Division of Chemistry, Japan Atomic Energy Research Institute, Tokai-Mura, Ibaraki 319-11

(Received October 25, 1974)

The HT and DT yields from the nuclear transformation of $^6Li(n,\alpha)T$ in H_2O-D_2O binary mixtures were studied in the liquid phase. The $(HT/H_2O)/(DT/D_2O)$ ratio was nearly constant at 1.60 ± 0.08 over the whole range of mol fractions of D_2O in the presence of I_2 as a scavenger. Using the kinetic model with reasonable assumptions, the relative efficiencies for the kinetic moderation of H_2O, HDO, and D_2O were determined. The results indicate that the collision of recoil T atoms with HDO, with a large fractional energy loss, must occur as frequently as with H_2O.

As is the case with organic compounds,[1-3] the two most important energetic reactions of recoil T atoms with H_2O or D_2O are the hydrogen abstraction and the hydrogen substitution;

$$T + H_2O(D_2O) \longrightarrow HT + OH(DT+OD) \quad (1)$$

$$T + H_2O(D_2O) \longrightarrow HTO + H(DTO+D) \quad (2)$$

The yields of Reactions 1 and 2 are 11 and 68% with H_2O and 10.6 and 68% with D_2O respectively.[4,5] The apparent absence of the isotope effect must result from the fact that the preference of the abstraction of H over D atoms is counterbalanced by the "moderator" isotope effects[6] of H_2O and D_2O on recoil T atoms.

In a previous paper,[5] the "moderator" isotope effect was estimated to be 1.5 by comparing the acetone-*t* yield at zero mol fraction (m.f.) of acetone in the H_2O-acetone and D_2O-acetone binary systems. This, in turn, gives the "reactivity integral"[6] isotope effect of 1.5.

The present paper will deal with the recoil T reactions in the H_2O-D_2O mixture. This system has the advantage that the relative reactivity of recoil T atoms is directly proportional to the observed HT/DT at any given m.f. of D_2O; thus, no correction for the "moderator" isotope effect is required.

Experimental

The experimental procedure has been described in detail in the previous paper.[5] Five-ml portions of various mixtures of H_2O and D_2O containing 0.025 g of $LiNO_3$ were sealed in a 13-ml quartz ampoule with a breakable tip. The neutron irradiation was carried out in the JRR-4 in a flux of 3×10^{13} $n\cdot cm^{-2}\cdot s^{-1}$ for 1 min. The dose rate of γ-rays at the irradiation port was estimated to be 1×10^8 $r\cdot h^{-1}$. During the irradiation, samples were cooled by letting cooling water flow through and were maintained at 20—30 °C.

After the irradiation, the gaseous products collected by means of a Toepler pump were divided into two parts. One of them was injected into an alumina column, 6 m long, for the determination of the product yield. The other was subjected to the isotopic separation. A 5-m ferric oxide-γ-alumina column was used. The γ-alumina was 40—60 mesh, chemically coated with Fe_2O_3. The column was operated at the temperature of liquid N_2. The activity measurement was performed using a gas-flow proportional counter.

The activity of the condensates was measured by means of a liquid scintillation counter. One hundred μl of a solution was dissolved in 10 ml of the liquid scintillator, prepared by dissolving 112 g of naphthalene, 275 mg of POPOP, and 6 g of DPO in 1 l of dioxane.

The conversion factor required to correlate the activities measured by the two different methods was obtained in the following experiments. An aliquot of the tritiated water of a known specific activity was passed through a carbon-wool column heated at 1100 °C. The resulting hydrogen was directly introduced into the radio-gas chromatograph. Another aliquot of the water was radio-assayed by means of the liquid scintillation counter. The counting efficiency of the radio-gas chromatograph was 1/3.8 of that of the liquid scintillation counter. The activities of the gaseous products can, then, be compared with those of the liquid phase.

Results and Discussion

Relative Reactivities of O–H and O–D Bonds. In Fig. 1 the HT and DT yields in 0.07 M $LiNO_3$ solution containing 1.2×10^{-3} M I_2 are plotted as a function of the m.f. of D_2O. It seems that H_2O is more efficient than D_2O as a moderator for recoil T atoms, since the HT yield curve is slightly convex upward, while the DT yield curve is concave. However, at a given composition of H_2O and D_2O, a comparison of the relative reactivities of O–H and O–D bonds does not require any correction for the "moderator" isotope

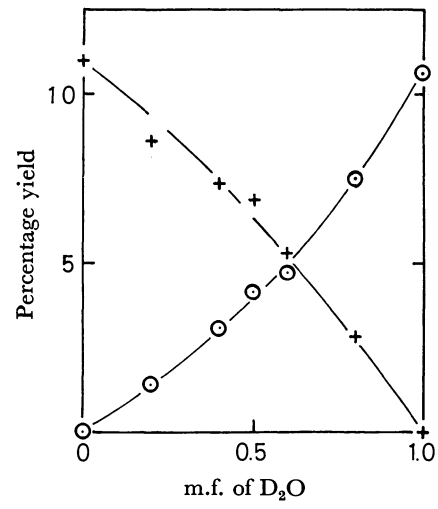

Fig. 1. Yields of HT and DT formed by reactions of recoil T atoms in H_2O-D_2O binary mixtures.

0.4	12.3	7.75	1.59	0.90	1.40
0.2	10.8	7.00	1.54	1.13	1.62
0.0	11.0	—	—	—	—
			av. 1.60 ± 0.08	α_{H_2O}: α_{HDO}: α_{D_2O} $=1.56\pm0.16:1.45\pm0.12:1$	

effect, since both bonds are exposed to the same tritium flux. Thus, the $(HT/H_2O)/(DT/D_2O)$ ratio is directly proportional to the reactivity of these bonds. The values summarized in Table 1 are almost constant at 1.60 ± 0.08 over the whole range of the m.f. of D_2O. This suggests that the hot reactions with the two bonds have very similar energy dependences and can be used for estimates of the magnitude of the "reactivity integral" isotope effect, I_{HT}/I_{DT}.

In the present case, the $(HT/H_2O)/(DT/D_2O)$ ratio is related to I_{HT}/I_{DT} by the following equation;[7]

$$\frac{(HT/H_2O)}{(DT/D_2O)} = \frac{S_{OH}}{S_{OD}} \cdot \frac{I_{HT}}{I_{DT}} \tag{3}$$

where S_{OH} and S_{OD} are the collision cross sections for the T atoms with O–H and O–D bonds, averaged over the proper range of energies.

With the value of 1.60 ± 0.08 for the $(HT/H_2O)/(DT/D_2O)$ ratio, Eq. 3 can be simplified as;

$$\frac{I_{HT}}{I_{DT}} = 1.60 \times \frac{S_{OD}}{S_{OH}} \tag{4}$$

Therefore, if the collision cross sections of these bonds are equal, the "reactivity integral" isotope effect is determined to be 1.60 ± 0.08.

However, in the mixtures of H_2O and D_2O isotopic mixing occurs;

$$H_2O + D_2O \rightleftharpoons 2HDO \tag{5}$$

Its equilibrium constant has been reported to be 3.78 ± 0.03 by Pyper *et al.*[8] and 3.94 ± 0.03 by Gold *et al.*[9] Thus, the actual reaction systems are composed of H_2O, HDO, and D_2O, and the value of 1.60 must be the overall "reactivity integral" isotope effect between the O–H and O–D bonds in these chemical forms. In the abstraction of hydrogen from D_2O, both the primary and the secondary isotope effects exist, while from HDO either the primary or the secondary isotope effect exists, depending upon which hydrogen atom is abstracted. If the secondary isotope effect on the abstraction of hydrogen is as important as in the substitution of hydrogen[1,2] the yield must be larger from H_2O than from HDO on a per-bond basis. The HT/DT ratios from various reaction systems, including the CH_4–CD_4, CH_2D_2, and CH_3F–CD_3F systems, always stay within the range of 1.28—1.35.[2] These results are consistent only with the view that the primary isotope effect makes a major contribution to the isotope effect observed. Thus, although no unequivocal data are available, it may be considered that, in the present reaction system, the secondary isotope effect is less important than the primary isotope effect.

Relative Moderating Abilities of H_2O, HDO, and D_2O. The Estrup-Wolfgang kinetic theory[2] incorporates no mechanistic assumptions and has successfully been applied to various reaction systems. However, it has very seldom been applied to the condensed phases,[12] since therein the reactions of recoil atoms are often influenced by the various effects characteristic of the liquid phase, such as the cage effect and the local heating of the matrix.

Data on the reactions of recoil T atoms in condensed phases are, in virtually all cases, completely consistent with the model based on reactions in the gaseous phases. It has been reported that the reactions with various hydrocarbons gave similar yields in the gas and liquid phases.[2] The only differences found could be attributed to the more rapid collisional deactivation of excited products in the liquid phases. This clearly indicates that the effects which usually play a significant role in the liquid phase make only a minor contribution to the reactions of recoil T atoms in the liquid phases. Thus, the application of the kinetic theory to the present reaction systems is reasonable.

According to the kinetic theory, the probability that a hot atom will react with the component, j, to form the product, i, is expressed by this equation;[13]

$$P_i = \left(\frac{N_i}{N_s}\right) = \left(\frac{f_j}{\alpha}\right) I_i - \left(\frac{f_j}{\alpha}\right)^2 K_i + \cdots \tag{6}$$

where I_i and K_i are the "reactivity integral"[14] and the "energy shadowing" terms respectively. The f_j is the collision probability of a hot atom with the component, j. In the present reaction mixtures,

$$\begin{aligned} f_{H_2O} &= (X_{H_2O} \cdot S_{H_2O})/(\textstyle\sum X_j S_j) \\ f_{HDO} &= (X_{HDO} \cdot S_{HDO})/(\textstyle\sum X_j S_j), \text{ and} \\ f_{D_2O} &= (X_{D_2O} \cdot S_{D_2O})/(\textstyle\sum X_j S_j) \end{aligned} \tag{7}$$

where $\sum X_j S_j = X_{H_2O} \cdot S_{H_2O} + X_{HDO} \cdot S_{HDO} + X_{D_2O} \cdot S_{D_2O}$ and where X_j is the m.f. of the component, j. The α is the weighted sum of the average energy loss upon collision with H_2O, HDO, and D_2O:

$$\alpha = \alpha_{H_2O} \cdot f_{H_2O} + \alpha_{HDO} \cdot f_{HDO} + \alpha_{D_2O} \cdot f_{D_2O} \tag{8}$$

The sum of the HT and DT yields is not large and is almost constant at 11% over the whole range of the

m.f. of D_2O. Thus, if the energy range of the recoil T atoms needed to produce HT or DT lies entirely above the range to produce HTO or DTO, one can reasonably ignore the "energy shadowing" term. On the other hand, as it is probable that the former lies below the latter, or that both energy ranges overlap each other, one must take into account the "energy shadowing" effects caused by the substitution reactions.

However, as for the reactions among the isotopic water molecules, it is considered unlikely that the shapes and the energy ranges of the excitation curves for the abstraction and substitution of hydrogen vary significantly with the reactant molecules. This consideration leads to the view that a fraction of recoil T atoms, eliminated by the substitution reaction prior to the abstraction reaction, is close to the constant, K, among the samples. This is consistent with the fact that the total water-t yield is almost constant over the whole range of the m.f. of D_2O. Thus, the $(1-K)\cdot N_s$ atoms of tritium are available for abstraction reaction. Consequently, as a reasonable approximation, one can derive the following equations on the assumption that $S_{H_2O}=S_{HDO}=S_{D_2O}$:

i) for the case of a single reactant of H_2O or D_2O;

$$\frac{N_{HT}}{(1-K)\cdot N_s}=\frac{f_{H_2O}}{\alpha_{H_2O}}I_{H_2O},\quad \frac{I_{H_2O}\cdot(1-K)}{\alpha_{H_2O}}=0.11 \tag{9}$$

$$\frac{N_{DT}}{(1-K)\cdot N_s}=\frac{f_{D_2O}}{\alpha_{D_2O}}I_{D_2O},\quad \frac{I_{D_2O}\cdot(1-K)}{\alpha_{D_2O}}=0.106 \tag{10}$$

ii) for the case of a binary mixture;

a. the HT yield from the reactions with H_2O;

$$\left(\frac{N_{HT}}{N_s}\right)_{H_2O}=(1-K)\cdot\frac{f_{H_2O}}{\alpha}\cdot I_{H_2O}$$

$$=\frac{(1-K)\cdot(X_{H_2O}/\alpha_{H_2O})\cdot I_{H_2O}}{X_{H_2O}+(\alpha_{HDO}/\alpha_{H_2O})\cdot X_{HDO}+(\alpha_{D_2O}/\alpha_{H_2O})\cdot X_{D_2O}} \tag{11}$$

b. the HT yield from the reactions with HDO;

$$\left(\frac{N_{HT}}{N_s}\right)_{HDO}=\frac{(1-K)\cdot(X_{HDO}/\alpha_{H_2O})\cdot I_{HDO}}{X_{H_2O}+(\alpha_{HDO}/\alpha_{H_2O})\cdot X_{HDO}+(\alpha_{D_2O}/\alpha_{H_2O})\cdot X_{D_2O}} \tag{12}$$

By equating I_{HDO} with $(I_{H_2O})/2$ and by substituting Eq. 9 into Eqs. 11 and 12, we obtain the following equation for the total HT yield from the H_2O–D_2O binary mixtures:

$$\left(\frac{N_{HT}}{N_s}\right)=\frac{0.11\cdot X_{H_2O}+0.055\cdot X_{HDO}}{X_{H_2O}+(\alpha_{HDO}/\alpha_{H_2O})\cdot X_{HDO}+(\alpha_{D_2O}/\alpha_{H_2O})\cdot X_{D_2O}} \tag{13}$$

The corresponding equation for the total DT yield from the mixture is;

$$\left(\frac{N_{DT}}{N_s}\right)=\frac{0.106\cdot X_{D_2O}+0.053\cdot X_{HDO}}{X_{D_2O}+(\alpha_{HDO}/\alpha_{D_2O})\cdot X_{HDO}+(\alpha_{H_2O}/\alpha_{D_2O})\cdot X_{H_2O}} \tag{14}$$

Thus, if we know the $(\alpha_{H_2O}/\alpha_{D_2O})$ value, the relative efficiency of H_2O, HDO, and D_2O as the kinetic moderators can be determined using Eqs. 13 and 14. In Table 1 are also included the values of $(\alpha_{HDO}/\alpha_{H_2O})$ and $(\alpha_{HDO}/\alpha_{D_2O})$. For the calculation, the $\alpha_{H_2O}/\alpha_{D_2O}$ value of 1.5 was used, this value has previously been determined from the ratios of the acetone-t yields at zero m.f. of acetone in the H_2O–acetone and D_2O–acetone systems.[5] As an average, the values of 1.56 ± 0.16 for $\alpha_{H_2O}/\alpha_{D_2O}$ and of 1.45 ± 0.12 for $\alpha_{HDO}/\alpha_{D_2O}$ are deduced. Although the qualitative and quantitative significance of the present relative moderating abilities is largely dependent on the model and the asumptions introduced, the uncertainties involved do not affect the semiquantitative conclusion: $\alpha_{H_2O}\approx\alpha_{HDO}>\alpha_{D_2O}$.

A non-reactive collision of a recoil T atom with a molecule is very "cushioning".[7] In such a collision, a large fraction of the excess kinetic energy of the atom is transferred to the various degrees of freedoms in the struck molecule. The complexity of the molecule and the case of the energy transfer through the bonds are considered to be the important parameters governing the efficiency of the energy transfer. The consequence of the former is well demonstrated by the experimental results[7,15]: the α values increase in this order, D_2, CH_4, C_2H_6, n-C_3H_8, n-C_4H_{10}, n-C_5H_{12}, and iso-C_5H_{12}, indicating their dependence on the number of atoms involved and the complexity of the molecule. On the other hand, the latter parameter is closely related to the vibrational frequency of the bonds, since the energy transfer occurs through the bond vibrations: as the frequency becomes higher, the transfer becomes faster. The present results are consistent with this consideration: the O–H bond has a vibrational frequency higher than that of the O–D bond,[16] and the collision of recoil T atoms with HDO, with a large fractional energy loss, must occur as frequently as with H_2O.

The CD Spectra of (L-Aspartato) (L-2,4-diaminobutyrato) cobalt (III) Complexes

Masatoshi WATABE and Sadao YOSHIKAWA*

General Education Department, Kogakuin University, Hachioji, Tokyo 193

**The Department of Synthetic Chemistry, Faculty of Engineering, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*

(Received October 30, 1974)

Systematic correlations in CD spectra are found when the CD spectra of the isomers of the [Co(L-aspartato)-(L-2,4-diaminobutyrato)] complex, the $[Co(N)_3(O)_3]$ type, are compared with those of the isomers of the [Co-(L-2,4-diaminobutyrato)$_2$]$^+$, the $[Co(N)_4(O)_2]$ type, and those of the isomers of the [Co(L-aspartato)$_2$]$^-$, the $[Co(N)_2(O)_4]$ type.

The coordination of two optically active tridentate ions such as aspartate (=asp) or 2,4-diaminobutyrate (=2,4-dba), with cobalt(III) can result in three geometric isomers. One of these isomers has been easily characterized, without ambiguity, on the basis of the electronic absorption spectra. The assignment of the other two isomers has been attempted by using the CD spectra, but no distinct characterization has yet been established.[1-5] The CD spectra of these complexes are different from those of the complexes containing bidentate and tetradentate ligands. The two *cis*(*N*) isomers of the [Co(L-2,3-dpa)$_2$]$^+$(L-2,3-dpa= L-2,3-diaminopropionate ion)[2] were assigned by using X-ray analysis, while the isomers of the [Co(L-2,4-dba)$_2$]$^+$ were characterized by using the PMR spectra in comparison with those of the [Co(L-2,3-dpa)$_2$]$^+$. The CD spectra of the complexes containing asp, dba, and dpa did not show any distinct relation between the sign of the CD components and the absolute configuration of these isomers. Legg and Neal, by comparing these CD spectra with those of the [Co(EDDS)]$^-$-(EDDS=ethylenediaminedisuccinate) and the [Co(EDDAMS)]$^-$(EDDAMS=ethylenediamine-*N*,*N*-diacetic-*N'*-monosuccinate),[6] proposed that the assignment done by Douglas[4] for the configuration of the two *cis*(*N*) isomers of the [Co(L-asp)$_2$]$^-$ had better be reversed.

We ourselves have previously reported the preparation and the separation of the isomers of the [Co(L- or D-asp)(L-2,4-dba)] complex.[7] These isomers have been characterized by using the PMR spectra. They have the same membered chelate rings as the [Co(L-2,4-dba)$_2$]$^+$ and the [Co(L-asp)$_2$]$^-$. This paper will describe whether the CD spectra of the isomers of the [Co(L-asp)(L-2,4-dba)] join those of the [Co(L-asp)$_2$]$^-$ and those of the [Co(L-2,4-dba)$_2$]$^+$.

Experimental

The preparation and the separation of the isomers were reported in a previous paper.[7] Three geometrical isomers were obtained for the [Co(L-asp)(L-2,4-dba)], they were designated L1, L2, and L3 in the order of elution in the ion-exchange chromatography. The electronic absorption spectra and the CD spectra were measured with a JASCO J-20 spectrophotometer. The measurements were carried for an aqueous solution except for the L1 isomer, the solution of which contains *ca.* 50% H_2SO_4.

Results and Discussion

Figure 1 shows the possible geometric isomers of the [Co(L-asp)(L-2,4-dba)]. The facial isomer (L3) can easily be distinguished from meridional isomers by comparing the electronic spectra of the three isomers of the [Co(L-asp) (L-2,4-dba)].

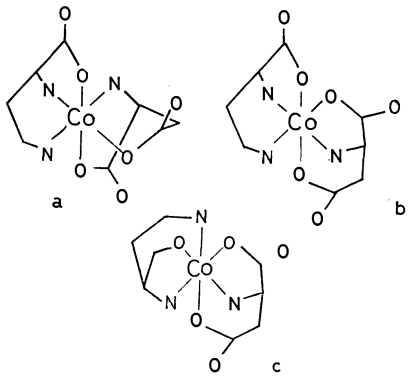

Fig. 1. The three possible geometrical isomers of the [Co(L-asp)(L-2,4-dba)] a: *trans*(*O*)*cis*(*N*), b: *cis*(*O*) *trans*(*N*), c: *cis*(*O*)*cis*(*N*). The isomers are named by considering 5-membered N and O atoms.

CD Spectra. The L-2,4-dba and the L-asp coordinated have 5-membered, 6-membered, and 7-membered chelate rings. When γ-amine nitrogen atoms of the L-2,4-dba for the [Co(L-2,4-dba)$_2$]$^+$ are replaced by oxygen atoms, one by one, the [Co(L-2,4-dba)$_2$]$^+$ may change to the [Co(L-asp)(L-2,4-dba)], and then to the [Co(L-asp)$_2$]$^-$. At this time, the relative positions of the 5-, 6-, and 7-membered chelate rings are not changed. The observed CD spectra may be classified into three groups (the A, B, and C rows in Fig. 2) by assuming that: (1) the difference between the N and O atoms coordinated may be disregarded, (2) the γ_{max} of the CD spectra varies with the change in the number of *X* and *Y* for the $[Co(N)_x(O)_y]$ system, and (3) the additivity of the vicinal effect holds for these nine isomers. Each of the three groups is composed of three isomers containing a different $[Co(N)_x(O)_y]$ type. In each series, one exact geometrical configuration is revealed by the electronic absorption spectra, *trans*(*O*)-*cis*(*N*) for [Co(L-2,4-dba)$_2$]$^+$, *cis*(*O*)*cis*(*N*) for [Co(L-asp)(L-2,4-dba)], and *cis*(*O*)*trans*(*N*) for [Co(L-asp)$_2$]$^-$ (see Fig. 2). The CD spectrum of the α isomer (the

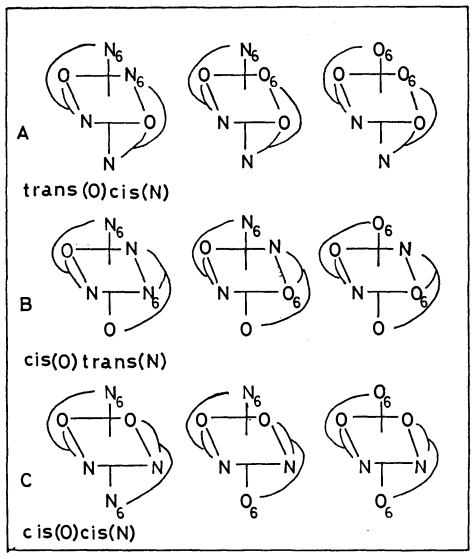

Fig. 2. Configurational analogies of the [Co(L-2,4-dba)$_2$]$^+$ (left), the [Co(L-asp)(L-2,4-dba)] (middle), and the [Co(L-asp)$_2$]$^-$ complexes (right).

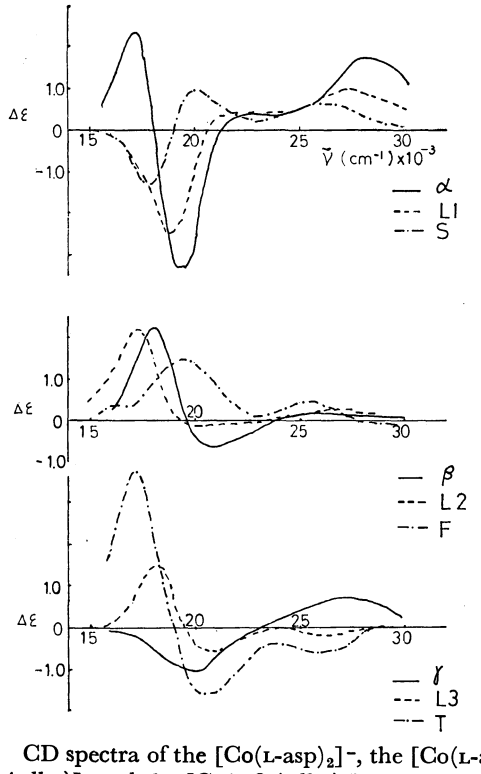

Fig. 3. CD spectra of the [Co(L-asp)$_2$]$^-$, the [Co(L-asp)-(L-2,4-dba)], and the [Co(L-2,4-dba)$_2$]$^+$.

three isomers obtained for the [Co(L-2,4-dba)$_2$]$^+$ are named α, β, and γ in the order of elution in ion-exchange chromatography), the configuration of which has the *trans(O)* geometry, resembles that of L1 of the [Co(L-asp)(L-2,4-dba)] rather than that of L2 (Fig. 3). The L1 isomer is assigned to the *trans(O)cis(N)* according to the above assumption (Fig. 2-A). Since the CD spectrum of L1 resembles that of the S isomer (the three isomers obtained are named F, S, and T in the order of elution in ion-exchange chromatography) of the [Co(L-asp)$_2$]$^-$, S must have the *trans(O)cis(N)* configuration. This last assignment, while not consistent with that of Douglas *et al.*,[4] agrees with that done by Legg and Neal.[6] When these three CD spectra are compared with each other in the order of [Co(L-2,4-dba)$_2$]$^+$→[Co(L-asp)(L-2,4-dba)]→[Co(L-asp)$_2$]$^-$, the value of the large negative peak at about 18×10^3 cm^{-1} is found to decrease gradually and the ν_{max} is found to shift to the longer wavelength side. The intensities of these CD spectra in the second absorption band region are also aligned in the order of α>L1>S. The β isomer for the [Co(L-2,4-dba)$_2$]$^+$ has the *cis(O)trans(N)* configuration.[3] The *cis(O)trans(N)* of [Co(L-asp)(L-2,4-dba)] lies in the same series as the *cis(O)trans(N)* isomer of the [Co(L-2,4-dba)$_2$]$^+$ (Fig. 2-B), and the CD spectrum of the L2 isomer considerably resembles that of the β isomer (Fig. 3). The configuration of the L2 isomer must be *cis(O)trans(N)*. The *cis(O)trans(N)* of the [Co(L-asp)$_2$]$^-$ lies also in the same series, and the CD spectrum of the F isomer resembles those of both the β isomer and the L2 isomer, especially by having the same $\Delta\varepsilon$ in the second absorption region, except for the large splitting in the first absorption band as a result of the *trans(N)* configuration. In the last series, the CD spectrum of the L3 isomer resembles that of the T isomer, but neither resembles that of the γ isomer. However, the CD intensities in the second absorption region of these complexes are aligned in the order of γ>L3>T. This indicates a gradual change in the vicinal effect.

We have also confirmed the alternative assignment of the two *cis*(N) isomers of the [Co(L-asp)$_2$]$^-$ and the [Co(L-asp)(ida)]$^-$, first identified by Legg and Neal.[6]

The authors wish to thank Drs. M. Saburi and S. Yano for helpful discussions.

(Received January 24, 1975)

Copper(II) forms a 2: 1 complex with cyclodextrin in an alkaline solution. The complexes with α- and β-cyclodextrins were isolated from solutions by the addition of ethanol. They are labile, and, upon heating, the Cu(II) is reduced to Cu(0). The role of the hydroxide ion was examined by means of potentiometric and conductometric titrations; it was found that the reaction of 1 mol of α-cyclodextrin with 2 mol of $Cu(OH)_2$ consumes 2 mol of the hydroxide ion, whereas 3 mol of the hydroxide ion are consumed for the reaction of β-cyclodextrin. Polarimetric measurements showed that the optical rotation of cyclodextrin changes from dextrorotatory to levorotatory upon the formation of the Cu(II)–cyclodextrin complex. It was suggested, with a molecular model, that the two pairs of C_2 and C_3' secondary hydroxyl groups of contiguous glucose units are cross-linked by the $Cu(OH^-)_2Cu$ ion bridge in the α-cyclodextrin complex and by $Cu(OH^-)(O^{2-})Cu$ ion bridge in the β-cyclodextrin complex. Furthermore, the circular ring of cyclodextrin may be distorted to the ellipsoidal form by the complex formation, causing a pronounced change in the optical rotation.

Cyclodextrins are cyclic oligomers composed of six or more α-D-glucopyranose units linked 1→4 as in amylose. The molecular shape of cyclodextrin is schematically depicted as a torus.[1] One side of the torus is hemmed round by the C_2 and C_3 secondary hydroxyl groups of the glucopyranoses. Even the smallest one of the cyclodextrins, α-cyclodextrin, has 12 hydroxyl groups arranged side by side around one edge of the torus. The analogy with the structure of porphyrin, which has four amino groups in the vicinity of one another in a molecule, suggests the possibility that cyclodextrins are good ligands for metallic cations. Although the hydroxyl group has a poor ability for coordinating to metallic cations, some diol compounds can form complexes with copper(II).[2] Therefore, copper(II) was selected for the study of the formation of cyclodextrin complexes with metallic cations. Some preliminary results have previously been reported.[3]

Experimental

Materials. The α-, β-, and γ-cyclodextrins were prepared by the method of Lane and Pirt.[4] They were separated and purified according to the directions of Cramer and Henglein.[5] The $CuSO_4 \cdot 5H_2O$ was purified by recrystallization from water. The EDTA, murexide (ammonium purpurate), methyl α-D-glucopyranoside, and potassium chloride, all of a reagent grade, were used without further purification.

Methods and Procedures. The solubilization of $Cu(OH)_2$ in an alkaline solution containing cyclodextrin: Two aqueous solutions, 0.2 to 2.0 M NaOH and 0.02 M $CuSO_4$, of an equal volume were mixed. The precipitate of $Cu(OH)_2$ was formed immediately. The supernatant was virtually colorless. Solid cyclodextrin was then added to the mixture. The mixture was stirred well and then allowed to stand at 25 °C for about 1 hr. The supernatant thus became blue. The concentration of the dissolved Cu(II) was titrimetrically determined by the use of EDTA and murexide, as a titrant and an indicator respectively, after the neutralization of the supernatant by aqueous HCl and the addition of a few drops of 30% NH_4OH.

Isolation of Cu(II)–Cyclodextrin Complexes: To 10 ml of 0.5 M NaOH containing 0.02 M cyclodextrin, we added 15 ml of 0.04 M $CuSO_4$. The Cu(II) thus precipitated was filtered off, and 25 ml of ethanol was added to the filtrate. A blue precipitate appeared; this was then filtered off, washed with aqueous ethanol, and air-dried at room temperature. The Cu(II) content in the isolated complex was titrimetrically determined with EDTA as has been described above. The Cu(I) content was spectrophotometrically determined by the use of ammonium molybdate(VI)[6] after the complex had been dissolved in water. The Cu(0) content was determined by subtracting the Cu(II) and Cu(I) contents from the total Cu content, which was titrimetrically determined with EDTA after the complex had been oxidized by heating in concentrated HNO_3. The cyclodextrin content was determined by the measurement of the optical rotation of an aqueous solution of the complex buffered at pH *ca.* 7, where the complex dissociates into Cu(II) and cyclodextrin. In this determination, the specific rotations of the α- and β-cyclodextrins were taken to be 150.5 and 162.5 ° respectively.[7]

The potentiometric titration was carried out by the use of a Toa Electronics pH meter, Model HM-5A, with an indicator electrode for a high alkaline solution, Model HG-4005, and a reference electrode, Model HC-205. To a 50-ml beaker, we added 25 ml of 0.02 M $CuSO_4$ in 2.5 M KCl containing 0.01 M cyclodextrin or 0.02 M methyl α-D-glucopyranoside. The solution was then stirred and degassed with N_2 for 30 min. An indicator electrode and a reference electrode were immersed in the solution, to which, then, 2.28 M KOH was added, drop by drop with a syringe, at room temperature.

The polarograms of the Cu(II)–cyclodextrin complexes were measured by means of a Yanagimoto polarograph, Model P-8. The saturated calomel electrode, used as a reference electrode, was connected with the cell solution by means of a KCl-agar bridge. The cell solution was degassed and thermostated at 25 °C. The dropping mercury electrode had the following characteristics in 1 M NaOH: $m=2.314$ mg/s, $t=3.53$ s.

The polarimetric measurements were carried out at room temperature with an automatic polarimeter of the Japan Spectroscopic Co., Model DIP-SL. A Hitachi spectrophotometer, Model 124, was used for the colorimetric determination of Cu(I).

Results and Discussion

Copper(II) hydroxide is practically insoluble in aqueous NaOH. However, upon the addition of cyclodextrins, the Cu(II) ion does dissolve to form a blue solution.[3] Figure 1 shows the plots of the concentrations of the dissolved Cu(II) *vs.* those of cyclodextrins added in alkaline solutions. Each plot was linear, with a slope of about 2.0. The solubilization of $Cu(OH)_2$ in an alkaline solution also took place on the addition of methyl α-D-glucopyranoside. However, the slope of the similar plot in this case was not 2.0, but 1.0.

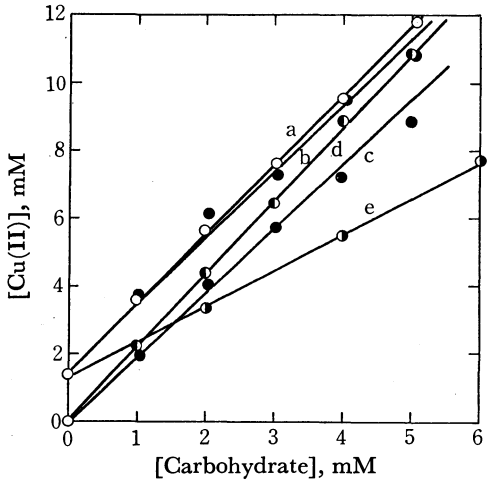

Fig. 1. Plots of the concentration of the dissolved Cu(II) *vs.* those of carbohydrates added.
a, α-cyclodextrin in 1.0 M NaOH; b, β-cyclodextrin in 1.0 M NaOH; c, β-cyclodextrin in 0.2 M NaOH; d, γ-cyclodextrin in 0.2 M NaOH; e, methyl α-D-glucopyranoside in 1.0 M NaOH.

The complexes of Cu(II) with α- and β-cyclodextrins were isolated as has been described in the Experimental section. The isolated complexes were not very stable. Thus, when the complexes were allowed to stand at room temperature for a week or were heated at 110 °C *in vacuo* for a few hours, the color of the complexes changed from blue to green. The contents of Cu(II), Cu(I), Cu(0), and cyclodextrin in the air-dried and heated samples were determined (Table 1). The results clearly show the formation of 2:1 complexes between Cu(II) and cyclodextrins. However, upon heating, the Cu(II) in the complexes is reduced in part to Cu(0). It is not yet obvious which of the substances–cyclodextrin and ethanol used as a precipitant–acts as a reductant.

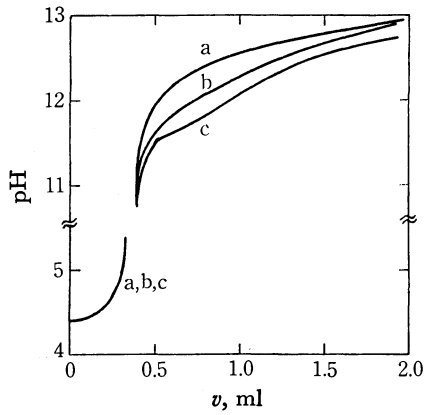

Fig. 2. Potentiometric titration of 0.02 M $CuSO_4$ in 2.5 M KCl with 2.28 M KOH in the absence (a) and in the presence of 0.01 M α- and β-cyclodextrins (b and c, respectively).

Potentiometric Titration. Cyclodextrins form complexes with Cu(II) only in an alkaline solution. In order to examine the role of the hydroxide ion, the potentiometric titration of $CuSO_4$ was carried out in the absence and in the presence of cyclodextrins, using aqueous KOH as a titrant. The ionic strength of the Cu(II) solution was kept at about 2.5 M with 2.5 M KCl. The reproducibility of the experiments was very good when an indicator electrode for high alkaline solutions was used (Fig. 2). In the absence of cyclodextrin, $Cu(OH)_2$ was precipitated by the addition of a drop of a KOH solution and did not dissolved even at a high alkaline pH. In the presence of α-cyclodextrin, on the other hand, the $Cu(OH)_2$ precipitated in the acidic pH region was re-dissolved at alkaline pH. A blue transparent solution was obtained at pH 12.4. Curves a and b in Fig. 2 are the potentiometric titration curves for $CuSO_4$ solutions in the absence and in the presence of α-cyclodextrin respectively. The pH value for the latter was always lower than that for the former at every volume of the titrant over the whole alkaline pH region. This fact suggests that the hydroxide ion is consumed in the formation of the Cu(II)–cyclodextrin complex. Curve c in Fig. 2 shows the potentiometric titration curve for a $CuSO_4$ solution containing β-cyclodextrin. The $Cu(OH)_2$ precipitated in the acidic pH region was re-dissolved at pH 12.2 to form a bluish transparent solution. The pH value at every volume of the titrant throughout the alkaline region was not only lower than that for a solution containing no

a) CD: Cyclodextrin. b) Cu=Cu(O)+Cu(I)+Cu(II).

cyclodextrin, but also lower than that for a solution containing α-cyclodextrin. On the other hand, the potentiometric titration curve for a $CuSO_4$ solution containing methyl α-D-glucopyranoside was virtually identical with that for a solution containing no carbohydrate. The $Cu(OH)_2$ precipitated in the acidic pH region did not completely dissolve until the pH value reached 13.1.

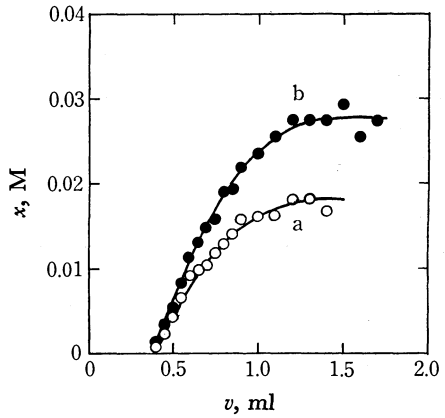

Fig. 3. Plots of the amount (x) of the hydroxide ion consumed for the formation of the complexes between 0.02 M $Cu(OH)_2$ and 0.01 M α- and β-cyclodextrins (a and b, respectively) *vs.* the volume (v) of 2.28 M KOH added.

Figure 3 shows the plots of the amount (x) of the hydroxide ion consumed for the complex formation *vs.* the volume (v) of the titrant. The x value was calculated from the difference of pH at each volume of the titrant on the assumption that the activity coefficient of the proton equals unity.[8] The x values for the reaction of 0.97 mmol of $Cu(OH)_2$ with cyclodextrin were 0.90 and 1.37 mmol for α- and β-cyclodextrins respectively. This fact suggests that, to form one mol of the Cu(II)–α-cyclodextrin and Cu(II)-β-cyclodextrin complexes, two and three mol respectively of the hydroxide ion are consumed. The reaction may be represented as follows:

$$2Cu(OH)_2 + AH_4 \rightleftarrows \underset{\mathbf{A}}{[Cu_2(AH_2^{2-})(OH^-)_2]} + 2H_2O$$

$$\mathbf{A} + OH^- \rightleftarrows \underset{\mathbf{B}}{[Cu_2(AH^{3-})(OH^-)_2]^-} + H_2O \qquad (1)$$

$$\mathbf{B} + OH^- \rightleftarrows \underset{\mathbf{C}}{[Cu_2(A^{4-})(OH^-)_2]^{2-}} + H_2O$$

$$\mathbf{C} + OH^- \rightleftarrows [Cu_2(A^{4-})(OH^-)(O^{2-})]^{3-} + H_2O$$

where AH_4 means cyclodextrin. Among these complexes, the $[Cu_2(A^{4-})(OH^-)_2]^{2-}$ complex may be the most stable one for α-cyclodextrin, whereas the $[Cu_2(A^{4-})(OH^-)(O^{2-})]^{3-}$ complex may be the most stable for β-cyclodextrin.

Conductometric Titration. The role of the hydroxide ion in the Cu(II)–cyclodextrin complex formation was also examined by means of conductometric titration. In Eq. (1), $Cu(OH)_2$ is practically insoluble and cyclodextrin is a neutral molecule, so that the contribution of these compounds to the specific conductance

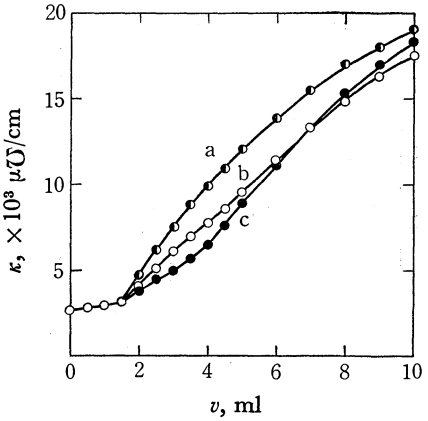

Fig. 4. Conductometric titration of 0.02 M $CuSO_4$ with 0.5 M NaOH in the absence (a) and in the presence of 0.01 M α- and β-cyclodextrins (b and c, respectively).

of a solution is negligible. Since there is no doubt that the ionic equivalent conductance of the hydroxide ion is much greater than that of the complex ion, the specific conductance of an alkaline solution would be appreciably decreased by the formation of a complex between $Cu(OH)_2$ and cyclodextrin.

When an aqueous solution of 0.5 M NaOH was added, drop by drop, to 25 ml of 0.02 M $CuSO_4$, the specific conductance (κ) of the solution changed, as is shown by Curve a of Fig. 4. No significant increase in κ was observed until *ca.* 2.0 ml of NaOH had been added. It was also observed that this process is accompanied by the precipitation of $Cu(OH)_2$ in the conductivity cell. Since the ionic equivalent conductance of Cu(II) and Na^+ (53.6 and 50.1 $cm^2℧$/equiv. respectively at 25 °C[9]) are approximately equal, a decrease in κ due to the consumption for the formation of insoluble $Cu(OH)_2$ may almost be compensated for by an increase in κ due to the addition of Na^+. The value of κ then increased with the continued addition of NaOH over 2.0 ml. A similar titration was carried out in the presence of 0.01 M α-cyclodextrin (Curve b of Fig. 4). After the addition of NaOH over 2.0 ml, the value of κ was somewhat less than that for the solution containing no cyclodextrin. This fact indicates that a part of the hydroxide ion is consumed for the formation of the Cu(II)–cyclodextrin complex. No clear inflection point was observed, although it could be said that an inflection point exists at v=*ca.* 4.0 ml. This may be due to the fact that the cyclodextrin is a weak acid and does not fully ionize even in the presence of Cu(II) until the pH of the solution becomes sufficiently high.

In order to estimate more accurately the amount of the hydroxide ion consumed, the difference ($\Delta\kappa$) in κ between the two solutions was plotted against the volume (v) of NaOH added. As is shown in Fig. 5, the value of $\Delta\kappa$ increased rapidly after the value of v exceeded 1.5 ml. Then, it reached its maximum. After that, $\Delta\kappa$ decreased almost linearly with an increase in v. The decrease in $\Delta\kappa$ may be due to an increase in the volume of the cell solution, to an increase in the ionic strength, and/or to the consumption of the hydroxide ion to form $Cu(OH)_4^{2-}$ in a strong alkaline solution

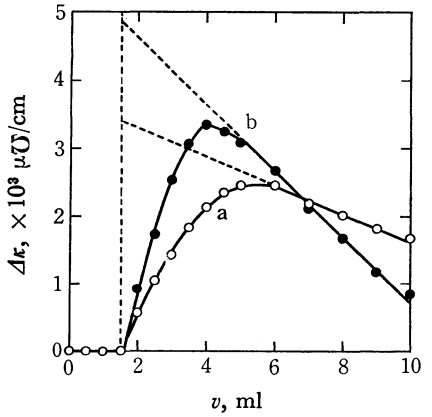

Fig. 5. Plots of $\Delta\kappa$ *vs.* the volume of 0.5 M NaOH added.
a, 0.01 M α-cyclodextrin; b, 0.01 M β-cyclodextrin.

containing no cyclodextrin. To exclude these effects on $\Delta\kappa$, the linear portion of the $\Delta\kappa$ *vs.* v plot was extrapolated to $v=1.5$ ml, where the solubilization of $Cu(OH)_2$ began to occur in the presence of cyclodextrin. The value of $\Delta\kappa$ thus obtained ($\Delta\kappa_0$) was 3.40×10^3 μ℧/cm. Similar results were obtained with regard to the formation of the complex between Cu(II) and β-cyclodextrin (Curve c's of Figs. 4 and 5). The $\Delta\kappa_0$ value was 4.85×10^3 μ℧/cm in this case.

If the ionic equivalent conductance of the complex ion (λ_a) is known, the amount (x) of the hydroxide ion consumed for the complex formation can be estimated by means of the following equation:

$$x = \Delta\kappa_0/(\lambda_b-\lambda_a) \qquad (2)$$

where λ_b is the ionic equivalent conductance of the hydroxide ion (198.3 cm^2℧/equiv. at 25 °C[9]). This was done by means of polarography. Figure 6 shows the

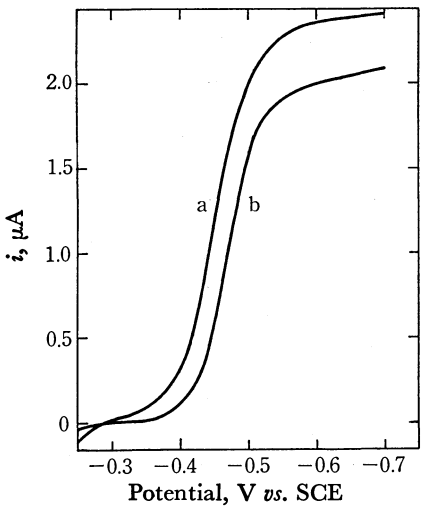

Fig. 6. Polarograms of the Cu(II) complexes with α- and β-cyclodextrins (a and b, respectively) in 1 M NaOH.
[Cu(II)], 0.466 mM; [Cyclodextrin], 20.0 mM

polarograms of the Cu(II)-cyclodextrin complexes in 1 M NaOH. The limiting current for each wave was proportional to the square root of the effective pressure on the mercury drop; this fact indicates that each wave is diffusion-controlled. The diffusion constants of the Cu(II)-α- and β-cyclodextrin complexes were evaluated to be 3.13×10^{-6} and 2.32×10^{-6} cm^2/s respectively on the basis of the Ilkovic equation.[10] The diffusion constant (D) is related to the ionic equivalent conductivity (λ) by the Nernst equation:[11]

$$D = \lambda RT/ZF^2 \qquad (3)$$

where R is the gas constant; T, the temperature; Z, the ionic valence, and F, the Coulomb constant. To calculate the value of λ_a, the value of Z was assumed to be 2 for the α-cyclodextrin complex and 3 for the β-cyclodextrin complex on the basis of Eq. (1). The λ_a values thus obtained were 23.4 and 26.0 cm^2℧/equiv. for the α- and β-cyclodextrin complexes respectively. Accordingly, the x values were determined to be 0.019 and 0.028 M for the α- and β-cyclodextrin complexes respectively; that is, about 2 mol of the hydroxide ion was consumed for the reaction of one mole of α-cyclodextrin with 2 mol of $Cu(OH)_2$, whereas 3 mol of the hydroxide ion were consumed for the same reaction of β-cyclodextrin. These results agree with those of the potentiometric titration.

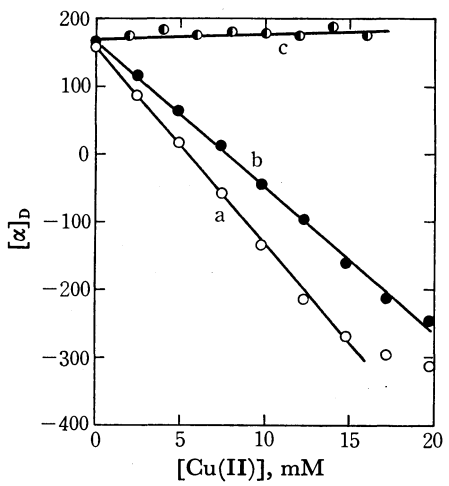

Fig. 7. Plots of the specific rotations of α- and β-cyclodextrins (a and b, respectively) and methyl α-D-glucopyranoside (c) *vs.* the concentration of Cu(II) in 1 M NaOH.

Optical Rotation of Cu(II)–Cyclodextrin Complexes. The specific rotation of cyclodextrin was drastically changed by the formation of the Cu(II) complex. Cyclodextrins themselves are dextrorotatory. The specific rotations of α- and β-cyclodextrins in 1 M NaOH are virtually the same as those in distilled water. However, upon the addition of Cu(II) in an alkaline solution of each cyclodextrin, the specific rotation ($[\alpha]_D$) of the cyclodextrin became levorotatory. Figure 7 shows the plots of $[\alpha]_D$ *vs.* the concentration of Cu(II) added to a solution of 10.3 mM cyclodextrin in 1 M NaOH. The $[\alpha]_D$ value for each cyclodextrin decreased linearly with an increase in the concentration of Cu(II). The slope of the plot for α-cyclodextrin is larger than that for β-cyclodextrin. On the other hand, the specific rotation of methyl α-D-glucopyranoside in an alkaline solution showed virtually no change upon the addition of Cu(II) to form the complex between Cu(II) and

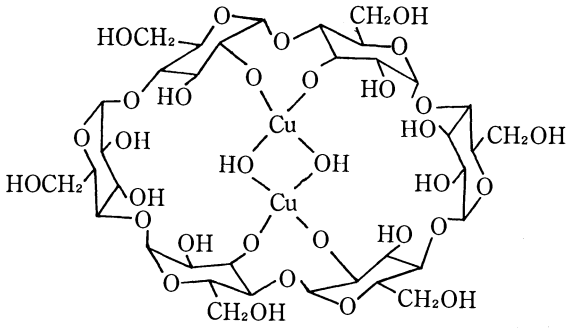

Fig. 8. The suggested structure of the Cu(II)–α-cyclodextrin complex.

methyl α-D-glucopyranoside. These results indicate that the conformation of cyclodextrin remarkably changes upon the formation of the Cu(II) complex and that the conformation change occurs in the whole cyclodextrin ring rather than in the glucopyranose-unit ring alone.

The structure of the complexes was studied with framework molecular models. It was presumed that two Cu(II) ions are bond by two hydroxide ions in the complex of $Cu_2(A^{4-})(OH^-)_2^{2-}$ for α-cyclodextrin.[3] The models showed that the secondary hydroxyl groups in α-cyclodextrin coordinate to the $Cu(OH^-)_2Cu$ residue, as is shown in Fig. 8; that is the C_2 and C_3' hydroxyl groups of contiguous glucopyranose units coordinate to the Cu(II) ions. It was impossible for the $Cu(OH^-)_2Cu$ residue to be bound to another combination of the hydroxyl groups, such as two pairs of the hydroxyl groups at C_2 and C_3, in the same glucopyranose unit. Furthermore, it was revealed that the distance between the two pairs of the C_2 and C_3' hydroxyl groups (*ca.* 10 Å) was considerably longer than that of the $Cu(OH^-)_2Cu$ ion bridge (*ca.* 6 Å). Accordingly, if the $Cu(OH^-)_2Cu$ residue was connected to the secondary hydroxyl groups of the cyclodextrin, the overall ring was significantly distorted from circular to ellipsoidal, as is depicted in Fig. 8. This fact may be related to the great change in the optical rotation of the cyclodextrin with the formation of the Cu(II) complex.

In the Cu(II)-β-cyclodextrin complex, the degree of the distortion of the overall ring may be somewhat smaller than that in the Cu(II)–α-cyclodextrin complex, for β-cyclodextrin is larger and more flexible than the α-cyclodextrin ring. This may be the reason why the

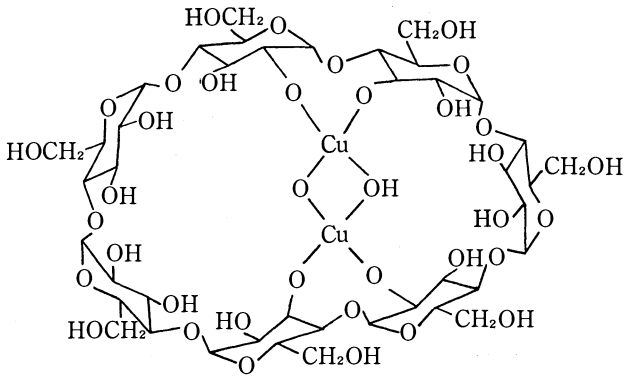

Fig. 9. The suggested structure of the Cu(II)–β-cyclodextrin complex.

slope of $[\alpha]_D$ *vs.* the concentration of Cu(II) for β-cyclodextrin is smaller than that for α-cyclodextrin (Fig. 7). The structure of the Cu(II)–β-cyclodextrin complex was presumed to be as is depicted in Fig. 9.

The spectrophotometrical and the detailed polarographical behavior of the Cu(II)–cyclodextrin complexes will be reported in subsequent articles.

The authors wish to thank Professor Kunio Okamoto, Kyoto University, for the use of a polarimeter.

X-Ray Study of the Compound Obtained by the Reaction of N^{δ}-Salicylidene-L-ornithine and Palladium(II) acetate. The Crystal Structure of (N^{α}-Salicylidene-D-ornithinato) (N^{α}-Salicylidene-L-ornithinato)dipalladium(II)-Dimethyl Sulfoxide

(Received January 30, 1975)

X-Ray structure analysis has elucidated that the reaction of N^{δ}-salicylidene-L-ornithine and palladium(II) acetate in DMF results in the amine exchange and racemization of the ligand, yielding (N^{α}-salicylidene-D-ornithinato)(N^{α}-salicylidene-L-ornithinato)dipalladium(II). The yellow crystals are monoclinic, $a=15.15(2)$, $b=9.80(1)$, $c=15.67(2)$ Å, $\beta=111.3(1)°$, space group $P2_1/c$, and $Z=2$. The structure was solved by the Patterson and Fourier techniques and was refined by the least-squares method to $R=0.105$. The complex molecule has a center of symmetry by which D- and L-Schiff-base ligands are interrelated. Each Pd atom has a square-planar coordination by means of two O and N^{α} atoms of one ligand, and the N^{δ} atom of the other one, the two N atoms being in the *trans* position. The $H_2N^{\delta}-(CH_2)_3-\underset{|}{C}H-N^{\alpha}$ fragments of the two ligands bridge the two Pd atoms, giving a 14-membered ring.

The stereoselectivity of metal complex[1] is an important subject in the coordination chemistry. We planned to study the stereochemical behavior of the dissymmetric complexes of labile metal ions for some amino acids and attempted to prepare the optically active Ni(II), Cu(II), and Pd(II) complexes involving the quadridentate Schiff-base ligand N^{δ}-salicylidene-ornithine. However, none of the products obtained from the reactions of the acetates of these metal ions with the L-enantiomer of the ligand in DMF showed any optical activity. Since the Pd(II) complex was isolated as good crystals, an X-ray crystal structure analysis was undertaken in order to discover why the optical activity due to the dissymmetric ligand disappears during the reaction.

Experimental

Preparation. N^{δ}-Salicylidene-L-ornithine (sal-L-orn) was prepared following the procedure of Witkop *et al.*[2] The yellow crystals decompose at 201—202 °C; the temperature agrees well with the temperature reported by them. A suspension of equimolar amounts of sal-L-orn and palladium(II) acetate in DMF was stirred for several hours until they had been completely dissolved. Brownish yellow crystals were then precipitated by the addition of twice as many moles of dipyridyl as the sal-L-orn and subsequently recrystallized from hot DMSO. Since the compounds are efflorescent, the elemental analyses could not be carried out. The exact composition of the compound was determined by means of X-ray structure analysis, as will be described below.

X-Ray Measurement. Since the compound decomposes rapidly in air, the crystals were sealed in thin-walled Lindemann glass capillaries. Two well-formed specimens with the approximate dimensions of $0.12\times0.27\times0.23$ and $0.12\times0.25\times0.43$ mm were used for the intensity measurements, one mounted about the b axis and the other, about the c axis. The unit-cell dimensions were determined by a least-squares refinement of 45 independent measurements of the 2θ values from Weissenberg photographs calibrated by silicon powder ($a=5.4307$ Å). Crystal data: $Pd_2(C_{12}H_{14}N_2O_3)_2(C_2H_6SO)_4$, mol wt 993.7. Monoclinic, $a=15.15(2)$ Å, $b=9.80(1)$ Å, $c=15.67(2)$ Å, $\beta=111.3(1)°$, space group $P2_1/c$, $Z=2$ ($D_x=1.51$, $D_m=1.52$ g cm^{-3}), $F(000)=1008$, $V=2169$ Å^3, $\mu=90.7$ cm^{-1} (for Cu$K\alpha$).

Multiple film, equi-inclination Weissenberg photographs for the $h0l$-$h6l$ and $hk0$-$hk10$ layers were taken with Cu$K\alpha$ radiation ($\lambda=1.5418$ Å). The intensities were estimated visually by the use of a calibrated intensity scale. After corrections for the usual Lp-factor and the spot shape, the structure amplitudes were placed on a common arbitrary scale by internal correlation. A total of 3641 independent reflections were collected. However, 622 of these were too weak to be observed, and so they were assumed to be zero. No correction for absorption was made.

Structure Determination

In the beginning of the structure analysis we knew only that the crystal contains the palladium atoms, the salicylidene-ornithine ligand, and probably DMSO molecules. A trial calculation of the density indicated that there may be four Pd atoms in a unit cell. The initial coordinates for the Pd atom were determined from a three-dimensional Patterson map. Two sulfur and eight light atoms were located on a Fourier map phased by the heavy atom. The positions of all the remaining non-hydrogen atoms were found by successive Fourier syntheses. At this point it was revealed that the complex corresponded to dimeric(N^{α}-salicylidene-D-ornithinato) (N^{α}-salicylidene-L-ornithinato)-dipalladium(II)·4DMSO; the optically active N^{δ}-salicylidene-L-ornithine used initially seems to be isomerized to the N^{α} analogue and to be racemized during the reaction with palladium(II) acetate. Several cycles of block-diagonal least-squares refinement gave an R factor of 0.142, isotropic temperature factors being used for all the atoms. Five more cycles of the refinement with anisotropic temperature factors converged to $R=0.105$ for 3119 non-zero reflections. The weighting scheme employed was:

TABLE 1. FRACTIONAL POSITIONAL PARAMETERS ($\times 10^4$) AND ANISOTROPIC TEMPERATURE FACTORS ($\times 10^4$) WITH e. s. d. 's IN PARENTHESES

Temperature factors are of the form: $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+hkB_{12}+hlB_{13}+klB_{23})]$.

$w = 0.2$ for $F_o < 7.2$

$w = 1.0$ for $7.2 \leqq F_o \leqq 43.0$

$w = (43.0/F_o)^2$ for $F_o > 43.0$

The scattering factors for the zerovalent Pd, S, N, C, and O atoms were taken from "International Tables for X-ray Crystallography." In the final cycle, the shifts in the atomic parameters were less than their standard deviations. A difference Fourier synthesis computed at this stage did not show the peaks corresponding to any of the hydrogen atoms. The final atomic parameters and their estimated standard deviations are listed in Table 1. A table of the observed and calculated structure factors is preserved by the Chemical Society of Japan (Document No. 7516).

Results and Discussion

A perspective view of the complex, which shows the coordination geometry and the numbering of the atoms, is given in Fig. 1. The complex assumes a dimeric structure. The two halves of this dimer are related by a crystallographic center of symmetry: thus, the molecule is of an inactive *meso* form, with two enantiomeric Schiff-base ligands. The H_2N^{δ}–$(CH_2)_3$–CH–N^{α} fragments of the two ligands bridge the two Pd atoms, giving the 14-membered ring, as is shown in Fig. 2. The two Pd atoms are separated by 5.31 Å. Each Pd atom has a square-planar coordination and is bonded to the phenolic oxygen, O(1); the carboxylate oxygen, O(2); and the imino nitrogen, N(1), of one salicylidene-

ornithine ligand, and to the terminal amino nitrogen N(2) of the enantiomeric one. One of the hydrogen atoms attached to C(11) lies close to the Pd atom, as is shown in Fig. 2. (The coordinates of the H atoms were calculated by assuming the C–H distance to be 1.08 Å.) The Pd···H distance (2.93 Å) seems to be slightly shorter than the sum of the van der Waals radii (3.1 Å);[3] this suggests that there is a weak interaction between the Pd and H atoms, giving a distorted square-pyramidal coordination of the Pd atom. It is,

(C) $0.197X + 0.728Y - 0.657Z + 2.878 = 0$
(D) $0.114X + 0.758Y - 0.642Z + 2.847 = 0$

where X, Y, and Z are coordinates in Å units relative to a, b, and c^* axes, respectively.

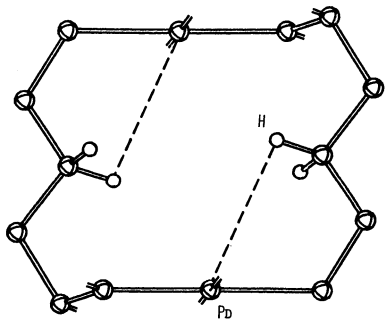

Fig. 2. Fourteen-membered ring formed from H_2N^{δ}-$(CH_2)_3$-CH-N^{α} fragments of the two ligands and two Pd atoms. Calculated positions of some H atoms are given in the Figure in order to show the short Pd···H contacts.

however, possible judging from the molecular models that the hydrogen atom merely sterically occupies the apical coordination position.

The least-squares planes of various parts of the complex and the dihedral angles between them are listed in Table 2. The Pd atom lies on the best least-squares plane (Plane A) defined by the four ligator atoms (Fig. 3). The salicylidene moiety is bent away from Plane A in the opposite direction of another salicylidene-glycinato Pd moiety, while the glycinato residue is bent in its direction.

The bond distances and angles are summarized in Table 3. The Pd–N(2) distance (2.04 Å) is in good agreement with the value found for that in bisethylenediamine palladium(II) (2.04 Å).[4] The Pd–O(2) and Pd–O(1) distances (1.98 and 1.97 Å) are approximately in agreement with the values found for those (2.02 and 1.99 Å) in bis(L-prolinato)palladium(II)[5] and bis(N-isopropyl-3-methylsalicylaldiminato)palladium(II)[6] respectively. The Pd–N(1) distance (1.95 Å) is shorter than those of 2.02 and 2.03 Å in bis(N-isopropyl-3-methylsalicylaldiminato)palladium(II).[6] The other bond distances and angles in the salicylidene-glycinato moiety are similar to those found in (N-salicylidene-glycinato)copper(II).[7]

The stereoview along the b axis and the numbering of the atoms of DMSO molecules are shown in Fig. 4. The crystal is composed of the dimeric Pd(II) complexes and the DMSO molecules. All the intermolecular atomic contacts are of the van der Waals type except for the N(2)–H···O(4) hydrogen bond (2.90 Å), which is shown by a dotted line in Fig. 4. The DMSO molecules are normal in their dimensions,[8] but the relatively large thermal motion suggests that there is some disorder in the molecular arrangement.

In the synthesis of the complex, we used only N^{δ}-salicylidene-L-ornithine as the ligand. Nevertheless, the product contained both the enantiomeric N^{α}-salicylidene-L- and -D-ornithinate anions. This means that, in the ligand, the amine-exchange reaction

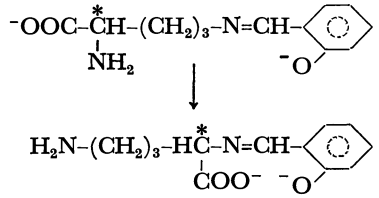
proceeds thus:



Furthermore, the recemization reaction apparently takes place during the reaction of N^{δ}-salicylidene-L-ornithine and palladium(II) acetate in DMF and the subsequent recrystallization from DMSO.

So far several studies have been made of the mechanisms of amine-exchange and racemization reactions in the metal chelates of some Schiff bases. Verter and his co-workers proposed the mechanism of amine-exchange reaction in bis[N-(phenyl derivatives)-salicylaldimine]copper(II) [9] whereas Weinstein *et al.* presented that of the racemization reaction in (N-pyridoxylidene-L-valinato)copper(II).[10] The former may be applicable to the present complex, though whether the reaction occurs by means of an intra- or an intermolecular mechanism is unknown. The latter is different in situation from the present case.

Most of the calculations were made by using a local version of the UNICS programs.[11] The authors wish to express their thanks to Dr. Ken Hirotsu and Dr.

Fusao Takusagawa, who adapted these programs to a FACOM 270-30 computer at Osaka City University. Figure 4 was drawn by using the TECS program written by Dr. Takusagawa.

Catalytic Activities of a Polyoxime-cobalt Complex for the Addition Reaction of an Alcohol to Acrylaldehyde and for the Polymerization of Styrene

Sung Jho KIM and Takeo TAKIZAWA

Faculty of Pharmaceutical Sciences, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received March 14, 1974)

A new polymeric cobalt-chelate complex was prepared from cobalt acetate and a polyoxime consisting mainly of 1,2-bis(hydroxyimino)trimethylene units. The polymeric complex in the solid state at 77—300 K, both in air and under a vacuum, gives an ESR signal with a *g*-value of about 2 and can initiate the polymerization of styrene and catalyze the "Michael"-type addition reaction of an alcohol to acrylaldehyde, yielding exclusively *β*-alkoxypropionaldehyde, after being treated with phenylthiol and sodium borohydride. The catalytic activities depend greatly on the cobalt content and are much greater than those of its monomeric analogue in composition, bis(dimethylglyoximato)cobalt. The absorption spectrum of the polymeric complex treated with the reagents is similar to that of monomeric or polymeric analogues containing monovalent cobalt atoms.

The metal-chelate complexes of a new polyoxime have been investigated in terms of physical and chemical properties in comparison with those of the monomeric analogues corresponding in composition, the metal-chelate complexes of dimethylglyoxime. The polyoxime was derived from an alternating copolymer of ethylene and carbon monixide ($\left[-CH_2CH_2)_{1.2}\overline{C}-\right]_x$, $(C_{17}H_{24}O_5)_x$, $(308.4)_x$, molecular weight 4000): it is considered to consist mainly of 1 2-bis(hydroxyimino)trimethylene units ($\left[-(CH_2)_{1.6}\overline{(C}-\underset{HON}{\overset{\|}{C}})_{0.8}\overline{(C)}_{0.2}\right]_x$, $(C_{17}H_{24}N_8O_9)_x$, $(484.3)_x$). A reversible uptake of molecular oxygen by a polyoxime-cobalt complex(POX-Co) and catalytic activities of a polyoxime–copper complex have been reported.[1-3]

$$CO + C_2H_4 \longrightarrow -CH_2CH_2-\underset{O}{\overset{\|}{C}}- \longrightarrow$$

$$-CH_2-\underset{HON}{\overset{\|}{C}}-\underset{NOH}{\overset{\|}{C}}- \xrightarrow{Co(CH_3CO_2)_2\cdot 4H_2O} \text{POX-Co}$$

Here we will describe the catalytic activities of POX-Co in the polymerization of styrene and in the "Michael"-type addition reaction of an alcohol to acrylaldehyde, yielding exclusively *β*-alkoxypropionaldehyde. A di- or trivalent cobalt complex of dimethylglyoxime(cobaloxime (II) or (III)) can be converted into a monovalent cobaloxime(I) by treatment with reductants.[4] On the other hand, POX-Co does not show any change upon treatment with reductants alone. However, a combination of sodium borohydride and a polymeric complex prepared by the treatment of POX-Co with phenylthiol(POX-Co-S) or the resulting complex(POX-Co-R) shows catalytic activities.

Experimental

Materials. By adding 4.5, 2.5, 1.5, 1.2, or 0.8 g of bis(acetate) tetraaquocobalt ($Co(CH_3CO_2)_2 4H_2O$) into a solution of 3.0 g of the polyoxime in a mixture of dioxane and methanol (1:1 by volume, 5×10^{-3} g/ml) under nitrogen, a complex with a cobalt content of 19.12 (POX-Co-1), 14.84 (POX-Co-2), 10.38 (POX-Co-3), 7.83 (POX-Co-4), or 5.71% (w/w) (POX-Co-5) was prepared; these complexes correspond to the complexes with the composition ratios of Co*/OX= 1/4, 1/6, 1/8, 1/12, and 1/16 (where Co* and OX are the numbers of cobalt atoms and oxime groups in the complex). The catalysts employed were derived from POX-Co-1—5. As an example, the preparation of the catalyst derived from POX-Co-1 will be described. In a 50 ml flask we placed 1.0 g of POX-Co-1, 1.0 g of phenylthiol (excess) and 20 ml of methanol. The mixture was then stirred at room temperature for 24 hr under nitrogen. This yielded a red-purple powder, which was then separated by filtration, washed with methanol, and dried at 80 °C for 8 hr *in vacuo* (yield: 1.5 g, POX-Co-S-1). POX-Co-1 has a composition corresponding to a cobalt/phenylthio group of *ca.* 1/1. The IR spectrum of POX-Co-S-1 showed characteristic bands of the phenyl group (3040, 1485, 735, and 685 cm^{-1}, KBr disc). In a 50 ml flask we placed 1.6 g of POX-Co-S-1 with a cobalt content of 14.59%, 75 mg of $NaBH_4$ (a slight excess), and 20 ml of isopropyl alcohol. The mixture was stirred for 4 hr at 70 °C under nitrogen. After 0.5 hr it changed into a green solution (probably monovalent cobalts are present); the brown precipitate which was deposited was then washed with 1% of acetic acid and water and dried at 80 °C for 8 hr over P_2O_5 *in vacuo* (yield: 1.0 g POX-Co-R-1). The results of the elemental analysis and the IR spectrum of POX-Co-R-1 were almost the same as those of POX-Co-1. When the mixture was stirred in air, phenyldithiobenzene was formed catalytically, and the resulting red-purple powdery complex, with IR spectrum and elemental analysis almost the same as those of POX-Co-S-1, did not show any change upon treatment with $NaBH_4$. The other catalysts, with lower cobalt contents, POX-Co-S-2—5 and POX-Co-R-2—5, were derived from POX-Co-2—5 similarly. In the preparation of POX-Co-S-2—5, 280 (POX-Co-S-2), 210 (POX-Co-S-3), 140 (POX-Co-S-4) or 105 mg (POX-Co-S-5) of phenylthiol per 1.0 g of POX-Co-2—5 was employed; in that of POX-Co-R-2—5, a slight excess of $NaBH_4$ was used. These catalysts are insoluble powders. The elemental analyses of these compounds are summarized below. Found Copolymer: C, 65.80; H, 7.58%. Calcd for $\left[-(CH_2CH_2)_{1.2}\overline{C}-\right]_x$, $(C_{17}H_{24}O_5)_x$, $(308.4)_x$: C, 66.23; H, 7.79%. Found Polyoxime: C, 42.51; H, 4.98; N, 22.54%. Calcd for $\left[-(CH_2)_{1.6}\overline{(C}-\underset{HON}{\overset{\|}{C}})_{1.6}\overline{(C}-\underset{O}{\overset{\|}{C}})_{0.2}\right]_x$, $(C_{17}H_{24}N_8O_9)_x$, $(484.4)_x$: C, 42.15; H, 4.96; N, 23.14%. Procedures. *Polymerization*: In a three-necked flask equipped with a condenser, a gas-inlet tube, and a dropping funnel containing redistilled styrene, we placed the catalyst, the medium and the other reactants ($NaBH_4$, aq NaOH, *etc.*). The amounts of these reactants are given in Table 1. The mixture was stirred at 70 °C under nitrogen; after 0.5 hr it changed into a green solution (probably monovalent cobalts are present). The styrene was then added. After 3.0 hr the mixture was poured into methanol, and the resulting precipitate was collected by filtration. The precipitate was put in hot toluene, and the resulting solution was filtered to remove the catalyst. The filtrate was concentrated and then poured into methanol, after which the precipitated polystyrene (molecular weight, 5200—7400) was collected by filtration.

Addition Reaction: In a 25-ml glass tube we placed 0.1 g of POX-Co-R, 1/10 mol of purified acrylaldehyde, and 1/5 mol of an alcohol. The tube was then swept free of air with nitrogen, sealed, and stirred at 60—70 °C for 2 hr in a water bath. The product was characterized using IR, NMR, and gaschromatographic techniques.

Measurement. The absorption spectrum was measured at room temperature under nitrogen using a Cary-11 Recording Spectrophotometer. The ESR spectrum was taken with a Nihon Denshi Electron Spin Resonance Spectrometer, Model JEOL-P-10 X-band, using the 100 kHz field. The molecular weights of the ethylene/carbon monoxide copolymer and the polystyrene were determined using a Perkin-Elmer Molecular Weight Apparatus.

Results and Discussion

Table 1 shows that the polymeric complexes are much more effective than cobaloximes; this is obvious in the catalyst systems including a strong alkali. The addition of 1.0 ml of 15% aqueous potassium hydroxide or 300 mg of sodium isopropoxide instead of 15% aqueous sodium hydroxide had the same enhancing effect; however that of 1.0 ml of aqueous lithium hydroxide or calcium hydroxide did not. The absorption spectrum of the green solution obtained as a result of the reaction of POX-Co-S, POX-Co-R or phenylpyridinatocobaloxime(III) with sodium borohydride is similar to that of a cobaloxime(I) or vitamine B_{12s} (containing a Co(I)),[6] as is shown in Fig. 1. The formation of a cobaloxime(III) with a Co–C bond resulting from the reaction of a cobaloxime(I) with styrene has also previously been shown.[7] These facts suggest that a species containing a Co(I) plays an important role in the polymerization. It is well known that unstable monomeric binuclear Co(II) complexes including a cobaloxime(II) disproportionate into a Co(I) and a Co(III) complex in a strong alkaline solution.[8] POX-Co-R may consist partly of binuclear Co(II) units, which might contribute to make the polymeric catalyst more effective. However, a system containing a binuclear cobaloxime(II) (dimeric pyridinato- or aquocobaloxime(II)) could not polymerize styrene under the same conditions as those employed for the polymeric catalyst. POX-Co-R can be converted into POX-Co-S again by the addition of phenylthiol under nitrogen; this is supported by a comparison of their elemental analyses, IR spectra, and reactivities towards sodium borohydride.

Table 1. Polymerization of styrene

Catalyst system	Medium[b] ROH, R=	Product PS[c] (g)/Co (gram atom)
PhS-Co-Pyr[d]+I[e]	i-C_3H_7	4.0×10^3
PhS-Co-Ryr+I+II[f]	i-C_3H_7	3.4×10^3
POX-Co-S-1+I+II	CH_3	—

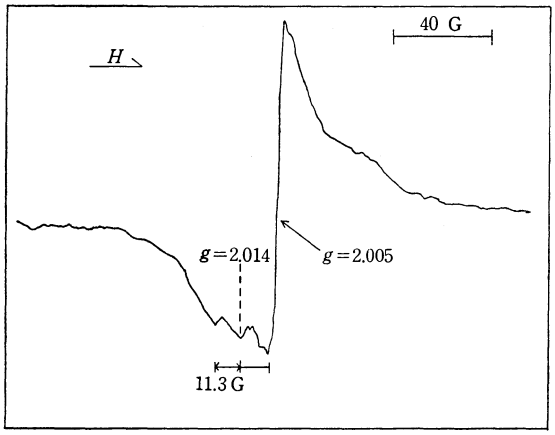

Fig. 2. ESR spectrum of the polyoxime–cobalt complex (POX–Co-R-1). Measured in the solid state (powder) at 77 K under vacuum.

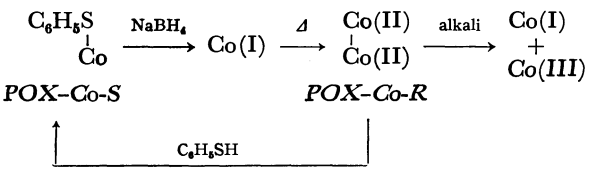
Table 2. "Michael" type addition reaction of an alcohol to acrylaldehyde[a)]

Catalyst	Alcohol, ROH R=	Product, $ROCH_2CH_2CHO$ mol/gram atom of Co
POX–Co–1	CH_3	0.1×10
POX–Co–R–1	CH_3	13.1×10
–R–1	C_2H_5	2.2×10
–R–1	i-C_3H_7	0.1×10
–R–1	n- or t-C_4H_9	—
–R–2	CH_3	15.2×10
–R–3	CH_3	14.9×10
–R–4	CH_3	0.1×10
–R–5	CH_3	—

Catalyst used: 100 mg. ROH used: 1/5 mol. Acrylaldehyde used: 1/10 mol. a) Carried out at 60—70 °C for 2 hr under nitrogen.



This interconversion was also confirmed by ESR spectroscopy. POX–Co-R exhibits an ESR signal at 77—300 K both in air and under a vacuum, as is shown in Fig. 2. The signal disappears as a result of the interconversion of POX–Co-R into –Co-S. The intensity of the signal increased with an increase in the cobalt content of the complex. The signal may be due to the low spin Co(II) of some units of POX–Co-R.

In the addition reaction, contrary to the results for the polymerization, the catalytic activity of POX–Co-R is not proportional to the cobalt content, and methanol is the most reactive among the alcohols used, as is shown in Table 2. When acrylonitrile, methyl acrylate or crotonaldehyde was employed instead of acrylaldehyde, it was recovered unchanged. On the other hand, bis(dimethylglyoximato)cobalt(II),[8)] which may be the monomeric analogue of POX–Co-R-1 in composition, and cyanopyridinato- and chloropyridinatocobaloxime-(III)[9)] catalyze like ordinary base-catalysts, such as sodium hydroxide and sodium acetate, the addition reaction of an alcohol not only to acrylaldehyde but also to acrylonitrile and methyl acrylate. The different behavior of the polymeric complexes in both catalyses must be partly ascribed to the varieties in the structure and properties of their units; however, there is, so far, no satisfactory explanation of the difference.

Studies on Xanthenyl and Thioxanthenyl Derivatives. Reactions of Xanthenyl and Thioxanthenyl Halides with Substituted-Ethylenes

Sami Bassili AWAD,* Nadia Fouad ABDUL-MALIK, and Sadek Elsayed ABDOU

Department of Chemistry, Faculty of Science, University of Cairo, Giza, Egypt

(Received August 23, 1974)

Xanthenyl and thioxanthenyl chlorides (**1**) were added to 1,1-bis-(*p*-alkoxyphenyl)-2-substituted-ethylenes (**2**) to give 1,1-bis-(*p*-alkoxyphenyl)-2-substituted-2-[xanthen(or thioxanthen)-9-yl]ethylenes (**3**). The 2-nitro-derivatives (**3**) were converted in boiling methanolic potassium hydroxide into the allenes, 1,1-bis-(*p*-alkoxyphenyl)-2-[xanthen(or thioxanthen)-9-ylidene]ethylenes (**4**). The 2-methyl(or chloro)-derivatives (**3**) reacted with bromine in the presence of hydrogen bromide, to yield xanthylium or thioxanthylium tribromide (**5**) and the corresponding 2,2-disubstituted-ethylene (**6**). The tribromides (**5**) reacted with the ethylene (**2**, Z=H) to give, after spontaneous dehydrobromination, the corresponding 2-bromo-derivatives (**3**, Z=Br).

In a preceding publication,[1] it has been shown that xanthenyl and thioxanthenyl chlorides (**1a,b**) were added to 1,1-bis-(*p*-alkoxyphenyl)ethyleness (**2**, Z=H) and their 2-bromo(or chloro)-derivatives (**2**, Z=Br or Cl) to give the corresponding 1,1-bis-(*p*-alkoxyphenyl)-2-[xanthen (or thioxanthen)-9-yl]ethylenes (**3**, Z=H) and the orresponding 1,1-bis(*p*-alkoxyphenyl)-2-bromo(or chloro)-2-[xanthen(or thioxanthen)-9-yl]ethylenes (**3**, Z=Br or Cl), respectively. We now show that each of xanthenyl and thioxanthenyl chlorides (**1a, b**) was added to 1,1-bis-(*p*-alkoxyphenyl)-2-nitro(and methyl)ethylenes (**2a—f**) to give, after spontaneous dehydrochlorination, the corresponding 1,1-bis-(*p*-alkoxyphenyl)-2-nitro-(and methyl)-2-[xanthen(or thioxanthen)-9-yl]ethylenes (**3a—l**). The 1,1-bis-(*p*-alkoxyphenyl)-2-nitroethylenes (**2a—c**) are prepared by treating the corresponding 1,1-bis-(*p*-alkoxyphenyl)-2-bromoethylenes (**2**, Z=Br) with silver nitrite.

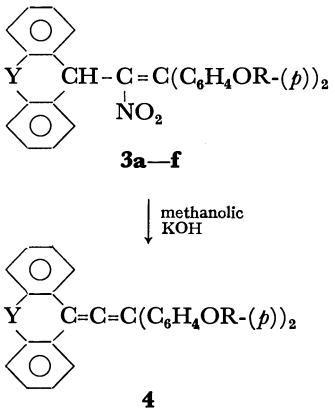
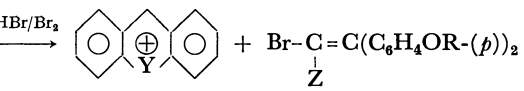
* The author to whom the correspondence is due to.

The structure of the 2-nitro-derivatives (**3a—f**) was confirmed by analytical and spectral data, and *via* treatment with methanolic potassium hydroxide to give the corresponding allenes namely, 1,1-bis-(*p*-alkoxyphenyl)-2-[xanthen(or thioxanthen)-9-ylidene]ethylenes (**4**) which were identical with the allenes previously obtained[1] by dehydrohalogenation of compounds **3** (Z=Br or Cl).



It has been shown[1] that xanthenyl(or thioxanthenyl)-ethylenes (**3**, Z=H or Br), in the presence of hydrogen bromide, cleaved with bromine to give mainly xanthylium or thioxanthylium tribromide (**5**) and 2-bromo-ethylenes **6** (Z=H or Br). The 2-methyl, and 2-chloro-xanthenyl(or thioxanthenyl)-derivatives (**3**, Z=CH_3 or Cl) cleaved similarly to give compounds **5** and **6**.



5: Y=O, S

6: Z=CH_3, Cl

On the other hand, the tribromides (**5**) reacted with 1,1-bis-(*p*-alkoxyphenyl)ethylenes (**2**, Z=H) to afford mainly in each case the corresponding 1,1-bis-(*p*-alkoxyphenyl)-2-bromo-2-[xanthen(or thioxanthen)-9-yl]ethylenes (**3**, Z=Br). This could be achieved through the reaction of the ethylenes **2** (Z=H) with the molecular bromine originated from the compounds **5** to give compounds **6** (Z=H) together with compounds **7**. The latter reacted readily, *in situ*, to give, after spontaneous dehydrobromination of the inter-

Table 1. 1,1-bis-(*p*-alkoxyphenyl)-2-nitro(and methyl)-2-[xanthen(and thioxanthen)-9-yl]ethylenes

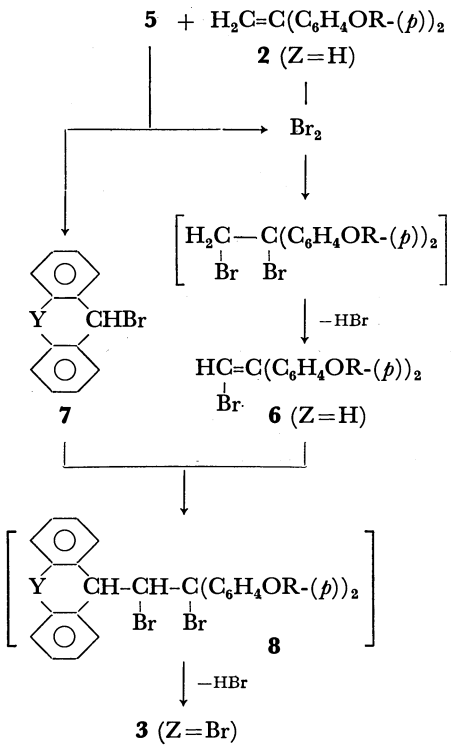
mediate **8**, the 2-bromo-derivatives **3** (Z=Br).



In support of the above scheme, the following may be mentioned:

(i) The tribromides **5** reacted readily with 1,2-di-*p*-methoxyphenylethylene to give mainly the relatively stable 1,2-di-*p*-methoxyphenyl-1,2-dibromoethane and the corresponding xanthenyl (or thioxanthenyl) bromide (**7**).

(ii) When treated with excess dimethylaniline, for one minute, the tribromides **5** afforded *p*-bromodimethylaniline together with 9-*p*-dimethylaminophenylxanthene(or thioxanthene).

(iii) It has been reported that compounds **5**[2,3] lost their halogen when treated with alkali or hydroxylic solvents, to give xanthene(or thioxanthene) and xanthone(or thioxanthone).

(iv) Xanthenyl(or thioxanthenyl) bromide (**7**) was added readily to 1,1-bis-(*p*-methoxyphenyl)-2-bromoethylene (**6**, Z=H) at room temperature or at −5 °C to give compound **3** (Z=Br).

Experimental

All melting points are uncorrected. The infrared spectra were recorded with a Pye-Unicam SP 1000 spectrophotometer.

*1,1-Bis-(*p*-alkoxyphenyl)-2-nitroethylenes (2a—c).* A mixture of each of 1,1-bis-(*p*-alkoxyphenyl)-2-bromoethylene (0.01 mol), silver nitrite (0.03 ml) and acetone (50%, 100 ml) was heated to boiling for 10 hr and then filtered while hot. The filtrate was cooled and the product was collected and purified by crystallization from 80% ethanol. Yields: 80, 75 and 60% respectively. **2a** Mp and mixed mp[4] 112 °C. Found: C, 67.12; H, 5.42; N, 4.72%. Calcd for $C_{16}H_{15}NO_4$: C, 67.36; H, 5.26; N, 4.91%. **2b** Mp 65 °C. Found: C, 69.35; H, 5.82; N, 4.87%. Calcd for $C_{18}H_{19}NO_4$: C, 69.00; H, 6.07; N, 4.50%. **2c** Mp 102 °C. Found: C, 69.95; H, 6.62; N, 3.91%. Calcd for $C_{20}H_{23}NO_4$: C, 70.38; H, 6.74; N, 4.10%.

*1,1-Bis-(*p*-isopropoxyphenyl)-2-methylethylene (2f).* 0.1 mol of *p,p'*-di-isopropoxybenzophenone was added to a solution of methylmagnesium iodide (0.2 mol) in dry ether (100 ml) and the mixture was left overnight. The reaction mixture was decomposed with a cold solution of ammonium chloride. The ethereal layer was separated, washed with water, dried (Na_2SO_4) and filtered. The solvent was recovered and the oily product was distilled *in vacuo* to give **2f**, Bp 120 °C /20 Torr. Found: C, 80.48; H, 8.12%. Calcd for $C_{21}H_{26}O_2$: C, 80.13; H, 8.39%.

*1,1-Bis-(*p*-alkoxyphenyl)-2-nitro(or methyl)-2-[xanthen(or thioxanthen)-9-yl]ethylenes (3a—1).* Ten mmol of each of compounds **2a—f** was added to a solution of ten mmol of each of xanthenyl and thioxanthenyl chlorides (**1a, b**) in ether (100 ml) (prepared by passing hydrogen chloride through a cold ethereal solution of 9-xanthenol[5] or 9-thioxanthenol[6] till saturation). The mixture was left overnight. Ether was distilled off and the product was crystallized from ethanol to give the corresponding derivatives **3a—1** (Table 1).

Yields: 50—60%. IR for each of compounds **3a—f**: 2990 (CH), 1525 and 1360—1290 (NO_2) cm^{-1}.

*1,1-Bis-(*p*-alkoxyphenyl)-2-[xanthen(or thioxanthen)-9-ylidene]-ethylene (4).* A solution of each of the 2-nitro-derivatives **3a—f** (1 g) in methanolic potassium hydroxide (2 g in 100 ml) was heated to boiling (water-bath) for 5 hr, cooled, diluted with water and extracted with ether. The solvent was washed with water, dried (Na_2SO_4) and recovered. The residue was crystallized from ethanol–ether to give almost colorless crystals identified (mp and mixed mp[1]) as compounds **4a—f**. Yield 90%.

*Reactions of Bromine with Compounds 3. (a) With 1,1-Bis-(*p*-alkoxyphenyl)-2-methyl-2-[xanthen(or thioxanthen)-9-yl]ethylenes (3g—1):* (i) Bromine (1.6 g, 0.01 mol) in chloroform (5 ml) was added to a solution of compound **3** g (2.17 g, 0.005 mol)

in the same solvent (20 ml) which was previously saturated with hydrogen bromide. Instantaneous deep orange precipitate of xanthylium tribromide (2.1 g), mp and mixed mp[2] 164 °C, was formed. The filtrate was evaporated *in vacuo* and the residue was crystallized from ethanol to give colorless crystals (1.5 g) identified (mp and mixed mp[7]) as 1,1-bis-(*p*-methoxyphenyl)-2-bromo-2-methylethylene.

(ii) The repetition of (i) using compound **3h** (2.25 g, 0.005 mol) gave thioxanthylium tribromide (2.2 g) as scarlet-red precipitate, mp and mixed mp[3] 185 °C, and 1,1-bis-(*p*-methoxyphenyl)-2-bromo-2-methylethylene (1.5 g).

(iii) The same reaction above using **3j** or **k** (0.005 mol) gave xanthylium tribromide (2.1 g) or thioxanthylium tribromide (2.2 g) together with, in each case, 1,1-bis-(*p*-ethoxyphenyl)-2-bromo-2-methylethylene (1.7 g), mp 71 °C. Found: C, 63.50; H, 5.46; Br, 22.20%. Calcd for $C_{19}H_{21}BrO_2$: C, 63.16; H, 5.81; Br, 22.16%.

*(b) With 1,1-Bis-(*p*-alkoxyphenyl)-2-chloro-2-[xanthen(or thioxanthen)-9-yl]ethylenes (6, Z=CH_3 or Cl).* When the above experiments (a; i, ii, iii) were repeated using the corresponding *p*-methoxy (or ethoxy)-2-chloro-derivatives (0.005 mol), similar results were obtained. Thus in each case the corresponding xanthylium tribromide (2.1 g) or thioxanthylium tribromide (2.2 g) together with 1,1-bis-(*p*-methoxyphenyl)-2-bromo-2-chloroethylene (1.6 g), mp and mixed mp[8] 103 °C or 1,1-bis(*p*-ethoxyphenyl)-2-bromo-2-chloroethylene, mp and mixed mp[8] 115 °C, were isolated respectively.

(c) When the above experiments, (a) and (b), were carried out using equimolecular quantities of bromine (0.005 mol), the same products were obtained together with unchanged derivatives equal to half the quantities of the corresponding starting materials.

*Reaction of Xanthylium(or thioxanthylium)-tribromide (5) with 1,1-Bis-(*p*-alkoxyphenyl)ethylenes (2, Z=H).* Compound **6** (0.005 mol) was added to a solution of each of the ethylenes **2**, (Z=H) (0.005 mol) in chloroform (50 ml) and the whole mixture was heated to boiling (water-bath) for 3 hr. The solvent was recovered and the residue was crystallized from ethanol to give colorless crystals identified (mp and mixed mp[9]) as 1,1-bis-(*p*-alkoxyphenyl)-2-bromo-2-[xanthen-9-yl]-ethylene (**3**, Z=Br) respectively. Yield 90%.

When the above experiments were repeated using compound **5** (Y=S) (0.005 mol), 1,1-bis-(*p*-alkoxyphenyl)-2-bromo-2-[thioxanthen-9-yl]ethylene with mp which showed no depression when mixed with authentic samples[1] was obtained. Yield 85%.

*Reactions of 5 with 1,2-Di-(*p*-methoxyphenyl)ethylene.* (a) A mixture of compound **5** (Y=O) (2.1 g) (0.005 mol), 1,2-di-(*p*-methoxyphenyl)ethylene (1.2 g) and chloroform (50 ml) was heated to boiling for 1 hr. The solvent was concentrated, diluted with petrol (60—80 °C) and cooled to give 1,2-dibromo-1,2-di-(*p*-alkoxyphenyl)ethane (1.9 g), mp and mixed mp[10] 178 °C. The filtrate was concentrated till near dryness and the residue was crystallized from dry petrol (40—60 °C) to give xanthenyl bromide (**7**) (1 g), mp and mixed mp[2] 87 °C.

(b) Repetition of experiment (a) using compound **5** (Y=S) (2.18 g, 0.005 mol) gave the 1,2-dibromo-1,2-di-(*p*-methoxyphenyl)ethane (1.9 g) and thioxanthenyl bromide (1.1 g).

Reactions of 5 (Y=O, S) with Dimethylaniline. A mixture of compound **5** (Y=O or S) (1 g) and dimethylaniline (10 ml) was heated to boiling for 1 min, cooled, made alkaline with aqueous sodium hydroxide and then steam-distilled. In each case, dimethylaniline passed over followed by *p*-bromodimethylaniline (0.3 g), mp and mixed mp[11] 55 °C. The non-steamable portion was cooled and filtered off. The product was crystallized from ethanol to give 9-*p*-dimethylaminophenylxanthene (0.6 g), mp and mixed mp[12] 157 °C, or 9-*p*-dimethylaminophenylthioxanthene (0.6 g), mp 175 °C. Found: N, 4.72; S, 9.94%. Calcd for $C_{21}H_{19}NS$: N, 4.41; S, 10.09%.

Addition of Xanthenyl Bromide (7) to Compound 6 (Z=H). Xanthenyl bromide (0.005 mol) in chloroform (20 ml) was added to a solution of compound **6** (Z=H, R=MeO) (0.005 mol) in chloroform (20 ml) cooled to −5 °C. The reaction mixture was kept at −5 °C for 1 hr and then chloroform was washed with cold sodium hydroxide solution (5%), water, dried, filtered and recovered. The residue was crystallised from ethanol to give colorless crystals identified (mp and mixed mp[1]) as 1,1-bis-(*p*-methoxyphenyl)-2-bromo-2-[xanthen-9-yl]ethylene. Yield 40%.

Enthalpies of Combustion of Organic Compounds. II. L- and D-Glutamic Acid

Minoru SAKIYAMA and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received November 1, 1974)

Synopsis. Enthalpies of combustion of L- and D-glutamic acid in the crystalline state have been measured by oxygen bomb calorimetry. Standard enthalpies of formation at 298.15 K have been determined.

Among optically active aliphatic amino acids, the enthalpy of combustion has been determined for both isomers in few compounds. The only exception is leucine in the crystalline state and the values obtained by Huffman *et al.*[1] of both isomers coincide with each other. In this paper the enthalpies of combustion of L- and D-glutamic acid in the crystalline state are reported. The idealized combustion reaction to which the energies and enthalpies of combustion refer is the following one at 25 °C:

$$C_5H_9O_4N(c) + 5.25O_2(g) = 5CO_2(g) + 4.5H_2O(l) + 0.5N_2(g).$$

Materials. L-Glutamic acid (Takara Kōsan Co. Ltd.) and D-glutamic acid (Ajinomoto Co. Ltd.) were purified by recrystallization from aqueous solution. Crystals were dried, pelletted and stored on silica gel for at least 72 h before combustion. X-Ray diffraction using Cu-Kα radiation shows that the crystals belong to the β-phase[2] (the most stable modification).

Apparatus, Procedures and Calculations. An isoperibol, rotating, precision bomb-calorimeter[3] was used without rotation. In order to facilitate complete combustion of the samples, *ca.* 0.2 g of liquid paraffin (Wakō Pure Chemical Co. Ltd.) was used as an auxiliary oil. No weight loss was observed when the liquid paraffin was placed in an open dish in air for several hours. The standard energy of combustion of the oil was determined by six combustion experiments. The results of the individual combustion experiments in term of $\Delta E_c^\circ/M$ at 298.15 K are −45909.9, −45924.5, −45905.4, −45913.0, and −45909.4 J g^{-1}. Mean and standard deviations of the mean are −45909.3±4.1 J g^{-1}. Calorimetric procedures and methods of calculation are similar to those described previously.[3] The energy equivalent of the standard calorimetric system[3] was found from six calibration experiments by using benzoic acid (Standard Reference Material 39i, National Bureau of Standards, U.S.A) to be 15164.4±0.8 J K^{-1}, where the uncertainty is the standard deviation of the mean.

Auxiliary Quantities. The molecular weights were computed on the basis of the 1961 table of atomic masses. The composition formula and the values (for 25 °C) of density, ρ, specific heat capacity, c_p, and $(\partial E/\partial p)_T$ for the combustible substances are given in Table 1. Two crucibles were used. One (#1, wt. 11.141 g) is made of Pt-10% Rh alloy with density and specific heat capacity of 20.50 g cm^{-3} and 0.1464 J K^{-1} g^{-1}, respectively, at 25 °C. The other (#2, wt. 11.137 g) is made of platinum with density and specific heat capacity of 21.40 g cm^{-3} and 0.1362 J K^{-1} g^{-1}, respectively, at 25 °C.

Table 1. Auxiliary quantities used in the calculation of standard energy of combustion

	ρ / g cm^{-3}	c_p / J K^{-1} g^{-1}	$(\partial E/\partial p)_T$ / J kPa^{-1}g^{-1}
L- and D-Glutamic acid $C_5H_9O_4N$	1.538	1.19	(−0.60)[a]
Auxiliary oil $CH_{1.855}$	0.882	2.22	−2.60
Fuse $CH_{1.860}O_{0.930}$	1.5	1.70	−2.94

a) Estimated value.

Results

Six combustion experiments were carried out with L- and D-glutamic acid. Data from combustions selected as typical are given in Table 2. Notations follow those given by Hubbard *et al.*[5] except for the following: Δm (H_2O cal.), excess water in the calorimeter can; ΔE (std. state), sum of items 81—85, 87—89, 93, and 94 in ref. 5. Results of the individual combustion experiment in terms of $\Delta E_c^\circ/M$ at 298.15 K are summarized as follows: −15298.6, −15293.1, −15293.8, −15307.3, −15299.3, −15307.1, mean and standard deviation of the mean −15300.3±2.5 J g^{-1} for L-glutamic acid and −15304.3, −15304.0, −15309.2, −15301.5, −15309.7,

Table 2. Typical combustion experiments

	L-Glutamic acid	D-Glutamic acid
m^1(compd.)/g	1.16927	1.17672
m^1(auxil. oil)/g	0.20518	0.19690
m^1(fuse)/g	0.00265	0.00234
m^1(H_2O tot.)/g	1.081	1.090
m^1(Pt)/g	11.141	11.157
Δm^1(H_2O cal.)/g	−0.074	0.104
P^1(gas)/MPa	3.040	3.040
T_i/°C	23.15799	23.17928
T_f/°C	24.98876	24.99227
ΔT_{corr}/°C	0.02458	0.02448
$n^f(HNO_3)$/mol	0.000793	0.000815
ΔE_{ign}/J	5.60	5.78
$\Delta E_{dil_n}(HNO_3)$/J	−0.11	−0.12
$\Delta E_{decomp}(HNO_3)$/J	46.69	48.00
ΔE(std. state)/J	17.71	17.70
ε^1(cont.)/J K^{-1}	18.17	18.08
ε^f(cont.)/J K^{-1}	20.39	20.28
ΔE°_c/J g^{-1}	−15299.3	−15301.5

Table 3. Thermodynamic quantities of L- and D- glutamic acid

	ΔE_c° / kJ mol^{-1}	ΔH_c° / kJ mol^{-1}	ΔH_f° / kJ mol^{-1}
L-Glutamic acid	-2251.09 ± 0.93	-2250.47 ± 0.93	-1003.32 ± 1.16
D-Glutamic acid	-2251.94 ± 0.68	-2251.32 ± 0.68	-1002.47 ± 0.97

-15305.1, mean and standard deviation of the mean -15305.6 ± 1.3 J g^{-1} for D-glutamic acid. Thermochemical quantities have been calculated from these results and are given in Table 3. In the calculation of the standard enthalpies of formation, CODATA key values[6] were employed for the standard enthalpy of formation of $H_2O(l)$ and $CO_2(g)$. Uncertainties in Table 3 are uncertainty interval recommended by Rossini,[7] *i. e.*, twice the final overall standard deviation of the mean.

Discussion

The difference in the standard enthalpies of combustion of L- and D-glutamic acids as observed in the present work is 0.85 kJ mol^{-1}, which is 0.038% of the ΔH_c° values and well within the sum of each uncertainty interval. It may be stated that no difference is found between the enthalpy of combustion values of L- and D-glutamic acid within the limit of precision of the present work.

The enthalpy of combustion of L-glutamic acid has been reported by Fischer and Wrede,[8] Emery and Benedict,[9] Huffman *et al.*,[10] Oka,[11] and Tsuzuki and Hunt.[12] In compilations published recently,[13,14] Tsuzuki's value[12] ($\Delta H_c^\circ=-2244.09\pm0.75$ kJ mol^{-1}, where uncertainty is the uncertainty interval) is adopted as a selected value. The present result on L-glutamic acid is in agreement with that of Huffman *et al.*[10] ($\Delta H_c^\circ=-2248.52\pm1.17$ kJ mol^{-1}, where uncertainty is the uncertainty interval) within the assigned uncertainty intervals, while the present result is 6.3 kJ mol^{-1} more negative than the selected value mentioned above. Nothing has ever been reported on the enthalpy of combustion of D-glutamic acid.

The authors would like to express their hearty thanks to Dr. K. Toi, Ajinomoto Co. Ltd., and Dr. F. Sakiyama, the Institute for Protein Research, Osaka University, for their cooperation in obtaining the purified samples. The assistance of Mr. A. Kamaguchi and Miss. T. Sato is appreciated.

Oxidation of a Conductive Polymer-TCNQ Salt with Atmospheric Oxygen

Kenji NAKATANI, Tadayoshi SAKATA, and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received February 3, 1975)

Synopsis. The oxidation reaction of conductive poly-4-vinylpyridinium ($P4VP^+$) tetracyano-*p*-quinodimethanide-($TCNQ^-$) with oxygen has been studied. The main product of this reaction is found to be α,α-dicyano-*p*-toluoylcyanide. An interesting difference in reactivity was observed between the polymer salt and the ethanol solution of the monomer salt.

In a previous paper,[1] we reported the electronic spectra of the $P4VP^+TCNQ^-$ and the complex salt including neutral TCNQ ($P4VP^+TCNQ^-TCNQ_x$), which form highly conductive films.[2] The conduction mechanism was discussed. The $P4VP^+TCNQ^-$ film is green in a vacuum but by the introduction of oxygen, the color changes gradually to light brown and the conductivity descreases. Hatano *et al.* reported the oxidation of the γ-methylpyridinium TCNQ salt in acetonitrile solution by oxygen.[3] Sanada *et al.* reported that the deterioration of TCNQ salts of cationic polymer was caused by oxygen and moisture.[4] However, the mechanism of the oxidation and its product have not been clarified.

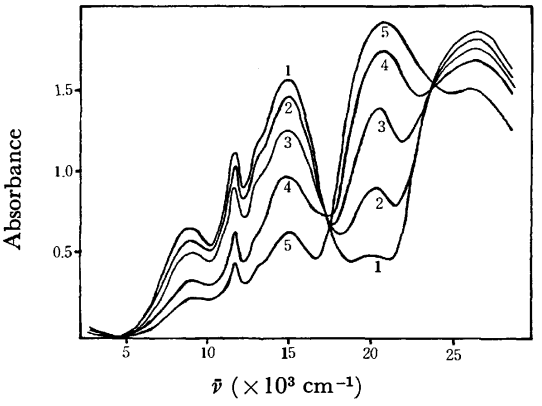

Fig. 1. Electronic absorption spectral change of the polymer film after the introduction of air at 288 K.
1: 2 min, 2: 1 hr 15 min, 3: 3 hr 50 min, 4: 20 hr, 5: 66 hr.

Coherent films of $P4VP^+TCNQ^-$ were deposited on quartz plates and kept in a vacuum. The change of absorption spectra after the introduction of oxygen was measured at various temperatures. As shown in Fig. 1, the intensities of the absorption bands attributable to TCNQ monomer at 845 nm, $TCNQ^-$ aggregate at 665 nm, and the charge transfer band between $TCNQ^-$ radicals at 1100 nm decreased with time after the introduction of oxygen, and a new absorption band appeared at 475 nm. Another absorption was found to appear in the infrared region above 1800 nm (Fig. 2), which disappeared with the lapse of time. Since this IR absorption is attributable to a charge resonance band between $TCNQ^-$ and neutral TCNQ, neutral TCNQ is concluded to be one of the products, formed by an electron transfer reaction such as:

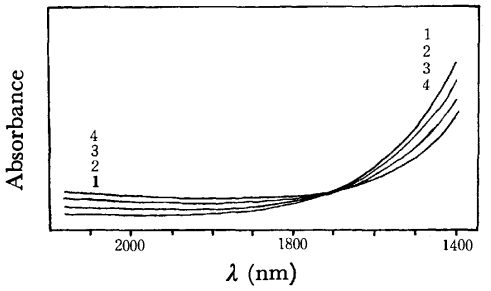

Fig. 2. Infrared absorption spectral change after the introduction of air at 300 K.
1: 0 min, 2: 15 min, 3: 40 min, 4: 90 min.

$$TCNQ^- + O_2 \longrightarrow TCNQ + O_2^-$$

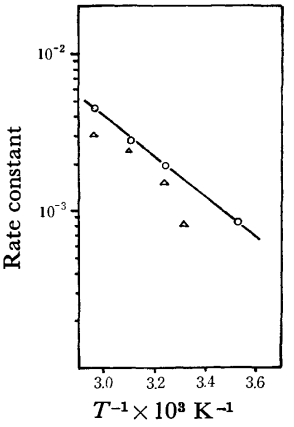

Fig. 3. Logarithmic rate constant plot *versus* inverse absolute temperature, calculated
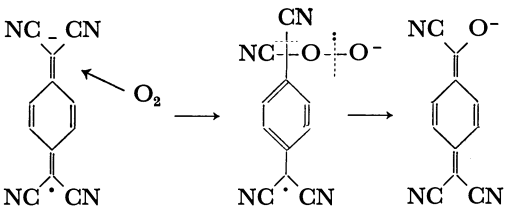
○: from the change of TCNQ monomer band,
△: from the change of CT absorption band.

The logarithm of the absorbance of $TCNQ^-$ monomer band at 845 nm and that for the charge transfer band between $TCNQ^-$s at 1100 nm of the film under atmosphere of oxygen show a good linear relation with time, showing that the reaction is of the first order as regards the concentration of $TCNQ^-$. The activation energy obtained from the Arrhenius plot of the rate constants obtained from the absorption band is 5.7 kcal/mol. The reaction rate constant calculated from the decay of the monomer band was found to be larger than the one calculated from that of the charge transfer band.

The oxidized polymer film was extracted with ethanol and the extract was separated by thin-layer chromatography using acetone–benzene (1:1). The main orange-colored product was identified to be α,α-dicyano-*p*-toluoylcyanide, because the band shape and peak

positions (λ_{max}=476, 276 nm) of the electronic spectrum agreed with those of sodium α,α-dicyano-*p*-toluoylcyanide, synthesized according to the literature.[5] The IR spectra of the main reaction products also show all the strong bands of the synthesized sodium salt (for example, $\nu_{C=O}$=1645 cm^{-1}, $\nu_{C\equiv N}$=2200, 2160 cm^{-1}), together with some impurity bands.[6] The R_f value in the thin-layer chromatography of the orange-colored product agreed with that of the sodium α,α-dicyano-*p*-toluoylcyanide. The reaction might proceed as follows,



This deterioration reaction of the polymer TCNQ salt is sensitive to the environment of the anion. *N*-methylpyridinium TCNQ was not deteriorated by oxygen even when it was exposed to air for several weeks.

When the aerated ethanol solution of Li^+TCNQ^- was irradiated in the UV region, the color of the solution changed remarkably from green to orange. The resulting photochemical reaction product was found to be also α,α-dicyano-*p*-toluoylcyanide.

It is interesting that the polymer film reacts with oxygen in the dark, while the reaction of Li^+TCNQ^- in solution needs UV excitation.

Charge Transfer Interactions between Oxygen and the Anion Radicals of Tetracyanoquinodimethane and Tetracyanoethylene

Tadayoshi SAKATA, Toshihiro OKAI,* and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received February 24, 1975)

Synopsis. The spectra of the anion radicals of tetracyanoquinodimethane and tetracyanoethylene formed on porous Vycor glass change by introducing O_2 at 77 K. The main features are broadening and slight energy shift of the bands and appearance of a new band. These changes are explained by assuming the charge transfer interactions between O_2 and the anion radicals.

Anion radicals are expected to act as strong electron donors, since their ionization potentials are very low. It is expected therefore that they interact or react easily with O_2, a weak electron acceptor. Tsubomura *et al.* studied extensively the charge transfer (CT) interactions between O_2 and a large number of organic molecules.[1-3] In this paper, the interactions between O_2 and anion radicals of tetracyanoquinomethane (TCNQ) and tetracyanoethylene (TCNE) formed on Vycor glass are reported.

TCNQ and TCNE were adsorbed on porous Vycor glass plates *in vacuo* and their anions were produced by introducing triethylamine. The electronic absorption spectra of the anions agreed well with those reported in the literature.[4,5] The sample was cooled down to 77K and oxygen was introduced into the sample cell, since these anion radicals react easily with O_2 at room temperature.

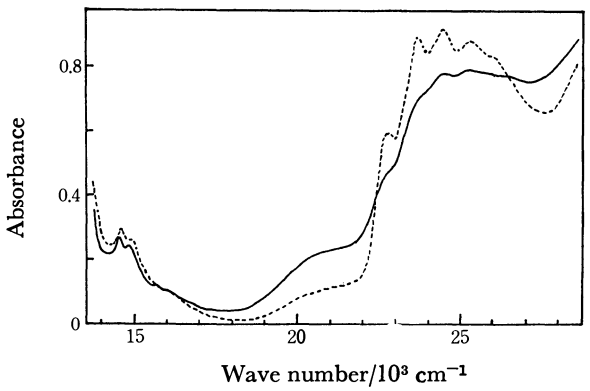

Fig. 1. Absorption spectra of $TCNQ^-$ at 77 K before (----) and after (——) the introduction of O_2.

Figure 1 shows the electronic absorption spectra of the anions before and after the introduction of O_2 at 77 K. The band systems at ~15000 cm^{-1} showing some vibrational structures are attributable to the first excited state of $TCNQ^-$.[6] The strong band systems centered at around 25000 cm^{-1} is attributable to the second excited state of the anion. The weak absorption at 20500 cm^{-1} might be due to an impurity because it cannot be observed in the spectrum of $TCNQ^-$.[7]

* Present address: Nippon Paint Co., Ltd., Osaka.

The spectra show that the second band system of the anion becomes broad and the first one shifts slightly to red (~50 cm^{-1}), its intensity decreasing by the introduction of O_2. It is also shown that the absorption from 18000 to 22000 cm^{-1} swells, suggesting the appearance of a new absorption band. When O_2 is removed, the spectrum is mostly restored, showing that these spectral changes due to O_2 are reversible. Swelling of the absorption around 18000—22000 cm^{-1} with the introduction of O_2 and its reversibility with removal of O_2 were also observed in the case where *N,N,N',N'*-tetramethyl-*p*-phenylenediamine was used as a reducing agent instead of triethylamine.

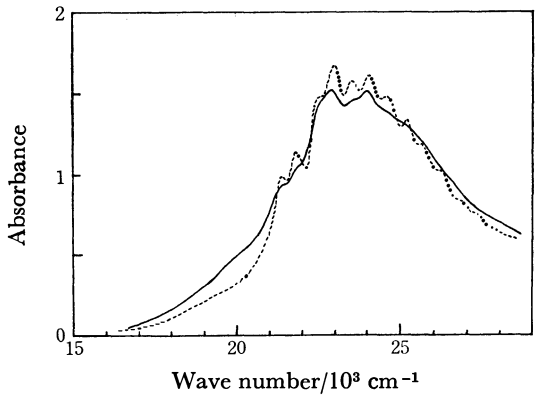

Fig. 2. Absorption spectra of $TCNQ^-$ at 77 K before (----) and after (——) the introduction of O_2.

Figure 2 shows similar results on $TCNE^-$. The vibrational structure characteristic of $TCNE^-$ almost disappears upon introduction of O_2, and the absorption around 20000 cm^{-1} swells, suggesting the appearance of a new band. The reversibility with O_2 removal was also observed.

These results can be explained by assuming weak charge transfer (CT) interactions between O_2 and the anion radicals (A^-). The vertical CT energy (E^v_{CT}) from A^- as an electron donor to O_2 can be expressed by[10]

$$E^v_{CT} = I^v_p(A^-) - E^v_A(O_2) + P(A\cdots O_2^-) - P(A^-\cdots O_2) \quad (1)$$

where I^v_P and E^v_A are the vertical ionization potential and the vertical electron affinity, respectively, and $\Delta P = P(A\cdots O_2^-) - P(A^-\cdots O_2)$ represents the change in the polarization energy during the optical transition. Taking $I^v_P(A^-)$ to be roughly equal to $E_A(A)$, $I^v_P(TCNQ^-)$ and $I^v_P(TCNE^-)$ are estimated to be 1.7 eV[11] and 2.0 eV,[12] respectively. The adiabatic electron affinity of O_2 was determined to be 0.43 eV.[13] The vertical one, $E^v_A(O_2)$, is probably a littly negative.[1] As a counter balance to the adoption of $E_A(A)$ values for $I^v_P(A^-)$ which must cause some underestimation, it seems most

appropriate here to take $E_A^V(O_2)$ to be roughly zero. Inspite of the difficulty in evaluating the polarization energies rigorously, it seems reasonable to assume 1.0 eV for the value of ΔP.[14] Under these evaluations, the transition energies E_{CT}^V for $TCNQ^-\cdots O_2$ and $TCNE^-\cdots O_2$ are obtained as 2.7 eV (22000 cm^{-1}) and 3.0 eV (24000 cm^{-1}), respectively, in fair agreement with the spectral position where swelling occurs.

The reversible change of the absorption spectra around 20000 cm^{-1} for both anions is thus reasonably attributable to the CT interactions between O_2 and the radical anions. The small red shift and intensity change for the first band of $TCNQ^-$ and the broadening of the band shape in both cases are then explained by the CT interaction between O_2 and the anion radicals.

14) For the CT complex between O_2 and I^- in ethanol, E_{CT}^V is about 4.4 eV.[15] Using $I_P^V(I^-)=3.1$ eV and $E_A^V(O_2)=0.15$ eV, ΔP is obtained as 1.45 eV. Therefore $\Delta P=1.0$ eV in our case seems to be a reasonable value, taking the difference of the environments and the ionic radii into consideration.

The Syntheses and Properties of Mixed Cobalt(III) Complexes Containing 2-Mercaptoacetic Acid or 3-Mercaptopropionic Acid

Kiichi Hori

Department of Chemistry, Faculty of Science, Yamagata University, Yamagata 990

(Received December 6, 1974)

Synopsis. The following mixed cobalt(III) complexes were prepared and characterized: $[Co(SCH_2COO)en_2]X$ and $[Co(SCH_2CH_2COO)en_2]X$, where X is a chloride or iodide ion. Those complexes are common mononuclear complexes, in which the mercaptocarboxylic acids of the ligands function as bidentate ligands.

As a part of a series of the coordinating behavior of thiols in cobalt(III) complexes, mixed cobalt(III) complexes containing 2-aminoethanethiol[1] or 2-mercaptoethanol[2] have been reported. For those complexes, two type are found, one being mononuclear and the other binuclear; the coordinated thiolic sulfurs of the ligands are terminal and bridged respectively. This work was undertaken in order to prepare mixed cobalt(III) complexes containing 2-mercaptoacetic acid or 3-mercaptopropionic acid and to compare the results with the previous ones.

Experimental

Preparation. *$[Co(SCH_2COO)en_2]X$ (X is Cl or I)*: Twenty millilitters of an aqueous solution containing 0.9 g of 2-mercaptoacetic acid and 1.1 g of sodium hydroxide were stirred, drop by drop, into a solution of 2.8 g of *trans*-$[CoCl_2en_2]Cl$ in water (40 ml). The mixture was further stirred for 30 min and concentrated to half its volume *in vacuo*, and then we added 4 g of potassium iodide. On standing, a crude product of iodide was precipitated. Recrystallization was carried out from water.

Found: C, 18.64; H, 4.71; N, 14.35%. Calcd for $C_6H_{18}O_2N_4SICo$: C, 18.19; H, 4.59; N, 14.15%.

When the concentration of the starting solution was higher, $Na_3[Co_3(SCH_2COO)_6]$[3] was also obtained.

The solution of the corresponding chloride was obtained from the solution of iodide by passing it over chloride-form anion-exchange resin. The solution was concentrated *in vacuo* and then cooled. The chloride thus precipitated was recrystallized from a small volume of water by adding ethanol.

Found: C, 24.18; H, 5.88; N, 18.11%. Calcd for $C_6H_{18}O_2N_4SClCo$: C, 24.64; H, 5.97; N, 18.39%. Absorption maxima, nm(log ε): 518(2.14), 382(shoulder) (2.4), and 282 (4.03).

$[Co(SCH_2CH_2COO)en_2]X$ (X is Cl or I): These complexes were prepared by a method similar to that described above, except that 1.05 g of 3-mercaptopropionic acid were used instead of 2-mercaptoacetic acid.

Found (Iodide): C, 20.71; H, 5.31; N, 14.06%. Calcd for $C_7H_{20}O_2N_4SICo$: C, 20.49; H, 4.92; N, 13.66%. Found (Chloride): C, 26.25; H, 6.17; N, 17.33%. Calcd for $C_7H_{20}O_2N_4SClCo$: C, 26.37; H, 6.34; N, 17.58%. Absorption maxima, nm (log ε): 525(2.14), 385(shoulder) (2.4), and 291(4.10).

Apparatus. The same instruments as described previously were used.[2]

Results and Discussion

The absorption spectra of the complexes are shown in Fig. 1, together with those of the related complexes. The absorption spectra of the complexes are similar to that of $[Co(SCH_2CH_2NH_2)en_2]Cl_2$,[1] but they are not similar to that of $[Co_2(SCH_2CH_2NH_2)_2dien_2]Cl_4$,[1] which is a binuclear complex bridged by the thiolic sulfurs of ligands. The maximum values of the first absorption band for the present complexes and $[Co(SCH_2CH_2NH_2)en_2]Cl_2$ are regularly shifted to longer wavelengths in the order of the 2-aminoethanethiolato, 2-mercaptoacetate, and 3-mercaptopropionate complexes. The molar conductivities of the complexes show the values of 103—107 mho·cm^{-1}, indicating that they are 1:1-type electrolytes. From all of these facts, it was concluded that the complexes have configurations similar to that of $[Co(SCH_2CH_2NH_2)en_2]Cl_2$, in which a thiolic sulfur of the ligand is combined with a cobalt(III) ion.

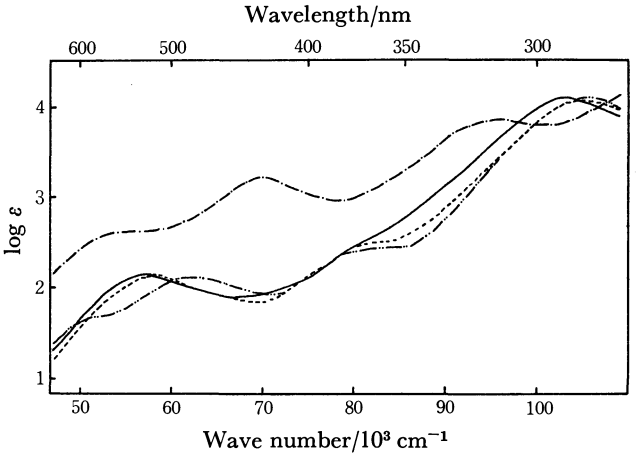

Fig. 1. Absorption spectra of the complexes.
-·-·-: $[Co(SCH_2CH_2NH_2)en_2]Cl_2$, ----: $[Co(SCH_2COO)en_2]Cl$, ——: $[Co(SCH_2CH_2COO)en_2]Cl$, -··-: $[Co_2(SCH_2CH_2NH_2)_2dien_2]Cl_4$.

The infrared spectral data of the complexes are summarized in Table 1, together with those of the related complexes. The assignments of the bands shown in the table were made tentatively by reference to the spectra of the related complexes. In all the complexes, the bands indicating the presence of the coordinated ethylenediamine and carboxylato groups are observed.[4,5] No ν(S–H) band are observed in the 2500—2600 cm^{-1} region. From the infrared spectra it was also considered that the complexes have the configurations shown above. In $[Co(SCH_2CH_2COO)en_2]Cl$, the wave number of the ν_a(COO) band is higher than those of usual carboxylato

complexes. It was assumed, comparing the spectra of the chloride and the related complexes and considering the deuterated effects, that the shift in the chloride is due to the intramolecular hydrogen bond. The ν(Co–N) and ν(Co–O) bands of the complexes were assigned by considerations similar to that of the cobalt(III) complexeswith (2-aminoethylthio) acetic acid.[6] The ν(Co–S) band for the present cobalt(III) complexes is expected, from the bands assignments of the related complexes,[7] to appear in the 280—370 cm^{-1} region. Therefore, among the bands appearing in those region for the complexes we selected the corresponding bands, considering the effects due to deuterations.

The complexes are changed by the reactions with alkyl halides to $[Co(R–SCH_2COO)en_2]X_2$ or $[Co(R–SCH_2CH_2COO)en_2]X_2$, in which the coordinated thiolic sulfurs are alkylated like $[Co(SCH_2CH_2NH_2)en_2]Cl_2$.[8]

The Determination of Formation Constants by Measurements of Molar-volume Changes

Norio WATANABE and Susumu TAKAMOTO

Department of Chemistry, Faculty of Science, Gakushuin University, Mejiro, Toshima-ku, Tokyo 171

(Received February 7, 1975)

Synopsis. Density measurements were made with a solution containing equivalent amounts of diethylenetriamine and the copper(II) ion, and with solutions of different concentrations of potassium hydroxide. The measurements were also made with systems in which the above-mentioned solutions were mixed. The molar-volume changes due to the complex formation were calculated from the density.[1] The results were used for the calculation of the formation constant of the monohydroxo-diethylenetriamine-copper(II) ion.

When ions of opposite charges combine in aqueous solutions, the molar-volume change can be expected to increase as the electroconstriction is weakened.[2] This phenomenon has been established in various acid-base systems.[1,3,4] When a copper(II) ion is coordinated with dienthylenetriamine (abbreviated as dien) at a ratio of 1: 1, the copper(II) ion tends to assume a square-planar structure, with a water molecule at one of its four coordination sites.[5] With the increase in the pH of this solution, the coordinated water molecule easily dissociates a proton and the electric charge of the Cu-dien$(OH_2)^{2+}$ complex changes from +2 to +1. Therefore, the addition of hydroxide ions to a solution containing the 1: 1 complex of Cu(II) and dien is expected to bring about an increase in the molar-volume change of Cu(II). In this study, the molar-volume change of Cu(II) mentioned above was determined at various concentrations of hydroxide ions. The results indicated the presence of a correlation between the formation of the complex and the molar-volume change. Consequently, the formation constant of this hydroxo complex was determined on the basis of the molar-volume change, and a comparison was made with the results obtained by the potentiometric titration method.[5].

Experimental

The copper nitrate solution was standardized gravimetrically by using 8-quinolinol. The diethylenetriamine was distilled twice and diluted with decarbonated water. Its solution was standardized by potentiometric titration using nitric acid of a known concentration. The potassium hydroxide was standardized by the method used in the case of dien. The density measurement was made by means of a pycnometer (14 cm^3 in volume) in a constant-temperature bath maintained at 25.0±0.01 °C.

The initial compositions of the solutions before mixing were as follows:

Solution 1: 0.050 M Cu(II), 0.050 M dien, and the pH controlled at 4.7 by using nitric acid.

Solution 2: Potassium hydroxide in ten different concentrations ranging from 0 to 0.2 M.

Results and Discussion

Martell and his co-workers[4] indicate, on the basis of there potentiometric study, that, in solutions containing equivalent amounts of Cu(II) and dien, the three nitrogen atoms of dien are all coordinated with a copper(II) ion above pH 4 and that the possibility of the formation of a dimer and a dihydroxo complex is small. They also concluded that a normal complex, Cu-dien$(OH_2)^{2+}$, was completely formed in the pH range from 4 to 8. Therefore, the following equilibrium has been established above pH 8:

$$\text{Cu-dien}(OH_2)^{2+} = \text{Cu-dien}(OH)^{+} + H^{+} \qquad (1)$$

The molar-volume changes of Cu(II) due to the mixing of Solution 1 and Solution 2 are shown in Fig.1

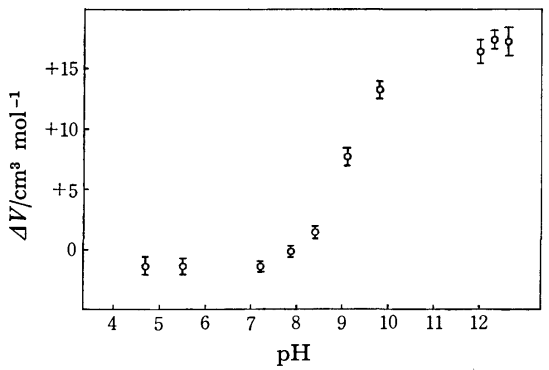

Fig. 1. Molar volume changes of Cu(II) due to the mixing of Solution 1 and Solution 2.

as a function of the pH of the mixed solution. In Solution 1 (pH 4.7 before mixing), Cu-dien$(OH_2)^{2+}$ complex ions are completely formed. In Fig. 1, the molar-volume change remains constant at −1.4 (cm^3 mol^{-1}) in the pH range from 4.7 to 7.2. This agrees with the finding obtained by the potentiometric titration, that the Cu-dien$(OH_2)^{2+}$ complex is completely formed in the solution of pH 4—8. The gradual increase in the molar-volume change in the pH range from 7.9 to 10 corresponds to the shift of the equilibrium (1) to the right, resulting in the increase in the Cu-dien$(OH)^{+}$ complex. At pH>12, the molar-volume change reaches a limiting value +17.1 (cm^3 mol^{-1}); this suggests that Cu-dien$(OH)^{+}$ complexes are completely formed in this pH range.

The molar-volume change of −1.4 (cm^3 mol^{-1}) at pH 4.7—7.2 is denoted by the symbol V(Cu-dien(OH_2)). Similarly, the molar-volume change of +17.1 (cm^3 mol^{-1}) at pH>12 is denoted by the symbol V(Cu-dien(OH)). By analogy with the equation commonly used in spectrophotometric studies,[5] the equilibrium concen-

trations of Cu-dien$(OH_2)^{2+}$ and Cu-dien$(OH)^+$, denoted by C_1 and C_2 respectively, can be expected to be given by Eq. (2) in terms of the molar-volume change, ΔV, at pH 8—11.

$$\frac{C_2}{C_1} = \frac{V(\text{Cu-dien}(OH_2)) - \Delta V}{\Delta V - V(\text{Cu-dien}(OH))} \quad (2)$$

Equation (2) can be used for the determination of the formation constant of Cu-dien$(OH)^+$, as can be expected from:

$$K_{\text{Cu-dien}(OH)} = \frac{C_2 \cdot [H^+]}{C_1} \quad (3)$$

The hydrogen-ion concentration $[H^+]$ was obtained by converting the reading of the pH meter using the hydrogen-ion activity coefficients by means of the Debye-Hückel equation. In order to eliminate the effects of other ions no foreign electrolytes such as KNO_3 was used in the present study. As a consequence, the ionic strength after mixing varies in the range from 0.15 to 0.2. By means of Eqs. (2) and (3), the formation constants of Cu-dien$(OH)^+$ were calculated to be:

$$pK_{\text{Cu-dien}(OH)} = 9.0 \text{ at pH } 9.1$$

$$pK_{\text{Cu-dien}(OH)} = 9.1 \text{ at pH } 9.8$$

The formation constants thus obtained from the molar-volume change data agree well with those of Martell and his co-workers ($pK=9.0$), determined by potentiometric titration.[4]

The authors wish to thank Dr. Reita Tamamushi and Dr. Takusei Hashitani for their helpful advice and encouragement.

The Intramolecular Hydrogen Bonding in *o*-Hydroxybenzyl Alcohol

Nobuo MORI and Kenzo MORIOKA

Department of Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received November 25, 1974)

Synopsis. IR and PMR spectral investigations showed that *o*-hydroxybenzyl alcohol in a dilute solution in CCl_4 existed predominantly in two internally bonded forms, **A** and **B**, and probably also in **C**.

The infrared ν_{OH} data of *o*-hydroxybenzyl alcohol (**1**) in a dilute solution in CCl_4 have previously been reported,[1] but not discussed in detail in relation to the hydrogen bonding, probably because of its complicated system involving two hydroxyl groups and three hydrogen-accepting sites. This problem will be elucidated in this note.

In our infrared reinvestigation, **1** in a dilute CCl_4 solution obviously showed, in the ν_{OH} region, three bonded OH bands at 3620, 3605, and 3429 cm^{-1}; the first two overlapped one another, and there was no significant band due to a free aliphatic OH absorption. From a comparison with the data of the corresponding methyl ethers (**2** and **3**) listed in Table 1, the 3429 cm^{-1} band can undoubtedly be assigned to the aromatic OH group bonded to the aliphatic OH-oxygen atom, and the 3605 cm^{-1} band probably masks a free aromatic OH band which should appear near 3610 cm^{-1}. The ε value of this masked band can be calculated to be *ca.* 24 by using the ε values of the other aromatic OH bands ($=20.2\times 90.0/75.7$).

The 3620 and the 3605 cm^{-1} bands must then be allocated to the aliphatic OH species bonded to two hydrogen-accepting sites, the aromatic OH-oxygen atom and the π-electrons; the weaker 3620 cm^{-1} band can correspond to the π-bonded OH absorption of α-unsubstituted benzyl acohols, which always appears near 3617 cm^{-1}, independently of the ring-substituent,[2] while the stronger 3605 cm^{-1} band can be assigned to the O-bonded OH group. **4** shows only a single O-bonded OH band at 3608 cm^{-1}.

The above assignments are consistent with the OH-PMR data. The OH chemical shifts from TMS for *m*- or *p*-substituted benzyl alcohols at an infinite dilution in CCl_4 decrease with an increase in the sigma value of the substituent and with a decrease in the integrated-intensity ratio of the infrared π-bonded OH band,[3] as Fig. 1 shows; this indicates that the π-bonded OH-protons are subject to a diamagnetic anisotropy effect of the benzene ring and that this effect is dominant over a possible deshielding effect of the OH···π-bond. On the contrary, the OH-proton of **3** and **4** resonates at a lower field, and this down-field shift increases with an increase in the relative intensity of the infrared 3605 cm^{-1} band. The PMR and IR data are consistent with one another if the 3605 cm^{-1} band is due to the O-bonded OH group and if a deshielding effect of the hydrogen bond is

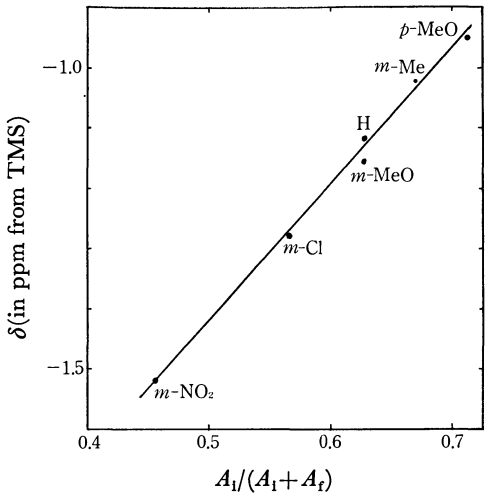

Fig. 1. Correlation between the OH-chemical shift (δ) and the relative population of the π-bonded OH species ($A_i/(A_i+A_f)$).

1		—	3620(45.3)*	3605(90.4)	3429(75.7)
2		3612(20.2)	—	—	3395(90.0)
3		3639(20.6)*	3619(37.7)*	3605(46.7)	—
4		—	—	3608(76.5)	—

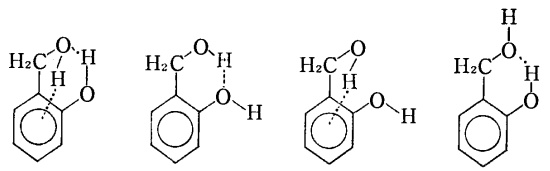
* Shoulder.

Table 2. Dilution shift for the OH-proton

	X							
	p-CH_3O	*m*-CH_3	H	*m*-CH_3O	*m*-Cl	*m*-NO_2	*o*-CH_3O	2,6-di-CH_3O
δ (in ppm from TMS)	−0.95	−1.02	−1.12	−1.16	−1.28	−1.52	−1.57	−1.82

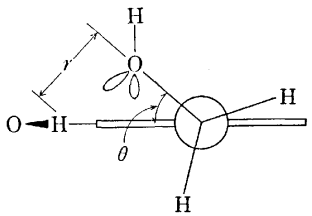
operative on the OH-proton; in this case, the proton is further subject to an anisotropy effect of the ring-current, which will be rather paramagnetic, because it must be located nearby on the plane of the benzene ring.

On the basis of the above findings and considerations, and, further, if the ν_{OH} of a free OH group is not decreased by the bonding of the O atom with another OH group,[5] the monomeric *o*-hydroxybenzyl alcohol in CCl_4 may exist predominantly in two internally bonded forms: **A**, in which the aromatic OH group is bonded to the oxygen atom of the π-bonded aliphatic OH group, and **B**, in which the aliphatic OH group is bonded to the free aromatic OH-oxygen atom, and probably also in **C**, in which the aromatic and the aliphatic OH group are free and π-bonded respectively, but not in **D**, in which the aromatic OH group is bonded to the free aliphatic OH-oxygen atom:



A **B** **C** **D**

In **A**, the aromatic OH group will lie substantially on the plane of the benzene ring, as was suggested in the case of 2,6-dialkylphenols,[8] and the C–O axis of the hydroxymethyl group will be staggered by θ around the ring plane and located at an O–H distance (r) which is not much longer than the O-H bond distance of 0.96 Å, in such a manner that one of the sp^3-orbitals occupied by the n-electrons of the oxygen atom is directed toward the aromatic O–H bond so as to overlap with the antibonding orbital of the latter, as is shown in the figure:



Such torsion of the C–O axis from the normal position[9] in relation to the ring plane must be caused by the hydrogen bonding with the aromatic OH group. A Büchi's Dreiding-model examination shows that, when θ is, *e.g.*, 30°, r is equal to *ca.* 1.5 Å; in this case, the two OH groups will be able to be O- and π-bonded respectively, because (1) this O···H distance corresponds empirically to a spectral shift of *ca.* 100 cm^{-1} of the bonded OH in aliphatic diols,[6] and to the much larger shift which can be expected for the bonded aromatic OH group in the figure, and (2) π-bonding is suggested in the quasi-equatorial form, with θ being somewhat larger than 30°, of 1-tetralols.[10]

Experimental

All the alcohols are known and those except commercially available products were prepared by the usual methods; their purity was checked by their physical constants, PMR spectra and/or chromatograms.

The IR spectra were recorded at *ca.* 25 °C on a JASCO-DS-403G spectrometer (concentration: 0.003 mol/l or less in CCl_4: cell-thickness: 5.0 cm).

The PMR spectra were recorded on a JEOL-LNM-4H-100 spectrometer operating at 100 MHz; dilution experiments were carried out at concentrations down to 0.01 mol/l in CCl_4. The results are summarized in Tables 1 and 2.

A Convenient Synthesis of Substituted Pyrocatechols

Kyoko NISHIZAWA and J. Yasuo SATOH*

Meiji College of Pharmacy, Yato-machi, Tanashi, Tokyo 188

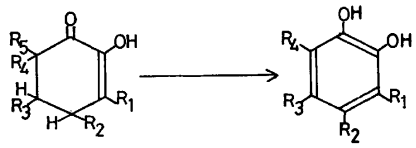
* *Department of Chemistry, St. Paul's (Rikkyo) University, Nishi-Ikebukuro, Toshima-ku, Tokyo 171*

(Received January 28, 1975)

Synopsis. It was found that substituted pyrocatechol derivatives were formed by the reaction of polychlorinated cyclohexane-1,2-diones with lithium carbonate in DMF.

Substituted pyrocatechol derivatives have been reported to be formed from methyl substituted phenols and benzenes[1] in several steps. However, no report has appeared on their synthesis from cyclohexanone and methylcyclohexanones. In previous papers[2] we reported that polychlorinated cyclohexane-1,2-diones (**1a**—**1e**) were obtained in good yields from the reaction of cyclohexanones with a large excess of copper(II) chloride. The resulting products have a *gem*-dichloro functional group in the α-position with respect to the carbonyl group. It seems that this functional group would make them capable of leading to the following substituted pyrocatechol derivatives (**2a**—**2e**) by dehydrochlorination. We have studied the reaction of these polychlorinated compounds (**1a**—**1e**) with lithium carbonate in DMF.

The product obtained from **1a** showed no absorption of an α,β-unsaturated ketone, but showed the out-of-plane bending vibration of aromatic hydrogens in the IR spectrum (Table 1). In the NMR spectrum, there was no peak due to an aliphatic proton, but a peak at 5.71 ppm (broad, 2H) due to phenolic hydroxyl groups and a peak at 6.84 ppm (singlet, 2H) due to aromatic protons.



(1) (2)

Fig. 1.

The results indicate that the product obtained is an *o,o'*-disubstituted pyrocatechol derivative, identified to be compound **2a**. In the same manner, the corresponding pyrocatechol derivatives **2b**, **2c**, **2d**, and **2e** were obtained from compounds **1b**, **1c**, **1d**, and **1e**, respectively. Physical properties of the products are given in Table 1.

The present work demonstrates that substituted pyrocatechol derivatives, which heretofore were prepar-

ed with difficulty, can be synthesized readily from cyclohexanones *via* chlorination with copper(II) chloride followed by the above reaction.

Experimental

All melting points are uncorrected. Thin-layer chromatography was carried out on silica gel (Wakogel B-5), and detected with iodine. Column chromatography was carried out on silica gel (Wakogel C-100). The IR spectra were measured with a Hitachi 215 grating infrared spectrophotometer by the KBr disk method. The NMR spectra were recorded on $CDCl_3$ with TMS as an internal standard with a Hitachi R-20A nuclear magnetic resonance spectrometer. The chemical shifts are presented in terms of the δ value.

The general procedure was to reflux the polychlorocyclohexane-1,2-dione[2] (1 g) with 1.5 molar equiv. of Li_2CO_3 in DMF (20 ml) for 30 min in a nitrogen atmosphere. Ethereal extract of the reaction mixture was washed with 5% HCl. The product was chromatographed and crude material obtained from benzene–ether (9: 1) eluates was recrystallized from toluene.

The authors wish to thank Professor A. Hagitani, Rikkyo University, for his guidance and helpful suggestions.

A Facile Synthesis of 6-Chloro-D-tryptophan

Tamon MORIYA, Katsuaki HAGIO, and Naoto YONEDA

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16-89, Kashima-3-chome, Yodogawa-ku, Osaka 532

(Received March 24, 1975)

Synopsis. A nonnutritive sweetener, 6-chloro-D-tryptophan (**4**), was synthesized from D-tryptophan (**1**) by nitration, hydrogenation and diazotization, followed by a reaction with cuprous chloride. The optical rotation of **4** agreed with that of an authentic sample which had been prepared by the resolution of racemic **4** methanesulfonate.

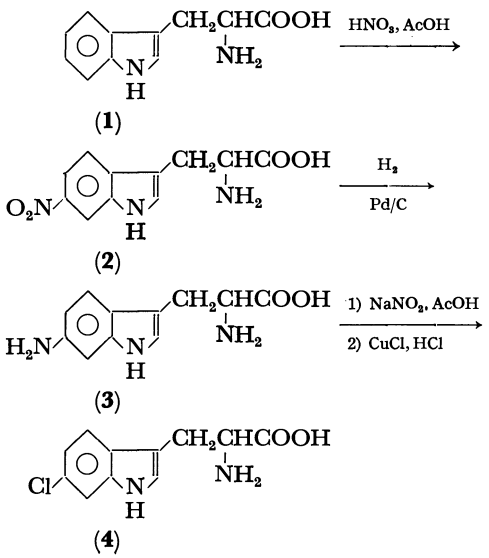
6-Chloro-D-tryptophan (**4**) is known as a nonnutritive sweetener with a good sucroselike taste.[1] The use of racemic **4** as a sweetening agent is undesirable because the L-isomer has a somewhat bitter taste. In respect of the synthetic method, it has been reported only that racemic **4** had been prepared from 6-chloroindole *via* its gramine derivative.[2] Now we wish to report that the D-isomer of **4** was successfully synthesized through three steps starting from D-tryptophan (**1**), which can readily be obtained on an industrial scale.

The nitration of **1** was carried out by a slight modification of Fazi's method.[3] A suspension of **1** in acetic acid was treated with fuming nitric acid, without any isolation of the nitrate of **1**, to give the nitrate of 6-nitro-D-tryptophan (**2**) (yellow needles, 59.7%), which was then converted to the free amino acid (**2**) [yellow needles, $[\alpha]_D^{25}$ +12.5° (c=0.2, 20% EtOH), 78.9%] by the addition of sodium carbonate.

The hydrogenation of **2** over palladium-carbon in aqueous hydrochloric acid furnished the amino derivative (**3**)[4] [colorless needles, $[\alpha]_D^{25}$ −13.1° (c=1, 1M HCl), 91.2%].

At the final step of the synthesis, the Sandmeyer reaction for **3** was examined. It was reported that the reactions of nitrous acid with tryptophan and its derivatives led to the deamination of the N^{α}-amino group[5] and to the formation of N^{1}-nitrosamine derivatives.[6] In this study, the 6-amino group of **3** was selectively diazotized in acetic acid, though the reaction using hydrochloric acid gave complicated products. The resulting diazotized compound was treated with cuprous chloride to give 6-chloro-D-tryptophan (**4**) [colorless prisms, $[\alpha]_D^{25}$ −11.3° (c=1, 1M HCl), 50.8%]. Both the spectral data and the optical rotation of **4** were in agreement with those of an authentic sample which had been obtained by the resolution of racemic **4** methanesulfonate by means of a preferential crystallization procedure in our laboratory.[7]

The new method promises to be both economical and convenient for the preparation of 6-chloro-D-tryptophan and would also serve for the synthesis of a variety of 6-substituted derivatives of optically active tryptophans.



Experimental

All the melting points are uncorrected. The IR spectra were obtained on a Shimadzu IR-27G spectrophotometer. The NMR spectra were recorded on a Hitachi R-20A instrument, using TMS as the internal standard. The observed rotations were measured with a Perkin-Elmer Model 141 polarimeter.

6-Nitro-D-tryptophan (2). To a suspension of D-tryptophan (40.8 g, 0.2 mol) and urea (0.5 g) in glacial acetic acid (500 ml) was added a solution of fuming nitric acid (d 1.50, 7.5 ml) in glacial acetic acid (30 ml). The resulting yellow clean solution was stirred at 0 °C until it changed to a suspension. Then, to the suspension was slowly added, drop by drop at 15 °C, additional fuming nitric acid (d 1.50, 17.5 ml) in glacial acetic acid (70 ml). After stirring for 18 hr at 20—25 °C, the resulting yellow precipitate was collected by filtration to yield **2**·HNO_3·1/2H_2O (28.33 g, 44.1%). The filtrate was then diluted with 300 ml of water ,and the solution was concentrated to 300 ml *in vacuo*. On standing in a refrigerator overnight a further crop of **2**·HNO_3·1/2H_2O (10.01 g, 15.6%) was deposited from the remainder. The recrystallization of the crude **2**·HNO_3·1/2H_2O from diluted nitric acid gave hygroscopic yellow needles; mp 192—194 °C (decomp). IR (KBr); 1750, 1500, and 1330 cm^{-1}.

Found: C, 41.01; H, 4.40; N, 17.19%. Calcd for $C_{11}H_{11}N_3O_4$·HNO_3·1/2H_2O: C, 41.13; H, 4.08; N, 17.44%.

The crude **2**·HNO_3·1/2H_2O (25.0 g) in hot water (200 ml) was converted to the free amino acid (**2**·H_2O, 16.4 g, 78.9%) by the addition of sodium carbonate (4.2 g). Yellow needles (from ethanol), mp 250—252 °C (decomp). $[\alpha]_D^{25}$ +12.5 ° (c=0.2, 20% EtOH). IR (KBr); 3200, 1620, 1495, and 1330 cm^{-1}. NMR (D_2O–NaOH); δ 1.5—3.2 (2H, m), 3.3—3.6 (1H, m), 7.10 (1H, d, J=8.7 Hz), 7.23 (1H, s), 7.28 (1H, dd, J=2.2, 8.7 Hz) and 7.54 ppm (1H, d, J= 2.2 Hz).

Found: C, 49.50; H, 4.50; N, 16.18%. Calcd for $C_{11}H_{11}N_3O_4$·H_2O: C, 49.44; H, 4.90; N, 15.72%.

Hydrochloride: Yellow needles (from dil. HCl); mp 243 °C (decomp). IR (KBr); 3520, 3280, 3000, 1730, 1490, and 1340 cm^{-1}.

6-Amino-D-tryptophan (3). A mixture of **2**·H_2O (12.46

g, 0.047 mol) in 2.2% hydrochloric acid (320 ml) and methanol (200 ml) containing 10% palladium-carbon (1.0 g) was shaken at 25 °C under an atmospheric pressure of hydrogen until the absorption of hydrogen ceased. After 3.41 (3.2 molar equivalents) of hydrogen had been absorbed (3.5 hr), the catalyst was removed and the filtrate was concentrated to dryness *in vacuo*. The residue was dissolved in water (30 ml), and the pH of the solution was adjusted to 6.0 with a saturated aqueous sodium bicarbonate to separate **3**·H_2O as colorless needles (10.06 g, 91.2%); mp 252 °C (decomp). (from ethanol). $[\alpha]_D^{25}$ −13.1 ° (c=1, 1 M HCl), IR (KBr); 3580, 3290, 3150, 1590, 1400, 1345, and 802 cm^{-1}. NMR (DMSO-d_6); δ 2.7—3.3 (2H, m), 3.3—3.7 (1H, m), 6.34 (1H, dd, J=8.3, 1.5 Hz), 6.50 (1H, d, J=1.5 Hz), 6.86 (1H, s), 7.19 (1H, d, J=8.3 Hz) and 10.3 ppm (1H, broad).

Found: C, 55.82; H, 6.33; N, 17.59%. Calcd for $C_{11}H_{13}N_3O_2 \cdot H_2O$: C, 55.68; H, 6.37; N, 17.71%.

6-Chloro-D-tryptophan (4). To a solution of **3**·H_2O (4.75 g, 0.02 mol) in acetic acid (80%, 120 ml) was added an aqueous solution (20 ml) of sodium nitrite (1.38 g, 0.02 mol) drop by drop at 0 °C with stirring. The resulting solution was stirred for 20 min longer and then added to a solution of cuprous chloride [prepared from cupric sulfate pentahydrate (7.46 g, 0.03 mol)] in 15% hydrochloric acid (110 ml) at 0 °C over a 10-min period. After stirring at room temperature for 15 hr and then at 80 °C for an hour, the reaction mixture was concentrated to dryness *in vacuo*. The residue, in 400 ml of water, was treated with hydrogen sulfide, and then the cupric sulfide was removed by filtration. The filtrate was concentrated to separate colorless prisms of crude **4**·HCl. A solution of **4**·HCl in water (30 ml) was treated with active charcoal and neutralized (pH 6.0) with 10% sodium hydroxide. The precipitate was collected and recrystallized from aqueous alcohol to afford **4** as colorless prisms (2.42 g, 50.8%); mp 264—265 °C (decomp). $[\alpha]_D^{25}$ −11.3 ° (c=1, 1 M HCl). IR (KBr); 3400, 3080, 1665, 1585, 810, and 530 cm^{-1}. NMR (D_2O–NaOH); δ 2.8—3.4 (2H, m), 3.5—3.7 (1H, m), 7.06 (1H, dd, J=8.3, 2.0 Hz), 7.40 (1H, d, J=2.0 Hz) and 7.61 ppm (1H, d, J=8.3 Hz).

Found: C, 55.49; H, 4.54; N, 11.90; Cl, 14.74%. Calcd for $C_{11}H_{11}N_2O_2Cl$: C, 55.35; H, 4.65; N, 11.74; Cl, 14.86%.

The authors wish to thank Director Dr. Ichiro Chibata and Dr. Muneji Miyoshi for their encouragement in this study.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (7), 2219—2220 (1975)

A Convenient Synthesis of α-Bromophenylacetic Acid from Benzaldehyde Using Methyl (Methylthio) methyl Sulfoxide

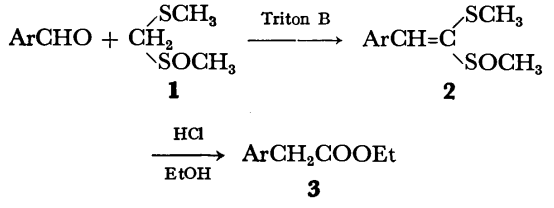
Katsuyuki OGURA, Shigeko FURUKAWA, and Gen-ichi TSUCHIHASHI

Sagami Chemical Research Center, Nishi-Ohnuma, Sagamihara, Kanagawa 229

(Received March 31, 1975)

Synopsis. 1-Methylsulfinyl-1-(methylthio)-2-phenylethylene (**2a**) and 1-methylsulfinyl-1-(methylthio)-2-(*p*-chlorophenyl)ethylene (**2b**) reacted with bromine in various solvents to give α-bromophenylacetic acid derivatives. It should be noted that α-bromophenylacetic acid and α-bromo(*p*-chlorophenyl)acetic acid were mainly obtained by the reaction of bromine with **2a** and **2b**, respectively, in acetic acid.

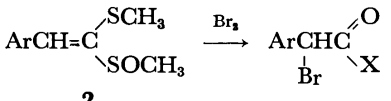
As previously reported,[1] methyl (methylthio) methyl sulfoxide (**1**)[2,3] can condense with aromatic aldehydes in the presence of trimethylbenzylammonium hydroxide (Triton B) to afford the corresponding 1-methylsulfinyl-1-(methylthio)-2-arylethylenes (**2**), which are easily converted into ethyl arylacetates (**3**) on treatment with hydrogen chloride in ethanol, providing a new method for the synthesis of ethyl arylacetates (Scheme 1). Further, the reaction of the condensation product (**2**) with bromine has been examined, and we now wish to describe on a novel synthetic route from benzaldehyde to α-bromophenylacetic acid.



(a, Ar=C_6H_5; b, Ar=*p*-ClC_6H_4)

Scheme 1.

The reaction of 1-methylsulfinyl-1-(methylthio)-2-phenylethylene (**2a**) with bromine was carried out in carbon tetrachloride, methanol, and acetic acid. When **2a** was treated with bromine in carbon tetrachloride, methanethiol ester (**4a**) of α-bromophenylacetic acid was isolated in 25% yield. The structure of **4a** was assigned by its IR and NMR spectra and elemental analysis (see Experimental Section).

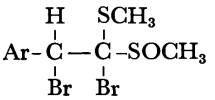


a	Ar=C_6H_5	X=SCH_3
b	=C_6H_5	=OCH_3
c	=C_6H_5	=OH
d	=*p*-ClC_6H_4	=OH
e	=*p*-ClC_6H_4	=OCH_3

Scheme 2.

In methanol, bromine reacted with **2a** to give methyl α-bromophenylacetate (**4b**) in 64% yield. It should be noted that a better result was obtained when acetic acid was used as a solvent. Thus, the reaction with bromine in acetic acid afforded α-bromophenylacetic acid in 73% yield.

By a similar reaction in acetic acid, α-bromo(*p*-chlorophenyl)acetic acid (**4d**) was also obtained in 60% yield, starting from 1-methylsulfinyl-1-(methylthio)-2-(*p*-chlorophenyl)ethylene (**2b**).[4,5] Since **2a** and **2b** were easily derived from the corresponding aldehydes by the reaction with methyl (methylthio) methyl sulfoxide (**1**),[1] the present reactions completed a simple two-step synthesis of α-bromophenylacetic acid and α-bromo(*p*-chlorophenyl)acetic acid from benzaldehyde (over-all yield: 66%) and *p*-chlorobenzaldehyde (over-all yield: 44%), respectively.



5

The transformation of **2** into **4** may be accounted for by a mechanism which involves an intermediacy of **5**, which is finally converted into **4** by the subsequent hydrolysis.

Experimental

*Reaction of 1-Methylsulfinyl-1-(methylthio)-2-phenylethylene (**2a**) with Bromine.* *a) In Carbon Tetrachloride*: Bromine (0.21 ml, 4.0 mmol) was added to a solution containing **2a** (798 mg, 3.8 mmol) in carbon tetrachloride (10 ml) under cooling with ice, and the resulting solution was stirred at room temperature for 2 hr. After the addition of water (5 ml) and extraction with methylene chloride, the organic layer was dried over anhydrous sodium sulfate and evaporated under reduced pressure. The residue was chromatographed (silica-gel column, eluted with *n*-hexane and benzene) to give 263 mg (0.95 mmol, 25%) of a pale yellow oil, which was identified as methanethiol ester (**4a**) of α-bromophenylacetic acid by its physical properties and elemental analysis. IR (neat): 1685 cm^{-1} ($\nu_{C=O}$); NMR ($CDCl_3$): δ 2.33 (s, 3H, $COSCH_3$), 5.36 (s, 1H, –CHBr–), 7.34 (m, 5H, C_6H_5); Found: C, 44.16; H, 3.50; S, 13.00%. Calcd for C_9H_9BrOS: C, 44.09; H, 3.70; S, 13.08%.

b) In Methanol: A solution containing **2a** (526 mg, 2.5 mmol) in methanol (5 ml) was stirred at room temperature for 41.5 hr after the addition of bromine (0.33 ml, 5.7 mmol) under cooling with ice. The solution was evaporated under reduced pressure, and the residue was chromatographed [silica-gel column, eluted with benzene–*n*-hexane (1 : 4)] to afford 363 mg (1.58 mmol, 64%) of a pale yellow oil, which was identified as methyl α-bromophenylacetate (**4b**) by the comparison of its IR and NMR spectra with those of an authentic specimen prepared by esterification (conc. sulfuric acid–methanol) of α-bromophenylacetic acid.

c) In Acetic Acid: Bromine (0.13 ml, 2.6 mmol) was added,

together with acetic acid (1 ml), to a solution containing **2a** (533 mg, 2.5 mmol) in acetic acid (1 ml). The resulting solution was stirred at room temperature for 17.5 hr and, after the evaporation under reduced pressure, the residue was chromatographed (silica-gel column, eluted with methylene chloride) to give 394 mg (1.83 mmol, 73%) of pale yellow crystals, which were once recrystallized from cyclohexane to afford colorless crystals, mp 51.5—52 °C; IR (KBr): 3100—2300 and 1700 cm^{-1}; NMR (CCl_4): δ 5.24 (s, 1H), 7.33 (m, 5H), 11.35 (s, 1H); Found: C, 44.82; H, 3.28%. Calcd for $C_8H_7BrO_2$: C, 44.68; H, 3.28%.

The structure of this product was assigned as α-bromophenyacetic acid (**4c**) by its physical properties and elemental analysis. Furthermore, its NMR and IR spectra were completely accordant with those of an authentic sample (mp 71.5—72 °C; lit,[6] mp 68—69 °C) obtained by the reaction of mandelic acid with hydrobromic acid and sulfuric acid.[6] The melting point of the crystals obtained by the reaction of **2a** with bromine was raised to 81—82 °C, after several recrystallizations from cyclohexane. This melting point is in accord with those reported in the other literatures (ranging from 78.5 to 84 °C).[7]

*Reaction of 1-Methylsulfinyl-1-(methylthio)-2-(*p*-chlorophenyl)-ethylene (2b) with Bromine.* *a) In Methanol*: Bromine (0.09 ml, 1.8 mmol) was added to a solution containing **2b** (408 mg, 1.7 mmol) in methanol (5 ml) and the resulting solution was stirred at room temperature for 22 hr. After the evaporation under reduced pressure, the residue was chromatographed [silica-gel column, eluted with benzene–*n*-hexane (1:4)] to give 189 mg (0.72 mmol, 43%) of methyl α-bromo(*p*-chlorophenyl)acetate (**4e**) and 198 mg (1.06 mmol, 52%) of methyl (*p*-chlorophenyl)acetate. The structures of these products were assigned by the comparison of their IR and NMR spectra with those of the corresponding authentic samples.

b) In Acetic Acid: Bromine (0.11 ml, 2.1 mmol) was added, together with acetic acid (1 ml), to a solution containing **2b** (502 mg, 2.0 mmol) in acetic acid (1 ml) and the resulting solution was stirred at room temperature for 19 hr. After the evaporation under reduced pressure, the residue was chromatographed [silica-gel column, eluted with benzene–*n*-hexane (1:4)] to give 342 mg of colorless crystals, which were shown by the NMR analysis to consist of (*p*-chlorophenyl)acetic acid (35 mg, 0.21 mmol, 10%) and α-bromo-(*p*-chlorophenyl)acetic acid (307 mg, 1.23 mmol, 60%). The latter was isolated by recrystallization from cyclohexane as colorless crystals, mp 83—86 °C (lit,[8] mp 95—96 °C), which were identified with α-bromo(*p*-chlorophenyl)acetic acid (**4d**) by the comparison of their NMR ($CDCl_3$) and IR ($CHCl_3$) spectra with those of an authentic specimen.[8]

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (7), 2221—2222 (1975)

Rearrangement of Tetramethyl-*trans*-decalin Derivatives[1)]

Tochiro TATEE, Takahiko TSUYUKI, and Takeyoshi TAKAHASHI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received April 1, 1975)

Synopsis. The dihydroxydecalin (**6**) was treated with iodine at 140 °C to give the octalins (**13** and **14**). Treatment of the β-epoxide (**8**) with boron trifluoride etherate gave the octalins [**17** and **18** (or **19**)] and the oxide (**20**).

Backbone rearrangements in the steroid and terpenoid fields are well documented.[2a,b)] Intracyclic tension in the rigid polycyclic ring provokes of backbone rearrangements to give the products less constrained. Electronic effects resulting from the presence of functional groups and kinetic effects due to the nature of reagents can modify the development of rearrangement.[3a,b)]

It has been shown that a treatment of the decalols (**1** and **2**) with iodine at 140 °C gave a mixture of olefins (**3**, **4**, and **5**), respectively.[4)] It would be expected that a dihydroxydecalin (**6**) having a hydroxyl group at C-6 might effect a rearrangement to give a ketone (**7**). Similarly, a rearrangement of an epoxide (**8**) to form an enol benzoate (**9**) might be expected.

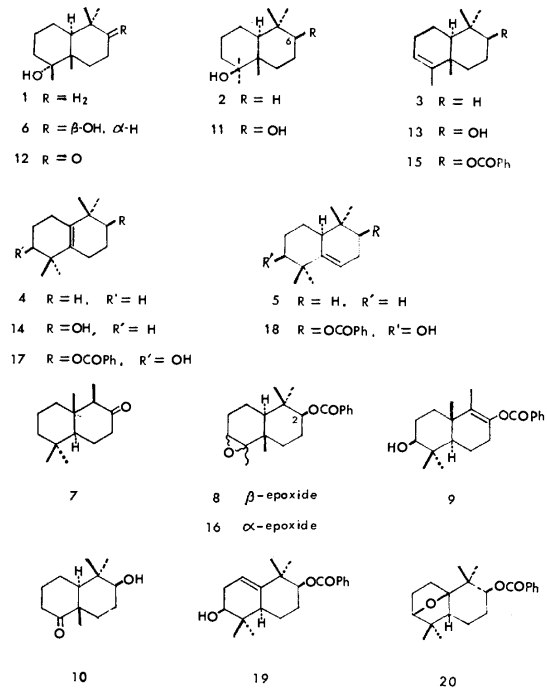
Recent communication on the epoxides of bisnorlabdane derivatives and on related epoxides[5)] prompted us to report our result.[1)] We wish to describe the rearrangements of **6** and **8**.

