(Received Fcbruary 12, 1974)

An LCAO MO SCF calculation has been carried out on H_2O–HF system with a minimal STO-3G basis set, with respect to three assumed models, *i.e.* SIGMA, PI, and BIFURCATED models. A configuration analysis of the wave function has shown that charge-transferred electron configurations weakly mix into the original electron configuration in the SIGMA and PI models, while the contribution of charge-transferred configurations is negligibly small in the BIFURCATED model. The SIGMA model has been found to be most stable mainly due to the Coulombic attraction energy between the two species. The intermolecular electron density between the two interacting systems has been investigated by means of a concept of orbital interaction, leading to a conclusion that the mixing-in of the occupied MO's of H_2O with the unoccupied MO's of HF contributes slightly to the hydrogen bond in the SIGMA and PI models.

Over the last two decades, hydrogen bonding has been of increasing interest to both experimental and theoretical chemists.[1–14] Recent *ab initio* calculations by the use of LCAO MO SCF methods on several hydrogen-bonding systems have given satisfactory results in explaining the physical and chemical properties of those systems, such as the stable geometries, hydrogen-bonding energy and charge-transfer along the bond formation.[15–26] In these studies, the quantities which describe the hydrogen bonding are usually defined as the differences between those of a composite system and those of the isolated systems. Then, we should note that the resultant differences are far smaller than the corresponding quantities of normal chemical bonds. Therefore, they may depend, to some extent, upon the basis set adopted to construct the MO's. Morokuma and Winick pointed out, however, the addition of p-type functions to hydrogen and of d-type functions to oxygen in the calculation of water dimer would yield an excess stabilization, unless the MO's of monomers were of the Hartree-Fock limit.[17] Hence, we should be careful about the inclusion of the polarization functions.

Apart from these works on the Hartree-Fock level, there have been several theoretical ways to approach hydrogen-bonding. For instance, Coulson and Danielsson studied the hydrogen bond in water dimer on the basis of the valence-bond theory.[27] These theories could present chemically graspable pictures of hydrogen bond between a proton donor (A–H) and a proton acceptor (B). Although these approaches are only qualitative in comparison with the works performed by accurate MO calculations a partitioning of the interaction energies,[28–36] and the calculation of the weights of various electron configurations[37] will supply us some valuable information for an understanding of the basic feature of hydrogen bond.

Here, we take a simple hydrogen-bonding system composed of H_2O and HF[19] and analyze the wave function of the system, calculated by an *ab initio* MO method, into several important electron configurations by the aid of a configuration analysis procedure.[38–40]

Results of Calculation

The SCF MO's, ϕ_i, were constructed by linear combinations of the basis atomic orbitals (AO), χ_r,[41]

$$\phi_i = \sum_r c_r{}^i \chi_r$$

In this work, we employed the minimal set of the Slater type orbitals (STO's), which were expanded into three Gaussian type orbitals (GTO's).[42,43] In this STO-3G expansion, the values of the exponents (α_m) and the coefficients (d_m) of the GTO were taken after Stewart.[44]

$$\chi_r = \mathrm{STO}(\zeta) = \sum_{m=1}^{3} d_m \mathrm{GTO}(\alpha_m)$$

The exponents of the STO's, ζ, were taken to be the optimized values in regard to the two monomers, H_2O and HF, obtained by Hehre, Stewart, and Pople.[45] They are given in Table 1.

TABLE 1. THE EXPONENTS ζ OF THE STO'S

Molecule	Type of STO	Value
HF	H_{1s}	1.33 (1.00)[a]
	F_{1s}	8.65 (8.70)
	F_{2s}	2.55 (2.60)
	F_{2p}	
H_2O	H_{1s}	1.28 (1.00)
	O_{1s}	7.66 (7.70)
	O_{2s}	2.25 (2.275)
	O_{2p}	

a) Calculated by the Slater rule as a reference.

As for the hydrogen-bonding system, we considered three different geometries, SIGMA, PI, and BIFURCATED, as illustrated in Fig. 1. The geometrical parameters are given in Fig. 1 with respect to the SIGMA model. In the three models of H_2O–HF, the distance from the oxygen atom of H_2O to the fluorine atom of HF, R(O–F), was taken to be 2.72 Å. It may be natural here to suppose that the O–H and H–F bond distances will vary, depending on the type of interaction. Therefore, the most stable geometry of the hydrogen-bonding system will be determined by a delicate balance between the stabilization due to the intermolecular interaction and the destabilization due to the deformation of the two species from the most stable geometries in an isolated state. Accordingly, our assumption of the fixed nuclei of H_2O and HF in interacting states might involve an un-

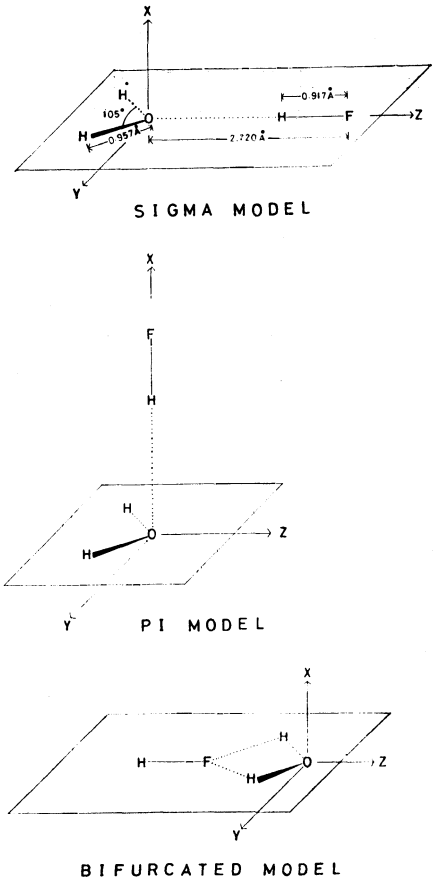

Fig. 1. The assumed models of hydrogen bonding in H_2O and HF.

certainty in studying this weakly interacting system. However, the deformations of the interacting species are usually small[19] and we hope that an approach based on an isolated molecule approximation would provide us some chemically important information on hydrogen bond.

Under the assumption mentioned above, the energy of hydrogen bond may be defined as,

$$E = E_T(H_2O\text{-}HF) - E_T(H_2O) - E_T(HF)$$

where $E_T(X)$ is the total energy of the system X (the electronic energy plus the nuclear repulsion in the fixed nuclei).

The results of the MO calculation on H_2O, HF, and H_2O–HF systems are given in Table 2. The calculation of $(-V/2T)$ (V is the potential energy and T is the kinetic energy) indicates that the assumption of the same ζ values for the composite system as those for the isolated species is not so poor. So, it seems likely that ζ's are not so sensitive to the change in the electron distribution arising from hydrogen bond formation.

The atomic populations on the three hydrogen-bonding systems calculated here show that the amount of charge transferred from H_2O to HF (ΔQ) is 0.029 in SIGMA, 0.038 in PI and −0.004 in BIFURCATED respectively. In the last model with the negative value of ΔQ, HF serves as an electron donor and H_2O as an electron acceptor. Among the three models, the PI model gives the largest ΔQ. This seems to come from the fact that the PI model contains the most effective charge-transfer interaction. This point will be discussed later in detail.

Examining $E_T(H_2O\text{–}HF)$, we see that the SIGMA model is most stable among the three models, in agreement with the result of Kollman and Allen (the linear structure in their notation).[19]

As shown in Table 2, the SIGMA model has a larger dipole moment (3.69 D) than the sum of the moments of the monomers (3.15D=1.39D+1.76D). The increase in the dipole moment comes mainly from

Table 2. Results of MO calculation on HF, H_2O and H_2O·HF at the optimized ζ of STO-3G. The values in the parenthesis are by other MO works or experimental (exptl.) ones.

Molecule	Total energy E_T(a.u.)	Test of virial theorem $(-V/2T)$	Atomic population	Dipole moment (D)	The orbital energy of the HOMO (eV)
HF	−98.5577 (−98.5274)[45] (−100.0708)[46]	1.0019	H——F 0.7768 9.2232	1.39 $(1.82)^{[48]}_{exptl.}$	−12.11 (15.77)[50]

Table 3. The weights of some electronic structures of the three H_2O–HF hydrogen bond models

Electronic structures	Weights (%) SIGMA model	PI model	BIFURCATED model
$H_2O \cdot HF$	96.8740	96.5512	99.4809
$H_2O^- \cdot HF^+$	0.0636	0.0038	0.4701
$H_2O^+ \cdot HF^-$	2.8572	3.2888	0.0355
$H_2O \cdot HF^*$	0.0922	0.0584	0.0059
$H_2O^* \cdot HF$	0.0272	0.0364	0.0045
$H_2O^{-2} \cdot HF^{+2}$	0.0000	0.0000	0.0004
$H_2O^{+2} \cdot HF^{-2}$	0.0114	0.0145	0.0000
$H_2O^{+-} \cdot HF^{-+}$	0.0011	0.0001	0.0001
$H_2O^* \cdot HF^*$	0.0001	0.0000	0.0000
Total	99.9268	99.9532	99.9975

the charge-transfer from H_2O to HF. The enhancement of the moment, however, would also arise from the polarization interaction between the two monomers.

Configuration Analysis

The result of the configuration analysis of the wave function of the composite system in terms of the electron configurations of the two isolated species is given in Table 3. There, the first electronic structure ($H_2O \cdot$ HF) stands for the original electron configuration without any electron shifting. In addition to this dominant configuration, several important charge-transferred and locally excited terms are presented. Here, ($H_2O^- \cdot HF^+$) indicates mono-transferred configurations with one electron migrated from HF to H_2O, and ($H_2O^* \cdot HF$) locally mono-excited configurations in H_2O. The other terms in Table 3 may be understood in a similar way.[52] In these three models, the total weight covered by only these rather simple electron configurations is very close to 100%. This suggests that the other configurations omitted in Table 3, *i.e.* highly-transferred and highly-excited configurations can be neglected without a serious loss of accuracy.

As for the SIGMA and the PI models, the mono-transferred term ($H_2O^+ \cdot HF^-$) plays an important role, with the larger weight in the PI model (3.29%) than in the SIGMA model (2.86%). This superiority of the PI model to the SIGMA model in ($H_2O^+ \cdot HF^-$) arises from the more efficient charge-transfer interaction in the former than in the latter, as has been expected from the calculation of ΔQ. The next important term in these models is ($H_2O \cdot HF^*$), having a larger weight in the SIGMA model (0.09%) than in the PI model (0.06%). Considering the contributions of various electron configurations, we can approximately describe the electronic structure of H_2O–HF solely by the two terms, ($H_2O \cdot HF$) and ($H_2O^+ \cdot HF^-$).[53] This calculation seems to support our insistence mentioned before

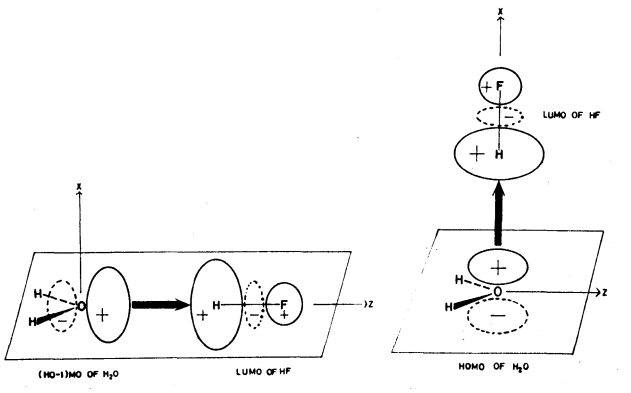

Fig. 2. A schematic representation of the dominant orbital interaction in the SIGMA and the PI models.

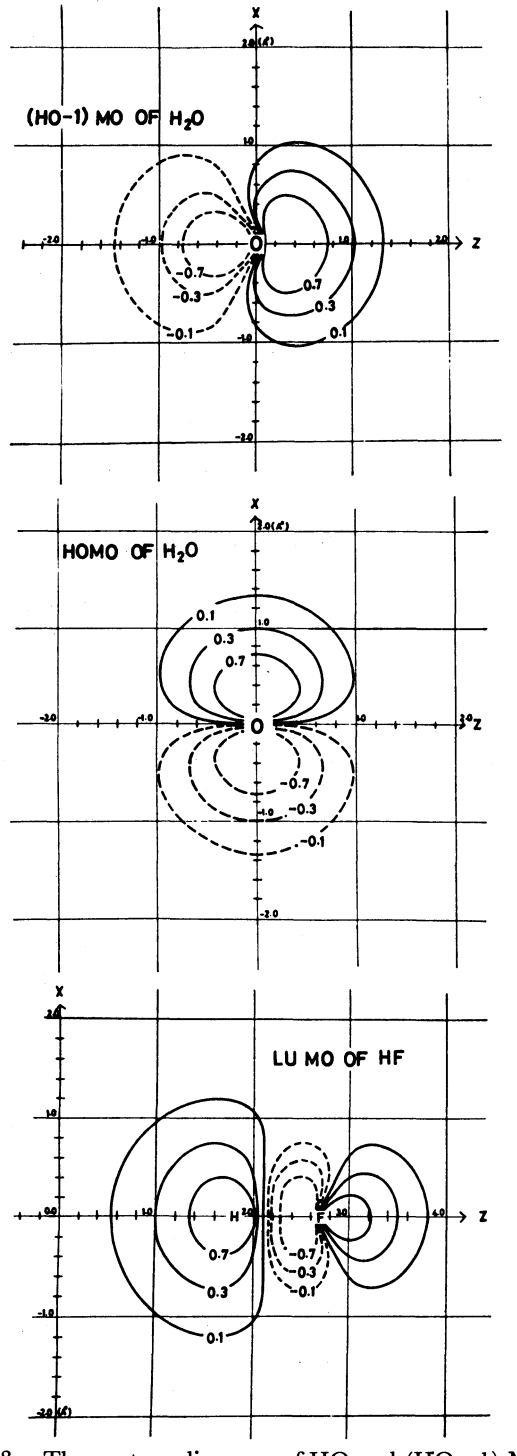

Fig. 3. The contour diagrams of HO and (HO−1) MO's of H_2O and the LUMO of HF.

that this simple hydrogen-bonding system can be regarded as an electrostatic and exchange model with a minor charge-transfer effect.

In order to examine this point a little more in detail, we evaluated the Coulomb interaction energy (E_Q) and the delocalization energy (E_D) with respect to the SIGMA and the PI models, obtaining E_Q(SIGMA)$=-0.398$ eV, E_Q(PI)$=-0.325$ eV, E_D(SIGMA)$=-0.027$ eV, and E_D(PI)$=-0.034$ eV.[54] This calculation indicates that the SIGMA model is more stabilized than the PI model through the electrostatic interaction, although the delocalization interaction is stronger in the PI model than in the SIGMA model as has been expected from the configuration analysis of the wave function. Figure 2 illustrates schematically the dominant charge-transfer interaction in the SIGMA and the PI models. The shapes of the highest occupied (HO) MO and the next highest occupied (HO–1)MO of H_2O and the lowest unoccupied (LU) MO (taken real) are shown in Fig. 3.

In the BIFURCATED model, the extremely large weight of the original configuration (99.48%) allows us one-term approximation by ($H_2O\cdot HF$). In this model, HF is an electron donor and H_2O serves as an acceptor with ($H_2O^-\cdot HF^+$)$=0.47\%$ and ($H_2O^+\cdot HF^-$)$=0.04\%$ in accordance with the calculation of ΔQ. The delocalization energy of the BIFURCATED model was found to be as small as -0.002 eV.

Chemical Binding between H_2O and HF

In the above, we found that relative orientation of H_2O and HF is mostly determined by the Coulombic and exchange interactions. However, if the hydrogen-bonding is purely electrostatic, the increase of the electron density in the region between H_2O and HF would not be yielded. The result of the present calculation, on the contrary, shows the considerable increase in the density in the intermolecular region. In order to detect the origin of this change in the electron distribution, we partition the total intermolecular electron density which is termed here $\rho(1|1)_{\text{total}}$ into the following four terms.[55,56]

$$\rho(1|1)_{\text{total}} = \rho(1|1)_{\text{exchange}} + \rho(1|1)_{\text{CT}} + \rho(1|1)_{\text{back CT}} + \rho(1|1)_{j,l}$$

$$\rho(1|1)_{\text{exchange}} = 2\sum_{g=1}^{10}\sum_{i=1}^{5}\sum_{k=1}^{5} C_i^{(g)} C_{k+7}^{(g)} \{a_i(1)b_k(1) + b_k(1)a_i(1)\}$$

$$\rho(1|1)_{\text{CT}} = 2\sum_{g=1}^{10}\sum_{i=1}^{5} C_i^{(g)} C_{l+7}^{(g)} \{a_i(1)b_l(1) + b_l(1)a_i(1)\} \quad (l=6)$$

$$\rho(1|1)_{\text{back CT}} = 2\sum_{g=1}^{10}\sum_{k=1}^{5}\sum_{j=6}^{7} C_j^{(g)} C_{k+7}^{(g)} \{a_j(1)b_k(1) + b_k(1)a_j(1)\}$$

$$\rho(1|1)_{j,l} = 2\sum_{g=1}^{10}\sum_{j=6}^{7} C_j^{(g)} C_{l+7}^{(g)} \{a_j(1)b_l(1) + b_l(1)a_j(1)\} \quad (l=6)$$

In the above equations, a_i and a_j stand for the occupied and unoccupied MO's of H_2O, and b_k and b_l ($l=6$) are the occupied and unoccupied MO's of HF. The expansion coefficients, $C_i^{(g)}$, are defined in the following way.

$$\phi_g = \sum_{i=1}^{5} C_i^{(g)} a_i + \sum_{j=6}^{7} C_j^{(g)} a_j + \sum_{k=1}^{5} C_{k+7}^{(g)} b_k + C_{l+7}^{(g)} b_l$$

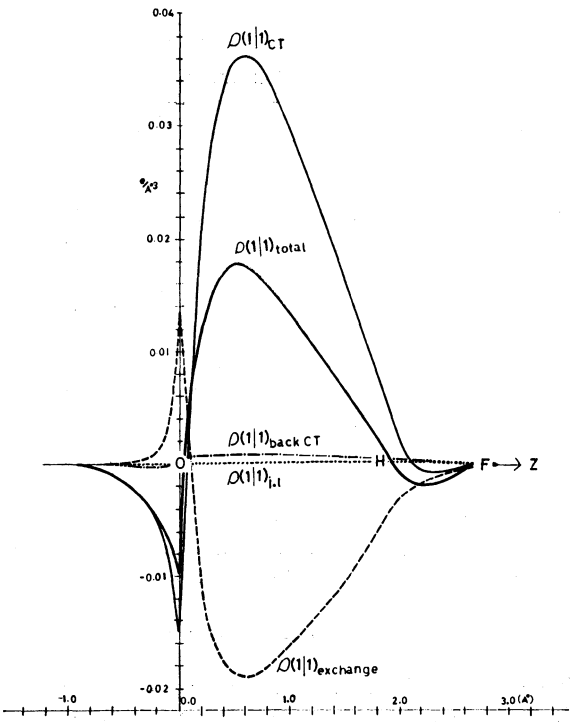

Fig. 4. The intermolecular densities in the SIGMA model.

We must mention here that the partitioning of $\rho(1|1)$ and the classification of the terms are made in an approximate sense. The density $\rho(1|1)_{\text{exchange}}$ is the intermolecular density accumulated between H_2O and HF through the overlapping of a_i with b_k (both of them are occupied MO's), $\rho(1|1)_{\text{CT}}$ comes from the interaction between the occupied MO's of H_2O and the unoccupied MO of HF, and $\rho(1|1)_{\text{back CT}}$ is due to the interaction between the unoccupied MO's of H_2O and the occupied MO's of HF. The density $\rho(1|1)_{j,l}$ stands for the density change in the intermolecular region through the overlapping of the unoccupied MO's of the two monomers. The sum $\rho(1|1)_{\text{total}}$ of these partitioned electron densities creates the usual intermolecular bond-order density. In Fig. 4, the profile of the contour map of these components with respect to the SIGMA model is illustrated. We see the change in the intermolecular electron density is composed almost exclusively of $\rho(1|1)_{\text{exchange}}$ and $\rho(1|1)_{\text{CT}}$.

$$\rho(1|1)_{\text{back CT}} < 0.0009\ \text{e/Å}^3$$

$$\rho(1|1)_{j,l} < 0.0001\ \text{e/Å}^3$$

The electron density $\rho(1|1)_{\text{exchange}}$ is negative, contributing to $\rho(1|1)_{\text{total}}$ in an antibonding way. On the contrary, $\rho(1|1)_{\text{CT}}$ presents a positive electron density in the intermolecular region, and it overcomes the negative $\rho(1|1)_{\text{exchange}}$ yielding the positive $\rho(1|1)_{\text{total}}$. This $\rho(1|1)_{\text{CT}}$ comes almost solely from the mixing of the ionic configuration ($H_2O^+\cdot HF^-$) into the original electron configuration. Therefore, the charge-transfer interaction, though small as a whole, has an important role to enforce the hydrogen bond, in addition to the purely electrostatic interaction between the two monomers. Among the terms appearing in $\rho(1|1)_{\text{CT}}$, the charge-transfer interaction between the

(HO−1) MO of H_2O and the LUMO of HF shown in Fig. 2 contributes dominantly to the electronic structure of the SIGMA model.

By means of a highly accurate MO calculation, Kollman and Allen showed that $\rho(1|1)_{total}$ was negative.[19] It seems likely that the bond-order density (or the Mulliken overlap population[57]) depends on the basis set. However, no matter whether $\rho(1|1)_{total}$ is positive or negative, $\rho(1|1)_{exchange}$ and $\rho(1|1)_{CT}$ will play their characteristic roles as mentioned above to weaken or reinforce the intermolecular chemical binding.

One of the present authors (S. Y.) thanks Mr. K. Ishida for his advice in making the computer program.

An MO-Theoretical Treatment of the Cationic Ring-Opening Polymerisation. I. Ethylene Oxide

Gernot FRENKING, Hiroshi KATO,* and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

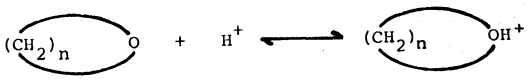
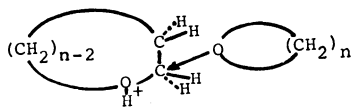
(Received July 26, 1974)

The stereochemical course of the acid-catalyzed ring-opening polymerisation of ethylene oxide (e.o.) has been investigated on the basis of the CNDO/2 method. By the calculation of the total energy of the interacting system of e.o. and protonated e.o. the most favored reaction path is indicated. The activation energy is found to consist only of the desolvation process. The effect of the deformation of the molecular geometry upon the net charge, the total energy, and the shape of particular MO's is discussed. It is concluded that the ring strain does not influence the rate. By means of configuration analysis, the dominance of the HOMO–LUMO interaction in the later stage of the reaction has been established. The initiation and propagation reactions follow the same reaction mechanism.

Extensive experimental studies in the field of ring-opening polymerisation (ROP) have been made.[1] In contrast to numerous papers reporting those results, however, there have been very few theoretical treatments of this field.[2] The experimental results concerning the reaction path of the acid-catalyzed ROP of cyclic ethers can be summarized as follows:[3] The initiator is first formed by a reversible protonation:



The initiation is considered to be the addition of a monomer to this protonated monomer. There is much evidence that the process of the ring-opening addition takes place as an S_N2-like backside attack. The propagation step is essentially constructed by a succession of similar processes at the terminal monomeric unit of a polymer chain:



The backside attack is indicated by an inversion at the attacked carbon atom. However, still remains some doubt about the sequence of the bond interchange and the transition state. There has been discussed a "borderline S_N2-mechanism,"[4] where the old C–O bond is already partly broken at a rather early stage of the attack. Recent kinetic studies of the cationic ROP of some four-membered cyclic ethers show that the entropy of activation is the dominating factor in the reactivity.[5]

In the present and forthcoming papers, we want to report the results of our MO-theoretical treatment of various aspects of the reactivity and stereochemistry of heterocyclic-ring compounds in ROP. We start with ethylene oxide (e.o.), since it may serve as a simple model case for other, more complicated compounds.[6] Using the CNDO/2 method, we treat the isolated e.o. and its protonated compound, and also their interacting system. In order to determine the most favored geometries and reaction path, we examine the effect of changes in several geometrical parameters. Furthermore, utilizing the frontier theory[8] and configuration analysis,[9] the mechanisms of cationic ROP are investigated.

Calculations and Used Geometries

All our MO-calculations were based upon the CNDO/2 model of Pople *et al.*[7]

Figure 1(a) shows the energy levels of the MO's of e.o. and protonated e.o., together with the chosen geometry. Figure 1(b) shows the resulting net charges.

We calculated the total energy of the combined system of e.o. and protonated e.o. with different geometries. Figure 2 shows the geometries which gave the energy minimum at the fixed C–O′ distance for each of the frontside and backside attacks.[16] Further-

more, the neutral e.o. has been placed in a planar and perpendicular position to the protonated e.o. plane. Among all of these calculations, the geometries adapted in Fig. 2 gave the lowest energy values with regard to the above-mentioned parameters (see Table 1).

In the next step, we examine the energy minimum as to the attacking direction with the two C–O' distances of 2.0 and 2.5 Å. We also calculate the energy of the final product of this reaction of ROP. Its geometry is shown in Fig. 3, while the resulting energy is listed in Table 1.

Finally, we investigate the deformation of the ring of protonated e.o., since the geometry of the attacked protonated e.o. changes toward the geometry of the final product throughout the reaction. The considered deformations are indicated in Fig. 4, where the deformations of 1 and/or 4 are taken in the frontside attack course and those of 2, 3, and/or 4 for the backside attack.

The results are listed in Table 1. The table also

gives the values of the transferred charge from the neutral to the protonated compound and the values of the energy of the C–O′ bonding (E_{AB} in CNDO/2). Figures 5(a) and 5(b) show the total energies in relation to the C–O′ distance. The datum for $r=\infty$ is the simple sum of the values for the separated molecules.

Discussion

In spite of the use of many approximations, the results give interesting insights into the reaction path. Comparing the frontside and the backside attacks with the energy values shown in Fig. 5(a) and 5(b), it can be seen that there is not much difference with $r_{C-O'}$ values larger than 2.0 Å. After this stage, the backside attack is strongly favored from an energetic point of view.

It has been proposed in several papers by Fukui *et al.*[8] that "a majority of chemical reactions should take place at the position and in the direction of the maximum overlapping of the HOMO (Highest Occupied MO's) and the LUMO (Lowest Unoccupied MO's)." The HOMO of e.o., which is not shown here, is indeed mainly localized on the lone-pair oxygen p_z orbital (AO coefficient 0.88). There are two nearly degenerated LUMO's of the protonated e.o. (a' at −3.086 eV and a'' at −2.419 eV, with the point group C_s). They correspond to the a_1 and b_2 LUMO's of e.o. (point group C_{2v}). The consideration of both of them has previously been emphasized in the calculations of the anionic ROP of e.o.[10] The shapes of

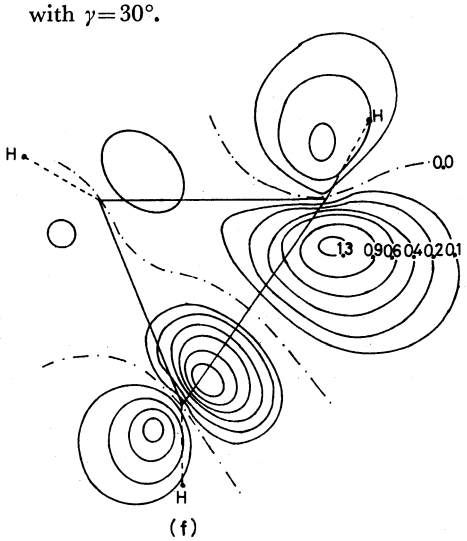
(e): a' LUMO at C–O bond length $+0.2$ Å, H-shift with $\gamma = 30°$.



(f): a'' LUMO at C–O bond length $\times 0.2$ Å, H-shift with $\gamma = 30°$.

Fig. 7. Change of the two LUMO's under some deformations of the geometry of protonated e.o.

these LUMO's in the molecular plane are shown in Figs. 6(a) and 6(b). Both of them have a node between oxygen and carbon, but the a' LUMO has its main extension in an antibonding region between oxygen and hydrogen. (In Fig. 6(a) the contour lines not on the molecular plane do not appear.) Therefore, it may be presumed that it is the a'' LUMO which plays the dominant role in the ring cleavage.

This LUMO mainly extends in the initial geometry at the frontside. However, it is noticed that the shapes and energies of these LUMO's may vary with the geometry. Figures 7(a)—(f) collect the shapes of the LUMO's with various geometries which give the local minima for the respective $r_{C-O'}$ values, as given in Table 1. With these geometries, the notations a' and a'' lose their exact meaning because of the loss of symmetry, but they are still kept for the sake of convenience. Figure 7(b) clearly indicates that the shift of the hydrogens, which is expected to occur at an earlier stage of the reaction, as is shown in Table 1 and Fig. 5, results in a reversal of the maximum extension of the a'' LUMO from the frontside to the backside direction, whereas the extension of the a' LUMO at the attacked carbon atom is reduced. This tendency is even more accelerated with the deformation of the ring frame and a further hydrogen shift, as is shown in Figs. 7(c) and 7(d). Figures 7(e) and 7(f) show a similar trend for the frontside reaction.

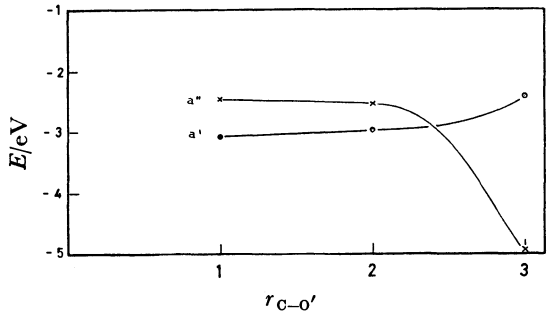


Fig. 8. Change of the energy level of the two LUMO's of protonated e.o. with some deformations which correspond to the reaction path of the backside attack (see Fig. 5(b)).
1: initial geometry, 2: C–O bond length normal, H-shift γ −30°, 3: C–O bond length +0.2 Å, H-shift γ −60°.

That it is the a'' LUMO and not the a' LUMO which is dominating in the HOMO–LUMO interaction can also be seen from the change in the energy level along with the change in the geometry, as is indicated for the backside attack in Fig. 8. The narrowing of the frontier orbitals has already been pointed out by Fukui *et al.*[8]

Some additional calculations have been carried out for the backside attack. We calculated the composed system by placing the neutral e.o. at a $r_{C-O'}$ distance of 2.5 Å along the y-axis in a planar arrangement to the protonated compound, as the Coulomb attraction should be the dominating force in this case. The numerical results, given in Table 1, show a greater stabilisation than the corresponding value for the assumed backside path. Furthermore, we varied the geometry parameters with a $r_{C-O'}$ distance of 1.5 Å. The values for β (see Fig. 2) have been taken as 75 and 45°, and the hydrogen shift with $\gamma=-45°$ (see Fig. 4). However, all these calculations gave no further stabilisation compared to the values for $\beta=60°$ and $\gamma=-60°$ (see Table 1). As our results for the principal reaction mechanism are independent of the exact location, we did not make any further calculations concerning the exact reaction path.

Additional information is given by the results of the configuration analysis[9,11] listed in Table 2, where some absolute values of coefficients for the ground state, monotransferred (delocalized), and intramolecular monoexcited (polarized) configurations are presented. The large value of the coefficient of the ground-state configuration at the early stage of the reaction indicates the dominance of the Coulomb interaction. However, the dramatically increasing value of the monotransferred configuration at $r_{C-O'}=1.5$ Å, especially that corresponding to the transfer from of e.o. the HOMO to the LUMO of protonated e.o.,[12] shows the importance of this kind of interaction at the final stage of the reaction.

From Table 1 it can be seen that the values for $E_{C-O'}$ and the quantities of charge transfer show no remarkable parallelism with the total energy, nor is there any interdependence between them. Roughly speaking, both values increase with the lowering of the total energy. It is interesting that, with the distance $r_{C-O'}$ of 1.5 Å, the backside attack shows a significantly lower total energy, but smaller $E_{C-O'}$ and transferred charge, than the frontside attack.

It is worthwhile to examine the charge transfer in more detail. Table 3 shows the change in the net charge of each atom at the different reaction stages for the local minimum energy (see Fig. 5). The numbers represent the differences from the net charge calculated for the isolated molecules with the respective geometry, where the + sign refers to the decrease in the atomic electron density caused by the interaction, and the — sign, to its increase. In contradiction to the whole protonated e.o. molecule coming more negative (less positive), the attacked carbon atom, 2, be-

comes more positive. Similarly, the oxygen atom, 1′, of the neutral molecule is still at $r_{C-O'}$=2.0 Å, more negative than in the isolated molecule, before it becomes more positive at $r_{C-O'}$=1.5 Å.

The potential curve of the reaction path anticipated from Fig. 5 indicates the absence of an energy barrier. This can easily be understood in view of the important role played by the solvent in ionic reactions. It has been found that this is particularly important for the reactivity of cyclic ethers in ROP.[13] Polar solvents stabilizing the monomers much better bring about a remarkable decrease in the reactivity of the monomers in ROP, compared with less polar solvents. Our calculations indicate that the activation energy originates only from the desolvation process. Therefore, the location of the transition state along the reaction path of Fig. 5(a) remains rather uncertain, however, the facts that the deformation of the ring frame occurs rather late ($r_{C-O'}$ <2.0 Å) and is accompanied by a rapid decrease in the total energy suggest that the transition state is placed somewhere earlier, with a geometry where the ring frame of the protonated e.o. is not yet deformed. If this is true, it follows that, in kinetically-controlled reactions where the activation energy determines the reaction rate, the ring strain is not influential on the rate. This has already been pointed out by Saegusa *et al.*[14] in reporting on their kinetic studies of 4-, 5-, and 7-membered cyclic ethers in cationic ROP. They found that the activation entropy is the most important factor in determining the reactivity.

There remains one problem. So far we have dealt only with the initiation step, but it has been stressed that the propagation step is quite different in its reaction rate, the latter being faster than the former.[15] The difference is as follows: in the propagation step, e.o. attacks an oxyethylated e.o. cation instead of a protonated one, and the length of the substituent chain is supposed to be not very important in connection with the reaction rate. Accordingly, we calculated the LUMO of the product of the initiation step. Figure 9 shows its shape in the ring plane. As the AO coefficients of this MO at atoms not placed in the ring plane are smaller than 0.03, it can be thought that the charges are located only in this plane. A comparison with the *a″* LUMO of the protonated e.o. (Fig. 6(b)) shows a great similarity. In the case of alkylated e.o., however, the LUMO is not degenerated, being the lowest one not undergoing deformation due to the interaction. Also, the charge distributions (Fig. 3) of

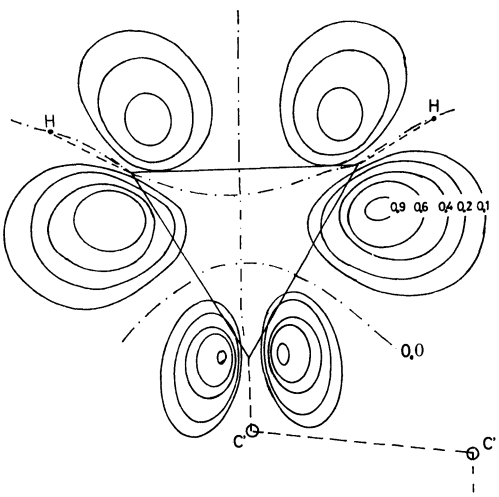

Fig. 9. The LUMO of the final product of the initiation reaction with the geometry of Fig. 3, indicating the values in the ring plane.

the atoms located at the ring are nearly the same as those of the protonated e.o. (Fig. 1(b)). From those facts, it can be expected that the mechanisms of the propagation reaction is not very different from the initiation.

The question is left why the rate of the propagation reaction is higher than the initiation reaction. The orbital energies of the LUMO's of the respective cations lead us to the opposite results. The LUMO of protonated e.o. (−3.086 eV) is lower than the LUMO of the oxyethylated e.o. (−1.629 eV). However, our results have shown that the bond breaking is more important than the bond making. The E_{AB} values for the C–O bond which is going to break during the reaction indicate a weaker bond for the oxyethylated e.o. (−0.816 eV) than for the protonated e.o. (−0.829 eV). This gives an explanation of the difference in the reaction rate.

From these calculations, the stereochemical course can be summarized as follows: the attack of the e.o. starts along the y-axis and is, in the beginning, governed by the Coulomb attraction only. The approach toward one carbon atom is accompanied by a shift of the connected hydrogens at a rather early stage of the reaction and produces a change in the a'' LUMO extension towards the attacking oxygen. This in turn accelerates the reaction by an increase in the charge transfer resulting from better HOMO–LUMO interaction. The deformation of the ring frame at a later stage accelerates this process still more and causes remarkable decreases in the total energy and also the C_2–O_1 bonding energy and increases in the amount of charge transfer and the C–O′ bonding energy. In this way, the deformation of the protonated compound leads to a reaction path with a lower energy for the backside attack than for the frontside attack.

One of the authors (G.F.) wishes to express his gratitude to Professor Takeo Saegusa and Dr. Shiro Kobayashi for a valuable discussion; he is also indebted to Dr. Hiroshi Fujimoto, Mr. Satoshi Inagaki, Mr. Tsutomu Minato, and Mr. Shigeki Kato for making avalaible the computer programs.

All three authors wish to express their appreciation to the Data Processing Center of Kyoto University for the generous permission to use the FACOM 230-60 computer there.

Thank is given to the Japanese Minister of Education and the Deutscher Akademischer Austauschdienst for giving grant to one of the authors (G.F.).

The Catalytic Action of Fe(III) in the U(IV)-U(VI) Electron Exchange Reaction

Hiroshi TOMIYASU and Hiroshi FUKUTOMI*

Department of Chemistry, Faculty of Science, Shinshu University, Asahi, Matsumoto 390
**Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Meguro-ku, Tokyo 152*

(Received September 8, 1973)

The catalytic action of ferric ions in the U(IV)–U(VI) electron exchange reaction has been studied in the presence of a high concentration of hydrochloric acid. The exchange rate is found to be accelerated by the addition of ferric ions; the observed rate law is given by:

$$R = k_0[\mathrm{U(IV)}][\mathrm{U(VI)}] + k_c[\mathrm{Fe(III)}]_0\sqrt{[\mathrm{U(IV)}][\mathrm{U(VI)}]}$$

An activation energy of 19.7 kcal/mol was calculated for the iron-catalyzed reaction in the U(IV)–U(VI) electron exchange reaction. This value is much smaller than that of 32.2 kcal/mol, which was found in the non-catalytic reaction. The kinetics and equilibrium of the reaction between Fe(III) and U(IV) have also been studied in order to investigate in detail the mechanism of the catalytic reaction. A one-electron-transfer mechanism producing U(V) as an intermediate is estimated from the rate law and supported by the kinetics and equilibrium studies of the Fe(III)–U(IV) reaction.

In the earlier papers dealing with the electron exchange reaction between U(IV) and U(VI) in concentrated hydrochloric acid,[1–4] it was shown that the rate of the electron exchange reaction (1) markedly increased with the acidity;

$$^{235}\mathrm{U(IV)} + {}^{238}\mathrm{U(VI)} \rightleftharpoons {}^{238}\mathrm{U(IV)} + {}^{235}\mathrm{U(VI)} \quad (1)$$

The present investigation was undertaken in order to determine the electron exchange rate between U(IV) and U(VI) in the presence of the smallest amount of Fe(III) and in order to observe the catalytic action of Fe(III).

Experimental

All of the chemicals used in this work were analytical reagent grade. The preparation and analysis of materials for the exchange reaction and the procedure in the kinetic experiment have been described in detail elsewhere.[2,3] The concentration of the Fe(III) stock solution was standardized for the potassium dichromate solution by passing an aliquot through a column of zinc amalgam. The desired concentrations of U(IV), U(VI), Fe(III), and hydrogen ions were obtained by adding appropriate amounts of hydrochloric acid and triply-distilled water. An aqueous solution of Fe(III) has an intense absorption maximum (*i.e.*, a molar extinction coefficient of 3.5×10^3 in 8M HCl) at 370 nm, whilst a negligibly small absorption and a weak absorption were observed at this wavelength in the solutions of Fe(II) and U(IV) and in U(VI) respectively. Therefore, the spectrophotometric determination of Fe(III) in the reaction mixtures was performed at 370 nm, using as a reference solution U(VI) which has the same concentration of U(VI) as the reaction mixtures. The spectrophotometric measurement was carried out by using a Shimadzu-50L recording spectrophotometer. The cell used for the measurement was filled with nitrogen gas and hermetically sealed to prevent the air oxidation of U(IV) and Fe(II). The electron exchange rate was measured by a mass-spectrometric analysis of the uranium isotope in U(VI).[2,3]

Results and Discussion

Kinetics and Equiliblium of the Reaction between U(IV) and Fe(III). Betts studied the kinetics of the oxidation of U(IV) by Fe(III) at a low acidity[5] and showed that the reaction proceeded *via* the following two steps:

$$\mathrm{U(IV)} + \mathrm{Fe(III)} \xrightarrow{k_2} \mathrm{U(V)} + \mathrm{Fe(II)} \quad (2)$$

$$\mathrm{U(V)} + \mathrm{Fe(III)} \xrightarrow{k_3} \mathrm{U(VI)} + \mathrm{Fe(II)} \quad (3)$$

Reaction (2) was found to be the rate-determining step, with a rate constant of 12.3 $M^{-1}\,s^{-1}$ in 1M HCl at 24 °C.

In an attempt to gain a better understanding of the interaction between U(IV) and Fe(III), several investigations have been conducted in our laboratory in concentrated hydrochloric acid solutions. Since the concentration of U(IV), [U(IV)], was large enough in the kinetic run compared with the Fe(III) concentration, [Fe(III)], [U(IV)] may be regarded as constant during the reaction. If Reaction (2) is the rate-determining step, the rate law may be written as a first-order rate equation with respect to [Fe(III)]:

$$\ln\{[\mathrm{Fe(III)}]/[\mathrm{Fe(III)}]_0\} = -2k_2[\mathrm{U(IV)}] \quad (4)$$

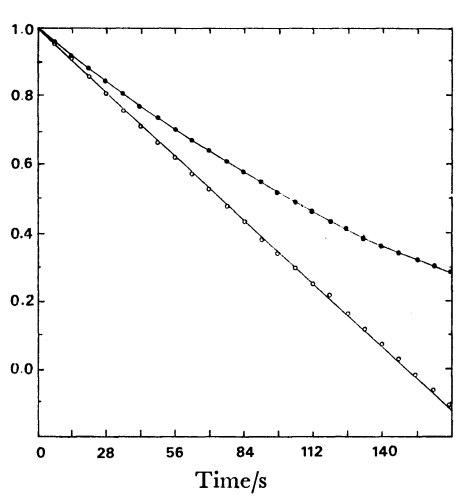

Fig. 1. Typical kinetic run for the oxidation of U(IV) by Fe(III) at 25 °C in 8 M HCl solution.
●: log {[Fe(III)]/[Fe(III)]$_0$} *vs.* time, *t*
○: Left-hand side of Eq. (7) *vs.* time, *t*
[Fe(III)]$_0$=2.9×10^{-4} M, [U(IV)]=1.88×10^{-2} M

where $[Fe(III)]_0$ denotes the initial concentration of Fe(III). As is shown in Fig. 1, a plot of $\log\{[Fe(III)]/Fe(III)]_0\}$ against time, t, indicates a gradual departure from linearity. This fact suggests that the above-mentioned mechanism was unsuccessful under these conditions and leads us to assume that Reaction (2) is reversible:

$$U(IV) + Fe(III) \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} U(V) + Fe(II) \qquad (2')$$

Therefore, we may now write the following differential equation:

$$-\frac{d[Fe(III)]}{dt} = k_2[U(IV)][Fe(III)] - k_{-2}[U(V)][Fe(II)] + k_3[U(V)][Fe(III)] \qquad (5)$$

The application of a steady-state approximation to [U(V)] gives:

$$[U(V)] = \frac{k_2[Fe(III)][U(IV)]}{k_{-2}[Fe(II)]+k_3[Fe(III)]} \qquad (6)$$

The substitution of Eq. (6) into Eq. (5) and integration yields:

$$\log\left(\frac{[Fe(III)]}{[Fe(III)]_0}\right) - \frac{1}{2.303(k_3/k_{-2}-1)}\left(\frac{[Fe(III)]_0}{[Fe(III)]}-1\right) = -\frac{2k_2[U(IV)]}{2.303(1-k_{-2}/k_3)}t \qquad (7)$$

Although the values of k_2, k_{-2}, and k_3 in Eq. (7) are not known, the left-hand side of Eq. (7) can be calculated for an arbitrary value of k_3/k_{-2}. If the assumptions are valid, a plot of the value of the left-hand side in Eq. (7) against t should give a straight line for some value of k_3/k_{-2}. As may be seen in Fig. 1, a straight line was obtained by introducing the value of $k_3/k_{-2}=5.83$, which was computed by the least-square method. From the slope, k_2 was calculated at 0.32 $M^{-1}\,s^{-1}$. It should be noted that the linear correlation was kept, even when U(VI) had previously been added to the reaction mixture, and that the value of k_2 was independent of the U(VI) concentration. This fact reveals that the backward reaction in Eq. (3) is so slow that it makes no appreciable contribution to Eq. (7).

The value of k_2 obtained in 8M HCl is much smaller than that of 12.3 $M^{-1}\,s^{-1}$ which was reported by Betts in 1M HCl. Some experiments were made in an 8M $HClO_4$ solution in order to investigate why the rate is reduced in 8M HCl as compared with that in 1M HCl. Unlike in 8M HCl, a plot of $\log\{[Fe(III)]/Fe(III)]_0\}$ *vs.* t gave a straight line under the conditions of $[U(IV)]=7.7\times10^{-3}$ M, $[Fe(III)]_0=3.8\times10^{-4}$ M and 8M $HClO_4$, and a much larger value of 2.4 $M^{-1}\,s^{-1}$ was obtained for k_2. Although this value is still smaller than that in 1M HCl, the effect of the hydrogen ion itself on the rate appears to be not very large, since the hydrolyzed species of U(IV) is more reactive with Fe(III) than U^{4+} at a low acidity.[12] Therefore, the high concentration of chloride ions seems to play a major role in reducing the reaction rate in 8M HCl. This is consistent with the findings in previous studies[13,14] that U(IV) is stabilized by forming a chloro complex in concentrated hydrochloric acid and that the oxidation rate by molecular oxygen is very slow compared with that in low acid concentrations. In addition, the redox potential between Fe(III) and Fe(II) may be changed in the presence of a high concentration of chloride ions. This change would influence the rate of the reaction between U(IV) and Fe(III) and would also play an important role in the mechanism where the reaction does not proceed by a simple first order with respect to Fe(III).

In the course of a kinetic study of the reaction between U(IV) and Fe(III), it has become apparent that the reduction of Fe(III) by U(IV) did not proceed to completion, no matter how large an excess of U(IV) was present. This can be seen in Fig. 2, where the absorption spectra were measured after the reaction between U(IV) and Fe(III) had reached equilibrium. The maximum peak at about 370 nm shows that trace amounts of Fe(III) are able to exist under the conditions mentioned above. The equilibrium concentration of Fe(III), $[Fe(III)]_{eq}$,* was estimated from the

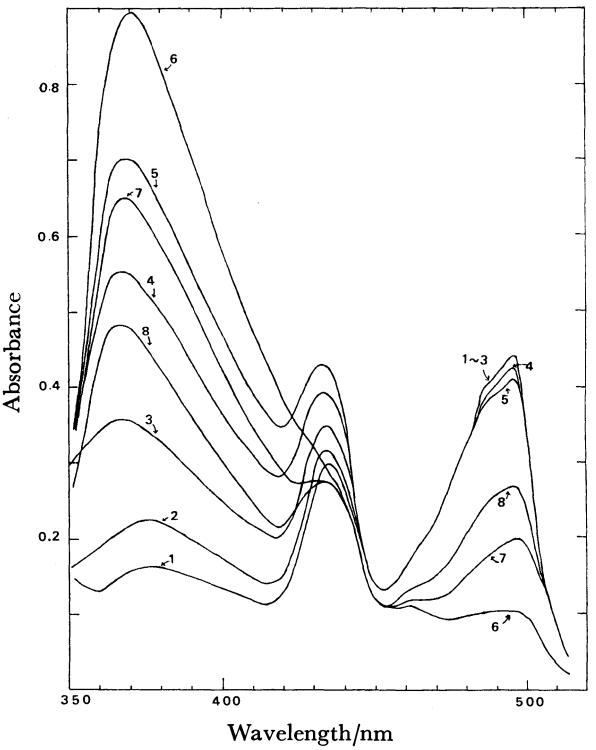

Fig. 2. Absorption spectra in the solution including Fe(III), Fe(II), U(IV), and U(VI) in 8 M HCl at 25 °C.
As reference solution, U(VI) which was the same concentration as in sample solution was used.
$[Fe(III)]_0$ is: (1) 1.40×10^{-3} M, (2) 1.96×10^{-3} M, (3) 2.80×10^{-3} M, (4) 4.20×10^{-3} M, (5) 5.60×10^{-3} M, while [U(IV)] and [U(VI)] are kept constant at 1.9×10^{-2} M and 2.1×10^{-2} M respectively.
[U(IV)] is: (6) 3.71×10^{-3} M, (7) 7.72×10^{-3} M, (8) 1.09×10^{-3} M, while $[Fe(III)]_0$ and [U(VI)] are kept constant at 3.6×10^{-3} M and 1.6×10^{-2} M respectively.

* In the equations from (9) to (16), [ ] shows the equilibrium concentrations. However, in order to distinguish the equilibrium concentration of Fe(III) from the time-dependent concentration, [Fe(III)], in Eq. (7) or Fig. 1, inferior letters, eq, will be used, as in $[Fe(III)]_{eq}$.

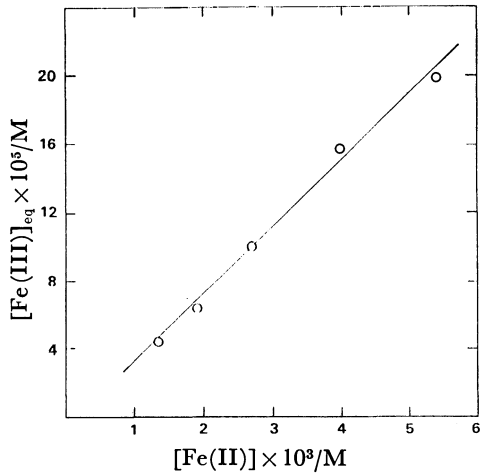

Fig. 3. Plot of $[Fe(III)]_{eq}$ *vs.* [Fe(II)] in Fe(III), Fe(II), U(IV), and U(VI) mixture.
[U(IV)] and [U(VI)] are kept constant at 1.8×10^{-2} M and 2.2×10^{-2} M respectively.

absorbance at this wavelength and was found to be associated with $[Fe(III)]_0$ and [U(IV)]. In Fig. 3, $[Fe(III)]_{eq}$ is plotted against [Fe(II)], which was calculated from the difference between $[Fe(III)]_0$ and $[Fe(III)]_{eq}$; a linear relationship is obtained. This might be explained stoichiometrically by the following reaction:

$$U(IV) + 2Fe(III) = U(VI) + 2Fe(II) \quad (8)$$

If these species are in equilibrium, the equilibrium constant, K, is given by:

$$K = \frac{[U(VI)][Fe(II)]^2}{[U(IV)][Fe(III)]^2_{eq}} \quad (9)$$

or

$$[Fe(III)]_{eq} = \frac{1}{\sqrt{K}}[Fe(II)]\sqrt{\frac{[U(VI)]}{[U(IV)]}} \quad (10)$$

As is shown in Fig, 4, the concentration of Fe(III) yields a stright line when plotted as a function of $1/\sqrt{[U(IV)]}$, keeping the value of $[Fe(III)]_0$ constant; the intercept of the straight line is found to be 0, within the limits of experimental error. These results are

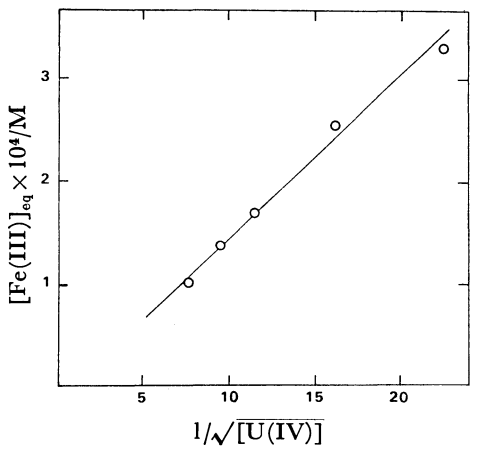

Fig. 4. Plot of $[Fe(III)]_{eq}$ *vs.* $1/\sqrt{[U(IV)]}$ in Fe(III), Fe(II), U(IV) and U(VI) mixture.
$[Fe(III)]_0$ and [U(VI)] are kept constant at 3.6×10^{-3} M and 1.6×10^{-2} M.

evidence in support of Eq. (10). Unfortunately, the relationship between $[Fe(III)]_{eq}$ and [U(VI)] could not be experimentally examined, because Fe(III) seems to interact with U(VI) and the absorption peak of Fe(III) shifts slightly depending upon the U(VI) concentration. However, there seems no doubt that Eq. (10) can be used for a solution containing Fe(III), Fe(II), U(IV), and U(VI). The values of $\sqrt{K}$ calculated from Eq. (10) are listed in Table 1, with the concentrations of these species.

U(IV)–U(VI) Electron Exchange Reaction in the Presence of Fe(III). The U(IV)–U(VI) electron exchange reaction in the presence of Fe(III) was measured by the mass-spectrometric analysis described before, and the results were treated by using the McKay equation.[6] The rate constants in the presence of Fe(III) are listed in Table 2, along with various $[Fe(III)]_0$ values. It can be seen from Table 2 that the rate constants increase with $[Fe(III)]_0$. A plot of the rate constant, k, *versus* $[Fe(III)]_0$ yields a straight line (Fig. 5). The intercept of the line should give the rate constant in the absence of Fe(III); it agrees very closely with the value of 3.0×10^{-5} M^{-1} s^{-1} obtained in the previous paper. In Fig. 6, a plot of k *versus* $1/\sqrt{[U(VI)]}$ is shown under the conditions of constant $[Fe(III)]_0$ and [U(IV)] values; it gives a straight line. These results lead to the following rate law, although the [U(IV)] dependence on the rate has not yet been shown:

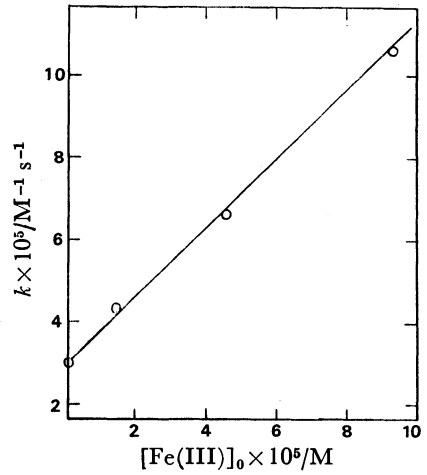

Fig. 5. Rate constant, k, as a function of $[Fe(III)]_0$ at 30 °C in 8 M HCl solution.
$[U(IV)]=2.79\times10^{-2}$ M, $[U(VI)]=2.59\times10^{-2}$ M.

$$k = k_0 + \frac{k_c[Fe(III)]_0}{\sqrt{[U(IV)][U(VI)]}} \qquad (11)$$

where k_0 and k represent the rate constants for the noncatalytic and catalytic paths respectively. In Table 3, the rate constants obtained from the kinetic runs under two different conditions are listed. As may be seen in Table 3, the two values of k_c are nearly equal and are in good agreement with those listed in Table 2. It thus appears that the kinetic order with respect to [U(IV)] in Eq. (11) well explains the experimental results.

The temperature dependence of k, ranging from 20 to 70 °C, is shown in Fig. 7. As may be seen in Fig. 7, the plots show a slight deviation from the linear relationship in the range of low temperatures. This result also implies that the U(IV)–U(VI) electron exchange, in which the least amount of Fe(III) is involved, consists of at least two reaction paths. A graph of

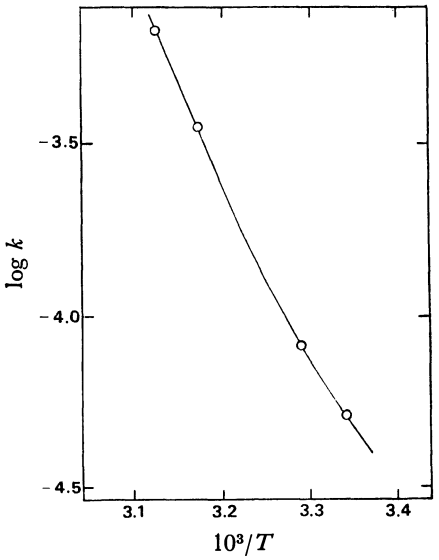

Fig. 7. Temperature dependence of k.

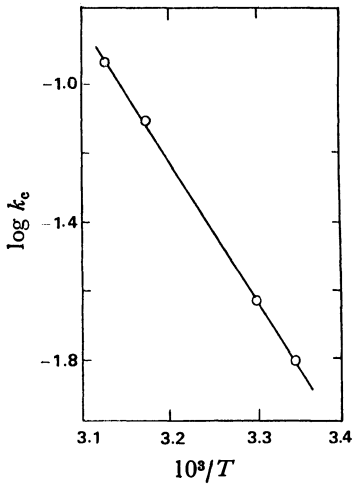

Fig. 8. Temperature dependence of k_c.

log k_c *versus* $1/T$ gives a straight line (Fig. 8), and the activation energy of 19.7 kcal/mol is calculated for the catalytic reaction. This value is much smaller than that of the non-catalytic reaction, that is, 32.2 kcal/mol.[2]

From the results mentioned above, the most probable mechanism for a catalytic reaction is seemed to be a one-electron transfer reaction through the formation of U(V). The initiation step might be the oxidation of U(IV) by Fe(III) (k_2 path), followed by a faster reaction (k_3 path):

$$U(IV) + Fe(III) \rightleftarrows U(V) + Fe(II) \qquad (2)$$

$$U(V) + Fe(III) \rightleftarrows U(VI) + Fe(II) \qquad (3)$$

Gordon and Taube studied the electron exchange reaction between U(V) and U(VI):

$$U(V) + U(VI) \rightleftarrows U(VI) + U(V) \qquad (12)$$

and estimated that the rate constant was 52.0 M^{-1} s^{-1} in a 1.0 M $HClO_4$ solution.[7] This value is much larger than that of k_2 (0.32 M^{-1} s^{-1}) obtained in a concentrated hydrochloric acid solution, as has been

described above. Therefore, it would be reasonable to assume that Reaction (12) proceeds much faster than Reaction (2), so that the electron exchange (12) occurs immediately after the formation of U(V) by Reaction (2) (k_2 path).

On the basis of this assumption, the rate law for the Fe(III)-catalyzed reaction may be given by:

$$R_c = k_2[\mathrm{U(IV)}][\mathrm{Fe(III)}] \tag{13}$$

where R_c is the rate of the Fe(III)-catalyzed reaction. The substitution of Eq. (10) into Eq. (13) gives:

$$R_c = \frac{k_2}{\sqrt{K}}[\mathrm{Fe(II)}]\sqrt{[\mathrm{U(IV)}][\mathrm{U(VI)}]} \tag{14}$$

Hence, the overall exchange rate, R, and the rate constant, k, may be expressed by:

$$R = k_0[\mathrm{U(IV)}][\mathrm{U(VI)}] + \frac{k_2}{\sqrt{K}}[\mathrm{Fe(II)}]\sqrt{[\mathrm{U(IV)}][\mathrm{U(VI)}]} \tag{15}$$

and:

$$k = k_0 + \frac{k_2}{\sqrt{K}}\frac{[\mathrm{Fe(II)}]}{\sqrt{[\mathrm{U(IV)}][\mathrm{U(VI)}]}} \tag{16}$$

The disproportionation of U(V) may make some contribution to the U(IV)–U(VI) electron exchange reaction.[8–11]

$$2\mathrm{U(V)} \rightleftarrows \mathrm{U(IV)} + \mathrm{U(VI)} \tag{17}$$

The rate law, however, is valid even if the disproportionation is faster than Reaction (12). In the course of a kinetic study of the oxidation of U(IV) by Fe(III), it may be clear that the disproportionation of U(V) is slow compared with Reaction (3) (k_3 path). This is because, if the disproportionation of U(V) were very fast, the reaction between U(IV) and Fe(III) would proceed simply by first-order with [Fe(III)], a plot of $\log\{[\mathrm{Fe(III)}]/[\mathrm{Fe(III)}]_0\}$ against t should give a straight line, and the linear relationship with respect to Eq. (7) as in Fig. 1 would not be obtained.

Since $[\mathrm{Fe(III)}]_0$ in Eq. (11) is nearly equal to [Fe(II)], as may be seen in Table 1, Eq. (16) is completely consistent with Eq. (11). This leads to the following relation:

$$k_c = k_2/\sqrt{K} \tag{18}$$

From the Fe(III)-catalyzed U(IV)–U(VI) electron exchange reaction, k_c can be obtained experimentally as 1.3×10^{-2} M^{-1} s^{-1} at 25 °C. On the other hand, k_2 and $\sqrt{K}$ were 0.32 M^{-1} s^{-1} and 31.3 respectively at 25 °C, as is shown in Fig. 1 and Table 1. From these results, $k_2/\sqrt{K}$ was calculated to be 1.0×10^{-2} M^{-1} s^{-1}. The $k_2/\sqrt{K}$ ratio gives the estimated rate constant for the Fe(III)-catalyzed U(IV)–U(VI) electron exchange reaction, assuming the rate law (16) and assuming that the value of 1.0×10^{-2} M^{-1} s^{-1} is in satisfactory agreement, within the limits of experimental error, with that of 1.3×10^{-2} M^{-1} s^{-1} obtained by the direct measurement of the U(IV)–U(VI) electron exchange reaction. This final result supports very strongly the mechanism we have discussed in this paper.

NH_2 Radicals Trapped on the Surface of Porous Vycor Glass at 77 K*

Norio SHIMAMOTO,** Keiichiro HATANO,*** Takashi KATSU, and Yuzaburo FUJITA
Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received January 26, 1974)

The results of ESR studies of the amino radicals produced by the photolysis of ammonia adsorbed on the surface of porous Vycor glass at 77 K are described. The observed ESR signal patterns of the amino radicals were remarkably affected by the amount of ammonia on the surface. The isotropic and anisotropic spectra were analyzed by the use of isotopically-substituted amino radicals.

Although several ESR studies have been devoted to the formation of NH_2 radicals by the irradiation of ionizing radiation on ammonia in various matrices[1-3] and on solid surfaces,[4-6] there are few studies of the photolysis of ammonia on solid surfaces. In this report, the results of ESR studies of the amino radicals produced by the photolysis of ammonia adsorbed on the surface of porous Vycor glass (PVG) at 77 K will be presented, in connection with a previous study of methylamino radicals.[7]

Experimental

PVG rods (Corning code No. 7930; 4 mm in diameter; 2 cm in length; surface area of 75 m^2/sample) were used. After the pretreatment of the PVG rod with oxygen at 550—600 °C and evacuation for a few hours in a quartz sample tube attached to a conventional high-vacuum system, a specified amount of ammonia was introduced into the sample tube at room temperature. The sample tube was then gradually cooled to the temperature of liquid nitrogen and then submitted to irradiation and ESR measurements. Gaseous ammonia from a concentrated aqueous solution was dried by passing it through a column packed with potassium hydroxide tablets; it was subsequently purified by vacuum distillation. Gaseous $^{15}NH_3$ was prepared from a $(^{15}NH_4)_2SO_4$ (99.8 ^{15}N atomic %) solution by alkalifying with KOH. The ESR spectra were recorded at 77 K with a JEOL P-10 spectrometer. The irradiation of the sample was carried out with a low-pressure mercury lamp (UL2-2HQ, 200W, Ushio Electric Inc.) at 77 K without any filters.

Results and Discussion

The observed ESR signal patterns of the amino radicals were greatly affected by the preadsorbed amount of ammonia on the surface of PVG.

Larger than the Monolayer Amount. An isotropic spectrum of apparent seven lines such as is shown in Fig. 1a was observed after irradiation with the full light of a low-pressure mercury lamp for 5 min at 77 K. A similar spectrum of the NH_2 radical produced by γ-irradiation on anhydrous ammonia at 77 K has been reported by Al-Naimy *et al.*[2] The spectrum can be assigned to the freely tumbling NH_2 radicals, free from any interaction with the surface. Further irradiation caused a selective growth of a particular triplet with an anisotropic nature, as can be seen from the dotted line spectrum in Fig. 1a. On slight warming, the isotropic spectrum decayed faster than the remaining triplet. Hereafter, the radicals with the isotropic and anisotropic natures will be denoted as A-type and B-type radicals respectively. The A-type

*** Present address: Faculty of Pharmaceutical Sciences, Nagoya City University, Mizuho-ku, Nagoya.

spectrum of the ND_2 radical is shown in Fig. 2a. The ratio of the hf constants of the H and D nuclei in the NH_2 and ND_2 radicals, $A^H/A^D=6.5$, is exactly in agreement with the theoretical ratio, supporting the above assignment. The A-type spectrum of $^{15}NH_2$ is shown in Fig. 3a; in this case the linewidth is too broad for the hf constants of H and ^{15}N to be determined separately. However, the total spreading of the spectrum, 72 G, coincides well with the expected value of $(A^{15N}+2A^H)=(A^{14N}\times g^{15N}/g^{14N}+2A^H)=71$ G, where $A^H=25$ G, $A^{14N}=15$ G of $^{14}NH_2$, and $g^{15N}/g^{14N}=1.4$ were used. Thus, the hf constants of the A-type of $^{15}NH_2$ radical can reasonably be evaluated as is shown in Table 1.

Less than 1/10 of the Monolayer Amount. When the adsorbed amount was in the range $1>\theta>1/10$, a similar ESR spectrum of the triplet, such as is shown in Fig. 1a, was observed even after short irradiation.

a) The values are evaluated from the total spreading of the spectra.

A further decrease in the adsorbed amount, $\theta<1/10$, resulted in the appearance of a well-resolved complicated spectrum, as is shown in Fig. 1b. The photolysis of ND_3 ($1>\theta>1/10$) was also carried out to ascertain whether the extra triplet in Fig. 1a or 1b is caused by two protons or a single ^{14}N nucleus in the radical. Since the triplet was replaced by a quintet in the case of ND_3 photolysis, as is shown in Fig. 2b, and since the ratio of the hf constants between both radical species coincided with the expected value, the triplet is attributable to the proton hf splitting of the NH_2 radical.

In general, the ^{14}N hf splitting has an anisotropic nature in adsorbed states; this is the reason why the deuteron hf splitting on $m_I=\pm1$ lines of nitrogen is only partially resolved. Morton *et al.*[8] have reported a large anisotropy in the ^{15}N hf splitting of the $^{15}NH_2$ radical trapped in γ-irradiated $K^{15}NH_2SO_3$ single crystals: the principal values of the ^{14}N hf splitting calculated from their data by using the nuclear g-factor ratio are $A_{xx}^{^{14}N}=38.3$, $A_{yy}^{^{14}N}=1.4$, and $A_{zz}^{^{14}N}=0.2$ G, where the x-axis is taken along the $2p\pi$ orbital of the nitrogen atom. Assuming an axial symmetry of ^{14}N hf splitting and a nearly isotropic splitting for the proton in the NH_2 radical rotating about the unpaired spin orbital,[9] the hf constants of ^{14}N and H were determined to be as is shown in Table 1.

Although almost all the ESR lines in Fig. 1b can thus be assigned to the NH_2 radical of the B-type, there exist some other lines which are not due to this radical species, indicating the existence of other radical species. Recently, Brotikovskii *et al.*[4] have observed spectra due to the overlap of three different radical species in γ-irradiated NH_3–SiO_2 systems at 77 K; namely, the R_1, R_2, and R_3 radicals in their notation. Among these radicals, the R_1 radical obviously corresponds to the B-type radical in our case: the hf constants of the R_1 radical are $A_{//}^{^{14}N}=37.5$, $A_{\perp}^{^{14}N}=3$, and $A^{H}=24$ G, values which almost coincide with those of our B-type radical. The three lines marked with arrows in Fig. 1b correspond to those of the R_3 radical, which can probably be assigned to another NH_2 radical species interacting more strongly with a different site from that of the R_1 or B-type radical species, resulting in an apparent quenching of the ^{14}N hf splitting as a result of a strong interaction with the surface. The spectrum corresponding to the R_2 radical, which has been tentatively assigned by Brotikovskii *et al.* to the S–NH radical (S denotes a surface site), was perceptible only at an initial stage of irradiation on a sample evacuated at higher temperatures; this is in accordance with their results, where the R_2 radical was the predominant species on the surface of SiO_2 preheated at 800 °C *in vacuo*.

When $^{15}NH_3$ was photolyzed under the same conditions as are shown in Fig. 1b, the ESR spectrum shown in Fig. 3b was observed. The total spreading of the $^{15}NH_2$ spectrum should be equal to $(A_{//}^{^{14}N}+2A^{H})=(A_{//}^{^{14}N}\times g^{^{14}N}/g^{^{14}N}+2A^{H})=100.5$ G, which is exactly in agreement with the observed total spreading of 100 G.

From the above results, it may be concluded that the primary radical of the photodecomposition of ammonia adsorbed on the surface of PVG with the light of a low-pressure mercury lamp is the NH_2 radical, and that the spectral pattern of the NH_2 radical depends remarkably on the amount of ammonia preadsorbed on the surface.

For comparison, the ESR data for NH_2 radicals trapped in various matrices are listed in Table 1, along with those for the photoproduced NH_2 radicals on the surface of PVG.

The isotropic ^{14}N and H hf constants of NH_2 trapped in anhydrous NH_3 and on PVG are nearly in accordance with each other, while the $A_{iso}^{^{14}N}$ of NH_2 trapped in an argon matrix is significantly smaller than the others. The latter change in the hf constants is a common phenomenon arising from the different radical environment. Rao and Symons[9] have discussed their observation of various values of $A_{iso}^{^{14}N}$ with changes in the medium. The change in $A_{iso}^{^{14}N}$ observed with the change of medium from argon to anhydrous NH_3 or NH_3 adsorbed on PVG may be due to a weak hydrogen-bonding interaction between the radical and host NH_3 molecules. However, this hydrogen bond is considered to be not strong enough to prevent the free tumbling of the radical, since the observed ESR signal pattern shows an isotropic nature even at 77 K. Nearly constant values of $A_{iso}^{^{14}N}$ both in anhydrous ammonia and on PVG indicate that the A-type NH_2 radical is trapped in a condensed phase of ammonia free from any interaction with the PVG surface. Accordingly, the A-type radical may be said to decay rapidly by means of the radical recombination due to the softening of the matrix on slight warming.

The values of $A_{//}^{^{14}N}$ scatter slightly depending on the radical environments, as is shown in Table 1. This may be partly due to an ambiguous estimation of the value from the positions of the outermost humps of the powder-pattern spectra, and partly to different interaction forces with the surfaces, as in the case of methyl radicals trapped on the PVG surfaces.[10] The radicals of the B-type with an axially symmetric hf tensor of ^{14}N, interacting strongly with the surface silanol group through the $2p\pi$ orbital of the radical rather than the hydrogen bond, are immobilized on the surface and, consequently, are allowed to rotate only around the $2p\pi$ orbital. Thus, the translational motion of the radical is so restricted to prevent the radical recombination that the B-type NH_2 radical was observed even at −20 °C in a thermal-decay experiment.

The authors wish to express their thanks to Professor Masamichi Tsuboi and Dr. Akiko Hirakawa of this faculty for their kind gift of ^{15}N-ammonium sulfate.

The Electronic Structures of Several Aliphatic Carbonyls. The Effects of Polar Substituents

Yoshiro YONEZAWA* and Takayuki FUENO

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received February 13, 1974)

The electronic structures of several aliphatic carbonyls, X_2CO, CH_3COX, and $(XCO)_2$ (X=H, F, CN, CH_3), have been investigated by the INDO method. Variations in the calculated electron density, the $n\pi^*$-excitation energy, the electron affinity, and the ionization potential with α-X substitution are explained qualitatively in terms of the σ-attracting and π-donating character of F, the π-attracting nature of CN and XCO, and the σ,π-donating property of CH_3. The lowest $^3n\pi^*$ excitation energies and ionization potentials calculated by the UHF method are in reasonable agreement with the experimental values in most cases. The partitioning of the total energy suggests that the C–O bonds of X_2CO compounds in the lowest $^3n\pi^*$ state and the radical anions derived from them are somewhat longer than those of the parent molecules, primarily because of the decrease in the electron-core attraction. The C–C bonds in some $(XCO)_2$ compounds appear to be cloven as easily as the C–X one on thermal activation and electron impact.

The structural and photochemical properties of aliphatic carbonyls in the excited state have already received considerable attention.[1,2] However, no all-valence-electron study of the electronic structure has yet been carried out. We thus applied the INDO method to several aliphatic carbonyls, X_2CO, CH_3COX, and $(XCO)_2$ (X=H, F, CN, CH_3), in the ground and excited states, as well as to the radical anions and cations derived from them. The total energies were partitioned into one- and two-atom terms,[3,4] and we tried to determine how the interatomic interactions influence the electronic excitation, ionization, and electron attachment.

Method of Calculation

The INDO calculations of the closed- and open-shell configurations were carried out by the usual procedure.[3] The total energy of the molecule is written as a sum of one- and two-atom terms:[3,4]

$$E_{\text{total}} = \sum_{A} E_A + \sum_{A<B}\sum E_{A-B} \tag{1}$$

$$E_{A-B} = E^1_{A-B} + E^2_{A-B} + E^3_{A-B} \tag{2}$$

where the two-atom terms are given by:

$$E^1_{A-B} = 2\sum_{r}^{A}\sum_{s}^{B} P_{rs}S_{rs}\beta^{\circ}_{AB} \tag{3}$$

$$E^2_{A-B} = -\frac{1}{2}\sum_{r}^{A}\sum_{s}^{B} P^2_{rs}\gamma_{AB} \tag{4}$$

$$E^3_{A-B} = (P_{AA}P_{BB} - P_{AA}Z_B - P_{BB}Z_A)\gamma_{AB} + Z_AZ_B/R_{AB} \tag{5}$$

Here, P_{rs} and S_{rs} are the bond order and the overlap integral between the r and s atomic orbitals; β°_{AB}, γ_{AB}, and R_{AB} are the empirical bonding parameter, the two-center repulsion integral, and the distance between the A and B atoms respectively, and P_{AA} and Z_A are the electron density and the core charge at the atom A respectively. When wavefunctions of the unrestricted Hartree-Fock (UHF) type are used, Eq. (4) takes this form:

$$E^2_{A-B} = -\sum_{r}^{A}\sum_{s}^{B}[(P^{\alpha}_{rs})^2 + (P^{\beta}_{rs})^2]\gamma_{AB} \tag{6}$$

where P^{α}_{rs} (P^{β}_{rs}) is the bond order between the r and s atomic orbitals of the α- (β-) spin electron. We have used the original INDO parameters of Pople *et al.*[3] throughout this work.

Most of the molecular geometries employed were taken from the literature.[5,6] No experimental data are available for the geometries of carbonyl cyanide and oxalyl cyanide;[7] the former was assumed to be $\overline{CO}$=1.20 Å, $\overline{CC}$=1.47 Å, $\overline{CN}$=1.16 Å, and $\angle CCC=120°$, and the latter, to be $\overline{CO}$=1.22 Å, $\overline{C(CN)}$=1.47 Å, $\overline{CC}$=1.50 Å, $\overline{CN}$=1.16 Å, $\angle CCC=120°$, and $\angle OCC=123°$. The same geometries were employed for $^3n\pi^*$ molecules and for radical ions. All the oxalyl compounds were assumed to be in the *s-trans* conformation.

Results and Discussion

Ground State. The electron densities on the carbonyl group of X_2CO compounds are given in Table 1. It is expected, from the values of the Hammett's substituent constants, that the F atom has a σ-attracting and π-donating character, that the CN and XCO groups have σ,π-attracting nature, and that the CH_3 group has a σ,π-donating property.[8] As to the electron density at the carbonyl oxygen, it is noticeable that the population of the 2pz atomic orbital (perpendicular to the molecular plane) increases

with an increase in the π-donating ability of the substituents.

The frontier orbital energies, total energies, and dipole moments are summarized in Table 2. The calculated dipole moments show a good agreement with the experimental values except for the oxalyl compounds, which will take both *cis* and *trans* conformations under the present experimental conditions.

The orbital energies of the highest occupied and lowest vacant levels are correlated with the first ionization potential and the electron affinity respectively. The highest occupied orbital of each molecule is an n orbital localized almost completely at the carbonyl oxygen, *i.e.*, the $2p_y$ atomic orbital (perpendicular to the molecular axis). The energy levels of this orbital rise in this order: F$\ll$H, CN$<$$CH_3$, XCO. The F substituent lowers this level because of its σ-attracting character. On the other hand, the lowest vacant orbital is essentially a π^* orbital. The energy levels rise in this order: CN, XCO$\ll$F, $CH_3<$H. The CN and XCO substituents lower the π^* level because of their π-attracting nature.

The Lowest Excited State. The lowest nπ^* singlet and triplet excitation energies, $\Delta E^V(^1n\pi^*)$ and $\Delta E^V(^3n\pi^*)$, as calculated by the virtual-orbital approximation without configuration interaction, are given in Table 3. These energies are expressed by:

$$\Delta E^V(^1n\pi^*) = (E_{\pi^*}-E_n) - J_{n\pi^*} + 2K_{n\pi^*} \quad (7)$$

and;

$$\Delta E^V(^3n\pi^*) = (E_{\pi^*}-E_n) - J_{n\pi^*} \quad (8)$$

where $(E_{\pi^*}-E_n)$ is the frontier orbital energy gap and where $J_{n\pi^*}$ and $K_{n\pi^*}$ are the interorbital Coulomb and exchange integrals respectively. $J_{n\pi^*}$ decreases with the replacement of the H atom by the CH_3, CN, and XCO groups as a result of the expansion of the π^* orbital of the carbonyl group. $K_{n\pi^*}$ is small because of the different symmetries of the n and π^* orbitals.

The nπ^* energy change caused by α-X substitution will be discussed qualitatively on the basis of the orbital energies alone, because the variation in $(E_{\pi^*}-E_n)$ with the substituents is generally greater than the changes in $J_{n\pi^*}$ and $K_{n\pi^*}$. Thus, an inspection of the relative heights of the frontier orbitals as discussed in the preceding section suggests that the nπ^* excitation energies increase in this order: XCO$<$CN, $CH_3<$H$<$F. Such energy shifts show a reasonable agreement with the experimental data (Table 3).

The nπ^* excitation energies from Eqs. (7) and (8) are 1—2 eV greater than experimental values. Although there are some obvious ways to improve the

Kanda, This Bulletin, **40**, 2742 (1967).

correlation, we did not attempt to do so. Instead, we dealt with the lowest $^3n\pi^*$ excited state by the UHF method, retaining the original INDO parametrization.

The triplet excitation energies, $\Delta E^U(^3n\pi^*)$, in the UHF method are defined as:

$$\Delta E^U(^3n\pi^*) = E^U_{total}(^3n\pi^*) - E_{total}(\text{ground}) \quad (9)$$

These values are generally in better agreement with the experimental values than $\Delta E^V(^3n\pi^*)$.

Radical Ions. The radical anions and cations derived from the parent molecules were treated by the UHF method. The electron affinities, E_A, and ionization potentials, I_D, were obtained from:

$$E_A = E_{total}(\text{ground}) - E^U_{total}(\text{anion}) \quad (10)$$

$$I_D = E^U_{total}(\text{cation}) - E_{total}(\text{ground}) \quad (11)$$

and are summarized in Table 4.

The calculated electron affinities are 0.5—1.0 eV greater than the $(-E_{\pi^*})$ obtained from Table 2, but still appear to be much smaller than the experimental ones. The E_A values increase in this order: H, F< CH_3<XCO<CN. The oxalyl compounds might have as large electron affinities as carbonyl cyanide.

The ionization potentials calculated from Eq. (11) are 1—3 eV smaller than the $(-E_n)$ from Table 2 and compare well with the experimental values. In both the X_2CO and CH_3COX compounds, they show this ordering: CH_3<XCO, H, CN<F. It should be noted that the effects of α-X substitution on E_A and I_D given here are almost identical with those already mentioned for the π^* and n orbital energies in the ground state.

Partitioning of the Energy. The two-atom terms for several X_2CO and $(XCO)_2$ compounds in the ground state (G), and lowest $^3n\pi^*$ state (T), as well as those for radical anions (A) and cations (C) derived

from the parent molecules, are summarized in Table 5. The E_{C-X} of X_2CO changes markedly with the α-X substitution. The E_{C-C} of $(XCO)_2$ compounds also varies with the substituents and is either greater or smaller in magnitude than E_{C-X}. This must be related at least in part to the ease of thermal decomposition of both C–X and C–C bonds for oxalyl compounds.[9] The non-bonded two-atom terms, E_{X-X}, increase in this order: CN–CN<H–H<F–F. This suggests a small steric repulsion between the CN groups.

Table 6. Partitionings of the two-atom terms E_{C-O} for X_2CO and E_{C-C} for $(XCO)_2$ compounds (eV)

Molecule	State[a]	E^1_{A-B}	E^2_{A-B}	E^3_{A-B}
		E_{C-O} Terms		
H_2CO	G	−49.91	−11.52	15.37
	T	−43.95	−8.27	16.27
	A	−45.45	−9.30	16.52
	C	−49.45	−10.86	17.30
F_2CO	G	−51.85	−10.98	15.65
	T	−43.67	−7.22	18.43
	A	−47.13	−9.16	16.35
	C	−48.44	−8.84	20.34
		E_{C-C} Terms		
$(HCO)_2$	G	−33.37	−4.85	7.64
	T	−32.90	−5.56	7.31
	A	−36.16	−6.38	7.11
	C	−29.97	−3.94	8.11
$(FCO)_2$	G	−31.70	−4.50	8.44
	T	−30.78	−5.01	7.83
	A	−34.33	−5.90	7.13
	C	−27.93	−3.53	9.48

a) The symbols G, T, A, and C denote the ground state, the lowest triplet state, radical anion, and radical cation, respectively.

The various types of two-atom terms, Eqs. (3)—(5), for the E_{C-O} values of several X_2CO compounds in the G, T, A, and C states are summarized in Table 6, together with those for the E_{C-C} of $(XCO)_2$ compounds. It has been established that formaldehyde is non-planar, with a somewhat lengthened carbonyl bond, in the lowest $^3n\pi^*$ state.[10] The E_{C-O} of X_2CO in the T state is considerably decreased in magnitude from the parent molecules. Most of the decrease originates from E^1_{C-O}, which corresponds to the off-diagonal core matrix elements, while the decreases in the electron-exchange term, E^2_{C-O}, and the electrostatic term, E^3_{C-O}, are both relatively immaterial. At any rate, the large decrease in $|E_{C-O}|$ upon excitation suggests a drastic reorganization of electrons in the carbonyl moiety. This, in turn, is probably related to the fact that these molecules have longer carbonyl bonds in the excited state. The increases in the E_{C-O} and E_{C-C} values of $(XCO)_2$ are not so great as that of the E_{C-O} of X_2CO.

As for the radical anion (A), E_{C-O} is decreased by 7—8 eV in magnitude from the parent molecules. As was true in the case of the T state, most of the decrease originates from E^1_{C-O}. Probably, these radical anions will also have a longer carbonyl bond than the parent molecules. In oxalyl compounds, the decrease in $|E_{C-O}|$ is rather small and is nearly counterbalanced by the increase in $|E_{C-C}|$.

The change in the sum of two-atom terms, $\sum\sum_{A<B} E_{A-B}$, from the parent molecule is rather small for radical cations. However, it is noticeable that the $|E_{C-C}|$ values of some oxalyl compounds are decreased by 5—6 eV upon ionization, primarily as a result of the decrease in $|E^1_{C-C}|$. Thus, it is likely that the C–C bond is cloven as easily as the C–X bond in such cases.

Investigation of the Concept of Free Volume by Means of a Correlation Function Method

Kiyoshi ARAKAWA and Kazumitsu KOJIMA

Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received March 6, 1974)

An investigation of the validity of the free volume theory of liquid has been undertaken on the basis of the theory of correlation functions. A formula for free volume without use of a geometrical model has been proposed and discussed. The magnitude of equivalent free volumes obtained from the formula has been found to be nearly equal to that calculated from the entropy of vaporization by means of the free volume theory. The results give support to the physical reality of the concept of free volumes. The communal entropy deduced agrees with that obtained by an expansion formula to the first order of density. A formula for compressibility has also been derived, which gives satisfactory results in comparison with observed data.

The Lennard-Jones and Devonshire (LJD) theory and the Yvon-Born-Green-Kirkwood (YBGK) theory were the starting points of extensive researches in the field of the theory of liquids.[1] The free volume theory originated from the LJD theory has been applied extensively to liquids[2] and solutions[3,4] as an approximate representation of their thermodynamic properties.

On the semi-emprical basis of the free volume theory, several critical studies have been carried out, among which those by Kirkwood[5] and by Hildebrand[6] are the most important. Concerning Kirkwood's critique (1950) with respect to the formulation of the theory, several improvements have been made.[7-9] The problem of communal entropy was also investigated by Hoover and Ree[10] and others by means of the Monte Carlo method.

Hildebrand proposed a serious question on the physical reality of the concept of free volume from results showing that free volumes calculated from identical thermodynamical data showed a marked discrepancy among the models adopted.[6] Thus it seems worth-while to attempt to place the concept of free volume on a sounder theoretical basis and to give a difinite explanation.

Since the proposition of Percus-Yevick and H N C equations in 1958—1960, development in the equilibrium theory of liquids using correlation functions is remarkable.[11-16] Some noticeable results from model experiments by Bernal and King[17] have been obtained, as well as those from computer experiments[18] by means of the Monte Carlo method and molecular dynamics.

At present, the application of these new theories to real liquids is limited except for that to liquid argon and liquid metals, model theories such as the free volume theory of liquids still playing an important role for the explanation of various properties of fluids.

We have examined the theoretical basis of the free volume theory according to recent liquid theories using correlation functions, with the purpose of elucidating the physical meaning of the concept of free volume.

Theoretical

Theoretical Consideration on the Nature of Free Volume. The Percus-Yevick integral equation is expressed as follows.[11-16]

$$h(r) = c(r) + \rho\int c(|\boldsymbol{r}-\boldsymbol{r}'|)h(|\boldsymbol{r}'|)\mathrm{d}\boldsymbol{r}' \tag{1}$$

$$c(r) = g(r)\exp(u(r)/kT)[\exp(-u(r)/kT)-1], \tag{2}$$

where $c(r)$ is the direct correlation function, $h(r)=g(r)-1$ the total correlation function, $g(r)$ the radial distribution function, and $u(r)$ the two body potential.

The equation has been solved analytically by Wertheim[19] and Thiele[20] for the fluid of hard spheres. The equation of state obtained has been found to be identical with that deduced from the scaled particle theory by Reiss *et al.*,[21] which is expressed as

$$p = \rho kT(1+y+y^2)/(1-y)^3, \quad y = \pi\rho a^3/6, \tag{3}$$

where ρ is the number density, a the diameter of a hard sphere and y the volume fraction of hard sphere molecules.

The partition function Z for a hard sphere fluid is derived from Eq. (3) to be

$$Z = \left[\frac{V}{N}(1-y)\exp\left(1-\frac{3y(2-y)}{2(1-y)^2}\right)\right]^N\left(\frac{2\pi mkT}{h^2}\right)^{3/2N}. \tag{4}$$

For a hard sphere fluid with an internal potential V_N, it is expressed as

$$Z = \left[\frac{V}{N}(1-y)\exp\left(1-\frac{3y(2-y)}{2(1-y)^2}\right)\right]^N\left(\frac{2\pi mkT}{h^2}\right)^{3/2N} \times \exp(-\langle V_N\rangle_{\mathrm{av.}}/kT). \tag{5}$$

A formula similar to this expression was first introduced by Longuet-Higgins and Widom[22] and also given by Miller.[23] We have given an explanation of its theoretical basis in connection with the mean spherical model (MSM) approximation proposed by Lebowitz *et al.*[24] (see Appendix).

The free volume fraction f is defined as follows.

$$f \equiv (1-y)\exp\left(-\frac{3y(2-y)}{2(1-y)^2}\right). \tag{6}$$

From Eq. (5), we then have

$$Z = \left[\left(\frac{2\pi mkT}{h^2}\right)^{3/2} efv\right]^N \exp(-\langle V_N\rangle_{\mathrm{av.}}), \tag{7}$$

where $v=V/N$ is the volume per molecule in liquid.

According to the free volume theory of liquid,[5] the partition function is expressed as a function of free volume, independent of the above theory as follows.

$$Z = \left[\left(\frac{2\pi mkT}{h^2}\right)^{3/2} ev_f\right]^N \exp(-\langle V_N\rangle_{\mathrm{av.}}/kT) \tag{8}$$

where $v_f = V_f/N$ is the free volume (fluctuational volume[25]) per molecule.

Equating Eqs. (7) and (8), we have

$$f = v_f/v \quad \text{or} \quad f = V_f/V \tag{9}$$

from which the nomenclature of f comes.

From Eqs. (6) and (7) we can calculate the values of V_f. Values of the free volume fraction f as a function of y, together with the values of V_f calculated for two liquids CCl_4, $c\text{-}C_6F_{11}CF_3$ are given in Table 1.

Table 1. Free volume fraction and free volume

y		0.50	0.51	0.52	0.54	0.60	0.64
$f\times 10^3$		5.55	4.25	3.20	1.72	0.152	0.0152
V(cm³/mol)	CCl_4	0.54	0.41	0.31	0.17	0.015	0.0015
	$c\text{-}C_6F_{11}CF_3$	1.09	0.83	0.63	0.34	0.030	0.0030

Determination of the Equilibrium Values of Volume Fraction y and Free Volume V_f in Liquids. In the case of the face-centered cubic packing of hard sphere molecules, where all molecules are in contact with each other, the magnitude of y is $\sqrt{2}\pi/6 = 0.74$, which is the maximum value of y.

Bernal and King proposed the "random network model" for the structure of liquid state on the basis of a series of model experiments,[17] giving the magnitude of y to be 0.64 for the liquid state at its triple point.

For determination of the equilibrium values of y, the equation of state derived from Eq. (5) is used.

$$pV = NkT\left(\frac{1+y+y^2}{(1-y)^3}\right) - V\frac{\partial\langle V_N\rangle_{av.}}{\partial V} \tag{10}$$

When $\langle V_N\rangle_{av.}$ is taken to be propotional to the n-th power of volume V as usual, we have

$$pV = NkT\left(\frac{1+y+y^2}{(1-y)^3}\right) + n\langle V_N\rangle_{av.}. \tag{11}$$

For the determination of y the equation of state at vanishing pressure,[4,26] which is obtained by equating the right-hand side of Eq. (11) to zero, is used, together with the relation $-\langle V_N\rangle_{av.} = \Delta H_{vap.} - RT$ ($\Delta H_{vap.}$; the heat of vaporization). Thus, we get

$$RT\left(\frac{1+y+y^2}{(1-y)^3}\right) = n(\Delta H_{vap.} - RT). \tag{12}$$

The equilibrium values of y thus determined using the experimental data[27] of n and $\Delta H_{vap.}$ for CCl_4 and $c\text{-}C_6F_{11}CF_3$ are 0.50 and 0.54 at 25 °C, respectively. In the case of CCl_4 the magnitude of y determined by the consideration of compressibility is 0.51, in line with that determined by Eq. (12).

The values of V_f for CCl_4 and $c\text{-}C_6F_{11}CF_3$ at 25 °C are thus determined to be 0.41 and 0.34 cm³/mol, respectively, from the values of y given in Table 1. The values are nearly equal to those for "$\Delta S_{vap.}$" given by Hildebrand (Table 2). This shows that the values of V_f obtained directly from $\Delta S_{vap.}$ by means of the free volume theory are consistent with those of the "equivalent free volume" determined here as a statistical average by use of correlation functions (Eqs. (6), (9), and (12)).

For deriving Eqs. (1)—(9) (except Eq. (8)), no approximation based on a geometrical model was introduced. The free volume fraction defined by Eq. (6) consists of a factor $1-y$ and an exponential factor $\exp(-3y(2-y)/2(1-y)^2)$. The former factor is equal to the fraction of void space for the total volume V, and the latter is supposed to come from the volume exclusion effect of hard sphere molecules in their thermal motions. The free volume V_f is thus regarded as a statistical average of fluctuational void space. This brings the free volume fraction f as a function of y only. Agreement of the values of V_f for $\Delta S_{vap.}$ with those determined through f (Eq. (6)) gives a comfirmative support of the concept of free volume calculated from $\Delta S_{vap.}$ as a thermodynamic parameter.

Table 2. Free volumes at 25 °C (cm³/mol)[a]

	V	V_f				
		van der Waals[b]	$\Delta S_{vap.}$[c]	Cage[d]	Cubic[e]	This work
CCl_4	96	7.7	0.24	0.042	0.34	0.41
$c\text{-}C_6F_{11}CF_3$	196	10.9	0.36	0.034	0.27	0.34

a) The values of V_f for models b)—e) are cited from Table 1 in the note by Hildebrand.[6] They were calculated from identical data[27] on the basis of the relation $\partial S/\partial V = R(\partial \ln V_f/\partial V)$. The difference between the values is ascribed to the geometrical feature of each model.[6] b) Calculated from the definition $V_f = V - b$. c) Calculated from $\Delta S_{vap.}$ using the relation $\Delta S_{vap.} = R\ \ln(V_g/V_f)$, where V_g is the volume of gaseous state in equilibrium. d) The fluctuational volume for a cage model; $(V_f)_{cage} = [R/V^{2/3}(\partial S/\partial V)]^3$. e) The fluctuational volume for simple cubic packing.

Communal Entropy. The communal entropy ΔS is obtained as

$$\Delta S = k \ln (ef)^N. \tag{13}$$

Inserting Eq. (6) into Eq. (13), we get

$$\Delta S = Nk\left[1 + \ln(1-y) - \frac{3y(2-y)}{2(1-y)^2}\right]. \tag{14}$$

The volume fraction y is expressed by (ρ/ρ_0), where ρ_0 is the closest number density at face-centerd cubic packing.

$$\rho_0 = \sqrt{2}/a^3$$

and

$$y = \frac{\pi}{6}\rho a^3 = \frac{\sqrt{2}\pi}{6}\left(\frac{\rho}{\rho_0}\right) = 0.740475\left(\frac{\rho}{\rho_0}\right).$$

Thus the communal entropy ΔS is expressed by the power of (ρ/ρ_0) as follows.

$$\Delta S/Nk = 1 - 2.9619(\rho/\rho_0) - 2.741515(\rho/\rho_0)^2 \tag{15}$$

The expansion of $\Delta S/Nk$ by (ρ/ρ_0) agrees to the first order term with the formula obtained by Hoover and Ree[28] by means of the Mayer f function expansion. The linear dependence of the communal entropy at small density has been confirmed by means of a Monte Carlo calculation.[10]

Compressibility. From Eqs. (6) and (10), we can derive the following formula for the isothermal compressibility κ_T of liquid, using the relation

$$\langle V_N\rangle_{av.} = \Delta H_{vap.} - RT = \frac{\text{Const.}}{V^n} \tag{16}$$

$$\kappa_T = \left[\frac{1}{\kappa_0} - \frac{n(n+1)}{V}(\Delta H_{vap.} - RT)\right]^{-1}, \quad (17)$$

where κ_0 is the isothermal compressibility for the fluid of hard spheres and expressed by

$$\kappa_0 = \left(\frac{V}{NkT}\right)\left[\frac{(1-y)^2}{(1+2y)}\right]^2. \quad (18)$$

The first term in $(\kappa_T)^{-1}$ in Eq. (17) comes from the repulsion of hard spheres in thermal motions and the second term from the attraction between molecules.

Using Eqs. (17) and (18), we have calculated the values of compressibility of various liquids and the results are given in Table 3. As the values of a we have used those estimated from the results of studies of X-ray diffraction,[29,30] second virial coefficient,[2] viscosity[2] and molecular structure theory,[31] noting that the estimated values of a should be consistent with the values of y determined through Eq. (12). The agreement between calculated and observed values is very good. Equations (17) and (18) could therefore be used for determination of the equivalent hard sphere diameter of molecules.

Table 3. Compressibility

	a (Å)	n	T (K)	y	$\kappa_{obs.}$ (10^{-12} dyn^{-1} cm^2)	$\kappa_{calc.}$ (10^{-12} dyn^{-1} cm^2)
Ar	3.40	1.00	87.3	0.43	215.2	226.8
CCl_4	5.40	1.09	298	0.51	106.7	90.9
C_6H_6	5.20	1.05	293	0.50	101.5	101.1
C_6H_{12}	5.60	1.00	298	0.51	116.0	95.1

Appendix

A similar equation to Eq. (5) has been used by Longuet-Higgins and Widom[22] and also by Miller[23] for a discussion of thermodynamic properties of fluids. We have undertaken here to give a theoretical basis for the approximation.

Using the exact solution of Percus-Yevick equation for the fluid of hard spheres together with the mean spherical model (MSM) approximation,[24] we postulate as follows as regards the direct correlation function $c(r)$,

$$\begin{aligned} c(r) &= c_0(r) \quad \text{for } r \leq a \\ c(r) &= -u(r)/kT \quad \text{for } r > a, \end{aligned} \quad (A1)$$

where $c_0(r)$ is Wertheim-Thiele's analytical solution.

The MSM approximation assumes (1) the Ornstein-Zernike equation, (2) $g(r)=0$ for $r<a$ and (3) $c(r)=-u(r)/kT$ for $r>a$. When $u(r)\to 0$, the MSM approximation is reduced to the Percus-Yevick equation for the fluid of hard spheres with no attraction. Thus the direct introduction of Wertheim-Thiele's solution to MSM as in Eq. (A1) is reasonable as a zeroth order approximation, if $u(r)$ is not much larger than kT. In the approximation Eq. (A1), the change of $c(r)$ from $c_0(r)$ for $r \leq a$ which results from the presence of $u(r)$ for $r>a$ is ignored.

The compressibility equation is expressed as

$$\partial(p/kT)/\partial\rho = 1 - \rho\int c(r)\mathrm{d}r. \quad (A2)$$

Inserting Eq. (A1) into Eq. (A2), we obtain

$$\begin{aligned} \partial(p/kT)/\partial\rho &= 1 - \rho\int_0^a c_0(r)4\pi r^2\mathrm{d}r + \frac{\rho}{kT}\int_a^\infty u(r)4\pi r^2\mathrm{d}r \\ &= \frac{(1+2y)^2}{(1-y)^4} + \frac{\rho}{kT}\int_a^\infty u(r)4\pi r^2\mathrm{d}r. \end{aligned} \quad (A3)$$

Integrating with respect to ρ, we have

$$p/\rho kT = \frac{1+y+y^2}{(1-y)^3} + \frac{2\pi\rho}{kT}\int_a^\infty u(r)4\pi r^2\mathrm{d}r. \quad (A3)$$

If we put $(2\pi/kT)\int_a^\infty u(r)4\pi r^2\mathrm{d}r \equiv$ const.

Eq. (A4) becomes identical with that used by Longuet-Higgins & Widom, and also by Miller.

Circular Dichroism in Lyotropic Liquid Crystals of Polyglutamate Solutions

Nobuaki TSUCHIHASHI*, Hiroyuki NOMORI, Masahiro HATANO, and Shigeo MORI**

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

**Faculty of Engineering, Tohoku University, Aramaki, Sendai 980*

***Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki, Kanagawa 210*

(Received March 14, 1974)

A poly-γ-ethyl-L-glutamate solution with a cholesteric color exhibits a circular dichroism due to the selective reflection of circularly polarized light of one sense by the cholesteric helical structure existing in the solution. On the other hand, an induced circular dichroism is observed in the wavelength region corresponding to the absorption bands of an achiral dye molecule when the molecule is dissolved in the poly-γ-benzyl-D-glutamate liquid crystalline phase. The two modes of circular dichroism are correlated to the structure and the chirality of the cholesteric phase of concentrated polyglutamate solutions.

Polyglutamate having α-helical conformation forms a lyotropic liquid crystalline phase when dissolved in various organic solvents in concentrations exceeding a critical value.[1,2] Robinson *et al.*[2] have extensively studied the structure of the liquid crystalline phase, and suggested two types of supramolecular structure, cholesteric and nematic, for the lyotropic liquid crystalline phase of a polyglutamate solution.

The cholesteric structure, which is the most common for the liquid crystalline phase of the polyglutamate solution, has been described as follows. In any given domain of the solution, rigid rod-like polyglutamate molecules are packed in a set of equispaced parallel planes in which the polyglutamate molecules lie parallel to one another. The molecules in one plane have a slight twist relative to those in adjacent planes about an axis of torsion perpendicular to the set of planes. Incorporation of successive layers of appropriately oriented polyglutamate molecules results in a helical structure, causing an extraordinarily high optical rotatory power to the solution. The sign of the optical rotation changes with variation of the solvent specics, reflecting the inversion of the helical sense by the variation of the solvent species.[2a,2e] Robinson *et al.* presumed this optical rotation to be due to the selective reflection of circularly polarized light of one sense by the helical structure. They demonstrated by their experiment using a quarter-plate that the light reflected by the concentrated poly-γ-ethyl-L-glutamate solution in ethyl acetate is right circularly polarized.[2e]

The nematic structure has been elucidated as the untwisted array of equispaced parallel planes in which polyglutamate molecules are packed parallel to one another; the nematic structure is regarded as the cholesteric structure where the pitch of the helix is expanded to infinity, no optical rotatory power being caused. The nematic structure can be realized by dissolving polyglutamate in a particular solvent mixture[2d] or by untwisting the cholesteric structure by the application of magnetic field.[3]

Saeva and Wysocki[4,5] reported that the achiral dye molecule becomes optically active when the dye molecule is dissolved in a thermotropic cholesteric phase, and in this case, a strong circular dichroism (CD) is induced in the wavelength region of the absorption (AB) bands of the dye molecule. Saeva[6] also indicated that the induced circular dichroism of the achiral molecule in the thermotropic liquid crystalline phase can be used as a probe to determine the existence and the chirality of the cholesteric liquid crystalline phase.

We detected the circular dichroism corresponding to the optical rotation due to the selective reflection of circularly polarized light of one sense by the cholesteric helical structure in the liquid crystalline phase of the polyglutamate solution. We found the induced circular dichroism due to the achiral molecule dissolved in the lyotropic liquid crystalline phase of the polyglutamate solution. The two modes of circular dichroism are discussed in relation to the structure and the chirality of the cholesteric liquid crystalline phase of the concentrated polyglutamate solution.

Experimental

Materials. A lyotropic liquid crystal with a cholesteric color was obtained by the polymerization of 27 g of *N*-carboxyanhydride of γ-ethyl-L-glutamate in 50 ml of vinyl acetate using a mixture of triethylamine and β-dimethylaminoethanol (95 : 5 in molar ratio) as an initiator. The resulting solution was directly used for CD measurement.

Poly-γ-benzyl-D-glutamate (PBDG) was obtained by the polymerization of *N*-carboxyanhydride of γ-benzyl-D-glutamate, the degree of polymerization of the resultant polymer being 910. The liquid crystalline phase of the PBDG solution was formed when PBDG was dissolved in dichloromethane, chloroform or 1,1,2,2-tetrachloroethane at a concentration of 0.75 M of the glutamyl residue. Achiral dyes were added to this concentrated PBDG solution. Acridine orange (AO) was purified by the method described elsewhere.[7] The solvents used were spectral grade ones and used without further purification.

Methods. The CD measurement of the poly-γ-ethyl-L-glutamate (PELG) solution was carried out with a JASCO MOE-7 magnetorotatory dispersion spectropolarimeter with a CD attachment. The CD and the AB spectra of the systems of the dyes dissolved in the PBDG solution were recorded on a JASCO J-20A or J-15 spectropolarimeter. In all cases, the sample solutions were slowly introduced into a quartz cell having a 0.5 mm path length.

Results and Discussion

Circular Dichroism Due to the Selective Reflection by the Cholesteric Structure. Robinson *et al.* found a cholesteric color in the PELG solution in ethyl acetate, where the cholesteric pitch is comparable with the

wavelength of the visible light. They demonstrated that the origin of this cholesteric color is the selective reflection of circularly polarized light of one sense by the cholesteric pitch.[2d,2e]

We found a brilliant iridescent color also for the PELG solution in vinyl acetate. This gives evidence to the existence of a cholesteric structure in this solution. The solution was thus expected to exhibit a circular dichroism due to the selective reflection by the cholesteric structure. A positive CD band was observed for the PELG solution in the visible region with a peak around 800 nm (Fig. 1). This is attributable to the selective reflection of circularly polarized light of one sense by the cholesteric pitch since no AB band exists in this wavelength region for any component of the PELG solution.

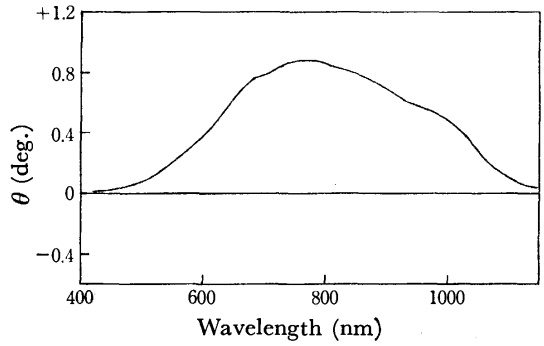

Fig. 1. CD spectrum due to the selective reflection of the lyotropic cholesteric phase of the PELG solution in vinyl acetate.

The circular dichroism due to the selective reflection by the cholesteric structure for the lyotropic liquid crystalline phase enables us to determine the cholesteric helical sense on the basis of the observed CD sign in comparison with the results of Saeva and Wysocki[4-6] concerning the thermotropic liquid crystalline phase, where the sign of the circular dichroism due to the selective reflection by the cholesteric structure is positive for the right-handed cholesteric helical sense and negative for the left-handed one. The PELG solution in vinyl acetate is concluded to be the cholesteric phase of right-handed helical sense, since the solution displays a positive CD band due to the selective reflection by the cholesteric structure.

The magnitude of a CD band is defined as the absorbance for the left circularly polarized light minus that for the right circularly polarized light. The sample in the Robinson experiment would thus exhibit a negative CD band, since the light reflected by their sample was right circularly polarized, indicating that the apparent absorbance for the right circularly polarized light is larger in their sample. The CD sign, the cholesteric helical sense of the PELG solution in vinyl acetate, is opposite to that of the Robinson sample, while polyglutamate in both studies is the same in configuration. It has been confirmed by observation of the circular dichroism due to the selective reflection of circularly polarized light of one sense by the cholesteric helical structure that the helical sense of the lyotropic cholesteric structure in the PELG solution depends on the solvent in which polyglutamate is dissolved. An analogous situation has already been shown by the optical rotatory measurements for the PBLG cholesteric phase.[2a,2e]

We have the well-known relationship between the cholesteric pitch P and the wavelength of the maximum reflectivity λ_m:

$$\lambda_m = n \times P$$

where n is the average refractive index of the cholesteric phase. The value of λ_m can be determined from the wavelength of the CD peak due to the selective reflection by the cholesteric structure. Thus, the cholesteric structure in the PELG solution in vinyl acetate is found to have a cholesteric pitch *ca.* 570 nm, the value of n being 1.4.

Induced Circular Dichroism of Dye Molecules in PBDG Liquid Crystalline Phase. We found that achiral dye molecules become optically active when they are dissolved in the PBDG liquid crystalline phase and that definite CD bands appear in the wavelength region where the AB bands of the dyes exist. Acridine orange gave a large positive circular dichroism around 500 nm when dissolved in the concentrated solution of PBDG in 1,1,2,2-tetrachloroethane. Positive CD peaks were also observed for *N*-ethylcarbazole in the solution of PBDG in tetrachloroethane in near ultraviolet region. Typical CD spectra of the systems of AO and *N*-ethylcarbazole dissolved in the concentrated PBDG solution are given in Figs. 2 and 3, respectively, together with their AB spectra. Due to the existence of many strong AB bands in the systems, CD measurement in a wavelength region shorter than 280 nm could not be carried out successfully.

It was confirmed by CD measurements for the concentrated PBDG solution without dye molecules that no CD band due to the selective reflection exists in the wavelength region in which the CD bands due to the

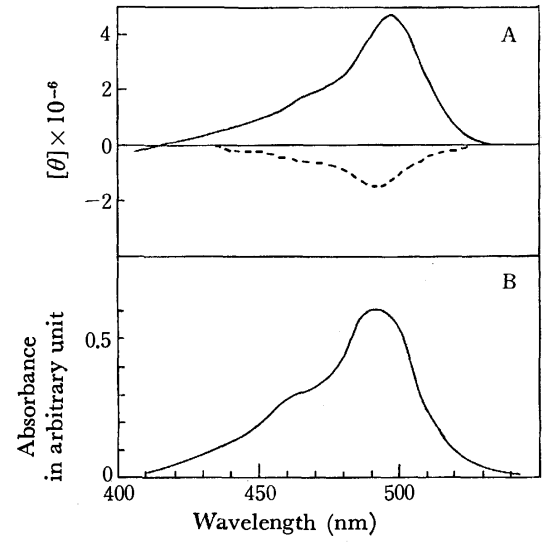

Fig. 2. (A) CD spectra of AO induced in the cholesteric phases of the PBDG solutions in tetrachloroethane (——), and in dichloromethane (------) and (B) absorption spectrum of AO in the PBDG solution in tetrachloroethane. [θ] was calculated on the basis of the concentration of AO.

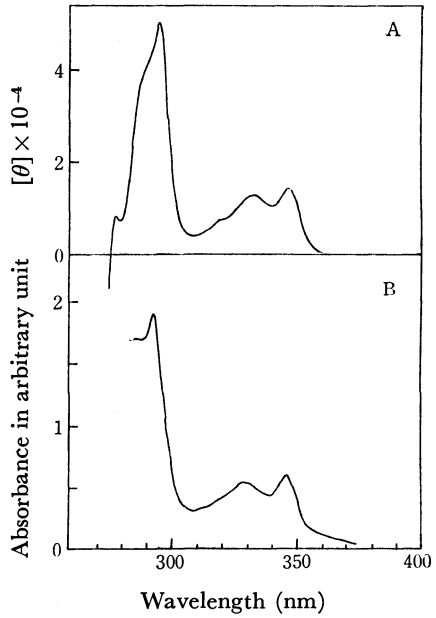

Fig. 3. (A) CD spectrum of *N*-ethylcarbazole induced in the cholesteric phase of the PBDG solution in tetrachloroethane and (B) absorption spectrum of *N*-ethylcarbazole in the PBDG solution in tetrachloroethane. $[\theta]$ was calculated on the basis of the concentration of *N*-ethylcarbazole.

dye molecules appear. No CD band could be detected in the dilute solution of PBDG containing AO. The circular dichroism observed for the system of AO dissolved in the cholesteric liquid crystalline phase of the PBDG solution in dichloromethane or tetrachloroethane disappeared when the cholesteric structure in this system was untwisted to the nematic structure by the application of magnetic field.

The possibility that the dissymmetric field of the α-helix constituting the cholesteric phase causes the circular dichroism can be eliminated. We see that the circular dichroism observed for the achiral dyes dissolved in the concentrated solution of PBDG are induced by the dissymmetric field effect of the cholesteric helical structure formed in these systems on the electronic transitions of the dyes. This is similar to cases of dyes buried in thermotropic liquid crystalline phases.[4-6,8]

Thus, the achiral dyes in the cholesteric liquid crystalline phase of the PBDG solution are intercalated in the helical structure in this phase and are oriented relative to this helical structure. As a result, they appear in the dissymmetric field due to the cholesteric helical structure.

The CD bands observed for *N*-ethylcarbazole in the PBDG solution in tetrachloroethane is simply positive in sign in the wavelength region 280—370 nm (Fig. 3). This is not the case in Saeva's results[5] where the CD curve for *N*-ethylcarbazole in the thermotropic liquid crystalline phase consists of two regions with opposite signs. As Sackmann and Voss[8] indicated, the CD sign depends on the polarization character of the corresponding electronic transition of the dye molecule only when the helical arrangement of the dye molecule along the cholesteric helical axis is realized. Our results show that such a helical arrangement is absent for the dye molecule in the lyotropic liquid crystalline phase.

A similar induced circular dichroism was reported recently by Saeva and Olin,[9] their results agreeing with ours.

Relations between the CD Profile and the PBDG Cholesteric Structure. The CD spectra of AO were observed not only in the solution of PBDG in tetrachloroethane but also in the solutions of PBDG in dichloromethane and in chloroform. The CD sign observed for AO around 500 nm changed with solvent, being negative in the dichloromethane solution and positive in the tetrachloroethane solution. The CD sign in the region for the chloroform solution turns positive from negative with time. For all the cases investigated, the CD magnitude around 500 nm increased when the solution was left to stand after being introduced into the observation cell. It took several hours or even days for the equilibration of the CD magnitude. Figure 4 shows the change of the CD magnitude with time for AO in the solution of PBDG in tetrachloroethane. Such a time dependent character of the circular dichroism was also observed for the system containing *N*-ethylcarbazole.

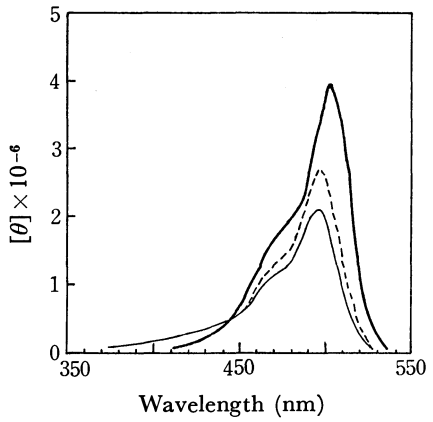

Fig. 4. Change in the CD magnitude observed for AO in the cholesteric phase of the PBDG solution in tetrachloroethane; (——) recorded immediately after the introduction of the sample into the observation cell, (------) 1 hour after and (——) 2 days after. $[\theta]$ was calculated on the basis of the concentration of AO.

In the course of maturation of the PBDG cholesteric phase in the observation cell, the microscopic observation showed that the cholesteric phase which had been disturbed through the introduction into the cell attained to its equilibrated state, exhibiting the retardation lines characteristic of the cholesteric phase on a time scale comparable with that of the change in CD magnitude. It is assumed that the recovery of the PBDG cholesteric structure to its equilibrium state increases the CD magnitude of the bands. Such a long relaxation is observed also in the NMR studies[3] on the magnetic field induced reorientation of the PBLG liquid crystalline phase and regarded as characteristic of polyglutamate liquid crystalline solutions.

We postulate that the circular dichroism is brought

about by the dissymmetric field of the cholesteric helix. The sign of the dissymmetric perturbation from the helical structure is known to change by the inversion of the helical sense. Thus, the fact that the sign of the circular dichroism induced for the dye molecule in the solution of PBDG in dichloromethane is opposite to that in tetrachloroethane leads to the conclusion that the helical sense of the cholesteric structure is inversed by the change of the solvent from dichloromethane to tetrachloroethane. The cholesteric helical sense is determined not only by the steric isomerism of polyglutamate in the solution but also by the mode of the interaction of polyglutamate with the solvent. Inversion of the CD sign with time for AO in the solution of PBDG in chloroform suggests that the interaction between PBDG and chloroform reduces the energy difference between the cholesteric helical senses in this system.

We could detect no circular dichroism due to the selective reflection for the PBDG cholesteric phase as a result of very large cholesteric pitch in this phase. Robinson *et al.* reported that the sign of the optical rotation is positive for the cholesteric liquid crystalline phase of the solution of PBLG in dichloromethane.[2a,2e] This might show that there exists a negative Cotton effect at the longer wavelength region corresponding to the cholesteric pitch band. If so, the sense of the cholesteric helix for the solution of PBLG in dichloromethane is left-handed. We can therefore expect the right-handed helical sense to exist in the PBDG cholesteric phase in dichloromethane. On combining this and the above-mentioned result concerning the induced circular dichroism, the negative sign of the circular dichroism induced for the dye in the PBDG cholesteric phase in dichloromethane is taken as diagnostic of the right-handed cholesteric helical sense in this system.

Thus, the inversion of the cholesteric helical sense is demonstrated again by the observation of the sign of the induced circular dichroism for the achiral dyes dissolved in the cholesteric liquid crystalline phase of polyglutamate.

The authors are grateful to Professor Kunio Seto for his encouragement throughout this investigation and to Professors Hiroshi Kojima and Kimiyoshi Goto for the measurements of circular dichroism with a JASCO MOE-7 magnetorotatory dispersion spectropolarimeter. They are also indebted to Mr. Yukio Sato for the purification of AO and for valuable discussions.

An MO Theoretical Investigations of the Electronic Spectra of Divalent Sulfur Compounds

Hideki SAKAI, Tokio YAMABE, Hiroshi KATO*, Shinichi NAGATA, and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

**College of General Education, Nagoya University, Nagoya 464*

(Received March 20, 1974)

The singlet transition energies and oscillator strengths of several divalent sulfur compounds are calculated by the semi-empirical ASMO–SCF method. It is shown that the UV absorption bands with transition energies of 5—6 eV observed in these sulfur compounds can be assigned to n-σ_1*, n-σ_2*, or σ-σ_1*, implying that the 3d orbitals of the sulfur atom do not play an important role in these electronic transitions or may contribute absorption bands with higher transition energies.

It is well known that a number of divalent sulfur compounds have characteristic electronic absorption bands in the near-ultraviolet region; they have often been identified as n-σ*, σ-σ*, n-3d, n-4s, *etc.* In 1965, Clark *et al.*[1] obtained satisfactory vacuum-ultraviolet spectra of several divalent sulfur compounds, *i.e.*, hydrogen sulfide, alkyl sulfides, cyclic alkyl sulfides, and thiols, and tried to give their assignments on the basis of a simple schematic molecular orbital (MO) diagram according to the Walsh rule. Subsequently, several calculations of their assignments have been carried out by semi-empirical MO methods.[2–4] The results obtained, however, show disagreement with each other in their assignments, as will be shown in this text.

In the present paper, we intend to describe some investigations concerning the singlet transition energies and the assignments of some saturated divalent sulfur compounds based on the MO calculations of the semi-empirical ASMO–SCF method.

Method

The calculations are carried out by the semi-empirical ASMO–SCF method,[5] where the approximation of the zero differential overlap is adopted for valence electron system; the contributions of the 3d atomic orbitals of the sulfur atom are also included. In parametrizing the core resonance integrals,

$$H_{rs} = -KS_{rs}(I_r+I_s)/2,$$

where the notations are the same as those in Ref. 5; we adopted a value of 0.8 for the K constant.

The compounds treated in this work are H_2S, CH_3SH, $(CH_3)_2S$, C_2H_4S, and C_3H_6S. Their geometries are shown in Table 1, where tetrahedral angles are assumed for the alkyl groups. The ultraviolet (UV) absorption spectra of these compounds observed by Clark *et al.*[1] are referred for the sake of comparison with the calculated values.

TABLE 1. MOLECULAR STRUCTURE OF SULFUR COMPOUNDS USED FOR CALCULATIONS

Compound	Bond angle RSR′ (deg)	Bond distance H–S (Å)	Bond distance C–S (Å)
H_2S	92.2	1.35	
CH_3SH	100.0	1.33	1.82
CH_3SCH_3	100.0		1.82
C_2H_4S	48.4		1.82
C_3H_6S	78.0		1.82

Results and Discussion

H_2S. The results of H_2S are presented in Fig. 1. According to the present calculations, the lowest singlet transition, $^1A_2$ (b_1—b_2*), is symmetry-forbidden and may not be detectable by UV spectroscopy, while the next one, $^1B_1$ (b_1—a_1*), with the transition energy (ΔE) of 6.54 eV and the oscillator strength (f) of 0.037 may be reasonably identified as the first absorption band of H_2S (ΔE=6.32 eV, f=0.04) observed by Clark *et al.*[1] At first they assigned it to the $^1A_1$ (a_1—a_1*) transition according to the Walsh diagram; subsequently, though, Thompson *et al.*[3] calculated the transition energy by their own semi-empirical method and predicted that the excitation must be that of an electron from the lone-pair orbital to either the 3d or the 4s orbital to be significantly atomic in nature (*i.e.*, the Rydberg state). However, their oscillator strengths are quite small ($f=4\times10^{-6}$ for the 3d and 0.006 for the 4s orbital) compared with the observed value (f=0.04), whereas our calculation gives a reasonable oscillator strength (0.037).

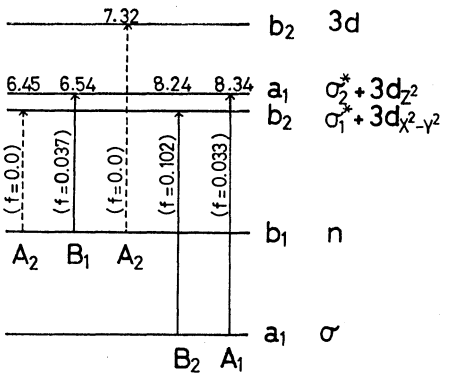

Fig. 1. Singlet transitions of H_2S. Observed values;[1] 6.32 eV (f=0.04), 7.85, 8.02.

The orbital (a_1*) to which the excitation occurs shows an antibonding character, although it includes a 33% contribution from the 3d orbital. Indeed, preliminary calculations excluding 3d orbitals show no significant change for this transition in its transition energy (0.14 eV) and its oscillator strength, implying

that the 3d orbitals do not essentially change the antibonding nature of the σ* level.

On the other hand, in their non-empirical calculations Polezzo *et al.*[6] and Hillier *et al.*[7] assigned the lowest forbidden transition, $^1A_2$, with excitation energies of 6.70 and 6.51 eV respectively, to the observed lowest transition of 6.32 eV. It may be more reasonable, however, to assign it to $^1B_1$ (b_1—a_1*), because the $^1A_2$ transition is forbidden and, therefore, is not expected to be observed, while the oscillator strength of $^1B_1$ (f=0.037) is in good agreement with the observed one (f=0.04).

It is well known that there exists a vibrational structure in this absorption band; from their analysis of the vibrational structure, Thompson *et al.*[3] concluded that it is due to the symmetrical bending mode and that the band is the transition from the lone-pair orbital to the 3d or the 4s orbital because of a slight anharmonicity. Moreover, they have insisted that if the transition were one to the antibonding orbital, there would be more anharmonicity and other stretching modes in the vibrational structure. Such would also be expected if the transition were from the bonding orbital to the antibonding orbital. However, there is evidence that the structure of the excited H_2S molecule (H_2S*), which corresponds approximately to the transition from the lone-pair orbital, is not altered so much as to give a considerable anharmonicity in comparison with the ground-state H_2S molecule. That is, the structure of the ground-state H_2S^+ cation radical,[8] which is probably similar to H_2S* with respect to its molecular structure, is almost unchanged from that of H_2S, showing that a large anharmonicity in the vibrational structure is unnecessary.

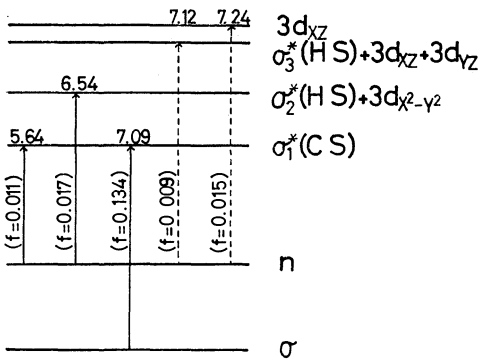

Fig. 2. Singlet transitions of CH_3SH. Observed values;[1] 5.21 (log ε=2.30), 6.08 (3.45), 6.74 (3.30).

CH_3SH. The results for CH_3SH are presented in Fig. 2. According to our calculations, CH_3SH has three low-lying singlet transitions; they are, in the order of increasing energy: n-σ_1* (from the lone pair to the C–S antibonding orbital), n-σ_2* (from the lone pair to the S–H antibonding orbital), and σ-σ_1* (C–S excitation). The lower n-σ_1* transition with a CH_3SH value of 5.64 eV corresponds to the forbidden transition, $^1A_2$ (b_1—b_2*), of H_2S. Clark *et al.* assigned the observed three lowest transitions of CH_3SH, 5.21, 6.08, and 6.70 eV, to the n-σ* type, the intramolecular charge transfer (from the C–S bonding orbital to the H–S antibonding orbital), and the C–S excitation respectively. Their assignments for the first and the third transitions are in agreement with ours. The second, however, is not in agreement; *i.e.*, our result shows that the C–T band has a higher energy (ΔE= 7.87 eV) than the C–S excitation and that in addition, another n-σ* (H–S) transition exists (ΔE=6.54 eV) between them. On the other hand, the calculations excluding the 3d orbitals showed almost no change in the first and the third transitions, though the second one is changed in the ordering of the energy levels; the calculations show an energy shift of some extent (ΔE=7.47 eV, f=0.067). It can easily be seen from these results that the σ-σ* transition seems not to be affected considerably by the basis set of calculations with respect to the energy and the intensity, so it may be reasonabe to assign the σ-σ_1* and the n-σ_2* transitions to the second or the third band of the observed spectra of CH_3SH.

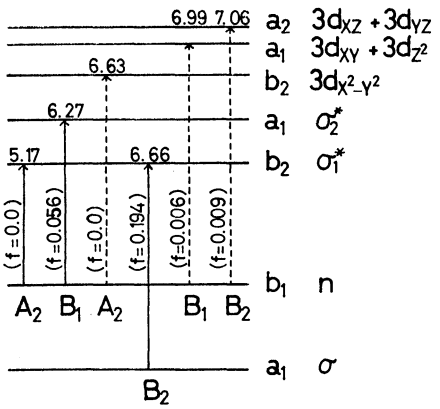

Fig. 3. Singlet transitions of $(CH_3)_2S$. Observed values;[1] 5.20 (very weak), 5.61 (f=0.016), 6.14 (f=0.06).

Alkyl Sulfide. Recently, Rosenfield *et al.*[9] have reported their studies of the rotational strengths of the alkyl sulfides, and before their work there were a few discussions of the transitions of the alkyl sulfides (*e.g.*, Carroll *et al.*[2] and Clark *et al.*);[1] their results are minutely discussed in the paper of Rosenfield *et al.* Our results for $(CH_3)_2S$ are presented in Fig. 3. According to our calculations, it can be seen that the assignments for the first two bands, which are the b_1—b_2* (n-σ_1*) transition and the b_1—a_1* (n-σ_2*) transition, are in agreement with those of Rosenfield *et al.* Furthermore, they have assigned the third band to the n-3d transition on the basis of the optical-active data and the oscillator strength. According to our results, the third is the b_1—b_2* (n-3d) transition at 6.63 eV; this is, however, symmetry-forbidden, so the third band in the UV spectrum of this compound may be assigned to the next strong a_1—b_2* (σ—σ_1*) transition. Moreover, it is clear from the studies of Rosenfield *et al.* of the electric and magnetic moments of the transitions that the a_1—b_2* transition may be optical-active when the sulfide chromophore is in a dissymmetrical field. Therefore, it seems that the observed moderately strong absorption band at 6.14 eV can reasonably be assigned to the a_1—b_2*, but not the n—3d, transition.

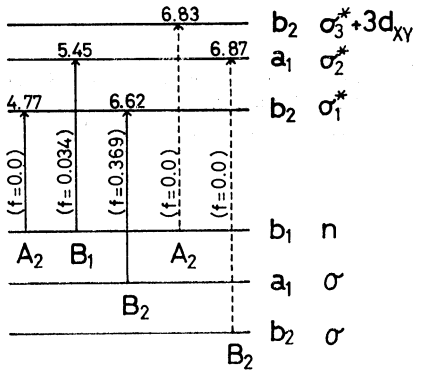

Fig. 4. Singlet transitions of C_2H_4S. Observed values;[1] 4.80 ($\log \varepsilon = 1.30$), 5.10 (1.32), 5.69 (2.30), 5.85 (3.60), 5.99 (3.60), 6.11 (3.60).

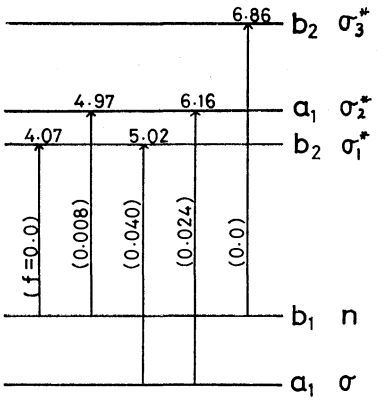

Fig. 5. Singlet transitions of C_3H_6S. Observed values;[1] 4.46 ($\log \varepsilon = 1.00$), 4.71 (1.11), 5.58 (3.30), 5.83 (3.11), 6.20 (3.45).

Cyclic Sulfides. The results of C_2H_4S are presented in Fig. 4. The calculated lowest singlet transition energies are 4.77, 5.45, and 6.62 eV, which correspond to the b_1—b_2* (n—σ_1*), b_1—a_1* (n—σ_2*), and a_1—b_2* (σ—σ_1*) transitions respectively. Those σ* levels (b_2* and a_1*) at which the transitions occur bear little d-character. The calculated transitions can reasonably be assigned to the absorption spectrum of C_2H_4S; *i.e.*, the first band, which is characterized by the transition energy of 5.1 eV with a very weak intensity ($\log \varepsilon_{max} = 1.3$) in solution, may be assigned to the b_1—b_2* (n—σ_1*) transition, because, although the transition is apparently symmetry-forbidden, the ring distortion, which may occur as a result of excitation in such a strained molecule, has little effect on the oscillator strength. According to our additional MO calculations, in which the CSC ring is distorted by changing the length of one S–C bond only, the oscillator strength of the n—σ_1* transition is about 10^{-4}; this value does not change greatly with the extent of distortion. The vapor-phase UV spectrum of this transition band, however, shows two broad peaks at 4.80 and 5.10 eV, while in the solution spectrum[14] only one is observed in the same region. For these two peaks, Williams *et al.*[4] have assigned two different transitions based on their CNDO/2 calculation including 3d orbitals. However, it is obvious from the CD and ORD spectra of the optical-active steroidal episulfides[12,13] that there is only one electronic transition band in this region. The splitting of this band in the vapor-phase UV spectrum is probably due to the non-vertical transition, as was recently pointed out by Strausz *et al.*[10] based on the non-empirical MO calculations. The second lowest transition, b_1—a_1* (n—σ_2*), may be easily assigned to the observed absorption of 5.69 eV. The third transition, a_1—b_2* (σ—σ_1*), might be assigned to the three observed peaks, 5.85, 5.99, and 6.11 eV, which are probably the vibrational splittings corresponding to the CH_2 bending (1120 cm^{-1} in the Raman spectrum[11]) or the ring deformation (1040 cm^{-1} in the Raman spectrum).

The results for C_3H_6S are presented in Fig. 5. The two lowest observed absorption bands, 4.46 and 4.71 eV, can also be assigned to the symmetry-forbidden b_1—b_2* (n—σ_1*) transition of 4.07 eV, while the other transitions may be assigned to the b_1—a_1* (n—σ_2*), a_1—b_2* (σ—σ_1*), and a_1—a_1* (σ—σ_2*) transitions in the order of increasing energy. The σ* levels (b_1* and a_1*) at which these transitions occur have little d-character. For this compound, Williams *et al.*[4] have also given assignments which are different from the situation with C_2H_4S; *i.e.*, they assigned the first two absorption bands as one electronic transition. Their result for the first transition is equivalent to ours, but they seem to overestimate the role of the 3d orbitals; *i.e.*, their result for the lowest vacant orbital shows 30% of the 3d orbital contribution. The discrepancy is due to the difference in the parametrizations adopted for the MO calculations.

Conclusion

It has been shown that the saturated divalent sulfur compounds have similar electronic transitions in the lower-energy region. They are usually the n—σ_1*, the n—σ_2*, and the σ—σ_1* transitions, although there are a few exceptions caused by the substituents on the sulfur atom or the molecular symmetries. The 3d orbitals of the sulfur atom may not play an important role in the lower-energy transitions.

The authors are indebted to the Data Processing Center of Kyoto University, where the numerical calculations have been performed.

Charge-transfer and Proton-transfer in the Formation of Molecular Complexes. XI.[1] Phase Transitions in Hertel's Picric Acid Complexes

Yoshio MATSUNAGA, Eiji OSAWA, and RYUZO OSAWA*

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 9, 1974)

The isomerization from true phenolates to charge-transfer complexes by phase transitions in Hertel's five amine–picric acid complexes was confirmed by spectroscopic examinations. The amines and the estimated heats of transition were as follows: *o*-bromoaniline, 6.7; *o*-iodoaniline, 6.2; 1-chloro-2-naphthylamine, 8.0; 1-bromo-2-naphthylamine, 8.2; 1,6-dibromo-2-naphthylamine, 3.3 kcal/mol. The transition temperatures and/or the heats in the naphthylamine complexes were shown to be markedly reduced by crushing the crystals. The charge-transfer complexes have electrical resistivities lower by a factor of many decades than the isomeric phenolates. Phase transitions without isomerization were found in the metastable 1-halo-2-naphthylamine complexes of the charge-transfer type.

In connection with our work on new complex isomers,[1–3] a physicochemical study of the isomeric pairs of Hertel's five picric acid complexes has been undertaken. Phase transitions accompanied by a color change from yellow to red in the solid phase were found by Hertel in the complexes with *o*-bromo- and *o*-iodoanilines and 1-chloro-, 1-bromo-, and 1,6-dibromo-2-naphthylamines.[4] Some years ago, Briegleb and Delle carried out spectroscopic studies of the isomeric pairs in the complexes of the last two amines.[5,6] Their conclusions that the yellow low-temperature forms are true phenolates and that the red high-temperature forms are charge-transfer (CT) complexes are in accordance with ours for some new complex isomers. However, the vibrational spectra of the low-temperature forms presented by Briegleb and Delle show patterns due to the NH_2 groups which one would not expect in true phenolates. Consequently, spectroscopic examinations of all the above-mentioned pairs were performed in the present work. Then, changes in the enthalpy and in the electrical resistivity by the transitions were studied in order to find additional manifestations of the complex isomerization. Anomalous changes in the electrical resistivity have been found at the transition temperatures of a number of organic materials—*e.g.*, hexamethylbenzene,[7,8] phenanthrene,[9,10] phenanthrene–picric acid,[11] and some tetracyanoquinodimethane anion-radical salts.[12–14] As it has been recognized that a lowering of resistivity is generally associated with complex formation,[15] the change at the transition accompanied by the isomerization from a true phenolate to a CT complex might be quite drastic.

Experimental

Materials. The picric acid and the *o*-haloanilines were commercially obtained. The derivatives of 2-naphthylamine were prepared as has been described in a previous paper of ours.[3] The complexes were precipitated by mixing component compounds which had been separately dissolved in chloroform or methanol. The 1,6-dibromo-2-naphthylamine complex was obtained as yellow fine crystals, but it slowly turned reddish brown upon filtration, as has been reported by Hertel.[4] The complex was redissolved in methanol, and then the solution was slowly evaporated to dryness by letting it stand at room temperature. In this way, the yellow form could be isolated.

Measurements. The spectroscopic, calorimetric, and X-ray measurements were made as has been reported in previous papers of the present series.[2,3] The procedure used for recording the electrical resistivity curve has been described in a paper by Koizumi and Matsunaga.[11]

Results and Discussion

Vibrational Spectra. As an example, Fig. 1 presents the spectra of two forms of the *o*-bromoaniline complex. The red form was obtained by the solidification of the fused sample between rocksalt plates. The presence of the NH_3^+ group in the yellow form is clearly indicated by broad bands appearing at 2575 and 2825 cm^{-1}. Upon transition, they are replaced by rather sharp bands located at 3375 and 3475 cm^{-1}. The latter pattern arises from the stretching vibration of the NH_2 group.

The spectra of the 1-bromo-2-naphthylamine complex are shown in Fig. 2. Unlike the spectrum of the yellow form reported by Briegleb and Delle, our spectrum

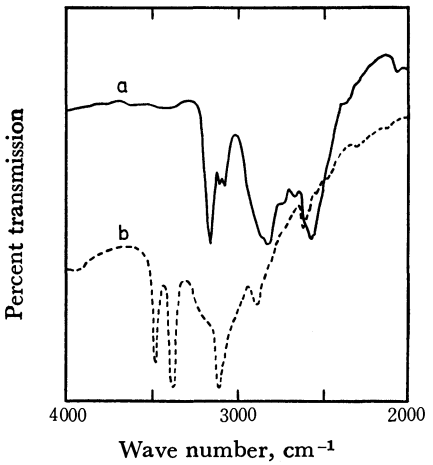

Fig. 1. Vibrational spectra of a) the yellow form and b) the red form of the *o*-bromoaniline–picric acid complex.

* Present address: Bridgestone Tire Co., Kodaira, Tokyo.

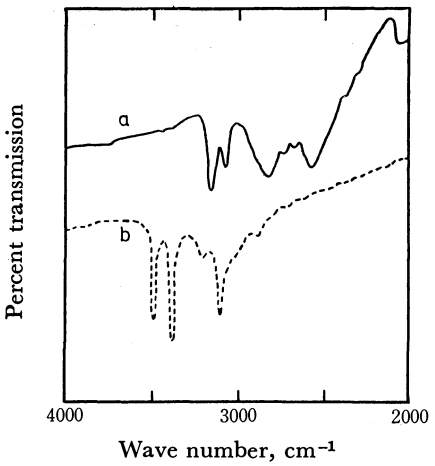

Fig. 2. Vibrational spectra of a) the yellow form and b) the reddish brown form of the 1-bromo-2-naphthylamine–picric acid complex.

shows no band assignable to the NH_2 group. This disagreement may be attributed to the extent of dissociation of the complex on the surface of the alkali halides. One may suppose that the complex in a potassium bromide disc employed by the German workers was well dispersed; therefore, an appreciable amount of the free amine might exist in equilibrium. On the other hand, the complex examined by our technique may be essentially free from such a complication because of its small surface area. It must be added that no color change could be observed upon heating above the transition temperatures when we examined the *o*-haloaniline complexes by the KBr disc technique. The presence of the proton-transfer from picric acid to the amine molecule in the low-temperature form and its absence in the high-temperature form were similarly confirmed for the other combinations.

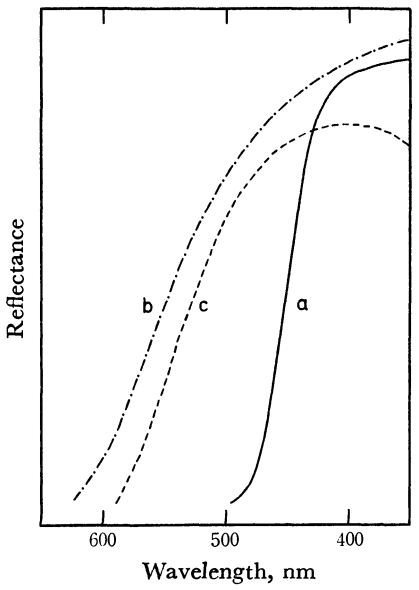

Fig. 3. Reflectance spectra of a) the yellow form and b) the red form of the *o*-bromoaniline–picric acid complex and c) the corresponding *s*-trinitrobenzene complex.

Electronic Spectra. Briegleb and Delle have shown that the absorption bands characteristic of the high-temperature forms of the bromo- and dibromo-naphthylamine complexes are similar to the CT absorption bands in the corresponding *s*-trinitrobenzene complexes. As the electron-acceptor strength of picric acid is nearly the same as that of *s*-trinitrobenzene, the similarity in the spectrum has been considered as evidence that the high-temperature forms of the picric acid complexes are of the CT type. In Fig. 3, the spectra of the yellow and red forms of the bromoaniline-picric acid are compared with that of the trinitrobenzene complex. Here again, the absorption band which appears when the complex is heated above the transition temperature is located close to that of the CT absorption band in the trinitrobenzene complex. In the same way, the appearance of CT absorption in the high-temperature forms was firmly established for all the complexes.

TABLE 1. TRANSITION TEMPERATURES AND ENTHALPY CHANGES IN THE PICRIC ACID COMPLEXES

Amine	Temp. (°C)		ΔH (kcal/mol)
	This work	Hertel	
o-Bromoaniline	103—110	95	6.7
o-Iodoaniline	100—107	90	6.2
1-Chloro-2-naphthylamine	128—138	130	8.0
	74—76[a)]	—	1.4[a)]
1-Bromo-2-naphthylamine	118—125	114	8.2
	76—79[a)]	—	0.8[a)]
1,6-Dibromo-2-naphthylamine	99—108	96	3.4

a) Transitions in the charge-transfer complexes.

Calorimetric Data. The transition temperatures and enthalpy changes are listed in Table 1. These values were for polycrystalline samples as deposited from solutions. It must be noted that the endothermic peaks recorded at a heating rate of 3 °C/min are anomalously broad. The temperature intervals defined by the points of departure from and return to the baseline of the calorimetric curves in Table 1 are several times broader than those of the ordinary transitions—*e.g.*, that in hexamethylbenzene used for the calibration. Moreover, our temperatures tend to be higher than those reported by Hertel.[4)] Especially in

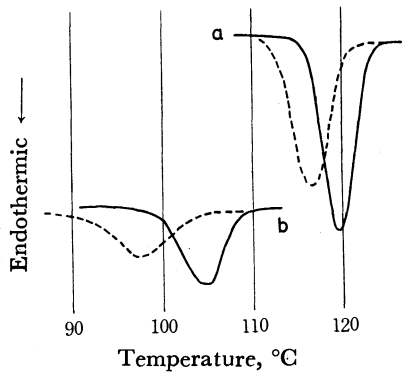

Fig. 4. DSC thermograms of the picric acid complexes of a) 1-bromo-2-naphthylamine and b) 1,6-dibromo-2-naphthylamine before grinding (——) and after grinding (------).

the case of the haloaniline complexes, even the lower limit of the interval is as much as 10 °C higher. When the polycrystalline samples of the bromo- and dibromonaphthylamine complexes were crushed, all the peaks were found to shift significantly to lower temperatures (see Fig. 4). Only a few minutes were enough to produce these changes by grinding. The points of departure from the baseline in the calorimetric curves of the ground samples are located below the transition temperatures reported by Hertel. In addition, the endothermic peaks become a little broader and the amounts of heat of the transition become as much as 20% less than the values given in Table 1. In the case of the chloronaphthylamine complex, the peak was found at almost the same temperature interval before and after grinding; however, the decrease in the heat was comparable with those in the other two naphthylamine complexes. On the other hand, grinding for a short time does not seem to affect much the transitions in the haloaniline complexes. Although small shifts in the transition to lower temperatures were observed, grinding did not result in any observable change in the amount of the heat. These observations suggest that the behavior in complex isomerization is more or less modified by the imperfections incorporated into the crystals by grinding.

The high-temperature forms of the naphthylamine complexes can be cooled to room temperature without any color change. Nevertheless, X-ray examinations revealed that the 1-halonaphthylamine complexes of the CT type at room temperature are different from those obtained by heating the salts above the transition temperature. The existence of phase transitions without complex isomerization between these two forms could be established by the calorimetric method, as is indicated in Table 1. It may be added that the corresponding trinitrobenzene complexes also exhibit phase transitions a little below the transition temperatures in the picric acid complexes of the CT type; that is, they are at 0.9 kcal/mol at 65 °C in the chloronaphthylamine complex and at 1.4 kcal/mol at 60 °C in the bromonaphthylamine complex. All the heats of transition accompanied by complex isomerization listed in Table 1 are appreciably larger than those without isomerization. Such a relation may be recognized as a general tendency, but it is not always true. The heat of transition with isomerization can be as small as 2.2 kcal/mol, as has been found in *o*-chloroaniline–trinitrobenzoic acid,[3] while that without isomerization can be as large as 3.5 kcal/mol, as has been reported for anthracene–picric acid.[11]

Electrical Resistivity. The logarithm of the resistivity of the *o*-haloaniline complexes recorded at ascending temperatures is plotted against the reciprocal temperature in Fig. 5. In the first run, the slope becomes progressively steeper. The activation energy for semiconduction (E), defined by $\rho=\rho_0\exp(E/kT)$, is about 2.25 eV at 60 °C and 4.0 eV at 95 °C in the case of the bromoaniline complex, while the values for the iodoaniline complex are 2.55 and 7.2 eV. At the end of the run, the samples were found to be dark red. Therefore, no anomaly locating the lower limit of transition temperature interval in these complexes was found by our resistivity measurements. On the other hand, the upper limit in the bromoaniline complex may be located in the vicinity of 100 °C. This marked lowering of the upper limit compared to the value in Table 1 may be attributed to the effect of imperfections incorporated by compression to as much as 3 ton/cm^2 employed in the preparation of the sample rod. After the first run, the samples were quickly cooled and the second run was immediately recorded. The slopes in the range from 60 to 80 °C are nearly constant—that is, 1.6 and 2.0 eV. The resistivity values at room temperature may be estimated as 10^{13}—10^{14} ohm cm by extrapolation; they are in good agreement with that of a closely-related CT complex, the 5×10^{13} ohm cm value of the *p*-chloroaniline–*s*-trinitrobenzene.[16] Nevertheless, the activation energies in this temperature range can hardly be considered those

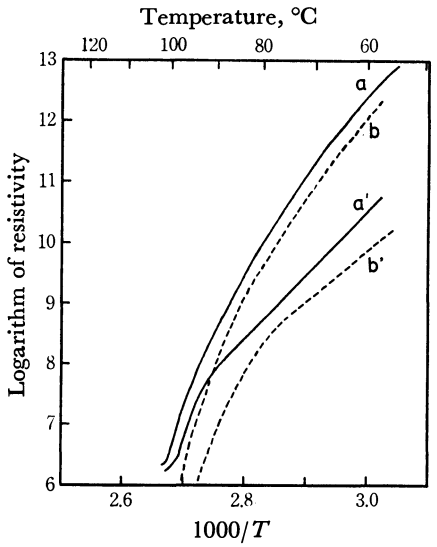

Fig. 5. Electrical resistivities of the picric acid complexes of a) *o*-bromoaniline and b) *o*-iodoaniline. a′ and b′ are the second runs.

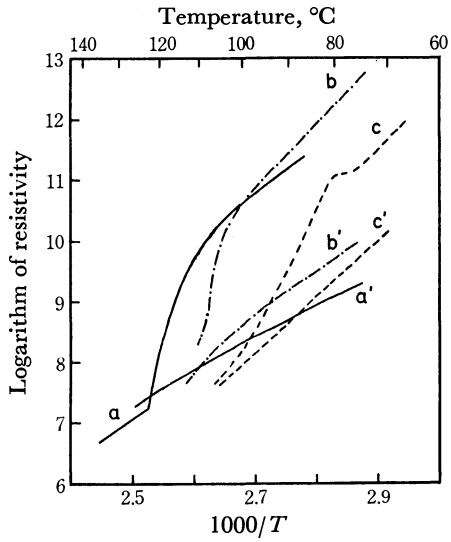

Fig. 6. Electrical resistivities of the picric acid complexes of a) 1-chloro-2-naphthylamine, b) 1-bromo-2-naphthylamine, and c) 1.6-dibromo-2-naphthylamine. a′, b′, and c′ are the second runs.

of the CT complexes. At room temperature, standing overnight is enough for the red form of the *o*-haloaniline complex to return to the stable yellow form. The rate can, of course, be expected to be very much faster in the measured temperature range. Moreover, the slope becomes as steep as that in the first run at high temperatures. Such behavior may suggest that a part of the sample changes into the yellow form during the process of reheating. The transition in the reverse direction in the naphthylamine complexes is slower than those in the aniline complexes. Therefore, the electrical behavior shown in Fig. 6 seems easily explainable. The yellow form of the chloronaphthylamine complex shows an activation energy of 1.5 eV below 100 °C. Then, the slope becomes gradually steeper. The completion of the isomerization may account for the constancy of activation energy above 123 °C. In the second run, the average of the activation energy is about 1.1 eV and the extrapolation to higher temperature almost coincides with the linear part of the first run. As might be expected, the CT complex is more conducting by two orders of magnitude at the beginning of the transition, which may be located around 100 °C. The resistivity extrapolated to room temperature is 10^{16} ohm cm in the yellow form and 10^{12} ohm cm in the red form. Similar anomalous behavior in the transition-temperature interval and a large difference in the electrical resistivity between the complex isomers can also be noted in the other two complexes (see Fig. 6). The activation energy for semiconduction in the yellow form of the bromonaphthylamine complex is 2.2 eV, and that in the red form, 1.4—1.9 eV. The corresponding values in the dibromonaphthylamine complex are 2.1 and 1.8 eV respectively. According to the resistivity measurements, the transformation in the latter complex occurs in the interval from 85 to 100 °C. The large shift to the lower-temperature side and the great breadth in the compressed sample compared to the values given in Table 1 seem to be in accord with the observation of the grinding effects made by the calorimetric method; however, the general tendency here is more pronounced than that demonstrated by the calorimetric curve.

The authors wish to express their thanks to Professor Toshio Yokokawa for letting them use the X-ray diffractometer.

Anomalous Phosphorescence of *p*-Methylacetophenone in Nonpolar Solvent at 77 K

Yoshifumi TANIMOTO, Noboru HIROTA,* and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received May 29, 1974)

Absorption and phosphorescence spectra were studied for *p*-methylacetophenone in 3-methylpentane–isopentane mixed solvent at low temperature. From the concentration and temperature dependencies of the absorption spectrum, it is concluded that the monomer-dimer equilibrium exists in the solution of the *p*-methylacetophenone at low temperature. The phosphorescence of *p*-methylacetophenone in the mixed solvent at low temperature was found to be composed of two components, with lifetimes of 23 and 42 ms at 77 K. They are ascribed to the π,π^* triplet states of the monomer and dimer, respectively.

A number of aromatic carbonyl compounds exhibit anomalous phosphorescence with non-exponential decay.[1-9] Yang and Murov[1] studied phosphorescence for a series of aromatic carbonyl compounds and found that 1-indanone exhibits two phosphorescences with different lifetimes at 77 K, the short-lived one being assigned to the n,π^* triplet state, but the assignment of the long-lived one was open to question. They reported that simple aryl alkyl ketones like acetophenone and propiophenone also show a similar phenomenon.

Callis and Wilson[5] studied the absorption and emission spectra of Michler's ketone in glassy solutions at 77 K. They concluded that, in most commonly used glasses, the solute molecules are surrounded by two or three different types of environments and consequently anomalous luminescence appears. Wagner, May, and Haug[6] analyzed the viscosity dependence of dual phosphorescence of phenyl alkyl ketones at 77 K and ascribed the higher and lower frequency emissions to the n,π^* triplet state of the rigidly held molecule and to that of the conformationally relaxed one, respectively.

Griffin[4] explained anomalous phosphorescence of some acetophenone derivatives in terms of coexistent n,π^*, π,π^*, and charge-transfer triplet states. This explanation, however, is doubtful in view of the fact that, since the molecular relaxation time is of the order of 10^{-12} s,[10] a thermal equilibrium among the nearby triplet states is established within their decay and their phosphorescence decay times must be equal to each other, as was formulated by Mao and Hirota.[11a]

The mechanism of the anomalous phosphorescence observed with aromatic carbonyl compounds is still open to question. Hirota[12] found that the phosphorescence of *p*-methylacetophenone shows non-exponential decay and its apparent decay time changes with the concentration of the solution. In the present study, we have undertaken a study of the mechanism of the anomalous phosphorescence observed with this molecule in nonpolar solvent.

Experimental

p-Methylacetophenone (Tokyo Kasei, EP Grade) was purified with a Perkin-Elmer F21 gaschromatograph. Isopentane and 3-methylpentane were treated with active alumina column, dried with calcium chloride, and finally distilled over sodium metal. 3-Methylpentane–isopentane (1:6 volume ratio) mixed solvent (hereafter abbreviated to 3MP–P solvent) was used as nonpolar solvent.

Low temperature absorption spectra were measured with a Cary spectrophotometer model 14, quartz cells of 1 and 10 mm light-path lengths being used. Temperatures between 97 and 300 K were obtained by controlling a flow of cold nitrogen gas from an evaporation vessel containing liquid nitrogen.

Phosphorescence excitation spectra (PE spectra) were measured at 77 K with a phosphoroscope by exciting samples at various wavelengths with the aid of a 500 W xenon lamp and a Spex 1700-II monochromator. In order to eliminate the effect of stray light, an interference filter (λ_{max}=422 nm, transmittance 30%) was set in front of an EMI 6256S photomultiplier used as a detector.

Phosphorescence spectra were measured at 77 K with the Spex monochromator by exciting samples with an Avco Everett model C950 pulsed nitrogen gas laser. The excitation-wavelength dependence of phosphorescence was observed with an Avco Everett model 1000 tunable wavelength laser as a monochromatized excitation source and a PAR model 121 lock-in amplifier. Time-resolved phosphorescence spectra and phosphorescence decay times were measured with a combination of the pulsed nitrogen gas laser and a PAR model 160 boxcar integrator.

Results and Discussion

Absorption Spectra. Three absorption bands were observed with *p*-methylacetophenone in 3MP–P solvent; the n,π^* transition band at ~360 nm, the π,π^* transition band at ~290 nm corresponding to the α band of benzene, and the π,π^* transition band with the charge-transfer character (the CT transition band) at ~260 nm.

Figure 1 shows the absorption spectra in the 290 nm region measured at 100 K with solutions of various concentrations of *p*-methylacetophenone. Since 3MP–P solvent is not rigid at 100 K, the system can rapidly attain equilibrium. For the solution with a concentration of 2.7×10^{-4} M, a band maximum appears at 288.1 nm. With increasing concentration of the solution its intensity decreases and a new band appears at 291.2 nm. The intensity of the new band increases with increasing concentration and isosbestic points appear at 287.5 and 288.7 nm.

* On sabbatical leave from the Department of Chemistry, State University of New York at Stony Brook.

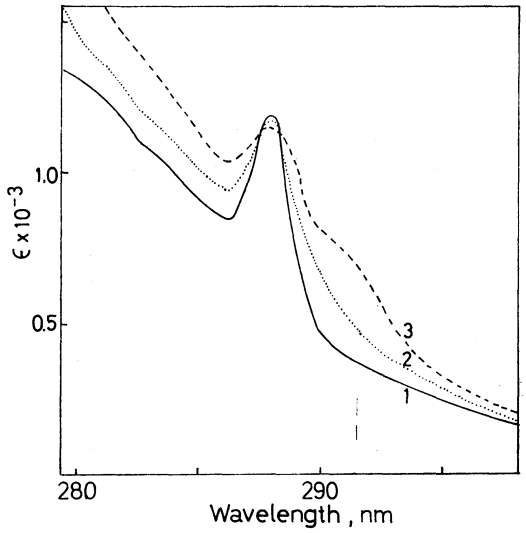

Fig. 1. Absorption spectra (280 nm—300 nm) observed at 100 K with 3MP–P solutions with various concentrations of *p*-methylacetophenone: the concentrations of *p*-methylacetophenone are 2.7×10^{-4}, 5.4×10^{-4}, and and 1.1×10^{-3} M for curves 1, 2, and 3, respectively.

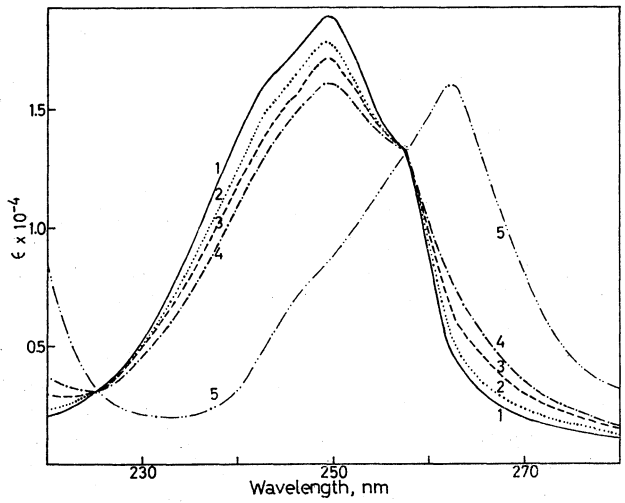

Fig. 2. Absorption spectra (220 nm—280 nm) observed at various temperatures with the 3MP–P solution of *p*-methylacetophenone (5.4×10^{-4} M): curve 1 at 120 K; curve 2 at 110 K; curve 3 at 107 K; curve 4 at 97 K. In this figure, the absorption spectrum of the dimer obtained with the aid of the observed spectrum at 97 K and the equilibrium constant is shown for the purpose of comparison (curve 5).

Figure 2 shows the temperature effect on the absorption spectrum in the range 280—220 nm observed for the solution with a concentration of 5.4×10^{-4} M. The spectra shown in this figure were observed in the temperature range 120—97 K.[13] The intensity of the band at 249 nm decreases with decreasing temperature. On the other hand, the absorption intensity at ~263 nm increases with decreasing temperature and isosbestic points appear at 225 and 258 nm.

The n,π^* transition band at ~360 nm was obtained through the PE spectrum. Figure 3 shows the observed concentration dependence of the band. *p*-Methylacetophenone has a band maximum at 360 nm in the solu-

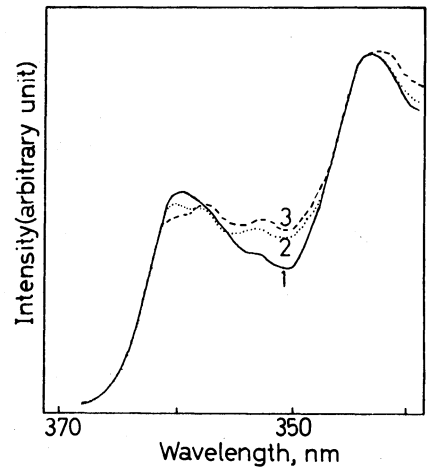

Fig. 3. The phosphorescence excitation spectra (340 nm —370 nm) of *p*-methylacetophenone observed at 77 K in 3MP–P solutions: the concentrations of *p*-methylacetophenone are 1.0×10^{-5}, 1.0×10^{-4}, and 1.0×10^{-3} M for curves 1, 2, and 3, respectively.

tion with a concentration of 1×10^{-5} M. With increasing concentration of the solution, the intensity of the 360 nm band decreases, and a new band at 357 nm gradually grows.

The results show that an equilibrium exists between the monomer and associated species and the new bands at 357, 291.2, and ~263 nm which appear in the relatively concentrated solutions are due to the associated species, most probably the dimer.

From the results shown in Fig. 2, we tried to obtain the monomer-dimer equilibrium constant and the enthalpy (ΔH) and entropy (ΔS) changes for the dimer formation. In view of the fact that the isosbestic points appear at 225 and 258 nm and that the absorption spectrum of the dimer has a peak at about 261—264 nm and its intensity increases with decreasing wavelength below 225 nm, we assumed that the apparent molar extinction coefficient of the dimer around 240 nm is equal to that at the isosbestic point at 225 nm. We further assumed that the absorption spectrum measured at 120 K is entirely due to the monomer. This might be reasonable since the intensity of the monomer band remains constant above this temperature, while below this temperature it increases with a

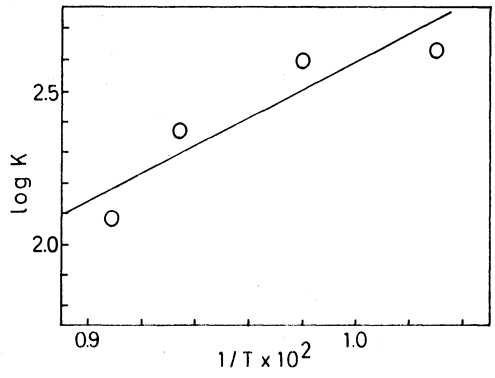

Fig. 4. Temperature dependence of the monomer-dimer equilibrium constant (K) of *p*-methylacetophenone.

rise in temperature. Thus we achieved a rough estimate of the concentrations of the monomer and dimer, C_M and C_D, and the equilibrium constant $K=C_D/C_M^2$ from the absorption intensity around 240 nm observed with a solution of a fixed concentration of *p*-methylacetophenone.[14] In actuality, K was obtained at 242.5, 240.0, and 237.5 nm. The values obtained at these wavelengths are in good agreement with each other at a fixed temperature. The logarithm of the average value of K's obtained at the three wavelengths is plotted against the reciprocal of temperature ($1/T$) in Fig. 4. From this plot, we obtained ΔH and ΔS to be -2 kcal/mol and -10 e.u., respectively. These values are very rough but reasonable for weak association.[15]

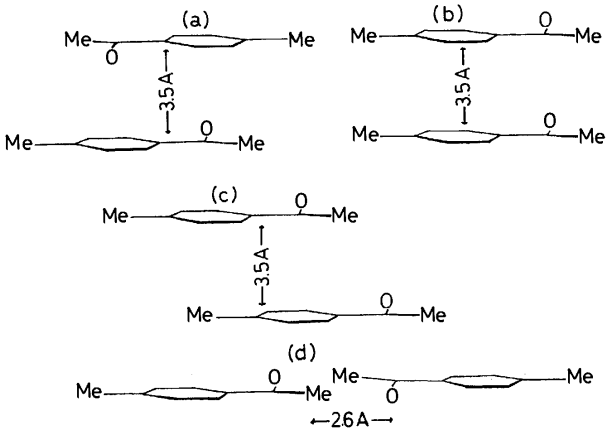

Fig. 5. Geometries of the *p*-methylacetophenone dimer taken for the CNDO/2 calculation.

Let us consider the geometry of the dimer. Using the MO's evaluated by the CNDO/2 method,[16] we calculated the band shifts due to the dimer formation considering interaction between permanent dipole moments in both the ground state and the appropriate excited states and also interaction between transition dipoles.[17] Figure 5 shows the dimer conformations which were used. Figure 5(a) shows the geometry of the dimer which best reproduces the observed band shifts. The experimental observation that the π,π^* and CT bands showed red shift by dimer formation while the n,π^* band showed blue shift can be explained qualitatively by this dimer conformation. This geometry may be reasonable in view of the fact that the stabilization due to the dipole-dipole interaction in the ground state of the dimer is conceivably large for this conformation.

Phosphorescence Spectra. Figures 6(a) and 6(b) show the integrated and time-resolved phosphorescence spectra of *p*-methylacetophenone in 3MP–P solvent at 77 K. The integrated phosphorescence has band maxima at 393.8, 420.8, and 451.8 nm, and the phosphorescence shows non-exponential decay. The time resolved spectra measured 1 and 70 ns after the excitation by the nitrogen gas laser have peaks at 393.0, 420.3, and 450.8 nm, and at 395.8, 420.9, and 453.2 nm, respectively. Thus, we interpret the phosphorescence spectrum as having two components: the band maxima for the longer-lived component lie at slightly

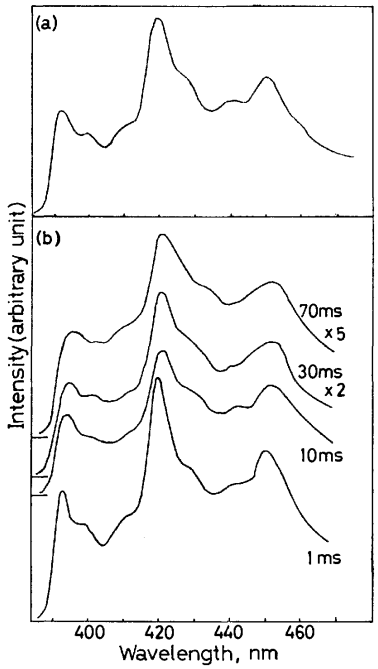

Fig. 6. Integrated (a) and time-resolved (b) phosphorescence spectra observed at 77 K with the 3MP–P solution of *p*-methylacetophenone (1.4×10^{-3} M).

lower energy. The phosphorescence decay curve observed at 420 nm at 77 K is shown in Fig. 7. From the analysis of this curve, the lifetimes of the short- and long-lived components were determined to be 23 and 42 ms, respectively. This indicates that two kinds of molecular species exist in the 3MP–P solution of *p*-methylacetophenone at 77 K.

It is reasonable to ascribe the short- and long-lived phosphorescences to the monomer and dimer of *p*-methylacetophenone, which exist in equilibrium in solution as concluded from the absorption measurement.

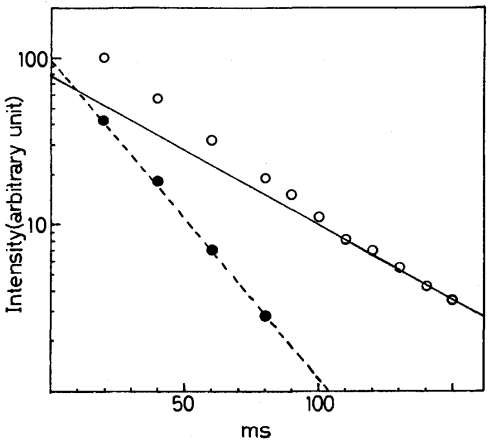

Fig. 7. Analysis of the phosphorescence (420 nm) decay curve observed at 77 K with the 3MP–P solution of *p*-methylacetophenone (8.4×10^{-4} M):
○; the observed decay curve
—; the long-lived component with the lifetime of 42 ms
●; the short-lived component, the difference between the observed decay curve and the long-lived component.

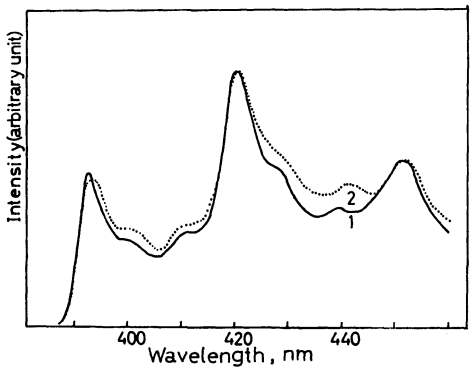

Fig. 8. Phosphorescence spectra observed at 77 K with the 3MP–P solution of *p*-methylacetophenone (1.4×10^{-3} M): excitation was made at 360 nm for curve 1 and at 357 nm for curve 2.

This is supported by the fact that the phosphorescence decay with the short- and long-lived components can be observed only in the low temperature region in which a considerable amount of the dimer exists in solution.[18]

In order to check this mechanism of the anomalous phosphorescence observed with *p*-methylacetophenone and also to determine which of the long-lived and short-lived components corresponds to the monomer or dimer, we measured the excitation-wavelength dependence of the phosphorescence spectrum.

Figure 8 shows the phosphorescence spectra obtained by the excitation at 360 and 357 nm at which the absorptions of the monomer and dimer mainly occur, respectively (Fig. 3). Although both spectra are similar to each other, the band maxima of the spectrum excited at 360 nm appear at slightly higher frequencies than the corresponding maxima of the spectrum excited at 357 nm. It is therfore, concluded that the dimer phosphorescence appears in lower frequencies than the monomer one. Combining this result with the time-resolved phosphorescence, we are led to the conclusion that the higher frequency phosphorescence with the lifetime of 23 ms and the lower energy one with the lifetime of 42 ms are ascribed to the monomer and dimer, respectively. The assignment is supported by the observed tendency that the band positions in the phosphorescence spectrum observed with *p*-methylacetophenone in 3MP–P shift to longer wavelengths with decreasing temperature in the range 90—80 K and also with increasing concentration of *p*-methylacetophenone.[19]

The phosphorescent states of the monomer and dimer of *p*-methylacetophenone may be regarded as π,π^* triplet states, since both lifetimes are too long to be ascribed to the n,π^* triplet state.[11b]

Cheng and Hirota[11b] presented a linear relationship between $k_z^{1/2}$ and ΔE_T^{-1} for aromatic carbonyl compounds. Here, k_z and ΔE_T are the decay rate constant of the T_z sublevel and the energy difference between the n,π^* and π,π^* triplet states, respectively. Since $1/\tau=k=\sum_i n_i k_i$, we can calculate the ΔE_T from the observed lifetime, if we assume $k_x=k_y=0$.[20] Here, τ and k are the mean lifetime and the mean decay rate constant, respectively, and k_i and n_i the decay rate constant and population fraction of the T_i sublevel, respectively. At 77 K $n_i=1/3$ is used. Thus, ΔE_T's are calculated to be 348 and 475 cm^{-1} for the monomer and dimer, respectively.

The authors would like to express their sincere thanks to Dr. Michiya Ito, Faculty of Pharmaceutical Sciences, The University of Tokyo, for valuable suggestions and discussions. N. H. acknowledges support from the National Science Foundation (U.S.) during his stay in Japan under the U.S.-Japan Scientific Collaboration Program.

13) The spectrum measured at room temperature does not cross the isosbestic points and the absorption peak shifts slightly toward shorter wavelengths. This shift may be due to the difference in the environment between room temperature and ~100 K.
14) We determined the K value roughly on the assumption that the molar extinction coefficient of the dimer band at 291.2 nm is equal to that of the monomer band at 288.1 nm. The value thus obtained is 200 M^{-1} l at 100 K—almost half the corresponding value 400 M^{-1} l at 102 K obtained by the method given in the text. This discrepancy seems to be unavoidable because of the roughness of both methods, in particular the method mentioned here. Importance should be attached to the fact that both methods give values of the same order of magnitude.

18) By extrapolating the straight line in Fig. 4, we can estimate the equilibrium constants at 90 and 80 K to be 1280 and 5480 M^{-1} l, respectively. By the use of these values, the concentration ratio of the dimer to the monomer is evaluated for the *p*-methylacetophenone solution of 1×10^{-3} M to be 3: 5 and 4: 3 at 90 and 80 K, respectively. Furthermore, considering the fact that the lifetimes of the two components are rather close to each other, we may explain the observation that the phosphorescence decay of

the 3MP–P solution containing 8.4×10^{-4} M *p*-methylacetophenone fits considerably well into a single exponential curve at 87 K but deviates from it at 77 K.

19) The phosphorescence of *p*-methylacetophenone in 3MP–P is weak, particularly above 90 K. It is therefore difficult to measure its intensity in a wide temperature range accurately enough for the monomer-dimer equilibrium and the temperature dependence of the phosphorescence intensity to be treated quantitatively.

20) This assumption is reasonable since k_x for most aromatic carbonyl compounds is predominantly large among the three decay rate constants.[11b)]

Polarized Reflection and Absorption Spectra of the [2.2]-Paracyclophane Crystal

Kiyokazu FUKE* and Saburo NAGAKURA*,**

*The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106
**The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received June 18, 1974)

The reflection spectra of a [2.2]-paracyclophane crystal were measured in the 17000—62000 cm^{-1} region with incident light polarized parallel and perpendicular to the a-axis. From analysis of the reflection spectra by the Kramers-Kronig method, the a-axis and c-axis polarized absorption spectra in the 38000—60000 cm^{-1} region were obtained. The c-axis polarized spectrum was obtained for the first time. The 43000 cm^{-1} band in the c-axis spectrum was assigned to the transitions to the $^1B_{1u}$ (p) and $^1B_{1u}$ (CT) states. The band around 48000 cm^{-1} was assigned to the transition to the $^1B_{3u}^-$ state, corresponding to the transition to the $^1E_{2g}^-$ state in benzene.

The electronic absorption spectra of [2.2]-paracyclophane (abbreviated hereafter to PC) in single crystal and in solution together with those of tetramethyl [2.2]-paracyclophane and multilayered cyclophanes in solution were reported previously.[1] Comparing the observed transition energies, oscillator strengths, and directions of transition moments with those obtained theoretically by considering the interaction between the ground, locally excited, and charge-transfer configurations, better assignments than those by others[2-4] were made.

It was difficult in the previous study,[1] however, to obtain the c-axis polarized absorption spectrum of the PC crystal in the region higher than 38000 cm^{-1} since the intensity was too strong for direct absorption measurement. In order to overcome this difficulty, we have undertaken to obtain polarized absorption spectra of PC single crystals by reflection measurement in the 17000—62000 cm^{-1} region and to verify our previous assignments by analysis of accurately determined polarization ratios.

Experimental

PC was purified by column chromatography on silica gel and then sublimed *in vacuo*. Single crystals were obtained by recrystallization from chloroform solution. The (011) faces of the crystals, on which reflection spectra were measured, were identified by optical conoscopy and X-ray analysis.

Reflection spectra at room temperature were measured with a reflection spectrophotometer.[5] Since PC sublimes gradually in high vacuum even at room temperature, reflection measurements in the vacuum ultraviolet region were performed under one atmosphere of dry nitrogen. The spectra shown in Fig. 1 are the averages of six determinations. Actual measurements of reflection spectra were made with the incident light polarized parallel and perpendicular to the a-axis. The refractive index, n, and the absorption index, k, were calculated by the Kramers-Kronig method.[6] The molar absorption coefficient, ε, for light polarized parallel or perpendicular to the a-axis was calculated with the formula

$$\varepsilon = \frac{4\pi nkv}{2.303M}$$

where v is the frequency in cm^{-1} and M the molarity of the crystal (5.91 mol/l for PC). The c-axis polarized spectrum was obtained from the ε values for the light polarized paralell and perpendicular to the a-axis in the (011) plane,

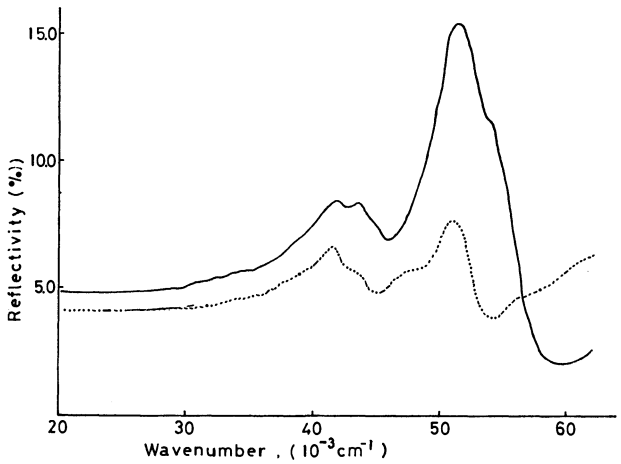

Fig. 1. Reflection spectra observed on the (011) face of the PC crystal. The solid and dotted cruves were obtained with the incident light polarized perpendicular and parallel to the a-axis, respectively.

the orientation of molecules in a unit cell being considered. In the actual evaluation the following equation was used:

$$\varepsilon_c = \frac{\varepsilon_{\perp a} - \cos^2 49°14' \, \varepsilon_a}{\cos^2 40°46'}$$

Results

Absorption spectra derived from the reflection spectra at room temperature are shown in Fig. 2. These spectra correspond fairly well to the absorption spectrum in solution. Here we are not concerned with the weak bands (bands I and II[1]) which appear in the 29500—38000 cm^{-1} region in solution but with bands III—VII which appear in the 38000—59400 cm^{-1} region.

The a-axis spectrum in the 38000—50000 cm^{-1} region agrees with the spectrum of the (001) face obtained by direct absorption measurement.[1] In the region above 56000 cm^{-1}, the intensity of the a-axis spectrum is slightly increased with increasing wave number. The reliability of this result was confirmed by varying the trial reflection curve[7] for the frequency region higher than our experimental limit. With all the trial curves, we found an a-axis polarized transition band in this region.

The c-axis spectrum in the wave number region higher than 38000 cm^{-1} was obtained for the first time.

The absorption intensity in this region is too strong to be measured directly. The observed band positions and the oscillator strengths in solution and in crystal are listed in Table 1.

Discussion

The PC crystal belongs to the D_{4h}^{14} space group (tetragonal) and has two molecules per unit cell.[8] The molecular point group and the molecular site group are both D_{2h}. PC is thus an example in which the site symmetry is the same as the full molecular point group symmetry. The unique symmetry axis of two molecules in a unit cell and their benzene-ring planes are perpendicular to each other. Therefore, a Davydov splitting is expected neither for the transition to the $^1B_{2u}$ state polarized parallel to the y molecular axis nor for the transition to the $^1B_{3u}$ state polarized parallel to the x molecular axis. Both transition bands are expected to appear in the spectra polarized along the a and b crystal axes, while the band corresponding to the transition to the $^1B_{1u}$ state polarized parallel to the z molecular axis is expected to appear in the spectrum polarized along the c crystal axis.

In the a-axis component of the crystal spectrum derived from the observed reflection spectrum, a weak band appears at 39400 cm^{-1}, in agreement with the direct absorption measurement.[1] The oscillator strength of this band was roughly estimated to be 0.01_5 in the present study. These results support the previous assignment[1] that the band at 39400 cm^{-1} is due to the transition to the $^1B_{2u}$ (α-parentage) excited state.

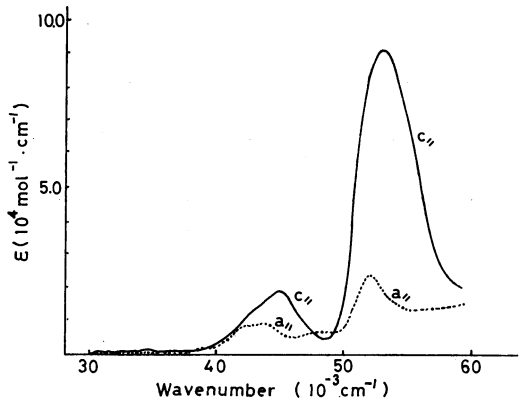

Fig. 2. Polarized absorption spectra of PC derived from the reflection spectra.

The 43000 cm^{-1} band in the a-axis spectrum and the 45000 cm^{-1} band in the c-axis spectrum (Fig. 2), correspond to the 44500 cm^{-1} band in solution. Two bands polarized along the long molecular axis are expected to appear in this region of the c-axis spectrum;[1] one of them corresponds to the *p*-band of *p*-xylene which is strongly polarized along the long molecular axis[9-11] and the other is due to the transition to the charge-transfer (CT) state stabilized by interaction with a locally excited configuration corresponding to the β-band of *p*-xylene. The former band is theoretically predicted to appear at 41400 cm^{-1} (f=0.220) and the latter at 46930 cm^{-1} (f=0.327). The band observed at 45000 cm^{-1} in the c-axis spectrum can be separated into two bands; a stronger band at higher frequencies and a weaker band at lower frequencies. Thus, the observed c-axis spectrum supports the prediction.

Let us consider the 43000 cm^{-1} band in the a-axis spectrum. From the polarization, this band can be ascribed to a transition to the $^1B_{2u}$ or $^1B_{3u}^-$ state. Two bands polarized along the a-axis are theoretically predicted to appear in this region. They are due to transitions to the $^1B_{3u}^-$ and $^1B_{2u}$ (CT) states. The transition energies and oscillator strengths are calculated to be as follows: 46680 cm^{-1}, 0.425 for the transition to the $^1B_{2u}$ state and 45300 cm^{-1}, 0 for the transition to the $^1B_{3u}^-$ state. The observed spectrum (Fig. 2) shows that another band (band V in the previous paper) polarized along the a-axis appears at 48700 cm^{-1} as a shoulder. It is therefore reasonable to consider that the a-axis polarized bands at 43000 and 48700 cm^{-1} are due to the predicted transitions to the $^1B_{2u}$ and $^1B_{3u}^-$ states. Since the calculated transition energies are close to each other for both transitions, it is difficult to determine which transition corresponds to the 43000 cm^{-1} band. By comparing the observed and predicted intensities, however, it is more probable that the 43000 and 48700 cm^{-1} bands are due to the transitions to the $^1B_{2u}$ and $^1B_{3u}^-$ states, respectively.

The $^1B_{3u}^-$ state is mainly composed of a locally excited configuration corresponding to the excitation to the $^1E_{2g}^-$ state of benzene. A number of studies have been made on the band corresponding to the transition to the $^1E_{2g}^-$ state which is forbidden for benzene.[12-21] Quite recently, a band at 46300 cm^{-1} was assigned to this transition.[19,20] Thus it is reasonable to assign the 48700 cm^{-1} band of PC to the $^1B_{3u}^- \leftarrow {}^1A_{1g}$ transition.

The 52000 and 53200 cm^{-1} bands polarized along the a- and c-axis, respectively, correspond to the 53000 cm^{-1} band in solution. From the consideration of the absorption intensities and polarizations, the 52000 cm^{-1} band can be assigned to a transition to a $^1B_{2u}$ state (theoretically at 62380 cm^{-1} and β-parentage) and the 53200 cm^{-1} band to a $^1B_{1u}$ state (theoretically at 62610 cm^{-1} and β-parentage). Both bands correspond to the strong β bands of *p*-xylene.

The a-axis spectrum has an absorption band at 59000 cm^{-1}. This band may correspond to a shoulder at 58000 cm^{-1} in solution. In view of the polarization, the 59000 cm^{-1} band is tentatively assigned to a transition to a $^1B_{3u}^+$ excited state (theoretically predicted to appear at 62270 cm^{-1}). This transition band corresponds to the $^1E_{2g}^+ \leftarrow {}^1A_{1g}^-$ transition band of benzene which appears at 169—172 nm.[19] In the crystal, however, a transition to the conduction band is also possible in the region above 55000 cm^{-1}. This makes the assignment of the 59000 cm^{-1} band ambiguous.

All the assignments are listed in Table 1. The transition energies for observed bands in the crystal show consistent trends; the bands of the a-axis spectrum show a red shift, while those of the c-axis spectrum show no shift or a small blue shift compared with those of the solution spectrum. These results can be qualitatively

Table 1. Observed and calculated transition energies (ΔE in 10^3 cm^{-1}), oscillator strengths (f), and polarizations of PC

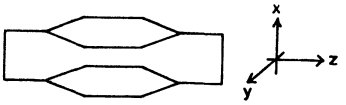
a) We are concerned here with absorption bands in the frequency region higher than 38000 cm^{-1}, so bands I and II have been omitted from this table. b) For comparison with the solution values, these values were obtained by multiplying observed oscillator strengths of the c- and a-axes polarized bands by 1/3 and 2/3, respectively. c) $\Delta\nu=\Delta E_{soln}-\Delta E_{cryst}$. d) Theoretical values taken from Ref. 1. e) Roughly estimated because of overlapping of the corresponding bands. f) Polarization direction is indicated in parentheses:



g) Transitions to these states are mainly caused by intensity borrowing from the β states of the benzene ring.

interpreted by the simple exciton theory of molecular crystals[20] as follows.

In the case of the PC crystal, there are two translationally nonequivalent molecules per unit cell located at (0,0,0) and (1/2, 1/2, 1/2). Exciton states are given by the following linear combinations of $\mathbf{k}=0$:

$$\Psi_i^f = (2N)^{-1/2} \quad (\varphi_1^f \pm \varphi_2^f) \tag{1}$$

where i refers to the irreducible representation in the factor group ($i=1$ and 2 refer to E_u and A_u, respectively). φ_i^f is a one-site exciton function of Site i and State f. To first order, the energy of the i-th factor group component of the f-th electronic state of the crystal is given by:

$$E_i^f - E_0 = \varepsilon^f + D^f + J_i^{ff}(\mathbf{k}). \tag{2}$$

ε^f is the excitation energy of the free molecule from the ground state to the f-th excited state, D^f the environmental shift, and J_i^{ff} the sum of intermolecular excitation exchange integrals usually taken to be a sum of dipole-dipole interactions. In the case of the PC crystal, we have $J_i^{B_{2u},B_{2u}}=J_i^{B_{3u},B_{3u}}=0$, and $J_i^{B_{1u},B_{1u}}\neq 0$ because of the orientation of the two molecules in the unit cell. The calculated excitation exchange integrals are listed in Table 2. We see that the crystal states from the B_{2u} and B_{3u} excited states of the free molecule have zero Davydov splittings. The band shifts between solution and crystal are interpreted by the second term of Eq. (2). The B_{1u} molecular excited state splits in the crystal into the A_u and E_u exciton states with an energy difference of 325 cm^{-1}/Å^2. However, since the unique symmetry axis of the crystal (c-axis) is parallel to the long axis of all molecules, only the transition to the A_u state is optically allowed (c-axis polarized). The D^f term usually has a negative value for a crystal of an aromatic compound. This is easily seen from the a-axis spectrum. Thus the shift of each absorption band in the c-axis spectrum results from cancellation of the second and third terms in Eq. (2).

Table 2. Excitation exchange integrals (J_i^{fg}, cm^{-1}/Å^2)

	$^1B_{1u}$	$^1B_{2u}$	$^1B_{3u}$
$^1B_{1u}$	163	0	0
$^1B_{2u}$	0	0	−75
$^1B_{3u}$	0	−75	0

These values were obtained by the summation of dipole-dipole interaction terms within 50 Å spheres.

We are greatly indebted to Drs. Junko Nakamura and Suehiro Iwata, The Institute of Physical and Chemical Research, and to Dr. Koji Kaya, Tohoku University, for their helpful advice.

The Crystal Absorption Spectra of Some Hexachloroiridate(IV) Salts

Akio URUSHIYAMA, Masayoshi NAKAHARA, and Yukio KONDO

Department of Chemistry, Faculty of Science, Rikkyo University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171

(Received June 24, 1974)

The absorption spectra of the single-crystals of several hexachloroiridate(IV) salts and the doped crystals of the hexachlorostannate(IV) salts and the hexachloroplatinate(IV) salt with the $IrCl_6^{2-}$ anion were measured. Distinct dichroisms appeared in the polarized absorption spectra of all the anisotropic crystals studied. The splittings of the bands and the dichroisms of the spectra were interpreted in terms of the lowering of the symmetry of the $IrCl_6^{2-}$ anions in the crystal. The absorption bands at 19760 and 20000 cm^{-1} in the spectra of $(CH_3NH_3)_2Sn(Ir)Cl_6$ could be assigned to the $E'_g \rightarrow E''_u$ and $E'_g \rightarrow E'_u$ transitions respectively from their polarizations in the double group, D_{3d}*. Similarly, the bands at 23100, 23500, and 24500 cm^{-1} were assigned to the $E'_g \rightarrow E'_u$, $E'_g \rightarrow E''_u$, and $E'_g \rightarrow E'_u$ transitions respectively. The polarized absorption spectra of $Na_2IrCl_6 \cdot 6H_2O$ and $Na_2Pt(Ir)Cl_6 \cdot 6H_2O$ were also interpreted, assuming that the $IrCl_6^{2-}$ anions in these crystals were of the D_{4d} symmetry.

The nature of the electronic absorption spectra of the transition-metal hexahalogenocomplexes was first discussed by Jørgensen,[1] and since then many reports have appeared in this field, especially concerned with Ir(IV) complexes.[2] In these studies the absorption spectra and the magnetic circular dichroisms of the complexes have been measured in solution or by means of the doped crystals because of their large molar extinction coefficients ($\log \varepsilon > 3$). The hexahalogenostannate(IV) salts and the hexahalogenozirconate(IV) salts have been frequently employed as the host lattice. However, π(halogen)$\rightarrow t_{2g}$(metal) electron-transfer absorption bands of the complexes have been known to change considerably in their shapes and positions according to their matrices.[3] In fact, different absorption spectra have been obtained in these studies of Ir(IV) complexes doped into various host lattices and in solution.

One of the present authors (Y. K.) has previously measured the single-crystal polarized absorption spectra of $Na_2IrCl_6 \cdot 6H_2O$, and observed its remarkably distinct dichroism. This dichroism evidently indicates that the complexes are fairly much distorted from O_h in this anisotropic crystal. Therefore, for a detailed discussion of the absorption spectra, it seems important to study the absorption bands under a reduced symmetry of the complex, especially in the anisotropic crystals.

In the present work, the single-crystal absorption spectra of several hexachloroiridate(IV) salts and the doped crystals of the hexachlorostannate(IV) salts and of the hexachloroplatinate(IV) salt with $IrCl_6^{2-}$ anion were measured. The spectra thus measured were interpreted in terms of the lowering of the symmetry of the complexes in the crystal.

Experimental

The visible absorption spectra of the crystalline samples were measured by means of a microspectrophotometer composed of a Hitachi EPS-3T spectrophotometer and a specially-designed stainless-steel box containing a microscope. For the low-temperature studies, the box could be evacuated and was equipped with a stainless-steel cylinder that could hold *ca.* 500 ml of liquid nitrogen. The liquid nitrogen flowed from this cylinder to a specially-designed cooling stage of the microscope through a copper tube. Depending on the cross-section of the crystalline sample, a condenser and an objective with an appropriate power (×4, ×10: ordinary glass objective, ×20, ×40: reflection type optics; Zeiss-Jena) were used. The slit image of the spectrophotometer on the stage of the microscope was about 0.15 mm, as the ×4 lens system was employed, while the ×40 lens system could condense it to about 15 μm in length. The crystalline sample should be large enough to cover the slit image on the stage completely for the measurement. For some doped crystals, the low-temperature absorption spectra were measured. These doped crystals were mounted over a hole in an aluminum plate, which was then placed on the cooling stage of the microscope. Apiezon N grease ensured good thermal contact between the crystal, the aluminum plate, and the cooling stage. The thermocouple indicated that the samples were cooled to about 90 K.

Excellent single-crystals of the hexachloroiridate(IV) salts were obtained when one drop of the 6M HCl solution of the salt was put between two plates of the quartz slide and the plates were then allowed to stand overnight in air in order to evaporate the solvent. The crystals thus obtained were examined under a polarizing microscope, and the absorption spectra of the appropriate samples were measured. The thickness of the samples was not measured in the present studies. However, it could be estimated to be less than 1 μm, assuming that the molar extinction coefficient of the complexes in solution does not change in the crystal. Doped crystals of various hexachlorostannate(IV) salts and sodium hexachloroplatinate(IV) with the $IrCl_6^{2-}$ anion were grown from a slowly-evaporating solution of the salts in 6M HCl containing small quantities (*ca.* 0.05%) of the $IrCl_6^{2-}$ anion. It was found that, in most cases, the $IrCl_6^{2-}$ anions were condensed into the host crystals to some extent. Crystals about 0.5 mm thick were selected and used for the measurements. The polarized absorption spectra of the anisotropic crystals were measured on their extinction directions using a Rochon polarizer. The Raman spectra of the solid powder of the hexachlorostannate(IV) salts were obtained by a laser excited Raman spectrometer. The X-ray crystallographic studies were done with a Weissenberg camera.

Results and Discussion

K_2IrCl_6, $(NH_4)_2IrCl_6$, $K_2Sn(Ir)Cl_6$, $(NH_4)_2Sn(Ir)Cl_6$. These crystals of the hexachloroiridate(IV) salts and the host hexachlorostannate(IV) salts belong to the cubic crystal system, with the space group *Fm3m*.[6] The crystallographically-required symmetry of the complexes in these crystals is O_h. The absorption spectra

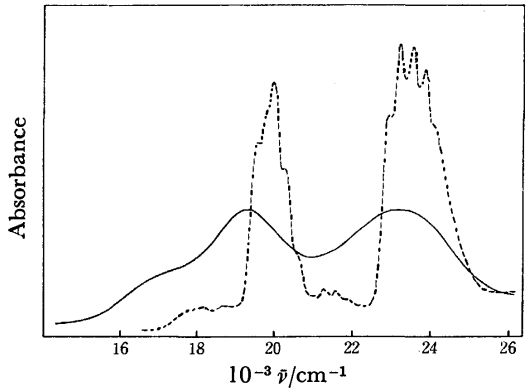

Fig. 1. Crystal absorption spectra of K_2IrCl_6 (——), and $K_2Sn(Ir)Cl_6$ at 90 K (------).

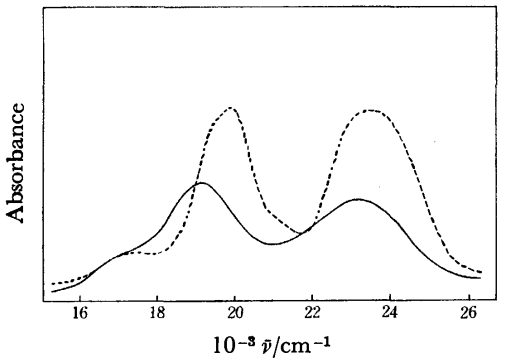

Fig. 2. Crystal absorption spectra of $(NH_4)_2IrCl_6$ (——), and $(NH_4)_2Sn(Ir)Cl_6$ (------).

of the single-crystals and the doped crystals are shown in Figs. 1 and 2. The familiar intense absorption bands of the $IrCl_6^{2-}$ anion were observed in the 20000 and 23500 cm^{-1} regions in all the cases; also, in some cases, there were weak absorption bands in the 17000 and 21500 cm^{-1} regions. Schatz *et al.*[7-9] investigated the absorption spectra and the magnetic circular dichroisms of π(halogen)$\rightarrow t_{2g}$(metal) electron-transfer absorption bands of the $IrCl_6^{2-}$ anion and concluded that the intense absorption bands in the 20000 and 23500 cm^{-1} regions could be assigned to the $^2T_{2g}\rightarrow{}^2T_{1u}$ and $^2T_{2g}\rightarrow{}^2T_{2u}$ transitions respectively, assuming the $IrCl_6^{2-}$ anion

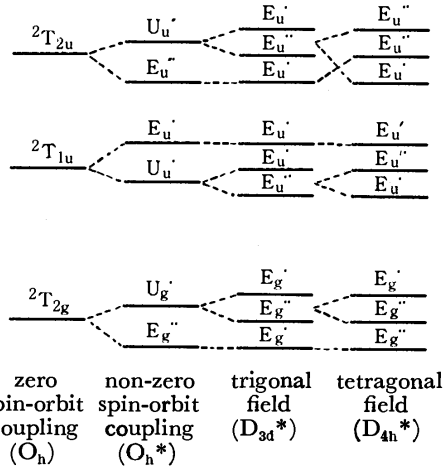

Fig. 3. Schematic energy level diagram of the electron transfer configurations of d^5 complex.

to have the O_h symmetry. Figure 3 shows the schematic energy levels of the electron-transfer configurations of the d^5 complex. It was found that the band maximum of the $^2T_{2g}\rightarrow{}^2T_{1u}$ transition of the pure crystals was always located at a lower wave number than that of the doped crystals. This fact has already been interpreted by Jørgensen in terms of the compression effect in the pure crystals. The absorption spectrum of $K_2Sn(Ir)Cl_6$ in Fig. 1 is consistent with that reported by Sleight[10] in 1968. That is, in the $^2T_{2g}\rightarrow{}^2T_{1u}$ absorption region, five components—at (1) 19570 cm^{-1}, (2) 19880(sh) cm^{-1}, (3) 20040 cm^{-1}, (4) 20350 cm^{-1}, and (5) 20650(sh) cm^{-1}—can be found. It can be considered that the (1) and (2) components form one set of vibrational fine structures, while the (3), (4), and (5) components form another set of vibrational structures. On the other hand, in the $^2T_{2g}\rightarrow{}^2T_{2u}$ absorption region, only one component, with its vibrational fine structures beginning at 22990 cm^{-1}, was observed. Sufficient evidence for the splitting of this band could not be obtained. However, it may be noted by a careful observation of the absorption spectra in Figs. 1 and 2 that each $^2T_{2g}\rightarrow{}^2T_{2u}$ band seems to have a shoulder on the higher-wave number side of the band. Measurements with higher resolution are necessary for any discussion of the band splittings of the complexes in the crystallographically-required O_h.

$(CH_3NH_3)_2IrCl_6$, $(CH_3NH_3)_2Sn(Ir)Cl_6$. The structure of $(CH_3NH_3)_2SnCl_6$ was determined by Wyckoff.[11] The crystals of $(CH_3NH_3)_2SnCl_6$ belong to the trigonal crystal system, with the space group *R3m*. The crystallographically-required symmetry of the complex is D_{3d}. The three-fold axis (z axis) of the complex should be normal to the well-developed face of the thin hexagonal plate of the crystal, in accord with the unique axis of the crystal. The crystals of $(CH_3NH_3)_2IrCl_6$, which also grow as thin hexagonal plates, must be isomorphous to $(CH_3NH_3)_2SnCl_6$, since they showed a similar Debye-Scherrer pattern in this work. The low-temperature absorption spectrum of $(CH_3NH_3)_2Sn(Ir)Cl_6$, with the light propagated along the unique axis of the crystal, has already been studied by Bird *et al.*[12] In the present work, using a carefully selected crystal, the polarized absorption spectra by

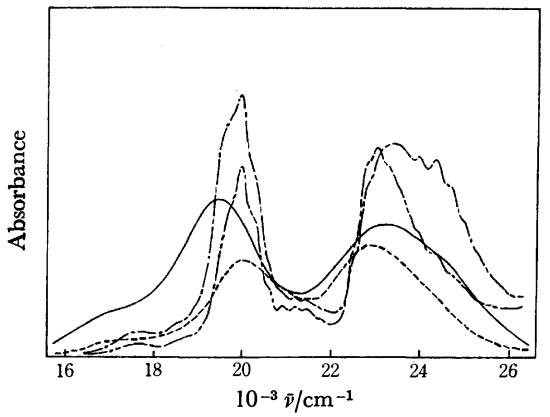

Fig. 4. Polarized absorption spectra of $(CH_3NH_3)_2IrCl_6$ (—— $\perp C_3$, ------ $//C_3$), and $(CH_3NH_3)_2Sn(Ir)Cl_6$ at 90 K (----- $\perp$ C_3, —— // C_3).

light propagated perpendicular to the unique axis of the crystal could be obtained. Figure 4 shows the polarized absorption spectra of $(CH_3NH_3)_2IrCl_6$ and $(CH_3NH_3)_2Sn(Ir)Cl_6$. It was found that the two crystals showed distinct dichroisms with similar patterns, although $(CH_3NH_3)_2IrCl_6$ was studied at room temperature. This reasonably indicates that the $IrCl_6^{2-}$ anions are appreciably distorted in these crystals. Bird *et al.* considered that the $IrCl_6^{2-}$ anion doped into $(CH_3NH_3)_2SnCl_6$ does not suffer any appreciable distortion from O_h symmetry, since the splitting of the $\nu_5(t_{2g})$ line of the $SnCl_6^{2-}$ anion in the crystal could not actually be observed in their Raman studies. However, in the present work, the measurements of the Raman spectra of the powdered host stannate(IV) salts showed that the $\nu_5(t_{2g})$ line of the $SnCl_6^{2-}$ anion in $(CH_3NH_3)_2SnCl_6$ has a small shoulder. This fact also suggests that the symmetry of the $IrCl_6^{2-}$ anion doped into $(CH_3NH_3)_2SnCl_6$ is reduced from O_h. The Raman lines of the solid stannate(IV) salts are listed in Table 1.

TABLE 1. VIBRATIONAL FREQUENCIES (Raman active)

	$\nu_1(a_{1g})$	$\nu_2(e_g)$	$\nu_5(t_{2g})$
K_2SnCl_6	325.6 cm^{-1}	246.2 cm^{-1}	147.2 cm^{-1}
$(CH_3NH_3)_2SnCl_6$	316.0	241.1	174.0
			161.7 sh
$\{(CH_3)_2NH_2\}_2SnCl_6$	313.9	245.4	173.2
		236.7	159.3
$\{(CH_3)_3NH\}_2SnCl_6$	306.4	241.8	171.3
		232.1	162.7

The absorption spectrum of $(CH_3NH_3)_2Sn(Ir)Cl_6$, measured with polarized light whose electric vector was perpendicular to the unique axis, was essentially consistent with that given by Bird *et al.* However, as the crystal was cooled to 4 K in their studies, their spectrum appeared in a better resolution than ours, particularly in the $^2T_{2g}\rightarrow{}^2T_{1u}$ absorption region. They noted that the absorption band in this region consisted of three peaks centered at 19760, 20000, and 20300 cm^{-1}, but they considered that the peak at 20300 cm^{-1} belonged to the member of the vibrational fine structure of the component at 20000 cm^{-1}. Thus, they concluded that the spectrum contained two absorption components in this region, and they identified these two components arising from the excited state spin-orbit splitting in the O_h* double group. However, in the polarized absorption spectrum with its electric vector parallel to the three-fold axis of the complex, the component at 19760 cm^{-1} seemed to be considerably reduced in intensity compared with that at 20000 cm^{-1}. As is shown in Fig. 3, the $^2T_{1u}$ state is split into three levels, which transform as E_u', E_u'', and E_u' respectively in the D_{3d}*, double group while the ground state must still be E_g' because of the large spin-orbit coupling constant (ξ_{Ir}—3000 cm^{-1}). The Laporte allowed transitions of $E_g'\rightarrow E_u''$ and $E_g'\rightarrow E_u'$ should have their transition moments directed along xy and xyz respectively in the D_{3d}* double group. Therefore, the absorption component at 19760 cm^{-1}, the intensity of which along the z axis of the complex was remarkably reduced, must be due to the $E_g'\rightarrow E_u''$ transition. The component at

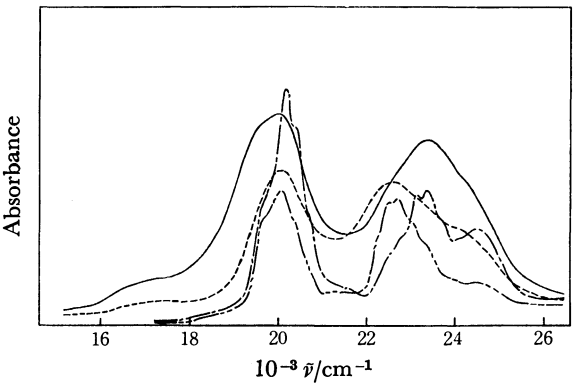

Fig. 5. Polarized absorption spectra of $\{(CH_3)_2NH_2\}_2IrCl_6$ (——, -----), and $\{(CH_3)_2NH_2\}_2Sn(Ir)Cl_6$ at 90 K (-----, ——).

20000 cm^{-1} must be assigned to $E_g'\rightarrow E_u'$, as it has the transition moment also along the z axis. Two E_u' levels arise from $^2T_{1u}$, but it cannot be determined easily which E_u' level corresponds to this component. However, according to the calculations by Piepho *et al.*,[13] the $E_g'\rightarrow E_u'(D_{3d}^*)[U_u'(O_h^*)]$ must have a dipole strength of $D=1/4$. Therefore, this electronic transition must contribute largely to the absorption band at 20000 cm^{-1}.

The intense absorption-band group between 22500 and 26000 cm^{-1} has been considered to be due to the $^2T_{2g}\rightarrow{}^2T_{2u}$ transition in O_h. There have been several discussions concerning the composition of the band group in this region.[8,12] However, the absorption spectrum with the light polarized parallel to the unique axis of the crystal clearly revealed an absorption maximum at 23100 cm^{-1}, while this maximum did not appear in the spectrum with the light propagated along the unique axis. Thus, the band group in this region seems to consist of three components—namely, a band with some vibrational fine structures centered at 23100 cm^{-1}, a structureless band at 23500 cm^{-1}, and a band representing the extensive vibrational structures centered at 24500 cm^{-1}. The component appearing clearly at 23100 cm^{-1} in the z spectrum seems to have its intensity also in the xy direction; therefore, it could be considered to be of the xyz polarization. The vibrational fine structures centered at 24500 cm^{-1} could be seen also in the z spectrum; this component was overlapped with the slope of the band at 23500cm^{-1} to increase its intensity apparently in the xy spectrum. Therefore, the component centered at 24500 cm^{-1} could be regarded as the xyz polarization. Three levels which transform as E_u', E_u'', and E_u' in the D_{3d}* double group arise from the $^2T_{2u}$ state. The present polarization studies suggest the following assignments: the bands centered at 23100, 23500, and 24500 cm^{-1} are the components due to $E_g'\rightarrow E_u'$ (xyz polarization), $E_g'\rightarrow E_u''$ (xy polarization), and $E_g'\rightarrow E_u'$ (xyz polarization) respectively. Referring again to the dipole strength (D) calculated by Piepho *et al.*, the band at 23100 cm^{-1} can further be assigned to $E_g'\rightarrow E_u'(D_{3h}^*)[E_u''(O_h^*)]$-$(D=2/3)$, and that at 24500 cm^{-1}, to $E_g'\rightarrow E_u'(D_{3h}^*)$-$[U_u'(O_h^*)](D=1/12)$. McCaffery *et al.*[8] studied the MCD spectra of this doped crystal with the light

propagated along the unique axis of the crystal. These spectra showed two negative $[\theta]_M$ maxima, at 23000 and 24500 cm^{-1}, and may be interpreted in terms of the overlapping of the peaks corresponding to $E_g' \rightarrow E_u'$-(C=0.60), $E_g' \rightarrow E_u''$(C=−0.225), and $E_g' \rightarrow E_u'$(C=0.075) respectively in the D_{3d}* double group.

The single-crystal of $(CH_3NH_3)_2IrCl_6$ showed polarized absorption spectra with a pattern similar to that of the doped crystal. As the crystal is isomorphous to the host one, the same statements can be made concerning these spectra.

$\{(CH_3)_2NH_2\}_2IrCl_6$, $\{(CH_3)_2NH_2\}_2Sn(Ir)Cl_6$.

Figure 5 shows the polarized absorption spectra of $\{(CH_3)_2NH_2\}_2IrCl_6$ and $\{(CH_3)_2NH_2\}_2Sn(Ir)Cl_6$. The crystals of $\{(CH_3)_2NH_2\}_2SnCl_6$ belong to the orthorhombic crystal system, with the space group of Pnn2 or Pnnm. The complex in this crystal is crystallographically required to possess one of three symmetries, C_1, C_s, or C_2. Solid $\{(CH_3)_2NH_2\}_2IrCl_6$ gave a Debye-Scherrer pattern similar to that of $\{(CH_3)_2NH_2\}_2SnCl_6$. Both Raman lines, $\nu_2(e_g)$ and $\nu_5(t_{2g})$, of the $SnCl_6^{2-}$ anion in the $\{(CH_3)_2NH_2\}_2SnCl_6$ were found to be clearly split, as is shown in Table 1. This suggests that the complex must have suffered a severe distortion force in the crystal to convert it to a low symmetry. The single-crystal and the doped crystal showed polarized absorption spectra with similar patterns. It was found that the $^2T_{2g} \rightarrow {}^2T_{2u}$ absorption band was clearly split into three components in the spectra of the doped crystal at 90 K. However, a detailed discussion of the polarized absorption spectra is not possible because the actual symmetry of the complex is not known.

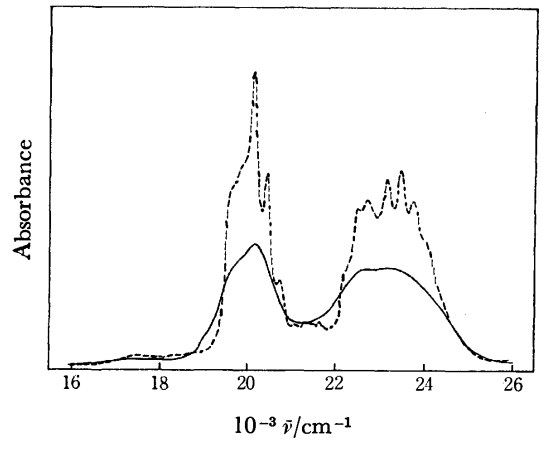

Fig. 6. Crystal absorption spectra of $\{(CH_3)_3NH\}_2IrCl_6$ (——), and $\{(CH_3)_3NH)\}_2Sn(Ir)Cl_6$ at 90 K (------).

$\{(CH_3)_3NH\}_2IrCl_6$, $\{(CH_3)_3NH\}_2Sn(Ir)Cl_6$.

Figure 6 shows the absorption spectra of $\{(CH_3)_3NH\}_2IrCl_6$ and $\{(CH_3)_3NH\}_2Sn(Ir)Cl_6$. The host crystal of $\{(CH_3)_3NH\}_2SnCl_6$ belongs to the cubic crystal system with the space group *Pa3*.[6] The crystallographically-required symmetry of the complex is D_{3d}. The Debye-Scherrer photograph of $\{(CH_3)_3NH\}_2IrCl_6$ is similar to that of $\{(CH_3)_3NH\}_2SnCl_6$. As is shown in Table 1, not only the $\nu_5(t_{2g})$ but also $\nu_2(e_g)$ Raman lines of $SnCl_6^{2-}$ in the host crystal were found to be split. This indicates that the complex in this crystal may have a lower symmetry than D_{3d}, contrary to the results of the X-ray studies. It was found in the spectrum of the doped crystal that the bands due to both $^2T_{2g} \rightarrow {}^2T_{1u}$ and $^2T_{2g} \rightarrow {}^2T_{2u}$ were split into two components with clear vibrational structures. The absorption spectrum of $\{(CH_3)_3NH\}_2IrCl_6$ appeared to be almost the same as that of the doped crystal at room temperature. However, as the crystals belong to the cubic crystal system, polarized absorption studies were not possible.

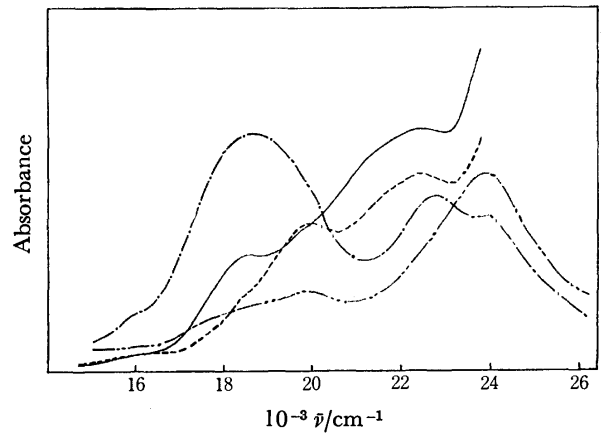

Fig. 7. Polarized absorption spectra of $Na_2IrCl_6 \cdot 6H_2O$ (-----: A direction, ——: B direction), and $Na_2Pt(Ir)Cl_6 \cdot 6H_2O$ (——: A direction, ------: B direction).

$Na_2IrCl_6 \cdot 6H_2O$, $Na_2Pt(Ir)Cl_6 \cdot 6H_2O$. Figure 7 shows the polarized absorption spectra of $Na_2IrCl_6 \cdot 6H_2O$ and $Na_2Pt(Ir)Cl_6 \cdot 6H_2O$. The crystals of $Na_2IrCl_6 \cdot 6H_2O$ and $Na_2PtCl_6 \cdot 6H_2O$ belong to the triclinic crystal system, being isomorphous with each other.[14] For both samples, the polarized absorption spectra measured were not related to their crystal axes. However, although, in the absorption spectra of the doped crystal, the $^2T_{2g} \rightarrow {}^2T_{2u}$ absorption region was overlapped with the slope of the strong absorption band of the $PtCl_6^{2-}$ anion, the patterns of the absorption spectra appeared to be comparable to that of $Na_2IrCl_6 \cdot 6H_2O$ in the $^2T_{2g} \rightarrow {}^2T_{1u}$ region. That is, the $^2T_{2g} \rightarrow {}^2T_{1u}$ absorption bands were split into two components, with strong dichroisms for both samples.

One of the present authors (Y. K.)[4] had previously measured the polarized absorption spectra of $Na_2IrCl_6 \cdot 6H_2O$, and had found a remarkably strong dichroism; hence, there has been a doubt as to the chemical composition of the fine crystals studied. Therefore, the sample crystals used in the course of this work were prepared by the evaporation of a 6M HCl solution of the salts in order to avoid any aquation of the complexes. Since all the crystals of $Na_2IrCl_6 \cdot 6H_2O$ thus obtained exhibited a distinct dichroism under the polarizing microscope, and since all the doped crystals of $Na_2Pt(Ir)Cl_6 \cdot 6H_2O$ prepared also showed a clear dichroism, it seems reasonable to say that the sample crystals certainly consist of $IrCl_6^{2-}$ anions. Griffith *et al.*[15] reported, on the basis of their ESR studies, that the $IrCl_6^{2-}$ anion doped into $Na_2PtCl_6 \cdot 6H_2O$

could be considered to be approximately of a D_{4h} symmetry. $Na_2IrCl_6 \cdot 6H_2O$ is isomorphous to $Na_2PtCl_6 \cdot 6H_2O$, and it showed polarized absorption spectra similar to those of $Na_2Pt(Ir)Cl_6 \cdot 6H_2O$, as has been described already. This suggests that the $IrCl_6^{2-}$ anion in the $Na_2IrCl_6 \cdot 6H_2O$ crystal can be considered to be approximately of a D_{4h} symmetry. The schematic energy levels in the D_{4h}* double group are shown in Fig. 3.

The bands at 18750 cm^{-1} ($Na_2IrCl_6 \cdot 6H_2O$) and at 18600 cm^{-1} ($Na_2Pt(Ir)Cl_6 \cdot 6H_2O$) which appeared in one polarization direction (the A direction in Fig. 7) would correspond to $E_g'' \rightarrow E_u'(D_{4h}^*)[U_h'(O_h^*)]$ (xy polarization). These distinct dichroisms observed in this region indicate that the $IrCl_6^{2-}$ anions of the D_{4h} symmetry lie in an ordering in the crystals favorable for the polarization studies. The band at 19850 cm^{-1} ($Na_2IrCl_6 \cdot 6H_2O$), which appeared as a shoulder in the spectrum of the A direction, almost covered by the slope of the band at 18750 cm^{-1}, could be considered to have its transition moment in either polarization direction of the spectra. The band at 19900 cm^{-1} ($Na_2Pt(Ir)Cl_6 \cdot 6H_2O$) clearly appeared in two directions of the spectra. These two bands can naturally be assigned to $E_g'' \rightarrow E_u''(D_{4h}^*)[U_u'(O_h^*)]$ (xyz polarization). On the basis of the evidence, the band at 22800 cm^{-1} ($Na_2IrCl_6 \cdot 6H_2O$) was considered to be of the xy polarization. Hence, it corresponds to $E_g'' \rightarrow E_u'(D_{4h}^*)[U_u'(O_h^*)]$. Different absorption maxima could be observed at 23950 cm^{-1} in the B direction and at 24040 cm^{-1} in the A direction of the polarized absorption spectra of $Na_2IrCl_6 \cdot 6H_2O$ shown in Fig. 7. This observation indicates that the actual symmetry of the complex in the crystal is reduced further than D_{4h}. However, assuming that the complexes are in the D_{4h} symmetry, these bands must correspond to the $E_g'' \rightarrow E_u''$ (xyz polarization) transitions arising from the $^2T_{2u}$ excited state.

The authors wish to express their thanks to Professor C. K. Jørgensen and American Cyanamid Company for the gift of some samples. Special thanks are due to Dr. Teruo Nomura for his valuable suggestions in the X-ray studies, Mr. Hiroshi Saito for his help with the Raman measurements, and Professor Gene S. Lehman for his kindness in reading the original manuscript.

ESR Studies of Reduced Molybdovanadophosphoric Heteropoly Acids. II. Homogeneous Reduction

Masayuki OTAKE and Tadaaki OTAKI

The Central Research Laboratories, Mitsubishi Chemical Industries Ltd., Hisamoto 290, Takatsu-ku, Kawasaki 213

(Received January 31, 1974)

ESR spectra of the chemically reduced molybdovanadophosphoric heteropoly acids ($H_{3+x}Mo_{12-x}V_xPO_{40}\cdot nH_2O$, where $x=1$ and 2) were observed in the solution and glassy state in various organic solvents. On addition of equimolar amounts of reductants such as $SnCl_2\cdot 2H_2O$, $HSCH_2CH_2SH$, and CH_3SCH_3, a transient ESR signal(B) appeared with eight hfs lines referred to as V(IV), $I=7/2$, and with $\langle g\rangle=1.96$ and $\langle T\rangle=-0.83\times10^{-2}$ cm^{-1}. However, it disappeared within *ca.* 5 hr at 20 °C and another signal(C) with $\langle g\rangle=1.962$ and $\langle T\rangle=-1.00\times10^{-2}$ cm^{-1} gradually increased in intensity. The hyperfine coupling constant of the transient species was thus unusually small as compared with that of the ordinary V(IV) species and the C species. The mechanistic pathways of the reduction were discussed. The splitting observed in the low-field parallel components of the B signal was satisfactorily explained by a "geometrical charge isomerism" characteristic of the structure of the heteropoly anion. The origin of the unusually small hfs constant was discussed in the light of its molecular structure.

In a previous paper,[1] it was demonstrated that partial substitution by vanadium ions for the molybdenum in molybdophosphoric acid is effective for clarifying the mechanism of the reduction and the nature of the reduced species. The results might be summarized as follows:

A) Localization of an electron on the vanadium ions giving rise to an ESR signal was confirmed.

B) In the low stage of reduction, only one paramagnetic center exists in the heteropoly cage, *i.e.*, Mo(V) for molybdophosphoric and V(IV) for vanadium substituted heteropoly acids.

C) As with usual vanadyl complexes, the terminal oxygen of the octahedral oxyanions in the heteropoly cage plays an important part in the localization of the electron on the V=O moiety.

D) As a reduction mechanism, a modified Pottkamp and Umland scheme[2] was proposed, in which almost all the reduced molybdenum ions are tetravalent, Mo(IV)–OH.

The present study was undertaken to obtain more advanced knowledge on the mechanism of the reduction. The polarographic reduction of the above compounds has been extensively studied.[3] However, discrepancies were observed in the results, apparently arising from failure to take into account the hydrolytic instability of the heteropoly anion in the dilute aqueous solution. In order to prevent hydrolysis we chose several organic compounds. Reduction was carried out at room temperature in various organic solvents, using stannous chloride, ethylene dithioglycol and several other sulfur compounds as reducing agents. The difference in the redox potential and the functional groups was expected to allow the formation of a different reduced state corresponding to the individual reductant. Large coupling constants and the strong anisotropic nature of the vanadium(IV) ion, introduced in the cage structure, were useful in the present study.

Experimental

Molybdovanadophosphoric acids $H_{3+x}Mo_{12-x}V_xPO_{40}$, where $x=1$ and 2, were prepared as reported[1] according to the method of Tsigdinos and Hallada.[4] The acids are soluble in organic compounds such as nitrile (acetonitrile), ketones (acetone and methyl ethyl ketone) and esters (methyl isobutyrate and *n*-butyl acetate). In order to avoid contamination with water, the heteropoly acids were evacuated at 100 °C to less than 10^{-3} mmHg, most of the water being removed. Commercial reagents of guaranteed grade were used without further purification. Contamination of the solvents with water was estimated to be less than 0.1%. The reductant solution was added to a solution of the heteropoly acid with the aid of a calibrated microsyringe. An X-band ESR spectrometer, JES-P-10, Japan Electron Optics Lab. Co., was used. Measurements were carried out both at 293 and 77 K. Analysis of the spectra was carried out as described.[1]

Results

Reduction with $SnCl_2\cdot 2H_2O$ in Acetonitrile. The original molybdovanadophosphoric acids gave weak ESR signals both in their solid state and in solution. When a solution of the heteropoly acid and the reductant were mixed, the original orange solution turned blue and a new ESR signal(B), consisting of eight hfs lines referred to as vanadium(IV) ion with $I=7/2$, appeared with remarkably enhanced intensity. How-

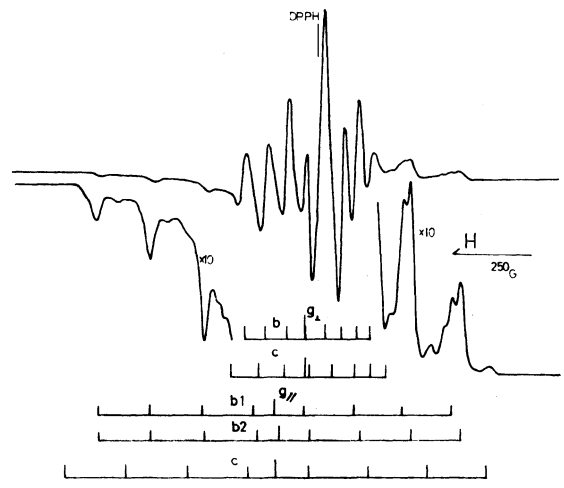

Fig. 1. ESR spectrum (1st derivative, 77 K) of $H_4Mo_{11}V_1PO_{40}$ reduced with $SnCl_2$ in acetonitrile, 0.1 M.

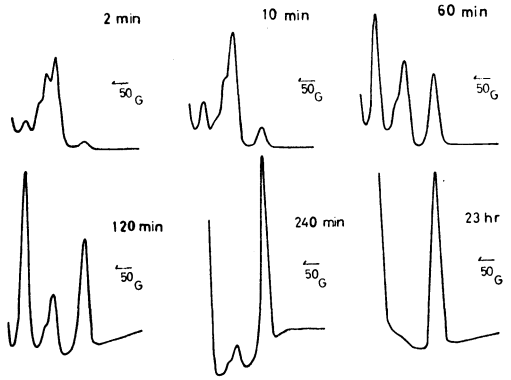

Fig. 2. The change with time of the ESR spectrum (1st derivative, 77 K) of $H_4Mo_{11}VPO_{40}$ reduced with $SnCl_2$ in acetonitrile ($m_n=-7/2$ and a part of $m_n=-5/2$, parallel hfs components)

ever, the spectral pattern changed with time, and another signal(C) gradually grew in intensity, superimposing on the former one which finally disappeared in *ca.* 5 hr at 20 °C. An illustration of the first-derivative spectrum ($x=1$ acid) is given in Fig. 1, in which both signals B and C are superimposed on each other. Splittings are observed in the low-field parallel components of signal B, which indicates that there are at least two kinds of B species. Its hfs coupling constants differ from those of C, while the *g*-values of both signals are almost the same. Signal C was found to be identical with that of a solution of the heteropoly acid reduced in a stream of hydrogen at 280 °C. The rate of formation and decay of the transient species B were measured more precisely by freezing the solution at liquid nitrogen temperature, after keeping the mixture for several minutes at 20 °C. Figure 2 shows how the parallel $m_n=-7/2$ hfs components of signals B and C change with time. The splitting of the parallel component of signal B is most remarkable in this spectral region. Results of the analysis of the spectrum are summarized in Table 1.

Reduction with $HSCH_2CH_2SH$ in Acetonitrile. Various amounts of ethylene dithioglycol were added to a 0.1 M solution of the $x=1$ acid in acetonitrile, but the effect of the quantity of reductant on the ESR spectral pattern was almost negligible except for that on signal intensity. The spectrum, like that in Fig. 1, indicates again the spontaneous formation of species B which disappears within a few hours. The line shape changed gradually, leaving only eight hfs lines of species C. Results of the analysis are given in Table 1. No Mo(V) signal, such as that of dithioglycol-Mo(V) complex ($\langle g\rangle=2.002$, $\langle T\rangle=32$ G)[5] was detected.

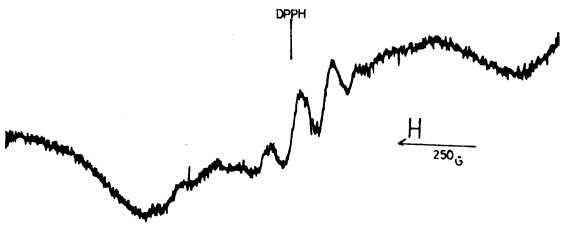

Fig. 3. ESR Spectrum (1st derivative, 20 °C) of $H_5Mo_{10}V_2PO_{40}$ reduced heterogeneously with hydrogen at 280 °C, *n*-butyl acetate solution, 0.1 M.

Other Sulfur Compounds as Reductant. Dimethyl sulfide and thiomalic acid dissolved in acetonitrile caused reduction of the $x=1$ heteropoly acid, giving ESR spectra similar to the spectrum of dithioglycol. The ESR parameters obtained are listed in Table 1.

Reduction with $SnCl_2\cdot 2H_2O$ in Other Solvents. Reduction in a solution of acetone and methyl ethyl ketone gave ESR signals similar to those in Fig. 1. However, the splitting of low-field parallel components of signal B was not so marked as in the case of the spectrum in the acetonitrile solution. Figure 3 illustrates an effect of the solvents on the ESR spectrum of the reduced $x=2$ heteropoly acid, in which the partly reduced acid is dissolved in *n*-butyl acetate. Separation of the hfs components is obviously incomplete.

Discussion

The reduction of molybdovanadophosphoric heteropoly acids with chemical reagents was found to proceed *via* a two step reaction. A number of polarographic studies of molybdophosphoric or other heteropoly acids have been reported[2,3] but not dealing with the forma-

TABLE 1. ESR PARAMETERS OF THE REDUCED $x=1$ HETEROPOLY ACID[a]

tion and decay of transient species. Pottkamp and Umland[2] reported a very slow change in the polarogram of 12-molybdophosphoric acid in *n*-butyl acetate. However, their observation in the polarogram seems to have no connection with ours in ESR, since the rate of appearance of signal B was very fast, and the signal was retained for *ca.* 5 hr at 20 °C.

If the reaction is assumed to follow the first-order kinetics, and $k_1 \gg k_2$, as follows,

$$\underset{\substack{\text{(non-reduced)}\\\text{Diamagnetic}}}{A} \xrightarrow{k_1} \underset{\substack{\text{(Transient)}\\\text{Paramagnetic}}}{B} \xrightarrow{k_2} \underset{\substack{\text{(Final)}\\\text{Paramagnetic}}}{C} \qquad (1)$$

then we obtain the relation

$$C_B/(C_C - C_0 + C_B) = \exp(-k_2 \cdot t) \qquad (2)$$

where C_B and C_C are the concentration of species B and C, respectively, at time t, and C_0 is the initial concentration of C. The time-dependency of $C_B/(C_C - C_0 + C_B)$, determined from the peak heights of each $m_n = -7/2$ parallel line (Fig. 2) is plotted in Fig. 4. The linear relation apparently supports Scheme (1).

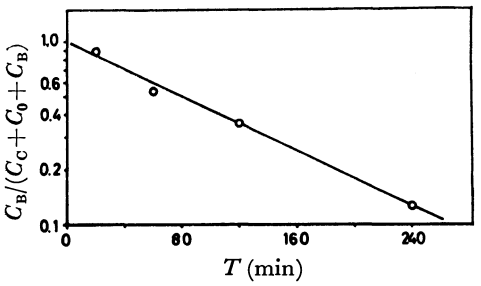

Fig. 4. The change with time of the relative peak heights of the transient (B) and the final (C) species, see text.

The mechanism for satisfying the present observation can be explained as follows.

(a) Species B is assigned as a reduced heteropoly acid and species C as a hydrolysed product from B with such a form as $[VO(H_2O)_x(Solvent)_y]^{2+}$. According to Flynn and Pope,[6] hydrolysis of 5-tungstovanadate(IV) occurs in an aqueous solution to form hydrated vanadyl ion, $[VO(H_2O)_5]^{2+}$. The T value of the hydrate (-1.06×10^{-2} cm^{-1}) is somewhat larger than that of the original heteropoly anion (-0.94×10^{-2} cm^{-1}). The T value of signal C in the present study ($\approx -1.00 \times 10^{-2}$ cm^{-1}) is close to but difinitely smaller than that of the hydrated vanadyl ion. Assumption of the solvation to form $[VO(H_2O)_x(Solvent)_y]^{2+}$ may explain, even partly, such a shift of T. However, the remarkably small $g_{//}$ of species C is closer to that of both B and 11-tungstovanado(IV)phosphate polyanion[7] rather than to that of the usual VO^{2+} complexes whose $g_{//}$ lies in the range 1.93—1.96 (Table 2). Smith and Pope[8] further disclosed the "hydrolytic disproportionation" of the $x=1$ tungstovanadophosphate anion into the $x=0$ and $x=2$ anions. This model partly supports the present observation that g-values of B ($x=1$, in this model) and C ($x=2$) are nearly the same, but it is not suitable for kinetics or for explaining the large difference in the hfs constants. Another contradiction in this decomposition scheme is that ESR spectra of the heteropoly acids reduced with a variety of chemical reagents show a formation of species B with similar rates of formation and similar ESR parameters and its decay into species C. The ESR signal of this species is identical with that of a fresh solution of the heterogeneously reduced heteropoly acid, while reduction with hydrogen at 280 °C never causes decomposition of the compounds.

