schemes have been adopted to account for the photoreaction between acenaphthylene and 1,3-pentadiene,[10] and photodimerization of 2-cyclopentenone *etc.*[11] The relevant species, **1**, **2**, **3**, sensitizer, and quencher are denoted by A, D, P, S, and Q, respectively. Under the usual steady state assumption, the quantum yield for the photosubstitution is given by Eq. (10). In the absence of Q, a linear correlation between Φ_p^{-1} and $[D]^{-1}$ is expected to hold. This expectation was fulfilled, as shown in Fig. 1. The intercept and slope correspond to $(k_p+k_{-r})/(\Phi_{isc}\cdot k_p)$ and $k_{d-3}\cdot(k_p+k_{-r})/(\Phi_{isc}\cdot k_r\cdot k_p)$, respectively. Assuming the above estimated intersystem-crossing efficiency (0.8), one can evaluate a quotient, k_p/k_{-r}, as summarized in Table 5. Equations (12) and (13) indicate that the quenching constant (K) obtained from Stern-Volmer plots depends on the concentration of D. The lifetime of ^3A ($\tau_0=1/k_{d-3}$) and the rate constant k_r can be estimated from the K-values obtained at two different concentration of D. These results are summarized in Table 6, where k_{d-3}/k_r is also included. The values for k_{d-3}/k_r in Table 6 are in good agreement with those in Table 5. The agreement between the values obtained with two different methods may be taken to substantiate the proposed reaction scheme. The most important point in the reaction scheme is the presence of a deactivation step (Eq. (8)), which is suggested to take place after ^3A collides with D. The following argument affords

	Rate	
$A \xrightarrow{h\nu} {}^1A$	I_a	(1)

k_{diff}, $(M\cdot s)^{-1}$	6.7×10^9	3.7×10^{10}	8.1×10^9	1.5×10^{10}

further evidence in favor of the presence of C. The quantum yield of **3** in dichloromethane is less than that in carbon tetrachloride by a factor of 10. It is quite unlikely that Φ_{isc} for ^1A is appreciably different for the two solvents. The lifetime (τ_0) of ^3A is also practically the same for the two cases (Table 6). Then, it is most reasonable to suggest that deactivation takes place after the collision of ^3A and D but before the formation of P. The associated species C is thus included in the reaction schemes. The k_r-value in Table 6 is found to be practically the same as k_{diff} in each solvent. The corresponding value in the photoreaction of the 1,3-pentadiene-acenaphthylene system has been reported to be of the order of 10^4 M^{-1} sec^{-1}.[10] The k_r-values obtained in the photodimerizations of both 2-cyclopentenone and 2-cyclohexene also are of the order of 10^8 $M^{-1}sec^{-1}$.[11] This comparison in k_r clearly indicates that the collision between ^3A and D is extraordinarily effective for producing C. It should also be noted that the quotient k_p/k_{-r} decreases with the increase in solvent polarity, as estimated by Dimroth's E_T-values (Table 5). The associated species C is expected to be a type of donor-acceptor complex, since charge-transfer absorption is observed for the system containing **1** and **2** even in their ground states. It is well known that radiationless transitions of excited DA complexes are strongly enhanced in polar solvents.[12] Then, the decrease in the quotient k_p/k_{-r} is suggested to be due to the increase in k_{-r} in the polar solvent rather than to a decrease in k_p. In this connection, it should also be noted that the lifetime (τ_0) of ^3A in both diethyl ether and chlorobenzene is shorter than that in either dichloromethane or carbon tetrachloride (Table 5). This is also explained as due to the contribution of donor-acceptor interactions, since the former two solvent molecules are much better electron donors than the latter. In short, it is concluded that the photosubstition reaction proceeds *via* an associated species C, which is characterized as an electron donor-acceptor complex between **1** in the triplet state and **2** in the ground state.

Photocyclization. In the presence of COT as a quencher, Stern-Volmer plots of the photocyclization reaction from **3** to **4** followed a nice straight line until more than 75% of the reaction was quenched (Fig. 3). This reaction is sensitized by the additives with $E_T>$ 49 kcal/mol, but quenched by those with $E_T<45$ kcal/mol. Thus the reactive species in this reaction is concluded to be a triplet species with energy between 45 and 49 kcal/mol. The slope of Stern-Volmer plot decreased considerably when either anthracene ($E_T=$ 42 kcal/mol) or acridine ($E_T=45$ kcal/mol) was used as a quencher. The reduction in quenching efficiency may be explained as due to the contribution of back energy-transfer from these particular quenchers to **3**. On the basis of these observation, the energy of the reactive triplet is estimated to be close to 44 kcal/mol. The quantum yield for the formation of **4** varies considerably with the change in solvents, as summarized in Table 2. Two properties of the solvents appear to be effective in reducing the quantum yield: one is the polarity as given by Dimroth's E_T-value and the other is the electron-donating ability, as can be noticed in comparing Φ_p-values between carbon tetrachloride and toluene (or benzene) solutions. A similar trend was also observed for the lifetime of **3** in various solvents (Table 4). Then, the solvent effects on these two quantities are compared in Table 7, where the values in carbon tetrachloride are taken as the reference. Fairly good correspondence is observed as far as the values for the first three solvents are concerned. The values in dichloromethane indicate, however, that the effect on the cyclization is much larger than that on the lifetime. It is rather unlikely that either the intersystem-crossing efficiency or the rate of photocyclization of **3** is so strongly reduced as to explain sufficiently the large decrease in Φ_p in polar solvents given in Table 2. A better explanation will be that the photocyclization from **3** to **4** proceeds *via* a metastable intermediate, which may revert to **3** with a strongly solvent-dependent rate constant.

Table 7. Solvent effects on the photocyclization of **3**[a]

Solvent	Relative life-time of **3**	Relative Quantum Yield of **4**
Carbon tetrachloride	1.00	1.00
Benzene	0.40	0.31
Diethyl ether	0.05	0.11
Dichloromethane	0.18	0.03

a) 6×10^{-5} M solutions.

Experimental

Materials and Equipment. Solvents and sensitizers of guaranteed grade were each purified before use. The following compounds were synthesized according to the methods given in the references in parentheses: **1** (Ref. 13, mp 115—116 °C) and **2** (Ref. 14, mp 61—62 °C). The photoproducts were isolated by the use of column chromatography on silica gel (Mallinckrot, silic acid 100 mesh). The IR, NMR, mass, and electronic spectra were recorded on a JASCO DS-301, Varian A-60, JEOL JES-01SG, and Shimadzu UV-200 spectrometer, respectively.

*Photoreaction between **1** and **2** in Preparative Scale.* A dioxane solution (100 ml) containing **1** (1.3 g) and **2** (1.4 g) was internally irradiated with a high-pressure mercury lamp (Riko-Sha UVL-700P) equipped with a pyrex water jacket in nitrogen atmosphere for 8 hr. After the solvent, **1** and **2** were almost completely removed under reduced pressure, and then the residue was subjected to column chromatography. Elution with benzene–hexane mixture afforded **3** (670 mg) and **4** (10 mg). 3-Bromo-4-(*N*-phenyl-2-pyrryl)-2,5-furandione (**3**): mp 140—141 °C; IR (KBr) 1826 and 1759 (C=O), 1248 and 1237 (COC) cm^{-1}; UV (Dioxane): λ_{max} 233 (ε 14700) and 402 nm (11400); Mass, *m/e* 319 (M^+) and 317; NMR (Acetone): δ 6.57 (1H, q, 4-H), 7.16 (1H, q, 5-H), 7.44 (5H, m, C_6H_5), and 7.58 (1H, q, 3-H), $J_{3,4}=2.8$, $J_{3,5}=1.8$ and $J_{4,5}=4.0$ Hz. Found: C, 53.24; H, 2.58; N, 4.40%. Calcd for $C_{12}H_8BrNO_3$: C, 52.87; H, 2.54; N, 4.40%. Pyrrolo[1,2-a]-quinoline-4,5-dicarboxylic anhydride (**4**): mp 251—251.5 °C; IR (KBr): 1835 and 1769 (C=O), 1185 and 1190 (COC) cm^{-1}; UV(Dioxane): λ_{max} 241 (ε 26400), 288 (9210), 381 (4350) and 440 nm (5960); Mass, *m/e*

237 (M^+); NMR (DMSO): 6.6—8.6(m). Found: C, 70.39; H, 3.05; N, 5.74%. Calcd for $C_{12}H_7NO_3$: C, 70.89; H, 2.97; N, 5.90%.

Decarboxylation of **4**. Fifteen mg of **4** was dissolved into 0.5 ml of 5 M NaOH solution, and the solution was placed in a glass tube. Small amounts (0.1 g) of soda lime was added and the tube was heated above 300 °C under reduced pressure. Yellow crystal sublimed out of the tube and was identified as 5,6-benzopyrocholine (**5**)[15]: mp 107—108 °C; UV (acetonitrile): λ_{max} 226 (ε 31000), 242 (20000), 249 (22000), 263 (9800), 275 (7900), and 348 nm (6,400).

Determination of Quantum Yields. (A) Irradiation with a Collimated Beam: This method was used to determine the absolute quantum yield of both the photosubstitution (at 313 and 334 nm in benzene, and at 313 nm in carbon tetrachloride) and the photocyclization reactions (at 436 nm in benzene) without any sensitizer. The light source was a Ushio 500-W super-pressure mercury arc lamp (Ushio HB-5001B). Each monochromatic light was isolated by the use of the following combined filters: (1) 313 nm: Toshiba UV-D25 glass filter, window glass (1.5 mm), and a layer (5 cm) of nickel sulfate solution (1.05 M); (2) 334 nm: Toshiba UV-D25 glass filter, a layer (5 cm) of aqueous cupric nitrate (0.05 M), and a layer (5 cm) of aqueous solution containing nickel sulfate (0.19 M) and potassium chromic sulfate (0.015 M); (3) 436 nm: A layer (5 cm) of aqueous potassium nitrate solution (2.8 M) and a layer (5 cm) of cupric sulfate(0. 035 M) in 10% aqueous ammonium hydroxide solution. The sample solution was degassed and was placed in a cylindrical cell, which was irradiated with a collimated beam of the above described monochromatic light. After the irradiation, the amounts of photoproducts (**3** or **4**) were spectrophotometrically evaluated. The intensity of the monochromatic light was determined by the use of a potassium ferrioxalate actinometer.

(B) Irradiation of Sample Tubes Assembled on a Rotating Cylinder: The relative quantum yields in the energy-transfer experiments, the concentration dependence of the quantum yields, and the solvent effects were studied by the use of the following experimental set up. Sample solutions were appropriately prepared in each experiment, and were placed in a pyrex tube (10 mm inner diameter). The required number of sample tubes were fixed on the surface of a rotating cylinder (7.5 cm diameter), which rotated at a speed of approximately 100 rpm. The center of the rotating cylinder was located 13 cm away from the center of a 400 W high-pressure mercury arc lamp (Riko-Sha UVL-400 HA). The lamp was equipped with two coaxial, Pyrex jackets, which provided two layers of filter solutions (1 cm path length for each) surrounding the light source. The following filter solutions were used in order to irradiate the samples with the lights shown below: (1) 313 nm: An aqueous solution of potassium chromate (0.0025 M) and an aqueous solution containing nickel sulfate (0.95 M) and potassium chromic sulfate (0.075 M); (2) 334 nm: An aqueous solution of cupric nitrate (0.25 M) and an aqueous solution containing nickel sulfate (0.95 M) and potassium chromic sulfate (0.075 M); (3) 436 nm: An aqueous solution of potassium nitrite (14 M). The amount of photoproducts was determined by the use of the electronic absorption spectra.

Oxygen-accelerated Generation of the Bromocarbenoid Reagent of Zinc from Diethylzinc and Bromoform. Bromocyclopropanes from Olefins

Sotaro MIYANO and Harukichi HASHIMOTO

Department of Applied Chemistry, Faculty of Engineering, Tohoku University, Aramaki, Sendai 980

(Received May 6, 1975)

Oxygen greatly accelerates the generation of the bromocarbenoid reagent of zinc from diethylzinc and bromoform. Olefins, including cyclohexene, cyclooctene, 1-hexene, *cis*- and *trans*-2-butene, isobutene, and 2-methyl-2-butene were bromocyclopropanated in yields of *ca.* 60—85% using a diethylzinc–bromoform–oxygen system. The bromocarbenoid showed high *syn*-selectivity for the addition to cyclooctene and *cis*-2-butene. 9-Bromo-9-deutero[6.1.0]nonane was obtained from cyclooctene using $CDBr_3$. Styrene inhibited the formation of the bromocarbenoid reagent and polymerized under the reaction conditions, suggesting a free radical chain mechanism for the formation of the carbenoid reagent.

Monobromocyclopropanes have usually been obtained *via* the reduction of *gem*-dibromocyclopropanes, and numerous reducing agents have effectively been employed in the conversion.[1,2] Several bromocarbene[3] or bromocarbenoid[4] reagents have been reported, but useful methods for the direct synthesis of monobromocyclopropanes from olefins are only limited to those with less available reagents.[5,6] The Furukawa procedure for the cyclopropanation of olefins using the diethylzinc–polyhalomethane system[7] is applicable only to the polyhalomethanes which contain at least one iodine atom. Thus, dibromoiodoform was used for the synthesis of 7-bromonorcaranes from cyclohexene, but the preparation of the mixed haloform is not efficient.[8]

In the course of our investigation of the zinc-carbenoid reaction, we found that oxygen greatly accelerates the formation of the bromocarbenoid reagent of zinc from diethylzinc and bromoform.[9] In this report, a convenient synthesis of monobromocyclopropanes from olefins by means of the bromocarbenoid reagent is described.

Results and Discussion

Accelerating Effect of Oxygen on the Formation of 7-Bromonorcarane from Cyclohexene, Diethylzinc, and Bromoform. Table 1 shows the results of the reaction of diethylzinc and bromoform with cyclohexene. When the reaction was carried out in a nitrogen atmosphere, no apparent changes of the reaction mixture were observed after 6 hr at a reaction temperature of 50 °C, and a large amount of unchanged bromoform was recovered with the formation of 7-bromobicyclo[4.1.0]-heptanes (7-bromonorcaranes, **1**) in a poor yield (Run 1). On the other hand, by passing dry air at a rate of 10 ml/min into a space above the reaction mixture at room temperature, fuming occurred accompanying an exothermic reaction with the precipitation of white solids, and the reaction terminated within one hour with the complete consumption of the bromoform affording **1** in a fairly good yield (Run 3). The dilution of cyclohexene with *n*-hexane reduced the yield of **1** (Runs 4—8). Besides 3-ethylcycloheptene, small amounts of norcarane, cycloheptene, and 1,3-cycloheptadiene were also detected in the reaction mixture in a combined yield of less than 5%. In a previous paper, the authors reported the formation of these by-products during the iodocyclopropanation of cyclohexene with iodoform and diethylzinc.[10] The ratio of *syn*-**1** to *anti*-**1** decreased as the molar ratio of diethylzinc to bromoform increased, and *syn*-**1** appeared to react with the excess ethylzinc bromide present in the reaction mixture *via* a ring opening producing 3-ethylcycloheptene.[10] The reaction temperature is one of the important reaction variables. When the reaction was carried out in cyclohexene, a satisfactory yield of **1** was obtained with a $CHBr_3$/Et_2Zn molar ratio of *ca.* 1.2 at reaction temperatures from 0 to 10 °C (Table 2).

TABLE 1. REACTION OF DIETHYLZINC AND BROMOFORM WITH CYCLOHEXENE[a]

Run	Cyclohexene ml	Et_2Zn mmol	 Yield[b], %	*syn*/*anti* ratio	Yield[b], %
1[c]	50	50	9.4	2.6	0
2[d]	50	50	52	1.3	6.1
3[e]	50	50	59	1.6	5.1

7[d]	10	50	39	1.4	6.7
8[d]	10	70	32	1.1	12

a) Reactions were carried out in cyclohexene (Runs 1—3) and in 40 ml of *n*-hexane (Runs 4—8); $CHBr_3$, 50 mmol; 50 °C, 1—1.5 hr. b) Glc yield based on $CHBr_3$. c) In a nitrogen atmosphere, 6 hr. d) Dry air was introduced into the space above the reaction mixture at a rate of 10 ml/min during the reaction. e) The reaction was started at room temperature, and the temperature of the reaction mixture increased to 35—40 °C upon contact with air.

Bromocyclopropanation of Several Olefins. The accelerating effect of oxygen on the zinc-carbenoid reaction with diethylzinc and bromoform was utilized for the bromocyclopropanation of several olefins (Table 2). The yields of the products were determined by glc, and the reaction conditions were not necessarily optimum. Bromocylopropanes were separated by distillation and, if necessary, by preparative glc, and were confirmed by NMR spectral studies and elemental analyses. The results show that the $CHBr_3$–Et_2Zn–oxygen system provides a convenient route to mono-

Table 2. Bromocyclopropanation of several olefins with $CHBr_3$-Et_2Zn-oxygen[a]

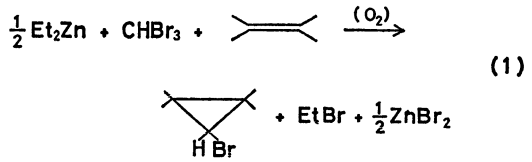
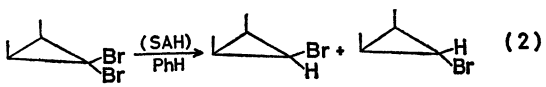
bromocyclopropanes from some olefins (reaction 1).



(1)

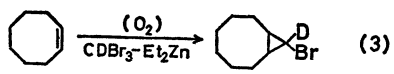
It is known that asymmetrical carbenes and carbenoids tend to add to substituted olefins producing sterically more hindered cyclopropanes (*syn*-isomer).[11] For example, Martel and Hiriart have reported that a *syn*/*anti* ratio of as high as 50 was obtained with the addition of the bromocarbenoid reagent formed from methylene bromide and potassium bis(trimethylsilyl)-amide to cyclooctene.[6b] The bromocarbenoid reagent of zinc also preferentially produced *syn*-isomers, and high *syn*-selectivity of the bromocarbenoid to *cis*-2-butene is noteworthy. The glc study showed the presence of less than 2% of the *anti*-isomer in the zinc-carbenoid reaction mixture. For comparison, the *anti*-isomer was obtained *via* the reduction of *gem*-dibromo-*cis*-2,3-dimethylcyclopropane with sodium bis-(2-methoxyethoxy)aluminum hydride (SAH) according to the method described by Sydnes and Skatteböl[12] (reaction 2).



(2)

syn/*anti*=0.14

Deuterium labeling of the cyclopropane ring can easily be accomplished with $CDBr_3$ (reaction 3). It is obvious that higher isotopic purity is obtained and the deuterium source is utilized more effectively by this procedure than by conventional methods.[13]



(3)

Reaction of Diethylzinc and Bromoform in Styrene. Upon treatment of diethylzinc and bromoform in styrene for 8 hr at 50 °C in a nitrogen atmosphere, no product ascribed to the carbenoid reaction was detected on the glc, and 91% of the bromoform was recovered unchanged. Even in the presence of oxygen, the carbenoid reaction scarcely occurred and the polymerization of styrene preceded (Table 2).

A free radical chain mechanism for the formation of the zinc-carbenoid reagent from diethylzinc and CH_2IX (X=Cl, I) is proposed.[14] Similar reaction paths may also occur for the diethylzinc–bromoform system on the basis of the accelerating effect of oxygen and the inhibiting effect of styrene on the formation of the bromocarbenoid reagent of zinc from diethylzinc and bromoform (reactions 4—7).

Experimental

The glc analysis was carried out on a Shimadzu GC 3AF apparatus equipped with hydrogen-flame detectors; three different stainless steel columns (3 m×3 mm) were used, packed with Diasolid M coated with Silicone DC 550, Silicone DC 410, and Apiezon Grease L, respectively. Preparative glc was carried out on a Shimadzu GC 2C apparatus with an Apiezon Grease L or Silicone DC 550 filled column. The infrared spectra were obtained with a JASCO Model IR-E spectrophotometer. The proton NMR data were obtained at 60 MHz with a Hitachi R-24A spectrometer or at 100 MHz with a Varian AHA-100 spectrometer. All the chemical shifts are given in units of δ relative to the internal TMS reference (*ca.* 1—5 wt% solution in CCl_4). Elemental analysis was performed at the Elemental Analysis Center, Chemical Research Institute of Nonaqueous Solutions, Tohoku University.

Materials. The bromoform was washed successively with water, dil. sodium hydrogen sulfite, and water, dried

over calcium chloride, and distilled twice in a nitrogen atmosphere (bp 69—70 °C/50 mmHg). Reagent grade commercial olefins were distilled over calcium hydride. The diethylzinc was distilled under reduced pressure. The materials were stored in nitrogen. The deuterobromoform (Merck Co., deuterium content>99%) containing no stabilizer was used without further purification. The nitrogen was purified by passage through a column packed with an activated Ni catalyst (Nikki Kagaku Co., Ltd., N 111 cat.) in a furnace at 130—140 °C followed by drying with silica gel.

Bromocyclopropanation of Olefins. The bromocyclopropanation of cyclohexene and *cis*-2-butene are representative. The reaction rate depended somewhat on the rate of the introduction of air and the stirring speed of the reaction mixture, but the yields of bromocyclopropanes and the *syn/anti* ratio were not so sensitive to these reaction variables as long as the reaction temperature was maintained within a given range.

*7-Bromonorcaranes (**1**)*: The reaction was carried out in a 200 ml round-bottomed flask equipped with a magnetic stirrer, a reflux condenser, a pressure-equilibrating dropping funnel topped with a gas inlet cock, and a thermometer. The flask was flushed with prepurified nitrogen. In the flask, 40 ml of cyclohexene and 5 ml (50 mmol) of diethylzinc were placed. The mixture was stirred, and then warmed to 50 °C. Bromoform (12.6 g, 50 mmol) dissolved in 10 ml of cyclohexene was dropped from the dropping funnel to the solution over a 10 min period in a nitrogen atmosphere. Dry air was introduced *via* the gas inlet cock into the space above the reaction mixture at a rate of 10 ml/min. Fuming was observed accompanying an exothermic reaction, and white solids precipitated for 0.5 hr, with the reaction continuing for another 0.5 hr. The reaction mixture was hydrolyzed with dil. hydrogen chloride, extracted with ether, and washed successively with dil. hydrogen chloride, dil. sodium hydrogen sulfite, dil. sodium hydrogen carbonate, and water. An aliquot of the solution was used for glc analysis. After the solution had been dried over anhydrous magnesium sulfate, ether and cyclohexene were removed by distillation *in vacuo*. The residue was fractionated through a short Vigreux column. A portion boiling at 70.5—71.3 °C/13 mmHg was collected (3.4 g) as a mixture of *syn*-**1** and *anti*-**1** in a *syn/anti* ratio of 1.5 (lit,[15] bp 78 °C/16 mmHg, *syn/anti*=2.5). The assignment of the *syn*- and *anti*-isomer was based on the assumptions described before.[10] Found: C, 48.29; H, 6.42%. Calcd for $C_7H_{11}Br$: C, 48.02; H, 6.33; Br, 45.65%. The NMR spectra were consistent with those of **1**:[16] H_7[17] for the *syn*-**1**, δ 3.24 (t, A_2X system, $J_{1,7}=7.5$ Hz); H_7 for the *anti*-**1**, δ 2.51 (t, A_2X system, $J_{1,7}=3.4$ Hz). The glc analysis of the reaction mixture indicated the presence of several by-products in small amounts, among which cycloheptene, norcarane, 1,3-cycloheptadiene, and 3-ethylcycloheptene were confirmed by a comparison of the retention times with those of authentic samples.[10]

*9-Bromobicyclo[6.1.0]nonanes (**2**)*: A mixture of diethylzinc (5 ml, 50 mmol) and bromoform (12.7 g, 50.4 mmol) was treated in 50 ml of cyclooctene at 50 °C. Distillation gave a portion boiling at 87—89 °C/4.5 mmHg (5.2 g) as a mixture of *syn*-**2** and *anti*-**2** in a *syn/anti* ratio of 5.1 (lit,[15] 40—42 °C/0.13 mmHg for *syn*-**2**[18]). Found: C, 53.23; H, 7.44%. Calcd for $C_9H_{15}Br$: C, 53.22; H, 7.44; Br, 39.34%. NMR: H_9 for the *syn*-**2**[19]; δ 3.20 (t, A_2X system, $J_{1,9}=7.3$ Hz). The *anti*-**2** showed an identical retention time on the glc with a freshly packed Silicone DC 550 or Silicone DC 410 column with that of authentic sample (*vide infra*), but it decomposed on preparative glc under the conditions necessary to resolve isomeric **2**.

9-Bromo-9-deuterobicyclo[6.1.0]nonanes: A portion boiling at 82—83 °C/4 mmHg (1.8 g) indicated a *syn/anti* ratio of 5.0. Found: C, 53.40; H+D, 7.51%. Calcd for C_9H_{14}-DBr: C, 52.95; H, 6.91; D, 0.99; Br, 39.15%. The NMR spectrum showed no absorption assigned to H_9.

*1-Bromo-2-*n*-butylcyclopropanes (**3**)*: A mixture of diethylzinc (5 ml, 50 mmol) and bromoform (12.6 g, 50 mmol) was treated in 50 ml of 1-hexene at 50 °C. Distillation gave a portion boiling at 73.5—74.2 °C/28.5 mmHg (2.4 g) as a mixture of *syn*-**3** and *anti*-**3** in a *syn/anti* ratio of 2.2. Found: C, 47.24; H, 7.38%. Calcd for $C_7H_{13}Br$: C, 47.48; H, 7.40; Br, 45.13%. Each isomer was separated by preparative glc. NMR for *syn*-**3**: δ 2.96 (1H, H_1, sextet-like, ABMX system, $J_{1,2}\approx J_{1,3(cis)}=7.4$ Hz,[20] $J_{1,3(trans)}=4.3$ Hz), 1.55—1.25 (6H, 3-CH_2-, br,), 1.15 (1H, $H_{3(cis)}$, octet-like), 1.0—0.7 (4H, Me+H_2, m), 0.48 (1H, $H_{3(trans)}$, octet-like, $J_{2,3(trans)}=5.6$ Hz, $J_{3(gem)}=6.1$ Hz. NMR for *anti*-**3**: δ 2.7—2.4 (1H, H_1, m), 1.5—1.1 (6H, 3-CH_2-, br), 1.1—0.8 (5H, Me+H_2+$H_{3(trans)}$, m), 0.8—0.6 (1H, $H_{3(cis)}$, m).

syn-*1-Bromo*-cis-*2,3-dimethylcyclopropane (**4**)*: The reaction was carried out in a pressure bottle of 100 ml inner volume equipped with a pressure-equilibrating dropping funnel of 50 ml volume. Into the bottle, 15 g of *cis*-2-butene was distilled, into which 2 ml (20 mmol) of diethylzinc was dissolved. The bottle was cooled in an ice-water bath, and bromoform (2.6 ml, 30 mmol) was added from the dropping funnel to the solution. Another pressure bottle of 140 ml volume containing oxygen at *ca.* 1.5 kg/cm^2 was connected to the reaction bottle through a needle valve and the reaction mixture was stirred for 2 hr. After the usual work-up, distillation gave a 2.7 g portion boiling at 124—125 °C which was composed of *syn*-**4** at a purity of *ca.* 90% contaminated with several unidentified impurities (lit,[3] bp 119—120 °C, *syn/anti*=30). Some decomposition was observed during distillation. Pure **4** was obtained by preparative glc. Found: C, 40.38; H, 6.22%. Calcd for C_5H_9Br: C, 40.29; H, 6.09; Br, 53.62%. NMR:[3] δ 3.25—3.05 (1H, H_1, m), 1.10—0.95 (8H, 2Me+H_2+H_3, m, rather sharp peak at δ 1.05). Detailed glc analysis showed he presence of only trace amounts of *anti*-**4** (*ca.* 1.5%) (*vide infra*) in the reaction mixture.

1-Bromo-trans-*2,3-dimethylcyclopropane*: Bp 64 °C/122 mmHg, yield 2.3 g. Found: C, 40.36; H, 6.35%. Calcd for C_5H_9Br: C, 40.29; H, 6.09; Br, 53.62%. NMR:[3] δ 2.66 (1H, H_1, dd, ABX system, $J_{1,2(trans)}=3.9$ Hz, $J_{1,3(cis)}=6.7$ Hz), 1.3—1.1 (6H, 2Me, t-like), 1.1—0.3 (2H, H_2+H_3, m).

1-Bromo-2,2-dimethylcyclopropane: Bp 55—55.5 °C/120 mmHg, yield 1.52 g. Found: C, 40.39; H, 6.20%. Calcd for C_5H_9Br: C, 40.29; H, 6.09; Br, 53.62%. NMR:[21] δ 2.74 (1H, H_1, dd, ABX system, $J_{1,3(trans)}=4.4$ Hz, $J_{1,3(cis)}=7.9$ Hz), 1.26 (3H, Me, s), 1.13 (3H, Me, s), 0.95 (1H, H_3, dd, $J_{3(gem)}=6.2$ Hz), 0.60 (1H, $H_{3(trans)}$, dd).

syn-*1-Bromo-2,2,3-trimethylcyclopropane (**5**)*: A portion boiling at 66.5—68 °C/70 mmHg contained *ca.* 15% complex by-products, and the *syn*-**5** was purified by preparative glc. Found: C, 44.45; H, 6.48%. Calcd for $C_6H_{11}Br$: C, 44.19; H, 6.80; Br, 49.01%. NMR:[3] δ 2.86 (1H, H_1, d, AX system, $J_{1,3}=7.2$ Hz), 1.3—0.9 (9H, 3Me, t-like), 0.9—0.3 (1H, H_3, m).

Reaction of Bromoform and Diethylzinc in Styrene. Dry air was introduced at a rate of 10 ml/min for 8 hr to a mixture of diethylzinc (5 ml, 50 mmol) and bromoform (12.6 g, 50 mmol) in 50 ml of styrene at 50 °C. The reaction mixture was worked up as usual. Glc analysis showed the presence of 74% of unchanged $CHBr_3$ and only traces of the carbenoid

reaction products. After the bulk of the styrene and unchanged $CHBr_3$ were distilled off *in vacuo*, 18.0 g of a pale yellow resinous material remained, which was dissolved in 20 ml of benzene and precipitated with 700 ml of methanol affording 12.4 g of polystyrene as a white powder. The IR absorption spectra (KBr pellet) of the precipitate was identical with those of polystyrene film. NMR: δ 7.4—6.8 (br) and 6.8—6.2 (br) (5H, benzene ring), 2.3—0.6 (br) (3.18H).

*Reduction of 9,9-Dibromobicyclo[6.1.0]nonane (**6**) with Sodium Bis(2-methoxyethoxy)aluminum Hydride (SAH).*[12] The **6** was prepared by a method analogous to that described by Dale and Swartzentruber[22] (bp, 109.5—111.5 °C/3.5 mmHg, lit,[23] bp 45 °C/0.15 mmHg). To a solution of **6** (5.64 g, 20 mmol) in 10 ml of benzene was added a 2 molar amount of SAH as a 70% solution in benzene (12 ml) which was refluxed for 3 hr. After the usual work-up, distillation of the reaction mixture gave a portion boiling at 78 °C/3 mmHg (0.9 g) which consisted of a mixture of *syn*-**2** and *anti*-**2** in a *syn*/*anti* ratio of 0.24. The NMR spectrum of the H_9 of *anti*-**2** appeared at δ 2.5—2.0 as a multiplet.[16]

*Reduction of 1,1-Dibromo-*cis*-2,3-dimethylcyclopropane (**7**) with SAH.* The **7** was prepared by a treatment of bromoform (9.0 ml, 0.104 mol) and *tert*-BuOK (prepared from 4 g of K) in *cis*-2-butene (*ca.* 30 ml) and *n*-hexane (30 ml) in a pressure bottle at 0—5 °C overnight, bp 55 °C/20.5 mmHg, yield 13.8 g. Treatment of **7** (7.3 g, 31 mmol) with a 2 molar amount of SAH in benzene gave 0.9 g of a mixture of *syn*-**4** and *anti*-**4** in a *syn*/*anti* ratio of 0.16, bp 63.5 °C/122.5 mmHg. NMR for the *anti*-**4**:[3] δ 2.3—2.1 (1H, H_1, m), 1.3—1.0 (8H, $2Me+H_2+H_3$, m).

Photochemical *cis-trans* Isomerization of 2,4,5-Triphenylimidazolines[1]

Teruo MATSUURA and Yoshikatsu ITO

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received May 16, 1975)

Irradiation of *cis-* (amarine; I) and *trans-* (isoamarine; II) 2,4,5-triphenylimidazolines in acetonitrile or benzene gave a photostationary mixture of *cis-* and *trans*-isomers, the latter predominating over the former. On irradiation in a dilute acetone solution under the conditions that acetone absorbed most of the incident light, *cis-trans* isomerization occurred only with isoamarine but not with amarine. In acetone, 2,4,5-triphenylimidazole (III) was also formed. Two kinds of intermediate species for the *cis-trans* isomerization were proposed; imidazolinyl radicals IV and/or V formed by hydrogen abstraction with the excited state of acetone (in acetone) and a biradical or a zwitterionic species VIa formed by cleavage from the excited state of I or II (in acetonitrile or benzene). Evidences for the intermediacy of VIa are presented.

In a previous paper,[2] it has been shown that imidazolines, on irradiation in acetone solutions, are dehydrogenated to give the corresponding imidazoles *via* imidazolinyl radicals which are formed by hydrogen abstraction with excited acetone. In the course of this investigation 2,4,5-triphenylimidazolines, amarine (I; *cis*) and isoamarine(II; *trans*), were found to undergo *cis-trans* isomerization simultaneously with dehydrogenation to 2,4,5-triphenylimidazole(III; lophine). Since such a type of *cis-trans* isomerization in heterocyclic systems appeared relatively rare,[3] the photochemical *cis-trans* isomerization of I and II was examined in some details.

Results and Discussion

cis-trans *Isomerization of I and II under Various Conditions.* Amarine(I) and isoamarine(II) were irradiated with a 100 W high-pressure mercury lamp (Pyrex) or a 10 W low-pressure mercury lamp (Vycor, mainly 2537 Å) under bubbling nitrogen in various solvents at different concentrations. The results are summarized in Table 1. The material balance of the photoreaction induced by Pyrex-filtered light was considerably good, and products other than I, II and lophine (III) were obtained only in small yields (*vide infra*).

In acetonitrile, no lophine (III) was formed and a photostationary mixture of I and II with predominance of the thermodynamically more stable isomer II was obtained from either I or II. Piperylene, a triplet quencher, failed to quench the *cis-trans* isomerization at various concentrations (Table 2), indicating that the excited state responsible for the isomerization may be singlet or short-lived triplet, provided that the triplet energies of I and II exceed that of piperylene.

In benzene, which is known as a triplet sensitizer except a few exceptional cases,[4] only a trace of III was detected and the photostationary mixture of I and II was obtained in the similar ratio to that in acetonitrile. Both I and II were found to isomerize at such a low concentration (0.17×10^{-2} M) that more than 99% of the incident light was absorbed by benzene. It was also found that the II/I ratio in the isomerization of I in benzene decreased with increase in the amount of added piperylene (Table 3), possibly due to partial quenching of the benzene triplet. These results suggest that the *cis-trans* isomerization of I and II may take place at least partly from their short-lived triplet state.

In acetone, lophine (III) was always formed to a

a) A: high-pressure mercury lamp (Pyrex), B: low-pressure mercury lamp (2537 Å). b) Not determined.
c) Determined after 30 min irradiation. d) II/I ratio is 0.43 after 0.5 hr, 0.083 after 1 hr.

Table 2. Quenching of excited I with piperylene in acetonitrile[a)]

Piperylene added(M)	0	0.0604	0.12	0.179	0.237	0.295	0.573
III/I ratio[b)]	0.24	0.31	0.33	0.30	0.27	0.26	0.27

a) Initial concentration of I: 2.05×10^{-2} M. Light source, irradiation time, and temperature: 450-W high pressure mercury lamp (Pyrex), 3 hr, and 30±1 °C, respectively. b) Irradiation of I without piperylene showed that the value of II/I ratio increased almost linearly with increased irradiation time in the earlier stage of photolysis.

Table 3. Quenching experiment with piperylene in benezene[a)]

Initial concentrations[b)] of I ($\times10^3$ M)	1.71	1.87	1.72
Piperylene added(M)	0	0.0421	0.633
II/I ratio	1.6	1.4	0.8

a) Light source: 10-W low pressure mercury lamp (Vycor). Irradiation time: 3 hr b) At these concentrations of I, more than 99% of the incident light is absorbed by benzene.

considerable extent regardless of the light sources, and the *cis-trans* isomerization was found to be dependent on the initial concentration of I and II. At low concentrations (*ca.* 3×10^{-4} M), at which more than 99% of the incident light was absorbed by acetone, the isomerization occurred only from isoamarine(II) toward amarine(I) but not from I toward II. At high concentrations (*ca.* 3.5×10^{-2} M), at which about 50% of the incident light was absorbed by acetone, either I or II afforded a photostationary mixture of I and II with predominance of I over II in contrast to the case in acetonitrile and in benzene. These results obviously indicate that the mechanism of the *cis-trans* isomerization in acetone solution is different from that in acetonitrile or benzene solution.

In the course of our study on the photochemical dehydrogenation of imidazolines to imidazoles in acetone,[2)] it has been shown that excited acetone can abstract a hydrogen atom at 4- or 5-position of imidazolines to yield imidazolinyl radicals IV and/or V and the acetone ketyl radical, and that the resultant imidazolinyl radical can be led either to the original imidazolines, a hydrogen atom being supplied by the acetone ketyl radical, or to the corresponding imidazoles. It is, therefore, quite reasonable to suppose that the photochemical *cis-trans* isomerization of I and II in dilute acetone solutions accompanied with dehydrogenation of both I and II to III proceeds through the imidazolinyl radicals IV and/or V as depicted in Scheme 1 (A).[2)] The completely stereoselective isomerization toward I in dilute acetone solutions must require that the hydrogen transfer from the acetone ketyl radical to the imidazolinyl radicals IV and/or V occurs only in the direction toward the thermodynamically less stable isomer I but not toward II. The result implies that the *cis-trans* isomerization of I or II from their excited states does not sensitized by acetone; in other words the acetone triplet acts only as a hydrogen

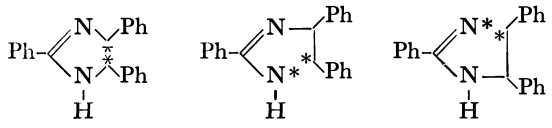
Scheme 1.

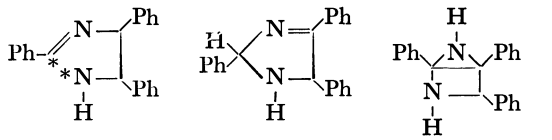
transfer agent but not as a donor of excitation energy. The acetone ketyl radical may attack IV and/or V predominantly from the opposite side of a bulky phenyl group as shown below. At high concentrations of I and II in acetone, *cis-trans* isomerization through a common intermediate(s) (VI) from their excited states as in acetonitrile or benzene [Scheme 1 (B)] is possibly competing with *cis-trans* isomerization *via* the imidazolinyl radicals. Thus, it is reasonably explained that the II/I ratio observed at higher concentrations in acetone is smaller than that observed in acetonitrile or benzene. It should be noticed that these two processes shown in Scheme 1 provide a typical example of kinetically (A) and thermodynamically (B) controlled *cis-trans* isomerizations, and that reaction A provides an additional example of the so-called chemical sensitization.[4a)]

Irradiation of I in isopropyl alcohol or ether under the similar conditions also resulted in the *cis-trans* isomerization with predominance of II over I.

The Nature of the Intermediate VI. It seems reasonable to assume a homolytic or a heterolytic bond cleavage of ring bonds (VIa, VIb, VIc or VId) as the intermediate step of *cis-trans* isomerization in acetonitrile or benzene. Other pathways involving migration of 4-hydrogen (VIe or VIf[5)]) are also possible



VIa VIb VIc

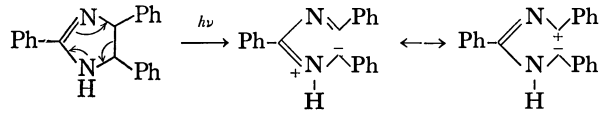


VId VIe VIf

*=· or +, −

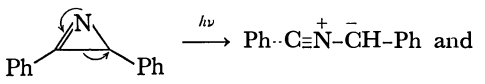
although less probable because of the following reasons. If 1,3-hydrogen shift occurs stepwise and homolytically in the process, I (or II)⇌VIe, the imidazolinyl radical IV must be transiently formed and consequently lophine (III) must be formed concurrently. Since III was unable to be detected among the products at least in acetonitrile, the 1,3-hydrogen shift, if it occurs, should proceed concertedly in a suprafacial manner[6] and should not result in *cis-trans* isomerization *via* the intermediary formation of VIe. The intermediate VIf also has the difficulty in explaining the results that deuterium incorporation is very inefficient during irradiation of I in acetonitrile–D_2O (below 1.9% after over the half of I employed isomerized into II).

Among possible biradical or zwitterionic intermediates (VIa—VId), VIa is the most plausible one in view of bond dissociation energy data for similar types of bonds : $PhCH_2$—CH_2Ph (45—48 kcal/mol)[7] and $PhCH_2$—$NHCH_3$ (58 kcal/mol).[8] The bond dissociation energy data for –C=N—C< and –N—C=N– bonds are not available, but they may have a higher value than those for other bonds in the imidazoline ring considering the less resonance-stabilized nature of >C=N· or ·C=N– radical. The photochemical homolytic cleavage of C–C bonds has been recently reported.[3,9] Furthermore, the hetrolytic cleavage to generate VIa has some analogy to that of azirines[10] and 2,3-dihydropyrazines.[11]

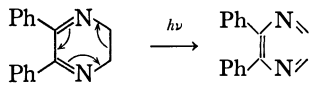


I or II VIa

Compare with

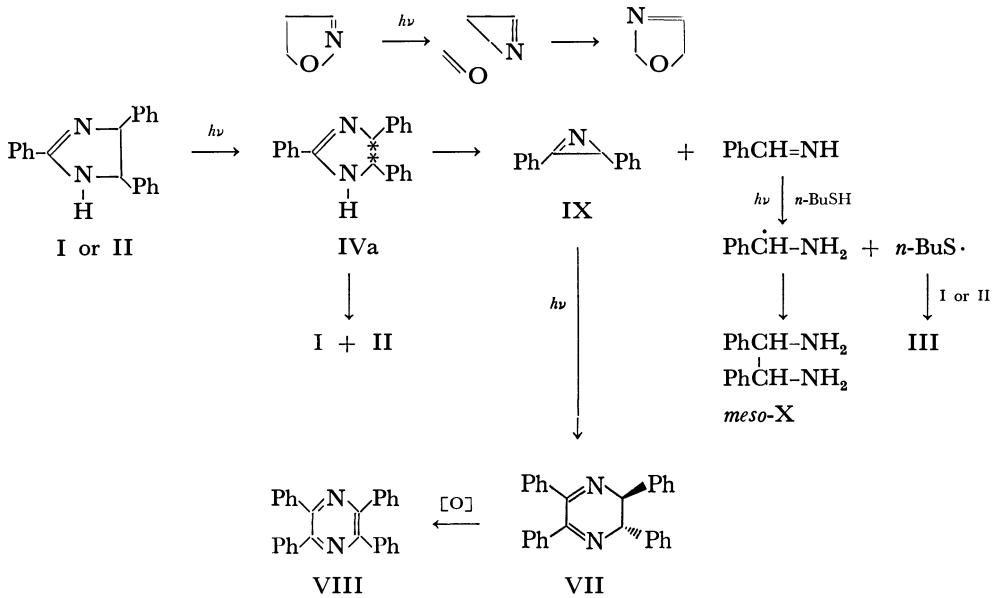


and



In order to see whether the rupture of C_4–C_5 bond of I or II (VIa) occurs, it was attempted to isolate by-products, which may be formed from the plausible intermediate VIa, and also to trap VIa by radical scavengers such as *n*-butyl mercaptan,[12] oxygen, and 2,2,6,6-tetramethylpiperidine-1-oxyl[13] and by the solvent isopropyl alcohol.[9a]

Amarine (I) was irradiated in acetonitrile with light through Pyrex to give a mixture of products from which *trans*-2,3,5,6-tetraphenyl-2,3-dihydropyrazine (VII, 2%) was isolated by chromatography. In addition, 2,3,5,6-tetraphenylpyrazine (VIII), which was probably formed by autoxidation of VII[14b] during work-up, was detected on tlc. A small amount (1—2%) of lophine (III) was also obtained in this case. Since VII and VIII are known to be formed photochemically from 2,3-diphenyl-2*H*-azirine (IX),[14] it is reasonably assumed that IX is an intermediate in the transformation of I into VII. The formation of IX can be rationalized by fragmentation of I or II through the intermediate

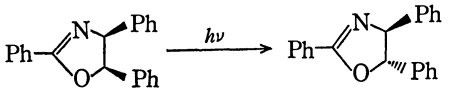


Scheme 2.

VIa (Scheme 2), similar to that of 2-isoxazolines to give an azirine and a carbonyl compound which recombine to form 3-oxazoline.[15]

Attempts for trapping VIa with 1-butanethiol (0.38 M in acetonitrile), 2,2,6,6-tetramethylpiperidine-1-oxyl (0.127 M in benzene), and the solvent isopropyl alcohol were unsuccessful. However, irradiation (Pyrex) of I in acetonitrile in the presence of 1-butanethiol afforded VII(2%), VIII (3%), III(48%), I(17%), II(9%) and *meso*-stilbenediamine (X, 2%). The last compound X appears to be a product derived from benzaldimine, the counterpart of IX (Scheme 2). Photoreductive dimerization of imines with a suitable hydrogen donor is well-known.[16] The formation of a large amount of III may be attributed at least partly to hydrogen abstraction with the 1-butanethiyl radical.[17]

It is worthwhile to mention about the preliminary results of photolysis of *cis*-2,4,5-triphenyloxazoline(*cis*-XI). Upon photolysis (2537 Å) *cis*-XI afforded its *trans*-isomer (14%) and benzaldehyde. It should be noticed that this reaction is also explained by cleavage of the C_4–C_5 bond in the first step. If the O_1–C_2 bond is first broken, benzonitrile must be formed considering the photofragmentation of 2-isoxazolines.[15]

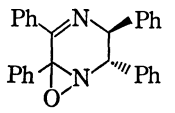


cis-XI *trans*-XI

+ PhCHO + unidentified product(s)

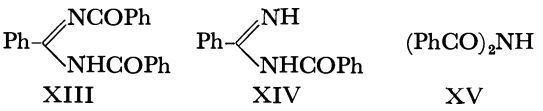
The formation of VII may be rationalized by other mechanisms (Scheme 3). The pathways a and b were eliminated by the fact that photolysis of lophine(III) or a mixture of III and *dl*-stilbenediamine did not yield even a trace of VII and VIII. The pathway c, which must involve complex reactions, is also improbable, because the photolysis of I in acetonitrile in the presence of a small amount of benzaldehyde resulted in the decrease (less than 1%) of yields of VII and VIII. And a new product, which was assigned as oxaziridine XII (2% yield) on the basis of spectral data and an independent synthesis, was obtained in addition to I and II.

Irradiation (Pyrex) of I in acetonitrile under bubbling oxygen gave *N*,*N*′-dibenzoylbenzamidine (XIII, 43%),

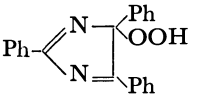


XII

N-benzoylbenzamidine (XIV), dibenzamide (XV) (the total yield of XIV and XV is 16%) and II (13%). At first glance, the oxidation of I to XIII appeared to proceed *via* trapping of the intermediate VIa by oxygen. It is, however, known[18,19] that the photochemical oxidation of III produces a lophine hydroperoxide (XVI), which decomposes gradually to XIII. In the present photooxidation of I, neither III nor XVI could be detected (tlc). But, at low temperature (−78 °C) at which the intermediate XVI is known to be stable and to be accumulated as the primary photooxidation product of III,[18] I resisted to photooxidation and only underwent *cis-trans* isomerization. Therefore, it can not be unambiguously known whether XIII, XIV, and XV were formed *via* VIa.



XIII XIV XV

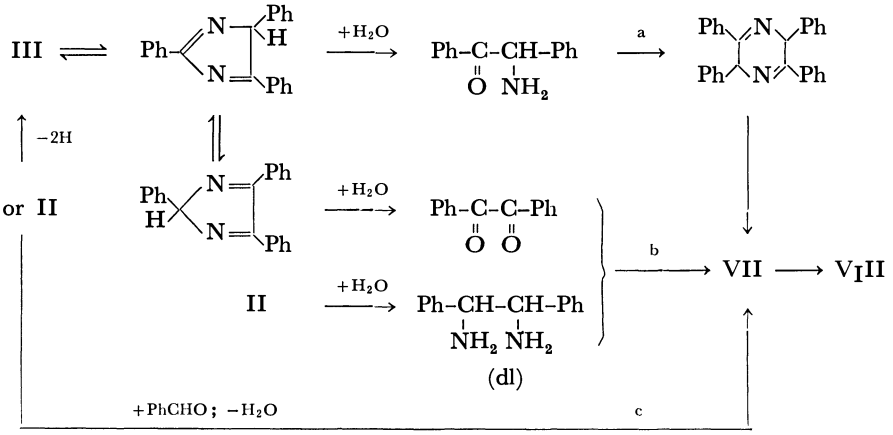


XVI

In conclusion, the *cis-trans* isomerization of I and II, the bond energy data, the isolation of VII and X, and the photoproducts of *cis*-XI are well accommodated by a mechanism involving the scission of C_4–C_5 bond. The result of photochemical oxidation of I is not inconsistent with this mechanism.

Experimental

All the melting points are uncorrected. NMR spectra were taken on an NEVA T-60 spectrometer with tetramethylsilane as the internal standard. IR and UV spectra were measured on a JASCO IRS spectrophotometer, and on a MODEL ORD/UV-5 Japan Spectrometer, respectively. Column chromatography was carried out with Mallinckrodt silica gel (100 mesh) as the adsorber. Thin layer chromatography (tlc) was carried out with Merck Kieselgel GF_{254} using UV



Scheme 3.

light and iodine for compound detection. Synthesis of amarine (I) and isoamarine (II) has been described.[2] All the solvents were distilled before use.

cis-trans *Isomerization of I and II under Various Conditions (Table 1).* A solution of I or II dissolved in a solvent, 110 ml when a 100-W highpressure mercury lamp (Pyrex filter) was used, 220 ml when a 10-W lowpressure mercury lamp (Vycor filter, mainly 2537 Å) was used, and 500 ml (acetone) for low concentration experiments, was irradiated several hours under bubbling nitrogen. After evaporation of the solvent under reduced pressure, the residue was subjected to NMR analysis (CCl_4–DMSO-d_6) and the II/I ratio was determined from the peak intensities of singlets at τ 4.55 for I and τ 5.10 for II. The yields of lophine (III) and recovered imidazolines (I+II) were determined by UV analysis (EtOH) and NMR analysis (CCl_4+DMSO-d_6; pinacol or 2-methylimidazoline as the internal standard), respectively. In solvents except acetone, none or a trace of III was detected by careful tlc analysis.

Quenching of the cis-trans *Isomerization of I.* Pyrex tubes (volume 20 ml) containing a fixed amount of I and freshly distilled piperylene (bp 45—47 °C) in acetonitrile were sealed after bubbling nitrogen through the solution and irradiated externally on a merry-go-round apparatus. After removing the solvent and the piperylene under reduced pressure, the II/I ratio was determined by NMR technique (Table 2).

The results of Table 3 were obtained by irradiating a fixed amount of I and piperylene in benzene (220 ml) under bubbling nitrogen and then by determining the II/I ratio by NMR spectroscopy.

Isolation of Byproducts and Experiments to Trap VIa in the cis-trans *Isomerization of I.* All irradiations were done with a 100-W high pressure mercury lamp (Pyrex filter) under bubbling nitrogen, unless otherwise specified. The photoproducts obtained after removing the solvent under reduced pressure were separated and characterized in the following way.

A) Isolation of Byproducts. The product mixture (after 17 hr irradiation)[20] from a solution of I (1.17 g) in acetonitrile (110 ml) was chromatographed on silica gel (40 g). Elution with 200 ml of 1 : 1 benzene–chloroform gave 12 mg of a solid which contained a trace of 2,3,5,6-tetraphenylpyrazine (VIII) (tlc). Further elution with 400 ml of the same solvent, followed by preparative tlc, afforded 35 mg (2%) of VII identified by IR, NMR, and tlc and 15 mg (1—2%) of III identified by IR and tlc. Further elution with the same solvent and finally with acetone gave 760 mg of II and 350 mg of I, respectively (total yield of I and II, 95%).

B) Irradiation of I with Trapping Reagents. i) 1-Butanethiol: A chloroform-insoluble part of the product mixture (after 15 hr irradiation) from a mixture of I (2.33 g; 0.035 M) and 1-butanethiol (9.0 ml; 0.38 M) in acetonitrile (220 ml) was recrystallized from acetone and 135 mg of III was obtained. The residue from the mother liquor was chromatographed on silica gel (70 g). Elution with 700 ml of chloroform afforded a yellow solid, which after preparative tlc (benzene) yielded 60 mg (3%) of 2,3,5,6-tetraphenylpyrazine (VIII) mp 260—261 °C (acetone–chloroform) (lit. mp 252 °C[21]) and 40 mg (2%) of *trans*-2,3,5,6-tetraphenyl-2,3-dihydropyrazine(VII), mp 205—206 °C (chloroform–ethanol) (lit. mp 199.5—200.5 °C[22]). The IR spectrum of VII were identical with that of an authentic sample.[22] The IR sepctrum of VIII was identical with that in the Sadtler Standard Spectra. Further elution with 800 ml of chloroform yielded 990 mg of III (the total yield of III, 48%). Further elution with chloroform and acetone, followed by preparative tlc (1 : 1 chloroform–acetone), yielded I (380 mg) and II (210 mg) and 40 mg (2%) of *meso*-stilbenediamine(X), mp 121—123 °C (ligroin–ether) (lit. mp 118—120 °C[23]) which was identical with an authentic sample.[24]

ii) Oxygen: The product mixture obtained from photolysis (15 hr) of a solution of I (1.07 g) in acetonitrile (110 ml) under bubbling oxygen instead of nitrogen was separated by preparative tlc (30—50 : 1 chloroform–acetone). Following products, in the order of increasing R_f values, were isolated: (1) *N,N'*-Dibenzoylbenzamidine(XIII); 460 mg (43%), which was unstable on silica gel (Kieselgel GF_{254}) or alumina (Aluminiumoxide GF_{254}) and decomposed to a mixture of XIII, XIV, and XV as reported earlier[18,19] but could be obtained in a sufficiently pure state for IR and NMR measurements. Its identity was confirmed by comparison with an authentic sample.[19] (2) *N*-Benzoylbenzamidine (XIV) and (3) dibenzamide(XV); combined yield, 165 mg (16%). These two compounds had the same R_f value of tlc ($CHCl_3$) and XIV decomposed on tlc to give XV. Recrystallization of the mixture from 3 : 1 ligroin–acetone, however, could yield pure XV, mp 152—154 °C (lit. mp 147—148 °C[25]) which was identified by NMR and IR spectra and had UV spectrum identical to the published data.[26] The residue from the mother liquor consisted of mainly XIV, whose NMR and IR spectral data were in accord with those of an authentic sample.[19] (4) Isoamarine (II); 140 mg (13%). Amarine (I) was not detected. Low-temperature (−78 °C) oxidation of I was also carried out in the same manner and the reaction was followed by tlc, giving results that only I and II were detected, but III, XIII, XIV, XV and XVI[18] could not be detected.

iii) 2,2,6,6-Tetramethylpiperidine-1-oxyl.[27] A mixture of I (1.14 g, 0.0191 M) and this free radical (3.96 g, 0.127 M) in benzene (200 ml) was irradiated under nitrogen with light at 313 nm isolated from a 100-W mercury lamp with a chromate–carbonate filter.[28] The reaction was followed by tlc confirming the occurrence of *cis-trans* isomerization. In addition, a small amount of III was detected.[29] However, products expected from the trapping of VIa by the nitroxyl radical could not be observed until 52 hr of irradiation. At this point an aliquot of the photolysate was submitted to preparative tlc (30 : 1 chloroform–ethanol) and an almost equal amount of I and II and a small amount of III were isolated. The nitroxyl radical was fairly stable under these conditions and was largely recovered unchanged (*ca.* 72%).

iv) Isopropyl Alcohol. After 70 hr of irradiation, the photolysate from I (1.01 g) in isopropyl alcohol (100 ml) contained no significant product except I and II as the main product and traces of III, VII and VIII by tlc analysis.

Photolysis of I in the Presence of Benzaldehyde. The mixture obtained by the photolysis (15 hr) of a solution containing 1.01 g (3.41×10^{-2} M) of I and 50 μl (4.81×10^{-3} M) of benzaldehyde in acetonitrile (110 ml) with a 100-W high pressure mercury lamp (Pyrex) under bubbling nitrogen was evaporated and the residue was chromatographed on silica gel (30 g). Elution with chloroform, followed by preparative tlc (benzene or 20—50 : 1 chloroform–acetone) of the eluates, yielded 3 mg (<0.5%) of VIII, 5 mg (<0.5%) of VII, 20 mg (2%) of III and 23 mg (2%) of XII. Further elution with chloroform and acetone afforded 530 mg (52%) of II and 435 mg (43%) of I. The structure of XII, mp 184—185 °C (petroleum ether–methanol), was assigned from its spectral and analytical data; ν (film) 1665, 1325 cm^{-1}; τ (CCl_4) 2.17—3.17 (20H, m, arom), 4.88 (1H, d, J=3 Hz) and 4.98 (1H, d, J=3 Hz); λ_{max}(EtOH) 242 (ε 18400) nm.

Found: C, 83.48; H, 5.65; N, 6.82%. Calcd for $C_{28}H_{22}N_2O$: C, 83.55; H, 5.51; N, 6.96%.

Synthesis of XII. To a solution of 90 mg (2.33×10^{-4} M) of VII in 1 ml of chloroform was added dropwise 450 mg (2.93×10^{-4} M) of perbenzoic acid (9% chloroform solution) with stirring. The mixture was stirred for further 1 hr at room temperature, and evaporated to dryness. The residue was separated by preparative tlc (chloroform) and 15 mg (23%) of XII was isolated as the main product which showed an IR spectrum identical with that of XII obtained photochemically. The method to prepare oxaziridines by the action of peracids or aerated aldehydes on Schiff's bases is well-known.[30]

Photolysis of III in the Presence or Absence of dl-*Stilbenediamine.* Two Pyrex tubes, each containing a solution of III (10 mg) in acetonitrile (20 ml) and a solution of III (11 mg) and *dl*-stilbenediamine (5 mg) in acetonitrile (20 ml), were irradiated externally with a 400-W high pressure mercury lamp (Pyrex) under bubbling nitrogen for 8 hr. By careful examination of the photolysate by tlc VII and VIII were not detected at all.

Deuterium Incorporation Experiment. A solution of 94 mg of I in a mixture of acetonitrile (15 ml) and D_2O (5 ml) placed in a Pyrex tube was sealed after bubbling nitrogen and irradiated externally with a 450-W high pressure mercury lamp for 16 hr. After evaporation of the photolysate under reduced pressure, the residue (II/I=1.2 by NMR) was dissolved in chloroform (20 ml) and washed four times with 20 ml of water to remove deuterium bound to nitrogen. The solution was evaporated after drying over Na_2SO_4 and was separated by preparative tlc (3 : 2 chloroform–acetone) to give I (25 mg) and II (34 mg). The latter was recrystallized from ether–ethanol and analyzed by mass spectroscopy (Hitachi RMU-6C) to determine deuterium content. It was estimated as less than 1.9% from comparison with the mass spectrum of the nondeuterated II.

Photolysis of cis-*2,4,5-Triphenyloxazoline (XI).* A solution of XI[31] (1.03 g) in acetonitrile (220 ml) was irradiated with a 10-W low pressure mercury lamp (Vycor) under bubbling nitrogen for 15 hr. After removing the solvent under reduced pressure, the residue (1.03 g) was chromatographed on silica gel (50 g). Elution with benzene (400 ml) afforded 35 mg of a yellow oil which contained *ca.* 1 mg of benzaldehyde (IR) by vpc analysis. Further elution with benzene (400 ml), followed by preparative tlc (2 : 1 chloroform–benzene), afforded 144 mg of *trans*-2,4,5-triphenyloxazoline, mp 86—87.5 °C (from petroleum ether) (lit. mp 83—85 °C[31]), which gave satisfactory spectral and analytical data. Further elution with benzene (1600 ml), followed by preparative tlc (5 : 1 chloroform–benzene), afforded a white solid (345 mg); mp 122—135 °C (from petroleum ether–acetone), which was unidentified.

The Addition Reaction of Benzenesulfinic Acid to *N*-Substituted Maleimides

Itsuo MATSUDA, Keiichi AKIYAMA, Takaaki TOYOSHIMA*, Shinji KATO*, and Masateru MIZUTA*

General Engineering Group, Toshiba Chemical Co., Ltd., c/o Toshiba Research and Development Center, Komukai Toshiba-cho, Saiwai-ku, Kawasaki, Kanagawa 210

**Department of Industrial Chemistry, Faculty of Engineering, Gifu University, Kagamigahara, Gifu 504*

(Received May 26, 1975)

It was found that benzenesulfinic acid reacted with *N*-substituted maleimides in aqueous ethanol to give sulfoneimides in good yields. The rate for the reaction was determined by the use of the neutralization titration, the effect of a substituent in *N*-substituted maleimides on the rate was studied, and the reaction route of benzenesulfinic acid with *N*-substituted maleimide was deduced.

The facile addition of nucleophiles to the double bond of maleimide compounds is well known and has been extensively studied.[1-6] The analogous reaction employing sulfinic acid has, however, received little attention. Therefore, this study was conducted in order to determine the course of the maleimide-sulfinic acid reaction and its potential adaptability to the preparation of polymers.

Although the nucleophilic property of sulfinic acid has been considered interesting, the nucleophilic addition reaction of sulfinic acid with maleimide has not yet been reported.

It is well known that the acidity of sulfinic acid is stronger than that of carboxylic acid and that sulfinic acid is unstable;[7] it easily disproportionates, and it decomposes. Sulfinic acid is known to react with α, β-unsaturated compounds in a buffer solution or in the presence of weak acids, such as boric or acetic acid.[8]

TABLE 1. ANALYTICAL DATA AND PHYSICAL PROPERTIES OF ADDUCTS (**3**)

The present paper will deal with the addition reaction of benzenesulfinic acid to seven *N*-substituted maleimides, conducted in aqueous ethanol. By measuring the unreacted benzenesulfinic acid by means of neutralization titration, the rate constants of the reaction were calculated; the effect of the substituent in *N*-substituted maleimides on the reaction is discussed, and the course of the reaction is deduced.