The hydroxyketone (**10**)[6)] was treated with methylmagnesium iodide to give a mixture of diols (**6** and **11**). Pure **6** was obtained by crystallization from light petroleum. The configuration of the tertiary hydroxyl group in **6** was confirmed by conversion of **6** into **1**[4)] *via* a ketol (**12**). Treatment of **6** with iodine at 140 °C gave the unsaturated alcohols (**13** and **14**).

A benzoate (**15**) derived from **13** was epoxidized with *m*-chloroperbenzoic acid to give **8** and **16**. The β-epoxide (**8**) was treated with boron trifluoride etherate in benzene to yield three products. The PMR and IR spectra of the most polar product showed the presence of a benzoyloxyl and a hydroxyl group and the absence of olefinic proton. Therefore the structure (**17**) was given for the most polar compound.

The presence of a benzoyloxyl and a hydroxyl group along with an olefinic proton in the second polar product was shown by its PMR and IR spectra, which led to the structure (**18** or **19**) for this substance. The PMR spectrum of the least polar product indicated the presence of one proton (δ 3.90, d, J=4 Hz) on a carbon atom attached to ethereal oxygen on a five membered ring[7)] and of a benzoyloxyl group. No signal due to olefinic proton was observed. The absence of hydroxyl absorption in the IR spectrum and the mass spectrum showing a molecular ion peak at *m/e* 328 along with the observations mentioned above suggested the structure (**20**) for the least polar product.

As a result, the dehydration of **6** with iodine and the treatment of **8** with boron trifluoride etherate gave the rearranged products in which the 1,3-diaxial interaction was released. A further rearrangement of a methyl group resulting in new formation of 1,3-diaxial interaction, did not take place. The hydroxyl group (at C-6 of **6**) and the benzoyloxyl group (at C-2 of **8**) did not develop further rearrangement to give **7** and **9**, respectively, under the conditions described above.



Experimental

Instruments utilized for measurements of spectral data and the other experimental indications were the same as those described in Ref. 4.

1α,6β-Dihydroxy-1β,5,5,9β-tetramethyl-trans-*decalin (6).* To the Grignard reagent prepared from methyl iodide (5 g) and magnesium (637 mg) in dry ether (25 ml) at 0 °C was added a solution of the ketol (**10**;[6)] 1.31 g) in dry ether (20 ml). The reaction mixture was stirred at 0 °C for 2 hr. After usual treatment, the residue (1.43 g) was chromatographed on a column of silica gel (150 g). Elution with a mixture of light petroleum and ether (2: 1) gave a mixture of epimeric diols (**6** and **11**; 1.07 g; yield: 76% from **10**), which was crystallized from light petroleum to afford the pure **6**, mp 151.5—152.5 °C, IR (Nujol) 3570, 3400, 3350 cm^{-1}; PMR ($CDCl_3$) δ 0.83, 0.97, 1.02, and 1.11 (each 3H, s; t-CH_3), 3.26 (1H, m; -CH-OH); mass *m/e* 226 (M^+; 1%) and *m/e* 43 (100%); Found: C, 74.04; H, 11.51%. Calcd for $C_{14}H_{26}O_2$: C, 74.28; 11.58%. The mother liquid of crystallization containing the epimeric diol (**11**) was not examined further.

The Decalol (1). The diol (**6**; 40 mg) in acetone (5 ml) was oxidized with Jones' reagent (0.1 ml) at 0 °C. After usual work-up, a ketol (**12**; 41 mg) was obtained as an oil, IR (liquid) 3480 and 1700 cm^{-1}; mass *m/e* 224 [M^+ ($C_{14}H_{24}O_2$); 26%] and *m/e* 43 (100%). To the ketol (**12**) were added

diethyleneglycol (2 ml), 80% hydrazine hydrate (0.3 ml) and potassium hydroxide (20 mg), and the resulting mixture was refluxed for 3 hr and the temperature of the reaction mixture was raised to 200 °C. Water was added and the mixture was extracted with ether. After usual work-up, the residue was chromatographed on a column of silica gel (5 g). Elution with a mixture of light petroleum and ether (10: 1) gave the known decalol (**1**;[4] 8 mg).

Dehydration of the Diol (6) with Iodine. The diol (**6**; 167 mg) was heated at 165 °C. To the resulting melted material cooled to 140 °C was added iodine (6.7 mg) and the mixture was kept for 20 sec. The cooled reaction mixture was extracted with ether. After usual work-up, the residue was chromatographed on a column of silica gel (12 g) impregnated with 20% silver nitrate. Elution with a mixture of light petroleum and ether (10: 1) gave 2-hydroxy-1,1,5,5-tetramethyl-1,2,3,4,5,6,7,8-octahydronaphthalene (**14**; 31 mg; y: 21%), as an oil, IR (liquid) 3380 cm^{-1}; PMR ($CDCl_3$) δ 0.97 (9H, s; $3\times t$-CH_3), 1.02 (3H, s; t-CH_3), and 3.47 (1H, q, J= 4 and 8 Hz; -C<u>H</u>-OH); mass *m/e* 208 [M^+($C_{14}H_{24}O$); 16%] and *m/e* 175 (100%). Elution with a mixture of light petroleum and ether (5: 1) gave 3β-hydroxy-4,4,8,8aβ-tetramethyl-*trans*-1,2,3,4,4a,5,6,8a-octahydronaphthalene (**13**; 70 mg; y: 45%), mp 99—99.5 °C (from light petroleum), IR (Nujol) 3280 and 1655 cm^{-1}; PMR ($CDCl_3$) δ 0.82 (3H, s; t-CH_3), 1.00 (6H, s; $2\times t$-CH_3), 1.58 (3H, d, J=2 Hz; C=C-CH_3), 3.25 (1H, q, J=5 and 11 Hz; -C<u>H</u>-OH), and 5.16 (1H, m; CH=C); mass *m/e* 208 [M^+; 14%] and *m/e* 175 (100%); Found: C, 80.97; H, 11.65%. Calcd for $C_{14}H_{24}O$: C, 80.71; H, 11.61%.

Benzoylation of the Unsaturated Alcohol (13). The unsaturated alcohol (**13**; 50 mg) in pyridine (0.5 ml) was heated at 95 °C with benzoic anhydride (143 mg) for 24 hr. After usual treatment, the unsaturated benzoate (**15**; 55 mg; y: 74%) was obtained; mp 146—147.5 °C, IR (Nujol) 1710 cm^{-1}; PMR ($CDCl_3$) δ 0.98 (3H, s; t-CH_3), 1.08 (6H, s; $2\times$ t-CH_3), 1.60 (3H, d, J=2 Hz; C=C-CH_3), 4.6—4.9 (1H, m; -C<u>H</u>-OBz), and 5.1—5.3 (1H, m; CH=C); mass *m/e* 312 [M^+; 4%] and *m/e* 105 (100%); Found: C, 80.67; H, 9.18%. Calcd for $C_{21}H_{28}O_2$: C, 80.73; H, 9.03%.

Epoxidation of the Unsaturated Benzoate (15). The unsaturated benzoate (**15**; 51 mg) in benzene (5 ml) was treated with *m*-chloroperbenzoic acid (33 mg) at room temperature for 24 hr. After usual work-up, the residue (107 mg) was chromatographed on a column of silica gel (10 g). Elution with benzene–ether (20: 1) afforded a mixture of the α- and β-epoxides (**16** and **8**). The mixture was subjected to further separation on a column of silica gel (8 g). Elution with a mixture of light petroleum-benzene-ether (25: 25: 2) gave 2β-benzoyloxy-5β,6β-epoxy-1,1,5α,10β-tetramethyl-*trans*-decalin (**8**; 13 mg; y: 24%), mp 190—190.5 °C (from light petroleum), IR (Nujol) 1710 cm^{-1}; PMR ($CDCl_3$) δ 0.95, 1.01, 1.15, and 1.23 (each 3H, s; CH_3), 2.96 (1H, triplet-like singlet; C<u>H</u>-C, with O bridge), and 4.6—4.9 (1H, m; -C<u>H</u>-OBz); mass *m/e* 328 [M^+; 0.5%] and *m/e* 105 (100%); Found: C, 76.93; H, 8.34%. Calcd for $C_{21}H_{28}O_3$: C, 76.79; H, 8.59%. Further elution with the same solvent mixture gave 2β-benzoyloxy-5α,6α-epoxy-1,1,5β,10β-tetramethyl-*trans*-decalin (**16**; 19 mg; y: 36%), mp 151—152 °C (from light petroleum), IR (Nujol) 1710 cm^{-1}; PMR ($CDCl_3$) δ 0.94, 1.04, 1.15, and 1.24 (each 3H, s; CH_3), 2.90 (1H, t, J=2.5 Hz, C<u>H</u>-C with O bridge), and 4.6—4.9 (1H, m; -CH-OBz), mass *m/e* 328 [M^+ ($C_{21}H_{28}O_3$); 0.1%] and *m/e* 105 (100%).

Treatment of the β-Epoxide (8) with Boron Trifluoride Etherate. The β-epoxide (**8**; 14 mg) in dry benzene (0.2 ml) was treated with freshly distilled boron trifluoride etherate at room temperature for 17 min. Aqueous sodium hydrogen carbonate solution (0.3 ml) was added and the ethereal extract was passed through a column of silica gel (2 g). Light petroleum–ether (1: 1) eluents, after evaporation of the solvents, were subjected to separation by preparative thin-layer chromatography [solv. benzene–ether (3: 1)]. The material corresponding to the most polar spot (R_f 0.45—0.55) gave 6β-benzoyloxy-2β-hydroxy-1,1,5,5-tetramethyl-1,2,3,4,5,6,7,8-octahydronaphthalene (**17**; 4 mg), as an oil, IR (liquid) 3500 and 1715 cm^{-1}; PMR ($CDCl_3$) δ 0.99, 1.03, 1.06, and 1.14 (each 3H, s; t-CH_3), 3.44 (1H, q, J=4 and 10 Hz; -C<u>H</u>-OH; axial-H), and 4.88 (1H, q, J=4 and 9 Hz; -C<u>H</u>-OBz; axial-H); mass *m/e* 328 [M^+ ($C_{21}H_{28}O_3$); 0.4%] and *m/e* 105 (100%). The product corresponding to the second polar spot (R_f 0.55—0.62) gave 6β-benzoyloxy-2β-hydroxy-1,1,5,5-tetramethyl-1,2,3,4,4a,5,6,7-octahydronaphthalene (**18**) or 2β-benzoyloxy-6β-hydroxy-1,1,5,5-tetramethyl-1,2,3,4,4a,5,6,7-octahydronaphthalene (**19**), as an oil, (3.5 mg), IR (liquid) 3520 and 1695 cm^{-1}; PMR ($CDCl_3$) δ 1.00 (6H, s; $2\times t$-CH_3), 1.09 (3H, s; t-CH_3), 1.16 (3H, s; t-CH_3), 3.48 (1H, br. s, $W_{1/2}$ *ca.* 5.5 Hz; -C<u>H</u>-OH; equatorial-H), 4.88 (1H, q, J=5.5 and 8 Hz; -C<u>H</u>-OBz; axial-H), and 5.42 (1H, triplet like singlet; CH=C); mass *m/e* 328 [M^+ ($C_{21}H_{28}O_3$); 0.2%] and *m/e* 105 (100%). The product corresponding to the least polar spot (R_f 0.71—0.86) gave 2β-benzoyloxy-6β,9β-epoxy-1,1,5,5-tetramethyl-*trans*-decalin (**20**; 4.5 mg), as an oil, IR (liquid) 1710 cm^{-1}; PMR ($CDCl_3$) δ 1.00 (3H, s; t-CH_3), 1.05 (6H, s; $2\times t$-CH_3); 1.08 (3H, s; t-CH_3), 3.90 (1H, d, J=4 Hz; -CH-O-C-), and 4.86 (1H, t, J=2.5 Hz; -C<u>H</u>-OBz; equatorial-H); mass *m/e* 328 [M^+ ($C_{21}H_{28}O_3$); 9%] and *m/e* 105 (100%).

Effect of Alkylation on the Iodine 6s Rydberg States of Iodoalkanes

Shunji KATSUMATA, Hidechika WAKABAYASHI, and Katsumi KIMURA

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received February 10, 1975)

Synopsis. In a series of alkyl iodides far UV absorption and photoelectron spectra indicate that, unlike higher Rydberg members, the lowest Rydberg states are rather sensitive to the alkyl groups, linearity holding between the term values and the first ionization potentials.

Previously, Kimura *et al.* studied the effects of alkyl groups on the ionization potentials (IP) of alkyl compounds by He(I) photoelectron (PE) spectroscopy[1-3] and used the PE data for the assignment of a far UV absorption spectrum of ethyl fluoride.[4] In the present work we have studied the far UV absorption spectra of a series of alkyl iodides $C_mH_{2m+1}I$(m=1—4), emphasis being laid on the effects of the alkyl groups on the lowest Rydberg states.

A far UV spectrum of methyl iodide has been interpreted in terms of several Rydberg series by Herzberg,[5] Price,[6] and many other workers.[7-10] Using a pressure broadening technique, Robin and Kuebler[8] confirmed that the absorption bands of methyl iodide in the 180—205 nm region can be attributed to the first members of the 5p→ns Rydberg series converging to the $^2E_{3/2}$ and $^2E_{1/2}$ ionic states. Boschi and Salahub[9,10] studied far UV spectra of many alkyl iodides in detail and indicated that the 5p→ns Rydberg series except the first members can be explained in terms of nearly constant quantum defects (about 4.2). In the course of our recent study of alkyl iodides, we found that only the lowest Rydberg states are sensitive to the alkyl groups.

Absorption measurements were carried out in vapor phase (0.06—0.25 Torr) in the region 165—210 nm by a 50 cm vacuum UV spectrophotometer previously used.[4] The experimental technique employed is essentially the same as that used before.[11,12] Except for the synthesized *s*- and *t*-butyl iodides, the commercial compounds were used. All the samples were purified by distillation.

Typical examples of the far UV spectra are shown in Fig. 1, indicating the Herzberg B, C, and D bands

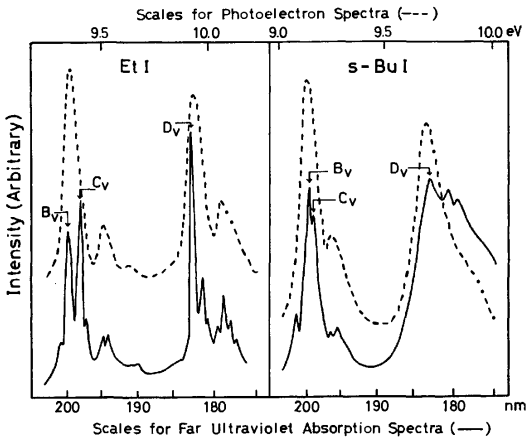

Fig. 1. Far UV absorption spectra of ethyl and *s*-butyl iodide in the 175—205 nm region, compared with the first two PE ionization bands.

due to the (5p→6s) transitions. Bands B and C correspond to the $^2E_{3/2}$ ionic state and band D to the $^2E_{1/2}$. The far UV spectra obtained for the compounds except *s*-butyl iodide which has not been studied so far are essentially the same as those reported by Boschi and Salahub.[9,10] The lowest Rydberg transition energies are summarized in Table 1, which were obtained from the mean positions of the vertical-transition peaks (B_V and C_V as shown in Fig. 1). The separation between the D_V peaks and the B_V—C_V average positions give rise to the spin-orbit splittings (Δ) summarized in Table 1 together with the corresponding PE data.

The term values (T) are the differences between the transition energies (E) and the first IP's (I_1) previously determined.[1,3] The term value is equivalent to the Rydberg-state IP. The Rydberg formula is expressed by $I_1-E=R/(n-\delta)^2$, where n is the principal quantum number and δ is the quantum defect. The lowest Rydberg bands largely deviate from the above formula with $\delta\approx4.2$.[9,10] We obtained the δ values (Table 1)

Table 1. The 5p→6s ($^2E_{3/2}$) Rydberg states of alkyl iodides

Compound	E (cm^{-1})	I_1[a] (eV)	T (cm^{-1})	δ	Δ (eV) Far UV	Δ (eV) PE[a]

from the Rydberg formula using the experimental T values. The following remarks may be added on the lowest Rydberg states of the alkyl iodides.

(1) The T's for the 5p→6s ($^2E_{3/2}$) Rydberg states are plotted against the number of carbon atoms in the alkyl group in Fig. 2(a), indicating a downward trend with increasing alkylation. Such a trend for other series of alkyl compounds has been indicated by Robin and Kuebler.[13,14]

(2) In Fig. 2(b), the T's are plotted against the first IP's, indicating a good linear relationship, although only *t*-butyl iodide deviates slightly from linearity. This linearity is important, being pointed out for the first time, and is based on the fact that the lowest Rydberg transition energies (Table 1) are almost constant throughout the series of compounds. For the higher members of the 5p→*n*s Rydberg series, however, no such linearity holds.

(3) The δ's are plotted against the first IP's in Fig. 2(c), indicating again approximate linearity. The δ values of 3.84—3.97 are considerably smaller as compared with that (about 4.2) used for the higher members.[9,10]

(4) The far UV absorption spectra are compared with the previously obtained PE spectra[1,3] (broken curves in Fig. 1). Both the optical and PE spectra are surprisingly similar in shape. Such similarity has already been pointed out for other simple compounds by Basch *et al.*[15] and Narayan.[16] As can be seen from Table 1, the spin-orbit splittings in the 5p→6s Rydberg states are very close to those in the first ionized states.

(6) The variation of the first IP's in the alkyl iodides was previously interpreted in terms of the mixing of the iodine 5p orbitals with the *p*-type alkyl-group orbitals.[1,3] In a large number of aliphatic compounds, Robin[13] pointed out the importance of the n=3 orbitals of the alkyl groups in the lowest Rydberg orbitals. In the present study, unlike the higher Rydberg states, the lowest Rydberg states and the first ionized states show striking similarities with respect to the alkyl-group substitution. This strongly suggests that, as the alkyl group changes from the methyl group to the higher one, the variation in the mixing of the iodine 6s orbital with the alkyl-group n=3 orbital in the lowest Rydberg states is approximately equal to the variation in the mixing of the iodine 5p orbitals with the alkyl-group *p*-type orbitals in the ground states. The longest-wavelength absorption bands of the alkyl iodides appearing in the 250—270 nm region were assigned earlier to the $n\rightarrow\delta^*$ transitions by Kimura and Nagakura.[17]

Dielectric Relaxation and Molecular Structure. XVI. Dielectric Behavior of Tertiary Alcohols

Taro KOSHII, Hiroaki TAKAHASHI, and Keniti HIGASI

Department of Chemistry, Waseda University, Shinjuku, Tokyo 160

(Received April 2, 1975)

Synopsis. The relaxation time and the activation energy of the principal dispersion of tertiary alcohols do not increase but *decrease* with increase in the number of the carbon atoms in the molecule. This observation seems to be in accord with a hypothesis that the principal dispersion is associated with the size of the hydrogen-bonded cluster of alcohols.

It is well known for *n*-alkyl bromides[1] and alkyl acetates,[2,3] that the relaxation time and the activation energy regularly increase with increase in the number of carbon atoms in the molecular chain. The same trend has been found also in normal primary alcohols.[4] The purpose of this note is to report that an exception to this general tendency is found in the case of tertiary alcohols.

Recently, the dielectric behavior of 2-methyl-2-butanol and 3-methyl-3-pentanol have been studied by the method described before.[5] The relaxation times, τ, of these tertiary alcohols and 2-methyl-2-propanol[6] are plotted, in Fig. 1, against the carbon number of the alcohol. It will be seen that the τ curve in the full line decreases with increase in the number of carbon atoms; it exhibits a striking contrast to the broken curve for normal primary alcohols.[4] Moreover, the curves for the reduced relaxation time, τ/η,[7] against the number of carbon atoms also show a downward slope for tertiary alcohols. The activation enthalpies, ΔH^*, of these tertiary alcohols[8] are plotted in Fig. 2 together with those of normal primary alcohols.[4] The ΔH^* *vs.* carbon number curve shows a decrease for the tertiary alcohols, while that for normal alcohols increases. For tertiary alcohols treated here, the larger the molecule becomes, the smaller are the τ and ΔH^* values. This indicates that the principal dispersion of these alcohols is not determined by the molecular size; that is, their relaxation is not a property of a monomer. Since the steric hindrance around the OH group increases with increase in the carbon number, the size of clusters by hydrogen bonds would become smaller possibly in the order of 2-methyl-2-propanol>2-methyl-2-butanol>3-methyl-3-pentanol. The above statement seems to be in accordance with the hypothesis that the principal dispersion is associated with the size of the hydrogen-bonded cluster of alcohols.[8]

Studies on Ferrocene and Its Derivatives. I. Reactions of Formylferrocene with α-Amino Acids

A. M. OSMAN, M. A. EL-MAGHRABY, and Kh. M. HASSAN
Faculty of Science, University of Assiut, Egypt

(Received May 2, 1973)

Synopsis. The condensation reactions of formylferrocene (I) with various α-amino acids and their esters were studied. The products are new Schiff bases (II) which may be of medicinal value.

From a medicinal point of view, ferrocene is considered to be potent for treatment of iron deficiency anaemia.[1,2] However, it needs to be prepared in the form of a suitable derivative.

The present investigation is an attempt to prepare some new derivatives of ferrocene, likely to be used as haematinics, by interaction of formylferrocene (I) with α-amino acids or their esters. The reaction proceeded smoothly in ethanol and in the presence of sodium carbonate to give quantitative yields of the Schiff bases (II). The time of reaction and purity of the products were controlled by thin layer chromatography (tlc):

$$\underset{\text{(I)}}{\text{Fc-CHO}} + \text{H}_2\text{N-CH(COOR')-R} \xrightarrow[\text{Na}_2\text{CO}_3]{\text{EtOH}} \underset{\text{(II)}}{\text{Fc-CH=N-CH(COOR')-R}}$$

(Fc=ferrocenyl; R=alkyl and others; R'=H or ethyl)

The prepared Schiff bases are brown crystals, sparingly soluble in hot water, easily soluble in ethanol and alkali solution, and insoluble in most organic solvents. They are easily hydrolyzed by dilute acids to their original components. Compounds (II) are likely to inherit the properties of the reactant entities and possess some new medicinal properties.

The results of the above reactions are given in Table 1.

Experimental

General Method of Preparation of Schiff Bases (II). An equimolecular mixture of formylferrocene (I) and an α-amino acid or its ester was refluxed for about two hours in absolute ethanol in the presence of 2 mol of anhydrous sodium carbonate. The reaction mixture was filtered while hot, whereby the Schiff base precipitated after concentration as a brown solid. In certain cases, addition of a few drops of absolute ether is necessary to precipitate the reaction product. The time of reaction and purity of the products were controlled by thin-layer chromatography. Purification of the Schiff bases was effected by dissolution in a minimum volume of absolute ethanol, and precipitation with absolute ether. The results are presented in Table 1: melting points were uncorrected, and the solvent used for tlc estimation of R_f value was a 20: 1 benzene–ethanol mixture.

Hydrolysis of Schiff Bases (II). A sample of the Schiff base (II; R=H, R'=Et) was covered with 2 M HCl, then heated for about half an hour. The reaction mixture was filtered while hot, whereby formylferrocene (I) was isolated as dark brown crystals (mp 223—224 °C). It was identified by means of the mixed melting point test with an authentic sample, and by the identical R_f value (0.26, benzene). The filtrate from the reaction mixture was concentrated and cooled to precipitate the amino acid hydrochloride, which on neutralisation deposited the free amino acid (identified by mp and R_f value).

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (7), 2227—2228 (1975)

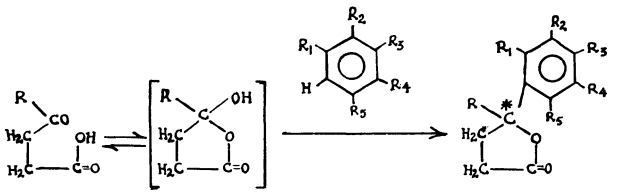
Synthesis of Succin-as-eins. II.[1] Dyes Derived from β-(2-Fluoroyl) propionic, β-(3-Phenanthroyl)propionic Acids and Carbazole-3,6-bis(γ-ketobutyric Acid)

R. GOPAL* and P. C. GUPTA
Department of Chemistry, University of Allahabad, India

(Received May 10, 1974)

Synopsis. A number of succin-as-eins have been prepared by condensing β-(2-fluoroyl)propionic, β-(3-phenanthroyl) propionic acids and carbazole-3,6-bis(γ-ketobutyric acid) with phenol, resorcinol, catechol, quinol, phloroglucinol, pyrogallol, and orcinol.

The γ-keto acids have been found to cyclize to their γ-hydroxylactones,[2] which yield acetyl derivatives[3,4] retaining their cyclic structures. The β-(2-fluoroyl) propionic acid[5] (I: R=$C_{13}H_9$) and β-(3-phenanthroyl) propionic acid[6] (I: R=$C_{14}H_9$) gave a new series of cyclic compounds, succin-as-eins (IIIa—g)[1] on condensation with phenols such as phenol, resorcinol, catechol, quinol, phloroglucinol, pyrogallol, and orcinol. Similarly, carbazole-3,6-bis(γ-ketobutyric acid) (VI)[7] gave a new series of cyclic bis-compounds (VIIa—g) on condensation with respective phenols. The condensation process proceeds through the equilibrium process of lactol (II) of acid (I) as described earlier.[1,8]



I II IIIa—g

(IIIa) $R_1=R_2=R_4=R_5=H$; $R_3=OH$
(IIIb) $R_2=R_4=R_5=H$; $R_1=R_3=OH$
(IIIc) $R_3=R_4=R_5=H$; $R_1=R_2=OH$
(IIId) $R_2=R_3=R_5=H$; $R_1=R_4=OH$
(IIIe) $R_2=R_4=H$; $R_1=R_3=R_5=OH$
(IIIf) $R_4=R_5=H$; $R_1=R_2=R_3=OH$
(IIIg) $R_2=R_4=H$; $R_5=CH_3$; $R_1=R_3=OH$
(IV) $R_2=R_4=R_5=H$; $R_1=R_3=OCOCH_3$
(V) $R_5=H$; $R_2=R_4=Br$; $R_1=R_3=OH$

Scheme 1.

The IR (KBr) spectra of IIIa—g, VIIa—g, VIII, and IX show strong bands between 1760—1750 cm^{-1} (γ-lactone). The respective diacetyl (IV: 1760, 1200, and 1125 cm^{-1}) and dibromo (V: 1760 cm^{-1}) derivatives of fluorenyl resorcinol succin-as-ein (IIIb: R=$C_{13}H_9$) and phenanthryl resorcinol succin-as-ein (IIIb: R=$C_{14}H_9$) are also indicative of γ-lactone and resorcinol molecule in it. The pentacetyl (VIII: four acetoxy and one *N*-acetyl) and tetrabromo (IX) derivatives of carbazole-3,6-bis-resorcinol succin-as-ein (VIIb) are indicative of two resorcinol molecules in it. The absorption maxima (λ_{max}) of IIIa—g given in Table 1

VIIa—g

Scheme 2

and V are comparable with their analogous succineins and phthaleins, but those of VII except that of VIIa given in Table 2 and IX have been found higher than their analogous phthaleins and succineins.

Experimental

All melting points are uncorrected. The λ_{max} (UV and visible) have been recorded on Model DU-2 Beckmann Spectrophotometer and IR determined using a Perkin-Elmer Infracord Spectrometer.

The preparation and purification of the compounds (III) were done in identical manner as described earlier[1,2,8] taking respective acids (I) and phenols (yield, 40—45%). In the preparation of VII, the phenols were taken in twice molar amounts for the acid (VI), and concd H_2SO_4 was used as condensing agent (yield, 45—50%).

Acetylation of IIIb. Each dye (IIIb: $R=C_{13}H_9$ and $R=C_{14}H_9$) (0.5 g), acetic anhydride (10 ml), and fused sodium acetate (2 g) were refluxed at 135—140 °C for 3.5 hr to give a curcumin yellow compound, (IV: $R=C_{13}H_9$) (0.5 g), mp 180 °C; λ_{max}^{EtOH} (ε): 365 nm (8840) and a light yellow compound (IV: $R=C_{14}H_9$) (0.51 g), mp 142 °C; λ_{max}^{EtOH} (ε): 350 nm (6810) which were recrystallized from 80% ethanol.

Found: C, 73.01; H, 4.68; CH_3CO, 19.12%. Calcd for $C_{27}H_{22}O_6$: C, 73.30; H, 4.97; CH_3CO, 19.45%.

Found: C, 73.76; H, 4.72; CH_3CO, 18.66%. Calcd for $C_{28}H_{22}O_6$: C, 74.00; H, 4.84; CH_3CO, 18.94%.

Bromination of IIIb. Each dye (IIIb; $R=C_{13}H_9$ and $R=C_{14}H_9$) (0.5 g) was dissolved in glacial acetic acid (10 ml) and to this a solution of bromine in glacial acetic acid (8 ml) was slowly added in cold to give deep red crystals (V: $R=C_{13}H_9$) (0.51 g), mp 300 °C; λ_{max}^{EtOH} (at pH 7.2) (ε): 520 nm (2476), and red crystals (V: $R=C_{14}H_9$) (0.51 g), mp 196 °C; λ_{max}^{EtOH} (at pH 9.1) (ε): 525 nm (2006) which were recrystallized from 90% ethanol.

Found: Br, 32.22%. Calcd for $C_{23}H_{16}O_4Br_2$: Br, 32.62%.
Found: Br, 29.88%. Calcd for $C_{24}H_{16}O_4Br_2$: Br, 30.27%.

Acetylation of Dye (VIIb). The dye (VIIb) (0.5 g) was treated similarly to the case of IIIb to give a red crystalline pentacetyl compound (VIII) (0.6 g), mp>300 °C (from acetone–ether); λ_{max}^{EtOH} (ε): 320 and 330 nm (6072).

Found: C, 66.51; H, 4.32; CH_3CO, 28.0%. Calcd for $C_{42}H_{35}O_{13}N$: C, 66.22; H, 4.59; CH_3CO, 28.25%.

Bromination of Dye (VIIb). To the dye (VIIb) (0.5 g) in glacial acetic acid (10 ml) was added saturated solution of bromine in acetic acid (15 ml). The contents were left at room temperature for 3 days to give a brown product. The acetone solution of brown product on refluxing with sodium acetate gave a deep red tetrabromo compound (IX) (0.54 g), mp>300 °C (from 80% ethanol); λ_{max}^{EtOH} (at pH 8.1) (ε): 510 and 520 nm (2167); (at pH 10.5): 580 and 600 nm (8670).

Found: Br, 36.50%. Calcd for $C_{32}H_{21}O_8NBr_4$: Br, 36.88%.

One of the authors (R.G.) thanks the C.S.I.R., New Delhi for a grant and fellowship and Director, Defence Laboratory, Jodhpur for granting permission to publish the work.

Calculation of the Ionization Yield in He by Incident Ar^+ and H^+ Ions with the Initial Energies of 1 and 0.1 MeV

Shin-ichi OHNO

Japan Atomic Energy Research Institute, Tokai-mura, Ibaraki 319-11

(Received November 18, 1974)

Synopsis. The classical binary-encounter theory was used to calculate the $G(He^+)$ due to the direct action of incident particles and that due to the secondary electrons. The results show that both values depend greatly on the quality of the radiation used.

The passage of heavy ions in matter causes the formation of various excited and ionized atoms through two processes: (i) the direct action of the incident ion and (ii) the indirect action resulting from the electrons ejected in (i). This note will present the results of calculation of the number of He^+ ions produced in (i) and (ii) respectively when a 1- or 0.1-MeV Ar^+ or the proton has been completely absorbed in He at 0 °C and 1 atm.

Method of Calculation

Non-empirical calculation was made on the basis of the classical binary-encounter approximation.[1] The advantage of this method is that it gives, in a simple way, an estimate of the cross sections as reasonable as the Born approximation over a wide range of energies of the incident particles.[2]

The incident particle with a mass of M, a charge of Ze, and a velocity of V_1 is assumed to collide with the atomic electron with a mass of m, a charge of e and a velocity of v_1. Let V_2 and v_2 be their respective velocities after the collision. When the energy transferred, $E=(1/2)m(v_2^2-v_1^2)$, exceeds the ionization energy, I, of the atomic electron, the ionization of the atom occurs, the kinetic energy of the ejected electron being $E-I$.

The differential cross section, σ_E, for transferring the energy, E, is expressed as:[2]

(i) If $2V_1 \geq v_2 + v_1$, $E \leq 2m_1V_1(V_1 - v_1)$,

$$\sigma_E = \frac{2\pi Z^2e^4}{mV_1^2}\left(\frac{1}{E^2}+\frac{2mv_1^2}{3E^3}\right) \quad (1)$$

(ii) If $v_2 - v_1 \leq 2V_1 \leq v_2 + v_1$, $2mV_1(V_1 - v_1) \leq E \leq 2mV_1(V_1 + v_1)$,

$$\sigma_E = \frac{\pi Z^2e^4}{3V_1^2v_1E^3}\left\{4V_1^3-\frac{1}{2}(v_2-v_1)^3\right\} \quad (2)$$

(iii) If $E/V_1 \geq m(v_2 + v_1)$,

$$\sigma_E = 0 \quad (3)$$

The energy spectrum, $y_p(T)$, of the incident particle as defined by Spencer and Fano,[3] can be expressed as the inverse of its stopping power. The stopping power may be obtained by integrating $E\sigma_E$ over E from E_{min} to E_{max}. E_{min} was set equal to 21.2 eV, the lowest singlet excitation energy of He. E_{max} is given by $2mV_1(V_1+v_1)$. Once $y_p(T)$ is obtained, the number of the He^+ ions produced directly by the incident particle of initial energy, T_0, may be calculated:

$$N_p(He^+) = N\int_I^{T_0} Q_{ion}(T)\cdot y_p(T)dT \quad (4)$$

Here, $Q_{ion}(T)$ is the probability that the He^+ ion will be formed in a collision with the particle with the energy of T and is obtained by integrating σ_E over a pertinent range of E. N is the number of He atoms per unit of volume, and I, the first ionization energy of He (24.6 eV). The G-value is given by $100\cdot N_p(He^+)/T_0$.

The ionization yield due to secondary electrons was calculated as follows. The energy spectrum of the electrons was obtained by Eqs. 1, 2, and 3, with the aid of the $y_p(T)$-curve mentioned above. Then, we could use the previous results[4] to calculate the ionization yields in He due to these ejected electrons.

It should be mentioned that, in the present calculation of the stopping power of the incident particle, we neglected the contributions from such modes of energy loss as the excitations and charge exchange of the projectile (Ar^+) and nuclear collisions. These omissions may slightly decrease the $G(He^+)$ due to incident particles, but the main features of the present results would not be changed.

The applicability of the present method is demonstrated by the facts that (i) the total yield of the ionization and excitation in He by incident 100-keV electrons calculated by the present method is in agreement with the experimental results,[4,5] and that (ii) the observed spectrum of the kinetic energy of the ejected electron on impacting 100-keV protons on He[6] can be well represented by Eq. 1, as is shown in Fig. 1.

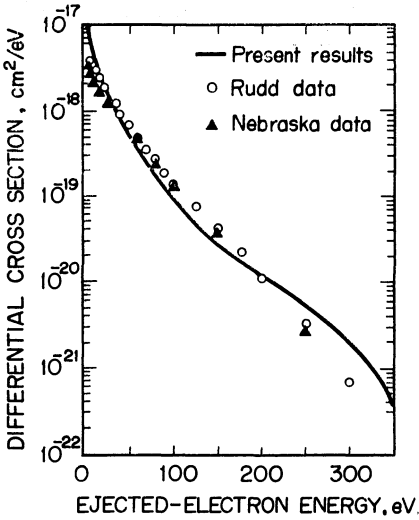

Fig. 1. Differential cross section for ejection of electrons by 100-keV protons in He.

Results

In Fig. 2, the values of $T\cdot Q_{ion}(T)\cdot y(T)$ are plotted againsnt $\ln(T)$ according to Platzman's method.[7] The

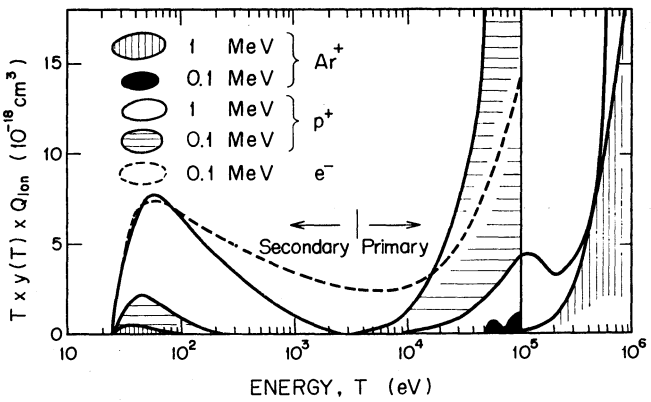

Fig. 2. Contribution of different portions of the slowing-down spectra of the incident particles ("Primary") and the ejected electrons ("Secondary") to the total ionization of He. Coordinate values for 1-MeV incident particles should be multiplied by 10.

area under the curve is proportional to the yield, thus demonstrating the contribution to the yield from a given energy range of the ion or the electrons. In the cases of 1- and 0.1-MeV Ar^+, the yield due to secondary electrons is small compared to that due to the interaction of the incident ion. In the case of the 1-MeV proton, the two processes give approximately the same yield. The energy spectrum of the secondary electrons in this case is similar to that in the case of the incident 100-keV electron.

The *G*-values of the two processes for each incident particle are compiled in Table 1.

Table 1. *G*-values of He^+ for different radiations

Incident particle	Energy (MeV)	Direct[a]	Indirect[b]	Total
Ar^+	1	0.59	0.02	0.61
Ar^+	0.1	0.016	0	0.016
p^+	1	1.75	1.04	2.79
p^+	0.1	1.35	0.15	1.50
e^-	0.1			2.42[c]

a) Ionization due to the direct action of incident particles.
b) Ionization due to the electrons ejected in a).
c) From Ref. 4.

Conclusion

The observed *G*-values of the radiolysis products generally depend on the type and energy of the radiation used. Many radiation chemists seem to ascribe this effect to the different spatial distributions and not to the different primary yields of the products initially formed in the radiation action. The present calculation has been concerned only with the primary yield and not with the spatial distribution. The results clearly show that the primary yield itself depends on the quality of the radiation used. Thus, the yields in addition to the spatial distributions must be taken into consideration for a better understanding of the "LET-effect" in radiation chemistry.

The author is indebted to Dr. Kazuhiko Izui, Japan Atomic Energy Research Institute, and Prof. Shin Sato, Tokyo Institute of Technology, for their helpful discussions.

Normal Vibrations of Benzenesulfonate and Benzene-d_5-sulfonate Ions

Toyozo Uno, Akio Kuwae, Yutaka Saito, and Katsunosuke Machida
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606
(Received January 23, 1975)

Infrared and Raman spectra of sodium benzenesulfonate and its fully *C*-deuterated derivative have been recorded in the solid state and in the aqueous solution. The normal coordinate analysis has been made for $C_6H_5SO_3^-$ and $C_6D_5SO_3^-$ ions based on the C_{2v} symmetry. A valence force field was assumed and the force constants were refined by the least squares method. It was found that the diagonal force constants for the CH out-of-plane bending vibrations at the *ortho* and the *para* positions are greater than the corresponding constant for the *meta* position. This result reflects well the effect of the electron attractive substituent in monosubstituted benzene derivatives. The force constants obtained were transferred to *p*-toluenesulfonate ion successfully.

The infrared spectra of benzenesulfonic acid salts have been studied by a few investigators with limited interest in the asymmetric and the symmetric stretching frequencies of the SO_3^- group.[1-3] Exceptionally, Margoshes *et al.*[4,5] quoted a band at 750 cm^{-1} as a datum to illustrate a correlation between the out-of-plane CH deformation frequencies and the electronegativity and the mass of the substituent in a series of monosubstituted benzenes. No reports seem to have been published yet on the overall vibrational assignments for benzenesulfonate ion. In the present work, we have investigated the infrared and Raman spectra of sodium benzene- and benzene-d_5-sulfonates, assigning the fundamental frequencies in detail and carrying out the normal coordinate analysis for both the in-plane and the out-of-plane vibrations. Special attention has been drawn on the infrared band at 750 cm^{-1} due to the CH out-of-plane deformation vibration in which all the hydrogen atoms move in phase. This band appears normally in the region between 770 and 720 cm^{-1} for monosubstituted benzenes. As well known for the cases of nitrobenzene and benzoic acid derivatives, the in-phase CH out-of-plane deformation frequency is raised when the substituent becomes strongly electron attractive. Although the $-SO_3^-$ group is supposed to be an electron attractive substituent, benzenesulfonate ion shows this band in the middle of the normal range, 750 cm^{-1}. In this respect it is of interest to clarify the role of the mass and the electronegativity of the substituent in determining the CH out-of-plane deformation frequencies.

Experimental

Commercially available sodium benzenesulfonate and sodium *p*-toluenesulfonate were recrystallized from methanol. Sodium benzene-d_5-sulfonate was kindly supplied by Dr. Y. Tanaka of Okayama University. The infrared spectra were recorded on a Koken DS-301 spectrophotometer equipped with NaCl prisms (4000—650 cm^{-1}), on a Perkin Elmer Model 521 grating spectrophotometer (800—250 cm^{-1}) and on a Hitachi FIS-3 grating spectrophotometer (400—33 cm^{-1}). The measurements were made for the mulls with Nujol or hexachlorobutadiene over the whole range, and for the aqueous (H_2O and D_2O) solutions between 1700 and 650 cm^{-1}. The Raman spectra of the crystalline powder samples sealed in capillary tubes were measured on a JEOL S-1 laser Raman spectrophotometer. The slit width was 12 cm^{-1}. The Raman polarization measurement was made for the saturated aqueous solution. The 514.5 nm line of a Coherent 52 G Ar^+ laser was used as the excitation source. The infrared and the Raman specra of sodium benzene- and benzene-d_5-sulfonates are shown in Figs. 1 and 2. The observed fundamental frequencies are listed in Table 1 together with the assignments and the calculated frequencies.

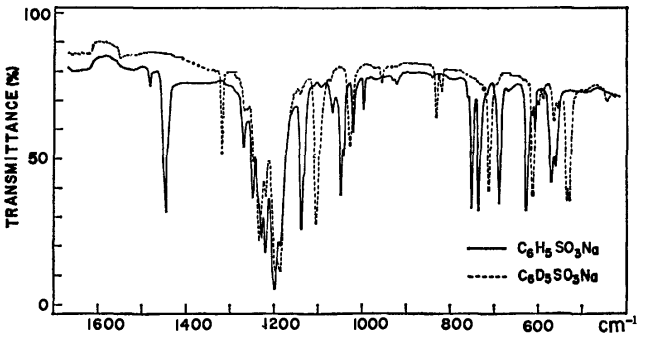

Fig. 1. Infrared spectra of sodium benzenesulfonate and sodium benzene-d_5-sulfonate.

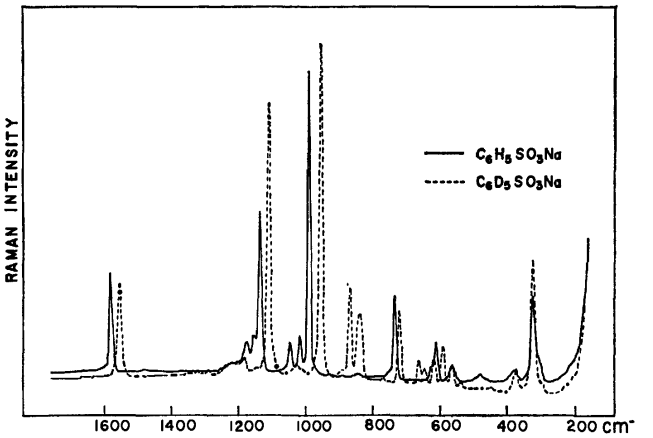

Fig. 2. Raman spectra of sodium benzenesulfonate and sodium benzene-d_5-sulfonate.

Assignments

For sodium benzene-d_5-sulfonate, one of the b_2 CD in-plane deformation frequencies expected around 850 cm^{-1} could not be found in either the infrared or the Raman spectrum. All the other fundamentals due to the ring in-plane vibrations of benzene- and benzene-d_5-sulfonate ions were easily assigned by referring to the available data for toluene,[6] chlorobenzene[7,8] and their ring deuterated compounds.[6,8,9]

a) Combination band of in-plane fundamentals.

The infrared bands observed at 1194 and 1049 cm^{-1} for the crystal of sodium benzenesulfonate are assigned to the asymmetric and the symmetric SO_3^- stretching vibrations, respectively.[1] The former band is broad and splits complicatedly, but in the aqueous solution this splitting disappears and only a single broad absorption is observed in the same frequency region. The symmetric stretching band is sharp and shifts to 1033 cm^{-1} on going to the aqueous solution. Sodium benzene-d_5-sulfonate shows the corresponding infrared bands at 1193 and 1030 cm^{-1}. In analogy with the case of benzenesulfonyl chloride[10] the C-S stretching vibration is thought to couple with a ring vibration, contributing to the infrared bands at 1137 and 735 cm^{-1} of sodium benzenesulfonate and those at 1107 and 711 cm^{-1} of sodium benzene-d_5-sulfonate.

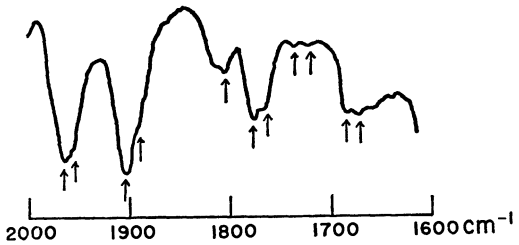

Fig. 3. Infrared summation bands in the region between 1600 and 2000 cm^{-1}. The arrows show the observed absorptions.

Except for the strong infrared band at 750 cm^{-1}, the assignments of the CH out-of-plane deformation frequencies were accomplished with the aid of an analysis of the summation bands in the region between 2000 and 1600 cm^{-1}.[11] (see Fig. 3) The agreements between the sums of the fundamentals and the observed summation frequencies are good as shown in Table 2. Among these summation bands, the band near 1800 cm^{-1} due to the combination of the two a_2 vibrations is the least sensitive to the change of the substituent, since the a_2 vibrations do not involve the motion of the substituent when it is approximated to be a point mass. One of the a_2 fundamentals of benzenesulfonate ion is observed at 965 cm^{-1} in the infrared spectrum probably because the molecular symmetry is lowered in the crystal. The remaining a_2 fundamental is easily estimated from the summation frequency 1805 cm^{-1}. The assignments of the b_1 out-of-plane ring deformation frequencies were made by analogy with toluene[6] and chlorobenzene[7,9,12], and by referring to the result of the normal coordinate calculation with the starting set of force constants.

After the ring vibrational frequencies were identified, the infrared and the Raman bands left unassigned below 700 cm^{-1} were attributed to the symmetric and the asymmetric deformation vibrations and the rocking vibrations of the SO_3^- group by referring to the corresponding frequencies of methanesulfonate ion.[13] The presently assigned SO_3^- group frequencies are reasonable in comparison with those for *p*-aminobenzenesulfonate ion.[14]

Normal Coordinate Analysis

The structure determination by the X-ray analssis has not yet been made for sodium benzenesulfonate. Accordingly, the structure of benzenesulfonate ion was estimated in this work from analogy with the results of the X-ray analysis for magnesium and zinc salts.[15] The benzene ring was assumed to be a regular hexagon being coplanar with one of the S–O bonds. The six angles around the sulfur atom were taken to be tetrahedral. We adopted the molecular symmetry C_{2v} for benzenesulfonate ion by eliminating the interaction terms between the ring and the substituent from the force field.[16] The torsional motion around the C–S bond was excluded from the calculation. Figure 4 shows the structure parameters and the internal coordinate system.

The force field was assumed to be of the valence type and the initial values of force constants for the ring

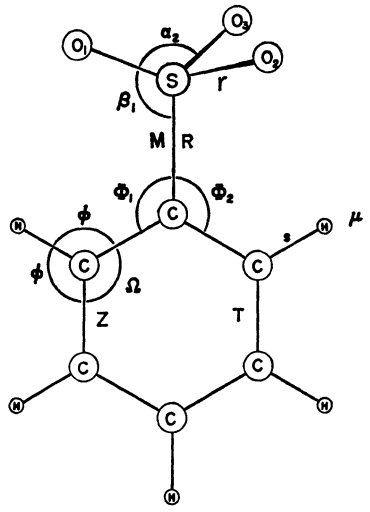

Fig. 4. The structure and the internal coordinates used in the calculation. Bond lengths(in Å): CH, 1.084; CC, 1.397; CS, 1.82; SO, 1.39.

part were taken from toluene.[6] For the sulfonate part, the initial constants were set equal to the F matrix elements obtained from the Urey-Bradley force constants for methanesulfonate ion.[13] In the region above 500 cm^{-1}, the transferred force constants reproduced fairly well the fundamental frequencies already assigned, and the remaining frequencies could be selected so as to reproduce the calculated values as closely as possible under the restriction from the Raman polarization and the isotope effects. Preliminary calculations showed, however, that the agreement between the observed and the calculated frequencies below 500 cm^{-1} could not be improved within the framework of the transferred force field, so that we introduced the interaction constants $F_{\Phi-\rho SO_3}$ and $F_{M-\rho SO_3'}$ with initial values zero. These constants are defined by the terms in the potential function

$$V = \cdots\cdots + F_{\Phi-\rho SO_3} S_\Phi S_{\rho SO_3} + F_{M-\rho SO_3'} S_M S_{\rho SO_3'} + \cdots\cdots,$$

where the coordinates S_Φ, $S_{\rho SO_3}$, S_M and $S_{\rho SO_3'}$ are given by

$$S_\Phi = (\Phi_2 - \Phi_1)/\sqrt{2}$$

$$S_{\rho SO_3} = (2\beta_1 - \beta_2 - \beta_3)/\sqrt{6}$$

$$S_M = M$$

and

$$S_{\rho SO_3'} = (\beta_2 - \beta_3)/\sqrt{2},$$

respectively.

We attributed zero weights to the CH stretching frequencies and accordingly fixed the CH stretching constant K_s to the transferred value. The simultaneous least squares refinement of all the other force constants was found to result in divergence. Accordingly, the iteration was performed alternately for the force constants related to the substituent and for those related to the benzene ring, until the sum of the squared residuals became stationary. In this process, any force constants showing large dispersions were fixed automatically, and for this reason most of the off-diagonal substituent constants were left highly indeterminate. Fortunately,

the ring frequencies were hardly affected by these constants, and the force constants for the ring part were believed to converge to the best values. The diagonal constants for the CH out-of-plane deformation coordinates at the *meta* and the *para* positions of the substituent, H_{μ^m} and H_{μ^p}, respectively, were constrained to the same value in the calculation for toluene by Lau and Snyder[6], but they were treated as the independent parameters in the present work. The final set of force constants are listed in Table 3.

Discussion

The mixing between the CH out-of-plane deformation and the ring torsional vibrations of benzenesulfonate ion is appreciable in the a_2 and the b_1 species. The infrared bands at 750 and 688 cm^{-1} characteristic of monosubstituted benzenes are contributed almost equally from the CH out-of-plane deformation and the torsional vibrations. The C-S out-of-plane deformation vibration also contributes to the 750 cm^{-1} band, explaining the fact that this frequency is sensitive to the mass of the substituent.[5] For the deuterated compound, the b_1 SO_3^- asymmetric deformation vibration couples with the torsional vibrations in the fundamentals at 611 and 599 cm^{-1}. The infrared band of the undeuterated compound at 478 cm^{-1} corresponds to the X-sensitive band at 508 cm^{-1} of nitrobenzene[17] and also to the 460 cm^{-1} band of benzenesulfonyl chloride.[10] According to the present calculation, this band is due to a coupled mode of the SO_3^- out-of-plane rocking, the C-S out-of-plane deformation and the ring torsional vibrations.

In the presently obtained force field of benzenesulfonate ion, the CH out-of-plane deformation constants for the *ortho* and the *para* hydrogen atoms are appreciably greater than that for the *meta* hydrogen atoms. The electronic theory due to Margoshes *et al.* states that the increase of the local π-electron density on the ring carbon facilitates the rehybridization from sp_2 to sp_3 orbitals on the out-of-plane deformation of the CH bond.[4] The present result is consistent with the prediction of this theory for the *meta*-orienting substituent. A similar conclusion was already obtained by Kakiuchi *et al.* in their simplified treatment of the CH out-of-plane deformation vibrations of some monosubstituted benzenes.[18,19] Usually, the characteristic infrared band due to the in-phase CH out-of-plane deformation vibration of monosubstituted benzene derivatives shifts to the high-frequency side when the substituent becomes more electron-attractive. Margoshes *et al.* also pointed out that, in the case of mono-atomic substituent X, a negative correlation exists between the frequency of this band and the reduced mass of the bond C–X.[5] For benzenesulfonate ion, the electron drawing character of the substituent tends to raise this frequency, while the large mass of the sulfur atom tends to lower it, and these effects cancell each other. In order to estimate the mass effect we tried a calculation in which the mass of sulfur is replaced by that of carbon and the bond length C-S by that of C–C in toluene, leaving the force constants unchanged. This calculation gave rise to an increase of the in-phase CH out-of-plane deformation frequency by about 10 cm^{-1}, to which the diminutions in the mass and the bond length were found to con-

tribute equally.

In order to check the transferability of the force constants among related compounds, the normal coordinate calculation for *p*-toluenesulfonate ion was performed in the same way as that for benzenesulfonate ion. The force constants for the methyl group were transferred from toluene[6] and the others from the final set for benzenesulfonate ion. By using these constants, the observed frequencies of sodium *p*-toluenesulfonate were reproduced well except for two infrared frequencies 694 and 482 cm^{-1} to which the torsional vibrations contribute mainly. With the purpose to attain a better fit between the observed and the calculated frequencies, the force constants related to the CH out-of-plane deformation and the torsional vibrations were refined by the least squares method. After several cycles of refinements, the torsional constant H_z converged to an intermediate value between those of toluene and benzenesulfonate ion, and fairly good fit was obtained without large changes of the CH out-of-plane deformation constants. The results are shown in Table 4. The large differences in the torsional constants among differently substituted benzene derivatives indicate that the easiness of the torsional motion is highly sensitive to the ring-electron density, which in turn is related closely to the number and the kind of the substituents. For the other force constants, we may conclude that the transferability between benzenesulfonate and *p*-toluenesulfonate ions is fairly good.

The authors wish to express their thanks to Prof. T. Takenaka and Prof. S. Hayashi of Kyoto University for the use of Perkin-Elmer Model 521 and Hitachi FIS-3 grating infrared spectrophotometers. Thanks are also due to Dr. Y. Tanaka of Okayama University for supplying the sample of sodium benzene-d_5-sulfonate. Throughout this work, FACOM 230—60 and 230—75 computers of Kyoto University Computer Center were used.

Lifetimes of Electrons in Irradiated Liquid Alkanes

Kenji FUEKI

Department of Synthetic Chemistry, Nagoya University Chikusa-ku, Nagoya 464

(Received March 26, 1975)

A calculation has been made of lifetimes of electrons in irradiated liquid alkanes on the basis of the lifetime distribution function for the geminate electrons derived from the exponential distribution function for electron ranges. The results show that the intrinsic electron lifetimes correlate with the electron mobilities and most of the geminate electrons recombine within 1 ns in the alkanes at room temperature. A consideration is given to the effect of pulse duration time on the apparent electron lifetime and the observable yield of electrons in *n*-hexane.

In recent years there has been much interest in the behavior and properties of electrons in nonpolar liquids in some branches of chemistry and physics. In radiation chemistry considerable efforts have been paid to this research field both theoretically and experimentally. As such an effort, a number of studies have been made of ranges of electrons in irradiated liquid hydrocarbons, in which various spatial distribution functions for the thermalized electrons have been used and tested by comparison with experiment. At present it appears that a Gaussian-power function[1] and an exponential function[2–4] are the best among the prescribed forms of electron distribution functions for liquid alkanes. As an alternative approach to an understanding of the behavior of electrons in irradiated liquid hydrocarbons, we may discuss the lifetime distribution of the thermalized electrons. Most of previous studies on this subject have dealt with only very limited hydrocarbons such as cyclohexane and *n*-hexane.[5–8] Also, values of the diffusion constant of the electron used in earlier studies are inappropriate in the light of recent electron mobility data. The diffusion constant of the electron is a crucial factor in determining electron lifetimes. More recent studies have used the appropriate values of the diffusion constant of the electron.[9,10] Schuler and his coworkers[11] have developed a phenomenological model for the description of electron lifetimes in irradiated liquid hydrocarbons which is based on their scavenging function.

In this work, we attempt to calculate the lifetime distribution of electrons in irradiated liquid alkanes on the basis of the exponential distribution function for electron ranges and recent experimental data on electron mobilities. Here we deal with seven alkanes (*n*-pentane, cyclopentane, neopentane, *n*-hexane, cyclohexane, 2,2-dimethylbutane and 2,2,4-trimethylpentane) for which the electron mobilities vary over three orders of magnitude.

Model and Lifetime Distribution Function

First, we assume a model in which an instantaneous pulse of radiation is given to dielectric liquids and ranges of electrons produced are expressed by the exponential distribution function as given by Eq. (1).

$$\begin{aligned} \phi(r) &= 0, && r \leq r_0 \\ \phi(r) &= (1/4\pi br^2)\exp[(r_0-r)/b], && r \geq r_0 \end{aligned} \tag{1}$$

where b is the range parameter and r_0 is the reaction radius. Using the time-distance relationship, $t=r^3/3Dr_c$, derived from the Nernst-Einstein relation[5] and $4\pi r^2\phi(r)\mathrm{d}r=f(t)\mathrm{d}t$, we get Eq. (2) for the lifetime distribution function or the existence function for geminate ion-electron pairs.

$$F(t) = \int_t^\infty f(t)\mathrm{d}t = \exp\{(3Dr_c)^{1/3}[t_0^{1/3}-(t+t_0)^{1/3}]/b\}, \quad 0 \leq t \leq t_f$$

$$t_0 = r_0^3/3Dr_c,\ r_c = e^2/\varepsilon kT \tag{2}$$

where D is the sum of the diffusion constants of the ion and electron, e is the electronic charge, ε is the dielectric constant of a liquid, k is Boltzmann's constant and T is the absolute temperature. Equation (2) represents the fraction of electrons present at time t after an instantaneous pulse of radiation. t_f is a characteristic time difined as $F(t_f)=G_{fI}/G_t$, where G_{fI} and G_t are the free ion yield and the total ion yield, respectively. t_f means the time at which the geminate recombination of ion-electron pairs practically completes.

We may define another characteristic time $t_{1/e}$ for the geminate recombination. $t_{1/e}$ is the time at which the value of $F(t)$ falls to 1/e of its value at $t=0$. Since t_0 is very small, $t_{1/e}$ is given, to a very good approximation, by Eq. (3).

$$t_{1/e} = b^3/3Dr_c \tag{3}$$

$t_{1/e}$ is exactly given by Eq. (3) for $r_0=0$.

Since the Nernst-Einstein relation neglects the effect of outward diffusive motion of electrons on the geminate recombination times, the use of this relation tends to underestimate the geminate recombination times. In the calculations of electron lifetimes, therefore, we have also attempted to correct for this effect in a similar manner to that used in Ref. 12. Such a corrected time t' is given by Eq. (4)

$$t' = t[1+(4/3r_c)(3Dr_c)^{1/3}t^{1/3}]^{3/2} \tag{4}$$

We now consider a square pulse of duration τ. In this case the existence function is expressed by Eq. (5), assuming $r_0=0$.

$$F(t) = (1/\tau)\int_0^\tau \exp[a(t^*-t)^{1/3}]\mathrm{d}t^* \tag{5}$$

where $a=(3Dr_c)^{1/3}/b$ and time is measured from the onset of the pulse. Performing the integration in Eq. (5) leads to Eq. (6).

$$\begin{aligned} F(t) &= (3/\tau a)\{(2/a^2) - [t^{2/3} + (2/a)t^{1/3} + (2/a^2)] \\ &\quad \times \exp(-at^{1/3})\}, \quad t \leq \tau \\ F(t) &= (3/\tau a)\{[(t-\tau)^{2/3} + (2/a)(t-\tau)^{1/3} + (2/a^2)] \\ &\quad \times \exp[-a(t-\tau)^{1/3}] - [t^{2/3} + (2/a)t^{1/3} + (2/a)^2] \\ &\quad \times \exp(-at^{1/3})\}, \quad t \geq \tau \end{aligned} \tag{6}$$

It can be shown that $F(t)$ in Eq. (6) for $\tau=0$ reduces $F(t)$ in Eq. (2) with $r_0=0$.

Values of physical parameters used in the calculations are listed in Table I. Since the diffusion constant of the electron is usually much greater than that of the ion, the diffusion, constant D may be approximated by the diffusion constant of the electron, D_e, which is related to the electron mobility μ_e by $D_e=kT\mu_e/e$. The electron mobility in n-hexane at -80 °C was calculated from a mobility equation $\mu_e=\mu_0\exp(-E/RT)$ where $\mu_0=120$ cm^{2}V^{-1} s^{-1} and $E=4.3$ kcal mole^{-1}.[16,22] The results of the calculations are given in Tables 2 and 3, and Figs. 1—3. The results in Table 2 and Fig. 1 were obtained using $r_0=5$ Å, and those in Table 3 and Figs. 2 and 3 were calculated with $r_0=0$.

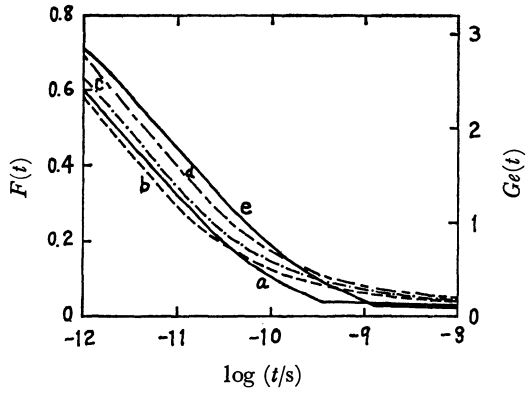

Fig. 1. Decay of electron population in cyclohexane and n-hexane at 23 °C. Time is measured from the input of an instantaneous pulse of radiation. a: cyclohexane, exponential function; b: cyclohexane, Schuler's function ($\alpha=12$ M^{-1}, $k=4.3\times10^{12}$ M^{-1} s^{-1}); c: cyclohexane, Schuler's function ($\alpha=12$ M^{-1}, $k=2.7\times10^{12}$ M^{-1} s^{-1}); d:cyclohexane, Schuler's function ($\alpha=12$ M^{-1}, $k=1.8\times10^{12}$ M^{-1} s^{-1}); e: n-hexane, exponential function.

Results and Discussion

Lifetimes of Electrons in Liquid Alkanes. In Table 2 are presented the calculated characteristic times for the geminate recombination of ion–electron pairs in seven alkanes at 23 °C. In the calculations two approximations were used for the time-distance relation: one is the forced diffusion approximation (FD), in which the Nernst-Einstein relation is used; the other is the forced diffusion approximation with a random diffusion correction (FRD), in which Eq. (4) is used for the corrected time t'. It is seen in Table 2 that the FRD approximation yields the characteristic recombination times greater than does the FD approximation. The differences between values obtained with these two approximations are greater for t_f and t_f' than for $t_{1/e}$ and $t_{1/e}'$. This is understandable noting that $t_{1/e}$ or $t_{1/e}'$ represents the geminate recombination time for the electrons not very far away from their parent ions and on which the strong Coulomb field acts, while t_f or t_f' represents the recombination time for the electrons distant from their parent ions and being subjected to the thermal force almost as strong as the Coulomb force. It can be seen from Tables 1 and 2 that the greater is the electron mobility, the greater is the ratio of $t_{1/e}'$ to $t_{1/e}$, for instance, this ratio is the greatest for neopentane and the smallest for n-hexane, while the ratio of t_f' to t_f is about the same (~3) for all the hydrocarbons studied. The magnitude of t_f or t_f' decreases with increasing electron mobility. Similarly, the value of $t_{1/e}$ or $t_{1/e}'$ decreases with increasing electron mobility with one exception of neopentane for which $t_{1/e}$ or $t_{1/e}'$ is somewhat greater than expected from the electron mobility in neopentane. Such an exception is due to the fact that the electron range b in neopentane is much greater than those in the other hydrocarbons as shown in Table 1 and that $t_{1/e}$ is proportional to b^3 (see Eq. (3)). The use of $G_{fi}=0.86$ and $G_t=3.7$ for neopentane yields $b=250$ Å[2] which is close to the b value given in Table 1.

Figure 1 shows the calculated time dependence of electron population in cyclohexane and in n-hexane after an instantaneous pulse of radiation. In Fig. 1 $G_e(t)$ represents the yield of electrons present at time t, calculated setting $G_e(t)=G_t$. Curve a was calculated using the exponential distribution function and the FRD approximation for electrons in cyclohexane. Curves b, c and d for cyclohexane were calculated using S huler's distribution function for electron life times[11] with the reactivity parameter, $\alpha=12$ M^{-1},[23] and the absolute rate constant, $k=4.3\times10^{12}$,[24] 2.7×10^{12},[25] and 1.8×10^{12} M^{-1} sec^{-1},[18] respectively, for the reaction of electrons with carbon tetrachloride. It is seen in

TABLE 1. PHYSICAL PARAMETERS USED IN THE CALCULATIONS AT 23 °C

Liquid	r_c[a] (Å)	b[b] (Å)	μ_e ($cm^2/V \cdot s$)	G_{fi}[a]	G_t

TABLE 3. CALCULATED HALF-LIFE TIMES AND YIELDS OF ELECTRONS IN PULSE-IRRADIATED *n*-HEXANE

t (°C)	τ	$t_{1/2}$	G (e^-)
−80	ns	ns	
	10	13.5	0.52
	5	7.8	0.77
	1	2.4	1.5
	0.1	0.64	2.5
	0	0.13	4.0
23	ps	ps	
	200	290	0.63
	100	170	0.90
	20	53	1.6
	0	3.5	4.0

Fig. 1 that curves b and c are very close to curve a and that curve d gives somewhat higher values of $F(t)$ or $G_e(t)$ than does curve a, but curve d is also comparable to curve a on the time scale. It should be noted, however, that curve a underestimates considerably electron lifetimes in the long-time limit for the geminate ion-electron recombination. Schuler's lifetime distribution function predicts the time dependence of $t^{-1/2}$ in the long-time limit,[11] while Eq. (2) does not predict the $t^{-1/2}$ dependence. This discrepancy arises from the fact that the use of the Nernst-Einstein relation is not appropriate for the description of motion of electrons distant from their parent ions since Brownian motion of electrons is as important as the electron drift in the Coulomb field for such electrons. Curve e shows $F(t)$ or $G_e(t)$ calculated using the exponential distribution function and the FRD approximation for electrons in *n*-hexane. The shape of the curve is similar to that for cyclohexane, but the geminate recombination time in *n*-hexane is longer than that in cyclohexane. It is noted that in the calculations, an extremely low dose rate is assumed, resulting in an indefinitely long lifetime of the free electrons.

Lifetimes of Electrons in Pulse-Irradiated n-*Hexane.* Figures 2 and 3 show the growth and decay of electron population in *n*-hexane at −80 °C and 23 °C, respectively, calculated using Eq. (6) for a square pulse of duration τ. The duration time τ is taken as 0.1, 1, 5 and 10 ns at −80 °C and 20, 100 and 200 ps at 23 °C. It can be seen from Figs. 2 and 3 that the electron population increases with time, reaches a maximum at $t=\tau$ and then decreases with increasing time. It is also seen that the shorter is the duration time of the pulse, the higher is the maximum of electron population and the greater is the apparent decay rate of electrons. Table 3 summarizes the half-life time, $t_{1/2}$, for the decay of electrons and the yield of electrons, $G(e^-)$, at the maximum of electron population. The half-life time for $\tau=0$ is the shortest at each temperature and indicates the intrinsic lifetime of the geminate electrons at that temperature. The lifetimes of electrons at −80 °C are much longer than those at 23 °C. This difference arises from the fact that the electron mobility at −80 °C is much lower than that at 23 °C as shown by the temperature dependence of the mobility equation.

Comments on Pulse Radiolysis Observations of Electrons in Liquid Hydrocarbons. Optical absorption spectra of trapped electrons were observed by the pulse radiolysis technique in liquid hydrocarbons: *n*-hexane, cyclohexane, methylcyclohexane and isopentane at 20 °C;[26] *n*-hexane and 3-methylhexane at −80 °C;[27] methylcyclohexane at −113 °C;[28] squalane at −165∼−70 °C;[29] propane at −185 and −165°C.[30] The decay of electrons observed at room temperature obeys the second-order kinetic law and these electrons are regarded as the free electrons.[26] Studies of the decay of electrons at low temperatures suggest that the initial decay of electrons observed is due to the geminate recombination with their parent ions.[27-30] However, there are only very limited experimental data available for a quantitative comparison between theoretical calculations and the observed characteristics of decay of electrons. Such a comparison has recently been made successfully for electrons in pulse-irradiated liquid propane.[31] It is hoped that a more detailed experimental study will be undertaken on the decay of the geminate electrons in *n*-hexane to test the applicability of the present model.

Ranges and Lifetimes of Electrons in Irradiated Liquid Hydrocarbons. Application of the Modified Exponential Distribution Function

Masatoshi BABA and Kenji FUEKI

Department of Synthetic Chemistry, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 2, 1975)

A modified exponential function is developed for the description of the spatial distribution of electrons in irradiated liquid hydrocarbons. This distribution function is applied to calculations of ranges and lifetimes of electrons in a number of hydrocarbons. The temperature dependence of electron ranges is also investigated for some of the hydrocarbons. A calculation is made of electron scavenging in cyclohexane using this distribution function and the forced diffusion approximations.

Recently, there has been considerable interest in the behavior, properties and reactions of electrons in nonpolar liquids. Many studies have been made of spatial distributions[1-12] and lifetimes[13-18] of electrons in irradiated liquid hydrocarbons. It has been shown that the simple exponential distribution function can well account for some experimental results on electrons in liquid hydrocarbons.[6,10] However, the electron population probability derived from the simple exponential distribution function increases monotonously with decreasing ion-electron separation distance and becomes very large near or at zero distance. Such a behavior at very small distances seems unrealistic on general grounds.

In this work, we develop a modified exponential function for the spatial distribution of electrons, which removes the unrealistic behavior of the simple exponential distribution function at small distances and still retains the characteristics of the exponential distribution function at large distances, and apply it to calculations of ranges and lifetimes of electrons in a number of liquid hydrocarbons including alkanes, alkenes, dienes, alkynes and aromatics. We also investigate the temperature dependence of electron ranges in some of the hydrocarbons. Further, using this distribution function and the forced diffusion approximations, we attempt to calculate the dependence on the scavenger concentration of the yield of electrons scavenged in a cyclohexane solution, and compare these results with that obtained from Schuler's scavenging function.

Outline of Calculation

The Modified Exponential Distribution Function. The spatial distribution function for the thermalized electrons used in the present calculations is given by Eq. (1).

$$\phi(r) = (1/2)(\pi b_{ME} r)^{-3/2}\exp(-r/b_{ME}) \quad (1)$$

where r is the separation distance of an ion-electron pair, b_{ME} is the electron range parameter and determined from Eq. (6). $\phi(r)$ is a normalized function: $\int_0^\infty \phi(r)4\pi r^2 dr=1$, and unlike the simple exponential distribution function, the function $\Phi(r)=4\pi r^2\phi(r)$ behaves in such a way that it changes smoothly with r, taking a maximum value at a finite value of r and becoming zero at $r=0$.

We define the average electron range by Eq. (2).

$$\bar{r}_{ME} = \int_0^\infty r\phi(r)4\pi r^2 dr = (3/2)b_{ME} \quad (2)$$

The Geminate Ion-Electron Recombination Time. Using the Nernst-Einstein relation, we can derive Eq. (3a) which gives the time-distance relationship for the geminate ion-electron pair.[13]

$$t = r^3/3Dr_c \quad (3a)$$

Here D is the sum of the diffusion constants of the ion and electron, and r_c is the Onsager distance, $r_c=e^2/\varepsilon kT$, where e is the electronic charge, ε is the dielectric constant of a liquid, k is Boltzmann's constant and T is the absolute temperature. If we make a correction for the effect of outward diffusive motion of electrons on the geminate recombination times in a similar manner as that used in Ref. 14, we obtain Eq. (3b) as the corrected time-distance relationship.

$$t' = (r^3/3Dr_c)[1+(4r/3r_c)]^{3/2} \quad (3b)$$

It is seen in Eq. (3b) that the greater is the ion-electron separation distance r, the greater is the correction term $[1+(4r/3r_c)]^{3/2}$. We define by Eq. (4a) or (4b) the average recombination time for the geminate ion-electron pairs, namely, the average lifetime of the geminate electrons.

$$\tau_g = \bar{r}_{ME}^3/3Dr_c, \quad (4a)$$

$$\tau_g' = (\bar{r}_{ME}^3/3Dr_c)[1+(4\bar{r}_{ME}/3r_c)]^{3/2} \quad (4b)$$

Since the diffusion constant of the electron is usually much greater than that of the ion, the diffusion constant D may be approximated by the diffusion constant of the electron, D_e, which is related to the electron mobility μ_e by $D_e=kT\mu_e/e$.

The Free Ion Yield. The free ion yield G_{fi} is expressed by Eq. (5).

$$G_{fi} = G_t\int_0^\infty \phi(r)\exp(-r_c/r)4\pi r^2 dr \quad (5)$$

Substituting $\phi(r)$ given in Eq. (1) into Eq. (5) and integrating it, we get a simple equation in closed form (Eq. (6)).

$$G_{fi} = G_t[1+2(r_c/b_{ME})^{1/2}]\exp[-2(r_c/b_{ME})^{1/2}] \quad (6)$$

where G_t represents the total ion yield. In the present calculations G_t is assumed to be 4.3 for all the hydrocarbons. Equation (6) is used for determining b_{ME}.

The Yield of Electrons Scavenged by a Scavenger. The yield of electrons scavenged by a scavenger, $G(e_{sc}^-)$, is calculated using Eq. (7a) or (7b).

$$G(e_{sc}^-) = G_t\int_0^\infty \phi(r)[1-\exp(-kSt)]4\pi r^2 dr, \quad (7a)$$

$$G(e_{sc}^-) = G_t\int_0^\infty \phi(r)[1-\exp(-kSt')]4\pi r^2 dr \qquad (7b)$$

where k is the rate constant for reaction of electrons with the scavenger and S is the concentration of the scavenger. The time t or t' is given as a function of r by Eq. (3a) or (3b).

Results and Discussion

The results of the calculations are given in Tables 1—4 and Figs. 1 and 2.

Electron Ranges. In Tables 1, 2 and 3 are listed the ranges of electrons, b_{ME} and $\bar{r}_{ME}$, calculated from Eqs. (6) and (2) using experimental values of G_{fl} for alkanes; alkenes, dienes, and alkynes; and aromatics, respectively. For comparison the electron ranges, $\bar{r}_E$, obtained from the simple exponential distribution function, $\phi(r)=(4\pi b_E r^2)^{-1}\exp(-r/b_E)$, are also given for alkanes in Table 1. It should be noted that $\bar{r}_E$ is equal to b_E for the simple exponential distribution function. The value of $\bar{r}_{ME}$ or b_{ME} correlates with that of G_{fl}: the greater is the free ion yield, the greater is $\bar{r}_{ME}$ or b_{ME}. Such a correlation has been found with other spatial distribution functions for electron ranges.[12] It is seen in Table 1 that generally $\bar{r}_{ME}$ is somewhat greater than $\bar{r}_E$ for the same compound, although $\bar{r}_{ME}$ is equal to $\bar{r}_E$ for neopentane. Figure 1 illustrates a comparison between the modified and simple exponential distribution functions for electrons in cyclohexane at room temperature. In the calculations of these distribution curves, b_{ME}= 41.4 Å and b_E=57.5 Å were used, which were ob-

tained using G_{fi}=0.148 and G_t=4.3. Table 4 shows the calculated temperature dependence of electron ranges b_{ME} for some of the hydrocarbons. It can be seen from Table 4 that b_{ME} increases with increasing temperature for these hydrocarbons except for butadiene where b_{ME} is nearly constant over the temperature range studied. Values of the parameter $b_{ME}d$ are also given in Table 4, where d is the liquid density. The value of $b_{ME}d$ is nearly constant for each of the hydrocarbons, although it decreases with increasing temperature for butadiene and tends to increase with increasing temperature for cyclohexene at higher temperatures. Thus, it appears that the electron range in liquid hydrocarbons is, approximately, inversely proportional to the medium density.

Geminate Recombination Times. The geminate ion-electron recombination times or the lifetimes of geminate electrons, τ_g and τ_g', are given for alkanes, alkenes and aromatics in Tables 1, 2 and 3, respectively. It can be seen from these tables that the values of τ_g or τ_g' are in the time range of 1—10 ps for most of the hydrocarbons and in the time range of 10—100 ps for some of the hydrocarbons. It is also seen that the geminate recombination time correlates with the electron mobility: the greater is the electron mobility, the shorter is the geminate recombination time. The geminate recombination times for electrons in liquid methane and neopentane are longer than expected from the electron mobilities in these liquids. This is due to the fact that the electron ranges are very large in methane and neopentane. It is interesting to note that the electrons in methane and neopentane are quasi-free electrons. The corrected

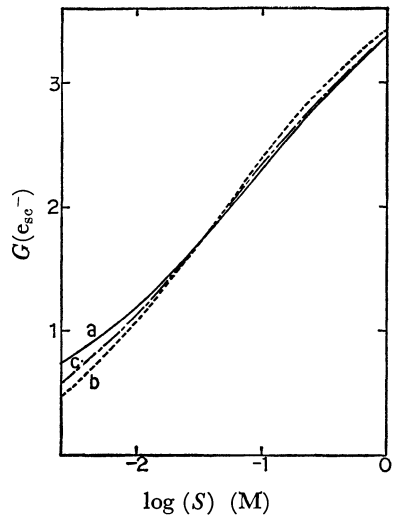

Fig. 2. Concentration dependence of the yield of electrons scavenged in a cyclohexane solution. a: calculated from Schuler's scavenging function, b: calculated from Eq. (7a), c: calculated from Eq. (7b). See the text for the parameters used in the calculations.

geminate recombination time, τ_g', is greater than the geminate recombination time, τ_g, derived directly from the Nernst-Einstein relation. The ratio of τ_g' to τ_g is different for individual compounds and depends on the value of $\bar{r}_{ME}/r_c$ as seen from Eqs. (4a) and (4b). For instance, the values of τ_g'/τ_g are large for methane and neopentane for which the values of $\bar{r}_{ME}/r_c$ are large.

Electron Scavenging in Cyclohexane. Figure 2 shows the yields of electrons scavenged, $G(e_{sc}^-)$, by a scavenger (carbontetrachloride) in cyclohexane, which were calculated as a function of the scavenger concentration. In Fig. 2, curve a was calculated using Schuler's scavenging function with $G_{fi}=0.12$, $G_t=4.2$ and $\alpha=12\ M^{-1}$.[26] It is well known that Schuler's scavenging function can satisfactorily reproduce the observed dependence on the scavenger concentration of the yield of electrons scavenged in irradiated liquid hydrocarbons. Curves b and c were calculated using Eqs. (7a) and (7b), respectively. The value of the parameter, k/D, involved in Eq. (7a) or (7b) was chosen so that the calculated curve fits reasonably curve a. The value of k/D thus chosen is 8.5×10^{14} $M^{-1}\,cm^{-2}$ in Eq. (7a) and $5.9\times10^{14}\,M^{-1}\,cm^{-2}$ in Eq. (7b). It is seen in Fig. 2 that curve a is closer to curve c than curve b and that curve c is very close to curve a at the scavenger concentrations higher than 10^{-2} M. However, curve c deviates from curve a at the scavenger concentrations lower than 10^{-2} M, and the deviation tends to increase with decreasing scavenger concentration. The value of k can be obtained from k/D making use of μ_e. Taking $\mu_e=0.24\ cm^2\,V^{-1}\,s^{-1}$,[20] k is calculated to be 5.2×10^{12} $M^{-1}\,s^{-1}$ from $k/D=8.5\times10^{14}\,M^{-1}\,cm^{-2}$ and $3.6\times10^{12}\,M^{-1}\,s^{-1}$ from $k/D=5.9\times10^{14}\,M^{-1}\,cm^{-2}$. The expermental values of k have been reported to be 4.3×10^{12},[27] 2.7×10^{12},[28] and $1.8\times10^{12}\,M^{-1}\,s^{-1}$ [20] for the reaction of electrons with carbon tetrachloride in cyclohexane. The values of k derived in the present work are reasonably compared with the experimental values, in particular, the value of $3.6\times10^{12}\,M^{-1}\,sec^{-1}$ is in good agreement with the experimental values. Thus, it appears that the present treatment can well account for the concentration dependence of electron scavenging in cyclohexane except for the low concentration region. Since the electrons scavengeable at low scavenger concentrations are mostly far away from their parent ions, Brownian motion of these electrons is as much effective as their drift motion in the Coulomb field and the use of the Nernst-Einstein relation is not appropriate for the description of the behavior of such electrons. The Smoluchowski equation must be properly solved for electrons in such a situation.[29]

(Received April 17, 1975)

The semiempirical SCF-MO-CI calculation was applied to the electron donor-acceptor (EDA) interaction in 9,10-dicyanoanthracene and naphthalene system which exhibits the exciplex fluorescence and also the fluorescence due to the EDA complex stable in the ground state. On the basis of energy contour maps of the ground and excited states and of electronic transitions in the EDA system, the relaxation process from the F.C. excited state of the EDA complex to an identical fluorescent state with the exciplex was discussed on the intermolecular interaction, and also on the intramolecular interaction in (9,10-dicyanoanthracene)-$(CH_2)_3$-(naphthalene) systems.

There are numerous investigations relating to the electronic and geometrical structures of excimers. Excimers are believed to have a sandwich structures and to be stabilized by the exciton as well as charge resonance interaction. For exciplex it has been thought that the CT interaction is more important than the exciton interaction from many points of view.[1] Most molecular orbital calculation of the EDA complex as well as the exciplex were based on the configuration interaction between the ground and locally excited states of each component molecule including the charge transfer interaction, which is so called the method of "composite molecules".[2] On the other hand, some of investigators attempted to calculate the electronic structure of the EDA complex as a single conjugate system of π-electrons.[3,4]

Ohta, Kuroda and Kunii reported a method to calculate the electronic structure of the EDA complex, where the complex was treated as a single conjugated system of π-electrons.[6] The electronic state was calculated by the semiempirical SCF-MO-CI method within π-electron approximation by including all β terms. They accounted well for electronic transitions of the EDA complex of tetracyanoethylene with polycyclic aromatic hydrocarbons by this method.[5,6]

We have reported both exciplex and EDA complex fluorescence in the same EDA systems of 9,10-dicyanoanthracene (DCA) and naphthalenes.[7-9] The previous paper suggested that the geometrical arrangement between the excited electron acceptor and the ground state donor in the primary process of the exciplex formation was different from that of the Frank-Condon (F.C.) excited state of the corresponding EDA complex formed in the ground state.[7] In the intermolecular system, however, the fluorescence behavior of EDA complex and exciplex led to the conclusion that the fluorescent state of the exciplex may be identical with that of the corresponding EDA complex.[8] On the other hand, the geometrical conversion from their F.C. excited state of the EDA complex to the fluorescent state is sterically forbidden in the intramolecular system of 1-(9,10-dicyano-β-anthryl)-3-(α or β-naphthyl)propane.[9]

* To whom all correspondence should be addressed.

In this paper, the electronic interactions between 9,10-dicyanoanthracene and naphthalene both in the ground and excited states were calculated by assuming the complex as a single π-conjugate system. On the basis of energy contour maps of the ground and excited states and of electronic transitions in this EDA system, the electronic and geometrical structures of the fluorescent state of the exciplex and the EDA complex were discussed.

Method of calculation

The Pariser-Parr-Pople type semiempirical LCAO-SCF-MO's including configuration interaction of the EDA complex are calculated by assuming the complex as a single π-conjugate system. The molecular orbitals of the complex are calculated within the zero-differential-overlap approximation but with the including all two center resonance integrals.[5,6] In this method two center resonance integrals were evaluated by Katagiri-Sandorfy's formula,[10]

$$H_{\mu\nu} = \frac{1}{4}(C_\mu + C_\nu + \gamma_{\mu\mu} + \gamma_{\nu\nu} - 2\gamma_{\mu\nu})S_{\mu\nu} \qquad (1)$$

where C_μ is one center penetration integral and $S_{\mu\nu}$ is the overlap integral of atomic orbitals. If two atomic orbitals are associated to same molecule in these systems, $S_{\mu\nu}$ is evaluated from single Slater atomic orbitals, and if two atomic orbitals are associated to different molecule, we used SCF-atomic orbitals.[11] Two center repulsion integrals, $\gamma_{\mu\nu}$, were evaluated by Nishimoto-Mataga's formula,[12] and one center repulsion integrals, $\gamma_{\mu\mu}$, were estimated according to the Pariser-Parr's method.[13] Core energy, $H_{\mu\mu}$, is assumed to be minus of the ionization potential, which is given by Hinze and Jaffe.[14] Intermolecular core-core repulsion integrals, $\gamma_{\mu\nu}{}^c$, were estimated by following Dewar-Klopman's formula modified by Ohta *et al.*[5,15,16]

$$\gamma_{\mu\nu}{}^c = \gamma_{\mu\nu} + \left(\frac{1}{R_{\mu\nu}} - \gamma_{\mu\mu}\right)\exp\left[\alpha(R_{\mu\nu} - D_\mu - D_\nu)\right] \qquad (2)$$

Table 1 shows parameters used here which were also adopted in the calculations of the EDA complexes between tetracyanoethylene (TCNE) and various polycyclic aromatic hydrocarbons and also various excimers of aromatic hydrocarbons.[5,6]

TABLE 1. USED PARAMETERS IN THIS CALCULATION

	$H_{\mu\mu}$ (eV)	$\gamma_{\mu\mu}$ (eV)	C (eV)	D (a.u.)	ζ
C+	−11.16	11.13	14.5	2.0	1.625
N+	−16.18	11.52	20.0	1.0	1.950

$\alpha = -1.75$

The iteration of SCF-MO calculation was repeated, until the deviation in the total electronic energy by iteration becomes less than 10^{-4}%. For the prediction of electronic transitions, the CI calculation was carried out taking into consideration of the forty lowest singly excited configurations. The character of MO and the nature of the electronic transition in the bimolecular system are derived with same procedures as those references.[5,6]

The ground state total energy of each geometrical conformation was calculated by subtracting the total energy of component molecules (DCA and naphthalene) from summation of the electronic and core-core repulsion energies. The total energy in the first excited singlet state was evaluated from the total energy in the ground state and the first electronic transition energy.[5,6]

The energy contour maps of the ground and the first singlet excited state were depicted by moving a center of naphthalene on DCA molecule, where the intermolecular distance was assumed to be 3.4Å and molecular planes were parallel each other.[17] The calculation to depict one contour map was performed with 20 conformations taking into account of symmetry. The angle between the long axes of DCA and naphthalene, θ, were adopted to be 30°, 60°, and 90°, as shown in Fig. 1. Actual computation was carried out by the use of HITAC 8700/8800 operating system of the University of Tokyo.

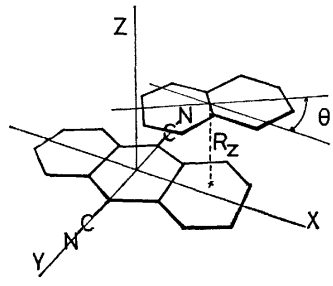

Fig. 1. The conformation and the geometrical parameters used for these calculations, where θ is the angle between the long axes and R_z is distance between the molecular planes (parallel) of these component molecules.

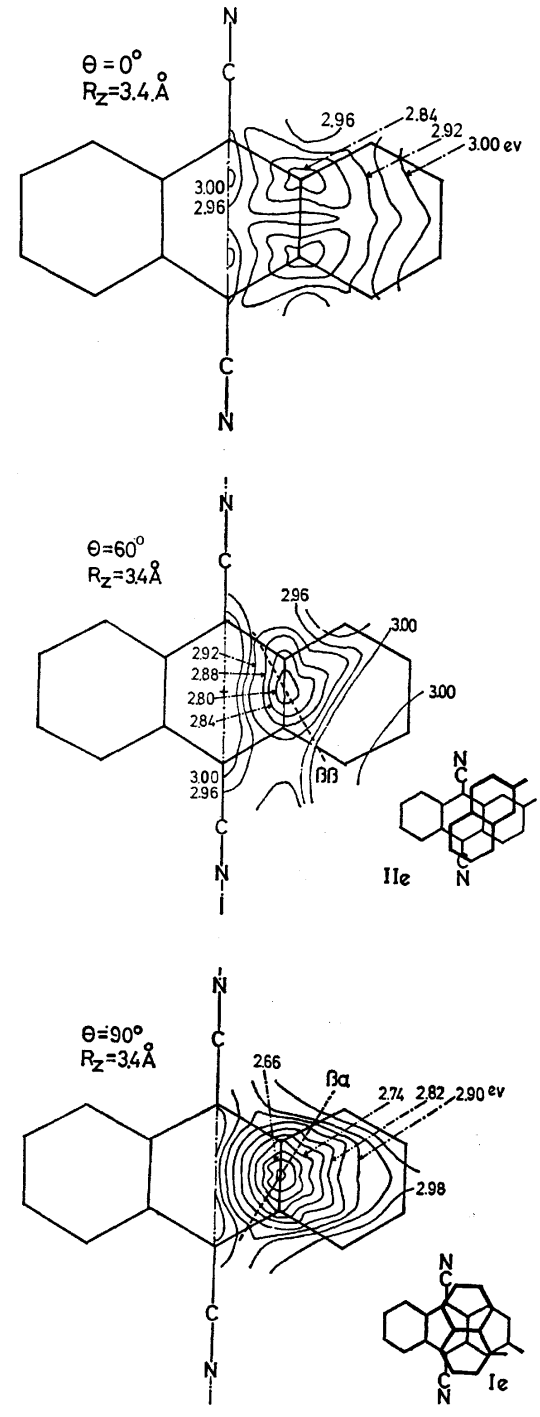
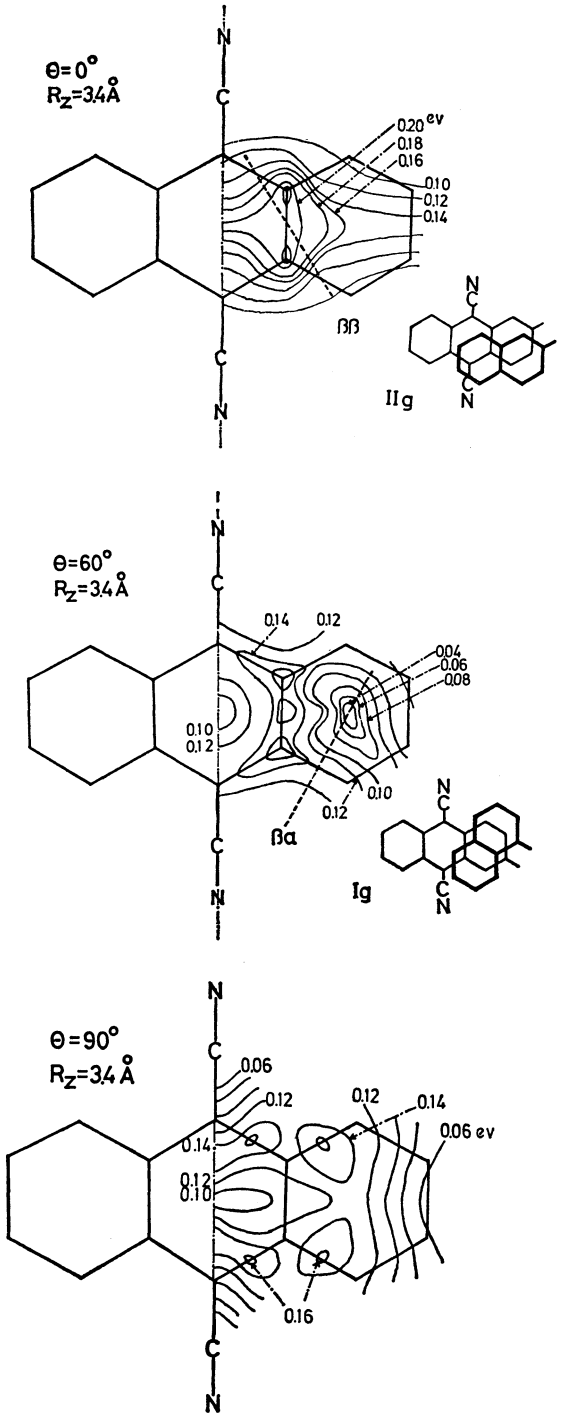


Figs. 2—4. The energy contour maps in the excited states for each angle of θ.

Results

The energy contour maps of the first excited singlet state obtained in the DCA and naphthalene system are shown in Figs. 2—4 for θ=0°, 60°, and 90°, respectively. Although there are minimum points in the excited state for θ=0° and 60°, the most stable structure in the excited state is in the conformation of θ=90° as shown in Figs. 4. The ground state energy contour maps also shown in Fig. 5—7 for each angle of θ. Here, the most stable geometries in the excited state are represented by Ie and IIe and those geometries in the ground state are Ig and IIg as shown in Figs. 3—6. Unfortunately, there is no minus point of the total energy in the ground state which might mean a stabilization in the complex formation in the ground state. However, this is not important in this stage because we don't take into account explicitly a solute-solvent interaction and fix an intermolecular distance at 3.4 Å. It seems that the relative total energy is more important in the EDA complex formation. Inspection of these energy contour maps reveals that the most stable



Figs. 5—7. The energy contour maps in the ground states for each angle of θ.

structure in the ground state is in the conformation of $\theta=60°$, as shown in Fig. 6.

The nature of excitation was estimated by following equation which are identical with those described in the previous paper by Ohta, Kuroda and Kunii,[6]

$$\left.\begin{aligned} \mathrm{LE(D^*A)} &= \sum_{ij} b_{ij}{}^2{}_{,m} D_i D_j, \\ \mathrm{LE(DA^*)} &= \sum_{ij} b_{ij}{}^2{}_{,m} A_i A_j, \\ \mathrm{CT(D^+A^-)} &= \sum_{ij} b_{ij}{}^2{}_{,m} D_i A_j, \\ \mathrm{CT(D^-A^+)} &= \sum_{ij} b_{ij}{}^2{}_{,m} A_i D_j, \end{aligned}\right\} \quad (3)$$

Table 2. The electronic excitation energies, oscillater strengths and characters of transition of the lowest three excitations

Structure	Excitation energy (eV)	Oscillater strength	Character of Transition[a] CT(D+A−)	LE(DA*)

	3.57 (347)	0.02	31	34

a) Residual characters are LE(D*A) and CT(D⁻A⁺) in mere trace amount.

where D_i, D_j, A_i, and A_j are expressed in Eq. (4), and $C_{i\mu}$ is coefficient of the atomic orbital, and $b_{ij,m}$ are coefficient of each excitation (i-th MO→j-th MO, Φ_{ij}) in CI calculation of the m-th excited state (Eq. (5)).

$$D_i = \sum_{\mu=1}^{n_d} C_{i\mu}{}^2, \quad A_i = \sum_{\mu=n_d+1}^{n_d+n_a} C_{i\mu}{}^2 \quad (4)$$

$$\Psi_m = \sum_{ij} b_{ij,m} \Phi_{ij} \quad (5)$$

In Eq. (4), n_a and n_d are given numbers to atoms in acceptor and donor molecules, respectively. The electronic transition and the character of transition are listed in Table 2 for several structures including Ig and Ie as mentioned above. The character of transition and oscillater strength are remarkably varied with the conformation of the EDA complex. These electronic transition characters summarized in Table 2 represent that the first electronic transition (absorption) from the ground state conformation (Ig or IIg) and also transition (fluorescence) from the excited singlet state (Ie or IIe) are the CT transition (D→A) equally mixed with the local excitation (^1L_a) of DCA.

Discussion

The great difference between the inter- and intramolecular systems is their degrees of freedom. In the intermolecular system each component molecule can take any conformation with no restriction. Therefore, the molecular conformation in the intermolecular EDA system may be dependent only on the electronic interaction in the ground state and also in the excited state of this system. Since the exciplex is the electronic interaction between the ground and the excited state molecules, the fluorescent conformation of the exciplex may be the energy minimum conformation in the energy contour map of the excited state. The energy minimum conformation for $\theta=90°$ seems to be most stable in the excited state than those for $\theta=0°$ and 60°, as shown in Figs. 2—4. Then, the exciplex and the

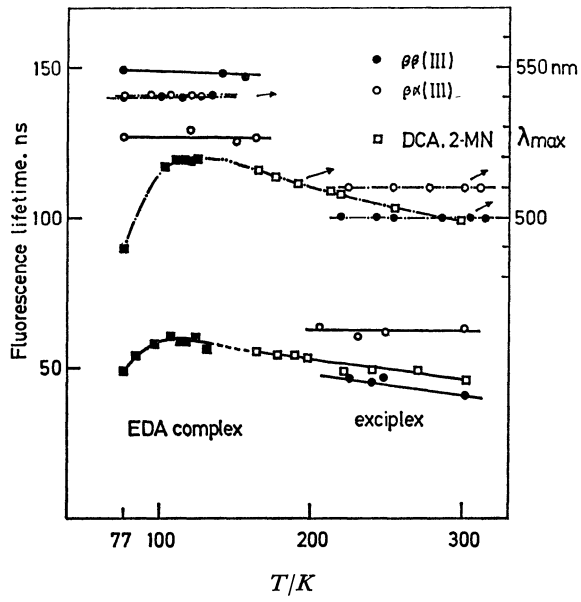

Fig. 8. The temperature dependence of the EDA complex and exciplex fluorescence maxima and fluorescence lifetimes of $\beta\alpha$-, $\beta\beta$(III) and DCA, 2-methylnaphthalene (2-MN) systems in 3-methylpentane. The broken lines and solid lines refer to the right and left ordinates, respectively. (extracted from the previous papers, Refs., 7) and 8)).

fluorescent state of the EDA complex, as will be mentioned later, seem to be in the geometrical conformation of Ie.

DCA and various naphthalenes form the corresponding EDA complex in the ground state as reported in the previous papers.[7-9] The fluorescence maxima and lifetimes of the exciplex (above~150 K) and EDA complex (below~120 K) were reported to continuously vary in the intermolecular system of DCA-naphthalenes, while these maxima and lifetimes were also reported to change discontinuously in the intramolecular system of 1-(9,10-dicyano-β-anthryl)-3-(α or β-naphthyl)propane (abreviated to $\beta\alpha$- and $\beta\beta$(III)) in the temperature region of 180—200 K.[7,8] The fluorescence behavior is illustrated in Fig. 8 extracted from previous papers for subsequent discussion. In the energy point of view, the conformation of these EDA complexes might be Ig for $\theta=60°$ as mentioned in the last section. Mataga and Murata,[18] and also Kobayashi *et al.*[19] reported that in fluid media the geometrical conformation of the F.C. excited state of the EDA complex of tetracyanobenzene (TCNB) and aromatic hydrocarbons reorient to a great extent to a fluorescent conformation. On the other hand, Itoh and Mimura demonstrated an experimental evidence of an identical fluorescent state of the exciplex and the EDA complex in the DCA and alkylnaphthalene system.[8] The geometrical conversion from the F.C. excited state of the complex (Ig) to the fluorescent equilibrium state (Ie) may be smoothly achieved in fluid media at low temperature. In the rigid matrix at 77 K, however, the fluorescence of the EDA complex seems to be from an non-relaxed or incompletely relaxed state near F.C. excited state of the EDA complex as mentioned in the previous paper.

As mentioned last section, the electronic transitions of the local excitation (^1L_a) and the CT transition are comparably mixed each other, and the electronic transition character of the first transition is dependent very much on the geometry. These results calculated here are consistent with the experimental results of the photoelection study that the fluorescence of the EDA complex of these systems has considerable CT character reported in the previous papers.[20-22] Furthermore, the electronic transition in Ig are in agreement with the absorption spectra of the EDA complexes of the DCA-naphthalene systems at 77 K.

In the intramolecular systems of $\beta\alpha$- and $\beta\beta$(III), the geometrical conformation between DCA and naphthalene moieties are restricted by trimethylene chain. The allowed traces of a center of naphthalene over the DCA molecule with an approximate spacing of 3.4 Å are shown by dotted lines in energy contour maps for $\beta\alpha$- and $\beta\beta$(III), respectively. A molecular model suggests that $\beta\alpha$(III) does not take the conformation of $\theta=0°$, while $\beta\beta$(III) does not take $\theta=90°$. Therefore, the geometry of the exciplex of the former may be Ie and that of the latter is IIe. On the other hand, the ground state geometry of $\beta\alpha$(III) seems to be Ig and that of $\beta\beta$(III) seems to be IIg by considering a steric hindrance of the trimethylene conformation.

In the intermolecular interaction, the geometrical conversion from the F.C. excited state of the EDA complex (Ig) to the fluorescent state (Ie) is not restricted in the fluid media, as mentioned above. In the intramolecular interaction, however, this kind of the geometrical conversion retaining the space of the electron donor and acceptor, *e.g.* Ig→Ie in $\beta\alpha$(III) and IIg→IIe in $\beta\beta$(III) seem to be forbidden by the trimethylene chain. As the result, the fluorescent state of the EDA complex in $\beta\alpha$- and $\beta\beta$(III) may be approximately the F.C. excited state of the complex formed in the ground state which are completely different from that of the corresponding exciplex. The electronic transitions calculated based on the geometrical conformations of Ig and IIg are consistent with the electronic absorption spectra and fluorescence polarizations of the corresponding EDA complexes reported previously.[22]

A Study of the Exchange Reaction between Water and Surface Hydroxyl Groups on Magnesium Oxide by Means of Infrared Diffuse Reflectance Spectroscopy

Nobutsune TAKEZAWA and Haruo KOBAYASHI

Department of Chemical Process Engineering, Hokkaido University, Sapporo 060

(Received October 9, 1974)

Infrared diffuse reflectance spectroscopy was applied to the study of the exchange reaction between water and surface hydroxyl groups on magnesium oxide. The results led to the conclusion that (i) no reaction occurs *via* the combination of hydroxyl groups, and (ii) the hydroxyl groups react with adsorbed water reversibly. Two types of hydroxyl groups present on the surface are involved in the rate determining step.

A study of adsorption by means of diffuse reflectance spectroscopy provides valuable information on the state of the adsorbed species.[1-3] In an earlier stage of investigation, experiments were carried out in the visible and ultraviolet regions. Little work had been done in the infrared region until Kortuem and Delfs published their work in this spectral region.[4] Since then, it has been applied to the study of adsorption or inorganic analysis,[5-11] but no kinetic study has been carried out on catalytic reactions.

Some infrared spectral studies of the adsorption were conducted on alkaline earth metal oxides.[8,9,12-16] We have applied the infrared diffuse reflectance method to the exchange reaction between water and surface hydroxyl groups on magnesium oxide.

Experimental

Experiments were carried out in a manner similar to that in the previous work.[7-9] About 50 mg of magnesium oxide* in powder form** (J. T. Baker Co., Ltd.) was packed in a cell to a thickness of about 2 mm. The cell was attached to a Nippon Bunko model DR-3 diffuse reflectance apparatus (Japan Spectroscopic Co., Ltd.), the spectra being recorded with a Nippon Bunko Model IR-G infrared spectrophotometer.

Prior to the experiments, the sample was heated at 310 °C for 5 hr in a stream of purified nitrogen. Deuterium oxide vapor saturated at room temperature or at 0 °C was allowed to flow over the sample with a nitrogen stream to react with surface hydroxyl groups at 240—310 °C. The reaction between water and surface deuteroxyl groups was also carried out in a similar manner.

The reflectivity of the sample was practically independent of its amount for a sample weighing more than 35 mg.*** No. emission band was observed.

Results and Discussion

Water Adsorption. Part of the original sample was in the form of magnesium hydroxide, as confirmed by the presence of a strong absorption band at 3700 cm^{-1}.[8,9] When the sample was heated at 310 °C for 5 hr, the band disappeared and two new absorption bands were observed at 3730 and 3610 cm^{-1}. These bands were previously assigned to the OH stretching vibrations of different types of surface hydroxyl groups.[8,9,17] According to Anderson *et al.*,[17] the model for chemisorbed water consists of hydroxyl group adsorbed on a surface magnesium ion, the remaining hydrogen forming another hydroxyl group with an adjacent surface O^{2-} ion. The former (referred to as OH_h) gives rise to the absorption band at 3730 cm^{-1} and the latter that at 3610 cm^{-1} (referred to as OH_l). After the sample is once heated as described above, the intensities of these bands change no more by further heating at 240—310 °C. It was confirmed that no water was desorbed under these conditions. The positions and the intensities of these bands remained unchanged in the presence of water vapor (H_2O).

Adsorption of water was carried out with a conventional adsorption apparatus. It was found that the adsorption of water is initially rapid followed by slow adsorption. The adsorbed amount slightly increases with time in the latter stage of the adsorption. Finally, 0.09 ml STP/g MgO of water was held on the sample at 23 mmHg 290 °C after 2 hr. Over 90% of adsorbed water was rapidly desorbed upon degassing. The amount of the reversibly adsorbed water is roughly proportional to 0.25 th power of the partial pressure of water. The retention volume of water was determined as a function of the temperature of the gas chromatographic column in which magnesium oxide was packed. The heat of adsorption of water was estimated to be 6.9 kcal/mol from the temperature dependence of the retention volume.

Thus, it is concluded that water is reversibly adsorbed on magnesium oxide. The amount of spectroscopically active hydroxyl groups on magnesium oxide was kept constant irrespective of the presence or absence of water vapor.†

The Reaction between Water and Surface Hydroxyl Groups. In contrast to the above results, the intensities of the absorption bands due to the hydroxyl groups decreased appreciably when deuterium oxide vapor was brought into contact with magnesium oxide. New bands due to surface deuteroxyl groups appeared at 2760 (OD_h) and 2670 (OD_l) cm^{-1}. The positions of OH_h and OH_l remained unchanged in the course of the reaction. When water vapor (H_2O) was allowed to flow

* The average particle size of the sample was about 12 μ.

** The surface area of magnesium oxide was 16 m^2/g.

*** The reflectivity of the sample should be independent of its amount for a quantitative analysis of the diffuse reflectance spectra.

† The total amount of hydroxyl groups was estimated from that of water released by heating at 750 °C for 1 hr. It was found that the water amounted to 0.92 ml STP/g MgO.

over the sample which had been partially deuterated, the bands due to the deuteroxyl groups decreased, whereas those due to hydroxyls increased according to the reaction between H_2O and OD. The reaction proceeded at a faster rate as compared to the reaction of D_2O with OH. When the partial pressure of water vapor was lowered to one fifth of that in the former run, the rate was reduced by 34%. The rate is, therefore, proportional to 0.25 power in the partial pressure of water, indicating that the reaction proceeds in proportion to the amount of reversibly adsorbed water.

Evaluation of the Rate of the Reaction. For estimating the rate of the reaction, the relation between the reflectivity and the adsorbed amount should be obtained. According to Frei *et al.*,[18] total reflectivity R at given wave number $\tilde{\nu}$ of binary system can be written with reference to the Kubelka-Munk equation[19] as

$$(1-R)^2/2R = k_1/s_1 + k_2/s_2, \quad (1)$$

where k_1 and k_2 are the absorption coefficients and s_1 and s_2 the scattering coefficients. The reflectivity R can be determined with reference to the standard material of $R=1$. Mamiya[7] recently pointed out that alkali halide particles can be used as a standard meterial and that its reflectivity decreases by only 4% with an increase in its size from 1—5 μ to 40—80 μ. Potassium bromide with an average particle size of 15 μ was therefore employed. It is assumed that the term k_1/s_1 in the right hand side of Eq. (1) is the reflectance function of the sample itself whereas k_2/s_2 is that due to hydroxyl or deuteroxyl groups. Since the value of k_1/s_1 can be estimated from the background spectrum by means of the Kubelka-Munk equation $(1-R_1)^2/2R_1=k_1/s_1$ (R_1: the reflectivity of the sample), the k_2/s_2 value is readily estimated from Eq. (1). The integrated intensity n_iI_i of surface species i can thus be given by the following equation, assuming that s_2 is independent of wave number for the absorption band in question:

$$n_iI_i = \int k_2/s_2 d\nu = \int\left[\frac{(1-R)^2}{2R} - \frac{(1-R_1)^2}{2R_1}\right]d\tilde{\nu} \quad (2)$$

where n_i is the amount of the species i and I_i its intensity per unit amount.

Figure 1 illustrates the plot of the n_iI_i-values for OH_h and OD_h against the time of the reaction D_2O+OH at 290 °C. We see that the intensity of OH_h monotonically decreases with time whereas that of OD_h increases. Similar results were obtained for OH_l and OD_l, whereas these trends were reversed for the reaction between OD and H_2O.

The difference $I_i\Delta n_i$ between the n_iI_i-values at $t=0$ and $t=t$ is proportional to the change in the amount of the species i in the course of the reaction. Figure 2 shows the relation between these difference for OH_h and OD_h. The linear relationship indicates that OH_h was replaced by OD_h in the course of the reaction. On the assumption that one OH_h was replaced by one OD_h, the slope α of the plot gives the ratio I_{OD_h}/I_{OH_h}. The total intensity $n_{OH_h}I_{OH_h}+n_{OD_h}(I_{OD_h}/\alpha)$ which is proportional to the sum of the

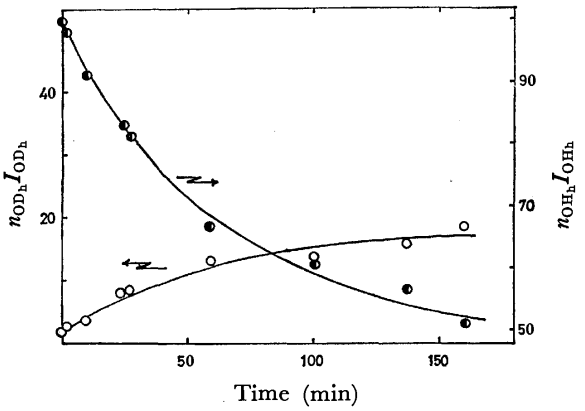

Fig. 1. The change in the intensities of surface OH_h and OD_h in the course of the reaction D_2O+OH at 290 °C.
◐: OH_h ○: OD_h

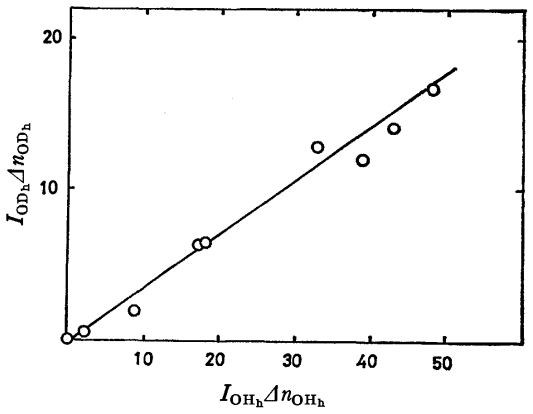

Fig. 2. The plots of the change in OH_h, $I_{OH_h}\Delta n_{OH_h}$ *versus* that in OD_h, $I_{OD_h}\Delta OD_h$.

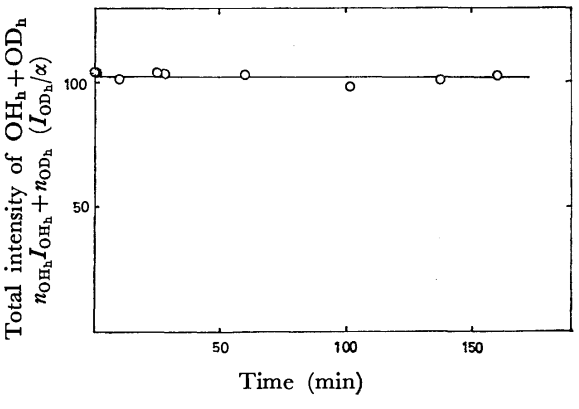

Fig. 3. Total intensity of OH_h+OD_h *versus* time of the reaction D_2O+OH at 290 °C.

amount of OH_h and OD_h was therefore determined from Eq. (2) and the value of α. Figure 3 shows the plot of the total intensity against the time of the reaction. This indicates that the sum of the amount of OH_h and OD_h remained practically constant during the course of the reaction. It is also valid for OH_l and OD_l although the intensities of these species could not be determined as accurately as those of OH_h and OD_h. The results were, therefore, consistent with those described above, indicating that the amount

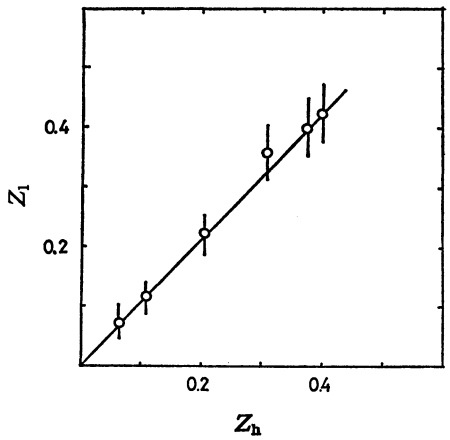

Fig. 4. Relation between the atomic fraction Z_l of OD_l and Z_h of OD_h in the course of the reaction D_2O+OH at 290 °C.

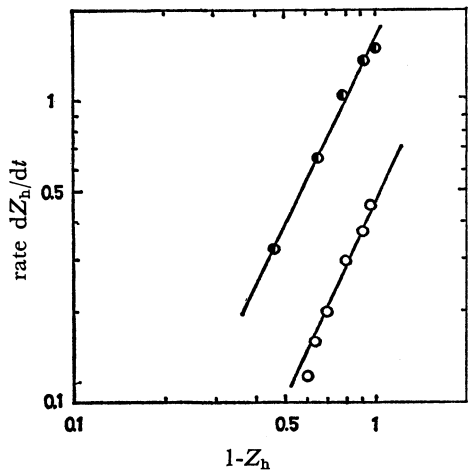

Fig. 5. Rate dZ_h/dt of the increase in the atomic fraction of OD_h *versus* atomic fraction $(1-Z_h)$ of OH_h. The reaction D_2O+OH was carried out at 290 °C(○) and at 310 °C(◐).

of hydroxyl groups can be determined by the Kubelka-Munk equation (1). The ratio of $n_{OD_h}(I_{OD_h}/\alpha)$ to the total intensity gives the atomic fraction of OD_h. Similarly, the atomic fraction of OD_l can be determined.

Mechanism of the Reaction. The amount of surface hydroxyl groups did not change unless deuterium oxide was present in ambient gas. No reaction occurred *via* the combination of a pair of hydroxyl groups. The exchange reaction proceeded at a rate proportional to the amount of reversibly absorbed deuterium oxide.

Figure 4 illustrates the relation between the atomic fractions Z_h of OD_h and Z_l of OD_l in the course of the reaction between D_2O and OH. The results indicate that the atomic fraction of OD_l is practically the same as that of OD_h in the course of the reaction. The rate of the reaction of D_2O with OH_h is illustrated as a function of the atomic fraction $(1-Z_h)$ of OH_h (Fig. 5). It is evident that the rate is proportional to $(1-Z_h)^2$. On the other hand, the rate of the reaction between H_2O and OD is proportional to Z_h^2 and is not proportional to $(1-Z_h)$ or Z_h as is often the case in exchange reactions. We conclude that two hydroxyl groups participate in the reaction. Since the atomic fraction of OH_h is the same as that of OH_l, both species might be simultaneously involved in the reaction. Under the present experimental conditions, reversibly adsorbed deuterium oxide reacts with both species in the rate determining step.

Formulation of Stokes' Radii in DMF, DMSO and Propylene Carbonate with Solvent Structure Cavity Size as Parameter

Niro MATSUURA, Kisaburo UMEMOTO, and Yasuyuki TAKEDA

Department of Pure and Applied Sciences, College of General Education, The University of Tokyo, Komaba, Meguro-ku, Tokyo 153

(Received October 15, 1974)

Conductance of univalent ions in DMSO (dimethyl sulfoxide), DMF (dimethylformamide) and PC (propylene carbonate) was determined by use of tetrabutylammonium-tetrabutylborate as standard electrolyte of equal cationic and anionic conductance. Empirical formulation of Stokes' radius was attempted on the assumption of a structure-cavity affecting the ionic transport in a medium of aprotic and polar solvent as well as water. By application of classical fluid dynamics Stokes' radius r_s is given in terms of $-(2/3)\ r_c+(1/\sigma_s)\ (r_c-r_o)^2$, where r_c is crystal ionic radius, r_o and σ_s are parameters characteristic of the cavity and molecular sizes, respectively, with respect the solvent.

According to hydrodynamic theory the force acting on the hard shere with a radius a moving with a steady velocity of v_∞ in an incompressible fluid with a viscosity coefficient η is given by Eq. (1).

$$F = 4\pi\eta \cdot a \cdot v_\infty + 2\pi\eta \cdot a \cdot v_\infty \quad (1)$$

Equation (1) implies two terms of the friction drag acting tangentially on the sphere and the normal drag. The deviation from Stokes' law is obvious in ionic transport, if the crystal ionic radius is employed for a hard sphere chosen as a model. If the ion were to take as shape greatly deformed from the sphere under the influence of solvent structure according to the size fittness between the structure cavity and ions, the normal drag of the second term in (1) would be greatly reduced. A modification of Stokes' theory is required even in the frame of hydrodynamic theory by consideration of the sticky and slipping boundary.[1] The slippy boundary between the moving sphere and the medium leads to a Stokes' force of $4\pi\eta \cdot a \cdot v_\infty$ with the second term in (1) dropped. The solvation of ions explains qualitatively the deviation from Stokes' law, but a concept of negative solvation,[2] or some other hypotheses is inevitable. For a quantitative aspect of ionic transport, a number of more elaborate and sophisticated theories of solvation have been proposed, such as the Zwanzing theory of dielectric drag,[3] Uedaira's micro-viscosity of a solvent molecule just around the ions,[4] and a chemical-bond theory of solvent structure with a microscopic dipole moment.[5]

In recent works,[6~8] the transfer free energy of ions in aprotic solvents, involving PC, EC, DMF, and DMSO, were determined. These and similar data of enthalpy reported by Krishnan and Friedman[9] enable us to estimate the entropy of transfer of ions from water to the aprotic solvents. A large negative value of solvation entropy suggests that a certain liquid structure of solvent plays an important role in decreasing solvation entropy by producing an ordered arrangement even in these aprotic solvents. Accordingly, a comparative study of the Walden product was attempted in this work in various aprotic solvents other than water.

Unusual behavior of ionic conductance has been observed in some ionic species whose solvated radius (apparent Stokes' radius) is smaller than the crystal ionic radius. Kiso has compiled a large number of ionic conductance data with a variety of charges and sizes, concluding that a maximum ionic conductance can be seen for an ionic diameter of about 2.8 Å in aqueous medium which corresponds to the cavity size of water structure.[10] On this basis, Kiso proposed a slipped transport with a minimum friction involving a tangential shear alone, if the ionic size fits the size of a cavity present in the fluid medium. This model is helpful for understanding the apparent Stokes' radius which shows occasionally a radius smaller than the actual crystal ionic radius.

Experimental

Conductance of Cell. A conductance cell of 500 ml capacity was constructed according to the Erlenmeyer flask design of Kraus *et al.*[11] An electrode chamber is attached to the flask in such a way that the chamber liquid is thoroughly mixed with the solution in the main body of the cell. The electrodes were two platinum of 12 mm diameter, their distance being 10 mm. The cell constant of 0.4070 cm^{-1} was determined by eight KCl aqueous solutions in the concentration range from 3×10^{-3} to 8.5×10^{-3} M as referred to the value of 146.98×10^{-6} mho for KCl solution at 1×10^{-3} M at 25 °C.[12]

Procedure. Precaution was taken for precise conductance measurement particularly against pollution by impurities of water vapor, CO_2 and O_2. For preventing temperature and composition changes of liquid in the conductance cell, the temperature was controlled by a double chambered thermostat at 25±0.01 °C. The cell temperature change was readily detected by the shift of resistance readings exceeding 0.01%. The starting pure solvent was subjected to constant stirring with a teflon coated rotor of a magnetic stirrer for one hour, additional half-hour stirring being sufficient for each addition of electrolyte salt of about 100 mg. Direct transfer of the solvent from the 500 ml measuring flask kept in the thermostat to the conductance cell was made within 15 s. Stepwise increase of the electrolyte concentration was made by quick operation of transfer from weighing bottle to the conductance cell. Calibration for drainage on the wall of the flask, amounting to 0.5 ml or less, does not affect the acuracy of electrolyte concentration more than 0.1%. Repeated determination of cell constant was made for a series of runs with a given solvent system. Resistance was measured on a Model Yokogawa-Hewlette-Packard Universal Bridge.

Materials. The method of purification of solvent and electrolyte was as described.[6] The standard electrolyte of *n*-tetrabutylammonium *n*-tetrabutylborate, $(n\text{-Bu})_4N\cdot B(n\text{-Bu})_4$,[13] was synthesized from borontrifluoride etherate and *n*-butylmagnesium bromide as starting materials, purification

by recrystallization being repeated thrice for the crude preparation with a melting point of 110.6 °C to a final product with a melting point of 111.5 °C. All other chemicals were obtained from the Wako-Pure Chemicals Ltd.

Results and Discussion

The conductance of individual univalent ions at infinite dilution was studied in order to see how the ionic size regulates the ionic transport in non-aqueous solvent. The conductance at infinite dilution Λ° was determined by extrapolation of the observed Λ values from Λ-$\sqrt{c}$ plots for ten concentration points from 0.5×10^{-4} to 5×10^{-3} M. For dividing λ_∞ into each component of $\lambda_\infty^\pm$ an assumption was made of an equal conductance value for $(n\text{-Bu})_4\,N^+$ and $(n\text{-Bu})_4\,B^-$. The results on $\lambda_\infty^\pm$ are listed in Table 1 together with the calculated "apparent" Stokes' radius, r_s, according to the relation: $r_s=e\cdot E/6\pi\eta\lambda_\infty$. An empirical formulation of apparent Stokes' radius was attempted as a function of crystal ionic radius, r_c,[14] by introducting a solvent-dependent parameter, r_0. Starting with the assumption that hydrodynamic theory is valid even for ionic transport, we divided the force, for the sake of the formulation of r_s, into the tangential drag and the normal drag, corresponding to the first and the second terms, respectively, in Eq. (1). Hydrodynamic theory predicts that an air bubble of radius a passing through a liquid medium with velocity v_∞ has a drag force of $4\pi\eta a v_\infty$. If the moving ions make use of a vacant space of the solvent-structure cavity, the deviation of Stokes' law in ionic transport could be concentrated in the second ferm of the normal drag in Eq. (1) under the influence of the discrepancy between the ion-size and the cavity space. On this account, a correction was made by introducing a cavity-size parameter, r_0, for the second term of Eq. (1) in the form of Eq. (6) in consideration of the solvent-structure effect.

$$6\pi\eta\lambda_\infty r_s = 4\pi\eta\lambda_\infty r_c + f(r_c-r_0)$$

For finding the form of the function, $f(r_c-r_0)$, the value of $(r_s-(2/3)r_c)$ was plotted against r_c from the data shown in Table 1.

The results are shown in Figs. 1 and 2, in which $f(r_c-r_0)$ is approximated to a hyperbolic function in the form of $k(r_c-r_0)^2$.

It can be seen from the curves that a very small constant value, r_s°, is needed in some arbitary way for minimizing the deviation from $k(r_c-r_0)^2$ in Eq. (6).

Table 1. IONIC CONDUCTANCE OF INDIVIDUAL UNIVALENT IONS, λ_∞, AT 25 °C

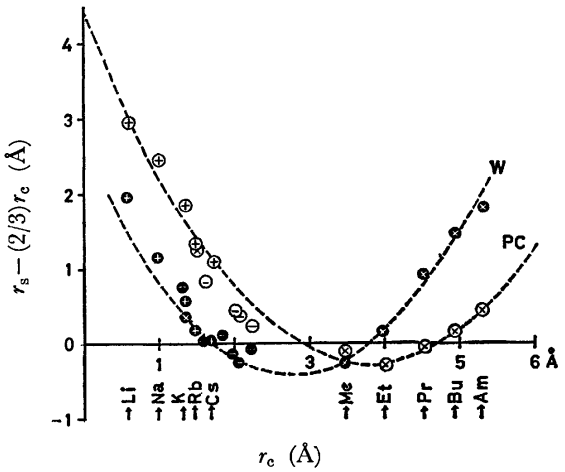

Fig. 1. Hyperbolic curves in the $\{r_s-(2/3)r_c\}$ plots against r_c for univalent ions with crystal ionic radius of r_c and with the apparent Stokes' radius r_s in water(W) and in propylene carbonate(PC), represented by; $r_s-(2/3)r_c=0.53(r_c-2.8)^2-0.6$ for water and $r_s-(2/3)r_c=0.31(r_c-3.8)^2-0.3$ for PC.

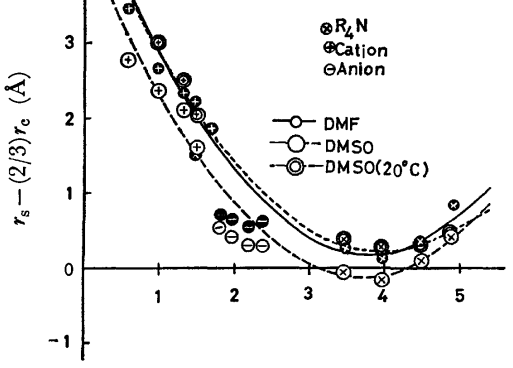

Fig. 2. Similar curves as Fig. 1 in DMF(dimethylformamide) and DMSO(dimethyl sulfoxide) represented by; $r_s-(2/3)r_c=0.32(r_c-3.75)^2+0.2$ for DMF and $r_s-(2/3)r_c=0.33(r_c-3.7)^2-0.2$ for DMSO.

Table 2. Parameters employed for the formulation of Stokes' radii by Eq. (6) from the plots shown in Figs. 1 and 2

Solvent	k Å^{-1}	r_0 Å	r_s^0 Å	σ_s Å	$1/\sigma_s$ Å^{-1}	Donor Number
PC	0.31	3.80	−0.3	3.23	0.31	15.1
DMF	0.32	3.75	+0.2	3.13	0.32	26.6
DMSO	0.33	3.70	−0.2	3.05	0.33	29.8
Water[a)]	0.53	2.80	−0.6	1.93	0.52	18.0

a) From the data of ionic conductance in aqueous system well established and available to be referred in the Hand-book (Landolt Bernstein Tabellen, II. Band, 7. Teil, 259, pp. 266 (1960)).

The correction r_s° is too small to affect greatly the accuracy in the predicted k and r_0 values which are required for the formulation. The parameters k and r_0 could be determined by application of least squares rule to the average values, $\sqrt{r_s-(2/3)\ r_c-r_s^\circ/r_c}$.

The results are given in Table 2.

It should be noted that the parameter k is a constant varying inversely with the size of a solvent molecule, σ_s, defined by $\sqrt[3]{(3/4\pi)V_s^\circ}$, where V_s° is the molar volume of solvent at 25 °C. In order to see if this observation on k values is right, works on conductance are extended to many other non-aqueous solvents whose data are available in literature. In a similar way to our treatment stated before, calculated Stokes' radii of univalent cations were formulated by a second order linear equation in a more general form of $a\cdot r_c^2+b\cdot r_c+c=r_s$, where a, b, and c are constants and a is identical with the constant k.

The results are given in Table 3 for a dozen solvents. In is interesting to see that a linear relationship between the molarvolume radius σ_s and the coefficient a or parameter k exsists in satisfactory agreement. Furthermore, the coefficient b has a value approximately equal to −2 and another constant coefficient c is proportional to the molecular radius of solvent, σ_s. The constant c

Table 3. Coefficients of a second order linear function of r_c (crystal ionic radius) employed for formulation of apparent Stokes' radius, r_s at 25 °C

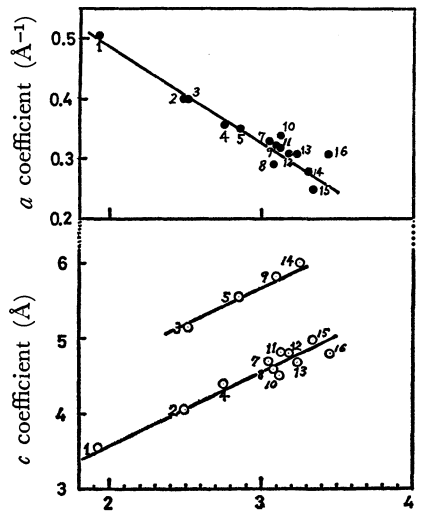

Fig. 3. A linear correlation between molar-volume radius σ_s of solvents and constant coefficients, a and c in the second order linear equation of r_c for representation of apparent Stoke's radius r_s. Solvent numbers refered to Table 3.

is a distance measured from the center of point charge, that is r_s at $r_c=0$, to a solvent molecule in a kinetically restricted movement, designated by $\sqrt{\mu \cdot e/\varepsilon kT}$, where μ and ε are the dipole moment and dielectric constant respectively, of solvent at T K. A linear dependence of c on σ_s can be understood from the fact that the solvation sphere of a point charge ion has a distance proportional to the molar-volume radius of solvent, σ_s. Figure 3 shows the plots of a (or k) and c against σ_s. A close correlation can be seen between the apparent Stokes' radii or Walden products and the molecular size of the solvent. One exceptional case was observed in a system of *N*-methylformamide whose unusually high association by hydrogenbond could be responsible.

Stokes' radii of Bu_4N^+ion (Table 3) have essentially the same value of 3.8, indicating that the Walden product rule holds in a large number of non-aqueous solvents, as far as this particular ion is concerned. The only exception is seen in *N*-methylformamide and its homologue, probably due to their strong hydrogen bonded association. In our formulation of r_s, the curves plotted against r_c differ very slightly among the solvents with an appreciable change of dielectric constant. For example, pyridine ($\varepsilon=12.3$, $\sigma_s=3.18$ Å), DMF ($\varepsilon=36.1$, $\sigma_s=3.13$ Å) and PC ($\varepsilon=64$, $\sigma_s=3.23$ Å), yield three very close curves (Fig. 4). On the other hand, there is a large difference in the shape of curves and the location of the minimum point discriminating one solvent from another between acetonitrile, formamide and water (Fig. 5). It seems likely that the donor number of the solvent is also no influential factor in the ionic transport, although it is a good measure of the medium effect of non-aqueous solvent.[7] From the second order linear equation a minimum Stokes' radius appears at r_c (minimum) $=-b/2a$, which can be regarded,

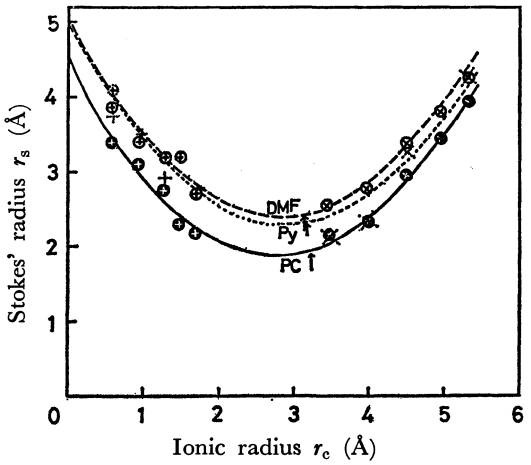

Fig. 4. Stokes' radius representation by crystal ionic radius in $a \cdot r_c^2+b \cdot r_c+c$ with constant coefficients a,b and c (in the Table 3), broken line with open circle for DMF, dotted line with cross for Pyridine and full line with black circle for PC.

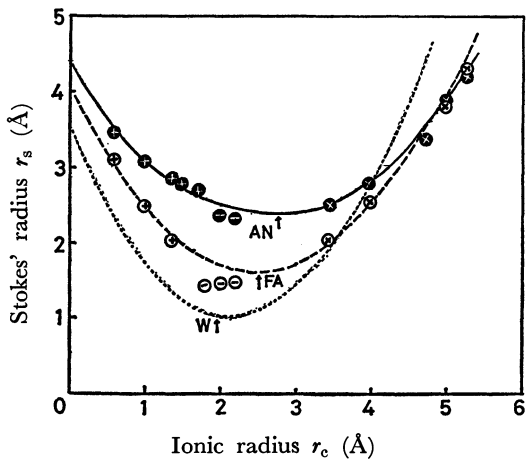

Fig. 5. Similar curves as Fig. 4. Full line for acetonitrile(AN), broken line for formamide and dotted line for water (Stokes' radius omitted).

to first approximation, as $1/a$ or k since the value of $-b$ is close upon 2 (Table 3). This is the reason why a minimum Stokes' radius appears when the ion radius fits well with the molar-volume radius of the solvent. These facts lead to the conclusion that there should be a contribution of a structure cavity or a free-volume space in the solvent medium to the ionic transport depending on the size of moving ions relative to the size of solvent molecules.

(Received December 2, 1974)

The absolute intensities of the infrared absorption bands, ν_3 of methyl iodide, ν_2 of methyl cyanide, and ν_8 of methyl cyanide, were measured in various solvents at various concentrations. Even after the effect of the internal field is eliminated, very large solvent effects remain in the absorption intensities due to the intermolecular interactions. An equation based on the model of the dipole-dipole interaction is proposed to interpret the experimental results. Comparison with the experimental data confirms the validity of the model.

Much attention has been given to the change of infrared intensities in going from the gas to the liquid phase or from the gas phase to solutions. Many equations have been proposed to predict the ratio of the intensities of the gas and the liquid phases, among which that of Polo and Wilson[1] is the most familiar. Mallard and Straley[2] and Person[3] proposed an equation for the intensity ratio of the gas phase and solutions, which is identical to that of Polo and Wilson to the limit of pure liquid. These two equations deal with the integrated intensities and neglect the anomalous dispersion of the refractive index in the region of the adsorption band. The validity of the assumption of a single refractive index was studied theoretically by Schatz.[4] Although Schatz claims that the equation of Polo and Wilson is valid even for strong absorption bands if one chooses an appropriate value for the single refractive index, its usefulness is restricted to rather weak absorption bands.[5] The same problem has been treated by many other authors.[6-9] In the case of very strong absorption bands, one must take into account the frequency dependence of the refractive index rigorously, as shown theoretically and experimentally by Bakhshiev and coworkers[10] and by Crawford and coworkers.[11] These authors have presented an equation giving the relation between the apparent and the true absorption indices at each frequency. It is accepted that, when one compares the observed intensities at various phases, one must make a correction for the effect of the so-called internal field according to the scheme of Polo-Wilson or Mallard-Straley-Person for a weak absorption band and of Bakhshiev-Crawford for a strong absorption band. After being undergoing correction following the aforementioned schemes, the intensities of liquids or solutions agree well with the gas-phase intensities, if no specific solute-solute or solute-solvent interaction in liquids or solutions exists.[6,10-12]

It should be noted that the above treatment deals only with the change of the internal field surrounding an absorbing molecule and does not consider the effects of intermolecular interactions. Some authors such as Buckingham,[13] Mirone,[14] and Bakhshiev and coworkers[15] have discussed the effects of intermolecular interactions on infrared intensities. They used the reaction field of Onsager.[16] Experimental works concerning these theories are very scarce.[17-20]

In the present paper, the authors report the absolute intensities of a few absorption bands of methyl iodide and methyl cyanide in various solvents at various concentrations, and show that the effects of solvents are very large in some cases, even after the elimination of the effect of the internal field. The vibrational bands and solvents are as follows, ν_3 (the C-I stretching vibration) of methyl iodide, solvents: methyl cyanide and carbon disulfide, ν_2 (the C≡N stretching vibration) of methyl cyanide, solvents: carbon tetrachloride and 1,1,1-trichloroethane, and ν_8 (the CCN bending vibration) of methyl cyanide, solvents: carbon tetrachloride and nitromethane. In these systems no serious specific solute-solute or solute-solvent interaction is expected other than the dipole-dipole interaction. An equation is proposed to connect the absolute intensity of a pure liquid or a solution to that of the gas phase, based on the model of the dipole-dipole interaction.

Experimental

Commercial chemicals were used. Methyl iodide was distilled just before the observation to remove the pale yellowish color. Other samples were used without further purification although the infrared spectrum of methyl cyanide showed a samll amount (about 0.5 wt%) of water in it: the presence of water in methyl cyanide seems to cause no serious error.

Binary solutions were prepared just before the observation to attain appropriate concentrations by measuring the weight of each component. Mole percentage and molar concentrations were calculated by use of the density data.[21] Additivity of the volumes of both components was assumed.

The infrared spectra of the ν_2 band of methyl cyanide were measured in carbon tetrachloride- and 1,1,1-trichloroethane-solutions at various concentrations with a Perkin-Elmer 112G single-beam infrared spectrometer. A Perkin-Elmer 12C single-beam infrared spectrometer mounted with a CsBr prism was used to measure the ν_8 band of methyl cyanide in carbon tetrachloride- and nitromethane- solutions. The same spectrometer mounted with a KBr prism was used to measure the ν_3 band of methyl iodide in methyl cyanide- and carbon disulfide-solutions. The frequencies were calibrated following the standard method with the use of atmospheric water-vapour or carbon dioxide lines for the 112G spectrometer, and atmospheric water-vapour and methanol vapor lines for the 12C spectrometer.[22] The spectrometers were operated under a resolution of about 1 cm^{-1} except for the case of the ν_8 band of methyl cyanide, where the resolution was about 2 cm^{-1}. The effect of the finite slit width on the observed spectra was found to be very small. It was confirmed that the observed spectra were free of stray-light. All the measurements were carried out at room temperature

(25 °C). Each spectrum was measured at least twice.

A variable-length cell with KRS-5 window was used in the measurements. The thickness of the sample-cell was determined at each observation by the method of interference fringes.[23]

The observed spectra were reduced to the absorption-index curves, $k(\nu)$'s[24] where ν is the wavenumber in cm^{-1}, and the absolute intensities, Γ's, were calculated by means of the definition:[25]

$$\Gamma = \frac{4\pi}{c_m}\int_{band} k(\nu)\ d(\nu)$$

where c_m is the molar concentration (mol/cm^3). The integration of $k(\nu)$ over the absorption band was estimated by fitting a Lorentzian curve to the observed $k(\nu)$ curve by the method of least-squares. Care should be taken so that all the observed absorption bands contain hot bands in their lower-frequency sides. The hot bands cause the asymmetry of the main bands and it was found to be difficult to remove them by the usual method of least-squares. Thus, only the high-frequency sides of the bands were used in numerical calculations. The standard deviations were estimated from the deviations of the calculated Lorentzian curves from the observed absorption curves and from the maximum errors in the thicknesses of the sample-cell.

Since all the observed absorption bands are weak, Mallard-Straley-Person's scheme[2,3] was applied to the correction for the effect of the internal field, according to the equation

$$\Gamma_c = n_s\left[\frac{(n/n_s)^2+2}{n^2+2}\right]^2\Gamma$$

where n_s and n are the refractive indices of the solution and the solute, respectively, and Γ_c is the corrected intensity which is to be compared with the intensity of the gas phase. The refractive index was measured by the use of an Abbe's refractometer for each solution at the room temperature. The absolute intensity, Γ_c, is related to the transition dipole moment, m_1, of the vibrational transition by the equation[26]

$$\Gamma_c = \frac{8\pi^3}{3hc}N_a(m_1)^2$$

where h is Planck's constant, c the velocity of light, and N_a Avogadro's number. The observed intensity, Γ_c, is shown at each concentration in Figs. 1—4. The values of Γ's, Γ_c's, and $|m|$'s are given in Tables 1—3.

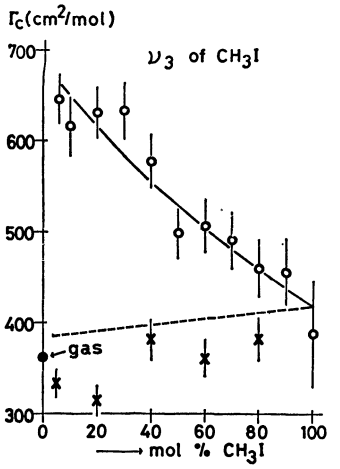

Fig. 1. Concentration-dependence of the absolute intensity of the ν_3 band of methyl iodide. The open circles and crosses indicate the observed intensities in methyl cyanide-solutions and in carbon disulfide-solutions, respectively. The vertical lines indicate standaed deviations. The solid line shows the concentration-dependence for methyl cyanide-solutions, calculated from the parameters of Table 4. The broken line shows the concentration-dependence for carbon disulfide-solutions, predicted from the same parameters of Table 4.

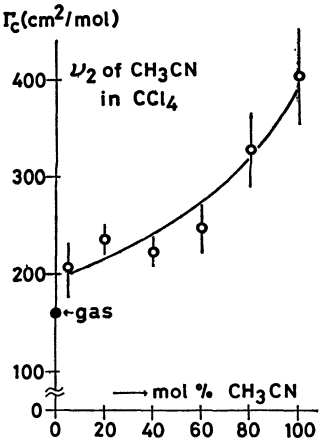

Fig. 2. Concentration-dependence of the absolute intensity of the ν_2 band of methyl cyanide in carbon tetrachloride-solutions. The open circles indicate observed intensities and the vertical lines standard deviations. The solid line shows the concentration-dependence calculated from the parameters of Table 4. The closed circle corresponds to the gas-phase intensity of Jesson and Thompson.[33]

Results and Discussion

We see from the figures that the absolute intensities greatly change in solutions even after correction for the internal fields. This indicates that the transition moment, m_1, changes in solutions as a result of intermolecular interactions. Thus we can obtain information on intermolecular interactions in liquids or solutions from the experimental data. In the following, we deal with the theoretical consideration on the change of infrared intensity in solutions.

The electric dipole moment, m, of a molecule under the influence of electric field, $\mathfrak{F}$, is given by

$$m = \mu + \alpha\langle\mathfrak{F}\rangle_{av} \qquad (1)$$

where μ and α are the electric dipole moment and the electric dipole polarizability, respectively, of an isolated molecule, and molecule, and $\langle\ \rangle_{av}$ means the average over all possible configurations of the surrounding molecules. All the quantities appearing in Eq. (1) can be expanded in powers of the normal coordinates of the vibrations. In the expansion of m, we take only the term that is linear on the normal coordinate, q, of the vibration:

$$m_1 = \mu_1 + \alpha_1\langle\mathfrak{F}_0\rangle_{av} + \alpha_0\langle\mathfrak{F}_1\rangle_{av} \qquad (2)$$

where the suffixes "0" and "1" mean respectively the zeroth and the first terms of the expansion, namely:

$$A_0 = \langle 0|A|0\rangle \qquad (3)$$

and

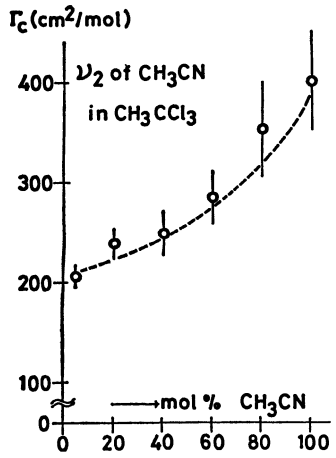

Fig. 3. Concentration-dependence of the absolute intensity of the ν_2 band of methyl cyanide in 1,1,1-trichloroethane-solutions. The open circles indicate observed intensities and the vertical lines standard deviations. The broken line shows the concentration dependence predicted from the parameters of Table 4.

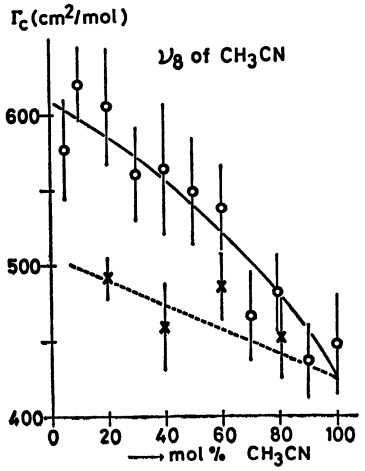

Fig. 4. Concentration-dependence of the absolute intensity of the ν_8 band of methyl cyanide. The open circles and crosses indicate the observed intensities in carbon tetrachloride-solutions and in nitromethane-solutions, respectively. The vertical lines indicate standard deviations. The solid line shows the concentration-dependence for carbon tetrachloride-solutions, calculated from the parameters of Table 4. The broken line shows the concentration-dependence for nitromethane-solutions, predicted from the same parameters of Table 4.

$$A_1 = \left(\frac{\partial A}{\partial q}\right)\langle 0|q|1\rangle \qquad (4)$$

The calculation of $\langle\mathfrak{F}_0\rangle_{av}$ and $\langle\mathfrak{F}_1\rangle_{av}$ has been made by Buckingham[13] and Bakhshiev and co-workers[15] using the reaction field of Onsager:[16] their results are expressed in terms of the dielectric constants of the surrounding macroscopic media. On the other hand, the present authors have recently calculated $\langle\mathfrak{F}_0\rangle_{av}$ based on a model of dipole-dipole interaction to explain the equilibrium of *trans*- and *gauche*-1,2-dibromoethanes in the liquid and in solutions,[27] and

have shown that the latter calculation explains well the part of the averaged electric field that changes in solutions, although the absolute value does not agree with that calculated from the reaction field. We calculate $\langle\mathfrak{F}_0\rangle_{av}$ and $\langle\mathfrak{F}_1\rangle_{av}$ following the same model of dipole-dipole interaction as before.

The basic idea of the model is that the solute and the solvent molecules are dispersed uniformly and homogeneously in a vacuum instead of in a continuous dielectric medium. Each molecule has its physical quantities (say, dipole moment, polarizability, *etc.*) identical with those in the gas phase, but since the density is so high (or the average intermolecular separation between the nearest neighbour is so short) in the

liquid phase or in solutions, the magnitudes of these quantities are modified as a consequence of intermolecular interactions, a typical example being Eq. (2). Following the same procedure as before, we obtain:[27]

$$\langle\mathfrak{F}_0\rangle_{av}=\frac{4\pi^2}{27}N_a^2\mu_0\left[\left(\frac{\mu_0^2}{kT}+\alpha_0\right)\frac{\rho}{W_m}c_m+\left(\frac{\mu_{0s}^2}{kT}+\alpha_{0s}\right)\right]+\frac{2\pi^4}{25\times243}N_a^4\mu_0\times\left[\frac{\mu_0^6}{(kT)^3}\left(\frac{\rho}{W_m}\right)^3c_m+\frac{\mu_0^2\mu_{0s}^4}{(kT)^3}\frac{8^3}{A^3}c_{ms}\right] \quad (5)$$

$$\langle\mathfrak{F}_1\rangle_{av}=\frac{4\pi^2}{27}N_a^2\mu_1\left[a_0\frac{\rho}{W_m}c_m+a_{0s}\frac{8}{A}c_{ms}\right] \quad (6)$$

where

$$A=\left\{\left(\frac{W_m}{\rho}\right)^{1/3}+\left(\frac{W_{ms}}{\rho_s}\right)^{1/3}\right\}^3 \quad (7)$$

and m_1, μ_1, α_0, and α_1 are those already described in Eq. (2), μ_0 is the permanent dipole moment of the solute molecule, W_m, ρ, and c_m are respectively the molecular weight, density, and molar concentration (mol/cm³) of the solute (the same symbols suffixed by "s" refer to those of the solvent), and N_a is the Avogadro number.

Calculation showed that $\langle\mathfrak{F}_1\rangle_{av}$ is very small as compared with $\langle\mathfrak{F}_0\rangle_{av}$ and that the terms containing α_0 and α_{0s} in the parentheses of the first term of Eq. (5) have much smaller contributions than the rest. We have therefore neglected these terms and analysed the experimental data by the following equation:[29]

$$m_1=\mu_1+\alpha_1\langle\mathfrak{F}_p\rangle_{av} \quad (8)$$

where

$$\langle\mathfrak{F}_p\rangle_{av}=\frac{4\pi^2}{27}N_a^2\mu_0\left[\frac{\mu_0^2}{kT}\frac{\rho}{W_m}c_m+\frac{\mu_{0s}^2}{kT}\frac{8}{A}c_{ms}\right]+\frac{2\pi^4}{25\times243}N_a^4\frac{\mu_0^3}{(kT)^3}\left[\mu_0^4\left(\frac{\rho}{W_m}\right)^3c_m+\mu_{0s}^4\frac{8^3}{A^3}c_{ms}\right] \quad (9)$$

Equation (8) relates the intensity data and the parameters, μ_1 and α_1. We can thus determine the magnitudes of μ_1 and α_1, using the intensity data at different concentrations and the calculated $\langle\mathfrak{F}_p\rangle_{av}$. In the calculation of $\langle\mathfrak{F}_p\rangle_{av}$, permanent dipole moments were taken to be 3.92 D for methyl cyanide,[30] 1.65 D for methyl iodide,[30] 1.79 D for 1,1,1-trichloroethane,[31] and 3.10 D for nitromethane.[30] For the ν_3 transition of methyl iodide, we obtained $\lvert\mu_1\rvert$ of 0.0391 D and $\lvert\alpha_1\rvert$ of 0.1134 Å³ from the experimental data of methyl cyanide-solutions by the method of least squares. Similarly, we obtained $\lvert\mu_1\rvert$ and $\lvert\alpha_1\rvert$ for the ν_2 and the ν_8 transitions of methyl cyanide, both from the data of carbon tetrachloride-solutions. The obtained values of $\lvert\mu_1\rvert$ and $\lvert\alpha_1\rvert$ are given in Table 4. The calculated concentration-dependence of the absolute intensities, corresponding to the determined $\lvert\mu_1\rvert$ and $\lvert\alpha_1\rvert$, is shown by solid lines in Figs. 1, 2, and 4.

In order to confirm the validity of the present theory and the obtained parameter-values, the concentration-dependencies of the absolute intensity for the other solvents were calculated using the values of $\lvert\mu_1\rvert$ and $\lvert\alpha_1\rvert$ of Table 4. The calculated curves are compared with the observed intensities in Figs. 1, 3, and 4 (broken lines).

We see that the agreement between the observed and the predicted concentration-dependence of the absolute intensities is fairly good for all the absorption bands. This indicates that the present model of dipole-dipole interaction can well represent the mechanism that causes a variation of the infrared absorption intensities in solutions. Incidentally, the gas-phase intensity data[32-34] are included in Figs. 1 and 2. It is seen that the calculated intensities approach the gas-phase intensities in the limit of the infinite dilution by nonpolar solvents, which indicates that the present estimation of $\lvert\mu_1\rvert$ is very reasonable. It should be noted that, although the signs of μ_1 and α_1 can not be determined from the intensity measurements, the signs of the products, $\mu_1\alpha_1$'s, can be determined from the solvent effect data. The conclusion is that $\mu_1\alpha_1>0$ for the ν_3 transition of methyl iodide, since as $\langle\mathfrak{F}_p\rangle_{av}$ becomes large so does $\lvert m_1\rvert$. Similarly we obtain the result $\mu_1\alpha_1>0$ for the ν_2 transition of methyl cyanide and $\mu_1\alpha_1>0$ for the ν_8 transition of methyl

Table 4. Values of $\lvert\mu_1\rvert$ and $\lvert\alpha_1\rvert$
(The values were determined by the method of least-squares from the data of methyl cyanide-solutions for ν_3 of methyl iodie, and from the data of carbon tetrachloride-solutions for ν_2 and ν_8 of methyl cyanide. Values in parentheses are standard deviations)

cyanide. Dickson *et al.*[32] concluded that $\mu_1<0$ for the ν_3 transition of methyl iodide. Thus we can say that $\alpha_1<0$ for this particular transition.

We must remember that the calculation of $\langle\mathfrak{F}_0\rangle_{av}$, based on the same model as in the present paper, resulted in very different values from those calculated on the basis of the reaction field in the case of 1,2-dibromoethane in liquid and in solutions,[27] although the former can well explain that part of the field which changes in concentration- or temperature-variation. The same situation is expected for the present cases. If we have data for the dielectric constant as each concentration, and calculate $\langle\mathfrak{F}_p\rangle_{av}$ by use of the reaction field formalism, somewhat different values for $|\alpha_1'|$s from the present results may be obtained. Thus the present values of $|\alpha_1|$'s can not be too much relied upon. In fact, we obtain $|\alpha_1|$ of 0.11 Å^3 for the ν_2 transition of methyl cyanide, if we use the gas-phase absolute intensity of Raman scattering measured by Schrotter and Bernstein.[39] neglecting the anisotropy of α_1. It seems, however, that the present approach has something to do with the real mechanism of molecular interaction that causes the intensity change, from the fact that the two-parameter equation, Eq. (8), can reproduce the intensity change very well.

The authors wish to express their gratitude to all the members of the Shimanouchi Laboratory for their valuable discussions. The authors are particularly grateful to Professor Takehiko Shimanouchi, the University of Tokyo, for giving them the opportunity to publish this work.

33) J. P. Jesson and H. W. Thompson, *Spectrochim. Acta*, **13**, 217 (1958), referred to in B. H. Thomas and W. J. Orville-Thomas, *J. Mol. Structure*, **7**, 123 (1971), in the unit of 10^3 darks. We converted the latter into the unit of cm^2/mol by the relation:

$$\Gamma(\text{cm}^2/\text{mol}) = \text{A(darks)} \times 10^3/\nu_0$$

where ν_0 is the wavenumber (cm^{-1}) at the band center.
34) Kondo's preliminary result[35] is 103 darks or 272 cm^2/mol for the gas-phase intensity of the ν_8 band of methyl

cyanide, which conflicts with the present result. Among other authors, Gordon[36] reports 113 darks and Hendricks[37] reports 130 darks. It seems that some unexplained cause exists which makes the intensity of this particular absorption band in carbon tetrachloride-solution very different from that of the gas phase.

(Received January 21, 1975)

The laser Raman scattering by potassium *n*-alkyl carboxylates and sodium *n*-alkyl sulfates was measured in the solid state and aqueous solutions, and the concentration dependence of molecular conformations of these molecules was studied. For aqueous solutions of potassium *n*-hexanoate and potassium *n*-pentanoate, the Raman intensities of the accordion vibrations of the all-*trans* form relative to the skeletal deformation vibrations of the *gauche* isomers were found to increase with an increase in the concentration. This intensity change is remarkable at the critical micelle concentration. A concentration dependence of the intensity of the Raman lines was also observed in the frequency region of 1600—600 cm^{-1}. These observations revealed that the percentage of the all-*trans* form of the surfactant molecules increases with an increase in the concentration above the critical micelle concentration.

The infrared absorption spectra of straight-chain fatty acids and their salts have been extensively studied by many investigators,[2–15)] and the vibrational assignment of the infrared absorption bands has been almost completely established. However, very few Raman studies of these compounds have been reported.

In our preceding paper[16)] on the Raman spectra of a homologous series of sodium *n*-alkyl sulfates and of potassium *n*-alkyl carboxylates, the sulfate ions were found to take the *trans* form about the CH_2–O bond in an aqueous solution. Moreover, it was concluded that the conformational randomness of the *n*-alkyl hydrocarbon skeleton of these surfactant molecules increases with the number of carbon atoms.

In the present study, the concentration dependence of the relative Raman intensities was investigated for aqueous solutions of potassium *n*-alkyl carboxylates and sodium *n*-alkyl sulfates, and the conformation change in the surfactant molecules accompanying the formation of micelles was discussed.

Experimental

The samples of potassium *n*-butanoate (Pn-B), potassium *n*-pentanoate (Pn-P), potassium *n*-hexanoate (Pn-H), and potassium *n*-octanoate (Pn-O) were prepared from the corresponding aliphatic acids and potassium hydroxide, and were purified by recrystallization. The samples of sodium *n*-butyl sulfate (SBS), and sodium *n*-hexyl sulfate (SHS) were prepared from sulfuric acid, *n*-alkyl alcohol, and sodium hydroxide. The purity was checked by elementary analysis. Found for SBS: C, 26.94; H, 5.20%. Calcd for $C_4H_9O_4SNa$: C, 27.27; H, 5.15%. Found for SHS: C, 35.27; H, 6.70%. Calcd for $C_6H_{13}O_4SNa$: C, 35.11; H, 6.39%.

The measurements of the Raman spectra of these surfactants were carried out at room temperature with the use of a JEOL model-02AS Raman spectrometer and the 488.0 nm line of an Ar^+ gas laser. The temperature dependence of the intensities of the Raman lines was measured by the use of a JRS-S1 Raman spectrometer. The Raman spectra of the surfactants in the solid state were obtained by focusing the laser beam into a cavity of the small disk of samples. For the measurements of aqueous solutions, the potassium *n*-alkyl carboxylates were dissolved in a 0.1 M KOH solution to avoid hydrolysis, but the sodium *n*-alkyl sulfates were simply dissolved in water.

Results and Discussion

The Raman spectra of Pn-B, Pn-P, and Pn-H in aqueous solutions are shown in Fig. 1, while the frequencies observed in the solid state and in aqueous solutions are listed in Table 1. The vibrational assignment of these Raman lines was carried out on the basis of the infrared-absorption spectra of fatty acids and their salts.[13–15)]

A weak peak commonly observed at 1550 cm^{-1} in aqueous solutions corresponds to the infrared-absorption band of an aqueous solution at 1550 cm^{-1} and is assigned to the COO^- anti-symmetric stretching vibration. The two Raman lines of the solid surfactants at 1550 and 1580—1600 cm^{-1} may possibly

a) vs: very strong, s: strong, m: medium, w: weak, wb: weak and broad, vw: very weak, vwb: very weak and broad, sh: shoulder.

be the split components of the COO^- anti-symmetric stretching vibration. A strong Raman line at 1450—1465 cm^{-1} is commonly observed in the solid state and an aqueous solution, and is due to the CH_2 scissoring vibrations. A common Raman line of the surfactant solutions around 1400—1420 cm^{-1} also appears in the solid state; this line corresponds to the infrared-absorption band of the aqueous solutions at 1400 cm^{-1}, and is ascribed to the COO^- symmetric stretching vibration. A Raman line observed at 1380 cm^{-1} in the solid samples and aqueous solutions is due mainly to the terminal-methyl symmetric deformation.

The weak broad Raman line of the solid surfactants at 690—700 cm^{-1} corresponds to the infrared-absorption band at 690—700 cm^{-1}; it is assigned to the COO^- scissoring vibration. This vibrational mode is observed at 650 cm^{-1} in the aqueous solutions, with a considerable shift in the frequencies. A broad Raman line of the aqueous solutions is observed at 615—620 cm^{-1}; in the solid state this Raman line appears at 580—590 cm^{-1}, with a frequency shift, and is attributed to the COO^- wagging vibration. A broad Raman peak is commonly observed at 500—530 cm^{-1} in the solid surfactants and aqueous solutions; it is assigned to the COO^- rocking vibration. These Raman lines do not depend very much upon the chain length. However, there are several Raman lines which are characteristic of each molecule; they are related to the molecular conformations.