(b) Another explanation is to assign species B as an intermediate of the reduction and C as the final reduced state of the heteropoly acid in scheme (1), which can remove the contradictions of the first mechanism. It is very probable that the rate of heterogeneous reduction is too fast for the intermediate B to coexist with the final reaction product C, and thus only signal C is observed in the ESR of the reduced mass or its solution. It is of interest to investigate how the two species differ structurally or electronically from each other. If the McConnel linear relation between the hfs parameters and the electron density is also applicable in the present compounds, the hfs constant of signal B, unusually smaller than that of the ordinary vanadyl(IV) compounds as exemplified in Table 2, would indicate that the electrons are much more delocalized over the entire species. There are at least two or three isomers in each of species B and C as is obvious in the low-field splitting of their ESR spectra (Fig. 1 and Figs. 1 and 2 of the previous paper.[1]). They give a hint to elucidating the structure of the two species. An abbreviated scheme of the Keggin-type heteropoly anion structure is given in Fig. 5. Part A represents how the corner-sharing[12] bonds constitute the tetrahedral environment of the central phosphate anion with $(Mo_3O_9)^E$, meaning an edge-sharing unit[12] whose structure is illustrated in part B. Each molybdenum oxyanion has one terminal oxygen with double-bond nature that serves as the main site for the electron-exchange in the chemical redox reactions. Thus we can count and characterize the

neighboring oxyanions for one molybdenum (or vanadium substituting for it) ion as is given in Table 3. Since every Mo–O bond is of highly covalent nature as is understandable from their IR spectra,[13] it is reasonable to expect that all the oxyanions are bound by the electron delocalization through the edge- and corner-sharing oxygen ions. In this respect, the edge-sharing oxyanions can make greater contribution to the delocalization of the electron brought into the heteropoly anion by reduction, since they share the d_{z^2} atomic orbital of the molybdenum ions which is directly connected with the terminal oxygen ion contributing to the electron exchange reaction. Intermediate B would then have the same molecular structure as the original heteropoly anion A, but with one reduced molybdenum(V) or vanadium(IV) ions, and one or two molybdenum(IV) ions in the neighboring positions. The difference in the position and nature of the reduced ions in relation to the paramagnetic ion can cause a different contribution to the delocalization of the paramagnetic electron. This can be regarded as the geometrical charge isomerism in the heteropoly anion. In the final reduced species C, the localization of the electron on the paramagnetic ion is more marked and its electronic state is similar to the vanadyl(IV) ion. Such a decrease in the delocalization of electron is understandable if we assume the protonation of the molybdenum(V or IV) ions coexisting in the heteropoly cage with V(IV) ion. The protonation or abstraction of hydrogen can occur at the terminal oxygen ion with double-bond nature, so that delocalization of the electron in the neighbouring ions is disturbed. This model for species C is what was proposed previously. However, a theoretical investigation based on the molecular orbital describing the heteropoly anion seems necessary for a more complete explanation for the difference in hfs parameters of the two species.

a) Shortest path from one molybdenum oxyanion.

The low-field parallel lines of species B were found to be split into two or three components. The splitting (≈35 G) is nearly twice as large in magnitude as that in the reduced species in the solid spectrum (≈15 G).[1] In the solution, however, the splitting of signal C disappears, since it is not large enough for detection due to the line broadening of the solution spectrum. In the ESR spectrum of the authentic tungstovanado(IV)phosphate anion,[7] the splittings are not observed. They are thus characteristic of the chemically reduced heteropoly anion in which both V(IV) and Mo(IV) ions coexist in the heteropoly cage. The splittings are completely due to the "geometrical charge isomerism", the larger splitting in species B being related to the larger electron delocalization.

Organic solvents have been found to show an interesting effect on the spectrum. All the line-widths were somewhat larger than that of the solid. The spectrum in Fig. 3 differs from that in Fig. 1, particularly in the line-width. The line-width of the former is estimated to be *ca.* 150 G[9] and that of the latter *ca.* 25 G. This increase (solvents being *n*-butyl acetate and acetonitrile, respectively) is much larger than that in the solvent viscosity, 0.732 and 0.359 cp, respectively. This is related to the specific interaction of the heteropoly acids with esters,[10] in which hydrogen-bonding between the carboxyl group and the heteropoly acid forms a strongly solvated species.

Conclusion

Homogeneous reduction of the molybdovanadophosphoric heteropoly acids dissolved in organic solvents was investigated in order to clarify the mechanism of the reduction. Two kinds of ESR signals, B and C, were observed with a substantially different hfs parameter but with nearly equal *g*-tensor. The first-order kinetics of the decay and formation of these species was observed. A mechanism based on the assignment of species C to be some decomposition product from B had several contradiction. Signal B, which appeared just after mixing the reductant and disappeared within *ca.* 5 hr, had unusually small *T*-tensor values and was assigned to be the intermediate of the reduction. Signal C, whose intensity increased gradually, was assigned to be the final reduced species. A small structural difference in the heteropoly cage of the two species was assumed.

There are at least two isomers in both species B and C, which gave a complicated splitting in the low-field ESR spectra. This observation was characteristic of the chemically reduced heteropoly anion and was explained by the "geometrical charge isomerism".

The authors are indebted to the director of the Central Research Laboratories, Mitsubishi Chemical Industries Ltd., for permitting publication of this paper, to Dr. K. Wada for helpful discussions, and to Miss Y. Komiyama for her help in the measurement of the ESR spectra.

The Extraction of Alkali Metal Picrates with Dibenzo-18-Crown-6

Akira SADAKANE, Tadashi IWACHIDO,* and Kyoji TÔEI

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama 700

(Received May 2, 1974)

The distribution of alkali metal picrate complexes of macrocyclic polyether (dibenzo-18-crown-6) between water and benzene was investigated. The polyether-cation complexes were found to be of a 1:1 stoichiometry. The formation of 2:1 complexes was recognized for Rb and Cs in a large excess of the polyether. The extractability of complex cation-picrate ion-pairs decreases in this sequence: K>Rb>Cs>Na>Li. The values of the extraction constants ($\log K_{ex}$) were determined to be 4.65, 3.75, and 3.07 for K, Rb, and Cs compounds respectively. The thermodynamic quantities for the extraction process were calculated from the change in the extraction constants with the temperature. The extraction reactions are all exothermic, accompanied by an entropy decrease.

Macrocyclic polyethers, widely investigated by Pedersen[1] in the last decade, are known as ligands which can form fairly stable stoichiometric complexes with certain cations. It is quite noteworthy that some of these compounds have a great affinity even for alkali metals, though non-cyclic polyethers are commonly not considered strong complexing agents. The most stable complex is formed with a cation which fits well into the molecular cavity of a given ligand, whereas a stable complex is not formed if the ion is too large or too small to lie in the cavity. For instance, polyethers such as 18-crown-6 and its analogues, containing six oxygen atoms linked by six ethylene groups, have ether rings 2.6—3.2 Å[2] in diameter; therfore, they complex with the potassium ion (ionic diameter, 2.66 Å) selectively. X-Ray analyses[3-5] of crystalline complexes show that the metal cation is located in the center of the ether ring. Cations larger than the optimum size can not be accommodated well into the molecular hole, so they tend to form a 2:1 or 3:2 polyether-cation complex of a sandwich type.[2,6-8]

As regards the extraction of an ion-pair species, it has been widely accepted that the extractability of the ion-pair increases with the bulkiness, indicating that the concept of water structure-enforced ion-pairing[9] is applicable. Accordingly, a complex ion-pair species formed by the association of a complexed cation and a large anion, which is considered more hydrophobic and bulkier than an uncomplexed one, is expected to be more extractable.

The present work was undertaken in order to investigate the distribution equilibria and the dependence of the extractability on the size of the alkali metal picrate complexes.

Dibenzo-18-crown-6 was chosen as the complexing agent, since the properties of the polyether and the complexes formed with alkali metals had been well characterized.[1] The picrate anion was chosen as the counter ion so that the ion-pair formed could be determined colorimetrically. Benzene was chosen as the solvent for its non-ionizing property, though it was not necessarily the best solvent. The analysis of the extraction equilibria may be facilitated by the use of non-ionizing solvents, since uncomplexed alkali metal picrates are scarcely extracted into the solvents and the complex ion-pairs do not dissociate in the solvents.

Experimental

Materials. Dibenzo-18-crown-6 was synthesized by the method of Pedersen[1] from catechol and bis(2-chloroethyl)-ether. Recrystallization from benzene gave white, fibrous crystals. The polyether thus obtained had a melting point and an infrared spectrum identical with those of an authentic sample. The alkali metal picrates were prepared by adding a corresponding carbonate solution to an aqueous solution of picric acid; the resulting precipitates of caesium, rubidium, and potassium picrates were recrystallized from water, and the precipitates of sodium picrate, from a water-ethanol (1:3) mixture. The sodium picrate was found to be monohydrate by means of a thermogravimetric method. Benzene of a guaranteed-grade was washed with a sodium hydroxide solution and then water, distilled, and saturated with water. The resulting water-saturated benzene was stored so as to prevent any dissolution of the carbon dioxide. Deionized water was carefully decarbonated by boiling and was saturated with benzene just before each experimental run in order to minimize the volume change on mixing.

Extraction Procedure. An aliquot of an aqueous alkali metal picrate solution and a lithium hydroxide solution (5×10^{-5} M) were transferred into a 50 ml centrifuge tube equipped with a well-grounded stopper and diluted to 20 ml with water (to give these final concentrations: Na and K$<10^{-2}$ M, Rb$<3\times10^{-3}$ M, and Cs$<5\times10^{-3}$ M). 20 ml of a benzene solution containing the polyether ($<10^{-2}$ M) was then added. The resulting mixture was shaken in a thermostated water bath (10—30$\pm$0.1 °C) for 20 min and subsequently allowed to stand for 20 min to complete the phase separation. All the extractions were carried out at pH>6.7.

Determination of the Picrates. The concentrations of the picrates in the organic and aqueous phases were determined spectrophotometrically (Hitachi Spectrophotometer, Type 124) at 425 and 353 nm respectively with appropriate quartz cells 2—50 mm in length. The molar extinction coefficients, ε, of the complex ion-pairs in the organic phase were determined to be 9930, 9800, and 9600 for caesium, rubidium, and potassium compounds respectively. The ε values of the 2:1 polyether-cation complexes for rubidium and caesium were virtually identical with those of the 1:1 complexes. The ε value of the picrate ion in the aqueous phase was also determined to be 14400.

The Distribution Coefficient of the Polyether. A benzene solution containing the polyether ($<5\times10^{-3}$ M) was shaken with pure water under the conditions described above. The aqueous phase thus separated was concentrated by evaporation

to less than one-third of its original volume in order to remove any dissolved benzene. The concentration of the polyether was then determined spectrophotometrically at 272 nm (ε= 5050). Measurements were carried out at five different temperatures, ranging from 10 to 30 °C.

Results and Discussion

Extraction Equilibria. The equilibrium between an aqueous solution containing the alkali metal cation, M^+, and the picrate anion A^-, and an organic solution containing dibenzo-18-crown-6, L, can be written as:

$$M_a^+ + L_o + A_a^- \rightleftarrows MLA_o$$

$$K_{ex} = \frac{[MLA]_o}{[M^+]_a[L]_o[A^-]_a} \quad (1)$$

where MLA denotes the complex ion-pair extracted in the organic phase; the molar concentrations are given in brackets. The overall extraction equilibrium can be analyzed in terms of the following four constituent equilibria.

i) Transfer of the uncomplexed polyether from the organic to the aqueous phase:

$$L_a \rightleftarrows L_o \qquad D^L = \frac{[L]_o}{[L]_a} \quad (2)$$

ii) Complexation of alkali metals with the polyether:

$$L_a + M_a^+ \rightleftarrows ML_a^+ \qquad K_a^{ML} = \frac{[ML^+]_a}{[L]_a[M^+]_a} \quad (3)$$

iii) Association of the complexed cations with the picrate anion:

$$ML_a^+ + A_a^- \rightleftarrows MLA_a \quad K_a^{MLA} = \frac{[MLA]_a}{[ML^+]_a[A^-]_a} \quad (4)$$

iv) Transfer of the complex ion-pairs from the aqueous to the organic phase:

$$MLA_a \rightleftarrows MLA_o \qquad D^{MLA} = \frac{[MLA]_o}{[MLA]_a} \quad (5)$$

Distribution Ratios of the Picrates. The distribution ratios of the picrates, q^A, was calculated from either the concentration in the organic phase, A, or that in the aqueous phase, $A^\circ - A$:

$$q^A = \frac{A}{A^\circ - A} \quad (6)$$

where the superscript o denotes the initial concentration. From the mass balances, the following relations can be obtained:

$$[A^-]_a = A^\circ - A - \frac{A}{D^{MLA}} = f(A) \quad (7)$$

$$[M^+]_a = M^\circ - A - g(A) \quad (8)$$

$$g(A) = \frac{A}{D^{MLA}}\left(\frac{1}{f(A)K_a^{MLA}} + 1\right)$$

$$[L]_o = \frac{L^\circ - A - g(A)}{1 + 1/D^L} \quad (9)$$

The substitution of Eqs. (7)—(9) into Eq. (5) gives:

$$q' = \frac{A}{A^\circ - A - A/D^{MLA}} = \frac{K_{ex}(L^\circ - A - g(A))(M^\circ - A - g(A))}{1 + 1/D^L} \quad (10)$$

The q' is related to q^A by the following equation:

$$\frac{1}{q'} = \frac{1}{q^A} - \frac{1}{D^{MLA}} \quad (11)$$

Assuming that $A^\circ - A \gg A/D^{MLA}$, $D^L \gg 1$, and $M^\circ - A$, $L^\circ - A \gg g(A)$, Eq. (11) can be reduced to:

$$q^A = K_{ex}(M^\circ - A)(L^\circ - A) \quad (12)$$

In the above formulations, complexes with other than the 1 : 1 stoichiometry are not considered; this exclusion is supported by the method of continuous variation (Fig. 1). The theory indicates that the maximum

Temp.: 25 °C. Absorbances: org. phase, at 425 nm.

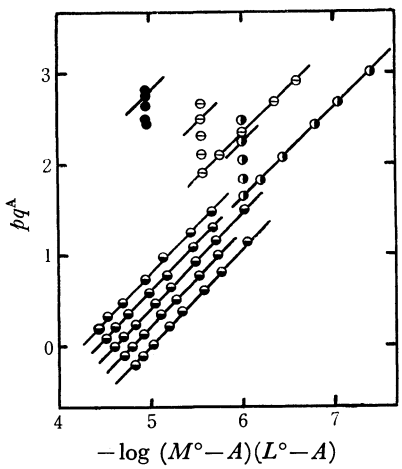

Fig. 2. Plots of pq^A against $-\log (M^\circ - A)(L^\circ - A)$. The symbols used are identical with those in Fig. 1. The vertically-arrayed five points are those obtained at the different temperatures: 30, 25, 20, 15, and 10 °C (from top to bottom).

extraction occurs when equimolar solutions of alkail metal salts and the polyether are added to a system. The equimolar composition corresponds to the point of 2/3 on the abscissa of Fig. 1. As can be expected from Eq. (12), a linear relationship exists between pq^{A} and $-\log(M^{\circ}-A)(L^{\circ}-A)$ values (Fig. 2), indicating that each ion-pair is of the 1:1 stoichiometry. The values of the extraction constants, K_{ex}, calculated from the plots in Fig. 2 are given in Table 1. Since the extractability of the complex sodium ion-pair was so small that the molar extinction coefficient could not be determined, it was assumed that $\varepsilon=9800$, the average value of the other alkali metal compounds.

TABLE 1. EXTRACTION CONSTANTS AND THERMODYNAMIC QUANTITIES

MLA	L	NaLA	KLA	RbLA	CsLA
$\log K_{ex}$	2.9[a]	2.2[b]	4.65	3.75	3.07
ΔH°(kcal/mol)	2.0	−8.9[b]	−16.3	−16.4	−16.0
ΔS°(e.u.)	20	−20[b]	−33.4	−37.8	−39.6

a) $\log D^{L}$ value. b) Estimated value.

The value of K_{ex} for the potassium compound shows that about a half of the potassium is transferred into the benzene phase, when the same volumes of the polyether (10^{-2} M) and the picrate (10^{-2} M) solutions are equilibrated at 25 °C. Figure 3 shows that dibenzo-18-crown-6 is highly selective for potassium, as had been expected.

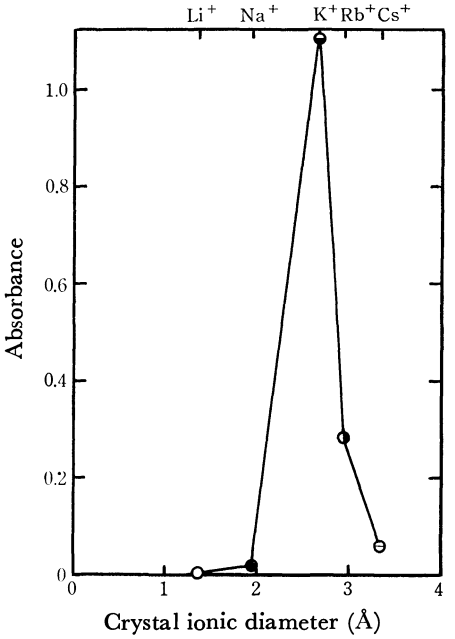

Fig. 3. Extractabilities of alkali metal picrate complexes of dibenzo-18-crown-6 at 25 °C.
M°, L°, $A^{\circ}=10^{-3}$ M. Absorbances: org. phase, at 425 nm with 50 mm cell.

When the polyether was present in excess ($L^{\circ}/M^{\circ}>5$), a plot of pq^{A} against $-\log(M^{\circ}-A)(L^{\circ}-2A)^{2}$ was found to be linear for rubidium and caesium. The implication of such a relationship can easily be understood by assuming a further complexation of complex ion-pair with the polyether:

$$L_o + MLA_o \rightleftarrows ML_2A_o \quad K_o^{ML,A} = \frac{[ML_2A]_o}{[L]_o[MLA]_o} \qquad (13)$$

The existence of such an ion-pair has been demonstrated with some polyethers in the solid state[2,6-8] or in a methanol solution.[10] This may support, though not directly, the above assumption. The overall extraction equilibrium can also be formulated as:

$$M_a^{+} + 2L_o + A_a^{-} \rightleftarrows ML_2A_o$$

$$K_{ex}' = \frac{[ML_2A]_o}{[M^{+}]_a[L]_o^{2}[A^{-}]_a} \qquad (14)$$

The values of $\log K_{ex}'$ were determined from the plots to be 6.5 and 5.6 for the rubidium and caesium compounds respectively. The corresponding association constants, $K_o^{ML,A}$, of the rubidium and caesium ion-pairs can be calculated to be $10^{2.7}$ and $10^{2.5}$ respectively by dividing K_{ex}' by K_{ex}. These values are of a magnitude similar to that of the stability constant obtained by Frensdorff[10] in methanol ($[CsL_2]/[CsL][L]=10^{2.92}$).

No ion-pair of the ML_2A type was found with potassium, not even in a large excess of the polyether ($L^{\circ}/M^{\circ}<18$).

Since the umcomplexed polyether is sparingly soluble in water (about 10^{-5} M at room temperature), it seems reasonable to assume that the ion-pair of ML_2A type can not exist in the aqueous phase, not even when the polyether is present in a large excess in the organic phase.

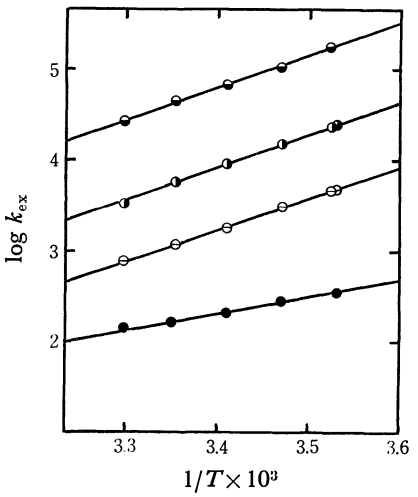

Fig. 4. Plots of $\log K_{ex}$ against $1/T$.
The symbols used are identical with those in Fig. 1.

Thermodynamic Quantities. The values of the extraction constants increase monotonously with a decrease in the temperature. A plot of $\log K_{ex}$ against $1/T$ shows a straight line for each alkali metal (Fig. 4). The value of the enthalpy change, ΔH°, was calculated from the slope. The value of the entropy change, ΔS°, was calculated from the corresponding ΔH° and K_{ex} values by using these thermodynamic relations: $\Delta G^{\circ}=-RT\ln K_{ex}$ and $\Delta G^{\circ}=\Delta H^{\circ}-T\Delta S^{\circ}$.

It can be seen that the entropy contribution, $T\Delta S^{\circ}$, to the free energy change, ΔG°, is smaller than the thermal effect and has the same sign. There is no

significant difference in $\Delta H°$, but the negative values in $\Delta S°$ apparently increase in going from sodium to caesium compounds. The thermodynamic quantities, $\Delta H°_{(15)}$ and $\Delta S°_{(15)}$, for the

$$M_a^+ + L_a + A_a^- \rightleftarrows MLA_o \qquad (15)$$

process were obtained by subtracting the $-\Delta H°_{(2)}$ and $-\Delta S°_{(2)}$ values from the corresponding $\Delta H°$ and $\Delta S°$ values: K, $\Delta H°_{(15)} = -14.3$ kcal/mol and $\Delta S°_{(15)} = -13.4$ e.u.; Rb, -14.4 and -17.8; and Cs, -14.0 and -19.6. The values of $\Delta H°_{(5)}$ and $\Delta S°_{(5)}$ can also be calculated in a similar way if the quantities of the association processes in the aqueous phase represented by Eqs. (3) and (4), $\Delta H°_{ass}$ and $\Delta S°_{ass}$, are known, or *vice versa*, but neither of the quantities is easy to obtain because of the very low solubility of the polyether in water. The thermodynamic quantities for the association processes of dicyclohexyl-18-crown-6 have been reported by Izatt *et al.*:[11] K, $\Delta H°_{ass} = -3.88$ kcal/mol and $\Delta S°_{ass} = -3.8$ e.u.; Rb, -3.33 and -4.2; and Cs, -2.41 and -3.7. If the values of $\Delta H°_{ass}$ and $\Delta S°_{ass}$ for dibenzo-18-crown-6 are assumed to be identical with dicyclohexyl-18-crown-6, the values of $\Delta H°_{(5)}$ and $\Delta S°_{(5)}$ may be calculated to be about -11 kcal/mol and -10——16 e.u. respectively for each alkali metal.

From the above discussion, it follows that the association processes in the aqueous phase play only a minor role in determining the magnitude of the entropy change associated with the overall extraction process, and that the difference in $\Delta S°$ values is determined to a large extent by the difference in $\Delta S°_{(5)}$ values. A plot of $\Delta S°_{(15)}$ against the reciprocal of the cation radius was found to be linear, indicating that the magnitude of $\Delta S°_{(15)}$ is a result largely of electrostatic interaction as well as the relative hydration and number of product and reactant species. The trend in $\Delta S°_{(15)}$ values is consistent with Krasnov's observation:[12] for the extraction of triphenylmethane dye salts by chloroform, the larger the cationic radius, the more negative the distribution entropy becomes.

Though the effect of solvent polarity on the extractability of complex ion-pairs was not investigated systematically, a preliminary test has shown that polar solvents, such as isobutyl methyl ketone and nitrobenzene, give rise to an enhanced extractability. This observation is consistent with the results obtained by Frensdorff:[13] the extractability of the potassium picrate complex of dicyclohexyl-18-crown-6 decreases in this solvent sequence: methylene chloride>trichlorotrifluoroethane>*n*-hexane. Methylene chloride ($K_{ex} = 10^{5.85}$)[13] is found to be better than benzene ($K_{ex} = 10^{4.65}$) as a solvent of the potassium picrate complex of dibenzo-18-crown-6.

Thus, dibenzo-18-crown-6 and its analogues will be considered promising reagents for the separation and extraction of potassium.

Binuclear Metal Complexes. X.[1] Preparation and Magnetism of Mononuclear and Binuclear Copper(II) Complexes of Schiff Bases Derived from 4,6-Diacetylresorcine and Polyamines

Noriaki MANADA, Hisashi OKAWA, and Sigeo KIDA

Department of Chemistry, Faculty of Science, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received May 10, 1974)

New binuclear complexes $Cu_2X_2dar(en\text{-}R)_2$ and $[Cu_2dar(dien)_2](ClO_4)_2\cdot H_2O$ were synthesized, $H_2dar(A)_2$ being a Schiff base prepared from 4,6-diacetylresorcinol and an amine A; A stands for *N,N*-dialkylethylenediamine-(=en-R, R=C_2H_5 or *iso*-C_3H_7) or diethylenetriamine(=dien). Mononuclear complexes CuXHdar(en-R) were also prepared for comparison. Two copper(II) ions of the binuclear complexes are separated from each other by the benzene ring. Magnetic susceptibilities of the compounds were measured in the temperature range 77.4~300 K. It was found by means of the plots of χ_A^{-1} *versus* T that all the compounds obey the Curie-Weiss law. The Weiss constants for the binuclear complexes (−10~−34 K) indicate the presence of antiferromagnetic interactions between copper(II) ions through the conjugated π-system of 4,6-diacetylresorcinol moiety, whereas those of the mononuclear complexes are practically zero, showing that the intermolecular interaction is negligibly small.

A number of reports[2-4] have appeared on polynuclear copper(II) complexes which exhibit subnormal magnetic moments. In most of them the copper(II) ions are kept in close proximity by bridging groups.

Some polynuclear copper(II) complexes which exhibit magnetic moments lower than 1.73 B.M., in spite of the considerably long distance between the metal ions, are polymeric copper(II) complexes formed by a catena-μ-group such as pyrazine,[5] quinoxaline[6] and their derivatives,[7,8] and binuclear copper(II) complexes of complicated ligands such as 1,2,4,5-tetraaminobenzene-derivatives[9] and oxamide-derivatives.[10] The magnetic behaviors of these complexes could be explained on the basis of antiferromagnetic exchange interaction between the copper(II) ions through the π-conjugated system of the ligand. In order to obtain an additional information on long distance spin-coupling in binuclear copper(II) complexes, we have prepared a new class of binuclear copper(II) complexes with the use of di-Schiff bases of 4,6-diacetylresorcinol. The complexes obtained are $Cu_2X_2dar(en\text{-}R)_2$ (X=Cl or Br and R=C_2H_5(Et) or *iso*-C_3H_7(*i*-Pr)) and $[Cu_2dar(dien)_2](ClO_4)_2\cdot H_2O$, where $H_2dar(en\text{-}R)_2$ and $H_2dar(dien)_2$ are the di-Schiff bases of 4,6-diacetylresorcine with *N,N*-dialkylethylenediamines and diethylenetriamine, respectively. Two copper(II) ions are separated from each other by 4,6-diacetylresorcinol moiety.

The mononuclear copper(II) complexes CuXHdar-(en-R) (X=Cl or Br and R=Me, Et or *i*-Pr) were prepared, $H_2dar(en\text{-}R)$ denoting the mono-Schiff bases prepared from 4,6-diacetylresorcinol and *N,N*-dialkylethylenediamine. The new compounds were characterized on the basis of elemental analyses, and IR and visible spectra. Magnetic properties of the binuclear complexes were discussed in comparison with those of the mononuclear complexes.

Experimental

Syntheses. 4,6-Diacetylresorcinol was synthesized according to Baker's method.[11]

$Cu_2X_2dar(en\text{-}R)_2$ Complexes. These complexes were prepared by practically the same method. A typical procedure is as follows for $Cu_2Cl_2dar(en\text{-}Et)_2$. *N,N*-Diethylethylenediamine (232 mg, 2 mmol) and 2,2-dimethoxypropane (1 g) were added to an anhydrous methanolic solution (50 ml) of 4,6-diacetylresorcinol (194 mg, 1 mmol) and the reaction mixture was refluxed for 4~5 hr. To this solution were added anhydrous copper(II) chloride (268 mg, 2 mmol) and triethylamine (202 mg, 2 mmol), and the mixture was refluxed for 1~2 hr. Triethylamine was added as a proton-acceptor, without which the binuclear complexes could not be obtained probably due to the decomposition of the Schiff base. The brown needles separated were collected and washed with anhydrous methanol.

$[Cu_2dar(dien)_2](ClO_4)_2\cdot H_2O$. To an anhydrous methanolic solution (50 ml) of 4,6-diacetylresorcinol (194 mg) were added $[Cu(dien)H_2O](ClO_4)_2$ (750 mg), 2,2-dimethoxypropane (1 g) and triethylamine (202 mg). The mixture was heated under stirring for 2 hr and concentrated to 20 ml to give pink prisms which were filtered and recrystallized from methanol.

CuXHdar(en-Me) and CuXHdar(en-Et) Complexes. These complexes were prepared by practically the same method. A typical procedure is as follows for CuClHdar(en-Me). *N,N*-Dimethylethylenediamine (88 mg, 1 mmol) and 2,2-dimethoxypropane (1 g) were added to an anhydrous ethanolic solution (50 ml) of 4,6-diacetylresorcinol (194 mg, 1 mmol) and the reaction mixture was refluxed for 2~3 hr. Anhydrous copper(II) chloride (134 mg, 1 mmol) and triethylamine (101 mg, 1 mmol) were added to the solution which was refluxed for 1 hr and allowed to stand at room temperature overnight. The blue prisms separated were collected and washed with anhydrous ethanol.

CuClHdar(en-i-Pr). *N,N*-di(*iso*-propyl)ethylenediamine (144 mg, 1 mmol) and 2,2-dimethoxypropane (1 g) were added to an anhydrous methanolic solution (50 ml) of 4,6-diacetylresorcinol (194 mg, 1 mmol), and the reaction mixture was refluxed for 2~3 hr. Anhydrous copper(II) chloride (134 mg, 1 mmol) and triethylamine (101 mg, 1 mmol) were added to the solution which was refluxed for 1 hr. The hot solution gave the binuclear complex $Cu_2Cl_2dar(en\text{-}i\text{-}Pr)_2$ as brown crystals, which were filtered and the filtrate was allowed to stand overnight. The brown needles obtained from the filtrate were collected and washed with anhydrous methanol.

Analytical data are given in Table 1.

Measurements. Infrared spectra were measured with a

Hitachi Grating Infrared Spectrometer model 215 in the region 4000~650 cm^{-1} on a KBr disk. Reflectance spectra were measured with a Shimadzu Multipurpose Spectrometer model MPS-50L at room temperature. Magnetic susceptibilities were determined by the Faraday method in the range from liquid nitrogen temperature to room temperature. Effective magnetic moments μ_{eff} were calculated by the equation

$$\mu_{eff} = 2.828\sqrt{(\chi_A - N\alpha)T}$$

where χ_A is the atomic susceptibility corrected for diamagnetism by the use of Pascal's constants[12] and $N\alpha$ denotes the temperature independent paramagnetism of copper(II) ions.

Results and Discussion

The yield of the binuclear complex $Cu_2X_2dar(en\text{-}R)_2$ is highly dependent on the substituent R. We were successful in obtaining $Cu_2X_2dar(en\text{-}i\text{-}Pr)_2$ in a high yield and $Cu_2X_2(en\text{-}Et)_2$ in a low yield, all the attempts to obtain $Cu_2X_2(en\text{-}Me)_2$ being unsuccessful. Attempts to prepare the binuclear complexes, $[Cu_2dar(en\text{-}R)_2Sol_2](ClO_4)_2$ (Sol denotes a solvent molecule, such as water, methanol or ethanol) were unsuccessful. This is probably because the desired compounds decompose in the solvent into monomeric species. On the other hand, $[Cu_2dar(dien)_2](ClO_4)_2\cdot H_2O$ was easily obtainable. It seems that the larger chelate effect operates for $[Cu_2dar(dien)_2](ClO_4)_2\cdot H_2O$ as compared with $[Cu_2dar(en\text{-}R)_2Sol_2](ClO_4)_2$. The ligand field effect can contribute to the stabilization of $[Cu_2dar(dien)_2](ClO_4)_2\cdot H_2O$.

Table 2. IR and visible spectral data of complexes

Complex	IR (cm^{-1})		Reflectance ($\times 10^3$ cm^{-1})	
	C=O	C=N	d-d	C.T.
$Cu_2Cl_2dar(en\text{-}Et)_2$	—	1590	16.1	20.9
$Cu_2Br_2dar(en\text{-}Et)_2$	—	1595	16.0	20.6
$Cu_2Cl_2dar(en\text{-}i\text{-}Pr)_2\cdot MeOH$	—	1595	15.7	20.8
$Cu_2Br_2dar(en\text{-}i\text{-}Pr)_2$	—	1595	15.4	20.0

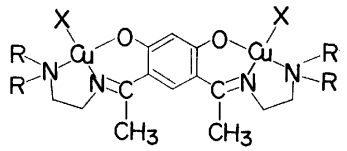
The infrared and visible spectral data of the binuclear and the mononuclear complexes are given in Table 2. In the binuclear copper(II) complexes no absorption band was found in the region 1700~1600 cm^{-1}, while in the mononuclear copper(II) complexes a strong band due to the C=O stretching vibration of free acetyl group was found near 1630 cm^{-1}. The absorption band which is attributable to the C=N stretching vibration is observed in the region 1600~1580 cm^{-1}. This band is superposed by the skeletal vibration of the aromatic ring. The broad and strong band around 1100 cm^{-1} in $[Cu_2dar(dien)_2](ClO_4)_2\cdot H_2O$ is attributable to the non-coordinated perchlorate ion. The reflectance spectra of $Cu_2X_2dar(en\text{-}R)_2$ and CuXHdar(en-R) show a ligand field band in the region 16.1~15.4 kK. A band was observed at 20~22.5 kK in addition to the d-d band. Since no such a band is present in the spectrum of $[Cu_2dar(dien)_2](ClO_4)_2\cdot H_2O$, and the bands for $Cu_2Cl_2dar(en\text{-}R)_2$ and CuClHdar(en-R) are located at higher energy region as com-



$Cu_2X_2dar(en\text{-}R)_2$ X=Cl, Br R=Et, *i*-Pr

TABLE 3. MAGNETIC DATA OF COMPLEXES

Complex	θ(K)	μ_{eff}(T)	
$Cu_2Cl_2dar(en\text{-}Et)_2$	−20	1.66 (78.1)	1.80 (288.0)
$Cu_2Br_2dar(en\text{-}Et)_2$	−12	1.66 (83.7)	1.75 (290.0)
$Cu_2Cl_2dar(en\text{-}i\text{-}Pr)_2 \cdot MeOH$	−34	1.66 (81.0)	1.85 (297.8)
$Cu_2Br_2dar(en\text{-}i\text{-}Pr)_2$	−10	1.62 (80.6)	1.75 (297.8)
$[Cu_2dar(dien)_2](ClO_4)_2 \cdot H_2O$	−17	1.69 (83.9)	1.75 (297.8)
CuClHdar(en-Me)	−1	1.76 (83.6)	1.78 (297.8)
CuBrHdar(en-Me)	−2	1.75 (78.3)	1.79 (297.8)
CuClHdar(en-Et)	−2	1.73 (86.0)	1.76 (293.0)
CuBrHdar(en-Et)	0	1.74 (84.1)	1.78 (295.4)
CuClHdar(en-*i*-Pr)·1/2MeOH	0	1.74 (81.2)	1.74 (297.8)

pared with those for the bromo homologues, it is natural to assign the band to the charge transfer band from the halogen ion to the copper(II) ion. This implies that the halogen ion is coordinated to the copper(II) ion. It is thus concluded that the complexes have the structures given in Fig. 1.

The magnetic susceptibilities of the binuclear and mononuclear copper(II) complexes were measured over the temperature range 77.4~300 K. The effective magnetic moments at room temperature and near liquid nitrogen temperature are given in Table 3. The effective magnetic moments of the binuclear copper(II) complexes and those of the mononuclear

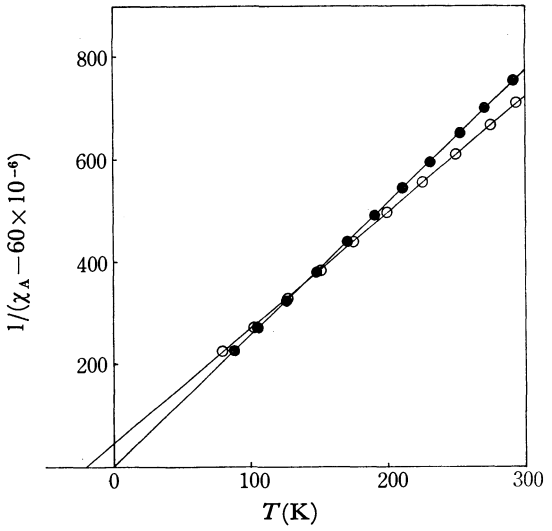

Fig. 2. Plots of reciprocal atomic susceptibilities of (○) $Cu_2Cl_2dar(en\text{-}Et)_2$ and (●) CuClHdar(en-Et) as a function of temperature.

copper(II) complexes show nearly the same values; all the values being larger than the spin-only value, 1.73 B.M. Although the magnetic moment of each mononuclear copper(II) complex near liquid-nitrogen temperature is nearly equal to that at room temperature, the magnetic moments of the binuclear copper(II) complexes are considerably lower than those at room temperature. The reciprocal of $\chi_A - 60\times10^{-6}$ was plotted against temperature. Typical examples for the binuclear and the mononuclear complexes are shown in Fig. 2. The magnetism for the complexes is interpreted in terms of the Curie-Weiss law, $\chi_A = C/(T-\theta)$. The Weiss constants of the complexes are also given in Table 3. The Weiss constants of the mononuclear complexes are nearly zero. This fact clearly indicates that the intermolecular magnetic spin-exchange interaction is negligibly small. On the other hand, the Weiss constants of binuclear copper(II) complexes are in the range −10~−34 K. In comparison with the magnetic properties of mononuclear copper(II) complexes, the antiferromagnetisms of the binuclear copper(II) complexes are attributable to an intramolecular spin-exchange interaction through the π-pathway of 4,6-diacetylresorcine moiety.

The expenses of the research were defrayed by a grant from the Ministry of Education.

Reaction of Iron(III)-Form Ion Exchanger with Acetylacetone

Kunio Ohzeki, Mayumi Ikeuchi, and Tomihito Kambara
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received May 16, 1974)

It was found that ferric ions are removed from resin by acetylacetone(Hacac) to form trisacetylacetonatoiron-(III), $Fe(acac)_3$. By the addition of a small amount of pyridine-water mixture to the iron(III)-form resin in acetylacetone milieu, the ferric ions are quantitatively removed from the resin, and in their place the pyridinium ions are adsorbed onto it. The reaction was successfully applied to the synthesis of $Fe(acac)_3$ in over 95% yield.

The conversion of a metallic ion on the cation exchanger into a chelate compound based on the ion exchange reaction in organic medium was investigated.

It was anticipated that if the resin suspended in an organic solvent is brought in contact with a chelating reagent such as β-diketone, the metal ions on the resin will be pulled out into the solvent in the form of metal chelate and the protons liberated from the β-diketone are adsorbed on the resin in place of the metal ions, as shown by

$$(RSO_3)_3Fe + 3Hacac = 3RSO_3H + Fe(acac)_3 \quad (1)$$

where R denotes the resin matrix.

In this paper the reaction of iron(III)-form Amberlyst 15 with acetylacetone is described.

Experimental

Apparatus and Reagents. Absorption measurements were carried out on a Shimadzu QV-50 spectrophotometer and a Hitachi 356 two-wavelength double-beam spectrophotometer with 10 mm cells. A Hitachi 063 type gas chromatograph with a thermal conductivity detector was used. Acetylacetone and pyridine (analytical grade, Wako Pure Chemical Inc.) were used without further purification.

Preparation of Iron(III)-Form Resin. The sulfonic acid cation exchanger, Amberlyst 15,[1] with a macroreticular structure was used, Commercial Amberlyst 15 was crushed and sieved to a fraction of 60—80 mesh. The resin was first washed with ethyl alcohol to remove impregnated toluene, and then with water, and treated with 4 M hydrochloric acid. The water-washed hydrogenform resin was treated with 0.1 M ferric nitrate. The resulting iron(III)-form resin is washed with water until the washings showed no color reaction with potassium ferrocyanide,[2] air dried, and then stored in a desiccator.

A part of ferric ion on the resin might be expected to coordinate hydroxyl ion, *e.g.*, $(RSO_3)_2FeOH$. In this case, the corresponding ion exchange reaction would proceed as follows,

$$(RSO_3)_2FeOH + 3Hacac = 2RSO_3H + Fe(acac)_3 + H_2O \quad (2)$$

Determination of Ferric Ions on the Iron(III)-Form Resin. The ferric ions on the 100 mg portion of the dried iron(III)-form resin were eluted with 2 M hydrochloric acid and determined spectrophotometrically with *o*-phenanthroline method. It was found that the 4.52 ± 0.10 meq of ferric ions are adsorbed per 1 g of the dried iron(III)-form resin.

Conversion of Ferric Ion on the Resin into Acetylacetonate. A test tube containing 5 mg of dried iron(III)-form resin and 3 ml of acetylacetone was dipped into the water bath kept at 70 ± 1 °C and shaken by hand for 5 min. A pyridine-water mixture was then added and warmed again for 5 min. After filtration, the resin was washed with ethyl alcohol and then with water. The ferric ions remaining on the resin were eluted by 2 M hydrochloric acid, and determined spectrophotometrically by the *o*-phenanthroline method.

Results and Discussion

Reaction of Ferric-Form Resin with Acetylacetone. In the course of the reaction, the color of the solution turned red as a result of the formation of tris(acetylacetonato)iron(III) complex identified by spectrophotometry. It was found that although the reaction shown by Eqs. (1) and/or (2) occurs, a considerable amount of iron is firmly retained on the resin. The phenomenon has not bee clarified.

Effect of Pyridine and Water. Conditions were studied for the complete liberation of iron from the resin. Addition of a pyridine-water mixture was found to be highly effective (Figs. 1 and 2). Addition of an appropriate amount of pyridine or water was effective to some extent, but a mixture of the two was the most effective, more than 99% of iron ions being removed from the resin by addition of the 2:1 to 1:5 pyridine-water mixture, 5—7% of the volume of acetylacetone employed. In the presence of the pyridine-water mixture, the dissociation of Hacac takes place as follows.

$$py + H_2O = pyH^+ + OH^-$$

$$Hacac + OH^- = acac^- + H_2O$$

The resulting acetylacetonate anion attacks the ferric

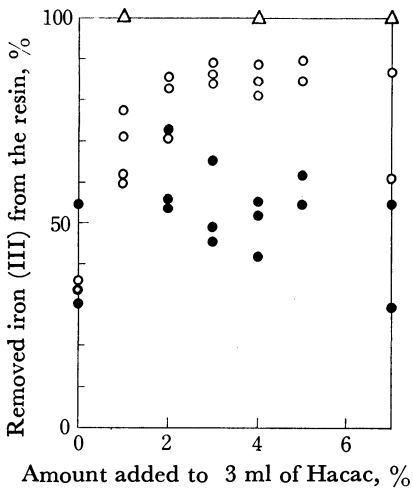

Fig. 1. Effect of the addition of pyridine (●), H_2O (○), and their 1:2 mixture (△) on the removal of the iron-(III) from the 5 mg of the resin with 3 ml of Hacac.

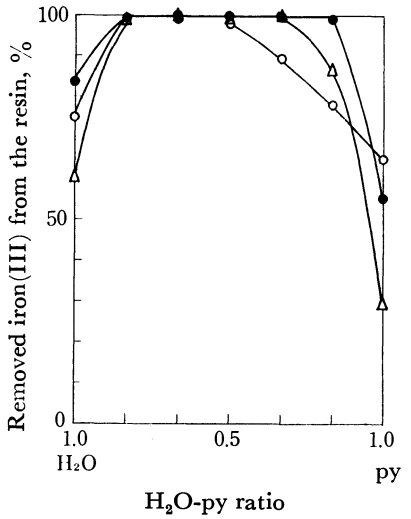

Fig. 2. Effect of the pyridine-water mixture with various ratio on the removal of the iron(III) from the 5 mg of the resin with 3 ml of Hacac. The ratio of the pyridine-water mixture added to Hacac is 1% (○), 5% (●), 7% (△) in Hacac, respectively.

ion on the resin, while the pyridinium ion competes with the ferric ion for the site, namely, the former withdraws the ferric ion from the resin and the latter is adsorbed on the resin in place of the ferric ion. One reaction predicted is shown by

$$(RSO_3)_3Fe + 3Hacac + 3py \xrightarrow{H_2O} 3RSO_3Hpy + Fe(acac)_3 \quad (3)$$

It was necessary to analyze the $Fe(acac)_3$ in the resulting solution and to detect the pyridinium ion on the resin.

Absorption Spectra of the Resulting Solution. After completion of the above procedure, the resin was filtered and washed with acetylacetone, all the washings being collected into a 20 ml volumetric flask, and then a 5 ml portion of the solution was taken out and the flask was filled up to 10 ml with Hacac. A comparison of the absorption spectra of the solution and that of synthesized one in which the corresponding amount of $Fe(acac)_3$ is dissolved in Hacac is shown in Fig. 3. The synthesis of $Fe(acac)_3$ is described later. It may be said that the compound is formed quantitatively by the reaction of iron(III)-form resin with Hacac.

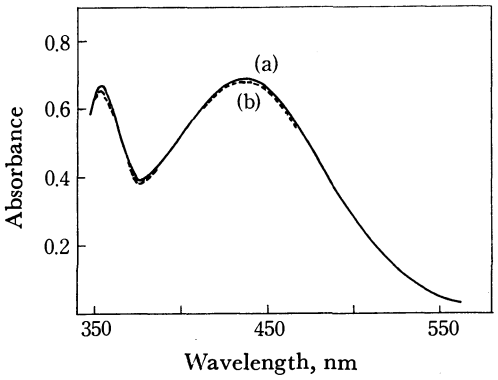

Fig. 3. Comparison of absorption spectra of $Fe(acac)_3$ in Hacac. (a) Synthesized chelate, 1.888×10^{-4} M, (b) Solution obtained by present method *vs.* Hacac.

Test for Pyridinium Ion on the Resin. The resin separated by filtration was further washed with ethyl alcohol and then with water until the washings gave no pyridine odor. A small amount of the 1 M sodium hydroxide was poured onto the resulting resin to elute the presumed pyridinium ion on the resin. The eluate having a strong pyridine odor was analyzed by gas chromatograph on the 1 m column packed with 30% PEG 4000 on 80—100 mesh Chromosorb W, at 90 °C. A pyridine peak appeared on the chromatogram indicating that the pyridinium ion had been adsorbed on the resin. The desorption of iron might proceed according to scheme (3). The sequence of addition of reagents is important, because if pyridine and water are present at the beginning of the reaction, they are adsorbed onto the metal ions on the resin and hinder the contact of Hacac with metal ions as confirmed experimentally.

Application to the Synthesis of the Chelate Compound. Treat 500 mg of iron(III)-form resin with 10 ml of Hacac and then add 0.5 ml of pyridine-water (1 : 2) solution. After the reaction, separate the resin by filtration and wash it with a small amount of Hacac, and collect the filtrate into a test tube. Heat to 130 °C and boil off the excess Hacac and pyridine by bubbling nitrogen gas. Collect the crude $Fe(acac)_3$ at the bottom of the test tube, and press it with glass wool. Narrow the neck of the test tube, and put it into a vessel connected to a vacuum pump, by heating the bottom of the tube to 190 °C at 1 Torr. The chelate deposits at the neck of the test tube. The mp of the chelate 181—183 °C (reported,[3] 181.3—182.3 °C); results of elemental analysis: Found: C, 50.98; H, 5.94%. Calcd for $Fe(C_5H_7O_2)_3$: C, 51.01; H, 5.99%. The yield of duplicate synthesis was 96 and 97%, respectively.

The reaction may commonly occur between the metallic form ion exchanger and chelating agent. Recently Higgins[4] applied the method to the preparation of cesium lanthanoid hexafluoroacetylacetonates. A reaction of this kind might have a wide applicability.

(Received February 26, 1974)

A new type of S_N2' reaction in which the nucleophile enters to the leaving group occurs in the acylolysis of 4β-bromo-3-keto-5β-steroids (**1**) to give 2α-acyloxy-3-keto-5β-steroids (**2**) as a product. This reaction pathway was observed by NMR and by tlc.

During the course of our studies on the chemistry of A-substituted 5β-steroids, we have found that the substitution reaction of 4β-bromo-3-keto-5β-steroid (**1a**) with potassium salts of organic acids under refluxing conditions is accompanied with a new rearrangement of a substituent from C_4 to C_2 resulting in the 2β-acyloxy-3-keto-derivative (**3a**) in good yield.[2] A rearrangement in the substitution reaction of steroidal α-halogenoketone has been investigated by several groups in recent years. For example, on acetolysis of 2α-bromo-5α-cholestan-3-one, Fieser and Romero[3] obtained 2α-acetoxy- and 4α-acetoxy-5α-cholestan-3-ones in a 1 to 1 ratio (40%). The fact that 4α-acetoxy-5α-cholestan-3-one was obtained proved that the rearrangement in the substitution reaction from C_2 to C_4 had partially taken place. Under the same condition, 2α-acetoxy-cholest-4-en-3-one was also obtained through the rearrangement from C_6 to C_2 in the substitution reaction of 6β-bromo-cholest-4-en-3-one in 17% yield.[3] Fieser and Romero suggested the following sequence as a possible mechanism for this rearrangement: enolization→allylic isomerization of the bromine atom→substitution with acetoxy-ion. This mechanism was also applied implicitly to the rearrangement from C_2 to C_4. Clarke *et al.* reported that when this reaction was carried out with 6β-bromotestosterone acetate as the reactant, the 2β-acetoxy-derivative was obtained, not the 2α-derivative.[4] They stated that the 2β-acetoxy-group epimerized to the α-acetoxy-derivative, which is a more stable form under the conditions. As a result, they concluded that the primary product was the 2β-acetoxy-derivative.

From the fact that halogeno-ketones as well as allylic halides undergo rearrangement in the substitution reaction, Newman suggested that the substitution reactions of a halogeno-ketone system also belong to the S_N2' reaction.[5] That is to say, these reactions are considered to involve nucleophilic substitution in the enolic form of the ketone; hence an allylic mechanism is reasonable. In these reactions the nucleophile has a *cis*-relationship to the leaving group when it attacks a γ-carbon (allylic position).[6] This consideration for the transition state seems consistent with the previous investigations of the S_N2' reactions in cyclic allylic compounds, in which only *cis*-substitutions have been investigated.[6] In the cases of the steroidal α-bromo-ketones,[3,4] mentioned above, the entering and the leaving groups are in *cis*-relationship to each other, also. In a recent communication, however, we reported a new type of S_N2' reaction in which the nucleophile enters *trans* to the leaving group.[7]

That is to say, when the 4β-bromo-3-keto-5β-steroid (**1a**) were treated with (a) potassium acetate–acetic acid, (b) potassium acetate–dioxane–water, (c) acetic acid–triethylamine and (d) potassium pivalate–dioxane–water at 90—95 °C, and with (e) tetramethylammonium acetate–dioxane at room temperature, the 2α-acyloxy-3-keto-derivatives (**2a, b, c**) was formed as a primary product.

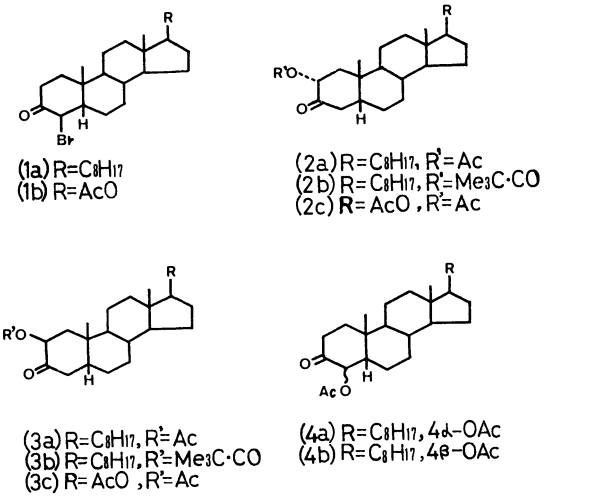

Fig. 1.

In the present paper, we wish to describe in full the details of the mechanism of the new reaction.

Results and Discussion

In each case above, 2α-acyloxy-5β-cholestan-3-ones (**2a, b**) was produced first. Since the isomerization of the 2α-acyloxy- to the 2β-acyloxy-derivative (**3a**) is relatively fast for cases (a) and (c), it was impossible to isolate the intial product, 2α-acyloxy-5β-cholestan-3-one, in high yield, but the 2α-acyloxy-derivative was obtained almost stereospecifically in 5 hr by reaction (b) and in 5 days by reaction (e).

In order to examine the stereochemical pathway of this reaction, **1a** was treated with potassium acetate in acetic acid (reaction (a)). The progress of the reaction was followed by tlc at certain time intervals. It could be observed that only the initial product (**2a**) was formed during the first 0.5 hr; and then during the next 0.5 hr, this initial product began to isomerize to the **3a**. This isomerization gradually continued, and the ratio of **2a** to **3a** became 1 : 1 at 3 hr. After 6.5 hr,

the **2a** completely disappeared.

In reaction (d), the NMR spectrum of the reactant, terminated after 1 hr, had peaks at 5.20 ppm (t, J= 9.5 Hz, which probably is in a boat conformation due to the severe interaction of the 2α-pivaloyloxy group with C_9–H and C_9–C_{10} in the chair conformation) and 4.80 ppm (d, J=11.5 Hz) due to the 2β-H in the 2α-pivaloyloxy-derivative and the 4α-H in the starting material respectively. When the reaction, which had once been terminated, was continued for 8 hr, the NMR spectrum of the reactant showed peaks at 5.04 ppm (dd, J=6.0 and 14.5 Hz) and 5.20 ppm, due to the 2β- (**3b**) and 2α-pivaloyloxy-derivatives (**2b**), respectively. In the NMR spectrum of the reactant after 30 hr, the triplet at 5.20 ppm disappeared and the quartet at 5.04 ppm remained. This suggested that an α-side attack is also possible for such a bulky nucleophile as Me_3CCOO^-. These NMR spectra are shown in Fig. 2. Such a phenomenon was already observed in reaction (b) by using a 220 MHz spectrometer to observe the change in the signals due to the methyl protons of the 2α- and 2β-acetoxy groups.[7]

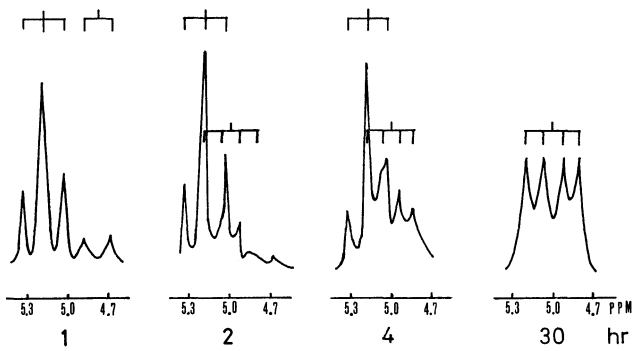

Fig. 2. 60 MHz NMR signals due to C_2H in the case of reaction (d) at intervals. Starting material: 4.80 ppm; α-Isomer: 5.20 ppm; β-Isomer: 5.04 ppm.

As the mechanism of the acylolysis, it is possible to consider that normal substitution occurs at C_4 with acyloxy-ion, and subsequently the acyloxy group formed rearranges to C_2.

Therefore, the 4α-acetoxy-derivative (**4a**) was synthesized from 5β-cholestan-3-one to find out whether or not the acetoxy-derivative changes to the 2α-acetoxy-isomer. Because this 4α-acetoxy-derivative contaminated with a trace of 4β-acetoxy-derivative, the crystallization of **4a** was unsuccessful. The structure of **4a** was confirmed by the comparison of NMR spectral data with the three other isomers (2α-, 2β-, and 4β-acetoxy-derivatives). When the 4α-acetoxy-derivative without further purification was treated with potassium acetate–acetic acid under the same conditions for the acetolysis described above, the 4β-acetoxy-derivative (**4b**) formed quantitatively. A parallel study[11] on 4α,17β-diacetoxy-5β-androstan-3-one found essentially the same behaviour. On the other hand, when the 4β-acetoxy-derivative was treated under the same conditions, the starting material was recovered.[8] From these results, it was ascertained that, in the acylolysis of 4β-bromo-5β-cholestan-3-one, the possibility of normal substitution products rearranging to give the 2-acyloxy-isomer is eliminated.

There is a further possibility that the substitution reaction by acyloxy ion takes place after a rearrangement of the bromine from C_4 to C_2 in the 4β-bromo-3-keto-derivative (**1**). Recently, one of the authors reported the first example of rearrangement of a halogen in an α-halogeno-ketone from the α- to the α′-carbon in such acylolysis.[9] That is, in the acetolysis of 1β-halogeno-5β-cholestan-2-one with potassium acetate–acetic acid at 98 °C, 3-halogeno-ketones could be isolated along with the 3-acetoxy-2-keto-derivative. But in the case of the reaction of 4β-halogeno-3-keto-5β-steroids, the 2-halogeno-3-keto-derivatives were not obtained, nor could they be observed by following the reaction with NMR and tlc. The foregoing facts would suggest that the rearrangement of 4β-halogeno-3-keto-5β-steroids to 2-halogeno-derivatives does not occur under our conditions. This result was identical with Liston's observation that 2β- and 4β-bromo-17β-acetoxy-5β-androstan-3-ones are not interchanged or equilibrated.[10]

While this report was being prepared, Wareneboldt and Weiler reported that the reaction of 17β-acetoxy-4β-bromo-5β-androstan-3-one (**1b**) with sodium acetate–acetic acid gave 2β,17β-diacetoxy-5β-androstan-3-one (**3c**) under refluxing conditions.[11] They did not observe formation of the 2α-acetoxy-isomer (**2c**), but they discussed the mechanism of the acetolysis by reference to the possible pathways for the reaction of *cis*-S_N2' type catalogued by Bordwell.[12] That is to say, in the acetolysis of 17β-acetoxy-2β-bromo-5β-androstan-3-one, it is cleanly converted to the 2β-acetoxy derivative in refluxing acetic acid–sodium acetate at a rate comparable to the 4β-bromo-derivative. From this finding, they suggested a carbonium ion pathway for this reaction. Thus both bromoketones give the same intermediate. If the acetolysis proceeds by such a mechanism, it can be considered that, for acetoxy ion attack, the steric environment at C_2 is not so different from that at C_4. From the conception of "product development control",[13] moreover, a 4β-substituted product may be anticipated from the carbonium ion. However, Weiler's product was only the

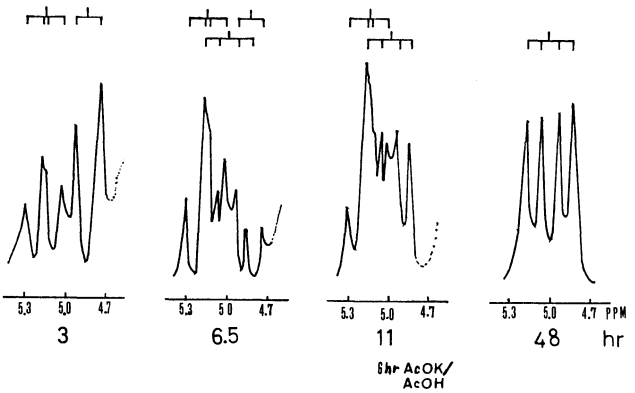

Fig. 3. 60 MHz NMR signals due to C_2H in the case of **1b**–potassium acetate–dioxane–water (100 mg/500 mg/7 ml/0.5 ml). Starting material: 4.80 ppm: α-Isomer: 5.14 ppm; β-Isomer: 5.02 ppm.

2β-acetoxy-derivative, not the 4-isomer. Therefore, we examined the acetolysis of 17β-acetoxy-4β-bromo-5β-androstan-3-one under our conditions. In both the case of reaction (a) and (b), the 2α-acetoxy-derivative (**2c**) was also formed as a primary product. In the former, however, the 2α-acetoxy-derivative was converted rapidly to the 2β-isomer (**3c**). In the latter case, it could be observed that the initial product was isomerized gradually to the 2β-isomer by the NMR spectra in each reaction step (Fig. 3).

According to these results, it is inferred that the acetolysis of 17β-acetoxy-4β-bromo-5β-androstan-3-one (**1b**) belongs to the *trans*-S_N2' reaction, and the primary product is the 2α-acetoxy-derivative (**2c**). Therefore, it does not seem reasonable that the carbonium ion pathway can be applied to the S_N2' reaction of the *trans* type. However, it seems reasonable that the acetolysis of 2α-bromo-5α-cholestan-3-one[3] proceeds by a carbonium ion pathway. To make sure that the reaction proceeded by such a pathway, the acetolysis of 2α-bromo-5α-cholestan-3-one was followed by taking NMR spectra at certain intervals. From these results, it turned out that 2α- and 4α-acetoxy-5α-cholestan-3-one in one to one proportion was already produced at an early stage. The ratio was retained during the acetolysis. The same results were also obtained in the case of 4α-bromo-5α-cholestan-3-one. Thus, it can be considered that with the 5α-series, this reaction proceeds by a carbonium ion pathway.

The *trans*-S_N2' reaction proceeded perfectly without allowing the normal substitution to take place, that is, the reaction of 4β-bromo-3-keto-5β-steroids with nucleophilic reagents gave 2-substituted 3-keto-5β-steroids only. Therefore, the acetoxy-ion present at high concentration in the reaction system is likely to attack the C_2-position directly by the S_N2' reaction mechanism. On the α-side attack at C_2, the enolization of the 3-keto group by acylolysis of **1** allows ring A to be a relatively flat with respect to ring B.[7] This conformation provides a favorable environment for nucleophile to attack at C_2. Furthermore, α-attack occurs more readily than β-attack at this position, because of the steric effect of the 10-methyl group. The 2α-acyloxy-derivative (**2**) was, therefore, formed as the product of the *trans*-S_N2' reaction and then was isomerized to the more stable 2β-isomer. Whether the nucleophile enters *trans* or *cis* to the leaving group depends on the stereochemistry of the reactant.

On the basis of these results, we conclude that in the S_N2' reaction of the α-halogeno-ketone, the entering group is not always *cis* to the leaving group.

Experimental

Thin-layer chromatography was carried out on Wakogel B-5 (Wako Pure Chemical Industries Ltd.), and detected by sulfuric acid. IR spectra were measured (KBr) with a Hitachi model 215 infrared spectrophotometer. ORD spectra were obtained in dioxane with JASCO model ORD/UV-5 instrument. NMR spectra were recorded in carbon tetrachloride with tetramethylsilane as an internal standard using a Hitachi-Perkin Elmer R-20A and Varian HR-220 instruments.

Acetoxylation of 5β-Cholestan-3-one. The synthesis was carried out following the procedure of Henbest *et al.*[14] for the synthesis of 2α-acetoxy-5α-cholestan-3-one from 5α-cholestan-3-one. A solution of 5β-cholestan-3-one (5 g) and lead tetraacetate (6.4 g) in benzene (150 ml) containing boron trifluoride–ether complex (1 ml) was stirred at room temperature in a nitrogen atmosphere for 4 hr. The reaction mixture was washed with water, dried and evaporated. The resultant oily product was chromatographed on silica gel and elution with benzene–light petroleum (2: 3) gave 4β-acetoxy-5β-cholestan-3-one (**4b**) (1.7 g), which crystallized from ethanol as needles, mp 104—106 °C, IR: ν_{max} 1745, 1725, and 1225 cm^{-1}; ORD (*c* 0.4, dioxane) at 21 °C: $[\alpha]_{389}$ +67.5°, $[\alpha]_{321}$ +247.5°, $[\alpha]_{306}$ +170°, $[\alpha]_{301}$ +185°, $[\alpha]_{299}$ +170°, and $[\alpha]_{280}$ +450; NMR: 5.33 ppm (d, J=12 Hz, 1H); Found: C, 78.27; H, 10.92, $C_{29}H_{48}O_3$ requires C, 78.37; H, 10.88%.

Reaction of 4β-Acetoxy-5β-cholestan-3-one (4b) with Potassium Acetate–Acetic Acid. A mixture of **4b** (22 mg), potassium acetate (20 mg) and acetic acid (2 ml) was refluxed for 6 hr. After the usual work-up, the starting material was recovered from the reaction mixture.

3β,4β-Oxido-3α-acetoxy-5β-cholestane. The synthesis was carried out following the procedure of Williamson and Johnson.[15] A solution of 3-acetoxy-5β-cholest-3-ene (4.5 g) in dichloromethane (70 ml) was treated with *m*-chloroperbenzoic acid (3.0 g) at room temperature for 24 hr. The reaction mixture was poured into water and the dichloromethane layer was worked up in the usual manner. Crystallization of the resulting oil from acetone gave 3β,4β-oxido-3α-acetoxy-5β-cholestane (844 mg), mp 135—138 °C, IR cm^{-1}: ν_{max} 1745, 1225, and 1052; NMR: 2.86 ppm (s, 1H); Found: C, 78.33; H, 10.88, $C_{29}H_{48}O_3$ requires C, 78.26; H, 10.97%.

4α-Acetoxy-5β-cholestan-3-one (4a). A sample of 3β,4β-oxido-3α-acetoxy-5β-cholestane (636 mg), mp 135—138 °C, was placed in a 20 ml Erlenmeyer flask which was immersed for 5 min in an oil bath maintained at 160 °C. The resulting oil which failed to crystallize; IR: ν_{max} 1750, 1727, and 1235 cm^{-1}; NMR: 5.25 ppm (d, J=8.6 Hz, 1H). The synthesis was carried out following the procedure of Williamson and Johnson.[15]

Reaction of 4α-Acetoxy-5β-cholestan-3-one (4a) with Potassium Acetate–Acetic Acid. A mixture of (**4a**, oil) (22 mg), potassium acetate (20 mg) and acetic acid (2 ml) was refluxed for 6 hr. The NMR indicated that 4α-acetoxyderivative completely isomerized to the corresponding 4β-acetoxy-derivative (**4b**).

Acetolysis of 1a with Tetramethylammonium Acetate in Dioxane. A mixture consisting of **1a** (50 mg), tetramethylammonium acetate (210 mg) and dioxane (2.5 ml) was stirred at room temperature. After 5 days, the reaction mixture was poured into water and extracted with ether. The ether extracts were washed with water, dried and evaporated. Crystallization of the residue from ethanol gave (**2a**) (23 mg) as needles, mp 138—139 °C. The product was identical in infrared spectrum with authentic 2α-acetoxy-5β-cholestan-3-one.[2]

2β-Trimethylacetoxy-5β-cholestan-3-one (3b). A solution of **1a** (100 mg) in dioxane (5 ml) was stirred with pivalic acid (521 mg), potassium hydroxide (286 mg), and water (1 ml) at refluxing temperature. After 18 hr, the reaction mixture was poured into water, and extracted with ether. After the usual work up, crystallization from ethanol afforded needles (258 mg), mp 125—126 °C, IR: ν_{max} 1746, 1728, and 1158 cm^{-1}; ORD (*c* 0.96, dioxane) at 25 °C: $[\alpha]_{330}$ −31.3°, $[\alpha]_{310}$ −146°, $[\alpha]_{275}$ +407°; NMR: 5.04 ppm (q, J=6.0 and 13.5 Hz, 1H); Found: C, 79.19; H, 11.23, $C_{32}H_{54}O_3$ requires C, 78.96; H, 11.18%.

Followings of the Progress in Acylolysis of 1a. Each

amount (100 mg) of 4β-bromo-5β-cholestan-3-one (**1a**) was treated with (a) potassium acetate–acetic acid (500 mg/6 ml), (b) potassium acetate–dioxane–water (500 mg/7 ml/0.5 ml), (c) triethyl amine–acetic acid (3 ml/7 ml), (d) pivalic acid–potassium hydroxide–dioxane–water (521 mg/286 mg/5 ml/1 ml) at 90—95 °C, and (e) tetramethylammonium acetate–dioxane (420 mg/5 ml) at room temperature. Each reaction was stopped at certain time intervals. After the usual work up, the progress of the reaction was followed by tlc and by using NMR spectrometer. R_f values of the starting material (**1a**) and the resultant α-acyloxy-ketones in benzene–ether system (19: 1) are as follows; 4β-bromo- (**1a**): 0.77, 2α-acetoxy- (**2a**): 0.46, 2β-acetoxy- (**3a**): 0.61, 2α-pivaloxy- (**2b**): 0.45, and 2β-pivaloyloxy-5β-cholestan-3-one (**3b**): 0.64. The NMR spectra of method (b), as an example for the acetolysis, and method (d) are shown in Figs. 3 and 2, respectively.

Epimerization of 2α-Acetoxy-5β-cholestan-3-one. (i) A solution of **2a** (50 mg) in acetic acid (2 ml) was refluxed with potassium acetate (35 mg) for 3 hr. The tlc indicated that the 2α-acetoxy-derivative (**2a**) completely epimerized to the corresponding 2β-acetoxy-isomer (**3a**). (ii) Instead of using acetic acid as a solvent, dioxane was used. The epimerization was completed in 6 hr refluxing conditions.

*Acetolysis of 17β-Acetoxy-4β-bromo-5β-androstan-3-one (**1b**).* This method was identical with reaction (b), described above. 2α,17β-Diacetoxy- and 2β,17β-diacetoxy-5β-androstan-3-one formed could not be identified on the tlc. The NMR spectra of the reaction mixture at certain time intervals are shown in Fig. 3.

The authors wish to thank Professors Jisaku Kuroda, Machiko Tozawa, and Tunetaka Kushimoto for their many supports during this work.

Reaction of 1,3-Oxazinium Salt with Active Methylene Compounds

Isao SHIBUYA and Masahiro KURABAYASHI
National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153
(Received March 7, 1974)

2,4,6-Triphenyl-1,3-oxazinium perchlorate reacts with active methylene compounds to give several butadiene derivatives and various pyridine derivatives. The reactions seem to proceed as follows: The carbanion from an active methylene compound attacks the 6-position of the oxazinium ring, and opens the ring to form a butadiene as an intermediate, which is then recyclized to a pyridine derivative according to a characteristic mode. The mode of recyclization differs with the constituent of each active methylene. There are five modes characteristic of cyano-, ester-, amido- and benzoyl constituents and nitromethane. A compound containing two different constituents usually follows either of the two possible modes.

Pyrylium, 1,3-oxazinium, and 1,3,5-oxadiazinium salts constitute a homologous series with respect to the number of nitrogen atoms in their rings. It was found that 1,3-oxazinium[1,2] and 1,3,5-oxadiazinium salts,[2-5] as well as pyrylium salt, are 6π-cation compounds. The high reactivity of the salts toward many kinds of nucleophiles is known, in particular that of pyrylium salt.[6-9] Active methylene compounds are nucleophiles which introduce a carbon atom with one or two nucleophilic substituents. Dimroth and Neubauer showed that active methylene compounds react with 2,4,6-triphenylpyrylium salt (**1**) to produce various benzenes.[10,11] Schmidt *et al.* reported that 2,4,6-triphenyl-1,3-oxazinium perchlorate (**2**) gives 2-benzoylamino-3-cyano-4,6-diphenylpyridine (**4**) on reaction with malononitrile.[12,13] We showed that 2,4,6-triphenyl-1,3,5-oxadiazinium salt (**3**) reacts with several active methylenes to give pyrimidine derivatives.[14,15] It was found that an active methylene does not always behave in the same manner in reacting with **1** and **3**; for example, benzoylacetonitrile reacts with **1** to give 2,4,6-triphenylbenzonitrile, and with **3** to give 5-cyano-2,4,6-triphenylpyrimidine and 5-benzoyl-4-benzoylamino-2,6-diphenylpyrimidine; methyl cyanoacetate reacts with **1** to give 2,4,6-triphenylbenzonitrile and with **3** to give 4-benzoylamino-5-methoxycarbonyl-2,6-diphenylpyrimidine. In order to clarify the behavior of active methylenes reacting with **1**, **2**, and **3**, the reactions of **2** with these methylene were studied. The results are discussed together with those dealing with **1** and **3**.

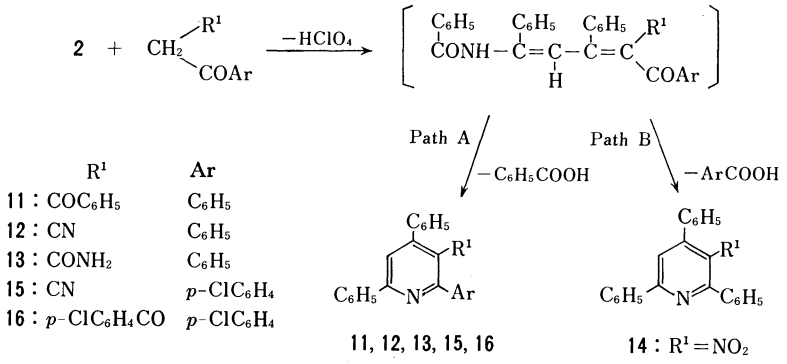
Results and Discussion

Methyl Cyanoacetate. Since methyl cyanoacetate reacts with **1** and **3** in different ways,[10,14] its reaction with **2** was examined. **5** was obtained in a good yield on refluxing this compound and **2** in dioxane in the presence of a 1.5 molar amount of triethylamine. The molecular weight of **5** was determined by mass spectroscopy to be 376. **5** has a cyano group (2205 cm^{-1}) and an ester group (1756, 1229 cm^{-1}). On the other hand, when 2-chloro-3-cyano-4,6-diphenylpyridine[13,16] was treated with benzoic acid in pyridine, the product was the same as **5**. Thus, **5** was identified to be 2-benzoyloxy-3-cyano-4,6-diphenylpyridine. It was found that this compound reacts with **1**, **2**, and **3** in different ways.

Diethyl Malonate. Diethyl malonate did not react on refluxing with **2**, but after treatment at room temperature it produced **6** which was determined to be an adduct of the oxazinium cation and the carbanion from this compound. Schmidt reported that **2** reacting with some active methylenes gives some adducts with butadiene structures.[13] It is assumed that **6** is a butadiene derivative. When **6** was heated above its melting point, **7** was derived. The molecular weight of **7** was determined to be 423. Its IR spectrum resembles that of **5** very closely, and shows the presence of two kinds of ester groups (1757, 1720, 1265, 1232 cm^{-1}). This and the results of elemental analysis indicate that **7** is 2-benzoyloxy-3-ethoxycarbonyl-4,6-diphenylpyridine. The type of reaction which gives **7** is thought to be the same as that for **5**. For **3**, this compound gives 4-benzoyloxy-5-ethoxycarbonyl-2,6-diphenylpyrimidine with the liberation of ethanol followed by benzoyl migration.[15] Therefore, this compound is regarded to react in the same way with **2** and **3** to give benzoyl-pyridine and -pyrimidine, respectively.

Cyanoacetamide and Ethyl Carbamoylacetate. When **2** was refluxed with cyanoacetamide in dioxane, **8** was obtained. Its IR spectrum coincided with that of 2-hydroxy-3-cyano-4,6-diphenylpyridine which was derived from dibenzoylmethane and this compound.[13] However, ethyl carbamoylacetate reacting with **2** gave **9** when left to stand at room temperature. This product is regarded as a butadiene derivative from its IR and NMR spectra. When heated above its melting point, **9** was converted into **10**. **10** is weakly acidic. Its IR spectrum has no absorption assigned to an amide group, but closely resembles that of **8**. Thus, **10** was determined to be 2-hydroxy-3-ethoxycarbonyl-4,6-diphenylpyridine. Since these two compounds possessing a carbamoyl group produce 2-hydroxypyridines, it may be certain that cyanoacetamide forms a butadiene derivative as an intermediate.

Dibenzoylmethane, Benzoylacetonitrile, Benzoylacetamide, Nitromethane, p-Chlorobenzoylacetonitrile, and Bis(p-chlorobenzoyl)methane. **11**, **12**, and **14** were obtained, respectively when dibenzoylmethane, benzoylaceto-



Scheme 1.

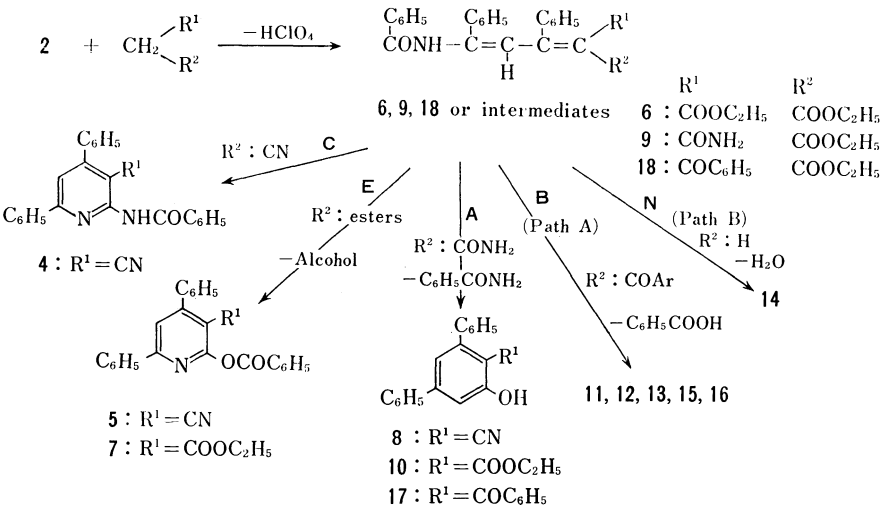
nitrile and nitromethane were refluxed with **2**, whereas treatment of **2** with benzoylacetamide at room temperature gave **13**. Their molecular weights were determined to be 411, 332, 350, and 352, respectively, the values being equal to the sums of the mass of the 2,4,6-triphenylpyridyl group (306) and that of each constituent, *i.e.*, the benzoyl (105), cyano (26), carbamoyl (44), and nitro groups (46), respectively. Their IR spectra were regarded as essentially the same except for the absorptions assigned to each group described above. On the other hand, **11** is identified to be 3-benzoyl-2,4,6-triphenylpyridine[17] with an authentic sample. Thus, **12**, **13**, and **14** were confirmed to be 3-cyano-, 3-carbamoyl-, and 3-nitro-2,4,6-triphenylpyridines. Two cyclization schemes can be assumed for the formation of **11**, **12**, or **13** as Scheme 1.

In order to determine which path is correct, the reaction of *p*-chlorobenzoylacetonitrile and bis(*p*-chlorobenzoyl)methane with **2** were examined. The resulting pyridines, **15** and **16**, respectively, have a *p*-chlorophenyl group in the 2-position. It is thus evident that these compounds possessing a benzoyl as well as a *p*-chlorobenzoyl group produce pyridines *via* path A. However, nitromethane gives **14** *via* path B. For benzoylacetamide, another product, **17**, was obtained together with **13** upon refluxing. **17** was confirmed to be 2-hydroxy-3-benzoyl-4,6-diphenylpyridine, since the IR spectrum of **17** closely resembles those of **8** and **10**.

Ethyl Benzoylacetate. This gave an adduct, **18**, upon treatment with **2** at room temperature. **18** was confirmed to be a butadiene similar to **6** and **9**. **18** was expected to give 3-ethoxycarbonyl-2,4,6-triphenylpyridine or 2-benzoyloxy-3-benzoyl-4,6-diphenylpyridine or both. However, heating of **18** above its melting point resulted in the recovery of **18**. This may be caused by the fact that bulky constituents such as benzoyl and ethoxycarbonyl groups sterically hinder the cyclization of **18**.

All the compounds employed in this investigation, except for ethyl benzoylacetate, gave various pyridines when treated with **2** as well as malononitrile. These reactions are thought to proceed as Scheme 2.

The carbanion from active methylene attacks the 6-position of the oxazinium ring, and opens the ring to form a butadiene as an intermediate, which then recyclizes to a pyridine derivative according to a characteristic mode. From the relation between the reagents employed and the constituents, which are parts of the pyridines produced, the cyclization processes can be classified into five modes. The first mode, **C**, is characteristic of the compound possessing a cyano group, and produces 2-benzoylaminopyridine with the migration of a benzoyl group. Malononitrile is of this mode. The second, **E**, takes in an ester group, *i.e.*, diethyl malonate and methyl cyanoacetate, and is characterized by the formation of 2-benzoyloxypyridines with



Scheme 2.

the liberation of an alcohol followed by the benzoyl migration. The third, **A**, takes place in cyanoacetamide, ethyl carbamoylacetate, and benzoylacetamide, and these derive 2-hydroxypyridines with the liberation of benzamide. The fourth, **B**, occurs in dibenzoylmethane, benzoylacetonitrile, and benzoylacetamide. This mode is characteristic of path A with the liberation of benzoic acid. For these four modes, the phenyl group in the 2-position of **2** is mobile, that is, on the cyclization to pyridines it migrates as a benzoyl group (**C**, **E**) or escapes as a benzoic acid (**B**) or a benzamide (**A**). However, nitromethane is considered to follow the fifth mode (**N**), and the phenyl group is introduced into the 2-position of **14** as such.

The compounds possessing the same two constituents follow this mode characterized by their own constituents. However, the compounds possessing two different constituents have two possible modes, and in practice, with the exception of benzoylacetamide, take either of the two. If we suppose that each compound follows the easiest mode, the relation **B**$\gtrsim$**A**>**E**>**C**, is observed between the four modes. However, for the same supposition, a different relation, **A**>**C**$\gtrsim$**B**>**E**, is derived from the results obtained from reactions of **3** with several active methylenes.[14,15] The most important factor characterizing the mode still remains undetermined. However, the reactions of **2** and **3** with active methylenes are useful for synthesizing pyridine or pyrimidine derivatives.

Experimental

The melting points of all products were measured in capillary tubes with a Mettler FPI apparatus at the rate 2 °C/min. The IR spectra were measured in KBr pellets with a JASCO DS-403G spectrometer. The molecular

weights were determined with a Hitachi RMU6E mass spectrometer equipped with a direct inlet and operating at an ionization electron energy of 70 eV. The NMR spectra were obtained in deuteriochloroform with a Varian XL-100 spectrometer with tetramethylsilane as an internal standard.

Genaral Procedures for the Reaction of **2** *with Active Methylene Compounds.* 2 mmol of **2** was added to a solution of 2 mmol of an active methylene compound and 3 mmol of triethylamine in 10 ml of dioxane. The mixture was stirred for ten minutes, and then either (A): refluxed for an hour, or (B): allowed to stand for a week at room temperature. The resulting mixture was poured into dilute hydrochloric acid. The precipitate was collected by filtration, and purified by recrystallization from an appropriate solvent. Results for the pyridine derivatives (**5**, **7**, **8**, and **10**—**17**) are given in Table 1. The butadienes were always obtained under the reaction conditions, B, and purified by recrystallization from methanol. Results for the butadienes are given in Table 2.

*Conversion of Butadienes to Pyridines (***7** *and* **10***).* 0.50 g of **6** was heated to above its melting point, *i.e.*, 140—150 °C for 20 min, and 0.5 g of **9** was treated at 180—190 °C for 2 hr (Table 1). **18** was treated in a similar way to that given above, at 150—160 °C for 4 hr, but recovered as such.

*2-Benzoyloxy-3-cyano-4,6-diphenylpyridine (***5***) from 2-Chloro-3-cyano-4,6-diphenylpyridine.* A solution of 1.00 g of 2-chloro-3-cyano-4,6-diphenylpyridine and 1.00 g of benzoic acid in 5 ml of pyridine was allowed to stand at room temperature for two days. The solvent was evaporated *in vacuo*, and the residue was washed with dilute hydrochloric acid and aqueous sodium hydroxide, and then recrystallized from ethanol to yield 0.22 g (16%) of **5**; mp 144.4 °C. The IR spectrum and molecular weight agreed completely with those of **5** derived from **2** with methyl cyanoacetate. Found: C, 79.83; H, 4.39; N, 7.53%. Calcd for $C_{25}H_{18}N_2O_2$: C, 79.77; H, 4.29; N, 7.53%.

Nucleophilic Substitution on Trivalent Nitrogen Atom.[1] Menschutkin Type Reaction of *O*-2,4-Dinitrophenylhydroxylamine with Uncharged Nucleophiles

Fumio YAMAMOTO and Shigeru OAE*

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

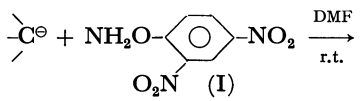
**Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31*

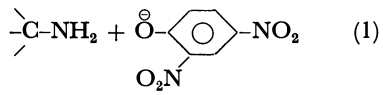
(Received May 27, 1974)

Kinetic investigation carried out on the reaction between *O*-2,4-dinitrophenylhydroxylamine and neutral nucleophiles revealed that the reaction is a typical S_N2 reaction on the trivalent nitrogen atom. Moreover, the order of reactivities of common nucleophiles was found to be somewhat similar to that of the nucleophilicities toward sp^3 carbon atom. However, unlike the S_N2 reaction on sp^3 carbon atom, the S_N2 reaction on the trivalent nitrogen atom found to be not very sensitive to the steric effect of substituted pyridine.

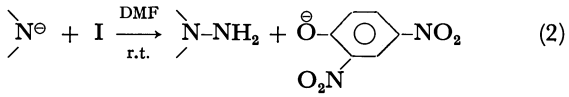
Nitrogen and carbon are adjacent elements in the periodic table and, as such, share certain common chemical properties, such as the ability to form trigonal and tetrahedral bonding skeletons, the octet electronic environment, *etc.* While the nucleophilic substitutions on carbon atom have been studied systematically in the past three decades, those on nitrogen atom have been investigated very little except for a few fragmental examples.[2,3] Those studied were chloramine[2] and hydroxylamine-*O*-sulfonic acid[3] which are too unstable to be subjected to the kinetic experiments, reacting only under the limited conditions, *e.g.*, in liq. ammonia solution.

Recently, Sheradsky[4] first observed the following reactions shown in Eqs. (1) and (2).





(1)



(2)

These reactions appear to be the most suitable for examining the nature of the S_N2 reaction on the nitrogen atom if the starting compound (I) can be made in pure form. Fortunately, the hydroxylamine (I) was able to be made in crystalline form, mp 113 °C.

We have therefore undertaken a kinetic study of Menschutkin type reactions with *O*-2,4-dinitrophenylhydroxylamine (I). Pyridine derivatives, aryl alkyl sulfide and triphenylphosphine were chosen as representative uncharged nucleophiles.

Results and Discussion

All these nucleophiles react smoothly with the hydroxylamine (I) in dioxane at room temperature and gave the readily isolable products, which are summarized in Table 1. The structures of the reaction products were determined on the basis of the spectral data and elemental analyses, details of which are given in the experimental section. These results indicate undoubtedly that the nucleophilic displacement takes place only at the nitrogen atom.

TABLE 1. REACTION PRODUCTS OF THE HYDROXYLAMINE (I) WITH SOME NUCLEOPHILES

Nucleophile	Product[a]		Mp °C	Yield (%)

50	3.83	$\Delta H^{\ddagger}_{40} = 14.9$ kcal/mol

constants against the initial concentration of pyridine in large excess, *e.g.*, from 10 to 100 times, over that of the hydroxylamine (I). Dioxane was employed as the solvent while temperature was set at 50 °C. From the slope of the line the second order nature of the reaction is apparent with $k_2 = 3.83 \times 10^{-4}$ M^{-1} s^{-1}. The observed second-order rate constants are listed in Table 2 along with the calculated activation parameters. Obviously, these values also suggest the reaction to proceed *via* the S_N2 path at the nitrogen atom. The values of the activation parameters are quite similar to and only somewhat smaller than that of Menschutkin reaction ($E_a = 13.6$ kcal/mol, $\Delta S^{\ddagger} = -33.1$ e.u., $\Delta H^{\ddagger} = 13.0$ kcal/mol)[5] of methyl iodide and the same base.

TABLE 3. SOLVENT EFFECTS FOR THE REACTION OF THE HYDROXYLAMINE(I) WITH PYRIDINE AT 40 °C

Solvent	D.C.	$k_2 \times 10^4$ ($M^{-1}s^{-1}$)
Dioxane	2.21	1.87
$CHCl_3$	4.81	3.30
Acetone	20.5	6.68
CH_3CN	37.5	7.32
DMF	36.7	14.01
CH_3OH	32.6	2.09
C_2H_5OH	24.3	2.52
H_2O–Dioxane (25%v/v)		5.00
H_2O–Dioxane (50%v/v)		7.16
H_2O–Dioxane (75%v/v)		7.66

Table 3 shows solvent effect for the reaction of the hydroxylamine(I) with pyridine at 40 °C. All these values indicate the same tendency as that of the Menschutkin reaction.[6] As the polarity of the solvent and the solvation of the leaving group, *i.e.*, 2,4-dinitrophenolate ion, increases with increasing water content, the reaction rate also increases.

Relative reactivites of a few representative nucleophiles are listed in Table 4.

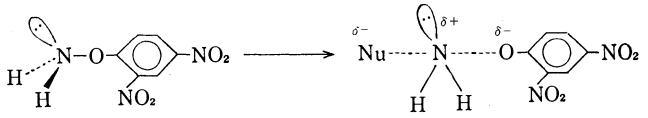
Inspection of the data in Table 4 indicates that the reactivity order of these common nucleophiles lie in somewhat similar order with those of the nucleophilicities toward sp^3 carbon atom.[7] However, unlike in the S_N2 reaction on sp^3 carbon atom, the rate of 2-picoline is somewhat higher than that of pyridine. Even for 2,6-lutidine bearing two methyl groups on both side of the nucleophilic center, the rate constant is not much smaller than pyridine. These observations clearly show that the S_N2 reaction on the trivalent nitrogen atom is not very sensitive to the steric effect of methyl substitution as compared to that on the sp^3 carbon atom.

TABLE 4. RELATIVE RATIOS OF S_N2 REACTIONS ON NITROGEN AND CARBON ATOMS

Compound	Nucleophiles				
	Pyridine	2-Picoline	2,6-Lutidine	$PhSCH_3$	Ph_3P
I	1[a]	1.1	0.3	8	60
CH_3I[c]	1[b]	0.3	0.02	3	58

a) $3.38 \times 10^{-4} M^{-1}s^{-1}$ at 50 °C. b) $2.20 \times 10^{-5} M^{-1}s^{-1}$ at 25 °C. c) Reference 7.

As the lone pair of the trivalent nitrogen atom of the substrate (I) is considered to bear a substantial s-character,[8] it is much more vulnerable to distortion than the C–H sigma bond at the transition state as shown below.



sp^2 transition state

The lone pair would not be solvated much in an aprotic solvent, but in a protic solvent it would be solvated markedly due to the hydrogen bonding.[9]

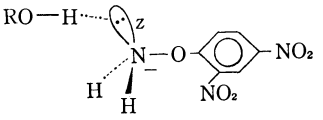


TABLE 5. STERIC EFFECT OF PYRIDINE DERIVATIVES IN VARIOUS SOLVENTS AT 40 °C

Solvent	Pyridine[a]	2-Picoline	2,6-Lutidine
Dioxane	1	1.10	0.29
CH_3CN	1	0.98	0.24
CH_3OH	1	0.79	0.19
H_2O–Dioxane (25%v/v)	1	0.89	0.20
H_2O–Dioxane (75%v/v)	1	0.77	0.19

a) The each value of k_2 are shown in Table 3.

Table 5 shows the magnitude of the steric effect of these substituted pyridines in both aprotic and protic solvents. On account of the hydrogen bonding as shown below, the steric effect increases by changing the solvent from aprotic to protic solvent. Since these nucleophiles are also solvated in protic solvents the reaction becomes more sensitive to the steric effect in protic solvent, and the order of reactivities approaches to that on the sp^3 carbon atom.

Experimental

Pyridine derivatives were purified according to the Coetzee and Padmanabhan's method.[10] Other nucleophiles were purified by distillation or by recrystallization of the commercial products. *O*-2,4-Dinitrophenylhydroxylamine(I) was prepared by the reaction of ethyl *O*-2,4-dinitrophenyl-acetohydroxamate with 70% perchloric acid in dioxane,[11] mp 113 °C (lt,[12] 112 °C). Found: C, 36.10; H, 2.64; N, 21.04%. Calcd for $C_6H_5N_3O_5$: C, 36.17; H, 2.54; N, 21.19%.

An equimolar mixture of the hydroxylamine(I) and nucleophile dissolved in dioxane was allowed to stand at room

temperature for a few hours. After evapolation of solvent the residual crystals were washed with hot benzene and recrystallized from ethanol or chloroform. The products were identified by elemental analysis and by comparing the NMR and IR spectra with those of the hydroxylamine(I) and nucleophilies.

Table 6. Elemental analysis data

Compound	Calcd (%)			Found (%)		
	C	H	N	C	H	N
Ia	47.49	3.62	20.14	47.41	3.61	20.30
Ib	49.32	4.14	19.17	49.46	4.05	19.50
Ic	50.98	4.61	18.29	50.90	4.60	18.31
Id	48.29	4.05	13.00	48.21	3.97	13.40
Ie	62.47	4.37	9.11	62.14	4.35	8.45

Kinetic Measurement. All kinetic runs were followed by pipetting 1 ml aliquots from 20 ml glass-stopped flask into 50 ml of ice water or ethanol a portion of which was subjected to measurement of the absorption spectra of 2,4-dinitrophenolate ion (λ_{max} 360 nm, ε 11000) by UV spectrometer. All the rate constants were determined from the pseudo-first-rate equation as follows.

$k=(2.303/bt)\log(a_\infty-a_0)/(a_\infty-a_t)$

a_∞: the final intensity of produced phenolate ion.

a_0: the initial intensity of produced phenolate ion.

a_t: the intensity of produced phenolate ion after t.

b: the initial concentration of nucleophile.

A typical run is shown in Table 7. (50 °C).

Table 7.

Time (min)	a_t	$\log(a_\infty-a_0)/(a_\infty-a_t)$	$k_1(s^{-1})\times10^4$
0	0.35		
3	0.51	0.0290	3.72
6	0.66	0.0577	3.70
9	0.82	0.0909	3.87
12	0.96	0.1219	3.89
18	1.21	0.1840	3.90
24	1.40	0.2377	3.83
30	1.59	0.2993	3.83
	2.86		

Hydroxylamine(I) $=1\times10^{-2}$M. Mean of k_1s.; 3.83 $\pm0.06\times10^{-4}$ $M^{-1}s^{-1}$. Pyridine(b)=1 M.

The Syntheses of Ripariochromene A and Methylripariochromene A[1]

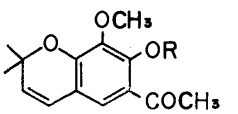
Masao TSUKAYAMA

Department of Applied Chemistry, Faculty of Engineering, University of Tokushima, Tokushima 770

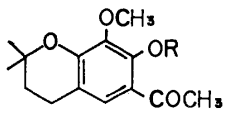
(Received August 9, 1974)

7,8-Dimethoxy-2,2-dimethylchroman was obtained from pyrogallol trimethyl ether and β,β-dimethylacrylyl chloride *via* the corresponding chroman-4-one. The Friedel-Crafts reaction of the chroman with acetyl chloride yielded 6-acetyl-7-hydroxy-8-methoxy-2,2-dimethylchroman. The dehydrogenation of the acetylchroman with DDQ in anhydrous benzene afforded ripariochromene A. Ripariochromene A was converted into methylripariochromene A

Ripariochromene A has recently been isolated, along with several chromenes, from Australian *Eupatorium riparium* Regel.[2] Its structure has been shown to be 6-acetyl-7-hydroxy-8-methoxy-2,2-dimethylchromene (I), with an unique 1,2,3-trioxygenated pattern, on the basis of the spectral evidence.[2] Methylripariochromene A (the methyl ether of I) (II) also has been isolated from Australian[2] and Jamaican *E. riparium* Regel.[3] The present paper will describe the syntheses of I[4] and II from 7,8-dimethoxy-2,2-dimethylchroman (III).



I R=H
II R=CH_3
X R=CH_3CO



VIII R=H
IX R=CH_3CO

The condensation of pyrogallol trimethyl ether (IV) and β,β-dimethylacrylyl chloride (V) in the presence of anhydrous aluminum chloride over a 52 hr period gave 7,8-dimethoxy-2,2-dimethylchroman-4-one (VI). When the above condensation was allowed to proceed for a relatively short period of time, 2-hydroxy-3,4-dimethoxyphenyl 2-methyl-1-propenyl ketone (VII) was obtained, along with a small amount of VI. The NMR spectra of VI and VII showed the presence of one methylene group (δ 2.68 ppm) and one hydrogen-bonded hydroxyl group (δ 13.13 ppm) respectively. The ketone (VII) was easily converted into the chromanone (VI) when heated with ethanolic hydrochloric acid or acetic acid. The Clemmensen-reduction of VI or the hydrogenolysis of the thioketal of VI with Raney nickel gave the chroman (III).[5] The hydrogenolysis afforded III in a better yield than did the Clemmensen-reduction. The Friedel-Crafts reaction of III with acetyl chloride gave 6-acetyl-7-hydroxy-8-methoxy-2,2-dimethylchroman (VIII) (δ 2.52 ppm). The dehydrogenation[6-8] of VIII with 2,3-dichloro-5,6-dicyano-*p*-quinone (DDQ) in anhydrous benzene gave the desired chromene (I) (mp 89.5—90.5 °C),[1] which was shown to be identical with natural ripariochromene A on the basis of a mixed-melting-point determination and by NMR, infrared, and ultraviolet spectral comparisons.

The chromene (I) was easily converted into the methyl ether (II) (colorless liquid).[2] The properties of this synthetic chromene (II) were in full accord with those of natural methylripariochromene A.

Experimental[9]

2-Hydroxy-3,4-dimethoxyphenyl 2-Methyl-1-propenyl Ketone (VII). With stirring and cooling at 0 °C, β,β-dimethylacrylyl chloride (5.2 g) was added, drop by drop, to a solution of anhydrous aluminum chloride (6.5 g), pyrogallol trimethyl ether (5.6 g), and anhydrous ether (100 ml). After stirring at room temperature for 6 hr, the mixture was poured into a mixture of ice and dilute hydrochloric acid, and extracted with ether. The ethereal extract was washed with aqueous sodium bicarbonate and water, dried, and evaporated. The residue was recrystallized from a mixture of acetone and *n*-hexane to give yellow needles (mp 66.5—67 °C), which gave a dark green ferric chloride reaction in ethanol; yield, 5.5 g (70%). IR: 1642 cm^{-1}. NMR: ($CDCl_3$) 2.03_s, 2.19_s ($2\times CH_3$); 3.88_s, 3.90_s ($2\times CH_3O$); 6.46_d (C_5–H), 7.55_d (C_6–H) (each J=9 Hz); 6.70_{bs} (CH=C); 13.13_s (OH).

Found: C, 65.93; H, 6.88%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

7,8-Dimethoxy-2,2-dimethylchroman-4-one (VI). The ketone (VII) (3 g) was heated under reflux with ethanol containing 2 M hydrochloric acid (100 ml) for 3 hr. After removing the ethanol under reduced pressure, the residue was poured into cold water (50 ml) and extracted with ether. The ethereal extract was washed with 5% aqueous sodium carbonate and water, dried, and evaporated. The residue was then recrystallized from aqueous ethanol to give colorless needles; mp 75—75.5 °C; yield, 2.7 g (90%). IR: 1693 cm^{-1} (Nujol). NMR: ($CDCl_3$) 1.44_s ($2\times CH_3$); 2.68_s (CH_2); 3.80_s, 3.89_s ($2\times CH_3O$); 6.55_d (C_6–H), 7.61_d (C_5–H) (each J=9 Hz).

Found: C, 66.14; H, 6.77%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

The ketone (VII) was also converted into the chroman-4-one (VI) in boiling glacial acetic acid containing a small amount of concentrated hydrochloric acid.

The chromanone (VI) was also obtained along with a small amount of the ketone (VII) by the Friedel-Crafts reaction of pyrogallol trimethyl ether with β,β-dimethylacrylyl chloride in anhydrous ether at room temperature for 52 hr. It gave a mp of 75—75.5 °C and a mixed mp of 75—75.5 °C with the above chromanone.

7,8-Dimethoxy-2,2-dimethylchroman (III). A mixture of the chromanone (VI) (2.7 g), anhydrous sodium sulfate (2 g), freshly-fused zinc chloride (2.5 g), and ethyl mercaptan (20 ml) was allowed to stand overnight in a refrigerator, and then for 3 hr at room temperature. The mixture was subsequently poured into cold water (50 ml) and extracted with ether. The ethereal layer was washed with 10% aqueous sodium hydroxide, water, dried, and evaporated. The residue gave a thioketal (colorless liquid) (3.8 g). The crude thioketal (3.8 g) was refluxed with Rany nickel (80 g) in ethanol (100 ml) for 3 hr to give III (colorless liquid) (2 g, 72%),

which was purified by column chromatography on silica gel with chloroform. IR: 1498, 1582, 1613 cm^{-1} (liquid). NMR: ($CDCl_3$) 1.35_s ($2\times CH_3$); 1.78_t (C_3–H), 2.72_t (C_4–H) (each 2H, $J=7$ Hz); 3.80_s ($2\times CH_3O$); 6.40_d (C_6–H), 6.74_d (C_5–H) (each $J=9$ Hz).

The chroman (III) was also prepared by the Clemmensen-reduction described by Schwarz *et al.* (yield, 22%).[5]

6-Acetyl-7-hydroxy-8-methoxy-2,2-dimethylchroman (VIII). The acetylation of the chroman (III) (2.5 g) with acetyl chloride (3 g) and anhydrous aluminum chloride (4 g) in anhydrous ether (50 ml) at room temperature gave, in the course of 6 hr, the desired acetyl chroman, VIII. It was then recrystallized from aqueous ethanol to give colorless needles (2.3 g; 45%; mp 97—98 °C) and gave a brown ferric chloride reaction in ethanol. IR: 1640 cm^{-1}. UV: λ_{max}^{EtOH} nm(log ε); 222.5 (4.30), 238 (4.00), 288 (4.22), 327 (3.66). NMR: ($CDCl_3$) 1.40_s ($2\times CH_3$); 1.83_t (C_3–H), 2.76_t (C_4–H) (each 2H, $J=7$ Hz); 2.52_s (CH_3CO); 3.84_s (CH_3O); 7.26_s (C_5–H); 12.40_s (OH).

Found: C, 67.19; H, 7.03%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

Acetate (IX). The acetic anhydride–pyridine method; mp 143—144 °C (colorless needles from aqueous ethanol); a negative ferric chloride reaction. IR: 1670, 1762 cm^{-1}. NMR: ($CDCl_3$) 1.39_s ($2\times CH_3$); 1.83_t (C_3–H), 2.83_t (C_4–H) (each 2H, $J=7$ Hz); 2.37_s, 2.48_s ($2\times CH_3CO$); 3.80_s (CH_3O); 7.38_s (C_5–H).

Found: C, 65.92; H, 6.97%. Calcd for $C_{16}H_{20}O_5$: C, 65.74; H, 6.90%.

6-Acetyl-7-hydroxy-8-methoxy-2,2-dimethylchromene (Ripariochromene A) (I). The chroman (VIII) (0.3 g) and DDQ (0.32 g) in anhydrous benzene (60 ml) were heated under reflux for 3 hr, and then the benzene was removed under reduced pressure. The residue was purified by column chromatography on silica gel with petroleum ether–ethyl acetate (9: 1) to give the desired chromene. It was recrystallized from petroleum ether to give colorless needles (mp 89.5—90.5 °C, not depressed by mixture with nautral riperiochromene A (lit, mp 88.5 °C[2])) and gave a light blue ferric chloride reaction in ethanol; yield, 0.11 g (37%). IR: 1635 cm^{-1}. UV: λ_{max}^{EtOH} nm(log ε); 258 (4.57), 293 (3.89), 348 (3.64). NMR: ($CDCl_3$) 1.47_s ($2\times CH_3$); 2.52_s (CH_3CO); 3.88_s (CH_3O); 5.58_d (C_3–H), 6.27_d (C_4–H) (each $J=9$ Hz); 7.10_s (C_5–H); 12.80_s (OH).

Found: C, 67.65; H, 6.35%. Calcd for $C_{14}H_{16}O_4$: C, 67.73; H, 6.50%.

6-Acetyl-7,8-dimethoxy-2,2-dimethylchromene (Methylripariochromene A) (II). The chromene (I) (49 mg) was refluxed with dimethyl sulfate (0.4 g) and anhydrous potassium carbonate (0.6 g) in anhydrous acetone (30 ml) for 24 hr, and then the acetone was removed. The mixture was extracted with ether, and the ethereal extract was washed with dilute hydrochloric acid and water, dried, and evaporated. The residue was purified by column chromatography on silica gel with chloroform to give the methyl ether[2] (colorless liquid) (48 mg, 92%), which gave a negative ferric chloride reaction. IR: 1673 cm^{-1} (CCl_4). UV: λ_{max}^{EtOH} nm(log ε); 255 (4.24), 290 (3.68). NMR: ($CDCl_3$) 1.47_s ($2\times CH_3$); 2.57_s (CH_3CO); 3.85_s, 3.94_s ($2\times CH_3O$); 5.57_d (C_3–H), 6.28_d (C_4–H) (each $J=9$ Hz); 7.20_s (C_5–H).

Found: C, 68.60; H, 7.22%. Calcd for $C_{15}H_{18}O_4$: C, 68.68; H, 6.93%.

Acetate (X). The acetic anhydride–pyridine method; colorless liquid; a negative ferric chloride reaction. IR: 1676, 1767 cm^{-1}. NMR: ($CDCl_3$) 1.48_s ($2\times CH_3$); 2.35_s, 2.45_s ($2\times CH_3CO$); 3.82_s (CH_3O); 5.63_d (C_3–H), 6.30_d (C_4–H) (each $J=9$ Hz); 7.29_s (C_5–H).

Found: C, 66.26; H, 6.26%. Calcd for $C_{16}H_{18}O_5$: C, 66.19; H, 6.25%.

The author wishes to express his deep gratitude to Professor Shûichi Hayashi and Dr. Mitsuru Nakayama, Hiroshima University, for their guidance and encouragement throughout the course of this work, and also to Dr. Thorleif Anthonsen, Norway Institute of Technology, for supplying the natural ripariochromene A and methylripariochromene A.

Reactions of 1-Azaazulan-2-one and Its 3-Substituted Derivatives[1]

Takashi TODA, Shoji RYU,* Yohichi HAGIWARA,** and Tetsuo NOZOE***

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received February 12, 1974)

Chemical properties of 1-azaazulan-2-one (I) and its 3-substituted derivatives such as 3-acetyl, 3-cycloheptatrienyl and 3-ethoxycarbonyl were investigated. It was shown that the electrophilic substitution reactions take place at the 3-position, replacement of the substituents occuring in some cases by the reactions with cationoid reagents. The Beckmann rearrangement, Curtius rearrangement, Hofmann degradation reaction, Stevens-McFadyen reaction, *etc.* of these compounds are described.

Since 1-azaazulan-2-one (I) (cyclohepta[*b*]pyrrol-2-one) and its 3-ethoxycarbonyl derivative (II) were synthesized,[2,3] new synthetic methods,[4] and some electrophilic and nucleophilic substitution reactions[2,3,5] of I and its derivatives have been investigated. However, the chemical properties of 3-substituted derivatives of I have not been published, except for its 3-formyl (III)[6] and 3-dimethylamino[7] derivatives. In some cases[2,8] abnormal reactions are known to take place on the seven-membered ring moiety of an azulene skeleton during the reactions of functional groups on the five-membered ring moiety. We have thus prepared 3-acetyl and 3-cycloheptatrienyl derivatives of I by means of cationoid reactions of I and investigated their chemical properties.

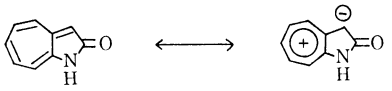
The reaction of I and 7-tropyl ethyl ether in the presence of a small amount of hydrochloric acid gave 3-(cycloheptatrien-7-yl)-1-azaazulan-2-one (IV). When IV was treated with mineral acids, bromine and *p*-tolyldiazonium chloride, compound (I), 3-bromo-1-azaazulan-2-one isolated as its *N*-acetate, and 3-(*p*-tolylazo)-1-azaazulan-2-one (VI) were obtained, respectively.

The Vilsmeyer reaction of I by means of dimethylacetamide afforded 3-acetyl-1-azaazulan-2-one (VII).[4a] The reaction of VII with iodine and pyridine gave 3*N*-pyridiniummethylcarbonyl-1-azaazulan-2-one and subsequent base treatment afforded 3-carboxy-1-azaazulan-2-one (VIII).[3] However, VIII could not be obtained by the usual iodoform reaction of VII. The catalytic reduction and Clemensen reduction of VII gave only resinous substances.[9]

Although VII gave the corresponding oxime (IX) and hydrazone (X), large excess hydrazine was necessary for the formation of X. When an equivalent amount of hydrazine was used, sparingly soluble azine derivative (XI) was formed as the sole product. In the Beckmann rearrangement of IX, the use of sulfuric acid caused only elimination of the substituent at the 3-position to give I, but the rearrangement proceeded smoothly and gave *N*-acetyl-3-acetylamino-1-azaazulan-2-one (XII)[3] when acetic anhydride was employed. The Wolff-Kishner reduction of X with potassium hydroxide in ethylene glycol gave only resinous substances, but with sodium ethoxide in absolute alcohol or potassium hydroxide in alcohol, it afforded *ca.* 40% of VII.

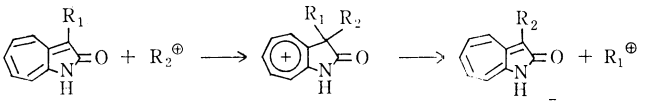
Treatment of 3-ethoxycarbonyl-1-azaazulan-2-one (II) with ammonia and hydrazine gave the corresponding 3-carbamoyl (XIII) and 3-hydrazidocarbonyl (XIV) derivatives, respectively. Reaction of XIII with bromine in methanol and subsequent acetylation gave XII. Diazotization of XIV afforded an unstable azidocarbonyl derivative (XV) which shows a strong characteristic absorption band at 2120 cm^{-1}.[10] Although XV could not be isolated in the pure state, heating in acetic anhydride caused the Curtius rearrangement to give 3-acetamido derivative (XII). The Stevens-McFadyen degradation of XIV by the reaction with tosyl chloride gave the expected 3-formyl derivative (III) in a good yield.

The electron density of I is high at the 3-position with a contribution of canonical formula such as Ia.[2,11] Thus, electrophilic substitution reactions of I proceed readily to give IV and VII in good yields.



I Ia

If substituents at the 3-position of I can be eliminated as stable cations such as tropylium ion, the exchange reaction of substituents takes place by attack of the second electrophilic reagents as shown below. This is the case of the reactions of IV with other electrophiles. The elimination reaction of acetyl oxime group of IX may be explained analogously.



In the case of the Hofmann and Curtius reactions of XIII and XV, an intramolecular reaction takes place between the electron rich center (C_3) and the electron deficient center (nitrogen) and the rearrangements proceed smoothly. Analogous elimination reactions at the 3-position of azulenes[12] and azaazulanes[5] have been observed.

All the compounds obtained are listed in the following table.

Experimental[13]

3-(Cycloheptatrien-7-yl)-1-azaazulan-2-one (IV). To a solution of 1.45 g of I in 30 ml of ethanol and 20 ml of benzene containing a few drops of concd. hydrochloric acid was added 2.95 g of tropyl ethyl ether with stirring and the reaction mixture was allowed to stand at room temperature for 3 hr. The precipitates formed were collected by filtration to give 2.10 g of orange scales of IV, mp 213—215 °C from dioxane.

Found: C, 81.68; H, 5.57; N, 5.95%. Calcd for $C_{16}H_{13}ON$: C, 82.21; H, 5.83; N, 5.79%.

Acetate of IV. A solution of 470 mg of IV in 10 ml of acetic anhydride was heated at 120 °C for 3 hr, and the solvent was removed under reduced pressure. The residue was recrystallized from cyclohexane to give 360 mg of orange yellow needles, mp 132—133 °C.

Found: N, 4.75%. Calcd for $C_{18}H_{15}O_2N$: N, 5.05%.

Bromination of IV. A solution of 235 mg of IV and 180 mg of bromine in 5 ml of acetic acid was stirred for one hr. After the solvent had been removed under reduced pressure, the residue was heated with 1 ml of acetic anhydride for 1 hr. Excess acetic anhydride was removed and the residue was recrystallized from ethyl acetate to give 200 mg of orange yellow needles, mp 245—247 °C which was identical with the authentic sample of *N*-acetyl-3-bromo-1-azaazulan-2-one.[3]

Azo-coupling Reaction of IV. *p*-Tolyldiazonium chloride prepared from 110 mg of *p*-toluidine was added with stirring to a solution of 235 mg of IV in 5 ml of dioxane cooled in an ice bath. After 3 hr, the precipitates formed were collected by filtration and recrystallized from cyclohexane–acetone to give 200 mg of 3-(*p*-tolylazo)-1-azaazulan-2-one, mp 153—154 °C which was identical with the authentic sample of the azo compound.[3]

3-Acetyl-1-azaazulan-2-one (VII). To a solution of 500 mg of I in 3 ml of dimethylacetamide cooled in an ice bath was added 1.0 g of phosphorus oxychloride with stirring. The reaction mixture was allowed to stand for 4 days at room temperature, and was then poured into crushed ice containing 1.0 g of sodium acetate and extracted with chloroform. The combined chloroform layer was washed with saturated sodium bicarbonate, water, dried over sodium sulfate, and then concentrated. The residue was chromatographed on alumina. Benzene–ether (1: 1) elutes afforded 380 mg of yellow needles of VII, mp 297—299 °C from cyclohexane–acetone.

1-Azaazulan-2-on-3-carboxylic Acid (VIII). A solution of 500 mg of VII and 800 mg of iodine in 5 ml of pyridine was stirred for 24 hr. To this was added 20 ml of 10% of sodium hydroxide and heated for 4 hr on a water bath. The solution was then acidified with 1 M hydrochloric acid to give precipitates. Recrystallization of the precipitates from methanol gave 260 mg of VIII, mp 200—202 °C (decomp.), which was identical with the authentic sample.[3]

Oxime of VII (IX). An equivalent of VII, two equivalents of hydroxylamine and of sodium acetate in alcohol were refluxed for 5 hr. After the alcohol had been removed, the residue was washed with water and recrystallized from alcohol to give the oxime in a quantitative yield, mp 241 °C (decomp.).

Found: C, 62.84; H, 5.24; N, 13.53%. Calcd for $C_{11}H_{10}O_2N_2 \cdot 1/2H_2O$: C, 62.55; H, 5.25; N, 13.26%.

Beckmann Rearrangement of IX. a) A solution of 290 mg of IX in 9 M sulfuric acid was heated on a water bath for 2.5 hr. After being cooled the reaction mixture was poured onto crushed ice, and the resulting precipitates were collected by filtration. Recrystallization from alcohol gave 157 mg of I.

b) A solution of 700 mg of IX in 10 ml of acetic anhydride was heated under reflux for 4 hr, and excess acetic anhydride was removed under reduced pressure. The residues were recrystallized from alcohol to give 420 mg of XII, mp 265—267 °C.

Found: C, 63.68; H, 4.45; N, 11.64%. Calcd for $C_{13}H_{12}O_3N_2$: C, 63.92; H, 4.95; N, 11.47%.

Hydrazone of VII (X). A solution of 1.13 g of VII and 12 equivalents of hydrazine hydrate and 0.5 ml of 6 M hydrochloric acid in 100 ml of alcohol was refluxed for 6 hr. The precipitates formed were collected by filtration. Recrystallization from alcohol containing hydrazine gave dark red needles of X, mp 270 °C; yield 986 mg.

Found: C, 65.76; H, 5.74; N, 20.23%. Calcd for $C_{11}H_{11}ON_3$: C, 65.67; H, 5.51; N, 20.88%.

When the reaction was carried out with 1.2 equivalent moles of hydrazine, the azine (XI) of VII was formed quantitatively. The azine is hard to purify and did not give good analysis.

Diacetate of XI. A solution of 242 mg of XI and 1 ml of acetic anhydride in 10 ml of pyridine was refluxed for 7 hr. The usual treatment gave 208 mg of diacetate of XI, mp 270 °C (decomp.); orange yellow needles from ethyl acetate.

Found: C, 68.09; H, 4.73; N, 11.99%. Calcd for $C_{26}H_{22}O_4N_4$: C, 68.71; H, 4.88; N, 12.33%.

Wolff-Kishner Reduction of X. A solution of 178 mg of X and 525 mg of potassium hydroxide in 200 ml of alcohol was refluxed for 8 hr. Alcohol was then removed under reduced pressure. The residue was washed with 1 M hydrochloric acid and water, and recrystallization from alcohol gave 124 mg of VII.

When the reaction was carried out with 2.4 equivalent moles of sodium ethoxide in absolute alcohol and treated as above, 40% of VII and 6.5% of XI were obtained together with some resinous substances. The reaction in boiling ethylene glycol gave only intractable resinous substances.

3-Carbamoyl-1-azaazulan-2-one (XIII). A solution of 500 mg of II in 10 ml of alcohol cooled in an ice bath was saturated with ammonia gas and allowed to stand for 6 hr at room temperature, and then heated on a water bath for 1 hr. After excess alcohol was removed, the residue obtained was recrystallized from cyclohexane–acetone to give yellow prisms of XIII, mp 186—187 °C; yield, 420 mg.

Found: C, 64.25; H, 4.71; N, 15.14%. Calcd for $C_{10}H_8O_2N_2$: C, 63.82; H, 4.29; N, 14.89%.

3-Hydrazinocarbonyl-1-azaazulan-2-one (XIV). A solution of 500 mg of II and 350 mg of hydrazine hydrate in 10 ml of alcohol was heated on a water bath for 1 hr and then concentrated. The residue formed was recrystallized from alcohol to give 450 mg of orange yellow needles of XIV, mp 198—200 °C.

Found: C, 59.03; H, 4.20; N, 20.55%. Calcd for $C_{10}H_9O_2N_3$: C, 59.10; H, 4.46; N, 20.68%.

Hofmann Degradation of XIII. A solution of 320 mg of XIII, 270 mg of bromine in 10 ml of absolute methanol containing 80 mg of sodium was refluxed for 1 hr, and excess reagents and the solvent were removed under reduced pressure. The residue was treated with 5 ml of boiling acetic anhydride for 3 hr, concentrated, and extracted with benzene. The combined benzene extracts were washed with water, dried over sodium sulfate and concentrated. The residue obtained was recrystallized from cyclohexane–acetone to give 270 mg of orange scales of XII, mp 265—267 °C, which was identical with the authentic sample of 1-acetyl-3-acetylamino-1-azaazulan-2-one.[3]

Curtius Rearrangement of XIV. A solution of 600 mg of XIV and 250 mg of sodium nitrate in 10 ml of dimethylformamide was stirred at room temperature. To this was added dropwise 2 ml of acetic acid and stirring was continued for 24 hr. Crystalline substances precipitated were collected by filtration, washed with water, and dried in a desiccator to give the acid azide (XV), mp 280—285 °C (decomp.); yield, 520 mg. ν_{KBr}: 2120, 1670, and 1590 cm^{-1}.

Five hundred mg of XV was heated under reflux for 5 hr in 5 ml of acetic anhydride, and acetic anhydride was removed under reduced pressure. The residue was recrystallized from acetone–cyclohexane to give 340 mg of XII, mp 263—265 °C.

Stevens-McFadyen Reaction of XIV. Five hundred mg of tosyl chloride was added in small portions with stirring to a solution of 500 mg of XIV in 5 ml of pyridine and 10 ml of dimethylformamide. The reaction was continued for 48 hr at room temperature. The precipitate formed was then collected by filtration and recrystallized from acetone–cyclohexane to give 360 mg of yellow needles, mp 283—285 °C, which was identical with the authentic sample of 3-formyl-1-azaazulan-2-one.[6]

This research was supported by grants from the Ministry of Education and Sankyo Co. Ltd.

(Received April 30, 1974)

The oxidation of cumene and acrolein was carried out using metal polyphthalocyanines as a catalyst. The catalyst activated an oxygen molecule to form a phthalocyanine–O_2 complex, which then abstracted the hydrogen atom of a reactant to initiate the oxidation. The catalyst had no effects on the decomposition of cumene hydroperoxide, formed selectively in the oxidation of cumene. The addition of a small amount of pyridine induced a drastic shortening of the induction period as well as a considerable increase in the oxidation rate. The initiation mechanism assumed on the basis of findings on the desorption of oxygen from the catalyst and on the effect of pyridine was confirmed by a kinetic study of the homogeneous liquid-phase oxidation of acrolein.

Metal phthalocyanines have been used as catalysts in the autoxidation of such hydrocarbons as cumene.[2–6] Kropf proposed that, in the oxidation of cumene below 100 °C, copper phthalocyanine activated a molecular oxygen through its coordination with the metal ion to form a phthalocyanine–O_2 complex, which then abstracted the tertiary hydrogen of cumene to initiate the oxidation.[2] However, Min'kov and Keier reported that a unimolecular decomposition of cumene hydroperoxide occurred at 40—70 °C, whereas a higher-order decomposition occurred at 90—110 °C; they concluded that the catalytic activity of copper phthalocyanine was associated not with the activation of oxygen, but with the decomposition of the hydroperoxide, over both temperature ranges.[3] Furthermore, a polymeric metal phthalocyanine (metal polyphthalocyanine, Me-polyPc) was also used as a catalyst in the liquid-phase autoxidation.[5,6] Inoue *et al.* presumed, in the oxidation of acetaldehyde ethylene acetal, that metal ions, especially Fe(II) ions, located in the conjugated system of phthalocyanines might act as active sites for the activation of oxygen as well as for the decomposition of the hydroperoxide. From the above description, it can be understood that the role of a phthalocyanine catalyst in an autoxidation reaction has not yet been clarified univocally.

In this investigation, many kinds of metal polyphthalocyanines were synthesized and used as catalysts for the decomposition of cumene hydroperoxide and the liquid-phase oxidation of cumene; this was done in order to elucidate how the catalyst affects the activation of oxygen and/or the decomposition of the hydroperoxide. Besides, the results obtained by the kinetic study of the homogeneous liquid-phase oxidation of acrolein supported the proposed initiation mechanism; that is, a phthalocyanine–O_2 complex abstracts the hydrogen atom of a reactant to initiate the oxidation.

Experimental

Materials. The metal polyphthalocyanines were synthesized according to the method reported by Epstein and Wildi.[7] Copper–Iron polyphthalocyanine, for example, was prepared in the following manner. A mixture of 1,2,4,5-tetracyanobenzene (4.00 g), $CuCl_2$ (0.80 g), $FeCl_2$ (0.70 g), and urea (0.25 g) was ground sufficiently and was then heated at 300 °C under a nitrogen atmosphere for 18 hr. The mixture was then heated for two additional hours at 350 °C. The resulting solid was washed with methanol to remove the unchanged metal chlorides; the catalyst thus obtained will be called a "crude" polyphthalocyanine below. Then the solid was extracted with boiling pyridine until the greenish color of the extract faded out, resulting in the removal of not only monomeric but also oligomeric metal phthalocyanine. The residue was dried and heated at 350 °C/ 10^{-1} mmHg for 30 hr; this will be called a "purified" polyphthalocyanine.

TABLE 1. ELEMENTAL ANALYSIS OF METAL POLYPHTHALOCYANINES

Me–polyPc	C	H	N
Cu–polyPc			
Found:	57.5%	1.53%	24.4%
Calcd 1:	57.1	1.0	26.7
Calcd 2:	61.9	1.0	28.8
Co–polyPc			
Found:	53.3	1.96	27.1
Calcd 1:	57.8	1.0	27.1
Calcd 2:	61.8	1.0	29.0

Calcd 1 and 2 are obtained as the structure of Me–polyPc is $[Me(C_6H_2(CN)_4)_2]_n$ and $Me(C_6H_2(CN)_4)_4$, respectively.

Eleven kinds of catalysts were obtained as a dark solid-powder and were not dissolved in any organic solvents. No data have been obtained on the molecular weight of the catalysts. Considering that when a monomeric phthalocyanine and a polymeric one in which the degree of polymerization remain low are slightly dissolved in boiling pyridine they assume a characteristic color, the molecular weight of the "purified" catalyst may be quite large. This was also presumed because the IR absorption peak ascribed to the terminal -CN group in the catalysts was not observed.[8] The results of the elemental analyses of some catalysts are shown in Table 1. If the structure of a Me-polyPc thus obtained is similar to that of a monomeric phthalocyanine, its molecular formula can be expressed as $Me(C_6H_2(CN)_4)_4$. When the degree of polymerization becomes sufficiently large, the expression may be transformed to $[Me(C_6H_2(CN)_4)_2]_n$. The

results shown in Table 1 also indicate that the prepared catalysts are highly-polymerized phthalocyanines. The metal contents in Cu–Fe polyPc were measured by the spectrophotometric method reported by Underwood.[9] Copper and iron ions existed in the catalyst in the ratio of 2.7:4.1, an iron-rich catalyst being thus prepared. The total contents of metal ions in Cu–Fe polyPc were 86 and 160% of the theoretical values when calculated by means of the molecular formulae of $[Me(C_6H_2(CN)_4)_2]_n$ and $Me(C_6H_2(CN)_4)_4$ respectively. However, no data have yet been obtained with respect to the disposition of the two kinds of metal ions in the enlarged conjugated system.

Procedure. The catalytic decomposition of cumene hydroperoxide and the oxidation of cumene were carried out using the apparatus and the procedure described in a previous paper.[10]

The kinetic study of the homogeneous liquid-phase oxidation of acrolein was carried out according to a new method using an oxygen analyzer, model 777, manufactured by the Toshiba-Beckman Co.[11] A 22 ml reactor equipped with a sensor of the analyzer was filled with benzene as a solvent and a certain amount of a catalyst. A solution containing a desirable concentration of oxygen was prepared by bubbling of the corresponding gaseous mixture of oxygen and nitrogen. Immediately after a certain amount of acrolein has been charged into the reactor, the reaction system filled with the solution was closed. The continuous change in the concentration of dissolved oxygen corresponding to the amount of oxygen absorbed was recorded by the analyzer.

The behavior of oxygen on metal polyphthalocyanines was examined in the following manner. A "purified" metal polyphthalocyanine stored under a nitrogen atmosphere was charged into a 100 ml flask and heated at 350 °C/10^{-2} Torr for 5 hr. The catalyst was then cooled to room temperature and allowed to be in contact with pure oxygen for 24 hr. Then the atmosphere was removed again, and the inner pressure was strictly maintained at 2.1×10^{-2} Torr for 3 hr. The temperature was then raised to about 350 °C at a constant rate of 2 °C per min, and the increase in the inner pressure was measured.

Results and Discussion

The decomposition reaction of cumene hydroperoxide was carried out at 82 °C in a *p*-xylene solution. As is illustrated in Fig. 1, cumene hydroperoxide was not decomposed within 4 hr in the presence of "purified" Cu–Fe polyPc, Cu–polyPc, or Fe–polyPc, whereas it was almost completely decomposed after 4 hr using the "crude" Cu–Fe polyPc catalyst. The valency of a transition metal ion or ions can be changed in the conjugated-ring system of a phthalocyanine. When cumene hydroperoxide is catalytically decomposed through the Haber-Weiss mechanism,[12] the catalytic activity generally depends on the redox potential of a metal ion. The redox potentials of monomeric phthalocyanines were obtained in a pyridine solution as −0.98 and −0.49 V *vs.* SCE with regard to iron and cobalt phthalocyanine respectively.[13] Considering that the reduction potential of a hydroperoxide is −0.7 to −0.8 V,[14] a monomeric phthalocyanine, especially iron phthalocyanine, can possibly decompose the hydroperoxide. On the other hand, the potential of a polymeric phthalocyanine may be decreased with the enlargement of the π-electrons conjugated ring system;

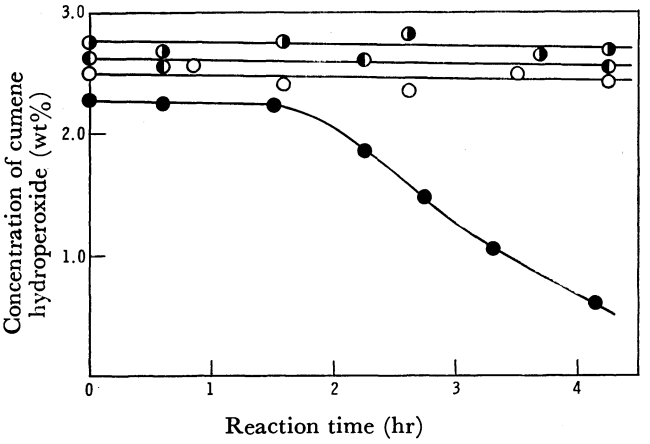

Fig. 1. The decomposition of cumene hydroperoxide by metal polyphthalocyanines. Reaction conditions; Me-polyPc 4.9×10^{-3} M, solvent *p*-xylene, at 81.5°C. ○ Cu–Fe polyPc, ◑ Cu–polyPc, ◐ Fe–polyPc, ● crude Cu–Fe polyPc.

chelation is recognized to make a metal ion stable and, consequently, to lower the potential. The "purified" metal polyphthalocyanine is considered not to decompose cumene hydroperoxide because of its lower redox potential. The opposite results mentioned above relating to the decomposition of a hydroperoxide may be ascribed to the degree of purification of a metal polyphthalocyanine.

The behavior of oxygen on a metal polyphthalocyanine was examined in order to confirm the mechanism of the activation of oxygen. Oxygen was desorbed from a metal polyphthalocyanine as the temperature rose. The differential pressure per centigrade of the desorbed oxygen is plotted against the temperature in Fig. 2. The first peak of Cu–Fe polyPc was also observed either in the case of Cu–polyPc or Fe–polyPc in the temperature range of 80—150 °C, but the second peak was characteristic of Cu–Fe polyPc. In addition, the first peak of Cu–polyPc existed over a higher temperature range than that of Fe–polyPc. These results imply that a strongly-chemisorbed oxygen existed on a

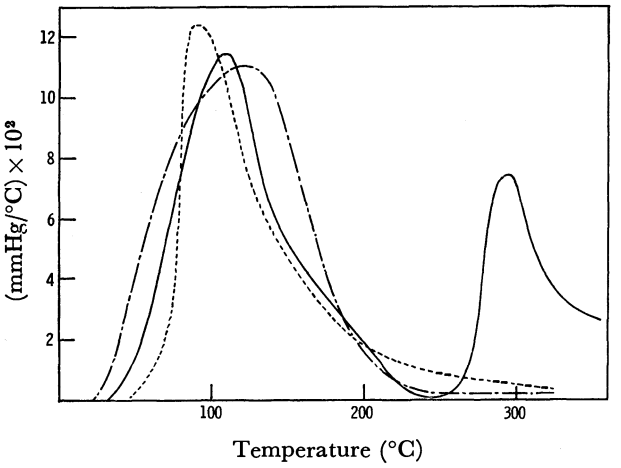

Fig. 2. Desorption of oxygen on metal polyphthalocyanines Me-polyPc 180 mg, —— Cu–Fe polyPc, —·— Cu–polyPc, ------ Fe–polyPc.

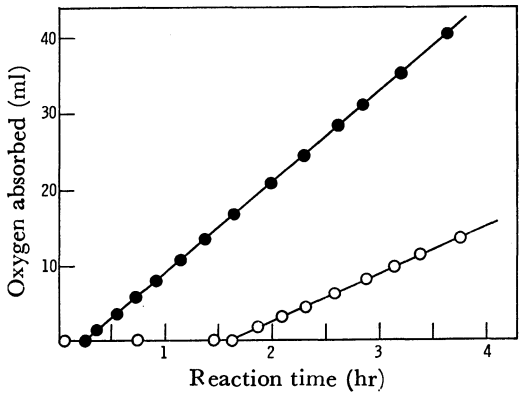

Fig. 3. The oxidation of cumene with Cu–Fe polyPc. Reaction conditions; cumene 0.652 M, Cu–Fe polyPc 4.82×10^{-3} M, in *p*-xylene at 81.5 °C. ● with pyridine, 2.25×10^{-1} M.

metal polyphthalocyanine catalyst, especially on Cu–Fe polyPc; that is, the catalyst activates a molecular oxygen, as has been described by Inoue *et al.*[5]

It was examined in the oxidation of cumene whether or not the activated oxygen could abstract a hydrogen atom to initiate the oxidation. The oxidation of cumene in *p*-xylene was carried out at 82 °C using a metal polyphthalocyanine in the presence and in the absence of pyridine. No oxygen was absorbed without the catalyst for 6 hr, while in the presence of Cu–Fe polyPc the uptake of oxygen started at a steady rate after an induction period of 100 min (Fig. 3). A drastic shortening of the induction period as well as a considerable increase in the oxidation rate were induced by the presence of a small amount of pyridine. A similar absorption curve of oxygen was also obtained when pyridine was added after one hour. The oxidation under the reaction conditions shown in Fig. 3 gave cumene hydroperoxide as the only product. The active oxygen in the hydroperoxide was estimated to be 1.9×10^{-3} mol after a 4 hr reaction time; this amount corresponded to 108% of the amount of oxygen absorbed. This means that a "purified" metal polyphthalocyanine can produce cumene hydroperoxide selectively without its decomposition.

Table 2. Effect of metal ions in polyphthalocyanines

Metal	$-dO_2/dt$ $\times10^6$ M s^{-1}	Induction period, min
Cu–Fe	2.36	14
Cu–Fe[a]	2.38	10
Cu–Co	1.76	12
Cu–Mn	1.69	17
Cu	1.51	0
Co	1.41	18
Cr	1.30	8
Fe–Co	1.27	19
Mn	1.26	23
Fe	1.17	5
Co–Mn	1.13	33
Fe–Mn	0.57	16

Reaction conditions were the same as in Fig. 4.
a) under the same reaction condition

Table 2 illustrates the effects of metal ions in polyphthalocyanines on the rate of oxidation and shows that metal polyphthalocyanines including a copper ion are more effective; the order of activity is different from that reported in the oxidation of acetaldehyde ethylene acetal.[5] The active order of copper, iron, and copper–iron polyphthalocyanines is found to correspond to the order of the peak temperature based on the desorption of oxygen from the catalysts, as is shown in Fig. 2. That is to say, the catalysts on which oxygen is chemisorbed more strongly may be active in initiating the oxidation, resulting in an increase in the oxidation rate. This suggests that the metal ion, particularly the copper ion, is effective in forming its complex with oxygen, which may abstract the tertiary hydrogen of cumene.

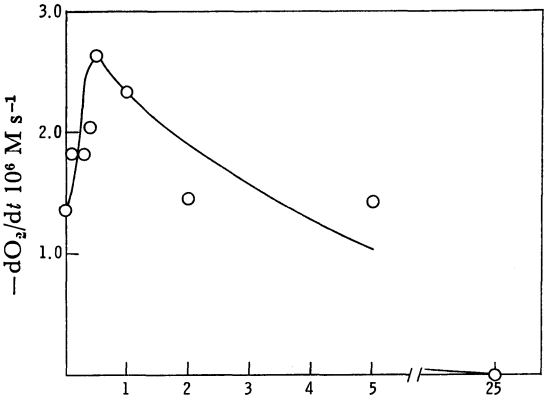

Fig. 4. Effect of pyridine on the rate of oxidation. Reaction conditions; cumene 0.652 M, Cu–Fe polyPc 4.80×10^{-3} M, in *p*-xylene at 81.5 °C, total volume of the solution 55 ml.

The effect of pyridine on the oxidation rate was also examined (Fig. 4). The absorption rate of oxygen varied considerably depending on the amount of pyridine added, though Inoue *et al.* related only a negative effect of added pyridine. The maximum rate was obtained when 0.5 ml of pyridine was added to 55 ml of the total volume of the oxidation solution; this rate was 2.1 times that in the absence of pyridine. The excess addition showed rather a negative effect on the rate, and the oxidation did not proceed over 6 hr in the presence of more than 25 ml of pyridine. Though almost the same absorption rate was given in the case of the addition of 5.0 ml as that observed in the absence of pyridine, the induction period was shortened to 9 min.

With respect to pyridine, Elvidge and Lever found that manganese phthalocyanine could carry an oxygen molecule reversibly in a pyridine solution.[15] Calvin *et al.* explained this oxygen-carrying mechanism by a spectrophotometric method and pointed out the activation of oxygen by the coordination of pyridine at the *trans*-position. The effect of pyridine on this oxidation of cumene, consequently, may also be related to the initiation mechanism with which a metal polyphthalocyanine is concerned. However, the activation mechanism by Calvin *et al.* cannot be applied to a metal

polyphthalocyanine, because it is completely insoluble in the reaction solution. As the distance between the layers of the planar crystalline of a monomeric phthalocyanine was reported to be 3.38 Å,[17] there is no room for pyridine to enter between the layers of the catalyst to activate a molecular oxygen at the *trans*-position.

On the other hand, Barret *et al.* reported that iron phthalocyanine formed a 1 : 6 adduct with aniline, four molecules of aniline being coordinated with the conjugated system, and two, with the central metal, iron.[18] This explanation may make it possible to consider that an adequate amount of pyridine is coordinated with the conjugated-ring system of a metal polyphthalocyanine and acts in the same manner as that at the *trans*-position to facilitate the activation of oxygen at the central metal ions on the surface of the catalyst by moving electrons through the ring system. This can lead to the shortening of the induction periods to approximately 10 min. The excess amount of pyridine may occupy all the coordination sites including metal ions to deactivate the catalyst. The decrease in the oxidation rate upon the addition of more than 5.0 ml of pyridine may be ascribed to the decrease in the amount of available activated oxygen. This consideration is supported by the result that the oxidation did not occur in such solvents as DMF and DMSO, which have higher coordination strengths. Besides, the negative effect of pyridine may be partly attributed to the formation of a charge-transfer complex between the cumylperoxy radical and pyridine, as has been reported by Thomas.[19]

The assumed initiation mechanism involving the activation of oxygen by the catalyst is confirmed by the kinetic study. The method of the homogeneous liquid-phase oxidation is suitable for the investigation of the effect of oxygen on the rate of oxidation, because the transfer-process of oxygen from the gas phase to the liquid phase is not involved in the measurement of the absorption rate of oxygen.[11] The oxidation of acrolein was studied instead of that of cumene, as the reaction temperature was limited below 45 °C by the use of the oxygen analyzer.

Acrolein was not oxidized even in the presence of Cu–Fe polyPc at 40 °C in benzene; the concentration of dissolved oxygen remained constant over 24 hr. When a small amount of pyridine was added, the concentration of oxygen began to decrease and assymptotically became zero towards the end of the reaction. The effect of pyridine was similar to that described in the oxidation of cumene, and it should be noticed in the case of acrolein that the presence of pyridine was indispensable to the initiation of the oxidation. The kinetic study was carried out with pyridine (5.6×10^{-1} M), where the accelerating effect on the rate was observed.

Assuming that the autoxidation proceeds through the known chain mechanism including the assumed initiation step, the stationary-state treatment gives the following theoretical rate equation:

$$\mathrm{RH} + \mathrm{cat} + \mathrm{O_2} \xrightarrow{k_1} \mathrm{R}\cdot$$

$$\mathrm{R}\cdot + \mathrm{O_2} \xrightarrow{k_2} \mathrm{RO_2}\cdot$$

$$\mathrm{RO_2}\cdot + \mathrm{RH} \xrightarrow{k_3} \mathrm{RO_2H} + \mathrm{R}\cdot$$

$$\left.\begin{array}{l} 2\mathrm{R}\cdot \xrightarrow{k_4} \\ \mathrm{R}\cdot + \mathrm{RO_2}\cdot \xrightarrow{k_5} \\ 2\mathrm{RO_2}\cdot \xrightarrow{k_6} \end{array}\right\} \text{non-radical products}$$

where RH denotes the acrolein molecule

$$-\mathrm{dO_2/d}t = [k_1(\mathrm{RH})(\mathrm{cat})(\mathrm{O_2})]^{1/2} \times \frac{k_2k_4^{-1/2}(\mathrm{RH})(\mathrm{O_2})}{(\mathrm{RH}) + (k_2k_4^{-1/2}/k_3k_6^{-1/2})(\mathrm{O_2})}$$

The rate constant, $k_2k_4^{-1/2}$ and $k_3k_6^{-1/2}$, have been reported to be 3.7×10 and 5.5×10^{-2} ($\mathrm{M^{-1/2}\,s^{-1/2}}$) respectively in the oxidation initiated by di-*t*-butyl diperoxyoxalate in benzene at 40 °C.[20] Consequently, the k_1 constant can be calculated under various reaction conditions (Table 3). Runs 1—4 show the effect of the catalyst concentration. The decrease in the chain length with the increase in the catalyst concentration may be partly ascribed to the termination of radicals by the catalyst, considering that a negative catalyst effect[21] was observed at higher concentrations of the catalyst. Runs 1 and 5—7 show the dependence on the concentration of acrolein. In the case of a constant concentration of the catalyst, the chain length was given as close to 30. The k_1 constant is given as $(6.3\pm0.3)\times10^{-2}\,\mathrm{M^{-2}\,s^{-1}}$ under all the reaction conditions.

Table 3. Effect of the concentration of acrolein and the catalyst on the rate of oxidation

Run	$-\mathrm{dO_2/d}t$ $\times10^6$ M s^{-1}	(RH) M	$(\mathrm{O_2})^{a)}$ $\times10^3$ M	(cat) $\times10^3$ M	R_i $\times10^8$ M s^{-1}	Chain length	k_1 $\times10^2$ $\mathrm{M^{-2}\,s^{-1}}$
1	5.10	0.34	1.39	4.72	13.7	37	6.1
2	3.55	0.34	1.39	2.31	6.6	54	6.1
3	2.64	0.34	1.39	1.22	3.7	72	6.3
4	1.85	0.34	1.20	0.76	2.0	94	6.3
5	14.3	0.48	3.05	4.72	45.1	32	6.6
6	3.00	0.20	1.63	4.72	10.0	30	6.4
7	1.49	0.14	1.30	4.72	5.3	28	6.3

a) The concentration of oxygen at which the rate of oxidation reached maximum. Reaction conditions: amount of pyridine added, 1.0 ml; 40 °C in benzene; initial concentrations of oxygen were set as about 2.0×10^{-3} M except the case of the run 5.

The influence of the concentration of oxygen can be determined in an experiment in the homogeneous liquid-phase oxidation. In Run 5, the oxidation rate decreased with the decrease in the concentration of oxygen after a certain induction period. During the oxidation, the change in the concentration of acrolein was negligible because the ratio of the concentration of acrolein to that of oxygen was set as about 10^2. The theoretical rate equation can be transformed as follows:

$$-\mathrm{dO_2/d}t = \frac{k_1^{1/2}k_2k_4^{-1/2}A^{3/2}B^{1/2}(\mathrm{O_2})^{3/2}}{A + (k_2k_4^{-1/2}/k_3k_6^{-1/2})(\mathrm{O_2})}$$

where A and B denote the concentrations of acrolein (0.48 M) and the catalyst (4.72×10^{-3} M) respectively. Then k_1 can be calculated from the differential value

Table 4. Effect of the concentration of oxygen on the rate of oxidation

(O_2) $\times 10^3$ M	$-dO_2/dt$ [a] $\times 10^6$ M s^{-1}	R_i $\times 10^8$ M s^{-1}	Chain length	k_1 $\times 10^2$ M^{-2} s^{-2}
3.05	14.3	45.1	32	6.6
2.67	13.1	39.7	33	6.6
2.29	11.6	33.6	33	6.5
1.91	10.2	28.5	36	6.6
1.53	8.57	22.9	37	6.7
1.14	6.67	17.0	39	6.6
0.76	4.50	11.0	41	6.4
0.38	2.21	5.8	38	6.8

a) The rate of oxidation at each concentration of oxygen. Reaction conditions: initial concentration of acrolein, 0.48 M; of the catalyst, 4.7×10^{-3} M; and of oxygen, 6.8×10^{-3} M (0.89 atm. of partial pressure of oxygen); pyridine added, 1.0 ml; 40 °C in benzene.

of the decreasing curve of oxygen (rate of oxidation) at each concentration of oxygen (Table 4). The k_1 constant is given as $(6.6\pm0.2)\times10^{-2}$ M^{-2} s^{-1} over the range of concentration of oxygen from 0.38 to 3.05×10^{-3} M.

The value of k_1 did not change with the change in the concentrations of the catalyst, acrolein and oxygen, which supported the initiation mechanism: a phthalocyanine–O_2 complex abstracts the hydrogen of a reactant to initiate the oxidation.

Chlorination of Methylcyclohexane in Molten Salt Media

Shōichi KIKKAWA, Takatoshi HAYASHI*, Masakatsu NOMURA, and Noboru ŌTSU
Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565
(Received June 6, 1974)

The chlorination of methylcyclohexane in several molten metal chloride mixtures ($ZnCl_2$/KCl/NaCl, CuCl/KCl/NaCl, $AlCl_3$/KCl/NaCl, and $CuCl_2$/KCl/NaCl) has been carried out, using nitrogen gas as a diluent, at three levels of temperature (250, 350, and 450 °C). The reactions in both $ZnCl_2$ and CuCl melts were studied extensively, the former representing the molecular-type melt and the latter standing for the partially-ionic-type one. These reactions gave 1-, 2-, 3-, and 4-chloro-methylcyclohexanes and 1-, 3-, and 4-methylcyclohexenes as primary products, along with smaller amounts of toluene and methylcyclohexadiene. The formation of these olefins were interpreted by the subsequent elimination (by a carbonium-ion mechanism) of HCl catalytically enhanced by these melts from the methyl-chlorocyclohexane derivatives. The difference observed in the product distributions between $ZnCl_2$ and CuCl melts was also explained by the studies of the effect of hydrogen chloride produced in these reactions over molten salts.

A great many studies have been carried out on the chlorination of hydrocarbons in the liquid and gas phases, and many detailed data on the reactivities and reaction mechanism are available. However, the chlorination employing molten salts as a reaction medium[1] has been investigated much less systematically. Melts have the advantages of a high solubility of chlorine and of good thermal conductivity, which effects the removal of the local heat, accompanied by exothermic chlorinations.

The present authors have carried out the chlorinations of ethylbenzene,[2] alicyclic hydrocarbons (C_3–C_4),[3] and cyclohexane[4] in molten salts and found that molten salts act not only as thermally stable reaction media, but also show catalytic activities. The present paper deals with the reaction of methylcyclohexane with chlorine in molten salts.

Since this compound has primary, secondary, and tertiary hydrogen in the molecule, useful information about their relative reactivities and about the reaction mechanism of chlorinations in molten salts can be expected to be obtained by analyzing the isomer distribution of the products.

Experimental

Materials. Commercial methylcyclohexane (I) was distilled after sulfuric acid washing. Commercially-available 4-methylcyclohexene (V) was employed without further purification. The 1-methylcyclohexene (III)[5] and 3-methylcyclohexene (IV) [contaminated with (V)] were prepared according to the reported methods.[6] The 1-chloro- (VI),[7] 3-chloro- (VIII)[8] and 4-chloro-methylcyclohexane (IX),[9] and chloromethylcyclohexane (X)[10] were synthesized by the procedures cited in the literature.

The samples prepared had the following physical constants: III, bp 110—113 °C (108—111 °C); I, bp 100—101 °C (100 °C); V, bp 56—57 °C/28.5 mmHg (50—52 °C/12 mmHg); VIII, bp 45.5 °C/18 mmHg (43.8—44.0 °C/14 mmHg); IX, bp 41—41.5 °C/12 mmHg (41 °C/10 mmHg); X, bp 66—69 °C/20 mmHg (67—68 °C/20 mmHg).

Reagent-grade zinc chloride, cuprous chloride, cupric chloride, and aluminum chloride (Wako Pure Chemical Industries, Ltd., Osaka) were used without further purification.

Apparatus. The apparatus used for the chlorination is shown schematically in Fig. 1. A vertical cylindrical Pyrex tube 30 mm in diameter, equipped with a gas inlet tube (inner diameter of the nozzle of the inlet tube: 1.0—1.5 mm) some distance from the lower end, was heated by means of a coil heater connected to an electric controller (the gas inlet tube was immersed 10 cm in the melts). The mixture of salts was melted and dried with N_2 for 60 min before carrying out the chlorination. After constant flow rates of the nitrogen (0.2 mol/hr) and chlorine (0.1 mol/hr) had been attained, the supply[11] of the reactant was started; the reaction products were collected at the exit in an acetone–Dry Ice trap and analyzed by gas chromatography after the removal of the chlorine by washing with a sodium hypochlorite solution. A blank test on the gas-phase reaction (non-catalytic) was carried out in a U-glass tube covered with aluminum foil to avoid the influence of diffused daylight and immersed 10 cm in a fused salt bath.

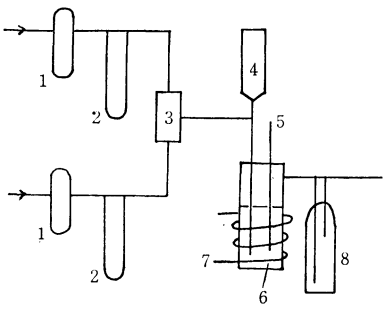

Fig. 1. Block diagram of the apparatus used.
1: $CaCl_2$ tube, 2: flow meter, 3: mixing chamber, 4: starting material, 5: thermocouple, 6: molten salt, 7: heater, 8: Dry Ice–acetone trap

Analysis of Reaction Products. The isomeric products were analyzed by means of gas chromatography [on a Shimadzu-GC-3AH gas chromatograph equipped with TCD using a combined column of Pluronic L-84 (4.5 m × 3.0 mm) and Apiezone grease (0.75 m × 3.0 mm) at 85 °C]. The oven temperature was fixed at 85 °C to avoid dehydrochlorination in the injection port of the gas chromatograph. Hydrogen was used as the carrier gas at a flow rate of about 46 ml/min.

Preparative gas chromatography and proton magnetic resonance were used when necessary for product identification.

* Present address: Department of Chemistry, Ritsumeikan University, Kita-ku, Kyoto 603.

Results and Discussion

Identification of Chlorination Products. A gas chromatogram of the GC-Mass analysis of products obtained in the $ZnCl_2$/KCl/NaCl (3: 1: 1 mole ratio)[12] melt is shown in Fig. 2.

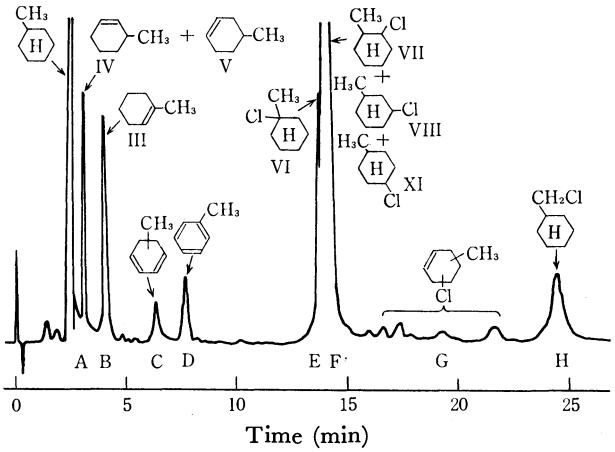

Fig. 2. Glc fractionation of chlorination products of methylcyclohexane in $ZnCl_2$/KCl/NaCl melt.
Conditions of GC-MS (Hitachi K 53 GC-Hitachi RMU-60 MS) analysis: PEG-1540 (0.02′×50 feet), 70 °C, He (0.5 kg/cm²).

The mass spectra of Peak A and Peak B (shown in Fig. 2) indicated the parent peak at *m/e*=96 [Peak A, *m/e* 96, M^+ (13), 81, M^+-CH_3 (100), 68, retro Diels Alder fraction of 3-methylcyclohexene, (39), 54, retro Diels Alder fraction of cyclohexene. Peak B, *m/e* 96, M^+ (46), 81 (100), 68 (75), 67 (43), 55 (50). The number in brackets indicates the relative intensity].[13,14] Both peaks had retention times corresponding to 3-methylcyclohexene(IV) or 4-methylcyclohexene(V) and 1-methylcyclohexene(III) respectively. Since, under these conditions, IV and V were not separated on our columns, Peak A was regarded as a mixture of V and IV. Peak D was confirmed as toluene(XIII) by mass spectral studies (*m/e* 92, M^+ (63), 91 (100), 65 (27), 63 (32)). The mass spectra of Peak C indicated the presence of methylcyclohexa-1,3-diene derivatives(XII) (*m/e* 94, M^+ (25), 91 (25), 79 (100), 77 (75)). Peak E and Peak F showed the following mass spectra [*m/e* 97, M^+-Cl, 81, $96-CH_3$ (most abundant in both peaks), 68, 67, retro Diels-Alder fraction of methylcyclohexene (secondarily abundant in Peak F), 55, retro Diels-Alder fraction of C_6H_{10} (secondarily abundant in Peak E)] and corresponded to the identical retention times of VII, VIII, and IX on the PEG 1540 column, while VI showed a bit of separation, as is shown in Fig. 2. However, using a serially-combined column of Pluronic L-84 and Apiezone glease L, VI was separated distinctly from VII, VIII, and IX (when still had identical retention times), while the fraction of VI was obtained by preparative gas chromatography and was confirmed as 1-chloro-methylcyclohexane by means of its NMR datum (τ, 8.30, CH_3, singlet in CCl_4). The small peaks between Peak F and Peak H were estimated to correspond to methylchlorocyclohexene derivatives (XI) by mass spectral studies (*m/e* 132, 134, M^+, 94 (base peak), 77, 53). Peak H was confirmed to be due to chloromethylcyclohexane by means of mass spectral studies (*m/e* 134,

c) Conv. (%)$=\frac{\text{Recv. Liq.}-\text{Recovered methylcyclohexane}}{\text{Recv. Liq.}}\times 100$. d) Low boiling hydrocarbon. e) A large amount of polymeric products was obtained. The polymer obtained by means of the reprecipitation in methanol of their benzene solution was analyzed to give molecular weight (by Mechrolab Osmometer Model 301) 1040—1100 and C, 79.56; H, 6.45% ($C_{1.04}H_1$). f) The %yield of XIV was as follows. 11.6% (Exp. No. 8), 6.5% (No. 9), 16.7% (No. 10), and 7.5% (No. 12). The formation of dichloromethylcyclohexane was estimated by mass spectral studies of the fraction obtained by the preparative gas chromatography. g) AlCl:KCl:NaCl=3:1:1 (mole ratio). h) $CuCl_2$:KCl:NaCl=3:1:1 (mole ratio). i) In this experiment chlorine was not supplied because $CuCl_2$ acts as chlorinating reagent. j) At 250 °C, no reaction.

132, M^+, 83, M^+-CH_2Cl) and because its retention times were identical with those of the authentic compound.

Reaction of Methylcyclohexane with Chlorine in Molten Salts. The distribution of chlorination products for I is summarized in Table 1, together with the reaction conditions. With both the $ZnCl_2$ melt and the CuCl melt,[15] the conversions at 250 °C were low, but higher conversions were attained at both 350 and 450 °C. In the melt of $AlCl_3$, it was found difficult to carry out chlorination above 300 °C because of the sublimation of $AlCl_3$. A marked difference in the product distribution can be seen between a catalytic reaction in molten salts and a non-catalytic thermal reaction. In the catalytic reaction, the yield of olefin derivatives including toluene shows a high value, while the formation of these is small in the thermal reaction.

The values of f_0 (representing the sum of olefin yields) and f'_0 (f_0+toluene yields) are plotted against the reaction temperatures in Fig. 3.

In the case of the $AlCl_3$ melt, a high % yield of olefin in the recovered liquid products was observed. The small amount of recovered liquid products containing the reactant is due to the formation of a considerable amount of intractable polymeric products remaining on the surface of molten salt in the reactor.

Both the $CuCl_2$ melt and the CuCl melt showed nearly the same olefin yields, whereas, with the $CuCl_2$ melt, a higher yield of dichloro compounds was observed; this fits the finding by Kunugi[16] that the chlorine addition to olefin was predominant with the $CuCl_2$ melt. Figure 3 also indicates that the relative activities for olefin formation are $ZnCl_2$ melt>CuCl

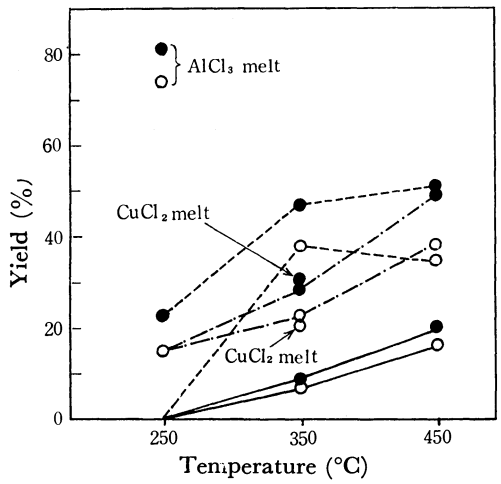

Fig. 3. Olefin yields (f_0 and f'_0) obtained from chlorination of methylcyclohexane in various fused salts at different temperatures.

melt. It is interesting to note that toluene formation was accompanied by no olefin derivatives in the $ZnCl_2$ melt at 250 °C.

As is shown in Table 1, the formation of VI was favored over that of VII, VIII, and IX in the melt of $ZnCl_2$ at both 350 and 450 °C, while the reverse was true with the CuCl melt. These observations will be discussed later.

Reaction of Methyl-Chlorocyclohexanes in Molten Salts. The results of the reaction are shown in Table 2. Three methyl-chlorocyclohexane isomers showed nearly

a) Reaction condition was the same as described in B). b) Low boiling compounds containing cyclohexane.
c) f_{iso}=(III+VI)/(V+IX).

a 100% conversion at 350 and 450 °C in the $ZnCl_2$ melts, while they indicated a lower conversion in the CuCl melt. The catalytic activity difference between these melts is particularly pronounced at 250 °C with VIII and IX as reactants.[18] In the reaction of VI, the primary elimination products were confirmed to be methylene-cyclohexane (II) and 1-methylcyclohexene (III) [see Footnote b) in Table 2A)]. The ratio of II/III, which represents the preference between the "Hofmann" and "Saytzeff" orientations, was 0.1 in the melt of $ZnCl_2$, but 0.01—0.03 in the melt of CuCl. The higher ratio of the $ZnCl_2$ melt compared with that of the CuCl melt may be explained as follows. Since the $ZnCl_2$ melt is known to have a more molecular character[19] than the CuCl melt, the presence of the $\left(\text{C}_6\text{H}_5^{\pm}\text{–CH}_3\ ZnCl_3^-\right)$ complex is seemingly possible in the melt of $ZnCl_2$, where $ZnCl_3^-$ (base) may be well situated to abstract more acidic CH_3 protons, thus leading to the formation of the thermally-unstable olefin II in the higher ratio of II/III compared with the case of the CuCl melt,[21] though 1-methylcyclohexene remains as the primary product.

In the reaction of VIII and IX, considerable amounts of VI and III were formed, together with direct dehydrochlorination products (particularly in the melt of $ZnCl_2$). Table 4 indicates that the direct dehydrochlorination products of VIII and IX, *i.e.*, IV and V, hardly isomerize even in the presence of HCl to III,

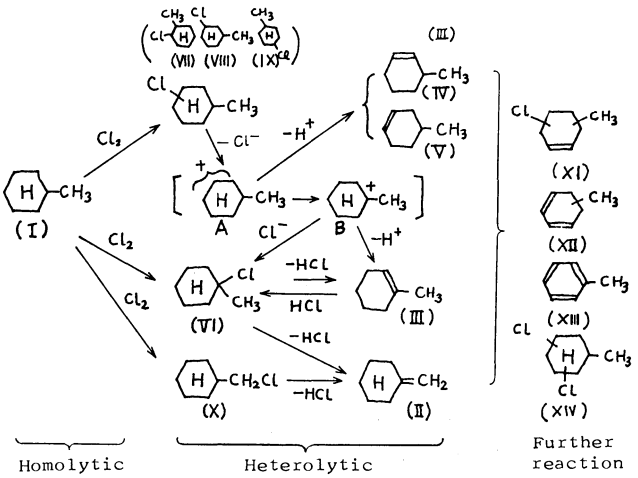

Fig. 4. Reaction scheme.

which is expected to react with HCl to give VI. Therefore, these findings can be explained in terms of rearrangements of the secondary carbonium ion[22] produced by chloride-ion abstraction from VIII or IX to the most stable tertiary carbonium ion (see Fig. 4 for the structures of probable intermediates). The value of f_{iso}(=rearranged products/direct dehydrochlorination products) was used here as a measure of the extent of isomerization. The melts of $ZnCl_2$ showed a higher f_{iso} value than that of CuCl; this can also be explained by the molecular character[19] of the $ZnCl_2$ melt.

a) Starting material; 2.0 g. Duration of reaction; 20 min, Flow rate of HCl; 0.1 mol/hr, HCl: olefin=1:0.7, Depth of salts; 5.0 cm. b) Remarks are the same as described in Table 3.

Reaction of Methyl-Chlorocyclohexane and Methylcyclohexene with HCl in Molten Salts. In the reaction of methylcyclohexane with chlorine in molten salts, chlorine substitution and the subsequent elimination of HCl occurred; both reactions produced corresponding amount of HCl, whose effects on the reaction in molten salts should be noted. Therefore, the following experiments in the presence of added HCl were carried out; the results are listed in Tables 3 and 4. As is shown in Table 3, the reaction of VI shows a substantial recovery of the reactant in the presence of HCl, even in the $ZnCl_2$ melt, which can be expected to assist the dehydrochlorination reaction. This indicates that the olefins formed readily reacted with HCl to give the starting material. This is also confirmed by the experimental results cited in Table 4. That is, the addition of HCl to III took place preferentially with $ZnCl_2$ melts.

However, with VIII and IX as the reactants, a large amount of VI was obtained, along with direct dehydrochlorination products (IV and V), especially in the melt of $ZnCl_2$. In the $ZnCl_2$ melt, the reaction of VIII and IX afforded VI in a yield of about 40%, while the yield of VI reached only a small percentage in the CuCl melt. The preferred formation of these rearranged products with the $ZnCl_2$ melt may be considered to be due to the rearrangement of the Intermediate A to the Intermediate B (in Fig. 4), which is favored in the molecular $ZnCl_2$ melt.

Accordingly, the finding that, in the chlorination of I in molten salts, VI was a main product in the $ZnCl_2$ melt, while a mixture of VII, VIII, and IX was the primary product in the CuCl melt, could be explained by such experimental results. That is, in the $ZnCl_2$ melt, which favors carbonium-ion formation, most of the products, VII—IX, formed by the chlorination of I are converted to III *via* the carbonium-ion mechanism; they then reacts extensively with HCl to afford VI. On the other hand, these rearrangements were not assisted to such an extent by the CuCl melt. In addition, the reaction of IV and V with HCl in the $ZnCl_2$ melt gave slight addition products (3% yield), while the addition of HCl to III took place extensively with the $ZnCl_2$ melt. This is explained by the known stabilities of the carbonium ions (formed by the addition of protons to olefins), which are tertiary (from III)> secondary (from IV—V).

Reaction Process of Methylcyclohexane with Chlorine in the Presence of Molten Salts. In a previous paper[2,4] (the chlorination of cyclohexane in molten salts), the chlorination (substitution reaction) was assumed to proceed by means of a homolytic mechanism, and the subsequent elimination, by means of a heterolytic mechanism. The experimental evidence in favor of this assumption is the observation that the overall reaction was remarkably retarded by the addition of a radical inhibitor (cyclohexene), but the product distribution showed much the same distribution as that in the absence of cyclohexene. Similar observations were made in the reaction of I with chlorine in molten salts; therefore, in these studies, we also considered chlorination to follow a homolytic mechanism and the subsequent elimination and isomerization to follow a heterolytic mechanism.

The most important results obtained here (especially at 350 and 450 °C) may be summarized as follows: 1) The chlorination of I in both the $ZnCl_2$ melt and the CuCl melt affords mono-chlorinated products, VI—IX, along with olefin products, III—V. 2) The reactions of VIII and IX in both melts also give dehydrochlorination products (IV and V), along with III. The relative activities for dehydrochlorination are $ZnCl_2$ melt>CuCl melt. 3) The addition of HCl to III (to form VI) occurs more extensively in the $ZnCl_2$ melt than in the CuCl melt. The addition of HCl to IV and V hardly occurs over either melt. 4) The $ZnCl_2$ melt assists the abstraction of a chloride ion from the organic molecule to a greater extent than the CuCl melt; *i.e.*, the $ZnCl_2$ melt favors carbonium-ion formation from chloro compounds. 5) III and VI are formed from VIII—IX, especially in the $ZnCl_2$ melt, *via* a carbonium-ion mechanism involving the rearrangement of Intermediate A (from VIII—IX) to Intermediate B and the subsequent substitution by chloride ions or the removal of the protons. These results lead us to the reaction scheme shown in Fig. 4, where the inferred intermediates are also given.

18) A possible explanation for this is as follows. As the thermal contribution becomes more significant in the elimination reaction in CuCl melt (owing to its low catalytic activity), the reaction is reluctant to proceed at such a low temperature as 250 °C even in the presence of CuCl melt, whereas the reaction shows a considerable high conversion in the presence of $ZnCl_2$ melt due to its strong catalytic activity. This probably caused the considerable difference between both conversions, being also affected by the fact that lower reactive secondary chloride (VII, VIII, and IX) may be more sensible to the change of reaction condition than the reactive tertiary chloride (VI).

The Acid-Catalyzed Cyclization of 2,3-Dimethyl-2-phenethyl-3-cyclohexen-1-one

Takenori KUSUMI, Nobuo OHNO, and Hiroshi KAKISAWA
Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo 112
(Received July 17, 1974)

The cyclization of 2,3-dimethyl-2-phenethyl-3-cyclohexen-1-one **6a** with aluminum chloride gave 4a,*cis*-10a-dimethyl-3,4,4a,9,10,10a-hexahydro-1(2*H*)-phenanthrone **8a**. The stereochemistry of the latter was established by synthesizing 4a,*cis*-10a-dimethyl-1,2,3,4,4a,9,10,10a-octahydrophenanthrene **10** through Diels-Alder reaction of 3-formyl-4a,*cis*-8a-dimethyl-4a,5,6,7,8,8a-hexahydro-2(1*H*)-naphthalenone **20** with butadiene.

The acid-catalyzed cyclization of aryl-olefin systems is widely used in the synthesis of steroids and polycyclic terpenes. Two asymmetric centers are produced at the ring junctions of the newly constructed ring. Recently the stereochemical investigation of this 'cyclialkylation' is reported by Ireland *et al.*[1] In their and hitherto reported cyclialkylation reactions, two newly formed angular substituents are restricted mostly to hydrogen and methyl groups, and there has been no report upon such cyclialkylation that gives rise to two angular methyl groups, which should be of importance especially in the synthetic study of triterpenes.

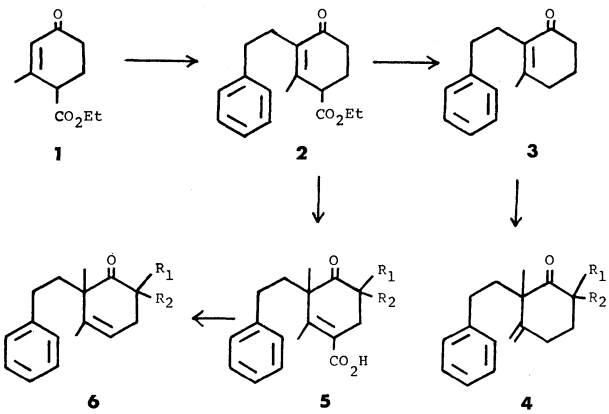
This report deals with the cyclialkylation of 2,3-dimethyl-2-phenethyl-3-cyclohexen-1-one **6a**, which affords the octahydrophenanthrene **8b** carrying two methyl groups at the angular positions.

The synthesis of 4a,*cis*-10a-dimethyl-1,2,3,4,4a,9,10,10a-octahydrophenanthrene **10** which serves as a standard for establishing the stereochemistry of 4a,10a-dimethyl-1,2,3,4,4a,9,10,10a-octahydrophenanthrenes is also described.

Results and Discussion

Synthesis and Cyclization of the Phenethylcyclohexenone 6a. Hageman's ester **1** readily availabe by condensation of ethyl acetoacetate and paraformaldehyde[2] was treated with phenethyl bromide and sodium hydride in benzene-dimethylformamide (DMF) to give the phenethyl derivative **2**, which was boiled with potassium hydroxide in ethanol affording the cyclohexenone **3**.[3] Methylation of **3** with methyl iodide and sodium hydride (one equivalent) in benzene-DMF gave a mixture of mono, di, and trimethylated products (**4a—c**) accompanied by unchanged **3**. The formation of the exocyclic double bond by the methylation was revealed by the NMR spectrum (4.83 and 4.90 ppm, each br. s, 2H) of the product. The yield of the methylated product was estimated as 30% by vpc. However, it was practically difficult to separate the desired monomethylated derivative **4a** from the reaction mixture.

The yield of the methylation was raised as high as 50% when the ketoester **2**, in which the carbethoxy group at C-4 activates the enone system, was treated with methyl iodide and sodium hydride in toluene. The crude product was directly hydrolyzed with potassium hydroxide in ethanol to afford a mixture of the ketoacids **5a—c** easily separable from the cyclohexenone **3** which was produced from the unreacted ester **2** through the hydrolysis and decarboxylation. The mixture of the acids **5a—c** was treated with copper chromite catalyst in quinoline[4] to yield the decarboxylated products **6a**, **b**, and **c**. From the vapor phase chromatogram the ratio of **6a**, **b**, and **c** was estimated as 62: 28: 10.



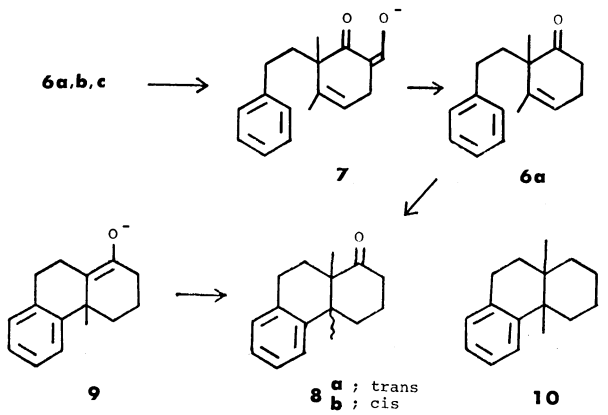
a: $R_1=R_2=H$, b: $R_1=CH_3$, $R_2=H$, c: $R_1=R_2=CH_3$

Isolation of the desired monomethylated derivative **6a** was achieved as follows; formylation of the mixture of **6a—c** followed by alkaline extraction gave a solution of the enolate **7** which was hydrolyzed to produce **6a**. Di and trimethylated derivatives, **6b** and **c**, could be removed in the course of the alkaline extraction.

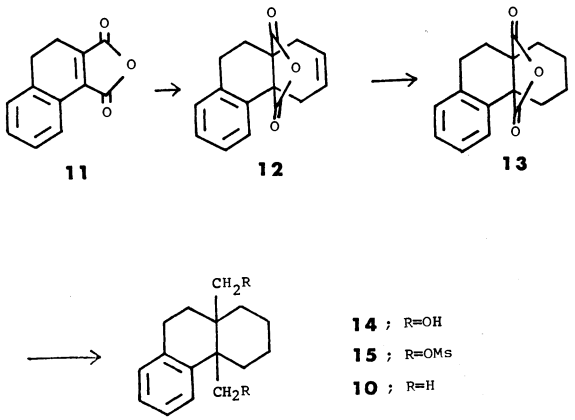
Treatment of **6a** with aluminum chloride in carbon disulfide at 0 °C gave a crystalline substance (mp 64—65 °C) as a single product in 73% yield. Treatment of **6a** with 85% phosphoric acid at 120 °C afforded the same product.

The IR spectrum of the product represents a carbonyl absorption at 1702 cm^{-1} and the NMR spectrum shows two sharp singlets at 1.10 and 1.27 ppm ascribable to tertiary methyls beside a 4H-multiplet at the aromatic region. From these spectral properties the structure **8** was assigned for the crystalline product.

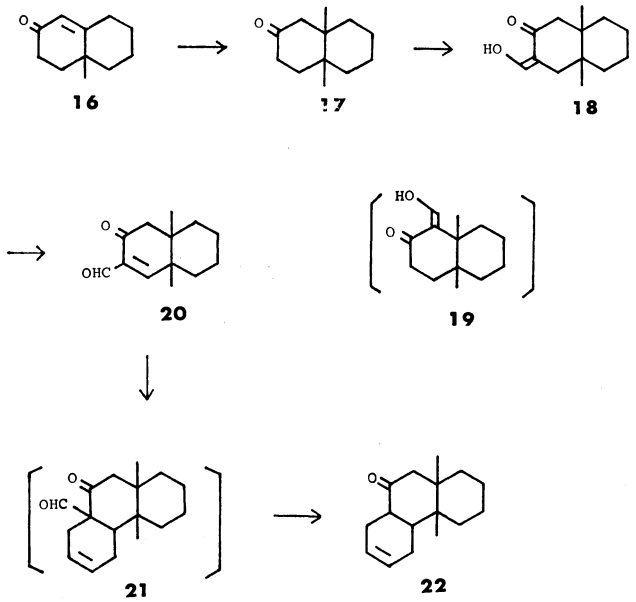
The NMR and the vpc showed that the only one of the two possible stereoisomers, **8a** and **b**, was afforded by the cyclization reaction. Whitlock and Overman have obtained *trans* **8a** and *cis* **8b** through Simmons-Smith reaction of the enolate **9**,[5] and our product **8** is revealed to accord with *cis* **8b** by comparison with its mp and the NMR spectrum. However, no basis to determine the stereochemical relationship of the two angular methyl groups is appeared in their report. Therefore we focussed our attention upon synthesizing the *cis*-dimethylhydrophenanthrene **10** by the stereochemically unambiguous method.



Synthesis of the cis-*Dimethylhydrophenanthrene* **10**. The anhydride **12**, prepared by Diels-Alder reaction[6] of **11** and butadiene, was hydrogenated on palladium–charcoal in ethanol affording **13**. This was treated with lithium aluminum hydride in ether to produce the diol **14**. It is obvious from surveying the series of the reaction employed that the two hydroxymethyl groups of **14** should be situated in a *cis* sence. The diol **14** was treated with methanesulfonyl chloride in pyridine at 0 °C to give the dimesylate **15**. Reduction of **15** with lithium aluminum hydride in ether or tetrahydrofuran, however, produced an intractable mixture of rearranged hydrocarbons, ethers and alcohols, and the desired *cis*-dimethyl compound **10** could not be obtained from the mixture.

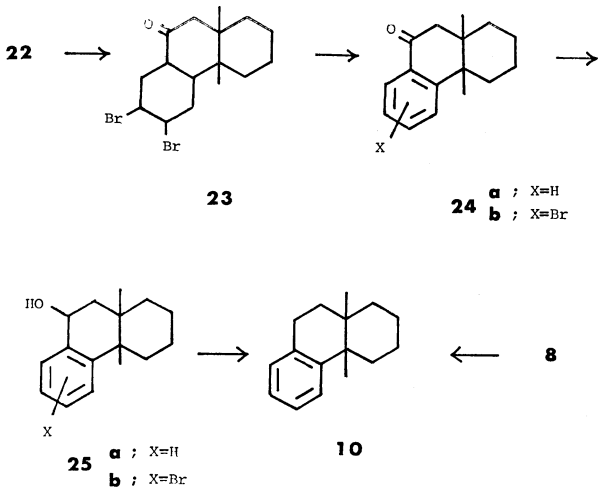


We, therefore, turned our effort to another approach to **10**. The *cis*-dimethyldecalone **17** was prepared by treatment of the octalone **16** with methylmagnesium iodide–cuprous salt[7] or dimethylcopperlithium,[8] the latter giving the higher yield. The *cis*-relationship of the two methyl groups in **17** has been already established.[7] The decalone **17** was formylated with ethyl formate and sodium methoxide to give **18** in good yield. The NMR spectrum of **18** exhibits two pairs of AB quartet centered at 2.28 (2H, J=15 Hz) and 2.29 (2H, J=19 Hz) ppm attributable to the methylene groups at C-1 and C-4, which excludes the another possible isomer **19**. The regiospecific formylation at C-3 is ascribed to severe steric hindrance around C-1 of the decalone **17**. The formylketone **18** was converted into **20** by oxidation with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) in dioxane.[9] The NMR spectrum of the ketoaldehyde **20** shows five sharp singlets at 10.06 (1H, –CHO), 7.40 (1H, olefinic proton at C-1), 2.43 (2H, $-CH_2-$ at C-4), 1.16 (3H, $-CH_3$), and 1.05 (3H, $-CH_3$) ppm. The ketoaldehyde **20** was heated with butadiene at 200 °C, and the product was chromatographed to give rise to a ketonic substance in 7% yield. The IR spectrum of this ketone shows a strong absorption at 1710 (C=O) and a weak one at 1665 cm^{-1} (C=C). Its NMR spectrum exhibits two sharp singlets at 1.04 (3H) and 1.06 (3H) assignable to two quarternary methyls and a broad singlet at 5.60 (2H) ppm due to two olefinic protons. No signal showing the presence of an aldehyde proton was observed. From these spectral properties the structure **22** could be assigned for the ketone, and this was further justified by its mass spectrum. The molecular peak appears at *m/e* 232.184 accordant with the molecular weight of **22** (232.183 Calcd for $C_{16}H_{24}O$). Carbon monoxide was apparently removed from the initial Diels-Alder adduct **21** in the course of the reaction.



The tricyclic ketone **22** was converted into the dibromide **23** through the agency of bromine in chloroform. Dehydrobromination of **23** with quinoline[10] and subsequent dehydrogenation with DDQ gave a mixture of **24a** and **b**. The mixture was treated with lithium aluminum hydride affording **25a** and **b**. Reduction of the mixture with sodium in liquid ammonia in the presence of ethanol[11] and purification with column chromatography gave rise to the *cis*-dimethylhydrophenanthrene **10** as an oil. Its NMR spectrum exhibits two sharp singlets at 0.95 and 1.19 due to the angular methyl groups, a broad triplet at 2.84 (2H, J=7 Hz) ppm corresponding to the benzylic protons and a complex multiplet in the aromatic region (4H, 7—7.7 ppm). The IR and the mass spectra are also consistent with the structure **10**.

Finally the tricyclic ketone **8**, which had been obtained by the cyclization of **6a**, was reduced by hydrazine and sodium hydroxide to produce a hydrocarbon. The IR spectrum and the behavior on tlc and vpc of the hydrocarbon were identical with those of **10**. These facts show that the two angular methyl groups of **8**



are in a *cis*-relationship.

The acid-catalyzed cyclization of **6a** proceeds in such a manner as to yield *cis* **8b** exclusively.

Experimental

NMR spectra were obtained with a Hitachi EPI-S2 spectrophotometer. Ultraviolet spectra were taken on a Hitachi EPS-3T. Melting points and boiling points are uncorrected.

3-Methyl-2-phenethyl-2-cyclohexen-1-one **3** was prepared according to the method described in Ref. 3.

Methylation of 3-Methyl-2-phenethyl-2-cyclohexen-1-one **3**. Into a suspension of sodium hydride (270 mg as a 50% dispersion in mineral oil) in dry benzene (30 ml) and DMF (10 ml) was added a solution of **3** (1.0 g) in benzene (5 ml) during 1 hr in an atmosphere of nitrogen. After the mixture was stirred at room temperature for 20 hr, a solution of methyl iodide (730 mg) in benzene (5 ml) was added during 1.5 hr. After being stirre at 40—45 °C for 18 hr, the mixture was washed with dilute hydrochloric acid, sodium bicarbonate solution and dried over sodium sulfate. Evaporation of the solvent gave an oil (1.1 g), which consisted of the starting ketone **3** and the methylated products **4a—c**. The ketone **3** could be removed by preparative thin layer chromatography, but the methylated products showed the single spot on tlc and approximate retention times on vpc, and the further attempt to isolate **4a** was discontinued. The mixture of **4a—c** has the following spectral properties; ν(film) 1705, 1630, 1600, 895, 750, 700 cm^{-1}; δ ($CDCl_3$) 4.83 (br.s, 1H), 4.90 (br.s, 1H) ppm; *m/e* 256 (M^+ of **4c**), 242 (M^+ of **4b**), 228 (M^+ of **4a**).

Methylation of **2**.[3] A solution of **2** (28.7 g) in dry toluene (170 ml) containing sodium hydride (5.90 g) was stirred at 110 °C until no more hydrogen was evolved (1.5 hr). The cooled reaction mixture was treated with methyl iodide (71.0 g) and the mixture was stirred at refluxing temperature for 70 hr. Ethanol was added to the cooled mixture and the mixture was poured into water. The toluene layer was separated, and the aqueous layer was extracted with ether. The combined organic layer was washed with sodium bicarbonate solution and dried. The solvent was removed to afford a yellow oil (29.6 g). This was dissolved into 15% ethanolic sodium hydroxide (120 ml) and the solution was heated under reflux for 23 hr. Water was added and the mixture was further refluxed for 1 hr. The ethanol was removed and the residue was treated with water and extracted with ether. The ethereal layer was washed with sodium bicarbonate solution. The aqueous layers were combined and acidified with 1.4 M hydrochloric acid to pH 1.0. Extraction with ether and removal of the ether gave a mixture of the acids **5a—c** (15.3 g). From the ethereal layer was obtained the ketone **3** (8.9 g).

Decarboxylation of the Acids **5a—c**. A mixture of the acids **5a—c** (15.3 g), copper chromite catalyst[4] (1.5 g), and freshly distilled quinoline (60 ml) was heated to reflux in a metal-bath for 10 min. The cooled reaction mixture was poured into ether and the catalyst was filtered away. The filtrate was washed with dilute hydrochloric acid, sodium bicarbonate solution and brine, and dried over sodium sulfate. The crude deep brown oil obtained after removal of the ether was fractionated under reduced pressure to afford a light yellow oil (6.9 g; bp 108—123 °C/0.2 mmHg). The oil was found to consist of **6a** (62%), **6b** (28%), and **6c** (10%) by vpc (PEGS-10% on chromosorb W; 228°C).

Isolation of **6a** *from the Mixture* **6a—c** *by Formylation*. Into an ice-cooled suspension of powdered sodium methoxide (1.35 g) in dry benzene (30 ml) was added with stirring a solution of the above mixture **6a—c** (3.07 g) in ethyl formate (2.0 g) under a nitrogen atmosphere. The mixture was allowed to stand at room temperature overnight. Ice-water was added, and the alkaline-insoluble materials (**6b** and **c**) were taken up into ether. The aqueous alkaline solution was kept at 90 °C for 4 hr. The cooled solution was extracted with ether, dried over sodium sulfate. Removal of the ether afforded the cyclohexenone **6a** (1.18 g), ν (film): 3020, 1705, 1620, 1600, 750, 695 cm^{-1}; δ (CCl_4): 1.18 (s, 3H), 1.79 (br.d, 3H), 2.0—2.7 (m, 8H), 5.73 (m, 1H), 7.2 (br.s, 5H) ppm; *m/e* 228.150; Calcd for $C_{16}H_{20}O$: 228.150; bp 110 °C/0.1 mmHg.

Cyclization of 2,3-Dimethyl-2-phenethyl-3-cyclohexen-1-one **6a**. *(A) With Aluminum Chloride*: The cyclohexenone **6a** (96 mg) was stirred with anhydrous aluminum chloride (143 mg) in dry carbon disulfide (5 ml) at 0 °C for 3 hr. The mixture was filtered and the filtrate was washed with dilute hydrochloric acid. Evaporation of the solvent gave a colorless solid (70 mg; 74%). Recrystallization from benzene–hexane gave pure **8b**, mp 64—65 °C; ν (KBr): 1702, 1498, 755 cm^{-1}; ν ($CHCl_3$): 1700, 1603, 1498 cm^{-1}; δ ($CDCl_3$): 1.10 (3H, s), 1.27 (3H, s), 1.5—3.0 (m, 10H), 7.0—7.3 (4H, m) ppm; δ (C_6H_6): 1.00 (3H, s), 1.06 (3H, s) ppm. Found: C, 84.03; H, 8.80%. Calcd for $C_{16}H_{20}O$: C, 84.16; H, 8.83%.

(B) With Phosphoric Acid: The cyclohexenone **6a** (593 mg) was heated at 120—125 °C with 85% phosphoric acid (50 ml) for 12 hr. The cooled mixture was poured into ice-water, and extracted twice with ether. The ether was evaporated to give 650 mg of oil which was chromatographed on alumina (50 g). Elution with benzene gave **8b** (443 mg; 75%), which was identical with the ketone obtained by the method (A).

4b,5,8,8a,9,10-Hexahydrophenanthrene-4b,8a-dicarboxylic Anhydride was prepared according to the Ref. 6; mp 84 °C.

4b,5,6,7,8,8a,9,10-Octahydrophenanthrene-4b,8a-dicarboxylic Anhydride **13**. The anhydride **12** (1.7 g) was dissolved in ethyl acetate (100 ml) and platinum oxide (400 mg) was added. The mixture was stirred under hydrogen. The hydrogen absorption ceased after the uptake of 267 ml of hydrogen and the catalyst was filtered away. The filtrate was concentrated to give an oil (1.71 g) which solidified on standing. Recrystallization from benzene–ligroin gave colorless needles; mp 97—98 °C; ν (KBr): 1850, 1775 cm^{-1}.

4b,8a-Bis(hydroxymethyl)-4b,5,6,7,8,8a,9,10-octahydrophenanthrene **14**. Into a stirred suspension of lithium aluminum hydride (2.1 g) in tetrahydrofuran (250 ml) was added a solution of the anhydride **13** (1.35 g) in tetrahydrofuran

(10 ml). The reaction mixture was heated under reflux for 17 hr. The complex was decomposed with water and the white precipitates were filtered away. The filtrate was concentrated to give a colorless solid (1.31 g). Recrystallization from ethanol afforded colorless needles (1.1 g); mp 130—132 °C; ν (KBr): 3300—3200 cm^{-1}.

4b,8a-Bis(methanesulfoxymethyl)-4b,5,6,7,8,8a,9,10-octahydrophenanthrene ***15***. The diol **14** (200 mg) was dissolved in pyridine (40 ml) and the solution was cooled at 0 °C in an ice-bath. Methanesulfonyl chloride (2.8 ml) was added in a portion, and the reaction mixture was stirred at 0 °C for 1 hr. This was poured onto ice, and the aqueous solution was extracted with ether. The ethereal solution was washed successively with 2 M hydrochloric acid, sodium bicarbonate solution, water and brine. After the ethereal solution was dried over sodium sulfate, the solvent was evaporated to yield a colorless solid (354 mg), which was washed with small portions of ether. The dimesylate has the following spectral properties; ν (KBr): 1335, 1170, 980 cm^{-1}; δ ($CDCl_3$): 2.85 (3H, s), 3.05 (3H, s), 4.30 (2H, s), 4.41 (2H, ABq, J=9 Hz), 7.2 (4H, m) ppm.

Reduction of 15 with Lithium Aluminum Hydride. A mixture of the dimesylate (285 mg) and lithium aluminum hydride (600 mg) in ether (100 ml) was heated under reflux with stirring overnight. After the usual treatment a colorless oil was obtained. The IR spectrum of the crude product showed strong absorption at 1170 cm^{-1} suggesting the presence of ethers in the product. The oil was chromatographed on silicic acid. Elution with hexane gave a mixture of hydrocarbons (90 mg) whose NMR spectrum showed no distinct methyl signals.

*3,4,4a,5,6,7,8,8a-Octahydro-4a,*cis*-8a-dimethyl-2(1H)-naphthalenone* ***17***. Into a suspension of cuprous iodide (34.8 g) in ether (400 ml) was added methyllithium (2 eq) in ether at −20 °C under a slow stream of nitrogen. Into the dark brown solution was added a solution of **16** (20 g) in ether (50 ml) at 0 °C during 25 min. After the reaction mixture was stirred at 0 °C for 2.5 hr, aqueous ammonium chloride solution was added cautiously. After violent evolution of gas ceased, the mixture was transferred into a separatory funnel. The ethereal layer was separated and washed with brine and dried over sodium sulfate. Evaporation of the ether afforded a crystalline solid (20.4 g) which was purified by chromatography (1 kg of alumina). Elution with hexane–benzene (8:2) yielded **17** (17.7 g; 80%). Further purification by sublimation (50 °C/1 mmHg) gave colorless crystals; mp 119—127 °C (lit, 109—116 °C). The IR and NMR spectra were identical with those of **17** prepared by Marshall's method.[7]

*3-Formyl-4a,*cis*-8a-dimethyl-3,4,4a,5,6,7,8,8a-octahydro-2(1H)-naphthalenone* ***18***. Sodium methoxide prepared by dissolving sodium (186 mg) in dry methanol (3 ml) was heated at 160 °C at 1 mmHg for several minutes to remove the trace of methanol. The solid was dispersed into dry benzene (20 ml) and a solution of the decalone **17** (300 mg) in freshly distilled dry ethyl formate (670 mg) was added at 0 °C during 15 min. After the temperature was maintained at 0 °C for 1 hr, the mixture was stirred at room temperature overnight. The yellow slurry was treated with ice-water and the aqueous layer was separated and washed with ether. The alkaline solution was acidified with hydrochloric acid, and the acidic material was extracted with ether. The usual treatment of the ether extract gave a slightly red oil (349 mg) which was used in the next reaction without further purification; ν (film): 1645, 1595 cm^{-1}; δ ($CDCl_3$): 0.98 (s, 6H), 2.28 (ABq, J=15 Hz, 2H), 2.29 (ABq, J=19 Hz, 2H) ppm.

*3-Formyl-4a,*cis*-8a-dimethyl-4a,5,6,7,8,8a-hexahydro-2(1H)-naphthalenone* ***20***. A solution of the formylketone **18** (5.6 g) and DDQ (6.2 g) in dry dioxane (60 ml) was allowed to stand at room temperature for 30 min. Fine precipitates separated out rapidly. The precipitates were filtered off, and the filtrate was diluted with methylene chloride. The solution was washed with 2% aqueous sodium hydroxide solution until the aqueous layer showed no coloration. The organic layer was washed with water and brine, and dried over sodium sulfate. Evaporation of the solvent gave a red oil (3.2 g) which was purified by distillation at reduced pressure, bp 109 °C/0.2 mmHg (2.6 g). The oil solidified on cooling and recrystallization from hexane afforded light yellow crystals; mp 35—36 °C; ν (CCl_4): 1705, 1690, 1615 cm^{-1}; δ (CCl_4): 1.05, 1.16 (each 3H, s), 2.43 (2H, s), 7.40 (1H, s), 10.06 (1H, s) ppm. Found: C, 75.65; H, 8.77%. Calcd for $C_{13}H_{18}O_2$: C, 75.69; H, 8.80%.

*4b,*cis*-8a-Dimethyl-1,4,4a,5,6,6a,7,8,9,10,10a-dodecahydro-10-oxophenanthrene* ***22***. The ketoaldehyde **20** (1.6 g) and butadiene (1.26 g; 3 eq) in dry dioxane (5 ml) was heated at 200—210 °C for 24 hr in a sealed tube. The resulting oil was chromatographed on silicic acid (100 g), and elution with hexane–benzene (3:7) yielded the ketone **22** (107 mg). The analytical sample was obtained by micro distillation of a small portion of this material at 120—140 °C bath temperature (0.4 mmHg). Found: *m/e* 232.184. Calcd for $C_{16}H_{24}O$: 232.183.

*2,3-Dibromo-4b,*cis*-8a-dimethyl-1,2,3,4,4a,4b,5,6,7,8,8a,9,10,10a-tetradecahydro-10-oxophenathrene* ***23***. Into a stirred solution of the tricyclic ketone **22** (111 mg) in freshly distilled chloroform was added a solution of bromine (92 mg) in dry carbon tetrachloride (4 ml) at −60 °C during 40 min. The mixture was stirred at −60 °C for 10 min, and the solvent was evaporated under reduced pressure to yield a yellow oil (211 mg) which crystallized on cooling.

Dehydrobromination of the Dibromide 23. A solution of the dibromide **23** (211 mg) in freshly distilled quinoline (2 ml) was heated at 160—170 °C for 4 hr. The reaction mixture became dark brown. This was cooled and poured into water, and the product was extracted with ether. The ethereal layer was washed several times with 1 M hydrochloric acid, sodium bicarbonate solution, and dried over sodium sulfate. Removal of the solvent gave a brown oil (123 mg); ν (film): 1705, 1668, 1615, 1600 cm^{-1}. The crude product was treated with DDQ (192 mg) in dry benzene (10 ml) at 80 °C for 1 hr. The dark brown mixture was filtered through alumina (15 g). The alumina was further eluted with benzene (200 ml). Evaporation of the benzene gave a yellow oil (106 mg). The oil was adsorbed on silicic acid (20 g) and eluted with hexane–benzene to afford mainly three fractions (a), (b), and (c). Fraction (a) (31 mg); the starting dibromide **23**: fraction (b) (22 mg); the bromoketone **24b**, ν (film): 1705 cm^{-1}: fraction (c) (38 mg): a mixture of **24a** and **b**, *m/e* 306 and 308 (M^+ of **24b**), 228 (M^+ of **24a**).

*4b,*cis*-8a-Dimethyl-4b,5,6,7,8,8a,9,10-octahydrophenanthrene* ***10***. A mixture of the ketones (fraction (c); 34 mg) was dissolved in ether (5 ml) and lithium aluminum hydride (359 mg) was added. The mixture was stirred at room temperature overnight. After decomposition of the excess hydride a colorless oil was obtained (32 mg); ν (film): 3400 cm^{-1}. Into liquid ammonia (10 ml) was added a solution of the above oil in dry ethanol (0.5 ml). Sodium (80 mg) was added in small portions. The ammonia was evaporated and the residue was treated with water. The product was extracted with ether and purified by column chromatography to give a colorless oil (20 mg); ν (film): 2900, 1480, 1460, 1438, 1375, 1034, 751, 737, 718 cm^{-1}; δ (CCl_4): 0.95 (3H, s), 1.19 (3H, s),

2.84 (2H, t, J=7 Hz), 7—7.7 (4H, m) ppm; *m/e* 214.169; Calcd for $C_{16}H_{22}$: 214.172.

By Wolff-Kishner Reduction of 8b. A mixture of **8b** (46 mg), 80% hydrazine hydrate (0.5 ml) and potassium hydroxide (680 mg) in diethylene glycol (5 ml) was refluxed for 1 hr. Water was then distilled until the temperature of the reaction mixture reached 200 °C, and the distillate was collected. The reaction mixture was kept at 200 °C for 3 hr. Water was added and the mixture was acidified with conc. hydrochloric acid. The mixture and the distillate were combined and extracted with benzene. After drying over sodium sulfate, the benzene was removed on a rotary evaporator to give a colorless oil (30 mg) which was purified with chromatography (silicic acid; 2 g). Elution with hexane afforded a colorless oil (20 mg). The IR spectrum, R_f value on tlc, and retention time on vpc were identical with those of **10** obtained in the above procedure.

The authors wish to thank Mr. T. Kinoshita (Sankyo Co., Ltd.) for the mass spectrum measurement.

Polymerizationn of Vinyl Compounds by Dihydridotetrakis-(triphenylphosphine)ruthenium(II)

Sanshiro KOMIYA, Akio YAMAMOTO, and Sakuji IKEDA

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro, Tokyo 152

(Received July 18, 1974)

Dihydridotetrakis(triphenylphosphine)ruthenium(II) **1** initiates the polymerization of α-substituted olefins of high *e*-values such as acrylonitrile and forms unstable complexes with olefins of low *e*-values. Molecular weight of the polymer obtained by the polymerization of acrylonitrile with **1** was independent of polymerization time and increased linearly with the monomer concentration. The rate of polymerization was measured by a dilatometry and compared with the rate of decomposition of **1** in the presence of acrylonitrile followed by a spectroscopic method. The rate of decomposition of **1** was found to be equivalent to the rate of initiation of polymerization and can be expressed by the following equations:

$$-\frac{d}{dt}[Ru] = k[Ru], \quad \frac{1}{k} = A + \{B + C[PPh_3]\}/[monomer]$$

On the basis of the kinetic results and the independence of molecular weight of the polymer on time, a mechanism involving a slow initiation step followed by rapid propagation and termination steps is proposed.

Recent developments in the study of olefin polymerization by isolated transition metal allyl,[1] benzyl,[2] and alkyl[3] complexes have shed some light on the mechanism of coordination polymerization by Ziegler type catalysts. The polymerization mechanism with these isolated monometallic complexes has been accounted for as combination of elementary steps comprising the coordination of a monomer to the transition metal complex with a metal-carbon bond, the succeeding monomer insertion into the metal-carbon bond activated by coordination of the monomer and the spontaneous termination. A similar polymerization activity is expected for a transition metal hydride complex, and in fact some transition metal hydrides[4] are known to initiate the vinyl polymerization.

No detailed study, however, has been made to our knowledge on the vinyl polymerization by an isolated transition metal hydride except for the study by cobalt hydride.[5] Dihydridotetrakis(triphenylphosphine)ruthenium **1**,[6] which is a stable hydride complex easy to handle, catalyzes a variety of reactions of olefins, such as hydrogenation, H–D exchange, isomerization and polymerization, and serves as an appropriate model compound for studying the mechanisms of the olefin catalysis. This paper is mainly concerned with the kinetics of polymerization of acrylonitrile (AN) by **1**. Other ruthenium dihydride complexes with different substituted phosphine ligands have been examined as catalysts for vinyl polymerization and compared with **1**.

Results and Discussion

Polymerization of Vinyl Compounds by Ruthenium Hydride Complexes. The ruthenium hydride complex **1** reacts with a variety of olefins, substituted and unsubstituted. Table 1 summarizes the results of the reactions of **1**. The olefins in Table 1 are arranged in the decreasing order of Alfley Price's *e*-value[7] which parallels the electronegativity of the olefin. The most electronegative α,β-substituted olefins such as tetracyanoethylene and maleic anhydride give stable olefin-coordinated π-complexes and the α-substituted oefins of medium *e*-values are polymerized by **1**, whereas less electronegative olefins such as styrene and ethylene form unstable olefin-coordinated π-complexes. We have

TABLE 1. REACTIONS OF $RuH_2(PPh_3)_4$ WITH OLEFINS

Monomer	*e*-Value[a]	Time	Temp.	Polymer yield (MW)	Complex isolated
Tetracyanoethylene (TCNE)			r. t.	—	$Ru(TCNE)_3(PPh_3)_2$
Maleic anhydride (MAnh)	2.25	6 days	r. t.	—	$Ru(MAnh)_n(PPh_3)_{5-n}$

briefly reported on the formation of the ruthenium complexes with ethylene and styrene.[8]

Kinetics of Polymerization by 1. Complex **1** is suitable for studying the kinetics of the vinyl polymerization as well as other isolated iron alkyl[3] and cobalt hydride[5] complexes, because the change of the complex can be conveniently followed by a spectroscopic method and compared with the kinetics of polymerization followed by a dilatometry.

When **1** is dissolved in dimethylformamide (DMF) and acrylonitrile is added to the solution, the visible spectrum of **1** changes with time showing an isosbestic point at 455 nm. By observing the decrease of the absorbance at 470 nm, the rate of decomposition of **1** in the presence of acrylonitrile can be followed. The decomposition rate can be expressed by the following equation, where [Ru] represents the total concentration of the dihydridoruthenium complex in solution and k_s denotes the pseudo-first-order rate constant observed by the spectroscopic method:

$$-\mathrm{d[Ru]}/\mathrm{d}t = k_s[\mathrm{Ru}] \qquad (1)$$

The rate of polymerization of acrylonitrile by **1** in DMF was followed by dilatometry and Fig. 1 demonstrates a typical time-yield curve. The polymerization is initiated without induction period and the yield levels off with time and approaches a constant value depending on the concentration of the catalyst. The dilatometric and spectroscopic experiments were carried out under the conditions that the change of the monomer concentration is negligible.

The plot of the logarithms of $(Y_\infty - Y_t)$ where Y_∞ is the yield at infinite polymerization time and Y_t is the yield at time t in Fig. 2 *versus* time gives a straight line (Fig. 2) indicating the following relationship:

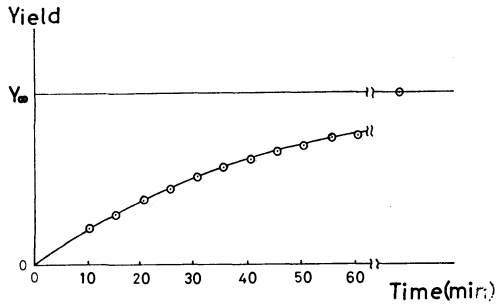

Fig. 1. Time-conversion curve of the polymeriuation of acrylonitrile by $RuH_2(PPh_3)_4$ in dimethylformamide 25 °C. [AN]=2.69 mol/l; [PPh_3]=0.109 mol/l.

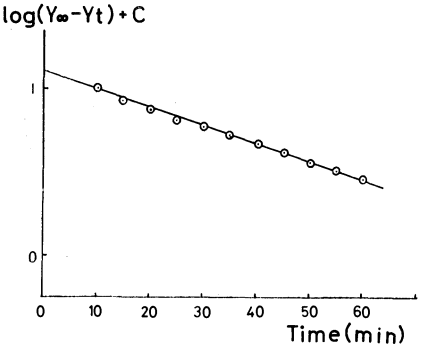

Fig. 2. The plot of logarithms of $(Y_\infty - Y_t)$ in Fig. 1 against time.

$$\log (Y_\infty - Y_t) = -kt + \text{const} \qquad (2)$$

Examination of the molecular weights of the polymers obtained after different intervals revealed that the molecular weight of the polymer was independent of the polymerization time. Since the concentration of the catalyst changes with time as expressed by Eq. (1), it can be concluded that the molecular weight is independent of the catalyst concentration.

Since the molecular weights of the polymers obtained at different conversions are almost constant, the yield of the polymer can be regarded as proportional to the number of the polymer chains produced. This suggests that the polymerization process of the vinyl monomer by **1** consists of a slow initiation step followed by rapid propagation and termination steps as in the polymerization by dialkylbis(dipyridyl)iron.[3] If we assume that the ruthenium complex initiates the polymerization with an initiator efficiency f by insertion of one monomer into the Ru–H bond followed by insertion of monomers into the Ru–C bonds, and that the growth of the polymers is terminated spontaneously after reaching a certain degree of polymerization $\overline{DP}$, which is constant, the polymerization rate can be expressed as follows:

$$R_p = \frac{\mathrm{d[Y]}}{\mathrm{d}t} = f \times \overline{DP} \times \left(-\frac{\mathrm{d[cat]}}{\mathrm{d}t}\right) \qquad (3)$$

where [Y] is the yield expressed in mol of the monomer unit polymerized and [cat] is the molar concentration of the catalyst.

From Eqs. (1) and (3) the following equation can be derived:

$$\log (Y_\infty - Y_t) = -k_s t + \log (f \times \overline{DP} \times [\mathrm{cat}]_0) \qquad (4)$$

where $[\mathrm{cat}]_0$ represents the initial concentration of the catalyst. Equation (4) is equivalent to Eq. (2). Thus if our assumptions are valid, it can be expected that the rate constant k measured from the dilatometry is equal to k_s, the rate constant obtained spectroscopically for the decomposition of the ruthenium complex **1**. Figure 3 demonstates the dependences of k and k_s on the monomer concentration. Both rate constants increase and level off with increasing monomer concentration and a satisfactory agreement is observed between k and k_s.

The plot of the reciprocal values of k in Fig. 3 against the reciprocal of the olefin concentration gives straight

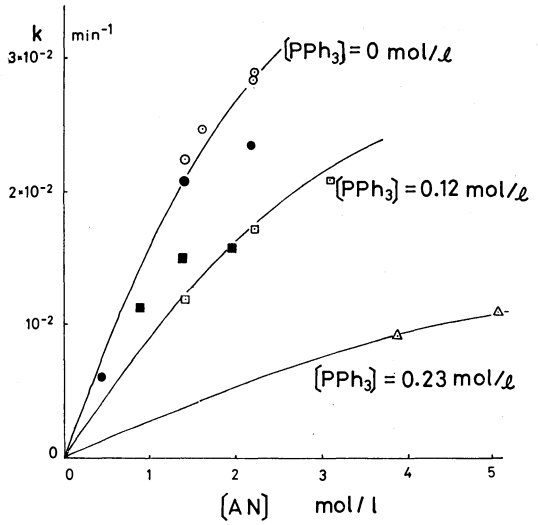

Fig. 3. Plot of the pseudo-first-order rate constants, k (observed by dilatometry ⊙, ⊡, △) and k_s (determined by spectrophotometry ●, ■).

lines converging to a constant (Fig. 4).

The addition of triphenylphosphine to the system has an inhibition effect on the polymerization and the linear dependence of the reciprocal of k on the concentration of the added triphenylphosphine is shown in Fig. 5.

These kinetic results are summarized by Eq. (5):

$$\frac{1}{k} = A + \{B + C[PPh_3]\}/[\text{monomer}] \tag{5}$$

These results are consistent with the mechanism shown below:

$$RuH_2(PPh_3)_4 + DMF \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} RuH_2(PPh_3)_3(DMF) + PPh_3 \tag{6}$$

$$RuH_2(PPh_3)_3(DMF) + AN \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} RuH_2(AN)(PPh_3)_3 + DMF \tag{7}$$

$$RuH_2(AN)(PPh_3)_3 \xrightarrow{k_3} \text{insertion} \tag{8}$$

$$\downarrow nAN$$

propagation

$$\downarrow$$

termination
(catalyst inactivation)

In the mechanism proposed here, we assume the predissociation of a triphenylphosphine ligand from $RuH_2(PPh_3)_4$ in solution (DMF) to give a solvent-coordinated species, $RuH_2(PPh_3)_3(DMF)$. Coordination of a monomer molecule (AN) displacing the coordinated solvent to give the monomer-coordinated species leads to activation of the Ru–H bonds and to insertion of the coordinated monomer into one of the Ru–H bonds. The first insertion is reagrded as the rate-determining step which is followed by rapid monomer insertions (propagation step). When the polymer reaches a certain length the polymer bonded with the complex may be spontaneously split from the complex which becomes thus inactive (termination step).

The kinetic result is in agreement with the scheme shown in Eqs. (6)—(8). By assuming the equilibrium for Eqs. (6) and (7) and the rate-determining step for Eq. (8), the following equations may be derived.

$$-\frac{d}{dt}[Ru] = k[Ru] = \frac{k_1k_2k_3[AN][Ru]}{k_1k_{-2}[DMF] + k_1k_2[AN] + k_{-1}k_{-2}[PPh_3]} \tag{9}$$

$$\frac{1}{k} = \frac{1}{k_3} + \frac{1}{K_1K_2k_3}\cdot\frac{[PPh_3]}{[AN]} + \frac{1}{K_2k_3}\cdot\frac{[DMF]}{[AN]} \tag{10}$$

where $K_1 = \frac{k_1}{k_{-1}}$, $K_2 = \frac{k_1}{k_{-2}}$

Equation (10) is in agreement with the experimental result shown by Eq. (5). The intercept to which the straight lines in Fig. 4 converge corresponds to $1/k_3$, the reciprocal of the rate constant for the insertion of acrylonitrile into the ruthenium-hydrogen bond. In the previous studies using $R_2Fe(dipy)_2$ and $CoH(N_2)$-

$(PPh_3)_3$ the dissociation of the ligand was rate-determining at high concentration of the monomer and the similar intercept as shown in Fig. 4 corresponded to the reciprocal of the dissociation rate of the ligand from the complex. On the other hand the kinetic decomposition behavior of $RuH_2(PPh_3)_4$ differs from those of $R_2Fe(dipy)_2$ and $CoH(N_2)(PPh_3)_3$ in that the dissociation of **1** in solution is extensive and the rate of insertion into the Ru–H bond constitutes the rate-determining step over the whole olefin concentration range. Estimation of the activation energy for the insertion of acrylonitrile into Ru–H bond based on the temperature dependence of k_3 at 25.0, 31.5, and 37.1 °C gave the value of *ca.* 20 kcal/mol.

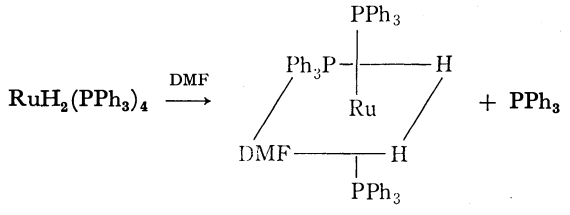
Analysis of Fig. 4 allows the estimation of K_1 and K_2 for the equilibria of Eqs. (6) and (7). In the absence of added triphenylphosphine $1/k$ can be expressed as follows:

$$\frac{1}{k} = \frac{1}{k_3} + \frac{[DMF]}{k_3K_2}\frac{1}{[AN]}$$

Using the value of k_3, estimated from the intercept of Fig. 4 as 1/18 min^{-1}, and the concentration of DMF computed as 12 mol/l, K_2 at 37.1 °C was estimated as 4.5 from the slope of Fig. 4 where $[PPh_3]=0$. The value of K_1 at 37.1 °C was evaluated as 0.011 from the slope of Fig. 4 at PPh_3 concentration of 0.12 mol/l and using Eq. (10) with k_3 and K_2 values. Estimation of the degree of dissociation at [Ru]=1.33 mol/l using the values of 0.011 and 12 mol/l for K_1 and [DMF] indicates that over 98% of $RuH_2(PPh_3)_4$ is dissociated in DMF liberating triphenylphosphine.

The validity of this mechanism is supported by the following evidence.

(1) ^1H NMR spectrum of **1** in DMF shows two sets of hydridic protons at τ 18.2 (triplets of a doublet) and τ 16.3 (quartet) indicating the *cis* dihydride configuration[9] as shown below.



^{31}P NMR spectrum of **1** also supports the above configuration in which a triphenylphosphine ligand is completely dissociated in solution. The olefin will most probably displace the solvent molecule and coordinate to ruthenium occupying the site where the solvent was previously coordinated.

(2) The formation of such an intermediate monomer-coordinated hydride complex at 0 °C[10] was confirmed in the case of methacrylonitrile, although in the case of acrylonitrile the direct evidence for the formation of the acrylonitrile-coordinated complex could not be obtained because of the high polymerization activity of **1** toward acrylonitrile. Under the conditions that the polymerization of methacrylonitrile with **1** does not take place, the methacrylonitrile-coordinated complex was separated as a yellow solid which showed a ν(Ru–H) band at 1900 cm^{-1} and ν(C≡N) band at 2182 cm^{-1} which is shifted to lower frequency from the frequency of the uncoordinated methacrylonitrile by 40 cm^{-1}, the fact indicating the coordination of methacrylonitrile to ruthenium probably through the double bond.[11]

Copolymerization of Vinyl Monomers with 1. For obtaining further information concerning the mechanism of vinyl polymerization by **1**, copolymerizations of some sets of monomer combinations have been examined. Copolymerization of acrylonitrile with methyl methacrylate in a 1 : 1 monomer ratio by **1** gave only an acrylonitrile homopolymer and the copolymerization of methacrylonitrile with methyl acrylate in the same ratio gave a methacrylonitrile homopolymer, whereas acrylonitrile and methyl acrylate gave a copolymer.

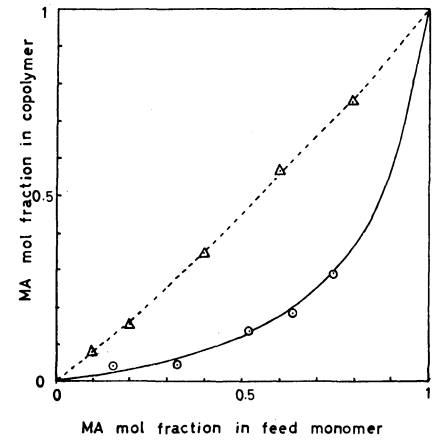


Fig. 6. Copolymerization of acrylonitrile with methyl acrylate by $RuH_2(PPh_3)_4$ catalyst. $[RuH_2(PPh_3)_4]$, 2.07 mol/l.
Solvent: toluene; solvent/monomer=1; temperature: 25 °C
—— experimental points; ------ radical polymerization.[17]

Figure 6 shows the copolymerization curve of acrylonitrile with methyl acrylate by **1**. The copolymerization curve is obviously different from that by a free-radical initiator. The monomer reactivity ratios estimated by a Fineman-Ross method[12] were as follows:

$$r_{AN} = 4.8 \pm 0.1, \quad r_{MA} = 0.1 \pm 0.05$$

Our previous study[3] on the copolymerization of vinyl monomers with an alkyl iron complex coordinated with dipyridyl ligands has shown the tendency that an electronegative monomer can be introduced in preference to the less-electronegative monomer into the copolymer, in such a way that acrylonitrile had a higher monomer reactivity ratio than methacrylonitrile and methyl acrylate higher than methacrylonitrile. The present result with **1** is somewhat different from the result with the alkyliron complex in that **1** showed a higher polymerization activity toward methacrylonitrile rather than acrylonitrile.

Termination. In order to obtain further insight into the mechanism of propagation and termination the dependences of the molecular weights of polymers on various factors were examined. As mentioned earlier, the molecular weight of the polymer was found

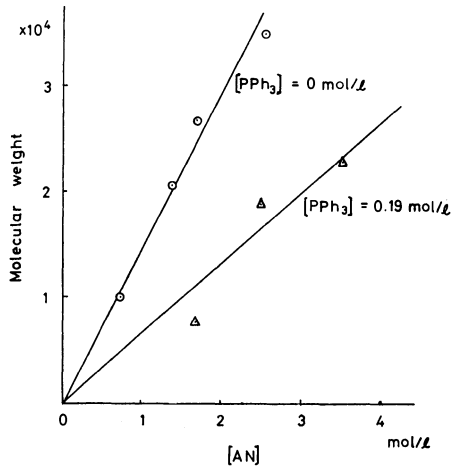

Fig. 7. The effect of the concentration of acrylonitrile on the molecular weight of polyacrylonitrile at 25 °C in DMF.

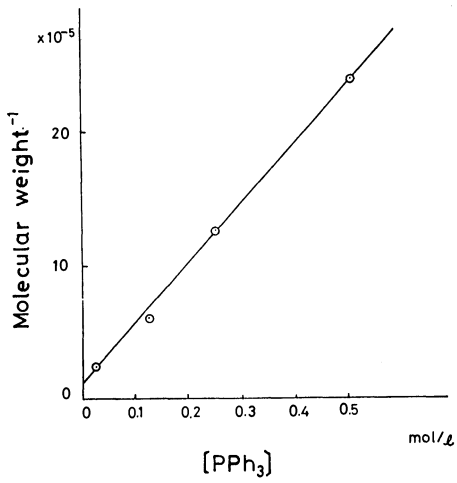

Fig. 8. The effect of the concentration of the added triphenylphosphine on the molecular weight of polyacrylonitrile at 25 °C in benzene.

to be independent of the polymerization time, the conversion, and the initiator concentration. Figure 7 demonstrates that the molecular weight of the polymer is proportional to the monomer concentration. Examination of the effect of the added triphenylphosphine concentration on the polymer weight revealed the relationship as shown in Fig. 8. The result indicates that triphenylphosphine competes with the monomer in the propagation and the coordination of triphenylphosphine to the complex having growing polymer chain leads to termination.

As we have noted in our previous paper concerning the vinyl polymerization with the alkyliron complex, the solvent may also compete with the monomer in the propagation step leading to the termination of the growing polymer chain. Thus the degree of polymerization ($\overline{DP}$) may be expressed by the following equations:

$$\overline{DP} = \frac{R_p}{R_t} = \frac{k_p[\text{Cat*}][\text{M}]}{k_t[\text{Cat*}][\text{PPh}_3] + k_t'[\text{Cat*}][\text{solv}]} \quad (11)$$

$$= \frac{k_p[\text{solv}]}{k_t[\text{PPh}_3] + k_t'[\text{solv}]} \quad (12)$$

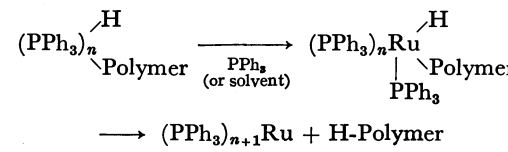
$$\frac{1}{\overline{DP}} = \frac{1}{[\text{M}]}\left\{\frac{k_t}{k_p}[\text{PPh}_3] + \frac{k_t'}{k_p}[\text{solv}]\right\} \quad (13)$$

where [M], [PPh_3], [solv], and [Cat*] denote the concentrations of the monomer, added triphenylphosphine, the solvent and propagating polymer chain attached to the catalyst, and k_p, k_t, and k_t' the rate constants for propagation, terminations caused by coordination of triphenylphosphine and the solvents, respectively. The results demonstrated in Figs. 7 and 8 are in agreement with Eqs. (12) and (13).

The fact that the straight lines in Fig. 7 pass through the origin indicates that the chain transfer reaction with monomer can be neglected.

From the slopes [PPh_3]=0 and 0.19 in Fig. 7 and utilizing Eq. (12) an approximate value of k_t/k_t' was computed as 90, indicating that the termination process involving the participation of triphenylphosphine is the predominant reaction and the contribution of the solvent to the termination is small.

Two possibilities are considered as the mechanism of termination. One is the β-hydrogen elemination from the growing polymer chain by ruthenium regenerating the ruthenium dihydride and the other is the hydrogen migration from the ruthenium hydride to the growing polymer chain as shown below:



The β-hydrogen elimination mechanism does not appear reasonable, because the ruthenium hydride thus reproduced should be still active for initiating the polymerization. On the other hand the hydrogen migration mechanism as shown above seems more probable since the zero-valent ruthenium complex thus produced may not be active any more. The hydrogen migration mechanism is further supported by the result that $RuH_2(PPh_3)_4$ reacts with ethylene and styrene giving Ru(ethylene)(PPh_3)$_3$ and Ru(styrene)(PPh_3)$_3$ accompanied by the formation of 1 mol each of ethane and ethylbenzene per complex **1**.[8] Ethane and ethylbenzene were probably formed by the insertion of ethylene and styrene into a Ru–H bond giving hydrido-alkyl ruthenium complexes, resembling the propagating species, from which the alkanes are reductively eliminated by the migration of hydrogen from the remaining Ru-H to the alkyl group.

Polymerization of Vinyl Monomers by Dihydrido-ruthenium-(II) Complexes Having Various Phosphine Ligands. Some dihydrido-ruthenium complexes other than triphenylphosphine initiate the polymerization of a few vinyl monomers. Table 2 shows the polymerization activities of the dihydrido-tuthenium complexes of the type RuH_2L_4 where L=PPh_2H,[13] PPh_2Me,[9] $PPhMe_2$.[14] The results summarized in Tables 1 and 2 indicate that the triphenylphosphine-coordinated complex is most reactive toward the vinyl compounds examined and initiate the vinyl polymerization or forms π-complexes with a wide range of vinyl compounds whereas the other phosphine-coordinated complexes

reacted only with acrylonitrile and methacrylonitrile.

Two factors may be involved in determining the reactivity of the ruthenium complex toward the olefins. One is the dissociation of the phosphine ligand from the coordinatively saturated complex RuH_2L_4 for accomodating the incoming olefin to coordinate, and the other is the intrinsic reactivity of the coordinatively unsaturated RuH_2L_3 toward olefins. The fact that the triphenylphosphine-coordinated complex was most reactive may be largely due to the reason that the bulky triphenylphosphine ligand is extensively dissociated in solution as demonstrated by the NMR spectrum of **1** in DMF whereas the other phosphine-coordinated complexes are dissociated only to a minor extent as revealed by their NMR spectra.[9,13,14] The polymerization of acrylonitrile by phenyldimethylphosphine-coordinated complex might be caused, at least partially, by the free ligand itself which may be formed by dissociation from RuH_2L_4. The free tertiary phosphines are known to initiate the vinyl polymerization[15] and the polymerization activity of the phosphine ligand itself decreased in the order of $PPhMe_2 > PPh_2Me \sim PPh_2H > PPh_3$; free phenyldimethylphosphine initiated a quite rapid polymerization of acrylonitrile whereas the polymerization by free triphenylphosphine was quite sluggish and can be neglected in comparison with the rapid polymerization by the triphenylphosphine-coordinated complex. Methacrylonitrile was not polymerized by none of the free phosphines and the polymerization activities of $RuH_2(PPh_3)_4$ and $RuH_2(PPh_2H)_4$ must be associated with the intrinsic reactivities of the complexes. The most important factors in determining the intrinsic reactivity of the complex concerned may be the interaction of the complex with the olefin and the insertion of the olefin into the metal-hydrogen bond. Electronic as well as steric factors must be operative there and it is often difficult to predict the reactivity of the particular complex on the basis of our present knowledge. That the diphenylphosphine-coordinated complex was very reactive as the initiator for methacrylonitrile, moderately reactive for more electronegative acrylonitrile and inactive for methyl methacrylate and styrene suggests that an optimum activity may be developed by appropriate choice of the ligand which modifies the electron density of the dihydrido-ruthenium complex to interact with the particular olefin.

Experimental

Preparation of Materials. Dihydridotetrakis(triphenylphosphine)ruthenium(II) $RuH_2(PPh_3)_4$ was prepared as previously described.[6] It was found later that by the reflux of the system containing $RuCl_3$, PPh_3, and $AlEt_3$ in THF, the yield of the hydrido complex was increased. The addition of excess triphenylphosphine to the toluene solution of **1** caused easier recrystallization because of the prevention of the dissociation of triphenylphosphine. Dihydrido complexes containing various phosphine ligands were prepared by the method reported previously.[9,13,14] Monomers and solvents were purified by usual method and kept under nitrogen at −20 °C before use.

Chemical Reactions. The reactions were usually carried out in an ampoule in which **1**, an olefin and a solvent were transferred in a nitrogen atmosphere or by trap-to-trap distillation in a vacuum. After the set time of polymerization, the ampoule was opened and the content was poured into acidic methanol. The precipitate was filtered, washed with methanol and dried in a vacuum. Yields and molecular weights are listed in Table 1. In some cases complex formations were observed which will be reported separately.

Copolymerization by Complex 1. Copolymerization of vinyl monomers by **1** was performed in a sealed amoule in which **1** (2.07 mol/l), toluene and olefin were transferred under nitrogen or by a trap to trap distillation in a vacuum. The ampoule was kept in a thermostatted bath at 25 °C for a few hours. The content was poured into a large excess of methanol. The copolymer formed was filtered and washed with methanol a few times and dried in a vacuum. Composition of each monomer component in the copolymer was analyzed by elemental analysis performed by Mr. T. Saito of our laboratory with a Yanagimoto CHN Autocorder Type MT-2. The results are as follows.

MA mole fraction in monomers	N% in copolymer	yield	MA mole fraction in copolymer
0.745	16.00	0.2%	0.288
0.631	19.54	0.3	0.186
0.523	20.96	0.4	0.137
0.328	23.85	1.0	0.042
0.155	24.88	2.0	0.034

Dilatometry. Kinetic study of polymerization was carried out by dilatometry under nitrogen. Acrylonitrile was added into a DMF solution containing the catalystat. a constant temperature under vigorous stirring of the solution The solution was immediately transferred into a dilatometer in a thermostatted bath under nitrogen and the decrease of the volume of the solution was followed.

Molecular Weight. The molecular weight of the polymer was determined by a viscometry using an Ubbelode viscometer. Molecular weight-viscosity equation of $[\eta] = 39.2 \times 10^{-5} \times MW^{0.75}$ (25 °C in DMF) was employed for determining the molecular weight of polyacrylonitrile.[16]

Estimation of Decomposition Rate Constants k_s of 1 in the Presence of Acrylonitrile. Decomposition rate of **1** was followed by observing the decrease of absorbance in the visible spectra at a constant temperature. The pseudo-first-order rate constant k_s was estimated from the slope of $\log(A_\infty - A_t)$ *vs* time, where A_∞ and A_t represent the absorbances at infinite time and at time t.

The authors thank Dr. T. Yamamoto for his helpful discussions and for the support of the work by Ministry of Education.

Selenium Catalyzed Synthesis of of Carbonates. The Reaction of Alkoxide with Carbon Monoxide and Oxygen in the Presence of Selenium

Kiyoshi KONDO, Noboru SONODA,* and Hiroshi SAKURAI

The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565

**Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565*

(Received July 22, 1974)

A novel selenium catalyzed synthetic reaction of carbonates was investigated. The reaction of alkoxides with carbon monoxide in the presence of stoichiometric amount of selenium gave carbonates in high yields under atmospheric pressure at 20 °C in THF. When the resultant reaction solution was made to react continuously with the mixture gas of carbon monoxide and oxygen, catalytic formation of carbonates was achieved. Isolation of Se-alkyl monoselenocarbonate from the reaction mixture by addition of alkyl halide indicated that carboalkoxy sodium selenide might be formed as an intermediate in the course of present reaction. In connection with these reactions, the reaction of carbonyl selenide with sodium alkoxide in alcohol was also studied.

There are many reports on the synthesis of carbonates,[1] and a very common synthesis is one by the reaction of phosgene with alcohol. Synthesis of carbonates by the reaction of cupric alkoxide and carbon monoxide was reported[2,3] by Saegusa *et al.*, and it was described[4] that carbonylation of ethanol by palladium chloride in the presence of sodium carbonate proceeded under mild conditions to give diethyl carbonate. Recently we reported[5–7] a novel synthesis of urea derivatives by the reaction of amine with carbon monoxide in the presence of selenium under mild conditions with simple operations. From further investigations on the reaction between carbon monoxide and selenium in the presence of a base, it has been noticed[8] that stoichiometric amount of carbonates based on used selenium was found to be formed by the reaction of carbon monoxide with aliphatic alkoxides under mild conditions.

Now we wish to report full results of the reaction of alkoxides with mixture gas of carbon monoxide and oxygen in the presence of selenium, which provides a new, convenient method for catalytic synthesis of carbonates [reaction (1)].

$$\mathrm{RONa} + \mathrm{CO} + \frac{1}{2}\mathrm{O_2} \xrightarrow[\substack{20^\circ\mathrm{C},\ 1\ \mathrm{atm.}\\ \mathrm{ROH,\ THF}}]{\mathrm{Se}} (\mathrm{RO})_2\mathrm{CO} + \mathrm{NaOH} \qquad (1)$$

Thus various carbonates were prepared under mild conditions with simple operations. From the investigation of the reaction path, a key intermediate was successfully trapped in the form of Se-alkyl monoselenocarbonate by alkylation with alkyl halide, and sodium hydrogen selenide was found to play an important role for the circulation of selenium. It was also confirmed that reaction of carbonyl selenide, prepared from direct reaction between carbon monoxide and selenium at elevated temperature, with sodium alkoxides was closely resembled to the present synthetic reaction.

Results and Discussion

It was confirmed that sodium alkoxide reacted easily with metallic selenium and carbon monoxide to form dialkyl carbonate [reaction (2)]. For instance, sodium ethylate and ethyl alcohol were dissolved in tetrahydrofuran (THF), to which was added metallic selenium at 20 °C, and carbon monoxide was blown into the solution for 2 hr with vigorous stirring. At this stage of the reaction, quantitative formation of diethyl carbonate based on selenium used in the reaction mixture was confirmed from glpc analyses. It is notable that the procedure is very simple. The results are shown in Table 1.

$$\mathrm{Se} + \mathrm{CO} + \mathrm{NaOR} \xrightarrow[20^\circ\mathrm{C},\ 1\ \mathrm{atm.}]{\mathrm{ROH,\ THF}} (\mathrm{RO})_2\mathrm{CO} + \mathrm{NaSeH\ and/or\ Na_2Se} \qquad (2)$$

Table 1. Stoichiometric synthesis[a] of carbonates

Run No.	RONa R	ROH mol	$(RO)_2CO$ Yield %[b]

10	*t*-Bu	0.10	14
11	Ph	0.10	—[d]

a) Metallic selenium (0.001 g atom), sodium alkoxide (0.04 mol), and alcohol were made to react with carbon monoxide (60 ml/min) at 20 °C in 50 ml THF for 2 hr with vigorous stirring. b) Yield % based on selenium used. c) Amorphous selenium was used. d) No reaction took place.

The yield of carbonates from primary alcohols was higher than that from secondary or tertiary alcohols, and in the case of phenol no reaction took place. These results clearly showed the excellent and novel oxidizing ability of selenium[9] in the presence of a strong base. Then, catalytic reaction [reaction (1)] could be successfully performed by passing mixture gas of carbon monoxide and oxygen continuously into the resultant reaction mixture given by the reaction (2). The

Table 2. Catalytic synthesis[a] of carbonates

Run No.	RONa R	Catalytic reaction time[b] (hr)	Oxidizing efficiency %[c]
1	Me	0	99
2	Me	1	225
3	Et	0	99
4	Et	1	240

8	*t*-Bu	2	113
9	$-CH_2CH_2OH$	2	270[d]
10	$-CH_2CHMeOH$[e]	2	220[d]

a) RONa (0.05 mol), ROH (0.05 mol), and metallic selenium (0.001 g atom) were made to react with carbon monoxide for 30 min, and then with mixture gas of carbon monoxide and oxygen (60 ml/min and 1 mmol/hr respectively) in 50 ml THF at 20 °C for catalytic reaction time. b) The time (hr) for which mixture gas of carbon monoxide and oxygen was bubbled, and the results at catalytic reaction time 0 hr corresponded to those in Table 1. c) See to Ref. 10. d) DMF (50 ml) was used for the solvent in the case of glycols. e) $-CHMe-CH_2OH$ may be contained.

results obtained by the present catalytic reaction were shown in Table 2. The circulation of selenium in the reaction system was shown in terms of oxidizing efficiency[10] of selenium, and the efficiency decreased as catalytic reaction time prolonged. This tendency might be explained by the facts that sodium hydroxide formed in the reaction system interferred the formation of carbonate and prolonged contact of carbonate with sodium hydroxide in alcohol decreased the amount of formed carbonate. Cyclic aliphatic carbonates such as ethylene carbonate, propylene carbonate were similarly synthesized when dimethylformamide[11] (DMF) was used.