Experimental

Materials. The benzenesulfinic acid was extracted, by means of diethyl ether (40 ml) in a separating funnel, from a mixture of sodium benzenesulfinate (16.4 g, 0.1 mol) dissolved in chilled water and concd HCl (7.9 ml, 0.095 mol). By removing the diethyl ether, benzenesulfinic acid (10 g, mp 74—76.0 °C) was obtained in a 70% yield; it was then preserved below 0 °C before use. The structure was confirmed by comparison with the spectral data in the literature.[8,10]

Seven *N*-substituted maleimides were prepared by the usual method[9] and recrystallized from ethanol; the following materials were used: *N*-phenylmaleimide, 87.5—88.5 °C; *N*-(*p*-ethoxyphenyl)maleimide, 133.0—135.0 °C; *N*-(*p*-methoxyphenyl)maleimide, 146.0—148.0 °C; *N*-(*p*-methylphenyl)maleimide, 147.0—150.0 °C; *N*-(*p*-chlorophenyl)-maleimide, 115.0—117.0 °C; *N*-(*m*-chlorophenyl)maleimide, 93.0—95.0 °C; *N*-(*m*-nitrophenyl)maleimide, 132.0—133.0 °C.

Preparation of Adducts of Benzenesulfinic Acid with N-Substituted Maleimides. A typical preparation is presented. The yields and physical properties and elemental analyses are summarized in Table 1.

*N-Phenyl-2-phenylsulfonylsuccinimide (**3d**).* A solution of benzensulfinic acid (0.002 mol) in water (100 ml) was added to a solution of *N*-phenylmaleimide (0.002 mol) in ethanol (100 ml) at 15 °C, after which the mixture was stirred for 10 hours. The recrystallization of the separated precipitates from ethanol gave 0.605 g (yield 96%) of **3d** as white needles.

Measurement of the Reaction Rate. Since a reaction product precipitates soon after the mixing of a benzenesulfinic acid aqueous solution with an *N*-substituted maleimide alcoholic solution, the conventional method for measuring a reaction rate was inapplicable. Therefore, the procedures used were as follows. *N*-substituted maleimide was dissolved to 0.02 mol/l with ethanol, and benzenesulfinic acid was dissolved to 0.02 mol/l with water. After aliquot portions (10 ml) of the *N*-substituted maleimide solution had been pipetted into several 50-ml glass-stoppered flasks for one run and put in a water bath kept at a prescribed temperature (accuracy±0.1 °C), just as much (10 ml) of the benzenesulfinic acid solution was added to each flask. The time of the mixing-in of the benzenesulfinic acid solution was considered the starting point of the reaction. After the glass-stoppered flasks containing the reaction mixture (20 ml) had then been taken out at regular time intervals, the reaction mixture put in the flasks was immediately subjected to the measurement of the remaining unreacted benzenesulfinic acid by means of neutralization titration with 0.1 M KOH alcoholic solution, using phenolphthalein as the indicator. All the kinetic runs were followed as above. All the rate constants were determined from the second-rate equation as follows:

$$k_2 t = \frac{1}{A_0}\left(\frac{a}{a_0-a}\right) = \frac{1}{A_0}\left(\frac{a_0}{a_0-a}-1\right)$$

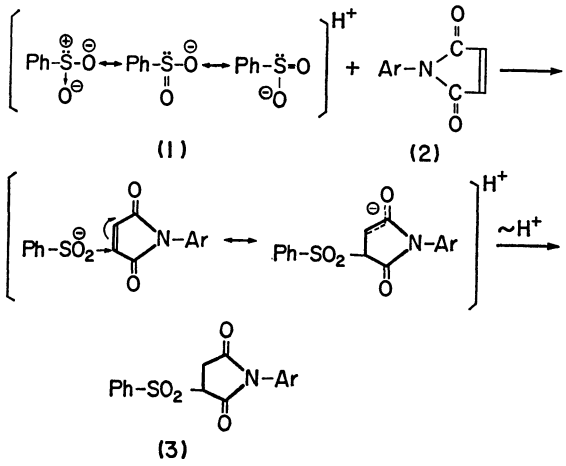
Results and Discussion

The addition reaction of benzenesulfinic acid to *N*-substituted maleimide is shown in the following scheme.



Although the reaction of benzenesulfinic acid with *N*-phenylmaleimide was attempted in ethanol or acetone at room temperature, no adduct could be detected. When a strong acid such as HCl or H_2SO_4 was used as the catalyst in ethanol or acetone, no adduct could be detected, either. However, when aqueous ethanol or aqueous acetone was used as the solvent, the adduct, *i.e.*, *N*-phenyl-2-phenylsulfonyl-succinimide (**3d**), was obtained in a good yield.

This is evidently because, as is shown in Table 3, as the polarity of the solvent increases with an increase in the water content, the reaction rate also increases; *i.e.*, the polarity of the solvent is important for the addition of benzenesulfinic acid to *N*-substituted maleimide.

All the *N*-substituted maleimides react smoothly with benzenesulfinic acid in aqueous ethanol at room temperature and gave readily isolable products; these products are summarized in Table 1. The structures

of the reaction products were determined on the basis of the spectral data and elemental analyses, the details of which have been given in the Experimental section. These results undoubtedly indicate that the nucleophilic addition of benzenesulfinic acid takes place only at the carbon-carbon double bond of *N*-substituted maleimide, thus forming sulfon-imide.

The kinetic measurements were carried out by following the remaining unreacted benzenesulfinic acid by means of neutralization titration.

Figure 2 shows Hammett's plot of log k/k_0 *vs.* the σ value at 15 °C. As a result, the introduction of all the substituents was found to accelerate the rate of addition reaction.

The above results suggest that the reaction mechanism involves a charged intermediate or transition state which is stabilized by the medium. The course shown above, involving considerable charge separation, may be concluded to be a reasonable mechanism for the reaction; it is in agreement with the observed kinetic order.

Nonenzymatic Hydrolysis of Adenosine 5′-Triphosphate in Micellar and Reversed Micellar Systems

Manabu Senō, Shinsaku Shiraishi, Koji Araki, and Hideo Kise
Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
(Received June 9, 1975)

The nonenzymatic hydrolysis of adenosine 5′-triphosphate (ATP) in micellar and reversed micellar system was examined as an approach to elucidate the function of ATPase. In aqueous micellar systems an anionic surfactant does not affect the hydrolysis rate, but a cationic surfactant, cetyltrimethylammonium bromide(CTAB), retards the hydrolysis. This deceleration effect is interpreted to be owing to the pH change or accumulation of hydroxide ions at the cationic micellar-water interface which serves as reaction site. In the reversed micellar system where aqueous ATP phase is solubilized in *n*-hexane by dodecylammonium propionate(DAP), the hydrolysis rate of ATP is enhanced by several times as compared with that in an aqueous system. Addition of Mg^{2+} or Ca^{2+} enhances the hydrolysis rate markedly only in the DAP reversed micellar system. The catalytic effect of the DAP reversed micellar system is discussed with respect to the polarity of water phase solubilized in the core of reversed micelles.

Adenosine 5′-triphosphate(ATP) plays an important role in repository and transfer of chemical energy in many enzymatic processes in living systems. Energy transfer in these systems usually involves the reactions of ATP into adenosine 5′-diphosphate (ADP). Though many studies have been made as to the structure and function of ATPase, the mechanism of its catalytic action is not yet clear. To improve this situation, some nonenzymatic model reactions have also been examined, and it has been observed that the hydrolysis reaction of ATP is enhanced either by the addition of metal ions or polyamines,[1,2] or in the presence of aprotic polar solvent.[3]

On the other hand, surfactant micelles affect rates of various reactions and are noticed as a model for enzymatic action. Recently, Fendler *et al* observed that reversed micelles in nonpolar solvents showed a significant rate enhancement in several reactions and pointed out that reversed micelles could provide a favorable model for the micro-environment of enzyme active sites.[4]

In the present investigation, we carried out the nonenzymatic hydrolysis of ATP both in an aqueous micellar system and in a reversed micellar system, and examined the micellar effect on hydrolysis rate to shed light on the function of ATPase.

Experimental

Materials. Disodium salt of ATP was purchased from Sigma Chemical Co. and was used without further purification. Cetyltrimethylammonium bromide(CTAB) and sodium dodecylsulfate(SDS) were recrystallized three times from methanol–ether. Dodecylammonium propionate(DAP) was prepared by Kitahara's method and purified three times by recrystallization from *n*-hexane;[5] mp 55—56 °C (lit, 54—56 °C)[5]. Found (Calcd): C, 69.68(69.44), H, 12.38 (12.82), N, 5.32(5.40)%. Magnesium chloride and calcium chloride of analytical grade were used after dried.

Reactions. *Reaction in Aqueous Micellar System*: A sample solution, pH of which was adjusted by using a buffer solution or addition of small amount of a *dil* NaOH solution, was prepared by dissolving ATP and surfactant *etc.* The solution was maintained at 50 °C with stirring. A pH meter of Toa HM-5A was used for pH measurement. The mixture was heterogeneous at low CTAB concentration (below about 6×10^{-3} M when ATP concentration was 2×10^{-3} M at 50 °C) because of the precipitation of CTAB–ATP salt, but at higher CTAB concentration the precipitate was dissolved to form a homogeneous solution. Reactions were carried out only when the mixture was homogeneous.

Reaction in Non-aqueous Reversed Micellar System: A sample solution was prepared by solubilizing an aqueous ATP solution in *n*-hexane using DAP (Fig. 1). When the amount of the aqueous solution added is too large for the DAP concentration, the aqueous solution is not solubilized completely, and when too small, DAP does not dissolve completely. The solubilized system was obtained in a range of $[H_2O]$/[DAP] ratio of 0.55—2.2 at DAP concentration of 0.2 M at 50 °C, and reactions were carried out only under these conditions at 50 °C.

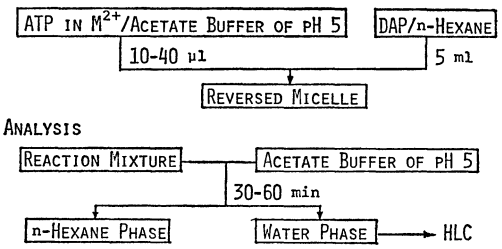

Fig. 1. Experimental procedure for the reversed micellar system.

Analysis. ATP and its hydrolysis products, *i.e.* ADP, adenosine 5′-monophosphate(AMP) and adenosine, were determined by a high speed liquid chromatography (hlc) under following conditions: column, Hitachi anion exchanger #2630; column temprature, 45 °C; mobile phase, 0.25 M NaCl in 0.01 M HCl solution; flow rate, 1.2 ml·min^{-1}; detector, Iatron UV photometer LC-1 at 254 nm. When *n*-hexane was used as a solvent, ATP and its hydrolysis products were extracted from the reaction mixture with water prior to hlc analysis. Under the condition that less than 10 per cent of initial amount of ATP was hydrolyzed, the hydrolysis product was mainly ADP, and the amount of AMP or adenosine produced was negligibly small. Therefore, the hydrolysis rate of ATP was determined from the change in ADP concentration in this range.

Other Measurements. UV spectra of pyridine 1-oxide were observed by a Hitachi spectrophotometer model EPS-3T using a thermostated cell. Aggregation numbers of DAP

in the reversed micellar system were estimated from the average molecular weights of micelles, which were measured by a Hewlett-Packard vapour pressure osmometer model 302B at 37 °C.

Results and Discussion

The rate of hydrolysis reaction of ATP in an aqueous solution obeys a pseudo first order rate kinetics for ATP concentration (Eq. (1));

$$\mathrm{ATP} + \mathrm{H_2O} \xrightarrow{k_{app}} \mathrm{ADP} + \text{phosphoric acid}$$

$$-\frac{d[ATP]}{dt} = k^{\circ}_{app}[ATP] \quad (1)$$

where k°_{app} is a pseudo first order rate constant. The hydrolysis rate in the micellar system shows also a first order dependence on ATP concentration, and the pseudo first order rate constants, k^{m}_{app} in an aqueous micellar system and k^{r}_{app} in a reversed micellar system were determined experimentally.

ATP Hydrolysis in Aqueous Micellar Solutions. Effects of surfactants on k^{m}_{app} are shown in Table 1. The addition of an anionic surfactant, SDS, has little or no effect on k_{app}, but the addition of a cationic surfactant, CTAB, reduces it. Since the addition of tetramethylammonium bromide (TMAB) which does not form micelles shows no effect on the hydrolysis rate, the deceleration effect of CTAB is thought to be caused by the formation of its cationic micelles. Figure 2 shows the effect of CATB concentration on k^{m}_{app}. When the CTAB concentration is higher than 8×10^{-3} M, the value of k^{m}_{app} is reduced by half compared to k°_{app} and is almost independent of CTAB concentration.

Table 1. Hydrolysis rate constants of ATP in aqueous micellar solutions at 50 °C

Surfactant or salt added	$k_{app}\times10^{6}$ (s^{-1})	$k_{rel.}$
None	1.12	=1
SDS	1.04	0.92
CTAB	0.676	0.60
TMAB	1.09	0.97

ATP=2×10^{-3} M; Surfactant or salt=2×10^{-2} M; in pH 4.1 acetate buffer.

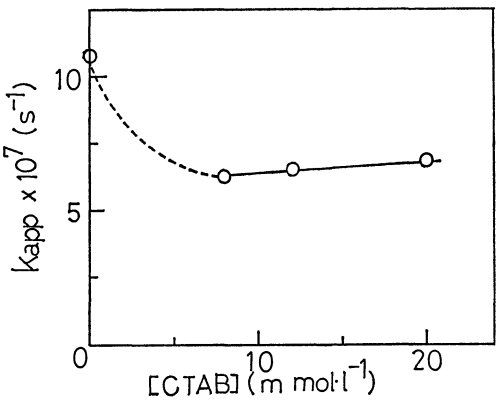

Fig. 2. Effect of CTAB concentration on the hydrolysis rate of ATP(2×10^{-3} M) at 50 °C in pH 4.1 acetate buffer.

The rate of hydrolysis could not be measured at lower CTAB concentration, where ATP did not dissolve uniformly.

The effect of addition of methanol to the reaction mixture with or without CTAB was examined, and result is shown in Fig. 3. With an increase in methanol content, the value of k^{m}_{app} in micellar solution becomes close to that of k°_{app}, and both the values are almost the same at methanol contents higher than about 50 v/v%, where CTAB micelles were destroyed almost completely.[6] This fact ensures that the effect of CTAB on hydrolysis rate is caused by its cationic micelles.

The effect of pH on hydrolysis rate both in aqueous and in CTAB micellar systems is given in Fig. 4. The value of pH of these solutions was adjusted by addition of a *dil* NaOH solution and determined by a glass electrode pH meter. Both of k°_{app} and k^{m}_{app} decrease as pH increases, and abrupt decreases are observed around pH 7 for k°_{app} and pH 6 for k^{m}_{app}. These pH values are nearly equal to those of the second dissociation of γ-phosphate of ATP in these systems (pk°_{2}= 7.1 and pk^{m}_{2}=6.1), which were determined from titration curves shown in the same figure. This result indicates that the hydrolysis rate is closely related with

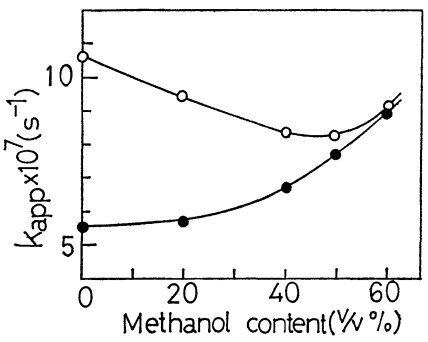

Fig. 3. Effect of methanol on the hydrolysis rate of ATP (2×10^{-3} M) both in aqueous (○), and in CTAB (1.2×10^{-2} M) micellar (●) solutions at 50 °C.

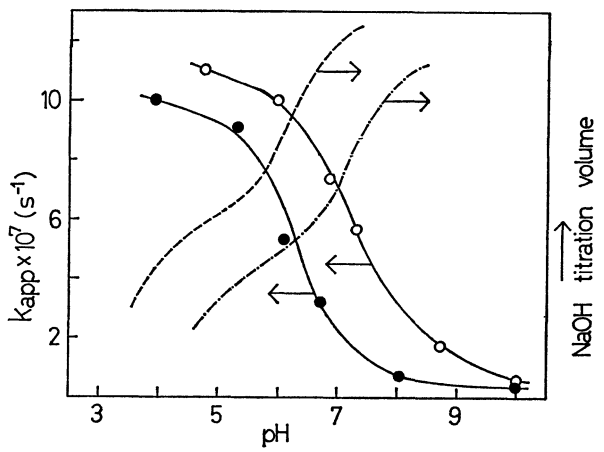

Fig. 4. Effect of pH on the hydrolysis rate of ATP (2×10^{-3} M) in aqueous (○), and in CTAB (1.2×10^{-2} M) micellar (●) solutions; and titration curves of ATP in aqueous (·—·), and in CTAB (1.2×10^{-2} M) micellar (----) solutions; at 50 °C.

the near environment of ATP or the dissociation state of ATP. Furthermore, it is to be noted that shifting the curve of k^{o}_{app} *vs.* pH to the lower pH side by about 1 makes it similar to that of k^{m}_{app} *vs.* pH. This result might imply that the pH value at the reaction site in micellar solution is higher by about 1 than that determined by a pH meter, which measures the pH value in the bulk aqueous phase.[7] This leads to the following interpretation of the result. ATP molecules exist at the interface between water and micelle, where hydroxide ions are accumulated by its cationic character to give a rise in pH. The deceleration effect of CTAB micellar system on hydrolysis rate of ATP is owing to this accumulation effect at micellar interface.

ATP Hydrolysis in Reversed Micellar Systems. The hydrolysis of ATP was also examined in a reversed micellar system in nonpolar medium. *n*-Hexane was used as a nonpolar solvent and DAP as an oil-soluble surfactant. ATP, which is insoluble in organic solvents, could be solubilized in *n*-hexane by addition of a small amount of water in the presence of DAP to form a reversed micellar system. By assuming that ATP molecules would exist in the core of reversed micelle or, in other words, in the water phase dispersed in *n*-hexane, the rate constant k^{r}_{app} in this system was obtained by a similar procedure to that in aqueous systems. The value of k^{r}_{app} thus obtained was proportional to the DAP concentration and inversely proportional to the water concentration in the range examined; the result could be represented by the expression;

$$-\frac{d[ATP]}{dt} = k^{r}_{app}[ATP] = k'\frac{[DAP]}{[H_2O]}[ATP] \qquad (2)$$

as shown in Fig. 5. The value of k^{r}_{app} is 1—5 times larger than that of k^{o}_{app}; that is, ATP hydrolysis is enhanced in the reversed micellar system.

Effects of Metal Ions. It is known that Mg^{2+} and Ca^{2+} play an important role in the enzymatic hydrolysis of ATP in living systems. In this respect, the effects of these ions on hydrolysis of ATP in aqueous micellar and reversed micellar systems were examined by adding these chlorides into the systems. The values of k^{o}_{app} and k^{m}_{app} are little affected, but that of

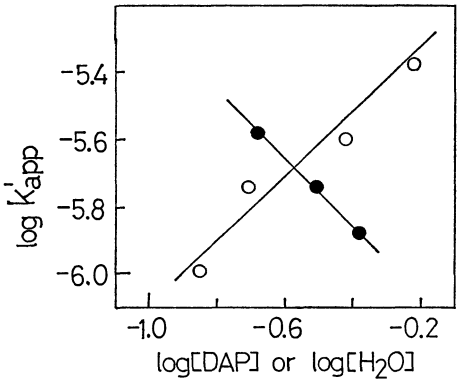

Fig. 5. Dependences of the hydrolysis rate of ATP (6×10^{-4} M) both on DAP concentration (○) where water concentration was 3.33×10^{-1} M, and on water concentration (●) where DAP concentration was 2×10^{-1} M; in *n*-hexane at 50 °C.

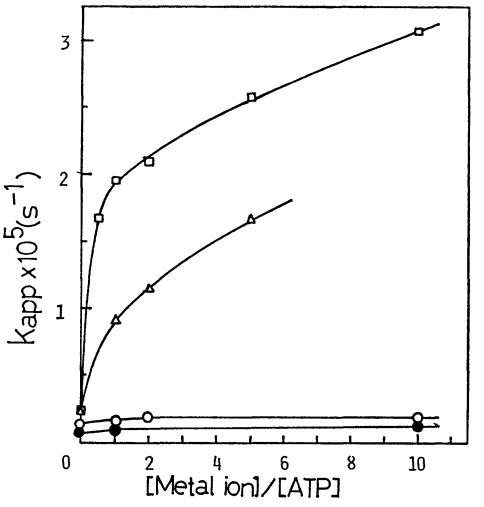

Fig. 6. Effect of divalent metal ions on hydrolysis rate of ATP (6×10^{-4} or 2×10^{-3} M) at 50 °C; (□): M^{2+}, reversed micellar system in *n*-hexane (DAP= 2×10^{-1} M, $H_2O=3.33\times10^{-1}$ M); (△): Ca^{2+}, reversed micellar system in *n*-hexane (DAP=2×10^{-1} M, $H_2O=3.33\times10^{-1}$ M); (○): Mg^{2+}, aqueous solution (pH=4.1); (●): Mg^{2+}, aqueous micellar system (CTAB=1.2×10^{-2} M, pH=4.1).

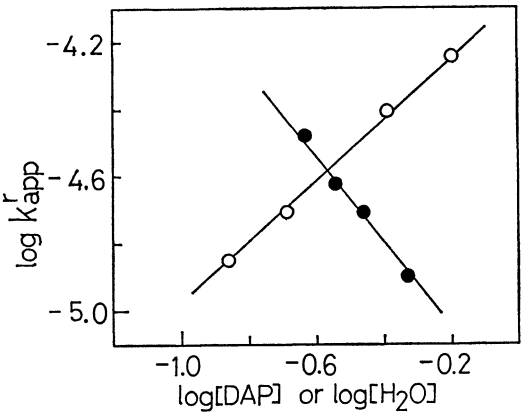

Fig. 7. Dependences of the hydrolysis rate of ATP (6×10^{-4} M) in the presence of Mg^{2+} (1.2×10^{-3} M) both on DAP concentration (○) where water concentration was 3.33×10^{-1} M, and on water concentration (●) where DAP concentration was 2×10^{-1} M; in *n*-hexane at 50 °C.

k^{r}_{app} markedly increases with an increase in the amount of Mg^{2+} added, and the value of k^{r}_{app} levels off at about $Mg^{2+}/ATP=1$ as are shown in Fig. 6. This indicates that the hydrolysis rate is enhanced by the formation of 1 : 1 complex of Mg^{2+}–ATP. Addition of Ca^{2+} also shows a rate enhancement in the reversed micellar system though its effect is smaller than that of Mg^{2+}.

The effect of amounts of DAP and water on k^{r}_{app} was examined at $Mg^{2+}/ATP=2$. The result shows that the hydrolysis rate obeys Eq. (2) as is shown in Fig. 7.

Rate Enhancement in Reversed Micellar System. The hydrolysis reaction of ATP is enhanced in reversed micellar system, and especially when Mg^{2+} or Ca^{2+} is added. The hydrolysis rate is followed by Eq. (2)

whether the divalent cation is added or not. This result suggests that the micellar reaction mechanism itself is not affected by the presence of divalent cation.

The aggregation number of DAP in the reversed micellar system was measured by a vapor pressure osmometer and the result is shown in Table 2. The aggregation number is small and therefore the number of water molecules solubilized in the core of the reversed micelle is very small. So, it is hard to consider the ion condensation at the interface as being observed in the aqueous cationic micellar system. Some other factors must contribute to the rate enhancement.

It is important to note that k^{r}_{app} depends on [DAP]/[H_2O] ratio. Menger *et al.* measured the Z value of water phase solubilized in octane by an anionic surfactant, di-2-ethylhexyl sodium sulfosuccinate, by using pyridine 1-oxide and 2-toluidinylnaphthalene-6-sulfonate as probes, and observed that the value depends on [H_2O]/[Surfactant] ratio.[8] We also measured the polarity of water solubilized in DAP reversed micelles in *n*-hexane by using pyridine 1-oxide as a probe. The change in absorbance maxima of pyridine 1-oxide near 260 nm is given in Fig. 8 as a function of [H_2O]/[DAP] ratio. The polarity of water in the core of the reversed micelle shows a good linear dependence on [H_2O]/[DAP] ratio, and lies midway between those of ethanol and chloroform at [H_2O]/[DAP]=0.55. On the other hand, Nelson *et al.* observed that the hydrolysis rate of ATP was enhanced in aqueous solution of aprotic polar solvent such as dimethyl sulfoxide, dioxane or formamide.[3] Considering them altogether, the rate enhancement of ATP hydrolysis in the DAP reversed micellar system is supposed to be caused by lowering in the polarity of water phase in the core of the reversed micelle, and the [DAP]/[H_2O] term in Eq. (2) may represent the degree of lowering in the polarity.

Table 2. Aggregation number of DAP in the reversed micellar solutions at 37 °C

[H_2O]/[DAP] ratio	Aggregation number
0.55	4.56
1.10	4.53
1.75	4.61
2.20	4.66
2.75	5.23

DAP=2×10^{-1} M; in *n*-hexane.

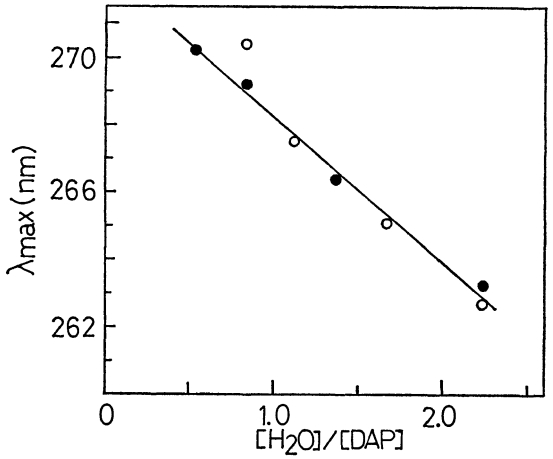

Fig. 8. Dependences of the absorbance maxima (λ_{max}) of pyridine 1-oxide (7.7×10^{-5} M) on [H_2O]/[DAP] ratio in reversed micellar system in *n*-hexane at 50 °C; (○): DAP concentration was 2×10^{-1} M at various water concentrations; (●): water concentration was 3.33×10^{-1} M at various DAP concentrations. λ_{max} of pyridine 1-oxide in various solvents was reported; 254.4 nm in water, 263.3 nm in methanol, 265.1 nm in ethanol, and 276.1 nm in chloroform.[9]

It is well known that a divalent cation, most often Mg^{2+} or Ca^{2+}, is required to activate ATPase in living system, but these metal ions show low or almost no activity in aqueous nonenzymatic hydrolysis of ATP. It is interesting that these metal ions are effective only in the reversed micellar system. Nelson *et al.* also observed that Mg^{2+} was much effective on ATP hydrolysis and Tagaki *et al.* on hydrolysis of phenyl phosphosulfate both in less polar media.[3,10]

Mg^{2+} and Ca^{2+} are hard acids and, therefore, have a stronger interaction with phosphate, which is a base harder than adenine ring. Moreover, it was found that Mg^{2+} ion, a harder acid than Ca^{2+}, is more effective than Ca^{2+} in the reversed micellar system. It was suggested from this consideration that the effect of these ions on ATP hydrolysis is caused by the neutralization of negative charges on phsophate part of ATP. By supposing that the hydrolysis of ATP proceeds *via* nucleophilic mechanism, this reasoning would be plausible. On this respect, it is interesting to note that the mechanism of γ-phosphate splitting of ATP by ATPase is nucleophilic.

Reaction of Organoboranes with Lithium Aldimines. A New Procedure for the Synthesis of Unsymmetrical Ketones[1]

Yoshinori YAMAMOTO,* Kaoru KONDO, and Ichiro MORITANI[2]

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

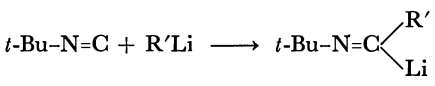
(Received June 26, 1975)

Unsymmetrical ketones are obtained in good yields *via* the reaction of dialkylchloroboranes with lithium aldimines followed by treatment with (i) thioglycolic acid and (ii) H_2O_2–NaOH. The reaction permits the introduction of both primary and secondary alkyl groups into R and R′ substituents of ketones (RR′C=O), and can even be extended to the accommodation of a functional group. The reaction of B-*n*-hexyl-9-borabicyclo[3.3.1]-nonane with lithium aldimine derived from *n*-butyllithium also gives unsymmetrical ketone, 5-undecanone, upon treatment with H_2O_2–NaOH.

In recent years, various procedures for the synthesis of ketones *via* organometallics have been developed.[3] The synthesis through organoboranes is the most useful and convenient. Symmetrical ketones are obtained from the reaction of trialkylboranes with carbon monoxide in the presence of water[4] or with sodium cyanide and trifluoroacetic anhydride,[5] or *via* the reaction of dialkylborinates with α,α-dichloromethyl methyl ether and lithium triethylcarboxide.[6] Unsymmetrical ketones are available *via* the reaction of thexyldialkylboranes with carbon monoxide[7] or with sodium cyanide,[8] *via* the reaction of trialkylboranes with α,β-unsaturated carbonyl derivatives,[9] α-bromoketones,[10] diazoketones,[11] α-lithio derivative of 1,1-bis(phenylthio)pentane,[12] or α-azidostyrene,[13] or *via* the reaction of lithium alkynyltrialkylborates with electrophilic reagents.[14] Although thexylborane can combine two different olefins with a different reactivity toward the B–H bonds, union of two different olefins with similar reactivity such as 1-hexene and 1-butene is unsuccessful.[15] This causes an unsatisfactory result for the union of two primary alkyl groups such as *n*-hexyl and *n*-butyl in the unsymmetrical ketone synthesis.[15] We report a new synthesis of unsymmetrical ketones *via* the reaction of organoboranes with lithium aldimines.

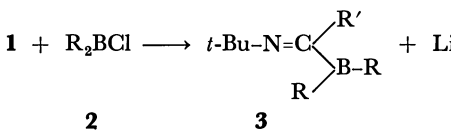
Results and Discussion

Lithium aldimines (**1**) are obtained by addition of alkyllithiums to isocyanides which do not contain α-hydrogens[16] (Scheme 1). The reaction of dialkylchloroboranes (**2**) with **1** gives the corresponding adduct (**3**) (Scheme 2).



$$t\text{-Bu-N=C} + \text{R'Li} \longrightarrow t\text{-Bu-N=C}\begin{matrix}\text{R'}\\ \text{Li}\end{matrix} \quad (1)$$

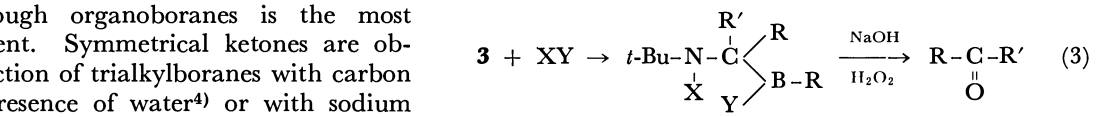
1



$$\mathbf{1} + \text{R}_2\text{BCl} \longrightarrow t\text{-Bu-N=C}\begin{matrix}\text{R'}\\ \text{B-R}\\ \text{R}\end{matrix} + \text{LiCl} \quad (2)$$

2 **3**

It was anticipated that such a compound as **3** can react with an electrophile to induce alkyl transfer from boron to carbon,[17] in which case alkaline hydrogen peroxide oxidation of **4** might give ketone (**5**), where the one alkyl group (R) arises from **2** and the other (R′) from alkyllithium (Scheme 3).



$$\mathbf{3} + \text{XY} \rightarrow t\text{-Bu-N-C}\begin{matrix}\text{R'}\\ \text{X}\\ \text{Y}\\ \text{B-R}\\ \text{R}\end{matrix} \xrightarrow[\text{H}_2\text{O}_2]{\text{NaOH}} \text{R-C(=O)-R'} \quad (3)$$

4 **5**

As a typical case we examined the reaction of di-*n*-hexylchloroborane (10 mmol) with lithium aldimine derived from *n*-butyllithium (10 mmol) and *t*-butylisocyanide (10 mmol). The borane was added to the lithium aldimine at 0 °C, trifluoroacetic anhydride (20 mmol) then being added to the resultant mixture as an electrophile. After being stirred for 1 hr at room temperature, the mixture was subjected to alkaline hydrogen peroxide oxidation, giving 5-undecanone. However, it was obtained in a relatively low 56% yield. This was apparently due to the improper choice of reaction temperature since boranes similar to **3** undergo dimerization.[18] When the reaction was performed at −78 °C, the ketone was obtained in a remarkably improved 95% yield. Various ketones prepared are listed in Table 1.

Unsymmetrical ketones can be prepared by utilizing olefins and alkyl halides as building blocks that can be varied independently. There appears no difficulty in introducing a primary alkyl group containing a functional substituent. However, isopropyl cyclopentyl ketone (**12**) is obtained in only 44% yield, suggesting that the combination of two secondary alkyl groups proceeds with some difficulty under the reaction conditions. This might be due to the difficulty for the transfer of sterically bulky alkyl groups. The relative migratory aptitudes of alkyl groups in the related boranes are in the order primary>secondary>tertiary.[19] We selected several electrophiles and examined the yield of **12** in order to find the best reagent in the present reaction system. The results are summarized in Table 2.

Thioglycolic acid is recommended as a reagent inducing the migration. The present procedure offers the following advantages over the previous methods;[7,8] (i) accommodation of an alkyl group such as isopropyl which can not be introduced *via* the hydroboration methods, (ii) the combination of two different alkyl groups such as *n*-hexyl and *n*-butyl which is not attainable through thexylborane. The only disadvantage is the loss of one alkyl group (R) (Scheme 3). This

may be overcome by utilizing $RBCl_2$ instead of R_2BCl.

We examined the reaction of *n*-hexyldichloroborane with lithium aldimine derived from *n*-butyllithium (Scheme 4).

$$CH_3(CH_2)_5BCl_2 + t\text{-Bu-N=C}\begin{matrix}(CH_2)_3CH_3\\ Li\end{matrix} \xrightarrow[2)\ H_2O_2\text{-NaOH}]{1)\ HSCH_2CO_2H} CH_3(CH_2)_5\overset{\overset{O}{\|}}{C}(CH_2)_3CH_3 \quad (4)$$

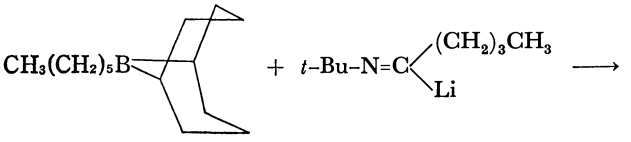
6 50%

The yield of product (**6**) depends upon the additive (Table 3), thioglycolic acid giving the best result. However, the yield never exceeded 50%, the reason not being clarified.

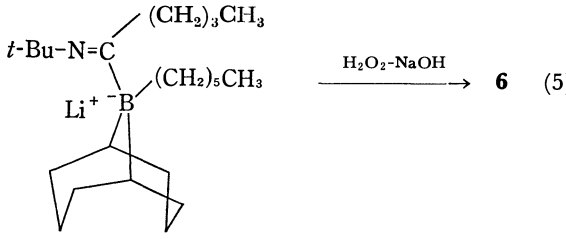
Additives such as $HSCH_2CO_2H$, C_2H_5SH, PhSH, and $(CF_3CO)_2O$ may act as electrophiles in the manner described above (Scheme 3). The other additives ($PhNH_2$ and C_2H_5SNa–C_2H_5SH) are not electrophilic, but nucleophilic. It seems that these reagents attack the electron deficient boron atom, inducing the migration of hexyl group *via* the borate complex. We might conclude that such a borane as **3** undergoes rearrangement under the influence of both electrophilic and nucleophilic reagents, though the latter agents are less effective. In fact, such rearrangement under electrophilic and nucleophilic conditions is observed in the case of α-bromoboranes.[20]

We then tried the reaction of *n*-hexyl-9-borabicyclo-[3.3.1]nonane (*n*-hexyl-9-BBN) (**13**) with lithium aldimine derived from *n*-butyllithium (Scheme 5).

The simple oxidation of reaction mixture gave **6** in 69% yield. When thioglycolic acid was employed before the oxidation, **6** was produced in only 4% yield. Instead, a large amount of diol was detected by glpc analysis, which presumably arose from the migration of 9-BBN ring. This suggests that the borate intermediate (**14**) undergoes rearrangement more easily than the borane intermediate (**3**); presumably the migration in **14** proceeds without assistance of electrophilic or nucleophilic reagents to produce the borane intermediate.[21]



13



14

The reaction of trialkylboranes with lithium aldimines was in sharp contrast with that of dialkylchloroboranes. In the case of R_2BCl, the migration of second alkyl group (R) was very difficult under the conditions (i) $HSCH_2CO_2H$–(ii) H_2O_2–NaOH (Scheme 3). On the other hand, in the case of R_3B, the migration was very facile, leading to the trialkylcarbinylborane ($R_2R'C$–B<). [22] However, this was avoided by the removal of thioglycolic acid as shown in Scheme 5. In contrast to **13**, the reaction with tri-*n*-hexylborane with *n*-butyllithium aldimine followed by treatment with H_2O_2–NaOH gave 7-*n*-butyl-7-tridecanol in 19% yield along with **6**.[22] This can be explained by the fact that the ease of migration of the primary alkyl group (*e.g.* *n*-hexyl) is greater than that of the secondary one (*e.g.* 9-BBN ring).

In conclusion, the reaction of dialkylchloroboranes with lithium aldimines is recommended for the syn-

thesis of unsymmetrical ketones. When the loss of one alkyl group in R_2BCl causes a serious problem, the utilization of 9-borabicyclo[3.3.1]nonane derivatives might remove the difficulty.

Experimental

All boiling points are uncorrected. The IR spectra were obtained on a Hitachi 215 spectrophotometer. The NMR spectra were obtained on a JEOL JNM-MH-60 spectrometer, TMS being chosen as an internal standard. The elemental analysis was performed by Mr. Y. Harada in our Department. Glpc analyses were carried out on a Yanagimoto GCG 550T using a 2 m column packed with Carbowax 20 M or SE-30 10 wt% on Celite 545 AW.

Materials. Reagent grade solvents were purified by standard techniques and kept over a drying agent. B_2H_6: THF, $BH_2Cl : OEt_2$, $BHCl_2 : OEt_2$, dialkylchloroboranes, tri-*n*-hexylborane, *n*-hexyl-9-borabicyclo[3.3.1]nonane, and *n*-hexyldichloroborane were prepared according to the known procedures.[23] Commercial 1-hexene, cyclopentene, the electrophiles, and *n*-butyllithium in hexane were used. Other alkyllithiums were prepared by standard procedures (ethyllithium in ether,[24] isoamyllithium in ether,[24] and isopropyllithium in pentane[25]). Titration was performed according to the method of Gilman and Haubein[26] or that of Watson and Eastham.[27] 5-Bromo-1-pentene[28] and *t*-butylisonitrile[29] were prepared according to the methods previously reported.

Reaction of Lithium Aldimine with Dialkylchloroborane. General Procedure: In a 200-ml flask maintained under N_2 and fitted with a septum inlet, magnetic stirrer, and reflux condenser, were placed *t*-butylisonitrile (3.6 ml, 30 mmol) and dry ether (60 ml). The solution was cooled to 0 °C and a solution of alkyllithium (30 mmol) was added dropwise. The mixture was stirred for 30 min at 0 °C and then cooled to −78 °C with a dry-ice acetone bath. Dialkylchloroborane (30 mmol) was added, and the resulting mixture was kept at −78 °C for 30 min. Thioglycolic acid (4.2 ml, 60 mmol) or trifluoroacetic anhydride (8.4 ml, 60 mmol) was then added, the temperature being regulated to reach room temperature over 1 hr. Oxidation was accomplished by the addition of 6 M aqueous NaOH (10 ml)–30% H_2O_2 (10 ml). The organic phase was separated and the aqueous layer was extracted with ether. The combined organic layer was dried over anhydrous K_2CO_3. The solvent was removed under reduced pressure and the product was filtered through the column of silica (*ca.* 200 g). The ketones were eluted with benzene in substantially pure form. The ketones were then distilled under reduced pressure and/or subjected to a preparative glpc to obtain analytically pure materials. Alcohols were removed from the column with ether. No attempt was made to attain optimum yields of individual ketones, but all were subjected to the general procedure described above. The spectral data, boiling points and n_D are summarized in Table 4. Authentic samples of **6** and **8**, commercially available, were used. The other authentic samples (**7**, **9**, **11**, and **12**) were independently prepared by the reported procedures (Table 4). Elemental analysis was performed on the unknown compound (**10**); (Found: C, 51.40; H, 8.33; Br, 33.00%. Calcd for $C_{10}H_{19}BrO$: C, 51.07; H, 8.14; Br, 33.98%). For the synthesis of **6**—**11** except **12**, trifluoroacetic anhydride was utilized as an electrophile, satisfactory results being obtained. Utilization of thioglycolic acid in these cases improved the yields. Pronounced effect of this reagent was observed in the preparation of **12** (Table 2).

*Reaction of Di-*n*-hexylchloroborane with* n*-Butyllithium Aldimine. Temperature Effect.* Lithium aldimine was prepared as described above. Di-*n*-hexylchloroborane (10 mmol, 2.4 ml) was added at 0 °C to the solution of lithium aldimine. The resulting mixture was stirred for 30 min at 0 °C. Trifluoroacetic anhydride (20 mmol, 2.8 ml) was then added. The mixture was allowed to reach room temperature over 1 hr. Oxidation was accomplished in the normal way. The aqueous layer was saturated with K_2CO_3 and the organic layer was analyzed by glpc with *n*-dodecane as an internal standard. The reaction at −78 °C was carried out according to the general procedure.

Check for the Effectiveness of Electrophiles in the Preparation of ***12***. All reactions (10 mmol scale) were carried out according to the general procedure. Neat electrophiles (20 mmol) (Table 2) were added directly to the reaction mixture, except that H_2S dissolved in ether was added. After oxidation, the aqueous layer was saturated with K_2CO_3 and the organic layer was analyzed by glpc with *n*-dodecane as an internal standard. Increase in the amount of electrophiles did not significantly improve the yield of **12**, though a decrease in the amount lowered the yield.

12	50—52/3 (84/30)[35]	1.4444	1714	1.03 (d, 6H, J=7), 1.61 (broad s, 8H), 2.32—3.16 (m, 2H)

Reaction of n-*Hexyldichloroborane with* n-*Butyllithium Aldimine.* The reaction (10 mmol scale) was carried out according to the general procedure, except for the utilization of *n*-hexyldichloroborane (10 mmol, 1.8 ml) and of pentane as the solvent. Various additives (20 mmol) to induce the migration were examined (Table 3). Analyses were performed by glpc.

Reaction of n-*Hexyl-9-borabicyclo[3.3.1]nonane with* n-*Butyllithium Aldimine.* Lithium aldimine (10 mmol) was prepared as described above. To this solution was added *n*-hexyl-9-borabicyclo[3.3.1]nonane (**13**) prepared from 1-hexene (10 mmol, 1.25 ml) and 9-borabicyclo[3.3.1]nonane (10 mmol) at −78 °C and the resulting mixture was kept at this temperature for 30 min. Oxidation was accomplished after the reaction was allowed to reach room temperature over 1 hr. Analysis was carried out by glpc. Ketone (**6**) was produced in 69% yield.

Thioglycolic acid (20 mmol, 1.4 ml) was added at −78 °C before oxidation. Oxidation and subsequent analysis were performed according to the general procedure. Along with the minor product (**6**, 4%), a large peak with longer retention time was detected in glpc, the precise structure of which was not determined.

Restricted Rotation Involving the Tetrahedral Carbon. XVII. Isolation of Three "Diastereomeric" Rotamers of a Triptycene Type Compound and Stereoselectivity in the Synthesis[1]

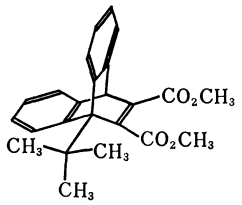
Gaku YAMAMOTO and Michinori ŌKI*

Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113

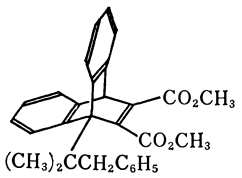
(Received July 4, 1975)

Three rotameric forms of 2,3-dichloro-9-(1,1-dimethyl-2-phenylethyl)-11,12-bis(methoxycarbonyl)-9,10-dihydro-9,10-ethenoanthracene (**3**) were isolated as stable entities at room temperature. The structural assignment of the rotamers based on the PMR characteristics. Since the synthesis of **3** produced only the *ap* form, another reaction involving benzyne was carried out to test the generality of the stereoselectivity. Thus the *ap* form and the *sc* form of 2,3-dichloro-9-(1,1-dimethyl-2-phenylethyl)triptycene (**4**) were prepared separately. Equilibration of isomers of **4** was carried out and the barrier to isomerization was obtained as 36.6 kcal/mol.

A triptycene type compound (**1**) was found to possess an extremely high barrier to rotation about the bond between the *t*-butyl group and the skeleton.[2] As an extention, racemic and *meso* forms of **2** were isolated[3] and the racemic form was resolved into enantiomers.[1]

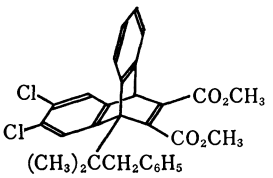


(**1**)

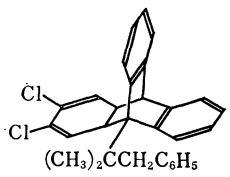


(**2**)

Since **2** has no asymmetric carbon atom, optical resolution was necessary to isolate all the possible rotational isomers. However, if a like compound has a center of asymmetry, the frozen rotation should result in the formation of stable diastereomers, although the compound has only one asymmetric center. If this is the case, the three isomers should be separated by physical means such as chromatography. We wish to report, in the first half of this paper, the realization of such expectation: three isomers of 2,3-dichloro-9-(1,1-dimethyl-2-phenylethyl)-11,12-bis(methoxycarbonyl)-9,10-dihydro-9,10-ethenoanthracene (**3**) were isolated by chromatography.[4]

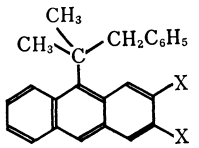


(**3**)



(**4**)

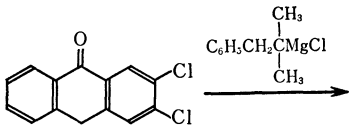
The second half of this paper is mainly concerned with the stereoselectivity in the Diels-Alder type reaction of 9-(1,1-dimethyl-2-phenylethyl)anthracene (**5**) and its 2,3-dichloro derivative (**6**). Since the reaction of **5** with dimethyl acetylenedicarboxylate is known to produce the *meso* form almost exclusively[1,3] and **6** was found to react similarly, it must be interesting to see the generality of the stereoselectivity. We wish to report that the Diels-Alder reaction of **6** as well as **5** is really stereoselective and rotameric *sc* (*dl*) and *ap* (*meso*) forms of a triptycene derivative can be prepared separately.[5]



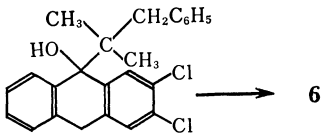
X=H (**5**)
X=Cl (**6**)

Results and Discussion

The required anthracene **6** was prepared by Grignard reaction between 2,3-dichloroanthrone (**7**) and 1,1-dimethyl-2-phenylethylmagnesium chloride followed by dehydration.



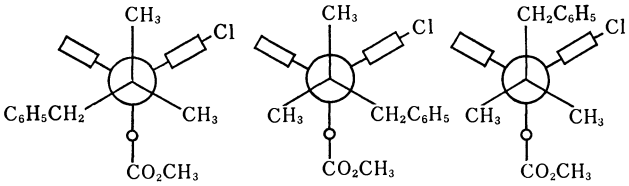
(**7**)



6

Diels-Alder reaction between **6** and dimethyl acetylenedicarboxylate was carried out by heating the substrates in toluene. Chromatography of the product followed by recrystallization gave pure compound in 42% yield which was a sole isomer, as judged from the PMR data (see Table 1). If one considers the mechanical loss during the purification processes this yield must be taken as an indication of high selectivity of the reaction.

The assignment of the structure caused trouble, because there are three possible isomers and only one



(**3a**) *M-sc* Form (**3b**) *P-sc* Form (**3c**) *ap* Form

(only the 9-(*R*) forms are shown)

was isolated. Thus, in order to obtain other isomers, thermal equilibration was carried out.

The equilibration of rotational isomers (**3a**, **3b**, and **3c**) was reached within 8 hr by heating an *o*-dichlorobenzene solution of **3** at 150 °C. A half-life of **3** under these conditions was *ca.* 2 hr, although it was not possible to run the kinetic study due to the heavy overlap of the signals concerned. The isomer ratio at the equilibrium was estimated to be 3 : 3 : 2.

The equilibrated mixture was chromatographed on silica gel, benzene being used as an eluent. Separation of the least populated isomer was not difficult by this means, because it was eluted most sluggishly among the isomers. This isomer gave identical spectral data with the one obtained by the Diels-Alder reaction and is named Isomer C. Separation of the remaining two isomers was tedious but spectroscopically pure isomers were obtained by repeating the chromatographic operations ten times.* These were named Isomers A and B, respectively, according to the ease of elution. Heating these isomers in *o*-dichlorobenzene caused redistribution of the isomers and afforded the equilibrium mixtures with the identical composition, as judged from the PMR spectra. Thus the rotational isomers could be separated by physical means, because they correspond to diastereomers with each other in spite of the fact that they have only one asymmetric carbon atom.

The PMR data are summarized in Table 1. Theoretically two methyls and two benzyl methylene protons should be nonequivalent because they are located closely to the chiral center. Some peaks showed coincidence of the chemical shifts in one solvent, although they appeared as two different ones in another solvent.

Having all the possible isomers in hand, we may proceed to the assignment of the structures. The PMR spectral data in Table 1 did not seem to be helpful because the differences in chemical shifts of various corresponding signals were too small to draw a definite conclusion. Fortunately however, examination of the whole region of the PMR spectra indicated that there were typical differences in the patterns of signals at the lowest part of the aromatic region. Since the severe steric effect is given by the 9-*t*-alkyl group, the peri protons are expected to give signals at the low field due to the compression effect. The integrated areas (2H) correspond well to the number of the peri protons also.

For the assignment of the structure, comparison of

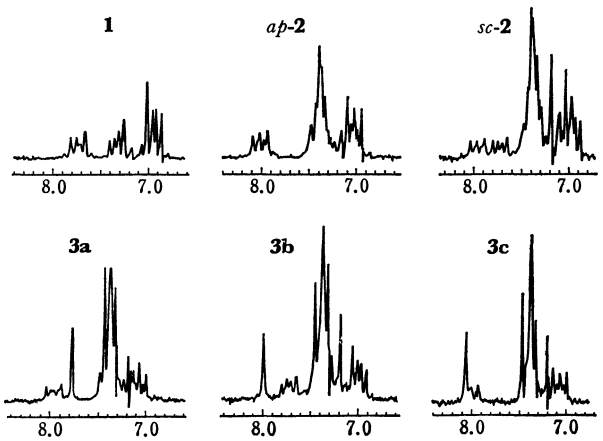


Fig. 1. Shapes of the peri proton signals.

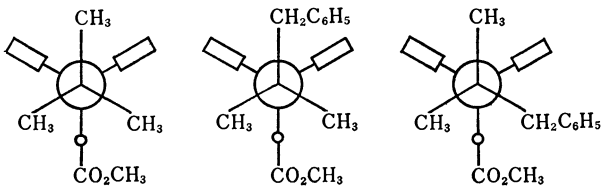

(**1'**) (*ap*-**2**) (*sc*-**2**)

* The PMR spectral charts of these compounds are given in a short communication.[4]

Table 1. Physical properties and PMR data of the isomers of **3**

the chemical shifts and/or shapes of the signals with the model compounds may be helpful. Thus the peri proton signal shapes of the isomers are shown in Fig. 1 together with those of **1**, *ap*-**2**, and *sc*-**2**.

Inspection of the Newman-type projections of **1** and **2** reveals that the peri protons in **1** are equivalent because they are both located between two methyls, and those in *ap*-**2** are also equivalent because they are both placed between a methyl and a benzyl group. On the other hand, peri protons in *sc*-**2** are not equivalent: one is placed between two methyls and the other between a methyl and a benzyl group. The spectra in Fig. 1 conform with this expectation and it can now be concluded that the multiplet signal centered at δ 7.7 corresponds to a peri proton placed between two methyl groups and the multiplet centered at δ 8.0 to a peri proton placed between a methyl and a benzyl groups.

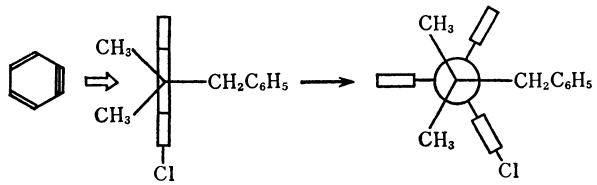
Now that the isomers in question have a chlorine atom ortho to the peri proton, the assignment may be possible by taking advantage of the substituent. Fortunately a chloro substituent in the aromatic ring is known to give little effect on the chemical shift of the protons ortho to it.[6] The chloro substituents in **3** will cause the appearance of an apparent singlet of the peri proton because they erase the ortho and meta couplings and the para coupling is small. Thus it may be assumed that a peri proton ortho to the chloro group gives a singlet at about the same chemical shift with the corresponding protons in **1** and **2**.

Since Isomer A, which is eluted first, gives a sharp signal at δ 7.7 and a multiplet centered at δ 8.0, it should have two kinds of peri protons: one is ortho to a chloro group and placed between two methyl groups and the other is placed between a methyl and a benzyl group. **3a**, which is the *M-sc* form, is qualified to meet the above conditions. Thus Isomer A is the *M-sc* form. Likewise, Isomer B which is eluted closely behind Isomer A is concluded to have a peri proton which is ortho to a chloro substituent and placed between a methyl and a benzyl group and another peri proton which is placed between two methyl groups. Thus isomer B is **3b** which is the *P-sc* form. Isomer C should possess both peri protons placed between a benzyl and a methyl group and thus is the *ap* form (**3c**).

After the establishment of the structural assignment, the composition of the equilibrium mixture may be compared with the data of **1** which gave $K=3.0$ at various temperatures in favor of the *sc* form.[3,4] Since **3a** and **3b** are the *sc* forms and **3c** the *ap*, the sum of **3a** and **3b** may be taken in discussing the thermal stability of the isomers. Then the ratio is obtained as *sc* : *ap* $=3:1$ which coincides with the equilibrium constant of **1**. From these data, it may be concluded that the two chloro groups in compound **3** play little role in determining the thermodynamic stability. This is so probably because the chloro groups are located distantly from the *t*-alkyl group. The same population of the *M-sc* and *P-sc* forms is another indication that the remote chloro groups have scarce effect on the stability.

The almost exclusive formation of the *ap* form in the Diels-Alder reaction is interesting. This stereoselectivity matches that obtained in the reaction of **5** with dimethyl acetylenedicarboxylate, in which *ca.* 85% of the product was the one formed by the attack from the least hindered side. A possible explanation was described in a preceding paper.[1] Although it may be possible to postulate that the rotation about the C_9–C_{alkyl} bond is frozen, the postulate is not consistent with the facts that no anomaly is found in PMR spectra and the selectivity is not exclusive in the case of **5**. Some steric and electronic effects may be responsible in causing the results.

It is then tempting to investigate the scope of the selectivity. Accordingly Diels-Alder reaction between **6** and benzyne was carried out. If the reaction is really stereoselective, an expected product is the *sc* form (*dl* form), because the attack of benzyne from the

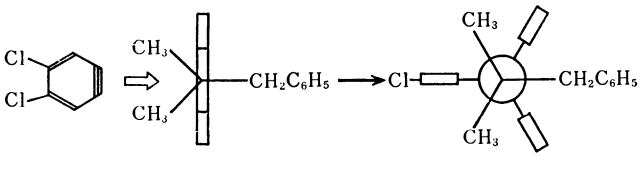


(*sc*-**4**)

Scheme 1.

least hindered side will proceed as depicted in scheme 1. Only one product was isolated indeed. A PMR spectrum of the product shows the presence of a non-equivalent set of methyls and that of benzyl methylene protons to indicate that it is really an *sc*-form. The peri proton signals are also consistent with this assignment and the following signals are found: a multiplet centered at δ 7.73 corresponding to 1 H which is placed between two methyl groups, a multiplet centered at δ 7.95 corresponding to 1 H which is placed between a methyl and a benzyl group, and a sharp singlet at δ 8.03 corresponding to 1 H which is ortho to a chloro substituent and placed between a methyl and benzyl group.

The stereoselectivity discussed above seemed to open up a way for the synthesis of individual rotational isomers. If the combination of **6** and benzyne gives the *sc* (or *dl*) isomer, the combination of **5** and 4,5-dichlorobenzyne should give the *ap* (or *meso*) form (Scheme 2). The actual synthesis proceeded as expected and a sole product was obtained, of which structure was evident from the PMR data: one methyl signal (δ 2.02, 6H), a sharp singlet (δ 3.86) for the benzyl methylene, two peri protons (a multiplet centered at δ 7.95) placed between a methyl and a benzyl group, and one peri proton (δ 7.78) which is ortho to a chloro substituent and placed between two methyl groups.



(*ap*-**4**)

Scheme 2.

The equilibration between *ap*-**4** and *sc*-**4** proceeded sluggishly: no isomer was detected after heating either *ap*-**4** or *sc*-**4** in *o*-dichlorobenzene at the boiling point for 60 hr. Apparently, the higher temperature was needed to cause equilibration in the practical rate. The choice of a solvent caused trouble, however. A high boiling solvent tends to have the higher viscosity at room temperature, causing the difficulty in PMR spectroscopy. 1-Chloronaphthalene was chosen as a solvent from these aspects.

In principle, the population of each isomer can be determined by careful integration of the methyl or other signals. In practice, however, due to the heavy overlap of the signals, it was not possible to obtain the population directly from the simple integration. Thus calibration curves were drawn by the procedure described in the experimental section and first order rate constants k_1 (*ap*→*sc*) and equilibrium constants K were obtained at four temperatures in the range of 211—259 °C. The results are given in Table 2.

Table 2. Rates of isomerization of *ap*-**4** and the equilibrium constants for *ap*-**4** ⇌ *sc*-**4**

T °C	k_1 (s^{-1})	K
259	4.1×10^{-4}	2.0
245	1.6×10^{-4}	2.0
232	7.5×10^{-5}	2.0
211	1.3×10^{-5}	2.0

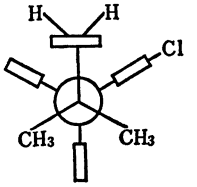
Table 3. Kinetic parameters for isomerization *ap*-**4** → *sc*-**4**

E_a=36.6 kcal/mol	ΔH=35.7 kcal/mol
log A=11.7	ΔS=−7.9 eu

Arrhenius and Eyring plots of k_1's gave the good linear relationship and thermodynamic parameters were obtained as shown in Table 3. The Arrhenius activation energy of 36.6 kcal/mol is one of the highest barriers to the isomerization of this type.[7] Interconversions of the atropisomers may be most reasonably assumed to proceed through rotation about the axis bond, although other possibilities such as a retro-Diels-Alder reaction and ionic or radical type fission-recombination mechanisms cannot be ruled out. Then this barrier is one of the highest to rotation about a C_{sp^3}–C_{sp^3} bond.

The equilibrium constant remained constant throughout the temperature range examined. Thus the equilibrium is controlled by the entropy factor. Indeed there are two enantiomeric *sc* forms which are energetically identical. In this case also, two chloro groups in a benzo group seems to give little effect on the enthalpy of the atropisomers.

Finally we wish to comment on the conformation of the benzyl group in the compounds studied here. The typical features of the PMR spectra are that 1) a peri proton gauche to the benzyl group gives the signal at *ca.* δ 8.0 which is lower by *ca.* 0.3 ppm than a peri proton *trans* to the benzyl and 2) the coupling constants of the benzyl methylenes are *ca.* 14 Hz. These features are best explained if one assumes the conformation such as **8**, because, in this conformation, the peri protons gauche to the benzyl group are located in the deshielding region of the benzene ring and the coupling constants agree with the theoretical value of this conformation.[9] Molecular models support this conformation on the ground of the steric effect and a fact that the chemical shifts of the methyl groups in *ap*-**4** are close to that of the methyl groups of 9-*t*-butyltriptycene may be another support, because the methyls are located in the region where little anisotropy effect of the benzene ring is expected.



(**8**)

Experimental

2,3-Dichloroanthrone. A suspension of 39 g (0.14 mol) of 2,3-dichloroanthraquinone[9] and 8 g of red phosphorus in 1.5 l of acetic acid and 66 ml of hydriodic acid was heated under reflux for 5 hr. The resulted mixture was concentrated by removal of *ca.* 700 ml of the solvent by distillation and the concentrate was cooled to room temperature. The solid was collected by filtration and extracted with 300 ml of boiling benzene. The benzene extract was cooled to give 26 g (70%) of yellow crystals, mp 198—200 °C. This compound was directly used for the next synthesis.

2,3-Dichloro-9-(1,1-dimethyl-2-phenylethyl)anthracene (**6**). To a chilled solution of a Grignard reagent prepared from 42 g (0.25 mol) of 1,1-dimethyl-2-phenylethyl chloride, was added 22.8 g (0.1 mol) of 2,3-dichloroanthrone powder in small portions during the course of 1 hr. The reaction mixture was decomposed with aqueous ammonium chloride. The ethereal solution was filtered and evaporated. The resulting oil was dissolved in 200 ml of carbon tetrachloride and heated with *ca.* 30 g of phosphorus pentoxide under reflux for 5 hr. The carbon tetrachloride solution was decanted and evaporated. The residue was chromatographed on alumina. Elution with 9 : 1 hexane-benzene gave 2.95 g (7.9%) of yellow fluorescent crystals, mp 121—123 °C. PMR (δ, CCl_4): 1.73 (6H, s), 3.63 (2H, s), 6.9—8.3 (12H, m). Found: C, 76.68; H, 5.11; Cl, 18.48%. Calcd for $C_{24}H_{20}Cl_2$: C, 75.99; H, 5.31; Cl, 18.69%.

ap-*2,3-Dichloro-9-(1,1-dimethyl-2-phenylethyl)-11,12-bis(methoxycarbonyl)-9,10-dihydro-9,10-ethenoanthracene* (**3c**). A solution of 1.53 g (4.0 mmol) of the anthracene (**6**) and 1 ml of dimethyl acetylenedicarboxylate in toluene was heated under reflux for 5 hr. The reaction mixture was chromatographed on silica gel with benzene as an eluent. Recrystallization of the product from benzene-methanol gave 0.87 g (42%) of colorless crystals, mp 215.5—216.5 °C. Found: C, 69.24; H, 5.07; Cl, 13.68%. Calcd for $C_{30}H_{26}O_4Cl_2$: C, 69.10; H, 5.03; Cl, 13.60%.