In the lower frequency region of the Raman spectrum of each solid sample a strong Raman line is observed, and its frequency is inversely proportional to the number of carbon atoms when it is greater than five. This relationship has been found for the accordion-like skeletal deformation frequencies of *n*-paraffins.[17,18] Accordingly, this line must be ascribed to an accordion vibration of the surfactant molecule. Moreover, in the aqueous solution of each sample there is a medium Raman line which closely corresponds to the accordion vibration observed in the solid state; its frequency is also proportional to the reciprocal number of the carbon atoms. This Raman line should be assigned to the accordion-like vibration due to the extended molecular form in the aqueous solution. This observation is also compatible with the fact that the extended molecular form is abundant in the liquid state for low homologous *n*-paraffins.[17,18]

Potassium n-*Butanoate.* The Raman lines of Pn-B at 812, 876, 1052, and 1321 cm^{-1} are not observed in the solid state; accordingly, these lines are ascribed to the rotational isomer about the CH_2–CH_2 bond. Two Raman lines are observed at 1080 and 1290—1300 cm^{-1} in the solid state and in an aqueous solution. They are not identified in the infrared-absorption spectra of Pn-B.[15] The two Raman lines of the solid Pn-B at 478 and 356 cm^{-1} are also observed at 482 and 354 cm^{-1} in an aqueous solution. These lines correspond closely to the infrared-absorption bands of *n*-butyric acid at 487 and 364 cm^{-1}, which have been assigned to the CCO deformation vibration and the CCC deformation vibration[14] respectively.

Potassium n-*Pentanoate.* The weak Raman lines of the Pn-P solution at 764, 858, 936, 978, 1017, and 1224 cm^{-1} are not found in the spectrum of the solid surfactant; accordingly, they are attributed to the *gauche* isomers about the CH_2-CH_2 bonds. Four Raman lines at 839, 884, 1023, and 1275 cm^{-1} are found for both the solid Pn-P and an aqueous solution, but they are not observed in the infrared-absorption spectra.[15] The accordion vibration of Pn-P is identified at 355 cm^{-1} in the solid state and at 362 cm^{-1} in an aqueous solution. Three Raman peaks of the aqueous solution at 380, 432, and 483 cm^{-1} are not found in the spectrum of the solid state; they are thus ascribed to the skeletal deformation vibrations of the *gauche* isomers.

Potassium n-*Hexanoate.* Three Raman lines of the aqueous solution at 908, 1039, and 1214 cm^{-1} disappear in the solid state and are, therefore, attributed to the *gauche* isomers. The Raman lines of Pn-H are observed at 780—785, 860, 1025—1030, 1070—1080, and 1260—1270 cm^{-1} in both the solid state and an aqueous solution, but none of these lines is observed in the infrared-absorption spectra of Pn-H.[15] The accordion vibration of Pn-H is observed at 325 cm^{-1} in the solid state and at 327 cm^{-1} in an aqueous solution. Since only the Raman peak of the aqueous solution at 397 cm^{-1} disappears in the solid state, it must be assigned to the skeletal deformation vibrations of the *gauche* isomers.

Potassium n-*Octanoate.* The three Raman lines of the aqueous solution at 850, 875, and 1077 cm^{-1} disappear in the solid Pn-O; accordingly, they can serve as indicators of the *gauche* isomers. Three Raman lines of Pn-O are also observed at 960, 1000, and 1120 cm^{-1} in the solid state and in aqueous solution, but these lines do not appear in the infrared-absorption spectra.[16] The accordion vibration of Pn-O gives rise to the Raman lines at 248 cm^{-1} in the solid state and at 250 cm^{-1} in an aqueous solution. The two Raman lines at 430 and 450 cm^{-1} are due to the coupled vibrational modes of the skeletal deformation vibrations and the CCO deformation vibration of the *trans* isomer. The three Raman lines of the aqueous solution at 314, 350, and 397 cm^{-1} are not observed in the solid state; accordingly, they are attributed to the skeletal deformation vibrations of the *gauche* isomers.

Temperature Dependence of Raman Spectra of Aqueous Solutions. Figures 2(a) and (b) show the Raman spectra of Pn-H and Pn-P, respectively, in the aqueous solutions at two different temperatures. The Raman intensity of the accordion vibration of the all-*trans* form seems to decrease as the temperature is raised. In the case of Pn-H, the Raman intensities of the peak at 327 cm^{-1} relative to the peaks at 397, 424, and 470 cm^{-1} are lower at 96 °C, while for Pn-P the intensities of the peak at 362 cm^{-1} relative to other peaks are lower at 96 °C than at 20 °C.

Concentration Dependence of the Relative Raman Intensities of Potassium Aliphatic Carboxylates. Figures 3(a) and (b) show the change in the intensities of Raman lines with the concentration of Pn-H and Pn-P in the skeletal deformation vibration region. The intensities of the Raman lines were found to be con-

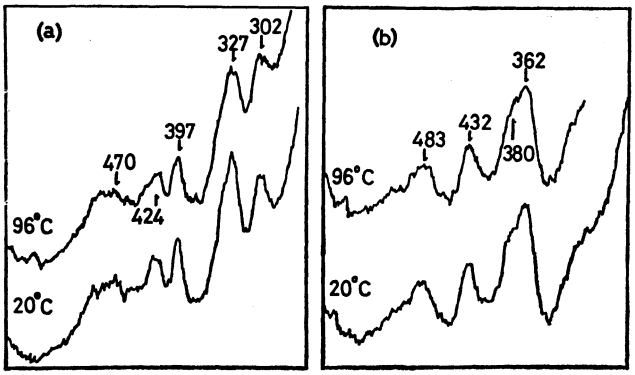

Fig. 2. Temperature dependence of the Raman spectra of (a) Pn-H (450 mg/cc) and (b) Pn-P (400 mg/cc) in aqueous solutions.

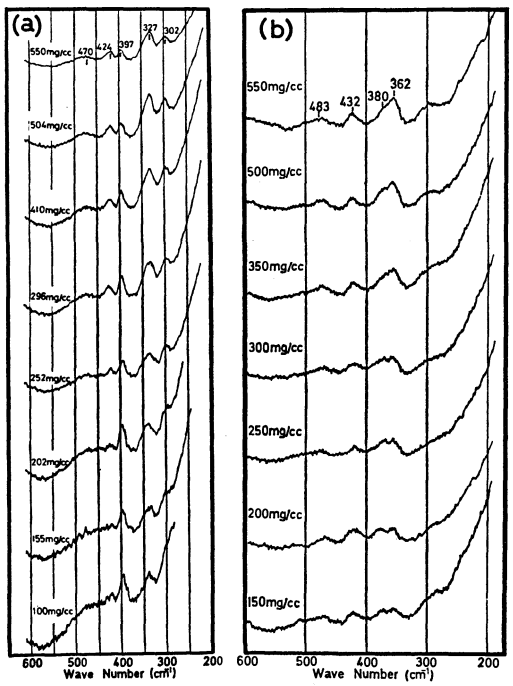

Fig. 3. Raman spectra of (a) Pn-H and (b) Pn-P in aqueous solutions at various concentrations.

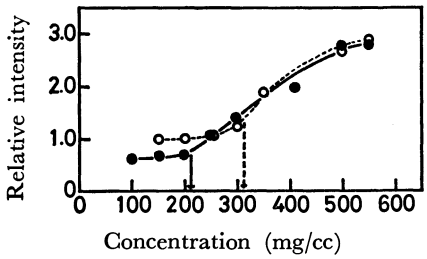

Fig. 4. Concentration dependence of the peak height ratio (I_{327}/I_{397}) of the Pn-H solution (solid line) and that (I_{362}/I_{432}) of the Pn-P solution (broken line). Weak background due to the water spectrum was substracted from the surfactant spectrum using the Raman scattering of distilled water as the base line. Solid and broken arrows indicate the critical micelle concentrations of Pn-H and Pn-P, respectively.

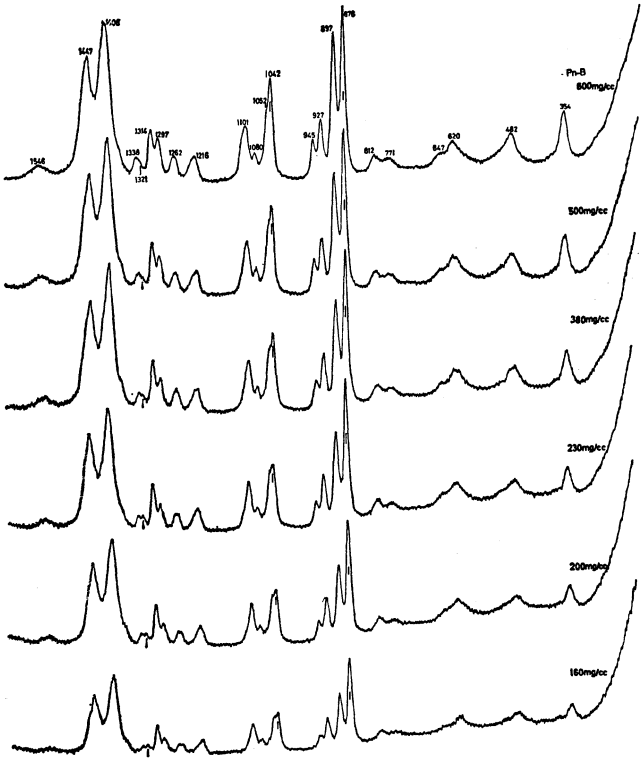

Fig. 5. Raman spectra of Pn-B in aqueous solution at various concentrations.

siderably influenced by the concentration. The relative Raman intensity of the accordion vibration of Pn-H at 327 cm^{-1} increases with an increase in the concentration, while the relative intensity of the peak at 397 cm^{-1} due to the *gauche* isomer decreases. The peak-height ratio of the two Raman lines, I_{327}/I_{397}, is plotted against the concentration in Fig. 4. It is almost constant below ca. 200 mg/cc, but gradually increases with the concentration above this point. Since this intensity change occurs around the critical micelle concentration (CMC), (210 mg/cc),[18] the spectral change is considered to be caused by the formation of micelles.

In the case of Pn-P, the intensity of the accordion vibration at 362 cm^{-1} increases with an increase in the concentration. In Fig. 4, the peak heights of the accordion vibration relative to the skeletal deformation vibration of the *gauche* isomer, I_{362}/I_{432}, are plotted against the concentration. The ratio is unchanged below the CMC (310 mg/cc),[19] but it increases gradually above this concentration. Thus, for Pn-P as well as for Pn-H, the all-*trans* form of the skeletal backbone seems to be more stable in the micelles than in the mono-molecular dispersion state.

For the aqueous solution of Pn-B, the concentration dependence of the relative intensities of the Raman lines was observed in the frequency region of 600—1600 cm^{-1} rather than in the region of 200—600 cm^{-1}. As is shown in Fig. 5, the relative intensities of the Raman lines at 897, 1042, and 1297 cm^{-1} increase with an increase in the concentration, but that of the peak at 1321 cm^{-1} decreases. Since the former three lines exist in the Raman spectrum of the solid

Pn-B, they are ascribed to the all-*trans* form, whereas the latter Raman line disappears in the solid state and is assigned to the *gauche* isomers. In Fig. 6(a), the peak heights of the Raman lines at 897 and 1042 cm^{-1} relative to the peak at 1101 cm^{-1} are plotted against the concentration of Pn-B. In the concentration region below the CMC (440 mg/cc),[18] both I_{897}/I_{1101} and I_{1042}/I_{1101} are constant and then increase above the CMC. On the contrary, the ratio of I_{1321}/I_{1338} decreases slightly above the CMC.

The concentration dependence of the Raman lines of Pn-P and Pn-H was found in the frequency region of 600—1600 cm^{-1} as well as in the low-frequency region. As is shown in Fig. 6(b), the peak heights of the Raman lines of Pn-P at 931, 1109, 1298, and 1447 cm^{-1} relative to the peak at 1062 cm^{-1} increase with an increase in the concentration above the CMC (310 mg/cc).[19] These lines correspond to the Raman lines of the solid Pn-P at 927, 1107, 1293, and 1448 cm^{-1}; therefore, they are attributed to the all-*trans* form. The intensity of the peak at 1224 cm^{-1} relative to that of 1242 cm^{-1} also decreases with an increase in the concentration above the CMC.

A similar variation was also observed for some of the Raman lines of Pn-H. As is shown in Fig. 6(c), the relative peak height of I_{935}/I_{1062} increases with an increase in the concentration above the CMC (210 mg/cc),[18] but that of I_{1214}/I_{1227} decreases. Since the Raman line of the aqueous solution at 935 cm^{-1} corresponds to the very strong line of the solid Pn-H at 925 cm^{-1}, this line must be due to the all-*trans* form.

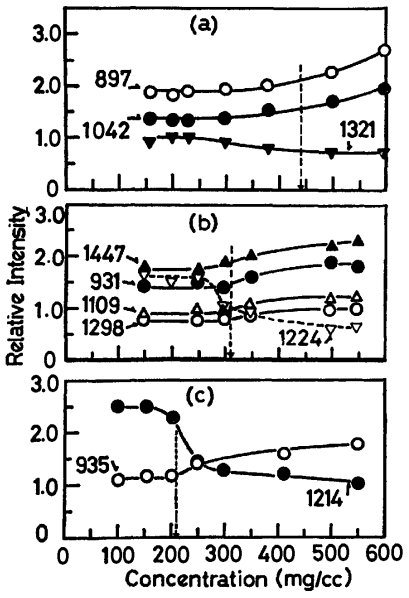

Fig. 6. Concentration dependence of the relative Raman peak heights in aqueous solutions; (a) Pn-B, the peak heights of the 897 and 1042 cm^{-1} lines relative to the 1101 cm^{-1} line; the peak height of the 1321 cm^{-1} line relative to the 1338 cm^{-1} line; (b) Pn-P, the peak heights of the 931, 1109, 1298, and 1447 cm^{-1} lines relative to the 1064 cm^{-1} line; the peak height of the 1224 cm^{-1} line relative to the 1242 cm^{-1} line; (c) Pn-H, the peak heights of the 935 cm^{-1} line relative to the 1062 cm^{-1} line; the peak height of the 1214 cm^{-1} line relative to the 1227 cm^{-1} line.
The baseline was simply drawn from the basin at *ca.* 1500 cm^{-1} to that at *ca.* 700 cm^{-1} in each spectrum.

For the aqueous solution of Pn-O, the relative peak height of I_{844}/I_{897} is almost constant below *ca.* 70 mg/cc, but this ratio decreases with the concentration over this point. On the contrary, the relative intensity of I_{1064}/I_{897} increases in the concentration region above *ca.* 70 mg/cc. Since the Raman line of the Pn-O solution is observed in the solid state, it must be attributed to the all-*trans* form. The concentration of 70 mg/cc is not exactly the CMC, but it is very close to the reported value of the CMC (70—110 mg/cc).[18]

For the surfactant molecules with longer chains, the CMC becomes lower; accordingly, the observation of the precise Raman intensity around the CMC is more difficult. However, it is evident that the formation of micelles causes the intensity change of the Raman spectra and that this spectral change is associated with the conformational changes in the *n*-alkyl hydrocarbon chains.

Concentration Dependence of the Raman Intensities of Sodium n-*Butyl Sulfate and Sodium* n-*Hexyl Sulfate.* In our previous study,[16] the Raman lines of SBS in an aqueous solution at 792 and 947 cm^{-1} were assigned to the CH_2 rocking vibration and the C–C stretching vibration of the *gauche* isomers respectively. The relative peak heights of these Raman lines were also found in the present study to decrease with an increase in the concentration. Similar behavior was observed for the Raman line of the *gauche* isomers at 824 cm^{-1}.

For the aqueous solution of SHS, the two Raman lines of the *gauche* isomers at 806 and 987 cm^{-1} show the concentration dependence of the Raman intensities. The relative peak heights of I_{806}/I_{896} and I_{987}/I_{896} decrease with an increase in the concentration, whereas the ratio of I_{1125}/I_{896} increases. These intensity changes also occur around the CMC (140 mg/cc).[19] The concentration dependence of the relative Raman intensities of sodium *n*-alkyl sulfates are also probably due to the conformation changes in the *n*-alkyl chains.

The authors wish to express their gratitude to Professor Tatsuo Miyazawa of the University of Tokyo for his interest and continuing encouragement during this work, and to Mr. Shuichi Muraishi of the Japan Electron Optics Laboratory for his measurements of the temperature dependence of the Raman spectra.

Semiempirical Relations in Molecular Liquids. I. Molecular Structure, Melting Temperature, and Effective Hard Core Diameter of Molecules[1)]

Yoshitsugu OONO

Department of Applied Science, Faculty of Engineering, Kyushu University, Higashi-ku, Fukuoka 812

(Received January 29, 1975)

A simple method for the estimation of the effective hard core diameter of a molecule (at melting point), which is the only parameter in the application of the scaled particle theory to molecular liquids, is proposed. For a nearly spherical molecule, the effective hard core diameter a in Å can be given by

$$a = 1.072\, P^{2/5} T_m^{-1/10},$$

where P is the parachor of the molecule in cgs unit and T_m is the melting temperature in K. The factor 1.072 is equal to that predicted by the scaled particle theory.

The statistical mechanics of simple liquids has recently been developed and equilibrium properties can be calculated fairly accurately.[2)] On the other hand, statistical mechanical theories for molecular liquids remain undeveloped. Insight into the relationship between molecular structure and physical properties of molecular liquid is desirable.

The significant structure theory[3)] can predict physical properties of molecular liquids semiempirically, but its theoretical basis seems to be obscure. Another semiempirical theory so far developed is the scaled particle theory (SPT),[4)] which has a sound physical basis for a nearly spherical molecule. The SPT was originally developed[5)] to treat systems of hard spheres. However, it has been shown[6)] that, if the effective hard core diameters of the molecules are properly chosen, molecular liquids can be described by the SPT fairly well. So far, surface tension,[6,7)] isothermal compressibility,[7,8)] thermal expansivity,[8)] Henry's constant,[6)] heat capacity,[8)] and heat of vaporization[9)] have been calculated or correlated with each other by the SPT. The only parameter used in the SPT is the effective hard core diameter a of the molecule. If we know a and the density of the liquid, then we can calculate surface tension, isothermal compressibility, *etc.* The value of a can be estimated from density with the aid of information on the molecular structure.[4)] However, measurement of density at temperatures other than room temperature is not very easy.

In this paper we propose a method for estimating the effective hard core diameter of molecules at melting point from the knowledge of the molecular structure and the approximate value of the melting temperature which can be easily measured. This paper gives a simple method for estimation of da/dT, where T is temperature.

Theory

Outline of the Scaled Particle Theory. The semiphenomenological version of the SPT[4,6)] can be summarized as follows. The chance p_0 that the spherical cell of radius r is devoid of molecular centers satisfies the relation

$$d \ln p_0(r)/dr = -4\pi r^2 \rho G(r), \tag{1}$$

where ρ is the number density. $G(r)$ is so defined that $\rho G(r)$ measures the concentration of molecular centers just outside the spherical cell. According to fluctuation theory, we have

$$p_0(r) \propto \exp[-W(r)/kT], \tag{2}$$

where W is the reversible work required to produce a spherical hole of radius r. By thermodynamic consideration we have

$$dW = pdV + \sigma dA, \tag{3}$$

where p is the pressure, σ the surface tension which has the form $\sigma=\sigma_0(1-2\delta/r)$, V the volume of the hole, and A the surface area of the hole. Using Eqs. (1), (2) and (3), we obtain

$$G(r) = \frac{p}{\rho kT} + \frac{\sigma}{\rho kT}\frac{dA}{dV}. \tag{4}$$

On the other hand, we know $G(r)$ exactly for $r \leq a/2$:[4)]

$$G(r) = 1/(1-4\pi\rho r^3/3) \tag{5}$$

Equating G, dG/dr, and $G'' \equiv d^2G/dr^2$ calculated from both Eqs. (4) and (5) at $r=a/2$, we get p, σ_0, and δ as functions of $y=\pi\rho a^3/6$.

Some Remarks on the Application of the SPT to Molecular Liquids. Since it is known that G'' is not continuous at $r=a/2$, it is desirable not to use G'' in order to obtain p, σ_0 and δ. If G'' is not used, then not all the three quantities, p, σ_0, and δ, can be obtained. However, we can obtain σ_0 and δ as functions of y and p. For σ_0 we have

$$2\pi\sigma_0 a^2/3kT = 2y(1-y) + 3y^2/(1-y^2) - 2py. \tag{6}$$

Equation (1) is exact even if the particle has no hard core. The hard core assumption is used in Eq. (5), but the equation also holds in the case of the particle exerting attractive forces besides hard core repulsion. This implies that we can choose the so-called augmented van der Waals equation of state[10)] for the pressure p in Eq. (6), *i.e.*, attractive forces affect σ_0 and δ only through p.

If the molecule has a sufficiently hard core, then Eq. (5) is a good approximation, so that the SPT can be used for the case of molecular liquids with nearly spherical repulsion core. We can therefore use the observed pressure in Eq. (6). Then the last term on the right-hand side of Eq. (6) is negligible at higher densities. Consequently, surface tension scarcely depends on the details of van der Waals attractive forces at higher densities.

Basic Relation. With observed data on σ_0, ρ, and T, the quantity y can be determined from Eq. (6) with py discarded, *i.e.*,

$$\sigma_0 T^{-1} \rho^{-2/3} = 4.28 \times 10^{-17} y^{1/3}(2+y)/(1-y)^2, \tag{7}$$

Table 1. Table of the function $s(y)$ defined by Eq. (9)

y	$s(y)$
0.30	0.985
0.40	1.037
0.50	1.065
0.52	1.068
0.54	1.070
0.56	1.071
0.58	1.072
0.60	1.071
0.62	1.070

where σ_0 is in dyn/cm, T in K, and ρ in cm^{-3}. The effective hard core diameter obtained from Eq. (7) is a slightly decreasing function of temperature. Dependence of a on temperature has been estimated by Mayer.[11] However, since the data on gas viscosity are needed, his method is not useful.

Surface tension can be calculated semiempirically from the parachor P and the density by

$$P = \pi N_A \sigma_0^{1/4} a^3/6y, \quad (8)$$

where N_A is the Avogadro number. Eliminating σ_0 from Eqs. (7) and (8), we obtain

$$s(y) \equiv aP^{-2/5}T^{1/10} = 1.65y^{1/3}[(1-y)^2/y^{1/3}(2+y)]^{1/10}, \quad (9)$$

where P is in cgs unit and a in Å.

As can be seen from Table 1, $s(y)$ depends on y slightly. The function $s(y)$ is nearly constant when y is about 0.55. It can be shown that for many organic compounds the values of y at the melting point fall in the range 0.5—0.6. Thus we expect that the equation

$$aP^{-2/5}T^{1/10} = C, \quad (10)$$

where C is a constant, holds fairly accurately at melting point.

Validity of the Relation (10)

Validity of the relation (10) is demonstrated in Figs. 1—4. The effective hard core diameter a is calculated from surface tension data by means of Eq. (7) and extrapolated linearly to the melting point. Data are taken from Refs. 12—14, in which the values of calculated parachor are also cited. The linear relation between a and T is assumed to a first approximation. The lines in Figs. 1—4 denote Eq. (10) with $C=1.072$, the value being consistent with that in Table 1. It can be concluded from Figs. 1—4 that Eq. (10) holds fairly accurately when molecules are nearly spherical.

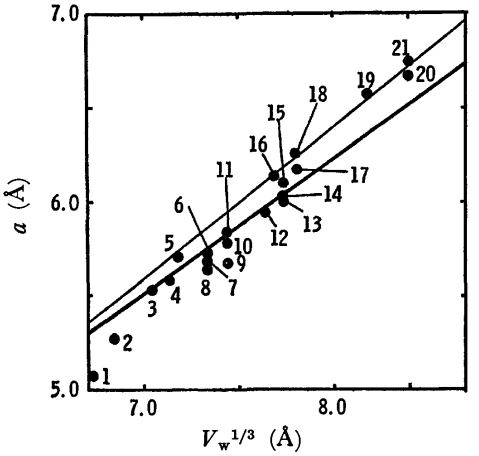

Fig. 7. Linear relation between a and $V_w^{-1/3}$.
——: $a=0.80\,V_w^{-1/3}$, ——: $a=0.79\,V_w^{-1/3}$
1: benzene, 2: fluorobenzene, 3: chlorobenzene, 4: bromobenzene, 5: toluene, 6: m-dichlorobenzene, 7: o-dichlorobenzene, 8: p-dichlorobenzene, 9: p-xylene, 10: o-xylene, 11: m-xylene, 12: 1,2-dichloro-4-methylbenzene, 13: 1,2,3-trimethylbenzene, 14: 1,3,5-trimethylbenzene, 16: isopropylbenzene, 17: 1-methylnaphthalene, 18: t-butylbenzene, 19: p-t-butylmethylbenzene, 20: p-diisopropylbenzene, 21: o-diisopropylbenzene.

Figure 5 shows that the relation (10) holds also for the case of non-spherical molecules. Normal alkanes asymptotically satisfy Eq. (10) with $C=1.080$, but this value cannot be explained in terms of the SPT (Table 1).

Discussion

For many organic liquids the factor $T^{-1/10}$ at melting point is *ca.* 0.6. Hence the main factor in Eq. (10) is $P^{2/5}$. Although $a \propto P^{2/5}$ holds approximately, the factor $T^{-1/10}$ markedly improves the approximate relation as shown in Fig. 6. Thus the factor $T^{-1/10}$ is indispensable for making C in Eq. (10) constant.

In the application of the SPT to molecular liquids the parameter a is considered to be the effective hard core diameter of the molecule. Thus if the physical picture of the SPT is correct, then a should be correlated with the actual dimension of a molecule. In the case of simple liquids, a and the distance where the repulsive potential is zero is almost the same.[5] In the case of molecular liquids, it is difficult to define or determine the dimension of complex molecules. For the sake of convenience, we choose, as a measure of actual dimension of a molecule, the cubic root of the van der Waals volume V_w estimated and tabulated by Bondi.[15] A roughly linear relation between a at melting point and $V^{1/3}$ is shown in Fig. 7. The physical picture of the

SPT is correct at least in the case of liquids consisting of nearly spherical molecules.

The value of a at room temperature can be calculated from the density at room temperature which can be measured very easily. The value of a at melting point can be estimated if the melting point is known. A rough measurement of the melting point is also very easy and da/dT can thus be estimated. We can therefore estimate a at desired temperature from density at room temperature, molecular structure and melting point. The da/dT estimated by the method mentioned above is rather large.[16] Hence the quantity should not be considered to represent the softness of the intermolecular repulsive force quantitatively but should be treated as a mere parameter for better applications of the SPT to molecular liquids.

The author wishes to express his thanks to Professor T. Oyama for critical reading of the manuscript.

The Syntheses and Spectroscopic Investigation of Copper(II), Nickel(II), and Cobalt(II) Complexes of 8-Quinolinecarboxamide

Masahide NOJI, Yoshinori KIDANI, and Hisashi KOIKE*

Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467

(Received August 20, 1974)

The syntheses of the bivalent metal complexes of 8-quinolinecarboxamide (abbreviated as 8-QCA) were attempted; the complexes obtained have the compositions of $M(8\text{-QCA})_2X_2$ (M=Cu(II), Ni(II), and Co(II) ions; X=Cl^-, Br^-, I^-, and NO_3^-) and $Cu(8\text{-QCA})Cl_2$. The diffuse reflectance, the infrared and far-infrared spectra, and the magnetic moments of these metal complexes were measured. The coordination sites of 8-QCA have been suggested for the amide oxygen and the quinoline nitrogen from the diffuse reflectance spectra and the infrared spectra. The values of 3.13—3.21 B.M. and 4.81—5.03 B.M. were observed for $Ni(8\text{-QCA})_2X_2$ and $Co(8\text{-QCA})_2X_2$ respectively. From these magnetic moments, an octahedral structure has been proposed for the nickel and the cobalt complexes, whose far-infrared spectra (600—200 cm^{-1}) also supported this structure, with a *trans*-planar coordination of the 8-QCA molecules around the metal ions. Since the $Cu(8\text{-QCA})_2X_2$ complexes are of the mononuclear form, judging from the magnetic moments of 1.87—1.93 B.M., and since the far-infrared spectra suggested a structure belonging to the C_{2h} point group, a distorted octahedral configuration is conceivable.

Some quinoline derivatives, such as 8-hydroxyquinoline and 8-mercaptoquinoline, which are able to form a chelate ring with metal ions are well known to show a strengthened antibacterial action upon the addition of some kinds of metal ions. The present authors have long been interested in the metal chelates of the quinoline derivatives because of their biological significance, in this investigation the syntheses of the bivalent metal complexes of 8-quinolinecarboxamide (abbreviated as 8-QCA in this paper) were attempted.

It has previously been reported that, when a carboxamide group participates in metal-complex formation, it can coordinate on metal ions with or without the proton released from the carboxamide group. The former is called a cationic complex, and the latter, a neutral complex; both of them have been found in the metal complexes of 2-pyridinecarboxamide.[1] However, 8-QCA does not form neutral complexes in an aqueous solution because of the formation of metal hydroxides; only the cationic complexes were obtained. The complexes have the compositions of $Cu(8\text{-QCA})Cl_2$ and $M(8\text{-QCA})_2X_2$ (M=Cu(II), Ni(II), and Co(II) ions; X=Cl^-, Br^-, I^-, and NO_3^-). The coordination sites and the structures of the cationic chelates of 2-pyridinecarboxamide and its related derivatives with the bivalent metal ions have been studied by Sekizaki and Yamasaki;[2-7] it has also been concluded that the chelate-ring formation took place through the amide oxygen and the pyridine nitrogen, as confirmed by X-ray analyses.[8-10]

The magnetic moments, the diffuse reflectance spectra, and the infrared and far-infrared spectra of the bivalent metal complexes of 8-QCA were measured as part of the analyses. The data will be compared with those of the metal complexes of 2-pyridinecarboxamide, and the coordination sites and the structures of the metal complexes of 8-QCA will be discussed.

* Present address: School of Medical Technology and Nursing, Fujita Gakuen University, Kutsukake, Toyoake City, Aichi Prefecture 470-11.

Experimental

Materials. The metal halides and metal nitrates were analytical-grade products of Wako Pure Chemical Industries, Ltd.

Synthesis of 8-Quinolinecarboxamide. To an excess of thionyl chloride (25 g) we added 5 g of 8-quinolinecarboxylic acid, which has been synthesized according to the method reported by Campbell *et al.*;[11] the resultant solution was refluxed for 4 hr at 80 °C on a water bath. When the excess of thionyl chloride was distilled away under reduced pressure, crude 8-quinolinecarbonyl chloride was obtained as a reddish brown residue, which was subsequently dissolved in 50 ml of methanol. The methanol solution was added gradually to a large excess of an ice-cold methanol solution of ammonia, from which crude 8-quinolinecarboxamide was then deposited as yellow crystals. It was recrystallized twice from water. Yield, 60%.

Found: C, 69.69; H, 4.78; N, 16.30%. Calcd for $C_{10}H_8N_2O$: C, 69.76; H, 4.68; N, 16.26%.

Preparations of Metal Complexes. *1) Dichloro(8-quinolinecarboxamide)copper(II), Bis(8-quinolinecarboxamide)copper(II) Bromide, Bis(8-quinolinecarboxamide)copper(II) Nitrate, and Bis(8-quinolinecarboxamide)cobalt(II) Bromide*: To 15 ml of an ethanol solution containing 1 mmol of the corresponding metal salt, we added 344 mg (2 mmol) of the ligand dissolved in 20 ml of ethanol; the mixture was then kept standing at room temperature. The objective complexes were obtained as a crystalline powder. They were collected by filtration and washed with hot ethanol.

2) Bis(8-quinolinecarboxamide)nickel(II)Chloride, Bis(8-quinolinecarboxamide)nickel(II) Bromide, and Bis(8-quinolinecarboxamide)cobalt(II) Iodide: These complexes were obtained by treating ethanol solutions containing 1 mmol of the corresponding metal salt with 2 mmol of the ligand in 20 ml of ethanol. The resultant solution was evaporated to 2/3 volume on a water bath. After it had been kept standing overnight at room temperature, a crystalline powder was deposited.

3) Bis(8-quinolinecarboxamide)nickel(II) Iodide, Bis(8-quinolinecarboxamide)nickel(II) Nitrate, and Bis(8-quinolinecarboxamide) cobalt(II) Iodide: After mixing 1 mmol of the corresponding metal salt in 20 ml of an ethanol solution containing 2 mmol of the ligand, the solution was warmed on a water bath; a crystalline powder was then deposited out.

The results of elemental analyses of the obtained metal

complexes are shown in Table 1.

Magnetic and Spectroscopic Measurements. The magnetic moments were measured with a Shimadzu MB-2-type magnetic balance. The diffuse reflectance spectra were measured with a Hitachi EPS-3T spectrophotometer equipped with an integrating-sphere accessory by means of the method described in a previous paper.[12] A JASCO IRA-2 spectrophotometer and a JASCO DS-701 spectrophotometer were used to record the infrared spectra in the region of 400—4000 cm^{-1} and in the region of 200—600 cm^{-1} respectively by the Nujol and HCB mull methods.

Results and Discussion

Magnetic Moments. The magnetic moments observed for the bivalent metal complexes of 8-QCA are shown in Table 2.

The copper complexes give normal magnetic moments in the region of 1.87—1.93 B.M., indicating no spin interaction among the adjacent copper ions. All the nickel complexes, $Ni(8\text{-}QCA)_2X_2$, give magnetic moments of 3.13—3.21 B.M., which fall within the region of 2.9—3.4 B.M. reported for octahedral complexes.[13] The magnetic moments observed for $Co(8\text{-}QCA)_2X_2$ are 4.81—5.03 B.M., corresponding to the reported values of 4.7—5.2 B.M. for octahedral cobalt complexes.[14]

Diffuse Reflectance Spectra. As is shown in Fig. 1, the absorption maxima (λ_{max}) in the diffuse reflectance spectra of $Cu(8\text{-}QCA)_2Br_2$ and $Cu(8\text{-}QCA)_2(NO_3)_2$ are observed at 700 and 675 nm.

Table 2. Magnetic moments of $M(8\text{-}QCA)_2X_2$ and $Cu(8\text{-}QCA)Cl_2$ (18—21 °C)

Complexes	Moments observed	Moments calcd for spin-only formula
$Cu(8\text{-}QCA)Cl_2$	1.90 B. M.	1.73 B. M.
$Cu(8\text{-}QCA)_2Br_2$	1.93	1.73
$Cu(8\text{-}QCA)_2(NO_3)_2$	1.87	1.73
$Ni(8\text{-}QCA)_2Cl_2$	3.13	2.82
$Ni(8\text{-}QCA)_2Br_2$	3.21	2.82
$Ni(8\text{-}QCA)_2I_2$	3.19	2.82
$Ni(8\text{-}QCA)_2(NO_3)_2$	3.19	2.82
$Co(8\text{-}QCA)_2Br_2$	4.98	3.88
$Co(8\text{-}QCA)_2I_2$	5.03	3.88
$Co(8\text{-}QCA)_2(NO_3)_2$	4.81	3.88

The λ_{max} values of these copper complexes are rather close to those of the metal chelates of 2-acetylpyridine[15] and 2-pyridinecarboxamide,[2] the N,O-coordination of the ligand having been determined. Therefore, the coordination sites of 8-QCA with a copper ion are considered to be the amide oxygen and the quinoline nitrogen.

The 1 : 1 complex, $Cu(8\text{-}QCA)Cl_2$, gives its absorption maximum at 650 nm, much like those of the 2 : 1 copper complexes; however, a new and characteristic shoulder is observed around 450—480 nm, as is shown in Fig. 1. The appearance of the shoulder may be due to the structural differences between the 1 : 1 complex and the 2 : 1 complexes. However, the λ_{max} value of the neutral copper chelate of 2-pyridinecarboxamide, $Cu(pia)_2$, the N,N-coordination of the ligand of which has been determined, was found at 530 nm in a chloroform solution.[1] The large difference in the λ_{max} values between $Cu(pia)_2$ and $Cu(8\text{-}QCA)Cl_2$ may indicate that the binding sites of 8-QCA are the amide oxygen and the quinoline nitrogen in the latter complex.

The nickel complexes, $Ni(8\text{-}QCA)_2X_2$, have the similar λ_{max} value of 680 nm, as is shown in Fig. 2.

Since the octahedral nickel complexes of the ligand with the N,N-coordination like ethylenediamine and bipyridyl are known to show their d-d bands in the region of 560—570 nm,[16,17] the large difference in the λ_{max} values between $Ni(8\text{-}QCA)_2X_2$ and both the $Ni(en)_2^{2+}$ and $Ni(bip)_2^{2+}$ systems may exclude the possibility of the N,N-coordination, that is, coordination through the amide nitrogen and the quinoline nitrogen. The other possibility is the coordination through the amide oxygen and the quinoline nitrogen,

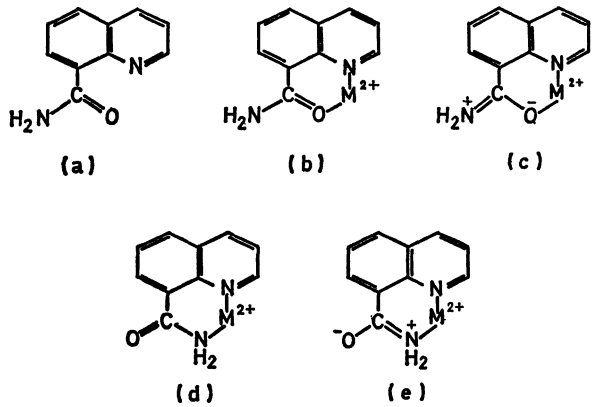

Fig. 4. Resonance forms for the ligand and the metal complexes.

this possibility is supported by the resemblance of the diffuse reflectance spectra between $Ni(8\text{-}QCA)_2X_2$ and both $Ni(piaH)Cl_2$ and $Ni(2AP)_2X_2$ (piaH= 2-pyridinecarboxamide; 2AP=2-acetylpyridine).[2,15]

The $Co(8\text{-}QCA)_2X_2$ complexes give rather complicated diffuse reflectance spectra, shown in Fig. 3, with two or three absorption bands in the wavelength region of 550—600 nm which are characteristic of octahedral cobalt complexes. However, no tendency to the longer-wavelength shift has been reported for cobalt complexes with the variation in the N,N-, N,O-, and O,O-coordinations, and the bonding sites of 8-QCA can not be deduced from the diffuse reflectance spectra.

Infrared Spectra. The infrared data of the $M(8\text{-}QCA)_2X_2$ complexes are summarized in Table 3, together with those of the ligand and the 1 : 1 copper complex. The ligand gives two peaks, at 3300 and 3150 cm^{-1}, due to the stretching vibrations of the amino group. The asymmetric OCN stretching frequency of the amide group[2] is observed as two peaks at 1665 and 1648 cm^{-1}, with its symmetric stretching peak at 1370 cm^{-1}.

The deformation mode of the amino group is observed at 1610 cm^{-1} as a shoulder.

Upon complex formation, the asymmetric N–H stretching frequencies either shift toward frequencies higher by 50—60 cm^{-1} or remain at nearly the same frequency as that of the ligand. The asymmetric and symmetric OCN stretching vibrations shift toward lower and higher frequencies respectively. These

Table 4. Assignments in far-infrared spectra (in cm^{-1})

Complexes	Chelate ring def.	ν_{M-N}	ν_{M-O}	ν_{M-X}	Amide torsion	Unassigned
$Cu(8\text{-}QCA)Cl_2$	480	—	244	290	360	
$Cu(8\text{-}QCA)_2Br_2$	486	271	240	—	349	
$Cu(8\text{-}QCA)_2(NO_3)_2$	483	275	236	—	356	210
$Ni(8\text{-}QCA)_2Cl_2$	488	254	227	—	340	
$Ni(8\text{-}QCA)_2Br_2$	480	257	225	—	320	208
$Ni(8\text{-}QCA)_2I_2$	476	255	220	—	323	
$Ni(8\text{-}QCA)_2(NO_3)_2$	478	258	220	—	330	242
$Co(8\text{-}QCA)_2Br_2$	478	239	217	—	322	
$Co(8\text{-}QCA)_2I_2$	475	242	216	—	323	
$Co(8\text{-}QCA)_2(NO_3)_2$	475	233	223	—	317	

results show that the ligand may take the resonance form (a), while for the $M(8\text{-}QCA)_2X_2$ complexes various forms, (b)—(e) in Fig. 4, are conceivable.

Since the asymmetric and symmetric OCN stretching vibrations arise mainly from the C=O and C-N stretching respectively, the N,N-coordination predicts that the contribution of the (d) resonance form would be larger that than of the (e) form because of the Coulombic repulsion in the latter form. In the (d) form the symmetric OCN stretchings are expected to shift toward the lower frequency side, while the asymmetric OCN stretchings remain at frequencies similar to that of the ligand. The observed frequency shifts of the amide group are opposite to the predicted shift for the N,N-coordination. However, when the $M(8\text{-}QCA)_2X_2$ complexes are in a resonance between the (b) and (c) forms, the *N,O*-coordination predicts the shifts of the asymmetric and symmetric OCN stretching to be to the lower- and higher-frequency side respectively. Therefore, the N,O-coordination seems reasonable for the $M(8\text{-}QCA)_2X_2$ complexes and $Cu(8\text{-}QCA)Cl_2$.

The same infrared spectral behavior of the amide group has been reported for $[M(H_2O)_2\ (piaH)_2]X_2$, where the N,O-coordination has been determined by *X*-ray analyses.[9-10]

Far-infrared Spectra. The ligand shows a peak at 233 cm^{-1} due to the amide torsion, a peak at 458 cm^{-1} assignable to the in-plane deformation of C=O, and other peaks due to quinoline-ring vibrations. Upon the complex formation, new peaks are observed in the region of 470—490 cm^{-1} and are assigned to the chelate-ring deformation. In the $M(8\text{-}QCA)_2X_2$ complexes, the peaks found around 320—360 cm^{-1} are assigned to the amide torsion.

$Cu(8\text{-}QCA)_2X_2$ and $Cu(8\text{-}QCA)Cl_2$: For $Cu(8\text{-}QCA)Cl_2$, a broad band due to the Cu-Cl stretching vibration is observed at 290 cm^{-1}, while the other peaks appear at 244 cm^{-1} below 300 cm^{-1}. The other 2 : 1 complexes give two common peaks in the regions of 271—275 cm^{-1} and 236—240 cm^{-1}, the peaks being assigned to the Cu-N (quinoline) and the Cu-O (amide) stretching respectively.

$Ni(8\text{-}QCA)_2X_2$: Since the $Ni(8\text{-}QCA)_2X_2$ complexes are supposed to be octahedral, the two nickel-ligand stretching vibrations can be expected to appear at relatively constant frequencies. In fact, the stretching vibrations assignable to the Ni-N (quinoline) and the Ni-O (amide) are found in the regions of 254—258 cm^{-1} and 220—227 cm^{-1} respectively.

$Co(8\text{-}QCA)_2X_2$: The peaks assignable to the Co-N (quinoline) and Co-O(amide) stretching vibrations are found in the regions of 239—242 cm^{-1} and 216—217 cm^{-1} for the bromide and iodide. For the nitrate, the peaks at 223 and 233 cm^{-1} are assigned to the Co–O (quinoline) and Co–O (amide) stretching vibrations.

Since the 2 : 1 complexes, $M(8\text{-}QCA)_2X_2$, do not give the peaks assignable to the metal-anion stretching vibrations above 200 cm^{-1}, the coordination of the anions on the metal ions can not be deduced. These assignments are summarized in Table 4.

In the assignments of the metal-ligand stretching vibrations in the $M(8\text{-}QCA)_2X_2$ complexes, the far-infrared data of the bivalent metal complexes of quinoline and oxine are used as references. Ohkaku and Nakamoto[18] reported that the octahedral bivalent metal chelates of oxine, $[M(oxine)_2(H_2O)_2]$, have their M-O and M-N stretching vibrations at the frequencies shown in Table 5. Frank and Rogers[19] studied the far-infrared spectra of the bivalent metal complexes of quinoline, $M(Q)_2Cl_2$(Q=quinoline), and assigned the M-N stretching vibrations as is shown in Table 5. In general, it is recognized that metal complexes with larger stability constants give the metal-ligand stretching vibrations at higher frequencies so long as the structures of the objective complexes are similar to one another. Though here no study has been made of the stability constants of 8-QCA with bivalent metal ions, it can be assumed that the stability constants of 8-QCA fall in between those of oxine and quinoline as far as the same metal ions are concerned. In other words, the

Table 5. Far infrared data reported for $M(oxine)_2(H_2O)_2$ and $M(Q)_2Cl_2$ (in cm^{-1})

Complexes	ν_{M-O}	ν_{M-N}
$Cu(oxine)_2(H_2O)_2$	310.5	289
$Ni(oxine)_2(H_2O)_2$	301.2	264
$Co(oxine)_2(H_2O)_2$	295	240
$Zn(oxine)_2(H_2O)_2$	264	207
$Cu(Q)_2Cl_2$		259
$Ni(Q)_2Cl_2$		223
$Co(Q)_2Cl_2$		226
$Zn(Q)_2Cl_2$		205

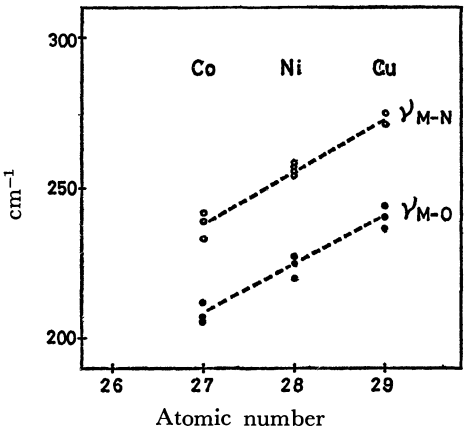

Fig. 5. A plot of M–N and M–O stretching frequencies *vs.* atomic number for $M(8\text{-QCA})_2X_2$.

copper 2 : 1 complexes should give the stretching vibration of the M–N (quinoline) in the frequency region of 259—289 cm^{-1}, and the nickel and the cobalt complexes, in the regions of 233—264 cm^{-1} and 226—240 cm^{-1} respectively. The M–O (amide) stretching frequencies are considered to be lower than the M–N (quinoline) stretching vibrations.

In order to ascertain the validity of the assignments, the stretching vibrations of the M–N (quinoline) and the M–O (amide) were plotted against the atomic number of the metal ions, as is shown in Fig. 5; linear relationships were found. The fact that the metal-ligand stretching vibrations number two throughout the metal complexes studied suggests a *trans*-planar coordination of the ligand molecules around the metal ions, since the octahedral structure with a *trans*-planar configuration of 8-QCA molecules on the metal ions belongs to the C_{2h} point group, which may be expected to produce two peaks due to the M–N (quinoline) and M–O (amide) stretching vibrations.

Conclusion

Through the analyses of the magnetic moments, the diffuse reflectance spectra, and the infrared and far-infrared spectra, the following conclusions have been deduced for the $M(8\text{-QCA})_2X_2$ complexes and $Cu(8\text{-QCA})Cl_2$:

1) The coordination sites seem to be the amide oxygen and the quinoline nitrogen.

2) For $Ni(8\text{-QCA})_2X_2$ and $Co(8\text{-QCA})_2X_2$, an octahedral structure with a *trans*-planar coordination of 8-QCA is suggested by the magnetic moments and the far-infrared spectra.

3) For $Cu(8\text{-QCA})_2X_2$, a distorted octahedral structure with a *trans*-planar coordination of 8-QCA is conceivable, judging from the magnetic moments and the far-infrared spectra. As for $Cu(8\text{-QCA})Cl_2$, no definite structure can be deduced from the present data.

The authors wish to thank Dr. N. Yamanaka of the Government Industrial Institute, Nagoya, for permitting them to use a Shimadzu MB-2 magnetic balance. Thanks are also due to Misses M. Ishiguro and S. Iwauchi of the Analytical Center of Nagoya City University for the elemental analyses.

Synthesis and Thermochromic Properties of New Five-coordinate Copper Chelates

Noriko IWASAKI, Kozo SONE, and Heijiro OJIMA*

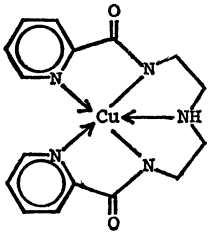
Department of Chemistry, Faculty of Science, Ochanomizu University, Otsuka, Bunkyo-ku, Tokyo 112

**Department of Chemistry, Aichi Kyoiku University, Kariya, Aichi 448*

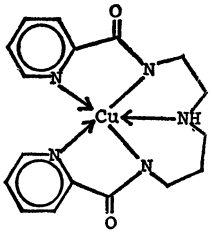
(Received February 4, 1975)

Two new five-coordinate copper(II) chelates [Cu(PCdien)] and [Cu(PCenpn)] were prepared, and the thermochromism of the former in methanolic solution was studied. When this violet-blue solution (ν_{max}: 16500 cm^{-1}) was heated nearly to the boiling point of methanol, the color of the solution became gradually yellowish (ν_{max}: 21000 cm^{-1}). The absorption spectra of these cold and hot solutions were compared with those of similar four-coordinate Cu(II) complexes in various solvents, and the yellow color was ascribed to a tetra-coordinated species of [Cu(PCdien)], which is formed by the partial rupture of the pentacoordinated structure caused by the intramolecular steric strains. No thermochromic property of the PCenpn chelate was observed.

Recently we prepared two new five-coodinate copper(II) chelates shown below, and found that one of them shows a peculiar thermochromism in its methanolic solution. The results of these studies will be described in this paper.



[Cu(PCdien)]=*N*-(picolinoyl)-*N'*-(picolinoylaminoethyl)-ethylenediaminato copper(II)



[Cu(PCenpn)]=*N*-(picolinoyl)-*N'*-(picolinoylaminoethyl)-propanediaminato copper(II)

Experimental

Synthesis of the Chelates. [Cu(PCdien)] can be prepared from diethylenetriamine and methyl picolinate; 13.7 g (0.1 mol) of the latter is added dropwise into 5.2 g (0.05 mol) of the former, and the mixture is heated at 140 °C for 1 hr and then at 160 °C for 2 hr. A concentrated aqueous solution containing 12.5 g (0.05 mol) of $CuSO_4 \cdot 5H_2O$ is added to it, and then one containing 4 g (0.1 mol) of NaOH. The deep green, tarry precipitate which separates out is washed with cold methanol, and the dark blue crude crystals which remain are recrystallized from hot methanol. The product obtained is the monohydrate of [Cu(PCdien)] (Found: Cu, 16.23; N, 17.59; H_2O, 4.20%. Calcd for $C_{16}H_{17}N_5O_2Cu \cdot H_2O$: Cu, 16.17; N, 17.82; H_2O, 4.58%.); the anhydrous chelate can be obtained by its dehydration in vacuum at 90 °C, (Found: Cu, 17.00%. Calcd for $C_{16}H_{17}N_5O_2$ Cu: Cu, 16.95%).

[Cu(PCenpn)] can be obtained in a similar way from 3-(aminoethylamino)-propanediamine and methyl picolinate. After heating the ligand mixture and mixing it with solutions of $CuSO_4 \cdot 5H_2O$ and NaOH, the mixture is evaporated under reduced pressure almost to dryness, and extracted with methanol. The extract is then evaporated to dryness again, and the residue is recrystallized from water (pH 9). The product has the composition of $[Cu(PCenpn)] \cdot 1.5H_2O$ (Found: Cu, 15.27; N, 16.93; H_2O, 6.70%. Calcd for $C_{17}H_{19}N_5O_2Cu \cdot 1.5H_2O$: Cu, 15.28; N, 16.84; H_2O, 6.50%.) and can be made anhydrous as in the case of [Cu(PCdien)] (Found: Cu, 16.53%. Calcd for $C_{17}H_{19}N_5O_2Cu$: Cu, 16.34%.).

Physical Measurements. The visible absorption spectra of the solutions were measured with a Shimadzu Multi-convertible Spectrophotometer Double-40, using 5 mm and 10 mm cells. Measurements with hot and cold solutions were carried out as promptly as possible after their preparation, without use of thermospacers; this is because the thermochromic changes are quite slow and no serious error was expected to result. All other measurements were carried out with conventional techniques.

Results and Discussion

Both of the chelates are violet-blue crystals, and dissolve in methanol forming violet-blue solutions with ν_{max} and ε_{max} values shown in Table 1. When these solutions are heated almost to boiling, the color of the solution of [Cu(PCenpn)] remains nearly unchanged, but that of [Cu(PCdien)] becomes gradually green, and then remarkably yellowish. This color change is fairly slow, and the solution must be refluxed

TABLE 1. CHARACTERISTIC DATA ON [Cu(PCdien)] AND [Cu(PCenpn)]

a) Methanolic solutions. b) 10^{-3} M solutions in methanol: these data show that both of the chelates are only partially ionized in solution. c) Anhydrous chelate. d) Hydrated chelate.

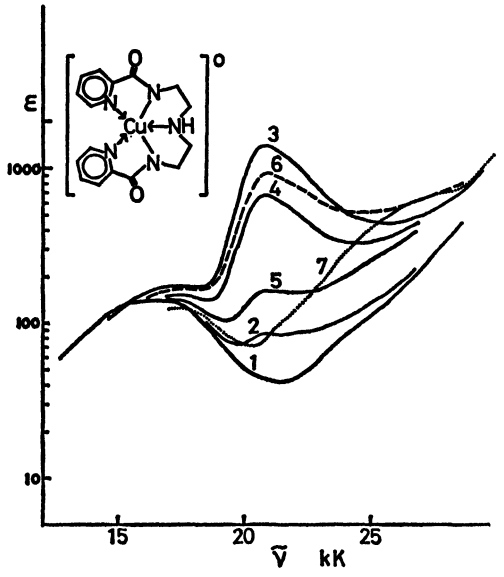

Fig. 1. Absorption spectra of [Cu(PCdien)] in methanol.

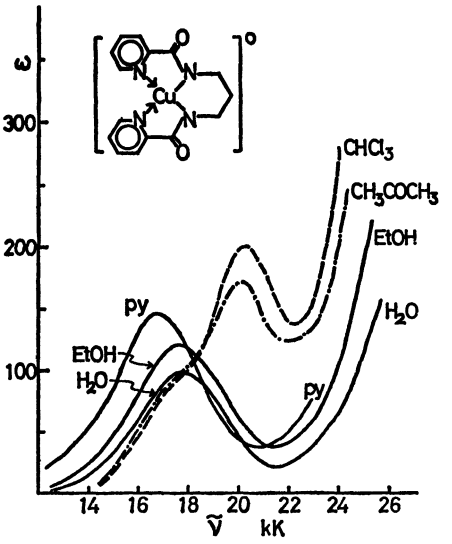

Fig. 2. Absorption spectra of I in various solvents.

for some minutes for its full development. The reverse change from yellow to violet-blue occurs on cooling, but this change is much slower, and the solution reverts to its original violet-blue state only after standing for several days in a freezer (*ca.* −15 °C).

The general outlook of the spectral changes observed in the course of this process is shown in Fig. 1. Curve 1 shows the spectrum of a fresh, cold solution (2.0×10^{-3} M) prepared by keeping the weighed sample together with methanol in a freezer overnight. When this solution is left standing at room temperature (26 °C) for some time (*ca.* 1/2 hr), a weak band at *ca.* 21000 cm^{-1} is observed (Curve 2).[1] This band becomes very much stronger by heating; Curve 3 is the spectrum of the same solution after refluxing at *ca.* 68 °C for 10 min, when the apparent color change appears to be nearly complete. Curve 4 is observed when the refluxed solution is cooled and kept in a freezer for a day; Curve 5, after four more days, and Curve 6 when the solution is then refluxed again.

The spectral changes can thus be repeated; however, as can be seen from these Curves, the amount of the observed spectral change tends to decrease in the course of repetition. This seems to be due to an irreversible decomposition of the chelate, which, also slowly, takes place in solution; in fact, when we let the solution stand for a long time (5 days) at room temperature, the solution becomes remarkably greenish and only poorly thermochromic. Curve 7 shows the absorption curve of such an "aged" solution.

Although the exact mechanism of this thermochromism is still unknown, a clue for its understanding can be found in the earlier work of Ojima.[2] Figure 2 shows his data on the absorption curves of the chelate I in various solvents.

It can be seen that the ν_{max} and ε_{max} values are largest in $CHCl_3$ (20200 cm^{-1} and 200, respectively), and the ν_{max} decreases in the order of $CHCl_3\rightarrow CH_3COCH_3\rightarrow H_2O\rightarrow EtOH\rightarrow py$, while the ε_{max} seems to pass through a minimum and then increases again. Table 2 summarizes these data, and similar data observed with the chelates II and III.[3]

In $CHCl_3$, which is a poorly coordinating solvent, we can expect the chelate I to assume a four-coodinate structure. This structure will be approximately planar, but the formation of a perfectly planar structure will be hindered by the strains in the chelate rings and by the repulsion between the hydrogen atoms on the pyridine rings. Going to a more strongly coordinating solvent, however, the chelate will become gradually tetragonal, and when the solvent becomes very basic (*e.g.* pyridine), the chelate may become eventually pentacoordinated. The spectral changes in Fig. 2 and Table 2 can probably be taken as the reflection of these structral changes.[4]

We now see that the absorption curves of [Cu(PCdien)] in cold and hot methanol are, respectively, very similar to those of I in pyridine and chloroform. Model studies show that the pentacoordinated structure of [Cu(PCdien)] is, although sterically possible (trigonal bipyramid seems to be more favorable than square pyramid), quite highly strained; therefore, though the chelate may retain its pentacoordinated structure in a very cold solution, a rupture of the chelate ring (probably at the Cu←NH bond) will take place on heating, leading to a tetracoordinated structure. The spectral analogy mentioned above can thus be understood, at least in a qualitative way. The tetracoordinated structure is, however, again expected from model studies to be considerably strained; indeed, the very high ε_{max} value of the high-temperature species observed in Fig. 1 (apparent value: 1400 at 20800 cm^{-1}) may be related to this high strain and poor

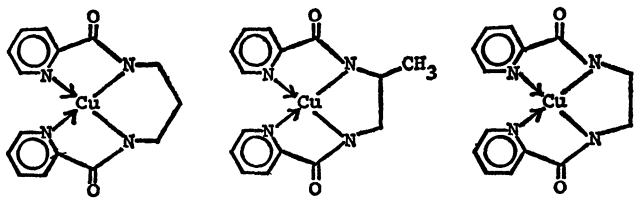

TABLE 2. ν_{max} AND ε_{max} VALUES OF THE CHELATES I—III IN VARIOUS SOLVENTS

Chelate	ν_{max} (10^3 cm^{-1}: ε_{max} in parentheses)				
	$CHCl_3$	CH_3COCH_3	H_2O	EtOH	py
I	20.2(198)	20.0(171)	17.7(97)	17.3(117)	16.3(145)
II	20.4(397)	—	18.5(225)	18.5(252)	17.4(252)
III	17.1(216)	—	18.7(212)	18.3(228)	17.5(256)

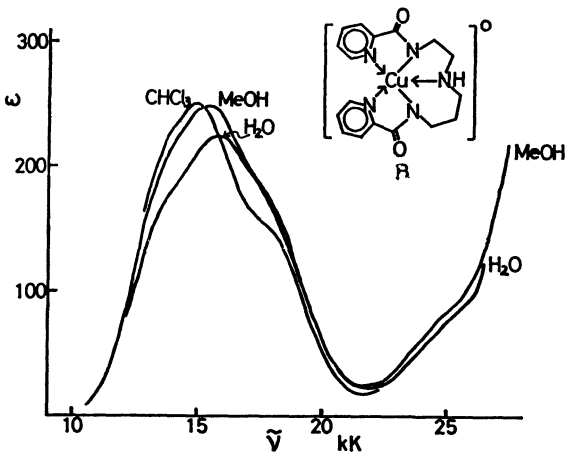

Fig. 3. Absorption spectra of [Cu(PCenpn)] in various solvents.

symmetry of the chelate. Moreover, the change between these two structures will need a large amount of conformational change, so that it (and the reverse reaction, too) will need a large activation energy, and a part of the chelate may be lost in the course of these changes by some kind of decomposition.

It is also of interest to note that the chelate [Cu(PCenpn)], which is not thermochromic in methanol (and H_2O and $CHCl_3$, in which it is also soluble), shows absorption curves which are all very similar (Fig. 3), and characteristic of the CuN_5-type pentacoordinated chelates already studied by Ojima and Nonoyama.[5] The slight structural change from [Cu(PCdien)] to [Cu(PCenpn)], *i.e.* the introduction of one 6-ring instead of a 5-ring, seems to greatly lessen the intramolecular strain, and avoid the rupture of the chelate ring upon heating.

Our thanks are due to Miss Junko Ida for her help in the experiments.

References

1) When the solution is kept longer at room temperature, however, this band does not gain in intensity so much, and the solution begins gradually to "age", *i.e.*, to show a curve similar to Curve 7 and to become poorly thermochromic.

2) H. Ojima, *Nippon Kagaku Zasshi*, **88**, 333 (1967).

3) A serious exception among these data is that of the chelate III in $CHCl_3$; here ν_{max} and ε_{max} are much lower than expected from other data. This, however, may be due to the effect of intermolecular association leading to an apparently higher coordimation number of copper(II), which will be favored in such a poorly coordinating solvent.

4) It may be pointed out that the spectral change from H_2O or EtOH to py resembles, to some extent, the change observed when $[Cu(NH_3)_4(OH_2)_2]^{2+}$ is transformed in aqueous solution into $[Cu(NH_3)_5(OH_2)]^{2+}$, which probably holds its water only very weakly; *cf.*, *e.g.*, B. J. Hathaway and A. A. G. Tomlinson, *Coord. Chem. Rev.*, **5**, 1 (1970).

Use of a Glass Electrode in the Potentiometric Study of Acid-Base Equilibria of Zinc and Cadmium Acetates in Acetic Acid

Kiyoshi SAWADA, Mitsuji NAKANO, Hidenari MORI, and Motoharu TANAKA

Laboratory of Analytical Chemistry, Faculty of Science, Nagoya University, Nagoya 464

(Received April 10, 1975)

Potentiometric study of acid-base equilibria of zinc and cadmium acetates in acetic acid was undertaken with a glass electrode filled with a LiCl-$HClO_4$ acetic acid solution. Potentiometric titration of 0.1 m $LiClO_4$ acetic acid solution with perchloric acid and lithium acetate reveals that the glass electrode gives rise to the Nernstian response. The equilibrium constant of the reaction, $HClO_4+LiOAc \overset{K_f}{\rightleftharpoons} LiClO_4+HOAc$ is found as $\log K_f=7.86$. The titration of zinc and cadmium acetate with perchloric acid and lithium acetate points to the following equilibria: $M(ClO_4)_2+LiOAc \overset{\beta_1}{\rightleftharpoons} M(OAc)(ClO_4)+LiClO_4$, $M(ClO_4)_2+2LiOAc \overset{\beta_2}{\rightleftharpoons} M(OAc)_2+2LiClO_4$, $M(ClO_4)_2+3LiOAc \overset{\beta_3}{\rightleftharpoons} LiM(OAc)_3+2LiClO_4$. Logarithmic overall formation constants of the acetato complexes, β_1, β_2 and β_3 were determined as 4.04, 7.00 and 9.2 respectively for zinc, and 3.43, 5.46 and 8.0 respectively for cadmium. In addition zinc forms tetraacetate complex with the overall formation constant of $\log \beta_4=12.4$.

Acetic acid has been used as a convenient solvent for the titration of weak bases.[1,2] The huge number of acid-base equilibria in the solvent have been investigated for the analytical purpose, and equilibrium constants of many systems have been obtained by potentiometry, colorimetry, conductometry and other methods.

Various hydrogen ion indicator electrodes have been utilized in potentiometric studies. The hydrogen electrode, being a fundamental electrode, has difficulty in handling and fails sometimes to give a satisfactory reproducibility.[3-6] Glass and chloranil electrodes have been used as indicator electrodes for the acid-base titration,[1] and dissociation constants of acids and bases have been estimated from the relative electromotive forces of the electrodes.[7-11]

In early works, because of a poor precision of instrument, a considerable error was inevitable in potentiometric measurements in acetic acid solution having high electrical resistance.[12] Mukherjee[5] and Bruckenstein and Kolthoff[8] have claimed the reproducibility to less than one millivolt. However the scatter of emf by the variation of electrolyte concentration and the deviation from reversible response point to the reproducibility of the electrodes to about five millivolts. According to studies on the reversibility of the electrode,[4,6,11,13-15] the reproducibility of a potentiometry in acetic acid does not seem to be as good as claimed.

Thus, as stated by Popov,[2] some of the problems can not be resolved without additional careful works on the electrode systems in acetic acid. The poor precision of some earlier works may be due to the absence of medium salt, which lowers the electrical resistance of the solution and keeps the activity coefficient constant, and the presence of impurities such as water.

In the present paper, the response of a glass–calomel electrode cell filled with acetic acid solution is investigated with care. The potentiometric study with this electrode system is undertaken on the acid-base equilibria of zinc and cadmium acetate, *i.e.*, the formation of acetato complexes, for which the formation of higher acetato complex has been pointed out as a result of solubility measurements.[16]

Experimental

Reagents. Acetic acid, perchloric acid and lithium acetate,[17] lithium perchlorate[18] and zinc acetate[19] were prepared by the methods described previously.

Cadmium Acetate: G. R. grade $Cd(OAc)_2\cdot 2H_2O$ was recrystallized twice from acetic acid containing acetic anhydride.

Measurements. *Glass Electrode*: The inner solution of a commercially available glass electrode was replaced by a 0.1 mol/kg LiCl-0.1 mol/kg $HClO_4$ acetic acid solution. An Ag-AgCl electrode was utilized as an inner reference electrode. After standing in 0.1 mol/kg $LiClO_4$ acetic acid solution for 2 days at 100 °C, the glass electode was stored in the same solution. The glass electrode prepared in this manner exhibits smaller drift of potential than the commercially available glass electrode containing aqueous inner solution.

Calomel Electrode: The method of preparation of the calomel electrode composed of 0.27 mol/kg LiCl acetic acid solution has been described elsewhere.[18] The reproducibility of the electrode was found to be less than 0.3 mV. The electrode was connected with the sample solution through a salt bridge. Both salt bridge and sample solution contain 0.1 mol/kg $LiClO_4$ as a medium salt.

Potentiometry. The chemical cell used is written as follows:

Ag|AgCl|0.1 mol/kg LiCl, 0.1 mol/kg $HClO_4$ AcOH soln.|glass electrode glass|sample soln. (0.1 mol/kg $LiClO_4$HOAc soln.)‖0.1 mol/kg salt $LiClO_4$ HOAc soln.‖0.27 mol/kg LiCl HOAc soln.|Hg_2Cl_2|Hg bridge calomel electrode

The potential was measured, in a water-jacketted vessel thermostated at 25.0±0.1 °C, with an Orion research digital pH/mV meter model 801.

The glass electrode shows a variation of about one millivolt of electrode potential in a few days, so the standard potential of the cell should be measured every day.

Results and Discussion

Response of Glass Electrode in Acetic Acid. The following two equilibria are relevant to lithium perchlorate in acetic acid:

$$HClO_4 + LiOAc \overset{K_f}{\rightleftharpoons} LiClO_4 + HOAc \quad (1)$$

and

$$Li^+ + ClO_4^- \overset{K_{LiClO_4}}{\rightleftharpoons} LiClO_4 \quad (2)$$

Perchloric acid and lithium acetate are weak electrolytes in this medium[1] and we have

$$H^+ + ClO_4^- \overset{K_{HClO_4}}{\rightleftharpoons} HClO_4 \quad (3)$$

$$Li^+ + OAc^- \overset{K_{LiOAc}}{\rightleftharpoons} LiOAc. \quad (4)$$

When perchloric acid is added to lithium perchlorate solution, we have the following relationship:

$$[H^+] + [HClO_4] - C_{HClO_4} = [OAc^-] + [LiOAc] \quad (5)$$

where C_{HClO_4} denotes the total concentration of the added perchloric acid. As the ionic dissociation in acetic acid is very weak,[1] Eq. (5) is approximated to Eq. (6).

$$[HClO_4] - C_{HClO_4} = [LiOAc] \quad (6)$$

Substitution of the formation constant of Eq. (1), K_f, into Eq. (6) leads to Eq. (7).

$$[HClO_4]^2 - C_{HClO_4}[HClO_4] - [LiClO_4]K_f^{-1} = 0. \quad (7)$$

Solving the quadratic equation, we obtain

$$[HClO_4] = \frac{1}{2}\{C_{HClO_4} + (C_{HClO_4}^2 + 4[LiClO_4]K_f^{-1})^{1/2}\}. \quad (8)$$

From the constant of the equilibrium (3), K_{HClO_4}, the free hydrogen ion concentration is given by:

$$[H^+] = [HClO_4]K_{HClO_4}^{-1}[ClO_4^-]^{-1}. \quad (9)$$

And from the condition of electroneutrality, we have

$$[H^+] + [Li^+] = [OAc^-] + [ClO_4^-]. \quad (10)$$

When the concentration of perchloric acid added, C_{HClO_4}, is much smaller than that of lithium perchlorate,

$$[OAc^-] \text{ and } [H^+] \ll [Li^+] \text{ and } [ClO_4^-]. \quad (11)$$

Consequently Eq. (10) is reduced to

$$[Li^+] = [ClO_4^-]. \quad (12)$$

Then the equilibrium constant of Eq. (2) is written as follows:

$$K_{LiClO_4} = [LiClO_4][Li^+]^{-1}[ClO_4^-]^{-1} = [LiClO_4][ClO_4^-]^{-2}. \quad (13)$$

The free lithium perchlorate concentration, $[LiClO_4]$, being approximated as the total concentration, C_{LiClO_4}, Eq. (13) is rewritten as follows:

$$[ClO_4^-]^2 = C_{LiClO_4}K_{LiClO_4}^{-1}. \quad (14)$$

Substitution of Eqs. (8) and (14) into Eq. (9) leads to

$$[H^+] = \frac{1}{2}\{C_{HClO_4} + (C_{HClO_4}^2 + 4C_{LiClO_4}K_f^{-1})^{1/2}\} \times K_{LiClO_4}^{1/2}/(C_{LiClO_4}^{1/2}K_{HClO_4}) \quad (15)$$

As the lithium perchlorate concentration may be regarded as constant,

$$[H^+] = \frac{1}{2}\{C_{HClO_4} + (C_{HClO_4}^2 + 4C_{LiClO_4}K_f^{-1})^{1/2}\}K \quad (16)$$

where $K = K_{LiClO_4}^{1/2}/(C_{LiClO_4}^{1/2}K_{HClO_4}) = \text{constant}$.

Thus, as the activity coefficient of hydrogen ion is kept constant, the electromotive force of the cell at 25.0 °C is given by:

$$E = E_0 + \frac{RT}{nF}\ln[H^+] = E_0' + 59.1 \log \frac{1}{2}\{C_{HClO_4} + (C_{HClO_4}^2 + 4C_{LiClO_4}K_f^{-1})^{1/2}\}. \quad (17)$$
$$(E_0' = E_0 + 59.1 \log K)$$

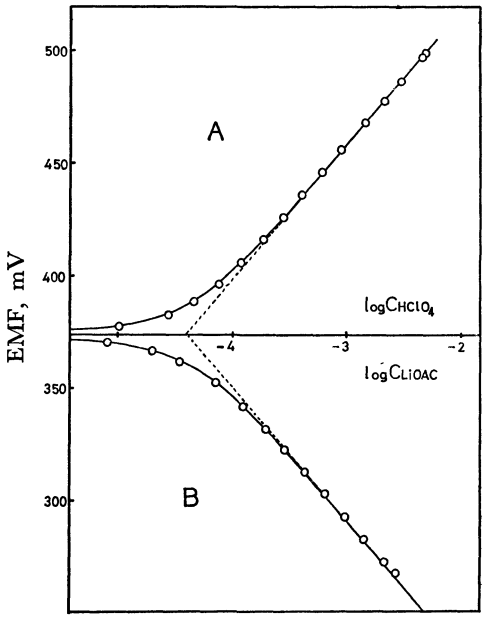

Fig. 1. Electromotive force of 0.1 mol/kg $LiClO_4$ acetic acid solution as a function of logarithmic concentration of perchloric acid (A) and lithium acetate (B). Solid lines are the normalized curve, $X = \log x$, $Y = 59.1 \log (x + \sqrt{x^2+4})$.

In Fig. 1 (A), electromotive force of 0.1 molal lithium perchlorate acetic acid solution is plotted as a function of logarithmic concentration of added perchloric acid. In order to compare the data with normalized curve, $X = \log x$, $Y = 59.1 \log (x + \sqrt{x^2+4})$, Eq. (17) is rewritten as follows:

$$E = E_0' + 59.1 \log \frac{1}{2} C_{LiClO_4}^{1/2} K_f^{-1/2} \times [C_{HClO_4} C_{LiClO_4}^{-1/2} K_f^{1/2} + \{(C_{HClO_4} C_{LiClO_4}^{-1/2} K_f^{1/2})^2 + 4\}^{1/2}] = E' + 59.1 \log [C_{HClO_4} C_{LiClO_4}^{-1/2} K_f^{1/2} + \{(C_{HClO_4} C_{LiClO_4}^{-1/2} K_f^{1/2})^2 + 4\}^{1/2}]. \quad (18)$$
$$\left(E' = E_0' + 59.1 \log \frac{1}{2} C_{LiClO_4}^{1/2} K_f^{-1/2}\right)$$

By the curve fitting, $\log C_{LiClO_4}^{-1/2} K_f^{1/2} = 4.44$ was obtained from the reading of abscissa in Fig. 1 (A). As $C_{LiClO_4} = 0.1$ mol/kg the formation constant of lithium perchlorate was found as $\log K_f = 7.88 \pm 0.05$; and by the extrapolation to $C_{HClO_4} = 1$ the apparent standard potential, E_0' was estimated as $E_0' = 636$ mV.

The titration of 0.1 mol/kg lithium perchlorate solution with lithium acetate is shown in Fig. 1 (B). In the same way as in the preceding case, the free acetate ion concentration is given as follows:

$$[OAc^-] = \frac{1}{2}\{C_{LiOAc} + (C_{LiOAc}^2 + 4C_{LiClO_4}K_f^{-1})^{1/2}\} \times K_{LiClO_4}^{1/2}/(C_{LiClO_4}^{1/2}K_{LiOAc}) \quad (19)$$

where C_{LiOAc} denotes the total concentration of added lithium acetate. By using Eq. (19) and autoprotolysis constant of acetic acid, $K_{HOAc}=[H^+][OAc^-]$, the electromotive force of lithium perchlorate solution ($C_{LiClO_4}=0.1$ mol/kg and $C_{LiOAc} \ll C_{LiClO_4}$) is written as

$$E = E_0 + \frac{RT}{nF}\ln\frac{K_{HOAc}}{[OAc^-]} = E_0 + 59.1 \log K' - 59.1 \log \frac{1}{2}\{C_{LiOAc} + (C_{LiOAc}^2 + 4C_{LiClO_4}K_f^{-1})^{1/2}\}. \quad (20)$$

($K'=K_{LiClO_4}^{1/2}/(C_{LiClO_4}^{1/2}K_{LiOAc})=$constant)

In the same manner as in the titration with perchloric acid, comparison of the experimental results with the normalized curve, Eq. (19), gives $\log C_{LiClO_4}^{-1/2}K_f^{1/2}=4.42$, *i.e.*, $K_f=7.84$ and $E_0+59.1 \log K'=113$ mV.

The experimental values are in excellent agreement with normalized curve (solid lines in Fig. 1), and the formation constant of lithium perchlorate, K_f, obtained by the titration with perchloric acid agrees well with the value obtained by the titration with lithium acetate. Thus the glass electrode described in the experimental section gives rise to a reversible electromotive force.

In addition, from the difference of the apparent standard potentials, $E_0'_{(HClO_4)}$ and $E_0'_{(LiOAc)}$, K_f is estimated as $\log K_f=7.86$.

As the concentrations of perchloric acid and lithium acetate are much smaller than that of lithium perchlorate, the fraction of the two aggregated species with lithium perchlorate, $HClO_4 \cdot LiClO_4$ and $LiOAc \cdot LiClO_4$, if any, would be constant.

$$HClO_4 + LiClO_4 \rightleftharpoons HClO_4 \cdot LiClO_4 \quad (21)$$

$$LiOAc + LiClO_4 \rightleftharpoons LiOAc \cdot LiClO_4 \quad (22)$$

In Fig. 1 (B) the deviation of data from the normalized curve at higher lithium acetate concentration should indicate the dimerization of lithium acetate, *i.e.*,

$$2LiOAc \rightleftharpoons (LiOAc)_2 \quad (23)$$

Formation of Zinc-Acetato Complex. Reaction of perchloric acid with zinc acetate in solution containing 0.1 mol/kg lithium perchlorate is written as follows:

$$pZn(OAc)_2 + qHClO_4 \rightleftharpoons Zn_p(OAc)_{2p-q}(ClO_4)_q + qHOAc \quad (24)$$

$$pZn(OAc)_2 + qLiClO_4 \rightleftharpoons Zn_p(OAc)_{2p-q}(ClO_4)_q + qLiOAc. \quad (25)$$

It has previously been confirmed that zinc acetate exists as a monomer in acetic acid [19]. When $q>2p$, the species formed should be written as $H_{q-2p}Zn_p(ClO_4)_q$ or $Li_{q-2p}Zn_p(ClO_4)_q$, which can be negligible as will hereinafter be mentioned.

The total concentration of perchlorate, C_{ClO_4}, is given by the following:

$$C_{ClO_4} = C_{LiClO_4} + C_{HClO_4} = [LiClO_4] + [HClO_4] + \sum q[Zn_p(OAc)_{2p-q}(ClO_4)_q], \quad (26)$$

$$\sum q[Zn_p(OAc)_{2p-q}(ClO_4)_q] = C_{LiClO_4} + C_{HClO_4} - [LiClO_4] - [HClO_4]. \quad (27)$$

The total lithium perchlorate concentration, C_{LiClO_4}, is given by Eq. (28).

$$C_{LiClO_4} = [LiClO_4] + [LiOAc]. \quad (28)$$

Substitution of Eq. (28) to Eq. (27) leads to

$$\sum q[Zn_p(OAc)_{2p-q}(ClO_4)_q] = C_{HClO_4} - [HClO_4] + [LiOAc] \quad (29)$$

Thus the formation function of perchlorate of zinc, $\bar{n}^*$, is written as follows:

$$\bar{n}^* = (\sum q[Zn_p(OAc)_{2p-q}(ClO_4)_q])C_{Zn}^{-1} = (C_{HClO_4} - [HClO_4] + [LiOAc])C_{Zn}^{-1} \quad (30)$$

As the free concentration of lithium perchlorate, $[LiClO_4]$, can be approximated by the total concentration, C_{LiClO_4}, Eq. (30) becomes

$$\bar{n}^* = (C_{HClO_4} - [HClO_4] + C_{LiClO_4}[HClO_4]^{-1}K_f^{-1})C_{Zn}^{-1} \quad (31)$$

In Fig. 2 the results of potentiometric titration of various concentration of zinc acetate solutions containing 0.1 mol/kg lithium perchlorate are plotted as a function of mole ratio $a \equiv C_{HClO_4}/C_{Zn}$. By using the following equation:

$$E = E_0' + 59.1 \log [HClO_4] \quad (E_0'=636 \text{ mV}), \quad (32)$$

free perchloric acid concentration, $[HClO_4]$, can be calculated from the electromotive force E.

The formation function, $\bar{n}^*$, calculated by Eq. (31) is plotted as a function of $\log [HClO_4]$ in Fig. 3 (open symbols). The plot lies on the same curve irrespective of the zinc acetate concentration. This implies that there is no difference in the degree of polymerization between zinc acetate and the species formed, *i.e.*, all species involved in this reaction are monomer (*i.e.*, $p=1$). Over a range of $\bar{n}^*$ not exceeding 2, the reaction of zinc acetate with perchloric acid is

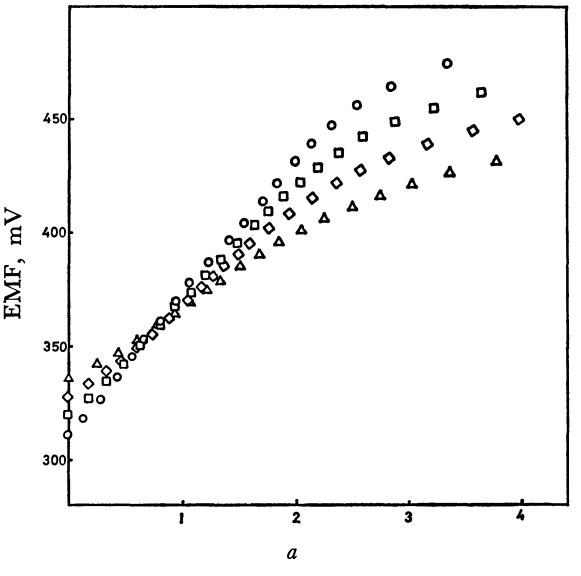

Fig. 2. Electromotive force of various concentrations of zinc acetate as a function of mol ratio $a \equiv C_{HClO_4}/C_{Zn}$. C_{Zn}: ○, 1.769; □, 0.885; ◇, 0.442; △, 0.221×10^{-3} mol/kg.

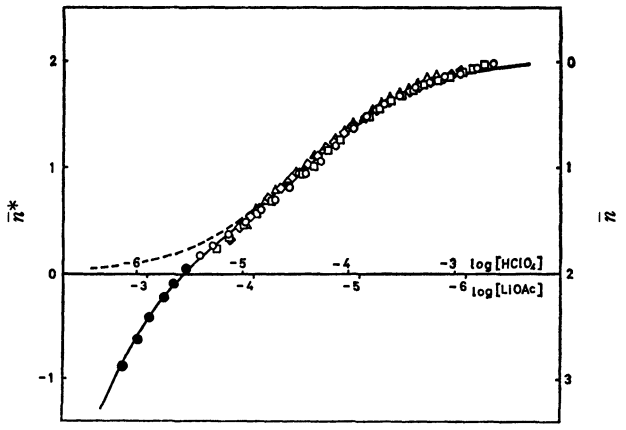

Fig. 3. Plot of formation function of zinc perchlorate, $\bar{n}^*$, and of zinc acetate complex, $\bar{n}$, ($\bar{n}=2-\bar{n}^*$), as a function of log [$HClO_4$] and log [LiOAc] ($=\log K_f^{-1}C_{LiClO_4}-\log$ [$HClO_4$]). Open symbols are the results of titration with perchloric acid. C_{Zn}: ○, 1.769; □, 0.885; ◇, 0.442; △, 0.221×10^{-3} mol/kg. Filled circle is the results with lithium acetate ($C_{Zn}=1.769\times10^{-3}$ mol/kg). Dotted line is the normalized curve, $X=\log x$, $Y=(ax+2x^2)/(1+ax+x^2)$. Solid line is the normalized curve, $X=\log x$, $Y=(ax+2x^2+3bx^3+4cx^4)/(1+ax+x^2+bx^3+cx_4)$.

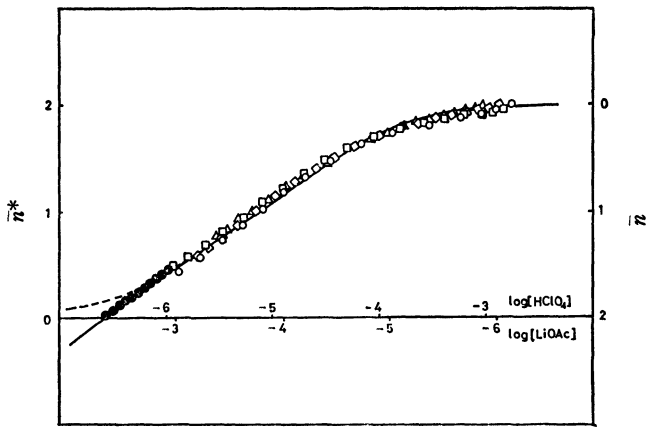

Fig. 4. Plot of formation function of cadmium perchlorate, $\bar{n}^*$, and of cadmium acetato complex, $\bar{n}(\bar{n}=2-\bar{n}^*)$, as a function of log [$HClO_4$] and log [LiOAc] ($=\log K_f^{-1}C_{LiClO_4}-\log$ [$HClO_4$]). Open symbols are the results of titration with perchloric acid. C_{Cd}: ○, 4.000; □, 2.000; ◇, 1.000; △, 0.500×10^{-3} mol/kg. Filled circle is the results with lithium acetate ($C_{Cd}=2.000\times10^{-3}$ mol/kg). Dotted line is the normalized curve, $X=\log x$, $Y=(ax+2x^2)/(1+ax+x^2)$. Solid line is the normalized curve, $X=\log x$, $Y=(ax+2x^2+3bx^3)/(1+ax+x^2+bx^3)$.

written as follows:

$$Zn(OAc)_2 + HClO_4 \overset{\beta_1}{\rightleftharpoons} Zn(OAc)(ClO_4) + HOAc \quad (33)$$

$$Zn(OAc)_2 + 2HClO_4 \overset{\beta_2}{\rightleftharpoons} Zn(ClO_4)_2 + 2HOAc. \quad (34)$$

By the use of equilibrium constants of Eqs. (33) and (34),

$$\beta_1^* = [Zn(OAc)(ClO_4)][Zn(OAc)_2]^{-1}[HClO_4]^{-1} \quad (35)$$

$$\beta_2^* = [Zn(ClO_4)_2][Zn(OAc)_2]^{-1}[HClO_4]^{-2}, \quad (36)$$

we obtain

$$\bar{n}^* = ([Zn(OAc)(ClO_4)] + 2[Zn(ClO_4)_2])C_{Zn}^{-1} = (\beta_1^*[HClO_4] + 2\beta_2^*[HClO_4]^2) \times (1+\beta_1^*[HClO_4] + \beta_2^*[HClO_4]^2)^{-1}. \quad (37)$$

Fitting the experimental results with the normalized curve, $X=\log x$, $Y=(ax+2x^2)/(1+ax+x^2)$, we obtained $\log\beta_1^*=4.92$ and $\log\beta_2^*=8.76$ (Fig. 3, dotted line).

Now, zinc acetate solution containing 0.1 mol/kg $LiClO_4$ was titrated with lithium acetate. The formation function calculated by Eq. (38) is plotted in Fig. 3 (filled circles).

$$\bar{n}^* = (-C_{LiOAc}+[HClO_4]-[LiOAc])C_{Zn}^{-1} \quad (38)$$

The plot deviates from the dotted line and goes down to under zero, the fact pointing to the formation of acetato complexes higher than diacetato species, *i.e.*, formation of $Li_{n-2}Zn(OAc)_n$ ($n>2$, $n=2-q$).

The reaction of zinc acetate with perchloric acid can be rewritten by the reaction of zinc perchlorate with lithium acetate as follows:

$$Zn(ClO_4)_2 + LiOAc \overset{\beta_1}{\rightleftharpoons} Zn(OAc)(ClO_4) + LiClO_4 \quad (39)$$

$$Zn(ClO_4)_2 + 2LiOAc \overset{\beta_2}{\rightleftharpoons} Zn(OAc)_2 + 2LiClO_4 \quad (40)$$

These equilibrium constants, β_1 and β_2, are related with β_1^* and β_2^* as follows:

$$\beta_1 = [Zn(OAc)(ClO_4)][LiClO_4][Zn(ClO_4)_2]^{-1}[LiOAc]^{-1} = K_f\beta_1^*\beta_2^* \quad (41)$$

$$\beta_2 = [Zn(OAc)_2][LiClO_4]^2[Zn(ClO_4)_2]^{-1}[LiOAc]^{-2} = K_f^2\beta_2^* \quad (42)$$

The free lithium acetate concentration, [LiOAc], and formation function of acetato complex, $\bar{n}$, are written as follows:

$$[LiOAc] = C_{LiClO_4}K_f^{-1}[HClO_4]^{-1} \quad (43)$$

$$\bar{n} = 2 - \bar{n}^*. \quad (44)$$

In Fig. 3 $\bar{n}$ going up to 3 at higher lithium acetate concentration, the formation of triacetato and tetraacetato complexes is anticipated.

$$Zn(ClO_4)_2 + 3LiOAc \overset{\beta_3}{\rightleftharpoons} LiZn(OAc)_3 + 2LiClO_4 \quad (45)$$

$$Zn(ClO_4)_2 + 4LiOAc \overset{\beta_4}{\rightleftharpoons} Li_2Zn(OAc)_4 + 2LiClO_4. \quad (46)$$

Thus the formation function of acetato complex is written as follows:

$$\bar{n} = ([Zn(OAc)(ClO_4)] + 2[Zn(OAc)_2] + 3[LiZn(OAc)_3] + 4[Li_2Zn(OAc)_4])C_{Zn}^{-1} = (\beta_1'[LiOAc] + 2\beta_2'[LiOAc]^2 + 3\beta_3'[LiOAc]^3 + 4\beta_4'[LiOAc]^4)(1+\beta_1'[LiOAc] + \beta_2'[LiOAc]^2 + \beta_3'[LiOAc]^3 + \beta_4'[LiOAc]^4)^{-1} \quad (47)$$

where conditional overall formation constants are defined as $\beta_1'=\beta_1[LiClO_4]^{-1}$, $\beta_2'=\beta_2[LiClO_4]^{-2}$, $\beta_3'=\beta_3[LiClO_4]^{-2}$ and $\beta_4'=\beta_4[LiClO_4]^{-2}$.

By comparison of the plot of $\bar{n}$ *vs.* log [LiOAc] with the normalized curve, $X=\log x$, $Y=(ax+2x^2+3bx^3+4cx^4)(1+ax+x^2+bx^3+cx^4)^{-1}$, β_3' and β_4' are determined from b ($=\beta_3'/\beta_2'^{3/2}$) and c ($=\beta_4'/\beta_2'^2$), where β_1' and β'_2 have been obtained previously. Thus from the

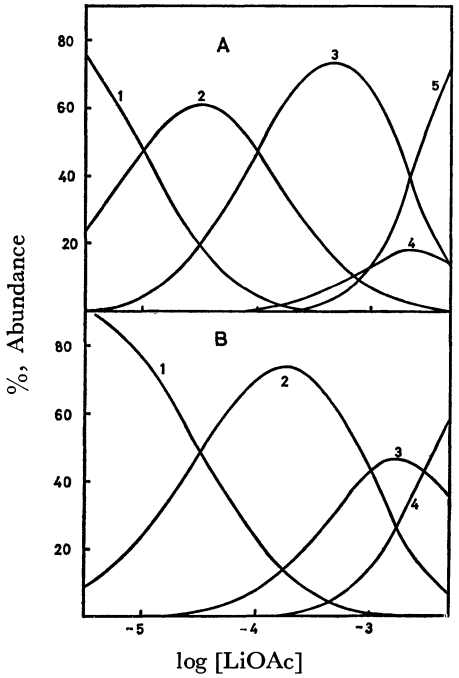

Fig. 5. Distribution diagram of acetato complexes of zinc (A) and cadmium (B) in 0.1 mol/kg $LiClO_4$ acetic acid solution.
1, $M(ClO_4)_2$; 2, $M(OAc)(ClO_4)$; 3, $M(OAc)_2$; 4, $LiM(OAc)_3$; 5, $Li_2M(OAc)_4$.

best fit curve (Fig. 3, solid line), the formation constants of acetato complexes are found as $\log \beta_1 = 4.04 \pm 0.1$, $\log \beta_2 = 7.00 \pm 0.1$, $\log \beta_3 = 9.2 \pm 0.3$ and $\log \beta_4 = 12.4 \pm 0.5$.

Formation of Cadmium-Acetato Complex. Potentiometric titration of cadmium acetate solution containing 0.1 mol/kg $LiClO_4$ with perchloric acid and lithium acetate has been carried out in the same manner as in the titration of zinc acetate. The results are shown in Fig. 4. In the case of cadmium complexes higher than triacetato complex are not observed over the studied range of lithium acetate concentration. The following equilibria are found to be relevant to the cadmium acetate:

$$Cd(ClO_4)_2 + LiOAc \overset{\beta_1}{\rightleftharpoons} Cd(OAc)(ClO_4) + LiClO_4 \quad (48)$$

$$Cd(ClO_4)_2 + 2LiOAc \overset{\beta_2}{\rightleftharpoons} Cd(OAc)_2 + 2LiClO_4 \quad (49)$$

$$Cd(ClO_4)_2 + 3LiOAc \overset{\beta_3}{\rightleftharpoons} LiCd(OAc)_3 + 2LiClO_2 \quad (50)$$

with overall formation constants of $\log \beta_1 = 3.43 \pm 0.1$, $\log \beta_2 = 5.46 \pm 0.1$ and $\log \beta_3 = 8.0 \pm 0.3$.

Fig. 5 depicts the distribution diagrams for acetato complexes of zinc (A) and cadmium (B) in 0.1 mol/kg $LiClO_4$ acetic acid solution calculated from the formation constants obtained in the present paper. Touller and Trémillon have investigated the formation of the acetato complexes of zinc, cadmium and other metals by the use of amalgam electrodes.[20] The formation constants of cadmium–acetato complexes reported by them are in fair accord with ours. The agreement of their constants for zinc with ours is poor presumably because they neglected the higher acetato complexes.

The Cycloaddition Reaction of Isonitrile to Ketenimine Formed by the Reaction of Isonitrile with Carbene*

Naruyoshi OBATA, Haruo MIZUNO, Takeo KOITABASHI, and Takeo TAKIZAWA
Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113
(Received March 10, 1975)

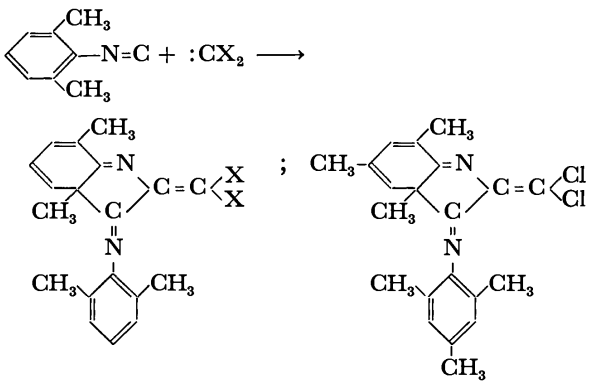
The reaction of several 2-, 4-, and/or 6-methyl-substituted phenylisonitrile with dihalocarbene and diphenylcarbene has been studied. The reaction of methyl-substituted phenylisonitrile with dihalocarbene gave indolenine or indoloquinoline derivatives *via* ketenimine intermediate which might be produced by α-addition of carbene to isonitrile. In contrast, the reaction of 2,6-dimethylphenylisonitrile with diphenylcarbene presumably formed by photolysis of diphenyldiazomethane gave *N*-(2,6-dimethylphenyl)diphenylketenimine, and further caused a cycloaddition reaction with isonitrile to yield indonimine derivatives. The structure of these products are discussed on the basis of the spectral data and chemical reactions. The mechanistic pathway of these reactions and the effect of methyl substituent in the cyclization stage are also discussed.

The reactivity of both carbene and isonitrile has been well recognized as divalent carbon.[1,2] It is expected that the reaction of electrophilic carbene with nucleophilic isonitrile gives the ketenimine derivatives in analogy with the superficial dimerization of carbene.[1,3] Halleux[4] discovered that the reaction of cyclohexylisonitrile with dichlorocarbene generated by $CHCl_3$-*t*-BuOK method[5] led to *N*-cyclohexyldichloroacetamidate. He showed that ketenimine was an intermediate in this reaction. The reactions of cyclohexyl- or *t*-butylisonitrile with diphenylcarbene to form ketenimine derivatives were also reported.[6]

The reactions of aromatic isonitrile with dihalocarbene or diphenylcarbene are of great interest not only with respect to the cycloaddition reaction of isonitrile to aromatic ring** of aryl-substituted ketenimine intermediate but also in connection with the mechanism of the oligomerization of phenylisonitrile to give indigodianil.[7] The reaction of phenylisonitrile with or without methyl substituent(s) at *ortho*-position with dihalocarbene and diphenylcarbene were investigated.

Results and Discussion

Reaction of Arylisonitrile with Dihalocarbene. The reaction of 2,6-dimethylphenylisonitrile with 2 mol equivalent of CHX_3-*t*-BuOK was carried out at 0 °C. After work-up in the usual way, indolenine derivative (Ia) (mp 135 °C, 40%) or (Ib) (mp 122 °C, 27%) was obtained. A similar result was also obtained in the reaction of 2,4,6-triphenylmethylisonitrile with dichlorocarbene giving (Ic) (mp 148 °C, 20%). No acetamidate derivatives reported by Halleux[4] was isolated in these reactions. Elemental analysis and molecular weight determination indicated that compounds Ia—Ic consisted of two molecules of isonitrile and one molecule of dihalocarbene. In the IR region, each of them showed characteristic four peaks at 1500—1700 cm^{-1} which were due to the C=C or C=N stretching. In the NMR spectrum, Ia and Ib showed multiplets at τ 3.05 (3H) and 3.5—4.7 (3H) and three sharp singlets at τ 7.85 (6H), 8.1 (3H) and 8.8 (3H). The signals at τ 3.05 and 3.5—4.7 showed that both aromatic protons and diene protons[9] were present in this compound. Three signals at high field might be attributed to the aromatic methyl protons, unsaturated methyl protons and saturated methyl protons. Consequently, it is most likely that an aromatic ring of two 2,6-dimethylphenylisonitrile was transformed into a cyclohexadiene ring. This was further evidenced by the NMR spectrum of compound Ic which showed three broad singlets at τ 3.15 (2H), 3.78 (1H) and 4.65 (1H) due to aromatic protons and uncoupled protons.



Ia: X=Cl
Ib: X=Br
Ic:

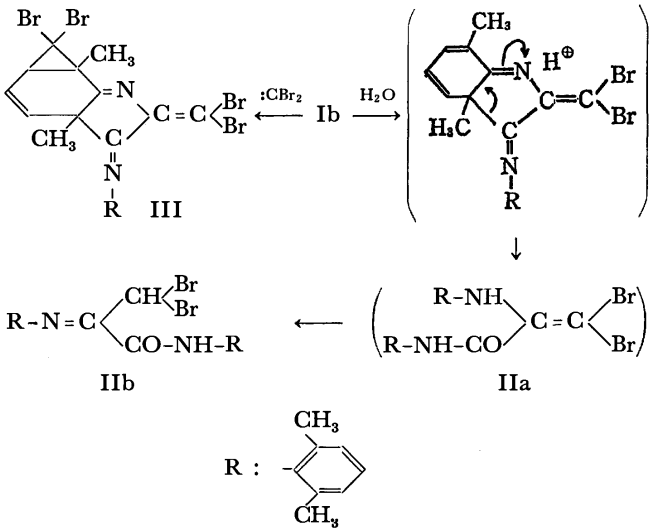
Scheme 1.

The structure of I was confirmed by the following reaction. Compound Ib was hydrolysed by dilute hydrochloric acid to give only polymer but silica gel-catalyzed hydrolysis gave amide (IIb) (mp 143 °C) in an appreciable yield. Elemental analysis and molecular weight determination indicated that compound IIb has a composition of one molecule each of Ib and H_2O. The characteristic peaks at 1640 ($\nu_{C=N}$), 1720 ($\nu_{C=O}$) and 3400 cm^{-1} (ν_{N-H}) in the IR spectrum of IIb suggested the presence of amide group. The NMR spectrum exhibited a complex multiplet at τ 3.0 (6H) and broad singlets at τ 1.43 (1H), 4.13

* A part of this work has been published. T. Takizawa, N. Obata, Y. Suzuki and T. Yanagida, *Tetrahedron Lett.*, **1969**, 3407, M. Muramatsu, N. Obata, and T. Takizawa, *Tetrahedron Lett.*, **1973**, 2133. It was also presented at the 20th Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1967 and at the 23rd Annual Meeting of the Chemical Society of Japan, Tokyo, April, 1970.

** It was reported that the reaction of aromatic imine with *t*-butylisonitrile in the presence of boron trifluoride resulted in the formation of indole and azetidine derivatives.[8]

(1H), 7.7 (6H) and 7.88 (6H). The signals at τ 3.0 7.7 and 7.88 indicated the presence of two 2,6-dimethylphenyl group. The signal at τ 1.43 was assigned to the N-H proton of the amide group because of the disappearance of the signal by the addition of deuterium oxide. The signal at τ 4.13 was attributed to dibromomethin proton.[10] Thus the structure of the amide IIb is not enamine form (IIa) but imine form as shown in Scheme 2. Hydrolysis of Ib might take a route of the ring opening initiated by a protonation and resulting in regeneration of aromatic ring.

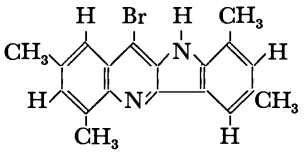


Scheme 2.

If the Seyferth method,[11] decomposition of phenyl(tribromomethyl)mercury, is employed for the generation of dibromocarbene, it might be expected to trap the intermediate giving compound I because of high reactivity of this carbene to multiple bond.[12]

Thus the reflux of the mixture of phenyl(tribromomethyl)mercury and 2 mol equivalent of 2,6-dimethylphenylisonitrile in benzene for 2 hr under nitrogen stream resulted in the formation of Ib (35%), IIb (22%), III (mp 193—195 °C following decomposition, 1.2%) and polymer.*** The identity of the structures Ib and IIb with that obtained above was established by mixing mp. Compound III was found to be the 1 : 1 adduct of Ib and dibromocarbene from elemental analysis and molecular weight determination. In fact the reaction of Ib with phenyl(tribromomethyl)-mercury in benzene gave III in an appreciable yield. In the IR region, III exhibited a characteristic absorption at 1020 cm^{-1} which was due to the cyclopropane skeleton.[13] On comparison of the NMR spectrum of III with that of Ib, it was found that III exhibited an extra multiplet at τ 4.40 (2H), but no multiplet at τ 3.7 (1H) observed in Ib. These spectral data indicated that III was produced by the addition of carbene to methyl substituted double bond[1,14] of cyclohexa-(1,3)-diene Ib. Thus the structure of III is formulated as shown in Scheme 2. Compound IIb might be formed in the hydrolysis of Ib at work-up stage by silica gel chromatography, since IIb could not be obtained on rapid treatment of reaction mixture with silica gel chromatography. The reaction of phenyl-(tribromomethyl)mercury with large excess isonitrile gave only Ib in good yield under the conditions without hydrolysis. On the other hand, the reaction of isonitrile with large excess phenyl(tribromomethyl)mercury gave III, carbene addition product to Ib, in good yield.

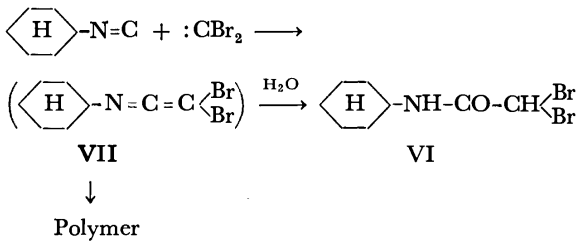
The reaction of 2,4-dimethylphenylisonitrile with dibromocarbene was carried out in the same way in order to investigate the effect of methyl substituent at *ortho* positions in this cycloaddition reaction. In contrast to the reaction mentioned above, a large quantity of polymer and a small amount of indoloquinoline derivative (IV) (mp 194—195 °C, 4%) were obtained. Compound IV was found to have the composition of HBr-elimination from 2 : 1 adduct of isonitrile and dibromocarbene on the basis of elemental analysis and the mass spectrum.



IV

In the IR region, IV exhibited characteristic absorption at 3240 cm^{-1} due to N-H stretching frequency. The UV absorption spectrum of IV showed characteristic maxima at 282 (log ε: 4.83), 350 (4.22), and 385 nm (3.67), which were similar to those of indolo (3′ : 2′—2 : 3)quinoline reported by Clemo and Felton.[15] This shows that compound IV has an indoloquinoline chromophore. The NMR spectrum exhibited five broad singlets at τ 2.05 (1H), 2.4 (1H), and 3.0 (1H) and four sharp singlets at τ 7.0 (3H), 7.45 (3H), 7.55 (3H) and 7.6 (3H). The singlet at τ 2.6 was assigned to N-H protone because of its broadness and the disappearance of the signal by addition of deuterium oxide. In fact, compound IV gave *N*-acetyl derivative (V) (mp 200—202 °C) in the reaction of IV with acetic anhydride. The other four broad signals at low field and four sharp singlets at high field were attributed to uncoupled aromatic protons and four methyl protons in a different atomosphere, respectively. Considering these spectral evidences, it was concluded that the structure of IV should be indoloquinoline derivative as shown in the figure.

The reaction of 4-methylphenylisonitrile, no substituent at *ortho* position, with dibromocarbene in the same condition as above resulted only in the formation of polymer. A similar result was obtained in the



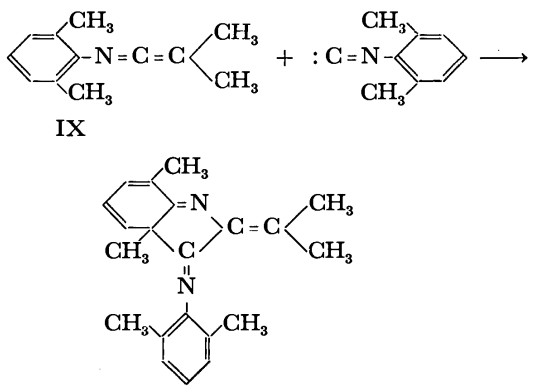
Scheme 3.

*** All polymers obtained in the reaction of arylisonitrile with dihalocarbene showed a similar absorption in the IR spectrum.

reaction of cyclohexylisonitrile with dibromocarbene, and a trace amount of *N*-cyclohexyldibromoacetamide (VI) (mp 142 °C) was isolated. Compound VI might be produced in the reaction of intermediate *N*-cyclohexyldibromoketenimine (VII) with H_2O which was present as an impurity.

When this reaction was carried out by the $CHCl_3$-*t*-BuOK method for generation of carbene, *N*-cyclohexyldibromoacetamidate was isolated as a result of the addition of *t*-BuOH or *t*-BuOK to VII[4]. The formation of polymer, main product in these cases, might also be taking a route of cationic polymerization initiated by the attack of isonitrile to ketenimine VII. This indicates that the reaction of aromatic isonitrile with dihalocarbene generated by either the CHX_3-*t*-BuOK method or the Seyferth method to give the cycloaddition products I and IV and/or polymer might proceed *via* *N*-aryldihaloketenimine intermediate VIII. In fact the reflux of *N*-(2,6-xylyl)dimethylketenimine (IX) prepared by a modification of the Stevens method[16] with 2,6-dimethylphenylisonitrile resulted in the formation of indolenine derivative (X) (mp 103 °C, 26%). The properties and spectra of compound X were essentially similar to those of I.

Thus it is clear that ketenimine VIII is the real intermediate in these cycloaddition reactions. The most reasonable mechanistic pathway of the reaction of arylisonitrile with dihalocarbene might be illustrated

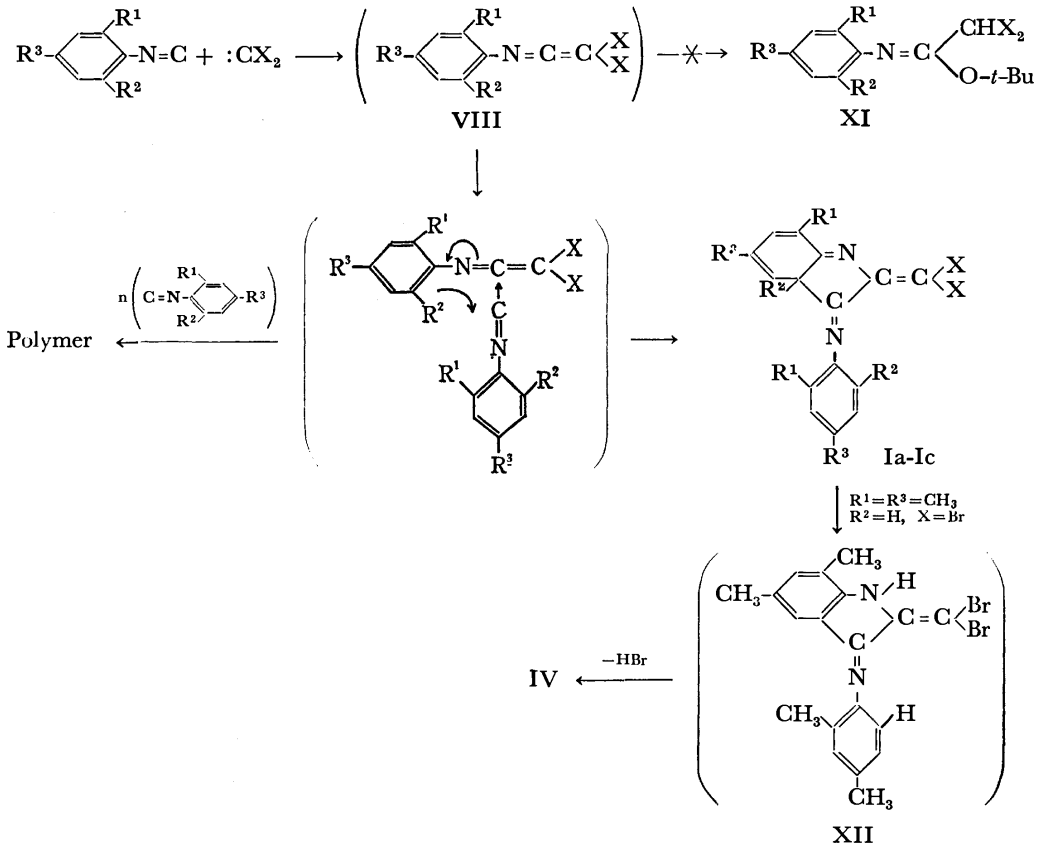


IX

Scheme 4.

by the following scheme (Scheme 5).

Indolenine Ia—Ic could be formed by 1,4-cycloaddition reaction of isonitrile to the ketenimine intermediate VIII formed by the α-addition of carbene or carbenoid† to isonitrile. The fact that the reaction of 2,6-dimethylphenylisonitrile with dihalocarbene generated by CHX_3-*t*-BuOK method gave no *N*-2,6-dimethylphenyldihaloacetamidate (XI) but indolenine derivatives I, might be due to the steric requirement of attacking species, *t*-butoxy anion and 2,6-dimethylphenylisonitrile to ketenimine VIII in the cyclization stage. It was considered that for the formation of IV primary cycloaddition products such as I caused



VIII XI Ia-Ic XII

Scheme 5.

† We believe that a ketenimine intermediate is formed by the reaction of isonitrile with carbene which is produced by the decomposition of Ph–Hg–CBr_3 and basic α-elimination from haloform, although other mechanisms cannot be excluded completely.

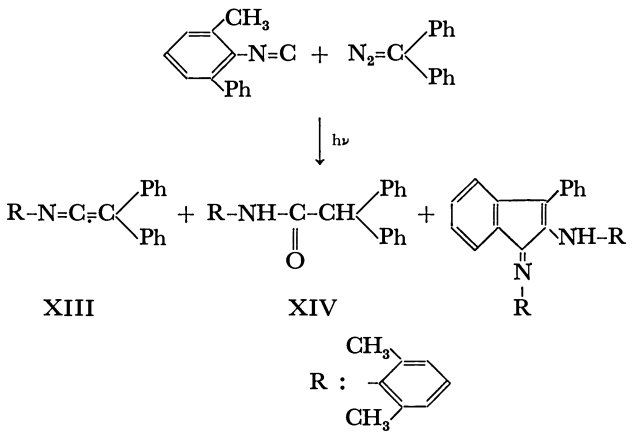
the prototropy to give indole derivative (XII), from which hydrogen bromide might be eliminated by phenyl(tribromomethyl)mercury or phenylmercuric bromide, decomposition product of carbene precursor.[17] The formation of polymer might also be taking a route of cationic polymerization initiated by the nucleophilic attack of isonitrile to ketenimine VIII, since the order of reactivity of the cationic polymerization of isonitrile,[18] *i.e.*, cyclohexyl-≳4-methylphenyl->2,4-dimethylphenyl->2,6-dimethylphenylisonitrile, was identical with that of the formation of polymer in these reactions. This reactivity of isonitrile must be controlled by the steric effect of methyl substituent at *ortho* positions.

Photolysis of Diphenyldiazomethane in the Presence of 2,6-*Dimethylphenylisonitrile.** For further investigation of the cycloaddition reaction of isonitrile with phenyl-substituted ketenimine at cumulated carbon, diphenyldiazomethane as a precursor of diphenylcarbene[1,2,7] was subjected to photolysis in the presence of 2,6-dimethylphenylisonitrile.

The *n*-hexane solution of diphenyldiazomethane and a molar equivalent of 2,6-dimethylphenylisonitrile was irradiated with a 500 W high pressure mercury lamp for 4 hr. IR absorption spectrum of the reaction mixture showed a new peak at 2020 cm^{-1} besides the peaks due to isonitrile and diazo compound. Subsequent removal of solvent at room temperature and rapid separation by means of alumina chromatography gave *N*-(2,6-xylyl)-diphenylketenimine (XIII) (mp 60—61 °C, 1%), *N*-(2,6-xylyl)-diphenylacetamide (XIV) (mp 210—211 °C, 24%) and a very small amount of 1-(2,6-dimethylphenylimino)-2-(2,6-dimethylanilino)-3-phenylindene (XV) (mp 197—198 °C). The structures of XIII and XIV were established by comparison with authentic samples prepared by a modification of the Stevens method.[16] The infrared and NMR spectra of XIII and XIV were consistent with the assigned structures. Ketenimine XIII was easily hydrolyzed by dilute hydrochloric acid or alumina to produce amide XIV in a quantitative yield. Consequently, the amide XIV corresponding to XIII was formed by hydration of ketenimine XIII on an alumina column.

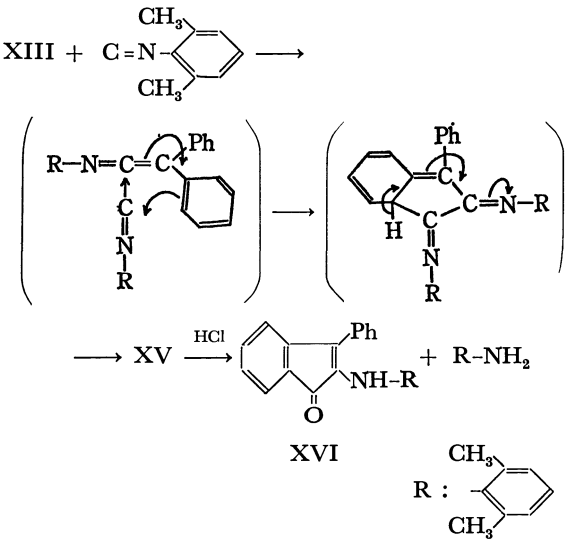
The results indicate that ketenimine was formed in at least 25% yield in the photochemical reaction. We believe that the formation takes the route of photolysis of diphenyldiazomethane to produce diphenylcarbene and electrophilic attack of this carbene to isonitrile, although other mechanisms for the formation of ketenimine cannot be excluded completely.[6]

The reflex of benzene solution of equimolar mixture of ketenimine XIII and 2,6-dimethylphenylisonitrile resulted in the formation of XV in 73% yield. In the IR region, XV exhibited characteristic absorption bands at 3300, 1655 and 1620 cm^{-1} which might be attributed to N–H group, C=N or C=C double bond, respectively. The UV absorption spectrum of XV showed a characteristic peak at 272 nm (log ε: 4.61). The NMR spectra exhibited a multiplet at τ 3.0—4.0 (16H) and a singlet at τ 7.85 (12H). The structure of XV was further confirmed by the following reaction. Compound XV was hydrolyzed by



Scheme 6.

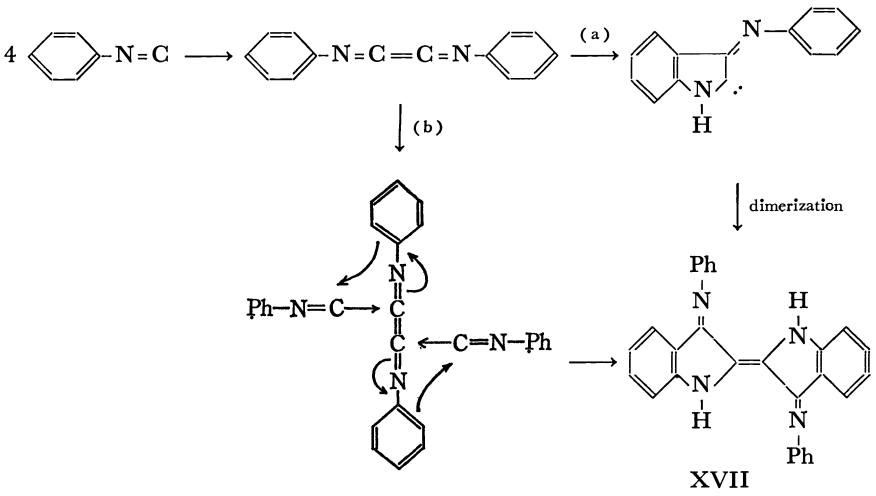
dilute hydrochloric acid in THF to give 2-(2,6-dimethylanilino)-3-phenylindone (XVI) (mp 133—134 °C) and 2,6-xylydine in good yield. The structure of XVI was established by elemental analysis, molecular weight determination and a comparison of spectral data, IR and UV, with those of known 2,3-diphenylindone.[19] Thus the structure of XV was established as shown in Scheme 6. Its formation indicated that the cycloaddition of isonitrile to ketenimine did not occur in the 2,6-dimethylphenyl ring but in phenyl ring of ketenimine preferentially in the fashion of 1,4-cycloaddition, as shown in the following scheme (Scheme 7).



Scheme 7.

This reaction as well as that of 2,4-dimethylphenylisonitrile with dibromocarbene to give IV, *i.e.*, the cycloaddition of isonitrile to non-substituted phenyl ring, seems to show that the methyl substitution at *ortho* position did not favour the cycloaddition reaction of isonitrile to phenyl ring of ketenimine.

Also, all these cycloaddition reactions of isonitrile to ketenimine easily produced by the reaction of isonitrile with carbene seem to suggest the mechanism of the formation of indigodianil (XVII) in the oligomerization of phenylisonitrile. Grundmann[7] proposed the following mechanism for this oligomerization, the



Scheme 8.

dimerization of isonitrile and intramolecular cyclization of the dimer to give carbene followed by its dimerization (path a). But the reactions we investigated so far suggest another possible mechanism, *i.e.*, dimerization and intermolecular double cycloaddition of isonitrile to cumulate double bond (path b).

In conclusion, the reaction of several methyl-substituted phenylisonitrile with dihalocarbene gave indolenine or indoloquinoline derivatives and/or polymer *via* ketenimine intermediate. This was evidenced by the reaction of *N*-(2,6-xylyl)dimethylketenimine with 2,6-dimethylphenylisonitrile to give indolenine such as I. This intermediate ketenimin was isolated only in the photolysis of diphenyldiazomethane in the presence of isonitrile, the formation of which might be taking a route of dimerization of divalent carbon, presumably diphenylcarbene and isonitrile. In the reaction of isonitrile with tri-aryl-substituted ketenimine, two possibilities to form indole and indene derivatives as the result of the cycloaddition of isonitrile to phenyl ring of ketenimine were indicated. Although the electronic effect of methyl group in these reactions does not seem to be an important factor, the steric effect of methyl substituent is supposed to play a more important role on both the direction of the cycloaddition of isonitrile to ketenimine and the reactivity of isonitrile, *i.e.*, the reactivity of cationic polymerization of isonitrile.

Experimental††

Starting Materials. Isonitrile was prepared by the I. Ugi procedure[20]. Phenyl(tribromomethyl)mercury was prepared by the Seyferth method[11].

Reaction of 2,6-Dimethylphenylisonitrile (A) with $CHCl_3$–t-BuOK, Indolenine Derivative (Ia). 2.4 g (0.02 mol) of chloroform was added, with cooling for 30 min, to a stirred suspension of 1.3 g (0.01 mol) of 2,6-dimethylphenylisonitrile and t-BuOK (0.02 mol) in 20 ml of peteroleum ether. The reaction mixture was poured into ice-water, extracted with petroleum ether, washed with water and dried, giving yellow solid. Recrystallization from ether gave 0.7 g (40%) of Ia, mp 135.5 °C. The structure of Ia was established by the following data.

Found: C, 65.80; H, 5.27; N, 8.01; Cl, 20.87%; mol. wt, 329. Calcd for $C_{19}H_{18}N_2Cl_2$; C, 66.08; H, 5.22; N, 8.11; Cl, 20.58%; mol. wt, 345. IR(KBr): 1680, 1630, 1595 cm^{-1} ($\nu_{C=C}$ or $\nu_{C=N}$). UV λ_{max}^{EtOH}: 305 (log ε: 3.99); 350 nm (4.14). NMR($CDCl_3$): τ 3.05 (m, 3H), 3.5—4.7 (m, 3H), 7.85 (s, 6H), 8.1 (s, 3H), 8.8 (s, 3H).

(B) with $CHBr_3$-t-BuOK, Indolenine Derivative (Ib). A similar reaction was carried out between 0.01 mol of 2,6-demethylphenylisonitrile and 0.02 mol of $CHBr_3$–*t*-BuOK in petroleum ether. After a similar work-up, 0.58 g (27%) yellow crystals of Ib, mp 122 °C was obtained, after recrystallization from ether–petroleum ether (1 : 1).

Found: C, 52.31; H, 4.28; N, 6.21; Br, 36.38%; mol. wt, 438. Calcd for $C_{19}H_{18}N_2Br_2$: C, 52.56; H, 4.71; N, 6.45; Br, 36.12%; mol. wt, 434. IR (KBr): 1680, 1630, 1590, 1505 cm^{-1} ($\nu_{C=C}$ or $\nu_{C=N}$). UV λ_{max}^{EtOH}: 230 (log ε: 4.30), 310 (3.86), 352 nm (4.04).

Reaction of 2,4,6-Trimethyphenylisonitrile with $CHCl_3$-t-BuOK, Indolenine derivative (Ic). A similar reaction was carried out between 1.45 g (0.01 mol) of 2,4,6-trimethylphenylisonitrile and 0.02 mol of $CHCl_3$–*t*-BuOK. The reaction mixture was poured into ice-water and extracted with ether. The extracts were washed with water and dried ($MgSO_4$). After removal of the solvent, the residue was chromatographed on a column of silica gel. Elution with hexane–benzene (3 : 2) gave yellow solid. Recrystallization of this material from ether gave 0.3 g (20%) of indolenine derivative (Ic), mp 148 °C.

Found: C, 67.41; H, 5.78; N, 7.85; Cl, 18.37%; Calcd for $C_{21}H_{22}N_2Cl_2$: C, 67.56; H, 5.94; N, 7.51; Cl, 18.72%. IR (KBr): 1680, 1615, 1600, 1520 cm^{-1} ($\nu_{C=C}$ or $\nu_{C=N}$). UV λ_{max}^{EtOH}: 230 (log ε: 4.48), 290 (4.05), 305 (3.02), 360 nm (4.12). NMR($CDCl_3$): τ 3.15 (broad s, 2H), 3.78 (broad s, 1H), 4.65 (broad s, 1H), 7.7 (s, 3H), 7.88 (s, 6H), 8.1 (s, 3H), 8.32 (s, 3H), 8.82 (s, 3H).

Hydrolysis of Ib. A solution of 100 mg (2.3 mmol) of Ib and 1 g of silica gel in 30 ml aqueous methanol was refluxed for 24 hr and allowed to stand for several days at room temperature. After silica gel chromatography, 16 mg

†† All melting points were uncorrected. IR spectra were determined using a Nihonbunko DS 402 G infrared spectrophotometer. UV spectra were recorded with a Carry 11 recording spectrophotometer. NMR spectra were obtained with a Varian A-60 spectrometer, using tetramethylsilane as an internal standard. The molecular weight was determined by use of a Hitachi 105 vapor pressure osmometer.

(15%) of amide IIb was obtained. The structure of IIb was established by the following data.

Found: C, 50.68; H, 4.65; N, 6.35; Br, 35.44%; mol. wt, 443. Calcd for $C_{19}H_{20}ON_2Br_2$: C, 50.44; H, 4.42; N, 6.19; Br, 35.39; mol. wt, 443. IR (KBr): 3400 (ν_{N-H}), 1720 ($\nu_{C=O}$), 1640 cm^{-1} ($\nu_{C=N}$). UV λ_{max}^{EtOH}: 255 nm ($\log \varepsilon$: 3.49). NMR($CDCl_3$): τ 1.43 (broad s, 1H), 3.0 (m, 6H), 4.13 (s, 1H), 7.7 (s, 6H), 7.88 (s, 6H).

Reaction of 2,6-Dimethylphenylisonitrile with Phenyl(tribromomethyl)mercury. A solution of 2.49 g (0.019 mol) of 2,6-dimethylphenylisonitrile and 5.03 g (9.5 mmol) of phenyl(tribromomethyl)mercury in 30 ml dry benzene was refluxed for 2 hr under nitrogen stream. The reaction mixture was cooled and filtered. The residue was washed with benzene and combined, and the combined benzene solution was evaporated. The residue was chromatographed on a column of silica gel. From the eluent with hexane, 1.15 g (35%) of Ib (from hexane) and 0.034 g (1.2%) of III were obtained mp 193—195 °C (from hexane). III gave the following analytical and spectral data. Found: C, 39.80; H, 2.86; N, 4.77; Br, 51.64%; mol. wt, 582. Calcd for $C_{20}H_{18}N_2Br_4$: C, 39.60; H, 2.97; N, 4.62; Br, 52.81%; mol. wt, 606. IR (KBr): 1680 ($\nu_{C=N}$), 1618 ($\nu_{C=C}$), 1020 cm^{-1} ($\nu_{cyclopropane}$). UV λ_{max}^{EtOH}: 230 ($\log \varepsilon$: 4.13), 290 nm (4.20). NMR($CDCl_3$): τ 3.05 (m, 3H) 4.4 (m, 2H), 7.85 (s, 3H), 8.05 (s, 3H), 8.4 (s, 1H), 8.75 (s, 3H).

From the eluent with benzene over 4 days, 0.92 g (22%) of IIb, mp 143 °C (from hexane) was obtained. However, IIb could not be obtained by rapid treatment with silica gel chromatography (one or two days).

When the reaction was carried out with the reverse mol ratio of 5 mmol of 2,6-dimethylphenylisonitrile to 10 mmol of phenyl(tribromomethyl)mercury, III was obtained in 10% yield. On the contrary, when 5 moles excess isonitrile to phenyl(tribromomethyl)mercury was used, the yield of Ib rose to 65% and IIb and III could not be obtained.

Reaction of Ib with Phenyl(tribromomethyl)mercury. A solution of 0.43 g (1 mmol) of Ib and 0.53 g (1 mmol) of phenyl(tribromomethyl)mercury in 30 ml dry benzene was refluxed for 2 hr under nitrogen stream. After the reaction mixture was filtered, the solvent was removed by evaporation and the residue was chromatographed on a column of silica gel. 51 mg (12%) of III and a trace amount of IIb were obtained.

Reaction of 2,4-Dimethylphenylisonitrile with Phenyl(tribromomethyl)mercury. A solution of 1.79 g (14 mmol) of 2,4-dimethylphenylisonitrile and 3.62 g (7 mmol) of phenyl(tribromomethyl)mercury in dry benzene 30 ml was refluxed for 2 hr under nitrogen stream. After work-up in the usual way and silica gel chromatography, 40 mg (2%) of IV, mp 194—195 °C (from hexane) and a large amount of polymer were obtained.

When a benzene solution of phenyl(tribromomethyl)-mercury was added to a refluxing solution of 2 equivalent isonitrile in benzene, the yield of IV rose to 4%. The structure of IV was established by the following data.

Found: C, 64.48; H, 4.98; N, 8.15; Br, 22.34%; mol. wt, (mass spectrum) 353. Calcd for $C_{19}H_{17}N_2Br$: C, 64.59; H, 4.82; N, 7.93; Br, 22.66%; mol. wt, 353. IR (KBr): 3240 cm^{-1} (ν_{N-H}). UV λ_{max}^{EtOH}: 282 ($\log \varepsilon$: 4.83), 350 (4.22), 385 nm (3.67). NMR (CCl_4): τ 2.05 (s, 1H), 2.4 (s, 1H), 2.6 (s, 1H), 3.0 (s, 1H), 7.0 (s, 3H), 7.45 (s, 3H), 7.55 (s, 3H), 7.6.

Reaction of Cyclohexylisonitrile with Phenyl(tribromomethyl)-mercury. A similar reaction was carried out between 0.9 g (8.2 mmol) of cyclohexylisonitrile and 2.19 g (4.1 mmol) of phenyl(tribromomethyl)mercury in benzene 20 ml. After silica gel chromatography, 18 mg (0.7%) of *N*-cyclohexyldibromoacetamide VI, mp 142 °C (from ether) and a large amount of polymer were obtained. Compound VI gave the following analytical and spectral data.

Found: C, 32.22; H, 4.46; N, 5.07%. Calcd for $C_8H_{13}NOBr_2$: C, 32.13; H, 4.38; N, 4.69%. IR (KBr): 3310 (ν_{N-H}), 1670 cm^{-1} ($\nu_{C=O}$).

N-acetyl Indoloquinoline V. A solution of 25 mg (0.071 mmol) of IV in 1.5 g of acetic anhydride was heated at 80 °C for 1 hr. The reaction mixture was poured into water, extracted with ether and dried ($MgSO_4$). The solvent was removed and recrystallization from ethanol gave 13 mg (47%) of *N*-acetyl indoroquinoline V, mp 200—202 °C.

Found: C, 64.04; H, 4.73; N, 7.98%. Calcd for $C_{21}H_{19}ON_2Br$: C, 63.80; H, 4.81; N, 7.09%.

Photolysis of Diphenyldiazomethane in the Presence of 2,6-dimethylphenylisonitrile. A equimolar mixture of diphenyldiazomethane 0.74 g and 2,6-dimethylphenylisonitrile 0.5 g in *n*-hexane 30 ml was irradiated with a 500 W high pressure mercury arc lamp at 15 °C in a quartz vessel. After photolysis for 4 hr, the solvent was evaporated at room temperature and the residue was subjected to alumina column chromatography. Elution with *n*-hexane gave *N*-(2,6-xylyl)diphenylketenimine (XIII), mp 61—62 °C, in 7 mg (0.7%) yield. The structure was established by the following data and by melting point determination with the authentic sample prepared by a modification of the Stevens method.[16] Compound XIII showed the characteristic infrared absorption at 2020 cm^{-1} ($\nu_{C=C=N}$).

Found: C, 89.15; H, 6.50; N, 4.97%. Calcd for $C_{22}H_{19}N$: C, 88.85; H, 6.44; N, 4.71%. Further elution with benzene gave a trace amount of purple crystalline 1-(2,6-dimethylphenylimino)-2-(2,6-dimethylanilino)-3-phenylindene (XV), mp 197—198 °C, formed by the reaction of XIII with 2,6-dimethylphenylisonitrile.

Finally *N*-(2,6-xylyl)-diphenylacetamide (XIV), mp 210—211 °C, was obtained in 0.25 g (24%) yield from the eluent with methylenedichloride. The structure of amide XIV corresponding to XIII was identified by comparison with the authentic sample prepared by the following method.

Preparation of Ketenimine: (A) N-(2,6-xylyl)dimethylketenimine(IX) was prepared by a modification of the Stevens method[16], bp 93—95 °C/0.5 mmHg. The characteristic infrared absorption was at 2020 cm^{-1} which was due to the heterocumulated double bond. (B) *N*-(2,6-xylyl)-diphenylketenimine (XIII) was also prepared by the same procedure[16]. Ketenimine XIII showed the mp 62° C (from *n*-hexane) and the characteristic infrared absorption band at 2020 cm^{-1} ($\nu_{C=C=N}$).

Reaction of 2,6-Dimethylphenylisonitrile with N-(2,6-Xylyl) dimethylketenimine (IX). Indolenine Derivative (X). A solution of 1.73 g (0.013 mol) of 2,6-dimethylphenylisonitrile and 2.29 g (0.013 mol) of *N*-(2,6-xylyl)dimethylketenimine in dry benzene 20 ml was refluxed for 6 hr. The solvent was removed and the residue was chromatograp ed on a colunm of alumina. Elution with hexane gave 0.34 g (26%) of X, mp 103 °C (from petroleum ether) and recovered isonitrile 1.18 g.

Found: C, 82.96; H, 7.95; N, 9.23%; mol. wt, 300. Calcd for $C_{21}H_{24}N_2$: C, 82.85; H, 7.95; N, 9.20%; mol. wt, 304. IR (KBr): 1665, 1635, 1625, 1595, 1535 cm^{-1}, UV λ_{max}^{EtOH}: 230 ($\log \varepsilon$: 4.24), 299 (3.95), 325 nm (3.90). NMR ($CDCl_3$): τ 3.05 (m, 3H), 3.7—4.6 (m, 3H), 7.65 (d, 6H), 7.85 (d, 6H), 8.05 (s, 3H), 8.9 (s, 3H).

Reaction of 2,6-Dimethylisonitrile with N-(2,6-Xylyl)diphenylketenimine (XIII). Indonimine Derivative (XV). A solution of 0.66 g (0.005 mol) of 2,6-dimethylphenylisonitrile and

1.50 g (0.005 mol) of *N*-(2,6-xylyl)diphenylketenimine in dry benzene 20 ml was refluxed for 3 hr. After the solvent was removed by evaporation, a precipitated purple solid was obtained. Recrystallization from hexane-methylenechloride resulted in 1.59 g (73%) of indone imine XV, mp 197—198 °C.

Found: C, 86.60; H, 6.69; N, 6.60%; mol. wt, 420. Calcd for $C_{31}H_{28}N_2$: C, 86.88; H, 6.59%; mol. wt, 429. IR (KBr): 3300 (ν_{NH}), 1655 ($\nu_{C=N}$), 1620 cm^{-1} ($\nu_{C=C}$). UV λ_{max}^{EtOH}: 272 nm (log ε: 4.61). NMR(CCl_4): τ 3.0—4.0 (m, 16H), 7.85 (s, 12H).

Hydrolysis of Indonimine XV. A solution of 0.3 g of XV in 0.3% HCl–THF (20 ml) was refluxed for 3 hr. The reaction mixture was extracted by methylenechloride. After removal of the solvent, the residue was subjected to alumina column chromatography. Elution with benzene gave 2-(2,6-dimethylanilino)-3-phenylindone XVI, mp 133—134 °C (*from petroleum ether*).

Found: C, 83.88; H, 6.07; N, 4.90%. Calcd for $C_{22}H_{19}NO$: C, 84.31; H, 6.17; N, 4.47%. IR (KBr): 3340 (ν_{N-H}), 1717 cm^{-1} ($\nu_{C=O}$). UV λ_{max}^{EtOH}: 269 (log ε: 4.36), 320 sh (3.44), 560 nm (2.80). NMR(CCl_4): τ 2.5—4.7 (m, 14H), 7.95 (s, 6H).

Synthetic Studies of Laurencin and Related Compounds. I. The Synthesis of *t*-3-Bromo-*r*-2,*c*-8-diethyl-3,4,7,8-tetrahydro-2*H*-oxocin

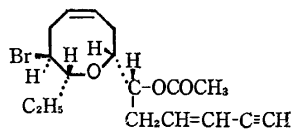
Tadashi MASAMUNE, Satoshi NUMATA, Hajime MATSUE, Akira MATSUYUKI, Takehiro SATO, and Hisashi MURASE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

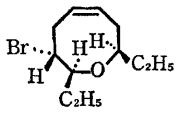
(Received March 29, 1975)

The synthesis of the titled bromohydrooxocin (**2**), one of model compounds for synthetic approaches to laurencin (**1**), is described. *trans*- and *cis*-2,5-Diethyl-2,5-dihydrofurans (**25**), prepared by treatment of furan with bromine and then with ethyl magnesium bromide, was submitted, after oxidation with ozone, to the Robinson-Schöpf condensation with methylamine to give *trans*- and *cis*-2,4-diethylbicyclononanones (**19a** and **19b**), whose configurations were discussed on the NMR spectra. These compounds were converted into *trans*- and *cis*-diethylhydrooxocinones (**38a** and **38b**), respectively, according to a six-step process analogous to the Paquette procedure. It is to be noted that (i) thermally induced, intramolecular dienyl 1,5-hydrogen transfer (**36** to **37**), one of the key reactions in the process, took place without difficulty with *cis*-aminodiene (**36b**), while the rearrangement did not proceed smoothly with *trans*-aminodiene (**36a**), and (ii) *trans*-ketone (**38a**) was isomerized readily into *cis*-ketone (**38b**). Further hydride reduction of *cis*-ketone (**38b**) followed by bromination with carbon tetrabromide and triphenylphosphine yielded the aimed bromohydrooxocin (**2**) as a major product, which possessed the same relative configuration concerning the ring substituents as laurencin (**1**).

One decade ago, we reported the isolation and structure elucidation of laurencin (**1**), a bromine-containing, acetylenic seaweed component.[1] Many related compounds have since been identified as constituents of marine algae,[2] and these natural halogenocyclic ethers have been attractive as a synthetic target owing to their unusual skeleton. We describe herein the preparation of *t*-3-bromo-*r*-2,*c*-8-diethyl-3,4,7,8-tetrahydro-2*H*-oxocin (**2**), which possesses the same relative configuration concerning the ring substituents as laurencin (**1**). In view of the fact that the synthetic process involved no complexity due to the side chain with an enyne grouping and gave information of conformational change or isomerization caused by introduction of substituents into oxocanes,[3] this hydrooxocin (**2**) was a most useful model compound for the natural cyclic ethers.

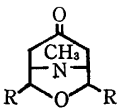


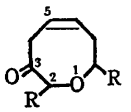
1



2

Although hydrooxocins are not readily accessible synthetically as compared with hydrooxoepine,[4,5] several methods for preparing the oxocins have been reported; namely, radical cyclization of olefinic alcohols,[6] dichlorocarbene homologation,[7] the Dieckmann condensation,[8] and so on.[9] In addition, Paquette and coworkers have recently published an elegant synthetic method,[10] which involves 9-methyl-9-aza-3-oxabicyclo-[3.3.1]nonan-7-one[11] (**3**) as an intermediate, prepared by the Robinson-Schöpf condensation, and leads to formation of 7,8-dihydro-2*H*-oxocin-3(4*H*)-one (**4**). While compound **4** possesses a most appropriate framework for the preparation of **2**, we first attempted to synthesize the compound in a manner analogous to the biogenesis, because "laurediols" (**5**), polyenyne glycols regarded as one of the precursors of the titled compounds, had been isolated from the seaweed.[12]





3 R=H
19a R=C_2H_5, *trans*
19b R=C_2H_5, *cis*

4 R=H
38a R=C_2H_5, *trans*
38b R=C_2H_5, *cis*

The preparation of undeca-5,8-dien-3-ol (**6**) a "laurediol" analog for **2**, was carried out as follows. The Grignard reagent from hex-1-yn-4-ol[13] (**7**) was coupled[14] with *trans*-pent-2-enyl bromide[15] (**8**) over cuprous bromide as catalyst to give *trans*-undec-8-en-5-yn-3-ol (**9**), oil, in 65% yield, which on hydrogenation over Lindler catalyst[16] afforded **6**, oil, in almost quantitative yield. Attempted cyclization reactions of **6** with lead tetraacetate or with hypobromous acid afforded complex tarry material, which resisted further purification. Compound **9** was then oxidized with

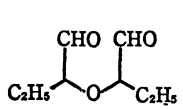
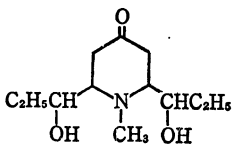
perbenzoic acid to the 8,9-epoxide (**10**), which was converted by hydrogenation under the same conditions as **9** into 8,9-epoxyundec-5-en-3-ol (**11**) in 95% yield from **9**. This was further hydrogenated over Adams platinum to give 8,9-epoxyundecan-3-ol (**12**). Treatment of **11** with potassium hydroxide in refluxing aqueous DMSO resulted in no expected cyclization and produced undeca-4,6-diene-3,9-diol (**13**). The same treatment of saturated epoxide (**12**), however, led to simple cleavage of the epoxy ring, giving undecane-3,4,9-triol (**14**), mp 91—93 °C. Likewise, unsaturated epoxide (**11**), when treated with sodium methoxide in refluxing methanol or with potassium *tert*-butoxide in refluxing *tert*-butyl alcohol, afforded the corresponding unsaturated alkoxyglycols (**15** and **16**). Furthermore treatment of **11** with acids, *p*-toluenesulfonic acid in benzene or hydrogen chloride in methanol, also effected only the cleavage of the epoxy ring to give unsaturated triol monotosylates (**17**) or diol chlorides (**18**). Thus, all attempts to cyclize **11** to hydrooxocins under various conditions failed.

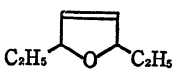
The synthesis of compound **2** was then undertaken by a modification of the Paquette procedure,[10] which required the preparation of 2,4-diethyl-9-methyl-9-aza-3-oxabicyclo[3.3.1]nonan-7-ones (**19**) as key intermediates. Attempted preparation of 2,4-diethyl-3-oxaglutaraldehydes (**20**), necessary as the starting substance for **19**, by the Williamson synthesis of methyl acetal[17] of 2-hydroxybutyraldehyde (**21**) and that[17] of 2-chlorobutyraldehyde (**22**) with bases (NaH) followed by acid treatment gave only tarry material. On the other hand, the Robinson-Schöpf condensation of **21** with methylamine and acetonedicarboxylic acid afforded a basic mixture, which was expected to contain piperidone derivatives (**23**) convertible into bicyclononanones **19** by ring closure. However, attempted formation of cyclic ethers **19** by tosylation of the basic mixture followed by base treatment[18] or by acid treatement[19] again failed; only a small amount of non-basic, undecane-3,6,9-trione (**24**), mp 78—80 °C, was isolated by chromatography of the tarry product.



20



23



25

The synthesis of bicyclononanones **19** was finally achieved as described below. Treatment of furan (1 mol) with bromine (1 mol) at −40——45 °C in ether produced 2,5-dibromofurans,[20] which were treated with ethyl magnesium bromide (2 mol) at −40——10 °C.[21] The resulting 2,5-diethyl-2,5-dihydrofurans (**25**), bp 51—54 °C/35 mmHg, obtained in 20% yield, were ozonized at −78 °C in ethyl acetate to give oxaglutaraldehydes **20** in 70% yield. This dialdehyde mixture (**20**) reacted with methylamine and acetonedicarboxylic acid in an aqueous buffered solution of pH 5.0 at room temperature for 43 hr[11] to give basic products, from which a mixture of *trans*- and *cis*-2,4-diethylbicyclononanones (**19a** and **19b**), showing the same R_f value on tlc, was separated after chromatography. While the *trans*-isomer (**19a**), mp 89—90 °C, could be isolated in 9.8% yield from furan by fractional recrystallizations of the mixture, the *cis*-isomer (**19b**), mp 86—88 °C, was obtained in 1.8% yield in pure state as follows. The mixture of **19a** and **19b**, freed from pure **19a** obtained by the recrystallizations, was reduced with lithium aluminum hydride (LAH) to give a mixture of alcohols, from which two alcohols could be isolated by preparative tlc. The more polar alcohol (**26b**) was converted into the *cis*-ketone (**19b**) with chromic anhydride–pyridine complex in dichloromethane,[22] and the less polar alcohol (**26a**) into the *trans*-ketone (**19a**) by the same treatment (15 min). Interestingly, the latter alcohol (**26a**), when treated for a long time (overnight) under the oxidation conditions, produced *N*-formyl ketone (**27a**) in good yield. This compound (**27a**) showed two singlets (1H in total) due to a formyl proton in the NMR spectrum, which would result from slow rotation of the bond between the carbonyl carbon and nitrogen atoms.[23]

The *trans*- and *cis*-configurations of two ethyl groups in compounds **19a** and **19b** were deduced from the NMR spectra. These spectra, coupled with spin decoupling and/or contact shift [Eu(dpm)$_3$] studies, were interpreted by comparison with those of closely related compounds **28**,[24] **29**,[25] **30**[26] and **31**,[27] as well as by consideration of the influence of alkyl substituents on the chemical shifts of cyclohexane ring protons,[28] and the result is summarized in Table 1. As shown in Table 1, the signals due to equatorial and/or axial protons at C_1, C_2 and C_8 coincided with the corresponding protons at C_5, C_4 and C_6 in the spectrum of **19b**, indicating the existence of a plane of symmetry in the molecule. On the other hand, this equivalency was not observed in the spectrum of **19a**. Thus the two ethyl groups at C_2 and C_4 in question must be *cis*-oriented (β and β or α and α) in **19b**, and *trans*-oriented in **19a** (β and α or α and β). Since *cis*-2-acetoxy-4-ethyl-9-methyl-9-aza-3-oxabicyclo[3.3.1]nonan-7-one (**32**) exists in a double-chair conformation irrespective of the presence of the diaxial 2,4-substituents,[29] these and unsubstituted compounds (**19a**, **19b** and **3**) would undoubtedly adopt the double-chair conformation. The remaining problem was the conformation (and hence the configuration) of the two ethyl groups of **19b**. Judging from only the coupling constants, $J_{1,2}$ and $J_{4,5}$ (each 2 Hz) in **19b** and $J_{1,2}$ (0 Hz) and $J_{4,5}$ (2 Hz) in **19a**, it might not be unreasonable to assign equatorial conformations (α-configurations) to both the ethyl groups of the *cis*-isomer (**19b**). However, the constants in question depend delicately on the whole conformational change.[26] Furthermore, the ethyl methylene protons of **19b** (*cis*) appeared at remarkably low fields, as compared with those of **19a** (*trans*), the difference in δ-value being 0.20—0.35 ppm. In general, axial methyl protons at the α-carbon atom in oxacyclohexane systems absorb at lower fields than the corresponding equatorial protons[30] and are also deshielded when disposed 1,3-diaxially (*syn*-axially) to other methyl protons[31] and/or nitrogen lone pair electrons.[32] These facts strongly suggested that each of the relevant ethyl groups in **19b** would probably take an axial (and

a) The spectra were measured in CCl_4 at 100 MHz, and the abbreviations "H_{2e} and $J_{1,2e}$" refer to "equatorial proton at C_2 and coupling constant between H_1 and H_{2e}," respectively. b) The coupling constants were estimated by first-order approximations. c) The coupling constant, $J_{2a,2e}$ and $J_{4a,4e}$, in compound **3** were 11.5 and 11.5 Hz.

hence a β-configuration) rather than an equatorial conformation. The spectrum of the *trans*-isomer(**19a**) could be understood well on the same ground. This conformational assignment was consistent with that to the 7-deoxo derivatives (**33a** and **33b**) of **19a** and **19b**, which would also exist in a double-chair conformation; that is, the C_2- and C_4-proton signals were observed at δ 3.46 and 3.68 in the NMR spectrum of the *trans*-isomer (**33a**), while the corresponding signals coincided and appeared at higher field, δ 3.14, in that of *cis*-isomer (**33b**). The ethyl methylene protons in question of the *trans*-isomer (**33a**) were found by spin decoupling studies to be coupled to these C_2 and C_4 protons at higher field (near δ 1.35) than those of the *cis*-isomer **33b** (near δ 1.70).

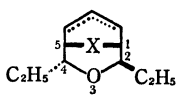
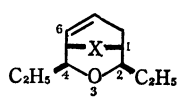
31 X=CH_2, Y=NCH_3, Z=O

Compound **19a** was reduced with lithium aluminum hydride in refluxing ether to give an epimeric alcohol mixture, consisting mainly of α-alcohol[11,26)] (**26a**). This alcohol mixture was dehydrated with sulfuric acid in acetic acid at 155 °C[33)] and produced a mixture of diastereoisomeric olefins (**34a**) in 95% yield from **19a**. This olefin mixture (**34a**) was converted quantitatively into the saturated *trans*-compound (**33a**) by hydrogenation over platinum in ethanol. Likewise, *cis*-ketone (**19b**) was convered into an epimeric alcohol mixture (main, **26b**) and then dehydrated under the comparable conditions to give an olefin (**34b**) in 90% yield, which on hydrogenation formed the *cis*-saturated compound (**33b**).

trans- and *cis*-Olefins (**34a** and **34b**) were converted into the corresponding methiodides, *trans*- (**35a**, a mixture of diastereoisomers), mp 179—182 °C, and *cis*-isomers (**35b**), mp 190—191 °C. These methiodides were submitted to the Hofmann degradation under the carefully controlled conditions to give *trans*- (**36a**, a mixture of diastereoisomers), oil, and *cis*-2,8-diethyl-3-dimethylamino-3,8-dihydro-2*H*-oxocins (**36b**), oil, in good yields, respectively.



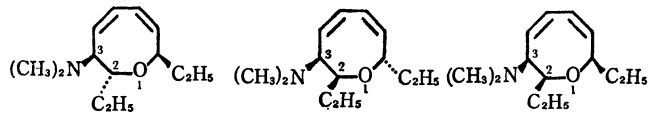


34a X=NCH_3
34b X=NCH_3
35a X=$\overset{+}{N}(CH_3)_2$ I^-
35b X=$\overset{+}{N}(CH_3)_2$ I^-

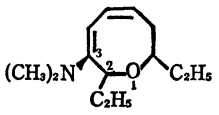
Heating of *cis*-aminodiene (**36b**), with 3-dimethylamino, and 2- and 8-ethyl groups all β-oriented, at 120—125 °C for 15 min resulted in facile intramolecular dienyl 1,5-hydrogen transfer, giving *cis*-dienamine (**37b**), oil, as a single product in almost quantitative yield. To the contrary, conversion of a mixture of *trans*-aminodienes (**36a**), one with the three groups β-, α- and β-oriented and the other with those β-, β- and

α-oriented, into the desired *trans*-dienamine (**37a**), oil, did not proceed smoothly as expected under the comparable conditions. The product was a multi-component mixture including **37a**, which was estimated to account for at most 60% of the total bases under the best conditions examined. The difference in reactivity between *trans*- and *cis*-aminodienes (**36a** and **36b**) indicated that this thermally induced, α-oriented-hydrogen shift from C_3 to C_7 in *trans*-isomer (**36a**), presumably concerted and suprafacial [1,5] sigmatropic rearrangement,[34] would be hindered by the presence of an α-oriented ethyl group either at C_2 or C_8.[35]

These *trans*- (without further purification) and *cis*-dienamines (**37a** and **37b**) were hydrolyzed in refluxing dil fluoroboric acid and produced *trans*- and *cis*-2,8-diethylhydrooxocinones (**38a** and **38b**), both oil, in 18 and 45% yields from bicyclononanones (**19a** and **19b**), respectively. In accordance with the assigned structures, both β,γ-unsaturated ketones (**38a** and **38b**) displayed absorption maxima near 310 nm (ε= 50—200) and near 1715 and 1650 cm^{-1} in the UV and IR spectra. Interestingly, the UV absorption intensity (ε 90—162) of the latter (**38b**) was about twice stronger than that (50—100) of the former (**38a**), indicative of larger overlap of π-electrons of the double bond and carbonyl group in *cis*-isomer (**38b**) as compared with that in *trans*-isomer (**38a**).

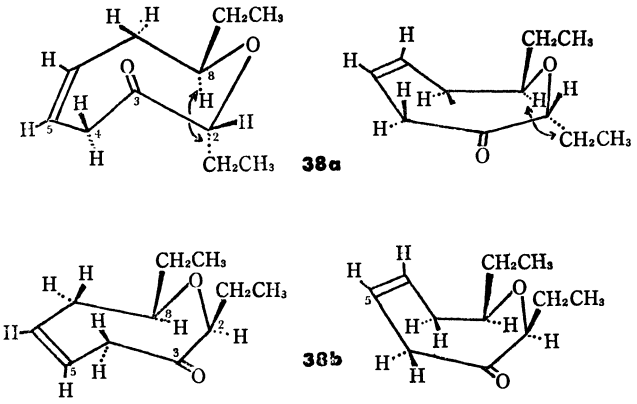


36a **36b**



37a *trans*
37b *cis*

The NMR spectra of these isomers (**38a** and **38b**) indicated a noteworthy difference concerning the C_4-protons. The protons of the latter (**38b**) appeared at δ 2.78 and 3.82 as two doublets with the same vicinal coupling constants of 6 Hz ($J_{4,5}$), while those of the former (**38a**) at δ 2.93 and 3.52 as two double doublets with different vicinal coupling constants ($J_{4,5}$) of 3 and 2 Hz. If the Karplus equation[36] held for the constants in question, the observed values suggested that the dihedral angles between the C_4- and C_5-protons would become about 30° and 150° in the *cis*-isomer (**38b**), and the corresponding angles about 65° and 55° in the *trans*-isomer (**38a**). These angles implied that the olefinic proton at C_5 in *cis*-isomer (**38b**) would be located in the outer side of two planes formed by the two carbon at C_4 and C_5 and each of two hydrogen atoms at C_4 and that in *trans*-isomer (**38a**) in the inner side of the planes. On the other hand, the two ethyl groups would reasonably be oriented towards the outer side of the ring in each of the isomers so as to decrease the possible serious steric interaction. Examination of



38a **38b**

Fig. 1.

the Dreiding model, considering these dispositions as well as the UV intensities, indicated that only two forms as shown in Fig. 1 were possible as plausible conformations for each of the *trans*- and *cis*-hydrooxocinones (**38a** and **38b**). These conformations suggested that the *trans*-ketone (**38a**) would be less stable than the *cis*-ketone (**38b**), because the α-ethyl group in either one of **38a** (Fig. 1) would be disposed 1,3-*syn*-axially to the α-oriented α-hydrogen to the oxygen atom. As expected, the *trans*-ketone (**38a**) was readily epimerized to the *cis*-isomer (**38b**) by treatment with base (5% KOH in ethanol, room temperature, 20 min) almost quantitatively. This isomerization was most valuable for further investigations, because the two side chains at C_2 and C_8 of laurencin (**1**) possesses the *cis*-configuration.

Reduction of *cis*-diethylhydrooxocin (**38b**) with sodium borohydride produced a mixture of alcohols, from which epimeric alcohols (**39** and **40**) were isolated after chromatography in 50 and 15% yields, respectively. These alcohols (**39** and **40**) displayed characteristic peaks due to one of the C_4-protons and the C_3-proton in the NMR spectra; the major alcohol (**39**) showed a double doublet (J=8 and 12 Hz) and a multiplet at δ 2.63 and 3.68, and the minor alcohol (**40**) a double doublet (J=3, 7 and 13 Hz) and a double triplet (J= 3, 3 and 9 Hz) at δ 2.81 and 3.75, respectively. The observed signal patterns in the latter (**40**), apart from the chemical shifts, were completely superimposable over those of the corresponding protons (C_4- and C_3-protons) in laurencin (**1**), indicating that the minor alcohol (**40**) possessed the same relative configuration as to the three substituents as **1**, while the major alcohol (**39**) took the different configuration only at the carbon atom bearing the hydroxy group.

The major alcohol (**39**) was then treated with carbon tetrabromide and triphenylphospine to give bromohydrooxocin (**2**), oil, as an only isolable product in moderate yield, which showed a pair of molecular ion peaks at *m/e* 248 and 246 in the mass spectrum. Since this bromination usually proceeds in S_N2 manner,[37] the C_3-configuration of **2** was expected to be inverted. In fact, compound **2** revealed a clear, double triplet with coupling constants of 3, 3 and 9 Hz at δ 4.05 due to the C_3-proton, though the C_4-proton in question near δ 3.15 was not discernible as a separate peak owing to overlap with the C_2- and C_8-protons. Thus, bromodiethylhydrooxocin (**2**) took the same relative

configuration concerning the three substituents at C_2, C_3 and C_8 as the aimed natural compound, laurencin (**1**).

40

Experimental

All the mps and bps were uncorrected. The homogenity of each compound was always checked by tlc over silica gel (Wakogel B-5) and/or by glc (Hitachi K-53) over 10% SE-30. Column chromatographies were carried out over silicic acid (Merck, Kieselgel 60 or Mallinckrodt, silicic acid 100 Mesh). The UV and IR spectra were measured in ethanol and carbon tetrachloride, respectively, unless otherwise stated. The NMR spectra were obtained in carbon tetrachloride, unless otherwise stated, at 100 MHz, and the chemical shifts were given in δ-values, TMS being used as an internal standard. The abbreviations "s, d, t, q, qui, m, br, and do" in the NMR spectra denote "singlet, doublet, triplet, quartet, quintet, multiplet, broad, and double," respectively.

*(E)-Undec-8-en-1-yn-3-ol (**9**).* A stirred solution of hex-1-yn-4-ol[13] (**7**, 5.5 g) in anhydrous ether (50 ml) was mixed with ethyl magnesium bromide, prepared from ethyl bromide (13 g) and magnesium turnings (2.8 g) in ether (90 ml), and refluxed until evolution of ethane ceased. To the mixture cooled at 0 °C were added *trans*-pent-2-enyl bromide[15] (**8**) (9.4 g) and anhydrous cuprous chloride (0.6 g).[14] The whole mixture was refluxed for 2.5 hr, then stirred at room temperature for 14 hr and, after being cooled, treated with aqueous saturated ammonium chloride. After separation of the ether layer, the aqueous layer was extracted with ether repeatedly. All the ether solutions were combined, washed with 1 M hydrochloric acid, 5% aqueous sodium bicarbonate and water, dried over sodium sulfate, and evaporated to leave oil, which was distilled to give **9** (6.12 g), bp 111—114 °C/20 mmHg; IR, ν_{max} 3540, 2200, 1061, and 967 cm^{-1}; NMR (CCl_4 and D_2O), δ 0.93 and 0.98 (total 6H, each t J=7 Hz, $2CH_2CH_3$), 1.49 and 2.02 (each 2H, qui J=7 Hz, CH_2 at C_2 and C_{10}), 2.28 and 2.82 (each 2H, m, CH_2 at C_4 and C_7), 3.55 [1H, qui J=6.5 Hz, CH(OH)], 5.30 and 5.64 (each 1H, do t, J=14, 5, 5 and 14, 7, 7 Hz, CH=CH). Found: C, 79.35; H, 10.68%. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.92%.

The acetate (**9a**) was prepared quantitatively by treatment of **9** (0.1 g) with acetic anhydride (1.0 ml) and pyridine (1.0 ml) at room temperature overnight; IR ($CHCl_3$), ν_{max} 1730, 1021, and 965 cm^{-1}; NMR, δ 1.97 (3H, s, $OCOCH_3$), and 4.72 [1H, qui, J=6.5 Hz, $CH(OCOCH_3)$].

*(5Z,8E)-Undeca-5,8-dien-3-ol (**6**).* Hydrogenation of **9** (1.0 g) was carried out over Lindlar catalyst[16] (1.5 g) at room temperature in ethanol and ceased after 1.5 hr, when 150 ml of hydrogen (1.0 mol) had been consumed. After removal of the catalyst and solvent, the residue was dissolved in dichloromethane, washed with saturated sodium chloride and water, dried and evaporated to dryness to give **6** (1.0 g); IR, ν_{max} 3570, 3470, 1015, and 968 cm^{-1}, NMR (CCl_4 and D_2O), δ 0.93 and 0.97 (total 6H, each t J=6.5 Hz, $2CH_2CH_3$), 1.41 (2H, qui J=6.5 Hz, CH_2 at C_2), 1.96 (2H, m, CH_2 at C_{10}), 2.16 (2H, t J=6.5 Hz, CH_2 at C_4), 2.73 (2H, br t J=4.5 Hz, CH_2 at C_7), 3.45 [1H, qui J=6.5 Hz, CH(OH)], and 5.38 [4H, m, 2(CH=CH)]. Found: C, 78.78; H, 11.80%. Calcd for $C_{11}H_{20}O$: C, 78.51; H, 11.98%.