The circulation of selenium in the catalytic system may be explained by the following Eqs. (3) and (4), which exhibit the regeneration[12] of selenium by the facile oxidation of hydrogen selenide with oxygen.

$$Na_2Se \underset{RONa}{\overset{ROH}{\rightleftharpoons}} NaSeH \underset{RONa}{\overset{ROH}{\rightleftharpoons}} H_2Se \quad (3)$$

$$H_2Se + \frac{1}{2}O_2 \longrightarrow H_2O + Se \quad (4)$$

In order to examine if the sodium hydrogen selenide played a significant role in the catalytic reaction, the reaction of alcoholic sodium alkoxide with the mixture gas of carbon monoxide and oxygen in the presence of sodium hydrogen selenide[13] in THF was carried out and was found to proceed successfully, clarifying that the catalytic reaction (1) might be rewritten as following equation.

$$RONa + CO + \frac{1}{2}O_2 \xrightarrow[ROH,\ THF]{NaSeH} (RO)_2CO + NaOH \quad (5)$$

The catalytic reaction was found to stop if oxygen-rich mixture gas was treated, and the ratio of carbon monoxide to oxygen was found to be such that sodium hydrogen selenide could be present in the catalytic reaction system.

In order to attain the knowledge of the reaction path, we have tried to trap an intermediate by addition of excess amount of alkyl halide into the reaction mixture. Gas-Mass spectroscopic analyses of the reaction mixture of sodium ethylate, carbon monoxide, selenium and *n*-butyl iodide at 0 °C showed the formation of di-*n*-butyl selenide and di-*n*-butyl diselenide together with the trace amount of formation of Se-*n*-butyl ethyl monoselenocarbonate, which might be formed by the reaction (6). The authentic sample of monoselenocarbonate[14] was prepared by the following unambiguous route [reaction (7)].

$$Se + CO + NaOEt \longrightarrow Na^+[EtO\text{-}\overset{\overset{O}{\|}}{C}\text{-}Se]^-$$

$$\xrightarrow[-NaI]{+n\text{-BuI}} EtO\text{-}\overset{\overset{O}{\|}}{C}\text{-}Se\text{-}Bu\text{-}n \quad (6)$$

$$n\text{-BuLi} + Se \xrightarrow[0°C]{THF} n\text{-BuSeLi} \xrightarrow[0°C,\ -LiCl]{+Cl\text{-}CO\text{-}OEt} n\text{-BuSe-}\overset{\overset{O}{\|}}{C}\text{-OEt} \quad (7)$$

ca. 15%

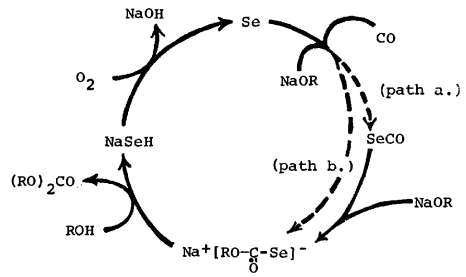
The retention time of the gas chromatography and the fragmentation pattern in the mass spectra of the trapped selenocarbonate were identical with those of the authentic sample. Very fast alcoholysis of the intermediate, ethoxycarbonyl sodium selenide[15] would yield the carbonate and sodium hydrogen selenide, and the driving force of the alcoholysis reaction would be attributed to the precipitation of the sodium hydrogen selenide in THF.

It was suggested[5] that carbon monoxide was readily oxidized with selenium in the presence of a strong base under mild conditions to give carbonyl selenide (SeCO).[17] Then we performed the reaction of isolated carbonyl selenide prepared by the reaction[18] of carbon monoxide with selenium at elevated temperature (550—600 °C) trapped at −120 °C, into which was added an alcoholic solution of sodium alkoxide at −80 °C. Gas chromatographic analyses revealed the quantitative formation of carbonates (dimethyl, diethyl, and di-*n*-butyl carbonate) [reaction (8)].

$$SeCO + RONa \xrightarrow[-80°C]{ROH} (RO)_2CO + NaSeH \text{ and/or } Na_2Se \quad (8)$$

The reaction of carbonyl selenide with sodium alkoxide was so fast and almost quantitative even at low temperature that it might be impossible to detect the formation of free SeCO, even if it were generated, from the reaction mixture under any reaction condition at room temperature.

These experimental findings suggested that present selenium catalyzed synthesis of carbonates might well be described by the reaction Scheme 1, in which the intervention of carbonyl selenide as an intermediate in the catalytic cycle would offer a reasonable interpretation (path a), though there should be another path, in which intermediacy of carbonyl selenide might not necessarily be required (path b).



Scheme 1. Reaction path for the formation of carbonates.

In every synthesis of carbonates, however, small amounts of formates[19] were detected as the by-products, which have long been known to be produced by a base catalyzed reaction of carbon monoxide.[20]

Experimental

Materials. Alcohols (methyl, ethyl, *n*-propyl, *i*-propyl, *n*-butyl, *t*-butyl, cyclohexyl, benzyl alcohol, ethylene glycol, propylene glycol, and phenol) were all purchased from commercial sources, and purification was carried out by distillation over corresponding sodium alkoxide under nitrogen and each purity was qualified by glpc. Metallic selenium (99.99%) of Nakarai Chem. Co. and amorphous selenium prepared by reduction of selenium dioxide with sulfur dioxide were used. Carbon monoxide (99.999%) of Seitetsu Chem. Co. and oxygen (99.999%) of Osaka Sanso Co. were applied. The chemical grade of metallic sodium, sodium hydride, and sodium borohydride were used for the sodium-metallation of alcohols or preparation of sodium hydrogen selenide. The chemical grade of *n*-butyl lithium (Merck Co.), *n*-butyl iodide, ethyl chloroformate were also commercially available. Tetrahydrofuran (THF) stored with KOH were dried over sodium wire and lithium aluminum hydride, and freshly distilled under nitrogen just before use. Dimethylformamide (DMF) was distilled under vacuum just before use. Authentic samples of the carbonates and formates were purchased or synthesized by the use of phosgene or formic acid with sodium alkoxide in alcohol.

Apparatus. The product analyses were generally carried out by gas chromatography with use of PEG-20M and SE-30 in 1 or 3 meter stainless steel column. They were performed by means of Shimadzu Model GC-3BF with ion flame detector, Varian Aerograph Model 90-P, Hitachi Model K-53 with thermal conductivity detector for separation, and Hitachi Model O63 with ion collector detector for Gas-Mass. IR spectra (Shimadzu IR-27C, and Hitachi EPI-S2) and NMR spectra (Hitachi Perkin-Elmer R-20) were also used for the analyses. Mass spectra were obtained on a Hitachi Perkin-Elmer RMU-60 or on a Hitachi Model RMS-4 Mass Spectrometer for Gas-Mass.

Procedures. Reactions were generally carried out in a three necked 100 ml flask fitted with a thermometer, a cooler at whose top the gas outlet was equipped, and a gas inlet tube. Gas flow meter and nujol-sealed gas bubbler were attached between the gas inlet tube and gas supply. Gas outlet tube was also connected to the nujol-sealed gas bubbler. In catalytic synthesis of carbonates oxygen was supplied by use of 20 ml syringe. A magnetic stirrer was used for effective vigorous stirring of the reaction mixture.

The Stoichiometric Synthesis of Carbonates. A preparative example of the stoichiometric synthesis of diethyl carbonate was as follows; 0.05 mol of sodium ethylate and 0.05 mol of ethyl alcohol were dissolved in 50 ml THF to which was added 0.01 g atom sample of metallic selenium at 20 °C, and carbon monoxide was blown into the resultant solution at a rate of 60 ml/min for 2 hr with vigorous stirring. At this stage of the reaction glpc analyses revealed the quantitative formation of diethyl carbonate based on selenium in the reaction mixture. Thereafter oxygen was added into the solution at a rate of 10 ml/min without the addition of carbon monoxide. Filtration followed by distillation gave diethyl carbonate (1.086 g, 92% based on selenium used). In order to see the relative reactivity of alcohols, we showed the results of controlled experiments with the use of mole ratio of reactants as shown in Table 1, taking identical procedures as described in this section.

The Catalytic Synthesis of Carbonates. As already described in the section of Results and Discussion, the procedure of the catalytic synthesis only differed from the stoichiometric synthesis in the way that the catalytic reaction was successfully performed by passing continuously the mixture gas of carbon monoxide and oxygen into the resultant solution afforded by the stoichiometric reaction. The ratio of the reaction mixture was as shown in Table 2. In this experimental section was shown the typical example of catalytic synthesis of diethyl carbonate by the reaction of sodium ethylate (0.05 mol) and ethyl alcohol (0.05 mol) with carbon monoxide (60 ml/min) in the presence of metallic selenium (0.001 g atom) dissolved in 50 ml THF for 30 min with vigorous stirring. Catalytic reaction was then performed by adding the mixture gas of carbon monoxide and oxygen for the time given in Table 2. The flow rate of carbon monoxide was 60 ml/min and oxygen was added 1 mmol/hr. At the end of the catalytic reaction, the feed of carbon monoxide was stopped, and only oxygen gas was added (10 ml/min) for 30 min. Isolation of carbonate was identical with example in the case of stoichiometric synthesis.

The Catalytic Synthesis of Diethyl Carbonate in the Presence of Sodium Hydrogen Selenide. Sodium hydrogen selenide (0.005 mol) was prepared according to the method,[13] to which were added THF (50 ml) solution of sodium ethylate (0.05 mol) and ethanol (0.05 mol), and then the mixture gas of carbon monoxide (60 ml/min) and oxygen (0.005 mmol/hr) for 2 hr. About 0.012 mol of diethyl carbonate was found to be formed from glpc.

An Attempted Experiment for the Trapping of the Intermediate. Sodium ethylate (0.05 mol) and ethyl alcohol (0.05 mol) were dissolved in 50 ml THF to which was added 0.01 g atom sample of metallic selenium at 0 °C, and carbon monoxide was added at a rate of 60 ml/min for 30 min with vigorous stirring. Then cold (0 °C) THF solution (25 ml) of *n*-butyl iodide (0.1 mol) was added dropwise in 20 min; during the addition, a gentle flow of carbon monoxide (10 ml/min) was continued. The product analyses were performed by use of Gas-Mass Spectrometer (Hitachi Model O63 Gas Chromatograph and Hitachi Model RMS-4 Mass Spectrometer) with 3 meter PEG-20M column. The chromatogram with its retention time between those of di-*n*-butyl selenide and di-*n*-butyl diselenide was attributed to Se-*n*-butyl ethyl selenocarbonate (*ca.* 0.5%) from the mass spectrum.

The Synthesis of Authentic Sample of Se-n-Butyl Ethyl Mono selenocarbonate. Metallic selenium (0.05 g atom) was stirred vigorously under nitrogen at 0 °C in 50 ml THF well dried over $LiAlH_4$ and freshly distilled under nitrogen, to which was added 0.052 mol of *n*-butyl lithium in hexane dropwise. THF (25 ml) solution of ethyl chloroformate (0.06 mol) at 0 °C was added dropwise and the resultant solution was kept stirring for 15 hr at 0 °C. Filtration of the lithium chloride followed by distillation under vacuum gave Se-*n*-butyl ethyl monoselenocarbonate (*n*-Bu–Se–CO–

OEt) (1.58 g, 15%) with very unpleasant odor: bp 85 °C/5 mmHg IR (direct) 1717 cm^{-1} (ν_{CO}). Mass (70 eV) *m/e* 210 (M^+), 165 (*n*-Bu-Se-CO^+), 137 (*n*-Bu-Se^+), 108 ($SeCO^+$), 73 (EtO-CO^+). Found: C, 40.04; H, 6.83%. Calcd for $C_7H_{14}O_2Se$: C, 40.20; H, 6.75%.

The Reaction of Carbonyl Selenide with Sodium Alkoxide. The preparation of carbonyl selenide was carried out as described in the literature.[18] For the trapping of generated carbonyl selenide gas, we used EtBr-cold bath (−120 °C) with liq. N_2. Carbonyl selenide was then treated with excess sodium alkoxide in alcohol at −80 °C. Addition of oxygen at room temperature to the reaction mixture followed by filtration was found to contain stoichiometric amount of corresponding carbonate from glpc.

New Furanosesquiterpenes from *Ligularia Fischeri* Turcz.[1] 1β, 10β-Epoxyfuranoeremophilan-6β-ol and Its Derivative

Toshichika Sato, Yoshihiko Moriyama, Hajime Nagano,
Yoshiaki Tanahashi, and Takeyoshi Takahashi
Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113
(Received September 17, 1974)

Two new furanosesquiterpenes, isolated from *Ligularia Fischeri* Turcz. (collected at Shiramine), were shown to be 1β,10β-epoxyfuranoeremophilan-6β-ol (**1**) and 1β,10β-epoxyfuranoeremophilan-6β-yl 2-hydroxymethylprop-2-enoate (**2**).

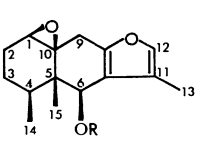
It has been reported by Ishii *et al.* that *Ligularia Fischeri* Turcz. (collected at Kurama) contained several sesquiterpenes, namely, ligularol,[2] ligularone,[2] furanoeremophilane,[3] eremoligenol,[3] 6β-hydroxyeremophilenolide,[3] liguloxide,[4] liguloxidol,[4] and liguloxidol acetate.[4] During chemical investigation on the genus *Ligularia* (Compositae) and related plants,[5] two new furanosesquiterpenes were isolated from *Ligularia Fischeri* Turcz. (collected at Shiramine).[6] We wish to describe the structure determination leading to 1β, 10β-epoxyfuranoeremophilan-6β-ol (**1**) and 1β,10β-epoxyfuranoeremophilan-6β-yl 2-hydroxymethylprop-2-enoate (**2**) for these sesquiterpenes.

An ether extract of the roots of the plant was subjected to separation by column and preparative thin layer chromatography to give **1** and **2**. Compound **1**, a colorless oil, was positive to the Ehrlich test. A molecular ion peak at *m/e* 248 ($C_{15}H_{20}O_3$) was observed in the mass spectrum. The IR, UV, and PMR spectra showed the presence of a secondary methyl, a tertiary methyl, a β-methyl substituted furan moiety with an α-proton,[5] a proton on an oxygen-bearing carbon, an allylic methylene linked to a carbon with no proton, an allylic proton on a hydroxyl-bearing carbon, and a hydroxyl group (*cf.* Table and Experimental).

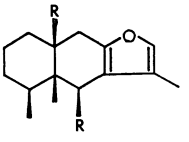
These spectral data observed for **1** are closely related to those of furanoeremophilane-6β,10β-diol (**3**),[7,8] recently isolated from *L. japonica* Less. Treatment of **1** in tetrahydrofuran with lithium aluminium hydride under reflux yielded a diol, which was found to be identical with **3**. This showed the presence in **1** of a furanoeremophilane skeleton (**4**); a hydroxyl group of **1** must be placed on C-6β. The presence of homoallylic coupling (J=2 Hz) between a proton at C-6α and one of the allylic methylene protons (proton at C-9α) was shown by PMDR experiments. Therefore the proton at C-6α was inferred to be in a quasi-axial conformation.

A nature of two of the three oxygen atoms involved in **1** was thus characterized. The IR spectrum of **1** showed no carbonyl absorption. In the PMR spectrum of **1**, the signal due to a proton on an oxygen-bearing carbon (C-1) appeared at δ 3.06, while the corresponding signal was absent in the spectrum of **3**. The conversion of **1** to **3**, as well as the spectral data of **1** mentioned above, suggested that the third oxygen of **1** was involved as an epoxy ring and located on C-1β and C-10β as shown in **1**.

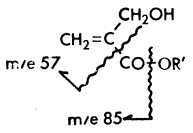
These observations received support from induced paramagnetic shift experiments[9] on **1** (Table), coupled with PMDR technique. The shift reagent, Eu(dpm)$_3$, associated more strongly with a hydroxyl rather than an ether group.[10] Signals due to protons at C-4 and C-15 shifted very largely. A small shift was observed for signals due to protons at C-14. Therefore, the epoxy ring was shown to be in a β-configuration; an 1α,10α-epoxide structure must cause a large shift for signals due to C-14 protons. As the absolute stereochemistry of the diol was determined as shown in **3**,[8] the structure including absolute configuration of **1** should be represented by 1β,10β-epoxyfuranoeremophilan-6β-ol (**1**). The results summarized in Table are best interpreted on the basis of a stereostructure (**1'**), in which rings A and B adopt a half-chair and a half-boat conformation respectively.



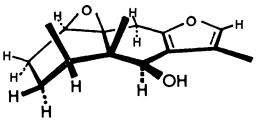
1 R = H
2 R = -CO-C(=CH$_2$)-CH$_2$OH
5 R = -CO-CH(-CH$_3$)-CH$_2$OH



3 R = OH
4 R = H



2'



1'

The IR and UV spectra of **2** showed the presence of α,β-unsaturated ester group (*cf.* Experimental). A molecular ion peak at *m/e* 332 ($C_{19}H_{24}O_5$) was observed in the mass spectrum of **2**. The ester (**2**) was reduced with lithium aluminium hydride in ether to give **1**. Treatment of **2** with methanolic potassium hydroxide at room temperature afforded **1**. An acyl residue present in **2** was therefore inferred to be [C_3H_5O]–CO–. In the PMR spectrum of **2**, there appeared signals due to protons of a terminal methylene and a hydroxymethyl group (*cf.* Experimental), other than those due to the structure moiety of **1**. Hydrogenation of **2** in ethanol in the presence of palladium-charcoal yielded a dihydro derivative (**5**). In the PMR spectrum of **5**, a methyl signal at δ 1.26 and a methine proton signal at δ 2.77 newly appeared, while

TABLE. PMR SPECTRAL DATA OF **1**

	1α-H	2α-H	2β-H	3α-H	3β-H	4α-H	6α-H	9α-H	9β-H	12-H	13-H	14-H	15-H	OH

signals due to a terminal methylene group were absent.

These observations led to a structure **2'** for the ester (**2**). This received support from an appearance of intense peaks at *m/e* 85 and *m/e* 57[11] due to fissions as shown in **2'**; these peaks were absent in the mass spectrum of **1**. The structure including absolute stereochemistry of the ester must be 1β,10β-epoxyfuranoeremophilan-6β-yl 2-hydroxymethylprop-2-enoate (**2**). The same acyl group as that of **2** has been described to be present as a part of the structures of vernodalin[11] and cynaropicrin.[12]

Experimental

IR spectra were measured using a Hitachi EPI-G2 spectrometer. UV spectra were determined on a Hitachi EPS-3 spectrometer. Measurements of optical rotation were carried out using a JASCO DIP-SL polarimeter. Mass spectra were taken on a Hitachi RMU-6-Tokugata mass spectrometer with a direct inlet system operating at 70 eV. PMR spectra were measured using a JEOL 4H-100 (100 MHz), a JEOL 3H-60 (60 MHz), a Hitachi R-20 (60 MHz) or a Hitachi R-24 (60 MHz) spectrometer. Chemical shifts were expressed in δ downfield from TMS as an internal standard, and coupling constants in Hz. Thin layer chromatography (tlc) was carried out on Kieselgel G nach Stahl, Kieselgel GF_{254} nach Stahl, and Kieselgel 60 PF_{254} (E. Merck, Darmstadt). For column chromatography Wakogel C-200 (Wako Pure Chem. Ind.) was used. All mps were determined on a hot block and reported uncorrected.

Isolation. Dried and sliced roots (226 g) of *Ligularia Fischeri* TURCZ. (collected at Shiramine, Ishikawa Prefecture) were extracted thrice with ether (total 4.5 l) at room temperature. Evaporation of the solvent gave a residue (7 g) which was chromatographed on a column of silica gel (100 g). The eluted fractions were examined by tlc (silica gel). After elution with light petroleum–ether (100: 1; 1.9 l) and then light petroleum–ether (50: 1; 750 ml), fractions eluted with light petroleum–ether (9: 1; 600 ml) were combined. Evaporation of the solvents gave a residue, which was purified by silica gel column chromatography and preparative tlc to afford 1β,10β-epoxyfuranoeremophilan-6β-ol (**1**; 50 mg), an oil, $[\alpha]_D$ −45° (*c* 0.11, EtOH); UV (EtOH) λ_{max} 215.5 nm (ε 7000); IR (liquid) 3450, 1645, and 1570 cm^{-1}; PMR data are described in Table; mass spectrum *m/e* 248 [relative intensity 7%, M^+ ($C_{15}H_{20}O_3$)] and 123 (100%).

Subsequent elution with light petroleum–ether (4: 1; 1 l) gave, on removal of the solvents, a residue, which was purified by silica gel column chromatography to yield 1β,10β-epoxyfuranoeremophilan-6β-yl 2-hydroxymethylprop-2-enoate (**2**; 2.6 g), an oil, $[\alpha]_D$ −9° (*c* 0.84, EtOH); UV (EtOH) λ_{max} 215 nm (ε 15000); IR (liquid) 3460, 1718, 1645, 1570, and 1160 cm^{-1}; PMR ($CDCl_3$) δ 1.05 (3H, d, J=7 Hz; protons at C-14), 1.22 (3H, s; protons at C-15), 1.79 (3H, d, J= 1.5 Hz; protons at C-13), 2.15 (1H, d, J=16 Hz; proton at C-9β), 3.10 (1H, br.s; proton at C-1α), 3.23 (1H, dd, J=16 and J=2 Hz; proton at C-9α), 6.46 (1H, m; proton at C-6α), 7.09 (1H, q, J=1.5 Hz; proton at C-12), 4.38 (2H, br.s; CH_2=C(–CH_2OH)–), 5.92 (1H, dt, J=1.6 and J=1.2 Hz; CH_2=C(–CH_2–)–), 6.32 (1H, dt, J=1.6 and J=1 Hz; CH_2=C(–CH_2–)–), and 2.92 (1H, br.s; OH; disappeared on addition of D_2O); mass spectrum *m/e* 332 (6%, M^+), *m/e* 109 (100%), *m/e* 85 (94%), and *m/e* 57 (50%). Found: C, 68.62; H, 7.43%. Calcd for $C_{19}H_{24}O_5$: C, 68.65; H, 7.28%. The ester (**2**) was unstable on exposure to the air, and could be stored under a nitrogen atmosphere in an icebox.

Reduction of 2 in Ether with Lithium Aluminium Hydride. To a solution of **2** (143 mg) in dry ether (10 ml) was added lithium aluminium hydride (50 mg) and the mixture was stirred at room temperature under a nitrogen atmosphere. After completion of the reaction, the excess reagent was decomposed with water. Extraction with ether and evaporation of the solvent gave a residue, which was chromatographed on a column of silica gel to afford an oil (15 mg). This oil was found to be identical with **1** in all respects.

Hydrolysis of 2. To a solution of potassium hydroxide (0.2 g) in methanol (4 ml) was added **2** (141 mg) and the mixture was stirred for 12 hr under a nitrogen atmosphere at room temperature. After removal of the solvent, the residue was extracted with ether to give **1** (86 mg).

Reduction of 1 in Tetrahydrofuran with Lithium Aluminium Hydride. Compound **1** (132 mg) in dry tetrahydrofuran (6 ml) was refluxed with lithium aluminium hydride (50 mg) for 2.5 hr under a nitrogen atmosphere. The mixture was treated as usual and the resulting residue was chromatographed on a column of silica gel (12 g) using light petroleum–ether (7: 1) as eluent to give a crystalline product (45 mg), mp 123 °C; $[\alpha]_D$ +37° (*c* 0.23, EtOH); Found: C, 72.23; H, 9.07%. Calcd for $C_{15}H_{22}O_3$: C, 71.97; H, 8.86%. This compound was found to be identical with an authentic sample of furanoeremophilane-6β,10β-diol (**3**)[7,8] in respects of mp, mixed mp, $[\alpha]_D$, IR, PMR, mass spectrum, and tlc.

Hydrogenation of 2 Over Palladium-charcoal. A solution of **2** (42 mg) in ethanol (10 ml) was hydrogenated in the presence of 10% palladium-charcoal (8 mg) at room temperature. Filtration of the catalyst and evaporation of the solvent gave a residue, which was purified by preparative tlc to afford 1β,10β-epoxyfuranoeremophilan-6β-yl 2-hydroxymethylpropanoate (**5**; 8 mg), an oil, IR (liquid) 3440, 1730, 1640, and 1565 cm^{-1}; PMR ($CDCl_3$) δ 1.09 (3H, d, J=7 Hz;

protons at C-14), 1.22 (3H, s; protons at C-15), 1.87 (3H, d, J=1.5 Hz; protons at C-13), 2.16 (1H, d, J=16 Hz; proton at C-9β), 3.10 (1H, br.s; proton at C-1α), 3.27 (1H, d, J=16 Hz; proton at C-9α), 6.43 (1H, m; proton at C-6α), 7.08 (1H, q, J=1.5 Hz; proton at C-12), 1.26 (3H, d, J=7 Hz; -CO-CH(-CH_3)-), 2.77 (1H, m; -CO-CH(-CH_2OH)-), 3.78 (2H, m; -CO-CH(-CH_2OH)), and 1.6 (1H, br.s; OH; disappeared on addition of D_2O); mass spectrum *m/e* 334 [1%, M^+ ($C_{19}H_{26}O_5$)], *m/e* 87 (20%, [CO-CH(CH_2OH)-CH_3]$^+$), *m/e* 59 (25%, [$HOCH_2$-CH-CH_3]$^+$), and *m/e* 55 (100%).

Reaction of 2-Halo-1-Olefin-1-Carboxylic Acid with Cu_2O and Isonitrile

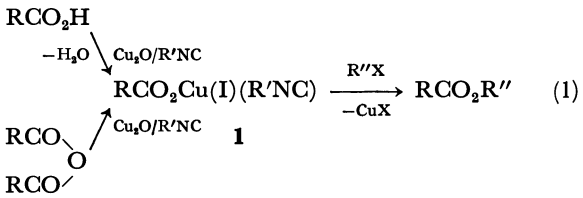
Yoshihiko Ito, Toshiro Konoike, Syotaro Fujii, Junichiro, Setsune, and Takeo Saegusa*

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received October 26, 1974)

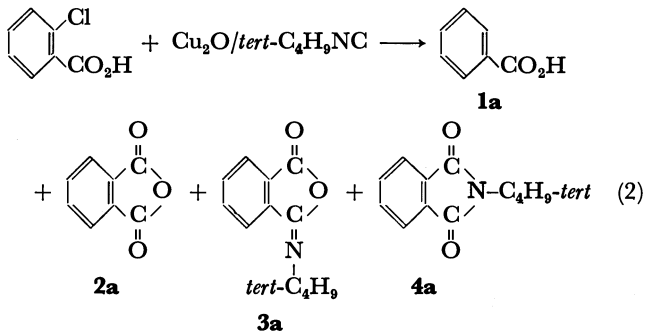
A reaction of 2-halo-1-olefin-1-carboxylic acids with isonitrile and Cu_2O is described. *o*-Chlorobenzoic acid is treated with *tert*-butyl isocyanide and Cu_2O at 80 °C to produce benzoic acid (**1a**), phthalic anhydride (**2a**), *N-tert*-butylphthalisoimide (**3a**) and *N-tert*-butylphthalimide (**4a**) in 5, 14, 18, and 32% yields, respectively. With 2-chloro-1-cyclohexene-1-carboxylic acid, a similar result is observed. However, the reaction of acyclic 2-chloro-1-olefin-1-carboxylic acid such as β-chlorocrotonic acid with isonitrile and Cu_2O does not give any products corresponding to **1**—**4**. These reactions are interestingly compared with the reaction of *o*-iodobenzoic acid and copper(I) acetylide producing 3-alkylidenephthalide. A reaction mechanism involving a transient intermediate of α,β-unsaturated β-lactone (**11**) is proposed for the present reaction.

In the preceeding papers, we have reported that carboxylic acid[1] and carboxylic acid anhydride[2] are readily esterified with alkyl halides in the presence of Cu_2O/Isonitrile complex. For this esterification, a reaction mechanism has been established in which Cu(I) carboxylate isonitrile complex (**1**) was initially generated by the reaction of Cu_2O/Isonitrile complex with carboxylic acid or with carboxylic acid anhydride, and then **1** reacted with alkyl halides to produce the corresponding carboxylic esters. Aromatic halides could not react with **1**.



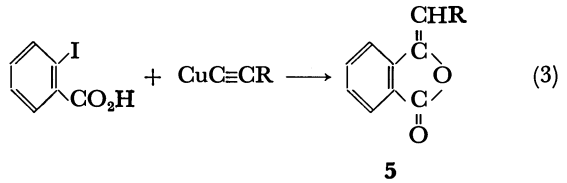
(1)

Now, we found that *o*-chlorobenzoic acid reacted with Cu_2O/*tert*-butyl isocyanide complex to give the following products, **1a**, **2a**, **3a**, and **4a**.



(2)

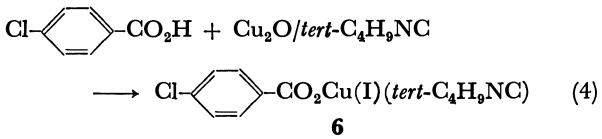
Similar reactions were observed with 2-chloro-1-cyclohexene-1-carboxylic acid and 2-chloro-1-cyclopentene-1-carboxylic acid. These reactions are interestingly compared with the following reaction reported by Castro *et al.*, *i.e.*, the reaction of *o*-iodobenzoic acid and copper(I) acetylide producing 3-alkylidenephthalide.[3]



(3)

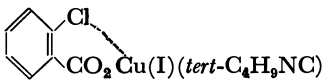
Results and Discussion

On heating a mixture of *p*-chlorobenzoic acid, Cu_2O and *tert*-butyl isocyanide in benzene at 80 °C for 12 hr under nitrogen, Cu(I) *p*-chlorobenzoate (*tert*-butyl isocyanide) complex (**6**) was only produced in an almost quantitative yield.[1]

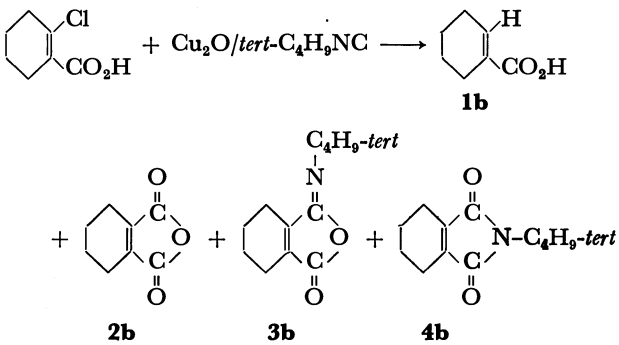


(4)

However, the reaction of *o*-chlorobenzoic acid with Cu_2O/*tert*-butyl isocyanide was quite different from that of *p*-chlorobenzoic acid. Four products **1a**, **2a**, **3a**, and **4a** were isolated by glpc in 5, 14, 18, and 32% yields, respectively. Products **2a** and **4a** appear to have been derived by the hydrolysis and rearrangement of **3a**, respectively. The rearrangement of isoimide **3** to imide **4** has been documented in a literature.[4] The remarkable difference of reactivity between the *ortho*- and the *para*-isomers strongly suggests that Cu(I) *o*-chlorobenzoate (*tert*-butyl isocyanide) complex (**7**) is

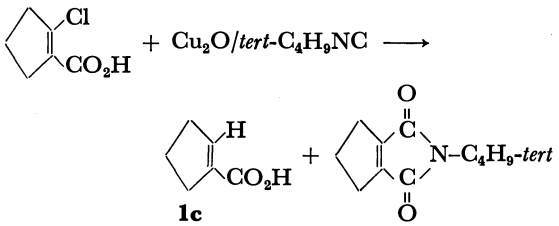


stabilized by chelation with chlorine in the *ortho* position to the carboxyl group. With 2-chloro-1-cyclohexene-1-carboxylic acid, which is considered to have an analogous geometrical circumstance, a similar result was observed. Four products, **1b**, **2b**, **3b**, and **4b** were isolated in 5, 13, 20, and 41% yields, respectively.



These reactions occurred slowly even at room tem-

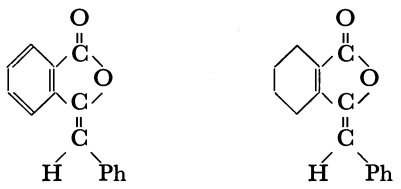
perature. For instance, in the reaction of 2-chloro-1-cyclohexene-1-carboxylic acid with Cu_2O/*tert*-butyl isocyanide at 20 °C for 70 hr, **1b**, **2b**, **3b**, and **4b** were produced in 1, 2, 32, and 5% yields, respectively. Also, the reaction of 2-chloro-1-cyclopentene-1-carboxylic acid with Cu_2O/*tert*-butyl isocyanide at 80 °C produced **1c** and **4c** but in low yields.



1c **4c**

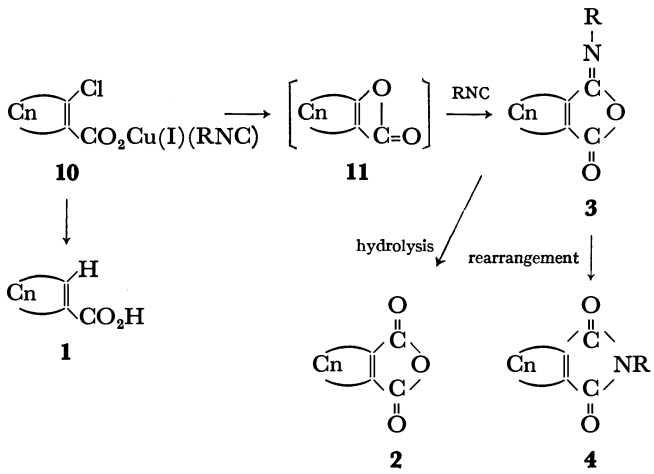
However, the reaction of acyclic 2-chloro-1-olefin-1-carboxylic acid such as β-chlorocrotonic acid with Cu_2O/isonitrile did not give any product corresponding to **1**—**4**.

The treatment of *o*-bromobenzoic acid with a mixture of *tert*-butyl isocyanide and phenylacetylene in the presence of Cu_2O in pyridine solvent afforded a major product of 3-benzylidenephthalide (**8**, 53%) as reported by Castro *et al.*,[3] and by-products of **1a**, **3a**, and **4a**.

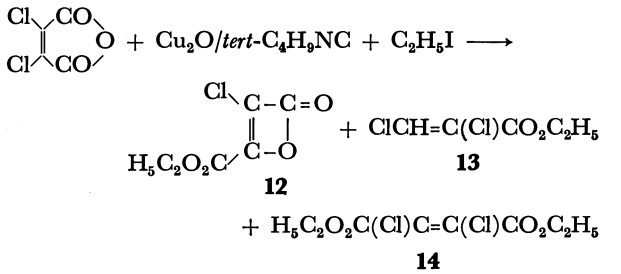


8 **9**

Similarly, 2-chloro-1-cyclohexene-1-carboxylic acid reacted with a mixture of *tert*-butyl isocyanide and phenylacetylene to produce **9** (70%) with **2b**, **3b**, and **4b**. The following scheme may possibly proposed for the reaction of Cu_2O/isonitrile with 2-halo-1-cyclic olefin-1-carboxylic acid, which involves a transient intermediate of **11**.

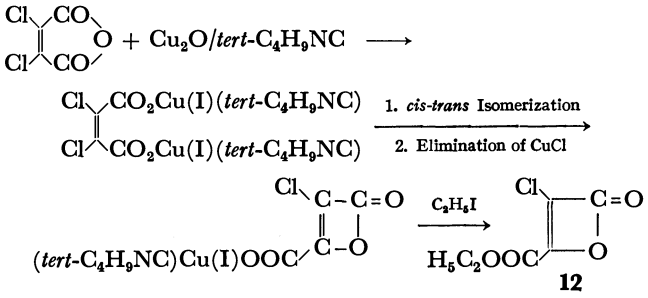


Intramolecular elimination of CuCl from **10** leading to lactone **11** is followed by the reaction with isonitrile. It is also conceibable that the elimination of CuCl from **10** and the reaction of **11** with isonitrile occur synchronously. The formation of **1** is understandable from the fact that aromatic halide is readily reduced by a system of Cu_2O–pyridine–acetic acid.[5] Concerning the intermediate of **11**, it may be pertinent to mention the following reaction. A reaction of dichloromaleic anhydride with Cu_2O/*tert*-butyl isocyanide in the presence of ethyl iodide afforded **12** in 42% yield along with **13** (5%) and **14** (10%).



12 **13** **14**

The structure of **12** was established by IR, elemental analysis and its chemical reaction (see Experimental Section). The formation of **12** will be reasonably explained by a scheme shown below.



Experimental

Reaction of o*-Chlorobenzoic Acid with* Cu_2O/tert*-Butyl Isocyanide.* A mixture of 3.4 g (20 mmol) of *o*-chlorobenzoic acid, 1.43 g (10 mmol) of Cu_2O and 1.66 g (20 mmol) of *tert*-butyl isocyanide in 10 ml of benzene was heated at 80 °C for 20 hr with stirring under nitrogen. The reaction mixture was treated with 10 ml of petroleum ether to remove Cu(I)Cl-(*tert*-butyl isocyanide) complex, and filtered. The filtrate was concentrated *in vacuo*, and subjected to glpc analysis. Four products **1a**, **2a**, **3a**, and **4a** were isolated. The structures of **1a** and of **2a** were established by comparison of IR spectra with the respective authentic samples. Structures of **3a** and **4a** were determined by IR, NMR, and elemental analysis. **3a**: Found: C, 69.93; H, 6.36; N, 6.94%. Calcd for $C_{12}H_{13}NO_2$: C, 70.91; H, 6.45; N, 6.89%. IR (cm^{-1}): 1850, 1820, 1780, 1710. NMR ($CDCl_3$ with TMS): 1.48 (s, 9H), 7.70 (s, 4H). **4a**: Found: C, 70.69; H, 6.28; N, 6.91%. Calcd for $C_{12}H_{13}NO_2$: C, 70.91; H, 6.45; N, 6.89%. Mass M^+=203. IR (cm^{-1}): 1778, 1712. NMR ($CDCl_3$ with TMS): 1.68 (s, 9H), 7.71 (s, 4H).

Reaction of 2-Chloro-1-cyclohexene-1-carboxylic Acid with Cu_2O/tert*-Butyl Isocyanide.* According to the procedure described above, a mixture of 1.60 g (10 mmol) of 2-chloro-1-cyclohexene-1-carboxylic acid, 0.72 (5 mmol) of Cu_2O and 0.83 (10 mmol) of *tert*-butyl isocyanide in 5 ml of benzene was reacted at 80 °C for 30 hr. Products **1b**, **2b**, **3b**, and **4b** were isolated by glpc. The structures of **1b** and **2b** were confirmed by comparison of their IR spectra with those of the authentic samples. Structures of **3b** and **4b** were determined by IR, NMR, and elemental analysis. **3b** (mp 75—77 °C): Found: C, 69.26; H, 8.29; N, 6.62%. Calcd for

$C_{12}H_{17}NO_2$: C, 69.54; H, 8.27; N, 6.76%. IR (cm^{-1}): 1810, 1775, 1690. NMR ($CDCl_3$ with TMS): 1.34 (s, 9H), 1.72 (m, 4H), 2.32 (m, 4H). **4b** (mp 66 °C): Found: C, 69.40; H, 8.22; N, 6.84%. Calcd for $C_{12}H_{17}NO_2$: C, 69.54; H, 8.27; N, 6.76%. IR (cm^{-1}): 1770, 1710. NMR ($CDCl_3$ with TMS): 1.53 (s, 9H), 1.69 (m, 4H), 2.22 (m, 4H). Similarly, the reaction of 2-chloro-1-cyclopentene-1-carboxylic acid with Cu_2O/*tert*-butyl isocyanide was carried out. Among several products, **1c** (5%) and **4c** (2%) were identified. **1c** was identified by comparison with the authentic sample. **4c**: Found: C, 68.52; H, 7.61; N, 7.58%. Calcd. for $C_{11}H_{15}NO_2$: C, 68.37; H, 7.82; N, 7.25%. IR (cm^{-1}): 1770, 1710. NMR ($CDCl_3$ with TMS): 1.54 (s, 9H), 2.50 (m, 6H). Mass $M^+=193$.

Competitive Reaction of 2-Chloro-1-cyclohexene-1-carboxylic Acid with tert-*Butyl Isocyanide and Phenylacetylene in the Presence of Cu_2O in Pyridine.* A mixture of 2.00 g (13 mmol) of 2-chloro-1-cyclohexene-1-carboxylic acid, 1.01 g (7 mmol) of Cu_2O, 1.33 g (13 mmol) of phenylacetylene, and 1.58 g (19 mmol) of *tert*-butyl isocyanide in pyridine (25 ml) was heated at reflux under nitrogen gas for 14 hr. After the reaction mixture was filtered, the filtrate was subjected to fractional distillation *in vacuo*. Products **9**, **2b**, **3b**, and **4b** was isolated by glpc in 4, 23, and 2% yields, respectively. Product **9** (70%) was crystallized from ligroin (mp 118—120 °C); Found: C, 79.26; H, 6.61%. Calcd for $C_{15}H_{14}O_2$: C, 79.62; H, 6.24%. NMR ($CDCl_3$ with TMS): 1.75 (broad, 4H), 2.40 (broad, 4H), 5.85 (s, 1H), 7.2, 7.8 (m, 5H).

*Reaction of Dichloromaleic Anhydride with Cu_2O/*tert*-Butyl Isocyanide in the Presence of Ethyl Iodide.* A mixture of 1.67 g (10 mmol) of dichloromaleic anhydride, 1.43 g (10 mmol) of Cu_2O, 1.66 g (20 mmol) of *tert*-butyl isocyanide and 3.12 g (20 mmol) of ethyl iodide was stirred at 80 °C for 10 hr under nitrogen. After the reaction mixture was treated with petroleum ether, and filtered, the filtrate was evaporated. Products **12**, **13**, and **14** was isolated by glpc. Identity of **13** and of **14** was established by comparison of their IR spectra with those of the authentic samples. Structure determination of **12** was performed by IR, NMR, elemental analysis and its chemical reaction. **12**: Found: C, 40.84; H, 2.82; Cl, 20.37%. Calcd for $C_6H_5O_3Cl$: C, 40.81; H, 2.85; Cl, 20.82%. IR (cm^{-1}) 1875—1830, 1790, 1750, 1655. Treatment of **12** with HCl saturated ethanol at 80 °C for 2 hr gave two products **15** and **16** in the ratio of 4 to 1.

A Semi-empirical Calculation of the Substituent Effects on ^{1}H Chemical Shifts in Aromatic Side-chains

Jun NIWA

College of General Education, Nagoya University, Chikusa, Nagoya 464

(Received June 14, 1974)

The diamagnetic contribution of the hydrogen atom in the C–H bond and that from its bonded carbon have been semi-empirically expressed. By considering the "ring-current" effect in addition to such contributions, a semi-empirical expression has been obtained for ^{1}H chemical shifts relative to the unsubstituted compound in substituted aromatic side-chains. The applicability of the expression has been examined for *m*- and *p*-substituted phenylacetylenes, styrenes, toluenes, and benzaldehydes.

The well-known expression for obtaining a simple relationship for the magnetic shielding constant of the hydrogen atom, σ^A, in an aromatic side-chain can be described as a sum of the following contributions:[1]

$$\sigma^A = \sigma^{AA}_{dia} + \sum_{B\neq A}(\sigma^{AB}_{dia}+\sigma^{AB}_{para}) + \sigma^{A,ring} \quad (1)$$

where σ^{AA}_{dia} is the local diamagnetic term of the hydrogen atom, A; where σ^{AB} is the contribution from currents on the B atom to the shielding of A, and where $\sigma^{A,ring}$ is the contribution to the shielding of A from the "ring current".

Recently, Kajimoto and Fueno[2] have presented an improved LCAO MO expression for the shielding of a hydrogen atom, A (σ^A), in aliphatic compounds; their expression is derived on the basis of Ramsey's equation,[3] containing two of Pople's three assumptions,[4] (1) a zero-differential atomic integral and (2) an average excitation energy approximation, but without invoking (3) the magnetic dipole approximation. They have concluded that the diamagnetic shielding from the neighboring carbon (σ^{AB}_{dia}) constitutes an important contribution, together with the σ^{AA}_{dia} term to the chemical shifts, whereas the paramagnetic term (σ^{AB}_{para}) remains almost constant for various substituted olefinic compounds.

It is well established that the contribution from the "ring current" should be taken into consideration for the ^{1}H chemical shifts in aromatic side-chains.[5] Figeys and Flammang have indicated that the introduction of a substituent into a benzene ring decreases the effect of the "ring current" and that this effect can be interpreted as arising from the fact that an additional contribution due to the "quinonoid" structure in the resonance hybrid leads to some degree of decrease in the ring current.[6] Yamada, Yukawa, and Tsuno have shown that the extent of the contribution of the "quinonoid" structure depends on the resonance ability of the substituent introduced,[7] and they have presented an equation ($\Delta\sigma^{A,ring}$) to describe the contribution relative to the unsubstituted compound to the ^{1}H chemical shifts in *m*-substituted aromatic side-chains, utilizing Johnson and Bovey ring-current shifts:[5b]

$$\Delta\sigma^{A,ring} = -0.4f(\rho, z)|\sigma_\pi| \quad (2)$$

where $f(\rho, z)$ is the Johnson and Bovey ring-current shift in ppm, which is expressed as a function of the geometric factors for the proton located at the cylindrical co-ordinates, ρ and z, and where σ_π is Yukawa-Tsuno's parameter for measuring the resonance ability of the substituent.[8]

In the present paper, we will first attempt to evaluate the diamagnetic term, σ^{AB}_{dia}, semi-empirically. Second, we will reveal that Eq. (2) can also be applied to the case of *p*-substituted compounds. By taking the "ring-current" effect into account in addition to the diamagnetic terms, σ^{AA}_{dia} and σ^{AB}_{dia}, we have obtained a semi-empirical expression for the ^{1}H chemical shifts relative to the unsubstituted compound in substituted aromatic side-chains. We will report to what degree of accuracy the expression reproduces the chemical shifts observed for protons in side-chain of *m*- and *p*-substituted phenylacetylenes, styrenes, toluenes, and benzaldehydes.

Results and Discussion

Kajimoto *et al.*[2] have shown that the local diamagnetic term of the hydrogen atom, A (σ^{AA}_{dia}), is given by Eq. (3), using Slater's effective nuclear charge modified to $z_{eff}=1.2-0.3(q_H-1)$ for the 1s orbital of hydrogen:

$$\sigma^{AA}_{dia} = (e^2/3mc^2)p^A_{1s,1s}\langle\phi^A_{1s}|1/r_A|\phi^A_{1s}\rangle = 17.75\times10^{-6}(-0.3q^2_H+1.5q_H) \quad (3)$$

where q is the electron density on the 1s orbital of hydrogen. The value of σ^{AA}_{dia} relative to the unsubstituted compound is linearly correlated with the increment in the electron density on the hydrogen atom:

$$\Delta\sigma^{AA}_{dia} = a\times10^{-6}\Delta q^A \quad (4)$$

where the value of a has been obtained as 16.0 by Kajimoto *et al.*[2] for the case of substituted olefinic compounds.

They have also derived an LCAO MO expression for the σ^{AB}_{dia} term in the case of olefinic compounds:

$$\sigma^{AB}_{dia} = (e^2/3mc^2)\sum_I p^B_{II}\langle\phi^B_I|1/r_{AB}|\phi^B_I\rangle \quad (5)$$

$$= 10^{-6}\{8.362q^B_{2s}+10.073q^B_{2pz}+7.564(q^B_{2px}+q^B_{2py})\} \quad (6)$$

where q's are the electron densities on specified atomic orbitals and where the C–H bond length is taken to be 1.08 Å.[2] The value of σ^{AB}_{dia} relative to the unsubstituted compound can be correlated with the increment in the total (2s and 2p) electron density on the B atom:

$$\Delta\sigma^{AB}_{dia} = 8.39\times10^{-6}\Delta q^B \quad (7)$$

In order to empirically evaluate the σ^{AB}_{dia} term we will replace the quantum mechanical average of r^{-1} from each atomic orbital on the B atom with the inverse

Table 1. Comparison of values (in ppm) of σ_{dia}^{AB} calculated by Eq. (7) with those calculated by Eq. (10) in monosubstituted ethylenes

$XCH{=}CH_2$ (B)(A)

Substituent	q^B	$8.70\Delta q^B$	$8.39\Delta q^B$
H[a]	3.9945	0.00	0.00
H[b]	4.0312	0.00	0.00
OCH_3[a]	4.1058	0.97	0.93
CN[a]	3.9748	−0.17	−0.17
NO_2[a]	3.9483	−0.40	−0.39
CH_3[a]	4.0253	0.27	0.26
Cl[b]	4.0667	0.31	0.30

a) All electron densities were calculated by the INDO method. b) The electron density was calculated by the CNDO/2 method. The values of the third and fourth columns for chloroderivatives are relative to the unsubstituted compound, the electron density of which was calculated by the CNDO/2 method.

distance of A from the point charge on B. Then Eq. (5) becomes:

$$\sigma_{dia}^{AB} = (e^2/3mc^2)r_{AB}^{-1}q^B \quad (8)$$

$$= b \times 10^{-6} q^B \quad (9)$$

The expression of Eq. (9), relative to the unsubstituted compound, is given as:

$$\Delta\sigma_{dia}^{AB} = b \times 10^{-6}\Delta q^B \quad (10)$$

When Eq. (8) is applied to substituted ethylenes, where the C–H bond length is taken to be 1.08 Å, the value of b is 8.70. Table 1 shows that the respective values of $\Delta\sigma_{dia}^{AB}$, as calculated by Eqs. (7) and (10) for substituted ethylenes, agree within errors of only a few percent. Moreover, when the C–H bond length is taken to be 1.064 Å in the ethynyl bond, $\sigma_{dia}^{AB}=8.83\times 10^{-6} q^B$ using Eq. (8). In acetylene, the value of σ_{dia}^{AB} is 35.82 ppm, while the strict MO calculation by Katô has given 35.71 ppm for it, taking the 2s and 2p orbitals on carbon into account.[9] These results mean that Eq. (8) is applicable to the calculation of the substituent effect on the σ_{dia}^{AB} term in the cases of olefinic and ethynyl protons.

The paramagnetic term, σ_{para}^{AB}, calculated according to Pople's expression[4] remains almost constant for the series of compounds examined, so long as we assume the same average excitation energy and the same value of the integral $\langle r_{AB}^{-3}\rangle$ for the same series of compounds.

With regard to the "ring-current" effect on the ^1H chemical shifts in aromatic side-chains, Eq. (2) can not axiomatically hold in the case of the proton at the position *para* to substituent, where a conjugative interaction through the benzene ring between the substituent and the side-chain group might result in the difference in the "ring-current" effect compared with the case of *m*-substituted compounds.

The "ring-current" effect on the ^1H chemical shift in monosubstituted benzene may consist of two factors: the ring-current intensity due to the total π-electron density on the benzene ring and the decrease in the ring current arising from the contribution of the "quinonoid" structure due to an introduced substituent. The degree of the contribution of the "quinonoid" structure to the benzene ring due to an introduced substituent may be reflected in changes in the absolute values of the π-electron densities on carbon atoms at the C_1 and C_4 positions.

If it is assumed that the contributions of the "quinonoid" structure arising from the introduction of the X and Y substituents (Y: the side-chain group) are put one upon another in either *m*- or *p*-substituted compounds, as is shown in Fig. 1, the relative contribution of the

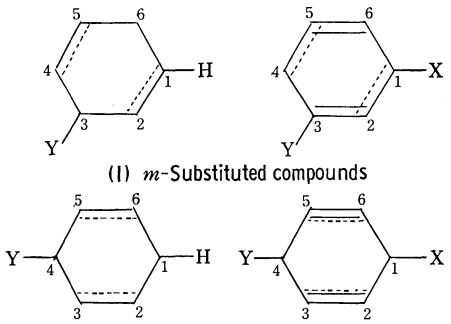

Fig. 1. Offset of quinonoid structure due to the side-chain group Y in *m*- and *p*-substituted aromatic compounds.

"quinonoid" structure between the substituted and the unsubstituted compounds can be determined only by the contribution of the X substituent, because the contributions of the side-chain group, Y, cancel each other out in the same series of compounds. Accordingly, if the total π-electron density (q_{ring}^{π}) of the aromatic ring of the *m*-substituted compound is equal to that of the *p*-substituted one, bearing the same substituent, and if the absolute values of the relative π-electron densities on C_1 (and C_4) between the substituted and the unsubstituted compounds ($|\Delta q_\pi(C_1)|$ and $|\Delta q_\pi(C_4)|$) are equal in the two compounds, the contributions by the X substituent may be regarded as equal in the two compounds. The results summarized in Table 2 show that the q_{ring}^{π} value of the *m*-substituted compound scarcely differs from that of the *p*-sbustituted one, and that the values of $|\Delta q_\pi(C_3)|$ (and $|\Delta q_\pi(C_4)|$) are almost equal in *m*- and *p*-substituted compounds. Therefore, it may be concluded that the relative contributions of the "ring current" to the unsubstituted compound are equal in *m*- and *p*-substituted compounds.

By combining Eqs. (2), (4), and (10), we obtain the following equation for the ^1H chemical shifts, $\delta(\equiv\Delta\sigma^A)$, in ppm, relative to the unsubstituted compound in *m*- and *p*-substituted aromatic side-chains:

$$\delta_{calc} = a\Delta q^A + b\Delta q^B - 0.4f(\rho, z)|\sigma_\pi| \quad (11)$$

Since the electron density on an aromatic side-chain can be altered by the substituent polar effect (the mesomeric and inductive (through bond) effects), its contribution to the ^1H chemical shift in the side-chain may be included in the first and second terms of Eq.

a) Electron densities were calculated by the INDO method. Values of bond lengths and bond angles of compounds examined were chosen from Ref. 10. b) The total π-electron density on the aromatic ring. c) Absolute values of relative π-electron densities on C_1 and C_4 between the substituted and the unsubstituted compounds. Numbering of atoms C_1 and C_4 correspond to that in Fig. 1. d) Electron densities were calculated by the CNDO/2 method. e) A planar model was used for amino groups.

TABLE 3. VALUES OF *a*, *b*, AND $f(\rho, z)$ IN Eq. (9) in ppm

Side-chain system		*a*	*r*[a]	*s*[a]	*b*	$f(\rho, z)$
$XC_6H_4C{\equiv}CH$		16.7	0.9998	0.0009	8.83	−0.21[b]
XC_6H_4	α	16.1	0.9999	0.0070	8.70	−0.25[c]
$C{=}C$	β	16.2	0.9999	0.0006	8.70	−0.54[c]
H_γ H_α	γ	16.1	1.0000	0.0004	8.70	−0.58[c]
$XC_6H_4CH_3$		16.0	0.9999	0.0008	8.52	−0.57[b]
XC_6H_4CHO		15.2	0.9999	0.0010	8.43	−0.61[b]

a) *r*: correlation coefficient, *s*: standard deviation. b) Cited from Ref. 7. c) Calculated from the table of the Johnson and Bovey's ring current shifts (Ref. 11). The basis of this calculation consists in that the total π-electron density on aromatic ring scarcely differs from that of benzene (see Table 2) and that the contribution due to the "quinonoid" structure of the side-chain group cancels each other out in the same seires of compounds.

(11) to a first approximation. In order to examine the applicability of Eq. (11), we have chosen ethynyl, olefinic, saturated aliphatic, and formyl groups as model

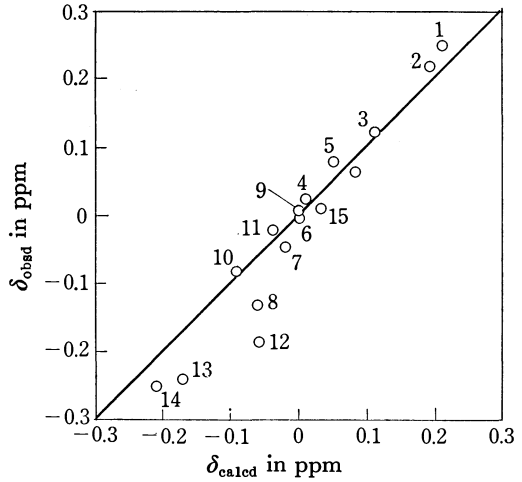

Fig. 3(a). Plots of δ_{calcd} against δ_{obsd} for protons, Hα, in *m*- and *p*-substituted styrenes. Numbered points correspond to entries in Table 4-(ii), (a).

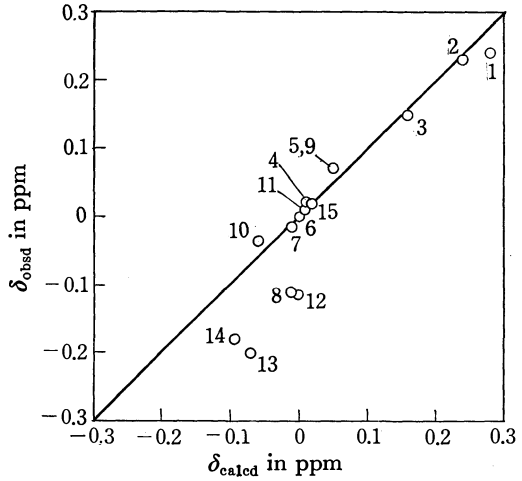

Fig. 3(b). Plots of δ_{calcd} against δ_{obsd} for protons, Hβ, in *m*- and *p*-substituted styrenes. Numbered points correspond to entries in Table 4-(ii), (b).

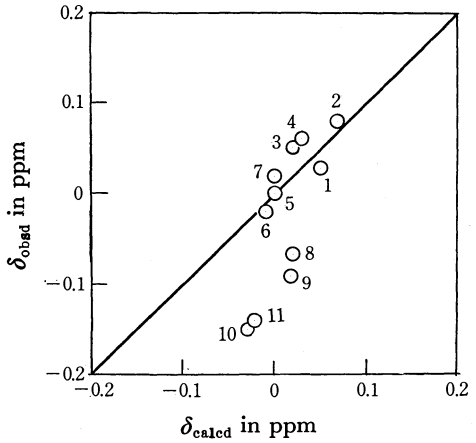

Fig. 4. Plots of δ_{calcd} against δ_{obsd} in *m*- and *p*-substituted toluenes. Numbered points correspond to entries in Table 4-(iii).

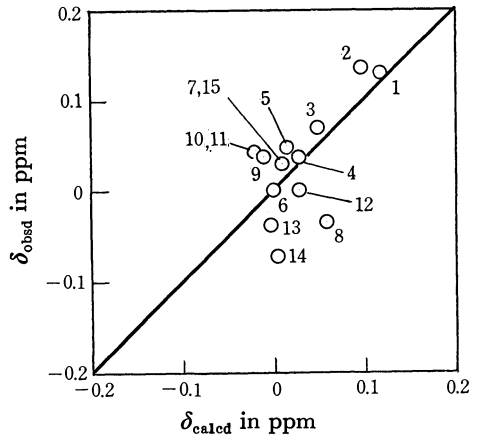

Fig. 3(c). Plots of δ_{calcd} against δ_{obsd} for protons, Hγ, in *m*- and *p*-substituted styrenes. Numbered points correspond to entries in Table 4-(ii), (c).

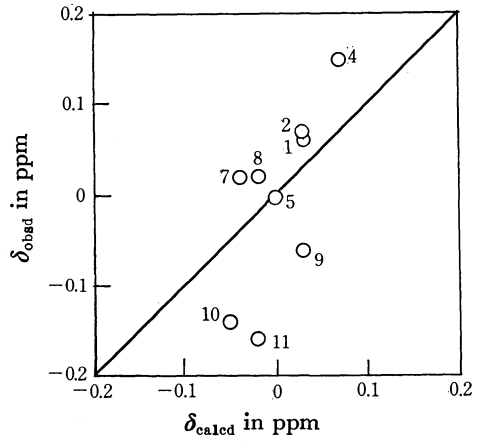

Fig. 5. Plots of δ_{calcd} against δ_{obsd} in *m*- and *p*-substituted benzaldehydes. Numbered points correspond to entries in Table 4-(iv).

systems of aromatic side-chains. Above all, the advantage of styrenes in examining the success of Eq. (11) is that they have three hydrogen atoms situated in different magnetic environments in the side-chain.

The values of a, b, and $f(\rho, z)$ obtained for the compounds examined are listed in Table 3. In Table 4, the chemical shifts calculated by Eq. (11) are compared with those observed for *m*- and *p*-substituted phenylacetylenes, styrenes, toluenes, and benzaldehydes. Even though it is a rather optional expansion to apply Eq. (8) to calculation of the σ_{dia}^{AB} term in the cases of toluenes and benzaldehydes, the results of the calcula-

a) All values are relative to the unsubstituted compound. b) All electron densities in substituted phenylacetylenes and benzaldehydes were calculated by the INDO method except for chloroderivatives, for which was used the CNDO/2 method. c) The chemical shifts were measured in carbon tetrachloride. Cited from Ref. 7. d) All electron densities were calculated by the CNDO/2 method. e) The chemical shifts were measured in cyclohexane. Cited from Ref. 12. f) The electron densities in these compounds were cited from the data, calculated by the CNDO/2 method in Ref. 12. g) The σ_π-values necessary to calculate the $\Delta\sigma^{A,ring}$, which have not been established, were obtained from the correlation between π-electron densities on the carbon at *para*-position to substituent in monosubstituted benzenes and the known σ_π-values of the other substituents: σ_π(*p*-C≡CH), −0.005 and σ_π(*p*-CH=CH_2), −0.05. h) The chemical shifts were measured in CCl_4. Cited from Ref. 13. i) The chemical shifts were measured in carbon tetrachloride except for nitro- and cyano-derivatives, those of which are relative to the unsubstituted compound measured in $CDCl_3$. (Ref. 14)

tion show that the application of Eq. (11) is not unreasonable.* In Figs. 2—5, plots of the calculated chemical shifts are shown against the observed shifts. As may clearly be seen in Figs. 2, 3(a), and 3(b), the calculated chemical shifts correctly reproduce the observed shifts in the case of terminal protons, which are three bond lengths removed from the ring carbon, to which the side-chain group is bonded. On the other hand, in protons directly bonded to the carbon atom adjoining the aromatic ring (Figs. 3(c), 4 and 5), the correlation between the calculated and the observed shifts collapses to some degree. This result may be mainly attributed to the inadequacy introduced by ignoring magnetic contributions from atoms other than the bonded carbon. Even in this case, the accuracy of the chemical shifts calculated by Eq. (11) is not inferior to those which have been calculated strictly theoretically.[2,4] Therefore, Eq. (11) provides us with a brief method for predicting the substituent effect on ^1H chemical shifts in *m*- and *p*-substituted aromatic side-chains.

The INDO and CNDO/2 calculations were carried out on FACOM-230 computers at the Computation Centers of Kyoto University and Nagoya University. We wish to express our gratitude to Professor Hiroshi Kato of our college and to Dr. Naoya Nakagawa of the University of Electro-Communications for their helpful instructions and encouragements.

* When Eq. (8) is applied to calculation of the relative chemical shifts (in ppm) for methyl protons in ethyl derivatives CH_3CH_2X, the chemical shifts calculated and observed give respectively the values of 0.01 and −0.28 for X=OCH_3, −0.16 and −0.05 for X=CH_3, −0.29 and −0.70 for X=NO_2. The accuracy of the chemical shifts calculated for ethyl derivatives is not inferior to that of the chemical shifts calculated for monosubstituted ethylenes by Kajimoto *et al.*[2] This result implies the propriety of the application of Eq. (8).

Pyridoxal Catalysis in the α,β-Elimination of S-(p-Substituted phenyl)cysteines[1]

Yukito MURAKAMI and Hiroki KONDO

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received February 6, 1974)

The pyridoxal-catalyzed α,β-elimination of S-(p-substituted phenyl)cysteines was studied at 50 °C and μ= 0.10 (KNO_3) in 79% (v/v) aqueous acetonitrile in the presence of organic bases of different strength. The rate increased with an increase in basicity. The kinetic solvent isotope effect (k_{H_2O}/k_{D_2O}) of 1.15 is consistent with the reaction mechanism in which the α-proton abstraction occurs by the direct attack of a base on the proton. The elimination rate was insensitive to a change in the electronic nature of a leaving thiophenol, indicating that the α-proton abstraction can be referred to the rate-determining step. The rate showed a considerable dependence on the water content, as reflected on the activation parameters for reactions in 79% (v/v) aqueous acetonitrile as well as in water. The larger destabilization due to water-solvation at the transition state in the aqueous reaction system seems to cause a lower reactivity relative to the organic solvent system. The catalysis of benzene analogs demonstrated that the hydroxyl group adjacent to the aldehyde in pyridoxal plays a major role in the nonenzymatic α,β-elimination reactions.

Pyridoxal-dependent enzymes catalyze various metabolic reactions of amino acids such as transamination, decarboxylation, and elimination reactions. Pyridoxal alone can go through some of these reactions in cooperation with metal ions.[2] The reaction mechanism for the pyridoxal-metal ion catalysis of the α,β-elimination reaction of O-phosphothreonine was elucidated in a previous paper.[3] Nonenzymatic pyridoxal-catalyzed reactions in the absence of metal ions, on the other hand, have been studied only to a limited extent partly because of the poor reactivity of amino acids in such systems.

Recently, De Marco and Rinaldi reported that pyridoxal phosphate catalyzes the α,β-elimination reactions of some cysteine derivatives, cystathionine and lanthionine, at 38 °C in weakly alkaline media.[4] S-Phenylcysteine itself was deaminated only at high temperature (100 °C) in an alkaline solution in the absence of both pyridoxal and metal ions.[5] However, no mechanistic elucidation was attempted in those studies. We have found that S-(p-substituted phenyl)-cysteines decompose by pyridoxal catalysis under comparatively mild conditions. Since S-substituted cysteines can be the substrates for the tryptophanase catalysis,[6] this work may provide a valuable information for elucidation of the enzymatic mechanism and for devising effective apoenzyme models.

Experimental

Materials. S-(p-Substituted phenyl)cysteines were prepared by the reactions of the corresponding thiophenols with α-acetoamidoacrylic acid and the subsequent acid hydrolysis.[7] 4-Nitrosalicylaldehyde was synthesized according to the procedure given in the literature.[8] Pyridoxal hydrochloride was obtained from Mann Research Laboratories, Inc., New York, U.S.A. and deuterium oxide (>99.7%) was from Carl Roth OHG, Karlsruhe, West Germany. The other commercial reagents were purified before use when necessary.

Kinetic Measurements. The reaction rate was followed by determining pyruvate as the 2,4-dinitrophenylhydrazone. The analytical method was essentially based on that of Metzler and Snell.[9] A solution containing 0.44×10^{-3} M substrate, 1.00×10^{-3} M pyridoxal, 0.10 M potassium nitrate, and a specified amount of a base was placed in stoppered test tubes which were then immersed in a constant temperature bath at 50.0±0.1 °C. The test tubes were taken out one by one at appropriate time intervals. A 5-ml sample from each test tube was transferred to a 25-ml volumetric flask containing 2 ml of 0.1% 2,4-dinitrophenylhydrazine in 2 M hydrochloric acid, and then allowed to stand at room temperature for 30 min. To this mixture was added 10 ml (or less for high concentrations of piperazine and piperidine) of the potassium phosphate–sodium hydroxide buffer, which was prepared by dissolving potassium dihydrogen phosphate (5.4 g), disodium hydrogen phosphate dodecahydrate (21.4 g), and sodium hydroxide (8.0 g) in 500 ml of water. The whole volume was diluted with water to 25 ml. The precipitated pyridoxal hydrazone was filtered off with fluted filter paper. The filtrate was treated with 10 ml of toluene to remove excess 2,4-dinitrophenylhydrazine. A 15-ml sample solution was taken out from the lower aqueous layer and diluted to 25 ml with 2.5 M sodium hydroxide. The absorbance at 530 nm was measured within 30 min on a Hitachi EPS-2 recording spectrophotometer.

Product Analysis. A reaction mixture (*ca.* 100 ml) containing 1.00×10^{-3} M pyridoxal, 0.44×10^{-3} M S-(p-nitrophenyl)cysteine, and 0.05 M morpholine in 79% (v/v) aqueous acetonitrile was warmed at 50 °C for 3 hr. A portion of the mixture was taken out for the analysis of p-nitrothiophenol and its oxidized product, bis(p-nitrophenyl) disulfide. When assayed by the conventional Folin method,[10] the sample solution developed a blue color characteristic of the reduced phosphotungstate complex. The nitrogen gas was bubbled through the rest of the reaction mixture for 30 min after addition of 10% sodium hydroxide (*ca.* 10 ml). Ammonia collected in 0.05 M hydrochloric acid was assayed by standard Nesslerization. Formation of pyruvic acid was detected by means of visible spectroscopy upon converting it into the corresponding 2,4-dinitrophenylhydrazone. In reference to the above survey, the decomposition of S-(p-nitrophenyl)-cysteine yielded three products, p-nitrothiophenol, pyruvic acid, and ammonia.

Results

The α,β-elimination reactions of S-(p-substituted phenyl)cysteines were carried out with an initial sub-

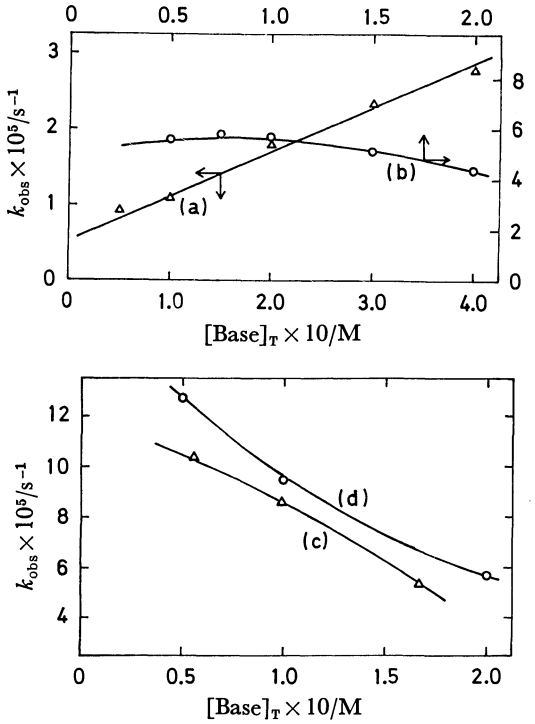

Fig. 1. Correlations between base concentration and apparent first-order rate constant for the pyridoxal-catalyzed α,β-elimination of *S*-(*p*-nitrophenyl)cysteine at 50 °C and $\mu=0.10$ (KNO_3) in 79% (v/v) acetonitrile with the following organic bases: (a), imidazole; (b), morpholine; (c), piperazine; (d), piperidine. Total initial concentrations: substrate, 0.44×10^{-3} M; pyridoxal, 1.00×10^{-3} M.

strate concentration of 0.44×10^{-3} M along with the presence of 1.00×10^{-3} M pyridoxal and a specified amount of organic bases in aqueous acetonitrile. Each reaction rate followed first-order kinetics with respect to the total concentration of unreacted substrate. The correlations between the apparent first-order rate constant and the total base concentration are shown in Fig. 1, *S*-(*p*-nitrophenyl)cysteine being adopted as a substrate. The rate increases as the imidazole concentration increases, but is insensitive to the change of morpholine concentration in the concentration range examined. Increase in either piperazine or piperidine concentration results in the rate decrease. Since the substrates underwent no decomposition in the absence of pyridoxal, the reaction was truly pyridoxal-catalyzed. The product analysis (see Experimental) provides an evidence for the α,β-elimination process.

Rate constants for the pyridoxal-catalyzed elimination of *S*-(*p*-substituted phenyl)cysteines in 79% (v/v) acetonitrile in the presence of 0.10 M morpholine were plotted against Hammett σ-values for the *p*-substituents of the leaving thiophenols (Fig. 2); the slope being 0.17. This small value of the reaction constant implies that the β-elimination is hardly affected by the electronic nature of the leaving group.

The apparent first-order rate constant for the pyridoxal-catalyzed elimination of *S*-(*p*-nitrophenyl)cysteine in the presence of 0.10 M morpholine in 79% (v/v) aqueous acetonitrile was 5.67×10^{-5} s^{-1} and the corresponding value in acetonitrile–deuterium oxide (79:21 by volume) was 4.93×10^{-5} s^{-1}; the solvent isotope effect (k_{H_2O}/k_{D_2O}) is 1.15.

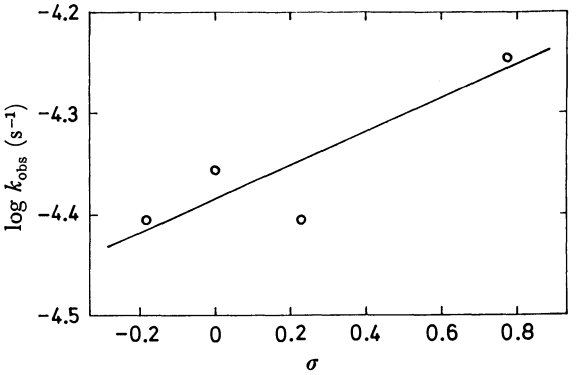

Fig. 2. Hammett plot for the pyridoxal-catalyzed α,β-elimination of *S*-(*p*-substituted phenyl)cysteines at 50 °C and $\mu=0.10$ (KNO_3) in 79% (v/v) acetonitrile with the total initial concentrations: substrate, 0.44×10^{-3} M; pyridoxal, 1.00×10^{-3} M; morpholine, 0.10 M.

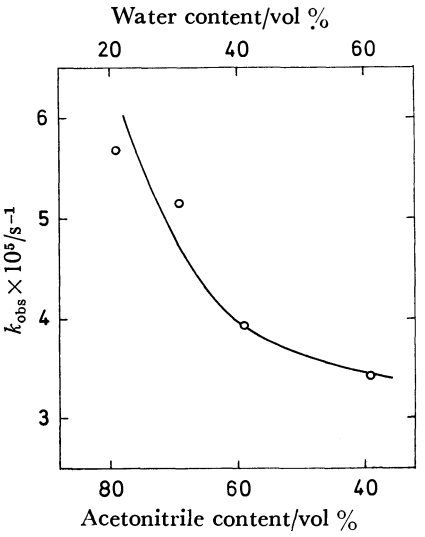

Fig. 3. Correlation between water content and reaction rate for the pyridoxal-catalyzed α,β-elimination of *S*-(*p*-nitrophenyl)cysteine at 50 °C and $\mu=0.10$ (KNO_3) with the total initial concentrations: substrate, 0.44×10^{-3} M; pyridoxal, 1.00×10^{-3} M; morpholine, 0.10 M.

The correlation between elimination rate of *S*-(*p*-nitrophenyl)cysteine and solvent composition was also examined (Fig. 3). The rate decreased considerably with the increase in water content. Activation parameters for the pyridoxal-catalyzed elimination of *S*-(*p*-nitrophenyl)cysteine and *S*-phenylcysteine in 79% (v/v) aqueous acetonitrile as well as in water are listed in Table 1. The activation entropy of large negative value is in line with the bimolecular nature of the reactions.

Catalytic activities of the benzene analogs of pyridoxal were investigated in order to clarify the catalytic roles of the ring-substituents of pyridoxal (Table 2). 4-Nitrosalicylaldehyde showed a catalytic activity to a similar extent. While 4-nitrobenzaldehyde, bearing no *o*-hydroxyl group, was practically inactive, salicylalde-

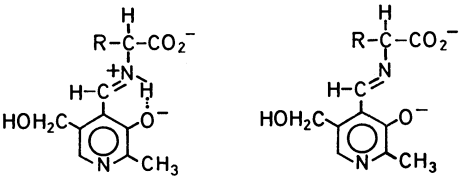
hyde, lacking an electron-withdrawing nitro group, showed some catalytic effect.

Discussion

Reaction Mechanism. The pyridoxal-dependent enzymes may involve various functional groups of nucleophilic and base character in their apoenzyme moieties in a manner as approved for proteinases. The catalytic activity of the latter is provided by the concerted actions of those functional groups at their active sites. In the present study, the catalytic effect of some organic bases of different base-strength was examined in the pyridoxal-catalyzed elimination reaction in connection with the catalytic nature of base moieties which are planted in an apoenzyme skeleton. The rate constants are plotted against the pK_a of the conjugate acids of organic bases obtained in water (Fig. 4), the base concentration for the reaction being maintained at 0.10 M. The rate increases as the basicity of the organic bases rises from imidazole to morpholine, but a leveling-off trend is observed beyond p$K_a\cong9$, *i.e.*, for piperazine and piperidine. The Schiff base formed between pyridoxal and an amino acid can be present in two forms in an alkaline solution, the protonated species (**1**) and the deprotonated one (**2**)



1 2

at the azomethine nitrogen. The former species pyridoxylidenevaline absorbs at 414 nm and the latter at 367 nm in aqueous media.[11)] The corresponding absorption maxima for the same Schiff base in methanol are 418 and 373 nm, respectively.[12)] The pK_a for these protonated aldimines is *ca.* 10 in aqueous phase.[3)] The visible spectra for solutions containing 1.00×10^{-3} M pyridoxal, 1.00×10^{-3} M phenylalanine (pseudo-substrate), and 0.10 M organic base showed λ_{max} (in 79% (v/v) CH_3CN) at 423 nm with imidazole and morpholine, at 382 nm with piperidine, and at the intermediate region with piperazine. This blue shift on going from weak to strong in basicity can be attributed to the deprotonation from the azomethine nitrogen. The deprotonated form can give out a weaker electron-withdrawing effect at the α-carbon, which results in the reduction of reactivity of the amino acids. Thus, the nonlinear Brønsted correlation (Fig. 4) can be interpreted in terms of these protonation-deprotonation equilibria.

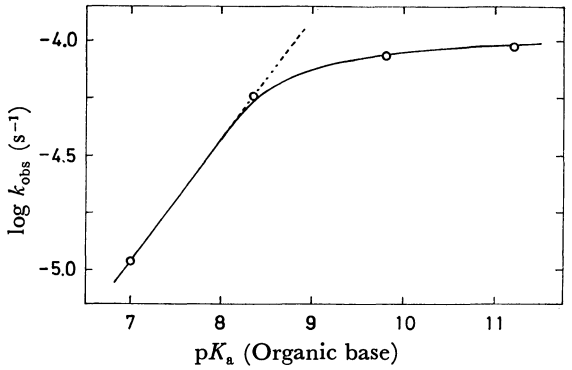


Fig. 4. Brønsted plot for the pyridoxal-catalyzed α,β-elimination of S-(p-nitrophenyl)cysteine at 50 °C and μ=0.10 (KNO_3) in 79% (v/v) acetonitrile with the initial total concentrations: substrate, 0.44×10^{-3} M; pyridoxal, 1.00×10^{-3} M; organic base, 0.10 M. pK_a-Values in aqueous phase have been adopted for organic bases.

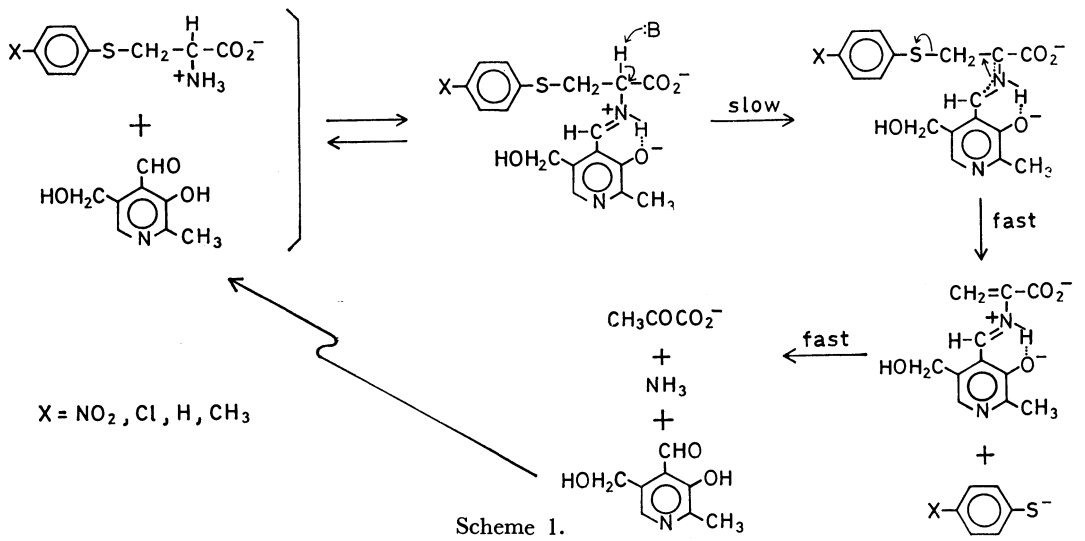
The bimolecular attack by an organic base, which can be referred to the α-proton abstraction in the rate-determining step, is reflected on the activation entropy by a large negative value. The problem remains as to whether the α-proton abstraction occurs by the direct attack of a base on the proton or in the presence of a water molecule between them. The small solvent isotope effect (k_{H_2O}/k_{D_2O}) seems to support the former mechanism.

The reaction rate is insensitive to the electronic nature of a leaving thiophenol as can be seen from the Hammett plot (Fig. 2). If the C–S bond fission were to occur in the rate-determining step through either E1 or E1CB mechanism, a larger dependence on the substituent constant would be expected. A comparatively small activation enthalpy also suggests the C–H bond cleavage in the rate-determining step.

On the basis of all the evidences given above, the

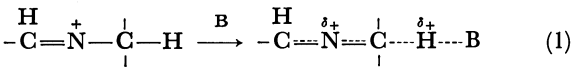


Scheme 1.

most plausible mechanism for the present reaction is as shown in Scheme 1. The Schiff base formation between substrate and pyridoxal occurs in the initial stage as the pre-equilibrium step[3,11] prior to the rate-determining α-proton liberation.

Solvent Effect. In order to observe various reactions of amino acids proceeding to a detectable extent in the absence of any apoenzyme moiety, pyridoxal catalysis requires either an elevated temperature or the presence of metal ions. In organic solvent system, however, these reactions often proceed readily at room temperature even in the absence of metal ions; the transamination from pyridoxamine to α-keto acids and the reverse reaction occurs readily in absolute ethanol without any metal ion.[13] The nonenzymatic reaction between pyridoxamine and α-ketoisovalerate was found to proceed quite smoothly at room temperature in methanol through the cooperation of zinc(II) ion.[14] Our results (Fig. 3) indicate that the α,β-elimination rate depends on the water content of the solvent system in accord with the related reactions of amino acids. The Schiff base formation is generally much favored in organic solvents. However, the rate enhancement due to the solvents cannot be explained in terms of this effect alone, since the Schiff base formation has nothing to do with the rate-determining step.

Alternatively, solvation effects seem to be responsible for the rate acceleration in organic solvents, as evident from the activation parameters listed in Table 1. Since the reaction seems to proceed through the less polar transition state (Scheme 1) relative to the initial one due to the delocalization of a positive charge as represented by Eq. (1), the reaction center may be solvated by organic solvent molecules more effectively and water molecules would be less tightly bound to the center.



(1)

Stabilization of the transition state becomes much greater in 79% (v/v) acetonitrile than in the aqueous system. Contrarily, the polar initial state, due to a positive charge located at the Schiff base nitrogen, can be solvated by water molecules more tightly than by organic solvent molecules. Thus, the initial state would be more stabilized in water than in 79% (v/v) acetonitrile. These effects give rise to a larger activation enthalpy for the aqueous reaction system. This solvation effect is also reflected on the activation entropy values. These features would be more drastic in a higher acetonitrile content, but the lower solubility of the substrates kept us from carrying out the experiments.

Catalysis by Pyridoxal Analogs. In order to clarify the catalytic roles of various functional groups placed in pyridoxal, the catalytic activities of its benzene analogs were examined as listed in Table 2. As a result, the presence of the hydroxyl group *ortho* to the aldehyde is of primary importance for yielding catalytic activity, even though an additional electron-withdrawing group, the nitro group or the pyridyl nitrogen, accelerated the reaction rate to a greater extent. For the noenzymatic transamination reaction between glutamic acid and 3-hydroxypyridine-4-carbaldehyde, Thanassi *et al.* proposed that the general acid catalysis of the hydroxyl group acting on the azomethine bond facilitated the isomerization of this bond.[15] For the present elimination reaction, however, there is no need for such isomerization to be involved and another explanation must be invoked for the role of the hydroxyl group.

The Schiff base formed between pyridoxal and amino acid is known to possess a six-membered ring structure by a strong intramolecular hydrogen bonding (Scheme 1). Thus, the stability of the Schiff base may be greatly reduced by the deprotonation from the azomethine nitrogen or the absence of a hydroxyl group. The deprotonation at the azomethine nitrogen gives out a reduced electron-withdrawing effect on the α-carbon. In conclusion, the hydroxyl group adjacent to the aldehyde in pyridoxal plays an indispensable role in the nonenzymatic α,β-elimination of amino acids.

The Cd 5 $^3P_0$ State in the Cadmium-photosensitized Reaction and the Quenching of the Resonance Radiation at 326.1 nm by Nitrogen, Carbon Monoxide, and Carbon Dioxide

Shunzo YAMAMOTO, Motoaki TAKAOKA, Shigeru TSUNASHIMA, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received July 8, 1974)

The emission of the resonance line at 326.1 nm (5 $^3P_1 \rightarrow 5\ ^1S_0$) and the absorptions of Cd($^3P_0$) at 340.4 nm (5 $^3D_1 \leftarrow 5\ ^3P_0$) and of Cd($^3P_1$) at 346.6 nm (5 $^3D_2 \leftarrow 5\ ^3P_1$) have been measured as functions of the pressure of foreign gases at 250 °C. At the pressures higher than 1 Torr of any rare gas, an equilibrium was established between 5 $^3P_1$ and 5 $^3P_0$ states. The efficiency of nitrogen in producing the 5 $^3P_0$ state from the 5 $^3P_1$ state was found to be more than 10^3 times those of rare gases. The quenching efficiencies of nitrogen, carbon monoxide, and carbon dioxide for the resonance radiation at 326.1 nm were also measured by using argon as the diluent gas. The half-quenching pressures obtained were 73 ± 3, 0.47 ± 0.01, and 0.096 ± 0.003 Torr for nitrogen, carbon monoxide, and carbon dioxide respectively.

The energy state, 5 $^3P_0$, of cadmium is 86.1 kcal mol^{-1} above the ground state, Cd 5 $^1S_0$, and 1.6 kcal mol^{-1} below the Cd 5 $^3P_1$ state. Recently, Breckenridge and Callear observed the formation of the Cd($^3P_0$) state in the system of cadmium vapor and methane illuminated by the resonance line at 228.8 nm (5 $^1P_1 \rightarrow 5\ ^1S_0$).[1] In the 326.1 nm cadmium-photosensitized reactions, however, the participation of the 5 $^3P_0$ state has not yet been ascertained, although, by analogy with the Hg–NH_3 system, Morten *et al.* assumed the 5 $^3P_0$ state as the precursor of the emitting species in the cadmium-photosensitized emission of ammonia.[2] On the other hand, the 6 $^3P_0$ state of mercury atoms was studied by several groups,[3–7] and now it is well established that the Hg 6 $^3P_0$ state plays an important role in the mercury photosensitization.

In a previous short communication,[8] we reported that the 5 $^3P_0$ state of cadmium atoms produced in the cadmium-photosensitized reactions in argon, nitrogen, and ammonia can be observed by the absorptions at the wavelengths of 340.4 nm (5 $^3D_1 \leftarrow 5\ ^3P_0$) and 467.8 nm (6 $^3S_1 \leftarrow 5\ ^3P_0$).

The present paper will report the details of the absorption measurement of Cd($^3P_0$) and Cd($^3P_1$) as well as the quenching of the resonance radiation at 326.1 nm (5 $^3P_1 \rightarrow 5\ ^1S_0$) by nitrogen, carbon monoxide, and carbon dioxide.

Experimental

The apparatus used in the present experiment was previously outlined.[8] The reaction cell was a quartz tube, 2 cm in diameter and 30 cm long, with two flat planes. The exciting resonance lamp was a home-made, U-shaped cadmium lamp made of Pyrex, while the light source for the measurement of the absorption was made of quartz. Both lamps were kept in electric furnaces at 250 ± 1 °C and operated by an alternating current (50 Hz). The intensity from the lamp, therefore, changes with the frequency of 100 Hz. However, since the lifetimes of Cd($^3P_1$) and Cd($^3P_0$) are known to be very short compared with the period of the change in the light intensity,[9] the light intensities observed in the present experiment are regarded as the averages over the period. The vapor pressure of cadmium in the cell was kept constant (3.2×10^{-3} Torr) by maintaining the temperature of the cadmium storage at 240 ± 1 °C in all the photosensitized reactions. The light intensity from the cell was measured by means of a combination of a monochromator (Shimadzu photoelectric spectrophotometer, model QV-50), a 1P28 photomultiplier, and a Ritsu photometer, type 101A, and was recorded by means of a Yokogawa Laboratory recorder, type 3043. The slit of the monochromator was properly opened, so that the observed intensity was one integrated over the spectral line profiles at 326.1, 340.4, and 346.6 nm. The pressure of the gases was measured by a W & T model 62–075 pressure gauge supplied by the Nagano Keiki Co.

The cadmium metal used was high-purity cadmium (99.9999%) manufactured by the Osaka Asahi Metal Co. Pure-grade rare gases (He, Ne, Ar, Kr, and Xe) purchased from the Takachiho Shoji Co. were used after repeated adsorption and desorption on a molecular sieve at the temperature of liquid nitrogen. Pure-grade N_2, CO, and CO_2 were used after they had been treated as previously described.[10]

Since the absorption of the 326.1 nm resonance line with the cadmium vapor at 3.2×10^{-3} Torr is small (the *f*-value of the Cd 326.1 nm line is 0.002,[9] nearly 1/20 of that of the Hg 253.7 nm line), 30% of the absorption occurs in a path length of 1 cm. Therefore, the formation of the Cd($^3P_1$) state in the cell is almost uniform.

Results

Pressure Dependence of the Emission Intensity at 326.1 nm. When the cell containing cadmium vapor was illuminated by means of the exciting lamp, the emission was observed at 326.1 nm. Upon the addition of rare gases, the intensity of the emission increased with the increase in the pressure, as is shown in Fig. 1. Rare gases other than Ne showed almost the same pressure dependence of the intensity. The deviation observed in the case of Ne is probably due to the impurity, which could not be removed by the method described above. When N_2 was added, the intensity increased slightly up to a few Torr and then gradually decreased with the increase in pressure. In the case of CO and CO_2, the intensity decreased rapidly, even in the low-pressure region. The efficiencies of CO and CO_2 in quenching the resonance radiation must be considerably larger than that of N_2.

The Absorption of the 346.6 nm Spectral Line by Cd($^3P_1$).

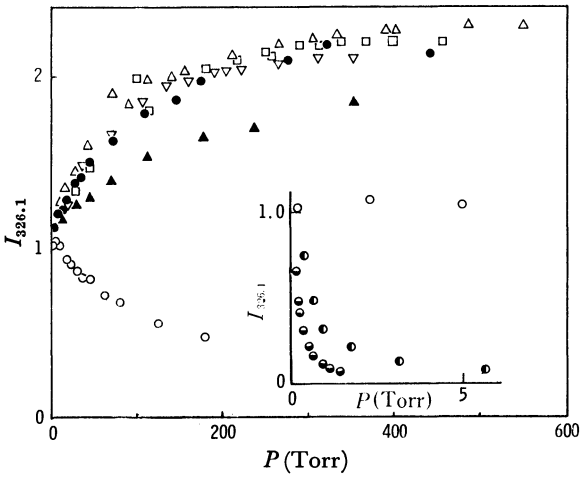

Fig. 1. The intensity of the resonance radiation at 326.1 nm as a function of the pressure of the foreign gas. △: He, ▲: Ne, ●: Ar, □: Kr, ▽: Xe, ○: N_2, ◐: CO, ◒: CO_2.

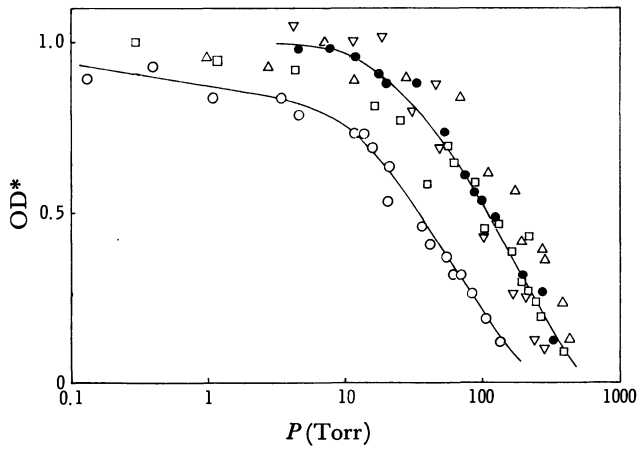

Fig. 2. The relative optical density of Cd($^3P_1$) atoms at 346.6 nm as a function of the pressure of the foreign gas. △: He, ●: Ar, □: Kr, ▽: Xe, ○: N_2.

Figure 2 shows the pressure dependence of the relative optical density at 346.6 nm. For all the gases used, the optical density was constant in the low-pressure region and decreased gradually with the increase in the pressure. The curves for rare gases are in agreement with each other within the limits of experimental error. In the case of N_2, the optical density began to decrease at lower pressures.

The Absorption of the 340.4 nm Spectral Line by Cd($^3P_0$). Figure 3 shows the relative optical density at 340.4 nm as a function of the pressure. All the curves have maxima. Obviously, the efficiency in producing the Cd($^3P_0$) state increases in the order: He<Ar~Kr<Xe<N_2. The pressure dependences of the decrease in optical density in the high-pressure region agree approximately with each other for all the rare gases. In nitrogen, the optical density began to decrease at a pressure lower than that in rare gases. This is similar to the tendency observed in the absorption of the 346.6 nm spectral line by Cd($^3P_1$).

The absorption of the 467.8 nm spectral line by Cd($^3P_0$) was also measured, although the data are not

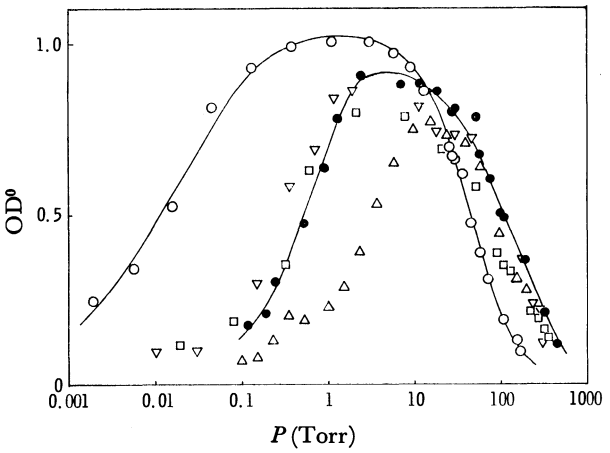

Fig. 3. The relative optical density of Cd($^3P_0$) atoms at 340.4 nm as a function of the pressure of the foreign gas. △: He, ●: Ar, □: Kr, ▽: Xe, ○: N_2.

shown here. The pressure dependence of the relative optical density was almost the same as that obtained with the absorption of the 340.4 nm line.[8] The optical density at 467.8 nm was much smaller than that at 340.4 nm.

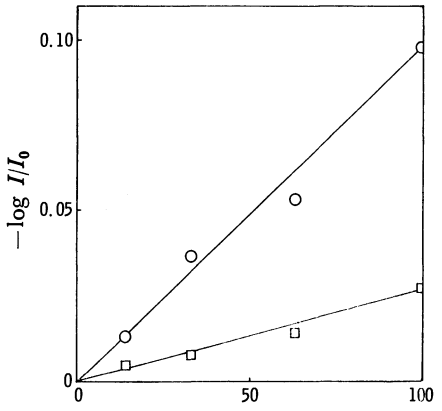

Fig. 4. The optical densities at 340.4 nm (P_{Ar}=18 Torr) (○) and at 346.6 nm (P_{Ar}=25 Torr) (□) as functions of the intensity of the exciting light.

The Lambert-Beer Law. In atomic absorption spectroscopy, it should be checked whether the Lambert-Beer law can be applied or not. In order to investigate this point in the present experiment, we measured the absorptions at 340.4 and 346.6 nm as functions of the intensity of the exciting lamp. The intensity was changed by inserting a screen between the cell and the exciting lamp. The results are shown in Fig. 4. Plots of the optical densities *vs.* the light intensity, to which the concentration of excited atoms should be proportional, give straight lines which pass through the point of origin. These results show that the Lambert-Beer law holds in the present measurements.

$$-\log (I/I_0)_{346.6} = OD^* = \varepsilon^* l[Cd^*] \quad (I)$$

$$-\log (I/I_0)_{340.4} = OD^0 = \varepsilon^0 l[Cd^0] \quad (II)$$

where, ε^* and ε^0 are the apparent extinction coefficients of the Cd($^3P_1$) and Cd($^3P_0$) atoms for the absorption of the spectral lines at 346.6 and 340.4 nm from the light

source for the absorption measurement and where l is the length of the cell.

Pressure Dependence of the Apparent Extinction Coefficient. Both the emission intensity at 326.1 nm and the optical density of the absorption at 346.6 nm are measures of the concentration of $Cd(^3P_1)$ atoms. As was shown above, the optical density at 346.6 nm can be correlated to the concentration of $Cd(^3P_1)$ atoms by Eq. (I). On the other hand, this concentration should be correlated to the emission intensity at 326.1 nm by the following equation:

$$I_{326.1} = \tau^{-1}[Cd^*] \qquad \text{(III)}$$

where τ is the effective lifetime of the $Cd(^3P_1)$ atoms. As is shown in Fig. 2, the optical density of the $Cd(^3P_1)$ atoms decreases at pressures higher than 10 Torr, while, as is shown in Fig. 1, the emission intensity at 326.1 nm does not decrease in this pressure region. This apparent discrepancy must be due to the different pressure dependences of ε^* and τ^{-1}.

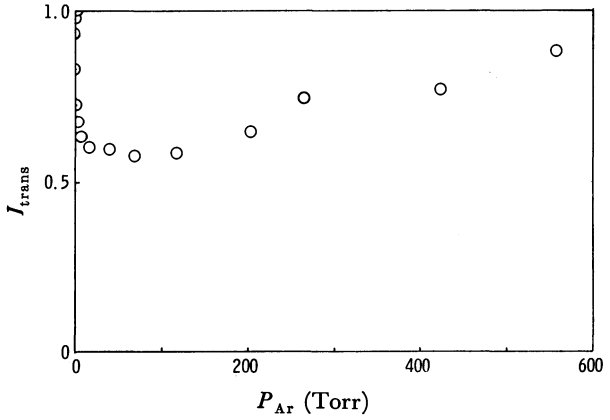

Fig. 5. The intensity of the transmitted light at 326.1 nm as a function of the pressure of argon. The vapor pressure of cadmium is 1.0×10^{-4} Torr (180 °C).

In order to examine the pressure dependence of the apparent extinction coefficient, we measured the intensity of the transmitted light at 326.1 nm from the light source for the absorption measurements at various pressures of argon, while keeping the cadmium vapor pressure constant, 10^{-4} Torr. The results are shown in Fig. 5. Obviously, the intensity of the transmitted light at 326.1 nm decreased initially with the increase in the argon pressure and then gradually increased with the further increase in pressure. The significance of this experiment will be discussed later.

In practice, we wanted to measure the pressure dependence of ε^* and ε^0. However, we could not do so because we have no proper method of producing constant concentrations of Cd* and Cd^0 by changing the argon pressure.

As will be shown later on the basis of the kinetic analysis, τ is estimated to be independent of the examined pressures of rare gases. Consequently, it may be concluded that the apparent discrepancy described above is due to the pressure dependence of the apparent extinction coefficient, ε^*.

Quenching of the Resonance Radiation at 326.1 nm by N_2, CO, and CO_2. As was mentioned above, the absorption intensity at 326.1 nm is dependent upon the pressure of foreign gases. Therefore, the curves obtained with N_2, CO, and CO_2 in Fig. 1 cannot be pure quenching curves for the $Cd(^3P_1)$ atoms. In order to minimize the effect of the pressure broadening, quenching gases were diluted with argon and the total pressure was kept constant. The experimental data thus obtained are listed in Table 1, from which we can estimate the quenching efficiencies of N_2, CO, and CO_2 quantitatively.

TABLE 1. THE INTENSITY OF THE RESONANCE RADIATION AS A FUNCTION OF THE PRESSURE OF N_2, CO OR CO_2. THE TOTAL PRESSURE IS CONTROLLED BY ADDING ARGON

Discussion

The Pressure Broadening of the Absorption Line. As Fig. 5 shows, the intensity of the transmitted light at 326.1 nm decreased with the increase in argon pressure up to 100 Torr. This is probably due to the pressure broadening of the absorption line of the cadmium atoms in the ground state. This reasoning is also applicable to the increase in the emission at 326.1 nm with the increase in the pressure of rare gases, which is shown in Fig. 1. However, the increase in the emission intensity with the increase in the pressure is much slower than the decrease in the transmitted light shown in Fig. 5. This is probably because the spectral line from the exciting lamp is much broader than that from the light source for the absorption measurement.

Upon the further increase in argon pressure over 100 Torr, the absorption line of the cadmium atoms in the ground state will be broadened more than the spectral line from the light source. Consequently, the apparent extinction coefficient will be reduced. This explanation matches the observed increase in the intensity of the transmitted light at 326.1 nm shown in Fig. 5. On the other hand, the emission intensity, which is shown in Fig. 1, does not suffer from such an effect at the pressures examined, because the spectral line from the exciting lamp is much broader than that from the light source for the absorption measurements.

In Figs. 2 and 3, we show the pressure dependences of the absorption of Cd($^3P_1$) and Cd($^3P_0$) atoms. The decrease in the optical densities at the higher pressures of rare gases may be explained by the reasoning presented above. That is, the quenching efficiency of rare gases is negligibly small and the decrease in the optical densities over 10 Torr of rare gases is due to the decrease in the apparent extinction coefficients, ε^* and ε^0. In the case of N_2, however, both the pressure broadening of the absorption line and the quenching of the excited atoms have to be considered.

Formation and Quenching of Cd($^3P_0$) Atoms. In order to make a kinetic analysis of the steady-state processes occurring in a cell under a constant illumination, the following reactions are considered:

(1)	$Cd(^1S_0) + h\nu(326.1) \longrightarrow Cd^*(^3P_1)$	I_a
(2)	$Cd^* \longrightarrow Cd + h\nu$	k_0
(3)	$Cd^* + M \longrightarrow Cd + M$	k_1
(4)	$Cd^* + M \longrightarrow Cd^0(^3P_0) + M$	k_2
(5)	$Cd^0 \longrightarrow Cd$ (on wall)	k_3
(6)	$Cd^0 + M \longrightarrow Cd + M$	k_4
(7)	$Cd^0 + M \longrightarrow Cd^* + M$	k_5

where M stands for rare gases, N_2, CO, or CO_2. If Cd is replaced by Hg, this reaction mechanism is the same as that proposed by Kimbell and LeRoy[3] for the case of the Hg–N_2 system except for the emission from the $^3P_0$ state. Such an emission could not be observed in the present system. Reaction (5) is a diffusion-controlled reaction, and its rate may be expressed as $k_3[Cd^0]/[M]$. Therefore, the steady-state-treatment of Reactions (1)—(7) gives the following relation:

$$\frac{I_a}{[Cd^0]} = \frac{A}{[M]^2} + \frac{B}{[M]} + C + D[M] \qquad \text{(IV)}$$

where A, B, C, and D are constants depending on the foreign gas. For rare gases, we can ignore Reactions (3) and (6), as has been discussed in the previous section. Therefore,

$$A = k_0k_3/k_2,\ B = k_3,\ C = k_0k_5/k_2 \text{ and } D = 0,$$

while, for nitrogen,

$$A = k_0k_3'/k_2',\ B = k_3'(k_1'+k_2')/k_2',$$
$$C = k_0(k_4'+k_5')/k_2' \text{ and } D = (k_1'k_4'+k_2'k_4'+k_1'k_5')/k_2'.$$

where the prime indicates the value in nitrogen. By using Eq. (II), the left-hand side of Eq. (IV) can be expressed as follows:

$$\frac{I_a}{[Cd^0]} = \frac{I_a}{OD^0}\varepsilon^0 l \qquad \text{(V)}$$

Since the pressure dependence of the apparent value of ε^0 can be estimated from Fig. 3, as has been discussed in the previous section, we can calculate the relative values of A, B, C, and D by the method given in the Appendix. The results are tabulated in Table 2. This procedure is the same as that used by Kimbell and LeRoy for the analysis of the Hg($^3P_0$) atoms.[3] The solid lines in Fig. 6 were drawn by substituting the values in Table 2 into Eq. (IV).

Table 2. The constants involved in Eq. (IV)

Gas	A (Torr^2 s^{-1})	B (Torr s^{-1})	C (s^{-1})	D (Torr^{-1} s^{-1})
He	0.030	4.00	0.98	0
Ar	0.015	0.58	0.98	0
Kr	0.015	0.58	0.98	0
Xe	0.005	0.33	0.98	0
N_2	8×10^{-6}	0.008	1.03	0.033

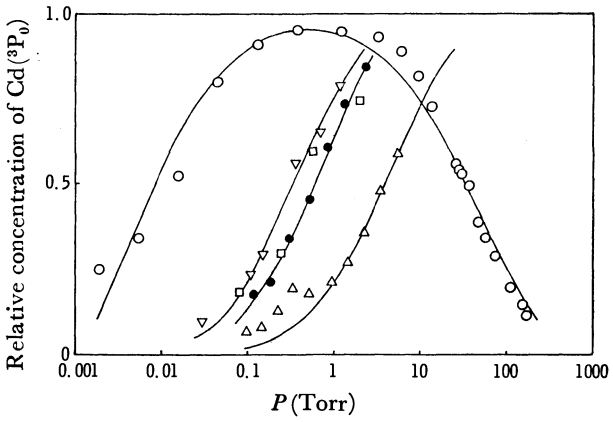

Fig. 6. The relative concentration of Cd($^3P_0$) atoms as a function of the pressure of the foreign gas. —: He, ●: Ar, □: Kr, ▽: Xe, ○: N_2. Solid lines were obtained by substituting the values in Table 2 into Eq. (IV).

From the values of A, it is found that the values of k_2 (or k_2') increase in the order: He<Ar~Kr<Xe≪N_2. This order corresponds to the efficiency of the formation of Cd($^3P_0$) atoms. A comparison suggests that the efficiency of N_2 in producing Cd($^3P_0$) is more than 10^3 times those of rare gases. The value of B for rare

gases is equal to k_3, which is directly proportional to the diffusion coefficient of $Cd(^3P_0)$ atoms in rare gases. The order of the k_3 values with respect to the kind of rare gases seems to be reasonable, because the diffusion coefficient in a lighter gas may be larger than that in a heavier gas. The values of C for all the gases examined are approximately equal. This constancy should hold for rare gases, because $C=k_0k_5/k_2$ and the ratio of k_5/k_2 should be equal to the equilibrium constant between [Cd⁰] and [Cd*]. In the case of nitrogen, this equilibrium constant should be expressed by k_5'/k_2'. The constancy of C, therefore, suggests that k_4' is much smaller than k_5'.

The equilibrium between [Cd⁰] and [Cd*] at 250 °C can be calculated as follows:

$$[Cd^0]/[Cd^*] = \frac{1}{3}\exp(1.6/RT) = 1.54$$

The ratio of the optical densities of Cd⁰ and Cd* atoms is 2.5±0.4 at pressures higher than 10 Torr. The difference in number is due to the difference in extinction coefficient. Below 10 Torr, Reaction (5) seems to play a part in the reaction mechanism.

Quenching of the Resonance Radiation by N_2, CO, and CO_2. When only argon is present in the cell, Reactions (3) and (6) may be ignored; if the pressure is higher than 10 Torr, Reaction (5) may also be ignored. Therefore, the following equation should hold in the steady state:

$$I^{Ar}_{326.1} = k_0[Cd^*] = I_a \qquad (V)$$

Here, $I^{Ar}_{326.1}$ is the intensity of the emission at 326.1 nm. When nitrogen is a substrate, the steady-state-treatment gives the following relation:

$$I^{N_2}_{326.1} = \frac{I_a}{1+\left\{\frac{k_1'}{k_0}+\frac{k_2'k_4'}{k_0(k_4'+k_5')}\right\}[N_2]} \qquad (VI)$$

By substituting Eq. (V) into Eq. (VI) and by using the $k_5' \gg k_4'$ relation, we can obtain the following equation:

$$\frac{I^{Ar}_{326.1}}{I^{N_2}_{326.1}} = 1 + \frac{1}{k_0}\left(k_1'+\frac{k_2'k_4'}{k_5'}\right)[N_2] \qquad (VII)$$

This equation can be used to compare the emission intensity at the same pressures of Ar and N_2.

Similarly, the following equations can be obtained for the absorptions at 346.6 and 340.4 nm:

$$\frac{OD^{*Ar}}{OD^{*N_2}} = 1 + \frac{1}{k_0}\left(k_1'+\frac{k_2'k_4'}{k_5'}\right)[N_2] \qquad (VIII)$$

$$\frac{OD^{0Ar}}{OD^{0N_2}} = 1 + \frac{1}{k_0}\left(k_1'+\frac{k_2'k_4'}{k_5'}\right)[N_2] \qquad (IX)$$

Here, the superscripts Ar and N_2 designate that these values were obtained in Ar and N_2 respectively.

Figure 7 shows the experimental plots for Eqs. (VII), (VIII), and (IX). The straight line obtained shows the validity of the three equations. The half-quenching pressure, which corresponds to the reciprocal of the slope, was calculated to be about 60 Torr.

When a quenching gas is diluted with argon and the total pressure is kept constant, the following Stern-Volmer expression can be obtained:

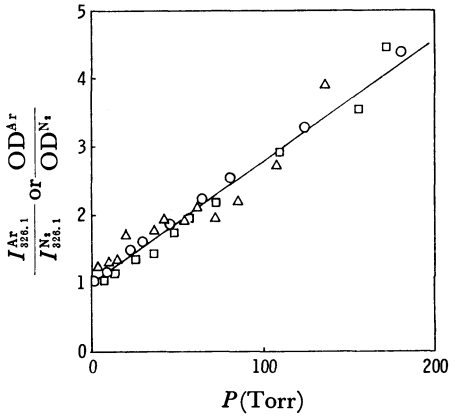

Fig. 7. Experimental plots for Eq. (VII) (○), Eq. (VIII) (△) and Eq. (IX) (□).

$$\frac{I^0_{326.1}}{I_{326.1}} = 1 + \frac{k_1'}{k_0}[N_2] + \frac{k_4'[N_2]}{k_0}\,\frac{k_2[Ar]+k_2'[N_2]}{k_4'[N_2]+k_5[Ar]+k_5'[N_2]} \qquad (X)$$

Here, $I^0_{326.1}$ and $I_{326.1}$ are the emission intensities at 326.1 nm in the absence and in the presence of a quencher, N_2. Since $k_5' \gg k_4'$ and $k_2'/k_5' = k_2/k_5$, Eq. (X) can be reduced to the form:

$$\frac{I^0_{326.1}}{I_{326.1}} = 1 + \frac{1}{k_0}\left(k_1'+\frac{k_2'k_4'}{k_5'}\right)[N_2] \qquad (XI)$$

The right-hand side of this equation is exactly the same as those of Eqs. (VII), (VIII), and (IX). The experimental plots obtained with N_2 at various total pressures are shown in Fig. 8, together with the plots obtained by using CO and CO_2 as the quencher. All the plots for each quencher lie on each straight line, and no dependence on the total pressure can be seen. This result strongly suggests that k_0 is independent of the pressure in the range examined. In other words, the lifetime of the $Cd(^3P_1)$ atoms, τ, is independent of the pressure of the foreign gas in the pressure range examined.

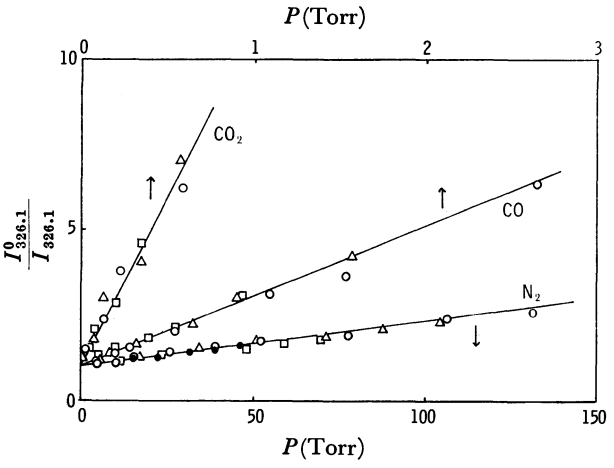

Fig. 8. Stern-Volmer plots for the quenching of the resonance radiation at 326.1 nm by N_2, CO and CO_2. The quenching gas is diluted with argon. For N_2, the total pressures are 210 (○), 140 (△), 94 (□), and 63 (●) in Torr. For CO and CO_2, the total pressures are 80 (○), 48 (△), and 28.5 (□) in Torr.

Table 3. Half-quenching pressures for the resonance radiation at 326.1 nm (Torr)

Quencher	This work	Ref. 10
N_2	73±3	220±3
CO	0.47±0.01	0.34±0.09
CO_2	0.096±0.003	0.06±0.03

Table 3 summarizes the half-quenching pressures calculated from the linear plots in Fig. 8. The value obtained for nitrogen is in fair agreement with that obtained from the plots in Fig. 7. The small discrepancy may be due to the complete neglect of k_4' in relation to k_5' in Eqs. (VII), (VIII), and (IX). The third column in Table 3 shows the half-quenching pressures reported in the previous paper.[10] These values were obtained by paying no attention to the pressure broadening of the absorption lines. Therefore, the values obtained in the present paper should be more reliable.

The authors are indebted to Dr. Soji Tsuchiya of the University of Tokyo for his valuable discussions.

Appendix

By substituting Eq. (V) into Eq. (IV), we can obtain the following equation:

$$\frac{I_a}{OD^0}\varepsilon^0 l = \frac{A}{[M]^2} + \frac{B}{[M]} + C + D[M] \qquad \text{(XII)}$$

The A, B, C, and D constants can be obtained by examining the relationship between $I_a\varepsilon^0/OD^0$ and [M] in the low-, medium-, and high pressure regions. When the pressure of the foreign gas is low, the last term on the right-hand side of Eq. (XII) can be ignored. For this pressure region, the following equation can be obtained:

$$\frac{I_a}{OD^0}\varepsilon^0 l[M]^2 = A + B[M] + C[M]^2 \qquad \text{(XIII)}$$

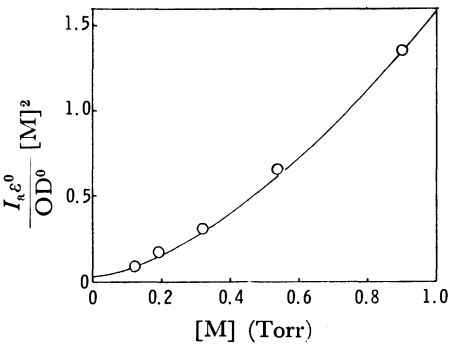

Fig. 9. $I_a\varepsilon^0[M]^2/OD^0$ in arbitrary unit as a function of argon pressure in the low pressure range.

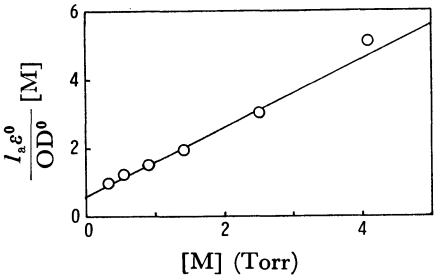

Fig. 10. $I_a\varepsilon^0[M]/OD^0$ in arbitrary unit as a function of argon pressure in the medium pressure range.

In Fig. 9, the relative value of $I_a\varepsilon^0[M]^2/OD^0$ for argon is plotted against [M] for the pressures below 1 Torr. From the curve, the relative values of A, B, and C were obtained. In Fig. 10 the relative value of $I_a\varepsilon^0[M]/OD^0$ for argon is plotted against [M] for the pressure region from 0.4 to 5.0 Torr. A linear relationship was thus obtained. This shows that the first and last terms on the right-hand side of Eq. (XII) can be ignored in this pressure region. From the intercept and the slope of the straight line in Fig. 10, the relative values of B and C can be obtained. These values were found to agree with the values obtained above. Similar treatments were carried out in order to determine the constants, A, B, and C for other foreign gases. The D constant for N_2 was obtained by taking the simple average of the quantity:

$$\{(I_a\varepsilon^0)/OD^0 - (A/[N_2]^2 + B/[N_2] + C)\}/[N_2]$$

in the pressure region from 5 to 200 Torr.

The T←S_0 Absorption of the Acetophenone Crystal

Yoshifumi TANIMOTO, Tohru AZUMI,* and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
**Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Sendai 980*

(Received August 30, 1974)

The polarization and Zeeman splitting of the T←S_0 absorption were measured with the acetophenone single crystal at 4.2 K. From the analyses of the polarization behavior and the Zeeman splitting pattern, it is concluded that the 26110 cm^{-1} band is in-plane polarized and has the character of the n,π^* type transition.

Aromatic carbonyls show interesting properties from both spectroscopic[1-14] and photochemical[15,16] points of view since their lowest π,π^* and n,π^* triplet states are close to each other. Acetophenone is one of the most typical aromatic carbonyls and the nature of its lowest triplet state has been studied by several authors.[2,7,8,10-14] Though there have been a number of studies for this molecule in rigid glass solutions and in mixed crystals, only a couple of papers have been published concerning the crystalline acetophenone.[13,14] From the consideration of absorption intensity, Dym and Hochstrasser[13] asserted that the longest wavelength T←S_0 absorption band at 26108 cm^{-1} is due to the n,π^* type transition. On the other hand, Case and Kearns[14] obtained the T←S_0 absorption spectra of the acetophenone single crystal at 4.2 K by the phosphorescence excitation (PE) method and concluded that its lowest triplet state is of π,π^* type. To clarify this discrepancy, we measured the polarization and Zeeman splitting of the T←S_0 absorption band of the acetophenone single crystal. In our preliminary report[17] on this subject, we indicated that the 26108 cm^{-1} band was due to the π,π^* type transition. Thereafter, we have accurately determined the crystal structure of acetophenone by the X-ray crystal analysis technique.[18] In the present paper, we report the analysis of the polarization and Zeeman splitting data made on the basis of the newly determined crystal structure.

Experimental

Acetophenone single crystals were grown from ethanol solutions. The crystal axes were determined with the aid of the X-ray diffraction technique. Since only thin crystals were obtained, three or four pieces of the crystals were piled up for the measurement of the T←S_0 absorption.

Polarization of the T←S_0 absorption was measured in a usual way. Light from a 500 W xenon lamp was passed through a home-made polyvinyl alcohol-iodine polarizer[19] which was set in front of a sample in liquid helium, and focussed on the sample. Transmitted light was detected by a Spex 1700-II grating monochromator equipped with an EMI 6256S photomultiplier tube.

To obtain a strong magnetic field enough for the measurement of the Zeeman splitting in the T←S_0 absorption bands, a solenoid type superconducting magnet was prepared. A superconducting wire (Supercon T48B, National Research Co.) was coiled on a brass bobbin (20ϕ×80 mm) 15400 turns. Its main properties are as follows: the coil impedance is 90 Ω, the inductance is 7.4 mH at room temperature, the critical field is 50000 Oe, and the critical current is 24 A at 4.2 K.

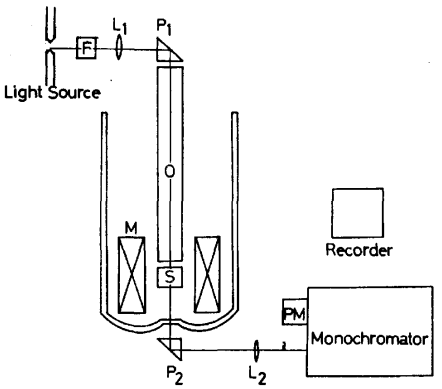

Fig. 1. Experimental setup for the Zeeman splitting measurement.
F, filter; L_1, L_2, lenses; P_1, P_2, prisms; O, optical pipe; S, sample holder; M, superconducting magnet; PM, photomultiplier tube.

Experimental arrangement for measuring the Zeeman splitting in the T←S_0 absorption is schematically shown in Fig. 1. Light from a 1 kW xenon lamp was focussed on a prism and led into a sample surrounded by the superconducting magnet. Transmitted light passing through a window at the bottom of a cryostat was led into a Spex 1700-II monochromator. Magnetic field strength was monitored by a field plate (FP15V1, Siemens A. G.) inserted in the sample holder.

Results and Discussion

Polarization of the T←S_0 Absorption. Figure 2 shows a polarized T←S_0 absorption spectrum observed with the (110) plane of the acetophenone crystal. The

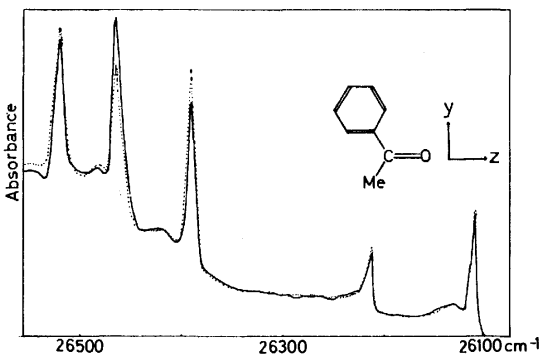

Fig. 2. Polarized T←S_0 absorption spectrum.
Light propagation is perpendicular to (110). The solid and broken lines indicate the absorbances polarized parallel and perpendicular to [1$\bar{1}$1], respectively.

solid and broken lines in the figure show the absorption spectra polarized, respectively, parallel and perpendicular to [1$\bar{1}$1]. As has been reported earlier,[13,14] strong bands appear at 26110, 26389, 26455, and 26520 cm^{-1}.

The observed longest wavelength band at 26110 cm^{-1} has been assigned to the 0–0 band of the transition to the lowest triplet state,[13,14] and we will mainly focus our attention to this band. Polarization ratio ($P=D_{//}/D_{\perp}$) is 1.0±0.3 for this band. Here $D_{//}$ and $D_{\perp}$ are the absorbances for linearly polarized light whose electric vectors are, respectively, parallel and perpendicular to [1$\bar{1}$1]. Molecular axes, x, y, and z are taken to be perpendicular to the molecular plane and perpendicular and parallel to C=O in the plane, respectively (see Fig. 2).

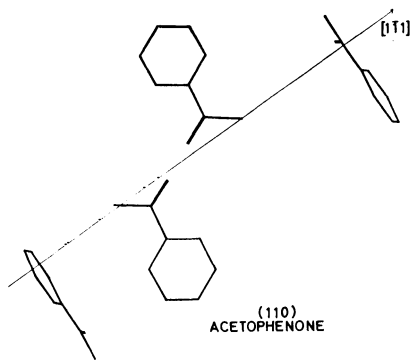

Fig. 3. (110) Projection of the structure of the acetophenone crystal.

The molecular orientation in the acetophenone crystal was determined by the X-ray crystal analysis technique.[18] The projection of the molecules in a unit cell on the (110) plane is shown in Fig. 3. From the crystal analysis data and the observed polarized spectrum shown in Fig. 2, it is concluded that the transition under consideration is polarized within the molecular plane. In order to determine the direction of the polarization within the plane, the polarization values (P) for various directions of the polarization in the plane are calculated and are shown in Fig. 4. From the figure the direction of the polarization under consideration is concluded to be inclined by ~40° or ~110° from y axis. The former and the latter directions of the polarization will be denoted by Polarizations I and II, respectively.

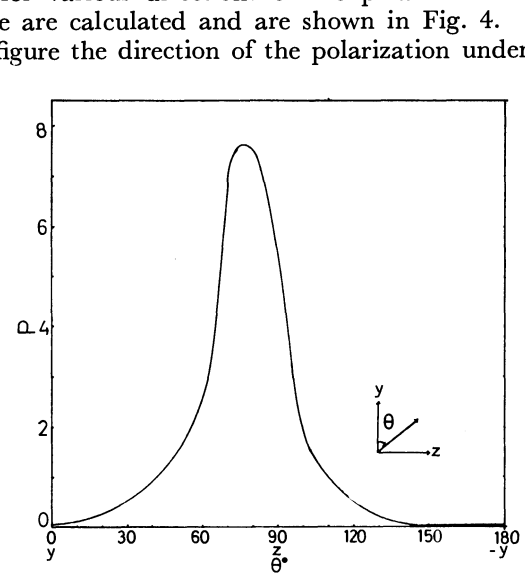

Fig. 4. Polarization ratio (P) calculated in the molecular plane.

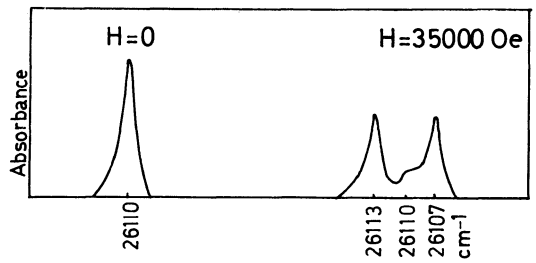

Fig. 5. Absorption profiles of the 26110 cm^{-1} band measured under the magnetic field of zero and of 35000 Oe. The field is perpendicular to (110).

The Zeeman Effect upon the T←S_0 Absorption. In Fig. 5, the Zeeman splitting pattern for the 26110 cm^{-1} band of the T←S_0 absorption at 4.2 K is shown. The directions of magnetic field and light propagation are perpendicular to the (110) plane. Magnetic field strength is 35000 Oe.

To obtain the relative intensities among the Zeeman levels quantitatively, we analyzed the spectrum by the computer simulation method. The band shape is assumed to be of the Gaussian type. Then, absorbance $D°(a)$ at a cm^{-1} at zero field, is written as follows:

$$D°(a) = D_{max} \exp\left(-(a-m)^2/2\sigma^2\right)$$

At high field, the pattern of the splitting may reasonably be calculated by neglecting the contribution from the zero-field splitting parameters. Assuming that for each split component σ is invariant with magnetic field, absorbances of the split sublevels, $D_1(a)$, $D_0(a)$, and $D_{-1}(a)$, are expressed as follows:

$$D_0(a) = \alpha\beta \exp\left(-(a-m)^2/2\sigma^2\right)$$

$$D_{\pm1}(a) = \beta \exp\left(-(a-m\mp\Delta E)^2/2\sigma^2\right)$$

where, $\alpha=D_0(m)/D_{\pm1}(m\pm\Delta E)$, ΔE is Zeeman energy (cm^{-1}), and β is the normalization term which keeps the total integrated intensity invariant with magnetic field. By comparing the observed and calculated band shapes, the value of α was determined to be 0.22 for the 26110 cm^{-1} band.

Characteristics of the 26110 cm^{-1} Band. Let us consider the character of the 26110 cm^{-1} band in detail. First, we examine the polarization of the absorption. Assuming that the acetophenone molecule is planar, the expected polarizations of the T←S_0 absorptions are shown in Table 1. The experimental result that the observed absorption is polarized in-plane indicates that the relevant triplet state is one of either T_y and/or T_z of the n,π^* state or T_x of the π,π^* state. Usually, the former possibility is assumed on the basis of the estimated magnitude of the matrix elements. However, we shall try to give the assignments from the experimental view points.

To make the assignment more concrete, let us consider the α value of the Zeeman splitting of the transition obtained above. Let absorbances for the transitions

TABLE 1. POSSIBLE POLARIZATION OF THE $T \leftarrow S_0$ TRANSITION

Triplet state	Active sublevel	Polarization
n, π^*	T_x	out-of-plane
	T_y, T_z	in-plane
π, π^*	T_x	in-plane
	T_y, T_z	out-of-plane

Here we assumed only that the acetophenone molecule is planar. The contribution of the three-center integrals is considered in the spin-orbit coupling calculation.

of the Zeeman levels, T_1^i, T_0^i, and T_{-1}^i of the i'th molecule in the crystal be denoted by D_1^i, D_0^i, and D_{-1}^i.[20] (We hereafter use the superscript and subscript, i, to denote the position of the molecule in the crystal.) We obtain the following equation:

$$\begin{bmatrix} D_1^i \\ D_0^i \\ D_{-1}^i \end{bmatrix} = c \begin{bmatrix} \frac{1-l_i^2}{2} & \frac{1-m_i^2}{2} & \frac{1-n_i^2}{2} \\ l_i^2 & m_i^2 & n_i^2 \\ \frac{1-l_i^2}{2} & \frac{1-m_i^2}{2} & \frac{1-n_i^2}{2} \end{bmatrix} \begin{bmatrix} U_x^i \\ U_y^i \\ U_z^i \end{bmatrix} \quad (1)$$

where, c is a proportionality constant, l_i, m_i, and n_i are direction cosines of the molecular axes, x, y, and z, respectively, with regard to the field direction, and U_x^i, U_y^i, and U_z^i represent the contribution to the transition intensity from the respective sublevels at zero field.

Since, in a crystal, α is represented by the equation,

$$\alpha = \sum_i D_0^i / \sum_i D_{\pm 1}^i \quad (2)$$

α can be calculated with the aid of crystallographic and polarization data. Assuming that only one sublevel is the active one,[21] α's were calculated as shown in Table 2. From the table, it is clear that there are

TABLE 2. THE VALUES OF α CALCULATED FOR THE ACETOPHENONE CRYSTAL

Active sublevel	Polarization I	Polarization II
T_x	2.17	10.7
T_y	0.18	0.18
T_z	1.47	0.16

three cases in which the calculated α-values are reasonably close to the observed value for the 26110 cm^{-1} band (α=0.22), *i.e.*, the active sublevel, T_y, with Polarizations I and II (calculated α's are both 0.18), and the active sublevel, T_z, with Polarization II (calculated α is 0.16). Thus, we may conclude that the active sublevel is not T_x. Then, in conjunction with the polarization data discussed above, the possibility of π,π^* state is discarded. It is therefore concluded that the observed transition at 26110 cm^{-1} has the character of the n,π^* type, and the active sublevel is either T_y or T_z. Unfortunately, from the experiments discussed in this paper, we are unable to determine which of the sublevels T_y or T_z is the active state.

Our conclusion on the 26110 cm^{-1} band agrees with the assertion made by Dym and Hochstrasser,[13] but disagrees with the conclusion of Case and Kearns.[14] The result of the latter authors seems to be ambiguous since they did not use the accurate crystal structure of acetophenone for the analysis of the polarized PE spectra.

We also analyzed the 26389 cm^{-1} band which was assigned to the n,π^* triplet state by Case and Kearns. From $P=0.8\pm0.3$ and $\alpha=0.27$, this band has also the character of the n,π^* type transition.

In the preliminary paper,[17] we calculated α with the aid of Eq. (1) on an inadequate assumption,[22]

$$U_j^i = U_j \quad (j=x, y, z)$$

and were led to the misinterpretation that the 26110 cm^{-1} band had the character of the π,π^* type transition.

It may be emphasized that our result is concerned only with the transition character of the longest wavelength band at 26110 cm^{-1} and cannot give any conclusion about the nature of the upper state of this band itself. In this connection, it may be necessary to mention the result obtained by Cheng and Hirota[12e] who studied the dynamic properties of the lowest triplet state of the acetophenone trap in its crystal with the aid of the microwave phosphorescence double resonance technique. From the analysis of the results, they concluded that the lowest triplet state is the π,π^* state mixed with the nearby n,π^* triplet state and that the main emissive spin sublevel is T_z. As they discussed, however, the radiative character of the lowest triplet state is mainly controlled by the n,π^* component which contributes to the state only by a few per cent. Therefore, our result on the transition character of the 26110 cm^{-1} band is not inconsistent with their result.

We thank Professor Noboru Hirota, State University of New York at Stony Brook, and Dr. Hisaharu Hayashi, The Institute of Physical and Chemical Research, for their helpful advice.

An Electron Spin Resonance Study of the Anion Radicals of Some Nitrotropolonates and 2-Methoxy-5-nitrotropone

Yusaku IKEGAMI and Shuichi SETO

Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira 2-1-1, Sendai 980

(Received September 2, 1974)

The anion radicals of 5-nitro-, 3-nitro-, and 3,5-dinitro-tropolonates and of 2-methoxy-5-nitrotropone were generated electrolytically in *N,N*-dimethylformamide. Hyperfine structures of these ESR spectra were reasonably interpreted with the spin density calculations. The results for the 3-nitro- and 3,5-dinitro-tropolonates suggested that the 3-nitro groups were twisted about 40 and 55°, respectively, from the ring plane.

Studies on the anion radicals of tropone[1] and its some derivatives[2] revealed that the anion radicals of tropone derivatives are usually unstable and could only be generated by the electrolytic reductions for some tropones under the presence of a large amount of supporting electrolyte. Since nitro-substituted aromatic compounds are easily reduced to form the stable anion radicals, the generation of the anion radicals of nitro-substituted tropone derivatives will be expected. As a part of the electron spin resonance (ESR) study on the nonbenzenoid aromatic radicals, the electrolytic generations of the anion radicals from 5-nitro-, 3-nitro-, and 3,5-dinitro-tropolones and 2-methoxy-5-nitrotropone have been successfully examined. This paper reports the ESR spectra and the structures of these radicals. The McLachlan calculation[3] was adopted to the spin density estimation in order to interpret the ESR hyperfine structures.

Results and Discussion

5-Nitrotropolonate Anion Radical. Figure 1 shows the ESR spectrum of the radical generated by the electrolysis of a 0.007 M solution of 5-nitrotropolone in degassed *N,N*-dimethylformamide (DMF) at *ca.* 2.0 V, using tetra-*n*-propylammonium perchlorate as the supporting electrolyte. Hyperfine structure of the spectrum is readily interpreted in terms of splitting from one nitrogen nucleus and two sets of pairs of equivalent protons. The observed splitting constants are given in Table 1. Since tropolones are usually strong acid like phenols, the formation of radicals would be understood in a similar manner to the formation of phenolate and benzoate anion radicals, such as nitrophenolate and 4-cyanobenzoate anion radicals,[4-6] which were produced by the electrolyses of the corresponding phenols and benzoic acids in the presence of a large amount of supporting electrolyte. Accordingly, the equivalence of two sets of protons in the radical produced should be explained with the assumption that the radical has a symmetrical structure arising from a resonance form I, rather than a structure of tropolone anion radical in which a highly mobile tautomerism with the jump of the hydroxylic proton would be required.

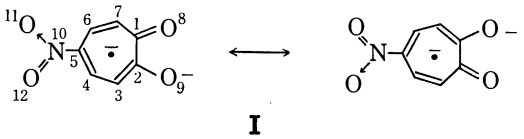
a) With the relation $a_i=Q^H_{CH}\rho_i$, in which $|Q^H_{CH}|$=23.7 G was adopted. b) Calculated by the McLachlan procedure. The following parameters were adopted: $\alpha_8=\alpha_9=\alpha+2.0\beta$, $\beta_{1,8}=\beta_{2,9}=1.8\beta$, $\beta_{C-N}=1.2\beta$, $\alpha_N=\alpha+2.2\beta$, $\alpha_{NO}=\alpha+1.4\beta$, $\beta_{N-O}=1.67\beta$, and $\lambda=1.2$.



I

The Hückel MO calculations with the approximate configuration interaction treatment of McLachlan were carried out for the 5-nitrotropolonate anion radical in order to estimate the spin density distribution and to assist in assigning the splitting constants. The values of parameters used here for the nitro group were taken from the work by Rieger and Fraenkel.[5] Because of the lack of reliable MO parameters for the C⋯O group in the tropolonate ion, the parameters for this group in formula I were varied over the following ranges: $\alpha+1.0\beta\leqq\alpha_8=\alpha_9\leqq\alpha+2.2\beta$ and $1.0\beta\leqq\beta_{1,8}=\beta_{2,9}\leqq2.0\beta$, where α and β are the Coulomb and resonance integrals, respectively, for benzene. All other bond length variations were neglected, since the bond alternation in the seven-membered anion ring was not worthy of consideration even for the tropone anion radical.[1] To find out the parameters appropriate to

the C⋯⋯O group, the calculations were compared with the experimental splitting constants for the protons, adopting the relation $a_i=Q^H_{CH}\rho_i$, where $|Q^H_{CH}|=23.7$ G. A good agreement with the experimental values was obtained by using the parameters $\alpha_8=\alpha_9=\alpha+2.0\beta$ and $\beta_{1,8}=\beta_{2,9}=1.8\beta$.[7] The spin densities are given in Table 1. The calculation of $a^{NO_2}_N$ with a relation $a^{NO_2}_N\approx Q_N\rho_N+2Q_{ON}\rho_{O'}$,[5] where Q_N and Q_{ON} have the values of 99 ± 10 and 36 ± 6 G, respectively, was also in satisfactory agreement with the experimental value (calcd 8.53 and exptl 8.04 G).

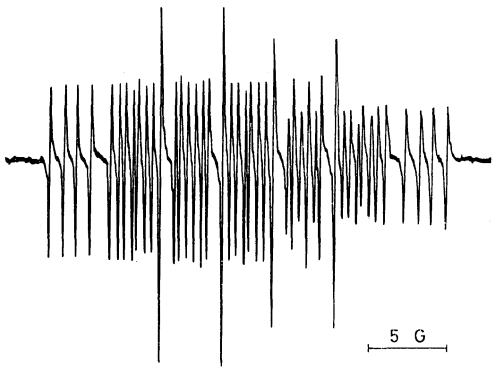


Fig. 2. ESR spectrum of the 3-nitrotropolonate anion radical generated by the electrolytic reduction in DMF (g=2.0039).

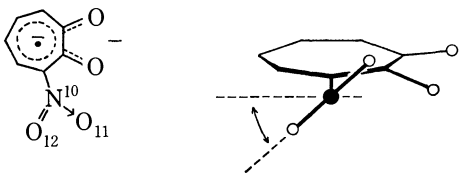
a) See the footnote a) in Table 1. b) Calculated by the McLachlan procedure. The values of parameters are the same as those used for the 5-nitro isomer except $\beta_{C-N}=1.2\beta\cos 40°$.

3-Nitrotropolonate Anion Radical. Electrolytic reduction of 3-nitrotropolone in DMF generated the stable anion radical which exhibited the ESR spectrum shown in Fig. 2. Hyperfine structure of this spectrum is analyzed with five splitting constants given in Table 2 and is interpreted as arising from the structure IIa. The McLachlan calculation was then applied to this structure. Using the same parameters with those for the 5-nitro isomer, however, the spin density calculations did not show a good agreement with the experimental values. It was then assumed that the disagreement is caused by the twisting of the nitro group from the seven-membered ring plane, as depicted by IIb.



IIa IIb

In order to confirm the effect of steric hindrance between the nitro group and the CO oxygen on the ring proton splittings, the spin densities were calculated with the modification that the resonance integral of the C–N bond was estimated to be $1.2\beta\cos\theta$, where θ is a twisting angle between the nitro group and the ring. The dependence of the spin densities at the ring positions 4, 5, 6, and 7 on the angle θ is shown in Fig. 3. As seen from the figure, the theoretical spin densities at the positions 4 and 6 approach each of the corresponding experimental spin densities around 37 and 43°, respectively. The calculated values for the positions 5 and 7 with $\theta=40°$ were not far from the corresponding experimental values though some deviations are recognized. Allowing some deviations in the calculations from the experimental values, the McLachlan calculation led to the conclusion that the nitro group was twisted about 40° from the ring plane. The spin densities calculated by using $\beta_{3,10}=0.92\beta$ corresponding to this twisting angle are given in Table 2.

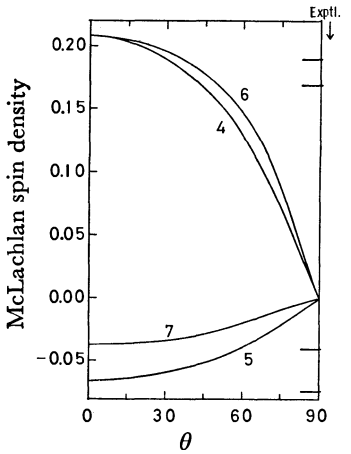


Fig. 3. Spin densities ρ calculated for the 3-nitrotropolonate anion radical by the McLachlan procedure as a function of the twisting angle θ between the ring and the nitro group. The numbers on the curves indicate the positions in the radical. See the footnote in Table 2 for the parameters in the calculation.

3,5-Dinitrotropolonate Anion Radical. The 3,5-dinitrotropolonate anion radical was produced by the electrolysis of the corresponding tropolone in DMF, similarly to the above 5- and 3-nitrotropolonates. The ESR spectrum of the radical shown in Fig. 4 is analyzed with five splitting constants, two of which represent the couplings with two different nitrogen atoms and the others the couplings with three different hydrogen atoms.

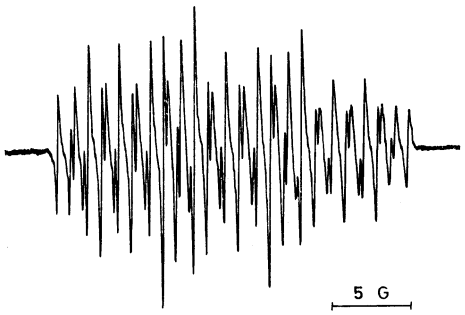

Fig. 4. ESR spectrum of the 3,5-dinitrotropolonate anion radical generated by the electrolytic reduction in DMF (g=2.0043).

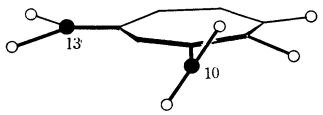
With reference to the structures of the 5- and 3-nitrotropolonate anion radicals, it is readily assumed that the nitro group at 3-position is twisted considerably from the ring plane while the nitro group at 5-position is co-planar with the ring, as depicted by III. In order to confirm the twisting of the nitro group and to assist in assigning the splitting constants, the spin density calculations were carried out with the modification in which the resonance integral of the C–N bond at 3-position was estimated to be $1.2\beta \cos\theta$. The nitro



III

group at the position 5 was treated to be co-planar with the ring. Figure 5 shows the dependence of the spin densities at ring positions 4, 6, and 7 and at the nitrogen atoms. As seen from the figure, the theoretical spin densities at the positions 4 and 6 approach each of the corresponding experimental values around 58 and 50°, respectively. Allowing some deviations in the MO calculation for such a complex molecule, it may

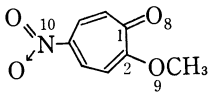
a) See the footnote a) in Table 1. b) McLachlan spin density. The values of parameters are the same as those used for the 5-nitrotropolonate anion radical except β_{C-N} (for 3-NO_2) = $1.2\beta \cos 55°$.

be concluded that the nitro group at 3-position is twisted about 55° from the ring plane. The spin densities calculated with $\beta_{3,10}=0.69\beta$ corresponding to this angle are given in Table 3. A remarkable difference of the splitting constants at 3- and 5-nitrogen atoms is reasonably understood from the contrast between the calculated spin densities at 3- and 5-nitro groups.

2-Methoxy-5-nitrotropone Anion Radical. Treatment of 2-methoxy-5-nitrotropone (IV) with lithium or sodium metal in degassed 1,2-dimethoxyethane showed neither change in its color nor the appearance of ESR signal. On the other hand, the electrolytic reduction



IV

of IV in DMF showed a strong ESR signal, while the yellow color of the solution turned dark brown gradually during the electrolysis. The ESR spectrum is shown in Fig. 6 and the hyperfine structure was analyzed with six splitting constants listed in Table 4. The analysis was confirmed by the spectral simulation assuming a half-width of 100 milligauss for the lines.

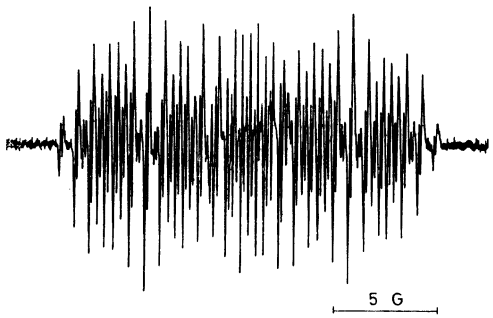


Fig. 6. ESR spectrum of the 2-methoxy-5-nitrotropone anion radical generated electrolytically in DMF (g= 2.0035).

10 (NO_2)	3.36		0.1293
11, 12 (NO_2)			0.1225

a) See the footnote a) in Table 1. b) McLachlan spin densities calculated with the following parameters: $\alpha_8=\alpha+1.2\beta$, $\beta_{1,8}=1.8\beta$, $\alpha_9=\alpha+2.0\beta$, $\beta_{2,9}=0.8\beta$, $\alpha_N=\alpha+2.2\beta$, $\alpha_{NO}=\alpha+1.4\beta$, $\beta_{C-N}=1.2\beta$, $\beta_{N-O}=1.67\beta$, and $\lambda=1.2$.

The nitrogen splitting constants (4.88 G) was readily assigned according to the type of splitting. Other assignments were given on the basis of the spin density calculation.

On account of the complexity of the molecule IV, choice of the parameters for the calculation affects very much on the spin density distribution. But, the treatments for the nitrotropolonates above-mentioned, 2-methoxytropone,[2] and 2-methoxyazulene[8] anion radicals may be helpful to the selection of the parameters, except those for the carbonyl group which could not be evaluated appropriately in the study on the tropone anion radical.[1] Therefore, the parameters for the carbonyl group in IV were varied over the following ranges: $\alpha+1.0\beta \leqq \alpha_8 \leqq \alpha+2.0\beta$ and $1.0\beta \leqq \beta_{1,8} \leqq 2.0\beta$. The values $\alpha_9=\alpha+2.0\beta$ and $\beta_{2,9}=0.8\beta$ were chosen for the methoxy group. Assuming the co-planarity of the nitro group with the ring plane, a satisfactory agreement between the calculated and experimental spin densities was finally obtained when the parameters, $\alpha_8=\alpha+1.2\beta$ and $\beta_{1,8}=1.8\beta$, were adopted. The values are given in Table 4. Thus, the ESR hyperfine structure of the 2-methoxy-5-nitrotropone anion radical was reasonably interpreted.

During the course of the electrolytic generation of the anion radical of IV in DMF, the gradual transformation of the radical into a second paramagnetic species was observed in the ESR spectrum. The ESR spectrum of the second species fits in well with that shown in Fig. 1. This indicates that the electrolysis of IV for a long period led to the demethylation forming the 5-nitrotropolonate anion radical. The reaction may be interpreted on the analogy of the demethylation of 2,4,6-trinitroanisole in the presence of triethylamine and an aprotic solvent.[9]

Experimental

The materials, 5-nitrotropolone, mp 154 °C, 3-nitrotropolone, mp 197 °C, 3,5-dinitrotropolone, mp 174 °C, and 2-methoxy-5-nitrotropone, mp 232 °C, were prepared by the method of Nozoe *et al.*[10] and each recrystallized from methanol. *N,N*-Dimethylformamide (DMF) was degassed by at least five freezing-pumping cycles after being purified and distilled on to a molecular sieve which had been flame-dried in a vacuum.

Electrolytic generation of each free radical was performed by using a cell with platinum electrodes at room temperature. Tetra-*n*-propylammonium perchlorate was used as the supporting electrolyte.

The ESR spectra were measured with a Hitachi X-band ESR spectrometer, model 771, using a field modulation of 100 MHz. Analyses of the ESR hyperfine structures were confirmed by spectral simulation, for which a JEOL spectrum computer, JEC-5, was used. Numerical calculations were carried out at the Computer Center of Tohoku University.

The authors are grateful to Professor Takehiro Abe for his helpful discussion and to Dr. Hidetoshi Watanabe for his cooperation throughout the study.

Electrical Properties of TeO_2.[1] I.

Kazuo Doi, Tomoaki Sasaki, and Kenzo Hijikata

Institute of Inorganic Chemistry, Department of Chemistry, Nihon University, 3-25-40 Sakurajosui, Setagaya-ku Tokyo 156

(Received December 15, 1973)

The electrical conductivity σ of polycrystalline tellurium dioxide (paratellurite; purity: 6-nine) was measured as a function of the oxygen partial pressure (1—760 mmHg) at temperatures between 475 and 550 °C. The relations between the experimental values of $\log \sigma$ and $1/T$ were well represented by straight lines, giving the apparent activation energy of about 1.36 eV. The oxygen-pressure dependence of the isothermal conductivity was well expressed by the $\sigma \propto P_{O_2}^{1/6}$ relation; this may be interpreted by assuming that electron holes with fully-ionized oxygen interstitials predominantly act as charge carriers. The p-type behavior in the conduction process was also confirmed by thermal emf measurements.

There have been a few papers on the piezoelectric,[2] elastic and photoelastic[3] characteristics of tellurium dioxide. There have not, however, been any reports on the electrical conductivity as a function of the oxygen partial pressure or on whether the predominant semiconductivity is of the p- or n-type in tellurium dioxide. Therefore, the aim of this investigation was to observe the temperature and oxygen-pressure dependences of the electrical conductivity for highly pure polycrystalline paratellurite, and, on the basis of these, to obtain some information on the defect type of paratellurite, which had not yet been elucidated.

Experimental

Specimens. Highly pure powders of paratellurite were prepared from 6-nine tellurium metal (Osaka Asahi Metal Co., Ltd.). The white precipitate which was obtained by dissolving the tellurium metal into dilute pure nitric acid (Super Special Grade: Wako Pure Chemical Industries, Ltd.), was filtered, washed fully with distilled water, and dried in a vacuum at 80 °C. The dried powders were heated to 400 °C for 1 hr in a Pt-crucible to drive off the residual nitric acid. The X-ray diffraction patterns of the resulting powders indicated a well-crystallized structure of paratellurite. Pellets (10 mm in diameter and 3 mm thick) were made by compacting the powders at 2 ton/cm^2 and by then sintering the compacts for 150 hr at 630 °C in the Pt-crucible in air. The densities of the sintered disks were approximately 64% of the theoretical yield.

The impurities of the specimens before and after the conductivity measurements were found to be Mg and Cu by means of emission spectrographic analysis,[4] and no other elements were detected. Chemical analysis indicated Mg: 0.5 ppm and Cu: 0.0 ppm. The specimens before and after the measurements were both estimated to be 6-nine purity.

Measurements. The electrical conductivity was measured by a two-terminal method in a comparatively low temperature range so as to be able to neglect the influence of the evaporation of tellurium dioxide on the measurements.

A detailed schematic diagram of the apparatus for electrical conductivity measurements has been presented elsewhere.[5] Two thermocouples (0.3 mmϕ Pt–Pt13%Rh) were welded to each electrode of a platinum plate. The platinum arms of the thermocouples were used to measure the AC and DC conductivities and the Seebeck effect.

The various partial pressures of oxygen were provided by oxygen-nitrogen tank mixtures (dew points: −50 °C).

The specimen temperature was controlled within ±0.15 °C by regulating the SCR power supply. The AC conductivity was taken by means of a bridge (Type TR-1C: Ando Electric Co., Ltd.), applying selected frequencies in the range of 0.03—3 kHz to the specimens in all runs, while the DC conductivity was determined on an electrometer (Type TR-8651: Takeda Electric Co., Ltd.). The equilibrium value between the specimen conductivity and the oxygen partial pressure in the surrounding atmosphere was determined after the specimen resistance had been stabilized for 2 hr; this value remained constant for 30 hr or more.

The conductivity values were obtained with a good reproducibility in all the cases tried.

Results

The DC conductivity data nearly coincided with those at 30 Hz, as is shown in Fig. 1. The measured conductivity value was reproducible for both increasing and decreasing temperatures and for the ambient oxygen partial pressures.

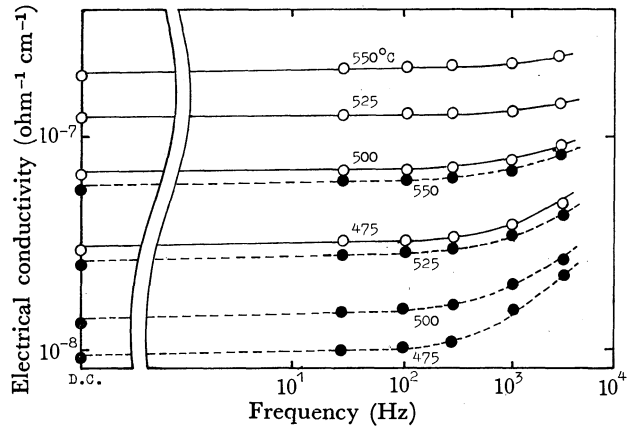

Fig. 1. Frequency dependence of the electrical conductivity TeO_2.
—○—○—: the values measured under oxygen gas (760 mmHg)
—●—●—: the values under nitrogen gas (760 mmHg)

Plots of $\log \sigma$ *vs.* $1/T$ at various oxygen partial pressures are shown in Fig. 2. In the temperature range examined, the plots were well represented by a straight line at each oxygen pressure. From these results, the apparent activation energy for the electrical conductivity of the paratellurite was calculated as about 1.36 eV in all the atmospheres tested. The oxygen

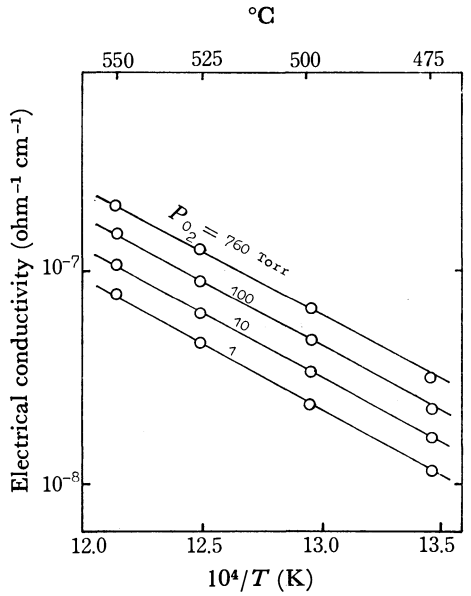

Fig. 2. The electrical conductivity of TeO_2 (at 30 Hz) *vs.* the reciprocal of absolute temperature. $P_{O_2}+P_{N_2}=760$ mmHg

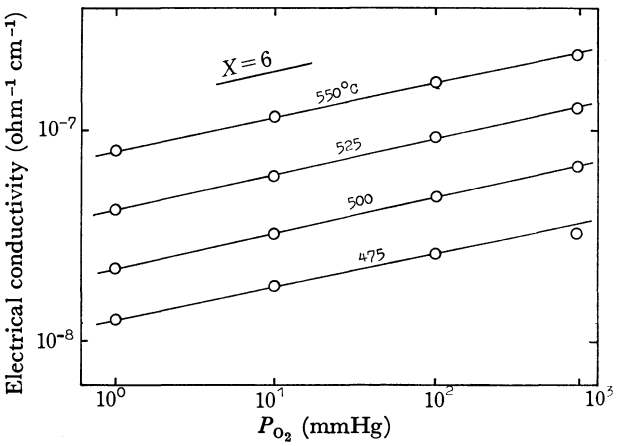

Fig. 3. The relation between the electrical conductivity of TeO_2 (at 30 Hz) and the oxygen partial pressure. X is defined in the conductivity expression $\sigma \propto P_{O_2}^{1/X}$.

partial pressure dependence of the electrical conductivity for the polycrystalline paratellurite is indicated in Fig. 3.

As may be seen, the electrical conductivity increased with an increase in the oxygen partial pressure in the surrounding atmosphere; therefore, it seems that the semiconductive nature of paratellurite is the p-type under the present experimental conditions. The p-type character of paratellurite was also confirmed from the sign of the Seebeck voltages under the temperatures examined.

The linear relationship of the conductivity isotherm can be written as $\sigma=K\cdot P_{O_2}^{1/X}$, with $X=6$.

Discussion

It could be assumed that the contamination of the specimen by its surroundings and the evaporation of the specimen were negligible in the present investigation, because a linear relationship between $\log\sigma$ and $1/T$ was obtained with a good reproducibility for both increasing and decreasing temperatures under ambient oxygen partial pressures, as may be seen in Fig. 2.

The coincidence of the DC conductivity data with those of AC (at 30 Hz) indicated that the predominant semiconduction for the paratellurite is electronic rather than ionic for the oxygen partial pressure and temperature range examined.

Considering the purity of the specimen used in this study, it may be assumed that the influence of the impurities on the pressure dependence of the conductivity is negligible.

The electrical conductivity increased with an increase in the oxygen partial pressure at each temperature, and the electrical conductivity was expressed as a function of the oxygen partial pressure by the relation: $\sigma=K\cdot P_{O_2}^{1/6}$.

If this character were intrinsic behavior, it could be determined by applying the Baumbach-Wagner law[6] whether the predominant defect is cation vacancies or anion interstitials resulting from the deviation of stoichiometry.

1) Cation-vacancy Model.

$$O_2(\text{gas}) \rightleftarrows 2O(\text{lattice}) + Te_v^{+m} + m\oplus \qquad (1)$$

where Te_v^{+m} is the cation vacancy and $\oplus$, the electron hole, and where the degree of ionization, m, takes integral values up to 4.

$$\text{Then,} \quad K'\cdot P_{O_2} = [Te_v^{+m}][\oplus]^m \quad m = 1, 2, 3, 4. \qquad (2)$$

Here, K' is an equilibrium constant and the square brackets indicate the concentration. If the electroneutrality condition can be simplified as $m[Te_v^{+m}]=[\oplus]$,

$$\text{then,} \quad \sigma = [\oplus] \propto P_{O_2}^{1/m+1}. \qquad (3)$$

Therefore, the cation-vacancy models have oxygen-pressure dependences of 1/2, 1/3, 1/4, and 1/5 ($m=$ 1, 2, 3, 4).

2) Anion-interstitial Model.

$$1/2O_2(\text{gas}) \rightleftarrows O_{\text{int}}^{-n} + n\oplus \qquad (4)$$

where O_{int}^{-n} is the oxygen interstitials; the degree of ionization, n, may be 1 or 2. Applying the mass action law,

$$K''\cdot P_{O_2}^{1/2} = [O_{\text{int}}^{-n}][\oplus]^n \qquad (5)$$

If the electroneutrality condition is now shown as:

$$n[O_{\text{int}}^{-n}][\oplus], \text{ then } [\oplus] \propto P_{O_2}^{1/2(n+1)} \qquad (6)$$

Thus, the oxygen-interstitial model has a pressure dependence of 1/4 or 1/6 ($n=1, 2$).

The slope, 1/6 ($X=6$), corresponded to the predominance of doubly-ionized oxygen interstitials, with electron holes as the charge carriers, as has been described above.

This suggests that oxygen atoms (ions) from oxygen gas in the surrounding atmosphere dissolve into the crystal of paratellurite. The crystal structure of paratellurite has been studied by several authors.[7,8] Lindqvist[9] suggested that paratellurite is four-fold coordinated by a polyhedron, being a somewhat distorted trigonal bipyramid with bond distances of

$Te-O_{eq}=1.90\pm0.02$ Å and $Te-O_{ax}=2.08\pm0.02$ Å, and lacking one atom in the equatorial position.

Therefore, it can be inferred that the oxygen atoms (ions) predominantly penetrate into these lacking sites in the crystal of paratellurite.

The authors wish to thank Dr. Hajime Kishi, Mr. Ko Yokomizo, and Mr. Takeo Hirasawa, Mitsubishi Central Research Institute, Mitsubishi Metal Corp., Oomiya, Japan, for their spectrographic and chemical analyses.

Nuclear Magnetic Resonance Studies of Bicyclic Thiophene Derivatives. I. Ring Current Effects of the Benzene Ring on the H_α and H_β Signals of the Thiophene Ring in Benzoylthiophene, Thienopyrimidine and Thienodiazepine Derivatives

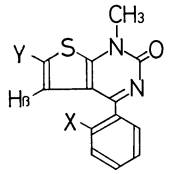
Toshiyuki HIROHASHI, Shigeho INABA, and Hisao YAMAMOTO

Takarazuka Research Laboratories, Sumitomo Chemical Co., Takatsukasa, Takarazuka, Hyogo 665

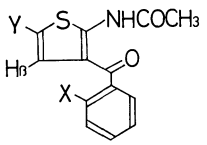
(Received March 14, 1974)

Various thiophene derivatives such as 4-phenylthienopyrimidines (**1**), 2-acetylamino-3-benzoylthiophenes (**2**), 5-phenyl-1,4-thienodiazepines (**3**) and 5-phenyl-1,4-thienodiazepine-4-oxides (**4**) have been prepared. Their proton magnetic resonance spectra show that H_α and H_β of the thiophene ring become more shielded with an increase in bulk of *ortho* substituent of the benzene ring. This is attributed to the shielding effect of the benzene ring; a steric repulsion between *ortho* substituent of the benzene ring and some atoms on another moiety of each molecule. Such a repulsion should bring the benzene ring out of the plane of the thiophene ring. The degree of shielding on H_β by the benzene ring is found to increase in the order **1**<**2**<**3**<**4**. This can be taken to indicate that the amount of steric repulsion depends not only on the bulk of *ortho* substituent of the benzene ring but also on the geometry of each ring system of **1**—**4**.

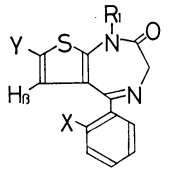
From pharmaceutical interest, we have prepared a number of thiophene derivatives including 4-phenylthienopyrimidines (**1**), 2-acetylamino-3-benzoylthiophenes (**2**), 5-phenyl-1,4-thienodiazepines (**3**), and 5-phenyl-1,4-thienodiazepine-4-oxides (**4**). In order to



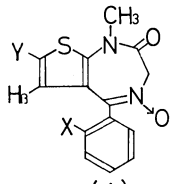
(1)



(2)

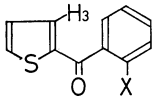


(3)



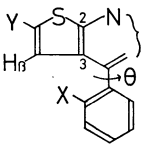
(4)

study the correlation between the biological activity and conformation of the molecules, we made studies by means of NMR spectroscopy. It was reported by Martin *et al.*[1-3] that H_3 in 2-benzoylthiophenes (**5**)



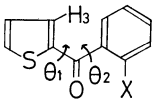
(5)

becomes more shielded with an increase in bulk of the *ortho* substituent (X) of the benzene ring. They found that, when a bulky substituent (X) is introduced, the dihedral angle between the thenoyl plane and benzene plane (*i.e.* θ_2 in formula [II]) is increased, and as a result, the shielding effect on H_3 by the benzene ring becomes more pronounced. H_β of **1**—**4** corresponds to H_3 of 2-benzoylthiophene **5**, since both protons are in close proximity with the benzene ring. However, compounds **1**—**4**, in which C=O or C=N moiety is fixed nearly co-planar with the thiophene plane by a ring formation as shown by formula [I], have a freedom of internal rotation (*i.e.* torsional angle between the

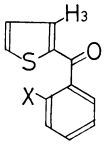


[I]

benzene and thiophene planes; θ in formula [I]). In **5**, there are two internal rotation axes (see θ_1 and θ_2 in formula [II]). Thus, there are two possible limiting



[II]

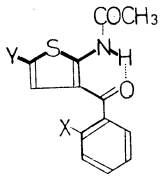


[III]

conformations of [II] and [III] for this type of compound.[2] In [III], it is apparent that the ring current effect of the benzene ring on H_3 should not be great. The chemical shifts of H_β in compounds **1**—**4** can therefore be correlated with the torsional angle θ more simply than the correlation between the chemical shifts of H_3 in compound **5** and the torsional angle θ_2. In this paper, the results of our proton-magnetic resonance measurement of compounds **1**—**4** are reported with interpretation in terms of the conformation of the compounds.

Results

NMR data for the thiophene derivatives are given in Tables 6—9. The signals of H_α and H_β of the thiophene ring show a simple AB type coupling. By substituting H_α with chlorine, we can easily tell which chemical shift is caused by H_β. High field shift of H_β by the chlorination is found to amount to 0.15 ppm. This assignment is supported by the fact that the H_α signal of the thiophene ring in compound **2** shows an extra doublet due to coupling with an amide proton (Table 7). The carbonyl oxygen of **2** is considered to form an intramolecular hydrogen bonding with an amide proton to form a six membered ring as represented by formula [IV]. This is judged from our



[IV]

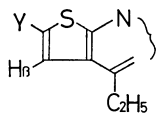
finding the amide proton signal at an extraordinarily low field (11.9±0.1 ppm). Gribble and Bousquet found the amide proton signal at about the same position in 2-acetylamino-benzophenone.[4] When Y is a hydrogen, H_α couples with the amide proton (J=0.8 Hz) through five zig-zag bonds (thick lines, [IV]). This supports the postulation of the intramolecular hydrogen bonding.[5,6] From Tables 6—9 it is evident that H_α and H_β are shielded increasingly by the benzene ring in the order X: H<F<Cl<Br<I for **1**—**4**. The amount of increase is greater for H_β than for H_α. However, the amount of increase in the series **1**—**4** seems to differ from one another.

Discussion

Shielding Effect of the Benzene Ring on H_α and H_β. Let us define the degree ($\Delta\delta$) of shielding on H_α and H_β caused by the benzene ring in compound **1**—**4** as

$$\Delta\delta = \delta_s - \delta$$

where δ is the chemical shift of H_α or H_β in each compound with the benzene ring, and δ_s is that in the corresponding compound in which the benzene ring is substituted by an ethyl group: Degrees of shielding



[V]

($\Delta\delta$) are listed in Tables 1—4. The $\Delta\delta$ value should include not only the ring current effect of the benzene ring, but also a through-space effect of C–X bond anisotropy and a through-bond effect of the halogen atom X. The benzene ring current itself is lowered by the inductive or mesomeric effect of the substituent X.[7] The amount of chemical shift caused by such effects, however, is considered to be sufficiently small in comparison with that caused by the benzene ring current on the basis of the following examinations.

be −0.05 ppm for **1a**, −0.02 ppm for **1b**, 0.06 ppm for **2a**, −0.01 ppm for **3a** and −0.04 ppm for **4a**. Although the size of a methyl group is reported to be a little larger than that of the chlorine atom,[1,17] it is reasonable to consider that the torsional angle θ of the benzene ring with respect to the thiophene ring is nearly equal in the methyl-compound to that in the chloro-compound. The difference $[\delta H_\beta(X=CH_3)-\delta H_\beta(X=Cl)]$ might be attributed to the bond anisotropy effect of C–X (X=halogen) bond on H_β. Since the difference was found to be small, the bond anisotropy effect is considered to be very small. Nomura and Takeuchi[8] also provided an evidence that the bond anisotropy effect of C–X (halogen) must be small or nonexistent in aromatic systems.

Mesomeric and/or Inductive Effect of the ortho *Substituent X on the Benzene Ring Current.* We prepared compounds **2aF**, **2bF**, **3aF**, and **3bF**, where the *para* substituent of the benzene ring is chlorine. The chemical shift of H_β determined for each compound was $\delta H_\beta(Z=Cl)$, which was compared with the chemical shift of H_β of the corresponding compound where Z is a hydrogen: $\delta H_\beta(Z=H)$ (see Tables 7 and 8). The difference $[\delta H_\beta(Z=H)-\delta H_\beta(Z=Cl)]$ was found to be 0.07 ppm for **2a**, 0.03 ppm for **2b**, 0.02 ppm for **3a**, and 0.00 ppm for **3b**. The torsional angle of the benzene ring with respect to the thiophene ring should be nearly equal in the compound with Z=Cl to the corresponding compound with Z=H. The mesomeric and/or inductive effect of the *ortho* substituent (X=Cl) to the benzene ring current should be nearly equal to that of the *para* substituent (Z=Cl). The difference $[\delta H_\beta(Z=H)-\delta H_\beta(Z=Cl)]$ might be attributed to the mesomeric and/or inductive effect of the *ortho* substituent (X=Cl) on the benzene ring current. This effect was found to be very small. The above data seem to indicate that the through-bond effect of substituent X on the chemical shift of H_β is also very small. Martin *et al.* also examined the effect of *para* substituent Z(=H, F, Cl, Br, I, OCH_3, CH_3) in the benzene ring upon the chemical shift of H_3 in compound **5** (see formula [VI]).[1] They reported that the *para* substituent Z does not affect the chemical shift of H_3.

[VI]

Relative Amount of $\Delta\delta$ of H_α with Respect to That of H_β. We would like to show, by use of the Johnson and Bovey diagram (a figure of the isoshielding lines of benzene nucleus given by Johnson and Bovey[9]), that our observed relative amounts of $\Delta\delta$ of H_α with respect to that of H_β are explained by taking only the effect of benzene ring current into account. Let us take 2-acetamido-3-benzoylthiophene (**2a**) as an example. If we assume that the thiophene ring is in the same plane as the C–CO–C plane, the Dreiding models of this compound indicate that the center of the benzene ring and H_β and H_α come nearly on a straight line (formula [VII]). Here, the distance from the center of the benzene ring to H_β is 3.3 Å and to H_α 5.9 Å. The straight line and the distances are maintained even if the benzene ring rotates around the C–C bond by θ. In the Johnson and Bovey diagram, the position of H_β is expressed by a circle ($\mathbf{P}_\beta$) with its center at the origin and its radius of a length corresponding to 3.3 Å. The position of H_α is likewise expressed by a similar circle ($\mathbf{P}_\alpha$) whose radius has a length corresponding to 5.9 Å (Fig. 1). Here, the isoshielding lines of benzene nucleus are a modification of the figure given by Johnson and Bovey.[9] The observed shielding effect ($\Delta\delta$) of H_β of compound **2aA** is 0.07 ppm (Table 2). Therefore, the position of H_β should

[VII]

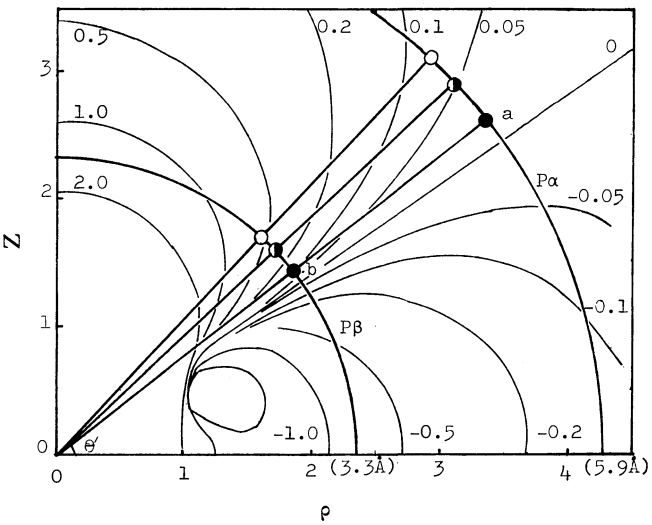

Fig. 1. Positions of H_α and H_β of compounds **2aA**—**2aC** as function of the isoshielding lines (expressed in ppm) of benzene nucleus; Z and ρ are expressed in ring radii (1.39 Å) according to Johnson and Bovey.[9] (●) Hα or H_β position of compound **2aA**, (◑) **2aB**, and (○) **2aC**. θ' is an angle between the benzene ring plane and the line which connect H_α, H_β, and center of the benzene ring. This is not the torsional angle (θ) between benzene ring plane and thiophene ring plane. When θ' is 60°, the torsional angle θ is nearly 90°.

be fixed at a point **b**. Connect point **b** with the origin. Since H_α is on the straight line connecting the center of the benzene ring and H_β in the molecule, the point representing H_α in the Johnson and Bovey diagram should also be on the straight line connecting the origin and point **b**. Let us denote the intersection of straight line **O–b** and circle $\mathbf{P}_\alpha$ by **a**. This corresponds to 0.01 ppm, which is almost equal to the observed value (−0.01 ppm) of $\Delta\delta$ for H_α (Table 2). In a similar way, the theoretical $\Delta\delta$ value for H_α derived from the observed $\Delta\delta$ value for H_β is nearly equal to the actually observed value for H_α in each compound **1a**, **2a**, **3a**, **3c**, and **4a** (Table 5).

a) Difference = $\Delta\delta(H_\alpha)$(observed) − $\Delta\delta(H_\alpha)$(theoretical).

Steric Effects. The correlation between the $\Delta\delta$ value (chemical shift caused by the ring current of the phenyl group) of H_β and the bulk of the *ortho* substituent X of phenyl group is shown in Fig. 2. We see that $\Delta\delta$ value increases with an increase of the bulk of X. This might be attributed to the steric repulsion between X of the phenyl ring and some atoms on another moiety of the molecule. Such a repulsion should bring the benzene ring out of the plane of thiophene ring. The $\Delta\delta$ value increases in going from compound **1** to compound **4** throgh compounds

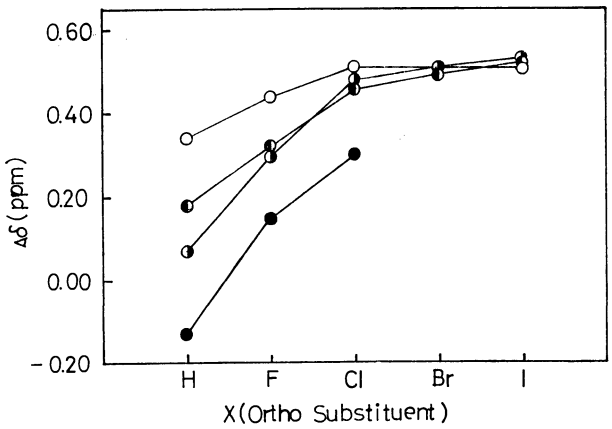

Fig. 2. Shielding effect ($\Delta\delta$) of benzene ring on H_β. (●) Compound **1**, (◑) compound 2, (◐) compound 3, and (○) compound **4**.

2 and **3**; *i.e.* **1**<**2**<**3**<**4**. This seems to indicate that the amount of steric repulsion depends not only on the bulk of X but also on the geometry and/or flexibility of the ring system condensed at 2-C and 3-C of the thiophene ring in each molecule (formula [I]). Such a steric repulsion is considered to be great even when X=H. Thus, the $\Delta\delta$ value markedly increases from compound **1** to compound **4** when X=H. This must mean that θ' greatly increases from compound **1**(X=H)→**2**(X=H)→**3**(X=H)→**4**(X=H). When X=F, on the other hand, the increase in the $\Delta\delta$ value (or the θ' value) in going from compound **1**(X=F)→**2**(X=F)→**3**(X=F)→**4**(X=F) is much smaller. When X=Cl, the corresponding increase in the $\Delta\delta$ value is even smaller. When X=Br or I, the $\Delta\delta$ value does not depend on the ring structure condensed at 2-C and 3-C of the thiophene ring. This might be explained by considering that the plane of the benzene ring is nearly perpendicular to the plane of the thiophene ring in compounds **2**—**4**, when X=Br or I.

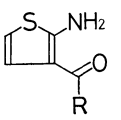
Experimental

^1H NMR spectra were recorded at 60 MHz on a Hitachi NMR spectrometer R-20-B in dilute deuteriochloroform solution (about 10% w/v). The probe temperature was 35 °C. TMS was used as an internal reference standard. The chemical shifts expressed in δ-values (ppm) downfield from TMS were measured directly from the spectra or from a frequency counter with a precision of ±0.01 ppm. The coupling constants, measured by repeated sweeping at an expanded width (60 or 120 Hz), are expressed numerically in Hz with an accuracy of ±0.1 Hz. IR spectra were recorded as nujol mulls on a Hitachi Infrared Spectrophotometer, EPI-G-3, being expressed in terms of wave numbers. UV spectra were determined in 95% ethanol with an ultraviolet spectrophotometer, Hitachi-323 or Shimadzu D-40-R, being expressed as λ_{max} nm(ε). Melting points were determined with a Thomas-Hoover melting point apparatus and are uncorrected. Solvents for recrystallization are abbreviated as follows; ethanol (EtOH), 2-propanol (IPA), and dimethylformamide (DMF).

1) 2-Amino-3-benzoyl(or propionyl)-thiophenes.



Method A: ***A–G.*** The compounds were prepared by the method of Gewald[10] from appropriate ω-cyanoacetophenones and mercaptoacetaldehyde.

A *(R: phenyl).* Yield 32.9%: mp 152—153 °C (from EtOH) (lit,[11] 147 °C).

B *(R: o-fluorophenyl).* Yield 60.0%: mp 145—146.5 °C (from IPA). IR: 3350, 3230, 3130, 1610.

C *(R: o-chlorophenyl).* Yield 47.0%: mp 137—139 °C (from IPA). IR: 3380, 3275, 1597, 1522.

D *(R: o-bromophenyl).* Yield 34.0%: mp 152—152.5 °C (from IPA). IR: 3350, 3230, 3100, 1590.

E *(R: o-iodophenyl).* Yield 27.6%: mp 162—165 °C

(from IPA). IR: 3350, 3230, 3100, 1590.

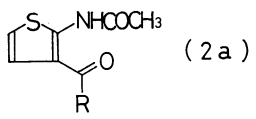
F *(R: p-chlorophenyl).* Yield 27.6%: mp 180—181.5 °C (from EtOH). IR: 3320, 3200, 3100, 1595.

G *(R: o-methylphenyl).* Yield 63.8%: mp 158—159 °C (from EtOH). IR: 3320, 3200, 3100, 1590.

*Method B: 2-Amino-3-proprionylthiophene (**H**).* This was prepared by the hydrolysis of 2-acetamido-3-propionylthiophene (**2aH**) with potassium hydroxide in aqueous ethanol at 95 °C for 10 min.

H *(R: ethyl).* Yield 87.7%: mp 140—142 °C (from Ether). IR: 3370, 3250, 3130, 1600, 1570.

*2) 2-Acetamido-3-benzoyl(or propionyl)-thiophenes (**2a**).*



(2a)

Method A: ***2aA—2aG.*** The compounds were prepared by the method of Gewald[10] from 2-amino-3-benzoylthiophenes with acetylchloride.

2aA *(R: phenyl).* Yield 67.6%: mp 115.5—116.5 °C (from Ether). IR: 3200, 3100, 3085, 1687, 1610. NMR: 2.31 (3H, s, $COCH_3$). UV: 248.5 (14400), 270 (12700), 343 (9200). Found: C, 63.54; H, 4.58; N, 5.70%. Calcd for $C_{13}H_{11}NO_2S$: C, 63.65; H, 4.52; N, 5.71%.

2aB *(R: o-fluorophenyl).* Yield 83.5%: mp 143.5—144.5 °C (from Ether). IR: 3235, 3100, 1698, 1622, 1618. NMR: 2.34 (3H, s, $COCH_3$). UV: 239 (13700), 276 (11900), 345 (9600). Found: C, 59.04; H, 4.01; N, 5.26%. Calcd for $C_{13}H_{10}NO_2SF$: C, 59.30; H, 3.83; N, 5.32%.

2aC *(R: o-chlorophenyl).* Yield 68.9%: mp 132—132.5 °C (from Ether). IR: 3225, 3075, 1682, 1618. NMR: 2.34 (3H, s, $COCH_3$). UV: 236 (14300), 275 (10800), 343 (9600). Found: C, 55.90; H, 3.80; N, 5.00%. Calcd for $C_{13}H_{10}NO_2SCl$: C, 55.82; H, 3.60; N, 5.01%.

2aD *(R: o-bromophenyl).* Yield 76.2%: mp 122.5—123.5 °C (from Ether). IR: 3215, 3075, 3055, 1691, 1618. NMR: 2.34 (3H, s, $COCH_3$). UV: 236 (14800), 276 (10600), 343 (9500). Found: C, 48.22; H, 3.04; N, 4.24%. Calcd for $C_{13}H_{10}NO_2SBr$: C, 48.16; H, 3.11; N, 4.32%.

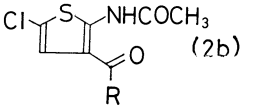
2aE *(R: o-iodophenyl).* Yield 26.1%: mp 125.5—127 °C (from Ether). IR: 3225, 3100, 3070, 1697, 1622. NMR: 2.33 (3H, s, $COCH_3$). UV: 232 (21800), 276 (10900), 344 (10100). Found: C, 42.37; H, 2.64; N, 3.77%. Calcd for $C_{13}H_{10}NO_2SI$: C, 42.07; H, 2.72; N, 3.77%.

2aF *(R: p-chlorophenyl).* Yield 23.6%: mp 107—108.5 °C (from Ether). IR: 3220, 3100, 1706, 1611. NMR: 2.32 (3H, s, $COCH_3$). UV: 268 (16100), 348 (9400). Found: C, 56.01; H, 3.62; N, 5.04%. Calcd for $C_{13}H_{10}NO_2SCl$: C, 55.82; H, 3.60; N, 5.01%.

2aG *(R: o-methylphenyl).* Yield 41.9%: mp 90—91.5 °C (from Ether). IR: 3235, 3105, 3087, 1695, 1623. NMR: 2.34 (3H, s, ϕ-CH_3), 2.35 (3H, s, $COCH_3$). UV: 237 (14200), 271 (10900), 338 (9700). Found: C, 64.86; H, 5.07; N, 5.34%. Calcd for $C_{14}H_{13}NO_2S$: C, 64.84; H, 5.05; N, 5.40%.

*Method B: 2-Acetamido-3-propionylthiophene (R: ethyl) (**2aH**).* To a suspension of 2-methyl-4*H*-thieno[2,3-*d*]-[1,3]oxazin-4-one (21.9 g) in dry ether (500 ml) was added dropwise a Grignard solution prepared from ethyl bromide (24.3 g), metallic magnesium (4.77 g) and ether (110 ml) at 15—20 °C. The mixture was stirred at room temperature overnight. First, water (500 ml), then conc, hydrochloric acid (120 ml) were added dropwise thereto under ice-cooling. The organic layer was separated and washed with 28% ammonia water, then condensed *in vacuo* and the residue crystallized to give 2-acetamido-α,α-diethyl-3-thiophenemethanol (8.6 g) as a by-product, mp 138—140 °C. The condensed filtrate was purified over a column of silica gel (240 g) and eluted with chloroform. Concentration of the chloroform elution gave the product (**2aH**) (3.13 g) as crystals. Recrystallization from ether gave colorless prisms, mp 73.5—74.0 °C. IR: 3220, 3100, 1665, 1640. NMR: 1.20 (3H, t, $CH_2\underline{CH_3}$), 2.26 (3H, s, $COCH_3$), 2.86 (2H, q, CH_2). UV: 236 (16600), 260 (7500), 267 (7100), 323 (8600). Found: C, 54.81; H, 5.52; N, 7.13%. Calcd for $C_9H_{11}NO_2S$: C, 54.80; H, 5.62; N. 7.10%.

*3) 2-Acetamido-3-benzoyl(or propionyl)-5-chlorothiophenes (**2b**)*



(2b)

These were prepared by the method of Hromatka *et al.*[12] from 2-acetamido-3-benzoyl (or propionyl)-thiophene (**2a**) with sulfurylchloride.

2bA *(R: phenyl).* Yield 66.6%: mp 102.5—103.5 °C (from Ether). IR: 3220, 1698, 1610, 1600. NMR: 2.28 (3H, s, $COCH_3$). UV: 253 (18300), 353 (9200). Found: C, 55.69; H, 3.52; N, 4.94%. Calcd for $C_{13}H_{10}NO_2SCl$: C, 55.82; H, 3.60; N, 5.01%.

2bB *(R: o-fluorophenyl).* Yield 62%: mp 159—160.5 °C (from EtOH). IR: 3220, 3080, 1682, 1608. NMR: 2.31 (3H, s, $COCH_3$). UV: 256 (17400), 354 (9200). Found: C, 52.28; H, 3.09; N, 4.57%. Calcd for $C_{13}H_9NO_2SClF$: C, 52.45; H, 3.05; N, 4.71%.

2bC *(R: o-chlorophenyl).* Yield 77.3%: mp 180—181 °C (from EtOH). IR: 3230, 3075, 1682, 1613. NMR: 2.32 (3H, s, $COCH_3$). UV: 242 (19600), 350 (9500). Found: C, 49.93; H, 2.85; N, 4.45%. Calcd for $C_{13}H_9NO_2SCl_2$: C, 49.70; H, 2.89; N, 4.46%.

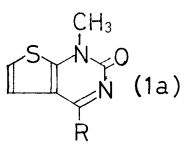
2bD *(R: o-bromophenyl).* Yield 75.9%: mp 162—163 °C (from EtOH). IR: 3225, 3065, 1688, 1612. NMR: 2.33 (3H, s, $COCH_3$). UV: 244 (19400), 350 (9400). Found: C, 43.56; H, 2.51; N, 3.87%. Calcd for $C_{13}H_9NO_2SBrCl$: C, 43.54; H, 2.53; N, 3.91%.

2bE *(R: o-iodophenyl).* Yield 48.5%: mp 124—126 °C (from Ether). IR: 3220, 3070, 1681, 1610. NMR: 2.35 (3H, s, $COCH_3$). UV: 232 (22200), 349 (9500). Found: C, 38.47; H, 2.26; N, 3.46%. Calcd for $C_{13}H_9NO_2SClI$: C, 38.50; H, 2.24; N, 3.45%.

2bF *(R: p-chlorophenyl).* Yield 40.9%: mp 119—121 °C (from Ether). IR: 3250, 1705, 1605. NMR: 2.31 (3H, s, $COCH_3$). UV: 263 (20300), 355 (9400). Found: C, 49.71; H, 2.87; N, 4.42%. Calcd for $C_{13}H_9NO_2SCl_2$: C, 49.70; H, 2.89; N, 4.46%.

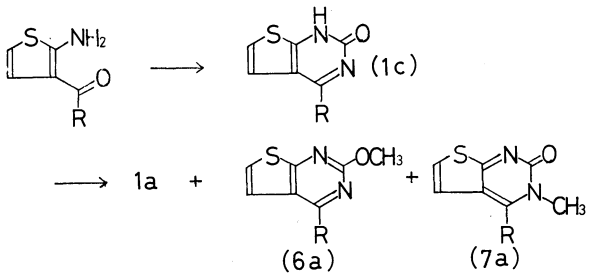
2bH *(R: ethyl).* Yield 17.2%: mp 156.5—157.5 °C (from Ether). IR: 3215, 3075, 1684, 1642. NMR: 1.19 (3H, t, J=7.1, $CH_2\underline{CH_3}$), 2.27 (3H, s, $COCH_3$), 2.78 (2H, q, J=7.1, CH_2). UV: 240 (19200), 331 (8000). Found: C, 46.70; H, 4.40; N, 5.97%. Calcd for $C_9H_{10}NO_2SCl$: C, 46.66; H, 4.35; N, 6.05%.

*4) 1-Methyl-4-phenyl(or ethyl)-1,2-dihydrothieno[2,3-d]-pyrimidin-2-ones (**1a**).*



(1a)

Method A: ***1aA—1aC.***



A mixture of 2-amino-3-benzoyl-thiophene and ethyl carbamate was heated at 200 °C for one hour in the presence of zinc chloride to give 4-phenyl-1,2-dihydrothieno[2,3-*d*]-pyrimidin-2-one (**1c**), which was methylated with methyl-iodide in the presence of sodium hydride to afford **1a**, 2-methoxy-4-phenylthieno[2,3-*d*]-pyrimidine (**6a**) and 3-methyl-4-phenyl-2,3-dihydrothieno[2,3-*d*]-pyrimidin-2-one (**7a**). The procedure was applied to the synthesis of 1-alkyl-4-phenyl-1,2-dihydroquinazolin-2-one.[13]

1cA *(R: phenyl).* Yield 100%: mp 247—249 °C (from EtOH–DMF). IR: 3050, 1630 (broad).

1aA *(R: phenyl).* Yield 27.6%: mp 256—257.5 °C (from EtOH). IR: 3040, 1642, 1630. NMR: 3.78 (3H, s, N-CH_3). UV: 248.5 (29800), 349 (6000). Found: C, 64.44; H, 4.15; N, 11.48%. Calcd for $C_{13}H_{10}N_2OS$: C, 64.44; H, 4.16; N, 11.56%.

6aA *(R: phenyl).* Yield 5.8%: mp 160—161.5 °C (from EtOH). IR: 3050, 1580.

7aA *(R: phenyl).* Yield 1.5%: mp 175—181 °C (from EtOH). IR: 3065, 3050, 1660. UV: 251 (26900), 276 (6400), 366 (5500). Found: C, 63.27; H, 4.34; N, 10.81%. Calcd for $C_{13}H_{10}N_2OS$: C, 64.44; H, 4.16; N, 11.56%.

1cB *(R: o-fluorophenyl).* Yield 30.5%: mp 278—279 °C (from Acetone). IR: 3100, 3050, 1600 (broad).

1aB *(R: o-fluorophenyl).* Yield 13.2%: mp 222—223 °C (from EtOH). IR: 3055, 1660, 1618. NMR: 3.75 (3H, s, N-CH_3). UV: 247 (31000), 348.5 (6200). Found: C, 60.36; H, 3.42; N, 10.76%. Calcd for $C_{13}H_9N_2OSF$: C, 59.99; H, 3.49; N, 10.76%.

6aB *(R: o-fluorophenyl).* Yield 1.7%: mp 175—176.5 °C (from EtOH). IR: 3040, 1610.

7aB *(R: o-fluorophenyl).* Yield 3.6%: mp 191—192.5 °C (from EtOH–$CHCl_3$). IR: 3090, 3050, 1660, 1650, 1615. UV: 252 (26600), 276 (5600), 370 (5500). Found: C, 59.75; H, 3.46; N, 10.77%. Calcd for $C_{13}H_9N_2OSF$: C, 59.99; H, 3.49; N, 10.76%.

1cC *(R: o-chlorophenyl).* Yield 36%: This was used in the next step without further purification.

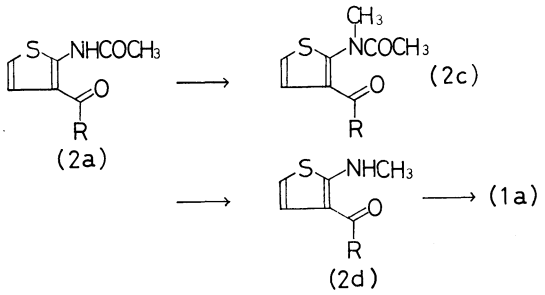
1aC *(R: o-chlorophenyl).* Yield 13.7%: mp 225—226 °C (from EtOH–$CHCl_3$). IR: 3080, 1660, 1645. NMR: 3.78 (3H, s, N-CH_3). UV: 245 (28000), 343 (6000). Found: C, 56.56; H, 3.14; N, 9.93%. Calcd for $C_{13}H_9N_2OSCl$: C, 56.42; H, 3.28; N, 10.12%.

6aC *(R: o-chlorophenyl).* Yield 3.6%: mp 172.5—174.5 °C (from Ether). IR: 3050, 1590, 1570, 1540.

7aC *(R: o-chlorophenyl).* Yield 8.3%: mp 190—192 °C (from EtOH–Ether). IR: 3075, 3060, 1660. UV: 252 (24900), 277 (5300), 366 (5200). Found: C, 56.61; H, 3.35; N, 9.82%. Calcd for $C_{13}H_9N_2OSCl$: C, 56.42; H, 3.28; N, 10.12%.

Method B: ***1aG, 1aH.***

2a was treated with sodium hydride and methyl iodide in the usual manner[13] to afford *N*-methyl-2-acetamido-3-benzoyl (or propionyl)-thiophene (**2c**), which was hydrolyzed with potassium hydroxide by the same method as for 2-amino-3-propionylthiophene (1, method B) to give 2-methylamino-3-benzoyl(or propionyl)thiophene (**2d**). **2d** was then treated with ethyl carbamate by the same method as for **1aA—1aC** (4, method A) to afford **1a**.



2cG *(R: o-methylphenyl).* Yield 100% (oil). This was used in the next step without further purification.

2dG *(R: o-methylphenyl).* Yield 52.2%: mp 78—79.5 °C (from isopropyl ether). IR: 3250, 1610.

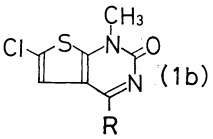
1aG *(R: o-methylphenyl).* Yield 31.7%: mp 193—199 °C (from EtOH). IR: 3040, 1638. NMR: 2.33 (3H, s, ϕ-CH_3), 3.77 (3H, s, N-CH_3). UV: 244.5 (26900), 340 (6000). Found: C, 65.55; H, 4.71; N, 11.05%. Calcd for $C_{14}H_{12}N_2OS$: C, 65.60; H, 4.72; N, 10.93%.

2cH *(R: ethyl).* Yield 65.4%: mp 78.5—79.5 °C (from Ether). IR: 3100, 1670.

2dH *(R: ethyl).* Yield 55.9% (oil). IR: 3300, 1615.

1aH *(R: ethyl).* Yield 10.9%: mp 155.5—157 °C (from EtOH). IR: 3055, 1640. NMR: 1.37 (3H, t, J=7.4, $CH_2\underline{CH_3}$), 2.91 (2H, q, J=7.4, CH_2), 3.70 (3H, s, N-CH_3). UV: 241 (28900), 327 (4900). Found: C, 55.45; H, 5.23; N, 14.34%. Calcd for $C_9H_{10}N_2OS$: C, 55.65; H, 5.19; N, 14.42%.

*5) 6-Chloro-1-methyl-4-phenyl-1,2-dihydrothieno[2,3-*d*]-pyrimidin-2-ones (**1b**).* ***1bA—1bC, 1bG.***



These were prepared by the method of Hromatka *et al.*[12] from 1-methyl-4-phenyl(or ethyl)-1,2-dihydrothieno[2,3-*d*] pyrimidin-2-one (**1a**) with sulfuryl chloride.

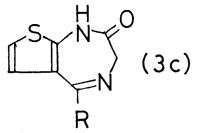
1bA *(R: phenyl).* Yield 64.8%: mp 136—140 °C (from EtOH). IR: 1673. NMR: 3.69 (3H, s, N-CH_3). UV: 252.5 (27100), 356 (6200). Found: C, 56.28; H, 3.72; N, 10.03%. Calcd for $C_{13}H_9N_2OSCl$: C, 56.42; H, 3.28; N, 10.12%.

1bB *(R: o-fluorophenyl).* Yield 24.0%: mp 192.5—194 °C (from EtOH). IR: 1677, 1622. NMR: 3.68 (3H, s, N-CH_3). UV: 251.5 (28300), 356 (6400). Found: C, 52.81; H, 2.65; N, 9.49%. Calcd for $C_{13}H_8N_2OSClF$: C, 52.98; H, 2.74; N, 9.50%.

1bC *(R: o-chlorophenyl).* Yield 52.4%: mp 164—166 °C (from EtOH–Ether). IR: 1677, 1600. NMR: 3.73 (3H, s, N-CH_3). UV: 250 (25400), 352 (6300). Found: C, 50.13; H, 2.50; N, 9.00%. Calcd for $C_{13}H_8N_2OSCl_2$: C, 50.18; H, 2.59; N, 9.00%.

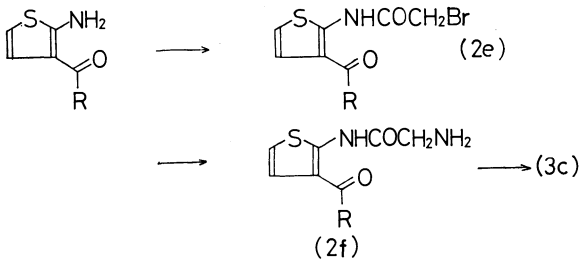
1bG *(R: o-methylphenyl).* Yield 14.4%: mp 139—140 °C (from EtOH). IR: 1661, 1601. NMR: 2.34 (3H, s, ϕ-CH_3), 3.72 (3H, s, N-CH_3). UV: 249 (26800), 347 (6700). Found: C, 57.91; H, 3.85; N, 9.65%. Calcd for $C_{14}H_{11}N_2OSCl$: C, 57.83; H, 3.81; N, 9.63%.

*6) 5-Phenyl(or ethyl)-1,3-dihydro-2H-thieno[2,3-*e*]-1,4-diazepin-2-ones (**3c**).* ***3cA—3cC, 3cH.***



(3c)

Method:



(2e)

(2f)

(3c)

3-Benzoyl(or propionyl)-2-bromoacetamido-thiophene (**2e**) was prepared from 2-amino-3-benzoyl(or propionyl)-thiophene with bromoacetylbromide. Ammonolysis of **2e** in chloroform saturated with gaseous ammonia afforded 2-aminoacetamido-3-benzoyl(or propionyl)-thiophene (**2f**), which was cyclized in dimethylsulfoxide at 100 °C to afford **3c**. The procedure was applied to the synthesis of benzodiazepine by Sternbach *et al.*[14]

2eA *(R: phenyl).* Yield 77.3%: mp 142—144 °C (from EtOH). IR: 3090, 3070, 1670, 1620.

2fA *(R: phenyl).* Yield 49.0%: mp 137.5—139 °C (lit[15], 145—147 °C).

3cA *(R: phenyl).* Yield 53.2%: mp 200.5—201.5 °C (lit[15], 203 °C).

2eB *(R: o-fluorophenyl).* Yield 77.1%: mp 101—102 °C (from Ether). IR: 3200, 1680, 1620.

2fB *(R: o-fluorophenyl).* Yield 79.1%: mp 127.5—129 °C (from CH_2Cl_2). IR: 3380, 3320, 3170, 3060, 1665, 1600.

3cB *(R: o-fluorophenyl).* Yield 75.4%: mp 201—201.5 °C from (EtOH). IR: 3060, 1685, 1615. NMR: 4.45 (2H, s, CH_2). UV: 242 (26600), 313 (2800). Found: C, 60.08; H, 3.43; N, 10.67%. Calcd for $C_{13}H_9N_2OSF$: C, 59.99; H, 3.49; N, 10.76%.

2eC *(R: o-chlorophenyl).* Yield 80.1%: mp 109—110 °C (from Ether). IR: 3060, 1670, 1600.

2fC *(R: o-chlorophenyl).* Yield 78.3%: mp 154—156 °C (from CH_2Cl_2). IR: 3390, 3320, 3220, 3050, 1685, 1635.

3cC *(R: o-chlorophenyl).* Yield 32.0%: mp 225—226 °C (from EtOH). IR: 3060, 1695, 1607. NMR: 4.47 (2H, s, CH_2). UV: 241 (22900), 311 (2900). Found: C, 56.68; H, 3.23; N, 10.04%. Calcd for $C_{13}H_9N_2OSCl$: C, 56.42; H, 3.28; N, 10.12%.

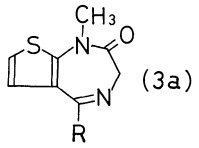
2eH *(R: ethyl).* Yield 68.7%: mp 107.5—108.5 °C (from Ether). IR: 3150, 3100, 1660, 1640.

2fH *(R: ethyl).* Yield 90.7%: mp 114—116 °C (from CH_2Cl_2). IR: 3400, 3340, 3150, 3080, 1640.

3cH *(R: ethyl).* Yield 17.0%: mp 137—140 °C (from Ether). IR: 3165, 3070, 1698, 1694, 1620. NMR: 1.16 (3H, t, $CH_2\underline{CH_3}$), 2.69 (2H, q, $CH_2\underline{CH_3}$), 4.19 (2H, s, $COCH_2N$)). UV: 233 (24200), 294 (3300). Found: C, 55.46; H, 5.08; N, 14.25%. Calcd for $C_9H_{10}N_2OS$: C, 55.65; H, 5.19; N, 14.42%.

7) 1-Methyl-5-phenyl(or ethyl)-1,3-dihydro-2H-thieno[2,3-e]-1,4-diazepin-2-ones (3a).

Method A: ***3aA—3aC, 3aH.*** These were prepared from 5-phenyl(or ethyl)-1,3-dihydro-2*H*-thieno[2,3-*e*]-1,4-diazepin-2-one (**3c**) with sodium hydride and methyliodide in the usual manner.[14]



(3a)

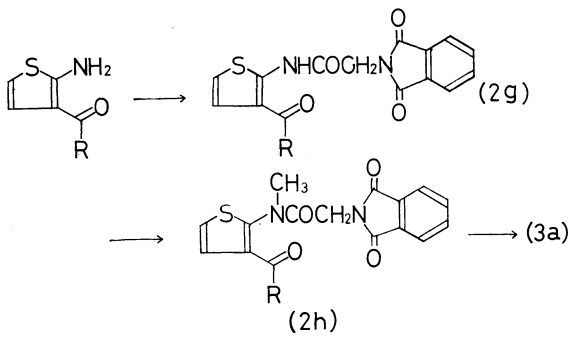
3aA *(R: phenyl).* Yield 86%: mp 134—135 °C (from (EtOH). (lit, 136—137.5 °C).[15]

3aB *(R: o-fluorophenyl).* Yield 84.3%: mp 115.5—117 °C (from EtOH). IR: 3040, 1680, 1600. NMR: 3.50 (3H, s, N-CH_3), 4.44 (2H, s, CH_2). UV: 243 (25300), 315 (2800). Found: C, 61.37; H, 4.12; N, 10.20%. Calcd for $C_{14}H_{11}N_2OSF$: C, 61.29; H, 4.04; N, 10.21%.

3aC *(R: o-chlorophenyl).* Yield 56.0%: mp 109.5—111.0 °C (from Ether). IR: 3080, 3070, 1682. NMR: 3.52 (3H, s, N-CH_3), 4.47 (2H, s, CH_2). UV: 212.5 (27700), 240.5 (21600), 311 (2800). Found: C, 57.68; H, 3.66; N, 9.46%. Calcd for $C_{14}H_{11}N_2OSCl$: C, 57.83; H, 3.81; N, 9.64%.

3aH *(R: ethyl).* Yield 18.1%: mp 82—83 °C (from Ether). IR: 3040, 1682, 1627. NMR: 1.17 (3H, t, J=7.4, $CH_2\underline{CH_3}$), 2.68 (2H, q, J=7.4, $\underline{CH_2}CH_3$), 3.44 (3H, s, N-CH_3), 4.21 (2H, s, $COCH_2N$). UV: 235 (22000), 295 (3200). Found: C, 57.64; H, 5.75; N, 13.30%. Calcd for $C_{10}H_{12}N_2OS$: C, 57.67; H, 5.81; N, 13.45%.

Method B: ***3aD—3aG.***



(2g)

(2h)

(3a)

3-Benzoyl-2-(*N*-phthalimidoacetyl)amino-thiophene (**2g**) was prepared from 2-amino-3-benzoylthiophene with phthaloylimidoacetylchloride. Methylation of **2g** with sodium hydride and methyliodide in the usual manner afforded 3-benzoyl-2-(*N*-methyl-*N*-phthalimidoacetyl)amino-thiophene (**2h**), which was treated with hydrazine hydrate to afford **3a**.[16]

2gD *(R: o-bromophenyl).* Yield 69.3%: mp 205—208 °C (from Acetone). IR: 3200, 3100, 1780, 1720, 1705, 1615.

2hD *(R: o-bromophenyl).* Yield 58.4%: mp 170—172 °C (from Acetone). IR: 1765, 1725, 1690, 1650.

3aD *(R: o-bromophenyl).* Yield 31.7%: mp 109—113 °C (from EtOH). IR: 3080, 3060, 1677. NMR: 3.51 (3H, s, N-CH_3), 4.46 (2H, s, CH_2). UV: 215 (26200), 240 (20500), 312 (2700). Found: C, 49.85; H, 3.46; N, 8.51%. Calcd for $C_{14}H_{11}N_2OSBr$: C, 50.16; H, 3.31; N, 8.36%.

2gE *(R: o-iodophenyl).* Yield 50.2%: mp 206—208 °C (from Acetone). IR: 3230, 1775, 1720, 1690, 1610.

2hE *(R: o-iodophenyl).* Yield 71.1%: mp 167—175 °C (from Acetone). IR: 3110, 1770, 1725, 1695, 1650, 1620.

3aE *(R: o-iodophenyl).* Yield 45.4%: mp 136—137.5 °C (from EtOH). IR: 3045, 1679, 1669. NMR: 3.53 (3H, s, N-CH_3), 4.46 (2H, s, CH_2). UV: 220 (28000), 313 (2700). Found: C, 43.91; H, 2.84; N, 7.22%. Calcd for $C_{14}H_{11}N_2OSI$: C, 43.99; H, 2.90; N, 7.33%.

2gF *(R: p-chlorophenyl).* Yield 78.4%: mp 215—216 °C (from Acetone). IR: 3220, 1765, 1710, 1605.

2hF *(R: p-chlorophenyl).* Yield 78.5%: mp 211—212 °C (from Acetone). IR: 3080, 1765, 1720, 1680, 1660.

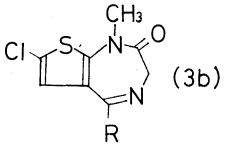
3aF *(R: p-chlorophenyl).* Yield 76.5%: mp 139.5—141 °C (from EtOH). IR: 3040, 1678. NMR: 3.49 (3H, s, N-CH_3), 4.40 (2H, s, CH_2). UV: 251 (30100), 317 (2900). Found: C, 57.77; H, 3.71; N, 9.60%. Calcd for $C_{14}H_{11}N_2OSCl$: C, 57.83; H, 3.81; N, 9.64%.

2gG *(R: o-methylphenyl).* Yield 42.6%: mp 211—213 °C (from Acetone). IR: 3250, 3050, 1775, 1720, 1690.

2hG *(R: o-methylphenyl).* Yield 78.0%: mp 153.5—155 °C (from Acetone). IR: 3100, 1765, 1720, 1690, 1640.

3aG *(R: o-methylphenyl).* Yield 74.0%: mp 125—127 °C (from EtOH). IR: 3075, 1675, 1612, 1605. NMR: 2.08 (3H, s, ϕ-CH_3), 3.53 (3H, s, N-CH_3), 4.45 (2H, s, CH_2). UV: 240 (24700), 307 (2900). Found: C, 66.64; H, 5.21; N, 10.28%. Calcd for $C_{15}H_{14}N_2OS$: C, 66.64; H, 5.22; N, 10.36%.

*8) 7-Chloro-1-methyl-5-phenyl(or ethyl)-1,3-dihydro-2H-thieno[2,3-e]-1,4-diazepin-2-ones (**3b**), **3bA—3bF**, **3bH**.*



(3b)

These were prepared by the method of Hromatka *et al.*[12] from 1-methyl-5-phenyl(or ethyl)-1,3-dihydro-2*H*-thieno[2,3-*e*]-1,4-diazepin-2-one (**3a**) with sulfuryl chloride.

3bA *(R: phenyl).* Yield 80.0%: mp 117.5—119.0 °C (from EtOH), (lit[12], 120—122 °C).

3bB *(R: o-fluorophenyl).* Yield 73.5%: mp 101.5—103 °C (from IPA). IR: 1693, 1681, 1613. NMR: 3.43 (3H, s, N-CH_3), 4.44 (2H, s, CH_2). UV: 244 (24200), 320 (2900). Found: C, 54.25; H, 3.17; N, 8.81%. Calcd for $C_{14}H_{10}N_2OSClF$: C, 54.45; H, 3.26; N, 9.07%.

3bC *(R: o-chlorophenyl).* Yield 28.0%: mp 82.5—84 °C (from Ether). IR: 1692. NMR: 3.47 (3H, s, N-CH_3), 4.47 (2H, s, CH_2). UV: 243 (20800), 319 (2900). Found: C, 51.62; H, 3.22; N, 8.47%. Calcd for $C_{14}H_{10}N_2OSCl$: C, 51.70; H, 3.10; N, 8.62%.

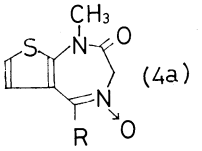
3bD *(R: o-bromophenyl).* Yield 49.2%: mp 86—89 °C (from Ether). IR: 1690. NMR: 3.46 (3H, s, N-CH_3), 4.46 (2H, s, CH_2). UV: 242 (20200), 319 (3000). Found: C, 45.95; H, 2.75; N, 7.60%. Calcd for $C_{14}H_{10}N_2OSBrCl$: C, 45.49; H, 2.73; N, 7.58%.

3bE *(R: o-iodophenyl).* Yield 32%: mp 217—221 °C (hydrochloride), (from EtOH). IR: 3110, 3035, 2350 (broad), 1905, 1720, 1633. NMR (Measured as a free base): 3.48 (3H, s, N-CH_3), 4.46 (2H, s, CH_2). Found: C, 36.98; H, 2.41; N, 6.10%. Calcd for $C_{14}H_{10}N_2OSClI \cdot HCl$: C, 37.11; H, 2.45; N, 6.18%.

3bF *(R: p-chlorophenyl).* Yield 83.5%: mp 212—213.5 °C (from $CHCl_3$-EtOH). IR: 1693, 1678. NMR: 3.44 (3H, s, N-CH_3), 4.42 (2H, s, CH_2). UV: 251 (27200), 323 (2900). Found: C, 51.58; H, 3.09; N, 8.43%. Calcd for $C_{14}H_{10}N_2OSCl_2$: C, 51.71; H, 3.10; N, 8.61%.

3bH *(R: ethyl).* Yield 16.0%: mp 76.5—77.5 °C (from Ether). IR: 1680, 1620. NMR: 1.18 (3H, t, J=7.3, $CH_2\underline{CH}_3$), 2.65 (2H, q, J=7.3, $\underline{CH}_2CH_3$), 3.40 (3H, s, N-CH_3), 4.24 (2H, s, CH_2). Found: C, 49.45; H, 4.45; N, 11.29%. Calcd for $C_{10}H_{11}N_2OSCl$: C, 49.49; H, 4.57; N, 11.54%.

*9) 1-Methyl-5-phenyl(or ethyl)-1,3-dihydro-2H-thieno[2,3-e]-1,4-diazepin-2-one-4-oxides (**4a**), **4aA—4aE**, **4aG**, **4aH**.*



(4a)

Method: These were prepared by the method of Hromatka *et al.*[15] from 1-methyl-5-phenyl(or ethyl)-1,3-dihydro-2*H*-thieno[2,3-*e*]-1,4-diazepin-2-one (**3a**) with *m*-chloroperbenzoic acid.

4aA *(R: phenyl).* Yield 67.0%: mp 158—159 °C (from EtOH-CCl_4). IR: 3070, 1688. NMR: 3.53 (3H, s, N-CH_3), 4.73 (2H, s, CH_2). UV: 245 (20500), 313 (7700). Found: C, 61.26; H, 4.46; N, 9.96%. Calcd for $C_{14}H_{12}N_2O_2S$: C, 61.70; H, 4.40; N, 10.30%.

4aB *(R: o-fluorophenyl).* Yield 83.0%: mp 80.5—85 °C (from EtOH). IR: 3400, 3070, 3020, 1688, 1679, 1609. NMR (Measured after removal of crystalline ethanol): 3.57 (3H, s, N-CH_3), 4.78 (2H, s, CH_2). UV: 246 (20600), 267 (17200), 310 (6900). Found: C, 57.08; H, 5.19; N, 8.20%. Calcd for $C_{14}H_{11}N_2O_2SF \cdot C_2H_5OH$: C, 57.13; H, 5.10; N, 8.33%.

4aC *(R: o-chlorophenyl).* Yield 73.5%: mp 163—163.5 °C (from EtOH-CCl_4). IR: 3050, 1696. NMR: 3.57 (3H, s, N-CH_3), 4.77 (2H, s, CH_2). UV: 249 (19700), 310 (6400). Found: C, 54.77; H, 3.55; N, 8.93%. Calcd for $C_{14}H_{11}N_2O_2SCl$: C, 54.82; H, 3.62; N, 9.13%.

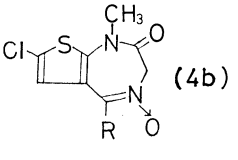
4aD *(R: o-bromophenyl).* Yield 61.0%: mp 162—163.5 °C (from EtOH-CCl_4). IR: 3100, 1685. NMR: 3.59 (3H, s, N-CH_3), 4.77 (2H, s, CH_2). UV: 254 (19400), 310 (5800). Found: C, 47.52; H, 3.03; N, 7.70%. Calcd for $C_{14}H_{11}N_2O_2SBr$: C, 47.88; H, 3.16; N, 7.98%.

4aE *(R: o-iodophenyl).* Yield 18.2%: mp 161 °C (decomp.) (from EtOH-CCl_4). IR: 3100, 3080, 1671. NMR: 3.60 (3H, s, N-CH_3), 4.78 (2H, s, CH_2). UV: 229.5 (24400), 252 (19800), 305 (sh) (6700). Found: C, 42.35; H, 2.66; N, 7.00%. Calcd for $C_{14}H_{11}N_2O_2SI$: C, 42.23; H, 2.78; N, 7.03%.

4aG *(R: o-methylphenyl).* Yield 54.7%: mp 149.5—150.5 °C (from EtOH). IR: 3115, 1687. NMR: 2.24 (3H, s, ϕ-CH_3), 3.61 (3H, s, N-CH_3), 4.78 (2H, s, CH_2). UV: 242.5 (21100), 275 (20400), 305 (7100). Found: C, 62.76; H, 5.14; N, 9.70%. Calcd for $C_{15}H_{14}N_2O_2S$: C, 62.92; H, 4.93; N, 9.78%.

4aH *(R: ethyl).* Yield 46.8%: mp 169—171.5 °C (from EtOH-Ether). IR: 3075, 3050, 1690. NMR: 1.20 (3H, t, $CH_2\underline{CH}_3$), 2.85 (2H, q, $\underline{CH}_2CH_3$), 3.54 (3H, s, N-CH_3), 4.62 (2H, s, CH_2). UV: 254.5 (22500), 298 (5800). Found: C, 53.61; H, 5.40; N, 12.52%. Calcd for $C_{10}H_{12}N_2O_2S$: C, 53.55; H, 5.40; N, 12.49%.

*10) 7-Chloro-1-methyl-5-phenyl(or ethyl)-1,3-dihydro-2H-thieno[2,3-e]-1,4-diazepin-2-one-4-oxides (**4b**).*



(4b)

Method A: ***4bA***, ***4bB***. These were prepared by the method of Hromatka *et al.*[12] from 1-methyl-5-phenyl-1,3-dihydro-2*H*-thieno-[2,3-*e*]-1,4-diazepin-2-one-4-oxide(**4a**) with sulfurylchloride.

4bA *(R: phenyl).* Yield 40.1%: mp 194—195 °C (from EtOH-CCl_4). IR: 3075, 1691. NMR: 3.48 (3H, s, N-CH_3), 4.74 (2H, s, CH_2). UV: 243 (23600), 275 (18100), 315 (sh) (6900). Found: C, 54.96; H, 3.64; N, 9.11%. Calcd for

$C_{14}H_{11}N_2O_2SCl$: C, 54.81; H, 3.61; N, 9.13%.

4bB *(R: o-fluorophenyl).* Yield 83.2%: mp 153—154 °C (from *n*-Hexane–Ether). IR: 1693, 1680. NMR: 3.50 (3H, s, N-CH_3), 4.78 (2H, s, CH_2). UV: 242.5 (23900), 269.5 (21800), 315 (sh) (6200). Found: C, 52.08; H, 3.08; N, 8.41%. Calcd for $C_{14}H_{10}N_2O_2SClF$: C, 51.78; H, 3.10; N, 8.62%.

Method B: ***4bC***, ***4bH***. These were prepared by the method of Hromatka *et al.*[15] from 7-chloro-1-methyl-5-phenyl-(or ethyl)-1,3-dihydro-2*H*-thieno[2,3-*e*]-1,4-diazepin-2-ones (**3b**) with *m*-chloroperbenzoic acid.

4bC *(R: o-chlorophenyl).* Yield 54.3%: mp 95—97 °C (from CCl_4). IR: 1710, 1678. NMR: 3.51 (3H, s, N-CH_3), 4.79 (2H, s, CH_2). UV: 250 (21700), 265 (22000), 315 (sh) (5500). Found: C, 36.47; H, 2.09; N, 5.57%. Calcd for $C_{14}H_{10}N_2O_2SCl_2 \cdot CCl_4$: C, 36.39; H, 2.04; N, 5.66%.

4bH *(R: ethyl).* Yield 25.2%: mp 171—172 °C (from Ether). IR: 1689. NMR: 1.19 (3H, t, J=7.4, $CH_2\underline{CH_3}$), 2.78 (2H, q, J=7.4, $\underline{CH_2}CH_3$), 3.48 (3H, s, N-CH_3), 4.63 (2H, s, CH_2). Found: C, 46.52; H, 4.63; N, 10.88%. Calcd for $C_{10}H_{11}N_2O_2SCl$: C, 46.42; H, 4.29; N, 10.83%.

The authors express their deep gratitude to Prof. Masamichi Tsuboi, the University of Tokyo, and Dr. Makoto Sunagawa in this laboratory for their guidance and encouragement throughout this work. They are also indebted to Mr. Tadashi Doi and Miss Keiko Kawazoe for measurement of the UV spectra, and to Mr. Hiromi Sato for his co-operation in the synthetic experiments.

Studies of the Crystallization Processes of *N*-Methylquinolinium TCNQ Ion-radical Salts

Mutsuaki MURAKAMI and Susumu YOSHIMURA

Matsushita Research Institute Tokyo, Inc., Ikuta, Tama-ku, Kawasaki 214

(Received March 22, 1974)

We studied the crystallization processes of the complex ion-radical salt of 7,7,8,8-tetracyanoquinodimethan (TCNQ) and the *N*-methylquinolinium cation. A variety of solvents, rates of crystallization, and concentrations of the solution gave three groups of crystals. The crystals in the first group, which were crystallized as black rods, occluded the solvent molecules in the crystals, and their resistivities were in the range of 2.8—26 Ω cm. Those in the second group were crystallized into the form of fine needles or fine powders. Although the TCNQ-to-cation ratios in the salts varied from 1.6 to 2.2, their electrical resistivities were almost all the same (about 1.0 Ω cm), and these crystals were thought to have a metastable crystal structure. The crystals in the third group were crystallized in the form of triclinic prisms, which belonged to a stable crystal of a high resistivity (1100 Ωcm). The appearance of multiple forms is interpreted on the basis of Ostwald's "Law of Stages" of crystallization and also on the basis of information on the structures of the one-dimensional TCNQ columns of the other complex ion-radical salts of TCNQ.

Molecular compounds based on 7,7,8,8-tetracyanoquinodimethane (TCNQ) have attracted much attention in studying the behavior of electrons in the molecular crystals, because they exhibit a wide range of resistivity, 10^{-3}—10^{11} Ω cm, and also because their physical properties can, in some cases, be regarded as attributes of a one-dimensional conductor.[1] A great effort to synthesize new materials of TCNQ has led to discoveries of various kinds of phase transitions[2-7] and also of the possibility of high-temperature superconductivity.[8] The wide range of the physical properties of the TCNQ compounds is due to their possibility of being crystallized in a variety of forms. There are two limits of crystal structure, between which many variations exist, depending upon the kind and nature of the second component. One structure, which is generally found in compounds called "non-ionic charge-transfer complexes" is characterized by alternating stacks of TCNQ and the second molecule (donor), the mode of the overlap of the two neighboring molecules being nearly direct. The other is a structure in which the TCNQ molecules are stacked plane-to-plane with each other. The latter type of crystal is usually found in the ion-radical salts formed between TCNQ and organic or metallic cations and is believed to contribute to the high conductivity. It has been suggested by various works on the crystallization of the TCNQ molecular compounds that the crystal structure and the physical properties of the compounds are determined not only by the nature of the second component, but also notably by the crystallization processes. This statement may be illustrated by the following four phenomena: (1) The appearance of polymorphic modifications in simple salts of 3,3'-diethylthiacarbocyanium,[9] Rb[10,11] and *N*-methylphenazinium cations.[12] (2) Compounds of different stoichiometries, such as 1:2 salts of various onium cations, 2:3 salts of Cs,[13] morpholinium,[5] trimethylammonium,[14] and *N*-methylquinolinium cations.[15] (3) Unstable crystals, such as morpholinium$_3$(TCNQ)$_4$,[5] *N*-ethylquinolinium(TCNQ)$_2$[15] and methyldiethylcyclohexylammonium(TCNQ)$_2$.[15] (4) The formation of solvent-inclusion compounds such as benzidine·TCNQ(BD·TCNQ).[16,17]

In this paper we wish to report our experimental results on the crystallization of an ion-radical salt formed from the *N*-methylquinolinium (MeQ) cation and TCNQ and show that the MeQ·TCNQ salt can be crystallized either of the above four types of crystals. We will also discuss the effect of the crystallization process on the resulting forms of crystals, considering the unstable nature of the one-dimensional TCNQ columns, and will report that the appearance of multiple forms can be commonly observed in the TCNQ ion-radical salts.

Experimental

Materials. Crude TCNQ was refluxed for several hours with active carbon in acetonitrile; the filtered solution had then been allowed to stand overnight, orange crystals of TCNQ were collected. This procedure was repeated several times.

For the preparation of MeQ(TCNQ)$_x$ salts, *N*-methylquinolinium iodide and a two-molar excess of TCNQ were dissolved and mixed in a boiling solvent. After a suitable period, the crystals were collected, washed with the solvent, and finally washed with ether.

Determination of the Molecular Ratio of TCNQ to the Cation. The accuracy of the elemental analysis of TCNQ was too poor for us to assess the amount of the excess neutral TCNQ molecules in the salt, because the complete combustion of the salt was difficult to achieve. The electronic absorption spectrum was adopted instead. The electronic spectra of TCNQ salts in acetonitrile of high purity were measured with a Cary 14R spectrometer. Acetonitrile was purified by repeated distillations over a small amount of Li(TCNQ). The spectrum was considered to be the overlap of the absorptions of both $TCNQ^0$ and $TCNQ^-$. The value of the molar extinction coefficient for $TCNQ^0$ was 68000 $l \cdot mol^{-1} \cdot cm^{-1}$ at the wavelength of 395 nm. The coefficient of $TCNQ^-$ was obtained from the simple salt of MeQ(TCNQ), which exhibited two major maxima, at 420 and 842 nm, with coefficients of 26800 and 51600 $l \cdot mol^{-1} \cdot cm^{-1}$ respectively; the coefficient at 395 nm was 21800 $l \cdot mol^{-1} \cdot cm^{-1}$. We obtained the molar ratios of TCNQ to the MeQ cation from the following equation, assuming that the $TCNQ^0$-to-cation ratio is the same as the $TCNQ^0$-to-$TCNQ^-$ ratio:

$$TCNQ/MeQ = 1 + (\varepsilon^{-}_{842}/\varepsilon^{0}_{395})(r_2 - r_1)$$

where r_1 and r_2 are the ratios of the optical density at 395 nm to that at 842 nm in the absorption spectra of the simple and complex salts respectively (r_1=0.422) and where ε^{-}_{842} and ε^{0}_{395} are the molar extinction coefficients of $TCNQ^-$ at 842 nm (51600) and of $TCNQ^0$ at 395 nm (68000) respectively. In a conventional calculation,[18] a value of r_1 obtained from Li(TCNQ) has been used instead of that from the corresponding simple salt, but there may be no reason for believing that the absorption coefficient of $TCNQ^-$ is always the same, regardless of the kind of cation component.[19]

Measurements of Electrical Resistivity and Activation Energy. The resistivity data at room temperature were obtained on pressed pellets 13 mm in diameter, and about 5 mm thick, with four-probe electrodes pressed on the pellets with a resistivity-measuring apparatus, Model VR 4 (Kokusai Electric Co., Ltd.). For the activation-energy measurements (from −50 to 50 °C), samples in the form of pressed rods 3 mm in diameter and about 10 mm in length were prepared; on them four-point contacts were made with silver paint.

Measurement of Infrared Absorption Spectra. The infrared absorption spectra were measured using the method of Nujol mull with a Hitachi grating infrared spectrometer, Model 215, in the wave number range between 4000 and 650 cm^{-1}. In case of highly-conducting salts, special care was required in the preparation of a uniform film in order to avoid the scattering of light.

Other Measurements. The measurements of differential scanning calorimetry (DSC) and thermogravimetric analysis (TGA) were made with Shimadzu thermoflex apparatuses, SC-20 and TG-20, in a nitrogen gas atmosphere and at a heating rate of 5 °C/min.

The X-ray diffraction patterns of powder samples were obtained at room temperature with a Philips PW 1051 X-ray diffractometer by the use of a copper-Kα line.

Results and Discussion

Multiple Forms of MeQ·TCNQ Salts and Their Classification. The experimental results of the crystallization of the salts formed from the MeQ cation with TCNQ are shown in Table 1, which also summarizes the relative intensities of the electronic absorptions at 395 and 842 nm of acetonitrile solutions, the cation-to-TCNQ ratio, the crystal forms and the electrical properties at room temperature. The first typical feature of the results is that the molar ratio of the MeQ cation to TCNQ could not be assigned to an integer ratio of 1:2 or 2:3, but varied from 1.6 to 2.2 with the kind of solvent. When acetone was used as the solvent, fine needle crystals ($MeQ(TCNQ)_{1.6}$) appeared first, and then triclinic prism crystals ($MeQ(TCNQ)_{2.1}$) were obtained after a day. The second feature is that the apparent form of the crystal varied with the method of preparation; three different forms were recognized, apart from the crystal in the form of fine powders reprecipitated in cold water from a hot dimethylformamide solution (IIc). They were a rod, a fine needle, and a triclinic prism. The electrical resistivity corresponded to the crystal form and not to the content of neutral TCNQ molecules. The crystals in the form of black rods exhibited relatively low resistivities (from 2.8 to 26 Ω cm). The lowest resistivity was found in the fine needle crystal, while the highest was found in the triclinic prism crystal. The reprecipitated fine powders have almost the same resistivity as that of fine needle crystals, so they can be classified into the same group.

At this stage we can classify these crystals into three groups on the basis of both their crystal forms and their resistivities. The first group, I, consists of two compounds with relatively low resistivities which were crystallized in the form of black rods from acetonitrile and nitromethane solutions. The II group includes three types of highly-conducting crystals. The first of them, IIa, was crystallized from dichloromethane, and the second, IIb, from an acetone solution. Both of them were in the form of fine, black needles; they could be formulated as $MeQ(TCNQ)_{2.2}$ and $MeQ(TCNQ)_{1.6}$, respectively The last sample of this group, IIc, is $MeQ(TCNQ)_{2.2}$, which was obtained in the form of a fine powder. We single out as a III group the salt of the highest resistivity, $MeQ(TCNQ)_{2.1}$, which was crystallized in the form of a triclinic prism. In works by Melby *et al.*[13] and Siemons, Bierstedt, and Kepler,[20] the $MeQ(TCNQ)_x$ salt synthesized in an acetonitrile solution was regarded as a stoichiometric 1:2 complex. However, it is one of the multiple forms of $MeQ(TCNQ)_x$ salts, because Frandois *et al.*[15] have reported a crystal of 2:3 stoichiometry from an acetonitrile solution.

Figure 1 shows the infrared spectra of the six crystals obtained. The IR spectra are also divided into three groups which strictly correspond to the above classification based on the crystal forms and resistivities. The optical absorption spectra of the TCNQ ion-radical salts in both infrared and visible regions reflect the structure of the TCNQ columns. Broadenings of the vibrational bands in the infrared range from 2500 to 700 cm^{-1} are generally observed and may reasonably be related to the electron delocali-

TABLE 1. CHARACTERISTIC PROPERTIES OF $MeQ(TCNQ)_x$ COMPLEX SALTS

Solvent	Electronic spectra r_2 ($\varepsilon_{395}/\varepsilon_{842}$)	Composition (Cation: TCNQ)	Crystal form	Resistivity ρ_{20} (Ω cm)	Activation energy E (eV)	Classification
CH_3CN	1.16	1: 1.6	Rod	2.8	0.07	Ia
CH_3NO_2	1.58	1: 1.9	Fine rod	26	0.13	Ib

zation and then to the orderliness of the TCNQ columns. Especially, the bands from 1100 to 1300 cm^{-1} in the spectra of highly-conducting TCNQ complexes are not due to pure intramolecular vibrations, but to some kind of vibronic interaction of conduction electrons with intramolecular TCNQ vibrations.[21]

At first, the spectra will be compared with the spectrum of a thin film of quinolinium(TCNQ)$_2$, Q(TCNQ)$_2$,[22] which exhibits a considerably broader CN stretching band at 2210—2000 cm^{-1}, with sharp lines at 2206 and 2199 cm^{-1}, and strong bands at 1270 and 1050 cm^{-1}, corresponding to, respectively, the CH bending and C–CN stretching modes of the TCNQ molecules.[23,24] The low-resistivity crystal, II, had the pattern most similar to that of Q(TCNQ)$_2$, and the coincidence of the positions and width of the CH bending and C–CN stretching bands was fairly good. The bands of the III crystal were less broad and appeared at a higher-energy side than in the case of either II or Q(TCNQ)$_2$. For example, peaks were found at 1300 cm^{-1} for the CH bending band and at 1130 cm^{-1} for the C–CN stretching band. The IR spectrum of the III-type crystal suggests that there is a different TCNQ column structure, probably with considerable distortions, which will give rise to electron localization and then to an increase in the values of both the resistivity and the activation energy. The I-type crystals, although they had as low resistivity as II, exhibited different patterns. The poor resolution and large broadening of the CN stretching band at about 2210 to 2000 cm^{-1} are similar to those of the low-resistivity crystal, II, but the positions of both the CH bending band (about 1320 cm^{-1}) and the C–CN stretching band (about 1120 cm^{-1}) are more similar to those of the intermediate resistivity compound, III.