Isomerization of **3c** *and Separation of the Isomers.* Heating a solution of **3c** in *o*-dichlorobenzene at 152 °C for 10 hr caused equilibration of the rotamers, the composition being 3 : 3 : 2. The least populated isomer was the *ap* form. The solvent was evaporated *in vacuo* and the residue was taken up in benzene. The chromatographic behavior of the *ap* form was different enough to separate it from other two but those of *M-sc* and *P-sc* forms were quite close to

cause the heavy overlap of the chromatographic bands. Nonetheless it was possible to isolate pure *M-sc* and *P-sc* forms after repeated chromatographies. The *M-sc* form and *P-sc* form resisted crystallization but they showed no peaks attributable to impurities in PMR spectra. Heating either the *M-sc* or the *P-sc* form in *o*-dichlorobenzene at 152 °C caused isomerization and gave the equilibrium mixture of the identical composition with the one obtained from the *ap* form. This can be taken as another piece of evidence for the structures of the *sc* forms.

sc-*2,3-Dichloro-9-(1,1-dimethyl-2-phenylethyl)triptycene* (sc-**4**). To a boiling solution of 1.30 g (3.43 mmol) of **6** and 2 ml of isoamyl nitrite in *ca.* 20 ml of methylene chloride, was added a solution of 600 mg (4.4 mmol) of anthranilic acid in 10 ml of tetrahydrofuran over a period of 1 hr. The mixture was heated for another hour and then the solvent was evaporated. The residue was chromatographed on alumina with the use of 9 : 1 hexane–benzene as an eluent. Recrystallization of the product from tetrahydrofuran–methanol gave 1.29 g (83%) of colorless crystals, mp 215.5—216.5 °C. Found: C, 79.40; H, 5.47: Cl, 15.65%. Calcd for $C_{30}H_{24}Cl_2$: C, 79.12; H, 5.31; Cl, 15.57%. PMR (δ, $CDCl_3$): 1.99 (3H, s), 2.08 (3H, s), 3.75 and 3.89 (2H, q, J=14.6 Hz), 5.17 (1H, s), 6.7—7.6 (12H, m), 7.73 (1H, m), 7.95 (1H, m), 8.03 (1H, s).

4,5-Dichloroanthranilic acid was obtained by hydrogenation of 4,5-dichloro-2-nitrobenzoic acid[10] and used for generation of dichlorobenzyne.

ap-*2,3-Dichloro-9-(1,1-dimethyl-2-phenylethyl)triptycene* (ap-**4**). Treatment of the anthracene (**6**) with 3,4-dichloroanthranilic acid and isoamyl nitrite in boiling methylene chloride–tetrahydrofuran, as described in the preparation of the *sc* form, caused precipitation of reddish brown solid which was found to be the corresponding diazonium carboxylate from the IR spectrum ($N^+{\equiv}N$, 2280 cm^{-1}). The solution contained *ca.* 7 : 3 mixture of the anthracene and the triptycene. Thus the decomposition of the diazonium salt seemed to require the higher temperature.

A mixture of 3.10 g (10 mmol) of the anthracene and 2.38 g of the diazonium salt (*ca.* 11 mmol) in 80 ml of chlorobenzene was heated at 100 °C for 1 hr. Evolution of gas and disappearance of the solid were observed. The solvent was evaporated and the residue was taken up in hexane. Chromatagraphy on alumina with the use of 9 : 1 hexane–benzene gave colorless crystals which were recrystallized from tetrahydrofuran–methanol. The *ap* form was obtained as colorless crystals, mp 200—201 °C, in 3.97 g (88%) yield. Found: C, 79.29; H, 5.53; Cl, 15.68%. Calcd for $C_{30}H_{24}Cl_2$: C, 79.12; H, 5.31; Cl, 15.57%. PMR (δ, $CDCl_3$): 2.02 (6H, s), 3.86 (2H, s); 5.17 (1H, s), 6.8—7.6 (12H, m), 7.78 (1H, s), 7.96 (2H, m).

Equilibration and Determination of Rates of Isomerization. *ap*-**4** was dissolved in 1-chloronaphthalene to make up 4.8 (w/w)% solution and sealed in an NMR sample tube. The sample tube was immersed in a boiling solvent bath and PMR spectra were determined at 34 °C with appropriate intervals. The solvents used for the bath and the boiling points were as follows: diphenyl ether 259 °C, diethylene glycol 245 °C, *m*-nitrotoluene 232 °C, nitrobenzene 211 °C.

A calibration curve was drawn by the following procedure. A 4.8 (w/w)% solution in 1-chloronaphthalene was prepared for each of the *ap* and the *sc* form. These two solutions were mixed in various ratios to make up solutions of which concentration remained 4.8 (w/w)% when the sum of both forms was taken. For each solution thus made up, the ratio of the apparent height of the methyl signals of the *ap* form to that of the lower field methyl signal of the *sc* form was observed and plotted against

$$-\log\left\{1-\left(1+\frac{1}{K}\right)\frac{[sc]}{[sc]+[ap]}\right\}$$

which was calculated from the known $[sc]/[ap]$ values. Using this calibration curve, the apparent height ratios observed in the kinetic run directly gave the

$$-\log\left\{1-\left(1+\frac{1}{K}\right)\frac{[sc]}{[sc]+[ap]}\right\}$$

values which were necessary for kinetic analysis. These values were plotted against time and the slope of the straight line produced the desired rate constants. The equilibrium constants at various temperatures were found to be constant, 2.0, within the experimental error.

Measurement of the Spectra. The PMR spectra were recorded on a Hitachi R-20B spectrometer operating at 60 MHz. Samples were dissolved either in $CDCl_3$ or in C_6D_6 to make up *ca.* 10 (w/w)% solutions, unless otherwise stated.

Studies on Interaction of Isocyanide with Transition Metal Complexes. XIII.[1] Preparation of Carbene Complexes of Nickel, Iron, and Cobalt through Protonation of Monoimino and Polyimino Type Complexes

Yasuhiro YAMAMOTO and Hiroshi YAMAZAKI

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received July 7, 1975)

Reactions of η-$C_5H_5Ni(CNR^1)[C(R)=NR^1]$ ($R=CH_3$, p-ClC_6H_4; $R^1=C_6H_{11}$, $(CH_3)_3C$) and η-$C_5H_5Fe(CO)_2$-$[C(CH_2C_6H_4X\text{-}p)=NC_6H_{11}]$ (X=H, Cl) with HBF_4 gave the cationic carbene complexes, η-$C_5H_5Ni(CNR^1)$-$[C(R)NHR^1]BF_4$ and η-$C_5H_5Fe(CO)_2[C(CH_2C_6H_4X\text{-}p)$ $NHC_6H_{11}]BF_4$. η-$C_5H_5Co[-C(=NR)-CPh=CPh-C(=NR)-]$ (**1a**; $R=2,6\text{-}(CH_3)_2C_6H_3$: **1b**; $R=p\text{-}CH_3C_6H_4$) reacted with HBF_4 to give η-$C_5H_5Co[-C(NHR)-CPh=CPh-C(=NR)-]BF_4$ (**2a, b**). Compound **2a** exists as two isomers, induced by the restricted rotation about the C–N bond. Treatment of **1a** with HCl gave η-$C_5H_5Co[-C(NHR)-CPh=CPh-C(=NR)-]Cl$ (**3b**). The H(N) proton showed some fluxional behavior in its proton NMR spectrum. Reaction of **1b** with CF_3COOH gave the dicationic complex η-$C_5H_5Co[-C(NHR)-CPh=CPh-C(NHR)-](CF_3COO)_2$ **4b**. Compound **2** reacted with R^1NC ($R^1=(CH_3)_3C$, $2,6\text{-}(CH_3)_2C_6H_3$) to give η-$C_5H_5Co(CNR^1)[-C(=NR)-CPh=CPh-C(=NR)-]$**5**. Reaction of **5** with HBF_4 gave again the cationic carbene complex η-$C_5H_5Co(CNR^1)[-C(NHR)-CPh=CPh-C(=NR)-]BF_4$.

Since the current interest of the metal-stabilized carbene complexes started with the preparation of $W[C(OCH_3)Ph](CO)_5$,[2] several preparative methods of the carbene complexes have been reported.[3–5] Among them, the acetyl complexes of iron, molybdenum, and ruthenium are known to take up a proton or a carbonium ion to give the corresponding cationic carbene complexes, when reacted with protic acids or trialkyloxonium salt (Eq. (1)).[6,7]

$$M\text{—}\underset{\underset{O}{\|}}{C}\text{—}R + R^{1+} \longrightarrow [M\leftarrow\underset{\underset{OR^1}{|}}{C}\text{—}R]^+ \qquad (1)$$

One would expect that more facile protonation of the imino type complex in comparison with the acetyl derivative may occur because of the higher inherent basicity of nitrogen over oxygen. Treichel *et al.* reported briefly that the reaction of $Pt(PPh_3)_2I[C(Ph)=NCH_3]$ with NH_4^+ produced $Pt(PPh_3)_2I[C(Ph)NH\text{-}CH_3]^+$.[8] Lappart and coworkers reported recently that treatment of rhodium complexes with imidoyl chloride in the presence of hydrogen chloride gave the carbene complexes.[9,10] This reaction has been believed to proceed with protonation of the imino complex formed as the unstable intermediate.

We report in this paper that the imino type compounds of nickel,[11] iron,[12,13] and cobalt[14] react readily with protic acids to give stable cationic carbene complexes.

Experimental

All reactions were carried out under an atmosphere of nitrogen. Melting points were taken on a Mitamura capillary melting point apparatus, and are uncorrected. Infrared spectra were recorded on a Shimadzu IR-27G spectrophotometer. Proton magnetic resonance spectra were obtained on JEOL C-60HL or Varian HA-100B spectrometers, using tetramethylsilane as an internal reference. Isocyanides[15] were prepared by procedures described in the literature. The organometallic complexes, η-C_5H_5Ni-$(CNR^1)[C(R)=NR^1]$ ($R=CH_3$, Ph or p-ClC_6H_4; $R^1=C_6H_{11}$ or $(CH_3)_3C$),[11] η-$C_5H_5Fe(CO)_2[C(CH_2C_6H_4X\text{-}p)=NC_6H_{11}]$ (X=H or Cl)[12], η-$C_5H_5Fe(CO)[-C(=NC_6H_{11})$-$C(NHR^1)-C(R)-C(NHR^2)]$ ($R=H$ or Ph; $R^1=C_6H_{11}$ or $CH_3)_3C$; $R^2=(CH_3)_3C$ or C_6H_{11})[13] and η-$C_5H_5Co[-C(=NR)-CPh=CPh-C(=NR)-]$ ($R=(CH_3)_3C$, p-$CH_3C_6H_4$ or $2,6\text{-}(CH_3)_2C_6H_3$)[14], were prepared according to the published methods.

Preparation of Carbene Complexes. *(a)* η-$C_5H_5Ni(CNC_6H_{11})[C(C_6H_4Cl\text{-}p)NHC_6H_{11}]BF_4$. A mixture of η-C_5H_5-$Ni(CNC_6H_{11})[C(C_6H_4Cl\text{-}p)=NC_6H_{11}]$ [0.22 g, 0.5 mmol), 42% HBF_4 (3 ml) and benzene (15 ml) was stirred for 1 hr at room temperature. The reddish orange solution changed to dark yellow. The benzene layer was separated and the aqueous layer was extracted twice with CH_2Cl_2 (5 ml). The combined extracts were washed with water and dried over anhydrous magnesium sulfate. The solvent was evaporated almost to dryness under reduced pressure, and the residue was crystallized from CH_2Cl_2–*n*-hexane at −30 °C to give the dark yellow crystalline material (0.22 g, 82%). Other nickel carbene complexes were also prepared according to procedures similar to those described above.

(b) η-$C_5H_5Fe(CO)_2[C(CH_2Ph)NHC_6H_{11}]BF_4$. A mixture of η-$C_5H_5Fe(CO)_2[C(CH_2Ph)=NC_6H_{11}]$ (0.7 g, 1.9 mmol), 42% HBF_4 (2 ml) and benzene (15 ml) was stirred for 2 hr at room temperature. Yellow crystalline material was separated. Methylene chloride was added to dissolve the crystals. The organic layer was washed with water and dried over $MgSO_4$. The solvent was removed *in vacuo* and the residue was crystallized from CH_2Cl_2–*n*-hexane at −30 °C to give yellow crystals (0.77 g, 85%). Other iron carbene complexes were also prepared according to procedures similar to those described above.

(c) η-$C_5H_5Co[-C\{=NC_6H_3(CH_3)_2\text{-}2,6\}-CPh=CPh-C\{NHC_6$-$H_3(CH_3)_2\text{-}2,6-\}-]BF_4$. A mixture of η-$C_5H_5Co[-C\{=NC_6H_3(CH_3)_2\text{-}2,6\}-CPh=CPh-C\{=NC_6H_3(CH_3)_2\text{-}2,6\}-]$ (0.18 g, 0.32 mmol), 42% HBF_4 (1 ml) and benzene was stirred at room temperature for 1 hr. The resulting orange crystals were filtered and washed with ether (0.18 g, 86%).[16]

(d) η-$C_5H_5Co[-C(=NC_6H_4CH_3\text{-}p)-CPh=CPh-C(NHC_6H_4$-$CH_3\text{-}p)-]Cl$. A mixture of η-$C_5H_5Co[-C(=NC_6H_4CH_3$-$p)-CPh=CPh-C(=NC_6H_4CH_3\text{-}p)-]$ (0.16 g, 0.3 mmol) and 6M-HCl (4 ml) was kept at room temperature for 2 hr. The orange layer changed to pale yellow. The resulting brown crystalline solid was filtered off, washed with water, and then extracted with benzene. After drying over Na_2SO_4, the solvent was removed under reduced pressure, and the residue was crystallized from *n*-hexane to give the title compound (0.095 g, 56%) as brown crystals.

(e) η-$C_5H_5Co[-C(NHC_6H_4CH_3$-p$)$-CPh=CPh-C(NHC_6H_4$-$CH_3$-p$)-](CF_3COO)_2$. To a solution of **1b** (0.12 g, 0.22 mmol) in CH_2Cl_2 (2 ml) was added CF_3COOH (0.2 ml) at room temperature. The resulting dark brown solution was concentrated to 1 ml under reduced pressure, and *n*-hexane was added. The dark brown crystals (0.17 g, 85%) were filtered off.

Reaction of η-$C_5H_5Ni(CNC_6H_{11})[C(Ph)NHC_6H_{11}]BF_4$ *with* CH_3ONa. A mixture of the carbene complex (0.075 g, 0.13 mmol), CH_3ONa (0.1 g), and CH_3OH (10 ml) was stirred at room temperature for 30 min. The solution changed rapidly from dark yellow to reddish brown. The solvent was evaporated, and the residue was dissolved with CH_2Cl_2. The solution was washed with water and dried over Na_2SO_4. Removal of the solvent and crystallization of the residue from benzene–*n*-hexane gave η-$C_5H_5Ni(CNC_6H_{11})$ [C(Ph)$=$NC$_6$H$_{11}$] (0.84 g, 83%).

Analogous procedures were applied for the deprotonation reactions of the iron and cobalt carbene complexes.

Reaction of **2a** *with* $(CH_3)_3CNC$. A mixture of **2a** (0.25 g, 0.38 mmol) and *tert*-butyl isocyanide (0.83 g, 1.0 mmol) in THF (15 ml) was kept at room temperature for 20 hr, followed by removal of the solvent and dark orange crystals of **5a** (0.19 g, 73%; mp 234—236 °C (decomp. with melting)). The infrared spectrum consisted of 2153-(N≡C), 1623(C=N), and 1584 cm^{-1}(C–N). The proton NMR spectrum in $CDCl_3$ showed four singlets at 1.48(s, $(CH_3)_3$), 2.17(CH_3), 2.23(CH_3), and 4.41(C_5H_5) ppm, and a complex signal at *ca.* 7.00 (C_6H_5 and C_6H_3) ppm. Found: C, 77.65; H, 6.41; N, 6.34%. Calcd for $C_{42}H_{42}N_3Co$: C, 77.88; H, 6.54; N, 6.49%.

Kinetic Analysis. The methods developed by Gutowsky and Holm was applicable for the determination of the kinetic parameters.[17] The difference between the chemical shifts of the methyl protons of the two isomers at various temperatures are listed in Table 1.

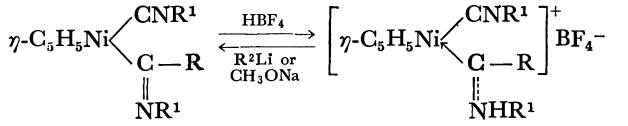
Results and Discussion

Nickel Carbene Complexes. Imino type complexes of nickel react with an excess of HBF_4 in benzene or CH_2Cl_2 at room temperature to produce the cationic carbene complexes (Eq. (2)), which undergo deprotonation by alkyllithium or CH_3ONa to recover the parent imino type complexes.



(2)

These compounds are freely soluble in methylene chloride and acetone, but less soluble in benzene. The infrared spectra show the strong NH-stretching bands at 3300—3100 cm^{-1}, which shift to 2700—2500 cm^{-1} on deuteration. The isocyanide absorptions are observed in the range of 2200—2500 cm^{-1}, which are 40—70 cm^{-1} higher than those for the neutral parent compounds.

The proton NMR spectra of these complexes indicate the presence of isomers. The spectrum of η-C_5H_5Ni-[CNC$(CH_3)_3$][C(Ph)NHC$(CH_3)_3$]BF_4 shows a pair of signals for each of the following: C_5H_5, $(CH_3)_3CN$=, and $(CH_3)_3CNH$– protons (the isomer ratio 3 : 1). This is reasonably explained in terms of the orientation of the N–H group. The hydrogen atom could assume either a *cis* or a *trans* orientation to the metal group with respect to the C–N bond, as follows:

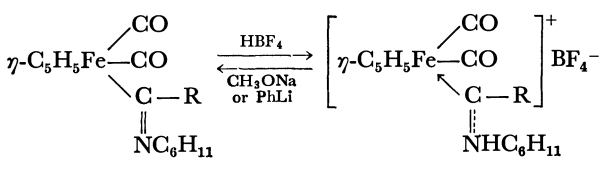
M$=\eta$-$C_5H_5Ni(CNR^1)$

Analogous isomerism was observed in the [(*p*-chlorophenyl)(*N*-*tert*-butylamino)]carbene complex (the isomer ratio 1.7 : 1). The [(alkyl or aryl)(*N*-cyclohexylamino)]carbene complexes, however, do not show the presence of isomers. This may arise from the bulkiness of the *N*-substituted group.

We have no direct means to distinguish between the two isomers. However, it is known that the predominant isomer in the metal carbene complexes is generally the one with the least steric interaction within the carbene groups.[4,5] Examination of molecular models of the carbene complexes suggested that the *cis* isomer had less steric interaction than the *trans* isomer.

The ratio between *cis* and *trans* isomers does not depend on the solvents and temperatures ($\lesssim$100 °C), showing restricted rotation about the C_{carb}–nitrogen bond (Table 3). Evidence of restricted rotation about C_{carb}–heteroatom bonds has also been obtained, *e.g.*, in the series *trans*-[MX{C(NHR)Q}L_2]ClO_4 (where M$=$Pt or Pd; R$=$Ph or *p*-$CH_3C_6H_4$; Q$=$PhNH, EtNH, CH_3O or EtO; L$=$$PEt_3$, $PPhMe_2$, or $AsMe_3$; X$=$Cl or Br).[18,19]

Iron Carbene Complexes. The reaction of η-$C_5H_5Fe(CO)_2$[C$(CH_2C_6H_4X$-*p*$)$=NC$_6$H$_{11}$] (X=H or Cl) with HBF_4 proceeds with protonation at the imino nitrogen atom to give the cationic carbene complex in nearly quantitative yield, which was characterized by the infrared N–H stretching frequency. The reaction of this compound with CH_3ONa or PhLi occurs readily with deprotonation to regenerate the parent imino type complex (Eq. (3)).



(3)

The proton NMR spectra of the carbene complexes at room and low temperatures ($\geq$−60 °C) do not

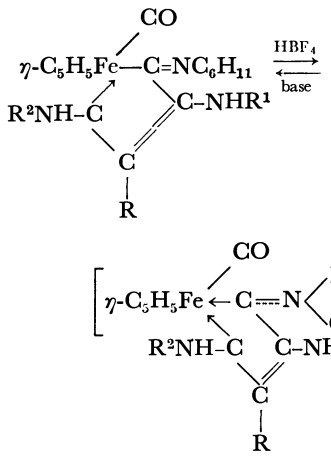
show the presence of any isomers. Consideration of molecular models indicates that the predominant isomer is the *cis* form similar to the above mentioned nickel complexes.

The two C–O stretching frequencies appear within the range 1958—2043 cm^{-1}, 43—26 cm^{-1} higher than the value of ν(CO) of the parent complexes. They decrease in the order CO, RNC, PPh_3, and $C(CH_2Ph)$-NHC_6H_{11} for L in the complexes $[\eta$-$C_5H_5Fe(CO)_2L]X$ (X=BF_4 or PF_6), as shown in Table 5. The decrease is probably comparable with the order of the enhanced donor property of L.

The cyclic neutral monoamino carbene complexes react also with HBF_4 to give the cationic bisamino carbene derivatives (Eq. 4).



(4)

The infrared spectra show the NH-stretching frequencies in the range 3654—3097 cm^{-1}. In the proton NMR spectra the resonances due to the NH groups appear at *ca.* 6.7 (2H) and 9.8 (1H) ppm as two broad signals.

Diamino carbene complexes lose a proton again to regenerate the parent complexes by treatment with

CH_3ONa or NaOH.

Cobalt Carbene Complexes. The reaction of organocobalt complexes are summarized in Scheme I. η-Cyclopentadienyl-2,5-di(*N*-2,6-dimethylphenylimino)-3,4-diphenylcobaltacyclopentene (**1a**) takes up readily a proton to give the cationic carbene complex (**2a**), when reacted with a large excess of HBF_4 in benzene or NH_2Cl_2 at room temperature. The infrared spectrum shows three bands at 1769 (C=N), 1630 (C=O), and 1587 (O–N) cm^{-1}, higher than those for the parent complex (**1a**). In addition to these, a new weak absorption due to the NH stretching frequency appears at 3203 cm^{-1}. The high frequency due to the C–N double bond suggests the highly strained five-membered

ring structure, resulting from the coordination of the C–C double bond to the cobalt atom as well as **1a**.[14] The proton NMR spectrum shows the presence of the two isomers in the ratio 2 : 1. The resonances due to the *ortho*-methyl groups occur at 2.16(s), 1.78(bs), and 2.36(bs) ppm in the relative intensity of 6 : 4 : 2, respectively. The first resonance is assignable to the methyl groups of the *N*-substituted imino group, and the latter two to those of the isomeric *N*-substituted amino one. The four structures for the compound (**2a**) are illustrated as follows:

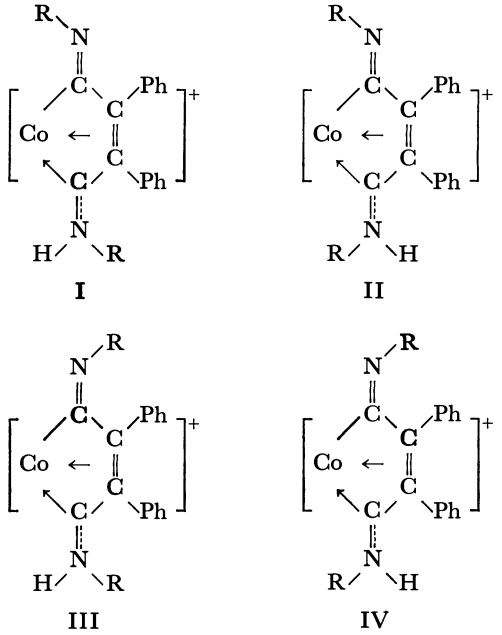

Fig. 1. Possible structures of **2a**. η-C_5H_5 and BF_4^- groups are omitted for clarity, where R is 2,6-dimethylphenyl group.

An X-ray crystallographic examination of η-C_5H_5Co-[–C(=NPh)–CPh=CPh–C(=NPh)–][14] as an analog of **1a** has shown that the *N*-phenyl group has the *cis* orientation to cobalt with respect to the C–N double bond. Accordingly, we tentatively assign two isomers to I and II. The interconversion between I and II was observed by various temperature PMR spectra. The *ortho*-methyl protons of the *N*-2,6-dimethylphenylimino group of two isomers appear at 1.78 and 2.36 ppm as relatively broad singlet at 17 °C. They became broader and their chemical shift difference became smaller on heating. At 63 °C, the spectrum consisted of one single broad signal. Finally the broad signal turned into a sharp singlet (2.06 ppm) above *ca.* 75 °C. These changes in PMR patterns are reversible.

Kinetic parameters for the rotation barrier about the C_{carb}–N bond[20] were determined by PMR line-broading technique of variable temperature PMR spectra. The approximate activation energy was 4.8 kcal/mol, and frequency factor, 1.5×10^5 s^{-1}; the former value is lower than that of C_{carb}–O bond (11.5—13.8 kcal/mol) for $Cr[C(OCH_3)(C_6H_4X)](CO)_5$.[21] The relatively low activation energy, in comaprison with those of rotation barriers of organic amides (6.8—7.8 kcal/mol),[22] may be ascribed to the presence of a labile amino-proton, which leads to facile deprotonation on successive treatment with H_2O.

η-Cyclopentadienyl-2,5-di(*N*-*p*-tolylimino)-3,4-diphenylcobaltacyclopentene (**1b**) also undergoes protonation with HBF_4 to give the carbene complex (**2b**), which however shows an absence of isomers. When **1b** was allowed to react with aqueous HCl, a neutral carbene complex (**3b**) is formed. The infrared spectrum of **3b** shows three significant absorptions at 3260(NH), 1628(C=N), and 1594(C=C) cm^{-1}. The absorption due to the C–N double bond is 102 cm^{-1} lower than that (1730 cm^{-1}) for the parent compound, suggesting the absence of intramolecular coordination of the double bond to the cobalt atom. The proton NMR spectrum in $CDCl_3$ shows a sharp singlet at 2.39 ppm due to two *para*-methyl groups. The origin for this singlet may arise either (1) from an accidental degeneracy of two chemical shifts or (2) from the fluxional behavior of hydrogen in the PMR time scale. The *para*-methyl groups in the PMR spectrum of this complex in CD_3COCD_3 retain a sharp singlet resonance, whereas **2b** shows two respective singlets at 2.16 and 2.40 ppm for the two *para*-methyl groups. In the temperature variations of the PMR spectra of **3b**, a sharp singlet changes to a relatively broad singlet at *ca.* −35 °C, which is converted to a doublet at *ca.* −60 °C. These changes are reversible. These observations are consistent with predictions for the fluxional behavior of hydrogen. Similar behavior has been observed in the carbene complex of platinum.[23]

The compound **1b** reacts readily with CF_3COOH in CH_2Cl_2 to give **4b**. The infrared spectrum shows two bands at 3170 and 3125 cm^{-1} (NH) and three peaks at 1772, 1707, and 1691 cm^{-1} (C=O). The PMR spectrum in $CDCl_3$ shows two sharp singlets at 2.50 and 4.83 ppm due to the *para*-methyl and cyclopentadienyl groups, respectively.

When **2a** was treated with *t*-butyl isocyanide, both deprotonation and release of the coordinated double bond occur to give **5a**, characterized by the absence of ν(NH) and the presence of ν(N≡C) at 2152 cm^{-1}. The compound **5a** takes up a proton again to give the cationic carbene complex (**6a**), when treated with HBF_4. The analogous type of complex (**6b**) is obtained by the reaction of **5b** with HBF_4. The infrared spectra of these compounds (**6a** and **6b**) show the absorption at 3267 (for **6a**) and 3260 cm^{-1} (for **6b**) due to the N–H stretching frequency. The C=N stretching frequencies appear at 1632 and 1634 cm^{-1}, respectively. They are within the range of the normal carbon–nitrgon double bonds, suggesting the absence of coordination of the carbon–carbon double bond to the cobalt atom.

In their PMR spectra the four *ortho*-methyl groups for **6a** and the two *para*-metnyl ones for **6b** show a broad singlet at 2.26 ppm and a sharp singlet at 2.38 ppm, respectively. The respective singlets are converted to doublets consisting of the relative intensity of 1 : 1 in the low temperature PMR spectra, again showing the proton exchange in the PMR time scale as well as that in the neutral complex (**3b**). The observation of the fluxional behavior arising from rapid migration of a proton seems to originate from the planarity of the five-membered ring system containing cobalt.

Kinetics and Stereochemistry of Alkaline Cleavage of 1,1-Diacetyl-2-arylcyclopropane[1]

Osamu Itoh, Nobuyuki Yamamoto, Katsuyuki Nakano, Toshio Sugita, and Katsuhiko Ichikawa*

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received July 10, 1975)

The kinetics and the stereochemistry of alkaline cleavage of several 1,1-diacetyl-2-arylcyclopropanes (**1**) in ethanol–water mixture are reported. The rates can be expressed approximately by a third order equation, rate= k_2[**1**][OH^-]^2. With *para*-substituted derivatives (*p*-CH_3, H, *p*-Cl and *p*-Br) of 2-phenyl ring, the reaction constant ρ was obtained as +4.3 by plotting log k_2 against normal Hammett σ. At 0 °C, the main products were thermodynamically unstable *cis*-1-acetyl-2-arylcyclopropanes. The *cis* to *trans* ratio in the products decreased with increasing reaction temperature. The reaction mechanism has been discussed in relation to the cleavage reaction of unenolizable acyclic β-diketone. The large ρ value and preferred formation of *cis* product suggest that the substituent effects of 2-aryl group are transmitted through cyclopropane ring much more effectively to *trans* direction than to *cis* direction.

Pearson and Mayerle showed that the alkaline cleavage of dimethylacetylacetone, which belongs to unenolizable β-diketone, is second-order (rate=k_1-[ketone] [OH^-]).[2] The same kinetics and mechanism might be expected in the same cleavage of 1,1-diacetyl-2-arylcyclopropanes with hydroxide ion, since they are also unenolizable β-diketone, and the effects of the substituents at phenyl ring on the cleavage rates appear to provide a convenient tool to study the transmitting ability of the effects through cyclopropane ring. The present paper describes the stereochemistry and kinetics of alkaline cleavage of several 1,1-diacetyl-2-arylcyclopropanes in ethanol–water (75 : 25 by volume) mixture containing potassium hydroxide.

Cleavage of 1,1-diacetyl-2-phenylcyclopropane (**1**-H) with potassium hydroxide (0.05—0.6 M) gave *cis*- and *trans*-1-acetyl-2-phenylcyclopropane (**2**-H) with no detectable amount of by-product. Gas-chromatographic analysis showed that the *cis* to *trans* ratio in the products at 0 °C (concn of KOH=0.4 M) was 90 : 10, while the value decreased with increasing reaction temperature (40—60 °C) to 50 : 50. Considering that the *cis*-isomer should be thermodynamically much more unstable than *trans* isomer, it appears that the cleavage at lower temperatures predominantly gives kinetically controlled products. With *p*-methylphenyl (**1**-CH_3), *p*-chlorophenyl (**1**-Cl) and *p*-bromophenyl (**1**-Br) derivatives, almost the same results were obtained. Although the detailed analysis to determine whether the *trans* isomer was formed through the rearrangement of *cis*-isomer or directly from **1** was not performed, the change of *cis* : *trans* ratio with time appears to show that the *trans*-isomer resulted partly through rearrangement and in part directly, even at higher temperature (Fig. 1).

Curve IV in Fig. 1 was obtained by the estimation from the isomerization rate of *cis*-**2**-H to *trans*-**2**-H which will be reported in a succeeding paper.[3]

The rates of cleavage were determined by following the concentrations of potassium hydroxide. Quantitative analysis by gas chromatography could be applied to determine the *cis-trans* ratio of the products but not to the reaction mixture because of the partial decomposition of **1**-H.

In contrast to the reported case of 3,3-dimethyl-2,4-pentanedione,[2] the rates can be expressed approximately by a third-order equation, rate=k_2[**1**][OH^-]^2. The results are shown in Table 1.

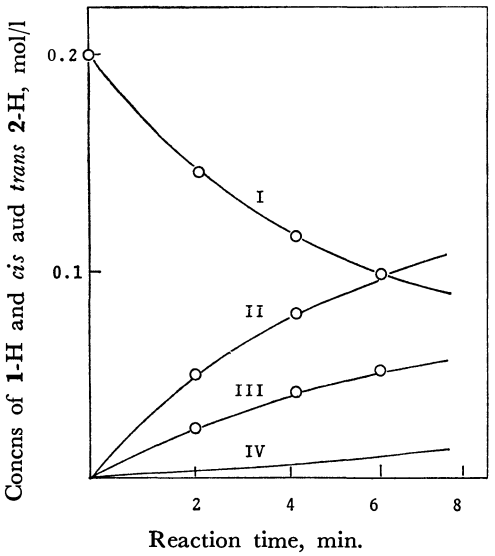

Fig. 1. Plot of the cleavage reaction of **1**-H in 75% ethanol at 25 °C. The initial concentrations of **1**-H and potassium hydroxide were 0.200 and 2.00 M, respectively. Curve I, II and III show the observed concentrations of **1**-H, sum of *cis* and *trans*-**2**-H, and *trans*-**2**-H, respectively.

Deviations from the third-order equation in lower concentration ranges of potassium hydroxide cannot be neglected and is considered to be due to the second-order term k_1[**1**] [OH^-] which must be added to the main term of the third-order.

The substituents at the *para* position of phenyl ring in **1** showed profound effects on the cleavage rates. Data with the substituents of methyl, chloro and bromo are given in the following table.

Hammett plot of the rates against normal σ values gave a straight line with a ρ value of +4.3. This large value shows that the substituent effect can be transmitted effectively through cyclopropane ring.

Pearson and Mayerle showed that the cleavage rates of acetylacetones by hydroxide ion consist of two terms; one is associated with one mole of ketone and

one mole of hydroxide ion (k_1, splitting of acetic acid from the monoanion formed by the addition of hydroxide ion to carbonyl) and the other with one mole of ketone and two moles of hydroxide ion (k_2, splitting of acetate ion from the dianion formed by proton abstraction from hydroxyl group of the monoanion with hydroxide ion), and the ratio of k_2/k_1 decreases by methyl substitution and becomes almost zero in the case of 3,3-dimethyl-2,4-pentanedione.[2)] The explanation for the changes of the ratio is not easy and they mentioned simply that this may be due to a weakening of carbon–carbon bond which renders less necessary the helping effect of double charged anion in cleaving. The difference of the reaction-order of the cleavage of 3,3-dimethyl-2,4-pentanedione and that of the present case is also difficult to explain. Binding the carbons of the two methyl groups in dimethylacetylacetone makes the carbon between the carbonyls a ring member of cyclopropane, reduces the steric requirement, and changes the character of the carbon. How it works in the reaction mechanism is difficult to predict, and remains unsolved.

One of the special features of the present cleavage is the formation of thermodynamically unstable *cis* product. A straightforward explanation may be as follows. First addition of hydroxide ion must occur at the *trans* acetyl group of **1** because of a larger steric hindrance of the adduct at *cis* acetyl group. Second attack of hydroxide ion forms dianion C (Fig. 2). Splitting of acetate anion from C forms carbanion F which gives *cis*-product through proton abstraction from the solvent.[4)]

If the addition of hydroxide ion to carbonyl is reversible and faster than the cleavage of C, as was pointed out by Pearson and Mayerle, other reaction pathways must be examined. Possible ones are depicted in Fig. 2. Equilibrium concentrations of A and C are higher than those of B and E, respectively,

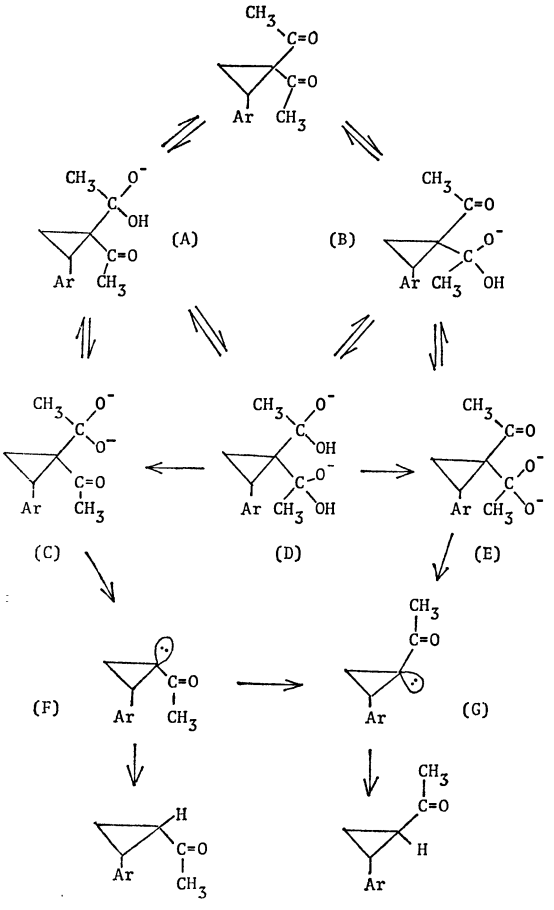

Fig. 2. Possible pathways of the cleavage of **1**.

because of the steric effects. The cleavage rate of E, however, must be faster than that of C because of the same effects. If the equilibria shown in Fig. 2 are attained rapidly, the relative rates of the cleavage of C and E determine the stereochemistry and the *trans* product must be obtained. To explain why the *cis* is the main product, at least at 0 °C, some other kind of factor than the steric which is more effective to accelerate the cleavage of C must be considered. An assumption that the substituent effects are transmitted more effectively to *trans* direction than to *cis* through cyclopropane ring may explain the present results. Although they may not be enough to rationalize the assumption, the fact that the carbanion formation by proton abstraction from ring methylene of *cis*-**2**-H with hydroxide ion proceeded much more rapidly than that from *trans*-**2**-H[3] appears to support the proposal.

The substrates **1** have been prepared by demercurations of 3,3-diacetyl-2-arylpropylmercuric acetates (**3**-H, **3**-Cl, **3**-Br and **3**-CH_3 for phenyl, *p*-chlorophenyl, *p*-bromophenyl and *p*-tolyl, respectively). Although **1**-H can be obtained by the demercuration of the corresponding chloride of **3**-H with potassium hydroxide as was reported previously,[5] applications of the same method to the others gave only poor yields. It was found, however, that the demercuration of **3** proceeded smoothly in dimethyl sulfoxide (DMSO) at about 120 °C and gave much better yields of **1**. At higher temperatures than 120 °C, the yields of **1** became low because of the formation of isomeric dihydrofurans. **3** were prepared by the reactions of acetylacetone with β-acetoxy-β-arylethylmercuric acetates (**4**-H, **4**-Cl, **4**-Br and **4**-CH_3 for phenyl, *p*-chlorophenyl, *p*-bromophenyl and *p*-tolyl, respectively), which were obtained by acetoxymercuration of styrenes, in acetic acid containing perchloric acid or boron trifluoride.[5] Typical examples of the results are shown in Table 3.

Table 3. Preparation of **1** by the demercuration of **3**

a) After recrystallization from *n*-heptane.

Experimental

*Preparation of **1** through **4** and **3**.* The following example shows the typical experimental procedure for the preparation of **1**. Into a mixture of acetic acid (300 ml) and mercuric acetate (1.0 mol), styrene (1.0 mol) was added and stirred at room temperature for 1 hr, and then acetylacetone (2.0 mol) was added. Under keeping the mixture below 40 °C, 60% perchloric acid (160 g) was added dropwise and stirred for 2 hr. The reaction mixture was poured into 20% aqueous solution of sodium acetate (1000 g). Crystals of **3**-H formed were collected, washed with ether, and recrystallized from ethanol (1.2 l), 370 g (0.80 mol). Purified **3**-H (0.80 mol) was dissolved into hot DMSO (660 ml) and kept at 120 °C for 30 min. After removing metallic mercury formed, the reaction mixture was poured into saturated aqueous solution of sodium chloride (1.5 l). Brownish raw crystals were collected and recrystallized from *n*-heptane (1.8 l) to give pure **1**-H (56 g, 35% yield), mp 57.5—59.0 °C.

Starting from *p*-substituted styrenes, which were prepared by reduction of the corresponding acetophenones and subsequent dehydration,[6] **3** were obtained in 75—80% yields and then **1** in 33—57% yields. Purifications of **3** were essential to get better yields of **1** (Table 4).

Table 4. Analyses of **1**

	Found (%)			Calcd (%)		
	C	H	X	C	H	X
1-H	76.85	7.17		77.20	6.98	
1-Cl	65.87	5.48	14.86	65.91	5.54	14.98
1-Br	55.27	4.76	28.67	55.54	4.66	28.42

Because of the lack of the sufficient amount of the material, **1**-CH_3 was not analyzed.

IR spectra were recorded on HITACHI EPI-G2. IR of **1**-H (KBr): $\nu_{C=O}$, 1700(s) and 1680(s); δ_{C-H} of CH_3, 1370(s) and 1360(s); $\delta_{C=O}$, 1260(s); δ C-H of benzene ring, 780(s), 740(m), and 700(s). NMR spectra (in deuteriochloroform with TMS as an internal standard) were recorded on a Varian Associates HR-220 at 220 MHz at room temperature. δ values are summarized in Table 5.

*Alkaline Cleavage of **1**.* Into 100 ml volumetric flask, **1**-H (2.02 g, 0.01 mol), ethanol-water (75 : 25 by volume) mixture and potassium hydroxide dissolved in the same mixture (25 ml of 1.6 M solution) were added. After keeping the flask at 20 °C for 5 hr, the mixture was neutralized with hydrochloric acid (32.6 ml of 1 M). This result showed that 74% of the theoretical amount of potassium hydroxide were consumed. After ethanol was removed by distillation, the mixture was extracted with ether and dried over sodium sulfate. After removing ether, the product was analyzed by gas chromatography (YANACO GC-550 TPH, 1.5 m of 3 mmφ, Apiezon-L grease, helium). No other peak than **1**-H and *cis*- and *trans*-**2**-H was observed. The product was distilled *in vacuo*, bp 107—110 °C/7 mmHg. By column chromatography (Wakogel C-200, 30 mmφ × 40 cm, hexane-ethyl acetate (90: 10 by volume)), *cis*- and *trans*-**2**-H were isolated. Repeating the same procedure, pure *cis*- and *trans*-**2**-H were obtained. IR of *trans*-**2**-H was identical with that reported by Pierre *et al.*[7] IR of *cis*-**2**-H (bp 123—124 °C/11 mmHg) showed no absorption at 1358(m) and 1190(m) cm^{-1} which were observed in *trans*-**2**-H. IR (liq. film): $\nu_{C=O}$, 1703(s) and 1698(s); $\delta_{CH\ of\ CH_3}$, 1388(s); $\delta_{C=O}$, 1170(s); $\delta_{CH\ of\ benzene\ ring}$, 770(m), 720(w), and 695(m). Found: C, 82.61; H, 7.81%. Calcd for $C_{11}H_{12}O$: C, 82.46; H, 7.55%.

The cleavage products of *para*-substituted **1** gave the same pattern of gas chromatograms as that of **1**-H, showing that the reaction proceeded as in the case of **1**-H. Since sufficient amounts of pure *trans* products could not be isolated, NMR spectra were obtained for only *cis*-products and are shown in the following table. The differences of the chemical shift of **1**-H due to the anisotropy of aromatic ring made possible the discrimination of *cis*- and *trans*-**2**.

Kinetics. The rates were determined by following the potassium hydroxide concentrations by the titration

The Chlorination of Norbornene by Metal Chlorides and the Product Isomerization

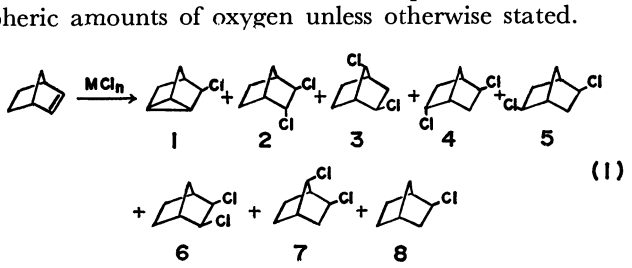
Sakae UEMURA,* Akira ONOE, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611
(Received July 15, 1975)

The reaction of norbornene with $CuCl_2$, $TlCl_3 \cdot 4H_2O$, $PbCl_4$, $SeCl_4$, $SbCl_5$, and VCl_4 in CCl_4, CH_2Cl_2, or CH_3CN gave a mixture of nortricyclyl chloride (**1**), and six isomeric dichloronorbornanes [*trans*-2,3-(**2**), *exo*-2-*anti*-7-(**3**), *trans*-2,5-(**4**), *exo-cis*-2,5-(**5**), *exo-cis*-2,3-(**6**), and *exo*-2-*syn*-7-(**7**)], the product distribution depending very much on metal chlorides and reaction conditions. The reactions did not show any participation of a chlorine molecule which may be released from metal chlorides. The ability of $SeCl_4$ and VCl_4 to chlorinate olefins was found for the first time. From a synthetic viewpoint $CuCl_2$ was a good reagent for obtaining **2**, while $TlCl_3 \cdot 4H_2O$ and $SbCl_5$ were recommended for either **3** or **7**. The reactions with the following metal chlorides did not give any dichloronorbornanes; $SnCl_4$, $BiCl_3$, $TiCl_4$, $FeCl_3$, $NbCl_5$, $TaCl_5$, and WCl_6. It was revealed that isomerization of **2** or **7** to a mixture of **3**, **4**, and **5** occurred very rapidly by $SbCl_5$ and smoothly by $TlCl_3 \cdot 4H_2O$. The chlorination of norbornene and their products isomerization were mainly explained by assuming a chloronorbornyl cation as an intermediate.

Recently we have shown that the chlorination of norbornene by $SbCl_5$[1] and $MoCl_5$[2] gave a quite different distribution of the products with that by Cl_2[3] and (dichloroiodo)benzene.[4] Namely, *exo*-2-*anti*-7-(**3**), *trans*-2,5-(**4**), and *exo-cis*-2,5-dichloronorbornane(**5**) were the main products in the case of $SbCl_5$, while *exo-cis*-2,3-isomer(**6**) was mainly obtained in the case of $MoCl_5$. On the other hand, a mixture of nortricyclyl chloride(**1**) and *exo*-2-*syn*-7-isomer(**7**) (ionic condition) and a mixture of *trans*-2,3-iosmer(**2**) and **6** (radical condition) were mainly obtained in chlorination by Cl_2 or $PhICl_2$. In the chlorination of olefin by metal chloride it is sometimes difficult to distinguish whether it is a specific reaction by metal chloride itself or it involves a chlorine molecule released from metal chloride. The clear-cut different product distribution described above, however, suggests that norbornene is a good olefinic substrate to study whether the reaction involves a chlorine molecule. Therefore we carried out its chlorination by various metal chlorides with the intentions of giving a further insight on the nature of metal chloride chlorination and also of finding any metal chlorides for selective formation of each of **1**–**7** if possible.

Results and Discussion

Reaction conditions, the yields of the products, and the isomer distributions are summarized in Table together with the reported data of $MoCl_5$[2] and $AuCl_3$[5] (Scheme 1). The data of typical ionic and radical chlorination by Cl_2[3] were also added for comparison. All reactions were carried out by addition of norbornene to a solution of metal chloride in the presence of atomospheric amounts of oxygen unless otherwise stated.



(1)

* To whom all correspondence should be addressed.

$CuCl_2$. The reaction proceeded smoothly in CH_3CN where LiCl was added to increase the reaction rate and the solubility of copper(II) salt to give **2** and **6** almost selectively (Run 1), while no reaction occurred in CCl_4, CH_2Cl_2, and $CHCl_3$ as solvents. Although the isomer distribution in the products, which was shown to be kinetically controlled one, was similar to that in radical chlorination by Cl_2[3] or $PhICl_2$,[4] the reaction was not affected by addition of *m*-dinitrobenzene (Run 2) and no change in the product distribution was observed even when the reactions were conducted under bubbling oxygen or nitrogen. Therefore it is clear that the chlorinating species is not a chlorine molecule which may be released from $CuCl_2$, but $CuCl_2$ itself or its LiCl complex.

$TlCl_3 \cdot 4H_2O$. Chlorination by this salt in CCl_4 at refluxing temperature afforded a mixture of **3**, **4**, **5**, and **7**, the ratio of a mixture of **3**—**5** to **7** being increased by prolonging the reaction time (Runs 3 and 4). The reaction proceeded even at −10 °C where the compounds other than **3** and **7** were scarcely obtained (Run 5). We showed in separate experiments that **7** isomerized smoothly to a mixture of **3**—**5** in CCl_4 at 5—76 °C in the presence of $TlCl_3 \cdot 4H_2O$, while no isomerization occurred at −10 °C (See Experimental). Therefore it can be concluded that the isomer distribution in Run 5 is kinetically controlled. The formation of *exo*-2-chloronorbornane(**8**), HCl addition product to norbornene, was observed in Runs 3 and 4. The evolution of HCl by interaction of $TlCl_3 \cdot 4H_2O$ with CCl_4 at refluxing temperature has been known.[6]

$PbCl_4$. Chlorination by this salt was carried out by addition of olefin to a yellow CH_2Cl_2 solution of $PbCl_4$[7] which was produced *in situ* by action of HCl on $Pb(OAc)_4$ at −60 °C. The characteristic feature of this reaction was found in selective formation of **3** and **7** without any other isomers when the reaction was conducted at −40 °C (Run 6). It was shown in separate experiments that neither interconversion between **3** and **7** nor isomerization of other isomers to **3** and **7** occurred in CH_2Cl_2 at −30——40 °C in the presence of $PbCl_4$ and/or $PbCl_2$. Therefore the isomer distribution in Run 6 is kinetically cotnrolled. The reaction also proceeded in CCl_4 at −10 °C (Run 7),

though the formation of **1** was observed in this case probably because of the slight release of a chlorine molecule from $PbCl_4$ at this temperature. Since excess HCl is present in solution, **8** was always formed as a side-product.

$SbCl_5$. We have reported previously that the chlorination of norbornene by this chloride in CCl_4 gave mainly **3**, **4**, and **5** in good yields.[1] In view of the observation that **7** was isomerized to a mixture of **3**—**5** by $TlCl_3 \cdot 4H_2O$, we reexamined the product distributions under various conditions. When norbornene was added drop by drop in a period of *ca.* 0.5—3 min to a CCl_4 solution of $SbCl_5$ (Run 8), none of **7** was obtained and the main products were **3**—**5** as shown in our previous report.[1] However, when norbornene was added all at once (Runs 9—11), **3** and **7** were obtained as the main products, while the amounts of **4** and **5** in the products were very small. In these cases the product distribution appeared to be nearly constant irrespective of the total reaction time and its temperature. When the reverse addition was employed (Run 12), namely addition of a CCl_4 solution of $SbCl_5$ to a CCl_4 solution of norbornene, the product distribution was nearly the same as those in Runs 9—11 almost irrespective of the speed of the addition. In separate experiments we observed that $SbCl_5$ was a very effective catalyst for isomerization of **2** and **7** to a mixture of **3**—**5**, while $SbCl_3$ showed no effectiveness for such isomerization. For example, almost all of **2** or **7** were converted to a mixture of **3**—**5** by treating with $SbCl_5$ at 20 °C in only 10 min (See Experimental). The chlorination of norbornene by $SbCl_5$ occurs very rapidly under the conditions we employed and it was nearly complete as soon as norbornene was added to a solution of $SbCl_5$ (Run 9). Thus we can conclude that in Run 8 initially formed **7** was isomerized to a mixture of **3**—**5** by excess $SbCl_5$ present in a solution, while in Runs 9—11 and also in Run 12 $SbCl_5$ did not exist in such extent as making the isomerization of **7** complete, because $SbCl_5$ turned to $SbCl_3$ as soon as chlorination took place. Since there have been no convenient methods of preparing **4** and **5**, the method described here (Run 8) seems to be useful for this purpose.

$SeCl_4$ and VCl_4. We have tried to chlorinate norbornene by several other commercial metal chlorides with which chlorination of olefin has never been reported. As a result both $SeCl_4$ and VCl_4 were revealed to chlorinate olefins. The following metal chlorides did not give any dichloroalkanes under the conditions we have employed (cyclohexene and norbornene as substrates; at 20—76 °C in CCl_4); $SnCl_4$, $BiCl_3$, $TiCl_4$, $FeCl_3$, $NbCl_5$, $TaCl_5$, and WCl_6.

As to chlorination by $SeCl_4$, there have been no reports on direct chlorination of olefins, although the reaction of $SeCl_4$ with unsaturated linkages to produce organoselenium dichlorides has been well known.[8] However, chlorination occurred with norbornene in CCl_4 to give several dichloronorbornanes in which **7** was the main product (Runs 13 and 14). Since we

Table. Chlorination of norbornene

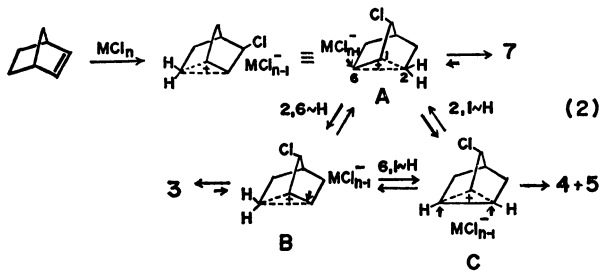
showed in separate experiments that **7** did not isomerize to other isomers under the reaction conditions, the isomer ratios in Runs 13 and 14 seem to be kinetically controlled. The reaction of cyclohexene with $SeCl_4$ gave *trans*-dichlorocyclohexane in a 44% yield together with chlorocyclohexane by stirring at 20 °C for 2 hr. In order to see whether these dichloroalkanes were produced *via* organoselenium compounds, we prepared separately bis(2-chlorocyclohexyl)selenium dichloride by the reported method[8] (mp 142 °C; lit,[8] mp 141—142 °C) and heated it to reflux in CCl_4 for 2 hr in the presence or absence of $SeCl_4$. As a result none of dichlorocyclohexane was obtained. This shows that chlorination by $SeCl_4$ does not proceed through the formation of organoselenium compounds at least in CCl_4 solvent.

The chlorination of norbornene by VCl_4 proceeded smoothly in CCl_4 to give all of **1**—**7** in which the main product was the *cis*-dichlorinated isomer **6** (Runs 15 and 16). Although the chlorinating action of VCl_4 has been noted in the chlorination of aromatic hydrocarbons,[9] there have so far been no reports on the direct chlorination of olefins. Since we showed that no isomerization occurred between each isomer under the conditions of Runs 15 and 16 and also that the isomer distribution was nearly the same even when the reaction was stopped in a shorter time, the isomer ratios shown in Table are clearly kinetically controlled. Although a preferential formation of **6** is quite characteristic, chlorination of norbornadiene and cyclohexene gave hardly any *cis*-dichloroalkanes. Therefore, the molecular *cis*-addition mechanism which was proposed in the chlorination by $MoCl_5$[2] does not seem to be applicable in this case. It should be added that radical scheme can be excluded because no change in the isomer distribution and the yields of the products was observed when the reactions were conducted under the presence of *m*-dinitrobenzene or bubbling oxygen.

By considering the product distribution in each reaction described above, we can conclude that chlorination by any metal chlorides does not involve a chlorine molecule which may be released from metal chlorides. Since a fractional distillation can nearly separate **2** from **6** and also **3** from **7**, additional useful conclusion can be drawn from a synthetic viewpoint. For obtaining **2** chlorination by $CuCl_2$ (Run 1) is recommended, while for either **3** or **7** the reactions with $TlCl_3 \cdot 4H_2O$ (Run 5) and $SbCl_5$ (Run 12) should be employed because of its simplicity, high selectivity, and high yields of the products. In order to obtain **4** and **5**, the method of Run 8 by the use of $SbCl_5$ is applicable, though it is necessary to use preparative glc for the separation of each isomer.

Reaction Scheme and Product Isomerization. The results that chlorinations by $TlCl_3 \cdot 4H_2O$, $PbCl_4$, $SbCl_5$, and $SeCl_4$ gave mainly **3** and **7** as kinetically controlled products (usually **7**>**3**) seem to be explained by Scheme 2. Namely, at first a chloronorbornyl cation **A** may be formed as an intimate ion-pair with gegen-ion MCl_{n+1}^- because of low polarity of solvent. In some extent the cation may be converted to another isomeric bridged ion **B** through 2,6-hydride shift. As noted earlier,[10] the low cationic character



at C_1 in **A** and **B** due to the inductive effect of the adjacent chlorine atom probably prevents the attack of MCl_{n+1}^- on C_1, and makes the almost exclusive attack on C_6 and C_2 possible, leading to the formation of **7** and **3** respectively. It is also apparent by similar reason that 6,1- or 2,1-hydride shift to give **C** would be less important than 2,6-shift, and hence **4** and **5** are minor products. Such equilibrium as shown in Scheme 2 has been assumed to explain the result of the acetolysis and isomerization of *syn*- and *anti*-7-chloro-*exo*-norbornyl *p*-toluenesulfonate.[11]

In the chlorination by VCl_4, the reaction scheme for the formation of **2** and **6** is not yet clear. The isomer distribution in the minor products, however, suggests that the reaction proceeded through Scheme 2 to some extent.

Chlorination by $CuCl_2$ which gave 2,3-dichloronorbornanes almost selectively and only a small amount of carbon skeleton rearranged product, on the contrary, does not seem to proceed through Scheme 2. Coordination of copper salt on double bond may be one of the determining factors for such selective formation.

Isomerization of **2** or **7** to a mixture of **3**—**5** by rather strong Lewis acids such as $SbCl_5$ and $TlCl_3 \cdot 4H_2O$ in CCl_4 may be explained by Scheme 2. Thus, the abstraction of *exo*-Cl (on C_2) by MCl_n gives the cations **A** and **B** from **7** and **2** respectively which then afford **3**—**5** by recombination with Cl^- of MCl_{n+1}^-. We also observed the slow isomerization of **3** to **4** and **5** by $SbCl_5$ and $TlCl_3 \cdot 4H_2O$ at 20 °C and 76 °C respectively. This isomerization may involve the abstraction of *exo*-Cl from **3**. It should also be noted that no isomerization of **6** by $SbCl_5$ was observed at 20 °C for 10 min in CCl_4. The reason why **6** is so stable compared to **2** is not yet clear.

Experimental

All materials except $PbCl_4$[7] were commercial products and used without further purification. The identification of each product was described in previous papers.[1,2] The product distributions were analyzed by glc by the use of Shimadzu apparatus 5APTF and 4BMPF on both EGSS-X(15%)-Chromosorb-W (3 m) and PEG 6000 (25%)-Chromosorb-W (3 m) columns (carrier gas, N_2; bromobenzene or *trans*-dichlorocyclohexane as internal standard). In the reaction with VCl_4 or $SeCl_4$, **6** or **7** was isolated respectively by a fractional distillation in almost pure state and analyzed by NMR to ascertain the structure (Varian A-60 spectrometer; in CCl_4).

Synthesis of **2**. A homogeneous mixture of $CuCl_2$ (26.8 g, 200 mmol), LiCl (8.4 g, 200 mmol), CH_3CN (200 ml) and norbornene (4.7 g, 50 mmol) was stirred for 5 hr under reflux. After being cooled down to room temperature the

mixture was concentrated to *ca.* 50 ml by evaporation of solvent, added by water (300 ml), and then extracted with benzene. Distillation of the extract through a fractionating column (30 cm) with glass packings afforded two fractions leaving only a small amount of residue; D_1 5.0 g (bp 89—94 °C/19 mmHg) and D_2 0.86 g (bp 88—92 °C/10 mmHg). The fraction D_1 was shown by glc to contain **2** (95%) and small amounts of **6** and **7**. The fraction D_2 was revealed to be a mixture of **2**(15%), **6**(75%), and **7**(10%).

*Synthesis of **3** and **7**.* To a CCl_4 (170 ml) solution of norbornene (4.7 g, 50 mmol) was slowly added a yellow homogeneous CCl_4 (30 ml) solution of $SbCl_5$ (10.0 g, 33.4 mmol) at 20 °C for 5 min. After 5 min, water was added to the reaction mixture and the precipitated SbOCl was filtered off. Similar fractional distillation of the filtrate as described above afforded three fractions; D_1 2.1 g (bp 95—98 °C/18 mmHg), D_2 1.2 g (bp 102—109 °C/18 mmHg), and D_3 0.43 g (bp 75—77 °C/5 mmHg). The fraction D_1 was shown by glc to contain **3**(90%) and small amounts of **2**, **4**, **5**, and **7**. The fraction D_3 was shown to be a mixture of **3**(13%), **7**(84%) and small amounts of **4** and **5**.

*Isomerization of **7** or **2** to a Mixture of **3**—**5** by $TlCl_3 \cdot 4H_2O$.* A CCl_4 (25 ml) solution containing **7** (0.22 g, 1.33 mmol) and $TlCl_3 \cdot 4H_2O$ (0.80 g, 2.09 mmol) was stirred at 76 °C for 2 hr. After being cooled down to room temperature, organic layer was washed with water and analyzed by glc. The products were **2**(3.6%), **3**(27.6%), **4**(28.8%), **5**(34.6%), and **7**(5.4%); recovered yield of dichloronorbornanes was 90%. Similar treatment of **7** at 5 °C for 3 hr gave a mixture of **2**(0.4%), **3**(39.4%), **4**(19.8%), **5**(1.6%), and **7**(38.8%); yield, 91%. When **2**(1.04 mmol) was stirred in CCl_4 (25 ml) with $TlCl_3 \cdot 4H_2O$ (1.68 mmol) at 76 °C for 2 hr, it isomerized to a mixture of **2**(6.9%), **3**(21.3%), **4**(36.6%), and **5**(35.2%); yield, 89%. No isomerization of **2** or **7** to other isomers was observed at −10 °C.

*Isomerization of **7** or **2** to a Mixture of **3**—**5** by $SbCl_5$.* A CCl_4 (25 ml) solution containing **7** (1.47 mmol) and $SbCl_5$ (1.67 mmol) was kept at 20 °C for 10 min. Glc analysis of CCl_4 layer after usual work-up procedure revealed the presence of a mixture of **2**(5.4%), **3**(40.7%), **4**(24.3%), **5**(29.4%), and **7**(0.2%); yield of a mixture, 96%. Similar treatment of **2**(1.12 mmol) with $SbCl_5$ (1.69 mmol) gave a mixture of **2**(4.2%). **3**(17.6%), **4**(36.3%), and **5**(41.9%); yield, 98%.

(−)-(1*S*,4*R*,5*R*)-Guaia-6,9-diene from Geranium Bourbon

Yoko NAGAHAMA, Hideo NAOKI, and Yoko NAYA

The Institute of Food Chemistry, Shimamoto-cho, Mishima-gun, Osaka 618

(Received July 28, 1975)

A sesquiterpene from Geranium Bourbon has been found to be guaia-6,9-diene in accordance with the report of Pesnelle *et al.*; it had previously been erroneously assigned as 3,7-diene by Herout *et al.* The details of the evidence on the structure, along with its stereochemistry, are described.

In the course of the study of Geranium oil[1] (Geranium Bourbon), we have isolated guaia-6,9-diene (I), which was identical with the compound previously reported[2] as "guaia-3,7-diene." This had been pointed out by Pesnelle *et al.*[3] In this paper, we wish to report the evidence for the correction of the structure, together with its stereochemistry, since we have not yet seen any detailed publication relating to the revised structure, I.