*(Z)-8,9-Epoxyundec-5-en-3-ol (**11**).* To a solution of **9** (2.5 g) in chloroform (60 ml) was added perbenzoic acid (3.0 g) at 0 °C, and the solution was allowed to stand in a refrigerator for 20 hr. The reaction mixture was worked up as usual to yield 8,9-epoxyundec-5-yn-3-ol (**10**, 2.7 g); IR ($CHCl_3$), ν_{max} 3420, 974, 939, 908, and 878 cm^{-1}; NMR ($CDCl_3$ and D_2O), δ 0.94 and 0.99 (total 6H, each t J=7 Hz, $2CH_3CH_2$), 1.57 and 1.60 (total 4H, each qui J=6.5 Hz, $2CH_3CH_2$), 2.40 (4H, m, $2CH_2$ at C_4 and C_7), 2.84 (2H, m, 2CH at C_8 and C_9), 3.62 [1H, qui J=6.5 Hz, CH(OH)]. Found: C, 71.35; H, 11.16%. Calcd for $C_{11}H_{20}O_2$: C, 71.59; H, 10.94%.

Compound **10** (1.4 g) was hydrogenated over Lindlar catalyst (2.3 g) in the same manner as **9** and afforded **11** (1.35 g); IR, ν_{max} 3440, 974, and 888 cm^{-1}; NMR (CCl_4 and D_2O), δ 0.92 and 0.96 (total 6H, each t J=6 Hz, $2CH_3CH_2$), 1.42 (4H, m, $2CH_3CH_2$), 2.22 (4H, m, $2CH_2$ at C_4 and C_7), 2.62 (2H, m, 2CH at C_8 and C_9), 3.43 [1H, qui J=6 Hz, CH(OH)], and 5.48 (2H, m, CH=CH). Found: C, 70.68; H, 12.16%. Calcd for $C_{11}H_{22}O_2$: C, 70.92; H, 11.90%.

*8,9-Epoxyundecan-3-ol (**12**).* Compound **11** (320 mg) in ethanol (10 ml) was hydrogenated over Adams platinum (105 mg as $PtO_2 \cdot H_2O$) at room temperature. The reaction was ceased after 1.5 hr, when 44 ml of hydrogen (1.0 mol) had been absorbed. After being worked up as usual, the reaction mixture gave **12** (330 mg); IR ($CHCl_3$), ν_{max} 3590, 3430, 960, and 893 cm^{-1}. Found: C, 69.88; H, 12.68%. Calcd for $C_{11}H_{24}O_2$: C, 70.16; H, 12.85%.

*Undeca-4,6-diene-3,8-diol (**13**).* A solution of **11** (60 mg) in a mixture of dimethyl sulfoxide (DMSO, 20 ml), potassium hydroxide (1 g) and water (10 ml) was heated at 155—160 °C for 3 hr. After being cooled, the reaction mixture was poured onto ice and extracted with chloroform repeatedly. The chloroform extracts were washed with 2 M hydrochloric acid, 5% aqueous sodium bicarbonate and saturated aqueous sodium chloride, dried over magnesium sulfate and evaporated to give **13** (53 mg); IR, ν_{max} 3530, 3370, 1055, 990, and 951 cm^{-1}, which was treated with acetic anhydride (0.6 ml) and pyridine (0.6 ml) at room temperature for 4.5 hr to yield the diacetate (**13a**, 56 mg); UV, λ_{max} 231 nm (ε 15600); IR, ν_{max} 1736, 1224, and 1007 cm^{-1}; NMR, δ 0.90 and 0.92 (total 6H, each t J=6.5 Hz, $2CH_3CH_2$), 1.58 (4H, br m, $2CH_3CH_2$), 1.97 and 2.01 (total 6H, each s, $2CH_3COO$), 2.41 (2H, br t J=6.5 Hz, CH_2 at C_4), 4.77 and 5.28 [each 1H, qui and q J=6.5 Hz, $2CH(OCOCH_3)$], and 4.30 (4H, m, 2CH=CH). Found: C, 66.86; H, 9.11%. Calcd for $C_{15}H_{24}O_4$: C, 67.13; H, 9.02%.

*Undecane-3,4,9-triol (**14**).* Compound **12** (200 mg) was treated with the afore-mentioned alkaline DMSO solution (45 ml) in the same manner as **11**. The reaction mixture was worked up as usual to leave oily residue, which showed a practically single spot on tlc and crystallized on trituration with ether. The crystalline material was recrystallized from ether-hexane to give **14** (45 mg), mp 91—93 °C; IR (Nujol), ν_{max} 3280, 1072, and 969 cm^{-1}. Found: C, 64.80; H, 11.68%. Calcd for $C_{11}H_{24}O_3$: C, 64.71; H, 11.76%.

The triacetate (**14a**) showed the following spectra; IR ($CHCl_3$), ν_{max} 1723 cm^{-1}; NMR, δ 0.88 and 0.90 (total 6H, each t J=7 Hz, $2CH_3CH_2$), 1.45 (12H, br m, $6CH_2$), 2.03 (9H, s, $3CH_3COO$), and 4.85 [3H, br m, $3CH(OCOCH_3)$].

*Treatment of **11** with Sodium Methoxide.* Compound **11** (115 mg) was refluxed in a methanol solution containing sodium methoxide, prepared from sodium (345 mg) and methanol (15 ml), for 18 hr. The mixture was worked up as usual to give oil, which showed a single spot on tlc and

was identified as unsaturated methoxyglycols (**15**) on the spectral data; IR, ν_{max} 3420 and 1100 cm^{-1}; NMR (CCl_4 and D_2O), δ 0.93 (6H, t J=7 Hz, $2C\underline{H}_3CH_2$), 1.45 (4H, br m, $2CH_3C\underline{H}_2$), 2.18 (4H, br m, $2C\underline{H}_2CH{=}CH$), 3.33 (3H, s, $C\underline{H}_3O$), 3.52 (3H, br, 3C$\underline{H}$ at C_3, C_4 and C_9), and 5.48 (2H, m, C$\underline{H}$=C$\underline{H}$).

Treatment of ***11*** *with* p-*Toluenesulfonic Acid.* A solution of **11** (400 mg) in dry benzene (35 ml) containing *p*-toluenesulfonic acid (38 mg) was refluxed for 20 hr and, after being cooled, washed with a 5% sodium bicarbonate solution, dried and evaporated to leave oil (380 mg), which was found to consist of two components by tlc. The oil was separated into two fractions by chromatography over silicic acid (Mallinckrodt, 10 g) with a 3 : 1 mixture of benzene and ethyl acetate. The more polar fraction (197 mg) was identical with the unreacted starting epoxide **11**, and the less polar was identified as undecenetriol monotosylate(s) (**17**, 87 mg); IR, ν_{max} 3360, 1188, and 1176 cm^{-1}; NMR, δ 0.92 (6H, t J= 6.5 Hz, $2C\underline{H}_3CH_2$), 1.32 and 2.06 (4H and 2H, br, $3C\underline{H}_2$), 2.43 (3H, s, $C\underline{H}_3C_6H_4$), 3.50 [2H, m, 2C$\underline{H}$(OH)], 4.40 [1H, m, C$\underline{H}(OSO_2)$], 4.61 (2H, br s, 2O$\underline{H}$), 5.43 (2H, br, C$\underline{H}$=C$\underline{H}$), and 7.25 and 7.75 (each 2H, ABq J=8.5 Hz, $C_6\underline{H}_4$).

*The Robinson-Schöpf Condensation of 2-Hydroxybutyraldehyde (****21****) Followed by Acid Treatment.* The aldehyde (**21**) was prepared from the dimethyl acetal[17]; IR, ν_{max} 3600, 3490, 1079, 1062, and 970 cm^{-1}; NMR, δ 0.93 (3H, t J=7 Hz), 2.40 (1H, br s, disappeared on addition of D_2O), 3.32 and 3.37 (each 3H, s), and 4.03 (1H, d J=6 Hz), and was used for the next reaction without isolation. A solution of the acetal (13.5 g) in acetic acid (2.5 ml) and water (10 ml) was refluxed for 50 min and, after being cooled, poured into an aqueous solution (125 ml) containing anhydrous disodium phosphate (14.6 g) and citric acid (9.4 g). After addition of methylamine hydrochloride (6.1 g) and acetonedicarboxylic acid (14.6 g), the solution was adjusted to pH 5.0 by addition of aqueous sodium hydroxide, then diluted with water to 250 ml of the total volume, and stirred at room temperature for 48 hr. The solution was made acidic and shaken with dichloromethane to remove neutral and acidic substances. The acidic solution was made strongly basic and extracted with dichloromethane repeatedly. The dichloromethane solutions were combined and evaporated to leave dark brown oil, which was mixed with 20% sulfuric acid (20 ml). The mixture was refluxed for 2 hr, cooled, made basic, and again extracted with dichloromethane. The extracts were dried and evaporated to leave brown oil (3.9 g), which was chromatographed over silicic acid (Mallinckrodt, 100 g), using benzene–ethyl acetate (6 : 1). Several fractions gave crystalline material, which on recrystallization from hexane yielded undecane-3,6,9-trione (**24**) (0.34 g), mp 78—80 °C; IR ($CHCl_3$), ν_{max} 1714 cm^{-1}; NMR ($CDCl_3$), δ 1.05 (6H, t J= 7 Hz), 2.47 (4H, q J=7 Hz), and 2.70 (8H, s). Found: C, 66.62; H, 9.03%. Calcd for $C_{11}H_{18}O_3$: C, 66.67; H, 9.09%.

Compound **24** (55 mg) in dry methanol (10 ml) was reduced with sodium borohydride (100 mg) at 0 °C for 35 min and afforded oily alcohol (64 mg), which was treated with acetic anhydride (1.0 ml) and pyridine (1.5 ml) at room temperature overnight to give undecane-3,6,9-triol triacetate (88 mg), oil; IR, ν_{max} 1741, 1247, and 1018 cm^{-1}; NMR ($CDCl_3$), δ 0.88 (6H, t J=7 Hz), 2.02 (9H, s), and 4.81 (3H, m W_H=14 Hz). Found: C, 61.58; H, 9 02%. Calcd for $C_{17}H_{30}O_6$: C, 61.79; H, 9.15%. The triacetate (78 mg) was hydrolyzed with 5% potassium hydroxide in refluxing methanol (45 min) to give the triol (50 mg), which was reconverted into **24** (37 mg), mp 78—79 °C, by oxidation with Jones reagent (0.5 ml) in acetone (8 ml) at 0 °C for 1.75 hr.

trans- *and* cis-*2,5-Diethyl-2,5-dihydrofurans (****25****).* To a solution of freshly distilled furan (42 g) in ether (800 ml) cooled at −45 °C was dropwise added bromine (28 ml), and the solution was stirred at the temperature for 10 min. To the solution was added the Grignard reagent, prepared from ethyl bromide (210 g) and magnesium turnings (40.0 g) in ether (1000 ml), under stirring at such a rate that the temperature did not exceed −10 °C, and the whole mixture was kept at room temperature overnight. After careful addition of water under cooling to decompose excess of the Grignard reagent, the ether layer was separated, and the aqueous layer was extracted with ether. The ether solutions were combined, washed with water, dried and evaporated to leave oily residue, which was distilled to give **25** (25.0 g), bp 51—54 °C (35 mmHg); δ 0.88 (6H, t J=7 Hz), 1.50 (4H, m), 4.65 (2H, m), and 5.70 (2H, s). Found: C, 76.36; H, 11.02%. Calcd for $C_8H_{14}O$: C, 76.14; H, 11.18%.

trans- *and* cis-*2,4-Diethyl-9-methyl-9-aza-3-oxabicyclo[3.3.1]-nonan-7-ones (****19a*** *and* ***19b****).* Into a solution of **25** (11.0 g) in ethyl acetate (350 ml) cooled at −78 °C was bubbled ozone, until the solution became purplish. The solution was treated with potassium iodide and then with aqueous sodium thiosulfate at room temperature. The acetate solution was separated and the aqueous layer was extracted with ethyl acetate. The ethyl acetate solutions were combined, washed with water, dried and evaporated to leave crude 2,4-diethyl-3-oxaglutaraldehydes (**20**) (9.6 g), IR ($CHCl_3$), ν_{max} 1730 cm^{-1}, which were used for the next reaction without further purification.

To an aqueous solution (100 ml) containing anhydrous disodium phosphate (14.6 g) and citric acid (9.4 g) were added the crude aldehydes (**20**) (9.6 g), methylamine hydrochloride (6.1 g) and acetonedicarboxylic acid (14.6 g). The whole solution was adjusted to pH 5.0 by addition of conc sodium hydroxide solution, diluted with water to 250 ml of the total volume, and then stirred at room temperature for 43 hr. The reaction mixture, after being made acidic, was washed with ether, made basic and then extracted with chloroform repeatedly. The chloroform solutions afforded dark brown oil (8.4 g), which was separated by chromatography over alumina (Merck, 200 g), using benzene, benzene–ether (2 : 1, 1 : 1 and 1 : 2) and ether, successively. Fractions eluted with benzene and benzene–ether (2 : 1 and 1 : 1) gave oily (4.6 g) and crystalline bases (4.2 g), showing the same single spot on tlc. The latter was recrystallized twice from hexane to yield **19a** (2.5 g), mp 89—90 °C; Mass, *m/e* 211 (M^+) and 110 (base); IR (Nujol), ν_{max} 1705, 1164, 1059, 983, 908 and 843 cm^{-1}; NMR (Table 1). Found: C, 68.47; H, 10.29; N, 6.60%. Calcd for $C_{12}H_{21}O_2N$: C, 68.21; H, 10.02; N, 6.63%.

The remaining bases (1.7 g), obtained on the recrystallizations, were combined with the oily bases (4.6 g) and reduced with LAH (2.3 g) in ether (300 ml) at room temperature overnight and, after being worked up as usual, afforded a mixture of alcohols (6.3 g). These alcohols were separated into three fractions, more polar (0.5 g), middle (main **26b**, 1.8 g) and less polar fractions (main **26a**, 3.6 g), by preparative tlc (80 plates) over silica gel (Wakogel B-5), using ethanol as solvent; each plate was made of the gel (10 g) with area of 20×20 cm. The middle fractions (1.8 g) were oxidized with chromium trioxide (2.8 g), celite (4.5 g) and pyridine (4.5 ml) in dichloromethane (75 ml) at room temperature for 15 min. After removal of the celite by filtration, the dichloromethane solution was evaporated to leave oily residue, which was dissolved in chloroform and then extracted with dil hydrochloric acid. The acidic solution, after being

made basic, was extracted with chloroform repeatedly. The chloroform solution was washed with water, dried and evaporated to give crystalline substance, which on recrystallization from hexane yielded **19b** (1.0 g), mp 86—88 °C; Mass, *m/e* 211 (M^+) and 110 (base); IR (Nujol), ν_{max} 1714, 1167, 1026, 973, 917, and 853 cm^{-1}; NMR (Table 1). Found: C, 68.32; H, 10.20; N, 6.60%. Calcd for $C_{12}H_{21}O_2N$: C, 68.21; H, 10.02; N, 6.63%. The less polar fractions (3.6 g) were oxidized under the same conditions as mentioned above to give **19a** (1.9 g), mp 89--90 °C.

trans-*2,4-Diethyl-9-formyl-9-aza-3-oxabicyclo[3.3.1]nonan-7-one (27a).* A solution of the crude *trans*-alcohol (main **26a**, 0.97 g) in pyridine (30 ml) was treated with chromium trioxide (3.0 g) at room temperature overnight and poured into ice-water. After being worked up as usual, the reaction mixture gave crude amide (0.88 g), which was purified by chromatography over silicic acid to yield **27a** (0.63 g), oil; Mass, *m/e* 225 (M^+); IR ($CHCl_3$), ν_{max} 1722 and 1663 cm^{-1}; NMR ($CDCl_3$), δ 8.12 and 8.26 (each s, total 1H).

trans-*2,4-Diethyl-9-methyl-9-aza-3-oxabicyclo[3.3.1]nonanes (34a).* A solution of **19a** (5.55 g) in ether (50 ml) was refluxed with LAH (2.0 g) for 16 hr. After addition of water, the resulting precipitate was removed by filtration and washed with ether. The filtrate was separated into aqueous and ether layers, and the aqueous layer was extracted with ether. All the ether solutions were combined, washed with water, dried and evaporated to give an epimeric alcohol mixture (main **26a**, 5.55 g), oil; Mass, *m/e* 213 (M^+) and 112 (base); IR, ν_{max} 3410, 1123, 1074, 1024, and 947 cm^{-1}; NMR, δ 0.92 (6H, t J=7 Hz, $2CH_2C\underline{H}_3$), 2.41 (3H, s, $NC\underline{H}_3$), 3.57, 3.71 and 3.64 (total 3H, do d J=6 and 9 Hz, do do d J=2, 5 and 8 Hz, and br, 3H at C_2, C_4 and C_7, respectively), 4.87 and 5.00 (total 1H, each s, O$\underline{H}$).

To the alcohol mixture (4.75 g) cooled in glacial acetic acid (1.87 g) was added dropwise conc sulfuric acid (6.11 g). The mixture was heated at 150 °C for 2.5 hr, cooled and poured into ice-water. The aqueous solution was made basic and filtered to remove a small amount of tarry substance. The filtrate was extracted with chloroform, and the chloroform solution gave **34a** (4.13 g), oil; Mass, *m/e* 195 (M^+) and 94 (base); IR, ν_{max} 1125, 1067, and 980 cm^{-1}; NMR, δ 0.87 (3H, t J=6 Hz, $2CH_2C\underline{H}_3$), 2.23 (3H, s, $NC\underline{H}_3$), 3.40 (2H, complex m, 2H at C_2 and C_4), 5.40 and 5.80 (each 1H, m, C$\underline{H}$=C$\underline{H}$). Found: C, 73.98; H, 10.55; N, 7.30%. Calcd for $C_{12}H_{21}ON$: C, 73.79; H, 10.84; N, 7.17%.

cis-*2,4-Diethyl-9-methyl-9-aza-3-oxabicyclo[3.3.1]non-6-ene (34b).* A solution of **19b** (0.50 g) in ether (20 ml) was reduced with LAH (0.30 g) at room temperature for 17 hr. After being worked up as usual, the solution gave an epimeric alcohol mixture (main **26b**, 0.50 g), oil; Mass, *m/e* 213 (M^+) and 112 (base); IR, ν_{max} 3360, 1133, 1116, 1026, and 951 cm^{-1}; NMR, δ 0.91 (6H, t J=7 Hz, $2CH_2C\underline{H}_3$), 2.44 (3H, s, $NC\underline{H}_3$), 3.51 (2H, t J=7 Hz, 2H at C_2 and C_4), 3.30 and 3.75 (total 1H, each br, H at C_7), 4.92 and 5.04 (total 1H, each br s, O$\underline{H}$).

The alcohol mixture (0.50 g) was treated with conc sulfuric acid (0.60 g) and glacial acetic acid (0.20 g) at 160 °C for 2 hr. The mixture gave oily olefin (**34b**) (0.41 g); Mass, *m/e* 195 (M^+) and 94 (base); IR ($CHCl_3$), ν_{max} 1120, 1085, and 1050 cm^{-1}; NMR ($CDCl_3$), δ 0.94 (6H, t J=7 Hz, $2CH_2C\underline{H}_3$), 2.43 (3H, s, $NC\underline{H}_3$), 2.98 (1H, do d J=6 and 10 Hz, H at C_2 or C_4), 3.17 (1H, do t J=2, 7.5 and 7.5 Hz, H at C_4 or C_2), 5.64 and 5.72 (each 1H, ABq J=11 Hz, C$\underline{H}$=C$\underline{H}$). Found: C, 74.02; H, 10.83; N, 7.28%. Calcd for $C_{12}H_{21}ON$: C, 73.79; H, 10.84; N, 7.17%.

trans- *and* cis-*2,4-Diethyl-9-methyl-9-aza-3-oxabicyclo[3.3.1]nonanes (33a and 33b).* A mixture of olefins (**34a**) (0.41 g) was hydrogenated over platinum (0.20 g as $PtO_2 \cdot H_2O$) in ethanol at room temperature for 1 hr, when 48 ml of hydrogen (1 mol) had been consumed. After removal of the catalyst, the mixture was evaporated, diluted with water, and extracted with chloroform. The chloroform solution was washed with water, dried and evaporated to give **33a** (0.40 g), oil; Mass, *m/e* 197 (M^+) and 96 (base); IR, ν_{max} 1180, 1066, and 862 cm^{-1}; NMR, δ 0.85 and 0.88 (total 6H, each t J=7 Hz, $2CH_2C\underline{H}_3$), 2.46 (3H, s, $NC\underline{H}_3$), 3.46 (1H, do d J=6 and 9 Hz, H at C_4 or C_2), and 3.68 (1H, do do d J=2.5, 6 and 8 Hz, H at C_2 or C_4).

Compound **34b** (60 mg) was hydrogenated over platinum (50 mg) in ethanol (10 ml) at room temperature for 17 hr, when 7 ml of hydrogen (1 mol) had been absorbed. The mixture afforded **33b** (43 mg), oil; Mass; *m/e* 197 (M^+) and 96 (base); IR, ν_{max} 1066 and 1036 cm^{-1}; NMR, δ 0.92 (6H, t J=7.5 Hz, $2CH_2C\underline{H}_3$), 2.57 (3H, s, $NC\underline{H}_3$), and 3.14 (2H, do t J=4, 7 and 7 Hz, 2H at C_2 and C_4).

trans- *and* cis-*2,4-Diethyl-9,9-dimethyl-9-azonia-3-oxabicyclo-[3.3.1]nonene Iodides (35a and 35b).* A *trans*-olefin mixture (**34a**, 3.64 g) was treated with methyl iodide (10 ml) in refluxing ethanol (40 ml) for 2 hr. The mixture was evaporated to leave crude methiodides (6.14 g), which crystallized on trituration with ether and were recrystallized from acetone–isopropyl ether to give **35a** (5.58 g) mp 179—182 °C; Mass, *m/e* 195 ($M^+ - CH_3I$), 142 (CH_3I), and 94; IR (Nujol), ν_{max} 1110, 1076, 998, and 914 cm^{-1}; NMR ($CDCl_3$), too complex to be interpreted. Found: C, 46.10; H, 7.28; N, 4.10%. Calcd for $C_{13}H_{24}ONI$: C, 46.26; H, 7.12; N, 4.15%.

A solution of *cis*-olefin (**34b**, 0.35 g) in ethanol (20 ml) was refluxed with methyl iodide (5 ml) to give crude methiodide (0.60 g), which crystallized on trituration with ether and was recrystallized from acetone–isopropyl ether to yield **35b** (0.52 g), mp 190—191 °C; Mass, *m/e* 195 (M^+—CH_3I), 142 (CH_3I), and 94 (base); IR (Nujol), ν_{max} 1135, 1112, 1078, 1030, and 993 cm^{-1}; NMR ($CDCl_3$), δ 1.00 and 1.04 (total 6H, each t J=7 Hz, $2CH_2C\underline{H}_3$); 3.50 and 3.73 (each 3H, s, $2NC\underline{H}_3$), 3.90 (1H, br t J=6 Hz, H at C_2 or C_4), 4.52 (1H, br s, W_H=7 Hz, H at C_4 or C_2), 5.90 and 5.93 (each 1H, ABq J=10 Hz, C$\underline{H}$=C$\underline{H}$). Found: C, 46.15; H, 7.26; N, 4.20%. Calcd for $C_{13}H_{24}ONI$: C, 46.26; H, 7.12; N, 4.15%.

trans- *and* cis-*2,8-Diethyl-3-dimethylamino-3,8-dihydro-2H-oxocins (36a and 36b).* An aqueous solution of **35a** (765 mg) was eluted through a column of Amberlite IRA-400 (hydroxide form). The alkaline eluate was evaporated below 45 °C under reduced pressure (below 15 mmHg) to leave the quarternary methoxide (**36a**), which was decomposed by heating at 45—50 °C under nitrogen (15 mmHg) for 10 min. The resulting liquid was extracted with ether, dried and evaporated to give **36a** (403 mg), oil; Mass, *m/e* 209 (M^+); IR, ν_{max} 1130, 1100, 1082, 1036, 1008, and 686 cm^{-1}; NMR δ 0.89 and 0.95 (total 6H, each t J=7 Hz, $2CH_2C\underline{H}_3$), 1.51 (4H, m, $2C\underline{H}_2CH_3$), 2.16 (6H, s, $2NC\underline{H}_3$), 3.31 (2H, m, 2H at C_2 and C_3), 4.18 (1H, br m, H at C_8), 5.22 (1H, do d J=3 and 12 Hz, H at C_4), 5.68 (2H, m, 2H at C_5 and C_6), and 6.06 (1H, do d J=5 and 12 Hz, H at C_7).

Compound **35b** (310 mg) was treated in the same manner as **35a** and afforded **35b** (159 mg), oil; Mass, *m/e* 209 (M^+); IR ($CHCl_3$), ν_{max} 1117, 1108, 1060, 1041, and 1016 cm^{-1}; NMR ($CDCl_3$), δ 0.99 and 1.02 (total 6H, each t J=7 Hz, $2CH_2C\underline{H}_3$), 1.54 (4H, m, $2C\underline{H}_2CH_3$), 2.20 (6H, s, $2NC\underline{H}_3$), 3.34 (1H, br do d J=5 and 7.5 Hz, H at C_3), 3.57 (1H, br do d J=2, 5 and 10 Hz, H at C_2), 4.03 (1H, br t J=7 Hz, H at C_8), 5.36 (1H, do d J=2 and 12 Hz, H at C_7), 5.46 (1H, do d J=7.5 and 12 Hz, H at C_4), 5.66 (1H, br do d J=5 and 12 Hz, H at C_5), and 6.04 (1H, br do d J=5 and 12 Hz,

H at C_6).

*trans- and cis-2,8-Diethyl-3-dimethylamino-7,8-dihydro-2H-oxocins (**37a** and **37b**).* Compounds **36a** (1.40 g) were heated at 120—125 °C (bath temperature) for 15 min under nitrogen to give a 4 : 6 mixture (1.40 g) of unidentified product(s) (**38**) and **37a**. The ratio was estimated by comparison of the signals due to dimethylamino groups in the NMR spectrum of the whole reaction product with that in the spectrum of **38**, which remained unchanged as basic component(s) in the next transformation of **37a** to **38a**. Treatment of **36a** under other conditions [heating at 105 °C for 2 hr, heating at 145 °C for 2 min, or distillation *in vacuo* (15 mmHg) at 110 °C (each bath temperature)] did not increase the yield of **37a**. Compound **37a** showed the following spectra; IR, ν_{max} 1603 and 1063 cm^{-1}; NMR, δ 0.82 and 0.90 (total 6H, each t J=7 Hz, $2CH_2C\underline{H}_3$), 1.36 (4H, complex m, $2C\underline{H}_2CH_3$), 2.30 (2H, m, 2H at C_7), 2.56 (6H, s, $2NC\underline{H}_3$), 2.65 (1H, m, H at C_8), 4.36 (1H, t J=7 Hz, H at C_2), 4.98 (1H, d J=5 Hz, H at C_4), 5.38 (1H, do d J=5 and 12 Hz, H at C_5), and 5.82 (1H, do do d J=2, 4.5 and 12 Hz, H at C_6). The whole product was used in the next reaction without further purification.

Compound **36b** (750 mg) was heated at 70—80 °C (bath temperature) for 20 min under nitrogen to give a 1 : 1 mixture (750 mg) of **36a** and **37b**. However, **36b** (750 mg) when heated at 120—125 °C for 10 min, afforded **37b** (750 mg), as a sole product, as far as the product was examined by tlc and NMR. This dienamine (**37b**) was characterized by the following spectra and used for the next reaction without further purification: IR, ν_{max} 1603 and 1043 cm^{-1}; NMR ($CDCl_3$), δ 0.86 and 0.93 (total 6H, each t J=7 Hz, $2CH_2C\underline{H}_3$), 1.60 (4H, complex m, $2C\underline{H}_2CH_3$), 2.30 (2H, m, 2H at C7), 2.57 (6H, s, $2NC\underline{H}_3$), 2.86 (1H, br do do d J=6, 6 and 8 Hz, H at C_8), 3.60 (1H, do d J=6.5 and 9 Hz, H at C_2), 5.02 (1H, d J=4.5 Hz, H at C_4), 5.76 (1H, m, H at C_6), and 6.13 (1H, br do d J=4.5 and 12 Hz, H at C_5).

*trans-2,8-Diethyl-7,8-dihydro-2H-oxocin-3(4H)-one (**38a**).* An aqueous solution (14 ml) containing **37a** (1.40 g) and 7% fluoroboric acid (2.8 ml) was refluxed for 15 min, cooled, neutralized with aqueous sodium carbonate, and extracted with ether (100 ml) and then with dichloromethane (2×100 ml). The organic solutions were combined, dried and evaporated to leave oil (860 mg), which was dissolved in ether. The ether solution was shaken with 1 M hydrochloric acid to separate neutral (540 mg) and basic components (**38**, 320 mg). A part (470 mg) of the neutral substance, showing a single spot on tlc, was purified by chromatography over silicic acid (Merck, 20 g) with a 25 : 1 mixture of benzene and ethyl acetate to yield **38a** (307 mg) in pure state, oil; Mass, *m/e* 182 (M^+), 153, 96, and 81 (base); UV (isooctane), λ_{max} 295 nm (ε 96) (sh), 305 (108), 313 (76), and 325 (50) (sh); IR (film), ν_{max} 1717, 1660, 1120, 1089, 1081, 1048, and 1005 cm^{-1}; NMR ($CDCl_3$), δ 0.96 and 1.00 (6H, each t J=7 Hz, $2CH_2C\underline{H}_3$), 1.58 (2H, m, $C\underline{H}_2CH_3$ at C_8), 1.64 (2H, qui J=7 Hz, $C\underline{H}_2CH_3$ at C_2), 2.05 (2H, m, 2H at C_7), 2.93 and 3.52 (each 1H, do d J=16, 3 and 16 and 2 Hz, 2H at C_4), 3.70 (1H, m, H at C_8), 3.86 (1H, t J=7 Hz, H at C_2), and 5.63 (2H, m, 2H at C_5 and C_6). Found: C, 72.64; H, 9.95%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

*cis-2,8-Diethyl-7,8-dihydro-2H-oxocin-3(4H)-one (**38b**).* A solution of **37b** (700 mg) and 7% fluoroboric acid (1.5 ml) in water (7 ml) was refluxed for 15 min, cooled and then worked up as usual to leave oil (608 mg), showing a single spot. The oil was purified by chromatography in the same way as **37a**, giving **38b** (470 mg) in pure state, oil; Mass, *m/e* 182 (M^+), 153, 96, and 81 (base); UV (isooctane), λ_{max} 294 (ε 142) (sh), 303 (162), 313 (156), and 324 nm (90); IR (film), ν_{max} 1718, 1641, 1120, 1108, 1091, 1068, and 1013 cm^{-1}; NMR ($CDCl_3$), δ 0.99 (6H, t J=7 Hz, $2CH_2C\underline{H}_3$), 1.62 (4H, m, $2C\underline{H}_2CH_3$), 2.25 (2H, m, 2H, at C_7), 2.77 (1H, do d J=13 and 6 Hz, H at C_4), 3.36 (1H, m, H at C_8), 3.71 (1H, do d J=5 and 7 Hz, H at C_2), 3.82 (1H, do d J=13 and 6 Hz, H at C_4), 5.71 (2H, m, 2H at C_5 and C_6). Found: C, 72.23; H, 9.94%. Calcd for $C_{11}H_{18}O_2$: C, 72.49; H, 9.96%.

A solution of *trans*-ketone (**38a**, 10 mg) in methanol (4 ml) was stirred with base (5% KOH) at room temperature for 20 min, diluted with water (20 ml), and extracted with ether (2×30 ml). The ether solution, after being worked up as usual, gave oil (10 mg), which was identical with *cis*-ketone (**38b**) in all respects (tlc, IR, and NMR). Treatment of **38a** with acid (refluxing 7% HBF_4, 15 min, or *p*-TsOH in dichloromethane, room temperature, 20 hr) proved to give no **38b** by tlc.

*2,8-Diethyl-3,4,7,8-tetrahydro-2H-oxocin-3-ols (**39** and **40**).* Compound **38b** (60 mg) was reduced with sodium borohydride (40 mg) in methanol (10 ml) at 0 °C for 40 min. The reaction mixture was made acidic (pH 4—5) with 2 M hydrochloric acid, concentrated and extracted with ether (2×50 ml). The ether solution was washed with saturated brine, dried and evaporated to leave oil (65 mg), showing two spots on tlc. The oil was separated roughly into three fractions by column chromatography over silica gel (Merck, 2 g, benzene : methanol=9 : 1). Fractions (30 mg) eluted early showed a single spot and gave **39** (30 mg), oil; Mass, *m/e* 155 (M^+-C_2H_5), 137, and 108; IR (film), ν_{max} 3420, 1066, and 1010 cm^{-1}; NMR ($CDCl_3$), δ 0.94 and 0.97 (total 6H, each t J=7 Hz, $2C\underline{H}_3CH_2$), 1.56 (4H, m, $2CH_3C\underline{H}_2$), 2.30 (3H, m, 3H at C_4 and C_7), 2.63 (1H, do d J=8 and 12 Hz, H at C_4), 3.33 (2H, m, 2H at C_2 and C_8), 3.68 (1H, m, H at C_3), and 5.76 (2H, m, 2H at C_5 and C_6). Middle fractions (30 mg) consisted mainly of **39** (tlc). Fractions eluted later showed a single spot on tlc and gave **40** (5 mg), oil; Mass, *m/e* 155 (M^+—C_2H_5), 137, and 108, IR (film), ν_{max} 3400, 1066, and 1011 cm^{-1}; NMR ($CDCl_3$), δ 1.02 (6H, t J=7 Hz, $2C\underline{H}_3CH_2$), 1.58 (4H, m, $2CH_3C\underline{H}_2$), 1.62 (1H, s, O<u>H</u>), 2.30 (3H, m, 3H at C_4 and C_7), 2.82 (1H, do do d J=3, 7 and 13 Hz, H at C_4), 3.32 (2H, m, 2H at C_2 and C_8), 3.75 (1H, do t J=3, 3 and 9 Hz, H at C_3), and 5.88 (2H, m, 2H at C_5 and C_6).

*t-3-Bromo-r-2,c-8-diethyl-3,4,7,8-tetrahydro-2H-oxocin (**2**).* To a stirred solution of alcohol **39** (50 mg) and carbon tetrabromide (135.5 mg) in dichloromethane (4 ml, dried through molecular sieves) was added dropwise a solution of triphenylphosphine (71.3 mg) in dry dichloromethane (6 ml) at room temperature during 3 hr, and the whole mixture was stirred at the temperature overnight. After removal of the solvent under reduced pressure, the residue was extracted with pentane (total 30 ml) repeatedly. The pentane solution was evaporated carefully under atmospheric pressure to leave oily residue, which was passed through a column filled with silica gel (1 g), pentane being used as solvent. Early fractions gave a mixture (10 mg) of carbon tetrabromide and **2**, and the following fractions showed a single spot on tlc and afforded **2** (25 mg), oil; Mass, *m/e* 248 and 246 (M^+), 219 and 217 (M^+—C_2H_5), and 190 and 188 (M^+—$2C_2H_5$), and 109; IR (film), ν_{max} 1282, 1118, 1080, 1032, and 809 cm^{-1}; NMR ($CDCl_3$), δ 0.97 (6H, t J=7 Hz, $2C\underline{H}_3CH_2$), 1.28 (2H, br s, $CH_3C\underline{H}_2$), 1.57 (2H, m, $CH_3C\underline{H}_2$), 2.20 (3H, m, 3H at C_4 and C_7), 4.30 (3H, m, 3H at C_2, C_4 and C_8), 4.05 (1H, do t J=3, 3 and 9 Hz, H at C_3), and 5.90 (2H, m, 2H at C_5 and C_6).

(Received April 16, 1975)

The titled compound (**11**) was prepared from lividomycin A. A partially protected cyclic 1,6-carbamate derivative (**6**), which has free hydroxyl groups at C-4′ and C-6′, was prepared, and the 6′-hydroxyl group was selectively tosylated. Replacement of the tosyl group by azido group, followed by partial hydrolysis of the carbamate ring gave the aminol (**9**). Acylation of the free C-1-amino group with (*S*)-4-amino-2-hydroxybutyric acid and hydrogenation of the azido group led to **11**. Preparation of 4′,6′-di-*O*-methyllividomycin A (**13**) was also described.

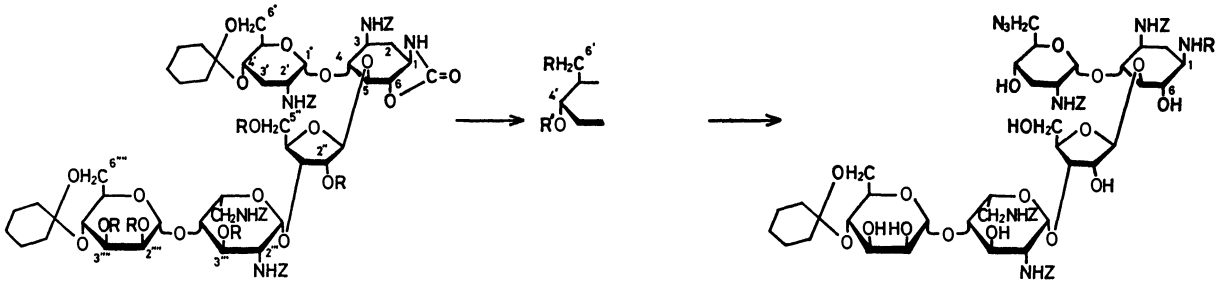
In the foregoing paper,[1] we reported the synthesis of 1-*N*-((*S*)-4-amino-2-hydroxybutyryl)lividomycin A (**1**). The compound had an improved antibiotic spectrum, being active against resistant organisms producing neomycin-kanamycin phosphotransferase I (P-ase I). We have further undertaken to prepare its 6′-amino-6′-deoxy derivative namely the titled compound which is synonymous with 1-*N*-((*S*)-4-amino-2-hydroxybutyryl)-3′-deoxy-4‴-*O*-mannosylneomycin B expecting to obtain a more effective compound, because introduction of an amino group at C-6′ of related aminoglycoside antibiotics generally enhances the antibacterial activity of the parent antibiotic.

Penta-*N*-benzyloxycarbonyllividomycin A (**2**) described in the foregoing paper[1] was treated with 1,1-dimethoxycyclohexane in the presence of acidic catalyst to give di-*O*-cyclohexylidene derivative (**3**) as the major product. It should be noted that the similar reaction of **2** with benzaldehyde dimethyl acetal gave a tri-*O*-benzylidene derivative[1] as the major product. Addition of methanol to the reaction mixture containing di-*O*-cyclohexylidene derivatives as major products caused hydrolysis of the minor products, and this treatment easily afforded the purified **3**. The positions of the cyclohexylidene groups in **3** were proved by periodate oxidation of **3** and by *O*-methylation of **6** that is later described. Periodate oxidation of **3** followed by acidic hydrolysis gave no trace of mannose, indicating the absence of a cyclohexylidene group at C-2 and C-3 of the mannose moiety. It is also noteworthy that **3** contains no 1-methoxycyclohexyl group, which is formed[2] at C-5 of the ribose moiety in the case of similar cyclohexylidenation of tetra-*N*-benzyloxycarbonylribostamycin; this result is compatible with the benzylidenation of penta-*N*-benzyloxycarbonyllividomycin A.[1]

Treatment of **3** with sodium hydride in DMF[1,3] gave the 1,6-cyclic carbamate (**4**) which was then benzoylated. The penta-*O*-benzoyl derivative (**5**) was more soluble in organic solvents than the corresponding tri-*O*-benzylidene derivative of lividomycin A described previously.[1] Controlled hydrolysis of **5** with aqueous acetic acid successfully removed only the cyclohexylidene group at C-4′,6′. Possibly this selectivity is due to participation of the *O*-benzoyl group at C-3‴′. We have experienced the similar phenomenon in the other examples which will be published elswhere. For structural confirmation, the mono-*O*-cyclohexylidene derivative (**6**) was methylated with diazomethane in the presence of BF_3-etherate to give the di-*O*-methyl derivative (**12**) and treated successively with barium hydroxide, acetic acid, and palladium and hydrogen to give the 4′,6′-di-*O*-methyllividomycin A (**13**), whose acidic methanolysis did not give 3′-deoxyparomamine in the hydrolyzate, indicating that the hydroxyl groups at C-4′ and C-6′ (not those at C-4‴′ and C-6‴′) were methylated.

Tosylation of **6** gave the 6′-*O*-tosyl derivative (**7**). The selective 6′-*O*-tosylation was supported by the fact that tritylation was difficult for **7**.

Compound **7** was treated with sodium azide in DMF to give the 6′-azido derivative (**8**). Treatment of **8** with dilute solution of barium hydroxide hydrolyzed the 1,6-cyclic carbamate as well as the benzoyl ester



Z : $CO_2CH_2C_6H_5$

	R		R	R′

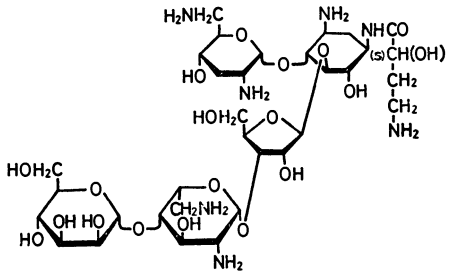
9	H (s)
10	$COCH(OH)CH_2CH_2NHZ$

groups to give **9** which has a free amino group at C-1. Condensation of **9** with (*S*)-4-benzyloxycarbonylamino-2-hydroxybutyric acid[4] by an active ester method using *N*-hydroxysuccinimide and dicyclohexylcarbodiimide (DCC) in THF gave the 1-*N*-acyl derivative (**10**). The cyclohexylidene group of **10** was removed by acidic treatment and the product was catalytically hydrogenated to remove the benzyloxycarbonyl groups and to reduce the azido to the amino group to afford the titled compound (**11**).

The derivative **11** showed antibacterial activity against resistant bacteria producing P-ase I as expected, but the activity did not exceed that of 1-*N*-((*S*)-4-amino-2-hydroxybutyryl)lividomycin A.[1] The 4',6'-di-*O*-methyllividomycin A (**13**) showed no antibacterial activity.



11

Experimental

General procedure was the same as described in the foregoing paper.[1]

*1,3,2',2''',6'''-Penta-*N*-benzyloxycarbonyl-4',6';4'''',6''''-di-O-cyclohexylidenelividomycin A (**3**).* To a solution of penta-*N*-benzyloxycarbonyllividomycin A (**2**) (7.87 g) in dry DMF (170 ml), *p*-toluenesulfonic acid (200 mg) and 1,1-dimethoxycyclohexane (18 ml) were added and the solution was heated at 30 °C for 3.5 hr under reduced pressure (~30 Torr). Methanol (80 ml) was added and the solution was allowed to stand for 30 min. Examination by tlc using chloroform–methanol (20 : 1) showed that by the methanol treatment, three spots initially observed collapsed to single major one (R_f 0.26). After addition of saturated sodium hydrogen carbonate solution, the solvent was removed by coevaporation with toluene. The residue was chromatographed on a column of silica gel with chloroform–methanol–triethylamine (30 : 1 : 0.1). The portion containing **3** was evaporated to give a solid of **3**, 3.73 g (43%); $[\alpha]_D^{27}$ +43° (*c* 1, $CHCl_3$).

Found: C, 60.92; H, 6.39; N, 4.22%. Calcd for $C_{81}H_{101}N_5O_{28}$: C, 61.08; H, 6.39; N, 4.40%.

*3,2',2''',6'''-Tetra-*N*-benzyloxycarbonyl-4',6';4'''',6''''-di-O-cyclohexylidenelividomycin A 1,6-Carbamate (**4**).* To an ice-cold solution of **3** (300 mg) in dry DMF (3 ml), 50% oily sodium hydride (40 mg) was added under a nitrogen atmosphere and the mixture was stirred for 3 hr in the cold. After neutralization with acetic acid, the resulting viscous solution was poured into a mixture of chloroform and saturated sodium chloride solution under stirring. The separated organic layer was washed with saturated sodium chloride solution and water, and dried over sodium sulfate. The solution was evaporated and the residue (270 mg) was chromatographed on a short column of silica gel with chloroform–methanol–triethylamine (25 : 1 : 0.1). The portion containing **4** was evaporated to give a solid of **4**, 195 mg (70%); $[\alpha]_D^{27}$ +41° (*c* 1, $CHCl_3$); IR (KBr): 1760 cm^{-1}.

Found: C, 59.58; H, 6.32; N, 4.45%. Calcd for $C_{74}H_{93}N_5O_{27}$: C, 59.87; H, 6.31; N, 4.72%.

*2'',5'',3''',2'''',3''''-Penta-*O*-benzoyl-3,2',2''',6'''-tetra-*N*-benzyloxycarbonyl-4',6';4'''',6''''-di-*O*-cyclohexylidenelividomycin A 1,6-Carbamate (**5**).* To a solution of **4** (210 mg) in dry pyridine (4.2 ml), benzoyl chloride (530 mg) was added and the solution was allowed to stand at −10 °C overnight. A few drops of water was added and the solution was allowed to stand for 1 hr. Powdered sodium hydrogen carbonate (300 mg) was added and the mixture was evaporated. The residue was extracted with chloroform and the solution was washed with water, potassium hydrogen sulfate solution, sodium hydrogen carbonate solution, and water and dried over sodium sulfate. After evaporation, the residue was dissolved in a mixture of ethyl acetate–benzene–triethylamine (2 : 5 : 0.02) and the solution was filtered through a short column of silica gel with aid of the above solvent system to remove impurities. Evaporation of the filtrate gave a solid, which was reprecipitated from benzene–*n*-hexane to give **5**, 220 mg (78%); $[\alpha]_D^{27}$ +13° (*c* 1, $CHCl_3$).

Found: C, 65.15; H, 5.70; N, 3.43%. Calcd for $C_{109}H_{113}N_5O_{32}$: C, 65.29; H, 5.68; N, 3.49%.

*2'',5'',3''',2'''',3''''-Penta-*O*-benzoyl-3,2',2''',6'''-tetra-*N*-benzyloxycarbonyl-4'''',6''''-*O*-cyclohexylidenelividomycin A 1,6-Carbamate (**6**).* To a solution of **5** (600 mg) in acetone (15 ml), acetic acid (6.25 ml) and water (3.75 ml) were added and the solution was allowed to stand at 37 °C for 8 hr. Sodium hydrogen carbonate (4 g) was added and the mixture was concentrated. The resulting sludge was shaken with chloroform. The separated organic layer was washed with saturated sodium hydrogen carbonate solution, and water, dried over sodium sulfate, and evaporated. On tlc with chloroform–methanol (30 : 1), the residue showed two main spots of R_f 0.71 (**5**) and R_f 0.29 (**6**) along with two faint spots. The residue was chromatographed on a column of silica gel (22 g) successively with chloroform–methanol–triethylamine (50 : 1 : 0.1, totally 120 ml) and chloroform–methanol–triethylamine (30 : 1 : 0.1). From the early fractions, **5** (240 mg, 40%) was recovered. From the later fractions, **6** was obtained; it was reprecipitated from chloroform–*n*-hexane, 290 mg (50%); $[\alpha]_D^{27}$ +11° (*c* 1, $CHCl_3$).

Found: C, 64.47; H, 5.53; N, 3.55%. Calcd for $C_{103}H_{105}N_5O_{32}$: C, 64.27; H, 5.50; N, 3.64%.

*2'',5'',3''',2'''',3''''-Penta-*O*-benzoyl-3,2',2''',6'''-tetra-*N*-benzyloxycarbonyl-4'''',6''''-O-cyclohexylidene-6'-O-tosyllividomycin A 1,6-Carbamate (**7**).* To a cold solution (−10 °C) of **6** (770 mg) in pyridine (16 ml), *p*-toluenesulfonyl chloride (390 mg) was added and the solution was allowed to stand at the temperature overnight and worked up in a similar manner as described for the preparation of **5** from **4**, 764 mg (92%); $[\alpha]_D^{31}$ +12.5° (*c* 2, $CHCl_3$); IR (KBr): 1175 cm^{-1} (Ts); NMR ($CDCl_3$): δ 2.39 (3H s, $SO_2C_6H_4C\underline{H}_3$).

Found: C, 63.23; H, 5.33; N, 3.14; S, 1.55%. Calcd for $C_{110}H_{111}N_5O_{34}S$: C, 63.55; H, 5.38; N, 3.37; S, 1.54%.

*6'-Azido-2'',5'',3''',2'''',3''''-Penta-*O*-benzoyl-3,2',2''',6'''-tetra-*N*-benzyloxycarbonyl-4'''',6''''-O-cyclohexylidene-6'-deoxylividomycin A 1,6-Carbamate (**8**).* To a solution of **7** (720 mg) in dry DMF (18 ml), sodium azide (230 mg) was added and the mixture was stirred at 60 °C for 6 hr. On tlc with chloroform–ethanol (30 : 1), **8** (R_f 0.40) appeared instead of **7** (R_f 0.47). Chloroform (200 ml) was added and the solution was washed with saturated sodium chloride solution (50 ml × 4), and water, and dried over sodium sulfate. After evaporation of the solvent, the residue was dissolved in a mixture of chloroform–ethanol–triethylamine (40 : 1 : 0.1)

and the solution was filtered through a short column (20 g) of silica gel with aid of the above solvent system to remove impurities. Evaporation of the filtrate gave **8**, 633 mg (94%); $[\alpha]_D^{28}$ +12.5° (*c* 2, $CHCl_3$); IR (KBr): 2100 (N_3), 1775 cm^{-1}.

Found: C, 63.26; H, 5.39; N, 5.61%. Calcd for $C_{103}H_{104}N_8O_{11}$: C, 63.44; H, 5.38; N, 5.75%.

*6′-Azido-3,2′,2‴,6‴′-tetra-*N*-benzyloxycarbonyl-4‴′,6‴′-O-cyclohexylidene-6′-deoxylividomycin A (**9**).* To a solution of **8** (520 mg) in dioxane (32 ml), 0.025 M barium hydroxide solution (16 ml) was added and the mixture was stirred at 60 °C for 30 min. Additional aliquot (16 ml) of the barium hydroxide solution was added and the mixture was stirred for 2 hr until the mixture became neutral. The treatment was repeated once again. Subsequent procedures were carried out as described for the preparation of **5** from **3** in the foregoing paper[1] except for the use of chloroform–methanol–triethylamine (6 : 1 : 0.01) for the chromatography, 340 mg (91%); $[\alpha]_D^{31}$ +48° (*c* 2, $CHCl_3$).

Found: C, 56.53; H, 6.08; N, 7.23%. Calcd for $C_{67}H_{86}N_8O_{25}\cdot 1/2H_2CO_3$: C, 56.52; H, 6.11; N, 7.81%.

*6′-Azido-3,2′,2‴,6‴′-tetra-*N*-benzyloxycarbonyl-1-*N*-[(S)-4-benzyloxycarbonylamino-2-hydroxybutyryl]-4‴′,6‴′-O-cyclohexylidene-6′-deoxylividomycin A (**10**).* To an ice-cold solution of (*S*)-4-benzyloxycarbonylamino-2-hydroxybutyric acid[4] (58.5 mg) and *N*-hydroxysuccinimide (26.6 mg) in THF (1 ml), DCC (47 mg) was added and the solution was allowed to stand for 1 hr under cooling. To the resulting suspension containing dicyclohexylurea, a solution of **9** (270 mg) and triethylamine (30 mg) in THF (2.5 ml) was added and the mixture was stirred at 0 °C for 1 hr and then at room temperature overnight. Filtration followed by evaporation gave a solid, which was chromatographed on a column of silica gel with chloroform–ethanol–triethylamine (10 : 1 : 0.2) to give **10**, 126 mg (40%); $[\alpha]_D^{20}$ +35° (*c* 1, $CHCl_3$); IR (KBr): 2090 cm^{-1} (N_3).

Found: C, 57.84; H, 6.25; N, 7.40%. Calcd for $C_{79}H_{98}N_9O_{29}$: C, 57.94; H, 6.03; N, 7.70%.

*6′-Amino-1-*N*-((S)-4-amino-2-hydroxybutyryl)-6′-deoxylividomycin A (**11**).* A solution of **10** (110 mg) in a mixture (10 ml) of acetone–acetic acid–water (3 : 5 : 2) was heated at 60 °C for 2 hr. Evaporation gave a residue, which was dissolved in aqueous dioxane (2 : 5, 4 ml). After addition of a few drops of acetic acid, the solution was hydrogenated over palladium black. Chromatography of the product on a column of CM-Sephadex C-25 (NH_4 form) with a linear gradient of aqueous ammonia (0∼0.3 M) gave a solid, which showed a single peak of **11**, 41 mg (64%); $[\alpha]_D^{20}$ +68° (*c* 1, H_2O); ppc, $R_{f\ \text{lividomycin A}}$ 0.6; IR (KBr): 1650, 1580 cm^{-1}.

Found: C, 42.46; H, 7.19; N, 10.19%. Calcd for $C_{33}H_{63}N_7O_{19}\cdot H_2CO_3\cdot 2H_2O$: C,42.54; H, 7.25; N, 10.21%.

*2‴,5‴,3‴′,2‴′,3‴′-Penta-O-benzoyl-3,2′,2‴,6‴′-tetra-*N*-benzyloxycarbonyl-4‴′,6‴′-O-cyclohexylidene-4′,6′-di-O-methyllividomycin A 1,6-Carbamate (**12**).* To a solution of **6** (140 mg) in dry dichloromethane (3 ml) in an ice-cold bath, boron trifluoride etherate (5 mg) was added, and diazomethane in dichloromethane was added until the solution became yellow. Triethylamine was added and the solution was evaporated to give a residue, which was dissolved in chloroform. The solution was washed with saturated sodium hydrogen carbonate solution, and water, dried over sodium sulfate, and evaporated. The residue was chromatographed on a column of silica gel with chloroform–ethanol–triethylamine (50 : 1 : 0.1); 65 mg (46%); $[\alpha]_D^{20}$ +21° (*c* 1, $CHCl_3$); NMR ($CDCl_3$): δ 3.22, 3.33 (each 3H s, OCH_3).

Found: C, 64.82; H, 5.63; N, 3.50%. Calcd for $C_{105}H_{109}N_5O_{12}$: C, 64.57; H, 5.63; N, 3.59%'

*4′-6′-Di-O-methyllividomycin A (**13**).* A sample of **12** was treated with barium hydroxide solution in a similar manner as described for the preparation of **9**. The product was treated with acetic acid and then with palladium black and hydrogen as described for the preparation of **11** to afford **13** (65%); $[\alpha]_D^{20}$ +83° (*c* 1, H_2O); PPC, $R_{f\ \text{lividomycin A}}$ 3.1; NMR (D_2O): δ 3.41 (6H s, OCH_3).

Found: C, 43.75; H, 7.10; N, 7.96%. Calcd for $C_{31}H_{59}N_5O_{18}\cdot H_2CO_3\cdot H_2O$: C, 44.19; H, 7.30; N, 8.05%.

*Acidic methanolysis of **13**.* A suspension of **13** in 0.4 M methanolic hydrogen chloride was heated at 80 °C for 10 hr. As a control experiment, lividomycin A was similarly treated. Paper chromatography of the both hydrolyzates gave the following results: Methanolysis of **13**: $R_{f\ \text{DST}}$* 1.4 (faint), 2.1 (3′-deoxy-4′,6′-di-*O*-methylparomamine), and 2.9 (methyl 2,6-diamino-2,6-dideoxyidoside?). Methanolysis of lividomycin A: $R_{f\ \text{DST}}$ 0.8 (3′-deoxyparomamine), 1.4 (faint), and 2.9.

The Rearrangement of 10-Bromo-10,11-dihydrodibenzo[*b,f*]thiepin-11-one and Related Compounds in an Alkaline Solution

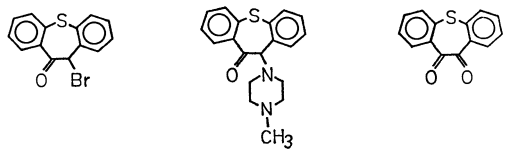
Ikuo UEDA*

Research Laboratories, Fujisawa Pharmaceutical Co., Ltd., Kashima, Yodogawa-ku, Osaka 532

(Received December 2, 1974)

The reaction of 10-bromo-10,11-dihydrodibenzo[*b,f*]thiepin-11-one (**1**) with sodium methoxide in methanol has been shown to lead to thioxanthone (**4**) and 10-hydroxy-10,11-dihydrodibenzo[*b,f*]thiepin-11-one (**5**). If the reaction of **1** in an aqueous sodium hydroxide solution is carried out, six products, **4**, **5**, 9-hydroxy-thioxanthene-9-carboxylic acid (**6**), thioxanthene-9-carboxylic acid (**7**), thioxanthene (**8**), and 10,11-dihydrodibenzo[*b,f*]-thiepin-10-one (**9**), are formed. The structures of the products were established by elementary analysis, by an examination of the spectral data, by gas chromatography, and by an independent synthesis. The results were discussed in terms of the mechanism proposed.

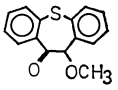
The synthesis of 10-(4′-methylpiperazino)10,11-dihydrodibenzo[*b,f*]thiepin-11-one (**2**) for a biological evaluation has been described by Jílek *et al.*[1] The treatment of 10-bromo-10,11-dihydrodibenzo[*b,f*]thiepin-11-one (**1**) with 1-methylpiperazine has also been shown to lead to Compound **2** and to 10,11-dihydrodibenzo[*b,f*]thiepin-10,11-dione (**3**) and 10,11-dihydrodibenzo[*b,f*]thiepin-10-one (**9**).[1]



(**1**) (**2**) (**3**)

Chart 1.

As part of an investigation of the synthesis of the derivatives of dibenzo[*b,f*]thiepin with potential biological activity,[2] the present author has attempted to prepare 10-methoxy-10,11-dihydrodibenzo[*b,f*]thiepin-11-one(I) from **1** and sodium methoxide. However, instead of the expected compound I, a neutral product, thioxanthone (**4**), was obtained in a 23% yield.



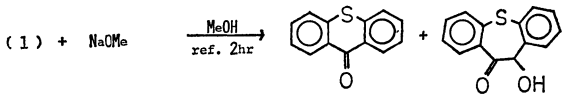
(I)

Chart 2.

The present paper will deal with detailed studies of the reaction of **1** and related compounds (**16**) and (**21**) with alkali.

Results and Discussion

In order to obtain information on the formation of **4**, the author first treated **1** with sodium methoxide in methanol under reflux. The reaction products separated by column chromatography on silica-gel from the reaction mixture were **4** and 10-hydroxy-10,11-dihydrodibenzo[*b,f*]thiepin-11-one (**5**) as is outlined in Scheme 1. Evidence for the **5** structure is based on



(**4**) (23%) (**5**) (<5%)

Scheme 1.

the NMR and IR spectra; NMR ($CDCl_3$, ppm) δ 4.9 and 6.21 (1H, d, J=5.5 Hz, 11-proton) and 7.0—9.0 (8H, m, aromatic protons), IR (nujol, cm^{-1}) 3400(OH) and 1650(CO). The yields shown are for isolated recrystallized products.

When Compound **1** was treated with a sodium hydroxide solution for 2 hr at 80 °C, six products were obtained, as is outlined in Scheme 2. The acidic product (**6**) separated from the aqueous phase in a 50% yield did not show a constant melting point. The IR spectrum of **6** in Nujol mull indicated absorption bands at 1675 cm^{-1} (CO) and 3450 cm^{-1} (OH), and the NMR spectrum exhibited a signal of aromatic protons at δ 7.2—7.8 in deuteriochloroform. The treatment of its potassium salt (**10**; R=OH) with methyl iodide in DMF at room temperature gave a yellow crystalline (mp 130—131 °C), which was identified as methyl 9-hydroxy thioxanthene-9-carboxylate(**11**) from the results of elementary analysis and its IR and NMR spectra. When **6** was treated with methanol containing a small amount of concentrated hydrochloric acid, methyl 9-methoxythioxanthene-9-carboxylate (**13**) was obtained in a 67% yield. From these experimental results, Compound **6** was identified as 9-hydroxythioxanthene-9-carboxylic acid. Thin-layer chromatography of the mother liquor of the recrystallization of **11** showed the presence of methyl thioxanthene-9-carboxylate (**12**)[3] upon comparison with a sample prepared by an independent route. Therefore, the tlc shows the formation of 9*H*-thioxanthene-9-carboxylic acid (**7**). It was proved therefore, that the acidic reaction products, **6**, contain a small amount of **7**.

Compounds **4** and **9** as neutral products were isolated from the reaction mixture and were found to be identical in IR and NMR spectra with authentic samples. The gas chromatography of the neutral reaction mixture showed the presence of **5** and thioxanthene (**8**) by comparison with the retention time of authentic samples.[4] The yield of **6** is for an isolated product; the

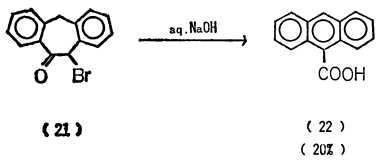

Scheme 7.

yields of **4**, **5**, **7**, **8** and **9** were determined by gas-chromatography of the crude reaction mixture, as is shown in Scheme 2.

The variation of the solvent in the reaction of **1** with alkali changed the products and the product ratios. For example, in water the acidic products were obtained in the highest yield. The formation of neutral products increased with an increase in the amount of methanol. Under anhydrous reaction conditions the acidic products were not isolated from the reaction mixture (see Experimental part).

The treatment of **1** in DMSO gave **3** in an 83.3% yield; it was converted to **6** in an aqueous sodium hydroxide solution.

Mechanisms. Compound **3** has been shown to lead to **6** in an aqueous sodium hydroxide solution and to 9-methoxythioxanthene-9-carboxylic acid (**14**) in methanol.[1] In acid hydrolysis, the formation of 9-Hydroxythioxanthene-9-carboxylate from both **3** and **6** has been reported.[5]

From the above-mentioned experimental results, the plausible mechanistic interpretations shown in Scheme 5 for the formation of **5**, **6**, **7**, and **9** from the reaction of **1** with a base can be advanced. The reaction of **1** with the hydroxy anion gives a secondary alcohol **5**, which is then dehydrogenated to afford diketone **3**.[6] The formation of **6** can be explained as resulting from the base-catalyzed benzilic acid rearrangement of the diketone **3**, as has been described in the literature.[1,9] Compound **9** may be formed by the reductive debromination of **1**. The formation of **7** from **1** and a base can also be explained as resulting from an intermediate, C, formed by the nucleophilic attack of the hydroxy anion on the carbonyl group of **1**. The two products, **4** and **8** appear to have been derived by the dehydration-decarbonylation of **6** and the decarboxylation of **7** respectively.

Table 1. Reaction of **1** with alkali

	Reaction condition[a]		Products		Product ratio[c]
	Base	Solvents (ml)	Acidic[b] (%)	Neutral (g)	
1	Na	MeOH(15)	—	0.5	—
2	NaOH	H_2O(7.5)/MeOH(7.5)	0.5(35.7)	0.4—0.5	1.0—1.2
3	NaOH	H_2O(15)	0.7(50.0)	0.3	2.3

a) 1.5 g of **1** and two equivalent of sodium or sodium hydroxide, are used for all of experiments. Alkali concentration; 2 to 3%, Reaction temperature; 80 °C, time; 2 hr. b) Percentage of acidic substances was calculated on the basis of **3**. c) Weight ratio of acidic and neutral substances.

Similarly, the treatment of 10-bromo-10,11-dihydrodibenz[*b,f*]oxepin-11-one (**16**)[7] in an aqueous sodium hydroxide solution gave 9-Hydroxyxanthene-9-carboxylic acid (**17**), xanthone (**18**), and 10,11-dihydrodibenz-[*b,f*]oxepin-11-one (**19**) in 41%, 11%, and 28% yields respectively. No xanthene-9-carboxylic acid or xanthene was isolated. The oxidation of **16** in DMSO gave **20** in a 93% yield (Scheme 6).

The treatment of 10-bromo-10,11-dihydro-5H-dibenzo[*a,d*]cyclohepten-11-one (**21**)[8] in an aqueous sodium hydroxide solution gave anthracene 9-carboxylic acid **21** in a 20% yield. No neutral products were obtained in this reaction.

Experimental

All the melting points are uncorrected. The IR spectra were taken with a Hitachi EPI-2 spectrometer. The NMR spectra were recorded by means of a Varian A-60 spectrometer in $CDCl_3$, using TMS as the internal standard.

Reaction of 10-Bromo-10, 11-dihydrodibenzo[b,f]*thiepin-11-one* ***1*** *with Alkali. The Reaction of* ***1*** *with Sodium Methoxide in Absolute Methanol*: A solution of 3.0 g of **1** in methanol containing sodium methoxide (prepared from 400 mg of sodium metal and 30 ml of methanol) was refluxed for 3 hr. After the removal of the methanol *in vacuo*, the residue was treated with a mixture of water and ethyl acetate. The ethyl acetate layer was washed with water, dried, and evaporated. A benzene solution of the oily residue (1.5 g) was adsorbed on 75 g of a silica gel (Mallinchrodt®, 100 mesh) and eluted with benzene. The subsequent evaporation of the eluent gave yellow crystals, which were recrystallized three times from cyclohexane to give 0.5 g (23%) of thioxanthone **4** as yellow needles; mp 210—212 °C; Found: C, 73.58; H, 3.65; S, 15.30%. Calcd for $C_{13}H_8OS$: C, 73.58; H, 3.80; S, 15.08%.

Rod-like crystals were obtained from the mother liquors of recrystallization and were crystallized from cyclohexane to give pale yellow, rod-like crystals; mp 121—124 °C. NMR($CDCl_3$, ppm) δ 4.90 and 6.21 (1 H, d, J=5.5 Hz, 11-proton), and 7.0—9.0(8H, m, aromatic protons). IR; ν_{max} (Nujol) 3400(OH), 1650(CO) and 1580 (aromatic)cm^{-1}. The structure of this compound was assumed to be 10-hydroxy-10,11-dihydrodibenzo[*b,f*]thiepin-11-one **5** on the basis of the IR and NMR spectra.

Reaction of ***1*** *with Aqueous Sodium Hydroxide.* A suspension of 3.0 g of **1** in an aqueous sodium hydroxide solution (sodium hydroxide, 0.8 g; water, 30 ml) was stirred for 2 hr at an inner temperature of 80 °C. After cooling, the oil was extracted with ethyl acetate, and the ethyl acetate layer was washed with water, dried, and evaporated. The residue thus obtained was recrystallized from cyclohexane to give 0.8 g (34.8%) of crystals **9**; mp 63—65 °C.

The aqueous layer was acidified with dil. hydrochloric acid and then allowed to stand to cool. The precipitate was filtered and air-dried at room temperature to give 1.3 g (50%) of crystals **6**.

Methyl 9-Hydroxy-thioxanthene-9-carboxylate ***11.*** A 0.4-g portion of **6** was dissolved in 10 ml of methanol containing 0.19 g of potassium hydroxide, and then the methanol was removed *in vacuo* below 30 °C. The colorless solid thus obtained was suspended in 15 ml of DMF. To the mixture we added 1 ml of methyl iodide, and the mixture was stirred for 48 hr at room temperature. To this solution we then added 1 ml of methyl iodide, after which stirring was continued for 48 hr. The reaction mixture was poured into 50 ml of water, made alkaline to pH 10 to 11 with a 10% sodium hydroxide solution, and extracted with ethyl acetate; the solution was then chromatographed on a silica-gel column using ethyl acetate as the eluent. The evaporation of the effluent offered pale yellow crystals, which were recrystallized from cyclohexane to give 0.3 g(67%) of pale yellow crystals **11**; mp 131—131.5 °C. Found: C, 66.15; H, 4.43; S, 11.80%. Calcd for $C_{15}H_{12}O_3S$: C, 66.17; H, 4.44; S, 11.76%.

Methyl 9-Methoxy-thioxanthene-9-carboxylate ***13.*** A 1.5-g portion of **6** was dissolved in a mixed solvent of 15 ml of methanol and 5 ml of conc. hydrochloric acid. The solution was then refluxed for 2 hr. After the removal of the methanol, the residue was extracted with ethyl acetate, and the ethyl acetate layer was dried over magnesium sulfate and evaporated. The solid thus obtained was recrystallized from cyclohexane to give **13**; mp 136.5—138 °C. Found: C, 67.17; H, 4.87; S, 11.06%. Calcd for $C_{16}H_{14}O_3S$: C, 67,12: H, 4.93; S, 11.18%. NMR($CDCl_3$, ppm) δ 2.98(3H, s, CH_3O-), 3.56(3H, s, $COOCH_3$), and 7.1—7.9(8H, m, aromatic protons). IR ν_{max} (Nujol) 1740(CO) and 1250(-O-)cm^{-1}.

10,11-Dihydrodibenzo[b,f]*thiepin-10,11-dione* ***3.*** *Oxidation of* ***9*** *by Selenium Oxide*: To a solution of 6.8 g of **9** in 15 ml of dioxane, we added a solution of 3.33 g of selenium oxide in a mixed solvent of 40 ml of dioxane and 2.5 ml of water. This solution was refluxed for 2 hr. The inorganic substance was then filtered off, and the filtrate was evaporated *in vacuo*. The residue thus obtained was recrystallized from cyclohexane to give 3.5 g (66.3%) of **3**; mp 135—136 °C (lit,[1] 135—136 °C).

Oxidation of ***1*** *by DMSO*: A solution of 1.5 g of **1** in 15 ml of DMSO was stirred for 1 hr on a boiling-water bath. After the subsequent removal of the DMSO *in vacuo*, the residue was recrystallized from cyclohexane to give 1.0 g(83.3%) of **3** as yellow needles; mp 135—136 °C.

10,11-Dihydrodibenz[b,f]*oxepin-10,11-dione* ***20.*** A solution of 2.5 g of **16** in 25 ml of DMSO was stirred for 2 hr on a boiling-water bath. After the subsequent removal of the DMSO *in vacuo*, the residue was recrystallized from benzene to give 1.8 g (93%) of **20**; mp 118—119 °C (lit,[9] 119 °C).

The Reaction of ***16*** *with Alkali.* A suspension of 5.0 g of **16** in an aqueous sodium hydroxide solution (sodium

hydroxide, 1.36 g; water, 50 ml) was stirred for 2 hr at 80 °C. After cooling, the oil was extracted with ethyl acetate. The aqueous layer was acidified with 10% hydrochloric acid, allowed to stand to cool, and then extracted with ethyl acetate. The ethyl acetate layer was washed with water, dried over magnesium sulfate, and evaporated. The residue thus obtained was recrystallized from a mixed solvent of benzene and hexane to give 1.75 g (14%) of **17**, IR; ν_{max} (Nujol) 2400(HO), 1740 and 1720(COO)cm^{-1}. NMR ($CDCl_3$, ppm) δ 7.2—7.8 and 8.2—8.3(8H, m, aromatic protons). The neutral reaction products were chromatographed on a silica-gel column using a mixture of benzene and cyclohexane (1 : 5) as the eluent. Compounds **18** and **19** were isolated in 11% and 28% yields respectively. These compounds were identical with samples of **18**[10] and **19**[11] obtained by an independent route as regards IR and NMR spectra.

*The Reaction of **21** with Alkali.* A solution of 2.1 g of **21**[8] in aqueous sodium hydroxide(sodium hydroxide, 0.5 g; water, 21 ml) was heated at 80 °C for 2 hr with stirring. The reaction mixture was then extracted with ethyl acetate, and the aqueous layer was acidified with dil. hydrochloric acid. The precipitate was filtered and recrystallized from a mixed solvent of acetone and *n*-hexane to give 0.3 g(20%) of crystals; mp 217 °C. NMR($CDCl_3$, ppm) δ 7.3—8.0 (aromatic protons). IR; ν_{max} (Nujol) 2700, 2500 (OH) and 1675(CO)cm^{-1}. The IR and NMR spectra of the compound were identical with those of anthracene 9-carboxylic acid, and the melting point of this compound was not depressed by admixture with the authentic sample.

The author wishes to thank H. Manabe for the spectra data, and T. Ikeda and his associates for the microanalyses.

Synthesis of Chloro(organo-oxy)tin(IV) from Organo-hydroxylic Compound and Tin(II) Chloride

Mitsuo MASAKI, Kiyoshi FUKUI, Izuhiko UCHIDA, and Hiroshi YASUNO

Polymer Research Laboratory, Ube Industries, Ltd., Minami-kaigan, Goi, Ichihara, Chiba 290

(Received December 13, 1974)

The reaction of an organo-hydroxylic compound and tin(II) chloride with a chlorine compound containing positively polarizable chlorine was found to yield trichloro(organo-oxy)tin(IV) or its disproportionation products, dichlorobis(organo-oxy)tin(IV) and tin(IV) chloride. The reaction of tin(II) chloride and *N*-chlorosuccinimide (NCS) with methanol or ethanol afforded methoxy- or ethoxy-trichloro(succinimide)tin(IV) (**1**), while the reaction with *n*-butanol led to the formation of dibutoxydichlorotin(IV) (**2**) and tetrachlorobis(succinimide)tin(IV) (**3**). The reaction of tin(II) chloride and NCS with alcohols in the presence of cyclohexanone oxime gave dialkoxydichloro(cyclohexanone oxime)tin(IV) (**6**). Cyclohexanone oxime and hexahydro-2*H*-azepin-2-one (3,4,5,6-tetrahydro-2*H*-azepin-7-ol) could be used as the organo-hydroxylic reagent in the reaction, while 1-chloronitrosocyclohexane and *N*-chlorohexahydro-2*H*-azepin-2-one were also useful as the chlorine compound. Thus, dichlorobis(cyclohexanone oximato)tin(IV) (**9**), dichlorobis(hexahydro-2*H*-azepin-2-onato)tin(IV) (**13**), and an adduct of **9** with tetrachlorobis(hexahydro-2*H*-azepin-2-one)tin(IV) (1 : 1) were prepared. Two stable complexes, bis(benzophenone oximato)dichlorobis(hexahydro-2*H*-azepin-2-one)tin(IV) (**15**) and dichlorobis-(2-pyridinethiolato)tin(IV) (**11**), were synthesized by the reactions of **13** with benzophenone oxime and 2-pyridinethiol respectively. The complex **13** was also synthesized by the reaction of *N*-trimethylsilylhexahydro-2*H*-azepin-2-one with tin (IV) chloride.

Halogeno(organo-oxy)tin(IV), such as alkoxychlorotin(IV), can be prepared *via* substitution reactions from tin(IV) halides,[1] tetraalkoxytin(IV),[2] and other organotin(IV) compounds.[3] However, these reactions have some limitations on their use as general preparative methods, as has been shown in the literature. There have been two reports on the formation of halogeno (organo-oxy)tin(IV) from tin(II) halides. Nesmejanov and Kozechkow[4] have suggested the probable formation of dichlorodiethoxytin(IV) in the reaction of tin (II) chloride with diarylmercury in ethanol, based upon the isolation of the corresponding aromatic hydrocarbon and metallic mercury. Melinichenko *et al.*[5] reported briefly a reaction of mercury acetate with tin(II)chloride in acetic acid, the reaction gave diacetoxydichlorotin (IV) and mercury.

This paper will describe a new, convenient method for the synthesis of trichloro(organo-oxy)tin(IV) or dichlorobis(organo-oxy)tin(IV), which consists of the reaction of hydroxylic compounds with tin(II) chloride in the presence of a chlorine compound containing positively polarizable chlorine, such as *N*-chlorosuccinimide(NCS), *N*-chlorohexahydro-2*H*-azepin-2-one(NCC), and 1-chloro-1-nitrosocyclohexane(CNC). This reaction is illustrated in Scheme 1. In the first step of the reaction, trichloro(organo-oxy)tin(IV) is formed as a complex with a ligand(YH) derived from the chlorine compound (Y-Cl), which is isolated in a good yield in several cases. The second step is a disproportionation of the complex, giving dichlorobis-(organo-oxy)tin(IV) and a complex of tin(IV) chloride with the ligand (YH). The disproportionation occurs, depending on the nature of the organo-oxy group (RO-) and the ligand (YH), under the conditions used for the first-step reaction.

$$ROH + SnCl_2 + Y\text{-}Cl \xrightarrow{\text{1st step}} ROSnCl_3 \cdot YH$$

$$2\,ROSnCl_3 \cdot YH \xrightarrow{\text{2nd step}} (RO)_2SnCl_2 + (YH)_2SnCl_4$$

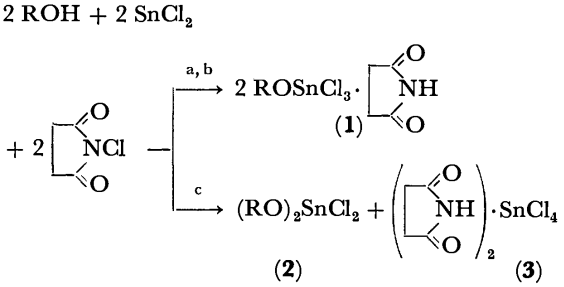
ROH: Methanol, Ethanol, *n*-Butanol, Cyclohexanone oxime, and Hexahydro-2*H*-azepin-2-one.

Y-Cl: *N*-Chlorosuccinimide, 1-Chloro-1-nitrosocyclohexane, and *N*-Chlorohexahydro-2*H*-azepin-2-one.

Scheme 1.

Results and Discussion

When methanol, tin(II) chloride, and NCS were allowed to react in a molar ratio of 1 : 1 : 1 in ethylene dichloride (EDC), trichloromethoxy(succinimide)tin (IV) (**1a**) was produced in an 86% yield. An analogous treatment of ethanol, in place of methanol, afforded trichloroethoxy(succinimide)tin(IV) (**1b**) in an 87% yield. However, the treatment of *n*-butanol, tin(II) chloride, and NCS under similar conditions gave di-*n*-butoxydichlorotin(IV) (**2c**) and tetrachlorobis(succinimide)tin(IV) (**3**) instead of *n*-butoxytrichloro(succinimide)tin(IV) (**1c**).

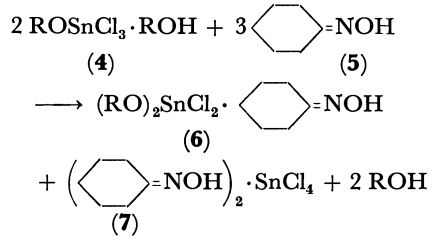


These facts indicate that **1c** readily undergoes disproportionation, while **1a** and **1b** are stable under similar conditions.

The complexes **1a** and **1b** were identified with specimensprepared by the reactions of trichloro(methanol)methoxytin(IV) (**4a**) and trichloro(ethanol)ethoxytin(IV) (**4b**) respectively with succinimide. Such a ligand-exchange reaction has also been reported by Paul *et al.*,[6] who, however, observed only the formation

of complexes of trichloromethoxytin(IV) with various ligands including amides, primary amines and nitrogen heterocycles. Analogously, ligand-exchange reactions occurred when **4a** was treated with an equimolar amount of hexahydro-2*H*-azepin-2-one, its *N*-methyl derivative, or cyclohexanone oxime.

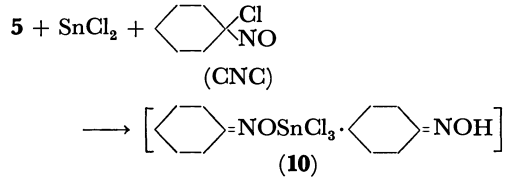
However, when **4a** was treated with a 1.5 fold molar amount of cyclohexanone oxime (**5**), a disproportionation reaction occurred and dichloro(cyclohexanone oxime)dimethoxytin(IV) (**6a**) and tetrachlorobis(cyclohexanone oxime)tin(IV) (**7**) were formed in 94 and 97% yields respectively.



A similar treatment of **1b** or **4b** with **5** gave dichloro(cyclohexanone oxime)diethoxytin(IV) (**6b**) in a good yield. Di-*n*-butoxydichloro(cyclohexanone oxime)tin (IV) (**6c**) was obtained by the treatment of **2c** with an equimolar amount of **5**, providing a confirmation for the formation of **2c** in the reaction mentioned above. The complexes **6** were unexpectedly stable enough to be handled in atmosphere, while dialkoxydichlorotin (IV) or its complexes are, in general, very sensitive to moisture and readily decompose in atmosphere.

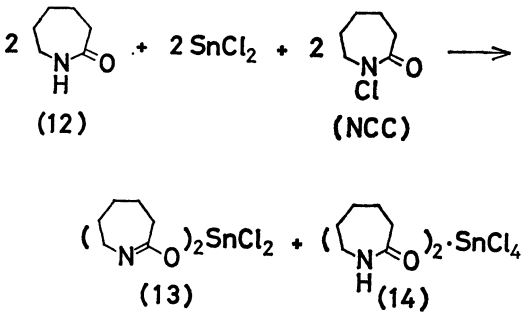
The complexes **6** could also be obtained by the reactions of **5**, tin(II) chloride and NCS in the alcohols. In these reactions, the development of blue color was transiently observed, indicating the formation of 1-chloro-1-nitrosocyclohexane (CNC) as one of the reaction intermediates. Since the reaction of **5** with NCS was experimentally confirmed to result in the formation of CNC and succinimide,[7] the use of CNC as a chlorine compound (Y-Cl)[8] in the reaction of Scheme 1 was examined.

As a variation of the hydroxylic compound in the reaction of Scheme 1, **5** was used. The reaction of **5**, tin(II) chloride, and CNC in a molar ratio of 1 : 1 : 1 afforded dichlorobis(cyclohexanone oximato)tin(IV) (**9**) and **7** in good yields. These results shows that trichloro(cyclohexanone oximato)(cyclohexanone oxime)tin(IV) (**10**), formed in the first step, readily undergoes a disproportionation, while trichloro(cyclohexanone oxime)methoxytin(IV) (**8**) is stable under similar conditions. The complex **9** is very sensitive to atmospheric moisture, and the formation of **9** was confirmed by several reactions. The treatment of **9** with alcohols afforded **6** in good yields, and the reaction of **9** with double the molar amount of 2-pyridinethiol gave dichlorobis(2-pyridinethiolato)tin(IV) (**11**) and **5** in 83 and 72% yields respectively.

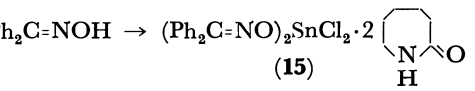


The complex **11** was very stable and was also obtained quantitatively from the reaction of bis(acetylacetonato)-dichlorotin(IV) with 2-pyridinethiol in a molar ratio of 1 : 2.

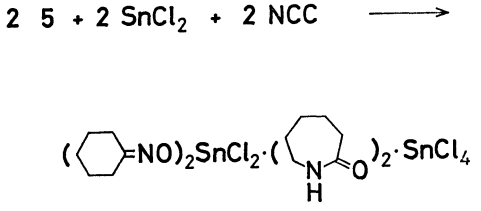
N-Chlorohexahydro-2*H*-azepin-2-one (NCC) was also useful as a chlorine compound for the reaction shown in Scheme 1. When hexahydro-2*H*-azepin-2-one (**12**), tin(II) chloride, and NCC were allowed to react in a molar ratio of 1 : 1 : 1 in benzene, dichlorobis(hexahydro-2*H*-azepin-2-onato)tin(IV) (**13**) and tetrachlorobis(hexahydro-2*H*-azepin-2-one)tin(IV) (**14**) were both formed in good yields. The complex **13** was isolated as an adduct with benzene (3 : 1), an alternative synthesis of which will be described below.



The formation of **13** was supported by two reactions. The first is the reaction with 2-pyridinethiol affording **11** and **12**, while the second reaction consists of a treatment with benzophenone oxime, yielding bis(benzophenone oximato)dichlorobis(hexahydro-2*H*-azepin-2-one)tin(IV) (**15**).[9]

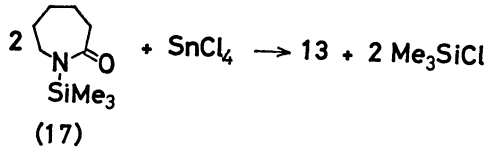


When **5**, tin(II) chloride, and NCC were allowed to react in a molar ratio of 1 : 1 : 1 in benzene, an adduct of **9** with **14** (1 : 1) (**16**) was formed in a good yield. The adduct **16**[10] was also isolated from the reaction of **13** with **7**.



(16)

As an alternative synthesis of **13**, the reaction of *N*-trimethylsilylhexahydro-2*H*-azepin-2-one (**17**) with tin (IV) chloride was performed. When **17** was treated with tin(IV) chloride in a molar ratio of 2 : 1 in benzene, and when trimethylsilyl chloride and the solvent were then removed by evaporation, **13** was obtained as a residue in an elemental analytically pure state. The structural supports for **13** were obtained by a study of the IR, NMR, and mass spectra.



(17)

The IR spectrum of **13** exhibits three strong intensity bands at 1620, 1520, and 330 cm^{-1}. The last band[11] can be assigned to the Sn–Cl vibration in a six-coordinated octahedral tin(IV) complex,[6,12,13] the appearance of only one band in the 300—350 cm^{-1} region suggests a *trans* configuration for two Sn–Cl bonds.[13-15] The C=O stretching band of **12** at 1660 cm^{-1} shifts to a spectral region lower by 30 and 50 cm^{-1} on *O*-coordinated complex formation with boron trifluoride and tin(IV) chloride respectively, indicating that the band at 1620 cm^{-1} of **13** may be due to C=O stretching. Furthermore, the band at 1520 cm^{-1} can be assigned to C=N stretching on the basis of the facts that dichlorobis(3,4,5,6-tetrahydro-2*H*-azepin-7-yl sulfato)-tin(IV) shows only one band, at 1520 cm^{-1}, in the 1500—1700 cm^{-1} spectral region, a band which can be assigned to C=N stretching,[16] and that **17** exhibits no band in the 1500—1700 cm^{-1} spectral region except for a carbonyl band at 1630 cm^{-1}.[16,17]

The proton NMR spectrum of **13** shows three peaks, at 8.20 (12H in β, γ, and δ positions), 7.35 (4H in α) and 6.60 (4H, in ε), and no remarkable splitting of the peaks is observed. This indicates that the two azepine rings in **13** are identical or very similar, because the NMR peaks of α or ε protons may be expected to split when one azepine ring in **13** is bonded only on the nitrogen atom with the tin atom and the other is bonded only on the oxygen atom with the tin atom. This supposition follows from the NMR data of several *N*- or *O*-substituted **12** which are shown in Table 1.

Table 1. NMR-spectra of hexahydro-2*H*-azepin-2-one and its derivatives (τ, in $CHCl_3$)

Compounds	β,γ and δ(6H)	α(2H)	ε(2H)
Unsubstituted	8.25	7.55	6.80
O-Methyl-	8.30	7.60	6.58
N-Methyl-	8.30	7.47	6.60
N-Chloro-	8.20	7.40	6.10
N-Trimethylsilyl-	8.30	7.48	6.78

These spectral observations lead to a probable structure for **13**, which is shown in Fig. 1, although it is not yet clear whether the two oxygen-tin bonds are *cis* or *trans*.

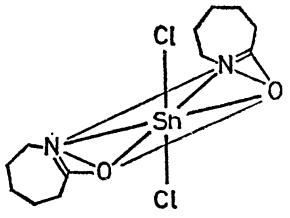


Fig. 1. A probable structure for **13**. An alternative structure, in which two oxygen-tin bonds are *trans*, is also possible.

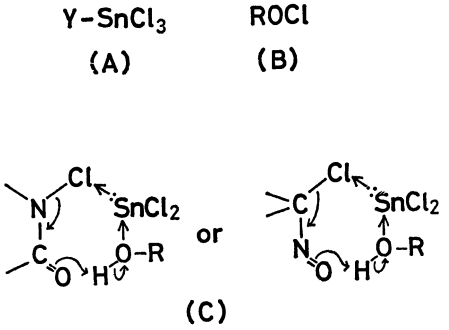
The complex **13** could not be prepared by the conventional methods of synthesis mentioned in the above introductory part. The recrystallization of **13** from benzene-ethyl ether afforded the adduct with benzene (3 : 1).

Some comments can be made about the mechanism of the reaction shown in Scheme 1, although there has not, so far as we aware, been any report on the oxidation of bivalent tin into a tetravalent state with a halogen compound containing positively polarizable halogen under non-aqueous conditions.[18] Three modes of the pathway can be postulated for the first step reaction. The first involves an initial reaction of tin (II) chloride with the chlorine compound giving a trichlorotin(IV) derivative (A), followed by the replacement of the latter with the hydroxylic compound. The second involves the initial formation of a hypochlorite-type compound (B) from the hydroxylic compound and the chlorine compound and the subsequent reaction of B with tin(II) chloride. The third pathway consists of a concerted mechanism involving a cyclic transition state (C).



The first-step reaction or the overall reaction of Scheme 1 is independent of the order in which the hydroxylic compound or the chlorine compound is added to tin(II) chloride, although in several cases some reactions have been observed between the two reactants before the addition of the third reactant. For instance, a reaction was observed to occur when NCS was added to tin(II) chloride; the reaction gave a product which might be an *O*-coordination complex of tin(II) chloride with NCS or trichloro(succinimidato)-tin(IV). Although the product could not be confirmed because of its very hygroscopic character, the reaction is so slow as still to be incomplete after stirring for 12 hr at room temperature or for several hours at 80 °C. On the other hand, the reaction of NCS and tin(II) chloride with alcohols or **12** is essentially completed within several hours at room temperature or within 1 hr at 80 °C. Furthermore, the reaction between **5**, tin(II) chloride, and CNC proceeds smoothly in benzene at room temperature, while scarcely no reaction of CNC with tin(II) chloride occurred under the same conditions. It is clear, therefore, that the first pathway is not predominant. The second pathway seems also not to be favored, since NMR spectral investigations do not indicate an isomerization of CNC or NCC into the corresponding hypochlorite-type compound (B) in the presence of **5** or **12**, in spite of the successful reactions of **5**, tin(II) chloride, and CNC and of **12**, tin(II)

chloride, and NCC.

At present, in view of these observations, it seems that the first-step reaction of Scheme 1 can best be explained by the third pathway, although the first and second pathways may be competitive to some extent according to the combination of reactants.

Experimental

All the compounds containing tin or silicon atoms, except the $(acac)_2SnCl_2$, **6** and **11**, were handled in a dry nitrogen atmosphere. The reagents and organic solvents for the reactions were used as anhydrous states. All the melting points are uncorrected. The products were identified, unless otherwise mentioned, by comparisons of the melting points and IR spectra with those of authentic samples.

*Trichloromethoxy(succinimide)tin(IV) (**1a**).* *a) From Methanol, $SnCl_2$, and NCS*: To a solution of NCS (3.34 g, 25 mmol) in EDC (120 ml) was added $SnCl_2$ (4.74 g, 25 mmol) with stirring at room temperature. A slightly exothermic reaction occurred, and the temperature of the mixture rose by 3.5—5 °C. To the stirred mixture was added drop by drop a solution of methanol (0.9 g, 28 mmol) in EDC (30 ml) at room temperature, after which the mixture was refluxed for 1 hr. The resulting solid was collected by filtration, washed with EDC, and dried to give 7.62 g (86%) of **1a**; mp 192.5—197.5 °C(decomp). IR(KBr): 3140, 3050, 1785, 1700, 1640, 515, 445, 360, 340(sh), 320, 300 and 285 cm^{-1}.

Found: C, 16.95; H, 2.46; N, 3.79; C, 29.63%. Calcd for $C_5H_8Cl_3NO_3Sn$: C, 16.91; H, 2.27; N, 3.94; Cl, 29.95%.

*b) From **4a** and Succinimide*: A mixture of **4a**[1a] (7.20 g, 25 mmol) and succinimide (2.45 g, 25 mmol) in EDC (250 ml) was heated under atmospheric pressure until 100 ml of the solvent had been distilled off. The resultant solid was collected by filtration, washed with EDC, and dried to give 8.26 g (93%) of **1a**; mp 192.5—197.5 °C (decomp).

*Trichloroethoxy(succinimide)tin(IV) (**1b**).* *a) From Ethanol, $SnCl_2$ and NCS*: In a manner similar to Method *a)* used for **1a**, NCS (3.34 g, 25 mmol) was treated with $SnCl_2$ (4.74 g, 25 mmol) in EDC (120 ml) and subsequently with ethanol (1.2 g, 26 mmol) in EDC (30 ml), thus giving 8.0 g (87%) of **1b**; mp 188.5—189.5 °C (decomp). IR (KBr): Essentially identical in pattern with that described in *a)* for **1a**.

Found: C, 19.68; H, 2.87; N, 3.60; Cl, 28.63%. Calcd for $C_6H_{10}Cl_3NO_3Sn$: C, 19.52; H, 2.73; N, 3.79; Cl, 28.81%.

*b) From **4b** and Succinimide*: In a manner similar to Method *b)* used for **1a**, **4b**[1a] (7.90 g, 25 mmol) was treated with succinimide (4.90 g, 50 mmol) in benzene (250 ml) to give 8.42 g (91%) of **1b**.

*Trichloro(hexahydro-2H-azepin-2-one)methoxytin(IV) (**18**).* In a manner similar to Method *b)* used for **1a**, **4a** (14.41 g, 50 mmol) was treated with **12** (5.66 g, 50 mmol) in benzene (300 ml) to give 17.86 g (97%) of **18**; mp 196—199 °C (decomp). IR (KBr): 3350, 1610, 530, 510, 350, 320, 295 and 285 cm^{-1}.

Found: C, 22.95; H, 3.61; N, 3.51; Cl, 29.10%. Calcd for $C_7H_{14}Cl_3NO_2Sn$: C, 22.77; H, 3.61; N, 3.51; Cl, 28.80%.

*Trichloromethoxy(1-methylhexahydro-2H-azepin-2-one)tin(IV) (**19**).* In a manner similar to Method *b)* used for **1a**, **4a** (7.20 g, 25 mmol) was treated with 1-methylhexahydro-2*H*-azepin-2-one (3.18 g, 25 mmol) in benzene (170 ml) to give 8.76 g (91%) of **19**; mp 217.5—219 °C (decomp.) IR (KBr): 1600, 525, 450, 350, 325, 310 and 280 cm^{-1}.

Found: C, 25.04; H, 4.29; N, 3.63; Cl, 27.91%. Calcd for $C_8H_{16}Cl_3NO_2Sn$: C, 25.07; H, 4.21; N, 3.66; Cl, 27.75%.

*Trichloro(cyclohexanone oxime)methoxytin(IV) (**8**).* In a manner similar to Method *b)* used for **1a**, **4a** (14.41 g, 50 mmol) was treated with **5** (5.66 g, 50 mmol) in benzene (300 ml) to give 14.76 g (80%) of **8a**; mp 158.5—160 °C (decomp). IR (KBr): 3180, 3100, 1130, 1080, 1060, 510, 490, 345, 320 and 310 cm^{-1}.

Found: C, 22.70; H, 3.78; N, 4.05; Cl, 28.63%. Calcd for $C_7H_{14}Cl_3NO_2Sn$: C, 22.77; H, 3.82; N, 3.79; Cl, 28.80%.

*Dichloro(cyclohexanone oxime)dimethoxytin(IV) (**6a**).* *a) From **4a** and **5***: To a solution of **4a** (7.20 g, 25 mmol) in methanol (100 ml) was added **5** (4.24 g, 37.5 mmol): the mixture was then stirred for 2 hr at room temperature. The resulting precipitates were collected by filtration, washed with methanol and dried to give crude **6a** (4.28 g, 94%). Recrystallization from EDC-methanol gave an analytical sample as colorless crystals; mp 156 °C (decomp). IR (KBr): 2760—2260 (centered at 2500), 2200—1800 (centered at 2050), 1110, 1040, 1010, 590, 520, 475, 350, 310 and 275 cm^{-1}.

Found: C, 26.24; H, 4.74; N, 3.71; Cl, 19.47%. Calcd for $C_8H_{17}Cl_2NO_3Sn$: C, 26.30; H, 4.66; N, 3.84; Cl, 19.45%.

The methanolic filtrate and washings were concentrated to dryness, and the residue was treated with benzene to give colorless precipitates. Filtration afforded 5.92 g (97%) of **7**.[19]

*b) From Methanol, $SnCl_2$, NCS and **5***: To a suspension of NCS (3.34 g, 25 mmol) in methanol (100 ml) was added $SnCl_2$ (4.74 g, 25 mmol) at room temperature: the temperature of the mixture thereby rose by 11 °C. The resultant solution was stirred for 2 hr at room temperature. To the solution was added **5** (4.24 g, 37.5 mmol) at room temperature, after which stirring was continued for 2 hr. The resultant solid was collected by filtration, washed with methanol (50 ml), and dried to give 4.41 g (97%) of **6a**.

The combined filtrate and washings were then concentrated, and the residue was treated with EDC (150 ml) to give 5.19 g (85%) of **7** as colorless precipitates.

The EDC solution was concentrated, and the residue was extracted with boiling benzene (100 ml). After the insoluble residue had been removed by filtration, the hot benzene solution was allowed to stand at room temperature, thus affording 2.08 g (85%) of succinimide, as colorless crystals.

*Dichloro(cyclohexanone oxime)diethoxytin(IV) (**6b**).* *a) From **4b** and **5***: In a manner similar to Method *a)* used for **6a**, **4b** (7.90 g, 25 mmol) was treated with **5** (4.24 g, 37.5 mmol) in ethanol (200 ml), thus affording crude **6b** (4.51 g, 92%). Recrystallization from EDC-ethanol gave colorless crystals; mp 157—158 °C (decomp). IR (KBr): Essentially identical in pattern with that described in *a)* for **6a**.

Found: C, 30.47; H, 5.45; N, 3.47; Cl, 18.30%. Calcd for $C_{10}H_{20}Cl_2NO_3Sn$: C, 30.57; H, 5.39; N, 3.57; Cl, 18.05%.

The ethanolic filtrate and washing were concentrated and the residue was treated with EDC (100 ml), thus affording 5.75 g (94%) of **7** as colorless precipitates.

*b) From Ethanol, $SnCl_2$, NCS and **5***: In a manner similar to Method *b)* used for **6a**, NCS (3.34 g, 25 mmol) was treated with $SnCl_2$ (4.74 g, 25 mmol) in ethanol (200 ml) and subsequently with **5** (4.24 g, 37.5 mmol). 4.68 g (96%) of **6b** were thus obtained, together with 5.6 g (92%) of **7** and 1.99 (81%) of succinimide.

*Di-n-butoxydichloro(cyclohexanone oxime)tin(IV) (**6c**).* *a) From **2c** and **5***: The reaction of NCS (3.34 g, 25 mmol), $SnCl_2$ (4.74 g, 25 mmol), and *n*-butanol (1.9 g, 25.6 mmol) in EDC (120+30 ml) was performed in a manner identical with that described in *a)* for **1a**. The resulting reaction mixture was filtered to give 3.11 g (54%) of **3**. Recrystallization from EDC gave an analytical sample as colorless needles; mp 149.5—152.5 °C (decomp). Found C, 20.95;

H, 2.43; N, 5.90%. Calcd for $C_8H_{10}Cl_4N_2O_4Sn$: C, 20.95; H, 2.26; N, 6.11%.

Since it became clear that **3** was partially soluble in the EDC used as the solvent, but was scarcely soluble in benzene, the same reaction was repeated, but in benzene (90+30 ml), in order to make the separation of **3** from the reaction mixture easy. The resulting reaction mixture was filtered to give 4.76 g (83%) of **3**. To the filtrate was added **5** (2.83 g, 25 mmol) and the mixture was stirred for 2 hr at room temperature. The resultant solid was collected by filtration, washed by being suspended in EDC (50 ml×2), and dried to give 0.85 g of **7**. The combined filtrate and washings were concentrated, and the residue was treated with *n*-butanol to give 3.15 g (56%) of **6c** as colorless precipitates. Recrystallization from EDC-*n*-butanol gave an analytical sample; mp 152—156 °C (decomp). IR (KBr): Essentially identical in pattern with that described in *a)* for **6a**.

Found: C, 37.55; H, 6.24; N, 3.06; Cl, 16.00%. Calcd for $C_{14}H_{29}Cl_2NO_3Sn$: C, 37.45; H, 6.51; N, 3.21; Cl, 15.79%.

b) From n-*Butanol, $SnCl_2$, NCS and* **5**: In a manner similar to Method *b)* used for **6a**, NCS (3.34 g, 25 mmol) was treated with $SnCl_2$ (4.74 g, 25 mmol) in *n*-butanol and subsequently with **5** (4.24 g, 37.5 mmol). The resultant reaction mixture was filtered to give 8.71 g of a mixture of **6c** and **7** as a powdery solid. This mixture was then treated with EDC (100 ml) to give 2.49 g (41%) of **7** as an insoluble solid. The EDC solution separated from **7** was concentrated, and the residue was treated with *n*-butanol (100 ml) to afford 3.94 g (70%) of **6c** as colorless precipitates. The solution separated from **6c** was combined with the *n*-butanolic filtrate separated from the above mixture, and then concentrated. The residue was treated with boiling benzene (150 ml) to give 2.58 g (42%) of **7** as an insoluble solid. Thus, the total yield of **7** was 5.07 g (83%). The hot benzene solution separated from **7** was allowed to stand at room temperature to give 1.94 g (79%) of succinimide as colorless crystals. The benzene solution separated by filtration was concentrated, and the residue was treated with *n*-butanol (30 ml) to give a further 1.55 g portion (28%) of **6c**. Thus, the total yield of **6c** was 5.49 g (98%).

1-Chloro-1-nitrosocyclohexane (CNC). To a solution of **5** (11.31 g, 100 mmol) in benzene (100 ml) was added NCS (13.35 g, 100 mmol); the mixture was then stirred for 5 hr at room temperature, whereby a intensive blue color was developed. The resultant solid was collected by filtration, washed with benzene, and dried to give 9.18 g (93.6%) of succinimide. The combined filtrate and washing were washed with water (50 ml×2), dried over Na_2SO_4, and concentrated to give crude CNC (11.74 g, 80%). Distillation gave 7.42 g (50%) of CNC; bp 54—54.5 °C/15 mmHg (lit,[7a] 52 °C/12 mmHg).

*Dichlorobis(cyclohexanone oximato)tin(IV) (**9**).* To a stirred mixture of $SnCl_2$ (9.47 g, 50 mmol) and **5** (5.65 g, 50 mmol) in benzene (70 ml) was added drop by drop a solution of CNC (7.38 g, 50 mmol) in benzene (30 ml) below 12 °C with ice cooling. The mixture was stirred overnight at room temperature, and then the resulting solid was collected by filtration, washed with EDC (50 ml), and dried to give 11.96 g (98%) of **7**. The benzene filtrate was concentrated to dryness, giving crude **9** as a very hygroscopic, semicrystalline solid (10.58 g). IR (KBr): 2940, 2850, 1600, 1435, 990, 970 and 590 cm^{-1}.

Structural support for **9** was obtained by reactions with alcohols, and 2-pyridinethiol. The reaction with the latter reagent is described in the *b)* section for **11**.

Reaction with Alcohols: Crude **9** (3.0 g) was added to 50 ml of methanol, ethanol, or *n*-butanol, and the mixture was stirred for 1 hr at room temperature. The resulting precipitates were collected by filtration to give **6a** (1.79 g, 67%), **6b** (1.92 g, 67%) or **6c** (2.4 g, 74%). The products were confirmed by means of their melting points and IR spectra, which were identical with those of the respective authentic samples prepared above.

The alcoholic filtrate was concentrated, and the residue was extracted with boiling *n*-hexane (50 ml×3). The combined extracts were concentrated to dryness, giving **5** as a crystalline residue. The yields of **5** in reactions with methanol, ethanol and *n*-butanol were 0.70 g (85%), 0.64 g (79%) and 0.75 g (91%) respectively.

*Dichlorobis(hexahydro-2H-azepin-2-onato)tin(IV) (**13**). a) From **17** and $SnCl_4$*: To a stirred solution of **17**[17] (9.27 g, 50 mmol) in benzene (60 ml) was added drop by drop a solution of $SnCl_4$ (6.51 g, 25 mmol) in benzene at room temperature, after which the stirring was continued for 5 hr. The resultant solution was concentrated to dryness on an oil bath at 40 °C under reduced pressure in order to remove the benzene and trimethylsilyl chloride. **13** was obtained as a colorless crystalline residue (10.64 g, theoretical yield is 10.35 g); mp 85—86 °C. An analytical sample was obtained by drying the residue at 70 °C. IR (KBr): 1620, 1520, 1455, 530, 470, 330 and 275 cm^{-1}. MS (*m/e*): 414 (M^+), 379 (M−Cl), 302 (M−$C_6H_{10}NO$) and (M−Cl−$C_6H_{10}NO$).

Found: C, 34.95; H, 5.06; N, 6.63; Cl, 17.54%. Calcd for $C_{12}H_{20}Cl_2N_2O_2Sn$: C, 34.82; H, 4.87; N, 6.77; Cl, 17.13%.

*b) Adduct of **13** with Benzene (3 : 1)*: A solution of **13** (8.30 g of the crystalline residue obtained above) in benzene (50 ml) was stirred for 4 hr at room temperature and allowed to stand overnight. A trace of an insoluble substance was filtered off, and ethyl ether (60 ml) was added to the filtrate. After stirring for 7 hr, the resulting colorless solid was collected by filtration, washed with a small quantity of benzene, and dried at room temperature to give 1.15 g of the adduct; mp 100—101 °C. IR (KBr): 1620, 1550 and 680 cm^{-1}. MS: Identical peaks shown in *a)* for **13**.

Found: C, 38.22; H, 5.08; N, 6.10; Cl, 16.32%. Calcd for $(C_{12}H_{20}Cl_2N_2O_2Sn)_3C_6H_6$: C, 38.19; H, 5.00; N, 6.36; Cl, 16.14%.

*c) Preparation of a Solution of **13** (from **12**, $SnCl_2$, and NCC)*: To a suspension of $SnCl_2$ (4.74 g, 25 mmol) in benzene (60 ml) was added **12** (2.83 g, 25 mmol), after which the mixture was stirred for 30 min at room temperature. To the resultant solution was added drop by drop a solution of NCC[20] (3.69 g, 25 mmol; bp 55 °C/4×10^{-3} mmHg) in benzene (40 ml) below 10 °C, with ice cooling. After the addition, the mixture was stirred for 15 hr at room temperature, and then it was filtered to give **14**[21] as a colorless powdery solid (5.89 g, 96.7%) and a solution, which was confirmed to contain **13** (12.5 mmol in the theoretical yield) by treatment with 2-pyridinethiol or benzophenone oxime, and by the isolation of the adduct of **13** with benzene.

*d) Isolation of the Benzene Adduct from the Solution Prepared in c) for **13***: The solution was concentrated to give a caramel-like residue, which was then dissolved in benzene (10 ml) after which the solution was stirred for 20 hr at room temperature. The resultant solid was collected by filtration, washed with a small quantity of benzene, and dried at room temperature to give 2.61 g (47%) of the adduct, whose mp, IR and MS were identical with those of the specimen obtained in *b)* for **13**. Found: C, 38.23; H, 5.14; N, 6.01; Cl, 16.45%.

Dichlorobis(2-pyridinethiolato)tin(IV) (II). a) From Bis

*(acetylacetonato)dichlorotin(IV) (**20**) and 2-Pyridinethiol*: To a stirred solution of **20** (3.88 g, 10 mmol) in benzene (100 ml) was added 2-pyridinethiol (2.22 g, 20 mmol), after which the mixture was refluxed for 30 min. The resultant solid was collected by filtration, washed with EDC, and dried to give 3.86 g (94%) of **11** as a slightly pale yellow, powdery solid; mp 275—277 °C (decomp). IR (KBr): 1580, 1550, 1435, 1420, 410, 400, 310, 300 and 270 cm^{-1}. MS (*m/e*): 410 (M^+), 375 (M−Cl), 340 (M−Cl_2), 300 (M−PyS) and 265 (M−Cl−PyS).

Found: C, 29.38; H, 1.83; N, 6.87; Cl, 17.24; S, 15.81%. Calcd for $C_{10}H_8Cl_2N_2S_2Sn$: C, 29.30; H, 1.97; N, 6.83; Cl, 17.30; S, 15.64%.

*b) From **9** and 2-Pyridinethiol*: A solution of **9** was prepared by the reaction of 25 mmol portions of $SnCl_2$, **5**, and CNC in benzene (100 ml), followed by a separation from the resultant **7**. To the solution was added 2-pyridinethiol (2.78 g, 25 mmol) at room temperature, and the mixture was stirred for 2 hr. The resulting solid was collected by filtration, washed with EDC (50 ml), and dried to give 4.28 g (83%) of **11**; mp 275—277 °C (decomp.)

The combined filtrate and washings were concentrated, and the residue was extracted with boiling *n*-hexane (50 ml × 3). The combined extracts were then concentrated to dryness to give 2.05 g (72%) of **5** as crystals.

*c) From **13** and 2-Pyridinethiol*: To the solution of **13** in benzene, prepared by Method *c)* for **13** was added 2-pyridinethiol (2.78 g, 25 mmol), and the mixture was treated in a manner identical with that described in *b)* for **11**, thus giving 4.67 g (91%) of **11**.

*Bis(benzophenone oximato)dichlorobis(hexahydro-2H-azepin-2-one)tin(IV) (**15**).* To a solution of **13** (5.28 g, 12.75 mmol, prepared by Method *a)* for **13**) in benzene (100 ml) was added benzophenone oxime (5.03 g, 25.5 mmol), and the mixture was stirred overnight. The resultant solid was collected by filtration, washed with benzene (70 ml), and dried in a nitrogen atmosphere at room temperature to give 9.34 g (90.5%) of **15**; mp 178.5—180.5 °C. IR (KBr); 3280, 1630, 940, 700, 540, 450, 340(sh), 330, 320 and 295 cm^{-1}.

Found: C, 56.50; H, 5.05; N, 6.74; Cl, 8.75%. Calcd for $C_{38}H_{42}Cl_2N_4O_4Sn$: C, 56.41; H, 5.20; N, 6.93; Cl, 8.78%.

A similar treatment of the solution of **13** in benzene prepared by Method *c)* for **13** with benzophenone oxime (4.93 g, 25 mmol) afforded 8.39 g (83%) of **15**.

*An Adduct of **9** and **14** (1 : 1) (**16**).* *a) From **13** and **7***: To a solution of **13** (5.44 g, 13.15 mmol, prepared by Method *a)* for **13**) in benzene (100 ml) was added **7**[16] (6.40 g, 13.15 mmol), and the mixture was stirred for 15 hr at room temperature. The resultant solid was collected by filtration, washed with benzene (40 ml), and dried overnight at 70 °C under reduced pressure to give 11.19 g (94.5%) of **16** as a colorless, powdery solid; mp 103—108 °C (sintering begins at 98 °C). IR (KBr): 3330, 3280, 3190, 1630, 1010, 990, 525, 510, 350(sh), 320—310 and 290 cm^{-1}.

Found: C, 32.34; H, 4.72; N, 5.90; Cl, 23.83%. Calcd for $C_{24}H_{42}Cl_6N_4O_4Sn_2$: C, 31.97; H, 4.66; N, 6.22; Cl, 23.62%.

*b) From **5**, $SnCl_2$, and NCC*: A solution of NCC (7.38 g, 50 mmol) in benzene (30 ml) was added drop by drop to a stirred mixture of **5**, (5.66 g, 50 mmol) and $SnCl_2$ (9.48 g, 50 mmol) in benzene (90 ml) below 14 °C; the stirring was continued overnight at room temperature after the addition. The resulting solid was collected by filtration, washed with benzene, and dried at room temperature under reduced pressure for 7 hr to give 21.03 g (81%) of **16** containing benzene (1.82 mol per 1 mol of **16**) as a colorless powdery solid; mp 97—98 °C.

Found: C, 40.21; H, 5.07; N, 5.34; Cl, 20.68%. Calcd for $C_{24}H_{42}Cl_2N_4O_4Sn\cdot(C_6H_6)_{1.82}$: C, 40.22; H, 5.12; N, 5.37; Cl, 20.40%. The solid was further dried for 6.5 hr at 50 °C and then for 7.5 hr at 70 °C under reduced pressure to give benzene-free **16**. Found: C, 32.44; H, 4.75; N, 6.11; Cl, 23.94%.

The authors wish to express their gratitude to Professor Emeritus Masao Horio of Kyoto University and President Shotaro Sugiura of the Polymer Research Laboratory, Ube Industries, for their constant encouragement throughout this work. The authors also wish to express thanks to Professor Teruaki Mukaiyama of Tokyo Institute of Technology for his valuable suggestions.

9) An alternative structure, bis(benzophenone oxime)-dichlorobis(hexahydro-2*H*-azepin-2-onato)tin(IV), can be excluded on the basis of the fact that benzophenone oxime does not form a complex even with tin(IV) chloride, while **12** readily forms complexes with chlorotin(IV)'s, such as alkoxytrichlorotin(IV) and tin(IV) chloride.

10) The structural consideration of the adduct (**16**) is now in progress; the results will be published elsewhere, together with other experimental results.

11) A referee suggested the possibility that the band at 330 cm^{-1} may be due to the Sn–O vibration. Although positive evidence is lacking to date, we still favor the assignment of the band to the Sn–Cl vibration. This is based on the facts that, in the literature, [6,13,22] the strong-intensity bands in the 300—350 cm^{-1} region in the spectra of most hexa-coordinated tin(IV) complexes containing both Sn–O and Sn–Cl bonds have been assigned to the Sn–Cl vibration and the bands in the 400—600 cm^{-1} region have been assigned to the Sn–O vibration. The spectrum of **13** shows a medium-intensity band at 515 cm^{-1} which can be assigned to Sn–O vibration, because the complexes **1**, **18**, **19**, **8**, **6**, **15**,

and **16** exhibit absorption bands in the 500—550 cm^{-1} region in the respective spectra, while no band is observed in the 500—600 cm^{-1} region in the IR spectrum of **11**.

18) Although the oxidation of tin(II) halide with a molecular halogen is known to give tin(IV) halide, molecular chlorine can not be used as a chlorine compound in this method. Even if molecular chlorine caused the first step reaction competitively with the formation of tin(IV) chloride, the final product would be only a complex of tin(IV) chloride with an organo-hydroxylic compound, because the trichloro(organo-oxy)tin(IV) formed in the reaction would be immediately converted into the complex by the by-produced hydrogen chloride (Y=Cl, in Scheme 1).

The Formation of Ethers from Nerol and *l*-Linalool in the Presence of Boron Trifluoride Etherate

Kimiko NAGAI

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received January 6, 1975)

Upon treatment with boron trifluoride etherate at room temperature, *dl*-linaloyl neryl, *dl*-geranyl linaloyl, *dl*-neryl α-terpenyl, and dineryl ethers were obtained from nerol and linaloyl neryl, *l*-geranyl linaloyl, *dl*-neryl α-terpenyl, and *l*-linaloyl piperityl ethers, from *l*-linalool. Of these ethers, linaloyl piperityl ether was thought to be formed by the cyclization of linaloyl neryl and geranyl linaloyl ethers.

In connection with previous papers on the formation of ethers from geraniol,[1] *d*-borneol, *dl*-isoborneol,[2] and *l*-isopulegol,[3] the action of boron trifluoride etherate ($BF_3 \cdot Et_2O$) on nerol (I) and *l*-linalool (II) was examined in the present work; five ethers were obtained, and their structures were determined to be *dl*-linaloyl neryl (III), *l*-geranyl linaloyl (IV), *dl*-neryl α-terpenyl (V), dineryl (VI), and *l*-linaloyl piperityl (VII) ethers.

To date, several works have been reported on the reaction of I and II with an acidic catalyst, but they have dealt with the characterization of monomeric products; there are no descriptions of higher-boiling products.[4,5]

Results and Discussion

Nerol and *l*-linalool were treated with boron trifluoride etherate under the various conditions listed in Table 1. Each reacted mixture was fractionated into monomeric (bp 60—90 °C/4 mmHg) and dimeric (bp 90—120 °C/4 mmHg) fractions, and the monomeric fraction was further separated by elution chromatography into the two portions of hydrocarbons and the oxygen-containing compounds.

Characterization of Monomeric Products. The monomeric hydrocarbon portions thus separated from reacted mixtures of I and II commonly showed eight peaks in glc, although their relative intensities were different. The components, after being isolated through preparative glc, were identified as myrcene, α-terpinene, dipentene, β-ocimene X,[6] β-ocimene Y,[6] γ-terpinene, *p*-cymene, and terpinolene by mass and IR spectroscopy and by glc admixing authentic samples.

The monomeric oxygen-containing portions from reacted mixtures of I and II were examined by glc and IR, NMR, and mass spectroscopy; linalool, α-terpineol, and geraniol were identified in the case of I other than unreacted alcohol, and *d*-α-terpineol, nerol, and geraniol, in the case of II.

Characterization of Dimeric Products. The dimeric fractions from the reacted mixtures of I and II were eluted over a silica gel column with benzene to separate the individual components. Thus, III, IV, V, and VI were characterized in the case of I, and III, IV, V, and VII, in the case of II, as will be shown below.

dl-*Linaloyl Neryl Ether (III)*: A colorless, oily compound was isolated from dimeric fractions of both I and II as a less polar substance than geranyl linaloyl ether.[1] The molecular formula of this compound was determined to be $C_{20}H_{34}O$, which corresponds to that of terpene ether based on the molecular ion in the mass spectra; the IR spectrum showed characteristic ether bands at 1118, 1098, 1048, and 1039 cm^{-1}, and the NMR spectrum revealed proton signals of five vinylic methyl groups at δ 1.60 (6H), 1.67 (6H), and 1.72 (3H), whose chemical shifts are in good correspondence with those of the isopropyridene of II (δ 1.60, 1.67, each 3H, br. s)[8] and of isopropyridene (δ 1.60, 3H, br. s, δ 1.68, 3H, d, $J=1$ Hz) and the vinylic methyl signals (δ 1.72, 3H, d, $J=1$ Hz) of I.[8] The correspondence of the proton signals was also observed between vinylic methyls of geranyl linaloyl ether[1] and its mother alcohols. This evidence suggests that the compound is linaloyl neryl ether.

The ether was subjected to catalytic hydrogenation over an Adams catalyst in acetic acid to give an octahydro derivative, $C_{20}H_{40}O$, which was identified as tetrahydrolinaloyl tetrahydroneryl ether based on the coincidence of the IR and NMR spectra with those of an authentic ether synthesized from *dl*-tetrahydrolinalool and tetrahydronerol (tetrahydrogeraniol) according to Williamson's procedure.[7] Thus, it is certain that the compound was *dl*-linaloyl neryl ether (III).

l-*Geranyl Linaloyl Ether (IV)*: This ether, $C_{20}H_{34}O$, $[\alpha]_D^{18}$ −16.7°, was isolated as a secondary, eluted, colorless, oily compound from dimeric fractions of II. The IR, NMR, and mass spectra were superimposable on those of the geranyl linaloyl ether which had been obtained in the reaction of geraniol with boron trifluoride etherate and whose structure has been proposed.[1] The compound took up four molar equivalents of hydrogen in catalytic hydrogenation over platinum oxide in acetic acid to give an octahydro derivative which was identical with tetrahydrogeranyl tetrahydrolinaloyl ether in glc and spectroscopy. This ether, IV, was also detected as a trace in glc of the reacted mixture from I.

dl-*Neryl α-Terpenyl Ether (V)*: A third colorless, oily ether was isolated from dimeric fractions of I and II as a more polar substance than geranyl linaloyl ether.

The $C_{20}H_{34}O$ ether absorbed three molar equivalents of hydrogen in catalytic hydrogenation over platinum oxide in acetic acid to give a hexahydro derivative, $C_{20}H_{40}O$, which was identified as tetrahydroneryl dihydro-α-terpenyl ether by a comparison of the IR, NMR, and mass spectra with those of an authentic synthesized ether.

The IR and NMR spectra of the ether exhibited the presence of an ether linkage (1162, 1141, 1056, and 1040 cm^{-1}; δ 3.87, 2H, d, $J=7$ Hz) connecting an allylic methylene and a tertiary carbon, gem-dimethyls

a) Ten grams of the alcohol were used in each experiment. b) Composition of reacted mixtures was determined with the aid of gas chromatography.

on an oxygen-bearing carbon atom (1381 and 1369 cm^{-1}; δ 1.13, 6H, s), four vinylic methyls (1675 and 830 cm^{-1}; δ 1.60, 3H, br. s, δ 1.67, 6H, br. s. and δ 1.72, 3H, d, J=1 Hz), three vinylic protons (δ 5.30, 3H, m), and four allylic methylenes (δ 2.10, 8H, br. s). Moreover, the proton signals of the four vinylic methyls showed a good correspondence with those of a vinylic methyl and an isopropyridene group of nerol and of a vinylic methyl of α-terpineol. Thus, the ether could be characterized as *dl*-neryl α-terpenyl ether (V).

Dineryl Ether (VI): The $C_{20}H_{34}O$ ether, which was isolated as the most polar substance in the elution chromatography of the dimeric fractions from I, took up four molar equivalents of hydrogen in catalytic hydrogenation over platinum oxide in acetic acid to give an octahydroether, $C_{20}H_{42}O$, whose IR, NMR, and mass spectra were superimposable upon those of ditetrahydroneryl ether synthesized from tetrahydronerol.

The IR and NMR spectra of the ether showed the presence of an ether linkage connecting two allylic methylenes (1100, 1068 cm^{-1}; δ 4.03, 4H, d, J=7 Hz), each of which was coupled with a vinylic proton (1672 and 835 cm^{-1}; δ 5.30, 4H, m), and both of isopropyridene and vinylic methyl (δ 1.60, 6H, br. s and δ 1.67, 1.72, each 6H, d, J=1 Hz).[8] The methyl signals of the isopropyridene and vinylic methyl also corresponded to those of nerol. Thus, it is certain that this compound was dineryl ether (VI).

l-Linaloyl Piperityl Ether (VII): The most polar compound, $C_{20}H_{34}O$, $[\alpha]_D^{18}$ −38.3°, which was isolated from the dimeric fraction of II showed absorption bands attributable to an ether linkage at 1148, 1118, 1108, and 1085 cm^{-1} and an *m/e* 137 (14%) ion, $C_{10}H_{17}$, characteristic of the mass spectra of the terpene ethers mentioned above. The compound gave a dihydro derivative, $C_{20}H_{36}O$, in catalytic hydrogenation over platinum oxide in methanol and a saturated hexahydro derivative, $C_{20}H_{40}O$, in catalytic hydrogenation over the same catalyst in acetic acid. The evidence revealed the compound to be a mixed ether of acyclic and monocyclic terpene alcohols.

The NMR spectrum of the compound showed a typical ABX signal attributable to a terminal vinyl group (δ 5.95, q, J_{AX}=18 Hz, J_{BX}=10 Hz; δ 5.15, q, J_{AB}=2 Hz, J_{AX}=18 Hz; δ 4.95, q, J_{AB}=2 Hz, J_{AX}=10 Hz, each 1H), overlapped with signals of other olefinic protons. This signal disappeared in the spectrum of the dihydro derivative, which contained the proton signals attributable to two secondary methyls (δ 1.11 and 1.16, each 3H, d, J=6 Hz), three vinylic methyls (δ 1.60 and 1.68, 6H and 3H, each br. s), two vinylic protons (δ 5.08, 2H, m), two allylic methylenes (δ 2.00, 4H, br. s), an oxygen-bearing methine (δ 3.95, 1H, d, J=7 Hz), and a methyl attached to an oxygen-bearing tertiary carbon (δ 1.10, 3H, s); the signal of the last methyl showed an upper-field shift by 0.18 ppm compared with that of the corresponding methyl group in the original ether (δ 1.28, 3H, s), as well as those of the methyls attached to an oxygen-bearing tertiary carbon in both linalool (δ 1.28, 3H, s) and dihydrolinalool (δ 1.10, 3H, s). On the other hand, the hexahydro derivative of VII was heated with hydroiodic acid and also treated with acetic anhydride and boron trifluoride etherate to give menthyl iodide and menthyl acetate respectively. The evidence certainly indicates that the ether is linaloyl l-*p*-menthenyl ether.

As the position to which the linalooxy residue is attached, three carbons, $C_{(3)}$, $C_{(5)}$, and $C_{(6)}$, of the l-*p*-menthenyl moiety are possible.

As has been mentioned above, both oxygen-bearing

Table 2. Conversion of *dl*-linaloyl neryl ether and *dl*-geranyl linaloyl ether by boron trifluoride etherate

	Linaloyl neryl ether (%)	Geranyl linaloyl ether (%)
Unreacted ether	2.0	6.2
Monoterpene hydrocarbons	33.0	6.8
Linalool	—	8.2
α-Terpineol	20.1	4.7
Nerol	—	trace
Geraniol	—	2.3
Linaloyl piperityl ether	25.0	57.0
Polymer	13.5	10.1
Other compounds	6.4	4.7

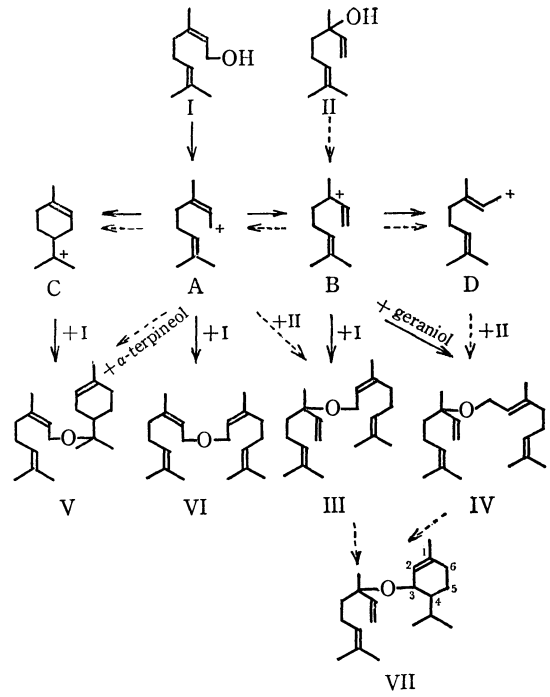
methines of VII and its dihydro derivative commonly showed the doublet at δ 3.95 (J=7 Hz), while the methine group of the hexahydro derivative of VII showed the triplet at δ 3.40. Such an upward shift and change in the signal pattern depending upon the saturation of the 1-*p*-menthene residue picked up the $C_{(3)}$ from the above possible position as the ether-linked position. Thus, the structure of the ether is probably *l*-linaloyl piperityl ether.

The Dreiding model examination of VII, furthermore, showed the following facts: when the isopropyl group holds the pseudoequatorial conformation, the dihedral angle between $C_{(2)}$–H and $C_{(3)}$–H is approximately 80°, and that between $C_{(3)}$–H and $C_{(4)}$–H, 170°; when the isopropyl group holds the axial conformation, they are, respectively, 45° and 75°. On the other hand, the NMR spectra of VII and its dihydro derivative showed a doublet with 7 Hz as the proton signals due to the C_3-methine groups. According to Karplus' equation[9] these results indicate that both $C_{(3)}$–H and $C_{(4)}$–H in the molecule of VII are in the axial conformation. This ether was also obtained by treating III and IV with boron trifluoride etherate, as is shown in Table 2.

The Course of Formation. Under the same conditions (Experiments 1 and 7), although I and II showed a nearly equal conversion, an appreciable difference was observed in the relative yields of the hydrocarbons, alcohols, ethers, and residues (polymers): the yields of the monoterpene alcohols and the ethers were higher in the case of I, whereas the monoterpene hydrocarbons and the residue (polymer) were obtained in higher yields from II (*cf.* Table 1).

All the monoterpene hydrocarbons identified in the present investigation can be explained as being formed by the deprotonation of the carbonium ions listed in Scheme 1, A, B, C, and D, which may be produced from I and II in the presence of boron trifluoride etherate, and the formation of all the monoterpene alcohols is attributable to the coupling of these cations and the hydroxyl anions.

Of the ethers, the III, V, and VI characterized in the reaction of I and the III and IV characterized in the reaction of II may be formed by a combination between these carbonium ions and the mother alcohol, I or II; besides, VII, as has been mentioned above, is



Scheme 1.

attributable to the cyclization of III and IV. Regarding the formation of IV in the reaction of I and that of V in the reaction of II, the contribution of geraniol and α-terpineol, which are produced in large amounts in these reactions, may be supposed.

Experimental

Apparatus. The IR spectra were taken either in liquid film or a CCl_4 solution, and the NMR spectra, on a 60 MHz spectrometer in a $CDCl_3$ solution, using TMS as the internal reference. The mass spectra were measured by means of a Hitachi RMS-4 spectrometer under these operating conditions: 80 eV, ionization-chamber voltage; 80 μA, total emission; 1800 eV, ion-accelerating voltage, and 200 °C, ionization-chamber temperature. The combined glc-mass analyses were carried out on a Shimadzu-LKB 9000 gas chromatograph, and the mass spectrometer, in connection with a 3 mm×3 m glass tube packed with Carbowax 20 M (10%) on Diasolid (60—80 mesh) under a 5 °C/min temperature program from 50 °C to 120 °C; 70 eV, ionization voltage; 3500 eV, ion-accelerating voltage and 200 °C, ionization temperature. The glc was carried out on a FID-type apparatus in connection with stainless-steel column (3 mm×3 m) packed with Carbowax 6000 (10%) on Diasolid (60—80 mesh), DEGS (10%), on Shimalite W (60—80 mesh) and Silicone SE-30 (10%) on Uniport B (60—80 mesh) under the 20 ml/min flow rate of a N_2 carrier.

Materials. Commercial nerol and *l*-linalool were used after repeated fractional distillation. They each showed one peak in glc with DEGS- and Carbowax 6000-packed columns, and the IR spectra of these materials coincided with authentic ones.[10] Nerol: bp 109 °C/10 mmHg, n_D^{20} 1.4630, $[\alpha]_D^{20}\pm0°$ ($CHCl_3$); linalool: bp 70 °C/4 mmHg, n_D^{25} 1.4650, $[\alpha]_D^{16}-19.7°$ ($CHCl_3$), phenylurethane, mp 63—64 °C.

A chemical-grade reagent of $BF_3\cdot Et_2O$ (BF_3 47%) was used without any purification.

Reaction of Nerol (I) and l-Linalool (II) with $BF_3\cdot Et_2O$.

To each 10 g portion of I and II, the amount of $BF_3 \cdot Et_2O$ listed in Table 1 was added, drop by drop. The mixture was then allowed to react under several temperatures for periods from 24 hr to 72 hr. The reacted mixtures were shaken with a saturated aqueous solution of sodium carbonate to decompose the remaining $BF_3 \cdot Et_2O$, washed with water, dried over anhydrous sodium sulfate, and fractionated under reduced pressure to separate two fractions (bp 60—90 °C/4 mmHg and 90—120 °C/4 mmHg).

Characterization of Monoterpene Compounds. Each low-boiling fraction (bp 60—90 °C/4 mmHg) separated from the reacted mixtures of I and II was eluted over a silica gel column with *n*-hexane and then ethyl acetate to separate it further into two hydrocarbon and alcohol portions. The hydrocarbon portions from I and II, both showing eight peaks in glc with a Carbowax 6000-packed column, was gas-chromatographed by admixing them with authentic samples and subjected to combined glc-mass analysis; they were thus identified as myrcene, β-ocimene X, β-ocimene Y, α-terpinene, γ-terpinene, dipentene, *p*-cymene, and terpinolene.[11] The IR spectra of these compounds which were taken after the isolation by preparative glc showed good agreement with those of authentic samples.

The alcohol portions from I and II each showed three peaks other than the peak of unreacted alcohol in glc with DEGS. By comparison with authentic samples through glc, and by taking the IR spectra of isolated individual components, the components were identified as linalool, α-terpineol, and geraniol in the case of I and as α-terpineol, $[\alpha]_D^{20}+31.0°$, nerol, and geraniol in the case of II. α-Terpineol phenylurethane (mp 112—113 °C) and geraniol phenylurethane (mp 123.5—124.0 °C) were also prepared.

Characterization of Dimeric Products from Nerol (I). The high-boiling fractions (bp 90—120 °C/4 mmHg) from reaction mixtures of I showed the existence of four compounds in tlc carried out with silica gel and benzene and in glc with Silicone SE-30- and Carbowax 20M-packed columns at 200 °C. By elution over a silica gel column with benzene, the compounds were isolated.

dl-*Linaloyl Neryl Ether (III).* The compound showing a peak of t_R 8.7 on the SE-30 was isolated as the most quickly-moving colorless, viscous oil in the elution chromatography with benzene. n_D^{17} 1.4714. $[\alpha]_D^{17}\pm0°$ ($CHCl_3$), $C_{20}H_{34}O$ (M^+ 290). $\nu_{max}^{CCl_4}$ cm^{-1}: 3080, 930, 1645 ($CH_2=CH-$), 1673, 840 ($-CH=\underline{C}-$), 1118, 1098, 1048, 1039 (C–O–C). $\delta_{ppm}^{CDCl_3}$: 1.27 (3H, s, $C\underline{H}_3-\underline{C}-O$), 1.60 (6H, br. s, $C\underline{H}_3-\underline{C}=\underline{C}-$), 1.67 (6H, br. s, $C\underline{H}_3-\underline{C}=\underline{C}-$), 1.72 (3H, d, $J=1$ Hz, $C\underline{H}_3-\underline{C}=\underline{C}-$), 3.80 (2H, d, $J=7$ Hz, $-\underline{C}=CH-C\underline{H}_2-O-$), 4.90—5.97 (5H, m, $C\underline{H}_2=C\underline{H}-$ and $-C\underline{H}=\underline{C}-$). Mass: *m/e* 41(80%), 69(base), 71(21), 81(67), 93(36), 95(36), 101(34), 121(11), 123(9), 136(18), 137(21), 153(6), 154(7), 247(2, $M^+-C_3H_7$), 290 (1, M^+, $C_{20}H_{34}O$).

Catalytic Hydrogenation of III: Compound III (200 mg) was hydrogenated over platinum oxide (20 mg) in acetic acid (6 ml) to give an octahydro derivative as a colorless oil in a good yield. $\nu_{max4}^{CCl_4}$ cm^{-1}: 1381, 1366 ($CH_3-\underline{C}H-CH_3$), 1149, 1072 (C–O–C). $\delta_{ppm}^{CDCl_3}$: 0.90 (15H, d, $J=6$ Hz, $C\underline{H}_3-\underline{C}H-$), 1.10 (3H, s, $C\underline{H}_3-\underline{C}-O-$), 3.30 (2H, t, $J=6$ Hz, $-\underline{C}-O-C\underline{H}_2-CH_2-$). The spectra were superimposable on those of the tetrahydrolinaloyl tetrahydroneryl ether synthesized in the following section.

Synthesis of Tetrahydrolinaloyl Tetrahydroneryl Ether. Tetrahydronerol (3 g) was dissolved in a mixture of hydrobromic (48%, 10 g) and concentrated sulfuric acids (3 g), and the solution was refluxed for 6 hr. The reacted mixture, after being cooled to room temperature, was successively washed with water, a 10% aqueous solution of sodium bicarbonate, and water, dried over sodium sulfate, and fractionated under ordinary pressure. The tetrahydroneryl (tetrahydrogeranyl) bromide was thus obtained as a colorless oil (bp 222—223 °C) in a yield of 60%. $\nu_{max}^{CCl_4}$ 4 cm^{-1}: 1391, 1374 ($CH_3-\underline{C}H-CH_3$). $\delta_{ppm}^{CDCl_3}$: 0.85 (9H, d, $J=6$ Hz, $C\underline{H}_3-\underline{C}H-$), 1.21 (8H, br.s, $-C\underline{H}_2-$), 3.42 (2H, t, $J=7$ Hz, $-CH_2-C\underline{H}_2-Br$).

dl-Tetrahydrolinalool (1 g) was refluxed with metallic sodium (0.3 g) in dried ether (10 ml) for 18 hr. After the unreacted sodium had been filtered off, the tetrahydroneryl bromide (0.5 g) prepared above was added to the filtrate; the mixture was then refluxed again for 18 hr. The mixture thus reacted was washed with water, dried over anhydrous sodium sulfate, and fractionated under reduced pressure to give tetrahydrolinaloyl tetrahydroneryl ether as a colorless oil in a 10% yield. n_D^{18} 1.4850, $[\alpha]_D^{20}\pm0°$ ($CHCl_3$). ν_{max}^{liq} cm^{-1}: 1381, 1366 ($CH_3-\underline{C}H-CH_3$), 1149, 1072 (C–O–C). $\delta_{ppm}^{CDCl_3}$: 0.89 (15H, d, $J=6$ Hz, $C\underline{H}_3-\underline{C}H-$), 1.10 (3H, s, $C\underline{H}_3-\underline{C}-O-$), 3.30 (2H, t, $J=6$ Hz, $-\underline{C}-O-C\underline{H}_2-CH_2-$).

dl-*Neryl α-Terpenyl Ether (V).* The compound, t_R 10.5 on the SE-30, was isolated as a colorless oil by elution chromatography with benzene. n_D^{17} 1.4809, $[\alpha]_D^{20}\pm0°$ ($CHCl_3$), $C_{20}H_{34}O$ (M^+ 290). $\nu_{max}^{CCl_4}$ cm^{-1}: 1381, 1369 ($CH_3-\underline{C}H-CH_3$), 1162, 1141, 1056, 1040 (C–O–C), 1675, 830 ($-\underline{C}=CH-$). $\delta_{ppm}^{CDCl_3}$: 1.13 (6H, s, $(C\underline{H}_3)_2-\underline{C}-O-$),1.60 (3H, br. s, $C\underline{H}_3-\underline{C}=CH-$), 1.67 (6H, br. s, $C\underline{H}_3-\underline{C}=CH-$), 1.72 (3H, d, $J=1$ Hz, $C\underline{H}_3-\underline{C}=CH-$), 3.87 (2H, d, $J=7$ Hz, $-\underline{C}=CH-C\underline{H}_2-O-$), 5.30 (3H, m, $-C\underline{H}=\underline{C}-$). Mass: *m/e* 41(53%), 69(68), 81(base), 83(20), 93(27), 95(53), 107(7), 109(4), 117(38), 119(34), 121(14), 136(36), 137(51), 154(9), 272(2, M^+-H_2O), 290 (1, M^+, $C_{20}H_{34}O$).

Catalytic Hydrogenation of V: Compound V (250 mg) was subjected to catalytic hydrogenation over platinum oxide (30 mg) in acetic acid (7 ml) to give a hexahydro derivative as a colorless oil in a good yield. $\nu_{max}^{CCl_4}$ cm^{-1}: 1383, 1368 ($CH_3-\underline{C}H-CH_3$ and $CH_3-\underline{C}-CH_3$), 1173, 1150, 1121, 1070 (C–O–C). $\delta_{ppm}^{CDCl_3}$: 0.86 (12H, d, $J=6$ Hz, $C\underline{H}_3-\underline{C}H-$), 1.08 (6H, s, $(C\underline{H}_3)_2-\underline{C}-O-$), 3.31 (2H, t, $J=6$ Hz, $-\underline{C}-O-C\underline{H}_2-CH_2-$). Mass: *m/e* 39(5%), 41(22), 43(48), 55(34), 57(80), 59(40), 69(22), 71(78), 81(10), 85(65), 99(17), 123(7), 139(9), 140(7), 141(38), 142(6), 199(base), 211(4), 281(4, M^+-CH_3), 296(2, M^+, $C_{20}H_{40}O$). The spectra were in good agreement with those of the tetrahydroneryl dihydro-α-terpenyl ether to be synthesized in the following section.

Synthesis of Tetrahydroneryl Dihydro-α-terpenyl Ether. Dihydro-α-terpineol (1 g) was refluxed with metallic sodium (0.3 g) in dried ether (10 ml) for 18 hr. After the unreacted sodium had then been filtered off, the tetrahydroneryl bromide (0.5 g) prepared in the above section was added to the filtrate, the mixture being refluxed for 18 hr. The reacted mixture was afterwards treated by a usual procedure to give tetrahydroneryl dihydro-α-terpenyl ether as a colorless oil in a yield of 15%. $\nu_{max}^{CCl_4}$ cm^{-1}: 1382, 1368 ($CH_3-\underline{C}H-CH_3$), 1173, 1150, 1121, 1070 (C–O–C). $\delta_{ppm}^{CDCl_3}$: 0.86 (12H, d, $J=6$ Hz, $C\underline{H}_3-\underline{C}H-C\underline{H}_3$), 1.08 (6H, s, $(C\underline{H}_3)_2-\underline{C}-O-$), 3.31 (2H, t, $J=6$ Hz, $-\underline{C}-O-C\underline{H}_2-CH_2-$). Mass:

m/e 41(22%). 43(48), 55(34), 57(80), 59(40), 69(22), 71(78), 81(20), 85(65), 123(7), 139(9), 141(38), 199(base), 281(4), 296(2, M^+, $C_{20}H_{40}O$).

Dineryl Ether (VI). The compound, t_R 11.8 on the SE-30, was isolated as the last colorless oil in the elution chromatography of the dimeric fraction of I. n_D^{17} 1.4771; $C_{20}H_{34}O$ (M^+ 290). $\nu_{max}^{CCl_4}$ cm^{-1}: 1672, 835 (-C=CH-), 1100, 1068 (C-O-C). $\delta_{ppm}^{CDCl_3}$: 1.60 (6H, br. s, CH_3-C=CH-), 1.67 and 1.72 (each 6H, d, J=1 Hz, CH_3-C=CH-), 4.03 (4H, d, J=7 Hz, -C=CH-CH_2-O-), 5.30 (4H, m, -CH=C-). Mass: *m/e* 41(96%), 69(base), 81(72), 83(27), 93(49), 95(36), 107(12), 117(45), 119(45), 121(14), 123(13), 135(13), 136(28), 137(21), 154(12), 290(1, M^+, $C_{20}H_{34}O$).

Catalytic Hydrogenation of VI: Compound VI (200 mg) was hydrogenated over a platinum oxide catalyst (20 mg) in acetic acid (6 ml) to give an octahydroether in a good yield. ν_{max}^{liq} cm^{-1}: 1390, 1383, 1371 (CH_3-CH-CH_3), 1119 (C-O-C). $\delta_{max}^{CDCl_3}$: 0.85 (18H, d, J=6 Hz, CH_3-CH-), 3.40 (4H, t, J=6 Hz, -CH_2-CH_2-O-). Mass: *m/e* 39 (19%), 41(62), 43(base), 55(50), 57(52), 69(37), 70(31), 71(30), 83(24), 85(18), 97(15), 140(10), 141(6), 163(6), 298(1, M^+, $C_{20}H_{42}O$). The spectra were superimposable upon those of the ditetrahydroneryl ether to be synthesized in the following section.

Synthesis of Ditetrahydroneryl Ether. Tetrahydroneryl bromide (1 g) was added to a dried ether solution of sodium tetrahydronerolate which had been prepared from tetrahydronerol and metallic sodium, the mixture being refluxed for 18 hr. The ditetrahydroneryl ether was thus obtained as a colorless oil in a 12% yield. ν_{max}^{liq} cm^{-1}: 1390, 1383, 1371 (CH_3-CH-CH_3), 1119 (C-O-C). $\delta_{ppm}^{CDCl_3}$: 0.85 (18H, d, J=6 Hz, CH_3-CH-), 3.40 (4H, t, J=6 Hz, -CH_2-CH_2-O-). Mass: *m/e* 39(19%), 41(62), 43(base), 55(50), 57(52), 69(37), 70(31), 71(30), 83(24), 85(18), 97(15), 140(10), 141(6), 298(1, M^+, $C_{20}H_{42}O$).

Characterization of Dimeric Products from l-Linalool (II). The high-boiling fraction (bp 90—120 °C/4 mmHg) from each reaction product of II showed the existence of four compounds in the tlc carried out with silica gel and benzene and in the glc carried out with the Silicone SE-30- and Carbowax 20 M-packed columns at 200 °C. These compounds were isolated by being eluted over a silica gel column with benzene and were characterized as is shown below.

l-Geranyl Linaloyl Ether (IV). The colorless oil, t_R 9.5, was isolated as the secondary eluted compound from the dimeric fraction of II by silica gel column chromatography with benzene. n_D^{15} 1.4834, $[\alpha]_D^{18}$ −16.7° ($CHCl_3$); $C_{20}H_{34}O$ (M^+ 290, Rast's mol. wt. 293). ν_{max}^{liq} cm^{-1}: 1670, 830 (-C=CH-), 1000, 917 (CH_2=CH-), 1108, 1050 (C-O-C). $\delta_{max}^{CDCl_3}$: 1.28 (3H, s, CH_3-C-O-), 1.60, 1.68 (15H, br. s, CH_3-C=CH-), 3.82 (2H, d, J=6 Hz, -CH_2-O-C-), 4.95—5.95 (6H, m, CH_2=CH- and -CH=C-). Mass: *m/e* 41 (62%), 55(21), 69(base), 81(50), 93(32), 95(29), 109(10), 121(14), 123(17), 137(22), 153(26), 290(2, M^+, $C_{20}H_{34}O$). These spectra were coincident with those of geranyl linaloyl ether.[1)]

Catalytic Hydrogenation of IV: Compound IV (100 mg) was hydrogenated over a platinum oxide catalyst (10 mg) to give an octahydro derivative as a colorless oil in a good yield. ν_{max}^{liq} cm^{-1}: 1381, 1366 (CH_3-CH-CH_3), 1149, 1072 (C-O-C). $\delta_{max}^{CDCl_3}$: 0.90 (15H, d, J=6 Hz, CH_3-CH-), 1.10 (3H, s, CH_3-C-O-), 3.30 (2H, t, J=6 Hz, -C-O-CH_2-CH_2-). These spectra were coincident with those of tetrahydrogeranyl tetrahydrolinaloyl ether synthesized as will be shown below.

Synthesis of dl-*Tetrahydrogeranyl Tetrahydrolinaloyl Ether.* Tetrahydrogeranyl bromide (1.0 g) and sodium *dl*-tetrahydrolinaloolate (1 g) were treated according to the above-mentioned procedure to give tetrahydrogeranyl tetrahydrolinaloyl ether in a 10% yield. n_D^{18} 1.4850; $[\alpha]_D^{20}$ ±0° ($CHCl_3$). ν_{max}^{liq} cm^{-1}: 1381, 1366 (CH_3-CH-CH_3), 1149, 1072 (C-O-C). $\delta_{max}^{CDCl_3}$: 0.89 (15H, d, J=6 Hz, CH_3-CH-), 1.10 (3H, s, CH_3-C-O-), 3.30 (2H, t, J=6 Hz, -C-O-CH_2-CH_2-).

l-Linaloyl Piperityl Ether (VII). The compound, t_R 11.2, was isolated as the most slowly-moving component by the elution chromatography of the dimeric fractions of II. n_D^{18} 1.4871; $[\alpha]_D^{18}$ −38.3° ($CHCl_3$), $C_{20}H_{34}O$ (M^+ 290, Rast's mol. wt. 286). ν_{max}^{liq} cm^{-1}: 3080, 1650, 991, 918 (CH_2=CH-), 1680, 835 (-C=CH-), 1388, 1371 (CH_3-CH-CH_3), 1148, 1118, 1108, 1085 (C-O-C). $\delta_{ppm}^{CDCl_3}$: 1.11, 1.16 (each 3H, d, J=6 Hz, CH_3-CH-), 1.28 (3H, s, CH_3-C-O-), 1.60, 1.68 (6H and 3H, each br. s, CH_3-C=CH-), 2.00 (4H, br. s, -CH_2-C=C-), 3.95 (1H, d, J=7 Hz, -O-CH-CH=C-), 4.95 (1H, q, J_{AB}=2 Hz, J_{BX}=10 Hz), 5.15 (1H, q, J_{AB}=2 Hz, J_{AX}=18 Hz), 5.95 (1H, q, J_{AX}=18 Hz, J_{BX}=10 Hz), 5.08 (2H, m, -CH=C-). Mass: *m/e* 41(56%), 43(23), 55(17), 69(base), 71(6), 80(7), 81(34), 93(20), 95(26), 107(12), 109(8), 121(11), 123(31), 137(14, $C_{10}H_{17}$), 275(2, M^+-CH_3), 290(2, M^+, $C_{20}H_{34}O$).

Dihydro Derivative of VII: When VII (150 mg) was submitted to catalytic hydrogenation over platinum oxide (20 mg) in methanol (6 ml), one molar equivalent of hydrogen was taken up. The reacted mixture was treated according to a usual procedure to obtain a dihydro derivative as an oil. ν_{max}^{liq} cm^{-1}: 1660, 835 (-C=CH-), 1385, 1376 (CH_3-CH-CH_3), 1140, 1024 (C-O-C). $\delta_{ppm}^{CDCl_3}$: 0.90 (3H, t, J=6 Hz, CH_3-CH_2-), 1.10 (3H, s, CH_3-C-O-), 1.11, 1.16 (each 3H, d, J=6 Hz, CH_3-CH-), 1.60, 1.68 (6H and 3H, br. s, CH_3-C=CH-), 2.00 (4H, br. s, -CH_2-CH=C-), 3.95 (1H, d, J=7 Hz, -C-O-CH-CH=C-), 5.08 (2H, m, -CH=C-).

Hexahydro Derivative of VII: The dihydro derivative of VII (120 mg) was again submitted to catalytic hydrogenation over platinum oxide (10 mg) in the same methanol solvent (7 ml) at room temperature; the hexahydro derivative was thus obtained. On the other hand, VII (300 mg) was also hydrogenated over platinum oxide (30 mg) by using acetic acid instead of methanol as a solvent at room temperature to give the same hexahydro derivative. ν_{max}^{liq} cm^{-1}: 1384, 1375 (CH_3-CH-CH_3), 1131, 1020 (C-O-C). $\delta_{ppm}^{CDCl_3}$: 0.85 (9H, d, J=6 Hz, CH_3-CH-), 1.11, 1.61 (each 3H, d, J=6 Hz, CH_3-CH-CH_3), 3.40 (1H, t, J=6 Hz, -O-CH-CH_2-), 1.10 (3H, s, CH_3-C-O-). Mass: *m/e* 41(33%), 43(40), 55(48), 69(40), 70(base), 71(43), 81(15), 83(43), 95(18), 97(22), 109(20), 111(19), 123(27), 126(19), 137(14), 139(6),

153(10), 238(28), 267(55, $C_{18}H_{35}O$), 281(16, M^+-CH_3, $C_{19}H_{37}O$), no molecular ion.

Ether Cleavage of the Hexahydro Derivative of VII with Hydroiodic Acid: Hexahydro derivative (200 mg) was refluxed with hydroiodic acid ($d=1.7$, 1 ml) for 10 min. The reaction product extracted from the reacted mixture was eluted over a silica gel column with *n*-hexane to separate a nonhydrocarbon portion as a colorless oil showing a peak at t_R 10.3 in glc with Silicone SE-30; 5% yield. n_D^{20} 1.5088. $\nu_{max}^{CCl_4}$ cm^{-1}: 1389, 1380, 1360, 1171. $\delta_{ppm}^{CDCl_3}$: 0.82, 0.92 (9H, d, $J=6$ Hz, $C\underline{H}_3$-CH-), 4.09 (1H, dt, $J=3$, 10 Hz, $-CH_2-C\underline{H}-I$). Mass: *m/e* 41(50%), 43(45), 55(70), 69(65), 83(base), 95(10), 97(12), 127(3, I^+), 139 (40, $C_{10}H_{19}$), 266 (1, M^+, $C_{10}H_{19}I$). These IR, NMR, and mass spectra were all superimposable on those of menthyl iodide which had been prepared by heating a mixture of menthol (2.0 g), red phosphorus (0.1 g), and resublimed iodide (1.0 g) at 150 °C for 2 hr.

Ether Cleavage of the Hexahydro Derivative of VII with Acetic Anhydride and $BF_3.Et_2O$: Hexahydro derivative (100 mg) was treated with acetic anhydride (0.2 ml) and $BF_3\cdot Et_2O$ (0.02 ml) in dried ether (1 ml) at room temperature for 48 hr. The reaction product separated according to a usual manner was chromatographed over silica gel with *n*-hexane and then a mixture of *n*-hexane and ethyl acetate (95 : 5) to separate an oxygen-containing compound as a colorless oil showing a peak at t_R 5.5 in glc with Silicone SE-30 in a yield of 5%. $\nu_{max}^{CCl_4}$ cm^{-1}: 1735, 1245, 1125 (-CO-OCH_3), 1389, 1371 (CH_3-CH-CH_3). $\delta_{ppm}^{CDCl_3}$: 0.80, 0.89 (9H, d, $J=6$ Hz, $C\underline{H}_3$-CH-$C\underline{H}_3$, $C\underline{H}_3$-CH-), 4.70 (1H, dt, $J=4$, 10 Hz, $-C\underline{H}-OCOCH_3$), 2.00 (3H, s, $-OCOC\underline{H}_3$). Mass: *m/e* 41(42%), 43(base), 55(22), 67(18), 81(27), 95(31), 109(5), 123(11), 138(19, M^+-CH_3COOH), 198 (trace, M^+). The IR, NMR, and mass spectra were respectively superimposable on those of a synthetic sample of *l*-menthyl acetate.

Conversion of III and IV by $BF_3\cdot Et_2O$. The III ether (200 mg) was dissolved in dried ether (1 ml) and mixed with 0.02 ml of $BF_3\cdot Et_2O$. On the other hand, IV (300 mg) was dissolved in dried ether (1.5 ml) and mixed with 0.03 ml of $BF_3\cdot Et_2O$. After the two mixtures had been allowed to stand at room temperature for 18 hr, a small amount of water was added to each of the reacted mixture to decompose the excess reagent. The reacted mixtures thus treated were then gaschromatographed on the DEGS separation column to determine their compositions; *cf.* Table 2. In these cases, the characteristics of the monoterpene hydrocarbons were assumed based on the retention times, while the monoterpene alcohols, linalool, α-terpineol, nerol, and geraniol, were tentatively identified by comparing the retention times with those of authentic samples. Linaloyl piperityl ether, after being isolated by preparative glc, was identified through a determination of the IR, NMR, and mass spectra.

The author wishes to express her sincere gratitude to Professor Shûichi Hayashi and Assistant Professor Mitsuru Nakayama, of Hiroshima University, for their kind guidance and discussion during this work.

The Synthesis of 11-(2′-Dimethylaminoethyl)-5-methyl-5,11-dihydrodibenzo[*b*,*e*][1,4]thiazepin and Related Compounds. Neurotropic and Psychotropic Agents

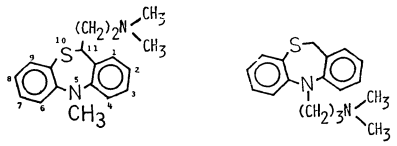
Ikuo UEDA* and Suminori UMIO

Research Laboratories, Fujisawa Pharmaceutical Co., Ltd., Kashima, Yodogawa-ku, Osaka 532

(Received January 6, 1975)

The synthesis of 11-(2′-dimethylaminoethyl)-5-methyl-5,11-dihydrodibenzo[*b*,*e*][1,4]thiazepin and related compounds is described. 11-Lithiolated 5-methyl-5,11-dihydrodibenzo[*b*,*e*][1,4]thiazepin (**18**) was employed as the key intermediate in the preparation of these compounds.

Morimoto had indicated, from his molecular orbital treatment using the Hückel approximation, that the dibenzo[*b*,*e*][1,4]thiazepin ring has approximately the same π-electron level as phenothiazine.[1] This result led the present authors to investigate the synthesis of 11-substituted dibenzo[*b*,*e*][1,4]thiazepin derivatives (**I**).



I **14e**

Chart 1.

In this paper, the authors will describe a synthesis of 11-substituted 5-methyl-5,11-dihydrodibenzo[*b*,*e*]-[1,4]thiazepin and related compounds which, in our animal studies, displayed an imipramine-like activity.[2]

Results and Discussion

The synthesis of Compound **I** was attempted by the following two methods. Method A involved the preparation of 11-substituted dihydrodibenzo[*b*,*e*][1,4]-thiazepins by the cyclization of α-substituted phenyl benzyl thioethers, while Method B involved the preparation of 5-methyl-11-substituted dibenzo[*b*,*e*][1,4]-thiazepins by the electrophilic substitution reaction of 5-methyl-5,11-dihydrodibenzo[*b*,*e*][1,4]thiazepin lithiolated(**18**) with alkyl halides and other reagents (Chart 2).

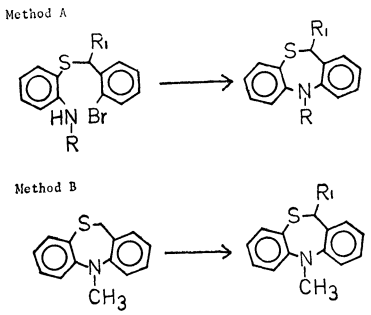


Chart 2.

The starting materials, α-substituted phenyl benzyl thioethers(**3**), were prepared by a patented procedure[3] or its modifications. The treatment of sodium thiophenolate with benzyl halides (**2**) in ethanol at room temperature or at the boiling point of the solvent used gave **3**, which was then allowed to react with 98% formic acid and with ethyl chloroformate to afford the **4** compounds in good yields. The catalytical hydrogenation of the Mannich base(**6**) with palladium carbon under atmospheric pressure gave an aminoalcohol(**9**). Compound **6** was reduced with sodium borohydride in methanol to give Compound **7**, which was then converted to benzyl chloride(**2d**) with thionyl chloride.

11. R_2=$OCH_2C_6H_5$

Chart 3.

The cyclization of **3a**, **b** and **4** at 120 to 140 °C in the presence of copper yielded 5,11-dihydrodibenzo-[*b*,*e*][1,4]thiazepins, **12** and **13**, in moderate yields, while the saponification of **13a**, **b** with an aqueous alcoholic sodium hydroxide solution gave Compound **12**. When R_1 in **3** was sterically bulky, such as a phenyl or dimethylaminoethyl group, either the starting material unchanged was recovered or resinous substances were formed. The alkylation of **12** with

* Abstracted from a portion of a Ph. D. Dissertation submitted by I. U. in March, 1974, to Osaka University.

sodium hydride and methyl iodide, allyl bromide, and dimethylaminoalkyl chloride[4] in DMF gave the corresponding 5-substituted 5,11-dihydrodibenzo[*b*,*e*]-[1,4]thiazepins(**14**) in moderate yields.

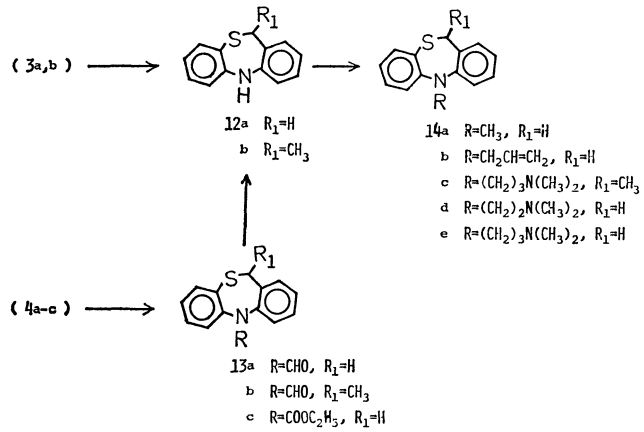

Chart 4.

It is known that compounds containing sulfur and/or nitrogen in the molecule are metalated at the carbon adjacent to the hetero atom by alkyl- or aryl-lithium to form organolithium compounds, which can then be used as synthetic intermediates.[5] The present authors employed this method for the preparation of 11-substituted dibenzo[*b*,*e*][1,4]thiazepin derivatives. In this case, the three sites shown by the a, b, and c arrows in Chart 5 are metalated with alkyl- or aryl-lithium.

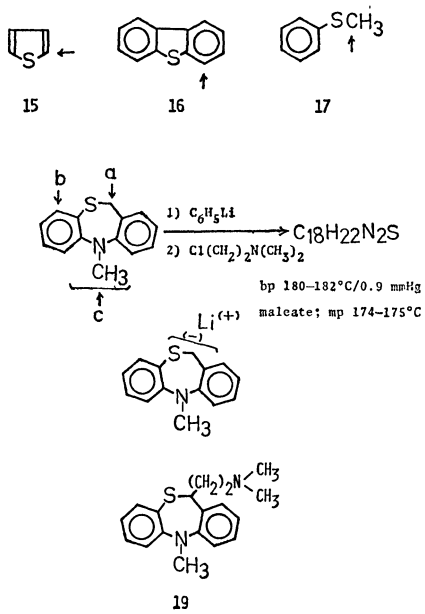

Chart 5.