The I-Type Crystals, Inclusion Compounds. The thermogravimetric analysis of the MeQ(TCNQ)$_x$ salts revealed that only the crystals classified as I suffered a weight loss. The TGA curves for Ia are shown in Fig. 2. For single crystals of Ia and Ib, the magnitudes of the losses were 8 and 10% in weight respectively, while the temperatures at which the weight started to decrease were 110 and 90 °C respectively. The loss component was trapped in a cell cooled with dry ice and was confirmed by means of the infrared absorption spectrum to be due to the escape of included solvent molecules, namely, acetonitrile for Ia and nitromethane for Ib. The amount of the included solvent was estimated from the magnitude of the loss; it was found that one mole of the solvent molecules was included per mole of the MeQ cation.

Measurements of differential scanning calorimetry (DSC) were made on Ia and Ib; endothermic peaks which exactly corresponded to the TGA curves were thus observed. The result for Ia is also shown in Fig. 2. The magnitudes of the heat associated with the transformation were ΔH=19.1 kcal/mol for Ia and 18.1 kcal/mol for Ib.

It is concluded that the MeQ(TCNQ)$_x$ salts classified as I in the previous section included solvent molecules in the crystal, while the crystals in the other groups did not. The factor determining the type of salt was the kind of solvent used in the preparation, and the included solvents were weakly bound in the host lattice and could leave it easily.

In the case of a BD·TCNQ system,[16,17] which is another example of the formation of inclusion compounds, the main factor determining the type of complex is the solvent used in the preparation. When the

molecular volume of the solvent is smaller than 75 cm^3/mol, the BD·TCNQ crystal includes the solvent, while the crystal does not include solvent molecules larger in volume than 80 cm^3/mol. The situation seems to be the same in the case of the MeQ(TCNQ)$_x$ salts. For example, the molecular volumes of the included acetonitrile and nitromethane are 52.2 and 53.7 cm^3/mol respectively, while the solvents not included were dichloromethane and acetone, their molecular volumes being 64.0 and 73.6 cm^3/mol respectively. The heat associated with the evaporation of the solvent molecules from the MeQ·TCNQ system is comparable with that of the solvents from the BD·TCNQ system, which has been reported to be 11.1 kcal/mol. It is striking that the two systems, which differ so sharply in crystal structure, exhibited similar behavior of solvent evaporation. These results suggest that the state of the solvent molecules is essentially the same for both the systems and that the solvent molecules may be situated in a site very weakly affected by the kind of donor or cation molecules.

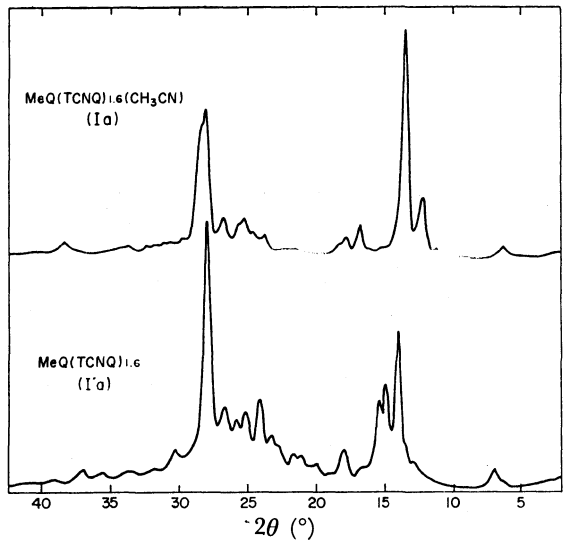

Fig. 3. X-ray diffraction patterns of MeQ(TCNQ)$_x$ salts. Ia: MeQ(TCNQ)$_{1.6}$(CH_3CN) and Ia': MeQ(TCNQ)$_{1.6}$.

The X-ray powder diffraction patterns of the Ia crystal and those treated at 120 °C for 30 min, Ia', are shown in Fig. 3. The pattern of Ia' was quite different from that of Ia; that is, the peaks of Ia at $2\theta=11.95$, 12.87, 12.96, and 27.51° disappeared after heat treatment, resulting in new peaks of Ia' at 13.50, 14.96, and 27.34°. The resistivities of these salts also changed from 2.8 Ω cm to about 3000 Ω cm. On the other hand, when Ia' was exposed to the vapor of acetonitrile in a low vacuum (about 100 mmHg) overnight at room temperature, the X-ray pattern became identical with that of Ia and the resistivity was restored to 4.0 Ω cm. Therefore, it is likely that when the solvent molecules leave the crystal, the crystal structure is greatly changed and that, when exposed to the vapor of a suitable solvent, the solvent molecules can easily be included in the crystal, thus restoring the initial structure. These properties are again in accord with the case of the BD·TCNQ system.

When IIa and III were exposed to the vapor of acetonitrile using the same method, the resistivity changed from 1.0 to 2.8 Ω cm for IIa and from 1100 to 5.0 Ω cm for III. From TGA measurements, the contents of acetonitrile molecules of the transformed crystals of IIa and III were determined to be 0.86 mol for the former and 0.90 mol for the latter per mole of the MeQ cation. This fact shows that the formation of the solvent-including salts does not depend on the initial crystal structure; all the crystals can include solvent molecules of a suitable size.

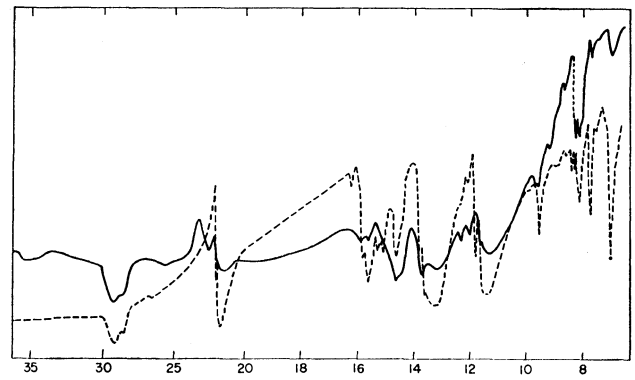

Fig. 4. Infrared absorption spectra of Ia: MeQ(TCNQ)$_{1.6}$(CH_3CN) (——) and Ia': MeQ(TCNQ)$_{1.6}$ (------).

The infrared spectrum of Ia' is shown in Fig. 4. As with the results of solvent evaporation, the resolution of the spectrum became relatively good and the width of the CN stretching band of TCNQ at 2200 cm^{-1} became narrower than that of Ia. On the contrary, the position of the characteristic bands, the CN stretching, CH bending, and C–CN stretching bands, remained unchanged. From these results, we will make some speculations on the mode of change in the TCNQ column structure, referring to the case of the BD·TCNQ system.[25,26] In a BD·TCNQ(S) crystal (where S stands for a solvent molecule), the BD and TCNQ molecules completely overlap each other to make columns as well as ordinary charge-transfer complexes, while the solvent molecules are situated in the channels between the BD·TCNQ columns and also form parallel columns. It has also been reported that the structure of the BD·TCNQ columns of the inclusion compound is almost the same as that of the solvent-free compound and that the spacings between the column axes of the latter compound are smaller than those of the former. The small change in the IR structure of the MeQ(TCNQ)$_x$(S) crystal suggests little change in the TCNQ column structure, thus excluding the possibility that the solvent molecules are located in the TCNQ columns. They may, thereby, be bound in the channels between the columns, as in the case of the BD·TCNQ system. Crystallographical studies of low-conductive TCNQ ion radical salts with 1:2[24] and 2:3 stoichiometries[27] show that there are relatively large hollows in the columns of the cation, hollows which correspond to the periodic distortions between two $TCNQ^-$'s of the

TCNQ columns. These hollows are thought to be the most probable sites for the solvent molecules. The solvent molecules have only the $TCNQ^-$ in their nearest neighbors; this is in contrast with the cations, which have both $TCNQ^0$ and $TCNQ^-$. This structure explains the low resistivity of the solvent-including crystals because the higher resistivity of the crystals with a distorted TCNQ column structure is caused by the intermolecular repulsion between the neighboring $TCNQ^-$ molecules. The X-ray powder patterns of Ia and Ia′ also support the above structure. A detailed discussion of the patterns and the mechanism of the transformation will be presented elsewhere.[28]

The resistivity, the infrared spectrum, and the X-ray powder pattern of the transformed crystal, Ia′, were very similar to those of the III-type crystal, irrespective of the content of the excess neutral TCNQ molecule. These facts suggest that the latter crystal has a stable structure of its TCNQ column, the stability being determined by the crystallization process. This will be discussed in the next section.

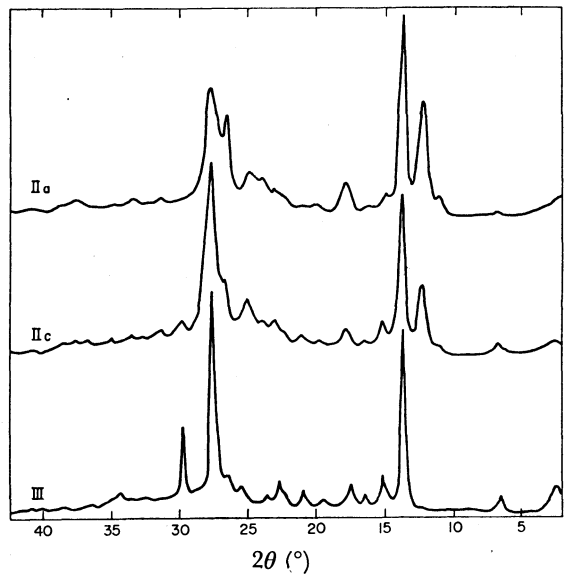

Fig. 5. X-ray diffraction patterns of $MeQ(TCNQ)_x$ salts. IIa: $MeQ(TCNQ)_{2.2}$, IIc: $MeQ(TCNQ)_{2.2}$ and III: $MeQ(TCNQ)_{2.1}$.

The II- and III-Type Crystals, Metastable and Stable Crystals. The X-ray powder patterns of the salts in Groups II and III are shown in Fig. 5. We can distinguish between the patterns of II and III. The IIa and IIc crystals had almost the same patterns, with little difference in the positions of the intense peaks. The pattern for IIa exhibited peaks at 11.8, 13.4, 26.5, and 27.5 degrees, and that for IIc, at 11.8, 13.4, 26.4, and 27.5 degrees. The main peak of III was found at 29.8°, and the peak at 11.8° was absent. Since the stability of the IIb crystal was poor, it was difficult to obtain its X-ray pattern as crystallized, but evidence was found that it may have a structure similar to that of IIa. The three compounds in Group II have, therefore, the same crystal structure, although they differ in both the TCNQ-to-cation ratio and the stability of the resistivity value.[28]

The difference in the crystallization process between II and III was the concentration of the solution. From a concentrated acetone solution (30 mmol/l), the III crystal was obtained one day after the first precipitate, IIb, had been removed by filtration. A dilute solution (13 mmol/l), however, gave only the III crystal in about a day. The IIb crystal was unstable, as has been mentioned above, and it exhibited changes in both resistivity and X-ray pattern at room temperature. For example, the resistivity of IIb was 0.8 Ω cm as crystallized but it increased to about 60 Ωcm after a week. The other crystals in Group II were also unstable or metastable crystals, because they exhibited a significant increase in resistivity at relatively lower temperatures (50—80 °C). The III crystal was thought to be a stable one, although in some cases it displayed a very small change in resistivity at elevated temperatures.

The appearance of the stable and unstable (or metastable) crystals from the same solution has been generalized thermodynamically by Ostwald in his "Law of Stages."[29] According to the law, multiple phases of different stabilities can appear in the order of their relative stabilities from a solution or melt left in a metastable state, because the crystallization takes place with the smallest loss of the free-energy content of the system. For the crystallization of the $MeQ(TCNQ)_x$ salts from a solution, the condition of a higher free-energy content may be established both in the earlier stage of crystallization from an acetone solution (high temperature and high concentration) and when the solubility of the salt is low (when dichloromethane or water was used as the solvent). Therefore, the lower resistivity of the II-type crystals can be explained quite reasonably if we assume them to be crystallized in a metastable state following the Ostwald law. The fact that the infrared spectra of II and III were almost the same as those of $Q(TCNQ)_2$ and *N-n*-propylquinolinium$(TCNQ)_2$, $NPQ(TCNQ)_2$, respectively is very helpful in understanding the structure of the TCNQ columns of the metastable and stable crystals.

In $Q(TCNQ)_2$,[30] the TCNQ molecules are stacked with an equal interplanar spacing and with an overlap mode so that one molecule is shifted longitudinally with respect to another by one-fourth the molecular length. A typical example of a distorted TCNQ column structure is $NPQ(TCNQ)_2$,[24] where the interplanar conformations of TCNQ in the column are not identical, but an extended interplanar spacing and a transversally shifted mode of overlap are found periodically.[31] Since we could not obtain any multiple phases or unstable crystals of either $Q(TCNQ)_2$ or $NPQ(TCNQ)_2$, the two structures seem to be representative of the stable TCNQ column structure of *N*-alkyl·$Q(TCNQ)_2$ salts at room temperature. Considering the size of the MeQ cation, it is not impossible that the $MeQ(TCNQ)_x$ salt assumes both types of crystal structures, the $Q(TCNQ)_2$ and $NPQ(TCNQ)_2$ types. The same discussion can apply to the case of the *N*-ethylquinolinium cation; in fact a similar phenomenon has been observed for the*N*-ethyl·$Q(TCNQ)_x$

salt,[15] a study of which is currently being made in our laboratory.

The crystallization rate was a controling factor in the difference between IIb and IIa or IIc. When an acetone solution of $MeQ(TCNQ)_x$ (20 mmol/l) was cooled from 60 to 5 °C at a rate of 0.8 or 0.2 °C/min, the IIb crystal (with a TCNQ-to-cation ratio of 1.6) was obtained. On the other hand, crystals which were obtained from an acetone solution of the same concentration cooled at a rate of 4 °C/min had a TCNQ-to-cation ratio of 2.2 and a low resistivity (about 1 Ω cm), so that they may be thought to be the same as IIa.

A calculation[30] of the stabilization energy of the $(TCNQ)_2^-$ system revealed that the most stable overlap configuration is that found in the $Q(TCNQ)_2$ crystal. The stability of the crystal as a whole is determined not only by the configuration energy of the TCNQ column, but also by the steric factor of the cations.[32] It is likely that a higher rate of crystallization gives rise to a stable configuration of TCNQ, resulting in an unstable structure as a whole. This seems to be the case in the crystallization of IIa or IIc, where the unstable structure may have been frozen with the aid of the steric hindrance of the cation molecules, probably by the rapid quenching of the crystal. This mechanism is supported by the dependence of the content of the neutral TCNQ in the II-type crystals on the crystallization rate. The higher rate prefers the stacking of the TCNQ molecules, defects being left in the column of the cation.

The authors offer their thanks to Dr. Katsue Hasegawa for his stimulating discussions. They are also indebted to Prof. Hiroo Inokuchi of the University of Tokyo for his valuable suggestions and to Dr. Hayao Kobayashi of Toho University and Prof. S. C. Wallwork of the University of Groningen for providing them with the details of crystal structures of $Q(TCNQ)_2$ and $NPQ(TCNQ)_2$ respectively and with unpublished structural data.

Group Interactions in Polyelectrolytes. IX. The Amination Kinetics of Chloromethylated Polystyrene in Binary Mixed Solvents

Hiroshi KAWABE

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received May 18, 1974)

All the aminations of chloromethylated polystyrene (CMPS) and benzyl chloride with *i*- and *s*-butylamine in *N*,*N*-dimethylformamide (DMF), in dioxane, and in DMF–dioxane mixtures conformed to the ordinary second-order kinetics. The activation parameters in the pure solvents revealed that the much higher amination rate in DMF than in dioxane was due to both the lower value of ΔH^* and the higher value of ΔS^* in DMF. The rate of amination in DMF–dioxane was investigated as a function of the composition of the mixed solvent. The observed rate constants in DMF–dioxane mixtures fell substantially on the curves calculated on the basis of Kondo and Tokura's theory concerning reaction rates in binary mixed solvents. It is suggested in this paper that the higher rate of amination in DMF is due to the strong solvation of the activation complex in DMF to form an addition product, and that it is also due to the relative increase in the configurational entropy of the reaction system at the transition state from dioxane to DMF.

The amination of chloromethylated polystyrene (CMPS) with primary and secondary amines in several solvents was studied kinetically by the present author. All the aminations of benzyl chloride, a low-molecular model of CMPS, and most of the aminations of CMPS with primary amines such as butylamines obeyed the ordinary second-order kinetics. The amination rate of CMPS was almost the same as that of benzyl chloride, and there was not much difference in the activation parameters between them.[1] On the other hand, the rate constants were greatly affected by the species of solvent. Although there was very little difference between the rates in dioxane and in methyl ethyl ketone, the rate was markedly enhanced in dipolar aprotic solvents such as *N*,*N*-dimethylformamide (DMF) and dimethyl sulfoxide (DMSO). It was observed that, in the aminations with 2-aminobutanol and *n*-butylamine, the enthalpy of activation (ΔH^*) decreased and the entropy of activation (ΔS^*) increased in DMF or DMSO as compared with those in dioxane.[2] This is probably because of the strong solvation of the polar activated complex in such dipolar solvents.

In the present study, in order to ascertain such a solvent effect, first, CMPS and benzyl chloride were aminated with *i*- and *s*-butylamine in dioxane and their activation parameters were compared with those in DMF. Second, the rate of the aminations were measured in DMF–dioxane mixed solvents. The selective solvent effect of DMF on the rate has been revealed by the fact that the rate increases greatly upon the addition of a small amount of DMF to the dioxane. A theory with regard to the dependence of the reaction rate on the composition of a binary solvent system was proposed by Kondo and Tokura[3] on the basis of the theory of the non-electrolyte solution, and it has been applied to the Menschutkin reaction of alkyl halide with tertiary amine and the benzoylation of amine in a mixed solvent such as benzene–nitrobenzene.[3,4] In the present study, the dependence of the amination rate on the composition of DMF–dioxane has been investigated on the basis of Kondo and Tokura's equation in order to elucidate the effects of solvents on the amination of CMPS.

Experimental

Materials. As the chloromethylated polystyrene (CMPS) we used the samples described in a previous paper (CMPS-9 and CMPS-10).[1] The amines, benzyl chloride, and the solvents, all of a reagent grade, were distilled before use; they were proved to be pure by their refractive indices. All the other chemicals were of a reagent grade.

Kinetic Measurements. The procedures of the kinetic measurements in the amination of CMPS and benzyl chloride were almost the same as those described in a previous paper.[2] The initial concentrations of the chloromethyl group (of CMPS and benzyl chloride) and amine were about 0.040 and 0.400 mol/l respectively. The temperature of the reaction mixture was kept constant (within ± 0.1 °C) by means of a thermostat.

Results and Discussion

Amination in Dioxane. The aminations of CMPS and benzyl chloride with *i*- and *s*-butylamine in dioxane conformed to the ordinary second-order kinetics, and the rate constant was computed on the basis of the following equation:

$$kt = \frac{1}{(a-b)} \ln \frac{b(a-x)}{a(b-x)} \quad (1)$$

where a and b are the initial concentrations of the amines and the chloromethyl group respectively, and where x is the concentration of hydrochloride formed after a certain time, t. The rate constants measured at different temperatures are listed in Table 1, where k_P and k_B are the rate constants of CMPS and benzyl chloride respectively. The table also lists the activation energy, E_a, and the frequency factor, A, as computed by means of the least-squares method. The activation parameters, ΔH^*, ΔS^*, and ΔG^*, which were computed on the basis of the equations described in a previous paper,[2] are tabulated in Table 2. (Since the errors in ΔG^* are much smaller than those in ΔH^* and ΔS^*, they are omitted from the table.)

As has been described in a previous paper,[1] the amination rates with butylamines are $k_P > k_B$ in dioxane, and $k_P < k_B$ in DMF. All the values of ΔH^* decreases from benzyl chloride to CMPS; however, ΔS^* decreases

TABLE 2. THERMODYNAMIC QUANTITIES FOR 25 °C IN THE AMINATION OF CMPS AND BENZYL CHLORIDE IN DIOXANE

Amine	Chloride	$\Delta H^{\ddagger}$ kcal/mol	$\Delta S^{\ddagger}$ e.u.	$\Delta G^{\ddagger}$ kcal/mol
i-Butyl	CMPS	12.3±0.2	−40.8±0.5	24.5
	Benzyl	12.5±0.1	−41.2±0.2	24.7
s-Butyl	CMPS	12.6±0.1	−41.3±0.3	24.9
	Benzyl	12.8±0.1	−42.0±0.3	25.4

slightly from benzyl chloride to CMPS in dioxane, and it increases a little in DMF. This difference in $\Delta S^{\ddagger}$ between CMPS and benzyl chloride is general for DMF and DMSO,[1,2] and it is considered to be characteristic of dipolar aprotic solvents.

On the other hand, the rates in DMF are much larger than those in dioxane; $\Delta H^{\ddagger}$ decreases and $\Delta S^{\ddagger}$ increases from dioxane to DMF. Similar changes in the activation parameters were also found in the amination with *n*-butylamine and 2-aminobutanol when the solvent was changed from dioxane to DMF or DMSO.[2] The decrease in $\Delta H^{\ddagger}$ is considered to be due to the strong solvation of the activation complex in a dipolar aprotic solvent; that is, it corresponds to the enthalpy of the formation of an addition product as a result of the interaction of the activation complex with the solvent. The increase in $\Delta S^{\ddagger}$ may be ascribed to the relative increase in the configurational entropy of the reaction system at the transition state from dioxane to a dipolar aprotic solvent.

Amination in DMF–Dioxane Mixtures. The amination of CMPS and benzyl chloride in DMF–dioxane conformed to the second-order rate equation. Figure

·····: Calculated on the basis of Eq. (3)

1, as an example, shows the plots of kt against t for the amination of CMPS with *s*-butylamine at 60 °C, where kt represents the right-hand term in Eq. (1) and where $\beta=x/b$. Table 3 lists the rate constants, computed on the basis of Eq. (1), of the amination with *i*-butylamine at 50 °C and those with *s*-butylamine at 60 °C.

The logarithms of the rate constant in DMF–dioxane, denoted here as log k_M, are plotted against the mole fraction of DMF in the mixed solvent, denoted as x_1, in Figs. 2 and 3. In the figures, the observed values (expressed by the circles) are on the straight lines represented by Eq. (2), which are omitted in the figures;

$$\log k_M = x_1 \log k_1 + x_4 \log k_4 \qquad (2)$$

where x_1 and x_4 $(=1-x_1)$ are the mole fractions of DMF and dioxane respectively in the DMF–dioxane system and where k_1 and k_4 are the rate constants in pure DMF and pure dioxane respectively. It is shown in the figures that the addition of a small amount of DMF to dioxane increases the rate constant markedly. This result, along with that described in the preceding section, suggests that the activated complex in the mixed solvent interacts selectively with DMF to form the solvated activated complex.

With regard to a reaction in a binary mixed solvent, Kondo and Tokura[3] calculated thermodynamically the Henry constant of each species in the reaction system; they derived theoretically the relation between the rate constant and the composition of the solvent mixture on the basis of molecular models. In the first model, where two reactants, A and B, and the activation complex, M*, yield regular solutions with Solvent 1 (S_1) and Solvent 4 (S_4), the rate constant in the mixed solvent, k_M, is expressed by:

$$\log k_M = x_1 \log k_1 + x_4 \log k_4 - x_1 x_4 \alpha_{14}/2.303 \qquad (3)$$

where α_{14} is an empirical coefficient which is related to the interaction between S_1 and S_4.

In the second model, where A and B yield regular solutions with both the solvents, but where M* reacts selectively with S_1 to form an addition product, denoted here as MS_1^*, k_M is given by:

$$\log k_M = x_1 \log k_1 + x_4 \log k_4 - [x_1 \log (K+1) - \log (x_1 K+1) + x_1 x_4 \alpha_{14}/2.303] \qquad (4)$$

where K is the equilibrium constant, expressed on the basis of the mole fractions of the species, in the formation of MS_1^* from M* and S_1.

In the present study, x_1 and x_4 are the mole fractions of DMF and dioxane respectively, and k_1 and k_4, the rate constants in pure DMF and pure dioxane respectively. The coefficient, α_{14}, is related to the molar excess free energy of mixing in the binary system, ΔG_M^E, by means of the following equation:

$$\Delta G_M^E RT = \alpha_{14} x_1 x_4 \qquad (5)$$

while ΔG_M^E can be obtained from the equilibrium vapor-pressure data in the system. The data in the DMF–dioxane system were presented by Quitzch;[5] the values of ΔG_M^E and α_{14} calculated from the data are shown in Fig. 4. At $x_1=0.5$, $\alpha_{14}(50\,°C)=0.403$ and α_{14}-

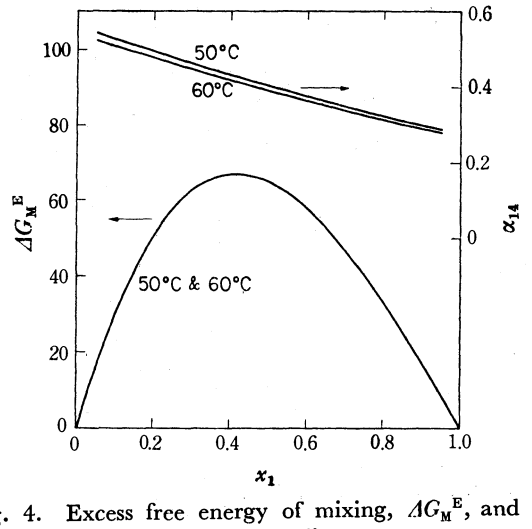

Fig. 4. Excess free energy of mixing, ΔG_M^E, and the coefficient, α_{14}, for the DMF-dioxane system.

$(60\,°C)=0.390$. The values of α_{14} and k_M at $x_1=0.5$ were introduced into Eq. (4) in order to obtain the K values, which are shown in Table 4. Then, the values of α_{14} and K were introduced into Eqs. (3) or (4) in order to calculate log k_M as a function of x_1. In Figs. 2 and 3, the broken lines and solid lines are those calculated on the basis of Eqs. (3) and (4) respectively. The observed values, expressed by the circles, are substantially on the lines calculated on the basis of Eq. (4). This agreement suggests that the activated complex is solvated selectively with DMF in DMF–dioxane.

Enhancement of the Amination Rate in a Dipolar Aprotic Solvent and Comparison of the Rate between CMPS and Benzyl Chloride. In Table 4, K is an equilibrium constant of the $M^*+S_1 \rightleftarrows MS_1^*$ reaction, which is expressed on the basis of mole fraction; this was then transformed to an equilibrium constant expressed

TABLE 4. EQUILIBRIUM CONSTANT IN THE SOLVATION OF THE ACTIVATED COMPLEX AND THERMODYNAMIC QUANTITIES

Amine	Chloride	Temp °C	K	K_c l/mol	ΔG^{*solv} kcal/mol	ΔH^{*solv} kcal/mol	$T\Delta S^{*solv}$ kcal/mol	$T\delta\Delta S^{*conf}$ a) kcal/mol

	Benzyl	50	43.8	3.57	−0.8	−1.4	−0.6	2.0
s-Butyl	CMPS	60	15.7	1.28	−0.2	−1.1	−0.9	2.0
	Benzyl	60	38.5	3.14	−0.8	−1.2	−0.4	2.0

a) $T\delta\Delta S_i^{*conf}$ represents $T(\Delta S_1^{*conf}-\Delta S_4^{*conf})$.

on the basis of the molar concentration, $K_c=[MS_1^*]/[M^*][S_1]$, by means of the following equation:

$$K = K_c/V_{soln} \quad (6)$$

where V_{soln} is the molar volume of the solution defined as:[3]

$$V_{soln} = (\sum_i m_i V_i)/\sum_i m_i \quad (7)$$

where m_i is the moles of a component, i, of the solution and where V_i is partial molar volume of the component. Provided that the solute components are negligible, V_{soln} (DMF–dioxane)=0.0816 l/mol at x_1=0.5 (at 25 °C). The values of K_c calculated on the basis of Eq. (6) are shown in Table 4. The free energy of solvation of the activated complex with DMF (S_1), ΔG^{*solv}, in Table 4 is calculated from the K_c values.

If the activated complex is solvated merely with DMF in DMF–dioxane, the enthalpy of the solvation of the activated complex, ΔH^{*solv}, will be the difference between the enthalpy of activation in DMF, ΔH_1^*, and that in dioxane, ΔH_4^*. The $T\Delta S^{*solv}$ values in Table 4 were thus calculated. Although there is very little difference in ΔH^{*solv} values between CMPS and benzyl chloride, the $T\Delta S^{*solv}$ of CMPS is a little lower than that of benzyl chloride. This difference may be attributed to the steric hindrance to the solvation in CMPS; that is, the formation of the addition product from the activation complex and the solvent molecules is obstructed by the neighboring groups of the polymer.

Although the values of ΔS^{*solv} are negative, the values of $(\Delta S_1^*-\Delta S_4^*)$ can be seen to be positive by comparing Table 7 in Ref. 1 with Table 2 in the present paper. Since the activated complex in the amination is ionic or rather polar, there must be a large difference in the configurational entropy of the reaction system at the transition state between the system containing such a polar solvent as DMF (the solubility parameter, δ=12.11) and the system containing dioxane (δ=9.88). Accordingly, $(\Delta S_1^*-\Delta S_4^*)$ is assumed to be composed of those two terms:

$$\Delta S_1^* - \Delta S_4^* = \Delta S^{*solv} + (\Delta S_1^{*conf} - \Delta S_4^{*conf}) \quad (8)$$

where ΔS_i^{*conf} is the change in the configurational entropy of the reaction system containing a solvent, i (i is 1 or 4), from its initial state to its transition state.

Thus, we obtain the following relation:

$$(\Delta G_1^* - \Delta G_4^*) - \Delta G^{*solv} = T(\Delta S_1^{*conf} - \Delta S_4^{*conf}) \quad (9)$$

The difference between $(\Delta G_1^*-\Delta G_4^*)$ and ΔG^{*solv}, therefore, corresponds to the difference in the configurational entropy changes of the reaction systems. Since the ΔS_i^{*conf} term is not directly related to the solvation of the activated complex, the values of $(\Delta S_1^{*conf}-\Delta S_4^{*conf})$, unlike those of ΔS^{*solv}, will be almost the same for DMPS and benzyl chloride. The numerical values of $T(\Delta S_1^{*conf}-\Delta S_4^{*conf})$ calculated on the basis of Eq. (9) are shown in Table 4; they are the same for all the cases shown in the table, as had been expected.

The results of the present study suggest that the remarkable increase in the amination rate from dioxane to DMF is caused not only by the decrease in the activation energy, which is equal to the solvation energy of the activated complex with DMF, but also by the large relative increase in the configurational entropy of the reaction system at the transition state from the reaction in dioxane to that in DMF.

The author wishes to express his thanks to Dr. Masaya Yanagita for his valuable discussions. He is also grateful to Mr. Yasunori Uchiyama for his helpful assistance in preparing the polymer and in carrying out the measurements.

Electrical Behavior of Alkali Metal Cation-TCNQ Anion Radical Simple Salts under Very High Pressures.

Ichimin SHIROTANI, Akifumi ONODERA,* and Nobuko SAKAI

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106
**Department of Material Physics, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560*

(Received May 27, 1974)

The electrical resistance of alkali metal cation–TCNQ anion radical simple salts was measured over the wide pressure range from 0 to 500 kbar at room temperature. The least resistivities for Group A (Li–, Na–, K–, and Rb(I)–TCNQ) are about 0.2—3 Ω cm, while those for Group B (Rb(II)– and Cs–TCNQ) are about 0.06—0.1 Ω cm. The possibility of insulator-metal transition at high pressures is discussed. Above 140—175 kbar the electrical resistance of simple TCNQ salts increases with an increase in the pressure and drifts upward with the time. The solid-phase reaction is observed under very high pressures.

The electrical,[1,2] optical,[3–5] and magnetic properties[6,7] and the crystal structures[8,9] in simple alkali metal cation–TCNQ anion radical salts (M–TCNQ) have been studied. Phase transitions have been observed in the temperature range from −150 °C to +230 °C;[10,11] further, new, pressure-induced phase transitions have been investigated at room temperature.[11] According to the differences in the physical properties and crystal structures, alkali metal–TCNQ salts may be classified into two groups. Li–, Na–, K–, and Rb(I)–TCNQ salts are contained in Group A. These salts have exhibited typical semiconductive behavior. The dimerized structure in the $TCNQ^-$ columns appears to be typical.[8] Rb(II)– and Cs–TCNQ, on the other hand, belong to Group B. The X-ray study of Rb(II)–TCNQ shows a triclinic structure consisting of linear chains of identical TCNQ molecules stacked face-to-face and equally separated from one another.[9] This columnar structure resembles that found in the crystals of such metallic TCNQ salts as *N*-methylphenazinium–TCNQ (NMP–TCNQ).[12,13] However, no insulator-metal transition has been observed in the wide temperature range from 170 to 570 K[2] and up to 14 kbar at room temperature.[11] The interplanar spacing between the $TCNQ^-$ anion in Rb(II) salt, 3.43 Å, is much longer than that, 3.26 Å, in NMP–TCNQ. If this distance, 3.43 Å, can be contracted to about 3.2 Å by compression, it seems that it would be possible to observe a pressure-induced phase transition to the conducting state at high pressures.

In this paper, we will present our findings on the pressure dependence of the electrical resistance of M–TCNQ salts and will discuss the possibility of insulator-metal transition at high pressures. Further, we will present some results on the solid phase reactions that were found under very high pressures.

Experimental

Conductivity measurements were performed using a split-sphere apparatus[14] constructed at Osaka University. A schematic diagram is shown in Fig. 1. A sphere made of hardened steel was split into six wedge-shaped segments, the centers of which were all truncated so that a central hollow space could be made. Into this space we placed eight cubic anvils made of tungsten carbide. A corner of each cubic anvil was cut off to form a triangular face. When these eight cubic anvils were put together, the eight triangular faces formed an octahedral hollow space in the center of the whole sphere. The specimen to be compressed was embedded in the pyrophyllite octahedron, which served as a pressure-transmitting medium.

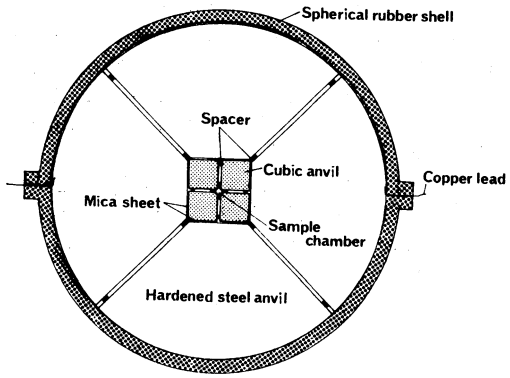

Fig. 1. Cross-section of the split-sphere apparatus showing the arrangement of inner cubes, outer segments, and spacers.

Since these inner and outer anvils were equally separated and put together with soft cardboard spacers sandwiched between them, it was possible to construct a sphere with a diameter slightly larger than before the splitting. When the anvil assemblage covered with a pair of semispherical rubber shells was compressed with a fluid, the sphere shrunk uniformly, reducing its diameter toward that of the original sphere. Quasi-hydrostatic high pressures could, as a result, be generated in the octahedral specimen chamber. The details of the sample arrangement and pressure calibration have been described elsewhere.[15]

The samples used in the experiment were Li–, Na–, K–, Rb(I)–, Rb(II)–, and Cs–TCNQ. The preparation of these compounds has been reported in detail previously.[2,11] The samples were studied in the form of powder pressure-fused into flat platelets.

Results and Discussion

According to the differences in their physical properties and crystal structures, simple TCNQ salts may be classified into two groups. As is shown in Table 1, Li–, Na–, K–, and Rb(I)–TCNQ salts are contained in Group A, while Rb(II)– and Cs–TCNQ belong to Group B. It is known that crystals of Rb(I)–TCNQ

TABLE 1. PHYSICAL PROPERTIES OF SIMPLE M–TCNQ SALTS

	Resistivity (Ω cm)		Transition temperature (K)		Location of charge transfer band[a,d] (10^3 cm^{-1})
	Single crystal[a] along the needle axis	Microcrystal[b]			
Li–TCNQ		5×10^5	No phase transition observed		8.0
Na–TCNQ	$\sim1\times10^3$	1×10^5	338[a]	348[c]	8.3
K–TCNQ	$\sim5\times10^3$	1×10^4	391	394	8.3
Rb(I)–TCNQ	$\sim3\times10^5$		374	381	8.6
Rb(II)–TCNQ	$\sim1\times10^2$		231	223	6.5
Cs–TCNQ	$\sim6\times10^2$	3×10^3	254	210	6.5

in Group A have a monoclinic symmetry and that the $TCNQ^-$ ions are stacked face-to-face to form columns of diadic units of $TCNQ^-$. Within a column, two different intermolecular spacings, 3.159 and 3.480 Å, appear alternately.[8] On the contrary, the TCNQ radical ions in Rb(II) salt form columns constructed from monadic units of $TCNQ^-$. The spacing between $TCNQ^-$ is 3.43 Å.[9] Figure 2 exhibits the mode of overlapping between the nearest $TCNQ^-$ ions in both Rb salts.

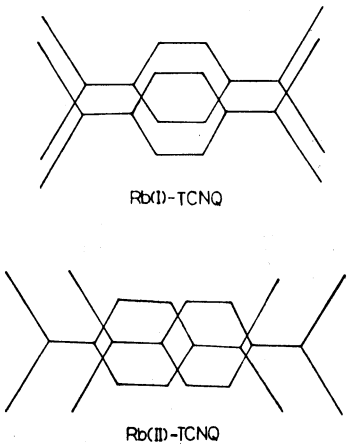

Fig. 2. The mode of overlapping between nearest $TCNQ^-$ in both Rb–TCNQ salts.

The columnar structures of TCNQ salts seem to be closely related to the electrical conductivity.[12] The TCNQ salts with diadic, triadic, and tetradic are low or intermediately conductive. The mode of overlapping between the nearest TCNQ ions in these salts is similar to that found in the Rb(I) salt. The highly-conductive salts, such as NMP–TCNQ, are constructed of monadic units of TCNQ. The mode of overlapping between the nearest TCNQ ions in these salts resembles that found in the Rb(II) salts.

The effect of the pressure on the electrical resistances of TCNQ salts in Group A is shown in Figs. 3a and 3b. Their electrical resistances decreased rapidly with an increase in the pressure and reached their minimum in the pressure range of 145—175 kbar. The behavior of the curve was reproducible below this pressure region. The least resistivities of the TCNQ salts are given in Table 2. The least resistivity of Li–TCNQ is much smaller than that of the other salts in Group A.

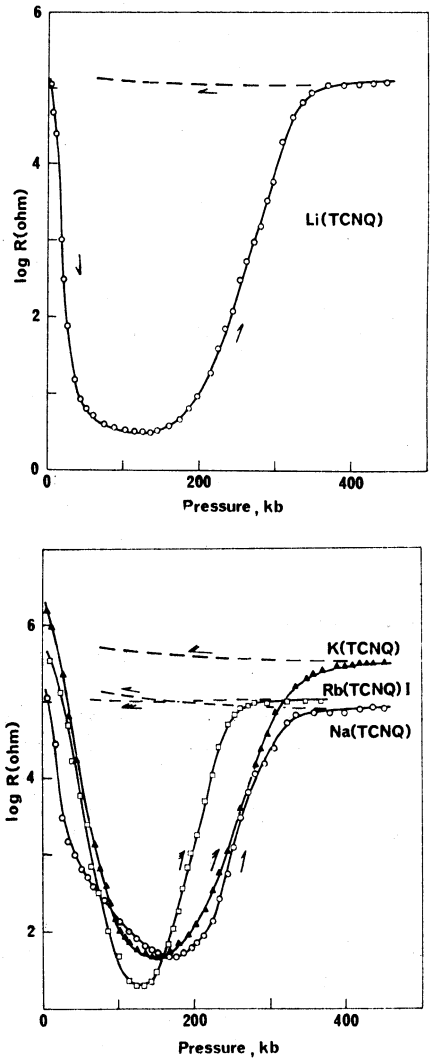

Fig. 3a and 3b. Pressure dependence of the electrical resistance of TCNQ salts in Group A.

In a previous paper,[11] we have reported that the electrical behavior of their single crystals is very complex under pure hydrostatic pressure. Several pressure-induced phase transitions are observed in the pressure range of 0—15 kbar at room temperature. However, the crystal structures do not change drastically.[16]

If the dimerized structure found in the columns of

Table 2. Minimum resistivity and minimum pressure

Compound	P_{min} a) ($\pm$5 kbar)	ρ_{min} b) (Ω cm)
Li-TCNQ	135	$\sim 2\times10^{-1}$
Na-TCNQ	174	$\sim 3\times10^{0}$
K-TCNQ	148	$\sim 3\times10^{0}$
Rb(I)-TCNQ	135	$\sim 1\times10^{0}$
Rb(II)-TCNQ	170	$\sim 6\times10^{-2}$
Cs-TCNQ	152	$\sim 1\times10^{-1}$

typical alkali metal-TCNQ salts is converted into the monomeric structure by the compression, and if the mode of overlapping between nearest $TCNQ^-$ ions in the column is then changed that of the Rb(II)-salt type, TCNQ salts may behave like metal at high pressures. However, the electrical resistances of Group A decreased monotonously with the pressure up to the pressure of minimum resistance. The least resistivities

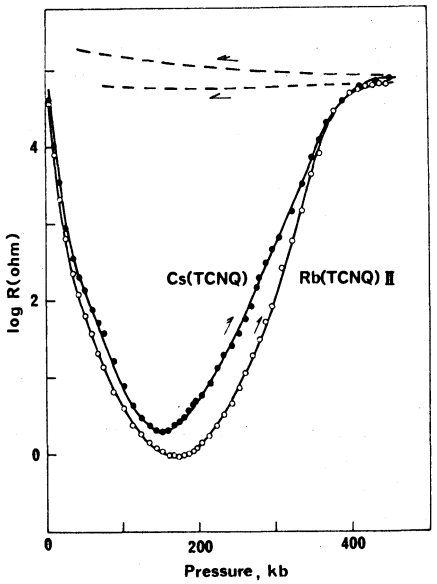

Fig. 4. Pressure dependence of the electrical resistance of TCNQ salts in Group B.

of all the TCNQ salts but Li-TCNQ were about 1—3 Ω cm at room temperature. No anomalous behavior arising from the phase transition to the metallic state was observed.

Figure 4 shows the effect of the pressure on the electrical resistances of TCNQ salts in Group B. The resistances decreased by a factor of approximately 10^4 in the first 150 kbar at room temperature. The least resistances are about one-tenth of those of Group A. The least resistivity in Rb(II)-TCNQ was about 6×10^{-2} Ω cm at 170 kbar. As is shown in Table 3, this value is less than the resistivities of a compacted specimen of the metallic TCNQ salts at atmospheric pressure.

The compressibility of Rb(II)-TCNQ has not been measured, but it is probably comparable to that of aromatic crystals.[16] From the relation between the pressure and the volume for molecular solids given by Samara and Drickamer, the average intermolecular distance at 170 kbar was estimated to be about 88% of that at atmospheric pressure.[17] Therefore, we can expect the interplanar spacing in Rb(II) salts around 170 kbar to be much shorter than 3.26 Å in NMP-TCNQ at 1 bar.

The magnetic-susceptibility and conductivity measurements for NMP-TCNQ indicate a metallic state above 200 K, with a continuous transition to an insulator below 200 K.[18] Similar behavior has also been observed in quinolinium-$TCNQ_2$ (Q-$TCNQ_2$),[19,20] acridinium-$TCNQ_2$ (Ac-$TCNQ_2$),[20] and tetrathiofulvalenium-TCNQ (TTF-TCNQ).[21,22] X-Ray studies of these metallic TCNQ salts show monoclinic or triclinic structures consisting of linear chains of identical TCNQ molecules stacked face-to-face and equally separated from one another.[12] This structure resembles that of Rb(II)-TCNQ. The electrical resistivities, the transition points, and the interplanar spacings between TCNQ molecules for metallic TCNQ salts are given in Table 3. These physical properties are also compared with those of Rb(II)-TCNQ near 170 kbar in this table.

On the basis of these data, we suggest that Rb(II)-TCNQ may show metallic behavior near 170 kbar.

The metal-insulator transitions in one-dimensional

Table 3. Comparison of physical properties between Rb(II)-TCNQ around 170 kbar and metallic TCNQ salts

	Rb(II)-TCNQ	NMP-TCNQ	Q-$TCNQ_2$	Ac-$TCNQ_2$	TTF-TCNQ

crystals such as TCNQ salts have been observed only along the conductive axis in the single crystals. The electrical resistivity along the needle axis in Rb(II) salt has been measured at hydrostatic pressures up to 14 kbar. The resistivity at this pressure is about 8 Ω cm at room temperature.[11] If the resistivity along the conductive axis were to be studied at higher pressures, an insulator-metal transition would probably be observed.

The compaction conductivity of microcrystals of metallic TCNQ salts indicates an exponentially-activated behavior because of inter-particle contact resistance. Their activation energy does not become zero even at very high pressures.[23] Recently, Heeger *et al.*[22] have reported a new experimental technique, a voltage-shorted compaction (VSC) device, for obtaining information on the bulk electrical properties from the compaction of samples. When this technique is used, the electrical behavior of microcrystalline sample does not show the thermally-activated process. For the study of the insulator-metal transition of compacted samples at high pressures, this technique may be very useful.

Solid-Phase Reaction. As is shown in Figs. 3 and 4, above 140—175 kbar the electrical resistances of the TCNQ salts increased rapidly with the increase in the pressure and drifted upward with the time. As is shown by the broken curve, this electrical behavior is irreversible. These phenomena arise from the solid-phase reaction. The minimum pressure[24] at which the reaction was induced is given in Table 2. It should be noted that for Group B this pressure is larger than for Group A except in the case of Na–TCNQ.

The pressure-induced solid-phase reactions for TCNQ and TCNQ salts have already been investigated under very high pressures by Drickamer *et al.*[25] The electronic absorption peaks at 300—900 nm and the infrared spectra on the basis of the C≡N stretching vibration disappear under very high pressures. This seems to indicate a reaction between C≡N bonds in adjacent TCNQ molecules. Considering the similar reaction for simple alkali metal–TCNQ salts, the difference in crystal structures may be very important. The interplanar distance and the magnitude of overlapping between C≡N bonds in TCNQ salts seem to be closely correlated with the pressure-induced solid-phase reaction. As has been mentioned above, Rb(I)–TCNQ has a short interplanar distance, 3.159 Å, and the overlapping between the C≡N bonds in Rb(I) salt is larger than that in Rb(II) salt. Therefore, we can expect that the reactivity of Group A is more sensitive to the pressure than that of Group B. The differences in minimum pressure shown in Table 2 may show the strength of the reactivity at high pressures.

The authors wish to acknowledge the excellent work of Mr. Ken-ichi Tanaka in the construction of the pressure vessel. We wish to thank Professor Hiroo Inokuchi and Dr. Hayao Kobayashi for their helpful discussions.

Isotropic Rayleigh Light Scattering in Two-component Systems. The Interdependence of the Concentration and the Density Scattering

Yoshinobu SHIOKAWA and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira 2-chome, Sendai 980

(Received June 19, 1974)

The isotropic Rayleigh ratios in two-component systems are discussed in terms of the fluctuation of the thermodynamic quantities. It is found that the isotropic Rayleigh ratio, R_{is}, is the sum of the concentration scattering, R_c, due to fluctuation of the concentration and the so-called density scattering, R_d:

$$R_{is} = R_c + R_d$$

Thus, the cross-term of the concentration scattering and the density scattering, suggested by Bullough, is not included in the above expression. Our conclusion is confirmed by the determination of the molecular weight of sucrose.

The light-scattering measurements have been mainly applied to macromolecules. In the last decade, however, several papers have appeared with relation to small molecules, *e.g.*, the determination of the activity coefficient in a binary solution[1,2] and of the degree of polymerization for the hydrolysis product of metal ions.[3,4]

According to Einstein,[5] the isotropic Rayleigh ratio of liquid in the direction perpendicular to the incident light beam is given by:

$$R_{is} = \left(\frac{\pi^2}{2\lambda^4}\right) V\overline{(\Delta\varepsilon)^2} \tag{1}$$

where λ is the incident wavelength and $\overline{(\Delta\varepsilon)^2}$ is the mean square fluctuation in the dielectric constant in the region of a certain volume, V.

In a pure liquid the scattering of light is called the density scattering because the density fluctuation makes predominant contributions to the dielectric-constant fluctuation.[6]

The scattering of light in a solution is attributed not only to the density scattering, R_d, but also to the concentration scattering, R_c, arising from the concentration fluctuation:[7]

$$R_{is} = R_d + R_c \tag{2}$$

Thus, the isotropic Rayleigh ratio in a solution has been considered as the sum of these two contributions.

On the other hand, Bullough,[7-9] and Sicotte and Rinfret[10] have suggested such an expression for the isotropic Rayleigh ratio in two-component systems; their expression contains a cross-term, R'', besides those two contributions:

$$R_{is} = R_d + R'' + R_c \tag{3}$$

The cross-term makes a significant contribution to the isotropic Rayleigh ratio when both components of a solution have a low molecular weight.

Most of the published papers on the determination of the activity coefficient have taken the cross-term, R'', into account. Later, Sicotte,[11] and Segudovic and Deželić[12] have made theoretical considerations of this cross-term.

The purpose of the present work is to reexamine Bullough's theory. Therefore, we will discuss the isotropic Rayleigh ratio in two-component systems in terms of the statistical fluctuation concept and will determine the molecular weight of sucrose on the basis of our consideration.

The scattering of light in an aqueous sucrose solution has been studied by Debye,[13] by Halwer,[14] and by Maron and Lou.[15] Debye and Halwer made an inadequate calibration of the instrument, however, nor did they make any correction for the depolarization. Moreover, Maron and Lou made mistakes in their correction for the depolarization.

Theoretical

It is necessary to estimate the fluctuations of the thermodynamic quantities so as to ascertain the fluctuation of the dielectric constant in a solution.

Consider a small part of a two-component system containing a given number, N_0, of moles of a solvent. The probability function for the thermodynamic quantities is given by:[16]

$$\omega = C\exp\left[-\frac{1}{2kT}(\Delta S\Delta T - \Delta V\Delta P + \Delta N\Delta\mu)\right] \tag{4}$$

where ΔS, ΔT, ΔV, ΔP, ΔN, and $\Delta\mu$ are the fluctuations of the entropy, the temperature, the volume, the pressure, the number of moles of the solute, and the chemical potential of the solute respectively, and where C is a normalization constant.

Now, choose P, T, and N as independent variables. By expanding ΔS, ΔV, and $\Delta\mu$ near the equilibrium state as a series, we obtain:

$$\omega = C\exp\left[-\frac{1}{2kT}\left\{-\left(\frac{\partial^2 G}{\partial P^2}\right)(\Delta P)^2 - 2\left(\frac{\partial^2 G}{\partial P\partial T}\right)(\Delta P\Delta T) - \left(\frac{\partial^2 G}{\partial T^2}\right)(\Delta T)^2 + \left(\frac{\partial^2 G}{\partial N^2}\right)(\Delta N)^2\right\}\right] \tag{5}$$

where G is Gibbs' free energy. This relation means that the fluctuation of number of moles of the solute and the pressure or the temperature are statistically independent:

$$\overline{(\Delta N\Delta P)} = \overline{(\Delta N\Delta T)} = 0 \tag{6}$$

We thus have:

$$\overline{(\Delta P)^2} = -kT(\partial^2 G/\partial T^2)/D$$

$$\overline{(\Delta P\Delta T)} = kT(\partial^2 G/\partial T\partial P)/D$$

$$\overline{(\Delta T)^2} = -kT(\partial^2 G/\partial P^2)/D$$
$$\overline{(\Delta N)^2} = kT/(\partial^2 G/\partial N^2)$$

where:

$$D = (\partial^2 G/\partial T^2)(\partial^2 G/\partial P^2) - (\partial^2 G/\partial P \partial T)^2$$

Using the well-known thermodynamic transformations, we obtain:

$$\overline{(\Delta P)^2} = -kT(\partial P/\partial V)_{S,N} \quad (7)$$
$$\overline{(\Delta P \Delta T)} = kT^2(\partial P/\partial T)_{V,N}/C_V \quad (8)$$
$$\overline{(\Delta T)^2} = kT^2/C_V \quad (9)$$
$$\overline{(\Delta N)^2} = kT/(\partial \mu/\partial N)_{T,P} \quad (10)$$

where C_V is the specific heat at a constant volume. Equations (7), (8), and (9) are quite similar to those for one-component systems.[16]

By expanding the dielectric constant as a series, we obtain:

$$\Delta\varepsilon = (\partial\varepsilon/\partial P)_{T,N}\Delta P + (\partial\varepsilon/\partial T)_{P,N}\Delta T + (\partial\varepsilon/\partial N)_{T,P}\Delta N$$

Considering Eq. (6), we find the mean squares of the fluctuation of the dielectric constant:

$$\overline{(\Delta\varepsilon)^2} = \left[\left(\frac{\partial\varepsilon}{\partial P}\right)^2_{T,N}\overline{(\Delta P)^2} + 2\left(\frac{\partial\varepsilon}{\partial P}\right)_{T,N}\left(\frac{\partial\varepsilon}{\partial T}\right)_{P,N}\overline{(\Delta T \Delta P)} + \left(\frac{\partial\varepsilon}{\partial T}\right)^2_{P,N}\overline{(\Delta T)^2}\right] + \left(\frac{\partial\varepsilon}{\partial N}\right)^2_{T,N}\overline{(\Delta N)^2} \quad (11)$$

By substituting $\overline{(\Delta P)^2}$, $\overline{(\Delta P \Delta T)}$, $\overline{(\Delta T)^2}$, and $\overline{(\Delta N)^2}$ into the above equation, we obtain:

$$\overline{(\Delta\varepsilon)^2} = \frac{kT}{V\beta_T}\left(\frac{\partial\varepsilon}{\partial P}\right)^2_{T,N}\left[1 + \left(\frac{\beta_T}{\beta_S} - 1\right)\chi^2\right] + \frac{kT}{(\partial\mu/\partial N)_{T,P}}\left(\frac{\partial\varepsilon}{\partial N}\right)^2_{T,P} \quad (12)$$

$$\chi = 1 + \frac{\beta_T(\partial\varepsilon/\partial T)_{P,N}}{\alpha_P(\partial\varepsilon/\partial P)_{T,N}}$$

where β_T is the isothermal compressibility, β_S is the adiabatic compressibility, and α_P is the isobaric expansivity.

Since we consider only a small part of the solution containing a given number, N_0, of moles of the solvent, we can regard the fluctuation of the number of moles of the solute as that of the concentration. From Eqs. (1) and (11), the expression for the isotropic Rayleigh ratio of the solution is the sum of the concentration scattering, R_c, due to the fluctuation of the concentration and the so-called density scattering, R_d, which is independent of the fluctuation of the concentration:

$$R_{is} = R_c + R_d \quad (13)$$

By using the $\varepsilon = n^2$ relationship, where n is the refractive index, we obtain:

$$R_c = \left(\frac{2\pi^2 kT}{\lambda^4}\right)Vn^2\left(\frac{\partial n}{\partial N}\right)^2_{P,T}\Big/\left(\frac{\partial\mu}{\partial N}\right)_{P,T} \quad (14)$$

$$R_d = \left(\frac{2\pi^2 kT}{\lambda^4\beta_T}\right)n^2\left(\frac{\partial n}{\partial P}\right)^2_{T,N}\left[1 + \left(\frac{\beta_T}{\beta_S} - 1\right)\chi^2\right] \quad (15)$$

Equation (15) is the same one as that shown by Coumou *et al.* for a pure liquid.[6] Consequently, we can regard the isotropic Rayleigh ratio in a solution as being additively composed of concentration scattering and the so-called density scattering.

Experimental and Results

Experimental. The light-scattering measurements were made with light with a wavelength of 436 nm using a Shimadzu electrophotometric light-scattering photometer, PG-21. The photometer was calibrated using benzene, so as to obtain 47.5×10^{-6} cm^{-1} for the total Rayleigh ratio.[17] This benzene was washed with concentrated sulfuric acid, passed through an activated aluminum oxide column, and carefully distilled prior to use. Measurements of the redistilled water used gave values for the Rayleigh ratio of 2.70×10^{-6} cm^{-1} and for the depolarization of 0.10. The aqueous sucrose solutions were purified by passing them through an activated carbon column[15] and were then tested for dissymmetry. The total Rayleigh ratio, R_t, and the depolarization, ρ, were determined for the sucrose solution thus obtained. Each sample was filtered directly into the cell through a Millipore filter 220 or 100 nm in pore diameter under the pressure of nitrogen.

The refractive index increments were determined at 25 °C using a Shimadzu photoelectric differential refractometer, DR-3, calibrated with aqueous solution of sodium chloride.[18]

The sucrose concentration was determined with both the density and the refractive index.[18]

Results. The isotropic Rayleigh ratio was found by[19]

$$R_{is} = \frac{6-7\rho}{6+6\rho}R_t \quad (16)$$

The so-called density scattering, R_d, of the sucrose solution was assumed to be equal to the isotropic Rayleigh ratio of water. The concentration scattering, R_c, was obtained by subtracting the isotropic Rayleigh ratio of water from the isotropic Rayleigh ratio, R_{is}, obtained by Eq. (16). The Rayleigh ratios, R_t, R_{is}, and R_c, for sucrose solutions which were obtained in this way are shown in Fig. 1. The variation in Δn for sucrose solutions is shown in Fig. 2, where Δn is the difference between the refractive index of a sucrose solution and that of water.

We can obtain the molecular weight of a solute by means of the following equations:

$$Hc/R_c = 1/M + 2Bc$$
$$H = (2\pi^2 n^2/\lambda^4 N_A)(\partial n/\partial c)^2_{P,T}$$

where c is the weight of a solute per ml of solution and B is the virial coefficient.

Figure 3 shows the plot of Hc/R_c for the sucrose concen-

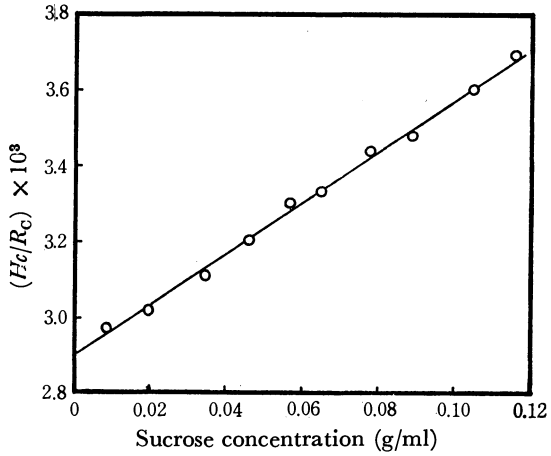

Fig. 3. Molecular weight determination of sucrose.

tration. This curve yields 344±6 as the molecular weight for sucrose, against a calculated value of 342.3.

Discussion

The good agreement of our experimental result with the calculated value confirms that the isotropic scattering is additively composed of the concentration scattering, R_c, and the so-called density scattering, R_d. This confirmation is also supported by the experimental results of Coumou and Mackor[1] and of Pethica and Smart.[20]

To elucidate the relationship between Eq. (3), which has been suggested by Bullough *et al.*, and our Eq. (13), we will express the fluctuation of the dielectric constant in terms of the density, the temperature, and the concentration thus:

$$\Delta\varepsilon = (\partial\varepsilon/\partial d)_{T,N}\Delta d + (\partial\varepsilon/\partial T)_{d,N}\Delta T + (\partial\varepsilon/\partial N)_{d,T}\Delta N \quad (17)$$

The density is given by $d=(N+N_0)/V$. We thus obtain:

$$\Delta d = -\frac{d}{V}\left(\frac{\partial V}{\partial P}\right)_{T,N}\Delta P - \frac{d}{V}\left(\frac{\partial V}{\partial T}\right)_{P,N}\Delta T + \left(\frac{\partial d}{\partial N}\right)_{P,T}\Delta N \quad (18)$$

Using Eqs. (6), (7), (8), (9), and (10), we obtain:

$$\overline{(\Delta d)^2} = -kT\left(\frac{d}{V}\right)^2\left(\frac{\partial V}{\partial P}\right)_{T,N} + kT\left(\frac{\partial d}{\partial N}\right)^2_{P,T}\Big/\left(\frac{\partial \mu}{\partial N}\right)_{P,T} \quad (19)$$

$$\overline{(\Delta d\Delta T)} = 0 \quad (20)$$

$$\overline{(\Delta N\Delta d)} = kT\left(\frac{\partial d}{\partial N}\right)_{P,T}\Big/\left(\frac{\partial \mu}{\partial N}\right)_{P,T} \quad (21)$$

Equations (10), (19), and (21) are equivalent to Eqs. (2.10), (2.12), and (2.9) in Ref. 21 respectively. Relation (20) shows that the fluctuations in the temperature and the density are statistically independent. However the fluctuations in the concentration and the density are not independent.

From Eq. (17), we obtain:

$$\overline{(\Delta\varepsilon)^2} = \left(\frac{\partial\varepsilon}{\partial T}\right)^2_{d,N}\overline{(\Delta T)^2} + \left(\frac{\partial\varepsilon}{\partial d}\right)^2_{T,N}\overline{(\Delta d)^2} + 2\left(\frac{\partial\varepsilon}{\partial d}\right)_{T,N}\left(\frac{\partial\varepsilon}{\partial N}\right)_{T,d}\overline{(\Delta d\Delta N)} + \left(\frac{\partial\varepsilon}{\partial N}\right)^2_{d,T}\overline{(\Delta N)^2} \quad (22)$$

It is easily shown that this relation is equivalent to Eq. (11). This relation means that the isotropic Rayleigh ratio is represented by Eq. (3) under the assumption that $(\partial\varepsilon/\partial T)_{d,N}=0$, an assumption which Bullough *et al.*[7-9,11,12] implicitly made use of. In this case, the concentration scattering is given by:

$$R_c = \left(\frac{2\pi^2kT}{\lambda^4}\right)Vn^2\left(\frac{\partial n}{\partial N}\right)^2_{d,T}\Big/\left(\frac{\partial \mu}{\partial N}\right)_{P,T} \quad (23)$$

However, the refractive index increment, $(\partial n/\partial N)$, is measured the pressure and the temperature being kept constant, while the density and the temperature are not. Unfortunately, attention has not been paid to this in several published papers.

It is clear from the above discussion that the isotropic Rayleigh ratio must be expressed by Eq. (13).

The authors wish to express their thanks to Professor C. Horie, Dr. A. Sato, and Mr. M. Hara for their valuable advice and encouragement throughout this work.

Combustion of Polymer Fuel-Spheres at Elevated Pressures

Takeo SAITO and Akira IWAMA

Institute of Space and Aeronautical Science, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received December 7, 1973)

Two kinds of polymer spheres polyurethane (PU) and carboxyl-terminated polybutadiene (CTPB), *ca.* 3 and 5 mm, respectively, in diameter and used currently as fuel and/or binder constituents in solid and hybrid rocket propellants, were ignited electrically with a nichrome fiber in several oxidizing gases over the range 5—30 kg/cm^2. Their combustion phenomena were studied photographically with a 16 mm movie camera. The combustion flame was observed by means of direct photographs, both the variation of diameter with time and the location of contact surface being measured with shadow photographs. It was shown that PU spheres are entirely liquefied, involving slight swelling just after ignition, and then burn in a similar manner to that of distilled hydrocarbon droplets. CTPB spheres were found to expand remarkably after ignition. At the first stage the surrounding product gases formed a diffusion flame, their apparent diameters remaining nearly constant for a short time. At the second stage the remainder of the carbonaceous substance continued to burn, turning to surface combustion. It can be predicted that in an actual rocket combustion chamber the surface of the fuel-binder for PU propellants is wet and that of CTPB propellants is covered with carbonaceous layer during the course of steady state burning. The overall mass burning rate is proportional to a half and 0.3 power of total pressure for PU and CTPB, respectively, depending slightly on the kind of inert gas for dilution of the oxidizing atmosphere in both cases. A combustion model for CTPB is presented and compared with experimental results.

PU and CTPB are important fuel and/or binder constituents in current hybrid and solid composite propellants. Saito[1] and Varney and Strahle[2] demonstrated that the two polymers are contrary to each other in pyrolysis behavior. This study was undertaken to clarify the burning aspects of these polymers having different pyrolysis properties in various oxidizing gases at elevated pressures.

Most experiments on polymeric materials for propellants have placed emphasis on combustion in midget hybrid motors. In such cases, the flow pattern of oxidizer exerts strong influence and the regressing surface of the polymer displays singular geometrical configuration by gas dynamic effects. Structure of the combustion zone is more complicated with the oxidizer flow line crossing boundary layer, transition from laminar flow to turbulent on the half way in the free channel, two phase flow including carbonaceous substance and piece of polymer torn off,[3] and solid-liquid-gas reaction. Study of the combustion of polymer at simplified condition is therefore necessary for explaining this complexity of hybrid and composite propellant combustion phenomena.

The combustion of plastic materials is drawing attention from the standpoint of pollution control and fire prevention but only few reports have appeared on the combustion of polymers. Essenhigh,[4] who studied some thermoplastic polymers burning in quiescent atmosphere, concluded that a burning constant of the Nusselt d^2 law is smaller than that of hydrocarbon oil droplet, *viz.*, the burning rate is larger because of the much closer approach of the surrounding flame to the droplet surface. We have examined whether the higher burning rate of the polymer, compared to hydrocarbon oils, is valid at elevated pressures and to predict the role of the elastomeric fuel-binder in hybrid and composite propellant combustion.

Equipment and Experimental Method

The experiments were performed with the apparatus and optical system shown in Fig. 1. The equipment consists of a high-pressure vessel with a window, 30 mm in width and 350 mm in length, mounted vertically at each side for observation purpose, a mixing chamber for producing a variety of ambient gases and a photographic system.

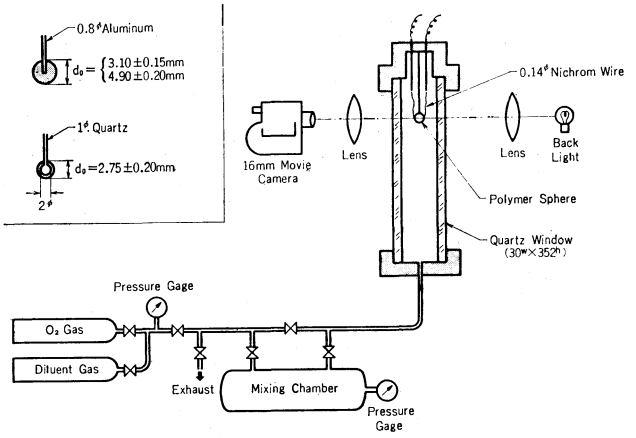

Fig. 1. Schematic diagram of the experimental apparatus.

The polymer spheres were suspended stationarily in the high-pressure vessel. PU spheres, *ca.* 3 mm in diameter, were cured at the tip of a quartz fiber; CTPB spheres, *ca.* 3 and 5 mm in diameter, were hardened and suspended at the tip of alumina fiber 0.8 mm in diameter. The spheres were ignited at the base by means of an electrically heated nichrome fiber 0.14 mm in diameter. A similar suspension method to that for CTPB was applied to PU, but the sphere could not be held stationary during the course of burning. The PU dribbled, rapidly fissuring urethane bonds and liquefying entirely to low viscosity fluid immediately after ignition. The urethane ingredient mixture was therefore cured by means of a one-shot process after being stuck to the spherical tip of a quartz fiber.

The combustion was studied with a 16 mm movie camera at the rate 49.1 frames/s. The optical system is composed of two close-up lenses and an enlargement lens set in front of a camera. Neutral density (ND) filters were used to reduce the intensity of the flame radiation on the films. While the burning spheres are shadow-photographed, the intense backward beam illuminating the sphere through the vessel is provided to drown out the surrounding flame. Variation of diameter and thickness of the boundary layers against time were measured with a film analyzer for the shadow photographs. The ambient pressure was in the range 5—30 kg/cm² (abs.). The pressurized gases, pure oxygen, oxygen diluted with nitrogen, argon and helium were used to study effects of dilution on thermal conductivity and diffusivity.

Results

Figures 2 and 3 show direct and shadow photographs of the burning PU and CTPB spheres, respectively. It is possible to distinguish two combustion phenomena for PU and CTPB. The flame of PU apparently corresponds to diffusional combustion which is similar to oil droplet combustion. On the other hand, CTPB demonstrates singularities outside the burning phenomena that were already observed on oil droplets.

Overall Mass Burning Rate. Total burning time is obtained from 16 mm movie shadow photograph records. For the *ca.* 2.7 mm diameter PU spheres in which a spherical quartz tip 2.0 mm in diameter is embraced, the total burning time t_b is obtained from the intersection of the extrapolation of variation curve of the square of diameter with the time axis. The average mass burning rate ($\dot{m}$) is calculated from initial mass of sample and total burning time.

PU: The average mass burning rate has a slight dependency upon the inert gases but an obvious dependency upon the total pressure in spite of large

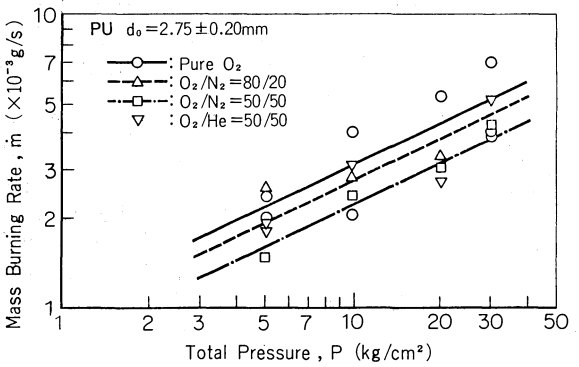

Fig. 4. Dependence of mass burning rate for PU on total pressure.

scattering of the data. The relation between mass burning rate and total pressure is given by $\dot{m}=\alpha P^{1/2}$ (Fig. 4). The effect of oxygen concentration in ambient gas on mass burning rate is included in factor α. Use of the diluent gases which differ in transport properties exerted a little influence on the mass burning rate, in particular He gas as a diluent indicates the tendency to increase $\dot{m}$ as compared with N_2 gas at the same oxygen concentration.

CTPB: The average mass burning rate for CTPB increases with an increase in the initial diameter of the sphere. Substitution of one diluent by another resulted in a somewhat different mass burning rate. For the sphere with initial diameter 4.9 mm, He and Ar included in oxygen gas lead to 10% higher mass burning rate than nitrogen gas dilution in the same fractions. However, such a difference due to the kind of diluent gas disappeared in the sphere of smaller initial diameter and lower oxygen fractions. This might be due to the coupling effect of thermal conductivity and diffusivity for inert gases. Figure 5 shows

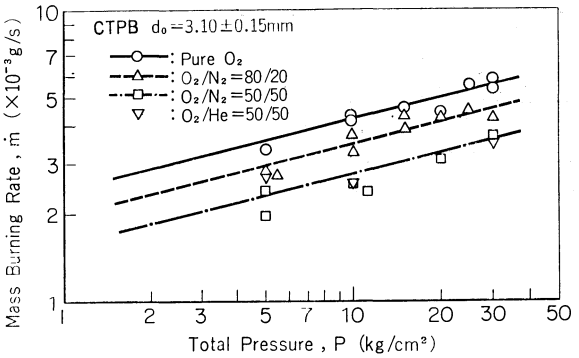

Fig. 5. Dependence of mass burning rate for CTPB on total pressure.

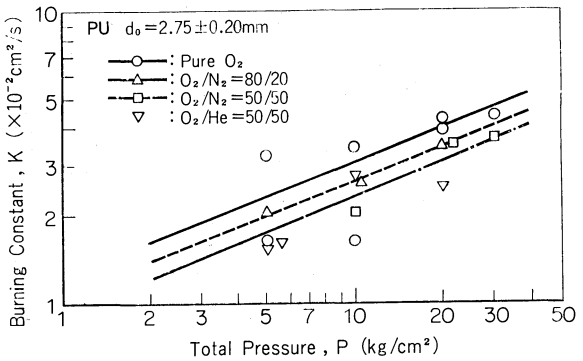

Fig. 7. Dependence of burning constant for PU on total pressure.

the dependency of the mass burning rate on total pressure given by $\dot{m}=\alpha' P^{0.3}$, where α' is a factor giving a measure of the dependency of oxygen fraction.

Square-of-Diameter Law. PU spheres swell a little just after ignition and liquefy quickly, their shape becoming ellipsoidal. According to Kobayashi's method,[5] the equivalent diameter is defined as

$$d = \sqrt[3]{a^2 b}$$

where a is a minor axis and b a major axis.

On the other hand, CTPB remains in the solid state in the core during most of the burning period and exhibits complex aspects at the surface. Closer examination revealed that the evolution of the shape of the burning drop is irregular and at lower pressures, in particular, the shape is apt to be far from spherical. The top of the drop shows a rough surface. The maximum horizontal diameter of the drop is therefore assumed to be an equivalent diameter for CTPB.

PU: After passing through a short expanding process, PU spheres decrease according to the d^2 law. Figure 6 shows plots of the variation of a PU drop diameter emerging on each frame of the 16 mm movie film. At a higher mass fraction of oxygen, discrete changes of apparent diameters exist which result from liquid-phase bubbling based on thermal cracking beneath the surface and which in turn bring about

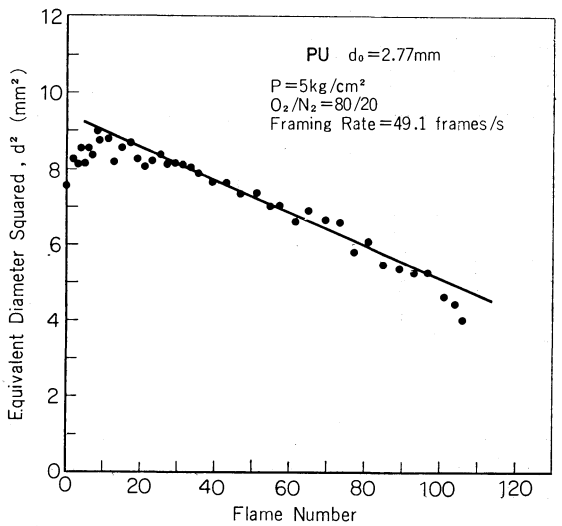

Fig. 6. Variation of equivalent diameter squared for PU with time.

flickering at the flame front.

The burning constant defined by $d_0^2-d^2=K(t-t_0)$ was derived by the method of least squares for diameter regressing drop during a limited period of steady state burning. In Fig. 7 the burning constant K is plotted *versus* P, the following relation being found.

$$K = \beta P^{0.4}$$

where β is a factor including dependence of oxygen fraction. Conventional oil droplets have 0.25[6] for this pressure index of the burning constant, the pressure index of PU being nearly equal to that for benzene.[7]

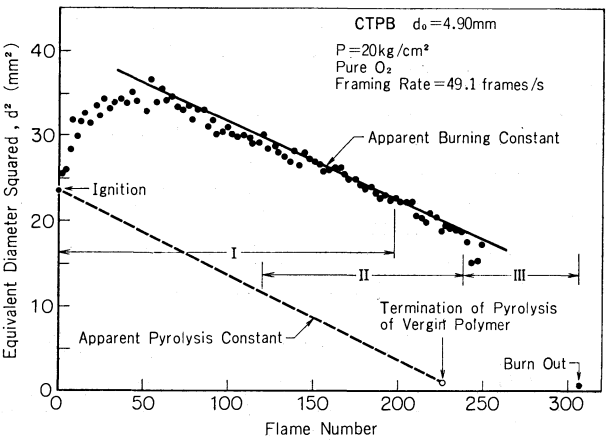

Fig. 8. Variation of equivalent diameter squared for CTPB with time.

CTPB: Figure 8 gives the change of the square of diameter during the life of a CTPB sphere in three stages:

(1) period between ignition and termination of gas emission from all burning surfaces except the top.

(2) period during surface combustion, *i.e.*, the period in which d^2 law holds. At this stage a superposition of the first stage exists.

(3) period during which the shapes change at random, the remaining cenosphere being extinguished.

At the first stage, the sphere of CTPB repeated swelling and contraction in low frequency in the order of 7—10 Hz for some time after ignition. However, the average diameter tends to be nearly constant, though for only a short time, after the initial transient period. Large scale heterogeneity of the evolving gases from surface resulted in formation of a lace pattern, producing a collection of numerous flamelets. The

porous carbonaceous substance which had become spherical was presumed to include virgin plastic. This was confirmed by interruption of burning half way, based on free falling of burning polymer spheres into a water pool.[8] From this time (second stage), the sphere began to regress along the curve of d^2 law. The coexistence of a diffusion flame formed by ambient oxygen and pyrolyzing gases with a surface combustion was observed. The linear relation between square diameter and time is valid even while virgin polymer remains, being covered with a carbonaceous layer. At the third stage, the cenosphere produced by an internal reaction occurring with the invasion of oxidizing gases into the porous layer, *i.e.*, produced by further cracking of the non-volatile carbonaceous residue, was swept out rapidly by the flame or flown away by natural convection. Apparent pyrolysis constant K_d (Fig. 8) is defined as the slope of the broken line d_0^2/t_d, linked between equivalent diameter squared at ignition d_0^2 and termination time of pyrolysis gas emission from all surfaces of burning polymer spheres. Here, the termination time of pyrolysis of virgin polymer, *i.e.*, termination of pyrolysis gas emission from all surfaces, which is defined much better than that from all surfaces except the top, was taken as t_d. Though the apparent burning constant K_r' for carbonaceous residue at the second stage, *i.e.*, the slope of the solid line, has very large scattering and even a tendency to decrease as ambient pressure increases, the corrected burning constant K_r divided by the squared swelling factor showed smaller scattering. At the third stage the shape of the porous carbonaceous residue, *i.e.*, cenosphere, changed entirely at random, and the horizontal diameter was therefore not measured. The scattering of the data prevented us from discriminating the effect of different diluent gas on the burning constant. However, it is evident that the burning constant may have weak dependency on P as shown in Fig. 9.

Extrapolation of the K–P curve at $O_2/N_2=50/50$ for PU (Fig. 7) gives *ca.* $K=0.9$ mm²/s for one atmosphere. K is assumed to be *ca.* 0.8 mm²/s at $O_2/N_2=20/80$ (in air). This corresponds to 50—80% less than constants

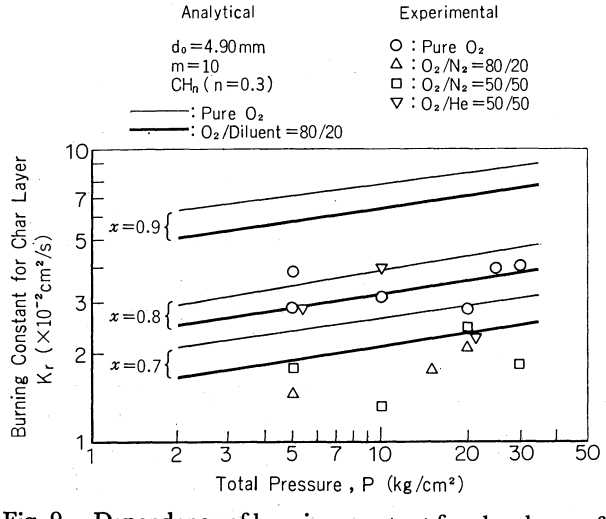

Fig. 9. Dependence of burning constant for char layer of CTPB on total pressure.

for various plastics reported by Essenhigh,[4] and suggests that PU would demonstrate substantially similar burning characteristics to those of the oil droplets.

Thickness of Contact Surface. The location of contact surface, *i.e.*, the boundary surface between surrounding ambient gas and ascending current due to natural convection, was determined by means of shadow photographs.

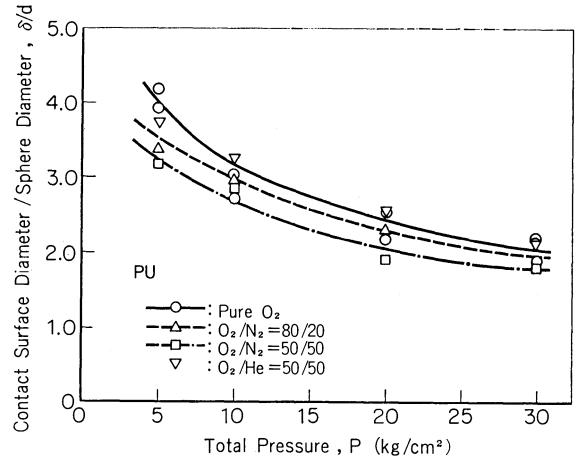

Fig. 10. δ/d for PU as a function of total pressure.

The ratio of apparent diameter of contact surface to diameter of PU sphere, δ/d, is given in Fig. 10, where δ is the maximum diameter of the contact surface envelope measured on the horizontal axis crossing at the center of the sphere. The contact surface measured in a vertical direction is five sixths of that in a horizontal direction at higher pressure and five sevenths at lower pressure. As ambient pressure decreases, δ/d increases and the contour of the contact surface expands a little in helium atmosphere because of its higher thermal conductivity.

The relationship[9] between contact surface diameter and volumetric flow rate of ascending current S is expressed by

$$\frac{\delta}{2}=\sqrt{\frac{S}{4\pi U}} \tag{1}$$

where U is the upward linear flow rate due to natural convection. Substituting $\dot{m}=\rho_g S$ into the equation and making use of the relation $\dot{m}=(\pi/4)\sigma dK$, we have

$$\frac{\delta}{d}=\sqrt{\frac{\sigma K}{8\rho_g r U}} \tag{2}$$

This equation implies that high temperature combustion of these polymers and higher density of environmental gas give a lower value of δ/d. Figure 10 shows agreement of experimental results with the trend indicated by Eq. (2). At the first stage of CTPB burning, the contact surface gives rise to oscillation in turn with the fluctuation of the burning surface. Figure 11 shows δ/d in the second stage where d^2 law holds. The contact surface becomes undulatory as oxygen fraction increases.

Swelling Factor. The swelling factor is defined as the ratio of the average maximum diameter at the first burning stage of CTPB to the initial diameter

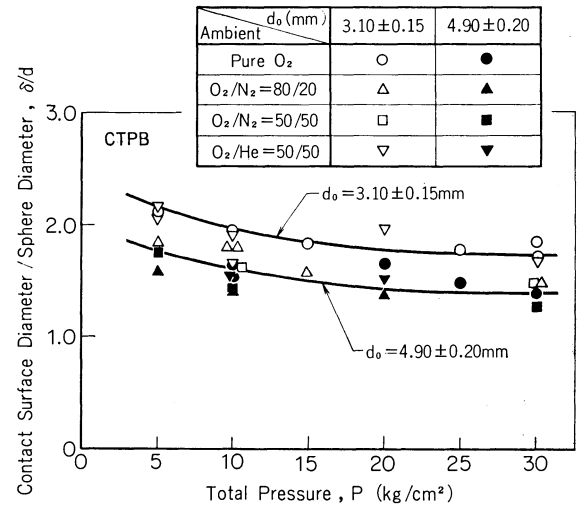

Fig. 11. δ/d for CTPB as a function of total pressure.

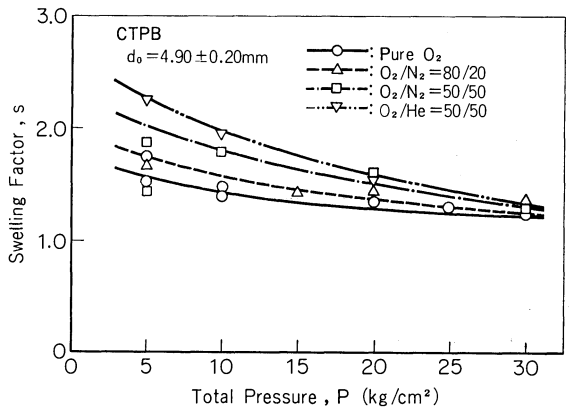

Fig. 12. Swelling factor for CTPB as a function of total pressure.

(Fig. 12). Variation of the swelling factor is affected by ambient pressure and oxygen fraction, although it is independent of the initial diameter. The use of helium gas as a diluent gave rise to an increase in the swelling factor as compared with that of N_2 diluent gas at the same oxygen fraction. Swelling for PU was negligible.

Analysis

A new combustion model for CTPB is proposed (Fig. 13). A number of semiempirical approximation apply to the region from the pyrolysis surface to the flame front:

(1) The surface of virgin polymer is maintained at constant temperature T_p with a carbonaceous layer remaining on the surface. ($\dot{m}_p=\dot{m}_g+\dot{m}_c$)

(2) The carbonaceous layer yields no dynamic interactions with the pyrolyzing gas flow (*e.g.*, its capillary flow resistance is negligible; pressure of the pyrolyzing gases passing through carbonaceous layer is constant).

(3) Quasi-steadily burning takes place.

(4) Conductive heat flux from the flame front controls the pyrolysis rate of polymer.

(5) The system is spherically symmetric.

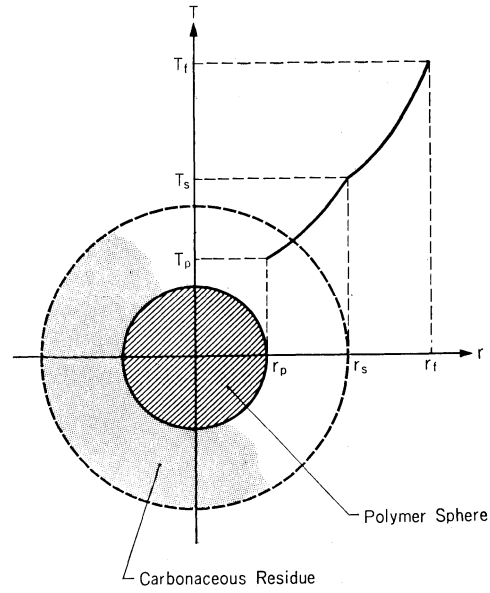

Fig. 13. A new combustion model for the sphere of CTPB.

(6) The heat released as a result of chemical reaction is removed by heat conduction and mass transport, *i.e.*, radiation and thermal convection are negligible.

(7) Temperature inclination inside virgin polymer is negligible.

The heat flow to the virgin polymer surface should balance only the heat needed for pyrolysis reaction, since the heat flow into the interior of the virgin polymer can be neglected on account of (7).

$$Q_v = h_v\dot{m}_p \doteq -4\pi r_p^2 q_v|_{r=r_p} \tag{3}$$

In addition, the heat flux to the virgin polymer surface is

$$q_v = -\bar{k}\frac{dT}{dr}\bigg|_{r=r_p} \tag{4}$$

where h_v is the pyrolysis heat per unit mass of polymer, $\dot{m}_p$ the mass pyrolysis rate and $\bar{k}$ the effective thermal conductivity of carbonaceous layer impregnated with pyrolyzing gases. The heat transport equation in terms of spherical coordinates would be written as

$$\rho_g c_p v_r \frac{dT}{dr} = \frac{\bar{k}}{r^2}\frac{d}{dr}\left(r^2\frac{dT}{dr}\right) \tag{5}$$

if the heat transfer between carbonaceous substance and gas flow is accomplished very quickly because of high porosity. Here, c_p is specific heat at constant pressure for gas and v_r the radial velocity. Equation (5) should be supplemented with boundary conditions:

$$T = T_s \text{ at } r = r_s$$
$$T = T_p \text{ at } r = r_p$$

The solution of Eq. (5) is given by

$$\frac{T-T_s}{T_p-T_s} = \frac{e^{-1/Ar}-e^{-1/Ar_s}}{e^{-1/Ar_p}-e^{-1/Ar_s}} \tag{6}$$

where $A=4\pi\bar{k}/c_p\dot{m}_g$ and $\dot{m}_g=4\pi r^2\rho_g v_r$. Substituting Eq. (6) into Eq. (4), we obtain

$$q_v|_{r=r_p} = -\bar{k}\frac{T_p-T_s}{Ar_p^2}\frac{e^{-1/Ar_p}}{e^{-1/Ar_p}-e^{-1/Ar_s}} \tag{7}$$

Substituting Eq. (7) into Eq. (3), we get

$$h_v\dot{m}_p = \frac{\dot{m}_g c_p(T_p - T_S)}{1-e^{-1/4(1/r_S-1/r_p)}} \tag{8}$$

The fraction of the polymer converted into gases on account of pyrolysis is defined as

$$\dot{m}_g = x\dot{m}_p, \qquad 0<x<1$$

Rewriting Eq. (8) with use of this definition, we have

$$\dot{m}_g = \frac{4\pi\bar{k}}{\left(\frac{1}{r_p}-\frac{1}{r_S}\right)c_p} \ln\left\{1+\frac{xc_p(T_S-T_p)}{h_v}\right\} \tag{9}$$

If polymer density σ is constant, the pyrolysis rate of the polymer can be expressed by

$$\dot{m}_p = -4\pi r_p^2\sigma\frac{dr_p}{dt} \tag{10}$$

Combination of Eqs. (9) and (10) gives

$$-xr_p^2\sigma\frac{dr_p}{dt} = \frac{\bar{k}}{c_p\left(\frac{1}{r_p}-\frac{1}{r_S}\right)} \ln\left\{1+\frac{xc_p(T_S-T_p)}{h_v}\right\} \tag{11}$$

On integration, we obtain

$$xr_0^2\left\{\frac{1}{2}-\frac{r_0}{3r_S}\right\} = t_d\frac{\bar{k}}{c_p\sigma} \ln\left\{1+\frac{xc_p(T_S-T_p)}{h_v}\right\} \tag{12}$$

where r_0/r_S is a factor combined with a swelling factor, s, as follows:

$$d_S^0 = d_0^2 + 0.8\{(sd_0)^2-d_0^2\} \tag{13}$$

The diameter of the carbonaceous layer is assumed to maintain a constant diameter squared which is averaged over the entire burning time at the first stage. Estimation of $\bar{k}$ in Eq. (12) is made by the equation

$$\bar{k} \approx \varepsilon k_g + (1-\varepsilon)k_s$$

where k_g and k_s are the thermal conductivity of pyrolyzing gases and carbonaceous substance, respectively, and ε the volumetric fraction of pyrolysis gases contained in char layer. We adopted the heat capacity of propane at $(T_S+T_p)/2$ for the approximation of heat capacity of the pyrolysis gases. From Eq. (12), we obtain the following relation for initial diameter:

$$d_0^2 = K_d t_d$$

where apparent pyrolysis constant K_d is:

$$K_d = \frac{4\bar{k}}{\left\{\frac{1}{2}-\frac{r_0}{3r_S}\right\}xc_p\sigma} \ln\left\{1+\frac{xc_p(T_S-T_p)}{h_v}\right\} \tag{14}$$

The equation indicates no explicit dependence of K_d on ambient pressure. It is apparent, however, that this expression becomes determinate when T_S or x is given as a function of total pressure and oxygen fraction by experiment.

The burning stage of CTPB transfers from gas-phase combustion of pyrolysis gas surrounding the surface of the carbonaceous layer to surface combustion similar to simple carbon. If the rate-determining process of regression for the carbonaceous layer is the diffusion of oxygen onto the surface, the specific reaction rate would be given by

$$R_S = -k_0(p_{ox}-p_S)$$

where k_0 is the velocity constant for mass transfer, p_{ox} the oxygen pressure in ambient gas and p_S the oxygen pressure on the surface of the carbonaceous layer. From the diffusion equation k_0 is given by

$$k_0 = \frac{DM_o}{RT_c\left(\frac{2r_c}{\delta}-1\right)} \tag{15}$$

where r_C is the carbonaceous layer radius, D the diffusivity for oxygen gas through combustion products, R the gas constant, δ the contact surface diameter and M_O the oxygen molecular weight. Since generally $p_{ox} \gg p_S$, the specific reaction constant can be given by

$$R_S = \frac{DM_o}{RT_c\left(1-\frac{2r_c}{\delta}\right)}p_{ox} \tag{16}$$

We shall now consider the stoichiometric reaction concerning the surface burning process which is given as follows.

$$CH_n + \left(1+\frac{1}{4}n\right)O_2 \longrightarrow CO_2 + \frac{n}{2}H_2O$$

On the other hand, the specific consumption rate for the carbonaceous sphere is given by

$$\frac{\dot{m}_c}{4\pi r_c^2} = -\rho_c\frac{dr_c}{dt} \tag{17}$$

From Eqs. (16) and (17), we get

$$-\frac{\rho_c}{M_c}\frac{dr_c}{dt} = \frac{1}{M_o\left(1+\frac{1}{4}n\right)}\frac{DM_o}{RT_c\left(1-\frac{2r_c}{\delta}\right)}p_{ox} \tag{18}$$

where ρ_C and M_C are apparent density for char layer and molecular weight for carbonaceous substance, respectively. We have herewith

$$\rho_c = \left(\frac{d_0}{d_S}\right)^3\sigma(1-x)$$

where d_S is as assumed in Eq. (13). Thus on integration of Eq. (18), we get

$$d_S^2-d_0^2 = \frac{8M_cDp_{ox}}{\left(1+\frac{1}{4}n\right)\rho_cRT\left(1-\frac{2r_c}{\delta}\right)}(t-t_0) \tag{19}$$

Since diffusion coefficient is proportional to ambient temperature and inverse to total pressure, apparent burning constant K_r' for carbonaceous layer is given by

$$K_r' = 8\frac{M_c}{1+\frac{1}{4}n}\frac{D^0p_{ox}}{\rho_cRT^0\left(1-\frac{d_c}{\delta}\right)}\frac{1}{P}\frac{T}{T^0} \tag{20}$$

where D^0 is diffusion coefficient at 273 K and one atmospheric pressure, the relation $T=(T_C+T_\infty)/2$ being adopted. Surface combustion temperature T_C at carbonaceous layer surface is then assumed to be proportional to total pressure; we can put $T_C=T_{C_0}P^{1/m}$. Here, T_{C_0} is the surface combustion temperature at atmospheric pressure dependent on oxygen fraction. $T_{C_0}=1500$ K is assumed for pure oxygen. The burning constant K_r, *i.e.*, K_r'/s'^2, is calculated by means of the above expression, where $s'^2=1+0.8(s^2-1)$ from Eq. (13).

Discussion

The process of combustion of CTPB sphere in a quiescent oxidizing gas is characterized by the develop-

ment of gaseous diffusion flame and subsequent surface combustion of char layer. High permeability for gases and high effective thermal conductivity of such a carbonaceous layer seem to introduce a mass burning rate about one and a quarter times as large as that of PU sphere. The comparatively greater apparent pyrolysis constant K_d for CTPB virgin polymer is also deduced to be mainly due to the thermal factor of the char layer.

The mass burning rates for PU and CTPB presumed at one atmosphere by the extrapolation method are given in Tables 1 and 2, respectively.

Table 1. Mass burning rate for PU at one atmosphere (mg/s)

Ambient	$d_0=2.75\pm 0.20$ mm
Pure O_2	1.1
$O_2/N_2=80/20$	0.9
$O_2/N_2=50/50$	0.75

Table 2. Mass burning rate for CTPB at one atmosphere (mg/s)

Ambient	d_0	
	4.90 ± 0.20 mm	3.10 ± 0.15 mm
Pure O_2	4.4	2.4
$O_2/N_2=80/20$	3.1	2.0
$O_2/N_2=50/50$	2.5	1.5

The first two stages are mostly the time denoted by t_d required for the burning of gases emitted from virgin polymer and a latter part of the second and the third stages are the time (t_s) of surface combustion including internal oxidation reaction. The partial superposition of the process of gas phase and surface combustion becomes considerably greater as the ambient pressure increases. For instance, t_d/t_b equals 0.75 and occurrence of the incipient surface combustion is observed when 35% of the total time of combustion has elapsed at 30 kg/cm² of pure O_2. This is shown in Fig. 14, where the broken line denotes the time when the emission of pyrolysis gases terminates from all burning surfaces except the top at the base of a supporting fiber. However, plotting for each emission is ommitted in order to avoid complexity of the figure. In this case the time of substantial superposition of both processes is approximately 20% of the total time of combustion. Afterwards, pyrolyzing gases are emitted only from the top of the sphere. At lower pressures such as 5 kg/cm² the total time of combustion can be written as

$$t_d + t_s = t_b$$

The region of gas-phase diffusional combustion, in turn, can be divided into a process in which vigorous emission of pyrolysis gases and periodically repeated swelling and contraction of sphere are observed and a process of d^2 law combustion in which a number of flamelets are established and a part of oxygen passing through undulatory flame front contributes to the process of the surface combustion. The value of t_d/t_b photographically obtained is sensitive not to the total pressure but to oxygen fraction under high pressure. However, the ratio of surface burning to the total burning time is a little stronger function of total pressure at the lower pressure below 10 kg/cm². At more elevated pressure, CTPB burning characteristics are substantially controlled by the physical nature of the carbonaceous layer.

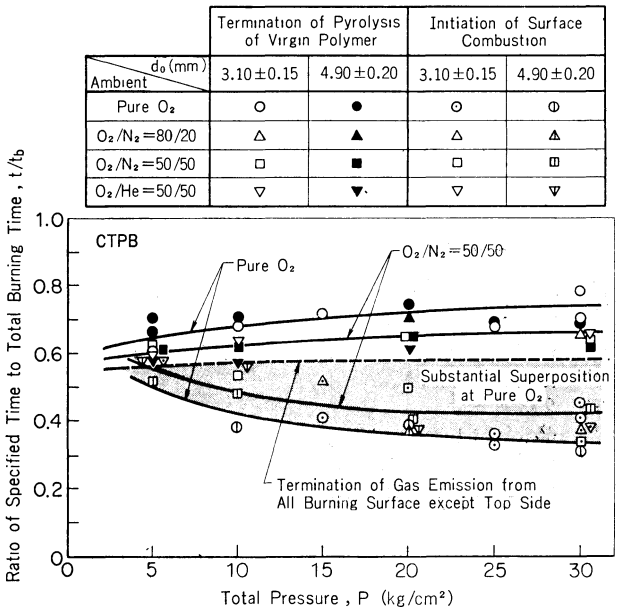

Fig. 14. Variation of ratio of specified time to total burning time with total pressure for CTPB.

The results are compared with analytical calculations for the CTPB combustion model for the case in which T_s is assumed to be a function of the total pressure of ambient gas for the gas-phase combustion at the first stage:

$$T_s = T_{s_0} P^{1/m'}$$

where T_{s_0} is the surface temperature of char layer during the first stage burning at one atmospheric pressure which is dependent upon oxygen fraction. T_{s_0} for pure oxygen gas as ambient gas is assumed to be 1000 K. According to the T_s-P diagram, a reasonable value for m' is 8—12. If the fraction of CTPB polymer converted into gases on account of pyrolysis reaction is presumed to be 0.7—0.9, the calculated results would be in good agreement with experimental data (Fig. 15). The parameters used in this calculation are $m'=10$, $\bar{k}=0.001$ cal/cm·s·deg. Similarly, the value x derived from the combustion constant for carbonaceous residue in Fig. 9 also is 0.7—0.8. In order to examine the validity of x, deduced from this analysis, a rough estimation of the apparent density of the carbonaceous layer was made by the interruption of burning at half way, yielding 0.11—0.32. The prediction based on the analytical results of the burning constant K_r for char layer of CTPB at one atmosphere including 20% oxygen by volume yielded $K_r=1$ mm²/s, which is nearly twice as large as the data of some plastics forming a carbonaceous layer at the second burning stage defined here such as cellulose acetate, phenolic resin and polycarbonate.[4]

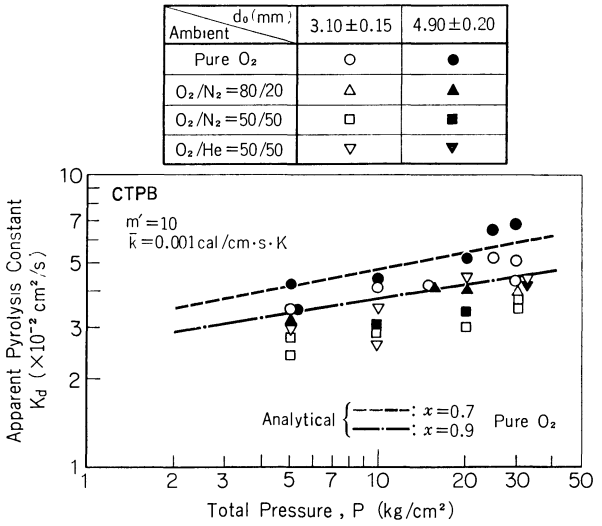

Fig. 15. Comparison of analytical results with experimental data for apparent pyrolysis constant for virgin polymer of CTPB.

Our emphasis on the CTPB burning aspects introduced by the existence of a freely-gas-permeable carbonaceous layer is to a certain extent justified by these experimental observations differing from the PU sphere burning such as common hydrocarbon droplets.

Conclusion

(1) The burning surface of PU spheres is always covered with a liquefied layer, while that of CTPB spheres remains a highly porous char layer under steady state combustion.

(2) The pressure index of the overall mass burning rates for PU and CTPB spheres are 0.5 and 0.3, respectively. Dependence of the burning constants upon the total pressure is given as follows:

$K=\beta P^{0.4}$ for PU. (experimental)

$K_d=\gamma P^{1/6}$ for virgin polymer of CTPB. (analytical)

$K_r=\gamma' P^{1/6}$ for char layer of CTPB. (analytical)

PU spheres which burn in a similar mechanism to that oil droplets regress with a rate having pressure index close to that of the burning constant for oil droplets.

(3) 70—90% of CTPB by weight is emitted as pyrolysis gases from virgin polymer on account of pyrolysis reaction and consumed in a gaseous diffusion flame with oxidizing gases, and the remainder proceeds to burn subsequently in a surface combustion mechanism.

(4) Analytical results based on a new combustion model for CTPB, which has a char layer structure formed by pyrolysis reaction, agreed with experimental observations, particularly in connection with the life of virgin polymer spheres and the fraction of the char layer.

On the Selectivity in the Catalytic Hydrogenation of Methylacetylene on Group VIII Metals

Noritetsu YOSHIDA* and Kozo HIROTA**

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received March 30, 1974)

The reaction of methylacetylene with hydrogen and deuterium was studied over five Group VIII metals (Pd, Pt, Rh, Ir, and Ru) at 25 °C. Among these metals, palladium was the most selective for the propylene formation; the selectivity varied from metal to metal (Pd>Pt>Rh>(Ni)>Ru>Ir). A new result was obtained over ruthenium; the isomerization of methylacetylene to allene occurred simultaneously with the hydrogenation over only this metal. In the reaction with deuterium, the stereoselectivity of the metals was investigated on the products by analyzing them by the microwave spectroscopic and mass spectrometric methods. Only three hydrogen atoms were deuterated in the propylene produced over Ni, Pd, and Pt; in conformity with the above, the deuterated positions of propylene-d_1 and -d_2 were limited to three in the methylene and methylidyne groups. No such tendency was observed for Ir, Rh, and Ru, where the methyl hydrogens were also deuterated. The relative yield of the *cis*-1,2-d_2 species, always the most abundant product, decreased in this order: Pd>Pt>Ir>Ru>(Ni)>Rh at 70% conversion. A reaction mechanism which explains the relative yields of isotopic isomers of deuteropropylenes except for the methyl-deuterated species was proposed, assuming an adsorbed radical as an intermediate. The calculated isomer distributions based on the scheme coincided well with those observed in the cases of Pd, Pt, and Ni, but not in those of Ir, Rh, and Ru.

For the catalytic hydrogenation of acetylenic compounds, there have been many investigations of the kinetics, but few about reactions with deuterium. Detailed results on the reaction of dimethylacetylene with deuterium were reported by Meyer and Burwell[1] using palladium–alumina, and by Webb *et al.*[2] using other noble Group VIII metals supported on alumina. Recently, Bond *et al.*[3,4] studied the reaction of acetylene with deuterium using noble Group VIII metals supported on alumina, and determined the relative yields of the isomeric ethylene-d_2 species by infrared spectroscopy.

From these studies, it is now definitely accepted[5] that the major process involved in producing an olefin from its corresponding acetylenic compound over metal catalysts is the successive addition of two hydrogen atoms, not the direct addition of a hydrogen molecule, as has usually been presumed before. However, the previously-proposed scheme cannot explain the observed results quantitatively; for instance, *trans*-olefin is always produced to some extent as the primary product, though in a much smaller quantity than *cis*-olefin.

In order to clarify this point, in the present research the stereoselectivity in the reaction of methylacetylene with deuterium was investigated over five Group VIII metals (Pd, Pt, Rh, Ir, and Ru) by measuring with a microwave spectrometer the relative yields of the isotopic isomers of the propylene-d_1 and -d_2 produced. The mechanism of stereoselectivity is discussed on the basis of the results for the five metals and those for Ni previously reported.[6]

Experimental

Materials. The purifications of methylacetylene, deuterium (Takachiho Chem. Ind. Co.) and electrolytic hydrogen were described in a previous report.[6] The rhodium-black was prepared by the reduction of the rhodium hydroxide produced by the reaction of rhodium trichloride with sodium hydroxide. The iridium-black was prepared by adding a 0.01 mol solution of iridium tetrachloride to an excess amount of a hot solution of sodium borotetrahydride. The palladium-black, platinum-black (Nakarai Chem. Co.) and ruhtenium-black (Mitsuwa Chem. Co.) used were commercial reagents. All the metals mentioned above were, before use, reduced with hydrogen at 230—240 °C for two days in the reaction vessel. The amount of each metal used and the BET areas (mesured with N_2 at −198 °C) are as follows:

Pd 2 mg (7.7 m²/g), Pt 40 mg (2.4 m²/g),
Rh 30 mg (10.9 m²/g), Ir 20 mg (14.2 m²/g),
Ru 150 mg (33.2 m²/g).

Procedure. The reaction of methylacetylene with hydrogen or deuterium was carried out under the same conditions and by the same procedure over all the five metals, as has previously been done over nickel.[6]

The standard mixture, which consisted of P_{D_2} (or P_{H_2})= 60 mmHg and $P_{C_3H_4}$=30 mmHg, was introduced into a reaction vessel (about 300 ml) containing the catalysts; this vessel was connected to a conventional vacuum apparatus. The reactions were carried out in a simple static system at 25 °C and followed from manometric measurements. When the desired degree of hydrogenation has been reached, the reaction mixture was taken out by expanding it into a reservoir (3 l) preliminarily evacuated. The composition of hydrocarbons in the mixture was analyzed by gas chromatography, using a 4 m column of 20 wt% of dimethylsulfolane on Neopak-1B at room temperature. The samples for the isotopic analysis were prepared by the gas-chromatographic separation of the mixture into components (propane, propylene, and methylacetylene) using the column described above.

The deuterium distributions in the propylene and methylacetylene produced were determined with a mass spectrometer (Hitachi RMU-5B) in the Institute for Protein Research,

* Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara Kanagawa 229, (Present address, 3-59-1-510 Yamatedai, Ohkubo, Akashi, Hyogo 674.)

** Present address, Chiba Institute of Technology, Yatsu, Narashino, Chiba 275.

Osaka University. In the analysis, the energy of the ionizing electrons was lowered sufficiently so that only the parent ion could be produced in the mass spectrum.

Propylene-d_1 (C_3H_5D) and -d_2 ($C_3H_4D_2$) have four and seven species of isotopic isomers respectively, as is shown in Fig. 1. The relative abundances of these species in the propylene produced were determined with a microwave spectrometer, installed at the Sagami Chemical Research Center, by measuring the relative intensities of the rotational 1_{01}—0_{00} transitions of the species. A detailed description of the analysis has previously been reported.[7] The distributions of the isotopic isomers thus determined are called the hyperfine distributions of propylene-d_1 and -d_2 respectively in order to discriminate them from the usual deuterium distribution, called the fine distribution, which is determined with a mass spectrometer.

Results

Reaction Curves. Some typical reaction curves with the standard mixture of hydrogen (or deuterium) and methylacetylene over six metals are shown against the time in Fig. 2, taking the pressure fall ($-\Delta P$) as the ordinate. As is shown in this figure, all the curves consist of two parts with different rates, producing a point called the acceleration point ($-\Delta P_a$). The reaction rates are accelerated abruptly at this point, except in the case of palladium, where negative acceleration is observed. Each part can be regarded as corresponding to a reaction stage, as has been confirmed by another finding. The possibility of polymerization during the reaction may be ruled out over the six metals, because the total pressure decreases asymptotically to the value expected from the stoichiometric equation; $C_3H_4+2H_2=C_3H_8$. This situation is supported by the fact that no polymers were detected in the gas phase.

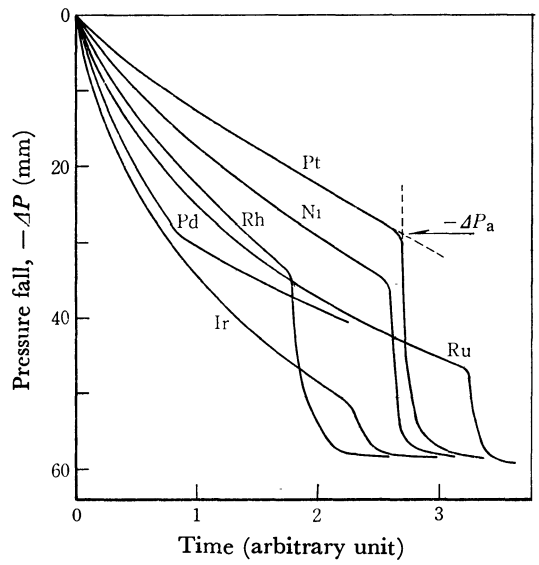

Fig. 2. Typical pressure-fall against time curves for the hydrogenation of 30 mm of methylacetylene at 25 °C. Ni, Pt, Ir $P^{\circ}_{H_2}=60$ mmHg; Pd, Rh, Ru $P^{\circ}_{D_2}=60$ mmHg.

The rates of the pressure fall during the course of the former stage was approximately proportional to the remaining hydrogen pressure. Furthermore, the initially-added propylene (26 mm) did not affect the hydrogenation rate over Ir, in accord with the results for 2-butyne with 1-pentene added[8] and that of acetylene with ethylene added.[9,10] The catalytic activities of the six metals were compared with one another by calculating the initial rate of methylacetylene removal per unit of area. The results in the reaction with deuterium were as follows:

A: Pd > Rh > Pt > Ni > Ir > Ru

A similar sequence has previously been reported in the hydrogenation of acetylene over evaporated metal films,[11] *i.e.*, Pd>Rh>Pt>Ni≫Fe>W. However, the A sequence does not coincide very well with that over supported metals.[12]

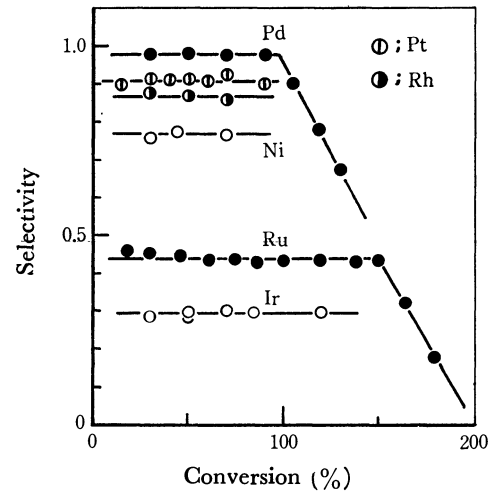

Fig. 3. Selectivity against conversion curves for the hydrogenation of methylacetylene at 25 °C. $P^{\circ}_{C_3H_4}=30$ mmHg, $P^{\circ}_{D_2}=60$ mmHg.

Selectivity. The selectivity, defined by $S=P_{C_3H_6}/(P_{C_3H_6}+P_{C_3H_8})$, was determined at various conversions of the reaction between methylacetylene and deuterium. It is shown in Fig. 3 against conversion which is defined by the percentage of the total pressure fall to the initial pressure of methylacetylene. The mean values of the selectivity, which is very different from metal to metal, are the following sequence:

B: Pd(0.98) > Pt(0.92) > Rh(0.87) > Ni(0.76) > Ru(0.44) > Ir(0.29).

This sequence is the same as that reported in the case of acetylene.[13]

The selectivity in the former stage is constant within the limits of experimental error, but it decreases rapidly in the latter stage, as is shown by the right halves of the corresponding curves of Pd and Ru in the figure. This finding indicates that methylacetylene is hydrogenated in the former stage to both propylene and propane in a certain ratio, while further hydrogenation of propylene to propane becomes dominant in the latter stage.

Formation of Allene. In the course of hydrogenation over ruthenium, a new finding was obtained; a trace of allene (CH_2=C=CH_2), which is an isomer of methylacetylene, appeared in the reaction mixture, together with the hydrogenation products. At a 70% conversion, the allene amounted to 4.3% of the initial methylacetylene. Allene was formed also in the absence of hydrogen over ruthenium; the initial rate of its formation was 1.8×10^{-6} mol/m^2·hr. This value was close to the rate of the hydrogenation, 6.8×10^{-5} mol/m^2·hr, represented by the rate of methylacetylene removal in the gas phase; therefore, allene could be detected during the hydrogenation. Over the other metals, however, allene could not be detected at all either during the hydrogenation or in the absence of hydrogen at 25 °C.

The high activity of ruthenium for the isomerization (CH_3–C≡CH⇄CH_2=C=CH_2) might be accounted for by its crystal structure, because ruthenium has the closed-packed hexagonal structure, whereas the other metals have the face-centered cubic structures. Further experiments will be required to confirm this supposition. The detailed results of the isomerization will be reported in the next paper.

Deuterium Distribution. The fine and hyperfine distributions of the propylene produced over palladium are shown in Table 1, where $\phi/100$ denotes the mean number of deuterium atoms in a propylene molecule; *i.e.*, $\sum i.d_i/100$ (i=1, 2, ----, 6). The measurement errors in the hyperfine distributions are indicated by 2.5 σ (σ: the standard deviation). Table 1 shows that neither the fine nor the hyperfine distribution changes substantially until the acceleration point or 97% conversion of the hydrogenation. Such constancy of the distribution was also observed in the case of nickel, as has previously been reported.[6] After the acceleration point, however, both distributions of propylene become dispersed, producing various kinds of species.

The fine and hyperfine distributions over six metal catalysts at a 70% conversion are compared in Tables 2 and 3 respectively. In Table 2, the fine distribution of methylacetylene is also listed. Table 2 shows that the most abundant deuteropropylene is the d_2 species,

but it is not the unique product, over every metal. Propylenes more highly deuterated than d_1 are not produced over Pd; similarly, their amounts are not significant over Pt and Ni. This finding is in accord with the results shown in Table 3; *i.e.*, the deuterium atom is not substituted for the hydrogen atoms in the methyl group of a propylene molecule. The constancy of the distributions until the acceleration point was observed over Pt as well as over Pd and Ni. Over the other metals, however, the yield of the propylene-d_2 species decreased slightly as the reaction proceeded. Simultaneously, the relative yield of the *cis*-1,2-d_2 species decreased; for example, the yields over Rh and Ru at a 30% conversion were 58.6 and 63.4% respectively, while that over Ir at a 50% conversion was 82.7%.[14]

It is interesting that methylacetylene-d_1 was formed markedly in the cases of Rh and Ru. According to the microwave spectroscopic analysis of methylacetylene at a 50% conversion over Rh, methylacetylene-d_1 consisted of 99.8% CH_3-C≡CD and 0.2% CH_2D-C≡CH. The methylacetylene-d_1 produced over the other metals is estimated to be almost CH_3-C≡CD, just as over Rh, because methylacetylenes more highly deuterated than d_2 could not be detected practically, as is shown in Table 2.

The dependence of the fine and hyperfine distributions on the experimental conditions was studied over Ni, following the previous report.[6] The results are shown in Table 4. When the initial partial pressure of deuterium was increased from 60 to 150 mm, neither of the distributions changes very much. An increase in the temperature, however, reduces the yield of *cis*-1,2-d_2 species slightly. The former result is in accordance with the constancy of the distributions until the acceleration point, as described above; a very similar tendency is estimated in the hyperfine distributions over Pd and Pt as well as over Ni.

Discussion

General. The finding that the selectivity remained constant up to the acceleration point can be explained by the stronger adsorption of methylacetylene than that of propylene or propane. This is supported by the fact that the initial rate was not affected by the initially-added propylene over Ir. Therefore, methylacetylene is considered to act as poison in the hydrogenation of propylene. However, it is noteworthy that differences in selectivity are found among the metals. This may be ascribed to the degree of the adsorbability of methylacetylene to each metal, which determines the ratio of the probability of producing propylene (Path A) to that of producing propane *via* the half-hydrogenated species (Path B).

a) 1,3-d_2 and 3,3-d_2 were not detected.

After the acceleration point in the reaction curve, the metallic surface is practically covered with olefin as a result of the rapid decrease in methylacetylene, so the selectivity in the former stage decreases gradually. As can be understood easily by the material balance, the higher the selectivity in the former stage, the later the acceleration point has to be for each metal.

The poisoning effect of strongly-adsorbed methylacetylene can also explain the findings that the fine and hyperfine distributions remained constant up to the acceleration point over Pd, Pt, and Ni. In the first stage of the reaction, deuterium exchange through the readsorption of the produced propylene cannot proceed because of this effect. After the acceleration point, however, propylene can readsorb with less of the poisoning effect of the methylacetylene than before that point. Consequently, the redistribution of hydrogen atoms among propylenes can proceed easily before propane is formed, various kinds of isomeric species being thus formed. This tendency is the same as that observed in the case of 2-butyne hydrogenation over palladium supported on alumina;[8] *i.e.*, *cis*-2-butene, the main product of the reaction, began to isomerize to *trans*-2- and 1-butene after the 2-butyne has almost disappeared from the gas phase. The small variation in the deuterium distributions with the time over Rh, Ir, and Ru cannot be explained only by this effect. An explanation of the finding requires the contribution of some surface processes which are of no importance in the cases of Pd, Pt, and Ni—for example, the processes leading to the formation of highly-deuterated propylenes, as will be discussed below.

Stereoselectivity. Table 3 shows that propylene-*cis*-1,2-d_2 is always the most abundant, indicating the *cis*-type addition of two hydrogen atoms to the triple bond to be very easy. Though this tendency has already been reported for several acetylenic compounds,[5] it must be noted that the reason for the favorable production of the *cis*-1,2-d_2 species over the *trans* isomer is due not to the thermodynamic but to the kinetic nature, because the two species are different only in the substituted position of deuterium, so their stabilities must be nearly the same.

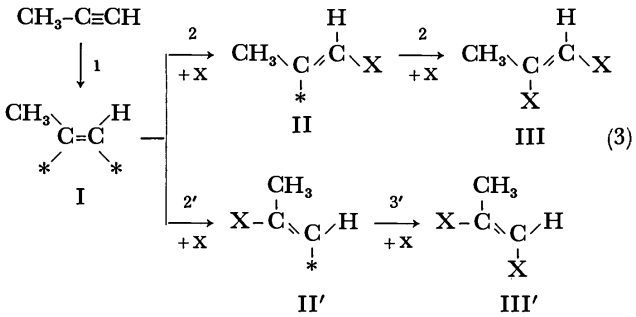
The relative yield of the *cis*-1,2-d_2 species over the six metals at 70% conversion decreased in this order;

C: Pd > Pt > Ir > Ru > (Ni) > Rh.

Palladium is also superior in stereoselectivity to produce the *cis*-1,2-d_2 species. The C sequence is practically the same as the sequence of the selectivity for producing propylene-d_2 formation—*i.e.*, Pd>Pt>Ir>Ni>Rh>Ru, as is shown in Table 2. The different positions of Ru in the two sequences might be related to the formation of allene during the reaction, which occurred only over ruthenium.

The especially high stereoselectivity of palladium has already been established. According to Burwell's research into the hydrogenation of gaseous dimethylacetylene (2-butyne),[8] *cis*-2-butene was produced exclusively over alumina-supported palladium as long as any unreacted dimethylacetylene remained. Such a surprisingly high stereoselectivity was not observed, however, in the case of methylacetylene in the present research. In the hydrogenation of acetylene with deuterium by Bond and Wells, the high stereoselectivity could not be obtained, either.[3] In this study, they determined the relative yields of three kinds of isomeric ethylene-d_2, such as *cis*-d_2, *trans*-d_2, and *asymmetric*-d_2, by means of infrared spectrometry; they reported that the yield of the *cis*-d_2 species was about 80% over Pd. These results may be due to the steric hindrance of methyl groups bonded to the C≡C group rather than to such an experimental difference as that a flow method was adopted in the case of dimethylacetylene. The above findings may be useful in discussing the mechanism of the hydrogenation process of methylacetylene, $CH_3–C{\equiv}CH + H_2 \longrightarrow CH_3–CH{=}CH_2$.

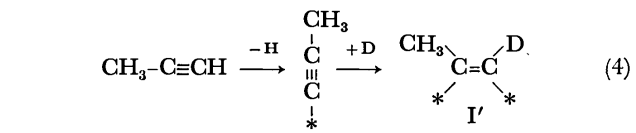
Mechanism. From the finding that the majority of the produced propylene consisted of the *cis*-1,2-d_2 species, Scheme (3) may be drawn for the mechanism of methylacetylene hydrogenation. It is based on the "associative mechanism," which is similar to that proposed for the catalytic hydrogenation of olefins.



(3)

In this scheme, X denotes the adsorbed H or D atom, and the adsorbed species, I, is supported by the IR spectroscopic studies of adsorbed acetylene over silica-supported palladium[15] and alumina-supported platinum.[16] Propylene-*trans*-1-d_1 and 2-d_1 can also be produced through these processes by the addition of one protium and one deuterium atom to I species, but the propylene-*trans*-1,2-d_2, 1,1-d_2 and *cis*-1-d_1 species can not be produced thus. For the formation of the latter three isomers, some possible processes in addition to Scheme (3) might be added; they will be discussed below.

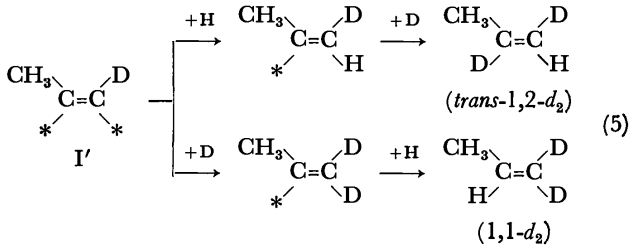
Firstly, the process concerned with producing associatively-adsorbed deuteromethylacetylene ($CH_3–C{\equiv}CD$, I′), as is shown by Process (4), is possible:



(4)

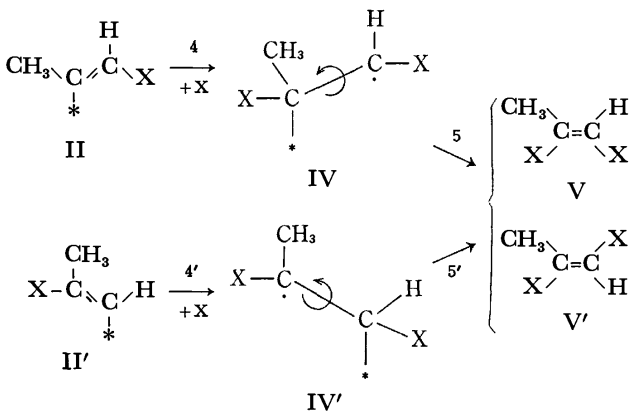
Methylacetylene is assumed in this process to be adsorbed by dissociating the acetylenic hydrogen and to pass into an associative adsorption by the addition of surface hydrogen without desorption from the surface. This process corresponds to that already proposed in the case of 1-butyne.[1] The extended scheme, (3) and (4), can explain the formation not only of propylene-*trans*-1,2-d_2, 1,1-d_2 and *cis*-1-d_1, but also of propylene-d_3, depending on whether I′ is attacked by H or D. However, the extended scheme is not yet sufficient to explain their yields quantitatively, since the *trans*-1,2-d_2 and 1,1-d_2 species can be expected to be produced in equal

amounts from I′, as is shown by Process (5), contrary to the experimental results obtained over Pd, Ni, and Pt.



Over Pd particularly, the observed yield of propylene-*trans*-1,2-d_2 was ten or more times that of propylene-1,1-d_2. Now, even if the isotope effect is considered, it will be nearly compensated for by the first and second steps in Process (5), so that the large difference observed can not be expected on the basis of the extended scheme, (3) and (4), alone. Therefore, the contribution of another process, which will be discussed in the next paragraph, must be considered in addition to the contribution of Processes (3) and (4).

Secondly, the processes including an adsorbed propyl radical might be added to Scheme (3) as competitive, as is shown in Process (6). The IV and IV′ species are assumed to be formed by hydrogen additions to the II and II′ species respectively, and an unpaired electron is denoted by ·. Since the single C–C bond in the IV and IV′ species can rotate during adsorption, the *trans*-1,2-d_2 species can be produced from the I′ species.



The observed difference between the yield of the *trans*-1,2-d_2 and that of the 1,1-d_2 species can now be interpreted by the following reasoning: the former species may be produced from both the adsorbed species, I and I′, but the latter, from only I′.

Quantitative Treatment of the Deuterium Distributions. The proposition presented above may be checked quantitatively, because the relative abundancies of the eight isomeric species of propylene produced are derivable by the use of the following parameters:

$$\left[\overset{H}{*}\right]\Big/\left[\overset{D}{*}\right] = x, \quad \left[CH_3\text{–}\overset{*}{C}\text{=}\overset{*}{C}D\right]\Big/\left[CH_3\text{–}\overset{*}{C}\text{=}\overset{*}{C}H\right] = y,$$

and;

$$\frac{\text{specific rate of Process (6)}}{\text{specific rate of Process (3)}} = \alpha.$$

Detailed formulae of the relative values for producing each species are shown in Table 5. The relative abundances of the isomeric species of propylene were thus calculated for suitable choices of the values for the parameters (x, y, α). They can be compared with the observed values derived from the fine and hyperfine distributions; those over Pd, Pt, and Ni are shown in Table 6. Over these metals, the methyl group of propylene was not substituted practically by deuterium, as is shown in Table 3. This is the reason why the calculation was carried out in only three metals at first. The degree of agreement between the calculated

y		0.12		0.14		0.86		1.34
α		0.28		0.46		0.67		0.02

and observed values may be satisfactory, especially so in the case of palladium. If the observed ratios of geseous methylacetylene-d_1 to methylacetylene-d_0 are adopted for y, agreement is impossible, suggesting that the rate of the desorption process is very small; therefore, a large difference in the deuterium distributions of methylacetylene may exist between the gas phase and the adsorbed phase over these three metals. On the contrary, the difference is estimated to be small in the cases of Rh and Ru from the fact that CH_3–C≡CD was produced in a large amount.

Consequently, the hydrogenation scheme may be expressed well by (3), (4), and (6), especially over nickel, palladium, and platinum. Over iridium, rhodium, and ruthenium, however, the scheme seems somewhat more complicated, because the attempt to obtain a good agreement between theory and experiment failed, in spite of the large variation in x, y, and α parameters. In Table 6, the results for Rh are listed together with those for Ni, Pd, and Pt. This disagreement is probably ascribable to the addition of some other processes, leading to the appearance of highly-deuterated propylenes, which are remarkable over Ir, Rh, and Ru.

The authors wish to express their gratitude to Professor Yonezo Morino and Dr. Shuji Saito, Sagami Chemical Research Center, for their considerable assistance with the microwave spectroscopic measurements.

Electric Properties of 1-Tetradecanol-Tetradecanoic Acid (Myristyl Alcohol-Myristic Acid) Mixed Bimolecular Films

Masataka OKUYAMA, Tadayoshi YOSHIDA, Tadaaki TANII, Masahito KUNUGI, and Isao ISHIZAKI

Department of Engineering Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466

(Received April 19, 1974)

Stable bimolecular films (bilayers) were found to be formed in aqueous solutions from myristyl alcohol or from mixtures of myristyl alcohol and myristic acid. The electric capacitance and resistance of these bilayers were measured in solutions of pH 3—8. The capacitance of mixed bilayers was larger than that of myristyl alcohol bilayers (0.58 μF/cm^2). When the bilayers were formed from sample solutions having mole ratios 1/1 and 2.3/1 (myristic acid to myristyl alcohol), the capacitance had minima at *ca.* pH 7. The resistance of mixed bilayers at *ca.* pH 5 was smaller than one tenth of that of the myristyl alcohol bilayer (*ca.* $7\times10^8\,\Omega\cdot$cm^2). The results are explained in terms of (i) van der Waals attraction between hydrocarbon chains, (ii) the tendency for myristic acid to form expanded layers, (iii) the head group attraction between the myristic acid ion and myristyl alcohol, and (iv) the tendency for myristic acid ions to dissolve in the aqueous phase.

Bimolecular films (bilayers) have been studied as a model of biological membranes.[1-5] Substances with simple structure were chosen for a systematic study on the relation between the properties and components of bilayers.

We were able to form stable bilayers of myristyl alcohol in water. At the air/water interface under normal conditions myristyl alcohol forms a condensed monolayer[6] while myristic acid forms an expanded monolayer.[7,8] Since mixed monolayers at water surface differ from those of the individual components, mixed bilayers in water are expected to differ in character from single component bilayers. In the present work the electric properties of single component bilayers (myristyl alcohol) have been compared with those of mixed bilayers (myristyl alcohol and myristic acid).

Experimental

Materials. Guaranteed Reagents (Nakarai Chemicals Ltd.) were used. Myristyl alcohol and myristic acid (purity >99%) were recrystallized. No impurities were detectable gas-chromatographically. Cyclohexane and *n*-decane were used as solvents without purification. The aqueous solution surrounding the bilayer was controlled by several buffer solutions, *i.e.* those of Sørensen (sodium chloride, sodium hydroxide, aminoacetic acid and hydrochloric acid), McIlvaine (sodium phosphate and citric acid), and Gomori (2,4,6-trimethylpyridine and hydrochloric acid). Chemicals of reagent grade (Wako Pure Chemical Industries Ltd.) were used for the buffer solutions.

Methods. The apparatus and procedures for bilayer-formation were similar to those employed by Hanai *et al.*[9] Sample mixtures of myristyl alcohol and myristic acid (total *ca.* 0.3 g) were dissolved in a *n*-decane–cyclohexane mixed solvent [(total 2 cm^3), 1/1 (v/v)]. This sample solution was spread over a hole (diameter: 0.7 mm) of a Teflon beaker in a buffer solution through a Teflon tube (diameter: 1 mm) attached to a syringe. In order to hasten the bilayer-formation, small bubbles were ejected successively from the end of another tube to the front of the hole. When a black film was observed through a microscope, the electric capacitance (C_m) of the film was measured with an AC bridge (Ando Electric Co. Ltd., Model TR-1c). Measurements were carried out in the frequency range 1—3 MHz.

Resistances (R_m) of the bilayers were also obtained by the DC transient method. The applied polarizing potential was 25 mV. The potential across the bilayer was measured with an electrometer of high input impedance (Takeda Riken Industry Co. Ltd., Model TR-8651) through a pair of reversible Ag/AgCl electrodes. The area of the bilayer was measured by a photographic method. The temperature of the bilayer and its surrounding solution was controlled with an accuracy of $\pm$0.2 °C by circulation of thermostated water.

Results

Over the pH range 1—12, bilayers of myristyl alcohol are stable with a lifetime of over one hour. However, with an increase in myristic acid content in mixed bilayers, the pH range for stability is greatly reduced. Only at pH—7, a stable bilayer can be obtained from a sample solution with a 4/1 myristic acid to myristyl alcohol mole ratio. Hereafter the various mixed bilayers will be referred to in terms of the molar ratios in the sample solutions from which the bilayers are formed. The mole ratio in bilayers is not always equal to that in the sample solution.

Conductance G_t and capacitance C_t of the whole system (*i.e.* of the bilayer and its surrounding aqueous solution) are dependent on frequency f. A plot of $G_t/2\pi f$ against capacitance gives a semicircle (Fig. 1). The capacitance at 1 kHz agrees with that obtained by the DC transient method (0.58 μF/cm^2).

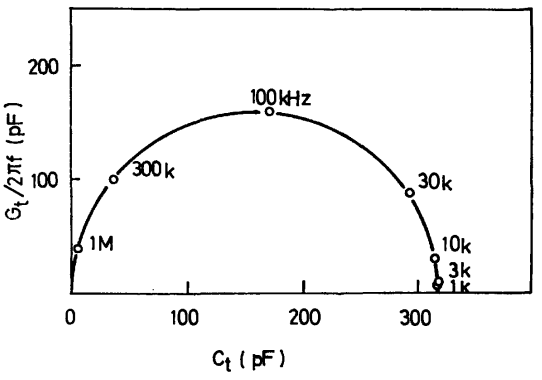

Fig. 1. Complex capacitance diagram of a whole system (a bilayer and its surrounding solution).
C_t, capacitance of a whole system; G_t, condnctance of a whole system; f, frequency; pH 5; The mole ratio of myristic acid to myristyl alcohol in sample solution is 1/1.

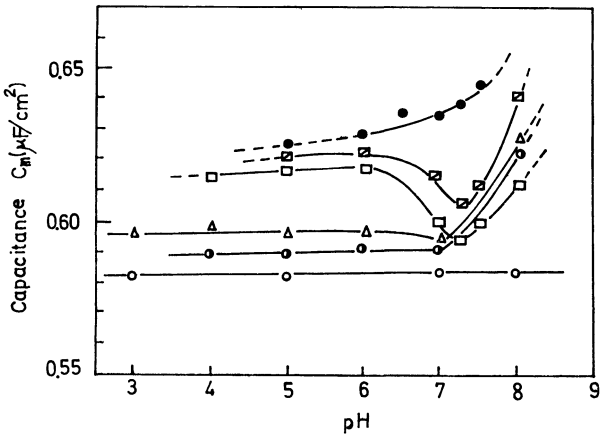

Fig. 2. The specific capacitances of bilayers as a function of pH (at 25 °C and 1 KHz). The mole ratio of myristic acid to myristyl alcohol in sample solution, ○, 0/1; ◑, 0.042/1; △, 0.25/1; □, 1/1; ⊠, 2.3/1 and ●, 4/1. ——, unstable bilayer.

The influence of pH on the capacitance C_m of bilayers (equal to C_t) is shown in Fig. 2. The capacitance is independent of the nature of the buffer solution. The capacitance of the myristyl alcohol bilayer remains constant (0.58 μF/cm²) regardless of pH, while that of all mixed bilayers increases with an increase in pH from 7 to 8. The capacitance of 1/1 and 2.3/1 mixed bilayers shows minima at pH 7 while that of the 4/1 bilayer shows no minimum over the pH range 4—8. The capacitance of mixed bilayers increases rapidly up to a mole ratio of 1/1 (Fig. 3).

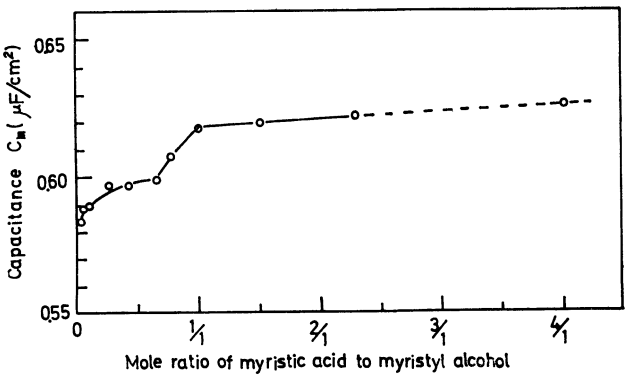

Fig. 3. Relation between the capacitance of mixed bilayer and the composition of sample solution from which the bilayer was formed (at 25 °C, 1 kHz, and pH 5). ——, unstable bilayer.

With temperature rise from 15 to 30 °C the capacitance of mixed bilayers increases gradually (Fig. 4). With increasing myristic acid content the temperature dependence of capacitance becomes more marked.

The DC resistance R_m of the myristyl alcohol bilayer has a constant value (7×10^8 Ω·cm²) regardless of pH (Fig. 5). The resistance R_m increases with pH for a 1/1 mixed bilayer. At pH 5 it is 4×10^7 Ω·cm², about one tenth of R_m for the myristyl alcohol bilayer.

Discussion

The semi-circular relationship between the capacitance of the whole system and its conductance divided by 2π times the frequency (Fig. 1) is similar to that obtained by Hanai *et al.*[9] for egg lecithin bilayers. They concluded from the shape of the complex plane plots that the static capacitance of the whole system was equal to the capacitance of the bilayer itself, $C_t(0\text{ Hz})=C_m(0\text{ Hz})$. For several systems we studied the static capacitance and the capacitance at 1 kHz agree with each other regradless of temperature and pH, $C_t(0\text{ Hz})=C_t(1\text{ kHz})$. Thus the static capacitance of the bilayer itself in various environments can be approximated by the observed capacitance of the whole

system at 1 kHz, $C_m = C_m(0\ \text{Hz}) = C_t(1\ \text{kHz})$.

Assuming the myristyl aclohol film to be a parallel plate condenser whose dielectric constant is 2.0, we find from the observed value of the static capacitance (0.58 μF/cm^2) that film thickenss is 31 Å, approximately twice the myristyl alcohol chain length. It seems reasonable to conclude that the film is bimolecular.

At pH 5, the capacitance of mixed bilayers increases with increasing myristic acid content (Figs. 2 and 3), *i.e.* the thickness of bilayers decreases. This is considered to be due to an increased expansion of the myristic acid parts in the mixed bilayers. The monolayer of myristic acid on water at pH 5 is not condensed, but expanded.[7,8] This property of myristic acid may appear in its mixed bilayers.

The occurrence of change of slope at a mole ratio 1/1 is noteworthy (Fig. 3), since peculiar phenomena at a mole ratio of 1/1 have been frequently reported in mixed monolayer of ionic and non-ionic surface active substances (though not as yet in mixed bilayers) *e.g.* Bernard and Dervichian.[10]

It is suggested that in mixed bilayers the myristic acid molecules oscillate chaotically and intertwine randomly although not to the degree pictured by Gaines.[11] The molecular motion, which we shall call "vermiculation", may be regarded as a type of micro Brownian motion which does not include the motion of the center of mass of the long chain molecule. Besides the myristic acid chains, even some chains of myristyl alcohol situated between myristic acid chains can vermiculate. Moreover, hydrocarbon chains in the bilayer may be more mobile than those in the monolayer, since a small amount of solvent (decane and cyclohexane) still remains among the chains in the bilayer (which will then comprise long chain molecules, solvent molecules and voids). Owing to vermiculation, the effective chain lengh (end-to-end distance) becomes shorter than the chain length of their fully extended forms. Consequently, the mixed bilayer is thinner than the single component bilayer of myristyl alcohol, the capacitance decreasing thereby.

With temperature rise the capacitance of the mixed bilayer increases, while that of the bilayer of myristyl alcohol does not change (Fig. 4). This could be also explained by the increasing tendency to the expanded state caused by temperature rise.

On the other hand some myristic acid ions in a one component monolayer dissolve in water at pH$>$5.[7] It is possible that myristic acid ions in the mixed bilayer may also dissolve at pH$>$5. Since the dissolution decreases the number density of the long chain compounds remaining in the bilayer, it should decrease the degree of molecular orientation in the bilayer, and decrease the thickness. This should give rise to an increase in capacitance. In fact, for the 4/1 bilayer the capacitance increases with increasing pH (Fig. 2). At pH$>$7.5, the bilayer is unstable, since too many long chain ions escape from bilayer into the aqueous phase. But for the 0.042/1 and 0.25/1 mixed bilayers, the increase of capacitance begins from pH 7. At pH$<$7, capacitance of these mixed bilayers is constant, regardless of pH values. Therefore, no myristic acid molecule in the two mixed bilayers seems to dissolve in the aqueous phase at pH$<$7. This might be explained in terms of the "ion-dipole attraction" discussed by Goodrich[12] and Spink.[7]

"Ion-dipole attraction" does not mean an attraction between the myristic acid ion and the dipole of water molecule, but the head group attraction between myristic acid ion and myristyl alcohol. The former attraction pulls the long chain ion into the aqueous phase out of the bilayer, while the latter induces the long ion to remain within the bilayer, the dissociation of myristic acid thus bringing about two opposing effects.

The van der Waals' attraction between the long chains and the ion-dipole head attraction causes the long chain molecules and ions to approach each other as closely as possible and to be fully extended normal to the bilayer surface. Under such conditions it is difficult for the myristic acid ions to escape from the mixed bilayer into the aqueous phase.

The results of our monolayer experiments might support the above conclusions. At pH 2—7 and 24 °C the surface pressure-molecular area (π-A) curve of 0.25/1 mixed monolayers was found to be independent of pH. Thus no myristic acid in the mixed monolayer is dissolved in the aqueous phase at pH$<$7.

With regard to interfacial forces, the bilayer/water interface more closely resembles the oil/water interface than the air/water interface. In general it is more difficult for long chain molecules to escape from an oil/water interface into water than from an air/water interface.[13] Therefore our monolayer experiments suggest that the dissolution of myristic acid in water from mixed bilayers is reduced by ion-dipole attraction with adjacent myristyl alcohol molecules.

Although the 1/1 mixed bilayer is rich in myristic acid content, it is difficult for such an intertwined structure as pictured by Gaines[11] to exist between pH 6 and 7. Since some myristic acid molecules ionize within the bilayer, ion-dipole attraction is added to the van der Waals attraction between the long chains so that some molecules and ions may be fully extended. Such an increase in bilayer thickness leads to a decrease in its capacitance. At pH 7—8, however, there is an increase in capacitance (Fig. 2) because of dissolution of myristic acid ions. Since myristic acid makes up a considerable proportion of the bilayer, the marked effect of its dissociation and hence dissolution more than compensates the effects due to ion-dipole interaction, such as a decrease in vermiculation.

In the 2.3/1 mixed bilayer, there are insufficient myristyl alcohol molecules for ion-dipole attraction to play a significant role. Thus the effect is much weaker than in the 1/1 bilayer. As a consequence dissolution of myristic acid in the aqueous phase is more pronounced and the minimum in capacitance at pH 7 is shallower (Fig. 2).

No minimum in the pH-capacitance curve is observed for the 4/1 bilayer. Since myristic acid makes up a very large proportion of the bilayer the marked effect of its dissociation and dissolution outweighs com-

peting effects. Figures 2 and 3 show that the 4/1 bilayer is the only, unstable one at pH 5. This may be attributed not only to a strong tendency towards expanded layers (because of the high myristic acid content) but also to the absence of ion-dipole attraction at pH 5.

The DC resistance of a 1/1 mixed bilayer is lower than that of a myristyl alcohol bilayer (Fig. 5). However, the former increases and approaches the latter when the pH increases from 6 to 7. The resultant increase in ion-dipole attraction together with the van der Waals attraction between the long chains causes the long chain molecules and ions in the bilayer to pack together as closely as in the crystalline state. Therefore it becomes more difficult for small ions (*e.g.* H_3O^+, OH^-, *etc.*) to cross the bilayer, or to pass between the long molecules along the direction of their orientation.

The results show that bilayers having a very low resistance typical of biological membranes may be produced by incorporating into the sample solutions substances which can form expanded monolayers. The structures of such mixed bilayers may be loosened by increases in temperature or changes in pH.

We wish to thank Dr. Hirofumi Okabayashi, this laboratory, Prof. Ryohei Matsuura, Kyushu University, Dr. Chiaki Muramatsu, Takemoto Yushi Co., Dr. Mitsuo Kimoto, Chukyo Yushi Co., and Dr. Yoichi Kato, Industrial Research Institute, Aichi Prefecture, for valuble discussions.

A part of this research was supported by a Scientific Research Grant from the Ministry of Education.

(Received July 18, 1974)

A parametrization in a CNDO-type MO method is presented for Pt compounds. By the use of this parametrization, the electronic spectra of $PtCl_4^{2-}$ are calculated; they agree well with the experimental spectra in transition energies and assignments. MO calculations with this parametrization are carried out on Pt(II)–ethylene, Pt(II)–acetylene, Pt(0)–ethylene, and Pt(0)–acetylene complexes. The calculated transition energies of Zeise's salt also agree well with the experimental values. In Pt(II) complexes, electrons are donated from ethylene and acetylene to the Pt atom, while they are little donated in Pt(0) complexes. The π-bonds of ethylene and acetylene are weaker in Pt(0) complexes than those in Pt(II) complexes. These results are the consequence of the stronger π-acceptor coordination bond in Pt(0) complexes than in Pt(II) complexes. Acetylene coordinates to the Pt atom more strongly than does ethylene. The coordination bonds of ethylene and acetylene are stronger in Pt(0) complexes than in Pt(II) complexes.

The organo-transition metal complexes are very attractive in view of the metal-carbon bonding character and of the models for intermediates which exist in an organic reaction catalyzed by transition metals.[1–4] Zeise's salt[5] is one of the well-known and most investigated organo-transition metal complexes.[2,6–17] Besides Zeise's salt, its bromo analogue,[2,12–14,17,18] Pt(II)–acetylene,[19,20] Pt(0)–olefin,[17,19,21–23] and Pt(0)–acetylene[17,19,24] complexes are also known. Some theoretical studies[8,25–29] have been carried out of these complexes. However, no SCF-MO calculation which explicitly includes electron-repulsion integrals has been carried out on Pt(II)–acetylene, Pt(0)–ethylene, and Pt(0)–acetylene complexes, while extended Hückel (EH) MO (noniterative) calculations have been done on them.[25,26,28,29] From the EH MO calculations, it has been proposed that the 6s orbital of the Pt atom scarcely contributes to the coordination bond of ethylene in both Pt(0) and Pt(II) complexes.[25] However, CNDO-type MO calculations reveal that the 5s orbital of the Ag atom mainly contributes to the coordination bond of olefin in $Ag(olefin)^+$ complexes.[30a] Thus, it is necessary to re-investigate the electronic structures of Pt(II)–acetylene, Pt(0)–ethylene, and Pt(0)–acetylene complexes. Also, it is of interest to compare the coordination bonds of these complexes with each other.

In this work, parametrizations are investigated in CNDO-type MO calculations on $PtCl_4^{2-}$. By the use of the established parameters, CNDO-type MO calculations are carried out on $PtX_3(C_2H_4)^-$, $PtX_3(C_2H_2)^-$ (X=Cl, Br), $Pt(PH_3)_2(C_2H_4)$, and $Pt(PH_3)_2(C_2H_2)$. Discussions are presented of the electronic structures of these compounds, and also of the coordination bonding characters of ethylene and acetylene in these complexes.

Calculation and Geometries

Calculation. A semi-empirical SCF-MO method with CNDO-type approximations is used in this work. While the method is almost the same as in our previous works,[30] some parameters are improved: (1) In our method, the resonance integrals are evaluated by means of the Wolfsberg-Helmholz equation.[31] The value of its parameter, K, is differently adopted between the AO pair including *d*-orbitals and those including only s and p orbitals; the notation K_1 is used in the former case, and the notation K_2 in the latter. While the value of K_2 is taken to be 0.80, as in our previous report,[30c] that of K_1 is determined to be 0.90 in this work, as will be described below. (2) While Ohno equation[32] was used in our previous works,[30] a modification of it which is newly presented in this work is introduced for the calculations of two-center Coulomb repulsion integrals including 6s and 6p orbitals of the Pt atom. The modification of Ohno equation is carried out for the following reason: The one-center Coulomb repulsion integrals, γ_{rt}, are calculated by the following Eq. (1) in Ohno method;

$$r_{rt} = 0.5(\gamma_{rr}+\gamma_{tt}). \quad (1)$$

This equation can be a good approximation when the AO·r and AO·t are alike.[33] In transition metals, however, this Eq. (1) can not be successfully applied to the calculation of one-center values of $\gamma_{nd(n+1)s}$ and $\gamma_{nd(n+1)p}$, since outer s and p orbitals are very different from valence-shell d-orbitals in their expansion. As examples, Table 1 presents a comparison between those values obtained by Eq. (1) and those obtained from the atomic spectra in Ni and Pd atoms; apparently, Eq. (1) gives too large values of $\gamma_{nd(n+1)s}$ and $\gamma_{nd(n+1)p}$

TABLE 1. VALUES OF $\gamma_{nd(n+1)s}$ AND $\gamma_{nd(n+1)p}$[a] OF THE Ni AND Pd ATOMS

	γ_{ds}[b]	$0.5(\gamma_{dd}+\gamma_{ss})$	Δ_{ds}[c]	γ_{dp}[b,d]	$0.5(\gamma_{dd}+\gamma_{pp})$	Δ_{dp}[c]
Ni	10.09_{eV}	12.34	−2.25	8.46	11.56	−3.10
Pd	9.14_{eV}	10.67	−1.53	7.71	10.05	−2.34

a) $n=3$ for the Ni atom and $n=4$ for the Pd atom. b) These values are obtained from Ref. 34. c) $\Delta_{ds}=-0.5(\gamma_{dd}+\gamma_{ss})$, $\Delta_{dq}=\gamma_{dp}-0.5(\gamma_{dd}+\gamma_{pp})$, d) The averaged value of various types of γ_{dp}.

as compared with the corresponding values obtained from the atomic spectra. In order to improve this defect, the following modification is carried out, only when either AO·r or AO·t is an outer orbital;

$$\gamma_{rt} = 14.3986/(d^2+R_{rt}^2)^{1/2}, \quad (2)$$

$$14.3986/d = 0.5(\gamma_{rr}+\gamma_{tt}) - a_r, \quad (3)$$

where AO·r is assumed to be an outer orbital and where R_{rt} is the distance (in Å unit) between the centers of AO·r and AO·t. The value of a_r depends on the outer AO·r, which is so determined that Eqs. (2) and (3) reproduce the experimental values of the one-center Coulomb repulsion integrals, such as $\gamma_{nd(n+1)s}$ and $\gamma_{nd(n+1)p}$, at $R_{rt}=0.0$; for example, the values of a_{4s} and a_{4p} of the Ni atom are taken as 2.25 and 3.10 eV respectively (see Table 1). The original Ohno equation is used in the other AO pairs, in which both AO's are outer orbitals or valence ones.

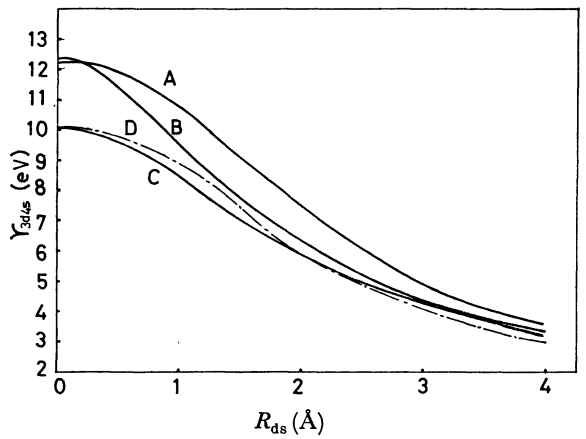

Fig. 1. Two-center Coulomb repulsion intergrals γ_{3d4s}[a] at various inter-atomic distances.
a) 3d; the 3d orbital of the Ni atom. 4s; the 4s orbital of the Ni atom.
A; The nonempirical value: the 3d orbital; the double-ζ type AO by Richardson *et al.* [36], the 4s orbital; the single Slater type AO by Clementi *et al.* [35].
B; Ohno's approximation.
C; The modified Ohno's approximation, Eqs (2) and (3).
D; These values are obtained by multiplying a correction factor to the nonempirical values so as to coincide the one-center value of γ_{3d4s} with that obtained from atomic spectra.

Figure 1 gives the values of the $\gamma_{3d\,4s}$ of the Ni atom obtained by various methods. The theoretically-calculated values (Line A) seem too large. Line D is obtained by multiplying the theoretically-calculated values by a correction factor so that the theoretical one-center value of $\gamma_{3d\,4s}$ may coincide with that obtained from the atomic spectra. Line C obtained by using the modified Ohno equation seems to be most agreeable with Line D throughout the R_{ds} range, while Line B obtained by the original Ohno equation is too large in the range of small R_{ds} values. Thus, the modified Ohno equation gives a more reasonable value of $\gamma_{3d\,4s}$ than does the original one.

In the case of the Pt atom, unfortunately, the experimental values of $\gamma_{5d\,6s}$ and $\gamma_{5d\,6p}$ can not be obtained because of the lack of atomic spectra. In the Pd atom, which forms compounds similar to those of the Pt's, a_{5s} should be taken as 1.53 eV and a_{5p} as 2.34 eV (see Table 1). By considering these values of the Pd atom, the authors examine various values of a_r within the following regions: 1.2—1.8 eV for a_{6s} and 2.2—2.8 eV for a_{6p}. From those examinations, $a_{6s}=1.5$ eV and $a_{6p}=2.5$ eV are chosen as the best values; they give good results on the electronic spectra of tetrachloroplatinate and Zeise's salt, as will be described in the following section.

For the Pt atom, the valence-state ionization potentials, I_r, are evaluated from the atomic spectra.[37] One-center Coulomb repulsion integrals, γ_{rr}, are estimated by the use of Eq. (2) in Ref. 30c. For the atoms of ligands, the values of I_r are taken from Hinze-Jaffé's work,[38] and those of γ_{rr} are evaluated from the same work[38] by the use of Pariser's approximation.[33] A double-ζ type d-function[39] is used for the 5d orbital of the Pt atom, while single Slater-type orbitals[35,40] are used for all the s and p orbitals. These data for the Pt atom are given in Table 2.

TABLE 2. IONIZATION POTENTIAL, I_r, ORBITAL EXPONENT, ζ_r, AND ONE-CENTER COULOMB REPULSION INTEGRAL, γ_{rr} OF THE PLATINUM ATOM

	ζ_r[a]	C[b]	I_r[c]	γ_{rr}[d]

Geometries. The structures of Zeise's salt[15] and its bomo analogue[18] are taken from the X-ray studies. Since the accurate structures of $PtX_3(C_2H_2)^-$, (X=Cl, Br), have not been known, the bond length of the Pt–X bond is taken as equal to the corresponding one of $PtX_3(C_2H_4)^-$ and the distance between the Pt atom and the center of the triple bond of acetylene is taken as equal to that of $Pt(PPh_3)_2(PhC{\equiv}CPh)$.[24] The bond length of the C≡C triple bond is taken as equal to that of *trans*-$PtCl_2$(*p*-toluidine)[(*t*-Bu)C≡C(*t*-Bu)].[20] The ethylene and acetylene moieties are considered to be dis-

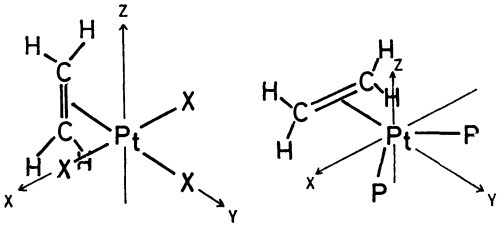

Fig. 2. Coordinate systems of Pt(II) and Pt(0) ethylene complexes.
The acetylene complexes are also the same as the above ones. X=Cl or Br, P=PH_3.

torted by their coordinations to the Pt atom.[2,16,20,21,24] Nevertheless, the ethylene and acetylene moieties are assumed not to be distorted because of the shortage of structural studies of these complexes. The structures of the Pt(0)–ethylene and Pt(0)–acetylene complexes are taken from the X-ray studies,[22,24] while the *cis*-bending of the CH_2 and CH groups and the small dihedral angle are neglected and PR_3 group is replaced by the PH_3 one for the sake of simplicity. These coordinate systems are shown in Fig. 2.

Results and Discussion

Parametrization. In order to investigate the parametrizations, MO calculations are carried out on $PtCl_4^{2-}$, since its electronic spectra have been well studied.[41,42] In these calculations, various values of K_1, a_{6s}, and a_{6p} are examined. Only some typical results are given in Tables 3 and 4. (Of course, various sets of values of K_1, a_{6s}, and a_{6p} are also examined besides the three given in Table 3.)

As is shown in Table 3, the A parametrization gives remarkably large electron densities on the 6s and 6p orbitals of the Pt atom. Furthermore, this parametrization gives too small transition energies for the intra-atomic 5d→6p transition, while these are really considered to have remarkably high transition energies.[41] Thus, this parametrization is abandoned.

By the use of the modified Ohno equation, the electron densities on 6s and 6p orbitals are extensively reduced from their values obtained by the A parametrization (see the B—D parametrizations in Table 3). Electron distributions do not depend very largely on the values of a_{6s} and a_{6p}, while the electron densities on 6s and 6p orbitals slightly decrease with an increase in the values of a_{6s} and a_{6p}. It should be noted that the use of the modified Ohno equation gives remarkably high transition energies for the intra-atomic 5d→6p transitions; thus, the defect in the A parametrization is overcome by the introduction of the modified Ohno equation.

The results on the electronic spectra are given in Table 4. The charge-transfer (C–T) bands (^1E_u and $^1A_{2u}$) are obtained at higher transition energies in all the calculations than the experimental ones, and the smaller values of a_{6s} and a_{6p} give relatively higher energies than do the larger values. Thus, the small values of a_{6s} and a_{6p} are abandoned. However, too large values of a_{6s} and a_{6p} result in too low transition energies (3.31 eV) of ^1E_g in the D parametrization, while it is experimentally obtained at 3.76 eV. The C parametrization seems to be the best one. The electronic spectra obtained by this parametrization agree well with the experimental spectra in transition energies and assignments, although the calculated C–T bands have considerably higher transition energies and the calculated d-d band, $^1B_{1g}$, has a considerably smaller transition energy than the corresponding experimental ones.[41,42] The values of a_{6s} and a_{6p} used in the C parametrization seem reasonable in view of the a_{5s} and a_{5p} values of the Pd atom.

When the value of K_1 is taken as 1.0, the C–T bands have too high transition energies; the first C–T bands is obtained at 6.06 eV, and the second one at 7.28 eV, where values of 1.5 and 2.5 eV are used for a_{6s} and a_{6p}. On the other hand, in the case of K_1=0.80, the assignments of d-d bands can not agree with the experimental ones. Thus, the value of K_1 is taken as 0.90 and the following parametrizations are adopted; a_{6s}=1.5 eV, a_{6p}=2.5 eV, and K_1=0.90 (the C para-

metrization).

These parametrizations are also examined in Zeise's salt. The MO calculation in which $K_1=1.0$ and the original Ohno equation are used gives too large electron densities on the outer orbitals (1.17 e on the 6s and 1.85 e on the 6p orbitals) and too small transition energies of the intra-atomic 5d→6p transitions (about 0.3—0.9 eV). The use of the modified Ohno equation improves these defects in this case also; intra-atomic 5d→6p transitions are obtained at *ca.* 10 eV, and the electron densities on 6s and 6p orbitals are reduced (Table 6).

Thus, by using the C parametrization, we can carry out MO calculations on Pt(II)–ethylene, Pt(II)–acetylene, Pt(0)–ethylene, and Pt(0)–acetylene complexes, as will be described in the following sections.

TABLE 5. CALCULATED TRANSITION ENERGIES OF ZEISE'S SALT

4.95	0.025	$^1A_1$		

a) Ref. 10. b) in eV unit.

Electronic Spectra of Zeise's Salt. The C parametrization gives good results for transition energies as is shown in Table 5. The transition at 3.72 eV is assigned to the d-d band. The transitions at 4.26, 4.67, and 5.16 eV are assigned to the C–T bands from the Cl^- ligand to the d-orbital of the Pt atom. Moore assigned the weak transitions at 2.71 and 2.96 eV to the spin-forbidden ones on the basis of his EH(ω) MO calculation.[8] Our calculation gives the spin-allowed d-d bands, $^1B_1$ ($d_{yz}\rightarrow d_{x^2-y^2}$), at 2.39 eV and ^1B_i ($d_{xy}\rightarrow d_{x^2-y^2}$) at 3.46 eV, which have very small oscillator strengths, $f_s=1\times10^{-4}$ and $f_s=4\times10^{-4}$ respectively. These results suggest that the observed weak absorptions at 2.71 and 2.96 eV can not be necessarily assigned to the spin-forbidden transitions on the basis of their small absorption coefficients. Thus, there also remains the possibility that these absorptions are spin-allowed d-d transitions.

Electron Densities of Pt–ethylene and Pt–acetylene Complexes. The results for electron densities are given in Table 6, together with the quantities of ΔQ, ΔP_π, and P_π^*, which are defined in the footnote of the table. In the Pt(II) complexes, the electron density of the C atom is decreased from the value of the free ethylene by *ca.* 0.01 e, and that of the free acetylene, by *ca.* 0.1 e. In the Pt(0)–ethylene and Pt(0)–acetylene complexes, the electron densities are increased by *ca.* 0.05 e and *ca.* 0.02 e respectively. The values of ΔQ are *ca.* 0.3 e in the Pt(II) complexes, while they are nearly equal to zero in the Pt(0) complexes. This different behavior in the electron transfer between the Pt(II) and Pt(0) complexes is due to the different character of the coordination bonds of ethylene and acetylene between these complexes; the σ-donor bond contributes mainly to the coordination bonds of ethylene and acetylene in the Pt(II) complexes, while the π-acceptor bond contributes largely to the coordination bonds in the Pt(0) complexes, as will be described below.

ΔP_π[b]		−0.155	−0.160	−0.343
P_π^*[c]		−0.036	−0.036	−0.206

a) The quantity of transfered electrons from ethylene or acetylene to PtX_3^- or $Pt(PH_3)_2$ part. b) $\Delta P_\pi=(P_\pi$ of complexes ethylene$)-(P_\pi$ of free ethylene). ΔP_π of acetylene complexes is defined as the same as that of ethylene ones, while only one π-bond (Y-axis) is considered because the other π-bond scarcely interacts with the Pt atom. c) The quantity of P_π is defined as the partial bond order in which π^*-type interactions of ethylene or acetylene are only considered.

The absolute value of ΔP_π of $PtBr_3(C_2H_4)^-$ is larger than that of $PtCl_3(C_2H_4)^-$, suggesting that the C=C double bond of $PtBr_3(C_2H_4)^-$ is weaker than that of $PtCl_3(C_2H_4)^-$. This result agrees with the experimental finding that the ethylene part in $PtBr_3(C_2H_4)^-$ has a lower stretching vibration of the C=C double bond than that in $PtCl_3(C_2H_4)^-$.[12–14] Since the absolute value of P_π^* is remarkably small in the Pt(II) complexes, the decrease in the π-bond order of the ethylene part is not due to the increase in its π^*-anti-bonding character, but to the decrease in its π-bonding nature.

The absolute values of ΔP_π in the Pt(0) complexes are larger than those in the Pt(II) complexes by *ca.* 0.17—0.2 e, suggesting that the C=C double and C≡C triple bonds in the Pt(0) complexes are weaker than those in the Pt(II) complexes. Between the Pt(0) and Pt(II) complexes, the difference in the values of ΔP_π coincides well with the difference in the value of P_π^*. Therefore, roughly speaking, it can be said that the stronger π-acceptor bond results in the larger increase in the π^*-nature and the weaker C=C and C≡C bonds in the Pt(0) complexes than in Pt(II) complexes.

Interaction between Pt and C Atoms. In this section, the quantity of E_{AB} is used as the bond index, which means the energy contribution of the AB bond to the total energy of the molecule;[43,44] it is written as below under approximations used in this MO method.[30]

$$E_{AB} = E_{AB}^{(1)} + E_{AB}^{(2)} + E_{AB}^{(3)} \quad (4)$$

$$E_{AB}^{(1)} = 2\sum_r^A \sum_t^B P_{rt} H_{rt} \quad (5)$$

$$E_{AB}^{(2)} = -0.5 \sum_r^A \sum_t^B P_{rt}^2 \gamma_{rt} \quad (6)$$

$$E_{AB}^{(3)} = \sum_r^A \sum_t^B (N_r - P_{rr})(N_t - P_{tt})\gamma_{rt} \quad (7)$$

The negative value of E_{AB} represents the bonding interaction between A and B atoms, and the larger absolute value reveals the stronger interaction.

In order to investigate the bonding character, $E_{AB}^{(1)}$ and $E_{AB}^{(2)}$ are divided into AO pair terms, $E_{ArBt}^{(1)}$ and $E_{ArBt}^{(2)}$, *etc.*, where Ar represents the AO·r on the A atom. $E_{AB}^{(3)}$ is not divided into AO pair terms, however, because this term represents approximately an electrostatic energy and its meaning is lost by the division into AO pair terms.

The absolute value of E_{Pt-C} decreases in the following order: Pt(0) complexes>Pt(II) complexes, and acetylene complexes>ethylene complexes. This result shows that acetylene coordinates to the Pt atom more strongly than does ethylene, and that the coordination bonds of ethylene and acetylene in Pt(0) complexes are stronger than those in Pt(II) complexes.

As is shown in Table 7, E_{Pt-C} is contributed to largely by the $E_{s-\pi}$ and $E_{p\sigma-\pi}$ in the Pt(II) complexes, where the former subscript, such as s and p_σ, indicates the AO of the Pt atom, and the latter one the AO of the C atom. The contributions of $E_{d\pi-\pi^*}$ and $E_{p\pi-\pi^*}$ are small. These results suggest that the coordination bonds of ethylene and acetylene are mainly contributed to by the σ-donor bond in the Pt(II) complexes, through which ethylene and acetylene donate their π-electrons to the 5d, 6s, and 6p orbitals of the Pt atom. This bonding nature agrees with the proposals by Behnke *et al.*,[45] Braterman,[46] and Cooper *et al.*[47] with regard to the coordination bond of olefin in Pt(II) complexes.

In the Pt(0) complexes, the absolute values of P_π^* and $E_{d\pi-\pi^*}$ are much larger than those of Pt(II) complexes, while the $E_{d\sigma-\pi}$ value in the Pt(0) complexes is smaller than that of the Pt(II) complexes. These results suggest that the π-acceptor bond contributes more to the coordination bond in the Pt(0) complexes than to that in the Pt(II) complexes. The d_σ-π interaction seems to be reduced by the formal d^{10} configuration of the Pt(0) atom, while this interaction is considerably large in the Pt(II) complexes because of the formal d^8 configuration of the Pt(II) ion. The large absolute values of $E_{S-\pi}$ and $E_{P\sigma-\pi}$ reveal that the σ-donor bond contributes remarkably to the coordination bond in the Pt(0) complexes.

In both the Pt(II) and Pt(0) complexes, the absolute values of E_{S-S} and $E_{P\sigma-S}$ are remarkably large, suggesting that a large σ-bonding interaction exists between the 2s orbital of the C atom and the 6s and $6p_\sigma$ orbitals of the Pt atom. Thus, the hybridization of the C atom of ethylene approaches from sp^2 to sp^3 and that of acetylene from sp to sp^2, not only because of the σ-donor and π-acceptor bond but also because of these s-s and p_σ-s interactions. This result also suggests that the *cis*-bendings of the CH_2 group of ethylene and the CH group of acetylene are brought about by the σ-donor bond, the π-acceptor bond, and these s-s and p_σ-s interactions.

The relative contribution of valence orbitals of the Pt atom should be discussed not in terms of the bond order but in terms of E_{ArBs}, since the bond order is not appropriate for the bond index because of its rotational variable character. As is shown in Table 7, the 6s orbital contributes to the coordination bond as much as the 6p orbital does, and the contribution of the 5d orbital is one-half or one-third of those of the 6s and 6p orbitals. Our results do not agree with the proposal of Nelson *et al.*[25] that the hybridization of the Pt atom is dp^2 or d^2p^2 in these complexes.

In conclusion, the 6s and 6p orbitals of the Pt atom contribute greatly to the coordination bonds of ethylene and acetylene, while the 5d orbital also considerably contributes to the Pt(II) complexes. The π-acceptor bond (d_π-π^*) contributes much to the Pt(0) complexes, while its contribution in the Pt(II) complexes is about one-third of that in the Pt(0) complexes. This stronger π-acceptor bond in Pt(0) complexes results in the larger electron density on the C atom, the smaller value of ΔQ, the weaker C=C and C≡C bonds, and the larger value of E_{Pt-C}, relative to those of the Pt(II) complexes. It should be noted that strong s-s and p_σ-s interactions exist between the Pt and C atoms besides the σ-donor and π-acceptor bonds.

These calculations were carried out by the Facom 230-60 and 230-75 computers of The Data Processing Center of Kyoto University.

The authors are grateful to Professor Kimio Tarama for his generous support of this work. They also wish to thank Dr. Hideyuki Konishi for his help with the

calculations of overlap integrals and Mr. Kazuhiro Ishida for his help with the nonempirical calculations of the Coulomb respulsion integrals.

The Thermodynamic Properties of C_9H_{18} Naphthenes. I. The Determination of the Equilibrium Constants for the Hydrogenation of Propyl- and Isopropylbenzene and Ethyltoluenes

Yasuo MIKI

National Chemical Laboratory for Industry, Mita, Meguro-ku, Tokyo 153

(Received July 30, 1974)

The equilibria for the hydrogenation of *n*-propylbenzene, isopropylbenzene, 1-methyl-2-ethylbenzene, 1-methyl-3-ethylbenzene, and 1-methyl-4-ethylbenzene were determined experimentally over the temperature range of 250 to 450 °C and under hydrogen pressures ranging from 5 to 50 atm. The data were then used to calculate the values of the free energy and the equilibrium constant of the above reactions and the values of standard free energy of formation from the elements for *n*-propylcyclohexane, isopropylcyclohexane, 1-methyl-*cis*-2-ethylcyclohexane, 1-methyl-*trans*-2-ethylcyclohexane, 1-methyl-*cis*-3-ethylcyclohexane, 1-methyl-*trans*-3-ethylcyclohexane, 1-methyl-*cis*-4-ethylcyclohexane, and 1-methyl-*trans*-4-ethylcyclohexane.

This paper will present the results of a study of the thermodynamic properties of C_9H_{18} naphthenes. Alkylbenzenes are known to react with hydrogen to form alkylcyclohexanes, and the equilibrium constant for the hydrogenation of *n*-propylbenzene(NPB) to *n*-propylcyclohexane (NPCH) can be calculated from the thermodynamic data.[1-3] Such free energy data are available for other C_9H_{12} alkylbenzenes, but not for other C_9H_{18} alkylcyclohexanes. The hydrogenation equilibrium constants have also been determined experimentally over the temperature range from 200 to 300 °C for NPB,[4] isopropylbenzene (IPB),[5] and 1,3,5-trimethylbenzene.[6]

The equilibrium constants for the hydrogenation of NPB, IPB, 1-methyl-2-ethylbenzene (1,2-MEB), 1-methyl-3-ethylbenzene (1,3-MEB), and 1-methyl-4-ethylbenzene (1,4-MEB) were determined over the temperature range from 250 to 450 °C.

From these data, the values of the free energy of formation from the elements were calculated for NPCH, isopropylcyclohexane (IPCH), 1-methyl-*cis*-2-ethylcyclohexane (*cis*-1,2-MECH), 1-methyl-*trans*-2-ethylcyclohexane (*trans*-1,2-MECH), 1-methyl-*cis*-3-ethylcyclohexane (*cis*-1,3-MECH), 1-methyl-*trans*-3-ethylcyclohexane (*trans*-1,3-MECH), 1-methyl-*cis*-4-ethylcyclohexane (*cis*-1,4-MECH), and 1-methyl-*trans*-4-ethylcyclohexane (*trans*-1,4-MECH).

These compounds are important as constituents of petroleum; hence, their properties should have considerable practical interest.

Experimental

Materials. The NPB and IPB used in these experiments were commercial, extra-pure-grade reagents and were purified by distillation in a vacuum in a helium atmosphere to give a product found by gas chromatography to be 100.0% pure. The NPCH (100.0% purity)and IPCH (99.9% purity) were obtained by the hydrogenation of NPB and IPB respectively. The *n*-octane (98% purity), 1,2-MEB (100.0% purity), 1,3-MEB (100.0% purity), and 1,4-MEB (100.0% purity) were commercial, extra-pure-grade reagents and were used without further purification. The *cis*-1,2-MECH, *trans*-1,2-MECH, *cis*-1,3-MECH, *trans*-1,3-MECH, *cis*-1,4-MECH, and *trans*-1,4-MECH were obtained from the *cis-trans* mixtures of 1,2-MECH's 1,3-MECH's and 1,4-MECH's produced by the hydrogenation of 1,2-MEB, 1,3-MEB, and 1,4-MEB respectively, using a Perkin-Elmer F21 Preparative Gas Chromatograph. Hydrogen gas was passed through a palladium catalyst column to remove the oxygen, and the resulting gas was dried with an ice bath as well as with a molecular sieve and silica gel.

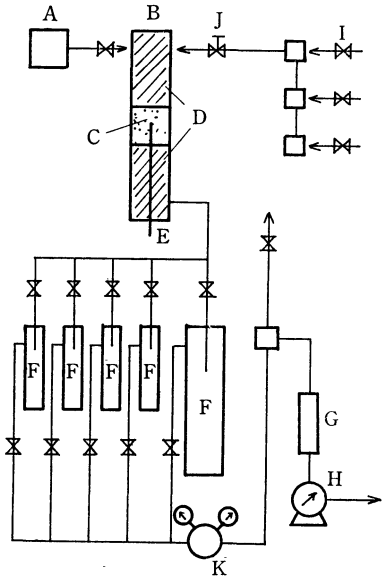

Fig. 1. Schematic diagram of reaction apparatus.
A: feed pump B: reactor C: catalyst bed
D: stainless steel bead E: thermocouple F: separator
G: flowmeter H: gasmeter I: stop valve
J: needle valve K: pressure controller

Apparatus. A flow diagram is shown in Fig. 1. The catalyst was supported inside a 14-mm-i.d. by 600-mm-long stainless steel tube. The dead space above and below the catalyst bed was packed with stainless steel beads. The catalyst temperature was measured by means of a chromel-alumel thermocouple located in a thermowell in the catalyst bed. The hydrocarbon feed rates were measured by means of a microfeed pump (Tamaseiki Co.).

The catalyst used in the present experiments was a 5 ml portion of Ketzenfine's 3% platinum on alumina (20—50 mesh). Each feed was a mixture of alkylbenzene and *n*-octane, or of alkylcyclohexane and *n*-octane. The hydrocarbon mixture feed was 1.2 ml per hr, and the mole ratio of hydrogen to the hydrocarbon mixture at the start was 17.8 ± 0.3.

The temperature variation through the catalyst bed was less than 0.5 °C when no reaction was taking place. During a run, the temperature rise due to the heat of reaction was less than 1 °C, depending on the extent of the reaction. The maximum variation in temperature through the catalyst bed during a run was usually of the order of 0.5 °C. The temperature used in the calculations was the average temperature of the last half of the catalyst bed.

A strain gauge (Kyowa Dengyo Co.) was used to measure the pressure at the inlet and outlet of the reactor. The pressure drop across the bed was negligible in the present experiments.

The reactions were carried out at temperatures ranging from 250 to 450 °C and under pressures ranging from 5 to 50 atm. In order to allow time for representative samples to be taken, the first hour was discarded.

Analysis. The products were analyzed by gas chromatography using a Hitachi Model K–53 with flame-ionization detectors and with a squalane capillary column (90 m × 0.25 mm) at 80 °C. The peak areas were measured with a Takeda Model TR-2215 electronic integrator.

Procedure

The hydrogenations of NPB, IPB, 1,2-MEB, 1,3-MEB, and 1,4-MEB are given by the following equations:

	Designation of Equilibrium Constant	
$3H_2(g)+NPB(g)=NPCH(g)$	K(n)	(1)
$3H_2(g)+IPB(g)=IPCH(g)$	K(i)	(2)
$3H_2(g)+1,2\text{-MEB}(g)=cis\text{-}1,2\text{-MECH}(g)$	K(*cis*-1,2-MECH)	(3)
$3H_2(g)+1,2\text{-MEB}(g)=trans\text{-}1,2\text{-MECH}(g)$	K(*trans*-1,2-MECH)	(4)
$3H_2(g)+1,2\text{-MEB}(g)=$equilibrium mixture of *cis*- and *trans*-1,2-MECH(g)	K(1,2-MECH)	(5)
$3H_2(g)+1,3\text{-MEB}(g)=cis\text{-}1,3\text{-MECH}(g)$	K(*cis*-1,3-MECH)	(6)
$3H_2(g)+1,3\text{-MEB}(g)=trans\text{-}1,3\text{-MECH}(g)$	K(*trans*-1,3-MECH)	(7)
$3H_2(g)+1,3\text{-MEB}(g)=$equilibrium mixture of *cis*- and *trans*-1,3-MECH(g)	K(1,3-MECH)	(8)
$3H_2(g)+1,4\text{-MEB}(g)=cis\text{-}1,4\text{-MECH}(g)$	K(*cis*-1,4-MECH)	(9)
$3H_2(g)+1,4\text{-MEB}(g)=trans\text{-}1,4\text{-MECH}(g)$	K(*trans*-1,4-MECH)	(10)
$3H_2(g)+1,4\text{-MEB}(g)=$equilibrium mixture of *cis*- and *trans*-1,4-MECH(g)	K(1,4-MECH)	(11)

The equilibrium constant, K, is given by this equation:

$$K = f_A/f_H^3 f_B = [(X_A+X)(1-3X)^3/(X_B-X)(X_H-3X)^3]K_\gamma P^{-3} \quad (12)$$

where

f_H, f_A, f_B = the fugacities of hydrogen, alkylcyclohexane, and alkylbenzene respectively

X_H, X_A, X_B = the mole fractions of the hydrogen, alkyl cyclohexane, and alkylbenzene respectively of the charge

X = the number of moles of alkylcyclohexane formed from 1 mol of the charge. In runs wherein the equilibrium is approached from the alkylcyclohexane side, $-X$ is the number of moles of alkylbenzene formed from 1 mol of the charge

P = the absolute total pressure of the equilibrium mixture at the end of the catalyst bed, atm

$K_\gamma = \gamma_A/\gamma_H^3\gamma_B$

$\gamma_H, \gamma_A, \gamma_B$ = the fugacity coefficients of hydrogen, alkylcyclohexane, and alkylbenzene respectively.

The fugacity coefficient, γ, was calculated with the aid of the concept of corresponding states, using generalized charts. The following equation, developed by Joffe,[7] was used to predict the fugacity coefficients of individual components in a gas mixture:

$$\log \gamma_i = \log \gamma_m + (H^\circ - H)(T_{cm} - T_{ci})/2.303RT \cdot T_{cm} + (Z_m - 1)(P_{cm} - P_{ci})/2.303P_{cm} \quad (13)$$

where

γ_i = the fugacity coefficient of the component, i, in the mixture

γ_m = the fugacity coefficient of the mixture

H = the molal enthalpy of the mixture at the given temperature and pressure

H° = the molal enthalpy of the mixture at a low pressure at which the gas is ideal

Z_m = the compressibility factor ($Z_m = PV/RT$) for the mixture

T_{ci} = the critical temperature of the pure component, i

P_{ci} = the critical pressure of the pure component, i

T_{cm} = the pseudocritical temperature of the mixture

P_{cm} = the pseudocritical pressure of the mixture

T = absolute temperature

R = gas constant.

The pseudocritical temperature and pressure of a mixture are sums of the products of the mole fraction of each pure component in terms of its critical temperature and pressure in accordance with the suggestion made by Kay;[8]

$$T_{cm} = \sum_i X_i T_{ci} \quad (14)$$

$$P_{cm} = \sum_i X_i P_{ci} \quad (15)$$

where X_i is the mole fraction of the component, i.

In the case of hydrogen, the pseudocritical constants recommended by Newton[9] were used in place of the experimental critical constants. The values of the critical constants of pure components were taken from the A.P.I. tables.[10] The derivatives of the fugacity coefficients of the mixture with respect to the composition variables may be evaluated by considering the fugacity coefficient of the pseudoreduced temperature, $T_{rm}(=T/T_{cm})$, and the pressure, $P_{rm}(=P/P_{cm})$, of the mixture. By using the pseudoreduced temperature and pressure instead of the true reduced temperature and pressure, γ_m was obtained from a generalized fugacity coefficient chart,[9] Z_m was read from a generalized compressibility factor chart,[11] and $(H^\circ - H)/T_{cm}$ for the mixture was obtained from a generalized enthalpy-pressure chart.[11] In the temperature range above $T_{rm}=1$, the enthalpy correction values read from the chart were multiplied by a correction factor recommended by York and Weber.[12]

Results

Tables 1—5 summarize the experimental results and gives the values of the equilibrium constants, K, calculated from the data. Figure 2 shows, for the equilibrium between NPB and NPCH, a comparison of the values derived from this report with values reported experimentally by Vvedenskii, Vinnikova, *et al.*[4] over

the temperature range of 200—300 °C, and with the values calculated from the thermodynamic data of NPB[3] and NPCH[2] using the following equation:

$$\Delta G_f^\circ(\text{NPCH}) - \Delta G_f^\circ(\text{NPB}) = \Delta G_h^\circ(\text{n}) = -2.303RT\log K(\text{n}) \quad (16)$$

where ΔG_f°(NPCH) and ΔG_f°(NPB) are the standard Gibbs energies of the formation of NPCH and NPB respectively, and where ΔG_h°(n) is the standard Gibbs energy of the hydrogenation of NPB to NPCH. Most of the runs were made with a NPB feed, the equilibrium being approached from the NPB side. In Runs A-2 and A-9, the equilibrium was approached from the NPCH side. The same results were obtained

agreement with the other results, proving that the hydrogenation product is an equilibrium mixture of the *cis* and *trans* isomers.

The following equations for the best straight lines of $\log K$ against $1/T$ were obtained by the least-squares method;

$\log K(\mathrm{n}) = 10975/T - 20.58 \pm 0.03$ (518 to 717 K)
$\log K(\mathrm{i}) = 10887/T - 20.60 \pm 0.04$ (518 to 696 K)
$\log K$(1,2-MECH) $= 9536/T - 18.36 \pm 0.04$ (535 to 696 K)
$\log K$(*cis*-1,2-MECH) $= 9453/T - 18.82 \pm 0.04$
$\log K$(*trans*-1,2-MECH) $= 9651/T - 18.70 \pm 0.04$
$\log K$(1,3-MECH) $= 10758/T - 20.51 \pm 0.03$ (538 to 720 K)
$\log K$(*cis*-1,3-MECH) $= 10885/T - 20.84 \pm 0.03$
$\log K$(*trans*-1,3-MECH) $= 10431/T - 20.56 \pm 0.03$
$\log K$(1,4-MECH) $= 10342/T - 19.81 \pm 0.04$ (540 to 716 K)
$\log K$(*cis*-1,4-MECH) $= 9993/T - 19.75 \pm 0.04$
$\log K$(*trans*-1,4-MECH) $= 10493/T - 20.21 \pm 0.04$

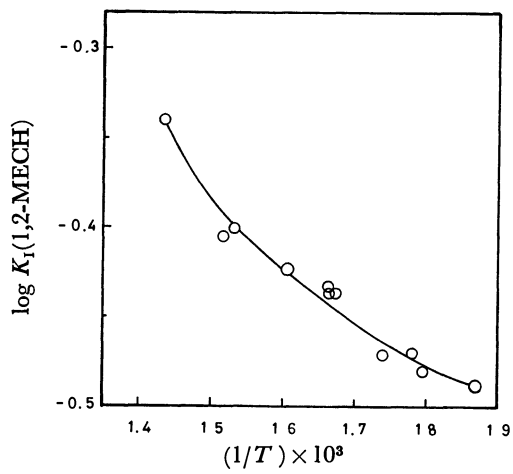

Fig. 7. Logarithm of equilibrium constants of *cis* to *trans* isomerization for 1-methyl-2-ethylcyclohexanes.

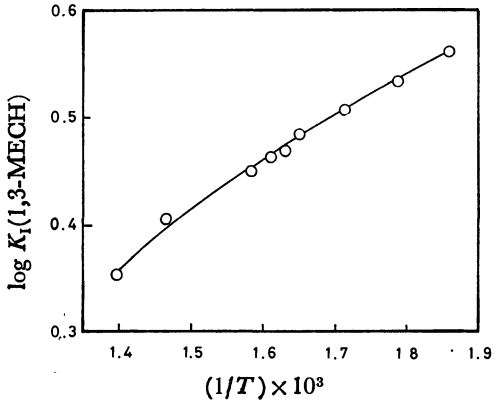

Fig. 8. Logarithm of equilibrium constants of *cis* to *trans* isomerization for 1-methyl-3-ethylcyclohexanes.

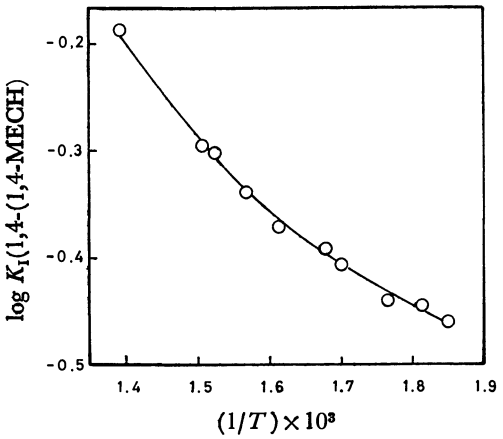

Fig. 9. Logarithm of equilibrium constants of *cis* to *trans* isomerization for 1-methyl-4-ethylcyclohexanes.

From these equations, the standard enthalpy of hydrogenation, $\Delta H_h°$, over the above temperature range for Reactions 1—11 were calculated.

In Figs. 7, 8, and 9 the logarithm of the equilibrium constants of the *cis*-to-*trans* isomerization, K_I, for 1,2-, 1,3-, and 1,4-MECH respectively are plotted against $1/T$.

Table 6 summarizes the values of $\Delta H_h°$ and of $\Delta G_h°$ calculated by Figs. 2—6 and of $\Delta G_I°$ calculated by Figs. 7—9 over the temperature range from 250 to 450 °C in the ideal gas state.

Table 7 summarizes, for the NPCH, IPCH, and six methylethylcyclohexanes, the values of the standard Gibbs energy of formation, $\Delta G_f°$, calculated from the values of $\Delta G_h°$ and of $\Delta G_f°$ of the corresponding alkylbenzenes,[3] over the temperature range from 250 to 450 °C in the ideal gas state.

Discussion

The structural analysis of dimethylcyclohexanes given by Beckett, Pitzer, and Spitzer[13] can be extended to the methylethylcyclohexanes. The stable form of cyclohexane is the chair form. NPCH and IPCH have their propyl groups only in the equatorial position because of the large strain energy in the axial position. A value of 0.8 kcal/mol has been given by Pitzer[14] for the strain energy, *a*, in *n*-butane twisted 120° about the central carbon-carbon bond (*gauche* conformation) as compared to the stable, planar conformation (*trans* conformation) of that molecule; the value of 0.61 kcal/mol is given by Bartell and Kohl.[15] Axial methylcyclohexane has two similar interactions and has been assigned a value of 1.8 kcal/mol, or $a=0.9$ kcal/mol, for the strain energy by Beckett, Pitzer, and Spitzer.[13]

The methylethylcyclohexanes have two isomers: (*cis*-1,2), (*trans*-1,3), and (*cis*-1,4) have one with an axial methyl and an equatorial ethyl group and one with an equatorial methyl and an axial ethyl group, while (*trans*-1,2), (*cis*-1,3), and (*trans*-1,4) have one with both alkyl groups axial and one with both alkyl groups equatorial. These isomers have more three rotational isomers for the ethyl group.

Table 8 summarizes various parameters arising from the isomerism of the methylethyl derivatives. Since *gauche* twists may be either right-handed (G) or left-handed (G'), there are more ways of realizing *gauche* than *trans* conformations. This is reflected in the multiplicity, *m*, listed in Table 8 for each type of isomer. The chair-boat isomerism has been ignored because of the latter's high strain energy.

For *cis*-1,3 derivatives, the axial form encounters much worse steric interference because both alkyl groups are on the same side of the plane. These steric interactions are similar to those of *n*-pentane with the adjacent G and G' conformations. This type of interference also exsists in rotational isomers with an axial ethyl group. The value of $2a$ given by Beckett, Pitzer, and Spitzer[13] has been assigned to this type of interference.

The calculated values of free energy are found by taking the mixture of isomers denoted in Table 8 and by giving *a* the value of 0.9 kcal/mol. They are in excellent agreement with the values of this report observed at 250 °C.

The author gratefully acknowledges helpful discussions with Dr. Toshiaki Kabe, Mrs. Shoko Yamadaya, and Mr. Masaaki Oba during this work.

(Received August 6, 1974)

A theory is presented which couples the proton chemical shift induced by the paramagnetic anisotropy with the chemical shift of the central cobalt-59 nucleus. The theory has been successfully applied to twenty cobalt-(III) α-aminocarboxylate complexes. It is shown that it can be used not only to assign proton NMR signals but also to determine the structure of the complex and, in certain cases, the conformation of ligand molecules.

Recently, Watabe *et al.*[1] have given a method for assigning proton magnetic resonance spectra of diamagnetic cobalt compounds. They have noted a general trend, with a few exceptions, for the chemical shift of a proton in a H–C–N–Co(III)–X fragment where X is a nitrogen or oxygen atom and occupies the *trans* (to N) position. The proton resonates at higher or lower field according to whether X is oxygen or nitrogen. This "through-cobalt" effect has been attributed tentatively to the polarizing power of the X atom.

During the course of an investigation on the proton chemical shifts in cobalt(III) ammine complexes, we found[2] that the shifts are primarily determined by the anisotropy in the second order paramagnetism of the central cobalt ion. A theoretical relation between the proton and the cobalt-59 shielding constants was derived and used successfully to reproduce the observed ammine proton chemical shifts. In connection with this work, a recent report given by Yajima *et al.*[3] gave us an impetus to study theoretically the cobalt-59 chemical shifts. We have shown that the additivity in cobalt-59 chemical shifts observed in solution[3] originates from the additivity in each (xx, yy, and zz) component of the shielding tensor.[4] The result, coupled with the relation between ^{1}H and ^{59}Co chemical shifts, enables us to predict the shift of protons under the influence of the paramagnetic anisotropy of the central cobalt(III) ion. Thus, the anisotropy in the second order paramagnetism of diamagnetic cobalt ions will be shown to manifest itself in proton chemical shift variations. Several cobalt(III) complexes exemplifying this situation are treated in this paper. The purpose of the present study is to substantiate the empirical rule of Watabe *et al.* in the light of magnetic anisotropies. The study has been limited to cobalt(III) α-aminocarboxylate complexes. The theoretical results derived here can be utilized not only for the assignment of proton NMR signals but also, in certain cases, for the determination of the geometrical structure of complexes.

Theory

Details of the theory were given in previous papers.[2,4] It is well established that proton chemical shielding under the influence of the anisotropic magnetic susceptibility is given by[5]

$$\sigma_{xx}(^{1}H) = (1-3\sin^2\theta\cos^2\phi)\chi^{p}_{xx}/R^3 \quad (1)$$

$$\sigma_{yy}(^{1}H) = (1-3\sin^2\theta\sin^2\phi)\chi^{p}_{yy}/R^3 \quad (2)$$

$$\sigma_{zz}(^{1}H) = (1-3\cos^2\theta)\chi^{p}_{zz}/R^3 \quad (3)$$

where χ^{p}_{ii} (i=x, y, z) is the principal value of the magnetic susceptibility tensor of cobalt(III) ion, the superscript p refers to the paramagnetic part (*vide infra*), R is the distance between the metal ion and the proton in question, and θ and ϕ are the polar coordinates of the proton in a frame of reference which diagonalizes the susceptibility tensor. In general, magnetic susceptibility and shielding tensors are given, respectively, by

$$\chi = -(1/2)(e^2/2mc^2)\langle 0|\sum_i\{\boldsymbol{l}(r_i^2)-\boldsymbol{r}_i\boldsymbol{r}_i\}|0\rangle + \sum_n \Delta E_n^{-1}\{\langle 0|\sum_i \boldsymbol{m}_i|n\rangle\langle n|\sum_i \boldsymbol{m}_i|0\rangle + \text{c.c.}\} \quad (4)$$

and

$$\sigma = (e^2/2mc^2)\langle 0|\sum_i\{\boldsymbol{l}(r_i^2)-\boldsymbol{r}_i\boldsymbol{r}_i\}/r_i^3|0\rangle - 2\sum_n \Delta E_n^{-1}\{\langle 0|\sum_i \boldsymbol{m}_i/r_i^3|n\rangle\langle n|\sum_i \boldsymbol{m}_i|0\rangle + \text{c.c.}\} \quad (5)$$

The latter is based on Ramsey's formulation.[6] All the notations have their usual meaning[2,4] and c.c. is to take the complex conjugate. From Eqs. (4) and (5), it has been shown,[2] after some mathematical manipulation, that the following relation holds for a cobalt(III) ion.

$$\chi^{p}_{ii} = -\sigma^{p}_{ii}/2\langle r^{-3}\rangle \quad (i=x, y, z) \quad (6)$$

Substitution of Eq. (6) into Eqs. (1)—(3) gives

$$\sigma_{xx}(^{1}H) = -(1-3\sin^2\theta\cos^2\phi)\sigma^{p}_{xx}(^{59}Co)/2R^3\langle r^{-3}\rangle \quad (7)$$

$$\sigma_{yy}(^{1}H) = -(1-3\sin^2\theta\sin^2\phi)\sigma^{p}_{yy}(^{59}Co)/2R^3\langle r^{-3}\rangle \quad (8)$$

$$\sigma_{zz}(^{1}H) = -(1-3\cos^2\theta)\sigma^{p}_{zz}(^{59}Co)/2R^3\langle r^{-3}\rangle \quad (9)$$

Covalency effects have been taken into account through Eq. (6). Thus, proton chemical shifts are directly related to cobalt-59 chemical shifts. The additivity in cobalt-59 chemical shifts gives the relations

$$\sigma^{p}_{xx}(^{59}Co) = \sigma^{p}(C) + \sigma^{p}(D) + \sigma^{p}(E) + \sigma^{p}(F) \quad (10)$$

$$\sigma^{p}_{yy}(^{59}Co) = \sigma^{p}(A) + \sigma^{p}(B) + \sigma^{p}(E) + \sigma^{p}(F) \quad (11)$$

$$\sigma^{p}_{zz}(^{59}Co) = \sigma^{p}(A) + \sigma^{p}(B) + \sigma^{p}(C) + \sigma^{p}(D) \quad (12)$$

These relations have been derived in the O_h-approximation for a complex (Fig. 1). Thus, we obtain the following results for the chemical shift of a proton in a ligand coordinated to cobalt(III) ion.

$$\sigma_{xx}(^{1}H) = -(1-3\sin^2\theta\cos^2\phi) \times (\sigma^{p}(C)+\sigma^{p}(D)+\sigma^{p}(E)+\sigma^{p}(F))/2R^3\langle r^{-3}\rangle \quad (13)$$

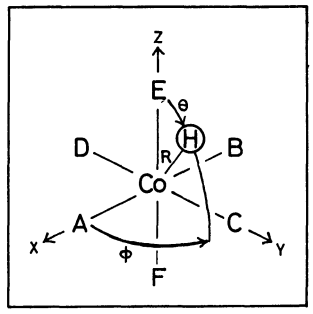

Fig. 1. The coordinate system for a complex [Co(ABCDEF)]. A, B, ……, F stand for ligand molecules or ions.

$$\sigma_{yy}(^1H) = -(1-3\sin^2\theta\sin^2\phi) \times(\sigma^p(A)+\sigma^p(B)+\sigma^p(E)+\sigma^p(F))/2R^3\langle r^{-3}\rangle \quad (14)$$

$$\sigma_{zz}(^1H) = -(1-3\cos^2\theta) \times(\sigma^p(A)+\sigma^p(B)+\sigma^p(C)+\sigma^p(D))/2R^3\langle r^{-3}\rangle \quad (15)$$

Analysis of cobalt-59 chemical shift data indicates that the magnitude of $\sigma^p(X)$ for various ligands is in the order

$$\sigma^p(N) > \sigma^p(O) > \sigma^p(Cl) \simeq \sigma^p(Br)$$

Typical values of $\sigma^p(X)$ for several ligands are given in Table 1.[4] The proton chemical shift to be observed in solution is given by

$$\sigma_{iso}(^1H) = (\sigma_{xx}(^1H)+\sigma_{yy}(^1H)+\sigma_{zz}(^1H))/3 \quad (16)$$

TABLE 1. σ^p (X) VALUES FOR SEVERAL LIGANDS[4]

Application to Cobalt(III) α-Aminocarboxylates Geometry. Quantities necessary for the calculation of Eqs. (13)—(15) can be estimated in the following way. An average of r^{-3} over a metal 3d orbital is transferred from that of $[Co(NH_3)_6]^{3+}$; $\langle r^{-3}\rangle = 5.77$ a.u.[2] Chemical shift values of cobalt-59 nuclei do not seem to have been reported for aminoacidato complexes. The best values might be the data for simple cobalt compounds for which shift data are available. Setting $\sigma^p(O)$ and $\sigma^p(N)$ at around −6000 and −4600 ppm, respectively, we obtain the result $\sigma^p(N)-\sigma^p(O)\simeq 1400$ ppm. This value was used for all the complexes we examined. Although this is a drastic approximation, the final results were not seriously affected (*vide infra*).

Geometrical factors R, θ, and ϕ were taken from data on α-aminocarboxylate backbones of $NH_4[Co(EDTA)]\cdot 2H_2O$[7] and $(+)_{495}$-$[Co(L\text{-glu})(en)_2]ClO_4$.[8] In the former complex, two structurally different glycine residues are present, the in-plane and out-of-plane groups. It has been reported that the out-of-plane ring is almost flat. The five-membered chelate ring in the latter complex formed by cobalt ion and L-glutamate ion is also nearly flat. This is in line with the observation that chelated α-aminoacidato rings are planar.[9-11] Thus, we assume the planar conformation for α-aminocarboxylate residues in the following. The cobalt-proton distance, R, is calculated for these complexes at about 3.47 A (6.56 a.u.). The relevant quantities are illustrated in Fig. 2. Under these conditions, we obtain

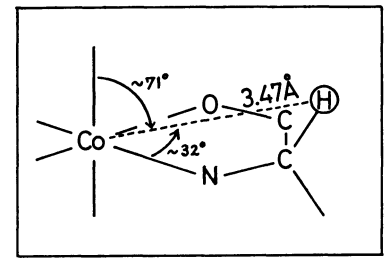

Fig. 2. The geometry of the α-aminocarboxylate residue.

$$(\sigma^p(N)-\sigma^p(O))/R^3\langle r^{-3}\rangle \simeq 0.859 \text{ ppm} \quad (17)$$

Unless otherwise stated, this value will be used for all complexes.

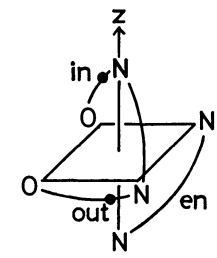

Fig. 3. Schematic presentation of *β-cis*-[Co(EDDA)(en)]$^+$ molecule. Closed circles refer to glycine methylene protons in question.

Illustrative Examples. [*Case I*] cis-O_2N_4 *Type*; *β*-cis-[*Co(EDDA)(en)*]$^+$: This complex contains two equivalent glycine methylene groups, in-plane and out-of-plane methylenes, designated as in-CH_2 and out-CH_2, respectively (Fig. 3). The ligand EDDA conformation in this inert chelate was reported to be fixed.[12] From Eqs. (13)—(16), the chemical shift of the methylene protons is given by

$$\sigma_{iso}(^1H) = (1-3\cos^2\theta)(\sigma^p(N)-\sigma^p(O))/6R^3\langle r^{-3}\rangle \quad (18)$$

The geometrical factors, coupled with Eq. (17), give

$$\sigma_{iso}(\text{in-CH}_2) \simeq -0.168 \text{ ppm} \quad (19)$$

$$\sigma_{iso}(\text{out-CH}_2) \simeq +0.099 \text{ ppm} \quad (20)$$

Thus, our estimation indicates that the out-CH_2 resonates at higher field and the in-CH_2 at lower field, the separation being about 0.26 ppm. Not much significance can be attached to this figure. Coleman *et al.*[13] observed a singlet at 3.71 ppm (from NaTMS) and an AB quartet at 3.59 ppm. Assignment was made based on a comparison with the spectra of *β-cis*-[Co(EDDA)(ox)]$^-$ and *β-cis*-[Co(EDDA)(mal)]$^-$, on the signal intensities, and the well established fact that, in coordinated EDDA, in- and out-CH_2 appear as a singlet and an AB quartet, respectively.[14,15] The assignment was further substantiated by the isotopic

deuterium exchange experiment. It was thus concluded that the singlet at higher field is the in-CH_2, which is in line with our prediction. The observed chemical shift difference between the in- and out-CH_2 is about 0.14 ppm smaller than that expected from the theory. This seems to be due to the valence angle distortion.

β-*cis*-$[Co(EDDA)(NH_3)_2]^+$ can be treated similarly. It suffices to say that the theory leads to a correct assignment.[16]

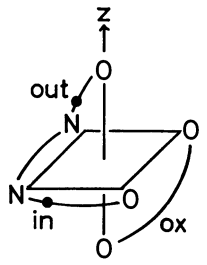

Fig. 4. β-*cis*-[Co(EDDA) (ox)]$^-$ molecule. Closed circles stand for the in- and out-methylenes.

[*Case II*] cis-N_2O_4 *Type*; β-cis-[*Co(EDDA)(ox)*]$^-$: The coordinate system is shown in Fig. 4. The two glycine methylene protons, in- and out-CH_2, can be treated in a similar manner to that for Case I if we replace $(\sigma^p(N)-\sigma^p(O))$ in Eq. (18) by $(\sigma^p(O)-\sigma^p(N))$. This leads to the conclusion that the out-CH_2 should appear at a higher field, which is also in line with the observation by Coleman *et al.*[13]

[*Case III*] mer-N_3O_3 *Type*; [*Co(ED3A)(NO₂)*]$^-$: It can easily be shown that the proton chemical shift is given by

$$\sigma_{iso}(^1H) = \sin^2\theta\cos 2\phi(\sigma^p(N)-\sigma^p(O))/2R^3\langle r^{-3}\rangle \quad (21)$$

Note that we have placed three oxygen atoms in the xz plane. We see at once that the resonance field of B methylene protons is higher than that of groups A and C (Fig. 5). A subtlety is involved in positioning A and C methylenes. There is clearly a minor difference in the chemical shift of these protons. All these predictions have been confirmed by observation.[13]

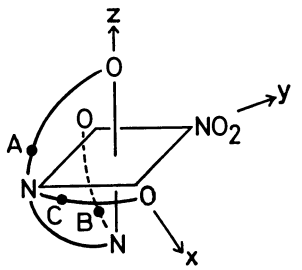

Fig. 5. [Co(ED3A)(NO₂)] ion. A, B, and C differentiate three methylene groups.

Assignments. c_1-cis-[*Co(gly)₂(en)*]$^+$: This molecule is of the *cis*-O_2N_4 type and can be treated as in Case I. The two acetate methylene groups are designated as A and B (Fig. 6). It is predicted by theory that group A should resonate at a higher field than B by about 0.2 ppm. Matsuoka *et al.*[17] observed two singlets at 3.60 and 3.44 ppm corresponding to two acetate methylenes. In this case, the valence angle

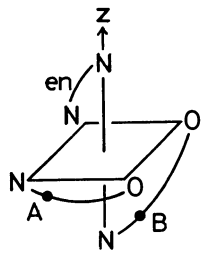

Fig. 6. c_1-*cis*-[Co(gly)₂(en)]$^+$ ion. A and B are the methylenes under consideration.

distortion is irrelevant and we may safely assign the former singlet to the B protons.

c_1-cis-[*Co(gly)₂(ox)*]$^-$: The difference between the two glycine methylene groups is shown in Fig. 7. According to our prediction B is situated in a higher field than A. It was reported[17] that two singlets at 3.58 and 3.43 ppm can be assigned to two glycine methylenes. Although the predicted separation around 0.05 ppm is rather small as compared with the observed value (0.15 ppm), it is highly probable that group B resonates at a higher field.

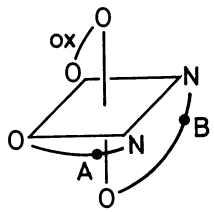

Fig. 7. c_1-*cis*-[Co(gly)₂(ox)]$^-$ ion. A and B stand for the two acetate groups in question.

cis*(O)*,cis*(N)*-[*Co(gly)₂(l-pn)*]$^+$: Two geometrical isomers exist in this *cis*-O_2N_4 type compound (Fig. 8). The complexes were obtained by the reaction of *trans*-$[CoCl_2(l\text{-}pn)_2]^+$ with glycine in an alkaline medium. Kojima and Shibata[18] obtained complexes 8a and 8b as more soluble and less soluble isomers, respectively. The glycine methylene chemical shifts are reported at 3.62 and 3.46 ppm for 8a and 3.59 and 3.46 ppm for 8b. The proton chemical shifts in these complexes can be treated in the same way as for c_1-*cis*-[Co(gly)₂(en)]$^+$. Thus, protons resonating at a higher field can be assigned to methylene group *trans* to the oxygen atom in both isomers.

cis-[*Co(IDA)₂*]$^-$: Cooke[19] measured the proton NMR spectrum and observed two signals at 3.75 and 3.635 ppm corresponding to two methylene groups.

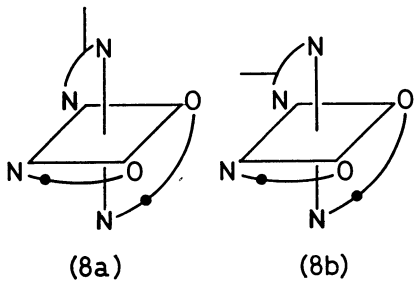

Fig. 8. Two possible isomers of *cis(O)*, *cis(N)*-[Co(gly)₂-(l-pn)]$^+$ molecule. Closed circles refer to protons in question.

This complex is of the *cis*-N_2O_4 type and can be treated as in Case II. We assign the high field signal to the out-of-plane methylenes.

mer-[*Co(gly)*$_2$(L-*glu)*]: Kawasaki and Shibata[20] prepared this complex by the reaction of $[Co(gly)_2(CO_3)]^-$ with glutamate ion in the presence of activated charcoal. They did not succeed in determining the structure. There are two possibilities; *cis(O),trans(N)*- and *cis(N)*, *trans(O)*-isomers. The chemical shift values have not been given but can be estimated from the spectrum. Two singlets at about 3.4 and 3.65 ppm can be observed. Thus, the shift difference is close to that found between groups B and C in $[Co(ED3A)(NO_2)]^-$. For the *cis(O),trans(N)*-structure, the shift difference should be much smaller, which follows from the analogy of the difference between groups A and C in $[Co(ED3A)(NO_2)]^-$. We are thus inclined to presume that the complex assumes the *cis(N),trans(O)*-structure (see Fig. 9). If this is the case, the glycine protons designated as B should appear at a higher field.

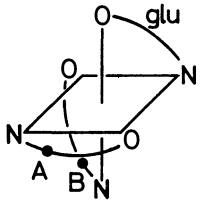

Fig. 9. *mer*-[$Co(gly)_2$(L-glu)] molecule. A and B are methylene groups.

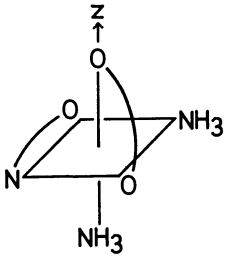

Fig. 10. *mer(cis)*-[$Co(CO_3)(gly)(NH_3)_2$] ion.

mer(cis)-[*Co(CO*$_3$*)(gly)(NH*$_3$*)*$_2$]: Let us examine the chemical shift of ammine protons of coordinated ammonia molecules (see Fig. 10). Kanazawa and Shibata[21] measured the NMR spectrum in trifluoroacetic acid. They observed the chemical shifts of ammonia protons at 5.1 and 5.8 ppm. The separation is larger as compared with separations found for glycine methylene protons discussed above. This is caused by the decrease in Co–H distance R. For the ammonia protons situated on the z-axis, the NH_3-rotation about its C_3-axis renders the factors $(1-3\sin^2\theta\cos^2\phi)$ and $(1-3\sin^2\theta\sin^2\phi)$ both averaged to $(2-3\sin^2\theta)/2$. It follows that protons of this ammonia molecule do not experience the magnetic anisotropy of the cobalt(III) ion. For the other ammonia protons, the following relation can be derived by taking the NH_3-rotation into account.

$$\sigma_{iso}(^1H) = -(3\cos^2\theta'-1)(\sigma^p(N)-\sigma^p(O))/4R^3\langle r^{-3}\rangle \quad (22)$$

Note here that θ' represents the angle between the Co–H vector and the x-axis. The geometrical factors are R=2.52 A (4.77 a.u.) and θ'=22.0.[2] These values, coupled with $(\sigma^p(N)-\sigma^p(O))\simeq 1400$ ppm, give $\sigma_{iso}(^1H)$ value of about −0.883 ppm. Thus, it can be concluded that this ammonia is shifted to low field.

mer(cis)-[*Co(CO*$_3$*)(β-ala)(NH*$_3$*)*$_2$], mer(cis)-[*Co(ox)-(gly)(NH*$_3$*)*$_2$], mer(cis)-[*Co(ox)(β-ala)(NH*$_3$*)*$_2$]: These three complexes can be treated in the same way as above. The protons of the ammonia molecule *trans* to the nitrogen should appear at a lower field and those *trans* to the oxygen at a higher field.

α-cis-[*Co(EDDA)(NH*$_3$*)H*$_2$*O*]$^+$: As expected, the glycine methylene protons exhibit two AB quartets. From a comparison of the spectrum with that of *β-cis*-$[Co(EDDA)(NH_3)_2]^+$ and *β-cis*-$[Co(EDDA)(H_2O)]^+$, the quartet at a lower field has been assigned[23] to glycine protons near the coordinated ammonia molecule. However, this assignment seems to be open to question. There are two possible ways of coordination for ammonia molecule, 11a and 11b. In either case, the theory based on the magnetic anisotropy of cobalt ion leads to an assignment just the opposite; the high field quartet should be due to the methylene near the coordinated ammonia.

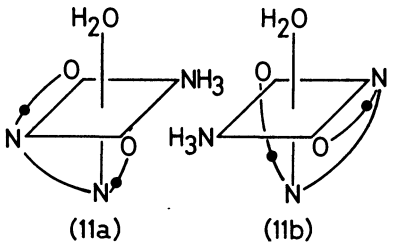

Fig. 11. Two possible ways of coordination of ammonia molecule in α-*cis*-$[Co(EDDA)(NH_3)H_2O]^+$. Closed circles stand for two glycine methylene groups.

Discussion

Several criteria have been proposed for the assignment of proton NMR spectra. They include valence angle distortions (and the consequential elongation of Co–O bonds),[25] bond anisotropies,[13–15,19] steric compressions,[24] selective labilization of α-hydrogen atoms,[26] and the paramagnetic anisotropy in the central metal ion.[1,2,4,27] The first effect, which is the most relevant to our problem, tends to vitiate a prediction based only on the paramagnetic anisotropy of metal ions. $[Co(EDTA)]^-$ and its derivatives offer such examples.

The molecular structure of $[Co(EDTA)]^-$ was determined by Weakliem and Hoard.[7] Their X-ray analysis revealed that while the out-of-plane rings are nearly flat, the in-plane rings suffer severe valence angle distortions, leading to a substantial elongation of the Co–O bonds. In accordance with this fact, the in-plane protons have been shown[14,25,28] to be more shielded than the out-of-plane ones. Similar situations have been noted for $[Co(PDTA)]^-$ and $[Co(CyDTA)]^-$.[26] These molecules belong to *cis*-N_2O_4 symmetry. From the result on *cis*-$[Co(IDA)_2]^-$, it is readily seen that the prediction based only on the paramagnetic anisotropy of the cobalt ion is contrary to observation. Thus, the valence angle distortion acts in these cases to offset paramagnetic anisotropy.

Another example of similar situation is provided by β-*cis*-[Co(EDDA)(mal)]$^-$. Coleman *et al.*[13] measured a spectrum consisting of a singlet and an AB quartet for glycine methylenes. The former resonates at a higher field, the separation being *ca.* 0.06 ppm. The assignment was based on the argument for β-*cis*-[Co(EDDA)(ox)]$^-$. The selective HD exchange experiment provided further support to this assignment. The out-of-plane methylene was shown to be more labilized and amenable to the isotopic exchange reaction. Thus, their assignment can be considered to be sound. Consideration of only the paramagnetic anisotropy leads to an erroneous conclusion, though the predicted separation between the in- and out-of-plane protons is rather small (0.05 ppm). All these examples indicate that we should be careful in applying the theory to ligands with valence angle distortions.

Watabe *et al.*[1] observed that in a number of cobalt(III) α-aminocarboxylate complexes, α protons adjacent to the amino group which is *trans* to N atom are shifted to low field and those *trans* to O atom to high field. This seems to be an over simplification. As Eqs. (13)—(15) indicate, the proton chemical shift is dependent on all the six coordinating atoms and on the position of the proton in question.

The authors wish to express sincere thanks to Dr. M. Watabe and Prof. S. Yoshikawa, Tokyo University, for permission to see their papers prior to publication, and for helpful discussions.

The Effect of the pH on the Adsorption of an Ampholytic Surfactant, *N*-Dodecyl-β-alanine, at the Aqueous Surface

Akio NAKAMURA, Kazuo TAJIMA, and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Tokyo 158

(Received August 7, 1974)

The effect of the pH on the adsorption of an ampholytic surfactant, *N*-dodecyl-β-alanine (NDA), at the nitrogen/solution interface was studied by the radiotracer method, using a tritiated compound. The saturated amount of NDA adsorption was found to depend on the pH of the bulk solution; it shows a flat maximum in the isoelectric region from pH 4 to 10, and decreases distinctly on the both acid and alkaline sides. The Gibbs adsorption isotherm for an aqueous solution of the ampholytic surfactant was derived. Using this relation, the amount of adsorption in the pH range from 2 to 6 was calculated from the surface tension *vs.* concentration and the surface tension *vs.* pH relations observed for the NDA solution. The calculated values were in good agreement with those obtained by the radiotracer method. The degree of dissociation of the adsorbed monolayer was estimated from the pH dependence of NDA and the chloride ion adsorption.

The present authors and their collaborator have previously reported radiotracer studies on the adsorption of an ampholytic surfactant, *N*-dodecyl-β-alanine (NDA),[1] at type of surfactant upon which the adsorption had not been studied precisely;[2] they found that, in the isoelectric pH region, the Gibbs adsorption isotherm can be applied in the same form as for an aqueous nonionic surfactant[3] and that the NDA molecules in the solution were mainly in the state of the simple zwitterion.[4]

It is evident that, for such an ampholytic surfactant, a change in the pH markedly influences the state of the solute species of NDA; this further affects the adsorption and the surface tension of the solution. However, the studies of the pH effects have been mainly restricted to properties of bulk solution.[4,5]

In the present report, the pH dependence of the adsorption of NDA is studied in the pH region from 1 to 13. A Gibbs adsorption isotherm applicable to such a system is derived and experimentally confirmed. The ionic states of the adsorbed molecules are discussed, taking account of the pH dependence of NDA and the chloride ion adsorption.

Experimental

Materials and Procedures. All of the reagents used, including tritiated NDA(TNDA), and the methods of the radioactivity and surface tension measurements are the same as have been described in the previous paper.[1]

Theoretical

Gibbs Adsorption Isotherm. The Gibbs adsorption isotherm is written, in its general form, as:[6]

$$-\mathrm{d}\gamma/RT = \sum_i \Gamma_i \mathrm{d}\ln a_i \qquad (1)$$

where γ denotes the surface tension, and Γ_i and a_i, the surface excess and activity of the i'th solute in the solution respectively. Equation (1) is rewritten for the ampholytic surfactant solution containing hydrochloric acid as:

$$\begin{aligned}-\mathrm{d}\gamma/RT = {} & \Gamma_{\mathrm{A}^\pm}\mathrm{d}\ln C_{\mathrm{A}^\pm} + \Gamma_{\mathrm{A}^+}\mathrm{d}\ln C_{\mathrm{A}^+} \\ & + \Gamma_{\mathrm{A}^-}\mathrm{d}\ln C_{\mathrm{A}^-} + \Gamma_{\mathrm{H}^+}\mathrm{d}\ln C_{\mathrm{H}^+} \\ & + \Gamma_{\mathrm{OH}^-}\mathrm{d}\ln C_{\mathrm{OH}^-} + \Gamma_{\mathrm{Cl}}\mathrm{d}\ln C_{\mathrm{Cl}} \qquad (2)\end{aligned}$$

where the $\mathrm{A}^\pm$, A^+, A^-, H^+, OH^-, and Cl subscripts refer to the zwitterion, the cation, the anion of NDA, the hydrogen ion, the hydroxide ion, and the chloride ion respectively. In Eq. (2) the activities can be replaced by the concentrations, since the surfactant concentrations are dilute, and the activity coefficients can be taken as unity. The concentration of HCl is not dilute in some cases, but this does not cause much error, as may be seen from the results.

Further, we have the following relations:

$$K_1 = C_{\mathrm{A}^\pm}C_{\mathrm{H}^+}/C_{\mathrm{A}^+} \qquad (3)$$

$$K_2 = C_{\mathrm{A}^-}C_{\mathrm{H}^+}/C_{\mathrm{A}^\pm} \qquad (4)$$

$$K_{\mathrm{w}} = C_{\mathrm{H}^+}C_{\mathrm{OH}^-} \qquad (5)$$

$$\Gamma_{\mathrm{A}^+} + \Gamma_{\mathrm{H}^+} = \Gamma_{\mathrm{OH}^-} + \Gamma_{\mathrm{A}^-} + \Gamma_{\mathrm{Cl}} \qquad (6)$$

where K_1 and K_2 express the first and second dissociation constants of NDA, considered as a dibasic acid, and K_{w}, the dissociation constant of water. Equation (6) represents the electrical neutrality of the adsorbed ionic species.

By substituting the logarithmic forms of Eqs. (3) and (4) into Eq. (2), we obtain:

$$\begin{aligned}-\mathrm{d}\gamma/RT = {} & (\Gamma_{\mathrm{A}^\pm}+\Gamma_{\mathrm{A}^+}+\Gamma_{\mathrm{A}^-})\mathrm{d}\ln C_{\mathrm{A}^\pm} \\ & + (\Gamma_{\mathrm{A}^+}-\Gamma_{\mathrm{A}^-}+\Gamma_{\mathrm{H}^+})\mathrm{d}\ln C_{\mathrm{H}^+} \\ & + \Gamma_{\mathrm{OH}^-}\mathrm{d}\ln C_{\mathrm{OH}^-} + \Gamma_{\mathrm{Cl}}\mathrm{d}\ln C_{\mathrm{Cl}} \qquad (7)\end{aligned}$$

Using

$$\Gamma^{\mathrm{A}} = \Gamma_{\mathrm{A}^\pm} + \Gamma_{\mathrm{A}^+} + \Gamma_{\mathrm{A}^-} \qquad (8)$$

as the total adsorption amount of NDA, and

$$C^{\mathrm{A}} = C_{\mathrm{A}^\pm} + C_{\mathrm{A}^+} + C_{\mathrm{A}^-} \qquad (9)$$

as the bulk concentration of NDA, we obtain, from Eqs. (5), (6), (7), and (8):

$$-\mathrm{d}\gamma/RT = \Gamma^{\mathrm{A}}\mathrm{d}\ln C_{\mathrm{A}^\pm} + \Gamma_{\mathrm{Cl}}\mathrm{d}\ln C_{\mathrm{H}^+}C_{\mathrm{Cl}} \qquad (10)$$

Equation (10), together with Eqs. (3), (4), and (9), then gives:

$$\begin{aligned}-\mathrm{d}\gamma/RT = {} & \Gamma^{\mathrm{A}}\mathrm{d}\ln C^{\mathrm{A}} + K\Gamma^{\mathrm{A}}\mathrm{d}\ln C_{\mathrm{H}^+} \\ & + \Gamma_{\mathrm{Cl}}\mathrm{d}\ln C_{\mathrm{H}^+}C_{\mathrm{Cl}} \qquad (11)\end{aligned}$$

where:

$$K = (C_{\mathrm{A}^-} - C_{\mathrm{A}^+})/C^{\mathrm{A}}$$

or, using Eqs. (3), (4), and (9),

$$K = (K_1K_2 - C_{\mathrm{H}^+}{}^2)/(C_{\mathrm{H}^+}{}^2 + K_1C_{\mathrm{H}^+} + K_1K_2) \qquad (12)$$

By differentiating Eq. (11) with respect to $\ln C^{\mathrm{A}}$,

keeping C_{Cl} constant, and with respect to ln C_{Cl}, keeping C^A constant, we obtain:

$$I_{Cl} = \Gamma^A + (K\Gamma^A + \Gamma_{Cl})\alpha \quad (13)$$

$$I_A = \Gamma_{Cl} + (K\Gamma^A + \Gamma_{Cl})\beta \quad (14)$$

where:

$$I_{Cl} = -(d\gamma/RTd \ln C^A)_{C_{Cl}} \quad (15)$$

$$I_A = -(d\gamma/RTd \ln C_{Cl})_{C^A} \quad (16)$$

$$\alpha = (d \ln C_{H^+}/d \ln C^A)_{C_{Cl}} \quad (17)$$

$$\beta = (d \ln C_{H^+}/d \ln C_{Cl})_{C^A} \quad (18)$$

Equations (13) and (14) finally give:

$$\Gamma^A = [(1+\beta)I_{Cl} - \alpha I_A]/[1+\beta+\alpha K] \quad (19)$$

$$\Gamma_{Cl} = -[\beta K I_{Cl} - (1+\alpha K)I_A]/[1+\beta+\alpha K] \quad (20)$$

From Eqs. (19) and (20), Γ^A and Γ_{Cl} can be calculated from the measurements of I_A, I_{Cl}, α, and β according to Eqs. (15) to (18).

The validity of Eq. (19) can be checked by comparing the Γ^A calculated from this equation with those measured directly by the radiotracer method. Equation (20) enables us to calculate Γ_{Cl}, the direct measurement of which is impossible due to the lack of a soft radioactive nuclide.

Adsorption equations for alkaline NDA solution containing sodium hydroxide can be derived by a similar calculation. The final expressions for Γ^A and Γ_{Na^+} are the same as in Eqs. (19) and (20) except for the sign of β being the opposite and the subscript Cl being replaced by Na^+.

Results and Discussion

Effect of the pH on the Saturated Amount of Adsorption. Figure 1 shows the adsorption isotherm obtained by the radiotracer method for TNDA solutions kept at a constant pH by the addition of HCl. The amount of adsorption increases with the NDA concentration for each pH and attains a saturation values at a bulk TNDA concentration above *ca.* 2.5×10^{-4} mol/l for the pH region from 3.5 to 6 and above *ca.* 6×10^{-4} mol/l for the more acid region. Also, it can be seen that the amount of NDA adsorption is independent of the pH in the range from 4 to 6 and that it decreases

below this region, with a minimum at pH 2. The measurements of the saturated amount of adsorption were further extended over the alkaline region, and the values plotted against the pH. The results are shown by Curve A in Fig. 2. In these measurements, the concentration of NDA was maintained at 6.0×10^{-4} mol/l, which was high enough to secure the saturated adsorption. Curve A shows that the saturated amount of adsorption is nearly constant in the pH region from 4 up to 10, including the isoelectric point of pH 7, and decreases on the acid and alkaline sides, with a minimum located near pH 2.

The slight increase observed below pH 2 is considered to be due to the salting out effect on the adsorption of HCl added in a relatively large amount. To confirm this effect, another measurement was made under a constant ionic strength adjusted by the addition of NaCl. The results are shown by Curve B in the same figure. The amount of NDA adsorption in this case is also seen to be nearly constant in the pH region from 4 up to 11, while it decreases rather sharply below and above this region, tending to constant values. The minimum values increases, and the minimum disappears.

In order to elucidate the pH dependence of ampholyte adsorption, it is necessary to know the dissociation equilibrium of ampholyte in the substrate solution with which the adsorbed monolayer is in equilibrium. For this purpose, the molar fractions of NDA cations, anions, and zwitterions are calculated using two dissociation constants, $K_1=3.2\times10^{-4}$, $K_2=1.3\times10^{-11}$ mol/l[4] of the NDA as a dibasic acid; they are plotted against the pH in Fig. 3. As is shown by the curves in the figure, the two dissociations occur step-by-step, and Curve (2) indicates that, in the pH region from 5.5 up to 9, most NDA molecules exist as zwitterions in a bulk solution. Thus, the agreement, as a whole, of the plateau region of adsorption at the surface (shown by Curve B in Fig. 2) with the zwitterionic region of the bulk solution (Curve (2) in Fig. 3) might be taken as the indication that the adsorbed NDA in this pH region consists mainly of zwitterions, considering the similarity of the ionic states between the surface and

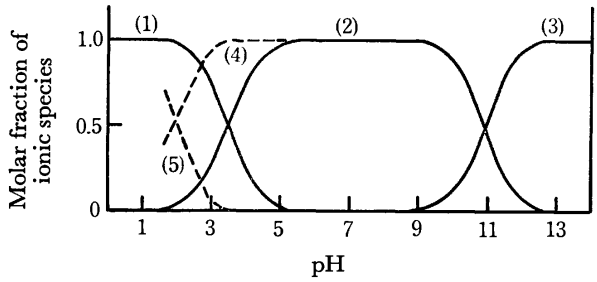

Fig. 3. Molar fractions of ionic species in the bulk solution and at the surface.

at the surface

the bulk. The agreement of the pH regions of relatively weak adsorptions on the acid and alkaline sides of Curve B in Fig. 2 with those of Curves (1) and (3) in Fig. 3 also indicates that cations (anions) are the main adsorbed species in the low (high) pH region.

According to these considerations, the adsorbed layer is cationic at pH 1, zwitterionic at pH values from 4 to 11, and anionic at pH 13 in Curve B of Fig. 2. Then, at the pH corresponding to the middle point between the adsorption amounts of cationic and zwitterionic molecules (Arrow 1), half of the molecules adsorbed at the surface are considered to exist as cations and half as zwitterions, while at a similar pH on the alkaline side (Arrow 2), half of the molecules adsorbed may exist as zwitterions and half as anions. These two pH values of the half-ionization of the adsorbed NDA are read as 2.5 and 11.7 respectively from Curve B. It is noticeable that the pH value of 2.5, *i.e.* the point of the half-ionization of carboxyl groups, is by 1.0 pH unit to the acid side of the point at which carboxyl groups half-ionize in the bulk solution, and that the pH value of 11.7, the point of the half-ionization of imino groups, is by 0.8 unit to the alkaline side of the point at which imino groups half-ionize in the bulk solution.

In the case of soluble and insoluble monolayers, such a shift of the half-ionization in the surface phase has been reported by many investigators on the basis of measurements of the surface potential,[7] the calcium ion adsorption,[8] *etc.*[9] These results have been explained in terms of the existence of a large potential difference, ψ, across the surface characteristic of the charged monolayer.[10] The electric charge attracts or repels hydrogen ions to or from the surface according to the Boltzmann equation:

$$[H^+]_s = [H^+]_b \exp(-\varepsilon\psi/kT)$$

or:

$$pH_s = pH_b + \varepsilon\psi/2.3kT \qquad (21)$$

where the s and b subscripts denote the surface and the bulk respectively, and ε, the protonic charge. It follows from Eq. (21) that:

$\psi > 0$ $pH_s > pH_b$ for a cationic monolayer

$\psi < 0$ $pH_s < pH_b$ for an anionic monolayer

This may explain the observed phenomena. In the case of the cationic monolayer formed in acid region, $pH_s > pH_b$ and the degree of ionization of carboxyl groups is larger at the surface than in the bulk solution. Accordingly, half-ionization at the surface occurs at a lower pH than the pH of half-ionization in the bulk solution. A similar consideration leads to the conclusion that the half-ionization of imino groups at the surface occurs at a higher pH than the pH of half-ionization in the bulk solution. Thus, we have a system of pH shifts occurring in two opposite directions each other as compared with the shift in one direction usually observed for insoluble monolayers which contain only one kind of dissociation group. The ψ values tentatively calculated according to Eq. (21) are 60 mV for the cationic monolayer and −50 mV for the anionic monolayer; these values are, however, roughly half of the values calculated according to the Gouy theory.[11] This discrepancy will be explained below.