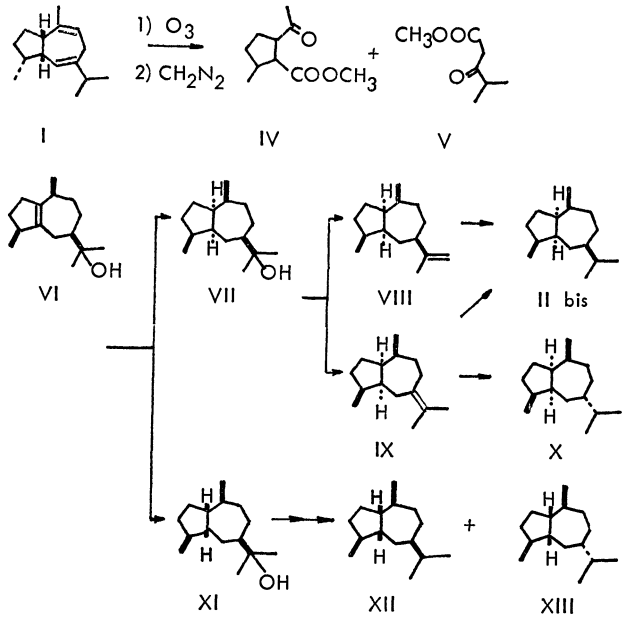
Commercial Geranium oil* was subjected to separation by column chromatography and preparative glc to obtain Compound I. Compound I, $[\alpha]_D$ −50.9°, was a colorless oil which exhibited its molecular ion peak at *m/e* 204 ($C_{15}H_{24}$) in its mass spectrum. Its IR spectrum revealed the absorptions of the isolated double bond and the trisubstituted ethylenes. In addition, no UV absorption maxima were observed in the region of 215—280 nm. The PMR spectrum exhibited two doublets, at δ 0.93 (6H, J=6.0) and at 1.02 (3H, J=6.0), which were assignable to an isopropyl and a secondary methyl group respectively; a broad singlet at 1.53 (3H) and a complex signal at around 5.35 (1H), accounting for the CH_3C=CH− system, as was confirmed by spin-spin decoupling, and a broad signal at around 5.16 (1H) coupled with a broad signal around 2.86 (1H), which was attributable to a vinyl proton adjacent to a methine.

The catalytic hydrogenation of I over PtO_2 in acetic acid afforded a mixture of two tetrahydro derivatives in the ratio of three to one. The IR spectrum of the major product (II), $[\alpha]_D$ +40.6°; M^+, *m/e* 208 ($C_{15}H_{28}$), was identical with that of Šorm's "guaiane."[4] On the other hand, in methanol over the same catalyst, I was reduced to a complex mixture of the dihydro isomers, accompanied by a small amount of II. The examination of the PMR spectrum of the main dihydro compound (III), M^+, *m/e* 206 ($C_{15}H_{26}$), revealed that CH_3C=CH had been reduced and that another trisubstituted double bond remained.

I was ozonized in ethyl acetate at −40 °C, followed by oxidative degradation. Its acidic fraction was treated with diazomethane-etherate. The methyl esters thus obtained were determined to be (IV) and (V) by an examination of their physical data. Compound IV exhibited the molecular ion peak at *m/e* 184 ($C_{10}H_{16}O_3$) in its mass spectrum. Its IR spectrum revealed the absorptions arising from nonconjugated C=O vibrations and the C–O bands of the methyl ester. The PMR spectrum exhibited a doublet at δ 0.9 (3H, J=6.5), indicating a secondary methyl; a singlet at 2.19 (3H) corresponding to $-COC\underline{H}_3$, and a signal at 3.69 (3H) which was assigned to $-COOC\underline{H}_3$. From all the above data, it seems that IV should contain a cyclopentane skeleton. Compound V, M^+, *m/e* 144 ($C_7H_{12}O_3$), obtained in a small amount, exhibited the absorption bands of carbonyl and methyl ester in its IR spectrum. Its PMR spectrum exhibited a doublet at δ 1.18 (6H, J=6.0), accounting for an isopropyl group, and a singlet at 3.67 (3H) which was assigned to a methyl ester group. Therefore, V should be methyl 4-methyl-3-oxopentanoate.

Now, in order to obtain the physical data of "guaiane" with definitely established stereochemistry, it was prepared from (−)-guaiol[5] (VI) *via* crystalline (−)-dihydroguaiol[6] (VII), with its known stereochemistry. VII was dehydrated by thionyl chloride–pyridine to afford two hydrocarbons, with isopropenyl (VIII) and isopropylidene (IX) groups respectively, in the ratio of three to two. The major hydrocarbon, VIII, was reduced to a saturated hydrocarbon (II *bis*), $[\alpha]_D$ −58°, which was found to be identical with "guaiane"[4] by a comparison of their IR spectra.

Hydrogenation of IX afforded a mixture of (II *bis*) and its isomer at C_7 (X) in the same ratio. On the other hand, oily (+)-dihydroguaiol[7] (XI), with a known stereochemistry, prepared from (−)-guaiol, afforded saturated (+)-hydrocarbon isomers (XII) and (XIII) in a similar manner. The IR spectra of X, XII, and XIII differed from that of (II *bis*), though



* Commercial Geranium oil was produced by Soda Aromatic Co., Ltd., in the Shodo island in 1974.

they exhibited quite similar mass spectra. Consequently, the structure including the absolute configuration of I was concluded to be (−)-(1*S*,4*R*,5*R*)-guaia-6,9-diene.

Experimental

The IR spectra were measured using a Hitachi EPI-G2 spectrometer. The UV spectra were taken on a Jasco Model ORD/UV-5 spectrometer. Measurements of optical rotation were carried out with a Perkin-Elmer 141 polarimeter. The mass spectra were measured using a Hitachi RMU-6 spectrometer with a indirect-inlet system operating at 80 eV. The PMR spectra were taken by a Hitachi R-20 B spectrometer at 60 MHz in CCl_4. The chemical shifts were expressed in δ downfield from TMS as an internal standard and coupling constants in Hz. The preparative glc conditions, using a model 920 Varian Aerograph fitted with a thermal-conductivity detector, were as follows: a 10-ft×3/8 in. aluminum column containing 20% Carbowax 20M on 60—80 mesh Diasolid-L. Nitrogen was used as the carrier gas, and the column temperature was set at 170—200 °C. All the melting points are uncorrected.

Isolation of I. Commercial geranium oil* (400 g) was successively chromatographed on SiO_2 and $AgNO_3$-SiO_2 (15%) columns and then eluted with *n*-hexane. On further purification by preparative glc, Compound (I) (400 mg) was obtained. Compound I was a colorless oil; $[\alpha]_D$ −50.9° (*c* 1.49, EtOH); IR (liq.) 1658 (C=C), 1360, 1375 (-$\underset{\underset{CH_3}{|}}{CH}$-$CH_3$), 854, 828 cm^{-1} (-C=C-); PMR (CCl_4) δ 0.93 (6H, d, J=6.0, an isopropyl group), 1.02 (3H, d, J=6.0: 4-CH_3), 1.53 (3H, br. s) and 5.35 (1H, m): a system of CH_3C=CH, 2.23 (1H, m) and 2.98 (1H, br. signal): protons at 8-C, 2.86 (1H, br. signal) coupled with 5.16 (1H, br. signal): protons at 5-C and 6-C, and 1.0—2.4 (7H, complex signals: methines and methylenes); mass spectrum *m/e* 204(38%, M^+, $C_{15}H_{24}$), 105(100%), 119(62%), and 161(52%).

Hydrogenation of I in Acetic Acid. I was reduced catalytically (PtO_2) in acetic acid at room temperature. After the filtration of the catalyst, the filtrate was diluted with water and extracted with ether. The evaporation of the ether gave a residue, which was purified on preparative glc (CW-20M, at 180 °C) to afford two compounds, (II) and (II′), in the ratio of three to one. The major product, II, was a colorless oil; $[\alpha]_D$ +40.6° (*c* 1.45, EtOH); δ 0.82 (6H, d, J=6.0), 0.83 (3H, d, J=6.0), 0.90 (3H, d, J=6.0), 1.0—2.3 (16H, complex signals); *m/e* 208 (9%, M^+, $C_{15}H_{28}$), 109(100%), 95(70%), 81(60%); the IR spectrum agreed with that of "guaiane."[4] The minor product, II′, was a colorless oil; δ 0.85 (6H, d, J=6.0), 0.88 (3H, d, J=6.0), 0.94 (3H, d, J=6.0), and 1.0—2.2 (16H, complex signals). Its IR spectrum was identical with that of the (X) prepared from guaiol (VI).

Hydrogenation of I in Methanol. A solution of I in methanol was hydrogenated in the presence of PtO_2 at room temperature. The filtration of the catalyst and the evaporation of the solvent left a residue, which was purified by preparative glc (CW-20M, at 180 °C) to afford (III), accompanied by a small amount of II. III was a colorless oil; ν_{max} 1655 cm^{-1} (C=C); δ 0.86 (3H, d, J=6.0), 0.95 (6H, d, J=6.0), 1.02 (3H, d, J=6.0), 1.1—2.5 (13H, complex signals), and 5.13 (1H, br. d, J=3.5); *m/e* 206 (5%, M^+, $C_{15}H_{26}$), 107(100%), 163(76%), 81(76%), 93(50%), and 121(22%).

Ozonolysis of I. A solution of I in ethyl acetate was ozonized at −40 °C. When the reaction was completed, hydrogen peroxide (30%) and a potassium bicarbonate solution (5%) were added to the ozonide for degradation. The solution was then allowed to stand overnight at 0 °C. The organic layer was further treated as usual to obtain acidic compounds. The acids thus obtained were treated with diazomethane-etherate to give the methyl esters, (IV) and (V). Compound IV was a colorless oil; ν_{max} 1710, 1725 (sh) (C=O), 1200, 1170 cm^{-1} (C-O); δ 0.9 (3H, d, J=6.5), 2.19 (3H, s), 3.69 (3H, s), 3.0—3.5 (2H, m), and 1.3—2.5 (5H, m); *m/e* 184 (3%, M^+, $C_{10}H_{16}O_3$), 81 (100%), 43(96%).

Compound V was obtained in a very small amount as a colorless oil; ν_{max} 1730 (C=O), 1200, 1170 cm^{-1} (C-O); δ 1.18 (6H, d, J=6.0), 3.67 (3H, s), 2.0—3.5 (3H, complex signals); *m/e* 144 (4%, M^+, $C_7H_{12}O_3$), 143(21%), 55(100%).

Hydrogenation of Guaiol VI.[8] A solution of 1.86 g of (−)-guaiol (VI)** in 30 ml of ethanol and 0.69 g of a Raney nickel catalyst was shaken for 20 hr at 100 °C under a hydrogen pressure of 100 atm. The filtration of the catalyst and the evaporation of the solvent yielded a mixture of dihydroguaiols. They were both diastereomers at the ring juncture and were revealed on the gas chromatogram in the ratio of 2 : 3. Separation by preparative glc (CW-20M, at 200 °C) led to the dihydroguaiol (VII)[6] (major) and (XI),[7] with known stereochemistries. VII was a colorless needle; mp 76—76.5 °C; $[\alpha]_D$ −44.8° (*c* 1.06, acetone); ν_{max} 3325 (-OH), 1166, 1134 cm^{-1} (C-O); δ 0.86 (3H, d, J=6.0), 0.95 (3H, d, J=6.0), 1.07 (3H, s), 1.10 (3H, s), and 1.2—2.4 (16H, m, including -OH); *m/e* 224 (M^+, trace, $C_{15}H_{28}O$), 206 (2%, M^+-18), 164(10%), 81(19%), and 59(100%). XI was a colorless oil; $[\alpha]_D$ +73.5° (*c* 0.93, acetone); ν_{max} 3380 (-OH), 1158, 1120 cm^{-1} (C-O); δ 0.95 (6H, br. d, J=9.5), 1.10 (6H, s), 1.2—2.0 (15H, complex signals), and 2.51 (1H, s, -OH); *m/e* 224 (M^+, trace, $C_{15}H_{28}O$), 206 (3%, M^+-18), 163(7%), 81(22%), and 59 (100%).

Dehydration of (−)-Dihydroguaiol VII with Thionyl Chloride-Pyridine. Thionyl chloride (1.38 equiv) was stirred, drop by drop into a solution of (−)-dihydroguaiol VII in pyridine at 5—10 °C. After observation by tlc of the completion of the reaction, the mixture was poured over ice and then extracted with pet. ether. The extract was washed with water, dried (Na_2SO_4), and evaporated to give a brown oil, which was purified on preparative glc to afford (VIII) and (IX). Compound VIII was a colorless oil; $[\alpha]_D$ −47.0° (*c* 0.57, EtOH); ν_{max} 3070, 888 cm^{-1} (=CH_2); *m/e* 206 (M^+, 14%, $C_{15}H_{26}$), 163(52%), 81(100%). Compound IX was a colorless oil; *m/e* 206 (M^+, 12%, $C_{15}H_{26}$), 163(44%), 81(100%).

Dehydration of (+)-Dihydroguaiol XI with Thionyl Chloride-Pyridine. (+)-Dihydroguaiol XI was worked up with thionyl chloride (1.38 equiv.) and pyridine as has been described above, affording two products, (VIII′) and (IX′). Compound VIII′ was a colorless oil; ν_{max} 3070, 888 cm^{-1} (=CH_2); *m/e* 206 (M^+, 25%, $C_{15}H_{26}$), 163(60%), 81(100%). Compound IX′ was a colorless oil; *m/e* 206 (M^+, 22%, $C_{15}H_{26}$), 163(48%), and 81(100%).

Hydrogenation of VIII in Ethanol. VIII in ethanol was hydrogenated over PtO_2 at room temperature. After the completion of the reaction, the catalyst and the solvent were removed. (II *bis*) was obtained as the sole product and identified with II by a comparison of their IR spectra;

** (−)-Guaiol was kindly presented by Inabata Koryo Co., Ltd.

a colorless oil; $[\alpha]_D$ −58.1° (*c* 0.74, EtOH); δ 0.82 (6H, d, J=6.0), 0.83 (3H, d, J=6.0), 0.90 (3H, d, J=6.0), and 1.0—2.3 (16H, complex signals); *m/e* 208 (M^+, 12%, $C_{15}H_{28}$), 109 (100%).

Hydrogenation of IX in Acetic Acid. IX was hydrogenated in acetic acid over PtO_2 at room temperature. After the filtration of the catalyst, water was added to the reaction mixture, extracting with *n*-pentane. The evaporation of the solvent left a mixture of (II *bis*) and X, in the ratio of 1 : 1; those substances were separated by preparative glc (CW-20M, at 170 °C). Compound X was a colorless oil; $[\alpha]_D \fallingdotseq 0°$ (*c* 0.13, EtOH); δ 0.85 (6H, d, J=6.0) 0.88 (3H, d, J=6.0), 0.94 (3H, d, J=6.0), 1.0—2.2 (16H, complex signals); *m/e* 208 (M^+, 14%, $C_{15}H_{28}$), 109 (100%).

Hydrogenation of VIII′ in Ethanol and IX′ in Acetic Acid. VIII′ was hydrogenated over the PtO_2 catalyst in ethanol in a way similar to that as in the case of VIII to afford a colorless oil (XII); $[\alpha]_D$ +58.1° (*c* 0.91, EtOH); δ 0.86 (6H, d, J=6.0), 0.92 (3H, d, J=6.0), 0.95 (3H, d, J=6.0), 1.1—2.0 (16H, complex signals); *m/e* 208 (M^+, 10%, $C_{15}H_{28}$), 109(100%). IX′ was reduced over the PtO_2 catalyst in acetic acid in a way similar to that in the case of IX to give XII and (XIII) on purification by preparative glc (CW-20M, at 180 °C). Compound XIII was a colorless oil; $[\alpha]_D$ +34.7° (*c* 0.23, EtOH); δ 0.84 (6H, d, J=6.0), 0.92 (3H, d, J=6.0), 0.97 (3H, d, J=6.0), 1.1—2.0 (16H, complex signals); *m/e* 208 (M^+, 12%, $C_{15}H_{28}$), 109(100%).

The authors wish to thank Dr. Yoshihiro Hirotsu of the university of Osaka for the hydrogenation under high pressure.

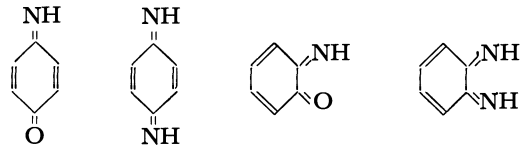
(Received August 6, 1975)

We have succeeded in obtaining *o*-benzoquinone monoimine (*o*-BQMI) and *o*-benzoquinone diimine (*o*-BQDI) by oxidizing *o*-aminophenol (*o*-AP) and *o*-phenylenediamine (*o*-PD), respectively, with freshly prepared lead dioxide at −10 °C in several organic solvents, and also with potassium hexacyanoferrate (III) in an aqueous buffer solution. The formations and reactions of *o*-BQMI and *o*-BQDI in aqueous buffer solution were investigated by a stopped flow technique together with a conventional electronic absorption measurements. Both *o*-BQMI and *o*-BQDI were formed in the pH range 8—12, and the hydrolysis of *o*-BQMI to produce *o*-benzoquinone was found in the pH range 6—8. Both *o*-BQMI and *o*-BQDI were found to be unstable at a room temperature to produce 2-aminophenoxazin-3-one (APZ) and 2,3-diaminophenazine (DAP), respectively, as the main products. The formation reactions of APZ and DAP were investigated by observing the spectroscopic course of the reactions in *o*-BQMI- *o*-AP and *o*-BQDI- *o*-PD system in diethyl ether.

p-Benzoquinone monoimine (*p*-BQMI) and *p*-benzoquinone diimine (*p*-BQDI) have long been considered as the intermediates in the oxidative coupling reactions of *p*-aminophenol and of *p*-phenylenediamine with aromatic amines and phenols.[1]



p-BQMI *p*-BQDI *o*-BQMI *o*-BQDI

Their derivatives have also been used as the developers in color photography.[2] Recently, J. F. Corbett investigated many dye formation reactions between *p*-BQMI and *p*-BQDI with several aromatic amines and phenols.[3] Inspite of the extensive studies on *p*-benzoquinone imines, investigations on the isomeric *o*-benzoquinone imines are scanty. Although *o*-BQDI has been obtained about seventy years ago,[4] instability of this compound prevented further work. Without direct evidence, *o*-BQMI and *o*-BQDI have been considered as the reaction intermediates in the oxidation reactions of *o*-aminophenol (*o*-AP)[5] and *o*-phenylenediamine (*o*-PD),[6] respectively. Recently, the intermediacy of *o*-BQDI was demonstrated for the first time in the dehydrogenation reaction of *o*-phenylenediamine with chloranil.[7]

In the present paper, we report that *o*-BQMI and *o*-BQDI were obtained by the oxidations of *o*-AP and *o*-PD, respectively, with active PbO_2 in several organic solvents and also with potassium hexacyanoferrate (III) in an aqueous buffer solution for the first time. As expected, these imines were found to be reactive, and the reactions of *o*-BQMI with *o*-AP and of *o*-BQDI with *o*-PD were investigated spectrophotometrically in diethyl ether.[8]

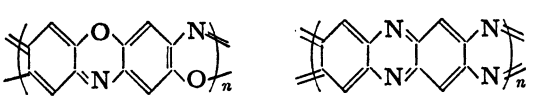
Experimental

Materials. *o*-Aminophenol and *o*-phenylenediamine were purified by repeated sublimations. Commercially available NaH_2PO_4, Na_2HPO_4, Na_3PO_4, $K_3Fe(CN)_6$, Ag_2O, and catechol were used without further purification. Active PbO_2 was prepared according to the literature.[9] The solvents diethyl ether, methyl alcohol, ethyl alcohol, toluene, acetone, acetonitrile, and chloroform were purified by the usual procedures.

Buffer Solutions. Buffer solutions were prepared by appropriate mixtures of 0.1 M aqueous solutions of NaH_2PO_4, Na_2HPO_4 and Na_3PO_4.

Syntheses of o-Benzoquinone Mono- and Di-imines. Freshly prepared PbO_2[9] (350 mg) and anhydrous sodium sulfate (100 mg) baked beforehand for 30 min were added to an organic solution (chloroform, diethyl ether, toluene, acetone, and acetonitrile) of *o*-aminophenol or *o*-phenylenediamine (2 mg in 25 ml solvent) under cooling with ice-salt (−10 °C) and vigorously stirred for five min. The solution was filtered, and the yellow colored filtrate was used directly for further investigations. All procedures were performed under anhydrous conditions. Both *o*-BQMI and *o*-BQDI were fairly stable only when kept below 0 °C in a dilute solution, and unstable at a room temperature or in a concentrated solution. This prevented us from carrying out their isolations.

Separation of Reaction Products. The reaction products in diethyl ether and aqueous buffer solutions were separated as follows. In the case of ether solutions, the reaction mixtures of *o*-AP–*o*-BQMI and *o*-PD– *o*-BQDI systems were kept overnight, and the ether was removed by distillation. The residue thus obtained was chromatographed on alumina (benzene–acetone mixed solvent as an elute) and the main reaction products were purified further by a Liquid Chromatograph LC-07 (Japan Analytical Industry Co. Ltd.). In the case of the buffer solutions, the mixtures of $K_3Fe(CN)_6$ and amines were also kept overnight, and the precipitate was collected by filtration. After the precipitate was dried completely, it was purified by the same manner as described above. The identifications of the reaction products as 2-aminophenoxazin-3-one (APZ), 2,3-diaminophenazine (DAP) and 2,2′-diaminoazobenzene (AB) were made by comparing their UV, VIS, IR and mass spectra with those of the authentic samples.[7,8] The yields of APZ, DAP and AB are: APZ, 1.57% (pH 4.5); 18.9% (pH 7); 16% (in diethyl ether); DAP, 4.76% (pH 4.5); 11.11% (pH 7); AB, 26.6% (in diethyl ether), respectively. Many byproducts other than APZ, DAP and AB were also obtained. Most of them may be such polymers as shown below.[10]



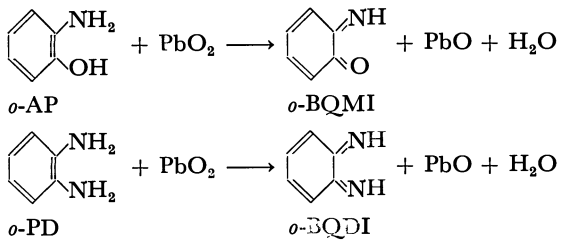
However, they could not be identified well because of the difficulties in their purifications.

* Present address: Sharp, Co. Ltd., Nagaike-cho, Abeno-ku, Osaka 545

Measurements. The electronic absorption spectra were measured by a Stopped Flow Rapid Reaction Analyser RA 1100 (Union Giken) in the cases of rapid reaction and by a Hitachi 124 spectrophotometer in the cases of slow reaction. Infrared spectra were measured by an IR-G Spectrometer (Japan Spectroscopic Co. Ltd.).

Results and Discussion

Formations of o-Benzoquinone Mono- and Di-imines in Organic Solvents. We tried to obtain *o*-BQMI and *o*-BQDI by oxidizing *o*-AP and *o*-PD, respectively, with active PbO_2[9] in several organic solvents. As a typical example, the experimental results in diethyl ether will be described below. Yellow colored solutions were obtained after the oxidations of *o*-AP and *o*-PD as described in the experimental section. Since the yellow compound obtained could not be isolated because of their instabilities, they were identified as *o*-BQMI and *o*-BQDI from their reactivities and electronic absorption spectra in diethyl ether, the latter of which are similar to that of the isoelectronic *o*-benzoquinone. Figure 1 shows the electronic absorption spectra of *o*-AP–PbO_2 and *o*-PD–PbO_2 systems and of *o*-benzoquinone (*o*-BQ) obtained by the oxidation of catechol with Ag_2O.[11] The close similarity of the absorption spectra of *o*-AP–PbO_2 and *o*-PD–PbO_2 systems to *o*-BQ (λ_{max} 365 nm, 350 nm and 372 nm, respectively) shows that the yellow compound obtained in the solution would be *o*-BQMI and *o*-BQDI. These identifications seem to be reasonable also when the reactions of these compounds with aromatic amines are considered as to be described later. The formation schemes of *o*-BQMI and *o*-BQDI are as follows.



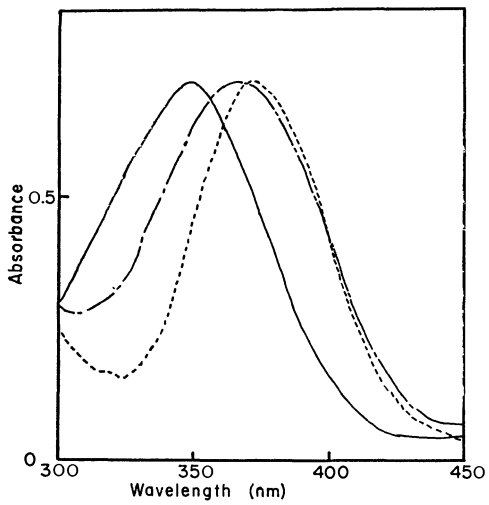


Fig. 1. Absorption spectra of *o*-BQ, *o*-BOMI, and *o*-BQDI. Concentration: 7.4×10^{-4} M.
····· *o*-BQ, ---- *o*-BQMI, —— *o*-BQDI.

The formations of *o*-benzoquinone imines in solution seem to be quantitative, since no starting amine was detected after the reaction. Thus, the extinction coefficients of *o*-BQMI and *o*-BQDI at absorption peaks were estimated as [12]: *o*-BQMI, λ_{max}=365 nm, ε=1100; *o*-BQDI, λ_{max}=350 nm, ε-1300.

Both *o*-BQMI and *o*-BQDI could be obtained also in toluene, chloroform, acetone, and acetonitrile, but not in methyl alcohol and ethyl alcohol, since their reactivities in these solvents are too large. Table 1 shows the absorption peaks of *o*-BQMI and *o*-BQDI in several solvents. The absorption peak tends to shift to the shorter wavelength region with increasing solvent polarity, being characteristic to $n\pi^*$ transition. We have also succeeded in obtaining the absorption spectra of *o*-BQMI and *o*-BQDI or their protonated species[13] in water by the following manner: An ether solution of *o*-BQMI or *o*-BQDI was poured into an aqueous buffer solution (pH 4.35), and the absorption spectra of the water phase was measured immediately. The results are also shown in Table 1.

Table 1. Absorption peaks of *o*-BQMI and *o*-BQDI in several solvents

	Toluene	Chloroform	Ether	Acetone	Aceto-nitrile	Buffer solution (pH 4.35)

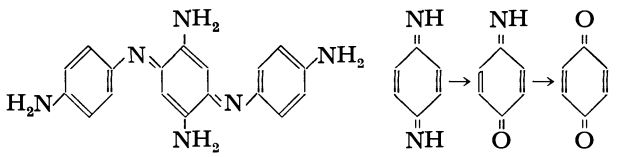
o-BQDI	358	352	350	346	338	382

Formations and Reactions of o-BQMI and o-BQDI in Aqueous Buffer Solution. J. F. Corbett studied the formations and reactions of *p*-BQMI and *p*-BQDI by oxidizing *p*-aminophenol (*p*-AP) and *p*-phenylenediamine (*p*-PD), respectively, with potassium hexacyanoferrate (III).[3,14] In *p*-AP–$K_3Fe(CN)_6$ and *p*-PD–$K_3Fe(CN)_6$ systems, no reaction occurs at pH<4, but the formations of dyes (unknown in the former system and Bandrowski's base in the latter system) occurred by the reaction of *p*-benzoquinone imines once formed with amines in the pH range 4—8. He also reported that the hydrolyses of *p*-BQMI and *p*-BQDI occurred to produce *p*-benzoquinone as shown below.[14]



Bandrowski's base *p*-BQDI *p*-BQMI *p*-BQ

In order to compare the reactivities of the isomeric *o*-benzoquinone imines, we have carried out the analogous studies of the reactions in *o*-AP–$K_3Fe(CN)_6$ and *o*-PD–$K_3Fe(CN)_6$ systems at pH 4.5, 6, 7, 8, 9, 10, 11, and 12. The initial fast reactions were followed by a stopped flow technique to obtain the spectral change from zero to a few seconds after mixing. The succeeding slow reactions were followed by a conventional electronic absorption measurements. The main features of the reactions and absorption peaks of various species

involved in the reactions are summarized in Table 2 and Table 3, respectively.

(1) o-AP–$K_3Fe(CN)_6$ System. In the pH range 4.5—6, no distinct change of the absorption spectra was observed for a few seconds, but a gradual formation of 2-aminophenoxazin-3-one (APZ) peaking at 435 nm for observed was several hours. In the pH range 7—8, *o*-BQMI was observed together with *o*-benzoquinone (*o*-BQ) and APZ. The typical results at pH 7 is shown in Figs. 2(a), 2(b), and 2(c) ($[o\text{-AP}]=2.0\times10^{-4}$ M, $[K_3Fe(CN)_6]=4.0\times10^{-4}$ M). The increase of the *o*-BQMI band at 390 nm together with the decrease of $K_3Fe(CN)_6$ band at 420 nm was observed for 0.1 s with an isosbestic point at 395 nm. Thereafter, the *o*-BQ band at 415 nm increased from 0.1—0.9 s, the assignment being made from the comparison of this band with the spectrum of *o*-BQ in aqueous solution which was obtained by extracting the ether solution of *o*-BQ with the buffer solution. APZ band increased gradually after 0.9 s. In the pH range 9—12, the

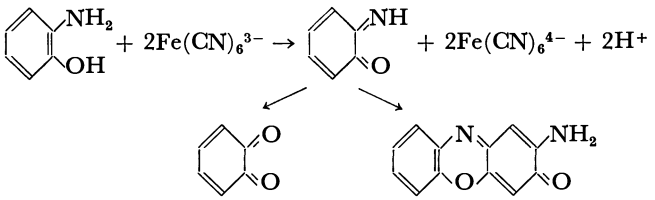
(1) 1 min, (2) 7 min, (3) 30 min.

formation of *o*-BQMI was clearly found at 390 nm with the decrease of $K_3Fe(CN)_6$. At the later stage of the reaction, APZ was found to be formed at pH 9 and 10, but the final reaction product at pH 11 and 12 could not be identified well. The spectral change at pH 9 is shown in Figs. 3(a) and 3(b) as a typical example ($[o\text{-AP}]=2.0\times10^{-4}$ M, $[K_3Fe(CN)_6]=4.0\times10^{-4}$ M).

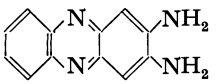
The above mentioned reactions of this system may lead us to the following conclusion. (1) the results in the pH range 4.5—10 show that APZ is the final reaction product of the oxidation of *o*-AP. (2) *o*-BQ observed in the pH range 6—8 is produced by the hydrolysis of *o*-BQMI. This is supported by the fact that *p*-benzoquinone is produced by the hydrolysis of *p*-BQMI or *p*-BQDI.[14] (3) The results in the pH

range 8—9 suggest that *o*-BQMI is a precursor to the APZ formation. This point may be made more conclusive later in this paper. The discussions (1)—(3) lead to the following reaction scheme:



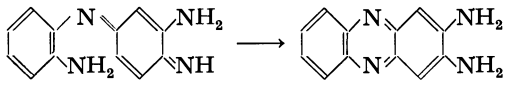
The formation scheme of APZ from *o*-BQMI will be discussed later.

(2) o-PD–$K_3Fe(CN)_6$ System. In the pH range 4.5—8, no distinct spectral change was observed by a stopped flow method at the initial stage of the reaction, but 2,3-diaminophenazine (DAP) (λ_{max}=445 nm (pH 4.5), 423 nm (pH 6), 418 nm (pH 7—12)) was found to be formed slowly with the decrease of $K_3Fe(CN)_6$.



DAP

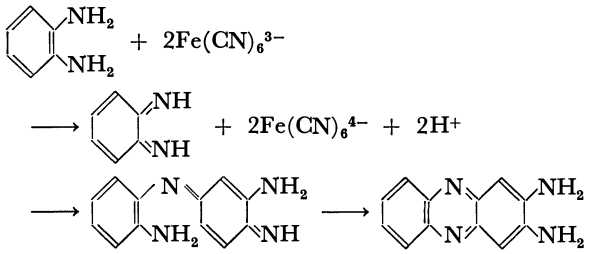
The red-shift of the absorption spectrum of DAP in acidic solution is probably due to the protonation of the amino group. The spectroscopic course of the reactions in the pH range 9—12 can be explained by a typical example at pH 12 (Figs. 4(a) and 4(b), [*o*-PD]=2.0×10^{-4} M, [$K_3Fe(CN)_6$]=4.0×10^{-4} M). Formation of *o*-BQDI was clearly observed with the decrease of $K_3Fe(CN)_6$ for about 0.35 s, the yield of *o*-BQDI being higher with increasing pH values. After the formation of *o*-BQDI, the increase of the absorption band around at 500 nm was observed, which then decreased to produce DAP with an isosbestic point at 478 nm. The compound peaking at 500 nm seems to be the precursor to the DAP formation, but could not be isolated because of its instability. We assigned it as 2-amino-*N*-(2-aminophenyl)-*p*-benzoquinone diimine (AABI) from the following reasons: (1) It is reasonable that cyclization of AABI produces DAP, which was clarified recently by J. F. Corbett *et al.*[15]



AABI DAP

(2) Absorption peak around 500 nm is reasonable in view of the fact that many *p*-indamine derivatives have their absorption peaks between 450—550 nm.[15,16]

These experimental results, especially of pH 9—12, show that *o*-BQDI may be a precursor to the DAP formation, and lead us to the following reaction scheme:



The formation scheme of AABI from *o*-BQDI will be discussed later. The high yield of *o*-BQDI at high pH range may be due to the efficient neutralization of the proton in the above oxidation process. The hydrolysis of *o*-BQDI was not observed, being in striking contrast to the cases of *o*-BQMI, *p*-BQMI and *p*-BQDI.

Reaction of o-BQMI and o-BQDI in Diethyl Ether.[8] As shown previously, oxidations of *o*-AP and *o*-PD with $K_3Fe(CN)_6$ in an aqueous buffer solution produce APZ and DAP, respectively, but the reaction rate in the initial stage is too fast to make clear the reaction scheme. Since in these reactions *o*-BQMI or *o*-BQDI is formed initially and APZ or DAP is produced thereafter as a main reaction product, *o*-benzoquinone imines are considered to be the intermediate for the products. To make clear the reaction scheme, the reactions of *o*-BQMI with *o*-AP and that of *o*-BQDI with *o*-PD were investigated in diethyl ether by measuring the change of the absorption spectra with time, because the reaction rate is considerably reduced in this solvent.

(1) o-BQMI–o-AP System. When a diethyl ether solution of *o*-BQMI was kept at a room temperature, some amount of APZ was produced slowly, *o*-BQMI being thus somewhat unstable in the solution. When *o*-AP was added to the *o*-BQMI solution, however, APZ was produced much faster. The fact shows that APZ is produced mainly by the reaction between *o*-BQMI and *o*-AP. Figs. 5(a) and 5(b) show the spectroscopic course of the reaction in *o*-BQMI- *o*-AP system ([*o*-BQMI]=3.1×10^{-4} M, [*o*-AP]=2.8×10^{-4}M) at a room temperature (Fig. 5(a), 0—5 hr after mixing; Fig. 5(b), 5—10 hr after mixing). The *o*-BQMI band at 365 nm decreased and a new band at 495 nm increased for the first five hr with an isosbestic point at 336 nm,[17] but thereafter the latter band decreased. Apparent induction period was observed for the increase of the characteristic APZ band at 405 and 425 nm (Fig. 5(a)), and isosbestic points appeared again at 465 and 336 nm in the later half of the reaction (Fig.

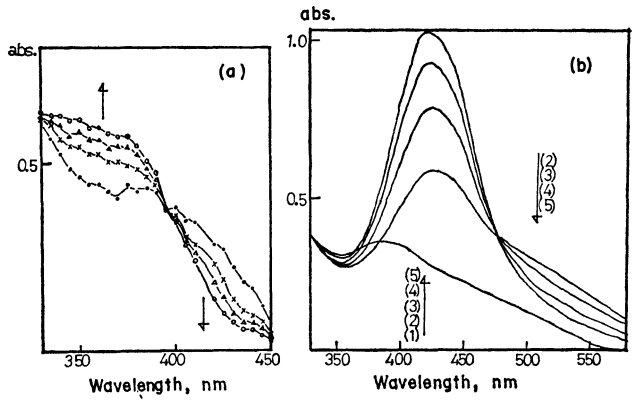


Fig. 4. Spectroscopic course of the reaction in *o*-PD–$K_3Fe(CN)_6$ system at pH 12. [*o*-PD]=2.0×10^{-4} M, [$K_3Fe(CN)_6$]=4.0×10^{-4} M.

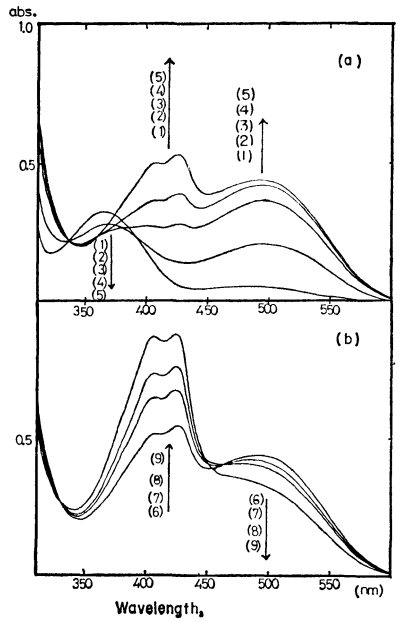

Fig. 5. Spectroscopic course of the reaction in *o*-BQMI–*o*-AP system in diethyl ether. [*o*-AP]$=2.8\times10^{-4}$ M, [*o*-BQMI]$=3.1\times10^{-4}$ M, estimated from the initial concentration of *o*-AP in the preparation of *o*-BQMI. (a) (1) 1 min, (2) 28 min, (3) 102 min, (4) 180 min, (5) 300 min. (b) (6) 312 min, (7) 417 min, (8) 462 min, (9) 567 min.

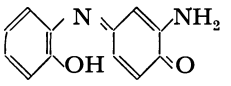
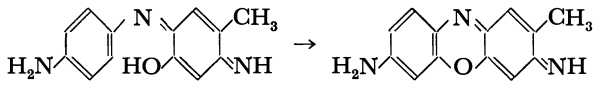
5 (b)). Fig. 5 (b) shows that the species peaking at 495 nm is a precursor to the APZ formation, but we could not isolate it because of its easy conversion into APZ during the isolation. We assigned this intermediate as 2-amino-*o*-indophenol (AIP) from the following

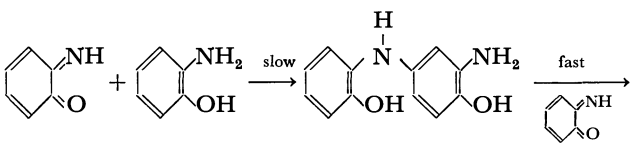


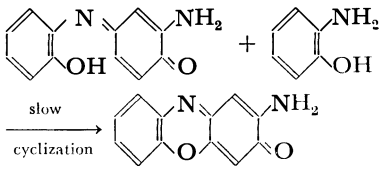
AIP

reasons: (1) It is quite reasonable that AIP has its absorption peak at 495 nm in view of the facts that many *p*-indophenol derivatives are reported to have their absorption peaks between 470 and 510 nm.[18] (2) As hydroxyindamine derivatives, for example, cyclize easily into phenoxazine-3-imine derivatives as shown below,[18] cyclization reaction of AIP to produce APZ is reasonable.[19]



AIP itself may be produced by the addition reaction of *o*-BQMI with *o*-AP. Namely, by this reaction a leuco base of AIP, though not detected, may be formed in the initial stage of the reaction, followed by the oxidation of this leuco compound with *o*-BQMI.[20] Thus, the reaction mechanism in the present system is expected to be as follows.





We believe that this scheme also holds in the reaction of *o*-AP–$K_3Fe(CN)_6$ system, although not clarified yet.

(2) o-BQDI– o-PD System. When diethyl ether solution of *o*-BQDI was kept at a room temperature, some amount of 2,2′-diaminoazobenzene (AB) was produced slowly, *o*-BQDI being thus somewhat unstable in the solution. When *o*-PD was added to the *o*-BQDI solution, however, AB was produced much faster. This fact shows that AB is produced mainly by the reaction between *o*-BQDI with *o*-PD. Figure 6 shows the spectroscopic course of the reaction in *o*-BQDI–*o*-PD system ([*o*-BQDI]$=3.8\times10^{-3}$ M, [*o*-PD]$=9.5\times10^{-4}$ M) at a room temperature. This figure shows that with decreasing intensity of the *o*-BQDI band at 352 nm, the intensity of AB band at 470 nm increased

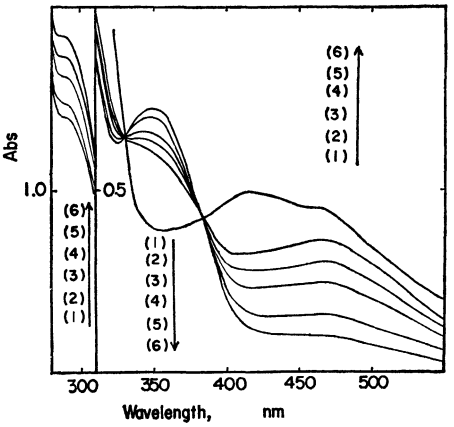


Fig. 6. Spectroscopic course of the reaction in *o*-BQDI–*o*-PD system in diethyl ether. [*o*-PD]$=9.5\times10^{-4}$ M, [*o*-BQDI]$=3.8\times10^{-3}$ M, estimated from the initial concentration of *o*-PD in the preparation of *o*-BQDI.
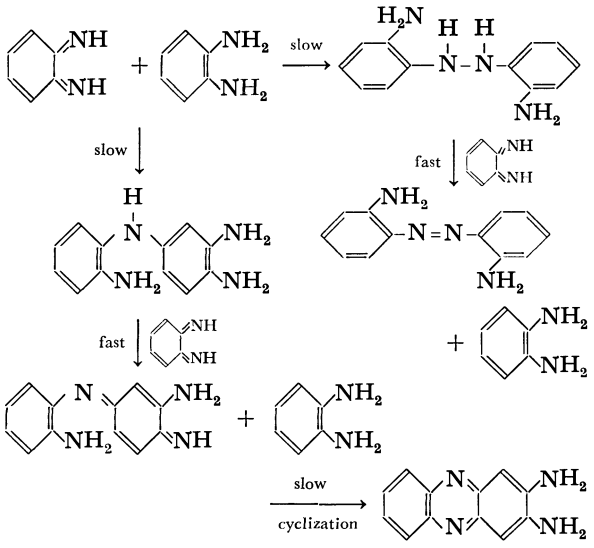
(1) 1 min, (2) 8 min, (3) 41 min, (4) 85 min, (5) 164 min, (6) 24 hr.



with an isosbestic point at 380 nm, followed by the formation of DAP (λ_{max} 430 nm) in the later stage of the reaction. The reaction scheme for the formations of AB and DAP in *o*-BQDI–*o*-PD system is supposed to be as shown below: DAP is probably produced through AABI[21] as in the case of *o*-PD–$K_3Fe(CN)_6$ system in water, and AABI itself may be produced by the oxidation of its leuco base with *o*-BQDI. The formation of AB through 2,2′-diaminohydrazobenzene is suggested from the similarity of the reaction to those of *p*-BQDI with several aromatic amines.[20]
Unfortunately, the intermediate AABI could not be detected clearly in diethyl ether, probably because the absorption band of AABI is covered with that of AB. The reason why AB is not produced sufficiently in aqueous buffer solution has not been clarified yet.

o-Benzoquinone imines have long been considered as the possible intermediates in the oxidation reactions of *o*-AP and *o*-PD,[5,6] and this has been demonstrated for the first time in the present study.

We express our sincere gratitudes to Professor T. Tanaka and his collaborators in Osaka University for affording facilities for the stopped flow measurements.

Optical Activation of α-Substituted Carbonyl Compounds by Asymmetric Transformation

Hajime MATSUSHITA, Masao NOGUCHI, Masahiko SABURI*, and Sadao YOSHIKAWA*

Central Research Institute, The Japan Tobacco and Salt Public Corporation, 6-2 Umegaoka, Midori-ku, Yokohama, Kanagawa 227

**Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received August 11, 1975)

Immonium salts of enamines of racemic α-substituted carbonyl compounds with optically active acids gave, on hydrolysis with water, the corresponding optically active carbonyl compounds. Several reaction conditions were examined and a plausible reaction mechanism, an asymmetric transformation, was proposed. Rates of racemization for the (+)-α-phenylpropionaldehyde were also determined.

The synthesis of optically active carbonyl compounds has been considered of interest in the field of terpenoids, steroids and alkaloids.[1] Resolutions of racemic carbonyl compounds (chemical and biochemical),[2,3] asymmetric destruction,[4] asymmetric synthesis[5] and asymmetric transformation[6] have been reported. In the resolution and asymmetric destruction, the maximum theoretical yield of either pure enantiomer based on the original weight of the racemic material is obviously 50%. In an asymmetric synthesis, there are many restrictions and higher yields in optical activity usually give lower yields of the product. On the other hand, in the asymmetric transformation, although a resolution method, the theoretical yield of one pure enantiomer exceeds 50%. One enantiomer was obtained in nearly 100% yield by this method.[7]

This paper deals with a phenomenon which can be accounted for by the asymmetric transformation. The enamines of racemic α-substituted carbonyl compounds were treated with optically active acids. Hydrolysis of the salts gave the optically active carbonyl compounds. This is a new method to get optically active α-substituted carbonyl compounds from their racemic forms.

Seven carbonyl compounds, α-phenylpropionaldehyde(**1**), 2-ethylhexanal(**2**), 2-methylcyclohexanone(**3**), 2-(2-cyanoethyl)cyclohexanone(**4**), methyl 3-(2-oxocyclohexyl)propionate(**5**), 2-(2-cyanoethyl)cyclopentanone(**6**) and methyl 3-(2-oxocyclopentyl)-propionate(**7**) were examined.

Pyrrolidine, piperidine and 2-methylpiperidine were used as the amine components of the enamines.

Experimental

Optical activities were determined with a JASCO Digital Automatic Polarimeter Model DIP 181. Gas chromatographic analyses were carried out on a 2 m column of 5% Carbowax 20M on Chromosorb W with a Hitachi Gas Chromatograph, Model K53.

Preparation of Enamines. Enamines of **1**, **2** and **3** were prepared by the usual azeotropic procedures with benzene as a solvent. Pyrrolidine enamines of **4**, **5**, **6** and **7** were synthesized according to the method of Stork *et al.*[8] The enamines obtained were directly subjected to the subsequent procedures without further purification.

Pyrrolidine enamine of **1**: bp 108—109 °C (6.5 mmHg), 91% yield; IR 1635 cm^{-1} ($\nu_{C=C}$). Piperidine enamine of **1**: bp 84—109 °C (7 mmHg), 85.9% yield; Mass *m/e* 201 (M^+, Parent); IR 1637 cm^{-1} ($\nu_{C=C}$); NMR($CDCl_3$) mixture of two geometrical isomers, 1.97 and 2.09 (C=C–CH_3, s), 5.82 and 6.11 (N–CH=C, s). 2-Methylpiperidine enamine of **1**: bp 129—130 °C (5 mmHg), 71.2% yield; Mass *m/e* 215 (M^+), 200 (Parent); IR 1638 cm^{-1} ($\nu_{C=C}$); NMR($CDCl_3$) mixture of two geometrical isomers though one isomer existed in a trace amount, 1.03 (N–C–CH_3, d, *J* 6.7 Hz), 2.09 (C=C–CH_3, s), 6.40 (N–CH=C, s).

Pyrrolidine enamine of **2**: bp 95—96.5 °C (9 mmHg), 92.3% yield; Mass *m/e* 181 (M^+), 138 (Parent); IR 1658 cm^{-1} ($\nu_{C=C}$).

Piperidine enamine of **2**: This was reported by Opitz *et al.*[9] 2-Methylpiperidine enamine of **2**: bp 97—99 °C (6 mmHg), 93.8% yield; Mass *m/e* 209 (M^+), 166 (Parent); IR 1664 cm^{-1} ($\nu_{C=C}$); NMR($CDCl_3$) 5.12 (N–CH=C, s). Pyrrolidine enamine of **3**: This was reported by House and Schellenbaum.[10]

Piperidine enamine of **3**: This was reported by Gurowitz and Jaseph.[11] 2-Methylpiperidine enamine of **3**: bp 136 °C (8.5 mmHg), 65% yield; Mass *m/e* 193 (M^+), 178 (Parent); IR 1634 cm^{-1} ($\nu_{C=C}$): NMR($CDCl_3$) 0.83 (N–C–CH_3, d, *J* 6.0 Hz), 1.70 (CH_3–C–C–N, s).

Salt of Enamines and Their Hydrolysis. The preparation and hydrolysis of the salt of piperidine enamine of **1** with D-10-camphorsulfonic acid (**8**) were carried out as follows.

Acid **8** (0.02 mmol) was added to a benzene solution (30 ml) of **1** (0.02 mmol), and the mixture was stirred until **8** was completely dissolved. Water (15 ml) was added dropwise to the solution in an ice bath with vigorous stirring. The reaction was continued until completion of the hydrolysis which was confirmed by gas chromatography. The benzene layer was separated, successively washed with water, 5% aqueous sodium carbonate and water, dried over anhydrous sodium sulfate; the optical activity was then measured.

Recovery of the carbonyl compound was determined with

a gas chromatograph. The same procedure was applied to the other enamines except for those of **4**, **5**, **6** and **7**. These were subjected to synthesis, after which the solvent (dioxane) was replaced with benzene, and the benzene solutions were then subjected to the same procedure as that for the enamine of **1**. The liberated carbonyl compounds were isolated by vacuum distillation, and the optical rotation of the distillates were measured.

Examination of the Solvent Effect. The immonium salt of **1** with **8** in several solvents was similarly hydrolyzed. The solvent was distilled off *in vacuo* and the residue was dissolved in benzene. The solution was washed and dried as in the case of the enamine of **1** and its optical activity was measured.

Rapid racemization took place when a few drops of 0.05 M KOH alcoholic solution were added to the solution.

Results and Discussions

Hydrolysis of the Immonium Salts. The results of the hydrolysis of the immonium salts are summarized in Table 1. Fairly optically active carbonyl compounds were obtained in all the cases examined. No by-products other than each carbonyl compounds were detected in the benzene solution. As blank experiments, phenylacetaldehyde and cyclohexanone, which have no asymmetric carbons, were examined. The immonium salts of *N*-(2-phenyl-1-propenyl)-piperidine[12] and *N*-(1-cyclohexenyl)piperidine[12] were treated according to the same procedure. Contamination of **8** was found to be negligible. The optical rotations of the α-phenylpropionaldehyde recovered were the most active ones of all, although that of the pure enantiomer is still unknown.

Investigation of Racemization. Optically active **1** was easily racemized with acid or base at 23 °C. The racemization rates in the presence of 12.5% CH_3COOH or $N(C_2H_5)_3$ in benzene, and 0.7% *p*-toluenesulfonic acid or 0.25% D-10-camphorsulfonic acid in benzene–ethanol (1 : 1) were measured. In every case, a plot of log α_0/α *vs.* time gives a straight line. The half-life period for each case was 200.7, 18.8, 21.8 and 19.9 min. Optically active **3** was racemized very quickly with a strong base, such as KOH. On the other hand, the racemization of **8** could not be detected under these conditions. This shows that the observed optical rotations were not due to the contamination of **8**. The rate of racemization of **1** was fairly high in the presence of **8**, which indicates that the real optical activity attained would have been larger than the observed activity.

Table 1.

Carbonyl compounds	Amines	$[\alpha]_D^{23}$	Recovery (%)

The Effect of Acid Component. The piperidine enamine of **1** was treated with each of several optically active acids in benzene solution, and the resulting mixture was hydrolyzed in an ice bath. The rate and the end point of the hydrolysis were measured by gas chromatography. The results are shown in Table 2. The salt with **8** was hydrolyzed rapidly, and gave high active **1**. On the other hand, the rates of hydrolysis of those with the other acids were slow, and the activities of the products were low. This tendency was also observed with other immonium salts. The most suitable acid among the acids examined was **8**. Its strong acidity as well as its steric factor might largely contribute to the introduction of optical activity.

Table 2. Effect of acid component

Acids	Time (min)	$[\alpha]_D^{23}$	Recovery (%)
L-Tartaric acid	80	−0.93 (*c* 7.3)	97.8
D-Camphoric acid	75	+2.61 (*c* 3.4)	53.3
D-Quinic acid	80	+0.56 (*c* 3.2)	29.8
8	35	+16.2 (*c* 3.67)	89.6

Solvent Effect. The immonium salts of the enamines of **1** with **8** were prepared in several solvents and subjected to hydrolysis. The amount of water used for the hydrolysis did not affect the activity. In non-polar aprotic solvents, such as benzene, high optically active **1** was obtained (Table 3). It is known that strong acid components and non-polar solvents are preferable for the stability of immonium salts.[13] The result of the solvent effects as well as the acid components suggests that the stability of an immonium salt is an important factor for the introduction of optical activity.

Mechanism of Introduction of Optical Activity. Enamines have been studied and applied by many workers since they were first described by Mannich and Davidsen.[12] The structure of enamines and their salts,[13] and mechanism of the hydrolysis[8] have been subjects of great interest.

It was found that formation of an enamine causes deprotonation from the α-carbon of the carbonyl compound, and formation of the immonium salt causes protonation to the carbon, which is the first step of hydrolysis. We found no evidence of the formation of immonium salts. However, the above mechanism seems to be appropriate to account for the observed stereospecificity. When the enamine of a racemic α-substituted carbonyl compound is

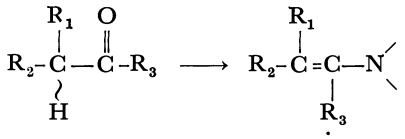
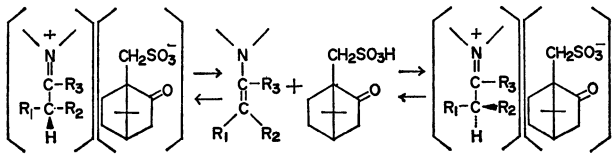
formed by the removal of the α-hydrogen atom, such an enamine has an enantiotropic plane but no asymmetric α-carbon atom.

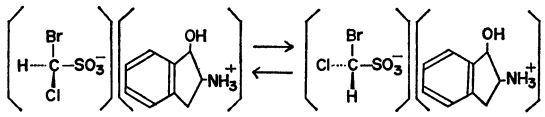


Racemic form Enamine

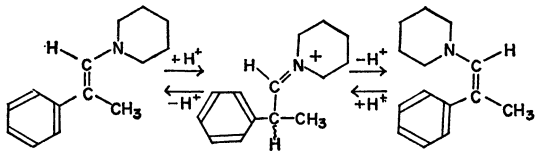
Addition of an optically active acid causes the protonation of the α-carbon to form the immonium salt. The immonium salt would exist as an equilibrium mixture of two diastereomeric isomers. The enamine could be considered to be an intermediate of the isomers in the solution.



Displacement of the balance of the interconversion reactions in favor of one diastereomeric isomer results in an optically active carbonyl compound. The lability of the enamine is shown by the equilibrium of the two geometrical isomers of the piperidine enamine of **1**. The proportion of the two isomers depends on temperature. Attainment of the equilibrium was fairly rapid, and accelerated by the use of some acid.



The mechanism mentioned above seems to be an asymmetric transformation reported by Read and McMath.[14] They reported the equilibrium of the two diastereomeric chlorobromomethanesulfonic acid with an equivalent of active 1-hydroxy-2-aminoindan in a dilute acetone solution, the resulting solution exhibit mutarotation. An examination of the rotation at equilibrium shows that the solution contains 81% of the salt of one isomer and 19% of that of the other one. Attempts to liberate the active acid from the solution were not successful.



From the mechanism of the asymmetric transformation, the factor which determines the degree of optical activity is considered to be the stability of diastereomeric immonium salts.

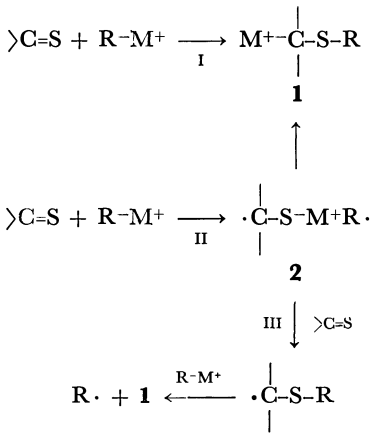
(Received August 14, 1975)

Thiobenzophenone reacts with butyllithium, phenyllithium, and sodium ethoxide in ethanol giving benzhydryl butyl sulfide, benzhydryl phenyl sulfide, and dibenzhydryl disulfide, respectively. On the other hand di-*t*-butyl thioketone affords 2,2,4,4-tetramethylpentane-3-thiol, 2,2,4,4-tetramethyl-3-phenylpentane-3-thiol, and 2,2,4,4-tetramethylpentane-3-thiol by the reaction with butyllithium, phenyllithium, and sodium ethoxide in ethanol, respectively. Product analyses and tracer experiments with deuteriums have revealed that these reactions proceed through a charge-transfer mechanism.

Thiophilic addition of nucleophiles to thiocarbonyl compounds has been reported by several groups.[1-4] Namely, Beak and Worley proposed three possible mechanisms for thiophilic reaction of thiocarbonyl groups (thiobenzophenone and phenyl trithiocarbonate) with phenyllithium.[1b] One of those is based on the concept that the bonding electrons of the thiocarbonyl group are intrinsically polarized with carbon negative relative to sulfur. Dipole moment[5] and SCF-LCAO-MO calculation[6] support the intrinsic polarity of the thiocarbonyl group proposed. Second mechanism involves the formation of a charge-transfer (CT) complex between a thiocarbonyl compound and a nucleophile followed by an in-cage radical combination giving an ion-pair, **1**. The presence of the thioketyl



radicals in the reacting solution has been confirmed by ESR spectroscopy.[1b,7] This mechanism, however, cannot explain why the free-radical R· in **2** attacks on the sulfur instead of attacking on the carbon, on which locates an unshared electron. The third mechanism consists of free-radical chain reactions. That the thiocarbonyl-sulfur is a good acceptor of a carbon free-radical has been proved.[8,9]

In this paper, we wish to report unequivocal evidence to support the CT-intermediate—radical-combination mechanism (Process II) for the reaction of thioketones with nucleophiles.

Results

Thiobenzophenone reacts with butyllithium affording benzhydryl butyl sulfide (**3**) in 70% yield as previously reported.[1,10] On the other hand, di-*t*-butyl thioketone[11] is reduced quantitatively by this reagent to the corresponding thiol, **4**, under the same condition.[10]

$$Ph_2C{=}S + Bu^nLi \longrightarrow Ph_2\overset{Li^+}{\overline{C}}{-}SBu^n \xrightarrow{H^+/H_2O} \underset{\mathbf{3}}{Ph_2CHSBu^n} \quad (1)$$

$$Bu^t_2C{=}S + Bu^nLi \longrightarrow Bu^t_2CH{-}S^-Li^+ + C_2H_5CH{=}CH_2$$
$$\downarrow H^+/H_2O \quad (2)$$
$$\underset{\mathbf{4}}{Bu^t_2CHSH}$$

That butyllithium-β,β-d_2 transfers the deuterium onto the thiocarbonyl-carbon and that the reaction with butyllithium gives **4**-*S*-*d* after the treatment of the reaction mixture with deuterium oxide prove the reaction scheme shown in Eq. 2. It is noteworthy that, in general, organolithium compounds are less susceptible to the reduction of carbonyl compounds than Grignard reagents.[12]

The reaction of thiobenzophenone with phenyllithium affords benzhydryl phenyl sulfide (**5**),[1] whereas the same reaction with di-*t*-butyl thioketone results in the formation of **6** and **7** in 25 and 35% yields, respectively.[10]

$$Ph_2C{=}S + PhLi \longrightarrow Ph_2\overset{Li^+}{\overline{C}}{-}SPh \xrightarrow{H^+/H_2O} \underset{\mathbf{5}}{Ph_2CHSPh} \quad (3)$$

$$Bu^t_2C{=}S + PhLi \longrightarrow Bu^t_2C\langle^{S^-Li^+}_{Ph} + Bu^t_2\overset{Li^+}{\overline{C}}{-}SPh$$
$$\xrightarrow{H^+/H_2O} \underset{\mathbf{6}}{Bu^t_2C\langle^{SH}_{Ph}} + \underset{\mathbf{7}}{Bu^t_2CHSPh} \quad (4)$$

Essentially the same result was obtained when the organolithium compound was substituted by the corresponding Grignard reagent.

The reaction of thiobenzophenone with ethanol in the presence of sodium ethoxide at room temperature *in vacuo* ($\sim 10^{-6}$ Torr) in the dark resulted in the quantitative formation of dibenzhydryl disulfide (**8**)[13] immediately. A similar reaction with di-*t*-butyl thioketone gave **4** in quantitative yield after a day at 60 °C. The

$$Ph_2C=S + C_2H_5OH/C_2H_5O^-Na^+ \longrightarrow Ph_2CHSSCHPh_2 \quad (5)$$
8

$$Bu^t_2C=S + C_2H_5OH/C_2H_5O^-Na^+ \longrightarrow Bu^t_2CHS^-Na^+ \xrightarrow{H^+/H_2O} \mathbf{4} \quad (6)$$

results listed in Table 1 were obtained from the reactions with deuterated alcohols, which indicate that thiobenzophenone abstracts a proton from the solvent whereas di-*t*-butyl thioketone abstracts a hydrogen atom.

All reactions in Eqs. (1)—(6) were not affected by the presence of equimolar (to the thioketone) amount of hydroquinone, or the presence of air except for the reaction in Eq. (6), which afforded the corresponding disulfide under an aerobic condition. In other words, the formation of **8** cannot be accounted for by the oxidation of benzhydryl mercaptan. Instead, it might be formed by the combination of benzhydryl mercapto radicals.

Discussion

Since the phenyl group, or even the *t*-butyl group,[14] is bound to the carbonyl-carbon in di-*t*-butyl ketone, the difference of the reaction mode cannot be attributed to the steric effect in the reactants. The present result is best interpreted by assuming CT-intermediates for each reactions. Preliminary INDO-type molecular orbital calculations on anion radicals of thioacetone and thiobenzaldehyde, models for di-*t*-butyl thioketone and thiobenzophenone, respectively, indicate that a phenyl group attached to the thiocarbonyl group increases intrinsic negative charge on carbon and spin density on sulfur, respectively, in comparison to an aliphatic substituent (Table 2). That is, structures (or the most important canonical forms, i. not exclusive) for the radical anions of thiobenzophenone and di-*t*-butyl thioketone may be represented by **9** and **10**, respectively.

$$Ph_2\bar{C}-S\cdot \qquad Bu^t_2\dot{C}-S^-$$
9 **10**

Consequently, thiobenzophenone and di-*t*-butyl thioketone are expected to form CT-intermediates, **11** and **12**, respectively, in reactions with nucleophiles.

$$Ph_2C=S + R^-M^+ \longrightarrow \overset{M^+\ R\cdot}{Ph_2\bar{C}-S\cdot} \quad (7)$$
11

$$Bu^t_2C=S + R^-M^+ \longrightarrow \overset{R\cdot\quad M^+}{Bu^t_2\dot{C}-\bar{S}} \quad (8)$$
12

Under an aprotic condition, **11** is stabilized by radical-combination, whereas **12** is stabilized by either radical-combination or hydrogen-transfer, when possible.

$$\mathbf{11} \xrightarrow{M^+} Ph_2\bar{C}-SR \xrightarrow{H^+} \mathbf{3}\ (R=Bu^n) \text{ or } \mathbf{5}\ (R=Ph) \quad (9)$$

$$\mathbf{12} \begin{cases} \xrightarrow{R=Ph} Bu^t_2C\langle^{S^-M^+}_{Ph} \xrightarrow{H^+} \mathbf{6} \\ \xrightarrow[R=R'CH_2Z]{} Bu^t_2CHS^-M^+ \xrightarrow{H^+} \mathbf{4} + R'CH=Z \end{cases} \quad (10)$$

(Z=CH_2, O)

Note that a thiyl radical has less ability than a carbon radical to abstract a hydrogen atom.[15]

Under a protic condition, on the other hand, **11** abstracts a proton from the solvent to form a stable thiyl radical rather than to form relatively unstable carbanion. The fate

$$\mathbf{11} + C_2H_5OH \longrightarrow Ph_2CHS\cdot + C_2H_5O^-Na^+ + C_2H_5O\cdot \quad (11a)$$
$$\downarrow$$
$$\mathbf{8}$$

and/or

$$\mathbf{11} \longrightarrow Ph_2\bar{C}SS\bar{C}Ph_2\ ^{Na^+Na^+} \xrightarrow{C_2H_5OH} \mathbf{8} + C_2H_5O^-Na^+ \quad (11b)$$
$$+$$
$$C_2H_5O\cdot$$

$$C_2H_5O\cdot + C_2H_5OH \longrightarrow C_2H_5OH + CH_3\dot{C}HOH \quad (12)$$

$$CH_3\dot{C}HOH \xrightarrow{-H\cdot} CH_3CH{=}O \quad (13)$$
$$(R^-M^+ = C_2H_5O^-Na^+)$$

of ethoxy radical is well known.[16] The reaction in Eq. (12) explains the scrambling of deuterium.