The reaction of **14a** with phenyl lithium and dimethylaminoethyl chloride in ether afforded Compound **19** in a 62.4% yield. Evidence for the **19** structure was provided by the results of elementary analysis and by the spectral data. Compound **19** showed an emprical formula, $C_{18}H_{22}N_2S$, upon elementary analysis; its IR spectrum showed bands at 2800(tertiary amino group, NCH_3) and 700(condensed

Fig. 1. NMR spectrum of **19** in $CDCl_3$.

aromatic)cm^{-1}, and the NMR spectrum in deuteriochloroform exhibited signals at δ 2.17—2.50(4H, m, CH_2CH_2) 2.28(6H, s, $N(CH_3)_2$) and 3.25(3H, s, $N-CH_3$)ppm. A signal due to methine proton was observed at δ 4.29(1H, t, J=7.0 Hz, $C_{11}-H$)ppm. These findings show that the electrophlic substitution reaction occurred on the 11-position of **14a**. The structure of this product was, therefore, identified as 5-methyl-11-(2′-dimethylaminoethyl)-5,11-dihydrodibenzo[*b*,*e*][1,4]thiazepin (**19**).

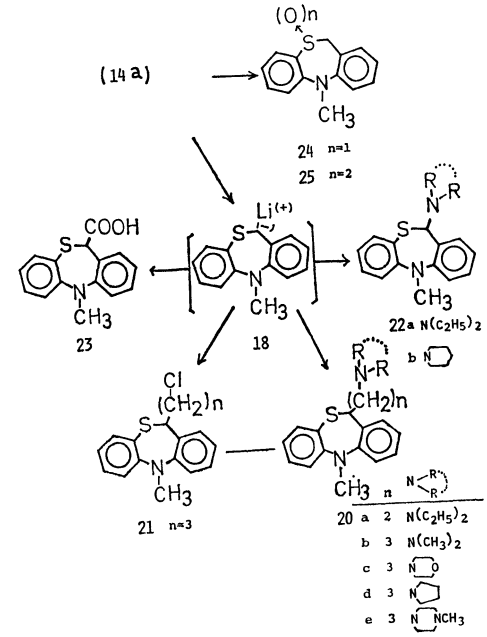

Chart 6.

The lithio derivative **18** was employed as a versatile intermediate for preparing 11-substituted 5,11-dihydrodibenzo[*b*,*e*][1,4]thiazepins; almost all the derivatives shown in Chart 6 were successfully prepared by this method. Thus, the reaction of **18** with carbon dioxide yielded 11-(5-methyl-5,11-dihydrodibenzo[*b*,*e*][1,4]thiazepin)carboxylic acid (**23**). The treatment of **18** with 1-bromo-3-chloropropane yielded a haloalkyl derivative(**21**), which was then allowed to react with 1-methylpiperazine to give **20e** in a moderate yield. It is hard to synthesize 11-amino compounds (**22**) by the usual method. However, **22** was prepared by this method in about a 20% yield. The reaction of **14a** with hydrogen peroxide in a mixed solvent of acetone and acetic

acid at room temperature or in a solution of acetone with refluxing led to 5-methyl-5,11-dihydrodibenzo-[b,e][1,4]thiazepin-10-oxide(**24**) or 5-methyl-5,11-dihydrodibenzo[b,e][1,4]thiazepin-10,10-dioxide (**25**).

Compound **19** and related compounds were shown to have an imipramine-like activity in experimental animals; **19** is the most valuable among these compounds.

Our pharmacological findings will be reported elsewhere in the near future.

Experimental

All the melting points are uncorrected. The IR spectra were taken with a Hitachi EPI-2 spectrometer. The NMR spectra were recorded by means of a Varian A-60 spectrometer in $CDCl_3$, using TMS as the internal standard.

The *o*-bromobenzylbromide was prepared by the bromination of *o*-bromotoluene by a previously reported procedure.[6] The *o*-bromo-1-chloroethylbenzene(**2b**)[7] (bp 98—105 °C/13 mmHg) and *o*-bromo-1-chloropropylbenzene(**2c**) (bp 100—110 °C/10 mmHg) were prepared by the reduction of *o*-bromoacetophenone and *o*-bromopropiophenone, and by the subsequent chlorination of the resulting substances.

*o-Bromo-3-dimethylaminopropiophenone (**6**).*[8] A mixture of *o*-bromoacetophenone (1.94 g), dimethylamine (10.7 g), paraformaldehyde (3.9 g), and conc. HCl (0.2 ml) in 15 ml of EtOH was refluxed for 2 hr on an oil bath and then cooled. The solid thus precipitated was filtered, washed with acetone, and recrystallized from a mixed solvent of acetone and MeOH to give **6** (2.10 g); mp 185—189 °C. Found: C, 45.20; H, 5.27; N, 4.66%. Calcd for $C_{11}H_{14}BrON \cdot HCl$: C, 45.15; H, 5.17; N, 4.79%.

*1-(o-Bromophenyl)-3-dimethylaminopropyl Alcohol (**7**).* To a solution of **6** (1.8 g) in 30 ml of MeOH, we added 5 ml of a 10% NaOH solution; $NaBH_4$ (500 mg) was then added in small portions, and the mixture was stirred for 2 hr at 50 °C. The solvent was then evaporated *in vacuo*. H_2O was added to the residue, and the aqueous layer was extracted with benzene. The benzene layer was dried over $MgSO_4$ and evaporated. The solid was recrystallized from a mixed solvent of benzene/petr. benzine to give **7** (1.3 g); mp 74—75 °C.

*1-o-Bromophenyl-3-dimethylaminopropyl Chloride (**2d**).* To a solution of **7** (1.0 g) in 30 ml of $CHCl_3$, $SOCl_2$ in $CHCl_3$ was added, drop by drop under cooling. The reaction mixture was stirred first at the same temperature for 30 min, and then at 50 °C for 2 hr, and subsequently cooled. The $CHCl_3$ was removed *in vacuo*, and the residue was recrystallized from acetone to give **2d** (0.8 g); mp 180.5—181 °C.

*1-Methyl-o-bromobenzyl-o'-aminophenylthioether (**3b**).* To NaOEt in an EtOH solution (prepared from Na (3.5 g) and abs. EtOH (80 ml)), then *o*-aminothiophenol (16.6 g) was added all at once. The mixture was stirred for 30 min. 1-Chloro-*o*-bromoethylbenzene **2b** (19.4 g) was added to this solution, and the mixture was refluxed for 2 hr. After the removal of the solvent, H_2O was added to the residue and the mixture was extracted with $CHCl_3$. The $CHCl_3$ layer was dried over $MgSO_4$ and evaporated. The oil thus obtained was distilled under reduced pressure. The fraction boiling at 169—172 °C/0.9 mmHg was collected to give **3b** (16.6 g; 60.6%). Found: C, 54.53; H, 4.41; N, 4.56; S, 10.70; Br, 25.79%. Calcd for $C_{14}H_{14}BrNS$: C, 54.55; H, 4.58; N, 4.54; S, 10.40; Br, 25.92%.

*1-Ethyl-o-bromobenzyl-o'-aminophenylthioether (**3c**).* In a similar manner, **3c**, a yellow viscous oil, was obtained in a 50% yield; bp 178—182 °C/0.55 mmHg. Found: C, 55.20; H, 4.78; N, 4.06; S, 10.20%. Calcd for $C_{15}H_{16}BrNS$: C, 55.91; H, 5.00; N, 4.35; S, 9.95%.

*N,N-Dimethyl-3-(o-bromophenyl)-3-(o'-aminophenylthio)-propylamine (**3d**).* To a solution of NaOEt in EtOH (EtOH; 100 ml, Na; 600 mg), *o*-aminothiophenol(1.0 g) and then 3.0 g of **2d** were added. The mixture was refluxed for 3 hr. A small amount of H_2O was then added to the reaction mixture, and the solvent was removed *in vacuo*. H_2O was added to the residue, and the mixture was extracted with $CHCl_3$. The $CHCl_3$ layer was dried over $MgSO_4$ and evaporated. An oil (3.9 g) was thus obtained; IR: ν_{max} (neat); 3400 and 3300 (primary amine), and 2800 cm^{-1} (tertiary amine). This oil was converted to an oxalate in a usual manner. The oxalate melted completely at 180 °C after having decomposed at 138—140 °C. Found: C, 50.04; H, 5.24; N, 6.27; S, 7.18; Br, 17.39%. Calcd for $C_{17}H_{21}N_2SBr \cdot C_2H_2O_4$: C, 50.12; H, 5.09; N, 6.15; S, 7.04; Br, 17.55%.

*o'-(N-Formylamino)phenyl-o-bromobenzylthioether (**4a**).*[4] A solution of **3a** (70 g) in 420 ml of 98% HCOOH was refluxed for 2 hr. The reaction mixture was then poured into ice water and extracted with $CHCl_3$. The $CHCl_3$ layer was washed with a 10% NaOH solution and H_2O, dried, and evaporated. The solid thus obtained was recrystallized from EtOH–cyclohexane to give 75 g of **4a**; mp 112—113 °C.

*o'-(N-Formylamino)phenyl-o-bromo-α-methylbenzyl thioether (**4b**)* was obtained in a 51.7% yield in a similar manner.

*o-Bromobenzyl-o'-(N-ethoxycarbonylamino)phenylthioether(**4c**).* To a solution of **3a** (2.9 g) in 5 ml of pyridine, we added $ClCOOC_2H_5$ (1.1 g) under cooling. Stirring was then continued for 2 hr. The mixture was allowed to stand overnight at room temperature, and then it was poured into water and extracted with ether; the ether layer was washed with H_2O and 10% HCl, dried over $MgSO_4$, and evaporated. The oil thus obtained was treated with EtOH to give a solid. The solid was recrystallized from aq. EtOH to give 1.5 g of **4c**, as colorless needles; mp 54–55 °C. Found: C, 52.72; H, 4.50; N, 3.97; S, 8.79; Br, 22.08%. Calcd for $C_{16}H_{16}NSO_2Br$: C, 52.47; H, 4.40; N, 3.82; S, 8.75; Br, 21.82%.

*5,11-Dihydrodibenzo[b,e][1,4]thiazepin (**12a**).* **3a** was prepared by Ullman reaction from *o*-bromophenyl-benzylthioether, which had itself been obtained by the reaction of *o*-aminothiophenol with *o*-bromobenzylbromide according to a patented procedure.[3]

A mixture of **3a** (100 g) and copper powder (10 g) in 1.01 of pyridine was stirred with refluxing at 110—115 °C in the presence of K_2CO_3(100 g) and then cooled. The solid was filtered off, and the filtrate was concentrated to one-third of the initial volume. The residue was poured into chilled 10% HCl, and the resulting semi-solid was extracted with ether. The ether layer was washed with H_2O, dried over $MgSO_4$, and evaporated. The residue was distilled under reduced pressure. The fraction boiling at 200—220 °C/0.4 mmHg was collected to give **12a** (80 g); mp 117—118 °C (lit, 121—122 °C).[3]

5-Formyl-5,11-dihydrodibenzo[b,e][*1,4*]*thiazepin (**13a**).*[4] A mixture of **4a** (70 g) and Cu powder (8.0 g) in 600 ml of pyridine was stirred with refluxing in the presence of K_2CO_3 (80 g). The solid was then filtered off, and the filtrate was concentrated *in vacuo*. The residue was poured into chilled dil. H_2SO_4, and extracted with $CHCl_3$. The $CHCl_3$ layer was washed with H_2O, dried, and evaporated to give **13a** (50 g); mp 123—124 °C.

5-Ethoxycarbonyl-5,11-dihydrodibenzo[b,e][*1,4*]*thiazepin (**13c**).* A mixture of **4c** (8.0 g), and K_2CO_3 (8.0 g) in 160 ml of pyridine was refluxed in the presence of Cu powder (0.8 g) for 4 hr. After the mixture had then been cooled, a solid was filtered off. The filtrate was poured into 20% H_2SO_4

and extracted with ether. The ether layer was washed with H_2O, dried, and evaporated. The solid thus obtained was recrystallized from 95% EtOH to give **13c** (4.2 g); mp 101.5—104 °C. NMR (δ); 1.23 (3H, t, J=7.0 Hz, $-CH_3$), 4.22 (2H, q, J=7.0 Hz, $-CH_2-$), 3.54 (1H, d, J=14 Hz, C_{11}–H), 4.88 (1H, d, J=14 Hz, C_{11}–H), 7.0—7.5 (8H, m, phenyl protons). Found: C, 65.46; H, 5.36; N, 5.17; S, 11.43%. Calcd for $C_{16}H_{15}NSO_2 \cdot 1/2H_2O$: C, 65.28: H, 5.49; N, 4.76; S, 10.89%.

Saponification of **13a** *with Alkaline Solution.* A solution of **13a** (50 g) and a 10% NaOH solution (110 ml) in 550 ml of 95% EtOH was refluxed for 2 hr. After the subsequent removal of the solvent *in vacuo*, the residue was poured into ice water and extracted with $CHCl_3$. The $CHCl_3$ layer was washed with H_2O, dried, and evaporated. The solid thus obtained was recrystallized from 99% EtOH to give **12a** (48 g); mp 120—121 °C.[4]

N-Formyl-11-methyl-5,11-dihydrodibenzo[b,e][*1,4*]*thiazepin* (***13b***): (mp 162—164 °C (from benzene-cyclohexane)) was obtained in a 75% yield by the Ullman reaction of **4b** at 110—115 °C. NMR (δ): 1.64 (3H, d, J=7.4 Hz, C_{11}–CH_3), 5.17 (1H, q, J=7.4 Hz, C_{11}–H), 7.0—8.0 (8H, m, phenyl protons). Found: C, 70.94; H, 5.04; N, 5.43; S, 12.74%. Calcd for $C_{15}H_{13}NSO$: C, 70.58; H, 5.13; N, 5.49; S, 12.80%.

11-Methyl-5,11-dihydrodibenzo[*b,e*][1,4]*thiazepin* (**12b**) (bp 190—200 °C (0.3 mmHg)) was obtained in a 50% yield by the saponification of **13b** with a 10% NaOH solution. NMR (δ): 1.51 (3H, d, J=7.5 Hz, C_{11}–CH_3), 4.33 (1H, q, J=7.5 Hz, C_{11}–H), 6.5—7.4 (8H, m, phenyl protons). Found: C, 73.71; H, 5.98; N, 6.09; S, 14.32%. Calcd for $C_{14}H_{13}NS$: C, 73.99; H, 5.77; N, 6.16; S, 14.08%.

5-Methyl-5,11-dihydrodibenzo[b,e][*1,4*]*thiazepin* (***14a***). To a suspension of NaH (50% mineral oil dispersion; 65 g) in a mixed solvent of toluene (500 ml) and DMF (500 ml), a solution of **12a** (200 g) in a mixed solvent of toluene (200 ml) and DMF (200 ml) was added, drop by drop. The mixture was then stirred for 2 hr at 50 °C, and a solution of CH_3I (283 g) in 200 ml of DMF was added. Stirring was continued for another 2 hr at 50 °C. After cooling, MeOH (100 ml) was added, drop by drop, to the reaction mixture to decompose the excess NaH. The mixture was then poured into ice water (1.0 l). The oil thus obtained was extracted with toluene. The toluene layer was washed with H_2O, dried, and evaporated *in vacuo*. The solid thus formed was recrystallized from *n*-hexane (2.0 l) to give **14a**; 117 g (87%). NMR (δ): 3.67 (3H, s, N–CH_3), 4.41 (2H, s, C_{11}–H), 6.5—7.5 (8H, m, phenyl protons).

Compounds **14d** and **14c**, prepared in a manner similar to those described above, are summarized in Table 1.

5-Methyl-5,11-dihydrodibenzo[b,e][*1,4*]*thiazepin-10-oxide* (***24***). To a solution of **14a** (22 g) in a mixed solvent of purified acetone (300 ml) and AcOH (300 ml), 30% H_2O_2 (20 g) was added, drop by drop, at a temperature below 25 °C; the reaction mixture was thereafter stirred for 25 hr at room temperature and poured into ice water (3.0 l). The solid thus precipitated was filtered off and recrystallized from MeOH to give **24**; 19.5 g (80%); mp 157 °C. NMR (δ): 3.44 (3H, s, N–CH_3), 4.30 and 4.55 (2H, d, J=12 Hz, C_{11}–H), 7.0—8.0 (8H, m, phenyl protons). Found: C, 69.69; H, 5.51; N, 5.78; S, 13.16%. Calcd for $C_{14}H_{13}NOS$: C, 69.13; H, 5.39; N, 5.76; S, 13.16%.

5-Methyl-5,11-dihydrodibenzo[b,e][*1,4*]*thiazepin-10,10-dioxide* ***25***. To a solution of **14a** (3.5 g) in 30 ml of purified aceton 30% H_2O_2 (3.0 g) was added, drop by drop; the reaction mixture was then refluxed for 3 hr. After the subsequent removal of the solvent, the residue was recrystallized from 99% EtOH to give **25**; 1.5 g (43.9%); mp 230—233 °C. NMR (δ): 3.37 (3H, s, N–CH_3), 4.86 (2H, s, C_{11}–H), 6.9–7.9 (8H, m, phenyl protons). Found: C, 65.09; H, 5.09; N, 5.19; S, 12.46%. Calcd for $C_{14}H_{13}NO_2S$: C, 64.80; H, 5.06; N, 5.40; S, 12.34%.

Preparation of Phenyllithium.[9] To a solution of bromobenzene (32 g, 0.204 mol) in 100 ml of abs. ether, we added Li metal (3.0 g, 0.43 mol) under a flow of nitrogen. Stirring was slowly started at room temperature, and the reaction begin. (The reaction mixture was heated up to ether reflux when the reaction was hard to initiate.) The reaction mixture was then refluxed for 30 min.

11-(2'-Dimethylaminoethyl)-5-methyl-5,11-dihydrodibenzo[b,e]-[*1,4*]*thiazepin* (***19***). To a solution of phenyllithium (prepared from bromobenzene (4.7 g) and Li metal (410 mg)), a solution of **14a** (6.1 g) in 80 ml of abs. ether was added, drop by drop, after which the mixture was stirred for 2—3 hr at room temperature. The color of the solution changed from gray to red- or black-brown. To the resulting solution we then added freshly distilled dimethylaminoethyl chloride (60 g). The mixture was stirred with refluxing for 5 hr and then cooled. The unchanged Li metal was removed, and the ether solution was washed with H_2O and extracted with HCl. The extract was made alkaline with a 10% NaOH solution under cooling. The oil thus obtained was extracted with $CHCl_3$, and the $CHCl_3$ layer was washed with H_2O, dried, and evaporated *in vacuo*. The residue was distilled under reduced pressure. A fraction boiling at 180—182 °C

(0.9 mmHg) was collected to give **19** of 5.0 g (62.4%). IR (ν) Nujol: 2800 (N-CH_3) and 700 (condensed aromatic) cm^{-1}, NMR (δ): 2.17—2.50 (4H, m, $-CH_2CH_2-$), 2.28 (6H, s, $N(CH_3)_2$, 3.25 (3H, s, N-CH_3), 4.29 (1H, t, J=7.0 Hz, C_{11}-H), 6.7—7.3 (8H, m, phenyl protons). Found: C, 72.30; H, 7.24; N, 9.56; S, 10.74%. Calcd for $C_{18}H_{22}N_2S$: C, 72.42; H, 7.43; N, 9.39; S, 10.72%.

The oil thus obtained was converted to maleate in a usual manner; mp 174—175 °C (decomp.) (from EtOH). Found: C, 63.28; H, 6.28; N, 6.59; S, 7.59%. Calcd for $C_{18}H_{22}N_2S \cdot C_4H_4O_4$: C, 63.75; H, 6.32; N, 6.72; S, 7.72%.

Compounds **20a—d**, prepared in a manner similar to that described above, are summarized in Table 2.

11-(4'-Methylpiperazinopropyl)-5-methyl-5,11-dihydrodibenzo[b,e][*1,4*]*thiazepin* (***20e***). To a reaction solution prepared by the reaction of **14a** (2.0 g) with phenyllithium, 1,3-propylene bromochloride (7.5 g) was added, after which the mixture was stirred with refluxing for 3 hr at 50 °C. After cooling, the ether layer was washed with H_2O, dried, and evaporated. Crude oil (2.0 g) was thus obtained.

A mixture of this crude oil and 1-methylpiperazine (20 ml) was heated at 120 °C for 7 hr with stirring. The reaction mixture was then poured into ice water and extracted with a 2 : 1 mixture of benzene and ether. The organic layer was extracted with 10% HCl, and the aqueous layer was made alkaline with a 10% NaOH solution. The oil thus obtained was extracted with $CHCl_3$, and the $CHCl_3$ layer was washed with H_2O, dried, and evaporated *in vacuo*. The oil in the AcOEt solution was chromatographed on alumina. The eluate was evaporated to give 1.1 g of a viscous oil which was distilled under reduced pressure. The fraction boiling at 240—260 °C (0.1—0.2 mmHg) was collected; 1.1 g of **20e**. The oil thus obtained was converted to maleate in a usual manner; mp 185—186 °C (decomp) (from 99% EtOH). Found: C, 60.05; H, 6.23; N, 7.05%. Calcd for $C_{22}H_{29}N_3S \cdot 2C_4H_4O_4$: C, 60.09; H, 6.21; N, 7.01%.

11-Diethylamino-5-methyl-5,11-dihydrodibenzo[b,e][*1,4*]*thiazepin* (***22a***). **18** was prepared from **14a** (2.3 g) and phenyllithium (prepared from bromobenzene (1.6 g) and Li metal (150 mg)) in abs. ether. To the resulting solution, we added a solution of diethylaminobromide[10] in abs. ether, after which the mixture was refluxed for 5 hr. After the removal of the unchanged Li, the ether solution was extracted with 10% HCl and the extract was made alkaline with a 10% NaOH solution under cooling. The oil thus obtained was extracted with $CHCl_3$, and the $CHCl_3$ layer was washed with H_2O, dried, and evaporated. The residue was distilled under reduced pressure. The fraction boiling at 200 °C (0.1 mmHg) was collected to give 0.5 g (16.8 %) of a yellow, viscous oil. Found: C, 71.94; H, 7.38; N, 9.28; S, 10.98%. Calcd for $C_{18}H_{22}N_2S$: C, 72.42; H, 7.43; N, 9.39; S, 10.73%.

11-Piperidino-5-methyl-5,11-dihydrodibenzo[*b,e*][*1,4*]*thiazepin* (***22b***) (bp 220—240 °C (0.3 mmHg)) was obtained in a 21.7% yield by the reaction of **14a** (6.1 g) lithiolated and *N*-chloropiperidine[10] in a manner similar to that described above. Found: C, 73.85; H, 7.23; N, 9.28; S, 10.43%. Calcd for $C_{19}H_{22}N_2S$: C, 73.51; H, 7.14; N, 9.02; S, 10.33%.

11-(5-Methyl-5,11-dihydrodibenzo[b,e][*1,4*]*thiazepin)-carboxylic Acid* (***23***). **18** was prepared by the reaction of **14a** with phenyllithium ((prepared from bromobenzene (3.0 g) and Li metal (300 mg)) in abs. ether. To the resulting solution we added, all at once, powdered dry ice (10 g) under cooling, after which the mixture was stirred with refluxing while CO_2 was passed through. The mixture was then poured into H_2O, and the ether layer was separated and extracted with a 10% $NaHCO_3$ solution. The aqueous layers were combined and made acid with 10% HCl. The oil obtained was extracted with $CHCl_3$ and the $CHCl_3$ layer was dried over $MgSO_4$ and evaporated *in vacuo*. The solid obtained was recrystallized from a mixed solvent of benzene and *n*-hexane, and then from benzene, to give 1.0 g, of **23**; mp 193—194 °C (decomp.). Found: C, 66.40; H, 4.99; N, 4.92; S, 11.57%. Calcd for $C_{15}H_{13}O_2NS$: C, 66.41; H, 4.83; N, 5.16; S, 11.79%.

The authors wish to thank H. Manabe for the spectra data and T. Ikeda and his associates for the microanalyses.

The Reaction of 2,4-Dehydrohomoadamantane: The Synthesis of Several 2-Mono- and 2,4-Di-substituted Homoadamantanes[1)]

Ryohei YAMAGUCHI, Takeo KATSUSHIMA, and Mituyosi KAWANISI

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyo-ku, Kyoto 606

(Received January 9, 1975)

The synthesis of several 2-mono- and 2,4-di-substituted homoadamantane derivatives is described. The photobromination of 2,4-dehydrohomoadamantane (I) at −78 °C gave *e,a*- and *e,e*-2,4-dibromohomoadamantanes (IIa and IIb). The treatment of a mixture of IIa and IIb with *t*-BuOK in HMPT gave *e*-2-bromohomoadamant-4-ene (IV) in an 84% yield. The methanolysis and hydrolysis of IV gave *e*-2-methoxyhomoadamant-4-ene (V) and *e*-2-hydroxyhomoadamant-4-ene (VI), with a retention of the configuration, in 90 and 99% yields respectively. The oxidation of VI with the CrO_3-pyridine complex gave homoadamant-4-en-2-one (VII) in a 94% yield. The reduction of VII with $LiAlH_4$ gave *a*-2-hydroxyhomoadamant-4-ene (VIII). The catalytic hydrogenations of VI, VII, and VIII gave *e*-2-hydroxyhomoadamantane (IX), homoadamantan-2-one (X), and *a*-2-hydroxyhomoadamantane (XI) respectively. The possibility that a homoallylic cation (XII) intervenes in the solvolysis of IV is proposed.

A large number of bridgehead-substituted (1- or 3-) homoadamantane derivatives (*cf.* Fig. 1) have been extensively studied.[2)] However, relatively speaking, there has been a remarkable absence from the chemical literature of references to the synthesis of bridge-substituted homoadamantane derivatives. Moreover, the few synthesized compounds have been restricted to those substituted only on the ethylene bridge (4- and/or 5-positions).[3)]

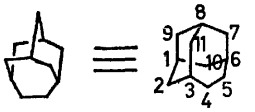

Fig. 1. Homoadamantane.

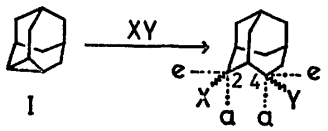
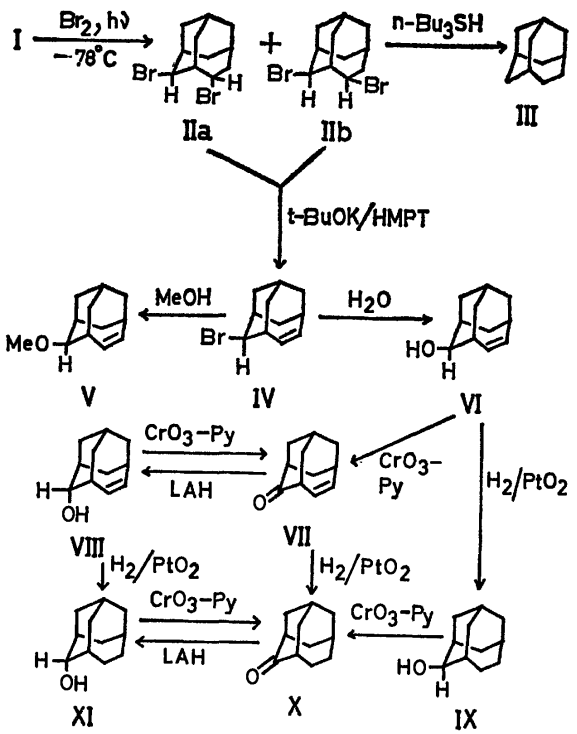
On the other hand, in the case of the adamantane system a good many bridge-substituted derivatives have been synthesized and studied.[2)] Particularly Udding *et al.* reported a very subtle synthesis of 2-mono- and 2,4-di-substituted adamantane derivatives by cleaving the cyclopropane ring of 2,4-dehydroadamantane with a variety of electrophilic reagents.[4)] We have ourselves previously reported the efficient synthesis of 2,4-dehydrohomoadamantane (I),[5)] a homologue of 2,4-dehydroadamantane. As a matter of cource, I might be a potential precursor of 2-mono- and 2,4-di-substituted homoadamantane derivatives. However, in comparison with the adamantane system there remain some difficulties; for example, an increase of one methylene carbon diminishes the high symmetry inherent to the adamantane system, causing a complex situation in the configurations of substituents in the homoadamantane system. In this paper we wish to report the first synthesis of several 2-mono- and 2,4-di-substituted homoadamantanes. The configurations of the substituents are tentatively named, as is shown in Scheme 1, after adamantane derivatives.[4)]



Scheme 1.

Results and Discussion

For cleaving the cyclopropane ring of I, we have chosen a radical-type reaction, *i.e.*, photobromination, taking account of the fact that an ionic reaction causes a skeletal alteration.[6)] Shea and Skell reported detailed studies of the photobromination of alkylcyclopropanes;[7)] we followed their procedures. When a solution of I and bromine in dichloromethane was irradiated at −78 °C for 5 min, a cleavage of the cyclopropane ring was observed, giving two dibromides (IIa and IIb, 52 : 48 by glc analysis) in an 82% yield, along with a small amount of monobromide. The structures of IIa and IIb were deduced to be 2,4-dibromohomoadamantanes on the basis of the following experimental results: (i) The reduction of IIa and IIb by tri-*n*-butyltin hydride gave homoadamantane (III), proving



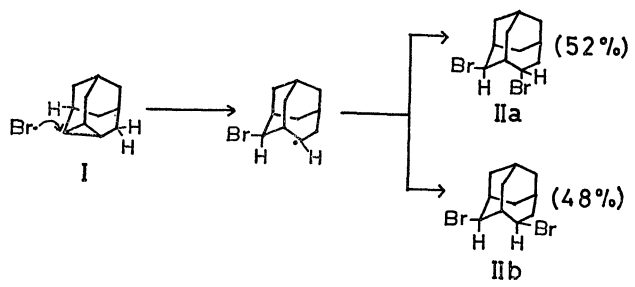
Scheme 2.

that IIa and IIb possess a homoadamantane skeleton. (ii) The treatment of IIa and IIb with a base could easily cause the elimination of one equivalent of hydrogen bromide to a sole compound (IV) (*vide infra*), indicating that one of the two bromine atoms is located on the ethylene bridge, and the other, on the methylene bridge.[8] (iii) As will be described later, the reaction of IV as well as the UV spectrum of homoadamant-4-en-2-one (VII) show that the substituents are obviously located at the 2- and 4-positions.

The treatment of a mixture of IIa and IIb with potassium *tert*-butoxide in hexamethylphosphoric triamide (HMPT) at 85—90 °C for 3 hr gave a sole product, 2-bromohomoadamant-4-ene (IV), in 80—90% yield. The above results indicate that the configuration of the bromine atom on the C-2 of IIa is identical with that of IIb. The PMR spectra of IIa, IIb, and IV are depicted in Fig. 2. As is shown in Fig. 2(c), the proton on the C-2 of IV does not couple with the adjacent bridge-head protons on the C-1 and C-3. The PMR studies using a shift reagent on 3-homoadamantanol established that the axial proton on the C-2 does not couple with the adjacent bridge-head proton, while the equatorial one does couple with the adjacent one, with a coupling constant of 4 Hz.[9] This report as well as the model investigation (FMM model) indicate that the proton on the C-2 must have the axial orientation. Thus, the structure of IV can be determined to be *e*-2-bromohomoadamant-4-ene.

The configurations at the C-4 positions of IIa and IIb were determined as follows. The difference between the chemical shift of the proton on the C-2 and that on the C-4 in IIa is larger than that in IIb, as is shown in Fig. 2(a) and 2(b). By analogy with the results for 2,4-dibromoadamantane,[10] we can deduce that IIa is *e,a*-2,4-dibromohomoadamantane and that IIb is *e,e*-2,4-dibromohomoadamantane.

The fact that the photobromination of I gives no *a,a*-2,4-dibromohomoadamantane is considered to be very similar to the case of 2,4-dehydroadamantane reported by Shea and Skell.[7,11] According to the mechanism suggested by them, the photobromination of I can proceed through the sequences shown in Scheme 3. It is of interest to note that the initial attack on the cyclopropane ring by the bromine atom is effected from the six-membered-ring side selectively. A larger steric requirement of the methylene hydrogen atoms on the C-5 than that of the methine hydrogen atom on the C-1 would inhibit the attack of the bromine atom from the seven-membered-ring side.



Scheme 3.

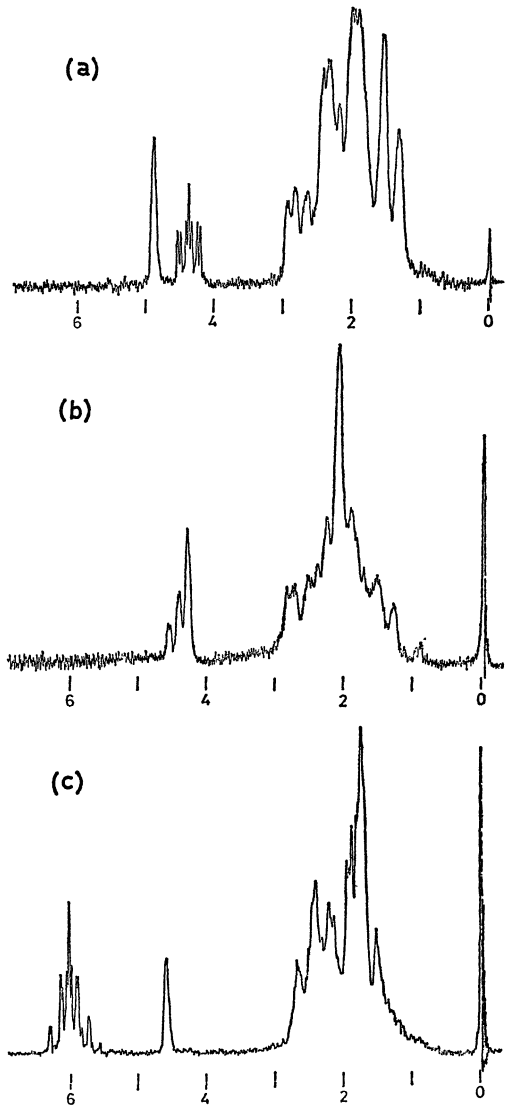


Fig. 2. PMR spectra of IIa, IIb, and IV.
(a): IIa, (b): IIb, and (c): IV.

The treatment of IV with methanol gave *e*-2-methoxyhomoadamant-4-ene (V) in a 90% yield, with a retention of the configuration. The configuration at the C-2 position of V was determined by PMR analysis in analogy with that of IV (see Experimental Section). When IV was hydrolyzed in 25% aqueous dioxane at the reflux temperature for 2 hr, *e*-2-hydroxyhomoadamant-4-ene (VI) was obtained in a 99% yield, again with a complete retention of the configuration. The oxidation of VI with a chromic anhydride–pyridine complex in dichloromethane gave homoadamant-4-en-2-one (VII) in a 94% yield. The UV spectrum of VII showed an n-π^* absorption at 300 nm (ε=127) (in EtOH); this suggests a homoconjugation between the carbonyl and the olefinic moieties.[12] The reduction of VII with lithium aluminum hydride in ether or sodium borohydride in ethanol gave *a*-2-hydroxyhomoadamant-4-ene (VIII) predominantly, along with a small amount of VI (VIII : VI=96 : 4 in the case of lithium aluminum hydride and 94 : 6 in the case of sodium borohydride, as determined by glc analysis). The PMR spectrum of VIII, shown in Fig. 3 (b),

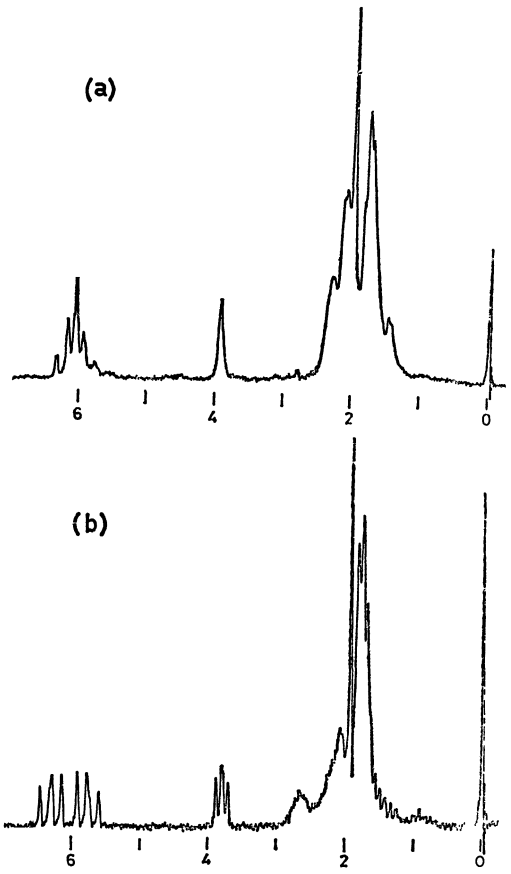

Fig. 3. PMR spectra of VI and VIII.
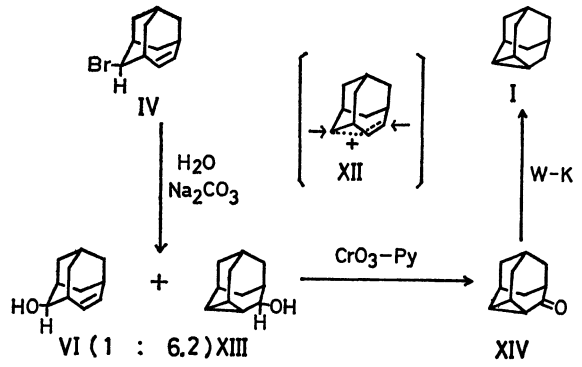
(a): VI, (b): VIII.

indicates that equatorial proton on the C-2 couples with the adjacent bridge-head protons with a coupling constant of *ca.* 4 Hz. The oxidation of VIII with a chromic anhydride–pyridine complex caused VIII to revert to VII, showing that no skeletal rearrangement took place during the above transformations.

The catalytic hydrogenations of VI, VII, and VIII utilizing platinum oxide in ethyl acetate gave the corresponding saturated compounds, *e*-2-hydroxyhomoadamantane (IX), homoadamantan-2-one (X), and *a*-2-hydroxyhomoadamantane (XI), in 98, 88, and 90% yields respectively. The oxidation of IX gave X. The reduction of X with lithium aluminum hydride in ether gave XI exclusively. The high stereoselectivities observed in the reductions of X as well as VII (*vide supra*) are similar to that observed in the reduction of bicyclo[3.3.1]nonan-2-one.[13] Moreover, it was confirmed that the Wolff-Kishner reduction of X gave the parent system, III. Thus, the above-mentioned transformations, depicted in Scheme 2, unequivocally confirm the structures of 2-mono- and 2,4-di-substituted homoadamantanes.

The complete retention of configuration at the C-2 position observed in the solvolysis of IV suggests the intervention of a homoallylic cation (XII).[14] In order to verify this possibility, we have solvolyzed IV in the presence of a buffer. When IV was hydrolyzed in 25% aqueous dioxane in the presence of sodium carbonate or potassium hydroxide, a new alcohol (XIII) was produced, along with a small amount of VI (XIII : VI=*ca.* 6 : 1 by glc analysis) (Scheme 4). The structure of XIII was deduced to be *e*-5-hydroxy-2,4-dehydrohomoadamantane on the basis of the following chemical and spectroscopic results: (i) The PMR spectrum of XIII had no signal due to the olefinic proton. (ii) The oxidation of XIII with the chromic anhydride–pyridine complex gave 2,4-dehydrohomoadamantane-5-one (XIV), which was then reduced by the Wolff-Kishner method to give I. (iii) A model investigation (FMM model) tells us that the axial proton on the C-5 of XIII must couple with the adjacent bridge-head protons, while the equatorial one does not, because the dihedral angle is nearly 90°. Since the PMR spectrum of XIII shows that the proton on the C-5 copules with the adjacent bridge-head protons with the coupling constant of *ca.* 6 Hz, XIII is determined to be *e*-5-hydroxy-2,4-dehydrohomoadamantane.



Scheme 4.

A complete understanding could, of course, be obtained by further precise experiments. However, the present results give powerful support to the notion that a homoallylic cation (XII) plays an important role in the solvolysis of IV.

Experimental

All the temperatures are uncorrected. The melting points were measured in a sealed tube in a liquid bath. The IR spectra were obtained on a Shimadzu IR-27 spectrometer. The UV spectra were recorded on a Hitachi EPS-2 spectrophotometer. The MS spectra were taken by using a Hitachi RMS-4 mass spectrometer. The PMR spectra were obtained on a Varian EM-360 spectrometer, TMS being chosen as the internal standard. The microanalyses were performed by Mrs. Kiyoko Fujimoto. No attempt has been made to maximize the yields of the reactions reported below.

2,4-Dihydrohomoadamantane (I). This compound was synthesized by the previously reported method.[5] A small contamination of homoadamant-4-ene can be easily removed by the treatment of the crude mixture with an appropriate amount of bromine in CH_2Cl_2, followed by column chromatography on silica gel eluted with *n*-hexane.

e,a-*2,4-Dibromohomoadamantane (IIa) and* e,e-*2,4-Dibromohomoadamantane (IIb).* A solution of I (1605 mg; 10.8 mmol) and Br_2 (0.54 ml, 1685 mg; 10.4 mmol) in 180 ml of CH_2Cl_2 was irradiated by means of a 300W medium-pressure mercury arc (soft glass filter) at −78 °C for 5 min. The reaction mixture was then warmed up to room temperature, washed successively with 10% aq. Na_2SO_3, aq. $NaHCO_3$, and brine, and dried (Na_2SO_4). The solvent was then

removed, and the residue (3008 mg) was chromatographed on silica gel (200 g). Elution by *n*-hexane gave first the unreacted starting material (208 mg) and then a monobromide of an unknown structure. Further elution by *n*-hexane gave IIa (187 mg), a mixture of IIa and IIb (2007 mg), and IIb (170 mg). The total yield of the dibromides, IIa and IIb (2364 mg), was 81.5%, calculated on the basis of the reacted I. The ratio of IIa to IIb was determined by glc analysis to be 52 : 48 (HVSG, 130 °C). IIa: mp 121—124 °C; IR (Nujol) 2950, 1460, 1380, 795, 720 cm^{-1}; PMR δ (CCl_4) 1.13—3.05 (broad complex m, 14H), 4.36 (d.d.d, 1H, J=2.8, 7.0, and 9.8 Hz), 4.89 (broad s, 1H); Found: C, 42.61; H, 5.26%. Calcd for $C_{11}H_{16}Br_2$: C, 42.88; H, 5.24%. IIb: mp 55—58 °C; IR (Nujol) 2950, 1460, 1380, 730 cm^{-1}; PMR δ (CCl_4) 1.07—3.05 (broad complex m, 14H), 4.41 (m, 2H); Found: C, 42.70; H, 5.27%. Calcd for $C_{11}H_{16}Br_2$: C, 42.88; H, 5.24%.

A mixture of IIa and IIb (115 mg; 0.37 mmol), *n*-Bu_3SnH (441 mg; 1.5 mmol), and benzene (2 ml) was refluxed under N_2 for 3 hr. The reaction mixture was then washed with brine and dried (Na_2SO_4). After the solvent had subsequently been removed, the residue was shown by glc analysis (PEG 20 M, 16 °C) to contain only one compound as a hydrocarbon component. This compound was isolated by preparative glc and determined to be homoadamantane (III) by comparison with the authentic sample [3b] (glc retention time, and MS and PMR spectra).

e-*2-Bromohomoadamant-4-ene (IV).* A solution of IIa and IIb (1668 mg; 5.42 mmol) and *t*-BuOK (705 mg; 6.29 mmol) in 17 ml of HMPT was heated at 85—88 °C for 3.5 hr under a nitrogen atmosphere. To the cooled reaction mixture we then added *n*-hexane, and the organic layer was repeatedly washed with brine and dried (Na_2SO_4). The solvent was then evaporated under reduced pressure, and the residue was sublimed (100—105 °C/10 mmHg) to give pure IV (1035 mg, 84.2%): mp 92—96 °C; MS: *m/e* 228 and 226 (M^+, 23 and 24%), 147 (100%); IR (Nujol) 2950, 1660 (weak), 1460, 1380, 1175, 790, 730, 695 cm^{-1}; PMR δ(CCl_4) 1.20—3.00 (broad complex m, 12H), 4.63 (broad s, 1H), 6.07 (m, 2H); Found: C, 58.40; H, 6.85%. Calcd for $C_{11}H_{15}Br$: C, 58.16; H, 6.66%.

The same treatment of pure IIa (126 mg; 0.41 mmol) with *t*-BuOK (74 mg; 0.66 mmol) in HMPT (3 ml) gave IV (82 mg, 88%).

The reaction was very sensitive to the reaction temperature, since IV was not very stable. When the temperature was higher, the resulting IV was converted to another compound, the structure of which was unknown. In our experiments, the yields were between 80 and 90%.

e-*2-Methoxyhomoadamant-4-ene (V).* A solution of IV (45 mg; 0.2 mmol) in 1 ml of methanol was heated at reflux for 5 hr. The reaction mixture was then concentrated under reduced pressure, and the residue was chromatographed on silica gel. Elution by *n*-hexane gave V (32 mg, 90%): bp 101—104 °C/22 mmHg; MS:*m/e* 178 (M^+, 100%); IR (neat) 2950, 1660 (weak), 1450, 1380, 1190, 1090, 945, 885, 735, 715 cm^{-1}; PMR δ (CCl_4) 1.10—2.57 (broad complex m, 12H) 3.20 (broad s, 1H), 3.26 (s, 3H), 6.00 (m, 2H); Found: C, 80.72; H, 10.39%. Calcd for $C_{12}H_{18}O$: C, 80.85; H, 10.18%.

e-*2-Hydroxyhomoadamant-4-ene (VI).* A solution of IV (449 mg; 1.98 mmol) in 20 ml of 25% aq. dioxane was heated at reflux for 2 hr. To the reaction mixture we then added aqueous $NaHCO_3$, and an organic material was extracted with CH_2Cl_2. The solution was washed with brine and dried (Na_2SO_4). The solvent was removed to give crude VI (322 mg, 99%): mp (from *n*-hexane) 226—229 °C; MS: *m/e* 164 (M^+, 96%), 91 (97%), 79 (100%); IR (Nujol) 3300, 2950, 1650 (weak), 1460, 1380, 1025, 710 cm^{-1}; PMR δ ($CDCl_3$) 1.10—2.70 (broad complex m, 12H), 2.01 (s, 1H, OH), 3.93 (broad s, 1H), 6.05 (m, 2H); Found: C, 80.34; H, 9.96%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%.

Homoadamant-4-en-2-one (VII). To a solution of pyridine (2.5 ml) in 12 ml of CH_2Cl_2, we gradually added CrO_3 (520 mg; 5.2 mmol). The solution was stirred at room temperature for 5 min, and then, to this solution, we added, drop by drop, a solution of VI (99 mg; 0.6 mmol) in 3.5 ml of CH_2Cl_2. The reaction mixture was stirred at room temperature for 2 hr and then washed successively 5% aqueous NaOH saturated with NaCl, 5% aqueous HCl (twice), aqueous $NaHCO_3$, and brine. The organic layer was dried (Na_2SO_4) and passed through a short alumina column. The solvent was removed to give crude VII (92 mg, 94%): mp (from *n*-hexane) 244—248 °C; MS: *m/e* 162 (M^+, 100%); IR (Nujol) 2950, 1710, 1650 (shoulder), 1460, 1380, 710 cm^{-1}; UV λ_{max} (EtOH) 300 nm (ε=127); PMR δ ($CDCl_3$) 1.63—3.23 (broad complex m, 12H), 6.10 (m, 2H); Found: C, 81.35; H, 8.88%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

a-*2-Hydroxyhomoadamant-4-ene (VIII).* To a suspention of $LiAlH_4$ (134 mg) in 10 ml of dry ether, we added, drop by drop, a solution of VII (120 mg; 0.74 mmol) in 10 ml of dry ether. The reaction mixture was then stirred at reflux temperature overnight. The usual work-up[15] and the removal of the solvent gave crude VIII, along with a small amount of VI (119 mg, 98%, VIII : VI=96 : 4 by glc analysis (PEG 20 M, 180 °C)). The crude material was chromatographed on alumina. Elution by a mixture of *n*-hexane and CH_2Cl_2 (7 : 3) gave pure VIII: mp 282—284 °C; MS: *m/e* 164 (M^+, 100%); IR (Nujol) 3300, 2950, 1665 (weak), 1460, 1380, 1060, 1040 cm^{-1}; PMR δ ($CDCl_3$) 1.20—2.90 (broad complex m, 12H), 1.92 (s, 1H, OH), 3.80 (d.d, 1H, J=4 and 4 Hz), 6.00 (m, 2H); Found: C, 80.25; H, 9.99%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%.

To a solution of VII (62 mg; 0.38 mmol) in 2 ml of EtOH, we added $NaBH_4$ (32 mg; 0.84 mmol), portion by portion, in an ice-bath. The reaction mixture was stirred at room temperature for 15 min, poured into water, and extracted with ether. The extract was washed with brine and dried (Na_2SO_4). The solvent was removed to give a crude product (59 mg, 93%; VIII : VI=94 : 6 by glc analysis).

The oxidation of VIII with the CrO_3-pyridine complex by the use of the procedure described above gave the starting material, VII, in a 97% yield.

e-*2-Hydroxyhomoadamantane (IX).* A solution of VI (32 mg; 0.2 mmol) and a small amount of PtO_2 in 2 ml of EtOAc was vigorously stirred under a hydrogen atmosphere. After 1 equivalent of H_2 had been absorbed, the PtO_2 was removed by filtration and the filtrate was evaporated under reduced pressure to give crude IX (31 mg, 98%): mp (from *n*-hexane) 257—260 °C; MS: *m/e* 148 (100%); IR (Nujol) 3300, 2950, 1460, 1380, 1030 cm^{-1}; PMR δ ($CDCl_3$) 1.00—2.30 (broad complex m, 16H), 2.00 (s, 1H, OH), 3.60 (broad s, 1H); Found: C, 79.27; H, 11.15%. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.92%.

Homoadamantan-2-one (X). The procedure was essentially the same as that described above. The VII compound (102 mg; 0.63 mmol) gave X (92 mg, 88%): mp (from petroleum ether) 260—263 °C; MS: *m/e* 164 (M^+, 100%); IR (Nujol) 2950, 1720, 1460, 1380 cm^{-1}; PMR δ($CDCl_3$) 1.07—2.80 (broad complex m, 16H); Found: C, 80.24; H, 10.00%. Calcd for $C_{11}H_{16}O$: C, 80.44%; H, 9.83%.

The Wolff-Kishner reduction of X was conducted by the

use of the procedure described for the reduction of 2,4-dehydrohomoadamantan-5-one (XIV) (*vide infra*). The treatment of X (54 mg; 0.33 mmol) with KOH (368 mg) and 100% hydrazine hydrate (273 mg) in diethylene glycol (2 ml) gave homoadamantane (III) (35 mg, 71%), which was identical with an authentic sample[3b] (glc retention time, and MS and PMR spectra).

a-2-*Hydroxyhomoadamantane (XI).* This compound was prepared similarly from VIII in a 90% yield: mp (from *n*-hexane) >290 °C; MS: *m/e* 148 (100%); IR (Nujol) 3300, 2950, 1460, 1380, 1060, 1015 cm^{-1}; PMR $\delta(CDCl_3)$ 1.11—2.50 (broad complex m, 16H), 1.73 (s, 1H, OH), 3.83 (d.d, 1H, $J=5$ and 3.5 Hz); Found: C, 79.22; H, 11.13%. Calcd for $C_{11}H_{18}O$: C, 79.46; H, 10.92.

To oxidation of IX or XI by the CrO_3–pyridine complex gave a ketone, X. The reduction of X with $LiAlH_4$ in ether gave exclusively the axial epimer (XI). A PMR study showed the absence of IX.

e-*5-Hydroxy-2,4-dehydrohomoadamantane (XIII).* A solution of IV (322 mg; 1.4 mmol) and Na_2CO_3 (278 mg) in 10 ml of 25% aqueous dioxane was heated at reflux for 3 hr. The reaction mixture was then cooled, poured into water, and extracted with CH_2Cl_2. The extract was washed with brine and dried (Na_2SO_4). The subsequent removal of the solvent gave crude products (220 mg, 98%) which contained VI and XIII (1 : 6.2 by glc analysis; PEG 20 M, 160 °C). The separation of VI and XIII was effected by column chromatography on silica gel. Elution by *n*-hexane and ether (95 : 5) gave pure XIII (97 mg) and, subsequently, a mixture of VI and XIII (121 mg). The properties of XIII were as follows: mp (from *n*-hexane) 264—265 °C; MS: *m/e* 164 (M^+, 26%), 146 (100%); IR (Nujol) 3300, 2950, 1460, 1380, 1035 cm^{-1}; PMR $\delta(CDCl_3)$ 0.67—2.33 (broad complex m, 14H), 1.67 (s, 1H, OH), 4.40 (t, 1H, $J=6$ Hz); Found: C, 80.59; H, 9.98%. Calcd for $C_{11}H_{16}O$: C, 80.44; H, 9.83%.

When KOH was used in place of Na_2CO_3, the same products were obtained (VI : VIII = 1 : 6.9). When $AgClO_4$ was used, the reaction proceeded at room temperature but the product distribution was almost the same as has been described above (VI : XIII = 1 : 7.2).

2,4-*Dehydrohomoadamantan-5-one (XIV).* To a solution of pyridine (1.5 ml) in 7 ml of CH_2Cl_2, we gradually added CrO_3 (267 mg; 2.7 mmol). The solution was stirred at room temperature for 5 min, and then to this solution we added a solution of XIII (50 mg; 0.3 mmol) in 2 ml of CH_2Cl_2. The reaction mixture was stirred at room temperature for 2 hr and washed successively with 5% aqueous NaOH saturated with NaCl, 5% aqueous HCl (two times), 5% aqueous NaOH, and brine. The organic layer was dried (Na_2SO_4) and passed through a short alumina column. The solvent was removed to give crude XIV (44 mg, 90%): mp (from *n*-hexane) 238—241 °C; MS: *m/e* 162 (M^+, 100%); IR (Nujol) 2950, 1710, 1460, 1380 cm^{-1}; PMR $\delta(CDCl_3)$ 0.70—2.57 (broad complex m, 14H); Found: C, 81.38; H, 8.88%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%.

The Wolff-Kishner reduction of XIV was conducted following the procedure reported for the reduction of 8,9-dehydro-2-adamantanone.[16] A solution of XIV (31 mg; 0.19 mmol), KOH (208 mg), and 100% hydrazin hydrate (153 mg) in 1 ml of diethylene glycol was stirred at 110 °C for 30 min and subsequently at 180 °C for 3 hr. The material sublimed on the condenser was dissolved in petroleum ether (40—60 °C) and dried (Na_2SO_4). The subsequent removal of the solvent gave a sole product (21 mg, 75%), which was confirmed to be I by comparison with an authentic specimen (glc retention time, and MS and PMR spectra).

The UV maximum in $CHCl_3$ at 380 nm for the 2,4-dinitrophenylhydrazone of XIV was appropriate for a conjugated carbonyl function in comparison with the UV maximum in $CHCl_3$ at 371 nm for the 2,4-dinitrophenylhydrazone of 4-homoadamantanone.[17]

The 2,4-dinitrophenylhydrazone of XIV: mp (from EtOH) 184—185.5 °C; UV λ_{max} ($CHCl_3$) 380 nm; Found: C, 59.46; H, 5.26; N, 16.10%. Calcd for $C_{17}H_{18}O_4N_4$: C, 59.64; H, 5.30; N, 16.37%.

The 2,4-dinitrophenylhydrazone of 4-homoadamantanone: mp (from EtOH) 210—211 °C; UV λ_{max} ($CHCl_3$) 371 nm; Found: C, 59.18; H, 6.11; N, 16.36%. Calcd for $C_{17}H_{20}O_4N_4$: C, 59.29; H, 5.85; N, 16.27%.

The authors wish to thank Dr. Takeshi Imagawa for his helpful discussion.

References

1) Throughout this paper we have adopted trivial nomenclature for simplicity. The IUPAC names for 2,4-dehydrohomoadamantane and homoadamantane are tetracyclo[5.3.1.$0^{5,3}$.$0^{4,9}$]undecane and tricyclo[4.3.1.$1^{3,8}$]undecane, respectively.

The Photoreactions of 2,3-Dicyanobarrelene[1)]

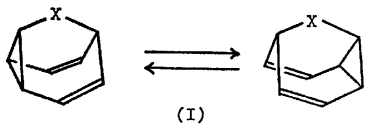
Katsuhiro SAITO* and Toshio MUKAI

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

(Received January 21, 1975)

The direct irradiation of 2,3-dicyanobarrelene (II) provided 1,2-dicyanocyclooctatetraene (III). On the other hand, the acetone-sensitized photoreaction of II afforded semibullvalene derivatives (IV and V). Investigations of their NMR spectra clarified that IV completely degenerates, whereas V inclines to the favorable form of the valence isomers.

It is well known that the activation energy of the Cope rearrangement of the I system is very low.[2-9)] Recently, Hoffmann and Stohrer thoretically considered the substituent effects on such valence isomerizations and proposed a general rule for the prediction of the favorable isomers.[10)] However, the substituted derivatives possessing the I skeletone are not numerous, so the adequacy of the rule has not been proved sufficiently. Therefore, it seemed that it would be interesting to synthesize new derivatives of this system and to study their properties from the viewpoint of the substituent effects on the valence isomerizations. This study will be concerted with the photoreactions of 2,3-dicyanobarrelene (II),[11)] which is expected to give cyano-substituted semibullvalenes suitable for the study of the valence isomerizations.



(I)

Fig. 1.

When a solution of II in *n*-hexane containing 10% of acetone was irradiated with a medium-pressure mercury lamp (Rayonet 300 nm) through a Pyrex filter, 1,2-dicyanocyclooctatetraene (III) was obtained in an almost quantitative yield. On the other hand, the irradiation of an acetone solution of II afforded 1,5-dicyanosemibullvalene (IV) and 3,4-dicyanosemibullvalene (V) in 4 and 56% yields respectively, in addition to 20% of III. As is well known in the photoreactions of barrelenes,[12)] the formation of semibullvalene derivatives (IV and V) may be ascribed to the acetone-sensitized reaction of II, although the cyclooctatetraene derivative (III) was also formed. It was also confirmed that IV and V are the primary photoproducts from II, because III did not afford IV and V upon irradiation under the same conditions.

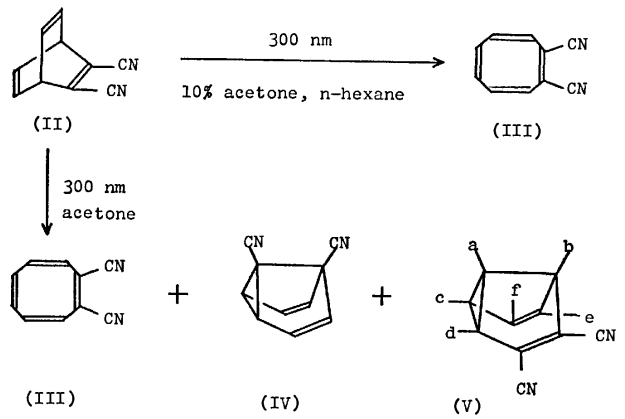


Fig. 2.

All the products, III, IV, and V, have the same molecular formula, $C_{10}H_6N_2$, and thier mass spectra exhibit the same molecular ion peak ($M^+=154$). The structures of the products were based on their spectral properties, shown below.

NMR (100 MHz, δ ppm): for III (in acetone-d_6), 6.2 (broad singlet 4H), 7.12 (broad singlet 2H); for IV (in $CDCl_3$), 4.78 (narrow multiplet 4H), 5.48 (narrow multiplet 2H); for V (in acetone-d_6), 3.45 (multiplet H_a), 3.72 (multiplet H_b), 4.32 (multiplet H_c), 4.55 (multiplet H_d), 5.26 (multiplet H_e), and 5.73 (multiplet H_f). Coupling constants in Hz; $J_{ab}=6.5$, $J_{ac}=4.0$, $J_{ad}=3.0$, $J_{be}=3.5$, $J_{cd}=3.0$, $J_{ce}=0.5$, $J_{cf}=3.5$, and $J_{ef}=4.0$.

UV (in methanol) nm (log ε): for III, 233 (4.31), 303 (2.79); for IV, 310 (2.31); for V, 310 (2.32).

IR (KBr): for III, 2226 cm^{-1}; for IV, 2240 cm^{-1}; for V, 2220 cm^{-1}.

The NMR spectrum of IV is very similar to that of 1,5-bis(trifluoromethyl)semibullvalene.[9)] The NMR spectrum of V is very complex, but the above data could be obtained using the double- and triple-resonance techniques.

The reaction mechanism for the formation of III can reasonably explained *via* a $2\pi+2\pi$-type intermediate (VI) which is derived from the singlet excited state.[12)] The formation of IV and V may be *via* a biradical intermediate (VII), which is an intermediate

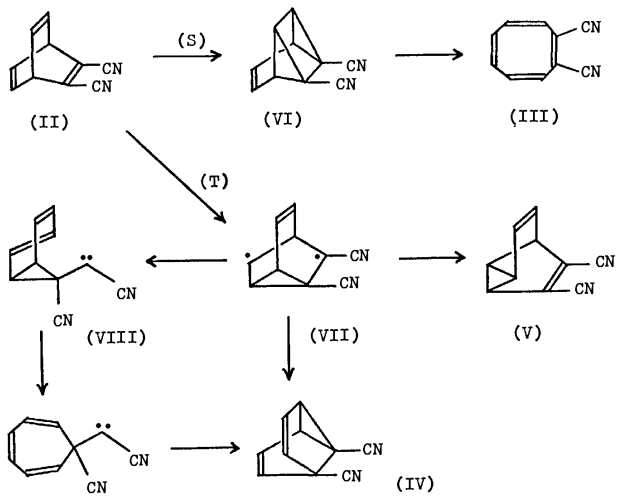

Fig. 3.

* Present address: Department of Chemistry, Nagoya Institute of Technology, Gokiso-cho, Showa-ku, Nagoya 466.

in di-π-methane rearrangements.[12] However, a path *via* a carbene intermediate (VIII) can not be eliminated for the formation of IV. The difference between the yields of IV and V can reasonably be explained by the stabilization ascribed to the formation of the double bond conjugated with two cyano groups.

Hoffmann and Stohrer pointed out that the symmetrically substituted semibullvalenes (possessing the same substituents at the positions which are symmetric with regard to the C_{2v}-axis or the mirror plane through C_3, C_7, and the center of the C_1–C_5 bond), should exist as degenerated valence isomers, except for an irrational compound (1,5-difluoro-2,4,6,8-tetracyanosemibullvalene).[10] That the NMR spectrum of IV shows two narrow multiplets with an area ratio of 2 : 1 implies that IV exists as a degenerated valence isomer; this fact coincides well with the prediction of Hoffmann *et al.*

According to the study of Hoffmann *et al.*,[10] the activation energies of the valence isomerizations of the symmetrically substituted semibullvalenes are sensitive toward substituents. In the case of the 1,5-dicyano derivative (IV), the activation energy may be expected to be considerably large and to be fixed more easily than those of other symmetric derivatives, bacause the stabilization effect of the cyano group operates more effectively on the reactant than on the transition state of the isomerization. From the above point of view, a low-temperature NMR study of IV was made, but the degenerated isomerization still occurs at low temperatures such as -100 °C, and no change was observed in the NMR spectrum.

3,4-Dicyanosemibullvalene (V) is likely to be fixed in the structure shown in Fig. 2. Hoffmann[13] and Günther[14] have proposed that an electron-withdrawing group attached to the C_1-position of a cyclopropane ring strengthens the C_2–C_3 bond and, instead, weakens the C_1–C_2 and C_1–C_3 bonds, whereas the electron-donating groups have the opposite effects. According to their proposition, when the substituent, R, in the structures in Fig. 4 are electron-withdrawing groups such as the cyano group, the C_2–C_8 bond of the structure (IX) weakens and, consequently, another valence isomer (X) should predominate. This is the case in our results. On the contrary, though, Liu and Krespan[9] have reported that 2,3-bis(trifluolomethyl)-semibullvalene, which has electron-withdrawing substituents at the same positions as V, is fixed in another structure, IX. Although this result seems to conflict with the above proposition, it can be reasonably explained as follows. The steric repulsion between the two trifluoromethyl groups which are located on a common plane in the X structure cause the shift of the isomerization to the IX structure, in which these two groups are in a twisted position. When the substituents are small, like the cyano group, the electronic effect dominates, whereas when the substituents become large, as the trifluoromethyl group, the steric effects seem to be predominant.

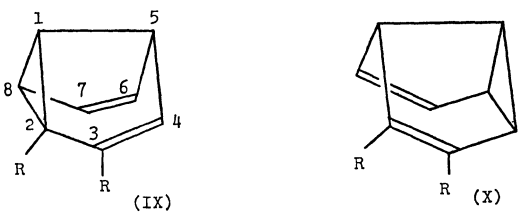

Fig. 4.

Experimental[15]

Direct Irradiation of 2,3-Dicyanobarrelene (II). A *n*-hexane solution of II containing 10% of acetone (100 mg/100 ml) was irradiated in a Pyrex vessel by means of a medium pressure mercury lamp (Rayonet 300 nm) for 2.5 hr. The subsequent evaporation of the solvent afforded a yellow crystalline product of III in a quantitative yield. III was recrystallized from methanol; mp 112 °C. Found: C, 77.72; H, 4.16; N, 18.35%. Calcd for $C_{10}H_6N_2$: C, 77.90; H, 3.92; N, 18.17%.

Acetone-sensitized Irradiation of 2,3-Dicyanobarrelene (II). An acetone solution of II (100 mg/100 ml) was irradiated in a Pyrex vessel by means of a medium pressure mercury lamp (Rayonet 300 nm) for 2.5 hr. After the subsequent removal of the solvent, an oily product (80 mg) was isolated by thin-layer chromatography (on silica gel, with benzene as the solvent). The NMR spectrum showed that this oil contained only III, IV, and V in a ratio of 25, 5, and 70; thus, the yields of III, IV, and V were calculated as 20, 4, and 56%, respectively. The distillation of this oil (85 °C, 0.02 mm/Hg) afforded an oily product, V. When the residue was separated by column chromatography using alumina, III was eluted with petroleum ether–benzene (3 : 7), and IV, with benzene. The recrystallization of IV from methanol afforded crystals with mp of 116 °C. Anal. for IV. Found: C, 77.94; H, 3.94; N, 18.17%. Calcd for $C_{10}H_6N_2$: C, 77.90; H, 3.92; N, 18.17%. Anal. for V. Found: C, 77.64; H, 3.90; N, 17.88%. Calcd for $C_{10}H_6N_2$: C, 77.90; H, 3.92; N, 18.17%.

The Molecular and Crystal Structure of DL-3-Chloro-2,4-pentanediol

Shunsuke KURIBAYASHI

Government Industrial Research Institute, Osaka Midorigaoka, Ikeda 563

(Received March 17, 1975)

The crystal structure of DL-3-chloro-2,4-pentanediol has been determined by X-ray analysis. The crystal is triclinic, with dimensions of $a=6.573$, $b=8.991$, $c=6.243$ Å, $\alpha=80.18°$, $\beta=94.25°$, and $\gamma=102.87°$. The five carbon atoms have a TT conformation, and the two OH groups have intermolecular hydrogen bondings, whose distances are 2.75 Å and 2.80 Å respectively.

As in the case of 2,4-pentanediol,[1,2] 3-chloro-2,4-pentanediol is separated into two parts by elution chromatograph; one of the parts seems to be racemic, and the other, the *meso* form. However in the case of 3-chloro-2,4-pentanediol, synthesized by the hydrogenation of 3-chloro-2,4-pentanedione, the *meso* form is eluted faster than the racemic form when separated by an ion-exchanger chromatograph. The conformation, configuration, and hydrogen bonding of these compounds have been investigated by NMR and IR spectra.[3,4] The structure determination was undertaken by means of the X-ray method for the racemic form, which crystallizes at room temperature, in order to elucidate the conformation, configuration, and hydrogen bonding of the molecule, and to compare the results with those obtained by NMR and IR spectroscopy.

Experimental

The colorless prismatic crystals or platelets were obtained by the distillation of this substance under a pressure of 22 mmHg. The crystal used for the X-ray diffraction was a needle elongated along the c-axis; the crystal was cut into the cubic form to make its shape suitable for X-ray diffractometry. The crystallographic data are shown in Table 1. The cell dimensions were determined by the least-squares method using 15 reflections. The intensity data were collected by using a Rigaku four-circle diffractometer with Mo$K\alpha$ radiation, in the region from 2.5° to 55° for 2 θ. The experiment was carried out by the ω-2 θ technique. Out of 1637 possible independent reflections, 1329 non-zero data were collected. No absorption or extinction correction was made. The crystal density was measured by the flotation method.

Structure Determination

A sharpened Patterson map was synthesized, from which the co-ordinate of the Cl atom was then deduced. Successive structure factor calculations and Fourier syntheses revealed all of the remaining non-hydrogen atoms. On the basis of these atomic locations, least-squares refinements using isotropic temperature factors were carried out. After 5 cycles of refinements, the R factor was found to be 0.198 for the non-zero reflections. Anisotropic temperature factors were then introduced for all of the non-hydrogen atoms. After 6 cycles of refinements, the R factor was reduced to 0.079 for the non-zero reflections. At this stage of analysis, the difference Fourier map was computed; all of the hydrogen atoms were located in it, but the peaks thus obtained were not very sharp, so their locations, except for those which were attached to oxygen atoms, were replaced by the calculated values, assuming that the CH bond lengths are 1.09 Å and that the bond angles of the carbon atoms are kept tetrahedral. With these positional parameters, 6 more cycles of least-squares refinements were carried out. In these procedures, the positional and thermal parameters of the hydrogen atoms which are attached to carbon atoms were not varied, and the thermal parameters of all of the hydrogen atoms were assumed to be the same as the isotropic parameters of those of the atoms to which they are bonded. By these procedures, the R factor was reduced to 0.053. The weighting scheme used here was:

$$|F_0|<F_{min}: \quad w=0.2$$

$$F_{min}\leq|F_0|\leq F_{max}: \quad w=1.0$$

$$F_{max}<|F_0|: \quad w=F_{max}/|F_0|$$

where $F_{max}=20.0$ and $F_{min}=10.0$. The numerical calculations were carried out on a TOSBAC 3400-41 computer, using the program written by Tamaichi Ashida which is included in the UNICS program system.[5] The final atomic co-ordinates and temperature factors are shown in Tables 2 and 3. The

observed and calculated structure factors are listed in Table 4.*)

Results and Discussion

The bond lengths, bond angles, and the molecular shape are shown in Fig. 1. The bond lengths, ranging from 1.514 to 1.524 Å for C–C and from 1.413 to 1.423 Å for C–O, are not significantly different from the respective mean values of 1.519 and 1.418 Å. The OH bond lengths are 0.80 and 0.82 Å, a little shorter than the ordinary OH bond lengths. The C–C–C bond angles are systematically about 6° greater than the C–C–O bond angles. This fact has also been pointed out for other polyols.[6–10] The five carbon atoms are nearly on a plane, and they take a TT sequence. The equation of the least-squares plane through five carbon atoms is given by:

$$-0.6454x + 0.5489y + 0.7445z = 0.4262$$

with respect to the crystallographic axes. The deviations of five carbon atoms from the plane are shown in Table 5. The calculations were carried out using the program written by Tosio Sakurai.[5] The torsional angles, listed in Table 6 were calculated by means of the program written by Reikichi Iwamoto of our laboratory. In Figs. 2 and 3, the packing of the molecules looking down the c- and a-axes in the unit cell are shown. As is shown in these figures, the two oxygen atoms are hydrogen-bonded to each other. Each hydroxyl group forms two hydrogen bonds intermolecularly, one as donor and the other as acceptor. These two hydrogen-bond distances are 2.800 and 2.752 Å respectively. As is commonly observed, the spread of C–O–H angles at the donor oxygen atom of

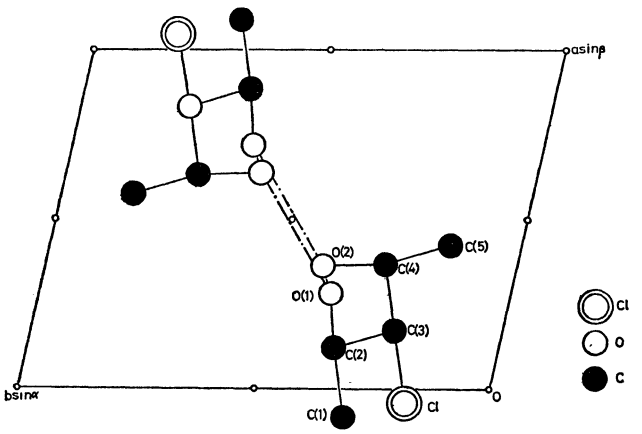

Fig. 2. The crystal structure of DL-3-chloro-2,4-pentanediol viewed down along the c-axis. Hydrogen bonds are shown by the chain lines.

* Table 4, which gives a complete list of the observed and the calculated structure factors, has been submitted to, and is kept by, the office of the Bulletin of the Chemical Society of Japan. (Document No. 7518).

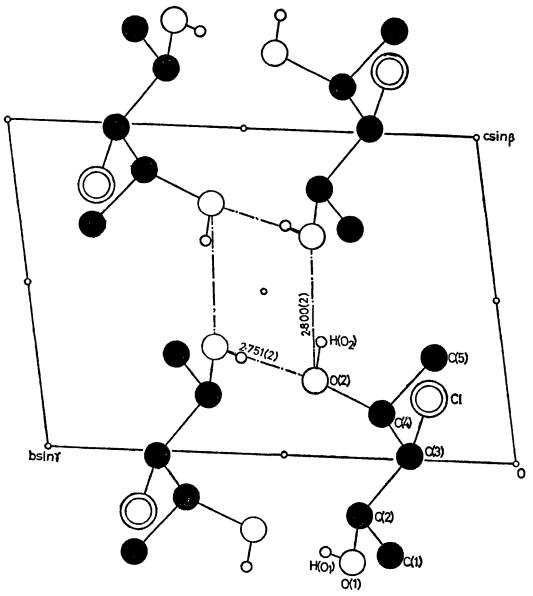

Fig. 3. The crystal structure of DL-3-chloro-2,4-pentanediol viewed down along the *a*-axis.

the hydrogen bond is less than those of H···O–C at the acceptor oxygen. The angles of the former are 112.5° and 115.4°, and of the latter, 124.0° and 137.9°. Surrounding the center of symmetry, four molecules are linked together by the hydrogen bonds. The shortest van der Waals contacts of C–C, C–O, C–Cl, O–O, and O–Cl are 3.52, 3.54, 3.60, 3.48, and 3.95 Å respectively.

As has been pointed out on the basis of NMR observation, the configuration of the molecule is proved to be the racemic form. From the IR spectra, measured in two concentrations, the conformations of racemic chloro-diol are thought to be mixtures of TT and TG, but in the crystalline state the conformations are TT only and all of the OH groups are linked together by intermolecular hydrogen bonds.

The author is indebted to Mr. Takahiko Kawaguchi and Professor Kaichi Sugita of Ritsumeikan University for supplying the sample and for giving him helpful advice.

The Crystal and Molecular Structure of *cis*-2,2-Diphenyl-3,4-dichlorothietane

Shigekazu KUMAKURA and Toshiko KODAMA*

Department of Chemistry, Saitama University, 255 Shimo-okubo, Urawa 338

(Received July 1, 1974)

The crystal structure of *cis*-2,2-diphenyl-3,4-dichlorothietane has been determined from three-dimensional X-ray data collected by the photographic method. The compound forms monoclinic crystals with $a=9.94(1)$, $b=12.56(1)$, $c=12.96(1)$ Å, $\beta=120.66(8)°$, and $Z=4$ in the space group of $P2_1/c$. The structure has been refined by the block-diagonal least-squares method to a final R value of 0.10, based on 1578 observed reflections. The conformation of the C–Cl bonds with respect to the thietane ring is (3e4a), consistent with that in solution derived from the dipole moments. The thietane skeleton of the compound is puckered, with a dihedral angle of 151.1°. The two C–S distances are 1.81 Å and 1.89 Å, and the average distance between the C–Cl bonds is 1.785 Å. The C–S and C–Cl bond characters are discussed in terms of the CNDO/2 method. The intermolecular S···S contact of 3.32 Å is remarkably short; it may be explained as a consequence of an attractive interaction between the dipole moments of the molecules.

cis-2,2-Diphenyl-3,4-dichlorothietane (abbreviated hereafter as *cis*-DCTE) was synthesised by the cycloaddition of thiobenzophenone to *cis*-dichloroethylene.[1] A study of the dipole moment of a series of thietane derivatives including this compound has revealed an unusually large bond moment for the C_α–Cl bond in *cis*-DCTE.[2] This X-ray study was undertaken in order to establish the geometry of the thietane ring and to shed light on the bond character of the C_α–Cl bond.

Experimental

The crystals of *cis*-2,2-diphenyl-3,4-dichlorothietane grown from an *n*-hexane solution are colorless plates. The cell dimensions and the space group were determined from oscillation and Weissenberg photographs taken around the *b* and *a* axes, using Cu$K\alpha$ radiation ($\lambda=1.542$ Å). They are listed in Table 1, together with other crystal data.

Two specimens with dimensions of $0.05\times0.05\times0.30$ mm and $0.05\times0.06\times0.20$ mm were used for the collection of the intensity data around the *b* and *a* axes respectively. Equi-inclination Weissenberg photographs were taken for *h*0*l*—*h*9*l* and for 0*kl*—7*kl*. The intensities of 1578 reflections were estimated visually and were corrected for the usual Lorentz, polarization, and spot shape factors. The absorption effect was neglected in view of the small size of the specimen.

Structure Analysis

The positions of the sulfur and chlorine atoms were deduced from a three-dimensional Patterson synthesis sharpened by a factor of $\exp(B\sin^2\theta/\lambda^2)$ ($B=3.0$ Å^2). The positions of the lighter atoms except for hydrogen were determined by the routine application of the heavy-atom method. Block-diagonal least-squares refinement using anisotropic temperature factors reduced the R value to 0.10. The positions of all the hydrogen atoms were given from the suitable geometry, but were not refined. The temperature factors for hydrogen were assumed to be isotropic, with the same values as those of the carbon atoms to which the hydrogen atoms are bonded. The following weighting scheme was employed for the least-squares refinement:

$$1.0 \text{ for } |F_o|\geq5.0$$

and

$$0.3 \text{ for } |F_o|<5.0.$$

The final difference map was flat within the range

of ± 0.3 eÅ^{-3}. The final positional and thermal parameters are listed in Table 2. A list of the observed and calculated structure factors is preserved by the Chemical Society of Japan.[3]

The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[4]

The calculations were carried out on a HITAC 5020E computer at the Computer Centre of the University of Tokyo and on a TOSBAC 3400 at Saitama University.

Description of the Structure and Discussion

The molecular conformation, bond lengths, bond angles, and their standard deviations are shown in Fig. 1, together with the atomic numbering scheme. The molecule is dissymmetric, and both enantiomorphs are present in the crystal.

The thietane ring is not planar. The dihedral angle (θ) between the planes, (C(2), C(3), C(4)) and (C(2), S, C(4)), is 151.1°. The C(2)–C(3)–C(4) angle and the average inner C–C–S angle are 98.1° and 87.8° respectively. The average distance of the C–C bonds in the ring is 1.565 Å. The C(2)–S of 1.89(1) Å is much longer than 1.812 Å, the mean of the 11 experimental values in the compounds containing the C–S single bonds.[5] Such lengthening has also been observed for the bonds of thietane rings in the following compounds: thietane itself (1.847(2) Å),[6] 2-isopropylidene-1,1,7,7,9,9-hexamethyl-3,5,10,11-tetrathiadispiro[3,1,3,2]undecane-8-thione (1.834(5) Å),[7] and *N*-(*p*-bromophenylcarbamoyl)thiamine anhydride (1.843(11) Å).[8] The longer bonds appear to be a common feature of such a strongly strained system. Thus, it might be unusual that the C(4)–S of 1.81(1) Å is much shorter than the C(2)–S. The C(4)–Cl of 1.78(1) Å is in agreement with the C(3)–Cl of 1.79(1) Å. This fact is in contrast to the unusually large bond moment of the C(4)–Cl.[9] In order to gain a better understanding of the C(4)–Cl and C(4)–S bond characters, a CNDO/2 calculation[10] was carried out for a model (*cis*-2,3-dichlorothietane) with skeletal dimensions assumed to be the same as those of *cis*-DCTE in the crystalline state. The lower electronic energy (−0.730 au) of the valence electrons for the C(2)–S bond of the model in comparison with that of C(4)–S (−0.660 au) may account for the shortening of the C(4)–S bond in *cis*-DCTE. A closer examination of the electronic energy matrix of the valence electrons reveals that this shortening may be attributed to increases in the π bond order and in the s character of the valence orbital of C(4). The atomic charge on Cl(1) in *cis*-DCTE is predicted to be slightly lower than that on Cl(2) (−0.121 e and −0.169 e for the respective atoms in the model), in contrast with the large value of the C(4)–Cl bond moment. The large C(4)–Cl bond dipole might be a consequence of additional contributions of the atomic polarization of component atoms in the molecule and the skeletal dipole due to the point-charge distribution. Here, it is noteworthy that a perturbation of the lowest vacant orbital to the ground-state electronic distribution could cause an increase in the ionic character of the C(2)–Cl bond (corresponding to the C(4)–Cl in *cis*-DCTE) and a decrease in that of the C(3)–Cl (corresponding to the C(3)–Cl) as a result of decreasing the electronic population in the lone pairs of sulfur.

Figure 1 shows that the conformation of *cis*-DCTE can be described as (3*e*4*a*). This conformation agrees

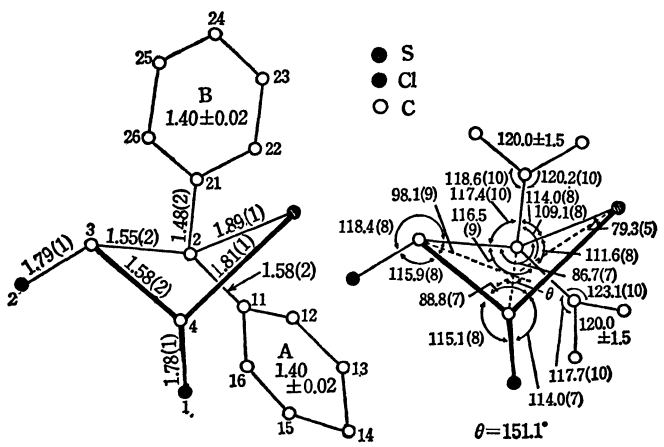

Fig. 1. Molecular geometry.

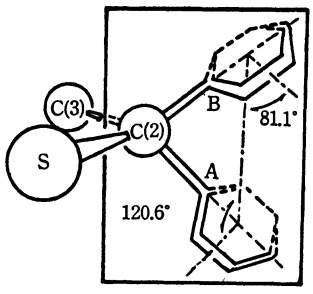

Fig. 2. Orientations of the phenyl groups.

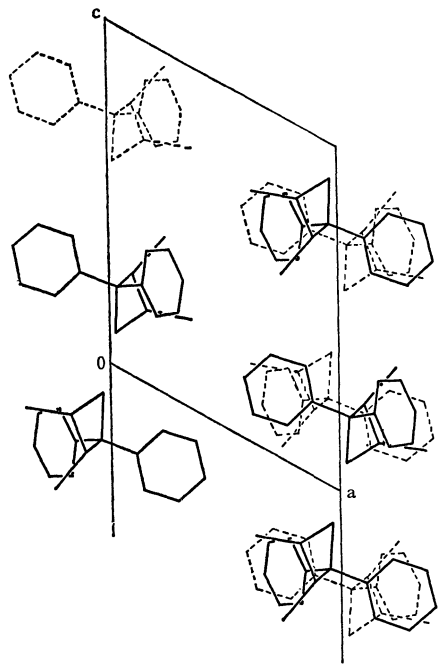

Fig. 3. Projection of the crystal structure of *cis*-DCTE viewed along the *b* axis.

Table 3. Closest intermolecular contacts

S···S^{i}	3.32 Å
S···C(15^{ii})	3.72
C(14)···C(26^{ii})	3.45
Cl(2)···C(13^{iii})	3.75

i=$-x$, $-y$, $-z$. ii=$-x$, $1/2+y$, $1/2-z$.
iii=x, $1/2-y$, $1/2+z$

with the results of the measurement of dipole moments in a benzene solution.

The phenyl groups, A and B, are practically planar. Their orientaions are shown in Fig. 2. The non-bonded distances of S···C(22), S···C(12), and Cl(2)···C(16) are 3.17, 3.10, and 3.33 Å respectively. Steric interactions between these non-bonded atoms play an important role in determining the orientations of the phenyl groups.

A projection of the crystal structure viewed along the *b* axis is presented in Fig. 3. The closest intermolecular contacts are listed in Table 3. They are normal except for that between S and S^{i}, which is significantly shorter than the usual contact of 3.70 Å.[11] The closest approach between the sulfur atoms is across a center of inversion. The dipole moments of the molecules involving these sulfurs are arranged in an antiparallel orientation. The dipole-dipole interaction energy was computed for the molecular pair related by a center of symmetry by rotating the component molecules around their respective centers of mass so as to alter their relative orientation and by placing the C–Cl and C–S bond moments on the centers of the corresponding bonds as a point dipole. The relative arrangement observed was found to be at the energy minimum, with a value of −5 kcal/mol. Therefore, the closest contact of the sulfur atoms might be explained as a consequence of attractive interaction between the molecular dipoles.

The authors are grateful to Dr. Atsuyoshi Ohno and Dr. Yutaka Ohnishi of the Sagami Chemical Research Center for kindly supplying the crystals of *cis*-DCTE and to Professor Takashi Shimozawa for his keen interest and valuable discussions. This research was supported in part by a Scientific Research Grant from the Ministry of Education, to which the authors' thanks are also due.

A Study of the Molecular Compound between Inosine and Tryptophan

Yoshihisa SUZUKI, Kentaro HARA, and Tsuneo HIRAHARA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received November 7, 1974)

Equilibria have been determined at 30 °C for the inosine–L-tryptophan–water and inosine–D-tryptophan–water systems. They show the formation of a molecular compound, which was demonstrated in U.S. Patent 3532684, over a wide range of variable ratios of the two components, inosine and tryptophan. The influence of some organic solvents on the formation of the molecular compound was examined, and it was shown that the water molecule is significantly involved in the formation of the crystalline molecular compound, and that solvent interactions play an important role. Similar crystalline molecular compounds were not formed by chemically closely related substances; the high specificity of the interaction between inosine and tryptophan was confirmed.

In 1968 it was demonstrated for the first time by two of the present authors and by others in a Japanese patent[1] that equimolecular amounts of inosine and tryptophan form a crystalline molecular compound which is sparingly soluble in water. It has also been pointed out in several subsequent patents[2,3] that the molecular compound of L-tryptophan with inosine is less soluble than that of D-tryptophan, and that DL-tryptophan is optically resolved by conversion to the molecular compound. It was also demonstrated in a Japanese patent of 1973[4] that the biological production of L-tryptophan is greatly increased by the addition of inosine to the reaction system, probably because the tryptophan produced in the solution is continuously removed, thus forming a sparingly soluble molecular compound with inosine. These facts suggest a specific strong interaction between inosine and tryptophan in an aqueous solution.

L-Tryptophan is known to show a molecular interaction in an aqueous solution with some purine ribonucleosides, such as adenosine, guanosine, cytidine, uridine, and thymidine.[5–7] However, none of them have ever given any stable crystalline molecular compound. In frozen aqueous solutions, some of these purine ribonucleosides form aggregates[8,9] with tryptophan; these aggregates are supposed to be 1 : 1 complexes, even though there is no complex formation at room temperature.[10] Recently, the equilibrium constants and the thermodynamic parameters for the complex between inosine and L-tryptophan have been reported by Ibáñez *et al.*[11]

This paper will describe the equilibria for the inosine–L-tryptophan–water and inosine–D-tryptophan–water systems, the importance of the water of crystallization in the formation of the crystalline molecular compound, and attempts to prepare an analogous crystalline molecular compound.

Results and Discussion

Tables 1 and 2 show the composition data of the equilibria at 30 °C for the inosine–L-tryptophan–water and inosine–D-tryptophan–water systems respectively. They show experimental errors within ±0.04% and ±0.02% (absolute value) for inosine and tryptophan respectively. The composition data of the solution in the equilibria for these two systems are illustrated in Fig. 1 (the isothermal solubility curves), which clearly demonstrates the formation of the molecular compound over a wide range of the two components, inosine and tryptophan. The molecular compound is readily formed, with a steep decrease in the solubility when a small amount of one of the components is added to the other component in the solution.

A small difference is observed between the solubility curves of inosine related to L-tryptophan and that related to D-tryptophan, as is shown in Fig. 1. This is significant for the resolution of the racemic compound of tryptophan. Information has already been given in the patents[3] that the molecular compound of inosine

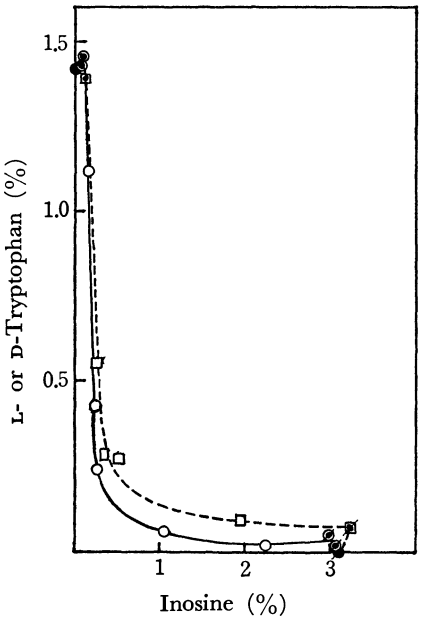

Fig. 1. An illustration of the composition of the solution phase in the equilibrium for the inosine-L-(or D-)tryptophan-water system at 30 °C.
The symbol marks of the solid phase are as follows:
○: L-Trp·Inosine·$3H_2O$ (molecular compound).
□: D-Trp·Inosine·H_2O (molecular compound).
●: L-Trp or D-Trp.
◐: Inosine (α-form).

with L-tryptophan is less soluble than that with D-tryptophan. The solubility difference of the curves in Fig. 1 is confirmed to be consistent with the above information over a wide region, even where the two components are not equimolar. Therefore, there is a possibility that the resolution of racemic tryptophan may be performed even when the amount of inosine is not equimolar.

It is known that racemic tryptophan is far less soluble than optically active ones. However, by the addition of a certain amount of inosine to the solution of racemic tryptophan, molecular compounds between inosine and optically active tryptophans were formed and precipitated because their solubilities are lower than the solubility of racemic tryptophan. The molecular compound of inosine with L-tryptophan was at first precipitated, leaving that of inosine with D-tryptophan in the solution.

It has been demonstrated[1,3] that the crystals of the molecular compound between inosine and L-tryptophan contain three molecules of water of crystallization, and that they lose two of them on heating in air, thus giving the monohydrate of the molecular compound. The experimental conditions used to obtain monohydrate from trihydrate were, for example, at 50 °C for 2 hr in air or at 110 °C for 40 min *in vacuo*.

It is found that the crystals of monohydrate thus obtained absorb moisture in air rapidly at first and gradually at the end, returning to original trihydrate in a few days. This process can be followed quantitatively by means of the X-ray powder diffraction spectra. Two strong peaks corresponding to the spacings of 7.63 Å and 6.33 Å are specific for the trihydrate, and two other strong peaks corresponding to the spacings of 7.25 Å and 6.92 Å are specific for the monohydrate. The change in the intensity of these four specific peaks reflects an increase and a decrease of these two forms in the crystals. However, when trihydrate crystals were very rapidly heated in air, it sometimes occurred that the X-ray diffraction spectra of trihydrate were unchanged even though the weight of the crystals was decreased by an amount as much as would correspond to two moles of water. This fact suggests that monohydrate crystals are sometimes able to retain the structure of original trihydrate crystals. Therefore, the two moles of water are likely to be nearly zeolitic water.

On the other hand, the crystals of the molecular compound between inosine and D-tryptophan were always obtained in monohydrate, and never in trihydrate. It is supposed that one mole of water in both molecular compounds is significantly involved in the formation of the molecular compound.

Trihydrate crystals of the molecular compound between inosine and L-tryptophan can be dried into anhydrous crystals by heating at 140 °C for 30 min *in vacuo*. The anhydrous crystals thus obtained also increased in weight because of the absorption of moisture when they were left in air. However, it was found that they never returned to being original hydrous crystals in air. Rather, they became amorphous.

The fact that one mole of water may play an important role in the formation of the crystalline molecular compound suggests the presence of solvent interaction in the intermolecular bonding between inosine and tryptophan. We examined the influence of several organic solvents on the trihydrate crystals of the molecular compound between inosine and L-tryptophan. Their crystals were practically insoluble; they remained unchanged in acetone, dioxane, tetrahydrofuran, and 1-butanol, while they were somewhat changed in appearance in methanol, ethanol, and 1-propanol. It was also confirmed by the X-ray method that the crystals of the trihydrate were partly changed into those of monohydrate in 85—95% (v/v) aqueous ethanol or aqueous 1-propanol, and that the crystals of L-tryptophan were found in the residue in addition to those of monohydrate in pure ethanol or pure 1-propanol. As was established in the patents,[3] the crystals added in methanol were changed into those of inosine. This last observation can be explained by the dissolution of the molecular compound, followed by the crystallization of inosine (leaving tryptophan in methanol).

It has been reported that the presence of ethanol destablizes the flavin–indole complexes.[12] The aggregates, which are supposed to be molecular complexes between nucleic acid derivatives and aromatic amino acids, in frozen aqueous solutions have been reported to be inhibited by the addition of organic solvents such as ethanol.[10] These destabilizing effects of the organic solvents on the molecular compounds demonstrate that solvent interactions play an important role in the formation of the molecular compound, especially in the present case when a water molecule is necessary to form the stable crystals.

Arcaya *et al.*[7] reported the interaction of L-aromatic amino acids including tryptophan with some ribonucleosides, and proposed a possible ring-ring-type interaction between an amino acid and nucleoside. This interaction is also possible in the present crystalline molecular compound between the imidazole ring in tryptophan and the purine ring in inosine. The fine hair-like appearance of the crystals of the molecular compound in this study suggests ring-ring vertical stacks with an alternative sequence of inosine and tryptophan. The growth of the linear vertical stacks would make for a long, slender crystal.

Besides such a ring-ring-type interaction based on the hydrophobic moiety in the molecule, the role of the hydrophilic moiety, such as the ribosyl or hydroxyl groups in the inosine molecule and the side-chain group in the tryptophan molecule, can never be disregarded in the formation of the crystalline molecular compound. Aiming to get some information about the role of such side chains, some compounds analogous to inosine and tryptophan were examined, and we attempted to make crystalline molecular compounds between them.

Several of the ribonucleosides illustrated in Fig. 2 were examined for interaction with L-tryptophan (**13**). Adenosine (**2**), guanosine (**3**), xantosine (**4**), hypoxanthine (**5**), and 9-β-D-ribopyranosyl hypoxanthine (**6**) all did not give any crystalline molecular compound

except crystalline mixtures of two original components. It is of interest that the isomerization of the ribose moiety in inosine from the furanosyl form to the pyranosyl form inhibited the formation of the molecular compound. Some nucleosides, such as cytidine, uridine, and 5-amino-1-β-D-ribofuranosyl-4-imidazolecarboxamide, also gave negative results. Several indole derivatives illustrated in Fig. 3 were examined with inosine (**1**). Indole (**7**), indole-5-carboxylic acid (**8**), indole-β-carboxylic acid (**9**), β-indolyl acetic acid (**10**), β-indolyl propionic acid (**11**), β-indolyl butyric acid (**12**), acetyl-L-tryptophan (**14**), tryptamine (**15**), and tryptophol (**16**) all failed to give any crystalline molecular compound. It was thus confirmed that the interaction between inosine and tryptophan is highly specific.

Experimental

Materials and Equipment. The inosine (α-form),[13] guanosine, adenosine, 5-amino-1-β-D-ribofuranosyl-4-imidazolecarboxamide, hypoxanthine, L-tryptophan, and acetyl-L-tryptophan were obtained from the Ajinomoto Co., Inc. The 9-β-D-ribopyranosyl hypoxanthine was prepared according to the method of a previous paper.[14] The D-tryptophan was presented by Dr. Takekazu Akashi of the Ajinomoto Co., Inc. The other materials were commercially purchased. The X-ray (Cu$K\alpha$) powder diffraction data for the determination of crystal forms were obtained by means of a Rigaku-denki diffractometer.

Preparation of the Crystals of the Molecular Compounds. (1) The trihydrate crystals of the molecular compound between inosine and L-tryptophan were prepared according to the patents.[1] (2) The monohydrate crystals of the molecular compound between inosine and D-tryptophan were prepared by evaporating an equimolar aqueous solution of the two components to dryness *in vacuo*. The analytical data were coincident with those in the patents.[3]

Determination of Equilibria. *Procedure*: The equilibria were approached by dissolving the crystals in water at 30± 0.5 °C. The details in Table 1 show the results obtained by dissolving inosine (Run No. 1), by dissolving L-tryptophan (Run No. 10), by dissolving both inosine and L-tryptophan (Runs No. 3, 4, 5 and 7), by dissolving the molecular compound trihydrate of inosine with L-tryptophan (Run No. 6), by dissolving both inosine and the molecular compound trihydrate (Run No. 2), and by dissolving both L-tryptophan and the molecular compound trihydrate (Runs No. 8 and 9). The data in Table 2 show the results obtained by dissolving both inosine and D-tryptophan (Runs No. 13, 15 and 16), and by dissolving the molecular compound monohydrate of inosine with D-tryptophan in water (Run No. 14) or that in aqueous inosine solution (Run No. 12). It took 16 hr for the equilibrium to be reached by tumbling the bottles containing the mixture on a water bath at a constant temperature. The mixture in the bottles was quickly filtered in a chamber kept at 30 °C with a glass filter. The wet residues and the filtrates were sampled by weight, diluted to appropriate volumes, and submitted to analysis. *Analysis*: The composition data were determined by the measurement of the UV absorption of the samples in 0.1 M HCl at 250 nm and at 280 nm, which are the specific wavelengths giving the maximum absorption for inosine and tryptophan respectively. The UV absorbances of the two materials, inosine and tryptophan, had previously been measured under our experimental conditions; the molar extinction coefficients were obtained for inosine at 250 nm ($\varepsilon_{I\ 250}$, 11700) and at

280 nm ($\varepsilon_{I\ 280}$, 2450), and for tryptophan at 250 nm ($\varepsilon_{T\ 250}$, 1390) and at 280 nm ($\varepsilon_{T\ 280}$, 5620). The analytical data of the mixture of inosine and tryptophan were obtained by the use of the following two equations:

$$A_{250} = \varepsilon_{I\ 250}\frac{C_I \times 10^{-3}}{MW_I} + \varepsilon_{T\ 250}\frac{C_T \times 10^{-3}}{MW_T}$$

$$A_{280} = \varepsilon_{I\ 280}\frac{C_I \times 10^{-3}}{MW_I} + \varepsilon_{T\ 280}\frac{C_T \times 10^{-3}}{MW_T}$$

where A_{250} is the UV absorbance at 250 nm, A_{280} is that at 280 nm, C_I(mg/l) is the concentration of inosine, C_T(mg/l) is that of tryptophan, MW_I is the molecular weight of inosine (268), and MW_T is that of tryptophan (204). C_I and C_T were thus determined by the measurement of A_{250} and A_{280}. The confirmation of the crystalline form in the residues was performed by means of the X-ray powder diffraction method.[3]

Behavior of the Molecular Compound in Several Organic Solvents. Finely powdered trihydrate crystals of the molecular compound between inosine and L-tryptophan (0.5 g) were added to one of several organic solvents (10 ml). After the mixtures had been vigorously shaken, the undissolved crystals were observed with a microscope. Some of them were examined also by means of the X-ray method in order to determine the crystal form.

Attempts at the Preparation of the Analogous Crystalline Molecular Compound. One of the nucleosides and L-tryptophan, or one of the indole derivatives and inosine, were dissolved (in a molar ratio of 1 : 1) in water. Then the mixture was evaporated to dryness *in vacuo* in a desiccator. The resultant solid was examined by means of X-ray diffraction. When the solid is the mixture of the two original components, its spectra may be consistent with those of a mechanical mixture of them. If any molecular compound is present in the solid, though, its spectra may show novel and specific peaks.

Radiation Chemical Studies with Cyclotron Beams. IV. The Effect of Water in the Heavy-ion Radiolysis of Liquid Acetone

Masao MATSUI and Masashi IMAMURA

The Institute of Physical and Chemical Research, Wako, Saitama 351

(Received November 13, 1974)

A study was made of the effect of water on the LET dependence of the product yields for liquid acetone. Acetone containing 2 wt% water was subjected to irradiation by energetic ^{4}He, ^{12}C, and ^{14}N ions as well as by ^{60}Co γ rays at room temperature; the LET range was up to 80 eV Å^{-1}. A significant effect of water was observed above 50 eV Å^{-1}, where $G(H_2)$ and $G(CO)$ showed continuous increases with an increase in LET. For pure acetone, $G(H_2)$ and $G(CO)$ showed their peak values at 50 eV Å^{-1}, indicating a saturation of decomposition in the ionization track, as has been reported previously. The present results may be interpreted in terms of the hydrogen-bonded network formed by the addition of water; this will expand the reaction zone outside the track and result in increases in the product yields without any waste of excessive energy in the high-LET region.

Radiolysis with heavy ions which have very high LET values is an interesting and important subject in radiation chemistry. Since the track structure of heavy ions differes appreciably from that of low-LET radiations, chemical reactions characteristic of high-LET radiations may be expected. However, few experimental studies have been carried out[1] despite the relatively extensive development of theories of the interaction of heavy ions with matter.[2-4]

In a previous paper of this series,[5] we reported the characteristic features of the radiolysis of liquid aliphatic ketones (acetone, methyl ethyl ketone, and diethyl ketone) with energetic C and N ions over a wide LET range. The most significant results reported in the preceding paper were: (1) the amount of major gaseous products (H_2 and CO) formed per unit track length tend to be constant, independent of the amounts of energy absorbed in the high-LET region ($>$*ca.* 60 eV Å^{-1}), and (2) the ratios of $G(H_2)$ to $G(CO)$ increase steadily with an increase in LET.

The first result indicates that the decomposition of ketones takes place only within a track core with a constant radius above a critical LET; therefore, $G(H_2)$ and $G(CO)$ apparently begin to decrease above this LET. The excessive energy thus accumulated within the track core may be supposed to increase the temperature of the core and induce some chemical reactions with high activation energies.

The second result can be explained in terms of such a thermal-spike effect in the track core; we assumed the thermal decomposition of free radicals to account for the increases in $G(H_2)/G(CO)$ as well as $G(H_2)$ and $G(CO)$ themselves. We also assumed the formation of highly excited states of ketone molecules which give product distributions different from those in the radiolysis with low-LET radiations.

Since these results are specific for pure ketones, and since no similar results have been observed for other organic liquids in the LET region studied, we plan to carry out a series of experiments which will lend further support to the assumptions presented above. This paper will report on one of them, presenting the radiolysis results obtained with liquid acetone containing a small amount of water over a wide LET range.

The γ-radiolysis of acetone as well as of other ketones in a liquid phase has been studied,[6] and the effect of water on the γ-radiolysis yields from liquid acetone has been demonstrated; [7,8] the resulting increase in $G(H_2)$ has been explained on the basis of ion-molecule reactions.[7] We have found that a small amount of water exerts a significant effect on the LET dependence of the product yields from acetone in the high-LET region. This effect, not explicable on the same basis as that in the γ-radiolysis, will be discussed in terms of a hydrogen-bonded network formed in the solution on the basis of the assumptions presented in the preceding paper.[5]

Experimental

The experimental procedures were essentially the same as those described previously;[5,9,10] only the essential points will, then, be mentioned. Ions of ^{4}He, ^{12}C, and ^{14}N were accelerated with the 160-cm cyclotron at the Institute of Physical and Chemical Research. Their energies and LET (represented by the energy-loss parameter defined as[5] $z = 1/E\int_0^E(-dE/dx)dE$) were 18.9 MeV, 6.7 eV Å^{-1}, 30.0—66.4 MeV, 54.4—39.2 eV Å^{-1}, and 18.0—47.5 MeV, 80.0—62.4 eV Å^{-1}, for He, C, and N ions, respectively. Irradiation was carried out at an ambient temperature.

Reagent-grade acetone (Wako Pure Chem. Ind.) was dried and distilled before use;[5] the water was triply distilled. The gaseous products from radiolyzed acetone were Toepler-pumped and were subjected to gas-chromatographic analysis.

Results

All the experiments reported in this paper were carried out with acetone containing 2 wt% H_2O. No differences beyond the experimental erros in the product yield were found between solutions containing 2 and 5 wt% H_2O either for the γ-radiolysis or for the heavy-ion radiolysis.

Iodine was used as a free-radical scavenger for the γ and He-ion radiolyses; in the presence of iodide, one could obtain "molecular" yields, which may be regarded as the yields of the products formed inside radiation spurs or tracks.

In the C- and N-ion radiolyses, iodine was not used, since the yields of H_2 and CO in these cases are little affected by scavengers and, therefore, may be regarded as being practically equal to the molecular yields. In the present study, emphasis has been placed on the characteristic reactions taking place inside the densely

ionizing tracks formed with heavy ions of high LET.

Figure 1 shows the variations with the LET (given by z) of $G(H_2)$ and $G(CO)$ determined for acetone containing 2 wt% H_2O (solid lines); these yields were obtained using He, C, and N ions accelerated to various energies. In contrast to the previous results obtained with pure acetone (dotted lines), [5] no peaks of $G(H_2)$ and $G(CO)$ were observed with aqueous acetone. $G(H_2)$ and $G(CO)$, which are lower than the corresponding values for pure acetone in the low-LET region, increase steadily with an increase in LET, and in the high-LET region they become even higher.

For comparison with earlier results,[7,8] the effect of water in the γ-radiolysis was also studied. In the absence of iodine, 2 wt% H_2O increases the total yields of H_2, CO, CH_4, and C_2H_6, but exerts no effect on those of C_2H_2 and C_2H_4. The molecular yields of these products obtained with iodine added at 1.8×10^{-3} M are lower for H_2 and CO and higher for saturated hydrocarbons than those for pure acetone; the molecular yields of unsaturated hydrocarbons are, however, practically unaffected. The effects of water on the total yields, except for the case of CO, are in qualitative agreement with the results obtained by Barker and Noble,[7] who determined the yields with acetone containing 0.4 wt% H_2O.

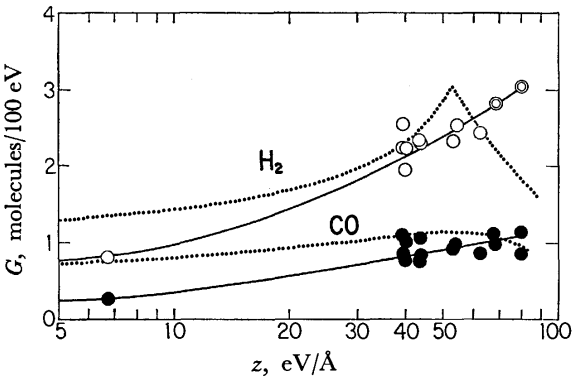

Fig. 1. LET dependence of $G(H_2)$ (○) and $G(CO)$ (●) for acetone containing 2 wt% H_2O.
LET dependence for pure acetone is shown by dotted lines for comparison (Ref. 5).

Discussion

Extensive studies of the primary processes in irradiated liquid acetone have been carried out by pulse radiolysis; they have revealed the formation of excited states[11-14] and molecular ions[11-19] in relatively high yields.

Electrons ejected by ionization attach to parent acetone molecules to form molecular anions; the total yield of the acetone cation and anion thus formed was determined and found to be approximately $G=1.5$.[13] Molecular anions will undergo recombination with cations to form excited states and neutral free radicals.

Earlier mass-spectrometric studies have shown that a rapid proton transfer does occur:[20,21]

$$(CH_3)_2CO^+ + (CH_3)_2CO \rightarrow (CH_3)_2COH^+ + CH_2COCH_3 \quad (1)$$

Sieck and Ausloos[19] suggested an important role of the ion-molecule reaction (1) as well as other reactions in liquid-phase radiolysis. However, in view of the fact that the transient absorptions of the acetone cation and anion are observable in the pulse radiolysis,[16,18] the rate constant of Reaction (1) may not necessarily be rapid in a condensed phase. Thus, there still remains an ambiguity concerning the ionic reactions taking place in liquid ketones.

A relatively high yield, $G=1.3\pm0.1$, has been reported for the excited states of acetone in a liquid phase; the excited states may be produced by direct excitation or by ion recombination.[14] Robinson and Rodgers[14] have also suggested, from their pulse-radiolysis study of acetone solutions, that the geminate recombination of ion pairs may produce excited states, too. In the radiolysis with heavy ions having high LET values, most of the initial ionic species are neutralized by the recombination inside densely ionizing tracks to form excited states.

In the γ-radiolysis of acetone, the effect of water on the product yields was explained by Barker and Noble[7] on the basis of the ion-molecule reaction (1). In fact, water is believed to react with the cation and anion of acetone molecules as follows:[16,18]

$$(CH_3)_2CO^+ + H_2O \rightarrow CH_3COCH_2 + H_3O^+ \quad (2)$$

$$(CH_3)_2CO^- + H_2O \rightarrow (CH_3)_2COH + OH^- \quad (3)$$

These reactions are probably responsible for the removal of the transient absorptions of the cation and anion by water; therefore, their rate constants must be higher than that of Reaction (1). However, since there is limited information available on the mechanism of ionic reactions taking place in the bulk, no further discussion can be made of the effect of water in the γ-radiolysis.

In the heavy-ion radiolysis, H_2 and CO are produced mostly inside the dense tracks and the ionic reactions are of less importance than in the γ-radiolysis. Water would interact with the excited states of the acetone molecules, which may be produced favorably in the heavy-ion radiolysis, as has been mentioned above.

It has been suggested that water may form a hydrogen-bonded network among acetone molecules, through which a rapid energy transfer may be expected to take place.[22] The significant effects of water on the product yields and their LET dependence in the heavy-ion radiolysis seem to be explainable in terms of the hydrogen-bonded network, as will be discussed below.

The previous results with pure ketones[5] indicate that, above the critical LET (50 eV $Å^{-1}$ for acetone), decomposition takes place only within the tracks of the limited radii. The excessive energy deposited in the tracks above the critical LET was assumed to cause the thermal decomposition of the free radicals with high activation energies, or to promote the formation of highly excited states of ketone molecules, resulting in more production of H_2 and CO. Under these conditions, however, some amounts of energy must be wasted not to form products, depending upon the amounts of energy deposited per unit track-length; therefore, the yields are reduced with an increase in LET, as is shown in Fig. 1 (dotted lines).

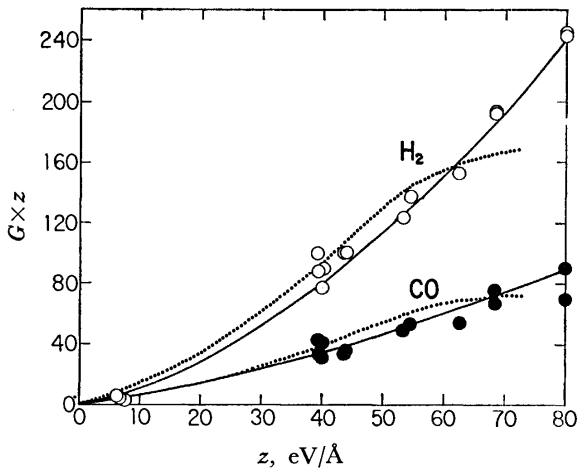

Fig. 2. Plots of Gz *vs.* z.
○, H_2; ●, CO. Dotted lines are for pure acetone (Ref. 5).

If the hydrogen-bonded network formed by water added to acetone could serve to transfer the excessive energy from the track outward the bulk, the reaction zone[23] in which acetone molecules can decompose would accordingly expand outside the track core.

Thus, the excessive energy, which would be wasted within the limited volume of the track in pure acetone at LET above 50 eV Å^{-1}, may be consumed efficiently and the yields may be expected to increase continuously with an increase in LET, as is shown in Fig. 1 (solid lines). In such expanding reaction zones, however, the occurrence of the thermal decomposition of free radicals or the formation of highly excited states will be more or less reduced, and the yields at LET below 50 eV Å^{-1} will be reduced compared with those for pure acetone. The experimental results are consistent with those expectations.

Figure 2 shows the plots of Gz *vs.* z, where Gz gives a measure of the number of molecules produced per 100 Å of track length. By comparing these plots (solid lines) with those for pure acetone (dotted lines),[5] one may see a steady expansion of the reaction zone with an increase in the LET; the plots for pure acetone show a saturation in the high-LET region.

The hydrogen-bonded network will also be operative to some extent in the radiolysis with low-LET radiations. The decreases in the molecular yields of H_2 and CO observed in the γ-radiolysis of aqueous acetone may be ascribed to the dissipation of energy from spurs to the bulk through the hydrogen-bonded network; the importance of this effect increases in liquid ketones with an increases in LET.

The authors wish to thank the members of the IPCR cyclotron operation group for their generous technical assistance throughout this study. The technical assistance of Miss Yuriko Moribe is also gratefully acknowledged.

The Micelle Formation of Alkylammonium Chloride in 1-Propanol–Water and Acetone–Water Mixtures

Shigeyoshi MIYAGISHI

Department of Industrial Chemistry, Faculty of Technology, Kanazawa University, Kodatsuno, Kanazawa 920

(Received January 30, 1975)

The change in the critical micelle concentrations (CMC) of alkylammonium chlorides (C_{12}—C_{18}) and in the degree of the dissociation of the micelle (α) of dodecylammonium chloride was determined by adding 1-propanol and acetone to water. Both the CMC and the α increased with an additive concentration, each reaching a maximum at a certain concentration (critical composition of solvent for micelle formation, CCSM) and decreasing beyond the CCSM. The increment in the CMC was more influenced by the alkyl-chain length in the surfactant molecule in the presence of 1-propanol than in that of acetone. The effective coefficient of electrical energy (K_g) and the cohesive energy difference per methylene group between the micelle and the monomer states (ω) were calculated from the CMC and the α. The K_g values in both mixed solvents were constant beyond the respective CCSM. The value of ω was less in the presence of 1-propanol than in that of acetone.

It is well known that such factors as additives, temperature, alkyl-chain length, and polar group in a surfactant molecule give rise to considerable changes in the micelle formation.[1–4] Many investigations have been reported into the cooperative effects among these factors; for example, the effects of each alkyl-chain length in a surfactant and an added alcohol molecule,[5] the influence of the temperature[6] and of a change in the counterions[7,8] in the presence of the organic additives, and the effect of the organic additives on the CMC of the surfactant with different ethylene oxide chain lengths.[9,10] These investigations have suggested that the most significant factor in the micelle formation is the interaction between the water and the alkyl-chain in a surfactant molecule. However, there have been few reports about the effect of the alkyl-chain over a wide range of organic additive concentrations. In the present work, the micellar behavior of alkylammonium chlorides (C_{12}–C_{18}) in 1-propanol–water and acetone–water mixtures was studied over the additive concentration range from 0 to about 0.4 in the mole fraction.

Experimental

The alkylammonium chlorides were prepared from vacuum-distilled alkylamines in a manner described previously.[7] They were used after having been recristallized from ethanol-ether several times. The procedures for the measurements of the CMC and of the degree of dissociation of the micelle (α) have been reported previously.[7] The experiments were carried out at 35.0 °C.

Results and Discussion

The Influence of 1-Propanol on the Micelle Formation. The natural logarithms of the CMC in the four surfactant solutions are presented as a function of the mole fraction of 1-propanol in Fig. 1, while the degrees of dissociation of the dodecylammonium chloride micelle are plotted in Fig. 2. The CMC of dodecylammonium chloride (DAC) first decreased, passed through a minimum, and then increased steeply with the 1-propanol concentration until it reached a maximum value at a certain concentration. Similar behavior was observed with regard to the CMC of tetradecyl- (TAC), hexadecyl- (HAC), and octadecylammonium chloride (OAC), although the minimum gradually disappeared as the alkyl-chain length increased. The CMC-decreasing effect can be explained mainly in terms of the solubilization of an additive in a micelle,[5] while the CMC-increasing effect can be explained as being due to the solvent power of the mixture.[10,11] The minimum on the CMC-solvent composition curve is controlled by the competition of the above two effects.

The mole fraction of 1-propanol at which the CMC reaches its maximum— denoted as the critical composition of the solvent for micelle formation (CCSM)[11]

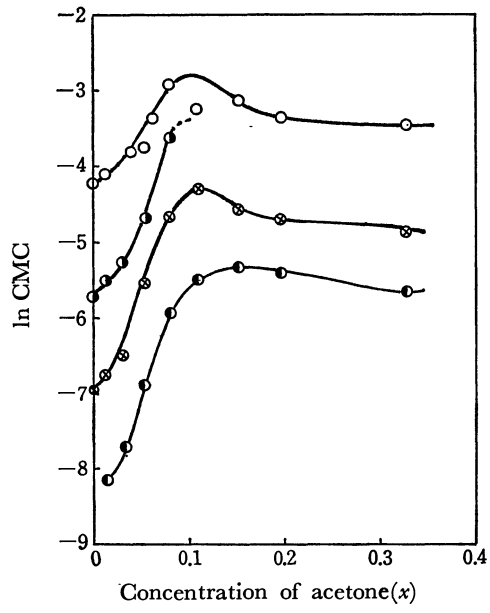

Fig. 3. The effect of acetone on CMC.
Symbols are identical with them in Fig. 1.

—is given in Table 1, together with the data for sodium tetradecyl sulfate (STS)[11] and polyoxyethylene dodecyl ether (POEDE).[12] The values of the CCSM were almost independent of the alkyl-chain length in the surfactant molecule and also of its head group. Also, the α increased with the 1-propanol concentration, reached a maximum at the same concentration as the CCSM, and decreased beyond it.

The Influence of Acetone on the Micelle Formation. The behavior of the alkylammonium chloride solutions containing acetone (Fig. 2, 3) was essentially the same as that of solutions in the presence of 1-propanol. However, both the solubilization effect and the solvent effect were less in the former mixed solvent than in the latter. There was no minimum in the values of the CMC as a function of the acetone concentration, and the increments in the CMC with acetone and the influence of the alkyl-chain length on their increments were less than in the presence of 1-propanol. The differences among the maximum CMC's of the alkylammonium chlorides were larger in the presence of acetone than in that of 1-propanol.

The CCSM in the acetone–water systems depended on the nature of the surfactants, but the values were scattered in the neighbourhood of 0.1—0.15. The heat of mixing in acetone–water systems has a minimum at 0.15,[13] and the viscosity and the tracer-diffusion coefficient of acetone have thier maximum and minimum, respectively, at about 0.2,[14,15] In the system of 1-propanol–water, the activity coefficient of 1-propanol changes rapidly in the neighbourhood of 0.1.[16] These authors, however, have avoided a detailed discussions concerning the structure change in the solutions. Any detailed discussion of the relation among these experimental facts must wait until details of the structure changes in the aqueous solutions become apparent. In the present paper, we will describe only the experimental fact; further investigation will be reported later.

In addition, it was found from the present experiment that the solubilities of these surfactants were less in acetone than in 1-propanol.

The Determination of K_g and ω. The CMC is expressed by this equation:[17]

$$\ln \mathrm{CMC} = -\frac{m\omega}{(1+K_g)kT} + \frac{K_g}{1+K_g}\ln\frac{2000\pi\sigma^2}{DNkT} + \frac{\ln(1000/Nv)-1}{1+K_g} \quad (1)$$

where m is the carbon number in a surfactant molecule, ω is the cohesive energy difference per methylene group between a micelle and a monomer states, K_g is the effective coefficient of the electrical energy, σ is the charge density, D is the dielectric constant of the solution, N is the Avogadro number, k is the Boltzmann constant, and T is the absolute temperature of the solution. As the second and the third terms on the right-hand side of this equation are almost independent of m,[17] the differentiation of Eq. (1) with respect to m gives the following equation:

$$\frac{\mathrm{d}\ln \mathrm{CMC}}{\mathrm{d}m} = -\frac{\omega}{(1+K_g)kT} \quad (2)$$

The values of $-\mathrm{d}\ln \mathrm{CMC}/\mathrm{d}m$ are plottedas functions of the additive concentrations in Fig. 4. It was found that $-\mathrm{d}\ln \mathrm{CMC}/\mathrm{d}m$ decreased rapidly with an increase in the concentration of the additives and reached constant values at the CCSM. The decreasing effect by the addition of 1-propanol was more than that by the acetone addition. In order to discuss these results in detail, we need to know the value of ω. We therefore attempted to determine K_g, and then ω was calculated from Eq. (2).

We define K_g as follows:

$$K_g = \phi/\phi_0 \quad (3)$$

where ϕ is the effective potential at the micelle surface

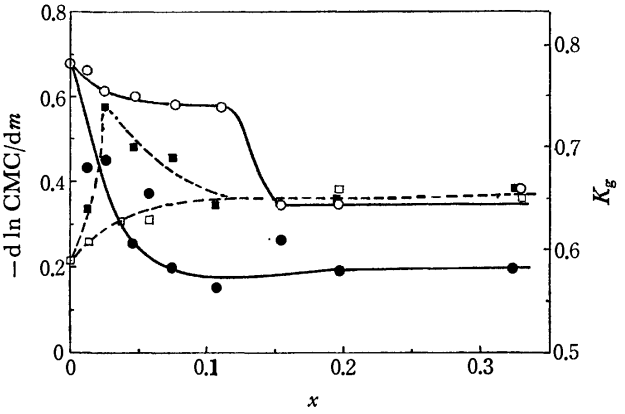

Fig. 4. The dependence of $-\mathrm{d}\ln\mathrm{CMC}/\mathrm{d}m$ and K_g on the additive concentrations.
○,□: Acetone, ●,■: 1-Propanol.
——: $-\mathrm{d}\ln\mathrm{CMC}/\mathrm{d}m$, ----: K_g.

and where ϕ_0 is the hypothetical potential when a counterion is not adsorbed on the micelle surface when the other conditions are constant. These potentials are given by the following two equations:

$$\phi = \frac{kT}{e}\ln\frac{2000\pi\sigma^2}{DNkTC_1} \tag{4-1}$$

$$\phi_0 = \frac{kT}{e}\ln\frac{2000\pi\sigma_0^2}{DNkTC_1} \tag{4-2}$$

where σ and σ_0 are the surface-charge densities of the micelle and of the hypothetical micelle, e is the electric elementary quantum, and C_i is the molarity of the couterion. By combining Eqs. (3) with (4—1) and (4—2), the following equation is obtained:

$$\frac{\varphi_0-\phi}{\phi} = \frac{1}{K_g} - 1 = \frac{2kT}{e\phi}\ln\frac{\sigma_0}{\sigma} \tag{5}$$

As σ/σ_0 is corresponds to α, Eq. (5) can be modified as follows:

$$K_g = \frac{e\phi/kT}{e\phi/kT - 2\ln\alpha} \tag{6}$$

On the other hand, according to a previous paper,[7] we have:

$$\frac{1-\alpha}{\alpha} = \frac{AMC_1}{1000}\exp(-\Delta G/kT) \tag{7}$$

where ΔG is the effective potential energy, M is the molecular weight of the solvent, and A is a constant. If ΔG can be given solely by an electrical term, we have the following equation:

$$\frac{\Delta G}{kT} = -\frac{e\phi'}{kT} = -\ln\frac{2000\pi\sigma'^2}{DNkTC_1} \tag{8}$$

where ϕ' and σ' are the potential and the charge density at a micelle surface in this case. Combining Eq. (7) with Eq. (8), we obtain:

$$\frac{e\phi'}{kT} = \ln\frac{1000}{AMC_1} + \ln\frac{1-\alpha}{\alpha} \tag{9}$$

As ϕ' is considered to be nearly equal to ϕ, the introduction of Eq. (9) into Eq. (6) gives the following equation:

$$K_g = \frac{\ln 1000/AMC_1 + \ln(1-\alpha)/\alpha}{\ln 1000/AMC_1 + \ln(1-\alpha)/\alpha^3} \tag{10}$$

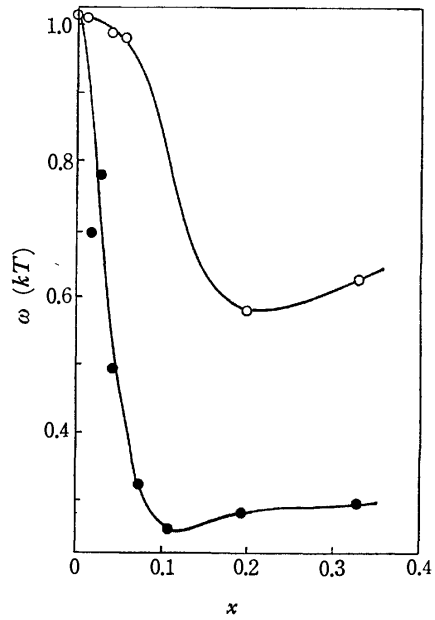

Fig. 5. The dependence of ω on the additive concentration.
○: Acetone, ●: 1-Propanol.

The concentration of the counterion, C_i, is equal to the CMC in the absence of an added electrolyte. Consequently, Eq. (10) becomes Eq. (11):

$$K_g = \frac{\ln(1-\alpha)/\alpha - \ln\mathrm{CMC} + \ln 1000/AM}{\ln(1-\alpha)/\alpha^3 - \ln\mathrm{CMC} + \ln 1000/AM} \tag{11}$$

The value of A is unknown, but it can be determined as follows. According to many papers published, ω in an aqueous solution is given as 1.08 kT. The value of $-\mathrm{d}\ln\mathrm{CMC}/\mathrm{d}m$ in the absence of an organic additive is given as 0.68 from Fig. 4. We can then obtain 0.59 as K_g from these two values and Eq. (2). Introducing 15×10^{-3} M, 0.18, 0.59, and 18 for the CMC, α, K_g, and M respectively in the aqueous solution into Eq. (11) gives 121 as A. Then, Eq. (11) may be rewritten as follows:

$$K_g = \frac{\ln(1-\alpha)/\alpha - \ln\mathrm{CMC} + \ln 1000/121M}{\ln(1-\alpha)/\alpha^3 - \ln\mathrm{CMC} + \ln 1000/121M} \tag{12}$$

The values of K_g calculated from Eq. (12) are shown in Fig. 4. Beyond the CCSM, they were almost constant. The values of ω calculated from Eq. (2) by using K_g and $-\mathrm{d}\ln\mathrm{CMC}/\mathrm{d}m$ are plotted in Fig. 5, which shows that ω decreased more rapidly in the presence of 1-propanol than in that of acetone and that the final value in the former solution was about one-half of that in the latter solution. These results suggest that the hydrophobic interaction in these micelle formation was less on the addition of 1-propanol than on that of acetone. However, we must note that the factors attributable to the decrease in ω are probably complicated; not only the hydrophobic interaction but also other factors, for example, the solubility parameters of the mixed solvents,[18] must be considered.

Fianlly, let us mention that the value of α calculated from Botré's equation[19] is not correct. Indeed, the decrease in the surfactant-ion concentration has been

considered above CMC.[20,21] However, the results determined on the basis of α are not unlike, for the divergence seems not be large when the experimental error of the determination of α is taken into consideration. Therefore, we believe that the qualitative behavior described above remains valid.

The author is greatly indebted to Professor Ryohei Matuura of Kyushu University, Assistant Professor Keishiro Shirahama of Saga University and Assistant Professor Morie Nishida for their encouragement and useful advice.

(Received February 25, 1975)

Ultrasonic absorption measurements in aqueous solutions of *tert*-butyl and allyl alcohols were carried out in the frequency range of 4.5—220 MHz at 25 °C. Two relaxation processes were observed in aqueous solution of *tert*-butyl alcohol and a single one in that of allyl alcohol. The former relaxation mechanisms were revealed to be due to the perturbation of the equilibria expressed by $AB \underset{\nearrow B}{\nwarrow} A \rightleftharpoons 1/3A_3$ where A and B were alcohol and water molecule respectively. The latter mechanism was due to that expressed by $AB \rightleftharpoons A+B$. The rate constants for all these processes were determined from the concentration dependence of the relaxation frequencies. The water structure in aqueous solutions was discussed in terms of a hydrophobic interaction, and it was concluded that the hydrophobic interaction decreased in this sequence, *tert*-butyl, *n*-propyl and allyl alcohols.

The effects of alcohols upon the properties of water continue to be investigated,[1] since the explanation of biological reaction mechanisms is intimately connected with liquid water structure. To understand the structural characteristics of liquids on a molecular scale, the application of wave technique with ultrasonic vibrations seems to be most appropriate. Though Blandamer and Waddington[2] have reported the ultrasonic absorption spectra in aqueous solutions of some alcohols, no quantitative analyses of the excess absorptions have been done. In a previous paper[3], the present authors have measured the ultrasonic absorption in aqueous solution of *n*-propyl alcohol and clarified the excess absorption mechanisms in relation to water structure. It becomes desirable to understand the properties of aqueous solutions of other alcohols and to compare the results in the case of *n*-propyl alcohol with those of other ones.

For this purpose, *tert*-butyl and allyl alcohols have been chosen and the ultrasonic absorption mechanisms in these aqueous solutions will be elucidated in this paper.

Experimental

The *tert*-butyl and allyl alcohols were reagent-grade commercial products and were distilled once. The purities of these alcohols were verified by gas chromatography to be higher than 99.5%. Solutions were prepared with doubly distilled water and we.e made up to the desired concentrations by weight. The measurements of the ultrasonic absorption were made in the frequency range of 4.5—220 MHz, using an ultrasonic pulse technique previously described[3,4]. The sound velocities were measured at 1.92 MHz using a sing-around technique. The densities were measured by means of a standard pycnometer. All the measurements were made at 25 °C.

Results and Discussion

Figures 1 and 2 show the representative ultrasonic absorption spectra in aqueous solutions of *tert*-butyl and allyl alcohols respectively. In general, the sound absorption caused by the several relaxation processes can be described by the following equation:

$$\alpha/f^2 = \sum A_i/[1+(f/f_{ri})^2] + B \qquad (1)$$

where α is the absorption coefficient; f the frequency; f_{ri} the relaxation frequency for the i-th process, and A_i and B, constants. The absorption spectra in aqueous solution of *tert*-butyl alcohol show the characteristic behavior due to a single relaxation process in the concentration range of less than 2.61 M and that due to double relaxation processes in the concentration range of more than 2.99 M. On the other hand, the measurements of α/f^2 for aqueous solution of allyl alcohol can be described by the relation for a single relaxation through out the concentration range measured. In the case of the single relaxation spectrum, a trial-and-error procedure was used to obtain the ultrasonic parameters which provided the straight line of the plots of α/f^2 *vs.* $[1+(f/f_r)^2]^{-1}$. The double relaxation spectrum was analyzed by a nonlinear least-squares routine, employing a Toshiba 3400 computer. In Table 1, the obtained values of the

ultrasonic parameters and the sound velocities are listed together with those of densities.

We have proposed that the excess absorptions in aqueous solution of *n*-propyl alcohol are due to the interaction between the alcohol and the water molecule, and the association and dissociation reaction of alcohol. Following this background, the excess absorption mechanisms in aqueous solutions of *tert*-butyl and allyl alcohols will be clarified. The model for the relaxation processes is as follows:

$$AB_m \underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}} mB + A \underset{k_{32}}{\overset{k_{23}}{\rightleftarrows}} \frac{1}{n}A_n \tag{2}$$

where A is the molecule of alcohol; B that of water, and k_{ij}, the rate constant. The detailed derivations for the expressions of the relaxation frequency and the maximum excess absorption per wavelength have been described in a previous paper.[3] If the left reaction step proceeds much faster than the right one, the relaxation frequencies for each step are expressed by:

$$2\pi f_{r1} = 1/\tau_1 = k_{21}(m^2C_2^{m-1}C_3 + C_2^m) + k_{12} \tag{3}$$

$$2\pi f_{r2} = 1/\tau_2 = k_{32} + k_{23}n^2C_3^{n-1} - \frac{n^2k_{21}k_{23}C_2^mC_3^{n-1}}{k_{12}+k_{21}(m^2C_2^{m-1}C_3+C_2^m)} \tag{4}$$

where C_2 and C_3 are the equilibrium molar concentrations of the components, B and A, respectively, and τ_i the relaxation time. The maximum excess absorption per wavelength, μ_{maxi}, is given by the next equation;

$$\mu_{maxi} = \frac{1}{2}A_i f_{ri} c = (\pi\rho c^2\Gamma_i/RT)(\Delta V_i - \alpha_p^\infty \Delta H_i/\rho C_p^\infty)^2 \tag{5}$$

where ρ is density; c, the sound velocity; R, the gas constant; T, the absolute temperature; α_p^∞, the high-frequency limit of the thermal expansion coefficient; C_p^∞, the high-frequency limit of the constant pressure specific heat, and ΔV_i and ΔH_i, the parameters related to the volume and enthalpy changes associated with the reaction under consideration. The Γ_i terms for the reaction expressed by Eq. (2) are:

$$\Gamma_1 = \frac{1}{V}\left(\frac{1}{C_1}+\frac{m^2}{C_2}+\frac{1}{C_3}-\frac{m^2}{C_T}\right)^{-1} \tag{6}$$

$$\Gamma_2 = \frac{1}{V}\left[\frac{n}{C_3}(n-\tau_1 k_{21} n C_2^m)+\frac{n-1}{C_T}(n-1+\tau_1 k_{21} n C_2^m)+\frac{1}{C_4}\right]^{-1} \tag{7}$$

where C_4 is the equilibrium concentration of the component A_n and where $C_T = C_1+C_2+C_3+C_4$.

Let us first consider the excess absorption mechanisms in aqueous solution of *tert*-butyl alcohol. The excess absorption in the lower frequency range (4—14 MHz) is observed only in the concentration range of more than 2.61 M, while that in the higher frequency range (50—120 MHz) is always observed through out the concentration range measured. From these facts, the perturbation of the left equilibrium in Eq. (2) may be expected to be associated with the excess absorption mechanism in the higher frequency range. If a single water molecule interacts with a single alcohol one and if the concentration of the aggregate of alcohol, C_4, is small compared with the other components, Eq. (3) can be rewritten as:

$$2\pi f_{r1} = 1/\tau_1 = k_{21}\sqrt{(C_a-\beta C_w+K_{12})^2+4\beta C_w K_{12}} \tag{8}$$

where K_{12} is the equilibrium constant defined by $K_{12} = k_{12}/k_{21}$; β, the mole fraction of the water monomer, and C_a and C_w the analytical concentrations of alcohol and water respectively. The introduction of the parameter, β, means that, in aqueous solutions of alcohols, an equilibrium between the monomer and hydrogen-bonded cluster of water is established and that only monomeric water molecules participate in the alcohol water interaction. Therefore, the parameter, β, might indicate the stability of the water structure.

Using the values of f_{r1}, C_a and C_w, the parameters, β, K_{12} and k_{21}, were determined so as to obtain a best fit of the data to Eq. (8). Figure 3 shows the calculated values of the relaxation frequencies, f_{r1}, for aqueous solution of *tert*-butyl alcohol along with the experimental ones. One can also evaluate the concentration dependence of the maximum excess absorption per wavelength. As has been described previously, the μ_{max1} is approximately proportional to $\rho c^2\Gamma_1$. The calculated values of $\rho c^2\Gamma_1 V$ are shown by a solid line in Fig. 4 also with the experimental values of μ_{max1}. In this figure, both peaks appear at almost the same concentration and the tendencies of both are identical. These facts lead to the conclusion that the excess absorption mechanism of aqueous solution of *tert*-butyl

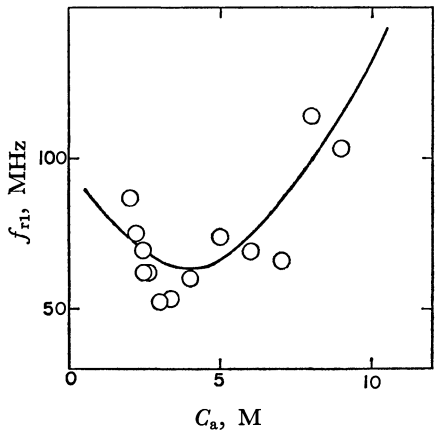

Fig. 3. Concentration dependence of the relaxation frequencies, f_{r1}, for aqueous solution of *tert*-butyl alcohol. The solid line indicates the calculated values.

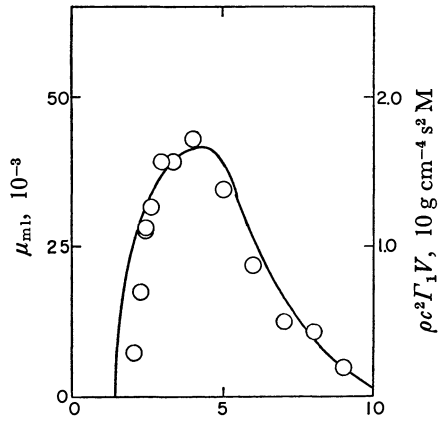

Fig. 4. The variations of μ_{max1} and $\rho c^2 \Gamma_1 V$ with the concentration of *tert*-butyl alcohol. The solid line represents the calculated values of $\rho c^2 \Gamma_1 V$. The circles are the experimental points of μ_{max1}.

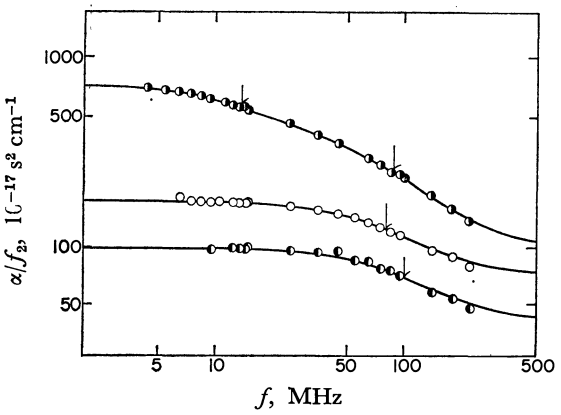

Fig. 6. Comparison of the ultrasonic absorption spectra in aqueous solution of *n*-propyl alcohol with that of allyl alcohol.
◑: 4.50 M, *n*-propyl alcohol, ○: 5.24 M, allyl alcohol, ◐: 4.19 M, allyl alcohol.

alcohol in the higher frequency range is attributed to the water alcohol interaction. Next, we will evaluate the excess absorption mechanism in the lower frequency range. Equation (4) is transformed to:

$$2\pi f_{r2} = 1/\tau_2 = n^2 k_{23} C_3^{n-1}(1-\tau_1 k_{21} C_2) + k_{32} \quad (9)$$

The aggregation number, n, was determined so as to obtain the straight line of the plots of f_{r2} *vs.* $C_3^{n-1}(1-\tau_1 k_{21} C_2)$, and from the slope and the intercept of this line the rate constants, k_{23} and k_{32}, were determined. Figure 5 shows the plots at $n=3$, where the best fit is obtained. The kinetic parameters obtained in this way are listed in Table 2. We also estimate the concentration dependence of the maximum excess absorption per wavelength for this reaction mechanism, but the value of $\rho c^2 \Gamma_2 V$ increases monotonically with the alcohol concentration.

Second, the excess absorption mechanism in aqueous solution of allyl alcohol, in which the excess absorption is not observed in the lower frequency range, will be clarified. In this solution, the association and dissociation reaction of alcohol may not be expected, about which we will discuss later. Therefore, it is sufficient to consider the perturbation of the left equilibrium as the excess absorption mechanism. For the sake of comparing the absorption spectra in aqueous solution of allyl alcohol with that of *n*-propyl alcohol, the spectra of the both solutions are shown in Fig. 6. As the behavior of the ultrasonic parameters in aqueous solution of allyl alcohol were close to those in aqueous solution of *tert*-butyl and *n*-propyl alcohols in the higher frequency range, the kinetic parameters for this mechanism in aqueous solution of allyl alcohol were also determined analogously to those obtained in the case of aqueous solution of *tert*-butyl alcohol. Figures 7 and 8 show the concentration dependence of the relaxation frequency and the maximum excess absorption per wavelength for aqueous solution of allyl alcohol. As may be seen in these figures, the calculated relaxation frequencies are very close to those of experimental values, and the position of the peak of the maximum excess absorption per wavelength appears at that of $\rho c^2 \Gamma_1 V$. These results make us conclude that the excess absorption mechanism in aqueous solution of allyl alcohol is due to the perturbation of the left equilibrium expressed by Eq. (2). The kinetic para-

meters obtained are listed in Table 2. The parameter, β, can be related to the free energy difference between the hydrogen bonded and non-hydrogen bonded water by means of this equation; $\beta/(1-\beta)=\exp(-\Delta F_w/RT)$. In Table 2, the free energy difference in aqueous solutions of alcohols are also listed. Litovitz and his coworkers[5] have estimated the free energy difference in pure water to be 0.63 kcal at 25 °C utilizing the ultrasonic absorption technique. Therefore, the parameter, β, which is the mole fraction of monomeric water, is 0.26. Comparing this value with those obtained by the present investigation of aqueous solutions of alcohols, it is clear that all the alcohols studied here act as water structure promoters. The effect of the water structure promoter may be the result of a hydrophobic interaction. Recent investigations[6,7] of aqueous solutions of several alcohols have shown that even molecules which consist of relatively small hydrophobic groups have an ability of hydrophobic interaction. Especially, Shirahama and *et al.*[8] have found the decreasing effects of the critical micelle concentration in aqueous solutions of several alcohols and have reported that the more hydrophobic and the more concentrated the added alcohol, the more marked becomes the decrease in the critical micelle concentration. They have also shown that the hydrophobic interaction decreases in this sequence, *tert*-butyl, *n*-propyl and ethyl alcohols. The smaller the parameter, β, the more does the hydrophobic interaction increase. The results obtained in the present investigation are consistent with the above interpretation. It is well known that the presence of a double bond in a molecule weakens the hydrophobic interaction. If the aggregate of alcohol is formed by hydrophobic interaction in aqueous solutions, the absence of the excess absorption in the lower frequency range in aqueous solution of allyl alcohol can be well interpreted in terms of the decrease in the hydrophobic interaction.

In conclusion, the excess absorption mechanisms in aqueous solutions of alcohols investigated here may be attributed to the interaction of a single alcohol molecule and water molecule, and to the association and dissociation reaction of alcohol molecules. Furthermore, a decrease in the hydrophobic interaction of alcohol causes the aggregate of alcohol to disappear.

The authors wish to express their thanks to Dr. K. Shirahama in Saga University for his helpful discussions. They are also grateful to Dr. H. Yano in Daiichi College of Pharmaceutical Science for permitting them to use an ultrasonic absorption apparatus equipped in the 100—220 MHz frequency range. This work was partially supported by the Sakkokai Foundation.

Group Interactions in Polyelectrolytes. X. The Amination Kinetics of Poly(vinyl haloacetals) and Related Compounds

Hiroshi KAWABE

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received February 3, 1975)

Polyvinyl chloroacetal (PVCA) and polyvinyl bromoacetal (PVBA) were prepared from polyvinyl alcohol, whose acetal contents were close to the value expected on the basis of Flory's calculation for the intramolecular reaction between neighboring substituents. The amination of these polyvinyl haloacetals and polyvinyl chloroethyl ether with 2-aminobutanol and diethanolamine was investigated kinetically in dimethyl sulfoxide. The $\Delta G^{\ddagger}$ values in the amination of these polymers were much higher than that of chloromethylated polystyrene (CMPS) reported previously; this was because of their higher $\Delta H^{\ddagger}$ values. The lower $\Delta H^{\ddagger}$ of CMPS was ascribed to the resonance structure of the activation complex due to the phenyl substituent at the α-carbon of the chloromethyl group. This was ascertained by comparing the $\Delta H^{\ddagger}$ value in the amination of phenethyl chloride with that of benzyl chloride. The amination of PVBA was faster than that of PVCA as a result of the lower $\Delta H^{\ddagger}$ of the former.

The amination of haloacetalized polyvinyl alcohol has already been investigated for the purpose of improving vinylon fibers[1] and for the preparation of ion-exchange fibers.[2] The amination proceeded in a heterogeneous system, and the reaction was reported to be accompanied by cross-linking. The amination kinetics of polyvinyl haloacetal in a homogeneous system has not yet been studied, though. The present author has now prepared chloroacetal and bromoacetal of polyvinyl alcohol (PVA); their acetal contents are very close to the value calculated by Flory.[3] The amination of these polyvinyl haloacetals with diethanolamine or 2-aminobutanol in dimethyl sulfoxide (DMSO) has been found to proceed to nearly a 100% conversion in a homogeneous system.

The amination rate of polyvinyl bromoacetal (PVBA) was higher than that of polyvinyl chloroacetal (PVCA). The amination rates of these polyvinyl haloacetals are, however, much lower than that of chloromethylated polystyrene (CMPS), which was reported previously.[4,5] The present author has also investigated the amination of polyvinyl chloroethyl ether (PVCE) of a low molecular weight; the rate was only a little higher than that of PVCA. The higher amination rate of CMPS, as compared with PVBA, PVCA, and PVCE, may be ascribed to its resonance structure in the transition state. Then, the amination rate of benzyl chloride, which is a model of the structural unit of CMPS, has been compared with that of phenethyl chloride, which is considered to lack in resonance. Further, the amination rates of both benzyl chloride and cuminyl chloride with several amines have been measured in order to examine the propriety of the compounds as structural unit models of CMPS.

The amination rates of PVBA, PVCA, and phenethyl chloride with diethanolamine have been found to be a little lower than the corresponding amination rates with 2-aminobutanol. On the other hand, each amination of CMPS and benzyl chloride with diethanolamine was a little faster than that with 2-aminobutanol.[4,5] This reverse reactivity of the two aminoalcohols has been discussed with the aid of the amination data on PVCA and phenethyl chloride with several alkylamines, in addition to the published data on CMPS and benzyl chloride.

Experimental

Materials. The polyvinyl alcohols used were Gohsenols of Nihon Gosei Chem. Ind. Co., NH-18 (degree of hydrolysis: 99.0—100%; degree of polymerization, $\overline{P}$=over 1500) and KH-17 (degree of hydrolysis: 78.5—81.5%; $\overline{P}$=over 1500). The cuminyl chloride was prepared by treating cumen (0.4 mol) and chloromethyl ether (0.87 mol), with stanic chloride (0.096 mol) as the catalyst, in toluene at −10°C. The yield of the purified product (bp 110 °C/15 mmHg, $n^{21.5}$ 1.5224) was 52.6%. The 2-aminobutanol was prepared by the procedure described in a previous paper;[6] n^{20} 1.4529, $[\alpha]_D^{20}$ −10.23. The other chemicals and solvents were of a reagent grade and were distilled before use; they were proved to be pure by their refractive indices.

Preparation of Polyvinyl Haloacetals. To ethylene dichloride, which absorbed dry hydrogen chloride, we added PVA (equivalent to a 1% concentration) and chloroacetaldehyde diethyl acetal (equimolar to the hydroxyl group of PVA), after which the mixture was left for several days at 20 °C. The mixture was then poured into methanol to precipitate the polymer. The polymer was purified by reprecipitation with ethylene dichloride-methanol and by washing it thoroughly with methanol. The polyvinyl chloroacetal (PVCA) thus obtained was dried *in vacuo* at 40 °C. The content of acetal (E%) in the polymer was calculated from the content of chlorine (Cl%) in the polymer by means of:

$$E\% = 145.64 \times [\mathrm{Cl}\,\%]/(58.62-[\mathrm{Cl}\,\%]) \quad (1)$$

Polyvinyl bromoacetal (PVBA) was also prepared by the same procedure except that the reprecipitation was carried out with DMSO-methanol. The acetal content was calculated from the bromine content (Br%) in the polymer by means of:

$$E\% = 83.97 \times [\mathrm{Br}\,\%]/(76.15-[\mathrm{Br}\,\%]) \quad (2)$$

Preparation of Polyvinyl Chloroethyl Ether. To a solution of 2-chloroethyl vinyl ether (10.6 g) in diethyl ether (50 ml), we added, drop by drop, a solution of boron trifluoride etherate (0.15 g) in diethyl ether (50 ml), after which the mixture was kept for 200 min at 25 °C. The mixture was then washed with 5% aqueous sodium hydroxide and water. The ethereal solution was then dried with calcium chloride, and the diethyl ether was removed by the use of an evaporator. The molecular weight of the polyvinyl chloroethyl ether

(PVCE) thus obtained was 945 ($\bar{P}=9$). Found: C, 44.53; H, 6.56; Cl, 30.35%. Calcd for $(C_4H_7OCl)_n$: C, 45.08; H, 6.63; Cl, 33.27%.

Amination Kinetics Measurements. The amination rates of PVBA, PVCA, PVCE, phenethyl chloride, cuminyl chloride, and benzyl chloride were measured by the procedures described previously for the amination of CMPS and benzyl chloride.[4]

Results and Discussion

Haloacetalization of Polyvinyl Alcohol (PVA). Noma *et. al.*[7] reported that, in the chloroacetalization of PVA with chloroacetaldehyde diethyl acetal in ethylene dichloride containing hydrogen chloride, the fractional conversion, after repeated treatments, nearly reached the calculated maximum value of 0.8647 which was given by Flory for the intramolecular reaction between neighboring substituents of a polymer having the 1.3-structure.[3] In the present study, the chloroacetalization of PVA by Noma's procedure has been examined in an attempt to prepare the PVCA

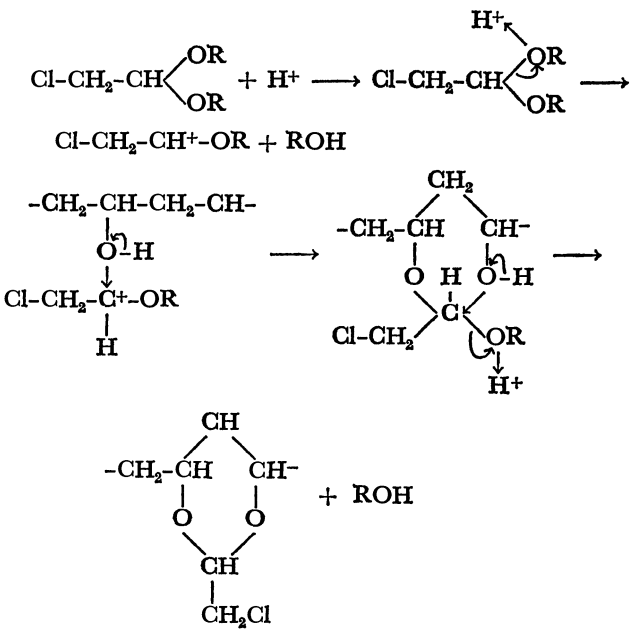
of maximum acetal content by only one treatment. The acetalization of PVA with bromoacetaldehyde diethyl acetal has also been investigated by means of the same procedure. The results are shown in Tables 1 and 2. The results of the elementary analysis of the haloacetals with the highest acetal content, which are shown in Table 3, indicate that the C, H, and halogen contents of each polymer are very close to the values calculated on the basis of the maximum conversion given by Flory.

In the above procedure, the reaction proceeded initially in a heterogeneous system, though the polymer was gradually swollen and finally dissolved in ethylene dichloride as the acetalization proceeded. The acetalization of PVA with chloroacetaldehyde diethyl acetal has also been investigated in DMSO; the results are summarized in Table 4. Although the reaction proceeded thoroughly in a homogeneous system, the acetal content of the product was low, and occasionally the gelation of the solution took place.

In the acetalization of PVA catalyzed by a proton, the probable mechanism of which is shown in the following scheme, the carbonium cation formed from the acetal may be subject to the nuclephilic attack by the oxygen of PVA to form the ether link, and the



succeding reaction with the neighboring hydroxyl group in the same mechanism may result in the formation of the acetal ring. Since DMSO is a basic aprotic solvent and since cations are very likely to solvate in this solvent, the activation energy of the acetalization in DMSO is possibly enhanced by this solvation.

Amination of Polyvinyl Chloroacetal (PVCA). The amination kinetics of PVCA with 2-aminobutanol and diethanolamine in DMSO can be fully expressed by this second-order rate equation:

$$kt = \frac{1}{a-b}\ln\frac{b(a-x)}{a(b-x)} \quad (3)$$

where k is the rate constant, where a and b are the initial concentrations of the amine and halogen groups respectively, and where x is the concentration of halide ions formed after time, t.

During the amination of chloromethylated polystyrene (CMPS) with diethanolamine in DMSO, the second-order rate constant, computed on the basis of Eq. (3), decreased as the amination proceeded; this deceleration was ascribed to the steric obstruction in the transition state by the neighboring substituted group.[5] The lack of this steric obstruction in the amination of PVCA with diethanolamine, which is indicated by its ordinary kinetic behavior, can be explained by the fact that the distance between the reactive groups in PVCA is longer than that in CMPS.

Table 5. Amination of PVCA in DMSO[a,b,c]

Amine	Temp. °C	$k\times10^3$ l/mol min	E_a kcal/mol	log A[d]

	85	1.49		
	90	2.08	16.5±0.2	8.26±0.12
	100	3.77		
	110	7.05		

a) PVBA was prepared from NH-18. b) Concentrations: a is about 0.36 and b is about 0.017 M. c) A is expressed by l/mol min.

The numerical values of k at different temperatures are tabulated in Table 5, together with the values of E_a, the activation energy, and A, the frequency factor expressed by l/mol min, both of which were computed by the least-squares method.

Amination of Polyvinyl Bromoacetal (PVBA). The amination kinetics of PVBA with 2-aminobutanol and diethanolamine also fit Eq. (3). The results of the amination are tabulated in Table 6. The amination rate of PVBA is about fifty times that of PVCA; this is a result of the lower E_a value of PVBA.

Amination of Polyvinyl Chloroethyl Ether (PVCE). The amination of PVCE with diethanolamine conformed to Eq. (3), and no deceleration was observed during the course of amination. Since the degree of polymerization of this polymer is very low ($\bar{P}=9$), and since its side chain is rather flexible, the steric obstruction between the reactive groups may be avoided by the free rotation in the main and side chains. The results of the kinetic measurements are shown in Table 7. The amination of PVCE is several times faster than that of PVCA.

Amination of Phenethyl Chloride. The amination rate of CMPS is much higher than those of PVCA, PVBA, and PVCE. In the comparison of the rate constants at 60 °C, for example, constants which are given by the extrapolation of the Arrhenious plots, the amination rate of CMPS is about ten thousand times that of PVCA. This large difference in their amination rates may be considered to originate in the stabilization of the transition state of CMPS because of its

a) In the table, BC represents for benzyl chloride and CC represents for cuminyl chloride.

resonance structure, associated with the phenyl substituent at the chloromethyl group. This conception has been examined by comparing the amination rate of benzyl chloride with that of phenethyl chloride, which has one methylene group between the phenyl group and the chloromethyl group. Table 8 lists the results of the amination of phenethyl chloride with 2-aminobutanol and diethanolamine. The amination rate of phenethyl chloride is considerably lower than that of benzyl chloride or CMPS; the former rate is almost comparable to those of the polymers without a phenyl group, as had been expected.

Amination of Cuminyl Chloride. In previous papers, benzyl chloride was chosen as a model of the structural unit of CMPS, and its amination rate was taken as a criterion. Another appropriate model of CMPS is cuminyl chloride, *p*-isopropyl chloromethyl benzene. The amination rates of cuminyl chloride with various amines have been measured; the rate constants are compared with those of benzyl chloride in Table 9. No significant difference is shown in the amination rate between the two chlorides in most cases. This result supports the propriety of benzyl chloride as a unit model of CMPS.

Amination of PVCA and Phenethyl Chlordie with Isobutylamine, s-Butylamine, and Diethylamine. As is shown in Tables 5, 6, and 8, the amination rates of PVCA, PVBA, and phenethyl chloride with 2-aminobutanol in DMSO are higher than the corresponding rates with diethanolamine. In the amination of CMPS and benzyl chloride in dimethyl formamide (DMF) and DMSO, however, the published data[4,5)] show that the amination rate with diethanolamine is higher than the rate with 2-aminobutanol. This difference in the reactivities of the two aminoalcohols is due to the difference in their enthalpy and entropy of activation, as will be discussed in the following section.

It will serve as a reference to examine the reactivities of some alkylamines in the amination of PVCA and phenethyl chloride and compare it with that in the amination of CMPS and benzyl chloride. In view of the data shown in Table 10, the reactivities of the amines decrease in the following order:

isobutyl>*s*-butyl>diethyl (PVCA; DMSO)
isobutyl>*s*-butyl≈diethyl (phenethyl chloride; DMSO)

TABLE 10. AMINATION OF PHENETYL CHLORIDE AND PVCA WITH ALKYLAMINES IN DMSO

Chloride	Amine	Temp. °C	k l/mol min
Phenethyl	Isobutyl	90	3.35×10^{-2}
	s-Butyl	90	1.09
	Diethyl	90	1.15
PVCA	Isobutyl	90	1.81×10^{-3}
		110	6.70
	s-Butyl	110	3.35
	Diethyl	110	2.29

On the other hand, in the amination of CMPS and benzyl chloride, the following order is given by the present author's previously published data.[5,8,9)]

diethyl>isobutyl>*s*-butyl (CMPS; DMF)
diethyl≈isobutyl>*s*-butyl (benzyl chloride; DMF)
isobutyl>*s*-butyl (CMPS, benzyl chloride; dioxane)

The order anticipated from the basicity of the amines is this: diethyl>isobutyl≈*s*-butyl, while the order anticipated from the steric hindrance in the transition state is: isobutyl>*s*-butyl>diethyl. Actually, the results indicate that isobutyl>*s*-butyl in all the cases; however, the reactivity of diethylamine is higher for CMPS and benzyl chloride and lower for PVCA and phenethyl chloride. The steric effect can be expected to be more significant for PVCA and phenethyl chloride than for CMPS and benzyl chloride, since the transition states in the amination of the former two are less polar and tighter than those of the latter two. The resonance in the transition states of the latter two, due to the phenyl substituent attached to the chloromethyl group, is thought to make their structures more polar and looser.

Activation Parameters. The activation parameters ($\Delta H^{\ddagger}$, $\Delta S^{\ddagger}$ and $\Delta G^{\ddagger}$) in the amination of PVCA, PVBA, PVCE, and phenethyl chloride are calculated and summarized in Table 11, in which the parameters of CMPS and benzyl chloride are also listed for comparison. The $\Delta G^{\ddagger}$ values of CMPS and benzyl chloride are much lower than those of the other polymers and phenethyl chloride. This difference in $\Delta G^{\ddagger}$ is due to the difference in $\Delta H^{\ddagger}$. In the amination of CMPS and benzyl chloride, the positive charge on the α-carbon of the chloromethyl group in the transition state can be delocalized because of the π-electrons of the phenyl group, and this resonance may lower the enthalpy of activation to a large extent.