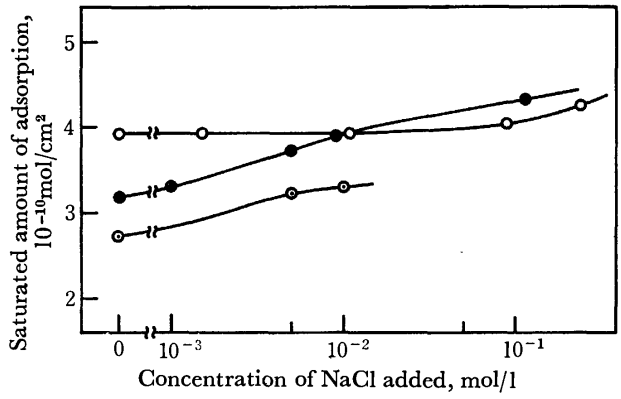

Fig. 4. Effect of polar head group and added NaCl on the saturated amount of adsorption.
Surfactants (Concentration)
○: NDA (5×10^{-4}mol/l) ●: SDS (4×10^{-3}mol/l)[12]
⊙: $D(EO)_6$ (4×10^{-5}mol/l)[13]

Effect of the Polar Head Structure and Added Salt on the Saturated Amount of Adsorption. The effect of salt on the saturated amount of adsorption of a few surfactants with equal hydrocarbon chain lengths hitherto measured directly by the radiotracer method using tritium labeled compounds are shown in Fig. 4, together with the present data. It is evident that the nature of the polar head and NaCl added affect the amount of adsorption. In the absence of added salt, the adsorption of NDA is relatively large compared with those of the sodium dodecylsulfate (SDS)[12] and hexaoxyethylenedodecylmonoether ($D(EO)_6$).[13] This may be due to the electrical repulsion between negatively charged groups in the case of SDS and due to bulky head groups in the case of $D(EO)_6$. The relatively large amount of adsorption for NDA is due to the zwitterionic and relatively compact head groups forming intra- and intermolecular salts, as has been reported for, for instance, the phospholipid monolayers.[8,14] It may be seen in Fig. 4 that the addition of a small amount of NaCl distinctly increases the adsorption of SDS and $D(EO)_6$, while it has no effect on NDA. In the case

of SDS, the increase in adsorption is mainly caused by the decrease in electrical repulsion between adsorbed molecules due to the increase in the ionic strength. In the case of $D(EO)_6$, the dehydration of weakly hydrated nonionic molecules may result in an increase in the adsorption.[15] The absence of these effects in the case of NDA in the neutral region in Fig. 4 and perhaps in the whole plateau region may explain the absence of any effect of NaCl addition. Figure 4 further shows the increase in the adsorption of NDA in the concentrated solution of NaCl, much as in the cases of SDS and $D(EO)_6$. This may be interpreted as a salting out effect of NaCl. A similar effect is also seen near pH 1 in Fig. 2, where HCl is added in a large amount.

Calculation of the Amount of Adsorption. Figures 5 to 8 show the plots of γ *vs.* $\log C^A$ (C_{Cl}=constant), of γ *vs.* pCl (C^A=constant), of pH *vs.* pCl (C^A=constant), and of pH *vs.* $\log C^A$ (C_{Cl}=constant) respectively, from which I_{Cl}, I_A, α, and β values required in Eqs. (19) and (20) may be calculated from the slopes of these

curves. Γ^A and Γ_{Cl} were calculated at the NDA concentrations of 2.25×10^{-4} mol/l and 5.0×10^{-4} mol/l. Similar results were thus obtained. Figure 9 shows the plot of Γ against pH for the latter case, together with the observed values obtained by the interpolation of the curves in Fig. 1. A good agreement is seen between the calculated and observed amounts of adsorption; this shows the validity of the Gibbs adsorption isotherm derived.

It is worth noting that, in the limiting cases of $\alpha=0$, which is actually the case near pH 2 and in the neutral pH region, Eq. (19) is reduced to a simple form:

$$\Gamma^A = I_{Cl} \qquad (22)$$

As was mentioned, in the neutral region NDA exclusively exists as one zwitterionic species, regardless of the pH, while near pH 2 NDA exist mainly as cations with excess of HCl. Therefore, Eq. (22) for NDA, in the neutral pH region and near pH 2, is valid much as in the cases of the adsorption of a nonionic surfactant ($D(EO)_6$)[3] and an anionic surfactant (SDS) with excess salt[16] respectively. In the intermediate

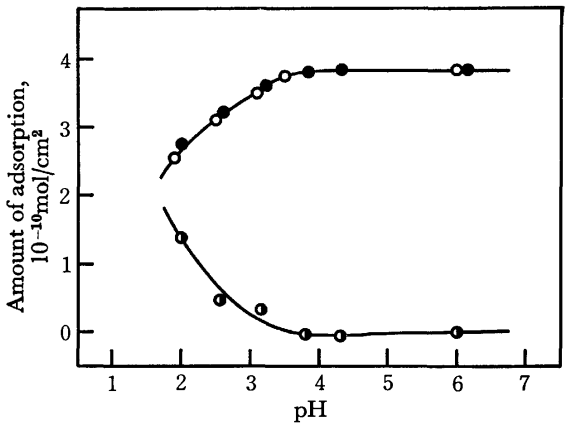

Fig. 9. Amount of adsorption of NDA and chloride ion *vs.* pH at NDA concentration of 5.0×10^{-4}mol/l.
○: observed values for NDA
●: calculated value for NDA
◑: calculated value for chloride ion

pH region from 2 to 5, the general form of Eq. (19) should be used.

As regards the adsorption of the chloride ion, calculated values are nearly zero in the pH region from 4 to 6, as may be seen in Fig. 9. This may imply the zwitterionic structure of NDA, which requires no counter ions. In a more acid region, the values increase with a decrease in the pH. Since the zwitterions change into cations at the surface in this region (Curves A and B in Fig. 2), the positive adsorption of chloride ion as counter ions can reasonably be expected. This enables another calculation of the degree of the ionization of zwitterions into cations at the surface, expressed as Γ_{Cl}/Γ^{A} at each pH, independently of the former estimation made from the curve of Fig. 2. The degrees of ionization, Γ_{Cl}/Γ^{A}, namely, the molar fraction of A^+ and the molar fraction of $A^{\pm}$ given as $1-\Gamma_{Cl}/\Gamma^{A}$, are shown in Fig. 3 as two broken (4) and (5) respectively. The point of the half-ionization pH at the surface estimated from Curve (5) is read as 2, which is 1.5 pH unit to the acid side of the point at which carboxyl groups half-ionize in the bulk solution, and is lower than the value obtained by the former method from the Curve B shown in Fig. 2. The discrepancy is probably due to the adsorbed film at the lowest pH in Fig. 2 not being in a pure cationic form, but containing some zwitterions. The ψ value in Eq. (21), calculated assuming a half-ionization at pH 2, was found to be 90 mV, roughly which is two-thirds of the values obtained according to the Gouy theory. The discrepancy might come from taking only the net charge density into account and neglecting the ampholytic nature of the adsorbed NDA in the estimation of ψ. At any rate, it may be noted that not only the total amount of adsorption, but also the composition of each ionic species or the state of the ionization of the adsorbed surface phase, can be determined for the ampholyte NDA. It is also shown that the composition is different between the surface and the bulk of the aqueous NDA solution.

An Analysis of the Surface Composition of Passive Film on Cu-Ni Alloys by means of Auger Electron Spectroscopy and X-Ray Photoelectron Specroscopy

Yoshio TAKASU, Shun-ichi MARU, Yoshiharu MATSUDA, and Hazime SHIMIZU*

Department of Industrial Chemistry, Faculty of Engineering, Yamaguchi University, Tokiwadai, Ube, Yamaguchi 755

**Electrotechnical Laboratory, Tanashi, Tokyo 188*

(Received August 20, 1974)

A potentiostatic polarization method, Auger electron spectroscopy (AES), and photoelectron spectroscopy (XPS) were used to examine the composition of the passive films formed on Cu–Ni alloys anodized in an acid. The Flade potential of pure nickel in 0.5 M $HClO_4$ at 25 °C was −0.085 V (*vs.* SCE), while those of the alloys varied linearly from 0.180 V at 95%Ni to 0.310 V at 47%Ni. Analysis by AES and XPS revealed that (a) the passive region contained nickel and copper in the same ratio as the alloy, and (b) the chemical species of the film were made of NiO and copper oxide (Cu_2O and/or CuO). The Flade potential was assumed to be governed by the mixed potential of the formation of such oxides.

Copper–nickel alloys find extensive use in saline water environments or in chemical instruments. Nickel-rich alloys in Cu–Ni are acid-resisting materials. Experimental studies have indicated that the presence of thin films on the surface of the alloys is primarily responsible for the excellent corrosion resistance of the nickel alloys,[1] but the composition of the initial films that form on the alloys on exposure to acid has not been experimentally determined. Coulometry should be applicable to an analysis of the composition of the passive films on Cu–Ni alloys, as attempted by Okuyama,[2] however, it has been difficult to obtain a clear E–Q curve.

Recently, Auger electron spectroscopy (AES) and photoelectron spectroscopy (XPS) techniques have become available for the investigation of very thin films on surfaces. Hulett and his co-workers[3] have studied the passive film on a Cu–Ni alloy which was formed in a NaCl solution by means of XPS; they found the passive film to be enriched with nickel.

On the other hand, one of the present authors has previously established a quantitative analysis of the surface alloy composition of the Cu–Ni alloy system by using AES.[4,5]

In this paper, an electrochemical observation of the passive films on Cu–Ni alloys in an acid and the direct analysis of the surface composition of the passive films by means of AES and XPS will be described.

Experimental

Polarization Measurements. An electronic potentiostat (Hokuto Denko Corp. HA-101) and a function generator (Kowa Electronics Ltd. FG-102) were used for polarization measurements. The corresponding current flow was drawn on a X-Y recorder.

Pure nickel and seven Cu-Ni alloys, 95, 86, 76, 67, 57, 47, and 42 at% nickel, were adopted in this study. The alloys were cast from 99.99% copper and 99.9% nickel, hot rolled, scalped, cold rolled to a thickness 0.01—0.005 cm, and annealed. The apparent surface area of each test electrode was 2.0 cm^2. It was abraded with emery paper (1500#) and then rinsed in water and acetone.

The reference electrode was a saturated calomel electrode. The electrolyte was composed of 0.5 M $HClO_4$, through which purified nitrogen could be bubbled in order to remove any dissolved oxygen. The cell was located in a thermostat maintained at 25±0.1 °C.

Surface Analysis. Specimens were anodized potentiostatically in their passive region between 450—850 mV *versus* SCE for one hour. After anodization, the specimens were rinsed with distilled water and dried while being stored until examination. Auger analysis was carried out by using a CMA-type Auger spectrometer (NEVA AES-200). The X-ray photoelectron spectra were measured by the use of a Hitachi XPS E-507 analyzer.

Results

Anodic Polarization Behavior of Cu–Ni Alloys. Figure 1 shows a typical polarization curve for 86%Ni alloy in 0.5 M $HClO_4$ at 25 °C; the potential sweep rate was automatically set at 1 mV/s. The potential was moved anodically from the active region to the passive region. Potentials corresponding to P_1 were found to be affected only a little by the potential sweep rate. A slower potential sweep rate resulted in a higher corrosion rate of the electrode in the active region. In consideration of this high corrosion rate, the potential sweep rate was set at 1 mV/s. It might be previsionally possible to consider the P_1 potential as the Flade potential.

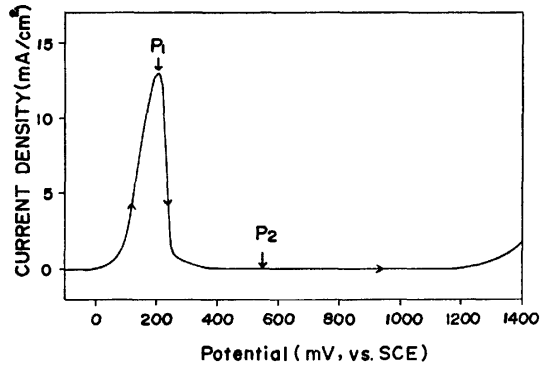

Fig. 1. Polarization curve for 86% Ni in dearated 0.5 M $HClO_4$ at 25 °C, 1 mV/s.

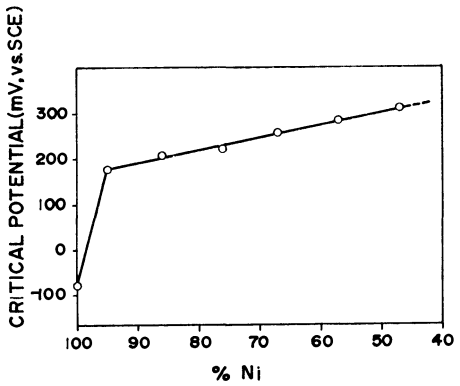

Fig. 2. Critical passivating potential (Flade potential) *versus* alloy composition.

The current density shows its minimum in the passive region at the P_2 potential. This was termed the passive current density. The Flade potential of Cu–Ni alloys in this experimental condition is shown in Fig. 2. Cu-rich alloys more than 42%Ni showed neither critical current at P_1 nor any minimum current at P_2. It is of interest that the Flade potential was changed almost linearly depending on the alloy composition.

TABLE 1. SURFACE CONTENT OF NICKEL TO COPPER IN PASSIVE FILM BY AES

Surface–Alloy Composition of the Passive Films. The surface content of nickel in relation to copper in the passive films on Cu–Ni alloys, as measured by AES, are summarized in Table 1. It was reported that the surface alloy composition of the Cu–Ni system could be quantitatively analyzed by using a calibration curve.[4] As is shown in the table, the passive films contain nickel and copper in the same ratio as the alloys.

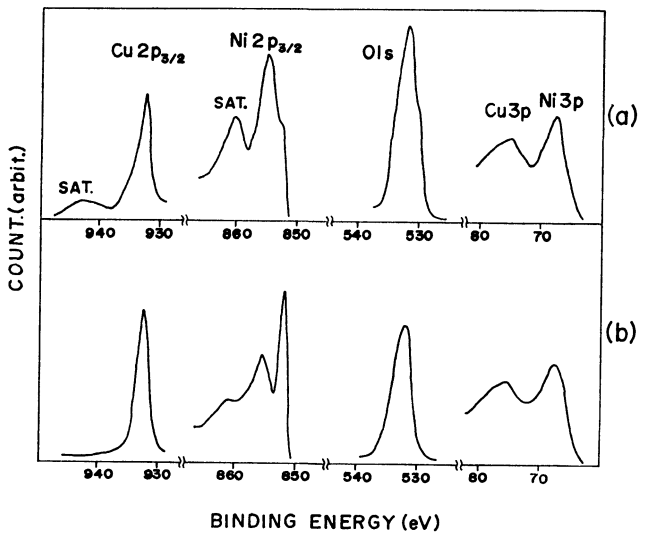

Fig. 3. Photoelectron spectra of (a) passive film and (b) abraded surface (76% Ni alloy).

Figure 3 compares the XPS spectrum from a surface of a 76%Ni specimen anodized at 500 mV *versus* SCE with that of an abraded specimen. The assignments of the peaks are marked in the figure. The intensity and the shape of the Cu3p peak and the peaks of the anodized surface and those of the abraded surface are almost identical. The O1s peak of the former is larger than that of the latter. It is noted that the peak with the binding energy of 852 eV almost disappears upon the anodization, while the peak with a binding energy about 3 eV higher grows stronger. This finding gives evidence of the formation of NiO in the passive film. The $Cu2p_{3/2}$ peak of the passive film is almost unchanged by the anodic polarization, but a weak peak at 943 eV was produced. This peak corresponds to the satellite peak from Cu_2O or CuO.[6] The XPS spectra from the $Cu2p_{3/2}$ and $Ni2p_{3/2}$ peaks for the other specimens are shown in Figs. 4 and 5 respectively. These spectra also show that NiO and copper oxide (Cu_2O and/or CuO) were formed on the surface by the anodic polarization.

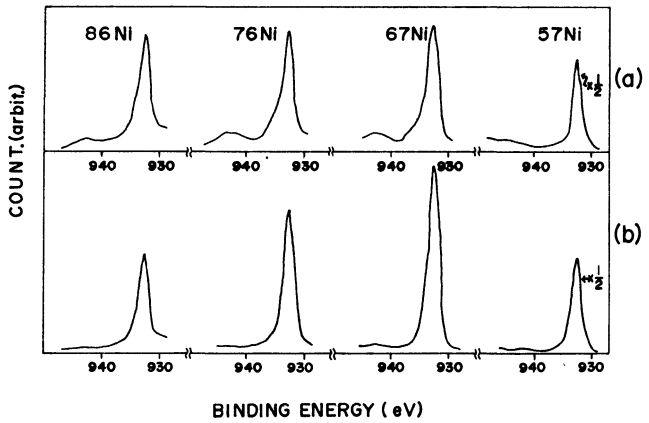

Fig. 4. Photoelectron spectra of (a) passive film and (b) abraded surface ($Cu2p_{3/2}$).

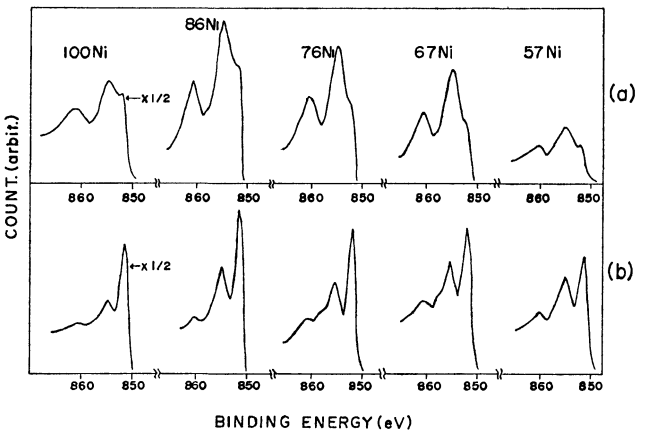

Fig. 5. Photoelectron spectra of (a) passive film and (b) abraded surface ($Ni2p_{3/2}$).

Discussion

Osterwald and Uhlig[1] insisted that a passive film of Cu–Ni alloy in 0.5 M H_2SO_4 at 25 °C was almost

identical with that on pure nickel; this phenomenon was observed on the alloy whose nickel content was over 30%Ni. However, they did not discuss copper oxide, although their data showed that the values of the Flade potential changed from 0.13 V (*vs.* SHE) at pure nickel to 0.38 V (*vs.* SHE) at 30.4%Ni.

As has been described above, Hulett and his coworkers[3] reported that the X-ray photoelectron spectrum of the passive films on 70%Ni alloy in a NaCl solution at 100 °C indicated primarily nickel oxide and was very similar to the spectrum obtained from pure nickel made passive in the same environment.

On the other hand, Okuyama[2] examined the composition of the passive film on the Cu–Ni alloy which was formed in a boric acid–sodium borate buffer solution (pH=8.39) by means of coulometry; he found that NiO, Ni_3O_4, and Cu_2O were formed in the film on the alloy whose nickel content was over 50%Ni.

These discrepancies among the data obtained by different investigators seem to be caused not only by the difference in the experimental conditions (the composition, the pH, and the temperature of the electrolyte), but also by the differing accuracies of the methods of surface analysis.

Therefore, this study makes it clear that (a) passive films formed in 0.5 M $HClO_4$ contain nickel and copper in the same ratio as the alloy, (b) and the chemical species of the film are composed of NiO and copper oxide (Cu_2O and/or CuO).

If one assumes NiO formation during the passivation of nickel at P_1, the reaction is as follows:[7]

$$Ni + H_2O = NiO + 2H^+ + 2e^- \quad (1)$$

$$E_{NiO} = -0.131\ V\ (vs.\ SCE, 25°C)$$

Moreover, the formation of Cu_2O or CuO during the passivation of copper at P_1 is shown by the following reactions:[7]

$$2Cu + H_2O = Cu_2O + 2H^+ + 2e^- \quad (2)$$

$$E_{Cu_2O} = 0.230\ V\ (vs.\ SCE, 25°C)$$

$$Cu + H_2O = CuO + 2H^+ + 2e^- \quad (3)$$

$$E_{CuO} = 0.329\ V\ (vs.\ SCE, 25°C)$$

As is shown in Fig. 2, the experimental datum on the pure nickel was −0.085 V, while those on the alloys varied linearly from 0.180 V at 95%Ni to 0.310 V at 47%Ni. The experimental data were somewhat different from the thermodynamical data shown in Eqs. (1), (2), and (3). However, some differences are usually observed between the results of thermodynamical calculation and the experimental data, depending on the variation in the activities of the species on the electrode and the measuring conditions, whether at equilibrium or at non-equilibrium. Therefore, it can be assumed that NiO and Cu_2O and/or CuO were formed in the passive film of the alloy, and that their Flade potential was governed by the mixed potential by the upper reactions. This estimation corresponds also to the findings obtained by AES and XPS. However, more precise data for the potentials at P_1 for several temperatures and pH would be needed for a more fruitful correlation.

Uhlig explained a critical composition for passivity in Cu–Ni alloys at about 30%Ni with a critical electronic configuration which is based on the "rigid band model."[8] However, recent experimental results on the electronic structure of the Cu–Ni alloy system support a "coherent potential approximation model,"[9,10] not such a "rigid band model"; that is, Cu-rich alloys in the Cu–Ni alloy system should also have holes in the 3d band. Accordingly, the reason why the Cu-rich alloy in Cu–Ni does not form passive films in acid must not include the idea of the "filled d-band."

The authors are grateful to professor Toshiro Yamashina of the Faculty of Engineering, Hokkaido University, for giving them the alloy samples; they also wish to thank Professor Shiichiro Teranishi, Assistant Professor Toshinobu Imanaka, and Dr. Yasuyuki Okamoto of the Faculty of Engineering Science, Osaka University, for their kindness and advice in using the photoelectron spectrometer.

Kinetics and Mechanisms of Hydrothermal Reaction of Granulated Blast Furnace Slag

Renichi KONDO, Salah A. ABO-EL-ENEIN,* and Masaki DAIMON

Inorganic Materials Department, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received August 17, 1973)

Kinetics and mechanisms of hydrothermal reactions of the systems slag-lime-water (I) and slag-quartz-lime-water (II) have been studied. In the initial stage of reaction in system (I), nearly amorphous calcium silicate hydrate with low lime content was formed and continued to grow in strength. Formation of hydrogarnet ($3CaO \cdot Al_2O_3 \cdot SiO_2 \cdot 4H_2O$) accompanied by the crystallization of calcium silicate hydrate caused a reduction in strength. In the reaction in system (II), a product with high lime content was formed which was then changed into a low lime product after complete consumption of free lime. Slag was highly reactive but inhibited reaction of quartz, especially during the initial stage of the hydrothermal solidification process. The rate of hydrothermal reaction as well as the characteristics of the products change considerably with temperature.

The reactivity of granulated blast furnace slag subjected to hydrothermal reaction for a long time was compared with that of quartz, silica glass[1] and other silicates.[2] However, the composition and physical state of the compounds obtained by the hydration of slag has not been clarified. Blast furnace slag, especially granulated one, has been used as a raw material for cement.[3] Advantages attained by the use of slags are: (1) omission of the process of combining CaO and SiO_2, and (2) economization of limestone and fuel. The hydraulic properties of slag are dependent on composition included in the quaturnary system SiO_2–Al_2O_3–CaO–MgO, the presence of constituents other than those main components and the amount of crystalline material in the quenched slag.

Kondo and Ohsawa[4] reported a method to determine the amount of granulated blast furnace slag as well as the rate of hydration of slag in cements. However, the kinetics and mechanisms of the hydrothermal reaction have not yet been studied.

Kondo and Daimon[5] analyzed the hydration of tricalcium silicate as an example of solid reactions having induction and acceleration periods. The first product, which may have a structure similar to the reactant, forms on the surfaces of reactant grains. The nuclei of the stable product are produced in the first product layer and act as reaction centers; the main reaction to form a stable product occurs rapidly in the acceleration period. In the hydration of calcium silicates, hydrates produced in this stage are poorly crystalline and metastable, turning gradually to more stable form.

In the present paper, we give the kinetics and mechanisms of two hydrothermal reactions: (I) slag-lime reaction; and (II) slag-quartz-lime reaction. Slag and quartz having narrow particle size distribution were used in order to obtain better results.

Experimental

Starting Materials. Granulated blast furnace slag consisting of calcium oxide, 44.0%; silica, 34.3%; alumina, 15.5%; and magnesia, 3.4% was used. These contents are approximately the average of compositions of slags produced in Japan. Slag was first ground and particles of radii 5—10 μ were then isolated by methanol elutriation. Quartz with particle radii 3.5—5 μ and very fine powder of highly purified, special grade calcium hydroxide were used.

Autoclaving. Two mixtures were prepared. (1) Slag (80 wt.%) and calcium hydroxide (20 wt.%) were mixed for 1 hr with use of ethanol to attain homogeneity. Ethanol was evaporated and 20 wt.% of water was then added to the dry mixture which was stirred for 3 min. From the paste produced, cylindrical specimens of 3.14 cm^2 in cross-sectional area and 1 cm in height were moulded at a pressure of 50 kg/cm^2 (157 kg/3.14 cm^2). (2) Slag (50 wt.%), quartz (30 wt.%) and calcium hydroxide (20 wt.%) were mixed and moulded according to the same procedure. The moulds were placed in containers at 100% humidity for 4 hr in order to attain initial setting, then D-dried for 24 hr and kept in vacuum desiccators.

The specimens were autoclaved; temperature was raised at a rate of 2 °C/min and then kept at 180.5±0.8 or 213.1±0.4 °C, each for 0.5, 2, 6, 12 and 24 hr. Steam was then released for cooling. Specimens were transferred to a desiccator, and then dried in CO_2 free nitrogen atmosphere at 105 °C for 24 hr in order to remove free water (saturated steam pressure, 10.0 and 20.0 atm at 180.5 and 213.1 °C, respectively).

Examination of Specimens. After being dried, the specimens were tested for compressive strength. Free CaO, uncombined slag, free silica and combined (non-evaporable) water contents were determined with crushed samples. A mineralogical examination was also made by means of X-ray diffraction, the hydrates formed being identified.

The free CaO content was determined as follows. The sample (0.5 g) was dispersed in a glycerol/ethanol mixture (1 : 5 v/v, 40 cm^3), together with a small amount of barium chloride (0.5 g) as a catalyst, and phenolphthalein as an indicator. This mixture was kept boiling while being titrated with a standard ammonium acetate solution. Boiling and titration were continued until pink coloring no longer appeared.

The amount of free silica was estimated from the amount of insoluble residue. The sample (0.5 g) was treated first with 2 M-hydrochloric acid (30 cm^3) at 60 °C. The residue was treated with 5% sodium carbonate solution (50 cm^3) at 100 °C for 15 min, ignited and weighed.

Combined water was regarded as being equal to the ignition loss with correction as regards the free lime, taking into consideration the fact that each one mole of free CaO is accompanied by one mole of non-evaporable water.

* Faculty of Science, Ain Shams University, Cairo, Egypt.

The uncombined (free) slag was determined by means of X-ray diffraction with calcium fluoride as an internal standard. Conversion of amorphous granulated slag into the crystalline form was carried out by heating at 900 °C for 5 min. The calibration curve was obtained with binary mixtures of crystalline slag and quartz with various weight ratios. The diffraction lines were selected to be those at 2.85 A (31.4° 2θ) and 3.153 A (18.3° 2θ) for crystalline slag (melilite) and CaF_2, respectively. Each sample was ground, heated at 900 °C on a platinum sheet for 5 min and then mixed with CaF_2 (10 wt.%) with the use of ethanol to ensure the homogeneous mixing. After being dried, diffraction pattern was obtained between 35° and 25° in 2θ, using Cu Kα. The percentage of uncombined slag was regarded as the average of the closest four determinations.

For the determination of free slag, the method by Kondo and Ohsawa[4] is applicable only to reactions at lower temperature provided that the hydration products are nearly amorphous. The method cannot be applied under hydrothermal conditions due to the fact that the crystalline hydration products remain insoluble.

Results and Discussion

(1) Slag–Lime–Water System. The free CaO, combined water and uncombined slag contents together with the compressive strength of the specimens autoclaved at 181 and 213 °C are shown in Figs. 1 and 2, respectively. These values were calculated on the basis of the ignited weights of specimens. The molar compositions of the formed hydrates as well as some other data are given in Tables 1 and 2. The reaction ratio of CaO was defined as the ratio of combined CaO to the total CaO concerned with added $Ca(OH)_2$. The thickness of the reacted layer on surfaces as a function of the reaction ratio (reacted slag/total slag) is shown in Fig. 3. The experimental values of α' were used to calculate q, the depth of the reacted layer. It was assumed that $\alpha'=1-(r_0-q)^3/r_0^3$, where r_0 is the radius of a particle before the reaction takes place. If we assume that the proportion of the particles having a radius r is constant, and the minimum and maximum sizes are a and b respectively, the relationship between

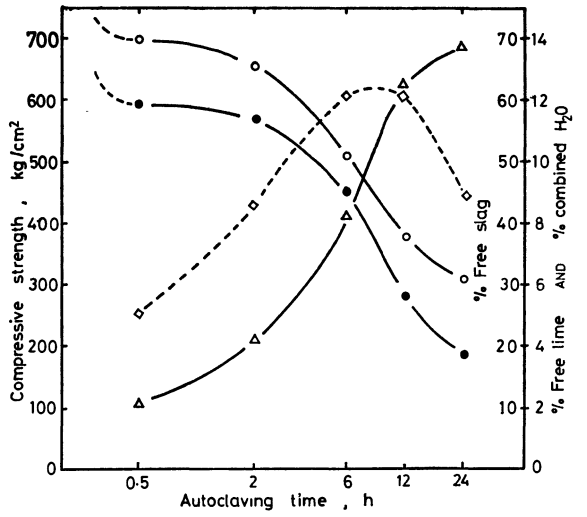

Fig. 1. Slag–lime–water system at 181 °C.

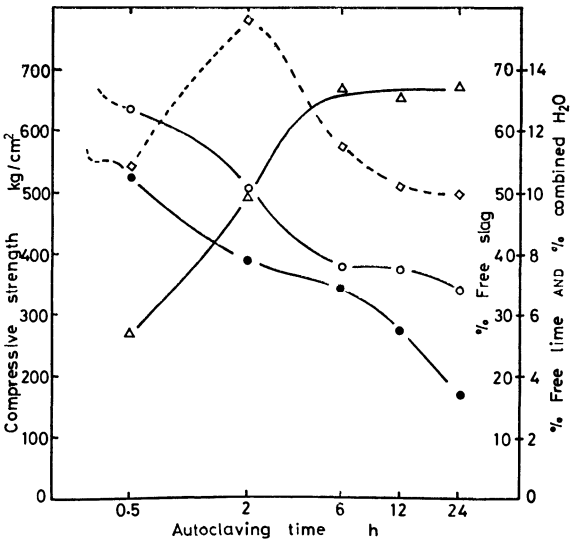

Fig. 2. Slag–lime–water system at 213 °C.
◇: strength, ○: free lime, ●: free slag, △: combined H_2O.

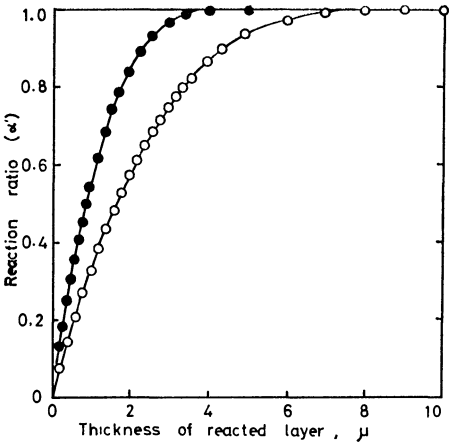

Fig. 3. Relation between reaction ratio and thickness of the reacted layer.
○: particle size 5—10 μ radius
●: particle size 3.5—5 μ radius

α' and q can be calculated by

$$1-\alpha'=\frac{\int_a^b(r-q)^3dr}{\int_a^b r^3dr}=\frac{1}{(b^4-a^4)}[(b-q)^4-(a-q)^4]$$

for $q<a$, and

$$1-\alpha'=\frac{\int_a^b(r-q)^3dr}{\int_a^b r^3dr}=\frac{1}{(b^4-a^4)}(b-q)^4$$

for $q\geq a$. For slag with particle radii 5—10 μ, the values of a and b are 5 and 10 μ, respectively. The depth of the reacted layer on the particles for all the specimens can be estimated from Fig. 3.

Reaction at 181 °C (10 atm): Nearly amorphous calcium silicate hydrates were formed as the initial product. X-ray diffraction study showed that during the first 6 hr the only phase identified was calcium silicate hydrates. Subsequent crystallization of calcium hydrosilicate led to the continuous growth of strength.

Hydrogarnet ($3CaO \cdot Al_2O_3 \cdot SiO_2 \cdot 4H_2O$) was also formed after 6 hr. Accumulation of hydrogarnet besides the crystallization of calcium silicate hydrate might reduce the strength.

Reaction at 213 °C (20 atm): By autoclaving for 30 min, nearly crystalline calcium silicate hydrates were formed as confirmed by X-ray diffraction. After 2 hr (Fig. 4) cubic crystals of hydrogarnet were formed, calcium silicate hydrate being crystallized in the form of interlocking fibres and rods. Continuous decrease in strength took place during the first 2 hr of autoclaving. This is also attributed to the accumulation of hydrogarnet and crystallization of calcium silicate hydrate.

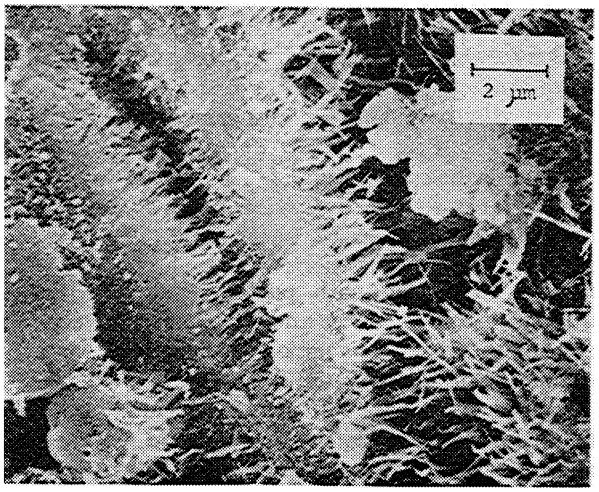

Fig. 4. The microstructure of slag-lime paste at 20 atm, 2 h autoclaving, interlocking fibres and rods of calcium silicate hydrates, beside cubic hydrogarnet.

Reaction Mechanism: It is suggested that a rapid hydrothermal change takes place until 20—25% of slag is hydrated. This stage corresponds to stage I in the induction period.[5]

A very slow hydrothermal reaction follows as a result of the formation of an almost impervious coating on the slag particles during the first stage; a dormant period which corresponds to stage II in the induction period.[5] The dormant period starts when about 25% of reactant is hydrated and lasts until about 30% is hydrated. The beginning and duration of the dormant period change with autoclaving temperature. At 181 °C, the percentage of ignited hydration product formed is 26.7% in 0.5 hr and 30.2% in 2 hr, so that the initial fast reaction is almost completed after 0.5 hr and the dormant period after about 2 hr. At 213 °C, the percentage of ignited hydration product is 34.9% in 0.5 hr, which is after the dormant period.

In the third stage crystallization of the initial products occurs. Diffusion through the crystallized product becomes free and a very fast interaction of water with the unhydrated part starts, lasting until about 80% of slag is hydrated. This leads to the formation of an "inner" product.

Hydration is retarded by accumulation of products. The diffusion through the pores of products becomes the rate determining factor. The mechanism is in line with that obtained by Brunauer and his co-workers[7] on low porosity cement pastes at 5—50 °C.

(II) Slag–Quartz–Lime–Water System. The experimental results are shown in Figs. 5 and 6 and Tables 3 and 4. Thickness of the reacted layer on the surfaces of the slag and quartz particles can be estimated by means of the relation given in Fig. 4.

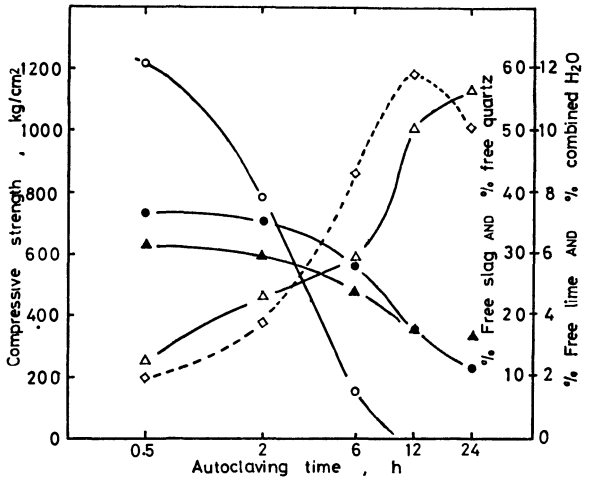

Fig. 5. Slag–quartz–lime–water system at 181 °C.
◇: strength, ○: free lime, ●: free slag,
△: combined H_2O, ▲: free quartz.

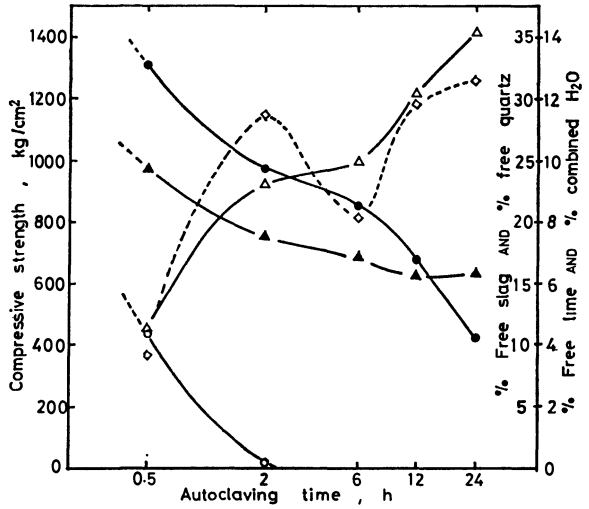

Fig. 6. Slag–quartz–lime–water system at 213 °C.
◇: strength, ○: free lime, ●: free slag,
△: combined H_2O, ▲: free quartz.

It was found that determination of uncombined slag by means of X-ray becomes difficult since the reaction products can also be converted into melilite when heated at 900 °C. The reaction ratio of slag obtained in system (I) are used.

Interaction of Slag and Quartz: The reaction ratios of both slag and quartz (Tables 3 and 4) indicate that the hydrothermal reactivity of granulated slag is greater than that of quartz, particularly in the initial stage of the reaction. The high reactivity of slag inhibits the reaction of quartz in the early stage of hydrothermal solidification. The reactivity of quartz in lime-quartz hydrothermal reaction given by Kondo[1] was higher than that we obtained. Evidence for the high reactivity of slag was obtained by comparison of the

compressive strengths obtained in the two systems in the present study. The strength attained in the early stage was greater in system (I) than in system (II) (Figs. 1, 2, 5, and 6). However, in the latter system, growth of strength reaching a maximum of about 1200 kg/cm^2 was obtained due to the formation of much calcium silicate hydrate and lesser hydrogarnet.

Reaction at 181 °C: Nearly amorphous high lime calcium silicate hydrates were formed during the first 2 hr of hydration (Table 3). X-ray diffraction revealed only the formation of ill-crystallized calcium silicate hydrate. The accumulation and later crystallization of the high lime product account for the continuous development of strength during the first 12 hr. Scanning electron microscope observation (Fig. 7) obtained after autoclaving for 6 hr indicates the unhydrated part of the grain was directly attached to an "inner product" 1.5 μ in depth, the "outer product" with loose structure and about 2 μ in thickness being observed outside the original grains as acicular and interlocking fibres. After consumption of all free CaO during a period of 12 hr, the maximum strength of the specimens was attained. The high lime product then started to transform into a low lime product in the form of fibres and rod like crystals. Crystallization results in a reduction of strength because of its low surface area.

Reaction at 213 °C: A high lime product was formed and crystallized during the first 2 hr of autoclaving. At that time all the free CaO was consumed, high lime product changed into low lime product, and a part of the previously bound CaO was released and then bound to a new part of the unhydrated reactants. This resulted in an increases of the total contents of binding centers in the specimens. The creation of new binding centers caused an increase of strength after 6 hr autoclaving.

Complex Formation between the Uranyl Ion and Citric Acid

Emiko OHYOSHI,† Junko ODA,* and Akira OHYOSHI*

Kurokami Radioisotope Laboratory, Kumamoto University, Kumamoto 860

**Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860*

(Received December 3, 1973)

A method to facilitate the analysis of the complex formation by a polybasic acid has been applied to the study of uranyl citrate complexes. The amount of the uranyl ion in equilibrium with the complexing agent was determined by the cation-exchange method. In this experiment, the uranyl-ion concentration was kept within a 10^{-5}—10^{-6} M range in order to eliminate polymeric species. By using a series of solutions prepared so as to keep $[H_3Cit^-]$ nearly constant and to vary $[H_2Cit^{2-}]$ and $[HCit^{3-}]$ in the 2.2—2.9 pH range, it has been found that three kinds of complexes, $UO_2H_3Cit^+$, UO_2H_2Cit, and UO_2HCit^-, were present in the solution. Approximate values of their formation constants were obtained.

In an investigation[1] of the photochemical reduction of U(VI) to U(IV) observed in citrate solutions, knowledge of the nature of uranyl citrate complexes and of their formation constants was required for the interpretation of the reduction mechanism. On the basis of potentiometric measurements, Rajan and Martell[2] reported that, in the 2—4 pH range, the uranyl ion combined through the dissociation of the three hydrogens from the carboxyl groups of citric acid, and also that the dimerization of this complex occurred with an increase in the uranyl-ion concentration. In this pH range, more protonated species, H_3Cit^- and H_2Cit^{2-}, are present in large proportions, and they possibly form complexes with the uranyl ion.

Matsushima[3] has studied the citrate complexes of some divalent metals by an extension of Schubert's method to a lower pH region. He found the complex of the MH_2Cit type as well as that of the $MHCit^-$ type and determined the stability constants of both. In this method, however, it is necessary to perform similar experiments at several different pH's, each of which is kept constant for the analysis of the different types of complexes.

In the present work, we have studied the complex formation between uranyl and various protonated citrate ions in a region of low concentrations of the uranyl ion by using a method devised to facilitate the analysis of the complexes with a polybasic acid.[4] The method used is based on the general principles of dissociation equilibria established in the presence of a weak acid and its salt.

Analysis of Metal (M^{2+}) Complexes Formed with Various Protonated Species. In our earlier papers[4,5] we assumed that only two species, H_3Cit^- and H_2Cit^{2-}, are advantageous for the formation of complexes in a low-pH region. However, as has been shown by the potentiometric study,[2] the complex of the UO_2-$HCit^-$ type cannot be excluded even at pH 2. Therefore, we have derived equations assuming three types of complexes, $M(H_3Cit)_i^{2-i}$, $M(H_2Cit)_j^{2-2j}$, and $M(HCit)_k^{2-3k}$, equilibrated in solution. When we use the cation-exchange method and can assume that the adsorption of the MH_3Cit^+ complex is negligible compared with that of the M^{2+} ion at a low ionic strength of 0.1 or 0.2,[6] the following equation can be derived:

$$\frac{K_d^\circ}{K_d} = 1 + \sum\beta_i[H_3Cit^-]^i + \sum\beta_j'[H_2Cit^{2-}]^j + \sum\beta_k''[HCit^{3-}]^k \quad (1)$$

where K_d° and K_d denote the distribution coefficients of uranyl species in the absence and in the presence of the complexing agent respectively, and where β_i, β_j', and β_k'' express the formation constants of the $M(H_3Cit)_i^{2-i}$, $M(H_2Cit)_j^{2-2j}$, and $M(HCit)_k^{2-3k}$ complexes respectively. When experiments were carried out by using a series of solutions in which the amount of the H_3Cit^- species remains nearly constant, while those of the H_2Cit^{2-} and $HCit^{3-}$ species vary, Eq. (1) can be given as a function of $[H_2Cit^{2-}]$ or $[HCit^{3-}]$:

$$\frac{K_d^\circ}{K_d} - 1 = \text{const.} + (\beta_1' + \beta_1''k_3/[H^+])[H_2Cit^{2-}] + (\beta_2' + \beta_2''k_3^2/[H^+]^2)[H_2Cit^{2-}]^2 + \cdots \quad (2)$$

or;

$$\frac{K_d^\circ}{K_d} - 1 = \text{const.} + (\beta_1'' + \beta_1'[H^+]/k_3)[HCit^{3-}] + (\beta_2'' + \beta_2'[H^+]^2/k_3^2)[HCit^{3-}]^2 + \cdots \quad (3)$$

where $k_3 = [H^+][HCit^{3-}]/[H_2Cit^{2-}]$. When we assume that all the complexes have a 1:1 molar ratio, Eqs. (2) and (3) are simplified as follows:

$$\frac{K_d^\circ}{K_d} - 1 = \text{const.} + (\beta_1' + \beta_1''k_3/[H^+])[H_2Cit^{2-}] \quad (4)$$

$$\frac{K_d^\circ}{K_d} - 1 = \text{const.} + (\beta_1'' + \beta_1'[H^+]/k_3)[HCit^{3-}] \quad (5)$$

From Eqs. (4) and (5), it can be seen that when we plot $K_d^\circ/K_d - 1$ *vs.* $[H_2Cit^{2-}]$ (A) or *vs.* $[HCit^{3-}]$ (B), two different types of curves should be obtained. The slope of the (A) plot increases with a decrease in $[H^+]$, while that of the (B) plot decreases with a decrease in $[H^+]$. The intercepts of both plots should be the same value. From this value and the $[H_3Cit^-]$ used, β_1 can be evaluated. Approximate values of β_1' and β_1'' can also be estimated from the slope of (A) at $[H_2Cit^{2-}]=0$ and from the slope of (B) at the relatively high value of $[HCit^{3-}]$, sufficient to show a straight line, respectively. In cases where successive complex formation takes place, we can obtain a similar curve, (A) or (B), by plotting the $(K_d^\circ/K_d - 1 - \text{const.})/[H_2Cit^{2-}]$ term *vs.* $[H_2Cit^{2-}]$ or the $(K_d^\circ/K_d - 1 - \text{const.})/$

† Present address: Yatsushiro Technical Colledge, Yatsushiro-shi, Kumamoto 866

[$HCit^{3-}$] term *vs.* [$HCit^{2-}$]; β_2' and β_2'' can also be estimated in a similar manner. A separate experiment will be necessary to obtain β_1 and β_2. The solutions used for this experiment can be prepare by varying the total citrate concentration at a constant pH, since we have already established the complexing ability of both ligands, H_2Cit^{2-} and $HCit^{3-}$.

Experimental

Materials. The stock solution of UO_2^{2+} was prepared by dissolving $UO_2(NO_3)_2 \cdot 6H_2O$ in 0.005 M HCl to give the concentration of 2.0×10^{-4} M, which was determined by EDTA titration. Citric acid (H_4Cit) in varying amounts was added to 0.2 M NaH_3Cit. A series of such solutions was diluted twice with distilled water and the uranyl stock solution. In these solutions, H_2Cit^{2-} and $HCit^{3-}$ decrease with an increase in the H_4Cit, while H_3Cit^- is maintained nearly constant (0.1 M). The ionic strength, governed by the amount of the salt, NaH_3Cit, was also maintained at 0.1. The compositions of the solutions used are given in Table 1. For the calculation of the respective ion concentrations, the dissociation constants of citric acid reported by Okac and Kolarik,[7] which were measured at $\mu=0.1$ (0.1 M KCl) and 8—20 °C, were used. The pH values calculated using this k_1 value and the amounts of acid H_4Cit and salt NaH_3Cit dissolved were in fair agreement with the measured pH values. Various concentrations of citrate at a constant pH of 3.91 were prepared by dissolving a mixture of H_4Cit and Na_3HCit (1.5: 1) in 0.1 M $NaClO_4$ to produce concentrations of $HCit^{3-}$, 10^{-5}—10^{-6} M. All the chemicals used were of a G. R. grade. The pH measurements were made with a Beckman Model SS-2 pH meter. A cation exchanger, Dowex 50 W-X8 (100—200 mesh), in sodium form was used.

Table 1. The composition of citrate solutions prepared to maintain [H_3Cit^-] nearly constant (0.1M)

0.118	0.99	3.06	5.02	2.88

Procedure. The cation-exchange experiments were carried out in a manner similar to that described previously.[4] The amount of U(VI) was determined as the uranyl-Arsenazo-(III) complex by spectrophotometry using a Shimadzu UV-200 spectrophotometer. This complex was stable even at pH 1, and its characteristic color (absorbance at 665 nm) could be used to determine the U(VI) in the presence of citric acid. Since the slope of the calibration curve slightly varied with the pH value, it was necessary to measure the absorbance of aliquots of slutions before the addition of the cation exchanger and after equilibrium had been reached at a constant pH. All the experiments were carried out in the dark to avoid any photochemical reduction of the uranyl ion.[1] The distribution coefficient, K_d, was calculated as follows:

$$K_d = \frac{\text{mmol of U(VI) in the resin/mass of dry resin (g)}}{\text{mmol of U(VI) in the soln./vol. of soln. (ml)}}$$

Results and Discussion

The hydrolyses of the uranyl ion in the pH range studied (pH 2—4) were checked by measuring $K_d°$ in 0.1 M $NaClO_4$, while adjusting pH's from 2.07 to 4.35. To maintain the pH at 4.35, the acetate buffer in varying concentrations ($\sim 10^{-3}$ M) was used. $K_d°$ was obtained by plotting $1/K_d$ *vs.* [acetate] and by extrapolating $1/K_d$ to a zero concentration of acetate. $K_d°$ values so obtained were practically constant ($2.3 \pm 0.1 \times 10^3$), indicating that hydrolysis does not occur in this pH range.

To check whether polymeric species were being formed or not, the K_d values were determined as a function of [U(VI)] at constant citrate concentrations. The results showed that, at pH 3.91, K_d gradually decreased at concentrations above 1×10^{-5} M, though it remained practically constant at lower pH's (2.2—2.9), indicating that polymeric species tend to be formed as the pH increases. The uranyl concentrations used in this experiment were in the 4×10^{-6}—6×10^{-6} M range at pH 3.91 and in the 6×10^{-6}—1×10^{-5} M range at pH's 2.2—2.9. The constancy of K_d was also obtained with a variation in the ratio of the volume of the solution to the mass of resin from 50—200 ml/g.

Using a series of solutions in a region of low pH's (2.2—2.9) where [H_3Cit^-] is kept approximately constant ([H_3Cit^-]$\simeq$0.1), and where [H_2Cit^{2-}] and [$HCit^{3-}$] both vary, uranyl citrate complexes have been studied by the cation-exchange method.

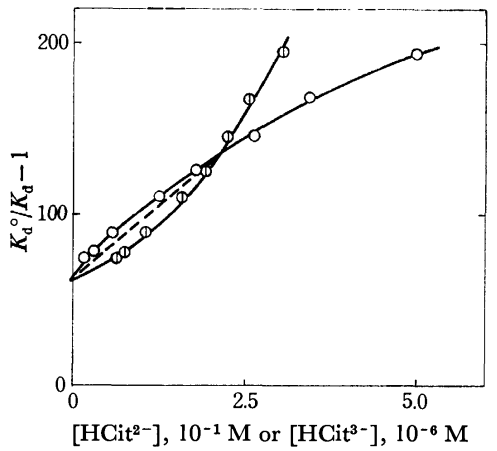

Fig. 1. Plots of $K_d°/K_d - 1$ *vs.* [H_2Cit^{2-}] and [$HCit^{3-}$] at [H_3Cit^-]=0.1 M and various pH values.

As is shown in Fig. 1, where we tried to plot $K_d°/K_d - 1$ as a function of [H_2Cit^{2-}] (Plot A) or [$HCit^{3-}$] (Plot B), the slope of Plot A increases with a decrease in [H^+] while that of Plot B decreases with a decrease in [H^+], and both plots have the same intercept. To examine the type of complex predominantly formed, a separate experiment was carried out using solutions in varying total citrate concentrations in the same range and at a constant pH of 2.88. From the fact that a linear relationship was obtained between $K_d°/K_d - 1$

and $[Citrate]_{total}$, it can be concluded that 1:1 complexes are the only predominantly-formed species.[3] Hence, the former type of curve (Plot A) corresponds to Eq. (4), while the latter (Plot B) corresponds to Eq. (5). From this it is evident that the $UO_2H_3Cit^+$, UO_2H_2Cit, and UO_2HCit^- complexes are all present in this pH range (2.2—2.9). At pH 2.28, where a major part of the complexes are assumed to be $UO_2H_3Cit^+$ from the curves in Fig. 1, the extent of adsorption of this species on the cation exchanger was studied at different ionic strengths of 0.1 and 0.2.[6] The results showed that the adsorption of $UO_2H_3Cit^+$ on the cation exchanger was negligible compared with that of UO_2^{2+} at these low ionic strengths. The formation constant of $UO_2H_3Cit^+$, β, can readily be obtained from the intercept of the two curves in Fig. 1, which equals 0.1β. The approximate values of β' and β'', the formation constants of UO_2H_2Cit and UO_2HCit^-, can be obtained, respectively, from the slope of Plot (A) at $[H_2Cit^{2-}]=0$ and from that of Plot (B) at relatively large values of $[HCit^{3-}]$, where Plot (B) approaches a straight line. The values of β, β', and β'' thus obtained are listed in Table 2.

At higher pHs, where almost all the uranyl complexes can be assumed to be of the UO_2HCit^- type we can estimate β'' with considerable accuracy. Figure 2 shows a plot of (K_d°/K_d-1) *versus* $[HCit^{3-}]$ at a constant pH of 3.91. The value of β'' calculated from the slope is also listed in Table 2. From the fact that the two values of β'' obtained by the different methods are in fair agreement, the method used in this study can be said to be applicable to the analysis of complexes formed with various protonated ligands present in a solution. The reliability of the β' thus obtained can be checked by the slope of the broken line in Fig. 1. Judging from Eqs. (4) and (5), when we plot the relations (A and B) taking a scale of $[H_2Cit^{2-}]$ equal to $10^3[HCit^{3-}]$, the two curves, A and B, should cross at $[H^+]=10^3k_3$, where $[H_2Cit^{2-}]=10^3[HCit^{3-}]$, and the slope of the broken line can be said to correspond to $\beta'+10^{-3}\beta''$ or $\beta''+10^3\beta'$ on the scale of $[H_2Cit^{2-}]$ or of $[Cit^{3-}]$ respectively. From these values and the β'' value obtained at pH 3.91, a more accurate value of β' can be calculated; it is also presented in Table 2. The two values of β' in Table 2 are in fair agreement.

Table 2. Formation constants of UO_2–citrate complexes ($\mu=0.1$, 25 °C)

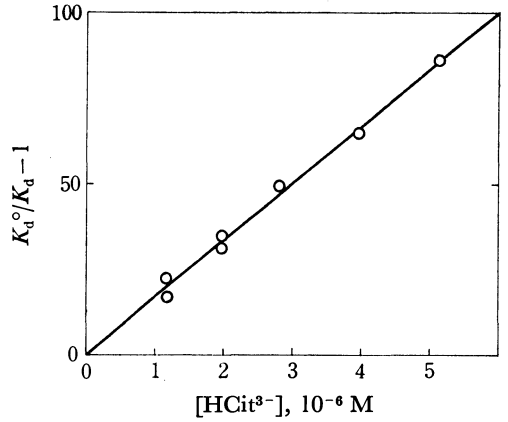

Fig. 2. A plot of K_d°/K_d-1 *vs.* $[HCit^{3-}]$ at pH 3.91.

For the formation constant of UO_2HCit^-, various values[2,8,9] have been reported. As is shown in Table 2, the logarithmic value of the formation constant contained in this study is in fair agreement with that determined potentiometrically by Rajan and Martell.[2] There are no published data for the formation constants of $UO_2H_3Cit^+$ and UO_2H_2Cit because three different complexes, $UO_2H_3Cit^+$, UO_2H_2Cit, and UO_2HCit^-, coexisting at low pH's could not be analyzed.

In conclusion, by controlling the concentration of H_3Cit^- in the solution, various species of uranyl citrate could easily be analyzed, and each formation constant could also be determined. The fraction of the species varying with the pH could be evaluated by considering these constants. The predominant species at pH's lower than 2 was $UO_2H_3Cit^+$. There was a mixture of $UO_2H_3Cit^+$, UO_2H_2Cit, and UO_2HCit^- in the pH range of 2—3, and at pH's higher than 3 almost all of the species were UO_2HCit^-.

The authors wish to thank the Ministry of Education for the financial support (No. 847009) granted to this research.

Studies of Ruthenium Complexes. VIII.[1] Kinetic Studies of the Thermal Substitution Reaction of Hexaammine and *cis*-Dihalogenotetraammineruthenium(III) Complexes in the Solid State

Akira OHYOSHI, Shunichi HIRAKI, Tomio ODATE, Susumu KOHATA, and Junko ODA

Department of Industrial Chemistry, Faculty of Engineering, Kumamoto University, Kumamoto 860

(Received March 30, 1974)

The Kinetics of the thermal substitution reaction of hexaammineruthenium(III) halides and *cis*-dihalogenotetraammineruthenium(III) halides have been studied in the solid state. The reaction rates and kinetic parameters were determined for these two reactions; $[Ru(NH_3)_6]X_3 \rightarrow [RuX(NH_3)_5]X_2 + NH_3$, (X=Br, I) and *cis*-$[RuX_2(NH_3)_4]X \rightarrow [RuX_3(NH_3)_3] + NH_3$, (X=Cl, Br). The values of the rate constant, the activation energy, and the activation entropy were 2.10×10^{-5} s^{-1} (at 161 °C), 23.3 kcal mol^{-1}, and −29.3 e.u. for the hexaammine bromide, and 2.92×10^{-5} s^{-1} (at 162 °C), 31.3 kcal mol^{-1}, and −10.1 e.u. for the *cis*-dibromotetraammine bromide. The S_N2 mechanism is more probable for the former reaction, while the S_N1 mechanism is more probable for the latter reaction.

It has previously been reported that the thermal-decomposition reaction of a chromium(III) complex having volatile ligands such as ammonia, water, and ethylenediammine is initiated by the replacement of a ligand by an outersphere anion.[2] On the other hand, the same reaction of a cobalt(III) ammine complex is initiated by an electron transfer from the ligand or an outersphere anion to the central cobalt(III) ion.[3] In our previous paper,[4] it was shown that the thermal reactions of halogenopentaammine and *cis*-dihalogenotetraammineruthenium(III) were initiated by the repalcement of coordinated ammonia by the outersphere halide ion in the cases of chloride and bromide, while the reaction was initiated by the ammonia release, without the substitution reaction, for iodoammine iodide compounds. Trehoux and his co-workers[5] estimated the product, $[RuCl(NH_3)_5]Cl_2$, in the course of the thermal decomposition of $[Ru(NH_3)_6]Cl_3$; however, there is no information on any kinetic studies of the reactions.

In the present paper, kinetic studies of the thermal substitution reactions of $[Ru(NH_3)_6]X_3$ and *cis*-$[RuX_2(NH_3)_4]X$ will be demonstrated and the reaction mechanisms will be discussed in comparison with those of analogous chromium(III) ammine complexes.

Experimental

Preparation of Complexes. The complexes, $[Ru(NH_3)_6]X_3$, (X=Br, I) and $[RuX_2(NH_3)_4]X$, (X=Cl, Br, I), were prepared by the methods described in the literature.[6,7] The complexes were confirmed by elemental analyses and by the visible and UV spectra. Found: H, 4.26; N, 19.25%. Calcd for $[Ru(NH_3)_6]Br_3$: H, 4.05; N, 18.92%. Found: H, 3.27; N, 14.54%. Calcd for $[Ru(NH_3)_6]I_3$: H, 3.08; N, 14.39%. Found: H, 4.67; N, 18.97%. Calcd for $[RuCl_2(NH_3)_4]Cl \cdot 2/5\ H_2O$: H, 4.53; N, 19.80%. Found: H, 2.91; N, 13.82%. Calcd for $[RuBr_2(NH_3)_4]Br$: H, 2.94; N, 13.70%. Found: H, 2.09; N, 10.23%. Calcd for $[RuI_2(NH_3)_4]I$: H, 2.18; N, 10.18%.

Derivatographic and Isothermal Kinetic Study. The differential thermal analysis (DTA) curves of the complexes were obtained by means of a Shimadzu D. T. 20B micro-differential thermal analyzer, while the thermogravimetric measurement was carried out using a Shimadzu T.G.C.20-type micro-thermobalance. All the experiments were made in a helium atmosphere at the heating rate of 5 °C/min, using 3—5 mg of the sample for each run.

From the results of isothermal thermogravimetry, the kinetic plot—the time conversion curves of the mass-loss were plotted at several constant temperatures. In this experiment, the temperature was rapidly elevated so as to pyrolyze the sample in a platinum cell placed in a furnace, the temperature was kept constant within ±0.5 °C.

A Hitachi 323 recording spectrophotometer was used for the measurement of the absorption spectra of the initial compounds and of the reaction products.

Results and Discussion

DTA and TG Studies. The DTA and TG curves of the hexaammineruthenium(III) trihalides are given in Fig. 1. Those of the *cis*-dihalogenotetraammine

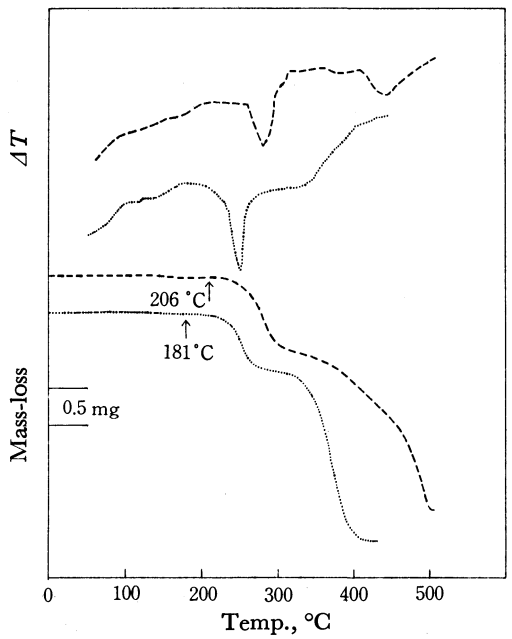

Fig. 1. DTA and TG curves of $[Ru(NH_3)_6]X_3$ in a helium atmosphere.
——: $[Ru(NH_3)_6]Br_3$, ····: $[Ru(NH_3)_6]I_3$

complexes have already been exhibited in a previous paper.[4] The DTA curves are characterized by endothermic peaks — at 280 °C (tribromide) and 251 °C (triiodide); these peaks correspond well to the first mass-loss on the TG curves. Similar results have been obtained for the cases of the *cis*-dihalogenocomplexes. The ranges of the reaction temperature were selected by reference to the results of DTA and TG studies.

Stoichiometry and Kinetic Study. The thermal decomposition products were one mole of ammonia and halogenopentaammine halide per mole of hexaammine halides in the region of the selected temperature. Thus, the thermal decomposition reaction can be expressed by Eq. (1):

$$[Ru(NH_3)_6]X_3 \longrightarrow NH_3 + [RuX(NH_3)_5]X_2, \quad (X=Br,\ I) \quad (1)$$

On the other hand, one mole of *cis*-dihalogenotetraammine halides was decomposed to form one mole of ammonia and trihalogenotriammines. The latter product was identified as the *trans*-isomer from the results of the UV and IR spectra measurements.[8,9]

$$cis\text{-}[RuX_2(NH_3)_4]X \longrightarrow NH_3 + trans\text{-}[RuX_3(NH_3)_3], \quad (X=Cl,\ Br) \quad (2)$$

In the thermal decomposition of *cis*-diiodotetraammine iodide, Reaction 3 has already been reported:[4]

$$cis\text{-}[RuI_2(NH_3)_4]I \longrightarrow 4NH_3 + RuI_3 \quad (3)$$

	4.48 (166)			
	5.16 (168)			
	11.73 (179)	31.3	−10.1	1.55×10^{11}
cis-$[RuI_2(NH_3)_4]I \rightarrow RuI_3 + 4NH_3$		28		
cis-$[CrCl_2(NH_3)_4]Cl \rightarrow [CrCl_3(NH_3)_3] + NH_3$	11.0 (136)	31	−2	

All the reaction products were identified by elemental analysis and/or absorption spectrophotometry. A detailed report on the stereoisomers of trihalogenotriammine will be published elsewhere.

Plots of $\log a/(a-x)$ *vs.* the reaction time for Reactions 1 and 2 are exemplified by those of *cis*-$[RuBr_2(NH_3)_4]Br$ and $[Ru(NH_3)_6]Br_3$ in Figs. 2 and 3, where "a" is the initial mass of the sample and where "$a-x$" is the mass at the reaction time, t. The plot gives a straight line with a good reproducibility for each kinetic measurement. Similar relationships were obtained for the other complexes. As a result, the thermal decomposition reaction can be regarded as a first-order reaction with respect to the reactant. The rate constant obtained from the slope of the straight line is listed in Table 1.

Arrhenius plots for the reactions are given in Fig. 4, while the kinetic parameters are listed in Table 1. The activation energy for the *cis*-diiodotetraammine iodide

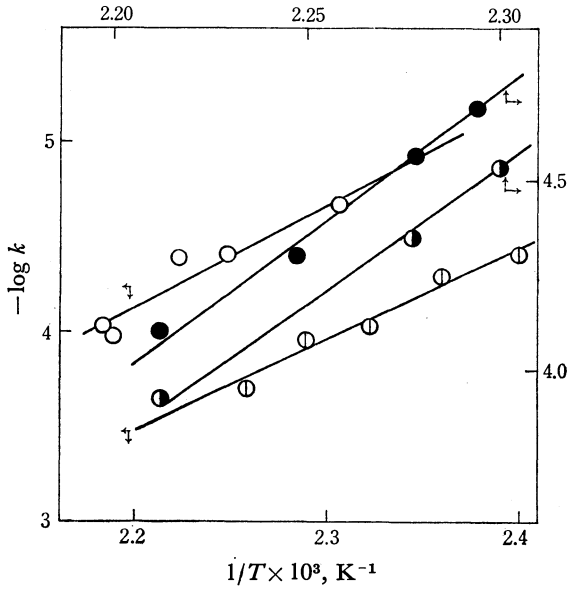

Fig. 4. Arrhenius plots of the substitution reactions for *cis*-$[RuX_2(NH_3)_4]X$, and $[Ru(NH_3)_6]X_3$.

$[Ru(NH_3)_6]X_3$·····○: Br, ⓘ: I

was determined by a graphic analysis of the Freeman-Carroll equation.

It can be seen that the rate constant for the deammonation reaction of hexaammine bromide is smaller than that of the hexaammine iodide. On the other hand, the rate constant for the *cis*-dichlorotetraammine chloride is smaller than that of the dibromotetraammine bromide. The influence of outersphere anion species is to enhance the reaction rate in the following order: Cl<Br<I.

By a comparison of the two series of complexes, it was found that the rate constant for the hexaammine halide is smaller than that of dihalogenotetraammine; however, the relation between the activation energies for the two series of complexes is inconsistent with that of the rate constants. Furthermore, the values of the activation entropy for the former series are smaller than those for the latter series. These facts suggest that there are some differences in the reaction mechanisms for the deammonation and the anation of the outersphere anion. The entering of an outersphere halide anion into the coordination-sphere is more difficult for the dihalogeno-complex halide because of the repulsion by the already-coordinated halide ligands.

Reaction Mechanism of the Deammonation-anation. For the sake of comparison, the kinetic data for the substitution reaction of the ruthenium(III) ammines are listed again, along with those for the chromium(III) ammines, in Table 1. Nagase and Tanaka[2] have demonstrated that the substitution reaction of the $[Cr(NH_3)_6]Cl_3$ complex proceeds according to the S_N2-type mechanism, while the same reaction of the bromide and iodide takes place *via* the S_N1-type mechanism. The appearances of the reactions of ruthenium(III) ammine halides are entirely different from those for the chromium(III) ammine complexes. The rate of the substitution reaction for ruthenium hexaammine iodide is about five times faster than that for the bromide. For the chromium hexaammine halide, the largest rate is found in the case of hexaammine chloride. The reaction of hexaammine iodide is different from those of chloride and bromide, and the rate is the smallest of the three compounds.

For the tetraammine series of complexes, the rate for

a) Unpublished work. b) Ref. 4.

the chromium(III) complex is much larger than that of the ruthenium(III) complex. Considering the small values of the activation energy and the negative values of the activation entropy, the mechanism for the reaction of hexaammineruthenium(III) halides seems to belong to the S_N2 category. On the other hand, for the dihalogeno complex halide the S_N1-like mechanism may be most probable. This is the most important difference in comparison with the chromium(III) complexes.[2)]

The contribution of the π-bonding nature between the metal and the ligand may be considered to account for the mechanisms of the hexaammine and dihalogenotetraammine complexes. Basolo and Pearson[10)] have described how the halide ion is a stronger electron-donor rather than an ammonia molecule through the π bond from ligand to metal. The electron-donating ligand makes it possible to dissociate other ligands at the *cis* or *trans* position and to increase the reaction rate by putting more negative charge on the metal. Thus, the halide ligands in the tetraammine halide are more effective in facilitating a S_N1 mechanism for the deammonation-anation reaction than the ammine ligand in the hexaammine halide.

The initiation temperatures of the deammonation reactions for the three series of ruthenium(III) ammine complexes are listed in Table 2, along with the data of the infrared spectra. If the thermal stability of a complex is reflected in the initiation temperature, the compounds containing the iodide ion are generally less stable. When the number of iodide ions in the innersphere increases, the thermal stability of the complex decreases. One of the reasons for this may be a weakening of the strength of the ruthenium-ammine bond by the increase in the covalency of the ruthenium-halide bond. This consideration is supported by the fact that the wave number of the Ru–N stretching vibration decreases upon the replacement of the ammine ligand by the iodide ion.

The authors wish to thank the Ministry of Education for the financial support granted to this research.

(Received April 30, 1974)

The *fac(N)*- and *mer(N)*-isomers of 4-diethylenetriaminemonoacetatocobalt(III) complexes with ethylenediamine, the oxalate ion, or the acetylacetonate ion as the additional ligand have been obtained by means of reactions between chloro(4-diethylenetriaminemonoacetato)aquocobalt(III) chloride and the bidentates under different conditions. The geometrical configuration of each isomer has been identified by means of the PMR spectra and the electronic absorption spectra. The methine hydrogen in the acetylacetonato complexes has been replaced with bromine, and the resulting complexes have also been characterized.

4-Diethylenetriaminemonoacetate (NH_2–CH_2–CH_2–CH_2–COO^- / $\overset{|}{N}$–CH_2–CH_2–NH_2, abbreviated as *i*-DTMA* in this article) is a tetradentate of the $A\overset{B}{\underset{B}{<}}C$ type. It is capable of coordinating to the cobalt(III) ion in two different modes, as is shown in Fig. 1. As a result, a di(unidentate)-(*i*-DTMA)-Co(III) aggregate and a (*s*-bidentate)-(*i*-DTMA)-Co(III) aggregate may exist in two stereoisomers, and a (*uns*-bidentate)-(*i*-DTMA)-Co(III) aggregate, in four. Schneider and Collman[1] first dealt with the cobalt(III) complexes with the tetradentate. They prepared one isomer in the dinitro, the dichloro, or the carbonato complex, and two isomers in the glycinato complex. They tentatively identified the coordination mode as *fac(N)* in all of their complexes; their assignment is considered to be correct. No cobalt(III) complex having the tetradentate with the *mer(N)*-mode has been isolated so far.

In the course of our previous studies of cobalt(III) complexes containing triethylenetetramine (trien),[2] ethylenediamine-*N*,*N'*-diacetate (EDDA),[3] and 1-diethylenetriaminemonoacetate (DTMA),[4] ** we observed that the coordination mode of the ligands depends largely upon the reaction temperature of the preparations and also, to some extent, upon the kind of ligand occupying the residual coordination sites. Therefore, it was supposed that the *mer(N)*-mode of the tetradentate, which was probably the more unstable and difficult mode, would occur as a result of a reaction at high temperatures. Thus, two isomers were obtained in the ethylenediamine, the oxalato, and the acetylacetonato complexes. This report will deal with their preparation and characterization.

* This abbreviation follows that of Schneider and Collman.[1]

** The following abbreviations are used in this article besides these ligands: en, ethylenediamine; acac, acetylacetonate; Bracac, 3-bromo-2,4-pentanedionate (bromoacetylacetonate); ox, oxalate; gly, glycinate.

Experimental

Materials, Analysis, Apparatus, and Measurements. All the chemicals were of a reagent grade and were used without further purification. The carbon, hydrogen, and nitrogen in the synthesized complexes were analysed by the Analyses Center of the Institute for Chemical Research, Kyoto University. The visible and ultraviolet absorption spectra were measured in aqueous solutions with a Hitachi EPS-3 Recording Spectrophotometer. The PMR spectra were recorded with a Japan Electron Optics JNM-100 Spectrometer (100 MHz), using deuterium oxide as the solvent and *tert*-butyl alcohol as the internal reference. The temperature of the probe was maintained at 22±1 °C.

Preparation. *(1)* fac(N)-*Chloro(4-diethylenetriaminemonoacetato)aquocobalt(III) Chloride Monohydrate*, fac(N)-[*Co(i-DTMA)Cl(H_2O)]Cl·H_2O*: Dinitro(4-diethylenetriaminemonoacetato)cobalt(III) monohydrate, [Co(*i*-DTMA)-(NO_2)$_2$]·H_2O, was prepared by the method of Schneider and Collman.[1] One gram of the dinitro complex was dissolved in 10 ml of hydrochloric acid (6 M) by heating, and the resulting solution was evaporated to dryness with the aid of an air stream blown onto the surface. During the dissolution, nitric oxides were evolved, and finally a greenish blue residue was obtained. (This is probably the dichloro complex.) A small amount (~3 ml) of water was then mixed with the residue, which dissolved at once, forming a violet solution. A bright violet precipitate soon appeared. The precipitate was transferred onto a filter with a methanol (80%)–water mixture and then washed with methanol and ether. Yield, 0.8 g. By treating the filtrates of the above procedure in the same way, an additional product was obtained. The total yield was 0.95 g.

Found: C, 21.80; H, 5.86; N, 12.58%. Calcd for [Co(*i*-DTMA)Cl(H_2O)]Cl·H_2O=$CoC_6H_{18}O_4N_3Cl_2$(326.07): C, 22.10; H, 5.56; N, 12.89%.

(2) mer(N)-*Chloro(4-diethylenetriaminemonoacetato)aquocobalt(III) Perchlorate*, mer(N)-[*Co(i-DTMA)Cl(H_2O)]ClO_4*:

Into 5 ml of 2 M $HClO_4$ 0.5 g of the *fac(N)*-chloroaquo complex (1) was added, after which the mixture was heated on a boiling water bath. The starting complex dissolved at once; dark violet crystals then appeared. After heating for 15 min, the crystals were collected and washed with a small amount of cold water, methanol, and ether. Yield, 0.5 g. By the evapoartion of the filtrate, an additional product was obtained. The total yield was 0.55 g.

Found: C, 19.20; H, 4.53; N, 11.18%. Calcd for [Co(*i*-DTMA) Cl (H_2O)] ClO_4 = $CoC_6H_{16}O_7N_3Cl_2$ (372.05): C, 19.37; H, 4.33; N, 11.29%.

(3) fac (N)-*4-Diethylenetriaminemonoacetato(ethylenediamine)-cobalt(III) Perchlorate*, fac(N)-[*Co*(i-*DTMA*)(*en*)](ClO_4)$_2$: After a solution which contained 0.6 g of the *fac(N)*-chloroaquo complex in 10 ml of water had been heated for 15 min on a boiling-water bath, 0.6 ml of aqueous ethylenediamine (20%) and 0.1 g of active charcoal were added to the solution, in this order. Upon the addition of the charcoal, the color rapidly changed to a brownish orange. The mixture was then heated for 5 min, the charcoal was removed by filtration, and 1 ml of 6 M $HClO_4$ was added; a large amount of deep orange precipitate appeared upon cooling. After the product had been allowed to stand for 1 hr in a refrigerator, the precipitate was separated and recrystallized from 25 ml of warm (~60 °C) water with the addition of a few drops of 6 M $HClO_4$. Yield, 0.6 g.

Found: C, 19.97; H, 4.77; N, 14.67%. Calcd for [Co(*i*-DTMA) (en)] (ClO_4)$_2$ = $CoC_8H_{22}O_{10}N_5Cl_2$ (476.13): C, 20.10; H, 4.64; N, 14.65%.

(4) mer (N)-*4-Diethylenetriaminemonoacetato(ethylenediamine)-cobalt(III) Perchlorate*, mer(N)-[*Co*(i-*DTMA*)(*en*)](ClO_4)$_2$: The filtrate obtained in the preparation of the *fac(N)*-isomer was concentrated to ~2 ml and then cooled; a pale yellowish orange precipitate thus appeared. It was recrystallized from 2 ml of warm water with the addition of a few drops of 6 M $HClO_4$. Yield, 0.1 g.

Found: C, 19.84; H, 4.70; N, 14.45%. Calcd for [Co(*i*-DTMA) (en)] (ClO_4)$_2$ = $CoC_8H_{22}O_{10}N_5Cl_2$ (476.13): C, 20.10; H, 4.64; N, 14.65%.

(5) fac (N)-*Oxalato(4-diethylenetriaminemonoacetato)cobalt-(III)*, fac(N)-[*Co*(i-*DTMA*)(*ox*)]: A mixture of 0.3 g of the *fac(N)*-chloroaquo complex (1) and 0.13 g of oxalic acid dihydrate in 5 ml of water was heated at ~65 °C for 30 min with stirring. Reddish violet crystals came out during the reaction. After the product had been cooled in an ice-water bath for 3 hr, the crystals were collected and recrystallized from 30 ml of hot (~80 °C) water. Yield, 0.2 g.

Found: C, 30.93; H, 4.54; N, 13.81%. Calcd for [Co(*i*-DTMA)(ox)] = $CoC_8H_{14}O_6N_3$ (307.15): C, 31.28; H, 4.59; N, 13.68%.

(6) mer(N)-*Oxalato(4-diethylenetriaminemonoacetato)cobalt-(III) Dihydrate*, mer(N)-[*Co*(i-*DTMA*)(*ox*)]·$2H_2O$: A solution of 0.3 g of the *fac(N)*-chloroaquo complex (1) in 5 ml of water was heated in a boiling-water bath for 15 min. Another solution, which contained 0.13 g of sodium oxalate in 5 ml of water, was also heated to 100 °C. Then the solutions were combined, and the mixture was kept at 100 °C for 10 min; a deep red solution was thus obtained. After the solution had been cooled in an ice-water bath for 1 hr, the red precipitate formed was collected on a filter and then fractionally extracted with 10 ml portions of warm (~60 °C) water four times. In the first extract (red-colored), an orange-red precipitate amounting 0.15 g was deposited by adequate cooling. The precipitate from the second extract contained the red-violet *fac(N)*-isomer to some extent. The deposits in the third and the fourth extracts consisted entirely of the *fac(N)*-isomer. The product from the first extract was recrystallized with 5 ml of warm water. Yield, 0.1 g.

Found: C, 27.88; H, 5.41; N, 12.35%. Calcd for [Co(*i*-DTMA)(ox)]·$2H_2O$ = $CoC_8H_{18}O_8N_3$ (343.18): C, 28.00; H, 5.29; N, 12.24%.

(7) fac (N)-*Acetylacetonato(4-diethylenetriaminemonoacetato)-cobalt(III) Perchlorate*, fac (N)-[*Co*(i-*DTMA*)(*acac*)]ClO_4: A solution of the *fac(N)*-chloroaquo complex (0.5 g) in 10 ml of water was heated in a boiling-water bath for 15 min. Another solution, which contained acetylacetone (0.2 g) and sodium hydroxide (0.08 g) in 10 ml of water, was also heated to 100 °C and was then mixed with the former by stirring. The color of the mixture soon changed from blue to dark red. After the addition of 1 ml of 6 M $HClO_4$, the solution was concentrated to ~5 ml. Upon cooling, red-violet crystals came out. After the product had been placed in a refrigerator overnight, the crystals were collected and then recrystallized from 15 ml of warm water with the addition of a few drops of 6 M $HClO_4$. Yield, 0.4 g.

Found: C, 31.95; H, 5.34; N, 10.37%. Calcd for [Co(*i*-DTMA)(acac)]ClO_4 = $CoC_{11}H_{21}O_8N_3Cl$ (417.69): C, 31.63; H, 5.07; N, 10.06%.

(8) mer (N)-*Acetylacetonato(4-diethylenetriaminemonoacetato)-cobalt(III) Perchlorate*, mer(N)-[*Co*(i-*DTMA*)(*acac*)]ClO_4: The filtrate separated from the crude *fac(N)*-isomer in the above preparation (~4 ml) was concentrated to ~2 ml and then placed in a refrigerator overnight. A red precipitate, which was clearly different from the red-violet product (7), thus appeared. The precipitate was recrystallized from 5 ml of warm water with the addition of a few drops of 6 M $HClO_4$. Yield, 0.1 g.

Found: C, 31.62; H, 5.19; N, 10.16%. Calcd for [Co(*i*-DTMA)(acac)]ClO_4 = $CoC_{11}H_{21}O_8N_3Cl$ (417.69): C, 31.63; H, 5.07; N, 10.06%.

(9) Bromination of the Acetylacetonato Complexes: The *fac(N)*-isomer of the acetylacetonato complex (0.3 g) was dissolved in 50 ml of an ethanol(50%)–water mixture, and then 0.15 g of *N*-bromosuccinimide was stirred in. The mixture was concentrated to 10 ml at ~50 °C with the aid of an air stream blown onto the surface. A brownish red precipitate came out as the evaporation proceeded. After the product had been cooled at 0 °C for 1 hr, the precipitate was collected and recrystallized from 10 ml of warm water with the addition of a few drops of 6 M $HClO_4$. Yield, 0.1 g.

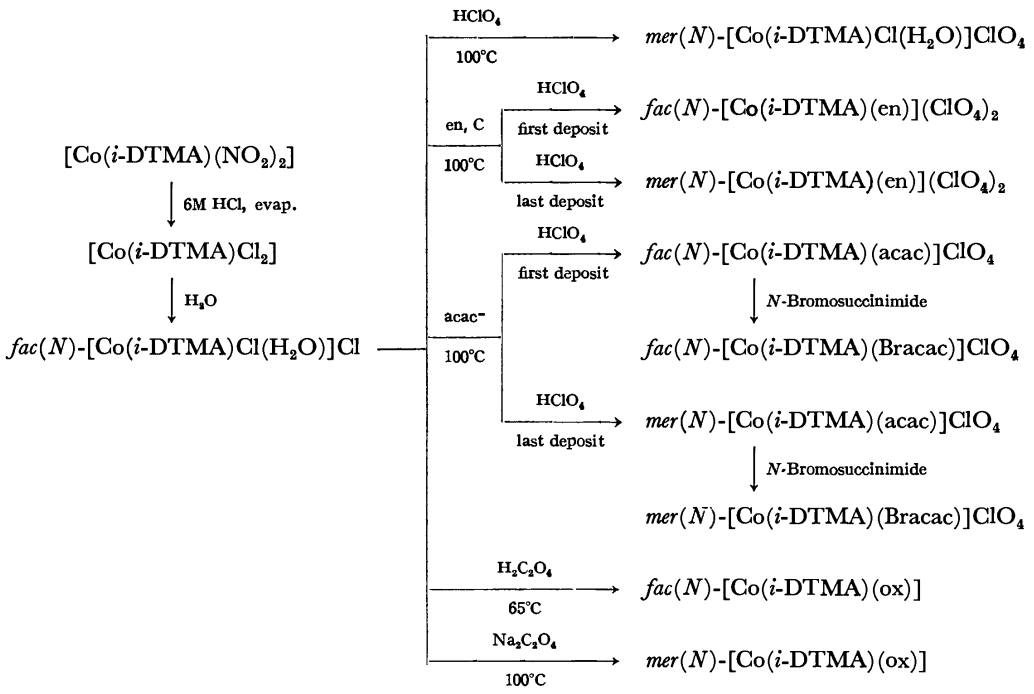
The *mer(N)*-isomer of the acetylacetonato complex was treated similarly. The yield of the bright red product was also 0.1 g.

Found: C, 26.34; H, 4.19; N, 8.41% for the brownish red isomer. C, 26.50; H, 4.18; N, 8.41% for the bright red isomer. Calcd for [Co(*i*-DTMA)(Bracac)]ClO_4 = $CoC_{11}H_{20}O_8N_3ClBr$ (496.59): C, 26.60; H, 4.06; N, 8.46%.

Results and Discussion

Preparation. The preparation routes in this study are shown schematically in Table 1. Schneider and Collman[1] obtained the dichloro complex, [Co(*i*-DTMA)Cl_2], by the evaporation of a suspension of the dinitro complex in concentrated hydrochloric acid, followed by the addition of ethanol. The evaporation product of the dinitro complex in our procedure probably consisted of the same dichloro complex as that of the pioneers. According to our experiment, however, the composition of the material is indefinite to some extent, since it changes quickly in the presence of moisture. The addition of a small amount of water

TABLE 1. PREPARATION SCHEME OF Co(III)-*i*-DTMA COMPLEXES



to the product, as has been described above, gives a satisfactory precipitate of the first aquation product from the dichloro complex, $[Co(i\text{-}DTMA)Cl(H_2O)]Cl \cdot H_2O$. The isolated solid is not hygroscopic at all, since it came out of the aqueous medium. The yield is nearly quantitative. It reacts with various anions and molecules to form substitution products. Therefore, it is a suitable starting substance for the preparation of the complexes of the series.

As has been described in the introduction, *i*-DTMA may coordinate with two different modes in octahedral complexes; judging from the results of Schneider and Collman,[1] the *fac*(*N*)-mode is considered to be more stable and/or to be easier to arise. Therefore, it was presumed that a high temperature was necessary for a *fac*(N)-isomer to isomerize to a *mer*(N)-isomer. It was also presumed that basic media were preferable for the isomerization, since the substitution and isomerization reactions of cobalt(III) complexes proceed faster in basic solutions than in acidic solutions.[5] Preparations were attempted on these assumptions; they were confirmed, at least qualitatively, as will be shown below.

In the preparation of the oxalato complexes, the red *mer*(*N*)-isomer, which will be identified in the following sections, occurred predominantly by means of the reaction between the starting complex and sodium oxalate at ~100 °C. On the other hand, the reaction with oxalic acid at ~65 °C produced the red-violet *fac*(*N*)-isomer. The use of sodium oxalate at ~65 °C also produced the red-violet isomer at first, but it turned to red after having been long kept at that temperature. These facts are consistent with the above assumptions. In the preparation of the ethylenediamine and the acetylacetonato complexes, two isomers of each complex were separated from the products obtained by the reactions at ~100 °C. It was observed that the yields of the *mer*(*N*)-isomers were extremely low when the reactions were performed at ~65 °C. These facts also confirm the assumptions.

The bromination of the acetylacetonato complexes at the central methine of the ligand was easily accomplished by the action of *N*-bromosuccinimide. This is in contrast with the fact that the acetylacetonatobis(ethylenediamine)cobalt(III) ion, $[Co(acac)(en)_2]^{2+}$, is not brominated even under forcing conditions.[6] On the other hand, there is much information indicating that tris(acetylacetonato)cobalt(III) and many analogues of the other metal ions, such as Cr(III), undergo bromination at the site.[7] Thus, the results indicate that the electrophilic substitution suffers an influence by the kinds of ligands which coordinate to the metal together with the reacting acetylacetonate.

Proton NMR Spectra. In the case of the coordination with the *mer*(*N*)-mode of the tetradentate, one ethylene bridge is forced to the δ and the other, to the λ conformation, and the out-of-plane glycinate ring skeleton must be planar. The oxalate and the acetylacetonate rings are considered to be planar, since these rings in many metal complexes have been confirmed to be planar by X-ray crystallographic analysis.[8] Therefore, the *mer*(*N*)-isomers of the oxalato and the acetylacetonato complexes possess a plane of symmetry; they belong to the C_s point group. On the other hand, the *fac*(*N*)-isomers have no element of symmetry; they belong to the C_1 point group. In the case of the ethylenediamine complex, neither isomer has an element of symmetry; since the conformation of the bidentate is not planar but *gauche*. However, the δ and the λ conformations of the bidentate give rise to no intrinsic difference in the *mer*(*N*)-isomer; the plane coplanar with the glycinate ring in the isomer may thus be taken as approximately a plane of symmetry.

a) The resonances of the glycinate ring protons of *fac*(*N*)-[Co(*i*-DTMA)(Bracac)]ClO_4 were not so clear because of the solubility limitation, but they were detectable by the comparison with the spectrum of the unbrominated complex. The spectrum of *fac*(*N*)-[Co(*i*-DTMA)(ox)] was not obtained owing to its low solubility.

Because of the symmetry described above, the glycinate ring protons in the *mer*(*N*)-isomers are exactly or approximately equivalent; hence, a singlet absorption due to the protons can be expected for the isomers. On the other hand, an AB quartet absorption is expected for the protons of the *fac*(*N*)-isomers. Thus, the PMR spectra make possible a decisive conclusion as to the structure of the complexes. Table 2 shows the observed resonances, which indicate the structure and composition. As may be seen there, one of the isomers of each complex exhibits a sharp singlet, and the other, a quartet, in the region of the glycinate absorption (around 3 ppm). The coupling constants, J_{AB}, of the latter are 17 Hz, in agreement with those obtained for other cobalt(III) complexes with a similar ring arrangement.[3] The coordination modes of the tetradentate in the isomers were, thus, assigned as has been indicated in the preceding section on preparation. It was observed that the absorption due to the methine proton of the acetylacetonato complexes (~4.5 ppm) disappeared completely in the spectra of the brominated products. This fact supports the actual bromination at the site of the ligand.

Electronic Absorption Spectra. Figures 2—5 show the visible and ultraviolet absorption spectra of the complexes studied, while the numerical values of the absorption maxima are summarized in Table 3.

As may be seen in Fig. 2, one of the chloroaquo complexes shows an intense first band with no distinct split, whereas the other shows a large split in the band. Such a large difference between their spectra cannot be expected if the tetradentate coordinates with the

4: the *mer*(*N*)-isomer of the bromoacetylacetonato complex

same mode in both isomers. Therefore, it can reasonably be inferred from the spectra and the possible four configurations that the former is the *fac*(*N*)-isomer, while the latter is the *mer*(*N*)-isomer, which is in agreement with the assignment from the PMR spectra. It is not known, however, which of the residual coordination sites (1 and 2 in Fig. 1) the chlorine atom occupies in each isomer.

The oxalato and the acetylacetonato complexes are of the [CoN_3O_3] type, and there is much information about the spectra of this type of complex, *e.g.* [Co(gly)$_3$].[9] There is a general trend for the *fac*-isomer to exhibit a more intense first band with no distinct split, whereas the *mer*-isomer exhibits a less intense first band with a wider band width or a deformation from the symmetrical shape. The configurations of the isomers were assigned on the basis of this trend, as has been indicated in the Preparation section, in agreement with the assignment based on the PMR spectra. These assignments are also consistent with the observation of the preparations, in which the *mer*(*N*)-isomers, the species considered to be difficult to produce, occurred at high temperatures.

It can be found that some regularities are present among the spectra of the acetylacetonato and the bromoacetylacetonato complexes. First, the bromination hardly affects the wave number of the first band, but slightly increases the intensity of the band. Second, the ligand specific band shifts to a lower wave number with the slight decrease in intensity by the bromination. It can be concluded from the spectral observations that the *fac*(*N*)- and *mer*(*N*)-configurations of each isomer of the acetylacetonato complex are mostly retained during the brominating reaction under the conditions used in the experiments.

Studies of Bivalent Metal Complexes of 2-Acetylpyridine[1)]

Yoshinori KIDANI, Masahide NOJI, and Hisashi KOIKE*

Faculty of Pharmaceutical Sciences, Nagoya City University, 3-1 Tanabe-dori, Mizuho-ku, Nagoya 467

(Received June 3, 1974)

Bivalent metal complexes of 2-acetylpyridine (abbreviated as 2AP), $M(2AP)_2X_2$, M being copper, nickel, cobalt, and zinc ions and X being chloride, bromide, and iodide ions, were synthesized in ethanol solutions. The far-infrared analyses were discussed with reference to their structures, which were determined by means of the magnetic moments and the diffuse reflectance spectra. Except for $Co(2AP)_2Cl_2$ and $Co(2AP)_2I_2$, an octahedral structure was suggested for the $M(2AP)_2X_2$ complexes. A tetrahedral structure was assigned to $Co(2AP)_2Cl_2$ and $Co(2AP)_2I_2$ on the basis of their magnetic moments of 4.55 and 4.25 B.M. respectively and the diffuse reflectance spectra. The stretching vibrations of metal-nitrogen, metal-oxygen, and metal-halogen have been discussed.

Only a few spectrochemical studies have been reported on the metal complexes of 2-acetylpyridine, Karson,[2,3)] however, studied the neutral metal complexes of $[C_5H_4NC\langle^{CH_2}_{O^-}]_2M$ being formed in aqueous solutions, where the metals were bivalent ions of copper, nickel, and cobalt. He also reported the cationic-metal-complex formation of 2-acetylpyridine in ethanol solutions, *i.e.*, $[C_5H_4NC\langle^{CH_3}_{O}]_2MX_2$, where the metals were the same as those of the neutral complexes and where X were chloride, bromide, and iodide ions, but he gave no detailed discussion.

For a better understanding of the biologically-important amide group, the present authors attempted studies of the cationic-metal complexes with 2-acetylpyridine (abbreviated as 2AP in this paper) in a series of 2-substituted pyridine-metal complexes. In analysing the data for 2AP-metal complexes, reference was made to the metal complexes of pyridine-2-carboxamide, since their structures and coordination sites have been determined by Yamasaki and Sekizaki,[4–8)] the conclusion was confirmed by Masuko *et al.*[9)]

This paper will deal with the magnetic moments and diffuse reflectance spectra for the determination of the structures of the complexes obtained, together with the band assignments in the far-infrared region for those containing different halide ions.

Experimental

Materials. The 2-acetylpyridine was purchased from the Tokyo Kogyo Co., Ltd., and was used without further purification. The bivalent metal halides (Cu, Ni, Co, and Zn) were special-grade products of Wako Pure Chemical Industries, Ltd.

Preparation of Complexes. 1) Dihalogenobis(2-acetylpyridine)copper(II): To 10 ml of an ethanolic solution containing 0.48 g (4 mmol) of the ligand, we added 0.34 g (2 mmol) of copper(II) chloride dihydrate dissolved in 10 ml of ethanol. Immediately a dark green powder was precipitated, it was then washed with ethanol. The same procedure was used to obtain the bromo complex by the addition of the ligand, together with copper bromide in ethanol. A yellowish-green powder was precipitated.

Found: C, 44.06; H, 3.77; N, 7.28; Cu, 16.7%. Calcd for $Cu(C_7H_7ON)_2Cl_2\cdot 1/4H_2O$: C, 44.12; H, 3.84; N, 7.35; Cu, 16.3%.

Found: C, 35.32; H, 3.12; N, 5.84; Cu, 12.7%. Calcd for $Cu(C_7H_7ON)_2Br_2\cdot H_2O$: C, 35.10; H, 3.36; N, 5.84; Cu, 13.0%.

2) Dihalogenobis(2-acetylpyridine)nickel(II): To 2 mmol of the ligand we added 4 mmol of nickel(II) chloride hexahydrate in 10 ml of ethanol, and the resultant solution was warmed gently on a water bath. A greenish-yellow powder was gradually precipitated. Bromo and iodo complexes were obtained as brown and reddish-brown precipitates by means of a procedure similar to that used for the chloro complex.

Found: C, 45.10; H, 3.85; N, 7.50; Ni, 15.8%. Calcd for $Ni(C_7H_7ON)_2Cl_2$: C, 45.21; H, 3.80; N, 7.53; Ni, 15.5%.

Found: C, 36.59; H, 3.18; N, 6.09; Ni, 12.7%. Calcd for $Ni(C_7H_7ON)_2Br_2$: C, 36.49; H, 3.06; N, 6.08; Ni, 12.8%.

Found: C, 30.35; H, 2.53; N, 4.86; Ni, 10.6%. Calcd for $Ni(C_7H_7ON)_2I_2$: C, 30.31; H, 2.53; N, 5.05; Ni, 10.6%.

3a) Bis(2-acetylpyridine)cobalt(II) Halides: To 2 mmol of the ligand in 10 ml of ethanol, we added 4 mmol of cobalt(II) chloride hexahydrate in 10 ml of ethanol, after which the solution was kept standing overnight at room temperature. A brown powder was thus precipitated. An iodide complex was obtained as a reddish-brown precipitate by means of the same procedure as was used for the chloride complex.

Found: C, 44.89; H, 3.69; N, 7.61; Co, 15.8%. Calcd for $Co(C_7H_7ON)_2Cl_2$: C, 45.19; H, 3.79; N, 7.35; Co, 15.5%.

Found: C, 30.35; H, 2.69; N, 5.11; Co, 10.4%. Calcd for $Co(C_7H_7ON)_2I_2$: C, 30.31; H, 2.55; N, 5.05; Co, 10.7%.

3b) Dibromobis(2-acetylpyridine)cobalt(II): A bromo complex was obtained as a dark brown precipitate by means of the same procedure as was used for the chloride complex.

Found: C, 36.58; H, 3.22; N, 6.03; Co, 12.8%. Calcd for $Co(C_7H_7ON)_2Br_2$: C, 36.47; H, 3.06; N, 6.07; Co, 12.5%.

4) Dihalogenobis(2-acetylpyridine)zinc(II): Two mmol of the ligand and 4 mmol of zinc chloride were dissolved in 10 ml of ethanol. After mixing the two solutions, the resultant solution was concentrated to half volume on a water bath and then kept standing overnight at room temperature. A yellowish-brown powder was thus precipitated. A bromo complex was obtained by mixing 2 mmol of zinc bromide and 4 mmol of the ligand in 30 ml of acetone. After the solution has been kept standing overnight at room temperature, a white crystalline precipitate was deposited out. An iodo complex was obtained as reddish-brown precipitate by means of the same procedure as was used for the chloro complex.

Found: C, 44.81; H, 3.74; N, 7.17; Zn, 16.9%. Calcd

for $Zn(C_7H_7ON)_2Cl_2$: C, 44.42; H, 3.73; N, 7.40; Zn, 17.3%. Found: C, 35.89; H, 2.97; N, 5.86; Zn, 14.0%. Calcd for $Zn(C_7H_7ON)_2Br_2$: C, 35.97; H, 3.02; N, 5.99; Zn, 14.3%. Found: C, 29.58; H, 2.85; N, 4.99; Zn, 11.6%. Calcd for $Zn(C_7H_7ON)_2I_2$: C, 29.95; H, 2.51; N, 4.75; Zn, 11.4%.

Magnetic and Spectroscopic Measurements. The magnetic moments were determined by the Curie method with a Shimadzu MB-2-type magnetic balance at room temperature (18—21 °C). The diffuse reflectance spectra were measured with a Hitachi EPS-3T spectrophotometer equipped with an integrating sphere accessory. For the measurements, the complexes were diluted to 0.25 molality with magnesium oxide, and from 150 mg of the mixture pellets were prepared under a 600 kg/cm² pressure after evacuation. A Nihon Bunko IRA-2 spectrophotometer was used to record the infrared spectra in the region from 4000 to 400 cm^{-1}. The infrared spectra were measured with KBr discs, Nujol, and HCB mulls. For the measurements of the far-infrared spectra from 600 to 200 cm^{-1}, a Nihon Bunko DS-701G spectrophotometer was used. Solid samples were measured as mulls in Nujol; they were placed between two polyethylene films and inserted into a holder. The spectrum of the ligand was measured as a thin liquid layer placed between two polyethylene films.

Results and Discussion

Magnetic Moments. The magnetic moments observed for the 2AP-metal complexes are listed in

TABLE 1. MAGNETIC MOMENTS OF 2-ACETYLPYRIDINE–METAL COMPLEXES

Complexes	Found	Calcd for the spin-only formula
$Cu(2AP)_2Cl_2 \cdot 1/4H_2O$	1.69 B.M.	1.73 B.M.
$Cu(2AP)_2Br_2 \cdot H_2O$	1.66	1.73
$Ni(2AP)_2Cl_2$	3.02	2.82
$Ni(2AP)_2Br_2$	3.00	2.82
$Ni(2AP)_2I_2$	2.97	2.82
$Co(2AP)_2CoCl_2$	4.55	3.88
$Co(2AP)_2CoBr_2$	5.40	3.88
$Co(2AP)_2CoI_2$	4.25	3.88
$Zn(2AP)_2Cl_2$	Diamagnetic	
$Zn(2AP)_2Br_2$	Diamagnetic	
$Zn(2AP)_2I_2$	Diamagnetic	

Table 1. The magnetic moments of the copper complexes are a little lower than that of the spin-only formula, but the presence of copper–copper interaction usually produces a much larger decrease in the magnetic moment. Therefore, they may exist as mononuclear complexes. The magnetic-moment values of the nickel complexes are around 3.0 B.M., corresponding to the reported values of 2.9—3.4 B.M. for octahedral nickel complexes. As for the cobalt complexes, the bromo complex has a higher magnetic moment (5.40 B.M.) than those of the chloride and the iodide (4.55 and 4.25 B.M. respectively). These values indicate an octahedral structure for the bromo complex and a tetrahedral structure for the other two complexes.

Diffuse Reflectance Spectra. The diffuse reflectance spectra of the complexes prepared are shown in Figs. 1—3. Both $Cu(2AP)_2Cl_2$ and $Cu(2AP)_2Br_2$ show d-d

transition bands at 750 nm, the band at 390 nm for the bromo complex can be assigned to a charge-transfer band, whereas the corresponding band is not observed

for the chloro complex, since the band is expected to appear there at a wavelength shorter than that of the bromo complex. The spectra of 2AP-copper complexes resemble that of the copper complex of pyridine-2-carboxamide,[5-7] the shift to the longer wavelength may be due to the difference in the coordinated aquo molecule and halide ions, so the same distorted octahedral structure is conceivable.

Figure 2 shows that $Ni(2AP)_2Cl_2$ gives d-d transition bands at 580 and 660 nm, while for $Ni(2AP)_2Br_2$ only one band, at 530 nm and with a shoulder at 760 nm, is observed. $Ni(2AP)_2I_2$ shows d-d transition bands at 510 and 670 nm, the latter being observed only as a shoulder. The additional band at 390 nm, characteristic of the iodo complex, may be due to the charge transfer. Moreover, the fact that the absorbance of the nickel complexes is nearly the same as those of the copper and cobalt complexes may indicate an octahedral structure for $Ni(2AP)_2X_2$, because one of the characteristic features of tetrahedral nickel complexes is that the molar absorption coefficient is relatively higher than those of the corresponding first-transition-metal complexes. Therefore, the d-d bands observed may be assignable to the $^3A_{2g}\rightarrow{}^3T_{1g}$ transition and the splitting may be due to the mixing of the spin orbital of $^3T_{1g}(F)$ and ^1E_g, as has been reported for the hexaaquonickel(II) complex.[10]

Figure 3 shows that, among the $Co(2AP)_2X_2$ complexes only $Co(2AP)_2Br_2$ indicates a d-d transition band at 560 nm, while for $Co(2AP)_2Cl_2$ and $Co(2AP)_2I_2$ only shoulders around 650 and 500 nm respectively are observed. The band of the bromo complex is characteristic of an octahedral cobalt complex and may be assigned to the $^4T_{1g}(F)\rightarrow{}^4T_{1g}(P)$ transition.[11] However, for the other two complexes no conclusion has yet been deduced for their structures, because they show no absorption maxima.

Infrared Spectra. In the region of 1700—1500 cm^{-1} some characteristic bands due to the carbonyl group and pyridine-ring vibrations are observed in the metal complexes. These bands are shown in Figs. 4 and 5, together with that of the ligand. The stretching vibration of the carbonyl group of the ligand appears at 1700 cm^{-1}, while those of C=N and C=C in the pyridine ring appear at 1582 and 1565 cm^{-1}. Upon complex formation the stretching vibration of the carbonyl group shifts to lower frequencies, while the peak at 1582 cm^{-1} shifts to frequencies a little higher. However, the peak at 1565 cm^{-1} does not shift at all. The lower-frequency shifts of the carbonyl group indicate an interaction between the metals and the oxygen atom, while the higher-frequency shifts of the peak at 1582 cm^{-1} may suggest a bond formation of the metals and the ring nitrogen, for the dipolar contribution of $C=N^+$ in the pyridine ring increases, as has been observed in pyridine hydrogen chloride.[12,13] These stretching vibrations of C=N are not metal-sensitive and appear at a constant frequency of 1595 cm^{-1}; however, the order of shifts to lower frequencies of the carbonyl-stretching vibrations is Ni>Co>Cu>Zn in the bromo complexes. The copper complexes give peaks at 1685 and 1683 cm^{-1} for the chloro and the bromo complexes; those frequencies are higher than those of the other metal complexes examined, indicating a weaker interaction of copper with the oxygen atom. For the nickel complexes, the lower-frequency shifts of the carbonyl group depend on the halide ions; the shifts are observed in the following order of Cl>Br>I: 1665, 1653, and 1650 cm^{-1}.

The chloro complex of zinc, whose peak due to the carbonyl group appears at 1675 cm^{-1}, giving a somewhat different spectrum from those of the other two metal complexes, perhaps suggesting its structural difference. A remarkable difference in the far-infrared spectrum is alo observed; the question will be discussed more detail below. The bromo and iodo complexes give peaks at 1688 and 1675 cm^{-1}; it may be con-

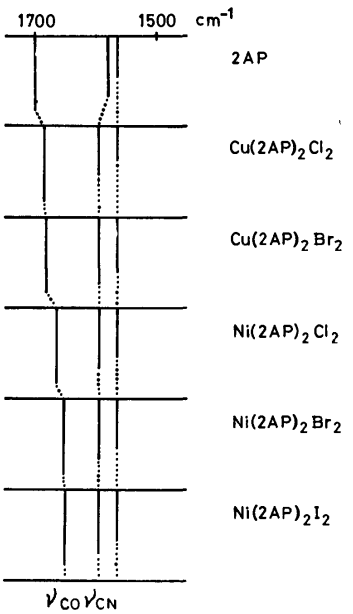

Fig. 4. Infrared spectra of the ligand, $Cu(2AP)_2X_2$, and $Ni(2AP)_2X_2$.

sidered from these shifts that zinc forms a weaker bond than those of the cobalt and nickel complexes.

These frequency shifts of the carbonyl group and the pyridine ring may lead to the conclusion of the chelate ring formation, which can easily be understood in view of the ligand structure and confirmed by the far-infrared data.

TABLE 2. FAR-INFRAREDRAL DATA FOR BIVALENT METAL COMPLEXES OF PYRIDINE AND α-PICOLINE (in cm^{-1})

Complexes	ν_{M-N}	ν_{M-X}	Structure
$CuCl_2 \cdot 2py$[a]	268	235(b)[b], 294(t)	Distorted polymeric octahedral
$CuBr_2 \cdot 2py$	269	202(b), 255(t)	Distorted polymeric octahedral
trans-$NiCl_2 \cdot 4py$	236	246	Monomeric octahedral
trans-$NiBr_2 \cdot 4py$	235	200	Monomeric octahedral
trans-$NiI_2 \cdot 4py$	240, 228	200	Monomeric octahedral
$NiCl_2 \cdot 2(\alpha\text{-pic})$[a]	239, 227	327, 297	Tetrahedral
$NiBr_2 \cdot 2(\alpha\text{-pic})$	239	256	Tetrahedral
trans-$CoCl_2 \cdot 4py$	217	230	Monomeric octahedral
trans-$CoBr_2 \cdot 4py$	200	214	Monomeric octahedral

$ZnBr_2 \cdot 2py$	220	254	Tetrahedral

a) In this table py and α-pic denote pyridine and α-picoline, respectively. b) Small letters in parentheses, *i.e.*, t and b, denotes terminal and bridging halides, respectively.

Far-infrared Spectra. There have been accumulated very many data, especially concerning metal-halide complexes of pyridine and its derivatives, indicating that a change in halide ions does not affect the stretching vibrations of the metal-ligand; therefore, the absorption peaks which do remain at a fairly constant frequency upon the variation in the halide ions are attributable to the metal-ligand vibrations in $M(2AP)_2X_2$. Some far-infrared data of pyridine-metal complexes are shown in Table 2; they were utilized for the analyses of the spectra of $M(2AP)_2X_2$. The structural change has been proved to have remarkable effects on the stretching vibrations of the metal-halide and the metal-ligand. Moreover, for the $M(2AP)_2X_2$ complexes the far-infrared data present valuable information for the determination of their structures. In assigning the stretching vibrations of metal-ligand and metal-halide in $M(2AP)_2X_2$, the chelate ring formation is taken into account to produce the objective stretching vibrations at higher frequencies than those of the corresponding metal-pyridine complexes.

The far-infrared spectra of $M(2AP)_2X_2$ in the region of 600—200 cm^{-1} are shown in Figs. 6—9.

As is shown in Fig. 6, 2AP gives peaks at 593 and 412 cm^{-1} assignable to the in-plane and out-of-plane ring bending. The peak at 485 cm^{-1} may be assignable to the in-plane deformation mode of the acetyl group, while the peaks at 360 and 213 cm^{-1} are attributable to the pyridine-ring vibration and the acetyl torsion respectively.

$Cu(2AP)_2X_2$. Figure 6 shows the far-infrared spectra of $Cu(2AP)_2X_2$. The chloro complex has a strong but broad band at 275 cm^{-1}, with shoulders at 290 and 250 cm^{-1}. The bromo complex shows three bands, at 290, 250, and 225 cm^{-1}. Therefore, the common bands at 290 and 250 cm^{-1} are assignable to the chelate-ring vibrations, the former being mainly due to the stretching vibration of copper-nitrogen, and the latter, to that of copper-oxygen. The stretching vibration of copper-chloride may be assignable to the band at 275 cm^{-1}, and that of copper-bromide, to the band at 225 cm^{-1}, which is shifted 20—30 cm^{-1} toward the lower-frequency side than those of the terminal halide-copper in $CuX_2 \cdot 2py$ (py=pyridine). The theoretical prediction for infrared-active bands in octa-

hedral $Cu(2AP)_2X_2$ coincides with the number of bands observed; therefore, an octahedral structure with a *trans*-planar coordination of 2AP with halide ions bonded to the copper ion perpendicular to the chelate ring may be proposed.

Ni(2AP)$_2$X$_2$. Because of the chelate-ring formation in nickel complexes of 2AP, the bond distances between the nickel ion and the nitrogen atom will be shortened and the stretching vibrations may be expected to appear at higher frequencies than those of NiX_2–4py (py=pyridine). As is shown in Fig. 7, among the halogeno complexes examined only the chloro complex gives a band at 250 cm^{-1} assignable to the stretching vibration of nickel-chloride. The common bands are observed around 310—305 cm^{-1} and 260—250 cm^{-1}. These spectra of $Ni(2AP)_2X_2$, resembling those of octahedral $NiX_2 \cdot 4py$ (py=pyridine) rather than those of tetrahedral $NiCl_2(\alpha\text{-picoline})_2$, suggest a *trans*-planar octahedral structure.

Co(2AP)$_2$X$_2$. Since $Co(2AP)_2Cl_2$ and $Co(2AP)_2I_2$ are considered to have a tetrahedral structure belonging to the C_{2v} point group, four infrared-active cobalt-2AP stretching bands are expected to appear. However, only three bands are observed for these complexes, as is shown in Fig. 8, the missing band, due to the symmetric cobalt-oxygen stretching vibration, may appear below 200 cm^{-1}. The magnetic moment indicates an octahedral structure for $Co(2AP)_2Br_2$, where if 2AP coordinates in a *trans*-planar configuration two cobalt-2AP stretching vibrations should appear. This is the case in the bromo complex, for only two bands attributable to the stretching vibrations of cobalt-nitrogen and cobalt-oxygen are observed.

Zn(2AP)$_2$X$_2$. Among the $Zn(2AP)_2X_2$ complexes the bands about 265 cm^{-1} are consistent except for the chloro complex and may be assigned to the stretching bands of zinc-nitrogen. The chloro complex gives two bands, at 330 and 310 cm^{-1}, which are close to the asymmetric and symmetric stretching bands of zinc-chloride in tetrahedral $ZnCl_2 \cdot 2py$ (py=pyridine).[14] Therefore, they can be assigned to the asymmetric and symmetric stretching bands of zinc-chloride, indicating a *cis*-conformation of the chloride ions in $Zn(2AP)_2Cl_2$. It is sure that the chloro complex has structure different from that of the other two complexes, but the unavailability of magnetic moments and diffuse reflectance spectra makes it difficult to draw any definite conclusions.

Table 3. Experimental assignments of 2-acetylpyridine–metal complexes in the far-infrared region

Complexes	ν_{M-X}	ν_{M-N}	ν_{M-O}	Unassigned
$Cu(2AP)_2Cl_2$	275	(290) a)	(250)	
$Cu(2AP)_2Br_2$	225	293	250	
$Ni(2AP)_2Cl_2$	250	305	(250)	
$Ni(2AP)_2Br_2$		305	253	226
$Ni(2AP)_2I_2$		310	263	218
$Co(2AP)_2Cl_2$		296	218	
		245		
$Co(2AP)_2Br_2$		270	210	
$Co(2AP)_2I_2$		293	(215)	
		247		
$Zn(2AP)_2Cl_2$	330	205		
	310			
$Zn(2AP)_2Br_2$		267		
$Zn(2AP)_2I_2$		263		

a) Parenthesis denotes a shoulder.

Our experimental assignments of the far-infrared spectra are listed in Table 3. When the $M(2AP)_2X_2$ complexes are compared with $[M(piaH)_2(H_2O)_2]Cl_2$ (piaH=pyridine-2-carboxamide) from the standpoint of the far-infrared spectra, the former complexes have the following characteristics:

1) The existence of the chelate-ring vibrations of $M(2AP)_2X_2$ at frequencies lower than those of the corresponding $[M(piaH)_2(H_2O)_2]Cl_2$ may suggest lower

stability constants in the former than in the latter.
2) $Cu(2AP)_2X_2$ gives the copper-2AP stretching vibrations at frequencies rather lower than the other $M(2AP)_2X_2$ complexes.
3) $Co(2AP)_2Cl_2$ and $Co(2AP)_2I_2$ have a tendency to take a tetrahedral structure.
4) In $Zn(2AP)_2Cl_2$ the coordination of the chloride ion to zinc is in the *cis*-configuration.

Conclusion

Through the analyses of the magnetic moments, the diffuse reflectance spectra, and the infrared spectra, the following structures can be tentatively proposed for $M(2AP)_2X_2$. $Cu(2AP)_2X_2$ ($X=Cl^-$ and Br^-) are considered to have a mononuclear distorted octahedral structure, with a *trans*-planar conformation of the 2AP molecules to copper. For $Ni(2AP)_2X_2$ ($X=Cl^-$, Br^-, and I^-), an octahedral structure with a *trans*-planar coordination of 2AP is proposed. A tetrahedral structure may be assigned to $Co(2AP)_2Cl_2$ and $Co(2AP)_2I_2$, while for $Co(2AP)_2Br_2$ an octahedral structure with a *trans*-planar coordination of 2AP is supported.

The authors wish to thank Dr. N. Yamanaka of the Government Industrial Institute, Nagoya, for permitting them to use a Shimadzu MB-2 magnetic balance. Thanks are also due to Misses M. Ishiguro and S. Iwauchi of the Analytical Center of their university for the elemental analyses.

Studies of Bivalent Metal Chelates of 2-Aminomethylpyridine

Masahide Noji, Yoshinori Kidani, and Hisashi Koike*

Faculty of Pharmaceutical Sciences, Nagoya City University, 3-1 Tanabe-dori, Mizuho-ku, Nagoya 467

(Received June 11, 1974)

Bivalent metal chelates of 2-aminomethylpyridine (abbreviated as 2AMP), $M(2AMP)_2X_2$ (M=Cu, Ni, Co, and Zn ion; X=Cl^-, Br^-, I^-), were synthesized in ethanol. The magnetic moments and the diffuse reflectance spectra were measured. The $Cu(2AMP)_2X_2$ complexes (X=Cl^- and Br^-) were considered to have a monomeric distorted octahedral structure. The $Ni(2AMP)_2X_2$ complexes (X=Cl^-, Br^-, I^-) were also suggested to have an octahedral structure. However, for $Co(2AMP)_2Br_2$ and $Co(2AMP)_2I_2$ a tetrahedral and a square planar structure were proposed on the basis of their magnetic moments of 4.20 and 2.78 B.M. respectively. The infrared spectra of the chelates were analysed in relation to their structures; a good relationship was found between the structures and the far-infrared spectra.

Various metal chelates of 2-aminomethylpyridine have been studied by Sutton[1-3] and Michelsen[4] with regard to their electronic absorption spectra and magnetic moments. The stability constants were reported by Walter *et al.*[5] and Goldberg.[6] However, no infrared spectroscopic investigation of these chelates has ever been made. The present authors have now synthesized bivalent metal chelates of 2-aminomethylpyridine (abbreviated as 2AMP in this paper) in ethanol, that is, $M(2AMP)_2X_2$ complexes, M being copper(II), nickel(II), cobalt(II), and zinc(II) ions and X being chloride, bromide, and iodide ions. Among these complexes, two cobalt chelates, $Co(2AMP)_2Br_2$ and $Co(2AMP)_2I_2$ were newly prepared, but the chloro chelate was not obtained in spite of several trials.

In order to study their structures, the magnetic moments and the diffuse reflectance spectra were measured. By referring these data, the far-infrared spectra were then analysed in relation to the structures of the chelates obtained.

Experimental

Materials. The 2-aminomethylpyridine, a product of the Aldrich Chemical Co., Ltd., was used without further purification. The metal halides used were analytical-grade products of Wako Pure Chemical Industries, Ltd.

Preparation of Chelates. *Bis(2-aminomethylpyridine)cobalt(II) Halides*: To a solution containing 0.43 g (4 mmol) of the ligand in 10 ml of ethanol, we added 0.44 g (2 mmol) of cobalt bromide dissolved in 20 ml of ethanol; a dark brown powder was thus precipitated. The precipitate was collected by filtration and washed with ethanol.

The corresponding iodide was synthesized by a procedure similar to that used for the bromide chelate, which was obtained as a reddish-brown powder.

Found: C, 31.77; H, 3.95; N, 12.43; Co, 13.2%. Calcd for $Co(C_6H_8N_2)_2Br_2 \cdot H_2O$: C, 31.81; H, 4.01; N, 12.36; Co, 13.0%.

Found: C, 27.55; H, 3.05; N, 10.71; Co, 11.2%. Calcd for $Co(C_6H_8N_2)_2I_2$: C, 27.24; H, 3.05; N, 10.59; Co, 11.1%.

The other metal chelates were synthesized in ethanol by treating 2 mmol of the metal halides with 4 mmol of the ligand. The results of the elemental analyses of the metal chelates obtained are shown in Table 1.

Magnetic and Spectroscopic Measurements. The magnetic moments were measured by the Curie method with a Shimadzu MB-2 magnetic balance at room temperature. The diffuse reflectance spectra were measured with a Hitachi EPS-3T spectrophotometer equipped with an integrating-sphere accessory. For the measurements the chelates were diluted to a 0.25 molality with magnesium oxide, and pellets containing 150 mg of the mixtures were prepared under a 600 kg/cm^2 pressure after evacuation. A Nihon Bunko IRA-2 spectrophotometer was used to record the infrared spectra in the region from 4000 to 400 cm^{-1} using the KBr disc method and the Nujol and HCB mull method. The far-infrared spectra in the region of 600—200 cm^{-1} were measured with a Nihon Bunko DS-701G spectrophotometer using the Nujol mull method.

Table 1. Elemental analysis of $M(2AMP)_2X_2$

Chelates	Found (%)				Calcd (%)			
	C	H	N	M	C	H	N	M
$Cu(C_6H_8N_2)_2Cl_2$	40.95	4.68	15.90	17.7	41.09	4.60	15.97	18.1
$Cu(C_6H_8N_2)_2Br_2 \cdot 1/2H_2O$	32.09	3.57	12.57	14.4	32.13	3.82	12.49	14.2
$Ni(C_6H_8N_2)_2Cl_2 \cdot 3/4H_2O$	40.35	4.82	15.63	16.6	40.13	4.90	15.60	16.3
$Ni(C_6H_8N_2)_2Br_2$	32.87	3.56	12.83	13.6	33.15	3.71	12.88	13.5

Results and Discussion

Magnetic Moments. The magnetic moments observed for $M(2AMP)_2X_2$ are listed in Table 2. The copper chelates give magnetic moments a little lower than that of the spin-only formula, indicating a negligible spin interaction among adjacent copper ions.

Table 2. Magnetic moments of $M(2AMP)_2X_2$ (19—21 °C)

Chelates	Observed	Calcd for spin-only formula
$Cu(2AMP)_2Cl_2$	1.64 B.M.	1.73 B.M.
$Cu(2AMP)_2Br_2$	1.71	1.73
$Ni(2AMP)_2Cl_2$	2.94	2.82
$Ni(2AMP)_2Br_2$	2.96	2.82
$Ni(2AMP)_2I_2$	2.94	2.82
$Co(2AMP)_2Br_2$	4.20	3.88
$Co(2AMP)_2I_2$	2.79	1.73
$Zn(2AMP)_2Cl_2$	Diamagnetic	
$Zn(2AMP)_2Br_2$	Diamagnetic	
$Zn(2AMP)_2I_2$	Diamagnetic	

The nickel chelates give values of the magnetic moments of 2.94—2.96 B.M., which are comparable to those reported for octahedral nickel complexes, *i.e.*, 2.9—3.4 B.M.

The magnetic moment of $Co(2AMP)_2Br_2$ is found to be 4.20 B.M., which is nearer to the values of 4.4—4.8 B.M. reported for tetrahedral cobalt complexes than to those of 4.7—5.2 B.M. for octahedral complexes.[7] On the other hand, $Co(2AMP)_2I_2$ gives a very low magnetic moment of 2.79 B.M., which can be related to the values of 2.4—2.8 B.M. reported for square planar cobalt complexes.[7]

All the zinc chelates show a diamagnetic character, as had been expected.

Diffuse Reflectance Spectra. The d-d transition bands appear at 610 nm, with a shoulder at 750 nm, for $Cu(2AMP)_2Cl_2$ and at 630 and 730 nm for $Cu(2AMP)_2Br_2$, as is shown in Fig. 1. The bands in the shorter-wavelength region are observed at a position similar to that of $Cu(2AMP)_2I_2$ in an aqueous solution,

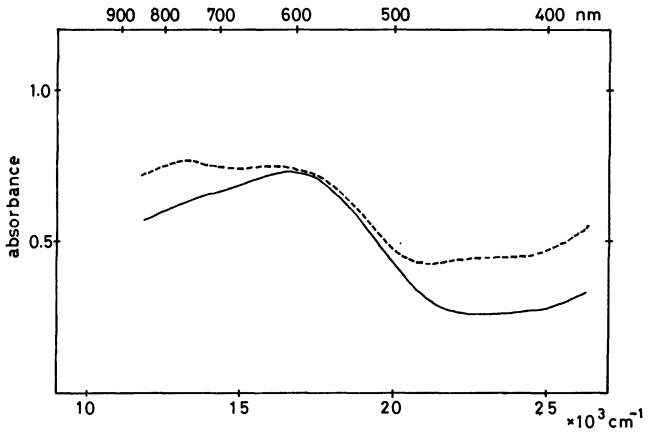

Fig. 1. Absorption spectra of $Cu(2AMP)_2X_2$ measured by the diffuse reflectance method.
—— $X=Cl^-$, ---- $X=Br^-$

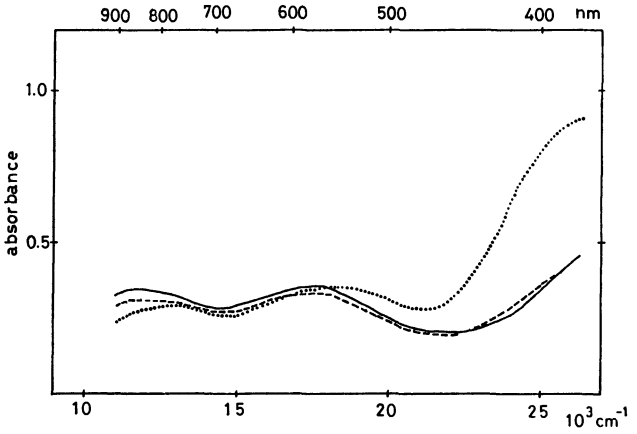

Fig. 2. Absorption spectra of $Ni(2AMP)_2X_2$ measured by the diffuse reflectance method.
—— $X=Cl^-$, ---- $X=Br^-$, ····· $X=I^-$

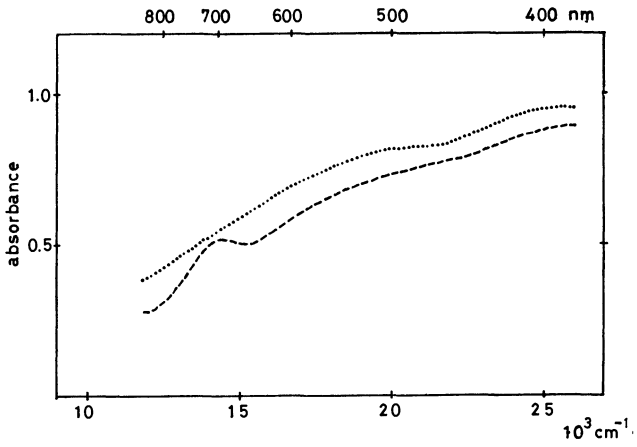

Fig. 3. Absorption spectra of $Co(2AMP)_2X_2$ measured by the diffuse reflectance method.
---- X=Br, ····· X=I

for which an octahedral structure has been proposed by Sutton.[8] Therefore, the same octahedral arrangement may be proposed for $Cu(2AMP)_2Cl_2$ and $Cu(2AMP)_2Br_2$, and the bands in the longer-wavelength region may arise from the orbital splitting due to a distortion from the octahedral configuration.

As is shown in Fig. 2, the three nickel chelates, $Ni(2AMP)_2X_2$, show spectra similar to one another, all with the d-d bands around 560—570 nm. The strong band at 380 nm of the iodo chelate may be assignable to the CT band, and a band is also observed at 770 nm. The corresponding bands for the chloro and bromo chelates appear around 850 nm. These d-d bands, all with low intensities, are characteristic of octahedral nickel complexes, which usually have molar absorption coefficients of 1—10. These diffuse reflectance spectra resemble the electronic absorption spectra of $[Nien_2(H_2O)_2]$ and $[Nibip_2(H_2O)_2]$; therefore, an octahedral structure can be assigned to $Ni(2AMP)_2X_2$, as has been postulated by Sutton.[1] The d-d bands in the shorter-wavelength region can be assigned to the $^3A_{2g}\rightarrow{}^3T_{1g}(F)$ and those in the longer-wavelength region, to the $^3A_{2g}\rightarrow{}^3T_{1g}(P)$ transition.[9]

The absorption spectra of $Co(2AMP)_2X_2$ are shown in Fig. 3. $Co(2AMP)_2Br_2$ shows the d-d band at 710 nm, as is characteristic of tetrahedral cobalt complexes, and in the shoter-wavelength region no distinct absorption maximum is observed. $Co(2AMP)_2I_2$ gives a very broad band around 500 nm, which is overlapped by the CT band at 380 nm. However, there has been reported little information as to the electronic absorption spectra of planar cobalt complexes; therefore, no difinite conclusion can be drawn from the diffuse reflectance spectrum for the structure of the iodide chelate.

Infrared Spectra. The chelate ring formation between 2AMP and the metal ions would bring about a lower-frequency shift of the stretching vibration of the amino group. The ligand shows both the asymmetric and symmetric stretching vibrations due to the amino group at 3370 and 3300 cm^{-1} respectively. These bands shift to a frequency side lower by 100—200 cm^{-1} upon the chelate formation, as is shown in Fig. 4.

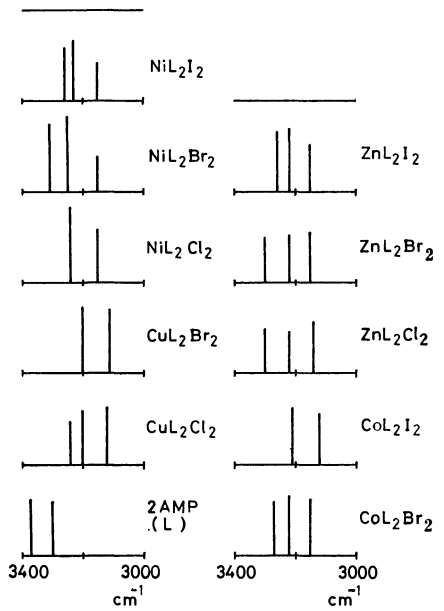

Fig. 4. Infrared spectra of 2AMP and $M(2AMP)_2X_2$ in the region of 3400—3000 cm^{-1}

The degree of the frequency shift is the largest for the copper chelates; among the other metal chelates, as is exemplified in the bromo system, the order of Cu(3200 cm^{-1})<Zn(3266 cm^{-1})<Co(3272 cm^{-1})<Ni(3305 cm^{-1}) is found for the asymmetric stretching vibrations. No regularity can be found in the effects of the halide ions on the stretching frequencies of the amino group.

The deformation frequency of the amino group in the ligand is observed at 1591 cm^{-1}; it shifts by about 10 cm^{-1} toward higher frequencies upon the chelate formation, contrary to the observation of the lower-frequency-side shifts of ammine complexes reported by Sacconi *et al.*[10]

Far Infrared Spectra. Figure 5 shows the far-infrared spectra of the ligand. It is very convenient to know that no peaks are observed below 400 cm^{-1}, since the metal complexes of pyridine derivatives usually

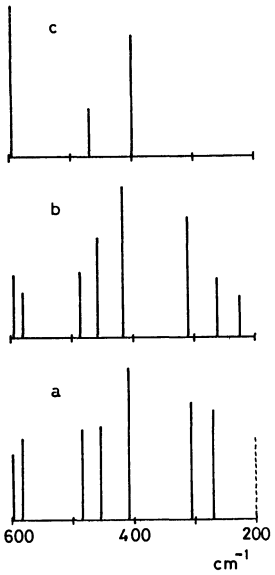

Fig. 5. Far-infrared spectra of 2AMP and $Cu(2AMP)_2X_2$
a: X=Cl, b: X=Br, broken line: shoulder
c: 2AMP

bring about absorption peaks due to the metal-pyridine nitrogen stretching vibrations below 400 cm^{-1}.

$Cu(2AMP)_2X_2$. The stretching vibration of copper-chloride is observed around 200 cm^{-1} as a broad peak; however, that of the copper-bromide is not observed above 200 cm^{-1}, as is shown in Fig. 5. The vibrations due to the chelate ring are found at 310—306 cm^{-1} and 270—263 cm^{-1}. The former may be assigned to the copper-amino nitrogen stretching, and the latter, to the copper-pyridine nitrogen stretching.

Clark and Williams[13] reported that the stretching vibration of copper-chloride in distorted octahedral pyridine complexes, $CuCl_2 \cdot 2py$ (py=pyridine), appeared at 294 and 235 cm^{-1} for the bridging-chloride and the terminal-chloride respectively. In this pyridine complex, the distance between the bridging-chloride and the copper ion was determined to be 3.05 Å by Dunitz,[14] but the peak at 200 cm^{-1} in $Cu(2AMP)_2Cl_2$ seems to indicate a longer bond distance between the chloride and the copper ion, with a stronger distortion from the octahedral structure than that of the pyridine complex. Therefore, a distorted octahedral structure is supported by the infrared spectra, coincinding with the result deduced from the magnetic moments and the diffuse reflectance spectra.

$Ni(2AMP)_2X_2$. As is shown in Fig. 6, the common peaks observed among the three nickel chelates are in two regions, 296—290 cm^{-1} and 255—250 cm^{-1}, which can be assigned to the nickel-amino nitrogen and the nickel-pyridine nitrogen stretching vibrations respectively. The nickel-chloride stretching is found at 205 cm^{-1}, and the corresponding peaks of the bromo and iodo chelates are not observed above 200 cm^{-1}. The additional peaks at 234 and 235 cm^{-1} of the bromo and iodo chelates are left unassigned. Since the octahedral nickel chelates with a *trans*-planar coordination of 2AMP molecules belong to the C_{2h} point group, two peaks due to the Ni-2AMP stretching and one

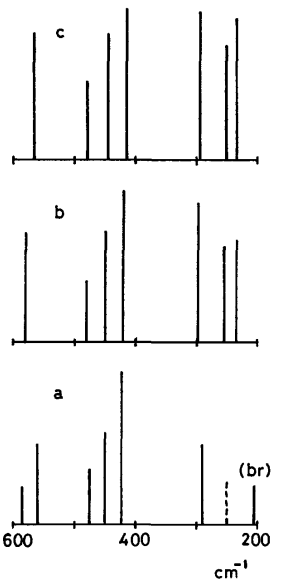

Fig. 6. Far-infrared spectra of $Ni(2AMP)_2X_2$
a: X=Cl, b: X=Br, c: X=I,
broken line: shoulder

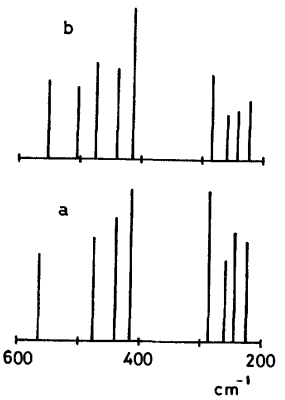

Fig. 7. Far-infrared spectra of $Co(2AMP)_2X_2$
a: X=Br, b: X=I

peak due to the nickel-halide stretching can be expected. Therefore, the far infrared spectra of $Ni(2AMP)_2X_2$ support an octahedral structure.

$Co(2AMP)_2X_2$. Figure 7 shows the far-infrared spectra of $Co(2AMP)_2X_2$. As it has been proposed from the magnetic moment that the bromide chelate is in a tetrahedral configuration which belongs to the C_{2v} point group, four Co-2AMP stretching bands can be expected. The measured spectrum of $Co(2AMP)_2Br_2$ shows four peaks assignable to Co-2AMP stretching vibrations and supports the tetrahedral structure.

The iodide chelate, which may be supposed from the magnetic moment to have a square planar configuration, also shows four peaks attributable to Co-2AMP stretching vibrations. If 2AMP molecules coordinate to cobalt ions in a *trans*-planar form belonging to the C_{2h} point group, two Co-2AMP stretching vibrations should appear. On the other hand, a *cis*-planar configuration, belonging to the C_{2v} point group, should bring about four Co-2AMP stretching vibrations; this is what is found for the iodide chelate.

$Zn(2AMP)_2X_2$. For the three zinc chelates, consistent peaks are observed in the regions of 243—240 cm^{-1} and 210—205 cm^{-1}. The peak at 270 cm^{-1} is characteristic of the chloro chelate and is assigned to the zinc-chloride stretching. These data seem to indicate an octahedral structure for the zinc chelates, with a *trans*-planar coordination of the 2AMP molecules to the zinc ion. The far-infrared assignments are listed in Table 3.

Table 3. The assignments of metal–nitrogen stretching frequencies of $M(2AMP)_2X_2$ (cm^{-1})

Chelates	ν_{M-X}	$\nu_{M-N\,(amino)}$	$\nu_{M-N\,(pyridine)}$	Unassigned
$Cu(2AMP)_2Cl_2$	200	306	270	
$Cu(2AMP)_2Br_2$		310	263	225
$Ni(2AMP)_2Cl_2$	205	290	250	
$Ni(2AMP)_2Br_2$		296	255	235
$Ni(2AMP)_2I_2$		296	252	234
$Co(2AMP)_2Br_2$		287(asym.)	245(asym.)	
		260(sym.)	224(sym.)	
$Co(2AMP)_2I_2$		287(asym.)	243(asym.)	
		260(sym.)	223(sym.)	
$Zn(2AMP)_2Cl_2$	270	240	210	
$Zn(2AMP)_2Br_2$		243	210	
$Zn(2AMP)_2I_2$		240	205	

The assignment of the metal-amino nitrogen to the higher-frequency region of the metal-2AMP stretching vibrations is made on the basis of the basicities of the objective nitrogen atoms. The dissociation constants of 2AMP have been reported to be $10^{-2.14}$ and $10^{-8.57}$ for the pyridine ring nitrogen and the amino nitrogen[11] respectively. The correlation between the pK values of the ligands and stability constants in heterocyclic ammine complexes with the silver ion has been reported to show a trend for the ligand with a higher pK value to have a larger stability constant.[12] This relationship can also be applied to other metal complexes. In the chelate ring of 2AMP with the bivalent metal ions, the linkage between the amino nitrogen and the metal ions may be much stronger than that of the pyridine nitrogen with the same metal ions, so that the former stretching vibration can be expected to appear at a higher frequency than that of the latter.

In order to ascertain the validity of the assignments

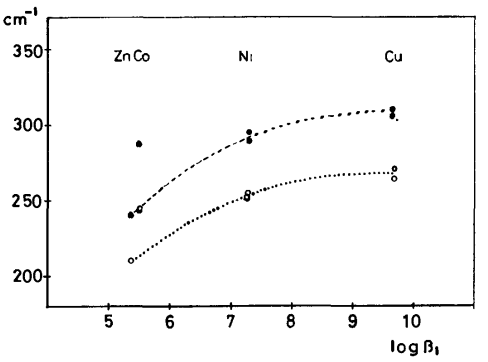

Fig. 8. Plots of M-N(amino) and M-N(pyridine) stretching frequencies *vs.* log β_1 for $M(2AMP)_2X_2$.
—●—●—●— M-N(amino)

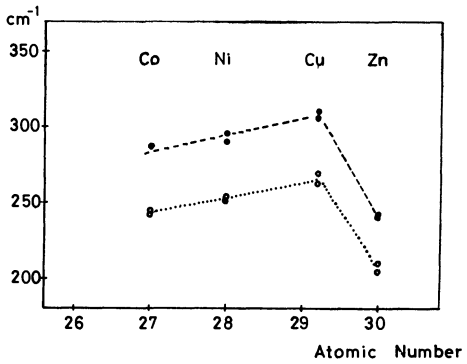

Fig. 9. Plots of M-N(amino) and M-N(pyridine) stretching frequencies *vs.* atomic number for $M(2AMP)_2X_2$.
—●—●—●— M-N(amino)
···○···○···○··· M-N(pyridine)

in the far-infrared spectra, plots were made of the metal-nitrogen stretching vibrations against the stability constants (log β_1) of $M(2AMP)_2X_2$ in aqueous solutions, as is shown in Fig. 8. The deviation of the cobalt chelates from the tendency shown by the other metal chelates may be attributed to their structural differences. However, the general trend for the metal-amino nitrogen stretching frequencies of the bromo chelates is in the following order; Zn(243 cm^{-1})<Cu(310 cm^{-1})> Ni(296 cm^{-1})>Co(287 cm^{-1}), coinciding with the Irving-Williams stability order. A further correlation, as is shown in Fig. 9, exists between the metal-2AMP stretching frequencies and the atomic numbers of the metal ions. The order found is the same as in the case of the stability constants; the Irving-Williams order also holds in spite of their structural differences.

Conclusion

The structures of the $M(2AMP)_2X_2$ complexes were studied by means of the magnetic moments, the diffuse reflectance spectra, and the far-infrared spectra. The $Cu(2AMP)_2X_2$ complexes are considered to have a monomeric distorted octahedral structure, while for $Ni(2AMP)_2X_2$ an octahedral configuration is proposed. The $Co(2AMP)_2Br_2$ complex has the magnetic moment of 4.20 B.M., and electronic absorption maximum at 710 nm, and four Co-2AMP stretching bands; therefore, an tetrahedral structure is proposed. A *trans*-planar configuration may be suitable for $Co(2AMP)_2I_2$, which has a very low magnetic moment of 2.79 B.M. and four Co-2AMP stretching vibrations in the far-infrared region. Only far-infrared spectra are available for $Zn(2AMP)_2X_2$, but the similarity of the spectra and the existence of the zinc-chloride stretching vibration seems to indicate an octahedral structure for the zinc chelates. The order of Zn<Cu>Ni>Co is found in the tentatively-assigned metal-2AMP stretching vibrations, coinciding with the Irving-Williams stability order.

The authors wish to thank Dr. N. Yamanaka of the Government Industrial Institute, Nagoya, for permitting them to use a Shimadzu MB-2 magnetic balance. Thanks are also due to Misses M. Ishiguro and S. Iwauchi of the Analytical Center of their university for the elemental analyses.

gen chloride was added drop by drop to this solution. The initially dark brown solution turned greenish gradually up to moss green at the end. Petroleum ether (200 ml) was added slowly to the solution to separate out a moss green precipitate, of which filtration and vacuum-drying resulted in a very dark green powder. Yield: 0.4 g, 48%. Found: Mn, 23.14; Cl, 30.20; C, 24.06; H, 3.55%. Calcd for $MnCl_2(acac)H_2O$= $C_5H_9O_3Cl_2Mn$: Mn, 22.61; Cl, 29.18; C, 24.72; H, 3.73%. After standing at room temperature the color changed to dark brown.

Preparation of Dichloro(acetylacetonato)bis(pyridine oxide)manganese(III): Pyridine oxide, O-py (2.3 g, 23.9 mmol) was added to a solution of $Mn(acac)_3$ (2.1 g, 6.0 mmol) in methylene chloride (40 ml), and the solution was kept at −78 °C. A methylene chloride solution of hydrogen chloride (12.0 mmol) was added dropwise to this solution. After the reaction an ochreous powder was isolated by the addition of 200 ml of petroleum ether. Yield: 2.0 g, 81%. Found: Mn, 14.06; Cl, 17.69; C, 44.40; H, 4.47; N, 6.24%. Calcd for $MnCl_2(acac)(O\text{-}py)_2$=$C_{15}H_{17}O_4N_2Cl_2Mn$: Mn, 13.23; Cl, 17.08; C, 43.40; H, 4.13; N, 6.75%.

The Reactions of $MnBr(acac)_2$ and $MnI(acac)_2$ with Hydrogen Bromide or Iodide: When a solution of hydrogen bromide (6.8 mmol) in methylene chloride was added at room temperature to a solution of $MnBr(acac)_2$ (1.1 g, 3.4 mmol) in the same solvent, a white precipitate of manganese(II) bromide was produced in a 100% yield, leaving a colorless supernatant solution. Found: Mn, 24.26; Br, 72.69%. The equimolar reaction of $MnBr(acac)_2$ with hydrogen bromide at −78 °C was also examined, but a product of the composition $MnBr_2(acac)\cdot nH_2O$ was not obtained. The reaction of excess hydrogen iodide with $MnI(acac)_2$ in methylene chloride afforded bis(acetylacetonato)manganese(II). Found: C, 45.10; H, 5.26%.

Preparation of Dibromobis(acetylacetone)manganese(II): Tris(acetylacetonato)manganese(III) (1.4 g, 3.8 mmol) was dissolved in a mixture (20 ml) of methylene chloride and acetylacetone (1: 1 by volume). A methylene chloride solution of hydrogen bromide (11.4 mmol) was added dropwise to this solution with vigorous stirring. White tiny crystals were carefully filtered, quickly washed with petroleum ether, and dried under vacuum. Yield 1.2 g, 77%. Found: Mn, 13.10; Br, 38.97; C, 28.20; H, 3.74%. Calcd for $MnBr_2(acacH)_2$= $C_{10}H_{16}O_4Br_2Mn$: Mn, 13.24; Br, 38.51; C, 28.93; H, 3.89%.

Preparation of the Base Adducts of Halogenobis(acetylacetonato)-manganese(III). $Mn(acac)_3$ was allowed to react with an equimolar amount of hydrogen halide in a mixture of diethyl ether, benzene and a base in a similar fashion as described above. Alternatively, $MnX(acac)_2$ was dissolved in acetylacetone containing excess base and heated to 60—70 °C. After filtration of the undissolved residue, the filtrate was kept in a desiccator for a long time to separate out the product.

Chlorobis(acetylacetonato)(pyridine oxide)manganese(III): Pyridine oxide (2.7 g, 28.5 mmol) was added to a solution of $Mn(acac)_3$ (2.5 g, 7.1 mmol) in a mixture of diethyl ether and benzene (4: 1 by volume). A solution of hydrogen chloride (7.1 mmol) in methylene chloride was added drop by drop to this solution. Ochreous crystals (1.8 g) were obtained in a 65% yield. Found: Mn, 14.51; Cl, 8.82; C, 46.21; H, 4.94; N, 4.29%. Calcd for $MnCl(acac)_2$-$(O\text{-}py)$=$C_{15}H_{19}O_5NClMn$: Mn, 14.32; Cl, 9.24; C, 46.95; H, 4.99; N, 3.65%.

Bromobis(acetylacetonato)dioxanemanganese(III) Monohydrate: $Mn(acac)_3$ (2.1 g, 6.0 mmol) was dissolved in a mixture of diethyl ether and benzene (130 ml, 3: 1 by volume) containing dioxane (40 ml). A solution of hydrogen bromide (6.0 mmol) in methylene chloride was added to this solution and allowed to react for 6—7 hr. Black-brown crystals of product (1.0 g) were obtained in a 38% yield. Found: Mn, 12.65; Br, 18.33; C, 38.33; H, 5.56%. Calcd for $MnBr(acac)_2(C_4H_8O_2)\cdot H_2O$=$C_{14}H_{24}O_7BrMn$: Mn, 12.51; Br, 18.19; C, 38.29; H, 5.51%.

Bromobis(acetylacetonato)(4-methylpyridine)manganese(III): $MnBr(acac)_2$ (1.1 g, 3.4 mmol) was dissolved in 50 ml of acetylacetone containing 4-methylpyridine, 4-Me-py (1.2 g, 12.9 mmol), and the mixture was warmed to 60 °C for a while and filtered. The filtrate was kept standing in a desiccator for two days to afford light red crystals. Yield: 0.3 g, 22%. Found: Mn, 13.14; Br, 17.67; C, 45.15; H, 5.02; N, 3.37%. Calcd for $MnBr(acac)_2(4\text{-}Me\text{-}py)$=$C_{16}H_{21}$-$O_4NBrMn$: Mn, 12.89; Br, 18.75; C, 45.09; H, 4.97; N, 3.29%.

Bis(acetylacetonato)diaquomanganese(III) Bromide Dihydrate: $MnBr(acac)_2$ (1.0 g, 3.0 mmol) was dissolved in 40 ml of acetylacetone saturated with water on a hot water-bath. The solution was then kept standing at room temperature to deposit olive-green needles, which were washed with diethyl ether. Yield 0.36 g, 30%. Found: Mn, 13.63; Br, 19.95; C, 30.28; H, 5.46%. Calcd for $[Mn(acac)_2(H_2O)_2]Br\cdot 2H_2O$=$C_{10}H_{22}O_8BrMn$: Mn, 13.56; Br, 19.72; C, 29.65; H, 5.47%. The corresponding chloride $[Mn(acac)_2(H_2O)_2]Cl\cdot 2H_2O$ was also derived in a similar way from $MnCl(acac)_2$ in a 32% yield, and identified by the IR spectra.

The Ligand Substitution of Chlorobis(acetylacetonato)manganese-(III) with Dibenzoylmethane. A solution of dibenzoylmethane, dbmH (1.7 g, 7.5 mmol) in methylene chloride (10 ml) was added slowly to a solution of $MnCl(acac)_2$ (1.0 g, 3.7 mmol) in the same solvent (20 ml), and the mixture was kept standing for 1 hr at room temperature to separate out light red crystals of $MnCl(dbm)_2$. Yield: 0.55 g, 30%. Found: Mn, 10.11; Cl, 6.33; C, 66.05; H, 4.22%. Calcd for $MnCl(dbm)_2$=$C_{30}H_{22}O_4ClMn$: Mn, 10.23; Cl, 6.60; C, 67.11; H, 4.13%.

Analysis. Each specimen of compounds was dried *in vacuo* at room temperature before subjecting to elemental analysis. The content of manganese was determined gravimetrically as manganese(II) sulfate, and those of chlorine and bromine as the silver salts. The concentration of hydrogen chloride and bromide in methylene chloride was measured by the method reported previously.[1]

Measurements. The visible and ultraviolet absorption spectra were measured by means of a Hitachi EPS-3T autorecording spectrophotometer. The infrared spectra were taken in Nujol on JASCO IR-E (4000—700 cm^{-1}), Hitachi EPI-L (700—200 cm^{-1}) and FIS-3 (400—30 cm^{-1}) infrared spectrophotometers.

The magnetic susceptibility was measured at various temperatures down to 77 K by the Gouy method with an automatically recording magnetic balance MB-2 of Shimadzu Seisakusho Co., Ltd. Hexaamminechromium(III) chloride was prepared and used as a reference. Found: H, 6.97; N, 32.50%. Calcd for $[Cr(NH_3)_6]Cl_3$=$H_{18}N_6Cl_3Cr$: H, 6.96; N, 32.26%.

The molecular weight was determined by the vapor-pressure osmometry with an apparatus manufactured by Knauer, Germany. Methanol and methylene chloride were used as the solvent, and benzil as a reference. The electric conductivity was measured in methanol or nitromethane by means of an MY-SERIAL 814007 apparatus of Yanagimoto Seisakusho, Ltd. The thermogravimetric measurement was performed with a thermo-spring-balance C-282 of Hamada Denki Seisakusho, Ltd.

Table 1. Molecular weight, conductance and magnetic moment data of halogenobis(acetylacetonato)manganese(III)[a]

Complex	Molecular weight			Molar conductance at 25 °C/ohm^{-1}·cm^2·mol^{-1}		Magnetic moment at (temp.)/B.M.
	in CH_2Cl_2 at 37 °C	in CH_3OH at 45 °C	Calcd	in CH_3NO_2	in CH_3OH	
$MnCl(acac)_2$	283	154	289	16	102	4.88 (20 °C)
$MnBr(acac)_2$	312[b]	157	333	18	88	4.93 (21 °C)
$MnI(acac)_2$	346	198	380	28	85	4.72 (22 °C)

a) The molecular weight was measured at 1.5—4.5 × 10^{-2} M, and the molar conductance at 5 × 10^{-4} M.
b) Measured at 25 °C.

Results

Tris(acetylacetonato)manganese(III) readily reacts with excess hydrogen chloride, bromide or iodide in organic solvents to produce manganese(II) chloride, bromide or bis(acetylacetonato)manganese(II), respectively. These redox reactions seem to proceed successively *via* a few intermediates. In fact several halogenobis(acetylacetonato)- and dichloroacetylacetonato-manganese(III) complexes have been isolated as intermediary products under the controlled reaction conditions.

Characterization of Halogenobis(acetylacetonato)manganese(III). The primary intermediate was afforded by the equimolar reaction between $Mn(acac)_3$ and hydrogen halide. The composition was established by the elemental analysis to be $MnX(acac)_2$, where X is Cl, Br, or I. As shown in Table 1 the magnetic moment at room temperature lies in the range of 4.72—4.93 B.M., indicating that they are all high-spin Mn(III) complexes.

The molecular weight determined in methylene chloride is near to the calculated value, indicating that each of the $MnX(acac)_2$ complexes exists essentially as a discrete molecule in the non-coordinating solvent. The measurement was performed at several concentrations in the range of (1.5—4.5) × 10^{-2} M, and no appreciable dependence of the molecular weight on concentration was noticed. However, close examination of the figures in Table 1 discloses that the discrepancy between the observed and the calculated values becomes larger in the order of X=Cl<Br<I. The molar conductance in nitromethane at 25 °C also indicates that they are essentially nonelectrolytes in this solvent, but the observed values show a slight increase in the same order. These results might indicate that the $MnX(acac)_2$ complexes have some tendencies to ionize even in the non-coordinating solvent increasing in the order of X=Cl<Br<I.

In methanol they dissociate almost completely and the observed molecular weight nearly coincides with half of the formular weight. The molar conductance in the same solvent reveals that the halide ion is extensively dissociated although the value is smaller in comparison with 118 ohm^{-1}·cm^2·mol^{-1} of tetraethylammonium iodide in methanol (113 ohm^{-1}·cm^2·mol^{-1} in nitromethane). It may be presumed that the complex is solvolyzed in methanol and the manganese(III) atom is six-coordinated:

$$MnX(acac)_2 + 2CH_3OH \longrightarrow Mn(acac)_2(CH_3OH)_2^+ + X^-$$

The assumed compound $[Mn(acac)_2(CH_3OH)_2]X$ could not be isolated, but recrystallization of $MnCl(acac)_2$ from acetylacetone saturated with water afforded $[Mn(acac)_2(H_2O)_2]Cl\cdot 2H_2O$. The corresponding bromide $[Mn(acac)_2(H_2O)_2]Br\cdot 2H_2O$ was also obtained from $MnBr(acac)_2$ in a similar way. Bis(acetylacetonato)-diaquomanganese(III) chloride had previously been prepared by Cartledge[7] by the trituration of $Mn(acac)_3$ with 1F hydrochloric acid or by the following reaction.

$$4MnCl_2 + KMnO_4 + 10acacH + 6H_2O = 5[Mn(acac)_2(H_2O)_2]Cl + KCl + 2HCl$$

Funk and Kreis prepared $MnCl(acac)_2$ and $MnCl_2(acac)$ by the reaction of manganese(III) chloride with acetylacetone in diethyl ether at −40 °C, but reported nothing about their properties.[8] The complexes $MnBr(acac)_2$ and $MnI(acac)_2$ are new compounds. On the other hand, the Mn(III) Schiff base (SBH_2) complexes of the type MnX(SB) have been studied rather extensively[9,10] in connection with the biological interest,[11] and their behaviors in solution were investigated. Van den Bergen, *et al.*[12] recorded the molar conductance of $MnBr(sal\text{-}N\text{-}Pr^n)_2$ and $MnOCOCH_3(sal\text{-}N\text{-}Pr^n)_2$ in nitromethane to be 4.96 and 0.192 ohm^{-1}·cm^2·mol^{-1}, respectively, and that of MnBr(salen) and MnI(salen) in methanol to be 69 and 71 ohm^{-1}·cm^2·mol^{-1}, respectively. Here sal-N-Pr^n denotes salicylaldehyde-*n*-propylimine, and salen*N,N'*-bis(salicylidene)ethylenediamine. The conductance data reported by Prabhakaram and Patel also reveal that the MnX(salen) complexes (X=Cl, Br, or I) dissociate very little in acetonitrile, while to a considerable extent in methanol and water.[13]

Infrared Spectra: In order to obtain informations concerning the structure of the $MnX(acac)_2$ complexes, their infrared spectra were measured in Nujol mull. In Fig. 1 the spectrum of $MnCl(acac)_2$ is compared with that of $FeCl(acac)_2$ which was prepared by the reaction of $Fe(acac)_3$ with hydrogen chloride in methylene chloride.[5] The parent complex $Mn(acac)_3$ shows the ν_s(C=O) and ν_{as}(C=C=C) bands at 1585 and 1520 cm^{-1}, and $Fe(acac)_3$ at 1565 and 1525 cm^{-1}, respectively. The higher frequency bands are lost in both $MnCl(acac)_2$ and $FeCl(acac)_2$, and shoulders are observed at 1546 and 1549 cm^{-1}, respectively. The δ(C–H) band around 1200 cm^{-1} is very much weaker

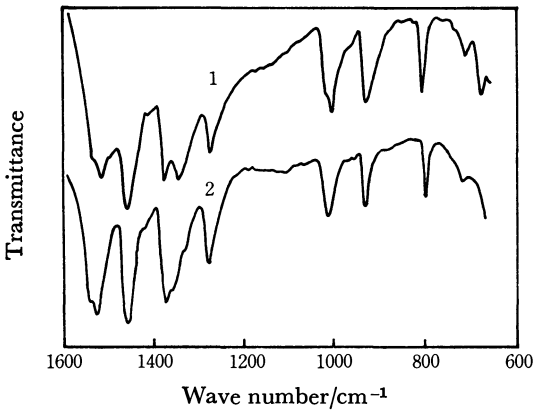

Fig. 1. Infrared spectra of $MnCl(acac)_2$ (curve 1) and $FeCl(acac)_2$ (curve 2).

in $MCl(acac)_2$ than in $M(acac)_3$, and the absorption assigned to $\nu_s(C{=}C{-}C)$ is shifted to the higher frequency 1280—1290 cm^{-1} region in the former mixed-ligand complex. Such a close resemblance in the IR spectra of $MnCl(acac)_2$ and $FeCl(acac)_2$ strongly suggests that both complexes have the same structure.

The molecular structure of $FeCl(acac)_2$ was determined by the X-ray analysis to be square-pyramidal with the chlorine atom located at the apical position,[14] and hence $MnCl(acac)_2$ can also be assumed to have the square-pyramidal structure, and not the trigonal-bipyramidal geometry. The IR spectra of $MnBr(acac)_2$ and $MnI(acac)_2$ are quite similar to that of the chloro complex, implying the structural analogy.

The infrared spectra in the 400—150 cm^{-1} region are shown in Fig. 2. The peak around 343 cm^{-1} is observed for each of the three $MnX(acac)_2$ complexes in common, and thus assigned to the ν(Mn–O) vibration. The corresponding absorption appears at 335 cm^{-1} in the parent complex $Mn(acac)_3$, and at 375 and 348 cm^{-1} in tris(salicylaldehydato)manganese(III).[12]

The stretching vibration of the terminal Mn(III)–Cl bond is observed in the 270—340 cm^{-1} region for the $MnCl_3L_3$ complexes where L is the oxide of pyridine, triphenylphosphine, or triphenylarsine,[15] and at 310 cm^{-1} for $MnCl(sal\text{-}N\text{-}Pr^n)_2$.[12] Thus the strong peak observed at 290 cm^{-1} for the present chloro complex $MnCl(acac)_2$ (Fig. 2) can reasonably be assigned to the ν(Mn–Cl) vibration. The corresponding strong absorption of $MnBr(acac)_2$ at 262 cm^{-1} is attributed to the ν(Mn–Br) vibration. Boucher[16] ascribed the most prominent absorption of the supposedly octahedral Mn(III) complex $MnX(H_2O)$ (protoporphyrin IX dimethyl ester) in the 650—160 cm^{-1} region to the manganese-halogen stretching vibration: 462 cm^{-1} for F^-, 262 cm^{-1} for Cl^-, 211 cm^{-1} for Br^-, and 190 cm^{-1} for I^-. These frequencies are rather low in comparison with the above-mentioned data, but show the expected decrease with the increasing mass of the halogen.

As is indicated in Fig. 2, $MnI(acac)_2$ exhibits two peaks in the ν(Mn–X) region. It can not be unequivocally concluded at the present stage of investigation which of the two bands at 254 and 219 cm^{-1} is related to the ν(Mn–I) vibration. Here we tentatively assign the 219 cm^{-1} peak to the ν(Mn–I) on a consideration of the mass effect. At any rate the fact that the frequencies of the ν(M–X) vibrations in the $MnX(acac)_2$ complexes lie in the region acceptable for the terminal Mn–X bonds is also compatible with the proposed five-coordinate structure.

Electronic Spectra: The $MnCl_5^{2-}$ ion was found to have a slightly elongated square-pyramidal structure in the bipyridinium[17] and phenanthrolinium[18] salts. Crystal polarized spectra of these Mn(III) compounds were recorded by Bellitto, *et al.*,[19] and it was concluded that three d-d transitions occur at $<20\times10^3$ cm^{-1}, and that the absorption present at *ca.* 24×10^3 cm^{-1} is due to

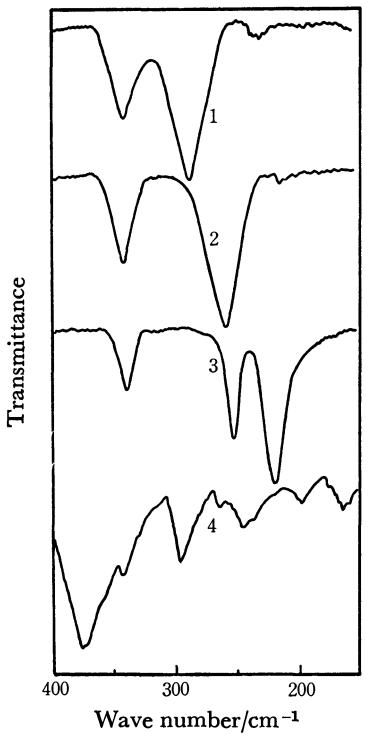

Fig. 2. Infrared spectra in the low-frequency region of $MnX(acac)_2$, where X=Cl (curve 1), Br (curve 2), or I (curve 3), and $MnCl_2(acac)\cdot H_2O$ (curve 4).

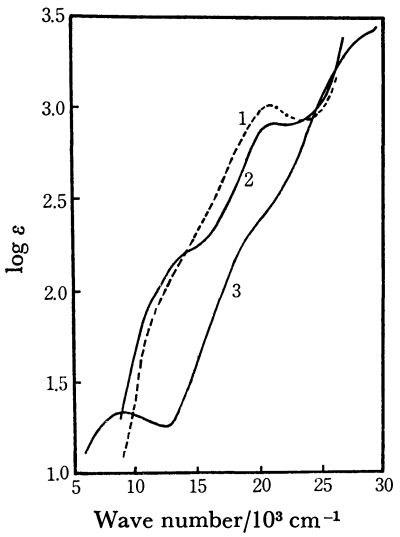

Fig. 3. Absorption spectra of $MnX(acac)_2$ in CH_2Cl_2, where X=Cl (curve 1), Br (curve 2), or I (curve 3).

a charge transfer transition. Boucher[20] also measured absorption spectra of several Schiff base complexes MnCl(SB), and assigned weak absorptions in the 12—21 $\times 10^3\,cm^{-1}$ region to the d-d transitions.

The observed visible absorption spectra of the present $MnX(acac)_2$ complexes in methylene chloride are reproduced in Fig. 3. The bromo complex shows a maximum at $20.8\times10^3\,cm^{-1}$ ($\varepsilon=850$) and two discernible shoulders at 14.3 and $11.8\times10^3\,cm^{-1}$. The chloro complex also exhibits a more intense maximum at $20.8\times10^3\,cm^{-1}$ ($\varepsilon=1070$) and very broad indistinct shoulders in the 14.3—$10\times10^3\,cm^{-1}$ region. On the other hand $MnI(acac)_2$ has shoulders at *ca.* 27.8 and $20\times10^3\,cm^{-1}$, and a broad maximum at $9.1\times10^3\,cm^{-1}$ ($\varepsilon=23$). Low energy absorptions below $20\times10^3\,cm^{-1}$ may be assigned to the d-d transitions. The reason is not clear why only the iodo complex shows a distinct maximum in the $9\times10^3\,cm^{-1}$ region, while its spectrum in methanol (Fig. 4) is quite similar to those of chloro and bromo complexes.

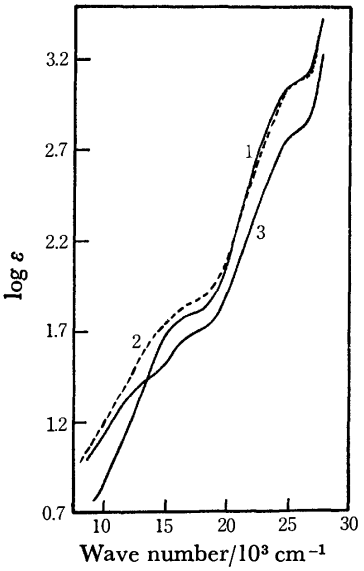

Fig. 4. Absorption spectra of $MnX(acac)_2$ in methanol, where X=Cl (curve 1), Br (curve 2), or I (curve 3).

The absorption bands at $20.8\times10^3\,cm^{-1}$ observed for methylene chloride solutions of both the chloro and bromo complexes and a shoulder at $27.8\times10^3\,cm^{-1}$ of the iodo complex seem to be ascribed to the same transition. In methanol all these absorptions appear equally as a shoulder at $25\times10^3\,cm^{-1}$. It is difficult to conclude that they are assigned to the charge transfers, since they are supported by the general (background) absorption though their extinction coefficients are apparently high.

Magnetic Properties: The magnetic susceptibility of the $MnX(acac)_2$ complexes was determined at lower temperatures down to 77 K. The reciprocal of the molar susceptibility corrected for diamagnetism was plotted in Fig. 5 against the absolute temperature. All of these three compounds gave good straight lines, indicating to obey the Curie-Weiss law $\chi_M'=C/(T+\theta)$. The θ values were obtained from an extrapolation of the straight line to be 13, 11, and 68 K for the chloro, bromo, and iodo complexes, respectively.

Preparation of Dibromobis(acetylacetone)manganese (II).

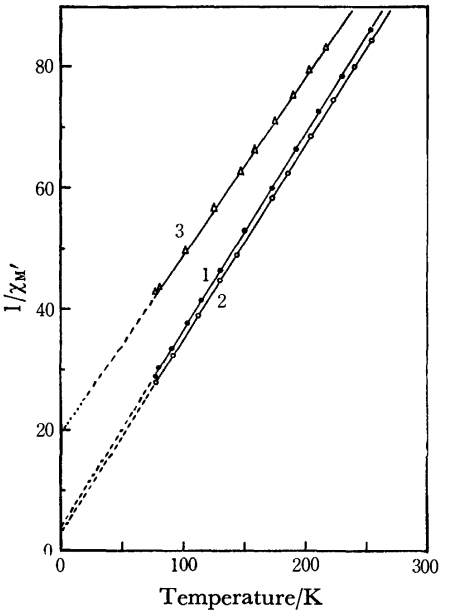

Fig. 5. Curie-Weiss plots for $MnCl(acac)_2$ (1), $MnBr(acac)_2$ (2) and $MnI(acac)_2$ (3).

As described already the reaction of excess hydrogen bromide with $Mn(acac)_3$ in methylene chloride afforded $MnBr_2$ quantitatively, but if acetylacetone had been added in advance to the solution, $MnBr_2(acacH)_2$ was produced in a good yield. This compound was previously prepared by the reaction of anhydrous $MnBr_2$ with acetylacetone,[21] but the present method offers a much more convenient route. Preparation of the corresponding chloro complex in a similar way was unsuccessful presumably because of instability of $MnCl_2(acacH)_2$.

The Six-coordinate Mixed Ligand Mn(III) Complexes. The five-coordinate complex $MnX(acac)_2$ is readily solvolyzed in methanol, producing the presumably six-coordinate cation $Mn(acac)_2(CH_3OH)_2^+$. Similarly the formula $[Mn(acac)_2(H_2O)_2]X\cdot2H_2O$ (X=Cl, Br) was assigned to the tetra-hydrate obtained by the recrystallization of $MnX(acac)_2$ from acetylacetone containing water. Non-existence of the ν(Mn–X) vibration in the IR spectrum of these salts indicates that the halide ion does not exist in the coordination sphere. As illustrated in Fig. 6 the thermogravimetric analysis of the bromide

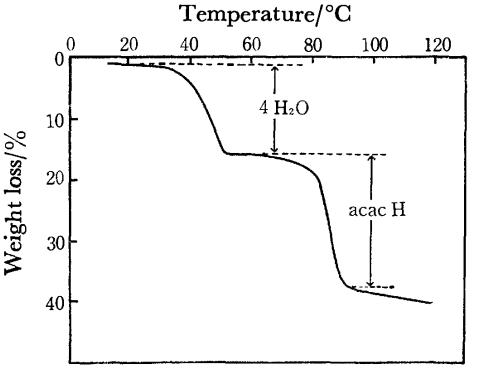

Fig. 6. Thermogravimetric analysis of $[Mn(acac)_2(H_2O)_2]Br\cdot2H_2O$ under vacuum at the heating rate of 10 °C/hr.

Fig. 7. The IR spectrum in the 1700—1500 cm^{-1} region of $[Mn(acac)_2(H_2O)_2]Cl \cdot 2H_2O$ (curve 1) and that after heating for a while at 50 °C (curve 2).

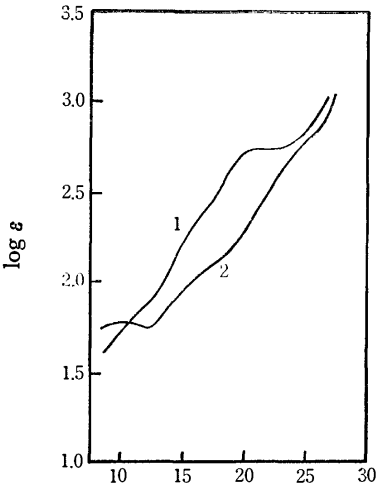

Fig. 8. Absorption spectra of $MnCl(acac)_2(O\text{-}py)$ in CH_2Cl_2 in the absence (curve 1) and the presence (curve 2) of added pyridine oxide.

in vacuo could not discriminate the two types of water involved in this compound. Water begins to vaporize gradually at around 35 °C and is lost completely at 50 °C leaving $MnBr(acac)_2$, which was recovered and identified on interuption of thermolysis.

As shown in Fig. 7 the IR spectrum of $[Mn(acac)_2(H_2O)_2]Cl \cdot 2H_2O$ exhibits two bands in the region of HOH bending vibration, and the band at 1650 cm^{-1} disappears in preference to that at 1620 cm^{-1} on heating for a while at 50 °C. The higher frequency vibration may be ascribable to the lattice water.

After the loss of water, weight of the specimen still continued to decrease with temperature and became nearly constant at 90 °C (Fig. 6). The weight loss in the 75—90 °C region corresponds to one mole of acetylacetone, and in fact the volatile material trapped at −78 °C was identified to be acetylacetone by the IR and UV assays. Composition of the residue (Mn: 21.89, Br: 31.01, C: 27.90, H: 3.21%) is close to MnBr(acac), and its IR spectrum indicates the remaining of the acetylacetonate group. Very dark color might suggest the contamination with some Mn(III) species, but the detailed course of the thermal decomposition and the exact nature of the residue are not certain.

Several neutral six-coordinate complexes of the type $MnX(acac)_2B$ were prepared, where X is Cl or Br and B is dioxane, 4-methylpyridine or pyridine oxide. Figure 8 reveals that the absorption spectrum of $MnCl(acac)_2(O\text{-}py)$ in methylene chloride resembles that of $MnCl(acac)_2$, but a spectrum in the presence of added pyridine oxide is quite similar to that of $Mn(acac)_3$. These results suggest that the base adduct is not so stable, but dissociates extensively in solution.

It is worth noting that 2,2′-bipyridine and 1,10-phenanthroline both react with MnBr(acac), reducing Mn(III) and resulting $MnBr_2(bipy)_2$ and $MnBr_2(phen)_2$, respectively. Another important finding is the lability of $MnX(acac)_2$. Although $Mn(acac)_3$ is substitution-inert and converted to $Mn(dbm)_3$ only under severe reaction conditions, the reaction of $MnX(acac)_2$ with dibenzoylmethane (dbmH) proceeds readily at room temperature, affording $MnX(dbm)_2$. The more detailed kinetic study of this interesting reaction is desirable.

Dichloro(acetylacetonato)manganese(III) Complexes. When $MnX(acac)_2$ (X=Cl or Br) was allowed to react with equimolar amount of HX in methylene chloride at room temperature, a precipitate of $MnCl_2$ or $MnBr_2$ was produced, but the solution still contained remaining $MnX(acac)_2$. Twice as many moles of hydrogen halide were necessary to complete the reaction resulting in a colorless solution. Then the manganese was quantitatively converted to MnX_2, and the freed acetylacetone in solution was determined spectrophotometrically to correspond to *ca.* 50% of acetylacetone contained in $MnX(acac)_2$. Thus the overall reaction is represented by the following reaction:

$MnX(acac)_2 + 2HX = MnX_2 + acacH +$ decomposition products. Here X is Cl or Br. In the case of $MnI(acac)_2$, a similar reaction did not produce MnI_2, but afforded $Mn(acac)_2$.

In contrast to $MnX(acac)_2$, the dihalogeno complex $MnX_2(acac)$ is not stable enough to allow isolation in the reaction at room temperature, but induces the reduction of Mn(III) to Mn(II). However, $MnCl_2(acac)H_2O$ and $MnCl_2(acac)(O\text{-}py)_2$ could be obtained by reactions at −78 °C. The IR spectrum of $MnCl_2(acac)H_2O$ in the 4000—700 cm^{-1} region is quite similar to that of $MnCl(acac)_2$ except that the former has bands related to the coorinated water at 3440 and 1605 cm^{-1}, and that the band assignable to the ν_s(C=C=C) vibrations are split into two bands at 1280 and 1310 cm^{-1}.

On the other hand the spectrum in the lower frequency region is remarkably different from that of $MnCl(acac)_2$ (Fig. 2). The strong absorption at 377 cm^{-1} may be assigned to the ν(Mn–O) vibration, and the 294 cm^{-1} peak to ν(Mn–Cl). It is not certain at the present stage of investigation whether the 235 cm^{-1} or other minor bands could be ascribed to the bridging Mn–Cl stretch. It seems worth noting that frequency

of the ν(Mn–O) vibration increases in the order of $Mn(acac)_3$ (335 cm^{-1})<$MnCl(acac)_2$ (343 cm^{-1})<$MnCl_2(acac)H_2O$ (377 cm^{-1}), and that of the ν(C=O) vibration decreases in the same sequence from 1585 to 1520 and 1510 cm^{-1}, reflecting the strengthening of the Mn–O(acac) bond by the chloride substitution.

Discussion

Except the most stable divalent state manganese can exist in several higher oxidation states[9] and even the Mn(III) species functions as an oxidant for various substrates.[22] Tris(acetylacetonato)manganese(III) is especially useful for organic substrates because of its solubility in organic solvents, and has been shown, for example, to effect the oxidative coupling of phenols[23] and oxidative intramolecular cyclization of *p*-hydroxybenzyl ketoximes.[24]

Even by the reaction with hydrogen halide in non-coordinating solvent, $Mn(acac)_3$ is reduced to the Mn(II) species. The detailed mechanism of this redox reaction could not be established by the present investigation, but the preceding reaction steps seem to proceed in the following sequence (Eq. (i)).

$$Mn(acac)_3 \xrightarrow{+HX} \left[(acac)_2Mn\begin{matrix}X\\ \diagdown acacH\end{matrix}\right] \xrightarrow{-acacH}$$

Intermediate **1**

$$(acac)\overset{X}{\underset{|}{M}}n(acac) \xrightarrow{+HX} \left[(acac)\overset{X}{\underset{|}{M}}n\begin{matrix}X\\ \diagdown acacH\end{matrix}\right] \quad (i)$$

Intermediate **2**

The intermediates **1** and **2** have not been identified, but are just presumed here. In the reaction of $MnCl(acac)_2$ with hydrogen chloride at −78 °C, addition of petroleum ether to the methylene chloride solution precipitated $MnCl_2(acac)H_2O$, but warming of the reaction mixture to room temperature instead of adding petroleum ether resulted in a precipitate of $MnCl_2$, and the filtrate contained $MnCl(acac)_2$. Thus, such a reaction as represented by Eq. (ii) might have occurred in methylene chloride at room temperature.

$$2[MnCl_2(acac)(acacH)] \longrightarrow MnCl_2 + MnCl(acac)_2 + acacH + \text{decomposition products} \quad (ii)$$

Intermediate **2**

The decomposition products are not identified, but are assumed to be resulted by reactions involving acetylacetone radicals. Equation (ii) can explain why twice as many moles of hydrogen chloride were necessary to convert $MnCl(acac)_2$ to $MnCl_2$ completely.

Electron transfer in the reaction between $Mn(acac)_3$ and a primary amine such as ethylenediamine was concluded in a previous paper[4] to occur in the following step (iii).

$$(acac)_2Mn\begin{matrix}acac\\ \diagdown en\end{matrix} \longrightarrow (acac)_2Mnen + acac\cdot \quad (iii)$$

Similarly in the reaction (ii), an electron might be transferred from the acetylacetonate ligand to Mn(III):

$$MnCl_2(acac)(acacH) \longrightarrow MnCl_2 + acacH + acac\cdot \quad (iv)$$

followed by the attack of an acetylacetone radical on a chloride ligand in another molecule of $MnCl_2(acac)(acacH)$:

$$acac\cdot + MnCl_2(acac)(acacH) \longrightarrow MnCl(acac)_2 + (acac\cdot)HCl \longrightarrow \text{decomposition} \quad (v)$$

The reaction of $MnBr(acac)_2$ with HBr seems to follow a similar sequence, while $MnI(acac)_2$ reacts with HI affording $Mn(acac)_2$ instead of MnI_2. Although $MnI(acac)_2$ is stable at room temperature, it readily liberates iodine molecules on heating or by the reaction with acids. Thus an electron must be transfered from an iodide ligand to the manganese atom in the presumable intermediate $MnI_2(acac)(acacH)$.

$$MnI(acac)_2 + HI \longrightarrow [MnI_2(acac)(acacH)] \longrightarrow Mn(acac)_2 + HI + I\cdot \quad (vi)$$

These considerations lead to the conclusion that the tendency of a ligand to deliver an electron to manganese(III) increases in the following sequence: Cl^-<Br^-<$acac^-$<I^-. In order to clarify the detailed mechanism of these redox reactions, further kinetic studies are desired.

The magnetic susceptibility of apparently five-coordinate manganese(III) complexes has been studied hitherto in connection with their structures. Goodwin and Sylva[25] determined the magnetic susceptibilities of $(bipyH_2)[MnCl_5]$, $(phenH_2)[MnCl_5]$, $MnCl_3(H_2O)$(bipy), $MnCl_3(H_2O)$(phen), $MnF_3(H_2O)$(phen), $MnCl_3$(terpy), $MnCl_3$(bipy), and $MnCl_3$(phen) over the temperature range 100—300 K. All compounds obey the Curie-Weiss law, and the first six have small θ values (7 to 25 K), indicating that they are simple paramagnetics. On the other hand the last two compounds have very large θ values (154 and 183 K, respectively), and the antiferromagnetic behavior was presumed to be due to their chloro-bridged dimeric structures.

The Curie-Weiss behavior of MnBr(salen) and MnI(salen) was reported by van den Bergen, *et al.*[12] (θ=22 and 20 K, respectively), and explained in terms of very weak antiferromagnetic interactions. Earnshaw, *et al.*[26] also measured the magnetic susceptibility of MnOAc(salen) over the temperature range 85—300 K. This compound obeys the Curie-Weiss law with θ=22 K, and was considered to have the antiferromagnetic interactions possibly due to the polymeric structure. Recent X-ray study[27] of this compound really confirmed the linear polymeric chains of Mn(salen) moieties bridged by acetate groups.

The present complexes $MnCl(acac)_2$ and $MnBr(acac)_2$ have magnetic moments of 4.88 and 4.93 B.M. at 20 and 21 °C, respectively, which are close to the calculated spin-only value of 4.90 B.M. These complexes obey the Curie-Weiss law, but their θ values (13 and 11 K, respectively) are not so large as the indicate the intermolecular linkage in the solid state. On the other hand $MnI(acac)_2$ has a lower μ_{eff} value of 4.72 B.M. at 22 °C, and a rather large θ value of 68 K.

It may be appropriate to presume that the iodo complex has a strong intermolecular interaction, the iodide ligand bridging two manganese atoms just as the azide group in $MnN_3(acac)_2$.[28] Such a structural feature might be responsible for the IR pattern in the ν(Mn–I) region which is different from those of the chloro and bromo complexes. The exact structure must be determined by the X-ray analysis in future.

The authors are grateful to Dr. Y. Nakamura for his helpful discussion and Mr. J. Gohda for the elemental analysis. The financial aid by the Ministry of Education and the kind supply of acetylacetone by the Daicel Co., Ltd. are also acknowledged.

(Received June 27, 1974)

Seven new compounds with the Sn–Mn bond have been prepared by carbonyl displacement with a weaker π-accepting ligand, L (L=$P(C_6H_5)_3$, $As(C_6H_5)_3$, $Sb(C_6H_5)_3$ for R_3Sn–$Mn(CO)_5$) or by reaction of the anion $[Mn(CO)_5]^-$ or $[Mn(CO)_4P(C_6H_5)_3]^-$ with R_3SnX (R=C_2H_5, n-C_3H_7, n-C_4H_9). A *trans* configuration is deduced for the mono-substituted compounds, R_3Sn–$Mn(CO)_4L$, on the basis of the infrared spectra in the ν(CO) region. The ^{119}Sn–Mössbauer and IR spectra are measured for sixteen compounds of the R_3Sn–$Mn(CO)_{5-n}L_n$ type (R=CH_3, C_2H_5, n-C_3H_7, n-C_4H_9, Cl, Br, I; L=$P(C_6H_5)_3$, $As(C_6H_5)_3$, $Sb(C_6H_5)_3$; n=0 or 1). Both the Mössbauer-isomer shift and the quadrupole splitting increase with an increase in the length of the alkyl chain attached to the tin atom. The replacement of CO on the manganese atom with the weaker π-accepting ligand, L, has a significant effect on the isomer shift and quadrupole splitting of the tin atom through the σ- and π-interaction between the tin and manganese atoms. An interpretation of the change in the chemical shift of the terminal methyl protons is also given for alkyl derivatives.

The natue of the Sn–Mn bonding and the effect of substituents on the nature of the Sn–Mn bonding have been studied by various kinds of spectroscopic means for a series of compounds, $R_{3-x}X_xSn$–$Mn(CO)_{5-n}L_n$.[1-8] It has been reported that not only the substituents attached to the Sn atom but also those attached to the Mn atom can exert significant effects on the Sn–Mn bonding nature. The present study was undertaken in order to provide further evidence for the effect of the substituent attached to the metal atoms on the nature of the Sn–Mn bonding by using ^{119}Sn–Mössbauer and proton NMR spectroscopic techniques. For this purpose, some new compounds with a Sn–Mn bond were synthesized; the effects of weak π-accepting ligands, such as $M(C_6H_5)_3$ (M=P, As, and Sb), on the Sn–Mn bonding in a series of R_3Sn–$Mn(CO)_4M(C_6H_5)_3$ compounds were also described.

Experimental

Preparation of Compounds. All the reactions were carried out under a nitrogen atmosphere.

Preparation of R_3Sn–$Mn(CO)_5$ ($R=C_2H_5$, n-C_3H_7, and n-C_4H_9). These compounds were synthesized by a procedure similar to Gorsich's method.[9] A solution containing 20 mmol of R_3SnCl in 50 ml of THF was stirred into a solution of THF containing 20 mmol of $NaMn(CO)_5$. After stirring at room temperature for 3 hr, the precipitates of sodium chloride were separated from the organic phase by centrifuging. The solution was then evaporated under reduced pressure, and traces of the solvent and unreacted trialkyltin chloride were distilled off through a fractionating column. A pale yellow liquid was obtained from the residual yellow oil by fractional distillation under reduced pressure. The boiling points of the products are presented in Table 1, along with the results of carbon and hydrogen analyses.

Preparation of $(C_2H_5)_3Sn$–$Mn(CO)_4P(C_6H_5)_3$. 0.86 g (2 mmol) of $Mn(CO)_4P(C_6H_5)_3$ was reduced to $NaMn(CO)_4P(C_6H_5)_3$ in 50 ml of THF by stirring with a 1% sodium amalgam at room temperature.[10] After stirring for 1 hr, the THF solution was decanted into another flask; 0.48 g (2 mmol) of triethyltin chloride in 50 ml of THF was then stirred in. The mixture was stirred at room temperature for 3 hr. The organic phase was separated from fine precipitates of sodium chloride by centrifugation. The orange solution was concentrated under reduced pressure, and some unreacted triethyltin chloride was distilled off at 60 °C (5×10^{-2} mmHg). The residual yellow powder was dissolved into 50 ml of n-hexane with refluxing. The hexane solution was then filtered, and the filtrate was concentrated to about 20 ml *in vacuo* to give yellow, needle-like crystals of $(C_2H_5)_3Sn$–$Mn(CO)_4P(C_6H_5)_3$ (0.8 g, yield 63%). Recrystallization was effected from the same solvent.

Preparation of $(CH_3)_3Sn$–$Mn(CO)_4P(C_6H_5)_3$ and $(CH_3)_3Sn$–$Mn(CO)_4As(C_6H_5)_3$. A mixture of 3.6 g (0.01 mol) of $(CH_3)_3Sn$–$Mn(CO)_5$ and 2.6 g (0.01 mol) of $P(C_6H_5)_3$ or 3.06 g (0.01 mol) of $As(C_6H_5)_3$ was heated at about 120 °C for 2 hr. The resulting yellow material was recrystallized from hexane several times to give pale yellow crystals. All the spectral data support the idea that both the products are mono-substituted, although the elemental analysis of the compound prepared from $P(C_6H_5)_3$ gives a little higher carbon content than the value calculated for $(CH_3)_3Sn$–$Mn(CO)_4P(C_6H_5)_3$.

Preparation of $(C_6H_5)_3Sn$–$Mn(CO)_4Sb(C_6H_5)_3$. A mixture of 1.6 g (3 mmol) of $(C_6H_5)_3Sn$–$Mn(CO)_5$ and 1.1 g (3 mmol) of $Sb(C_6H_5)_3$ was heated at about 190 °C for 2 hr. The reaction products were each extracted three times with 25 ml portions of a 2:1 mixture of ethanol and benzene. The extracts were then concentrated to about half the original volume *in vacuo*. Yellow crystals were precipitated on cooling. Recrystallization was effected from the same mixture of solvents.

The analytical data of these new compounds are shown in Table 1, along with some of their physical properties. All the other compounds were prepared by the methods described in Refs. 7 and 9.

Mössbauer Spectra. The ^{119}Sn-Mössbauer spectra were obtained against a $Ba^{119m}SnO_3$ source moving in a constant acceleration mode at room temperature. The sample was used as an absorber and was kept at 79 K in a cryostat. The calibration of the velocity was made as has previously been reported.[1]

NMR Spectra. The NMR data were obtained on dichloromethane solutions of the samples by means of a

Hitachi-Perkin-Elmer R-20B Spectrometer (60 MHz) at room temperature; the solvent was used as the internal standard. The chemical shift values listed in Table 2 were recalculated with respect to tetramethylsilane (TMS) at an infinite dilution.

IR Spectra. The IR spectra of the CO stretching region were recorded on a JASCO IR-G spectrometer in hexane or chloroform solutions by use of a 0.1 mm KBr liquid cell. The spectra were calibrated by making use of gaseous DCl by means of a superposition method.

All the spectral results are given in Table 2.

Results and Discussion

In a previous paper, it was reported that $(CH_3)_3Sn–Mn(CO)_5$ shows a quadrupole splitting, while $(C_6H_5)_3Sn–Mn(CO)_5$ shows a non-resolved quadrupole splitting.[1] A clearly-resolved quadrupole splitting is observed for the present series of trialkyltin-pentacarbonylmanganese as well. It seems reasonable, therefore, to conclude that a clearly-resolved quadrupole splitting is generally observed for trialkyltin-pentacarbonylmanganese. It was also found that the magnitude of the quadrupole splitting increases in accordance with the length of the alkyl chain and that the isomer shift value of trimethyltin-pentacarbonylmanganese is the lowest among the alkyltin-pentacarbonylmanganese compounds. As the quadrupole splitting of the Mössbauer spectra reflects mainly the p-electron imbalance in the 5p-orbitals of the tin atom, the increase in quadrupole splitting means an increased 5p-electron imbalance around the tin atom in accord with the increase of the length of the alkyl chain. The lowest isomer shift, found in $(CH_3)_3Sn–Mn(CO)_5$, indicates that the compound has the lowest s-electron density around the tin atom among the trialkyltin-pentacarbonylmanganese compounds. The NMR measurements showed that the coupling constant, J(^{119}Sn–C–H) observed for $(C_2H_5)_3Sn–Mn(CO)_5$ is lower than that of $(CH_3)_3Sn–Mn(CO)_5$ (48.9 Hz), indicating a lower s-character of the $Sn–CH_2$ bond in $(C_2H_5)_3Sn–Mn(CO)_5$. It can be concluded on the basis of the results obtained by the rehybridization theory[11,12] that the p-character of the Sn–C bond and the s-character of the Sn–Mn bond for $(C_2H_5)_3Sn–Mn(CO)_5$ are larger than those for $(CH_3)_3Sn–Mn(CO)_5$.

The proton NMR measurements showed that the τ-values of the terminal methyl proton increase in the order of $(C_2H_5)_3Sn–Mn(CO)_5 < (n\text{-}C_3H_7)_3Sn–Mn(CO)_5 < (n\text{-}C_4H_9)_3Sn–Mn(CO)_5 < (CH_3)_3Sn–Mn(CO)_5$, indicating that the methyl protons in $(CH_3)_3Sn–Mn(CO)_5$ are most highly-shielded. Many factors which affect the proton chemical shift have been discussed for some Group IV B alkyl derivatives,[13-16] and it has been

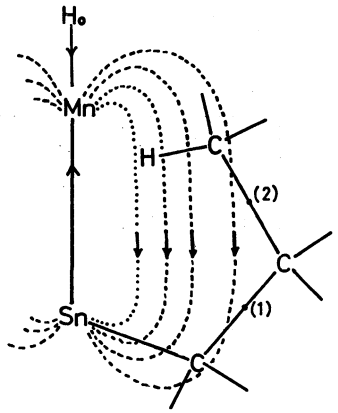

Fig. 1. The magnetic field induced by the applied field H_0 and the closest approach of methyl protons to Sn–Mn bond in $(n\text{-}C_3H_7)_3Sn\text{–}Mn(CO)_5$. (1) and (2) indicate the positions of methyl protons in ethyl and *n*-propyl derivatives, respectively. The terminal methyl protons can contact to Sn–Mn bond by rotating C–C bonds around their axis in the case of *n*-butyl derivative.

concluded that the predominant factor causing a shift to a lower field is the magnetic anisotropy effect for Group 4B ethyl derivatives.[13] As for the present series of alkyltin compounds, the magnetic anisotropy effect can account for the lower-field shift of the methyl protons in $(C_2H_5)_3Sn\text{–}Mn(CO)_5$, $(n\text{-}C_3H_7)_3Sn\text{–}Mn(CO)_5$, and $(n\text{-}C_4H_9)_3Sn\text{–}Mn(CO)_5$ as compared to $(CH_3)_3Sn\text{–}Mn(CO)_5$, as is shown in Fig. 1. However, a shift to a higher field in the order of $(C_2H_5)_3Sn\text{–}Mn(CO)_5 < (n\text{-}C_3H_7)_3Sn\text{–}Mn(CO)_5 < (n\text{-}C_4H_9)_3Sn\text{–}Mn(CO)_5$ can be explained neither in terms of the magnetic anisotropy effect nor in terms of the intramolecular van der Waals dispersion forces, since the magnetic anisotropy effect and the intramolecular van der Waals forces cause a lower-field shift. It is possible to consider that the small changes in the s-character of the Sn–Mn bond are the origin of the differences in the $\tau(CH_3)$ values of $(C_2H_5)_3Sn\text{–}Mn(CO)_5$, $(n\text{-}C_3H_7)_3Sn\text{–}Mn(CO)_5$, and $(n\text{-}C_4H_9)_3Sn\text{–}Mn(CO)_5$, since the isomer shift of ^{119}Sn changes in the same order, although such an inductive effect may be estimated to be very small.[13] One plausible explanation of this phenomenon is that the high-field shift of the methyl proton resonances going from ethyl to *n*-butyl compounds is due to the direct contact of the terminal methyl protons in $(n\text{-}C_3H_7)_3Sn\text{–}Mn(CO)_5$ and $(n\text{-}C_4H_9)_3Sn\text{–}Mn(CO)_5$ with electrons of the Sn–Mn bonding.[13]

In the effect of the replacement of CO on the manganese atom with weaker π-accepting ligands, the most striking feature is shown for $(CH_3)_3Sn\text{–}Mn(CO)_5$ and $(CH_3)_3Sn\text{–}Mn(CO)_4L$ or $(C_2H_5)_3Sn\text{–}Mn(CO)_5$ and $(C_2H_5)_3Sn\text{–}Mn(CO)_4L$ ($L=P(C_6H_5)_3$ and/or $As(C_6H_5)_3$). A well-resolved quadrupole splitting is observed for $(CH_3)_3Sn\text{–}Mn(CO)_5$ and $(C_2H_5)_3Sn\text{–}Mn(CO)_5$, whereas a non-resolved spectrum or a slightly-resolved spectrum is observed for the mono-substituted compounds, as is illustrated in Fig. 2. On the other hand, the replacement of CO with L causes a slight change in the isomer shift.

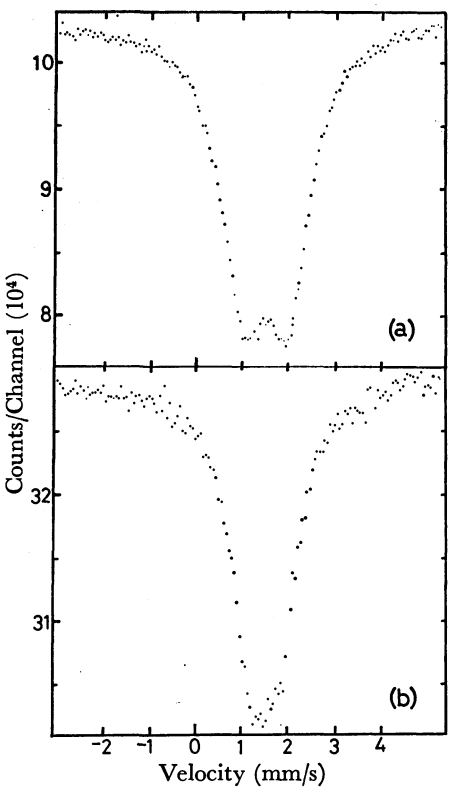

Fig. 2. ^{119}Sn-Mössbauer spectra of (a) $(C_2H_5)_3Sn\text{–}Mn(CO)_5$ and (b) $(C_2H_5)_3Sn\text{–}Mn(CO)_4P(C_6H_5)_3$ both at 78 K.

According to the X-ray analysis of $(C_6H_5)_3Sn\text{–}Mn(CO)_4P(C_6H_5)_3$, triphenylphosphine is coordinated to the manganese atom at the *trans* position with regard to the tin atom. The IR spectrum of this compound was checked, and two peaks were found in the CO stretching region (a very weak peak in the higher-energy region and a very strong one in the lower-energy region), as had been expected from its structural symmetry. All the mono-substituted compounds studied here show the same IR pattern in the CO stretching region as that of $(C_6H_5)_3Sn\text{–}Mn(CO)_4P(C_6H_5)_3$. The *trans* configuration may, therefore, be safely concluded to be found in all the substituted compounds. In the *trans* configuration, the tin atom is considered to compete with the ligand, L, to form a π-bonding with d_π-electrons of the manganese atom. Since the π-accepting ability of the ligand, L, is weaker than that of the substituted CO,[17] the d_π-electrons of the manganese atom are forced to enter both the vacant 5d orbitals of the tin atom and the remaining CO π-antibonding orbitals, thus influencing the efg around the tin nucleus. The NMR chemical-shift measurements provide other evidence of this interpretation; the methyl proton resonance is observed in a higher magnetic field for $(CH_3)_3Sn\text{–}Mn(CO)_4P(C_6H_5)_3$ than for $(CH_3)_3Sn\text{–}Mn(CO)_5$; *i.e.*, the shielding effect due to electrons around the proton nucleus is greater for $(CH_3)_3Sn\text{–}Mn(CO)_4P(C_6H_5)_3$ than for $(CH_3)_3Sn\text{–}Mn(CO)_5$. It seems reasonable to ascribe this result to the increase in the electron population around the proton nucleus stemming from the increase in the d_π-interaction between

the tin and manganese atoms. In contrast to the case of the alkyl drivatives, the quadrupole splitting of Cl_3Sn–$Mn(CO)_4L$ ($L=P(C_6H_5)_3$ and $As(C_6H_5)_3$) is slightly higher than that of the parent compound, Cl_3Sn–$Mn(CO)_5$. A similar contrast is observed in the values of the isomer shift on the comparison of Cl_3Sn–$Mn(CO)_4L$ with $(CH_3)_3Sn$–$Mn(CO)_4L$ or $(C_2H_5)_3Sn$–$Mn(CO)_4L$ ($L=P(C_6H_5)_3$, $As(C_6H_5)_3$, and CO). The reversed effect of the substitution of CO with weaker π-accepting ligands on the quadrupole splitting and isomer shift may also be ascribed to the increase of the σ- and π-interaction between the tin and manganese atoms through the substitution. The substitution of X in X_3Sn–$Mn(CO)_5$ increases the isomer shift with a decrease in the quadrupole splitting, whereas the substitution of R in R_3Sn–$Mn(CO)_5$ increases the isomer shift with an increase in quadrupole splitting, as may be seen in Table 2. Recently, Goodman *et al.* and Bancroft *et al.* have determined the sign of the quadrupole coupling constant, e^2qQ, of the tin atom in Cl_3Sn–$Mn(CO)_5$, $(CH_3)_2ClSn$–$Mn(CO)_5$, and $(CH_3)_3Sn$–$Mn(CO)_5$ by means of Mössbauer spectroscopy.[18,19] In the case of Cl_3Sn–$Mn(CO)_5$, there was concluded to be an excess of electron density in the p_z, d_{z^2}, d_{xz}, or d_{yz} orbitals because of the positive value of e^2qQ,[18] while an excess of electron density in the p_x, p_y, $d_{x^2-y^2}$, or d_{xy} orbitals was concluded for $(CH_3)_2ClSn$–$Mn(CO)_5$ and $(CH_3)_3Sn$–$Mn(CO)_5$ because of the negative value of e^2qQ.[19] As was mentioned above, the replacement of CO with weaker π-accepting ligands will increase the electron density in p_z, d_{xz}, and d_{yz} orbitals of the tin atom in $(CH_3)_3Sn$–$Mn(CO)_4L$ compared to the parent compound, thus reducing the electron imbalance around the tin atom, whereas the substitution will produce a positive contribution, thus increasing the electron density along the z axis in Cl_3Sn–$Mn(CO)_4L$ and augmenting the electron imbalance around the tin atom.

The fact that the zero quadrupole splitting in $(C_6H_5)_3Sn$–$Mn(CO)_5$ is not affected by the replacement of CO with L may well be explained in terms of the predominant π-delocalizing effect of the phenyl groups attached to the tin atom, as was described in a previous short communication.[4]

(Received July 12, 1974)

The deaquation-anation reaction of $[Ru(OH_2)(NH_3)_5]X_3$-type complexes in the solid state, as shown by the $[Ru(OH_2)(NH_3)_5]X_3(s) \rightarrow [RuX(NH_3)_5]X_2(s) + H_2O(g)$ equation, where X is Cl, Br, I, and NO_3 respectively, was kinetically studied by means of thermogravimetry (TG) along with differential thermal analysis (DTA). The activation energy and entropy in the reaction process (E_a kcal/mol, ΔS^* e.u.) are, respectively, found by isothermal kinetic study to be (22.7, −7.1) for the chloride, (23.4, −5.2) for the bromide, (26.7, 5.8) for the iodide, and (19.3, −15.9) for the nitrate. The reaction seems to proceed through the following two steps, except in the case of the iodide: $[Ru(OH_2)(NH_3)_5]X_3 \rightarrow [RuX(OH_2)(NH_3)_5]X_2 \rightarrow [RuX(NH_3)_5]X_2 + H_2O$. The first step is regarded as the rate-determining one.

Several kinetic studies on the deaquation-anation of cobalt(III)[3-6] and chromium(III)[7-9] pentaammine complexes in the solid state have been made, and the reaction heats have been reported. These metal ions have six and three 3d-electrons respectively, while ruthenium(III) has five 4d-electrons. This difference in the electronic structure of the central metal ion may be reflected in the behavior of the deaquation-anation reaction. In the present paper, the results of the deaquation-anation study of several aquapentaammineruthenium(III) complexes in the solid state will be compared with those of the corresponding cobalt(III) and chromium(III) complexes and the reaction mechanisms will be discussed.

Experimental

Materials. The aquapentaammineruthenium(III) complexes were prepared from the chloropentaammineruthenium(III) chloride by the method of Endicott and Taube.[10] The complexes were studied immediately after identification because they were unstable with respect to deaquation, even at room temperature. The water contents of the complexes were determined by studying the mass-loss on a thermobalance. Found for the chloride: H_2O, 5.55%. Calcd for $[Ru(OH)_2(NH_3)_5]Cl_3$: H_2O, 5.79%. Found for the bromide: H_2O, 3.37%. Calcd for $[Ru(OH_2)(NH_3)_5]Br_3$: H_2O, 3.37%. Found for the iodide: H_2O, 2.84%. Calcd for $[Ru(OH_2)(NH_3)_5]I_3$: H_2O, 3.08%. Found for the nitrate: H_2O, 4.22%. Calcd for $[Ru(OH_2)(NH_3)_5](NO_3)_3$: H_2O, 4.11%. Since there were some differences between the observed and theoretical values, and since this measurement was difficult to do for the perchlorate, the absorption spectrophotometry was also carried out in order to identify these complexes and to confirm their chemical purity.

Procedures. A Shimadzu-TGC 20 micro-thermobalance and DT 20B micro differential thermal analyzer were used for the thermal analysis. A Hitachi 323 recording spectrophotometer was used for the spectrum measurements.

About a 8—10 mg sample was heated in a dynamic helium atmosphere in a furnace at a heating rate of 5 °C per min. The isothermal rate measurement was carried out by using a thermobalance at several constant temperatures, and the conversion ratios were determined by mass-loss measurements. The reaction products were spectrophotometrically analyzed for their aqueous solution.

Results and Discussion

Differential Thermal Analysis and Thermogravimetry. The DTA and TG curves recorded for the aquapentaammine halides, nitrate, and perchlorate are shown in Fig. 1. For each complex, the mass-loss step, as shown by the TG curve, corresponds to the endothermic or exothermic peak in the temperature range of 62→81(max)→92 °C for the chloride, in that of 67→78(max)→91 °C for the bromide, in that of 58→76(max)→96 °C for the iodide, in that of 56→73(max)→83 °C for the nitrate, and in that of 127→156(max)→170 °C for the perchlorate. The DTA curve of perchlorate shows an exothermic peak different from those of the other complexes. This suggests that the ligand water-molecule is maintained even at a comparatively high temperature, since the bulky perchlorate ion can not easily migrate toward the inner sphere. This fact seems to account for the mechanism by which the

deaquation reaction is initiated by the migration of the outersphere anion.

The results of the elemental analysis and the spectral data of the reaction products are shown in Table 1. These data indicate that the reaction products accord with those of complexes resulting from the ligand-exchange reactions between the ligand water-molecule and the outersphere anions. Thus, all the peaks on the DTA curves and the mass-loss are attributable to the deaquation-anation reactions;

$$[Ru(OH_2)(NH_3)_5]X_3(s) \longrightarrow [RuX(NH_3)_5]X_2(s) + H_2O(g). \quad (1)$$

Isothermal Kinetic Study. Since the thermochemical reactions of all complexes except for the perchlorate were observed to consist of the deaquation and anation of the outersphere anion, the isothermal kinetic measurements were made using a thermobalance. The changes in the conversion ratios were determined from the mass-loss data at several temperatures. The plots of log $a/(a-x)$ *vs.* the reaction time, t, are exemplified for the chloride and the iodide in Figs. 2 and 3 respectively, where "a" is the initial mass of the sample and "$a-x$" is the mass at time t. The rate was considerably accelerated as the reaction proceeded, and the plots showed a tendency to deviate from the straight lines at higher reaction temperatures. Similar trends have previously been reported for the cases of the bromide and the nitrate.[2] The rate constants and the activation energies (E_a-I), which are obtained from the Arrhenius plots (Fig. 4), are given in Table 2, along with the activation entropy calculated from the E_a—I value and along with the reference values. Kinetic plots calculated by the method of Freeman and Carroll[12] are shown in Fig. 5, while the activation energies (E_a-II) are also listed in Table 2.

It can be seen that the rate constants for the ruthenium(III) complexes are larger than those of the cobalt(III) and chromium(III) complexes, and that the activation energies for the reactions of the ruthenium(III) complexes are generally smaller than those

for the corresponding cobalt(III) complexes. This is attributable to the presence of a lower unoccupied t^5_{2g} d-orbital for the ruthenium(III) ion and to the great softness of the 4d transition metal. The effects of the outer sphere anion on the thermal stability of the aquapentaammine complex are somewhat complicates. If the temperature of the mass-loss initiation indicates the thermal stability of a complex, this order is in agreement with that of the increase in the ionic radius and that of the decrease in the nucleophilic affinity, which is conveniently shown by the proton affinity in Table 2. The nitrate gives the largest value of the rate constant for the deaquation-anation reaction of the aquapentaammineruthenium(III), while it gives the smallest value for the cobalt(III) aquapentaammine complex. For the ruthenium complexes, the relation between the rate constant and the activation energy is generally consistent; that is, the larger rate constant corresponds to the smaller activation energy value. The activation entropy values are generally small and negative, except for the iodide. This means that the aquapentaammine complex has less randomness in the activated state and that, therefore, the deaquation-anation probably takes the S_N2 mechanism. On the other hand, the reaction may have a S_N1-like mechanism for the iodide.

Reaction Mechanism of the Deaquation-anation. Considering the reaction mechanism, it is convenient to divide Reaction (1) into two kinds of reaction schemes, 2—3 or 4—5:

$$[Ru(OH_2)(NH_3)_5]X_3 \longrightarrow [Ru(NH_3)_5]X_3 + H_2O \quad (2)$$

$$[Ru(NH_3)_5]X_3 \longrightarrow [RuX(NH_3)_5]X_2 \quad (3)$$

and

$$[Ru(OH)_2(NH_3)_5]X_3 \longrightarrow [RuX(OH_2)(NH_3)_5]X_2, \quad (4)$$

$$[RuX(OH_2)(NH_3)_5]X_2 \longrightarrow [RuX(NH_3)_5]X_2 + H_2O. \quad (5)$$

If Reaction Path 2 is the rate-determining step, the activation energies in all the cases of deaquation-anation reactions should be approximately close to each other. When the rate of the anation process (4) is smaller than that of the deaquation process (5), the deaquation-anation reaction is a S_N2-type mechanism. The experimental results shown in Table 2 support this reaction mechanism. As is also shown in Table 2, the rate constant for the nitrate is nearly two or three times larger than those for the other complexes and the activation energies for the latter are about 1.3—1.7 times that for the nitrate. This suggests that the deaquation-anation reaction takes place through

Reactions 4 and 5, that is the S_N2 mechanism. These relations are in agreement with that predicted from the crystal-field activation energy,[15] assuming a seven-coordinated intermediate in the reaction corresponding to Reaction 4. Moreover, the reaction in the solid state will be more likely to take the S_N2 mechanism than that in the aqueous phase, because the outersphere anion may be fixed by the lattice energy at the position neighboring the innersphere ligand in the solid state.

Mössbauer Spectroscopic Studies of the Effect of Anions in the Second Coordination Sphere in the EC-decay

Hirotoshi SANO and Toshiaki OHNUMA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Fukazawa, Setagaya, Tokyo 158

(Received July 16, 1974)

The ^{57}Fe–Mössbauer emission spectra of ^{57}Co-labelled $[Co(NH_3)_6](NO_3)_3$, $[Co(en)_3](NO_3)_3$, $K_3[Co(CN)_6]$, $K_3[Co(NO_2)_6]$, $[Co(NH_3)_6]_2(C_2O_4)_3 4H_2O$, $[Co(en)_3]_2(C_2O_4)_3 \cdot 9H_2O$, $[Co(NH_3)_6][Fe(CN)_6]$, $[Co(NH_3)_6][Cr(C_2O_4)_3] \cdot 3H_2O$, and $[Co(NH_3)_6][Fe(C_2O_4)_3] \cdot 3H_2O$ sources have been determined. It has been demonstrated that oxalate anions and trisoxalatochromate and trisoxalatoferrate complex anions located outside the first coordination sphere of the decayed atom are still involved in the local radiolytic processes initiated by the EC-decay. The yields of ^{57}Fe species found in the ferrous-charge state were interpreted by using the data of γ-radiolysis and hot-atom chemistry of the $^{59}Co(n,\gamma)^{60}Co$ reaction.

A number of Mössbauer spectroscopic studies have been made of the oxidation state of ^{57}Fe after the EC-decay of ^{57}Co as well as of that of ^{119}Sn after the IT(IC)-decay of ^{119m}Sn. The ^{57}Fe atom produced in the decay suffers a modest recoil, *ca.* 6 eV, and it acquires an average positive charge of 4 or 5 units within 10^{-14} s of its formation becaues of the Auger cascade.[1] The Auger cascade can be invoked as giving rise to charge states more positive than that of the parent ^{57}Co atom, but the factors for the stabilization of the less positive charge state have not been fully understood. One of the explanations of the after-effects of the ^{57}Co EC-decay has been worked out from the difference between the ionic radii of Co^{3+} and Fe^{3+}, which could manifest itself as an internal pressure acting on the decayed atom.[2] We have previously pointed out that a plausible mechanism is the radiolytic process initiated by the Auger process.[3–6] Nath *et al.* have recently suggested the possibility of the fragmentation and the reentry of the degraded ^{57}Fe ion, undergoing excited exchange with a host cobalt molecule.[7] Friedt *et al.* have suggested a similar radiolytic self-decomposition of the molecular environment of the decaying atoms, although they have concluded that the auto-radiolysis is limited to the nearest neighbors of the decayed atom because the electrons emitted during the Auger cascade have a low energy and a short mean path.[8] In the present work, we investigated the effect of anions in the second coordination sphere by comparing the Mössbauer spectra of the ^{57}Co-labelled complex compounds.

Experimental

^{57}Co-labelled Compounds. ^{57}Co-labelled $[Co(NH_3)_6](NO_3)_3$, $[Co(en)_3](NO_3)_3$, $K_3[Co(CN)_6]$, and $K_3[Co(NO_2)_6]$ were prepared from solutions each containing 50 mg of cobalt(II) and about 1 mCi of carrier-free ^{57}Co by following the methods described in Refs. 9, 10, 11, and 12 respectively. ^{57}Co-labelled $[Co(NH_3)_6]_2(C_2O_4)_3 \cdot 4H_2O$, $[Co(NH_3)_6][Fe(CN)_6]$, $[Co(NH_3)_6][Cr(C_2O_4)_3] \cdot 3H_2O$, $[Co(NH_3)_6][Fe(C_2O_4)_3] \cdot 3H_2O$, and $[Co(en)_3]_2(C_2O_4)_3 \cdot 9H_2O$ were made from solutions of ^{57}Co-labelled $[Co(NH_3)_6](NO_3)_3$ and $[Co(en)_3](NO_3)_3$ by adding solutions of $K_2C_2O_4 \cdot 2H_2O$, $K_3[Fe(CN)_6]$, $K_3[Cr(C_2O_4)_3] \cdot 3H_2O$, and $K_3[Fe(C_2O_4)_3] \cdot 3H_2O$ respectively, purchased or prepared by the methods described in Refs. 13 and 14. The purity was checked by elemental analysis and by X-ray diffraction. All the compounds were found to be at least 98% pure.

Mössbauer Spectroscopic Measurements. The source compounds were kept in a cryostat, and the Mössbauer spectra were measured against an ^{57}Fe-enriched stainless steel absorber moving in a constant acceleration mode at room temperature. Velocity calibrations were carried out by using an ^{57}Fe-enriched iron foil absorber moving against a stationary ^{57}Co(Pt) source at room temperature.

Results and Discussion

Figures 1 to 4 show the Mössbauer spectra of the source compounds measured at 78 K. The spectrum of the ^{57}Co-labelled $K_3[Co(C_2O_4)_3] \cdot 3.5H_2O$ source at

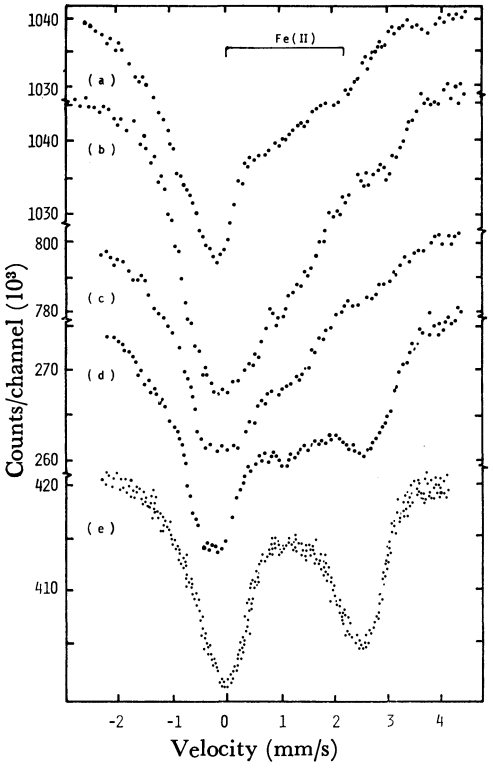

Fig. 1. Mössbauer spectra at 78 K of ^{57}Co-labelled (a) $K_3[Co(CN)_6]$, (b) $K_3[Co(NO_2)_6]$, (c) $[Co(NH_3)_6](NO_3)_3$, and (d) $[Co(en)_3](NO_3)_3$ sources. (e) Spectrum of ^{57}Co-labelled $K_3[Co(C_2O_4)_3] \cdot 3.5H_2O$ source at 93 K reproduced from ref. 15.

93 K is also reproduced in Fig. 1 from Ref. 15 for the sake of comparison. All the velocity scales were normalized with respect to metallic iron. The comparison of the spectra of the $[Co(NH_3)_6](NO_3)_3$, $[Co(en)_3](NO_3)_3$, $K_3[Co(CN)_6]$, and $K_3[Co(NO_2)_6]$ sources with the spectrum of the $K_3[Co(C_2O_4)_3]3.5H_2O$ source clearly shows that the oxalate ligand in the first coordination sphere has the largest effect in reducing the decayed atom, probably because of the decomposition of the oxalate ions to carbon dioxide.

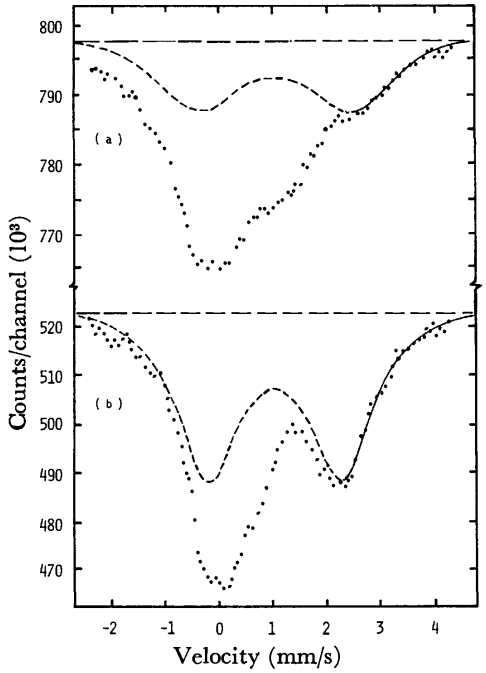

Fig. 2. Mössbauer spectra at 78 K of ^{57}Co-labelled (a) $[Co(NH_3)_6](NO_3)_3$ and (b) $[Co(NH_3)_6]_2(C_2O_4)_3\cdot 4H_2O$ sources. The peak component of ferrous ^{57}Fe species was estimated as indicated in a broken line by using the line shape in the high velocity region ($\gtrsim$2.5 mm/s, indicated in a solid line) where the contribution of ferric species is assumed to be negligible. The yield of ferrous ^{57}Fe species was evaluated from the area under the component and the total area of the spectrum.

As may be seen in Figs. 2 to 4, an increased yield of the ferrous ^{57}Fe species is unambiguously observed in the spectra of $[Co(NH_3)_6]_2(C_2O_4)_3\cdot 4H_2O$, $[Co(en)_3]_2(C_2O_4)_3\cdot 9H_2O$, and $[Co(NH_3)_6][Cr(C_2O_4)_3]\cdot 3H_2O$ and $[Co(NH_3)_6][Fe(C_2O_4)_3]\cdot 3H_2O$ sources compared with the spectra of the $[Co(NH_3)_6](NO_3)_3$, $[Co(en)_3](NO_3)_3$, and $[Co(NH_3)_6][Fe(CN)_6]$ sources respectively, although the yield of the ferrous ^{57}Fe species is lower in those compounds than in $K_3[Co(C_2O_4)_3]\cdot 3.5H_2O$. Since it is known that the water of crystallization has no reducing effect on the oxidation state of ^{57}Fe produced in the after-effect of the EC-decay in a number of ^{57}Co-labelled cobalt compounds,[15-19] it may be concluded that the increased yield of the ferrous ^{57}Fe species is due to the effect of oxalate ions. The higher yield of the ferrous ^{57}Fe species found in $[Co(en)_3](NO_3)_3$ than in $[Co(NH_3)_6](NO_3)_3$ may be explained by assuming a higher probability of bond rupture in the ethylenediamine ligand, thus producing nitrenium

Table 1. Summary of the yield of ferrous ^{57}Fe species produced after EC-decay, the $G(Co^{2+})$ value in γ-radiolysis,[20] and the radiochemical yield of cobaltous ^{60}Co species in the hot-atom chemistry of ^{59}Co(n, γ) ^{60}Co reaction[21]

Compound	Yield of $^{57}Fe^{2+}$ in EC-decay (%)	$G(Co^{2+})$	Yield of $^{60}Co^{2+}$ in ^{59}Co(n, γ) ^{60}Co (%)
$[Co(NH_3)_6](NO_3)_3$	40±1	1.1±0.2	66.7±0.2
$[Co(en)_3](NO_3)_3$	53±1	0.4±0.1	69.4±0.2
$[Co(NH_3)_6]_2(C_2O_4)_3\cdot 4H_2O$	72±1	2.9±0.2	91.0±0.2
$K_3[Co(C_2O_4)_3]\cdot 3H_2O$	85[15]	11.6±0.2	98.6±0.4

cations (H_2N^+ and $H_2NCH_2CH_2N^+H$), carbonium cations ($H_2NCH_2C^+H_2$, $H_2NCH_2C^+HNH_2$, and $H_2NC^+H_2$), cationic radicals, hydrogen molecules and cations, and electrons which may reduce the decayed atom.

We have reported previously that oxalate anions in the first or second coordination sphere exert some reducing effect both in the radiolysis and in the hot-atom chemistry in the ^{59}Co(n,γ)^{60}Co reaction of cobalt(III) complexes.[20,21] Table 1 summarizes the yields of ferrous ^{57}Fe as evaluated from the spectral area, the $G(Co^{2+})$ value in γ-radiolysis,[20] and the radiochemical yield of ^{60}Co in the hot-atom chemistry.[21] The effect of the oxalate ion on the reduction of the central cation observed in the EC-decay of ^{57}Co qualitatively parallels those data found for the $G(Co^{2+})$ values of γ-ray-irradiated cobalt(III) oxalate complexes and for the radiochemical yields of the divalent ^{60}Co species produced in the (n,γ) reaction. The low $G(Co^{2+})$

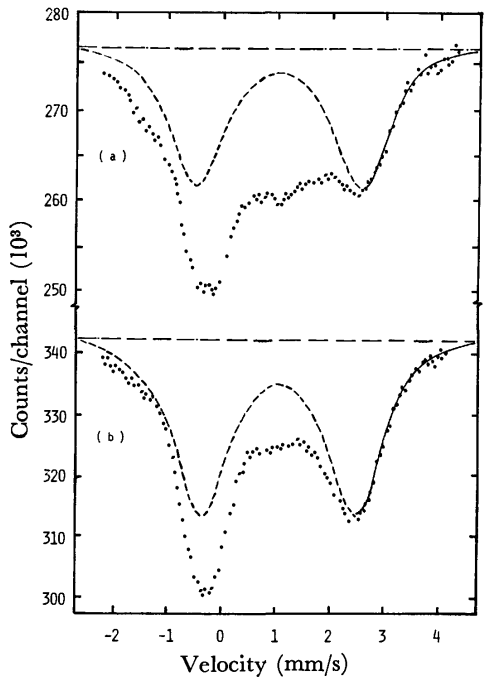

Fig. 3. Mössbauer spectra at 78 K of ^{57}Co-labelled (a) $[Co(en)_3](NO_3)_3$ and (b) $[Co(en)_3]_2(C_2O_4)_3\cdot 9H_2O$ sources. See the figure caption in Fig. 2 for the evaluation of the yield of ferrous ^{57}Fe species.

value found in the γ-radiolysis of $[Co(en)_3](NO_3)_3$ may be ascribed to the low yields of fragmentations, producing nitrenium cations, carbonium cations, cationic radicals, *etc.*, because of the lower LET value of γ-rays compared to those of Auger electrons and recoil ^{60}Co atoms.

Another interesting point concerns the comparison of the spectra of the $[Co(NH_3)_6][Cr(C_2O_4)_3]3H_2O$ and $[Co(NH_3)_6][Fe(C_2O_4)_3]\cdot 3H_2O$ sources. The larger yield of the ^{57}Fe species in the ferrous oxidation state observed in the trisoxalatoferrate(III) source compared to that observed in trisoxalatochromate(III) source may be explained by assuming a higher probability of the decomposition of oxalate ligands into carbon dioxide and electrons induced by the local radiolysis in trisoxalatoferrate. Sugimori and Tsuchihashi have reported that $K_3[Cr(C_2O_3)_3]\cdot 3H_2O$ shows a higher stability against external γ-ray irradiation than does $K_3[Fe(C_2O_4)_3]\cdot 3H_2O$, since the chromous state is much more unstable than is the ferrous state.[22] The $G(CO_2)$ values are evaluated to be 0.9 in the γ-ray irradiation of the trisoxalatochromate(III) and 7.5 in the trisoxalatoferrate(III).

The results indicate that not only the nearest neighbors of the decayed atom (the ligands in the first coordination sphere), but also the next nearest neighbors (the anions or ligands in the second coordination sphere), are involved in determining the oxidation state of the decayed atom in the local radiolytic process initiated by the EC-decay and the Auger effect. The $G(CO_2)$ value reported by Sugimori and Tsuchihashi (9.8) is approximately equal to our previous results of the $G(CO^{2+})$ values evaluated for $K_3[Co(C_2O_4)_3]\cdot 3H_2O$ (11.6). This suggests the following process:

$$C_2O_4^{2-} \longrightarrow 2CO_2 + 2e^-;$$

$$2Co(III) + 2e^- \longrightarrow 2Co(II).$$

It is obvious that the decomposition of each oxalate anion can reduce two metal cations from the trivalent to the divalent state. In the ^{57}Co-labelled compounds, however, the concentration of the decaying atom in the host matrix is so small that the electrons produced by each decomposition of oxalate ligands or anions located near the decaying atom may be used to reduce at most only one ^{57}Fe atom to the ferrous state.

As we have previously mentioned, the higher yield of ferrous ^{57}Fe in the EC-decay of $K_3[Co(C_2O_4)_3]\cdot 3H_2O$ compared to the yield of stannous ^{119}Sn in the IT(IC)-decay of $K_6Sn_2(C_2O_4)\cdot 4H_2O$ may be ascribed to the difference in the fluorescence yields of iron and tin atom.[4] The fluorescence yield of iron is known to be about 32%. The yield of ferrous ^{57}Fe reported in $K_3[Co(C_2O_4)_3]\cdot 3.5H_2O$ exceeds the value of the Auger yield of iron (68%) by 17%. As long as it is assumed that the yield of ferrous ^{57}Fe depends only upon the nearest neighbors of the decayed atom, the results can be explained in terms of two processes: (1) a direct X-ray radiolysis of oxalate ligands in the trisoxalato ^{57}Fe complex anions which escaped the Auger-electron radiolysis, and (2) an indirect electron transfer through the X-ray radiolysis of the adjacent host trisoxalatocobaltate(III) anions.

The yields of ferrous ^{57}Fe in $[Co(NH_3)_6]_2(C_2O_4)_3\cdot 4H_2O$, $[Co(en)_3]_2(C_2O_4)_3\cdot 9H_2O$, $[Co(NH_3)_6][Cr-$

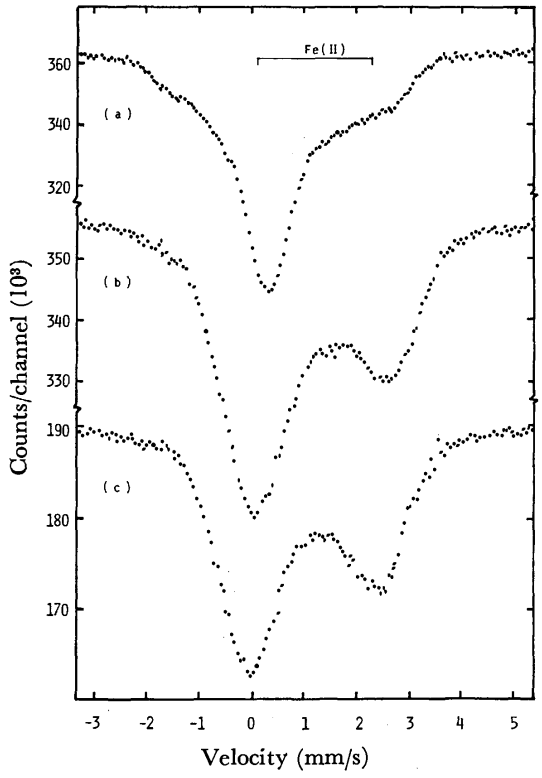

Fig. 4. Mössbauer spectra at 78 K of ^{57}Co-labelled (a) $[Co(NH_3)_6][Fe(CN)_6]$, (b) $[Co(NH_3)_6][Cr(C_2O_4)_3\cdot 3H_2O$, and (c) $[Co(NH_3)_6][Fe(C_2O_4)_3]3H_2O$ sources.

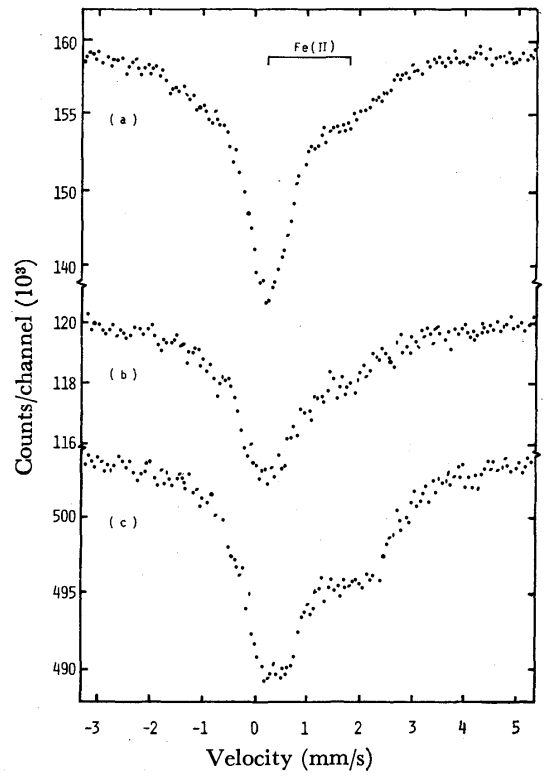

Fig. 5. Mössbauer spectra at 295 K of ^{57}Co-labelled (a) $[Co(NH_3)_6][Fe(CN)_6]$, (b) $[Co(NH_3)_6][Cr(C_2O_4)_3]\cdot 3H_2O$, and (c) $[Co(NH_3)_6][Fe(C_2O_4)_3]3H_2O$ sources.

$(C_2O_4)_3]\cdot 3H_2O$, and $[Co(NH_3)_6][Fe(C_2O_4)_3]3H_2O$ are, however, too high to be explained by the indirect electron transfer through the X-ray radiolysis. The exceptional dissimilarity found in the yield of ferrous ^{57}Fe compared to the $G(Co^{2+})$ value in $[Co(en)_3](NO_3)_3$ may also disprove the X-ray radiolysis mechanism for the interpretation of the main process initiated by the EC- or IT(IC)-decay. It may, therefore, be concluded that Auger electrons emitted from the decayed atom decompose oxalate ions outside the first coordination sphere or that the Auger process gives rise to an excitation-induced decomposition of the oxalate ions and that electrons thus produced are then transfered to the decayed atom, thus stabilizing a reduced oxidation state during the nuclear life-time of the first excited level of the Mössbauer nucleus.