Similarly, **12** affords a stable thiolate anion by hydrogen-abstraction instead of forming an unstable carbon radical.

$$\mathbf{12} \longrightarrow Bu^t{}_2CHS^-Na^+ + CH_3CH{=}O \quad (14)$$
$$(R^-M^+ = C_2H_5O^-Na^+)$$

About 20% of scrambling in the last reaction indicates that not all of the radical-ion pairs, **12**, undergo the spontaneous reaction shown in Eq. (14). Instead some of them dissociate and the ethoxy radical abstracts a hydrogen from ethanol (Eq. (12)). Note that the reaction with di-*t*-butyl thioketone is much slower than that of thiobenzophenone, which may describe larger scrambling in the reaction of di-*t*-butyl thioketon than in the reaction of thiobenzophenone.

The proposed mechanism is supported by the fact that the reaction of thiobenzophenone with sodium ethoxide in an aprotic solvent such as tetrahydrofuran or diglyme affords benzhydryl mercaptan in 79% yield together with small amount (10% yield) of the disulfide, **8**. Since there is no proton in the system and the sulfenate, expected to be formed by radical combination, is an unstable compound, **11** has to be stabilized by hydrogen-atom-transfer.

$$\mathbf{11} \xrightarrow{+H\cdot} Ph_2\bar{C}(^{Na^+})\text{-}SH \xrightarrow{\text{disproportionation}} Ph_2CHS^-Na^+$$
$$\downarrow H^+/H_2O \qquad\qquad \downarrow H^+/H_2O$$
$$Ph_2CHSH \qquad\qquad Ph_2CHSH$$

Experimental

Materials. Di-*t*-butyl thioketone,[11] thiobenzophenone,[17] hexyllithium,[18] and phenyllithium[19] were prepared according to literatures. Butyllithium was purchased from Merck & Co., Inc. Solvents were dried and purified by distillation prior to use. 1-Butanol-α,α-d_2 was obtained by reduction of methyl butyrate with lithium aluminium deuteride. Ethanol-*O*-*d* was purchased from Merck & Co., Inc. Butyllithium-β,β-d_2 was prepared according to the following scheme:

$$CH_3CH_2CO_2CH_3 \xrightarrow[2)\ H^+/H_2O]{1)\ LiAlD_4} CH_3CH_2CD_2OH \xrightarrow[H_2SO_4]{NaBr}$$

$$CH_3CH_2CD_2Br \xrightarrow[2)\ HCHO]{1)\ Mg} CH_3CH_2CD_2CH_2OH \xrightarrow[H_2SO_4]{NaBr}$$

$$CH_3CH_2CD_2CH_2Br \xrightarrow{Li} CH_3CH_2CD_2CH_2Li$$

General Procedure. All reactions were run both under nitrogen atmosphere with stirring and under high vacuum of about 10^{-6} Torr. For the latter reactions a solution of thioketone, a solution of organometallic reagent, and water were respectively vacuum-sealed in ampoules, which were connected with break-seals. The thioketone and organometallic reagent were mixed through a break-seal and, at the end of the reaction, water was added to the reaction mixture through the other break-seal. The apparatus was wrapped by aluminium foil to avoid unnecessary photoreactions.

Reaction of Di-t-butyl Thioketone with Butyllithium. In to 1.2 g of 20% hexane solution of butyllithium (4 mmol), was added 316 mg (2 mmol) of di-*t*-butyl thioketone at room temperature. The color of the thioketone disappeared immediately. Water (5 ml) was added to the reaction mixture and the organic materials were extracted with ether. The ether layer was dried over Drierite and the solvent was evaporated *in vacuo*. The residue was subjected to column chromatography over silica gel with benzene eluent, yielding 2,2,4,4-tetramethylpentane-3-thiol (**4**)[10] quantitatively.

Reaction of Di-t-butyl Thioketone with Phenyllithium. Into 7 ml of ether solution containing 420 mg (5 mmol) of phenyllithium was added 574 mg (3 mmol) of di-*t*-butyl thioketone at 0 °C. Usual work-up and column chromatography over silica gel with hexane eluent gave 210 mg (25% yield) of 2,2,4,4-tetramethyl-3-phenylpentane-3-thiol (**6**)[10] and 280 mg (35% yield) of di-*t*-butylmethyl phenyl sulfide (**7**).[10]

The sulfide, **7**, was oxidized with 30% hydrogen peroxide in acetic acid by keeping the solution in a refrigerator for 2 days. The solution was neutralized with sodium bicarbonate and the product was extracted with ether. The ether layer was dried over Drierite and the solvent was evaporated *in vacuo*. The white crystals thus obtained were recrystallized from hexane giving the corresponding sulfone: mp 138 °C. NMR $\delta^{TMS}_{CCl_4}$ 1.33 (s, 18H), 3.20 (s, 1H), and 7.33—7.90 (m, 5H). ν_{SO_2} 1130 and 1290 cm^{-1}. Found: C, 66.86; H, 9.22; S, 12.11%. Calcd for $C_{15}H_{24}O_2S$: C, 67.17; H, 8.92; S, 11.94%.

Reaction of Di-t-butyl Thioketone with Sodium Ethoxide in Ethanol. Into 5 ml of ethanol, 50 mg of metallic sodium was added. This ethanol solution was mixed with a solution of di-*t*-butyl thioketone (500 mg, 3.4 mmol) in 5 ml of ethanol. The whole mixture was kept at 60 °C for a day.

The reaction under nitrogen atmosphere, after work-up and column chromatography on silica gel with an eluent of a mixture of hexane–benzene (1 : 1), gave 250 mg (50% yield) of di(di-*t*-butyl)methyl disulfide: mp 74 °C. NMR $\delta^{TMS}_{CDCl_3}$ 1.15 (s, 18H) and 2.54 (s, 1H). IR 1215, 1362, 1387, 1475, and 2950 cm^{-1}. Found: C, 67.67; H, 12.13; S, 20.02%. Calcd for $C_{18}H_{38}S_2$: C, 67.85; H, 12.02; S, 20.13%. Mass spectrum M^+: *m/e* 318.

The reaction under high vacuum yielded, after work-up and column chromatography, 490 mg (98% yield) of **4**.

Reaction of Thiobenzophenone with Sodium Ethoxide in Ethanol. Into 1 ml of ethanol was dissolved 50 mg of metallic sodium and the solution was mixed with 2 ml of ethanol solution of thiobenzophenone (480 mg, 2.4 mmol) at room temperature. The reaction took place immediately. After addition of 2 ml of water, the precipitate was filtered off and recrystallized from a mixture of benzene and ethanol giving 480 mg (99% yield) of dibenzhydryl disulfide: mp 151—152 °C (lit,[20] 151—152 °C).

Reaction of Thiobenzophenone with Sodium Ethoxide in Tetrahydrofuran. Into 10 ml of tetrahydrofuran were dissolved 198 mg (1 mmol) of thiobenzophenone and 500 mg (7.35 mmol) of sodium ethoxide at room temperature. The reaction took place immediately. After addition of 10 ml of water, the organic materials were extracted with ether. The ether layer was dried over sodium sulfate and the solvent was removed *in vacuo*. The residue was chromatographed on a column of silicic acid and eluted with a hexane–benzene (8 : 2) mixture affording 157 mg of benzhydryl mercaptan[13] and 20 mg of dibenzhydryl disulfide.

Reaction of Di-t-butyl Thioketone with Sodium Ethoxide in Tetrahydrofuran. The reaction with di-*t*-butyl thioketone was similarly run as menthioned above and **4** was isolated in quantitative yield.

2,2,4,4-Tetramethylpentane-3-thiol. Into 10 ml of solution containing 40 mg of lithium aluminium hydride was added dropwise a solution of di-*t*-butyl thioketone (158 mg, 1 mmol) in 5 ml of ether under nitrogen atmosphere at 0 °C. After usual work-up, **4** was obtained in 72% yield (115 mg).[10]

Identification of Oxidized Products. An ether solution obtained from the reaction of di-*t*-butyl thioketone with hexyllithium was subjected to vpc analysis on Yanagimoto G-1800 (5% SD-200, 2 m, 27 °C, N_2 0.4 kg/cm^2, FID). Quantitative formation of hexene was thus confirmed. Another ether solution obtained form the reaction of di-*t*-butyl thioketone or thiobenzophenone with sodium isopropoxide in 2-propanol was quantitatively analyzed on vpc (Yanagimoto G-1800: 15% PEG, 1 m, 76 °C, N_2 0.4 kg/cm^2, FID). The formation of acetone was thus confirmed.

a) Atom-numbers are shown in Fig. 1.

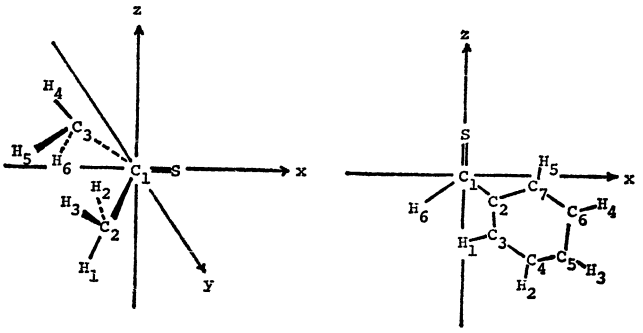

Fig. 1. Cartesian coordinates of thiocarbonyl compounds.

Into this ether solution was added ethanol solution of 2,4-dinitrophenylhydrazine. The isolated 2,4-dinitrophenylhydrazone (98% yield) melted at 128 °C (lit,[21] mp 128 °C).

Analyses of Deuterium Contents. Deuterium contents were analyzed on Varian T-60 NMR Spectrometer and Shimadzu LKB-9000S GC-MS Spectrometer attached by a MID-PM peak matcher.

Method of Calculation. Semi-empirical MO calculations were carried out with the usual unrestricted Hartree-Fock (UHF) method[22] using the INDO-type approximation. To evaluate the core resonance integrals, the Wolfsberg-Helmholz equation,[23] $H_{rs}=-KS(I_r+I_s)/2$, was used, where the value of the parameter K was taken to be 0.85. The two-center Coulomb repulsion integrals were calculated according to the Ohno's approximation.[24] The exponent of sulfur 3d orbitals and one-center Coulomb integrals between d orbitals were adopted to be 1.0 and 7.19, respectively, as reported by Nanda and Narasimhan.[25]

Other parameters including one-center exchange repulsion integrals were the same as those employed by Yonezawa and co-workers.[26] Furthermore, we discussed on the calculated results after a single annihilation proposed by Amos and Snyder.[27] The expectation values of the spin angular momentum operator S^2 from UHF method, $\langle S^2\rangle_{UHF}$, were near 0.75, which is the eigenvalue of the pure doublet state.

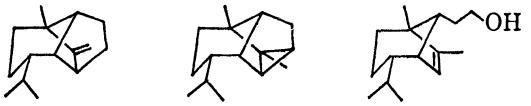
(Received August 14, 1975)

The title compound, the key intermediate for the synthesis of (+)-sativene and (+)-cyclosativene, has been synthesized through the alternative route starting with (−)-carvone.

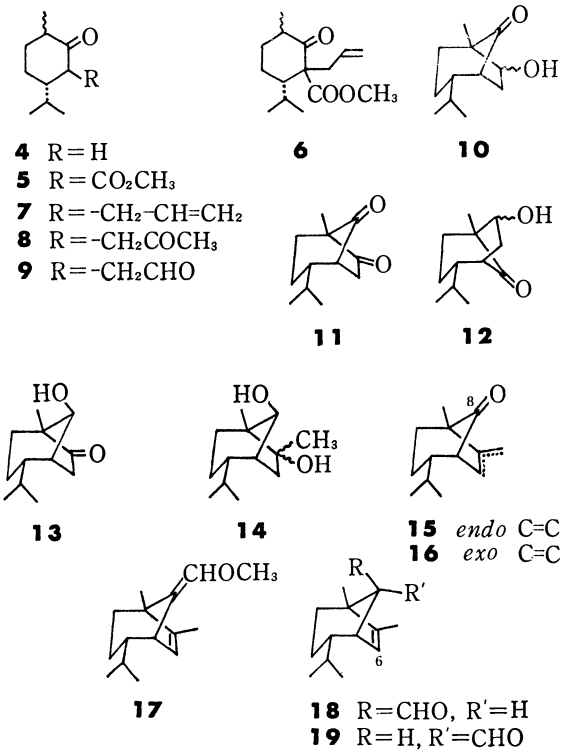
Recently Piers and co-workers[2)] reported the stereoselective total synthesis of (+)-sativene (**1**)[3,4)] and (+)-cyclosativene (**2**)[5,6)] through the common intermediate, (+)-1,7-dimethyl-4-*endo*-isopropyl-8-*syn*-(2-hydroxyethyl)bicyclo[3.2.1]oct-6-ene (**3**). We have independently investigated an approach to the synthesis of these sesquiterpenes in the optically active forms using the compound **3** as the key intermediate and wish to report our synthetic route of **3** starting from (−)-carvone in this paper.



1 **2** **3**

Introduction of a suitable substituent at the α-methylene of carvomenthone (**4**) for the construction of a five-membered ring was accomplished *via* alkylation of a β-ketoester **5**. Thus, the reaction of **4**, prepared from (−)-carvone[7)], with sodium hydride–dimethyl carbonate in dioxane gave **5**, which was allylated to **6** in an excellent overall yield. Demethoxycarbonylation of **6** was achieved by heating in dimethyl sulfoxide in the presence of an equimolar amount of sodium cyanide[8)] to produce **7** in 92% yield. It should be noted that decarboxylation of **6** under the usual alkaline conditions was unsatisfactory, resulting in opening of the ring.

Attempts to transform directly the allylic side chain into the acetonyl one, **7**→**8**, by employing oxymercuration-demercuration procedure did not give clear result, even if the various derivatives (alcohol, acetate, or tetrahydropyranyl ether) were used. The modified Lemieux-Johnson oxidation[9)] of **7** produced an aldehyde **9** which, without purification, was cyclized to a mixture of bicyclic aldols **10** (50% from **7**) by treating with 20% potassium hydroxide–methanol. The products **10**, which were separable into the crystalline, mp 80—82 °C, and oily isomers by chromatography on silica gel, are epimeric as shown from the close resemblance of the physical properties (IR, NMR, and ORD) and the conversion into a diketone **11**. But the actual configuration of the hydroxyl group in each epimer has not been determined at present and, fortunately, this ambiguity is not essential to our purpose. Then, a choice between the *endo* and *exo* isopropyl structures **10** and **12** can be made by the following consideration and finally on the basis of ORD of the compound **13**. The thermodynamically more stable carbon-framework, having the equatorial isopropyl group on the chair



4 R=H

cyclohexane ring as **10**, would be formed preferentially in such an equilibrium (reversible) reaction.

The mixture **10** was transformed into the isomeric aldol **13** in 50% overall yield by sequential application of the following procedures: (1) acetylation of the hydroxyl group in **10**, (2) reduction of the ketone with sodium borohydride, (3) protection of the newly formed hydroxyl group with dihydropyrane, (4) reduction of the acetate function with lithium aluminum hydride, (5) oxidation of the resulting alcohol with Collins' reagent[10)], and finally (6) hydrolytic removal of the pyranyl ether group. Aldol **13** thus obtained was a single crystalline compound, mp 80—81 °C, which shows the negative Cotton effect in ORD. This ORD property establishes the assigned absolute stereochemistry **13** having α (*endo*-equatorial) isopropyl group at C-4 as shown.[11)] The configuration of the hydroxyl group was tentatively assigned to be *anti* from the fact that hydride ion would be expected to attack the bridge ketone of **10** from the less hindered side (five-membered ring side) in such a ring system. Treatment of **13** with excess methyl lithium gave a methylated diol **14**. Oxidation of **14** with Collins' reagent followed by dehydration of the resulting ketol with phosphorous oxychloride–pyridine produced a mixture

of the *endo* and *exo* olefinic ketones **15** and **16** in roughly equal amounts, and iodine-catalyzed isomerization of the mixture in refluxing xylene[12] gave exclusively the desired isomer **15**.

Elongation of a two-carbon unit with the appropriate configuration, being *syn* with respect to the five-membered ring, at the C-8 position of **15** was accomplished by applying doubly the Wittig reaction using methoxymethylenetriphenylphosphorane. Reaction of **15** with methoxymethylenetriphenylphosphorane in dimethyl sulfoxide[13] gave **17** which was then hydrolyzed by treating with perchloric acid in ether to give a single aldehyde **18**. This substance must have the thermodynamically unfavorable *anti* (axial on the six-membered ring) formyl group since upon treatment with potassium carbonate in methanol it was changed exclusively to the isomeric *syn* aldehyde **19**. The assignment of the configuration of the formyl group was further supported by NMR spectrum; the signal of the olefinic proton at C-6 in **19** appeared at a higher field (0.1 ppm) than that in **18**, presumably due to the anisotropic effect of the *syn* formyl group. Again, **19** was subjected to the Wittig reaction followed by hydrolysis in the same manner as in the case of **15** to yield a homologous aldehyde, which was reduced to the desired alcohol **3** with lithium aluminum hydride.

The pure sample of **3** collected by preparative glpc, $[\alpha]_D = +133°$, was identical with the sample prepared by Piers, *et al.*[2]

Experimental

All melting points and boiling points are uncorrected. IR spectra were taken on a Hitachi EPI-S2 or a G2 spectrometer. NMR spectra were obtained on a JEOL Model C-60HL instrument using TMS as an internal standard and CCl_4 as the solvent unless otherwise indicated, and chemical shifts are given in δ and coupling constants in Hz. Mass spectra were taken on a Hitachi RMU-6D spectrometer. Specific rotations and ORD curves were recorded on a JASCO Model ORD/UV-5 spectrometer. Glpc analyses were performed on a JEOL Model JGC-1100 instrument. Elemental analyses were performed in the microanalytical laboratory of this institute.

*Methoxycarbonylation of (−)-Carvomenthone (**4**).* To a stirred mixture of sodium hydride (12.5 g, 0.52 mol) and dimethyl carbonate (50 g, 0.55 mol) in dry dioxane (100 ml) was added dropwise over 5 hr a solution of (−)-carvomenthone (**4**) (42 g, 0.27 mol) in dry dioxane (100 ml) at 85—95 °C under nitrogen. Stirring was continued at the same temperature overnight; the mixture turned to wine-red. The cooled mixture was poured into ice-water, acidified with dilute hydrochloric acid to pH 3, and extracted with ether three times. The combined extracts were washed with water twice and then saturated salt solution, and dried over anhydrous sodium sulfate. After removal of the solvent, distillation of the residual liquid gave 50 g (86%) of 3-isopropyl-2-methoxycarbonyl-6-methylcyclohexanone (**5**) as colorless liquid, bp 96—108 °C/3 mmHg, which gave a purple color with alcoholic ferric chloride. IR (neat) 1745, 1710 cm^{-1}; NMR 0.90—1.10 (m, 9H), 1.20—2.50 (m, 8H), 3.70 (s, 3H).

*2-Allyl-3-isopropyl-2-methoxycarbonyl-6-methylcyclohexanone (**6**).* To a suspension of sodium hydride (6.5 g, 0.25 mol) in dry dioxane (100 ml) was added dropwise over 1 hr a solution of **5** (49 g, 0.23 mol) in dry dioxane (100 ml) at 85—90 °C under nitrogen. After the evolution of hydrogen ceased, freshly distilled allyl bromide (30 ml, 0.35 mol) was added over a period of 1 hr, and the mixture was stirred at 80—85 °C overnight. After cooling to room temperature, the reaction mixture was poured into ice-water, neutralized with dilute hydrochloric acid to Congo Red, and extracted with ether three times. The combined extracts were washed with water and saturated salt solution, dried over anhydrous sodium sulfate, and freed from the ether. Distillation of the residual liquid gave 51.3 g (88%) of **6** as colorless oil, bp 110—120 °C/3 mmHg; IR (neat) 3070, 1740, 1715, 1645, 928, 880 cm^{-1}. Found: C, 71.99; H, 9.72%. Calcd for $C_{15}H_{24}O_3$: C, 71.39; H, 9.59%.

*2-Allyl-3-isopropyl-6-methylcyclohexanone (**7**).* Finely powdered sodium cyanide (10 g, 0.2 mol) was added to a solution of **6** (51 g, 0.2 mol) in dimethyl sulfoxide (200 ml), and the mixture was heated at 160 °C for 2 hr with vigorous stirring. The cooled reaction mixture was poured into ice-water and extracted with petroleum ether twice. The extracts were washed thoroughly with water and then saturated salt solution, dried over anhydrous sodium sulfate, and freed from the solvent. Distillation of the residual liquid gave 36 g (92%) of **7** as colorless oil, bp 80—90 °C/0.6 mmHg: IR (neat) 3070, 1705, 1640, 920 cm^{-1}; NMR 0.90—1.00 (m, 9H), 1.50—1.80 (m, 8H), 2.20—2.40 (m, 4H), 4.80—5.10 (m, 3H). Found: C, 80.53; H, 11.38%. Calcd for $C_{13}H_{22}O$: C, 80.35; H, 11.41%.

*7-Hydroxy-4-isopropyl-1-methylbicyclo[3.2.1]octan-8-one (**10**).* To a mechanically stirred solution of **7** (35 g, 0.17 mol) in dioxane (1000 ml) was added osmium tetroxide (1 g, 4 mmol) in the dark with cooling in an ice-bath and then a solution of sodium metaperiodate (50 g, 0.23 mol) in water (1.5 l) over a period of 6 hr. The stirring was continued in the dark overnight. Inorganic salt was removed by filtration and the filtrate was thoroughly extracted with ether. The combined extracts were washed with 10% sodium sulfide solution until the water layer became colorless, and then with water and saturated salt solution. Evaporation of the ether at room temperature under reduced pressure gave 32 g (91%) of the keto aldehyde **9**: IR ($CHCl_3$) 2700, 1715, 1120, 870 cm^{-1}, which was subjected to aldol cyclization without further purification.

To a solution of potassium hydroxide (225 g) in methanol (2.5 l) was added dropwise a solution of **9** (32 g) in methanol (500 ml) with cooling in an ice-bath. The mixture was allowed to stir at room temperature for 36 hr, neutralized with 10% hydrochloric acid, and thoroughly extracted with ether. After removal of the solvent, distillation of the residue gave 15 g of an epimeric mixture of **10**, bp 130—140 °C/0.25 mmHg, which partially crystallized on standing. Crystalline substance was collected and recrystallized from *n*-hexane–ether to afford 5.23 g of an epimer of **10**, mp 80—81 °C. The residual part was chromatographed on silica gel (500 g) using 3 : 1 petroleum ether–ether as eluent to give additional crystals (4.77 g) and a colorless oily epimer (7.23 g). Total yield was 52%. Crystalline epimer: IR ($CHCl_3$) 3600, 3450, 2900, 1735, 1200, 1040 cm^{-1}; NMR ($CDCl_3$) 0.90—1.00 (m, 9H), 1.30—1.90 (m, 7H), 2.20—2.60 (m, 2H), 2.50 (s, 1H, exchangeable with D_2O), 4.08 (m, 1H, changed to q by D_2O addition); ORD (EtOH) $[\phi]_{309}$ $+8.24\times10^3$, $[\phi]_{272}$ -9.02×10^3. Found: C, 73.29; H, 10.33%. Calcd for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%. Oily epimer: IR ($CHCl_3$) 3600, 3400, 2900, 1735 cm^{-1}; NMR 0.90—1.00 (m, 9H), 1.40—2.50 (m, 9H), 3.65 (s, 1H), 4.00 (m, 1H); ORD (EtOH) $[\phi]_{309}$ $+6.06\times10^3$, $[\phi]_{272}$ -8.20×10^3. Found: C, 72.69 H, 10.22%. MS *m/e* 196

(M^+). Calcd mol wt 196.

Jones oxidation of each epimer in the usual manner gave the same diketone **11** as a viscous oil: IR (CCl_4) 2900, 1770, 1745 (sh), 1730, 1045 cm^{-1}.

*4-Isopropyl-8-hydroxy-1-methylbicyclo[3.2.1]octan-7-one (**13**).* A solution of **10** (7.53 g) in pyridine (30 ml) was treated with acetic anhydride (10 ml) at room temperature for 15 hr. Usual work-up gave 9.24 g (100%) of a mixture of the keto acetate. Analytical sample was purified by evaporative distillation, bp 130 °C (bath temp)/2 mmHg. IR (neat) 1740, 1250, 1030 cm^{-1}; NMR 1.99 (s, 3H), 5.00 (m, 1H). Found: C, 70.49; H, 9.68%. Calcd for $C_{14}H_{22}O_3$: C, 70.55; H, 9.31%.

To a solution of the acetate (9.2 g) in methanol (120 ml) was added sodium borohydride (1.48 g) and one pellet of potassium hydroxide, and the mixture was stirred at room temperature for 2 hr. Usual work-up gave 9.03 g (97%) of a mixture of the oily hydroxy acetate. From the pure oily epimer of **10** the crystalline hydroxy acetate was obtained. Recrystallized sample from *n*-hexane had mp 32 °C. IR ($CHCl_3$) 3550, 3400, 1710, 1250, 1100 cm^{-1}; NMR 2.00 (s, 3H), 3.85 (d, J=6.0, 1H), 4.77 (q, J=3.8 and 8.3, 1H). Found: C, 70.18; H, 9.93%. Calcd for $C_{14}H_{24}O_3$: C, 69.96; H, 10.07%.

A solution of the hydroxy acetate (5.18 g) and dihydropyrane (5 ml) in dry ether (100 ml) containing a catalytic amount of *p*-toluenesulfonic acid was allowed to stir at room temperature for 3 hr. Usual work-up gave 8.2 g of the pyranyl ether. IR ($CHCl_3$) 1720, 1260, 1125, 1020, 970 cm^{-1}; NMR 1.60 (m, 6H), 2.00 (s, 3H), 4.60 (m, 2H).

To a cold suspension of lithium aluminum hydride (1.10 g) in anhydrous ether (150 ml) was added dropwise a solution of the pyranyl ether (8.30 g) in anhydrous ether (20 ml), and the mixture was stirred at room temperature for 4 hr. Usual work-up gave 7.33 g (88%) of the alcohol. IR ($CHCl_3$) 3600, 3400, 1120, 1070, 970 cm^{-1}; NMR 1.70 (m, 6H), 3.30—3.37 (m, 4H), 4.70 (m, 1H).

A solution of the above alcohol (7.33 g) in dichloromethane (500 ml) was treated with the Collins' reagent (31.0 g) at room temperature for 30 min. Usual work-up gave 7.03 g (96%) of the ketone. IR ($CHCl_3$) 1735, 1124, 1075, 1030, 970 cm^{-1}; NMR 1.70 (m, 6H), 3.50—3.90 (m, 3H), 4.75 (m, 1H).

A solution of the above product (212 mg) in 20% aqueous dioxane (5 ml) containing a catalytic amount of *p*-toluenesulfonic acid was heated at 70 °C for 1 hr. The mixture was diluted with water and extracted with ether twice. The combined extracts were washed with water and saturated salt solution, and evaporated to give 105 mg (71%) of crystalline **13**, mp 80—81 °C, recrystallized from *n*-hexane. IR (CCl_4) 3600, 3400, 1740 cm^{-1}; NMR 0.80—1.00 (m, 9H), 1.10—2.20 (m, 8H), 2.30—2.70 (m, 2H, 1H exchangeable with D_2O) 3.85 (d, J=6.0, 1H). ORD (EtOH) $[\phi]_{316}$ -1.99×10^3, $[\phi]_{275}$ $+2.50\times10^3$. Found: C, 73.37; H, 10.35%. Calcd for $C_{12}H_{20}O_2$: C, 73.43; H, 10.27%.

*7,8-Dihydroxy-1,7-dimethyl-4-isopropylbicyclo[3.2.1]octane (**14**).* A solution of **13** (105 mg) in ether (2 ml) was added dropwise to an ethereal solution of methyl lithium, prepared from lithium (400 mg) and methyl iodide (3 ml) in ether (20 ml), with cooling in an ice-bath, and the mixture was stirred overnight at room temperature under nitrogen. The mixture was carefully poured into ice-water and the water layer was extracted with two 30 ml portions of ether. Evaporation of the ether and recrystallization of the residual crystals from *n*-hexane–ether gave 60 mg (53%) of **14**, mp 116—117 °C: IR ($CHCl_3$) 3600, 3400, 1050 cm^{-1}; NMR ($CDCl_3$) 0.75—0.95 (m, 9H), 1.15 (s, 3H), 1.20—1.75 (m, 8H), 2.17 (m, 1H), 3.65 (d, J=6.0, 1H). Found: C, 73.72; H, 11.95%. Calcd for $C_{13}H_{24}O_2$: C, 73.53; H, 11.39%.

*1,7-Dimethyl-4-isopropylbicyclo[3.2.1]oct-6-en-8-one (**15**).* To a stirred slurry of the Collins' reagent (1.0 g) in dichloromethane (10 ml) was added a solution of **14** (123 mg) in dichloromethane (10 ml) at room temperature, and the mixture was stirred for 15 min. After the usual work-up, recrystallization of the residue from *n*-hexane gave 110 mg (90%) of the keto alcohol, mp 124 °C. IR (CCl_4) 3600, 3400, 1730 cm^{-1}; NMR 0.80—1.00 (m, 9H), 1.12 (s, 3H), 1.50—2.50 (m, 10H). Found: C, 74.10; H, 10.30%. Calcd for $C_{13}H_{22}O_2$: C, 74.24; H, 10.54%.

To a solution of the above keto alcohol (64 mg) in pyridine (0.5 ml) was added phosphorous oxychloride (0.04 ml), and the resulting mixture was heated gradually in an oil-bath until the bath temperature reached to 90 °C (30 min) and maintained at that temperature for 15 min. After cooling, the mixture was poured into ice-water in a separatory funnel with the aid of ether and the water layer was extracted with ether. The combined ether layers were successively washed with dilute hydrochloric acid, sodium bicarbonate solution, water, and saturated salt solution. Evaporation of the ether gave 46 mg of a *ca.* 1 : 1 mixture of **15** and the *exo*-isomer **16**, as indicated by glpc on a column of Carbowax 20M (2 m, 155 °C, He 1.4 kg/cm^2, retention times: 5.4 min and 6.3 min). IR (neat) 1755, 1655 cm^{-1}; NMR 1.70 (br. s), 4.90 (m), 5.75 (m).

A solution of the above mixture (550 mg) and a catalytic amount of iodine in anhydrous xylene (20 ml) was heated under reflux for 8 hr under nitrogen. The cooled reaction mixture was successively washed with dilute sodium thiosulfate solution, water, and saturated salt solution. Evaporation of the xylene followed by evaporative distillation of the residual liquid gave 470 mg of pure **15**, bp 100 °C (bath temp)/2 mmHg. IR (neat) 1755 cm^{-1}; NMR 0.80—1.20 (m, 9H), 1.75 (d, J=1.5, 3H), 1.20—2.40 (m, 6H), 2.75 (m, 1H), 5.75 (m, 1H). Found: C, 80.93; H, 10.29%. Calcd for $C_{13}H_{20}O$: C, 81.20; H, 10.48.%

*Wittig Reaction of **15** and Hydrolysis of the Product **17**.* A solution of methoxymethylenetriphenylphosphorane in dimethyl sulfoxide was prepared according to the literature using sodium hydride (0.66 g) and methoxymethyltriphenylphosphonium chloride (9.25 g) in dimethyl sulfoxide (57 ml). To this red solution was added a solution of **15** (1.10 g) in dimethyl sulfoxide (14 ml); and the resulting mixture was stirred at 53 °C overnight under nitrogen. Then, the reaction mixture was poured into ice-water and extracted with petroleum ether three times. The combined extracts were washed with 50% aqueous dimethyl sulfoxide, water (five times), and saturated salt solution, and freed from the solvent.

The crude oily product thus obtained was dissolved in ether and a few drops of 30% hydrogen peroxide was added with cooling in an ice-bath. After stirring for 30 min at room temperature, a large amount of petroleum ether was added and the resulting organic layer was passed through a short column of neutral alumina (Woelm V). Evaporation of the solvent gave 1.03 g (87%) of the oily methoxymethylene compound **17**. IR (CCl_4) 3060, 1705, 1430 cm^{-1}; NMR 1.60 (m, 3H), 2.70 (m, 1H), 3.42 (s, 3H), 5.35 (m, 1H), 5.50 (s, 1H). MS *m/e* 222 (M^+). Calcd for $C_{15}H_{24}O$: mol wt 222.

Compound **17** (213 mg) was dissolved in ether saturated with perchloric acid (5 ml). The reaction mixture was allowed to stand for 2 hr at room temperature and then washed with dilute sodium bicarbonate solution, water, and finally saturated salt solution. Evaporation of the ether gave

200 mg (100%) of the *anti*-aldehyde **18**: IR (CCl_4) 2740, 1725 cm^{-1}; NMR 1.65 (m, 3H), 5.50 (m, 1H), 10.10 (d, J=6.0, 1H).

Isomerization of ***18*** *to the* syn-*Isomer* ***19***. A solution of **18** (150 mg) in ether (3 ml) was added to a saturated methanolic solution of potassium carbonate (2 ml), and the mixture was stirred overnight at room temperature. Then, the mixture was diluted with water and extracted with ether. The extract was washed with water and saturated salt solution, dried, and freed from the ether, giving 128 mg (85%) of an oil, which consisted mainly of the desired compound, 1,7-dimethyl-8-*syn*-formyl-4-isopropylbicyclo[3.2.1]oct-6-ene (**19**): IR (neat) 2700, 1718, 1436, 1120 cm^{-1}; NMR 1.65 (br. s, 3H), 2.75 (m. 1H), 5.40 (m, 1H), 9.50 (d, J=4.0, 1H).

*(+)-1,7-Dimethyl-4-*endo-*isopropyl-8-*syn-*(2-hydroxyethyl)bicyclo[3.2.1]oct-7-ene* (***3***). A solution of **19** (430 mg) in dimethyl sulfoxide (10 ml) was treated with a solution of an excess methoxymethylenetriphenylphosphorane (4 equiv.) in dimethyl sulfoxide (10 ml) at room temperature overnight under nitrogen. The mixture was worked up as before to give 403 mg (87%) of the enol ether as a colorless oil: IR (CCl_4) 3050, 1650, 1430, 1100 cm^{-1}; NMR 1.62 (br. s, 3H), 3.50 (s, 3H), 5.25 (m, 1H), 5.80 (q, J=12.0 and 6.0, 1H), 6.25 (d, J=12.0, 1H).

A solution of the above product (112 mg) in ether (5 ml) was added to cold ether saturated with perchloric acid (5 ml). After stirring for 30 min at room temperature, the mixture was successively washed with dilute sodium bicarbonate solution, water and saturated salt solution, dried over anhydrous sodium sulfate, and freed from the ether, giving 106 mg (89%) of the aldehyde: IR ($CHCl_3$) 2700, 1725, 1450, 1370, 1120 cm^{-1}.

To a stirred suspension of lithium aluminum hydride (21 mg, 4 equiv) in anhydrous ether (5 ml) was added a solution of the above aldehyde (106 mg) in anhydrous ether (3 ml) at 0 °C, and the mixture was stirred for 1 hr at room temperature. Usual work-up gave 101 mg of an oil, which consisted of two components as indicated by glpc analysis (20% Carbowax 20M, 2 m×3 mm, 160 °C, He 0.95 kg/cm^2): the major peak with 77% of area at 7.8 min and the minor one with 23% of area at 9.4 min. The collected sample of the major product was identical with the authentic sample of **3**. IR (CCl_4) 3620, 3040, 1460, 1440, 1380, 1365, 1050 cm^{-1}; NMR 0.80—0.95 (m, 9H), 1.60 (br. s, 3H), 1.00—2.00 (m, 10H, 1H exchangeable with D_2O), 2.55 (m, 1H), 3.65 (d, J=7.5, 2H), 5.45 (m, 1H). $[\alpha]_D$=+133° (c, 1.52×10^{-2}, EtOH). Found: C, 80.46; H, 11.55%. Calcd for $C_{15}H_{26}O$: C, 81.02; H, 11.79%.

Minor product was assigned to be 8-*anti*-isomer from the following spectral data: IR (CCl_4) 3620, 3040, 1460, 1440, 1380, 1120, 1045, 1010 cm^{-1}, NMR 0.75—0.95 (m, 9H), 1.55 (br. s, 3H), 1.00—1.90 (m, 9H), 2.45 (m, 1H), 3.50 (m, 3H), 5.20 (m, 1H).

We thank Professor E. Piers and Dr. M. Soucy (University of British Columbia) for generous gift and the identification of the compound **3**.

Reaction of 2,4,6-Tri-*t*-butylnitrobenzene with Alkyl Grignard Reagents

Yoshio INAGAKI, Renji OKAZAKI, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received August 20, 1975)

Reactions of 2,4,6-tri-*t*-butylnitrobenzene (**1**) with alkylmagnesium halides afforded 2,4,6-tri-*t*-butylaniline (**2**), *N*-alkyl-2,4,6-tri-*t*-butylanilines (**3**), 6-alkyl-2,4-di-*t*-butylanilines (**4**), 4-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes (**5**), and 6-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,4-cyclohexadienes (**6**) depending on the Grignard reagents used. Reduction of the oxime **6** proved to be responsible for the formation of the aniline **4**. Comparison of the present reactions with those of 2,4,6-tri-*t*-butylnitrosobenzene (**7**) with Grignard reagent, *syn-anti*-isomers of the oxime **6**, and the formation mechanisms of the products have been discussed.

Only a few studies have been reported on the reaction between Grignard reagents and nitroarenes.[1-3] Grignard reagents have been reported to attack nitroarenes usually on the nitro group resulting in its reduction; for example, reactions of ethylmagnesium bromide with nitrobenzene and nitrotoluenes merely afforded the corresponding *N*-ethylanilines and azobenzenes.[3] The only one exception is an abnormal addition of a Grignard reagent to 1,3,5-trinitrobenzene leading to 1,3,5-trinitro-2,4,6-trialkylcyclohexanes.[2]

We describe here the reaction of 2,4,6-tri-*t*-butylnitrobenzene (**1**) with Grignard reagents giving some abnormal products,[4] and discuss the mechanism of their formation. This reaction was carried out with the intention of obtaining cyclohexadienone oximes (6-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes and 4-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,4-cyclohexadienes) whose properties we are interested in:[5] the only one route to the oximes is the reaction of 2,4,6-tri-*t*-butylnitrosobenzene (**7**) with Grignard reagents.[6] However, considering reducing ability of Grignard reagents, it seemed to be possible to prepare the oximes using the nitrobenzene **1** instead of the nitrosobenzene **7**, and such reaction is more convenient because **1** is the starting material in the preparation of **7**.[7]

Results and Discussion

Reaction Products. Reactions of **1** with a large excess of alkylmagnesium halides in ether at 0 °C afforded some of the following compounds: 2,4,6-tri-*t*-butylanilines(**2**), *N*-alkyl-2,4,6-tri-*t*-butylanilines (**3**), 6-alkyl-2,4-di-*t*-butylanilines (**4**), 4-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes (**5**), and 6-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,4-cyclohexadienes (**6**).

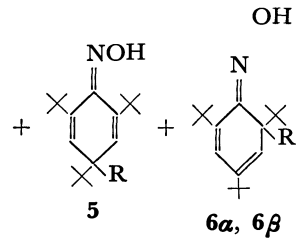
f	1-Ad*



* Ad represents adamantyl group.

The yields of the products and the reaction conditions are summarized in Table 1. The structures of the products were confirmed by the analytical and spectral data. Compound **6α** which was obtained also in the reactions of Grignard reagents with 2,4,6-tri-*t*-butylnitrosobenzene (**7**)[6] is one of the *syn*- and *anti*-isomers, and **6β** is the other. These two isomers could easily be distinguished from each other by the NMR spectra and separated by chromatography: R_f value of **6α** was smaller than that of **6β**. The NMR spectra of **6αa** showed two olefinic protons at δ 5.42 and 6.15, whereas **6βa** at 5.17 and 6.10, similarly **6αb** at 5.33 and 6.22, but **6βb**

a) Excess amount of magnesium was used in preparation of Grignard reagents except for Nos. 2 and 3. b) Excess amount of methyl iodide was used in preparation of Grignard reagent. c) 51% of **1** was recovered. d) A considerable amount of **1** was recovered.

at 5.13 and 6.12. The difference in the chemical shifts of the two olefinic protons of **6β** is larger than that of **6α**. There are other features on the NMR spectra: the signals due to the methyl group on the 6-position of **6αa** appeared at δ 1.32, but that of **6βa** at 1.61, similarly the methylene protons of the 6-ethyl group of **6αb** appeared at δ 1.4—2.3, but that of **6βb** at 3.00. Thus the signals of 6-alkyl group on **6β** appeared at a lower field than those of **6α**. This difference makes it possible to evaluate the isomer ratio.

Absorption maxima of **6αa**, **6αb**, **6βa**, and **6βb** are listed in Table 2. The isomers **6β** are characterized by the absorption maxima at longer wavelength by a few nm than those of **6α**.

Table 2. Absorption maxima of **6α** and **6β** in hexane

6	λ_{max} (nm)	ε
6αa	304	4400
6βa	308.5	4370
6αb	308	4400
6βb	310.5	3690

Although these data are insufficient to establish their configuration, we tentatively assign **6α** to structure (A) and **6β** to (B) on the following basis: (1) the protons *syn* to the hydroxyl group of the oximes have lower chemical shifts (δ) than those of the other isomer,[8] (2) the slight hypsochromic shift in the UV absorption of α-isomer is consistent with the larger twisting of the hydroxyimino group from the molecular plane, because the 2-*t*-butyl group is in the molecular plane but the 6-*t*-butyl and the 6-alkyl groups are out of the molecular plane, and (3) the larger R_f value of **6β** than that of **6α** in thin layer chromatography (tlc) is consistent with structure (B), in which the hydroxyl group is more thickly covered with two alkyl groups than that of (A).

(A)≡**6α** (B)≡**6β**

The formation of **5**, **6α**, and **6β**, which seemingly shows that the Grignard reagents attacked to *ortho*- and the *para*-positions of the nitro group, is unprecedented in the reactions of the Grignard reagents with nitro arenes,[1-3] though a similar compound, 1-hydroxyimino-2,4,6-tri-*t*-butyl-2,4-cyclohexadiene (**6**, R=H), could be obtained by the reduction of **1** with sodium-bis(2-methoxyethoxy)aluminum hydride (Vitride).[9] The direct formation of **3c** and **3d** from the readily available nitrobenzene **1** is of synthetic significance, considering the difficulties reported for alkylation of **2**.[10] The only alternative route to these compounds is the reaction of 2,4,6-tri-*t*-butylnitrosobenzene (**7**) with Grignard reagents,[6] but the present reaction seems to provide a more convenient method for preparation of these compounds.

Reaction Mechanism. Although a possibility of direct addition of Grignard reagents to **1** cannot be ruled out, reducing ability of Grignard reagents suggests that oximes **5** and **6**, and secondary amines **3** are probably produced by addition of Grignard reagents to the nitrosobenzene **7** formed by reduction of **1**, for the reaction rate depends on the amount of magnesium metal which was found to play an important role in the reduction process as discussed below: in the reaction with methylmagnesium iodide prepared by use of excess magnesium, **1** was consumed completely in 3.5 hr, but the reaction with methylmagnesium iodide prepared by use of an excess of methyl iodide resulted in 51% recovery of **1** even after 5 hr.

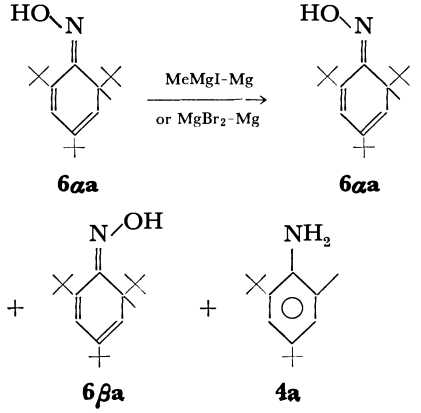
However, in Nos. 1, 4, and 5 in Table 1, the reaction products were different from those of the reaction with **7**; the reactions of **7** afforded the cyclohexadienone oximes (R=Me, Et, *i*-Pr, $PhCH_2$, 1-Ad) or **3a** (R=*t*-Bu) mainly but reduction products **2** and **4** only in small amounts.[6] This difference is ascribed to some secondary reactions discussed below.

The yields of **4** were decreased in the following order:

Me>Et>*i*-Pr

The yields of **6α** obtained in the reactions of **7** with Grignard reagents were also in the same order.[6] These facts suggest that **4** was formed *via* **6α**. Since a longer reaction time is required in the reaction with **1**, it is considered that further reaction of **6α** into **4** is effected in the case of **1**. In order to prove this pathway, reaction of **6αa** with methylmagnesium iodide in the absence of magnesium was carried out, and **6αa** was recovered quantitatively. However, reaction of **6αa** with methylmagnesium iodide in the presence of excess magnesium at room temperature for 3 hr afforded 32% of **4a** and 30% of **6βa** besides 38% recovery of **6αa** based on the NMR spectrum, and they were isolated by tlc in 18, 13, and 12% yields, respectively. This result suggests that magnesium metal in combination with magnesium halide is responsible for the reduction of **6α** into **4**.

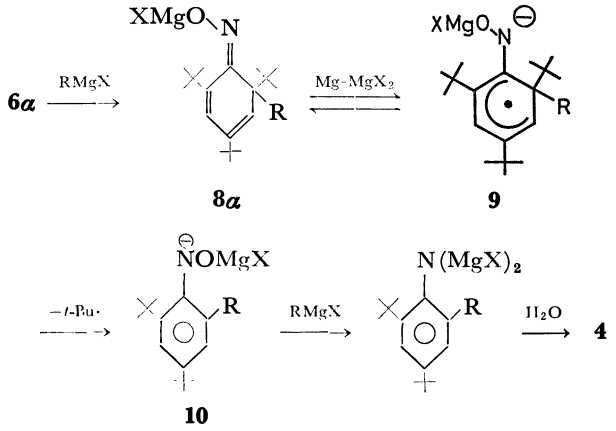
In fact, the reaction mixture of **6αa**, magnesium, and magnesium bromide (at room temperature for 2.8 hr) showed NMR signals due to **4a** and **6αa**. The molar ratio was found to be 8 : 3 (73 and 27% respectively) from the NMR spectrum, and the chromatographic separation afforded 27% of **4a** and 9% of **6αa**, which seemed to be contaminated by a trace of **6βa** according to the NMR spectrum.



6αa **6αa**

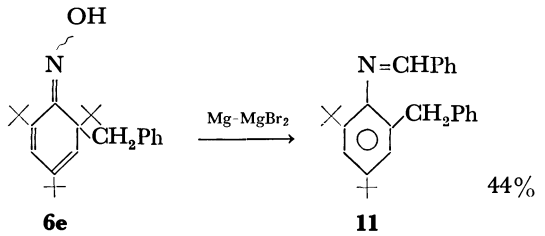
6βa **4a**

Therefore, the formation of **4** is interpreted as follows:



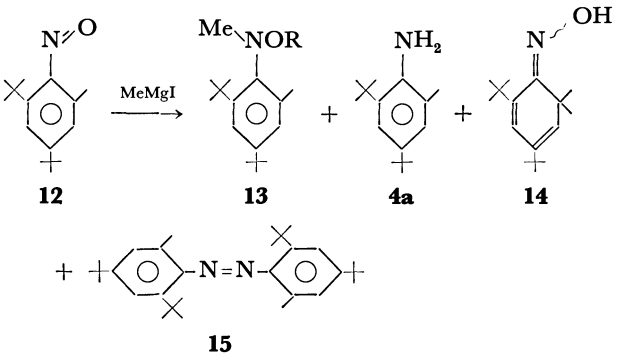
The isomerization of the oxime **6** may be ascribed to the reversibility between **8** and **9**.

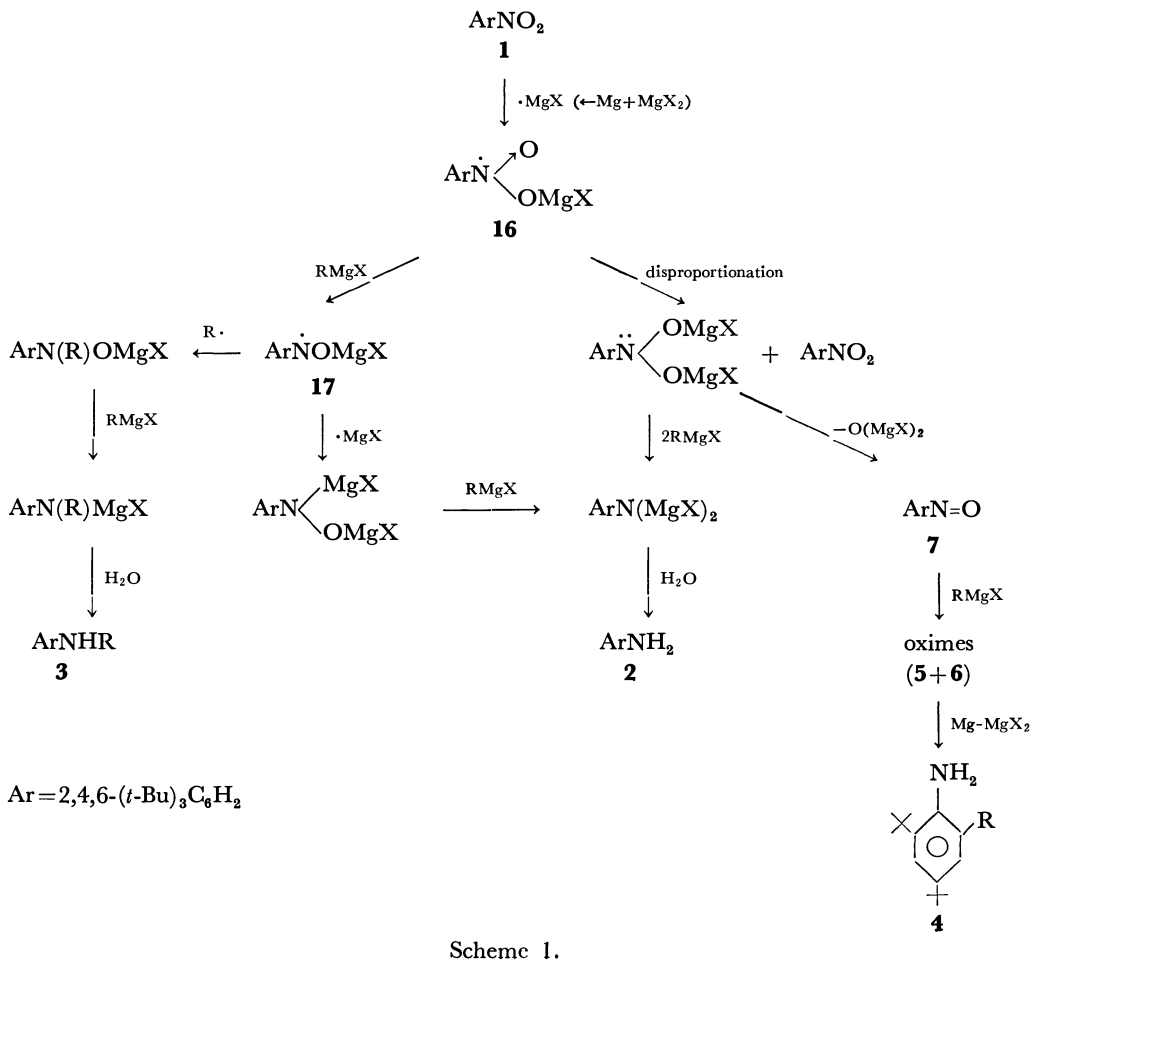
This interpretation may explain a reason why **4** was not produced in the case of benzylmagnesium chloride despite of the presence of excess magnesium,



because the reducing ability of Mg–$MgCl_2$ system may be weaker than that of Mg–$MgBr_2$ system. However, **6e** afforded an unusual product, 2-benzyl-4,6-di-*t*-butyl-*N*-benzylideneaniline (**11**) by reaction with Mg–$MgBr_2$. The formation mechanism is obscure.

In contrast to these lines of evidence suggesting that **4** was formed *via* **6**, any proof for reduction of the oxime **5** into 4-alkyl-2,6-di-*t*-butylaniline was not obtained. Actually, the reaction of **5c** with isopropylmagnesium bromide in the presence of magnesium metal resulted in complete recovery of **5c**. This selectivity in reduction is probably because an electron affinity of **5** is less than that of **6** as a simple HMO calculation demonstrates that the orbital energy (-0.445β)for the LUMO of 1,3,5-hexatriene has a lower value than that (-0.581β) of 2-vinyl-1,3-butadiene.[11] Namely, the single electron transfer into the





Scheme 1.

LUMO of **6** leading to the radical anion **9** is energetically more advantageous than that of **5**.

A route to **4** *via* 2,4-di-*t*-butyl-6-methylnitrosobenzene (**12**) can be ruled out: reaction of **12** with methylmagnesium iodide afforded **4a** only in a 22% yield besides 44% of *N*-(2,4-di-*t*-butyl-6-methylphenyl)-*N*-methylhydroxylamine (**13**), 17% of 1-hydroxyimino-2,4-di-*t*-butyl-6,6-dimethyl-2,4-cyclohexadiene (**14**), and 0.6% of 2,4,2′,4′-tetra-*t*-butyl-6,6′-dimethylazobenzene (**15**). The formation of considerable amounts of **13** and **14** was inconsistent with the result of the reaction of **1** with methylmagnesium iodide.

The formation of a large amount of **2** remains unresolved. The reduction of intermediary nitrosobenzene **7** might be possible but not be predominant, because the addition of Grignard reagents to **7** is faster than the reduction of **7** as suggested by the fact that only a small amount of **2** was obtained in the reaction of **7** with Grignard reagents.[6] Two processes may be possible: the one is a process involving a disproportionation of the radical anion **16**.[12] The other pathway involves reduction of **1** into an anion radical **17** which is considered to be the common intermediate for **2** and **3** as described in a previous paper,[6] and this route might explain the increased yield of the secondary amine **3** in the present reaction compared with the reaction of **7**.[6]

The probable reaction mechanism is summarized in Scheme 1.

It is concluded that the higher yields of oximes (**5** and **6**) can be obtained by the reaction of **1** with Grignard reagents in the absence of magnesium. Actually, the oxime **6αa** was obtained as a main product in No. 3 in Table 1 where an excess amount of methyl iodide was used in preparation of the Grignard reagent.

Experimental

All melting points were not corrected. The IR and UV spectra were recorded with Hitachi EPI-G2 and EPS-3 spectrophotometers respectively. The NMR spectra were measured with a Hitachi R-24 spectrometer using tetramethylsilane as an internal standard. The mass spectra were recorded with a Hitachi RMU-6L mass spectrometer. All reactions were carried out under nitrogen.

Materials. 2,4,6-Tri-*t*-butylnitrobenzene[10] (**1**) (mp 202.5—203.5 °C), 2,4-di-*t*-butyl-6-methylnitrosobenzene[7] (**12**) (mp 31.5—33.5 °C), 2,4-di-*t*-butyl-6-methylaniline[13] (**4a**) (mp 31.5—32.5 °C), 2,4,6-tri-*t*-butyl-*N*-methylaniline[10] (**3a**) (mp 109.5—111.0 °C), and 2,4,6-tri-*t*-butyl-*N*-ethylaniline[10] (**3b**) (mp 79.5—81.0 °C) were prepared by the reported methods. 2,4,6-Tri-*t*-butyl-*N*-isopropylaniline (**3c**), 2,4,6,*N*-tetra-*t*-butylaniline (**3d**), 6-alkyl-1-hydroxyimino-2,4,6-tri-*t*-butyl-2,4-cyclohexadienes (**6α**), and 4-alkyl-2,4,6-tri-*t*-butyl-2,5-cyclohexadienes (**5**) were prepared as described previously.[6]

Reaction of 2,4,6-Tri-t-butylnitrobenzene (1) with Methylmagnesium Iodide. To an ice-cold Grignard solution prepared from 2.02 g (83.1 mmol) of magnesium and 9.77 g (68.8 mmol) of methyl iodide in 25 ml of ether, a solution of 2.00 g (6.87 mmol) of **1** in 30 ml of ether was added dropwise with stirring over 1.7 hr. After additional stirring at 0 °C for 2 hr, the reaction mixture was poured into aqueous ammonium chloride and extracted with ether. The extract was washed with water and dried over anhydrous magnesium sulfate. After removal of the solvent, the residue was chromatographed on a silica gel dry column with carbon tetrachloride to be devided into nine fractions, each of which was eluted with ether. The first fraction gave 12 mg of orange crystals, which could not be purified. The third fraction afforded 45 mg of pale yellow crystals. The fourth fraction gave 111 mg of colorless crystals, which recrystallized from methanol to give the same material as that obtained from the third fraction by the spectral data, mp 143—145 °C; IR (KBr): 3000, 2950, 1625, 1600, 1455, 1420, 1390, 1360, 1240, and 1210 cm^{-1}; NMR (CCl_4): δ 0.78 (s, 9H), 1.18 (s, 9H), 1.27 (s, 27H), 1.54 (s, 9H), 6.50 (broad s, 1H), 6.60 (broad s, 1H), and 7.05 (s, 2H); λ_{max}(hexane): 241 and 260 nm (the absorbances of a solution (28.5 mg/l) were 1.09 and 0.61 respectively); Mass: *m/e* 260 (22%), 245 (100), and 231 (64). These data were insufficient to elucidate the structure. From the mother liquor 40 mg (2%) of 2,4,6-tri-*t*-butyl-*N*-methylaniline (**3a**) was isolated, and identified by the IR and NMR spectra. The sixth fraction afforded 720 mg (40%) of 2,4,6-tri-*t*-butylaniline (**2**) (by NMR and IR). The eighth fraction afforded 330 mg of tarry material, which was rechromatographed on alumina with carbon tetrachloride as eluent to give 262 mg (17%) of 2,4-di-*t*-butyl-6-methylaniline (**4a**) (by NMR and IR) and 60 mg of unidentified crystalline material. The other fractions afforded small amounts of unidentified materials.

Reaction of 1 with Methylmagnesium Iodide Prepared Using Excess of Methyl Iodide. Reaction of a Grignard solution prepared from 5.25 g (37 mmol) of methyl iodide and 816 mg (33.6 mmol) of magnesium in 15 ml of ether with 1.00 g (3.44 mmol) of **1** in 19 ml of ether for 5 hr at 0 °C afforded 507 mg (50.7%) of recovered **1**, 102 mg of a mixture of **2** and the oxime **6βa** (molar ratio 7 : 4 based on the NMR signal intensity), 54 mg (5%) of **5a**, and 190 mg (19%) of **6αa**, after a similar treatment. The mixture of **2** and **6βa** was rechromatographed on an alumina dry column with hexane to give 43 mg (5%) of **2** and 21 mg (2%) of **6βa**·**6βa**: mp 103—105 °C; IR (KBr): 3300, 3180 (νOH), 980, and 960 cm^{-1} (νNO); NMR (CCl_4): δ 0.89 (s, 9H), 1.09 (s, 9H), 1.24 (s, 9H), 1.61 (s, 3H), 5.17 (d, J=2 Hz, 1H), 6.10 (d, J=2 Hz, 1H), and 7.10 (broad s, 1H), λ_{max} (hexane): 305 nm (ε 4520); Mass: *m/e* 291 (M^+, trace) and 57 (100%).

Reaction of 1 with Ethylmagnesium Bromide. Reaction of a Grignard solution prepared from 2.03 g (83.5 mmol) of magnesium and 7.94 g (68.7 mmol) of ethyl bromide in 26 ml of ether with 2.00 g (6.87 mmol) of **1** in 30 ml of ether for 1.5 hr at 0 °C gave 80 mg (4%) of 2,4,6-tri-*t*-butyl-*N*-ethylaniline (**3b**) (by IR and NMR), 35 mg of white crystals, which failed to be purified (NMR (CCl_4): δ 0.91 (s, 9H), 1.11 (s, 9H), 1.28 (s, 9H), 5.15 (d, J=2 Hz, 1H), 6.15 (d, J=2 Hz, 1H), and the signals of the ethyl group were not resolved clearly), 169 mg of **2** (by IR and NMR), 871 mg of a mixture of **2** (570 mg) and 1-hydroxyimino-2,4,6-tri-*t*-butyl-4-ethyl-2,5-cyclohexadiene (**5b**, 301 mg, 14%) (by NMR), and 428 mg of tarry material. The mixture of **2** and **5b** was rechromatographed on an alumina dry column with hexane to give 508 mg of **2** and 228 mg (11%) of **5b**. Therefore, the total amount of **2** was 677 mg (38%, isolated), and 739 mg (41%) from NMR. The last tarry material was again chromatographed on a silica gel dry column with carbon tetrachloride to divide into A and B fractions. Fraction A gave 160 mg (8%) of an isomer of 1-hydroxyimino-2,4,6-tri-*t*-butyl-6-ethyl-2,4-cyclohexadiene (**6βb**) as white crystals, which were recrystallized three times from aqueous methanol, mp 122—123.5 °C; IR (KBr): 3300, 3170 (νOH), and 975 cm^{-1} (νNO); NMR (CCl_4): δ 0.74 (t, J=

7 Hz, 3H), 0.91 (s, 9H), 1.10 (s, 9H), 1.26 (s, 9H), 3.00 (q, J=7 Hz, 2H), 5.13 (d, J=2 Hz, 1H), 6.12 (d, J=2 Hz, 1H), and 6.95 (broad s, 1H); λ_{max} (hexane): 310.5 nm (ε 3690); Mass: *m/e* 305 (M^+, 0.8%) and 57 (100).

Found: C, 78.58, H. 11.25; N, 4.45%. Calcd for $C_{20}H_{35}NO$: C, 78.63; H, 11.55; N, 4.58%.

Fraction B afforded 113 mg (7%) of 2,4-di-*t*-butyl-6-ethylaniline (**4b**) as tarry material, which was treated twice with tlc (silica gel, benzene) and distilled twice molecularly to give white crystals, mp 34.5—37 °C; IR (neat): 3490 and 3405 cm^{-1} (νNH_2); NMR (CCl_4): δ 1.23 (t, J=7 Hz, 3H), 1.26 (s, 9H), 1.42 (s, 9H), 2.50 (q, J=7 Hz, 2H), 3.57 (broad s, 2H), and 6.95 (ABq, $\Delta\delta$=0.16, J=2 Hz, 2H), λ_{max} (hexane): 240 (ε 8620) and 289 nm (2490); Mass: *m/e* 233 (M^+, 21%) and 218 (100).