The lower reactivity of PVCA than PVBA is contrary to expectation in view of the inductive effect of the halogen group. The lower $\Delta G^{\ddagger}$ of PVBA is due to the lower $\Delta H^{\ddagger}$. This difference in $\Delta H^{\ddagger}$ is considered

Table 11. Activation parameters of the aminations[a)]

Amine	Halide	Temp. °C	$\Delta H^{\ddagger}$ kcal/mol	$\Delta S^{\ddagger}$ e. u.	$\Delta G^{\ddagger}$ kcal/mol
2-Amino-	PVBA	100	16.1±0.1	−29.3±0.3	27.0

amine	PVBA	100	15.8±0.2	−31.3±0.6	27.5
	PVCA	100	18.2±0.1	−32.2±0.2	30.0
	PC	100	16.2±0.3	−32.7±0.7	28.4
	BC	25	11.2	−35.0	21.6
	CMPS	25	11.2	−35.4	21.7

a) In the table, BC and PC represent for benzyl chloride and phenethyl chloride respectively.

to reflect mainly the difference in bond energy between the α-carbon and the leaving halogen group. The effect of solvation on the leaving halogen group may be minor in such a dipolar aprotic solvent as DMSO, unlike protic solvents, though the solvation resulting from the mutual polalization may be stronger for bromide ions than chloride ions.

As is shown in Table 11, the $\Delta G^{\ddagger}$ of the amination with diethanolamine is lower than that with 2-aminobutanol for CMPS and benzyl chloride, and *vice versa* for PVBA, PVCA and phenethyl chloride. The $\Delta H^{\ddagger}$ of the amination with diethanolamine is lower than that with 2-aminobutanol not only for CMPS and benzyl chloride, but also for PVCA and PVBA. Further, the higher $\Delta G^{\ddagger}$ of the amination of PVCA and PVBA with diethanolamine can be ascribed to the lower $\Delta S^{\ddagger}$ of the amination with diethanolamine. In view of the basicity of the aminoalcohols, the amination rate with 2-aminobutanol can be expected to be higher than that with diethanolamine. The lower $\Delta H^{\ddagger}$ of the amination with diethanolamine may, then, be ascribed to a certain stabilizing factor in the transition state. A possible factor is the hydrogen bonding between the hydroxyl group of aminoalcohol and the leaving chlorine group, which is considered to be more significant in the amination with diethanolamine. The lower $\Delta S^{\ddagger}$ values in the amination of PVCA and PVBA with diethanolamine than the corresponding values with 2-aminobutanol can be explained in terms of such a steric fatcor as has been discussed in the preceding section. Since the transition state in the amination of the halide without a phenyl substituent at the α-carbon lacks the resonance effect, and since its structure is considered to be tighter than that with the phenyl group, the former may be more susceptible to the steric effect. Therefore, the reverse reactivity of 2-aminobutanol and diethanolamine in the amination of CMPS and polyvinyl haloacetals can be referred to the same steric effect which brings about the reverse reactivity of *s*-butylamine and diethylamine in the amination of CMPS and PVCA.

The author wishes to express his thanks to Dr. Masaya Yanagita for his valuable discussions. He is also grateful to Mr. Tsutomu Watabiki, Mr. Masaaki Kodera, and Mrs. Midori Shiraishi for thier helpful assistance in preparing the polymer and in carrying out the measurements.

Group Interactions in Polyelectrolytes. XI. The Kinetics of *N*-Methylation of Poly(ethyleneimine)

Hiroshi KAWABE

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received March 6, 1975)

The *N*-methylation of polyethyleneimine (PEI) of low and high molecular weights as well as that of diethylenetriamine was investigated kinetically in 50% aqueous ethanol; during the procedure we observed deceleration due to the electrostatic effect of the neighboring charged groups. The rate equation was derived for the *N*-methylation of PEI, which proceeded in three steps with a marked deceleration beyond quarter-conversion and also beyond half-conversion. In the second and third steps of the *N*-methylation of PEI, additional energies equivalent to the electrostatic free energies due to the one and the two nearest-neighboring charged groups were required respectively, in addition to the intrinsic activation energy of the first step.

The amination of chloromethylated polystyrene with a large excess of primary and secondary amines was investigated kinetically in several organic solvents in order to establish that most of the amination with primary amines conformed to the ordinary second-order kinetics; however, the rate constant of the amination with secondary amines decreased as the amination proceeded.[1,2] Since no electrical charge forms on the polymer in this amination, the deceleration during the amination with secondary amine was ascribed to the steric obstruction by the neighboring substituted groups. On the other hand, a deceleration due to the electrostatic effect of the charge on the polymer was observed during the quarternization of the aminated chloromethylated polystyrene in 50% aqueous DMF.[2] Such a deceleration was also found in the quarternization of poly-4-vinyl pyridine with *n*-butyl bromide in tetramethyl sulfone or propyrene carbonate.[3] In these Menschutkin reactions of the polyamines, the deceleration was marked beyond half-conversion, and the reactions were treated kinetically as they proceeded in two steps. Although the *N*-methylation of ethylenediamine (EDA) with methyl iodide in water was not a Menschutkin reaction, the deceleration due to the electrostatic effect was also observed and the reaction could be described by the same kinetics as the quarternization of the aminated chloromethylated polystyrene.[4]

The *N*-methylation of diethylenetriamine (DETA), which has three amino groups, in 50% aqueous ethanol has been found to decelerate in three steps. Further, the *N*-methylation of polyethyleneimine (PEI), which has many amino groups, in 50% aqueous ethanol has also been found to proceed in three steps. These *N*-methylations have been investigated kinetically in the present study.

Experimental

Polyethyleneimine. Polyethyleneimine of a low molecular weight (PEI-L) was prepared by the cationic polymerization of ethyleneimine in dilute hydrochloric acid; the acid was removed by passing the reaction mixture through a column of Amberlite IRA-400 in the hydroxide form. The effluent was concentrated by the use of an evaporator and then lyophilized. Since this polymer was almost entirely absorbed in a column of Amberlite IRC-50 in the hydrogen form, its molecular weight was estimated to be relatively low.

Polyethyleneimine of a high molecular weight (PEI-H) was supplied by courtesy of the Nihon Shokubai Chem. Ind. Co. in a state of an aqueous solution (P-1000). The P-1000 was diluted and passed through a Dowex-50 (X-8, H-form) column and then through a Dowex-2 (X-8, OH-form) column, after which the effluent was concentrated and lyophilized.

Reagents. Commercial anhydrous ethylamine, ethylenediamine (EDA), and diethylenetriamine (DETA) of a reagent grade were treated with solid sodium hydroxide and distilled. Other organic solvents and reagents were also distilled before use. They were proved to be pure by their refractive indices. Deionized, decarbonized water was used throughout.

Kinetic Measurements. The procedure used for the kinetic measurements in the *N*-methylation of DETA and PEI was almost the same as that used for EDA.[4] The temperature of a reaction mixture, composed of an amine, methyl iodide, and a solvent, was maintained at 30±0.1 °C.

Conductometric Titration. Aqueous solutions of ethylamine, EDA, DETA, and PEI-L (0.010—0.016 amino group equivalent/l) were titrated with 0.1 M hydrochloric acid at 25+0.02 °C, and the conductivity measurements were made with the use of a Yanagimoto MY-7-type conductivity measuring set at 800 c.p.s.

Results

N-*Methylation of Diethylenetriamine (DETA).* In the *N*-methylation of DETA with methyl iodide in 50% aqueous ethanol, the second-order rate constant (k), computed on the basis of Eq. (1), decreased as the reaction proceeded:

$$kt = \frac{1}{a-b}\ln\frac{b(a-x)}{a(b-x)} \equiv \overline{kt} \qquad (1)$$

where a and b are the initial concentrations of the methyl iodide and the amino group respectively, and where x is the concentration of hydrogen iodide formed after time t. The course of the *N*-methylation is shown in Fig. 1, where β $(=x/b)$ is the fractional conversion and where $\overline{kt}$ represents the right-hand term of Eq. (1). The white circles in the figure represent the observed values of β, and the black circles, the values of $\overline{kt}$. The plot of $\overline{kt}$ *vs.* t could be represented approximately by three straight lines which intersect each other at $\beta\approx0.4$ and $\beta\approx0.65$. The apparent rate constants given by the slopes of these lines ($k_n' = \Delta\overline{kt}/\Delta t$) were:

$$k_1' = 5.66\times10^{-2},\quad k_2' = 2.03\times10^{-2}$$
$$k_3' = 8.83\times10^{-4}\ \text{l/mol min}$$

Although such reactions of compounds with two

—— Curve I, calculated on the basis of Eq. (5)
---- Curve II, calculated on the basis of Eq. (6).

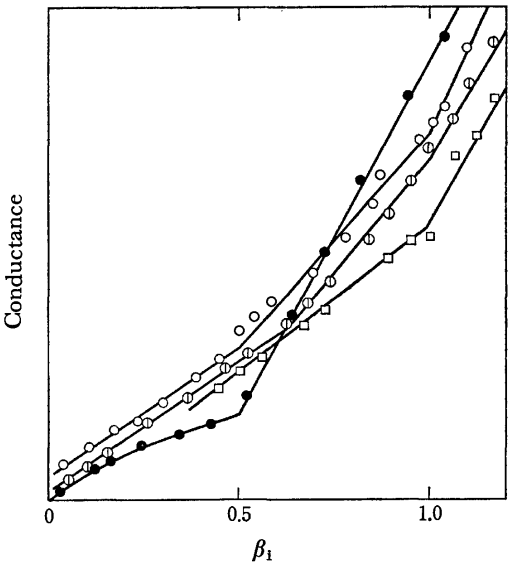

Fig. 2. Conductometric titration of PEI-L(●), DETA-(◑), EDA(○), and ethylamine(□) with hydrochloric acid.

reactive groups as the *N*-methylation of ethylenediamine (EDA)[4] and the alkaline hydrolysis of dimethyl succinate[5] could be treated as two-step reactions which decelerate markedly beyond $\beta=1/2$, the *N*-methylation of DETA, which has three reactive groups, may be treated as a three-step reaction which decelerates markedly at $\beta=1/3$ and $\beta=2/3$. The rate equation of this reaction is the same as that of the alkaline hydrolysis of triethyl citrate,[5] and the rate constants are given by:

$$k_1 = \frac{1}{[(3-2k_2/k_1)a-b]t} \ln \frac{1-\alpha}{1-(3-2k_2/k_1)\beta} \tag{2}$$

$$k_2 = \frac{\ln \dfrac{1-[3(2-k_3/k_2)/(4-k_3/k_2)\chi_1/b]}{1-[3(2-k_3/k_2)/(4-k_3/k_2)\beta]} \times \dfrac{1-\alpha}{1-\chi_1/a}}{[(2-k_3/k_2)a-(4-k_3/k_2)b/3](t-\tau_1)} \tag{3}$$

$$k_3 = (kt-C)/t \tag{4}$$

$$C = \ln[(1-\chi_2/a)/(1-\chi_2/b)] - k_2(a-b)\tau_2$$

where $\alpha=x/a$ and $\beta=x/b$; τ_1 is the time when the concentration of the first changed group (x_1) reaches approximately $b/3$, and χ_1 is the value of x at that time. C in Eq. (4) is a constant in a given reaction system. The calculated values of these constants were:

$k_1 = 6.08\times10^{-2}$, $k_2 = 4.77\times10^{-2}$,

$k_3 = 8.83\times10^{-4}$ l/mol min.

Further, when $a \gg b$, the course of this reaction can be calculated on the basis of the following two equations in the given ranges of β.
In the range of $\beta=0$—$2/3$:

$$\beta = \frac{2}{3} - \frac{3k_1-4k_2}{3(3k_1-2k_2)} e^{-3k_1at} - \frac{k_1}{3k_1-2k_2} e^{-2k_2at} \tag{5}$$

In the range of $\beta=1/3$—1:

$$\beta = 1 - \frac{2(k_2-k_3)}{3(2k_2-k_3)} e^{-2k_2a(t-t_{1/3})} - \frac{2k_2}{3(2k_2-k_3)} e^{-k_3a(t-t_{1/3})} \tag{6}$$

where $t_{1/3}$ is the value of t when $\beta=1/3$. The plot of β against t calculated on the basis of Eq. (5) is represented by the solid line (Curve I) in Fig. 1, from which $t_{1/3}$ is determined to be 19 min. The plot of Eq. (6) is represented by the broken line (Curve II) in the figure. The observed values represented by the white circles fall substantially on Curves I and II.

N-Methylation of Polyethyleneimine (PEI). Shepherd and Kitchener[6] reported that, although the pH titration curve of PEI of a relatively low molecular weight (number of monomeric units, n=35—40) could be described according to Katchalsky's theory[7] as a polybase with an intrinsic pK_0 value of 10 in a certain range of degree of ionization (β_1) (β_1=0.3—0.5), the titration curve deviated greatly from the theory in the $\beta_1>0.5$ range because of the intense electrostatic interaction due to two near-neighboring charged groups.

Figure 2 shows the results of conductometric titration of PEI-L (PEI of low molecular weight) with hydrochloric acid, in which a distinct inflexion point appears at β_1=0.5. The figure also shows the results for EDA and DETA, the inflexion points for which appear at β_1=0.5 and β_1=0.65 respectively, in addition to the points at β_1=1.0. For ethylamine, which has a single amino group, a distinct point appears only at β_1=1.0. These results for EDA and DETA are in accordance with the results of the *N*-methylation of the amines. The pH titration and the conductometric titration of PEI with a large molecular weight ($n\approx700$) were reported by Saber and Shams,[8] who found inflection points of the titration curves at β_1=0.6.

In view of the above-mentioned facts, the *N*-methylation of PEI is expected to decelerate markedly beyond $\beta=1/2$. On the other hand, it was found that the alkaline hydrolysis of polymethyl acrylate in 29% aqueous acetone decelerates at $\beta=1/4$, $1/2$, and $3/4$.[5,9] In the present study, PEI of low and high molecular weights (PEI-L and PEI-H) was *N*-methylated with methyl iodide, first in water; the results are shown in Fig. 3. The rate of the *N*-methylation becomes

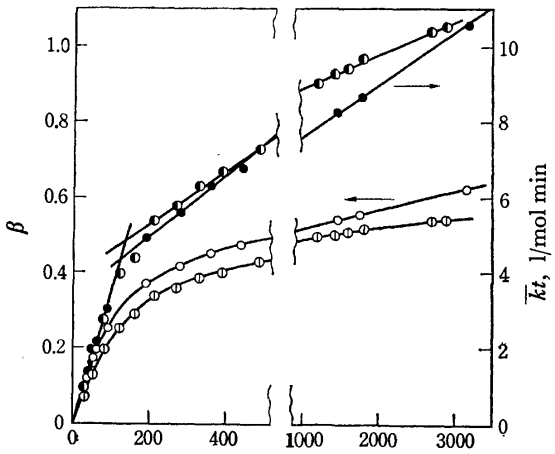

Fig. 3. *N*-Methylation of PEI with methyl iodide in water at 30 °C.
(PEI-L, $a=0.0831$, $b=0.0277$ mol/l; PEI-H, $a=0.984$, $b=0.0171$ mol/l)
◑,◐: PEI-L, ○,●: PEI-H.

very slow beyond half-conversion, as is to be expected; however, the plots of $\overline{kt}$ *vs.* t in the figure indicate additional intersecting points at $\beta=0.25$—0.3.

In the *N*-methylation of PEI in water, the complete kinetic measurements beyond $\beta=0.5$ were practically difficult because of its very slow rate; the solubility of methyl iodide in water was low, and its concentration was low. Therefore, PEI was also *N*-methylated in 50% aqueous ethanol; when the concentration of methyl iodide was increased, the *N*-methylation proceeded nearly to completion. The results are shown in Figs. 4 and 5, where white and black circles represent the observed values of β and $\overline{kt}$ respectively. The plot of $\overline{kt}$ *vs.* t is represented approximately by three straight lines which intersect each other nearly at $\beta=1/4$ and $\beta=1/2$. The plot in the range of $\beta=0.5$—0.85 is a straight line showing no inflection point, though an intersecting point at nearly $\beta=3/4$ in addition to those at $\beta=1/4$ and $1/2$ was observed in the case of the alkaline hydrolysis of polymethyl acrylate.

The numerical values of k_n' obtained as the slopes of the $\overline{kt}$ *vs.* t plots in Figs. 3, 4, and 5 are tabulated in Table 1. The values of k_n' are almost the same for PEI-L and PEI-H both in water and in 50% aqueous ethanol. This fact suggests, first, that the magnitude of the electrostatic effect of neighboring charged groups on the reactivity of amino groups of PEI at a given β value is almost independent of the molecular weight

Table 1. Rate constant k_n', l/mol min, in the *N*-methylation of PEI with methyl iodide at 30 °C

Solvent	Water		50% aq. Ethanol	
PEI	PEI-L	PEI-H	PEI-L	PEI-H
$k_1'\times10^2$	3.45	3.48	3.18	3.28
$k_2'\times10^3$	6.09	7.80	5.70	5.40
$k_3'\times10^4$	(8.10)[a]	(13.6)[a]	6.96	12.8

a) ( ) shows less acurate measurements.

of PEI. Second, a limited number of neighboring charged groups affect the reactivity, because the *N*-methylation of PEI as well as EDA and DETA is composed of a limited number of steps. Third, the dielectric constant of the microscopic environment surrounding the reactive groups is almost the same for the *N*-methylation both in water and in 50% aqueous ethanol.

Discussion

Kinetics of the N-*Methylation of PEI.* Since the *N*-methylation of PEI, unlike that of DETA, decelerates at $\beta=1/4$ and $\beta=1/2$, a somewhat different kinetic treatment is needed if we are to describe the former. In the following model compound composed of four reactive groups, the reactivity of X_2Y_2 is assumed to be the same as that of X_3Y namely $k_3=k_4$, since the reactivity of amino groups of PEI did not change in the $\beta>1/2$ range.

$$Y_4 \xrightarrow{k_1} X_1Y_3 \xrightarrow{k_2} X_2Y_2 \xrightarrow{k_3} X_3Y \xrightarrow[(=k_3)]{k_4} X_4$$

$$\mu_0 \qquad \mu_1 \qquad \mu_2 \qquad \mu_3 \qquad \mu_4$$

where X and Y represent the changed and unchanged groups respectively and where μ_0 and μ_n, represent the concentrations of the unchanged compound (Y_4) and the partially-changed one (X_nY_{4-n}), n groups of which have been changed at time t. These concentrations are given by the following:

$$\left.\begin{aligned}\mu_0 &= M - x_1 = (b/4) - x_1\\ \mu_n &= x_n - x_{n+1}\end{aligned}\right\} \tag{7}$$

where M is the initial concentration of the compound ($M=\sum_{n=0}^{4}\mu_n$) and where x_n is the concentration of the nth changed group at time t ($x=\sum_{n=1}^{4}x_n$).

The over-all rate of this reaction is given by the equation:

$$dx/dt = \sum_{n=1}^{4} dx_n/dt = (a-x)\sum_{n=1}^{4}(4-n+1)k_n\mu_{n-1} \tag{8}$$

The rate constants of this reaction, k_n, are given by the following equations on the assumption that $\sigma=4$ and $k_3=k_4$ (k_σ) in Eq. (6) of Ref. 5:

$$k_1 = \frac{1}{[(4-3k_2/k_1)a-3b/4]t}\ln\frac{1-\alpha}{1-(16/3-4k_2/k_1)\beta} \tag{9}$$

$$k_2 = \frac{\ln\dfrac{1-[2(3-2k_3/k_2)/(3-k_3/k_2)\chi/b]}{1-[2(3-2k_3/k_2)/(3-k_3/k_2)]\beta}\times\dfrac{1-\alpha}{1-\chi_1/a}}{[(3-2k_3/k_2)a-(3-k_3/k_2)b/2](t-\tau_1)} \tag{10}$$

$$k_3 = (\bar{k}t-C)/t \tag{11}$$

where C is a constant in a given reaction system; τ_1 is a time when $x_1=b/4$, and χ_1, a value of x at that time.

When $a \gg b$, on the assumption that the rate is substantially controlled by k_1 and k_2 in a range of $\beta=0$—$1/2$, β as a function of t is given by Eq. (12), which is the same equation as Eq. (3) in Ref. 9:

$$\beta = 1/2 - \frac{2k_1-3k_2}{2(4k_1-3k_2)}e^{-4k_1at} - \frac{k_1}{4k_1-3k_2}e^{-3k_2at} \tag{12}$$

In the range of $\beta=1/4$—1, the rate is given by Eq. (13), assuming that it is controlled by k_2 and k_3 ($=k_4$):

$$dx/dt = a[3k_2\mu_1+k_3(2\mu_2+\mu_3)] \tag{13}$$

On the assumption that $x_1=b/4$ and then $x=b/4+x_2+(x_3+x_4)$, μ_n is given by the following:

$$\left.\begin{aligned}&\mu_1 = x_1 - x_2 = b/4 - x_2\\ &\mu_2 = x_2 - x_3,\quad \mu_3 = x_3 - x_4\\ &2\mu_2 + \mu_3 = 2x_2 - (x_3+x_4) = b/4 + 3x_2 - x\end{aligned}\right\} \tag{14}$$

The combination of Eqs. (13) and (14) yields:

$$dx_2/dt = 3ka\mu_1 = 3k_2a(b/4-x_2) \tag{15}$$

$$dx/dt = a[(3k_2+k_3)b/4-3(k_2-k_3)x_2-k_3x] \tag{16}$$

By integrating Eqs. (15) and (16) we obtain:

$$\beta = 1 - \frac{3(k_2-k_3)}{4(3k_2-k_3)}e^{-3k_2a(t-t_{1/4})} - \frac{3k_2}{2(3k_2-k_3)}e^{-3k_3a(t-t_{1/4})} \tag{17}$$

where $t_{1/4}$ is the time when $\beta=1/4$. The over-all course of the reaction may be described by a combination of Eqs. (12) and (17).

Table 2. Rate constant k_n, l/mol min, in the *N*-methylation of PEI, DETA, and EDA with methyl iodide at 30 °C

Solvent / Amine	50% aq. Ethanol			Water
	PEI-L	PEI-H	DETA	EDA
$k_1\times10^2$	6.25	6.07	6.08	6.12
$k_2\times10^3$	9.00	9.15	47.7	13.0
$k_3\times10^4$	6.96	12.8	8.83	
k_2/k_1	0.14	0.15	0.78	0.21
k_3/k_1	0.011	0.021	0.015	

Table 3. Electrostatic free energies, kcal/mol, in the *N*-methylation of PEI, DETA, and EDA at 30 °C

Amine	PEI-L	PEI-H	DETA	EDA
$(\Delta G_{el}^{\neq})_2$	1.2	1.1	0.2	0.9
$(\Delta G_{el}^{\neq})_3$	2.7	2.3	2.6	

In Table 2 are tabulated the numerical values of k_n in the *N*-methylation of PEI-L and PEI-H in 50% aqueous ethanol, together with those in the *N*-methylation of DETA and EDA. The plots of β *vs.* t in the *N*-methylation of PEI, which are computed on the basis of Eq. (12), are the solid lines (Curve I) in Figs. 4 and 5, from which $t_{1/4}$ is determined to be 21 min for PEI-L and 44 min for PEI-H. The plots computed on the basis of Eq. (17) are represented by the broken lines (Curve II). The observed values represented by the white circles in the figures fall substantially on the curves; this suggests that the assumption used in the derivation of the rate equations is reasonable.

Electrostatic Interaction between Neighboring Groups in the N-*Methylation of PEI.* Since almost the same values of k_1 were obtained for PEI-L, PEI-H, DETA, and EDA, k_1 is taken to reflect the intrinsic reactivity of the amino group. The k_2 values of PEI are close to that of EDA, but different from that of DETA. However, the values of k_3 are almost the same for PEI-L, PEI-H, and DETA. The electrostatic free energies in these reactions, $(\Delta G_{el}^{\neq})_n$, are given by:

$$(\Delta G_{el}^{\neq})_n = RT\ln(k_0/k_n) \tag{18}$$

where k_0 is the intrinsic rate constant, $k_0=k_1$. The numerical values of $(\Delta G_{el}^{\neq})_n$ are shown in Table 3.

When the electrostatic interactions are assumed to be operative among only a few neighboring groups, $(\Delta G_{el}^{\neq})_n$ may be represented by:

$$(\Delta G_{el}^{\neq})_n = (Ne^2/D)\sum_i Z_i\bar{r_i} \tag{19}$$

where N is the Avogadro number: e, the unit of electrical charge; D, the dielectric constant ($D=81$); Z_i, the number of the electrical charge in the ith groups apart from the reactive group, and $\bar{r_i}$, the average distance between the reactive group and the ith group.

By setting the distance between the nitrogen atoms of EDA at 3.7 Å, $(\Delta G_{el}^{\neq})_2$ is calculated on the basis of Eq. (19) to be 1.1 kcal/mol, which is close to the value given in Table 3 calculated on the basis of Eq. (18).

However, the $(\Delta G_{el}^{\neq})_2$ value of DETA given in Table 3 is rather smaller than that given on the basis of Eq. (19), 0.6 kcal/mol, which is calculated by setting the distance between the end nitrogen atoms of the amine at 7.4 Å. The $(\Delta G_{el}^{\neq})_3$ of DETA is calculated to be 2.2 kcal/mol on the basis of Eq. (19) by assuming that the reactive group is affected electrostatically by the charges on the two end nitrogen atoms; this value is close to that given in Table 3. These results suggest that, in the *N*-methylation of polyethylene polyamine as well as DETA, the electrostatic contribution of the charge on the second-neighboring amino group is rather small, probably because the distance between these groups is so long that the effect of the second neighbors is cancelled by their counter ions. This can explain partly why the kinetic scheme of the *N*-methylation of PEI is somewhat different from that of the alkaline hydrolysis of polymethyl acrylate, in which the effect of the second-neighbors is distinct. The $(\Delta G_{el}^{\neq})_2$ value of PEI, which is close to that of EDA, is equivalent to the electrostatic free energy due to one first-neighboring charged group. The $(\Delta G_{el}^{\neq})_3$ of PEI, which is close to that of DETA, is equivelent to the electrostatic free energy due to two first-neighbors.

PEI, which is obtained by cationic polymerization, has a branched structure; the analysis of PEI indicates that approximately a quarter of all the amino groups are tertiary amino groups which correspond to branching points.[10] Consequently, in comparison with polymethyl acrylate, which has a linear structure, the structure of PEI is rather complex; however, the kinetics of the *N*-methylation of PEI has revealed that a limited number of neighboring groups interact electrostatically. In the *N*-methylation of PEI, composed of three steps, the first step is principally controlled by the intrinsic free energy of activation; however, the second step requires an additional free energy equivalent to the electrostatic effect of one nearest-neighboring group, and the third step requires an additional free energy equivalent to the effect due to two nearest-neighbors.

If the tertiary amino group of PEI, whose fraction is about 1/4, is finally *N*-methylated among all the species of amino groups, the reaction in the final stage will be accompanied by a larger $\Delta G_{el}^{\neq}$, because the tertiary group is apparently surrounded by three first-neighboring groups. Since the probability of this case is 1/4, and since its fractional contribution to the *N*-methylation of the total amino groups is 1/16, the deceleration due to this kind of interaction is significant, probably in the $\beta > 0.9$ range (at most). Actually, no such deceleration was observed, at least not in the range of measurements up to $\beta = 0.85$.

The author wishes to express his thanks to Dr. Masaya Yanagita for his valuable discussions. He is also grateful to Mrs. Midori Shiraishi for her helpful assistance in carrying out the kinetic measurements.

The Partial Molal Volumes of Normal Chain Alcohols in Water-Ethanol Mixtures at 25 °C

Masahiro MANABE and Masaharu KODA

Department of Technical Chemistry, Niihama Technical College, Niihama, Ehime 792

(Received April 4, 1975)

The partial molal volumes ($\overline{V}^0$) of *n*-alcohols (R_mOH, $m=1-7$) at an infinitely dilute concentration in water-ethanol mixtures of various compositions have been determined by means of dilatometry. The $\overline{V}^0$ value does not depend on the concentration of the solute alcohol within the region studied in any composition of the solvent mixtures. The excess volume, the difference between $\overline{V}^0$ and the molal volume (V^0), is negative and is at a minimum in water-rich mixtures (<16 wt% ethanol) for all of the alcohols studied. On the other hand, in the moderate composition range the excess volumes for R_4OH and higher alcohols are positive and reach a maximum distinct from the disappearance of the maximum for R_3OH and lower alcohols. The volumetric contribution of a methylene group ($\overline{V}^{me}$) to $\overline{V}^0$ was separately evaluated. From the results, a linear relation was found between $\overline{V}^0$ and the alkyl chain length of the alcohols in the mixtures of 0—8 and 55—100 wt% ethanol, while in the mixtures the relationship was rather quadratic. Such volumetric behavior was discussed on the basis of the structural properties of the water-ethanol mixtures.

It is well known that a substance with alkyl groups such as surfactants or tetraalkylammonium halides shows anomalous behavior in the water-rich region of water-organic solvents (cosolvent) mixtures. For example, the critical micelle concentration (CMC)[1-3] and the Krafft point[4] of surfactants decrease with an increase in the content of such cosolvents as lower alcohols. Some of the phenomena can be interpreted on the basis of the structure-making effect of water, (hydrophobic interaction) upon the addition of the cosolvent. In more cosolvent-rich aqueous mixtures, however, the CMC increases, *via* a minimum, with the cosolvent content[5] and the micelle formation can not be detected at any specific composition of the mixture,[6,7] Ralston and Hoerr[8] investigated the solubility of dodecylammonium chloride in water-ethanol mixtures at various temperatures and found a maximum of solubility in a moderate composition range of the mixed solvent (*ca.* 40—80 wt% ethanol). Such a maximum solubility was attributed to the micelle formation.[9] Lee and Hyne[10] reported, after a study of the partial molal volume of tetraalkylammonium chlorides in water-ethanol mixtures, that the partial molal volumes of the cation showed a minimum at the 0.1 mol fraction of ethanol as well as a maximum at the 0.3 mol fraction, while that of the anion showed a minimum at the 0.3 mol fraction. These results were interpreted in terms of the structure of the solvent. A knowledge of the volumetric properties of model compounds, such as *n*-alcohols in water-cosolvent mixtures, will help us to understand the behavior of amphipathic compounds in the mixtures, mainly in relation to the structural effect of the mixtures. No systematic study of a homologous series over a complete concentration range of water-cosolvent mixrures has ever been reported.

In this study, we have determined the partial molal volume of *n*-alcohols, a typical homologous series, in water-ethanol mixtures by means of dilatometry, which is capable of determining the partial molal volume of a higher alcohol at a much lower concentration than it possible with the density method. We have attempted to see how the partial molal volume of *n*-alcohols and the contribution of a methylene group to it vary with the composition of the mixed solvent.

Experimental

A series of *n*-alcohols with 1—7 carbon atoms (R_mOH) was used in the present work. The lower alcohols ($m=1-4$) were distilled after refluxion over C_aO, while the higher alcohols were distilled under atomspheric or reduced pressures. They were confirmed to be pure by gas-liquid chromatography. The water used as the solvent was obtained by the distillation of water deionized with ion-exchange resin.

The dilatometer used for the measurement of the partial molal volumes of solute alcohols in water-ethanol mixtures is shown in Fig. 1. It consists of a glass bulb with a capacity of 120—200 ml, equipped with a magnetic roter coated with Teflon, a vertical uniform capillary (1.8 mm internal diameter), and an injection aperture which is sealed with a silicone rubber fixed with a metal fitting. The capillary was calibrated exactly with mercury. The dilatometer was filled with a mixed solvent of a given composition through a polyethylene tube fine and long enough to reach the bulb under pressure reduced by means of an aspirator to remove any dissolved air.[11] In each run, about 30 mg of R_mOH (weighing 1/100 mg) was injected through the injection aperture into the dilatometer by means of a microsyringe

five times successively. After each of the injections, the solution was stirred with a magnetic stirrer until the dissolution was complete.

The height of the meniscus of the solution in the capillary was read to 0.01 mm with a cathetometer. The partial molal volume of the solute alcohol could be calculated from the difference in the height of the meniscus and the quantity of alcohol added. The final concentration of the solute alcohol in any mixed solvent was far lower than its solubility in water.[12] The measurement was carried out at least two runs for each system. The standard deviations of these partial molal volumes were about 0.5% of their mean values.

All of the measurements were made at 25 °C in a water thermostat, the temperature of which was carefully controlled at ±0.001 °C.

Results and Discussion

Concentration Dependence of the Partial Molal Volume. No appreciable change in the partial molal volume of solute alcohol with its concentration was found within the limits of experimental error during one run in any water-ethanol mixture. Some illustrative examples for R_6OH are shown in Fig. 2. Franks and Smith[13] suggested that in the absence of solute-solute interactions, the apparent molal volume had no concentration dependence in the region of infinite dilution. The present measurements were carried out at very low concentrations, lower than 1 g/l. The mean value of the partial molal volumes of alcohols determined in water is in good agreement with the published values[14] obtained by extrapolating the density data to an infinite dilution. Therefore, the mean value can be regarded as the partial molal volume ($\bar{V}^0$) of the solute alcohol in an infinitely diluted solution; it is shown in Table 1.

Ethanol-Content Dependence of the Partial Molal Volume. It is well known that many physicochemical properties show anomalous behavior in a predominantly aqueous

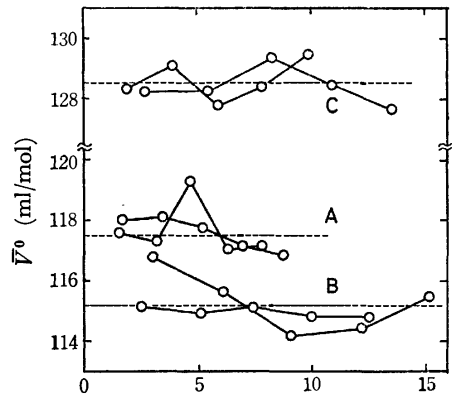

Fig. 2. Concentration dependence of $\bar{V}^0$ for R_6OH in water-ethanol mixtures. Experimental value (○), mean value (----). Ethanol content in wt%; A: 0, B: 12, C: 70.

composition range of water-lower alcohols binary systems.[15] Such behavior has generally been interpreted in terms of a structure-making effect, which continues up to a certain concentration of alcohol. The concentration dependence of the intensities of the X-ray diffraction band for water-cosolvent mixtures directly reveals the structural property; the high-intensity peak in a dilute aqueous solution of ethanol confirms the concept of a structure-making effect, and for the water-dioxane system the intensities falling below those calculated on the basis of additivity suggest a water-structure-breaking effect of dioxane.[16] The first derivatives of the viscosity-concentration curve, $d\eta/dC$, for the water-ethanol system increase to a maximum as the ethanol concentration increases; this fact suggests a structure-making effect. In the water-dioxane system, $d\eta/dC$ decreases with an increase

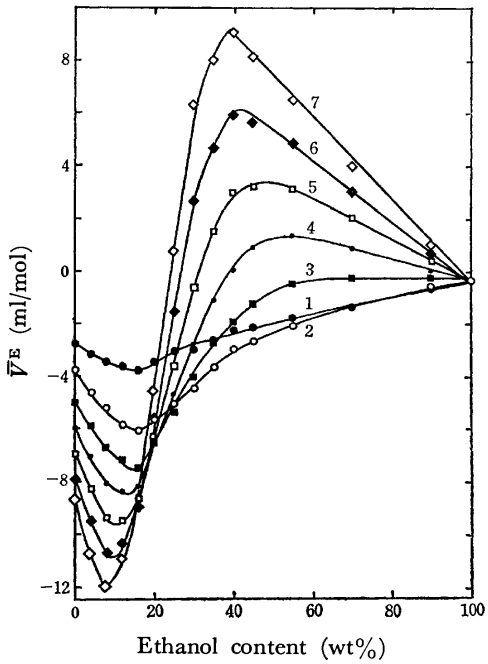

Fig. 3. The $\overline{V}^E$ values as a function of ethanol content in water-ethanol mixtures. The numbers indecate chain length of *n*-alcohols.

in the dioxane concentration, exhibition a structure-breaking effect, as has been pointed out by Franks.[5] The feature of the concentration dependence of the intensity of the X-ray diffraction band is in accordance with the dependence of the $d\eta/dC$ in both systems on the structural effect.

A comparison of the $\overline{V}^0$ values with each other and with V^0, a molal volume in the pure state for alcohols, makes it possible to calculate the excess molal volume ($\overline{V}^E$) from this definition, $\overline{V}^E=\overline{V}^0-V^0$, where V^0 is given by

$$V^0 = 16.69m + 25.30 \quad (m=2-7) \tag{1}$$

except for R_1OH. The two constants in this equation were determined by using the densities of pure alcohols reported in the literature.[17-19] The plots of $\overline{V}^E$ *vs.* the compositions of the water-ethanol mixtures are given in Fig. 3. The $\overline{V}^0$ values of R_2OH in the water–ethanol binary system are in good agreement with those obtained from the densities of the mixture.[20] The concentration dependence of $\overline{V}^E$ for R_2OH shows two distinct features. One is a negative dependence observed at lower ethanol concentrations (<16 wt% ethanol), and the other is a positive dependence observed at higher concentrations. The concentration at which the partial molal volume of R_2OH reaches its minimum is roughly compatible with that at which the intensity peak of the X-ray diffraction and the maximum of $d\eta/dC$ appear. Therefore, it may be concluded that the negative concentration dependence of $\overline{V}^E$ on R_2OH reflects a structure-making tendency, and the positive dependence of $\overline{V}^E$, a structure-breaking one. On the other hand, for the water-doxane system no such negative dependence of $\overline{V}^E$ on dioxane appears; only a positive one appears and the excess volume reaches positive values.[21] This may be attributed to the structure-breaking effect of dioxane.

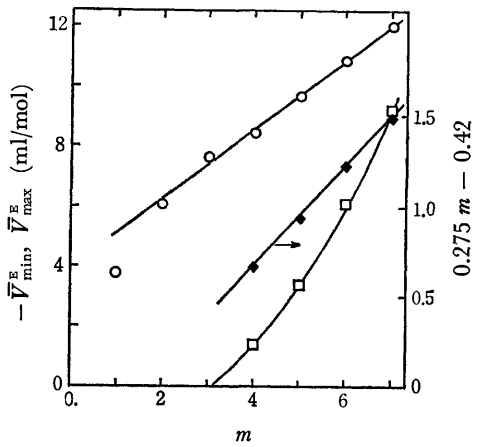

Fig. 4. Chain length dependence of $\overline{V}^E_{min}$ and $\overline{V}^E_{max}$.
○: $\overline{V}^E_{min}$, □: $\overline{V}^E_{max}$, ◆: $(\overline{V}^E_{max}+1.36)/m$,
——: $0.275\,m-0.42$, in Eq. (5).

Hardly no anomalous volumetric behavior for three-component systems has yet been reported.[10] In the present study, the system includes a very small quantity of the third component (*n*-alcohol), so that the interaction between solute molecules is negligible, judging from the independence of $\overline{V}^0$ of the solute concentration, as is shown in Fig. 2. Therefore, it may be considered that the added alcohol behaves volumetrically as a probe for the structuredness of a mixed solvent itself. As is shown in Fig. 3, the $\overline{V}^E$ values for all of the *n*-alcohols studied here are negative in the water-rich mixtures and decrease with an increase in the ethanol content (<16 wt% ethanol). This can be explained as follows: the solute alcohol is accommodated well in cavities which are formed with water molecules upon the addition of a small amount of ethanol in water, and the process of accommodation requires less space for the solute alcohol, leading to a decrease in the partial molal volume.

At a certain composition of ethanol, that at which the $\overline{V}^E$ value attains its minimum, the structuredness of the water–ethanol mixtures also reaches a maximum (8—16 wt% ethanol). The minimum value of $\overline{V}^E$, denoted by $\overline{V}^E_{min}$, exhibits a linear relation with the chain length of alcohols except for R_1OH, as is shown in Fig. 4. This relation may be expressed as:

$$\overline{V}^E_{min} = -1.17m - 3.86 \quad (m=2-7) \tag{2}$$

This relation may be converted into the following one for $\overline{V}^0_{min}$ by considering both Eq. (1) and the difinition of $\overline{V}^E$.

$$\overline{V}^0_{min} = 15.52m + 21.44 \quad (m=2-7) \tag{3}$$

where $\overline{V}^0_{min}$ is the minimum partial molal volume of a solute alcohol. This linear relation suggests that, at the specific composition of the mixed solvent where $\overline{V}^E$ reaches its minimum, the dissolved state of each methylene group is the same as that for the solute alcohol and the group occupies the cavities formed with water molecules in the same way. In other words, at the specific solvent composition the methylene groups may be dissolved into the corresponding state.

In the mixtures with moderate compositions of ethanol (8—55 wt%), the $\overline{V}^E$ value of the solute alcohol

increases with an increase in the ethanol content, while the value for R_4OH and higher alcohols becomes positive and reaches a maximum, denoted by $\overline{V}^E_{max}$, though the value for R_3OH and lower alcohols increases monotonously *i.e.*, $\overline{V}^E_{max}$ disappears, as is shown in Fig. 3. The increases in $\overline{V}^E$ for all of the alcohols with an increase in the ethanol content may contribute to the structure-breaking tendency of the solvent mixtures as the ethanol content increases. Such a volumetric behavior that $\overline{V}^E$ becomes positive and reaches a maximum value has not previously been known for any binary systems of water-lower alcohol mixtures. It may be due to the fact that higher alcohols are not sufficiently miscible with water. If a long-chain compound could be dissolved in water up to relatively high concentrations, such a volumetric behavior might appear even in the binary system, just as is seen in the water-dioxane binary system.[21] The appearance of $\overline{V}^E_{max}$ in the present ternary system means that the water–ethanol mixture at the composition corresponding to $\overline{V}^E_{max}$ has, essentially, a closer-packed structure around the solute alcohol molecule than any other mixture and pure ethanol. That is, the dissolution of the solute requires a maximum expansion of the solvent to accommodate the solute, with a consequent minimum free volume and $\overline{V}^E_{max}$ becomes higher as the size of the solute molecule increases. The plots of $\overline{V}^E_{max}$ against the chain length of alcohol are also shown in Fig. 4. The curve is concave upward, distinct from the linear relation between $\overline{V}^E_{min}$ and m, it may be expressed as in the following relation by the method of least squares in the second order:

$$\overline{V}^E_{max} = 0.275m^2 - 0.42m - 1.36 \quad (m=4-7) \tag{4}$$

This equation can then be rewritten as follows:

$$(\overline{V}^E_{max} + 1.36)/m = 0.275m - 0.42 \quad (m=4-7) \tag{5}$$

The value of the left-hand side falls on the straight line obtained from the right-hand-side values, as is shown in Fig. 4. When $\overline{V}^E_{max}=0$, $m=3.1$ from the equation; this value of m indicates the shortest chain length for $\overline{V}^E_{max}$ to appear, that is, for R_3OH and lower alcohols, the maximum of $\overline{V}^E$ does not appear. This finding does not conflict with the results shown in Fig. 3. That $\overline{V}^E_{max}$ is equal to zero means that the environment of the solute alcohol in the mixed solvent having a close-packed structure is volumetrically the same as that in pure ethanol, as is apparent from the definition of $\overline{V}^E$.

At a higher content of ethanol, the $\overline{V}^E$ values for all of the alcohols converge toward zero in pure ethanol with an increase in the ethanol content, as is shown in Fig. 3. This suggests that the properties of the water–ethanol mixtures come close to that of pure ethanol as the ethanol content increases. The fact that the $\overline{V}^E$ values for all of the alcohols in pure ethanol are equal to zero means that the mixing of any alcohol and ethanol is volumetrically ideal.

The compositions of the solvent at which $\overline{V}^E$ reaches its minimum and its maximum shift toward a lower ethanol content with an increase in the chain length of alcohols higher than R_3OH. In addition, the longer the alkyl chain length the larger $\overline{V}^E$ becomes.

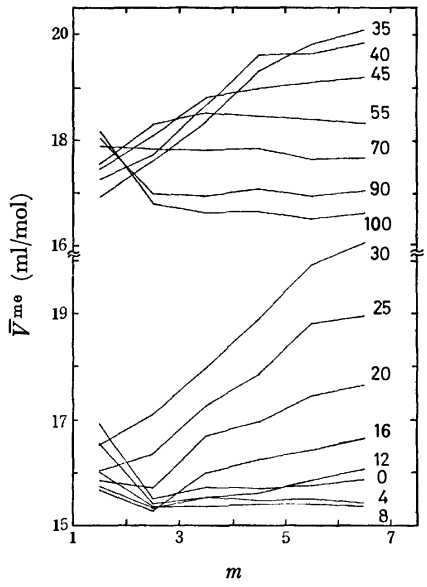

Fig. 5. Chain length dependence of $\overline{V}^{me}$ for *n*-alcohol. The numbers indecate the ethanol content in wt% in water-ethanol mixtures.

Such behavior can be discussed on the basis of the difinite volumetric contribution of the methylene group to the $\overline{V}^0$ of the solute alcohols.

Contribution of the Methylene Group to the Partial Molal Volume. The difference in $\overline{V}^0$ between two successive homologous alcohols is taken as the volumetric contribution of a methylene group ($\overline{V}^{me}$) to $\overline{V}^0$. Here, we will denote the contribution of the methylene group of a definite couple as $\overline{V}^{me}$ $(m, m+1)$, if necessary. The $\overline{V}^{me}$ value is plotted against the chain length, m, in Fig. 5; the features of the figure may be summarized as follows:

(I) $\overline{V}^{me}$ is independent of m in the mixtures at compositions lower than that at which $\overline{V}^E$ reaches its minimum (0—8 wt%).

(II) The increment in $\overline{V}^{me}$ is nearly linear with an increase in the chain length in the mixtures of 12—35 wt%.

(III) In the much more ethanol-rich region (40—100 wt%), $\overline{V}^{me}$ tends to be nearly constant with the methylene groups apart from the hydroxyl group in the alcohol molecule. The contribution of the methylene group obtained for both R_1OH and R_2OH, $\overline{V}^{me}$ (1, 2), is anomalous in the water or ethanol-rich mixtures compared with the moderate-content region. It is well known that various properties of *n*-alcohols usually have a linear dependence on the chain length. This is the case for $\overline{V}^{me}$ in water-rich and ethanol-rich mixtures, as is shown in Fig. 5. However, it is obvious from (II) that, in the mixtures with moderate compositions (12—35 wt%), $\overline{V}^0$ is the quadratic or the higher-order function of the chain length of the solute alcohol. In other words, even the methylene groups apart from the hydroxyl group in the alcohol molecule may be affected by the latter group. Therefore, the volumetric behavior of the alcohols in these mixtures is complex.

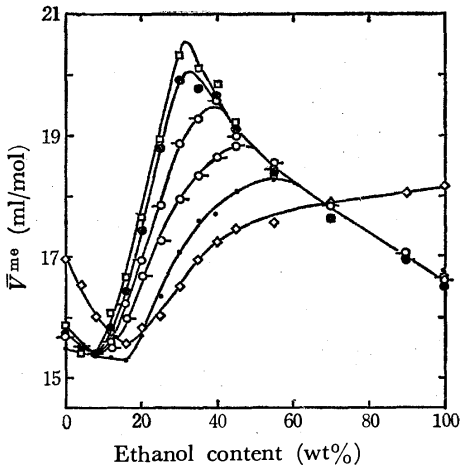

Fig. 6. The $\bar{V}^{me}$ values as a function of ethanol content in water-ethanol mixtures.
◇: (1,2), •: (2,3), ○-: (3,4), -○: (4,5),
●: (5,6), □: (6,7)
The numbers in parentheses indicate chain length of *n*-alcohols.

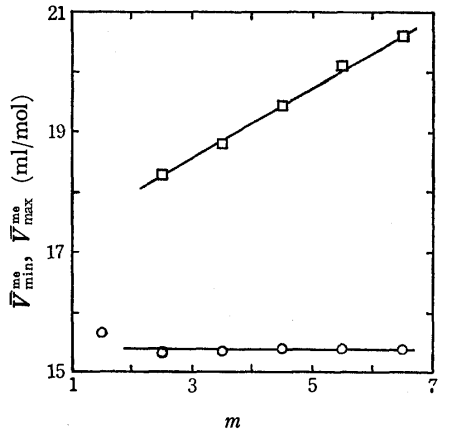

Fig. 7. Chain length depencence of $\bar{V}^{me}_{min}$ and $\bar{V}^{me}_{max}$.
○: $\bar{V}^{me}_{min}$, □: $\bar{V}^{me}_{max}$.

Figure 6 shows the relation between $\bar{V}^{me}$ and the ethanol content in the water-ethanol mixtures. The gross features of the curves are similar to those of the curves in Fig. 3; that is, the curve of $\bar{V}^{E}$ (1, 2) exhibits a minimum but no maximum and other curves in either case. It may be noted that the curve for $\bar{V}^{me}$ (2, 3) exhibits a maximum, although the curves for $\bar{V}^{E}$ of R_2OH and R_3OH exhibit no maximum in Fig. 3. The s-type curves except for that corresponding to lower alcohols gather to become a single line in the water and the ethanol-rich region, as may be seen from (I) and (II).

We denote the minimum and maximum of $\bar{V}^{me}$ in Fig. 6 as $\bar{V}^{me}_{min}$ and $\bar{V}^{me}_{max}$ respectively; then, $\bar{V}^{me}_{min}$ (1, 2) means $\bar{V}^{me}_{min}$ for the definite couple of R_1OH and R_2OH. The chain-length dependence of these values is shown in Fig. 7. It may be found from this figure that $\bar{V}^{me}_{min}$ is constant, 15.35 ml/mol, except for $\bar{V}^{me}_{min}$ (1, 2); this value is a little smaller than $d\bar{V}^{o}_{min}/dm$, 15.52 ml/mol, in Eq. (3). The ethanol content at which $\bar{V}^{me}_{min}$ appears is the same (8 wt%) for methylene groups further apart from the hydroxyl group. These features are different from the monotonous decrease in the ethanol content, during which $\bar{V}^{E}_{min}$ appears with an increase in the chain length, as is shown in Fig. 2. The chain-length dependence of $\bar{V}^{me}_{max}$ gives a linear relation;

$$\bar{V}^{me}_{max} = 0.58m + 16.83 \quad (m=2-7) \tag{6}$$

which is also shown in Fig. 7. The feature that the ethanol content of the mixture at which $\bar{V}^{me}_{max}$ appears decreases with the methylene group more apart from the hydroxyl group of the alcohol molecule is similar to that for $\bar{V}^{E}_{max}$ in Fig. 3. The appearance of $\bar{V}^{me}_{min}$ and $\bar{V}^{me}_{max}$ in the mixture must result from the structural effect of the mixture.

The authors wish to thank Professor Ryohei Matuura of Kyushu University and Assistant Professor Keishiro Shirahama of Saga University for their helpful discussions and advice.

Dufour Effect in Gases

A. BOUSHEHRI and S. AFRASHTEHFAR
Department of Chemistry, Pahlavi University, Shiraz, Iran
(Received December 6, 1974)

A study of the Dufour effect was made for five different gas mixtures: H_2–N_2, H_2–O_2, H_2–N_2O, He–N_2O and He–O_2. Measurements were made at 25 °C under 700 Torr. The values of the thermal diffusion factor were calculated for the above mixtures from the experimental data on the basis of the thermodynamics of irreversible processes.

The diffusion thermoeffect is perhaps the least investigated of the transport properties of gases. It involves the measurement of the transient temperature gradient which results from an initial concentration gradient as interdiffusion takes place. It is, of course, closely related to the inverse phenomenon of thermal diffusion. In this work five different gas mixtures are investigated. No previous measurements of the diffusion thermoeffect are known to have been made for H_2–N_2O, He–N_2O, and He–O_2 mixtures.

The effect was originally discovered by Dufour[1] in 1872, but not understood, until after its rediscovery by Clusius and Waldmann[2] in 1942. Rastogi and Madan[3] have recently studied the Dufour effect using a two-bulb interdiffusion apparatus with appropriately located thermocouples similar to the one used in the present work. Sawford *et al.*[4] and Mason *et al.*[5] have studied several aspects of the phenomenon in gases. A study of the temperature dependence of the diffusion thermoeffect was made by Boushehri.[6]

The Chapman-Enskog kinetic theory of this effect is well-known,[7,8] and provides a means of obtaining the thermal diffusion factor (α) from observations of the temperature difference as a function of time. The thermal diffusion factor was obtained very conveniently from the observation of the maximum temperature only. This maximum temperature difference occurs shortly after interdiffusion of the gases begins and there is thus no need to determine the temperature difference as a function of time which would be necessary if the Chapman-Enskog kinetic theory were used to calculate the thermal diffusion factor.

Theoretical Consideration

Our starting point is the well-known equation for the entropy production per unit volume (σ) in a motionless fluid of uniform density in which diffusion of matter and transfer of energy both occur[9]:

$$\sigma = J_{u,x}\frac{d}{dx}\left(\frac{1}{T}\right) - \sum_i J_{i,x}\frac{d}{dx}(\mu_i/T) \qquad (1)$$

where $J_{u,x}$ and $J_{i,x}$ are the energy flux density and mass flux density of component i in the x-direction (the "flux density" is defined as the amount of energy or mass crossing unit area perpendicular to the direction of flow—the x-axis-per unit of time); μ_i is the chemical potential per unit mass, and T is the absolute temperature. Equation (1) expresses the general idea that rate of production of entropy can be written as the algebraic sum of the product of "fluxes" and "forces" ($\sigma = J_k X_k$, where J_k has the form of a flux density and X_k—the thermodyanamic "force" has the general nature of a gradient).

It is convenient to write the entropy production in a different form. To do this, we begin with the relation:

$$d(\mu_i/T)/dx = (1/T)(d\mu_i/dx)_T - (H_i/T^2)(dT/dx)$$

where the specific enthalpy of component i is given by the Gibbs-Helmholtz equation:

$$H_i = -T^2[\partial(\mu_i/T)/\partial T]_p$$

We also introduce a new flux defined by

$$J_q = J_{u,x} - \sum H_i J_{i,x},$$

and Eq. (1) may then be written in the form:

$$\sigma = -\frac{J_q}{T^2}\frac{dT}{dx} - \sum \frac{J_i d\mu_i}{T dx} \qquad (2)$$

where J_i is an abbreviation for $J_{i,x}$. For a two-component system (i=1,2), Eq. (2) becomes

$$\sigma = -\frac{J_q}{T^2}\frac{dT}{dx} - \frac{J_1}{T}\frac{d\mu_1}{dx} - \frac{J_2}{T}\frac{d\mu_2}{dx} \qquad (3)$$

In this system, the two flows are not independent, since $J_1+J_2=0$. If we now use the Gibbs-Duhem equation,

$$C_1(d\mu_1/dx) + C_2(d\mu_2/dx) = 0$$

at constant temperature and pressure, Eq. (3) may be written as

$$\sigma = -\frac{J_q}{T^2}\frac{dT}{dx} - \frac{J_1}{C_2 T}\left(\frac{\partial \mu_1}{\partial C_1}\right)_{T,p}\frac{dC_1}{dx} \qquad (4)$$

where C_1 and C_2 are the mass fractions of components 1 and 2 respectively. Using the notation of Ref. 8, the mass fraction C_1 is related to the more familiar mole fraction n_{10} by

$$C_1 = \frac{n_{10}M_1}{n_{10}M + n_{20}M_2} \quad \text{and} \quad n_{10} = \frac{(C_1/M_1)}{(C_1/M_1)+(C_2/M_2)}$$

where M_1 and M_2 are the molar masses.

According to the linear thermodynamics of irreversible processes,[9] we may now write the phenomenological equations for the fluxes in terms of the thermodynamic forces:

$$J_q = -\frac{L_{qq}}{T^2}\frac{dT}{dx} - L_{q1}\frac{(\partial\mu_1/\partial C_1)}{C_2 T}\frac{dC_1}{dx} \qquad (5)$$

$$J_1 = -\frac{L_{1q}}{T^2}\frac{dT}{dx} - L_{11}\frac{(\partial\mu_1/\partial C_1)}{C_2 T}\frac{dC_1}{dx} \qquad (6)$$

In Eqs. (5) and (6), the forces and fluxes have been chosen from the expression(4) for the entropy production. The L's are the phenomenological coefficients. Although Truesdell has shown[10] that one cannot assume the validity of the Onsager reciprocal relations in general situations, it seems that we are justified

in doing so here.[11] Thus,

$$L_{1q} = L_{q1} \tag{7}$$

The phenomenological equations, when heat conduction and diffusion are considered separately, become

$$J_q = -\frac{L_{qq}}{T^2}\frac{dT}{dx}$$

$$J_1 = -\frac{L_{11}(\partial\mu_1/\partial C_1)}{C_2 T}\frac{dC_1}{dx}$$

These equations may be compared with Fourier's law for heat conduction [$J_q=-\lambda(dT/dx)$] and Fick's law for diffusion [$J_1=-\rho D_{12}(dC_1/dx)$] to yield expressions for the heat conductivity(λ) and diffusivity (D_{12}) coefficients:

$$\lambda = L_{qq}/T^2 \tag{8}$$

$$D_{12} = \frac{L_{11}(\partial\mu_1/\partial C_1)}{\rho C_2 T} \tag{9}$$

where ρ is the total mass density ($\rho=\rho_1+\rho_2$). We can also obtain a relationship involving the thermal diffusion factor by considering Eq. (6) [with $J_1=0$ in the stationary state] in conjunction with the difinition[7,8] [$(dC_1/dx)=-\alpha C_1 C_2 T^{-1}(dT/dx)$] of the thermal diffusion factor, α. Thus,

$$L_{1q} = L_{11}(\partial\mu_1/\partial C_1)_{T,p} C_1\alpha \tag{10}$$

We are now in a position to consider the Dufour effect. Suppose two gases (labelled with subscripts 1 and 2), initially at the same temperature, diffuse into each other. Equation (5), with the help of Eqs. (7), (8), and (9), then becomes:

$$J_q = -\lambda\frac{dT}{dx} - \rho_1\left(\frac{\partial\mu_1}{\partial C_1}\right)_{T,p} D_{12}\alpha\left(\frac{dC_1}{dx}\right) \tag{11}$$

From the difinition of J_q, it is apparent that it reduces to J_u in the limit when J_i approaches zero. By the conservation of energy, in the absence of convection, we have

$$\rho C_p\left(\frac{\partial T}{\partial t}\right) = -\frac{dJ_q}{dx}$$

where C_p is the constant pressure heat capacity of the mixture and $(\partial T/\partial t)$ is the variation of the temperature with time. Putting Eq. (11) into this equation, we obtain

$$\rho C_p\left(\frac{\partial T}{\partial t}\right) = \frac{d}{dx}\left[\lambda\frac{dT}{dx} + \rho_1\left(\frac{\partial\mu_1}{\partial C_1}\right)_{T,p} D_{12}\alpha\frac{dC_1}{dx}\right]$$

At the maximum temperature difference, ΔT_{max}, $(\partial T/\partial t)=0$. This condition holds in general when

$$\lambda\frac{dT}{dx} + \rho_1\left(\frac{\partial\mu_1}{\partial C_1}\right)_{T,p} D_{12}\alpha\frac{dC_1}{dx} = K \tag{12}$$

where K is a constant which depends on the geometry of the diffusion apparatus (in particular, the position of the thermocouples) and must be determined experimentally. It is possible to leave $K=0$ as Rastogi and Madan[3] did, but this is not the most general case.

Equation (12) can be put into a form suitable for calculating the thermal diffusion factor, α, from the maximum temperature difference, ΔT_{max}. We shall assume that the gases which interdiffuse are ideal, in so far as the expression for the chemical potential is concerned:

$$\mu_1 = \mu_1^\circ(T) + \frac{RT}{M_1}\ln\left[P(C_1/M_1)/(C_1/M_1+C_2/M_2)\right] \tag{13}$$

where μ_1° (T) is equal to a constant which is a function of temperature alone.

This equation may be substituted into Eq. (12) to give:

$$\lambda\frac{\Delta T}{\Delta x} + \frac{\rho_1 RTD_{12}\alpha}{C_1[M_1-C_1(M_1-M_2)]}\frac{\Delta C_1}{\Delta x} = K \tag{14}$$

where we have replaced differentials by finite changes, since the effect under consideration is very small (ΔT is written here in place of ΔT_{max}, and ΔT_{max} is usually less than 0.5 °C). Δx is the distance between the thermocouples.

Experimental

The apparatus used in the diffusion thermoeffect measurements was similar to that of Boushehri.[6] The apparatus consisted of two double-walled glass bulbs (50-ml capacity each) with a five junction thermocouple in each. The distance between the thermocouples (Δx) was 18.5 cm. The bulbs were connected *via* a stopcock having a bore of 8 mm in diameter. All runs were made at 25 °C under 700 Torr. The annular space between the double walls of the bulbs was evacuated to minimize heat loss. The maximum temperature difference between the thermocouples was obtained after the stopcock connecting the half cells was opened and interdiffusion was allowed to occur. The gases were supplied by the Fluka company and were used without further purification, since the results were not expected to be sensitive to small impurities. The minimum purity was at least 99.9%. The calculations were carried out at the Computer Center of Pahlavi University using the IBM 370 model 135.

Results and Discussion

Measurements were made at 25 °C and 700 Torr. It was observed that the temperature of the half-cell containing the lighter component always rose. The values of maximum temperature difference, $(\Delta T)_{max}$, are given in Table 1. No measurements of $(\Delta T)_{max}$ other than pure gases were carried out.

Equation (14) can be used to obtain α from ΔT_{max} provided that ΔC_1 is known together with the heat conductivity (λ), density (ρ_1) and diffusion coefficient (D_{12}). The apparatus constant K is usually eliminated by using a relative method, *i.e.* by performing the experiment with a pair of gases of known α. By knowing the time (typically a few seconds after initiating the diffusion process) at which ΔT reaches its

Table 1. Dufour effect in gaseous systems at 25 °C and 700 Torr

Systems	$(\Delta T)_{max}$ (in °C)	Warm side

Systems	α, from Equation (14)	α, from Equation (8.2—50) of Ref. 13	α, from thermal diffusion measurements
$H_2 + N_2$	0.35	0.348	0.35
$H_2 + O_2$	0.45	0.332	0.33[a]
$H_2 + N_2O$	0.40	0.312	0.48[b]
$He + N_2O$	0.36	0.391	—
$He + O_2$	0.34	0.386	—

a) The value of α for H_2+O_2 was estimated using Fig. 3 of Nain and Saxena.[14] b) The value of α, for H_2+N_2O was estimated using Table 1 of El Nadi and Faragi for mean temperature 368 K.[15]

maximum value after the start of the experiment, Fick's second law of diffusion[12] can be used to obtain ΔC_1, assuming that D_{12} is known for the gases concerned. For λ and ρ_1, the values for the pure component were used, since typical values of ΔC_1 were little different from unity. The apparatus constant K was calculated to be 2.72×10^{-5} by setting the value of α equal to 0.35 for hydrogen–nitrogen mixture.[12] Since the apparatus geometry remained the same in all experiments, this value of K was used in estimating α for the other systems. These are shown in Table 2. It may be noted that the Dufour effect gives the value of α at specific temperature which is in one respect an advantage compared to the thermal diffusion measurements. The values of thermal diffusion factors for equimolar mixtures obtained from Eq. (8.2—50) of the treatise of Hirschfelder *et al.*[13] with those obtained directly from thermal diffusion measurements are also given in Table 2. The values of α obtained from irreversible thermodynamics of the Dufour effects are subject to several sources of error such as convective mixing effects in our experiments or to the use of pure component values of λ and ρ_1 in Eq. (14). Since diffusion apparatus is employed (with only the addition of an appropriately placed thermocouples), it seems that this approach could provide information on both the diffusion coefficient and the thermal diffusion factor in the same series of experiments.

The authors thank Dr. J. Soulati for the loan of some items of the apparatus, the Ministry of Higher Education Research Foundation, and the Department of Chemistry of Pahlavi University for the research facilities. One of us (S.A.), acknowledges a Research Scholarship he has received from the Graduate School during his graduate studies.

Inorganic Chemistry Laboratory, Indian Association for the Cultivation of Science, Calcutta 700032, India

(Received August 23, 1974)

Non-isothermal studies of some adduct molecules of metallic halides with dioxane as the type $MX_2 \cdot y$(dioxane) in solid state, where M=Mn(II), Co(II), Ni(II), Cu(II), Zn(II) or Cd(II), X=Cl^- or Br^- and y=0.5—2, were carried out with a Derivatograph. These inorganic adduct molecules lose dioxane molecule in single or multiple steps on heating. Thermally stable intermediate products were isolated and characterised by elemental analysis and IR spectra. The activation energy for each step of decomposition of the adduct was evaluated from the analysis of TG, DTG and DTA curves. Enthalpy change was evaluated from the DTA peak area and the order of reaction was found to be unity for each step of decomposition. Thermal stability of the adducts was discussed.

The preparation and characterisation of inorganic adduct molecule with dioxane have been done by several groups of workers.[1–17] Recently, Barnes and Duncan[18,19] carried out thermal decomposition of dioxane adducts of some metal halides. They investigated the thermal properties of the adducts by thermogravimetry, differential enthalpic analyses *etc.*, but not by the simultaneous measurements of TG, DTG and DTA, and they did not evaluate activation energy and order of reaction for each step of decomposition of the dioxane adducts. The present work deals with thermal decomposition of several known and unknown dioxane adducts of some metal halides. The evaluation of activation energy for the decomposition of adducts was worked out simultaneously from TG, DTG and DTA curves. In addition to the evaluation of activation energy of decomposition, the present paper deals with the evaluation of order of reaction (n) and ΔH from DTA peak area. It also shows the effect on the change of cation and anion on the thermal properties of dioxane adducts.

Experimental

For the preparation of dioxane adducts of metal halides anhydrous dioxane in excess was added to the finely powdered anhydrous metal halides and the mixture was stirred for 24—48 hr under dry conditions. The mixture was kept in desiccator for slow evaporation of the excess dioxane. All the adducts were characterized by elemental analysis. The dioxane used was sufficiently purified and dried according to the standard procedure.[20]

The following adducts of metal halides were prepared:
1. $MnCl_2 \cdot 1D$ 2. $MnBr_2 \cdot 2D$ 3. $CoCl_2 \cdot 0.5D$ 4. $CoBr_2 \cdot 2D$
5. $NiCl_2 \cdot 1.5D$ 6. $NiBr_2 \cdot 2D$ 7. $NiBr_2 \cdot 1D$ 8. $CuCl_2 \cdot 0.75D$
9. $CuBr_2 \cdot 2D$ 10. $ZnBr_2 \cdot 1D$ 11. $CdCl_2 \cdot 0.5D$ 12. $CdBr_2 \cdot 1D$
where D denotes dioxane molecule.

A Paulik-Paulik-Erdey type MOM Derivatograph was used for thermal analysis. The particle size of the sample was within 150—200 mesh. Heating rate was about 1.5 °C/min. The volume of the sample in each case was same. Platinum crucible was used for thermal analysis. All these experiments were conducted in static air.

Results

The dioxane adducts of $MnCl_2$, $CoCl_2$, $NiCl_2$, $NiBr_2$, $CuCl_2$, $ZnBr_2$, $CdCl_2$, and $CdBr_2$ lose all dioxane molecules in a single step which is evident from their respective TG, DTG and DTA curves (Figs. 1—4). The adduct $MnBr_2 \cdot 2D$ loses dioxane molecule in two distinct steps forming stable $MnBr_2 \cdot 1D$ as an intermediate. $CoBr_2 \cdot 2D$ loses dioxane molecules in three steps, *i.e.*,

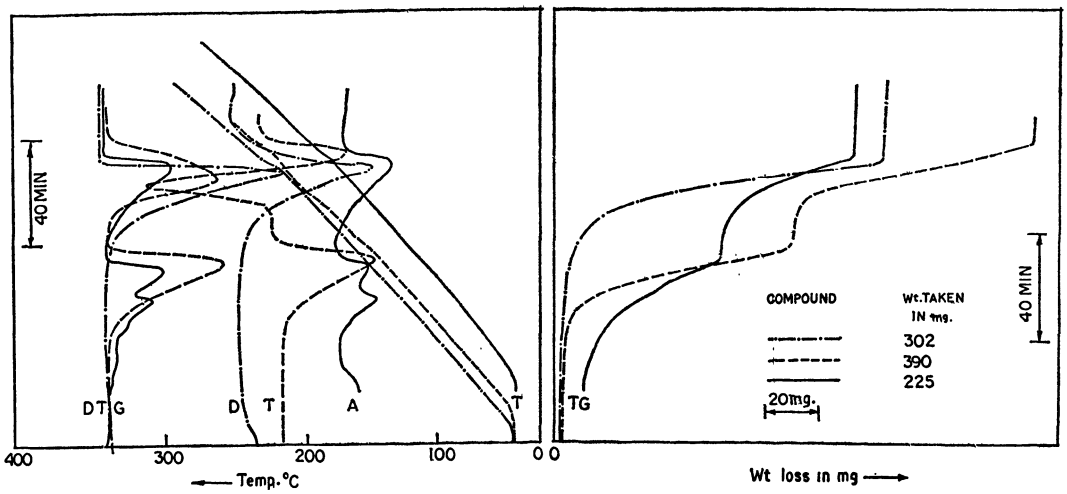

Fig. 1. The derivatograms for $MnCl_2 \cdot 1D$ (—·—·—), $MnBr_2 \cdot 2D$ (— — — —) and $CoBr_2 \cdot 2D$ (————).

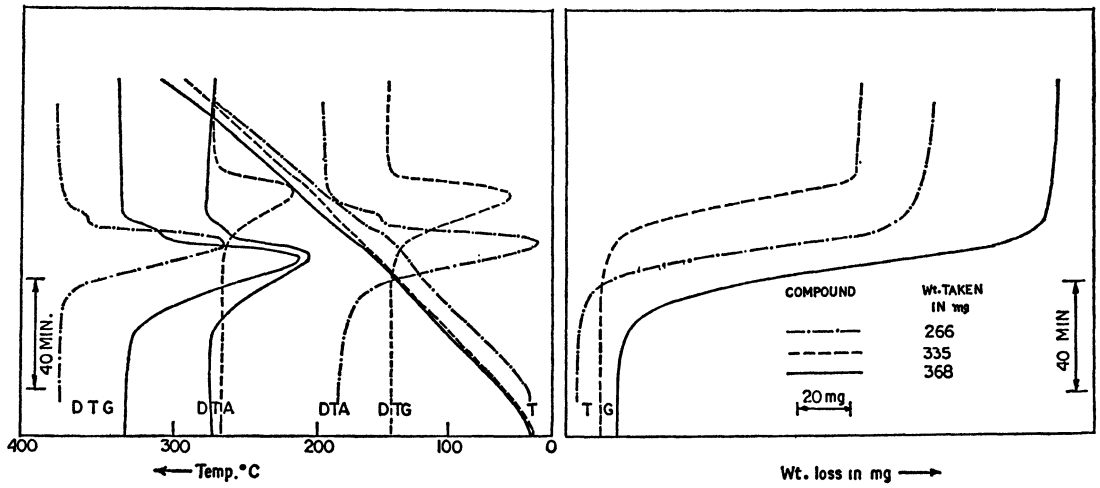

Fig. 2. The derivatograms for $NiCl_2 \cdot 1.5D$ (—·—·—), $NiBr_2 \cdot 1D$ (— — —) and $NiBr_2 \cdot 2D$ (———).

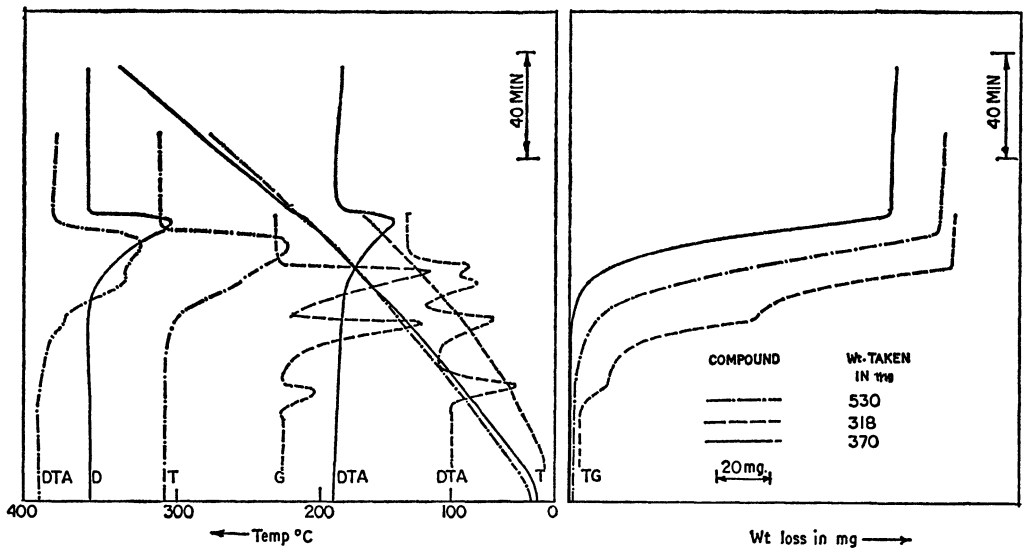

Fig. 3. The derivatograms for $CoCl_2 \cdot 0.5D$ (—·—·—), $CuBr_2 \cdot 2D$ (— — —) and $CuCl_2 \cdot 0.75D$ (———).

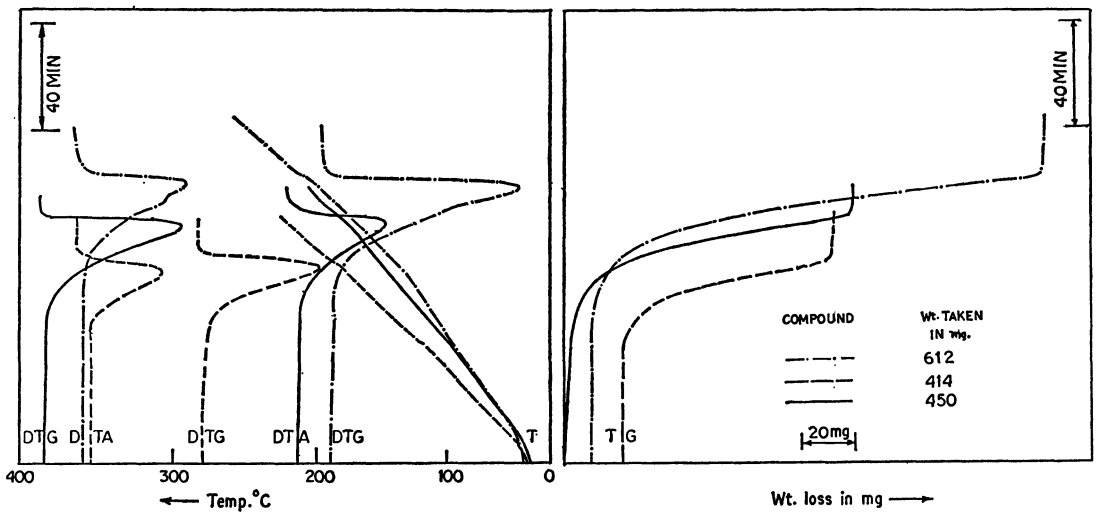

Fig. 4. The derivatograms for $ZnBr_2 \cdot 1D$ (—·—·—), $CdCl_2 \cdot 0.5D$ (— — —) and $CdBr_2 \cdot 1D$ (———).

$$CoBr_2\cdot 2D \xrightarrow{-0.5D} CoBr_2\cdot 1.5D \xrightarrow{-0.5D}$$

$$CoBr_2\cdot 1D \xrightarrow{-1D} CoBr_2$$

The first decomposition product $CoBr_2\cdot 1.5D$ is very unstable and second one is stable which is evident from its derivatogram (Fig. 1). Whereas, $CuBr_2\cdot 2D$ loses dioxane molecules in three steps, *i.e.*,

$$CuBr_2\cdot 2D \xrightarrow{-0.2D} CuBr_2\cdot 1.8D \xrightarrow{-0.8D}$$

$$CuBr_2\cdot 1D \xrightarrow{-1D} CuBr_2$$

All the intermediate products are unstable. DTA curve for the decomposition process of $CuBr_2\cdot 1D \rightarrow CuBr_2$ (Fig. 3) shows two overlapped endotherms. Whereas, its DTG curve indicates a single step of decomposition.

The decomposition of the adducts shows endotherm, except for tha of $MnBr_2\cdot 1D$ which shows an exotherm just followed by an endotherm in DTA curve. Temperature ranges of decomposition and the DTG peak temperatures for the adducts are listed in the second and third columns in Table 1, respectively.

Enthalpy change for each step of decomposition of the adducts was evaluated by the method of Sano[21,22] using copper sulfate pentahydrate as the standard and the values are tabulated in the last column in Table 1. When the two DTA peaks were too much overlapped with each other, the ΔH values were evaluated from the overall area of the DTA peaks concerned.

The activation energy for each step of decomposition of the adduct molecules was evaluated from the analysis of TG curves using Freeman and Carroll's[23] equation:

$$\frac{E_a}{2.3R}\Delta T^{-1}\Big/\Delta \log W_r = -n + \Delta \log \frac{dw}{dt}\Big/\Delta \log W_r,$$

where E_a is activation energy, n is order of reaction, T is absolute temperature, t is time, dw/dt is rate of weight loss with time, R is gas constant and W_r is weight loss at completion of reaction minus weight loss upto time t. The values are given in Table 1 and the corresponding curves are shown in Figs. 5 and 6. The order of reaction for each step of decomposition is unity.

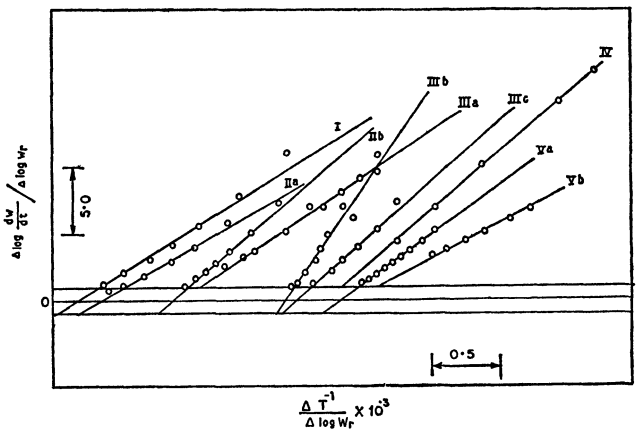

Fig. 5. Plots of $\Delta\log(dw/dt)/\Delta\log W_r$ *vs.* $\Delta T^{-1}/\Delta\log W_r \times 10^3$ from TG for the decomposition of $MnCl_2\cdot 1D \rightarrow MnCl_2$(I), $MnBr_2\cdot 2D \rightarrow MnBr_2\cdot 1D$(IIa), $MnBr_2\cdot 1D \rightarrow MnBr_2$(IIb), $CoBr_2\cdot 2D \rightarrow CoBr_2\cdot 1.5D$(IIIa), $CoBr_2\cdot 1.5D \rightarrow CoBr_2\cdot 1D$(IIIb), $CoBr_2\cdot 1D \rightarrow CoBr_2$ (IIIc), $NiCl_2\cdot 1.5D \rightarrow NiCl_2$(IV), $NiBr_2\cdot 1D \rightarrow NiBr_2$ (Va) and $NiBr_2\cdot 2D \rightarrow NiBr_2$(Vb).

Table 1. Thermal parameters for the decomposition of adduct molecules of some metallic halides with dioxane

a) Indicates overall enthalpy change. b) Activation energy and enthalpy change from DTA curve could not be evaluated due to irregular nature of the DTA peaks. c) Evaluation of activation energy was not possible due to much overlapping of the curves with each other.

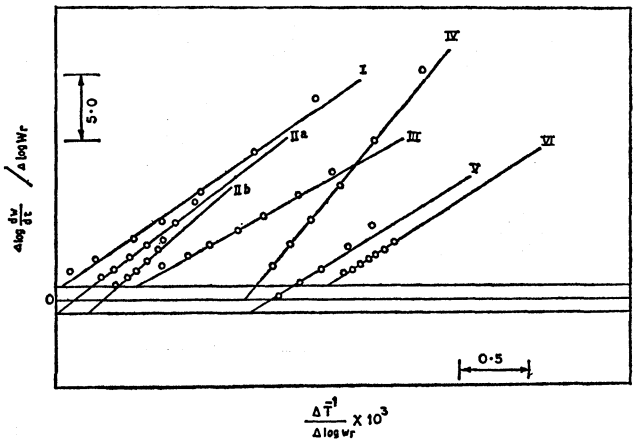

Fig. 6. Plots of $\Delta\log(dw/dt)/\Delta\log W_r$ *vs.* $\Delta T^{-1}/\Delta\log W_r \times 10^3$ from TG for the decomposition of $CuCl_2\cdot 0.75D \rightarrow CuCl_2$(I), $CuBr_2\cdot 1.8D \rightarrow CuBr_2\cdot 1D$(IIa), $CuBr_2\cdot 1D \rightarrow CuBr_2$(IIb), $ZnBr_2\cdot 1D \rightarrow ZnBr_2$(III), $CdCl_2\cdot 0.5D \rightarrow CdCl_2$(IV), $CdBr_2\cdot 1D \rightarrow CdBr_2$(V) and $CoCl_2\cdot 0.5D \rightarrow CoCl_2$(VI).

Activation energy for each step of decomposition was determined from the analysis of DTG curve using the method of Dave and Chopra.[24]

$$k = \frac{\left(\frac{A}{N_0}\right)^{n-1}\left(-\frac{dx}{dt}\right)}{(A-a)^n}$$

where N_0 is number of mol of sample at time t at which the DTG peak begins to appear, A and a are the total peak area and the area swept out till the time t, respectively, dx/dt is the displacement of the DTG curve from the base line and n is the order of reaction. The determination of order of reaction by this method is a trial and error process which amounts to calculating the rate constants corresponding to different values of n and finding out the best fitting curve for the Arrhenius plot which gives the value of n. In our work we found that by putting the value of the order of reaction $n=1$ (calculated from TG curve), we got the best fitting Arrhenius plot in all the cases. As a result

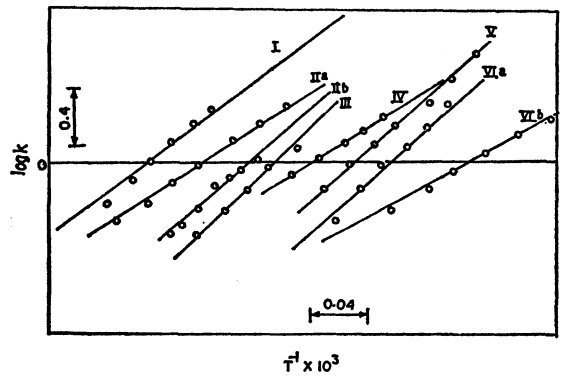

Fig. 7. Arrhenius plots, $\log k$ *vs.* $T^{-1}\times 10^3$, from DTG for the decomposition of $MnCl_2\cdot 1D \rightarrow MnCl_2$(I), $MnBr_2\cdot 2D \rightarrow MnBr_2\cdot 1D$(IIa), $MnBr_2\cdot 1D \rightarrow MnBr_2$(IIb), $CoBr_2\cdot 1D \rightarrow CoBr_2$(III), $CoCl_2\cdot 0.5D \rightarrow CoCl_2$(IV), $NiCl_2\cdot 1.5D \rightarrow NiCl_2$(V), $NiBr_2\cdot 1D \rightarrow NiBr_2$(VIa) and $NiBr_2\cdot 2D \rightarrow NiBr_2$(VIb).

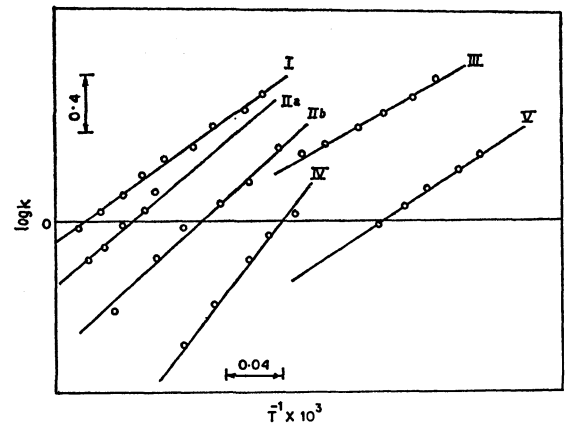

Fig. 8. Arrhenius plots, $\log k$ *vs.* $T^{-1}\times 10^3$, from DTG for the decomposition of $CuCl_2\cdot 0.75D \rightarrow CuCl_2$(I), $CuBr_2\cdot 1.8D \rightarrow CuBr_2\cdot 1D$(IIa), $CuBr_2\cdot 1D \rightarrow CuBr_2$(IIb), $ZnBr_2\cdot 1D \rightarrow ZnBr_2$(III), $CdCl_2\cdot 0.5D \rightarrow CdCl_2$(IV) and $CdBr_2\cdot 1D \rightarrow CdBr_2$(V).

we did not have to use the laborious trial and error method of Dave and Chopra. The values of the activation energies are given in Table 1 and the curves are shown in Figs. 7 and 8. We could not determine the activation energy by this method in some cases where the curves are too much overlapped.

Activation energy for each step of decomposition was also determined from the analysis of DTA curves using Brochardt equation[25] for first order reaction

$$k = \frac{C_p\frac{d\Delta T}{dt} + K\Delta T}{K(A-a) - C_p\Delta T}$$

where k is rate constant for the reaction, A is total DTA area, C_p is total heat capacity, K is cell constant, a is area at time t, $d\Delta T/dt$ expresses slope of the DTA curve at time t, ΔT is the displacement of the DTA curve from the base line at time t. As quantities $C_p\, d\Delta T/dt$ and $C_p\Delta T$ are, in general, small, the equa-

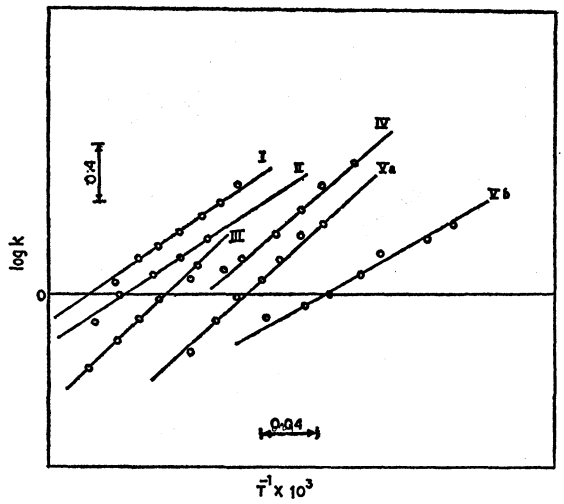

Fig. 9. Arrhenius plots, $\log k$ *vs.* $T^{-1}\times 10^3$, from DTA for the decomposition of $MnCl_2\cdot 1D \rightarrow MnCl_2$(I), $MnBr_2\cdot 2D \rightarrow MnBr_2\cdot 1D$(II), $CoBr_2\cdot 1D \rightarrow CoBr_2$(III), $NiCl_2\cdot 1.5D \rightarrow NiCl_2$(IV), $NiBr_2\cdot 1D \rightarrow NiBr_2$(Va) and $NiBr_2\cdot 2D \rightarrow NiBr_2$(Vb).

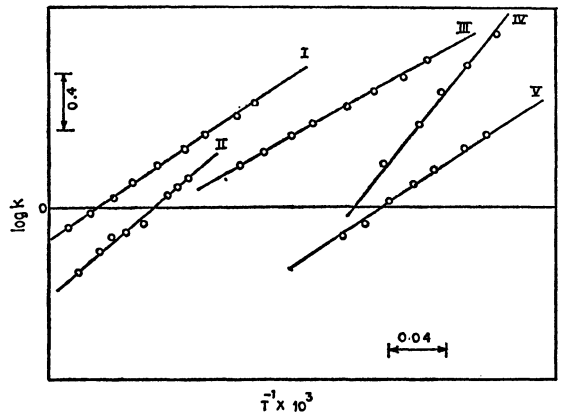

Fig. 10. Arrhenius plots, $\log k$ *vs.* $T^{-1} \times 10^3$, from DTA for the decomposition of $CuCl_2 \cdot 0.75D \rightarrow CuCl_2$(I), $CuBr_2 \cdot 1.8D \rightarrow CuBr_2 \cdot 1D$(II), $ZnBr_2 \cdot 1D \rightarrow ZnBr_2$-(III), $CdCl_2 \cdot 0.5D \rightarrow CdCl_2$(IV) and $CdBr_2 \cdot 1D \rightarrow CdBr_2$(V).

tion reduces to $k = \Delta T/(A-a)$. From the plot of $\log k$ *vs.* T^{-1} activation energy can easily be evaluated. The values are tabulated in Table 1 and the curves are shown in Figs. 9 and 10. Here also we could not determine the activation energy in some cases for too much overlapping of the DTA curves.

IR spectra of the adducts were taken to ensure the presence of dioxane molecule in the adducts.

Discussion

According to the observations by Barnes and Duncan[19] the adduct $MnBr_2 \cdot 2D$ loses all dioxane molecules in single step showing two overlapped endotherm. They could not isolate the intermediate product of composition $MnBr_2 \cdot 1D$. Whereas, we observed well-resolved DTA peaks for the two decomposition steps of $MnBr_2 \cdot 2D$ to $MnBr_2 \cdot 1D$ and of $MnBr_2 \cdot 1D$ to $MnBr_2$, the former showing an endotherm and the latter showing an exotherm followed by an endotherm in the DTA curve (Fig. 1). But the corresponding TG and DTG curves for the decomposition of $MnBr_2 \cdot 1D$ to $MnBr_2$ do not show any intermediate step. Earlier, dioxane adduct of $CoCl_2$ was known as $CoCl_2 \cdot 1D$. On the contrary, we isolated the adduct as $CoCl_2 \cdot 0.5D$ alone. The existence of $CoBr_2 \cdot 1.5D$, though not stable, was not pointed out earlier.[19] We isolated the adduct of $NiCl_2$ as $NiCl_2 \cdot 1.5D$, whereas, the composition of the adduct of the same salt was reported earlier[19] as $NiCl_2 \cdot 1D$. We could not isolate $NiBr_2 \cdot 1D$ from the thermal decomposition of $NiBr_2 \cdot 2D$ but isolated the same by keeping $NiBr_2 \cdot 2D$ in a vacuum desiccator for a long time. In case of $CuCl_2$ we repeatedly isolated the adduct $CuCl_2 \cdot 0.75D$ alone and never obtained 3 $CuCl_2 \cdot 2D$ and $CuCl_2 \cdot 2D$ reported earlier.[18] Whereas, dioxane adduct of $CuBr_2$ was reported by the same workers[19] as 3 $CuBr_2 \cdot 2D$ which showed single step of thermal decomposition. But we isolated the adduct as $CuBr_2 \cdot 2D$. In literature[1,19] two dioxane adducts such as $CdCl_2 \cdot 0.5D$ and $CdCl_2 \cdot 1D$ were reported. We could not isolate $CdCl_2 \cdot 1D$. The thermal decomposition of $CdCl_2 \cdot 1D$ reported earlier[19] did not show the existence of $CdCl_2 \cdot 0.5D$ from TG at any temperature.

The partial disagreement in our observations with those of the aforementioned works is possibly due to the difference in experimental conditions employed. Particular mention may be made of the wide difference of heating rate, *i.e.*, 8—10 °C/min used in the earlier works[19] compared to that of 1.5 °C/min used in our experiments.

DTG peak temperature for a series of adducts of the type $MBr_2(dioxane)_2$, where M is Mn(II), Co(II), Ni(II) or Cu(II), increases in the order: Cu(II) <Co(II) <Mn(II) <Ni(II) and for a series of adducts of the type MX_2dioxane, where M is Mn(II), Co(II), Ni(II), Cu(II), Zn(II) or Cd(II) and X is Cl^- or Br^-, increases in the order Cu(II) <Cd(II) <Co(II) <Zn(II) <Ni(II) <Mn(II). A similar order was found in the case of the decomposition of some pyridine 1-oxide coordination compounds.[26] Of the dioxane adducts of the halides of bivalent transition metal ion like Mn(II), Co(II), Ni(II) or Cu(II), the Mn(II) compound is thermally most stable. Among these metal ions Mn(II) is the hardest acceptor and oxygen donors like dioxane are hard donors. Naturally, dioxane will form the strongest donor acceptor bond with Mn(II) which is the hardest acceptor of the above series and the highest energy will be required to rupture the Mn(II)–dioxane bond.

It was observed that dioxane adduct of metal bromide is thermally less stable than the corresponding adduct of metal chloride. The value of enthalpy change for the decomposition of $CuBr_2 \cdot 1.8D \rightarrow CuBr_2 \cdot 1D$ is smaller than that for the first step of decomposition $CuBr_2 \cdot 2D \rightarrow CuBr_2 \cdot 1.8D$, though, in general, the latter step of decomposition gives larger ΔH value than the earlier step. It is noticed that the value of enthalpy change ranges from 7 to 47.5 kcal/mol.

Activation energies evaluated from TG, DTA and DTG do not differ much from each other, which shows that all the methods used for the evaluation of activation energies are standard. The differences in the activation energies of decomposition between the adducts do not show any systematic relationships with the kind or the nature of either cation (*i.e.*, the electronic configuration of the metal ion) or the anion.

In general, DTA curve shows endotherm for the decomposition of the similar type of adducts. This is seen in the decomposition of all the adducts except the decomposition of $MnBr_2 \cdot 1D \rightarrow MnBr_2$. Its nature of DTA and the corresponding TG and DTG curves possibly indicates some kinds of structural rearrangement at the beginning of the decomposition. The evolution of heat due to this rearrangement probably overcomes the endothermic effect due to decomposition at the beginning. This may explain the exotherm observed in the DTA curve.

The authors wish to express their hearty thanks to Dr. S.P. Ghosh, Research Officer of this laboratory for his kind discussion.

The Proof of a Triplet Ground State in the *N,N'*-Di-*t*-butyl-*m*-phenylenebinitroxide Biradical

Kazuo MUKAI, Hiroshi NAGAI, and Kazuhiko ISHIZU*

Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790

(Received January 30, 1975)

Synopsis. The magnetic susceptibility of the *N,N'*-di-*t*-butyl-*m*-phenylenebinitroxide biradical has been measured in the temperature range from 60 to 300 K. The susceptibility follows the Curie-Weiss law, with a paramagnetic Curie constant of 0.90±0.04 K·emu/mol and a Weiss constant of −19±2 K. This susceptibility suggests that the ground state of the biradical is a triplet and that an intramolecular pure triplet approximation, $2J \gg kT$, is reliable in the temperature region below 300 K. The negative Weiss constant is due to the negative exchange interaction, $J'<0$, between the triplets.

Recently, Calder *et al.*[1] have succeeded in the synthesis of *N,N'*-di-*t*-butyl-*m*-phenylenebinitroxide, which is a fairly stable nitroxide biradical, as is shown in Fig. 1. The biradical has π-conjugated monoradical halves linked by a central phenylene π bridge, so the magnitude of the intramolecular spin-spin interaction in the biradical can be expected to be greater than those in σ-bridged nitroxide biradicals.[2,3] Actually, they observed a large ESR zero-field splitting in rigid media, indicating the existence of the triplet state in the biradical. They also proposed that the triplet is the ground state, from a study of the temperature dependence of the ESR signal intensity measured in the solid-state matrix. It is not very clear, however, from the above-mentioned results whether or not the observed triplet state is the ground state; there remains the possibility that they observed an excited triplet state which is thermally populated at that temperature; this would be true if the exchange interaction with a negative value, J, were smaller than the thermal excitation.

In order to clarify the level scheme of the spin system of the biradical, the magnetic susceptibility of the solid nitroxide biradial has been measured in the temperature range between 60 and 300 K.

In recent years, several stable π-conjugated bi- or tri-radicals, in which monoradical parts are linked with each other at the *meta*-position of a central phenyl group, have been prepared.[4-9] The existence of a triplet or quartet state in these radicals is also confirmed by ESR measurements in rigid media at 77 K.[6-11] However, the properties of the ground state in these radicals have not been fully established, except in the cases of a few radicals.[4,12] Studies of the temperature dependence of the static magnetic susceptibility are essential if we are to investigate the level scheme of the spin systems of these polyradicals.

* To whom correspondence should be addressed.

Experimental

The biradical was prepared by the method of Calder *et al.*[1] An orange crystalline compound (mp 67—69 °C) (lit, 68—70 °C) was obtained by the oxidation with silver oxide of the corresponding dihydroxylamine in purified chloroform and by subsequent rapid recrystallization from *n*-hexane in a dry-ice–acetone bath.

The susceptibility measurements were carried out with a Shimadzu-type MB-2 magnetic torsion balance, equipped with a low-temperature cryostat. The temperatures were measured using an AuCo-Cu thermocouple. Manganese Tutton salt was used for the calibration of the thermometers and the field gradient.

Results and Discussion

The inverse molar susceptibilities obtained for the nitroxide biradical are shown in Fig. 1 as a function of the temperature. The data have been corrected for the diamagnetic contribution of $\chi_{dia} = -0.17 \times 10^{-3}$ emu/mol calculated by Pascal's method. The susceptibility follows the Curie-Weiss law, with a Curie constant of 0.90±0.04 K·emu/mol and a Weiss constant of −19±2 K.

Calder *et al.*[1] have observed ESR spectra due to

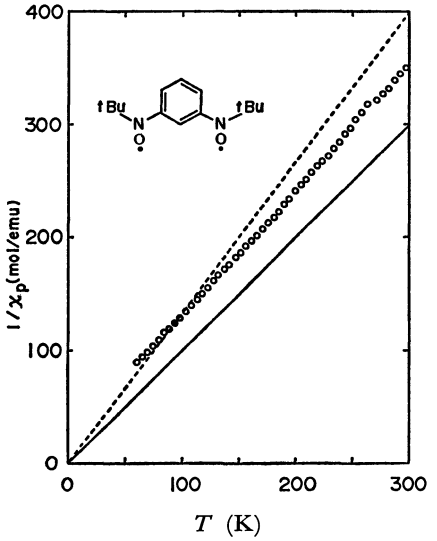

Fig. 1. Inverse molar susceptibility of *N,N'*-di-*t*-butyl-*m*-phenylenebinitroxide biradical *vs.* temperature. Solid and broken lines represent the Curie laws with Curie constants of 1.00 and 0.75 K·emu/mol, respectively.

transitions between the triplet states of the biradical in glassy media, as has been mentioned above. Therefore, the present susceptibility should be interpreted, in a first approach, by the singlet-triplet equilibrium (ST) model, in which the molar susceptibility is given by the following expression:

$$\chi_m = 2N_0g^2\beta^2/\{kT[3+\exp(-2J/kT)]\},$$

where the symbols have their usual meanings. At the high temperature limit, $|2J| \ll kT$, the susceptibility follows the Curie law and the Curie constant is 0.75 K·emu/mol from the above equation, regardless of the sign of the J parameter. This susceptibility corresponds to that of the noninteracting spin 1/2 particles. On the other hand, at the low-temperature limit, $|2J| \gg kT$, the Curie constant is 1.00 K·emu/mol for the positive J parameter. The positive exchange interaction requires the presence of the triplet ground state. This intramolecular triplet can behave as a pure triplet at low temperatures, because the exchange-interaction energy is much greater than the thermal excitation energy. If the J parameter is negative, the susceptibility falls off rapidly to zero after passing through its maximum at $T_{max} = -1.25\ J/k$. Accordingly, the Curie law does not hold in this temperature region.

Our experimental results show that the susceptibility of the biradical follows the Curie-Weiss law, with a Curie constant of 0.90 K·emu/mol in the temperature region below 300 K. This value is larger than the Curie constant of 0.75 K·emu/mol for noninteracting spin 1/2 particles, and is rather close to that of 1.0 K·emu/mol for pure triplet ($S=1$) ones. The discrepancy between the observed and calculated Curie constants for the pure triplet is probably due to the following two reasons: (i) the nitroxide biradical is not very stable and gradually changes to its diamagnetic aminoquinone imine *N*-oxide form by means of spontaneous topochemical change,[1] and (ii) the existence of a small amount of a monoradical impurity has been observed at the ESR spectra in a rigid solution at 77 K as a central singlet between the absorptions due to zero-field splitting.[1] These facts may explain the decrease in the Curie constant. The observed negative Weiss constant ($\theta = -19$ K) is due to the negative exchange interaction, $J' < 0$, between the triplets. All these results are very similar to those for *m*-phenylene-bis-verdazyl, whose magnetic susceptibility has also been explained as a contribution from its pure triplet ground state.[12]

The γ-Radiolysis of Liquid Nitrogen Containing Methane

Yona SIDERER* and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 22, 1975)

Synopsis. The γ-radiolysis of the liquid nitrogen–methane system has been investigated. As products, hydrogen cyanide, ethane, and the basic compounds were observed. The G(HCN) attained was 0.08 at higher concentrations of methane, while the G(basic compounds) was found to be in the order of 0.5. In order to explain these results, different precursors for the HCN and the basic compounds are considered.

Methane is the simplest hydrocarbon. Therefore, if γ-radiolysis is carried out with a system of liquid nitrogen containing a small amount of methane, the number of different products will be limited. In a study of the gas-phase γ-radiolysis of the nitrogen–methane system,[1] it has been reported that hydrogen cyanide is the only nitrogen-containing product. Also, in an investigation of the reaction of the active nitrogen with methane,[2] the main nitrogen-containing product has been found to be hydrogen cyanide.

At the temperature of liquid nitrogen, no reaction with an activation energy higher than a few kcal mol^{-1} will occur. Therefore, if the formation of hydrogen cyanide is accompanied by a complicated rearrangement, which is usually postulated in the gas-phase reactions of nitrogen atoms with hydrocarbons,[3] these reactions will be inhibited in the liquid nitrogen; *i.e.*, only the association reaction and the strong exothermic reaction will occur.

With these expectations in mind, we have carried out the γ-radiolysis of liquid nitrogen containing methane.

Experimental

The methane used was supplied by the Takachiho Shoji Co. Nitrogen gas of a high purity was purchased from the Nihon Sanso Co. and was used after being bubbled through sulfuric acid. The hydrogen cyanide used for identification was synthesized from potassium cyanide and sulfuric acid. The Nessler reagent was obtained from Wako Pure Chemical Industries, Ltd.; sulfuric acid (95%) from the Yotsuhata Co., Ltd., and potassium carbonate, from the Junsei Pure Chemical Co., Ltd.

The experimental procedure was almost the same as that reported previously.[4] A 10-ml portion of liquid nitrogen containing a known amount of methane was irradiated by ^{60}Co γ-rays at a dose rate of 3.21×10^{19} eV/g hr. After evacuating the nitrogen at 77 K, we analyzed the remains by using a gas chromatograph (DOP column) and by using Conway's method.[4] The gas-chromatographic analysis showed the presence of hydrogen cyanide and ethane, while Conway's method revealed the presence of a comparatively large amount of the basic compounds in the product.

* Present address: Weizmann Institute of Science, Department of Biochemistry, Rehovot, Israel.

Results

Figure 1 shows the G-values of hydrogen cyanide and ethane obtained as functions of the concentration of methane. At methane concentrations higher than 3×10^{-3} mol l^{-1}, the increase in G(HCN) with an increase in the concentration of methane is much smaller than that in $G(C_2H_6)$. Table 1 summarizes the G-values of the basic compounds measured by Conway's method. Although the data are scattered, they may be enough to show that the G(basic compounds) is in the order of 0.5. One experiment was carried out using hydrogen in place of methane. This result suggests that the basic compounds obtained with methane are not products of the reaction of nitrogen atoms with the hydrogen eventually formed in the system.

Discussion

Since the C-H bond strength of methane (101 kcal

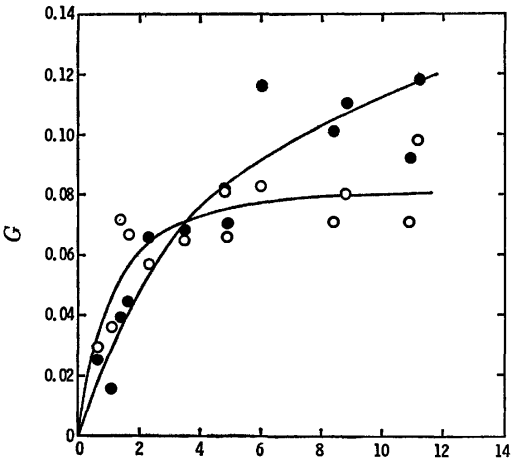

Fig. 1. The G-values of hydrogen cyanide (○) and ethane (●) as a function of the concentration of methane.

TABLE 1. THE G-VALUES OF AMMONIA MEASURED PHOTOMETRICALLY AFTER TREATING THE PRODUCT BY THE CONWAY METHOD AND USING NESSLER REAGENT

CH_4 (10^{-3} mol l^{-1})	H_2 (10^{-3} mol l^{-1})	$G(NH_3)$
0.56		0.44
1.29		0.36
2.01		0.60
2.83		0.51
3.57		0.41
	4.86	0.074

mol^{-1}) is much larger than the bond strength of N-H (86 kcal mol^{-1}),[5] the endothermic reaction:

$$CH_4 + N \longrightarrow NH + CH_3 \quad (1)$$

will not occur in the present system. The initiating reaction, therefore, must be the decomposition of methane in the collision of the excited nitrogen molecules with a long life (N_2^* $^3\Sigma_u^+$):

$$CH_4 + N_2^* \longrightarrow CH_3 + H + N_2 \quad (2)$$

In the gas-phase reaction, the following reaction:

$$CH_3 + N \longrightarrow HCN + H_2 \quad (3)$$

has often been assumed to occur; however, as was shown in the Results section, hydrogen cyanide is not the only nitrogen-containing product in the present experiment. Moreover, this reaction is not a spin-allowed one. A more plausible reaction in the present system is as follows:

$$CH_3 + N \longrightarrow CH_3N: \quad (4)$$

The intermediate, CH_3N:, may isomerize into methylene imine either in the liquid nitrogen or in the course of the warming up to room temperature.

It is known that methylene imine is not a stable compound at room temperature and that it polymerizes into a polymer. In fact, the mass-spectrometric analysis of the product showed the presence of a polymer, although it could not be identified. If Reaction (4) is a unique reaction between nitrogen atoms and methyl radicals, the formation of hydrogen cyanide cannot be explained. Another possible mechanism is as follows:

$$CH_3 + N \longrightarrow H_2CN + H \quad (5)$$

$$H_2CN + CH_3 \longrightarrow HCN + CH_4 \quad (6)$$

Reaction (6) was proposed by Safrany and Jaster in the investigation of the reaction of active nitrogen.[5] However, this reaction mechanism is not applicable to the present system. As has been shown in Fig. 1, the methane-concentration dependence of $G(HCN)$ is much smaller than that of $G(C_2H_6)$. If Reactions (5) and (6) are operative, the yield of hydrogen cyanide should be increased with the increase in the concentration of methyl radicals, which will itself increase with the concentration of methane.

As a possible source of hydrogen cyanide, let us consider the excited state of nitrogen atoms, ^2D, 2.38 eV above the ground state, ^4S. Even in the active nitrogen, the presence of the excited atoms ^2D has been reported, although the concentration is much less than that of the ground state.[3]

A tentative reaction mechanism to explain the present experimental results may be summarized as follows:

$$N_2 \begin{cases} \xrightarrow{\sim\sim} 2\,N\ (^4S),\ (^2D) \\ \xrightarrow{\sim\sim} N_2^*\ (^3\Sigma_u^+) \end{cases}$$

$$N_2^* + CH_4 \longrightarrow N_2 + CH_3 + H$$

$$CH_3 + N\ (^2D) \longrightarrow HCN + H_2$$

$$CH_3 + N\ (^4S) \longrightarrow CH_3N:$$

$$CH_3N: \longrightarrow \text{products}$$

(Conway's method)

$$\text{products} \longrightarrow NH_3 + \text{residue}$$

$$CH_3 + CH_3 \longrightarrow C_2H_6$$

$$(H + N \longrightarrow NH \cdots\cdots\rightarrow NH_3)$$

Further investigations are being made with a different approach.

This research was partially supported by a UNESCO Fellowship to Y.S.

Energy Difference between Rotational Isomers of 1,2-Dibromoethane

Jiro HIRAISHI and Takako SHINODA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received March 27, 1975)

Synopsis. The energy difference between the rotational isomers of 1,2-dibromoethane in the liquid state was determined to be 910±80 cal/mol on the basis of the relative intensity of the Raman band at 660 cm^{-1} (*trans* form) to that at 551 cm^{-1} (*gauche* form) in the temperature range from 24.5 to 105.1 °C.

The energy difference ($\Delta E=E_g-E_t$) between the *trans* and *gauche* forms of 1,2-dibromoethane in the liquid state has been determined by many investigators.[1-7] The values reported are in the range from 650 to 1000 cal/mol. Fujiyama and Shimanouchi observed the ratio of the intensity of the Raman band at 660 cm^{-1} of the *trans* form (I_t) and that of the band at 551 cm^{-1} of the *gauche* form (I_g) in the liquid state and concluded that $\ln(I_t/I_g)$ was not proportional to $1/T$ (T represents the absolute temperature at the measurement).[5] Recently a cryostat was constructed in our laboratory for the measurement of the Raman spectra in the temperature range from 150 °C to liquid helium temperature.[8] By use of the apparatus we re-examined the energy difference of 1,2-dibromoethane in the liquid state in order to ascertain the non-linear relation between $\ln(I_t/I_g)$ and $1/T$.

The Raman spectra were measured with the use of a Raman spectrometer, Kawaguchi Electric Works Ltd. model RL-62. The exciting light was 488.0 nm line of the Ar^+ laser, NEC model GLG 2003. The power of the exciting light was kept constant during the measurement by use of the light feed back system for the GLG 2003 laser made by Kawaguchi Electric Works Ltd. The spectrum between 500 and 750 cm^{-1} was recorded at 24.5, 34.9, 45.0, 55.2, 65.0, 75.2, 84.9, 95.1, and 105.1 °C. The spectrum at room temperature is given in Fig. 1. The weak band at 583 cm^{-1} is the CBr stretching vibration band of b species of the *gauche* form. The bands at 660 and 551 cm^{-1} were used for obtaining the energy difference. The temperature was measured within an accuracy of about 0.03 K with the use of a chlomel p-constantan thermocouple, the calibration of which was given elsewhere.[9] The drift of the temperature was less than 0.2 K during a measurement. The spectra were recorded five times for the measurement at each temperature. Five copies were made for each recording with the use of Fuji Xerox 1000 and weighed the area of each band. 25 data of I_t/I_g were obtained for the measurement at each temperature. The standard deviation of the 25 data was in the range from 1.0 to 3.5% of the averaged value.

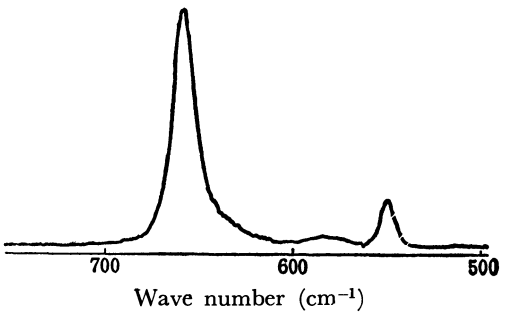

Fig. 1. The Raman spectra of 1,2-dibromoethane in the liquid state at room temperature.

Figure 2 illustrates the values of $\ln(I_t/I_g)$ against $1/T$, which indicates that $\ln(I_t/I_g)$ linearly depends on $1/T$. As the scattering intensity of the Stokes line[10] is proportional to $(1-e^{-h\nu/kT})^{-1}$, the temperature dependence of I_t/I_g can be expressed by the following equations:

$$\partial/\partial(1/T)[\ln(I_t/I_g)] = \Delta E/k + f(T)$$

$$f(T) = e^{-h\nu_g/kT}(h\nu_g/k)/(1-e^{-h\nu_g/kT}) - e^{-h\nu_t/kT}(h\nu_t/k)/(1-e^{-h\nu_t/kT})$$

where ν_t and ν_g represent the vibrational frequencies of the *trans* and *gauche* forms used for the determination of ΔE. The apparent value of ΔE directly obtained from Fig. 2 is 955±80 cal/mol. When $f(T)$ is taken into consideration, the value of ΔE decreases by 38 cal/mol at 24.5 °C and by 54 cal/mol at 105.1 °C. Consequently, the value of ΔE is determined to be 910±80 cal/mol.

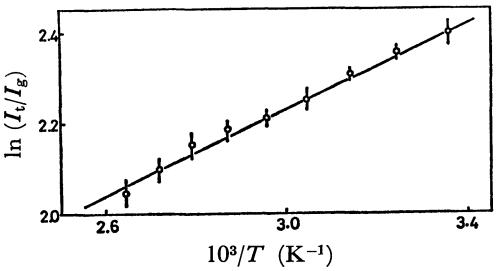

Fig. 2. Linearity between $\ln(I_t/I_g)$ and $1/T$.

As temperature range of the present study is wider and the measurement of temperature is more accurate than other vibrational spectroscopic measurements, we believe the present result is most reliable among them. I_t/I_g depends on the choice of the base line and also on the method of the separation of two bands ovelapping each other. As Fig. 1 shows, the two bands do not overlap each other so much and the base line is easily determined in this case. On estimating the error in I_t/I_g in Fig. 2, such systematic errors are not taken into account, which do not exceed 5%.

Gas-chromatographic Behavior of C_1, C_2, and C_3-Halocarbons Containing Iodine

Yoshihiro MAKIDE, Takefumi FUKUMIZU, and Takeshi TOMINAGA

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received April 18, 1975)

Synopsis. The regularity of the specific retention volume (V_g) in gas chromatography was investigated on a number of C_1, C_2, and C_3 halocarbons containing iodine. The log V_g value was found to correlate with the number of halogen and carbon atoms in the molecule.

Although the gas-chromatographic behavior of a number of C_1 and C_2 carbon mixed halides containing F, Cl, and Br has been investigated,[1,2] no extensive work has been reported on carbon mixed halides containing iodine. The object of this article is to report on our recent study of the regularity in the specific retention volume of C_1, C_2, and C_3 mixed halocarbons containing iodine in addition to F, Cl, and Br.

Experimental

Materials. Twelve kinds of iodine-containing halocarbons were used in the present work. Of these, CF_2ClI, $CFCl_2I$, CF_2BrI, C_2F_4ClI, $C_2F_3Cl_2I$, C_3F_6ClI, and C_3F_6BrI were prepared by the γ-irradiation of mixtures of adequate halocarbons and iodine.[3] CF_3I, C_2F_5I, C_2F_4BrI, $C_2F_4I_2$, $C_2F_3Cl_2I$, and C_3F_7I were purchased from PCR, Inc., USA. The other halocarbons containing no iodine and used in this work were obtained as has been described previously.[2]

Determination of Retention Volume. The retention times of the halocarbons on a Silicone DC 550 column (20 wt% coated on acid-washed Chromosorb W80-100 mesh, 3 mm i.d. × 5 m long) were measured at constant temperatures between 40 and 100 °C by using a gas chromatograph equipped with a thermal conductivity detector. The carrier gas was He, at the flow rate of 15 ml/min. The gas-chromatographic data were expressed in terms of the specific retention volume (V_g), normalized from the measured retention time.

Results and Discussion

The logarithm of the specific retention volume of each halocarbon measured between 40 and 100 °C was linearly related to the reciprocal of the absolute temperature of the column; thus, the heat of vaporization from the solution in the Silicone DC 550 stationary phase remained constant over this range of column temperature. Furthermore, the heats of vaporization calculated for all the halocarbons from the slopes of the log $V_g - 1/T$ curves were correlated almost linearly with the logarithms of the specific retention volumes at any temperature.

Figure 1 reveals the correlation of the logarithm of the specific retention volume with the halogen composition for C_2-halocarbons.[4] The observed retention volumes of the C_2-halocarbons containing iodine (filled circles in Fig. 1) were plotted nearly at the lattice positions of the network for $C_2F_{6-x-y-z}Cl_xBr_yI_z$. Such results have also been obtained for the halocarbons containing no iodine,[1,2] which are

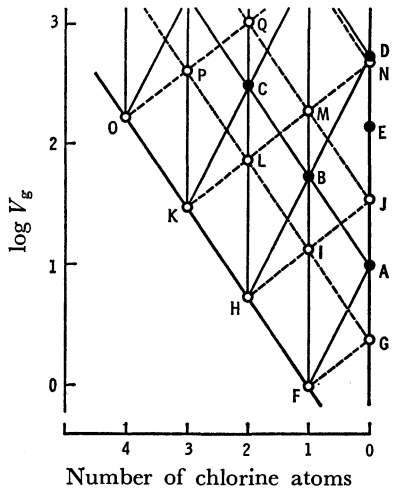

Fig. 1. Correlation between the logarithm of the specific retention volume on a Silicone DC 550 column (60 °C) and the halogen composition of C_2-halocarbons.
(A): C_2F_5I, (B): C_2F_4ClI, (C): $C_2F_3Cl_2I$, (D): $C_2F_4I_2$, (E): C_2F_4BrI, (F): C_2F_5Cl, (G): C_2F_5Br, (H): $C_2F_4Cl_2$, (I): C_2F_4ClBr, (J): $C_2F_4Br_2$, (K): $C_2F_3Cl_3$, (L): $C_2F_3Cl_2Br$, (M): $C_2F_3ClBr_2$, (N): $C_2F_3Br_3$, (O): $C_2F_2Cl_4$, (P): $C_2F_2Cl_3Br$, (Q): $C_2F_2Cl_2Br_2$.

represented by open circles in Fig. 1. A detailed examination of the additivity of log V_g with respect to the halogen composition indicates that, upon halogen substitution, the log V_g value is changed by a magnitude characteristic of the substitution: +0.76 by Cl-for-F, +1.17 by Br-for-F, and +1.76 by I-for-F (on a Silicone DC 550 column at 60 °C). The magnitude of the change in log V_g for the same type of halogen substitution was found to be identical irrespective of the number of carbon atoms in the molecule. Accordingly, the log V_g value of the halocarbons, $C_nF_{2n+2-x-y-z}Cl_xBr_yI_z$ (n=1, 2, and 3) on Silicone DC 550 at 60 °C, can be calculated as follows:

$$\log V_g = \alpha_n + 0.76x + 1.17y + 1.76z$$

where α_n is equal to −0.94, −0.80, and −0.61 for n=1, 2, and 3 (*i.e.*, C_1, C_2, and C_3) respectively.[5]

Figure 2 illustrates three-dimensionally the additivity of the log V_g values of all the C_2-halocarbons with respect to the number of F, Cl, Br, and I in the molecule. The log V_g value is expressed as the height from the ground plane. The four vertices of the larger tetrahedron correspond to C_2F_6, C_2Cl_6, C_2Br_6, and C_2I_6, while each edge includes C_2-halocarbons containing two kinds of halogens (*e.g.*, $C_2F_{6-x}Cl_x$ along the C_2F_6–C_2Cl_6 edge). C_2-halocarbons containing three kinds of halogens are located at the lattice positions on the surfaces of the tetrahedron except

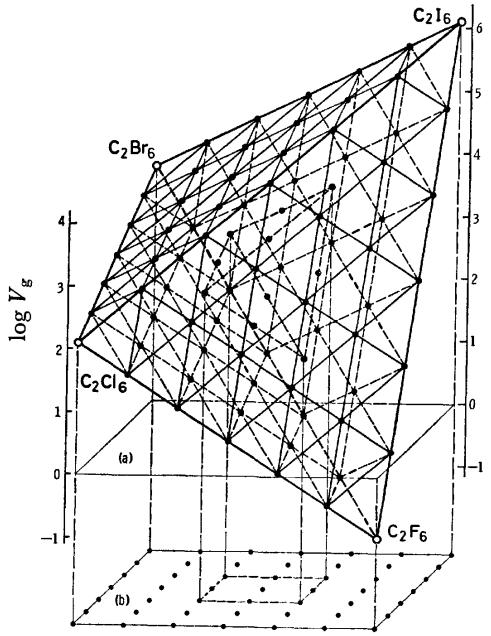

Fig. 2. Three dimensional diagram of the correlation between the logarithm of the specific retention volume and the halogen composition of $C_2F_{6-x-y-z}Cl_xBr_yI_z$.
(a): ground plane at log $V_g=0$.
(b): projection on a horizontal plane.

on the edges, while those which contain four kinds of halogens (*i.e.*, fluorochlorobromoiodocarbons) should be found along the edges of a smaller tetrahedron located inside (at the center) of the larger tetrahedron. The three-dimensional correlation diagram appears to be of analytical importance, since the order of elution or the relative difficulty of elution from a gas-chromatographic column can be predicted graphically for all the halocarbons. Such a correlation and relative order among these compounds can be retained at any temperature, although the absolute value of log V_g will be changed. Therefore, we may choose adequate column conditions for these compounds by

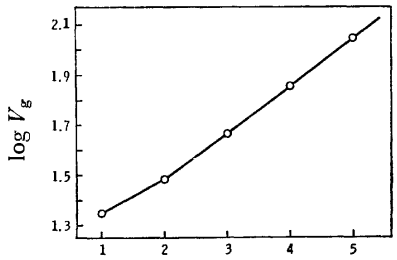

Fig. 3. Correlation between the logarithm of the specific retention volume and the number of carbon atoms in the series $C_nF_{2n-1}Cl_3$.

referring to the correlation diagram even if the log V_g—$1/T$ curves for all the compounds are not available.

In order to examine the dependence of log V_g on the number of carbon atoms, a series of $C_nF_{2n-1}Cl_3$ halocarbons (*i.e.*, $CFCl_3$, $C_2F_3Cl_3$, $C_3F_5Cl_3$, $C_4F_7Cl_3$, and $C_5F_9Cl_3$) are illustrated in Fig. 3. The log V_g value tends to increase with the number of carbon atoms, and the log V_g *vs.* carbon number curve apparently approaches a straight line as the number of carbon atoms increases. All other series of halocarbons C_nX_{2n+2} show similar behavior.

The present authors wish to thank Professor Nobufusa Saito for his encouragement and support.

Effects of HMPA in the Kharasch Type Reaction of Allylic Halides

Yoshihiro OHBE and Tsutomu MATSUDA

Department of Organic Synthesis, Faculty of Engineering, Kyushu University, Hakozaki, Higashi-ku, Fukuoka 812

(Received December 17, 1974)

Synopsis. Addition of HMPA was found to bring about an increase of cross-coupling products in the transition metal catalyzed reaction of allylic chlorides (allyl, crotyl, and methallyl) with Grignard reagents, the effect being most significant in copper (II) chloride catalyzed reactions.

In previous papers[1,2] it was shown that the Kharasch type reaction of an allylic halide with a Grignard reagent catalyzed by a transition metal halide resulted in the formation of a product mixture which could be understood by considering the following three processes (routes i, ii and iii), relative importance of the routes depending on the nature of an intermediate organometallic species and the structure of the Grignard reagent.

$$RMgX + MX_n \longrightarrow$$

$$\underset{\mathbf{A}}{R_nM} \longrightarrow R\text{-}R,\ R(-H),\ R(+H)$$

$$\underset{\mathbf{A}}{R_nM} \longrightarrow M^\circ$$

$$M^\circ + R'CH{=}CH\text{-}CH_2X \longrightarrow \underset{\mathbf{B}}{(R'\text{-}CH{=}CH\text{-}CH_2\text{-})_2M}$$

$$\mathbf{B} \xrightarrow{\text{i) } R''\underset{\displaystyle H}{C}HCH_2MgX} R'CH{=}CH\text{-}\underset{\displaystyle H}{C}H_2 + R''CH{=}CH_2$$

$$\mathbf{B} \xrightarrow{\text{ii) } RMgX} R'\text{-}CH{=}CH\text{-}CH_2\text{-}R$$

$$\mathbf{B} \xrightarrow{\text{iii) } R'\text{-}CH{=}CH\text{-}CH_2\text{-}X} (R'\text{-}CH{=}CH\text{-}CH_2\text{-})_2$$

and its isomers

Our previous studies were concerned mainly with the structure and behavior of the allylic metal intermediate (**B**).

The reactivity of a Grignard reagent can be considered as an important factor affecting the distribution of the products from allylic halide. The presence of an additive of strongly dative nature such as HMPA causes a considerable change in the reactions of Grignard reagents.[3]

We have examined the effect of HMPA in the Kharasch type reaction of allylic halides with the intention of increasing the selectivity of the reaction for obtaining cross-coupling products (route ii) by increasing nucleophilic activity of Grignard reagents.[4]

Results and Discussion

Table 1 shows the results obtained in the nickel (II) chloride catalyzed reactions of three typical allylic halides in the presence of two equivalents of HMPA to Grignard reagents, together with those without HMPA.

The effect of HMPA varies considerably with the type of halide. The product distribution from crotyl chloride was not influenced materially by the addition of HMPA except for a small increase in cross-coupling products. On the other hand, in the reaction with allyl chloride, a considerable decrease in the hydrogen transfer process (route i, formation of R(−H) and allyl (+H)) occurred accompanied by an increase in the cross-coupling product as well as R–R and homo-coupling products. A similar trend was observed with methallyl chloride to a lesser extent. The use of tetramethylethylenediamine (TMED) or dimethoxyethane (DME) produced a similar effect to that observed with HMPA, but resulted in a decrease in the total yield of products from methallyl chloride.

Dependence of the effect of HMPA on the type of catalyst was examined with methallyl chloride. The results are summarized in Table 2.

The use of one equivalent of HMPA in the presence of copper (II) chloride was found to be most effective for increasing the selectivity towards the cross-coupling process. The addition of HMPA seems to influence not only the reactivity of the Grignard reagents but also that of alkylmetal (**A**) and/or allylic metal intermediate (**B**).

It was found[5] that in the nickel(II) salt catalyzed

[ ]: Results in the absence of both catalyst and HMPA.

reaction of allyl chloride with *n*-butylmagnesium bromide, the addition of triethylphosphine or use of bis(triethylphosphine)nickel bromide gave rise to a considerable increase in *n*-octane (R–R, 40 and 56%) and the homo-coupling product (12 and 59%, respectively), but scarcely influenced the yield of the cross-coupling product. The fact that a decrease in the amount of HMPA to a half equivalent, still in a large excess over the catalyst (0.02 molar equivalent), resulted in a decrease in the effect of HMPA would help exclude the possibility. However, in an uncatalyzed reaction, HMPA acts to increase to some extent both the radical process (formation of R(—H) and R(+H)) and Wurtz type coupling.

The increase of the cross-coupling products throughout the catalyzed reactions can be rationalized by assuming that HMPA acts principally to increase nucleophilic activity of alkyl groups of the Grignard reagents, but does not influence β-hydrogen transfer (route ii). The effect of HMPA was hardly seen in the reactions of 2-cyclopentenyl- and 2-cyclohexenyl bromide (Table 3) which are known to produce preferentially cross-coupling products even without catalyst.

However, it is noticeable that the presence of HMPA serves to suppress the formation of cycloalkane and cycloalkene in the reactions with isopropylmagnesium bromide which is liable to cause β-hydrogen transfer (route i).

Experimental

Materials. Commercial organic halides (*n*-BuBr, EtBr, *n*-PrBr, *i*-PrBr, allyl-Cl, crotyl-Cl and methallyl-Cl) and additives (HMPA, TMEDA, and DME) were purified by distillation.

2-Cyclohexenyl bromide and 2-cyclopentenyl bromide were prepared by bromination of the corresponding cycloalkene by *N*-bromosuccinimide in CCl_4.

Reaction Procedure. A mixture of a Grignard reagent (0.05 mol) and an additive (0.1 mol) in ether was added to a suspension of a catalytic amount (0.25 mmol) of metallic halide in anhydrous ether under nitrogen. The mixture was stirred until the evolution of gas ceased (reaction A).

To the resulting solution, an equivalent amount of allylic halide (0.05 mol) in ether was added with vigorous stirring.

The mixture was then heated under reflux until the evolution of gas stopped (reaction B). The mixture was hydrolyzed in the usual manner. For crotyl chloride[1,2] and 2-cycloalkenyl bromide, the products were analyzed by gas chromatography with a 2 m column packed with Silicone 703 (20%)-Celite 545. For allyl chloride[1,2] and methallyl chloride, the ethereal solution containing an internal standard (cyclohexene) was directly injected onto a Golay column HB 2000, 45 m.

2-Methyl-1-hexene(R-Ally) and 2,5-dimethyl-1,5-hexadiene ($Ally_2$) were produced from methallyl chloride and 3-alkylcycloalkenes(R-Cyclo), respectively. 3-(2′-Cycloalkenyl)-cycloalkenes($Cyclo_2$) were formed from the 2-cycloalkenyl bromides. They were identified by comparison with authentic specimens obtained by the Wurtz coupling. No other isomers and products were detected. The composition of gaseous products obtained in reactions A and B was determined with a silica gel column (2 m) for methane and ethane, and a benzyl ether column (40%, 6 m) for other gaseous hydrocarbons.

The Synthesis of Flemichapparin-A and Its Derivatives

Shigetoshi YAMADA, Futara ONO, Takao KATAGIRI,* and Juntaro TANAKA*

Department of Industrial Chemistry, Junior College of Technology, Shizuoka University, Hamamatsu 432

**Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432*

(Received January 23, 1975)

Synopsis. Some chromenochalcones including Flemichapparin-A were synthesized in 53—63% yields from 6-acetyl-5,8-dihydroxy-2,2-dimethylchlomene and benzaldehydes.

Some chromenochalcones are naturally occurring compounds[1] and are expected to have some biological activities. Recently some papers on the synthesis of these compounds have appeared.[2]

The present authors have studied the synthesis of chromenochalcones, especially those which contain the isoprene skeleton in part.[3] These compounds contained Flemichapparin-A which was recently isolated from *Flemingia Chappar* Ham (Leguminosae). In this paper, we wish to report on these studies.

6-Acetyl-5,8-dihydroxy-2,2-dimethylchromene [IV] was obtained by the reaction of 2,4,5-trihydroxyacetophenone [III] with β-methylcrotonaldehyde [II] in pyridine.

The Claisen-Schmidt condensation of IV with various benzaldehydes (benzaldehyde, 2,4-dimethoxybenzaldehyde, 3,4-dimethoxybenzaldehyde and 4-methoxybenzaldehyde) gave chromenochalcones in 53—63% yields. Among these compounds, the data of I agreed with those of Flemichapparin-A.[1-c,2-d]

	R^1	R^2	R^3
[I]	H	H	H
[V]	OCH_3	H	OCH_3
[VI]	H	OCH_3	OCH_3
[VII]	H	H	OCH_3

Experimental

6-Acetyl-5,8-dihydroxy-2,2-dimethylchromene [IV]. β-Methylcrotonaldehyde (II, bp 39—40 °C/15 mmHg, 8.4 g, 0.1 mol) and 2,4,5-trihydroxyacetophenone (III, mp 198—200 °C, 8.4 g, 0.05 mol) were dissolved in pyridine (4.0 g, 0.05 mol) and were then heated with stirring at 150 °C for 10 hr. The reaction mixture was evaporated, and the residue was chromatographed on silica-gel. The fraction eluted by benzene afforded 6-acetyl-5,8-dihydroxy-2,2-dimethylchromene (IV, 58% yield) as yellow needles.

Mp 153—154 °C (recryst. from petroleum ether); IR (cm^{-1}, KBr disk): 3400 (-OH), 1640 (C=O), 1250 (-C-O-C-), 870 (penta substn. benzene); PMR (δ, $CDCl_3$): 1.50 (6H, s, $-C(CH_3)_2$), 2.49 (3H, s, $-COCH_3$), 5.28 (1H, broad s, -OH), 5.53 (1H, d, J=10.0 Hz, ), 6.70 (1H, d, J=10.0 Hz, ), 7.09 (1H, s, aromatic H), 12.60 (1H, s, -OH). Found C, 66.77; H, 6.03%. Calcd for $C_{13}H_{14}O_4$: C, 66.65; H, 6.02%.

Chromenochalcones. A solution of IV (234 mg, 0.001 mol) and benzaldehydes (0.001 mol) in ethanol (4 ml) was added, under cooling under nitrogen, to 2 g of KOH in methanol (4 ml). After the reaction mixture had then stood at room temperature for 3—5 days, dilution, acidification (with 5 ml of 0.1 M-HCl), extraction with ether, and chromatography on silica-gel eluted by *n*-hexane–AcOEt (95 : 5 v/v) afforded chromenochalcones, which were identified by means of IR, PMR, and elemental analysis.

2′,5′-Dihydroxy-3′,4′(5″,6″)2″,2″-dimethyl-α-pyranochalcone (I). Yield, 53%; mp 190—192 °C (orange plates). IR (cm^{-1}, KBr disk): 3400 (-OH), 1640 (C=O), 1240 (-C-O-C-), 970 (*trans* RHC=CHR), 760 (*cis* RHC-CHR). PMR (δ, $CDCl_3$): 1.54 (6H, s, $-C(CH_3)_2$), 5.60 (1H, d, J=10.0 Hz, ), 6.78(1H, d, 10.0 Hz, ), 7.20—7.70 (7H, m), 7.48 (1H, d, J=15.5 Hz, ), 7.90 (1H, d, J=15.5 Hz, ), 13.37 (1H, s, -OH). Found C, 74.18; H, 5.86%. Calcd for $C_{20}H_{18}O_4$: C, 74.52; H, 5.63%. The mp and PMR data agreed with that on Flemichapparin-A in the literature.[1-c] (lit,[1-c] mp 191—192 °C; PMR (δ, $CDCl_3$); 1.50, 5.58, 6.76, 7.20—8.00, 13.60).

2′,5′-Dihydroxy-2,4-dimethoxy-3′,4′(5″,6″)2″,2″-dimethyl-α-pyranochalcone (V). Yield, 63%, mp 214—215 °C (yellow plates). Photolysis of Aromatic Oxime Esters. Finding of Aromatic Substitution by Diphenylmethyleneimino Radicals

Hiroyuki OHTA and Katsumi TOKUMARU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received February 5, 1975)

Synopsis. Diphenylmethyleneimino radicals, $Ph_2C{=}N\cdot$, generated from photolysis of benzophenoxime benzoates undergo aromatic substitution on benzene as well as dimerization into azine. On the other hand, phenylmethyleneimino radicals, $PhCH{=}N\cdot$, generated from photolysis of benzaldoxime benzoate are oxidized to benzonitrile in preference to dimerization.

Recently increasing interest has been paid to photochemical behaviour of carbon-nitrogen double bond.[1] Our interest in free radicals containing carbon-nitrogen double bond moiety[2] led us to investigate generation and behaviours of imino radicals by conducting photolysis of aromatic oxime esters in benzene. Previously, Okada, Kawanisi and Nozaki reported that irradiation of aromatic ketoxime benzoates afforded the corresponding ketazines probably through combination of the intermediate ketimino radicals but benzaldoxime benzoate did not afford benzaldazine.[3] Vermes and Beugelmans reported that the irradiation of steroidal oxime esters gave their parent oximes and ketones.[4] We now add new findings to photochemistry of benzophenoxime benzoates and benzaldoxime benzoate in benzene to show that the ketimino radicals undergo, in addition to their dimerization into the ketazine, nuclear substitution on benzene, whereas the aldimino radicals are oxidized to benzonitrile in preference to their dimerization into benzaldazine.

Results and Discussion

Benzophenoxime benzoate (Ia), *p*-methoxybenzoate (Ib), *p*-chlorobenzoate(Ic) and benzaldoxime benzoate(II) were photolyzed in benzene with a 400 W high pressure mercury lamp through Pyrex wall under nitrogen or oxygen without any added sensitizer or with benzophenone or naphthalene. The volatile products were determined as summarized in Table 1.

Photolysis of Ia gave, along with benzophenone azine(III) (20%), benzophenone, biphenyl, phenyl benzoate, benzoic acid and *N*-(diphenylmethylene)-aniline(IVa). The presence of oxygen in the photolysis remarkably increased the yields of benzophenone and phenyl benzoate accompanied by decrease of the yields of IVa and biphenyl. These products are understood to arise from diphenylmethyleneimino radicals (V) or benzoxyl radicals generated by photochemical homolysis of nitrogen-oxygen linkage of Ia.

$$Ph_2C{=}NOCOAr\ (I) \xrightarrow{h\nu} Ph_2C{=}N\cdot\ (V) + ArCO_2\cdot$$

Ar: a, C_6H_5; b, *p*-$CH_3OC_6H_4$; c, *p*-ClC_6H_4

The resulting benzoxyl radicals undergo the established reactions. Thus, they undergo aromatic substitution induced by oxygen to afford phenyl benzoate[5] or decarboxylation into phenyl radicals which substitute

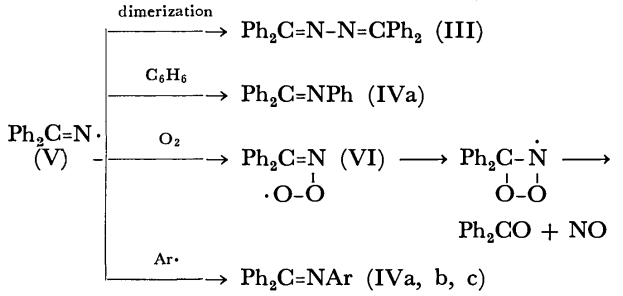
on benzene to give biphenyl and its yield is reduced under oxygen due to the consumption of phenyl radicals by oxygen.[6]

$$PhCO_2\cdot + C_6H_6 \rightleftharpoons PhCO_2C_6H_6\cdot \xrightarrow{O_2} PhCO_2C_6H_5$$

On the other hand, the imino radicals, V, arising from I either dimerize into the azine, III, or substitute on benzene to afford IVa, or give benzophenone.



In view that vinylic radicals react with oxygen resulting in the oxidative cleavage of their unsaturated bonds,[7] it is reasonable to suppose that an imino radical combines with an oxygen molecule to give peroxy radical (VI), which would undergo intramolecular addition followed by decomposition to give benzophenone and nitric oxide, though detection of nitric oxide was not attempted.[8] Formation of benzophenone in the irradiation under nitrogen could be attributable to either reaction of the imino radical with oxygen eventually present or hydrolysis of the resulting benzophenone imine benzoate[3] with water adventitiously present or possible rearrangement of Ia into oxaziridine followed by its cleavage.[4]

Production of the imine, IVa, from Ia is mostly ascribed to substitution of the imino radical on benzene not to recombination between the imino and phenyl radicals both generated from Ia, since irradiation of Ib and Ic in benzene also gave IVa along with negligible amount of *N*-(*p*-methoxyphenyl)imine(IVb) and *N*-(*p*-chlorophenyl)imine(IVc), respectively. So, it is clear that the geminate reaction between the imino radical and aryl radical arisen from I does not effectively take place.

In the irradiation of I, the presence of naphthalene, which was attempted to be used as a sensitizer, did not affect the products formation. However, use of benzophenone remarkably increased the yield of IVa and moderately increased the yield of biphenyl; thus, aromatic substitutions by the imino radicals and phenyl radicals seem to be promoted by the presence of benzophenone. This fact is not attributable to the action of benzophenone molecules in their ground state on cyclohexadienyl-type radicals resulting from the addition of the imino radicals or phenyl radicals on benzene molecules, since a control experiment showed that the presence of benzophenone in thermal decomposition of dibenzoyl peroxide in benzene did not increase the yield of biphenyl. Therefore, benzophenone in the excited state seems to be responsible for this effect.

Irradiation of II is now shown to afford benzonitrile as a main product. Production of biphenyl, benzoic acid together with the effect of oxygen to increase the yield of phenyl benzoate shows that II is also photolyzed through N–O bond cleavage like I. An observed effect of oxygen to promote the production of benzonitrile suggests that benzonitrile results from phenylmethyleneimino radicals(VII) through their hydrogen atom transfer with other radicals or oxygen molecules.[9]

$$PhCH{=}N\cdot\ (VII) + R\cdot \longrightarrow PhCN + RH$$

R·: $PhCO_2\cdot$, Ph· or O_2 *etc.*

A possibility that irradiation of II would give benzaldazine and its subsequent photolysis would give benzonitrile seems to be excluded on the basis that irradiation of II did not afford stilbene which would be produced from photolysis of benzaldazine.[9]

Experimental

Benzophenoxime benzoate (Ia), *p*-methoxybenzoate (Ib), *p*-chlorobenzoate (Ic) and benzaldoxime benzoate (II) were prepared according to literature.[10,11] Irradiation was carried out for 0.025 M benzene solution (400 ml) with a 400 W Riko high pressure mercury lamp. The reaction mixture was shaken with aqueous sodium hydrogen carbonate to extract benzoic acid and the remaining solution was used for product analysis. In vpc analysis with a Hitachi K53 gas chromatograph, benzonitrile and benzaldehyde were determined with a 4 m series of columns of silicone and polyethyleneglycol sebaciate at 160 °C, and biphenyl, benzophenone, phenyl benzoate and IVa were determined with a 6 m or 4 m column of silicone at 240 °C. Production of benzophenone azine was confirmed by its separation through column chromatography over silica gel.

A Convenient Synthesis of 2,3-Benzotropone from α-Tetralone by Ring-expansion

Masaru SATO, Takashi TANAKA, Josuke TSUNETSUGU, and Seiji EBINE

Department of Chemistry, Faculty of Science and Engineering, Saitama University, Urawa, Saitama 338

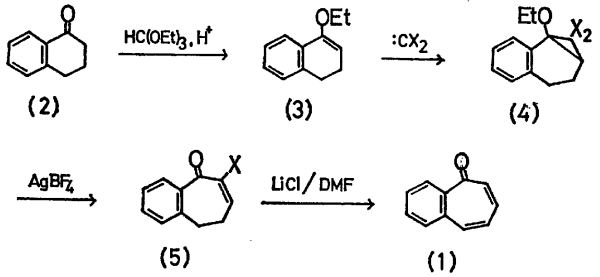
(Received February 6, 1975)

Synopsis. 2,3-Benzotropone (**1**) has conveniently been prepared from easily available α-tetralone (**2**) in good overall yield by the following successive reactions: dihalocarbene addition to enol-ether (**3**) derived from **2**, ring-expansion of the adduct (**4**) to halobenzocycloheptadienone (**5**), and dehydrohalogenation of **5** giving **1**.

2,3-Benzotropone (**1**) is synthesized from 2,3-benzosuberone *via* 7,7-dibromo-2,3-benzosuberone.[1] We now report an alternate method of synthesizing **1** from easily available α-tetralone (**2**) by ring-expansion by modification of Birch and co-workers' synthetic method for monocyclic tropone[2] and nezukone[3] from six-membered ring compounds.

α-Tetralone (**2**) was converted with ethyl orthoformate in the presence of an acid catalyst into 1-ethoxy-3,4-dihydronaphthalene (**3**) in excellent yield [IR(neat), 1636 cm^{-1} for olefinic double bond; NMR (CCl_4), δ 5.33 (t, 1H) for an olefinic proton, 4.32 (q, 2H) and 1.83 (t, 3H) for ethyl protons]. The enol-ether (**3**) reacted with dihalocarbene by Makosza's method[4,5] to give adducts (**4a**, X=Br and **4b**, X=Cl) in good yields (IR and NMR spectra showed the absence of olefinic structure). **4a** was treated with aqueous silver tetrafluoroborate in ethanol at room temperature overnight to give 7-bromo-2,3-benzocyclohepta-2,6-dien-1-one (**5a**)[1] in 79% yield. On the other hand, **4b** did not react at room temperature but reacted with silver tetrafluoroborate under reflux for 45 min in ethanol to give chloro-ketone (**5b**) (31% yield) and **1** (3% yield) along with recovery of the starting material (43%). On Birch and co-workers' synthesis of monocyclic tropones,[2,3] the corresponding seven-membered cyclic dienones were not isolated. The compounds **5a** and **5b** were dehydrohalogenated by the method of Holysz[6] to give **1** in 91 and 86% yields, respectively. Thus, the reaction sequence, **2**—**3**—**4a**—**5a**—**1**, can serve a convenient route for preparing **1** (45% over-all yield).

Reaction of **4a** and **4b** with silver tetrafluoroborate under reflux in ethanol and chromatographic separation of the reaction mixture gave **1** directly in 41 and 35% yields respectively, which also constitutes an additional convenient route to **1**.



a: X=Br, b: X=Cl

Experimental

*1-Ethoxy-3,4-dihydronaphthalene (**3**).* To a solution of α-tetralone (**2**) (20 g, 0.137 mol) and ethyl orthoformate (27.2 ml, 0.164 mol) in anhydrous alcohol (20 ml) was added a few drops of concentrated sulfuric acid. After refluxing for 30 min under nitrogen atmosphere, the solution was allowed to stand for 2 days at room temperature. The reaction mixture was basified with sodium ethoxide, and then evaporated under reduced pressure. The residue was chromatographed on alumina with elution of benzene to give 1-ethoxy-3,4-dihydronaphthalene (**3**) (20.2 g, 84.7%) as a colorless liquid, bp 100—101 °C/2 mmHg. Found: C, 82.86; H, 7.93%. Calcd for $C_{12}H_{14}O$: C, 82.77; H, 8.10%. IR(neat): 1636, 1250 and 1065 cm^{-1}; NMR(CCl_4): δ 1.83 (t, 3H, J=7 Hz), 2.52—2.90 (m, 2H), 3.07—3.33 (m. 2H), 4.32 (q, 2H, J=7 Hz), 5.33 (t, 1H, J=4.5 Hz), 7.40—7.7 (m, 3H) and 7.83—8.05 (m, 1H).

*Dibromocarbene Adduct (**4a**).* To a mixture of **3** (6.87 g, 0.04 mol), bromoform (7.0 ml, 0.08 mol) and triethylbenzylammonium chloride (0.15 g) was added 50% aqueous sodium hydroxide (14 ml) and the solution was stirred at 40 °C for 3 hr. The resulting solution was diluted with water and extracted with dichloromethane. The extract, after washing with water and drying over sodium sulfate, was evaporated and the residual oil was chromatographed on alumina with elution of benzene-hexane (1 : 1). The dibromocarbene adduct (**4a**) was obtained as a nearly colorless oil (10.2 g, 75%), which solidified on standing in a refrigerator. Recrystallization from ethanol gave colorless crystals, mp 61—62 °C. Found: C, 45.26; H, 4.38%. Calcd for $C_{13}H_{14}Br_2O$: C, 45.12; H, 4.08%. IR (KBr): 1053 cm^{-1}; NMR (CCl_4): δ 1.20 (t, 3H, J=7 Hz), 1.86—2.45 (m, 3H), 2.45—2.94 (m, 2H), 3.46 (q, 2H, J=7 Hz), 6.91—7.45 (m, 3H) and 7.52—7.81 (m, 1H).

*Dichlorocarbene Adduct (**4b**).* A mixture of **3** (3.5 g, 0.02 mol), chloroform (2.4 ml, 0.03 mol), 50% aqueous sodium hydroxide (3.8 ml) and triethylbenzylammonium chloride (170 mg) was stirred for 4 hr at 45 °C. The mixture was diluted with water, extracted with dichloromethane, the extract was dried over sodium sulfate, and evaporated. The residual oil was chromatographed on alumina to give the adduct (**4b**) (4.03 g, 78%) as a nearly colorless liquid, bp 118 °C/3.5 mmHg. IR (neat): 1061 and 895 cm^{-1}; NMR (CCl_4): δ 1.17 (t, 3H, J=7 Hz), 1.90—2.50 (m, 3H), 2.50—2.87 (m, 2H), 3.42 (q, 2H, J=7 Hz), 6.90—7.40 (m, 3H) and 7.50—7.70 (m, 1H). Found: C, 60.94; H, 5.46%. Calcd for $C_{13}H_{14}Cl_2O$: C, 60.72; H, 5.49%.

*Treatment of **4a** with Silver Tetrafluoroborate.* To a solution of silver tetrafluoroborate prepared from silver oxide (5.0 g, 0.022 mol), 42% fluoroboric acid (40 ml) and ethanol (80 ml) was added the dibromocarbene adduct (**4a**) (7.0 g, 0.020 mol), and the mixture was stirred at room temperature for 16 hr. The reaction mixture was poured into saturated aqueous sodium chloride to give a precipitate which was filtered and washed with dichloromethane thoroughly. The filtrate and the washings were combined and extracted with

dichloromethane. The extract was washed with aqueous sodium bicarbonate and with water, then dried over sodium sulfate, and evaporated. The residue was chromatographed on silica gel to give the starting substance (0.22 g, 3.1%), 7-bromo-2,3-benzocyclohepta-2,6-dien-1-one[1] (**5a**) (3.80 g, 79.4%), and an unknown oil A (0.52 g, ν_{CO} 1679 cm^{-1}). **5a** solidified on standing in refrigerator and recrystallized from ethanol to give pale yellow crystals, mp 39—40 °C.

When the same reaction was performed under refluxing for 2 hr, there resulted **5a** (0.19 g, 4%), **1** (1.28 g, 41%), an unknown oil B (0.50 g, ν_{CO} 1677 and 1713 cm^{-1}) and an unknown oil C (0.28 g, ν_{CO} 1728 cm^{-1}).

*Treatment of **4b** with Silver Tetrafluoroborate.* A solution of **3b** (1.80 g, 7 mmol) in ethanol (15 ml) was added to a solution of silver tetrafluoroborate prepared from silver oxide (1.85 g, 8 mmol) and 42% fluoroboric acid (15 ml), and the mixture was gently refluxed on a water bath for 45 min. After the same work-up as described in **4a**, the starting material (0.78 g, 43%), the chloro ketone (**5b**) (0.43 g, 31%) and **1** (0.05 g, 3%) were obtained. **5b** was a pale yellow oil. Found: C, 68.77; H, 4.60%. Calcd for $C_{11}H_9ClO$: C, 68.58;, H, 4.70%. IR (neat): 1661 (vs), 1613 and 1600 cm^{-1}. NMR (CCl_4): δ 2.47—2.80 (m, 2H), 2.90—3.18 (m, 2H), 7.0—7.5 (m, 4H) and 7.5—7.8 (m, 1H).

The 4 hr's refluxing of the solution of **4b** (1.56 g, 6 mmol), silver oxide (2.1 g, 9 mmol), 42% fluoroboric acid (16 ml) and ethanol (16 ml) gave **1** (0.33 g, 35%) and an unknown oil C (0.13 g).

*Dehydrobromination of **5a**.* A solution of **5a** (805 mg, 3.4 mmol), lithium chloride (4.2 g) in dimethylformamide (50 ml) and benzene (15 ml) was heated under nitrogen atmosphere. After the benzene was removed azeotropically (30 min), the solution was refluxed for one hr. It was poured into water and extracted with benzene. The extract was washed with water, dried over sodium sulfate, and evaporated. The residual oil was chromatographed on silica gel with benzene–ether eluent to give **1** (480 mg, 91%).

*Dehydrochlorination of **5b**.* Refluxing of a solution of **5b** (0.38 g, 2 mmol) and lithium chloride (2.5 g, 0.06 mol) in dimethylformamide (30 ml) for 2 hr under similar conditions followed by the same work-up as above gave **1** (0.27 g, 86%).

N-Alkyldiarylamines from 3-Alkyl-3-aryl-1-(2-carboxyphenyl)triazenes

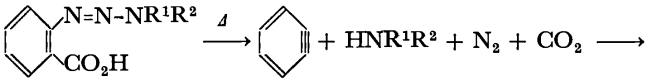
Jyuzo NAKAYAMA, Masayuki YOSHIDA, and Osamu SIMAMURA

Department of Chemistry, Faculty of Science, Tokyo University, Hongo, Tokyo 113

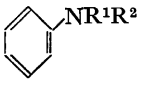
(Received December 24, 1974)

Synopsis. Heating 3-alkyl-3-aryl-1-(2-carboxyphenyl)triazenes in organic media afforded *N*-alkyldiarylamines in good yields, thus providing a useful synthetic route to this type of amines.

We have shown that 3-substituted 1-(2-carboxyphenyl)triazenes (I) are decomposed in boiling chlorobenzene in the presence of 2,3,4,5-tetraphenylcyclopentadienone to afford 1,2,3,4-tetraphenylnaphthalene, a benzyne adduct, in good yields,[1] while in the absence of the cyclopentadienone 1-(2-carboxyphenyl)-3,3-dimethyltriazene (I; $R^1=R^2=CH_3$) gave *N*,*N*-dimethylaniline (32%) and *N*-methyldiphenylamine (37%) the, products suggestive of the benzyne reaction with dimethylamine and *N*,*N*-dimethylaniline, respectively, in view of the work by Lepley and his co-workers.[2] Furthermore, heating 1-(2-carboxyphenyl)-3-methyl-3-phenyltriazene (Ia; $R^1=CH_3$, $R^2=C_6H_5$) gave *N*-methyldiphenylamine in 72% yield as the sole product. We, therefore, examined the formation of *N*-alkyldiarylamines (II) from 3-alkyl-3-aryl-1-(2-carboxyphenyl)triazenes (I) as a new synthetic route.

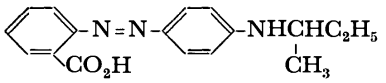


(I)

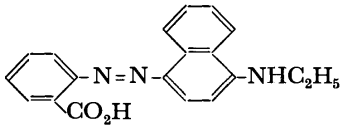


(II)

The triazenes (I) listed in Table 1 were prepared in excellent yields by diazotization of anthranilic acid by means of sodium nitrite and hydrochloric acid followed by treatment with potassium acetate and *N*-alkylarylamines. With *N*-*sec*-butylaniline and *N*-ethyl-1-aminonaphthalene, however, the azo-coupling reaction took place under the same reaction conditions, affording 4-(*sec*-butylamino)-2′-carboxyazobenzene (III) and 1-(2-carboxyphenylazo)-4-ethylaminonaphthalene (IV), respectively. Weakly basic amines such as diphenylamine and *N*-methyl-4-nitroaniline did not yield any amount of the expected triazenes (I).



(III)



(IV)

Decomposition of the triazenes (I) by heating in organic solvent under reflux gave *N*-alkyldiarylamines (II), and the results are summarized in Table 2. Generally, the yields of *N*-alkyldiarylamines (II) are satisfactory, but 1-(2-carboxyphenyl)-3-phenyltriazene[3] (I; $R^1=H$, $R^2=C_6H_5$) yielded, on being decomposed in boiling chlorobenzene, a mixture of chlorobiphenyls (69%), but no diphenylamine. Evidently, it decomposed homolytically in chlorobenzene to generate phenyl radicals, presumably *via* a diazocarboxylate (V).

a) Refl. stands for heated under reflux. b) By weighing the isolated material. c) 175/31 (Ref. 4). d) 150/13 (Ref. 4). e) 164/11 (Ref. 4). f) [87] (Ref. 5).

Thus, generally the triazenes (I) are prepared easily from diazotized anthranilic acid and appropriate *N*-alkylarylamines in excellent yields and decompose at moderate temperatures to give satisfactory yields of the amines (II); accordingly the present method provides a useful synthetic route to the amines (II), which are otherwise prepared by the alkylation of diarylamines.[4-6]

Experimental

3-Alkyl-3-aryl-1-(2-carboxyphenyl)triazenes (I). Anthranilic acid (13.7 g, 0.1 mol) was dissolved in a mixture of 200 ml of methanol and 25 ml of concentrated hydrochloric acid and diazotized by addition of a solution of sodium nitrite (6.9 g, 0.1 mol) in 15 ml of water at 0—5 °C. To the resulting diazonium solution were added 200 g of crushed ice, 20 g of powdered potassium acetate (0.2 mol), and an appropriate *N*-alkylarylamine (0.1 mol). The mixture was stirred for 1 hr at 0—5 °C and then for 30 min at room temperature. 3-Alkyl-3-aryl-1-(2-carboxyphenyl)triazene (I) was precipitated by adding 200 ml of water, collected, washed with water and recrystallized from benzene or ethanol.

4-(sec-Butylamino)-2'-carboxyazobenzene (III) and 1-(2-carboxyphenylazo)-4-ethylaminonaphthalene (IV). These azo-compounds (III and IV) were obtained when *N-sec*-butylaniline and *N*-ethyl-1-aminonaphthalene were used in the preparation of triazoles (I).

Compound III (Found: C, 68.44; H, 6.37; N, 14.42%. Calcd for $C_{17}H_{19}N_3O_2$: C, 68.66; H, 6.44; N, 14.13%), mp 156 °C, ν_{max} (KBr) 3370 (N-H), 2800—2300 (O-H), 1715 (C=O), and 828 (*p*-disubstituted benzene ring) cm^{-1}.

Compound IV (Found: C, 71.41; H, 5.47; N, 12.98%. Calcd for $C_{19}H_{17}N_2O_2$: C, 71.45; H, 5.37; M, 13.16%), mp 185—187 °C, ν_{max} (KBr) 3330 (N-H) and 1700 (C=O) cm^{-1}.

N-Alkyldiarylamines (II). A triazene (I, 10 g) was heated under reflux in 200 ml of solvent for several hr. On cooling, the reaction mixture was washed successively with 1 M sodium hydroxide, 1 M hydrochloric acid, and water and dried over anhydrous sodium sulfate. The solvent was removed under reduced pressure and the residue was purified by distillation or recrystallization. Elementary analyses and spectral data for new *N*-alkyldiarylamines (II, $PhNR^1R^2$) are shown below.

Compound IIe ($R^1=C_2H_5$, $R^2=p$-$CH_3C_6H_4$) (Found: C, 84.96; H, 7.87; N, 6.86%. Calcd for $C_{15}H_{17}N$: C, 85.26; H, 8.11; N, 6.63%), bp 106—108 °C/0.4 mmHg; NMR ($CDCl_3$) δ 1.15 (t, 3H), 2.15 (s, 3H), 3.66 (q, 2H), and 6.5—7.3 (m, 9H).

Compound IIf ($R^1=C_6H_5CH_2$, $R^2=p$-ClC_6H_4) (Found: C, 77.72;, H, 5.74; N, 4.90%. Calcd for $C_{19}H_{16}ClN$: C, 77.68; H, 5.49; N, 4.77%), mp 97—97.5 °C; NMR (CCl_4) δ 1.15 (t, 3H), 2.15 (s, 3H), 3.66 (q. 2H), and 6.5—7.3 (m, 9H).

Decomposition of 1-(2-carboxyphenyl)-3-phenyltriazene (I; $R^1=H$, $R^2=C_6H_5$) in chlorobenzene. A solution of the triazene (I, 0.62 g) in 50 ml of chlorobenzene was heated under reflux for 2 hr. The reaction mixture was washed successively with 1 M hydrochloric acid, 1 M sodium hydroxide, and water, and dried over anhydrous sodium sulfate. After removal of chlorobenzene under reduced pressure, the brown oily residue was subjected to column chromatography on silica gel. Elution with benzene afforded 0.29 g of chlorobiphenyl (69%), consisting of the *ortho* (55%) and a mixture (45%) of the *meta* and *para* isomers, as revealed by vpc analysis.

Synopsis. Interaction of an excited singlet state of terephthalonitrile with thiol is shown to be responsible for the title reaction on the basis of higher reactivity of terephthalonitrile relative to benzene and efficient quenching of fluorescene from terephthalonitrile by thiols.

We have shown that irradiation of mixtures of aromatic compounds and propanethiol tritiated at the S-H bond causes tritium uptake by the aromatic nucleus with distributions different from the results of substitutions by hydrogen ions and atoms.[1] In addition the rate of nuclear tritiation relative to benzene (k_{rel}) was found to be fairly high in benzonitrile and methyl benzoate (k_{rel}: 254 and 421, respectively). On the basis of these observations, the mechanism was proposed as involving a reaction of an excited aromatic molecule with propanethiol. The present paper describes the identification of light-induced hydrogen exchange reaction of terephthalonitrile with thiols and the determination of the excited state participating in the reaction.