These conclusions are consistent with our previous interpretation derived from the studies of $^{57}Co(acac)_3$ doped into a number of trisacetylacetonato complexes, where a remarkable dependence of the yield of ferrous ^{57}Fe is found on the kind of surrounding host matrix. A comparison of the spectrum of ^{57}Co-labelled $K_3[Co(CN)_6]$ with that of $[Co(NH_3)_6][Fe(CN)_6]$ does not show any positive evidence for the excited exchange of ^{57}Fe produced from the EC-decay of ^{57}Co with iron(III) atoms of hexacyanato complex anions, although a minor possibility of this can not be denied. The peak component assigned to the ferrous ^{57}Fe species decreases relative to that of the ferric species at room temperature, especially in the cases of the $[Co(NH_3)_6]_2(C_2O_4)_3\cdot 4H_2O$, $[Co(en)_3]_2(C_2O_4)_3\cdot 9H_2O$, $[Co(NH_3)_6][Cr(C_2O_4)_3]\cdot 3H_2O$, and $[Co(NH_3)_6][Fe(C_2O_4)_3]\cdot 3H_2O$ sources. Some typical spectra observed at 295 K are shown in Fig. 5. This suggests that the ferrous species have lower recoil-free fractions, since they are located in disturbed or thermally excited environments.

The Gas Chromatographic Determination of Carbonyl Compounds as Their Thiosemicarbazone

Yoshio BABA

National Research Institute for Pollution & Resources, Kawaguchi, Saitama 332

(Received August 12, 1974)

The gas chromatographic determination of carbonyl compounds in a contaminated air sample *via* their thiosemicarbazone was studied. As the method utilizes the selective detectability of the flame photometric detector for the sulfur compound, the isolation of the sulfur-containing derivatives of the carbonyl compounds is not required; this eliminates the inaccuracy stemming from the isolation of the derivatives from the sample solution. The isolation and subsequent regeneration of the carbonyl compound was carried out *via* the thiosemicarbazone metal complex; this affords a practical method of preparing the sample required for the identification of the individual carbonyl compound.

The identification and quantitative determination of carbonyl compounds is a commonly encountered problem in air-quality analysis—for example, the analysis of the carbonyl compounds in automobile exhausts and in concentrated air samples.

Derivatization *via* 2,4-dinitrophenylhydrazine (DNPH) followed by subsequent gas chromatographic analysis, has been widely used for carbonyl analysis. The carbonyl DNPH derivatives have been analyzed directly by gas chromatography,[1-6] or, after the hydrolysis of the carbonyl DNPH derivatives by heating them with mineral or organic acid, the regenerated carbonyl compounds have been analyzed.[7-8] The gas chromatographic analysis of the carboxylic acids produced by the ozonization of the carbonyl DNPH has also been reported.[9]

In this study, the carbonyl compound was converted into its thiosemicarbazone, and the latter sulfur-containing derivative was detected by means of a flame photometric detector (FPD). As the selective detectability of FPD for the sulfur compounds permits the selective determination of the carbonyl thiosemicarbazone in a contaminated sample—for example, in auto exhaust or in concentrated air sample which contains foreign compounds other than the carbonyl compounds, the isolation of the carbonyl compound derivative from the foreign compounds is not required. This fact, in conjunction with the specific and quantitative thiosemicarbazone formation reaction, could eliminate the inaccuracy stemming from the separation or extraction of the carbonyl compound derivative which is encountered in the direct carbonyl DNPH method.

Further, the unique property of thiosemicarbazone to form an insoluble metal complex with heavy metal salts can be utilized for the isolation, followed by regeneration, in the identification of the individual carbonyl compound by GLC-Mass analysis, which requires the isolation of the carbonyl compounds from other impurities, *e.g.*, hydrocarbons.

Experimental

Thiosemicarbazones. The general procedure for the preparation of all the thiosemicarbazones listed in Table 2 was as follows. The carbonyl compound (0.01 mol) was dissolved in 10 ml of 95% ethanol, and then approximately 0.2 ml of glacial acetic acid and 0.9 g (0.01 mol) of thiosemicarbazide were added. The reaction mixture was stirred at room temperature until the thiosemicarbazide dissolved (it usually took 0.5—1 hr) and was then refluxed for 0.5 hr. The solvent was evaporated under reduced pressure, and the crude product was recrystallized from 50% ethanol or methanol.

Determination of the Response Factors and the Relative Retention Values of Thiosemicarbazones. Gas chromatography was done by means of a Micro Tek Instruments Corp. Model 160 gas chromatograph equipped with a flame photometric detector and a 4 mm i.d. × 1 m glass column packed with Diasolid ZT (Silicone). The other analytical conditions are described in Tables 1 and 2.

In the determination of the response factors of the thiosemicarbazones listed in Table 1, the sample solution was prepared by mixing 1 ml of the solution of thiosemicarbazone (1×10^{-4} mol) in 10 ml of ethanol, with 10 μl of the internal standard solution (di-*n*-amyl sulfide 1×10^{-4} mol in 3 ml ethanol). The peak areas of each thiosemicarbazone and internal standard sulfide were determined by means of a digital integrator, while the response factor (F_i) was calculated by the use of the following equation:

$$F_i = A_s/W_s \times W_i/A_i$$

where: A_s and W_s=peak area (log) and the weight of the internal standard respectively, and A_i and W_i=peak area (log) and the weight of thiosemicarbazone respectively.

The relative retention values (α) of the thiosemicarbazones listed in Table 2 were calculated by means of the following equation:

$$\alpha = (X_1 - X_0)/(X_s - X_0)$$

where X_0, X_s, and X_1 are the distances (in time) from the point of injection to the maximum of the chromatographic peaks of the solvent (ethanol, detected by means of a FID monitor coequipped with FPD), the internal standard (di-*n*-amyl sulfide), and thiosemicarbazone respectively.

Separation and Regeneration of the Carbonyl Compounds via the Thiosemicarbazone/$AgNO_3$ Complex. A solution of silver nitrate (0.01 mol) in 5 ml of distilled water was added to a thiosemicarbazone (0.01 mol)/EtOH solution. After 30 min's stirring at room temperature, the reaction mixture was evaporated to dryness under reduced pressure. The residual, black-colored solid was washed with a hydrocarbon solvent (*e.g.*, *n*-hexane) and then dissolved in 20 ml of ethanol; 5 ml of 6 M-HCl was added, and the reaction mixture was stirred for 1 hr under refluxing, cooled, and filtered. The content of the carbonyl compound in the filtrate was determined by the gravimetric 2,4-dinitrophenylhydrazine method.

Results and Discussion

The thiosemicarbazones listed in Table 2 were prepared by Campaigne's method.[11] Unlike semicarbazide, the thiosemicarbazide is stable in its free form, and in the presence of a small amount of glacial acetic acid, the reaction proceeds readily at room temperature and the thiosemicarbazone formation reaction has the minor possibility of a side reaction. The thiosemicarbazone-formation reaction with the 15 carbonyl compounds listed in Table 2 proceeded readily at room temperature: an initially insoluble crystal of thiosemicarbazide dissolved in 0.5—1 hr, and either a clear solution or a crystal of newly-formed thiosemicarbazone was obtained. The small deviations in the melting points between the crude and the purified product indicated the absence of any side reaction or isomer formation.

It has been reported that, in the direct gas-chromatographic analysis of the carbonyl DNPH, the reproducibilities were poor, the response factors varied with the concentration, spurious decomposition peaks or double peaks hampered the analysis, and a homologous series of carbonyl DNPH derivatives had widely varying responses per mole when detected by FID.[1,2] All of these results indicated that the higher-molecular-weight carbonyl DNPH derivative resulted in a varying loss of the derivatives through thermal decomposition in the gas-chromatographic system.

However, the carbonyl thiosemicarbazone, which has a smaller molecular weight than the carbonyl DNPH, makes possible milder analytical conditions, which minimize the thermal decomposition of the derivatives. In this study, column temperatures of 125—200 °C, inlet temperatures of 150—200 °C, and a detector temperature of 170 °C were used, because the melting points and the decomposing points of the 15 thiosemicarbazones were in the ranges of 70—240 °C and 165—240 °C respectively.

Table 1. Response factors (F_1) and average deviations of thiosemicarbazones

The reproducibility and the uniformity of the response for various carbonyl compounds were evaluated with the thiosemicarbazones of 3 aliphatic aldehydes, 6 aliphatic ketones, 3 aromatic aldehydes, and one aromatic ketone. As is shown in Table 1, the response factors of these thiosemicarbazones, except in formaldehyde and *p*-hydroxybenzaldehyde, had a great uniformity and a high reproducibility over a wide range of homologous series.

The poor uniformity in the responses for the thiosemicarbazones of formaldehyde and *p*-hydroxybenzaldehyde is associated with a thermal decomposition of the derivatives in the gas-chromatographic system, because these two thiosemicarbazones have the same melting points as decomposition points.

Table 2. Relative retention values of thiosemicarbazones

C: N_2 30 ml/min, 200 °C isothermal, inlet temp. 200 °C.

The determination of the relative retention values of 15 thiosemicarbazones under the analytical conditions listed in Table 2 indicated that, using a 4 mm i.d. × 1 m glass column packed with Diasolid ZT, the direct gas-chromatographic analysis of the carbonyl thiosemicarbazone offers the best potential for the clear separation of the individual carbonyl compound commonly encountered in auto mobile exhausts[10] or in concentrated air samples.

In the gas-chromatographic analysis of the carbonyl compounds *via* their thiosemicarbazones, utilizing the selective response of the detector (FPD) for the sulfur compounds, purification is not required and a crude sample containing impurities can be used directly as the analytical sample. However, in the case of the identification of the individual carbonyl compounds by GLC-Mass analysis, the carbonyl compound to be iden-

Table 3. Separation and regeneration of the carbonyl compounds *via* thiosemicarbazone/$AgNO_3$ complex

Carbonyl compounds	Recovery (%)

Acetophenone	48.8
Crotonic aldehyde	65.3
Benzaldehyde	44.8

tified must be isolated from any foreign compounds.

The method of the regeneration of the parent carbonyl compound by treating carbonyl DNPH with mineral or organic acid cannot be applied to the unsaturated carbonyl compound and aromatic aldehydes. Similarly, method of producing the corresponding carboxylic acid by ozonization of the carbonyl DNPH cannot be applied to the unsaturated compound.

In this study, the isolation and subsequent regeneration of the parent carbonyl compounds was carried out through a heavy metal complex of thiosemicarbazone. Thiosemicarbazone is known to form an insoluble metal complex with heavy metal salts, *e.g.*, silver nitrate, cupric acetate, mercuric acetate, and mercuric cyanide. The metal complex can be decomposed to regenerate the thiosemicarbazone by a reaction with hydrochloric acid or hydrogen sulfide, and the thiosemicarbazone can be hydrolyzed to regenerate the parent carbonyl compound by heating it with mineral acid. In this work, the regeneration of the carbonyl compound *via* the thiosemicarbazone silver nitrate complex was studied in an attempt to isolate the carbonyl compound from the contaminated air sample. Table 3 indicates that the regeneration of the parent carbonyl compound, even with unsaturated or aromatic aldehyde, can be done with a 45—65% recovery.

In the analysis of the carbonyl compound in automobile exhaust by the carbonyl DNPH method, the presence of NO_x in the sample gas has been reported to interfere with the formation of the 2,4-DNPH derivative and the subsequent gas chromatographic analysis.[3)]

In this study, the effect of NO_2 on the preparation of thiosemicarbazone and the subsequent gas chromatographic analysis were examined with crotonic aldehyde, methyl ethyl ketone, and propionic aldehyde. In the presence of a 1/10 molar equivalent of NO_2, no evidence was found for the interference of NO_2 in the formation of thiosemicarbazones, which can be deduced by a comparison of the melting points of the crude and the purified products and by an examination of the gas chromatograms of the crude products.

In the presence of an equimolar amount of NO_2, although the saturated aldehyde and ketone were subject to no practical interaction with NO_2, an apparent interaction of NO_2 with the unsaturated aldehyde, crotonic aldehyde, was observed. The lower melting point of thiosemicarbazone and the appearance of foreign peaks in the gas chromatogram of the crude product indicated the occurrence of this side reaction.

Anodic Wave Polarography of *N*-2-Aminoethyl-*N*-2-hydroxyethylcarbodithioic Acid

Masao SUGAWARA and Tomihito KAMBARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received August 21, 1974)

N-2-Aminoethyl-*N*-2-hydroxyethylcarbodithioic acid (Hahdtc) in an alkaline medium gives at the dropping mercury electrode an adsorption prewave due to the two-electron oxidation of mercury. The electrode reaction at pH=13.1—10.1 was inferred to proceed according to

$$Hg + 2ahdtc^- \rightleftarrows Hg(ahdtc)_2 + 2e \quad (1)$$

The surface excess of the mercury(II) chelate was estimated to be 3.0×10^{-10} mol cm^{-2}.

The polarographic behavior of compounds containing carbodithioate group have been studied by many authors.[1-7] These compounds give anodic waves corresponding to the mercury compound formation, in most cases, accompanied by adsorption phenomena. For sodium diethylcarbodithioate (Naddtc), the one-electron oxidation process was attributed to the formation of mercury complex Hg(ddtc), in which mercurous ion is present in the monomeric form, followed by rapid disproportionation to $Hg(ddtc)_2$ and Hg.[1,4] In the case of the anodic wave of ammonium 1-pyrrolidinecarbodithioate (NH_4pcd), the electrode process was ascribed to the formation of the complex $Hg(pcd)_2$.[7]

In the present work, the polarographic behavior of *N*-2-aminoethyl-*N*-2-hydroxyethylcarbodithioic acid (Hahdtc) was investigated at the dropping mercury electrode.

Experimental

N-2-Aminoethyl-*N*-2-hydroxyethylcarbodithioic acid was synthesized as follows. To 80 g of carbon disulfide in 100 ml of ethanol, 24 g of 2-aminoethylaminoethanol dissolved in 100 ml of ethanol were added dropwise under cooling in a cold water bath. The product was filtered, washed with ethanol and recrystallized from water at 65 °C. After drying in air, the Hahdtc was stored in a desiccator containing silica gel as a desiccant. Found: C, 33.09; H, 6.74; N, 15.62; S, 35.58%. Calcd for $C_5H_{12}ON_2S_2$: C, 33.31; H, 6.71; N, 15.54; S, 35.57%.

The Hahdtc in an aqueous solution was unstable and its limiting current decreased by 15% after 4 hr. Therefore, the Hahdtc solution was freshly prepared before each experiment. All other reagents used were of A. R. grade.

Direct current polarogram was recorded by means of a Shimadzu polarograph, type RP-2, and AC polarogram was recorded by using a Shimadzu AC attachment, type BF-1. The dropping mercury electrode used had the following characteristics; mercury flow-rate $m=1.50$ mg s^{-1} in deionized water, drop time $t=4.91$ s in 0.1 mol dm^{-3} sodium hydroxide solution at open circuit and at a height of the mercury reservoir $h=58.0$ cm. The potential values presented here refer to the saturated calomel electrode, which was connected to the electrolysis solution through an agar bridge (3% agar, satd. potassium nitrate). The mercury of SCE was connected to a mercury pool counterelectrode *via* a 2200 μF capacitor.

The pH measurements were carried out with a Hitachi-Horiba glass electrode pH meter, type F-5.

A portion of the freshly prepared electrolysis solution containing Hahdtc and 0.1 mol dm^{-3} sodium hydroxide as the supporting electrolyte was taken into a polarographic cell, and the polarogram was recorded at (25±0.1) °C after deaeration by bubbling nitrogen gas.

Results and Discussion

Direct Current Polarography. The DC and AC polarograms of 4.0×10^{-4} mol dm^{-3} Hahdtc in 0.1 mol dm^{-3} sodium hydroxide solution are shown in Fig. 1. At concentrations of the Hahdtc lower than 1.0×10^{-4} mol dm^{-3}, one DC prewave, A, at −0.65 V is observed. At concentrations higher than 1.0×10^{-4} mol dm^{-3}, the DC main wave B at −0.32 V appears, while the limiting current of the prewave remained constant. The sum of the limiting currents of the prewave and main wave is proportional to the concentration of Hahdtc between 1.0×10^{-4} and 8.0×10^{-4} mol dm^{-3} as shown in Fig. 2. The height of the prewave is approximately proportional to $h_{corr.}$ and that of the total wave (A+B) is to $h_{corr.}^{1/2}$ (Table 1). The limiting current

of the total wave had the relative temperature coefficient of 1.60% K^{-1} in the temperature range from 15 to 35 °C; but the limiting current of the prewave was almost independent of temperature as shown in Fig. 3. These results indicate that the wave A is a typical adsorption prewave and the total wave is diffusion-controlled.

Logarithmic Analysis of DC Polarogram. If the electrode reaction in an alkaline medium is reversible and proceeds according to the following equation,

$$Hg + 2ahdtc^- \rightleftarrows Hg(ahdtc)_2 + 2e \quad (1)$$

the potential E of the electrode is given by

$$E = E_0 + \frac{RT}{2F}\ln\frac{1}{K} + \frac{RT}{2F}\ln\frac{[Hg(ahdtc)_2]_o}{[ahdtc^-]_o^2} \quad (2)$$

where K is the formation constant of $Hg^{II}(ahdtc)_2$, and subscript o denotes the concentration at the surface of the electrode. If the concentration of the Hahdtc is large enough, the average current i of the main wave B is expressed as[5]

$$i = i_t - i_A \quad (3)$$

$$i = k_1([ahdtc^-]^* - [ahdtc^-]_o) - i_A \quad (4)$$

where i_t is the theoretical current which would flow if the adsorption did not occur, i_A the limiting current corresponding to the adsorption prewave, k_1 the proportionality factor, and asterisk means the concentration in the bulk of solution. The total limiting current (i_A+i_B) of the prewave A and main wave B is proportional to the concentration of the Hahdtc in the bulk of the solution. Therefore,

$$i_A + i_B = k_1[ahdtc^-]^* \quad (5)$$

Since the complex $Hg(ahdtc)_2$ is absent in the bulk of the solution, the current i is given by

$$i = k_2[Hg(ahdtc)_2]_o \quad (6)$$

where k_2 is the proportionality factor. By combination of Eqs. (2), (4), (5), and (6), the following equation is obtained (at 25 °C).

$$E = E_0' - 0.030\log\frac{(i_B-i)^2}{i} \quad (7)$$

$$E_0' = E_0 + 0.030\log\frac{1}{K} + 0.030\log\frac{k_1^2}{k_2} \quad (8)$$

Thus, the plot of E *vs.* $\log\{(i_B-i)^2/i\}$ should give a straight line with a slope of 30 mV. As shown in Fig. 4, the experimental result agreed well with the theoretical prediction. Moreover, the half-wave potential $E_{1/2}$ of the main wave is given by

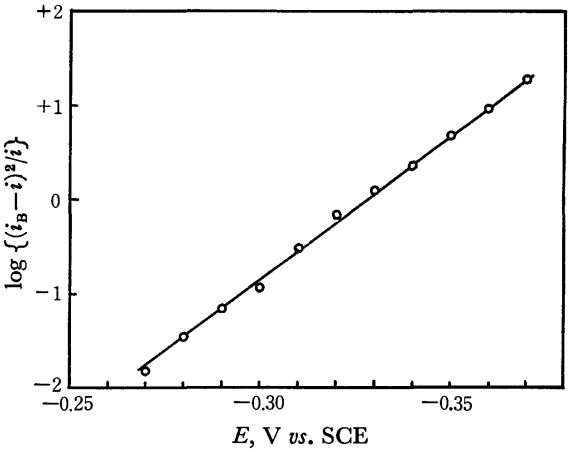

Fig. 4. Relationship between E and $\log\{(i_B-i)^2/i\}$ in 0.1 mol dm^{-3} NaOH at 25 °C.
Concentration of Hahdtc: 6×10^{-4} mol dm^{-3},
The plot has a slope of 33 mV.

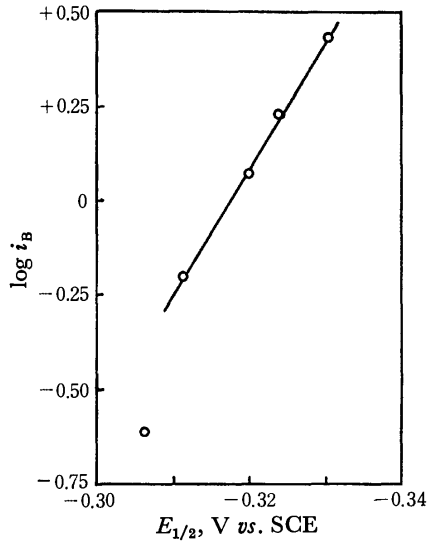

Fig. 5. Relationship between the half-wave potential $E_{1/2}$ of the main wave and log i_B in 0.1 mol dm^{-3} NaOH at 25 °C.
Concentration range of Hahdtc: (2.0—12)×10^{-4} mol dm^{-3},
The plot has a slope of 29 mV.

$$E_{1/2} = E_0' - 0.030 \log \frac{i_B}{2} \quad (9)$$

A plot of $E_{1/2}$ *vs.* log i_B is given in Fig. 5. The plot has a slope of 29 mV, in accordance with the theoretical prediction. These results indicate that the electrode reaction is a reversible oxidation process corresponding to the formation of the mercury(II) complex, Hg(ahdtc)$_2$. The same equation as that given by Eq. (7) would be obtained if the electrode process corresponded to the formation of the mercurous complex, Hg_2^I(ahdtc)$_2$. However, it was found that a gray or black precipitation was formed instantaneously when mercurous nitrate was added to the solution of Hahdtc and the UV spectrum of the filtrate was in agreement with that of the mercuric complex. The result indicates that mercurous ion is rapidly disproportionates to mercuric ion and mercury in the presence of Hahdtc.

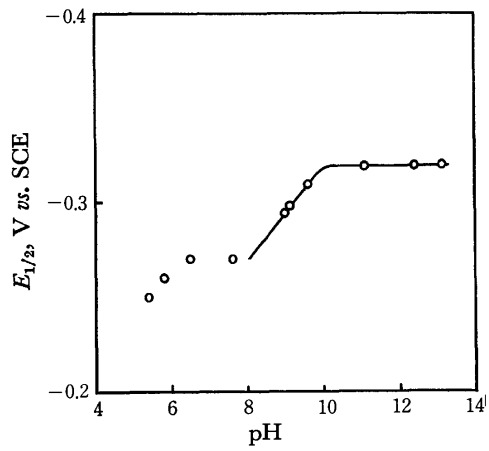

Fig. 6. Effect of pH on the half-wave potential $E_{1/2}$ of the main wave of the Hahdtc (Britton-Robinson buffer). In the pH range from 8.0 to 10.1, the plot has a slope of 25 mV.

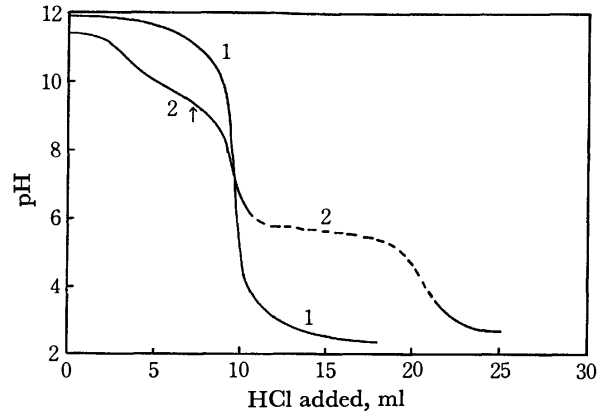

Fig. 7. Titration curve of the Hahdtc in sodium hydroxide solution with 0.104 mol dm^{-3} HCl.
Curve 1: 1 mmol NaOH; 2: 1 mmol NaOH+0.5 mmol Hahdtc, [KCl]=0.1 mol dm^{-3}.
The negative logarithm of the acid dissociation constant of amino group in the Hahdtc is estimated as 9.3, as indicated by arrow. The dashed line is the unstable region where the decomposition of Hahdtc into CS_2 and 2-aminoethylaminoethanol occurs.

Hence, it is safe to assume that the mercurous complex cannot give rise to the adsorption prewave.

Effect of pH. Effect of pH on the half-wave potential of the main wave is shown in Fig. 6. The half-wave potential is independent of pH between 10.1 and 13.1. However, at pH's lower than 10.1, the half-wave potential is shifted to more negative values with increasing pH. The pH value of the intersection of the extrapolated straight sections of the plot coincides approximately with 9.3, the value of the negative logarithm of acid dissociation constant of amino group in the Hahdtc obtained from the pH titration curve, shown in Fig. 7, which is very similar to those of other *N*-substituted carbodithioates.[8] The logarithmic analysis of DC polarogram obtained in a medium buffered at pH 9.1 indicated that a plot of E *vs.* $\log\{(i_B-i)^2/i\}$ gave a straight line with a slope of 35 mV. The result indicates that the electrode reaction is a reversible two-electron process also at the pH value. Moreover, the plot of $E_{1/2}$ *vs.* pH given in Fig. 6 had a slope of 25 mV in the pH range from 8.0 to 10.1. Therefore, the electrode reaction in the pH range from 8.0 to 10.1 may proceed according to the scheme

$$Hg + 2H^+ahdtc^- \rightleftharpoons HHg(ahdtc)_2^+ + H^+ + 2e \quad (1')$$

Further investigation in an acidic medium was impossible because Hahdtc decomposed rapidly.

Alternating Current Polarography. The Hahdtc gave two peaks on AC waves at potentials corresponding to the two DC waves (Fig. 1). The AC peak height of the prewave is considerably high in comparison with that corresponding to the main wave.

Electrocapillary Curves. The electrocapillary curves obtained in the presence and the absence of the Hahdtc are shown in Fig. 8. A marked decrease in drop time of the dropping mercury electrode is observed in the potential region between −0.2 and −0.7 V. At the potentials more negative than −0.7 V, the drop time

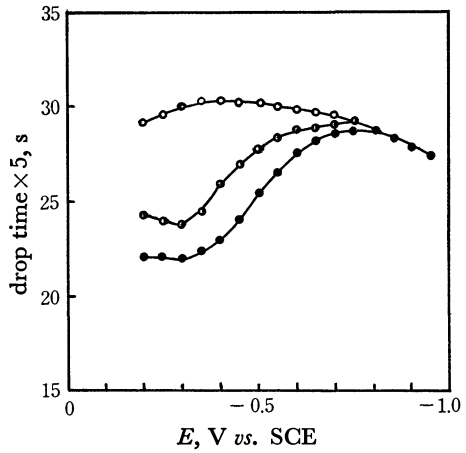

Fig. 8. Electrocapillary curves of Hahdtc in 0.1 mol dm^{-3} NaOH at 25 °C.
Concentration of Hahdtc ○: 0 ml dm^{-3}, ◑: 1×10^{-4} mol dm^{-3}, ●: 8×10^{-4} mol dm^{-3}, h=58.0 cm.

is almost equal to that in the supporting electrolyte. The results indicate that the electrode reaction product is adsorbed on the surface of mercury.

Surface Excess. The amount of substance of the adsorbed chelate molecules per unit area of the electrode surface was estimated to be 3.0×10^{-10} mol cm^{-2} by using the equation based upon the mean adsorption current of the DC polarogram.[9] From the above value, the area occupied by one molecule is calculated as 55×10^{-16} cm^2 under the assumption that a monolayer is formed.

Benzoyl Peroxide- and Photo-induced Reactions of Diethyl Mesoxalate in Cyclohexane and Toluene

Chyongjin PAC, Hiroshi SAKURAI, Kensuke SHIMA,* and Youichi OGATA*

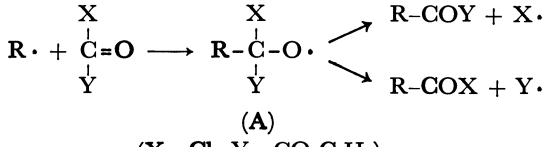
Institute of Scientific and Industrial Research, Osaka University, Yamadakami, Suita, Osaka 565

**Department of Industrial Chemistry, Faculty of Engineering, Miyazaki University, Miyazaki 880*

(Received May 29, 1974)

Benzoyl peroxide-catalyzed reactions of diethyl mesoxalate in cyclohexane gave ethyl cyclohexylglyoxylate (I) as the main product, accompanied by smaller amounts of diethyl cyclohexylhydroxymalonate (II), ethyl 2-oxobutyrate (III), and diethyl ethylhydroxymalonate (IV), while similar reactions in toluene gave no ethyl phenyl-2-oxopropionate. The α-ketoesters (I) and (III) and the hydroxymalonates (II) and (IV) were considered to arise from β-cleavage and hydrogen atom-abstraction, respectively, of alkoxy radicals A, which take place with addition of cyclohexyl and ethyl radicals to ketonic carbon of diethyl mesoxalate. Irradiation of cyclohexane and toluene solutions of diethyl mesoxalate gave II and diethyl benzylhydroxymalonate (V), respectively, as main products.

A number of reports have appeared on various free radical reactions which afford derivatives of carboxylic acids by direct introduction of such radicals as chloroformyl,[1,2] ethoxycarbonyl[3,4] and carbamoyl[5] radicals into hydrocarbons. However, α-ketocarboxylation and α-hydroxycarboxylation of hydrocarbons by free radical reactions have seldom been reported.[6] In a previous paper,[1] one of us (C.P.) reported on benzoyl peroxide-catalyzed reactions of ethyl chloroglyoxylate in cyclohexane which gave cyclohexanecarbonyl chloride as a main product, accompanied by a small amount of ethyl cyclohexylglyoxylate (I). The mechanism was interpreted in terms of a radical chain mechanism in which cyclohexyl radicals attack the carbon atom of the acid chloride function of ethyl chloroglyoxylate to cleave the carbonyl-carbonyl or carbon-chlorine bond. The mechanism would imply the addition of cyclohexyl radicals to carbonyl carbon of the acid chloride function and the subsequent β-cleavage of the radical A (Scheme 1).

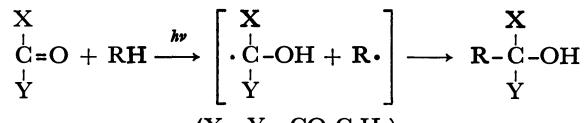


(A)

(X=Cl, Y=$CO_2C_2H_5$)

Scheme 1.

If this is the case, a benzoyl peroxide-induced reaction of diethyl mesoxalate (DEM, X=Y=$CO_2C_2H_5$) in cyclohexane is expected to give ethyl cyclohexylglyoxylate (I) as a main product. Moreover, if DEM in an electronically excited state behaves in a similar way to that of excited aliphatic ketones such as acetone,[7] photoreactions of DEM in hydrocarbons will serve as a convenient method for the preparation of α-hydroxyesters as shown in Scheme 2. Thus, DEM is expected to be available for preparation of some α-keto- and α-hydroxy-esters.



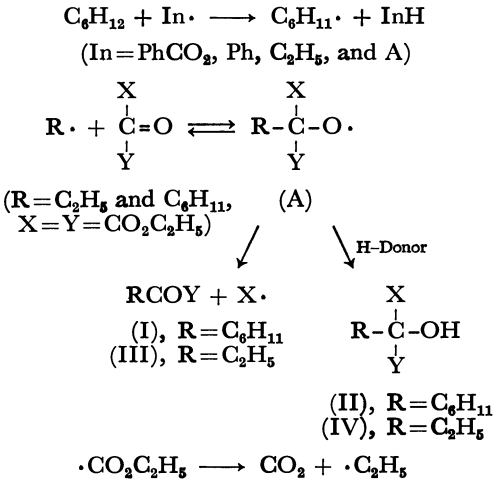
(X=Y=$CO_2C_2H_5$)

Scheme 2.

Results and Discussion

Benzoyl Peroxide-induced Reaction. When a cyclohexane solution of DEM (2.5 mol/l) containing a catalytic amount of benzoyl peroxide (BPO) (0.2 mol/l) was refluxed, ethyl cyclohexylglyoxylate (I), diethyl cyclohexylhydroxymalonate (II), ethyl 2-oxobutyrate (III) and diethyl ethylhydroxymalonate (IV) were obtained in 70—80% combined yields. The results are summarized in Table 1. Spectral data of the products (I)—(IV) are in line with the structures assigned (Table 2). The structures of (I) and (III) were unambiguously determined by direct compaison of their physical properties with those of the authentic samples and mixed melting point tests of their 2,4-dinitrophenylhydrazones with the authentic specimens.

The results support our prediction (Scheme 1), suggesting that ethyl and cyclohexyl radicals can add to ketonic carbon of DEM to generate alkoxy radicals A, which subsequently either abstract hydrogen atom from hydrogen donors to afford II and IV or undergo β-cleavage to give I and III. The mechanism is shown in Scheme 3.



Scheme 3.

This type of addition of alkyl radicals to the carbon-oxygen double bond has not been fully investigated. Free radical addition to carbon-carbon multiple bonds

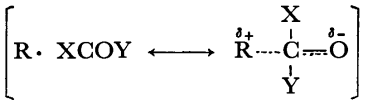
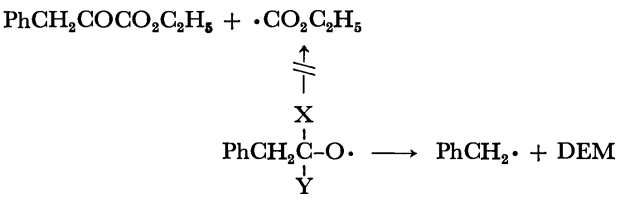
has been widely studied, several examples being reported on the addition of alkyl radicals to aldehydes,[8] biacetyl,[9] and hexafluoroacetone.[10] Reactions of cyclohexyl radicals with ethyl chloroglyoxylate[1] and oxalyl chloride[2] appear to fit the case. The reactions of alkyl radicals with some XCOY compounds are summarized in Table 3. There is a tendency of reactivities of XCOY toward alkyl radicals in relation to structures of XCOY; the formation of products by addition of alkyl radicals to carbonyl carbon of XCOY requires strong electron-withdrawing nature of X and/or Y and, moreover, the presence of a methoxyl group, a strong electron-donating group, in XCOY leads to lack of such addition reactions. Compare oxalyl chloride with phosgene and ethyl chloroglyoxylate with ethyl chloroformate and diethyl oxalate. This tendency of reactivities of XCOY toward alkyl radicals would be attributed to polar contributions to the transition state of additions of alkyl radicals to XCOY (Scheme 4). This transition state appears to be in line with that of β-cleavage of alkoxy radicals,[11] the reverse reaction of the addition of alkyl radicals to carbonyl compounds.



Scheme 4.

On the other hand, BPO-induced reactions of DEM in toluene gave no ethyl phenyl-2-oxopropionate. Volatile products were obtained in low yields and found to consist of various compounds, in which ethyl phenylglyoxylate and bibenzyl were detected as the main products. Since yields of the other products were very low, no structural determination was carried out. The result appears to be in line with the mechanism discussed above, since β-cleavage of the radical A (R=



(A)

Table 3. Addition reaction of alkyl radicals to XCOY

Radical (R·)	X	Y	Product	Ref.
C_6H_{11} and C_2H_5	$CO_2C_2H_5$	$CO_2C_2H_5$	RC(OH)XY, RCOX	This work
C_6H_{11} and others	CH_3	$COCH_3$	RCOX	9a
C_3H_7 and C_6H_{13}	CF_3	CF_3	RC(OH)XY	10a

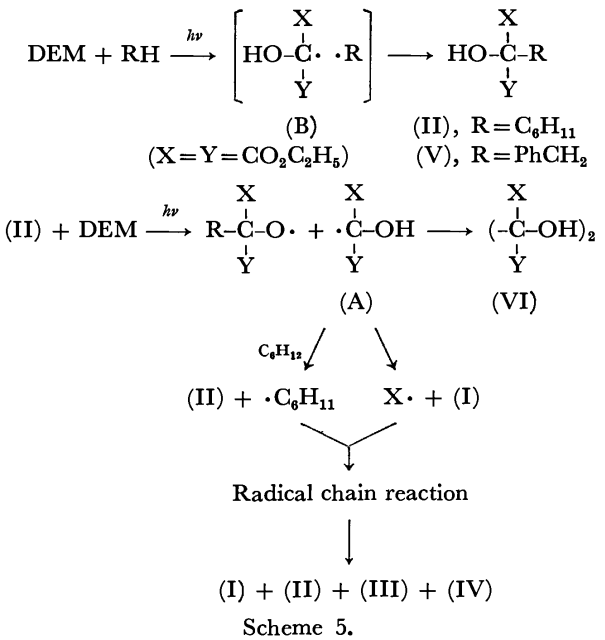
a) No significant formation of adducts from peroxide-induced reactions in cyclohexane.

$PhCH_2$) is expected to occur exclusively in regenerating benzyl radicals and DEM, as is clarified in β-cleavage of alkoxy radicals containing a benzyl group.[12]

Photo-induced Reaction. Irradiation of a cyclohexane solution of DEM (0.33 mol/l) with light longer than 320 nm at ambient temperature gave II as a main product, accompanied by small amounts of I, III, and IV (Table 1). The product distribution differes a great deal from that of the BPO-induced reaction, suggesting a different mechanism for the formation of II from the radical chain mechanism (Scheme 3). Dominant formation of II in the photoreaction might be interpreted by assuming that an excited DEM abstracts hydrogen atom from cyclohexane to afford a radical pair (B) in a solvent cage which predominantly undergoes the radical coupling to give II (Scheme 5).



Scheme 5.

However, the product distribution in the photoreaction was found to depend on the concentration of DEM in cyclohexane; as the concentration of DEM increases, yields of II begin to decrease at the concentration of *ca.* 0.5 mol/l, while the formation of I sharply increases (Fig. 1). Such a concentration effect could not be observed in BPO-induced reactions (Fig. 2). These results suggest an oxidation of II by excited DEM, giving radical (A). In a dilute solution, however, excited DEM has less chance to encounter II in its life. In the case of a concentrated solution, II is readily accumulated to a sufficient concentration for oxidation. If radical (A) is once generated by oxidation, then the radical chain reaction described in Scheme 3 can intervene. Thus, the higher the concentration of DEM, greater the tendency for radical chain reaction to occur. It is of interest to note that irradiation of a concentrated solution of DEM gave a mixture in low yields which revealed only the NMR signals of ethoxyl protons at δ 1.35 and 4.3 and an alcoholic proton at δ 3.9[13] in an area-ratio of 7.5: 5: 1. The NMR spectra suggest that the mixture contains diethyl 1,2-diethoxycarbonyl-1,2-dihydroxysuccinate (VI). VI could not be obtained in pure form by preparative gas chromatography under any condition. Further investigation for VI was, therefore, not carried out. The reaction mechanism is shown in Scheme 5.

In a similar way, irradiation of a toluene solution of DEM gave diethyl benzylhydroxymalonate (V) in a moderate yield, accompanied by minor amounts of other volatile compounds and some polymeric materials.

Experimental

Melting and boiling points are uncorrected. IR spectra were measured with a Hitachi EPI-S2 spectrophotometer, NMR spectra with a JEOL JNM-MH-100 apparatus for solutions in carbon tetrachloride containing tetramethylsilane as an internal standard, and mass spectra with a Hitachi RMU-6E apparatus. Analytical gas chromatography was carried out with a Shimadzu GC-3BF apparatus using a column of Silicone DC 550 (20% on Shimalite W, 2 m) at 200 °C, and preparative gas chromatography with a Shimadzu GC-2C apparatus using a column of Silicone DC 550 (20% on Shimalite W, 2.3 m) at 200 °C.

Toluene and spectrograde cyclohexane (Nakarai Chemicals) were distilled over metallic sodium wire. Benzoyl peroxide was recrystallized from chloroform-methanol. DEM was prepared from diethyl malonate according to the method in literature[14] and distilled from phosphorus pentoxide *in vacuo* prior to use.

BPO-Induced Reaction of DEM in Cyclohexane. A solution of DEM (8.7 g, 0.05 mol) and BPO (1 g, 0.004 mol) in cyclohexane (20 ml) was refluxed for 8 hr. After removal of cyclohexane, fractional distillation of the residue under reduced pressure gave two fractions, bp 60—100 °C/14 mmHg (2.5 g) and bp 110—135 °C/14 mmHg (4.5 g), and a residue (1 g). Gas chromatographic analyses showed that the former fraction contained predominantly DEM along with minor

Table 4. Analhytical data of α-keto- and α-hydroxy-esters and 2,4-dinitrophenylhydrazones of α-ketoesters

Compd.	Bp (°C/mmHg) or Mp (°C)	Found (%)			Formula	Calcd (%)		
		C	H	N		C	H	N
I	(125/22)	65.10	8.75		$C_{10}H_{16}O_3$	64.76	8.73	
I-DNP[a]	[161—161.5]	52.59	5.63	15.61	$C_{16}H_{20}N_4O_6$	52.74	5.53	15.38
II	(111.5/2)	60.44	8.59		$C_{13}H_{22}O_5$	60.64	8.67	
III	(72/32)	54.88	7.70		$C_6H_{10}O_3$	55.37	7.75	
III-DNP[a]	[140—141.5]	46.43	4.32	18.07	$C_{12}H_{14}N_4O_6$	46.45	4.55	18.06
IV	(120/21)	52.73	7.90		$C_9H_{16}O_5$	52.42	7.86	
V	(131/3.5)	63.14	6.81		$C_{14}H_{18}O_5$	63.15	6.95	

a) 2,4-Dinitrophenylhydrazone.

amounts of III, whereas the latter consisted of I, II, and IV over 90% in a *ca.* 8:1:4 ratio. From the former fraction, *ca.* 0.5 g of III was isolated by preparative gas chromatography. In a similar way, products I, II, and IV were also isolated by preparative gas chromatography. Analytical data of I—IV and 2,4-dinitrophenylhydrazones of (I) and (III) are listed in Table 4.

BPO-induced Reaction of DEM in Toluene. A mixture of DEM (8.7 g, 0.05 mol), BPO (1 g, 0.004 mol) and toluene (9.2 g, 0.1 mol) was heated at 114—115 °C for 8 hr. Fractional distillation under reduced pressure gave 6 g of DEM, 1.5 g of an oil (bp 70—146 °C/3 mmHg) and 1.5 g of a residue. Analytical gas chromatography showed that the oil consists of at least seven components. Two main components were isolated by preparative gas chromatography, identified as ethyl phenylglyoxylate and bibenzyl by driect comparison of their sepectral properties with those of authentic samples.

Photo-induced Reaction of DEM in Cyclohexane. A solution of DEM (8.7 g, 0.05 mol) in cyclohexane (150 ml) was irradiated by light filtered through a hexane solution of naphthalene (0.1 mol/l, 1 cm path length) from an Eikosha PIH 300 W high-pressure mercury arc at ambient temperature for 10 hr. After removal of cyclohexane, fractional distillation gave 2.2 g of DEM, 5 g of an oil (bp 130—137 °C/13 mmHg) and 1 g of a residue. Analytical gas chromatography of the oil showed that II was contaminated over 80%. Product (II) was purified by preparative gas chromatography and vacuum distillation.

Photo-induced Reaction of DEM in Toluene. A mixture of DEM (8.7 g, 0.05 mol) and toluene (23 g, 0.25 mol) placed in a test tube was irradiated by filtered light for 100 hr. Fractional distillation of the reaction mixture under reduced pressure gave 3.5 g of DEM, 3.5 g of an oil (bp 100—160 °C/6 mmHg) and 2 g of a residue. Analytical gas chromatography showed that the oil contains five products. From the oil, 1.8 g of the main product (V) was isolated by preparative gas chromatography and V was purified by vacuum distillation.

Concentration Effect to Product Distribution. In both BPO- and photo-induced reactions, 0.8 g (0.0046 mol) of DEM was used, the amounts of cyclohexane being varied. Conversion of DEM was set in 10—30%. In the case of BPO-induced runs, 0.1 g (0.4 mmol) of BPO was used. The reaction mixtures were directly subjected to gas chromatographic analyses, and the product distribution was determined. The results are shown in Figs. 1 and 2.

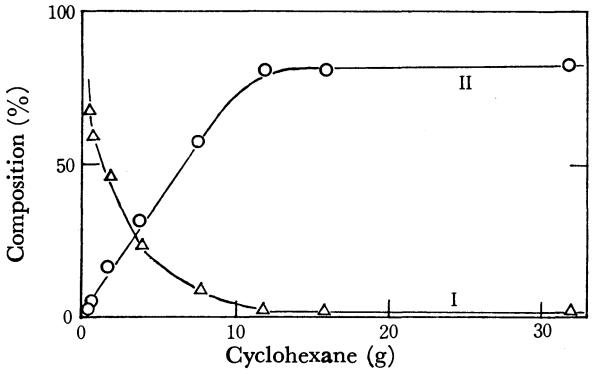


Fig. 1. Concentration effect on product distribution in photo-induced reaction of DEM in cyclohexane: DEM, 0.8 g; conversion, 10—30%.

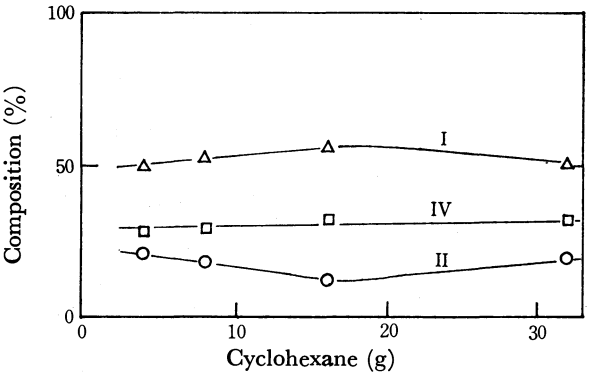

Fig. 2. Concentration effect on product distribution in BPO-induced reaction of DEM in cyclohexane: DEM, 0.8 g; BPO, 0.1 g; conversion, 10—30%.

Total Synthesis of (±)-Tetrahydroligularenolide[1]

Tochiro TATEE and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received May 29, 1974)

A total synthesis of (±)-tetrahydroligularenolide [(±)-**2**] is described. 10β-Methyl-5β-tetrahydropyranyloxy-*trans*-2-decalone (**6**) was converted in seven steps into 3-methoxycarbonyl-5,10-dimethyl-*trans*-2-decalone (**15**), which on alkylation with ethyl α-iodopropionate gave 3-(1-ethoxycarbonylethyl)-3-methoxycarbonyl-5,10-dimethyl-*trans*-2-decalone (**19**) and 6-(1-ethoxycarbonylethoxy)-7-methoxycarbonyl-1β,8aβ-dimethyl-1,2,3,4,4a,5,8,8a-*trans*-octahydronaphthalene (**20**). Hydrolysis of **19** proceeded with a loss of carbon dioxide to afford (±)-tetrahydroligularenolide [(±)-**2**].

It has been reported that a sesquiterpene lactone, ligularenolide, was isolated from "San-shion" [2] (the roots of *Ligularia* species), and its structure including an absolute stereochemistry was shown to be **1**,[3] which on hydrogenation over palladium-charcoal in ethanol gave tetrahydroligularenolide (**2**).[3] We wish to describe a total synthesis of (±)-tetrahydroligularenolide [(±)-**2**] with a 10-epi-eremophilane skeleton.[1] Some α,β-unsaturated γ-lactones of eremophilane type, (±)-eremophilenolide [(±)-**3**],[4,5] (±)-3α-hydroxyeremophilenolide [(±)-**4**][6] and (±)-3β-hydroxyeremophilenolide [(±)-**5**][6] have been synthesized. A conversion of (−)-5α,6α-epoxydihydroalantolactone into (−)-**2** has been described.[7] Recently, a total synthesis of (±)-**2** was reported;[4b] this synthesis includes a final introduction of a methyl group to C-11, while the present communication contains an alkylation by three carbon units and the subsequent lactonization.

2

Acetalization of a tetrahydropyranyloxy-*trans*-decalone (**6**)[8,9] with ethylene glycol in the presence of *p*-toluenesulfonic acid gave a cyclic acetal (**7**) with concomitant hydrolysis of a tetrahydropyranyl group. The alcohol (**7**) was oxidized with chromium trioxide in pyridine to afford the known ketone (**8**),[10] which was then treated with methyl magnesium iodide in ether to give a crude alcohol (**9**). Dehydration of **9** with phosphorus oxychloride and phosphoric acid in pyridine yielded a mixture of olefins, **10**[11] and **11** (in a ratio of 2: 1). Deacetalization of the olefin mixture to yield a mixture of **12** and **13**, and the subsequent hydrogenation in acetic acid in the presence of palladium-charcoal gave a dimethyldecalone (**14**)[12] (yield from **6**: 16%). Only one stereoisomer (**14**) was obtained; a *cis* relationship of the two methyl groups could be derived after completion of the synthesis of (±)-**2**.

Pinder and Torrence[12c] described a methoxycarbonylation of **14** with dimethyl carbonate and sodium hydride in dry benzene under a nitrogen atmosphere to yield **15** as the sole product. A similar treatment of **14** in dioxane gave a mixture of β-keto-esters, which was subjected to separation by silica gel chromatography to afford **15**[12c] (y: 75%) and **16** (y: 12%). The PMR spectrum of **16** showed a doublet (J= 12 Hz) at δ 3.27 due to an axial (β)-proton coupled with a ring juncture proton; the structure **16** was therefore shown for the latter ester.

As a model experiment of alkylation of **15**, α-methoxycarbonylcyclohexanone was alkylated[13] with ethyl α-halogenopropionate in the presence of sodium hydride (or potassium hydride) under a nitrogen atmosphere. *C*-alkylated (**17**) and *O*-alkylated (**18**) products were

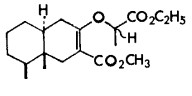
19



20a and 20b

obtained in the ratio listed in Table 1. When the reaction was carried out with ethyl α-iodopropionate, sodium hydride and benzene, the best yield of **17** was obtained.

The keto-ester (**15**) in benzene was alkylated with ethyl α-iodopropionate in the presence of sodium hydride under a nitrogen atmosphere. The resulting product showed three spots on tlc, and was subjected to separation by silica gel chromatography to give the *C*-alkylated (**19**; y: 30%) and the *O*-alkylated (**20a** and **20b**; y: 26%) products. The former substance (**19**) corresponding to the least polar spot was found to be a diastereomeric mixture by its PMR spectrum. The latter products (**20a** and **20b**) proved to be a diastereomeric mixture corresponding to the other two spots, and was subjected to further separation on a column of silica gel to give each diastereomer. Alkylation of **15** in benzene with ethyl α-bromopropionate and sodium hydride resulted in formation of a small amount of **19**, the *O*-alkylated products (**20a** and **20b**) were obtained as predominant products.

Hydrolysis of **19** with hydrochloric acid in acetic acid under reflux was effected with a loss of carbon dioxide to afford (±)-**2** (y: 57%), which was found to be the same (except optical rotational data) as (−)-tetrahydroligularenolide (**2**)[3] derived from natural (−)-ligularenolide (**1**).

Experimental

IR spectra were measured with a Hitachi EPI-G2 spectrometer, UV spectra with a Hitachi EPS-3 spectrometer, and mass spectra with a Hitachi RMU-6-Tokugata mass spectrometer with use of an indirect system operating at 70 eV. PMR spectra were measured with a JEOL JNM PS-100 (100 MHz), a JEOL JNM 3H-60 (60 MHz), a Hitachi R-20 (60 MHz) or a Hitachi R-24 (60 MHz) spectrometer. Chemical shifts were expressed in terms of δ downfield from TMS as an internal standard, and coupling constants in Hz. Gas chromatographic (glc) analyses were carried out on a Shimadzu gas chromatograph model GC-4APF. Thin layer chromatography (tlc) was carried out on Kieselgel G (E. Merck). Wakogel C-200 (Wako Pure Chemical Co.) was used for column chromatography. Melting points were determined on a hot block and are uncorrected.

2,2-Ethylenedioxy-5β-hydroxy-10β-methyl-trans-*decalin (7).* 10β-Methyl-5β-tetrahydropyranyloxy-*trans*-2-decalone (**6**; 5.6 g)[8,9] was dissolved in a mixture of benzene (200 ml) containing *p*-toluenesulfonic acid (120 mg) and ethylene glycol (3 ml), and the mixture was refluxed under a Dean-Stark water separator for 16 hr. The cooled solution was poured into a 5% aqueous potassium hydrogen carbonate solution, and then extracted with ether. The organic layer was washed with brine and dried over magnesium sulfate. The solvent was removed and the residue was chromatographed on a column of silica gel (300 g). Elution with a mixture of benzene and ether (9: 1) and removal of the solvents afforded an oil (**7**[10]; 3.6 g; y: 76%), IR (liquid) 3430 cm^{-1}; PMR ($CDCl_3$) δ 0.86 (3H, s; *t*-CH_3) and 3.96 (4H, s; $-OCH_2CH_2O-$); MS *m/e* 226 [M^+ ($C_{13}H_{22}O_3$); relative intensity, 4%] and *m/e* 99 (100%).

6,6-Ethylenedioxy-9-methyl-trans-*1-decalone (8).* A solution of chromium trioxide (9 g) in pyridine (90 ml) was added to a solution of **7** (3.6 g) in pyridine (90 ml), and the resulting solution was allowed to stand at room temperature overnight. Extraction with ether and the usual treatment gave an oil which was chromatographed on a column of silica gel. Elution with a mixture of benzene and ether (5: 1) gave an oil (2.7 g), which on solidification gave **8**, mp 44—47 °C (lit,[10a] mp 41—45 °C; lit,[10b] mp 45—47 °C), IR (Nujol) 1715 cm^{-1}; PMR ($CDCl_3$) δ 1.13 (3H, s; *t*-CH_3) and 3.92 (4H, s; $-OCH_2CH_2O-$); MS *m/e* 224 [M^+($C_{13}H_{20}O_3$); 4%] and *m/e* 99 (100%).

2,2-Ethylenedioxy-5-hydroxy-5,10-dimethyl-trans-*decalin (9).* To the Grignard reagent prepared from methyl iodide (25 g) and magnesium (2.5 g) in ether (30 ml) at 0 °C was added a solution of **8** (2.7 g) in ether (40 ml). The reaction mixture was stirred for 2 hr at room temperature, and then decomposed with aqueous ammonium chloride solution. Extraction with ether and the usual work-up gave a residue which was chromatographed on a column of silica gel (160 g). Elution with a mixture of benzene and ether (8: 1) gave a crude alcohol (**9**; 2 g), an oil (one spot on tlc), on removal of the solvents; IR (liquid) 3450 cm^{-1}; PMR ($CDCl_3$) δ 0.91 (3H, s; *t*-CH_3), 1.12 (3H, s; $CH_3-\overset{|}{\underset{|}{C}}-OH$), and 3.93 (4H, s; $-OCH_2CH_2O-$).

Dehydration of the Alcohol (9) and Subsequent Deacetalization. Crude alcohol (**9**; 2 g) in pyridine (100 ml) was added dropwise to a solution of phosphorus oxychloride (30 ml) and phosphoric acid (1 ml) in pyridine (60 ml) at 0 °C with stirring, and the mixture was warmed at 55 °C for 20 hr. The cooled mixture was poured into ice water, and the product was extracted with ether. After the usual treatment, a mixture of **10**[10b] and **11** (2: 1) was obtained as an oil (1.2 g); IR (liquid) 3090, 1640, 1375, 1360, 1140, and 1085 cm^{-1}; PMR ($CDCl_3$) δ 0.96 (s; *t*-CH_3 of **10**), 1.02 (s; *t*-CH_3 of **11**), 1.65 (d; J=2 Hz; CH_3–C=C), 3.94 (s; $-OCH_2CH_2O-$), 4.64 (m; C=CH_2), and 5.24 (m; C=CH); MS *m/e* 222 [M^+ ($C_{14}H_{22}O_2$); 2%] and *m/e* 99 (100%) [*cf.* lit,[10b,11] spectral data for pure **10**: bp 90—95 °C/0.04 mmHg, IR ($CHCl_3$) 1375 and 1130—1050 cm^{-1}; PMR ($CDCl_3$) δ 1.02 (s; *t*-CH_3), 1.65 (d, J=2 Hz; CH_3–C=C), 3.94 (s; $-OCH_2CH_2O-$), and 8.59 (m; C=CH)]. The signals at δ 0.96 and 1.02 appeared in an integrated intensity ratio of 2: 1.

A mixture of unsaturated cyclic ketals (1.2 g; **10** and **11**) was treated with acetic acid (48 ml) and water (12 ml) at 80 °C for 8 hr. The solvent was removed and the residue was passed through a column of silica gel (70 g) using benzene as an eluent. On removal of the solvent, a mixture of unsaturated ketones (**12** and **13**; 2: 1) was obtained as an oil (677 mg; yield from **7**: 24%); IR (liquid) 1715 and 1640 cm^{-1}; PMR ($CDCl_3$) δ 1.14 (s; *t*-CH_3 of **12**), 1.18 (s; *t*-CH_3 of **13**), 1.66 (d, J=2 Hz; CH_3–C=C), 4.59 and 4.65 (each m; C=CH_2), and 5.25 (m; C=CH); MS *m/e* 178 [M^+ ($C_{12}H_{18}O$); 55%] and *m/e* 93 (100%). The signals at δ 1.14 and 1.18 appeared in an integrated intensity ratio of 2: 1.

5β,10β-Dimethyl-trans-*2-decalone (14).* An olefin mixture (630 mg; **12** and **13**) in acetic acid (20 ml) was hydrogenated in the presence of 10% palladium–charcoal (155 mg) at room temperature for 2 hr. After filtration of the catalyst, the solvent was evaporated to give a residue which was chromatographed on a column of silica gel (30 g). Elution with a mixture of light petroleum and ether (8: 1) and removal of the solvents afforded a dimethyldecalone (**14**; 563 mg; y: 88%) (yield from **6**: 16%) as a sole product, an oil, bp 104—106 °C/2 mmHg, IR (liquid) 1715 cm^{-1}; PMR ($CDCl_3$) δ 0.86 (3H, m; *s*-CH_3) and 0.92 (3H, s; *t*-CH_3); MS *m/e* 180 [M^+($C_{12}H_{20}O$); 27%] and *m/e* 109 (100%) [lit,[12b] bp 83—86 °C/1 mmHg, IR (liquid) 1712 cm^{-1}; PMR ($CDCl_3$) δ 0.87 (m; *s*-CH_3) and 0.92 (s; *t*-CH_3)]. 2,4-Dinitrophenyl-

hydrazone (crystallized from ethanol): mp 157—158 °C. Found: C, 60.04; H, 6.53; N, 15.49%. Calcd for $C_{18}H_{24}N_4O_4$: C, 59.98; H, 6.71; N, 15.55% [*cf.* lit,[12a] 2,4-dinitrophenylhydrazone of (+)-**14**: mp 172.5—173.5 °C].

Methoxycarbonylation of the Dimethyldecalone (14). A mixture of the dimethyldecalone (**14**; 137 mg), dimethyl carbonate (1.08 g) and sodium hydride (120 mg of a 50% dispersion in mineral oil) in dioxane (3 ml) was stirred under a nitrogen atmosphere at 80—85 °C for 4 hr. The cooled mixture was treated with acetic acid (1 ml) and then extracted with ether. The extract was washed with water and dried over magnesium sulfate. The solvent was removed and the residue (239 mg) was chromatographed on a column of silica gel (20 g) using the following solvents as eluent: light petroleum (fr 1, 100 ml; frs 2—3, each 30 ml), light petroleum and ether (20: 1) (frs 4—12, each 30 ml), light petroleum and ether (10: 1) (frs 13—18, each 30 ml), and light petroleum and ether (5: 1) (frs 19—21, each 60 ml). Fraction 5 gave a keto-ester (**15**; 136 mg; y: 75%), an oil, bp 149—155 °C/2 mmHg (lit,[12c] bp 122—125 °C/0.25 mmHg), IR (liquid) 3200—2600, 1750, 1720, 1660, and 1620 cm^{-1}; UV (EtOH) λ_{max} 257 nm (ε 11000); PMR ($CDCl_3$) δ 0.68 (3H, s; *t*-CH_3), 0.89 (3H, m; *s*-CH_3), 3.76 (3H, s; $-CO_2CH_3$), and 12.19 (s; enolic proton); MS *m/e* 238 [$M^+(C_{14}H_{22}O_3$); 11%] and *m/e* 109 (100%). Fractions 13—14 afforded an isomeric keto-ester (**16**; 21 mg; y: 12%), mp 87—88 °C, IR (Nujol) 1740 and 1715 cm^{-1}; UV (EtOH) λ_{max} 258 nm (ε 130); PMR ($CDCl_3$) δ 0.89 (3H, m; *s*-CH_3), 0.97 (3H, s; *t*-CH_3), 3.27 (1H, d, J=12 Hz; $-\dot{C}H\underline{C}H(CO_2CH_3)CO-$), and 3.74 (3H, s; $-CO_2\underline{C}H_3$); MS *m/e* 238 [$M^+(C_{14}H_{22}O_3$); 4%] and *m/e* 109 (100%). Found: C, 70.26; H, 9.40%. Calcd for $C_{14}H_{22}O_3$: C, 70.55; H, 9.31%.

Alkylation of α-Methoxycarbonylcyclohexanone. To sodium hydride (910 mg of a 50% dispersion in mineral oil; washed thrice by decantation with dry light petroleum) was added α-methoxycarbonylcyclohexanone (3 g) in dry ether (50 ml) with stirring to give the enolate, which was filtered and washed with ether. Dry dimethyl sulfoxide (50 ml) and then ethyl α-bromopropionate (8 g) were added dropwise to the enolate, and the whole was stirred at room temperature for 19 hr under a nitrogen atmosphere. After addition of water (150 ml), the reaction mixture was extracted with light petroleum. The extract was washed with water, dried over magnesium sulfate and the solvent was removed to give an oil (7.6 g). Gas chromatographic analysis showed that the ratio of the *C*-alkylated (**17**) and the *O*-alkylated (**18**) products was *ca.* 2: 1. A part (326 mg) of the oil was subjected to separation by silica gel (20 g) column chromatography using the following solvents as eluent: light petroleum and ether (20: 1) (frs 1—2, each 50 ml; frs 3—9, each 30 ml), light petroleum and ether (10: 1) (frs 10—12, each 30 ml; frs 13—18, each 20 ml), and light petroleum and ether (5: 1) (frs 19—22, each 85 ml). Fractions 2 and 3 gave ethyl α-bromopropionate and a small amount of the starting material, respectively. From fractions 11—12, the *C*-alkylated product (**17**; 63 mg) was obtained as an oil, IR (liquid) 1750—1715 cm^{-1}; PMR ($CDCl_3$) δ 1.14 (3H, d, J=7 Hz; $C\underline{H}_3\dot{C}H-$), 1.26 (3H, t, J=7 Hz; $C\underline{H}_3CH_2-$), 3.18 (1H, q, J=7 Hz; $CH_3\dot{C}\underline{H}CO_2C_2H_5$), 3.75 (3H, s; $-CO_2CH_3$) and 4.13 (2H, q, J=7 Hz; $-CO_2C\underline{H}_2CH_3$); MS *m/e* 256 [$M^+(C_{13}H_{20}O_5$); 4%] and *m/e* 123 (100%). This material (50 mg) was further chromatographed on a column of silica gel (5 g). Elution with a mixture of light petroleum and ether (5: 1) gave the analytical sample. Found: C, 60.76; H, 7.83%. Calcd for $C_{13}H_{20}O_5$: C, 60.92; H, 7.87%. Glc retention time 10.0 min (column: neopentylglycol succinate, 160 °C, N_2, 85 ml/min) and 9.7 min (column: Diasolid H-523, 160 °C, N_2, 85 ml/min). Fractions 13—15 gave a mixture of **17** and **18** (53 mg). Fractions 16—22 afforded the O-alkylated product (**18**; 47 mg), an oil, IR (liquid) 1760—1720 and 1630 cm^{-1}; PMR ($CDCl_3$) δ 1.28 (3H, t, J=7 Hz; $C\underline{H}_3CH_2-$), 1.51 (3H, d, J=7 Hz; $C\underline{H}_3\dot{C}H-$), 3.70 (3H, s; $-CO_2CH_3$), 4.18 (2H, q, J=7 Hz; $-CO_2C\underline{H}_2CH_3$) and 4.56 (1H, q, J=7 Hz; $CH_3\dot{C}\underline{H}CO_2C_2H_5$); MS *m/e* 256 [$M^+(C_{13}H_{20}O_5$); 7%] and *m/e* 124 (100%). The product (49 mg) was further chromatographed on a column of silica gel (5 g). Elution with a mixture of light petroleum and ether (5: 1) gave an analytical sample. Found: C, 60.73; H, 8.05%. Calcd for $C_{13}H_{20}O_5$: C, 60.92; H, 7.87%. Glc retention time 14.2 min (column: neopentylglycol succinate, 160 °C, N_2, 85 ml/min) and 14.0 min (column: Diasolid H-523, 160 °C, N_2, 85 ml/min). The combined yield of the two alkylated products (**17** and **18**) was 77%.

Other experiments under various conditions were performed by similar procedures to those described above. The resulting mixture of products was subjected to analysis by glc; the results are summarized in Table 1.

Alkylation of the Keto-ester (15). (a) Sodium hydride (180 mg of a 50% dispersion in mineral oil), washed by decantation with dry benzene, was suspended in the same solvent (3 ml). The keto-ester (**15**; 190 mg) in dry benzene (6 ml) was added and the mixture was stirred at room temperature for 40 min. Ethyl α-iodopropionate (990 mg) was then added and the resulting mixture was refluxed under a nitrogen atmosphere for 17 hr. The cooled reaction mixture was treated with 1 M hydrochloric acid (2 ml), and extracted with ether after addition of water. The organic layer was washed with an aqueous sodium bicarbonate solution and water, and dried over magnesium sulfate. Evaporation of the solvents afforded an oil (1.04 g), which showed three spots due to alkylated products on tlc besides those due to ethyl α-iodopropionate and the starting material. The oil was subjected to separation by a column of silica gel (20 g) to give the following fractions: fr 1 [eluted with light petroleum and ether (30: 1); 50 ml], frs 2—4 [light petroleum and ether (20: 1); each 50 ml], frs 5—19 [light petroleum and ether (10: 1); each 15 ml], and frs 20—24 [light petroleum and ether (4: 1); each 30 ml].

Fractions 2—4 gave ethyl α-iodopropionate and a small amount of the starting material (580 mg in total). Fractions 10—16 afforded the *C*-alkylated product (**19**; 80 mg; y: 30%), an oil, IR (liquid) 1740 and 1720 cm^{-1}; PMR ($CDCl_3$) δ 0.81 (3H, s; *t*-CH_3), 0.88 (3H, m; *s*-CH_3), 1.24 (3H, d; J=7 Hz; $C\underline{H}_3\dot{C}H-$ in the side chain), 1.27 (3H, t; J=7 Hz; $C\underline{H}_3CH_2-$), 3.04 (1H, q; J=7 Hz; $CH_3\dot{C}\underline{H}CO_2C_2H_5$), 3.71 (3H, s; $-CO_2CH_3$) and 4.10 (2H, q; J=7 Hz; $-CO_2C\underline{H}_2-CH_3$); PMR ($C_6D_6$) δ 0.78 (3H, s; *t*-CH_3), 0.86 (3H, m; *s*-CH_3), 1.03 (3H, t; J=7 Hz; $C\underline{H}_3CH_2-$), 1.33 (3H, d; J=7 Hz; $C\underline{H}_3\dot{C}H-$ in the side chain), 3.29 (3H, s; $-CO_2-CH_3$), 3.32 (1H, q; J=7 Hz; $CH_3C\underline{H}\dot{C}O_2C_2H_5$), 4.02 (q, J=7 Hz; $-CO_2C\underline{H}_2CH_3$) and 4.04 (q, J=7 Hz; $-CO_2C\underline{H}_2-CH_3$ of the other diastereomer); MS *m/e* 338 [$M^+(C_{19}H_{30}O_5$); 1%] and *m/e* 205 (100%). The substance (11 mg) was further chromatographed on a column of silica gel (5 g). Elution with a mixture of light petroleum and ether (5: 1) gave an analytical sample. Found: C, 67.63; H, 9.06%. Calcd for $C_{19}H_{30}O_5$: C, 67.43; H, 8.94%. The product (**19**) corresponding to the least polar spot on tlc was a diastereomeric mixture as shown by the PMR spectral data mentioned above.

Fractions 17—23 gave the *O*-alkylated products (**20a** and **20b**; 69 mg in total; y: 26%), which corresponded to the other two spots. From fractions 20 and 21, more polar diastereomer (**20a**; 22 mg; one spot on tlc) was obtained

as an oil, IR (liquid) 1755, 1730, 1700, and 1640 cm^{-1}; UV (EtOH) λ_{max} 247 nm(ε 12000); PMR ($CDCl_3$) δ 0.68 (3H, s; *t*-CH_3), 0.87 (3H, m; *s*-CH_3), 1.28 (3H, t; J=7 Hz; CH_3CH_2–), 1.53 (3H, d; J=7 Hz; CH_3CH– in the side chain), 3.72 (3H, s; $-CO_2CH_3$), 4.19 (2H, q; J=7 Hz; $-CO_2CH_2CH_3$) and 4.59 (1H, q; J=7 Hz; $CH_3CHCO_2C_2H_5$); PMR (C_6D_6) δ 0.63 (3H, s; *t*-CH_3), 0.77 (3H, m; *s*-CH_3), 0.97 (3H, t; J=7 Hz; CH_3CH_2–), 1.47 (3H, d; J=7 Hz; CH_3CH– in the side chain), 3.51 (3H, s; $-CO_2CH_3$), 3.94 (2H, q; J=7 Hz; $-CO_2CH_2CH_3$) and 4.46 (1H, q; J=7 Hz; $CH_3CHCO_2C_2H_5$); MS *m/e* 338 [$M^+(C_{19}H_{30}O_5)$; 3%] and *m/e* 205 (100%). The product (15 mg) was further chromatographed on a column of silica gel (3 g). Elution with a mixture of light petroleum and ether (4: 1) gave an analytical sample. Found: C, 67.17; H, 8.97%. Calcd for $C_{19}H_{30}O_5$: C, 67.43; H, 8.94%. From fractions 17 and 18, a small quantity of crude less polar diastereomer (**20b**) was obtained. Characterization of the latter diastereomer is described below.

(b) Alkylation of the keto-ester (**15**; 71 mg) in dry benzene (10 ml) with ethyl α-bromopropionate (385 mg) and sodium hydride (71 mg of a 50% dispersion in mineral oil) was carried out as described in (a) to give a residue (270 mg), which was chromatographed on a column of silica gel (20 g) using the following solvents as eluent: light petroleum and ether (20: 1) (frs 1—3, each 50 ml), light petroleum and ether (10: 1) (fr 4, 50 ml; frs 5—24, each 15 ml), and light petroleum and ether (5: 1) (frs 25—33, each 15 ml). Fractions 12—15 gave the C-alkylated product (**19**; 4 mg). The O-alkylated products (**20a** and **20b**; 40 mg in total) were obtained from fractions 16—33. Fractions 16—22 showing a single spot on tlc afforded less polar diastereomer (**20b**; 15 mg), an oil, IR (liquid) 1750—1730, 1715, and 1640 cm^{-1}; UV (EtOH) λ_{max} 245 nm (ε 4800); PMR ($CDCl_3$) δ 0.65 (3H, s; *t*-CH_3), 0.84 (3H, m; *s*-CH_3), 1.27 (3H, t; J=7 Hz; CH_3CH_2–), 1.50 (3H, d; J=7 Hz; CH_3CH– in the side chain), 3.69 (3H, s; $-CO_2CH_3$), 4.17 (2H, q; J=7 Hz; $-CO_2CH_2CH_3$) and 4.55 (1H, q; J=7 Hz; $CH_3CHCO_2C_2H_5$); PMR (C_6D_6) δ 0.64 (3H, s; *t*-CH_3), 0.77 (3H, m; *s*-CH_3), 0.94 (3H, t; J=7 Hz; CH_3CH_2–), 1.53 (3H, d; J=7 Hz; CH_3CH– in the side chain), 3.50 (3H, s; $-CO_2CH_3$), 3.93 (2H, q; J=7 Hz; $-CO_2CH_2CH_3$) and 4.66 (1H, q; J=7 Hz; $CH_3CHCO_2C_2H_5$); MS *m/e* 338 [$M^+(C_{19}H_{30}O_5)$; 2%] and *m/e* 205 (100%). The material (10 mg) was further chromatographed on a column of silica gel (3 g). Elution with a mixture of light petroleum and ether (10: 1) gave an analytical sample. Found: C, 67.09; H, 8.98%. Calcd for $C_{19}H_{30}O_5$: C, 67.43; H, 8.94%. Fractions 25—33 gave more polar diastereomer (**20a**; 20 mg), whose spectral data were mentioned above.

(±)-Tetrahydroligularenolide [(±)-2]. A mixture of the *C*-alkylated product **19**; 65 mg), acetic acid (1 ml), water (0.3 ml), and 12 M hydrochloric acid (1.3 ml) was heated under reflux for 9 hr. Extraction with ether and the usual work-up gave an oil (49 mg), which was chromatographed on a column of silica gel (5 g). Elution with a mixture of light petroleum and ether (9: 1) and removal of the solvents afforded (±)-tetrahydroligularenolide [(±)-**2**; 24 mg; y: 57%], mp 83—84 °C, IR (CCl_4) 1770—1750 and 1690 cm^{-1}; UV (MeOH) λ_{max} 221 nm (ε 17000); PMR ($CDCl_3$) δ 0.58 (3H, s; *t*-CH_3), 0.91 (3H, d; J=6 Hz; *s*-CH_3), 1.80 (3H, t; J=1.5 Hz; CH_3–C=C), 2.77 (1H, d; J=14 Hz; proton at C-6β) and 4.58 (1H, m; proton at C-8); MS *m/e* 234 [$M^+(C_{15}H_{22}O_2)$; 21%] and *m/e* 123 (100%). Found: C, 76.79; H, 9.64%. Calcd for $C_{15}H_{22}O_2$: C, 76.88; H, 9.46%. IR (in CCl_4), PMR and mass spectra of this substance were found to be identical with those of the authentic tetrahydroligularenolide [(−)-**2**][3] obtained from natural ligularenolide [(−)-**1**].[3]

The Finkelstein Reaction in Acetonitrile - Alcohol Mixtures. An Approach to an Anion Solvation by Means of a Multi-step Solvation Model*

Yasuhiko KONDO, Toshio KATO, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received June 12, 1974)

The rate constants were determined for both processes of the Finkelstein reaction in acetonitrile–alcohol mixtures at 30 °C:

$$CH_3Br + I^- \underset{k_r}{\overset{k_f}{\rightleftharpoons}} CH_3I + Br^-$$

Theoretical equations were derived describing the dependence of the rate constant on the composition changes in the solvent mixtures. These equations describe the change in the rate constant in terms of changes in the activity coefficient. The results were analyzed by means of the equations; they lead to the conclusion that anions have multiple solvation equilibria with alcohols. The relative magnitudes of the step-by-step association constants and of the solvation numbers thus determined agreed with the results determined spectrophotometrically.

In various fields of solution chemistry, quantitative discussions of solvation phenomena are often based on the concept of multi-step solvation processes. The present authors developed a theoretical expression in terms of multi-step solvation for the activity coefficient when a solute is dissolved in a binary mixed solvent. The solvation behavior of a proton in methanol–water mixtures[1] was discussed in terms of such processes. Even though it is intuitively reasonable, however, the weakness of the concept lies in the lack of experimental evidence directly pertaining to the phenomenon.

According to Parker,[2] protic and dipolar aprotic solvents most clearly manifest their characteristics on anion solvation. Recent spectroscopic investigations of the anion-protic solvent interactions successfully support the idea, and quantitative data have been accummulated.[3,4] The Finkelstein reaction, for which reaction rates have been extensively reviewed,[5,6] can be expected to be a good probe for searching into the relation between solute-solvent interactions and reaction rates in solution.

In the present work, the authors have measured the reaction rates in alcohol–acetonitrile mixtures. After analyzing the results on the basis of theoretical expressions derived by the authors, the anion-alcohol interactions and reaction rates in solvent mixtures are discussed.

Experimental

Materials: The tetra-*n*-butylammonium bromide and iodide were prepared by refluxing tri-*n*-butylamine and the corresponding halide in methyl ethyl ketone. The crude products were recrystallized three times from an acetone–ether mixture and dried *in vacuo* at 65 °C for a few days before use.

The methyl iodide was shaken with a dilute potassium carbonate solution, washed with water, dried over anhydrous calcium chloride for one day, and distilled.

The methyl bromide was washed with concentrated sulfuric acid in a pressure vessel, distilled twice, and kept over phosphorus pentoxide in a pressure vessel.

The acetonitrile was refluxed over calcium hydride and distilled, and then distilled two times from phosphorus pentoxide and calcium hydride.

The methanol, ethanol, 2-propanol, and *t*-amyl alcohol were treated as has been described elsewhere.[7]

Kinetic Procedure: The solutions of alkyl halide and tetraalkylammonium salt were prepared by weight. 5 ml aliquots from each stock solution were mixed in a glass test tube, a capacity of 20 ml: and with a ground glass stopper; the reaction was then carried out in a thermostated bath held at 30.0±0.05 °C. After a given period of time, the reaction mixture was poured into a mixture of petroleum ether and water. The electrolytes were extracted from the organic layer, and the concentrations were determined by potentiometric titration using a silver nitrate solution.

Calculation of Rate Constants: The reaction scheme is as follows:

$$\underset{a-x}{MeBr} + \underset{b-x}{I^-} \underset{k_r}{\overset{k_f}{\rightleftharpoons}} \underset{x}{MeI} + \underset{x}{Br^-} \qquad (1)$$

$$K = \frac{x^2}{(a-x)(b-x)}$$

where a and b are the initial concentrations of the reactants.

The rate law and the forward rate constant, k_f, are given by these equations:

$$(dx/dt) = k_f(a-x)(b-x) - k_r x^2 \qquad (2)$$

$$k_f = \frac{1}{2(K^{-1}-1)Bt} \ln\left\{\frac{1+x/(A+B)}{1+x/(A-B)}\right\} \qquad (3)$$

$$K = (k_f/k_r) \qquad (4)$$

$$A = \frac{(a+b)}{2(K^{-1}-1)} \qquad (5)$$

$$B = \frac{\{(a-b)^2+4K^{-1}ab\}^{1/2}}{2(K^{-1}-1)} \qquad (6)$$

When the contribution from the reverse reaction is negligibly small, the rate constant is given by this equation:

$$K_f = \frac{1}{(a-b)t} \ln\left\{\frac{b(a-x)}{a(b-x)}\right\} \qquad (7)$$

The reaction rates were followed starting from the appropriate direction; *i.e.*, for the measurement of k_f we started

* This should be referred to as "Reaction Rates in Binary Mixed Solvents, VII," part VI; Y. Kondo, K. Uosaki, and N. Tokura, This Bulletin, **44**, 2548 (1971).

TABLE 1. DENSITIES OF SOLVENT MIXTURES (30 °C)

Mole fraction of MeCN	MeCN–MeOH	MeCN–EtOH	MeCN–2-PrOH	MeCN–*t*-AmOH
0.0	0.782	0.781	0.777	0.800
0.2	0.782	0.780	0.775	0.797
0.4	0.779	0.778	0.773	0.792
0.6	0.777	0.775	0.771	0.785
0.8	0.774	0.773	0.770	0.778
0.9	0.772	0.772	0.770	0.775
1.0	0.771	0.771	0.771	0.771

from methyl bromide and tetra-*n*-butylammonium iodide, and *vice versa*.

All the calculations were performed on the basis of Eqs. (3) and (7) with a NEAC 2200-700 computer.

Measurements of Density: The densities of the solvent mixtures, *i.e.*, acetonitrile–methanol, –ethanol, –2-propanol, and –*t*-amyl alcohol, were measured with a single-stem pycnometer with a capacity of *ca.* 30 ml. The interpolated values are summarized in Table 1.

Results

Rate measurements were carried out for both forward and reverse processes; the results are summarized in Table 2. They are the average values for duplicate or triplicate runs; the experimental uncertainty was estimated to be less than ±2%.

In 2-propanol and its mixtures with acetonitrile, the rate constants showed a slight dependence on the initial concentration of the tetra-*n*-butylammonium salts used as a nucleophile. This might be partly due to the partial dissociation of the electrolytes. For such a case, the data were determined over a four-fold change of the initial concentration of the salt at *ca.* 0.001—0.01 M; the listed average values differed by *ca.* 4—5% from the extrapolation to a zero concentration of the salt, but not more. Usually rate measurements were carried out at concentrations of 0.001—0.01 M for both reactants.

Discussion

Equilibrium Constants and Rate Constants in Single Solvents. It is important to determine whether or not the Finkelstein reaction proceeds exactly as indicated by this equation:

$$MeBr + I^- \underset{k_r}{\overset{k_f}{\rightleftharpoons}} MeI + Br^-$$

That is, it is important to determine whether or not the reaction has only one transition state.

The equilibrium constants as determined from the rate constants presented in Table 2 ($K=k_f/k_r=0.273$ in acetonitrile) and by approaching equilibrium from both directions ($K=\{(MeI)_e\,(Br^-)_e\}/\{(MeBr)_e\,(I^-)_e\}=0.274$ in acetonitrile, where the equilibrium concentrations were determined after letting the reaction mixture stand over four half lives) were in excellent agreement. The present result is a necessary corollary of the postulated mechanism.

The rate constants in methanol are much smaller than in acetonitrile, as was pointed out by Parker *et al.*[2] Even in the series of protic solvents, the rate constant shows a marked dependence on the solvent characteristics.

In the classical treatment of the solvent effect on the reaction rate,[8] the logarithmic rate constants are plotted against the reciprocal dielectric constants of the solvents. Such a plot is presented for our data in

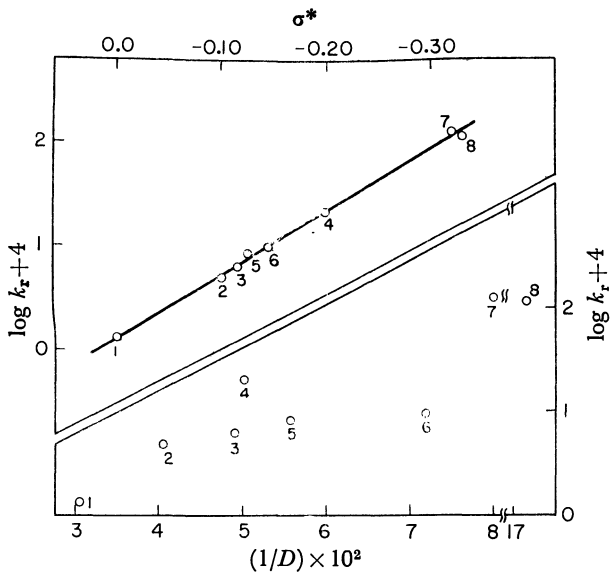

Fig. 1. Plots of log k_r *vs.* $(1/D)$ and of log k_r *vs.* σ*
1: MeOH, 2: EtOH, 3: *n*-PrOH, 4: 2-PrOH
5: *i*-BuOH, 6: *n*-AmOH, 7: *t*-BuOH, 8: *t*-AmOH

Fig. 1. Also, the same data are plotted against the Taft σ^* values.[9]

For the Finkelstein reaction, even for a homologous series of solvents, the dielectric constant does not seem to be an adequate solvent parameter. The Taft σ^* values correlate much better with the rate data. Further, it should be noted that the Taft σ^* values are fairly well correlated to the E_t values[10] for the present series of alcohols.

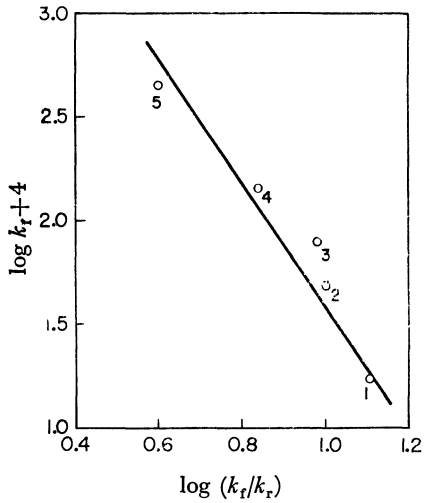

Fig. 2. Plots of log k_f *vs.* log (k_f/k_r)
1: MeOH, 2: EtOH, 3: *i*-BuOH, 4: 2-PrOH, 5: *t*-AmOH.

The logarithmic forward-rate constants, which reveal a marked solvent dependence, are plotted against the logarithmic equilibrium constants in Fig. 2. The slope is *ca.* −3.0. Since the solvent effect on the equilibrium constant is suspected to come mainly from the perturbation in the solvation free energies of the reactants and products due to the change in solvent, the abscissa may be taken as reflecting the sensitivity to the environmental change of the differential solvation energy between the two anions. In a similar way, the ordinate would serve as a measure of the solvent effect on the differential solvation energy between the reactant, the iodide ion, and an activated complex. Thus, the slope of −3.0 corresponds to an indication that the charge density difference between the iodide and the activated complex is considerably larger than the difference between bromide and iodide ions. In addition, the negative sign of the slope indicates that the charge density is more less in the transition state than in the initial state.

Generally speaking, the rate constants of the reaction in alcohol–acetonitrile mixtures show a marked negative deviation from the line connecting the values in pure solvents, *i.e.*, $x_1 \ln k_1 + x_4 \ln k_4$. According to a previous publication by the present authors,[11] this type of behavior can be expected where a solvent effect on the reaction rate mainly originates from the specific solvation of the reactant by the solvent slowing the reaction.

The above features appear to substantiate the position that, for the present system, the specific solvation of halide ions by alcohols is the major factor in producing such a big solvent influence on the reaction rate.

Reaction Rates in Binary Mixed Solvents: For the quantitative treatment of the solvent effects on the rate constants, the activity coefficient of a solute, *M*, in a solvent, s, was defined by Eq. (8):[12]

$$\beta_{M,s} = (m_{gM}/m_{lM})_s \tag{8}$$

where m_{gM} and m_{lM} stand for the molar concentration of a solute, *M*, in a gas phase over the solution and that of the solute, *M*, in solution.

Let us consider a case where a solute, *M*, exists in equilibrium with such a cluster as $M\cdot(S_4)_{Z^\circ-n}\cdot(S_1)_n$, where Z° is the true solvation number, where S_4 and S_1 stand for the 4 and 1 solvents, where these clusters are related to each other by the equations, and where the unsolvated solute, M, is in a vapor-liquid equilibrium:

$$M + Z^\circ S_4 = M\cdot(S_4)_{Z^\circ} \quad ; K_0$$

$$M\cdot(S_4)_{Z^\circ-j+1}\cdot(S_1)_{j-1} + S_1 = M\cdot(S_4)_{Z^\circ-j}\cdot(S_1)_j + S_4 \; ; K_j$$

When the mixture forms an ideal associated solution, the activity coefficient of a solute, M, in a solvent mixture composed of the 1 and 4 solvents, $\beta_{M,mix}$, is given by this equation:[1]

$$\lim_{x_M\to 0}\beta_{M,mix} = [f_M^\circ/\{1+\sum_{i=0}^{Z^\circ}(\prod_{j=0}^{i}K_j)x_4^{Z^\circ-i}x_1^i\}](V_{mix}/RT) \tag{9}$$

where x_1 and x_4 stand for the mole fraction of the 1 and 4 solvents respectively; f_M° is the fugacity of a pure solute, *M*, and V_{mix} is the molar volume of the mixed solvent.

Strictly speaking, all the solvation sites might not necessarily be equivalent to each other. In other words, the equilibrium constant on one solvation site might not be equal to that on the other site. We denote by $K_{se,m}$ the equilibrium constant for the solvent-exchange process on the *m*th solvation site. The $\sum_{i=0}^{Z^\circ}(\prod_{j=0}^{i}K_j)x_4^{Z^\circ-i}x_1^i$ term in Eq. (9) expresses the distribution of the clusters as a function of the solvent composition. In the solvent mixture each solvation site is occupied either by 1 or 4 solvents and, with respect to the *m*th solvation site, the ratio of the frequency of the occupation by the 4 solvent to that by the 1 solvent is x_4 to $K_{se,m}x_1$. Since there are Z° solvation sites around the solute, the distribution of such clusters as is specified by the occupation of the respective site either by the 1 solvent or the 4 solvent is given by the $K_0\prod_{m=1}^{Z^\circ}(x_4+K_{se,m}x_1)$ term. The activity coefficient of a solute, *M*, in the solvent mixture is given by this equation:

$$\lim_{x_M\to 0}\beta_{M,mix} = [f_M^\circ/\{1+K_0\prod_{m=1}^{Z^\circ}(x_4+K_{se,m}x_1)\}](V_{mix}/RT) \tag{10}$$

For a given solvent pair, there would exist a critical value, *z*, within the range, $1\leqq z\leqq Z^\circ$, beyond which the equilibrium constant, $K_{se,m}$, could approximately be equal to unity; that is to say, $K_{se,m}\fallingdotseq 1$ for $z+1\leqq m\leqq Z^\circ$, when the solvation sites are arranged and numbered in decreasing order of the equilibrium constant, for example, from the inner site to the outer site. Under

these conditions, the $\prod_{m=1}^{z}(x_4+K_{se,m}x_1)$ term can be approximated by $\prod_{m=1}^{z}(x_4+K_{se,m}x_1)$. When the term is expanded in series, Eq. (10) reduces to Eq. (11) and the K_j's are related to $K_{se,m}$'s by the following equations:

$$\lim_{x_M\to 0}\beta_{M,mix} = [f_M^\circ/\{1+\sum_{i=0}^{z}(\prod_{j=0}^{i}K_j)x_4^{z-i}x_1^i\}](V_{mix}/RT) \quad (11)$$

$$K_1 = \sum_{m=1}^{z}K_{se,m},\ K_1K_2 = \sum_{m>n}^{z}K_{se,m}K_{se,n},\ \cdots \prod_{j=1}^{z}K_j = \prod_{m=1}^{z}K_{se,m}$$

The z value means the "experimentally detectable" solvation number for the solvent pair or, in other words, the number of solvent molecules responsible for bringing about the observed difference in the solvation energy; it will be referred to as "specific solvation number", in contrast to the true solvation number.

For the following bimolecular reaction, the rate constant in a mixed solvent is given by this equation:[12]

$$X^- + RY \longrightarrow M^* \longrightarrow RX + Y^-$$

$$k_{mix} = k_g(\beta_{X^-,mix}\beta_{RY,mix}/\beta_{*,mix}) \quad (12)$$

where $\beta_{X,mix}$, $\beta_{RY,mix}$, and $\beta_{*,mix}$ stand for the activity coefficients of X^-, of RY, and of the activated complex in the mixed solvent respectively, and where k_g is the rate constant in an ideal gas.

As was described above, and as will be discussed below, there are indications that the rate of the Finkelstein reaction is mainly controlled by the specific solvation of the anion by a protic solvent and the concept of multi-step solvation should be taken into account in the quantitative treatment of the anion solvation in protic solvents.

In the following treatment, we assume that Eq. (11) applies only to the anion and that the other systems, *i.e.*, alkyl halide-solvent mixtures, and activated complex-solvent mixtures, are to be considered ideal mixtures; that is, $\beta_{RY,mix}=\beta_{*,mix}=1$.

For electrolytes, the $K_0 \gg 1$ condition will be satisfied; as a result, K_0 drops out of the equations, giving these approximate formulas, *i.e.*, Eqs. (13) and (14):

$$\ln k_{mix} = \ln k_1 + \ln(\prod_{j=1}^{z}K_j) - \ln\{\sum_{i=1}^{z}(\prod_{j=1}^{i}K_j)x_4^{z-i}x_1^i + x_4^z\} + \ln(V_{mix}/V_1) \quad (13)$$

$$(k_4/k_1) = (\prod_{j=1}^{z}K_j)(V_4/V_1) \quad (14)$$

The ratio of rate constants in pure solvents, Eq. (14), is mainly controlled by the $\prod_{j=1}^{z}K_j$ term, since the values of (k_4/k_1) lie *ca.* 10—10^3, whereas the values of (V_4/V_1) are *ca.* 1—2. The rate constant in acetonitrile is usually larger than in alcohols. We identify acetonitrile as the 4 solvent and alcohol as the 1 solvent.

Equation (14) gives the boundary conditions for $\prod_{j=1}^{z}K_j$. Under these conditions, the theoretical values of the rate constants were obtained as a function of the solvent compositions on the basis of Eq. (13) for a definite set of z and K_j's. The calculations were repeated by a trial and error-method, systematically changing the equilibrium constants for the respective solvation number and afterwards for the different values of z. These calculations were performed by hand.

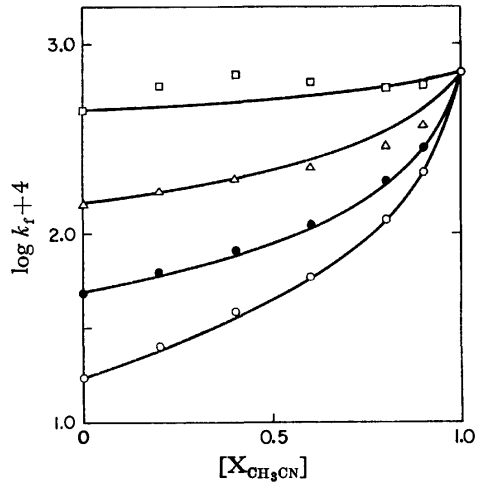

Fig. 3. Comparisons of the experimental results with the calculated values.

△: MeCN–2-PrOH, □: MeCN–*t*-AmOH.

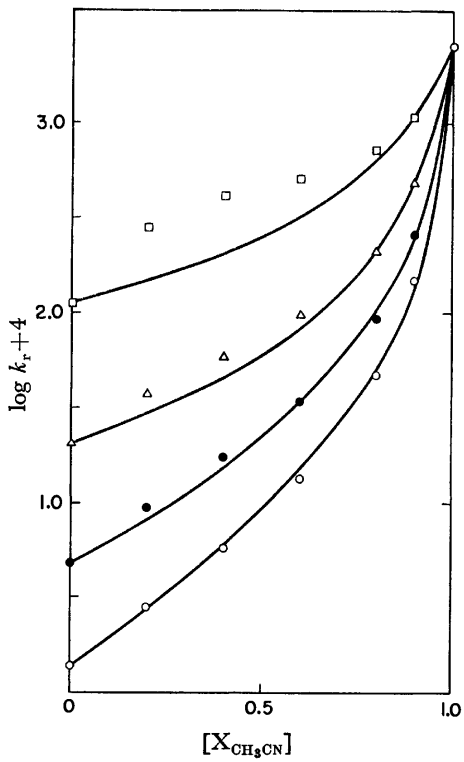

Fig. 4. Comparisons of the experimental results with the calculated values.
——: calculated.
○: MeCN–MeOH, ●: MeCN–EtOH,
△: MeCN–2-PrOH, □: MeCN–*t*-AmOH.

The calculated results are compared with the experimental data in Figs. 3 and 4. The parameters used in the calculations are summarized in Table 3.

The results in Table 3 indicate that the specific solvation number decreases with an increase in the size of the hydrocarbon moieties and of the anion. For the present systems, the specific solvation number, z, obtained above would correspond to the number of alcohol molecules interacting with the anion in a

Table 3. Experimentally determined parameters

Alcohols	I^-				Br^-					
	Z	$\prod_{j=1}^{z} K_j$	K_1	K_2	Z	$\prod_{j=1}^{z} K_j$	K_1	K_2	K_3	K_4
MeOH	2	31.36	24.1	1.30	4	1460	133	6.97	1.50	1.05
EtOH	1	16.00	16.0	—	3	595.4	75.5	4.23	1.86	—
2-PrOH	1	7.11	7.11	—	2	180.2	33.0	5.46	—	—
t-AmOH	1	3.28	3.28	—	2	47.67	14.0	3.40	—	—

different way from acetonitrile. As the protic solvent becomes more bulky, fewer protic solvent molecules can be in close proximity to the anion. This will lead to a decrease in the specific solvation number, z, that is, to a decrease in the number of protic solvent molecules interacting in a "protic" way.

This trend is observed in the equilibrium constants: $K_1>K_2>K_3>K_4\cdots$. This same trend was observed in proton solvation in methanol–water mixtures.[1]

A final point to be noticed is that, in the respective K_j values, the general trend in the interaction energy with a halide ion, *i.e.*, MeOH>EtOH>2-PrOH>*t*-AmOH, is retained.

According to the features summarized in Table 3, the solvation energy of a halide ion in a pure alcohol seems to be a composite quantity determined by two factors, a specific solvation number and the acidity of the alcohol.

Conclusions Reached by a Kinetic Procedure and by Spectroscopic Measurements. One conclusion about anion solvation has been drawn from the association equilibrium studies between phenol and halide ions by Taylor and Kuntz.[4] Both the static and dynamic procedures substantiate the concept of a multi-step solvation of anions due to protic solvents. The generalization about the interaction coefficient, *i.e.*, $K_1>K_2>K_3$, and the specific solvation number, *i.e.*, $z(Br^-)>z(I^-)$, are also supported by the two procedures. In addition, three independent studies, *i.e.*, the present work, IR studies,[4] and NMR studies,[3] give coincident results concerning the order of the interaction coefficients between the alcohol and the anion: $K_j(Br^-)>K_j(I^-)$.

From these results, a smaller anion seems to be better solvated in a less bulky solvent. The specific solvation number is larger as well. Among the multiple steps, the first solvent-exchange process makes an extraordinarily large contribution to the overall difference in the solvation energy.

Recently NMR studies of halide-alcohol association have been performed under conditions where one-to-one complex formation is favored (K_{eq}).[3] These results are shown in Fig. 5 as a function of the Taft σ^* values. The similarity in the slopes of the plots, *i.e.*, 2.8 and 2.5 for $\log K_1$ *vs.* σ^* and $\log K_{eq}$ *vs.* σ^*, lends support to the internal consistency of the assumptions involved in the above procedure.

As may be inferred from Figs. 3 and 4, with an increase in the size of the alcohols the plot of $\log k_{mix}$ *vs.* x tends to reveal an **S**-shape character. This type of behavior can not be simulated by the equations shown above. In such low dielectric solvents as *t*-amyl alcohol or its mixture with acetonitrile, electrolytes are only slightly dissociated; this might have some influence on the observed reaction rates. The possibility of the exchange of solvents in the transition state has been ignored in this treatment. The present work is incapable of confirming these possibilities.

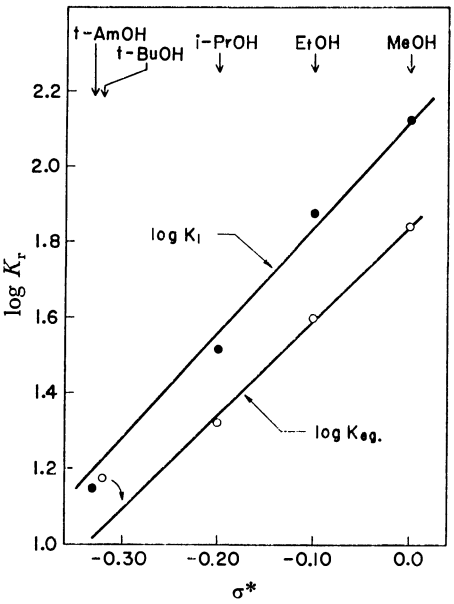

Fig. 5. Correlations of log K_1 and log K_{eq} values with Taft σ^*

From the results of our studies, it seems safe to regard the anion-alcohol interaction as taking place by means of a multi-step process; in a qualitative sense, the results obtained by several procedures are consistent.

We are grateful to Professor Donald Rosenthal, Clarkson College of Technology, for his comments on this manuscript.

The Photochemical Decomposition of Benzenediazonium *o*-Carboxylate in Several Solvents

Masahiko KATO, Taizo TAMANO, and Toshio MIWA

Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received June 17, 1974)

The photochemical decompositions of benzenediazonium *o*-carboxylate (**1**) in water, ethanol, acetone, and dichloromethane were studied. In every case, the initial loss of molecular nitrogen to give a zwitterion (**3**) and/or a diradical (**4**) was the primary process. In the solvents which are susceptible to hydrogen abstraction by a radical (ethanol and acetone), reduction takes place to give benzoic acid, through **4**, in a good yield. In water, from which a hydrogen atom is less easily abstracted homolytically, salicylic acid was the main product (24%), while benzoic acid was the minor one (9%). In CH_2Cl_2, the reduction product (benzoic acid, 20%) and biphenylene (10%) were formed. The formation of the latter compound prompted us to study the photochemical decomposition of **1** in CH_2Cl_2 in the presence of tropone. This reaction gave cycloaddition products, (**11**) and (**12**), in 3.2 and 0.7% yields respectively.

Aromatic diazonium compounds readily lose molecular nitrogen, leaving a positive charge or an odd electron on the carbon atom which have been originally bonded to the diazonium group, when irradiated in solution.[1]

It is well known that benzenediazonium *o*-carboxylate (**1**) decomposes to 1,2-dehydrobenzene (**2**), with the simultaneous loss of N_2 and CO_2, when flash-photolyzed in a solid state.[2] Although the production of **2** in solution by the photolysis of *o*-iodophenylmercuric iodide,[3] phthaloyl peroxide,[3,4] and benzothiadiazole 1,1-dioxide[5] had been confirmed, the photochemical behavior of **1** in solution has not yet been described.

The present authors were interested in comparing the fate of **1** and the reactivities of **2** under photolysis with those under thermolysis.[6] In this article, we wish to report on the photochemical reaction of **1** in several solvents. The results are summarized in Table 1, accompanied by some data of the thermal decomposition.

The table shows that the reaction proceeds with an initial loss of molecular nitrogen, followed either by a reaction with the solvent used or by a loss of carbon dioxide.[7]

The second stage of the reaction is observed to be as follows: (i) In the solvents which are susceptible to hydrogen abstraction by radicals (No. 4 and 5), the abstraction by the diradical (**4**) occurs as the main course of the decomposition to give benzoic acid, especially in the case of ethanol as a solvent in a high yield (92%). (ii) Irradiation in water, from which the hydrogen atom is less easily abstracted homolytically, gave salicylic acid as the main product (24%), along with some benzoic acid (9%). The formation of benzoic acid in water is remarkable, since the photochemical decomposition of *p*-nitrobenzenediazonium chloride in an aqueous solution proceeds heterolytically and gives no reduction product.[1c] The formation of benzoic acid was somewhat suppressed when **1** was irradiated either in dilute sulfuric acid or in aqueous sodium chloride; instead a nucleophilic attack by water on either (**1**–H^+)* or (**3**–H^+), or by the chloride ion on either (**1***) or (**3**), may occur. (iii) Dehydrobenzene is formed in only a trace amount in the solvents other

a) The amount of anthranilic acid used for preparation of **1**. b) The yields were calculated based on the amount of **1** used. c) A similar result was reported by Stiles *et al.*[13] d) *o*-Chlorobenzoic acid. e) Salicylic acid ethyl ether. f) Phenetole.

than dichloromethane, in which the photochemical decomposition proceeds to give an appreciable amount (10%) of biphenylene (**8**) through **2**. Since a nucleophilic attack by solvent is prohibited in this case, the rate of the loss of carbon dioxide from **4** is competitive with that of H-abstraction by **4**. In the photochemical decomposition of **1** in acetone, we could not detect the dehydrobenzene-adducts of **1**, **9** and **10**, reported earlier in the thermal decomposition of **1** in acetone,[8] because **4** does not lose CO_2 to give dehydrobenzene, but instead readily abstracts hydrogen from acetone to give benzoic acid under such a comparatively low temperature.

In contrast to the photochemical decomposition, the thermal decomposition of **1** proceeds in preference to the nucleophilic substitution on **1** in protic solvents upon the radical reaction through **4**, but in the aprotic solvents the intermediate, **4**, readily loses CO_2 thermally to give **2**.[9]

As it was found that the photochemical decomposition of **1** in CH_2Cl_2 gave **2** as the reactive intermediate, we tried the reaction with tropone. After the irradiation of **1** and tropone (1.5 equivalent mole) in CH_2Cl_2 for 3 hr, the 1,4-adduct (**11**) and the 1,6-adduct (**12**) were obtained in 3.2 and 0.7% yields respectively. The ratios of the amounts of **12** to **11** in several runs varies from 0.1—0.3, but the value was clearly larger than that of the thermal reactions, **12**: **11**=0.06—0.08. Although **11** and **12**, the adducts, were known to be sensitive to the irradiation conditions used to produce rearranged products, (**13**)—(**18**),[10,11] we could not detect such products in the present photolysis experiments.*

Experimental

Benzenediazonium o-Carboxylate (1). The starting material (**1**) was prepared as has been described before[12] and was used directly after having been washed successively with cold CH_2Cl_2 and cold ether. The purity of **1** was checked by means of its UV and IR spectra.[13] The wave lengths of the UV maxima of **1** in CH_2Cl_2 (257, 303 ^{infl} nm) were similar to those taken in water, but new maxima at 244 and 253 nm, due to biphenylene, appeared within a few minutes at room temperature.

Irradiation Apparatus. Irradiation was carried out internally in an immersion-type quartz vessel using an Ushio high-pressure mercury lamp (UM-452) through a Pyrex filter. During the irradiation, the vessel was cooled externally with ice–water.

General Procedure. A solution or suspension of **1** in an appropriate solvent was deoxygenated by bubbling in nitrogen gas for five minutes and then irradiated under nitrogen until the gas evolution had ceased. In the case of irradiation in an aqueous solution, the mixture was extracted with ether. In other cases, the solvents were evaporated *in vacuo* and the residues were taken up in ether or in CH_2Cl_2. These extracts were then washed with water and extracted successively with 5% aqueous $NaHCO_3$ and aqueous NaOH; finally, they were washed with water and dried (anhyd. Na_2SO_4). From this organic layer, the neutral part was obtained and separated by column chromatography (silicic acid/$CHCl_3$). From the extracts obtained with 5% aqueous $NaHCO_3$ and 1 M NaOH mentioned above, the acidic and the phenolic products were isolated respectively after acidification with 1 M HCl and extraction with ether. The acid mixture was further characterized by glc after transformation to its esters with diazomethane in ether. The identification of the products was carried out by a direct comparison of their IR, UV, and NMR data with those of authentic samples.

* In the present stage, the reason why the ratios of **12** to **11** are different to each other between thermal and photochemical reactions is not clear.

The glc Retention Times of the Individual Compounds. The identification by glc was carried out by means of a Shimadzu GC-1A instrument using a column, 2.1 m×ϕ8 mm, packed with 20% Apiezon L on Chromosorb E at 183 °C and a H_2 flow rate of 80 ml/min; retention times (min), methyl benzoate, 3.3; methyl salicylate, 5.4; methyl o-chlorobenzoate, 6.9; methyl o-ethoxybenzoate, 10.7.

Irradiation of 1 in CH_2Cl_2 in the Presence of Tropone. **1**, prepared from anthranilic acid (3.0 g, 22 mM) and suspended in CH_2Cl_2 (340 ml) containing tropone (4.5 g, 42 mM), was irradiated at 15 °C for 3 hr using the above-mentioned apparatus. After washing with 1 M NaOH and drying (anhyd. Na_2SO_4), the CH_2Cl_2-solution was concentrated to dryness to give a brown liquid, which was then chromatographed (benzene) on silicic acid (100 g). Fractions were collected every 100 ml; Fractions 3—4 gave a 1,6-cycloaddition product (**12**) (97 mg), and Fractions 5—6, a 1,4-cycloaddition product (**11**) (151 mg). The repeated chromatography and sublimation of each product gave: **11**, 91 °C/4 mmHg, 138 mg (3.2%), mp 84—84.5 °C, tlc (silica gel/benzene) R_f-value 0.29; **12**, 80 °C/4 mmHg, 28 mg (0.7%), mp 79.5—80 °C, R_f-value 0.38. These substances were identified by direct comparison with an authentic sample reported earlier.[10]

Similar results were obtained in acetonitrile as the solvent; **11**, 3.5% yield; **12**, 0.3% yield.

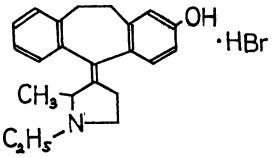
Structure of a Main Metabolite of Piroheptine Excreted in Urine of Rabbits; X-Ray Analysis of Its Hydrobromide

Yoji TOKUMA, Shigetaka KODA, Shinji TSUBOUCHI, and Yukiyoshi MORIMOTO
Research Laboratories, Fujisawa Pharmaceutical Co., Ltd., Yodogawa-ku, Osaka 532
(Received June 28, 1974)

The structure of a main metabolite of piroheptine excreted in urine after administered to rabbits has been determined by X-ray analysis of its hydrobromide, $C_{22}H_{26}NOBr$. The crystals are monoclinic with space group $P2_1/n$, the unit-cell dimensions are: $a=14.28$, $b=12.50$, $c=10.97$ Å, $\beta=96.06°$. The intensities were estimated visually from multiple-film equi-inclination Weissenberg photographs. The structure was solved by the heavy atom method. The atomic parameters were refined by the block-diagonal least-squares method, and the final R index was 0.11. The established structure is shown by the following formula (hereafter, named as piroheptine metabolite HBr)



It has been cleared that the hydroxylation in the metabolic process takes place at the 2-position in the benzene ring located far from the N-ethyl group on pyrrolidine ring, and piroheptine metabolite HBr and piroheptine HBr differ considerably in their conformations in the crystalline state.

Piroheptine[1] has been found to show potent antagonism against tremorine-induced tremor in mice.[2] Nojima *et al.*[3] have suggested that 3-(10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene-5-ylidene)-1,2-dialkylpyrrolidines and their salts seemed to have more than two conformations in solution on the basis of interpretation of PMR spectra. The conformation of piroheptine hydrobromide in the crystal has been found to correspond to the most stable one suggested by PMR study in solution.[4]

In the research of piroheptine metabolism, the main metabolite in urine of rabbits administered piroheptine was isolated by thin layer and gas liquid chromatography. High resolution mass spectrographical study revealed the mono-hydroxylation on benzene ring in the metabolic process, but not the position of hydroxylation. The X-ray analysis of the crystal of piroheptine metabolite hydrobromide was undertaken to elucidate the precise molecular structure and to compare it with piroheptine hydrobromide in the crystal.

Experimental

Piroheptine hydrochloride suspended in deionized water was orally given to rabbits in dose of 200 mg/kg. The urine collected for 24 hr was refluxed for 1 hr in 2 M HCl in order to hydrolyze the conjugated compounds. The main metabolite extracted from $CHCl_3$ was isolated by thin layer and gas liquid chromatography. After the main metabolite was dissolved in a slight excess of 50% HBr, it was heated in a water bath at 50 °C for 45 min and then was evaporated *in vacuo*. The residual oil was recrystallized twice in ethanol. The suitable crystals for X-ray work were obtained from the ethanol in the form of colorless prisms elongated along the *b* axis.

Unit-cell dimensions were determined by the least-squares calculation using the high angle spots of $CuK\alpha_1$ and $CuK\alpha_2$ on zero-layer Weissenberg photographs superimposed by the Al wire patterns for calibration. The density was measured by floatation in a benzene–carbon tetrachloride mixture. Crystal data are summarized in Table 1. The three dimensional intensity data were collected from multiple-film equi-inclination Weissenberg photographs for the layer lines 0 to 9 on the b axis and 0 on the a axis using nickel-filtered $CuK\alpha$ radiation. The intensities of reflection were visually estimated by comparison with a standard scale. The values of intensity ranged from 1 to 8600. Corrections were made for Lorentz, polarization factors and variation in spot size on higher layer photographs.[5] The intensity data from the a axis photograph were used only for layer scale adjustment of b axis photographs. Thus 2413 intensity data were obtained of which 379 were too weak to be observed.

Structure Determination

The coordinates of a bromide ion were deduced from the Patterson function. Fourier synthesis based on the coordinates of the bromide ion clearly revealed all the 24 light atoms. The positional and thermal parameters of the atoms were refined by the block-diagonal least-squares method which minimized $\sum w(|F_o|-|F_c|)^2$. Two cycles of the least-squares refinement were carried out, using isotropic temperature factors to all the atoms and ion. Four more cycles of the refinement were performed, assigning anisotropic temperature factors to only bromide ion. The R index was reduced to 0.11, excluding non-observed reflections ($R=0.13$ for all 2413 reflections). The weighting scheme adopted in the

standard deviations in the bond lengths and angles are about 0.016 Å and 1.0°, respectively. Carbon atoms C(22) and C(21) are located on 0.96 and 0.28 Å respectively out of the best plane through the four carbon atoms, C(13), C(15), C(20), and C(23), of the seven-membered ring which are jointed in the benzene rings connected in both sides. The C(20)–C(21)–C(22) angle, 119°, in the seven-membered ring has a large deviation from the tetrahedral angle. The similar angular deviation in seven-membered ring was also found in the crystal structure of piroheptine hydrobromide[4] and 5-(bromomethylene)-10,11-dihydro-5*H*-dibenzo[*a*,*d*]cycloheptene.[8]

Table 4. Best planes

(1) Equations[a]

Benezne plane I

$$0.474X - 0.742Y - 0.474Z = -0.945$$

Benzene plane II

$$0.441X + 0.873Y + 0.208Z = 2.658$$

Ylidene plane

$$-0.004X + 0.862Y - 0.507Z = -0.497$$

a) X, Y, and Z are the rectangular coordinates in Å unit.

(2) Displacements of atoms from the planes

Benzene plane I		Benzene plane II		Ylidene plane	
C(9)	−0.01 Å	C(15)	−0.01 Å	C(2)	−0.02 Å
C(10)	0.01	C(16)	0.02	C(3)	0.03
C(11)	0.01	C(17)	−0.02	C(4)	0.01
C(12)	−0.02	C(18)	0.01	C(14)	0.00
C(13)	−0.02	C(19)	0.00	C(13)	0.01

The atoms with asterisk were not included in the least-squares calculations.

(3) Dihedral angles between the planes

	Piroheptine metabolite HBr	Piroheptine[4] HBr
Benzene plane I and Benzene plane II	58°	63°
Benzene plane I and Ylidene plane	66	59
Benzene plane II and Ylidene plane	50	76

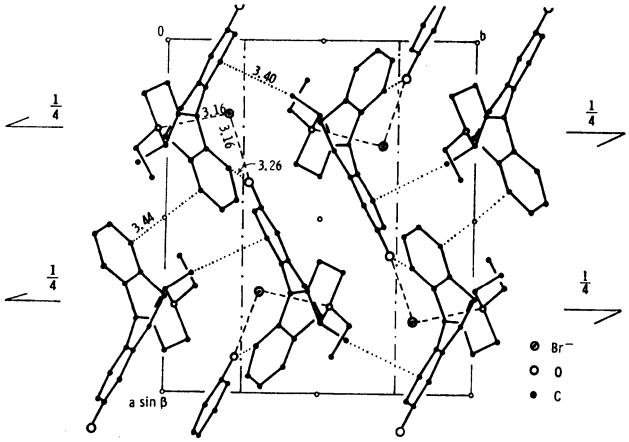

Fig. 5. A drawing of the structure viewed along the c axis. Hydrogen bonds and van der Waals contacts are indicated by broken and dotted lines, respectively.

The conformation of the pyrrolidine ring is shown in Fig. 3 with one of piroheptine hydrobromide.[4] Arabic numerals denote the displacements (in Å) of the atoms from the best plane of the pyrrolidine ring.

The conformation about the C(2)–N(1) bond is compared with one of piroheptine hydrobromide[4] in Fig. 4. The relation between the ethyl and methyl group is *cis*-position in contrast with the case of piroheptine hydrobromide that corresponds to the most stable one suggested by PMR study in solution.[4]

The 2-hydroxy-10,11-dihydro-5*H*-dibenzo[*a*,*d*]cyclohepten-5-ylidene part consists of the three planes. The equations for these planes, displacements of the individual atoms from the planes and dihedral angles between the planes are given in Table 4. The oxygen atom O(24) of hydroxyl group is situated on benzene plane II within the limits of error.

The drawing of the structure viewed along the c axis is shown in Fig. 5. It seems that two hydrogen bondings (N(1)–H···Br⁻ and O(24)–H···Br⁻) are formed in this crystal structure, and the N(1) is protonated. These hydrogen bondings are:

N(1)–H···Br⁻		O(24)–H···Br⁻	
N(1)···Br⁻	3.16 Å	Br⁻···O(24)*	3.16 Å
Br⁻···N(1)–C(2)	101°	Br⁻···O(24)*–C(18)*	122°
Br⁻···N(1)–C(5)	107		
Br⁻···N(1)–C(6)	113,		

asterisks denote the (1/2+x, 1/2−y, −1/2+z) transformation relative to the reference molecule at (x,y,z). These hydrogen bonds are indicated by the broken lines in Fig. 5. Some shorter intermolecular distances are indicated by dotted lines in Fig. 5. No unusually short contact is found in this structure.

The authors are indebted to Professor Masao Kakudo and Dr. Tamaichi Ashida, Institute for Protein Research, Osaka University, for many helpful discussions and suggestions during this analysis.

The Total Synthesis of (±)-Royleanone[1,2]

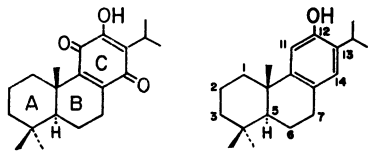
Yakudo TACHIBANA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received July 6, 1974)

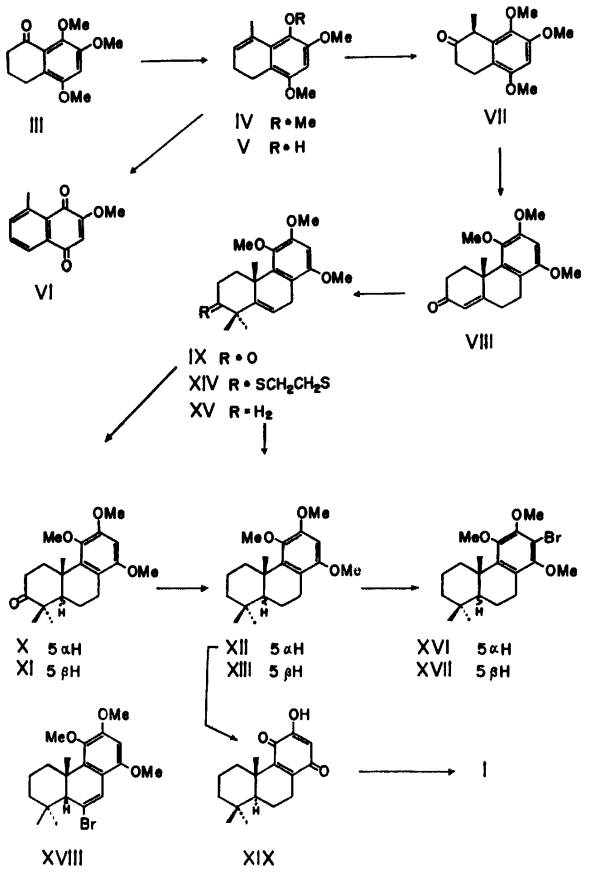
The total synthesis of (±)-royleanone (I) has been achieved. 5,7,8-Trimethoxy-1-tetralone (III) was converted into (±)-5,7,8-trimethoxy-1-methyl-2-tetralone (VII) *via* a dihydronaphthalene derivative (IV). The annelation of VII with methyl vinyl ketone gave a (±)-hexahydro-2-oxophenanthrene derivative (VIII), which was then further converted into (±)-11,12,14-trimethoxy-3-oxopodocarpa-5,8,11,13-tetraene (IX). The hydrogenation of IX over platinum oxide gave two dihydro derivatives, (X) and (XI), in a ratio of *ca.* 1: 7, these configurations in the A/B ring juncture were identified as *trans* and *cis* respectively. Therefore, IX was subjected to thioketalization, followed by desulfurization, to give (±)-11,12,14-trimethoxypodocarpa-5,8,11,13-tetraene (XV). The hydrogenation of XV over 10% palladium on carbon gave (±)-11,12,14-trimethoxypodocarpa-8,11,13-triene (XII), along with a small amount of its *cis* isomer (XIII). Finally, XII was converted into a hydroxy-1,4-quinone derivative (XIX), which was then treated with isobutyryl peroxide to give (±)-I, whose IR, UV, and NMR spectra were identical in every respect with those of natural royleanone.

Royleanone (I), a diterpenoid quinone, was isolated from the roots of *Inula royleana* D.C. by Edwards *et al.*[3] On the basis of chemical and spectral studies, they deduced its structure to be I. Kupchan *et al.*[4] also isolated royleanone from *Taxodium distichum* Rich (Taxodiaceae) and reported on its cytotoxity against Eagle's KB strain of human carcinoma of the nasopharynx. Although royleanone has been derived[3] from ferruginol (II)[5] in a 7% yield by oxidation with hydrogen peroxide, as a part of his own synthetic studies of quinone diterpenoids the present author attempted the total synthesis of (±)-royleanone (I) by the route of CB→A ring construction. The introduction of the isopropyl group at the C-13 position by using isobutyryl peroxide[6] was successfully carried out in the final step in the synthesis.



I II

5,7,8-Trimethoxy-1-tetralone (III),[7] which corresponds to the B and C rings in I, was chosen as the starting material. The Grignard reaction of III with methylmagnesium iodide and the subsequent dehydration of the resulting alcohol with dilute sulfuric acid gave 3,4-dihydro-5,7,8-trimethoxy-1-methylnaphthalene (IV), along with a small amount of a hydroxylic compound (IR 3530 cm^{-1}) (V). V showed a positive ferric chloride test, and the NMR spectrum in $CDCl_3$ showed a signal due to an aromatic proton at 6.45 ppm, while in Py-d_5 it shifted downfield to 6.68 ppm. Taking into account this pyridine-induced solvent shift and the ease of the cleavage of ether bonding *ortho* to a carbonyl group,[8] we tentatively identified V as 3,4-dihydro-8-hydroxy-5,7-dimethoxy-1-methylnaphthalene. With an intent to obtain (±)-5,7,8-trimethoxy-1-methyl-2-tetralone (VII), IV was treated with lead tetraacetate in acetic acid to give yellow crystals, whose structure was identified, on the basis of its spectral data (see Experimental section), as 2-methoxy-8-methyl-1,4-naphthoquinone (VI). Therefore, IV was oxidized with perbenzoic acid and then treated with dilute sulfuric acid to give VII. The construction of the A ring could be achieved by the annelation of VII with methyl vinyl ketone in the presence of sodium ethoxide in ethanol; after chromatographic purification, (±)-2,3,4,8,10,12-hexahydro-12-methyl-5,6,8-trimethoxy-2-oxophenanthrene (VIII) was obtained. This was further converted into (±)-11,12,14-trimethoxy-3-oxopodocarpa-5,8,11,13-tetraene (IX) with methyl iodide in the presence of potassium *t*-butoxide in *t*-butanol. Since the hydrogenation of IX over 10% palladium on carbon in acetic acid had not proceeded either at room temperature or at 50 °C, the catalyst was replaced by platinum oxide. After a smooth absorption of hydrogen, the crude product was separated by means of column chromatography on silica gel to give two corresponding dihydro derivatives, (X) and (XI), in a ratio of *ca.* 1: 7. In order to determine the configurations of the A/B ring juncture in X and XI, each of them was subjected to thioketalization with ethanedithiol in the presence of boron trifluoride etherate, followed by desulfurization with Raney nickel in boiling ethanol; after chromatographic purification (±)-11,12,14-trimethoxypodocarpa-8,11,13-triene (XII) and its *cis* isomer (XIII) were obtained respectively. The NMR spectrum of XII in CCl_4 showed signals due to three methyl groups at 0.89, 0.93, and 1.23 ppm,[9] while that of XIII showed corresponding signals at 0.51, 0.92, and 1.24 ppm. These NMR spectra, especially the signals of a significantly higher field at 0.51 ppm, strongly suggest the *cis* nature of the A/B ring juncture in XIII.[10] Therefore, the configurations of the A/B ring juncture in XII and XIII, also including those of X and XI, were identified as *trans* and *cis* respectively. Since natural royleanone possesses a *trans* A/B ring juncture, the above procedure was not effective for the preparation of the intermediate (X) because of its low yield. The desired *trans* compound (XII) could be effectively obtained by the following procedure. The ketone (IX) was first converted into its thioketal (XIV), which was then desulfurized with Raney nickel to give (±)-11,12,14-trimethoxypodocarpa-5,8,11,13-tetraene (XV). The hydrogenation of XV over 10% palladium on carbon in acetic acid afforded the requisite XII, along with a small amount of its *cis* isomer (XIII).



At this stage, some experiments regarding the introduction of isopropyl group at the C-13 position in XII and XIII were carried out.[11] The bromination of XII gave a bromide (XVI), while that of XIII under the same conditions gave two bromides, (XVII) and (XVIII). By the disappearance of the aromatic proton in the NMR spectrum the structure of XVI and XVII was determined to be nuclear-brominated (±)-13-bromo-11,12,14-trimethoxypodocarpa-8,11,13-triene and its *cis* isomer respectively. On the other hand, the NMR spectrum of XVIII showed three methyl signals, at 0.42, 1.06, and 1.21 ppm, together with three one-proton singlets attributable to the protons at the C-5, C-13, and C-7 positions at 1.89, 6.22, and 7.06 ppm respectively. Therefore, XVIII was identified as (±)-6-bromo-11,12,14-trimethoxy-5βH-podocarpa-6,8,11,13-tetra-ene. The treatment of XVI and XVII with sodium or phenylsodium in dry toluene, followed by the addition of either acetone or Dry Ice, resulted only in debromination giving XII and XIII respectively.

The final step of the present synthesis was carried out as follows; XII was demethylated with boron tribromide in methylene chloride, and the resulting hydroxylic product was oxidized in refluxing benzene with bubbling oxygen gas to give (±)-12-hydroxy-11,14-dioxopodocarpa-8,12-diene (XIX). This was then alkylated[6] with isobutyryl peroxide[12,13] in acetic acid at 100—105 °C to yield (±)-I as yellow crystals, whose IR, UV, and NMR spectra were found by a direct comparison to be identical in every respect with those of natural royleanone.

Experimental

The melting points are uncorrected. The NMR spectra were taken on a Hitachi Model R-20 spectrometer (60 MHz), with tetramethylsilane as the internal standard. The UV spectra were measured in ethanol, the IR spectra, in chloroform, and the NMR spectra, in carbon tetrachloride, unless otherwise stated. The chemical shifts are represented in terms of the δ values: s: singlet; bs: broad singlet; d: doublet; t: triplet; q: quartet; m: multiplet. Column chromatography was performed on Merck silica gel (0.08 mm).

3,4-Dihydro-5,7,8-trimethoxy-1-methylnaphthalene (IV). A solution of III (25 g) in dry benzene (250 ml) was dropped, over a period of 30 min, into a Grignard reagent (prepared from magnesium (3.1 g), methyl iodide (20 g) and dry ether (50 ml)) at room temperature. Stirring was continued at this temperature for 30 min, and then at 65 °C for 4 hr. The cooled mixture was poured into dilute hydrochloric acid (10%: 250 ml) and extracted with ether. The extract was washed with aqueous sodium thiosulfate and water and dried over sodium sulfate. After the removal of the solvent, the residue was refluxed for 4 hr in methanol containing dilute sulfuric acid (20%: 38 ml), cooled, and then extracted with ether. The extract was washed with saturated brine and dried over sodium sulfate. After the evaporation of the solvent, the crude product was chromatographed on silica gel (700 g), using benzene–hexane (7: 3) as the eluent, to give IV (19.1 g: 76%) as an oil and V (2.1 g: 11%) as a solid, which was then recrystallized from petroleum ether–ether; mp 51.5—52.5 °C. IV; NMR 2.13 (d, J=1.5 Hz, =CCH$_3$), 3.61, 3.70, 3.76 (each s, -OCH$_3$), 5.77 (m, =CH–), 6.30 (s, aromatic proton). Found: C, 71.92; H, 7.85%. Calcd for $C_{14}H_{18}O_3$: C, 71.77; H, 7.74%.

V; IR 3530 cm^{-1} (OH); NMR ($CDCl_3$) 2.28 (d, J=1.5 Hz, =CCH$_3$), 3.76, 3.86 (each s, 2-OCH$_3$), 5.56 (s, OH), 5.84 (m, =CH–), 6.45 (s, aromatic proton). NMR (Py-d_5) 2.59 (d, J=1.5 Hz, =CCH$_3$), 3.71 (6H, s, 2-OCH$_3$), 5.87 (m, =CH–), 6.68 (s, aromatic proton). Found: C, 70.97; H, 7.39%. Calcd for $C_{13}H_{16}O_3$: C, 70.89; H, 7.32%.

In another experiment, an azeotropic distillation of benzene solution of the crude Grignard reaction product containing two or three drops of concentrated hydrochloric acid, similar results were obtained.

2-Methoxy-8-methyl-1,4-naphthoquinone (VI). A mixture of IV (3.70 g), acetic acid (10 ml), and lead tetraacetate (freshly prepared from red lead oxide (11 g) and acetic acid (35 ml)) was stirred at room temperature for 2 hr; then ethylene glycol (4 ml) was added, and the mixture was stirred for an additional 30 min. The mixture was diluted with water and extracted with ether. The ether was washed with aqueous sodium hydrogen carbonate and water, dried over sodium sulfate, and then evaporated. The column chromatography and crystallization of the residue from methanol afforded VI (1.13 g: 35%); mp 151.5—152.5 °C; IR 1676, 1645, 1618 cm^{-1} (C=O); UV nm (ε): 243 (15700), 248.5 (15900), 276 (14700), 345 (3700); NMR ($CDCl_3$) 2.73 (s, =CCH$_3$), 3.87 (s, -OCH$_3$), 6.10 (s, =CH–), 7.4—8.1 (3H, m, aromatic protons) and an unreacted starting material (1.16 g). Found: C, 71.28; H, 4.84%. Calcd for $C_{12}H_{10}O_3$: C, 71.28; H, 4.99%.

(±)-5,7,8-Trimethoxy-1-methyl-2-tetralone (VII). A solution of perbenzoic acid (19 g) in chloroform (450 ml) was added to a cooled solution of IV (20 g) in chloroform (600 ml) at below 10 °C. After storage overnight in a refrigerator, the red solution was washed with a sodium hydroxide solution and water, and evaporated. The residue was refluxed

for 1.5 hr in methanol (110 ml) containing sulfuric acid (17 ml) and water (90 ml), and the product was extracted with ether. After a usual work-up, the crude product was purified by column chromatography on silica gel (400 g), using benzene–ether (95: 5) as the eluent, to give VII (10.32 g: 48%), which was subsequently recrystallized from petroleum ether–ether; mp 90—91 °C; IR 1707 cm^{-1} (C=O); NMR ($CDCl_3$) 1.36 (d, J=7 Hz, $-\dot{C}H\underline{C}H_3$), 3.77, 3.78, 3.87 (each s, 3-$OC\underline{H}_3$), 6.44 (s, aromatic proton). Found: C, 67.31; H, 7.36%. Calcd for $C_{14}H_{18}O_4$: C, 67.18; H, 7.25%.

(±)-2,3,4,9,10,12-Hexahydro-5,6,8-trimethoxy-12-methyl-2-oxophenanthrene (VIII). Under a stream of nitrogen, a solution of VII (6.9 g) in ethanol (150 ml) was added, by drop, to a solution of sodium ethoxide (prepared from sodium (1.32 g) and absolute ethanol (70 ml)) at room temperature. After stirring for 1 hr at room temperature, the mixture was cooled to −20——30 °C, and then freshly-distilled methyl vinyl ketone (2.95 g) in absolute ethanol (5 ml) was added. Stirring was continued for 7 hr at this temperature, for 1.5 hr at room temperature and at reflux for 30 min. After cooling, the mixture was poured into dilute hydrochloric acid (10%: 200 ml) and extracted with ether. The extract was washed with saturated brine, dried, and evaporated. The residue was purified by column chromatography on silica gel (350 g), using benzene–ether (97: 3) as the eluent, to give VIII (5.34 g), which was then recrystallized from petroleum benzin–methylene chloride; mp 134.5—135.5 °C; IR 1660 cm^{-1} (C=O); NMR ($CDCl_3$) 1.69 (s, $-\dot{C}\underline{C}H_3$), 3.80, 3.85, 3.87 (each s, 3-$OC\underline{H}_3$), 5.84 (s, $=C\underline{H}-$), 6.46 (s, aromatic proton). UV nm (ε): 236 (24200), 290.5 (4500). Found: C, 71.75; H, 7.34%. Calcd for $C_{18}H_{22}O_4$: C, 71.50; H, 7.33%.

(±)-11,12,14-Trimethoxy-3-oxopodocarpa-5,8,11,13-tetraene (IX). Under a stream of nitrogen, a solution of VIII (4.15 g) in *t*-butanol (50 ml) was added, by drop, to a solution of potassium *t*-butoxide (5.6 g) in *t*-butanol (60 ml) at 10—15 °C. After stirring for 1.5 hr at this temperature, freshly-distilled methyl iodide (8.5 g) was added in one portion. The mixture was further stirred for 3.5 hr at room temperature and refluxed for 30 min. After cooling, the mixture was poured into dilute hydrochloric acid (10%: 160 ml) and extracted with ether. After a usual work-up, the crude product was purified by column chromatography on silica gel, using benzene–ether (97 :3) as the eluent; on recrystallization from petroleum ether–methylene chloride it gave IX (3.51 g: 77%) as colorless needles; mp 153—154 °C; IR 1700 cm^{-1} (C=O); NMR ($CDCl_3$) 1.32 (6H, s, 2-$\dot{C}\underline{C}H_3$), 1.35 (s, $-\dot{C}\underline{C}H_3$), 3.27 (m, $-C\underline{H}_2-$), 3.81, 3.83, 3.87 (each s, 3-$OC\underline{H}_3$), 5.83 (t, J=4 Hz, $=C\underline{H}-$), 6.47 (s, aromatic proton). Found: C, 72.90; H, 7.97%. Calcd for $C_{20}H_{26}O_4$: C, 72.70; H, 7.93%.

Hydrogenation of IX over Platinum Oxide. A solution of IX (3.3 g) in acetic acid (180 ml) was hydrogenated in the presence of platinum oxide (490 mg) at room temperature. After the absorption of hydrogen had ceased (after *ca.* 480 ml), the mixture was filtered, the filtrate was then evaporated under reduced pressure. The crude solid was separated (2.4 g) and chromatographed on silica gel (170 g), using benzene–ether (98: 2) as the eluent. The remaining oil was also chromatographed on silica gel (70 g) with the same eluent. X (0.225 g) (recrystallized from petroleum benzin–acetone; mp 156—158 °C; IR 1700 cm^{-1} (C=O); NMR 1.08 (9H, s, 3-$\dot{C}\underline{C}H_3$), 3.74 (6H, s, 2-$OC\underline{H}_3$), 3.78 (s, $-OC\underline{H}_3$), 6.28 (s, aromatic proton); Found: C, 72.50; H, 8.97%. Calcd for $C_{20}H_{28}O_4$: C, 72.26; H, 8.49%) and XI (1.64 g) (recrystallized from petroleum benzin–acetone; mp 141.5—142.5 °C; IR 1700 cm^{-1} (C=O); NMR 0.95, 1.08, 1.31 (each s, 3-$\dot{C}\underline{C}H_3$), 3.74 (6H, s, 2-$OC\underline{H}_3$), 3.79 (s, $-OC\underline{H}_3$), 6.28 (s, aromatic proton); Found: C, 72.27; H, 8.53%. Calcd for $C_{20}H_{28}O_4$: C, 72.26; H, 8.49%) were thus obtained.

(±)-11,12,14-Trimethoxypodocarpa-8,11,13-triene (XII) and Its cis Isomer (XIII). A mixture of X (100 mg), ethanedithiol (0.3 ml), freshly-distilled boron trifluoride etherate (1.0 ml), and benzene (5 ml) was allowed to stand 1 day at room temperature. The mixture was washed with a sodium hydroxide solution and water and then dried over sodium sulfate. After the removal of the solvent, the crude product was refluxed for 3 hr with Raney nickel (W-7, prepared from Raney alloy (5 g) in ethanol (50 ml)) and allowed to stand overnight at room temperature. The subsequent filtration and evaporation of the solvent gave an oil, which was chromatographed on silica gel (10 g), using benzene–petroleum ether (70: 30) as the eluent, to give XII (62 mg: 65%) as an oil. NMR 0.89, 0.93, 1.23 (each s, 3-$\dot{C}\underline{C}H_3$), 3.67 (6H, s, 2-$OC\underline{H}_3$), 3.73 (s, $-OC\underline{H}_3$), 6.31 (s, aromatic proton). Found: C, 75.59; H, 9.50%. Calcd for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50%.

A similar treatment of XI (1.5 g) with ethanedithiol (1 ml), freshly-distilled boron trifluoride etherate (5 ml), and dry benzene (150 ml), followed by desulfurization with Raney nickel (W-7, prepared from Raney alloy (50 g)), gave XIII (1.09 g: 76%) after chromatographic purification on silica gel (150 g), using benzene–petroleum ether as the eluent. This was subsequently crystallized from petroleum ether; mp 69—72 °C; NMR 0.51, 0.92, 1.24 (each s, 3-$\dot{C}\underline{C}H_3$), 3.65, 3.68, 3.75 (each s, 3-$OC\underline{H}_3$), 6.24 (s, aromatic proton). Found: C, 75.22; H, 9.48%. Calcd for $C_{20}H_{30}O_3$: C, 75.43; H, 9.50%.

(±)-11,12,14-Trimethoxypodocarpa-5,8,11,13-tetraene (XV). A solution of IX (3.9 g), ethanedithiol (1.9 ml), freshly-distilled boron trifluoride etherate (11 ml), and dry benzene (60 ml) was allowed to stand 2 days at room temperature. After a usual work-up, the crude product was recrystallized from acetone to give a thioketal (XIV: 3.3 g 70%) as cubic crystals (mp 143—144 °C), which showed no carbonyl band in its IR spectrum. NMR ($CDCl_3$) 1.45, 1.46, 1.48 (each s, $-\dot{C}\underline{C}H_3$), 3.0—3.3 (6H, m, $-C\underline{H}_2-$), 3.75, 3.78, 3.83 (each s, 3-$OC\underline{H}_3$), 5.92 (m, $=C\underline{H}-$), 6.40 (s, aromatic proton). Found: C, 64.90; H, 7.54%. Calcd for $C_{22}H_{30}O_3S_2$: C, 65.01; H, 7.44%.

The above thioketal (3.2 g) was desulfurized with Raney nickel (W-7, prepared from Raney alloy (50 g)) in refluxing ethanol for 3 hr. After a usual work-up, the crude oil was purified by column chromatography on silica gel (150 g), using benzene–hexane (80: 20) as the eluent, to give XV (1.9 g: 76% from XIV) as an oil; NMR 1.17, 1.25, 1.45 (each s, 3-$\dot{C}\underline{C}H_3$), 3.72, 3.73, 3.78 (each s, 3-$OC\underline{H}_3$) 5.76 (m, $=C\underline{H}-$), 6.30 (s, aromatic proton). Found: C, 76.20; H, 8.76%. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%.

Hydrogenation of XV. A solution of XV (2.1 g) in acetic acid (50 ml) was hydrogenated in the presence of 10% palladium on carbon (550 mg) at room temperature, and then the mixture was filtered and evaporated. The crude oil was purified by means of column chromatography on silica gel (100 g), using benzene–petroleum ether (70: 30) as the eluent, to give XII (1.7 g: 81%). The NMR spectrum

of XII showed a small peak at 0.51 ppm, corresponding to the inseparable *cis* isomer (XIII). Its integration areas indicated the amount of XIII to be, at most, less than 15%.

Bromination of XII and XIII. A solution of bromine (290 mg) in carbon tetrachloride (5.8 ml) was stirred, drop by drop into a solution of XII (508 mg) in carbon tetrachloride (10 ml) over a period of 2.5 hr at 15—20 °C. After a usual work-up, the crude oil was chromatographed on silica gel, using benzene–petroleum ether as the eluent, to give XVI (533 mg: 84% as an oil; NMR 0.92, 0.95, 1.25 (each s, 3-$\overset{|}{\underset{|}{C}}C\underline{H}_3$), 3.70, 3.73, 3.81 (each s, 3-OC$\underline{H}_3$). Found: C, 60.75; H, 7.24%. Calcd for $C_{20}H_{29}O_3Br$: C, 60.45; H, 7.63%.

A similar treatment of XIII (420 mg) with bromine (230 mg) afforded XVII (293 mg: 53%) as an oil (NMR 0.56, 0.98, 1.25 (each s, 3-$\overset{|}{\underset{|}{C}}C\underline{H}_3$), 3.70, 3.76, 3.80 (each s, 3-OC$\underline{H}_3$); Found: C, 60.32; H, 7.48%. Calcd for $C_{20}H_{29}O_3Br$: C, 60.45; H, 7.36%) and XVIII (117 mg: 22%) as a solid, which was then recrystallized from petroleum benzin–methylene chloride (mp 142—143 °C; NMR 0.42, 1.06, 1.21 (each s, 3-$\overset{|}{\underset{|}{C}}C\underline{H}_3$), 1.89 (s, -$\overset{|}{\underset{|}{C}}$H), 3.64, 3.73, 3.79 (each s, 3-OC$\underline{H}_3$), 6.22 (s, aromatic proton), 7.06 (s, =C$\underline{H}$–). Found: C, 60.77; H, 6.76%. Calcd for $C_{20}H_{27}O_3Br$: C, 60.76; H, 6.88%).

After a suspension of XVI (186 mg) and sodium (50 mg) in dry toluene (3.5 ml) had been stirred at room temperature for 4.5 hr, acetone (5 ml) was added. Stirring was continued for an additional hr; the mixture was then poured into dilute hydrochloric acid (10%: 5 ml) and extracted with ether. The chromatography of the crude product on silica gel gave an oil whose IR and NMR spectra were identical with those of XII. A similar treatment of XVII gave XIII. Such debromination phenomena were also observed on the treatment of XVI and XVII with either *n*-butyllithium or phenylsodium in dry toluene.

(±)-12-Hydroxy-11,14-dioxopodocarpa-8,12-diene (XIX). A solution of boron tribromide (1.6 ml) in methylene chloride (10 ml) was stirred at −60 °C into a solution of XII (279 mg) in methylene chloride (5 ml) over a period of 5 min. Stirring was continued at −30 °C for 1 hr, and then at room temperature for 30 min. After the excess reagent and the solvent had been removed under reduced pressure, ice was added and the mixture was extracted with ethyl acetate. The extract was washed with a sodium thiosulfate solution and saturated brine, and then dried over sodium sulfate. After the removal of the solvent, the crude solid was chromatographed on silica gel (20 g), using benzene–ethyl acetate (50: 50) as the eluent, to give a trihydroxy derivative. Without further purification, a part of this colorless solid (142 mg) was oxidized in refluxing benzene (10 ml) with bubbling oxygen gas for 4 hr. On recrystallization from acetone–benzene, XIX (60 mg: 31%) was obtained as yellow crystals; mp 195.5—197 °C decomp.; IR (KBr) 3235, 1655, 1625, 1595 cm^{-1}; NMR ($CDCl_3$) 0.89, 0.92, 1.24 (each s, 3-$\overset{|}{\underset{|}{C}}C\underline{H}_3$), 5.95 (s, =C$\underline{H}$–), 7.19 (s, O$\underline{H}$); UV nm (ε): 276.5 (15400), 418 (600). Found: C, 74.53; H, 8.33%. Calcd for $C_{17}H_{22}O_3$: C, 74.42; H, 8.08%.

(±)-Royleanone (I). A solution of isobutyryl peroxide[13] (196 mg) in ether (2 ml) was added to a vigrously stirred solution of XIX (180 mg) in acetic acid (10 ml) at 110 °C, after which the mixture was stirred at 105 °C for 1 hr. After cooling, the mixture was diluted with water and extracted with ether. The ether was washed with a sodium hydrogen carbonate solution and saturated brine, and then dried over sodium sulfate. After the removal of the solvent, the crude solid (recovered starting material, XIX: 58 mg) was removed and the residual oil was chromatographed on silica gel (10 g), using benzene–chloroform (60: 40) as the eluent, to give (±)-I (107 mg: 76% based on the sample consumed) as yellow crystals, which were subsequently recrystallized from hexane; mp 153—154 °C; IR 3355, 1672, 1632, 1600 cm^{-1}, UV $\lambda_{max}^{CCl_4}$ nm(ε): 277(13800), 283(13400), 403(430); NMR ($CDCl_3$) 0.91, 0.94, 1.27 (each s, 3-$\overset{|}{\underset{|}{C}}C\underline{H}_3$), 1.16, 1.27 (each s, -CH(C$\underline{H}_3$)$_2$), 7.28 (s, OH); Mass *m/e* 316 (M^+). Found: C, 76.09; H, 8.97%. Calcd for $C_{20}H_{28}O_3$: C, 75.91; H, 8.92%.

The identity of the synthetic I with natural royleanone was confirmed by direct comparisons of their IR and NMR spectra. The following spectral data have been reported for natural royleanone;[3] IR ($CHCl_3$) 3350, 1672, 1632, 1602 cm^{-1}; UV $\lambda_{max}^{CCl_4}$ nm(ε): 277(15900), 283(15200), 403 (510).

Thanks are due to Professor O. E. Edwards, National Research Council, Ottawa, and to Professor S. Morris Kupchan, University of Virginia, for their kind supply of the spectral copies of natural royleanone. The author also wishes to express his warm thanks to Professor Kenji Fukui and Dr. Takashi Matsumoto, Hiroshima University, for their useful suggestions and con tinual encouragement.

Pyrimidine-Fused 1,4-Benzodiazepines. Reaction of 1,4-Benzodiazepines with Formamide-$POCl_3$

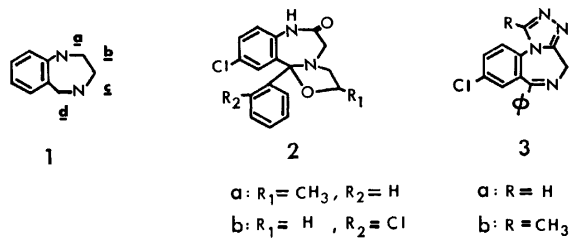
Shigeru KOBAYASHI

Medicinal Research Laboratories, Central Research Division, Takeda Chemical Industries, Ltd., Jusohonmachi, Yodogawa-ku, Osaka 532

(Received July 6, 1974)

Synthesis of new pyrimidine-fused 1,4-benzodiazepines was achieved practically in a single step by heating 1,4-benzodiazepines with formamide and $POCl_3$ in a sealed tube. A plausible mechanism of the reaction is proposed.

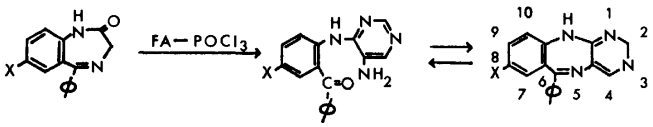
Various 1,4-benzodiazepines (**1**) with an additional ring attached to the parent ring system have been synthesized,[1] their interesting psychopharmacological properties being expected. Thus, 10-chloro-2,3,7,11b-tetrahydro-oxazolo[3,2-*d*][1,4]benzodiazepin-6(5*H*)-ones (**2a**: oxazolam, **2b**: cloxazolam) having an oxazole ring fused to the *d* face of the benzodiazepine system are now being clinically used as antianxiety agents.[2] 8-Chloro-6-phenyl-4*H*-*s*-triazolo[4,3-*a*][1,4]benzodiazepines (**3a**: estazolam, **3b**: alprazolam) having a triazole ring fused to the *a* face have also been reported to be pharmacologically active and are under extensive clinical evaluation.[3] However, the derivatives having a third ring fused to the *b* face are only scarcely reported.[4] This prompted us to synthesize 1,4-benzodiazepines having a pyrimidine ring fused to the *b* face described in this paper.



Previously, we reported a new synthetic route of pyrimidines from carboxamides containing a methylene group alpha to the carbonyl group. The reaction involves heating of the amides with formamide (FA) and phosphoryl chloride ($POCl_3$) in a sealed tube.[5] Since some pharmacologically important 1,4-benzodiazepin-2-ones (**4** and **7**)[6] possess the carboxamide group adjacent to a methylene group, we envisaged that similar treatment of these 1,4-benzodiazepin-2-ones might lead to the synthesis of new 1,4-benzodiazepines with a pyrimidine ring fused to the *b* face of the benzodiazepine system (Schemes 1 and 3).

Results and Discussion

Attempts to obtain 8-nitro-6-phenyl-11*H*-pyrimido[4,5-*b*][1,4]benzodiazepine (**6a**) in a single step by heating 1,3-dihydro-7-nitro-5-phenyl-2*H*-1,4-benzodiazepin-2-one[7] (**4a**) with FA and $POCl_3$ at 110 °C for 10 hr in a sealed tube were unsuccessful. The main product separated from the reaction mixture was a yellow crystalline compound which was proved to be 5-amino-4-(2-benzoyl-4-nitroanilino)pyrimidine (**5a**, a hydrolysis product of the C=N double bond of **6a**; yield, 25%). Evidences for the structure (**5a**) are mainly based on its mass spectrum, which shows intense peaks at *m/e* 335 (M^+, 100), 317 (62), 270 (38), 258 (43), 230 (83), 184 (41), 105 (33), and 77 (49%). Peaks at *m/e* 258, 230, 184, 105, and 77 are rationalized as shown in Scheme 2. Appearance of peaks at *m/e* 317 and 270 indicates the occurrence of cyclodehydration of **5a** to **6a** upon preheating (200 °C) or under electron impact in a vaporizing vessel of a mass spectrometer, and the concomitant loss of HNO_2 from **6a** (Scheme 2).[8]



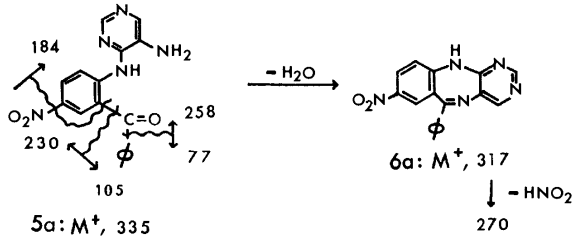
4a: X = NO_2
4b: X = Cl

5a: X = NO_2
5b: X = Cl

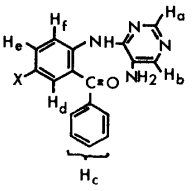
6a: X = NO_2
6b: X = Cl

Scheme 1.

This assignment was corroborated by its NMR spectrum ($CDCl_3$), which displays a broad singlet at δ 3.60 (2H, NH_2), a multiplet at 7.44—7.80 (5H, Hc), a singlet at 8.07 (1H, Hb), a double doublet at 8.40 (1H, J=3 and 9 Hz, He), a singlet at 8.50 (1H, Ha), a doublet at 8.54 (1H, J=3 Hz, Hd), a doublet at 9.18 (1H, J=9 Hz, Hf), and a broad singlet at 11.42 (1H, NH).



Scheme 2.



5a: X = NO_2
5b: X = Cl

The NMR spectrum of **5a** measured in DMSO-d_6 at room temperature gives a broad signal not clearly resolved in the aromatic region (δ 7.0—8.5). However, the NMR spectrum determined in DMSO-d_6 at about 100 °C shows a doublet at δ 7.21 (1H, J=9 Hz, C_{10}–H), a multiplet at 7.3—7.7 (6H, C_7–H and phenyl moiety), a double doublet at 8.10 (1H, J=2.5 and 9 Hz, C_9–H), a singlet at 8.29 (1H, C_4–H), a singlet at 8.37 (1H, C_2–H), and a broad singlet at 9.01 (1H, NH). These are rationalized by the structure **6a** (a cyclodehydration product of **5a**). Indeed, the NMR spectrum of **6a** is identical with that of **5a** when determined in DMSO-d_6 at about 100 °C. This result, together with the mass spectral observation, indicates that **5a** would cyclize to **6a** upon heating. In fact, cyclization of **5a** to **6a** easily proceeded when it was heated in DMSO at 100 °C for 10 min.[9] Cyclization of **5a** to **6a** also occurs when a solution of **5a** in a mixture of ethyl acetate and ethyl alcohol (2: 1, v/v) is heated at 70 °C for 1 hr in the presence of *p*-toluenesulfonic acid. The structure of **6a** is further supported by its mass spectrum which displays intense peaks at *m/e* 317 (M^+, 100%) and 270 (M^+-HNO_2, 52%) as indicated in Scheme 2.

The compound **6a** was found to be readily hydrolyzed to the pyrimidine **5a** when an ethyl acetate solution of **6a** was treated with 1 M HCl for a few minutes (Scheme 1).

When 1,3-dihydro-1-methyl-7-nitro-5-phenyl-2*H*-1,4-benzodiazepin-2-one (**7a**)[7] was treated with FA–$POCl_3$, 11-methyl-8-nitro-6-phenyl-11*H*-pyrimido[4,5-*b*][1,4]-benzodiazepine (**8a**) was obtained in a single step in a yield of 20% (Scheme 3); the reaction, though somewhat sluggishly (120 °C, 24 hr in a sealed tube), was not accompanied with hydrolysis. The mass spectrum of **8a** has a strong molecular ion at *m/e* 331 (100%) and the phenyl radical ion at *m/e* 77 (11%). Other important fragmentations are loss of HNO_2[8] (*m/e* 284, 26%), and losses of a phenyl group (*m/e* 254, 16%), and then HCN (*m/e* 227, 11%). The NMR spectrum shows a singlet at δ 3.36 (3H, N–CH_3), a multiplet at 7.35—7.87 (7H, phenyl protons, C_7–H, and C_{10}–H), a double doublet at 8.37 (1H, J=3 and 9 Hz, C_9–H), a broad singlet at 8.56 (1H, C_4–H), and a singlet at 8.72 (1H, C_2–H).

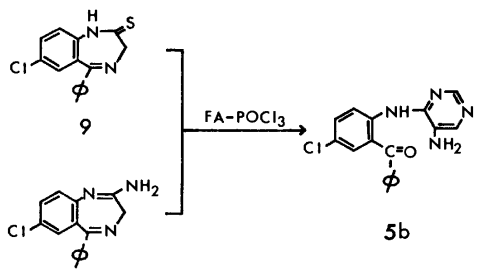
7b: X = Cl

8a: X = NO_2
8b: X = Cl

Scheme 3.

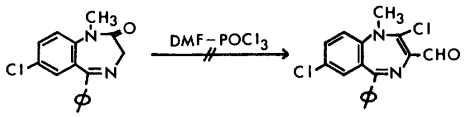
Similar reactions of the chloro derivatives (**4b** and **7b**) proceed along the same pathway. Thus, 7-chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepin-2-one (**4b**)[10] reacts with FA–$POCl_3$ to give 5-amino-4-(2-benzoyl-4-chloroanilino)pyrimidine (**5b**; yield, 23%), which cyclized to 8-chloro-6-phenyl-11*H*-pyrimido[4,5-*b*][1,4]benzodiazepine (**6b**) when heated with *p*-toluenesulfonic acid in a mixture of ethyl acetate and ethyl alcohol (1: 1, v/v) at 70 °C for 30 min. Cyclization of **5b** to **6b** was also accomplished when a solution of **5b** in DMSO was heated at 100 °C for 10 min. The NMR spectrum of **5b** ($CDCl_3$) showed a broad singlet at δ 3.49 (2H, NH_2), a multiplet at 7.46—7.68 (7H, Hc, Hd, and He), a singlet at 8.01 (1H, Hb), a singlet at 8.41 (1H, Ha), a doublet at 8.77 (1H, J=10 Hz, Hf), and a broad singlet at 10.80 (1H, NH), supporting the structure **5b**. In contrast, the *N*-methyl derivative[11] (**7b**) produced **8b** in a single step when treated with FA–$POCl_3$ at 110 °C for 40 hr in a sealed tube; yield, 18% (Scheme 3). Compound **6b** was also hydrolyzed easily to **5b** by treatment with 1 M HCl.

Compound **5b** was also obtained when 7-chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepine-2-thione (**9**),[12] and 2-amino-7-chloro-5-phenyl-3*H*-1,4-benzodiazepine (**10**)[13] were treated with FA–$POCl_3$ in yields of 10 and 25%, respectively (Scheme 4).



Scheme 4.

Recently, an introduction method of an α,β-unsaturated β-chloroaldehyde moiety to five,[14] six,[15] and seven-membered lactams[15a] has been reported, and α,β-unsaturated β-chloroaldehydes have been reported to provide pyrimidines when treated with FA at above 150 °C.[16] However, attempts to obtain the corresponding α,β-unsaturated β-chloroaldehyde (**11**) from 7-chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one (**7b**) by treating with Vilsmeier reagent (DMF–$POCl_3$), have thus far met with failure[17] (Scheme 5).

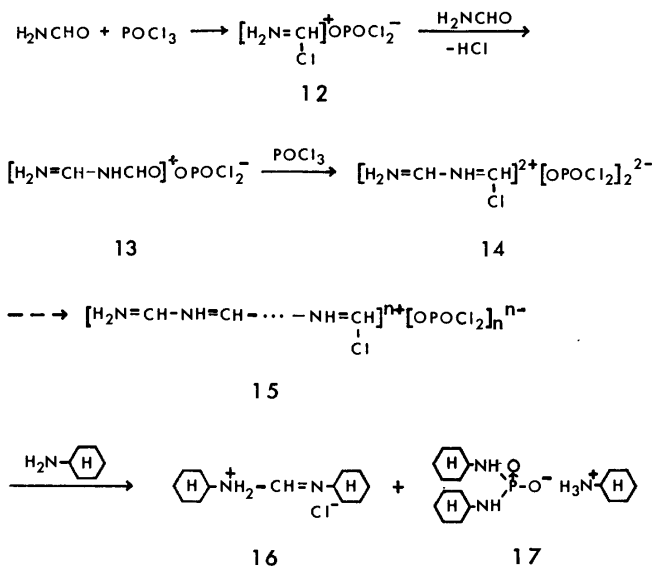


7b 11

Scheme 5.

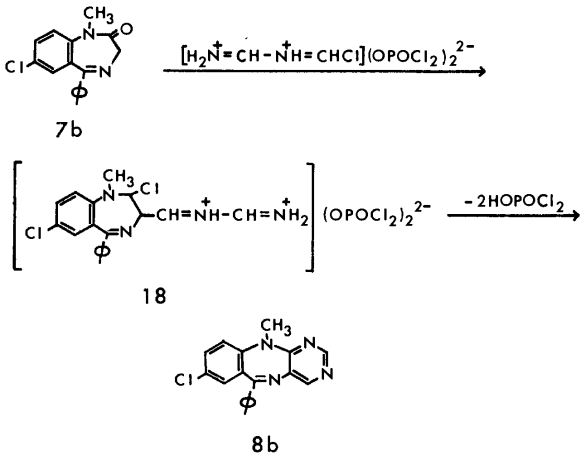
When FA was treated with $POCl_3$ at 120 °C for 1 hr in a sealed tube and the resulting complex was washed with $CHCl_3$, there were obtained hygroscopic pale yellow powders, which were treated with an excess amount of cyclohexylamine to give *N,N'*-dicyclohexylformamidine hydrochloride (**16**) and phosphoric dicyclohexylamidate cyclohexylammonium salt (**17**) (Scheme 6; for details, see Experimental section).

From the above-mentioned experimental results, a possible mechanistic interpretation of the present one-step synthesis can be advanced. The reaction of FA with $POCl_3$ gives a Vilsmeier compound **12**.[18] Its further reaction with FA produces **13**[19] which upon reaction with $POCl_3$ yields **14**. In the absence of **7b**,



Scheme 6.

the polymerization of the Vilsmeier compound would proceed until it reaches a possible intermediate of adenine (**15**, $n=5$) which cyclizes to yield adenine as reported previously.[20] However, when **7b** is present, it would react with **14** to give **18**, which cyclizes to give **8b** as shown in Scheme 7.



Scheme 7.

Another route which involves the reaction of **7b** with **12**, appears less plausible because, as previously mentioned, all attempts to isolate **11** were unsuccessful. Interesting enough, despite the similarity of the present reaction conditions to those of adenine synthesis, formation of adenine was greatly suppressed if **7b** is present in the reaction mixture. For instance, adenine is obtained in 40% yield if **7b** is absent, whereas its yield is quite poor (3%) in the presence of 0.5 mol equivalents of **7b**. These observations could be reasonably accounted for by the assumption that the dimeric Vilsmeier reagent (**14**) is more reactive than the monomer (**12**) for the reaction with carboxamides or formamides. If so, one could ingeniously explain the reason that addition of any alkyl amide or *N*-alkyl formamide to the reaction mixture of FA–$POCl_3$ leads to poor yields of adenine[21] and also that **11** is not produced from the reaction of **7b** with DMF–$POCl_3$ whereas the reaction leads to the formation of **8b** *via* its precursor **18**.

Experimental

Melting points were measured in open capillaries and are uncorrected. NMR spectra were recorded in $CDCl_3$ or in DMSO-d_6 (internal TMS standard) on a Varian T-60, A-60, or HA 100 spectrophotometer. Mass spectra were recorded on a Hitachi RMU-6D double focusing spectrometer with an ionizing voltage of 70 eV at a temperature of 200 °C. IR and UV spectra were recorded on a Hitachi EPI-S_2 recording spectrophotometer and a Hitachi EPS-2 recording spectrophotometer, respectively.

General Procedure. 1,4-Benzodiazepines (0.02 mol) and FA (0.05 mol) were charged in a stainless steel vessel (100 ml). $POCl_3$ (0.07 mol) was added into this mixture with cooling and the vessel was sealed. After being left standing for 10 min at room temperature, the vessel was heated at 110 °C for 10 hr with stirring. The reaction mixture was then cooled and dissolved in EtOAc. The EtOAc extract was carefully washed with 4M NaOH under cooling until the aqueous layer remained basic, and then with water until neutral. The organic layer was dried over Na_2SO_4 and evaporated. The residue was chromatographed on a silica gel column (Kieselgel 60, Merck) using $CHCl_3$–acetone (4: 1, v/v) as a solvent. Recrystallization from $CHCl_3$–EtOH gave a pure product.

The following compounds (**5** and **8**) were prepared by the general procedure.

5-Amino-4-(2-benzoyl-4-nitroanilino)pyrimidine (5a). 1,3-Dihydro-7-nitro-5-phenyl-2*H*-benzodiazepin-2-one (**4a**, 5.6 g, 0.02 mol) yielded 1.68 g of **5a**; mp 198—199 °C; MS (*i*): *m/e* 335 (M^+, 100), 317 (62), 270 (38), 258 (43), 230 (83), 184 (41), 105 (33), 77 (49); NMR (δ) $CDCl_3$: 3.60 (2H, bs), 7.44—7.80 (5H, m), 8.07 (1H, s), 8.40 (1H, dd, $J=3$ and 9 Hz), 8.50 (1H, s), 8.54 (1H, d, $J=3$ Hz), 9.18 (1H, d, $J=9$ Hz), 11.42 (1H, bs); IR ν_{max}^{KBr} (cm^{-1}): 1630 (C=O); UV (mμ) λ_{max} (ε) EtOH: 248 (16900), 398 (14000). Found: C, 60.90; H, 3.85; N, 20.83%. Calcd for $C_{17}H_{13}O_3N_5$: C, 60.89; H, 3.91; N, 20.89%.

5-Amino-4-(2-benzoyl-4-chloroanilino)pyrimidine (5b). (i) 7-Chloro-1,3-dihydro-5-phenyl-2*H*-1,4-bnezodiazepin-2-one (**4b**, 2.70 g, 0.01 mol) yielded 0.75 g of **5b**; mp 201—202 °C; MS (*i*): *m/e* 324 (M^+, 23), 306 (9), 271 (9), 247 (11), 219 (43), 105 (63), 77 (100); NMR (δ) $CDCl_3$: 3.49 (2H, bs), 7.46—7.68 (7H, m), 8.01 (1H, s), 8.41 (1H, s), 8.77 (1H, d, $J=10$ Hz), 10.80 (1H, bs); IR ν_{max}^{KBr} (cm^{-1}): 1630 (C=O); UV (mμ) λ_{max} (ε) EtOH: 253 (20300), 308 (10400). Found: C, 62.58; H, 3.88; N, 17.20%. Calcd for $C_{17}H_{13}ON_4Cl$: C, 62.87; H, 4.03; N, 17.25%.

(ii) 7-Chloro-1,3-dihydro-5-phenyl-2*H*-1,4-benzodiazepine-2-thione (**9**, 572 mg, 2 mmol) yielded 69 mg of **5b**.

(iii) 2-Amino-7-chloro-5-phenyl-3*H*-1,4-benzodiazepine (**10**, 540 mg, 2 mmol) yielded 165 mg of **5b**

11-Methyl-8-nitro-6-phenyl-11H-pyrimido[4,5-b][1,4]benzodiazepine (8a). 1,3-Dihydro-1-methyl-7-nitro-5-phenyl-2*H*-1,4-benzodiazepin-2-one (**7a**, 738 mg, 2.5 mmol) was heated at 120 °C for 24 hr under the same conditions, yielding 167 mg of **8a**; mp 163—164 °C; MS (*i*): *m/e* 331 (M^+, 100), 284 (26), 254 (16), 227 (11), 77 (11); NMR (δ) DMSO-d_6: 3.36 (3H, s, N–CH_3), 7.35—7.87 (7H, m, phenyl protons, C_7–H, and C_{10}–H), 8.39 (1H, dd, $J=3$ and 9 Hz, C_9–H), 8.56 (1H, bs, C_4–H), 8.72 (1H, s, C_2–H); UV (mμ) λ_{max} (ε) EtOH: 228 (24700), 267 (19600), 303 (21900). Found: C, 64.89; H, 3.84; N, 21.15%. Calcd for $C_{18}H_{13}O_2N_5$: C, 65.25;

H, 3.96; N, 21.14%.

8-Chloro-11-methyl-6-phenyl-11H-pyrimido[4,5-b][1,4]benzodiazepine (8b). 7-Chloro-1,3-dihydro-1-methyl-5-phenyl-2*H*-1,4-benzodiazepin-2-one (**7b**, 284 mg, 1 mmol) was heated at 110 °C for 40 hr under the same conditions, yielding 59 mg of **8b**; mp 208—209 °C; MS (*i*): *m/e* 320 (M^+, 100), 285 (24), 243 (36), 216 (44), 77 (56); NMR (δ) $CDCl_3$: 3.31 (3H, s, N-CH_3), 6.93—7.87 (8H, m), 8.53 (1H, bs, C_4-H), 8.66 (1H, s, C_2-H); UV (mμ) λ_{max} (ε) EtOH: 244 (23600), 280 (12800), 303 (12100). Found: C, 67.64; H, 4.11; N, 17.54%. Calcd for $C_{18}H_{13}N_4Cl$: C, 67.40; H, 4.08; N, 17.47%.

8-Nitro-6-phenyl-11H-pyrimido[4,5-b][1,4]benzodiazepine (6a). 5-Amino-4-(2-benzoyl-4-nitroanilino)pyrimidine (**5a**, 1.0 g) and *p*-TsOH·H_2O (50 mg) were dissolved in a mixture of EtOH–EtOAc (100 ml, 2: 1, v/v). The solution was refluxed for 1 hr. The solvent was removed under reduced pressure and the residue was dissolved in $CHCl_3$ (100 ml). The solution was washed with water and dried over Na_2SO_4, and the solvent was evaporated. Crystallization of the residue from MeOH–$CHCl_3$ gave 0.9 g of **6a**; mp 261—262 °C; MS (*i*): *m/e* 317 (M^+, 100), 270 (52); NMR (δ) DMSO-d_6: 7.21 (1H, d, J=9 Hz, C_{10}-H), 7.3—7.7 (6H, m, C_7-H and phenyl protons), 8.10 (1H, dd, J=2.5 and 9 Hz, C_9-H), 8.29 (1H, s, C_4-H), 8.37 (1H, s, C_2-H), 9.01 (1H, bs, NH); UV (mμ) λ_{max} (ε) EtOH: 227 (25000), 262 (13700), 303 (22000). Found: C, 63.52; H, 3.28; N, 21.97%. Calcd for $C_{17}H_{11}O_2N_5 \cdot 1/4H_2O$: C, 63.45; H, 3.52; N, 21.76%.

8-Chloro-6-phenyl-11H-pyrimido[4,5-b][1,4]benzodiazepine (6b). 5-Amino-4-(2-benzoyl-4-chloroanilino)pyrimidine (**5b**, 250 mg) and *p*-TsOH·H_2O (25 mg) were dissolved in a mixture of EtOH–EtOAc (10 ml, 1: 1, v/v). The solution was heated at 70 °C for 3 hr, then concentrated to about 4 ml and set aside in a refrigerator overnight. The resulting fluffy crystals were collected (226 mg); mp 240—241 °C; MS (*i*): *m/e* 306 (M^+, 100), 271 (76), 77 (6); NMR (δ) DMSO-d_6: 6.80 (1H, d, J=2.5 Hz, C_7-H), 7.21 (1H, d, J=8.5 Hz, C_{10}-H), 7.45 (1H, dd, J=2.5 and 8.5 Hz, C_9-H), 7.55 (5H, s, phenyl protons), 8.36 (1H, s, C_4-H), 8.46 (1H, s, C_2-H), 8.70 (1H, bs, NH); UV (mμ) λ_{max} (ε) EtOH: 244 (27500), 280 (15000), 303 (12800). Found: C, 66.16; H, 3.49; N, 18.33; Cl, 11.60%. Calcd for $C_{17}H_{11}N_4Cl$: C, 66.56; H, 3.62; N, 18.27; Cl, 11.56%.

Hydrolysis of 8-Chloro-6-phenyl-11H-pyrimido[4,5-b][1,4]benzodiazepine (6b). A solution of compound **6b** (122 mg, 0.4 mmol) in EtOAc (40 ml) was shaken with 1 M HCl (10 ml) for 1 min. The organic layer was washed with 5% $NaHCO_3$, then with water, dried over Na_2SO_4, and evaporated. Recrystallization of the residue from EtOH–$CHCl_3$ gave 122 mg of 5-amino-4-(2-benzoyl-4-chloroanilino)pyrimidine (**5b**).

8-Nitro-6-phenyl-11*H*-pyrimido[4,5-*b*][1,4]benzodiazepine (**6a**) was hydrolyzed under the same conditions to give 5-amino-4-(2-benzoyl-4-nitroanilino)pyrimidine (**5a**,80.3%).

N,N'-Dicyclohexylformamidine Hydrochloride (16) and Phosphoric Dicyclohexylamidate Cyclohexylammonium Salt (17). FA (1.35 g, 30 mmol) was charged in a stainless steel vessel (30 ml), which was cooled with dry ice–acetone. $POCl_3$ (10 g, 66 mmol) was added into a solidified mass of FA and the vessel was sealed tightly. After being left standing for 30 min at room temperature, the vessel was heated at 120 °C for 1 hr in an oil bath. The reaction mixture was cooled and washed with $CHCl_3$ to remove an excess of $POCl_3$. An excess of cyclohexylamine was added into the resulting pale yellow hygroscopic powders. Evaporation of cyclohexylamine under reduced pressure left a residue, which was treated with $CHCl_3$ and then with ethyl ether. The crude **16** (3.0 g) obtained was twice recrystallized from $CHCl_3$–EtOAc(1:1, v/v) to give 1.9 g of pure **16**; mp 230 °C decomp. (lit, mp 229—230 °C decomp.,[22] 228—230 °C decomp.[23]); MS (*i*): *m/e* 208 (M^+, 55), 110 (HC^+=NC_6H_{11}, 100), 98 (C_6H_{11}–NH^+, 50), and 83 (H_2C=$CHCH_2CH_2CH_2CH_2^+$, 52); IR ν_{max}^{Nujol} (cm^{-1}): 3100 (-C=N), 1680 (-C=NH^+-).

The sulfate was prepared by passing the hydrochloride through a column of Amberlite IRA-400 (SO_4^{2-}) and crystallized from EtOAc–EtOH (3: 1, v/v); mp 240 °C decomp. Found: C, 58.53; H, 9.56; N, 10.41; S, 6.00%. Calcd for $C_{13}H_{24}N_2 \cdot 1/2H_2O \cdot 1/2H_2SO_4$: C, 58.64; H, 9.77; N, 10.53; S, 6.02%.

From the recrystallization mother liquor for **16**, 100 mg of fine needles (**17**) was obtained; mp 173—174 °C decomp.; white precipitates were obtained by treatment with $AgNO_3$; positive for $(NH_4)_6Mo_7O_{24}$ reagent;[24] IR ν_{max}^{Nujol} (cm^{-1}): 1120 (monobasic phosphoramidate). Found: C, 60.32; H, 11.04; N, 11.78; P, 8.62%. Calcd for $C_{18}H_{38}O_2N_3P$: C, 60.17; H, 10.59; N, 11.70; P, 8.64%.

The author is grateful to Prof. K. Maruyama of Kyoto University for his valuable suggestions in this study. Thanks are also due to Drs. K. Morita, Y. Kuwada, and M. Ochiai of the same division for their discussions and encouragement throughout this work.

Synthetic Photochemistry. VI.[1] The Cycloaddition of Methyl Acetopyruvate with Cyclopentadiene: A Concomitant Formation of $(4+2)\pi$ and $(2+2)\pi$ Adducts

Hitoshi TAKESHITA, Akira MORI, and Yoshinori TOYONAGA

Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka 812

(Received July 12, 1974)

The irradiation of methyl acetopyruvate in cyclopentadiene using a high-pressure mercury lamp yielded two $(4+2)\pi$ and two $(2+2)\pi$ adducts. These products were inert under the photochemical conditions.

Since the observation of stereospecific $(6+2)\pi$ and $(4+2)\pi$ cycloadditions together with an ene reaction in the UV-light induced reaction of methyl acetopyruvate (I) with tropylidene (II),[2] we have been interested in reaction of I with cyclic diene systems in order to examine the general reactions of I with conjugated olefins. The results obtained with cyclopentadiene (III) are herein described.

When I and III were irradiated in the usual manner, cycloadditions proceeded rapidly to give four products, IV (25.0), V (30.0), VI (8.9), and VII (13.7%) together with some amounts of a cyclopentadiene-dimer. Isolation of the products was achieved by fractional recrystallization and by means of preparative chromatographic techniques. One of the photo-products, IV easily crystallized out from the reaction mixture and its IR (ν: 3380, 1738, and 1695 cm^{-1}) and NMR [δ: 1.69 (H_{7a}, dq, J=9.0, 1.7 Hz), 2.15 (H_{7a}, br, d, J=9.0 Hz), 2.19 (3H, s), 2.85 (H_1, br), 3.10 (H_4 and H_6, overlapping, br. d, J=1.7 Hz), 3.79 (3H, s), 3.84 (OH, s), 5.99 (H_2, ddd, J=5.5, 3.0, 0.8 Hz) and 6.32 (H_3, ddd, J=5.5, 2.8, 0.8 Hz)] spectra suggested that it was a norbornene derivative, a $(4+2)\pi$ adduct, since the splitting patterns of the olefinic protons were symmetrical, and since the presence of an aldol group was certain. In addition, the following observations provided further evidence for its structure: An irradiation of IV under the formation conditions caused no change, resulting in its complete recovery, but when IV was heated at 160 °C for 30 min, I was regenerated by a *retro*-Diels-Alder reaction. The catalytic reduction of IV gave a dihydro-derivative (VIII), in whose NMR spectrum the H_6-signal had $J_{6,7}$=2 Hz. Therefore, VIII and IV have an *endo*-H_6. When VIII was reduced by sodium borohydride at room temperature, an epimeric mixture of 1,3-glycols (IX and X) was produced. However the same reduction at 0 °C afforded only IX. An oily formal (XI) was obtained from IX by the reaction of dimethyl formal in the presence of a trace amount of *p*-toluenesulfonic acid and subsequent silica-gel column chromatography. In the NMR spectrum, the *gem*-protons of the formal group of XI appeared as a pair of AB-type doublets, and the magnitude of *gem*-coupling constant coincided well with that of a strain-free 1,3-dioxane system.[3] Therefore, the *cis*-relationship for the hydroxyl group and 1′-hydroxyethyl group of IX was verified, and the whole stereochemistry of IV was established as depicted.

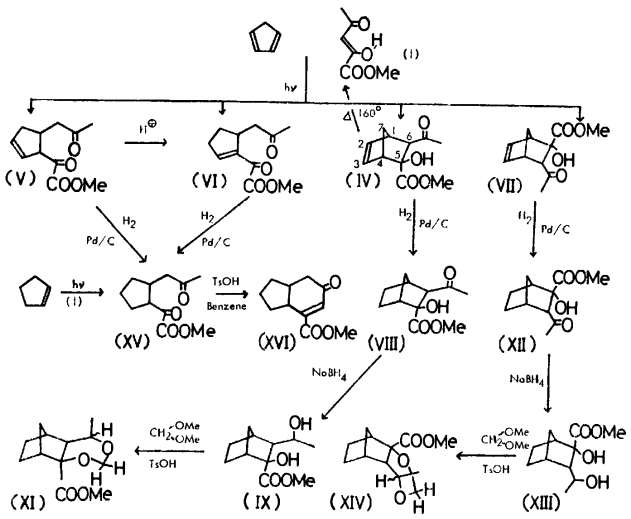
The product VII also exhibited symmetrical olefinic proton signals in its NMR spectrum [δ: 1.5—1.8 (2H, m), 2.10 (3H, s), 2.50 (1H, m), 3.10 (1H, m), 3.61 (1H, d, J=3 Hz), 3.81 (3H, s), 4.32 (1H, s, OH), 6.14 (1H, dd, J=6, 3 Hz), 6.46 (1H, dd, J=6, 3 Hz)]. In VII and its dihydro-derivative (XII), NMR splittings indicated that H_6 had an *exo*-orientation. The rest of the sterochemistry was deduced by a similar sequence to that for IV, *i.e.*, the formation of the strain-free formal (XIV) from XIII, a stereoselective sodium borohydride reduction product of XII.[4] The structure of VII is therefore as shown.

It is interesting to note that the structures of IV and VII suggest that the $(2+4)\pi$ photocycloaddition is non-stereo-selective, and the configurations of IV and VII are determined by the original geometry of I in the ground state.[5]

In this respect, there have been a couple of examples of the photo-cycloaddition of III and butadiene with α-acetoxyacrylonitrile;[6] the photochemical step of this reaction was however non-stereoselective and interpreted in terms of stepwise cyclization *via* a stable 1,4-biradical intermediate. The present results show some contrasts with this, and furthermore contrasts with the results of our previous study on the cycloaddition of I and II. Since the $(4+2)\pi$ addition in this case was stereospecific (expressed as $({}_s4+{}_s2)\pi$), but non-stereoselective, forming the *exo*- and *endo*-adducts, while the $(4+2)\pi$ addition in the case of I and II was also stereospecific (as $({}_s4+{}_s2)\pi$), but stereoselective with regard to the *exo-endo*-relationship, and non-regiospecific, giving a pair of double-bond isomers.[2]

V and VI were both shown to be $(2+2)\pi$ adducts; they gave the same dihydro-derivative (XV) which was identical with the adduct of cyclopentene and I. XV was dehydrated to an α,β-unsaturated keto-ester (XVI),[7] which was characterized by formation of a crystalline DNP. V and VI were separated by silica-gel column chromatography, but V was isomerized under mild conditions to VI. The NMR spectrum of VI revealed a characteristically broadened signal at δ: 7.08 (1H, m) which was ascribable to an α,β-unsaturated glyoxaloyl group (ν: 1680, 1700, 1740, and 1620 (strong) cm^{-1}). Thus, the structures of VI, an artifact formed during the work up, and V were deduced as follows.

Obviously, a merit of the photochemical addition reaction for synthetic purposes is an easy C–C bond formation at an unactivated C=C group, but an oridnary cycloaddition affords a cyclobutane derivative which sometimes reduces the usefulness of the process unless the transformation of the ring system can be achieved.



In this regard, the present results show that the utility of the photocycloaddition reaction may be extended to systems that are usually obtained by Diels-Alder-type reactions, and that the skeletal transformation of the adducts can be performed as having suitable functional groups.

In the present experiment, we could not detect an ene product, whose formation was a predominant process in the case of I and II.[2] This sharp contrast could be a reflection of a difference in chemical properties of the allylic methylenes, *i.e.*, the methylene hydrogens of III, being more acidic than that of II, would be unfavorable for abstraction by an electron-deficient n,π^*-excited carbonyl of I. Finally, a facile reaction with a cyclic diene such as those frequently used as triplet quenchers,[6] would be of theoretical interest in connection with the stereoelectronic factor of product formation.

Experimental

The NMR spectra were measured in deuteriochloroform solutions with either a Hitachi R-20 Model (60 MHz) or a JEOL PS-100 Model (100 MHz) spectrometer. Some of the NMDR experiments were carried out on a Varian HA-100 Model spectrometer owned by the Department of Chemistry, Tohoku University. The IR spectra were measured as a liquid film or in a KBr disk. Elemental analyses were performed by Mr. A. Abe, Division of Elemental Analyses, Kyushu University, stationed in the Department of Chemistry.

Photochemical Reaction of Methyl Acetopyruwate (I) with Cyclopentadiene (III). Isolation of the endo-*(4+2)π Adduct(IV) from the Product Mixture*: I (3.0 g) was dissolved in III (50 ml) and internally irradiated by a 450 W high-pressure mercury lamp for 4 hr. Then, the excess III was evaporated *in vacuo*, and the residue (16.7 g) was briefly passed through a silica-gel column to separate a hydrocarbon fraction, mainly a photodimer of III (13.7 g), and the product mixture, from which a crystalline mass, IV (680 mg), was separated out by refrigeration. Specimen of IV for analysis, colorless needles, mp 95—96 °C, was obtained by recrystallization from benzene–*n*-hexane. (Found: C, 62.80; H, 6.70%. Calcd for $C_{11}H_{14}O_4$: C, 62.84; H, 6.71%. *m/e*: 210 (M^+)).

Chromatographic Separation of the Mixture. Isolation of the (2+2)π Adducts, V and VI, and Enrichment of the exo-*(4+2)π Adduct (VII)*: The combined filtrate of IV was then fractionated by a silica-gel column chromatography to give V (a colorless liquid, 1.31 g), VI (a colorless liquid, 390 mg), an additional amount of IV (214 mg) and VII (a colorless liquid, 800 mg, a mixture with 25% of IV). V and VI were extremely sensitive to air, and easily polymerized.[8]

Catalytic Hydrogenation of IV. Formation of VIII: A methanol solution of IV (100 mg) was reduced in the presence of 5% palladium charcoal (200 mg) to give a colorless crystals (VIII), mp 98—99.5 °C (from benzene-*n*-hexane). (Found: C, 62.04; H, 7.55%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%. δ: 1.0—1.7 (6H, m), 2.10 (3H, s), 2.0—2.3 (1H, m), 3.20 (1H, d, J=2 Hz), 3.2—3.8 (1H, br., OH), and 3.80 (3H, s). ν: 3380, 1735, and 1708 cm^{-1}).

The DNP of VIII was obtained as yellow needles. Mp 195—198 °C (Found: C, 52.17; H, 5.10; N, 14.22%. Calcd for $C_{17}H_{20}O_7N_4$: C, 52.04; H, 5.14; N, 14.28%. δ: 1.97 (3H, s), 3.83 (3H, s), 7.80 (1H, d, J=9.5 Hz), 8.17 (1H, dd, J=9.5, 2.5 Hz), 8.95 (1H, d, J=2.5 Hz), and 10.85 (1H, br.s, NH). λ_{max}^{MeOH}: 363 nm(ε: 20800). ν: 3450, 3320, 1720, 1620, and 1598 cm^{-1}).

Sodium Borohydride Reduction of VIII. Isolation of a Dihydroxy-Ester (IX): a) VIII (48.3 mg) was dissolved in methanol (2 ml) and reduced with sodium borohydride (7.2 mg) for 3 hr at room temperature. The mixture was then acidified with hydrochloric acid and extracted by ether. A colorless oil (38 mg), initially obtained by cold-finger distillation, was gradually crystallized to give colorless needles (IX), mp 98—99 °C (from *n*-hexane). (Found: C, 61.48; H, 8.45%. Calcd for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%. δ: 1.23 (3H, d, J=6.5 Hz), 1.0—1.6 (6H, m), 2.0—2.5 (3H, m), 3.40 (2H, s, OH), 3.78 (3H, s), and 4.12 (1H, qd, J= 6.5, 3.3 Hz). ν: 3370 and 1745 cm^{-1}). The filtrate showed the presence of an epimeric glycol, X (δ: 1.26 (3H, d, J=6.5 Hz) and 3.78 (3H, s)), but no further characterization was attempted.

b) VIII (343 mg) was dissolved in cold methanol (4 ml) and reduced by sodium borohydride (22.1 mg) overnight at 0 °C. Then, the mixture was washed with dilute hydrochloric acid and extracted with benzene. Crystalline IX (128 mg) was obtained by silica-gel column chromatography in order to remove the recovered VIII. An absence of X in the mixture was assured by NMR spectral analysis.

Formation of a Formal-Derivative (XI) from IX: IX (28 mg) was dissolved in dimethyl formal (0.5 ml) and benzene (0.5 ml) in the presence of a catalytic amount of *p*-toluenesulfonic acid and refluxed for 3 hr. The mixture was then washed with water and extracted with benzene. A colorless liquid (23 mg) was obtained by cold-finger distillation of the extract. (Found: C, 63.77; H, 8.13%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%. δ: 1.28 (3H, d, J=7 Hz), 1.0—1.7 (5H, m), 1.9—2.5 (4H, m), 3.80 (3H, s), 3.7—4.1 (1H, m), 4.58 (1H, d, J=6 Hz), and 4.95 (1H, d, J=6 Hz). ν: 1732 cm^{-1}).

Catalytic Reduction of VII. Formation of a Dihydro-Derivative (XII): VII (170 mg, containing *ca.* 25% of IV) was dissolved in methanol (5 ml) and reduced by 5% palladium charcoal (300 mg) for 50 min, then the usual work up of the mixture afforded a colorless oil (124 mg) which appeared as a single peak on a gas-liquid chromatogram, but the NMR analysis indicated the presence of the dihydro-derivative (XII) and the previously characterized VIII in the same ratio as IV to VII in the starting material. (δ: 1.0—1.8 (6H, m), 2.15 (3H, s), 2.4—2.8 (2H, m), 3.25 (1H, br.d, J=3 Hz), 3.77 (3H, s), and 5.65 (1H, br., OH)).

Sodium Borohydride Reduction of XII: XII (125 mg, contaminated by *ca.* 25% VIII) was dissolved in methanol

(5 ml) and reduced with sodium borohydride (26.8 mg) for 5 hr. Then the mixture was acidified by dilute hydrochloric acid and extracted with benzene. The extract was subsequently passed through a silica-gel column to separate the desired glycol (XIII) from the less polar fraction as a colorless liquid (51 mg). (Found: C, 61.94; H, 8.45%. Calcd for $C_{11}H_{18}O_4$: C, 61.66; H, 8.47%. δ: 1.17 (3H, d, J=6.2 Hz), 1.0—2.6 (9H, m), 2.87 (2H, br. s, OH), 3.83 (3H, s), and 4.03 (1H, dq, J=7.5, 6.2 Hz). ν: 3525 and 1730 cm^{-1}).

Formation of a Formal-Derivative (XIV) from XIII: XIII (35 mg) was dissolved in dimethyl formal (0.5 ml) and benzene (0.5 ml) with a small amount of *p*-toluenesulfonic acid and heated under reflux for 2 hr. The mixture was then washed with water and extracted with ether to give a colorless liquid (30 mg) which showed a single peak on a gas-liquid chromatogram (Found: C, 63.57; H, 8.05%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%. δ: 1.33 (3H, d, J=7 Hz), 1.2—4.0 (10H, m), 3.79 (3H, s), 4.75 (1H, d, J=6.2 Hz), and 5.03 (1H, d, J=6.2 Hz). ν: 1740 cm^{-1}).

Isomerization of V into VI: A benzene solution of V (30 mg) was held on a silica-gel column for 48 hr, and subsequently eluted with benzene–ether (10: 1) mixture. The NMR spectrum showed that consisted solely of VI.

Catalytic Hydrogenation of V. Formation of a Dihydro-Derivative (XV): V (37.6 mg) was dissolved in methanol (2 ml) and reduced by 5% palladium charcoal (75 mg) to give XV as a faint yellow liquid (21.1 mg) (Found: C, 62.20; H, 7.63%. Calcd for $C_{11}H_{16}O_4$: C, 62.25; H, 7.60%. δ: 1.0—3.0 (10H, m), 2.02 (3H, s), and 3.80 (3H, s). ν: 1735 cm^{-1} (very strong)).

Catalytic Hydrogenation of VI. Formation of XV: VI (37.4 mg) was similarly hydrogenated to give XV (23 mg) which had an NMR spectrum identical with the previous sample of XV.

Photochemical Reaction of Cyclopentene with I. Formation of XV: I (503 mg) was dissolved in cyclopentene (5 ml) and externally irradiated by means of a high-pressure mercury lamp through a Pyrex glass filter for 8 hr. The excess olefin was then evaporated and the residue separated by silica-gel column chromatography. After elution of a hydrocarbon fraction (a cyclopentene-dimer), a pale yellow fraction (330 mg) was collected and purified by cold-finger distillation to give a faint yellow liquid which was identical with authentic XV obtained from V.

Acid-Induced Dehydration of XV. Formation of the α,β-Unsaturated Keto-Ester (XVI): XV (34 mg) was dissolved in benzene (5 ml) containing a small amount of *p*-toluenesulfonic acid and refluxed for 3 hr. The solution was washed with water and extracted with benzene. Removal of the solvent afforded a pale yellow residue which was further purified by cold-finger distillation to give a pale yellow liquid (27 mg). (*m/e*: 194 (M^+), 166, 163, 162, 152, 135 (base), 134, 107, 93, 91, 80, 79, 78, 67, 65, and 59. λ_{max}^{MeOH}: 209 nm(ε: 3640), 241 (5460). δ: 1.0—3.0 (10H, m), 3.76 (3H, s), and 6.50 (1H, br. s). ν: 1730 and 1680 cm^{-1}).

The DNP of XVI was obtained as bright-yellow needles. Mp 173—174 °C (Found: C, 54.16; H, 4.90; N, 14.83%. Calcd for $C_{17}H_{18}O_6N_4$: C, 54.54; H, 4.85; N, 14.97%. $\lambda_{max}^{CHCl_3}$: 380 nm(ε: 28800).

Further Irradiation of IV: IV (30 mg) was dissolved in deuteriochloroform and externally irradiated under its formation conditions. After 8 hr, no reaction has been detected by NMR spectral analysis.

Attempted Thermal Reaction of I and III: I (32.7 mg) and III (2 ml) were kept at room temperature for 4 hr, but no detectable reaction occurred other than slight dimerization of III. Then, the same mixture was heated on a steam bath for 1 hr, but evaporation of the olefin left unreacted I and the dimer of III.

Pyrolysis of IV: a) IV (31.3 mg) was dissolved in benzene (0.5 ml) and heated for 1 hr at 80 °C. IV was recovered quantitatively.

b) IV (33.4 mg) was dissolved in dichlorobenzene (0.4 ml) and heated for an hour at 160 °C. Silica-gel column chromatography of the mixture afforded a hydrocarbon fraction (oligomeric mixture of III) and colorless needles (15 mg) which were found to be I by mixed-mp, NMR, and IR comparisons.

Further Irradiation of V: V (35 mg) was dissolved in deuteriochloroform and externally irradiated under its formation conditions for 5 hr. NMR spectral analysis revealed no reaction.

Further Irradiation of VII. VII (60 mg, containing *ca.* 25% of IV) was dissolved in deuteriochloroform and irradiated under the formation conditions. No detectable reaction was observed after 4 hr.

The authors wish to thank Prof. S. Itô, Dr. Y. Fujise and Mr. K. Sasaki of Tohoku University, for help in carrying out laborious NMDR experiments on IV. H. T. and A. M. are also grateful for financial support from the Ministry of Education.

7) XVI was free from the stereoisomers judging from its NMR spectrum (see Experimental). The configuration of XVI was ascribed as *cis*-fused.

8) Correct figures for elemental analyses were not obtained despite an intensive effort.

N-Halogen Compounds of Cyanamide Derivatives. V.[1] The Preparation and Reaction of Δ^4-1,2,4-Thiadiazolines

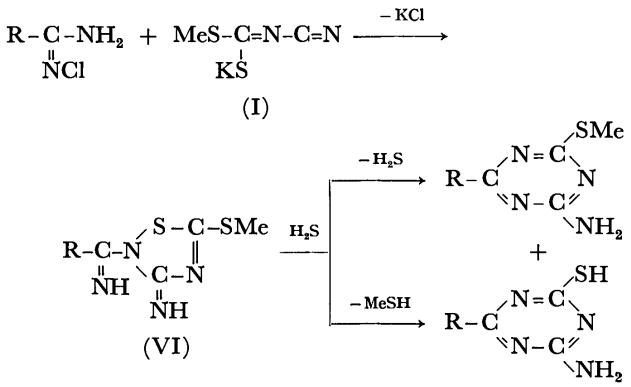
Toshio FUCHIGAMI and Keijiro ODO

Faculty of Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received August 15, 1974)

Five new Δ^4-1,2,4-thiadiazolines (TDZ), IIa,b, IIIa,b, and IV, were easily prepared by the reaction of potassium methyl cyanoiminodithiocarbonate (I) with *N*-chloro compounds of *O*-alkylisoureas, guanidines, and guanylurethane. 2-Methoxyimidoyl-3-imino-5-methylthio-TDZ (IIa), with a reactive imidoether group, was converted into the 2-carbamoyl-TDZ derivative (V) by treatment with excess dry hydrogen chloride. The reaction of IIa with aliphatic amines gave 2-amidino-TDZ derivatives (IIIc—e) in good yields in the presence of both free amines and amine hydrochlorides (molar ratio, 2: 1). The mechanism of this amidination was discussed.

In our previous work,[2] it was found that 2-imidoyl-3-imino-5-methylthio-Δ^4-1,2,4-thiadiazolines (VI) could easily be prepared by the reaction of *N*-chloroamidines with I and that VI was readily cleft by reduction at the N–S link and recyclized to two kinds of *s*-triazines.

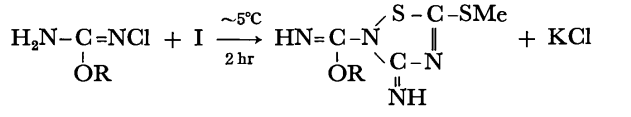


Scheme 1.

In this paper, we wish to report on the synthesis of new TDZ (IIa,b, IIIa,b, and IV) using *N*-chloro compounds of cyanamide derivatives (*O*-alkylisoureas, guanidines, and guanylurethane) and their properties, together with the reaction between IIa and amines to give 2-amidino-TDZ (IIIc—e).

Results and Discussion

Preparation and Reaction of 2-Alkoxyimidoyl-3-imino-5-methylthio-TDZ (IIa,b). *N*-Chloro-*O*-alkylisoureas readily reacted with I in methylene chloride to form IIa and b. The yield of IIa increased considerably when the solvent was acetonitrile, which is more polar than methylene chloride, while that of IIb did not. The same effect was also observed in the case of *N*-chloroguanidine (Table 3).

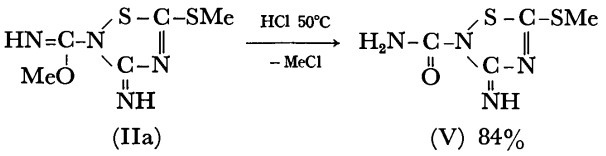


(II)

Table 1. Preparation of TDZ

R	Solvent	Product	Yield (%)
Me	CH_2Cl_2	IIa	63
	MeCN		79
Et	MeCN	IIb	41

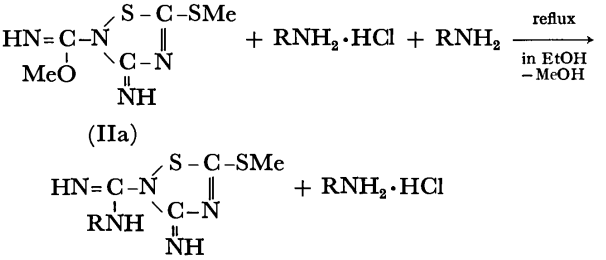
The structures of IIa and b were confirmed by means of elemental analysis and by a study of the IR spectrum. Compounds IIa and b can both be regarded as *N*,*N*-disubstituted-*O*-alkylisourea with a reactive imidoether group. By the treatment of IIa with excess dry hydrogen chloride in methanol, IIa was further converted into the 2-carbamoyl-TDZ derivative (V).



Scheme 2.

The reaction of IIa with amines was likewise examined. The reaction of IIa with amines in ethanol under reflux gave 2-amidino-3-imino-5-methylthio-TDZ (IIIc—e). It was found that IIIc—e were obtained as free bases in good yields in the presence of both free amines and amine hydrochlorides (molar ratio,

Table 2. Reaction of IIa with amines



(IIIc—e)

R	Free amine[a]	Amine salt[a]	R. Time (hr)	Product (Yield %)
Me	2	1	4.0	IIIc (80)
Et	1	0	4.0	(0)
	0	1	4.0	IIId (0)
	2	1	4.0	(97)
Bzl	1	0	2.5	IIIe (0)
	2	1	3.0	(75)
Ph	2	1	3.0	V (80)

a) Molar ratio.

2: 1). It is notable that no substitution reaction occurred in the absence of either free amine or amine hydrochloride. In the case of such a weak base as aniline, no substitution reaction occurred and V was obtained. The basicity of IIa seems to be stronger than that of aniline, so IIa may take hydrogen chloride from aniline hydrochloride to form V, thus evolving methyl chloride.

As is shown in Table 2, the methylthio group of IIa was found not to be reactive.

The mechanism of this amidination, judging from the above results, is as follows. Free amine attacks the protonated imidoether group of IIa to form a tetrahedral addition intermediate (**A**)—Step (**a**). Then, the elimination of methanol and a proton from A gives IIIc—e as a free base—Step (**b**). The first step and the second step seem to be subjected to acid catalysis (HCl) and base catalysis (free amine) respectively

(Scheme 3).

Preparation of Other TDZ. 2-Amidino-TDZ (IIIa,b). In a manner similar to that described above, *N*-chloroguanidines and I gave IIIa, and b. The yield of IIIa in acetonitrile increased considerably, as had been observed in the case of IIa. The low yield of IIIb may be attributable to the steric hyndrance of the piperidyl group. Since IIIa is too weak a base, IIIa could not be subjected to benzoylation by benzoyl chloride.

2-N-Carbethoxyamidino-TDZ (IV). In a similar manner, *N*-chloroguanylurethane and I gave IV in a good yield (85%). Its NMR spectrum showed three singlet signals, at δ 2.70 (SMe), 3.67 (OMe), and 8.50 (NH, broad). In the mass spectrum, the parent peak, *m/e* 247, and other fragment peaks appeared appropriately. It would be expected that the elimination of

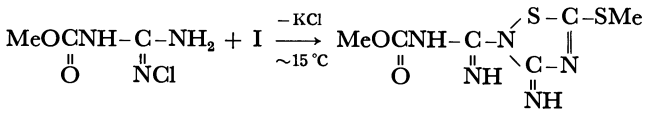
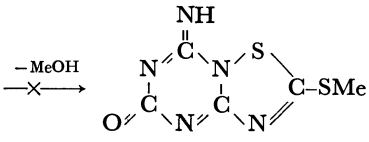
methanol from IV would give rise to the formation of a condensed ring. However, no product due to such a condensation was formed, and decomposition only took place when IV was heated gradually at 190 °C.



(IV) 80%



Scheme 4.

The physical properties and analytical data of the products are summarized in Table 4.

Compounds IIa, IIIa, and IV display approximately similar UV spectra (Fig. 1), perhaps because of their structural resemblance.[3]

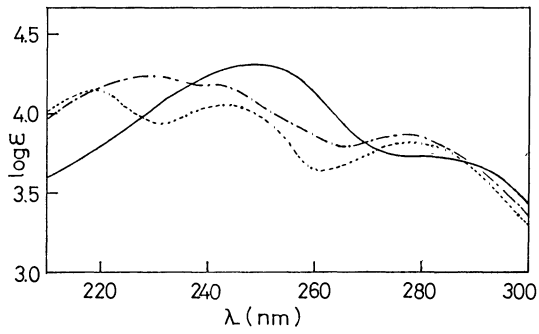


Fig. 1. Ultraviolet absorption of TDZ in water.
——: IIa, ——: IIIa, ----: V.

Experimental

The melting points are uncorrected. The IR spectra were taken with a Hitachi EPI-S 2 spectrophotometer. The NMR spectrum was recorded at 90 MHz in DMSO-d_6, with TMS as the internal standard, using a Hitachi R-22 spectrometer. The mass spectrum was taken with a JEOL JMS-D100 mass spectrometer. The UV spectra were taken with a Hitachi 624 spectrophotometer.

N-Chloro Compounds. *N*-Chloro-*O*-methylisourea,[4] *N*-chloro-*O*-ethylisourea,[4] *N*-chloroguanidine,[5] *N*-chloro-*N'*, *N'*-pentamethyleneguanidine,[6] and *N*-chloroguanylurethane were prepared by a previously described method.[7] *N*-chloroguanylurethane; yield, 80%; dp 124—125 °C; active chlorine 22.40% (calcd for $C_3H_6N_3O_2Cl$ 23.40%).

Potassium methyl cyanoiminodithiocarbonate (I) was prepared according to the method of Timmons *et al.*[8]

2-Methoxyimidoyl-3-imino-5-methylthio-Δ⁴-1,2,4-thiadiazoline (IIa). To a stirred mixture of I (10.20 g, 60 mmol) and methylene chloride (55 ml), we added a solution of *N*-chloro-*O*-methylisourea (5.97 g, 55 mmol) in methylene chloride (45 ml). The temperature was maintained below 5 °C during the reaction. After about 2 hr of continued stirring, the mixture was refluxed for 0.3 hr. After the precipitated salt had been removed by filtration, the filtrate was concentrated. Washing the residue with ether afforded IIa (7.10 g, 63%, mp 110—112 °C). Recrystallization from methanol gave a pure product; mp 112—115 °C. The above reaction, when carried out in acetonitrile by a similar method, gave IIa in a 79% yield.

2-Ethoxyimidoyl-3-imino-5-methylthio-Δ⁴-1,2,4-thiadiazoline (IIb). Using the same procedure, the crude product of IIb was obtained as an oily material from *N*-chloro-*O*-ethylisourea. The oily material was crystallized from aqueous methanol, and the yield was 41% (mp 99—100 °C). Recrystallization from aqueous methanol yielded an analytical sample; mp 108—109 °C.

2-Carbamoyl-3-imino-5-methylthio-Δ⁴-1,2,4-thiadiazoline (V). A slow stream of dry hydrogen chloride was passed through a solution of IIa (2.04 g, 10 mmol) in methanol at 50 °C for 2 hr. The white crystalline precipitate (V, 1.34 g) was collected by filtration, and the filtrate was concentrated. Washing the residue with a small amount of methanol or acetone gave V (0.25 g). The total yield was 84%; dp 237 °C. Recrystallization from DMF–methanol gave pure V; dp 237—238 °C.

Reaction of IIa with Amines. *2-N-Methylamidino-3-imino-5-methylthio-Δ⁴-1,2,4-thiadiazoline (IIIc)*: A solution of IIa (2.04 g, 10 mmol), 40% aqueous methylamine (20 mmol) and methylamine hydrochloride (0.68 g, 10 mmol) in ethanol (25 ml) was refluxed for 4 hr. After cooling, a crystalline precipitate was collected by filtration (IIIc, 1.45 g; mp 170—174 °C). After the concentration of the filtrate, the washing of the residue with water afforded IIIc (0.20 g, mp 170—174 °C). The total yield was 81%. Recrystallization from methanol gave pure IIIc; mp 183—184 °C.

Similarly, reactions with other amines were carried out. The products and reaction conditions are given in Table 2.

2-Amidino-3-imino-5-methylthio-Δ⁴-1,2,4-thiadiazoline (IIIa). To a stirred suspension of I (2.38 g, 14 mmol) in acetonitrile (30 ml), we gradually added *N*-chloroguanidine (1.31 g, 14 mmol). The temperature was maintained below 10 °C during the reaction. After about 1 hr of continued stirring, an insoluble matter (IIIa and KCl) was separated by filtration. Washing the solid with water (to remove KCl) and acetone afforded IIIa (2.41 g; 91%; dp 214—215 °C). Recrystallization from DMF gave pure IIIa; dp 225—228 °C. The above reaction, undertaken in methylene chloride in a similar manner, gave IIIa in a 55% yield.

2,N,N-Pentamethyleneamidino-3-imino-4-methylthio-Δ⁴-1,2,4-thiadiazoline (IIIb). To a stirred solution of I (1.19 g, 7 mmol) in acetonitrile (8 ml), we added a solution of *N*-chloro-*N'*,*N'*-pentamethyleneguanidine (1.13 g, 7 mmol) in acetonitrile (10 ml). After 1 hr of continued stirring below 10 °C, an insoluble matter was separated by filtration. The oily material obtained by concentrating the filtrate was dissolved in 2 M hydrochloric acid and (5 ml) and methanol (5 ml). After stirring the solution for 0.5 hr at room temperature, IIIb was precipitated by making the solution neutral (0.80 g; 44%; mp 130—132 °C). Recrystallization from methanol gave pure IIIb; mp 139 °C.

2-N-Carbethoxyamidino-3-imino-5-methylthio-Δ⁴-1,2,4-thiadiazoline (IV). To a stirred suspension of I (2.72 g, 16 mmol) in acetonitrile we gradually added *N*-chloroguanylurethane (2.42 g, 16 mmol), the temperature being kept below 15 °C. After about 1 hr of continued stirring, the mixture was refluxed for 0.1 hr. After the insoluble matter had then been separated by filtration, washing with water and ether afforded IV (3.30 g; 85%; dp 190 °C). Recrystallization from ethyl acetate–DMF (2: 1) gave pure IV; dp 190 °C.

We wish to thank Dr. Ichikawa of our laboratory for his invaluable discussions.

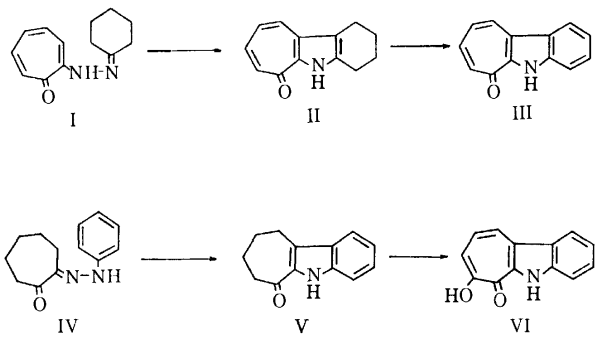
(Received August 26, 1974)

The application of Fischer's indole synthesis to cyclohexanone 2-troponylhydrazone gave 1,2,3,4-tetrahydroindolo[2,3-*b*]tropone (II), which was then dehydrogenated to indolo[2,3-*b*]tropone (III). 8-, 10-Isopropyl-, and 7-bromoindolo[2,3-*b*]tropone (XIIa—c) were also obtained by a similar method. The treatment of 2-troponylhydrazones of cycloheptanone and *N*-benzylpiperidone with dilute sulfuric acid or PPA gave 2,3-pentamethylenepyrrolo[2,3-*b*]tropone (XIII) and 2-benzyl-1,2,3,4-tetrahydrocyclohept[*b*]pyrido[3,4-*d*]pyrrol-6(5H)-one (XIV) respectively. The reaction of III with phosphoryl chloride or thionyl chloride yielded 8-chlorobenzo[*b*]-1-azaazulene (XV), which was subsequently converted into a hydrazino derivative (XVI). The oxidative decomposition of XVI with copper sulfate in acetic acid afforded benzo[*b*]-1-azaazulene (XVII).

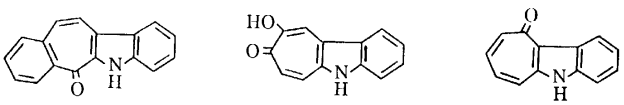
Several methods have been reported for the preparation of various indolotropones(cycloheptindolones). 1,2,3,4-Tetrahydroindolo[2,3-*b*]tropone (II) obtained by the application of Fischer's indole synthesis to cyclohexanone 2-troponylhydrazone (I) was dehydrogenated to indolo[2,3-*b*]tropone (III) and then derived to benzo[*b*]-1-azaazulene (XVII).[1)] On the other hand, indolo[3,2-*f*]tropolone (VI) was obtained by the SeO_2 oxidation of the compound V produced by the same indole synthesis from cycloheptanedione monophenylhydrazone (IV),[2)] and more recently benzoindolotropone (VII) was synthesized by similar methods.[3)]



I II III

IV V VI

Furthermore, indolo[3,2-*d*]tropolone (VIII) was obtained by the thermolysis of 5-azido-4-phenyltropolone,[4)] and compound III and its isomer (IX) were isolated from the photochemical products of acridine-10-oxide.[5)]



VII VIII IX

In this paper we wish to describe in full the experimental details of our earlier report,[1)] along with the results of a reexamination carried out recently.

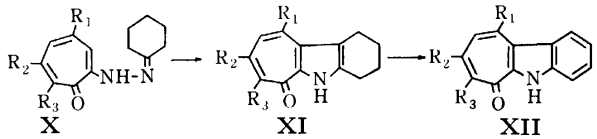
† Present address: No. 811, 2-5-1, Kamiyoga, Setagaya-ku, Tokyo 158.

†† Present address: Faculty of Science, Korean University, 1-700, Ogawa-cho, Kodaira-shi, Tokyo 187.

Results and Discussion

The heating of cyclohexanone 2-troponylhydrazone (I) with dilute sulfuric acid afforded the ring-closure product (II), which was then converted to indolo-[2,3-*b*]tropone (III) by dehydrogenation with chloranil or DDQ.

The application of the same treatment to 4-, 6-isopropyl-, and 7-bromo-2-troponylhydrazone (Xa—c) of cyclohexanone gave compounds XIa—c, the dehydrogenation of which subsequently afforded 8-, 10-isopropyl, and 7-bromo derivatives (XIIa—c) respectively.



X XI XII

a: R_1=i-Pr, R_2=R_3=H
b: R_2=i-Pr, R_1=R_3=H
c: R_3=Br, R_1=R_2=H

The structures of these new compounds were discussed on the basis of the spectral data. The IR spectrum of II exhibited characteristic absorption bands at 3140 cm^{-1} (NH st.), 2920 cm^{-1} (CH_2 st.), and 1620 cm^{-1} (C=O or C=C conjugated). Compound III showed IR-absorption bands at 3195 cm^{-1} (NH st.) and 1614 cm^{-1} (C=O or C=C conjugated), but no paraffinic C–H streching absorption bands (Table 1).

The NMR spectrum of II exhibited signals corresponding to two methylene groups at δ 2.5—2.9 ppm (4H, m, $-CH_2-$) and δ 1.7—1.9 ppm (4H, m, $-CH_2-$), besides signals of tropone-ring protons at δ 6.76 ppm (1H, t, d, J=7.0, 2.0 Hz, H_9), δ 7.1—7.4 ppm (2H, m, $H_{7,8}$), and δ 7.49 ppm (1H, d,d, J=9.0, 1.0 Hz, H_{10}). In the NMR spectrum of III, the signals due to the methylene groups disappeared and those of aromatic protons were observed as a complex multiplet at δ 7.0—8.3 ppm. The IR and NMR spectra of XIa—c and XIIa—c supported the structure described above (Tables 1 and 2).

The bromo compound, XIIc, was obtained by treating III with NBS. It was quite stable even when

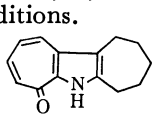
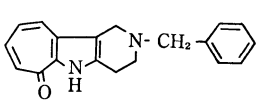
XIb	1.25 (6H, d, J=7.0, $-CH_3$), 1.7—1.9 (4H, m, $-CH_2-$), 2.6—3.0 (5H, m, $=-CH_2-$, $-CH-$), 6.73 (1H, d,d, J=7.0, 2.0, H_9), 7.12 (1H, d, J=2.0, H_7), 7.46 (1H, d,d, J=8.0, 1.0, H_{10})
XIIa	1.49 (6H, d, J=7.0, $-CH_3$), 4.18 (1H, sept., J=7.0, $-CH-$), 7.00 (1H, d,d, J=7.0, 2.0, H_9), 7.18—7.55 (4H, m, $H_{2,3,7,8}$), 7.76 (1H, d, J=6.0, H_4), 8.23 (1H, d, J=6.0, H_1)
XIIb	1.35 (6H, d, J=7.0, $-CH_3$), 2.98 (1H, sept., J=7.0, $-CH-$), 6.98 (1H, d,d, J=9.0, 2.0, H_9), 7.20—7.55 (4H, m, $H_{2,3,7,8}$), 7.73 (1H, d, J=7.0, H_4), 8.03 (1H, d, J=7.0, H_1), 8.05 (1H, d,d, J=9.0, 1.0, H_{10})

heated with conc. sulfuric acid, 85% phosphoric acid and when refluxed in methanol with sodium methylate. Thus, we were unable to derive indolo[3,2-*f*]tropolone (VI).

The 2-troponylhydrazones of cycloheptanone and *N*-benzylpiperidone were also easily converted to XIII and XIV respectively by heating with dilute sulfuric acid or PPA, but the ring closure of cyclopentanone 2-troponylhydrazone did not take place under the same conditions.

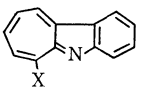


XIII

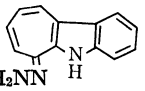


XIV

When compound III was heated with phosphoryl chloride or thionyl chloride, 8-chlorobenzo[*b*]-1-azaazulene (XV) was obtained; the original compound III had been obtained by the hydrolysis with aqueous sodium hydroxide. The reaction of XV with hydrazine hydrate gave the hydrazino derivative (XVI). The UV and visible absorption spectra suggested that XVI is probably indolo[2,3-*b*]troponehydrazone (Table 3).



XV: X=Cl
XVII: X=H



XVI

Table 3. Ultraviolet and visible absorption maxima

Compound	λ_{max} nm (log ε)
III	225 (4.40), 277 (4.40), 383 (3.81), 404 (3.89)
XVI	243 (4.39), 307 (4.06), 317 (4.06), 350 (4.17), 365 (4.08) (in CH_3OH)
XV	245 (4.41), 301 (4.51), 314 (4.62), 326 (4.55), 365 (3.78), 385 (3.79), 400 (3.38), 500 (2.74), 532 (2.74)
XVII	228 (4.34), 264 (4.14), 289 (4.54), 299 (4.56), 311 (4.62), 323 (3.50), 347 (3.66), 359 (3.70), 379 (3.68), 394 (3.22), 500 (2.58), 538 (2.57) (in cyclohexane)

By oxidative decomposition with copper sulfate in aqueous acetic acid, XVI was converted into benzo-[*b*]-1-azaazulene (XVII) as reddish-purple needles; mp 140—141 °C.

The structure was identified by a spectral comparison with an authentic sample.[2] The visible absorption spectra of XV and XVII are quite different from those of III and XVI, as is shown in Table 3.

Experimental**

All the melting points are uncorrected. The NMR spectra were obtained on a JEOL Model JMN-4H-100 spectrometer in $CDCl_3$ solution, with TMS as the internal standard.

Cyclohexanone 2-Troponylhydrazone (I). To a solution of 2-hydrazinotropone (21 g) in ethanol (210 ml), we added cyclohexanone (15 g), and the mixture was refluxed for 30 min. After cooling, the reaction mixture was diluted with water (210 ml). The separated material was collected and dried. Recrystallization from petroleum ether gave yellow needles (32 g, 96%); mp 75—76 °C. IR (KBr): 3220 (NH), 1625, and 1585 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 264 (log ε=4.31), 353 (4.24), and 415 (4.27) nm. Found: C, 71.92; H, 7.50; N, 13.08%. Calcd for $C_{13}H_{16}ON_2$: C, 72.19; H, 7.46; N, 12.95%.

1,2,3,4-Tetrahydroindolo[2,3-b]tropone (II). A mixture of I (30 g), water (500 ml), and conc. sulfuric acid (30 ml) was refluxed at 120 °C for 2 hr. After cooling, 30% aqueous sodium carbonate was added to adjust the pH value to 6 and then extracted with chloroform. The extract was dried over anhydrous sodium sulfate and condensed to dryness to give light yellow needles, which were subsequently recrystallized from benzene (15.8 g, 57%); mp 212—215 °C. UV: $\lambda_{max}^{CH_3OH}$ 237 (log ε=4.43), 293 (4.50), 360 (3.63), and 382 (3.65) nm. Found: C, 78.25; H, 6.40; N, 6.83%. Calcd for $C_{13}H_{13}ON$: C, 78.36; H, 6.58; N, 7.03%.

N-Benzyl Compound: Light yellow needles (from *n*-hexane); mp 136.5—137.5 °C. IR (KBr): 1628, 1558, and 1518 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 237 (log ε=4.39), 296 (4.47), 369 (3.50), and 387 (3.48) nm. Found: C, 82.86; H, 6.58; N, 4.65%. Calcd for $C_{20}H_{19}ON$: C, 83.00; H, 6.63; N, 4.84%.

** The authors are grateful to the Sankyo Co., Ltd., for doing a part of the elemental analyses.

N-Benzoyl Compound: Colorless micro prisms (from benzene–cyclohexane); mp 167—168 °C. IR (KBr): 3050, 2940 (CH), 1716, and 1620 cm^{-1} (C=O). UV: $\lambda_{max}^{CH_3OH}$ 237 ($\log \varepsilon$=4.47), 290 (4.29), 360 (3.54), and 378 (3.44) nm. Found: C, 79.25; H, 5.69; N, 4.76%. Calcd for $C_{20}H_{17}O_2N$: C, 79.18; H, 5.65; N, 4.62%.

Indolo[2,3-b]tropone (III). *Method A*: Dehydrogenation with chloranil. A mixture of II (7.0 g) and chloranil (18.0 g) in xylene (115 ml) was refluxed at 160—165 °C for 24 hr. After cooling, the reaction mixture was made alkaline by adding 2 M sodium hydroxide, and the insoluble material was filtered off. After the organic layer had been dried over anhydrous sodium sulfate, the solvent was removed to give a residue. The water layer and the insoluble material were then extracted with chloroform. The extract was dried and condensed to give the residue. The combined residue was recrystallized from benzene to give III as yellow needles (3.6 g, 52%); mp 245—246 °C.

Method B: Dehydrogenation with DDQ. DDQ (2.1 g) was added to a solution of II (1.0 g) in benzene (60 ml), and the mixture was refluxed for 5 hr. After cooling, the reaction mixture was poured into 10% sodium hydroxide, and the benzene layer was isolated. The water layer was extracted with chloroform. The organic layers were dried over anhydrous sodium sulfate and condensed, and the residues were recrystallized from benzene to give III as yellow plates (0.43 g, 45%); mp 245—246 °C. The IR spectrum was identical with that of a sample prepared by Method A and the mixed melting point was not depressed. Found: C, 80.02; H, 4.65; N, 7.14%. Calcd for $C_{13}H_9ON$: C, 79.97; H, 4.67; N, 7.18%.

N-Benzoyl Compound: Yellow needles (from cyclohexane–benzene); mp 196—196.5 °C. IR (KBr): 1706 cm^{-1} (C=O). UV: $\lambda_{max}^{CH_3OH}$ 222 ($\log \varepsilon$=4.48), 275 (4.46), 310 (4.17), 382 (3.71), and 400 (3.71) nm. Found: C, 80.42; H, 4.36; N, 4.44%. Calcd for $C_{20}H_{13}O_2N$: C, 80.23; H, 4.39; N, 4.68%.

Cyclohexanone 4-Isopropyltroponyl-2-hydrazone (Xa). A mixture of 2-hydrazino-4-isopropyltropone (0.2 g) and cyclohexanone (0.1 g) in ethanol (2 ml) was refluxed for 15 min on a water bath. The solvent was then removed, and a saturated solution of picric acid in ethanol was added to the residual oil. The picrate was treated with aqueous sodium bicarbonate and the separated oil was extracted with benzene. The extract was dried and condensed to leave a residual oil. The oil solidified under reduced pressure in a vacuum desiccator. The solid was purified from ethyl ether to give a yellow powder (0.18 g, 62%); mp 104—106 °C. IR (KBr): 3255 (NH), 1592, and 1542 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 270 ($\log \varepsilon$=4.40), 353 (4.23), 412 (4.27) nm. Found: C, 74.40; H, 8.57; N, 10.91%. Calcd for $C_{16}H_{22}ON_2$: C, 74.38; H, 8.58; N, 10.85%.

Picrate: Yellow needles; mp 127—128 °C. Found: C, 54.12; H, 5.18; N, 14.35%. Calcd for $C_{22}H_{25}O_8N_5$: C, 54.20; H, 5.17; N, 14.38%.

Cyclohexanone 6-Isopropyltroponyl-2-hydrazone (Xb). A mixture of 2-hydrazino-6-isopropyltropone (0.3 g) and cyclohexanone (0.16 g) in ethanol (2 ml) was treated by a method similar to that used for the preparation of Xa. Yellow rhombic crystals (0.2 g, 47%); mp 76—78 °C. IR (KBr): 3276 (NH), 1590, and 1541 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 265 ($\log \varepsilon$=4.40), 353 (4.21), and 4.08 (4.27) nm. Found: C, 74.15; H, 8.51; N, 10.79%. Calcd for $C_{16}H_{22}ON_2$: C, 74.38; H, 8.58; N, 10.85%.

Picrate: Orange yellow needles; mp 146—147 °C. Found: C, 54.51; H, 4.79; N, 14.22%. Calcd for $C_{22}H_{25}O_8N_5$: C, 54.20; H, 5.17; N, 14.37%.

Alternate Method for Preparation of Xa and Xb. A mixture (3.6 g) of two isomers of hinokitiol methyl ether from the methylation of hinokitiol with diazomethane were directly treated with 85% hydrazine hydrate to give a mixture of 4- and 6-isopropyl-2-hydrazinotropones, which were then converted into the hydrazones of cyclohexanone. The resulting hydrazones (Xa and Xb) were separated in the form of picrates by fractional crystallization.

The picrates were treated with a sodium bicarbonate solution to give Xa (1.0 g) and Xb (1.6 g).

10-Isopropyl-1,2,3,4-tetrahydroindolo[2,3-b]tropone (XIa). A solution of Xa (7.2 g) in 3 M sulfuric acid (90 ml) was refluxed at 110—120 °C for 2 hr. After cooling, the reaction mixture was made slightly alkaline by adding aqueous sodium hydroxide and extracted with benzene. The extract was dried and condensed, and the residue was recrystallized from benzene to give slightly red needles (3.0 g, 45%); mp 221—222 °C. Found: C, 79.32; H, 7.77; N, 5.96%. Calcd for $C_{16}H_{19}ON$: C, 79.63; H, 7.94; N, 5.80%. UV: $\lambda_{max}^{CH_3OH}$ 243 ($\log \varepsilon$=4.51), 294 (4.47), 365 (3.77), and 383 (3.82) nm.

8-Isopropyl-1,2,3,4-tetrahydroindolo[2,3-b]tropone (XIb). A solution of X (11.9 g) in 3 M sulfuric acid (150 ml) was treated by a method to that used for the preparation of XIa. Light yellow needles (5.9 g, 53%); mp 205—206 °C. UV: $\lambda_{max}^{CH_3OH}$ 242 ($\log \varepsilon$=4.48), 292 (4.46), and 373 (3.59) nm. Found: C, 79.48; H, 7.69; N, 5.85%. Calcd for $C_{16}H_{19}ON$: 79.63; H, 7.94; N, 5.80%.

10-Isopropylindolo[2,3-b]tropone (XIIa). A mixture of XIa (1.0 g) and DDQ (2.0 g) in dry benzene (60 ml) was refluxed for 4.5 hr. The reaction mixture was then poured onto 10% sodium hydroxide and the benzene layer was isolated. The water layer was subsequently extracted with chloroform. The organic layers were washed with water, dried over anhydrous sodium sulfate, and condensed to give yellow micro prisms (0.63 g, 64%), which were then recrystallized from benzene; mp 199—201 °C. Found: C, 80.81; H, 6.44; N, 5.82%. Calcd for $C_{16}H_{15}ON$: C, 80.98; H, 6.37; N, 5.90%.

8-Isopropylindolo[2,3-b]tropone (XIIb). *Method A*: Dehydrogenation with DDQ. A mixture of XIb (1.0 g) and DDQ (2.0 g) in dry benzene (60 ml) was treated by a method similar to that used for the preparation of XIIa. Light yellow micro prisms (0.69 g, 70%); mp 222—224 °C. UV: $\lambda_{max}^{CH_3OH}$ 226 ($\log \varepsilon$=4.46), 277 (4.48), 306 (4.28), and 394 (3.87) nm. Found: C, 81.25; H, 6.30; N, 5.96%. Calcd for $C_{16}H_{15}ON$: C, 80.98; H, 6.37; N, 5.90%.

Method B: Dehydrogenation with Pd–C. A mixture of XIb (0.5 g) and 5% Pd–C (0.2 g) in *p*-cymene (5 ml) was refluxed at 198—200 °C for 48 hr. The catalyst was then removed, and the filtrate was cooled to give light yellow micro needles (0.16 g, 32%), which were then recrystallized from benzene; mp 222—224 °C.

The IR spectrum was identical with that of the sample prepared by Method A, and the mixed melting point with the sample was not depressed.

Cyclohexanone Bromotroponylhydrazone (Xc). Cyclohexanone (2.5 g) was added to a solution of 2-bromo-7-hydrazinotropone (5.0 g) in ethanol (250 ml), and the mixture was refluxed for 20 min. The solvent was then removed, and the residue was recrystallized from ethanol to give yellow prisms (6.24 g, 91%); mp 134.5—135 °C. IR (KBr): 3270 (NH), 1620, 1597 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 275 ($\log \varepsilon$=4.33), 358 (4.20), and 430 (4.28) nm. Found: C, 52.76; H, 5.14; N, 9.47%. Calcd for $C_{13}H_{15}ON_2Br$: C, 52.98; H, 5.13; N, 9.49%.

7-Bromo-1,2,3,4-tetrahydroindolo[2,3-b]tropone (XIc). *Method A*: A solution of Xc (1.0 g) in water (10 ml) and conc. sulfuric acid (0.6 ml) was refluxed at 130—140 °C for

2 hr. After cooling, 4 M sodium hydroxide was added to adjust the pH values to 5—6 and the solution was extracted with chloroform. The extract was dried and condensed to give a residue. The residue was dissolved in ethanol and treated with activated charcoal to crystallize it as yellow needles (0.44 g, 41%); mp 274—275 °C (decomp.). IR (KBr): 3200 (NH), 1605, and 1545 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 250 (log ε=4.38), 300 (4.53), 375 (3.68), and 393 (3.76) nm. Found: C, 56.27; H, 4.40; N, 4.72%. Calcd for $C_{13}H_{12}ONBr$: C, 56.13; H, 4.36; N,5.04%.

Method B: To a solution of II (0.6 g) in benzene (50 ml), *N*-bromosuccinimide (0.58 g) and benzoyl peroxide (0.06 g) were added; the mixture was then refluxed with stirring for 1 hr.

The solvent was removed, and then the residue was made alkaline by adding aqueous sodium hydroxide and extracted with benzene. The extract was dried and condensed to leave a residue. This residue was dissolved in benzene–chloroform and passed through a silica-gel column. The product obtained from the yellowish effluent was recrystallized from ethanol to give yellow needles (0.12 g, 14%); mp 274—275 °C (decomp.). The IR spectrum was identical with that of the sample obtained by means of Method A.

7-Bromoindolo[2,3-b]tropone (XIIc). *Method A*: A mixture of XIc (0.2 g) and DDQ (0.35 g) in dry benzene (20 ml) was refluxed for 5 hr. The reaction mixture was then treated by a method similar to that used for the preparation of III. Orange micro needles (0.08 g, 41%); mp 291—292 °C. IR (KBr): 3215 (NH), 1600, and 1552 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 235 (log ε=4.25), 282 (4.47), 325 (4.10), 342 (4.04), 395 (3.82), and 416 (3.87) nm. Found: C, 56.59; H, 3.04; N, 5.19%. Calcd for $C_{13}H_8ONBr$: C, 56.75; H, 2.93; N, 5.09%.

Method B: *N*-Bromosuccinimide (0.07 g) and benzoyl peroxide (0.02 g) were added to a solution of III (0.07 g) in dry benzene (15 ml), after which the mixture was refluxed for 3 hr. The solvent was then removed, and the residue was treated with boiling water to leave an insoluble solid. The solid was collected and dried.