Found: C, 82.29; H, 11.74; N, 6.06%. Calcd for $C_{16}H_{27}N$: C, 82.35; H, 11.66; N, 6.00%.

Reaction of ***1*** *with Isopropylmagnesium Bromide.* Reaction of a Grignard solution prepared from 2.02 g (83.1 mmol) of magnesium and 9.30 g (75.6 mmol) of isopropyl bromide in 25 ml of ether with 2.00 g (6.87 mmol) of **1** in 29 ml of ether for 4.8 hr at 0 °C produced 330 mg (16%) of 2,4,6-tri-*t*-butyl-*N*-isopropylaniline (**3c**) (by NMR and IR), 1.23 g of white crystals, and 100 mg (6%) of 2,4-di-*t*-butyl-6-isopropylaniline (**4c**), which was recrystallized eight times from methanol, mp 86.0—87.5 °C; IR (KBr): 3485 and 3405 cm^{-1} (νNH_2); NMR (CCl_4): δ 1.20 (d, J=7 Hz, 6H), 1.26 (s, 9H), 1.43 (s, 9H), 2.89 (sep, J=7 Hz, 1H), 3.54 (broad s, 2H), and 7.00 (ABq, J=2 Hz, $\Delta\delta$=0.08, 2H); Mass: *m/e* 247 (M^+, 23%) and 232 (100).

Found: C, 82.77; H, 11.81; N, 5.87%. Calcd for $C_{17}H_{29}N$: C, 82.52; H, 11.82; N, 5.66%.

The white crystals were rechromatographed on an alumina dry column with hexane to give 449 mg (21%) of 1-hydroxyimino-2,4,6-tri-*t*-butyl-4-isopropyl-2,5-cyclohexadiene (**5c**) and 710 mg (40%) of **2**, which were identified by the spectral data.

Reaction of ***1*** *with* t-*Butylmagnesium Chloride.* Reaction of a Grignard solution prepared from 2.02 g (83.1 mmol) of magnesium and 6.34 g (68.5 mmol) of *t*-butyl chloride in 20 ml of ether with 2.00 g (6.87 mmol) of **1** in 27 ml of ether for 5.9 hr at 0 °C afforded 646 mg (28% based on consumed **1**) of 2,4,6,*N*-tetra-*t*-butylaniline (**3d**) (by NMR), 113 mg (5.7%) of recovered **1**, and 833 mg (49%) of **2** (by IR and NMR).

Reaction of ***1*** *with Benzylmagnesium Chloride.* Reaction of a Grignard solution prepared from 3.47 g (151 mmol) of magnesium and 9.59 g (75.5 mmol) of benzyl chloride in 25 ml of ether with 2.00 g (6.87 mmol) of **1** in 22 ml of ether for 3.5 hr at 0 °C gave 1.86 g of bibenzyl contaminated with a small amount of impurities, 535 mg of white crystals, 460 mg 1-hydroxyimino-4-benzyl-2,4,6-tri-*t*-butyl-2,5-cyclohexadiene (**5e**), 961 mg (38%) of 1-hydroxyimino-6-benzyl-2,4,6-tri-*t*-butyl-2,4-cyclohexadiene (**6e**) (by IR and NMR), and 594 mg of brown oil, which seemed to be mainly benzyl alcohol according to the IR and NMR spectra. The white crystals were treated with hexane. The insoluble part (100 mg) was identified as **5e** by IR and NMR. The soluble part was chromatographed on an alumina dry column with hexane to give 222 mg (12%) of **2** and 78 mg of **5e**, the total amount of which was 638 mg (25%).

Reaction of ***1*** *with* 1-*Adamantylmagnesium Bromide.* The Grignard reagent was prepared from 586 mg (24.2 mmol) of magnesium and 4.34 g (20.2 mmol) of 1-adamantyl bromide in 24 ml of ether over 2 hr. An ethereal solution (14 ml) of **1** (1.00 g, 3.44 mmol) was added to the Grignard reagent dropwise with stirring at 0 °C over 1 hr. After additional stirring for 4 hr, the reaction mixture was treated with aqueous ammonium chloride, extracted with ether and filtered to give 943 mg of light gray crystals, mp>220 °C (lit,[14] 288—290 °C); Mass: *m/e* 270 (M^+, 11%) and 135 (100). This compound was considered to be biadamantane. The filtrate was dried over anhydrous magnesium sulfate. After the solvent was removed, the residue was chromatographed on a silica gel dry column with carbon tetrachloride.

The first fraction (R_f=1.0—0.4) gave 2.153 g of pale yellow crystalline material, which seemed to contain **1** according to the NMR spectrum but the accurate amount could not be determined, NMR (CCl_4): δ 1.33 (s), 1.38 (s), 7.46 (s) [these three signals are due to **1**], and broad signals at 1.62, 1.79, and 1.81. The second fraction (R_f=0.4—0.2) afforded 352 mg of tarry material, which was rechromatographed on an alumina dry column with hexane to give 110 mg (12.2%) of **2** and 59 mg (4.2%) of 1-hydroxyimino-4-(1-adamantyl)-2,4,6-tri-*t*-butyl-2,5-cyclohexadiene (**5f**) as colorless tar, which showed the identical IR and NMR spectra with those of an authentic sample.[6] The other fractions gave unidentified materials.

*Reaction of 1-Hydroxyimino-2,4,6-tri-*t*-butyl-6-methyl-2,4-cyclohexadiene (**6αa**) with Methylmagnesium Iodide in the Presence of Excess Magnesium.* The Grignard reagent was prepared from 2.4 g (16.9 mmol) of methyl iodide and 530 mg (21.8 mmol) of magnesium in 9 ml of ether. Into a reaction tube containing an ethereal solution (0.5 ml) of **6αa** (50.0 mg, 0.171 mmol), 2 ml of the Grignard reagent with excess of magnesium metal was pipetted. After being stirred for 3 hr at room temperature, the reaction mixture was worked up as usual to give 36.1 mg of tarry material, which was a mixture of **6αa**, **6βa**, and 2,4-di-*t*-butyl-6-methylaniline (**4a**) (molar ratio: 19 : 15 : 16 ; 38, 30, and 32%, respectively, according to the signal intensity on the NMR spectrum). The separation of the products was carried out by tlc (silica gel, benzene) to afford 8.8 mg (17.6%) of an isomer of 1-hydroxyimino-2,4,6-tri-*t*-butyl-6-methyl-2,4-cyclohexadiene (**6βa**), 6.1 mg (12%) of **6αa**, and 5.0 mg (13%) of **4a**.

Reaction of ***6αa*** *with Magnesium and Magnesium Dibromide.* Anhydrous magnesium dibromide was prepared by the reaction of 1,2-dibromoethane (3.88 g, 20.7 mmol) with magnesium (624 mg, 26.4 mmol) in ether (14 ml).[15] The mixture separated into colorless upper layer and gray lower layer. The lower layer was pipetted with excess magnesium remaining therein into a reaction tube containing an ethereal solution (1 ml) of **6αa** (50.5 mg, 0.174 mmol). The mixture was stirred for 2.8 hr at room temperature and worked up as usual to give 46.5 mg of tarry material, whose NMR spectrum exhibited two sets of the signals due to **6αa** and **4a** in a molar ratio of 3 : 8 (27 and 73% respectively). The residue was subjected to preparative tlc (silica gel, benzene). The first fraction (R_f=0.68) gave 4.6 mg (9%) of **6αa**, which was identified by the NMR and IR spectra but contamination of a small amount of **6βa** was suggested by the following weak signals, NMR (CCl_4): δ 0.91 (s), 1.28 (s), 1.63 (s), and 5.25 (weak). The second fraction (R_f=0.24) afforded 18.9 mg of tarry material, whose NMR spectrum was nearly identical with that of **4a** but some other peaks were observed in the aromatic region. The purification by further tlc (silica gel, dichloromethane) gave 10.3 mg (27%) of **4a** (by IR and NMR).

Reaction of ***6e*** *with Magnesium and Magnesium Dibromide.* An ethereal solution (5 ml) of **6e** (203 mg, 0.55 mmol) and magnesium-containing 3 ml portion of an ethereal solution of magnesium dibromide prepared from magnesium (1 g, 41.2 mmol), 1,2-dibromoethane (5 g, 26.6 mmol), and ether (20 ml) were stirred for 3.5 hr at 0 °C. After hydrolysis, the

reaction mixture was chromatographed on an alumina dry column to give 29.4 mg (14.5%) of **6e** and 90 mg of tarry material, which was again chromatographed on a silica gel dry column with hexane–benzene (4 : 1) as eluent to give 46 mg (44%) of 2-benzyl-4,6-di-*t*-butyl-*N*-benzylideneaniline (**11**) as a yellow tar, which crystallized on standing and was recrystallized three times from aqueous ethanol to give pale yellow crystals, mp 92—93 °C; IR (KBr): 1625 (νC=N), 875 (1,2,4,6-substituted phenyl), 728, 695, and 685 cm^{-1} (two phenyls); NMR (CCl_4): δ 1.35 (s, 18H), 3.76 (s, 2H), and 7.0—7.7 (m, 13H); λ_{max} (hexane): 253 (ε 14300) and 349 nm (1730); Mass: *m/e* 383 (M^+, 38%), 368 (M^+-15, 100), 292 (M^+-PhCH_2, 11), 91 (33), and 57 (26).

Found: C, 87.60; H, 8.81; N, 3.64%. Calcd for $C_{28}N_{33}N$: C, 87.68; H, 8.67; N, 3.65%.

Reaction of 2,4-Di-t-butyl-6-methylnitrosobenzene (12) with Methylmagnesium Iodide. 1) To an ice-cold Grignard solution prepared from 9.47 g (71.8 mmol) of methyl iodide and 1.78 g 73.2 mmol) of magnesium in 30 ml of ether, an ethereal solution (20 ml) of 1.55 g (6.65 mmol) of **12** was added dropwise with stirring over 20 min. After additional stirring for 50 min at 0 °C and usual work-up, the residue was chromatographed on a silica gel dry column with carbon tetrachloride. The first fraction (R_f=1—0.81) gave 18 mg (0.6%) of 2,4,2′,4′-tetra-*t*-butyl-6,6′-dimethylazobenzene (**15**) as orange crystals, mp 156—158 °C; NMR (CCl_4): δ 1.37 (s, 36H), 2.24 (s, 6H), 7.04 (d, J=2 Hz, 2H), and 7.32 (d, J=2 Hz, 2H); λ_{max} (hexane): 238 (ε 9040), 247 (sh) (8750), 311.5 (15650), and 486 nm (1750); Mass: *m/e* 434 (M^+, 5.4%), 217 (35), and 57 (100).

The second fraction (R_f=0.81—0.48) gave 281 mg (17%) of 1-hydroxyimino-2,4-di-*t*-butyl-6,6-dimethyl-2,4-cyclohexadiene (**14**) as white crystals, which were recrystallized four times from methanol, mp 144.5—146 °C; IR (KBr): 3295, 3170 (νOH), and 965 cm^{-1} (νNO); NMR (CCl_4): δ 1.06 (s, 9H), 1.22 (s, 9H), 1.46 (s, 6H), 5.10 (d, J=2 Hz, 1H), 6.12 (d, J=2 Hz, 1H), and 6.96 (s, 1H); λ_{max} (hexane): 300 (sh) (ε 6510), 308.5 (7250), and 319 (sh) nm (4700); Mass: *m/e* 249 (M^+, 14%), 176 (100), and 57 (80).

Found: C, 77.34; H, 11.14; N, 5.33%. Calcd for $C_{16}H_{27}NO$: C, 77.06; H, 10.92; N, 5.62%.

The third fraction (R_f=0.48—0.36) gave 975 mg of pale yellow tarry material, which was a mixture of **13** (44%) and **4a** (22%) (molar ratio by NMR; 2 : 1). When 50 mg portion of the mixture was treated with tlc (silica gel, benzene), **13** and **4a** were isolated. The IR and NMR spectra of **4a** were identical with those of an authentic sample.[13] The compound **13** was tentatively identified as *N*-(2,4-di-*t*-butyl-6-methylphenyl)-*N*-methylhydroxylamine by the spectral data. **13**; pale yellow oil; IR (neat): 3560 and 3400 cm^{-1} (broad, νOH); NMR (CCl_4): δ 1.27 (s, 9H), 1.39 (s, 9H), 2.55 (s, 3H), 3.09 (s, 3H), 4.95 (broad s, 1H), and 6.98 (ABq, $\Delta\delta$=0.15, J=2 Hz, 2H). This compound changed into a crystalline material on standing, which seemed to be a mixture of many components because of the complexity of the NMR and mass spectra.

2) Reaction of a Grignard solution prepared from 1.16 g (47.7 mmol) of magnesium and 6.09 g (42.9 mmol) of methyl iodide in 15 ml of ether with 998 mg (4.28 mmol) of **12** in 12 ml of ether for 3.7 hr at 0 °C gave a small amount of **15**, 224 mg (21%) of **14**, and 620 mg of a mixture of **13** and **4a** (molar ratio: 1.7 : 1, which was calculated on the base of the intensity of the NMR signals due to the methyl group; a singlet at δ 3.09 of **13** and a singlet at 2.12 of **4a**).

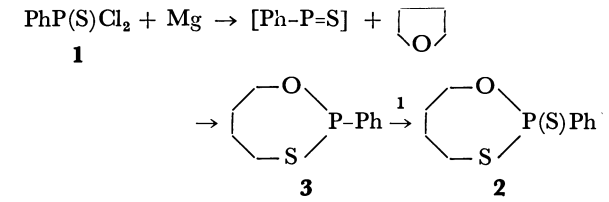
Phosphinidenes and Related Intermediates. IV.[1] Reactions of Phosphinothioylidenes with *cis*- and *trans*-Stilbene Oxides

Shigenobu NAKAYAMA, Masaaki YOSHIFUJI, Renji OKAZAKI, and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received September 28, 1974)

Phosphinothioylidenes were generated by the reaction of phosphonothioic dichlorides with magnesium. Reactions of phosphinothioylidenes with *cis*- and *trans*-stilbene oxides gave 1,3,2-oxathiaphospholane 2-sulfide derivatives (**6**, **7**, **9**, and **11**) stereospecifically, except for the reaction of phenylphosphinothioylidene with *trans*-stilbene oxide, along with *cis*- and/or *trans*-stilbenes. The formation mechanisms, which involve phenylphosphinothioylidene coordinated by the ethereal oxygen atom, and the conformation of 1,3,2-oxathiaphospholane 2-sulfides were discussed.

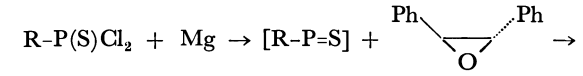
There is no report on reactions of phosphinidenes, phosphinylidenes, and phosphinothioylidenes with cyclic ethers, but reaction of phenylphosphinylidene with ketene acetal[2] and reaction of phenylphosphinidene with allyl ethyl sulfide[3] have been reported. In the previous paper,[1] it has been reported that phenylphosphinothioylidene generated by the reaction of phenylphosphonothioic dichloride (**1**) with magnesium reacted with tetrahydrofuran (THF) to give 2-phenyl-1,3,2-oxathiaphosphepane 2-sulfide (**2**), but phenylphosphinylidene generated from phenylphosphonic dichloride and magnesium gave no identified product with THF.



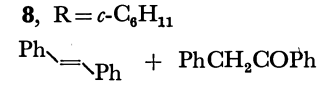
1 **3** **2**

This paper describes the reactions of phosphinothioylidenes with *cis*- and *trans*-stilbene oxides, which are more reactive than THF, to afford insertion products into the C–O bond of the epoxides and deoxygenation products of the epoxides.

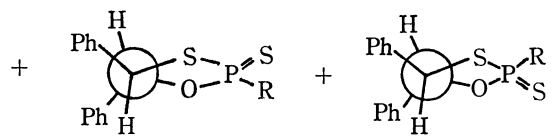
Phenylphosphinothioylidene generated from **1** and magnesium reacted with *trans*-stilbene oxide to give *trans*-stilbene (**4**), benzyl phenyl ketone (**5**), 2,*trans*-4,5-triphenyl- (**6**), and 2,*cis*-4, 5-triphenyl-1,3,2-oxathiaphospholane 2-sulfides (**7**) in 65, 9, 8, and 17% yields, respectively, based on *trans*-stilbene oxide consumed. Among the isomers of **6** and **7**, 2,*c*-4, *t*-5- (**6a**), 2, *t*-4,*t*-5- (**7a**), and 2,*c*-4, *c*-5-triphenyl-1,3,2-oxathiaphospholane *r*-2-sulfides could be isolated in a pure state.



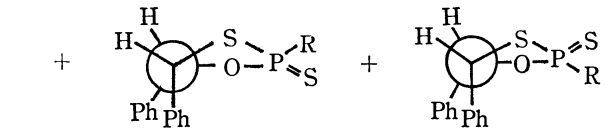
1, R=Ph
8, R=*c*-C_6H_{11}



4 **5**



6a, R=Ph **6b**, R=Ph



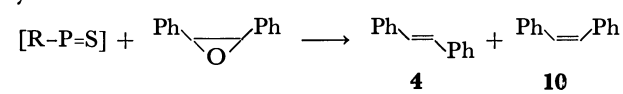
7b, R=Ph **7a**, R=Ph
9b, R=*c*-C_6H_{11} **9a**, R=*c*-C_6H_{11}

Cyclohexylphosphonothioic dichloride (**8**) reacted similarly with *trans*-stilbene oxide in the presence of magnesium to give **4**, 2-cyclohexyl-*t*-4, *t*-5-diphenyl- (**9a**), and 2-cyclohexyl-*c*-4, *c*-5-diphenyl-1,3,2-oxathiaphospholane *r*-2-sulfides (**9b**) in 34, 6, and 9% yields, respectively.

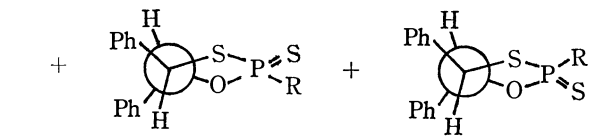
The structures of **6**, **7**, and **9** were confirmed by elemental analyses and spectral data. The assignment of *cis* or *trans* configuration between 4- and 5-phenyl groups in **6** and **7** was done by comparison of their spectral data with those of authentic samples synthesized by unequivocal routes. In the case of **9**, the assignment was done based on the similarity of the coupling constants of the methine protons to those of **7**.

A mixture of **6a** and **6b** was synthesized from *threo*-2-mercapto-1,2-diphenylethan-1-ol[4] and **1** using triethylamine as a base. Reaction of the *erythro* derivative[4] and **1** gave a mixture of **7a** and **7b** by use of pyridine as a base, but the use of triethylamine afforded only **7b**.

The assignment of *cis* or *trans* between 2- and 4-substituents in **6**, **7**, and **9** was done based on chemical shifts and coupling constants of the methine protons by use of molecular models as will be discussed later.



4 **10**



6a, R=Ph **6b**, R=Ph
11a, R=*c*-C_6H_{11} **11b**, R=*c*-C_6H_{11}

cis-Stilbene oxide reacted with **1** in the presence of magnesium to afford *trans*- (**4**), *cis*-stilbenes (**10**), and **6** in 28, 2, and 31% yields, respectively. Similarly the reaction of *cis*-stilbene oxide with **8** in the presence of magnesium gave **4**, **10**, and 2-cyclohexyl-*trans*-4,5-diphenyl-1,3,2-oxathiaphospholane 2-sulfides (**11**) in 16, 14, and 32% yields, respectively, based on *cis*-

stilbene oxide consumed. In these reactions, **7** and **9** could not be detected by NMR.

In the presence of magnesium(II) chloride, the reaction of **1** with magnesium and *trans*-stilbene oxide gave **4**, **5**, **6**, and **7** in 39, 5, 18, and 1% yields, respectively, based on *trans*-stilbene oxide consumed. The product ratio of **6** and **7** in this reaction is remarkably different from that in the absence of magnesium(II) chloride.

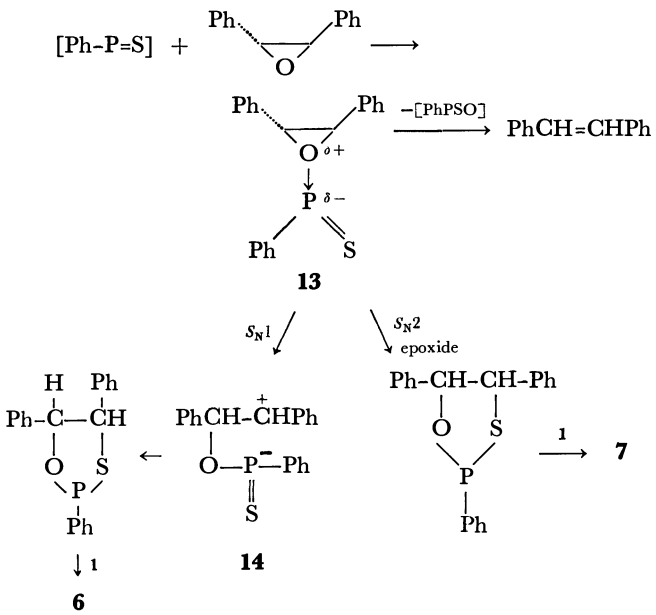
Reaction of *trans*-stilbene oxide with magnesium and magnesium(II) chloride gave no stilbenes but benzyl phenyl ketone (**5**) and *erythro*-2-chloro-1,2-diphenylethan-1-ol (**12**) in 53 and 43% yields, respectively, based on *trans*-stilbene oxide consumed. It is known that **5** is formed in the reaction of stilbene oxide with magnesium chloride.[5]

Reactions of phosphinylidenes with stilbene oxides gave different and complicated products, except for the formation of stilbenes. These results will be reported in near future.

Reaction Mechanism. Only the reaction of **1** with *trans*-stilbene oxide and magnesium gave **5** and a mixture of inverted and retained 1,3,2-oxathiaphospholane 2-sulfide derivatives, indicating a contribution of S_N1 pathway, but the other reactions gave only the inverted derivatives stereospecifically, suggesting the S_N2 character. Moreover, in the reaction of **1** with magnesium and *trans*-stilbene oxide, the presence of magnesium(II) chloride increased the formation of retention products (**6**) and decreased that of inversion products (**7**), supporting an increase of a contribution of S_N1 pathway by the epoxide coordinating to magnesium(II) chloride, because **6** is more thermodynamically stable than **7**.

Mechanism for the formation of **6** and **7** is considered as follows, though participation of Grignard type species, $[PhClPS]^-$ ^+MgCl, could not be ruled out completely.

The mechanism involves phenylphosphinothioylidene coordinated by the oxygen atom of *trans*-stilbene oxide (**13**) as an intermediate.



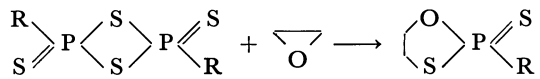
Stilbenes are considered to be produced by the decomposition of the intermediate (**13**), but isolation of the expected phosphonothioic acid was not tried.

The intermediate (**13**) attacks *trans*-stilbene oxide as sulfide anion in a S_N2 fashion or cleavages in a S_N1 manner to give **14**. Since the S_N2 attack suffers a steric hindrance by the phenyl groups in the *trans* relation and the anionic center of the zwitterion (**14**) is stabilized by the *P*-phenyl group, the S_N1 pathway becomes possible.

In the reaction with **8**, the S_N2 attack suffers a similar steric hindrance by the phenyl groups, but the cyclohexyl group does not stabilize the zwitterion analogous to **14**. Thus, the S_N1 pathway does not occur and the reaction becomes stereospecific.

In the case of *cis*-stilbene oxide, the reactions are stereospecific in the reactions with both **1** and **8**, because of almost no steric hindrance for the S_N2 attack.

The formation of **2** in the reaction of THF with phenylphosphinothioylidene[1] is explained by a similar mechanism. The following reaction has been reported to afford an analogous compound.[6]



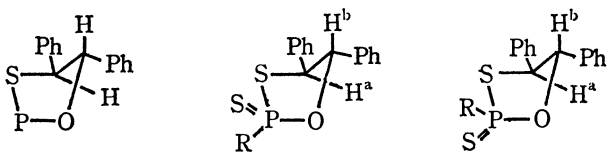
Conformation of ***6***, ***7***, ***9***, *and* ***11***. Their conformations were determined by consideration of NMR data and molecular models. The NMR data of the methine protons of **6**, **7**, **9**, and **11** are summarized in Table 1.

In the following discussion, it was assumed that protons in a 1,3-*cis* relation to a P=S group are deshielded, because protons in a 1,3-*cis* relation to a P=O group are deshielded in a five-membered ring[7] and it has been reported that P=O and P=S groups show a similar tendency in the case of six-membered rings.[8,9]

At first, the conformations of **6** and **11** are discussed.

The values of J_{HCCH}, J_{PSCH}, and J_{POCH} for all possible conformations were estimated using dihedral angles obtained from the molecular models. For J_{POCH}, a relationship proposed by Bergesen and Albriktsen[10] was used, but, for J_{PSCH}, a similar relationship was assumed considering that J_{PSCH} is usually larger than the corresponding J_{POCH}.[11]

From these considerations, the most plausible conformation is that such as (I), in which four atoms of C–S–P–O bonds form one plane. To determine the full conformation, the chemical shifts of two methine protons were taken into account.



(I) (Ia) R=Ph≡**6a** (Ib) R=Ph≡**6b**
(Ia′) R=*c*-C_6H_{11}≡**11a** (Ib′) R=*c*-C_6H_{11}≡**11b**

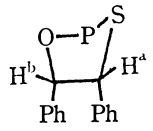
In the case of (Ia′), H^b should be deshielded by the P=S group, whereas, in the case of (Ib′), H^a should be deshielded. Thus, the $\delta_{H^b}-\delta_{H^a}$ value in (Ia′) becomes larger than that in (Ib′). Therefore, it is

Table 1. NMR data of methine protons of **6**, **7**, **9**, and **11** (in $CDCl_3$)

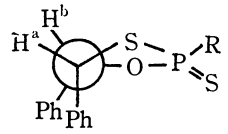
		6a	6b	7a	7b	9a	9b	11a	11b
δ	SCH<	5.08	5.17	5.3	5.07	5.2	5.00	4.77	4.93
(ppm)	OCH<	5.83	5.52	6.38	5.72	6.23	5.77	5.62	5.32
J_{HCCH} (Hz)		10.6	10.6	5	5	5	5.3	10.6	10.0
J_{PSCH}		0	0	14	12	12	12	0	0
J_{POCH}		1.5	2	5	8	5	7.3	1.6	0

reasonable to consider that **11a** and **11b** have the conformations such as (Ia') and (Ib'), respectively. Since it has been known that the effects on H^a and H^b are analogous, even though an alkyl group on the phosphorus atom is substituted by a phenyl group,[7,8] it may be reasonable to consider that **6a** and **6b** have the conformations such as (Ia) and (Ib), respectively.

Next, the conformations of **7** and **9** are discussed. On the basis of a similar consideration, the partial conformation (II) is the most reasonable for these compounds.



(II)



(IIa) R=Ph≡**7b** (IIb) R=Ph≡**7a**
(IIa') R=*c*-C_6H_{11}≡**9b** (IIb') R=*c*-C_6H_{11}≡**9a**

In the case of (IIa'), H^a and H^b should be shielded by the P=S group. In the case of (IIb'), H^a and H^b should be deshielded. Thus, it may be reasonable to consider that **9a** and **9b** have the full conformations such as (IIb') and (IIa'), respectively. In the cases of (IIa) and (IIb), it may be reasonable to consider that **7a** and **7b** have the full conformation such as (IIb) and (IIa), respectively.

Experimental

All melting and boiling points are uncorrected. The instruments used for spectral measurements were the same as those described in the previous paper.[1] All reactions were carried out under nitrogen.

Materials. The following compounds were prepared by the methods reported in the literature: phenylphosphonothioic (**1**)[12] (bp 134—138 °C/14 mmHg), cyclohexylphosphonothioic dichlorides (**8**)[13] (bp 96—97 °C/0.95 mmHg), *cis*-[14] (mp 37.3—37.6 °C), and *trans*-stilbene oxides[15] (mp 69.5—71 °C).

Reaction of **1** *in the Presence of* trans-*Stilbene Oxide.* *a) With Magnesium.* A solution of **1** (5.32 g, 25.2 mmol) in THF (7 ml) was added dropwise to a stirred mixture of magnesium (0.66 g, 27.5 mg-atom) and *trans*-stilbene oxide (2.47 g, 12.6 mmol) in THF (43 ml) under cooling with water occasionally, initiating by addition of a small amount of iodine. After the exothermal reaction ceased (about 1 hr), the mixture was refluxed with stirring for additional 2 hr. The solvent was removed *in vacuo*, and the residue was extracted with chloroform. The extract was washed with water, and dried with anhydrous magnesium sulfate. After evaporation, the residue was chromatographed using a silica gel dry column to give 0.45 g (2.3 mmol) of unchanged *trans*-stilbene oxide, 1.21 g (6.7 mmol) of **4**, 0.17 g (0.9 mmol) of **5**, mp 56—57 °C (from *n*-hexane) (lit,[16] 57 °C), 0.29 g (0.8 mmol) of a mixture of **6a** and **6b** (18 : 1 by NMR), and 0.62 g (1.7 mmol) of a mixture of **7a** and **7b** (1.1 : 1 by NMR). The yields of **4**, **5**, **6**, and **7** were 65, 9, 8, and 17%, respectively, based on *trans*-stilbene oxide consumed.

Recrystallization of the mixture of **6a** and **6b** from methanol gave pure **6a**, mp 112.5—113.5 °C. IR (KBr): 1107 (P-Ph) and 975 cm^{-1} (P-O-C); NMR ($CDCl_3$): δ 5.08 (d, J_{HCCH} 10.6 Hz, 1H, S-CH<), 5.83 (dd, J_{HCCH} 10.6. J_{POCH} 1.5 Hz, 1H, O-CH<), 7.0—7.4 (m, 10 H, 2Ph), 7.4—7.9 (m, 3H, $2H^m$ and H^p of P-Ph), and 7.9—8.45 (m, J_{PH^o} 16 Hz, 2H, $2H^o$ of P-Ph); Mass: *m/e* 368 (M^+).

Found: C, 65.36;, H, 4.43; S, 17.12%. Calcd for $C_{20}H_{17}OPS_2$: C, 65.20; H, 4.65; S, 17.40%.

Compound **6b** could not be isolated from the mixture in the pure state. NMR ($CDCl_3$): δ 5.17 (d, J_{HCCH} 10.6 Hz, 1H, S-CH<) and 5.52 (dd, J_{POCH} 2, J_{HCCH} 10.6 Hz, 1H, O-CH<). The signal of the three phenyl groups were not clearly distinguished from those of **6a**.

Recrystallization of the mixture of **7a** and **7b** from methanol gave pure **7a** and **7b**.

7a: mp 154—155 °C; IR (KBr): 1115 (P-Ph) and 955 cm^{-1} (P-O-C); NMR ($CDCl_3$): δ 5.3 (dd, J_{HCCH} 5, J_{PSCH} 14 Hz, 1H, S-CH<), 6.38 (t, $J_{HCCH}=J_{POCH}$ 5 Hz, 1H, O-CH<), 6.85-7.45 (m, 10 H, 2Ph), 7.45—7.8 (m, 3H, $2H^m$ and H^p of P-Ph), and 7.95—8.4(m, J_{PH^o} 16 Hz, 2H, $2H^o$ of P-Ph); Mass: *m/e* 368 (M^+).

7b: mp 129—131 °C; IR (KBr): 1102 (P-Ph) and 950 cm^{-1} (P-O-C); NMR ($CDCl_3$): δ 5.07 (dd, J_{HCCH} 5, J_{PSCH} 12 Hz, 1H, S-CH<), 5.72 (dd, J_{HCOCH} 5, J_{POCH} 8 Hz, 1H, O-CH<), 7.0—7.3 (m, 10 H, 2Ph), 7.3—7.65 (m, 3H, $2H^m$ and H^p of P-Ph), and 7.9—8.4 (m, J_{PH^o} 16 Hz, 2H, $2H^o$ of P-Ph); Mass: *m/e* 368 (M^+).

Found: C, 65.17; H, 4.66; S, 17.35%. Calcd for $C_{20}H_{17}OPS_2$: C, 65.20; H, 4.65; S, 17.40%.

b) With Magnesium-Magnesium(II) Chloride. A suspended mixture of magnesium (0.66 g, 27.5 mg-atom), magnesium-(II) chloride (2.61 g, 27.5 mmol), and *trans*-stilbene oxide (2.47 g, 12.6 mmol) in THF (45 ml) was stirred under reflux until magnesium(II) chloride had almost dissolved. At room temperature, a solution of **1** (5.30 g, 25.1 mmol) in THF (5 ml) was added drop by drop with stirring to the above mixture. A small amount of iodine was added to start the reaction. The reaction was so exothermic that the mixture was cooled with water occasionally. The reaction mixture was stirred until the exothermal reaction had ceased (about 1 hr), and then further stirred under reflux for 2 hr. After a similar work-up, the residue was chromatographed using

a silica gel dry column to give 0.17 g (0.9 mmol) of unchanged oxide, 0.82 g (4.6 mmol) of **4**, 0.11 g (0.6 mmol) of **5**, 0.76 g (2.1 mmol) of a mixture of **6a** and **6b**, and 0.04 g (0.1 mmol) of a mixture of **7a** and **7b**. They yields of **4**, **5**, **6**, and **7** were 39, 5, 18 and 1%, respectively, based on *trans*-stilbene oxide consumed.

*Reaction of **8** with Magnesium and* trans-*Stilbene Oxide.* A solution of **8** (4.34 g, 20.0 mmol) in THF (5 ml) was added drop by drop to a stirred suspension containing magnesium (0.53 g, 21.8 mg-atom), *trans*-stilbene oxide (2.00 g, 10.3 mmol), and THF (40 ml). When a small amount of iodine was added, an exothermal reaction occurred, and ended in about 1 hr. The mixture was stirred at room temperature for 14 hr. After a similar work-up, the residue was chromatographed using a silica gel dry column to give 0.63 g (3.5 mmol) of **4**, 0.23 g (0.6 mmol) of **9a**, and 0.33 g (0.9 mmol) of **9b**. The yields of **4**, **9a**, and **9b** were 34, 6, and 9%, respectively, based on *trans*-stilbene oxide used.

9a: mp 162.3—163.3 °C (from hexane); NMR ($CDCl_3$): δ 1.0—3.0 (m, 11H, *c*-C_6H_{11}), 5.2 (dd, J_{HCCH} 5, J_{PSCH} 12 Hz, 1H, S–CH〈), 6.23 (t, $J_{HCCH}=J_{POCH}$ 5 Hz, 1H, O–CH〈), and 7.08 (m, 10 H, 2Ph); Mass: *m/e* 374 (M^+).

Found: C, 64.28; H, 6.24; S, 17.13%. Calcd for $C_{20}H_{23}OPS_2$: C, 64.14; H, 6.19; S, 17.12%.

9b: mp 167—168 °C (from hexane); NMR ($CDCl_3$): δ 1.0—2.6 (m, 11H, *c*-C_6H_{11}), 5.00 (dd, J_{HCCH} 5.3, J_{PSCH} 12 Hz, 1H, S–CH〈), 5.77 (dd, J_{HCCH} 5.3, J_{POCH} 7.3 Hz, 1H, O–CH〈), and 7.12 (s, 10 H, 2Ph); Mass: *m/e* 374 (M^+).

Found: C, 64.37; H, 6.30; S, 17.04%. Calcd for $C_{20}H_{23}OPS_2$: C, 64.14; H, 6.19; S, 17.12%.

*Reaction of **1** with Magnesium and* cis-*Stilbene Oxide.* A solution of **1** (2.49 g, 11.8 mmol) in THF (5 ml) was added dropwise to a stirring mixture containing magnesium (0.30 g, 12.5 mg-atom), *cis*-stilbene oxide (1.15 g, 5.9 mmol), and THF (20 ml). To activate magnesium was added a small amount of iodine. After the exothermal reaction ceased, the mixture was further stirred under reflux for 2 hr. After a similar treatment, the residue was chromatographed using a silica gel dry column to give 0.10 g (0.5 mmol) of unchanged oxide, 0.27 g (1.5 mmol) of **4**, 0.02 g (0.1 mmol) of **10**, and 0.62 g (1.7 mmol) of a mixture of **6a** and **6b** (1.8 : 1 by NMR), but **7a** and **7b** were not detected by tlc and NMR. The yields of **4**, **10**, and **6** were 28, 2, and 31%, respectively, based on the *cis*-stilbene oxide consumed.

*Reaction of **8** with Magnesium and* cis-*Stilbene Oxide.* A solution of **8** (1.95 g, 9.0 mmol) in THF (5 ml) was added dropwise with stirring to a mixture of magnesium (0.23 g, 9.5 mg-atom) and *cis*-stilbene oxide (0.89 g, 4.5 mmol) in THF (18 ml). A small amount of iodine was added to start the reaction. After exothermal reaction ended, the mixture was refluxed for 2 hr. After a similar treatment, the residue was chromatographed using a silica gel dry column to give 0.02 g (0.1 mmol) of unchanged oxide, 0.12 g (0.7 mmol) of **4**, 0.11 g (0.6 mmol) of **10**, and 0.54 g (1.4 mmol) of a mixture of **11a** and **11b** (1.7 : 1 by NMR). However, **9a** and **9b** were not detected by NMR. The yields of **4**, **10**, and **11** were 16, 14, and 32%, respectively, based on *cis*-stilbene oxide consumed. The mixture of **11a** and **11b** could not be separated by tlc and fractional recrystallization. The following data are those of the mixture, mp 139—160 °C (from methanol or hexane); NMR ($CDCl_3$): δ 1.0—2.8 (m, *c*-C_6H_{11}), 4.77 (d, J_{HCCH} 10.6 Hz, S–CH〈 of **11a**), 4.93 (d, J_{HCCH} 10 Hz, S–CH〈 of **11b**), 5.32 (d, J_{HCCH} 10 Hz, O–CH〈 of **11b**), 5.62 (dd, J_{HCCH} 10.6, J_{POCH} 1.6 Hz, O–CH〈 of **11a**), and 7.25 (s, Ph); Mass: *m/e* 374 (M^+).

Found: C, 64.44; H, 6.21; S, 16.98%. Calcd for $C_{20}H_{23}OPS_2$: C, 64.14; H, 6.19; S, 17.12%.

*Preparation of **7a** and **7b**.* *a) Using Pyridine as Base.* A solution of *erythro*-2-mercapto-1,2-diphenylethan-1-ol[4] (0.23 g, 1 mmol) and pyridine (0.4 ml) in dry benzene (10 ml) was added with stirring to a solution of **1** (0.23 g, 1.1 mmol) in dry benzene (40 ml) over 6 hr. Stirring was continued at room temperature for 17 hr and then under reflux for 9 hr. After filtration of pyridinium chloride and similar work-up, the residue was chromatographed using a silica gel dry column to give 0.07 g (0.19 mmol, 19%) of a mixture of **7a** and **7b** (1 : 1).

b) Using Triethylamine as Base. A solution of *erythro*-diphenylethane derivative (0.42 g, 1.8 mmol) and triethylamine (1.2 ml) in dry benzene (10 ml) was added to a stirring solution of **1** (0.38 g, 1.8 mmol) in dry benzene (40 ml) over 9 hr. The mixture was further stirred at room temperature for 15 hr. Similar treatment gave 0.12 g (0.32 mmol, 18%) of **7b**, mp 129—131 °C (from methanol), but **7a** could not be detected by NMR.

*Preparation of **6a** and **6b**.* A solution of *threo*-2-mercapto-1,2-diphenylethan-1-ol[4] (0.55 g, 2.4 mmol) and triethylamine (1.6 ml) in dry benzene (10 ml) was added to a stirring solution of **1** (0.51 g, 2.4 mmol) in dry benzene (40 ml) over 8 hr, and the mixture was further stirred at room temperature for 16 hr. Similar treatment gave 0.05 g (0.15 mmol) of a mixture of **6a** and **6b**, and 0.24 g (1.0 mmol) of the starting ethane. The yield was 12% based on the diphenylethane derivative consumed.

Reaction of trans-*Stilbene Oxide with Magnesium–Magnesium(II) Chloride.* A mixture of magnesium (0.22 g, 9.3 mg-atom) and magnesium(II) chloride (0.86 g, 9.1 mmol) in THF (40 ml) was stirred under reflux for 2 hr until magnesium(II) chloride had dissolved. A few drops of carbon tetrachloride were added to activate magnesium, and the mixture was stirred under reflux. A solution of *trans*-stilbene oxide (1.57 g, 8.0 mmol) in THF (10 ml) was added dropwise to the above mixture, and the mixture was further stirred under reflux for 96 hr. Similar treatment gave 0.98 g (5.0 mmol) of unchanged oxide, 0.32 g (1.6 mmol) of **5**, 0.31 g (1.3 mmol) of *erythro*-2-chloro-1,2-diphenylethan-1-ol (**12**), mp 81—82 °C (from hexane) (lit,[17] 76—77 °C); Mass: *m/e* 196 (M^+-HCl). The yields of **5** and **12** were 53 and 43%, respectively, based on *trans*-stilbene oxide consumed.

This work was supported by a grant from the Ministry of Education.

Penetration-depth Dependence of Photochemical Conversions in the Dye-sensitized Heterogeneous Photopolymerization of Acrylamide

Toshihiro YAMASE and Tsuneo IKAWA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 22, 1975)

The Amethyst violet-sensitized photolysis of *p*-tolyl *p*-anilinobenzenediazo sulfone initiated the polymerization of acrylamide in ethanol–water (9.3 : 0.7, v/v) to yield insoluble polymers. The polymer particles formed scattered the incident 546 nm light, leading to a change in the rate of photopolymerization. Using a 632.8 nm laser beam for viewing the sample at various penetration depths normal to the 546 nm light beam, a new method of determining the penetration-depth dependence of the yield of polymers was presented on the basis of the approximately linear relationship between the optical density at 632.8 nm and the polymer concentration. The method had the advantage that the progress of the photopolymerization, which takes place rapidly, can be easily followed with a high sensitivity below a 2.2% monomer conversion. From an evaluation of the magnitude of both the shadowing and forward scattering arising from the increasing number of polymer particles at various depths, it was confirmed that 546 nm light scattered by polymer particles brought about an effective photopolymerization over a wide range of the depths as a forward-scattering effect. Furthermore, the exposure to the 546 nm beam intensity range from 142 μW/cm^2 to 15.6 μW/cm^2 at sample depths up to 10 mm exhibited equal contributions of shadowing and forward scattering at the depth of $\sim$1.5 mm.

In photochemical experiments, the photoabsorbing properties of a sample vary with the irradiation time. This behavior may be due to change in the fraction of the photoexcited molecules during such photochemical reactions as the photobleaching of dye and photolysis. It is conceivable that the rate of the photochemical reaction varies as a function of the penetration depth as a result of the attenuation of the light transmitted through. In the photochemistry of solutions, most of the experimental data obtained by means of continuous irradiation have been concerned with the apparent reactions over the entire penetration depths in the sample solution, although the dependence of the rate on the incident light intensity has been measured. Unfortunately, there are very few published data on the penetration-depth dependence of photochemical reactions in samples, presumably because of the difficulty of measurements. We, therefore, undertook the evalution of the photochemical conversions at various penetration depths, using the dye-sensitized heterogeneous photopolymerization of acrylamide which was initiated by the amethyst violet (AV)-sensitized photolysis of the *p*-tolyl *p*-anilinobenzenediazo sulfone (TABS) formed by a reaction between sodium *p*-toluenesulfinate and *p*-anilinobenzendiazonium sulfate in ethanol–water (9.3 : 0.7, v/v). This report will describe the experimental techniques and presents the depth-dependence of photochemical conversions in the heterogeneous polymerization of acrylamide.

Experimental

Materials. The ethanol (Tokyo Kasei Co. GR grade) was used without further purification. The other materials, obtained from the Tokyo Kasei Co., were used after purification. The *p*-anilinobenzenediazonium sulfate was dissolved in a mixture of 100 ml of glacial acetic acid and 150 ml of acetone and reprecipitated with 250 ml of ether. This salt was dried in a vacuum desiccator with phosphorus pentoxide. The sodium *p*-toluenesulfinate and AV were purified by recrystallizations from a water–ethanol mixture. The acrylamide was purified by recrystallization from ethanol.

Sample Preparations. Sample solutions were prepared in the dark by mixing 2 ml of a 2.1×10^{-3} M *p*-anilinobenzenediazonium sulfate aqueous solution, 5 ml of a 5×10^{-2} M sodium *p*-toluenesulfinate aqueous solution, and 4 ml of a 10^{-3} M AV ethanol solution, by adding 7.1 g acrylamide to the mixture, and by, then diluting it with ethanol to a total volume of 100 ml. It was confirmed that 4×10^{-5} M TABS was formed with an equilibrium constant[1] of 5.2×10^{3} M^{-1} in the resulting solution; stock solutions during the experimental procedure showed no change in the absorbance at the absorption maxima of 450 and 546 nm for TABS and AV respectively. AV dye was found to obey Beer's law at the range of dye concentration employed ($\leq4\times10^{-5}$ M).

Methods. The absorption spectra were recorded on a Hitachi 624 spectrophotometer. Unless specified otherwise, all the results were obtained with quartz cells (10 mm internal path length) containing oxygen-free solutions obtained by the usual freeze-pump-thaw cycles. The molecular weights of the polyacrylamide obtained were measured by viscosity measurements at 29.4 °C in 1 M NaCl using the following relationship:[2] $[\eta]=3.73\times10^{-4}\times(\mathrm{Mw})^{0.66}$. The schematic diagram of the apparatus used for the depth-distribution experiments is given in Figure 1. The 546 nm and 632.8 nm

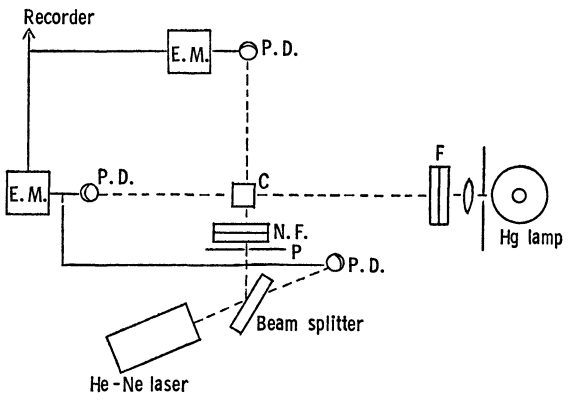

Fig. 1. Apparatus used for the depth distribution experiments.
F: 546 nm filters, N.F.: neutral density filters, P.D.: photodiode, E.M.: electrometer, C: sample cell, P: pinhole.

beam intensities were measured by means of a Coherent Radiation Laboratories Power Meter, Model 212. A 500-W super high-pressure Hg lamp was the source of the 546 nm light beam. A 2-mm aperture, a lens, and Toshiba Interference filters (KL-54+VO-52) were placed in the optical path before the cell to obtain the 546 nm light beam, which was focused at the range of the cell position with a beam diameter of 3 mm. The sample cell was positioned ~50 cm from the Hg lamp. The 632.8 nm beam from a He-Ne laser (Nippon Electric Co. GLB 2026B 1.2 mW output) was used as the analyzing light beam; its beam intensity was reduced by a beamsplitter (1 : 1), a 0.2 mm pinhole, and neutral density filters before entering the sample to prevent the photopolymerization of the sample. It was confirmed that the reduced 632.8 nm beam intensity of 0.32—0.40 μW (1.0—1.3 mW/cm²) brought about no chemical change in the sample during the experimental procedure. The intensities of the 546 and 632.8 nm light beams transmitted through the cell were monitored by means of Sharp SBC-102 photodiodes, and photocurrent signals obtained by the use of a Takeda Riken Co. electrometer TR-8651 were read out simultaneously on a Riken Denshi Co. Sp-H recorder. The calibration of the photodiode was accomplished with neutral density filters relating the electrical output of the photodiode to the fraction of light transmitted across the gap. The photocurrent output of each photodiode was directly proportional to each light-beam power. The reference beam passing through the beam splitter was converted to a signal in order to monitor the fluctuation in the beam intensity. Figure 2 shows the coordinate system for the sample. The 632.8 nm-analyzing-light beam interesects the 546 nm light beam at 90° in the sample solution. Various penetration depths up to 10 mm can be obtained by translating the sample cell in steps of 1 mm in the x direction in the stage of microscopy. When the 632.8 or 546 nm light beam is passed through the dispersion of the polymerizing medium, the beam is attenuated by diffraction, reflection, and refraction. If one polymer particle is considered, each of the three scattering mechanisms prevents the rays from maintaining their original direction. If the photodiode as a light detector is placed at a large distance from the dispersion so that it receives only parallel light, the refractive index will have little effect on the amount of light received. Thus, each photodiode was positioned ~30 cm from the sample cell. Multiple scattering occurs when light which has been scattered by one polymer particle is scattered again by another particle. This causes the photodiode to receive an excess amount of light. However, the error introduced by multiple scattering will be minimized if the photodiode has a high angular resolution and if the diameters of the light beams are small-3 mm and 0.2 mm for 546 and 632.8 nm respectively. The above possibility was confirmed by the following result: during the photopolymerization, a 632.8 nm beam detector may receive the 546 nm light scattered by the sample dispersions, too. However, the error due to the multiple scattering could be made negligible for the sample dispersions under the present experimental conditions, since no photocurrent arising from 546 nm scattered light was detected in the range of 10^{-8}—10^{-7} A corresponding to the 632.8 nm-analyzing-light-beam signal.

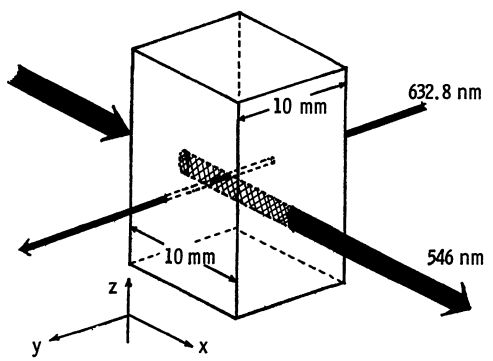

Fig. 2. Sample orientation.

Results

Fraction of 632.8 nm Laser Beam Transmission. While the deaerated sample solution was being continuously irradiated, the formation of the insoluble polyacrylamide produced a scattering of the incident light and resulted in a decrease in the fraction of the light transmitted. During the photopolymerization of acrylamide, no significant change occurred in the AV concentration. The polyacrylamide particles obtained seemed to be immovable during the irradiation (≤10 min) unless the solution was agitated. This result may be ascribed to equal specific gravities (~0.80) between the polymer particle and the solution. A long duration of the 546 nm light irradiation caused the polyacrylamide zone to bend down at the deep penetration depth in the cell. After the separation of the polymer particles produced in the 4-ml sample solution on a fine sintered glass filter, the filtrate was dumped into 200 ml of methanol, but no more polymers were precipitated as long as the monomer conversion was within 15%. This result confirmed that the amount of insoluble polymers observed in the irradiated sample cell covered sufficiently most of the polymers formed by dye sensitization, at least within a monomer conversion of 15%. The dependences of the molecular weight of the polyacrylamide on the monomer conversion and the incident 546 nm light intensity were also investigated. The experimental results are listed in Table 1. The molecular weight of 7—11 × 10^3 was slightly affected by both the monomer conversion (within 15%) and the incident 546 nm light intensity in the range from 17.5 to 350 μW/cm².

To prepare dispersions consisting of various polymer concentrations, dispersed solutions obtained by the above irradiation were diluted with ethanol. As-

Table 1. Dependences of molecular weight of polymer on monomer conversion and incident 546 nm light intensity[a)]

546 nm light intensity (μW/cm²)	Monomer conversion (%)	Molecular weight of polyer
350	14.1	7×10^3
350	11.2	9×10^3
350	6.3	$8—10\times10^3$
87.5	13.5	$7—11\times10^3$
35.0	15.4	$9—10\times10^3$
17.5	8.6	9×10^3

a) All systems contain 4×10^{-5} M AV, 4×10^{-5} M TABS, and 1 M acrylamide in ethanol-water (9.3 : 0.7, v/v).

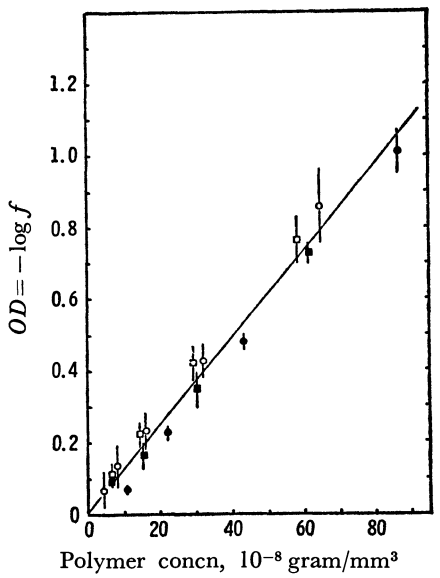

Fig. 3. Optical density ($OD=-\log f$) at 632.8 nm *vs.* concentration of polymer (10^{-8} gram/mm^3) in the dispersion obtained under various incident 546 nm light intensities. Cell thickness corresponding to the optical path length of the dispersion is 5 mm.
○: 350, ●: 87.5, □: 35.0, ■: 17.5 μW/cm^2.

suming uniform polymer concentrations in the resultant dispersions, the fraction (f) of the 632.8 nm laser beam transmitted through a dispersion (5-mm internal optical-path length) was measured. The attenuation of the incident 632.8 nm light was related to the polymer amount per unit volume of dispersion, since the AV absorption of 632.8 nm light could be neglected at low AV concentrations (below 4×10^{-5} M). The concentration of polyacrylamide, C, in 10^{-8} gram per cubic millimeter is plotted against the optical density OD ($=-\log f$) in Fig. 3. The error (vertical bars) in Fig. 3 was reflected in the fluctuation in the laser-beam intensity. An approximate linearity was shown by the curve up to $OD\approx1.1$. Above this value the experimental error was at its maximum because of the small photo-to-dark current signal ratio. The fact that the values corresponding to four different incident 546 nm light intensities seemed to lie on the same line may be explained in terms of the similar distribution of the polymer-particle size for all the dispersions, as was also suggested by the small effects of both the conversion and the incident-light intensity on the molecular weight. The slope of the rectilinear portion of the curve implied that OD was given by:

$$OD = -\log f = 2.4\times10^{-3}\,Cl = 0.17\,C'l \qquad (1)$$

where l and C' were an optical path length of the dispersion in mm and a monomer conversion in % respectively.

Recently, the light-transmission theory has been applied to non-uniform dispersions in an attempt to determine the relationship between the transmitted light and the characteristics of the dispersion. According to studies of liquid-liquid dispersions by McLaughlin and Rushton,[3] and fraction (f) of the parallel light transmitted through the liquid-liquid dispersion was independent of the drop-size distribution for all the cases studied and was expressed by the exponential relationship: $f=\exp(-al/4)$ (a is the interfacial area per unit of volume of dispersion).

It is interesting to note that Eq. (1) for our dispersions may be connected with the mathematical model simulating light transmission through liquid-liquid dispersions which was developed by McLaughlin and Rushton[3] although we have little information about the sizes and shapes of the polymer particles obtained.[4] At any rate, Eq. (1) allowed us to determine the penetration-depth dependence of the monomer conversion in the sample cell.

Photopolymerization at Various Depths. A 546 nm light beam with a diameter of 3 mm was used as an exciting light to measure monomer conversions at various penetration depths. The fraction (f) of the 632.8 nm laser beam passing through the sample at various depths normal to the 546 nm light beam was assumed to provide a one-dimensional representation of the optical-path variations in the sample as a function of x. The optical density ($=-\log f$) near the irradiated cell surface at $x\approx0.1$ mm was considered to provide the amount of the polymers obtained under a constant fraction of the incident 546 nm light beam, since there was no scattering medium in front of the cell surface during the irradiation. Figure 4 represents the variation in the optical densities at the depth of $x\approx0.1$ mm for various 546 nm light-beam intensities.

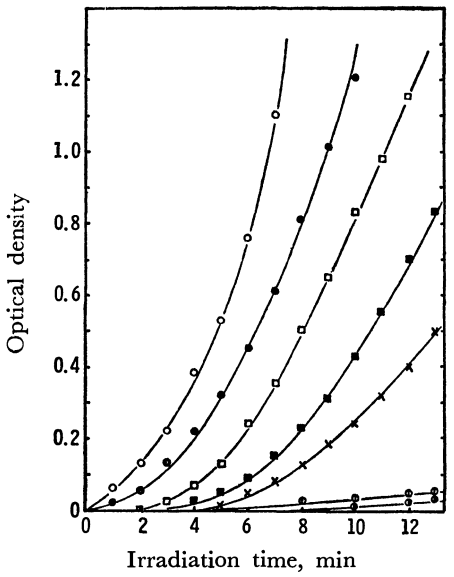

Fig. 4. Optical density at $x\approx0.1$ as a function of incident 546 nm beam intensity and irradiation time.
○: 142, ●: 99, □: 35.5, ×: 14.2, ⊕: 9.9 ◑: 7.1 μW/cm^2.

Figure 4 shows that the rate of the photopolymerization increased with the irradiation time up to the optical density of about 1.1, corresponding to a ~2.2% monomer conversion, and increased with an increase in the 546 nm-light-beam intensity. The results of the depth dependence of the optical density are shown in Fig. 5, where optical densities expressing the monomer conversions (Eq. (1)) are plotted against the irradi-

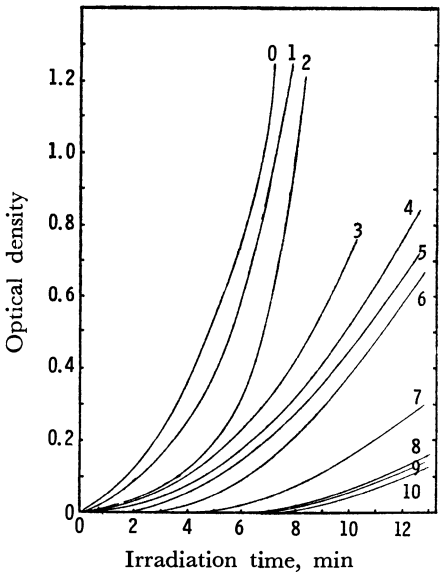

Fig. 5. Optical density as a function of irradiation time and the depth.
Numbers indicate the depth, x in mm. 546 nm light beam intensity incident on the sample is 142 μW/cm².

ation time or the corresponding values of the depth parameters. The plots show that the rate of photopolymerization decreases with an increase in the depth, x. The acceleration of the polymerization rate with the irradiation time at each depth may result from the accumulation of solid polyacrylamide in the system, as was discussed in connection with the heterogeneous thermal polymerization of acrylonitrile and vinyl chloride by Bamford and Jenkins[5] and Bengough and Norrish[6] respectively. When the exciting 546 nm light beam was turned on and off, the optical density at each depth showed a tendency to increase in the dark, but this dark reaction due to an after-effect was sluggish in comparison with the previous photo-reaction rate. The after-effect may be explained in terms of the occluded radicals observed in polyacrylamide particles, which induce continued polymerization and an increase in the optical density. The increase in the optical density during a period ($\leq$10 min) measured from the end of the 546 nm-light irradiation excluded the possibility of the significance of the diffusion of polymer particles to the outside of the 546 nm-light-beam path, since the optical density should decrease with an increase in the standing time after irradiation if the above possibility is operative. Therefore, most of the polyacrylamide particles may be considered to remain within the pathway of the exciting 546 nm light, at least during the irradiation time ($\leq$10 min). This implies that the dispersion length for the 632.8 nm laser beam is kept constant during the irradiation and that it is equal to a 546 nm-light-beam diameter of 3 mm.

Discussion

During the photopolymerization of acrylamide, the formation of insoluble polymers produced a scattering of the incident light, leading to a change in the rate of photopolymerization. The rate of the photopolymerization obviously increases when light which has been scattered by praticles induces the polymerization again ("scattering effect"). However, scattering by particles prevents a part of the exciting beam from maintaining its original direction, resulting in a less effective photopolymerization in the background ("shadowing effect"). To evaluate the magnitude of these effects of scattering and shadowing from the increasing number of polymer particles at various penetration depths, we first undertook an evaluation of the optical densities derived on the basis of the assumption that neither scattering nor shadowing occurred during the photopolymerization. This optical density will be represented by $d_1(x, t)$ as a function of the penetration depth (x) and the irradiation time (t); the optical densities without subscripts $d(x, t)$ represent the experimental values, as is shown in Fig. 5. We observed no significant permanent AV bleaching during the photopolymerization. Therefore, the 546 nm light intensity absorbed was assumed to be independent of t. Thus, the local 546 nm-light-beam intensity could be calculated, based on Beer's law, as a function of the x into the sample. When an aerobic sample solution[7] was exposed to the 546 nm light beam with its diameter of 3 mm, which would establish a beam-intensity range from 142 to 15.6 μW/cm² at sample depths up to 10 mm, the local 546 nm-light-beam intensity was given by Eq. (2):

$$\log I(x) = 2.152 - 0.096\,x \qquad (2)$$

where $I(x)$ was the beam power in μW/cm² at a certain depth, x mm.