When a solution of terephthalonitrile in benzene was irradiated with a high pressure mercury arc lamp under nitrogen atmosphere in the presence of *n*-pentanethiol-*d*, incorporation of deuterium occurs to an extent of 22% in the nucleus of terephthalonitrile recovered. With tritium labelled *n*-pentanethiol, tritiation took place in both the nuclei of terephthalonitrile and benzene, the relative rate of tritiation of terephthalonitrile (k_{rel}) being 3.8×10^3 and 4.1×10^3 (per C-H bond) in duplicate runs. The marked enhancement of the relative rate by introduction of one more cyano substituent into benzonitrile argues against that tritium atoms generated by photolysis of thiols contribute mainly to the exchange,[2] and involvement of an excited terephthalonitrile in the nuclear tritiation process is suspected. In this connection it is of interest to study on quenching of the excited singlet states of aromatic compounds by thiols.

TABLE 1. QUENCHING OF FLUORESCENCE FROM AROMATIC COMPOUNDS BY *n*-OCTANETHIOL IN AERATED BENZENE

Aromatic compound	$k_q\tau_s$, M^{-1}
Naphthalene	0.37
Anisole	9.38
Benzonitrile	36.7
Phthalonitrile	34.6
Isophthalonitrile	43.0
Terephthalonitrile	68.1

TABLE 2. QUENCHING OF TEREPHTHALONITRILE FLUORESCENCE BY THIOLS IN AERATED BENZENE

Thiol	$k_q\tau_s$, M^{-1}
n-Propanethiol	63.0
n-Pentanethiol	62.2
3-Methylbutanethiol	51.4
1-Methylbutanethiol	46.3
n-Octanethiol	68.1

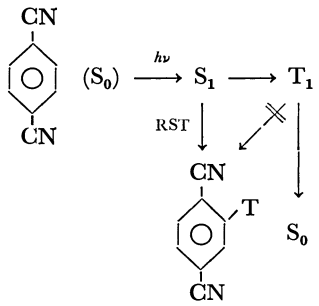
The fluorescence of aromatic compounds, such as benzonitrile and phthalonitriles, in benzene was quenched by the addition of *n*-octanethiol. Stern-Volmer plots of the reciprocal of relative fluorescence intensities against *n*-octanethiol concentrations were obtained for aromatic compounds; the slopes of these plots ($k_q\tau_s$) are presented in Table 1, where k_q is the rate constant for quenching of the excited singlet state of an aromatic compound by *n*-octanethiol and τ_s is the singlet lifetime of that aromatic compound. Similarly, the slopes ($k_q\tau_s$) obtained from the quenching of terephthalonitrile fluorescence by several thiols are given in Table 2.

It is notable, from Tables, that the slope ($k_q\tau_s$) is pronounced in benzonitrile and phthalonitriles in accord with their high rate of the tritiation reaction, while it is only slightly affected with respect to the structure of thiols. From the quenching of terephthalonitrile fluorescence by oxygen ($k_q\tau_s$: 289 M^{-1}) the terephthalonitrile singlet lifetime under air (τ_s) was obtained to be 1.3×10^{-8} s by assuming that the quenching rate by oxygen[3] is diffusion-controlled (1.5×10^{10} M^{-1} s^{-1}).[4] As the observed slope ($k_q\tau_s$) for terephthalonitrile is 68.1 M^{-1}, this leads to an estimate for k_q of 5.2×10^9 M^{-1} s^{-1}, which is higher than k_q of naphthalene, 2×10^7 M^{-1} s^{-1}, obtained from $k_q\tau_s$ of 0.37 M^{-1} and τ_s (aerated) of 1.5×10^{-8} s.[5] The result shows that *n*-octanethiol is an effective quencher of the excited singlet state of terephthalonitrile with the quenching rate constant near to the diffusion controlled one.

In order to examine a possibility that the triplet state of terephthalonitrile would interact with thiols, attempts have been made to observe the effect of *n*-pentanethiol on the triplet lifetime (τ_T) of terephthalonitrile. A convenient way of determining τ_T in solution at room temperature has often been to apply flash spectroscopy, but such a method was not applicable due to a failure in observing T-T absorption of the triplet state in the case of terephthalonitrile. A rewarding approach results from the measurement of the terephthalonitrile phosphorescence lifetime in EPA at 77 K, in which τ_T (1.6 s) is unaffected in the presence of high concentration of *n*-pentanethiol (1.1 M).

Thus, the tritiation from the triplet state appears to be improbable.

From all these results it is conceivable that interaction of the singlet excited terephthalonitrile with the ground state thiol is responsible to induce the hydrogen isotope exchange.



Experimental

Deuterium Exchange with Terephthalonitrile. A mixture of terephthalonitrile (1.57 mmol) and *n*-pentanethiol-*d* (16.5 mmol) in 30 ml of benzene was irradiated under nitrogen atomosphere for 20 hr with a 400 W high pressure mercury arc lamp. After removal of benzene and the thiol under reduced pressure, the residue was subjected to dry chromatography on silica gel. Elution with benzene gave 20 mg of the dinitrile. Deuterium included in the dinitrile was determined from its NMR spectrum in $CDCl_3$ using 1,4-dimethoxybenzene as an internal standard, reference being made to that of the authentic sample.

Tritium Exchange with Terephthalonitrile. A mixture of tritiated *n*-pentanethiol (0.992 mmol, 2.35×10^{12} dpm/mmol) and terephthalonitrile (0.499 mmol) in 10 ml of benzene was placed in a Pyrex tube, degassed by the usual chill and thaw cycles, and irradiated for 10 hr with a 1 kW high pressure mercury arc lamp using a merry-go-round photochemical reactor (RIKO Rotary Photochemical Reactor, Model RH 400-10W). After the irradiation, *n*-pentanethiol was removed by washing with aqueous sodium hydroxide and water. The amount of the dinitrile in the mixture (95 and 85% of the starting dinitrile for duplicate runs) was estimated by vpc on a 2 m column containing 10% XF 1150 on Chromosorb P at 200 °C. Benzene was recovered from the mixture by fractional distillation. To the residue 500 mg of the non-radioactive dinitrile was added and the combined dinitrile was purified by means of recrystallization until reproducible specific activities were obtained. The benzene distillate was washed further with aqueous basic hydrogen peroxide to remove traces of the radioactive thiol and submitted to tritium assay. Tritium activity was measured with a Packard Tri-Carb liquid scintillation spectrometer Model 3380. Each sample was counted for a period sufficient to reduce the randam error to 1% or less.

Quenching Studies. Fluorescence and phosphorescence spectra were recorded on a Hitachi fluorescence spectrophotometer MPF-2A.

Synthesis of Acyl Derivatives of β-Lysine for Peptide Synthesis

Tateaki WAKAMIYA, Hiroshi URATANI, Tadashi TESHIMA, and Tetsuo SHIBA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

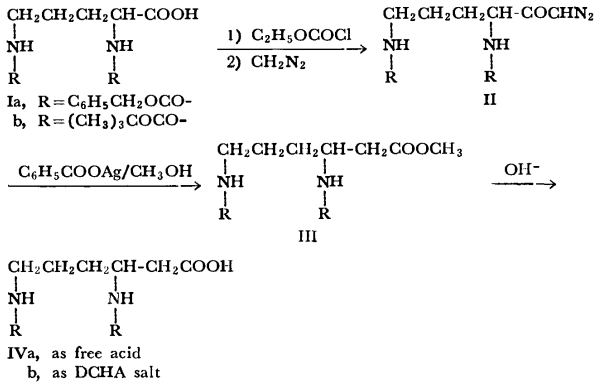
(Received May 17, 1975)

Synopsis. Dibenzyloxycarbonyl- and di-*t*-butyloxycarbonyl-L-β-lysine were synthesized from corresponding diacyl-L-ornithine by modified Arndt-Eistert reaction involving diazoketone preparation *via* the mixed carbonic carboxylic anhydride. These diacyl-β-lysine derivatives are required for total- or semi-syntheses of peptide antibiotics, tuberactinomycins or streptothricins.

β-Lysine had been first found as a naturally occurring amino acid in the hydrolyzate of viomycin,[1] and thereafter isolated from streptolin,[2] streptothricin,[3] and similar antibiotics. In our recent studies on tuberculostatic peptide, tuberactinomycins, the presence of this amino acid was confirmed in tuberactinomycin B, *i.e.* viomycin, and also in tuberactinomycin O.[4]

Synthesis of the amino acid had been achieved by van Tamelen *et al.* for the purpose of a determination of its chemical structure.[2,3] In their method, N^{α},N^{δ}-diphthalyl-L-ornithine was elongated by Arndt-Eistert reaction and then hydrolyzed to 3,6-diaminohexanoic acid, *i.e.* β-lysine. In the course of this reaction, two amino groups had to be blocked with phthalyl group for the complete protection against a possible change with the acid chloride reagent which was used in the preparation of the diazoketone. On the other hand, benzyloxycarbonyl or *t*-butyloxycarbonyl group is preferable from a standpoint of the peptide synthesis where easily removable protecting groups are required. If the use of the acid chloride can be avoided by application of the mixed carbonic carboxylic anhydride method for the preparation of acylaminodiazoketone as in the case of simple diazoketones,[5] those alkyloxycarbonyl type protections may be employed instead of phthalyl group. Actually, Penke *et al.* synthesized several diazoketones from benzyloxycarbonyl or *t*-butyloxycarbonyl amino acid using the mixed anhydride method or dicyclohexylcarbodiimide method.[6] More recently, Ondetti *et al.* prepared *t*-butyloxycarbonyl derivative of 3-amino-4-phenylbutyric acid by Arndt-Eistert reaction employing the mixed anhydride method from *t*-butyloxycarbonylphenylalanine. This derivative had been further used to a synthesis of the β-amino acid peptide.[7] In the present paper, $N^{\beta},N^{\varepsilon}$-dibenzyloxycarbonyl- and $N^{\beta},N^{\varepsilon}$-di-*t*-butyloxycarbonyl-L-β-lysine were synthesized based on the same principle of combination of the protecting group and the mixed anhydride method (Scheme 1). These compounds are important starting materials for synthetic studies of tuberactinomycins and streptothricins containing β-lysine residues.

N^{α},N^{δ}-Dibenzyloxycarbonyl-L-ornithine (Ia) and N^{α},N^{δ}-di-*t*-butyloxycarbonyl-L-ornithine (Ib) were first converted to their ethoxycarbonic anhydrides in the presence of *N*-methylmorpholine or triethylamine. The mixed anhydrides were immediately allowed to react with diazomethane for the preparation of diazoketones(II). Following Wolff rearrangement in methanol gave acyl-β-lysine methyl esters (III) as crystals, which were successfully saponified to their acid derivatives (IV).



Scheme 1.

Preparation of such diacyl-β-lysine opened a way to the semi-synthesis of tuberactinomycin analogues. Thus, as reported in our recent study, dialkyloxycarbonyl-L-β-lysine 1-succinimidyl esters were coupled with tuberactinamine N, a cyclic peptide moiety isolated from tuberactinomycin N by selective liberation of the branched γ-hydroxy-β-lysine with acid treatment, and then diacyl groups were removed under mild conditions.[8] Synthetic tuberactinomycin O thus obtained was identical with natural compound in all respects. Consequently, dibenzyloxycarbonyl- or di-*t*-butyloxycarbonyl-L-β-lysine newly prepared *via* modified Arndt-Eistert reaction from the corresponding diacyl-L-ornithine proved to be very useful derivatives for syntheses of its peptides.

Experimental

All melting points are uncorrected. The specific rotations were measured with a Perkin-Elmer 141 polarimeter.

$N^{\beta},N^{\varepsilon}$-Dibenzyloxycarbonyl-L-β-lysine Methyl Ester (IIIa). N^{α},N^{δ}-Dibenzyloxycarbonyl-L-ornithine[9] (4.00 g, 0.01 mol) was dissolved in 200 ml of ethyl acetate and the solution was cooled on ice-salt bath. To a cold solution, *N*-methylmorpholine (1.11 g, 0.011 mol) and ethyl chloroformate (1.20 g, 0.011 mol) were added under stirring. After 3 hr, precipitated amine hydrochloride was rapidly filtered off in the cold. Then diazomethane in ether was added to the filtrate and stirred at 0 °C overnight. Excess diazomethane was removed by warming at 50 °C and thereafter the reaction mixture was evaporated *in vacuo*. Oily diazoketone* thus

* When oily product was stored in refrigerator, diazoketone was crystallized. Recrystallization from ethyl acetate and *n*-hexane gave pale yellow needles, mp 79—80 °C or 93—94 °C (polymorphism). Found: C, 62.20; H, 5.70; N, 13.12%. Calcd for $C_{22}H_{24}O_5N_4$: C, 62.25; H, 5.70; N, 13.20%. Since the diazoketone was generally unstable, oily product was immediately used for next Wolff rearrangement.

obtained was dissolved in 80 ml of methanol, and silver benzoate (0.50 g, 0.002 mol) in 5 ml of triethylamine was added. The mixture was stirred overnight in the dark and then concentrated *in vacuo*. The residue was dissolved in ethyl acetate and insoluble material was filtered off. The filtrate was washed with saturated sodium hydrogencarbonate solution, saturated sodium chloride solution, 1 M hydrochloric acid, and then finally saturated sodium chloride solution to neutral. Organic layer was dried over anhydrous sodium sulfate and evaporated *in vacuo*. Crystalline residue was recrystallized from ethyl acetate and *n*-hexane, yield 3.64 g (85%), mp 105—107 °C, $[\alpha]_D^{15}$ −5.0° (*c* 0.3, dimethylformamide).

Found: C, 64.38; H, 6.59; N, 6.58%. Calcd for $C_{23}H_{28}O_6N_2$: C, 64.47; H, 6.59; N, 6.54%.

N^{β},N^{ε}-*Di*-t-*butyloxycarbonyl*-L-*β-lysine Methyl Ester (IIIb).* N^{α},N^{δ}-Di-*t*-butyloxycarbonyl-L-ornithine(Ib)** was derived to IIIb in a similar way *via* its diazoketone (IIb)*** except the use of citric acid solution in place of hydrochloric acid for washing. Methyl ester (IIIb) was obtained in a 86% yield, mp 60—61 °C, $[\alpha]_D^{25}$ −5.8° (*c* 1, dimethylformamide).

Found: C, 56.47; H, 8.89; N, 7.80%. Calcd for $C_{17}H_{32}O_6N_2$: C, 56.64; H, 8.95; N, 7.77%.

N^{β},N^{ε}-*Dibenzyloxycarbonyl*-L-*β-lysine (IVa).* Methyl ester IIIa (0.86 g, 2 mmol) was dissolved in a small amount of dioxane and 1.5 ml of 1.5 M aqueous sodium hydroxide was added. After stirring at 0 °C for 30 min and then at room temperature for 1 hr, the reaction mixture was diluted with water, and extracted with ethyl acetate. Aqueous layer was acidified with 1 M hydrochloric acid and extracted with ethyl acetate. Organic layer was washed with saturated sodium chloride solution to neutral and dried over anhydrous sodium sulfate. The extract was concentrated *in vacuo* to give IVa, which was recrystallized from ethyl acetate, in a yield of 0.68 g (82%), mp 155 °C, $[\alpha]_D^{15}$ +1.0° (*c* 1, dimethyl formamide).

Found: C, 63.79; H, 6.36; N, 6.78%. Calcd for $C_{22}H_{26}O_6N_2$: C, 63.75; H, 6.32; N, 6.76%.

N^{β},N^{ε}-*Di*-t-*butyloxycarbonyl*-L-*β-lysine (IVb).* Corresponding methyl ester IIIb (0.90 g, 2.5 mmol) was dissolved in 3 ml of methanol and 2 ml of 1.5 M aqueous sodium hydroxide was added. The reaction mixture was treated as in the preparation of IIIa except use of citric acid for acidification. Oily product was crystallized as dicyclohexylammonium salt which was recrystallized from ether and *n*-hexane, 1.18 g (89%), mp 106—107 °C, $[\alpha]_D^{25}$ −3.5° (*c* 1, 95% ethanol)

Found: C, 62.93; H, 10.19; N, 7.73%. Calcd for $C_{28}H_{53}O_6N_3 \cdot 1/2\ H_2O$: C, 62.65; H, 10.14; N, 7.83%.

** N^{α},N^{δ}-Di-*t*-butyloxycarbonyl-L-ornithine was prepared by acylation of L-ornithine hydrochloride with *t*-butyl azidoformate[10] or *t*-butyl 4,6-dimethylpyrimidyl-2-thiol carbonate[11] in the usual manner, and the yield was 77% and 87%, respectively. Mp 120—121 °C, $[\alpha]_D^{20}$ −6.0° (*c* 1, dimethylformamide). Found: C, 54.23; H, 8.49; N, 8.34%. Calcd for $C_{15}H_{28}O_6N_2$: C, 54.20; H, 8.49; N, 8.43%.

*** Diazoketon (IIb) crystallized as well as in the case of IIa. It was recrystallized from ethyl acetate and *n*-hexane. Mp 114—115 °C, $[\alpha]_D^{23}$ −43.1° (*c* 1, dimethylformamide). Found: C, 53.71; H, 7.92; N, 15.66%. Calcd for $C_{16}H_{28}O_5N_4$: C, 53.91; H, 7.92; N, 15.72%.

Di-*tert*-butyl Thioketone

Atsuyoshi OHNO, Kaoru NAKAMURA, Yukio NAKAZIMA, and Shinzaburo OKA
Institute for Chemical Research, Kyoto University, Uji, Kyoto-fu 611

(Received April 12, 1975)

Synopsis. Di-*tert*-butyl thioketone, a new aliphatic thioketone, has been prepared and its IR and UV spectral properties are studied.

Chemistry of thiocarbonyl compounds has been described on the bases of information mostly obtained from studies on aromatic thioketones, thionesters, and thioamides,[1] where the thiocarbonyl group is more or less resonance-participated by substituents. Information obtained from these compounds, therefore, may not be universal for the thiocarbonyl group and, before the description on the chemistry of thiocarbonyl compounds is generalized, it is desirable to study the chemistry of aliphatic thioketones.

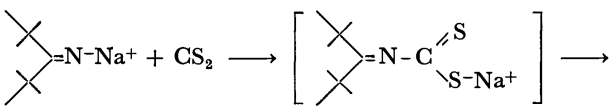
Aliphatic thioketones, however, have been the subject of little attention, because they are, generally, unstable. Namely, they are quite sensitive to air and, when possible, tautomerization to the corresponding enethiol is very fast.[1,2]

In this article, we wish to report synthesis and spectral properties of di-*tert*-butyl thioketone, **1**.

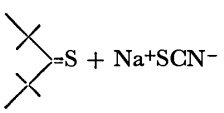
General procedure to synthesize an aliphatic thioketone employs acid-catalyzed reaction of the corresponding ketal with hydrogen sulfide or, less frequently, the reaction of a ketone with phosphorous pentasulfide.[1,2a] However, these procedures cannot be applied to the present system because of its inertness to S_N2-type reactions as well as difficulty to obtain the starting materials themselves.

Results and Discussion

Preparation. The thioketone, **1**, was prepared from sodium salt of di-*tert*-butyl ketimine, **2**[3] and carbon disulfide after Ahmed and Lwowski.[4] Since the intermediate, **3**, is stable enough to be dissolved in water,



2 **3**



1

excess carbon disulfide and other organic impurities can be extracted with ether from the water layer before **3** decomposes to the final product. This procedure is more effective than fractional distillation to obtain **1** in high purity. That is, it is difficult to obtain the product in purity of higher than 97% after twice extractions and repeated fractional distillations, whereas repeated extractions (more than several times) until the water layer becomes colorless makes it possible to improve the purity as high as 99.9% by single fractional distillation. The purity was determined by vpc.

Although the overall yield of the reaction product is 34%, the yield of the thioketone by the addition of carbon disulfide to **2** can be calculated to be about 80%, since the yield of the latter compound is reported to be 43%.[3] The reaction temperature should be kept below −10 °C during the addition of carbon disulfide in order to improve the yield of the thioketone.

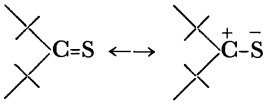
Detailed procedure will be described in Experimental Section.

Spectra. IR spectrum of **1** has an absorption at 1115 cm^{-1} due to $\nu_{C=S}$. The corresponding oxygen analog shows the absorption at 1686 cm^{-1} for $\nu_{C=O}$.[5] The ratio, $\nu_{C=O}/\nu_{C=S}$, is 1.52. Thioacetone, isopropyl methyl thioketone, and diisopropyl thioketone, exibit their $\nu_{C=S}$ at 1269, 1250, and 1240 cm^{-1}, respectively,[6] and their corresponding oxygen analogs show their $\nu_{C=O}$ at 1719,[7] 1719,[7] and 1716 cm^{-1},[5] respectively. The ratios, $\nu_{C=O}/\nu_{C=S}$, for these pairs are 1.35—1.38. The value for pairs of aromatic thioketones and ketones also falls in this range.[8] Thus, the frequency of the >C=S stretching vibration in **1** is extraordinally shifted toward the value as low as those of thioamides (1140± 80 cm^{-1}),[9] where the thiocarbonyl group has large single-bond character.[10]

Absorption maxima in electronic spectra of **1** are listed in Table 1 together with those of other aliphatic thioketones so far reported.[11]

As has been recognized from the IR spectrum, the energy level of the C–S π-orbital in **1** is much higher than those of other thioketones, whereas the absorption maximum for the π-π^* transition of this thioketone appears at normal position. This fact indicates that the energy level of the C-S π^*-orbital in **1** is lifted up as high as that of the π-orbital. On the other hand, the energy for the n-π^* transition of **1** is much lower (1300 cm^{-1}) than those of other thioketones, which indicates that the energy level of the n-orbital is more lifted up than the π^*-orbital in this thioketone. This is an unusual phenomenon in the sense that the energy level of a π^*-orbital is more affected than that of an n-orbital by electronic nature of substituents in ketones[12] and thioketones.[13] Present results may suggest larger steric effect of *tert*-butyl groups in **1** than that in di-*tert*-butyl ketone.

The results, consequently, may be best interpreted by allotting the largest contribution of the canonical structure **1b** for the structure of **1**.[14]



1a **1b**

Table 1. Electronic spectra of aliphatic thioketones

Thioketone	Solvent[a]	n → σ		π → π*		n → π*

a) E, Ethanol: C, Cyclohexane.

Experimental

*Preparation of Di-*tert*-butyl Thioketone (1).* A suspension of 7 g (0.3 mol) of finely divided sodium metal in 50 ml of petroleum ether was stirred under an atmosphere of nitrogen, while 16.6 g (0.2 mol) of pivalonitrile was added to this suspension over a period of 1 hr. The temperature was kept between 25 and 30 °C. The mixture was stirred for additional 15 min and was filtered under an atmosphere of nitrogen to remove unreacted sodium. The filtrate was cooled with an ice-salt bath and stirred, while 10 ml of carbon disulfide was added dropwise over a period of 1 hr. When carbon disulfide is added dropwise to the solution of **2**, the yellow color of the solution turned from dark to pale. Stirring was continued for additional 2 hr at room temperature, then 150 ml of water was added and the mixture was washed with ether (80 ml×5). The water layer was stood overnight at room temperature, whereas di-*tert*-butyl thioketone appeared as a red oil, which was separated from the water layer and the latter was extracted with ether. The red oil and the extract were combined and dried over calcium chloride. Distillation gave the thioketone (5.4 g) in 34% yield; bp 70.5—71.5 °C (18 Torr). NMR $\delta_{CCl_4}^{TMS}$ 1.43 (singlet).

Found: C, 67.85; H, 11.42; S, 20.50%. Calcd for $C_9H_{18}S$: C, 68.28; H, 11.46; S, 20.25%.

The purity of **1** was determined by vpc on Hitachi Perkin-Elmer F6 instrument (Golay column BDS 45 m, 80 °C, FID). The peak-area for **1** was compared to that of an unknown impurity contaminating.

Spectroscopy. The IR spectrum was recorded on Hitachi EPI-S2 with 2.5% CCl_4 solution. The electronic spectra were recorded on Shimadzu UV-200.

ESR Studies of Phenoxyl Radicals Produced by the PbO_2 Oxidation of Hindered Polyphenols. III. *p*- and *m*-Phenylene-bisgalvinoxyls, Stable Triplets

Kazuo MUKAI

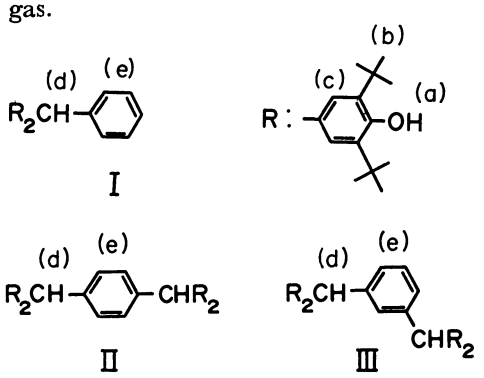
Department of Chemistry, Faculty of Science, Ehime University, Matsuyama 790

(Received February 10, 1975)

PbO_2 oxidation of two hindered polyphenols produced, in turn, primary, secondary, and ternary radicals. The ternary radicals are π-conjugated biradicals; the structures of the radicals were assigned to be *p*- and *m*-phenylenebisgalvinoxyls. Both zero field splitting parameters and hyperfine splitting constants were determined from ESR spectra.

PbO_2 oxidation of 4-substituted 2,6-di-*t*-butylphenols in organic solvents produces the corresponding phenoxyl radicals, which are known as "hindered phenoxyls". The magnetic properties of these phenoxyls in solution have been extensively studied with the aid of the electron spin resonance (ESR) spectra.[1]

The galvinoxyl radical is a well known stable phenoxyl radical, which can be separated as a pure solid with 100% radical concentration.[2-4] This radical shows some anomalous magnetic properties in the solid state.[4,5] Phenylgalvinoxyl (I-S) (see Fig. 1(a)) has an electronic structure similar to galvinoxyl, and exhibits a stability approaching that of galvinoxyl.[6] These radicals can be prepared from their diphenylmethane precursors, 3,3',5,5'-Tetra-*t*-butyl-4,4'-dihidroxydiphenylmethane and 3,3',5,5'-Tetra-*t*-butyl-4,4'-dihydroxydiphenylphenylmethane (phenol (I)), by their PbO_2 oxidation in 2-MeTHF under vacuum or nitrogen gas.



We have prepared two other *para*- and *meta*-phenylenebis(diphenylmethane) precursors (phenols (II) and (III)) which are related to phenol (I), and have succeeded in synthesizing the corresponding π-conjugated biradicals, *para*- and *meta*-phenylenebisgalvinoxyls (II-T) and (III-T) (see Figs. 1(b) and (c)).

The study of interelectronic interactions in organic π-conjugated biradicals has been of interest in recent years. However, the number of the stable π-conjugated biradicals reported are very limited: only about ten, as far as we know, including three of the phenoxyls.[7-9]

Experimental

3,3',5,5'-Tetra-t-butyl-4,4'-dihydroxydiphenylphenylmethane (phenol (I)). Phenol (I) was prepared according to the procedure used by Coffield *et al.*[10] 2,6-di-*t*-butylphenol (0.1 mol, 20.6 g) and benzaldehyde (0.1 mol, 10.6 g) were dissolved in 20 ml of ethanol in a three-necked flask, and a solution of KOH (6.6 g in 15 ml of ethanol) was added gradually under an atmosphere of nitrogen. The deep green solution was stirred overnight at 20 °C, and the solids were filtered out. The crude product was then taken up in ether to remove the potassium benzoate. Removal of the ether left a white crystalline solid, and this was recrystallized twice from ethanol, mp 164.0—164.5 °C (lit, mp 161—163 °C); UV spectrum (λ_{max}=278 nm, log ε=3.54, λ_{max}=286 nm, log ε=3.53 in *n*-hexane); NMR spectrum ($H^a\delta$=4.92 ppm (2), H^b 1.39 (36), H^c 6.80 (4), H^d 5.26 (1), H^e 6.98, 7.06, 7.16, 7.23 (total 5); δ in CCl_4 with TMS as internal standard).

para-Phenylene-bis(3,3',5,5'-Tetra-t-butyl-4,4'-dihydroxydiphenylmethane) (phenol (II)). 2,6-Di-*t*-butylphenol (15.2 g, 0.074 mol) and terephthalaldehyde (5.0 g, 0.037 mol) were dissolved under an atmosphere of nitrogen in 33 ml of ethanol under stirring, and a solution of KOH (4.8 g in 10 ml of ethanol) was added slowly. The color of the reaction mixture changed gradually from yellow to green at 30 °C. The reaction was continued overnight at 30 °C, and finally some white solids were precipitated in the viscous deep blue reaction mixture. The solids were filtered off and washed with ethanol. Then they were taken up in ethyl ether, washed with water, and dried over anhydrous sodium sulfate. After removal of the ethyl ether, the white solids were recrystallized first from benzene, second from *p*-xylene, and finally washed twice with acetone, mp 290—292 °C; Found: C, 83.07; H, 10.09%. Calcd for $C_{64}H_{90}O_4$: C, 83.24; H, 9.82%; UV spectrum (λ_{max}=278 nm, log ε=3.97, 284 nm; log ε=3.93 in tetrahydrofuran); NMR spectrum ($H^a\delta$=4.87 ppm (4), H^b 1.33 (72), H^c 6.80 (8), H^d 5.21 (2), H^e 6.94 (4); δ in CCl_4 with TMS as internal standard).

meta-Phenylene-bis(3,3',5,5'-Tetra-t-butyl-4,4'-dihydroxydiphenylmethane) (phenol (III)). Phenol (III) was synthesized by condensation of 2,6-di-*t*-butylphenol with isophthalaldehyde in KOH–ethanol solution under an atmosphere of nitrogen at 35 °C, following a method similar to that used with phenol (II). The reaction was continued for three days under stirring. The white solids obtained were recrystallized first from ethanol and second from methanol–acetone, giving white silky needles, mp 223.0—224.0 °C; Found: C, 83.06; H, 10.10%. Calcd for $C_{64}H_{90}O_4$: C, 83.24; H, 9.82%. UV spectrum (λ_{max} =277nm, log ε=3.82; 285 nm, log ε=3.80 in *n*-hexane); NMR spectrum (H^a δ=4.86 ppm (4), H^b 1.31 (72), H^c 6.73 (8), H^d 5.20 (2), H^e 6.84, 6.98, 7.07, 7.14 (total 4); δ in CCl_4 with TMS as internal standard).

Measurements. All the ESR measurements were carried out using a JES-ME-3X spectrometer equipped with a Takeda-Riken microwave frequency counter. ESR hyperfine splittings and *g*-values were measured relative to those of $(KSO_3)_2$-

Table 1. Hyperfine splittings (in G), fine structures (D) (in G), and g-values of phenoxyl radicals

Radical	Primary (P)			Secondary (S)		Ternary (T)		
	a_β^H	a_m^H	g-value	a_m^H	g-value	a_m^H	g-value	D
I	8.44	1.71	2.0044_4	1.34	2.0044_0	—	—	—
II	8.53	1.67	2.0044_3	1.34	2.0044_3	0.69	2.0044_5	20.0
III	8.74	1.68	2.0044_4	1.33	2.0044_2	0.69	2.0044_3	26.1

NO ($a^N=13.05\pm0.03$ G; $g=2.0054$[11]).

The NMR spectra were taken on a JEOLCO 4H-100 (100 MHz) nmr spectrometer.

Magnetic susceptibility measurements were carried out using a Shimadzu MB-2 type magnetic torsion balance.

Results and Discussion

An initial slight oxidation of the phenols (I)—(III) with PbO_2 in 2-MeTHF in a sealed, degassed system gives ESR spectra consisting of a doublet-triplet splitting. We assign the spectra to primary phenoxyl radicals (I-P), (II-P), and (III-P) formed from the parent phenols by abstraction of a phenolic hydrogen atom. The large doublet splittings in the primary radicals are clearly due to the *para* methylene group and the triplet splittings are explained by the *meta* hydrogens. The values of hyperfine splittings are listed in Table 1.

The spectrum due to radical (I-P) changes rapidly with time. Almost as soon as it was observed, a further quintet due to a secondary radical (I-S) was seen growing in the center of the spectrum, and this, after further oxidation, dominated the spectrum. The phenols (II) and (III) show similar behavior. The structure of the secondary radical (I-S), named phenylgalvinoxyl, is shown in Fig. 1(a); those from phenols (II) and (III) are analogous to those from phenol (I). The spectrum of (I-S) is shown in Fig. 2(a). The quintet splitting of the secondary radicals ($a^H=1.33$—1.34 G)[12] may be explained by four equivalently interacting hydrogens in the *meta* position.*

Phenylgalvinoxyl (I-S) is very stable and appears to be capable of existing for many days in 2-MeTHF in the absence of oxygen. The spectrum remains unchanged upon further oxidation. On the other hand, in the case of phenols (II) and (III), as the oxidation process proceeds, the five-line well resolved spectra of the secondary monoradicals begin to overlap with each other; finally, these are completely altered to a nine-line spectra with an equivalent splitting distance, as

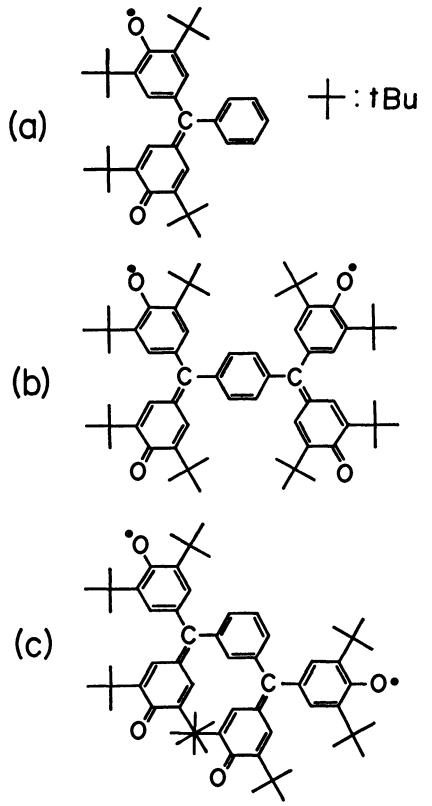


Fig. 1. Molecular structures of phenoxyl radicals. (a) Phenylgalvinoxyl (I-S). (b) *para*-Phenylenebisgalvinoxyl (II-T). (c) *meta*-Phenylenebisgalvinoxyl (III-T).

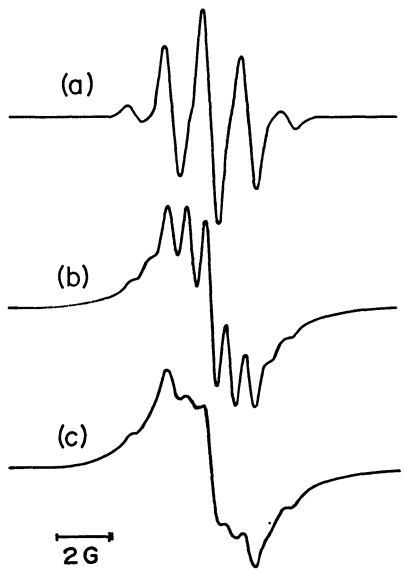

Fig. 2(a). First-derivative ESR spectrum observed for the monoradicals, (I-S), (II-S), and (III-S), produced by the PbO_2 oxidation of phenols (I-III) in 2-MeTHF.

Fig. 2(b) and (c). ESR spectra observed for the biradicals, (II-T) and (III-T), produced by the further oxidation of (II-S) and (III-S) in 2-MeTHF.

* In a recent ENDOR investigation, two kinds of hyperfine splittings due to *meta* ring protons are observed at −80 °C for this radical ($a^H_{m\text{-}1}=1.363$ G, $a^H_{m\text{-}2}=1.282$ G). T. Yamamoto, M. Kohno, T. Miyamae, K. Mukai, and K. Ishizu, *Chem. Lett.*, **1972**, 681.

shown in Fig. 2(b) and (c). These spectra, which consist of nine considerably overlapped lines, were unchanged at the lowest concentration at which they could be detected. Thus, they are thought to be due to the eight *meta* ring protons of phenoxyl biradicals, *p*- and *m*-phenylenebisgalvinoxyls ((II-T), a_m=0.69 G; (III-T), a_m=0.69 G). The structures of these biradicals are shown in Figs. 1(b) and (c).

When the solution containing the biradicals (II-T) and (III-T) is frozen into a rigid glass (77 K), one can observe some dipolar splittings, as are shown in Fig. 3(a) and (b). These spectra at 77 K can be interpreted on the basis of a randomly-oriented set of triplets with axial symmetry; thus the values of the dipolar splitting, D, are 20.0 G for the biradical (II-T) and 26.1 G for the biradical (III-T), as one half of the outer two lines' splitting.

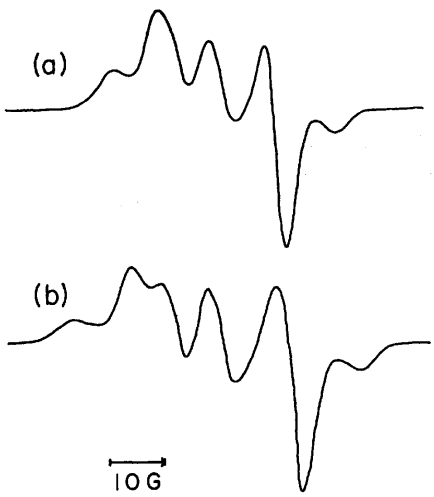

Fig. 3(a). ESR spectrum of the biradical (II-T) in 2-MeTHF at 77 K.
Fig. 3(b). ESR spectrum of the biradical (III-T) in 2-MeTHF at 77 K.

These small splittings may be explained by the large separation between the two galvinoxyl rings and the small unpaired spin density on the centered phenylene ring and the two carbon atoms bonded to the ring.**

The observed increase in the splitting constants, D(III-T)>D(II-T), is consistent with the structure. Using a model of two-point dipoles, that is, the relation $D=(3/2)g\mu_B r^{-3}$, the average interelectronic distances in the biradicals (II-T) and (III-T) are calculated to be 11.2 Å and 10.2 Å, respectively. The relative intensity of the central singlet varied with the samples, that is, with the radical concentration of the samples. A zero-field splitting of D=110 G has been reported for the bisgalvinoxyl biradical.[8] The calculated average interelectronic distance, using a model of two point dipoles, is about 6.3 Å. The comparison of the average interelectronic distances of 6.3 Å for bisgalvinoxyl and 11.2 Å for *p*-phenylenebisgalvinoxyl indicates that the two point dipole model is still acceptable for bisgalvinoxyl, because the length of the centered-phenylene ring is about 4.3 Å.

The ESR results for a 2-MeTHF solution of the secondary radicals (I—III-S) obtained from phenol (I—III) at room temperature consist of a five-line, well-resolved (a_m^H=1.33—1.34 G) spectra. On the other hand, the ESR measurements of the two phenoxyl biradicals in a rigid solution at 77 K indicate that a triplet state exists in these radicals. If there is a strong scalar exchange interaction, J, between the two electrons such that $J \gg a_m^H$, the spectrum will consist of 9 lines separated by $a_m^H/2$, corresponding to an interaction with 8 equivalent protons.[13] In fact, the ESR spectra of the phenoxyl biradicals (II-T) and (III-T) in 2-MeTHF show nine lines of equivalent hyperfine splittings (a_m^H=0.69 G), respectively. The poorer resolution in the biradical (III-T) with respect to the biradical (II-T) may be due to a larger dipolar interaction in the former. These circumstances are very similar to those of verdazyl[14-16] and tetrazolinyl[17] biradicals, which have a π-electron system related to that of *p*- and *m*-phenylenebisgalvinoxyl radicals; each of them has π-conjugated monoradical halves linked by *para* and *meta* positions of a central phenylene π-bridge, and shows comparatively small zero-field splittings (about 38—53 G).

Recent studies of magnetic susceptibilities of *p*- and *m*-phenylenebisverdazyl biradicals have showed the presence of a triplet ground state (S=1) in these biradicals.[18] The intramolecular positive exchange integrals, J/k, of these biradicals are much greater than 300 K. The magnetic susceptibility of Yang's biradical, known as a stable phenoxyl radical and possessing three-fold symmetry, follows the Curie-Weiss law with a paramagnetic Curie constant of 1.0 K·emu/mol and a Weiss constant of −4 K.[19] This susceptibility also suggests that an intramolecular pure triplet approximation is reliable in the temperature region below 300 K. On the other hand, the results of the paramagnetic shift of the bisgalvinoxyl show that this radical has a singlet ground state with a negative exchange integral of 93 K.[20] The comparison of the electronic structures in *para* and *meta* phenylenebisverdazyls and bisgalvinoxyls and the smaller dipole-dipole interaction in the latter suggest a smaller exchange interaction in the latter.

Phenyl-galvinoxyl is rather stable and Ley *et al.*[6] succeeded in isolating it as a solid with an 85% spin concentration. In an attempt to clarify the level scheme of the spin system of these biradicals, preliminary experiments were performed for making the biradical solids of (II-T) and (III-T) by the PbO_2 oxidation in THF and in ethyl ether, respectively, under nitrogen gas, following the method of Kharasch and Joshi.[2] Spin concentrations were obtained from the results of the paramagnetic susceptibility measurements at room temperature, after correcting for the diamagnetic contribution calculated by the Pascal method. The values were 64% for (II-T) and 68% for (III-T) as S=1/2, N=2N_0, assuming the Curie law. These low observed concentrations are probably due to both

** The orbital containing the unpaired electron of phenyl-galvinoxyl has, at least in the Hückel approximation, a node in the phenyl ring. Ref. C. Besev, A. Lund, T. Vänngård, and R. Håkansson, *Acta Chem. Scand.*, **17**, 2281 (1963).

diamagnetic and monoradical impurities in the individual samples, since it is difficult to oxidize these hindered polyphenols until the final biradicals, owing to their insolubility in ordinary solvents. In addition, these radicals are not as stable as galvinoxyl. Despite the low concentrations, at least the presence of two unpaired electrons per molecule has been confirmed for these radicals from the susceptibility measurements.

We wish to thank Professor Kazuhiko Ishizu and Professor Yasuo Deguchi for their helpful discussions. We also wish to express our gratitude to Mr. L. R. deAlvare for his kind help in preparing the manuscript. We are grateful to Mr. Taizi Itoh for the synthesis of phenol (III).

The Structure of the Cyclodextrin Complex. I. The Crystal and Molecular Structure of the α-Cyclodextrin-*p*-Iodoaniline Complex

Kazuaki HARATA

Research Institute for Polymers and Textiles, Sawatari 4, Kanagawa-ku, Yokohama 221

(Received February 17, 1975)

The crystal structure of the α-cyclodextrin–*p*-iodoaniline complex [$(C_6H_{10}O_5)_6 \cdot C_6H_6NI \cdot 3H_2O$] has been determined by the X-ray method. The space group is $P2_12_12_1$ with unit cell dimensions of $a=13.659(2)$, $b=15.413(3)$, and $c=24.486(5)$ Å. The structure was solved by the heavy-atom method and refined by least-squares techniques. The final *R*-value was 0.072. The *p*-iodoaniline molecule is included in the cavity with its axis coincident with the axis of α-cyclodextrin; the iodobenzene group is situated in the cavity, while the amino group sticks out from the cavity. The shortest contact between the α-cyclodextrin molecule and the "guest" *p*-iodoaniline molecule is 3.25 Å, indicating that the latter is rigidly fixed in the cavity of the former. The distances between the amino group and the hydroxyl group are greater than 4.0 Å; this fact well explains why the catalytic ability of α-cyclodextrin is low in the hydrolysis of *para*-substituted phenyl esters.

Cyclodextrins, which are cyclic α-1,4-linked D-glucose oligomers, form a number of inclusion compounds both in crystalline states and in an aqueous solution with a variety of "guest" molecules,[1-3] such as paraffins, alkyl halides, halogens, and aromatic compounds. X-Ray analyses of the α-cyclodextrin complex with potassium acetate,[4] iodine,[5] and water[6] have proved that the "guest" molecule is included in the cavity of α-cyclodextrin.

Cyclodextrins catalyze the hydrolysis of phenyl esters.[7] Bender and his co-workers suggested[8] that the hydrolysis occurs when the phenyl group is bound in the cavity of cyclodextrins and that the relative rates of reactions are controled by the stereo-specific complexing ability. The evidence for the formation of the inclusion compounds with aromatic molecules has been obtained from NMR,[9] kinetic,[10] and X-ray[2] studies, but the geometry of inclusion is yet unknown. The present paper will deal with the detailed crystal and molecular structure of the α-cyclodextrin–*p*-iodoaniline-(α-CDx-*p*-IAN) complex. A short communication has already been published.[11]

Experimental

Crystals of the α-CDx–*p*-IAN complex were prepared by mixing of a hot aqueous solution containing 10% α-CDx with *p*-IAN. They are colorless prisms elongated along the a-axis. The space group was determined by an inspection of the Weissenberg and oscillation photographs. The density was measured by the flotation method in a mixture of carbon tetrachloride and tetrabromoethane. The unit cell parameters and intensities were measured on a Rigaku AFC four-circle diffractometer with a specimen with dimensions of $0.2\times0.4\times0.7$ mm, using a graphite monochromatized Mo*K*α radiation ($\lambda=0.70926$ Å) and the ω-scanning mode. During the data collection the crystal turned blue, but no significant intensity change in the standard reflections was observed. 5007 independent reflections were obtained up to 50° in 2θ. No correction was made for absorption and extinction. The crystal data are shown in Table 1.

Table 1. Crystal data

$(C_6H_{10}O_5)_6 \cdot C_6H_6NI \cdot 3H_2O$	
Molecular weight	1245.9
Crystal system	Orthorhombic
Space group	$P2_12_12_1$
Z	4
Cell dimensions	$a=13.659(2)$Å
	$b=15.413(3)$
	$c=24.436(5)$
Cell volume	5144.4 Å^3
Density	$D_o=1.602$ g·cm^{-3}
	$D_x=1.610$

Determination and Refinement of the Structure

The crystal structure of the α-CDx-*p*-IAN complex was solved by the heavy-atom method using 1171 reflections with $2\theta\leqq30°$. The position of the iodine atom was deduced from a Patterson synthesis. An outline of the structure of the complex was obtained

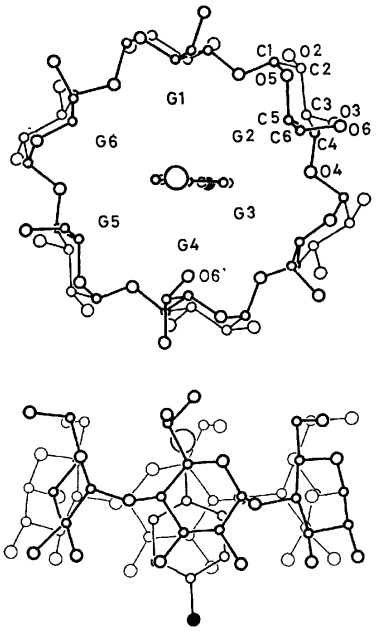

Fig. 1. Structure of the α-cyclodextrin–*p*-iodoaniline complex. The circles, in order of decreasing size, represent iodine, oxygen, and carbon atoms, and the black dots indicate nitrogen atoms.

TABLE 2. ATOMIC COORDINATES AND ANISOTROPIC TEMPERATURE FACTORS ($\times 10^4$) WITH STANDARD DEVIATIONS

The temperature factor expression used was $\exp[-(h^2B_{11}+k^2B_{22}+l^2B_{33}+hkB_{12}+klB_{23}+lhb_{31})]$.

from an electron density map calculated with the phases based on the iodine atom; the positions of the *p*-IAN molecule and six glucose residues were located, but the least-squares refinement of the atomic parameters was unsuccessful. The positions and orientations of the *p*-IAN molecule and six glucose residues except O(6) atoms were refined by the block-diagonal rigid-body least-squares technique.[4] The O(6) atoms and water molecules were found on a difference-Fourier map. The refinement was continued by the block-diagonal least-squares method. In these refinements, two of the oxygen atoms, G4O(6) and WO(3), were found to be disordered. The occupancies were estimated by assuming that the magnitude of the isotropic thermal factor of an occupant is the same as that of the other. They are 0.35, 0.65, 0.60, and 0.40 for G4O(6), G4O(6′), WO(3), and WO(3′) respectively. The final *R*-value was 0.072. The weighting schemes are as follows: $w=0.0$ for $F_o<3\sigma(F)$, and $w=1.0$ for $F_o\geq 3\sigma(F)$. The anomalous dispersion terms were ignored. The atomic scattering factors were taken from the "International Tables for X-ray Crystallography."[12] The atomic coordinates and the anisotropic temperature factors are listed in Table 2. The observed and calculated structure factors are listed in Table 4.[13] The computation was done on a HITAC 8450 computer in this Institute.[14]

Results and Discussion

Conformation of Glucose Residues. The structure of the α-CDx–*p*-IAN complex is illustrated in Fig. 1 with the absolute configuration corresponding to D-glucose. The average bond distances and angles in the glucose residues are normal (Fig. 2), varying in the ranges of ±0.05 Å and ±3° respectively (Table 3[13]). The valence angles of the α-1,4-linking oxygen atoms are 119—121°. These rather large angles are commonly observed in the α-CDx complexes: 118.8—119.4° in the potassium acetate complex, 116—122° in the iodine complex, and 116.2—119.4° in the water complex. In di-saccharides, α,α-trehalose[15] and β-maltose[16] give 115.8° and 117.2° respectively.

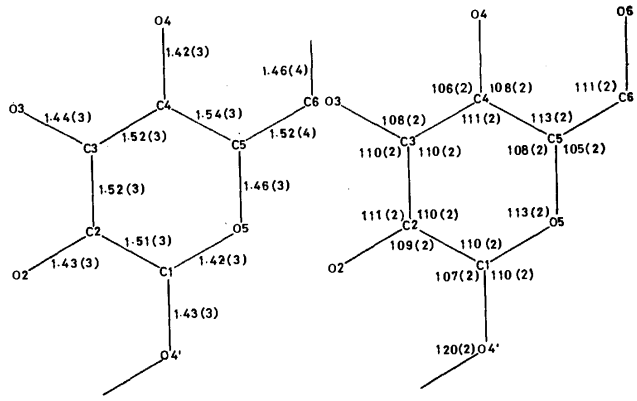

Fig. 2. Average bond distances and angles for the D-glucose residues with standard deviations.

Each glucose residue has the C1-chair conformation. The conformation angles around the pyranose ring vary from 45° to 66°. This range is similar to that found in the α-CDx–iodine complex (45—66°),[5] although it is rather wider than that of 52—66° in the α-CDx-potassium acetate complex,[4] that of 49—65° in the α-CDx-water complex,[6] and those found in di- and tri-saccharides.[15,17,18] In the G4 residue, the primary hydroxyl group takes two orientations: G4O(6) and G4O(6′). The former corresponds to a *gauche-gauche* conformation, and the latter to a *gauche-trans* conformation (Table 5). A similar disorder of the O(6) atom has been found in 1-kestose.[18] Both of those conformations have been found in the α-CDx-water complex, but in the α-CDx-potassium acetate complex the *gauche-gauche* conformation is not found because of the molecular packing and hydrogen bonds.

The macro-cyclic conformation of the α-CDx ring is described by the conformation angles including C(1)-O(4*)-C(4*) linkages. The C(1)-O(4*)-C(4*)-C(3*) and C(1)-O(4*)-C(4*)-C(5*) conformation angles are 123—132° and 104—115° respectively, while in the α-CDx-water complex they are 116.6—170.4° and

G3O(4)–BC(6)	3.63	G6C(3)–BC(2)	3.91

69.3—129.7° respectively. This suggests that the α-CDx ring becomes more symmetrical when a bulky group is included. The six O(4) atoms are near the least-squares plane as is shown in Table 6. The r.m.s. displacement of the atoms from the plane is 0.10 Å, compared to that of 0.13 Å in the α-CDx-iodine complex. The distance between the O(2) and O(3) atoms of adjacent glucose residues corresponds to the acceptable one for the hydrogen bond (Table 7).

Structure of p-*Iodoaniline.* The bond distances and angles of *p*-IAN are shown in Fig. 3. The I–C(1) distrance is in agreement with that of 2.09 Å found in *o*-iodobenzonitrile.[19] The N–C(4) distance is longer than that of 1.371 Å in *N,N*-dimethyl-*p*-nitroaniline[20] and that of 1.358 Å in *p*-nitroaniline.[21] The planarity of *p*-IAN is good, as is shown in Table 6.

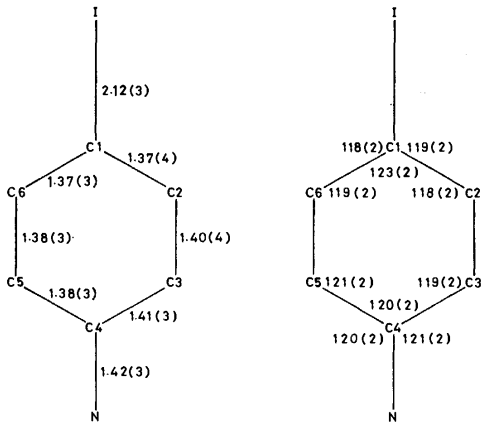

Fig. 3. Bond distances and angles with standard deviations in *p*-iodoaniline.

Geometry of Inclusion. As is shown in Fig. 1, the *p*-IAN molecule is included in the cavity of α-CDx, although the amino group sticks out. This suggests that the cavity is hydrophobic in nature and that α-CDx binds the hydrophobic portion of *p*-IAN. Selected intramolecular distances in the complex are shown in Table 7. The shortest interatomic distance of 3.25 Å, which is the distance between G2O(4) and BC(6), suggests that the "guest" molecule is rigidly fixed in the cavity. The iodine atom and G4O(6′) are in van der Waals contact. The amino nitrogen atom

is apart more than 4.0 Å from any atom in α-CDx.

Crystal Structure. The crystal structure is shown in Figs. 4 and 5. The packing scheme of α-CDx is depicted in Fig. 6. Molecular layers composed of α-CDx are stacked along the b-axis in the crystal. The cavities of α-CDx do not form continuous channels which are found in the α-CDx-potassium acetate complex, since adjacent layers are each slipped by about half a molecule along the c-axis. The *p*-IAN molecule is so bulky that the amino group sticks out from the open end of the cavity. In the iodine and water complexes, the "guest" molecule is enclosed in the cavity, both ends of which are closed by the adjacent α-CDx molecules.

Intermolecular distances of less than 3.0 Å are shown in Table 8. Although the hydrogen atoms are not located, O···O and O···N distances less than 3.0 Å are taken as hydrogen bonds since the C-O···O and C-O···N angles are in the usual range for hydrogen bonds. The hydrogen-bonding network is formed in the crystal. The nitrogen atom forms hydrogen bonds with G2O(2) and G5O(6) in the adjacent layer. WO-(1) forms hydrogen bonds with G4O(6), G3O(2), G6O(6), and WO(3), while both WO(3) and WO(3′) are hydrogen-bonded to G2O(6) and G5O(2). WO-(2), which is separated from the other water molecules, is hydrogen-bonded to G3O(6) and G1O(6).

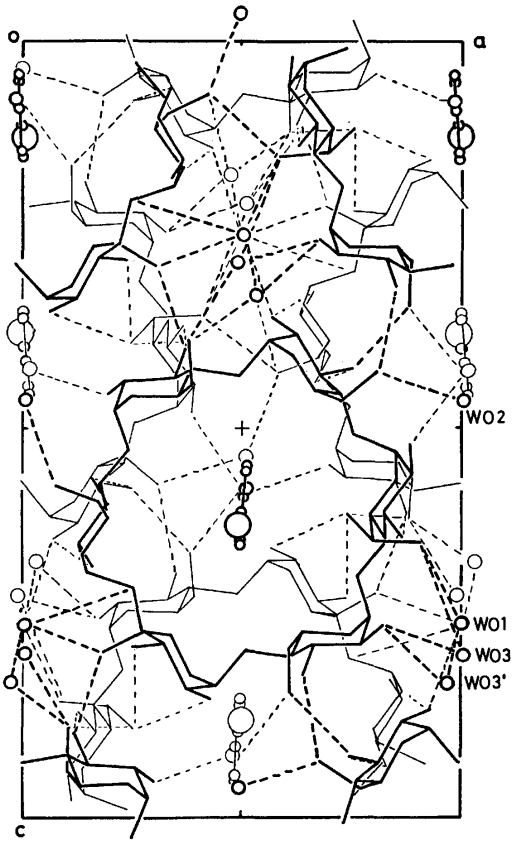

Fig. 4. Crystal structure viewed along the b-axis. Atoms represented by circles are those in *p*-iodoaniline and water molecules, and dashed lines indicate intermolecular distances less than 3.1 Å.

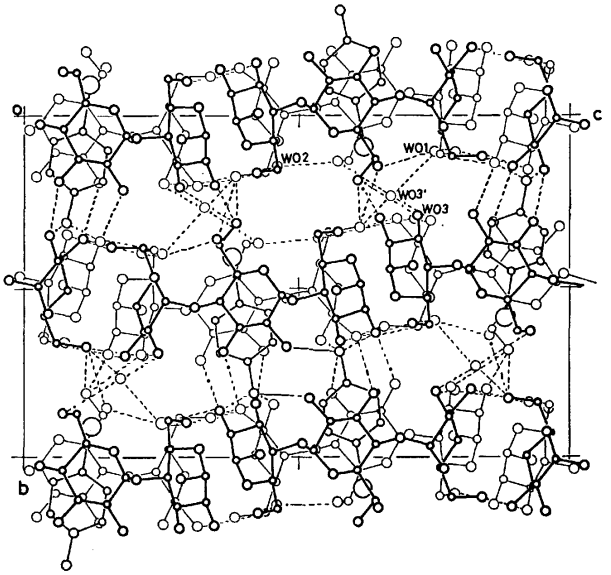

Fig. 5. Crystal structure viewed along the a-axis. Dashed lines indicate intermolecular distances less than 3.1 Å.

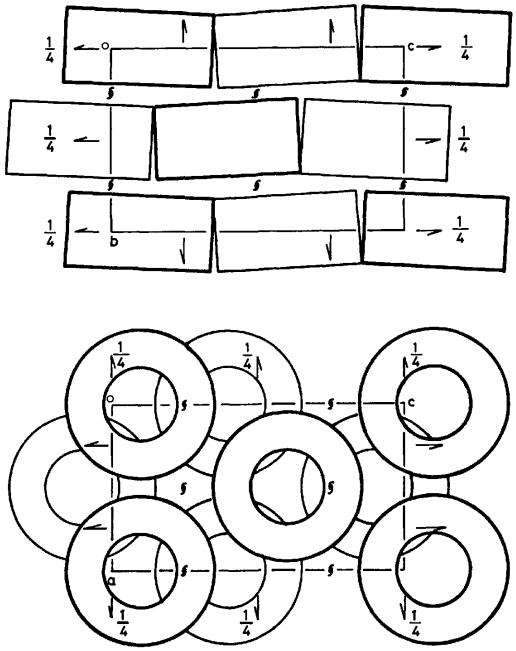

Fig. 6. The packing shemes of α-CDx in the crystal.

Between the layers, G1O(2), G1O(3), and G2O(3) form hydrogen bonds with G3O(2), G3O(3), and G4O(3) respectively.

Catalytic Property of α-Cyclodextrin. The cyclodextrin-catalyzed reactions have been interpreted in terms of the formation of inclusion compounds as intermediates. In the α-CDx-water complex, two of the primary hydroxyl groups of α-CDx have the *gauche-trans* conformation and form hydrogen bonds with water molecules in the cavity. In an aqueous solution, α-CDx seems to have a similar structure.[6] The cavity of α-CDx will release the water molecules when a "guest" molecule is included. Furthermore, the α-CDx ring will become more symmetrical and the *gauche-trans* conformation may turn to the *gauche-gauche* conformation, as in the iodine and *p*-IAN complexes.

It has been proved that the secondary hydroxyl group of α-CDx are catalytically reactive in the hydrolysis of substituted phenyl esters, and that the relative rates of the hydrolysis of *meta*-substituted phenyl esters are about 10^2 times faster than that of *para*-substituted phenyl esters. The structure of the α-CDx-*p*-IAN complex suggests that the hydrolysis of *para*-substituted phenyl esters will hardly occur if a substrate is included in the same manner as that of the *p*-IAN complex, since the distance between the secondary hydroxyl groups of α-CDx and the amino group of *p*-IAN is greater than 4.0 Å. On the other hand, *meta*-substituted phenyl esters must be in close contact with the secondary hydroxyl groups, judging from the inspection of molecular models, so the reaction will occur readily.

The author wishes to thank Professor J. Tanaka and Dr. H. Uedaira for their useful discussion.

The Crystal Structure of a Hofmann-en Type Pyrrole Clathrate, *catena*-μ-Ethylenediaminecadmium(II) *catena*-Tetra-μ-cyanonickelate(II)-Pyrrole (1/2)

Toschitake IWAMOTO and Mamoru KIYOKI

Department of Chemistry, College of General Education, The University of Tokyo, Komaba, Meguro, Tokyo 153

(Received April 24, 1975)

The crystal structure of the titled pyrrole clathrate $Cd(NH_2CH_2CH_2NH_2)Ni(CN)_4\cdot 2C_4H_5N$ has been determined from three-dimensional X-ray data collected by counter techniques. The clathrate crystallizes in the orthorhombic space group Pmmm with $a=7.618(3)$, $b=7.641(10)$, $c=7.861(4)$ Å, $Z=1$, $D_m=1.69$ g cm^{-3}, and $D_x=1.70$ g cm^{-3}. The structure has been refined by the full-matrix least-squares procedure to a conventional R index (on F) of 0.057 for 462 observed reflections. The metal complex host-framework has a three-dimensional infinite cage structure where the ambident ethylenediamine molecules span Cd atoms at the corners of unit cell along the [001] direction and the ambident cyanide ions make infinite two-dimensional networks parallel to (001) by spanning the Cd atoms with the Ni atom at (1/2, 1/2, 0). The two crystallographically independent pyrrole molecules are enclathrated in the molecular spaces of the cages in the host-framework. The statistical dispositions observed for en and pyrrol molecules can be interpreted in terms of motional behavior of these molecules in the crystal.

The crystal structures of the Hofmann type and analogous clathrates have been determined only for those of the benzene guest[1–7] except a Hofmann type biphenyl clathrate $Ni(NH_3)_2Ni(CN)_4\cdot 2C_{12}H_{10}$,[8] in spite that various polar molecules such as pyrrole, thiophene or aniline can be the guest.[9] With respect to the guest benzene molecule, the reorientational motion about its sixfold axis has been observed for Hofmann type clathrates above 140 K by wide-line PMR.[10] The atomic coordinates of the carbons in the crystal have been determined as the potential minima during the reorientational motion by single crystal X-ray analysis. It is a matter of interest how the polar molecules are arranged in the molecular spaces. The molecular electric dipole moments will play an important role in determining the arrangements of the polar molecules in the crystal. For the first attempt at the crystal structure analysis of the polar-guest clathrate of these types, a Hofmann-en type pyrrole clathrate $Cd(en)Ni(CN)_4\cdot 2C_4H_5N$ (en=$NH_2CH_2CH_2NH_2$) was taken up, since pyrrole has a large dipole moment (1.80 D) and since the structure of the Hofmann-en type benzene clathrate $Cd(en)Ni(CN)_4\cdot 2C_6H_6$ had already been determined.[3] The structural features of the pyrrole clathrate will be discussed in comparison with those of the benzene clathrate.

Experimental

The crystals of $Cd(en)Ni(CN)_4\cdot 2C_4H_5N$ were prepared by the method previously reported.[11] An approximately equidimensional crystal of $0.1\times 0.1\times 0.1$ mm in size was sealed in a thin-walled glass capillary (0.1 mmϕ) with a small amount of liquid pyrrole. Preliminary Weissenberg photographs suggested a tetragonal symmetry of the crystal and the cell-dimensions $a=7.62$ and $c=7.86$ Å, supporting the previous results obtained from the powder diffraction pattern.[11] Before intensity collection, however, the unit cell dimensions and the intensity distribution were reexamined on a Rigaku four-circle automated diffractometer,[12] and it was revealed that the crystal is orthorhombic with $a=7.618(3)$, $b=7.641(10)$ and $c=7.861(4)$ Å, the values being determined by the least-squares calculations with eight 2θ values in the range 20—40°, for Cu$K\bar{\alpha}$ radiation. The intensity data were collected with Cu$K\bar{\alpha}$ radiation monochromated by a graphite crystal ($\lambda=1.5418$ Å) using $2\theta-\theta$ scanning technique for 462 independent reflections with 2θ less than 120°. All the reflections had the non-zero intensities; 31 reflections had the values comparable with or less than three times the standard deviations. Three standard reflections were remeasured every 50 reflections; no significant variation in the intensities was observed. The Lp correction was applied, but no corrections for absorption and extinction were made. The density was measured by flotaion method in bromoform-xylene mixture.

Crystal data are:

$Cd(NH_2CH_2CH_2NH_2)Ni(CN)_4\cdot 2C_4H_5N$, M.W.=469.38

Orthorhombic, D_{2h}^1-Pmmm, $a=7.618(3)$, $b=7.641(10)$, $c=7.861(4)$ Å, $Z=1$. $D_m=1.69$, $D_x=1.70$ g·cm^{-3}. No systematic absence. $\mu(Cu K\bar{\alpha})=109.6$ cm^{-1}.

Structure Refinement

All the calculations were carried out on a HITAC 8800/8700 computer at the Computation Center of this University. The programs used were those in UNICS[13] and BLAN-2.[14] The atomic scattering factors used were those listed in the usual tabulation[15] for C and N, and those from Cromer and Waber[16] for Cd and Ni. In the least-squares calculations the quantity minimized was $\sum w(||F_o|-|F_c||)^2$ with $w=1/[\sigma(F_o)]^2$. The reliability indices of conventional $R_1=\sum w(||F_o|-|F_c||)/\sum|F_o|$ and $R_2=\sum w(||F_o|-|F_c||)^2/\sum|F_o|^2$ were defined in order to check the results of refinement. All the 462 observed reflections were used in the calculations.

Because of no systematic absence of the reflections, the possible space groups are P222, Pmm2 and Pmmm. Since the unit cell contains only a formula unit of $Cd(en)Ni(CN)_4\cdot 2C_4H_5N$, most of the atoms should lie on the special positions. From the three-dimensional Patterson synthesis, the Cd and the Ni atoms were placed at the positions 0,0,0 and 1/2,1/2,0, respectively. The centrosymmetric space group Pmmm was assumed prior to the other two non-centrosymmetric ones. The Fourier map phased with the heavy atoms gave clear peaks due to cyanide C and N atoms on the (001) plane, and the more diffused peaks due to en-C and -N atoms along the twofold axis parallel to [001]

Table 2. The bond lengths, interatomic distances less than 3.0 Å, and bond angles

Cd–N(1)	2.40(1) Å	Cd–N(2)	2.25(3) Å

N(3)–C(3)–C(4)	108(5)	N(4)–C(5)–C(6)	107(6)
C(3)–C(4)–C(4′)	109(7)	C(5)–C(6)–C(6′)	108(8)
C(3)–N(3)–C(3′)	105(6)	C(5)–N(4)–C(5′)	111(5)
N(2)–Cd–C(2)	14(1)		

Key to symmetry operations: C(2) at ((0,0,z), C(2′) at (0,0,$\bar{z}$); C(3) at (½,y,z), C(3′) at (½,y,z); C(4) at (½,y,z), C(4′) at (½,$\bar{y}$,z); C(5) at (x,½,z), C(5′) at ($\bar{x}$,½,z); C(6) at (x,½,z), C(6′) at ($\bar{x}$.½,z).

square-planar $Ni(CN)_4$ into a doublet, 2155 and 2146 cm^{-1} in the benzene, and 2154 and 2145 cm^{-1} in the pyrrole clathrates. In the orthorhombic D_{2h}^1-Pmmm unit cell of the latter, the Ni atom locates at the D_{2h} site, 1/2,1/2,0. The correlation among the molecular (effective) D_{4h}, the site D_{2h} and the crystal D_{2h} groups makes the degenerate E_u mode split into a B_{2u} and a B_{3u} modes. Although this interpretation cannot be directly applied to the benzene clathrate with the tetragonal C_{4h}^1-P4/m space group, the similar doublet structure suggests that the effective site symmetry of the Ni atom is lowered from tetragonal to orthorhombic probably owing to the reorientation of en molecules.

There are two crystallographically independent pyrrole molecules in the unit cell. The aromatic plane of one molecule is vertical to the (010) plane, and that of the other is vertcial to the (100) plane; the twofold axes of the molecules are parallel to [001]. Each pyrrole molecule is statistcially distributed with an equal probability in two orientations which are related one another by the mirror plane perpendicular to [001]. There are fairly large differences between the bond lengths and angles in the two independent molecules, but the differences are not significant in view of the large estimated standard deviations. The shapes of molecules appear to be elongated along the twofold axis and compressed along the direction vertical to the axis in comparison with the structure estimated by microwave spectroscopy.[18] In the molecular spaces, the reorientational motions of pyrrole molecules may occur, which are similar to that observed in a Hofmann type pyrrole clathrate $Cd(NH_3)_2Ni(CN)_4 \cdot 2C_4H_5N$ by wide-line PMR.[10] The large estimated standard deviations of atomic coordinates and the considerably large temperature factors support the motional behavior of the pyrrole molecules. Therefore, the atomic coordinates should be interpreted to be the postions of potential minima during their reorietnational motions, by which the directions of molecular dipoles are statistically in parallel and anti-parallel along the [001] direction.

The authors' thanks are due to Professor Niro Matsuura at this College for his kind support to this work.

C-S Stretching Vibrations and Molecular Conformations of Isobutyl Methyl Sulfide and Related Alkyl Sulfides

Norimasa NOGAMI,* Hiromu SUGETA, and Tatsuo MIYAZAWA[1)]

* *Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113*
Institute for Protein Research, Osaka University, Yamada-kami, Suita, Osaka 565

(Received May 16, 1975)

The Raman and infrared spectra of isobutyl methyl sulfide and related alkyl sulfides were measured. The Raman spectra of the liquid, unannealed solid, and annealed solid of isobutyl methyl sulfide were compared and skeletal normal vibrations of possible rotational isomers were treated. Three rotational isomers were found to coexist in the liquid state whereas only one isomer was observed in the annealed solid. The energy differences among the three rotational isomers were measured. The correlations between the CH_2–S stretching frequencies and molecular conformations were established, in common, for the molecules of isobutyl methyl sulfide, methyl propyl sulfide and ethyl methyl sulfide.

In our previous studies,[2,3)] Raman and infrared spectra of a series of dialkyl disulfides were analysed. The S–S and C-S stretching frequencies of the $\rangle C\text{-}CH_2\text{-}S\text{-}S\text{-}CH_2\text{-}C\langle$ group were found to depend upon the internal rotation about the CH_2-S and C-CH_2 bonds, respectively. The correlation for S-S stretching vibrations is useful for studying conformations of cystine groups of proteins in aqueous solution. On the other hand, C-S bonds are involved in methionine groups as well as in cystine groups of proteins. Accordingly, the molecule of methyl propyl sulfide was taken up as a model of the methionine group.[4)] New correlations were found between C-S stretching frequencies and the internal rotation about the C-CH_2 and CH_2-S bonds of the $\rangle C\text{-}CH_2\text{-}S\text{-}CH_3$ group. The Raman lines due to C-S stretching vibrations are now useful for studying conformations of methionine groups of proteins in aqueous solution.

In the present study, the Raman and infrared spectra of isobutyl methyl sulfide $CH_3\text{-}\underset{\displaystyle CH_3}{\underset{|}{CH}}\text{-}CH_2\text{-}S\text{-}CH_3$ were analysed. This molecule possibly serves as a model of *S*-methylcystein,

$$NH_3^+\text{-}\underset{\displaystyle COO^-}{\underset{|}{CH}}\text{-}CH_2\text{-}S\text{-}CH_3$$

The correlations for the C-S stretching frequencies of isobutyl methyl sulfide were compared with those of ethyl methyl sulfide, methyl propyl sulfide and isopropyl methyl sulfide.

Experimental

Isobutyl methyl sulfide, methyl propyl sulfide, and isopropyl methyl sulfide were prepared from methyl iodide and sodium salts of corresponding thiols. Ethyl methyl sulfide was obtained from commercial sources. All these samples were purified by distillation.

Raman spectra were recorded with a JEOL Raman Spectrometer (Model JRS-02AS) with an argon-ion laser (514.5 and 488.0 nm). Infrared spectra were recorded with a Hitachi EPI-G3 Infrared Spectrophotometer. The temperature of the sample in the low temperature cell for Raman scattering was measured with a copper-constantan thermocouple.

Normal Coordinate Treatment

As an aid for analysing the vibrational spectra in the low frequency region, normal vibrations were treated for the possible rotational isomers of isobutyl methyl sulfide. Methyl, methylene and methine groups were treated as single dynamic units. The structural parameters used in the calculation were the bond lengths of r(C-S)=1.81 Å and r(C-C)=1.54 Å, bond angles of ϕ(C-S-C)=98.67° and the tetrahedral angles for carbon atoms. The dihedral angles were 180° and ±60° for the *trans* (T) and *gauche* (G, G′) forms, respectively. The force constants of the Urey-Bradley type were transferred from related molecules (Table 1).

Table 1. Force constants[a)]

K(CH_3–S)	2.8	H(C–S–C)	0.16[b)]
K(CH_2–S)	2.3	H(C-C-S)	0.15
K(C–C)	3.6	H(C–C–C)	0.25
F(C–S–C)	0.21[b)]	Y(C–S)	0.05
F(C–C–S)	0.47	Y(C–C)	0.07
F(C–C–C)	0.33		

a) K(stretching) and F(repulsion), in unit of mdyn/Å; H(bending) in unit of mdyn/Å·rad²; and Y(internal-rotation) in unit of mdyn·Å/rad². This set was used previously.[4)] b) These were transferred from dimethyl sulfide.[7)] Others were from dialkyl disulfide (Sugeta, Go, and Miyazawa).

Isobutyl Methyl Sulfide

The Raman spectra of isobutyl methyl sulfide in the 850—150 cm^{-1} region are shown in Fig. 1. The top spectrum (Liquid) was observed for the liquid state. The second spectrum (Solid-1) was observed after freezing the sample rapidly. This solid sample was then annealed and the third spectrum (Solid-2) was observed.

Possible rotational isomers of isobutyl methyl sulfide are shown in Fig. 2. The conformations of the X$\rangle$C-CH_2-S– group are denoted with the atom located at the *trans* site (X) with respect to the sulfur atom. Thus, P_C and P_H refer to the conformations with carbon and hydrogen atoms, respectively, at the site X. The internal rotation about the CH_2-S bond is denoted by

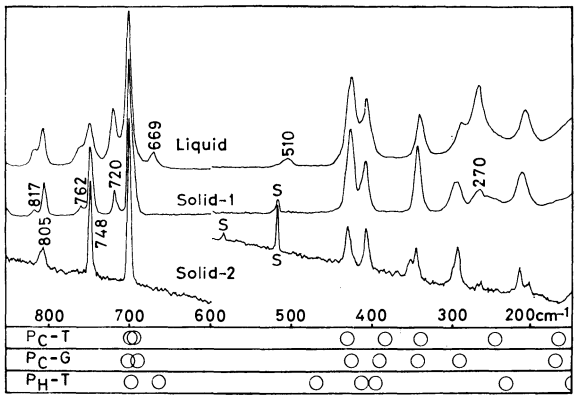

Fig. 1. The Raman spectra of the liquid (Liquid, at 300 K), unannealed solid (Solid-1, at 120 K), and annealed solid (Solid-2, at 120 K) samples of isobutyl methyl sulfide. Calculated frequencies are given with open circles. Spontaneous emission lines of the laser plasma are indicated as S.

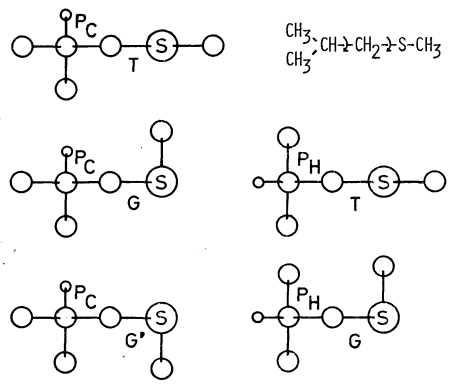

Fig. 2. Possible conformations of isobutyl methyl sulfide. Arrangements of sulfur and carbon atoms and methine hydrogen atom are given.

T (*trans*), G (right-handed *gauche*) and G′ (left handed *gauche*).

For each rotational isomer of isobutyl methyl sulfide, two C–S stretching vibrations are expected to appear in the region of 800—600 cm^{-1}. In fact, two strong Raman lines were observed at 748 and 701 cm^{-1} for Solid-2, indicating the presence of only one rotational isomer (to be called A hereafter). All the Raman lines of the isomer A were also observed in the spectrum of Solid-1, together with two additional lines at 762 and 720 cm^{-1}. These Raman lines are assigned to the C–S stretching vibrations of the second isomer (B), providing the evidence for the coexistence of two rotational isomers in the unannealed solid sample. All the Raman lines of the isomers A and B were also observed in the spectrum of the liquid state. The additional Raman line of the liquid at 669 cm^{-1} is assigned to the C–S stretching vibration of the third isomer (C).

The three rotational isomers (A, B, and C) are possibly the more stable ones among the five isomers shown in Fig. 2. The two isomers, P_C-G′ and P_H-G, are considered to be less stable because of strong steric repulsion between the terminal methyl groups. Accordingly the other isomers, P_C-T, P_C-G, and P_H-T, are expected to correspond to the three isomers experimentally observed in the Raman scattering.

It has been established that the C–Cl[6] and C–S[2] stretching frequencies of the P_H form are lower than those of the P_C form. The Raman line of the isomer C at 669 cm^{-1} is clearly due to the P_H-form. Furthermore, the Raman line of the isomer C at 510 cm^{-1} closely corresponds to the frequency (~470 cm^{-1}) calculated for the P_H-T isomer (Fig. 1). The vibrational frequencies calculated for the P_C-T and P_C-G forms in the 300 cm^{-1} region correspond to the Raman lines at 270 cm^{-1} (the isomer B) and at 299 cm^{-1} (the isomer A), respectively (Fig. 1). Thus, the isomers A, B, and C are now identified as the P_C-G, P_C-T, and P_H-T forms, respectively.

a) vs: very strong, s: strong, m: medium, w: weak, vw: very weak.

The vibrational assignments of the infrared and Raman frequencies of isobutyl methyl sulfide are listed in Table 2. The Raman lines due to the C-S stretching vibrations of isobutyl methyl sulfide and methyl propyl sulfide[4] are compared in Fig. 3. The assignments to molecular conformations of these two sulfides correspond to each other case surprisingly well. It may be noted that, for the molecule of methyl propyl sulfide, the rotational isomers P_H-G and P_H-G′ are possible. However, the isomer P_H-G′ is considered to be much less stable because of strong steric repulsion between the terminal methyl groups. On the other hand, the isomer P_H-G is expected to be more stable and, in fact, the Raman lines due to this isomer were observed as shown in Fig. 3.

Energy Difference. The relative intensities of the Raman lines at 669 cm^{-1} (P_H-T), 720 cm^{-1} (P_C-T), and 701 cm^{-1} (P_C-G) were measured over the temperature range from 180 to 290 K. The P_C-G isomer was found to be most stable. The energy difference between the P_C-T and P_C-G isomers is 0.2 ± 0.1 kcal/mol and the energy difference between the P_H-T and P_C-G isomers is 0.8 ± 0.1 kcal/mol, in the liquid state.

C-S Stretching Frequencies of Alkyl Sulfides

For each of the P_C-G, P_C-T, and P_H-G forms of isobutyl methyl sulfide and methyl propyl sulfide, two Raman lines due to C-S stretching vibrations were observed as shown in Fig. 3. For the P_H-T form, however, only one Raman line due to the C-S stretching vibration was observed and the other Raman line was missing.

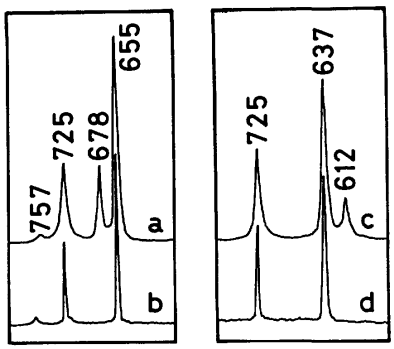

Fig. 4. The Raman spectra of the liquid (a) and annealed solid (b) of ethyl methyl sulfide and of the liquid (c) and annealed solid (d) of isopropyl methyl sulfide.

For studying the C-S stretching vibrations of the P_H-T form, Raman spectra were also measured of the liquid and annealed solid of ethyl methyl sulfide (Fig. 4).[7] The assignments of observed Raman lines to molecular conformations may be done with reference to the correlations found for the molecule of isobutyl methyl sulfide and methyl propyl sulfide. Thus the Raman lines of the annealed solid of ethyl methyl sulfide at 725 and 655 cm^{-1} may be assigned to the C-S stretching vibrations of the P_H-G form while the Raman line of the liquid at 678 cm^{-1} may be assigned to the P_H-T form.[8] The temperature dependence of the intensities of these three Raman lines suggests that the missing Raman line of the P_H-T form is overlapped by the Raman line of the P_H-G form at 725 cm^{-1}. This frequency is nearly equal to the average value (716 cm^{-1}) of the two CH_3-S stretching frequencies of dimethyl sulfide (antisymmetric: 741 cm^{-1}, symmetric: 691 cm^{-1}).[5] Accordingly the Raman line of ethyl methyl sulfide at 725 cm^{-1} is assigned to the CH_3-S stretching vibration. Similarly, the Raman line of methyl *tert*-butyl sulfide at 722 cm^{-1} is assigned to the CH_3-S stretching vibration.[12]

The CH_3-S stretching vibration was also studied for the molecule of isopropyl methyl sulfide. The Raman spectra of the liquid and annealed solid were observed, as shown in Fig. 4.[10] The Raman lines at 725 and 637 cm^{-1} have been assigned to the C_1 isomer and the line at 612 cm^{-1} to the C_S isomer.[11-13] The missing Raman line of the C_S isomer is now considered to be overlapped by the Raman line (at 725 cm^{-1}) due to the CH_3-S stretching vibration of the C_1 isomer.

Table 3. Characteristic C-S stretching frequencies (cm^{-1}) of alkyl sulfides

Molecule	Conformation				
	P_C-T	P_C-G	P_H-T	P_H-G	Mode
H, H, H: C-CH_2-S-CH_3	—	—	~725	725	S-CH_3
	—	—	678	655	CH_2-S
H, H, CH_3: C-CH_2-S-CH_3	719	(697)	~720	724	S-CH_3
	760	(746)	667	645	CH_2-S
H, CH_3, CH_3: C-CH_2-S-CH_3	720	(699)	~720	—	S-CH_3
	755	(743)	669	—	CH_2-S

The present analyses of the Raman spectra of isobutyl methyl sulfide and related alkyl sulfide lead to the conclusion that the CH_3-S stretching vibration is observed around 725 cm^{-1}, fairly independent of the changes in molecular conformations (except for the P_C-G form, see Table 3). On the other hand, the CH_2-S stretching frequencies are sensitive to the changes in molecular conformations. For the molecule of methyl propyl sulfide, the CH_2-S stretching frequencies are 645 (P_H-G), 667 (P_H-T), and 760 cm^{-1} (P_C-T). For the exceptional case of the P_C-G isomer, CH_3-S and S-CH_2 stretching modes are hybridized to yield normal vibrations at 746 cm^{-1} (pseudo-asymmetric) and 697 cm^{-1} (pseudo-symmetric). The average value (722 cm^{-1}) of these frequencies is, in fact, nearly equal to the 'intrinsic' frequency (725 cm^{-1}) of the CH_3-S stretching vibration.

Photoelectron Spectroscopic Study of Skew Compounds. III. *N,N'*-Dimethylhydrazine, Dimethyl Peroxide, and Dimethyl Disulfide[1]

Katsumi KIMURA and Kazuteru OSAFUNE[2]

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received May 16, 1975)

He I photoelectron spectra of $CH_3HNNHCH_3$, $(CH_3)_2O_2$, and $(CH_3)_2S_2$ have been measured and the spectra below 18 eV have been resolved into nine ionization bands corresponding to p-type localized molecular orbitals. Orbital assignments of the resulting vertical ionization energies have been carried out with CNDO/2 calculations in which orbital energies were calculated as a function of the dihedral angle in the region 0—180 °. The separation of the nonbonding photoelectron bands suggests that $CH_3HNNHCH_3$ exists in outer-inner skew form, whereas $(CH_3)_2O_2$ is in *trans* form. The sum rule consideration previously proposed by the present authors has been applied to the compounds studied here. The total sum of the vertical ionization energies in the p-type region for each compound has been well reproduced in terms of appropriate empirical parameters based on the photoelectron spectra of simple molecules. The effects of methyl substitution on the ionization-energy total sums for N_2H_4, H_2O_2, and H_2S_2 have been found to be very similar to those for ethane and ethylene.

Previously, on the basis of Walsh-type diagrams, the present authors have studied the He I photoelectron spectra of the simplest skew compounds, hydrazine[3] and hydrogen peroxide.[4] From these photoelectron studies,[3,4] it was indicated that the whole of the spectra may be interpreted in terms of possible dihedral angles through semi-empirical calculations and that the splittings of the ionization bands corresponding to the nonbonding orbitals largely depend on the dihedral angles.[5] In the present work, we have extended our photoelectron study to symmetric methyl-disubstituted skew compounds, $CH_3HNNHCH_3$, CH_3OOCH_3, and CH_3SSCH_3, to analyze their full He I spectra.

A high-resolution photoelectron spectroscopy using He I (584 Å) line is now well known as a powerful method to study valence orbital structure.[6] Recently, dependences of the dihedral angle on nonbonding splittings in skew compounds including alkyl hydrazines,[7,8] disulfides,[9-11] and peroxides[12] have been received much attention in molecular photoelectron spectroscopy. Recently, Rademacher[7] and Nelsen *et al.*[8] have studied photoelectron nonbonding splittings for a variety of alkyl hydrazines; Wagner and Bock[9] and Baker *et al.*[10] for several alkyl disulfides; Colton and Rabalais[11] for S_2Cl_2, S_2Br_2, and $(CH_3)_2S_2$; and Batich and Adam[12] for mono- and di-*tert*-butyl peroxide. Earlier He I photoelectron works of $CH_3HNNHCH_3$ and $(CH_3)_2S_2$ were carried out by Dewar *et al.*[13] and Frost *et al.*,[14] respectively, using a retarding grid technique. Kroto and Suffolk[15] have recently reported a high-resolution He I spectrum of $(CH_3)_2S_2$. Most of these authors[7-15] have also carried out semi-empirical SCF MO calculations to interpret the photoelectron spectra. Very recently, Davies[16] has carried out *ab initio* calculations for H_2O_2 and H_2S_2 to interpret the available photoelectron data. Apart from the theoretical studies associated with photoelectron spectra, many other theoretical treatments for simple skew compounds have been carried out to study angular dependences of electron density, total energy, transition energy, nonbonding interaction, rotational barrier, *etc.*[17,18]

Conformation of $CH_3HNNHCH_3$, $(CH_3)_2O_2$, and $(CH_3)_2S_2$ have been studied by several workers.[19-21] Aston *et al.*[19] suggested for $CH_3HNNHCH_3$ that its entropy data may be interpreted with either a single outer-inner skew form or a 70%: 30% mixture of the outer-outer and outer-inner skew forms which are shown schematically in Fig. 1. A recent infrared and Raman study by During and Harris[20] indicated that $CH_3HNNHCH_3$ in the liquid phase consists of a mixture of *gauche* forms. For $(CH_3)_2S_2$, an experimental value of 84°42′ for the dihedral angle was obtained by Sutter *et al.*[21] using a microwave technique. There are no available data for the dihedral angle for $(CH_3)_2O_2$.

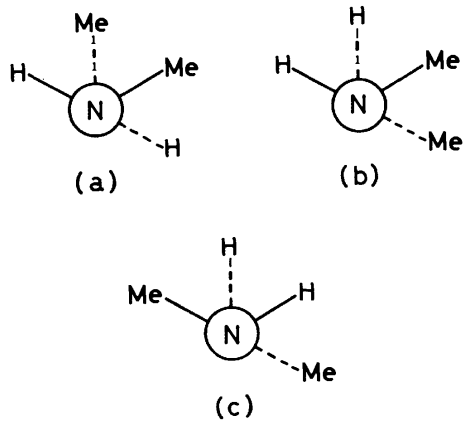

Fig. 1. *Gauche* forms of $CH_3HNNHCH_3$: (a) inner-inner form, (b) outer-inner form, (c) outer-outer form.

Under these circumstances, we considered it interesting to obtain conformational information from He I photoelectron spectra for the skew compounds studied here. From previous He I photoelectron studies of several series of aliphatic organic compounds, Kimura *et al.*[22] have indicated that the total sum of vertical ionization energies in the p-type region for each molecule may be reproduced in terms of vertical ionization energies of simple molecules. Therefore, such a sum rule consideration may be interesting for the compounds studied.

Experimental

Measurements of He I photoelectron spectra were carried out with the high-resolution photoelectron spectrometer used previously.[22] Calibration of the ionization energy scale was carried out using known ionization energies of Xe as an internal standard.[23] Gaseous samples were introduced through a vacuum glass line with a teflon needle valve. No metal tube was used to avoid decomposition.

sym-Dimethylhydrazine was librated from commercial dihydrochloride salt in aqueous alkaline solution, and then was dehydrated by barium oxide and finally distilled in vacuum. Dimethyl peroxide was prepared from dimethyl sulfate and hydrogen peroxide according to the method described by Hanst and Calvert[24] and purified by distillation in vacuum. Commercial dimethyl disulfide was purified by distillation in vacuum.

Theoretical Calculations

We carried out SCF MO calculations for $CH_3HNNHCH_3$, $(CH_3)_2O_2$, $(CH_3)_2S_2$, and H_2S_2, using the CNDO/2 method with the same parameterization as in the original paper.[25] The geometrical parameters used were taken from available structural studies,[26-28] which are summarized in Table 1. The CNDO/2 calculations of $(CH_3)_2O_2$, $(CH_3)_2S_2$, and H_2S_2 were performed for various dihedral angles from 0 to 180° with an interval of 10°. For $CH_3HNNHCH_3$, the calculations were carried out for the following conformations: 1) *cis* form, C_2; 2) *trans* form, C_2; 3) inner-inner skew form, C_2; 4) outer-inner skew form, C_1; and 5) outer-outer skew form, C_2. We used a FACOM-230/60 digital computer at the Computing Center of Hokkaido University.

Results

The He I photoelectron spectra of $CH_3HNNHCH_3$, $(CH_3)_2O_2$, and $(CH_3)_2S_2$ are illustrated in Figs. 2—4, respectively. According to our previous photoelectron studies of various series of aliphatic compounds,[22] all the photoelectron bands due to p-type localized molecular orbitals (LO's) are located below about 18 eV. The same situation may also occur for the compounds studied. As done previously,[22] in the present work, the resolution of the photoelectron spectra into individual bands was carried out on the basis of 1) spectral shape (maxima and shoulders), 2) the number of p-type LO's, and 3) the sum rule consideration. The numbers of p- and s-type LO's for several related compounds are summarized in Table 2, from which it is seen that there are five p-type LO's in N_2H_4, H_2O_2, and H_2S_2 and nine in the methyl-disubstituted compounds. The p-type bands in the photoelectron spectra

in Figs. 2—4 are indicated by solid and broken lines, the numbering of ionization bands being also shown. The vertical ionization energies thus obtained for $CH_3HNNHCH_3$ are summarized in Table 3 together with the MO assignments obtained from the CNDO/2 calculations, while the vertical ionization energies of $(CH_3)_2O_2$ and $(CH_3)_2S_2$ are shown in Table 4.

The Walsh-type diagrams[29] based on the CNDO/2 calculations for $(CH_3)_2O_2$ and $(CH_3)_2S_2$ are illustrated in Fig. 5, in which the calculated orbital energies are plotted against the dihedral angle.

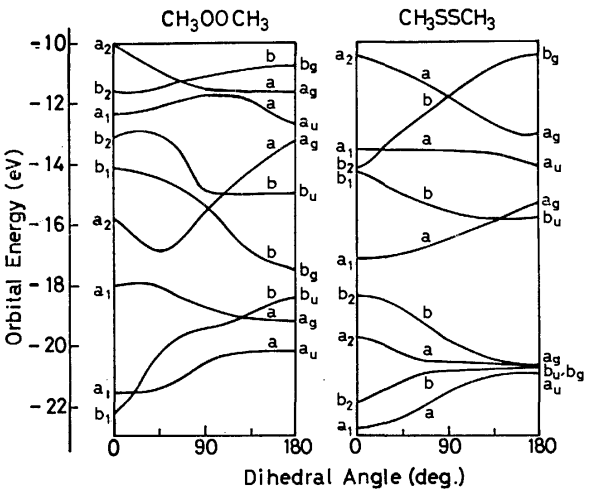

Fig. 5. Walsh-type orbital energy diagrams for $(CH_3)_2O_2$ and $(CH_3)_2S_2$, constructed on the basis of CNDO/2 calculations. (Energies for $(CH_3)_2O_2$ were reduced by 4 eV.)

Discussion

First we review the valence orbital structure of the simple skew compounds, N_2H_4, H_2O_2, and H_2S_2, using the available He I photoelectron spectra[3,4,9b] shown in Fig. 6 as well as Walsh-type orbital energy diagrams shown in Fig. 7, in which the diagrams of N_2H_4 and H_2O_2 were previously reported[3,4] and that of H_2S_2 was obtained from the present CNDO/2 calculations. It is seen that the orbital diagrams in Fig. 7 have the

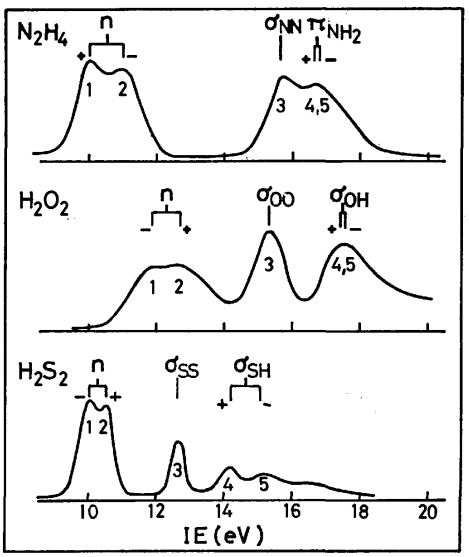

Fig. 6. Schematic drawing for the He I photoelectron spectra of N_2H_4, H_2O_2, and H_2S_2 reported in Refs. 3, 4, and 9b, respectively.

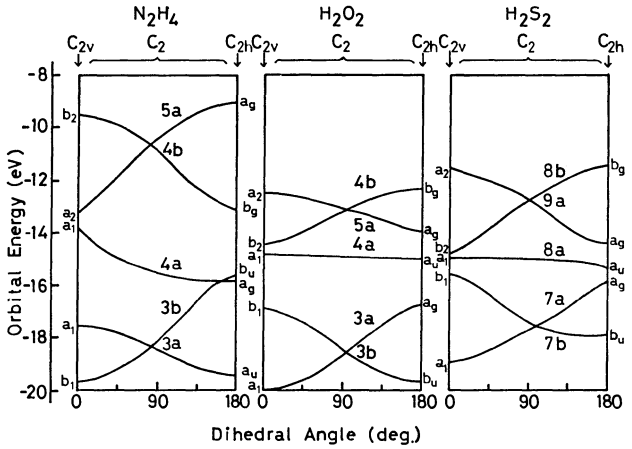

Fig. 7. Walsh-type orbital energy diagrams for N_2H_4, H_2O_2, and H_2S_2, constructed on the basis of CNDO/2 calculations. (Energies were reduced by 4 eV.)

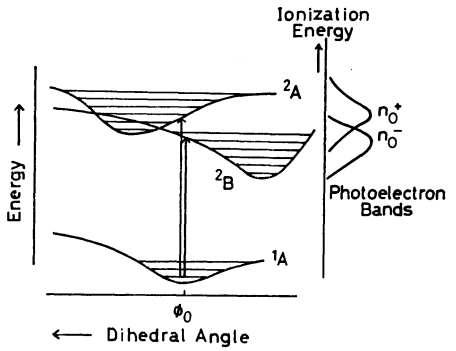

Fig. 8. Schematic drawing that explains the broadening of the nonbonding photoelectron bands of H_2O_2, using the potential curves of the ground and the ionic states expressed as a function of the dihedral angle. (ϕ_0 represents the equilibrium skew angle of the ground state molecule.)

following characteristics. 1) The two highest curves due to the $\pm$ combinations of the nonbonding orbitals cross each other at about 90°, the splitting being closely associated with the dihedral angle. Such angular dependences of the nonbonding orbital splitting have previously been reported by Yonezawa *et al.*[17] 2) The third curves due mainly to the N–N, O–O, and S–S bonds are quite insensitive to the dihedral angle. 3) The fourth and fifth curves also cross each other at about 90°.

Since experimental dihedral angles of 90—120° have been reported for N_2H_4, H_2O_2, and H_2S_2 from structural analysis studies,[30] it is seen from the Walsh-type diagrams in Fig. 7 that the orbital orderings are N_2H_4 [3a, 3b, 4a, 4b, and 5a], H_2O_2 [3b, 3a, 4a, 5a, and 4b], and H_2S_2 [7b, 7a, 8a, 9a, and 8b]. The difference in the orbital symmetry between N_2H_4 and H_2O_2 are due to the relative orientation of the nonbonding orbitals with respect to the C_2 axis. The recent *ab initio* calculations of Davies[16] gave rise to slightly different assignments that the above order of the 3b and 3a levels in H_2O_2 and that of the 7b and 7a levels in H_2S_2 are reversed. It should be mentioned that the experimental nonbonding splittings of N_2H_4, H_2O_2, and H_2S_2 (0.73,[3] 1.00,[4] and 0.27 eV,[9b] respectively) may be approximately reproduced by the CNDO/2 calculations using the available dihedral angles.

The photoelectron nonbonding bands in Fig. 6 are structureless and much broader compared with usual sharp nonbonding bands of aliphatic alcohols and amines.[6] It may be pointed out that the broadening of the nonbonding bands of the skew compounds may be interpreted in terms of differences in geometry between the ground and the ionized states. Since the original study by Walsh,[19] many workers have published qualitative and quantitative MO studies[31] using Walsh diagrams. Combining a ground-state orbital correlation diagram with the Walsh rule, we may qualitatively predict changes in geometry between the ground state and its ionized states. Now let us take H_2O_2 as an example. Ionization of an electron from the 4b orbital whose energy decreases with increasing dihedral angle (Fig. 7) gives rise to the ionized state ^2B which has a potential minimum at a smaller angle than the equilibrium ground-state dihedral angle (ϕ_0). The potential curves of the ground and the ionized states are schematically illustrated as a function of the dihedral angle in Fig. 8. On the other hand, in the case of the ionization from the 5a orbital, a reverse situation may occur, the orbital energy increasing with the dihedral angle (see Fig. 7). Therefore, the resulting potential curve (^2A) should have a minimum at a larger angle than ϕ_0 as shown in Fig. 8. The broadening of the nonbonding bands strongly suggests that the ^2B and ^2A ionized states are quite different in the equilibrium dihedral angle from the ground state.

N,N′-*Dimethylhydrazine.* The full photoelectron spectrum of $CH_3HNNHCH_3$ (Fig. 2) and its interpretation is reported here for the first time, although experimental nonbonding splittings for many alkyl hydrazines including $CH_3HNNHCH_3$ have previously been reported by Rademacher[7] and Nelsen *et al.*[8] There are only slight differences in vertical ionization energies between the literature values[7,8] and ours for the first two photoelectron bands which may be attributed to the nitrogen nonbonding orbitals.

As shown in Fig. 1, there may be three possible *gauche* configurations (inner-inner, outer-inner, and outer-outer forms). The present CNDO/2 calculations yielded nonbonding splittings of 2.72, 1.89, 0.62, 0.61, and 0.05 eV for *cis*, *trans*, inner-inner, outer-inner, and outer-outer forms, respectively. Our experimental nonbonding splitting was 0.67 eV which is close to the calculated splittings of the inner-inner and outer-inner forms, but largely differs from those of the *cis*, *trans*, and outer-outer forms. A possibility of inner-inner form may also be ruled out because of a steric interaction of the two methyl groups. Therefore, from the consideration of the nonbonding splitting, outer-inner skew form seems to be most plausible for $CH_3HNNHCH_3$.

An early electron diffraction study by Beamer[26] indicated that its experimental results are unfavorable to the *cis* configuration. Aston *et al.*[19] could rationalize the entropy data of $CH_3HNNHCH_3$ in terms of either

a single outer-inner (*gauche*) form or a 70%: 30% mixture of the outer-outer and outer-inner forms, respectively. The infrared and Raman study by During and Harris[20] also suggested that the molecule has more than a single form in its liquid and gaseous state. However, in the present study, the photoelectron spectrum may be interpreted in terms of only a single outer-inner form. This is supported by a very recent gas-phase electron diffraction study by Kuchitsu *et al.*[32]

The CNDO/2 results of $CH_3HNNHCH_3$ for the outer-inner form are summarized in Table 3, main orbital characters being also shown. For higher photoelectron bands, the present CNDO/2 calculations of $CH_3HNNHCH_3$ suggest that 1) the third band is of σ_{NN}, 2) the fourth and the fifth band are due to the $\pm$ combinations of the σ_{NC} orbitals, and 3) the last four bands are due to the methyl pseudo π orbitals.

Dimethyl Peroxide. For $(CH_3)_2O_2$ there are no available He I photoelectron spectra for comparison. This compound slightly decomposes at room temperature, the major products being methanol and carbon monoxide whose first vertical ionization energies are 10.91 eV[22d] and 14.01 eV,[6] respectively. The shoulder appearing at 10.9 eV in the spectrum may be due to a small amount of the decomposed methanol.

From the spectral shape as well as the number of p-type LO's we concluded that the spectrum below 18 eV in Fig. 3 consists of the nine p-type bands. The first three bands are well separated from one another. The CNDO/2 calculations indicated that the total energy becomes minimum at $\phi=180°$, where the nonbonding splitting amounts to 1.91 eV. This value is in good agreement with the experimental separation between the first and the second band, 11.61—9.71= 1.90 eV (Table 4). On the basis of the nonbonding splitting consideration, we tentatively propose that $(CH_3)_2O_2$ has a planar *trans* form in the gaseous phase. A similar situation was reported to occur for di-*tert*-butyl peroxide by Batich and Adam.[12]

The MO assignments of $(CH_3)_2O_2$ obtained by the CNDO/2 calculations are summarized in Table 4, in which the assignments for the second and the third photoelectron band are based on the consideration of the nonbonding splitting. The CNDO/2 calculations of $(CH_3)_2O_2$ in *trans* form indicated that the σ_{OO} level lies between the two nonbonding levels. This assignment may probably be incorrect, although the calculations gave rise to the reasonable nonbonding splitting, 0.91 eV. As shown in Table 4, we therefore concluded that the third photoelectron band to the σ_{OO} orbital.

Dimethyl Disulfide. The spectrum of $(CH_3)_2S_2$ in Fig. 4 is essentially the same as those previously reported by Kroto and Suffolk,[15] by Wagner and Bock,[9b] and by Colton and Rabalais.[11] However, our spectrum obtained here clearly shows the sixth band (appearing as a bump at 14.4 eV) which has not been pointed out by other workers, and also shows two slight shoulders at about 15.5 eV (indicated by broken lines in Fig. 4). On the basis of the number of p-type LO's in this compound, there should exist nine p-type ionization bands below 16 eV, therefore four ionization bands being located in the 14—16 eV range.

As has already been pointed out,[9b,11,15] the first and the second band of $(CH_3)_2S_2$ are due to the $\pm$ combinations of the sulfur nonbonding orbitals. The experimental nonbonding splitting (9.26—8.96=0.30 eV) was reproduced at dihedral angles of 84° and 98° in the present CNDO/2 calculations which showed that the total energy becomes minimum at 84°. It is interesting to see that this angle is very close to that (84°42′) determined by a microwave study by Sutter *et al.*[21] The MO symmetries and characters based on the CNDO/2 calculations (at $\phi=84°42'$) are summarized in Table 4. These MO symmetries are consistent with those reported by Wagner and Bock[9b] and Colton and Rabalais.[11]

According to the CNDO/2 calculations, the third inner orbital is of σ_{SS} in character and very insensitive to the variation of the dihedral angle (see Fig. 7). It may be pointed out here that the upper part of the correlation diagram of $(CH_3)_2S_2$ resembles those of H_2O_2, H_2S_2, and N_2H_4, but largely differs from that of $(CH_3)_2O_2$. This difference may be explained in terms of a difference in size between the sulfur 3p and oxygen 2p orbitals. In a photoelectron study by Sweigart and Turner,[33] it has been pointed out in oxygen- and sulfur-containing heterocyclic compounds that orbital interaction between sulfur nonbonding orbitals is mainly through-space interaction, whereas that between oxygen nonbonding orbitals is through bond dominant. Therefore, the difference in the pattern of the orbital energy diagrams between $(CH_3)_2O_2$ and $(CH_3)_2S_2$ in Fig. 5 may be attributed to the differences in the nonbonding orbital interactions.

Sum Rule Consideration. Using the experimental vertical ionization energies, we obtained the sum (T) over all the p-type bands in each compound by

$$T_{\text{expt.}} = \sum_i(-I_i) \qquad (1)$$

The results are summarized in Table 5, being plotted against the number (m) of substituted methyl groups

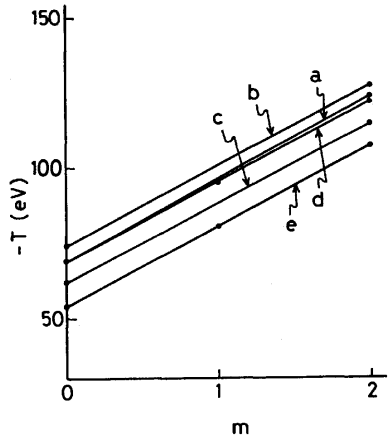

Fig. 9. Plots of the total sums of experimental vertical ionization energies *versus* the number of methyl groups for several series: (a) RHNNHR′, (b) ROOR′, (c) RSSR′, (d) RH_2CCH_2R', and (e) RHC=CHR′, where R=R′=H at $m=0$; R=H and R′=CH_3 at $m=1$; and R=R′=CH_3 at $m=2$.

TABLE 5. COMPARISON OF THE EXPERIMENTAL AND CALCULATED VALUES (in eV) ON THE PARTIAL SUM (P) AND THE TOTAL SUM (T) IN THE SUM RULE CONSIDERATION USING p-TYPE LO's

(I's)→(p-type LO's)	Expt.	Calcd.
$N_2H_4(C_2)$[a]	$T=-69.5$	-69.5[d]

$(I_2, I_4)\rightarrow b(n_N, \pi_{NH_2})$	$P=-27.3$	-27.3
$H_2O_2(C_2)$[b]	$T=-74.5$	-74.5[d]
$(I_2, I_3, I_5)\rightarrow a(n_O, \sigma_{OO}, \sigma_{OH})$	$P=-45.5$	-45.3
$(I_1, I_4)\rightarrow b(n_O, \sigma_{OH})$	$P=-29.1$	-29.2
$H_2S_2(C_2)$[c]	$T=-62.1$	-62.1[d]
$(I_1, I_3, I_5)\rightarrow a(n_S, \sigma_{SS}, \sigma_{SH})$	$P=-37.7$	-37.3
$(I_2, I_4)\rightarrow b(n_S, \sigma_{SH})$	$P=-24.4$	-24.8
$CH_3HNNHCH_3$ (C_1)	$T=-123.5$	-124.0
$(I_1, I_2, I_3, \cdots I_9)\rightarrow(2n_N, \sigma_{NN}, 2\sigma_{NC}, 4\pi_{CH_3})$		
$(CH_3)_2O_2(C_{2h})$	$T=-127.4$	-128.9
$(I_1, I_2, I_6, I_9)\rightarrow$Out-of plane $(2n_O, 2\pi_{CH_3})$	$P=-53.7$	-53.8
$(I_3, I_4, I_5, I_7, I_8)\rightarrow$In-plane $(\sigma_{OC}, 2\sigma_{OC}, 2\pi_{CH_3})$	$P=-73.7$	-75.1
$(CH_3)_2S_2(C_2)$	$T=-114.9$	-115.5
$(I_1, I_3, I_5, I_7, I_9)\rightarrow a(n_S, \sigma_{SS}, \sigma_{SC}, 2\pi_{CH_3})$	$P=-63.9$	-64.0
$(I_2, I_4, I_6, I_8)\rightarrow b(n_S, \sigma_{SC}, 2\pi_{CH_3})$	$P=-51.0$	-51.5

a) The I_i's were taken from Ref. 3: $I_1=9.91$, $I_2=10.61$, $I_3=15.61$, $I_4=I_5=16.66$ in eV units. b) The I_i's were taken from Ref. 4: $I_1=11.69$, $I_2=12.69$, $I_3=15.33$, $I_4=I_5=17.4$ in eV units. c) The I_i's were taken from Ref. 9b: $I_1=10.01$, $I_2=10.28$, $I_3=(12.6)$, $I_4=(14.1)$, $I_5=(15.1)$ in eV, where the values in parentheses were estimated from the reported photoelectron spectrum. d) Assumed to be equal to the experimental value.

in Fig. 9. Lines a, b, and c in Fig. 9 are drawn through the plots for the hydrazines, peroxides, and disulfides, respectively, to show variations in the total sum with m. Similar plots (lines d and e) are also shown in Fig. 9 for the methyl-substituted compounds of ethane and ethylene, clearly indicating linear relationships between T and m.[34] Previously, we have reported such linear tendencies for several series of methyl-, chloro-, and bromo-substituted compounds.[22f,g] We may point out here that, as seen from Fig. 9, lines a, b, and c are almost parallel to one another as well as to lines d and e. These experimental results indicate that the methyl-substitution effects of T for the hydrazines, peroxides, and disulfides are very similar to those for the alkanes and alkenes. The difference in T in each methyl substitution is estimated to be 27.0 eV in the hydrazines, 26.4 eV in the peroxides, 26.5 eV in the disulfides, while it is 26.0 eV in the alkanes and 26.8 eV in the alkenes.[22g]

As shown previously,[22] the total sum may be expressed approximately with the sum of empirical orbital energies (ε_i) over all the p-type LO's. The total sums for N_2H_4, H_2O_2, and H_2S_2 may be expressed by

$$T_{calc.} = 2\varepsilon(n_X) + \varepsilon(\sigma_{XX}) + 2\varepsilon(\sigma_X') \quad (2)$$

where X=N, O, and S, and σ_X' represents π_{NH_2}, σ_{OH}, and σ_{SH}, respectively. For $CH_3HNNHCH_3$, $(CH_3)_2O_2$, and $(CH_3)_2S_2$, the total sum may be given by

TABLE 6. EMPIRICAL ENERGIES (eV) USED FOR LOCALIZED MOLECULAR ORBITALS (LO's) IN THE SUM RULE CONSIDERATIONS

$\varepsilon(n_N)=-10.88$	$\varepsilon(\sigma_{NN})=-14.90$
$\varepsilon(n_O)=-12.61$	$\varepsilon(\sigma_{OO})=-16.10$
$\varepsilon(n_S)=-10.48$	$\varepsilon(\sigma_{SS})=-12.31$
$\varepsilon(\sigma_{NC})=-14.42$	$\varepsilon(\pi_{NH_2})=-16.40$
$\varepsilon(\sigma_{OC})=-15.19$	$\varepsilon(\sigma_{OH})=-16.60$
$\varepsilon(\sigma_{SC})=-12.42$	$\varepsilon(\sigma_{SH})=-14.30$
	$\varepsilon(\pi_{CH_3})=-14.30$

$$T_{calc.} = 2\varepsilon(n_X) + \varepsilon(\sigma_{XX}) + 2\varepsilon(\sigma_{XC}) + 4\varepsilon(\pi_{CH_3}) \quad (3)$$

With Eqs. (2) and (3), we estimated the total sums using the empirical energies ε_i given in Table 6, the resulting $T_{calc.}$ being also included in Table 5. All the ε values in Table 6 were previously used in the sum rule considerations of alkyl amines,[22d] alcohols,[22d] and thioalcohols,[35] except the $\varepsilon(\sigma_{XX})$'s which were determined so as to reproduce the experimental total sums of the parent compounds. As can be seen from Table 5, it is interesting to note that the experimental total sums for $CH_3HNNHCH_3$, $(CH_3)_2O_2$, and $(CH_3)_2S_2$ are reproduced in terms of the empirical LO energies with errors of 0.5, 1.5, and 0.6 eV, respectively.

Since N_2H_4, H_2O_2, H_2S_2, and $(CH_3)_2S_2$ are of molecular symmetry C_2, the LO's may be divided into two symmetry groups a and b. Therefore, the partial sums, P, belonging to these symmetry species were also calculated, as shown in Table 5. For $(CH_3)_2O_2$ which is proposed here to have C_{2h} symmetry, the LO's may be divided into the out-of-plane and in-plane ones, the resulting partial sums being also shown in Table 5. On the other hand, the experimental partial sums were obtained by appropriate combinations of I_i's on the basis of the MO assignments described before (Tables 3 and 4). Although no orbital interactions were taken into account for each set of equivalent LO's, a considerably good agreement is generally obtained between the experimental and theoretical partial sums as shown in Table 5.

Finally, we may point out the following point in connection with the sum rule considerations. Koopmans' theorem[36] was assumed for selecting the ε_i's from the photoelectron data of the simple molecules. However, if we consider each empirical value (in Table 6) without a negative sign as a hypothetical ionization energy, which is due to the ionization of an electron from the original unperturbed LO, then the present sum rule consideration may be thought as an additivity rule of ionization energy, independent of Koopmans' theorem.

The authors wish to thank Dr. S. Katsumata in this laboratory for his helpful discussion.

The Infrared Dichroism and Molecular Orientation of Modifying Reagents, L-β-Phenyllactic Acid and L-β-Phenyl-α-alanine, in Thin Films on Nickel Metal Surfaces

Aritada HATTA and Wataru SUËTAKA

Laboratory of Interface Science of Metals, Faculty of Engineering, Tohoku University, Aramaki Aoba, Sendai 980

(Received September 17, 1974)

The infrared absorption spectra of thin films of modifying reagents, L-β-phenyllactic acid and L-β-phenyl-α-alanine, formed on nickel metal plates were measured by the high-sensitivity reflection method. From the infrared dichroism in the reflection spectra, the molecular orientations in the thin films were deduced. The C=O and alcoholic O–H bonds of L-β-phenyllactic acid are oriented nearly vertical to the metal surface, whereas the carboxyl O–H bond and the benzene ring are parallel to the surface. The benzene ring and the C–N bond in L-β-phenyl-α-alanine are oriented nearly parallel to the metal surface, while the O···O axis of the carboxylate group is inclined to the surface.

Infrared spectroscopy has been extensively applied to the study of surface phenomena. For example, the adsorption of gaseous molecules on metal surfaces has been often investigated by employing transmission methods.[1] On the other hand, the method of reflection using a beam polarized parallel to the plane of incidence at high incident angles (the high-sensitivity reflection method) has facilitated the spectral investigation of surface phenomena on bulk metal surfaces because of its high sensitivity, which, in turn, results from the enhanced intensity of the oscillating electric field normal to the reflecting metal surface.[2] The spectrum of thin film on a metal mirror obtained by this method is a faithful reproduction of the absorption spectrum if the film is isotropic and consists of organic compounds.[3] When the film is anisotropic, the reflection spectrum shows infrared dichroism, and the relative intensities of the infrared bands can be used to deduce the molecular orientation in the film.[4] Because of these advantages, the high-sensitivity reflection method has been successfully used in the investigations of the chemisorption on clean metal surfaces,[5,6] the polymorphism[7] and molecular orientation[8] in thin films on metal surface, and the oxidation and corrosion inhibition of metals.[9]

In recent years, a new type of asymmetric synthesis has been studied by Izumi and his co-workers using a Raney nickel catalyst modified by certain optically active compounds.[10] They have found that the hydrogenation of methylacetoacetate over Raney nickel modified with optically active hydroxy or amino acids affords a definite optical isomer of methyl-β-hydroxybutyrate, its identity depending upon the optical activity of the compound used as the modifying reagent.[10] While the mechanism is still uncertain, it is worth noting that the effective modifying reagents available for such an asymmetric reduction are limited to optically active acids in which a OH or NH_2 group is attached at the asymmetric carbon atom. Therefore, it seems most likely that the geometry of the modifying reagent adsorbed on the Raney nickel catalyst plays an important role in the determination of the optical isomer of the reduction product. Hence, a particular interest is focused on the molecular orientation of modifying reagents on the Raney nickel catalyst.

The epitaxial growth of an organic crystal occurs on a single crystal when the organic molecule is adsorbed strongly on the crystal, and the molecular orientation in the overgrowing crystal correponds to the state of the adsorbed molecule.[11] Tanabe and Uyeda investigated the thin film of L-β-phenyl-α-alanine, formed from an aqueous solution on nickel film, by electron microscopy and diffraction, and suggested that this molecule is in a certain state of oriented adsorption at the interface.[12] However, they could not determine the orientation of the molecules because the crystal structure of L-β-phenyl-α-alanine was unknown.

The present study was undertaken in the hope of making clear the orientations of the modifying reagents, L-β-phenyllactic acid and L-β-phenyl-α-alanine, in thin crystal films formed on nickel surfaces, using the high-sensitivity reflection technique.

Experimental

The infrared spectra were taken by means of a JASCO model IR-G spectrophotometer equipped with a JASCO PR-1 assembly designed for use in a single-beam reflection operation.[4] In this method, however, the weak absorptions are subjected to interference from atmospheric water vapor. This problem was solved by the combined use of signal averaging and back-ground elimination procedures.[5] The calculations were performed on a JEOL model JEC-5 spectrum computer. The modifying reagents of L-β-phenyllactic acid and L-β-phenyl-α-alanine were prepared and supplied by the Institute for Protein Research, Osaka University, and were used without further purification. In the present study, an electrolytical nickel (99.9% purity) plate was used as substrate and mirror. To obtain a high reflectivity, the nickel plate was polished with silicon carbide and chromium oxide to reduce its roughness to a minimum. After having been treated with a 20% NaOH solution at 80 °C and having been rinsed in distilled water, the nickel plate was immersed into a 0.5% aqueous solution of a modifying reagent. The sample of the modified nickel plate was dried in air and was then subjected to the reflection measurement. A thin film of fine crystallites of the reagent was formed on the metal substrate upon the evaporation of the water.

Results and Discussion

L-β-Phenyllactic Acid. The absorption spectrum of this compound, $C_6H_5CH_2CH(OH)COOH$, in the randomly oriented state and the assignment of the absorp-

tion bands must be available if its reflection spectrum is to be discussed. For this purpose, the transmission spectrum of L-β-phenyllactic acid (PLA) was measured by the KBr disk method in the region of 400—4000 cm^{-1}. The spectrum thus obtained is shown in Fig. 1. The assignment, to be described below, is mainly based on comparison with the spectra of such related compounds as the sodium salt and *O*-deuterated compound of PLA, and DL-mandelic acid, its sodium salt, and its *O*-deuterated compound. The most important vibrational bands of PLA and its sodium salt are collected in Table 1. PLA shows a strong absorption at 3450 cm^{-1} and two broader absorptions centered around 2920 and 2570 cm^{-1}, all of which shifted to lower frequencies upon deuteration, as is shown in Table 1; these can be assigned to O-H stretching vibrations. The sodium salt of PLA shows a strong band at 3400 cm^{-1} and a weaker band at 3150 cm^{-1}, while no other band appears over the lower O-H stretching region. Therefore, the strong band at 3450 cm^{-1} observed with PLA is evidently due to the alcoholic O–H stretching, and the remaining broad bands in the lower-frequency region, to the carboxyl O-H stretchings. The strong absorption band observed at 1725 cm^{-1} can easily be assigned to the C=O stretching. The weak and narrow bands at 1500 and 1453 cm^{-1} of PLA are observed also for DL-mandelic acid and other related compounds, so these bands are assigned to the in-plane skeletal deformation of the benzene ring. The strong bands observed in the 1050—1300 cm^{-1} region are attributable to the C–O-H fragments. From the vibrational character, these bands involve the interacting in-plane deformation vibration of the C-O–H angle and the stretching one of the C–O bond, giving rise to two bands.[13] In PLA, there are two pairs of deuteration-sensitive bands, at 1245 and 1197, and at 1093 and 1070 cm^{-1}. The former pair disappears upon the change from –COOH to –COONa, while the latter shows no appreciable change. Therefore, we assigned the two bands at 1245 and 1197 cm^{-1} to the vibrations of the carboxylic C–O–H group, and the other pair, to alcoholic C-O–H. The intense bands at 708 (sh) and 700 cm^{-1} are assigned to the CH out-of-plane deformation or the skeletal deformation vibration of the benzene ring. These assignments are mainly based on the fact that the bands remain unshifted on the deuterations of O-H groups. The spectrum of mandelic acid changed with the deuteration and salt formation in the same manner as in the case of PLA, supporting the above-mentioned assignment.

The high-sensitivity reflection spectrum of the thin PLA film formed on a nickel metal surface is shown in Fig. 1. The absorption bands of the thin film appear at essentially the same frequencies as in the transmission spectrum of the bulk crystals. However, differences in relative intensities are noticed between the thin film and the bulk crystals. Because no new band appeared in the reflection spectrum, the thin film probably did not contain any compound other than PLA in any appreciable quantity. The spectral change, therefore, can be interpreted in terms of a molecular orientation in the thin film, as has been discussed in previous papers.[4,5,8] In the high-sensitivity reflection method employed in the present work, the oscillating electric vector of radiation in the vicinity of the reflecting

surface is practically polarized normal to that surface.[2] Therefore, any spectral change in the band intensities can reveal information about the direction of the transition moments of the molecule; moreover, if the molecular structure in the solid phase is known, the molecular orientation as a whole may also be obtained. On the basis of the assignments mentioned above, the orientation of PLA to the nickel metal surface can be determined by comparing the thin film spectrum with the bulk one. In the thin film spectrum shown in Fig. 1, it can clearly be seen that the O-H stretching band of the carboxyl group almost disappears, while the alcoholic O–H stretching band appears strong. The bands arising from the C–O stretching and C-O–H in-plane deformation vibrations of the carboxyl group appear at almost the same frequencies as that in the bulk spectrum. In addition, it is quite likely that the carboxyl O–H group is hydrogen-bonded in crystalline phases. Therefore, the disappearance of the carboxyl O-H stretching band can not be ascribed to the dissociation of the hydrogen bond between carboxyl groups. These facts indicate that the carboxyl O-H bond is aligned nearly parallel to the nickel substrates, while the alcoholic O–H bond is not. On the other hand, the band due to the C=O stretching vibration of the carboxyl group has the highest absorption intensity in the thin film spectra; hence, the transition moment and, therefore, the C=O bond are considered to be perpendicular to the nickel metal surface. Accordingly, the molecule is probably oriented in such a way that the plane containing a carbon and two oxygen atoms of the carboxyl group is perpendicular to the nickel metal surface.

Another marked difference between the bulk and the thin film crystal is seen in the bands of the 1050—1300 cm^{-1} region due to the vibrations of the carboxyl and alcoholic C–O-H groups; *i.e.*, the bands arising from the former group lose much of their intensity in the thin film, while the bands of the latter are unchanged. In view of the fact that the C-O-H bands represent the interacting C–O stretching and in-plane O–H deformation vibrations, the observed results support the different alignments for the carboxyl and alcoholic O-H bonds mentioned above.

On the other hand, the crystal structure of *p*-bromo-L-*β*-phenyllactic acid was investigated by Kakudo *et al.*; the molecular conformation in the crystal is shown in Fig. 2.[14] Therefore, the determination of the molecular orientation as a whole can most conveniently be performed by assuming that the molecular conformation of *p*-bromo-L-*β*-phenyllactic acid is applicable to the

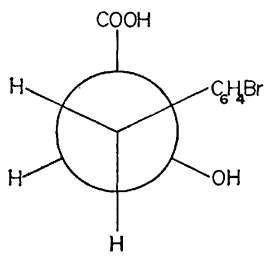

Fig. 2. Molecular conformation of *p*-bromo-L-*β*-phenyllactic acid, as viewed along the C_β—C_α bond.[14]

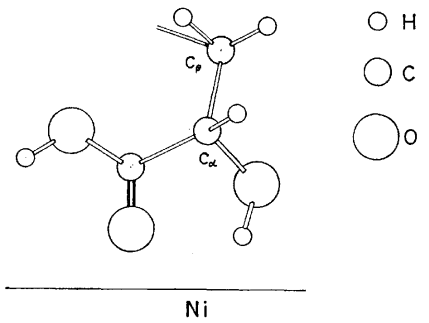

Fig. 3. Molecular orientation in thin L-*β*-phenyllactic acid crystal formed on nickel metal surface. The phenyl group is omitted from the figure.

case of PLA. The derived orientational model for thin PLA in crystal is shown in Fig. 3. In the thin film spectrum, the band at 700 cm^{-1} assigned to the CH out-of-plane deformation or skeletal deformation of the benzene ring remains as a strong band, while the bands assigned to the in-plane skeletal deformation of the benzene ring observed at 1453 and 1500 cm^{-1} decrease in relative intensity. These observations indicate that the plane of the benzene ring is aligned rather parallel to the nickel substrate.

The thickness of the films formed by the procedure described above is estimated from the band intensity in the reflection spectra to be a few hundred angstroms. The reflection spectra of films with such a thickness scarcely provide any direct information about the species chemisorbed on the nickel surface. However, the orientation of molecules in a thin film is governed by the orientation of the species which are adsorbed strongly on the substrate surface and which act as the nuclei of crystal growth.[11] The orientation of the PLA molecule in the film may, therefore, correspond to that of species strongly adsorbed on the nickel surface and playing an important role in the above-mentioned catalytic hydrogenation.

L-β-Phenyl-α-alanine. It is well known that L-*β*-phenyl-α-alanine exists in a crystal as a zwitter ion such as

$$C_6H_5CH_2\text{-}\underset{\displaystyle NH_3^+}{\underset{|}{CH}}\text{-}COO^-$$

As a result, it has the absorptions of an ionized carboxyl group and an NH_3^+ ion. Therefore, the important part of these characteristic bands can be expected to appear between 1400 and 1700 cm^{-1}, by analogy with other amino acids.[15] Figure 4 shows the transmission spectra of L-*β*-phenyl-α-alanine and its *N*-deuterated species, obtained by the KBr disk method in the region from 1400 to 1700 cm^{-1}. The strong three bands at 1500, 1565, and 1628 cm^{-1}, which disappear on *N*-deuteration, as is shown in Fig. 4, may be regarded as the bands due to the vibrations of the NH_3^+ group. The bands at 1410 and 1602 cm^{-1}, which remain unchanged on *N*-deuteration, can be assigned to the CO_2^- symmetric and anti-symmetric stretching vibrations respectively. The bands at 1500 and 1628 cm^{-1} can be assigned to the NH_3^+ symmetric deformation and degenerate deformation respectively by referring

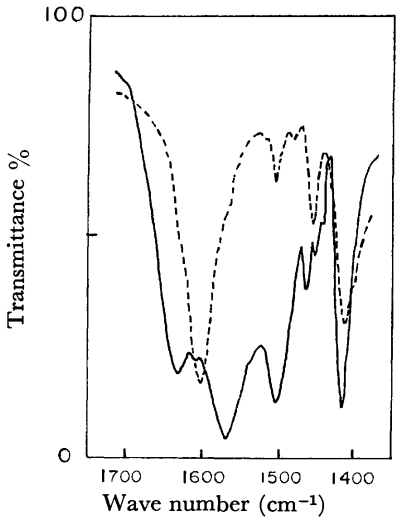

Fig. 4. Transmission spectra of L-β-phenyl-α-alanine (solid line) and its *N*-deuterated species (broken line).

to the assignments for DL-β-phenyl-α-alanine.[16] However, there is a marked difference between the spectrum of L-β-phenyl-α-alanine and that of DL-β-phenyl-α-alanine; the 1565 cm^{-1} band is present only in the former. This band is also observed with D-β-phenyl-α-alanine. According to Tsuboi *et al.*,[15] it is most likely that this band arises from the breaking down of the C_{3v} symmetry of the NH_3^+ group. Except for the 1565 cm^{-1} band, the spectrum of L-β-phenyl-α-alanine is identical with the spectrum of the DL-form, apart from slight shifts; hence, no further descriptions of it will be given.

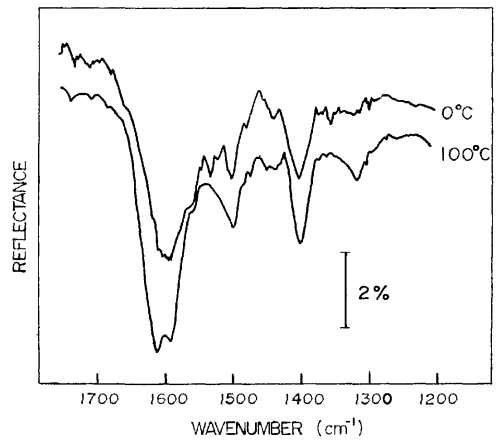

Fig. 5. High sensitivity reflection spectra of thin L-β-phenyl-α-alanine crystals formed on nickel metal surfaces. The temperature refers to the modifying temperature at which the sample was prepared.

Figure 5 shows the high-sensitivity reflection spectrum of the thin L-β-phenyl-α-alanine (L-phenylalanine) film formed on nickel metal surfaces at different modifying temperatures. The spectrum of the thin film is compared with that of the non-oriented sample obtained by using the KBr technique, as in the case of PLA. The thin film spectra show infrared dichroism, which is caused by the preferred orientation in the film; they correspond well to the results obtained by electron-optical methods.[12] The most remarkable feature is the weakness of the NH_3^+ band at 1565 cm^{-1} in the thin film spectra, irrespective of the modifying temperature. This change in intensity may be ascribed to the orientation of the NH_3^+ group, for another NH_3^+ deformation band appears at about 1610 cm^{-1} in the thin film. Another striking difference between the thin film and bulk crystals is seen in Fig. 5; the band at 1500 cm^{-1} due to the symmetric deformation of the NH_3^+ group remarkably decreases in intensity. This may be attributed to the molecular orientation in the thin L-phenylalanine crystal. In view of the fact that the vibrational mode of the NH_3^+ symmetric deformation has a transition moment along the C–N bond, it may be concluded that the C–N bond lies nearly parallel to the nickel substrate.

The most important bands yet to be discussed are those of the CO_2^- stretching vibrations appearing at 1400 and 1600 cm^{-1} in the thin films. It can be seen from Figs. 4 and 5 that the intensity of the band due to the CO_2^- symmetric stretching relative to that of the CO_2^- anti-symmetric stretching decreases with the change from the bulk crystals to the thin film. Considerations of these vibrational modes and the corresponding changing dipole moments provide a possible orientation for the CO_2^- group.

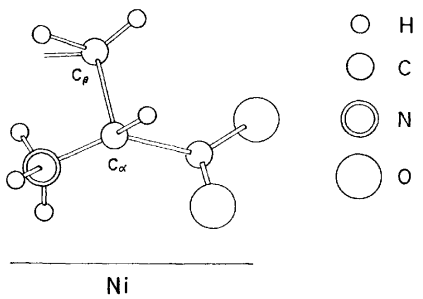

Fig. 6. Molecular orientation of thin L-β-phenyl-α-alanine film formed on nickel metal surface. The phenyl group is omitted from the figure.

No remarkable spectral change is found in the region below 1400 cm^{-1} except for the intensified bands at 700 and 740 cm^{-1}. Since these bands represent the out-of-plane deformations of the benzene ring, the above-mentioned results show the parallel orientation of the benzene ring to the nickel surface. Consequently, the most probable orientation is proposed by assuming that the molecular conformation obtained by X-ray work[14] is valid even for the thin film of the L-phenylalanine. The orientation model of the L-phenylalanine molecule in the thin film crystal is shown in Fig. 6. The aspect of the orientation is compatible with that obtained for α-alanine, so far as the common fragment is concerned,[12,17] suggesting that the nature of interaction between the molecule and nickel substrate is the same for both compounds.

The optical activity of the reaction product of catalytic hydrogenation changes with a change in the modifying temperature.[10] This change may be caused by the change in the posture of the modifying reagent on the nickel surface. The relative intensities of the bands

at 1322 and 1610 cm^{-1} in the thin-film spectra change with the modifying temperature, as can be seen in Fig. 5. This change may be attributed to the different molecular orientations in the films and may correspond to the change in the orientation of the species strongly adsorbed on the nickel surface. However, the results obtained are not sufficiently accurate, partly because of the interference from absorptions due to water vapor, to enable us to discuss the change in the orientation of the surface species with the temperature; any discussion must, therefore, be postponed until further information is available.

The authors wish to express their thanks to Professor Yoshiharu Izumi, Institute for Protein Research, Osaka University, for his kind supply of materials, and also to Dr. Tadao Harada for his useful suggestions.

Studies of Fragment Ion Distribution and Reaction by the Use of a Charge Spectrometer. VII. Fragmentation of Aliphatic Thiol Ions Produced by Charge Exchange with Positive Ions

Kenji YOSHIHARA, Masanao KOBAYASHI, Shigeru IKUTA, and Takanobu SHIOKAWA
Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Sendai 980
(Received December 11, 1974)

Fragmentation of molecular ions of methanethiol, ethanethiol, two kinds of propanethiols, and four kinds of butanethiols formed by charge exchange with positive ions has been studied using a tandem mass spectrometer. The results are compared with those of the corresponding alcohols obtained by Lindholm and coworkers, and similarities and differences between both series of ions are pointed out. The effect of the structure of the molecule on fragmentation is discussed. The fragment ions derived from primary scission are predicted on the basis of the EHMO calculation.

No report has yet been published on fragmentation of thiol ions formed by charge exchange with positive ions, whereas the phenomena were intensively studied with alcohols by Lindholm and coworkers.[1-4] We have been interested in the breakdown phenomena of methanol[5] and methylamine[6] after charge exchange. It is an important problem to understand what mechanisms are involved in the fragmentation of a series of compounds RX, where R is an alkyl group and X is a substituent. Although it would be interesting to elucidate the fragmentation processes of these compounds, previous authors have not studied them systematically. The effects of the size and structure of R, for example, have not been well understood so far.

In this report we have studied fragmentation mechanisms in a series of alkyl thiol ions, RSH^+, formed by charge exchange with positive ions, and found somewhat different behavior between thiols and alcohols. In the studies of electron impact mass spectroscopy, similarities between both series of compounds are usually emphasized, though the abundance of the parent peaks is different.[7] The differences of behavior of the fragmentation between both series of compounds have been made clear by observations using charge exchange reactions, where the energy transfered to the molecular ions is well defined.

Experimental

All the reagents, guaranteed by gas chromatographic analysis, were purchased from the Tokyo Kasei Co. Their purities were re-checked by gas chromatograph before use. The reagents were as follows: methanethiol CH_3SH, ethanethiol C_2H_5SH, 1-propanethiol $CH_3(CH_2)_2SH$, 2-propanethiol $CH_3CH(SH)CH_3$, 1-butanethiol $CH_3(CH_2)_3SH$, 2-methyl-1-propanethiol $(CH_3)_2CHCH_2SH$, 1-methyl-1-propanethiol $CH_3CH_2CH(SH)CH_3$, and 2-methyl-2-propanethiol $(CH_3)_3C$-SH.

Primary ions for the charge exchange reactions were $C_6H_6^+$, H_2S^+, $C_2H_2^+$, Xe^+, Kr^+, Ar^+, Xc^{2+}, Kr^{2+}, Ne^+, Ar^{2+}, and He^+; the source materials were of the high purity reported in the previous studies.[5,6,8-10]

A tandem mass spectrometer of the perpendicular type used here was described in the previous report.[11]

The pressure of the reaction chamber was kept below 6×10^{-6} Torr to avoid secondary reactions with other molecules.

Results

Methanethiol: The appearance potential of methanethiol is 9.44 eV,[12] and the parent ion is produced by the elimination of one of the lone-pair electrons located at the sulfur atom. The fragmentation of methanethiol is shown in Fig. 1. The following processes take place with an increase in excitation energy:

$$CH_3SH \longrightarrow CH_3SH^+ \quad (1)$$

$$CH_3SH^+ \longrightarrow CH_3S^+ + H \quad (2)$$

$$CH_3S^+ \longrightarrow CHS^+ + H_2 \quad (3)$$

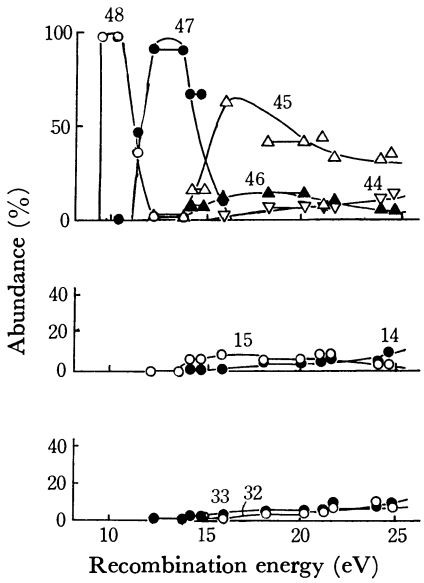

Fig. 1. Breakdown graph of CH_3SH.
m/e 48: CH_3SH^+, 47: CH_3S^+, 46: CH_2S^+, 45: CHS^+, 44: CS^+, 33: SH^+, 32: S^+, 15: CH_3^+, 14: CH_2^+.

These processes are similar to those in the case of methanol except that the elimination of one hydrogen occurs mainly in the S–H bond instead of in the C–H bonds. Rupture of the C–S bond occurs in such a manner that the abundance of CH_3^+ is higher than that of SH^+. S^+ is also produced in several percents in the higher energy region. For the appearance of the S^+ ion, rupture of both the C–S and S–H bonds must occur. It is clear that the S^+ ion is not derived from SH^+, judging from the breakdown curves in Fig.

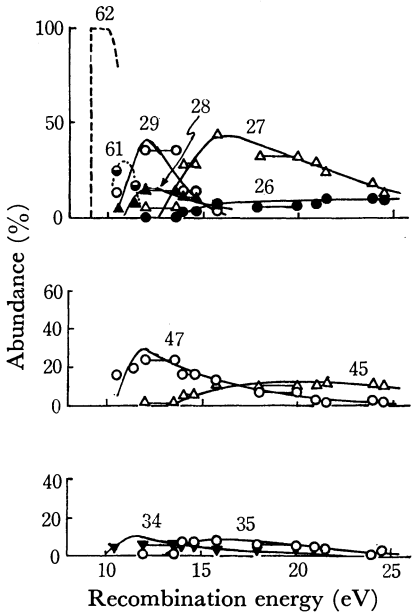

Fig. 2. Breakdown graph of C_2H_5SH.
m/e 62: $C_2H_5SH^+$, 61: $C_2H_5S^+$, 47: CH_2SH^+, 45: CHS^+, 35:SH_3^+, 34: SH_2^+, 29: $C_2H_5^+$, 28: $C_2H_4^+$, 27: $C_2H_3^+$, 26: $C_2H_2^+$.

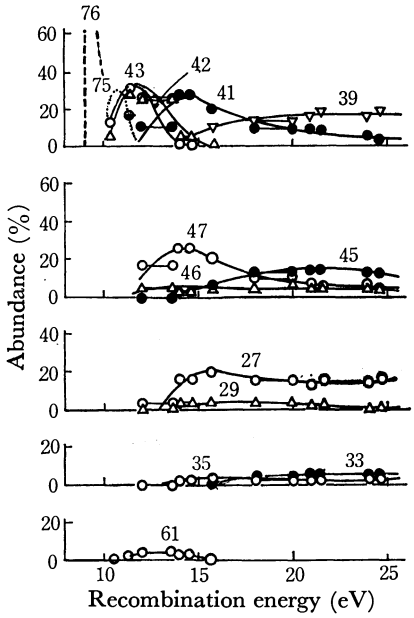

Fig. 3. Breakdown graph of 1-propanethiol.
m/e 76: $C_3H_7SH^+$, 75: $C_3H_7S^+$, 61: $C_2H_4SH^+$, 47: CH_2SH^+, 46: CH_2S^+, 45: CHS^+, 43: $C_3H_7^+$, 42: $C_3H_6^+$, 41: $C_3H_5^+$, 39: $C_3H_3^+$, 35: SH_3^+, 33: SH^+, 29: $C_2H_5^+$, 27: $C_2H_3^+$.

1. Therefore, the remaining possibility is as follows:

$$CH_3S^+ \longrightarrow CH_3 + S^+ \quad (4)$$

The tendency of the breakdown curves in Fig. 1 supports CH_3S^+ as the major precursor of S^+.

Ethanethiol: The fragmentation of ethanethiol is shown in Fig. 2.

The major processes in the breakdown phenomena of the parent ion are (i) rupture of the C–C bond and (ii) that of the C–S bond.

In the C–C bond rupture the following processes are observed:

$$C_2H_5SH^+ \longrightarrow CH_2SH^+ + CH_3 \quad (5)$$

$$CH_2SH^+ \longrightarrow CHS^+ + H_2 \quad (6)$$

In place of CH_2SH^+ in Reaction 5 the CH_3^+ ion whose abundance is a few percent at maximum is formed by the process:

$$C_2H_5SH^+ \longrightarrow CH_2SH + CH_3^+ \quad (7)$$

In the C–S bond rupture the following processes occur predominantly:

$$C_2H_5SH^+ \longrightarrow C_2H_5^+ + SH \quad (8)$$

$$C_2H_5^+ \longrightarrow C_2H_3^+ + H_2 \quad (9)$$

Besides these processes, hydrogen sulfide elimination from the parent ion occurs as follows:

$$C_2H_5SH^+ \longrightarrow C_2H_4^+ + H_2S \quad (10)$$

The relationship between energy and abundance in Fig. 2 clearly shows that the $C_2H_4^+$ ion is not derived from $C_2H_5^+$.

A small amount of SH_3^+ ion appears in the breakdown graph. This species is probably formed by the process:

$$C_2H_5SH^+ \longrightarrow C_2H_3 + SH_3^+ \quad (11)$$

SH_3^+ has an isoelectronic structure with PH_3 and shows high stability in the mediam energy region (15—20 eV).

1-Propanethiol: The breakdown graph of 1-propanethiol is shown in Fig. 3. (i) Rupture of the C–S bond and (ii) that of the C–C bonds are observed.

In the C–S bond rupture the following processes occur as energy increases:

$$C_3H_7SH^+ \longrightarrow C_3H_7^+ + SH \quad (12)$$

$$C_3H_7^+ \longrightarrow C_3H_5^+ + H_2 \quad (13)$$

$$C_3H_5^+ \longrightarrow C_3H_3^+ + H_2 \quad (14)$$

Elimination of hydrogen sulfide occurs in the low energy region in the same manner as Reaction 10.

$$C_3H_7SH^+ \longrightarrow C_3H_6^+ + H_2S \quad (15)$$

The mechanism of formation of the ion $C_2H_3^+$ is not clear, but the following processes are reasonable, judging from the energy relation in the figure:

$$C_3H_6^+ \longrightarrow C_2H_3^+ + CH_3 \quad (16)$$

$$C_3H_7^+ \longrightarrow C_2H_3^+ + CH_4 \quad (17)$$

The formation of SH_3^+ seen in Fig. 3 may be due to the rearrangement of $C_3H_7SH^+$ followed by decomposition:

$$C_3H_7SH^+ \longrightarrow [C_3H_5SH_3^+] \longrightarrow C_3H_5 + SH_3^+ \quad (18)$$

The probability of scission of the C(α)–C(β) bond is higher than that of the C(β)–C(γ) bond. A similar observation has been made in the case of 1-propanol.[3)]

$$C_3H_7SH^+ \longrightarrow CH_2SH^+ + C_2H_5 \quad (19)$$

$$C_3H_7SH^+ \longrightarrow C_2H_4SH^+ + CH_3 \quad (20)$$

As the energy increases CH_2SH^+ decomposes into a hydrogen molecule and CHS^+.

$$CH_2SH^+ \longrightarrow CHS^+ + H_2 \quad (21)$$

2-Propanethiol: The mass spectroscopic patterns obtained by electron impact[13)] show distinct differences in the cases of 1-propanethiol and 2-propanethiol. Posi-

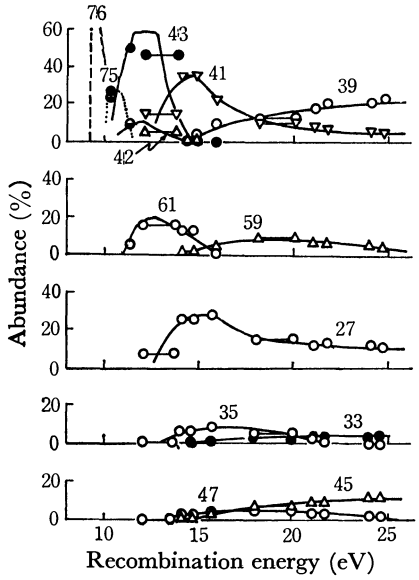

Fig. 4. Breakdown graph of 2-propanethiol.
m/e 76: $C_3H_7SH^+$, 75: $C_3H_7S^+$, 61: $C_2H_4SH^+$, 59: $C_2H_3S^+$, 47: CH_2SH^+, 45: CHS^+, 43: $C_3H_7^+$, 42: $C_3H_6^+$, 41: $C_3H_5^+$, 39: $C_3H_3^+$, 35: SH_3^+, 33: SH^+, 27: $C_2H_3^+$.

tive ion impact using a tandem mass spectrometer is often more useful to understand the fragmentation mechanisms than electron impact is.

The fragmentation of 2-propanethiol is shown in Fig. 4. In the case of the C–S rupture the following process takes place to give $CH_3CHCH_3^+$:

$$i\text{-}C_3H_7SH^+ \longrightarrow CH_3CHCH_3^+ + SH \quad (22)$$

As energy increases the ion $CH_3CHCH_3^+$ decomposes by the following processes:

$$CH_3CHCH_3^+ \longrightarrow C_2H_3^+ + CH_4 \quad (23)$$

$$CH_3CHCH_3^+ \longrightarrow C_3H_5^+ + H_2 \quad (24)$$

$$C_3H_5^+ \longrightarrow C_3H_3^+ + H_2 \quad (25)$$

The rearrangement product SH_3^+ is more abundant in 2-propanethiol (about 10% at maximum) than in 1-propanethiol (4% at maximum). This fact clearly shows that the hydrogen atoms attached to the β carbons are involved in the rearrangement reaction, and it is likely that the probability of the rearrangement depends on the number of the hydrogen atoms available.

In the case of the C–C bond rupture the following reaction occurs:

$$(CH_3)_2CHSH^+ \longrightarrow C_2H_4SH^+ + CH_3 \quad (26)$$

As the energy increases this $C_2H_4SH^+$ ion seems to decompose by the following processes:

$$C_2H_4SH^+ \longrightarrow C_2H_3^+ + H_2S \quad (27)$$

$$C_2H_4SH^+ \longrightarrow SH_3^+ + C_2H_2 \quad (28)$$

*1-Butanethiol (*n*-Butyl Mercaptan)*: The fragmentation of 1-butanethiol is shown in Fig. 5. In the case of the C–S bond rupture the hydrogen sulfide elimination process,

$$C_4H_9SH^+ \longrightarrow C_4H_8^+ + H_2S \quad (29)$$

occurs as well as the following process,

$$C_4H_9SH^+ \longrightarrow C_4H_9^+ + SH \quad (30)$$

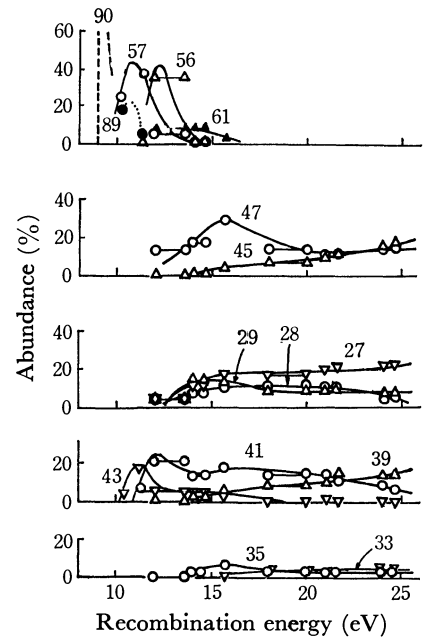

Fig. 5. Breakdown graph of 1-butanethiol.
m/e 90: $C_4H_9SH^+$, 89: $C_4H_9S^+$, 57: $C_4H_9^+$, 56: $C_4H_8^+$, 47: CH_2SH^+, 45: CHS^+, 43: $C_3H_7^+$, 41: $C_3H_5^+$, 39: $C_3H_3^+$, 35: SH_3^+, 33: SH^+, 29: $C_2H_5^+$, 28: $C_2H_4^+$, 27: $C_2H_3^+$.

$C_3H_7^+$ and $C_2H_5^+$ are probably produced by the direct scission of the C–C bonds from the parent ion; the molecular orbital calculation in Table 2 shows the presence of these ions as the primary scission products from the parents.

$$C_4H_9SH^+ \longrightarrow C_3H_7^+ + CH_2SH \quad (31)$$

$$C_4H_9SH^+ \longrightarrow C_2H_5^+ + C_2H_4SH \quad (32)$$

An alternative path for the formation of the ion $C_2H_5^+$ is $C_4H_9^+ \rightarrow C_2H_5^+ + C_2H_4$. The energy relationship in Fig. 5 shows that this process is possible. Formation of the $C_3H_3^+$ or $C_2H_3^+$ ions in the median and higher energy region in the figure will be explained by successive elimination of hydrogen molecules or by rupture of the C–C bonds in $C_4H_8^+$ *etc.*

The formation of $C_2H_4SH^+$ and CH_2SH^+ occurs by the following process:

$$C_4H_9SH^+ \longrightarrow C_2H_4SH^+ + C_2H_5 \quad (33)$$

$$C_4H_9SH^+ \longrightarrow CH_2SH^+ + C_3H_7 \quad (34)$$

2-Methyl-1-propanethiol (Isobutyl Mercaptan): The breakdown graph of this substance is shown in Fig. 6. The formation of $C_4H_8^+$ and $C_4H_9^+$ by the processes shown in Reactions 29 and 30 appears clearly in the figure. Besides these species, $C_3H_7^+$ in Reaction 31 and its degradation product ions, $C_3H_5^+$ and $C_3H_3^+$, appear also. The ion $C_2H_5^+$ or $C_2H_3^+$ may be a secondary or tertiary product due to a rearrangement of hydrogen atoms on the carbon skeleton. CH_2SH^+ in Reaction 34 is also detectable in this case.

*1-Methyl-1-propanethiol (*sec*-Butyl Mercaptan)*: Figure 7 shows the fragmentation of the substance. In this case formation of $C_4H_8^+$ by hydrogen sulfide elimination from the parent ion is a rather small possibility, and the ion $C_4H_9^+$ appears to be important. It is

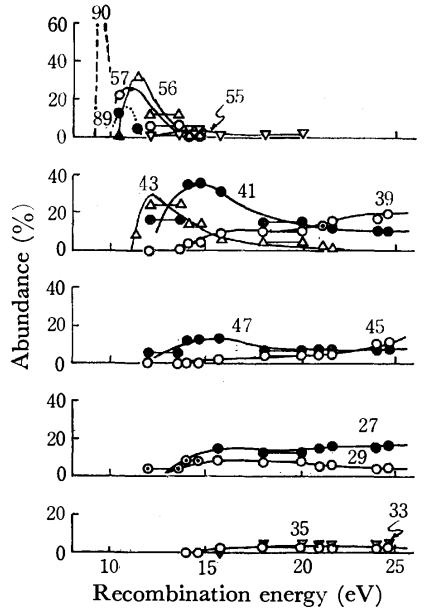

Fig. 6. Breakdown graph of 2-methyl-1-propanethiol. *m/e* 90: $C_4H_9SH^+$, 89: $C_4H_9S^+$, 57: $C_4H_9^+$, 56: $C_4H_8^+$, 55: $C_4H_7^+$, 47: CH_2SH^+, 45: CHS^+, 43: $C_3H_7^+$, 41: $C_3H_5^+$, 39: $C_3H_3^+$, 35: SH_3^+, 33: SH^+, 29: $C_2H_5^+$, 27: $C_2H_3^+$.

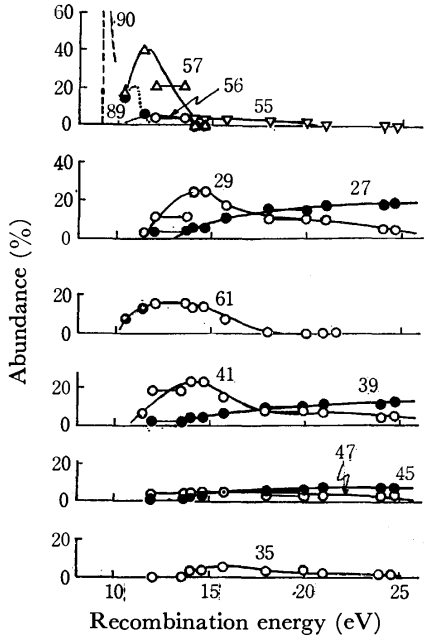

Fig. 7. Breakdown graph of 1-methyl-1-propanethiol. *m/e* 90: $C_4H_9SH^+$, 89: $C_4H_9S^+$, 61: $C_2H_4SH^+$, 57: $C_4H_9^+$, 56: $C_4H_8^+$, 55: $C_4H_7^+$, 47: CH_2SH^+, 45: CHS^+, 41: $C_3H_5^+$, 39: $C_3H_3^+$, 35: SH_3^+, 29: $C_2H_5^+$, 27: $C_2H_3^+$.

interesting to see that $C_2H_4SH^+$ is prominent in the lower energy region (10—15 eV). The ion $C_2H_5^+$ is produced probably by direct scission from the parent ion. $C_3H_5^+$ is produced not as a degradation product from $C_3H_7^+$, but as a product which is derived probably from $C_4H_9^+$ by elimination of CH_4.

$$C_4H_9SH^+ \xrightarrow{-SH} C_4H_9^+ \xrightarrow{-CH_4} C_3H_5^+ \qquad (35)$$

2-Methyl-2-propanethiol (tert-Butyl Mercaptan): Figure

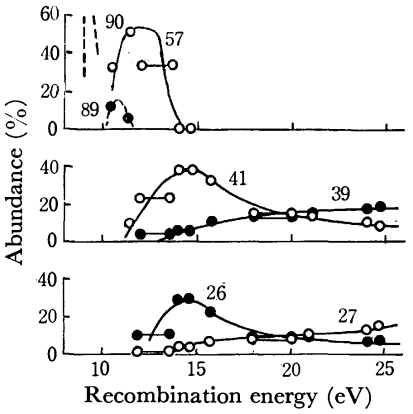

Fig. 8. Breakdown graph of 2-methyl-2-propanethiol. *m/e* 90: $C_4H_9SH^+$, 89: $C_4H_9S^+$, 57: $C_4H_9^+$, 41: $C_3H_5^+$, 39: $C_3H_3^+$, 29: $C_2H_5^+$, 27: $C_2H_3^+$.

8 shows the breakdown curves for this substance. The processes which are prominent for this substance involve formation of the $C_4H_9^+$ and $C_3H_5^+$ ions as in Reaction 35. Besides these, the ion $C_2H_5^+$ appears as a fragmentation product from $C_4H_9^+$ after rearrangement of the hydrogen atoms. In this case formation of $C_4H_8^+$ by elimination of hydrogen sulfide is only a slight possibility.

Discussion

The comparison of the present results of fragmentation in CH_3SH, C_2H_5SH, and 1-C_3H_7SH with those in CH_3OH, C_2H_5OH, and 1-C_3H_7OH obtained by Lindholm and coworkers[1-3] is summarized in Table 1. Only the main processes are listed in the table.

In methanethiol the main processes of hydrogen elimination are similar to those in methanol.[2,5] However, the SH^+ and S^+ ions are observed in methanethiol, whereas almost no OH^+ and O^+ ions are observed in methanol. The presence of SH^+ and the absence of OH^+ reflect the difference of bond strength between C–S and C-O. The bond energy of C-S (~70 kcal/mol) is larger than that of C-O (~90 kcal/mol).[14] The major precursor of the S^+ ion is not SH^+ but CH_3S^+, judging from the energy relation in Fig. 1.

In ethanethiol the fragmentation processes are rather different from those in ethanol. Hydrogen elimination is less important in ethanethiol than in ethanol. Elimination of hydrogen sulfide can be observed in ethanethiol, whereas almost no elimination of water is observed in ethanol. Formation of CH_2OH^+ in ethanol is much more important than that of CH_2SH^+ in ethanethiol, probably owing to the difference of stability between them. The rupture of the C-S bond occurs more easily than that of the C-O bond does.

In propanethiol hydrogen elimination from the parent ion is less important than in propanol. Hydrogen sulfide elimination from the parent ion $C_3H_7SH^+$ is prominent, but water elimination from $C_3H_7OH^+$ giving $C_3H_6^+$ is much more prominent than hydrogen sulfide elimination. The rupture of the C–S bond giving $C_3H_7^+$ is easier than that of the C–O bond, owing to the difference of the bond strength between them.

TABLE 1. COMPARISON OF FRAGMENTATION BY CHARGE EXCHANGE WITH POSITIVE IONS BETWEEN THIOLS AND ALCOHOLS

	Thiol	Alcohol
Methane	$CH_3SH^+ \xrightarrow{-H} CH_3S^+$ $CH_3S^+ \xrightarrow{-H_2} CHS^+$ $CH_3SH^+ \rightarrow CH_3^+ + SH^+$ $CH_3SH^+ \rightarrow S^+ + CH_3$	$CH_3OH^+ \xrightarrow{-H} CH_2OH^+$ $CH_2OH^+ \xrightarrow{-H_2} CHO^+$ $CH_3OH^+ \rightarrow CH_3^+ + OH$
Ethane	$C_2H_5SH^+ \xrightarrow{-H} CH_3CH_2S^+$ $CH_3CH_2S^+ \xrightarrow{-CH_3} CH_2SH^+ \xrightarrow{-H_2} CHS^+$ $C_2H_5SH^+ \xrightarrow{-SH} C_2H_5^+ \xrightarrow{-H_2} C_2H_3^+$ $C_2H_5SH^+ \xrightarrow{-H_2S} C_2H_4^+$	$C_2H_5OH \xrightarrow{-H} CH_3CHOH^+$ $CH_3CHOH^+ \xrightarrow{-CH_3} CH_2OH^+ \xrightarrow{-H_2} CHO^+$ $C_2H_5OH \xrightarrow{-OH} C_2H_5^+ \xrightarrow{-H_2} C_2H_3^+$
Propane	$C_3H_7SH^+ \xrightarrow{-H} C_3H_7S^+$ $C_3H_7S^+ \xrightarrow{-C_2H_5} CH_2SH^+ \xrightarrow{-H_2} CHS^+$ $C_3H_7SH^+ \xrightarrow{-SH} C_3H_7^+ \xrightarrow{-H_2} C_3H_5^+ \xrightarrow{-H_2} C_3H_3^+$ $C_3H_7SH^+ \xrightarrow{-H_2S} C_3H_6^+$	$C_3H_7OH^+ \xrightarrow{-H} C_3H_6OH^+$ $C_3H_6OH^+ \xrightarrow{-C_2H_5} CH_2OH^+ \xrightarrow{-H_2} CHO^+$ $C_3H_7OH^+ \xrightarrow{-OH} C_3H_7^+$ etc. $C_3H_7OH^+ \xrightarrow{-H_2O} C_3H_6^+$

⟹ important (>40%) ⟶ moderately important (40—20%) ⋯⋯→ less important (<20%)

Formation of CH_2SH^+ is less prominent than that of CH_2OH^+.