Recrystallization from benzene gave yellow needles (0.07 g, 92%); mp 291—292 °C. The IR spectrum was identical with that of the sample obtained by means of Method A.

Attempt at the Ring Closure of Cyclopentanone 2-Troponylhydrazone. Cyclopentanone 2-Troponylhydrazone: A mixture of 2-hydrazinotropone (0.3 g) and cyclopentanone (0.22 g) in acetic acid (6 ml) was refluxed for 1 hr. The reaction mixture was then treated by a method similar to that used for the preparation of I.

Orange yellow prisms (0.27 g, 61%); mp 78—79 °C. IR (KBr): 3230 (NH), 1637, and 1592 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 265 (log ε=4.34), 354 (4.26), and 418 (4.26) nm. Found: C, 70.94; H, 6.94; N, 14.02%. Calcd for $C_{12}H_{14}ON_2$: C, 71.26; H, 6.98; N, 13.85%.

When this hydrazone was heated with dilute sulfuric acid or 85% phosphoric acid, the starting material was recovered.

2,3-Pentamethylenepyrrolo[2,3-b]tropone (XIII). Cycloheptanone 2-Troponylhydrazone: A mixture of 2-hydrazinotropone (0.3 g) and cycloheptanone (0.3 g) in ethanol (5 ml) was refluxed for 30 min. The reaction mixture was then treated by a method similar to that used for the preparation of I.

Yellow needles (0.4 g, 79%); mp 91—92 °C. IR (KBr): 3255 (NH), 1595, and 1550 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 264 (log ε=4.35), 353 (4.25), and 415 (4.28) nm. Found: C, 73.15; H, 7.84; N, 12.21%. Calcd for $C_{14}H_{18}ON_2$: C, 73.01; H, 7.88; N, 12.17%.

Method A: Ring-closure with PPA. A solution of the hydrazone (2.0 g) described above in 105% PPA (30 ml) was heated at 150 °C for 2 hr. After cooling, the reaction mixture was diluted with water and neutralized by adding aqueous sodium bicarbonate.

The resulting precipitate was collected, dried, and recrystallized from benzene to give light yellow plates (1.1 g, 58%); mp 185—186 °C. IR (KBr): 3160 (NH), 1621, 1545, and 1525 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 235 (log ε=4.41), 295 (4.53), and 363 (3.63) nm. Found: C, 78.46; H, 7.02; N, 6.71%. Calcd for $C_{14}H_{15}ON_2$: C, 78.84; H, 7.09; N, 6.57%.

Method B: Ring-closure with dilute sulfuric acid. A solution of the hydrazone described above (0.5 g) in water (12 ml) and conc. sulfuric acid (0.8 ml) was refluxed for 1 hr. The reaction mixture was treated by a method similar to that used for the preparation of II. Light yellow plates (0.03 g, 7%); mp 185—186 °C.

The IR spectrum was identical with that of the sample prepared by means of Method A, and the mixed melting point with the sample was not depressed.

N-Benzoyl Compound: Colorless micro prisms (from cyclohexane); mp 157—158 °C. IR (KBr): 1720 cm^{-1} (C=O). UV: $\lambda_{max}^{CH_3OH}$ 237 (log ε=4.48), 288 (4.33), 360 (3.57), and 380 (3.50) nm. Found: C, 79.17; H, 5.53; N, 4.91%. Calcd for $C_{21}H_{19}O_2N$: C, 79.47; H, 6.03; N, 4.41%.

2-Benzyl-1,2,3,4-tetrahydrocyclohept[b]pyrido[3,4-d]pyrrol-6(5H)-one (XIV). 1-Benzyl-4-piperidone 2-Troponylhydrazone: A mixture of 2-hydrazinotropone (1.5 g) and 1-benzyl-4-piperidone (2.0 g) in ethanol (5 ml) was refluxed for 2 hr. The solvent was then removed, and the residue was recrystallized from ethanol to give yellow needles (2.6 g, 77%); mp 97—98 °C. IR (KBr): 3266 (NH), 1601, and 1590 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 263 (log ε= 4.34), 354 (4.28), and 418 (4.29) nm. Found: C, 74.29; H, 6.88; N, 13.81%. Calcd for $C_{19}H_{21}ON_3$: C, 74.24; H, 6.89; N, 13.67%.

A solution of the hydrazone described above (0.3 g) in PPA (4 ml) was heated at 150 °C for 30 min. After cooling, the reaction mixture was diluted with water; aqueous potassium carbonate was then added to adjust the pH value to 8. The solution was then extracted with chloroform. The extract was dried and condensed, and the residue was recrystallized from benzene or methanol to give colorless plates (0.04 g, 14%); mp 219—220 °C. IR (KBr): 3115 (NH), 1620, 1551, and 1501 cm^{-1} (C=O or C=C conjugated). UV: $\lambda_{max}^{CH_3OH}$ 236 (log ε=4.42), 291 (4.46), 366 (3.66), and 383 (3.66) nm. Found: C, 78.77; H, 6.33; N, 9.62%. Calcd for $C_{19}H_{18}ON_2$: C, 78.59; H, 6.25; N, 9.62%.

8-Chlorobenzo[b]-1-azaazulene (XV). *Method A*: Reaction of III with thionyl chloride. To a solution of III (0.6 g) in dry benzene (20 ml), we added thionyl chloride (1.9 g); the mixture was then refluxed at 90—100 °C for 20 hr. After cooling, the reaction mixture was poured into a saturated sodium bicarbonate solution and extracted with benzene. The extract was dried and condensed to leave a residue. It was recrystallized from benzene–cyclohexane to give violet needles (0.14 g, 21%); mp 144—146 °C. IR (KBr): 3040 (CH), 1602, and 1580 cm^{-1} (conjugated C=C or C=N). NMR (in $CDCl_3$): δ 7.3—8.7 ppm (m). Found: C, 73.51; H, 3.87; N, 6.98%. Calcd for $C_{13}H_8NCl$: C, 73.10; H, 3.77; N, 6.56%.

Picrate: Orange micro prisms; mp 204 °C (decomp.). Found: C, 51.56; H, 2.50; N, 12.44%. Calcd for $C_{19}H_{11}O_7N_4Cl$: C, 51.52; H, 2.48; N, 12.66%.

Method B: Reaction of III with phosphoryl chloride. A mixture of III (1.37 g) and phosphoryl chloride (6.23 g) was heated at 105—110 °C for 1 hr. After cooling, the

reaction mixture was poured onto ice water; the solution was then made slightly alkaline by adding aqueous sodium bicarbonate.

The solution was extracted with benzene. The extract was dried over anhydrous sodium sulfate and condensed to leave a residue. The recrystallization of this residue from cyclohexane–benzene gave violet needles (1.11 g, 67%); mp 144—145 °C.

The IR spectrum was identical with that of the sample prepared by means of Method A, and the mixed melting point with the sample was not depressed.

Hydrolysis of XV. To a solution of XV (0.1 g) in ethanol (4 ml), we added 2 M sodium hydroxide (4 ml), and the mixture was refluxed for 1 hr. The ethanol was then removed, water was added, the solution was acidified with 2 M hydrochloric acid, and the separated material was collected. It was subsequently recrystallized from ethanol to give yellow needles (mp 245—246 °C). The mixed melting point with III was not depressed.

8-Hydrazinobenzo[b]*-1-azaazulene (XVI).* A solution of XV (0.1 g) in methanol (10 ml) was added, drop by drop, to a solution of 80% hydrazine hydrate (0.2 g) in methanol (10 ml), and the solution was stirred at room temperature for 3 hr. The insoluble material was removed by filtration. The filtrate was evaporated; then water was added and extracted with benzene. The extract was dried and condensed to leave a residue. It was recrystallized from benzene–cyclohexane to give reddish-violet needles (0.04 g, 43%); mp 158—159 °C. IR (KBr): 3348, 3140 (NH), 1616, 1538, and 1486 cm^{-1} (conjugated C=C or C=N). Found: C, 74.53; H, 4.97; N, 19.68%. Calcd for $C_{13}H_{11}N_3$: C, 74.62; H, 5.30; N, 20.08%.

Benzo[b]*-1-azaazulene (XVII).* A mixture of XVI (0.34 g), acetic acid (20 ml), water (20 ml), and 2M copper sulfate (34 ml) was heated for 15 min on a water bath. After cooling, the reaction mixture was made slightly alkaline by adding 2 M sodium hydroxide and the solution was extracted with chloroform. The extract was dried and condensed to leave a residue. The residue was dissolved in benzene and passed through an alumina column. The product obtained from the reddish effluent was recrystallized from cyclohexane to give reddish-violet needles (0.07 g, 24%); mp 140—141 °C.

The IR and UV spectra were identical with those of the sample prepared by Treibs' method,[2a] and the mixed melting point with the sample was not depressed.

This work was financially supported by grants from the Ministry of Education of Japan and the Sankyo Co., Ltd., to which the authors' thanks are due.

One of the authors (Je-Kyun Sin) especially wishes to express his deep gratitude to Professor Yoshio Kitahara of Tohoku University for his kind guidance. We all also wish to thank Dr. Masafumi Yasunami of Tohoku University for his helpful suggestions regarding the spectra.

The Crystal Structure of Trichloroti-npentacarbonylmanganese, Cl_3Sn–$Mn(CO)_5$

Satoru ONAKA

Department of Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466

(Received March 8, 1974)

The crystal structure of trichlorotin–pentacarbonylmanganese, Cl_3Sn–$Mn(CO)_5$, has been determined by means of X-ray diffraction. The crystal is monoclinic; $a=14.10(1)$, $b=13.38(5)$, $c=13.27(2)$ Å, and $\beta=97.39(21)°$ with the $P2_1/c$ space group and with $Z=8$. The structure, established by the heavy-atom method, has been refined by a least-squares method based on 2581 reflections collected by diffractometry to give an R value of 10%. The asymmetric unit contains two quite similar molecules. The geometry around the tin atom is distorted tetrahedrally, while the manganese atom exhibits a distorted octahedral coordination. The four equatorial carbonyl groups are displaced from the equatorial plane toward the tin atom. There is an approximate mirror plane through the Sn–Mn–CO(axial) axis. The Sn–Mn bond distance, 2.590(5) Å, is shorter by about 0.08 Å than that of the triphenyl and trimethyl analogues. The mean Mn–C distance of 1.87 Å is longer than that of the trimethyl analogue. These changes in bond distances may be interpreted in terms of the π-interaction between the two metal atoms, which is more pronounced in the chloro-derivative than in the methyl derivative.

In a series of papers concerning the X_3M–$Mn(CO)_{5-n}L_n$ compounds (X stands for CH_3, C_6H_5, Cl, Br, and I; M for Si, Ge, and Sn; L for $P(C_6H_5)_3$, $As(C_6H_5)_3$, and $Sb(C_6H_5)_3$, and n=0 or 1), the effect of IV b metal atoms or the effect of the substituents of the component-metal atoms on the nature of the strength of the M–Mn bonds has been studied by means of IR,[1-4] NMR,[5] NQR,[6] and the ^{119}Sn–Mössbauer effect.[7,8] It has been concluded that the π-interaction between manganese and IV b metal atoms is influenced by the substituent, X or L. In order to provide further evidence of the effect of the substituents on the M–Mn bond nature and in order to confirm other results or estimations previously obtained,[4,6] it is desirable to obtain information regarding the details of the molecular structure in this series of compounds by the X-ray diffraction method. However, no trihalogeno compound, X_3Sn–$Mn(CO)_5$, has yet been subjected to X-ray crystal structure analysis,[9] though the crystal structures of $(C_6H_5)_3Sn$–$Mn(CO)_5$,[10] $(CH_3)_3Sn$–$Mn(CO)_5$,[11] and $(C_6H_5)_3Sn$–$Mn(CO)_4P(C_6H_5)_3$[12] have been determined by Bryan *et al.* This may be partly because of the instability of these trihalogeno compounds toward X-rays.[13] We succeeded in the preparation of stable and suitable crystals of Cl_3Sn–$Mn(CO)_5$ for X-ray analysis from a dichloromethane solution. In this paper, we wish to report on the crystal structure of Cl_3Sn–$Mn(CO)_5$ and to discuss the effect of the Cl atom as a substituent on the molecular geometry.

Experimental

Trichlorotin–pentacarbonylmanganese was synthesized by the method of Gorsich,[14] and the crystals of this compound were grown from various solutions in a form of pale yellow needles. Suitable crystals for X-ray analysis were obtained from crops from a dichloromethane solution.

Single-crystal X-ray Data. The space group and the lattice constants were determined from Weissenberg photographs; the latter were then refined by the least-squares method. The crystal data are given in Table 1. The intensity measurements were made by using two crystals, with dimensions of 0.29×0.35×0.37 mm and 0.29×0.35×0.41 mm, on a Rigaku four-circle automatic diffractometer. Mo $K\alpha_1$ radiation (λ=0.7107 Å) monochromated by graphite was used with a scintillation counter, an ω-2θ scan technique being employed. The scan speed was 4°/min in 2θ. Background measurements were made on both sides of every peak. 3585 reciprocal lattice points were surveyed in the $2\theta<45°$ range; a significant intensity was observed at 2581 points. Three standard reflections were measured every 50 measurements. The intensities for the second crystal were adjusted to those of the first crystal based on the three standard reflections. The intensities were corrected for the Lorents and polarization effects. No corrections were applied for absorption and extinction.

Determination of the Structure. All the calculations were carried out on a FACOM 230-60 computer at the Computation Center of Nagoya University, using the RSSFR-5 and HBLS-IV programs, which are included in the UNICS program system.[15] The positions of the tin atoms were deduced from the three-dimensional sharpened Patterson maps. The Fourier synthesis based on the positions of the tin atoms easily located the manganese atoms. The positions of the other atoms were readily determined from successive three-dimensional Fourier syntheses. A refinement of the structure was carried out by the block-diagonal least-squares method for thirty atoms in the asymmetric unit with isotropic thermal parameters. The unit weight was given for each reflection. The discrepancy index, R, was 11.7%. The difference Fourier synthesis at this stage left no appreciable peaks. A further refinement by the use of anisotropic thermal parameters reduced the R value to 9.98%. At the final stage, several strong reflections were excluded from the least-squares refinement, since they were considered to be

TABLE 3. FINAL POSITIONAL AND THERMAL PARAMETERS OF Cl_3Sn-$Mn(CO)_5$ WITH THEIR ESTIMATED STANDARD DEVIATIONS (in parantheses).

All values have been multiplied by 10^4. The anisotropic thermal parameters are of the form: $\exp[-(B_{11}h^2+B_{22}k^2+B_{33}l^2+B_{12}hk+B_{13}hl+B_{23}kl)]$.

seriously affected by the extinction effect. The neutral atomic scattering factors used were those listed in International Tables.[16] Table 2* lists the observed and calculated structure factors.

Results and Discussion

Table 3 gives the final positional and thermal parameters of atoms, along with their standard deviations. The molecular structure is shown in Fig. 1, along with the numbering scheme. The intramolecular atomic distances and bond angles are presented in Table 4. A projection of the molecule 1 down the Sn–Mn axis is drawn in Fig. 2. In Table 5, the torsional angles are listed. The molecular geometry of this compound is quite similar to those observed for triphenyltin-pentacarbonylmanganese and trimethyltin-pentacarbonylmanganese.[10,11] The geometry around the tin atom is distorted tetrahedrally, while that of the manganese atom is approximately octahedral.

As is shown in Table 4, the covalent Sn–Mn bond distances in Cl_3Sn–$Mn(CO)_5$ are 2.575(5) Å and 2.604(5) Å (average 2.59 Å), which are considerably shorter than those of $(CH_3)_3Sn$–$Mn(CO)_5$ (2.674 Å)

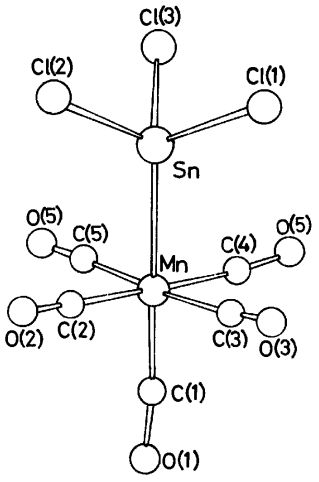

Fig. 1. The molecular structure of trichlorotin-pentacarbonylmanganese, Cl_3Sn–$Mn(CO)_5$.

* Table 2 is kept as Document No. 7426 at the Chemical Society of Japan.

Cl(3)–Sn–Mn–C(5)	41.5	42.4

and $(C_6H_5)_3Sn$-$Mn(CO)_5$ (2.674 Å).[10,11] This fact accords with our previous finding[1] that the Sn–Mn bond strength in Cl_3Sn-$Mn(CO)_5$ is greater than that of $(CH_3)_3Sn$-$Mn(CO)_5$. In order to correlate the Sn–Mn bonding-distance with the bonding nature, especially with the degree of the d_π-interaction between the tin and manganese atoms, let us examine the formula proposed by Pauling:[17]

$$R(\delta, Z) = 1.825 - 0.043Z - (1.600 - 0.100Z)\delta \quad (1)$$

where $R(\delta, Z)$ is the bonding radii of the metal atom concerned, Z is the effective nuclear charge (the number of electrons outside the rare-gas shell), and δ is the amount of the d-character in the bonding orbitals. The bonding radius of the manganese atom can be calculated as follows: if the single-bond radius of the chlorine atom in the Sn–Cl bond is assumed to be 0.99 Å,[18] the covalent radius of the tin atom is calculated to be 1.36 Å from the Sn–Cl bond distance in the present compound (mean, 2.35 Å). The subtraction of this value from the Sn–Mn bond distance leaves the value of 1.23 Å for the covalent radius of the manganese atom. In the same manner, we obtain 1.31 Å for the covalent radius of the manganese atom in $(CH_3)_3Sn$-$Mn(CO)_5$,[11] the single-bond radius of the methyl carbon being assumed to be 0.77 Å.[18] The application of these manganese radii to Pauling's equa-

tion yields δ values of 32.2 and 23.3% for Cl_3Sn–$Mn(CO)_5$ and $(CH_3)_3Sn$–$Mn(CO)_5$ respectively. The absolute magnitude of these values seems suspicious, because we used the value of 1.36 Å as the covalent-bond radius of the tin atom despite the usually-accepted covalent radius of the Sn(IV) of 1.399 Å. However, the most important feature is that the increased trend of the d_π-interaction going from $(CH_3)_3Sn$–$Mn(CO)_5$ to Cl_3Sn–$Mn(CO)_5$ predicted by normal coordinate analysis is clearly exhibited in the present results.

The results of normal coordinate analysis suggested also elongated Mn–C and shortened C–O bond distances in Cl_3Sn–$Mn(CO)_5$ compared with those in $(CH_3)_3Sn$–$Mn(CO)_5$. The finding that the mean Mn–C distance of the present molecule, 1.87 Å, is longer than that of $(CH_3)_3Sn$–$Mn(CO)_5$, 1.81 Å, is parallel to this prediction. However, the latter prediction is not clear, since the mean C–O distance, 1.13 Å, is close to the value, 1.15 Å, for $(CH_3)_3Sn$–$Mn(CO)_5$.

The mean Sn–Cl bond distance (2.35 Å) is equal to that of Cl_3Sn–$Fe(CO)_2(\pi\text{-}C_5H_5)$ (2.36 Å)[13] and slightly shorter than that of $Cl_2(C_6H_5)Sn$–$Fe(CO)_2(\pi\text{-}C_5H_5)$ (2.39 Å).[19] The observed Sn–Cl(2) bond distance in the molecule 1 is considerably shorter than the other Sn–Cl bond distances. It is not clear at present why this bond distance is shorter than the others.

Each molecule has an approximate mirror plane through the Cl(3)–Sn–Mn–C(1)–O(1) atoms. A slight rotation of the $SnCl_3$ moiety along the Sn–Mn bond about 3.9 ° for the molecule 1 and 2.8° for the molecule 2 leads to an exact mirror symmetry, and the rotational angles may be compared with those of 1° and 3.5° in $(CH_3)_3Sn$–$Mn(CO)_5$ and $(C_6H_5)_3Sn$–$Mn(CO)_5$ respectively.[10,11] Similar distortions are also observed in $(C_6H_5)_3Sn$–$Mn(CO)_4P(C_6H_5)_3$[12] and $(\pi\text{-}C_5H_5)Fe(CO)_2$–$Mn(CO)_5$.[20] There is a possibility that these distortions around the Sn–Mn axis are due to the Jahn-Teller effect, arising from the nonequivalence of ligands around the manganese atom.

Another interesting feature is that all the equatorial carbonyl groups are bent toward the tin atom with respect to the plane perpendicular to the Sn–Mn axis, the mean Sn–Mn–C (equatorial) bond angle being 87.8°. The diviations of the manganese atoms from the planes defined by four equatorial carbon atoms are 0.05 Å for the molecule 1 and 0.09 Å for the molecule 2. The equation of the least-squares plane is given by: $0.007X+0.940Y-0.341Z-3.464=0$ for the molecule 1 and $-0.106X+0.938Y+0.341Z-6.491=0$ for the molecule 2, where the coordinates X, Y, and Z, are in Å referred to the orthogonal axes, a, b, and c*. The same kind of distortion is observed in a number of molecules with direct metal-metal bonds: $(C_6H_5)_3Sn$–$Mn(CO)_5$,[10] $(CH_3)_3Sn$–$Mn(CO)_5$,[11] $(C_6H_5)_3Sn$–$Mn(CO)_4P(C_6H_5)_3$,[12] $(\pi\text{-}C_5H_5)Fe(CO)_2$–$Mn(CO)_5$,[20] $(C_6H_5)_2Sn[Mn(CO)_5]_2$,[21] $Hg[Mn(CO)_5]_2$,[22] $C_{15}H_{11}N_3$–$Cd[Mn(CO)_5]_2$,[23] and Br_3Ge–$Mn(CO)_5$.[9] The mean M–Mn–C (equatorial) bond angles in these compounds range from 87 to 83°. It seems that the steric effect of the substituents or the counter metal atom on M–Mn–C (equatorial) angles is unimportant. In earlier studies,[10,11] these distortions have been ascribed to the effect of molecular packing in crystals. Gapotchenko *et al.*, however, recently observed similar distortions even in an isolated molecule of Br_3Ge–$Mn(CO)_5$ by the electron-diffraction method.[9] The present author previously reported[4] that such distortion could also be expected in the case of Cl_3Sn–$Mn(CO)_5$ on the basis of the study of the dependence of the CO (equatorial) stretching IR intensity on the force constant, K(M–Mn), for a series of X_3M–$Mn(CO)_5$ molecules; he interpreted this relationship in terms of the interaction between the π^* orbitals of the four equatorial carbonyl groups and the M–Mn σ bond under the condition of the distorted M–Mn–C (equatorial) bond angle from 90°.

A distortion from the tetrahedral symmetry around the tin atom is usually observed in those compounds in which the tin atom is bonded to transition elements.[10–13]

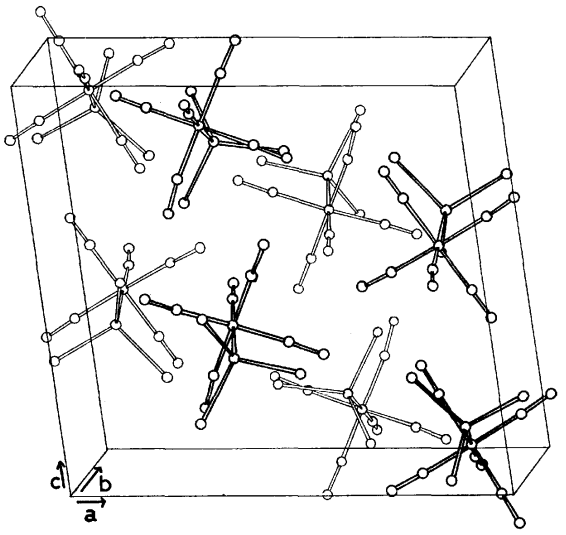

Fig. 3. Molecular packing in the unit cell.
Those molecules drawn by bold lines are located between 0 and 0.5b concerning the tin atom.

Figure 3 shows the molecular packing in a unit cell.[24] Table 6 lists intermolecular atomic contacts less than 4 Å. The shortest one is 3.07 Å, between two oxygen atoms. This distance and the other minimum non-bonded intermolecular distances given in Table 6 correspond to normal van der Waals interactions. All these distances in Cl_3Sn–$Mn(CO)_5$ are rather shorter than those in the trimethyl analogue,[11] and the molecular packing of the present compound is more compact than that of the trimethyl compound. In those regions where chlorine and carbonyl groups come into contact, the chlorine atom tends to be located equidistant from the carbon atoms of the carbonyl groups, as may be seen in Table 6.

The author is deeply indebted to Dr. Kyōyū Sasaki of Nagoya University for his helpful advice and his kind permission to use some programs. Thanks are also due to Professor Yukiyoshi Sasaki of the University of Tokyo for his preliminary experiments and permission to use the diffractometer and to Professor Yoshihiko Saito and Dr. Fumiyuki Marumo of the University of Tokyo for their valuable discussions.

The Interpretation of Surface Tension Data for Solutions of Ionic Surfactants in the Presence of Electrolyte

Denver G. HALL, Brian A. PETHICA, and Kozo SHINODA*

Unilever Research, Port Sunlight Laboratory, Port Sunlight, Wirral, Merseyside, England L62 4XN

**Department of Chemistry, Faculty of Engineering, Yokohama National University, Minami-ku, Yokohama 233*

(Received April 18, 1974)

An improved method is presented for interpreting surface tension data on solutions of an ionic surfactant to which has been added an electrolyte whose co-ion has the same valence as the surfactant ion. Adequate account is taken of co-ion adsorption and of deviations from ideality of the solution. When a monolayer of surfactant ions is formed and the distributions of free surfactant ions and co-ions in the region adjacent to it are determined predominantly by electrostatic repulsion, it is shown that the separate contributions to the total Gibbs excess of surfactant ions from the monolayer and the adjacent region can be obtained. Finally some experimental data are re-examined and a simple explanation is given for the minimum reported to occur in co-ion adsorption as the surfactant ion concentration is increased at constant co-ion concentration.

In a previous paper Shinoda and Nakayama[1] described a method based on the Gibbs adsorption isotherm of interpreting surface tension data for a solution of an ionic surfactant plus electrolyte. This method was applied to suitable data then available to determine amounts adsorbed. Later, Lucassen-Reynders[2] suggested that it should be modified to include co-ion adsorption. In both papers ideal behaviour of the bulk solution was assumed. In this paper a more rigorous analysis is given in which both co-ion adsorption and solution non-ideality are allowed for. Tajima, Muramatsu and Sasaki[3-6] have also considered this problem but from a viewpoint somewhat different and, in our opinion, less illuminating than that described below.

Theory

We let subscripts 1—4 refer to water, surfactant ions, counterions and co-ions respectively and take as our starting point the Gibbs adsorption isotherm which, for the system of interest, at equilibrium at constant T and p can be written as

$$\mathrm{d}\sigma = -\Gamma_2 RT\mathrm{d}\ln m_2 f_2 - \Gamma_3 RT\mathrm{d}\ln m_3 f_3 - \Gamma_4 RT\mathrm{d}\ln m_4 f_4 \quad (1)$$

where σ is the surface tension, Γ_2—Γ_4 are the surface excesses of species 2—4 referred to the dividing surface for which $\Gamma_1=0$, m_2—m_4 are the molalities of species 2—4, f_2—f_4 are the corresponding bulk ionic activity coefficients and the ionisation of water is considered to be negligible.

In the case that the valence of 3 is z_3 whereas species 2 and 4 are both monovalent, the electrical neutrality conditions for the interface and the bulk solutions enable us to write

$$\left.\begin{aligned} z_3\Gamma_3 &= \Gamma_2 + \Gamma_4 \\ z_3 m_3 &= m_2 + m_4 \end{aligned}\right\} \quad (2a, b)$$

Eliminating Γ_3 from Eq. (1) we obtain

$$\mathrm{d}\sigma = -\Gamma_2 RT\mathrm{d}\ln m_2 - \frac{(\Gamma_2+\Gamma_4)}{z_3} RT\mathrm{d}\ln m_3 - \Gamma_4 RT\mathrm{d}\ln m_4 - \Gamma_2 RT\mathrm{d}\ln\gamma_2 - \Gamma_4 RT\mathrm{d}\ln\gamma_4 \quad (3)$$

where

$$\left.\begin{aligned} \ln\gamma_2 &= \ln f_2 + \frac{\ln f_3}{z_3} \\ \ln\gamma_4 &= \ln f_4 + \frac{\ln f_3}{z_3} \end{aligned}\right\} \quad (4a, b)$$

From Eqs. (2), (3), and (4) after elementary manipulation we obtain

$$\frac{1}{RT}\left(\frac{\partial\sigma}{\partial m_2}\right)_{m_4} = -\left[\frac{\Gamma_2}{m_2} + \frac{\Gamma_2+\Gamma_4}{z_3(m_2+m_4)} + \Gamma_2\left(\frac{\partial\ln\gamma_2}{\partial m_2}\right)_{m_4} + \Gamma_4\left(\frac{\partial\ln\gamma_4}{\partial m_2}\right)_{m_4}\right]$$

$$\frac{1}{RT}\left(\frac{\partial\sigma}{\partial m_4}\right)_{m_2} = \frac{1}{z_3 RT}\left(\frac{\partial\sigma}{\partial m_3}\right)_{m_2} = -\left[\frac{\Gamma_4}{m_4} + \frac{\Gamma_2+\Gamma_4}{z_3(m_2+m_4)} + \Gamma_2\left(\frac{\partial\ln\gamma_2}{\partial m_4}\right)_{m_2} + \Gamma_4\left(\frac{\partial\ln\gamma_4}{\partial m_4}\right)_{m_2}\right]$$

$$\frac{1}{RT}\left(\frac{\partial\sigma}{\partial m_2}\right)_{m_4} = -\frac{1}{RT}\left(\frac{\partial\sigma}{\partial m_4}\right)_{m_2} = -\left[\frac{\Gamma_2}{m_2} - \frac{\Gamma_4}{m_4} - \Gamma_2\left(\frac{\partial\ln\gamma_2}{\partial m_2}\right)_{m_4} + \Gamma_4\left(\frac{\partial\ln\gamma_4}{\partial m_2}\right)_{m_4}\right] \quad (5a, b, c)$$

A considerable simplification results when it is legitimate to write

$$\gamma_2 = \gamma_4 \quad (6)$$

As under these circumstances and at constant T and p, γ_2, and γ_4 depend only on m_3.

For the case that a monolayer of adsorbed surfactant is present we write

$$\Gamma_2 = \Gamma_2^{\mathrm{m}} + \Gamma_2^{\mathrm{s}} \quad (7)$$

where Γ_2^{m} is the amount of surfactant ion in the monolayer and Γ_2^{s} is the contribution to Γ_2 from the region adjacent to the monolayer. Also we suppose that Γ_2^{s} and Γ_4 are determined primarily by electrostatic repulsion due to the monolayer and that, as a consequence of this, the distribution of surfactant ions in the region adjacent to the monolayer is sufficiently like that of the co-ions to enable us to write

$$\frac{\Gamma_2^s}{m_2} = \frac{\Gamma_4}{m_4} \tag{8}$$

If we now define the quantity α by

$$\alpha = -2\frac{(\Gamma_2^s+\Gamma_4)}{\Gamma_2^m}, \tag{9}$$

assume that $\gamma_2=\gamma_4$ and put $\beta=(\partial\ln\gamma_2/\partial m_3)$ Eqs. (5a, b, and c) become respectively

$$\frac{1}{RT}\left(\frac{\partial\sigma}{\partial \ln m_2}\right)_{m_4} = -\Gamma_2^m\left[1-\frac{\alpha m_2}{2(m_2+m_4)} + (1-\alpha/2)\left(\frac{m_2}{z_3(m_2+m_4)}+m_2\beta\right)\right] \tag{10a}$$

$$\frac{1}{RT}\left(\frac{\partial\sigma}{\partial \ln m_3}\right)_{m_4} = -\Gamma_2^m\left[(1-\alpha/2)\left(\frac{1}{z_3}+m_3z_3\beta\right)-\frac{\alpha}{2}\right] \tag{10b}$$

$$\frac{1}{RT}\left(\frac{\partial\sigma}{\partial \ln m_2}\right)_{m_4} = -\Gamma_2^m \tag{10c}$$

Discussion

Equation (10c) is the main result of this paper. It shows that even for non ideal solutions Γ_2^m, the amount of adsorbed surfactant present in the monolayer, can be obtained directly from measurements of the variation of surface tension with surfactant concentration at constant counterion concentration provided that Eqs. (7) and (8) are valid. These two equations are closely related. When species 2 and 4 distribute similarly with respect to each other and with respect to species 3,[7] (γ_2 is equal to γ_4), whereas Eq. (8) holds when species 2 and 4 distribute similarly with respect to the monolayer and is unlikely to be valid when Eq. (7) is invalid. According to Debye-Hückel theory, Eq. (7) must hold when m_3 is small and there is no significant ion association.

The concentration at which equating γ_2 and γ_4 leads to significant errors cannot be estimated from experimental data on surfactant solutions because insufficient data are available. However, freezing-point depression measurements[8] and EMF measurements[9-11] indicate that, below their critical micelle concentrations, most 1:1 ionic surfactants do not associate significantly and are reasonably well-behaved 1:1 electrolytes. If this is so, the value of m_3 at which Eq. (6) ceases to be a good approximation may be similar to corresponding values for mixtures of simple 1:1 electrolytes. The activity coefficients of such mixtures can be described quite well by the expression[12]

$$\ln\gamma_2 = \frac{-A\sqrt{m_3}}{1+\sqrt{m_3}} + B_{22}m_2 + B_{24}m_4 \tag{11}$$

where A, given by the Debye-Hückel limiting law, is the same for all 1:1 electrolytes, the Bs are empirical constants and $B_{24}=B_{42}$. At constant m_3 the sum of the last two terms of Eq. (5c) is given by $\Gamma_2(B_{22}-B_{24})-\Gamma_4(B_{44}-B_{42})$. Typical values of $(B_{22}-B_{24})$ are of the order 0.3 kg mol^{-1}.[13] Such values lead to errors in Γ_2 and Γ_2^m which are proportional to m_2 and which can be expected to be of the order 3% when $m_2=0.1$ mol kg^{-1}. When $\gamma_2=\gamma_4$, Eq. (11) becomes

$$\ln\gamma_2 = \ln\gamma_4 = \frac{-A\sqrt{m_3}}{1+\sqrt{m_3}} + Bm_3 \tag{12}$$

where $B=B_{22}=B_{24}=B_{44}$. From Eq. (12) we find that

$$\beta = \frac{-A}{2(1+\sqrt{m_3})}\left(\frac{1}{\sqrt{m_3}}-\frac{1}{1+\sqrt{m_3}}\right)+B \tag{13}$$

Since $A=2.342$ kg$^{1/2}$ mol$^{-1/2}$ at 298 K, whereas B is typically of order 0.4 kg mol^{-1}, it is evident that the final term of Eq. (13) can be ignored when m_3 is small. Also the term $m_2\beta$, which is always $\leqslant m_3\beta$, decreases with increasing m_3 at constant m_2. When $m_3=0.1$ mol kg^{-1}, $m_3\beta\simeq0.21$; whereas when $m_3=0.01$ mol kg^{-1}, $m_3\beta\simeq0.10$. Consequently, the activity terms in Eqs. (10) and (5) are not negligible when $m_3>0.01$ mol kg^{-1}, although that in Eq. (10a) is negligible when $m_3\gg m_2$.

Less information is available for mixtures of 2:1 eelctrolytes with a common divalent ion than for mixtures of 1:1 electrolytes. The errors which arise through equating γ_2 and γ_4 can be expected to be somewhat greater in this case than in that above.

No direct experimental evidence for the conditions under which Eq. (8) ceases to be a good approximation appears to be available and it is not obvious how such evidence can be obtained. However when Eq. (8) is valid, the dependence of σ on m_2 and m_3 should be independent of the nature of the co-ion, provided that it has the same valence as the surfactant ion and does not form part of the monolayer. The experimental data of Matuura *et al.*[14] suggest that this may be so. Whether or not it is provides an indirect test of Eq. (8).

When $m_4\gg m_2$ and Eq. (8) is valid, $\Gamma_2\simeq\Gamma_2^m$. This result can be expected to hold when $m_4\gg m_2$ even if Eq. (8) is not valid, provided that Γ_2^s is determined primarily by electrostatic effects. Hence experimental values of Γ_2 in the presence of excess salt are essentially values of Γ_2^m. The results of Brooks and Pethica[15] reinforce this conclusion. They found that the π *vs.* A curves obtained directly for insoluble monolayers of long chain surfactants at the *n*-heptane/aqueous NaCl interface are independent of chain length for a given head group. Also the curves are the same as the π *vs.* A curves for the shorter chain length homologues obtained from application of the Gibbs adsorption isotherm to the appropriate interfacial tension data. Such agreement can be regarded as confirming the Gibbs equation. Alternatively it is strong evidence that $\Gamma_2=\Gamma_2^m$ under the conditions concerned.*

Equations (10b and c) show that the surface tensions of the solutions of interest behave as if the solutions were ideal and as if the surface phase were a charged phase[1,16] consisting of Γ_2^m mol per unit area of surfactant ion and $\Gamma_2^m[(1-\alpha/2)[1/z_3+m_3z_3\beta]-\alpha/2]$ mol per unit area of counterion. Hence the above theory enables the data for the air-solution interface considered previously[1] to be reinterpreted as in Table 1.

The values of α for the hydrocarbon surfactants are considerably smaller when deviations from solution

* Although the equation used by Brooks and Pethica to obtain Γ_2 contains the approximation $\Gamma_4=0$, the errors attributable to this approximation are less than the experimental errors in this particular case.

Table 1.

Compound	$\Gamma_2^m \times 10^6$ mol m^{-2}	$-\frac{1}{RT}\left(\frac{d\sigma}{d \ln m_3}\right)_{m_2} \times 10^6$ mol m^{-2}	$z_3 m_3 \beta$	α	Ref
$C_7F_{15}CO_2H$	4.0	1.8	−0.10	0.47	1
$C_7F_{15}CO_2K$	3.9	2.0	−0.15	0.37	1
$(C_7F_{15}CO_2)_2Ba$	3.3	1.0	−0.13	0.10	1
$C_{11}H_{23}CO_2K$	4.2	2.9	−0.21	0.11	17
$C_{12}H_{25}NH_3Cl$	5.2	3.5	−0.21	0.13	17
$C_{12}H_{25}SO_4Na$	4.4	3.2	−0.21	0.07	17

ideality are taken into account than they are when such deviations are ignored. These values show that the negative adsorptions of co-ions, although small, are not negligible and should be allowed for when interpreting accurate data rigorously. Somewhat surprisingly, the values of α for the two monovalent fluorocarbon surfactants are considerably bigger than those of the hydrocarbon surfactants despite the similar values of Γ_2^m.

Subsequent to the work of Shinoda and Nakayama, Tajima *et al.*[3-6] have examined the adsorption of sodium dodecyl sulphate (SDS) at the air/solution interface in the presence of NaCl, both by measuring surface tension and by direct measurement of adsorption using radiotracers. An interesting feature of this work is the observed minimum in Γ_4 as m_2 is increased at constant m_4. This is precisely what one expects from the above theory as Eqs. (8) and (9) enable us to write

$$\Gamma_4 = \frac{-\Gamma_2^m \alpha m_4}{2(m_2+m_4)} \qquad (14)$$

which shows that Γ_4 can be expected to decrease initially as Γ_2^m increases; when Γ_2^m and α are both close enough to their limiting values to be essentially independent of m_2 the rate of increase of Γ_4 becomes smaller as m_4 becomes larger. An equally simple alternative explanation of this behaviour is difficult to envisage.

Also of interest is the increase in saturation adsorption of surfactant as m_4 is increased. We have from Eq. (9)

$$\Gamma_2 = \Gamma_2^m\left[1-\frac{\alpha}{2}\frac{m_2}{m_2+m_4}\right] \qquad (15)$$

which shows that Γ_2 increases with increasing m_2 more slowly than does Γ_2^m and that when Γ_2^m is constant, Γ_2 should decrease with increasing m_2. If we assume that Γ_2^m and α have attained their limiting values at the surfactant critical micelle concentration (CMC) and are both independent of m_4, we can use Eq. (15) to calculate the change in Γ_2 at the CMC as m_4 is increased. The results of such a calculation agree well with experiment when Γ_2^m is taken as 4.33×10^{-6} mol m^{-2} and α is taken as 0.56. However, this value of α is much larger than that shown in Table 1. Consequently we conclude that only a small proportion of the increase in saturation adsorption of surfactant with increasing m_4 is due to the effect described by Eq. (15).

Dielectric Dispersion and Relaxation Mechanism in Some Trifluoro Compounds at Microwave Frequencies

H. D. PUROHIT, H. S. SHARMA, and A. D. VYAS
Microwave Laboratory, University of Jodhpur, Jodhpur, India
(Received June 21, 1974)

The permittivity and dielectric loss of 2,2,2-trifluoroethanol and trifluoroacetic acid have been measured in benzene solutions at three microwave frequencies, 24.01, 9.83, and 6.01 GHz and also at 1 MHz and optical frequency at 35 °C. The permittivity and dielectric loss at different frequencies have been plotted against concentration (wt. fraction). The slopes of these straight lines have been used for the complex plane plots (a' *vs.* a''). The complex plane plots for 2,2,2-trifluoroethanol and trifluoroacetic acid are of the Cole-Cole type. The relaxation time (τ_0) and distribution parameter (α) have been calculated. The values of dipole moments (μ) of these compounds have also been calculated and reported. The relaxation mechanism in these two compounds has been explained.

Fluoro compounds have been of great interest because of their high value of permittivity in liquid state.[1] Ethanol and acetic acid are associated liquids and have a tendency to dimerize even at a very low dilution in benzene solution by intermolecular hydrogen bonding. The present investigations on 2,2,2-trifluoroethanol and trifluoroacetic acid have been made to study the effect of the replacement of CH_3 group by CF_3 group in ethanol and acetic acid on intermolecular hydrogen bonding. The dielectric dispersion and relaxation mechanism studies in these compounds have been carried out in dilute solutions of benzene[2] for the first time, to study their dielectric behaviour in explaining their molecular structure. The studies have been carried out in dilute solutions because this enables us to reduce to a considerable extent the dipole-dipole interaction and solute-solute co-operative phenomenon and also to avoid the ambiguity[3–5] concerning the internal field.

Method of Measurement and Analysis of Data.
The static permittivity was measured at a frequency 1 MHz by means of a Toshniwal dipolemeter type CL01 (INDIA) based on the principle of heterodyne beat method. The cell used for the purpose was calibrated with standard liquids. Refractive indices of all the solutions were measured for sodium D-line by the help of an Abbe's refractometer and the square of the refractive index gave the values of optical permittivity ($\varepsilon_\infty = n_D^2$).

The permittivity (ε') and dielectric loss (ε'') at microwave frequencies 24.01, 9.83, and 6.01 GHz were determined by the measurement of wavelength in the dielectric and standing wave ratio using a short circuited movable plunger by the method suggested by Heston *et al.*[6] adapted for short circuited termination. All measurements were carried out at 35 °C. The values of ε_0, ε_∞, ε', and ε'' thus obtained are recorded in Table 1.

The compounds used were obtained from Messrs Fluka, A. G. (Switzerland). They were of puriss grade having 99% purity. Their constants were checked with the literature values before use. Benzene, Analar grade (B.D.H., India) was used for making solutions and was distilled twice before use.

It has been observed that the permittivity and dielectric loss in solutions are linear functions of concentration.[7] Thus one can represent the permittivity and dielectric loss by the following equations:

TABLE 1. VALUES OF ε_0, ε', ε'', AND ε_∞ AT DIFFERENT FREQUENCIES FOR 2,2,2-TRIFLUROETHANOL AND TRIFLUOROACETIC ACID IN BENZENE SOLUTION AT CONSTANT TEMPERATURE OF 35 °C

The values of τ_0 and α for 2,2,2-trifluoroethanol and trifluoroacetic acid have been calculated from the Cole-Cole[8] arc plots using the slopes (a', a''). These plots are shown in the Figs. 1 and 2.

Higasi[9] has also proposed that the values of relaxation time and the distribution parameter may be determined from the measurement of a' and a'' at a single frequency

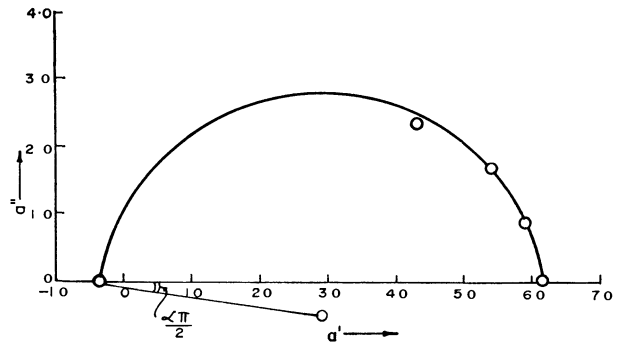

Fig. 1. The a', a'' plot of trifluoroethanol.

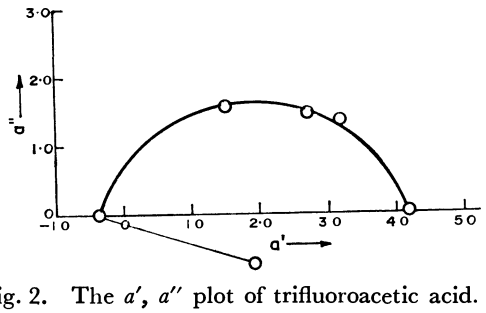

Fig. 2. The a', a'' plot of trifluoroacetic acid.

in the dispersion region. The equations for τ_0 and α are as follows:

$$\tau_0 = \frac{1}{\omega}\left(\frac{A^2+B^2}{C^2}\right)^{1/2(1-\alpha)} \quad (2)$$

$$1-\alpha = \left(\frac{2}{\pi}\right)\tan^{-1}\left(\frac{A}{B}\right) \quad (3)$$

$$\left.\begin{aligned}A &= a''(a_0-a_\infty) \\ B &= (a_0-a')(a'-a_\infty) - a''^2 \\ C &= (a'-a_\infty)^2 + a''^2\end{aligned}\right\} \quad (4)$$

For trifluoroethanol and trifluoroacetic acid, we have calculated τ_0 and α from Eqs. (2) and (3) using the data at 9.83 GHz. The values of τ_0 and α determined by these two methods have been compared in Table 3.

Table 3. Values of τ_0, α and μ for trifluoroethanol and trifluoroacetic acid

Compound	τ_0 (ps)		α		μ (D)
	Cole-Cole	Higasi	Cole-Cole	Higasi	
Trifluoroethanol	3.63	3.39	0.10	0.11	2.52[a]
Trifluoroacetic acid	8.91	8.58	0.21	0.22	2.26[b]

a) Present work, literature value not available. b) Literature value 2.28 D[20] (gas).

The dipole moments of these solute molecules have been calculated by the Eq. (5) proposed by Higasi[10]

$$\mu = A(a_0-a_D)^{1/2} \quad (5)$$

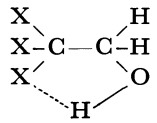
where A is a constant and is given by

$$A = \left[\frac{27kT}{4\pi N}\frac{M_2}{(\varepsilon_1+2)^2 d_1}\right]^{1/2} \quad (6)$$

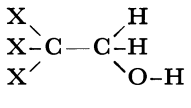
Here d_1 is the density of the solvent and M_2 is the molecular weight of the solute. The values of dipole moments (μ) are also recorded in Table 3.

Results and Discussion

The complex plane plot a' *vs.* a'' in case of 2,2,2-trifluoroethanol is a Cole-Cole plot. The low value of relaxation time $\tau_0=3.63$ ps corresponds to the relaxation time of the hydroxyl group. Further the small value of distribution parameter ($\alpha=0.10$) points to the fact that the predominant mode of relaxation is the rotation of the hydroxyl group and not the rotation of the molecule as a whole. The tan δ-concentration curve is a straight line and does not show anomalous absorption so that there is no possibility of association as in the case of ethanol and other alcohols in benzene solution[11] which have a tendency for dimerization even at very low concentration. Krishnamurthy and Sundarajan[12] have examined the possibility of two extreme conformations, the *cis* and *trans* forms which refer to hydroxyl hydrogen being near or away from halogens. They have computed the equilibrium constant and corresponding free energies for isomerization of *cis*⇌*trans*, from the knowledge of the experimental and theoretical moments for the two conformers. Their results indicate that for trichloro and tribromo ethanols the equilibrium lies to the left (Structure I). This



I *cis*



II *trans*

implies a stabilization of the *cis*-structure by intramolecular hydrogen bonding X—H–O. In tribromoethanol, the hydrogen-bonded form predominates to greater extent than in trichloroethanol. From spectroscopic studies Krueger and Mettee[13] have found that the intramolecular hydrogen bonding in trihaloethanols increases in the order $F_3C<Cl_3C<Br_3C$, a trend which is reverse of the normal accepted order of propensity of hydrogen bonding by halogens. The measurements of relaxation time and distribution parameter confirm the *trans*-structure (Structure II) of 2,2,2-trifluoroethanol. The dipole moment increases from tribromoethanol to trifluoroethanol *i.e.*

$Br_3C\cdot CH_2OH$	1.73 D[12]
$Cl_3C\cdot CH_2OH$	2.04 D[12]
$F_3C\cdot CH_2OH$	2.52 D*

(* present work.)

The dielectric studies of trifluoroacetic acid show that the molecule of trifluoroacetic acid remains in monomeric form in benzene solution as distinct from acetic acid and trichloroacetic acid[14] ($\mu=1.1$ D) which exist in the dimeric form even in dilute solutions. Tan δ-concentration curve is a straight line and shows no anomalous absorption. The complex plane plot a' *vs.* a'' is a Cole-Cole arc which shows that there is a symmetrical distribution of relaxation times. The relaxation time measurements ($\tau_0=8.91$ ps) show that the molecule relaxes predominantly by overall rotation, the other possibilities being rotation of carboxyl group about C–C axis and that of the hydroxyl group undergoing a torsional or restricted rotation, since the hydroxyl hydrogen does not lie in the plane of the rest of the carboxyl group. The large value of the distribution parameter ($\alpha=0.21$) points towards these possibilities.

The electron diffraction[15] and spectroscopic measurements[16,17] indicate the presence of a single bond between the hydroxyl oxygen and carboxyl carbon, with the hydroxyl group turned so that its hydrogen is well out of the OCO plane. By combining vectorially the group moment 1.73 D for the carboxyl group acting at the calculated angle 74° with the C–C bond, with the moment 2.35 D of 1,1,1-trifluoroethane[18,19] the value of 2.50 D is obtained which is in reasonable agreement with the observed value of 2.28 D[20] (gas). Thus the presence of the three atoms of fluorine which greatly increase the acidity of the molecule, does not greatly alter the moment of the carboxyl group. The hydroxyl hydrogen does not lie in the plane of the rest of the carboxyl group and is undergoing a torsional or restricted rotation with the hydrogen on an average well outside this plane.[20] The possibility of the existence of the molecule in isomeric planar form is not completely excluded.

The authors are indebted to Professor Krishnaji, University of Allahabad, Allahabad, for his helpful advice and discussions. Their thanks are also due to Professor A. N. Nigam, Head of Physics Department of this University for providing facilities for the study and to Professor G. P. Srivastava, University of Delhi, Delhi, for the facilities provided in connection with some measurements.

Kinetics and Mechanism of Oxidation of D(+)-Sorbose by Chloramine-T

R. SANEHI, K. C. GUPTA, R. M. MEHROTRA, and S. P. MUSHRAN*
Chemical Laboratories, University of Allahabad, Allahabad, India
(Received July 2, 1974)

The kinetics of oxidation of D(+)-sorbose by chloramine-T has been investigated in high alkaline media. The reaction shows a brief induction period after which a first order dependence in both chloramine-T and substrate is followed. The order in hydroxide ion is observed as fractional being 1.3 under the experimental conditions. The values of energy of activation, frequency factor and entropy of activation have been computed as 28.2 kcal mol^{-1}, 2.90×10^{19} l mol^{-1} s^{-1} and +29.8 e.u. respectively. A plausible mechanism consistent to the experimental result is proposed.

Reducing sugars have been oxidised using several oxidants. The most common oxidants used have been halogens and mainly bromine water. The earlier work on these investigations has been reviewed by Green[1] and Shafizadeh.[2] Isbell and co-workers[3,4] have investigated the oxidation of several reducing sugars by bromine and concluded that β-form of the sugar was more reactive than α-form. The kinetics of oxidation of several sugars (aldoses and ketoses) by chromium (VI),[5] peroxydisulphate[6] were investigated. Ghosh and co-workers[7] studied the kinetics and mechanism of oxidation of various reducing sugars by ammoniacal silver nitrate. The reactions were found to be first order dependent on silver nitrate and independent to the reducing substrate and a suitable mechanism was suggested. Recently Mushran and co-workers[8,9] have investigated the kinetics and mechanism of oxidation of various aldoses (*viz.* xylose, arabinose, ribose, mannose, and galactose) by chloramine-T in high alkaline media.

It was observed that the oxidation of ketose *viz.* D(+)-sorbose by chloramine-T takes place only in highly alkaline media. In this communication, the study of the kinetics of oxidation of D(+)-sorbose by chloramine-T is made and a suitable mechanism is suggested.

Experimental

Aqueous solution of D(+)-sorbose (AR, B.D.H. sample) was always freshly prepared. Stock solutions of chloramine-T, osmium (VIII) and sodium hydroxide were prepared as mentioned earlier.[10] All other chemicals used were of analytical grade. Double-distilled water was always used for preparation and dilution of the solutions. The reactions were carried out in outside blackened Jena glass bottles to avoid any photochemical influences.

The alkali sugar mixture was allowed to equilibrate for exactly 45 min after which chloramine-T was added to start the reaction. The kinetics was followed by estimating chloramine-T iodometrically in aliquot portion of the reaction mixture withdrawn in different interval of time.

Stoichiometry. Reaction mixture containing excess of chloramine-T over sorbose were allowed to equilibrate at 50 °C in respective sodium hydroxide concentration. The results showed that 1 mol of sorbose was oxidised by 1 mol of chloramine-T to the aldonic acid of lesser one carbon atom than the parent ketose and thus the stoichiometric equation may be represented as follows:

$$\underset{\text{Chloramine-T}}{CH_3C_6H_4SO_2N\cdot NaCl} + \underset{\text{D(+)-sorbose}}{CH_2OH\cdot C(-O-)(OH)\,(CHOH)_3\text{-}CH_2} + OH^- = CH_3C_6H_4SO_2NH_2 + \underset{\text{Xylonic acid anion}}{^-OOC(CHOH)_3\cdot CH_2OH} + HCHO + NaCl \quad (1)$$

The product formaldehyde was confirmed by spot test.[11]

Results

The kinetics of oxidation of D(+)-sorbose by chloramine-T in alkaline media was investigated and it was observed that the reaction shows a marked induction period. The influence of the change of equilibrating time of sugar-alkali mixture on induction period was studied. The results show that induction period diminishes as the time of equilibrating increases and after 45 min of equilibrating time, the induction period almost disappears (Fig. 1).

The kinetics of oxidation of D(+)-sorbose by chloramine-T was followed at several initial concentrations of reactants. It was observed that the reaction follows a first order dependence in chloramine-T. Pseudo first order rate constants (k_1) in chloramine-T, calculated from the slope of the linear log-time plots, increase linearly with the increase of sugar concentration. The second order rate constants $k_2=k_1/[\text{Sorbose}]$ were calculated and the average value of k_2 was ob-

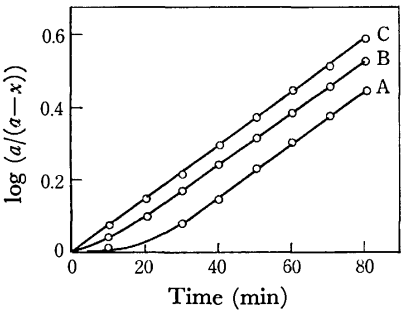

Fig. 1. First order plots at 32.5 °C.
[D(+)-sorbose]=2.0×10^{-2} M, [Chloramine-T]=2.0×10^{-3} M, [NaOH]=0.05 M, [KCl]=0.1 M and equilibrating time=0, 30, and 45 min for A, B, and C respectively.

* To whom correspondence should be made.

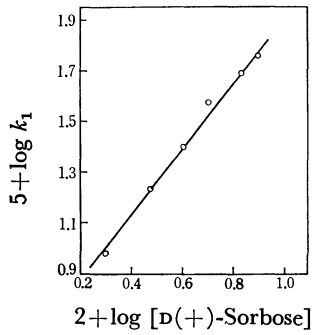

Fig. 2. Plot of log k_1 *vs.* log [D(+)-sorbose]. Conditions same as in Table 1 at [Chloramine-T]= 2.0×10^{-3} M.

tained as 13.3 l mol^{-1} s^{-1} (Table 1). The slope of the linear plot of log k_1 *vs.* log [D(+)-sorbose] (Fig. 2) was found to be unity which establishes a first order dependence in sugar concentration.

Table 1. Effect of reactants' concentration on rate constants[a)]

10^3[Chloramine-T] M	10^2[D(+)-sorbose] M	$k_1\times10^5$ s^{-1}	$k_2\times10^3$ l mol^{-1} s^{-1}
2.0	2.0	28.0	—
2.4	2.0	27.8	—
2.8	2.0	26.9	—
3.2	2.0	26.0	—
2.0	1.0	13.2	13.2
2.0	1.3	17.8	12.9
2.0	1.6	22.5	14.1
2.0	2.5	33.8	13.5
2.0	3.0	39.1	13.0

a) In presence of 0.05 M NaOH, equilibrating time=45 min and temp.=32.5 °C.

The kinetic investigations were carried out at several initial concentrations of hydroxide ions at constant ionic strength (μ=0.1 M). It was observed that the rate of oxidation of D(+)-sorbose is highly susceptible to change in alkali concentration. The order of the reaction in hydroxide ion was calculated from the slope of the plot of log k_1 *vs.* log [OH$^-$] (Fig. 3) as 1.3 for the oxidation of sorbose by chloramine-T.

The influence of neutral salts *viz.* $NaClO_4$ and KCl was investigated (Table 2). The results show that this reaction exhibits a positive salt effect.

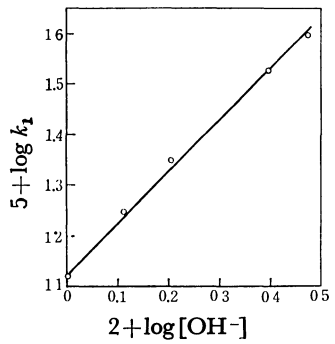

Fig. 3. Plot of log k_1 *vs.* log [OH$^-$] at 32.5 °C. [D(+)-sorbose]=2.0×10^{-2} M, [Chloramine-T]=2.0×10^{-3} M, equilibrating time 45 min and μ=0.1 M.

Table 2. Effect of neutral salts on the reaction rates[a)]

μ M	$k_1\times10^5$ s^{-1}	
	$NaClO_4$	KCl
0.05	30.9	30.0
0.10	38.1	37.3
0.20	46.1	44.1
0.35	52.6	56.4
0.50	66.8	—

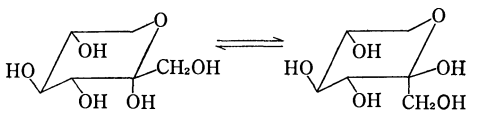
a) [Chloramine-T]=2.0×10^{-3} M, [D(+)-sorbose]= 2.0×10^{-2} M, [NaOH]=0.05 M, equilibrating time =45 min and temp.=32.5 °C.

A negligible effect of dielectric constant of the media on the reaction rate was observed. Like the oxidation of aldoses,[8,9)] osmium (VIII) ions were found to be inactive as a catalyst on the rate of oxidation of ketose by chloramine-T.

The effect of temperature was quite marked on the rate constants. The values of energy of activation, frequency factor and entropy of activation were obtained as 28.2 kcal mol^{-1}, 2.90×10^{19} l mol^{-1} s^{-1} and +29.8 e.u. respectively.

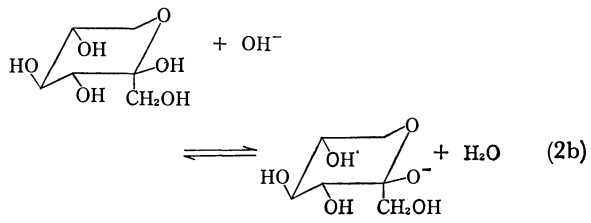
Discussion

Extensive investigations of Howorth and co-workers[12)] have shown that sugars exist as ring structures and not as open chain compounds. The most generally referred structure of sorbose is pyranose structure. It is well known that ketoses in alkaline solutions exist as anion derived from β-anomers.[13,14)] Thus the following steps are involved:



(2a)

α-D(+)-sorbopyranose β-D(+)-sorbopyranose



(2b)

anion of β-D(+)-sorbopyranose

It has been now generally accepted that β-form of the sugar is more reactive as compared to α-form. Furthermore, Hayman and Persky[14)] suggested that the anion of β-anomers is more reactive as compared to its unionised molecule.

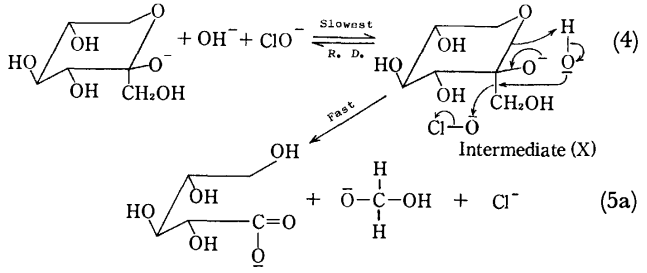
Chloramine-T (CAT) in alkaline solutions[15)] hydrolyses to *p*-chlorotoluene sulphonamide (CAT'), *p*-toluene sulphonamide (TSA) and hypochlorite ion (ClO^-) and the steps are given as follows:

$$CH_3C_6H_4SO_2N\cdot NaCl + H_2O \underset{\text{CAT}}{} \rightleftharpoons CH_3C_6H_4SO_2NHCl + NaOH \quad (3a)$$
CAT'

$$CH_3C_6H_4SO_2NHCl + NaOH \rightleftharpoons \underset{TSA}{CH_3C_6H_4SO_2NH_2} + Na^+ + ClO^- \quad (3b)$$

From close examinations of steps (3a) and (3b) and the catalysing nature of alkali reveal the fact that any one of the hydrolysis product *viz.* CAT itself, or ClO^- would be the oxidising species. Further, a positive effect of salt clearly points out to the fact that ClO^- ion would occur in the slowest and rate determining step.

Thus, first order dependence of the reaction rate in each chloramine-T and sorbose and fractional order (1.3) dependence in hydroxide ion leads to the contention that the rate determining step involves the anion of β-D(+)-sorbopyranose, hypochlorite ion and hydroxide ion. The oxidation products were found as formaldehyde and xylonic acid and a mechanism is suggested as follows:



$$\bar{O}\text{-}\underset{H}{\overset{H}{C}}\text{-}OH \xrightarrow{\text{fast}} HCHO + OH^- \quad (5b)$$

The mechanism of oxidation of D(+)-sorbopyranose (S) by chloramine-T may, therefore, be summarised as follows:

$$S + OH^- \underset{k_{-2}}{\overset{k_2}{\rightleftharpoons}} S^- + H_2O \quad \text{slow} \quad (2)$$

$$CAT + H_2O \underset{k_{-4}}{\overset{k_4}{\rightleftharpoons}} TSA + Na^+ + ClO^- \quad \text{fast} \quad (3)$$

$$S^- + ClO^- + OH^- \xrightarrow{k_5} \text{Intermediate (X) slowest and R.D.} \quad (4)$$

$$X \xrightarrow{k_6} \text{Products fast} \quad (5)$$

In the above scheme the step (2) is also slow but not so slow as the rate determining step (4). On adding sugar to the alkali solution, the concentration of sugar anion (S^-) increases with time. After some time when S^- becomes sufficiently high, the consumption of S^- in step (4) becomes regular and steady state is achieved. The steady state in oxidation of ketose is thus not achieved instantaneously as has also been observed in the first order rate plots (Fig. 1) where there are induction period effects. As the alkali sugar mixture has been equilibrated for 45 min for these investigations, the induction period has completely vanished. It has also been experimentally observed that the induction period minimises on increasing the temperature of the reaction mixture.

Applying steady state condition to (S^-), the rate of disappearance of ClO^- is given as:

$$-\frac{d}{dt}[ClO^-] = \frac{k_2k_5[S][ClO^-][OH^-]^2}{k_{-2}[H_2O] + k_5[ClO^-][OH^-]} \quad (6)$$

In highly alkaline solution, ClO^- may be taken as CAT and thus Eq. (6) becomes

$$-\frac{d}{dt}[CAT] = \frac{k_2k_5[S][CAT][OH^-]^2}{k_{-2}[H_2O] + k_5[CAT][OH^-]} \quad (7)$$

The derived Eq. (7) predicts first order dependence in both chloramine-T and sugar and a fractional order in hydroxide ion concentration. At very low concentration of alkali *i.e.* $k_{-2}[H_2O] \gg k_5[CAT][OH^-]$, the order in OH^- would be 2 and at very high concentration of alkali when $k_{-2}[H_2O] \ll k_5[CAT][OH^-]$, the dependence of the reaction rate on alkali would be unity. At the experimental conditions, however, both the extreme conditions are not achieved and thus the reaction shows a fractional order dependence in $[OH^-]$ ion being 1.3. Further from Eq. (7), the rate constant should decrease on increasing the chloramine-T concentration which has also been observed experimentally (Table 1).

A positive salt effect also confirms the rate controlling step (4). Since the rate determining step involves three similarly charged ions and, therefore, a high energy of activation value is expected and this is in agreement with the high experimental value observed *viz.* 28.2 kcal mol^{-1}.

R. S. and R. M. M. are thankful to CSIR and UGC, New Delhi for the award of Senior Research Fellowships.

X-Ray Photoelectron Spectroscopy of EDTA-Metal Chelates

Tooru YOSHIDA and Shigemasa SAWADA

Osaka Prefectural Industrial Research Institute, Enokojima, Nishi-ku, Osaka 550

(Received March 4, 1974)

Synopsis. Photoelectron spectra of metal chelates of ethylenediaminetetraacetic acid (EDTA) were measured. A nearly linear relationship holds between the chemical shifts of the N(1s) electron binding energies and the charge on the nitrogen atoms of the chelates, calculated by means of Pauling's electronegativity concept.

A technique for studying X-ray photoelectron spectroscopy (ESCA) and the results for EDTA were previously reported.[1] The use of ESCA to determine the effect of coordination on the electron density of a ligand is based on the fact that changes in the electron density about an atom are reflected on changes in the binding energies of the core electrons. It is the aim of this study to determine whether it will be possible to correlate the electronegativity of the metal or the calculated charge on the nitrogen atom with the chemical shift of N(1s) binding energy in the EDTA-metal chelates. The chelate compounds studied (commercial products, analytical grade) are given in Table 1. Al$K\alpha$ X-ray was used as an excitation source.

The C(1s), N(1s), and O(1s) electron spectra of the EDTA-Zn chelate are shown in Fig. 1. The spectra of all the other compounds show profiles similar to those of the EDTA-Zn chelate. Two peaks in the C(1s) electron spectrum correspond to the carbon atoms of a methylene group and a carbonyl group, respectively. The peak with the lower binding energy (the carbon of the methylene group) was used as an energy standard, its binding energy being taken to be 285.0 eV throughout this experiment. The N(1s) and O(1s) electron spectra of all compounds were single peaks with full-width at half-height (FWHH) of 2.0—2.2 eV and 2.1—2.3 eV, respectively. The measured

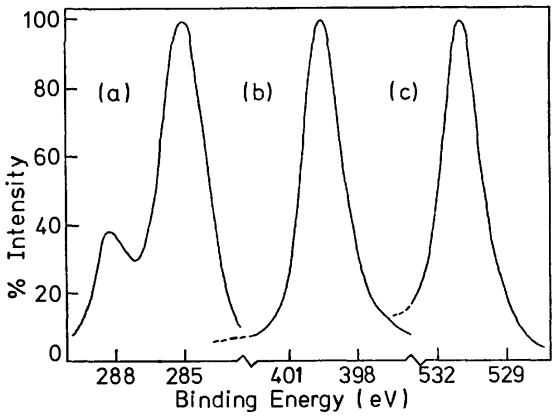

Fig. 1. (a) C(1s), (b) N(1s) and (c) O(1s) photoelectron spectra of the EDTA-Zn chelate.

N(1s) electron binding energies are given in Table 1. The chemical shifts ΔE are the differences between the N(1s) electron binding energies of free EDTA (the type of $(-CH_2)_3N$) and the chelates. The value of free EDTA was 399.1 eV.[1] The chemical shifts in all chelates are considered to be due to the decrease in the electron density on the nitrogen atoms caused by the coordination of lone-pair electrons of the nitrogen atoms to the metal.

In the charge-potential model[2] the chemical shift can be expressed in terms of the charge on the atom Q and the Coulomb potential energy V of an electron due to the other atoms of the molecule:

$$\Delta E = k_1 Q + V + k_2 \quad (k_1, k_2; \text{ constants})$$

In an ionic compound, V includes the contribution

from other ions and is thus a Madelung term. V may play a very important role in ionic compounds. However, for the covalent species the chemical shift should be dominated by the charge Q on the atom concerned.

The charge Q was calculated by means of the correlation $Q=q+\sum I$, proposed by Nordberg *et al.*,[3] where Q is the charge on an atom, q the formal charge of a concerned atom and $\sum I$ the summation of partial ionic characters of various bonds in which the atom is involved. The partial ionic character I was estimated by the relationship $I=1-\exp\{-0.25(\chi_A-\chi_B)^2\}$ derived by Pauling,[4a] in which χ_A and χ_B are the electronegativities of A and B atoms, respectively, in the A–B bond concerned.

In the case of EDTA chelates, the relation $Q=1+3I_{N^+-C}+I_{N^+-M}$ was obtained for the charge on the nitrogen atom since q is $+1$. I_{N^+-C} and I_{N^+-M} are the partial ionic characters in the nitrogen-carbon and nitrogen-metal bonds, respectively. The calculated charges using the value 3.3 as the electronegativity of N^+ [4b] are listed in Table 1.

On the other hand, the charge calculated in this way on the nitrogen atom of the type of $(-CH_2)_3N$ in free EDTA was -0.18. This value corresponds to the charge (-0.20) on the nitrogen atom in $(CH_3)_3N$ calculated by del Re,[5] by a semiempirical LCAO-MO method.

A nearly linear relation holds between the chemical shift of the N(1s) electron binding energy (ΔE) and the charge Q on the nitrogen atom in the bivalent metal chelates (Fig. 2). The chemical shifts of the N(1s) in Ba and Ca chelates are very small as expected from their calculated charges.

There are certain trends in the bivalent metal chelates between the chemical shift and the electronegativity of the metal, and between the chemical shift and the common logarithm of the stability constant[6] of the chelate. The chemical shift becomes larger as the electronegativity becomes larger, and the stability of chelates

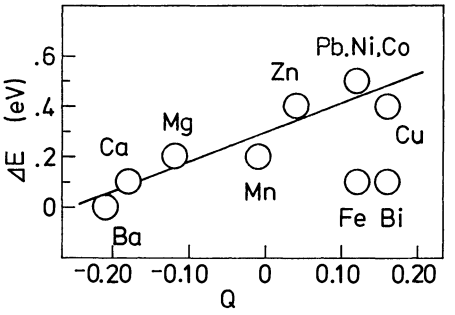

Fig. 2. Relationship between the chemical shift of N(1s) electron binding energy (ΔE) and the charge(Q) on the nitrogen atom.

becomes greater.

In the case of Fe(III) and Bi(III), their chemical shifts are small as compared to those expected from their calculated charges.

There is no appreciable difference in the O(1s) electron binding energy over all the chelates, values being 531.0—531.2 eV.

(Received March 29, 1974)

Synopsis. The ^{35}Cl nuclear quadrupole resonance in a stable organic free radical, 1,3-bisdiphenylene-2-*p*-chlorophenyl-allyl, has been measured from 4.2 to 1.6 K. On lowering the temperature, the resonance line became weaker and broader, and it disappeared near the Néel temperature. This behavior has been interpreted in terms of the presence of a hyperfine interaction.

The magnetic property of a stable organic free radical, *p*-Cl-BDPA (1,3-bisdiphenylene-2-*p*-chlorophenyl-allyl), has been investigated by examining the magnetic susceptibility and by ESR, PMR, and heat capacity measurements.[1-3] The *p*-Cl-BDPA radical has the molecular structure shown in Fig. 1. The

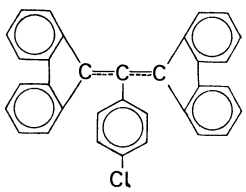

Fig. 1. Molecular structure of *p*-Cl-BDPA

unpaired electron is delocalized over the whole molecular framework. In the paramagnetic region, *p*-Cl-BDPA exhibits a one-dimensional antiferromagnetism, with a Heisenberg-type isotropic exchange interaction ($J/k=-4.4$ K), and undergoes a magnetic-phase transition to the antiferromagnetic state ($T_N=3.25$ K). In this note, we would like to report on our results on the ^{35}Cl nuclear quadrupole resonance (NQR) in a polycrystalline sample of *p*-Cl-BDPA. One of the objects of this study is to investigate the effects on the NQR of the electron-spin fluctuation near the magnetic-phase transition.

There have been few works so far concerned with the ^{35}Cl NQR measurements of paramagnetic organic substances, except for the charge-transfer complexes which exhibit a weak paramagnetism.[4] At room and liquid nitrogen temperatures, we could not find any ^{35}Cl resonance line in *p*-Cl-BDPA, probably because of the line broadening. In order to improve the signal-to-noise ratio, therefore, we carried out NQR measurements in the liquid-helium-temperature region, as a saturation effect at low temperatures usually encountered in diamagnetic substances could be excluded in our paramagnetic sample.

A sample of about 1.5 g of *p*-Cl-BDPA was prepared according to the procedure of Kuhn and Neugebauer,[5] as introduced in a previous paper.[1] The ^{35}Cl NQR line was searched for in the frequency range of 30—40 MHz at the temperature of liquid helium with a Dean-type super-regenerative detector,[6] equipped with the frequency modulation of 40 Hz. We could find one broad line on an oscilloscope; its signal-to-noise ratio was about three. The resonance frequency was determined to be 35.117 ± 0.005 MHz on the oscilloscope by use of a VHF signal generator (Meguro-Denpa-Sokki MSG-235) and a frequency counter (Takeda Riken TR-5667). The resonance was also studied by means of a recording technique employing a narrow-band amplifier and a phase-sensitive detection. A typical tracing is shown in Fig. 2(a). On lowering the temperature from 4.2 K by pumping of liquid helium, the resonance line became broader and weaker; it was not detected at 3.0 K, not even by the recording procedure, as is shown in Figs. 2(b) and (c). The resonance frequency did not appreciably change in the 4.2—3.5 K temperature range. Unsuccessful attempts were made to find new ^{35}Cl resonance lines at 1.6 K. When the temperature returned to 4.2 K, the resonance line was reproduced at the same frequency.

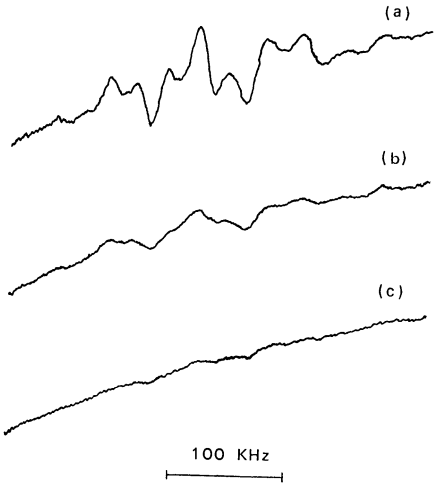

Fig. 2. Tracings of ^{35}Cl nuclear quadrupole resonance in a polycrystalline sample of *p*-Cl-BDPA.
(a) $T=4.2$ K, (b) $T=3.4$ K, (c) $T=3.2$ K
In each case the quenching frequency was about 40 kHz.

We have already investigated the mechanisms of the electron-proton hyperfine interaction in an organic free radical by PMR in single crystals of the DPPH–benzene complex.[7] Taking these results into account, the Hamiltonian for a free radical in which one chlorine nucleus interacts with the electric-field gradient at the chlorine site and one unpaired electron can be described by the following equation:

$$\mathcal{H} = \mathcal{H}_Q + a\boldsymbol{S}\cdot\boldsymbol{I} + \boldsymbol{S}\cdot\boldsymbol{D}\cdot\boldsymbol{I} \quad (1)$$

where $\mathcal{H}_Q$, a, and $\boldsymbol{D}$ are the quadrupolar Hamiltonian, the isotropic hyperfine coupling constant, and the traceless dipolar tensor respectively. The second term is an isotropic-hyperfine part arising from Fermi contact interaction, and the third term is an anisotropic part due to the electron-nuclear dipolar interaction. These terms depend upon the spin densities on the chlorine atom and the carbon atom adjacent to the chlorine. In our concentrated paramagnetic system, the correlation time is short in comparison with the nuclear precessional frequency because of the strong electron-exchange interaction; therefore, the resonance line is subjected to the so-called exchange narrowing, and then the electron spin, $\boldsymbol{S}$, of Eq. (1) is replaced by $\langle\boldsymbol{S}\rangle+\delta\boldsymbol{S}$. Here, $\langle\boldsymbol{S}\rangle$ is the time average of $\boldsymbol{S}$, and $\delta\boldsymbol{S}$ is the electron-spin fluctuation, which may provide a mechanism for nuclear-spin relaxation at low temperatures through the hyperfine interaction.[8] In the paramagnetic region, $\langle\boldsymbol{S}\rangle$ vanishes when there is no external field. Hence, the pure NQR eigenvalues are unaffected by the presence of the hyperfine interaction. The ^{35}Cl resonance frequency of *p*-Cl-BDPA is near that of chlorobenzene, which has been determined to be 34.6216 MHz at the temperature of liquid nitrogen.[9] This fact indicates that the electric-field gradient at the chlorine site is not intensively affected by the unpaired electron; that is, the unpaired electron is not delocalized very much on the *p*-chlorophenyl ring. From the electron-nuclear double resonance (ENDOR) results for *p*-Cl-BDPA,[10] the unpaired electron-spin density on the carbon atom adjacent to the chlorine can be estimated to be about 0.01 at most. The unpaired electron could also be distributed slightly on the chlorine atom.

The broadening of the resonance line may be interpreted as indicating that the correlation time becomes longer because of the short-range magnetic ordering below the temperature of the susceptibility maximum (T_m=5.6 K). This result corresponds to the line broadening of the ESR and PMR in this temperature region.[1,2] The disappearance of the ^{35}Cl resonance line near the temperature of 3.2 K is attributable to a magnetic-phase transition to the antiferromagnetic state at T_N=3.25 K.[3] This fact is consistent with the disappearance of the ESR and PMR lines near the Néel temperature.[1,2] In the antiferromagnetic state, the time-averaged spin, $\langle\boldsymbol{S}\rangle$, does not vanish even in the absence of an external magnetic field and is proportional to the sublattice magnetization, $M(T)$. Therefore, the pure NQR eigen values are affected by the internal field created by electron-spin through the hyperfine interaction of Eq. (1). Below the Néel temperature, a hyperfine splitting is expected in the ^{35}Cl NQR as a result of the weak hyperfine interaction between the chlorine nucleus and the unpaired electron, although the crystal structure of *p*-Cl-BDPA and the spin structure in the antiferromagnetic state are not determined. Unfortunately, however, new ^{35}Cl resonance lines could not be detected at 1.6 K in the 30—40 MHz frequency range. This result is probably due to the lack of spectrometer sensitivity, a line broadening in the antiferromagnetic state which has not been investigated in such a delocalized spin system, or some other effect. We hope to determine the crystal structure and the spin structure in the antiferromagnetic state in the future.

The authors would like to express their thanks to Dr. Nobuo Nakamura, Osaka University, for his helpful advice regarding the Dean-type spectrometer operation.

The Catalytic Reduction of Nitric Oxide by Carbon Monoxide over a Fe_2O_3 Catalyst

Yoshihiro SUGI, Naoyuki TODO, and Toshio SATO
National Chemical Laboratory for Industry, 2-19-19, Mita, Meguro-ku, Tokyo 153
(Received March 29, 1974)

Synopsis. When nitric oxide was admitted during the course of the reduction of N_2O by CO, a discontinuous increase in the N_2O pressure and a decrease in the NO pressure were observed. The reduction of N_2O stopped completely, and only the reduction of NO to N_2O proceeded.

Earlier papers[1-5] have noted the appearance of N_2O as an intermediate in the catalytic reduction of NO by CO. High activity at low temperatures and low N_2O formation are desirable properties of the catalyst for the removal of NO from stack gas. However, the fundamental aspects of the N_2O formation still remain ambiguous. Fe_2O_3 is one of the catalysts over which the N_2O formation is most prominent.[2] We wish to investigate the catalytic reduction of NO by CO over a Fe_2O_3 catalyst in a closed circulating system, in order to obtain more detailed information relating to the appearance of N_2O in the gas phase.

Experimental

The apparatus employed is a closed circulating system, the total volume of which is 861 ml.

The Fe_2O_3 catalyst was prepared by impregnating silicon carbide, pulverized into 14—30 mesh, with a $Fe(NO_3)_3$ solution. The catalyst thus obtained was dried at 110 °C and then calcined at 500 °C for 5 hr. The metal content was 10 wt% as Fe_2O_3, and its total surface area was 2.40 m^2/g.

Before initiating the experimental runs, the catalyst was degassed at 350 °C for 1 hr and was then treated with a mixture of NO and CO in the same composition, or with the same combination of N_2O and CO as that used for the reaction runs, and at the same temperatures. This procedure allowed us to obtain a good reproducibility in a series of experiments. The experimental runs were carried out at such circulating velocities of gasses that the reaction rate was not affected.

The analyses of the reactant and the product were conducted using a series of two gas-chromatographic apparatuses equipped with thermoconductivity detectors. The first apparatus was operated at 80 °C, using a stainless steel column (3 mm × 1 m) packed with Unipack 1A (60—80 mesh) obtained from Gasukuro Kogyo, Tokyo, for the N_2O and CO_2 separations. The second apparatus was operated at 60 °C, using a stainless steel Column (3 mm × 2 m) packed with Molecular Sieve 13X (60—80 mesh), for the N_2, NO, and CO separations. Helium was used as a carrier gas. The reproducibility of each component was within 0.3 Torr.

Results and Discussion

Figure 1 shows a typical result of the reduction o NO by CO over a Fe_2O_3 catalyst at 200 °C. Only the partial reduction of NO to N_2O took place at an early stage, and the reduction of N_2O to N_2 occurred after most of the NO had been consumed. At such a high temperature as 300 °C, a small amount of N_2 was produced even at an early stage, but the reduction of NO to N_2O was still dominant.† The initial rates of the reduction of N_2O to N_2 by CO in the absence of NO were comparable with those of NO to N_2O. We are, therefore, interested in the selective formation of N_2O in the reduction of NO by CO. Previous workers[1-4] using the flow system also observed N_2O formation in the reduction of NO by CO at low temperatures or at high space velocities, but little attention has been paid to the reasons why NO reduces to N_2O selectively and why scarcely reduction of the N_2O formed on the catalyst proceeds. Therefore, it is of interest to investigate the perturbation effect of NO on the reduction of N_2O by CO; NO was admitted during the course of the reduction of N_2O, as is shown in Fig. 2. A discontinuous increase in the N_2O pressure and a decrease in the NO pressure were observed upon the introduction of NO at a certain time, *A*. However, the CO and CO_2 pressures were changed continuously. Moreover, the reduction of N_2O and the N_2 formation stopped completely, and the reduction of NO to N_2O occurred. A similar effect of NO was also observed at 250 °C, although a slight formation of N_2 was found.

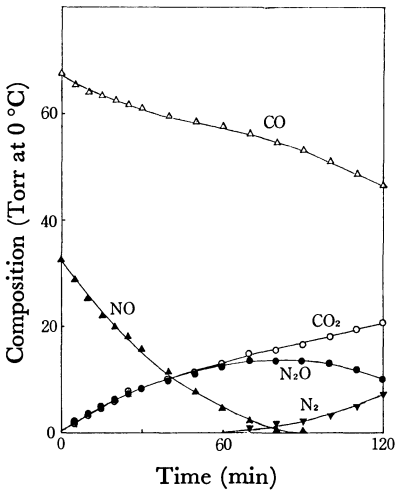

Fig. 1. The reduction of NO over 5 g of 10 wt% Fe_2O_3 on silicon carbide at 200 °C.

The following reaction schemes are generally accepted for the reduction of NO by CO:[1-4]

$$CO + cat \xrightarrow{k_1} CO_2 + cat^* \quad (1)$$

† No decomposition of NO to N_2O and O_2, or of N_2O to N_2 and O_2, in the absence of CO was observed under our conditions.

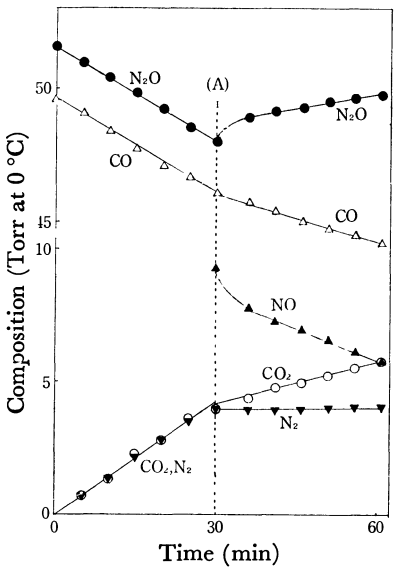

Fig. 2. The effect of NO on the reduction of N_2O by CO over 2 g of 10 wt% Fe_2O_3 on silicon carbide at 200 °C. NO (9.2 Torr) was introduced at a time *A*.

$$2NO + cat^* \xrightarrow{k_2} N_2O + cat \quad (2)$$

$$N_2O + cat^* \xrightarrow{k_3} N_2 + cat \quad (3)$$

where cat and cat* are an active site on the catalyst and its reduced site by CO respectively, and where k_1, k_2, and k_3 are the rate constants for each reaction. If the selective formation of N_2O is due to $k_2 \gg k_3$ (the last step may be rate-limiting), the introduction of NO during the course of the reduction of N_2O should result in the enhancement of the N_2 formation, because the concentration of N_2O on the catalyst should increase. Therefore, our results cannot be explained by the difference in rate constants, but must be related to the strong adsorption of NO on the catalyst.

Our results do not permit any definitive descriptions of the selective formation of N_2O in the reduction of NO by CO, but we have adopted the one presented below as a tentative postulate. The selective formation of N_2O observed at an early stage of the reduction of NO reflects the difference in adsorptivity between NO and N_2O: the adsorption of NO is stronger than that of N_2O. The NO and N_2O formed on the catalyst will establish an adsorption equilibrium, and the N_2O is displaced by NO before it is converted to N_2. As the temperature is raised, a part of the N_2O formed on the catalyst will be reduced to N_2 before the displacement by NO. The effect of NO on the reduction of N_2O shown in Fig. 2 also supports the above postulate: the discontinuous increase in N_2O pressure and the stopping of the N_2 formation may be ascribed to the displacement of N_2O by NO.

Extinction Coefficients of Maleate and Fumarate Radical Anions and Relative Yield of *cis-trans* Isomerization in Methanol Glass at 77 K

Ayako TORIKAI, Fumio NAKANO, Kenji FUEKI, and Zen-ichiro KURI

Department of Synthetic Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 3, 1974)

Synopsis. The photoisomerization of the γ-ray-induced maleate radical anion (DEM^-) to the fumarate radical anion (DEF^-) has been studied. The molar extinction coefficients of DEM^- and DEF^- have been determined to be $2.4_3\times10^4$ l mol^{-1} cm^{-1} and $3.4_0\times10^4$ l mol^{-1} cm^{-1} respectively. The yield of the isomerization from DEM^- to DEF^- is found to be 0.95.

In a previous paper,[1] we reported the photoisomerization of the maleate radical anion produced in 2-methyltetrahydrofuran (MTHF) glasses by γ-irradiation. The reaction intermediates observed were identified as radical anions. However, some problems remained to be resolved in the previous study. Because of the poor solubility of the *trans* isomer (dimethyl fumarate) to MTHF, for instance, the experiment changing the concentration of the *trans* isomer was not possible, so that the extinction coefficient could not be estimated accurately in that case.

We have now made an attempt to determine the molar extinction coefficients of the radical anions and to estimate the yield of the isomerization in rigid media. We have chosen diethyl maleate or diethyl fumarate–methanol systems in order to have a good solubility of the esters to methanol and for the convenience for optical studies.

Experimental

Spectro-grade methanol containing 5.7 mol% of triply distilled water was used as the solvent. The diethyl maleate (*cis*, DEM) and diethyl fumarate (*trans*, DEF) were purified by passage through an activated aluminum column. The samples were degassed by the freeze-pump-thaw technique. The samples were irradiated with Co-60 γ-rays at 77 K and, in most cases, at a dose rate of 2.0×10^{18} eV/g hr and a dose to 1.0×10^{18} eV/g. The photobleaching of γ-irradiated samples was carried out with visible light from a slide projector. The optical absorption spectra of γ-irradiated samples were measured at 77 K on a Hitachi EPU 2A spectrophotometer.

Results and Discussion

γ-Irradiated pure methanol glass gives an optical spectrum with an absorption maximum at 530 nm; this maximum has been assigned to the trapped electron (e_t) in methanol.[2]

When solutions containing DEM at low concentrations are irradiated, the spectrum shows absorption maxima at 530 and 345 nm(Fig. 1a). Upon an illumination with visible light (λ>490 nm), the 530 nm band diminishes in intensity, while the 345 nm band increases (Fig. 1b). The 345 nm band first shifts to 335 nm upon an illumination with visible light(no filter),

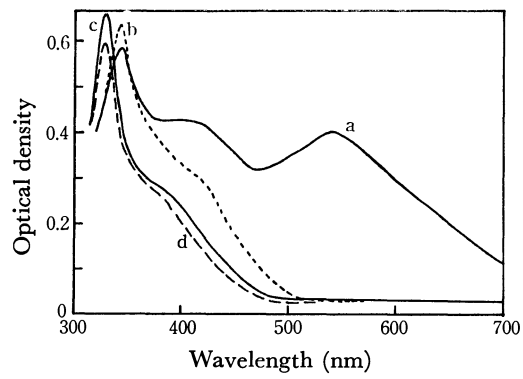

Fig. 1. Absorption spectra of γ-irradiated 0.08 mol% DEM in methanol at 77 K. a: sample γ-irradiated to a dose of 1.0×10^{18} eV/g, b: after 2 min illumination of sample a with visible light (λ—490 nm), c: after 2 min illumination of sample a with a visible light (no filter), d: after 60 min illumination of sample a with visible light.

while it is bleached by prolonged illumination (Fig. 1c, d). It is obvious from these experimental results that the *cis*→*trans* isomerization can occur by means of the illumination of visible light at wavelength shorter than 490 nm. The 345 and 335 nm bands are attributable to the DEM and DEF anion radicals respectively, judging from similar results in the previous work.[1] The reaction mechanism is proposed to be:

$$CH_3OH \rightsquigarrow CH_3OH^+ + e_t$$
$$DEM + e \longrightarrow DEM^-$$
$$DEM + e_t \xrightarrow{\lambda>490\,nm} DEM^-$$
$$DEM^- \xrightarrow{\lambda<490\,nm} DEF^-$$
$$DEF^- \xrightarrow{h\nu} DEF + e_m$$

The molar extinction coefficients (ε) of the radical anions were determined from the competitive reaction

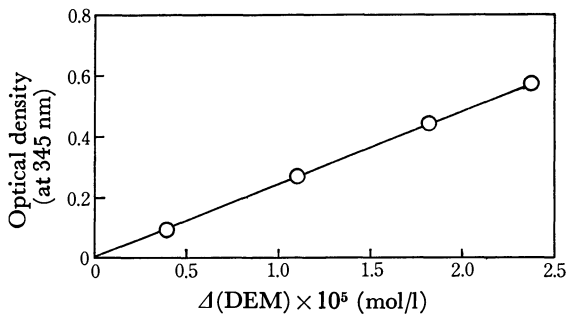

Fig. 2. Plot of optical density at 345 nm *vs.* Δ (DME) for γ-irradiated DEM in methanol at 77 K.

of mobile electrons between the esters and methanol (Fig. 2). Since the extinction coefficient of e_t has been known, the extinction coefficient of DEM^- can be determined by the following method, assuming that the decrease in e_t contributes to the increase in DEM^-. In Fig. 2, Δ(DEM) indicates $OD-OD'/\varepsilon(e_t)d$, where OD: optical density at 530 nm in pure methanol glass; OD': optical density at 530 nm in a DEM-methanol glass; $\varepsilon(e_t)$: molar extinction coefficient of e_t at 530 nm, and d: thickness of the cell. The value of $\varepsilon(e_t)$ has been reported to be 1.38×10^4 l mol^{-1} cm^{-1}.[3] The molar extinction coefficient (ε) of the DEM anion radical can be obtained from the slope of the straight line in Fig. 2. The ε of the DEF anion radical can also be obtained by the same method. The molar extinction coefficients of the DEM and DEF radical anions have been estimated to be $2.4_3\times10^4$ l mol^{-1} cm^{-1} at 345 nm and $3.4_0\times10^4$ l mol^{-1} cm^{-1} at 335 nm respectively.

The concentrations of DEM^- and DEF^- can be estimated by using these extinction coefficients. The DEM-methanol solutions were illuminated with visible light ($\lambda>490$ nm) after γ-irradiation at 77 K; the concentrations of DEM^- were estimated at this stage of the experiment. Subsequent illumination of the sample with visible light (2 min) produced DEF^-, and the concentrations of DEF^- were estimated. The concentrations of DEM^- and DEF^- obtained in this manner are shown in Fig. 3.

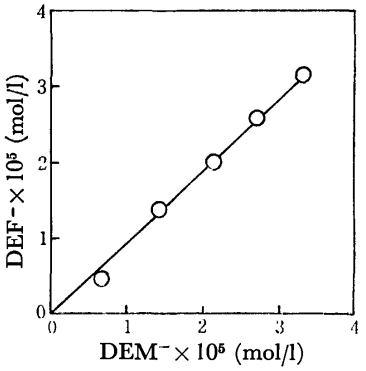

Fig. 3. Plot of the concentration of DEF^- *vs.* the concentration of DEM^- for photoisomerization of γ-irradiated DEM in methanol at 77 K.

The yield of the *cis*→*trans* isomerization is found to be 0.95 from the slope of the straight line in Fig. 3. This means that 95% of the DEM^- produced undergoes the *cis*→*trans* isomerization.

The ESR Spectra of the Anthanthrene and Binaphthylene Dioxide Cation-radicals

Kôichi IKEGAMI, Yoshio MATSUNAGA,* Kazuteru OSAFUNE, and Eiji OSAWA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received June 7, 1974)

Synopsis. The ESR spectra of the anthanthrene and binaphthylene dioxide cation-radicals were recorded and analysed.

Some aromatic hydrocarbons have been known to form stable cation-radicals when dissolved in concentrated sulfuric acid and to exhibit ESR spectra with well-resolved hyperfine structures. Perylene and tetracene are notable examples.[1,2] During the course of our work on photoemission from solid aromatic compounds, we noted that anthanthrene and a compound with the same framework, binaphthylene dioxide, have ionization potentials close to those of the above-mentioned hydrocarbons. Therefore, an examination of the ESR spectra of their cation-radicals was undertaken.

When 98% sulfuric acid solutions are diluted enough to resolve the hyperfine structure, the anthanthrene cation-radical gives sixty-one lines, with a total span of 27.6 G. The left-hand half of the spectrum is shown in Fig. 1. All the intervals except those in the terminal quintet are equal to d, while those in the quintet are 2d. The separation between the terminal quintet and the neighboring one, 9d, gives the second smallest coupling constant. As the total span is equal to 68d, the only possible constants for the remaining protons are 10d and 11d.[3] Therefore, a pair of the protons does not contribute to the hyperfine structure. The stick diagram reconstructed with these constants reproduces well the relative intensities of the experimental lines. McConnell has derived the $a_i=Q\rho_i$ relationship, which shows that the proton-coupling constant, a_i, of the aromatic free radical is proportional to the spin density, ρ_i, at the attached carbon atom, i.[4] As the HMO spin densities at the carbon atoms

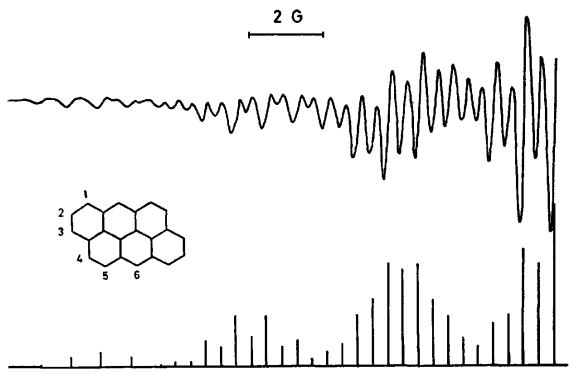

Fig. 1. First derivative of ESR spectrum of the anthanthrene cation-radical and the reconstructed stick diagram.

* To whom inquiries may be addressed.

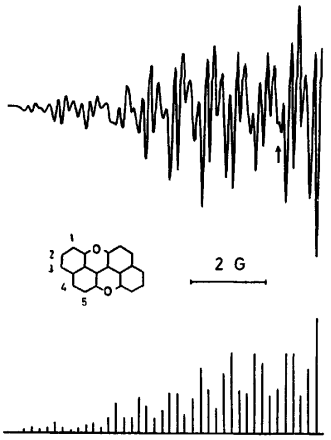

Fig. 2. First derivative of ESR spectrum of the binaphthylene dioxide cation-radical and the reconstructed stick diagram.

are 0.1074, 0.0003, 0.0969, 0.0436, 0.0431, and 0.1414 in the order of numbering given in Fig. 1, the large constants, 4.46, 4.06, and 3.65 G, may be assigned to the protons attached to the carbon atoms, 6, 1, and 3, and their equivalents respectively. The quintet with the spacing of 0.81 G arises from the coupling with the protons on the 4 and 5 carbon atoms and their equivalents.

The spectrum of the binaphthylene dioxide cation consists of seventy-seven lines, with an approximately equal spacing, d, if we ignore the partial resolution indicated by an arrow (see Fig. 2). The total span decreases to 15.7 G upon the introduction of two oxygen atoms into the framework. As the assignment of coupling constants did not seem easy, we employed the computing program proposed by Pomponiu and Balaban.[5] The summation of all the line intensities indicates that all the protons in this radical contribute to the hyperfine structure. The most probable partition of the thirty-eight intervals into five non-zero integers is d, 3d, 8d, 11d, and 15d. The stick diagram computed with these values appears to be consistent with the experimental spectrum. On the basis of the total span, the coupling constants can be approximated as 0.21, 0.62, 1.65, 2.27, and 3.10 G. The HMO spin densities on the carbon atoms calculated with the parameters of $\alpha_O=\alpha_C+2.0\beta_{CC}$ and $\beta_{CO}=0.8\beta_{CC}$[6] are 0.0591, 0.0175, 0.0754, 0.0947, and 0.0001, in the order of numbering in Fig. 2. The order of spin densities is different from that in the hydrocarbon cation-radical, but it is not affected by α_O even if this value is varied by $\pm 0.5\beta_{CC}$. Therefore, the largest constant may safely be assigned to the protons on the 4 carbon atom and the equivalent, and the second

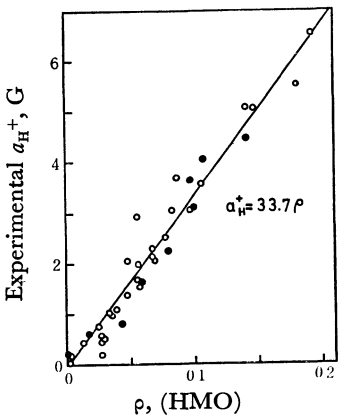

Fig. 3. Relation between experimental coupling constants, a_H^+, and HMO spin densities, ρ, for the anthanthrene and binaphthylene dioxide cations (●) and for other aromatic hydrocarbon cations (○).

largest, to those on the 3 carbon atom and the equivalent. On the other hand, the protons with the smallest constant are undoubletly attached to the 5 carbon atom and its equivalent, and those with the second smallest, to the 2 carbon atom and its equivalent. This cation-radical was found to be not quite stable; that is, a modification of the central part of the spectrum could be noted three days after the dissolution.

In order to verify the above choice of coupling constants, the constants for the present cation-radicals are plotted in Fig. 3 by shaded circles against the spin densities determined by the simple HMO theory. The plots show a linear relationship as good as those indicated by open circles for the eleven aromatic hydrocarbon cations compiled by Lewis and Singer.[7] We employed Q=33.7 G in this figure, following Griffith and Poole.[8]

The authors wish to express their thanks to Dr. Jun-ichi Aihara for his help in the calculation of the HMO spin densities.

Thermally Stimulated Current in Perylene Crystals

Mizuka SANO
Department of Materials Science, The University of Electro-Communications, Chofu, Tokyo 182
Fukuji EGUSA* and Hideo AKAMATU**
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received June 25, 1974)

Synopsis. A single current peak characteristic of thermally detrapped holes was observed at 220 K, the depth of the traps being determined to be 0.50±0.02 eV. This value showed no apparent correlation with the activation energy for photoconduction, 0.18±0.01 eV.

In many high-resistivity semiconductors, localized states in the forbidden energy gap play a dominant role in the mechanism of transport of charge carriers. Perylene crystals show a photocurrent under illumination of light in the visible and ultraviolet spectral regions.[1] A photocurrent signal induced by a light pulse, however, shows a diffused shape with a long tail of decay, indicating the presence of charge carrier traps. The low mobility of charge carriers in perylene crystals has been attributed to the trapping of carriers in an excess-electron-dimeric state.[2] In this note we would like to report a trap level of perylene crystals studied by means of thermally stimulated currents.

Single crystal platelets of chromatographically purified perylene, thickness *ca.* 100 μ, were obtained by sublimation. A crystal platelet, *ca.* 8×5 mm², was sandwiched between two electrodes, one with semi-transparent gold coating and the other lead foil covered with a 6 μ Mylar film. The crystal was mounted on the top of a copper block which could be cooled by a stream of cold nitrogen gas. The whole assembly surrounded by an electric heater was accommodated in a glass chamber (Fig. 1).

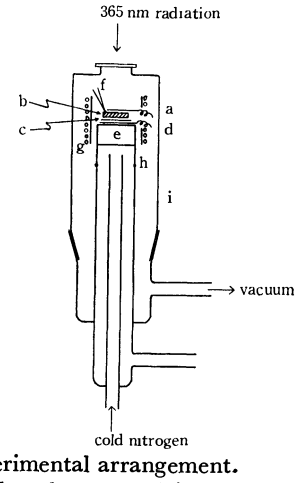

Fig. 1. Experimental arrangement.
(a) gold film electrode, (b) crystal, (c) Mylar film, (d) lead foil electrode, (e) copper block, (f) thermocouple, (g) electric heater, (h) Kovar seal, (i) glass chamber.

The gold electrode was connected to the positive side of a 90 V battery. The crystal was cooled to about 170 K and then illuminated through the electrode with 365 nm mercury radiation. After illumination for ten minutes, the polarity of the applied voltage was reversed, and thermally stimulated currents at a predetermined uniform heating rate were subsequently measured in the dark. The heating rate was controlled with an electric heater, an appropriate amount of helium gas being introduced into the chamber. The current through a 10^{10} ohm input resistor was recorded by a Takedariken vibrating reed electrometer, the temperature of the crystal being recorded simultaneously with a copper-constantan thermocouple junction pasted to the crystal surface with silicone rubber.

In the range 170—245 K, a single current peak characteristic of thermally detrapped holes was observed, indicating that there is one kind of trapping center observable in this temperature range. At a heating rate of 0.38 K/s, the peak appeared at 220 K. As the heating rate was increased to 0.45 K/s, the peak shifted to a higher temperature and became narrower (Fig. 2). Garlick and Gibson's method[3] was adopted for evaluation of the trap depth, on the assumption that the trapping centerslie with a uniform depth E. The thermally stimulated current i is expressed by the equation

$$i = n_t \nu \exp\left(-\frac{E}{kT}\right), \qquad (1)$$

where n_t is the number of carriers in the traps and ν is the effective attempt-to-escape frequency.

Plots of the logarithm of current against the reciprocal of the temperature gave a straight line in the initial current rising region. From the slope of the line, the depth of traps for holes was evaluated to be 0.50± 0.02 eV. When the crystal was illuminated through a

negatively biased gold film electrode, no thermally stimulated current could be observed. This means that electrons could not be injected from the electrode or the injected electrons were trapped too deeply to be released thermally. The nature of trapping centers could not be determined from the present experiment. The depth of hole traps for melt-grown anthracene crystals was determined to be 0.76 eV with the same experimental arrangement. This is in good agreement with the value obtained previously.[4] Similarity in the trap depths for organic crystals; 0.50 eV for perylene, 0.53—0.76 eV for anthracene,[4,5] and 0.36 eV for metal-free- and lead-phthalocyanine crystals[6] suggests that a physical cause of the same kind might be responsible for trapping of holes.

Variation of a photocurrent with temperature has been considered to be an evidence for the existence of trapping centers.[7] We measured the temperature dependence of a photocurrent for perylene single crystals by the method given in the leterature.[8] The photocurrent was found to increase with an increase in temperature in the range 200—330 K. Plots of the logarithm of photocurrent against the reciprocal of the temperature gave a straight line, the activation energy for photoconduction being evaluated to be 0.18 ± 0.01 eV. The value of the activation energy was found to be independent of the exciting wavelength in the visible spectral region. The activation energy for photoconduction, however, showed no apparent correlation with the trap depth. It might be associated with the process of carrier generation rather than the process of carrier transport.

The X-Ray Photoelectron Spectroscopy of *o*-Hydroxy Aromatic Azo Metal Complexes

Tooru YOSHIDA and Shigemasa SAWADA

Osaka Prefectural Industrial Research Institute, Enokojima, Nishi-ku, Osaka 550

(Received July 26, 1974)

Synopsis. The photoelectron spectra of azo metal complexes were measured. There was no significant change in the profile or the binding energy of the N(1s) peak upon coordination. It was deduced that, in the bond between the azo-group and the metal, there is a contribution of a π-bonding.

o-Hydroxy aromatic azo compounds, which are bidentate complexing agents containing an azo-group and a hydroxy group *ortho* to the azo-group, are of considerable practical and theoretical interest because of their ability to form stable chelate complexes with some metal ions. There have been many studies of them by means of physico-chemical methods. Ueno[1] has reported an IR study of *o*-hydroxy azobenzene and its metal chelates, while Jarvis[2] and Alcock *et al.*[3] studied the structures of Cu(II)bis(1-phenylazo-2-naphthol) and Ni(II)bis(1-*m*-tolylazo-2-naphthol) by X-ray analysis.

In recent years a method of X-ray photoelectron spectroscopy (ESCA) has been developed; it is capable of yielding information pertinent to the study of chemical bonds in that the binding energy of an inner-shell electron is characteristic in both its elemental identity and the chemical environment of the atom. The differences in binding energies between coordinated and uncoordinated ligand atoms have been used to support arguments concerning π back-bonding in some coordination compounds.[4] The purpose of this paper is to report the results of a study by this method of some *o*-hydroxy aromatic azo metal complexes.

The X-ray photoelectron spectra were measured on an AEI ES100 spectrometer under the control of a DS100/32 computer data-processing system. An AlKα (1486.6 eV) X-ray line was used as the excitation source. All the samples measured are given in Table 1. The 2-arylazophenol and 1-arylazo-2-naphthol derivatives were prepared by coupling diazotized amines with *p*-tolylphenol and β-naphthol respectively. Chelate compounds with a ligand-metal ratio of 2:1 were synthesized according to the procedures of Elkins and Hunter.[5] The samples were ground to powder, dusted onto a double-backed adhesive tape, and set inside the measuring chamber. The measurements were run at room temperature under a vacuum of about 10^{-6} Torr. A few volatile samples were introduced *via* a heatable reservoir shaft and condensed on a cooled copper holder.

The binding energy of the C(1s) peak was used as the energy standard throughout the present experiments; it was taken to be 285.0 eV, the C(1s) binding energies for all the samples being assumed to be constant.

The N(1s) spectra of all the compounds were composed of single peaks with full-width half-heights of 1.6—1.8 eV in all the free azo compounds and Cu chelates, and 1.5—1.7 eV in all the Ni chelates. In view of these results, the difference between the charge densities on the two nitrogen atoms of an azo-group is considered to be so small that they can not be distinguished by ESCA in all these compounds.

The measured values for the N(1s) binding energies are listed in Table 1. There were no remarkable changes in the N(1s) binding energy upon the coordination of all azo compounds to metals, although barely appreciable minus changes appear to be observed in 1-arylazo-2-naphthol derivatives. Therefore, it seems reasonable to assume that there is no significant change in the electron density around the azo-group on the complex formation.

There are chiefly two known modes of the formation of a bond between an azo-group and a metal atom. The one is Type (1), in which one lone-pair electron of a component nitrogen atom is coordinated to the

TABLE 1. N(1s) BINDING ENERGY VALUES

Sample	R	B.E. of N(1s) (eV)[a]			E (eV)[b]	
		Free	Cu-Chelate	Ni-Chelate	Cu-Chelate	Ni-Chelate
	$-OCH_3$	399.8	400.0	—	+0.2	—
	$-H$	400.0	400.1	400.2	+0.1	+0.2

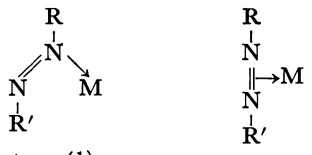
	$-H$	400.6	400.1	400.3	−0.5	−0.3
	$-NO_2$	400.5	400.0	400.2	−0.5	−0.3

a) Uncertainties are equal to ±0.1 eV. b) The differences between the N(1s) binding energies of the chelate and the free azo compounds.



metal, while the other is Type (2),[6] in which the whole of the N=N bond itself is coordinated to the metal, just as in metal-olefin complexes, in which the π-electrons of the carbon-carbon double bond are capable of coordination with a metal.

The results of the X-ray analysis[2,3] suggest that the bonds between the azo-group and the metals in the Cu and Ni chelates of 1-phenylazo-2-naphthol are of Type (1).

Aromatic compounds containing an N=N bond generally exhibit absorption bands at approximately 320—315 nm; these bands are attributed to the conjugation of the unsaturated nitrogen with the phenyl rings. Kleiman and Dubeck[7] have suggested that, on complex formation, the disappearance and the retaining of such absorption bands indicate that the nitrogen system in the complex is bonded to the metal as is shown in Type (2) and in Type (1) respectively.

The UV measurements in the above region for all the chelates listed in Table 1 indicate absorption peaks with almost the same intensities as those of free azo compounds.

Accordingly, it may be concluded that all the chelates used in this study belong to Type (1). In the case of Type (1), it appears that the charge densities on the nitrogen atoms of the azo-group are not equal. If this is really true, the ESCA spectrum of the N(1s) of the chelate should give a different profile from that of the free one, for instance, with two well-resolved peaks or a single broad peak. As has been stated previously, however, scarcely no such phenomena were observed in this study.

From these experimental facts, the data obtained in this experiment may be explained as follows.

In all the chelates in Table 1, there are two effects of opposing factors. One is the σ-bonding by the coordination of a lone-pair electron of a nitrogen atom to the bonding orbital of Cu or Ni; the other is the π-bonding by the coordination (back-donation) of the *d*-electrons of Cu or Ni to the vacant anti-bonding orbital of the azo-group. These effects result in a neat cancellation of the total electron drift and a small change in the total electron density in the neighborhood of the nitrogen atom. This is the explanation for the facts that the difference between the N(1s) binding energies of the free ligand and the chelate is too small in view of the stability of the chelates, and that the profile of the N(1s) of the chelate is almost the same as that of the free ligand.

Though the problem remains unsolved, it is noteworthy that the change in the N(1s) binding energies is very small throughout all the chelates.

The authors wish to thank Mr. Taichiro Hirohara for his elemental analysis of all the samples.

Photochemical Reduction of Vanadium(V) in Aqueous Perchloric Acid Solutions

Bojana G. JELIAZKOWA,* Shigeru NAKAMURA, and Hiroshi FUKUTOMI

Research Laboratory for Nuclear Reactors, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received December 19, 1973)

Synopsis. It was found that irradiation of V(V) solution gives V(IV) and an equivalent amount of oxygen. The dependence of the quantum yield on light intensity, acid concentration, wave number and the concentration of V(IV) was investigated.

It was found that reduction of vanadium(V) proceeds during irradiation of its aqueous perchloric acid solution with argon laser at 488 nm. The photochemical reduction of metal ions of a high valence state such as cerium(IV)[1-6] and iron(III)[7-11] has been studied and probable mechanisms have been discussed. However, no data have been given of vanadium(V).

Experimental

Irradiation of vanadium(V) solution was carried out with an ultra high pressure mercury lamp with solution- and glass-filters.[12] A qualtz cell for spectrophotometry (1 cm light-path length) with a suitable modification was used as a reaction vessel. The cell was thermostated at 20.0±0.1 °C in an optical bench. Stirring of the solution was carried out magnetically with a small glass-coated bar. The reactant solution was deaerated in the reaction vessel with pure nitrogen gas.

The concentration of vanadium(V) was determined photometrically at 270 nm. The value 863 $M^{-1}\cdot cm^{-1}$ was used as a molar extinction coefficient for V(V), and 143 $M^{-1}\cdot cm^{-1}$ for V(IV). The incident light intensity before and after the irradiation, and the transmitted light intensity during the irradiation were measured in an arbitrary unit with a photomultiplier. These relative intensities were converted into absolute values by means of a ferrioxalate actinometer. Inner filter effect of V(IV) is found to be negligible.

Oxygen gas generated by photolysis was identified and determined by gas-chromatography using an active carbon column and helium as a carrier gas. The equipment is shown in Fig. 1. After prolonged irradiation, the resulting gas was expelled and collected in the syringe (2 in Fig. 1) by bubbling with helium, and the gas sample was injected into a gas-chromatograph. The reaction vessel was replaced by an electrolytic cell, and the gas-chromatograph was calibrated by measuring the amount of oxygen produced by the electrolysis of 0.1 M sulfuric acid.

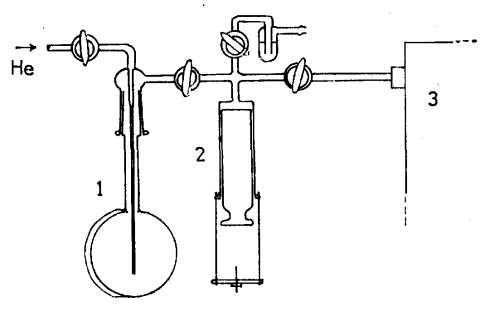

Fig. 1. Equipment used for the determination of oxygen
1: Cylindrical irradiation vessel, 2: syringe
3: gas-chromatograph.

All the solutions were prepared from analytical grade reagents. Triply distilled water obtained from an alkaline permanganate solution was used.

Results and Discussion

Stoichiometry. The EPR spectrum of the irradiated sample showed the octet signal of vanadium(IV). It was found that V(IV) is the final reduction product since no change was observed after prolonged irradiation of V(IV) solution. Under the conditions employed $VO_2(H_2O)_4^+$ was found to be the main species present in V(V) solutions and $VO(H_2O)_5^{2+}$ the main species of V(IV).[13-14]

The amount of oxygen evolved is equivalent to the amount of V(V) reduced by photolysis (Table 1). The overall reaction is thus given by the following scheme.

$$VO_2(H_2O)_4^+ + 1/2H_2O + H^+ \xrightarrow{h\nu} VO(H_2O)_5^{2+} + 1/4O_2 \quad (1)$$

Effect of Light Intensity on the Quantum Yield of V(IV). The results show that the quantum yield of V(IV) does not depend upon the intensity of the absorbed light (Table 2). This suggests that V(IV) is formed

Table 1. Yields of V(IV) and oxygen

$HClO_4$	Yield of V(IV)	Yield of O_2
1.0 M	2.3×10^{-6} mol	5.5×10^{-7}mol
	2.2×10^{-6}	5.5×10^{-7}
	1.6×10^{-6}	4.5×10^{-7}

Table 2. Dependence of the quantum yield of V(IV) on absorbed light intensity

Absorbed light intensity	Quantum yield of V(IV)
1.15×10^{-4} Einstein$\cdot l^{-1}\cdot min^{-1}$	0.0037
1.20×10^{-4}	0.0033
1.40×10^{-4}	0.0036
2.51×10^{-4}	0.0036
3.34×10^{-4}	0.0036
3.40×10^{-4}	0.0035
3.90×10^{-4}	0.0037
4.31×10^{-4}	0.0033
4.90×10^{-4}	0.0037

$[V(V)]=1.0\times10^{-3}$ M, $[HClO_4]=1.0$ M, at 313 nm.

* Present address: Department of Chemistry, Sofia University, Sofia, Bulgaria.

by reaction of the first order with respect to the concentration of some intermediate. A similar result was obtained in the photochemical reduction of cerium(IV).

Effect of the Wave Number of Absorbed Light on the Quantum Yield of V(IV). The wave number effect was studied without any particular attention to light intensity, since the quantum yields of V(IV) and O_2 were independent of light intensity. Figure 2 shows the dependence of the quantum yield of V(IV) on the wave number and the absorption spectrum of reactant $VO_2(H_2O)_4^+$. The value 3.4 eV corresponding to the wave number 27 kK (Fig. 2) is reasonable for the formation of ·OH radical by the reaction

$$V(V) + H_2O \xrightarrow{h\nu} V(IV) + \cdot OH + H^+ \qquad (2)$$

since it is assumed in similar reactions of cerium(IV)[3-5] and iron(III).[7-11] The standard oxidation potential of the thermal reaction corresponding to the reaction (2) is $E^0 = -1.82$ V, calculated from the standard oxidation potentials $E^0(V(V) \rightarrow V(IV)) = 1.00$ V and $E^0(H_2O \rightarrow \cdot OH) = -2.82$ V. The quantum yield of V(IV) increases gradually with wave number. This might indicate that the probability of the ·OH radical escaping from the solvent cage of V(IV) increases with the photon energy.

Effect of Perchloric Acid and Vanadium(V). We see from Table 3 that the quantum yield of V(IV) does not depend upon the concentration of perchloric acid in the region 0.01—1.0 M. The quantum yields of V(IV), determined at two vanadium(V) concentrations 5×10^{-4} M and 1×10^{-3} M, were found to be $(3.5 \pm 0.3) \times 10^{-3}$ and $(3.4 \pm 0.2) \times 10^{-3}$ respectively in 0.1 M $HClO_4$ at unit ionic strength ($NaClO_4$).

The fact that neither perchloric acid nor vanadium(V) affects the quantum yield of V(IV) is in line with the fact that neither hydrolysis nor polymerization of vanadium(V) occurs under the conditions employed.

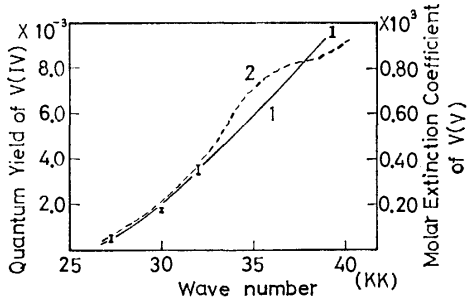

Fig. 2. The dependence of the quantum yield of V (IV) on wave number at 1.0 M $HClO_4$ and the absorption spectrum of $VO_2(H_2O)_4^+$.
1: Quantum yield of V (IV),
2: absorption spectrum of $VO_2(H_2O)_4^+$.

Table 3. Dependence of the quantum yield of V(IV) on the concentration of perchloric acid

($HClO_4$)	Quantum yield of V(IV)
0.01 M	$(3.3 \pm 0.2) \times 10^{-3}$
0.05	$(3.2 \pm 0.1) \times 10^{-3}$
0.10	$(3.4 \pm 0.2) \times 10^{-3}$
0.50	$(3.6 \pm 0.3) \times 10^{-3}$
1.00	$(3.5 \pm 0.2) \times 10^{-3}$

[V(V)] = 1×10^{-3} M, (ionic strength) = 1.0 M and at 313 nm.

Retardation Effect of Vanadium(IV). It was found that the quantum yield of V(IV) decreased with an increase in the concentration of V(IV) produced by photolysis. Since the inner filter effect of V(IV) was negligible and no change was observed after prolonged irradiation of V(IV), the effect of V(IV) is attributed to the back reaction

$$\cdot OH + V(IV) \longrightarrow OH^- + V(V) \qquad (3)$$

Expenses for this work were defrayed in part by the Ministry of Education and in part by a grant from the Japan Society for the Promotion of Science under the Japan-U.S. Cooperative Science Program. One of the authors (B. Jeliazkowa) wishes to express her appreciation to the International Post-graduate University Course sponsored by UNESCO.

Stability Constants of Several Aliphatic Uranyl Carboxylates

Bong-il KIM, Chie MIYAKE, and Shosuke IMOTO

Department of Nuclear Engineering, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received July 8, 1974)

Synopsis. The stability constants of uranyl carboxylates were determined spectrophotometrically; for butyrate, they were log K_1=2.96, log K_2=2.66, log K_3=2.43, and log K_4=2.23; for isobutyrate, log K_1=2.74, log K_2=2.20, and log K_3=1.66; for valerate, log K_1=2.91 and log K_2=2.52, and for isovalerate, log K_1=2.90 and log K_2=1.91.

The consecutive and gross stability constants of a number of mononuclear uranyl complexes with anions of common carboxylic acids, such as formic, acetic, propionic, lactic, oxalic, and succinic acids, were determined spectrophotometrically at an ionic strength of 1.0 in an aqueous solution.[1] As part of a series of studies we hereby report the stability constants of aliphatic uranyl carboxylates with the anions of butyric, isobutyric, valeric, and isovaleric acid obtained by the same method.

Experimental

Materials. All the chemicals were of an analytical grade, made by Nakarai Chemicals, Ltd., and were used without further purification. The solutions were prepared with double-distilled water. The uranyl perchlorate was recrystallized from water, and its constitution ($UO_2(ClO_4)_2$–$6H_2O$) was confirmed by the gravimetric determination of uranium as U_3O_8.

Measurements. Hitachi Perkin-Elmer 139 UV–VIS spectrometer was used to record the absorption spectra with cells 0.2, 0.5, and 1.0 cm thick, according to the respective concentration. The pH determinations were performed with a Hitachi pH meter, M-5. The temperature was controlled to 20+0.2 °C for the spectrophotometric and pH measurements. The systems studied are listed in Table 1. The ionic strength was maintained at 1.0 by adding an appropriate amount of $NaClO_4$ solution to the buffer solution. The procedure of the measurement was as has been described in a previous publication.[1]

Results and Discussion

The data obtained spectrophotometrically and potentiometrically were analysed by Fronaeus' method.[2,3] The linear relationship obtained between the total effective ligand concentration and total uranyl ion concentration for various extinctions suggests the existence of only mononuclear complexes under these conditions. The consecutive stability constants thus obtained are given in Table 2. As is to be expected, the stability of the complexes decreases with an increase in the coordinated ligand number for a given anion. The maximum ligand number attained (Table 3) increases steadily with the length of the carbon chain, reaching 4 for propionate and butyrate, but the steric requirement may prevent the fatty acid with a carbon chain of a sufficient length to occupy more than four of the coordination sites.

Figure 1 shows the relationship between the stability constant, K_1, for the first uranyl complex (UO_2A^+) and the value of K_{1HA} for the corresponding carboxylic acid. As may be seen from the figure, the four carboxylate anions studied here may fall in the group that is classified as showing "normal" behavior, as defined by a previous paper.[1] It is interesting that water lies on this linear line extrapolated to log K_{1HA} of 16. According to Schwarzenbach's classification of cations into the A-character cations and B-character cations, on the basis of complex-formation behavior,[4] both the uranyl ion and the proton may be said to have the A-character, in which the formation reaction entropy term mainly contributes to the association with the ligand and in which the heat of reaction is positive or slightly negative. On the other hand, the B-character association is dominantly controlled by the negative heat of formation.

The relationship between the number of the carbon of monocarboxylic acid and the first stability constant, K_{1MA}, of the respective various metal complexes shown in Fig. 2. The iron(III) ion and the indium(III) ion

behave much like the uranyl ion does, corresponding to the fact that these ions are classified as having the A-character. The copper(II) ion and the zinc(II) ion, belonging to the B-character group, remain nearly constant, independently on the temperature. Apart from Schwarzenbach's consideration, there is a possibility of interpreting these tendencies on the basis of the electronic energy level scheme of the metal ion. Alkali earth metal ions, Ca(II), Sr(II), and Ba(II), have stable configurations, with completely-filled $3s^2$-$3p^6$, $4s^24p^6$, and $5s^25p^6$ shells respectively. Since the levels of the 3d, 4d, and 5d orbitals, which accept the electrons of the approaching ligands, lie considerably higher than the filled 3p, 4p, and 5p levels respectively, the stability of the complex may not be affected by the dissociation behavior of carboxylic acid, log K_{1HA}, thus, they are decreased with the length of the carbon chain, which generally causes an increase in the stability of the acid. In the copper(II) ion, however, the unfilled 3d shell with 9 electrons has some capacity to accept electrons from ligands, so the tendency of the stability of the complex to decrease with the length of the carbon chain is compensated for by the increased donating properties of the corresponding acid. The zinc(II) ion seems also to fall in this category, because superposed 3d—4s levels may have the capacity to accept some electrons.

On the other hand, the iron(III) ion with a half-filled 3d shell can accept more electrons within the same 3d shell than can the copper(II) ion or the zinc(II) ion, even if some energy levels are more or less raised by the ligand-field effect. In the uranyl ion, 5f, 6d, and 7s orbitals are distributed in nearly equal energy levels, so there is much capacity to accept the electrons of ligands, though some of the orbitals are used to construct strong bonds of the uranyl ion by hybridization. In the indium(III) ion, which is completely filled up to the 4d shell, the 5s shell is more easily occupied by electrons from ligands than the 4s shell of the zinc(II) ion which is adopted by ligand electrons.

Tantalum Carbide Formed by the Carbonization of Ta_2O_5 in an Argon Plasma Arc

Osamu MATSUMOTO and Michio SAITO

Department of Chemistry, College of Science and Engineering, Aoyama Gakuin University, Chitosedai, Setagaya-ku, Tokyo 157

(Received August 3, 1974)

Synopsis. The formation of tantalum carbide by the carbonization of Ta_2O_5 with graphite by heating in an argon plasma arc was studied. Chemical and X-ray analyses showed that the product obtained was either stoichiometric or a defect carbide with the formula of TaC_{1-x}. The products were found to be superconductors.

Tantalum carbide is known to exist as from $TaC_{0.99}$ to $TaC_{0.85}$.[1] Giorgi *et al.*[2] found that the superconducting transition temperature decreased from 9.7 K to below 2.04 K as the carbon content decreased from 49.5 to 46.5 at%. In this case, tantalum carbide samples were prepared by heating mixtures of the elemental powders in a graphite crucible at 1850 °C under a vacuum of 10^{-5} Torr, with reaction times varying from 2 to 24 hr.

The present authors[3] previously formed niobium carbide by the carbonization of Nb_2O_5 with graphite by heating in an argon plasma arc and found that the product was a superconductor. Tantalum carbide was obtained by the carbonization of Ta_2O_5 with graphite in the same way. The products were confirmed, their properties, such as the density and the superconducting transition temperature, will be described in this note.

Ta_2O_5 (purity above 99.9%; H. C. Stark, Berlin) and graphite (spectroscopic grade; Tokai Electrode Mfg. Co.) were mixed in the desired molar ratio (C/Ta_2O_5). About one gram of the mixture was pressed into the tablet. Purified argon was used as the plasma gas. The plasma arc furnace and heating procedure were the same as have been described previously.[3,4] The temperature of the sample in the plasma arc was about 2900 °C. Heating was continued for 3 min. The products were investigated by X-ray diffraction and chemical analysis. The density of the products was measured picnometrically. The superconducting transition temperatures of some products were measured by means of 21 Hz mutual-inductance bridge and a Ge thermometer.

The chemical analysis data of the products with various C/Ta_2O_5 values are given in Table 1, while the X-ray analysis data of the products given in Table 2. The product obtained by $6.5 \leq C/Ta_2O_5 \leq 7.0$ was either stoichiometric TaC or a defect carbide with the formula TaC_{1-x}. Tantalum carbide, which has an fcc crystal structure, had a homogeneity range from 50.0 at% C to 43.5 at% C. The sum of the Ta and C contents of the products reached 100 wt%. It seems that only a little oxygen is present in the products in each case.* The lattice parameter of tantalum carbide, a, gradually increased with an increace in the carbon content. The product containing 50 at% C had a lattice parameter of 4.455 Å, which was comparable to that of the $TaC_{1.0}$ formed by the carbonization of metallic tantalum.[5]

* In the NbC formed by the carbonization of Nb_2O_5, the oxygen content in the product was found to be 0.008 wt% by radioactivation analysis.[3]

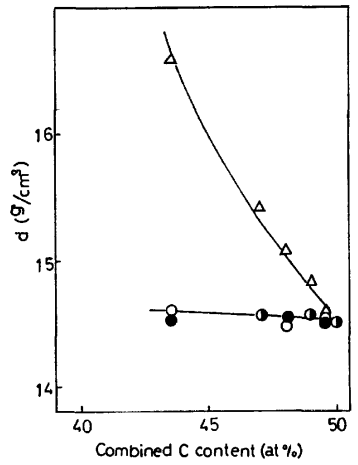

Fig. 1. Density *vs.* combined carbon content.
○: measured value, ●: calculated value assuming that the carbon position was vacant, △: calculated value assuming that the carbon position was substituted by Nb.

The relation between the density of the product at 25 °C and the combined carbon content is shown in Fig. 1. The density was about 14.5 g/cm³ for the product containing 50 at% C. This value agreed with the value calculated for stoichiometric TaC from the X-ray diffraction data. The density for TaC_{1-x} also agreed with that determined by means of X-ray diffraction, if we assumed that some carbon positions in the TaC lattice were vacant.

The relation between the superconducting transition temperature, T_c, of the product and the combined carbon content is shown in Fig. 2. The highest transition temperature was reached for the stoichiometric composition; it was 10.1 K. T_c decreased from 10.1 K to less than 4.2 K as the carbon content decreased from 50 to 47 at% C. This is similar to the decrease observed for tantalum carbide made by the carbonization

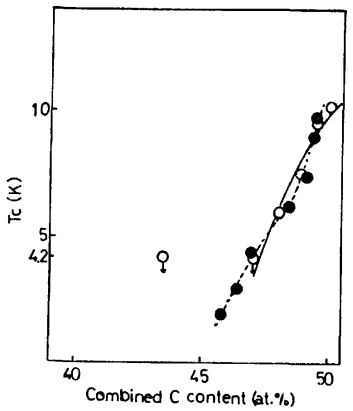

Fig. 2. T_c *vs.* combined carbon content.
○: this experiment, ●: Giorge *et al.*[2]

of metallic tantalum.[2]

The small amount of oxygen contained in the carbide remarkably decreases the T_c.[6] The oxygen content of the product formed in this work seems to be small. Therefore, it may be concluded that increasing the number of vacant carbon sites in the TaC lattice decreases the T_c. This conclusion is also supported by the results of the density measurement.

The Formation of the Rhodium Carbonyl Complexes from Chlorotris-[triphenylphosphine]rhodium with Alcohols in the Presence of Diene and Olefin

Akira YAMADA, Takashi FUKUDA, and Masaya YANAGITA
The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received February 8, 1974)

Synopsis. The decarbonylation of alcohols using chlorotris[triphenylphosphine]rhodium in the presence of diene or olefin occurs with the formation of the rhodium carbonyl complex and a hydrocarbon originating from the alcohol. The most suitable reaction system is rhodium compound/methanol/butadiene. The results suggest catalysis by a rhodium species.

It is well known that the decarbonylation of acyl halides and aldehydes by chlorotris[triphenylphosphine]rhodium ($RhCl(PPh_3)_3$: W-complex) yields chlorocarbonylbis[triphenylphosphine]rhodium ($RhCl(CO)(PPh_3)_2$: CO-complex) *via* an acyl complex as an intermediate.[1-3] A similar reaction of allylic alcohols by means of the W-complex occurs easily,[4-6] while the reaction of the common alcohols does not thus occur, though it does occur by means of another complex, $RhCl_3(PPh_3)_3$, with an alkaline base.[7] This note will briefly describe the successful abstraction of carbon monoxide from an alcohol molecule by means of the W-complex in the presence of diene or olefin.

When an alcoholic solution of the W-complex and diene or olefin was heated, the crystalline CO-complex[8] was formed quantitatively with the saturated hydrocarbon originating from the alcohol used. Only hydrogen gas instead of the hydrocarbon evolves from methanol. The reactions with other alcohols proceed at very low rates. These results are summarized in Table 1.

The title reaction requires a satisfactory dissolution of the W-complex into the reaction mixture at 80 °C. If one uses less of either alcohol or diene, the completion of the reaction requires a very long time. The reaction is insensitive to air and humidity. Olefin is also effective for the reaction, but shows a lower rate than diene. The presence of diene or olefin is essential to achieve the reaction, as is supported by Experiment No. 13 in Table 1. The reaction of allyl alcohol proceeds even in the absence of diene, as has previously been reported.[4-6]

The clarification of the reaction mechanism can be

made by an analysis of the by-products. When the W-complex/methanol/isoprene system was used, the hydrogenated products of isoprene could be observed as the main products, the total amount was found by gas chromatography to be 10 times as much as the yield of the CO-complex. Their compositions, shown on Table 2, resemble those of the reaction products from CO-complex/methanol/isoprene, but not those from W-complex/hydrogen/isoprene. It is noticeable that the products lack isopentane.

The above results indicate the following two conclusions: [1] on an identical rhodium atom, two hydrogen atoms of the methanol molecule migrate to isoprene and two others evolve as hydrogen gas, and [2] the CO-complex also induces the decarbonylation of the alcohol, suggesting a ligand-exchange reaction between carbonyl and isoprene. Consequently, the title reaction involves a catalytic scheme.

Experimental

In a glass autoclave, 100 mg of $RhCl(PPh_3)_3$ prepared according to the literature,[9] 5 ml of purified methanol, and 1 ml of distilled isoprene were placed. After evacuation, the reaction was carried out for 24 hr at 80 °C. The resultant yellow prism crystalline was isolated and washed with dry diethyl ether. The elemental-analytical results and IR spectrum of the product were identical with those of *trans*-$RhCl(CO)(PPh_3)_2$[8] prepared from $RhCl(PPh_3)_3$ and carbon monoxide. The crude product obtained in a lower yield was purified by recrystallization from methylene chloride–methanol. The hydrogenated products of diene and olefin and the evolved gas were analyzed by gas chromatography, using "benzyl cyanide–$AgNO_3$" and "Carbocieve" columns.

We wish to thank Dr. Jiro Tsuji of the Toray Co., Ltd., for his fruitful discussions and the Takeda Chem. Ind. Co., Ltd., and the Riken Vitamin Oil Co., Ltd., for their financial support.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (1), 355—356 (1975)

The Reaction of 3*H*-1,2-Benzodithiole-3-thione with Diphenyldiazomethane[1)]

Seizo TAMAGAKI, Ryoichi ICHIHARA, and Shigeru OAE*

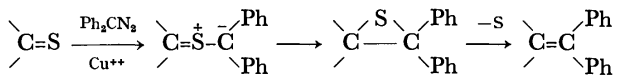
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

**Department of Chemistry, University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31*

(Received April 13, 1974)

Synopsis. 3*H*-1,2-Benzodithiole-3-thione (^{35}S=C<) reacted with diphenyldiazomethane in the presence of copper-(II) acetylacetonate to afford the corresponding 4,5-benzo-3-diphenylmethylene-1,2-dithiole with a predominant extrusion of the exocyclic sulfur atom, while with its selenium analog the exclusive loss of in-ring sulfur was observed, resulting in the formation of the selenium-migrated 4,5-benzo-3-diphenylmethylene-1,2-thiaselenole.

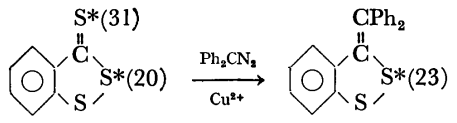
Recently, it has been extensively investigated by Schoenberg[2)] and other workers[3-7)] that thiocarbonyl compounds react with diphenyldiazomethane to afford, eventually olefinic compounds presumably *via* a transient ylide[8)] which would cyclize,[9)] and then eliminate sulfur, as is shown below:



Under similar conditions, however, 1,2-dithiole-3-thione (trithione), bearing a relatively stable thiocarbonyl moiety, has been reported to fail to give the anticipated olefin.[2)] In this report, we would like to present the results on one detailed mechanistic examination of the reaction between benzotrithione (I) and diphenyldiazomethane in the presence of a catalytic amount of copper salt. For the sake of comparison, ^{35}S-labeled 3*H*-1,2-benzodithiole-3-thione (^{35}S=C<) (II) and selenium-substituted 4,5-benzo-1,2-dithiole-3-selone (III) were synthesized and treated with diphenyldiazomethane.

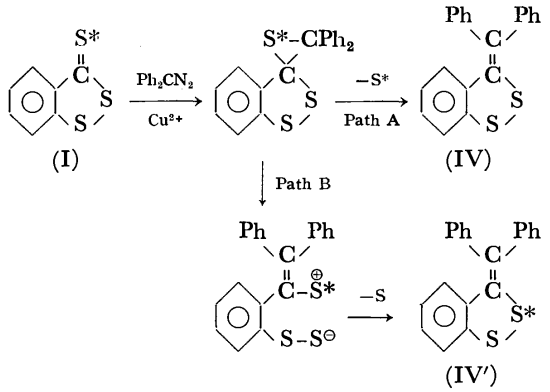
Results and Discussion

When 3*H*-1,2-benzodithiole-3-thione (I) was treated with three equivalents of diphenyldiazomethane in refluxing benzene in the presence of a catalytic amount of copper acetylacetonate, a product (IV) was obtained in a moderate yield. Similarly, the benzotrithione labeled with ^{35}S, both at the thione sulfur and the thiol sulfur by the ratio of 60: 40, was subjected to the same reaction. The ^{35}S-containing values are shown below:



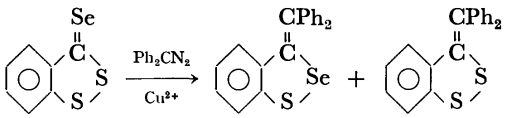
(I) or (II) (IV) (10^4 cpm/mol)

An inspection of the ^{35}S-labeling experiment suggests that the major part (72.7%) of the reaction apparently proceeds through the incipient formation of the thiirane ring, which is subsequently converted to the corresponding olefin, with the extrusion of the sulfur atom of the three-membered ring itself, as observed in usual cases (as is shown below (Path A)), while the remaining minor portion (27.3%) of the reaction is considered to take an alternative migration, Path B:



Scheme 1.

Meanwhile, sulfur migration proceeding along Path B was observed to take place exclusively when the corresponding selenium-substituted trithione (III) was allowed to react, but at the somewhat lower temperature of 60 °C. The selenium-migrated olefin, *i.e.*, 4,5-benzo-3-diphenylmethylene-1,2-thiaselenole (V), was found to be formed as a sole product in a 43% yield, apparently resulting from the extrusion of thiol sulfur rather than from that of exocyclic selenium. In this case, no formation of the corresponding olefinic sulfur product (IV) is noticiably not even by a careful gas-chromatographic analysis of the reaction mixture.



(III) (V) (IV not detected)

The marked difference in reaction modes between the sulfur (II) and selenium (III) compounds can not be explained with our present knowledge. Several lines of experiments to clarify this point are now under way here.

Experimental

Reaction of I with Diphenyldiazomethane. Treating 0.3 g (1.6 mmol) of I with 1.0 g (5.1 mmol) of diphenyldiazomethane in 30 ml of refluxing benzene containing copper acetylacetonate as the catalyst for 6 hr afforded a viscous liquid, which was then subjected to column chromatography through silica gel, using *n*-hexane as the solvent. The major, orange-colored portion (IV) eluted second was collected and recrystallized from *n*-hexane. The yield was 0.2 g (40%); mp 162—163 °C; IR (KBr) 1610, 1585, 1500, 1450, 1170,

970, 750, 700 cm^{-1}; UV λ_{max} ($CHCl_3$) 385 nm (ε: 7300). Found: C, 75.11; H, 4.39%. Calcd for $C_{20}H_{14}S_2$: C, 75.48; H, 4.43%. Mass spectrum *m/e*: 318 (M^+), 286 (M^+-S), 257 (metastable).

Reaction of III with Diphenyldiazomethane. A mixture of 0.2 g (0.7 mmol) of III, 0.3 g (1.5 mmol) of diphenyldiazomethane, and a small amount of the catalyst was treated at 60 °C for 3 hr. A procedure similar to that employed above gave 0.1 g of V; mp 175—176 °C. IR (KBr) 1580, 1490, 1060, 750, 695 cm^{-1}; UV λ_{max} ($CHCl_3$) 391 nm (ε: 6400). Found: C, 65.29; H, 3.75%. Calcd for $C_{20}H_{14}SSe$: C, 65.74; H, 3.86%. Mass spectrum *m/e*: 366 (M^+), 286 (M^+-Se), 223.5 (metastable).

We wish to thank Professor Takayuki Otsu for his helpful discussions and Dr. Reiko Kiritani of the Radiation Center of Osaka Prefecture for performing the ^{35}S-activity determination.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (1), 357—358 (1975)

The Syntheses of Several *N,N'*-Bis(hydroxymethyl)parabanic Acid Derivatives

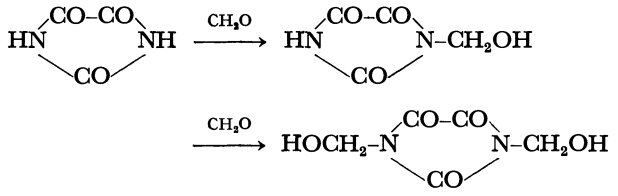
Shigeo TANIMOTO,* Ryozo TANIYASU, and Masaya OKANO
Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received July 17, 1974)

Synopsis. Starting from *N,N'*-bis(hydroxymethyl)-parabanic acid, the following new compounds have been synthesized: *N,N'*-bis(arylaminomethyl)parabanic acids, *N,N'*-bis(bromomethyl)parabanic acid, and *N,N'*-bis(alkoxymethyl)parabanic acids.

Though *N,N'*-bis(hydroxymethyl)parabanic acid (**1**) may serve as a reactive bifunctional heterocycle, little is known about its reactions or about its derivatives. The present communication will be concerned with the syntheses some of its derivatives.

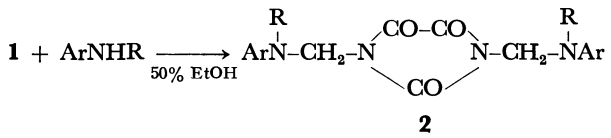
The preparation of **1** from parabanic acid and two moles of formaldehyde was first reported by Oda and Baba:[1]



1

When **1** was mixed with aromatic primary or secondary amines in 50% ethanol at room temperature, the corresponding bisarylaminomethyl compounds (**2**) were readily formed. They separated out from the reaction medium in good yields and were easily purified by recrystallization. Several bisarylaminomethyl compounds are listed in Table 1.

A similar transformation, proposed by Winstead and Heine[2] as a method for the identification of aromatic amines, involves the condensation of phthalimide with formaldehyde and aromatic amines in boiling 80% ethanol. Since our reaction proceeds smoothly without heating, it may also offer advantages in the identification of primary or secondary aromatic amines as well as in their removal from the mixture with tertiary amines.



2

The conversion of **1** into *N,N'*-bis(bromomethyl)-parabanic acid (**3**) was achieved by treatment with excess phosphorus tribromide in refluxing benzene. The bisbromomethyl compound thus obtained was considerably reactive toward nucleophiles. For example, when the reaction of **3** with primary or secondary aliphatic alcohols was carried out in the presence of potassium iodide, the expected *N,N'*-bis(alkoxymethyl)-

a) Besides elemental analyses, the structure of the products was confirmed by NMR. b) Recrystallized from ligroin.

parabanic acids (**4**) were obtained in yields of 45—78%. However, the reaction with methanol failed to give the desired product. The results are shown in Table 2.

Experimental

N,N'-*Bis(hydroxymethyl)parabanic Acid (1).* A mixture of 5.7 g (0.05 mol) of parabanic acid and 8.0 g (0.10 mol) of 37% formalin was refluxed for 3—4 hr. The reaction mixture soon became a clear solution. When the solution was then allowed to cool, a crystalline solid separated. This was collected and dried to give 6.4 g (74%) of a white powder. Recrystallization from ethanol gave the pure compound; mp 127—131 °C (lit,[1] mp 130 °C).

N,N'-*Bis(arylaminomethyl)parabanic Acids (2).* A typical procedure will be described; all the other products were obtained in an analogous manner. A mixture of 1.4 g (0.015 mol) of aniline and the same amount of 50% ethanol was added, drop by drop, to a solution of 1.1 g (0.0063 mol) of **1** in 30 ml of 50% ethanol at room temperature. The solution immediately turned yellow, and a crystalline solid soon began to precipitate. After standing for 3—4 hr, the precipitate was collected and recrystallized from ethanol. Yield, 1.5 g (73%); mp 71—74 °C.

N,N'-*Bis(bromomethyl)parabanic Acid (3).* To a stirred suspension of 5.0 g (0.029 mol) of **1** and 200 ml of dry benzene, we added 30 g (0.11 mol) of phosphorus tribromide; the reaction mixture was then refluxed for 3 hr, during which time a vigorous reaction occurred. The filtration of the concomitant resinous product from the reaction mixture, followed by the removal of the solvent *in vacuo*, provided 3.9 g (45%) of a crude light-yellow solid. Recrystallization from benzene gave light-yellow crystals of **3**; mp 159—162 °C. Found: C, 20.35; H, 1.36; N, 9.36%. Calcd for $C_5H_4Br_2N_2O_3$: C, 20.02; H, 1.34; N, 9.34%. When stored in a moist atmosphere, **3** showed signs of decomposition, as evidenced by brown-coloring and a lowered melting point.

N,N'-*Bis(alkoxymethyl)parabanic Acids (4).* A typical example will be given. A solution of 1.5 g (0.005 mol) of **3** in 50 ml of ethanol containing 1.7 g (0.01 mol) of potassium iodide was stirred for 4 hr at room temperature. The subsequent evaporation of the ethanol gave white crystals of *N,N'*-bis(ethoxymethyl)parabanic acid (**4**, R'=Et); yield, 0.8 g (70%); mp 103—105 °C.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (1), 359—360 (1975)

The Preparation of 3- and 4-Fluorophthalic Anhydrides by Fluorodenitration

Nobuo ISHIKAWA, Toshio TANABE, and Dan HAYASHI
Tokyo Institute of Technology, Department of Chemical Engineering, Meguro-ku, Tokyo 152

(Received July 22, 1974)

Synopsis. 3- And 4-fluorophthalic anhydrides were prepared by heating the respective nitrophthalic anhydrides with potassium fluoride with or without an aprotic polar solvent.

Mono and difluorophthalic anhydrides have been synthesized mainly by the oxidation of fluorinated *o*-xylenes.[1,2] However, these preparative routes involve a tedious Balz-Schiemann reaction in order to introduce the fluorine atom into an aromatic ring. A simple preparative method for 3-fluorophthalic anhydride has, however, been reported by Heller, who used a halogen exchange process which involves merely baking 3-chlorophthalic anhydride with potassium fluoride.[3] 3-Chlorophthalic anhydride, on the other hand, is most conveniently prepared by the chlorination of 3-nitrophthalic anhydride,[4] which is obtained by the nitration of phthalic anhydride together with the 4-nitro isomer.[5] In this connection, we examined the fluorination of 3- and 4-nitrophthalic anhydrides directly with potassium fluoride, since fluorodenitration on aromatic nitro compounds is not unusual in the literature.[6,7]

When 3-nitrophthalic anhydride was heated with about three moles of potassium fluoride at 180—190 °C, a temperature which is a little higher than the melting point of the nitro compound, the reaction proceeded smoothly, with the evolution of a brown gas of nitrogen oxide. The reaction was completed within a rather short period, 30—60 min, judging from the gas chromatographic observation. The yield of almost pure 3-fluorophthalic anhydride was about 65%. A higher temperature or a longer reaction time had unfavorable results; for instance, an explosive reaction occurred above 210 °C.

4-Nitrophthalic anhydride was also subjected to a similar process. The nitro group of this compound was less reactive for the fluorination, and the reaction required a higher temperature (190—195 °C) and a longer reaction time (—75 min). This is probably due to the weaker inductive effect of the electron-withdrawing dicarboxyl anhydride group, which is located farther from the nitro group than in the case of the 3-nitro isomer.

Since such polar aprotic solvents as dimethylformamide, dimethylsulfoxide, sulfolane, and hexamethyl phosphortriamide are well known to accelerate nucleophilic aromatic substitutions, including fluorination, we also used these solvents. In these aprotic solvents, the reactions seemed to proceed more easily and a lower temperature (80—90 °C) was enough for them to take place. However, the separation of the products from the reaction mixture was difficult because of their high solubility in these solvents as well as in water. We had to extract them with diethyl ether several times from the reaction mixture after dilution with water. This process made the yield of the fluorophthalic anhydride unreproducible. Further, a part of the fluorophthalic anhydride seemed to be attacked nucleophilically with these solvents.

The results of several runs carried out are shown in Table 1.

TABLE 1. FLUORODENITRATION OF NITROPHTHALIC ANHYDRIDES

10	3-NO_2	3	DMSO	80	60	61

Experimental

Nitrophthalic Acids and Their Anhydrides. The nitration of phthalic anhydride was carried out according to the procedure described in Org. Syn.;[5] it gave pure 3-nitrophthalic acid (mp 214—216 °C (lit,[5] 215—218 °C)) in a 30% yield after recrystallization from water. This acid was then converted into the anhydride (mp 163—165 °C (lit,[8] 163—164 °C)) by treating it with acetic anhydride.[8]

From the mixture of isomers of nitro compounds which was obtained from the mother liquors of the recrystallizations, 4-nitrophthalic acid (mp 159—160 °C (lit,[9] 164—164.5 °C)) was separated *via* esterification.[10] A subsequent treatment with acetic anhydride gave 4-nitrophthalic anhydride (mp 118—119 °C (lit,[9] 120—120.5 °C)).

Fluorophthalic Anhydrides. Without Any Solvent: A typical procedure was as follows. A mixture of 3-nitrophthalic anhydride (4.85 g, 0.026 mol) and potassium fluoride dehydrated by baking (4.35 g, 0.075 mol) was heated in an oil-bath and vigorously stirred for 30 min, keeping the temperature at 180—185 °C. During the reaction, nitrogen oxide gas evolved; it was led into a hood. After cooling, the reaction mixture was treated with benzene, and the fluorinated product was extracted by filtration. The solvent was then evaporated from the filtrate, giving 3-fluorophthalic anhydride (2.72 g, 66%, mp 159—160 °C). Recrystallization from benzene gave pure crystals (mp 161.5—162.5 °C (lit,[3] 160 °C)). IR (KBr): 1870, 1855, 1780 (C=O), 1265 (C–F) cm^{-1}. ^{19}F NMR (from int. C_6H_5F in C_6H_6): δ −3.4 ppm.

The reaction between 4-nitrophthalic anhydride and potassium fluoride was run in a similar manner, giving 4-fluorophthalic anhydride (mp 79—80 °C (lit,[2] 76—78 °C) (Table 1)). IR: 1855, 1830, 1780 (C=O), 1280 (C–F) cm^{-1}. ^{19}F NMR: δ −13.0 ppm.

With A Solvent: Nitrophthalic anhydride (5 g) and baked potassium fluoride (4.5 g) were heated in a solvent while being mechanically stirred. On cooling, the mixture was diluted with water, made acidic with hydrochloric acid, and extracted with diethyl ether several times. The ethereal extract was dried over magnesium sulfate and evaporated to give fluorophthalic anhydride (Table 1).

The Preparation of Several Copper(I) and Silver Polyfluoroalkanethiolates and of Polyfluoroalkyl Aryl (or Alkyl) Sulfides

Tomoya KITAZUME and Nobuo ISHIKAWA

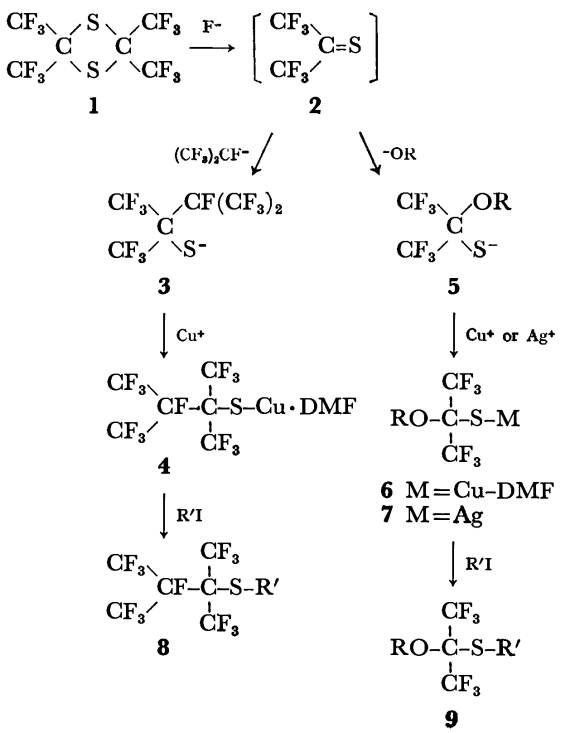
Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received July 29, 1974)

Synopsis. 2,2,4,4-Tetrakis(trifluoromethyl)-1,3-dithietane (**1**) in the KF-DMF system was treated with hexafluoropropene in the presence of CuBr to give copper(I) 1,1,2-tris(trifluoromethyl)tetrafluoropropanethiolate (**4**). A similar reaction of **1** with alcohols in the presence of CuBr or $AgNO_3$ gave copper(I) (**6**) and silver 1-alkoxy-1-trifluoromethyl-2,2,2-trifluoroethanethiolate (**7**) respectively. These copper(I) and silver polyfluoroalkanethiolates condensed with aryl or alkyl iodides to afford 1,1,2-tris(trifluoromethyl)-tetrafluoropropyl (**8**) and 1-alkoxy-1-trifluoromethyl-2,2,2-trifluoroethyl aryl(or alkyl) sulfides (**9**).

In our previous paper[1] on the nucleophilic reactions of 2,2,4,4-tetrakis(trifluoromethyl)-1,3-dithietane (**1**) in the presence of potassium fluoride in dimethylformamide, we reported that hexafluorothioacetone (**2**) seems to be released during the reaction by the action of the fluoride ion on **1**, and that reaction products between **2** and nucleophiles were obtained. That study has now been continued, examining a similar reaction in which the heptafluoroisopropyl anion was used as the nucleophile. The expected product, 1,1,2-tris(trifluoromethyl)tetrafluoropropanethiol (**3**) was isolated in the form of copper(I) salt (**4**), and it was found that this copper thiolate was a useful reagent for the preparation of branched perfluorohexyl aryl or alkyl sulfides (**8**).

Copper and silver 1-alkoxy-1-trifluoromethyl-2,2,2-trifluoroethanethiolates, **6** and **7**, were also obtained by the reaction of **1** with alcohols in the presence of metal ion, and these thiolates condensed easily with aryl iodides to give 1-alkoxy-1-trifluoromethyl-2,2,2-trifluoroethyl aryl sulfides, **9**.



The Preparation of Copper(I) 1,1,2-Tris(trifluoromethyl)-tetrafluoropropanethiolate. The heptafluoroisopropyl anion, which is formed readily by the action of the fluoride ion on hexafluoropropene, is known to be an effective nucleophile.[2] The reaction between 2,2,4,4-tetrakis(trifluoromethyl)-1,3-dithietane (**1**) and hexafluoropropene was examined in the presence of potassium fluoride in dimethylformamide. Since the resulting perfluoroalkanethiol was presumed to be readily oxidized, we carried out the reaction in the presence of copper(I) bromide in order to trap the thiol in the form of copper(I) thiolate. The reaction proceeded smoothly at 50 °C, and the expected copper thiolate was isolated from the reaction products in a yield of 52% by acetone extraction. This compound was a fairly stable solid, with a melting point of 78—80 °C; it was an adduct with one mole of dimethylformamide. The structure was evident from its IR, NMR, and mass spectra. In the IR spectrum, the presence of an amide group was revealed by the strong band at 1650 cm^{-1}. In the ^{19}F NMR spectrum, three signals appeared, at −18.8 (doublet), −17.0 (singlet), and 124.7 (multiplet) ppm;* they are probably due to $CF(CF_3)_2$, $C(CF_3)_2$, and $CF(CF_3)_2$, respectively. In the mass spectrum, two important fragment peaks, *m/e* 415 ($C_6F_{13}SCu^+$) and *m/e* 73 ($C_3H_7NO^+$), appeared, in addition to the molecular ion, M^+ 488. The other fragment peaks at *m/e* 351 and *m/e* 344 can be explained by the elimination of Cu and CF_3 respectively from *m/e* 415. The ions of *m/e* 182 (C_3F_6S), 132 (C_2F_4S), and 113 (C_2F_3S), which are characteristic of hexafluorothioacetone derivatives, also appeared.

The Preparation of Copper(I) and Silver 1-Alkoxy-1-trifluoromethyl-2,2,2-trifluoroethanethiolates. In our investigation of the reactions between 2,2,4,4-tetrakis(trifluoromethyl)-1,3-dithietane (**1**) and alcohols in the potassium fluoride–dimethylformamide system, 1-alkoxy-1-trifluoromethyl-2,2,2-trifluoroethanethiols (**5**) seemed to be formed; however, they were finally oxidized and isolated as disulfides.[1]

As we desired to capture the thiol, **5**, in the form of metal thiolates as evidence of the reaction pass, these reactions were carried out in the presence of silver or copper salt. When silver nitrate was used, silver thiolates were obtained as stable white crystals, which were isolated from the reaction products by extraction with acetone.

* All the ^{19}F NMR chemical shifts throughout this article are given in ppm from external trifluoroacetic acid.

a) ^{19}F Chemcal shifts are given in δ ppm from ext. CF_3CO_2H in CCl_4.

Copper thiolates were also obtained by using copper(I) bromide instead of silver nitrate in the above reaction. The product isolated from the acetone extract was an adduct with one mole of dimethylformamide, as in the case of **4**. The IR spectrum revealed a strong band at 1640 cm^{-1} due to the amide group; the other major bands were similar to those of **7**.

The Condensation of Silver and Copper(I) Thiolates with Aryl(or Alkyl) Iodides. The condensation of silver and copper alkanethiolates with aryl or alkyl iodides is well known.[3-5] The silver and copper thiolates mentioned above also underwent condensation with aryl and alkyl iodides to give polyfluoroalkyl aryl or alkyl sulfides (Tables 1 and 2). The reactions proceeded in dimethylformamide at 80—100 °C under a nitrogen atmosphere. Especially, the condensation of various substituted aryl iodides and the copper perfluorohexanethiolate (**4**) seems to be a useful synthetic method for higher perfluoroalkyl thiobenzenes, which are valuable intermediates for surface-active compounds.

Experimental

Copper(I) 1,1,2-Tris(trifluoromethyl)tetrafluoropropanethiolate-DMF Adduct (4). Hexafluoropropene was bubbled into a mixture of the dimer of hexafluorothioacetone, **1** (7.3 g, 0.02 mol), copper(I) bromide (5.7 g, 0.04 mol), potassium fluoride (4.5 g, 0.077 mol), and dimethylformamide (50 ml) at 50 °C until no more absorption of the gas took place. The reaction mixture was then poured into water, and the precipitates were separated by filtration and washed with water. This black solid was subjected to extraction with hot acetone, and the solvent was removed by evaporation to give an orange product; mp 78—80 °C (10 g, 52%). This was a 1:1 adduct of **4** with dimethylformamide. Found: C, 21.5; H, 1.71; N, 2.48; F, 50.5%. Calcd for $C_9H_7F_{13}NOSCu$: C, 22.2; H, 1.44; N, 2.87; F, 50.7%.

Copper(I) 1-Methoxy-1-trifluoromethyl-2,2,2-trifluoroethanethiolate (6). A mixture of **1** (3.64 g, 0.01 mol), methyl alcohol (0.64 g, 0.02 mol), copper(I) bromide (2.86 g, 0.02 mol), and potassium fluoride (1.71 g, 0.029 mol) in dimethylformamide (30 ml) was stirred for 24 hr at room temperature. The resulting mixture was worked up as above to give **6** (yield, 63%); mp 68—70 °C. Found: C, 24.3; H, 2.95; N, 4.21; F, 32.4%. Calcd for $C_7H_{10}F_6NO_2SCu$: C, 24.1; H, 2.88; N, 4.01; F, 32.6%. IR: 1640 cm^{-1} (-CO-N-).

Silver 1-Methoxy-1-trifluoromethyl-2,2,2-trifluoroethanethiolate (7) (R=Me). A mixture of **1** (3.64 g, 0.01 mol), methyl alcohol (0.64 g, 0.02 mol), silver nitrate (3.4 g, 0.02 mol), potassium fluoride (1.30 g, 0.022 mol), and dimethylformamide (30 ml) was worked up as above, giving a white product; mp 132—133 °C (4.04 g, 57%). Found: C, 15.2; H, 0.76; F, 35.2%. Calcd for $C_4H_3F_6OSAg$: C, 15.0; H, 0.94; F, 35.5%. NMR (in DMSO-d_6): ^{1}H, 5.76 (OMe, s); ^{19}F, −6.00 (CF_3, s).

The reaction with ethanol was run similarly; here the product (mp 150—151 °C) was obtained in a yield of 34%.

Condensation Reactions. A): A mixture of **4** (5.32 g, 0.011 mol), *o*-iodonitrobenzene (2.50 g, 0.01 mol), and DMF (50 ml) was stirred under an atmosphere of nitrogen at 80—90 °C for 24 hr. After the copper iodide had been removed by filtration, the filtrate was poured into water, and the precipitates were collected and recrystallized from *n*-hexane to give **8** (R′=*o*-$NO_2C_6H_5$) (mp 63—65 °C) in a yield of 45%. Found: C, 30.7; H, 0.96; N, 2.73; F, 51.9%. Calcd for $C_{12}H_4F_{13}NO_2S$: C, 30.5; H, 0.85; N, 2.96; F, 52.2%. IR: 1510, 1358 (NO_2) cm^{-1}.

B): A mixture of **6** (R=Me, 7.0 g, 0.025 mol), *o*-iodonitrobenzene (5.0 g, 0.02 mol) and DMF (50 ml) was worked up such as has been described above at 90—100 °C for 24 hr. The product was recrystallized from *n*-hexane to give **9** (R′=*o*-$NO_2C_6H_5$, 75%); mp 69—70 °C. Found: C, 36.0; H, 2.31; N, 4.25; F, 33.9%. Calcd for $C_{10}H_7F_6NO_3S$: C, 35.8; H, 2.10; N, 4.18 F, 34.0%. IR: 1525, 1358 (NO_2) cm^{-1}.

The Bromination of 1- and 2-Methylthiophenazine Derivatives

Masao TADA

The Research Institute for Tuberculosis, Leprosy and Cancer, Tohoku University, Hirosemachi, Sendai 980

(Received August 7, 1974)

Synopsis. The bromination of 1-methylthiophenazine has been investigated and found to occur in Position 4. 2-Methylthiophenazine and its 5-oxide have been found to be brominated in Position 1. The bromination of these compounds in acetic acid gave both a ring-substituted product and its oxidised product.

In a previous paper,[1] it was reported that the methylthio- and bis(methylthio)phenazine derivatives were readily synthesized by the reactions of halogenophenazine derivatives with methyl mercaptan. In connection with the synthetic study of methylthiophenazine derivatives with potential biological activities, this paper will describe the brominations of 1- and 2-methylthiophenazine derivatives, by which it becomes feasible to prepare bis(methylthio)phenazines as a second route of synthesizing them.

The bromination of 1- (**1**) and 2-methylthiophenazine (**2**) was carried out using bromine in chloroform, to give two bromo compounds, **3** and **4** respectively. When the bromination of **1** was carried out using bromine in acetic acid, both the ring-substituted product, **3**, and its oxidised product, **5**, were produced. Compound **2** was treated with bromine under similar conditions to form **4** and its oxidised product, **6**, in good yields. Compounds **5** and **6** were also obtained by the controlled oxidation of **3** and **4** respectively with potassium bromate. It has been reported that the bromination of alkyl aryl sulfides in acetic acid gives ring-substituted products,[2] while the chlorination in acetic acid gives oxidised products.[3] It may be anticipated that **1** and **2** will prove susceptible to electrophilic attack in the 4- and 1-positions respectively. This results from the localizing of a negative charge at C_4 in **1** and at C_1 in **2**.[2,4] The positions of the bromine atoms in **3** and **4** were confirmed by the substitution reactions of **3** and **4** with methyl mercaptan.

The reactions of **3** and **4** with the reagent afforded 1,4- (**7**) and 1,2-bis(methylthio)phenazine (**8**) respectively, which had both been derived from 1,4- and 1,2-dichlorophenazine.[1] It was thus confirmed that the oxidised products, **5** and **6**, are 1-bromo-4-methylsulfinyl- and 1-bromo-2-methylsulfinylphenazine respectively.

The bromination of 1- (**9**) and 3-methylthiophenazine-5-oxide (**10**) gave 1- (**11**) and 3-methylsulfinylphenazine-5-oxide (**12**) respectively, and no ring-substituted product was obtained in either case. 2-Methylthiophenazine-5-oxide (**13**) was treated with bromine under similar conditions to yield 1-bromo-2-methylthiophenazine-5-oxide (**14**), which was then converted into **4** by the reduction. The replacement reaction of **14** with an excess of methyl mercaptan afforded **8**, accompanied by the removal of the oxide group in *N*-oxide.

The oxidation of the methylthio compound (**3**) and its sulfoxide (**5**) with an excess of hydrogen peroxide in acetic acid gave sulfone (**15**). The treatment of **4** with a limited amount of hydrogen peroxide in acetic acid produced 1-bromo-2-methylsulfonylphenazine (**16**), which was also obtained from sulfoxide **6**. The oxidations of **4**, **6**, **14**, and **16** all afforded the same compound, 1-bromo-2-methylsulfonylphenazine-5-oxide (**17**).

Experimental

The melting points, the appearances, the solvents of recrystallization, and the results of elemental analyses are all listed in Table 1.

The Bromination of 1. *In Chloroform*: Into a solution of **1** (2.26 g, 10 mmol) in chloroform (30 ml), a solution of bromine (1.9 g, 12 mmol) in chloroform (10 ml) was stirred, drop by drop. The solution was stirred for a further 6 hr and then allowed to stand overnight at room temperature. The reaction mixture was evaporated under reduced pressure to dryness. The residue was suspended in diluted ammonia water, washed with water, dried, and chromatographed over alumina, using benzene as the solvent. From the effluent, **3** (1.12 g, 37%) was obtained.

In Acetic Acid: Into a solution of **1** (2.26 g, 10 mmol) in acetic acid (200 ml), a solution of bromine (1.9 g, 12 mmol) in acetic acid (10 ml) was stirred, drop by drop. The solution was then stirred for a further 3 hr and allowed to stand overnight. The mixture was then poured into water to yield crystals, which were subsequently dissolved in benzene. The benzene solution was then passed through a column of alumina and eluted with benzene. From the first effluent, **3** (0.87 g, 29%) was obtained. When the column was then further eluted with chloroform, **5** (0.84 g, 26%) was obtained.

The Bromination of 2. *In Chloroform*: **2** (2.26 g, 10 mmol) and bromine (1.9 g, 1.2 mmol) were treated as in the Procedure used in the preparation of **3** to afford **4** (2.36 g, 77%).

a) All the melting points are uncorrected. b) Granules, needles, and prisms are abbreviated as g, n, and p, respectively.
c) Decomposition point.

In Acetic Acid: **2** (2.26 g) was treated in the way described in the bromination of **1** to give both **4** (1.52 g, 50%) and **6** (1.02 g, 32%).

1-Bromo-4-methylsulfinylphenazine (5). Into a solution of **3** (305 mg) in acetic acid (50 ml), potassium bromate (56 mg) was stirred in small portions. The mixture was then warmed at 40 °C for 4 hr and allowed to stand overnight at room temperature. After the dilution of the water, sodium bicarbonate (10 g) was added to the reaction mixture. The crystals which separated were collected and washed with water to give **5** (310 mg, 97%).

1-Bromo-2-methylsulfinylphenazine (6). **4** (305 mg) was treated as in the above experiment to afford **6** (290 mg, 90%).

1,4-Bis(methylthio)phenazine (7). A mixture of **3** (305 mg) and a 20% aqueous solution (1.5 ml) of sodium methyl mercaptide in ethanol (150 ml) was refluxed for 6 hr and then diluted with water (100 ml). The crystals therby formed were collected and washed with water to yield **7** (230 mg, 85%), which showed no depression of melting point on admixture with an authentic specimen[1] of **7**.

1,2-Bis(methylthio)phenazine (8). *From 4*: **4** (915 mg) was treated as in the case of **7** to afford **8** (730 mg, 89%).

From 14: **14** (320 mg) was treated as in the case of **7** to give **8** (216 mg, 80%).

1-Methylsulfinylphenazine-5-oxide (11). Into a solution of **9** (1.41 g) in chloroform (50 ml), a solution of bromine (0.8 g) in chloroform (10 ml) was stirred, drop by drop. The mixture was then treated as in the Procedure used in the preparation of **3** to give **11** (530 mg, 41%). **9** (550 mg, 39%) was also recovered.

3-Methylsulfinylphenazine-5-oxide (12). **10** (1.41 g) was treated as in the above experiment to yield **12** (800 mg, 62%). **10** (260 mg, 18%) was also recovered.

1-Bromo-2-methylthiophenazine-5-oxide (14). **13** (1.41 g) was treated as in the case of **11** to give **14** (1.15 g, 72%).

A solution of **14** (160 mg) in dimethylaniline (4 ml) and acetic anhydride (10 ml) was refluxed for 4 hr and then evaporated to dryness under reduced pressure. The residue was chromatographed over alumina, using benzene as the solvent. From the effluent, **4** (110 mg, 72%) was obtained.

1-Bromo-4-methylsulfonylphenazine (15). *From 3*: To a solution of **3** (100 mg) in acetic acid (50 ml), a 30% aqueous solution (2 ml) of hydrogen peroxide was added. The mixture was warmed at 55 °C for 2 hr and then poured into water to give **15** (105 mg, 95%).

From 5: **5** (100 mg) was treated as in the case described above to afford **15** (85 mg, 81%).

1-Bromo-2-methylsulfonylphenazine (16). *From 4*: To a solution of **4** (610 mg) in acetic acid (35 ml), a 30% aqueous solution (3 ml) of hydrogen peroxide was added. The mixture was treated as in the procedure used in the preparation of **15** to give **16** (640 mg, 95%).

From 6: **6** (100 mg) and a 30% hydrogen peroxide aqueous solution (0.5 ml) were treated in the way described above to yield **16** (80 mg, 86%).

1-Bromo-2-methylsulfonylphenazine-5-oxide (17). *From 4*: To a solution of **4** (610 mg) in acetic acid (80 ml) and acetic anhydride (2 ml), a 30% aqueous solution (5 ml) of hydrogen peroxide was added. The mixture was warmed at 55 °C for 20 hr and then treated as in the above experiment to give **17** (630 mg, 89%).

From 6: **6** (320 mg) was treated as in the case described above to give **17** (317 mg, 90%).

From 14: *14* (100 mg) was treated as in the procedure in the preparation of **15** to yield **18** (95 mg, 86%).

From 16: *16* (220 mg) was treated as in the case of the From **4** above to give **17** (200 mg, 86%).

The author is grateful to Professor Yusaku Ikegami of Tohoku University for his encouragement and to Miss Mieko Sasaki to her experimental cooperation.

(Received July 18, 1974)

Synopsis. Ethyl chloroglyoxalate arylhydrazones (III) react with sodium phenolates in ethanol and give ethyl aryloxyglyoxalate arylhydrazones (IV). The latter ester hydrazones rearrange at high temperatures to the hydrazides (V). Structural assignments have been made on the basis of elemental and spectral analyses and independent chemical evidence whenever possible.

Arylhydrazones of aryl carboxylates (I)[2-5] have been recently found to undergo a Chapman-like rearrangement[6] on heating and give the hydrazides (II). In previous communications, the synthesis and thermal rearrangement of two types of these esters were discussed.[2-5] In view of our continuing interest in this reaction, we have extended it to arylhydrazones of dicarboxylic acid esters. In this communication we wish to report on the synthesis and thermolysis of a series of ethyl aryloxyglyoxalate arylhydrazones (IV).

$RC(OAr'):NNHAr$ (I) $\quad RCONHN(Ar')Ar$ (II)

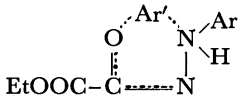
$EtOOCC(Cl):NNHAr$ (III) $\quad EtOOCC(OAr')=NNHAr$ (IV)

$EtOOCCONHN(Ar')Ar$ (V) $\quad EtOOCCON(Ar')NHAr$ (VI)

Treatment of ethyl chloroglyoxalate arylhydrazones (III)[7] with ethanolic sodium phenolate at room temperature gave the corresponding esters (IV) in 60—80% yields. The structure assignments of the latter esters were derived from their elemental analyses and the following spectral data. Thus, the IR spectra of all products (IV) obtained exhibit two characteristic strong absorption bands near 1245 and 1720 cm^{-1}. The former band was assigned to the asymmetric stretch of the aryl ether linkage[3,8] whereas the latter to the α,β-unsaturated ester carbonyl group.[9] The absorption in the UV region was in each case characterized by the presence of three bands in the 340—320; 290—270; and 240—225 nm regions. Such spectral characteristics are similar to those of typical hydrazones.[3,9,10] The physical constants of the esters (IV) prepared are shown in Table 1.

Next we have found that heating IVa ($Ar=Ar'=C_6H_5$) in xylene for 4 hr under reflux afforded a colorless product that was analyzed correctly to be $C_{16}H_{16}N_2O_3$. It was distinguished from the starting material (IVa) by the lack of the C–OAr band and the presence of two CO bands at 1740 and 1710 cm^{-1} in its IR spectrum. On the basis of these data, the product thus obtained was assigned the structure of the hydrazide (Va, $Ar=Ar'=C_6H_5$). That the product obtained was the hydrazide Va and not the isomeric hydrazide (VIa, $Ar=Ar'=C_6H_5$) was supported by the fact that it gives upon hydrolysis an asymmetric diphenylhydrazine identified as its benzoyl derivative.[11]

The foregoing results indicate that the thermolysis of IV results in a 1,4-shift of an aryl group from oxygen to nitrogen probably *via* a five-membered cyclic transition state of type VII.[3]



VII

Chemical evidence for the structure V was further provided by the thermal rearrangement of the two isomeric esters IVb ($Ar=C_6H_5$; $Ar'=4\text{-}CH_3C_6H_4$) and

IVc (Ar=4-$CH_3C_6H_4$; Ar′=C_6H_5). The products obtained from the thermolysis of these two esters were identical in all respects. Other ester hydrazones in series IV, when subjected to the same treatment gave the corresponding hydrazides (V) in 80—88% yields. Table 2 lists the rearrangement products obtained together with their properties.

Experimental

Mp's were determined on a Meltemp apparatus and are uncorrected. IR spectra were obtained on a Beckman IR 12 spectrophotometer in KBr. UV spectra were measured on a Unicam SP1000 spectrophotometer in 95% EtOH. Microanalyses were performed by Alfred Bernhardt, Microanalytisches Laboratorium, West Germany.

Ethyl chloroglyoxalate arylhydrazones (IIIa—c) used in the synthesis of IV were prepared from the corresponding substituted anilines by diazotization and coupling with ethyl α-chloroacetoacetate in NaOAc-buffered solution of EtOH as previously described.[7] The compounds prepared gave the following values on analysis: (Compound No., Ar, mp, N% found, N% calcd): IIIa, C_6H_5, 79—80 °C (lit,[7b] mp 77—79 °C); IIIb, 4-$CH_3C_6H_4$, 96—97 °C, 11.62, 11.65; and IIIc, 3-$CH_3C_6H_4$, 74—75 °C, 11.59, 11.65.

Ethyl Aryloxyglyoxalate Arylhydrazones (IVa—k). To an ethanolic solution of sodium ethoxide [prepared from sodium metal (0.11 g, 0.005 g·atom) and 20 ml of absolute ethanol] was added 0.005 mol of the appropriate phenol. After being stirred for 10 min, III (0.005 mol) was added and the mixture was stirred for further 60 min, then left overnight at room temperature. The crude product precipitated was collected, washed with water and finally recrystallized from ethanol. The compounds prepared and their physical constants are given in Table 1.

Thermolysis of IV. Ethyl phenoxylglyoxalate *p*-tolylhydrazone (IVb) (0.8 g) in xylene (25 ml) was refluxed for 4 hr, then cooled. The white solid precipitated was collected and recrystallized from ethanol. A yield of 0.65 g (80%) of the hydrazide (Vb) melting at 104—105 °C was obtained.

When the isomeric ester (IVc) was similarly treated, the same hydrazide (Vb) was obtained in 85% yield, mp 104 °C, not depressed when mixed with the product formed above by thermolysis of IVb.

The thermolysis of other ester hydrazones in series IV was performed by the same method described above and afforded the hydrazides listed in Table 2.

Hydrolysis of Va. Va (1 g) was refluxed in 95% ethanol (20 ml) and concd hydrochloric acid (20 ml) for 6 hr. The reaction mixture was concentrated to 1/4 volume, cooled, made alkaline and finally was extracted with ether. Treatment of the ether extract, after being dried, with benzoyl chloride while cooling and work up yielded white solid (0.5 g), which, on recrystallization from ethanol, gave *N′*-benzoyl-*N,N*-diphenylhydrazine, mp 189—190 °C. The mixture mp of the latter with an authentic sample[11] showed no depression.

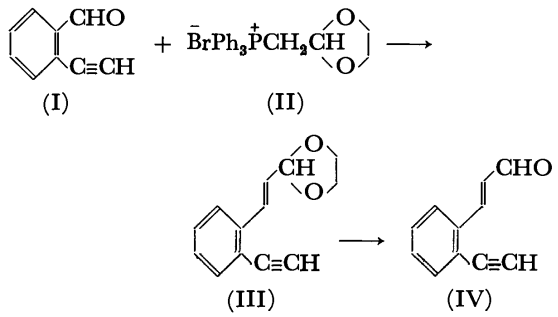
Synthesis of *o*-Ethynylcinnamaldehyde

Jūro Ojima, Akihiko Kimura, Yōji Yokoyama, and Tai Yokoyama
Faculty of Literature and Science, Toyama University, Gofuku, Toyama 930

(Received July 1, 1974)

Synopsis. A synthesis of *o*-ethynylcinnamaldehyde-(IV) starting from *o*-ethynylbenzaldehyde(I) by the Wittig reaction is described.

In a previous paper, we reported a synthesis of *o*-ethynylbenzaldehyde(I) and an attempt to synthesize dibenzo[18]annulene.[1] As an extension of our work on benz-fused annulenes, we found it necessary to synthesize *o*-ethynylcinnamaldehyde(IV). Howes *et al.* recently described syntheses and properties of [13],[15], [17]-membered annulenones and heteroannulenes.[2] For realizing the effect of annelation of benzene nuclei on the conjugated systems, the title compound is considered to be a key intermediate for syntheses of these benz-fused compounds.



The synthesis of *o*-ethynylcinnamaldehyde(IV) was carried out as follows.

The method of Müller-Cunradi and Pieroh[3] has been used extensively in the synthesis of $\alpha\beta$-unsaturated aldehyde. We used this method to prepare the title compound, the starting *o*-ethynylbenzaldehyde being recovered. Cresp, Sargent, and Vogel[4] have reported the use of 1,3-dioxolan-2-yl-methyltriphenylphosphonium bromide(II) in the syntheses of some $\alpha\beta$-unsaturated aldehydes. We applied their method to *o*-ethnylbenzaldehyde(I). The desired *o*-ethynylcinnamaldehyde-(IV) was obtained with a satisfactory yield.

Experimental

The melting point is uncorrected. The electronic spectrum and infrared spectrum were taken on Hitachi-124 and Hitachi-EPI-S2 spectrophotometers, respectively, and the NMR spectrum and mass spectrum on JEOL-JNM-MH-60 and JEOL-JMS'-OI-SG'-2 spectrometers, respectively.

o-Ethynylcinnamaldehyde(IV): Lithium methoxide prepared from lithium (327 mg, 0.047 gatm) in dry methanol (150 ml) was added dropwise with stirring under nitrogen at 80—90 °C for 3 hr to *o*-ethynylbenzaldehyde(I) (4.0 g, 0.031 mol) and 1,3-dioxolan-2-yl-methyltriphenylphosphonium bromide (II) (20 g, 0.047 mol) in dry *N,N*-dimethylformamide (150 ml). After addition of the base, the reaction mixture was stirred under nitrogen at 82—85 °C for further 5 hr.

The reaction mixture was then poured into water (1800 ml) and extracted thoroughly with ether. The ether extract was washed with saturated brine, dried over sodium sulfate and evaporated.

The residue thus obtained was stirred at room temperature with tetrahydrofuran (150 ml) and 10% aqueous hydrochloric acid (150 ml) for 3 hr. After addition of water (150 ml), the reaction mixture was extracted with ether and the extract was washed with water, saturated aqueous sodium bicarbonate and water successively. After being evaporated, the residue was chromatographed on alumina (200 g) and the column was eluted with a mixture of light petroleum ether–ether (9: 1). Solids obtained after evaporating were collected (3.12 g, 67%) and recrystallized from *n*-hexane affording yellow needles. Mp, 89—90 °C. Found: C, 84.33; H, 4.95%; mol wt (mass spectroscopy) 156 (M^+, 65%), 128 (base). Calcd for $C_{11}H_8O$: C, 84.59; H, 5.16%; mol wt 156.17: IR (KBr disc); 3250(s), 2060(w), 1685(s), 1620(m), 960(s): UV (in EtOH); λ_{max} (ε), 242 (24100), 247 (23100), 292 nm (21700): NMR (τ in $CDCl_3$) 0.14 (d, 1H, -CHO, J=8 Hz), 1.90 (d, 1H, vinyl H, J=16 Hz), 2.16—2.66 (m, 4H, aromatic), 3.20 (dd, 1H, vinyl H, J=8, 16 Hz), 6.53 (s, 1H, -C≡CH).

The authors are grateful to Prof. F. Sondheimer, University College London, for kindly providing unpublished results.

This research was financially supported by the grants from the Ministry of Education.

Some Considerations on the Electronic Spectra of Cyclic Polyenes

Sadhan BASU

Department of Pure Chemistry, University College of Science, Calcutta-9, India

(Received July 30, 1974)

Synopsis. The theoretical prediction of a convergence limit in the electronic spectra of cyclic polyenes is nicely borne out by exerimental findings.

In a recent communication hole particle formalism[1] has been used to explain the convergence limit in the π-electronic spectra of linear polyenes. The hole-particle pair creation operator expressed in terms of particle creation and destruction operators was written as

$$b_i = u_i c_i + v_i c_i^+ \qquad (1)$$

in order to diagonalize the Hamiltonian. For Boglyubov-Valentin[2,3] transformation this should be written as

$$b_i = u_i^* c_i + v_i^* c_i^+ \qquad (2)$$

where $-i$ is the time reversed partner of the state i. Since n is the only good quantum number in the FE function of linear polyenes there is no genuine time reversed partner for the states described by n. The transformation (1) was therefore an *ad-hoc* assumption. The FE function for cyclic polyenes in cylindrical coordinate may be written as[4]

$$\Psi n_z n_\rho m(Z, \rho, \Phi) = N e^{-Kz^2/2} H_{n_z}(\sqrt{K}z) e^{-C\rho^2/2} F_{n_\rho}^m(\sqrt{C}\rho) e^{im\Phi}$$

where $C^2 = 1/R^{2\alpha}$ and $K^2 = 4\pi^2 mk/h^2$, where R is the radius of the ring and k and α are two parameters determined from experimental data. For these functions state m has a time reversed partner $-m$ and the transformation (2) may be written as

$$b_m = u_m^* C_m + v_m^* C_m^+$$

which will be truely cannonical. Rest of the deductions will be the same as given in a previous paper and we will get for hole-particle energy as

$$E = \sqrt{\varepsilon_a - \varepsilon_f + \Delta^2}$$

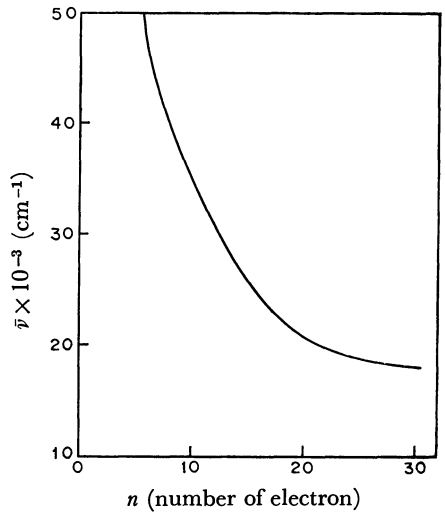

Fig. 1. $\bar{\nu}$ *vs.* n.

This means that even for cyclic polyenes there should exist a convergence limit. In Fig. 1 is given the plot of longest wave length transition *versus* the ring size for a number of conjugated cyclic systems known as Sondheimer hydrocarbon.[5] It is evident that the convergence do exist.

Solvent Effects under High Pressure. II.[1] Determination and Applications to Kinetic Studies of the E_T-Value at High Pressures

Katsuhiro TAMURA and Tatsuya IMOTO

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received February 5, 1974)

The E_T-value was determined for eight solvents at 25 °C over the pressure range 1—1,960 kg/cm². They increase with pressure; the pressure dependence is affected by the nature of the solvents. It was also found that there is a linear relationship between the pressure coefficient of E_T and that of the logarithm of the rate constant of a Menschutkin reaction: $\ln k = a + bE_T$. On the basis of this relationship, an equation was derived in which the volume of activation $\Delta V^{\neq}$ is represented by the pressure coefficient of E_T; the effect of solvents on $\Delta V^{\neq}$ is discussed by making use of this equation.

One of the most important factors in determining the rate of a chemical reaction is the choice of solvent. This becomes more important and complex for reactions under high pressure.

Frequently, solvent polarity is represented by its dielectric constant. However, this is a macroscopic measure of a solvent response to an electric field. For the analysis of chemical reactions it is necessary to know the microscopic situation, the solute-solvent interaction, at the active point in which reaction occurs. It seems impossible to express adequately all the interactions between solute and solvent molecules by using a single physical parameter of a solvent. The problem of the correlation has therefore been tackled empirically. A standard reaction or dye is chosen, and the significant parameters of the reaction or the dye are observed as the solvent is changed. These parameters may be rate constants for the reaction or spectral shifts of the dye, and they have been used as measures of solvent polarity and have been correlated with reaction rate. Various empirical measures of solvent polarity have been proposed in order to rank the ionizing power of solvents more accurately;[2,3] these avoid the need to understand fully the complexities of molecular interactions in solution.

Most polarity parameters useful at atmospheric pressure are not available at high pressure, because there are generally extraneous factors which completely shield the effects of the changes of solvent polarity with increasing pressure in either the standard reaction or the spectral shifts of the standard dye being investigated. The determination of the parameters would then be meaningless. Therefore, the effects of the change of solvent polarity with pressure on reaction rate must be studied by using an adequate polarity parameter. The so-called E_T-value proposed by Dimroth *et al.*[4] is defined as the transition energy of the solvatochromic absorption band of *N*-(4-hydroxy-3,5-diphenyl-phenyl)-2,4,6-triphenylpyridiniumbetaine (Scheme 1). This can be determined for many solvents, and one can get a direct insight into solute-solvent interactions, since the microscopic transition energy of an electron is measured. In addition, the E_T-value bears a good linear relationship to many other solvent polarity parameters. For these reasons, we adopted the E_T-value as a parameter to study the pressure dependence of the solvent polarity, and evaluated it for the kinetic studies at high pressure. It was consequently concluded that at least for Menschutkin reactions the E_T-value can be used as a convenient solvent polarity parameter under high pressure.

The pressure coefficients of the E_T-value were applied to the investigation of the solvent effects on the volumes of activation $\Delta V^{\neq}$. For Menschutkin reactions, an extensive study of the influence of the solvent on the $\Delta V^{\neq}$ has been made by Gonikberg and his collaborators.[5] As a general tendency concerning these reactions, the solvation term of $\Delta V^{\neq}$ is large and negative for solvents whose compressibilities are high and whose dielectric constants increase greatly with pressure. The reason for this is as follows. Since the transition state is partially ionic, the volume of the solvation shell will be decreased due to the electrostriction of the surrounding solvent molecules. The contraction becomes larger if the solvent used has a higher compressibility. However, there are numerous exceptions to this analysis based on the changes in compressibility or dielectric constant with pressure, especially, since the relationship between $\Delta V^{\neq}$ and the pressure-dependence of the dielectric constant is extremely complex.[6,7] So we attempted to analyze the solvent effects on $\Delta V^{\neq}$ by using the E_T-value, and $\Delta V^{\neq}$ was correlated with the pressure dependence of the E_T-value.

Experimental

Materials. Commercial nitrobenzene of special grade was purified as noted in the literature.[8] The other solvents used, commercial spectro grade, were used withot purification.

The standard indicator, *N*-(4-hydroxy-3,5-diphenyl-phenyl)-2,4,6-triphenylpyridiniumbetaine, used for the determination of the E_T-value, was synthesized according to the method described in the previous paper.[1] The betaine was recrystallized from a methanol–water mixture (1 : 1); mp 207—280 °C.[4,9] (Found: C, 83.58; H, 5.26; N, 2.61%).

Apparatus. Figure 1 illustrates a part of the Drickamer-type high pressure equipment used, with optical windows, for the determination of the E_T-value. This is modified to circulate water through the jacket around the equipment from a thermostat in order to keep the temperature constant (25 °C); the E_T-value is very sensitive to temperature. A sample solution in a cylindrical quartz cell with path length of 10 mm is separated with mercury from the *n*-hexane used as a pressure transmitting medium. When the absorption spectra are measured at high pressures, attention must be paid to the mercury pushed into the cell with pressure so as not block the light.

The pressure was measured with a Bourdon gauge con-

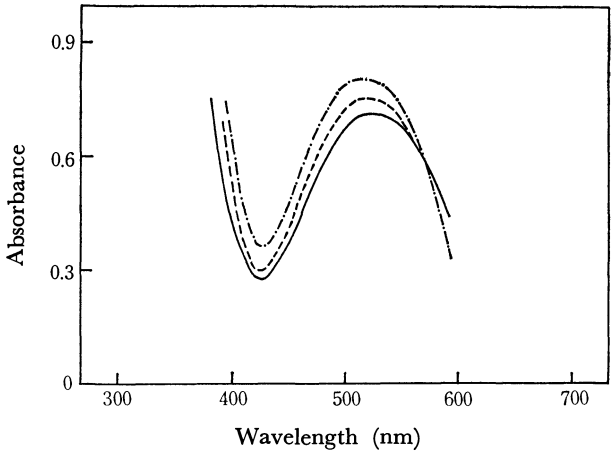

Fig. 2. Absorption spectra of the betaine in methanol at 25 °C and various pressures.
——: 1 kg/cm², — — —: 820 kg/cm², —·—·—: 1960 kg/cm²
The absorbance at high pressures is not corrected for the contraction of the solvent.

nected to the manual pump; it was calibrated by a manganin resistance gauge.

The area ratio of the pistons of the intensifier is 1 : 25. This indicates that the pressure ratio of the low pressure section to that of the high pressure must theoretically be equal to the reciprocal of the ratio of the pistons. However, the actual pressure measured in the high pressure section was lower than the theoretical value by about 20% due to friction between the packing and the piston cylinder.

The spectra were measured by means of Hitachi Model-139 Spectrophotometer. The details of the arrangement were described in the previous paper.[10]

Procedure. The quartz cell containing a sample solution of adequate concentration was set on a holder in the equipment, and then *n*-hexane was poured into it. This was allowed to stand for a few hours until the temperature of the system became 25 °C; it was then attached to the spectrophotometer. First the wavelength of the absorption maximum was measured at atmospheric pressure employing sensitivity values which had been determined relative to blank (100% transmittance) at each wavelength and at each pressure prior to the measurement of the absorption band. The described pressure was applied for about one hour, and then the measurement was carried out. The procedure for the measurement under high pressure is similar to that under atmospheric pressure.

Results

The betaine is a chemically stable indicator. It was confirmed that the betaine does not react with the mercury used to separate the sample solution from the pressure transmitting *n*-hexane, and its absorbance did not change with time. Also, the wavelength of absorption maximum (λ_{max}) was the same as before compression.

The position of λ_{max} at atmospheric pressure is very sensitive to the nature of the solvents, for example, the difference between the λ_{max} of methanol (516 nm) and that of acetone (675 nm) was about 160 nm. Pressure effects on the spectra were also observed, as shown for a methanol solution in Fig. 2. The absorption peak for this solution shifted to the shorter wavelength region (blue shift) with increasing pressure. The wavelengths of the absorption maximum at 1, 820, and 1,960 kg/cm² pressure were observed at 516, 512, and 508 nm, respectively. Similarly, such a blue shift with pressure was found in all other solvents used. The E_T-value can be calculated from the values of λ_{max} (in nm) with the following equation.

$$E_T = h\nu = 2.859\times10^4/\lambda_{max} \quad \text{kcal/mol}$$

The E_T-values and the λ_{max} for each solvent at various pressures are summarized in Tables 1 and 2. The error range in λ_{max} is $\pm1\sim\pm2$ nm, depending on the solvent. The E_T-values for benzene, nitrobenzene, and a benzene-nitrobenzene mixture (0.6 mole fraction of nitrobenzene) at 25 °C cannot be determined at or above 1,000 kg/cm² pressure since these solvents freeze under these conditions. Although the betaine was only slightly soluble in benzene, the measurement of the λ_{max} was possible. The E_T-value for benzene determined at atmospheric pressure was larger than the value in the literature,[4] while that for nitrobenzene was smaller, and those for the other solvents were in agreement. As a general tendency, the rate of increase of the E_T-value with respect to pressure decreases with increasing pressure. In order to compare the relative changes of the E_T-values with pressure, $(E_T)_p/(E_T)_1$ was plotted against pressure for each solvent as shown in Figs. 3 and 4. The curves are evidently dependent on the nature of the solvents; however, the differences between the solvents are small in our pressure range. This behavior is distinct from that of the *Z*-value, another solvent polarity parameter proposed by Kosower.[11,12]

For each solvent one can culculate the slope $(\partial E_T/\partial P)_T$. This term has the dimension of volume; in the case of iodide ion, it has in fact been considered the volume change upon excitation.[13]

TABLE 1. E_T-VALUE AND λ_{max} FOR A SERIES OF ALCOHOLS AND ACETONE AT 25 °C AND VARIOUS PRESSURES

Pressure (kg/cm²)		1	430	820	1170	1520	1960
MeOH	λ_{max}	516	513	512	510	509	508
	E_T	55.41	55.69	55.84	56.06	56.17	56.28
EtOH	λ_{max}	551	549	547	545	544	542
	E_T	51.89	52.11	52.32	52.49	52.59	52.72

◐: Benzene ●: 0.6 mole fraction mixture ○: Nitrobenzene

Before the evaluation of $(\partial E_T/\partial P)_T$ from a set of E_T-values, the functional dependence of E_T-value on pressure must be established. The following two functions were checked by the least mean squares method.

$$E_T = A + BP \quad (1)$$

$$E_T = A + BP + CP^2 \quad (2)$$

It was concluded that the linear Eq. (1) was well suited for benzene, nitrobenzene and the benzene-nitrobenzene mixture which were measured over a small pressure range; the second-order polynomial (2) gives an adequate description for the other solvents. The constants A, B, and C in the above two equations were evaluated by using a computer programmed least mean squares technique; they are listed in Table 3. One can evaluate $(\partial E_T/\partial P)_T$ by differentiating the linear and quadratic expressions with respect to pressure:

TABLE 3. THE CONSTANTS A, B, AND C IN Eqs. (1) AND (2), STANDARD DEVIATION, AND THE PRESSURE COEFFICIENT OF E_T

	$A\times10^{-1}$ (kcal/mol)	$B\times10^{4}$ (kcal/mol)/(kg/cm²)	$C\times10^{7}$ (kcal/mol)/(kg/cm²)²	$S.D.\times10^{2}$	$(\partial E_T/\partial P)_T$ (cm³/mol)
MeOH	5.542	6.662	−1.113	2.2	28.4
EtOH	5.188	6.139	−0.9515	1.2	26.2
iso-PrOH	4.838	5.865	−0.8907	0.5	25.0
iso-BuOH	4.904	4.595	−0.7782	1.0	19.6
Acetone	4.238	4.209	−0.5502	1.5	17.9
Nitrobenzene	4.145	2.891		0.4	12.3
0.6 mole fraction mix.	4.090	3.045		0.3	13.0
Benzene	3.510	2.795		0.6	11.9

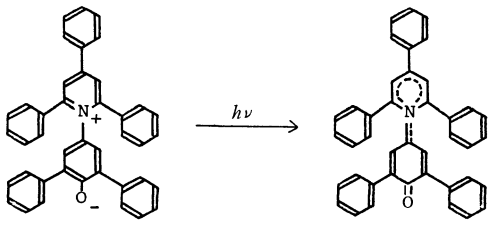
$$(\partial E_T/\partial P)_T = B \text{ or } (B + 2CP) \quad (3)$$

The values of $(\partial E_T/\partial P)_T$, together with standard deviations, are summarized for each solvent at atmospheric pressure in Table 3. The order of the quantity of $(\partial E_T/\partial P)_T$ for each solvent almost corresponds to that of E_T. As there is some scatter in the data shown in Figs. 3 and 4, the values $(\partial E_T/\partial P)_T$ as estimated from the slopes in the figures are not necessarily consistent with those calculated from Eq. (3).

Although the physical meaning of the $(\partial E_T/\partial P)_T$ cannot be interpreted strictly, owing to insufficient information about the excited state, the experimental results suggest that the ground state interaction between the ionic solute and the surrounding solvent molecules is stronger in a more polar solvent, and consequently that the overall volume contraction of the solvation shell becomes greater.

Discussion

Pressure Dependence of E_T-value. In the visible region, the betaine shows a large hypsochromic effect with an increase in solvent polarity; *i.e.*, the wavelength of the absorption maxima shifts toward the blue with increasing solvent polarity. This is apparently due to the disappearance of the electric charges of the betaine when it is excited, together with intramolecular charge transfer as shown in Scheme 1.[14] These phenomena have been often observed in n→π^* transitions.[15]



Scheme 1

The changes of E_T with pressure are due to the shifts of the energy levels in ground and excited states; however, precise information about the pressure dependence of the shifts of these levels cannot be obtained. A solute molecule, which in its ground state is in equilibrium with the surrounding solvent molecules that form its solvation shell, should be stabilized in the solution with increasing solvent polarity. According to the Franck-Condon principle an optical transition occurs within a time far shorter than the period of nuclear motions, and hence the molecule in the excited state (Franck-Condon state) is momentarily surrounded by a solvent shell whose size and orientation are those appropriate to the ground state. In the Franck-Condon state the solvation shell is unstable, because the dipole moment of the solute becomes small compared with that in the ground state, and the solute-solvent interactions become likewise smaller. Therefore, the more stable the ground state is, the more unstable is the excited state, owing to the increase in solvent polarity with pressure. The matter described above may be expressed qualitatively by Fig. 5. The energy level of the excited state rises with pressure, and on the contrary, that of the ground state falls. The slope of the curve may be dependent on the nature of the solvent. In the figure, the slopes have been selected arbitrarily for illustrative purposes.

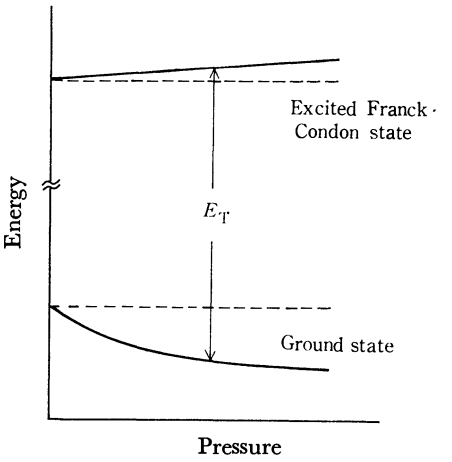


Fig. 5. Diagramatic representation of changes in ground and excited state energies for the betaine in a solvent as a function of pressure.

Correlation of Rate Constants with E_T-values. There are some examples of good linear relationship between E_T-values and logarithms of rate constants at atmospheric pressure. For example, as described in the previous paper,[1] the Menschutkin reaction of 3,5-lutidine with ethyl iodide in benzene-nitrobenzene mixtures shows good linearity. These relationships provide a valuable means of estimating the effect of solvents on the rate of chemical reactions, and of confirming abnormal solvent effects on reaction rates

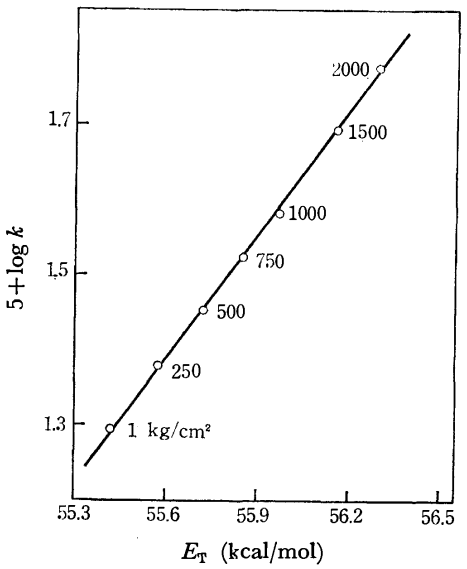

Fig. 6. A plot of $\log k$ *vs.* E_T for the Menschutkin reaction of pyridine with methyl iodide in methanol at various pressures.

or electronic transition. The reaction between pyridine and methyl iodide in six solvents (carbon tetrachloride, benzene, methanol, chlorobenzene, acetone, and nitrobenzene)[6] has a linear relationship, except for methanol, which is the only protic solvent. This means that the degree of solute-solvent interaction for methanol is different from that of the aprotic solvents.

We now discuss whether the E_T-value can also be employed for kinetic studies at high pressures. In order to investigate the linear relationship at high pressures, the logarithms of rate constants[6] of the reaction between pyridine and methyl iodide were plotted against the E_T-values with respect to four kinds of solvents (benzene, nitrobenzene, methanol, and acetone), up to 2,000 kg/cm². Figure 6 shows a plot of $\log k$ *vs.* E_T-value for methanol at various pressures. It is obvious that there is a good, linear relationship between them. Similar good linearity was observed in the plots for the other three solvents.[16] This relationship can be expressed in terms of the following linear equation.

$$\ln k = a + bE_T \tag{4}$$

The constants a and b were determined by means of the least mean squares method for each solvent; they are summarized in Table 4. The value of a becomes progressively larger as the E_T-value of the solvent increases, whereas the value of b becomes smaller.

Table 4. The constants a and b in Eq. (4) for various solvents

	Methanol	Acetone	Nitrobenzene	Benzene
a	−74.06	−99.69	−107.5	−144.3
b (mol/kcal)	1.186	2.192	2.439	3.824
E_T at 1 kg/cm²	55.41	42.39	41.45	35.10

By the use of the empirical equation (4), the volume of activation $(\partial E_T/\partial P)_T$. $\Delta V^{\ddagger}$ can be correlated with $(\partial E_T/\partial P)$.

According to the transition state theory[17] the volume of activation $\Delta V^{\ddagger}$ for a reaction is related to the pressure dependence of the rate constant by Eq. (5).

$$\left(\frac{\partial \ln k}{\partial P}\right)_T = -\frac{\Delta V^{\ddagger}}{RT} \tag{5}$$

If one differentiates Eq (4) with respect to pressure, one obtains

$$\left(\frac{\partial \ln k}{\partial P}\right)_T = b\left(\frac{\partial E_T}{\partial P}\right)_T + E_T\left(\frac{\partial b}{\partial P}\right)_T \tag{6}$$

The following equation can be obtained from the Eqs. (5) and (6) by assuming $(\partial b/\partial P)_T=0$ in our pressure range.

$$\Delta V^{\ddagger} = -bRT(\partial E_T/\partial P)_T \tag{7}$$

In order to discuss Eq. (7), the Menschutkin reaction of pyridine with methyl iodide has been chosen as an example; it has been cited in the case of discussing the linear relationship between ln k and E_T-value at high pressures. Table 5 lists both of the volumes of activation $\Delta V^{\ddagger}$, one calculated from the pressure dependence of k (Eq. (5)), and one evaluated using the values of $(\partial E_T/\partial P)_T$ and the constant b in Eq. (4) (summarized in Tables 3 and 4, respectively). By comparing these volumes of activation, it can be found that they appear to be in fairly good agreement. This means that the assumption, $(\partial b/\partial P)_T=0$, is valid and further the experimental equations (1), (2), and (4) are also adequate expressions. Eq. (7) shows that $\Delta V^{\ddagger}$ can be correlated with two components, b and $(\partial E_T/\partial P)_T$ representing the polarity effects of solvents. The b defined by Eq. (4) represents the sensitivity of rate constants to changes of solvent polarity.

Table 5. Comparison of the volumes of activation calculated from Eq. (7) with those obtained by Hartmann *et al.*[6]

	Methanol	Acetone	Nitrobenzene	Benzene
$\Delta V^{\ddagger}$ a) (cm³/mol)	−22.6	−28.8	−19.7	−31.9
$\Delta V^{\ddagger}$ b) (cm³/mol)	−21.6	−25.2	−19.3	−29.2

a) Hartmann's data. b) The values calculated from Eq. (7).

In order to discuss the solvent effects on the $\Delta V^{\ddagger}$ by means of Eq. (7), the solvent dependence of $\Delta V^{\ddagger}$, $(\partial E_T/\partial P)_T$ and b was compared with respect to the four solvents shown in Table 4, and it was found that there is a correlation between these values and the nature of the solvent, except for the case of nitrobenzene. The absolute values of $\Delta V^{\ddagger}$ and b become large in the order of methanol, acetone, and benzene, whereas that of $(\partial E_T/\partial P)_T$ becomes smaller in the same order. So far as these solvents are concerned, it seems that the contribution of b to the changes of $\Delta V^{\ddagger}$ with the nature of the solvent is greater than that of $(\partial E_T/\partial P)_T$.

As described above, the solvent effect on $\Delta V^{\neq}$ was discussed on the basis of the values of $(\partial E_T/\partial P)_T$ and b; however, at the present stage a more detailed discussion about the correlation between the $\Delta V^{\neq}$ and the corresponding $(\partial E_T/\partial P)_T$ cannot be given due to the unavailability of suitable kinetic data. The problem of solvation at high pressures is very complex, and mechanisms depend on reaction and solvent used. Therefore, the procedures mentioned here are severely limited; however, they may furnish a guide to studies of solvent effects on the volume of activation.

The authors are indebted to Prof. W. J. le Noble for his valuable comments.

The Circular Dichroism Spectra of the β-Cyclodextrin Complex with Naphthalene Derivatives

Kazuaki HARATA and Hisashi UEDAIRA

Research Institute for Polymers and Textiles, Sawatari, Kanagawa-ku, Yokohama 221

(Received May 13, 1974)

The circular dichroism spectra of β-cyclodextrin complexes with naphthalene derivatives were investigated. A remarkable difference in the spectra was observed between the 1-substituted naphthalene complex and the 2-substituted naphthalene complex, indicating that the steric effect of substituents on the formation of the complex is so strong that the structures may be different for these complexes. The calculation of the rotational strength by the method of Kirkwood-Tinoco revealed that the structure of the 2-substituted naphthalene complex is an axial inclusion.

Cyclodextrins, which are produced by the action of *Bacillus macerans* amylase on starch, are cyclic α-1,4-linked D-glucose oligomers. The rings with six, seven, and eight glucose residues in the molecule have different internal diameters ranging from 6 Å to 10 Å.

Cyclodextrins form a number of crystalline adducts with aromatic compounds, paraffins, alkyl halides, *etc.* Of those crystalline adducts, the α-cyclodextrin-iodine complex[1] and the α-cyclodextrin-potassium acetate complex[2] were found by X-ray structure analysis to be inclusion compounds, and the other crystalline adducts have been also regarded as inclusion compounds.

The evidence for the formation of inclusion compounds in a solution have been derived from the kinetic data[3] and the NMR spectra.[4] The interior cavity of the cyclodextrin ring is hydrophobic in nature and binds a hydrophobic portion of the guest molecule, usually forming a 1 : 1 complex. Moreover, cyclodextrins catalyze a number of chemical reactions, such as hydrolysis,[5] oxidation,[6] and decarboxylation,[7] and have been shown to be a good model for enzyme-catalyzed reactions. Tutt and Schwartz[8] showed, in their work on the β-cyclodextrin-catalyzed hydrolysis of penicillin derivatives, that the reaction rate of 2-naphthylpenicilin is four times as fast as that of 1-naphthylpenicillin, although the dissociation constant of the 2-naphthylpenicillin complex is five times as large as that of 1-naphthylpenicillin complex.

Our aim of the present paper is to reveal the structure of the β-cyclodextrin complex with naphthalene derivatives in an aqueous solution by means of the circular dichroism (CD) spectra. When optically-inactive compounds form complexes with cyclodextrins, these compounds exhibit optical activity.[9,10] The circular dichroism spectra of these complexes will give information about their structures, since the optical activity will be induced by the interaction between the cyclodextrin and the guest molecule.

Experimental

The β-cyclodextrin(β-CDx) and naphthalene derivatives were commercial products. β-CDx was recrystallized three times from an aqueous solution. Potassium salts of 1-naphthylacetic acid(1-NAT), 2-naphthylacetic acid(2-NAT), 1-naphthoic acid(1-NA) and 2-naphthoic acid(2-NA) were prepared because these acids are insoluble in water, and were recrystallized from ethanol. 1-Naphthylamine (1-NAM), 2-naphthylamine(2-NAM), 1,8-diaminonaphthalene(1,8-DAN) and 2,3-diaminonaphthalene (2,3-DAN) were recrystallized from a dilute HCl solution as hydrochlorides.

The circular dichroism and absorption spectra were measured using a JASCO J-10 Spectropolarimeter at room temperature. The concentration of β-CDx was adjusted to 0.01 M throughout the measurements. The CD spectra of the 1-substituted naphthalene derivatives were not measurable in the wavelength region longer than 250 nm because of the low intensity. In the region of high absorbancy, the intensity of the CD spectra has a large experimental error, about $\pm 1 \times 10^{-5}$ in $\Delta\varepsilon/\varepsilon$.

In the solution, the following equilibrium is established:

β-CDx + naphthalene derivatives ⇌ complex.

The intensity of the CD spectra depends on the concentration of the complex. In the present work, $\Delta\varepsilon$ was estimated by assuming that all the molecules of the naphthalene derivatives in the solution form the complex.*

Calculation

The coupled oscillator model of Kirkwood[11] may account for most of the rotational strength of a strong electric-dipole transition interacting with far-ultraviolet transitions of the vicinal groups. In the Kirkwood model as developed by Tinoco[12] the contributions of individual groups of perturbers were emphasized. According to the Kirkwood-Tinoco expression, the rotational strength is given as follows:

$$R_{0aj} = \frac{\pi \nu_a \nu_0^2 \mu_{0a}^2 (\alpha_{33} - \alpha_{11})_j (\mathrm{GF})_j}{c(\nu_0^2 - \nu_a^2)} \tag{1}$$

$$(\mathrm{GF})_j = \frac{1}{r_j^3}\left[\vec{e}_{0a}\cdot\vec{e}_j - \frac{3(\vec{e}_{0a}\cdot\vec{r}_j)(\vec{e}_j\cdot\vec{r}_j)}{r_j^2}\right]\vec{e}_{0a}\times\vec{e}_j\cdot\vec{r}_j$$

where $\vec{e}_{0a}$ is the unit vector in the direction of the electric dipole moment; $\vec{\mu}_{0a}$, that of the transition from 0 to a, and ν_a, its frequency; $\vec{e}_j$ is the unit vector in the direction of the symmetry axis of the j group, and $\vec{r}_j$ is the distance from the chromophor to the j group with the frequency ν_0 of the exited state; α_{33} and α_{11} are the electric polarizabilities parallel and perpendicular respectively to the symmetry axis of the j group. The values of α_{33}, α_{11},[13] and ν_0 are listed in Table 1. The ν_0 value of the C–C bonds

* Our discussion is not affected by this assumption.

TABLE 1. THE VALUES OF α_{33}, α_{11} AND ν_0.

Bond	$\nu_0 \times 10^{-15}$(1/s)	α_{33}(Å^3)	α_{11}(Å^3)
C-O	1.67	0.089	0.046
C-C	2.00	0.098	0.027

was estimated from the absorption spectra of cyclohexane.[14] The midway value of the first absorption bands of ethylether and ethanol[15] was used as the ν_0 value of the C–O bonds. The transition frequency, ν_a, and the dipole strength, μ_{0a}^2, were estimated from the absorption spectra. The coordinates of β-CDx, which was assumed to have a seven-fold symmetry axis, were estimated on the basis of the coordinates of a glucose residue taken from the X-ray data of the α-cyclodextrin-potassium acetate complex. The origin of the coordinate was fixed on the plane determined by the seven O_4 atoms as is shown in Fig. 6. In the calculation, the effects of all the C_6–O_5 and O–H bonds were neglected because of the flexibility; the effects of all the C–H bonds were also neglected since these bonds may be isotropic and may contribute little to the rotational strength.

Results and Discussion

Figures 1—4 show the absorption and CD spectra of β-CDx complexes with naphthalene derivatives. The CD curves of 1- and 2-substituted naphthalene complexes are remarkably different from each other. For example, in the 2-NAT complex, the ^1L_b and ^1L_a transitions both give negative CD curves, while the ^1B_b transition gives a positive CD curve. On the other hand, the 1-NAT complex shows two weak CD bands with positive and negative signs in the 200—250 nm region. The difference in spectral shape between the 1- and 2-substituted naphthalene com-

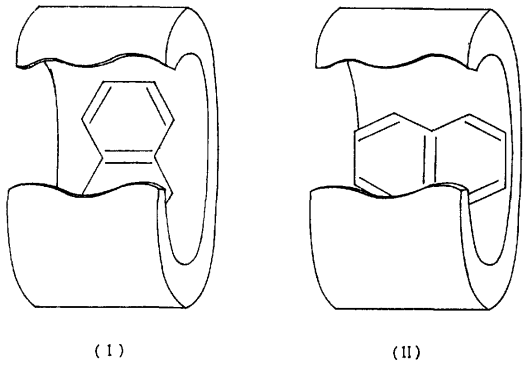

Fig. 5. The two models of the complex; equatorial inclusion (I) and axial inclusion (II).

plexes is considered to be due to the fact that the structure of the 1-substituted naphthalene complex is different from that of the 2-substituted naphthalene complex. As may be seen in Fig. 5, it is impossible for 2-substituted naphthalene, especially 2,3-DAN, to form an equatorial inclusion complex. Therefore, the CD spectra of the 2-substituted naphthalene complex will be atributed to the structure of the axial inclusion. In the case of the 1-substituted naphthalene complex, both types of inclusion are possible, and from a study of the molecular models it is not found which structure is more reasonable.

The two models of the inclusion compounds of β-CDx with naphthalene derivatives, shown in Fig. 5, were examined by comparing the calculated rotational strength with the observed one. The calculation of the rotational strength of the 2-NAT complex was

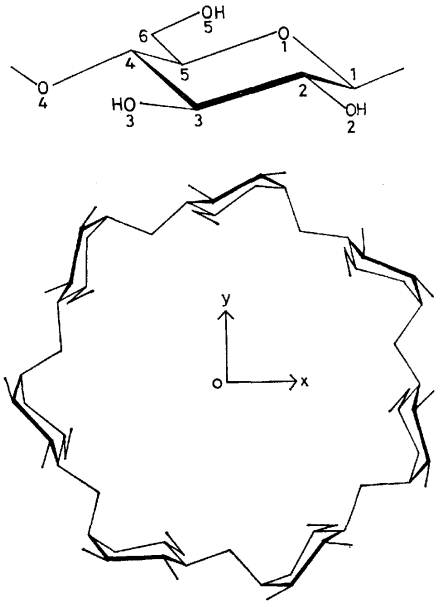

Fig. 6. The assumed structure of β-cyclodextrin.

	$R\times10^{40}$(cgs)	
	^1L_a	^1B_b
Calculation		
(I) Equatorial	1.52	−30.4
(II) Axial	−0.76	60.7
Experimental	−2.65	22.9

carried out by putting the center of the electric dipole moment on the point of origin and by assuming its direction to be the same as that of naphthalene.[16] In the cases of the ^1L_a and ^1B_b transitions, the results are listed in Table 2, along with the observed values. The signs of the calculated rotational strengths based on the axial inclusion complex are in agreement with the observed ones, whereas the signs based on the equatorial inclusion complex are opposite to those observed; thus, the structure of the 2-NAT complex is estimated to be an axial inclusion and the other 2-substituted naphthalene complexes are thought to have similar structures.

The naphthalene ring which is included in the cavity of β-CDx has two degrees of freedom along the symmetry axis of β-CDx, the translation and the rotation. If an electric dipole moment makes the θ angle with the z-axis, as is shown in Fig. 7, its position and direction are determined by θ, φ, and z. In the cases of the ^1L_a and ^1B_b transitions, the rotational strength was shown to be independent of φ. The z-dependence of the rotational strength is shown in Fig. 8. It is found that the complex gives a large CD value when the naphthalene group is situated in the cavity; the rotational strength of the ^1B_b transition takes its maximum value when the electric dipole moment is almost at the center of the cavity, while that

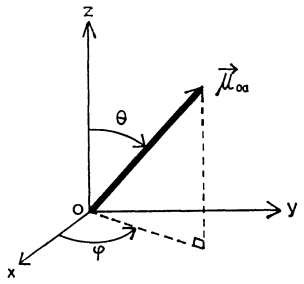

Fig. 7. The coordinate system of the electric dipole moment.

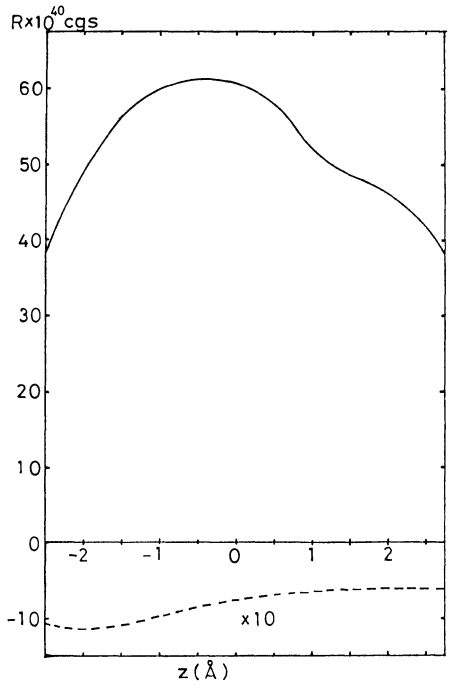

Fig. 8. The z-dependence of rotational strengths of ^1L_a (----) and ^1B_b (——) transition.

of the ^1L_a transition takes its minimum value at −2.0 Å.

It is interesting to calculate the dependence of the rotational strength of θ. If $\vec{e}_{0a}=(\sin\theta, 0, \cos\theta)$, Eq. (1) is expressed as follows:

$$R_{0a} = [A_{0a} + B_{0a}\cos 2\theta + C_{0a}\sin 2\theta]\mu_{0a}^2$$

where A_{0a}, B_{0a}, and C_{0a} are shown in Fig. 9. R_{0a} takes its maximum value at $\theta=0°$ and its minimum value at $\theta=90°$, since C_{0a} is negligible, so the transition with an electric dipole moment parallel to the z-axis gives a positive CD value and the transition with an electric dipole moment perpendicular to the z-axis gives a negative CD value. Thus, it is possible to estimate the orientation of the chromophor in the cavity of β-CDx if the direction of the electric dipole moment in the chromophor is known.

Conclusion

Both experiments and calculations proved that the structure of β-CDx complexes with 2-substituted naphthalene is an axial inclusion and that the assumed

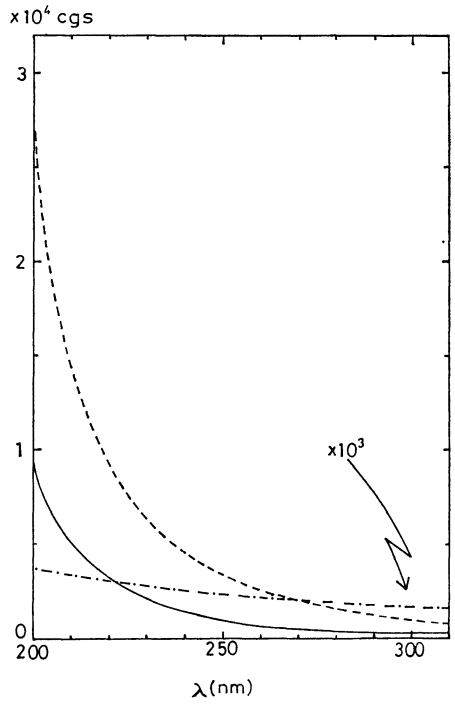

Fig. 9. The wavelength-dependence of A_{0a} (——), B_{0a} (----) and C_{0a} (-·-·-).

conformation of β-CDx is reasonable. The calculated rotational strength is in fairly good agreement with the observed value in spite of the use of a crude approximation. The calculated rotational strengths do not explain the CD spectra of the 1-substituted naphthalene complexes; the positive CD band in the 200—250 nm region suggests an axial inclusion, while the nagative CD band suggests the equatorial inclusion. It is possible that the two species exist in equilibrium.

Physico-chemical Studies of the Reversible and Irreversible Phase Transitions in Potassium Ferrocyanide Trihydrate and Its Deuterate Analogue*

Masaharu OGUNI, Takasuke MATSUO, Hiroshi SUGA, and Syûzô SEKI
Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560
(Received June 1, 1974)

Phase transitions of $K_4Fe(CN)_6 \cdot 3H_2O$ and its deuterate were studied through the measurements of differential thermal analysis curves, heat capacity, volume expansion and Raman spectra. Samples prepared by recrystallization from the aqueous solution were found to be in the metastable phase. The ferroelectric transition temperature between two stable monoclinic phases was determined to be 247.8 K and 252.7 K for the hydrate and deuterate, respectively. The enthalpy and entropy changes of the transition were estimated to be 2592 J mol^{-1} and 12.41 JK^{-1} mol^{-1}, respectively, for the hydrate, and 3017 J mol^{-1} and 14.36 JK^{-1} mol^{-1}, respectively, for the deuterate. The molecular mechanism of the transition was discussed in terms of entropy change. The transition was also concluded to be of the second order according to Ehrenfest's criterion. Irreversible transformation of tetragonal to monoclinic phase was observed for the first time for the deuterate as a new type of phase change having a Martensitic nature. These irreversible transformations took place in the temperature region covering 20 K below *ca.* 232 K and *ca.* 237 K for the hydrate and deuterate, respectively. The anhydrous salt showed no transformation in the temperature region between 13 K and room temperature.

A number of studies have been carried out on potassium ferrocyanide trihydrate and its deuterate as ferroelectrics having hydrogen-bond networks. Posperov and Zhdanov[1] (1947) disclosed the existence of both monoclinic and tetragonal crystal structures by X-ray diffraction at room temperature. Dielectric, optical and X-ray studies by Waku *et al.*,[2] Toyoda *et al.*[3] and Kiriyama *et al.*[4] also contributed to the elucidation of the structure, various types of twinning being found in particular by Toyoda *et al.* Proton and deuteron magnetic resonance methods were applied to the determination of the hydrogen position by Blinc *et al.*,[5] Tsang and O'Reilly,[6] Kiriyama *et al.*[4] and Habuda *et al.*[7] Neutron diffraction method was also applied by Taylor *et al.*[8] for the same purpose. Both the hydrate and deuterate crystals have layer structures which consist of hydrogen (or deuterium)-bonded water layers sandwiched between two double layers containing ferrocyanide octahedra and potassium ions. The monoclinic and tetragonal forms of both crystals which exist as stable and metastable modifications at room temperature, respectively, differ in the pattern of stacking of the layers, *viz.*, the layer structure can be constructed by rotating each successive layer 90° around the b-axis.[3] The monoclinic crystal has the space group C^6_{2h}–$A_{2/a}$ with four molecules in the unit cell and the tetragonal one the space group C^6_{4h}–$I_{4_1/a}$ with eight molecules in it. On being cooled, the monoclinic crystal undergoes a ferroelectric phase transition at 248.6 K and 255.1 K for the hydrate and the deuterate, respectively. The low-temperature space group is C^4_s–A_a, lacking the center of symmetry. On the other hand, the metastable tetragonal modification undergoes an irreversible phase transition to the twinned monoclinic one on being cooled below 218 K. The twinned crystal thus obtained shows only the reversible transition at 248.6 K for the hydrate on heating. The results of dielectric and optical investigations were reported for this irreversible transition by Krasnikova *et al.*[9]

The ferroelectric behavior was discovered by dielectric measurement by Waku *et al.*[10,11] in 1959. The origin of ferroelectricity can be classified into two types, the order-disorder mechanism and the displacive one. The former model involves alignment of the water molecules in the hydrogen-bonded layers, although there are two alternative models for the orientation of the water molecules as well as for the direction of spontaneous polarization.[4,6–8] Both models indicate that the compound has two different states per three water molecules at the disordered state. The latter, *viz.* the displacive mechanism, was derived from Moessbauer studies by Hazony *et al.*[12] and by Montano *et al.*[13] It involves a relative shift of the potassium ions, ferrocyanide ions and the water molecules within the crystal lattice. High pressure dielectric study was also reported by Krasnikova and Polandov[14] who constructed a phase diagram of the hydrate around the ferroelectric transition.

In spite of these studies, the thermal properties of the compound have remained relatively unexplored. The heat capacity on the monoclinic hydrate given by Nakagawa *et al.*[15] seems to be the only available datum. However, accuracy and precision of measurement were not specified and important characteristics of phase transition such as the entropy and enthalpy changes remained unclarified. We have thus investigated the properties of reversible phase transition based on the data of heat capacity and dilatometric measurements, in order to clarify the thermodynamic properties of the compounds. We have tried to elucidate the nature of the irreversible phase transition which was first discovered for the deuterate in the present investigation. The heat capacity of the anhydrous salt was also measured for the sake of comparison.

After the publication of our paper on heat capacity and dilatometric studies,[16] Malcolm *et al.*[17] reported the results of heat capacity and heat of solution on the monoclinic hydrate and anhydrous salt, and of the dissociation pressure of the monoclinic hydrate-anhydrous salt system. Compared with our results, their heat-capacity data are larger by nearly 0.5% for the hydrate except in the transition region, and smaller by about 0.6% for the anhydrous salt.

* A part of this paper has been published.[16]

Experimental

Material. The hydrate sample (special grade from Wako Pure Chemical Co., Ltd.) was recrystallized twice from its aqueous solution. The deuterate sample was prepared by recrystallization from the saturated solution in 99.75% heavy water (E. Merck) at a slow rate after dehydration of the purified hydrate *in vacuo* at 70 °C. Special care was taken to avoid photochemical decomposition. Crystals obtained were kept in a desiccator together with the anhydrous salt for over one month in order to remove excess water. The purity of the samples was determined from the weight loss caused by complete dehydration *in vacuo* at 70 °C. The water contents thus determined are given in Table 1.

Differential Thermal Analysis. Preliminary DTA studies were carried out in the transition regions for confirmation of results obtained by other workers. Details of the apparatus were already reported.[18] Granular (*ca.* 2 mm in size) and fine samples, both powdered in an agate mortar for a few minutes, were used.