By reference to the experimental conditions for the data acquisition of Fig. 4, the optical density in Fig. 4, $d(x\approx0.1, t)$ was assumed to represent $d_1(x\approx 0.1, t)$. When the 546 nm light-beam intensity incident on the sample was 142 μW/cm², the $d_1(x, t)$ estimation was made by calculating $I(x)$ for each depth, x, by Eq. (2) and by using the optical density-beam intensity curves obtained by replotting the optical densities in Fig. 4 against the incident-beam intensities for different times. A typical set of $d_1(x, t)$

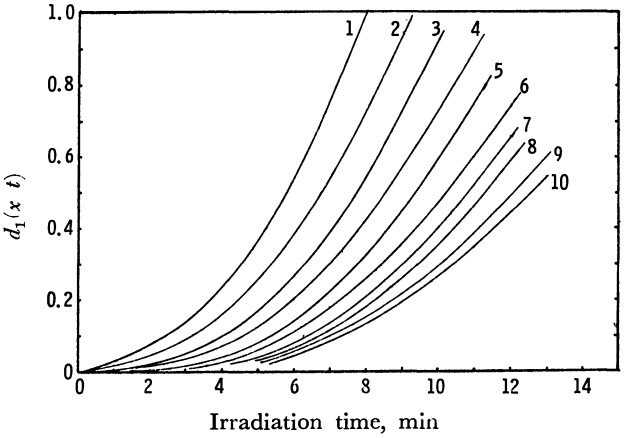

Fig. 6. $d_1(x, t)$ estimated as a function of irradiation time and depth.
Numbers indicate the depth, x in mm.

curves is shown in Fig. 6. It should be noted that the estimated set, $d_1(x, t)$, includes the contribution of the photopolymerization induced by the backscattered light from the dispersion layer with a thickness of 9.8 mm (=10−0.2), as represented by the experimental conditions in Fig. 4; therefore, the estimated set, $d_1(x, t)$, in Fig. 6 denotes the optical density derived on the basis of the assumption that neither forward scattering nor shadowing occurred. Actually, the thickness $(10-x)$ of the dispersion layer which induces a backscattering effect decreases with an increase in x. This may imply that the $d_1(x, t)$ estimated in Fig. 6 includes an excess contribution of backscattering as the x increases. However, the error introduced by this excess of backscattering becomes negligible if the backscattering effect is considered to decrease with an increase in x, since $d_1(x, t)$ decreases with an increase in x. The $d_1(x, t)$ data obtained provided the information necessary to determine the $d_{sh}(x, t)$, denoting the optical density which would be derived using the assumption that backscattering and shadowing, but not forward scattering, occurred during the photopolymerization. $d_{sh}(x, t)$ was given by Eq. (3) on the basis of the assumption of equal 546 nm light-energy densities at x:

$$d_{sh}(x, t) = -\int_0^t d_1(x, t')\frac{\partial F_1(x, t')}{\partial t'}dt' + d_1(x, t)F_1(x, t) \tag{3}$$

with $$F_1(x, 0) = 1 \tag{4}$$

where $F_1(x,t)$ was the fraction of the 546 nm light beam entering x. It should be noted that, in the estimation of $d_{sh}(x,t)$, forward scattering by polymer particles was left out of consideration. For the purpose of the approximate calculations of $d_{sh}(x,t)$, it was assumed that $dt \approx 1$(min), so Eq. (3) became:

$$\begin{aligned} d_{sh}(x, t) \approx\ & d_1(x, 0)\{F_1(x, 0) - F_1(x, 1)\} \\ & + d_1(x, 1)\{F_1(x, 1) - F_1(x, 2)\} \\ & + d_1(x, t-1)\{F_1(x, t-1) - F_1(x, t)\} \\ & \cdots\cdots\cdots\cdots \\ & \cdots\cdots\cdots\cdots \\ & + d_1(x, t)F_1(x, t) \end{aligned} \tag{5}$$

Assuming equal optical densities at the depth range from $x-0.5$ to $x+0.5$ mm (x=*integral*), $F_1(x,t)$ was given by:

$$F_1(x, t) = f_1(0, t)^{1/2l} \cdot f_1(1, t)^{1/l} \cdot f_1(2, t)^{1/l} \cdots\cdots f_1(x-1, t)^{1/l} \quad (l=3 \text{ and } x=0, 1, \cdots\cdots, 10) \tag{6}$$

with: $$F_1(0, t) = 1 \tag{7}$$

$$f_1(x, 0) = 1 \tag{8}$$

and:

$$d_1(x, t) = -\log f_1(x, t) = 2.4 \times 10^{-3} Cl = 0.17\, C'l \tag{9}$$

where $F_1(x,t)$ denoted the fraction of the 546 nm light beam entering the sample layer from $x-0.5$ to $x+0.5$ (x=*integral*) with a thickness of 1 mm (for x=0 and 10, entering the sample layer with a thickness of 0.5 mm), $f_1(x,t)$ was the fraction of the 632.8 nm laser beam transmitted through the dispersion of

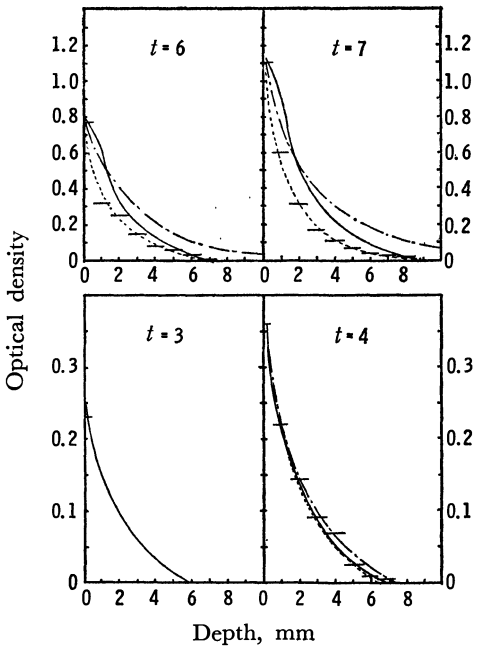

Fig. 7. Depth distribution of optical density for each of irradiation time t, in min.
—— $d(x, t)$, ——— $d_1(x, t)$, ---- $d_{sh}(x, t)$
For $t \leq 3$ three curves were identical.

$d_1(x,t)$ at x, and l was the dispersion length in the y direction and was assumed to be independent of x and t. From this assumption l should be equal to the 546 nm light-beam diameter of 3 mm. We computed $d_{sh}(x,t)$ using Eqs. (5)—(9). The results of these calculations for $d_{sh}(x,3)$, $d_{sh}(x,4)$, $d_{sh}(x,6)$ and $d_{sh}(x,7)$ are shown in Fig. 7, along with $d_1(x,t)$ and $d(x,t)$ for each t value. The horizontal hash marks for $d_{sh}(x,t)$ represent the equal values of this quantity, arising from the approximate calculation of $F_1(x,t)$ by means of Eq. (6). Figure 7 represents both the shadowing and forward-scattering effects on the photopolymerization as a function of x for each t value. The decrease in the optical density arising from the shadowing effect was represented by $d_1(x,t) - d_{sh}(x,t)$, while the increase in the optical density by the forward scattering was given by $d(x,t) - d_{sh}(x,t)$. For $t \leq 3$, neither significant shadowing nor forward scattering was apparently observed, as was represented by $d(x,t) \approx d_{sh}(x,t) \approx d_1(x,t)$, while for $t \geq 4$ both shadowing and forward-scattering effects on the photopolymerization were observed at various depths where the photopolymerization occurred and their magnitudes at each of the depth increased with an increase in t. Some values of the optical densities for $t \leq 3$ were larger than that for $t \geq 4$, as represented by $d(x \leq 1,3) \geq d(x \geq 4,6)$ or $d(x \geq 5,7)$. If the forward-scattering effect at each value of $x \geq 4$ for t=6 arose from polymer particles produced at the neighboring depth, the observation of the forward-scattering effect should be expected also at $x \leq 1$ for t=3, because of $d(x \leq 1,3) \geq d(x \geq 4,6)$. The observation of small effects of shadowing and forward scattering for $t \leq 3$ led us to the conclusion that the 546 nm scattered light due to the increasing number of polymer particles in the foregrounds brought about the forward-scattering effect

at deep penetrations. When the monomer conversion at $x\approx0$ became higher than 0.8% corresponding to $d(0,4)=0.4$, both shadowing and forward-scattering effects were apparently observed and increased with an increase in the monomer conversion, at least up to 2.2% corresponding to $d(0,7)=1.1$. $d(x,t)\approx d_1(x,t)$ at $x\approx1.5$ for $t=6$ or 7 could be explained by equal contributions of the shadowing and forward-scattering effects.

The observation of photopolymerization by the scattered light caused us to question whether the length of the dispersions in the y direction was unchanged during the irradiation, since the polymer particles in the 546 nm-light-beam path radiated 546 nm light in the form of scattered radiation to all directions, with angular distributions of its intensity, so that polymer particles might be formed also outside the original pathway of the transmitted light beam. To see if the assumption of an unchangeable length (l) of the dispersion in the y direction was realistic during the photopolymerization, the values of l were estimated for each t value. Assuming that the optical density was nearly uniform in the range from $x-0.5$ to $x+0.5$ ($x=integral$) in the x direction, the fraction of 546 nm light transmitted through the dispersion up to 10 mm in the x direction, $F(t)$, was given by Eq. (10):

$$F(t) \approx f(0,t)^{1/2l}\cdot f(10,t)^{1/2l}\cdot f(1,t)^{1/l}\cdots\cdots f(9,t)^{1/l} \quad (10)$$

with

$$d(x,t) = -\log f(x,t) \quad (11)$$

where $f(x,t)$ represented the measured fraction of the 632.8 nm laser beam transmitted through the dispersion, with a length of l mm in the y direction. It must be noted that the estimation of $F(t)$ in Eq. (10) is based on the assumption that equal dispersion densities exist at the position of the dispersion in the y direction. For data analysis, Eq. (10) was written in optical density forms:

$$\begin{aligned}-\log F(t) = D(t) &= \{d(0,t)/2 + d(10,t)/2 + d(1,t) \\ &\quad + \cdots\cdots + d(9,t)\}/l \\ &= d(t)/l \end{aligned} \quad (12)$$

with

$$d(t) = d(0,t)/2 + d(10,t)/2 + d(1,t) + \cdots\cdots d(9,t) \quad (13)$$

Eq. (12) predicted that a plot of $D(t)$ *vs.* $d(t)$ should be a straight line whose slope is related to $1/l$. Figure 8 is a plot of the experimental data of $D(t)$ and $d(t)$ for each t value. This figure shows that an approximate linear relation ($l=3$) was obtained up to $t\leq3$. Furthermore, it was pointed that, for $t\geq4$, l increased with an increase in t (for example, $l=6$ for $t=7$). The linear relationship up to $t\leq3$ seemed to be ascribable to no significant observation of the effects of shadowing and forward scattering, as is shown in Fig. 7. The

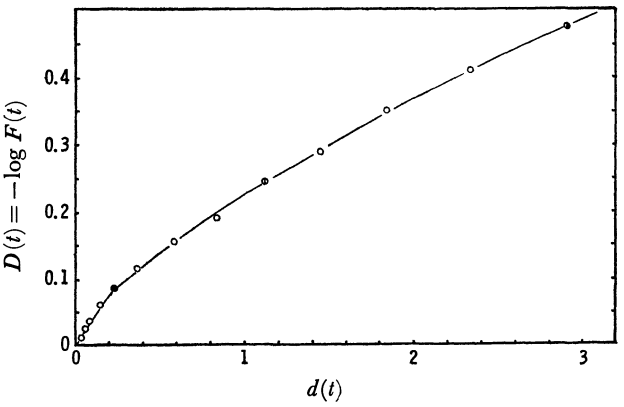

Fig. 8. $D(t)$ *vs.* $d(t)$ for each irradiation time (Ex. ● 3, ⓘ 5, ◑ 7 min).

observation of $d(x\leq1.5,\ t\geq6)>d_1(x\leq1.5,\ t\geq6)$ (Fig. 7) seemed to be evidence for the enlargement of l due to the forward-scattering effect from the increasing number of polymer particles at $x\approx0$, although the assumption that l was independent of x during the photopolymerization was not realistic. It is clear that the scattered light from the polymer particles which were positioned within the pathway of the 546 nm light beam (with a diameter of 3 mm) propagating in the x direction through the dispersion induced the polymer formation outside the original pathway of the 546 nm light beam transmitted. Therefore, it does not matter if the measured optical density $d(x,t)$ is regarded as an amount corresponding to the dispersion of $l=3$, no matter how the dispersion lengthened in the y direction during the photopolymerization.

Absolute Configuration of 3-Amino-1-phenylbutane

Yukio YAMAMOTO, Jun'ichi ODA, and Yuzo INOUYE
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received July 26, 1975)

Synopsis. The absolute configuration of (−)-3-amino-1-phenylbutane was established by the correlation to (*R*)-(−)-*N*-benzoylalanine methylester *via* (+)-*trans*-3-amino-1-phenylbut-1-ene.

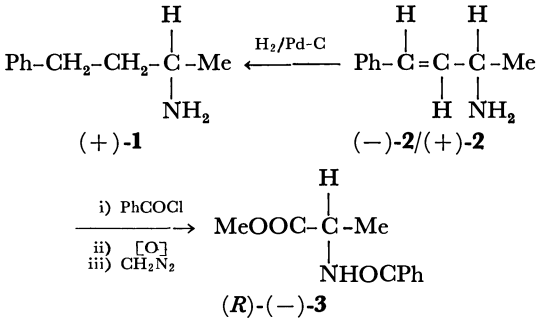
As regards the chirality of 3-amino-1-phenylbutane (**1**), two conflicting assignments have been made. Červinka[1] inferred the *R*-configuration to (+)-**1** by converting it into (+)-γ-*N*-benzoylaminovaleric acid whose configurational correlation had been achieved by the homologation of (*R*)-(−)-alanine.[2] In contrast, the opposite *S*-configuration was claimed for the same enantiomer (+)-(**1**) by Terent'ev based on chiroptical data.[3]

We were therefore inextricably confused by this situation and did not know which of these assignments should be relied upon as the correct one. Since the binary nature of chirality dictates *a priori* a 50 : 50 chance of predicting the correct configuration to a given chiral compound no matter what means one may employ, great caution must be exercised in drawing any conclusion on chirality. This is even more true because the deduced configuration may possibly divert one to an erroneous stereochemistry of asymmetric synthesis.[4]

In connection with the studies on self-immolative asymmetric synthesis, we established the absolute configuration of (+)-*trans*-3-amino-1-phenylbut-1-ene (+)-(**2**) by means of the independent chemical transformations[5] and, by virtue of this assignment, settled the disputed problem of the chirality of 3-amino-1-phenylbutane. (+)-3-Amino-1-phenylbut-1-ene (+)-(**2**) was converted to the *N*-benzoyl derivative and then was oxidized by the use of barium permanganate eventually to give (−)-*N*-benzoylalanine methylester (−)-(**3**). Since the *R*-configuration of the latter has been unequivocally established,[6] the parent amine (+)-(**2**) can be assigned the same configuration in view of the present conversion process, which does not jeopardize the chiral center.

Since the unsaturated amine (−)-(**2**) afforded the corresponding saturated amine with dextrorotation (+)-(**1**) on catalytic hydrogenation over palladium carbon[4], which is generally accepted to proceed without disturbing the chiral center, (−)-3-amino-1-phenylbutane (−)-(**1**) should be allotted the *R*-configuration in support of Terent'ev.[3]

The present transformations, when linked to those by Červinka,[1] Fischer,[7] and Balenović,[2] constitute a triligostatic stereochemical cycle[8] which involves (−)-*N*-benzoylalanine as one of the chiromers. The ligand metathesis is *a priori* ruled out for a triligostatic cycle and all the unit reactions involved in the cycle are of such a nature that no inversion of configuration occurs, so that this cycle is podal. In consequence, the disagreement between Červinka's configurational assignment and ours to **1** suggests a probable experimental fault committed in either the Červinka, Fischer, or Balenović process, inasmuch as the present chemical transformations are convincingly faultless.



Experimental

(+)-3-Amino-1-phenylbutane (+)-(**1**). (*S*)-(−)-*trans*-3-Amino-1-phenylbut-1-ene[5] (−)-(**2**) (5.0 g, $[\alpha]_D^{25}$ −8.9° (*c*, 10.0, benzene) was hydrogenated over palladium carbon in ethanol and an equivalent amount of hydrogen (830 ml at 25 °C) was absorbed. The resulted amine (**1**) distilled at 108—109 °C/18 Torr.; n_D^{27} 1.5081, $[\alpha]_D^{27}$ 10.1° (neat), (lit,[1] bp 110—115 °C/14 Torr., (lit,[9] bp 101—102 °C/14 Torr., n_D^{20} 1.5152 for the racemate). The acetylation of (+)-**1** (4.6 g) with acetic anhydride in pyridine afforded (−)-3-acetamido-1-phenylbutane (5.6 g, 95%); bp 149 °C/2 Torr., mp 68—69 °C, $[\alpha]_D^{26}$ −35.2° (*c*, 0.7, ethanol), (lit,[1] bp 142—150 °C/3 Torr., mp 55 °C). Found: C, 75.33; H, 9.11; N, 7.38%. Calcd for $C_{12}H_{17}NO$: C, 75.35; H, 8.96; N, 7.32%.

Hyperconjugative Deuterium Isotope Effects on the Redox Decomposition of Hydroxymercurated 2-Butenes in an Aqueous Solution

Miharu KOSAKI, Sumio SHINODA, and Yasukazu SAITO

Dapertment of Synthetic Chemistry, Faculty of Engineering, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 14, 1975)

Synopsis. The relative magnitude of the isotope effects of the deuterium atoms at the positions hyperconjugative to α- and β-carbons has been determined for the title reaction by monitoring the reaction of 2-butene-1,1,1,3-d_4 by PMR. On the basis of our results, the cation character in the transition state is concluded for both of the carbons, in support of the structure proposed previously.

The oxidation of olefins by aqueous mercuric salts is known to produce unsaturated aldehydes, saturated aldehydes, or allylic alcohols.[1] It has been found, however, that, under certain reaction conditions, saturated ketones are formed exclusively[2] by the redox decomposition of intermediate hydroxymercurated-olefins, which involves both an intramolecular hydrogen shift[3] and a two-electron transfer.[4] Recently an investigation from the viewpoint of kinetic deuterium isotope effects[5] was performed in order to elucidate the transition-state structure; the cation character was suggested on the basis of the secondary deuterium isotope effect for α-carbon, $CH_3CHOHCH-CH_3Hg^+$, which receives the migrating hydrogen and repels the reduced mercury during the reaction.[6]

With regard to β-carbon, $CH_3CHOHCHCH_3Hg^+$, however, it has no hydrogen other than the migrating one. In order to obtain complementary information about this carbon, 2-butene-1,1,1,3-d_4 is used in the present study, since the hyperconjugative isotope effects also reflect the cation character of the carbon at the reaction center.

Results and Discussion

Since the oxymercuration reaction of 2-butenes proceeds stereospecifically,[7] *cis*- and *trans*-2-butenes are hydroxymercurated into *threo*- and *erythro*-oxymercurials respectively. When unsymmetrically deuterated 2-butenes are used, two regio isomers are formed with respect to the position of the deuterium substituents.

The process of the formation of 2-butanone-d_4 from a mixture of the hydroxymercurated 2-butene-d_4's was followed by PMR *in situ*:

$$CH_3CDOHCHCD_3Hg^+ \longrightarrow CH_3COCHDCD_3 + Hg(0) + H^+ \quad (1)$$

$$CD_3CHOHCDCH_3Hg^+ \longrightarrow CD_3COCHDCH_3 + Hg(0) + H^+ \quad (2)$$

Some representative spectra taken in a time sequence are shown in Fig. 1. The methyl protons of *threo*- and *erythro*-$CD_3CHOHCDCH_3Hg^+$ were observed at δ 1.38 and δ 1.30 respectively, whereas those of *threo*- and *erythro*-$CH_3CDOHCHCD_3Hg^+$ coincidentally both appeared at δ 1.19. The singlet peak observed at δ 2.13 was assigned to the methyl protons of 2-butanone-3,4,4,4-d_4.[2]

Peak-area analyses were made for the mixture of the reactants in a manner reported previously.[6] By comparing each spectrum with preceeding ones, it was ascertained that the peak decrease at δ 1.19 was equal to the peak increase at δ 2.13; this feature can be expected from the stoichiometry of Reaction (1). From the semi-logarithmic time dependence of the peak-height at δ 1.19, the first-order[4] rate constant was obtained as $(6.23\pm0.21)\times10^{-5}$ s^{-1} for Reaction (1). By using the sum of the peaks at δ 1.38 and δ 1.30, the first-order rate constant was obtained as $(6.14\pm0.24)\times10^{-5}$ s^{-1} for Reaction (2). Since all the reactants were present in the same solution, these rate constants could be obtained under completely identical reaction conditions. Therefore, it was confirmed that the relative magnitudes of isotope effects had been determined accurately.[6]

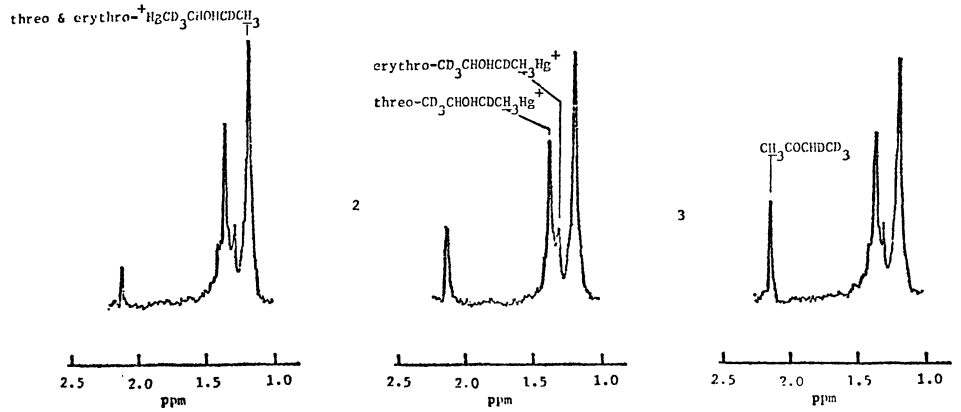

Fig. 1. The time sequential PMR spectra obtained *in situ* for the redox decomposition of the mixture of *threo*- and *erythro*-$CH_3CDOHCHCD_3Hg^+$ and -$CD_3CHOHCDCH_3Hg^+$ at 3.0 °C in an aqueous solution. These spectra were recorded after (1) 0.0 min, (2) 30.9 min and (3) 49.3 min.

Kinetic deuterium isotope effects have been considered to be almost precisely multiplicative. The mechanisms of the retro-Diels-Alder reaction of 9,10-dihydro-9,10-ethanoanthracene[8] and the base-induced dehydrotosylation and dehydrobromination of cyclohexyl derivatives[9] were discussed accordingly. With respect to the present reaction, the rate constant of Reaction (1) should be affected cumulatively by both migrating deuterium and the methyl deuterium of CD_3CHg; their effects are expressed in terms of the primary deuterium isotope effect, $(k_H/k_D)^{prim}$, and the hyperconjugative deuterium isotope effect, $(k_H/k_D)^{hyp(Hg)}$, respectively. As for Reaction (2), the effects of both α-deuterium (CDHg) and the other methyl deuterium (CD_3COH) should also be imposed on the rate cumulatively; the rate is affected by both the α-secondary deuterium isotope effect, $(k_H/k_D)^{\alpha}$, and the hyperconjugative deuterium isotope effect, $(k_H/k_D)^{hyp(OH)}$.

The ratio of the rate constants for Reactions (1) and (2) is, therefore, given as follows:

$$\frac{k(1)}{k(2)} = \frac{k_H/k(2)}{k_H/k(1)} = \frac{(k_H/k_D)^{\alpha}}{(k_H/k_D)^{prim}} \times \frac{(k_H/k_D)^{hyp(OH)}}{(k_H/k_D)^{hyp(Hg)}} \quad (3)$$

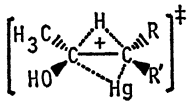
where k_H is the rate constant of $CH_3CHOHCHCH_3Hg^+$.

As far as the value of $(k_H/k_D)^{prim}/(k_H/k_D)^{\alpha}$ is concerned, the value of 1.15 was previously obtained for *cis*- and *trans*-2-butene.[6] By substituting the observed value of both $k(1)/k(2)$ and $(k_H/k_D)^{prim}/(k_H/k_D)^{\alpha}$ into Eq. (3), the ratio of the hyperconjugative isotope effects concerning the α- and β-carbons, $(k_H/k_D)^{hyp(OH)}/(k_H/k_D)^{hyp(Hg)}$, was calculated to be 1.17 ± 0.10, where the error limit was determined in view of those for both the rate constants and the isotope effects.

As is well known, the magnitude of the hyperconjugative deuterium isotope effect increases proportionally to the extent of the positive charge on the reacting carbon in the transition state.[10] With regard to the S_N1 solvolysis reactions, such magnitudes have been reported as 1.33[11], 1.34[12], and 1.40[12] per CD_3 at 25 °C. In contrast, values as small as 1.05 per CD_3 were found at 60.56 °C[13], 73.88 °C[13], and 105.02 °C[14] for the radical decomposition reactions.

Taking into account the considerable cation character of the α-carbon ($CH_3CHOHCHCH_3Hg^+$) in the present reaction,[6] it is now possible to estimate the extent of the β-carbon ($CH_3CHOHCHCH_3Hg^+$) by using the ratio of the hyperconjugative isotope effects, since it represents the relative extent of the cation character of these carbons. If the β-carbon had no cation character at all in the transition state, the ratio would be less than unity (*e.g.*, 1/1.3). The observed ratio of 1.17 ± 0.10, therefore, strongly suggests that the cation character of the β-carbon (COH) is almost comparable to, or rather larger than, that of the α-carbon (CHg).

The transition-state structure for the redox decomposition reaction of hydroxymercurated 2-butene proposed previously[6] is thus supported from the point of view of the hyperconjugative deuterium isotope effects.



(R, R′=H, CH_3)

Experimental

All the reagents and solvents were of a G. R. grade. The diglyme was dried by refluxing it with lithium aluminum hydride before use. The alumina catalyst (spherical, 1/8 mesh) was supplied by ALCOA (F-110). The BET surface area (N_2 adsorption) was 190 m^2/g. The catalyst (20.0 g) was loaded in a flow reactor, evacuated at 350 °C for 2 hr, and then exposed to the vapor of deuterium oxide (Merck, 99.75 atom % deuterated) at 200 °C.

Preparation of 2-Butene-1,1,1,3-d_4. 2-Butanone-1,1,1,-3,3-d_5 was obtained by the hydrogen-deuterium exchange of 2-butanone by a keto-enol equilibrium in a deuterium-oxide solution of potassium carbonate at 80 °C. Isotopic purities of 98% were ascertained by PMR analysis for both methyl and methylene groups. The hydrogenation of 2-butanone-1,1,1,3,3-d_5 by lithium aluminum hydride was effected in diglyme at 50 °C to obtain 2-butanol-1,1,1,3,3-d_5, which was then dehydrated into deuterated *n*-butenes catalytically at 170 °C by the use of the flow reactor, with a nitrogen-gas carrier. The analysis of the product by glpc (20% dimethylsulfolane on Celite) confirmed the composition of *cis*-2-butene (54.1%), *trans*-2-butene (14.6%) and 1-butene (31.3%).

Kinetic Studies of the Redox Decomposition. The gaseous olefin was introduced *via* a vacumm line into an aqueous solution consisting of 3.00 M of mercuric perchlorate at 0 °C until all the mercuric ions had been consumed by hydroxymercuration. The solution of hydroxymercurated *n*-butenes was diluted with identical amounts of a 3.00 M aqueous mercuric perchlorate solution. A part of the solution was transferred into a PMR sample tube and kept in a Dry Ice–ethanol trap. The reaction was started by inserting the tube into the probe of the PMR spectrometer. By this means the solution temperature was raised up to the probe temperature (3.0 °C; calibrated by the relative shifts of ethylene glycol); the reaction was then pursued for 60 min, with fifteen spectrum charts taken in sequence. During the reaction, no evolution of gas due to olefin formation by deoxymercuration was observed.

The authors wish to express their gratitude to Professor Yukio Yoneda for his helpful discussion and encouragement. This work was supported by a Grant-in-aid for Scientific Research from the Ministry of Education, Japan (No. 011013).

Complex Cation-radical Salts Derived from Phenothiazine and Related Compounds

Susumu Doi* and Yoshio Matsunaga**

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 29, 1975)

Synopsis A new class of complex cation-radical salts is formed by the reaction of phenothiazine bromide with phenoxazine, phenothiazine, its benzo derivatives, and phenoselenazine.

Phenothiazine has been known to form a number of cation-radical salts.[1,2] However, the incorporation of formally neutral molecules has been established in no case. We have now discovered the formation of complex phenothiazine and phenoselenazine cation-radical bromides and also of some mixed complex bromides.

Simple phenothiazine cation-radical bromide was prepared by the oxidation of the parent organic compound dissolved in ether with bromine, as has been described by Kehrmann and Diserens.[2] The bromine content was a little higher than that corresponding to the 1 : 1 salt. Found: C, 48.82; H, 3.07; N, 4.71; Br, 31.54%. Calcd for $C_{12}H_9NS \cdot Br_{1.18}$: C, 49.10; H, 3.09; N, 4.77; Br, 32.12%. We earlier noted that the vibrational spectra exhibited by the bromide samples thus prepared are often superpositions of the spectra of the A and B types in various ratios.[3] The present sample showed the spectrum of the B type. When the salt was ground with an equimolar amount of phenothiazine wetted with benzene, drastic changes in both the vibrational and electronic spectra were observed. In Fig. 1, the electronic spectrum of the product is compared with that of the starting bromide. The former salt retains the spectral pattern of the latter. In addition, a broad band appears at 5.2×10^3 cm^{-1}. The resulting electronic spectrum and also the vibrational spectrum coincide with those of the A type in the previous work. It must be realized that the spectrum of the A type is not of the polymorphic form of the simple cation-radical salt suggested earlier, but of the complex salt, $(C_{12}H_{19}NS)^+(C_{12}H_9NS)^0 \cdot X^-$, in which the positive charge may be equally shared by the two molecules of phenothiazine. The low-energy absorption band newly appearing in the complex salt may be a manifestation of such a delocalization of the positive charge.

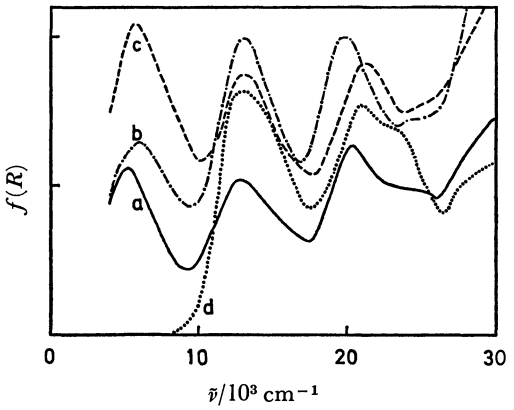

Fig. 1. Diffuse reflection spectra of the combinations of the phenothiazine bromide and a) phenothiazine, b) phenoxazine, and c) phenoselenazine, and d) the phenothiazine bromide alone.

The frequent superposition of the vibrational spectra of the A and B types in the bromide samples with an apparent composition of 1 : 1 implies that the simple cation-radical bromide, the complex cation-radical bromide, and polybromide (possibly tribromide) are all formed under similar conditions. Such complexity was further demonstrated by the transformation of the spectrum of the B type to that of the A type by storage. When the samples prepared over six years before were reexamined, only the spectrum of the A type could be detected. The following analytical results indicate a loss of bromine during the storage; nevertheless, the contents are still appreciably higher than that of the complex (2 : 1) bromide. Found: C, 53.16, 53.06; H, 3.25, 3.32; N, 4.98, 5.15; Br, 25.58, 25.54% for two independent samples. Calcd for $C_{12}H_9NS \cdot Br_{0.88}$: C, 53.46; H, 3.36; N, 5.20; Br, 26.08%. The rearrangement of the simple cation-radical bromide to a mixture of the complex cation-radical bromide and tribromide may account for the constitution of the product.

Additional evidence for the formation of the complex cation-radical salt was provided by the examination of the electrical resistivity and the Seebeck coefficient. Mixtures of the bromide and phenothiazine in five different mole ratios were heated to 80 °C in a short time to complete the reaction and also to remove all traces of the solvent. The vibrational spectra of the mixtures after the treatment were essentially the same as those made at room temperature except at a ratio of 4 : 1. Thus, the complex cation-radical bromide appeared to be more stable than the simple bromide.

The measurements were carried out on pressed pellets in the range from −90 to +50 °C by procedures described elsewhere.[4] The plot of the logarithm of resistivity against the reciprocal temperature gives a straight line. The resistivity values at 20 °C and the activation energies for semiconduction calculated on the basis of $\rho = \rho_0 \exp(\Delta E/kT)$ are presented in Table 1. The sharp maximum of the resistivity located at the 1 : 1 mole ratio supports the complex (2 : 1) salt formation. The Seebeck coefficient at 20 °C

* Present address: Central Research Laboratory, Showa Denko K. K., Tamagawa, Tokyo.

** To whom inquiries may be addressed.

is negative for all the samples, but the temperature-dependence is sensitive to the composition. As is shown in Fig. 2, the value is nearly constant at the 4 : 1 mole ratio. On the further addition of phenothiazine, the slope against the reciprocal temperature becomes negative and is exceptionally steep at the composition of the complex salt. In the presence of an excess of phenothiazine, the slope changes its sign.

Table 1. Electrical properties of the mixtures of the phenothiazine bromide and phenothiazine

Mole ratio	Resistivity at 20°C (ohm cm)	Activation energy (eV)	Seebeck coeff. at 20°C ($\mu V°C^{-1}$)
4 : 1	1600	0.27	−24
3 : 2	90	0.19	− 5
1 : 1	770	0.23	− 6
2 : 3	100	0.23	− 9
1 : 4	370	0.17	−15

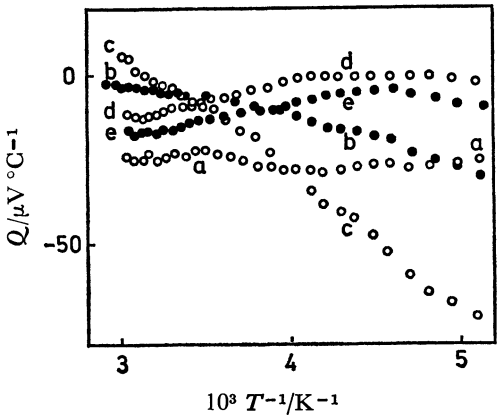

Fig. 2. Seebeck coefficients (Q) of the mixtures of the phenothiazine bromide and phenothiazine, a) 4 : 1, b) 3 : 2, c) 1 : 1, d) 2 : 3, and e) 1 : 4 (mole ratio).

On the basis of the close similarity between the vibrational spectrum of the A type and that of the phenothiazine-iodine complex, we were previously led to conclude that every phenothiazine molecule in the iodine complex bears an approximate unit-positive charge.[3] This conclusion must be revised in the light of the new findings presented above. It is now apparent that the iodine complex is a kind of complex cation-radical salt. The complex phenoselenazine cation-radical bromide was also prepared. The vibrational spectrum of this salt resembles that of the corresponding iodine complex reported previously.[5] The maximum of the low-energy electronic band appears at 6.4×10^3 cm^{-1}.

Figure 1 shows also the electronic spectra produced by the reaction of the phenothiazine bromide with phenoxazine and phenoselenazine in a mole ratio of 1 : 1. The maxima of the low-energy bands in these products are at 6.0 and 5.7×10^3 cm^{-1} respectively. The disagreement between the latter spectrum and the superposition of those of the two complex cation-radical salts suggests the formation of a complex salt containing both the thiazine and the selenazine. Similar spectral changes were observed in the combinations of the phenothiazine bromide and benzo[*a*]- and benzo[*c*]-phenothiazines. As the absorption bands in the phenothiazine bromide are overlapped by those of the benzophenothiazine bromides, the spectra of the products are dominated by the latter. The low-energy bands are located at about 4.5×10^3 cm^{-1}.

Although *p*-phenylenediamine and benzidine may be expected to have ionization potentials a little higher than the thiazines,[6] the reaction with the phenothiazine bromide resulted in the electron-transfer from the diamine to the thiazine. The dark blue products showed the spectra of the diamine cation-radical bromides.[7]

Enthalpies of Combustion of Organic Compounds. III.* D-, L- and DL-Alanines

Akeji KAMAGUCHI, Tomoko SATO, Minoru SAKIYAMA, and Syûzô SEKI
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received April 8, 1975)

Synopsis. Enthalpies of combustion of D-, L- and DL-alanines were measured by oxygen static bomb calorimetry. Derived thermodynamic quantities at 298.15 K for D-, L- and DL-isomers are as follows: $\Delta E_c^\circ = -1619.24 \pm 0.58$, -1620.26 ± 0.63 and -1617.97 ± 0.50 kJ mol^{-1}; $\Delta H_c^\circ = -1619.86 \pm 0.58$, -1620.88 ± 0.63 and -1618.59 ± 0.50 kJ mol^{-1}; $\Delta H_f^\circ(c) = -561.08 \pm 0.71$, -560.06 ± 0.76 and -562.35 ± 0.65 kJ mol^{-1}, respectively.

Measurements of heats of combustion of alanine, one of the fundamental amino acids, have been made on L-isomer by Tsuzuki *et al.*[1] and on L- and DL-isomers by Huffman *et al.*[2,3] On L-isomer, the value of ΔH_c° by Tsuzuki *et al.*[1] differs significantly from that by Huffman *et al.*[2] up to about 3%. On D-isomer there appeared no report hitherto. In this paper the enthalpies of combustion of D-, L- and DL-alanines in their crystalline states are reported. The idealized combustion reaction to which the energies and enthalpies of combustion given in this paper refer is the following one at 25 °C:

$$C_3H_7O_2N(c) + (3.75)O_2(g) = 3CO_2(g) + (3.5)H_2O(l) + (0.5)N_2(g).$$

Experimental

Materials. L-Alanine (Takara Kôsan Co., Ltd.), D-alanine (Ajinomoto Co., Ltd.) and DL-alanine (Nakarai Chemicals, Ltd.) were purified by recrystallization from aqueous solutions, twice, twice and four times, respectively. After the samples were first dried under vacuum (~0.1 kPa), they were pelletted and then stored for 6 months in a desiccator over anhydrous magnesium perchlorate. Specific rotatory power of the solutions ($c = 0.022$ mol dm^{-3} in 2.0 M HCl) was as follows: $[\alpha]_D^{20} = +14.3°$ (L-isomer), $-14.4°$ (D-isomer) and $-0.2°$ (DL-isomer), respectively. Each peak in the X-ray diffraction patterns obtained by using Cu-Kα radiation coincided with that calculated from the crystallographic data.[4,5]

Apparatus, Procedures and Calculation. An isoperibol rotating precision bomb-calorimeter reported previously[6] was used without rotation. It was pointed out, however, by Huffman *et al.*[2,3] that alanine was very troublesome to burn as it had a decided tendency to jump out of the crucible when burned partially. So, we designed a special deep crucible with a baffle (Pt-10% Rh), having the density and the specific heat capacity of 20.50 g cm^{-3} and 0.1464 J K^{-1} g^{-1} at 25 °C, respectively, (Fig. 1) and used it to facilitate complete combustion by keeping off such a jumping-out as described above. The energy equivalent was defined for the system made up of an empty bomb and a gimbal as before and was found from 13 calibration-experiments with benzoic acid (Standard Reference Material 39i, National Bureau of Standards, U.S.A.) to be 15159.78 ± 0.57 J K^{-1}, where uncertainty is the standard deviation of the mean. To make the combustion of the alanine sample more perfect, *ca.* 0.15 g of liquid paraffin (Wakô Pure Chemical Co., Ltd.) was used as promotor in each experiment. In this way we succeeded in performing perfect combustion. In order to make the ignition procedure reproducible in every run, we used two electrical timers: one for timing the begining and the other for timing the ending of ignition, respectively. Calculation was carried out as before. NEAC 2200 electronic computor of Osaka University was used to calculate Washburn corrections and to obtain the final data of energy of combustion.

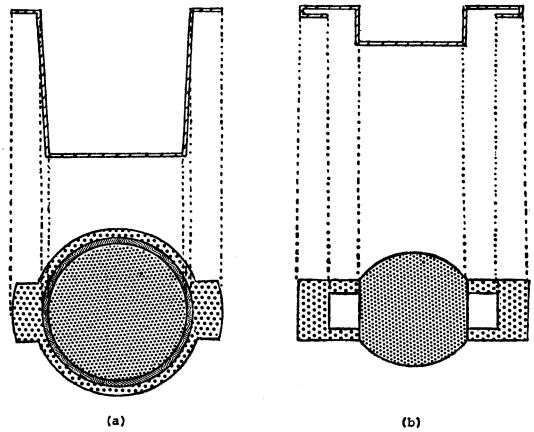

Fig. 1. (a) Crucible, (b) Baffle. (Scale, 14/17)

Auxiliary Quantities. Auxiliary data adopted in the calculation of ΔE_c°, *i.e.* the composition formula and the values (for 25 °C) of density, ρ, of specific heat capacity, c_p, and of $(\partial E/\partial P)_T$ for the combustible substances, are given in Table 1. Other auxiliary data used are as follows: M(compd.) = 89.0947 g mol^{-1}, m(Pt) = 29.511 g, V(bomb) = 0.3458 dm^3, $\Delta E_c^\circ/M$(fuse) = -16507 J g^{-1}, $\Delta E_c^\circ/M$(oil) = 45909.3 ± 4.1 J g^{-1}, where uncertainty is standard deviation of the mean. Six combustion experiments were carried out for D-, L- and DL-alanines, respectively. Data from combustions selected as typical are given in Table 2. Notations in Table 2 follow those by Hubbard *et al.*[7] except for the followings: Δm(H_2O cal.), excess water in the calorimeter can; ΔE (std. state), sum of items 81—85, 87—89, 93 and 94 in Ref. 7. The results of the individual combustion experiment in terms of ΔE_c° at 298.15 K are summarized as follows: -1618.83, -1619.90, -1619.43, -1619.68, -1619.04, -1618.54, mean and standard deviation of the mean -1619.24 ± 0.21 kJ mol^{-1} for L-alanine; -1620.55,

* This paper was read before the 10-th Japanese Calorimetry Conference, Tokyo (1974).

−1620.38, −1619.66, −1620.07, −1621.25, −1619.65, mean and standard deviation of the mean −1620.26± 0.25 kJ mol^{-1} for D-alanine; −1617.55, −1617.88, −1618.09, −1618.46, −1618.27, −1617. 57, mean and standard deviation of the mean −1617.97±0.15 kJ mol^{-1} for DL-alanine. Thermochemical quantities were calculated from those results and given in Table 3. In the calculation of the standard enthalpies of formation of the present samples, CODATA key values[8] for the standard enthalpies of formation at 298.15 K of $H_2O(l)$ and $CO_2(g)$; $\Delta H_f^\circ(H_2O, l) = -285.30\pm0.042$ kJ mol^{-1}, $\Delta H_c^\circ(CO_2, g) = -393.51\pm0.13$ kJ mol^{-1} were employed, where uncertainties represent the Task Group's estimates of the overall uncertainties at a 95 per cent confidence level. The standard enthalpy of formation of L-isomer in the gaseous state was calculated by using a enthalpy of vaporization reported by Svec *et al.*[9] All the uncertainties in this paper are uncertainty interval recommended by Rossini,[10] *i.e.* twice the final overall standard deviation of the mean, unless specified.

Discussion

In Table 4 our data are compared with those of Huffman *et al*[2,3] and Tsuzuki *et al.*[1] The difference between the ΔH_c° values of Huffman *et al.*[2] and of the present work for L-alanine is well within the sum of each uncertainty interval. But these values are quite far from that of Tsuzuki *et al.*,[1] the descrepancy being no less than 3%. The value of ΔH_c° of D-alanine observed in this work also coincides with those of L-alanine by Huffman *et al.*[2] and by the author within the sum of each uncertainty interval. Thus, as in the case of glutamic acid, previously described by two of the authors,[11] it is also concluded that the ΔH° values of different optical isomers of alanine coincide with each other. The ΔH_c° value of DL-alanine of this work is in good agreement with that of Huffman *et al.*[3] within the uncertainty interval.

The authors would like to express their hearty thanks to Dr. K. Toi of Ajinomoto Co., Ltd., and Dr. F. Sakiyama of the Institute for Protein Research, Osaka University, for their cooperation in obtaining the samples.

Solvent Extraction Equilibria of Thallium(III) from Weakly Acidic Chloride Solutions into 4-Methyl-2-pentanone

Yuko HASEGAWA, Shinji KURIHARA, Naohito MASUI, and Tatsuya SEKINE

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received July 4, 1975)

Synopsis. From the distribution data of thallium (III) between 4-methyl-2-pentanone and 4 mol dm^{-3} sodium perchlorate solutions containing chloride ions at pH 2, the $Na^+TlCl_4^-$ species in the organic phase and the $TlCl_2^+$, $TlCl_3$, and $TlCl_4^-$ species in the aqueous phase were recognized. The equilibrium constants for the formation and extraction of these complexes were determined.

The solvent extraction of thallium(III) chloride complexes for various analytical purposes has been carried out in most cases from hydrochloric acid solutions, and the chemical form of the extracted species is known to be $HTlCl_4$.[1] When the acidity of the aqueous phase is not high and/or the solvent is nonpolar, however, the extraction of thallium(III) chloride species containing no hydrogen ions can be expected. Walters and Dodson[2] demonstrated that, with 0.0365 mol dm^{-3} tributylphosphate (TPB) in hexane, thallium(III) was extracted as the $TlCl_3(TBP)_2$ species from aqueous solutions containing perchloric and hydrochloric acid at an ionic strength of 0.5 mol dm^{-3}, but Widmer and Dodson[3] showed that, with 0.730 mol dm^{-3} TBP in octane, the $HTlCl_4$ species was also extracted from the same solutions.

Since the thallium(III) tetrachloride complex anion can be well extracted, along with the hydrogen ion, from acid chloride solutions, the present authors considered that this complex anion might also be extracted with cations other than the hydrogen ion from weakly acid chloride solutions into solvating-type polar organic solvents. Therefore, they measured the extraction of thallium(III) from 4 mol dm^{-3} Na(Cl, ClO_4) solutions at pH 2 with 4-methyl-2-pentanone and with hexane containing 0.03 mol dm^{-3} TBP at 298 K and compared the results of these two series of experiments.

Experimental

All of the reagents were of an analytical grade. The sodium perchlorate was recrystallized three times from water. Both the 4-methyl-2-pentanone and TBP were washed with 0.1 mol dm^{-3} perchloric acid, water, and a 0.1 mol dm^{-3} sodium hydroxide solution successively, and then several times with water. Thallium(III) nitrate was dissolved in 4 mol dm^{-3} of a sodium perchlorate solution containing 0.1 mol dm^{-3} perchloric acid and a small amount of sodium chloride; a stock solution containing 1.0×10^{-2} mol dm^{-3} of thallium(III) was thus prepared. The metal concentration was checked by a colorimetric method using 8-quinolinol.[4] All of the procedures were carried out at 298 K. A portion of an aqueous 4 mol dm^{-3} Na(Cl,ClO_4) solution containing 1×10^{-6} to 1×10^{-3} mol dm^{-3} of thallium (III) and the same volume of 4-methyl-2-pentanone or hexane containing TBP was placed in a stoppered glass tube. The two phases were agitated vigorously for 30 s. After they had then been centrifuged, a portion of the aqueous phase was transferred into another glass tube and hydrochloric acid and a solution of Malachite Green were added. The concentrations of hydrochloric acid and Malachite Green in the resulting solution were 3×10^{-1} and 1×10^{-4} mol dm^{-3} respectively. This solution was shaken with benzene. The organic phase was then transferred into another tube and shaken with a solution containing hydrochloric acid and Malachite Green at the same concentrations as above in order to wash off the perchlorate ions coextracted with the metal complex. The thallium(III) in the sample was determined from the absorption of this organic solution at 635 nm. The molar extinction coefficient was 5.5×10^4. The distribution ratio of thallium(III) was defined as:

$$D = [\mathrm{Tl(III)}]_{\mathrm{org,total}}/[\mathrm{Tl(III)}]_{\mathrm{total}}$$

where 'org' denotes the chemical species in the organic phase and where a lack of a subscript denotes those in the aqueous phase. The total thallium(III) concentration in the organic phase was determined from the difference between its initial and equilibrium concentrations in the aqueous phase. When the metal concentration in the initial aqueous phase was high, a correction was made for the decrease in the free-chloride concentration due to the extraction of the chloride complex.

Results

The distribution ratio may generally be expressed by the following equation;

$$D = ([TlCl_3]_{org} + [Na^+TlCl_4^-]_{org})/\sum [TlCl_n^{3-n}] \quad (1)$$

Extraction with 4-Methyl-2-pentanone. The distribution ratio was found to be independent of the hydrogen-ion concentration, at least between pH 1 and 2.5. The open circles in Fig. 1 give the extraction data with 4-methyl-2-pentanone at pH 2. It was found that these extraction data could be analyzed by using the following equation, derived from Eq. (1):

$$D = K\mathrm{ex}_4[Na^+][Cl^-](K_3^{-1}[Cl^-]^{-1} + 1 + K_4[Cl^-])^{-1} \quad (2)$$

where

$$K_n = [TlCl_n^{3-n}][TlCl_{n-1}^{4-n}]^{-1}[Cl^-]^{-1} \quad (3)$$

$$K\mathrm{ex}_4 = [Na^+TlCl_4^-]_{org}[TlCl_3]^{-1}[Cl^-]^{-1}[Na^+]^{-1} \quad (4)$$

The values for the constants in Eq. (2) were determined by a curve-fitting method.[5] The solid curve for the open circles in Fig. 1 was calculated by introducing these values into Eq. (2). It is possible that a part of the $Na^+TlCl_4^-$ ion-pair undergoes dissociation in this polar organic solvent, but, for the reasons already presented in a previous paper,[6] this effect should be negligible under the conditions employed in the present study.

Extraction with TBP in Hexane. The distribution

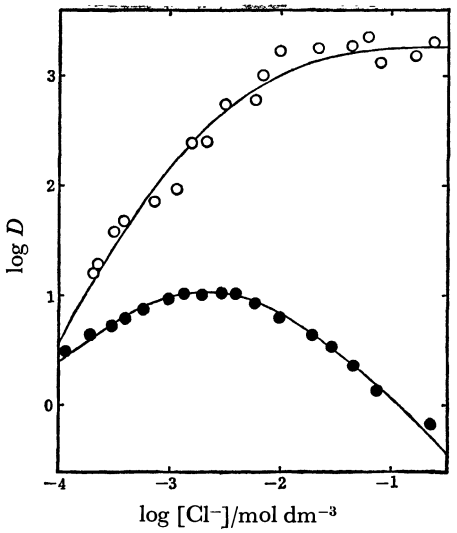

Fig. 1. Distribution ratio of thallium(III) as a function of chloride concentration. Org. phase: closed circles hexane containing 3.0×10^{-2} mol dm^{-3} of TBP and open circles 4-methyl-2-pentanone. Aq. phase: 4 mol dm^{-3} Na(Cl, ClO_4) at pH 2. Temperature 298 K.

Table 1. Equilibrium constants for the complexes

Org. phase: 4-methyl-2-pentanon for $K\text{ex}_4$ and hexane containing TBP for $K\text{ex}_3$.
Aq. phase: 4 mol dm^{-4} Na(Cl, ClO_4) at pH 2.
Temperature: 298 K.

log K_3	log K_4	log $K\text{ex}_3$	log $K\text{ex}_4$
3.22	2.12	4.26	4.79

ratio was found to be second-order dependent on the TBP concentration in its concentration range between 5×10^{-3} to 5×10^{-2} mol dm^{-3} and independent of the hydrogen ion concentration, at least between pH 0.6 and 2.5. The closed circles in Fig. 1 give the extraction data when the TBP concentration was 3×10^{-2} mol dm^{-3} at pH 2. It was found that the extraction data could be analyzed by using the following equation:

$$D = K\text{ex}_3[\text{TBP}]_{org}^2(K_3^{-1}[\text{Cl}^-]^{-1}+1+K_4[\text{Cl}^-])^{-1} \quad (5)$$

where:

$$K\text{ex}_3 = [\text{TlCl}_3(\text{TBP})_2]_{org}[\text{TlCl}_3]^{-1}[\text{TBP}]_{org}^{-2} \quad (6)$$

The data were also analyzed by the curve-fitting method. The stability constants of the aqueous complexes were found to be identical with those obtained by the 4-methyl-2-pentanone extraction. The values for the constants in Eq. (5) are listed in Table 1. The solid curve for the closed circles in Fig. 1 was calculated by introducing these values into Eq. (5).

Discussion

Since the data at the chloride concentrations lower than 1×10^{-4} mol dm^{-3} could not be obtained by the method employed in this study, the formation constants, K_1 and K_2, could not be determined. However, the Tl^{3+} and $TlCl^{2+}$ species should be negligible in the chloride-concentration range of the present study. The reported stability constants for the thallium(III) chloride complexes[2,7-9] are, for all practical purposes, in agreement with the present values; the values reported for log k_3 are 2.75 (0.4), 2.68 and 2.74 (0.5), 3.10 (1.2), 3.08, 3.15, and 3.55 (3), and 3.41 (4) and for log K_4 are 2.25 (0.4), 1.60 and 1.81 (0.5), 2.5 (1.2), 2.17, 2.22, and 2.36 (3), and 2.79 (4) respectively, when the ionic concentration in the solution is at the value in the parentheses. No evidence for the higher complexes was observed in the chloride-concentration range of the present study.

The extraction curve with TBP reported by Walters and Dodson[2] is quite similar to that in Fig. 1. However, the $K\text{ex}_3$ value given by the previous authors is 9.7×10^2 when the diluent was octane;[3] this is probably due to the difference in the salting-out effect. Such a large difference in the partition coefficient of metal complexes in TBP extraction when the electrolyte concentration in the aqueous phase was different was also found in a previous work on the extraction of the $In(SCN)_3$ species.[10]

It is marked that only the neutral complex, $TlCl_3$, was extracted into hexane containing a small amount of TBP, even from the aqueous phase of the high sodium-ion concentration, while only the anionic complex as an ion-pair was extracted into the polar solvent, 4-methyl-2-pentanone.

It is obvious that the chloride complexes of thallium(III) are much more stable than the corresponding complexes of indium(III) because, for the latter metal ion, only the first and second chloride complexes were found in the chloride concentration range from 10^{-4} to 10^{-1} mol dm^{-3}, and the extractability of the thallium(III) as chloride complex is much higher than that of indium(III), because the latter was not extracted into those solvents under conditions identical with those of the present study.[6,11]

Determination of Silver in Sea Water after Flotation with 2-Mercaptobenzothiazole

Masataka HIRAIDE and Atsushi MIZUIKE

Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received August 4, 1975)

Synopsis. Nanogram quantities of silver in 3000 ml of acidified sea water were quantitatively coprecipitated with 2-mercaptobenzothiazole. The precipitate was then floated with the aid of small nitrogen bubbles, and the silver determined by atomic-absorption spectrophotometry after wet oxidation. The silver concentration was 0.09 μg per liter.

Since the silver content of sea water is low (reported values: 0.0—2.9 μg per liter),[1,2] it must be concentrated from a large volume of sample before atomic-absorption spectrophotometric determination. Traces of silver ions in aqueous solutions can be collected on the precipitate formed by adding an acetone solution of 2-mercaptobenzothiazole,[3] but filtration of this amorphous precipitate is difficult. Centrifugation also is not applicable because of incomplete sedimentation. In the present work, the flotation technique[4] was successfully applied. The precipitate is readily separated from the main liquor without surfactants, and then the silver in it is determined by atomic-absorption spectrophotometry. Commercial 2-mercaptobenzothiazole contained appreciable amounts of silver, but it was easily purified by the amalgamation method.[5]

Experimental

Apparatus. A Nippon Jarrell-Ash model AA-1 Mark II atomic-absorption spectrophotometer with an SA-61 slit burner and a Hitachi model QPD53 recorder, and a Fujitsu well-type NaI(Tl) scintillation counter were employed. The flotation cell consisted of a 120 mm i.d. × 700 mm or 45 mm i.d. × 250 mm glass tubing tapered at the lower end with a sintered-glass disc (No. 4, 110 mm or 40 mm diam.) near the lower end.

Reagents. A 2-mercaptobenzothiazole solution (40 mg/ml) was prepared and purified as follows: 4 g of 2-mercaptobenzothiazole was dissolved in 90 ml of acetone in a 200-ml tall beaker, 2 ml of mercury was added, and the solution was stirred vigorously for 10 min with a magnetic stirrer. The mercury was separated by centrifugation, another 2 ml of mercury was added to the solution, and the above treatment was repeated once more. The solution was diluted to 100 ml with acetone. Standard silver solutions were prepared from silver nitrate. Water was purified by distillation and ion-exchange. All reagents used were of reagent grade. ^{110m}Ag was used as a tracer.

Recommended Procedure. Place 3000 ml of sea water (acidified to 0.1 M with nitric acid) in a 5000-ml beaker, and add 50 ml of 2-mercaptobenzothiazole solution in small portions while stirring with a magnetic stirrer. Stir the solution vigorously for 30 min. Transfer the contents of the beaker (excluding the stirring bar) to a flotation cell (120 mm i.d. × 700 mm), and wash the beaker with 50 ml of 1 M nitric acid. Pass nitrogen from the lower end of the cell for 1—2 min to effect complete agitation followed by flotation of the precipitate with small bubbles (*ca.* 0.1 mm diam.). Suck off the main liquor through the sintered-glass disc, and wash the precipitate with two 100-ml portions of 1 M nitric acid followed by two 100-ml portions of water (to remove the nitric acid). Discard the filtrate and washing solutions. Add 50 ml of acetone to the cell to dissolve the precipitate, collect the filtrate by suction in a 200-ml beaker, and wash the sintered-glass disc with 20 ml of acetone. Evaporate the solution to dryness on a water bath, cautiously add 20 ml of 13.8 M nitric acid, heat gently to dissolve the residue, and evaporate to 5 ml. Transfer the solution to a 50-ml beaker, and wash the 200-ml beaker with 15-ml of 13.8 M nitric acid. Evaporate the solution to near dryness and cool. Add 4 ml of 30% hydrogen peroxide in small portions (the residue becomes colorless) and evaporate to near dryness. Wash the walls of the beaker with 3 ml of 30% hydrogen peroxide and evaporate again to near dryness. Dissolve the residue in 3 ml of 13.8 M nitric acid, transfer the solution to a 5-ml volumetric flask, wash the beaker with water, and dilute to the mark. Determine the silver in the solution by atomic-absorption spectrophotometry under the following operating conditions: wavelength 328.1 nm, lamp current 10 mA, air 8.0 l/min, acetylene 2.5 l/min, slit-widths 0.10 (entrance) and 0.15 mm (exit). Construct a calibration curve by taking 1 ml of standard silver solutions containing 0—5.0 μg of silver and 3 ml of 13.8 M nitric acid in a 5-ml volumetric flask and diluting to the mark with water. Run a blank through the whole procedure using 3000 ml of 0.5 M nitric acid.

Tracer Experiments. The recovery of silver from 3000 or 100 ml of artificial sea water[6] or diluted nitric acid was examined radiochemically. For the 3000-ml samples, the gamma-activity of a 2-ml aliquot of the final 5-ml solution obtained by the recommended procedure was measured. For 100-ml samples, the separation of silver was carried out as follows. A hundred ml of artificial sea water or diluted nitric acid containing 0.05 μg of labeled silver was placed in a 200-ml beaker, 2.5 ml of 2-mercaptobenzothiazole solution was added, and the solution was stirred for 30 min. The contents of he beaker were transferred to a flotation cell (45 mm i.d. × 250 mm), the beaker was washed with 10 ml of water, and nitrogen was passed for 15 s. The main liquor was sucked off and discarded. Six ml of acetone was added to the cell to dissolve the precipitate, the filtrate was collected in a 10-ml volumetric flask, and diluted to the mark with acetone. The gamma-activity of a 2-ml aliquot was measured.

Results and Discussion

Purification of 2-Mercaptobenzothiazole. 2-Mercaptobenzothiazole is a readily available and inexpensive reagent, but containing 0.15—0.30 ppm of silver. Tracer experiments showed that more than 95% of silver was removed by the amalgamation method (80% removed by a single treatment). Silver in 50 ml of purified 2-mercaptobenzothiazole solution was less than 0.1 μg (from atomic-absorption spectro-

photometry).

Reaction Conditions. Tracer experiments were carried out on 100-ml samples to determine the optimal acidity for the separation of silver. The results are shown in Fig. 1. Silver, 0.05 μg, was recovered in yields greater than 95% from artificial sea water acidified to 0.04—1.5 M with nitric acid and from 0.3—1.5 M nitric acid. The low recoveries in nitric acid below 0.2 M were due to the passage of the precipitate through the sintered-glass disc (resulting from incomplete coagulation).

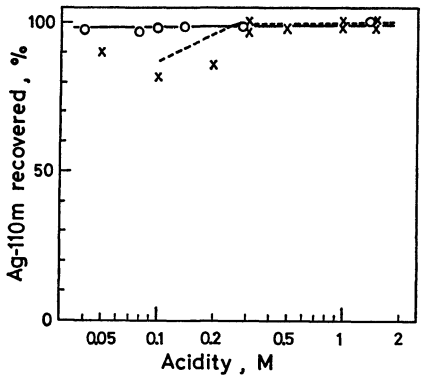

Fig. 1. Effect of acidity on silver recovery.
Solution volume: 100 ml; Ag: 0.05 μg;
2-mercaptobenzothiazole solution: 2.5 ml.
—○—: Artificial sea water, --×--: Diluted nitric acid.

Table 1. Determination of silver in sea water

Sample	Ag found (μg)	Ag in sample (μg/l)
1	0.30	0.10
2	0.28	0.09
3	0.28	0.09
4[a)]	0.30	0.10
5[b)]	0.57	0.09
6[c)]	0.72	0.07
		Av. 0.09

Solution volume: 3000 ml; Salinity: 35.16 ‰;
Location: 22°01'N, 152°00'E.
a) An acidic sample was filtered through a Millipore filter HA (0.45 μm). b) 0.30 μg of silver was added. c) 0.50 μg of silver was added.

From 3000 ml of artificial sea water (acidified to 0.1 M with nitric acid) and 0.5 M nitric acid, 0.05—5 μg of labeled silver was separated by the recommended procedure with the following recoveries: 96, 97% for 0.05 μg of silver, 96, 96, 96, 97, 97% for 1 μg, 97, 98% for 5 μg (in artificial sea water); 95, 95% for 0.05 μg, and 96% for 5 μg (in 0.5 M nitric acid).

Atomic-Absorption Measurements. The calibration curve was linear up to at least 5 μg of silver with a maximum deviation of 0.05 μg, and passed through the origin. The lower limit of determination was 0.1 μg. Fifty mg each of sodium, magnesium, potassium, and strontium, and 2.5 mg of calcium did not interfere with the determination of silver. The residue from evaporation of the final 5-ml solution weighed 25—35 mg, and the calcium in it was less than 1 mg (determined by EDTA titration).

Determination of Silver in Sea Water. The analyses were carried out on 3000-ml aliquots of a sample of surface sea water acidified to 0.1 M with nitric acid immediately after collection. The results are shown in Table 1. The blank through the whole procedure was less than 0.1 μg of silver. The time required for a determination was about 4 hr.

The authors wish to express their gratitude to Dr. Satoru Kanamori of Nagoya University for providing a sample of sea water. Their thanks are also due to Teruo Matsui for technical assistance.

An X-Ray Diffraction Study of a Concentrated Aqueous Sodium Iodide Solution

Masunobu MAEDA and Hitoshi OHTAKI

Laboratory of Solution Chemistry, Tokyo Institute of Technology, O-okayama, Meguro, Tokyo 152

(Received August 6, 1975)

Synopsis. X-Ray diffraction measurements of a 7 M NaI aqueous solution showed that iodide ion is surrounded by approximately six water molecules, the I^-–H_2O distance being 3.60 Å and that sodium ion is bonded to about four water molecules at the distance of 2.4 Å.

According to the results so far reported, halide–water distances in the first hydration sphere are about 3.2 Å for Cl^-, 3.4 Å for Br^-, and 3.7 Å for I^-.[1-3] These distances for Cl^- and Br^- ions are in good agreement with the sums of the respective crystal ionic radii and the molecular radius of water. For I^- ion, the anion–water bond length is more than 0.1 Å longer compared with the sum of the crystal radius of iodide ion and the radius of a water molecule. The halide ions are reported to be surrounded by seven to ten water molecules as their closest neighbors.[1-3] However, the number of water molecules around halide ions and the structural arrangement were not definitely determined. The recent X-ray and neutron scattering measurements of LiCl solutions by Narten *et al.*[4] revealed the six-coordinated structure for the hydrated Cl^- ion, although the bond is estimated to be rather weak. Then, questions arise how many water molecules are really coordinated to one iodide ion and if the I^-–H_2O bond is longer by 0.1 Å than the sum of the crystal radius of iodide and the radius of a water molecule.

Lithium and potassium ions were reported to be bonded to four water molecules in the first hydration sphere, their ion-water distances being 2.0 Å[4] and 2.9 Å,[1] respectively. For Na^+ ion, on the contrary, it was suggested that the cation is surrounded by six water molecules, 2.4 Å distant from the central ion.[5] In view of the previous results it seems unlikely that Na^+ ion has a different hydration number from Li^+ and K^+ ions.

In order to reconfirm these points, we have carried out X-ray diffraction measurements of a concentrated sodium iodide solution.

Experimental and Treatment of Data

The NaI aqueous solution was prepared by dissolving recrystallized sodium iodide in water. The concentration of NaI in the solution was found to be 7.009 M from the gravimetric analysis of I^- as AgI.

X-Ray scattering data were obtained at 25 °C on a θ–θ diffractometer (JEOL Co., Tokyo) equipped with a Philips Mo X-ray tube; the details of the measurements are described elsewhere.[6] The measured scattering angle range (2θ) was between 2° and 140°. The intensity data were corrected for background and polarization, and then scaled to absolute intensities $I(\theta)$ according to the ordinary procedures.[6-8] Reduced intensities $i(\theta)$ were extracted by subtraction of independent coherent and incoherent scatterings from the scaled intensities $I(\theta)$.[6]

The radial distribution function $D(r)$ was calculated by means of the Fourier transform of the reduced intensities $i(\theta)$ on the basis of the following equation.

$$D(r) = 4\pi r^2\rho_0 + 2r\pi^{-1}\int_0^{s_{max}} s\cdot i(s)\cdot M(s)\cdot\sin(rs)\mathrm{d}s \qquad (1)$$

Here ρ_0 is the average scattering density in electron units and $s=4\pi\sin\theta/\lambda$ ($\lambda=0.7107$ Å). The modification function $M(s)$ used is $(f_I^2(0)/f_I^2(s))\cdot\exp(-0.01s^2)$, where $f_I(s)$ is the coherent scattering factor of iodine atom at "angle" s. s_{max} is the maximum value of s ($\simeq 16.5$ Å^{-1}) reached in the experiments.

Results and Discussion

Figure 1 draws the radial distribution curve $D(r)$ and the differential curve $(D(r)-4\pi r^2\rho_0)$. These curves show three peaks at around 2.4 Å, 3.6 Å, and 4.8 Å. It is readily deduced from the previous results[2,3,5] that the first peak at 2.4 Å is due to the Na^+–OH_2 bond in the first hydration sphere and the second

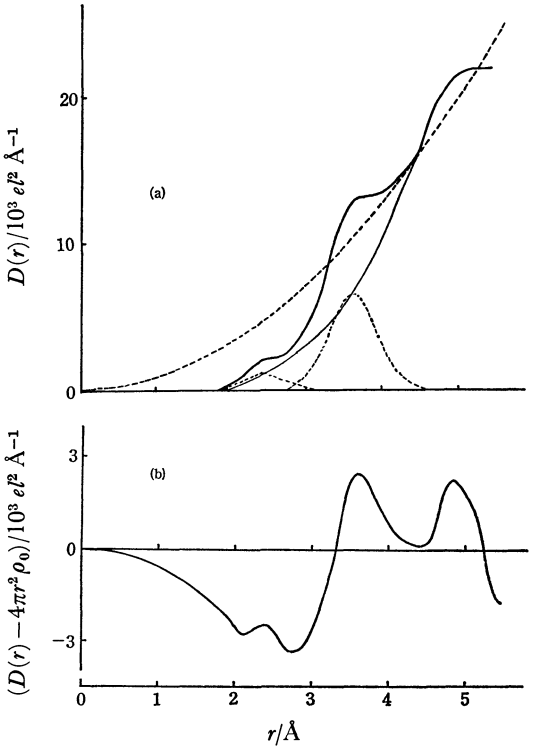

Fig. 1(a). Comparison between the $D(r)$ curve (thick solid line) and the peak shapes calculated for the Na^+–OH_2 and I^-–H_2O bonds.
The curve $4\pi r^2\rho_0$ is shown by the thick solid line, the calculated peak shapes by the fine dashed line, and the residual curve by the fine solid line.
(b) Differential curve, $D(r)-4\pi r^2\rho_0$.

peak at 3.6 Å represents the I^-–H_2O bond within the hydrated iodide ion.

The distances for sodium– and iodide–water bonds, and the hydration numbers were evaluated by the trial and error method in such a way that the residual curve brought about by subtraction of the theoretical peaks for the ion–water bonds from the $D(r)$ curve led to a smooth background curve.[6-8] The theoretical peak shapes were produced by the Fourier transform (Eq. (1)) of the theoretical intensities for a given structure calculated by Eq. (2).

$$i_{calc}(s) = \sum_i \sum_j n_{ij} f_i(s) f_j(s) \frac{\sin(r_{ij}s)}{r_{ij}s} \exp(-b_{ij}s^2) \qquad (2)$$

where $f_i(s)$ and $f_j(s)$ denote the scattering factors of atoms i and j, respectively, and n_{ij}, r_{ij}, and b_{ij} represent the frequency factor, the distance and the temperature factor of the interaction between any atoms i and j, respectively.

In Fig. 1a are illustrated the theoretical peak shapes (fine dashed line) for the Na^+–OH_2 and I^-–H_2O bonds and the resultant residual curve (fine solid line), together with the $D(r)$ curve. The values $r=2.40\pm0.03$ Å, $b=0.004\pm0.002$ Å^2, and n (hydration number)$=4\pm1.5$ for the hydrated Na^+ ion, and $r=3.60\pm0.02$ Å, $b=0.025\pm0.005$ Å^2, and $n=6\pm1$ for the hydrated I^- ion brought about a smooth remainder curve (fine solid line) with no indication of other residual peaks (Fig. 1a). These values were refined by direct comparison of the reduced intensities $s\cdot i(s)$ and the theoretical ones calculated from Eq. (2). The satisfactory agreement was obtained between the observed and calculated intensities in the s region larger than 3.5 Å^{-1}.

In conclusion, the distance (2.4 Å) for the Na^+–OH_2 bond is in good agreement with that reported previously.[5] On the contrary, the I^-–H_2O distance of 3.60 Å found in this work is shorter than that reported by Lawrence and Kruh in concentrated alkali iodide solutions.[2] Our I^-–H_2O bond length corresponds to the sum of the crystalline radius of I^- ion (2.16 Å)[9] and the radius of a water molecule (1.4 Å), as is true for the distances of the Cl^-–H_2O and Br^-–H_2O bonds.[2-4] The hydration number of I^- ion found in this work was a little smaller than that reported previously,[2,3] but the same as that of Cl^- ion.[4] Although the number of water molecules coordinated to Na^+ ion was not definitely determined because of the small scattering power of Na, our result showed that $n=4$ is more probable than 6.

It was difficult to clearly identify the asymmetric peak ranging from 4.5 Å to 5.2 Å; the peak may be ascribed to the Na^+–OH_2 and I^-–H_2O interactions in their second hydration spheres and H_2O–H_2O interactions within the hydrated I^- ion.

Phenylations of β-Nitrostyrene Derivatives with Benzene by the Use of Palladium(II) Acetate

Kimiaki YAMAMURA and Setsuo WATARAI

Institute of Chemistry, College of General Education, Kobe University, Tsurukabuto, Nada, Kobe, Hyogo 657

(Received November 13, 1974)

Synopsis. The phenylations of several β-nitrostyrene derivatives with benzene in the presence of palladium(II) acetate have been studied. The nitro group of the β-nitrostyrenes investigated affects the phenylations very strongly, because of its powerful electron-withdrawing nature, and a high reactivity and regiospecificity were observed.

Nucleophilic addition reactions to a carbon-carbon double bond conjugated with electron-withdrawing groups are well-known. We have ourselves previously reported the nucleophilic addition of ethanol to β-nitrostyrenes under very mild conditions.[1] Recently, Moritani and Fujiwara *et al.* reported a novel aromatic substitution reaction with olefins in the presence of palladium salts,[2] and also reported that an electron-withdrawing group on the olefinic carbon atom assists the phenylation reaction.[3] This prompted us to examine the phenylation reaction of β-nitrostyrenes by the use of palladium acetate.

A mixture of a β-nitrostyrene derivative and palladium acetate in a large excess of benzene and acetic acid was refluxed under stirring until the precipitation of black metallic palladium ceased. The results are summarized in Table 1. From β-nitrostyrene(I), 1,1-diphenyl-2-nitroethylene(III) was obtained predominantly; no α-nitrostilbene(II) was produced under the present reaction conditions. The selective formation of III from I in a good yield is interesting, since the treatment of *trans*-1-phenyl-1-propene under the same conditions gave *trans*-methylstilbene in a lower yield (24%) and *trans*-stilbene yielded triphenylethylene in a 28% yield on treatment with palladium acetate under similar conditions.[4] These facts indicate that, in this reaction, an electronic factor of the nitro group in I plays an important role. Both α-nitrostilbene (II) and 1,1-diphenyl-2-nitroethylene(III) reacted with benzene to give 1,1,2-triphenyl-2-nitroethylene(VII) (14.4 and 2.2% yields respectively), accompanied by considerable amounts of biphenyl and unidentified carbonyl compounds. The low yields of the phenylated compounds and the formation of appreciable amounts of by-products may be due to the steric hindrance of two phenyl groups and the nitro group. In fact, in their study of the phenylations of a series of phenyl-substituted ethylenes, Fujiwara *et al.* reported that the reactivity in olefin arylation using palladium salts was markedly influenced by a steric factor and that 1,1,2-triphenylethylene gave tetraphenylethylene in a 13% yield under similar conditions.[4] That the yield of VII from III was lower than those in the cases of II and triphenylethylene is interesting. This fact indicates that, in III, the nitro group on the carbon atom carrying the hydrogen which undergoes substitution interferes with the phenylation reaction.

Ethyl α-nitrocinnamate(IV) reacted with benzene under similar conditions to afford the corresponding phenylated product, VIII, in a 47.3% yield; here the steric factor does not seem to be as important as had been expected. This is presumably due to the powerful electron-withdrawing nature of the nitro and carboethoxy groups on the same ethylenic carbon atom. With β-bromo-β-nitrostyrene(V), the expected phenylated compound, 1,1-diphenyl-2-bromo-2-nitroethylene, was not obtained; instead, III was obtained as the main product, together with small amounts of VII and (*Z*)-α-nitrostilbene(IX).

Heck proposed a reaction mechanism for the arylation using palladium salts and an arylmercury compound, in which the first step is the *cis*-addition of arylpalladium acetate to the olefinic double bond, followed by the *cis*-elimination of hydridopalladium acetate.[5] When this mechanism is applied to the case of V, the following reaction pathway is considered. The yield of IX was very slight compared with that of III. This can be explained by considering that the initial complex, XI, was produced in preference to XII, because the phenyl group would tend to be introduced at the carbon atom adjacent to that bearing the nitro group. VII might be derived *via* III and

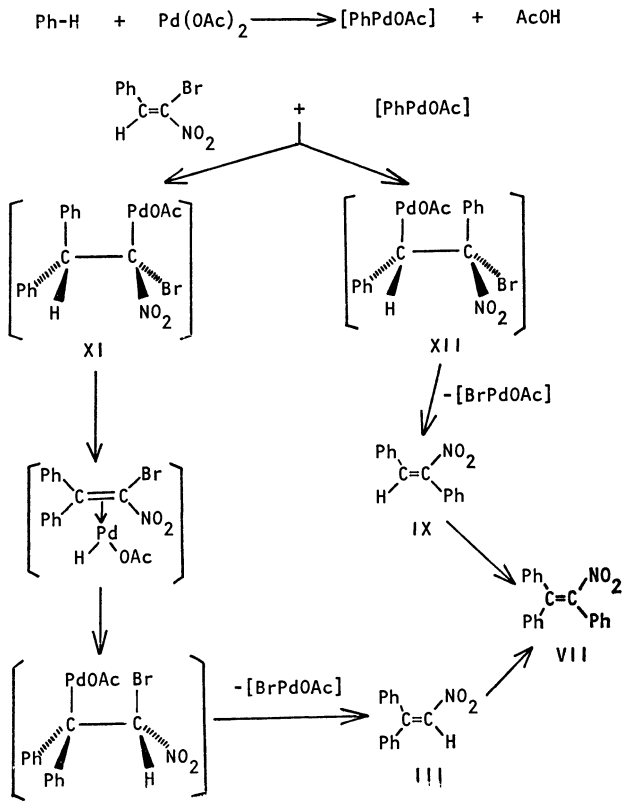

Table 1. Results of phenylation of β-nitrostyrenes

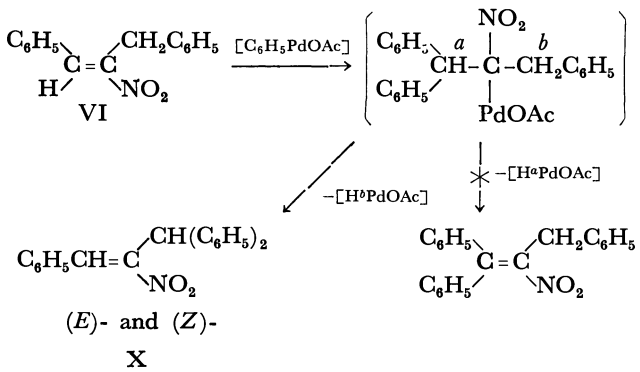
Starting β-nitrostyrene		Reaction time (hr)	Phenylated Product		Yield (%)[a]
$PhCH=CHNO_2$	I[b]	20	$Ph_2C=CHNO_2$	III	70.0
$PhCH=CPhNO_2$	II[b]	50	$Ph_2C=CPhNO_2$	VII	14.4
$Ph_2C=CHNO_2$	III	250	$Ph_2C=CPhNO_2$	VII	2.2
$PhCH=C(COOEt)NO_2$	IV[c]	20	$Ph_2C=C(COOEt)NO_2$	VIII	47.3
$PhCH=CBrNO_2$	V[b]	30	$Ph_2C=CHNO_2$	III	20.0[d]
$PhCH=C(CH_2Ph)NO_2$	VI[b]	20	$PhCH=C(CHPh_2)NO_2$	X	66.0[e]

a) Yields are of isolated and purified products. b) (*E*)-isomer. c) (*Z*)-isomer. d) Small amounts of (*Z*)-α-nitrostilbene(IX) and VII were also isolated. e) Total yield; (*E*)-: 34.0, (*Z*)-: 32.0 %.

IX. From 1,3-diphenyl-2-nitro-1-propene(VI), two unexpected compounds, (*E*)- and (*Z*)-1,3,3-triphenyl-2-nitro-1-propene(X), were obtained as the main products,[6] and at the end of reaction considerable amounts of the starting VI were recovered. When VI was treated with a 2-mol equiv. of palladium acetate under similar conditions, (*E*)- and (*Z*)-X were obtained in 34.0 and 32.0% yields respectively. The usual phenylated compound, 1,1,3-triphenyl-2-nitro-1-propene, was not obtained. The formation of X from VI may also be explained by the addition-elimination mechanism.[5]



(*E*)- and (*Z*)-X

In all of the β-nitrostyrenes investigated in this study, the reactivity and the direction of the introduction of the phenyl group are markedly influenced by the electronic factor of the nitro group. This finding is interesting because it has previously been reported that the direction of the introduction of an aromatic group to unsymmetrical olefins is influenced by the steric factor rather than by the electronic one.[7]

Experimental

Materials. Palladium acetate was prepared according to the method of Stephenson *et al.*[8] All the β-nitrostyrene derivatives except 1,3-diphenyl-2-nitro-1-propene(VI) were prepared by the method described in a previous paper.[1]

Preparation of VI. A mixture of freshly distilled benzaldehyde (0.05 mol), 1-phenyl-2-nitroethane (0.05 mol), and butylamine(0.02 mol) in 100 ml of toluene was refluxed for 16 hr. After the evaporation of the solvent, the residue was chromatographed over silica gel. Pale yellow crystals of VI were thus obtained in a 51% yield; mp 52 °C. IR (KBr), 1639, 1514, 1495, 1447, 1325, 767, 740, 695 cm^{-1}; NMR ($CDCl_3$), δ 8.30(s 1H, vinyl), 7.42 (s 5H, phenyl), 7.27 (s 5H, phenyl), 4.27 (s 2H, methylene). Found: C, 75.37; H, 5.44: N, 5.90%.

General Procedure for the Phenylation of β-Nitrostyrenes. A mixture of the β-nitrostyrene derivative (0.01 mol) and palladium acetate (0.01 mol) in 150 ml of benzene and 40 ml of acetic acid was refluxed until the precipitation of palladium metal ceased. After the filteration of palladium metal, the reaction mixture was poured into water. The organic layer was separated, and the aqueous layer was extracted with benzene. The combined extract was washed with water, and then the solvent was evaporated. The residue was chromatographed over silica gel, using a mixture of hexane-benzene (1 : 1) as the eluent. The first elution gave biphenyl, while subsequent fractions gave the phenylated products. The structures of the products were determined by means of their IR, UV, and NMR spectra and by elemental analyses. The following results were obtained:

a) The phenylation of I afforded III in a 70.0% yield.

b) The phenylations of II and III afforded VII in 14.4 and 2.2% yields respectively; mp 175 °C (lit,[9] 175 °C).

c) The phenylation of IV afforded VIII in a 47.3% yield; yellow crystals, mp 74 °C. NMR ($CDCl_3$) δ 7.47—7.09 (m, 10H, phenyl), 4.13 (q 2H, methylene, J=8 Hz), 1.05 (t 3H, methyl). Found: C, 68.63; H, 4.95; N, 4.68%.

d) The phenylation of V afforded III in a 20.0% yield, accompanied by small amounts of VII and XI.

e) The phenylation of VI with a 2-mol equiv. of palladium acetate afforded a mixture of (*E*)- and (*Z*)-isomers of X in a 66.0% yield. The physical data have been reported in a previous paper.[6]

Phenylation of trans-1-*Phenyl*-1-*propene.* Under conditions similar to those described above, *trans*-1-phenyl-1-propene gave *trans*-methylstilbene in a 24% yield.

The authors are indebted to Miss Masuko Nishinaka for her IR spectra measurements and elemental analyses and to Mrs. Kazuko Azumi for her technical assistance. Thanks are also due to Mr. Yasuo Morimoto for his skillful collaboration.

Reaction of *N*-Aroyl-*N*-arylhydroxylamines with *o*-Nitrobenzenesulfenyl Chloride

Shigeru OAE*, and Tadamitsu SAKURAI**

**Institute of Chemistry, The University of Tsukuba, Niihari-gun, Ibaraki 300-31*

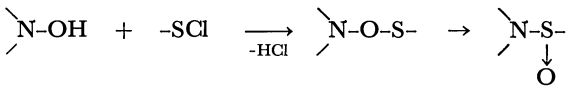
***Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Osaka 558*

(Received April 8, 1975)

Synopsis. Reactions of *N*-aroyl-*N*-arylhydroxylamines with *o*-nitrobenzenesulfenyl chloride were found to afford the corresponding *N*-aroylarylamines and *S*-(*o*-nitrophenyl) *o*-nitrobenzenethiosulfonate in good yields, respectively. Both the product distributions and the effect of substituents on the amount of reduction product suggest these reactions to proceed *via* homolytic cleavage of the N–O bond.

The rearrangement of allylic sulfenates to the corresponding sulfoxides with no allylic shift has been known to proceed *via* the homolytic scission of C–O bonds.[1] A similar mode of C–O bond scission has been observed in the rearrangements of both benzyl *p*-toluenesulfenate[2] and cyclohexenyl benzenesulfenate.[3]

However, the reaction of *N*,*N*-disubstituted hydroxylamines with the sulfenyl chloride could also lead to the formation of sulfinamide (III) by rearrangement as in the case of the allylic sulfenates as shown below. However, no such reaction has yet been investigated.



(I) (II) (III)

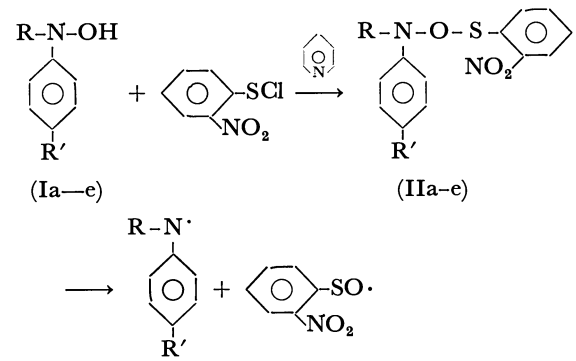
This paper describes the reaction of *N*-aroyl-*N*-arylhydroxylamines with *o*-nitrobenzenesulfenyl chloride, comparing the reaction route of the hydroxylamine with that of the corresponding alcohol.

Results and Discussion

The *N*-aroyl-*N*-arylhydroxylamines (Ia—e) were allowed to react with an equimolar amount of *o*-nitrobenzenesulfenyl chloride, and *S*-(*o*-nitrophenyl) *o*-nitrobenzenethiosulfonate and the corresponding *N*-aroylarylamines were obtained in good yields along with small amounts of *o*,*o*'-dinitrodiphenyl disulfide as shown in the Table. No rearrangement product (III) was found among the products.

Apparently, the more polar the solvent used, the greater was the yield of the unexpected reduction products, the *N*-aroylaryamines, while the introduction of an electron-releasing *p*-methyl group into the phenyl ring of the hydroxylamines resulted in an increase of the amount of the reduction product. Futhermore, the yield of the reduction product was not affected very much by the functional group (R) directly attached to the nitrogen atom of the hydroxylamines.

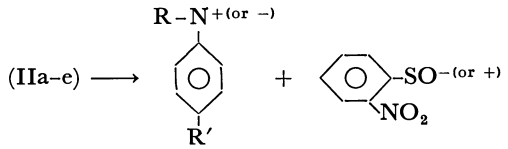
The *p*-nitrobenzenesulfinyl radical is known to be quite stable due to the electron-sharing 3d-orbital resonance, and to dimerize readily eventually yielding *S*-(*p*-nitrophenyl) *p*-nitrobenzenethiosulfonate.[4,5] Therefore, one may safely assume that the hydroxylamines (Ia—e) react with the sulfenyl chloride to give the intermediate (IIa—e), which undergoes homolytic scission of the N-O bond in (IIa—e) as shown below. The resulting acylamino radical undoubtedly affords the *N*-aroylarylamine by hydrogen abstraction and the *S*-(*o*-nitrophenyl) *o*-nitrobenzenethiosulfonate is formed by the dimerization of *o*-nitrobenzenesulfinyl radical, like the *p*-nitrobenzenesulfinyl radical.



(Ia—e) (IIa—e)

R=PhCO, R'=H (Ia); R=PhCO, R'=CH_3 (Ib); R=PhCO, R'=Cl (Ic); R=CH_3CO, R'=H (Id); R=Ts, R'=H (Ie)

If the N–O bond of (IIa—e) is assumed to cleave heterolytically, there are the following two possibilities for heterolysis.



These possibilities, however, may be ruled out by the following observations: (1) no substantial formation of the disulfide whose amount must be comparable to that of the thiosulfonate[5a,6] and (2) little influence by any polar functional group (R) on the yield of the reduction product was observed, unlike the reduction of *O*-(3,5-dinitrobenzoyl)-*N*-aroyl-*N*-arylhydroxylamines by cyanide ions in a dipolar aprotic solvent.[7] If the N–O bond of (IIa—e) were cleaved heterolytically, the nucleophilic attack of the chloride ion on the sulfenate-sulfur atom of (IIa—e) should give *o*-nitrobenzenesulfinyl chloride and the anilide anion. Thus, the alternative mechanism involving the homolysis of the N–O bond remains the most plausible possibility.

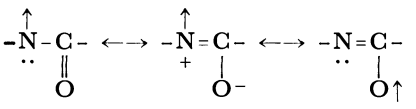
The lone-pair electron of the acylamino radical has been suggested to be extensively delocalized into the carbonyl group as shown by (b) in preference to the allylic resonance (c), placing the odd electron on the oxygen atom, being quite unimportant.[8]

TABLE 1. THE PRODUCTS OF THE REACTION OF R-N(OH)-C$_6$H$_4$-R′ WITH *o*-NITROBENZENESULFENYL CHLORIDE AT ROOM TEMPERATURE[a,b]

Substituents		Reaction Condition		Products and Yields, %	
R	R′	Solvent	Time (hr)	$(O_2N)(NO_2)C_6H_3$-S-SO$_2$-C$_6$H$_4$ [c]	R-NH-C$_6$H$_4$-R′ [d]
PhCO	H	CH_2Cl_2	24	41	57
PhCO	H	CH_3CN	24	60	76
PhCO	CH_3	CH_2Cl_2	24	57	86
PhCO	Cl	CH_2Cl_2	24	50	57
CH_3CO	H	CH_2Cl_2	24	46	53
Ts	H	CH_2Cl_2	24	46	57

Ts=*p*-$CH_3C_6H_4SO_2$-

a) The reactions were carried out in the presence of dissolved oxygen. b) A small amount of *o*, *o*′-dinitrodiphenyl disulfide was obtained in each run. c) Yield based on the sulfenyl chloride used. d) Yield based on the hydroxylamine used.



(a) (b) (c)

In addition, ESR spectroscopy revealed the electronic ground state of the acylamino radical to possess not a σ-, but a π-character. The π-radical is stabilized by the π-delocalization of an odd electron on the nitrogen atom in the phenyl ring. Consequently, the effects of the solvent and the substituent R′ on the amount of the reduction product can be interpreted in terms of the enhanced stability of the acylamino radical, formed by the homolytic scission of the N–O bond. The absence of any appreciable effect of the substituent R may be due to the negligible contribution of the allylic resonance (c) in the acylamino radical.

Thus, the different behaviors of the hydroxylamine and the alcohol in the reaction with the sulfenyl chloride appears to be attributable to the difference in the thermodynamical stabilities of the sulfinamide and the sulfoxide.

Experimental

Materials and Solvent. *N*-Aroyl-*N*-arylhydroxylamines (Ia—e) were prepared by the reactions of the corresponding *N*-arylhydroxylamines (2 mol) with aroyl chloride (1 mol) in dry ether at 0 °C. Repeated recrystallization from benzene-hexane gave mp, 121.5—122.0 °C (Ia), 110—111 °C (Ib), 156—157 °C (Ic), 68.5—69.5 °C (Id), and 145—146 °C (Ie; Found; C, 59.06; H, 4.98; N, 5.38%. Calcd for $C_{13}H_{13}NO_3S$: C, 59.30; H, 4.97; N, 5.32%). *o*-Nitrobenzenesulfenyl chloride was synthesized by the chlorination of *o*,*o*′-dinitrodiphenyl disulfide with dry chlorine gas in chloroform at room temperature. Repeated recrystallization from hexane gave light yellow needles, mp 74—75 °C (lit, 73—74.5 °C)[10]. All the solvents used were purified by the usual methods.

General Procedure for the Reactions of (Ia—e) with o-Nitrobenzenesulfenyl Chloride. Solutions of *o*-nitrobenzenesulfenyl chloride (4.58—6.62 mmol) in 20 ml of methylene chloride were dropped for 10 min with stirring into solutions of *N*-aroly-*N*-arylhydroxylamines (4.58—6.62 mmol) and pyridine (4.58—6.62 mmol) in 30 ml of methylene chloride at 0 °C. After keeping the mixtures at room temp. for 24 hr, the solutions were washed with water and dried over anhyd. sodium sulfate. Evaporation of the solvent afforded residual solids, which were then separated by column chromatography packed with silica gel using methylene chloride as the eluent. The structures of the products (shown in the Table) were identified by comparing their melting points and IR spectra with those of authentic compounds.

Synthesis of Sugar Derivatives of *N*-Alkyl-*N*-nitrosourea

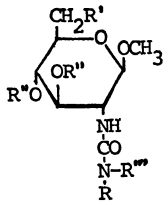
Tomoya MACHINAMI, Kazuki KOBAYASHI, Yoshiki HAYAKAWA and Tetsuo SUAMI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received May 29, 1975)

Synopsis. Thirteen sugar derivatives of *N*-alkyl-*N*-nitrosourea have been prepared as follows. The reaction of a sugar amine with alkyl isocyanate gives a sugar derivative of *N*-alkylurea. When the product is treated with sodium nitrite in aqueous acetic acid, it gives the *N*-alkyl-*N*-nitrosourea derivative.

Streptozotocin is a broad spectrum antibiotic and possesses antitumor[1] and mutagenic activities.[2] The antibiotic was isolated from a fermentation broth of Streptomyces achromogenes var. streptozoticus by the Upjohn research group[3] and its structure was established to be *N*-carbamoyl-*N'*-methyl-*N'*-nitroso-D-glucosamine.[4] An undesirable side effect of the antibiotic, its diabetogenic property, was removed by methylating an anomeric hydroxyl group of the D-glucosamine moiety.[5] Later an attempt was made to prepare its analogs,[6] since the nitrosoureido group seems to be an essential group for the appearance of an antitumor activity.[7]



Derivatives of methyl β-D-glucosaminide

We have been working on the preparation of carbohydrate derivatives of *N*-alkyl-*N*-nitrosourea, and we wish to report a synthesis of methyl glycosides of *N*-alkyl analogs of the antibiotic and *N'*-alkyl-*N*-carbamoyl-*N'*-nitroso derivatives of glycosylamines. All the compounds show remarkable antitumor activities.

Experimental

Melting points were determined in a capillary tube in a liquid bath and are uncorrected. Optical rotations were measured on a JASCO DIP-SL polarimeter. IR spectra were measured on potassium bromide disks with a JASCO IR-E spectrometer. PMR spectra were determined at 60 MHz on a Varian A-60D spectrometer in deuteriochloroform with reference to tetramethylsilane as an internal standard. Solutions were evaporated under reduced pressure at 25—30 °C. Catalytic hydrogenation was carried out under hydrogen atomosphere (3.4 kg/cm²) with a Parr apparatus in the presence of Raney nickel. Acetylation was carried out in a mixture of acetic anhydride and pyridine in the usual manner. De-*O*-acylation was performed by dissolving a compound in methanolic ammonia or in 0.01～0.06 M methanolic sodium metoxide.

General Procedure for N-*Alkylurea Derivatives.* Alky isocyanate was added to a solution of carbohydrate amine in methanol and the mixture was stirred for 20 min at 10 °C to give crystalline precipitates. The mixture was settled in a refrigerator and the crystals were collected by filtration.

General Procedure for N-*Alkyl*-N-*nitrosourea Derivatives.* The carbamoyl derivative was dissolved in aqueous acetic acid. Sodium nitrite was added to the solution under ice cooling with agitation to give crystals. The crystals were

collected by filtration and another crop of the product was obtained from the filtrate by evaporation.

Starting Materials. Compounds: **1, 4** and **7** were synthesized from methyl β-D-glucosaminide.[8] Compound **10** was prepared by selective mesylation of methyl 2-deoxy-2-(*N'*-methylureido)-β-D-glucopyranoside.[6a] Compound **13** was prepared from **10** by the four step reaction in 70% yield. Compound **16** was synthesized from methyl 2-*N*-benzyloxycarbonyl-β-D-glucosaminide[9] by the four step reaction in 37% yield. Compound **19** was prepared from 1-(β-D-glucopyranosyl)-3-methylurea[10] in 90% yield. Compounds: **21, 24** and **28** were synthesized from 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosylamine.[12] Compound **31** was prepared from 2,3,4,6-tetra-*O*-acetyl-β-D-aminopyranosylamine which was obtained by azidolysis and subsequent catalytic hydrogenation of 2,3,4,6-tetra-*O*-acetyl-α-D-mannopyranosyl bromide.[13,14] Compound **34** was prepared from 2,3,4-tri-*O*-acetyl-β-D-xylopyranosyl azide.[15] Compound **38** was prepared from 1-*O*-acetyl-2,3,5-tri-*O*-benzoyl-D-ribofuranosyl chloride.[16,17]

The *N*-alkyl-*N*-nitrosourea derivatives revealed a characteristic absorption for *N*-nitroso group at 1480—1495 cm^{-1} in their ir spectra. The position of the nitroso group was deduced from their PMR spectra by ascertaining the absence of a proton on the nitrogen atom possessing an alkyl group.

We wish to express our thanks to Mr. Saburo Nakada for the elemental analyses. We are also indebted to Mr. Shigeru Nishiyama, Mr. Kazuo Kikuchi and Mr. Yasuhiro Nagamatsu for assistance in the preparation of the compounds.

Synthesis of (2-Chloroethyl)-nitrosourea Derivatives of Carbohydrate

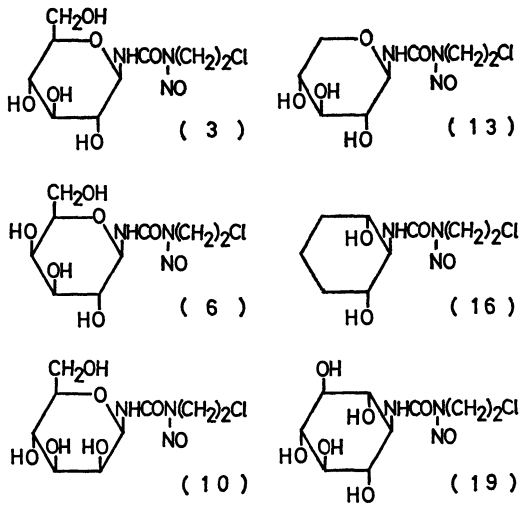
Tomoya MACHINAMI, Shigeru NISHIYAMA, Kazuo KIKUCHI, and Tetsuo SUAMI*

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received June 7, 1975)

Synopsis. Six antileukemic carbohydrate derivatives which have a (2-chloroethyl)-nitrosoureido group have been prepared by a reaction between amino sugars and 2-chloroethyl isocyanate, followed by nitrosation.

It has been suggested by Johnston *et al.*[1] that the replacement of a methyl group with a 2-chloroethyl group in numerous congeners of methyl-nitrosoureas increased antitumor activities against leukemia L1210, as was demonstrated with BCNU: 1,3-bis(2-chloroethyl)-1-nitrosourea and CCNU: 1-(2-chloroethyl)-3-cyclohexyl-1-nitrosourea.[1] More recently, two papers[2,3] have described a preparation of 2-chloroethyl analog of antitumor antibiotic streptozotocin.[4] In our laboratory, a synthesis of methyl glycoside of streptozotocin was initiated[5] and afterward, several nitrosourea derivatives of carbohydrate have been prepared by a reaction between amino sugars and alkyl isocyanate, followed by nitrosation.[6-8] In connection with the previous papers, we have attempted to prepare (2-chloroethyl)-nitrosourea derivatives, and in the present note, we wish to report a preparation of the derivatives of D-glycosylamines and polyhydroxycyclohexylamines by the analogous reaction sequence employed in the previous papers.[5-8] The position of the nitroso group in each compound has been established by PMR spectroscopy by demonstrating a spectral symmetry of the $ClCH_2CH_2N(NO)$ group (A_2B_2 system).[1]



All the six compounds showed a remarkable antitumor activity against L1210 leukemia in mice, which will be reported in a near future.

Experimental

Melting points were determined in a capillary tube in a liquid bath and are uncorrected. Solutions were evaporated under diminished pressure. Acetylation was carried out with acetic anhydride and pyridine in the usual manner. Optical rotations were measured on a Japan Spectroscopic

† See, Table 1. †† Compound did not give a correct analysis.

DIP-SL polarimeter. Elementary analyses were performed by Mr. Saburo Nakada to whom our thanks are due.

General Procedure for 1-(2-Chloroethyl)-3-(D-glycopyranosyl)urea and -3-(polyhydroxycyclohexyl)urea. *O*-Acetyl-D-glycosylamine or aminocyclitol was treated with 2-chloroethyl isocyanate (1.1—2.2 mol. equiv.) in a solvent. The reaction mixture was agitated for 1—2.5 hr under ice cooling and then evaporated. The residue was recrystallized from an appropriate solvent. The product was de-*O*-acetylated in methanolic ammonia or 0.1 M methanolic sodium methoxide.

General Procedure of Nitrosation. The carbamoyl derivative was treated with sodium nitrite (2 mol. equiv.) in 99% formic acid. After agitated for 1—2 hr under ice cooling, the solution was diluted with ice cold water and deionized with Amberlite IR-120(H^+). The solution was evaporated or lyophilized to give the product.

Starting Materials. Compound **1** was prepared from 2,3,4,6-tetra-*O*-acetyl-β-D-glucopyranosylamine,[9] compound **5** was from 2,3,4,6-tetra-O-acetyl-β-D-galactopyranosylamine,[9] and compound **8** was from 2,3,4,6-tetra-*O*-acetyl-β-D-mannopyranosylamine.[8] Starting from 2,3,4-tri-*O*-acetyl-1-azido-1-deoxy-β-D-xylopyranose,[10] compound **12** was prepared. Compound **15** was synthesized from 1,3/2N-aminocyclohexanediol[11] and compound **18** was from *scyllo*-inosamine.[12]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(12), 3765—3766 (1975)

Reaction of a Stable Free Nitrogen-Centered Radical, 3,4-Dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl, with Organoaluminum Compounds

Yozo MIURA, Yuzo MORIMOTO, and Masayoshi KINOSHITA

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received June 26, 1975)

Synopsis. Reactions of 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (**1**) with triethylaluminum, triisobutylaluminum, and diethylaluminum chloride were examined, and from the product analysis, these reactions are proposed to proceed by means of a homolytic substitution process.

In previous reports,[1,2] the reactions of 3,4-dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (**1**)[3] with Grignard reagents or alkyllithiums have been described, and these reactions have been proposed to proceed by means of a homolytic substitution process.

The extension of this investigation to organoaluminum compounds is of interest, because these reactions of the reagents with oxygen-centered radicals have been widely investigated,[4] and have been demonstrated to proceed through homolytic processes. However, reactions of organoaluminum compounds with nitrogen-centered radicals have been little investigated, and thus, no unambiguous examples of homolytic substitution reactions with nitrogen-centered radicals have been found,[4] thus

$$AlR_3 + R'O\cdot \longrightarrow AlR_2OR' + R\cdot$$

From this point of view, the reaction of **1** with organoaluminum compounds have been examined, and in this paper the results are described and the mechanism is discussed.

Experimental

All the melting points were uncorrected. Triethylaluminum, triisobutylaluminum, and diethylaluminum chloride were used as heptane solutions of 24, 26, and 22 w/w %, respectively. 3, 4-Dihydro-2,4,6-triphenyl-2*H*-1,2,4,5-tetrazin-1-yl (**1**) was prepared according to the procedure of Kuhn and Trischmann, and which was recrystallized from methanol, mp 141—142 °C (lit,[3] 139—140 °C).

The reactions of **1** with the organoaluminum compounds were carried out according to the similar procedure described in a previous report.[2] The amounts of regenerated **1** and of isolated coupling compounds (**2**) were determined similarly. The compounds (**2**) were recrystallized from methanol.

1-Ethyl-2,4,6-triphenyl-1,2,3,4-tetrahydro-1,2,4,5-tetrazine: 0.21 g (0.62 mmol), mp 133—134 °C (isolated from the reaction mixture with triethylaluminum); 0.23 g (0.67 mmol), mp 134—136 °C (with diethylaluminum chloride, lit,[2] 133—134 °C).

1-Isobutyl-2,4,6-triphenyl-1,2,3,4-tetrahydro-1,2,4,5-tetrazine: 0.22 g (0.59 mmol), mp 161—163 °C (lit,[2] 158—160 °C).

Results and Discussion

In the general procedure, when an organoaluminum compound is added to a degassed toluene solution of **1** at 0 °C, the characteristic green color of **1** (λ_{max} 720 nm, ε 4330 in benzene)[3] turned immediately to light brown, indicating that **1** reacted rapidly and completely with the reagent. The color remained when the solution was not exposed to moisture but, when it was poured into water, the original green color reappeared immediately, this coloration showing that **1** was regenerated. The organic layer was extracted with benzene and dried over sodium sulfate.

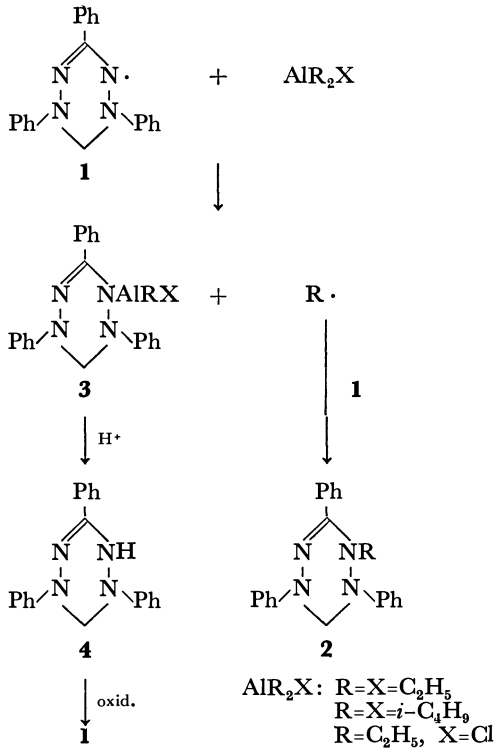
The benzene solution was examined by thin-layer chromatography (tlc, silica gel : benzene), and three spots were detected. Two spots were easily identified to correspond to **1** and a leuco compound (**4**), respectively, from the green color and by comparison with authentic samples in tlc. **4** is known to oxidize easily to **1** even when subjected to atmospheric oxygen,[3] thus the **1** detected was certainly formed from the oxidation of **4** in air. Therefore, the amount of regenerated **1** was determined, after **4** had been confirmed by tlc to be oxidized thoroughly to **1** on standing in air (for *ca.* two days), by optical density measurements at 720 nm in a benzene solution. The results are summarized in Table.

The residual unidentified spot is probably a coupling compound of **1** with an alkyl radical originally attached to the organoaluminum compound from its R_f value. The green benzene solution was concentrated under reduced pressure and the residue was subjected to columnchromatography (silica gel : benzene), resulting in the expected coupling compound, 1-alkyl-2,4,6-triphenyl-1,2,3,4-tetrahydro-1,2,4,5-tetrazine (**2**). Their structures were confirmed by mps, and

TABLE. THE RESULTS OF THE REACTION OF 3,4-DIHYDRO-2,4,6-TRIPHENYL-2*H*-1,2,4,5-TETRAZIN-1-YL (**1**) WITH ORGANOALUMINUM COMPOUNDS[a]

Aluminum compound	mmol	Regenerated **1** %	Isolated coupling compound (**2**)	
			R in **2**	%[b]
Triethylaluminum	1.5	39	Ethyl	45
Triisobutylaluminum	1.6	37	Isobutyl	47
Diethylaluminum chloride	1.5	42	Ethyl	41

a) **1** : 0.50 g (1.6 mmol), toluene : 20 ml, 0°C. b) : based on **1** used.



Scheme.

IR and MNR spectra, and the results are given in Table.

On the basis of these results, a reasonable reaction mechanism may be illustrated as shown in Scheme; **1** and an organoaluminum compound are converted into compound (**3**) and an alkyl radical, and the alkyl radical formed is captured exclusively by another unreacted **1** to give the coupling compound **2**. However, **3** is hydrolyzed immediately to a leuco compound (**4**) in contact with water, which is oxidized to **1** gradually by atmospheric oxygen.

The Convenient Syntheses of Biopterin and Its Three Opitical Isomers

Takashi SUGIMOTO and Sadao MATSUURA

College of General Education, Nagoya University, Chikusa Nagoya 464

(Received August 8, 1975)

Synopsis. Simple syntheses of biopterin (**4a**) and its three optical isomers (**4b, c, d**) are described. The condensation of 2,4,5-triaminopyrimidin-6(1*H*)-one (**1**) with each of the 5-deoxypentose phenylhydrazones (**2a, b, c, d**), followed by oxidation with $K_3[Fe(CN)_6]$ and H_2O_2 in the presence of KI, gives biopterin (**4a**) and the isomers (**4b, c, d**) respectively.

Biopterin [2-amino-6-(L-*erythro*-1,2-dihydroxypropyl)-pteridin-4(3*H*)-one] (**4a**), first isolated from human urine,[1,2] has attracted considerable interest because of its biological activities: biopterin is a growth factor for *Crithidia fasciculata*[1,2] and its tetrahydro derivative has been found to be a potent cofactor for phenylalanine,[3] tyrosine,[4] and tryptophan hydroxylases.[5] Because of this importance, much effort has been expended on the synthesis of biopterin (**4a**)[2,6,7,8] and its optical isomers (**4b, c, d**).[6c] The resulting methods, however, all suffer from difficulties, *e.g.*, in separating the biopterin (**4a**) from its isomer, isobiopterin (**5a**),[2,6,8] or in making appropriate starting materials.[7,8b,c] Accordingly, we sought a more general simple synthesis.

In 1970, Viscontini *et al.*[9] synthesized D-*erythro*-neopterin (**4e**) by the condensation of 2,4,5-triaminopyrimidin-6(1*H*)-one (**1**) with D-arabinose phenylhydrazone (**2e**). In this reaction, a tetrahydropteridine (**3e**) was formed which, on aerial oxidation at pH 7, gave neopterin (**4e**) unaccompanied by the 7-isomer (**5e**).

When we applied this method to the synthesis of biopterin (**4a**), though, using 5-deoxy-L-arabinose phenylhydrazone (**2a**) instead of **2e**, we obtained no biopterin. The only isolable product was the 6-unsubstituted pteridine (**4f**), apparently formed by the loss of the 6-dihydroxypropyl group during the oxidation step. A similar reaction was also observed by Viscontini and Provenzale.[8a] We investigated further the conditions of oxidation and found that the use of a mixture of $K_3[Fe(CN)_6]$ and H_2O_2 in the presence of KI in an acidic solution gave biopterin as the main product.

We synthesized 5-deoxy-L-arabinose by the method Hough and Taylor,[10] involving the oxidative degradation of L-rhamnose diethyl dithioacetal. 5-Deoxy-D-arabinose and 5-deoxy-L (and D)-xylose were made from the corresponding pentose by the procedures of Zinner, Wessely, and Kristen.[11] Heating 5-deoxy-L-arabinose phenylhydrazone (**2a**) with 2,4,5-triaminopyrimidin-6(1*H*)-one (**1**) in 50% aqueous methanol under nitrogen gave a compound unstable to oxidation, probably the tetrahydropteridine (**3a**), by analogy with **3e**.[9] When the intermediate was oxidized by air in a neutral or weakly alkaline solution, only the 6-unsubstituted pteridine (**4f**) was formed. However, when the same oxidation was carried out under acidic conditions, a small amount of biopterin (**4a**) was formed, together with **4f**. Eventually, we found that the intermediate (**3a**) was oxidized effectively to biopterin (**4a**) in an acidic solution using a mixture of $K_3[Fe(CN)_6]$ and H_2O_2 in the presence of a little KI. A small amount (*ca.* 20%) of the unsubstituted pteridine (**4f**) was formed, but no 7-isomer (**5a**) was detected. The separation of biopterin from **4f** and several other minor components was achieved easily by chromatography, first on a Florisil column using 2M-hydrochloric acid as the developer, then on another Florisil column by gradient elution using 0—1% ammonia,[12] and finally on a P-Cellulose column[6b,c] eluted by water. The structure of the product was confirmed by its UV spectra.

The three optical isomers (**4b, c, d**) were made similarly by the condensation of the pyrimidine (**1**) with the appropriate phenylhydrazone (**2b, c,** or **d**).

Experimental

The analyses were done by the Analytical Section, Meijo University, Nagoya; the UV spectra were measured with a Shimadzu model UV-210 spectrophotometer.

L-Erythro-*biopterin (4a)*. Phenylhydrazine (3.6 g) and one drop of acetic acid were added to 5-deoxy-L-arabinose[10] (4.0 g) in ethanol (5 ml). After stirring at 20 °C for 30 min, the mixture was diluted with ether (5 ml) and chilled to give fine needles (3.6 g) of the phenylhydrazone (**2a**), which were then collected by filtration and washed with ether. A solution of this product (3.6 g) and 2,4,5-triaminopyrimidin-6(1H)-one dihydrochloride (3.0 g) in 50% aqueous methanol (400 ml) was stirred under nitrogen at 20 °C for 2 hr, and then under reflux for 4 hr. After cooling to *ca.* 20 °C, potassium ferricyanide (5.0 g), potassium iodie (0.10 g), and hydrogen peroxide (35%, 5 ml) were added quickly to the solution, and the mixture was stirred by introducing air at 20—25 °C for 12 hr. The mixture was concentrated under reduced pressure to *ca.* 50 ml and then chilled. The dark solid was collected by filtration, washed with a little cold water, and then extracted with 1% ammonia (2×100 ml). The extracts were combined and evaporated to dryness under reduced pressure. The residue was dissolved in 2M hydrochloric acid (100 ml) and fractionated on a Florisil column[12] (4×40 cm), using 2M hydrochloric acid as the developer. Biopterin was well separated from several minor by-products, including **4f**, during this procedure. The fractions containing biopterin were evaporated to dryness under reduced pressure, and the residue was extracted again with 1% ammonia (200 ml); a considerable amount of an inorganic material remained undissolved. The extract was evaporated to dryness and chromatographed on a Florisil column (4×30 cm), and then developed by gradient elution with water (1.0 l) and 1% ammonia (1.0 l). The biopterin fractions were finally purified on P-Cellulose[11] (acid form; 3×30 cm; eluted with water) to remove a small amount of colored impurities. The evaporation of the final eluate gave a solid, which was dissolved in 1% ammonia (50 ml) and then added drop by drop into vigorously stirred boiling formic acid (1M, 50 ml). Chilling gave almost colorless needles (270 mg) of L-*erythro*-biopterin (**4a**); mp>300 °C (Found: C, 43.9; H, 4.5; N, 28.3%. Calcd for $C_9H_{11}N_5O_3 \cdot 1/2H_2O$: C, 43.9; H, 4.9; N, 28.4%).

Synthesis of the Optical Isomers (4b, c, d). 5-Deoxy-L-xylose (2.5 g), phenylhydrazine (2.0 g), and 6M-HCl (5 drops) were stirred in methanol (30 ml) at 40—45 °C for 15 min. Without isolating the phenylhydrazone (**2c**), the solution was treated with the pyrimidine dihydrochloride (5.0 g) as above. Chromatographic purification as before afforded colorless needles (495 mg) of L-*threo*-biopterin (**4c**);[6c] mp>300 °C (Found: C, 44.1; H, 4.5; N, 28.0%. Calcd for $C_9H_{11}N_5O_3 \cdot 1/2H_2O$: C, 43.9; H, 4.9; N, 28.4%).

Replacing the 5-deoxy-L-xylose in the foregoing condensation by 5-deoxy-D-arabinose and 5-deoxy-D-xylose gave 205 mg of D-*eryhtro*-biopterin(**4b**)[6c] (mp>300 °C) (Found: C, 42.5; H, 4.6; N, 27.9%. Calcd for $C_9H_{11}N_5O_3 \cdot H_2O$: C, 42.35; H, 5.1; N, 27.4%) and 250 mg of D-*threo*-biopterin (**4d**)[6c] (mp>300 °C) (Found: C, 43.75; H, 4.6; N, 28.4%. Calcd for $C_9H_{11}N_5O_3 \cdot 1/2H_2O$: C, 43.9; H, 4.9; N, 28.4%) respectively.

We thank Miss Noriko Itoh for her technical help and Dr. D. J. Brown of Australian National University for his help in preparation of this manuscript.

Michael Reactions of α-Phenylthio and α-Phenylsulfinyl Crotonic Esters with Cyclic Enones

Hisahiro HAGIWARA, Kiyoshi NAKAYAMA, and Hisashi UDA

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira-2, Sendai 980

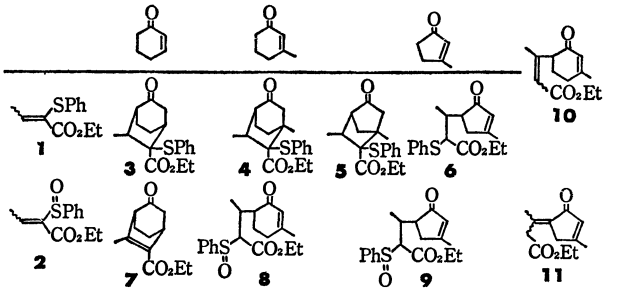
(Received August 12, 1975)

Synopsis. The Michael reactivities of ethyl α-phenylthio- and α-phenylsulfinylcrotonates with 2-cyclohexenone, 3-methyl-2-cyclohexenone, and 3-methyl-2-cyclopentenone have been investigated.

In connection with the study of α-phenylthio or α-phenylsulfinyl α,β-unsaturated esters[1] for synthetic utility, we have examined the reactivities of ethyl α-phenylthiocrotonate **1** and ethyl α-phenylsulfinylcrotonate **2** to cyclic enones as the Michael acceptor and addend.[2]

Compound **1** easily underwent the sequential Michael additions with the enolates of 2-cyclohexenone and 3-methyl-2-cyclohexenone, generated by treatment with lithium diisopropylamide in the presence of HMPA, to give the bicyclo[2.2.2]octane derivatives **3** and **4** in 70 and 77% yields, respectively.[3] (Table 1).

TABLE 1. MICHAEL ADDITION PRODUCTS OF **1** AND **2** WITH CYCLIC ENONES*



* All the products except **7** were mixtures of diastereoisomers.

In the reactions the addition of HMPA was essential, since an intractable mixture was produced when the reaction of **1** with 2-cyclohexenone was conducted in the absence of HMPA. On the other hand, in the reaction with 3-methyl-2-cyclopentenone the double Michael product **5** was the minor component (17%), the major one (58%) being the first Michael adduct **6**. Such a difference in the second Michael addition process between the six and five membered enones may be attributed to the difference of ring strain in the enolates of the bicyclo[2.2.2]octanone system in **4** and bicyclo[2.2.1]heptanone one in **5**; in the latter the ring-opened enolate, the first Michael adduct, appears to be more favorable in the equilibrium condition.

The sequential Michael addition was also observed in the reaction of **2** with 2-cyclohexenone, accompanied by desulfenylation during the work-up, giving rise to the bicyclo[2.2.2]octene derivative **7**. The reaction of **2** with 3-methyl-2-cyclohexenone and 3-methyl-2-cyclopentenone afforded only the first Michael adducts **8** and **9** in low yields. Failure for the second Michael additions of **8** and **9** would be ascribed to the stability of the anion, $-\bar{C}(SOPh)COOEt$, and the steric effect of the ring methyl group.

The structures of **3**, **8**, and **9** were further confirmed by transformation into the desulfenylated compounds **7**, **10**, and **11**, respectively.

Experimental

IR spectra were taken on a Hitachi EPI-S2 spectrophotometer using CCl_4 as a solvent. NMR spectra were obtained on a JEOL C-60HL instrument using TMS as an internal standard and CCl_4 as a solvent. The results are given in terms of the δ scale, the values of ester ethyl and phenyl protons except **1** and **2** being omitted. Analytical samples were purified by evaporative distillation and bath temperatures are given as the boiling points. Elemental analyses were carried out in the microanalytical laboratory of this institute.

Ethyl α-Phenylthio- and α-Phenylsulfinylcrotonates ***1*** *and* ***2***. Ethyl α-phenylsulfinylbutyrate (3.07 g, 12.8 mmol) was prepared by the reaction of ethyl α-bromobutyrate with sodium thiophenolate followed by oxidation with $NaIO_4$ in the usual manner. To this was added dropwise trifluoroacetic anhydride (4.2 g, 20 mmol) with stirring and ice-cooling (the Pummerer rearrangement and subsequent elimination of trifluoroacetic acid took place). The mixture was stirred at room temperature for 1.5 hr and then evaporated to dryness *in vacuo*. The residual liquid was dissolved in ether, passed through Woelm neutral alumina activity III, and freed from ether to give spectroscopically single ethyl α-phenylthiocrotonate **1** (2.34 g, 82%): bp 120—130 °C (3.5 mmHg, large scale distillation caused decomposition to produce a considerable amount of a substance with lower-boiling point, reducing the yield of **1**, *ca.* 52%); IR 1730, 1620 cm^{-1}; NMR 1.02 (3H, t, J=7.5), 2.05 (3H, d, J=6.8), 4.05 (2H, q, J=7.5), 7.15—7.50 (5H, m), 7.45 (1H, q, J=6.8); Anal. Found: C, 65.11; H, 6.62%. Calcd for $C_{12}H_{14}O_2S$: C, 64.85; H, 6.35%. The geometry of the double bond has not been determined.

Ethyl α-phenylsulfinylcrotonate **2** was prepared from **1** by oxidation with an equivalent amount of *m*-chloroperbenzoic acid in CH_2Cl_2 (0 °C, 10 min) in the usual manner and purified by chromatography on SiO_2. Yield: 67%. IR 1720, 1627 cm^{-1}; NMR 1.07 (3H, t, J=7.5), 2.26 (3H, d, J=7.5), 4.06 (2H, q, J=7.5), 7.25—7.80 (6H, q and m).

General Procedure for Michael Reactions of ***1*** *and* ***2*** *with Cyclic Enones.* To a solution of lithium diisopropylamide (1.20—1.30 mmol) in anhydrous THF (2 ml) and ether (1 ml) was added dropwise at −60 °C a solution of a cyclic enone (1.00 mmol) and then a solution of HMPA (1.00 mmol) in anhydrous THF (2 ml each). After being stirred at −60 °C for 1 hr, the solution was cooled at −75 °C and a solution of **1** or **2** (1.10 mmol) in anhydrous THF (2 ml)

was added. The operation was carried out under nitrogen. The progress of the reaction was followed by tlc. The reaction mixture was stirred at an appropriate temperature for an appropriate time, and then acidified with dil. HCl and thoroughly extracted with CH_2Cl_2. The extract was washed with saturated salt solution, dried, and freed from the solvent. The product was separated by preparative tlc on SiO_2 with 1 : 1 petroleum ether-ether for **3**—**6** and with 1 : 10 or ether alone for **8** and **9**. The reaction conditions (temperature and time) and the yields of products are shown for each case.

Ethyl 3-Methyl-5-oxo-2-(phenylthio)bicyclo[2.2.2]*octane-2-carboxylate* ***3*** *and its Conversion into* ***7***. Reaction conditions: −75——55 °C for 2 hr. Yield: 70%. IR 1725 (br.) cm^{-1}; NMR 0.80—1.50 (6H, complex d and t), 1.50—3.20 (9H, m).

To a cold solution of **3** (230 mg, 0.72 mmol) in CH_2Cl_2 (4 ml) was added dropwise a solution of *m*-chloroperbenzoic acid (85%, 147 mg, 0.72 mmol) in CH_2Cl_2 (4 ml), and the mixture was stirred at 0 °C for 30 min. Aqueous saturated $NaHSO_3$ was added and the water layer was extracted with CH_2Cl_2. The combined organic layers were washed with saturated $NaHCO_3$ and salt solution, dried, and evaporated. The residue was dissolved in toluene (5 ml) and heated under reflux for 30 min. Evaporation of toluene, followed by preparative tlc of the residue (SiO_2, 2 : 1 petroleum ether-ether) afforded **7** (41 mg, 27%): bp 120 °C (4 mmHg); IR 1725, 1700, 1632 cm^{-1}; NMR 1.50—3.37 (8H, m), 2.23 (3H, s); Anal. Found: C, 69.31; H, 7.63%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H. 7.74%.

Ethyl 1,3-Dimethyl-5-oxo-2-(phenylthio)bicyclo[2.2.2]*octane-2-carboxylate* ***4*** *and Desulfurization.* Reaction conditions: −75——50 °C for 1.5 hr. Yield: 77%. Bp 120—130 °C (5 mmHg); IR 1725 (br) cm^{-1}; NMR 0.80—1.45 (9H, complex s, d, and t), 1.50—3.50 (8H, m); Anal. Found: C, 68.80; H, 7.28%. Calcd for $C_{19}H_{24}O_3S$: C, 68.65; H, 7.28%.

A mixture of **4** (102 mg), Raney-Ni (pest, 0.5 ml), and acetone (3 ml) was heated under reflux for 20 min. The reaction mixture was passed through SiO_2 and evaporated. The residue was purified by preparative tlc (SiO_2, 1 : 1 petroleum ether-ether) to give ethyl 1,3-dimethyl-5-oxobicyclo[2.2.2]octane-2-carboxylate (**4**, PhS group = H) (33 mg, 42%): IR 1730 (br.) cm^{-1}; NMR 0.90—1.15 (6H, s and d), 1.40—3.00 (9H, m). Attempt to apply oxidation-desulfenylation procedure to **4** failed.

Ethyl 1,3-Dimethyl-5-oxo-2-(phenylthio)bicyclo[2.2.1]*heptane-2-carboxylate* ***5*** *and Ethyl α-Phenylthio-β-(2-oxo-4-methyl-3-cyclopentenyl)butyrate* ***6***. Reaction conditions: −75——70 °C for 30 min. Yield: 17% for **5** and 58% for **6**. **5**: bp 110—120 °C (2.5 mmHg); IR 1755, 1725 cm^{-1}; NMR 1.35 (3H, d, J=7.5) 1.62 (3H, s), 1.19—2.40 (5H, m), 2.99 (1H, m); Anal. Found: C, 67.95; H, 7.16%. Calcd for $C_{18}H_{22}O_3S$: C, 67.91; H, 6.97%. **6**: bp 130—140 °C (3 mmHg); IR 1725, 1693, 1627 cm^{-1}; NMR 0.74—1.35 (6H, complex d and t), 2.05 (3H, br. s), 1.50—3.90 (5H, m), 5.83 (1H, br.); Anal. Found: C, 67.86; H, 6.92%. Calcd for $C_{18}H_{22}O_3S$: C, 67.91; H, 6.97%.

When the reaction mixture was warmed up above −50 °C, **6** was the sole product.

Ethyl 3-Methyl-5-oxobicyclo[2.2.2]*oct-2-ene-2-carboxylate* ***7***. Reaction conditions: −75 °C for 1 hr and 20 °C for 1.5 hr. Yield: 48%. The IR and NMR spectra were identical with those of the sample derived from **3**.

Ethyl α-Phenylsulfinyl-β-(2-oxo-4-methyl-3-cyclohexenyl)butyrate ***8*** *and Pyrolysis.* Reaction conditions: −60—20 °C for 4 hr. Yield: 46%. IR 1730, 1670 cm^{-1}; NMR 0.75—1.42 (6H, complex d and t), 1.93 (3H, br. s), 1.80—4.42 (7H, m), 5.83 (1H, br.)

Pyrolysis of **8** in toluene was carried out in the same manner as described above to give ethyl β-(2-oxo-4-methyl-3-cyclohexenyl)crotonate **10** (70% yield): bp 120—130 °C (5 mmHg): IR 1715, 1670, 1640 cm^{-1}; NMR 1.96 (3H, s), 2.08 (3H, s), 1.78—3.10 (5H, m), 5.58—5.90 (2H, br.); Anal. Found: C, 70.51; H, 8.34%. Calcd for $C_{13}H_{18}O_3$: C, 70.24; H, 8.16%.

Ethyl α-Phenylsulfinyl-β-(2-oxo-4-methyl-3-cyclopentenyl)butyrate ***9*** *and Pyrolysis.* Reaction conditions: −60—20 °C for 2 hr. Yield: 23%. IR 1730, 1695, 1625 cm^{-1}; NMR 0.73—1.32 (6H, complex d and t), 2.16 (3H, br. s), 2.30—4.30 (5H, m), 5.92 (1H, br.).

Pyrolysis of **9** in toluene was carried out in the same manner as described above to give ethyl β-(2-oxo-4-methyl-3-cyclopentylidene)butyrate **11** (73% yield): bp 110—120 °C (5 mmHg); IR 1735, 1693, 1650, 1625 cm^{-1}; NMR 1.85 (3H, s), 2.10 (3H, s), 3.10 (2H, br. s), 3.87 (2H, s), 6.00 (1H, br. s); Anal. Found: C, 68.98; H, 7.40%. Calcd for $C_{12}H_{16}O_3$: C, 69.21; H, 7.74%.