Heat Capacity. The heat capacity of monoclinic modification in the range 15—300 K and that of tetragonal modification in the range 210—290 K were measured with an adiabatic calorimeter.[19] Accuracy of the measurement was better than 1% at liquid hydrogen temperature and 0.3% at room temperature. The amounts of each sample are given in Table 1. Helium gas and nitrogen gas at 100 kPa were used for the monoclinic and tetragonal samples, respectively, to facilitate heat transfer inside the calorimeter.

Monoclinic Hydrate: The sample was cooled twice down to liquid-nitrogen temperature for complete transformation to the monoclinic phase from the tetragonal modification. Samples were prepared by different methods for comparison, one being obtained by cracking a large single crystal into appropriate pieces in an agate mortar, and the other by cutting a large crystal with a razor blade. The former contained a small amount of powder in addition to the relatively large crystallites (3—5 mm), and the latter consisted of almost uniform size pieces (3—5 mm). The heat capacity curve of the crushed hydrate sample first measured showed a gentle hump in the temperature region slightly lower than the melting point of ice besides a ferroelectric phase transition. Re-examination was carried out with the same sample (see hydrate(a), Table 1) after removal of 35 mg of water from the loaded cell. The amount of water corresponds to the excess calculated from the heat-capacity hump on the assumption that it melted with the same heat of fusion as pure ice.

Monoclinic Deuterate: The same two kinds of deuterate samples as for (a) were used (see Table 1). Measurement (220—270 K) on the sample subjected to cutting treatment was carried out after the measurement of the irreversible transition region had been carried out.

Tetragonal Modification: The hydrate sample was crushed in an agate mortar, and the deuterate sample was cut with a razor blade. Measurements were carried out for samples pretreated under different pre-cooling conditions.

Dilatometric Study. The temperature dependence of the molar volume of the monoclinic hydrate was determined in the range 235—280 K in both cooling and heating with a glass-dilatometer containing degassed mercury as a confining liquid. The temperature of the methanol dry-ice bath surrounding the dilatometer was measured with a chromel-p-to-constantan thermopile. The height of the mercury column was measured with a cathetometer to the reading of 0.01 mm. The amount of the sample was determined to be 19.896 cm^3 at 26.2 °C in terms of density from X-ray data.[4]

Raman Spectroscopy. The Raman spectra of the monoclinic and tetragonal hydrates were obtained at room temperature with a Japan Spectroscopic Co., Ltd. model 750 Laser-Raman spectrometer. The incident beam was introduced parallel to the a-axis of the crystal and the scattered beam was taken out along the b-axis.

Results and Discussion

Differential Thermal Analysis (DTA). Results on the granular hydrate and deuterate recrystallized from their water and heavy water solutions, respectively, are shown in Figs. 1 and 2, respectively. In both figures Run 1 shows the cooling curves at the rate of *ca.* 1 K/min to 228 K for the hydrate and 234 K for the deuterate. These values are lower than the respective ferroelectric to paraelectric transition temperatures between their two monoclinic forms. The samples were kept for one and a half hours at the lowest respective temperatures for the purpose of testing the metastability of the tetragonal phase, and then heated up to room temperature. No change appeared throughout Runs 1 and 2, indicating that the crystals obtained were of the metastable tetragonal system, remaining metastable for a long enough time to allow calorimetric measurement in that modification. Runs 3 and 4 show the cooling curves down to 200 K and the subsequent heating ones up to room temperature, respec-

tively. Run 3 of the hydrate showed an exothermic effect at 234 K, whereas Run 4 no longer showed the corresponding endothermic peak but a new anomaly at 248 K. The same anomalies as found for the hydrate were observed at 231 K and 253 K for the deuterate, respectively. These results show that the metastable tetragonal crystals undergo irreversible transformation into the stable monoclinic modification when they are cooled below each transformation temperature, and that anomalies in Run 4 correspond to the reversible ferroelectric transition.

The appearance or disappearance of a shoulder in the exothermic peak in Run 3 for the deuterate changes with the sample. Runs 5 and 6 confirmed good reproducibility of the anomalies in Run 4. This indicates that the pre-cooling of the sample to a sufficiently low temperature is indispensable to studies on monoclinic modification although the sample thus obtained is heavily twinned. On the other hand, DTA curves of the powder samples did not give rise to any well-defined anomaly over the entire temperature range. The reason for this seems to be as follows. The sample might not only be partially dehydrated during the course of grinding but the surface of the crystal might also be perturbed so that complexity in the electric boundary conditions causes a broad distribution of the Curie temperatures. In fact, handling of the sample has a serious effect on experimental results, particularly with respect to the critical phenomenon.

Ferroelectric Reversible Phase Transition. Heat Capacity: The heat capacity of the crushed hydrate in the monoclinic form was measured twice. The heat capacity in the second run had no anomaly due to the loss of excess water and coincided with the first one in the temperature region below 240 K and above 273 K. A broadening at the transition point was found in the second measurement. This is attributed to partial dehydration of the sample, since the slight deficiency of water content might have a drastic effect on the shape of heat capacity curve in the transition region. Heat capacity values (13—300 K) from the first measurement (with correction for excess water) and the second measurements were adopted as the final data.

Heat capacity results are schematically shown in Fig. 3. The data of the sample obtained by cutting the crystal are adopted for respective transition regions. Selected values** for the hydrate and deuterate are given in Tables 2 and 3, respectively. Values for the sample subjected to cutting are given in series 9—11 in Table 10. Graphically smoothed heat capacities and derived thermodynamic functions for the hydrate and the deuterate are given in Tables 4 and 5, respectively. The heat capacity values of the hydrate obtained by Malcolm *et al.*[17] are larger by nearly 0.5% than the present values except in the transition region, while those obtained by Nakagawa *et al.*[15] are larger by about 50% at room temperature. We found that the anomaly due to the transition extends over a

wide region of temperature, having the transition point at 247.8 K and 252.7 K*** for the hydrate and deuterate, respectively. The anomalous part was estimated by separating the normal part from the total heat capacity. The normal part, determined from the smooth extrapolation of the higher and lower temperature sides of the transition region, is thus given by the equation

$$C_p(T) = A(\ln T)^3 + B(\ln T)^2 + C(\ln T) + D + E(\ln T)^{-1} + F(\ln T)^{-2}, \quad (1)$$

where $A = -0.101196 \times 10^4$, $B = 0.240747 \times 10^5$, C=

*** The revised data of transition point, which is 0.2 K higher than the old value,[16] were taken as the more accurate temperature of the steepest drop.

-0.227928×10^6, $D=0.107619\times10^7$, $E=-0.253369\times10^7$ and $F=0.237844\times10^7$ for the hydrate, and $A=-0.140903\times10^4$, $B=0.340826\times10^5$, $C=-0.328633\times10^6$, $D=0.158175\times10^7$, $E=-0.379924\times10^7$ and $F=0.364163\times10^7$ for the deuterate. Figure 4 shows the anomalous part of heat capacity thus derived which does not diverge at the transition temperature. Discrepancies between the samples subjected to different treatment are of significance; the sample obtained by cutting with a razor blade has a high, sharp peak at the transition temperature as compared with that of the sample obtained by crushing into pieces. Since there is no difference in the preparation of the two samples, the discrepancy in the heat capacity is considered to be due to this difference in handling. Partial dehydration from the crystal surface and/or stacking faults including other physical impurities, both of which are possibly caused by crushing, might be responsible for the local disappearance of clearly defined critical temperature. The discrepancy between the present data and those by Malcolm *et al.* (Fig. 5) arises from a similar cause.

No anomaly was observed in the heat capacity of anhydrous salt (Fig. 6). This confirms the view that the water molecules play an essential role in the transition phenomenon. The selected data and the derived

data are given in Table 8 together with the jump of heat capacity at the transition temperature, $\Delta C_p(T_{tr})$, where data for the sample subjected to cutting are adopted. The heat capacity jump at the transition point was estimated by the extrapolation of low and high temperature sides of C_p-values to the transition temperature by taking the rounding effect into consideration. A slight difference between the present value, 55.3 J K^{-1} mol^{-1}, and the old value,[16] 53.7 J K^{-1} mol^{-1}, for the hydrate comes from the difference in

Table 8. Thermodynamic quantities of ferroelectric reversible transition

	T_{tr} / K	ΔH_{tr} / J mol^{-1}	ΔS_{tr} / J K^{-1} mol^{-1}	ΔC_p / J K^{-1} mol^{-1}	$\Delta\alpha$ / K^{-1}

a) from Ref. 15, b) from Ref. 17.

heat capacity data; the present datum was determined from data of the cut sample and the previous one from those of the crushed sample. The entropy change of the transition thus estimated is 12.41 and 14.36 JK^{-1} mol^{-1} for the hydrate and deuterate, respectively. In the empirical classification of ferroelectric transitions, the present values of the entropy change definitely favor the order-disorder mechanism rather than the displacive one. In contrast, if we adopt the previous value 1.93 JK^{-1} mol^{-1} by Nakagawa *et al.* it may be explained also by the displacive mechanism. However, their data are not accurate enough to draw this conclusion. The entropy change expected from the structural data is $R\ln 2$ per mole of the substance, which is significantly smaller than the present values corresponding to $R\ln 4.45$ and $R\ln 5.62$ for the hydrate and deuterate, respectively.

Order of Transition: The heat capacity exhibits its jump without divergence at the transition temperature. This suggests that the transition would be of a second or higher order nature. If the phase transition is of the second order, the following Ehrenfest relation holds:

$$\left(\frac{dp}{dT}\right)_{tr} = \frac{\Delta C_p(T_{tr})}{T_{tr}V\Delta\alpha}, \tag{2}$$

where the left-hand side is the slope of the transition line, $\Delta C_p(T_{tr})$ and $\Delta\alpha$ are the jumps of heat capacity and thermal expansion coefficient, respectively, at the transition point, and T_{tr} and V the transition temperature and volume of the crystal, respectively. The volume *vs.* temperature curve for the hydrate shows no jump at the transition point. No hysteresis effect was found in the heating and cooling. This is also a characteristic of the second-order phase transitions. The best fit to the measured values is given by the following equation.

$$V_m = 0.03530\,T + 215.9170 \quad (T<248.5\text{ K}), \text{ and}$$
$$V_m = 0.02818\,T + 217.6863 \quad (T>248.5\text{ K})$$

where V_m is the molar volume in cm^3 and T in K. The change of thermal volume expansion coefficients, $\Delta\alpha$, at the transition point is 3.32×10^{-5} K^{-1}. Substitution of the measured $\Delta C_p(T_{tr})$ and $\Delta\alpha$ into the Ehrenfest relation gives 3.22×10^{7} Nm^{-2} K^{-1} for $(dp/dT)_{tr}$. This is to be compared with 3.77×10^{7} Nm^{-2} K^{-1}, the direct data of Krasnikova and others. The two values differ from each other by 17%, but the discrepancy is not significant in view of the difficulty of assessing the accuracy. The phase transition in the hydrate is of the second order or very close to it.

Energy to Reorient a Unit Dipole in the Completely Ordered State: The alignment of the water molecules is responsible for the ferroelectric transition. In the ferroelectric state, provided that the number of dipoles in the wrong orientation n is small compared with that of total dipoles N, the following approximate equation is valid;

$$\frac{n}{N} = \exp\left(\frac{\Delta s}{k}\right)\exp\left(-\frac{\Delta h}{kT}\right), \tag{3}$$

where Δh is the enthalpy required to orient a unit dipole in the environment of the almost ordered neighbors and Δs the entropy term associated with the free energy change. The anomalous heat capacity is given by

$$\Delta C_p = \frac{d(n\Delta h)}{dT} = \frac{N}{T^2}\frac{(\Delta h)^2}{k}\exp\left(\frac{\Delta s}{k}\right)\exp\left(-\frac{\Delta h}{kT}\right). \tag{4}$$

The value of $(-\Delta h/k)$ is evaluated from the slope of $\ln(\Delta C_p T^2)$ plotted against $1/T$ (Fig. 7). Linear fit to the plot between 130 and 190 K gives $n/N = 13.1\times\exp(-1006/T)$ for the hydrate, and $n/N = 10.4\exp(-905/T)$ for the deuterate. Thus, n/N values calculated at 190 K are 0.066 and 0.088 for the hydrate and deuterate, respectively. The reorientation enthalpies Δh are also estimated to be 8.36 and 7.52 kJ mol^{-1}, and the reorientation entropies 21.4 and 19.5 J K^{-1} mol^{-1} for the hydrate and deuterate, respectively.

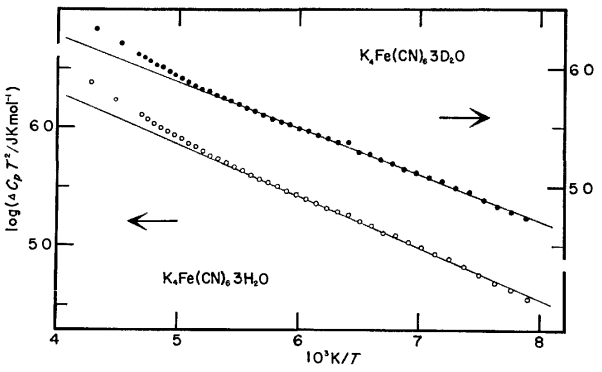

Fig. 7. Reorientation energy of a unit dipole in the completely ordered state.

The Metastable Phase and Its Irreversible Phase Transition. Heat Capacities Obtained under Different Pre-cooling Conditions: The heat capacities measured under different pre-cooling conditions are given in Tables 9 and 10 for the hydrate and deuterate, respectively. The process of measurement and results are as follows.

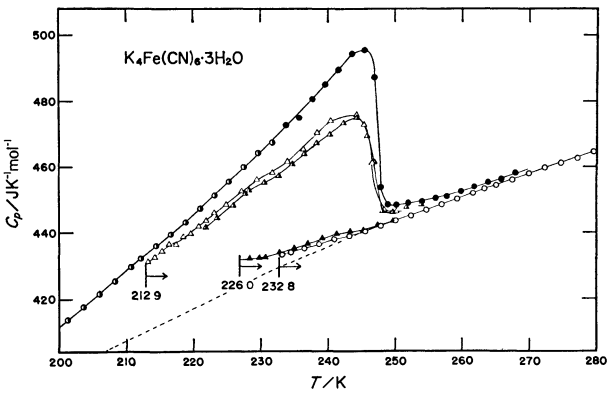

Fig. 8. Heat capacity of $K_4Fe(CN)_6 \cdot 3H_2O$ under different pre-cooling condition.
○: 1-st series, ▲: 2-nd and 3-rd series,
△: 4-th series, ◭: 5-th and 6-th series,
◑: 8-th, 9-th and 10-th series in Table 9,
●: cited from Table 2.

Measurements were carried out first in the temperature range 232.8—228.1 K with a specimen containing no monoclinic form (open circle, Fig. 8). The specimen was then cooled down to 226 K, where a slight exothermic phenomenon was observed corresponding to partial transformation of tetragonal into stable monoclinic phase. The heat capacity subsequently measured with increasing temperature (2nd and 3rd series) had a small hump in the vicinity of 240 K (symbol: ▲). This is due to the contribution of the reversible transition between the low and high temperature monoclinic phases. The 4th series (△) which started after cooling this specimen down to 212.9 K gave a much higher peak at 244 K. The measurements of the 5th and 6th (◭) series were carried out in order to confirm the reproducibility of the results under the same pre-cooling conditions. Spontaneous heat evolution was observed when the adiabatic condition was established after rapid cooling prior to measurement of the 4th series, but not of 5th and 6th series. The heat capacities of the 7th and subsequent three series coincided with those of the twinned monoclinic samples (Table 2). The heat capacity of the deuterate was measured under five different pre-cooling conditions. Reproducibility of heat capacity was checked at each stage by repeating the measurement, except for the last one in which the entire specimen was transformed into the monoclinic form. Measurement of the first series was commenced at 241.3 K

after the calorimeter had been cooled from room temperature and ended at 290.4 K. The specimen did not contain the monoclinic form at all, as evidenced by the fact that no heat capacity anomaly was observed in the 1st and 2nd series (open circle, Fig. 9). The 3rd series measured after cooling down to 231.5 K gave scattered data which coincided neither with the heat capacities of the monoclinic form nor with those of the 1st and 2nd series. The 4th series repeated under the same precooling conditions as for the 3rd one (▲) yielded a smooth curve in contrast. The heat capacity was significantly larger than that of the tetragonal form. The 5th and 6th series (◑) give heat capacities for the specimen pre-cooled to 227.3 K, which were larger than those of the previous series, the difference between heat capacities in these series being small as compared with that between the 3rd and 4th series. The difference was still less and hardly occurred between those of the 7th and 8th series (△) in which the specimen was pre-cooled to 221.3 K. The heat capacities in the 9th, 10th and 11th series (●) correspond to those of the twinned monoclinic phase. Spontaneous heat evolution was observed prior to the measurements of

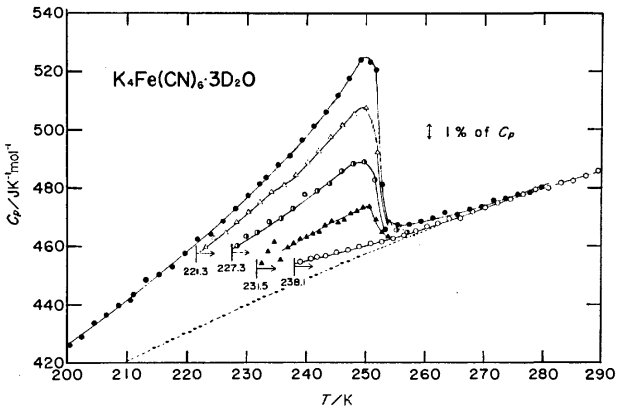

Fig. 9. Heat capacity of $K_4Fe(CN)_6 \cdot 3D_2O$ under different pre-cooling conditions.
The data of the 1-st, 2-nd (these two series: ○), 4-th (▲), 6-th (◑), 8-th (△), 9-th, 10-th and 11-th (these three series: ●) are selected by considering that these series would offer the reproducible data, while the 3-rd, 5-th and 7-th series were liable to yield scattered values.

the 3rd, 5th and 7th series as in the case of the hydrate.

From the results the following conclusions are reached. (1) The heat capacities obtained immediately after the establishment of the pre-cooling condition differ from the data of subsequent measurements performed under the same pre-cooling conditions. (2) All the data after the second agree with each other. (3) The mode of difference of heat capacity between the first and the following series depends upon the lowest temperature as well as the rate of the pre-cooling procedure, *etc.*

Similarity of the Monoclinic and Tetragonal Phases: The molecular arrangement of stable monoclinic and metastable tetragonal modifications at room temperature is quite the same in each layer and the modifications differ only in the mode of stacking. This suggests a slight difference in their lattice energies. Similarity of the two phases was also found in the Raman spectra and heat capacity values. The Raman spectra of each phase at room temperature were found to be in complete agreement except for a slight difference in intensity. Good coincidence in heat capacity and its dependence is shown in the case of the deuterate in Fig. 9. For the hydrate this cannot be definitely concluded for lack of data on the same sample in the temperature range where the short range ordering of the water molecules in the monoclinic phase is expected to vanish. However, between these two phases a distinct similarity in the thermal motion, and also in total enthalpy and entropy at room temperature is expected.

Properties of the Metastable Tetragonal Phase: The hydrate crystal in the tetragonal modification does not transform into the monoclinic phase in the temperature range between 232.8 K and room temperature. The tetragonal modification for the deuterate remains metastable at temperatures above 238 K. This is evident from the absence of heat capacity anomaly which should appear in the monoclinic modification (open circle, Figs. 8 and 9). It should be added that the hydrate sample crystals could be kept in a desiccator for six months without transformation. The heat capacity curve of the tetragonal modification (Figs. 8 and 9) deviates anomalously around 240 K. This is also the case for the tetragonal deuterate. The anomalous shape of the heat capacity curve suggests further contribution of a configurational one due to the development of the short range order of water molecule. In view of the structural similarity of the monoclinic and tetragonal phases within the hydrogen-bonded layer, the water molecules would be ordered in each layer around the same temperature where the stable monoclinic-monoclinic transition takes place.

Nature of the Phase Transition: The irreversible exothermic transformation of the tetragonal phase into the *twinned* monoclinic phase takes place below 232 K for the hydrate and below 237 K for the deuterate. This phase transformation develops in a strange way and is to some extent characteristic of the lowest temperature to which the specimen has been chilled down. Thus, the heat capacity curves measured exhibit different behaviors in accordance with the pre-cooled lowest temperatures (Tables 9 and 10, Figs. 8 and 9). In the

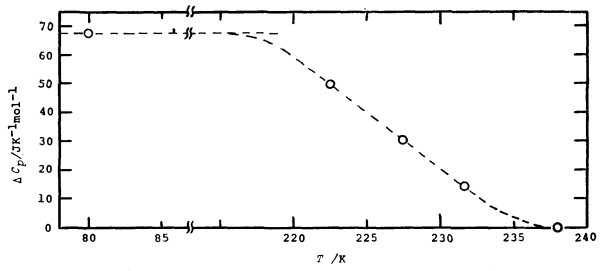

Fig. 10. The dependence of the peak heights of heat capacity on pre-cooling temperatures in $K_4Fe(CN)_6 \cdot 3D_2O$.

case of the deuterate the heat capacity peaks for the samples pretreated under different pre-cooling conditions appear at *the same temperature* 250 K, at which the pure monoclinic-monoclinic phase transition takes place. This indicates that the original tetragonal and the partially grown monoclinic phases coexist independently so that the peak height of the heat capacity has a linear relation to the ratio of amounts of the monoclinic to the tetragonal phases. The relation between the peak height and the precooled temperature is given in Fig. 10. This peculiar behavior suggests that the metastability of the tetragonal phase is due not to the absence of the nucleation by which the tetragonal phase is transformed into the complete monoclinic phase, but to the nature of the transformation: *viz.* in spite of enough macroscopic amount of stable monoclinic phase, the transformation in this crystal stops at any intermediate stage. This was evidenced by cessation of spontaneous heat evolution and also by the reproducibility of heat capacity data as long as the sample was not cooled below the lowest temperature to which the specimen had been brought. This new type of phase transformation with the characteristics of the Martensitic one[20] rarely observed in non-metals might occur from the following viewpoint based on the free energy difference between the monoclinic and tetragonal phases. The transformation does not seem to occur until the driving force attains a characteristic threshold value as in the case of Martensitic transition. This driving force will be given by the free energy difference between the two phases. On the other hand, the threshold value may arise from the sum of the interface and/or strain free energies, *etc.* associated with the creation of *twinned* monoclinic phase and it becomes larger with the increased amount of this monoclinic phase. As long as there is no reversible transformation in the tetragonal phase, the free energy diagram is such as depicted schematically in Fig. 11 for the deuterate, where the dotted area stands for the transformation region experimentally confirmed. The free energy difference at room temperature is imagined to be fairly small from similarity in structure as well as in thermal motion between the two modifications. This difference will increase with a fall in temperature through the reversible ferroelectric transition, since the heat capacity is larger for the monoclinic form than that for the tetragonal. The actual transformation will be initiated when the threshold value is reached with

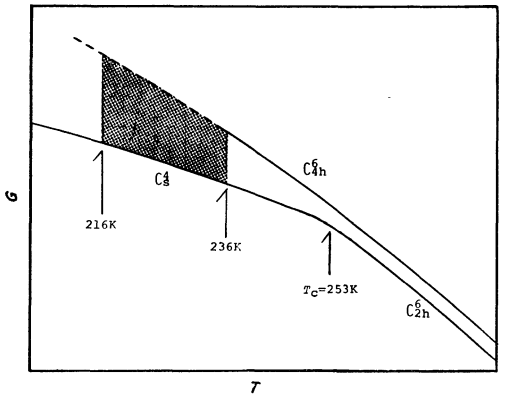

Fig. 11. Schematical free energy diagram of $K_4Fe(CN)_6 \cdot 3D_2O$. The upper curve, C^6_{4h}, corresponds to the tetragonal modification. The portion, C^6_{2h}, of the lower curve stands for the paraelectric monoclinic phase, and the portion, C^4_s, for the ferroelectric monoclinic phase. Dotted area is of the irreversible transition region to the monoclinic form.

decreasing temperature. If production of the *twinned* monoclinic phase were to lead to an increase of the threshold value preventing further transformation, the process would be stopped at the intermediate stage which is constrained by the balance between the temperature dependent-free-energy difference of two phases and the threshold value determined by the amount of the coexisting monoclinic phase. This view will also explain why the difference between the Curie temperature and the irreversible transition temperature is almost the same for the hydrate and deuterate, since the anomalous heat capacities behave analogously for these two compounds.

The created monoclinic crystal in the tetragonal phase has a *twinned* structure. In parallel with this it is interesting that the Martensitic materials are often composed of an assembly of thin plates.

According to the report of Krasnikova *et al.* in which irreversible transition was studied through the measurement of double refraction, the irreversible transition temperature becomes higher with the increase in the monoclinic fraction of a macroscopic sample. Our results indicate the opposite tendency as regards the transition point. This apparent contradiction will necessitate further elucidation of the intrinsic properties or textures of starting materials they used.

The Rate of Phase Transformation: A spontaneous temperature rise accompanied with irreversible transformation was observed immediately after rapid precooling. This phenomenon was carefully followed at five different temperatures in the transition region for the deuterate, an example being in Fig. 12. The procedure taken for every measurement of the spontaneous temperature rise was always the same. After the calorimeter was first cooled to a temperature 2 K above that at which the measurement was started, adiabatic conditions were established, and then the calorimeter was cooled again by introducing the exchange gas into the cryostat. When the desired temperature was reached, the cryostat was evacuated and the adiabatic control system was started to function. This round-about pro-

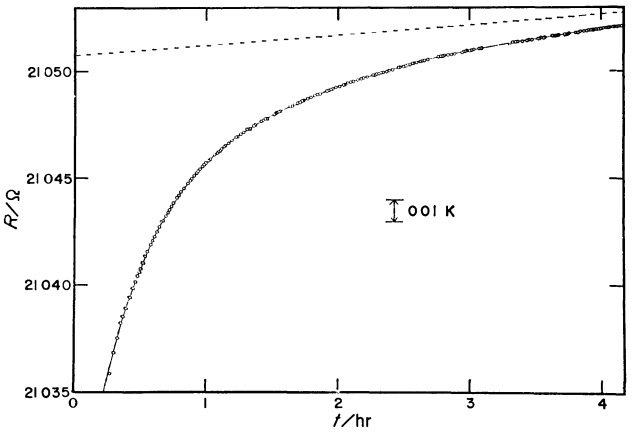

Fig. 12. A spontaneous heat evolution after rapid pre-cooling.

cedure was designed to realize as similar a cooling rate and temperature distribution in the cryostat as possible for each measurement. A control run performed after the entire specimen was transformed into the monoclinic form showed that the heat leak effect was small enough to be neglected as compared with the observed temperature rise. The broken line in Fig. 12 shows the natural drift observed in the control run. We tried to fit the time dependence of temperature into an exponential law with single time constant τ, on the assumption that the molar enthalpies of the monoclinic and tetragonal phases and the heat capacity of the calorimeter cell containing the sample were constant during the course of measurement. The time constant was evaluated with an estimated error of 20%, the observed temperature rise being fitted to the following equation.

$$T(t) - T(\infty) = A \exp(-t/\tau), \qquad (5)$$

where T and t are temperature and time, respectively, and A is a numerical constant. Fig. 13 shows the temperature dependence of the time constant which corresponds to the half-life. The value of τ decreases with decreasing temperature, except at the lowest

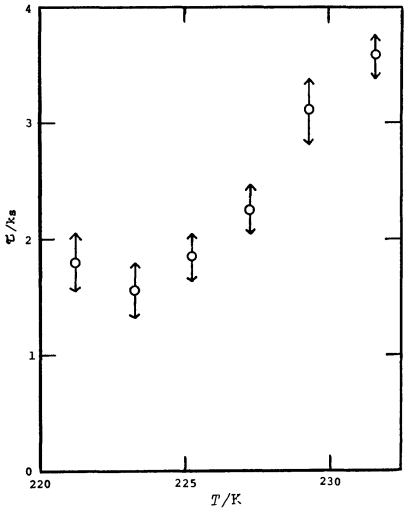

Fig. 13. Temperature dependence of time constant of spontaneous heat evolution in $K_4Fe(CN)_6 \cdot 3D_2O$.

temperature, in contrast to a thermal activation process. Explanation should be given taking into account the free energy difference between the tetragonal and monoclinic phases as the driving force of the transformation. The simplest expression will be

$$\frac{dX_m}{dt} = -B\{X_m(t)-X_m(\infty)\}\Delta G \qquad (6)$$

where X_m, B and ΔG stand for the molar fraction of the monoclinic phase, some positive constant dependent on temperature, and the free energy difference between the two phases, respectively. The time constant in Eq. (5) is identified with $1/(B\Delta G)$. As ΔG increases with decreasing temperature (Fig. 11), the initial decrease of τ on cooling can be attributed to the increase in the driving force of the transformation. The increase in the time constant by further decreasing temperature can be ascribed to the temperature factor through constant B.

Conclusion

Thermal properties we obtained give important information on the stability and phase transitions of $K_4Fe(CN)_6 \cdot 3H_2O$ and its deuterate. The amount of entropy change at the ferroelectric transition between two stable monoclinic phases strongly suggests the molecular mechanism of an order-disorder type. Behavior of heat capacity and molar volume changes at the transition point indicates that this phase change is very close to the second-order type, the Ehrenfest relation for the second-order phase transitions being found to hold. This is a rare example of the second-order transition tested by Ehrenfest's relation.

The metastable tetragonal crystals underwent an irreversible transition to the stable monoclinic phase. The transition was found to be a new type with some characteristics of the Martensitic transition which is rarely found in non-metallic compounds.

We wish to thank Professors Ryoichi Kiriyama and Hideko Kiriyama for fruitful discussions. We are grateful to Mr. Mitsuo Ôhama for the measurements of Raman spectra.

Nuclear Quadrupole Resonances of Tellurium Tetrachloride and Tellurium Tetrabromide

Tsutomu OKUDA, Koji YAMADA, Yoshihiro FURUKAWA, and Hisao NEGITA
Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received June 3, 1974)

The nuclear quadrupole resonances (NQR) due to ^{35}Cl and ^{81}Br in $TeCl_4$ and $TeBr_4$ have been observed and their Zeeman effects have been examined. Each spectrum consists of six resonance lines with equal intensities, which are assigned to the two species of $TeCl_3^+$ ions or $TeBr_3^+$ ions. The asymmetry parameter of the electric-field gradient is, at most, 5% in each case. The relative orientation among the zero-splitting patterns of six resonance lines is consistent with the crystal structure of $TeCl_4$, which consists of the tetramers of $(TeCl_3^+Cl^-)_4$, as was recently determined by X-ray diffraction analysis. The zero-splitting patterns of the $TeBr_4$ crystal are so similar to those of $TeCl_4$ that the former crystal seems likely to consist of tetramers of $(TeBr_3^+Br^-)_4$ as well. The average $\angle$X-Te-X bond angles in TeX_3^+ ions were found to be 95.9° for the chloride and 96.7° for the bromide. The values for the chloride are in good agreement with those obtained by the X-ray analysis. On the other hand, the bond character of the TeX_3^+ ions in TeX_4AlX_3 (X=Cl, Br) was compared with that of TeX_4 from NQR.

It has been described that the molecular shape of $TeCl_4$[1] in the gaseous state is a trigonal bipyramid with lone-pair electrons on one of its equatorial orbitals. From the nuclear quadrupole resonance study,[2] the molecular shape in the solid state has been presumed to be a trigonal bipyramid, as in the gaseous state, though six resonance lines were observed at the temperature of liquid nitrogen.

On the other hand, the structural study of solid TeX_4 (X=Cl, Br) by means of infrared spectroscopy[3-6] has suggested that the crystal consists essentially of the ionic structure $TeX_3^+X^-$ because of the existence of four infrared-active vibrations similar to those of $SbCl_3$ and $SbBr_3$.

Recently, from a three dimensional X-ray analysis of $TeCl_4$[7] it has been concluded that this compound crystallizes in the space group C2/c of the monoclinic system with $a=17.076$ Å, $b=10.404$ Å, $c=15.252$ Å, and $\beta=116.28$ °. As is show in Fig. 1, the crystal consists of tetramers formed with an arrangement of alternate $TeCl_3^+$ and Cl^- ions at the apexes of the distorted cube. The unit cell contains four tetramers, all of which are equivalent and have two-fold axes. Every Te atom has three terminal Cl atoms and three bridging Cl atoms at average distances of 2.31 Å and 2.93 Å respectively. The X-ray diffraction studies of $SeCl_4$ and $TeBr_4$[8,9] have shown that these compounds are isomorphous with $TeCl_4$.

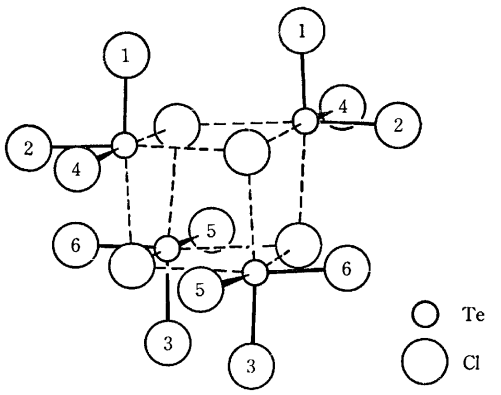

Fig. 1. Te_4Cl_{16} molecular unit in the $TeCl_4$ crystal. The number in the circle represents the order of the resonance lines from the lowest. The two-fold crystallographic axis passes vertically.

In the present experiment, the NQR spectra of $TeCl_4$ and $TeBr_4$ were observed in the temperature range from 77 K to 339 K, and the Zeeman effects on the spectra of the single crystals were examined at room temperature in order to clarify the bond character and molecular shape in the crystals. Furthermore, the bond characters were compared with those of TeX_3^+ ions in the TeX_4AlX_3 crystal.

Experimental

The single crystals of $TeCl_4$ and $TeBr_4$ were grown by the Bridgman-Stockbarger method. The NQR spectrometer used in this experiment was a super-regenerative oscillator with frequency modulation, and the absorption lines were observed on an oscilloscope. An LC-type super-regenerative oscillator was made to seach for the resonance lines of bromine isotopes in the region about 200 MHz. This oscillator was used only at room temperature and was put in the magnetic field for the study of the Zeeman effect. The resonance frequencies of the ^{81}Br nuclei were observed by the use of a super-regenerative oscillator consisting of Lecher-lines at various temperatures. The resonance frequencies were determined with a VHF signal generator and frequency counter of the Takeda Riken Co., TR-5578.

The Zeeman effect was examined by means of the zero-splitting cone method.[10] The orientation of the magnetic field for the zero-splitting was determined by means of polar coordinates (Φ, Θ), where Φ and Θ were the azimuthal and polar angles respectively, in the coordinate fixed to the sample. About forty experimental points were observed for each zero-splitting pattern. From these values, the best quadratic cone was obtained by the use of the least squares method, then the center of each zero-splitting pattern and the value of η were determined precisely.

Results and Discussion

The resonance frequencies of $TeCl_4$ and $TeBr_4$ are listed in Table 1. Powder samples of both $TeCl_4$ and $TeBr_4$ give rise to six resonance lines with equal intensities, although the ν_2' and ν_3' lines of $TeBr_4$ coincide at the temperature of liquid nitrogen. All the reso-

Table 1. ^{35}Cl and ^{81}Br NQR frequencies in TeX_4 (X=Cl, Br)

Compounds		Resonance frequencies (MHz) 26 °C	−196 °C
$TeCl_4$	ν_1	26.782	27.304
	ν_2	26.947	27.370
	ν_3	27.024	27.471
	ν_4	27.471	27.926
	ν_5	27.685	28.110
	ν_6	27.968	28.461
$TeBr_4$	ν_1'	185.18	188.13
	ν_2'	187.68	190.42
	ν_3'	187.81	190.42
	ν_4'	190.91	193.56
	ν_5'	195.36	197.88
	ν_6'	197.34	200.06

nance frequencies decrease continuously with an increase in the temperature, and the temperature coefficients are nearly equal in each compound. This must result from the fact that the crystal consists of tetramers which have an approximately Td symmetry and that the terminal halogens therefore undergo nearly equal thermal vibrations.

The zero-splitting patterns of $TeCl_4$ are shown in Fig. 2, where Cl_1, Cl_2,$\cdots$, Cl_6 indicate the direction of the z-axes of the field gradients at the chlorine atoms showing ν_1, ν_2,$\cdots$, ν_6 resonance lines respectively. Two zero-splitting patterns were observed for each resonance line, and a two-fold axis was determined, as is shown in Fig. 2. The two zero-splitting patterns of all the resonance lines except ν_2 were well separated from one another. However, the ν_2 line gave partly overlapping zero-splitting patterns. Therefore, the evaluation of the asymmetry parameter for this line was less accurate. As the asymmetry parameters of field gradients are small, it can be assumed that the z-axis coincides with the bond direction. Therefore, the assignment of the z-axes to chlorine atoms in the tetramer is based on the two-fold symmetry axis determined from Zeeman experiments and on the various angles determined from X-ray analysis. In

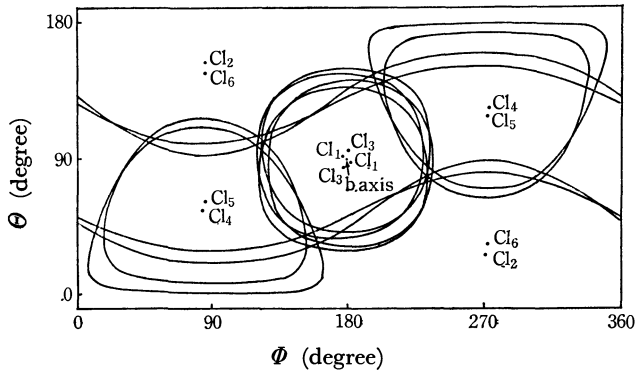

Fig. 2. Zero-splitting patterns of Zeeman lines of $TeCl_4$. The axis of $\Theta=0$ is taken as the rotation axis of the sample tube. The plane of $\Phi=0$ is arbitrarily chosen.

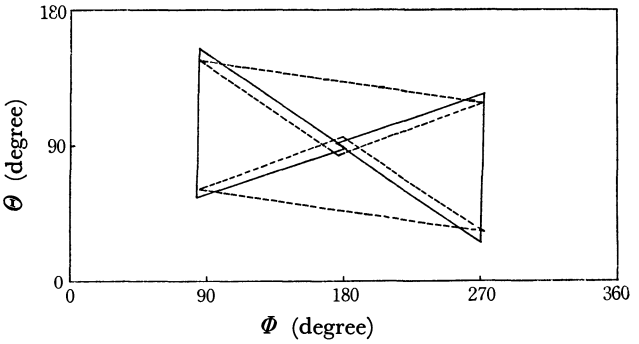

Fig. 3. Principal z-axes and its relationship in $TeCl_4$ crystal.

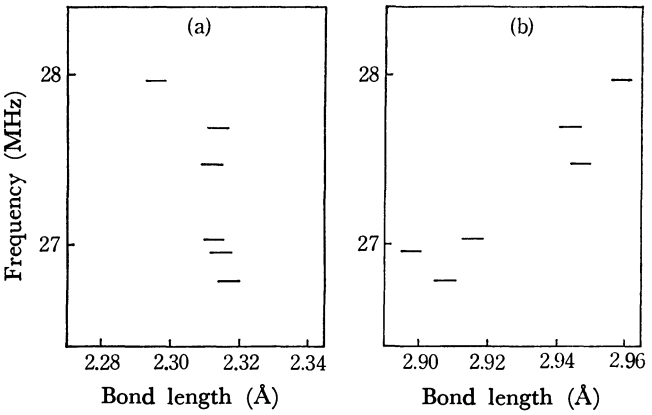

Fig. 4. The relationship between resonance frequencies and bond length in $TeCl_4$. a) resonance frequencies are plotted against their terminal bond length, b) resonance frequencies are plotted against the bond length of the bridging bond being located at the *trans* position to the terminal Cl atoms.

Fig. 3, the principal z-axes which are considered to arise from the same $TeCl_3^+$ ions are connected with solid or broken lines; triangles are thus formed. The triangles represented by solid or broken lines correspond to nonequivalent $TeCl_3^+$ ions in the crystal. Figure 3 supports the existence of the tetramers of $(TeCl_3^+Cl^-)_4$ for the $TeCl_4$ crystal, although these results are derived on the basis of the crystal structure from the X-ray analysis. The numbers in the circles in Fig. 1 show the chlorine species determined by the present experiment. In Fig. 4, the resonance frequencies of the terminal Cl atoms are plotted against the terminal bond length and the bond length of the bridging bonds which are located at the *trans* position to the terminal Cl atoms. This figure shows that each resonance frequency is affected by the bridging Cl atom which is located at the *trans* position to the terminal Cl atom. Therefore, the large spread in the resonance frequencies may be considered mainly due to the difference in the strength of the bonds between the bridging Cl atom and the Te atom.

The zero-splitting patterns of $TeBr_4$ are quite similar to those of $TeCl_4$. From the similarity of the zero-splitting patterns of $TeBr_4$ to those of $TeCl_4$, and from the fact that they are isomorphous with each other,[8,9] it is evident that the former crystal consists of tetramers of $(TeBr_3^+Br^-)_4$. It may be considered on the basis

	up to 5.0	53.867	49.1	42.2
	3.0±0.2	54.040	49.2	42.1
	2.8±1.0	54.932	50.1	41.1
	1.9±0.2	55.362	50.4	40.7
	2.5±0.5	55.926	51.0	40.0
$TeBr_4$	4.5±0.3	370.22	57.6	32.2
	up to 5.0	375.34	58.4	31.3
	4.4±0.2	375.50	58.4	31.3
	3.6±0.3	381.74	59.4	30.1
	1.5±0.5	390.71	60.8	28 3
	2.7±0.2	394.63	61.4	27.8

of the orientation of the z-axes that this tetramer has a two-fold axis and contains two nonequivalent $TeBr_3^+$ ions. As the NQR spectra and their Zeeman patterns in $TeBr_4$ are similar to those in $TeCl_4$, one $TeBr_3^+$ ions contributes to the ν_1', ν_2', and ν_4' lines, and the other, to the ν_3', ν_5', and ν_6' lines. Table 2 shows the bond angles of the TeX_3^+ ions obtained from NQR, together with those obtained by X-ray analysis. The former values are slightly larger than the latter.

In the $TeCl_4$ crystal, π-bond character of the terminal Te-Cl bond may be neglected for three reasons: a) the terminal Te-Cl bond length is nearly equal to the corrected sum of the single covalent bond radii of 2.34 Å,[11] b) the resonance frequencies show negative temperature coefficients, and c) the asymmetry parameters are small. Table 3 lists the asymmetry parameter of the electric-field gradient (η), the quadrupole coupling constant (e^2Qq), the number of unbalanced p electrons (U_p), and ionic character (i) for the Te-X bond. These parameters are related by the following equations:

$$h\nu = (e^2Qq_{obs}/2)(1+\eta^2/3)^{1/2}, \quad (1)$$

$$U_p = e^2Qq_{obs}/e^2Qq_{atom} = (1-s)(1-i), \quad (2)$$

where e^2Qq_{obs}/h is the observed quadrupole coupling constant and e^2Qq_{atom}/h is 109.74 MHz for ^{35}Cl and 643.03 MHz for ^{81}Br.[12] s is the s-electron character in the bonding orbital of the halogen, which is assumed to be 0.15.[13] The ionic character of the terminal Te-X bond in $TeBr_4$ is smaller than that of $TeCl_4$, as is shown in Table 2. The same tendency is seen between chloride and bromide, which have the same structure, and may be attributed to the differences in the electronegativities of the relevant halogen atoms.

As is obvious from the crystal structure, $TeCl_4$ acts as a Cl^- donor and forms a compound with the Cl^- acceptor. An example is $TeCl_4AlCl_3$,[14] the crystal structure of which has recently been determined to be as is shown in Fig. 5. The $TeCl_3^+$ ion has a shape similar to that in $TeCl_4$, but the Te–Cl bonds in $TeCl_4$-$AlCl_3$ are shorter than those in $TeCl_4$. Table 4 shows the NQR parameters of $TeCl_4AlCl_3$ and $TeBr_4AlBr_3$. The resonance frequencies are assigned to those of halogens in TeX_3^+ ions, because those in AlX_4^- ions are expected to be much lower. The quadrupole coupling constants in the TeX_4AlX_3 crystal are larger than those in $TeCl_4$ and $TeBr_4$ by about 9.3% and 10.0% respectively. According to the X-ray analysis of the crystals of $TeCl_4AlCl_3$,[14] $TeCl_4$,[7] and $(NH_4)_2$-$TeCl_6$[15,16] all the tellurium atoms are octahedrally coordinated by six chlorine atoms. Although the $TeCl_6^{2-}$ ion in $(NH_4)_2TeCl_6$ is a regular octahedron, the $TeCl_3^+$ ion in $TeCl_4AlCl_3$ forms a distorted octahedron, as is shown in Fig. 5. There is a linear relationship between the quadrupole coupling constants and the bond lengths of the terminal Te–Cl bonds. From this relationship, it is obvious that the bond character of Te–Cl in the $TeCl_4$ crystal is intermediate

A Torsional Braid Analysis of Polymethacrylates, Polyacrylate, Poly(vinyl alcohol), and Their Related Polymers during the Thermal Degradation

Noboru FURUSHO, Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA

Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 15, 1974)

The torsional braid analysis (TBA), thermogravimetry, and IR spectroscopy of polymethacrylates, polyacrylate, poly(vinyl alcohol), and their related polymers were carried out in air. The chemorheological properties of these polymers are markedly dependent on their chemical structures. First, the α-hydrogen atom plays an important role. In poly(methyl acrylate), the chemorheological behavior is similar to that of the polymers which have tendency to crosslink, whereas poly(methyl methacrylate) does not show any such behavior. A similar situation was found when comparing poly(acrylic acid) with poly(methacrylic acid). At the same time, the influence of the functional groups was examined. Second, the change in the mechanical properties due to crosslinking becomes more noticeable with an increase in the side-chain length of the methacrylate polymers. Furthermore, in addition to procedures used in the previous work, a new method of kinetic analysis of the heating-rate dependence was carried out in the case of poly(acrylic acid). The apparent activation energies estimated by this treatment are in good agreement with those estimated by other procedures.

Studies of the thermal degradation of polymers have been carried out by various methods—for example, pyrolysis gas chromatography, and thermogravimetry. Among those studies, relatively few studies have been done on the basis of the measurements of mechanical properties. Previously, we have reported some results of a thermal-degradation study of polymers by the measurement of their dynamic mechanical properties using the TBA method.[1,3] We found some interesting features not observable by other methods and proposed to use this method as a convenient tool for kinetic studies.

In the present paper, we wish to report some results of the TBA of polymethacrylates, polyacrylate, poly (vinyl alcohol) and their related polymers. Moreover, with the aid of the results of the thermogravimetry and IR spectroscopy, we will discuss the correlation between the chemorheological behavior and the chemical processes.

The purpose of this work is to elucidate the effects of the α-hydrogen atom, the side-chain length of the alkyl methacrylate polymers, and the character of the functional group on the chemorheological properties during the thermal degradation. We also intended to examine the applicability of the kinetic treatment usually used in thermogravimetry to the TBA studies.

Experimental

The poly(methyl acrylate)(PMA), poly(methyl methacrylate)(PMMA), poly(vinyl alcohol)(PVA), poly(acrylamide)(PAAm), poly(methyl vinyl ether)(PVME), and poly(vinyl acetate)(PVAc) were all commercial materials. The poly(acrylic acid)(PAA), poly(methacrylic acid)(PMAA), poly(ethyl methacrylate)(PEMA), poly(butyl methacrylate)(PBMA), poly(hexyl methacrylate)(PHMA), and poly(2-ethyl hexyl methacrylate)(PEHMA) were synthesized in the ordinary way.

The procedures of the torsional braid analysis(TBA) have been described in a previous paper.[1] The relative shear modulus ($G_r=(P_0/P)^2$) is calculated from the periods of oscillations, P, where the values of P_0 are the period of oscillation 10 min after the setting of the specimen under isothermal conditions or that at room temperature under the conditions of a constant heating rate (and where the values of P are the period at the time t or that at the temperature T). The logarithmic decrement ($\lambda=(1/n)\ln(A_{2n+1}/A_1)$) is calculated from the amplitudes of the damped oscillations, where n is the number of oscillations and where A_1 and A_{2n+1} are the amplitudes of the first and nth oscillations. The studies of the heating-rate dependence of the mechanical properties were carried out using an automatic TBA apparatus made by Takahashi *et al.*[2]

The IR measurements and the thermogravimetry(TG) were carried out in the same way as in a previous work.[3]

Results and Discussion

Chemorheological Behavior and Its Relation to the Chemical Process. The mechanical properties of these polymers are shown in the following figures. Each curve consists of several regions. The lower-temperature regions correspond to the physical process (glass transition, fusion, *etc.*). Their details will not be discussed here.

PMA and PMMA: In order to clarify the effect of the α-hydrogen atom on the chemorheological behavior, TBA measurements of PMA and PMMA, which both have ester groups and which differ each other in the point of whether the α-hydrogen atom exists or not, were carried out. As is shown in Fig. 1, the chemorheological properties of PMA and PMAA are very different from each other. In PMA, the gradual increase in G_r, its abrupt increase and the corresponding maximum of λ are observed above 150 °C. This situation resembles that in systems in which crosslinking occurs.[4]. However, for PMMA, no significant change is observed other than the glass transition at about 120 °C and the fusion at about 240 °C, in spite of the occurrence of a considerable weight loss above 200 °C; this weight loss is the result of the depolymerization. This mechanical behavior will be discussed below.

The IR spectra of these two heat-treated polymers remained essentially unchanged. The TG curve (Fig. 2) and the TBA curve (Fig. 1) show that, in PMA, the increase in G_r above 150 °C is not accompanied by any weight loss and that the decrease in G_r near 400 °C is closely connected with the large weight loss. Those observations are quite different from those of

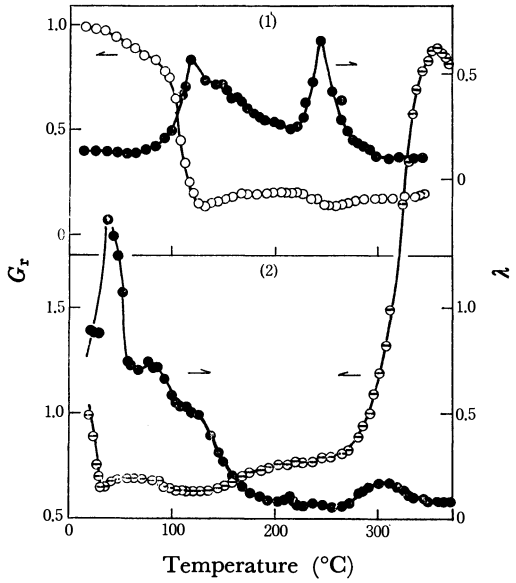

Fig. 1. G_r, λ *vs.* T plots of PMA and PMMA heated in air.
Heating rate: 1 °C/min. (1): PMMA, (2): PMA, G_r: ○⊖, λ: ●.

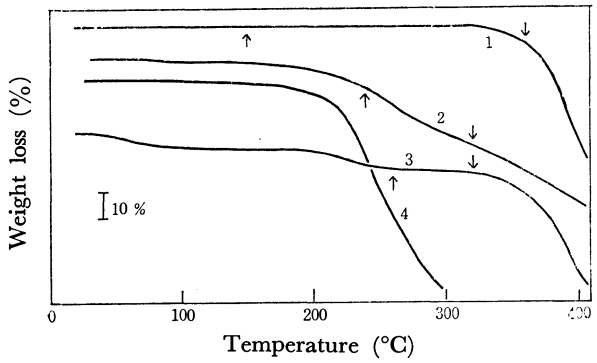

Fig. 2. TG curves of PMA, PMAA, PAA and PMMA in air.
Heating rate: 10 °C/min(1), 3 °C/min(2, 3 and 4). (1): PMA, (2): PAA, (3): PMAA, (4): PMMA. The arrows indicate the point at which G_r begins to increase (↑) and to decrease (↓).

the halogen-containing polymers, in which the chemorheological behavior is closely related to the weight loss resulting from the dehydrohalogenation.[3]

From the above discussion it may be concluded that, in PMA, the increase in G_r is attributable to the cross-linking caused by the α-hydrogen atom removal, while the decrease in G_r is due to the destruction of the network structure by the chain scission of the polymers, as is suggested by the large weight loss at higher temperatures. However, the nature of the slowing down of the rate of the increase in G_r just above 200 °C is not clear at present.

PAA and PMAA: From the study of PMA and PMMA, it has been made clear that the ester group does not affect the chemorheological behavior. Therefore, TBA measurements of PAA and PMAA were made. The PAA and PMAA are different from PMA and PMMA in only the point that PAA and PMAA have carboxyl groups instead of methyl ester groups.

In the cases of PAA and PMAA (Fig. 3), in contrast to the cases of their ester analogues, the chemorheological properties resemble each other. The IR spectra shown in Fig. 4 give important information on the mechanism of the mechanical change. In PAA, the peaks were observed at about 1050 and 1150 cm^{-1}, and a small shoulder, at about 1800 cm^{-1}. The former is probably due to the oxidative cross-linking, as has been suggested by Otani,[5] and the latter, to the formation of the anhydride structure.[6]

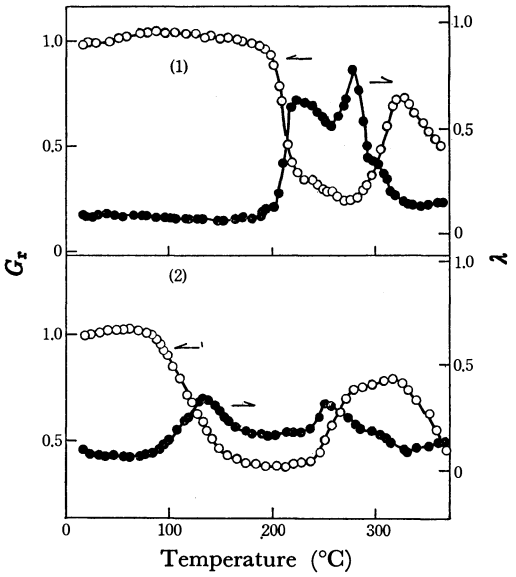

Fig. 3. G_r, λ *vs.* T plots of PMAA and PAA heated in air.
Heating rate: 1 °C/min. (1): PMAA, (2): PAA, G_r: ○, λ: ●.

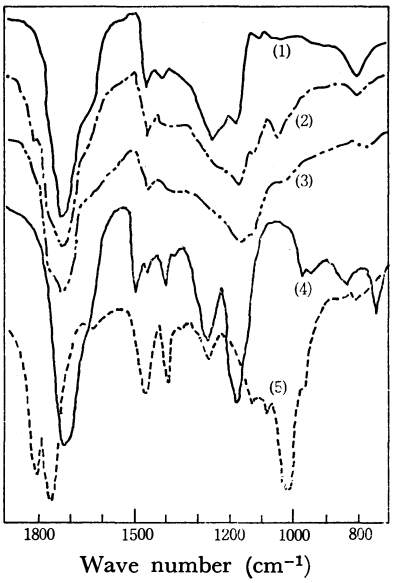

Fig. 4. IR spectra of PAA and PMAA heated in air.

On the other hand, the formation of the anhydride structure is slight. In PMAA, on the other hand, very intense peaks were found at about 1760 and 1810 cm^{-1}, shifted from 1720 cm^{-1}; these peaks can be assigned to the vibrations of the carbonyl group in the acid anhydride and the acid form. This finding suggests the formation of a typical acid-anhydride structure. Grant and Grassie have pointed out that this occurs both intramolecularly and intermolecularly.[7] Moreover, quite different behavior was found in the change in mechanical properties due to the chemical process by means of isothermal TBA measurements of the two polymers, as will be discussed below.

These results indicate that, in PAA, the α-hydrogen atom, not the carboxyl group, is the principal factor in determining the chemorheological behavior in air. On the other hand, in PMAA, the formation of both intermolecular and intramolecular anhydride structures is the predominant factor. From the viewpoint of weight loss, in both PAA and PMAA the weight loss occurs with the chemorheological change; this weight loss is presumably related to the formation of the anhydride structure. This situation is different from that in the case of PMA, in which only the α-hydrogen atom plays an important role in the chemorheological behavior.

PVA, PVME, PVAc, and PAAm: From a comparison of the results on PMA and PAA, it can be expected that the chemorheological properties of the polymers with the α-hydrogen atom will be greatly influenced by the functional group in the side chain. Therefore, TBA studies of PVA, PVME, PVAc and PAAm, which all have the α-hydrogen atom, just as PAA and PMA have, were carried out. The results for these polymers are shown in Figs. 5 and 6. It should be pointed out here that the increase in G_r at lower temperatures in PVME is due to the evaporation of

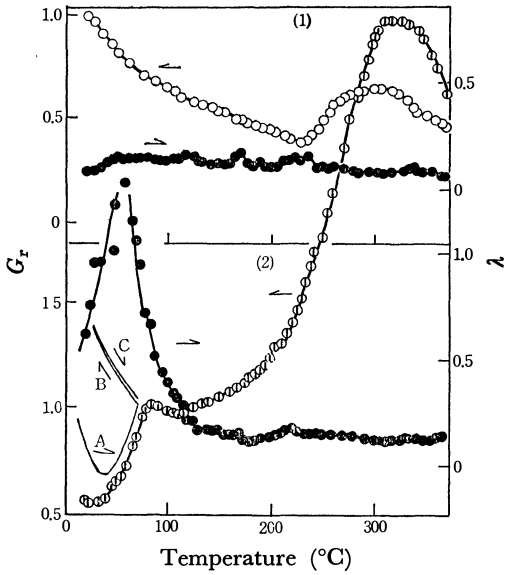

Fig. 5. G_r, λ *vs.* T plots of PVA and PVME heated in air.
The solid line shows the change in G_r of PVME during the repeated run (A-B-C). Heating rate: 1 °C/min. (1): PVA, (2): PVME, G_r: ○①, λ: ●.

the residual solvent used for the specimen preparation. The fact that an ordinary decrease in G_r is observed by heating it up to 100 °C supports this consideration (see Curves A—B—C in Fig. 5).

In these four polymers, as in PMA and PAA, a considerable increase in G_r is observed at higher temperatures. In the IR measurements and thermogravimetry, we found the formation of the carbon-carbon double bond and the imide group, and also a close relation between the increase in G_r and the weight loss. Moreover, in these polymers, it is known that such reactions as the dehydration in PVA,[8] the deacetylation in PVAc,[9] and the imidization in PAAm[10] occur at higher temperatures. Considering this, it may be concluded that the increase in G_r in these four polymers is closely connected to such reactions as dehydration, which involve the functional group in the side chain.

This situation resembles to some extent that in the halogen-containing polymers, in which the dehydrohalogenation is a dominant factor in their chemorheological properties. However, the findings that the IR absorptions of the double bond and of the imide group are not very intense and that the G_r increases without any weight loss from 120 to 180 °C in PVME suggest an undeniable role of α-hydrogen atom.

The order of the temperatures at which G_r begins to increase is; PVME<PVAc<PVA<PAAm. However, it is not clear that this order of temperatures corresponds to the order of the reactivities of the methoxyl, acetyl, hydroxyl, and amide groups because of the difference in the glass-transition temperatures and the undeniable effect of the α-hydrogen atom.

Polymethacrylates: The role of the α-hydrogen atom has been demonstrated in the above discussions. Furthermore, we compared poly(alkyl methacrylate)s, with a large number of hydrogen atoms in the side chain, with poly(methyl methacrylate), in which no

significant mechanical change other than the glass transition and fusion is observed. In the alkyl methacrylate series, as is shown in Figs. 7 and 8,* the chemorheological properties approach those in polyethylene, which has a tendency to crosslink, with an increase in the alkyl side-chain length. The feature that λ shows a maximum corresponding to the increase in G_r becomes perceptible from PBMA. Considering the absence of the significant mechanical change due to the chemical process in PMMA, the resemblance between the TBA curves of polyethylene and polyalkyl methacrylates, and the results of other workers, which will be discussed later, this increase in G_r and the corresponding maximum of λ can be explained by assuming that the crosslinking occurs between the hydrocarbon parts of the side chains.** However, the details of the relation of the mechanical change to the chemical process and the nature of the fact that the change in λ in polyalkyl methacrylates is smaller than that in polyethylene are not clear at present.

Graham found that gelation occurs in poly(heptyl methacrylate) and higher alkyl methacrylate polymers, and not in the polymers with a branched alkyl side-chain including longer ones. He pointed out that the length of the alkyl side chain is important and that the crosslinking probably occurs between side chains, but that the apparent relationship between the glass transition temperature and the behavior on γ-irradiation *in vacuo* is absent.[11] Burlant *et al.* have also found a similar role of hydrocarbon parts in the side chain during the γ-irradiation of polyalkyl acrylates.[12] On the other hand, in their study by UV irradiation in air, Morimoto and Suzuki observed gelation in PBMA and crosslinking without gelation in poly(lauryl methacrylate); they concluded that the degree of the crosslinking, estimated from the distribution of the molecular weight, increases with the increase in the glass transition temperature.[13] The results in the present study agree partially with those of the above two investigations. That is, they agree with Graham's suggestion of the importance of the side chain length, on the one hand, and with Morimoto's finding of the crosslinking in PBMA and higher alkyl methacrylate polymers, on the other hand. A systematic investigation is a subject in the future.

Relation of the Shapes of TBA Curves to the Degradation Mechanism. From the above discussions, the relation of the chemorheological behavior to the chemical process and the effect of the difference in chemical structure on the mechanical properties have been elucidated. Here, turning to the viewpoint of the relation of the shapes of the TBA curves to the degradation mechanism, it is possible to classify the curves into several types.

The first type is found in the case of PMMA, in which no significant mechanical change due to the chemical process is observed. Considering the PMMA and poly(α-methyl styrene), which are known to depolymerize mostly to monomers, behave chemorheologically in the same way,[14] it may be suggested that the flatness in the TBA curve can be explained by assuming that the modulus of the unchanged glass braid was observed as a result of the formation of substances with a lower mechanical reactance and/or the evaporation of such substances from the braid.

* In these figures, the ordinates are arbitrarily shifted in order to avoid the overlapping of the curves.

** It should be pointed out here that the scission of the main chain and other reactions occur simultaneously with the crosslinking.

In the second type, G_r increases considerably at higher temperatures, but the change in λ is slight; especially the change in λ due to the chemical process in the isothermal measurements was negligibly small. The PVA, PVME, PVAc, PAAm, and PMAA belong to this type. Halogen-containing polymers, reported in the previous paper,[3] also belong to this type. In these polymers, reactions which involve the functional group in the side chain, such as dehydration, deacetylation, and dehydrohalogenation, are closely connected with the chemorheological behavior.

The third type is characterized by a maximum of λ which corresponds to the considerable increase in G_r on the curves of the temperature dependence and by one of λ found at the transition between the two stages of increase in G_r in the isothermal measurements (Fig. 10). The PMA, PAA, and other samples, which have a tendency to crosslink, belong to this type. Probably, higher alkyl methacrylate polymers can also be classified into this type. On the relation of the shapes of the TBA curves to the degradation mechanism, further extensive work is necessary.

Kinetic Studies. In the previous work,[3] a kinetic approach was carried out, in which the measurements of the relative shear modulus due to the chemical process under isothermal conditions and the superposition of G_r *vs.* time curves were tested. In addition to these procedures, two new approaches were undertaken in this study. One was the superposition of the λ *vs.* time curves, while the other was the application of the kinetic treatment used in such thermal analysis as thermogravimetry.

The curves of the changes in the mechanical properties due to the chemical process under isothermal conditions are classified into two categories in Figs. 9 and 10. No kinetic studies of the polyalkyl methacrylates were made. The PMAA, PVA, PVME,

PVAc, and PAAm, in which the role of the functional group is important, as has been stated above, belong to the type shown in Fig. 9 (the case of PVME), where λ is omitted because of its slight change with the reaction time. On the other hand, the PMA and PAA belong to the other type, shown in Fig. 10 (PMA). A situation similar to that in the latter case, in which λ shows a maximum corresponding to the transition between the two stages of the increase in G_r, has been found in the samples in which crosslinking mainly occurs.[15] In all cases, the linearity of the curves was observed at the initial stage. As in a previous work,[3] the logarithms of the initial slopes and the time of the maximum, λ, were each plotted against the reciprocal temperature (K^{-1}). The apparent activation energies estimated from this analysis are listed in Table 1.

A typical superposed curve is shown in Fig. 11, where the relative shear moduli were plotted on the scale of $(1/P)^2$ instead of G_r ($(P_0/P)^2$), because P_0 varies considerably as a result of the progress of the reaction after the setting of the specimen at higher temperatures. The superposition procedure for the shear moduli was satisfactorily used except for the temperature region of about 200 °C in PAAm. Superposition was done in the following manner; first plot the values of $(1/P)^2$ and λ as a function of log t, and then shift their isothermal curves along with the axis of log t until they overlap the superposed curve. The quantities of the shift in relation to the reference curve are the shift factor, a. For the logarithmic decrements, only in the cases of PMA and PAA, which belong to the type shown in Fig. 10, was the superposition successful. In other polymers, the superposition was difficult because of the absence of any significant mark in the change in λ due to the chemical process in the isothermal curve. The apparent activation energies were estimated from the Arrhenius plot of the shift factor. Table 1 shows that the values obtained from the superpositions of λ's agree well with those from the moduli.

In PMAA, the activation energy estimated from the increase in G_r agrees well with that obtained by Grant

and Grassie, 37±3 kcal/mol (155±13 kJ/mol),[7] but the value in PVA is lower than that determined by Yamaguchi *et al.* by thermogravimetry, 35—55 kcal/mol (146—230 kJ/mol).[8] Popa *et al.* have pointed out that the apparent activation energies in PVA change greatly with the degree of conversion on the basis of the heating-rate dependence of the weight loss.[16] The values calculated by them become analogous to that estimated from the decrease in G_r as the conversion grows higher. Perhaps, this situation can be explained by considering that, at relatively lower conversions, in addition to the dehydration, the α-hydrogen atom affects the mechanical properties through crosslinking, which does not bring about any significant weight loss, whereas at higher conversions, the decrease in G_r is due to the chain scission, which leads to a weight loss.

The heating-rate dependence of the chemorheological behavior of PAA is shown in Fig. 12, where the shear moduli are plotted on the scale of $(1/P)^2$ and where the ordinates are shifted arbitrarily in order to avoid the overlapping of the curves. The glass transition temperature at about 140 °C remained unchanged. However, in the higher temperature region, the curves are displaced to higher temperatures as the rate becomes faster. These findings suggest that the inspection of the heating-rate dependence aids in the identification of the physical processes and the chemorheological processes.

It is known that the kinetic parameters can be determined by a study of the heating-rate dependence of the TG curve. Ozawa pointed out that the apparent activation energy can be obtained from the slope in the plot of the logarithm of the heating rate (log h)

against the reciprocal of temperature, T_m(K), at which certain reactions with various heating rates reach the same extent.[17] In the present study, the temperature at which λ shows a maximum corresponding to the increase or decrease in G_r was taken as T_m, assuming that the reactions reached the same extent at this point. From the linear plot of log h *vs.* $(1/T_m)$, the activation energies were estimated. As is shown in Table 1, the two values are both in excellent agreement with those from initial slopes. The nature of the discrepancy between the values (78 and 69 kJ/mol) from the shift factor and those from other means (119 and 135 kJ/mol from the slopes and 126 kJ/mol from log h *vs.* $(1/T_m)$) in the range from 270 to 360 °C in PAA is not clear at present.

It is noteworthy that the kinetic method used in the thermal analysis can be successfully applied for the chemorheological measurements, in which chemical processes are investigated through the change in structure that controls the mechanical properties. The examination of the application of this procedure to the other polymers, especially to the polymers grouped in Fig. 9 or to the halogen-containing polymers, is a subject for future study.

The authors wish to thank Mr. Yoshio Takahashi and Mr. Takeo Ozawa (Electrotechnical Laboratory) for their helpful advice and for affording the facilities for the use of the TG and the automatic TBA apparatus.

Pressure Effect on the Optical Spectra of Some One-Dimensional Pt-Complexes

Yoji HARA, Ichimin SHIROTANI, Yukako OHASHI, Katsuyuki ASAUMI, and Shigeru MINOMURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received July 15, 1974)

The absorption and luminescence spectra of the polycrystalline magnesium, barium, and potassium salts of tetracyano platinate (II) were measured at hydrostatic pressures up to 5.4 kbar. These three salts showed an anomalously large red shift with pressure in both the absorption and luminescence spectra. The X-ray powder diffraction measurement was carried out for the magnesium salt up to 70 kbar. At 70 kbar the Pt–Pt distance decreased from 3.16 Å to 2.93 Å, 7.3% in linear compressibility. In the low pressure region up to ~20 kbar, the Pt–Pt distance was observed to decrease greatly. The intramolecular transition $5dz^2 \rightarrow 6pz$ energy was calculated as a function of the Pt–Pt distance. By comparing the calculated and observed values, such a large red shift in the absorption spectra was tentatively explained in terms of electrostatic stabilization of the intramolecular transition $5dz^2 \rightarrow 6pz$ due to the decrease of the intermolecular distance and due to the consequent increase of the $5dz^2 \rightarrow 6pz$ intermolecular CT character.

In a previous paper,[1] we partly reported the optical behavior of quasi-one-dimensional solids under high pressure, such as potassium tetracyano platinate (II); $K_2Pt(CN)_4 \cdot 3H_2O$, magnesium tetracyano platinate (II); $MgPt(CN)_4 \cdot 7H_2O$, barium tetracyano platinate (II); $BaPt(CN)_4 \cdot 4H_2O$. When pressure was applied up to 5.4 kbar, the Mg-salt showed the largest red shift of the absorption peak that we had ever known, including organic compounds.

The optical properties of square planar complexes of platinum (II), which are composed of quasi-one-dimensional Pt-chains, at high pressures have long been a subject of interest. Through X-ray diffraction studies,[2] it has been shown that $MgPt(CN)_4 \cdot 7H_2O$, $BaPt(CN)_4 \cdot 4H_2O$, and many of their related compounds have the one-dimensional columnar stacking structure of $Pt(CN)_4^{2-}$.

Interrante and Bundy have investigated the X-ray diffraction patterns for $K_2Pt(CN)_4Br_{0.3} \cdot 2.3H_2O$,[3a] $Pt(NH_3)_4 \cdot PtCl_4$ (Magnus' green salt, MGS) and $Ir(CO)_2(acac)$[3b] at high pressures and found that the lattice constant and the metal-metal distance in d^8 metal complexes decrease with increasing pressure.

Yamada studied the polarized absorption spectra of $K_2Pt(CN)_4 \cdot 3H_2O$, $MgPt(CN)_4 \cdot 7H_2O$, $BaPt(CN)_4 \cdot 4H_2O$, and related compounds and found the existence of weak bonding between adjacent Pt ions.[4] Polarization spectral measurements for the Mg-, Ca-, Sr-, and Ba-salts led Moncuit and Poulet to assign the absorption band in the visible region to the intramolecular transition $5dz^2 \rightarrow 6pz$, polarized along the Pt-chain (c axis).[5]

Krogmann assigned the band to the transition from the $5zd^2$ band to the 6pz band formed by adjacent Pt ions.[6] Zahner *et al.*[7] considered the visible absorption band in nickel dimethylglyoxime ($Ni(DMG)_2$) and its related compounds to be the intramolecular transition $3dz^2 \rightarrow 4pz$. They also suggested that the electrostatic interaction between the adjacent metal ions was responsible for the red shift which they had observed for such compounds.

Ohashi *et al.* quantitatively explained the polarized spectra of $Ni(DMG)_2$ and its related compounds.[8]

In this paper, the optical properties of the tetracyano platinate (II) solids at high pressures will be shown. The Pt–Pt distance of the Mg-salt as a function of pressure was investigated by the X-ray diffraction study, and the result will also be shown. A calculation was tried to know the nature of the large red shift with pressure, since neither a qualitative nor semi-quantitative investigation has been carried out for the $MPt(CN)_4 \cdot nH_2O$ type solids. We show the results of the calculation for the absorption energy ($5dz^2 \rightarrow 6pz$ in the central Pt ion) as a function of Pt–Pt distance. These results will be compared with the experimental one.

Experimental

X-Ray Measurement. For high pressure X-ray powder diffraction studies, the Bridgman type apparatus with moving tungsten carbide anvils was used, where pressure was cramped. The samples were put in a hole of 0.3 mm diameter in the center of a boron disk of 3 mm diameter and 0.3 mm thickness. The radiation used was Mo$K\alpha$ with 0.7107 Å wavelength. A Zr filter was used. Camera diameter was 75.74 mm. The pressure was determined from measurements of the (200), (220), (222), (400), (420), and (422) reflections caused by the NaCl, using the pressure *vs.* compression values calculated by Decker.[9] As the Mg-salt was reactive with NaCl, it was measured solely without mixing with NaCl. It follows that no absolute determination of pressure values could be obtained.

The Mg-salt has the tetragonal structure.[10] The lattice constants "c" and "a" at each pressure were determined from measurements of the (022) and (232) reflections.

Spectral Measurement. The absorption spectra were measured as a function of pressure. The pressure was generated by an intensifier using white gasoline medium up to 5.4 kbar. The absorption and emission spectra were measured with nujol mulls and in the polycrystalline state held tightly between glasses, respectively. The optical measurements were performed with a Shimadzu double beam spectrophotometer.

Preparation of Samples. The K-, Mg-, and Ba-salts[11] were prepared as described in the literature. Attention was paid to the preservation of the Mg-salt so as to keep it in an atmosphere with a high vapor pressure of water.

Results and Discussion

Absorption and Luminescence Spectra. *$MgPt(CN)_4 \cdot 7H_2O$*: The Mg-salt is composed of one-dimensional Pt-chains with tetragonal crystal structure and has a

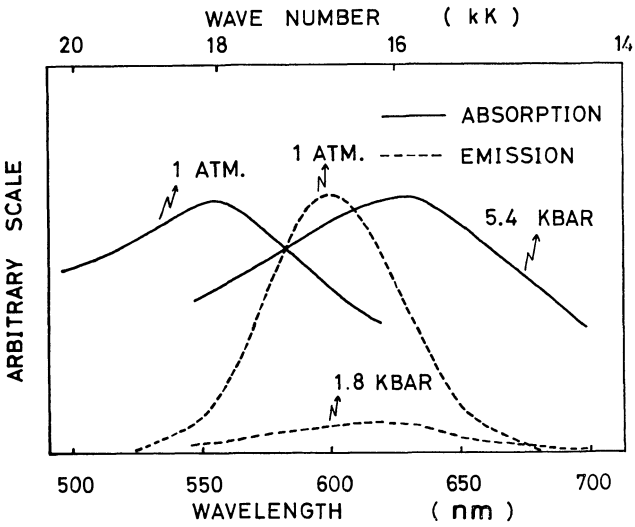

Fig. 1. Pressure effect on the absorption and luminescence spectra of polycrystalline $MgPt(CN)_4 \cdot 7H_2O$.

crimson color. The Pt–Pt distance was reported to be 3.16 Å.[2a] The effect of pressure on the absorption and on the luminescence spectra of the polycrystalline Mg-salt is shown in Fig. 1. The absorption peak of 555 nm (18.0 kK) showed an anomalously large red shift up to 629 nm (15.9 kK) at 5.4 kbar with increasing pressure, in a rate of -389 cm^{-1}/kbar.

The emission band of 600 nm (16.7 kK) at atmospheric pressure shifted to 620 nm (16.1 kK) at 1.8 kbar, in a rate of -320 cm^{-1}/kbar. The red shift observed both in the absorption and in the luminescence spectra was the largest so far detected by the present authors. The emission intensity decreased sharply with increasing pressure and was almost completely extinguished at pressures over 5 kbar.

$K_2Pt(CN)_4 \cdot 3H_2O$: In Fig. 2 the pressure effect on the absorption and luminescence spectra of the polycrystalline K-salt is displayed. The absorption peak of 382 nm (26.2 kK) showed a large red shift up to 402.5 nm (24.85 kK) at 5.4 kbar with increasing pressure, in a rate of -250 cm^{-1}/kbar.

The emission band of 437.5 nm (22.9 kK) at atmoshperic pressure shifted to 450 nm (22.2 kK) at 5.4 kbar, in a rate of -130 cm^{-1}/kbar.

$BaPt(CN)_4 \cdot 4H_2O$: The Ba-salt has the monoclinic crystal structure and a yellow-green color.[2b] The Pt–Pt distance is predicted to be 3.32 Å. Figure 3 shows the pressure effect on the absorption and

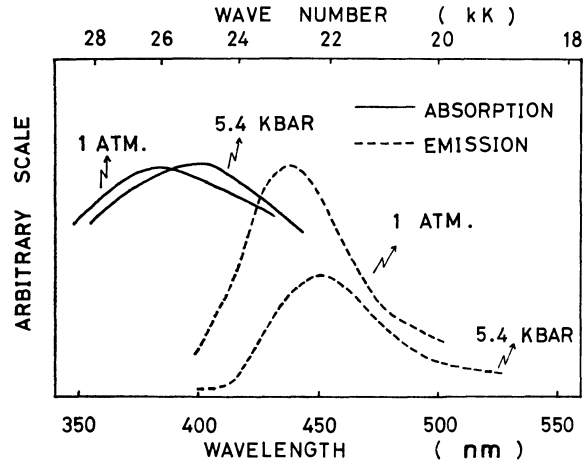

Fig. 2. Pressure effect on the absorption and luminescence spectra of polycrystalline $K_2Pt(CN)_4 \cdot 3H_2O$.

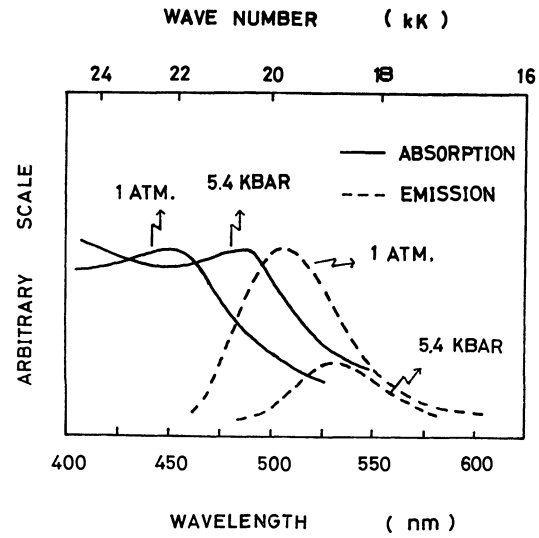

Fig. 3. Pressure effect on the absorption and luminescence spectra of polycrystalline $BaPt(CN)_4 \cdot 4H_2O$.

luminescence spectra of the polycrystalline Ba-salt. The absorption peak of 450 nm (22.2 kK) showed a large red shift up to 488 nm (20.5 kK) at 5.4 kbar with increasing pressure, in a rate of -315 cm^{-1}/kbar. The emission band of 505 nm (19.8 kK) at atmospheric pressure shifted to 530 nm (18.9 kK) at 5.4 kbar, in a rate of -167 cm^{-1}/kbar. These results are summarized with those for the Mg- and K-salts in Table 1.

Table 1. Absorption and emission maxima in the visible region, red shift, and Pt–Pt distance

Material	Absorption maximum nm (kK)	Red shift (cm^{-1}/kbar)	Emission maximum nm (kK)	Red shift (cm^{-1}/kbar)	Pt–Pt distance (Å)
$K_2Pt(CN)_4 \cdot 3H_2O$	382 (26.2)	-250	437.5 (22.9)	-130	>3.35[a]
$BaPt(CN)_4 \cdot 4H_2O$	450 (22.2)	-315	505 (19.8)	-167	3.32[b]
$MgPt(CN)_4 \cdot 7H_2O$	555 (18.0)	-389	600 (16.7)	-320	3.16[b]

a) S. Yamada, *Kagaku*, **41**, 651 (1971). b) Ref. 6.

The fact that the ratio of the quantum yield at each pressure to that of 1 atmosphere increased in the order K>Ba≫Mg might be explained in terms of the difference of the mixing of the intermolecular charge transfer $5dz^2 \rightarrow 6pz$ into both excited and ground state,[4] which will be discussed in more detail in a later part of the paper.

Moncuit *et al.* tentatively assigned the emission band to vibronically induced d–d transitions.[5] However, it is doubtful that such d–d transition may show such large red shift with pressure. It might be possible to assign it to the allowed 6pz (a_{2u})→$5dz^2$(a_{1g}) intramolecular transition.

X-Ray Diffraction. $MgPt(CN)_4 \cdot 7H_2O$ has a tetragonal unit cell with the metal chain axis aligned along the "c" unit cell direction with the "a" perpendicular to it. The lattice constants for the "c" and "a" unit cell dimensions are 6.32 and 14.54 Å, respectively.[2a] Figure 4 illustrates the pressure effect on the X-ray powder diffraction of the Mg-salt up to 70 kbar. Both the "c" and "a" unit cell dimensions decrease continuously over the pressure range. In the low pressure region up to ~20 kbar, the Pt–Pt distance, which is the half of the "c" unit cell dimension, was observed to decrease greatly. At 20 and 70 kbar the Pt–Pt distance decreased by 4.7% (3.01 Å) and 7.3% (2.93 Å) in linear compressibility, respectively. At 70 kbar the "a" unit cell dimension decreased to 14.11 Å, 2.9% in linear compressibility. These results are compared with those given by Interrante *et al.* in Table 2.

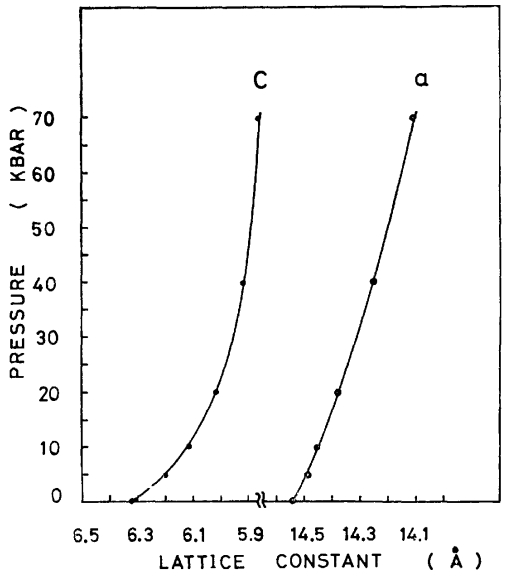

Fig. 4. Change in the "c" and "a" unit cell dimensions of $MgPt(CN)_4 \cdot 7H_2O$ with pressure.

TABLE 2. COMPARISON OF THE Pt–Pt DISTANCE OF SOME ONE-DIMENSIONAL Pt-COMPLEXES AT 1 atm. AND 70 kbar

Compound	Pt–Pt	Overall change in "a" dimension (Å)[d]
$MgPt(CN)_4 \cdot 7H_2O$	3.16 2.93[d] (7.3)[e]	0.43
$Pt(NH_3)_4 \cdot PtCl_4$[a] (MGS)	3.25 3.00 (7.7)[e]	~0.47
$Ir(CO)_2 \cdot (acac)$[a]	3.23 2.89 (10.5)[e]	
$K_2Pt(CN)_4 \cdot Br_{0.3} \cdot 2.3H_2O$[b]	2.89 2.78 (3.8)[f]	~0.47

a) Ref. 3b. b) Ref. 3a. c) Data at 1 atm. d) Data at 70 kbar. e) Linear compressibility at 70 kbar. f) Linear compressibility at 50 kbar.

As is seen from Table 2, firstly the linear compressibility along the c axis at 70 kbar increases in the order, $Ir(CO)_2 \cdot (acac) > Pt(NH_3)_4 \cdot PtCl_4 \simeq MgPt(CN)_4 7H_2O > K_2Pt(CN)_4 \cdot Br_{0.3} \cdot 2.3H_2O$. Here, the charges on each metal are Ir(+1), Pt(+2) in the Mg-salt and MGS, and Pt(+2.3) in $K_2Pt(CN)_4 \cdot Br_{0.3} \cdot 2.3H_2O$. The Coulombic repulsion due to the plus charges on the central metal ion presumably reflects the relative tendency for the extent of the linear compressibility along the "c" axis. Secondly, the overall change in the "a" dimension up to 70 kbar seems to be independent of the kinds of ligands.

Calculation. Ohashi *et al.* calculated the intramolecular transition ($3dz^2 \rightarrow 4pz$) energy of Ni $(DMG)_2$.[8] Here, we apply again the same method to the calculation of intramolecular transition($5dz^2$—6pz) energy of solid platinocyanide complexes and compare the calculated value with the observed one.

It was assumed,

(i) minus charge is located on the carbon atom and (ii) the Pt–C distance in the coordination plane was unchanged under pressure. The Pt–C distance was taken to be 2.06 Å, the same value as that of $K_2Pt(CN)_4 \cdot Br_{0.3} \cdot 2.3H_2O$.

We consider only the electrostatic effect on the 6pz and $5dz^2$ orbitals of the Pt^+ ion in the complex plane 1, due to Pt^+ ion in 2 and 3, and due to −3/4 charged CN ion in 1, 2, and 3, as is shown in Fig. 5. But we are compelled to neglect, for example, the CT effect and the electrostatic influence of the surrounding alkaline or alkaline earths cation, due to the lack of the corresponding data.

For each of the wave function ϕ_{5d} and ϕ_{6p}, the Slater-type AOs' were used. The orbital exponent values necessary for the calculation were taken as $\xi_{5d}=3.8815$, given by Clementi *et al.*,[12] and $\xi_{6p}=1.9820$, extrapolated from the data of the former authors.

We introduced next equation, the same as that given by Ohashi *et al.*,[8]

$$E_1 = E_1^{\nu} + \Delta_0 + \Delta(R)$$

Here, we put $\Delta(R)=\Delta(R_1)+\Delta(R_2)$, E_1 is the energy necessary for the local excitation of intramolecular transition $5dz^2 \rightarrow 6pz$. E_1^{ν} is the energy necessary for the transition from the $(5dz^2)^2$ valence state to the ($5dz^2$, 6pz) one. These quantities were obtained from the analysis of the observed atomic spectra.[13] Δ_0 is an electrostatic energy difference between 6pz and $5dz^2$ orbitals due to the formal charges on the atoms of the ligands in the complex plane 1, as is shown in Fig. 5. $\Delta(R_1)$ is the electrostatic energy difference between 6pz and $5dz^2$ orbitals of the Pt atom in the complex plane 1, due to the negative charges on the

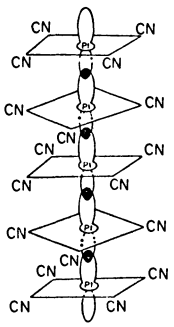

Fig. 5. The coordinate system used in the calculation on $[Pt(CN)_4^{2-}]_5$. Z axis is perpendicular to the complex plane. The complex plane numbers are also given.

TABLE 3. INTRAMOLECULAR TRANSITION $5dz^2 \rightarrow 6pz$ ENERGY CALCULATION FOR (A) Pt^+ AND (B) Pt^0

Pt-Pt distance	E_1 case (A) (kK)[a]	case (A) (kK) $\Delta(R_1)$	case (A) (kK) $\Delta(R_2)$	E_1 case (B) (kK)
3.50	26.04	−11.12	− 6.70	
3.32	23.64	−12.40	− 7.82	
3.16	21.18	−13.68	− 9.01	8.91
3.13	20.58	−14.00	− 9.28	8.69
3.09	19.90	−14.40	− 9.57	8.39
3.00	18.20	−15.28	−10.38	7.85
2.89	16.06	−16.32	−11.49	7.09

a) calculated values are recorded in kilokaysers.

ligand carbon atoms in the complex plane 2 and 3, and $\Delta(R_2)$ is the electrostatic energy difference between 6pz and $5dz^2$ orbitals of the Pt atom in the complex plane 1, due to the positive charges on the Pt atoms in the complex plane 2 and 3. Furthermore, the calculation was carried out for the case of (A) Pt^+ and (B) Pt^0. The results are summarized in Table 3.

As is indicated in Table 3, (i) case (A) reproduces the observed value well, (see the symbol X in Fig. 7), (ii) though $|\Delta(R_1)|$ is larger than $|\Delta(R_2)|$ for case (A), the contribution to the red shift is almost the same between them. In other words, the 6pz orbital is almost equally stabilized relative to the $5dz^2$ orbital by the −3/4 charged carbon and +1 charged Pt in the complex plane 2 and 3 with decreasing Pt–Pt distance.

Figure 6 illustrates the electrostatic energy of the 6pz and $5dz^2$ orbitals as a function of the Pt–Pt distance. Within the limit of the calculation, it is clear that the relative stabilization of the 6pz orbital to the $5dz^2$ one causes the red shift.

These calculated values are compared with the observed values in Fig. 7. The results of spectral measurements on the Mg-salt at pressures up to 5.4 kbar evidence a direct relationship between the magnitude of these spectral shifts and the interionic distance in the solid. The calculated values will represent the observed values including the K-, Ca-, and Ba-salts. But when the Pt–Pt distance becomes less than that of the Ba-salt, 3.32 Å, the discrepancy between the calculated and observed values becomes larger. This discrepancy can be explained in terms of (i) the mixing

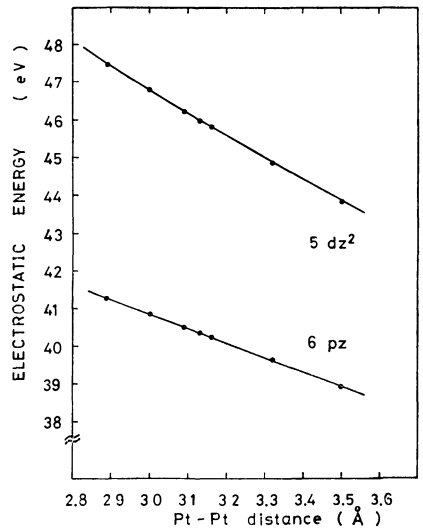

Fig. 6. The electrostatic energy dependence of the $5dz^2$ and 6pz orbitals of the central Pt ion on the Pt–Pt distance.

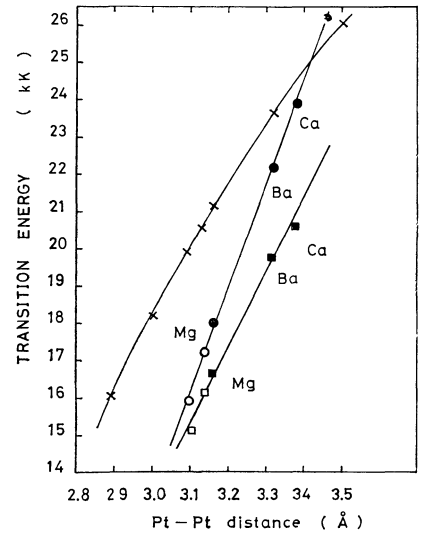

Fig. 7. The observed transition energy between $5dz^2$ and 6pz orbitals as a function of the Pt–Pt distance in various $Pt(CN)_4^{2-}$ derivatives:
Ca, $CaPt(CN)_4 \cdot 5H_2O$; Ba, $BaPt(CN)_4 \cdot 4H_2O$;
Mg, $MgPt(CN)_4 \cdot 7H_2O$;
The symbols ●, ○ and ■, □ refer to data obtained from absorption and luminescence experiments respectively, where the symbols ○ and □ refer to the one obtained for the Mg-salt at high pressures. The Pt–Pt distance is 3.13 Å at 2.5 kbar, 3.1 Å at 5 kbar and 3.09_5 Å at 5.4 kbar for the Mg-salt. The symbol X represents the calculated values of the intramolecular transition $5dz^2 \rightarrow$ 6pz energy for case (A) in Table 3.

effect of the $5dz^2 \rightarrow$6pz intermolecular charge transfer configuration between adjacent Pt ions into both of ground and excited state, (ii) the electrostatic effect of the surrounding alkaline or alkaline earths cations and (iii) the effect of a bond formation. According to our calculation, (ii) should decrease the intramolecular $5dz^2 \rightarrow$6pz energy by ~1.5 kK at most. Referring to the band calculation on MGS by Inter-

rante *et al.*,[3c] we tentatively evaluate (iii) to be ~2 kK at 3.0 Å in the Pt–Pt distance. Ohashi *et al.*[8] calculated the ground state stabilization energy due to (i) at 3.0 Å in the Ni–Ni distance of $Ni(DMG)_2$ to be ~2 kK. At 3.0 Å the calculated value is more than the observed value by 4.7 kK. So on a rough estimation, the excited state stabilization energy at 3.0 Å of platinocyanide complexes should be ~3.2 kK. Apart from this value, such mixing of CT character into the excited state should be closely related to the decrease of the emission intensity at high pressures (see the section for the Mg salt).

For the case of a single configuration coordinate Drickamer *et al.* obtained:[15]

$$\frac{(h\nu_{1max}-h\nu_{2max})_{abs.}}{(h\nu_{1max}-h\nu_{2max})_{emiss.}}=\left(\frac{\omega'}{\omega}\right)^4$$

Here, the 1 and 2 refer to two different pressures. They assumed harmonic potential wells with different force constants ω and ω' for the ground state and excited state respectively.

In our study, the ω'/ω values for the K-, Ba-salts at 5.4 kbar were found to be 1.178 and 1.172 respectively and 1.050 at 5.0 kbar for the Mg-salt. The smaller value for the Mg-salt is reasonable when one considers that the ground state mixes with the excited state through CT character much more in the Mg-salt than in the K- and Ba-salts. This is supported by the fact that the Mg-salt has a higher absorption intensity in the visible region than the other salts,[5] which should be due to the larger transition moment between the CT^- and CT^+ configuration than that between the ground and local excitation configurations for the intermolecular distance of ~3 Å[8].

Detection of Hydrophobic Stain on Cotton Surface by Fluorescent Probe*

Toshiko SEIMIYA** and Mary E. PURCHASE

Department of Design and Environmental Analysis, College of Human Ecology, Cornell University, Ithaca, New York, 14850

(Received August 6, 1974)

The minute amount of hydrophobic substances $10^{-8}\sim10^{-7}$ mol/cm^2 (geometric area) on cotton fabric surface can effectively be detected by fluorescent probe using magnesium-8-anilino-1-naphthalenesulfonate (ANS). The cotton fabrics were dyed in aqueous ANS solution (1×10^{-4} mol/l), before and after the staining with stearic acid, palmitic acid, tristearin, oleic acid, and squalene, and the intensities of fluorescence from the cotton surface was measured by reflectance spectrophotometer under the varying wavelength of ultra-violet (200—300 mμ). The intensity of fluorescence increased with the increase of fatty stain on the surface, but showed the tendency of saturation by exceeding the closest packing of the fatty acid monolayers. Correlation was also found between the fluorescent intensity and the yellowness (*b*-value) of naturally soiled cotton fabrics. The bleaching of the yellowed fabrics by sodium hypochlorite effectively reduced the *b*-value but did not change the fluorescence appreciably, and suggested that the hydrophobic substances still remained on the fabric surfaces in spite of their white appearance.

The surface reflectance of the whiteness of the cloths might be the most practical and fundamental standard of the cleanliness of the fabrics which agrees most with the human sense. Thus, the surface reflectometry is now the widely accepted method to detect the soils on fabric in the study of detergency. The reflectometry is versatile for its easy measurement in the practical systems, but its application is limited to the case where the amount of the soil adhering to the fabric is enough to change the reflectance of incident light by absorption. Generally speaking, the monomolecular layer of fatty acid adsorbed on soiled surface is too little in amount to change the intensity of light by a single reflection at solid/air interface.

A number of studies have been reported to estimate the trace amount of fatty substances on fabric surfaces, by extracting them with solvent followed by equilibrium lens[1] or gravimetric method[2,3] of analyses, as well as gas, liquid, thin layer or gel-filtration chromatography followed by spectroscopic analyses.[4–6] The radiotracer technique is also useful especially in detecting minute amounts of multi-component soils, without extraction procedure, by dual-lebelling and measuring the residual soil with a liquid scintillation counter,[7–11] or useful in the kinetic studies of detergency using an end-windowed dip-counter.[12] All these methods are excellent and have offered much useful information on the molecular mechanism of detergency, however, they always accompany some limitations in their application. For chromatographic analysis, all the soils should have such nature that is extractable by the certain solvent, which is not necessarily the case. And the latter radiotracer method, which utilizes artificial soils labelled with radioisotope, is only significant in the model system. Any physicochemical method which detects minute stains and gives a strict measure of cleanliness or dirtiness of the fabrics without an extraction procedure, should be helpful at present in the study of detergency as a measure of cleansing efficiency.

Some derivatives of naphthalenesulfonate are practically non-fluorescent when dissolved in water but fluorescent strongly when dissolved in organic solvent,[13] or one bound to the hydrophobic part of molecules.[14] These fluorescent dyes are utilized by a number of investigations in the determination of hyper-structure of proteins[15–17] or detergent micelles,[18] and in the analysis of various biological phenomena,[19] and are called as "fluorescent probe", or "hydrophobic probe."

The present paper deals with some experimental trials, using magnesium-8-anilino-1-naphthalenesulfonate as an adsorption indicator,[20] to detect minute fatty stain on cotton fabric stains, which are too small in amount to be detected by ordinary reflectance spectroscopy, or to be extracted for successive physicochemical analyses.

The results suggest that the fluorescent probe might offer a new measure of cleanliness of fabrics useful for the study of detergency.

Experimental

Materials. *Probe*: The fluorescent probe grade magnesium-8-anilino-1-naphthalenesulfonate (ANS) obtained from Eastman-Kodak Co., N. Y. was dissolved in distilled water to make a stock solution of 1×10^{-3} mol/l. The stock solution was kept in a dark and cool place until needed. The concentration of the dyeing solution about 1×10^{-4} mol/l was found optimal from the preliminary experiment to visualize the stain by naked eye under the ultraviolet light.

Hydrophobic Stains: Stearic acid, palmitic acid, oleic acid, tristearin, and squalene, all analytical grade (Fischer Scientific Co., N. J.) were dissolved in benzene to make the staining solution. The concentration ranged between $2\times10^{-4}\sim1\times10^{-2}$ mol/l.

Cotton: The cotton cloth for the specimen was obtained from the Test Fabric Inc., N. Y. in the form of plain-woven fabric without an optical brightner (20×20 threads/cm, 17.7 mg/cm^2 at the standard condition of the present experiment). In order to eliminate any residual greasy substance originally contaminating the fabrics, the specimens were purified by the following procedure.[11] The cotton cloth, cut into 45×45 cm, was washed in a Terg-O-Tometer in 0.25% Calgon solution for 10 min at 50 °C, rinsed twice for 5 min in distilled water, and air dried. The samples were further cut into a smaller 6×6 cm size and extracted with ethyl ether for

* The paper presented at the 28th Annual Meeting of Japan Chemical Society (Tokyo 1973)

** Present address: Faculty of Home Economics, Kyoritsu Women's University, Kanda, Tokyo, Japan.

24 hr by Soxhlet extracting apparatus, and stored in a greasless glass container after being dried in clean air.

Procedure. After the prolonged exposure of cotton sample to a standard condition (20±2 °C, 65±2% R.H.) to equilibrate it, 0.2 ml of the staining benzene solution was applied to the center of cotton cloth from a micro-syringe. The cloth stained was conditioned again after the evaporation of benzene, then dyed in 100 ml of ANS dyeing solution for 20 min, rinsed in 250 ml of 1/100 M NaCl aqueous solution, and damp dried between absorbing filter papers. The aqueous NaCl solution helped to wash off any extra ANS in the cloth without losing a large portion of the ANS bound to the hydrophobic stain.

The fluorescence from the cloth dyed with ANS was measured by a Bausch & Lomb 505 spectrophotometer equipped with reflectance attachment under varying wavelength of incident ultraviolet light (280~300 mμ). The intensity of fluorescence of the test specimen is expressed in percent to that of control cloth, which is the sample with a known amount of fatty stain dyed with ANS. All these procedures were carried out at room temperature (24—28 °C), and precautions were taken to avoid unnecessary exposure of the specimen to the light which might accelerate the decomposition of ANS.

Results and Discussion

Figures 1a and b demonstrate the hydrophobic stain of stearic acid on cotton fabrics visualized by fluorescent probe. Under an ultra-violet light the hydrophobic stain shows as a white circular area (Fig. 1a), which can not be observed under the ordinary white light from an incandescent source (Fig. 1b). The cotton cloth in Fig. 1 was stained with stearic acid by dropping an aliquot of benzene solution of stearic acid to the center of the cloth to make a circular stain, and dyed with ANS by the procedures mentioned above. The pictures were taken, one (Fig. 1a) under the ultra-violet light with a yellow filter on the lens, and the other (Fig. 1b) under the ordinary white light without a filter using panchromatic B & W film (Tri-X, Kodak). These experiments show the fluorescent probe being as effective as to detect minute 8.61×10^{-8} mol/cm² amount of stearic acid, by leaving it on the fabric surface without applying any extraction processes.

(a): Picture taken under the ultra-violet light using yellow filter.
(b): Picture of the same sample (a) taken under the white light.

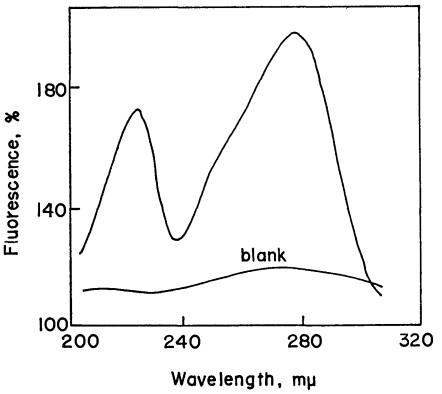

Fig. 2. Fluorescence of cloths with and without stearic acid stain against the wavelength of incident light.

Figure 2 shows the typical fluorescence intensity *vs.* wavelength of incident light curves of cotton dyed by ANS with and without the stearic acid stain. The amount of stearic acid put on cloth is 8.61×10^{-8} mol/cm². The intensity of fluorescence increased with stearic acid stain, and the two characteristic maxima were observed at 225 and 275 mμ of ultra-violet irradiation compared with the blank cotton surface which showed very weak fluorescence. Any appreciable differences in the fluorescence spectra have never been observed also for the other fatty acids as well as tristearin and squalene. The intensity of fluorescence increased with the amount of fatty stains, and the two characteristic maxima appeared around 225 and 275 mμ respectively.

The fluorescence intensities at these maxima were plotted against the amount of fatty stain on the cloth surface, and are shown in Figs. 3~6. The increase of fluorescence in these figures indicates the net increase of intensity from the blank cotton surface which is the clean specimen dyed with ANS without the oily stains. The saturation of fluorescence is observed for stains applied in excess of certain levels which seemed to be specific to the kind of stain. The amount of stain in these figures is expressed in moles per apparent (geometric) unit area of the fabrics (mol/cm²). The true surface area of the cloth, however, should be far larger than the geometric one,

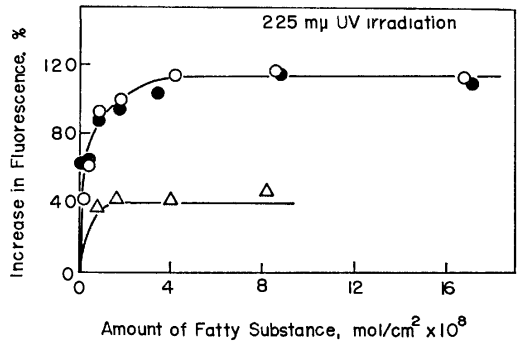

Fig. 3. Relation between fluorescence and amount of fatty substances on cotton fabrics.

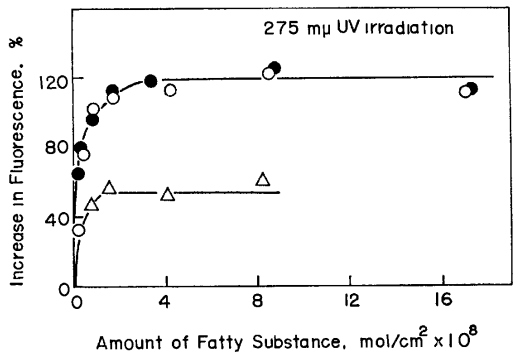

Fig. 5. Relation between fluorescence and amount of fatty substances on cotton fabrics.
○: Palmitic acid, ●: Stearic acid, △: Tristearin.

if we take into account the true surface area of each cotton fibers which compose the fabrics. The specific surface area of cotton fibers has been determined by several workers to be around $2.37\sim2.75\times10^3$ cm²/g.[21,22] Using these values, we can estimate the actual amount of the stains on cotton fiber in moles per true unit area. The closest monolayer coverage of cotton fibers in the cloth by fatty acid molecules should be attained at $3.00\sim3.98\times10^{-8}$ mol/cm² (geometric), assuming the molecular area of fatty acids to be 20.5 Å²/molecule.[23] The saturation of fluorescence in Figs. 3 and 5 occurred for the stain of both stearic and palmitic acids around at 4×10^{-8} mol/cm² which agreed with the monolayer value given above. The similar agreement between

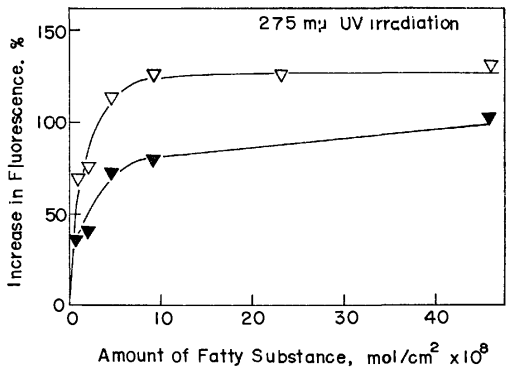

Fig. 6. Relation between fluorescence and amount of fatty substances on cotton fabrics.
▽: Oleic acid, ▼: Squalene

observed and calculated monolayer values is also observed for tristearin which has a molecular area[12] nearly three times larger than that of fatty acid. The saturation of fluorescence is observed for tristearin at smaller amount of stains (about 1/3 of fatty acid) as expected.

The fluorescent probe was also applied to naturally soiled cotton cloths (pillow cases) of different degree of yellowness, which were obtained by the repeated soiling and washing procedures. In Fig. 7, the intensity of fluorescence at 275 mμ ultra-violet irradiation from yellowed fabrics are plotted against the degree of yellowness (*b*-value) of the fabrics. Here, the *b*-values are estimated by using a Hunter D25 Color and Color-Difference Meter with the ultra-violet filter in place to eliminate any fluorescent effects of the cloths.[11] Stronger fluorescence was observed for more yellowed fabrics. The intensity of fluorescence

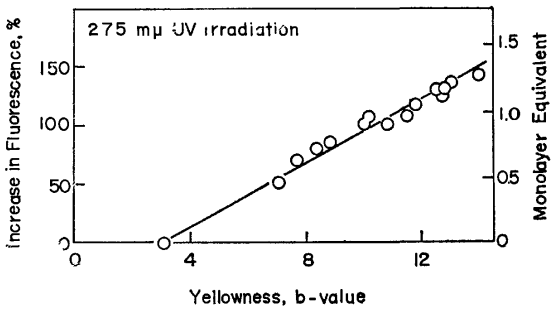

Fig. 7. Relation between *b*-value and fluorescence.

Table 1. Effects of bleaching on both *b*-value and fluorescence at 275 mμ ultra-violet irradiation

b-Value		Fluorescence	
Before bleaching	After bleaching	Before bleaching	After bleaching
9.47	3.54	85%	74%
10.44	3.74	100	80
11.84	3.87	120	100
12.89	4.01	125	81
12.99	3.65	130	110
13.58	4.47	140	112

is also expressed conveniently in monolayer equivalent of fatty acid as seen in the right hand ordinate.

The bleaching of yellowed fabrics by 0.5% aqueous sodium hypochlorite effectively reduced the *b*-value, but fluorescent probe still showed for these bleached white fabrics a fluorescence nearly as strong as that of unbleached cloths, as shown in Table 1. This might mean that any hydrophobic substances are still remaining on the fabrics in spite of their whiteness. It may be generally recognized that the yellowing of the cotton fabrics during the recycling process of soiling and washing in everyday life, is probably caused by the oxidation or polymerization of fatty substances which have not been removed by laundering.[3,24] The residual fatty substances after washing might be a so small amount as that of monomolecular layer, and might not be detected until accumulated and yellowed by usual reflectance measurements hitherto been utilized.

The fluorescent probe should offer an useful measure of cleanliness in the study of detergency not only for its simple and inexpensive background.

The authors wish to thank all the supporting staffs of Department of Design and Environmental Analysis of Cornell University, for their kind take-care in every stage of this research.

Photoelectron Spectra of the *cis*- and *trans*-Isomers of Some Ethylene Derivatives

Tsunetoshi KOBAYASHI, Katsuyuki YOKOTA, and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106

(Received August 20, 1974)

The photoelectron spectra of *cis*- and *trans*-stilbenes, fumaric acid, dimethyl maleate, and dimethyl fumarate were measured and interpreted, special attention being paid upon their difference between the corresponding *trans*- and *cis*-isomers. The two characteristics were found for the photoelectron spectra of *cis*- and *trans*-stilbenes: (1) the splitting between the first and fifth bands is smaller for the *cis*-isomer (steric-hindrance effect); (2) the splitting between the second and third bands is larger for the *cis*-isomer (through-space interaction). The difference in the carbonyl n orbital ionization potentials between dimethyl maleate and fumarate was interpreted in terms of through-bond interaction.

The effect of steric configuration upon photoelectron spectra (PES) of organic molecules is an interesting research subject not only from the study of their electronic structures but also from the application of the spectra to the structural determination. So far several studies have been carried out for the PES of *cis*- and *trans*-isomers of some ethylene derivatives. The PES of dichloroethylenes were studied by Jonathan and coworkers[1] and also by Lake and Thompson.[2] Chadwick and coworkers[3] studied the PES of dibromoethylenes. Bock and coworkers studied the PES of dicyanoethylenes,[4] dibromo- and dichloroethylenes,[5] and dithiomethoxyethylenes.[6] In a series of compounds mentioned above, the out-of-plane π orbital vertical ionization potentials, I_v's, of a *cis*-isomer are rather similar to those of the corresponding *trans*-isomer. In *cis*-dihalogenoethylenes or *cis*-dicyanoethylene in-plane orbitals often show I_v's different from those of the corresponding *trans*-isomer because of the difference in the through-bond and through-space interactions[7] between these isomers. Wittel and coworkers[8] have demonstrated the importance of spin-orbit coupling in the case of iodoethylenes.

We have studied the PES of *cis*- and *trans*-stilbenes, dimethyl maleate, and dimethyl fumarate for the purpose of clarifying experimentally and explaining theoretically the difference in PES between the corresponding *cis*- and *trans*-isomers. The PES of fumaric acid has also been studied for the sake of comparison. Concerning the PES of *cis*- and *trans*-stilbenes, a brief report was published by Maier and Turner[9] after our work had been completed. In this paper, we report the more details of the PES of *cis*- and *trans*-stilbenes.

Experimental and Theoretical

cis-Stilbene was purified with the alumina column chromatography, *trans*-stilbene and fumaric acid by recrystallization from ethanol and aqueous ethanol, respectively. Dimethyl maleate was purified by distillation and dimethyl fumarate by sublimation.

The PES of these compounds were measured with the photoelectron spectrometer described previously,[10] 584 Å He resonance line being used as the excitation source. The sample inlet and target chamber system was heated to 97 °C for *trans*-stilbene, 46 °C for *cis*-stilbene, 124 °C for fumaric acid and 38 °C for dimethyl fumarate and 47 °C for dimethyl maleate.

The CNDO/2[11] calculations of the compounds under consideration were carried out with a FACOM 230—60 computer at the Institute of Physical and Chemical Research. Their structures were properly assumed on the basis of the appropriate structural data given in Refs. 12, 13, and 14.

Results and Discussion

cis- and trans-Stilbenes. The observed PES of *cis*- and *trans*-stilbenes are shown in Fig. 1 and those

measured on the expanded energy scale around 9~10 eV are shown in Fig. 2, and the I_v's of these compounds and related ones obtained from the PES are summarized in Table 1.

The stilbenes commonly show three groups of bands in the region of 7.5~11 eV. This is also the region for the benzene $e_{1g}\pi$[15] (9.23 eV) and ethylene $b_{3u}\pi$ (10.51 eV[16]) bands. The stilbenes contain two benzene rings and one ethylene group. So it is quite reasonable to consider that the observed three groups of bands correspond to the five occupied π orbitals constructed mainly from the four benzene $e_{1g}\pi$ orbitals and one ethylenic π orbital.

The experimental orbital energy diagram obtained on the assumption $\varepsilon=-I_v$ (Koopmans' theorem[17]) is shown in Fig. 3.

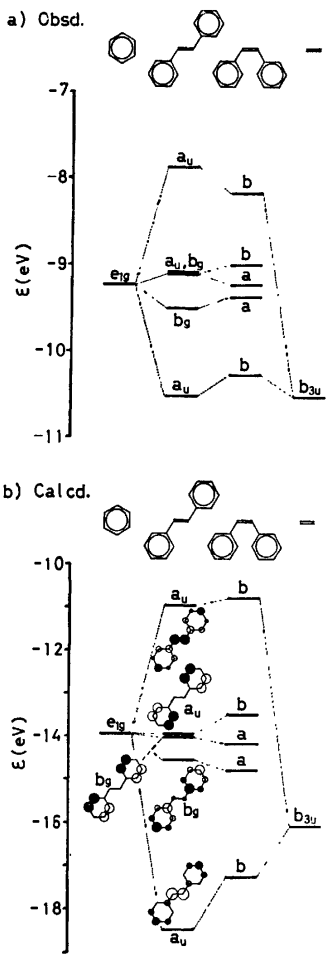

Fig. 3. Observed and calculated π orbital energy diagrams for stilbenes.

The CNDO/2 calculations and also qualitative consideration show that the first and fifth bands of each isomer should be assigned to the ionizations from two π orbitals in which the two benzene rings and the ethylene group interact strongly and, therefore, π electrons delocalize over the entire molecular carbon framework; the higher one corresponding to the highest occupied π orbital of each isomer is antibonding in the nature of the C–C bonds connecting the benzene rings with the ethylene group and the lower one corresponding to the fifth highest occupied π orbital of each isomer is bonding.

According to the CNDO/2 calculations the second and third bands of each isomer should be assigned to the two occupied π orbitals completely localized on the two benzene rings. This is consistent with the fact that the I_v's of both bands are close to that of the first band of benzene corresponding to the ionization from the $e_{1g}\pi$ orbitals.

According to the CNDO/2 calculations the fourth band of each isomer should be assigned to the π orbital almost completely localized on the benzene rings but slightly mixed with the antibonding π orbital of the ethylene group. The fact that the I_v of the band is only slightly greater than that of the first band of benzene, supports this assignment. The slight mixing of the vacant antibonding π orbital of the ethylene group shifts the fourth band to the slightly higher ionization energy side than the second and third bands.

The PES of *cis*- and *trans*-stilbenes are different from each other in the following points:

i) The splitting between the first and fifth bands of *cis*-stilbene (2.10 eV) is smaller than that of *trans*-stilbene (2.64 eV). This can be explained in terms of the fact that in the *cis*-isomer the conjugation between the ethylenic group π orbital and the benzene ring π orbitals decreases because of the twisting of the two benzene rings from the molecular plane caused by the steric hindrance effect between them.[13] This was pointed out also by Maier and Turner.[9]

ii) The second and third bands of *cis*-stilbene split by 0.2 eV but those of *trans*-stilbene are almost degenerate. This fact can be explained as follows. The corresponding π orbitals of *trans*-stilbene are completely localized on the two benzene rings and the I_v's of these orbitals should be equal to each other. On the other hand, in the case of *cis*-stilbene the two benzene rings approach each other so closely that the $p\pi$ atomic orbitals at the *ortho* positions can overlap with each other, though slightly. This is a reason why the second and third bands split from each other for the *cis*-isomer. This tendency was qualitatively reproduced by the CNDO/2 calculation (see Fig. 3). Therefore this difference between the *trans*- and *cis*-isomers is due to the so-called through-space interaction[7] at the classically non-bonded position.

Fumaric Acid, Dimethyl Fumarate, and Dimethyl Maleate. The PES of fumaric acid, dimethyl fumarate, and dimethyl maleate are shown in Fig. 4. The PES of dimethyl fumarate and dimethyl maleate measured on the expanded energy scale around 10~12 eV are shown in Fig. 5.

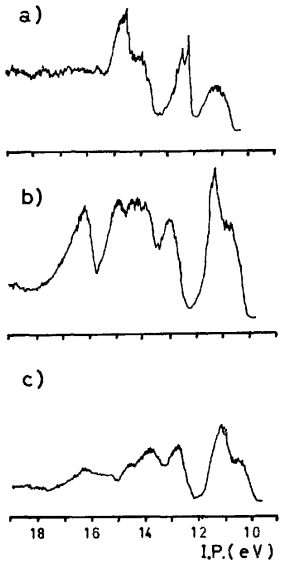

Fig. 4. Photoelectron spectra of (a) fumaric acid, (b) dimethyl fumarate, and (c) dimethyl maleate.

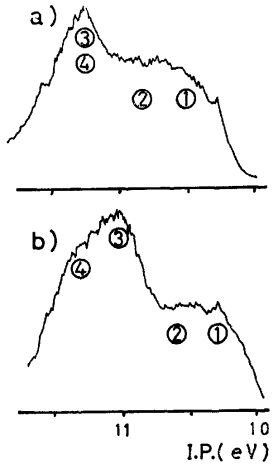

Fig. 5. Expanded photoelectron spectra around 11 eV: (a) dimethyl fumarate; (b) dimethyl maleate.

TABLE 2. VERTICAL IONIZATION POTENTIALS OF FUMARIC ACID, DIMETHYL FUMARATE, DIMETHYL MALEATE, AND RELATED COMPOUNDS IN eV

PES band	1	2	3	4	5
Fumaric acid	10.9	11.1	12.15	12.41	13.9
Dimethyl fumarate	10.5	10.8	11.27	11.27	12.91
Dimethyl maleate	10.3	10.6	11.04	11.3	12.77
Acetic acid[a)]	10.87	12.05			
Methyl acetate[a)]	10.48	11.16			

a) Ref. 18.

The vertical ionization potentials of these compounds and related ones obtained from their PES are summarized in Table 2.

The correlation diagram for the higher occupied orbitals of these compounds obtained on the assumption $\varepsilon = -I_v$ (Koopmans' theorem[17]) is shown in Fig. 6. The calculated orbital energy diagram given by the CNDO/2 method is also shown in Fig. 6 for the sake of comparison.

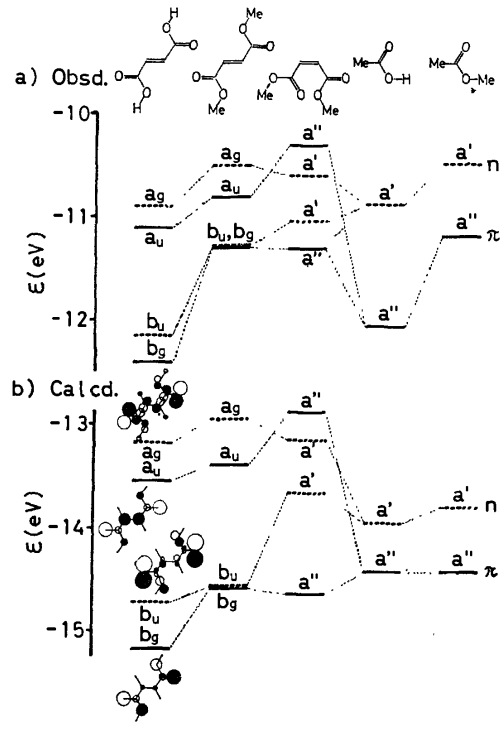

Fig. 6. Observed and calculated orbital energy diagrams for fumaric acid, dimethyl fumarate, and dimethyl maleate.

The PES of fumaric acid has two groups of bands in the region of 10.5~13 eV. This is also the region for the bands of the acetic acid carbonyl n (10.87 eV[18]) and carboxyl π (12.05 eV[18]) orbitals and also for the band of the ethylenic π orbital (10.51 eV[16]). So the observed bands under consideration may correspond to the molecular orbitals constructed by the interaction among the two n orbitals and two π orbitals of the two carboxyl groups and the ethylenic π orbital.

The calculated orbital energy diagram for fumaric acid can explain satisfactorily from the qualitative point of view the observed relative pattern of the first two groups of bands. The calculation suggests that the first group of bands may correspond to $a_g n$ and $a_u \pi$ orbitals and the second group of bands to $b_u n$ and $b_g \pi$ orbitals from the top, respectively.

Sweigart and Turner[18] studied the assignment of the PES of acetic acid and showed that the n band of the acid is quite sharp and the π band is rather broad. According to our CNDO/2 calculation of fumaric acid the fourth highest occupied molecular orbital, $b_g \pi$ orbital, is quite similar to the corresponding π orbital of acetic acid, and the third highest occupied molecular orbital, $b_u n$ orbital, is of the nonbonding nature and is almost completely localized on the two carbonyl groups. So it is reasonable to assign the sharp band at 12.15 eV to the ionization from the third highest occupied $b_u n$ orbital. Accordingly, the remaining fourth band at 12.41 eV may be assigned to the fourth highest occupied $b_g \pi$ orbital.

The first and second bands highly overlap with each other. The CNDO/2 calculation indicates that they are assigned to $a_g n$ and $a_u \pi$ orbitals, respectively.

Here let us turn to dimethyl fumarate and dimethyl maleate. The CNDO/2 calculations predict that the third and fourth highest occupied orbitals are nearly accidentally degenerate for dimethyl fumarate and split from each other for dimethyl maleate. The experimental result shown in Fig. 5 satisfies this prediction. Furthermore, according to the CNDO/2 calculations, the fourth highest occupied orbitals of both compounds are almost completely composed of the carbomethoxyl π orbitals and have almost the same energy. In agreement with this prediction, the observed fourth bands of both compounds show almost the same I_v's; 11.27 eV for dimethyl fumarate and 11.3 eV for dimethyl maleate. Therefore, the fourth bands of both compounds may reasonably be assigned to the fourth highest occupied π orbitals obtained by the CNDO/2 calculations. The fact that the I_v's of these bands are close to the carbomethoxyl π I_v of methyl acetate, 11.16 eV,[18] also supports this assignment.

The third band of dicarbomethoxyethylenes may be assigned to the n orbitals, b_un in dimethyl fumarate and a'n in dimethyl maleate. The b_un I_v of the former is larger than the corresponding a'n I_v of the latter. This difference between both isomers is brought about by through-bond interaction. According to the CNDO/2 calculations, the through-bond interaction between the carbonyl n orbitals is greater for the *cis*-isomer than for the *trans*-isomer.

According to the CNDO/2 calculations the first and second bands of dimethyl fumarate may be assigned to the a_gn and $a_u\pi$ orbitals, respectively, and those of dimethyl maleate to the a''π and a'n orbitals, respectively. The overall qualitative agreement between the pattern of the calculated orbital energy diagram and the observed spectral pattern may support the assignment predicted by the CNDO/2 method for fumaric acid, dimethyl fumarate, and dimethyl maleate.

The authors wish to express their sincere gratitude to Prof. H. Bock of the University of Frankfurt for his kindness to allow us to read his manuscripts before publication.

ESR Studies on the Anion Radicals of Some Triptycene and [2.2]Paracyclophane Derivatives

Toyoharu HAYASHI, Noboru MATAGA, Yoshiteru SAKATA,* and Soichi MISUMI*

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

**Institute of Sciencific and Industrial Research, Osaka University, Suita, Osaka* 565

(Received September 14, 1974)

ESR spectra of anion radicals of some triptycene and [2.2]paracyclophane derivatives were observed and analyzed in order to study the delocalization interactions between composite aromatic rings.

It is important to study the delocalization interactions between the groups when a molecule contains two or more π-electronic groups separated by saturated chemical bonds. The mechanisms of charge transfer complex formation and of electron transfer reaction are closely connected with this problem. One can investigate electron transfer between the composite aromatic rings in anion radicals of [2.2]paracyclophane and triptycene derivatives by means of ESR measurements.

Weissman[1] reported the fast exchange or delocalization of the unpaired electron between the two benzene rings of the [2.2]paracyclophane anion. Furthermore, Gerson and Martin[2] observed that the unpaired electron in the anion radical of [2.2]paracyclophane in DME(dimethoxyethane) is completely delocalized between the two benzene rings, while it is only partially delocalized in the case of the THF (tetrahydrofuran) solution. In the latter solution, the interaction of the unpaired electron with the counter ion seems to suppress the complete delocalization.

Recently, Williams *et al.*[3] made ESR studies on anion radicals of some paracyclophane derivatives, [2.2](9,10)anthracenophane and [2.2](1,4)naphthalenophane. On the basis of their experimental results, they indicated that the unpaired electron is completely delocalized in the case of [2.2](1,4)naphthalenophane. However, they failed to determine its constants. On the other hand, Dessau[4] reported the complete delocalization of aromatic cationic site in the study of triptycene cation radical.

We have made also some ESR and optical studies on triptycene 1,4-quinone anion and 1,4-dimethoxytriptycene cation radicals, and have found out that there are no significant intramolecular delocalizations of the excess electron or the positive hole in the case of these ion radicals.[5] These results may be of some interest from the viewpoint of the electronic structures of ions and molecular complexes in solution. In the present paper, we discuss the results of ESR studies on anion radicals of related compounds, including benzotriptycene (abbreviated as I–1), dibenzotriptycene (I–2), naphthobenzotriptycene (I–3), [2.2](9,10)anthracenophane (II–1), and others.

Experimental

Triptycene and paracyclophane derivatives were synthesized and purified as reported elsewhere.[6] Commercially available THF and DME were dried over sodium sulphate, refluxed over metallic sodium wire for a day, and fractionally distilled. These solvents were degassed completely in the presence of metallic sodium flakes, distilled several times, and finally stored over the sodium-potassium alloy in a vacuum.

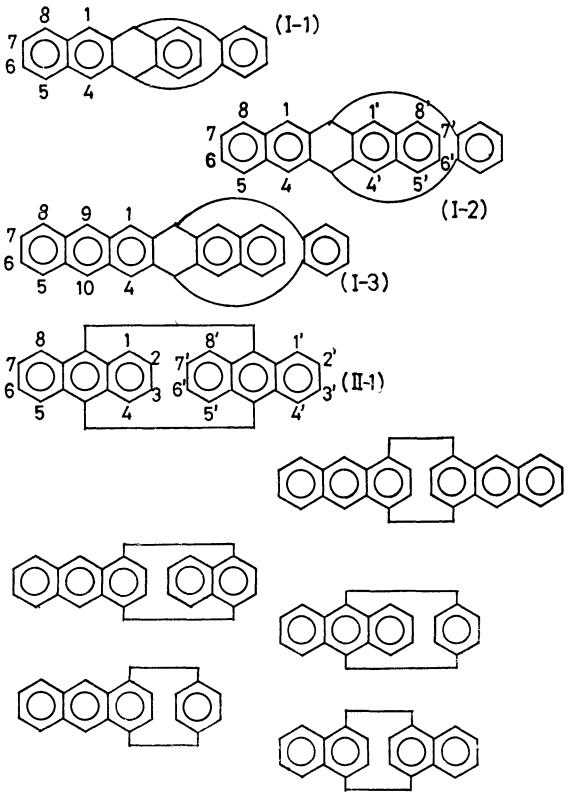

Fig. 1.

The purified solvent was distilled into the sample tube containing the compound. The solution was stirred with a magnetic stirrer and deaerated completely. Alkali metal mirror was formed inside the glass tube after distilling the alkali metal several times. The sample tube containing the alkali metal mirror and the sample solution (separated by a breakable seal from the mirror) was sealed off the evacuating system and immersed in a dry ice–ethanol bath. Then, the solution was put in contact with the metal mirror.

A tube containing anion radical solution prepared by the method as described above was placed in the microwave cavity cooled below −80 °C by the cold nitrogen gas flow. Temperature was then raised near to −50 °C carefully in order to attain the best condition for detecting the ESR signal. When the temperature was raised further, the anion radical was converted to some diamagnetic species and the ESR signal intensity was not recovered when the temperature was lowered again.

Some compounds were examined also by the method of electrochemical reduction in order to exclude the effect of the counter ion. These studies were conducted at room

temperature with dimethylformamide(DMF) solutions, and halfwave potentials were also determined. The electrochemical measurements were kindly performed by Drs. T. Kubota and H. Miyazaki of Shionogi Research Laboratory.

The ESR spectra were recorded with a JES-ME-2X or 3BX spectrometer using X-band. The simulation of the spectra, assuming the Lorentzian line shape and appropriate line widths, were made by using the HITAC-700.

Results and Discussion

Benzotriptycene Anion Radical. The anion radical was prepared by the electrochemical reduction in DMF at room temperature. The halfwave potential, $E_{1/2}=-2.58$ V *vs.* SCE, is nearly the same as that of naphthalene. The spectrum in Fig. 2 shows a hfs due to a set of four equivalent protons and a set of two equivalent protons. Their hfs constants are $A_1=3.43$ gauss(G) and $A_2=1.24$ G, respectively. In conformity with the case of 2,3-dimethylnaphthalene anion radical, we assume that the constant A_1 is due to the protons in positions 5, 6, 7, 8, namely H_5, H_6, H_7, H_8, and A_2 to protons H_1, H_4. The contribution from the two bridgehead protons are not very clear being masked by the relatively large line widths (about 0.5 G). It is suggested that four equivalent protons are further separated to two sets of two equivalent protons because of the fact that the line widths of outer lines are a little larger than those of inner ones. In any way, since we cannot observe any hfs due to the delocalization of the unpaired electron on two benzene rings, the odd electron seems to be well localized on the naphthalene ring.

Dibenzotriptycene Anion Radical. The spectrum obtained by either electrochemical reduction in DMF at the first reduction potential or reduction with sodium metal in DME at -78 °C is exactly the same. Therefore, the spectrum obtained by reduction with sodium metal does not seem to be affected significantly by the counter ion. The first and second half-wave

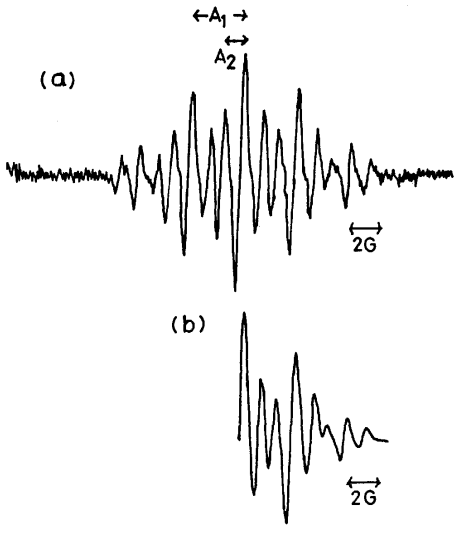

Fig. 2. (a) ESR spectrum of benzotriptycene (I-1) anion radical generated by electrolytic reduction; solvent DMF room temperature, (b) Computer simulated spectrum.

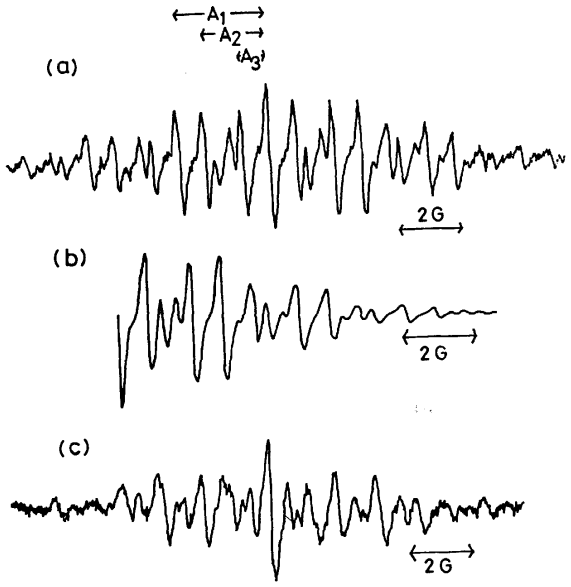

Fig. 3. (a) ESR spectrum of dibenzotriptycene (I-2) anion radical generated by sodium metal reduction; solvent dimethoxyethane (DME), temperature -50 °C. (b) Computer simulated spectrum. (c) Generated by electrolytic reduction at second reduction potential, solvent DMF, room temperature.

Table 1. Assignment of the hfs constants of dibenzotriptycene anion radical (I-2) in comparison with those of 2,3-dimethylnaphthalene anion radical (DMN) (in units of G)

	DMN	I-2
a_1, a_4 (a_1', a_4')	4.09	2.02
a_5, a_8 (a_5', a_8')	5.20	2.83
a_6, a_7 (a_6', a_7')	1.73	0.81
a (CH_3)	1.73	

reduction potentials were $E_{1/2}=-2.65$ V and -2.85 V *vs.*, SCE respectively. We have not yet completed the analysis of the spectrum at the second reduction potential. The spectrum obtained by the reduction with sodium metal in DME is shown in Fig. 3. Its hfs seems to be ascribed to three sets of four equivalent protons, their hfs constants being $A_1=2.93$ G, $A_2=2.09$ G, and $A_3=0.89$ G, respectively. The assignment of hfs constants was made as indicated in Table 1. One can see from the table that the hfs constants of (I-2) are about one-half of the corresponding ones of the 2,3-dimethylnaphthalene anion radical. Thus, it may be concluded that the unpaired electron is completely delocalized over the two naphthalene rings. However, it is not delocalized on the benzene ring.

Naphthobenzotriptycene Anion Radical. The ESR spectrum of (I-3) obtained by reduction of the neutral molecule with sodium metal in DME is shown in Fig. 4a. Its hfs can be ascribed to a set of two equivalent protons ($A_1=5.44$ G), a set of four equivalent protons ($A_2=2.88$ G), a set of two equivalent protons ($A_3=1.52$ G), and a set of two equivalent protons ($A_4=0.25$ G). The assignment of these hfs constants was made as indicated in Table 2, where they are

TABLE 2. ASSIGNMENT OF THE hfs CONSTANTS OF NAPHTHOBENZOTRIPTYCENE ANION RADICAL (I-3) IN COMPARISON WITH THOSE OF ANTHRACENE ANION RADICAL (A).
(in units of G)

	A	I-3
a_1, a_4, a_5, a_8	2.66	2.88
a_6, a_7	1.53	1.52
a_9, a_{10}	5.28	5.44

compared with those of anthracene anion radical. The assignment of A_4 to the bridgehead protons seems to be quite reasonable. As far as we know, there has been no clear-cut observation of hfs due to the bridgehead protons of triptycene. For example, Stock and Suzuki[7] investigated the semiquinone anion radicals of 1,4-dihydroxytriptycene and 9-methyl-1,4-dihydroxytriptycene, and Dessau[4] studied the cation radical of triptycene. However, the hfs due to the bridgehead protons was not observed clearly in both cases being covered with rather large line widths. In any way, the present result clearly show that the unpaired electron in (I-3) is well localized on anthracene ring.

In contrast to other compounds investigated here, (I-3) gave a quite different spectrum when the reduction was conducted in THF as indicated in Fig. 4b. Its hfs can be analyzed, but its origin is not yet elucidated. The hfs of the spectrum can be ascribed to three sets of two equivalent protons, their hfs constants being A_1=5.4 G, A_2=4.8 G, and A_3=1.8 G, respectively. It appears that we can ascribe formally this ESR spectrum to an unpaired electron being on the naphthalene composite ring. However, that the unpaired electron is on the naphthalene ring in (I-3) is highly improbable.

On reduction in THF, the solution becomes purple at first, which is also the characteristic color of the anion formed in DME solution, and then the color of solution changes drastically to blue on further reduction by sodium or potassium metal in Dry Ice-ethanol bath. We have confirmed that this phenomenon does not occur even in mixed solvents of DME and THF, the volume ratio of DME to THF being changed from 1 to 0.1.

This remarkable solvent effect might be explained as follows. It seems to be more easy to make anion-metal cation ion-pair in THF than in DME, since the solvation of ions is stronger in DME than in THF, leading to dissociation of the pairs in DME. Therefore, the ion-pair is formed in THF, and two anion radicals may be linked together, assisted by the positive counter ions, at the position of anthracene composite ring to become diamagnetic, since the unpaired electron is located on this ring. On further reduction, the naphthalene ring may react with alkali metal, and the ESR spectrum of naphthalene anion radical may be obtained. Some other explanations than this might be possible including the mechanism assuming the decomposition of the compound on reduction. Further studies on the problem is now going on in our laboratory.

[2.2](9,10)Anthracenophane Anion Radical. The anion radical prepared in DME at −78 °C gave too complicated ESR spectra to be analyzed completely. However, when the temperature was carefully raised near to but a little below 0 °C and again lowered to −50 °C, quite neat spectrum was obtained. The spectrum indicated in Fig. 5 shows hfs due to three sets of eight equivalent protons, and their hfs con-

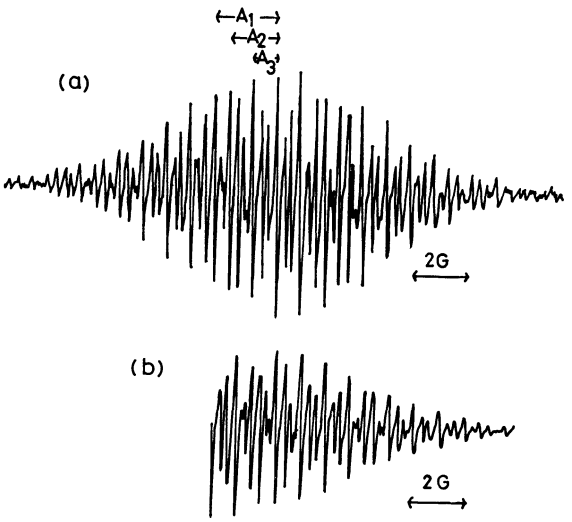

Fig. 5. (a) ESR specturm of [2.2](9,10)anthracenophane anion radical; solvent THF, temperature −50 °C, sodium metal reduction, (b) Computer simulated spectrum.

stants are $A_1=2.14$ G, $A_2=1.63$ G, and $A_3=0.82$ G, respectively. Computer simulated spectrum is in a good agreement with the observed.

Williams *et al.*[3] also reported the ESR spectra of (II-1). However, they failed to analyze the complicated spectra. Their spectra were similar to those we have obtained just after the preparation of the anion radicals at −78 °C in DME. Only the hfs constant of the methylene protons was determined by them to be 1.63 G, using the deuteration technique. This value of the hfs constant is exactly the same as our A_2 value. The complicated spectrum obtained immediately after the preparation of radicals at −78° C seems to be a superposition of the spectra of several species probably including some paramagnetic decomposition products. When the temperature was raised up to near 0 °C the decomposition products were presumably converted to some diamagnetic species, and finally some portion of (II-1) remained. Our assignment was performed by taking into consideration the ESR spectra of 9,10-dimethylanthracene and also the results of Williams *et al.* The hfs constants of (II-1) are compared with those of 9,10-dimethylanthracene in Table 3. These results seem to indicate that the unpaired electron is completely delocalized over the two anthracene rings.

We have measured also ESR spectra of anion radicals of other paracyclophane derivatives. Among them are [2.2]paracycloanthracenophanes, [2.2](1,4)-naphthaleno(1,4)anthracenophane, and anti-[2.2](1,4)-anthracenophane.[6] Their ESR spectra are very complicated, and we have not yet attained to any complete agreement between the experimental and computer simulated spectra. Only can it be said that the unpaired electron is fairly well delocalized over the different composite aromatic rings in the case of these paracyclophane derivatives in contrast to the case of triptycene derivatives where the localization of the unpaired electron on the aromatic ring with the largest electron affinity prevails. This result seems to be reasonable in view of the stronger interaction between the composite aromatic rings in the paracyclophane derivatives than in the triptycene derivatives.

From the results of the present investigation, one may conclude that, in the case of the triptycene derivatives, the unpaired electron is localized on a aromatic ring of the largest electron affinity, and when the triptycene derivative contains the same two aromatic rings, it is completely delocalized over them. In the case of paracyclophane derivatives, the unpaired electron is delocalized over two groups even if they are different from each other.

Table 3. Assignment of the hfs constants of [2.2]-(9,10)anthracenophane anion radical (II-1) in comparison with those of 9,10-dimethylanthracene anion radical (DMA) (in units of G)

	DMA	II-1
a_1, a_4, a_5, a_8 (a_1', a_4', a_5', a_8')	2.90	2.14
a_2, a_3, a_6, a_7 (a_2', a_3', a_6', a_7')	1.52	0.82
$a(CH_3)$ or $a(CH_2)$	3.88	1.63

The authors are grateful to Drs. T. Kubota and H. Miyazaki of Shionogi Research Laboratory for the electrochemical measurements.

The Triplet-Triplet Absorption Spectra and Electronic Structures of Some Cyano-Substituted Benzenes

Hiroshi MORITA, Satoru MATSUMOTO,* and Saburo NAGAKURA

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

(Received October 7, 1974)

Triplet-triplet (T–T) absorption bands were observed at 300, 297, and 320 nm for *m*- and *p*-dicyanobenzenes, and 1,3,5-tricyanobenzene, respectively. The nature of the observed spectra was investigated by calculating the wave functions of the triplet states and by analyzing them by the configuration analysis method. It was concluded that the T–T absorption bands of *m*- and *p*-dicyanobenzenes, and 1,3,5-tricyanobenzene correspond essentially to the transition from the locally (within the benzene ring) excited state to the intramolecular charge-transfer state.

Intramolecular charge-transfer (CT) interaction between the benzene ring and substituent groups is important to understand the electronic structures of some substituted benzene molecules. A large number of studies has hitherto been made on the effect of the interaction upon the singlet-singlet transition spectra of substituted benzenes and the intramolecular CT absorption characteristic of the interaction has been observed for various substituted benzene molecules.[1–10] Only a few studies, however, have been done on triplet-triplet transition spectra of substituted benzenes. Kimura and Tsubomura[11] studied theoretically the nature of the lowest triplet state for such substituted benzenes as phenol, anisole, aniline, *p*-phenylenediamine, and *N,N,N',N'*-tetramethyl-*p*-phenylenediamine (TMPD), paying special attention to the intramolecular CT character. Experimental studies have been made on the triplet-triplet absorption spectrum of the TMPD molecule.[12,13]

In the present study, in order to elucidate the electronic structures of the excited triplet states of benzonitrile (BN), *o*-, *m*-, and *p*-dicyanobenzenes (*o*-, *m*-, and *p*-DCNB), 1,3,5-tricyanobenzene (TRCNB), and 1,2,4,5-tetracyanobenzene (TCNB), we have measured their triplet-triplet (T–T) absorption spectra at 77 K and interpreted them with the aid of the configuration analysis[14] of the wave functions obtained by the Pariser-Parr-Pople SCF MO method[15,16] combined with the configuration interaction (CI) treatment.

Experimental

Commercially available *o*-, *m*-, and *p*-DCNB's of G.R. grade were purified by recrystallization from water, ethyl acetate, and methanol, respectively. TRCNB was prepared by the method described in the literature[17,18] and purified by recrystallization from methanol and thereafter from ethyl acetate. TCNB was purified by vacuum sublimation. Commercially available BN of G.R. grade was used without further purification.

The T–T absorption spectra were measured at 77 K in ethyl ether–isopentane (1 : 1) mixed solvent (EP). The samples were excited by a 500 W super-high-pressure mercury lamp. The details of the measurement were described in a previous paper.[19]

* Present address: Pioneering Research and Development Laboratories, Toray Industries, Inc., Sonoyama, Otsu, Shiga 520.

Theoretical

The π-electron structures of the ground and triplet excited states were calculated for all the molecules under consideration by taking the configuration interaction among all the singly excited configurations constructed from the Pariser-Parr-Pople SCF MO's.[15,16] The semi-empirical parameters chosen by Iwata *et al.*[20] for TCNB complexes were used for the present calculation. Electron paramagnetic resonance[21] and optical[22] studies of the lowest triplet states of benzene and methyl-substituted benzenes like toluene and mesitylene show that the geometrical structure of the benzene ring deviates from the hexagonal symmetry in the lowest triplet state. Slight distortion of the benzene ring from the hexagonal symmetry is also expected for the triplet states of the cyano-substituted benzene molecules under consideration. Because of the lack of the quantitative knowledge on the geometrical structures of their lowest triplet states, however, we assume in the present calculations that the molecules are planar and their benzene rings are of the hexagonal symmetry. The bond lengths are taken as follows; 1.39 Å for the C–C bond in the benzene ring, 1.46 Å for the C–C bond between the benzene ring and the substituent group, and 1.16 Å for the C≡N bond in the cyano group.

The wave functions obtained for some triplet states and the ground states of *m*- and *p*-DCNB's and TRCNB were analyzed with the aid of the configuration analysis method.[14] In the analysis, MO's of the benzene ring and those of the substituent groups were taken as the reference MO's. This choice of the reference MO's is appropriate to elucidate the intramolecular CT and locally excited (LE) characters for the triplet states of *m*- and *p*-DCNB's and TRCNB. In order to obtain the satisfactory convergence in the configuration analysis, it is necessary to take doubly excited configurations in addition to the singly excited ones.

Results and Discussion

As is shown in Fig. 1, the T–T absorption bands were observed at 300, 297, and 320 nm for *m*-DCNB, *p*-DCNB, and TRCNB, respectively. We measured the T–T absorption in the region 290~700 nm. But we

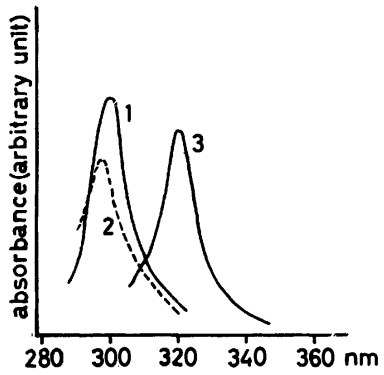

Fig. 1. T-T absorption spectra observed with (1) *m*-DCNB, (2) *p*-DCNB, and (3) TRCNB in EP solutions at 77 K.

could observe no band in the longer wavelength region for the respective molecules. Therefore, the observed bands are the longest wavelength band for the respective molecules. The observed T-T transition energies are listed in Table 1. We could observe no T-T absorption band for BN and *o*-DCNB in the wavelength region available in the present experiment. Concerning TCNB, we could not obtain any conclusive result on the T-T absorption.[23]

TCNB	(3.87)[e]	4.01	0.625	T_{11}

a) See Ref. 26. b) See Ref. 27. c) See Ref. 28. d) Degenerate upper state. e) See Ref. 23.

In Table 2, the calculated T-T transition energies and oscillator strengths of *m*-DCNB, *p*-DCNB, and TRCNB are tabulated. From the comparison between the observed and calculated transition energies and absorption intensities, the observed T-T absorption bands of *m*-DCNB, *p*-DCNB, and TRCNB are safely assigned to the transitions to the T_9, T_9, and degenerate T_7 states, respectively.

The triplet states of benzene, BN, *o*-DCNB, and TCNB were also calculated. The calculated transition energies of the T-T absorption bands that are expected to appear with considerable intensities in the longest wavelength region are tabulated in Table 1, together with the results of *m*- and *p*-DCNB's and TRCNB. The transition energies of benzene were calculated to be 2.91 and 5.49 eV for the transitions to the $^3E^+_{2g}$ and $^3E^-_{2g}$ states, respectively. These calculated values agree well with the observed values, 2.88 and 5.36 (or ~5.17) eV.[26-28] This agreement seems to show the validity of the present calculation and to support the assignment of the T-T absorption bands observed with *m*- and *p*-DCNB's and TRCNB. The transitions to the T_8 state of BN and the T_9 and T_{10} states of *o*-DCNB are theoretically expected to be observed with considerable intensity near 4.5 eV (~270 nm): this is consistent with the experimental fact that no corresponding bands were observed at wavelengths greater than 290 nm.

As shown in Table 1, the T-T transition energies of the substituted benzenes under consideration are calculated to be at least 1 eV smaller than that of benzene. This is due to the interaction between the locally excited and intramolecular CT (between the substituent group and the benzene ring) configurations. In order to clarify the situation in more detail, the results of the configuration analysis for the T_1 and T_9 states of *m*- and *p*-DCNB's are tabulated in Table 3 and those for the T_1 and T_7 states of TRCNB are tabulated in Table 4. In these tables, the results of the ground states of the respective compounds are

a) CT configurations from the benzene ring to the cyano groups. b) CT configurations from the cyano groups to the benzene ring.

also given for the purpose of comparison. In these tables, G^0 denotes the ground configuration, and Groups A and A' represent the singly and doubly excited LE configurations in the benzene ring, respectively; Groups B and B', the singly and doubly excited LE configurations in the substituent groups, respectively; Groups C and C', the singly and doubly excited CT configurations from the benzene ring to the substituent groups, respectively; Groups D and D', the singly and doubly excited CT configurations from the substituent groups to the benzene ring, respectively, and Group C+A, *etc.*, the doubly excited configurations composed of configurations in Groups C and A, *etc.*

As is clearly seen in Table 3, the results of the configuration analysis for *m*- and *p*-DCNB's are similar to each other; the ground singlet state (G) and the lowest triplet state (T_1) are mainly composed of the ground and LE configurations, while in the T_9 states, the contribution of the CT configurations is more predominant than that of the LE configurations. This shows that the observed T-T absorption bands of *m*- and *p*-DCNB's correspond to the transition from the LE state to the intramolecular CT state.

Concerning *p*-DCNB, the contribution of the CT configurations in Group C may increase the double bond character of the C-C bonds between the benzene ring and the cyano groups. Hence, the molecular geometry may tend towards a quinoid structure. In actuality, this tendency was observed by Hirota[29] from the measurement of the spin densities in the T_1

state of *p*-DCNB.

As is seen in Table 4, the nature of the T-T absorption band of TRCNB is analogous to that of *m*- and *p*-DCNB's. The T-T absorption bands of BN, *o*-DCNB, and TCNB listed in Table 1 also correspond to the transition from the LE state to the intramolecular CT state.

Use of the Copper(II)-Selective Electrode for the Determination of the Stability Constants of Copper(II) Complexes

Genkichi NAKAGAWA, Hiroko WADA, and Tomohiko HAYAKAWA

Nagoya Institute of Technology, Showa-ku, Nagoya 466

(Received March 12, 1974)

In the determination of stability constants of metal complexes, usually the measurements of the activities of free metal ions at very low levels are required. The electrode response of an Orion Model 94—29 copper(II) ion selective electrode at very low activity levels was studied in the various metal buffers composed of copper(II) ions and an excess of ligand. Usually the linear calibration range of the copper(II) ion selective electrode was extended to very low activity levels in the presence of a strong complexing agent. The stability constants of copper(II) complexes with acetate, ammonia, ethylenediamine, glycine, iminodiacetic acid, 1,10-phenanthroline, *etc.* were determined successfully. In the cases of EDTA and NTA, however, the lower limit of the linear calibration range was abnormally high and the stability constant of copper-EDTA or -NTA chelate could not be obtained. Some experimental results on the potentiometric titration of copper(II) ion with EDTA were also presented.

In recent years many types of ion-selective electrodes have been developed which are very useful for direct determination of various ions in solutions.[1-6] These electrodes have been also used in the study of solution equilibria[7,8] as well as for the detection of the end-point in titrations.[9-11] In these cases the measurements of activities of free ions at very low levels are usually required. However, less attention has been paid on the detection limit of the electrode.

In the present paper the potential response of an Orion solid-state copper(II) ion selective electrode Model 94—29 at very low activity levels of copper(II) ions is studied by the use of various metal buffers, and the stability constants of some copper(II) complexes are determined successfully.

Experimental

Reagents. *Stock solution of copper*: A 10^{-1} M copper(II) nitrate solution was prepared from metallic copper (99.99%). A series of standard solutions of copper(II) from 10^{-2} to 10^{-6} M was prepared by dilution of the stock solution immediately before measurements.

Complexing Agents: Reagent grade EDTA·2Na and NTA were recrystallized from water. Ammonia and ethylenediamine were purified by distillation. Other chemicals were of reagent grade and used without further purification. Deionized and redistilled water was used.

Apparatus. For the measurements of copper(II) ion activities, an Orion copper(II) ion selective electrode Model 94-29 and a Horiba SCE reference electrode were used with a Hitachi-Horiba F-5 expanded scale pH meter. The pH measurements were made with a Hitachi-Horiba M-5 pH meter equipped with Horiba glass and calomel electrodes.

Three Orion copper(II) ion selective electrodes were examined, and these showed the same characteristics of potential response.

The surface of a sulfide membrane of the electrodes was occasionally polished lightly with tooth paste to keep the electrodes at the best condition. During the potential measurement magnetic stirring with a Teflon bar was applied.

All experiments were carried out in air thermostated at 25±1 °C.

Results and Discussion

The potential response of the electrode. The experimental cell can be represented as follows.

copper(II) ion selective electrode | test solution μ=0.1(KNO_3) | 0.1 M KNO_3 | SCE

The measurements being carried out at a constant ionic strength of 0.1, the junction potential was kept constant and the cell emf is given:

$$E = \text{const.} + 2.303\frac{RT}{2F}\log a_{Cu^{2+}} \qquad (1)$$

The potential response of the copper(II) ion selective electrode at various copper(II) ion activity levels was examined in a pH range between 2 and 10. As shown in Fig. 1 the Nernstian response held down to 10^{-6} M of copper(II) ions in a pH range of 4—6. Below 10^{-6} M the calibration curve reached to a pla-

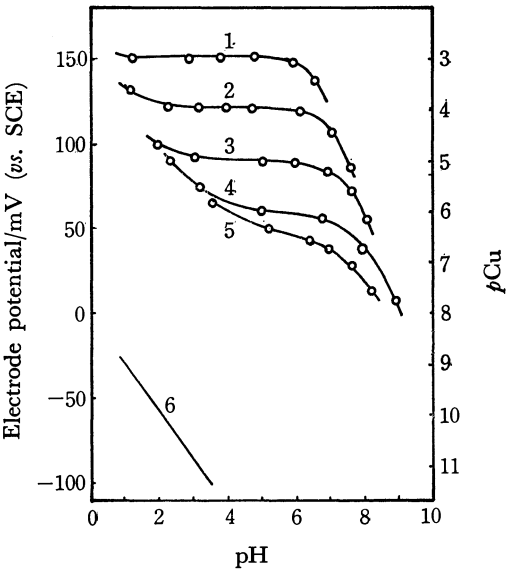

Fig. 1. Potential response of an Orion 94-29 copper(II) ion-selective.
$Cu(NO_3)_2$ 1: 10^{-3} M, 2: 10^{-4} M, 3: 10^{-5} M, 4: 10^{-6} M, 5: 0 (lower detection limit in 0.1 M MES buffer), 6: theoretical solubility of CuS.

teau, and the electrode no longer responded to change in copper(II) ion activity. This detection limit rose markedly in highly acidic solutions. At pH higher than 6 copper precipitates as a hydroxide.

The potential response of the copper(II) ion selective electrode was fast and the electrode attained a constant value within a few seconds at 10^{-2}—10^{-3} M and within a few minutes at 10^{-6} M copper(II) ion. In spite of very low activities of copper(II) ion, usually 2—5 minutes were sufficient in metal buffer solutions. The reproducibility of the electrode potential was within ±0.5 mV for 24 hours. However, since the drift of the potential during several months ranged to a few tens mV, it is advisable to calibrate the electrode with the standard copper(II) solution of 10^{-3} M before the measurements.

The Detection Limit of the Electrode. The membrane of the Orion copper(II) ion selective electrode consisting of mixed sulfides of copper(II) and silver is a source of copper(II) ions in test solutions, the lower activity limit of detection is governed by the solubility of the sulfide membrane. As seen from curves 5 and 6 in Fig. 1, however, the actual limit of detection was much higher than that calculated from the solubility of copper(II) sulfide. This disagreement may be partly attributed to copper(II) ion contamination of the test solution and partly to high activity of copper(II) ion at the surface of the sulfide membrane caused by the

2: NTA	4.95×10^{-3}	0.95×10^{-3}
3: IDA	2.43×10^{-3}	4.01×10^{-2}
4: Bipyridine	0.99×10^{-4}	4.98×10^{-3}

adsorption.

Many complexing agents forming stable complexes with copper(II) ions may reduce the activity of copper(II) ion in solutions or at the electrode surface. The detection limit of the electrode was measured in various ligand solutions containing no copper ion. As shown in Figs. 2 and 3, the detection limit was affected markedly by the type of complexing agent in the test solutions, its concentration and pH. Strong complexing agents lowered the detection limit to a large extent. For example, the lower activity limit of detection was around 10^{-6} M at pH 4 in the buffer solution composed of MES[12] which forms copper complex only negligibly, while in the presence of 0.001 M 1,10-phenanthroline the detection limit became to the order of 10^{-14} M at a pH higher than 5.

However, in spite of a high stability of copper(II)-EDTA chelate the detection limit in EDTA solutions was abnormally high. Since the stability of silver-EDTA chelate is relatively small, the activity of silver ion at the electrode surface may be much higher than that of copper. The Orion copper(II) ion selective electrode also responds to silver ion, thus the detection limit in this case may be determined by the activity of silver ion at the electrode surface. On the other hand, ligands which form fairly stable complexes with both silver and copper(II) ions, *i.e.* NH_3, ethylenediamine, 1,10-phenanthroline *etc.*, may shift the detection limit of the electrode to very low copper(II) ion levels.

Determination of the Stability Constants of Copper(II) Complexes. The stability constants of various cop-

per(II) complexes were determined by measuring the activities of free copper(II) ion in the metal buffer solutions which consist of copper complex CuL_n and the excess of the ligand L.

From the over-all stability constant of the complex CuL_n, the activities of free copper(II) ion in a metal buffer solution are given:

$$pCu = \log \beta_n + n \log[L] - \log[CuL_n] \quad (2)$$

When the solution contains a large excess of ligand and the formation of CuL_n is practically complete, $[CuL_n]=C_{Cu}$, and [L] can be represented by Eq. (3).

$$[L] = \frac{C_L}{\alpha_{L(H)}} \quad (3)$$

where C_L is the total concentration of the ligand, and $\alpha_{L(H)}$ is the side reaction coefficient taking into account the protonation of ligand and calculated from the concentration of hydrogen ion in the solution and the acid dissociation constants of the ligand. As pCu is obtained from the measured cell potential, β_n can be calculated by Eq. (2).

Figures 2 and 3 show the cell potential measured in various copper(II) buffer solutions. The relation between pCu and pL are plotted in Fig. 4. These plots yielded the straight lines of slope n. In the case of bipyridine the slope was 2 at pL>5 and 3 at pL<4, and β_2 and β_3 could be evaluated.

The stability constants determined are summarized in Table 1. Those values are in good agreement with the values reported in the literature.[13]

For the EDTA or NTA chelate, however, good results could not be obtained, because in these cases the activities of copper(II) ion in the solutions were much lower than the detection limit of the electrode, so the true activities of copper(II) ion were not obtained. Also this was the case for IDA at pH>7.

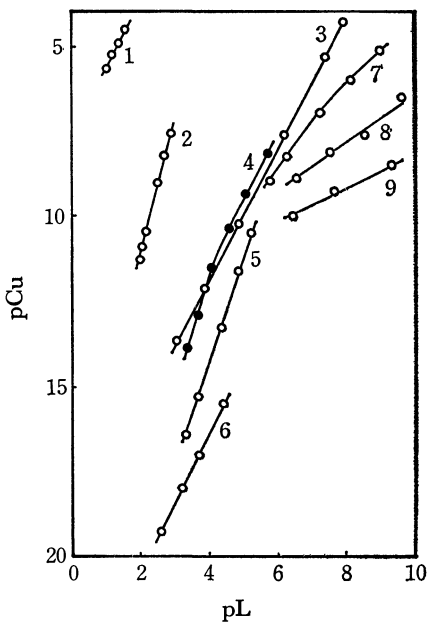

Fig. 4. Relations between pCu and pL.
1: OAc^-, 2: NH_3, 3: glycine, 4: bipyridine, 5: 1,10-phenanthroline, 6: ethylenediamine, 7: iminodiacetic acid, 8: NTA, 9: EDTA.

Table 1. Stability constants of copper(II) complexes (μ=0.1, 25 °C)

Ligand		Logarithmic values of β_n (measured)	(literature)
OAc^-	β_2	2.58 (μ=1.0)	2.7
NH_3	β_4	12.49	12.59
Ethylenediamine	β_2	19.40	19.60
Glycine	β_2	15.28	15.1
Iminodiacetic acid	β_1	10.54	10.5
Bipyridine	β_2	13.65	13.57
	β_3	16.75	17.0
1,10-Phenanthroline	β_3	19.10	21.0

These values were omitted for the calculation of the stability constant.

The use of the ion selective electrode provides the simple and reliable method for studying the stability of metal complexes. However, the lower limits of detection of the ion selective electrode should be checked under the same experimental conditions.

Application to EDTA Titration. The potentiometric titration curves of copper(II) ion with EDTA using the copper(II) ion selective electrode are shown in Fig. 5A. The titration curves after the equivalence point were leveled at the detection limit of the electrode and deviated from the typical sigmoid shape. Addition of a small amount of 1,10-phenanthroline *i.e.* 10^{-5} M improved titration curves markedly. As seen from Fig. 5B this is of special advantage when the metals stabilities of EDTA chelates of which are lower than that of copper, are to be determined by back titration of the

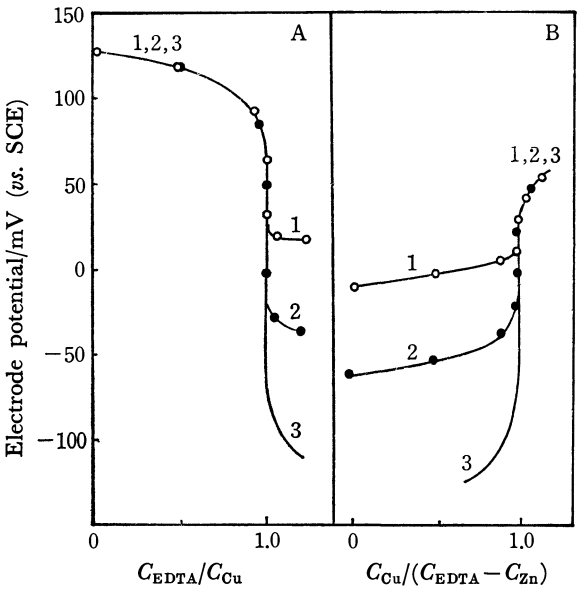

Fig. 5. Titration of copper with EDTA (A) and determination of zinc by back titration of excess EDTA with copper (B).
(A) 1: Cu 2×10^{-3}M, pH 5.8 (0.1M HOAc-OAc^-), 2: the same as 1 but 10^{-5} M 1,10-phenanthroline added, 3: theoretical curve.
(B) 1: Zn 2×10^{-3} M, EDTA 4×10^{-3} M, 2: the same as 1 but 10^{-5} M 1,10-phenanthroline added, 3: theoretical curve.

excess of EDTA with copper(II) ion standard solution. In these cases the potential jump at the equivalence point is depressed by the following exchange reaction:

$$ZnY^{2-} + Cu^{2+} \rightleftharpoons CuY^{2-} + Zn^{2+}$$

Thus the electrode response in the low copper(II) ion levels becomes increasingly important to obtain a sharp end point.

An Investigation of the Hebb-Wagner's d-c Polarization Technique I. Steady-state Chemical Potential Profiles in Solid Electrolytes

Jun-ichiro MIZUSAKI, Kazuo FUEKI, and Takashi MUKAIBO

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received September 24, 1974)

Using an electrochemical cell, Ag/AgX (X=Br or I)/C, the steady-state chemical potential profiles of silver in AgX were determined under d-c polarization conditions. Several Pt probes were attached to the AgX specimens, and the potential differences between the Ag electrode and the Pt probes were measured. It was found that, in order to obtain the correct chemical potential profiles, the Pt probes must be embedded in the specimen to avoid influences of the degradation of AgX at the surface of the specimen. The results obtained by the cell with carefully assembled probes revealed that Wagner's theory holds for AgX.

Hebb-Wagner's d-c polarization technique[1,2] is generally used for the determination of electronic transport numbers of mixed conductors. The cell arrangements employed in this technique are as follows:

⊖ cation reversible electrode/mixed conductor/ion-blocking electrode ⊕ (I)

or;

⊖ ion-blocking electrode/mixed conductor/anion reversible electrode ⊕ (II)

The theory of this technique, originated by Wagner,[2] is based on the assumption that there is no gradient of the electrochemical potential of blocked ions in the steady state; in other words, the driving force due to the electrical potential gradient is cancelled by that due to the chemical potential gradient. The chemical potential profiles in the steady state were calculated theoretically and illustrated graphically by Choudhury and Patterson.[3,4]

Direct measurements of the chemical potential profile in mixed conductors of predominantly electronic conduction were carried out by Hebb (Ag_2S[1]), Miyatani (Ag_2S,[5] Ag_2Te[6]), and Yokota (Cu_2S[7]). The observed results agreed well with those calculated in a similar manner.

As to the mixed conductors of a predominantly ionic conduction, the electrical potential profile of $PbBr_2$[8] has previously been measured. However, no explanation has been given to correlate the observed potential profiles with Wagner's theory.

The purpose of the present study is to measure the chemical potential profiles in ionic conductors, such as AgBr and AgI, using a cell of the (I) type to reveal whether or not Wagner's theory holds in these systems.

Experimental

Circut and Experimental Procedures. The circuit employed for the measurement is shown in Fig. 1. AgX (X=Br or I) was placed between Ag and graphite electrodes to construct a Hebb-Wagner's d-c polarization cell. Several Pt wires were attached to AgX as probes. This cell was placed in an electric furnace, the temperature of which was controlled by means of an electronic controller to within ±1 °C. The potential difference between the Ag and graphite electrodes was kept constant by means of a potentiostat. When the current flowing through the circuit reached a stationary value, the chemical potential profile in a steady-state was determined by measuring the potential differences between the Ag electrode and the Pt probes by means of a high impedance d-c digital voltmeter.

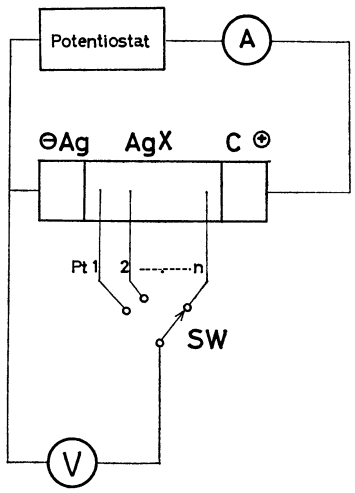

Fig. 1. Circuit diagram for the measurement.

The measurement was performed in a purified nitrogen flow of 2 cm s^{-1} at 350 and 400 °C for AgBr, and 500 °C for AgI.

Cells. Three types of cell arrangements were employed. In the first and second types, Pt probes were embedded in the specimen, while in the third type, Pt probes were in contact with the surface of the specimen.

The first type, Cell (i), is illustrated in Fig. 2. Reagent-grade AgBr was purified 50 times by zone refining and then solidified in a rod-shaped single crystal, 15 mm in length and 10 mm in diameter, by the Bridgeman method. Holes 0.8 mm in diameter were drilled from the side surface to the axis of the AgBr rod. In these holes, Pt wires (0.2 mm in diameter) protected by an alumina tube (0.8 mm in outer diameter and 0.4 mm in inner diameter) were buried as probes so that only the tips of the wires were in contact

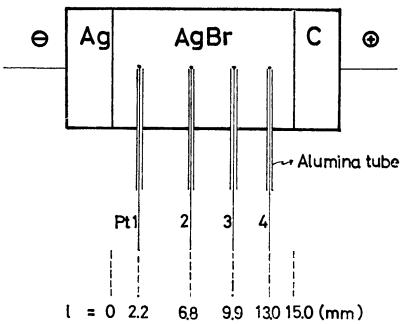

Fig. 2. Arrangement of Cell (i).

with the AgBr rod. The AgBr rod was then sandwiched by Ag and graphite electrodes and pressed by means of a spring to ensure contact.

As AgI experiences a phase transformation at 146 °C, the rod-shaped specimen prepared from the solidification of the molten AgI is quite brittle at room temperature and can not endure mechanical treatment such as the drilling of holes from the side surface. Therefore, instead of the first type, the second type, Cell (ii), was employed for the measurement of AgI. Figure 3 shows the arrangement of Cell (ii). Three pellets, 10 mm in diameter and a, b, and c mm thick respectively, were prepared by pressing reagent-grade AgI in a die. An Ag electrode, three AgI pellets, and a graphite electrode were assembled in series. The Ag and graphite electrodes and two of the AgI pellets, a and c mm thick, have holes, 0.8 mm in diameter, along the axis. Pt wires protected by an alumina tube were inserted in the holes from both ends, so that their tips were in contact with the end surfaces of the middle AgI pellet, b mm thick. In Cell (ii-A), the thicknesses of the AgI pellets employed were $a=3.0$ mm, $b=5.7$ mm and $c=1.1$ mm, and in Cell (ii-B), $a=1.1$ mm, $b=6.0$ mm, and $c=3.0$ mm.

The third type, Cell (iii-A) or Cell (iii-B), consists of an AgBr or AgI rod, 10 mm in diameter, solidified from the melt. Pt probes were wound around the rod at appropriate intervals. The rod was then sandwiched between Ag and graphite electrodes. The arrangement of Cell (iii-B) is shown in Fig. 4.

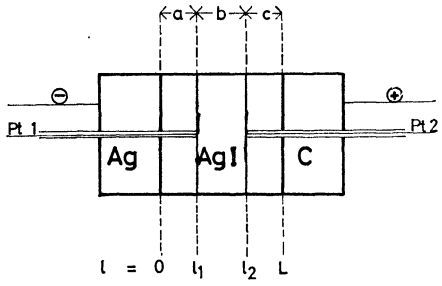

Fig. 3. Arrangement of Cell (ii).

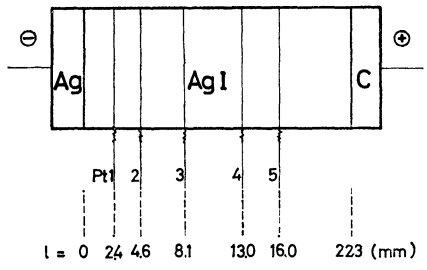

Fig. 4. Arrangement of Cell (iii-B).

Results and Discussion

The experimental results obtained by the use of Cell(i) and Cell(iii-A) are shown in Fig. 5. Those obtained by the use of Cell (ii) and Cell(iii-B) are shown in Fig. 6. The steady-state was attained within 48 hours.

Chemical Potential Profiles in the Steady-state. When AgX shows an n-type electronic conduction, μ_{Ag}, the chemical potential of silver in AgX in a steady-state,

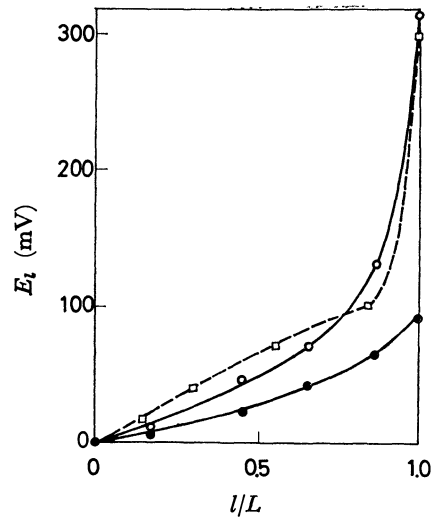

Fig. 5. Steady-state potential profiles of AgBr at 400 °C.
●; Cell (i), $E_L=93$ mV, $i=1.0$ μA cm^{-2}, $L=15.0$ mm.
○; Cell (i), $E_L=318$ mV, $i=1.4$ μA cm^{-2}.
□; Cell (iii-A), $E_L=300$ mV, $i=2.3$ μA cm^{-2}, $L=10.8$ mm.

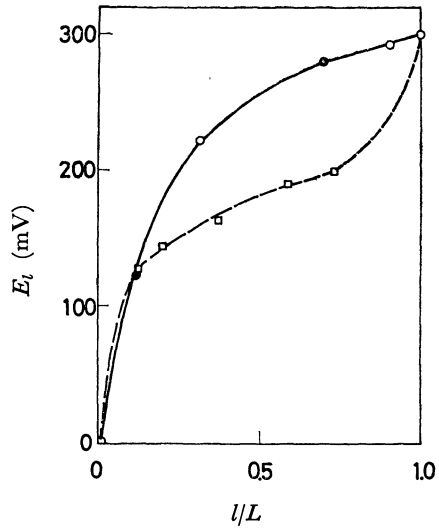

Fig. 6. Steady-state potential profiles of AgI at 500 °C.
○; Cell (ii-A), $E_L=300$ mV, $i=57$ μA cm^{-2}, $L=9.8$ mm. ●; Cell (ii-B), $E_L=300$ mV, $i=38$ μA cm^{-2}, $L=10.3$ mm. □; Cell (iii-B), $E_L=300$ mV, $i=45$ μA cm^{-2}, $L=22.3$ mm.

is represented in the same manner as is used in Wagner's theory, by this equation;

$$il = \frac{\sigma_e^0 RT}{F}\left\{1-\exp\left(\frac{\mu_{Ag}(l)-\mu_{Ag}^0}{RT}\right)\right\} \quad (1)$$

where μ_{Ag}^0 is the μ_{Ag} of metallic silver, $\mu_{Ag}(l)$ is μ_{Ag} distance of l from the Ag/AgX interface, and σ_e^0 is the electronic conductivity of AgX at the Ag/AgX interface. At the AgX/C interface, $l=L$; therefore,

$$iL = \frac{\sigma_e^0 RT}{F}\left\{1-\exp\left(\frac{\mu_{Ag}(L)-\mu_{Ag}^0}{RT}\right)\right\} \quad (2)$$

From Eqs. (1) and (2), we obtained:

$$\frac{l}{L}=\frac{1-\exp\left(\frac{\mu_{Ag}(l)-\mu_{Ag}{}^{0}}{RT}\right)}{1-\exp\left(\frac{\mu_{Ag}(L)-\mu_{Ag}{}^{0}}{RT}\right)} \quad (3)$$

In the case of p-type AgX

$$il=\frac{\sigma_h{}^{0}RT}{F}\left\{\exp\left(\frac{\mu_{Ag}{}^{0}-\mu_{Ag}(l)}{RT}\right)-1\right\} \quad (4)$$

where $\sigma_h{}^{0}$ is the conductivity due to hole conduction at the Ag/AgX interface. Therefore,

$$\frac{l}{L}=\frac{\exp\left(\frac{\mu_{Ag}{}^{0}-\mu_{Ag}(l)}{RT}\right)-1}{\exp\left(\frac{\mu_{Ag}{}^{0}-\mu_{Ag}(L)}{RT}\right)-1} \quad (5)$$

Eqs. (3) and (5) represent the relationship between $(\mu_{Ag}(l)-\mu_{Ag}{}^{0})$ and l/L for n-type and p-type AgX respectively.

Comparison of the Experimental Results with the Theoretical Results. Under the present experimental conditions, the Ag electrode at the Ag/AgX interface acts as a reversible electrode for both silver ions and electrons, while at the Pt/AgX or C/AgX interface, the Pt or graphite electrode is chemically inert in effect and reversible only for electrons. Therefore, the electrical potential difference, E_l, between the Pt electrode at l and the Ag electrode is written as:

$$E_lF=\eta_e{}^{0}-\eta_e(l) \quad (6)$$

where $\eta_e{}^{0}$ and $\eta_e(l)$ are the electrochemical potentials of electrons in AgX at the Ag/AgX interface and that at l respectively. Under the ion-blocking conditions, the electrochemical potential of silver ions is constant throughout the cell; therefore,

$$\eta_{Ag^+}{}^{0}=\eta_{Ag^+}(l) \quad (7)$$

Therefore, we can obtain from Eqs. (6) and (7):

$$E_lF=\mu_{Ag}{}^{0}-\mu_{Ag}(l) \quad (8)$$

In the same manner, the potential difference, E_L, between the Ag electrode and the graphite electrode located at L is:

$$E_LF=\mu_{Ag}{}^{0}-\mu_{Ag}(L) \quad (9)$$

The insertion of Eqs. (8) and (9) into (3) and (5) yields:

$$\frac{l}{L}=\frac{1-\exp\left(-\frac{E_lF}{RT}\right)}{1-\exp\left(-\frac{E_LF}{RT}\right)} \quad (10)$$

and:

$$\frac{l}{L}=\frac{\exp\left(\frac{E_lF}{RT}\right)-1}{\exp\left(\frac{E_LF}{RT}\right)-1} \quad (11)$$

The experimntal results for AgBr are represented in Fig. 7 as a plot of l/L *vs.* $\dfrac{1-\exp\left(-\frac{E_lF}{RT}\right)}{1-\exp\left(-\frac{E_LF}{RT}\right)}$, while those for AgI are given in Fig. 8 as a plot of l/L *vs.* $\dfrac{\exp\left(\frac{E_lF}{RT}\right)-1}{\exp\left(\frac{E_LF}{RT}\right)-1}$. In the Figure, the results obtained by the use of Cells(i) and (ii), in which the Pt probes embedded in the specimens show a good linearity. This indicates that Eq. (10) holds in Cell(i) and Eq. (11) in Cell(ii). Therefore, it may be concluded that AgBr and AgI are n-type and p-type conductors respectively under the present experimental conditions, as was found by Ilschner[9] and Raleigh,[10] and that Wagner's theory holds for the mixed conductors of a predominantly ionic conduction.

However, the results obtained by using Cell(iii),

in whish Pt probes are placed in contact with the surface of a specimen, do not agree with Wagner's theory.

Electronical Conductivity of AgBr. Inserting the values of a steady-state current, the applied potential difference, E_L, and the sample length, L, of Cell(i) into Eqs. (2) and (8), one obtains 3.0×10^{-6} ℧ cm^{-1} (350 °C) and 4.0×10^{-5} ℧ cm^{-1} (400 °C) as the σ_e^0 of AgBr. These values are in good agreement with the results obtained by Ilschner.

The Effect of the Degradation of AgI at the AgI/C Interface on the Potential Profiles. Using Eqs. (3) and (8), the σ_h^0 of AgI at 500 °C was calculated. The result obtained from Cell(ii–A) was 9.5×10^{-6} ℧ cm^{-1}. However, this value is about one order of magnitude larger than the value obtained by the extrapolation of Ilschner's data.[9] This fact suggests that the current passed through AgI might be an ionic current due to the degradation of AgI at the AgI/C interface.

When the ionic current is predominant in AgI, the ionic current, i_{ion}, correlates with the electrochemical potential difference of Ag^+ between Ag and graphite electrodes as follows:

$$\eta_{Ag^+}(L) - \eta_{Ag^+}{}^0 = \frac{i_{ion}LF}{\sigma_i} \qquad (12)$$

where σ_i represents the ionic conductivity of AgI. The length of the AgI specimen used in this work is less than 2.23 cm, the current density is less than 180 μA/cm^2, and the σ_i of AgI at 500 °C is 2.5 ℧ cm^{-1}.[11] Therefore, $i_{ion}L/\sigma_i<0.16$ mV. It is evident that the drop of the electrochemical potential of silver ions in the AgI specimen is negligibly small compared to the observed potential differences. Therefore, Eq. (7) holds in the present system and the observed potential profiles coincide with those under the complete ion-blocking conditions.

The Effect of the Degradation of AgX at the Side Surface of the Specimen on the Potential Profile. The equilibrium halogen vapor pressure with regard to each observed silver chemical potential can be calculated from the standard free energy of the formation of AgX and the equilibrium constant of the $X_2=2X$ reaction. As for AgBr in Fig. 5, the chemical potential near the AgBr/C interface corresponds to the bromine vapor pressure of the order of 10^{-8} atm, whereas those of the other part of the AgBr rod corresponds to the order of 10^{-10}—10^{-11} atm; as for AgI in Fig. 6, most of the AgI rod corresponds to the iodine vapor pressure of the order of 10^{-4}—10^{-5} atm. Therefore, a large difference in equilibrium halogen-vapor pressure exists between the nitrogen atmosphere and the AgX rod, resulting in the degradation of AgX at the surface of the rod.

As in Cells(i) and (ii), Pt probes were embedded in the specimen, whereas in Cell(iii) Pt probes were attached to the surface of the specimen; the disagreement of the results obtained by the use of Cell(iii) with the theoretical values may be due to this degradation of the AgX surface.

In conclusion, we must embed the Pt probes in the specimen in order to observe the correct chemical potential profiles in a solid electrolyte.

Summary

(i) Using an electrochemical cell, Ag/AgBr (or AgI)/C, the steady-state chemical potential profiles in AgBr and AgI were measured under the d-c polarization conditions.

(ii) It was found that Wagner's theory holds for mixed conductors of a predominantly ionic conduction.

(iii) It was concluded that Pt probes must be embedded in AgX in order to obtain the correct chemical potential profile.

(Received October 19, 1974)

The critical micelle concentrations (CMC) of dodecyltrimethylammonium bromide (DTAB) in aqueous urea solutions have been determined over a range of pressures up to 2500 atm at 25 and 35 °C. The partial molal volumes of DTAB in micellar ($\overline{V}_m$) and singly-dispersed states ($\overline{V}_s$) have also been determined in aqueous urea solutions at 25 °C. $\overline{V}_s$ increases with the addition of urea, while $\overline{V}_m$ remains approximately constant. The partial molal entropy change of micellization ($\Delta\overline{S}_m$) in water increases with an increase in the pressure up to about 1500 atm, while $\Delta\overline{S}_m$ in 3-m urea solution remains virtually unaltered in the low-pressure region. The results suggest that the "iceberg" structure of water around the hydrocarbon chain of the monomeric surfactant is effectively broken down by urea.

The effect of urea on the micelle formation has already been studied by many workers,[1-9] and it is well known that the addition of urea raises the critical micelle concentration (CMC) of surfactant solutions. A smaller negative free energy change and a smaller positive entropy change on micellization have been interpreted in terms of the breakdown of the water structure by urea.

The study of the pressure effect as well as the temperature effect on the CMC of a surfactant in aqueous solutions has given very important thermodynamic information on micelle-forming properties.[10-15] Therefore, the effects of the pressure and temperature on the CMC of a surfactant in aqueous urea solutions are expected to give a deeper insight into the surfactant solution than has hitherto been reported. A knowledge of the thermodynamic properties of model compounds such as surfactants in aqueous urea solutions helps to understand the urea denaturation of proteins and the effect of urea on the water structure.

In this study the CMC of dodecyltrimethylammonium bromide (DTAB) in aqueous urea solutions of various concentrations was determined over a range of pressures up to 2500 atm at 25 and 35 °C. Then the partial molal volumes of DTAB in aqueous urea solutions were determined above and below the CMC. The effect of urea on the thermodynamic parameters for micellization was also examined.

Experimental

The DTAB used was synthesized and purified by the method described previously.[16] The CMC of the DTAB solution determined by the conductivity method was 0.01554 in molality (m) at 25 °C. This value is in good agreement with that in the literature. All the solutions were prepared on a molal basis. Urea was recrystallized from an ethanol-water (95 : 5) mixture. The urea concentrations of 3.0 and 6.0 in molality correspond to the values in 2.64 and 4.75 in molarity (M) at 25 °C respectively.

The high-pressure apparatus used is the same as has been described previously.[17] The CMC of DTAB in aqueous urea solutions under high pressures was determined by the conductivity method in a way similar to that used under atmospheric pressures.

The densities of a series of solutions were simultaneously measured by using ten pycnometers with a capacity of about 20 ml; the error of measurements was within $\pm 5 \times 10^{-5}$ g/cm^3. The thermostated bath was controlled to 25 ($\pm$0.005) °C. The volume of solution per 1000 g of solvent (water+urea) was plotted against the molality of DTAB, resulting in a straight line below and above the CMC. The partial molal volume of DTAB in aqueous urea solutions was taken as the slope of the line; it was determined by the least-squares method. Since the partial molal volume is almost independent of the surfactant concentration over the concentration ranges studied here,[18,19] the experimental values thus obtained have been assumed to be identical with those corresponding to an infinite dilution.

Results and Discussion

The CMC of DTAB in several urea solutions is shown in Fig. 1 as a function of the pressure. The

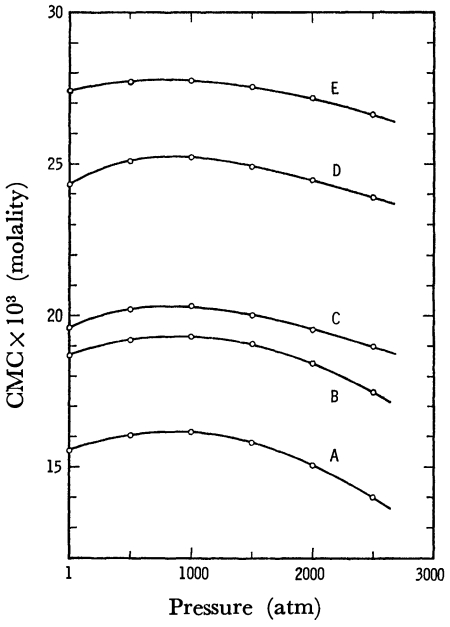

Fig. 1. Effect of pressure on the CMC in some urea solutions at 25 °C. Urea concentration; A: 0, B: 1.99, C: 2.94, D: 4.49, and E: 6.08 (mole/kg-H_2O).

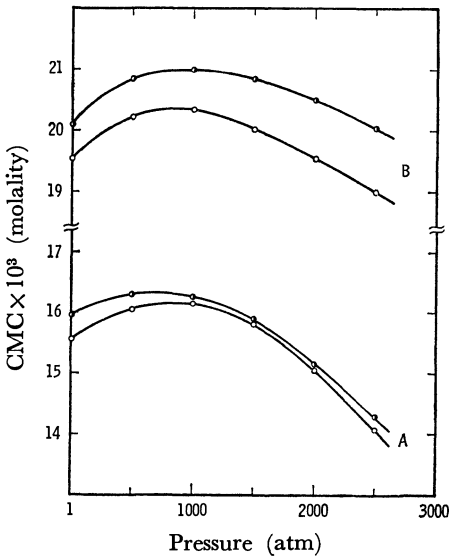

Fig. 2. Effect of pressure on the CMC in water and 3 m (2.94 molality) urea solution at two temperatures, 25 °C (○) and 35 °C (◑). A: in water, B: in 3 m urea solution.

CMC *vs.* pressure curve in water is in fair agreement with that of Tuddenham and Alexander.[11] At about 800 atm, the CMC *vs.* pressure curve has a maximum which remains even in a 6-m urea solution. The CMC of DTAB increases with the addition of urea in the whole pressure region studied. This increase in the CMC by urea at 1 atm is comparable with the results reported by other workers.[2,5,9] In Fig. 2, the effects of the temperature and pressure on the CMC of DTAB in water and a 3-m urea solution are compared. It is known that the CMC *vs.* temperature curve for DTAB reaches a minimum at about 25 °C in water[5,17] and at 15—20 °C in the 3-M urea solution.[5,9] As may be seen from Fig. 2, in water the increase in the CMC by the elevation of the temperature is reduced upon the application of pressure, while in the 3-m urea solution it becomes progressively greater as the pressure increases.

There remain some factors to be considered in the interpretation of the effect of urea on the micelle formation; the change in the dielectric constant of the solution, the solubilization of urea into the micelle, the change in the structured water around the hydrocarbon chain of the monomeric surfactant, and so on. It is known that the dielectric constant of a solution increases with the urea concentration up at least to 3 M;[20] this increase of the dielectric constant of urea solution is most likely responsible for the dissociation of the ionic micelle.[9] In the methanol–water mixture, however, the effective micellar charge increases with the methanol content to a 0.3 mole fraction of methanol[21] in spite of the decrease in the dielectric constant with the increase in the methanol content.[20] The CMC increases in both solutions. The micellar weight decreases not only in a methanol solution,[21,22] but also in an urea solution.[23] Thus, the change in the dielectric constant which is due to the change in the composition of solvent seems not to affect the micelle formation very much. Secondly, it is known that in general the addition of solubilizates lowers the CMC.[24] The solubilization effect of urea on the micellization is very little, if any, because the CMC increases with the addition of urea.

The change in the partial molal volume on micellization, $\Delta\overline{V}_m$, was calculated from the pressure dependence of the CMC through the following equation which has previously been discussed:[14,15]

$$\Delta\overline{V}_m = (1+\beta)RT\left(\frac{\partial \ln \mathrm{CMC}}{\partial P}\right)_{T,\,\Delta\overline{G}_m} \qquad (1)$$

where β is a constant which indicates the ratio of the number of the gegenion to that of the surfactant ion in a micelle. The values of $\Delta\overline{V}_m$ in water and aqueous urea solutions are calculated from Eq. (1) using the results shown in Fig. 1; they are given in Table 1. The value of β used was taken from the literature[9,25] except for that in a 6-m urea solution, which was assumed to be 0.76 by an extrapolation of the available data.

Table 1. Partial molal volumes of micellar and singly dispersed surfactant, and the changes of partial molal volume on micellization

Urea concn. (mol/kg)	β	From CMC $\Delta\overline{V}_m$	From density measurement $\overline{V}_m$	$\overline{V}_s$	$\overline{V}_m-\overline{V}_s$
0	0.744	4.1	295.5	287.0	8.5
2.94	0.756	4.2	295.4	290.2	5.2
6.08	(0.76)	1.5	294.7	291.0	3.7

The values of the partial molal volumes in the micellar ($\overline{V}_m$) and singly dispersed ($\overline{V}_s$) states and their difference ($\overline{V}_m$—$\overline{V}_s$) are also shown in Table 1. The values of $\Delta\overline{V}_m$ calculated from the pressure dependence of the CMC are somewhat smaller not only in water, as has been described previously,[14] but also in urea solutions than the $\overline{V}_m$—$\overline{V}_s$ determined from the density measurement. It is obvious from Table 1 that the partial molal volume change on micellization is reduced by the addition of urea. This reduction may be attributed to the increase in $\overline{V}_s$ with the addition of urea, as $\overline{V}_m$ is kept approximately constant.

The change in the partial molal volume for the transfer of the solute molecule, which has a hydrophobic tail, from water to urea solutions has been studied by several authors.[26,27] This volume change is positive, and it tends to increase as the length of the hydrocarbon chain increases. It is known that the transfer of hydrocarbons from a nonpolar environment to water results in a negative volume change;[28] this is considered to reflect the ordering of water molecules around the hydrocarbon chains, or the "iceberg" formation.[29] Therefore, the positive volume changes for the transfer of a monomeric surfactant from water to urea solutions are consistent with a structure-breaking role of urea in aqueous solutions. On the other hand, $\overline{V}_m$ is quite insensitive to the presence of urea. This constancy of $\overline{V}_m$ can be attributed to the loss of hydrocarbon-water contact due to the formation of micelles.

The change in the partial molal entropy on micelliza-

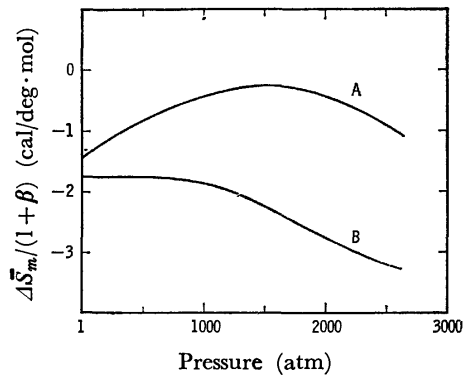

Fig. 3. Partial molal entropy change of micelle formation in the range of temperature, 25—35 °C, as a function of pressure. A: in water, B: in 3 m urea solution.

tion is given by the following equation, as has been described previously:[15]

$$\Delta\bar{S}_m = -(1+\beta)RT\left(\frac{\partial \ln CMC}{\partial T}\right)_{P,\,\Delta\bar{G}_m} \quad (2)$$

On the basis of the data shown in Fig. 2, the partial molal entropy change on micellization was calculated at the mean temperature, 30 °C. Of course, the value of the CMC has no minimum or maximum in the range of temperature of 25—35 °C.[5,9,17] Values of β under high pressures are not available at present. Thus, the $\Delta\bar{S}_m/(1+\beta)$ value calculated from the CMC's at two temperatures is shown in Fig. 3 as a function of the pressure. As β probably changes with the pressure,[15] the form of the pressure dependence of $\Delta\bar{S}_m$ may be slightly transformed from that shown in Fig. 3. It may be noted from Fig. 3, however, that the $\Delta\bar{S}_m$ in water increases initially with an increase in the pressure and then decreases with the pressure via a maximum at about 1500 atm, while the $\Delta\bar{S}_m$ in the 3-m urea solution remains virtually unaltered at low pressures and then decreases gradually with the pressure.

The pressure dependence of $\Delta\bar{S}_m$ is related to the temperature dependence of $\Delta\bar{V}_m$ as follows:

$$\left(\frac{\partial\Delta\bar{S}_m}{\partial P}\right)_T = -\left(\frac{\partial\Delta\bar{V}_m}{\partial T}\right)_P \quad (3)$$

Regarding micellization in water, it is known that $(\partial\Delta\bar{S}_m/\partial P)_T>0$ in the region of lower pressures; *i.e.*, $(\partial\Delta\bar{V}_m/\partial T)_P<0$.[15,18] The effect of the temperature on the partial molal volume for singly dispersed and micellar states leads to $(\partial\bar{V}_s/\partial T)_P>(\partial\bar{V}_m/\partial T)_P>0$.[18] The positive larger value for $(\partial\bar{V}_s/\partial T)_P$ than for $(\partial\bar{V}_m/\partial T)_P$ is attributable to the thermal expansion as well as to the breakdown of the "iceberg" structure around the hydrocarbon chain as a results of thermal motion. Thus, we can regard $(\partial\bar{S}_s/\partial P)_T<(\partial\bar{S}_m/\partial P)_T<0$ as true at low pressures. That is, the entropy decrease with the compression for the singly dispersed state outweighs that for the micellar state. According to Le Chatelier's principle, the compression leads to a decrease in volume and is more favorable to a structure-making of water around hydrocarbon. Therefore, it may be concluded that the compression causes the promotion of the "iceberg" formation around the hydrocarbon chain. In the micelle formation in the 3-m urea solution, on the other hand, $(\partial\Delta\bar{S}_m/\partial P)_T\simeq 0$ at lower pressures, judging from Fig. 3. Consequently, $(\partial\bar{S}_s/\partial P)_T\simeq(\partial\bar{S}_m/\partial P)_T<0$ and/or $(\partial\bar{V}_s/\partial T)_P\simeq(\partial\bar{V}_m/\partial T)_P>0$, which means that the "iceberg" structure of water around the hydrocarbon chain is effectively broken down by the urea added.

The Polarographic Behavior and Determination of Orotic Acid (Vitamin B_{13}) in Milk

Toshio YAO and Sōichirō MUSHA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozuumemachi, Sakai 591

(Received April 30, 1974)

The polarographic behavior of orotic acid at the dropping mercury electrode was studied in the Britton-Robinson buffer solution; it was found to be a complex function of the pH. Three polarographic waves were observed over the pH range from 2 to 12. In the 1M $HClO_4$ electrolyte, orotic acid showed a very well-defined, diffusion-controlled, two-electron polarographic reduction wave which enabled us to determine orotic acid polarographically. A polarographic method for the determination of orotic acid in milk was proposed, and the effect of the presence of surface-active substances like proteins was investigated. The proposed method is very simple and rapid, and permits the accurate determination of 4—1000 μg/g of orotic acid in milk.

In recent years, the electrochemical reduction and oxidation of biologically-important compounds have been investigated with much interest. An examination of the oxidation-reduction behavior of compounds of biological significance is often of considerable value. Although actual biological redox systems may be of extreme complexity as a result of enzyme interactions, much information can be obtained from the study of these compounds in aqueous solutions with regard to factors affecting the electron-transfer processes, such as the pH.

Orotic acid (2,6-dihydroxypyrimidine-4-carboxylic acid), one of the uracil derivatives, is also known as vitamin B_{13}. Icha[1] has described orotic acid as polarographically-active. However, no detailed study of the electrode process and no application of polarography to the analysis of orotic acid in biological materials have been carried out. Recently, Archer[2] determined the orotic acid content in milk bread by the colorimetric method[3] as modified by Brieskorn and Wallrauch.[4] This method, however, is time-consuming and complicated.

The present work was carried out in order to study the polarographic behavior of orotic acid in detail and to investigate the applicability of polarography to the rapid analysis of orotic acid in cow's milk.

Experimental

Chemicals. The orotic acid (reagent of the Wako Pure Chemical Co.) was recrystallized three times from distilled water before drying at 60 °C *in vacuo*. A 5 mM stock solution was prepared by dissolving an appropriate amount of orotic acid in distilled water. The solutions used for the analysis were prepared by the dilution of the stock solution with aqueous buffer solutions and acid solutions to give the desired concentrations. The other chemicals were of a reagent grade and were used without further purification.

Apparatus. The polarograms were recorded using a Yanagimoto P-8 type Polarograph. Cyclic voltammetry was performed with a versatile solid-state instrument constructed in this laboratory following the design of Goolsby and Sawyer,[5] while the voltammograms were recorded using a Hewlett Packard Model 7045A X-Y recorder.

The dropping mercury electrode had the following characteristics: mercury flow rate, $m=2.25$ mg/s and drop time, $t=3.38$ s at open circuit and at a height of the mercury reservoir of 70 cm in 1 M $HClO_4$. A hanging mercury-drop electrode was used as a working electrode for the cyclic voltammetric experiments, while a mercury pool was employed for the controlled potential coulometric measurements. The reference electrode was SCE, and a platinum coil was used as an auxiliary electrode. All the experiments were carried out at 25.0±0.1 °C.

Results and Discussion

Polarographic Behavior of Orotic Acid. Effect of the pH: The effect of the pH on the polarographic curves was investigated by recording the polarograms of 0.5 mM orotic acid in the Britton-Robinson buffer solution. The half-wave potential and the reduction current of orotic acid with respect to the pH values are shown in Fig. 1.

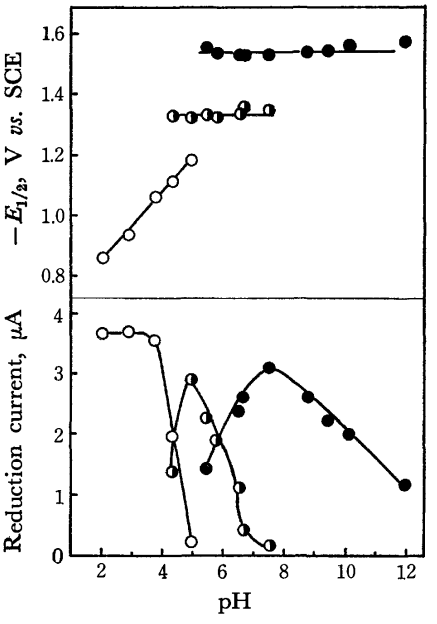

Fig. 1. The effect of pH on the reduction current and the half-wave potential of 0.5 mM orotic acid (Britton-Robinson buffer).
○: 1st wave, ◑: 2nd wave, ●: 3rd wave

Between pH 2 and 12, three polarographic reduction waves were observed. The first wave appeared in the pH range of 2—5. The half-wave potential shifted linearly towards a negative potential with an increase in the pH; this implies that hydrogen ions are consumed in the first reduction step. At pH values below 5, the half-wave potential of the first wave is given by the equation:

$$E_{1/2} = -0.635 - 0.108\ \mathrm{pH} \quad (1)$$

The height of the wave remained almost constant up to about pH 3.8. Above pH 3.8 it decreased sharply, and it vanished at about pH 5.1. The diffusion-current constant ($I=i_d/Cm^{2/3}t^{1/6}$) of the first wave at pH 3.1 was 3.92, corresponding to a two-electron Faradaic process.

The half-wave potentials of the second wave and the third wave were independent of the pH of the electrolyte. The second wave appeared in the pH range of 4—8, and the third wave, above pH 5. The reduction current of both waves was dependent on the pH. The sum of the heights of these three waves was almost constant up to about pH 7.5.

Calculation of αn_a *and* P: The values of αn_a and of P(the number of hydrogen ions involved per molecule of the reactant in the rate-controlling step) were calculated on the basis of Eqs. (2) and (3);[6,7] they are summarized in Table 1.

$$E_{1/4} - E_{3/4} = 0.0517/\alpha n_a \quad (2)$$

$$\mathrm{d}(E_{1/2})/\mathrm{d}(\mathrm{pH}) = -0.05915\,P/\alpha n_a \quad (3)$$

For the first wave, an average αn_a value of 1.32 and an average P value of 2.41 were determined. The average αn_a values of the second and third waves were 1.48 and 0.99 respectively.

Effects of the Drop-Time and the Temperature: The effect of the drop-time on the limiting current was investigated by recording the polarograms of 0.5 mM orotic acid at various heights of the mercury column. The $I/\sqrt{h}$ values, where h is the height of the column after correction for the back pressure, for all three polarographic waves were constant. The temperature coefficient of the limiting current of the three polarographic waves of orotic acid was 0.6—1.4% per degree in the temperature range from 15 to 45 °C. These results indicate that each of the three polarographic waves is diffusion-controlled.

Controlled Potential Coulometry. Coulometric reductions at the controlled potential of orotic acid in the Britton-Robinson buffer were performed in an attempt to determine the number of electrons involved in the overall electron transfer reactions. At pH 2.57 the potential of the mercury pool was first controlled at −1.15 V *vs.* SCE In this experiment, 5.23 coulombs were consumed in the reduction of 2.5×10^{-5} mol of orotic acid, which yielded n=2.17 for the first reduction wave. The experiments were repeated at pH 5.00 and 7.90 with new solutions containing the same amount of orotic acid and with the potentials of the working electrde controlled at −1.45 and −1.75 V respectively. The n values of the second and third reduction waves were 1.83 and 1.86 respectively. These experiments imply that two electrons are involved in each of the three polarographic steps.

Cyclic Voltammetry. Cyclic voltammetric experiments were performed at a hanging mercury drop electrode. The mercury drop was renewed each time. If the potential sweep was repeated at the same mercury drop, the peak height decreased and the peak potential shifted towards a more negative value, indicating the adsorption of a reduction product at the electrode. Orotic acid gave a cathodic peak corresponding to each of the three polarographic waves observed at various pH values, the heights of which were proportional to the square root of the scan rate in the range from 1.0 to 15 V/min. However, no anodic peak resulting from the reoxidation of the reduction product was observed at any scan rate or any switching potential.

Analytical Application. Effect of Buffer and Acid Components: Polarographic experiments revealed that a well-defined wave appeared at low pH values; the height of this wave was almost constant up to about pH 3.8. Therefore, the polarographic behavior of the first wave at low pH values was investigated by using other buffers (acetate and chloride buffer) and acids (HCl, H_2SO_4, and $HClO_4$) as electrolytes. In these electrolytes, the half-wave potential of orotic acid shifted towards a positive potential with a decrease in the pH. The $E_{1/4}$–$E_{3/4}$ value decreased with a decrease in the pH of the electrolytes. The buffer and acid components, however, had no influence on the wave-height.

When HCl and H_2SO_4 were used as supporting electrolytes, a large maximum appeared in any acid concentration. However, in the case of a $HClO_4$ background, no maximum appeared and the polarographic

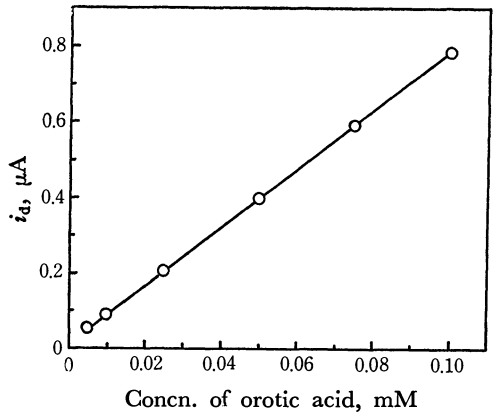

Fig. 2. Calibration curve for orotic acid in 1 M $HClO_4$.

wave was well-defined. The effect of the drop-time was investigated by recording polarograms of 0.1 mM orotic acid in 1 M $HClO_4$ at various heights of the mercury column. The limiting current of orotic acid was approximately proportional to $h^{1/2}$, indicating that the reduction current is controlled by diffusion. The diffusion current of orotic acid in 1M $HClO_4$ was proportional to the concentration in the $5\times10^{-6}-10^{-4}$ M range as is shown in Fig. 2.

Consequently, 1M $HClO_4$ was used as the supporting electrolyte in the following experiments for the determination of orotic acid.

Effect of Protein Addition: A polarographic wave of orotic acid was observed even in the presence of 50% milk. However, the proteins present in milk are surface-active, and so the polarographic wave of orotic acid was partly distorted by the adsorbed layer of proteins on the electrode. The limiting current was depressed, and the half-wave potential shifted towards a more negative potential.

The effect of proteins on polarograms of 0.1 mM orotic acid in 1M $HClO_4$ was investigated by adding proteins refined by centrifuging milk several times. The results are shown in Table 2. On the addition of more than 0.3% of proteins, the half-wave potential became more negative and the $E_{1/4}$—$E_{3/4}$ value increased. However, the wave height of orotic acid was not affected by the presence of less than 0.5% of proteins. These results indicate that the presence of a large amount of proteins produces a drawn-out wave at a more negative potential with an increase in the protein concentration, and that the removal of most proteins is necessary for the determination of orotic acid in milk.

Table 2. Effect of protein on the polarograms of 0.1 mM orotic acid in 1 M $HClO_4$

1.5	0.780	135	0.674

Determination of Orotic Acid in Milk: The method for the determination of orotic acid in milk is as follows: Weigh accurately a quantity of a sample expected to contain from 0.1 to 0.6 mg of orotic acid into a 100-ml beaker. Add 10—20 ml of 1M $HClO_4$, mix, and place the mixture in a water-bath at 65 °C for 30 min. Then remove the beaker from the water-bath, cool to room temperature, and filter the coagulated proteins through fluted filter-paper. Wash the precipitate with 20 ml of 1M $HClO_4$, transfer the solution into a 50-ml calibrated flask, and dilute to the mark with 1M $HClO_4$. Transfer this solution into a polarographic cell. Remove the dissolved air with nitrogen and record a polarogram.

Various types of artificial milk containing known amounts of orotic acid and known amounts of refined proteins were prepared, and the proteins present in these milk were removed by the proposed procedure. The recovery experiments were carried out by analyz-

a) Determined by using the calibration graph.
b) Determined by the standard addition method.

ing orotic acid in these filtrates. The $E_{1/4}$—$E_{3/4}$ values of the polarograms recorded were about 30 mV, indicating that most proteins were removed by this procedure(see Table 2). The results, shown in Table 3, indicate that a tolerable agreement between the amounts of orotic acid added and the amounts recovered is obtained by this procedure.

The precision of this analytical method for orotic acid was determined by analyzing three samples(A, B, and C) of cow's milk four times each. The determination was carried out by both the calibration graph method and the standard addition method. The results, shown in Table 4, were compared with those obtained by the colorimetric method.[2)]

Compared with the colorimetric method, which involves very time-consuming and complicated procedures, the proposed polarographic method is very simple and rapid and permits the accurate determination of 4—1000 μg/g of orotic acid in milk.

Thermal Dehydration and Decomposition Reactions of Bivalent Metal Oxalates in the Solid State

Kenzo NAGASE, Katsuya SATO,* and Nobuyuki TANAKA*

College of General Education, Tohoku University, Kawauchi, Sendai 980

**Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980*

(Received May 13, 1974)

The thermal dehydration and decomposition of the oxalates of Mg(II), Ca(II), Sr(II), Ba(II), Mn(II), Fe(II), Co(II), Ni(II), Cu(II) and Zn(II) were investigated by means of TG, DTA, DSC, EGA, X-ray powder diffraction analysis, and reflectance and infrared spectroscopies. In general, the temperature at which the oxalates were dehydrated increased with $1/r$, where r denotes the radius of metal ion. The heats of dehydration (ΔH_{H_2O}) of the alkaline earth metal oxalates increased with $1/r$, but those of transition metal oxalates decreased as $1/r$ increased. By considering the decomposition products, the reactions of anhydrous oxalates were classified into three groups and the relations between the decomposition temperatures and $1/r$ were discussed for each group.

The thermal decomposition reactions of metal oxalates have been extensively investigated. The thermographic curves of a number of metal oxalates have been described by Ugai[1] and many other researchers. Dollimore and his co-workers[2-4] measured changes in length or volume of samples subjected to heat treatment, or surface-area changes occurring on dehydration, and discussed the effect of dehydration on the subsequent decompositions. Lagier and his co-workers[5-7] found that, for the oxalates of Mg, Mn, Fe, Co and Zn, at least two phases of the compounds exist and that the phases observed depended on the method of preparation. They studied the dependence of dehydration of $CoC_2O_4 \cdot 2H_2O$ on the differences of the two phases. Kinetic studies on the dehydration and decomposition of a number of oxalates were carried out by isothermal and temperature elevation methods. In many cases, however, the parameters reported by each researcher for a given oxalate were different.

In the present paper, the thermal dehydration and decomposition reactions of bivalent metal oxalates were systematically discussed on the basis of the relations between the nature of the metal ions and the initial weight-loss temperatures or enthalpy changes.

Experimental

Materials. The oxalates of alkaline earth metals and transition metals investigated were precipitated with alkali oxalates (or oxalic acid) from solutions of soluble salts of the corresponding metals, washed thoroughly with water and dried in air. The elemental analyses for C and H agreed with the calculated values within $\pm 0.3\%$.

Measurements. Thermogravimetric (TG) and differential thermal analytic (DTA) curves were obtained with a Shinku Riko TGD-3000 at a heating rate of 5 °C/min in an atmosphere of nitrogen flowing at 50 ml/min. About twenty milligrams of powdered sample in a platinum crucible were used for each measurement. Differential scanning calorimetric (DSC) curves were recorded with a Rigaku Denki 8002 CS at a heating rate of 5 °C/min in an atmosphere of nitrogen flowing at 30 ml/min. About twenty milligrams of powdered sample were placed in a crucible made from 0.1 mm thick aluminum sheet. A lid of the same material was placed inside the crucible. The reference material was α-Al_2O_3. The instrument was calibrated against the heat of the transition of KNO_3 which appears at 128 °C with ΔH equal to 12.28 kcal/mol.

High temperature X-ray diffractions were measured in an atmosphere of nitrogen flowing at 30 ml/min with a Toshiba ADG-101 diffractometer equipped with a standard high temperature sample holder. Cu$K\alpha$ radiation and a nickel filter were used in all measurements. Infrared absorption spectra were measured from 2500 to 400 cm^{-1} in KBr disks with a Hitachi EPI-3G spectrophotometer. The sample was heated under conditions identical to those for the TG measurements. When the temperature of the sample reached the desired value, heating was stopped, the sample was cooled to room temperature and its infrared absorption spectrum was recorded. Diffuse reflectance spectra were measured with a Hitachi EPS-3T spectrophotometer equipped with a standard integrating sphere attachment. MgO was used as the reference material. The heated sample was treated in the same way as for the measurement of the infrared spectra.

Evolved gas (EG) curves were obtained using a conductometric technique. The evolved gas analyses (EGA) were carried out using an activated charcoal column (2 meters long) and a helium carrier gas (50 ml/min). In both cases the procedures described in a previous paper[8] were employed.

Results

TG and DTA curves in the temperature range from room temperature to 1000 °C in a flowing nitrogen atmosphere are given in Figs. 1 and 2. The thermal data obtained are summarized in Table 1 together with the radii of the metal ions (Goldschmidt's crystallographic radii). The TG curve of $CaC_2O_4 \cdot H_2O$ shows that the decomposition took place at three stages, as indicated in previous paper.[1] On the DTA curve, a small exothermic peak, which has not been previously reported, was observed at 290 °C without any weight-loss. $SrC_2O_4 \cdot 2H_2O$ decomposed to $SrCO_3$ after dehydration; $SrCO_3$ did not decompose further, but the γ-$SrCO_3$ to β-$SrCO_3$ phase transition was observed at 875 °C. The DTA curve for $SrC_2O_4 \cdot 2H_2O$ also had an exothermic peak at 259 °C which was more prominent than that of $CaC_2O_4 \cdot H_2O$. This change without weight-loss was not reversible (*i.e.* not reflected on the cooling curve), indicating that the lower-temperature form is metastable with respect to the higher-temperature one. The X-ray powder diffraction patterns showed that this change corresponds to recrystallization of poorly crystalline SrC_2O_4 formed

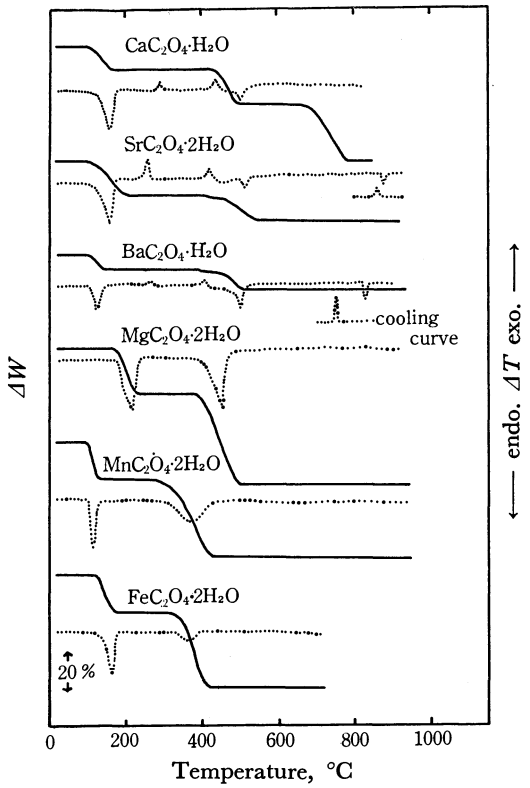

Fig. 1. TG (solid line) and DTA (dotted line) curves of metal oxalates in a flowing nitrogen atmosphere.

on dehydration. The heat of this process was found to be 3.2 kcal/mol by DSC. The TG and DTA curves of $BaC_2O_4 \cdot H_2O$ were very similar to those of $SrC_2O_4 \cdot 2H_2O$.

The oxalates containing metal ions with radii smaller than that of calcium ion decomposed to metal oxides or metals. The oxalates of Mg, Mn, Fe and Zn decomposed at lower temperatures as the radius of the metal ion increased and formed the metal oxides and an equimolar mixture of CO and CO_2, whereas the oxalates of Co, Ni and Cu decomposed at higher temperatures as the metal ion radius increased, and gave the metals and CO_2.

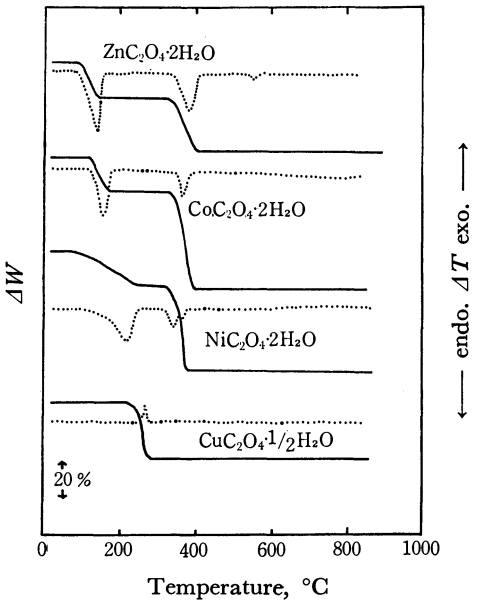

Fig. 2. TG (solid line) and DTA (dotted line) curves of metal oxalates in a flowing nitrogen atmosphere.

The reactions of the oxalates investigated may be expressed as,

$$MC_2O_4 \rightarrow MCO_3 + CO,$$
where M = Ca(II), Sr(II) and Ba(II) (1)

$$MC_2O_4 \rightarrow MO + CO + CO_2,$$
where M = Mg(II), Mn(II), Fe(II) and Zn(II) (2)

$$MC_2O_4 \rightarrow M + 2CO_2,$$
where M = Co(II), Ni(II) and Cu(II) (3)

These stoichiometries were confirmed by analyses of gaseous products, *cf.* Table 2.

The heats of dehydration (ΔH_{H_2O}) and of decomposition (ΔH_d) were measured by DSC. The results are given in Table 3. The values of ΔH_{H_2O} of alkaline earth metal oxalates increased almost parallel to the increase of the initial weight-loss temperatures(t_{H_2O}), while ΔH_{H_2O} of transition metal oxalates decreased with increasing t_{H_2O}. For decomposition of the an-

hydrous oxalates, the values of ΔH_d of the oxalates which gave metal oxides or metals as decomposition products had no particular relation to the initial weight-loss temperatures (t_d). The values of ΔH_d of oxalates which gave the corresponding metal carbonates could not be measured accurately.

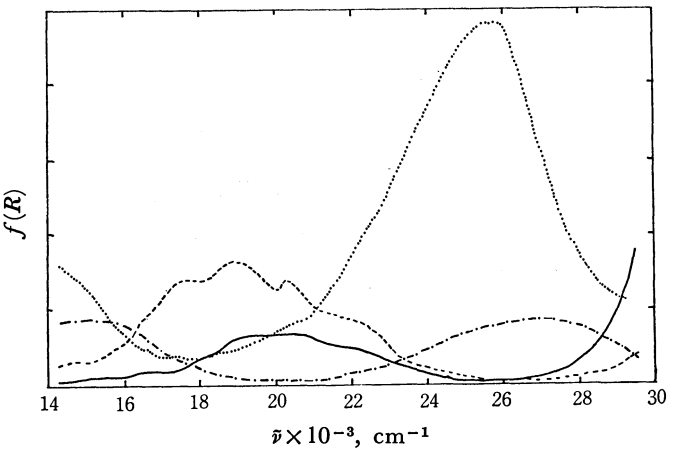

Fig. 4. Reflectance spectra of $CoC_2O_4\cdot 2H_2O$, $NiC_2O_4\cdot 2H_2O$ and their anhydrous compounds.
——: $CoC_2O_4\cdot 2H_2O$, ----: CoC_2O_4, -·-: NiC_2O_4, ····: NiC_2O_4.

The infrared absorption spectra were measured before and after the dehydration. In the region from 2500 to 650 cm^{-1}, the spectra of the anhydrous oxalates were almost the same as those of the hydrated oxalates, whereas in the region of 650 to 400 cm^{-1}, considerable differences were observed between MC_2O_4 and $MC_2O_4\cdot 2H_2O$ as shown in Fig. 3. The peaks near 500 cm^{-1} which were attributed mainly to ν(M–O (ox)) were shifted to higher frequencies by the removal of water molecules, where O(ox) represents an oxygen atom of oxalate ion. On dehydration, the color of $CoC_2O_4\cdot 2H_2O$ changed from pink to purple and that of $NiC_2O_4\cdot 2H_2O$ from bluish green to yellowish green. The reflectance spectra in the visible region of both the oxalates which were measured before and after the dehydration are given in Fig. 4. The d–d transition bands shifted slightly to lower frequencies and the value of $f(R)$ increased on dehydration, where R denotes the reflectance and $f(R)$ the Kubelka-Munk function, $f(R)=(1-R)^2/(2R)$.

Discussion

From X-ray analysis, structure of $MC_2O_4\cdot 2H_2O$ has been reported to be as shown in Fig. 5, where the oxalate ions act as a quadridentate ligand and the water molecules coordinate directly to the metal ions.[5] Therefore, t_{H_2O} and ΔH_{H_2O} are considered to reflect the nature of the metal ions.

The values of t_{H_2O} in Table 1 give information about the dissociation energy of M–OH_2. On the other hand, it is supposed that, since the water molecules are bonded to the metal ions by electrostatic forces, the

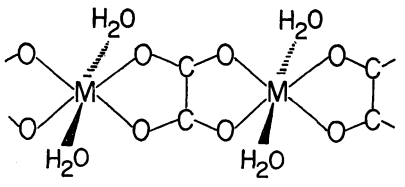

Fig. 5. Bonding structure of $MC_2O_4\cdot 2H_2O$.[5]

bond energy is a function of the size of metal ion. Therefore, the observation that t_{H_2O} increases with $1/r$, as seen in Table 1, seems to be reasonable. The bond energy of M–OH_2 may be estimated from the value of ν(M–O(ox)), since it seems that the more strongly the water molecules are bonded to the metal ion, the weaker the M–O(ox) bond is. On this basis, the experimental results, which are given in Fig. 3, suggest that the bond energies of M–OH_2 increase in the order: Mn<Zn<Fe<Co<Ni. Therefore, the results obtained from the thermal studies are consistent with those from infrared absorption spectra.

The heat of dehydration (ΔH_{H_2O}) gives the difference in potential energy between the hydrated and anhydrous oxalates. In the transition metal group the values of ΔH_{H_2O} decreased almost parallel with the increase in $1/r$. This indicates that the increase of the potential energy on the dissociation of M–OH_2 is somewhat cancelled by an increase in the bond energy of M–O(ox). In fact, the increase of the bond energies of M–O(ox) on removing the coordinated water molecules increased in the order: Mn<Zn<Fe<Co<Ni (*cf.* Fig. 3). The frequency shifts for ν(M–O(ox)) were as follows: Mn, 23; Zn, 45; Fe, 48; Co, 55; Ni, 63 cm^{-1}. In the case of the alkaline earth metal oxalates, the oxalates of Mg(II) and Sr(II) each contain two water molecules, while those of Ca(II) and Ba(II) each contain one water molecule. Therefore, a systematic interpretation similar to that made the transition metal oxalates may not be possible.

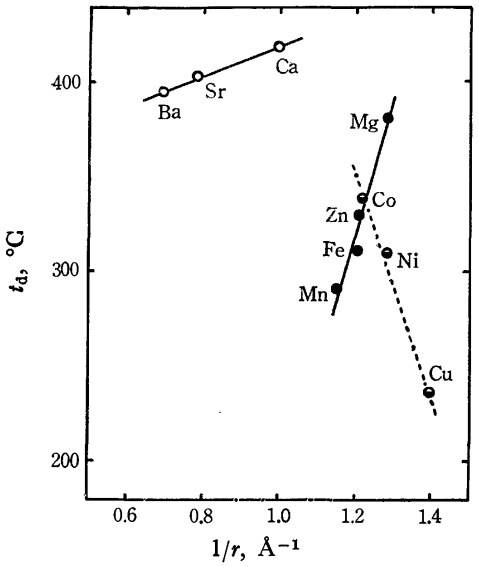

Fig. 6. Relation of initial weight-loss temperatures of the decomposition (t_d) with $1/r$.
○: $MC_2O_4 \rightarrow MCO_3+CO$, ●: $MC_2O_4 \rightarrow MO+CO+CO_2$, ◒: $MC_2O_4 \rightarrow M+2CO_2$.

The relation of the initial weight-loss temperature of for the decomposition (t_d) to $1/r$ depends on the decomposition mechanism as seen in Fig. 6. The M–O (ox) bond energies in the anhydrous oxalates are considered to be the larger, the smaller the complexed metal ions are. Therefore, decomposition of the oxalates to the metal oxides may be initiated by M–O (ox) bond breaking, since these oxalates decomposed at higher temperatures as $1/r$ increased. On the other hand, the oxalates of Co, Ni and Cu, which decompose at lower temperatures as $1/r$ increases, may decompose by electron transfer from the oxalate ion to the metal ions. This is supported by the fact that the electron affinities of metal ions, in general, increase with increasing effective ionic charge.

The authors are grateful to Prof. Yoshito Amako for his comments during the course of this study, and to Mr. Mitsuo Sato for the measurements of the infrared absorption spectra. They also wish to thank the Ministry of Education for financial support for this research.

(Received June 14, 1974)

The geometrical isomers, *cis*-dichloro-*trans*-(methanol)(hydroquinone)(2,2′-bipyridine)ruthenium(II) and *cis*-dichloro-*cis*-(methanol)(hydroquinone)(2,2′-bipyridine)ruthenium(II), [$RuCl_2$(MeOH)(QH_2)bipy] (complex I and II), were synthesized by reduction and substitution reactions of [RuO_4bipy] and [$RuO_2(OH)_2$bipy] with hydroquinone in hydrochloric acid solution, and methanol. *cis*-Chloro(hydroquinonato)bis(2,2′-bipyridine)-ruthenium(II), *cis*-[RuCl(QH)$(bipy)_2$], was obtained from the substitution reaction of complex I or II with 2,2′-bipyridine in methanol, and *cis*-chloro(hydroquinone)bis(2,2′-bipyridine)ruthenium(II) chloride, *cis*-[RuCl(QH_2)-$(bipy)_2$]Cl, was also obtained from the substitution of *cis-trans*-[$RuCl_2$(MeOH)(QH_2)bipy] in methanol containing hydrochloric acid. *cis*-Dihydroxobis(2,2′-bipyridine)ruthenium(II), *cis*-[$Ru(OH)_2(bipy)_2$], was obtained by heating an aqueous solution of *cis*-[RuCl(QH)$(bipy)_2$]. Trihydroxoaquo(1,10-phenanthroline)ruthenium(III), [$Ru(OH)_3(H_2O)$phen] was also synthesized from [RuO_3phen]$_2O$ and [$Ru(OH)_3$phen]$_2O$ by reduction reactions similar to those used for [$RuCl_2$(MeOH)(QH_2)bipy]. These complexes were characterized by the infrared, visible and ultraviolet absorption spectra, and also by polarographic and magnetic measurements. The structures are discussed.

The isolation and identification of metal complexes of hydroquinone has not yet been carried out. Wells and Kuritsyn[1] investigated the kinetics of the reduction of aquomanganase(III) ions with hydroquinone in aqueous perchlorate media using the stopped-flow technique. They suggested the presence of an intermediate Mn^{III}–hydroquinone complex, $Mn\cdot QH_2^{3+}{}_{aq}$, on the basis of the oscilloscope trace, and the higher value of the extinction coefficient of the intermediate complex than the extinction coefficients of Mn^{3+} and $MnOH^{2+}{}_{aq}$ at 470 nm.

In previous work,[2–5] [RuO_4bipy] and [RuO_3phen]$_2O$ were obtained by the reactions of ruthenium tetraoxide with 2,2′-bipyridine and 1,10-phenanthroline in carbon tetrachloride, and [$RuO_2(bipy)_2$], [RuO_2(bipy)-(phen)], [$RuO_2(phen)_2$], [$Ru(OH)_2(py)_2$bipy] and [$Ru(OH)_2(py)_2$phen] were obtained by the reduction and substitution reactions of [RuO_4bipy], [RuO_3-phen]$_2O$ and [$RuO_4(py)_2$] with 2,2′-bipyridine and 1,10-phenanthroline in methanol. In the present paper, six new complexes, *cis*-dichloro-*trans*-(methanol)-(hydroquinone)(2,2′-bipyridine)ruthenium(II), *cis*-dichloro-*cis*-(methanol)(hydroquinone)(2,2′-bipyridine)-ruthenium(II), [$RuCl_2$(MeOH)(QH_2)bipy] (complex I and II), [RuCl(QH)$(bipy)_2$], [$Ru(OH)_2(bipy)_2$], [RuCl(QH_2)$(bipy)_2$]Cl and [$Ru(OH)_3(H_2O)$phen], are reported, and their structures are discussed.

Experimental

Materials. Ruthenium(III) chloride monohydrate (extra pure grade) supplied by Mitsuwa Chemicals was used without further purification. Oxalic acid (extra pure grade), hydroquinone, 2,2′-bipyridine and 1,10-phenanthroline were supplied by Wako Pure Chemicals. The first three were purified by recrystallization from water, and phenanthroline by recrystallization from ethanol after drying at 110 °C for 3 hr. Commercial methanol was dried by treatment with magnesium ribbon and iodine and distilled. Lithium perchlorate (Mitsuwa chemicals extra pure grade) was purified by recrystallization from methanol after heating at 110 °C for 3 hr. Wako Pure Chemicals dimethyl sulfoxide was used without further treatment. Monodeuteriomethanol made by E. Merck, Germany, was used for deuteration without further purification.

Syntheses. Tetraoxo(2,2′-bipyridine)ruthenium(VIII), [RuO_4bipy]$\cdot 3H_2O$, dioxodihydroxo(2,2′-bipyridine)ruthenium(VI), [$RuO_2(OH)_2$bipy]$\cdot 3H_2O$, μ-oxobis[trioxo(1,10-phenanthroline)ruthenium(VII)], [RuO_3phen]$_2O$ and μ-oxobis[trihydroxo(1,10-phenanthroline)ruthenium(IV)], [Ru-$(OH)_3$phen]$_2O$: These complexes were synthesized as before,[2–4] and gave satisfactory elemental analyses.