In the case of ethanol, for example, Koch and Lindholm[1] discussed the suggestion that the ionized oxygen atom has a valency of three and has a tendency towards formation of a double bond between C and O^+. Owing to this tendency, the other bonds of the carbon atom are weakened. They considered the following three resonant structures:

$$\left.\begin{array}{ll} \text{(a)} & CH_3-CH_2-\overset{+}{O}-H \\ \text{(b)} & -CH_3\ CH_2=\overset{+}{O}-H \\ \text{(c)} & CH_3-\underset{H}{CH}=\overset{+}{O}-H \end{array}\right\} \quad (36)$$

A similar consideration can apply to the cases of the higher alcohols and also to the cases of the corresponding thiols. Stabilization through an electron-releasing conjugative effect is well known to occur in the following manner:

$$H_2C=\overset{+}{\underset{\cdot\cdot}{X}}-H \longleftrightarrow H_2\overset{+}{C}-\underset{\cdot\cdot}{\overset{\cdot\cdot}{X}}-H \quad (37)$$

$$H_3\overset{\ominus}{\underset{\cdot\cdot}{C}}-CH=\overset{\oplus}{\underset{\cdot\cdot}{X}}-H \longleftrightarrow CH_2=\underset{H}{CH}-\underset{\cdot\cdot}{\overset{\cdot\cdot}{X}}-H \quad (38)$$

where X is O or S. As the π-bonding between C2p and S3p is weaker than that between C2p and O2p, rupture of the C-S bond occurs more easily than that of the C–O bond does. This tendency is pronounced in Table 1. The ions CH_2OH^+ and CH_3CHOH^+ (or $CH_3CH_2CHOH^+$) are remarkable compared to the ions $C_2H_5^+$ and $C_3H_7^+$, which are produced by the C-O rupture in the cases of ethanol and 1-propanol. On the other hand, the ions CH_2SH^+ and CH_3CHSH^+ (or $CH_3CH_2CHSH^+$) are not more abundant than $C_2H_5^+$ and $C_3H_7^+$ in the cases of ethanethiol and 1-propanethiol.

Hydrogen sulfide or water elimination from the molecular ions occurs easily in the larger thiols or alcohols. This process seems to proceed through the intermediate $R\text{-}SH_2^+$ or $R\text{–}OH_2^+$, which probably weakens the double bond formation between R-S or R-O in Reaction 36 (a) and (b) and therefore results in the rupture of the bond R-S or R–O in the lower energy region.

For the compounds larger than *n*-propyl, the apparent similarity is more pronounced for thiols and alcohols.[7] Increase of the length of the carbon chain causes a larger contribution of the alkyl group which is common to thiols and alcohols. This makes the fragmentation pattern similar for larger thiols and alcohols. However, the larger cross section of the sulfur atom in thiols for charge exchange or electron impact compared with that of oxygen in alcohols makes the parent ion more prominent in thiols. This fact will be confirmed by the study using a double mass spectrometer cross section measurement.[15]

Next, let us consider the effect of the structure of the compound. Methyl elimination from 2-propanethiol (SH: secondary position) giving C_2H_4SH is remarkable, whereas that from 1-propanethiol has only a small probability. For 2-propanethiol the following resonance forms should be considered in the same manner as Reaction 36:

$$\left.\begin{array}{ll} \text{(a)} & CH_3-CH(CH_3)-\overset{+}{S}-H \\ \text{(b)} & -CH_3\ CH(CH_3)=\overset{+}{S}-H \\ \text{(c)} & CH_3-\underset{CH_3}{CH}=\overset{+}{S}-H \end{array}\right\} \quad (39)$$

As (b) and (c) are the same expression, only the res-

onance between (a) and (b) can be taken in account here. Thus it is easily understood why methyl elimination from the molecular ion is highly probable in 2-propanethiol. On the other hand, it is obvious that 1-propanethiol loses its methyl group by a different mechanism. The ionic species $CH_2=\overset{+}{S}-H$ is known to be more abundantly produced than $CH_3CH=\overset{+}{S}-H$ on electron impact of 1-propanethiol. Generally the β-cleavage is easier than the γ-cleavage for sulfur-containing ions.[16] The same tendency is more pronounced for the case of electron impact mass patterns in 1- and 2-propanols.[17]

The difference of the mass patterns between 1-(primary) and 2-(secondary) butanethiols can be understood in principle in the same manner as stated above. The prominent ions CH_2SH^+ in 1-butanethiol and $C_2H_4SH^+$ in 2-butanethiol and formed through the resonance containing the C=S double bond.

Fragmentation of the tertiary compound of butyl mercaptan is entirely different from the other butyl mercaptan. It is initiated by rupture of the labile C-S bond. Not only hydrogen migration but also rearrangement of the carbon structure are involved in the decomposition processes.

In previous papers,[18-20] we have studied the possibility of direct fragmentation of the molecular ions from their electronically excited states. We found that this is true for various systems, by comparing the experimental results with those obtained by calculation. As calculation of methanethiol has been done in the other paper[21] submitted in this bulletin, only the results of the calculation for two kinds of propanethiols and four kinds of butanethiols are shown here. According to the Extended Hückel Molecular Orbital (EHMO) method the energy levels and eigenvectors of the molecular orbitals are calculated, and the main characters of the MO's are determined on the basis of these calculated eigenvectors. When an electron is ejected from a certain molecular orbital by charge exchange, the bond corresponding to the molecular orbital is subjected to scission, resulting in formation of various fragment ions. The energy levels, the main characters, and the product ions expected are shown in Tables 2 and 3 for propanethiols and for butanethiols, respectively. The tendency of appearance of the ions is in good agreement with the experimental results in Figs. 3 and 4 for propanethiols, and the same is true

Table 2. Calculated MO energy, calculated MO assignment, and fragment ions for 1-propanethiol and 2-propanethiol

	Calculated MO energy (eV)	Main character	Produced ions
1-Propanethiol	10.39	n(S)	76

C_m: C in 2-methyl group.

for butanethiols (see Figs. 5—8). It is likely that there is direct scission, which will give the various fragment ions shown in Tables 2 and 3. Even if all of the fragment ions are not derived from the direct scission of the molecular ions, at least some parts of these ions are considered to be formed by the scission from the electronically excited molecular ions. As the fragmentation processes in the higher energy region are profoundly influenced by the secondary scission, it is obvious that the calculation performed above cannot apply to the processes in the higher energy region.

From Table 2, it is shown that fragmentation in 2-propanethiol is simpler than that in 1-propanethiol; this tendency is in agreement with that obtained in the experimental results (Figs. 3 and 4). Similarly, from Table 3 fragmentation of 2-methyl-2-propanethiol (tertiary compound) is expected to be simpler than that of any other compounds of butanethiol. This tendency is in agreement with that obtained by the experiments in Figs. 5—8.

It is noteworthy that this kind of study using a double mass spectrometer can supply information about ion-molecule reactions involving the excited parent ions; it is especially useful to obtain the energy-abundance relation among the fragment ions.

The authors thank Mr. Hiraga for his cooperation throughout this work.

The Role of Solvents in the Dimerization of the 2,3-Dichloro-5,6-dicyano-*p*-benzoquinone Anion Radical

Akihiko YAMAGISHI

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received January 6. 1975)

The reversible dimerization of the anion radical of 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ) has been studied in water, acetonitrile (MeCN), and other organic solvents. The analysis of the thermodynamic parameters of dimerization equilibria reveals that a large negative entropy term plays a primary role in determining the equilibrium constants. The temperature-jump measurement shows that the forward rate constant in water containing 5.8 M urea is nearly a diffusion controlled one, $(1\pm0.5)\times10^8$ M^{-1} s^{-1} at -6 °C. In MeCN–water mixtures, the backward reaction rate increases with the square of the MeCN concentration. This result suggests that a dimer is effectively decomposed by the successive attacks of the two MeCN molecules.

Since the theoretical work by Hausser and Murrell, the dimerization phenomena of ion radicals have been investigated extensively.[1-6] The main attention has been focused on the interaction between unpaired electrons. In this context, the dimerization in solution was compared to the stacking of ion radicals in the crystalline state.[4]

In the present work, the dimerization phenomena is taken up from a slightly different view-point: that is, the role of solvents played in the dimerization equilibria of ion radicals. Since the attractive force in a dimer arises from the charge-transfer interaction between two fragments, it must be a short-range force.[7] Thus the slight disturbance by solvent molecules on the geometrical structure of a dimer will cause a serious effect on the interaction of unpaired electrons, and accordingly on the stability of a dimer. In this sense the role of solvents in dimerization equilibria will be completely different from that in the ion-pair formation of a simple salt. In the latter case, the dielectric continuum theory has proved to be successful in interpreting the solvent effect on the ion-pair formation.[8] In the dimerization of ion radicals, however, more specific descriptions of solvents and solvation structures are needed in order to interpret the solvent effects on the dimerization equilibria. Until now, no systematic study on this topic has been carried out except for a few examples,[2,9] probably because the ion radicals dimerize only under extreme conditions such as low temperature, or oxygen-free conditions, or concentrated acidic media.[2-6]

In this paper, the study of the dimerization of the 2,3-dichloro-5,6-dicyano-*p*-benzoquinone anion radical (DDQ^-) is presented. DDQ^- dimerizes at room temperature in all solvents used. It is relatively stable in solution under air, although the stability depends on solvents and counter cations. The thermodynamic parameters of dimerization are obtained spectrophotometrically. The rate of dimerization is measured by a temperature-jump apparatus. From both the equilibrium and the rate data, the role of solvents in a dimerization reaction has been made clear, particularly from the view-point of the molecular processes involving radicals and solvent molecules. Some solvents are found to form a rigid solvation structure with a dimer, whereas others effectively decompose such a structure.

Experimental

The sodium (Na^+) and the tetraethylammonium (NEt_4^+) salts of DDQ were obtained by reducing DDQ with NaI and MEt_4I in acetonitrile (MeCN) respectively. MeCN, methanol (MeOH), and ethanol (EtOH) were purified as described elsewhere.[10] Acetone (Me_2CO), dimethylformamide (DMF), tetrahydrofuran (THF), and dimethoxyethane (DME) were distilled once. Water was deionized and distilled once. Tetra-*n*-propylammonium perchlorate (NPr_4ClO_4) was prepared by the reaction of NPr_4OH with $HClO_4$ in water. $NaClO_4$ of a C.P. grade was used after being dried at 130 °C.

The absorption spectra were measured with a Hitachi model EPS-3T spectrophotometer. In MeCN, Me_2CO and DMF, both Na^+DDQ^- and $NEt_4^+DDQ^-$ are stable enough for the precise spectroscopic measurements. In THF and DME, $NEt_4^+DDQ^-$ is found more stable than Na^+DDQ^-, although both salts decompose gradually. In EtOH, MeOH, and H_2O, both $NEt_4^+DDQ^-$ and Na^+DDQ^- decompose in the order of $H_2O>MeOH>EtOH$, which is inevitable even in a vacuum. The equilibrium measurements in such solvents as cause the decomposition of M^+DDQ^- were performed by reading the absorbances at the dimer and the monomer band repeatedly within several seconds. Here we assumed that the decomposition products of DDQ^- do not affect the dimerization equilibria. The extinction coefficients of DDQ^- monomer ε_M in these solvents were determined from the absorbance when the 0.1 ml of the MeCN stock solution of $NEt_4^+DDQ^-$ (*ca.* 10^{-3} M) was dissolved into the 2.0 ml of each solvent. ε_M was calculated from the known ε_M in MeCN (6.3×10^3 at 594 nm), assuming that the presence of a small amount of MeCN does not affect the magnitude of ε_M in each solvent. The extinction coefficients of DDQ^- dimer ε_D in all solvents except H_2O are assumed to be equal to that in MeCN. The details in determining ε_D in MeCN and water are described in the results.

The conductivity was measured with a Yanagimoto model MY-7 conductivity outfit. The temperature of a cell was maintained at 20 °C by circulating water. In THF, the concentration of $NEt_4^+DDQ^-$ was measured simultaneously by absorption spectra.

The rate was measured with a Union Giken temperature-jump apparatus. This appearatus instantly raises *ca.* 2 ml sample solution by 20—30 kV discharge through a co-axial cable. The cable has a length of 200 m, 0.02 μF capacitance, and 75 Ω characteristic impedance. The rise time of temperature was determined by observing the rate of a protonation reaction of phenolphthalein in H_2O at various ionic strength adjusted by NaCl. The temperature rise is attained within 2 μs when a sample solution has a conductivity higher

than $10^{-3}cm^{-1}\Omega^{-1}$. For the MeCN system, NPr_4ClO_4 is used as a conducting electrolyte. The reaction was monitored by the change of the transmittance at the dimer band near 710 nm. The amount of DDQ^- electrolyzed at discharge was concluded to be negligible since the concentration change was less than 5% after several times of discharge. The temperature of a sample solution was maintained by circulating EtOH cooled by liquid nitrogen. The temperature was measured by a thermocouple just before discharge. For the MeCN–water system, the sample solution was prepared by mixing a H_2O solvent containing 0.1 M NaCl and 6.0 M urea with the MeCN stock solution of $NEt_4^+DDQ^-$, both of which were pre-cooled at the desired temperature. The measurement was done about 3 minutes after preparing the solution. Thus, the concentration uncertainty of DDQ^- was estimated to be within 10%.

Results

Dimerization Equilibria in Various Solvents. A new absorption peak appears at 710 nm when Na^+DDQ^- is dissolved in MeCN to the concentration higher than 10^{-3} M (Fig. 1). In the concentration range of Na^+-

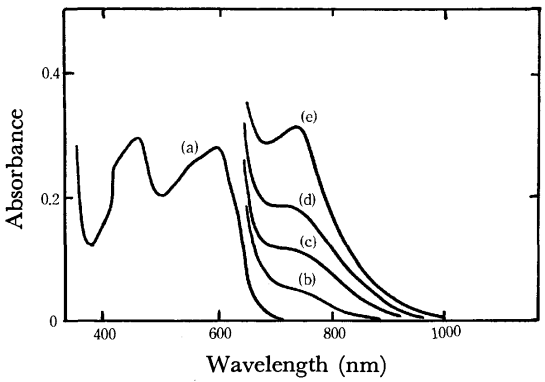

Fig. 1. The visible spectra of Na^+DDQ^- in MeCN at various concentrations: a) 4.5×10^{-5}, b) 1.9×10^{-3}, c) 2.9×10^{-3}, d) 3.7×10^{-3} and e) 4.6×10^{-3} M at 15 °C.

DDQ^- from 1×10^{-3} to 5×10^{-3} M, the absorbance at 710 nm increases exactly in proportion to the square of the concentration of Na^+DDQ^-. This phenomena is compared with the facts that the anion radicals of chloranil and *p*-benzoquinone dimerize in ethanol at low temperature, showing a new peak at 670 and 585 nm, respectively.[3,4] Assuming the dimer formation for DDQ^- ion,

$$2DDQ^- \rightleftarrows (DDQ^-)_2;\ K \qquad (1)$$

the absorbance at 710 nm, A_{710}, is related to the concentration of Na^+DDQ^-, C, as follows:

$$K = [(DDQ^-)_2]/[DDQ^-]^2 = A_{710}/\varepsilon_D(1-\alpha)^2C^2 \qquad (2)$$

where ε_D is a molar extinction coefficient of a dimer at 710 nm and α a degree of association. In deriving this relation, Na^+DDQ^- is assumed to dissociate completely in MeCN. This point is stated later in more detail. A_{710} would not increase linearly with C^2, since α becomes larger as C increases. The observation that A_{710} is exactly proportional to C^2 within an experimental error implies that K in the present system is too small to detect the variation of α with C. In this case, Eq. (2) reduces to

$$K = A_{710}/\varepsilon_D C^2, \qquad (3)$$
$$\varepsilon_D K = (1.7\pm0.2)\times10^4\ M^{-2} \text{ at } 15°C.$$

In order to obtain both K and ε_D, we first estimate ε_D in the following ways: (i) Assuming no absorption of a dimer at 594 nm where a monomer has an absorption peak, the decrease of the monomer band caused by dimerization is related to the dimer band absorption as below:

$$\Delta A_{594}/A_{710} = -2\varepsilon_M/\varepsilon_D \qquad (4)$$

where ε_M is a molar extinction coefficient of a monomer at 594 nm, 6.3×10^3. (ii) The addition of NPr_4ClO_4 is found to increase the absorption at 710 nm, giving no influence to the spectral shape of a monomer band. This effect is interpreted as the displacement of the equilibrium (1) to the righthand side due to the presence of the ionic atmosphere of NPr_4^+ ions. Therefore, the decrease of the absorbance at 594 nm when NPr_4ClO_4 is added into the MeCN solution is related to the increase of the absorbance at 710 nm as follows:

$$\Delta A_{594}/\Delta A_{710} = -2\varepsilon_M/\varepsilon_D. \qquad (5)$$

From relation (4), $\varepsilon_M/\varepsilon_D$ is obtained to be 1.0 ± 0.2, leading to $\varepsilon_D=(6.3\pm1)\times10^3$. From the difference spectrum of the sample solution containing 2.2×10^{-3} M $NEt_4^+DDQ^-$ and 0.123 M NPr_4ClO_4 with the solution of 2.2×10^{-3} M $NEt_4^+DDQ^-$ as reference, $\Delta A_{594}/\Delta A_{710}$ is obtained to be -2.4 ± 0.4, resulting in $\varepsilon_D=(7.2\pm2)\times10^3$. Thus the average value of ε_D is estimated to be $(7\pm1)\times10^3$ at 710 nm. Using this value, K is determined to be $2.5\pm0.5\ M^{-1}$ at 15 °C.

Similar new peaks around 710 nm are also observed, using DMF, Me_2CO, THF, DME, EtOH, and H_2O as solvents. In these solvents except for H_2O, K is calculated using the same ε_D value as obtained for MeCN and the proportional constant of A_{710} against C^2 in each solvent. For water, the K which is calculated in this way, is so large that we doubt the validity of the assumption that ε_D in H_2O is of the same magnitude as in MeCN. Thus ε_D in H_2O is determined independently by methods (i), additionally (iii) from the temperature-jump signals at the monomer and the dimer bands (Figs. 10 and 11). ε_D in H_2O is determined to be (i) $(2.5\pm0.8)\times10^4$ and (iii) $(2.4\pm0.8)\times10^4$. Taking the average of these values, ε_D is estimated to be $(2.5\pm1)\times10^4$. The large uncertainty for ε_D in H_2O arises from the gradual decomposition of DDQ^- in H_2O. In the temperature region of 0—30 °C, a straight line is obtained by plotting $\log K$ *versus* the reciprocal of absolute temperature for all solvents, from which the enthalpy and the entropy changes in reaction (1) are determined. They are given in Table 1.

It is likely that DDQ^- forms an ion-pair with a positive ion in solvents with small dielectric constants. Therefore, the conductivity of Na^+DDQ^- and NEt_4^+-DDQ^- is measured in MeCN and THF. The results are shown in Fig. 2.

$$M^+DDQ^- \rightleftarrows M^+ + DDQ^-;\ K_d \qquad (6)$$

In MeCN, the molar conductivity, λ, of M^+DDQ^- (M^+=Na^+, NEt_4^+) is almost constant with the change

TABLE 1. THE THERMODYNAMIC PARAMETERS OF THE DIMERIZATION EQUILIBRIUM OF $NEt_4^+DDQ^-$ IN VARIOUS SOLVENTS
λ denotes an absorption peak of a dimer.

Solvent	K(10 °C)/ M^{-1}	ΔH/ kcal·M^{-1}	ΔS/e.u.	λ/nm
MeCN	3.7	−9.7±1.0	−29±3	710
DMF	1.4	−7.0±0.2	−24±2	710
Me_2CO	1.1	−7.2±0.2	−25±2	720
THF	17	−3.0±0.2	−4.9±2	710
DME	13	−3.3±0.5	−6.5±2	710
EtOH	5.2	−5.0±1.0	−14±3	715
MeOH	5.0	−3.7±1.0	−11±4	712
H_2O	1300	−8.8±1.0	−17±2	712

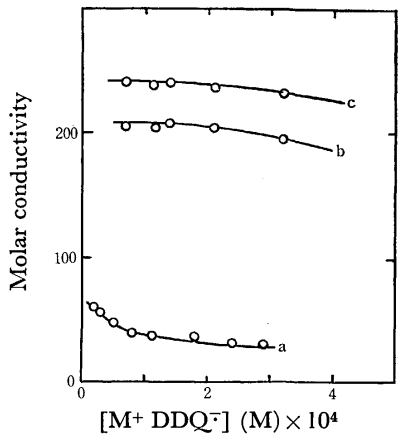

Fig. 2. The electric conductivity of M^+ DDQ^- in MeCN and THF at 20 °C. a) $NEt_4^+DDQ^-$ in THF, b) Na^+ DDQ^- in MeCN and c) NEt_4^+ DDQ^- in MeCN.

of the concentration. Thus, it is concluded that in MeCN, M^+DDQ^- dissociates completely to the free ions. Under this conclusion the limiting molar conductivity, λ_∞, of DDQ^- is estimated to be 150, since λ_∞ for Na^+ and NEt_4^+ are reported to be 70 and 86 respectively.[11] In other solvents whose dielectric constants are similar to that of MeCN, M^+DDQ^- is considered to dissociate completely. On the other hand, $NEt_4^+DDQ^-$ forms an ion pair at least partially in THF, because λ in THF is about 10% of that in MeCN, and increases as the decrease of the concentration. The approximate value of K_d is estimated by the equation

$$K_d = C\lambda^2/\lambda_\infty^2, \quad (7)$$

where λ_∞ is determined by extrapolating the straight line of λ *versus* $\sqrt{C}$ to the infinite dilution. K_d is determined to be about 10^{-5} M at 20 °C. This means that more than 90% of $NEt_4^+DDQ^-$ is ion-paired at $C=10^{-3}$ M. Thus, the dimerization equilibrium of NEt_4^+-DDQ^- in THF is almost expressed by the following equation:

$$2NEt_4^+DDQ^- \rightleftharpoons (NEt_4^+DDQ^-)_2 \quad (8)$$

The dimerization in DME is also considered to take place between two $NEt_4^+DDQ^-$s.

It is likely that DDQ^- is hydrogen-bonded on the oxygen atoms with the protonic solvents like EtOH, MeOH, and H_2O. The electronic spectra of NEt_4^+-

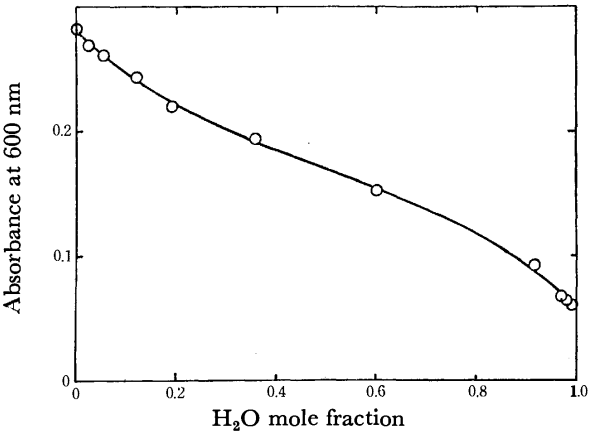

Fig. 3. The change of the absorbance of DDQ^- at 600 nm with the mole fraction of H_2O in an MeCN–H_2O mixed solvent. $[NEt_4^+DDQ^-]$ 4.6×10^{-5} M.

DDQ^- monomer depend on solvents and solvent composition. The absorption peak at 594 nm in MeCN displaces to the shorter wavelength when the salt is dissolved in alcohols or water. The qualitative feature of this phenomena is displayed by plotting the change of absorbance at 600 nm, A_{600}, against the mole fraction of H_2O (Fig. 3). The general trend of A_{600} with H_2O mole fraction well corresponds to the change of the ^{13}C coupling constant for *p*-benzoquinone anion radical (Q^-) in MeCN-H_2O mixtures recently observed by Stone and Maki.[12] In these investigations the change of the hyperfine coupling constants of carbon-13 is attributed to the specific solvation of Q^- by both MeCN and H_2O molecules. In the low concentration region of H_2O, Q^- is solvated by two MeCN molecules. In the medium concentration region of H_2O, Q^- is solvated by one MeCN and one H_2O molecule. In the high concentration region of H_2O, Q^- is solvated by two H_2O molecules. Therefore, it is concluded that in the present system there exists a competition between H_2O and MeCN for solvating DDQ^- ions although no theoretical basis for the solvent effect on the electronic spectra of DDQ^- is available at present. Contrary to the DDQ^- monomer, the absorption peak of a dimer is little affected by the solvents as given in Table 1. However, the remarkably large equilibrium constant in H_2O may clearly be related to the hydrogen-bonding property of water. This will be treated from the kinetic point of view in a later section.

The Effect of Cations on the Dimerization Equilibria. The presence of counter ions affects the dimerization equilibria remarkably. In Fig. 4, the increase of the absorbance at 710 nm is shown when $NaClO_4$, NEt_4ClO_4, and NPr_4ClO_4 are added. Although the ion-pairing of M^+DDQ^- is neglected in MeCN in the concentration range below 10^{-3} M, DDQ^- and $(DDQ^-)_2$ probably form ion-pairs with cations in the high concentration of cation. In case of $NaClO_4$, this is confirmed from the change of electronic spectra of a DDQ^- monomer and a dimer when a large amount of $NaClO_4$ is present (Figs. 5 and 6). The absorption of a dimer becomes broader as $NaClO_4$ is added, although the peak position is little altered. In case of a mono-

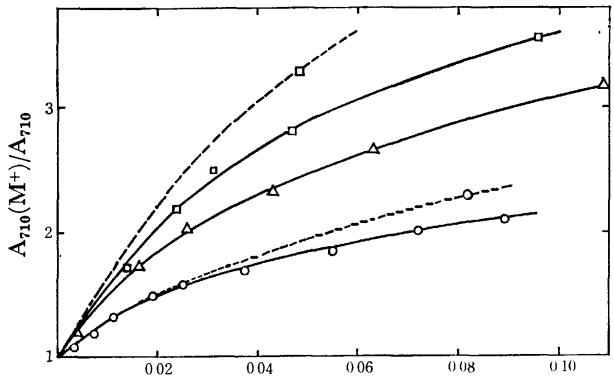

Fig. 4. The increase of the absorbance at 710 nm with the addition of various salts at 10 °C; $NaClO_4$ (□), NEt_4ClO_4 (△) and NPr_4ClO_4 (○). The dotted lines are a curve corrected against the concentration of free ions. The ordinate is taken as the ratio of the absorbace in the presence of salts, A_{710} (M^+), to that in the absence of salts, A_{710}.

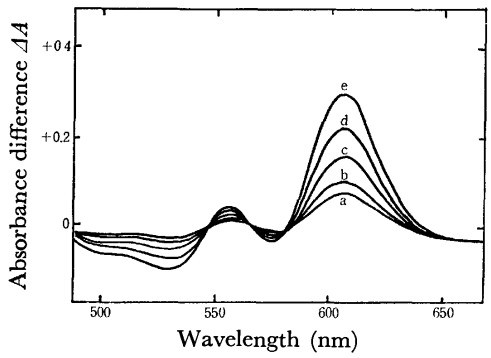

Fig. 5. The difference spectra of DDQ^- monomer at the high concentration of $NaClO_4$ at 10 °C. The sample solution contains [Na^+DDQ^-] 2.5×10^{-4} M, the reference [Na^+DDQ^-] 2.5×10^{-4} M and [$NaClO_4$] 0.047 M (a), 0.089 M (b), 0.16 M (c), 0.30 M (d) and 0.46 M (e).

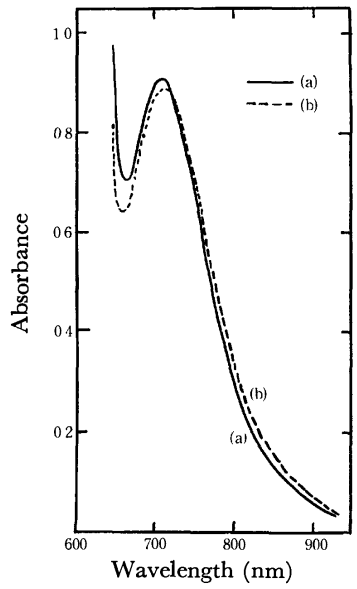

Fig. 6. The effect of $NaClO_4$ on the spectra of DDQ^- dimer. (a) [Na^+DDQ^-] 5.6×10^{-3} M (b) [Na^+DDQ^-] 2.8×10^{-3} M and [$NaClO_4$] 0.214 M.

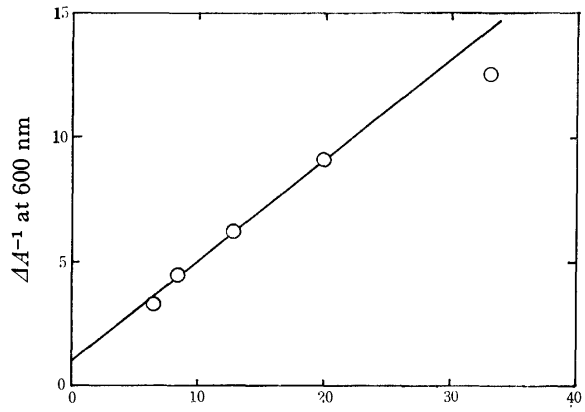

Fig. 7. The dependence of the absorbance change at 600 nm of DDQ^- monomer on the concentration of free Na^+ ion.

mer, the presence of the isosbestic points at 581, 565, and 547 nm in Fig. 5 implies that a free DDQ^- ion converts to another species, which is most likely to be a 1:1 ion-pair between Na^+ and DDQ^-. If this is correct, the change of absorbance ΔA in Fig. 5 is related to the free Na^+ concentration, $[Na^+]_f$ as follows:

$$\frac{1}{\Delta A}=\frac{1}{C(\varepsilon_1-\varepsilon_2)}\left(\frac{K_d}{[Na^+]_f}+1\right) \quad (9)$$

where C is the total concentration of M^+DDQ^-, and ε_1, ε_2 the extinction coefficients of DDQ^- and Na^+-DDQ^-, respectively. $[Na^+]_f$ is calculated from the conductivity results under the assumption that λ is directly proportional to the degree of the dissociation of $NaClO_4$. In Fig. 7, ΔA^{-1} at 600 nm is plotted against the reciprocal of $[Na^+]_f$. The straight line obtained from this plot confirms the formation of a 1:1 ion-pair between DDQ^- and Na^+. From the intrecept and the slope of the straight line, K_d is determined to be 0.40 M at 10 °C. On the other hand, NPr_4ClO_4 enhances the dimerization, although it gives no effect on the electronic spectra of DDQ^- monomer. This effect may be ascribed to the role of the ionic atmosphere of NPr_4^+ ions as stated previously.

Therefore, in the system containing a large amount of $NaClO_4$, the following equilibria are considered to exist:

$$DDQ^- + Na^+ \rightleftharpoons Na^+DDQ^-; \quad K_d \quad (6)$$

$$2DDQ^- \rightleftharpoons (DDQ^-)_2; \quad K \quad (1)$$

$$(DDQ^-)_2 + Na^+ \rightleftharpoons Na^+(DDQ^-)_2; \quad K_1 \quad (10)$$

$$Na^+(DDQ^-)_2 + Na^+ \rightleftharpoons (Na^+DDQ^-)_2; \quad K_2 \quad (11)$$

The absorbance at 710 nm is expressed as a function of the total concentration of Na^+DDQ^-, and the concentration of free Na^+ ion as follows:

$$A_{710}(Na^+) = (\varepsilon_D K+\varepsilon_3 KK_1[Na^+]_f+\varepsilon_4 KK_1K_2[Na^+]_f^2) \times(1+K_d^{-1}[Na^+]_f)^{-2}\cdot C^2 \quad (12)$$

where ε_3 and ε_4 are the molar extinction coefficient of $Na^+(DDQ^-)_2$ and $(Na^+DDQ^-)_2$, respectively. K_d, K, K_1, and K_2 are all dependent on ionic strength through the interaction of the ionic atmosphere of Na^+ ions with DDQ^- or $(DDQ^-)_2$. As a first approximation ε_3

and ε_4 are assumed equal to ε_D. The dependence of the equilibrium constant K on ionic strength can be eliminated by taking the ratio of the absorbance in the presence of $NaClO_4$, $A_{710}(Na^+)$, to that in the presence of the same amount of free NPr_4^+, $A_{710}(NPr_4^+)$, because in the latter system, only the reaction (1) takes place.

$$A_{710}(Na^+)/A_{710}(NPr_4^+) = (1+K_1[M^+]_f+K_1K_2[M^+]_f^2) \times (1+K_d^{-1}[M^+]_f)^{-2} \quad (13)$$

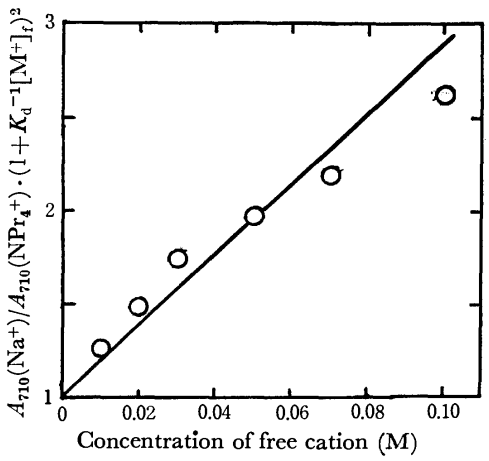

Fig. 8. The plot of A_{710} $(Na^+)/A_{710}$ $(NPr_4^+)\cdot(1+K_d^{-1}$ $[M^+]_f)^2$ against $[M^+]_f$ at 10 °C.

In Fig. 8 $A_{710}(Na^+)/A_{710}(NPr_4^+)\cdot(1+K_d^{-1}[M^+]_f)^2$ is plotted against $[M^+]_f$. All points are roughly on a straight line with a slope of 30 M^{-1}. Thus, it is concluded that in this concentration range of Na^+, there exists no appreciable amount of $(Na^+DDQ^-)_2$. The dimerization constant between Na^+DDQ^- and DDQ^-,

$$Na^+DDQ^- + DDQ^- \rightleftarrows Na^+(DDQ^-)_2;\ \tilde{K} \quad (14)$$

is expressed as

$$\tilde{K} = KK_1K_d.$$

Since K_1=30 M^{-1} and K_d=0.40 M, $\tilde{K}$=12 K at 10 °C, that is, the presence of Na^+ ion enhances the dimerization of DDQ^- by 12 times. The temperature dependence of the apparent dimerization constant gives that the apparent enthalpy change $-\Delta H$ decreases from 9.0±1.0 to 6.5±1.0 kcal M^{-1} as $[NaClO_4]$ increases from 0 to 1.14 M. This implies that the increase of the dimerization constant with the increase of Na^+ arises from the decrease of $-\Delta S$, but not from the increase of $-\Delta H$. This fact coincides with the small $-\Delta S$ observed in both THF and DME in which the dimerization occurs between ion-paired DDQ^- ions. As a result it is concluded that the entropy change for the dimerization becomes less negative, when the charge of anion radicals is screened by the counter cation. It may be probable that the large negative entropy change accompanied with dimerization is attributed to the freezing of solvent molecules due to the stronger solvation of a dimer than monomer ions. The neutralization of the charge of a dimer by a counter cation should result in the decrease of the solvating capacity of a dimer.

Kinetic Measurements. In order to look into the significance of the remarkably large dimerization constant in H_2O, the rates of dimerization in MeCN, H_2O, and MeCN-H_2O systems were measured by the temperature-jump method. Since the dimerization reaction of DDQ^- ions is largely exothermic, the equilibrium (1) displaces to the leftward at the sudden rise of temperature. In Fig. 9, the increase of the transmittance at 710 nm (dimer band) with time is shown for the MeCN solution of $NEt_4^+DDQ^-$ at −15 °C. The pseudo first-order rate constant k_{obsd} obtained from the signal is related to the forward and the backward rate constants of dimerization, $\vec{k}$ and $\overleftarrow{k}$, respectively, by Eq. (15):

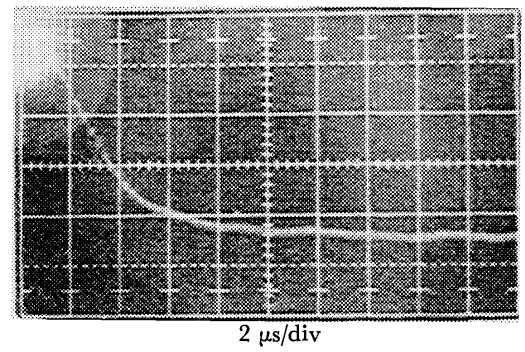

Fig. 9. The temperature-jump signal for the MeCN solution of $NEt_4^+DDQ^-$ at −15 °C. $[NEt_4^+DDQ^-]$ 5×10^{-3} M and $[NPr_4ClO_4]$ 2×10^{-2} M. Wavelength 710 nm.

$$k_{obsd} = 4\vec{k}[DDQ^-] + \overleftarrow{k} \quad (15)$$

Under the conditions of K=18.5 M^{-1} at −15 °C, and $[DDQ^-]\cong10^{-3}$ M, the first term in Eq. (15) is neglected. That is,

$$k_{obsd} = \overleftarrow{k}. \quad (16)$$

k_{obsd} is obtained to be 5×10^5 s^{-1} at −15 °C. However, the half-life time in Fig. 9 is almost equal to the minimum time for temperature-rise, 1.4 μs. Thus k_{obsd} is not related to $\overleftarrow{k}$ as in Eq. (16), instead it gives the lower limit of $\overleftarrow{k}$.

$$\overleftarrow{k} \geq 5\times10^5\ s^{-1} \text{ at } -15°C$$

Although the temperature of a sample solution is lowered down to −23 °C, no variation of k_{obsd} is observed. The lower limit of $\vec{k}$ is thus determined to be

$$\vec{k} = K\overleftarrow{k} \geq 2\times10^7\ M^{-1}\cdot s^{-1} \text{ at } -23°C,$$

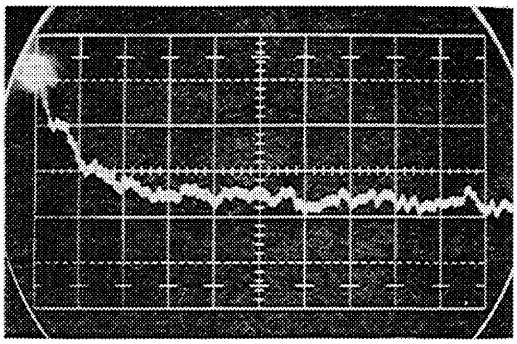
since K at −23 °C is about 32 M^{-1}.

When H_2O containing 5.8 M urea and 1.8 M MeCN is used as a solvent, the k_{obsd} obtained at −6.0 °C is apparently smaller than the rate of the temperature-rise (Figs. 10 and 11). As expected from Eq. (15), k_{obsd} increases linearly as the increase of the concentration of free DDQ^- (Fig. 12). The slope and the intercept of the straight line in Fig. 12 give the values of $4\vec{k}$ and $\overleftarrow{k}$ respectively. Thus we obtain

$$\vec{k} = (1\pm0.5)\times10^8\ M^{-1}\cdot s^{-1}$$

$$\overleftarrow{k} = (3\pm2)\times10^4\ s^{-1} \text{ at } -6°C.$$

and $K=\vec{k}/\overleftarrow{k}=(3\pm2)\times10^3$ M^{-1}. K agrees with the



10 μs/div.

10 μs/div.

Fig. 11. The temperature-jump signal for the H_2O solution of $NEt_4^+DDQ^-$ at −6 °C. [DDQ^-] 3.4×10^{-4} M. [Urea] 5.8 M. [MeCN] 1.8 M. [NaCl] 0.1 M. Wavelength 530 nm.

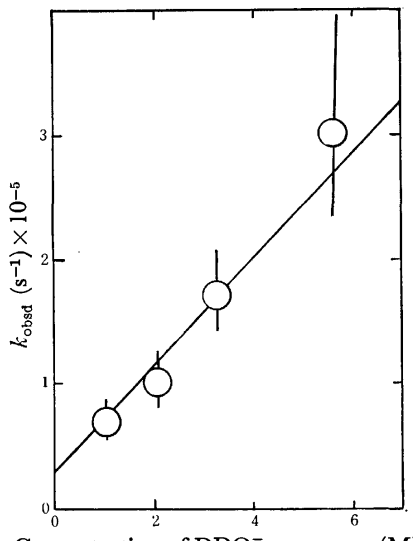

Fig. 12. The dependence of k_{obsd} on the concentration of free DDQ^- ion in H_2O (5.8 M urea and 1.8 M MeCN) at −6 °C.

value extrapolated from the equilibrium measurement at 0—15 °C, $K=(2\pm1)\times10^3\ M^{-1}$ at −6 °C.[13] Comparing the rate data in MeCN with those in H_2O, it is concluded that the large difference of the dimerization constants between these two solvents lies in the large difference of the decomposition rate constants of a dimer.

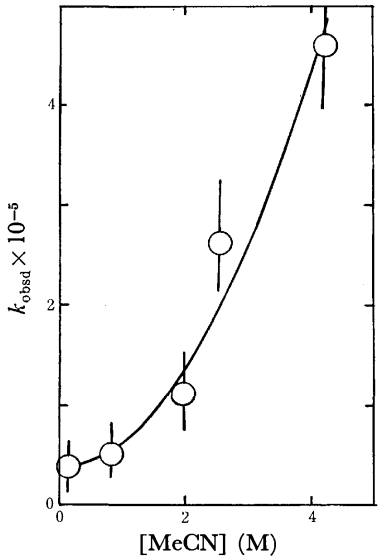

Fig. 13. The dependence of k_{obsd} on the concentration of MeCN in an MeCN/H_2O mixed solvent at −6 °C. [NEt_4DDQ^-] = $(1.5-3.0)\times10^{-4}$ M. [Urea] 5.8—4.8 M. [NaCl] 0.1—0.08 M.

In Fig. 13 is shown the effect of MeCN on k_{obsd} in an MeCN-H_2O mixed solvent. k_{obsd} increases superlinearly with the MeCN concentration. The dependence of k_{obsd} on the MeCN concentration is expressed approximately as

$$k_{obsd} = k_1 + k_2[MeCN]^2. \quad (17)$$

The forward reaction rate is considered to be independent of the solvent composition from the results obtained for pure MeCN and pure H_2O solvents. Thus, the backward rate constant is expressed from Eq. (17) as below.

$$\overleftarrow{k} = k_W + k_M[MeCN]^2 \quad (18)$$

k_W is the backward reaction rate in pure H_2O, while k_M, $(2.5\pm0.6)\times10^4\ M^{-2}\ s^{-1}$ (—6 °C), corresponds to the path where a dimer is decomposed by the attacks of MeCN molecules.

Discussion

From Table 1, it is quite clear that an entropy term plays an important role in determining the dimerization constants.[9] The order of $-\Delta H$ does not follow the order of the dimerization constants. In discussing the variation of the entropy change with solvents, it is instructive to divide ΔS into three parts according to their origins.

$$\Delta S = \Delta S_1 + \Delta S_2 + \Delta S_3 \quad (19)$$

ΔS_1 is an entropy change of the solvent molecules in the region where the solvent is considered to be a dielectric continuum and is polarized in proportion to the electrostatic field due to ion radicals. ΔS_2 is an entropy change of the solvent molecules in that region which constitues the solvation shell of the ion radicals. ΔS_3 is an entropy change accompanied with the loss

of degrees of freedom of motion of ion radicals due to dimerization. ΔS_3 is considered to be almost constant for all solvents, since a dimer always gives an absosrption peak around 710 nm, indicating that the geometry of a dimer is similar in all solvents.

ΔS_1 is estimated in the electrostatic way. The free energy of solvation of an ion of radius a and charge e is

$$\Delta F_I = -\left(1-\frac{1}{D}\right)\frac{e^2}{2a},$$

where D is a dielectric constant of a solvent. Thus, the change of free energy of solvation for the reaction of dimerization (1) is

$$\Delta F_I = -\frac{1}{2}\left(1-\frac{1}{D}\right)\left(\frac{4e^2}{r_D}-\frac{e^2}{r_M}\right),$$

where r_D and r_M are the radius of a dimer and a monomer respectively. The entropy change of dimerization is thus,

$$\Delta S_I = -\frac{\partial \Delta F_I}{\partial T} = \frac{\partial D}{D^2 \partial T}\left(\frac{2e^2}{r_D}-\frac{e^2}{r_M}\right) \qquad (20)$$

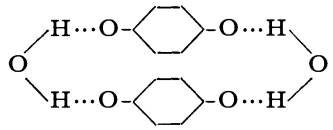
Since $\partial D/\partial T$ is negative, negative ΔS_I is obtained for the case of $r_D < 2r_M$, that is, the case that the effective radius of radicals contracts in dimerization. Taking $r_M = 4$ Å, $r_D = 6$ Å as typical values, the calculated value of ΔS_I in each solvent is given in Table 2. For MeCN, DMF, and Me_2CO, the experimentally observed ΔS is much larger than was predicted from Eq. (20). This implies that in these solvents, ΔS_2 or ΔS_3 contributes a great deal to the entropy change. Since MeCN, DMF, and Me_2CO are known as strong anion solvating solvents[14] it is concluded from the present results that at least a dimer is specifically solvated by MeCN solvent.

TABLE 2. THE ELECTROSTATIC ENTROPY CHANGE ΔS_1 OF DIMERIZATION REACTION CALCULATED USING Eq. (20).

Solvent	Dielectric constant at 15 °C	ΔS_1/e.u.
MeCN	38.3	−2.8
DMF	38.42	−2.8
Me_2CO	20.0	−6.6
EtOH	25.7	−5.8
MeOH	34.7	−4.7
H_2O	82.0	−1.5
THF	7.77	−17 (for Eq. (1))
		0 (for Eq. (8))

In THF and DME, both ΔH and ΔS are a little negative. As stated in the previous section, DDQ^- associates with a counter cation and the dimerization mostly occurs between ion-paired DDQ^- ions. Therefore, the less negative ΔS arises from the weak solvation of solvent molecules with the neutral ion-pair. ΔS_I is, of course, zero in these solvents. If ΔS_I and ΔS_2 are both zero, the observed ΔS corresponds to ΔS_3, which contains the loss of degrees of freedom of translation and rotations of monomer ions and the gain of degrees of freedom of vibrations of a dimer.

In EtOH, MeOH, and H_2O, both ΔH and ΔS are moderately negative. As stated previously, it is certain that these protic solvents form hydrogen-bonds with the oxygen atoms of DDQ^- ions. It is interesting to see how the hydrogen-bonding property affects the dimerization equilibria. As the results in Table 1 show, H_2O gives the largest $-\Delta H$ among these protonic solvents. Since ΔH and ΔS are the difference between two monomers and a dimer, the hydrogen bonding property seems to affect monomers and a dimer equally in EtOH and MeOH, resulting in the small value of the dimerization constants. On the other hand, H_2O favours the dimer side drastically by making ΔH largely negative. If some speculation can be permitted at this stage, these results indicate the structure of two water molecules acting as bridges between two DDQ^- ions, since H_2O is unique in having two protons in one molecule.[15]



The rate data shows the large difference of the dimerization constant between MeCN and H_2O lies in the large difference of the decomposition rates between these two solvents. In order to see the meaning of the forward rate constant in H_2O, the diffusion controlled reaction rate constant is calculated according to the equation given below:[16]

$$k = \frac{4\pi e^2 N D_f (N/1000)}{DRT[\exp(e^2N/DRTr_M)-1]} \qquad (21)$$

where N is Avogadro's number, D_f the diffusion coefficient of a particle, D the dielectric constant of a medium and R the gas constant. r_M represents the diameter of a monomer which is assumed to be a sphere. Putting in the reasonable values of $D_f = 1\times10^{-5}$ cm^2 s^{-1}, and $r_M = 4\times10^{-8}$ cm, we obtain at −6 °C,

$$k(\text{calcd}) = 1.0\times10^8 \text{ M}^{-1}s^{-1}$$

k(calcd) is about one order larger than the observed $\vec{k}$. Considering that k(calcd) involves a large uncertainty in estimating D_f and r_M, it is concluded that the forward rate of dimerization in H_2O is nearly a diffusion controlled one.[17] This result implies that no decrease of entropy which would make the rate slower than k_{calcd} takes place until two DDQ^- ions come into contact with each other. When two DDQ^- ions approach each other within few angstroms, the charge-transfer interaction is considered to begin to operate.[7] This final process will result in the decrease of entropy observed in the equilibrium measurements. Thus these results support the previous conclusion from the equilibrium measurements that the large negative entropy arises from the specific solvation of a dimer ΔS_2 but not from the macroscopic entropy change of ΔS_1 or ΔS_3.

The reverse reaction rate is found to increase with the square of the MeCN concentration. This fact suggests that the main path of the decomposition of a dimer in relatively high concentration range of MeCN is the successive attacks of two MeCN molecules toward the dimer solvated by H_2O molecules.

$$(DDQ^{\cdot-})_2 + MeCN \rightleftarrows (DDQ^{\cdot-})_2(MeCN) \quad (22)$$

$$(DDQ^{\cdot-})_2(MeCN) + MeCN \rightleftarrows 2(DDQ^{\cdot-})(MeCN) \quad (23)$$

Here reaction (23) is considered to be rate-determining. In the above scheme, $(DDQ^{\cdot-})(MeCN)$ is introduced from the result of Fig. 3, which indicates that in the H_2O mole fraction range of 0.2—0.8, the main species of $DDQ^{\cdot-}$ is the one solvated by one MeCN molecule. The reactions (21) and (22) coincide with the previous postulate that $(DDQ^{\cdot-})_2$ ion combines with two H_2O molecules as bridges between two $DDQ^{\cdot-}$ ions. Thus the decomposition of $DDQ^{\cdot-}$ dimer is caused by the displacement of two solvated H_2O molecules by MeCN molecules.

In this way, the large solvent effect on the dimerization equilibria is understood as due to the molecular processes involving ion radicals and solvent molecules.

The author appreciates Prof. Masatoshi Fujimoto for his continuous encouragement and also thanks Dr. Mitsuyuki Soma, Mr. Mutsuo Yamada, Mr. Fumiyuki Watanabe, and Mrs. Michiyo Yamagishi for their kind advice. This work was supported by the Ministry of Education.

The Photo-oxygenation Reactions of Diethyl Ether, *p*-Phenylenediamine, and *N,N*-Dimethylaniline

Kojiro MAEDA, Akihiro NAKANE,* and Hiroshi TSUBOMURA

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received February 3, 1975)

The products of photo-oxygenation reactions of ethyl-ether, *p*-phenylenediamine, and dimethylaniline were studied quantitatively and some radical intermediates were found by ESR measurements. The following quantum yields of the main products of these reactions were obtained: ethyl acetate (for ethyl ether), 0.49; *p*-benzoquinonediimine (for *p*-phenylenediamine), 0.01. As a possible reaction mechanism of the photo-oxygenation reactions of ethyl ether and *p*-phenylenediamine, it is proposed that at least part of the reaction is initiated by the charge transfer from the organic molecule to oxygen, followed by rapid proton detachment, yielding such radicals as EtO-$\dot{C}HCH_3$ and $\dot{N}HC_6H_4NH_2$ respectively.

In a previous paper, we have studied the photochemical reaction of the triethylamine–O_2 system under irradiation in the region of the charge transfer (CT) band.[1] By use of ESR spectroscopy and chemical analysis of the reaction products, the possible reaction mechanisms leading to various reaction products were speculated upon. This paper will present the results of similar studies of the photo-oxygenation of ethyl ether and some aromatic amines.

Experimental

Materials. Reagent grade diethyl ether was dried overnight with potassium chloride, and fractionally distilled through a Widmer column with Na-K amalgam. Reagent grade *p*-phenylenediamine (PPD) was purified by recrystallization from benzene and sublimed. *N,N*-Dimethylaniline (DMA) was dried with sodium hydroxide, vacuum distilled and preserved in a vacuum desiccator. Isopentane, *n*-heptane, and methylcyclohexane were purified by passing them through silica gel columns and then were distilled. Dioxane was dehydrated with sodium wire and then distilled.

ESR Measurements. The ESR measurements were made using a JES-ME-2X spectrometer of Japan Electron-Optics Laboratory Co. in the X-band. The magnetic field was measured by use of the proton magnetic resonance signal. The solution was put into a quartz capillary cell (5 mmϕ). After oxygen gas or air was bubbled into the cell, each sample was irradiated with a Ushio 500 W high pressure mercury lamp through Toshiba glass filters which transmit the light in the region of the CT band.

Analysis of the Photo-oxygenation Products. The reaction products were analyzed by the gas-chromatographic, chemical, IR, and UV techniques.

The analysis of peroxide was made by use of an electrochemical method suggested by Brewer and Milford.[2] The cathode was fine platinum and mercury was used as the anode. The polarizing potential was about 0.3 V and 0.2% KI aq. was used as the working solution.

The quantum yields of the reaction products were obtained with the aid of chemical actinometry using potassium ferrioxalate. A modified method of Hatchard and Parker[3] was used to prepare the actionometer solution. The irradiation was done through the reaction cell into the actinometer solution so that the light transmitted through the former was absorbed completely by the latter. The number of photons absorbed in the reaction cell was calculated as the difference between the number of photons absorbed in the actinometer with and without the presence of the reaction cell.

Results

The O_2-Ether System. No ESR signal was detected by the irradiation, at room temperature, of ether saturated with oxygen or of solutions of ether–O_2 in isopentane, *n*-heptane, and methylcyclohexane. When O_2-saturated ether at 1 atm was irradiated at 77 K with a UV-D25 filter (280—350 nm) for 3 min, a prominent quartet signal with a hyperfine coupling constant (hfs) of 26 G was obtained. This signal may be assigned to either the ethyl or the methyl radical. The former is more probable because of the high hyperfine coupling constant.[4,5] A similar result was obtained even when a mixture of methylcyclohexane and ether (in the vol. ratio of 1 : 1) was used as a solvent (Fig. 1(A)). When the input of the microwave power was raised up to about 100 mW, the quartet signal observed in the ether–O_2 system disappeared owing to saturation. On standing at 77 K, the ESR signal most likely assignable to an alkylperoxy radical appeared and became stronger

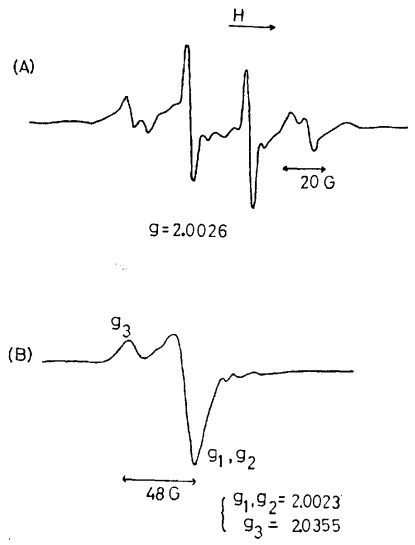

Fig. 1. ESR spectra of the species produced by the UV-irradiation of ether–O_2 at 77 K (A), followed by warming in the dark (B).

with time. When the sample cell was taken out from liquid nitrogen for several seconds and dipped in again, a different ESR signal with large anisotropic *g*-factor was obtained, as shown in Fig. 1(B). In isopentane, softer than methylcyclohexane at 77 K, an ESR spectrum quite similar to the latter one was observed from the beginning. Upon warming the matrix, the intensity decreased without any change in the spectral shape.

The reaction products were identified by comparison of the retention times of the gas chromatograms, using PEG-6000 as the column packing, with those of the pure products expected. The yields of the reaction products were determined by comparison of the areas under the gas-chromatographic peaks, with benzene used as an internal standard. Then, from the photon intensity measured by chemical actinometry, the quantum yields of the products were calculated; these are shown in Table 1.

Table 1. The quantum yields for the products of ethyl ether photo-oxygenation

Products	Quantum yield
Ethyl acetate	0.49
Ethyl formate	0.23
Acetaldehyde	0.17
Ethanol and/or[a] methanol	0.43

a) We were unable to separate ethanol and methanol in the gas-chromatogram.

The O_2-p-Phenylenediamine-Cyclohexane System. It is known that PPD in water or alcohol is thermally oxidized at room temperature to produce gradually the brown precipitate of Bandrowski's base.[6] When the cyclohexane or dioxane solution of PPD, more stable than the protic solutions, was irradiated in the region of the absorption band of PPD with bubbling oxygen, it turned to red. No change was observed when the same experiment was done in the deoxygenated state.

The spectrum of 9.54×10^{-5} M cyclohexane solution of PPD saturated with O_2 was shown in Fig. 2, together with the products of irradiation through a UV-D25 filter. The products were separated by thin layer chromatography and elution chromatography, the developing solvent being an acetone (1): benzene (1) solution, and were analyzed by IR, UV, and chemical techniques. The material which absorbs at about 380 nm was identified to be 4,4'-diaminoazobenzene (DAAB) by comparing its IR and UV spectrum with those of the synthesized DAAB. The two absorption bands at about 260 nm are assigned to *p*-benzoquinonediimine from the identity in the UV spectrum with the synthesized material.[7,8] Because of its high reactivity, we could not separate it from the reaction products. The shoulder at 470 nm agrees with the first band of Bandrowski's base,[9] and can most probably be assigned to it. 1.30×10^{-6} M peroxide was produced when a 1.27×10^{-4} M cyclohexane solution of PPD was irradiated.

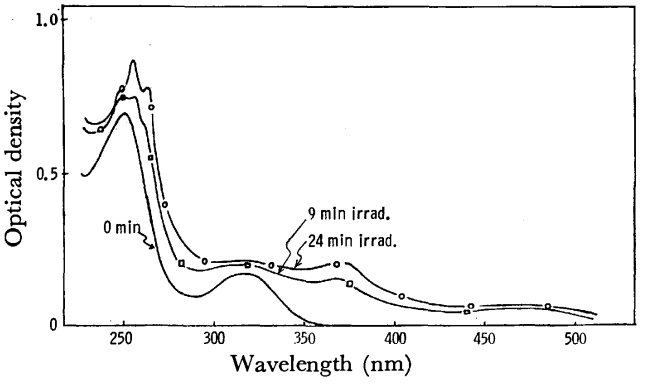

Fig. 2. Electronic spectral change of PPD in cyclohexane saturated with O_2 by the irradiation through a UV-D25 glass filter.

Each of the quantum yields for the reaction products was derived from the peak intensity of the UV absorption spectrum: *p*-benzoquinonediimine 0.01, DAAB 0.003, Bandrowski's base 0.002.

No ESR signal was detected for the dioxane solution irradiated at room temperature. But a weak broad singlet signal with the *g*-value of 2.016 was detected in cyclohexane irradiated at room temperature.

In the case of the cyclohexane solution at 77 K a broad singlet ESR spectrum was obtained. A similar spectrum was obtained for the dioxane solution. The *g*-values were 2.0050 and 2.0036, respectively. The broad singlet ESR bands became stronger with the irradiation time, without change in the shape. As the matrix was warmed, the signal intensity decreased.

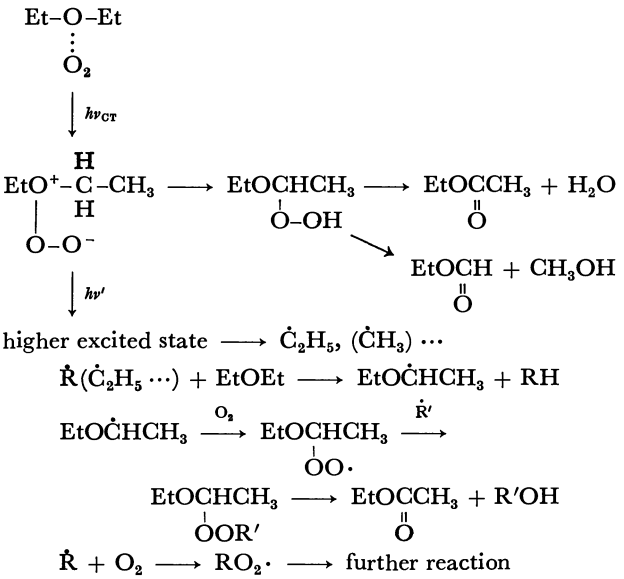
The O_2–Dimethylaniline System. The ESR spectrum obtained for this system irradiated through a UV-39 filter at 77 K was a broad singlet. For the case of O_2-saturated DMA at room temperature, the *g*-value was 2.0065, and for the case of DMA (1): cyclohexane (1) at room temperature, the *g*-value was 2.0048. Although it is impossible to determine the species relevant to the ESR signal which appeared by the irradiation at room temperature, it seems reasonable to assign it to *N*-methylanilino radical, because of the fairly large *g*-value and the circumstances of its appearance.

When oxygen gas was bubbled into DMA, it turned to yellow owing to the CT absorption with O_2.[10] The reaction products were analyzed by gas chromatography using PEG 6000+KOH as column packing. No product was identified except for *N*-methylaniline. Its quantum yield could not be obtained because of the poor yield. *N*-Methylaniline was also obtained by the irradiation of deaerated DMA.

Discussion

The Ether-O_2 System. The results obtained indicate that the reaction mechanism in this system is rather similar to that for the triethylamine-O_2 system studied by us.[1] The formation of ethyl (or, less probably, methyl) radical is observed by the ESR studied at 77 K. Upon warming, the ethyl (methyl) radical and possibly a small quantity of some other radicals produced become mobile, and either react with oxygen to form peroxy radicals or abstract hydrogen atoms from ether. Our observed experimental results showed that the peroxy radicals were gradually pro-

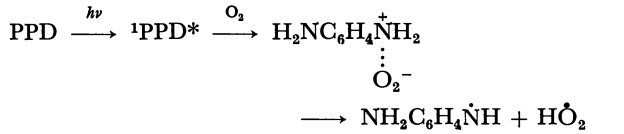
duced in the ether–O_2 system irradiated at 77 K even if the temperature was kept at 77 K. The formation of ethyl, and possibly other radicals, can be explained by assuming the photo-excitation of the metastable singlet CT state or $EtO\dot{C}HCH_3$ formed by hydrogen abstraction from ether. The over-all scheme for the formation of the main reaction products can be shown by the following equations:

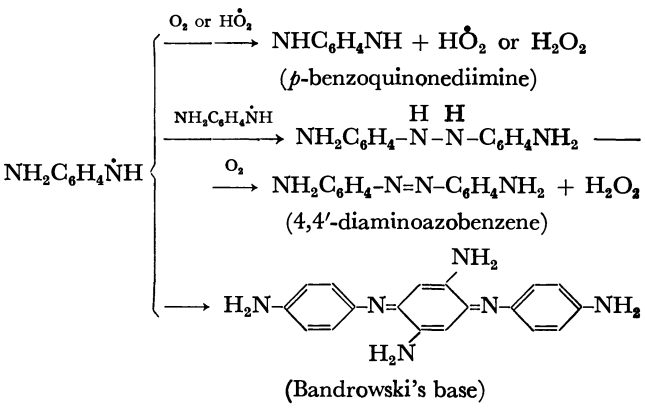


It might be worthwhile to note that no photodissociation of ether took place when deaerated ether was irradiated in the region of the CT absorption. Of course, reabsorption processes for the various radicals and other intermediates formed undoubtedly take place, which make the overall mechanism more complicated and harder to interpret.

The p-*Phenylenediamine–O_2 System.* The ESR signal detected in the irradiated cyclohexane solution at room temperature is attributable to the peroxy radical, but whether it is the hydroperoxy radical or alkylperoxy radical has not yet been proved. In view of the reaction products, it is more likely to assign it to the hydroperoxy radical. The ESR signal observed by irradiation at 77 K is most likely due to *p*-aminoanilino radical, in view of the *g*-value and the reaction products.

From the result described above, the reaction path might be as follows:





(Bandrowski's base)

The reaction path to lead to Bandrowski's base has not been clarified. But the studies of the dark reactions made in our laboratory between PPD and electron acceptors, *e.g.* *p*-benzoquinone, and the reactions between PPD^+ cations and other amines or PPD itself, indicated the formation of indamine-type compounds ($H_2N-C_6H_4-N=C_6H_4=NH_2^+$), Bandrowski's base, and, in certain cases, diazocompounds, $NH_2-C_6H_4-N=N-C_6H_4NH_2$.[6] Therefore, it seems very probable that both such thermal reactions and the photo-oxygenation reactions described in this paper pass through the PPD^+ cation, which, by subsequent proton transfer, forms the radical of the type $H_2N-C_6H_4-\dot{N}H$.

The authors thank Prof. Keiji Kuwata (Osaka University) and Prof. Yuzaburo Fujita (Tokyo University) for their valuable advice on the interpretation of the ESR spectra.

Solvent Effect of Methanol on the Rate of Formation Reaction of Monochloroiron(III) Complex in Aqueous Solution

Goro WADA and Yaeko KOBAYASHI

Department of Chemistry, Nara Women's University, Nara 630

(Received February 14, 1975)

The rate constants of the formation reaction of $FeCl^{2+}$ complex from Fe(III) and Cl^- ion were measured in water–methanol mixed solvents by use of a stopped-flow spectrophotometer. The apparent rate constant k is dependent upon the acid concentration of the medium, indicating that the reaction can proceed through two parallel paths, $Fe^{3+}+Cl^-$ (k_1) and $Fe(OH)^{2+}+Cl^-$ (k_H). Both k_1 and k_H increase with the increase in the mole fraction of methanol in the medium, x_M. Since k_H is much larger and is consequently much more accurately determined than k_1, considerations were mainly made on the nature of k_H. According to the dependence of k_H on the dielectric constant of the medium, it was found that the activation free energy of the $Fe(OH)^{2+}+Cl^-$ reaction consists of the electrical and non-electrical parts and that the dimension of the activated complex corresponds approximately to the distance of the outer-sphere approach between the reacting species. These facts are therefore in favor of an outer-sphere mechanism in the anation reactions of iron(III) by simple anions.

Many investigations have been done on the kinetics of fast formation reactions of transition metal complexes with various anions since the introduction of the flow method into the field of kinetic measurements;[1] in particular, the reaction of iron(III) with chloride ion, $Fe(III)+Cl^- \rightarrow Fe(III)Cl$, in aqueous solution was one of the earliest studied among the formation reactions of iron(III) complexes.[2]

The reaction is known to be dependent upon acid concentration and to proceed through two parallel steps of $Fe^{3+}+Cl^-$ and $FeOH^{2+}+Cl^-$, the latter being much faster than the former. Since the reaction occurs between ions of opposite signs, it may be supposed to be affected by the change of dielectric constant of the solvent. In order to prove this effect, mixed solvents of methanol and water were adopted; the reaction mechanism has been discussed in the present research.

Experimental

Materials. Iron(III) perchlorate was prepared by dissolving pure iron wire in perchloric acid, followed by oxidation with hydrogen peroxide. Methanol was purified by ordinary distillation of commercial methanol of S. P. grade under atmospheric pressure. Sodium chloride and sodium perchlorate were twice recrystallized from aqueous solution.

Determinations of Equilibrium Constants. The hydrolysis constant of Fe^{3+}, $K_H=[FeOH^{2+}][H^+]/[Fe^{3+}]$, the association constant between Fe^{3+} and ClO_4^-, $K_a=[Fe^{3+}\cdot ClO_4^-]/[Fe^{3+}][ClO_4^-]$, and the formation constant of $FeCl^{2+}$ complex, $K_1=[FeCl^{2+}]/[Fe^{3+}][Cl^-]$ at various mole fractions of methanol, x_M, were determined spectrophotometrically by use of a Hitachi-Perkin-Elmer UV-VIS spectrophotometer Model 139. The ionic strength of the solutions was adjusted with sodium perchlorate.

Kinetic Measurements. The measurements of the rate constants were performed by use of a Yanagimoto stopped-flow spectrophotometer SPS-1. Since the strict regulation of the reaction temperature was impossible in the present apparatus, the rate constants at desired temperatures were obtained by a graphical interpolation from those measured at temperatures close to the desired. The signals drawn on the memoriscope were photographed and analyzed.

Results and Discussion

Hydrolysis Constants of Fe^{3+}. When some of Fe^{3+}_{aq} is hydrolyzed to give $Fe(OH)^{2+}$ in slightly acid solution, the following relationship holds at total iron(III) concentration [Fe(III)]:

$$\frac{[Fe(III)]}{A_H} = \frac{1}{\varepsilon_H} + \frac{[H^+]}{\varepsilon_H K_H} \quad (1)$$

where A_H and ε_H represent the optical absorbance due to $Fe(OH)^{2+}$ ($A_H=\varepsilon_H[FeOH^{2+}]$), and the molar absorptivity of $Fe(OH)^{2+}$, respectively. From a linear relationship of $[Fe(III)]/A_H$ *vs.* $[H^+]$, ε_H and K_H can be obtained. At first, since A_H is not known yet, the total absorbance A and the total acid concentration $[HClO_4]$ are used in place of A_H and $[H^+]$ in Eq. (1), respectively. From the rough linearity, an approximate K_H is obtained, and therefore an approximate $[H^+]$ and A_H. The method of successive approximations gives the final value of K_H. The observation was performed at $[Fe(III)]=2\times10^{-4}$ M, $[HClO_4]=4\times10^{-3}$—9×10^{-3} M, $\mu=0.5$ M, 25 °C, and wavelength 350 nm. A typical case of the linear relationship of Eq. (1) at $x_M=0.395$ is shown in Fig. 1 and the values of K_H at various methanol concentrations are listed in Table 1, among which those for $x_M=0.15$—0.25 are

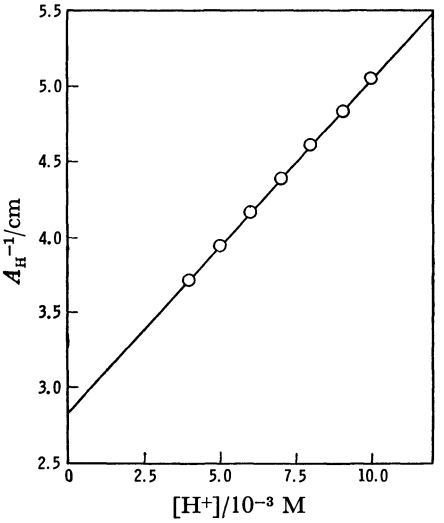

Fig. 1. Linear relationship between A_H^{-1} and $[H^+]$ at $[Fe(III)]=2\times10^{-4}$ M, $x_M=0.395$, $\mu=0.5$ M, 25 °C, and 350 nm.

reproduced from our previous literature.[3]

There exists the apparent feature that K_H increases with increasing methanol concentration; this is reasonable in view of the decrease in dielectric constant of the mixed solvent as the methanol concentration increases.

Ionic Association Between Fe^{3+} and ClO_4^-. When the perchloric acid concentration is relatively high in the mixed solvent, the phenomenon of ion-pair formation between Fe^{3+} and ClO_4^- ions has to be taken into account in the course of determination of the formation constant K_1, as will be described in the next section.[3]

The apparent molar absorptivity of the solution containing Fe^{3+} and perchloric acid, ε, may be expressed as follows:

$$\varepsilon = \frac{\varepsilon_0 + \varepsilon_H K_H/[H^+] + \varepsilon_a K_a[ClO_4^-]}{1 + K_H/[H^+] + K_a[ClO_4^-]} \quad (2)$$

where ε_0 and ε_a represent the molar absorptivity of Fe^{3+}_{aq} ion and the ion-pair $Fe^{3+}\cdot ClO_4^-$, respectively. Since K_a is very small, $K_a[ClO_4^-]$ is negligible compared to unity. When the acidity of the solution is high enough, $[FeOH^{2+}]$ may be negligibly small and, therefore, Eq. (2) is reduced to the following simple expression at a suitable wavelength:

$$\varepsilon = \varepsilon_0 + \varepsilon_a K_a[HClO_4] \quad (3)$$

The observations were performed at $[Fe(III)] = 1.0\times10^{-2}$ or 2.0×10^{-2} M and $[HClO_4] = 2.40$—3.60 M at a wavelength of 350 nm. The linear relationships of ε against $[HClO_4]$ are shown in Fig. 2, from whose slopes $\varepsilon_a K_a$ are obtained as listed in Table 1 at various x_M's. The values of $\varepsilon_a K_a$ will be necessary in the calculation of K_1.

Formation Constants of $FeCl^{2+}$. When Cl^- ion is added to the mixed solution containing iron(III) and perchloric acid, there occurs an additional complex formation between iron(III) and Cl^- ion. If the species of the complex formed is only $FeCl^{2+}$, Eq. (2) can be modified as follows:

$$\varepsilon = \frac{\varepsilon_0 + \varepsilon_H K_H/[H^+] + \varepsilon_a K_a[ClO_4^-] + \varepsilon_1 K_1[Cl^-]}{1 + K_H/[H^+] + K_a[ClO_4^-] + K_1[Cl^-]}$$

where ε_1 is the molar absorptivity of $FeCl^{2+}$.

By adopting reasonable approximations, as has been done above, the following equation can be derived at $[HClO_4] = 3.0$ M:

$$\varepsilon = \varepsilon_1 - \frac{\varepsilon - \varepsilon_0 - \varepsilon_a K_a[HClO_4]}{K_1[Cl^-]} \quad (4)$$

The linear relationship between ε and $(\varepsilon - \varepsilon_0 - \varepsilon_a K_a[HClO_4])/[Cl^-]$ was proved at $[Fe(III)] = (1-2)\times10^{-3}$ M, $[NaCl] = (1-5)\times10^{-3}$ M, and wavelength 350 nm. From the intercept and the slope of the straight line, ε_1 and K_1 are obtained. Since the concentration of free Cl^- ion, $[Cl^-]$, was not known at first, the total concentration of Cl^- ion, $[Cl]$, was used instead and the successive approximation yielded the final values of ε_1 and K_1. An example of the linearity of Eq. (4) is shown in Fig. 3 and the values of K_1 at various x_M are listed in Table 1. The values of K_1 are recognized to grow larger as the concentration of methanol becomes higher, as is expected from a viewpoint of the dielectric constants of mixed solvents.

Table 1. Hydrolysis constant, K_H, formation constant of $FeCl^{2+}$, K_1, and constant of ionic association for $Fe^{3+}\cdot ClO_4^-$, $\varepsilon_a K_a$, at different methanol concentrations, x_M, at 25 °C

x_M	K_H M	$\varepsilon_a K_a$ $M^{-2}\,cm^{-1}$	K_1 M^{-1}
0	1.65×10^{-3}	—	4.0
0.15	4.8×10^{-3}	3.33	2.6×10
0.20	6.2×10^{-3}	5.56	4.3×10
0.25	8.7×10^{-3}	7.06	5.0×10
0.395	1.38×10^{-2}	10.94	1.13×10^2
0.443	1.56×10^{-2}	12.57	1.37×10^2
0.519	1.90×10^{-2}	12.50	1.44×10^2

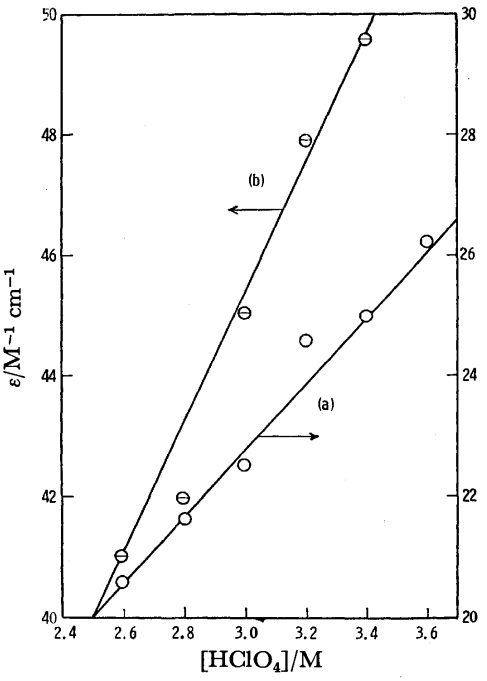

Fig. 2. Linear relationship between ε and $[HClO_4]$ at 25 °C and 350 nm. (a) $[Fe(III)] = 2.0\times10^{-2}$ M, $x_M = 0.2$; (b) $[Fe(III)] = 1.0\times10^{-2}$ M, $x_M = 0.935$.

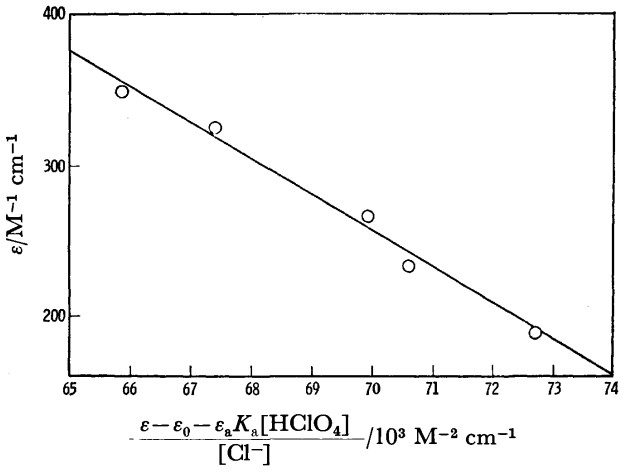

Fig. 3. Linear relationship between ε and $(\varepsilon - \varepsilon_0 - \varepsilon_a K_a[HClO_4])/[Cl^-]$ at $[Fe(III)] = 2\times10^{-3}$ M, $[HClO_4]$ 3.0 M, $x_M = 0.20$, 25 °C, and 350 nm.

Rate Measurements. In the wavelength range of 300—400 nm, $FeCl^{2+}$ species exhibits an absorption peak at 350 nm, while species other than $FeCl^{2+}$ absorb light very little as compared to $FeCl^{2+}$. Therefore, the observations of the rate constants, k, were carried out at this wavelength; the observed transmittance of the reaction solution decreased as the reaction proceeded. The initial concentrations of the dissolved species were as follows: $[Fe(III)]=(1.5—2.0)\times10^{-2}$ M, $[NaCl]=(1.5—2.0)\times10^{-2}$ M, and $[HClO_4]=(1.25—8.00)\times10^{-1}$ M. The occurrence of $FeCl_2^+$ and higher complexes was negligible.

Although the acid concentration is pretty high under the present circumstances, the $Fe(OH)^{2+}$ as a reactant and the $Fe(OH)Cl^+$ as a product must be taken into account in addition to Fe^{3+} and $FeCl^{2+}$ respectively. Then the following quantities are defined, the suffix e standing for the quantity at infinite time, namely at equilibrium:

$$[Fe] = [Fe^{3+}] + [FeOH^{2+}]$$

$$[FeCl] = [FeCl^{2+}] + [Fe(OH)Cl^+]$$

$$Q_1 = \frac{[FeCl]_e}{[Fe]_e[Cl^-]_e}$$

And the apparent reaction rate may be expressed by

$$\frac{d[FeCl]}{dt} = k[Fe][Cl^-] - k'[FeCl] \qquad (5)$$

where k and k' are the apparent forward and backward rate constants respectively. Since $Q_1=k/k'$ and $[Cl^-]=[FeCl]_e+[Cl^-]_e-[FeCl]$ and since $[Fe]$ is approximately equal to $[Fe]_e$ at a later reaction time close to equilibrium, the following rate equation may be obtained:

$$\frac{d[FeCl]}{dt} = k\left\{[Fe]_e+\frac{1}{Q_1}\right\}\{[FeCl]_e-[FeCl]\} \qquad (6)$$

By integrating Eq. (6), the following correlation may be established:

$$-\ln\frac{[FeCl]_e-[FeCl]}{[FeCl]_e-[FeCl]_0} = k\left\{[Fe]_e+\frac{1}{Q_1}\right\}t \qquad (7)$$

The suffix 0 indicates the quantity at zero time of integration, but not at the true initial time of the reaction, because the stopped-flow apparatus does not record the initial quantity but begins to record some time after the initiation of the reaction. The quantity $([FeCl]_e-[FeCl])/([FeCl]_e-[FeCl]_0)$ is equal to $(A_e-A)/(A_e-A_0)$, which is easily obtained from the observations. The value of Q_1 is considered to be approximately equal to K_1. Examples of the linear relationships of Eq. (7) are drawn in Fig. 4 at $x_M=0.25$. From the linearities are obtained the apparent rate constants, k.

Acid Dependence of k. When the values of k at different acid concentrations at a constant x_M and temperature are plotted against $[H^+]^{-1}$, a straight line is obtained, as shown in Fig. 5. Taking this fact into account, the following reaction scheme is available:

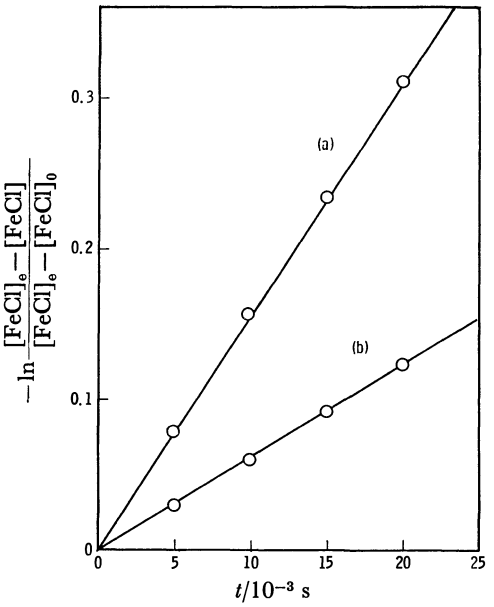

Fig. 4. Linear relationship between $-\ln([FeCl]_e-[FeCl])/([FeCl]_e-[FeCl]_0)$ and t at $F[e(III)]=[NaCl]=0.015$ M, $\mu=1.0$ M, $x_M=0.25$, and 350 nm. (a) $[HClO_4]=0.5$ M, 25.2 °C; (b) $[HClO_4]=0.8$ M, 22.5 °C.

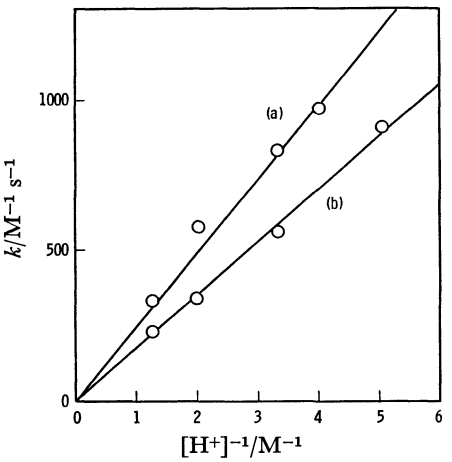

Fig. 5. Plot of k *vs.* $[H^+]^{-1}$ at $\mu=1.0$ M and 25 °C. (a) $x_M=0.25$; (b) $x_M=0.20$.

$$\begin{array}{ccc} Fe^{3+} + Cl^- & \underset{k_1'}{\overset{k_1}{\rightleftharpoons}} & FeCl^{2+} \\ {\scriptstyle H^+}\uparrow\downarrow{\scriptstyle -H^+} & & {\scriptstyle H^+}\uparrow\downarrow{\scriptstyle -H^+} \\ Fe(OH)^{2+} + Cl^- & \underset{k_H'}{\overset{k_H}{\rightleftharpoons}} & Fe(OH)Cl^+ \end{array} \qquad (8)$$

Therefore, k is represented by

$$k = \frac{k_1+k_HK_H/[H^+]}{1+K_H/[H^+]} \qquad (9)$$

on the assumption that the rates of protonation and deprotonation are much larger than those of the ligand substitution under consideration. When the acid concentration is high enough, the denominator of Eq. (9) can be regarded as nearly equal to unity and thus the linear relationship between k and $[H^+]^{-1}$ in Fig. 5 becomes clear.

TABLE 2. RATE CONSTANTS AT 25 °C AND ACTIVATION PARAMETERS AT DIFFERENT METHANOL CONCENTRATIONS

x_M	D^{-1}	k_1 $M^{-1}s^{-1}$	k_1' s^{-1}	k_H $M^{-1}s^{-1}$	$\Delta H_H^{*}+\Delta H_H^{\circ}$ kcal·mol^{-1}	$\Delta S_H^{*}+\Delta S_H^{\circ}$ cal·K^{-1}mol^{-1}	ΔG_{el}^{*} kcal·mol^{-1}	ΔG_0^{*} kcal·mol^{-1}
0	1.26×10^{-2}	7	2	1.2×10^{4}	19	13	−1.59	13.6
0.15	1.46×10^{-2}	9	0.4	2.6×10^{4}	20	18	−1.85	13.5
0.20	1.54×10^{-2}	2	0.05	2.8×10^{4}	21	22	−1.95	13.5
0.25	1.64×10^{-2}	6	0.1	2.8×10^{4}	—	—	−2.07	13.6
0.395	1.92×10^{-2}	21	0.2	6.3×10^{4}	24	34	−2.42	13.6
0.443	2.02×10^{-2}	30	0.2	7.6×10^{4}	—	—	−2.55	13.5
0.519	2.14×10^{-2}	30	0.3	1.00×10^{5}	23	33	−2.70	13.5

From the intercepts and the slopes of the straight lines expressed by Eq. (9), k_1 and k_H are calculated; these are listed in Table 2, along with the reverse rate constant k_1' calculated from $k_1/k_1'=K_1$. The values of k_1 and k_H in pure water agree well with those in the literature.[2] Although k_1 and k_1' are subjected to experimental errors to some extent, they still exhibit the trend that k_1 grows larger at higher x_M, while k_1' remains almost constant throughout the whole x_M range investigated. On the other hand, k_H is obtained more accurately than k_1, showing that k_H is approximately 10^3 larger than k_1 and that the higher the x_M, the larger the k_H value.

If we represent the hydrolysis equilibrium constant between the products in Scheme 8 as $K_{1H}=[Fe(OH)Cl^+][H^+]/[FeCl^{2+}]$, the following relation is given:

$$\frac{k_H}{k_H'}=\frac{K_{1H}}{K_H}\cdot\frac{k_1}{k_1'} \tag{10}$$

Since K_{1H} is supposed to be smaller than K_H on the basis of their electric charges, $(k_H/k_1)<(k_H'/k_1')$ is deduced, indicating that the hydrolyzed species is more favored in the backward reaction than in the forward.

Activation Parameters. A fact that both k_1 and k_H increase as x_M increases or the dielectric constant, D, of the mixed solvent decreases is consistent with an electrostatic expectation. According to Amis' equation,[4]

$$\ln k_H=\ln k_H^{\circ}-\frac{Z_AZ_Be^2}{kTrD} \tag{11}$$

$\ln k_H$ should show a linear relationship with respect to D^{-1} at constant temperature, where Z_A and Z_B stand for the numbers of electric charges on $Fe(OH)^{2+}$ and Cl^- ions respectively, e is the elementary electric charge, r is the distance between the two ions in the activated state, k is Boltzmann's constant, and k_H° is a rate constant which implies a rate constant at infinite dielectric constant. Figure 6 represents the relationship of $\ln k_H$ *vs.* the reciprocal dielectric constant of the mixed solvent, with a fine linearity from whose slope $r=$ 5.34 Å is obtained.

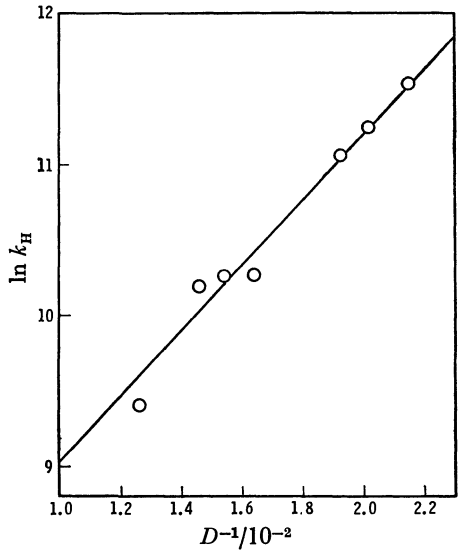

Fig. 6. Plot of $\ln k_H$ *vs.* D^{-1} at $\mu=1.0$ M and 25 °C.

When the values of radii $r(Fe^{3+})=0.67$ Å, and $r(Cl^-)=1.81$ Å, and of diameter $d(H_2O)=3.0$ Å are used, $r(Fe^{3+})+r(Cl^-)+d(H_2O)$ is equal to 5.5 Å, which is very close to the experimental result. Thus, the dimension of the activated complex is reasonable for a structure $[OH^-$–Fe^{3+}–H_2O–$Cl^-]$ which supports the outer-sphere mechanism of the reaction, and also indicates that a probable mixed solvation of methanol molecules in the coordination sheath of the complex at rather high x_M is independent of the reaction rate. This may be a proof of the reaction mechanism not only for the Fe(III)–Cl^- system[1,5] but for other similar systems such as Fe(III)–N_3^- [6] and Fe(III)–SCN^-.[7]

Temperature dependence of k_HK_H was measured; their Arrhenius plots against T^{-1} offer the activation parameters for the reaction in each solvent. Since the temperature dependence of K_H was not measured separately, $(\Delta H_H^{*}+\Delta H_H^{\circ})$ and $(\Delta S_H^{*}+\Delta S_H^{\circ})$ are the sum of the activated and the standard enthalpies and entropies for the reaction $Fe(OH)^{2+}+Cl^-\rightarrow Fe(OH)Cl^+$, respectively; the values are listed in Table 2. According to the values in Table 2, $(\Delta H_H^{*}+\Delta H_H^{\circ})$ exhibits a linear relationship with $(\Delta S_H^{*}+\Delta S_H^{\circ})$, as is

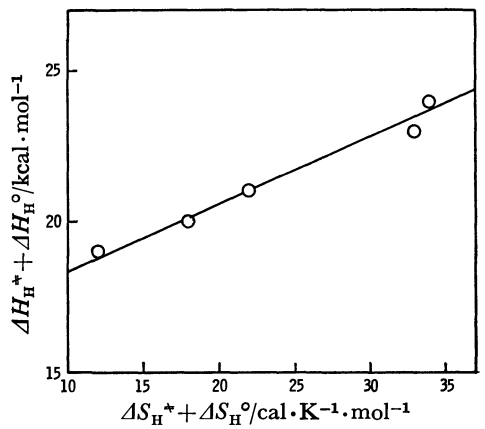

Fig. 7. Compensation relationship between $(\Delta H_H^{*}+\Delta H_H^{\circ})$ and $(\Delta S_H^{*}+\Delta S_H^{\circ})$.

shown in Fig. 7. This points out the occurrence of a compensation effect with an isokinetic temperature of 225 K, which is −48 °C.

The establishment of the linearity by Eq. (11) indicates that the free energy of activation ΔG_H^* consists of the electric part ΔG_{el}^* and the non-electrical one ΔG_O^*, the latter being indifferent to the composition of the solvent.

$$\Delta G_H^* = \Delta G_{el}^* + \Delta G_o^* \quad (12)$$

Since $\Delta G_{el}^* = NZ_AZ_Be^2/rD$ according to Eq. (11) where N is Avogadro's number, and $\Delta G_H^* = RT(\ln(kT/h) - \ln k_H)$, ΔG_O^* is also easily calculated. The results of this calculation are shown in Table 2. As a matter of course, ΔG_O^* is constant with a mean value of 13.5 kcal/mol. ΔG_{el}^* is related to the free energy change due to the approach of the two reacting ions as close as the distance of the activated complex in the dielectric medium and ΔG_O^* to that caused by the atomic and electronic configuration in the activated complex.

Circular Dichroism Spectra of *Unsym-cis(O)* Isomers of (L-Alaninate-*N*-monoacetato)(diethylenetriamine)cobalt(III) Complexes

Ken-ichi OKAMOTO,* Jinsai HIDAKA,** and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 10, 1975)

A couple of diastereomers, *ΔΔΛ-R(N)-L(C)* and *ΔΛΛ-R(N)-L(C)*, of *unsym-cis(O)*-(L-alaninate-*N*-monoacetato)(diethylenetriamine)cobalt(III)(1+) complex was prepared and characterized from the circular dichroism spectra, which presented an example for the additivity between the circular dichroism contributions due to the configurational (*ΔΔΛ* and *ΔΛΛ*) and the vicinal (*R(N)*+L(*C*)) chiralities.

In a previous paper[1] circular dichroism (CD) spectrum was reported for a *cis(O)*-[Co(L-alama)$(NH_3)_3$]$^+$ complex, where L-alama denotes L-alaninate-*N*-monoacetate(2-), which is an *O,N,O*-tridentate ligand. The present paper deals with the corresponding diethylenetriamine (dien) complex, *cis(O)*-[Co(L-alama)(dien)]$^+$. In a [Co(*O,N,O*-tridentato)(dien)]$^+$ type complex, four configurational isomers are possible as is seen in Fig. 1, neglecting the chirality which is produced by two meridionally coordinated non-planar tridentate ligands. In the *trans(O)* form the *O,N,O*-tridentate ligand spans in a meridional set of coordination sites, and in the remaining three *cis(O)* forms in a face of octahedron. Legg and Cooke[2] prepared all three geometrical isomers, *trans(O)*(a), *sym-cis(O)*(b), and racemic *unsym-cis(O)*(c+d), of [Co(ida)(dien)]$^+$, where ida is a simple *O,N,O*-tridentate ligand iminodiacetate(2−). Recently Yoshikawa *et al.*[3] reported optical resolution of the *unsym-cis(O)*-[Co(ida)(dien)]$^+$ by SE-sephadex column chromatography using an eluant containing tartar emetic.

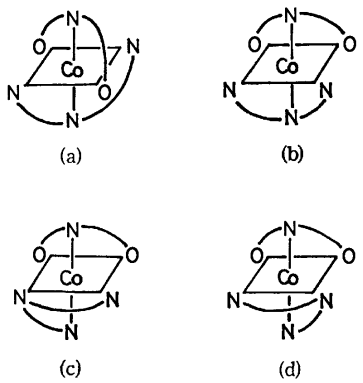

Fig. 1. Four possible isomers for a [Co(*O,N,O*-tridentato)(dien)]$^+$ type complex: (a) *trans(O)*, (b) *sym-cis(O)*, (c) *ΔΛΛ-unsym-cis(O)*, and (d) *ΔΔΛ-unsym-cis(O)*.

Since the ligand L-alama contains an asymmetric carbon atom, the isomers of cobalt(III) complex formed have two or more chiral centers, namely each one of asymmetric carbon (L) and nitrogen (*R* or *S*) atom, and in the case of *unsym-cis(O)* isomer a configurational chirality (*ΔΛΛ* or *ΔΛΛ*).[4] Thus the *unsym-cis(O)*-[Co(L-alama)(dien)]$^+$ complex offers a useful couple of diastereomers for examination of additivity of the configurational and vicinal CD.

The present paper is concerned mainly to the *cis(O)* isomers, especially *unsym-cis(O)*, and the *trans(O)* isomers are only briefly mentioned, because the stereochemistry of *trans(O)* isomers is rather complicated by possible existence of a new kind of chirality, which is produced by two meridionally coordinated non-planar tridentate ligands as in a established case of the optically resolved *mer*-[Co$(dien)_2$]$^{3+}$ complex.[5] Heretofore none of the *trans(O)* isomers of [Co(*O,N,O*-tridentato)(dien)]$^+$ type complexes have been optically resolved.

Experimental

Preparations. *(1)* Unsym-cis*(O)-(Diethylenetriamine)-(iminodiacetato)cobalt(III) Perchlorate Monohydrate*, unsym-cis*(O)-[Co(ida)(dien)]*$ClO_4 \cdot H_2O$: This was prepared by a modified method of Legg and Cooke.[2] To a suspension of 5.4 g of [$CoCl_3$(dien)][6] in 100 cm^3 of water was added a solution of 5.1 g of silver nitrate in 20 cm^3 of water. After the precipitated silver chloride was filtered off, to the filtrate was added a solution of 2.7 g of iminodiacetic acid which was neutralized in advance with potassium hydroxide. To the resulting mixture was added 3 g of charcoal and the mixture was constantly stirred at about 60 °C for three hours. After the reaction mixture had been cooled to room temperature, the charcoal was removed by filtration. The filtrate was poured into a column (35 mm × 500 mm) containing strong-acid cation exchange resin (Dowex 50 W × 8, 200—400 mesh, sodium form). After the column had been swept with water, the adsorbed band was eluted with 0.1 M aqueous solution of sodium perchlorate at a rate of 2.5 cm^3 per min. Three red bands were eluted. It had been already assigned from pmr spectra by Legg and Cooke that the first eluate contained *trans(O)* isomer, the second *sym-cis(O)* and the third *unsym-cis(O)*. So the third eluate was concentrated in a vacuum evaporator and a large amount of ethanol was added to the concentrated solution. The appeared complex was collected by filtration and recrystallized from a small amount of water by adding ethanol. The pure crystals were washed with ethanol and dried in air. Found: C, 23.76; H, 4.86; N, 13.69%. Calcd for [Co(ida)(dien)]$ClO_4 \cdot H_2O = C_8H_{18}N_4O_8ClCo \cdot H_2O$: C, 23.39; H, 4.91; N, 13.64%.

(2) $(+)_{589}$-Unsym-cis*(O)-(diethylenetriamine)(iminodiacetato)cobalt(III) chloride monohydrate*, $(+)_{589}$-unsym-cis*(O)-[Co(ida)(dien)]*$Cl \cdot H_2O$: Racemic *unsym-cis(O)*-[Co(ida)(dien)]$ClO_4 \cdot H_2O$ (0.84 g) was dissolved in an appropriate amount of water. The solution was poured into a column containing strong-base anion exchange resin (Dowex 1 × 8, 200—400 mesh, chloride form) and the column was eluted with water. Silver acetate (0.34 g) was added to the eluate

** Present address: Department of Chemistry, The University of Tsukuba, Ibaraki 300-31.

and the silver chloride resulted was filtered off. The filtrate was concentrated in a vacuum evaporator. A solution of 0.40 g of $(+)_{589}$-Na[Co(ox)$_2$(en)]·4H$_2$O[7] in a minimum amount of water was added to the concentrated solution. The mixture was concentrated by stream of air at room temperature and then kept in a refrigerator. The less soluble diastereomer deposited as violet crystals, and they were collected by filtration and recrystallized from 15 cm^3 of warm water (40 °C). The pure diastereomer was washed with ethanol and dried in air. Yield: 0.31 g. Found: C, 26.18; H, 5.09; N, 12.94%. Calcd for *unsym-cis(O)*-[Co(ida)(dien)]·$(+)_{589}$-[Co(ox)$_2$(en)]·3H$_2$O=C$_{14}$H$_{26}$N$_6$O$_{12}$Co$_2$·3H$_2$O: C, 26.18; H, 5.02; N, 13.08%.

An aqueous solution of the diastereomer was poured into a column (Dowex 1×8, 200—400 mesh, chloride form) and was eluted with water. The eluate was concentrated in a vaccum evaporator and an appropriate amount of ethanol was added to the concentrated solution to obtain the optically active complex, $(+)_{589}$-*unsym-cis(O)*-[Co(ida)(dien)]Cl·H$_2$O, which was washed with ethanol and dried in air. Found: C, 26.28; H, 6.09; N, 15.14%. Calcd for $(+)_{589}$-*unsym-cis(O)*-[Co(ida)(dien)]Cl·H$_2$O=C$_8$H$_{18}$N$_4$O$_4$ClCo·H$_2$O: C, 26.35; H, 6.08; N, 15.36%.

(3) Isomers of (L-Alaninate-N-monoacetato)(diethylenetriamine)-cobalt(III) perchlorate, [Co(L-alama)(dien)]ClO$_4$: These isomers were prepared by a similar procedure to that for (**1**) using L-alamaH$_2$·HCl·1/4H$_2$O[8] instead of idaH$_2$. The prepared isomers were separated by using a cation exchange column (30 mm×1300 mm) in a similar manner to that described in (1). Six red bands were eluted and they were numbered (i), (ii), ……, and (vi) in the order of elution. The yields for the isomers (v) and (vi) were very low. It was confirmed by the measurement of absorption spectra that the isomer (i) is a *trans(O)* isomer and the isomers (ii)—(vi) *cis(O)*. The eluates were separately concentrated in a vacuum evaporator and a large amount of ethanol was added to each of the concentrated solutions. The desired complex was collected by filtration and recrystallized from a small amount of water by adding ethanol and then dried in air. The isomer (v) was not obtained as solid salt because of its low yield, and some other isomers were contaminated with a small amount of sodium perchlorate as shown in the following analytical data. Found for isomer (i): C, 22.36; H, 4.50; N, 11.82%. Calcd for [Co(L-alama)(dien)]ClO$_4$·1/2H$_2$O·1/2NaClO$_4$=C$_9$H$_{20}$N$_4$O$_8$ClCo·1/2H$_2$O·1/2NaClO$_4$: C, 22.67; H, 4.44; N, 11.75%. Found for isomer (ii): C, 25.92; H, 5.13; N, 13.53%. Calcd for [Co(L-alama)(dien)]ClO$_4$·1/2H$_2$O=C$_9$H$_{20}$N$_4$O$_8$ClCo·1/2H$_2$O: C, 26.01; H, 5.09; N, 13.48%. Found for isomer (iii): C, 25.35; H, 4.91; N, 13.34%. Calcd for [Co(L-alama)(dien)]ClO$_4$·1/4H$_2$O·1/10NaClO$_4$=C$_9$H$_{20}$N$_4$O$_8$ClCo·1/4H$_2$O·1/10NaClO$_4$: C, 25.53; H, 4.88; N, 13.23%. Found for isomer (iv): C, 26.31; H, 5.00; N, 13.52%. Calcd for [Co (L-alama) (dien)] ClO$_4$·1/4H$_2$O=C$_9$H$_{20}$N$_4$O$_8$ClCo·1/4H$_2$O: C, 26.29; H, 5.03; N, 13.63%. Found for isomer (vi): C, 26.22; H, 5.03; N, 13.60%. Calcd for [Co(L-alama)(dien)] ClO$_4$·1/4H$_2$O=C$_9$H$_{20}$N$_4$O$_8$ClCo·1/4H$_2$O: C, 26.29; H, 5.03; N, 13.63%.

(4) Isomers of (Diethylenetriamine)(L-prolinate-N-monoacetato)-cobalt(III) Perchlorate, [Co(L-proma)(dien)]ClO$_4$: The isomers were prepared and separated by a similar procedure to that described in (**1**) using L-promaH$_2$[8] instead of idaH$_2$. Two red bands were eluted; the absorption spectra indicated that the first eluate contained *trans(O)* isomer, and the second *cis(O)*. The first eluate was concentrated to dryness in a vacuum evaporator and then the sodium perchlorate in the residue was extracted with a large amount of ethanol. The desired complex was filtered and recrystallized from a small amount of water by adding ethanol. The second eluate was also concentrated in a vacuum evaporator and a large amount of ethanol was added to the concentrated solution. The obtained complex was filtered and recrystallized from a small amount of water by adding ethanol. Both the pure complexes were washed with ethanol and dried in air. Found for the *trans(O)* complex: C, 30.20; H, 5.19; N, 12.76%. Calcd for [Co(L-proma)(dien)]ClO$_4$·1/4H$_2$O=C$_{11}$H$_{22}$N$_4$O$_8$ClCo·1/4H$_2$O: C, 30.22; H, 5.19; N, 12.81%. Found for the *cis(O)* complex: C, 30.28; H, 5.13; N, 12.90%. Calcd for [Co(L-proma)-(dien)]ClO$_4$=C$_{11}$H$_{22}$N$_4$O$_8$ClCo: C, 30.53; H, 5.13; N, 12.95%.

Measurements. The electronic absorption spectra were measured by a Beckman DU spectrophotometer and a Shimadzu spectrophotometer UV-200. The CD spectra were recorded with a Jasco Model J-10 or J-20 spectropolarimeter with the CD attachment, or with a Roussel-Jouan Dichrograph. All the measurements were made in aqueous solutions at room temperature.

Results and Discussion

Visible and near ultraviolet absorption data of the present [Co^{III}(N)$_4$(O)$_2$] type complexes are shown in Table 1 and the typical absorption curves of a *cis-trans* couple are in Fig. 2. The isomers obtained are divided into two groups on the splitting pattern of the first absorption band. An isomer of the first group has a

Table 1. Absorption maxima of the [Co(*O,N,O*-tridentato)(dien)]$^+$ complexes

Complex ion	σ_{max}(logε_{max})	
	I band	II band
unsym-cis(O)-[Co(ida)(dien)]$^+$	19.6(2.04)	28.2(2.11)
cis(O)-[Co(L-alama)(dien)]$^+$		
isomer ii, *sym-cis(O)*	20.5(1.87)	28.7(1.96)
isomer iii, *unsym-cis(O)*-R	19.3(2.05)	28.1(2.14)
isomer iv, *unsym-cis(O)*-R	19.4(2.06)	28.1(2.17)
isomer v, *cis(O)*	20.6(—)	28.7(—)
isomer vi, *cis(O)*	19.7(2.03)	28.1(2.12)
sym-cis(O)-R-[Co(L-proma)(dien)]$^+$	19.9(1.92)	28.4(1.99)
trans (O)-[Co(ida)(dien)]$^+$[2]	19.6(2.24)	27.8(2.28)
trans(O)-[Co(L-alama)(dien)]$^+$	19.9(2.28)	28.0(2.27)
trans(O)-R-[Co(L-proma)(dien)]$^+$	19.9(2.24)	27.4(2.31)

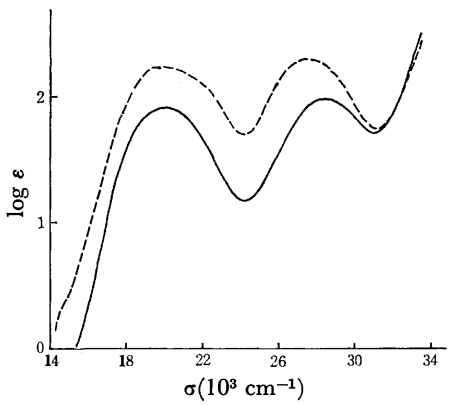

Fig. 2. Absorption curves of *cis(O)*-[Co(L-proma)-(dien)]$^+$ (——) and *trans(O)*-[Co(L-proma)(dien)]$^+$ (----).

shoulder at higher energy side of the major peak, and the second group only a symmetrical major peak (Fig. 2). It is concluded, therefore, that an isomer of the first group has a *trans*(*O*) structure and that the second group a *cis*(*O*). It is worthwhile to note that the first absorption bands of the *trans*(*O*) isomers of this type complexes are more intense than those of the *cis*(*O*) ones; $\log \varepsilon_{max}$ values are in a range of 2.24—2.28 for *trans*(*O*), while 1.87—2.06 for *cis*(*O*) (Table 1). The second absorption bands are also in the same trend, $\log \varepsilon_{max}$=2.27—2.31 for *trans*(*O*), while 1.96—2.17 for *cis*(*O*).

In the [Co(L-alama)(dien)]$^+$ and [Co(L-proma)-(dien)]$^+$ complexes, both the *cis*(*O*) and *trans*(*O*) isomers were obtained. Thus the L-alama and L-proma ligands take both the facial and meridional coordinations in the present dien complexes, in contrast to the corresponding triammine complexes, in which only the facial coordination occurred for both the ligands.[1]

In the preparation of [Co(L-proma)(dien)]$^+$ complex, each one of *trans*(*O*) and *cis*(*O*) isomers was obtained. A molecular model examination shows that the formation of *unsym-cis*(*O*) isomers is almost impossible because of the repulsion between the pyrrolidine ring of the L-proma ligand and the ethylenediamine moiety of the dien ligand. It is assigned, therefore, that the *cis*(*O*) isomer obtained takes *sym-cis*(*O*) configuration. As for the configuration of the coordinated asymmetric nitrogen atom, the L-proma ligand takes only *R* configuration stereospecifically.[9] Thus the two isomers obtained for the L-proma ligand are *trans*(*O*)-*R* and *sym-cis*(*O*)-*R* isomers.

One *trans*(*O*) and five *cis*(*O*) isomers were isolated for the [Co(L-alama)(dien)]$^+$ complex. Of the five *cis*(*O*) isomers the fifth eluate (isomer v) could not be examined by elemental analysis because of its extremely low yield, and then only the absorption spectrum was measured. Isomer vi was obtained in a lower yield than the earlier three isomers ii, iii, and iv. We have already found that for the coordinated asymmetric nitrogen atom of the L-alama ligand the *R* configuration is preferred to the *S* one; namely a repulsion exists in the L-alama ligand having the *S* asymmetric nitrogen atom, between the L-alaninate methyl group and a proton of the *N*-acetate chelate ring of the same ligand.[8] Therefore, the predominant isomers ii, iii, and iv may be assigned to *R* configuration and the poorly yielded isomers v and vi to *S*. From the consideration of the CD curves (see below), it is concluded that the isomers iii and iv take actually *R* structure, but ambiguities remain to the nitrogen configurations of the isomers ii, v, and vi.

cis(*O*)-*R*-[Co(L-alama)-$(NH_3)_3$]$^+$ [1]	18.1(−0.17) 19.8(+0.12) 21.9(−0.17)	28.4(−0.22)
sym-cis(*O*)-*R*-[Co(L-proma)-(dien)]$^+$	18.1(−0.05) 20.0(+0.37) 22.6(−0.07)	28.3(−0.34)
cis(*O*)-*R*-[Co(L-proma)-$(NH_3)_3$]$^+$ [1]	17.9(−0.30) 19.9(+1.04)	28.1(−0.46)
sym-cis(*O*)-[Co(L-alama)(dien)]$^+$		
isomer ii	18.3(+0.02) 21.5(−0.38)	26.8(−0.14)

The CD data of *cis*(*O*) isomers are collected in Table 2. Of the three predominant *cis*(*O*) isomers of the L-alama complex, the isomer ii has much weaker CD intensity than the other two, iii and iv. The CD curve of isomer iii is almost a mirror image to that of the isomer iv as is seen in Fig. 3. These facts show that the isomer ii is *sym-cis*(*O*) type, while the isomers iii and iv *unsym-cis*(*O*).

If the configurational and vicinal CD are separable, the following additivity formulas are derived for the two *unsym-cis*(*O*)-*R* isomers as in other similar cases studied previously,[1,8]

$$\Delta\varepsilon(\Delta\Delta\Lambda) = \Delta + R(N) + \text{L}(C)$$
$$\Delta\varepsilon(\Delta\Lambda\Lambda) = \Lambda + R(N) + \text{L}(C)$$

where $\Delta\varepsilon(\Delta\Delta\Lambda)$ and $\Delta\varepsilon(\Delta\Lambda\Lambda)$ are the CD of the isomer *ΔΔΛ* and *ΔΛΛ*, Δ and Λ the configurational contributions of Δ and Λ chiralities, $R(N)$ and L(C) the vicinal contributions of *R*-nitrogen and L-carbon chiralities, respectively. Since $\Delta = -\Lambda$, we have

$$\Delta = 1/2\times\{\Delta\varepsilon(\Delta\Delta\Lambda) - \Delta\varepsilon(\Delta\Lambda\Lambda)\}$$
$$\Lambda = 1/2\times\{\Delta\varepsilon(\Delta\Lambda\Lambda) - \Delta\varepsilon(\Delta\Delta\Lambda)\}$$
$$R(N) + \text{L}(C) = 1/2\times\{\Delta\varepsilon(\Delta\Delta\Lambda) + \Delta\varepsilon(\Delta\Lambda\Lambda)\}$$

The partial contribution curves calculated under an assumption that the isomers iii and iv are *ΔΛΛ-R* and *ΔΔΛ-R*, respectively, are shown in Fig. 4. The cal-

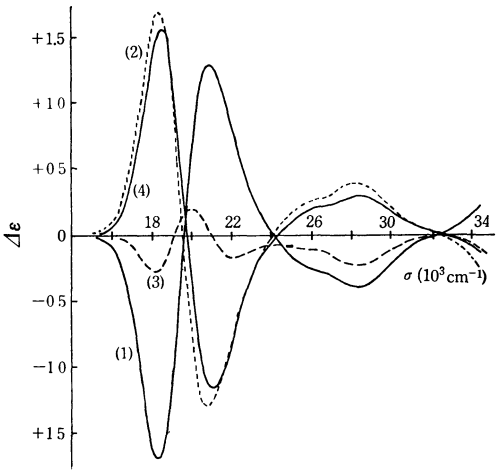

Fig. 4. CD curve analysis of *cis(O)*-[Co(L-alama)-(dien)]$^+$ complex: (1) *Δ* confirguational curve, $1/2\times\{\Delta\varepsilon(\text{iii})-\Delta\varepsilon(\text{iv})\}$; (2) *Δ* configurational curve, $1/2\times\{\Delta\varepsilon(\text{iv})-\Delta\varepsilon(\text{iii})\}$; (3) $\{R(N)+\text{L}(C)\}$ vicinal curve, $1/2\times\{\Delta\varepsilon(\text{iii})+\Delta\varepsilon(\text{iv})\}$; and (4) observed CD curve of $(+)_{589}$-*unsym-cis(O)*-[Co(ida)(dien)]$^+$.

culated *Δ* configurational curve shows a positive and a negative CD band from lower energy side in the first absorption band region and agrees well with the observed CD curve of $(+)_{589}$-*unsym-cis(O)*-[Co(ida)-(dien)]$^+$, which has been assigned to *ΔΔΔ* configuration by previous authors.[3] Since the higher energy component of the first absorption band of the *cis(O)*-$[Co(N)_4(O)_2]^+$ type complex is related to the $E(D_{4h})$ parentage, the above assignment is along the line of a

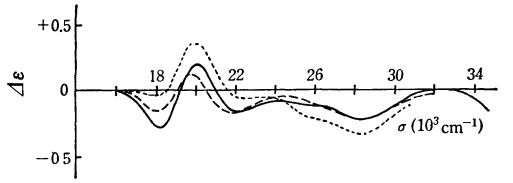

Fig. 5. CD curves of *cis(O)*-*R*-[Co(L-alama)$(NH_3)_3$]$^+$ (——)[1], *sym-cis(O)*-*R*-[Co(L-proma)(dien)]$^+$ (……), and vicinal effect curve of *unsym-cis(O)*-*R*-[Co(L-alama)-(dien)]$^+$ (——).

normal CD sign pattern for the first absorption band components.[10]

The calculated vicinal contribution $R(N)+\text{L}(C)$ for the *unsym-cis(O)*-*R*-[Co(L-alama)(dien)]$^+$ diastereomers coincides well with the observed CD curve of *cis(O)*-*R*-[Co(L-alama)$(NH_3)_3$]$^+$ complex[1] (Fig. 5). In conclusion, the additivity rule is well applicable to the present complexes to separate the configurational and vicinal CD curves, and the CD curve analysis (Figs. 4 and 5) established the configurations of the two *unsym-cis(O)* isomers of [Co(L-alama)(dien)]$^+$; namely the isomer iii has *ΔΛΛ-R* configuration and the isomer iv *ΔΔΛ-R*. The observed CD curve of the *cis(O)*-*R*-[Co(L-proma)(dien)]$^+$ is also similar to the vicinal curves of L-alama complexes (Fig. 5). This shows that the *cis(O)*-*R*-[Co(L-proma)(dien)]$^+$ complex has actually the *sym-cis(O)* structure as predicted from molecular model consideration. The *sym-cis(O)*-[Co(L-alama)-(dien)]$^+$ complex (isomer ii) shows somewhat different CD (Table 2), and the asymmetric nitrogen configuration of this isomer is not clear at present.

Preparation and Some Properties of Triorganosiloxy Derivatives of Cyclopentadienyl Titanium

Hideo SUZUKI and Toshio TAKIGUCHI

Department of Synthetic Chemistry, Faculty of Technology, Gunma University, Kiryu, Gunma 376

(Received September 5, 1974)

Several triorganosiloxy derivatives of cyclopentadienyl titanium were synthesized by the reactions of dicyclopentadienyl titanium dichloride or cyclopentadienyltitanium trichloride with triorganosilanols or their sodium salts. The products obtained include π-$Cp_2TiClOSiMe_3$, π-$CpTi(OSiMe_3)_3$, π-$CpTi(OSiMe_2Ph)_3$, π-$CpTi(OSiPh_2Me)_3$, π-$CpTi(OSiPh_3)_3$, π-$CpTi(OSiPh_3)_2Cl$ and π-$CpTi(OSiPh_3)Cl_2$. Some correlations were found to exist between the substituents on silicon atoms and cyclopentadienyl ring protons in NMR spectra and the Ti–O–Si bond absorptions in IR spectra. The chemical stabilities of the Ti–O–Si bonding in the products were dependent on the nature of the organic groups attached to the silicon atoms. The chemical resistance of the products against hydrolytic cleavage was regularly increased with successive replacement of methyl groups by phenyl groups.

In succession to our previous paper[1] dealing with preparation of some siloxy derivatives of cyclopentadienyl titanium, several new compounds in the series listed in Table 1 were obtained by analogous procedures. Most products were crystalline masses with moderate stability.

The NMR spectral investigations of the derivatives indicated that there are some correlations between the proton chemical shifts of cyclopentadienyl ring protons and the nature of the substituents on silicon.

The products generally reacted both with gaseous hydrogen chloride and with acetyl chloride, leaving the cyclopentadienyl groups intact and substituting the chlorine atoms for the siloxy groups, thus yielding partially triorganosiloxy-substituted cyclopentadienyltitanium chlorides.

The hydrolysis of the products was investigated by examining the relative intensities of the absorption bands due to the Si–O–Ti bond. It was found that the hydrolytic stability increased with successive replacement of methyl groups on silicon by phenyl groups.

No indication of any formation of ferrocene was obtained from the reaction between iron(II) chloride and the products.

Experimental

Triorganosilanols: Trimethylsilanol, bp, 98—99 °C, n_D^{20}, 1.3890, was prepared by hydrolysis of trimethylfluorosilane with 2 M-NaOH. Dimethylphenylsilanol, diphenylmethylsilanol, and triphenylsilanol were prepared by the method[2] reported previously.

Triorganosiloxy Derivatives of Cyclopentadienyl Titanium: A tetrahydrofuran (THF) solution of a silanol was added dropwise to a THF solution containing a theoretical amount of dicyclopentadienyltitanium dichloride or cyclopentadienyltitanium trichloride at room temperature under stirring and nitrogen atmosphere for about 30 min. At this point a THF solution of triethylamine (20% excess) was added to the mixture, which was stirred for another 10 hr. The precipitated triethylamine hydrochloride was then filtered off, and the filtrate was concentrated to give the triorganosiloxy derivative as a crude product. Purification either by distillation or by recrystallization from *n*-hexane gave the pure samples listed in Tables 1 and 2.

Reactivities: Some reactions of compounds I—VIII with gaseous hydrogen chloride, acetyl chloride, aqueous solution of sodium hydroxide, and ferrous chloride were investigated by means of NMR and IR spectral measurements.

Reaction with Gaseous Hydrogen Chloride: Dry hydrogen chlo-

Table 2. NMR and IR spectral data

	NMR (τ, 6% in $CDCl_3$)		IR (cm^{-1}, 2 mmol% in CS_2)	
	Cp	Me	Ti–O–Si	=CH(π-Cp)
I	3.71	9.92	939	807
II	3.74	9.66	940	808
III	3.76	9.38	945	810
IV	3.76		951	814
V	3.70	9.94	908	803
VI	3.81	9.71	910	810
VII	3.94	9.47	910	810
VIII	4.03		915	816

Table 3. Reaction of the compounds with gaseous hydrogen chloride

Sample	Product	NMR (τ)	Ratio[a]
I—IV	π-Cp_2TiCl_2	3.40	100
V	π-$CpTiCl_3$	2.95	100
VI	π-$CpTiCl_3$	2.95	100
VII	π-$CpTi(OSiPh_2Me)Cl_2$[b]	3.45	80
VIII	π-$CpTi(OSiPh_3)_2Cl$	3.84	80
	π-$CpTi(OSiPh_3)Cl_2$	3.51	11

a) Ratio of ring proton converted from the original compounds to the products. b) Not fully identified.

ride was introduced for 2 hr into a boiling solution of 0.2 mmol of a sample in 100 ml of benzene, and volatile materials were removed by evaporation *in vacuo*. The solid residue was then dissolved in $CDCl_3$ and studied spectroscopically. The results are listed in Table 3.

The two partially substituted products from VIII were prepared independently by the following reaction:

$$CpTiCl_3 + 2Ph_3SiONa \xrightarrow[PhCH_3]{} CpTi(OSiPh_3)_2Cl + CpTi(OSiPh_3)Cl_2$$

The product obtained are as follows; the numerals represent respectively mp (°C), yield (%), C%, H%, Cl%, Si%, Ti% [Calcd], NMR (π-Cp, τ in $CDCl_3$) and IR (TiOSi, cm^{-1} in CS_2):

$CpTi(OSiPh_3)_2Cl$: 168—170, 50, 71.15 [70.56], 5.45[5.04], 5.6[5.1], 7.7[8.0], 7.2[6.9], 3.83, 904.

$CpTi(OSiPh_3)Cl_2$: 118—119, 10, 59.88[60.01], 4.50[4.28], 14.7[15.6], 5.9[6.1], 10.6[10.2], 3.50, 938.

On NMR spectra of π-$CpTi(OSiMe_{3-n}Ph_n)_3$ in Table 2 and π-$CpTi(OSiPh_3)_nCl_{3-n}$, it is shown that an increase of the number of phenyl groups leads to a shift of the cyclopentadienyl signal toward high field. This is believed to be due mainly to the diamagnetic anisotropy from phenyl groups and to the electron accepting properties of chlorine atoms. These results are in line with the observations of Beachell and Butter, who reported a detailed study of NMR spectra of titanocene sandwich compounds.[3]

Reaction with Acetyl Chloride: To a solution of 0.1 mmol of a sample in $CDCl_3$ was added 0.1 mmol (for I—IV) or 0.42 mmol (for V—VIII) of acetyl chloride and the mixture was heated at 45 °C for 2 hr. It was then submitted to NMR spectral investigations. The results are shown in Table 4.

Hydrolysis with Aqueous Sodium Hydroxide Solution: A solution of 0.2 mmol of a sample in 8 ml of THF was divided into four portions A, B, C, and D. The last three samples (B, C, and D) were treated with the reagents shown below in order to learn their stabilities towards hydrolytic cleavage.

Table 4. Reaction of the compounds with acetyl chloride

Sample	AcCl ($\times$0.1 mmol)	Product	NMR (τ)	Ratio (%)[a]
I	1.4	π-Cp_2TiCl_2	3.40	100
II	1.4	π-Cp_2TiCl_2	3.40	90
III	1.4	π-Cp_2TiCl_2	3.40	41
IV	1.4	π-Cp_2TiCl_2	3.40	39
V	4.2	π-$CpTi(OSiMe_3)Cl_2$[b]	3.25	90
VI	4.2	π-$CpTi(OSiMe_2Ph)Cl_2$[b]	3.38	90
VII	4.2	π-$CpTi(OSiPh_2Me)_2Cl$[b]	3.75	72
VIII	4.2	π-$CpTi(OSiPh_3)_2Cl$	3.81	46

a), b) The same as in Table 3.

Run	Reagent	Temp.
B	0.1 M-NaOH	r.t.
C	H_2O	70°C
D	0.1 M-NaOH	70°C

After 2 hr, each solution was evaporated *in vacuo* and the residue was dissolved in 2 ml of carbon disulfide to give a sample for IR spectral investigations. The intensities of the Ti-O-Si bond absorption of each sample relative to the intensity of the original sample A are shown in Table 5.

Table 5. Reaction of the compounds with water and aqueous sodium hydroxide solution

Sample	Reagent (μl)	Absorption intensity ratio in IR on TiOSi (A=100)	
I[a]	20	60(B)	15(C,D)
II[a]	20	90(B)	30(C,D)
III[a]	50	65(B)	30(C,D)
	[20]	[100(B)]	[35(C,D)]
IV[a]	50	80(B)	35(C,D)
V	20	35(B)	15(C,D)
VI	20	75(B)	35(C) 25(D)
VII	50	100(B.C)	90(D)
	[20]	[100(B.C)]	[95(D)]
VIII	50	100(B.C.D)	

a) When these samples were treated, besides the absorption band at about 945 cm^{-1}, a band centered at 920 cm^{-1} due to disproportionation appeared; its intensity was I>II>III>IV and in the order of D>C>B with respect to the treatment conditions. NMR spectra investigations indicated formation of π-Cp_2TiCl_2, particularly in run C.

Attempted reaction with Iron(II) Chloride: Attempted reactions of compounds I—VIII with iron(II) chloride prepared from iron(III) trichloride and iron powder in THF did not lead to any formation of ferrocene; this seems to be attributed both to the rather unionic property of the cyclopentadienyltitanium bond and to the steric effect of the triorganiosiloxy groups.

The Synthesis of 1,3-Thiazine-2,4-dithiones by the Reaction of Carbon Disulfide with Cyclic Ketones or Their Ketimines

Motomu MURAOKA, Tatsuo YAMAMOTO, and Tatsuo TAKESHIMA*

Department of Chemistry, Faculty of Science, Josai University, Keyaki-dai, Sakado, Saitama 350-02

** Department of Chemistry, Faculty of Science, Chiba University, Yayoi-cho, Chiba-shi 280*

(Received November 8, 1974)

Cyclohexanone, 4-methylcyclohexanone, and phloroglucinol, when treated with carbon disulfide in the presence of triethylamine and aqueous ammonia, gave the respective 3,1-benzothiazine-2(1*H*),4-dithiones. Glutazines and 2-iminocyclopentanedithiocarboxylic acid underwent this reaction without ammonia.

We have previously shown that cyclohexanone, in the presence of sodium amide, reacts with carbon disulfide to give a small amount of 5,6,7,8-tetrahydro-3,1-benzothiazine-2(1*H*),4-dithione in addition to the major product, 5,6,7,8-tetrahydro-spiro[2*H*-3,1-benzothiazine-2,1'-cyclohexane]-4(1*H*)-thione.[1]

Concerning 1,3-thiazine-2,4-dithiones, there have also been a few reports.[2-4]

We wish now to report a method of preparing the thiazinedithiones, involving the treatment of ketones or ketimines with carbon disulfide, in the presence of triethylamine, and also aqueous ammonia if needed.

4

Cyclohexanone, 4-methylcyclohexanone, phloroglucinol, glutazine, and 3-substituted glutazines, in this reaction, afforded the expected thiazinedithiones or their tautomers—**1a**, **1b**, **2**, and **3a**—**c**, in yields ranging from 16 to 85%. Other ketones were reluctant to undergo this reaction. 2-Iminocyclopentanedithiocarboxylic acid,[5] on treatment with carbon disulfide and triethylamine, naturally gave 1,5,6,7-tetrahydrocyclopenta[*d*][1,3]thiazine-2,4-dithione (**4**), but 3-substituted 2-iminocyclopentanedithiocarboxylic acids did not undergo this reaction.

The structures were identified on the basis of their IR, UV, NMR, and mass spectra, together with elemental analyses and chemical reactions. Structure **2** was assigned on the basis of the following spectral data. The IR spectrum had an imino group band near 3260 cm^{-1}. The mass spectrum had the parent peak together with the most intense one, which corresponds to the elimination of the mercapto group from the molecular ion. On methylation or acetylation, the imino group band disappeared from both the IR and NMR spectra. Instead, the two doublets due to the two protons at 6- and 8-C of Compound **2** turned into two double doublets in the NMR spectrum of the acetyl derivative of this compound because of the restricted rotation of the acetyl group (in hexadeuteroacetone). These facts, together with the slightly broadened singlet corresponding to *ca.* two protons at τ −3.17 in the NMR spectrum of **2** (in heptadeuterodimethylformamide), led us to assign this structure: 1,7-dihydro-5-hydroxy-4-mercapto-7-oxo-3,1-benzothiazine-2-thione.

Experimental

The melting points, the appearances, the solvent of recrystallization, and the results of elemental analyses are all listed in Table 1.

*5,6,7,8-Tetrahydro-3,1-benzothiazine-2(1H),4-dithione (**1a**).* To a mixture of cyclohexanone (20 g), triethylamine (60 g), and aqueous 28% ammonia (40 ml), carbon disulfide (38 g) was added dropwise under cooling to 10 °C and vigorous stirring. The stirring was then continued for an additional 20 hr. A fairly viscous reaction mixture was acidified with dilute hydrochloric acid at 0 °C, and then a small quantity of ethanol was added to the red viscous oil which was thus separated. The red crystalline solid was dissolved in aqueous 28% ammonia to remove the insoluble material,[6] after which the solution was acidified again to give **1a** (11 g, 26%), which showed no depression of melting point on admixture with an authentic specimen[1] of **1a**.

*5,6,7,8-Tetrahydro-6-methyl-3,1-benzothiazine-2(1H),4-dithione (**1b**).* The preparation was the same as that described above (16%).[7] IR (KBr): 3120, 1590, and 1505 cm^{-1}. NMR [$(CD_3)_2SO$]: τ 6.56 (br, 1H), *ca.* 7.4 (m, 4H,) *ca.* 8.2 (m, 3H), and 8.97 ppm (d, 3H).

*5,6,7,8-Tetrahydro-5,7-dioxo-3,1-benzothiazine-2(1H),4-dithione (**2**).* A mixture of phloroglucinol dihydrate (5 g), carbon disulfide (12 g), triethylamine (1.5 g), and aqueous 28% ammonia (16 ml) was stirred for 50 hr at 32 °C. The yellow crystals which were then collected and washed with ether were dissolved in water, and the solution was acidified with

a) These compounds were isolated by the acidification of the respective reaction mixtures diluted with water.
b) Glutazine and the 3-substituted glutazines were prepared after Thorpe's method (*J. Chem. Soc.*, **85**, 1726 (1904)).

Table 3. IR and NMR[a] spectra of **3a**—**c** and **4**

Compound	cm^{-1} (KBr)	τ ppm in CD_3SOCD_3
3a	3070, 2915b, 2820b, 1650, 1615, 1575, 1537	4.43 (s, 1H), 4.67 (b, 1H), 7.06 (s, 1H), 7.18 (s, 1H)
3b	3310, 1635, 1605, 1550	−2.00 (br s, 1H), −1.80 (b, 1H), 6.62 (b, 1H), 8.07 (s, 3H) (further, 6.87 (q, 6H), 8.80 (t, 9H))
3c	3150, 1635, 1605, 1550	−0.13 (br s, 1H), 0.17 (b, 1H), 6.60 (b, 1H), 7.43 (q, 2H), 9.07 (t, 3H) (further, 6.87 (q, 6H), 8.83 (t, 9H))
4	3120, 1598, 1515	6.50 (b, 1H), 7.09 (t, 2H), 7.22 (t, 2H), 8.00 (m, 2H)

a) The NMR spectra of **3a**—**c** were obtained by the following conditions: **3a**; in CD_3SOCD_3-C_5D_5N (3: 1), **3b** and **3c**; as triethylammonium salt. (**3a**—**c** Were hardly soluble in most organic solvents and were denatured in dimethyl sulfoxide.)

dilute hydrochloric acid at 0 °C to give **2** (1.7 g, 23%). IR (KBr): 3260br, 1631, 1599, and 1532 cm^{-1}. NMR [$(CD_3)_2NCDO$] τ −3.17 and −3.10 (slightly br s, and br, >2H), 3.23 (d, J=2.4 Hz, 1H), 3.67 ppm (d, J=2.4 Hz, 1H). MS *m/e*: 243, 210, 178, 161, and 117.

Methylation of **2**. By methylation with diazomethane in a usual manner, a mixture of dimethyl and the trimethyl derivative of **2** was obtained. The hot solution which dissolved the mixture in methanol was cooled to separate out the dimethyl derivative of **2** (**2a**, 6%) [IR (KBr): 1620, 1574, and 1536 cm^{-1}; NMR (CF_3COOH): τ 3.11 (s, 2H), 5.91 (s, 3H), and 6.98 ppm (s, 3H); MS *m/e*: 271 and 224]. The solvent was evaporated from the mother liquor of **2a** to give the trimethyl derivative of **2** (**2b**, 28%).

Acetyl Derivative of **2**. To a solution of 2 (1 g) in pyridine, acetyl chloride (0.5 g) was added at 0 °C, after which the mixture was refluxed for 3 hr at 60 °C. The subsequent addition of water to the reaction mixture separated the acetyl derivative of **2** (**2c**) (0.8 g, 68%). IR (KBr): 1778, 1625, and 1530 cm^{-1}. NMR (CD_3COCD_3): τ 3.16 (dd, J=2.4 Hz, 1H), 3.52 (dd, J=2.4 Hz, 1H), 6.98 (s, 1H), 7.13 (s, 1H), and 7.66 ppm (s, 3H).

The Carbonyliron Complexes of Some Chlorocarbons

Takefumi MATSUKURA, Koichi MANO, and Akira FUJINO

Research Institute for Atomic Energy, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received December 16, 1974)

The (tetracarbonyl)iron complexes of perchloro-(3,4-dimethylenecyclobutene) and perchlorofulvene, and the (tricarbonyl)iron complex of the former chlorocarbon were synthesized. The structural evidences for those complexes were given on the basis of the DSC, their chemical behaviors, and the UV, IR and other spectral data. Particularly, their mass-, NQR- and ^{13}C-NMR-spectra were discussed in detail by comparing them with those of the substrate chlorocarbons.

Little has been reported on the carbonyliron complexes with chlorocarbons as organic ligand. The thermochemical stabilities of a number of $L \cdot Fe(CO)_4$ type complexes (L: substituted ethylene) were discussed from the MO theoretical point of view by correlating their V-[1] or D/A- values[2] respectively with the ν_{CO} frequencies or the force constants in IR spectroscopy. However, the highly retarded chemical reactivity of conjugated polyenic chlorocarbons may have been a barrier to promote the work in this field; for instance, tetrachloroethylene, the simplest olefinic chlorocarbon, reacts with nonacarbonyl diiron under ordinary conditions to give the complex, but only in 0.1% yield,[3] reflecting a severe effect of perchloro-substitution. To our present knowledge, no carbonyliron compounds complexed with other chlorocarbon have appeared in the literature.

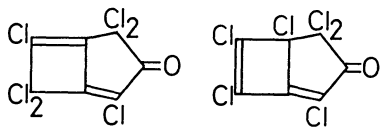
We examined the reactions between pentacarbonyl iron or nonacarbonyl diiron and three cyclic C_6Cl_6 chlorocarbons; *i.e.*, perchloro-(3,4-dimethylenecyclobutene) (**1**), -fulvene (**2**) and -benzene. Two kinds of complexes with the types of $L \cdot Fe(CO)_4$ and $L \cdot Fe(CO)_3$ were obtained from **1**, whereas only the one with the former type from **2**. Perchlorobenzene did not react with the reagents at all.

This paper describes the syntheses and some degradative reactions of those complexes, and discusses their structures mainly in terms of the IR-, mass-, NQR- and ^{13}C-NMR spectral data.

Results and Discussion

Syntheses and Degradative Reactions of Carbonyliron Complexes with Chlorocarbon Ligand. The chlorocarbon **1** reacted with nonacarbonyl diiron under the conditions specified in the experimental to furnish a complex (**3**), $C_6Cl_6Fe(CO)_4$ (mp 47.0 °C and decomp. *ca.* 76 °C, from the DSC). The oxidative degradation with Fe(III) or Ce(IV) smoothly liberated **1**. The thermal decomposition near 65 °C also proved the liberation of **1**, but there was no indication that dodecacarbonyl triiron formed through the trimerization of the component. The UV absorption for **3** were: $\lambda_{max}^{n\text{-hexane}}$ 230 (4.43), 287 (4.30) nm (log ε).

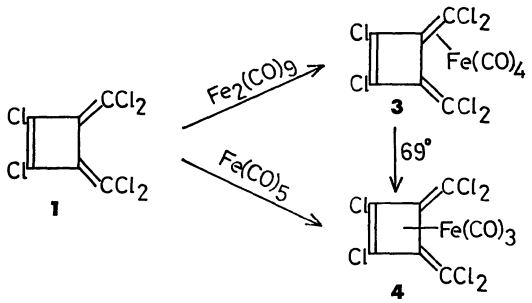
The second complex (**4**), $C_6Cl_6Fe(CO)_3$ (mp and dp: 90.5 and 105 °C, respectively, by DSC) was obtained by refluxing **3** in *n*-hexane with the inevitable production of **1**. The pyrolytic or oxidative liberation of **1** was essentially parallel to the above. Very drastic change in the UV spectrum ($\lambda_{max}^{n\text{-hexane}}$ 215 (4.36), 260_{sh} (3.99), 310_{sh} (3.70) and 386 (3.39); nm (log ε)) was observed in **4**. The only characteristically different behavior of **4** was the byproduction of a ketone (**5**) (mp 117 °C), C_7Cl_6O in the pyrolysis. The structure of perchloro-(bicyclo[3.2.0]hepta-1,5-diene-3-one) (**5a**) or its 1,6-diene alternative (**5b**) was assigned to **5** mainly on the basis of the UV spectral data.



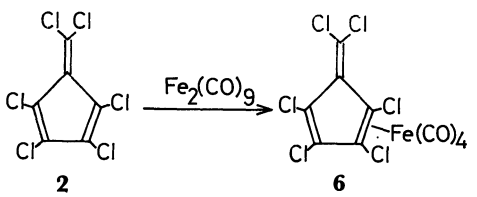
5a **5b**

The complex **4** was also produced by heating **1** and pentacarbonyl iron in a sealed tube at 85 °C, but in a poor yield.

The chlorocarbon **2** afforded in the analogous way the complex (**6**), $C_6Cl_6Fe(CO)_4$, through the reaction with nonacarbonyl diiron. The liberation of the substrate by either pyrolysis or the oxidative degradation was also confirmed. The observed mp by DSC was 72 °C. Interestingly, the exothermic degradation pattern of **6** suggested a two step successive loss of carbon monoxide, one at 84.5 °C, and the rest three at 93.5 °C.



1 **3** **4**



2 **6**

Further attempt was made to prepare the complex of h^4-type starting with **6** by the pyrolysis in *n*-hexane. Unfortunatelly, however, the product was too unstable

to be well caracterized; even very careful purification by chromatography near 0 °C resulted in failure in isolating the complex pure enough for succeeding analysis.

No formation of binuclear complex were observed in all the reactions of this work.

*IR Spectra** It was expected from the calculated HOMOs (by EHT) and the observed $\pi\rightarrow\pi^*$ energies of the chlorocarbons (−10.38 and 5.14 eV for **1** and −10.49 and 4.13 eV for **2**, respectively), that their interaction with $Fe(CO)_4$ (ionization potential: 7.0 eV[4]) would be much more advantageous for the complex formation than those in this case of dichloroethylenes (*e.g.*, for *trans*-isomer: HOMO −9.72 eV, $\pi\rightarrow\pi^*$ 6.49 eV[2]). There would be an effective stabilization in the total energy due to the back-donative bond formation.

The IR spectra of **3** gave rise to four very strong ν_{CO} bands at 2120, 2075, 2060 and 2035 cm^{-1}, indicative of the contribution of this back-donation from the central atom to the ligand, as well as of the equatorial position[5] of the latter in a trigonal bipyramidal structure. The band with the highest wave number and the lowest intensity due to A_1 asymmetric stretching vibration fell into the range between that for C_2Cl_4–$Fe(CO)_4$ (2134 cm^{-1}, the highest ever reported)[3] and those for 1,2-dichloroethylene-complexes (2106 cm^{-1})[2]. The $\nu_{C=C}$ bands corresponding to the free double bonds were at 1652 and 1595 cm^{-1}. An additional very weak band at 1375 cm^{-1} was detected by the special examination with a thick perchlorobutadiene mull; this should correspond to the double bond coordinated by the central atom. There have been no reports that describe such a drastic $\nu_{C=C}$ shift, but the $\Delta\nu_{C=C}$ value of *ca.* 170 cm^{-1} was within the acceptable range.[5]

The observed ν_{CO} bands of **4** were 2105 (vs) and 2065 (vs and broad) cm^{-1}, typical for diene–(tricarbonyl)iron complex.[6] The highest band was 52 cm^{-1} higher than the corresponding one of butadiene-$Fe(CO)_3$,[7] and will be the highest of all on reports as for the h^4-type complexes except some with cationic ligand.[8] Two strong $\nu_{C=C}$ bands with almost equal intensity were observed; the one at 1676 cm^{-1} for the free double bond and the other at 1375 cm^{-1} for the metal-coordinated.

The ν_{CO} bands (2120, 2070, 2065 and 2040 cm^{-1}, all vs) of **6** were almost the same as those for **3**. Therefore, the position of the organic ligand in the complex was assigned also to be equatorial in a trigonal bipyramidal structure, and the back-donation was nearly of the same extent. The $\nu_{C=C}$ bands appeared as two peaks (1570 and 1530 cm^{-1}, both s) splitted from the single broad one (1568 cm^{-1}, s) in **2**, and interestingly in this case, no band for the shifted $\nu_{C=C}$ was observed in the region 1500—1300 cm^{-1} even with a highly concentrated perchlorobutadiene solution.

Mass Spectra. The relative abundances are listed in Table 1 only for the main fragments including metal and/or C_6-skeleton from **1**, **2**, **3**, **4** and **6**. The distributions for the species less than C_5 were in all cases rather random and did not seem so informative. The successive loss of chlorine atom below *m/e* 282 in the cracking pattern was typically observed for all.

* Measured in C_2Cl_4 solution unless otherwise noted.

Table 1. Relative abundance in the mass spectra of **1**, **2**, **3**, **4** and **6**

m/e[a]	Ions	**1**	**2**[b]	**3**[c]	**4**	**6**
422	$C_6Cl_6\ Fe(CO)_x^+$ (x=3−0)	—	—	8	9	0
394				10	10	0
366				11	8	0
338				23	21	0
282	$C_6Cl_6^+$	77	100 (100)	42	5	100
247	$C_6Cl_5^+$	100	40 (39)	63	12	63
212	$C_6Cl_4^+$	33	21 (23)	100	100	30
177	$C_6Cl_3^+$	11	7	53	40	21
168	$Fe(CO)_4^+$	—	—	7	0	2
142	$C_6Cl_2^+$	23	17	84	67	49
140	$Fe(CO)_3^+$	—	—	9	0	0
126	$FeCl_2^+$	—	—	5	5	0
112	$Fe(CO)_2^+$	—	—	15	3	0
107	C_6Cl^+	11	10	28	20	54
91	$FeCl^+$	—	—	25	32	6
84	$Fe(CO)^+$	—	—	25	9	21

a) The *m/e*s are arranged monoisotopically, but their relative abundances are of all isotopic variants. b) Values in parentheses are from Ref. 9. c) Very poor production for *m/e* 450 (x=4).

However, some special comments can be made on the following points.

1) The cracking patterns are markedly different between **1** and **2** only in terms of the ratios of the relative abundance ($C_6Cl_6^+/C_6Cl_5^+$), although the distributions of other ions C_6Cl_x (x=3 or less) are essentially the same. Since the data for **2** meet well those reported by Meyerson *et al.*,[9] we suspect their suggestion that the cationized **1** would be the most possible intermediate fragment of perchloro-(1,2-dimethylenecyclobutane).

2) It was observed that the complex formation from **1** makes the fragmentation to C_6Cl_x (x=5 or less) dominant. This trend is rather common between **3** and **4**, and can be explained by the dominant elimination of FeCl or $FeCl_2$ from $C_6Cl_6Fe^+$ (*m/e* 338); the former elimination was evidenced by the relatively high abundance of the ion (*m/e* 91). The very small value for $C_6Cl_6^+$ from **4** seems to be related with the increased value for $FeCl^+$ ion, and further with the stability of L-Fe linkage in **4**.

3) On the other hand, **6** degradates under the same conditions quite differently; no $C_6Cl_6Fe(CO)_x^+$ fragments (x=4−0) were observed, and corresponding to this, the relative abundance of $FeCl^+$ was very small. The first fission of the L-Fe bond by electron impact must be the most essential fragmentation process in this case.

NQR Spectra. The NQR was particularly useful when, as our case, the direct comparison of the data between the ligand- and substrate-chlorocarbon is possible. The resonance lines for **1**, **3** and **4** are shown in Fig. 1, where the numerical figures indicate the values obtained by extrapolating the temperature dependence curve to 0 K for simpler and more precise

representation. It was generally experienced that the complex formation causes the intensification of the signals so effectively that the strong lines do appear even at room temperature. In all cases the number of crystallographically inequivalent chlorine atoms were found to be six.

It can be seen in Fig. 1 that some systematic frequency shifts exist through complex formation from **1**. The middle two lines for **3** near 37.5 MHz probably correspond to the two of four lines for **1** in the 38.0 MHz region which have already been assigned to the chlorine atoms at the exocyclic methylene carbons in the molecule.[10] Hence, the carbonyl iron-group presumably makes the π-bond with one of these double bond moieties, lowering the resonance frequencies for the chlorines attached to C_3', or C_4' of **1**. Another feature of the spectrum for **3** was the shifts of one of the two lines near 36.5 MHz assigned to the ring chlorines[10] to the higher frequency region, either because of the crystal field effect,** or as the result of some minor spatial interaction with one of the axial carbonyl groups. These interpretations may constitute the most principal reason for giving the structure of *acde*-tetracarbonyl-*b*-{1-1'-η-perchloro-(3,4-dimethylenecyclobutene)} iron finally to **3**.

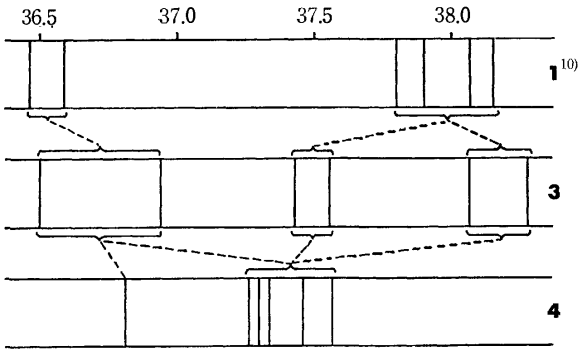


Fig. 1. NQR lines for **1**, **3**, and **4**.

In the resonance line pattern for **4**, the rest two lines with the highest frequency values also shifted downward joining together with the middle two for **3**. This suggests that the carbonyl iron interacts with both of the exocyclic double bonds of the ligand. In the 37.5 MHz region were observed actually five lines, one of which is obviously assigned to the chlorine atom on the four-membered ring. The upward shift is perhaps attributed to the spatial effect of the carbonyl group, deviating to some extent from the σ_v of the ligand, and hence, resulting in the lack of C_s symmetry of the complex molecule as a whole. The lowering of the resonance frequency caused by metal coordination is due to the releasing of the Cl-p_x electron through pi-conjugation according to the equation:[12]

$$fq \propto (N_x+N_y)/2 - N_z,$$

where N_x, N_y and N_z are the 3p AO population of a chlorine atom in x-, y- and z(C-Cl)-direction, respec-

** The frequency shifts seem more than those due to the crystal field effect which has been estimated to be less than 500 KHz in ordinary cases.[11]

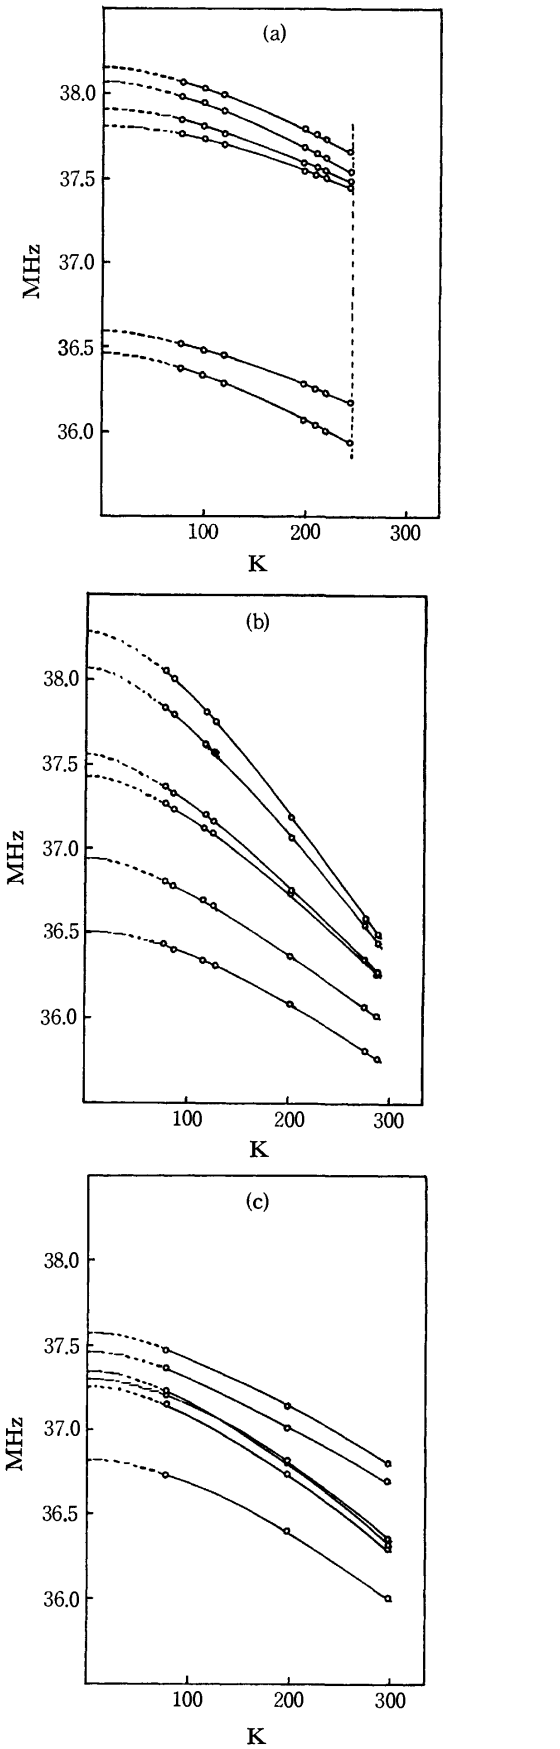

Fig. 2. Temperature dependences of NQR lines for **1**, **3**, and **4**. The vertical broken line in 2(a) indicates the fade-out temperature

tively. Thus, the structure of tricarbonyl-{1'-2'-η-perchloro-(3,4-dimethylenecyclobutene)}iron was assigned to **4**, although its stereochemical configuration has remained unsolved.

In order to see more detailed profile of the complexes in terms of the thermal molecular motion in crystals, the temperature dependence of those NQR lines were examined (Table 2 and Fig. 2). The fade-out of all six signals for **1** at 250 K or so (Fig. 2a) and the survival of the six strong ones for both **3** and **4** even at room temperature (Fig. 2b and 2c) may be a reflection of the situation that the complex formation is sensitively related to some restricted thermal molecular motion. The most salient feature among the Figs. 2a—c is the extraordinarily large temperature gradients of the curves in Fig. 2b for the signals ν_1 and ν_2 assigned to the chlorines at the exocyclic double bond moiety free from the coordination. The high steepness of the curves suggests that those two chlorines both become more affected locally than others by the thermal motion of the nearest carbonyl group as the temperature rises. This interpretation is also helpful for understanding the existence of the valence isomerization in **3**, about which a comment will be given later. The curves for **4** are all as easy as those for **1** making a clear contrast to that for **3**.

Table 2. Temperature dependence of NQR lines (MHz)

	Temp. (K)	ν_1	ν_2	ν_3	ν_4	ν_4	ν_6
3	0	38.28	38.07	37.56	37.43	36.94	36.50
	78	38.052	37.829	37.362	37.257	36.800	36.426
	200	37.190	37.070	36.760	36.732	36.350	36.090
	286	36.504	36.439	36.264	36.247	36.011	35.758
4	0	37.57	37.46	37.34	37.30	37.26	36.81
	78	37.461	37.362	37.223	37.198	37.145	36.733
	198	37.146	37.048	36.812	36.802	36.740	36.410
	298	36.803	36.705	36.366	36.324	36.308	36.042
6	0	38.21	38.07	37.80	37.63	37.60	36.41
	78	38.150	37.988	37.742	37.555	37.533	36.341
	198	37.939	37.639	37.478	37.239	37.200	36.027
	298	37.683	37.247	37.093	36.883	36.825	35.689

Figure 3 shows the resonance lines for **2** and **6**. Some published informations on the structural problem for **2** are available; *e.g.*, the phase transition between the ordered and the disordered forms studied by X-ray analysis,[13] two mutually different NQR assignments,[10,14] *etc.* Even on these backround, however, it appeared very difficult to find some systematic shift of the lines in this case. The slopes of the temperature dependence (Table 2 and Fig. 5) are somewhat easier than those for **2** and **4**.

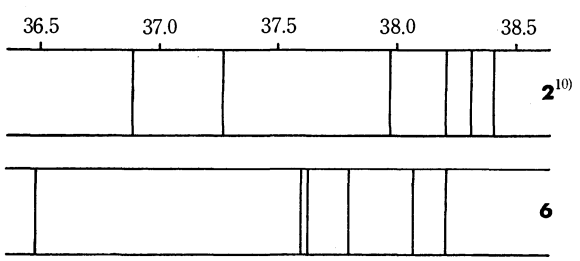

Fig. 3. NQR lines for **2** and **6**.

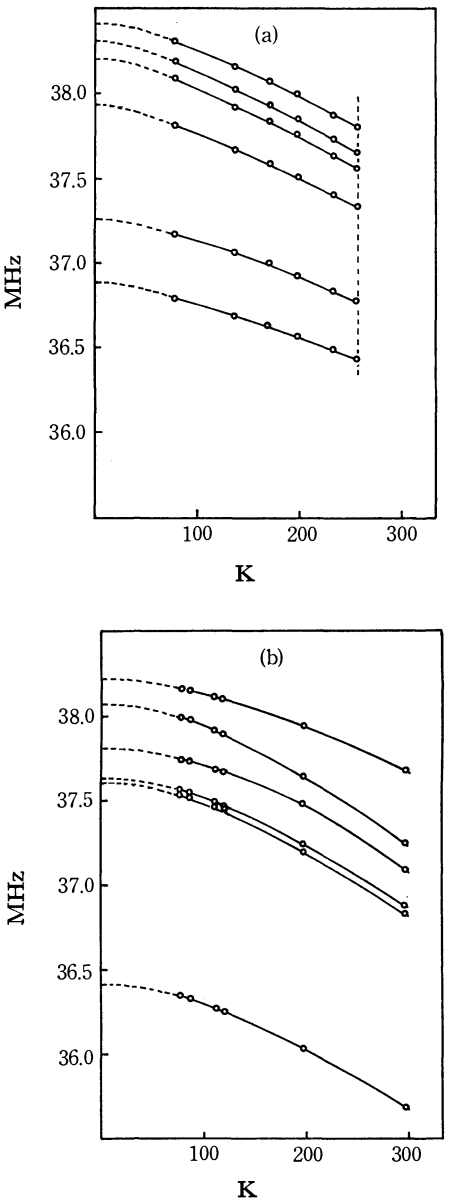

Fig. 4. Temperature dependences of NQR lines for **2** and **6**. The vertical broken line in 4(a) indicates the fade-out temperature.

The possible existence of phase transitions in those complexes were examined by means of DSC technique covering the low temperature range down to −160 °C. The observation of the inoccurence of such transition appeares parallel to our findings that the complex formation makes the molecular motion more restricted.

^{13}C-NMR Spectra. The ^{13}C-NMR spectra were taken for all the complexes and the substrate chlorocarbons. The FT-NMR measurement was accompanied by some technical difficulty because of the unstability of the complexes in solution, and, in addition, because of the extraordinarily long relaxation time of the excited species. However, successful results were obtained under

the conditions specified in Table 3.

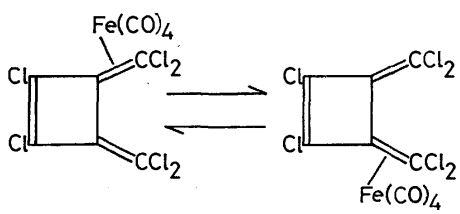
The reported data for ^{13}C-NMR of the carbonyliron complexes with hydrocarbon ligand inform, although they are very few, of a surprisingly large upfield shift for the signal related to the olefinic carbon coordinated by metal. In the case of butadiene–$Fe(CO)_3$ complex, a pair of highly shifted signals, 35.8 and 80.8 ppm downfield from TMS was reported.[15] In our results, the signals in the 65—80 ppm region can be assigned also to the carbons coordinated by the iron metal. The absorption of the carbonyl-C in the complexes **3** and **6** are both very broad and splitted into two parts particularly in the former. The main reason for this broadening would presumably be either a very long relaxation of the carbonyl-C or the mutual transposition of the four carbonyls with an appropriately slow rate. Especially interesting was the appearence of only three signals in the complex **3**, which should give the six for ligand carbons, if the structure discussed in the preceding section is correct. The possibility that the carbonyliron positions at the double bond in the four-membered ring of **1** was certainly excluded from consideration on the basis of our present NQR interpretation. The most possible and rational explanation is the rapid degenerate rearrangement of **3** in the *d*-chloroform solution as shown below.*** The fluctional transposition of the bond between the iron and the C=C moiety may be related to the characteristically steeper temperature dependence curves in Fig. 2b. Some analogous examples have been dealt with in the carbonyliron complexes of allene,[17] cyclooctatetraene,[18] *etc.* The signal for the carbonyl-C of **4** was a sharp singlet and differed from those of **3** and **6**. No extraordinary upfield shifts for the olefinic carbons were observed in this case. This would be an exception with the potential significance that the h^4-type complex formation with chlorocarbon does not affect the absorption of the ligand so much as does the similar coordination in the hydrocarbon-complexes.

The observation of seven signals in total for **6** (six for the olefinic-C and one for the carbonyl-C) explained the coordination of the central atom at 1,2- C=C bond of **2**. If the C=C bond at 5,5′ is coordinated, the number of signals for the ligand would be four. Thus, the structure of *acde*-tetracarbonyl-*b*-{1-2-η-perchloro-(5-methylenecyclopentadiene)}iron was assigned to **6**.

TABLE 3. ^{13}C-NMR CHEMICAL SHIFTS FOR **1, 2, 3, 4** AND **6** (ppm downfield from TMS)

Compound	Carbonyl-C	Olefinic-C
1†		136.15, 131.66, 109.84
3	202.68, 202.41	139.39, 117.88, 73.91
4	199.23	149.23, 116.97, 105.98
2†		136.58, 130.87, 130.27 117.42
6	201.70	146.11, 142.61, 126.11 115.99, 76.27, 68.57

Solvent: C_6D_6 for **4** and $CDCl_3$ for others. Temperature: 0—10 °C for **3**, **4** and **6**; 40—50 °C for **1** and **2**. Approx. concentration: 2.5 g/5 ml (sample/solvent) for **3**, **4** and **6**; 1.5 g/5 ml for **1** and **2**. Pulse width: 1μs. Pulse interval: 1.4 s. † See also Ref. 16.



*** An attempted measurement at the temperature lower than −40 °C was technically unsuccessful.

Experimental

The preparations and purifications of the complexes were all carried out under the atmosphere of nitrogen and with sufficiently deaerated solvent. Especially, the low temperature chromatography at 2—10 °C (on sillicic acid, Mallinkrodt, 100 mesh) was applied for the isolation.

The spectrometers used were JASCO-DS-402-G for IR, Hitachi EPS-2U for UV, Decca for NQR, JEOL-JMS D-100 and Hitachi RMU-6E for MS and Varian XL-100 for ^{13}C-NMR. For the NQR measurement a special rf-coil was designed for detecting signals with high sensitivity and a grid-dipmeter (Delica, Mita Musen Kenkyusho KK.) for checking the proper absorption frequencies were used. The DSC data were obtained by Rigaku DSC-8001.

acde-Tetracarbonyl-b-{*1-1′-η-perchloro-(3,4-dimethylenecyclobutene)*}*iron (3)*. An *n*-hexane solution (200 ml) of perchloro-(3,4-dimethylenecyclobutene) (**1**) (4.0 g, 14 mmol) was stirred with nonacarbonyl diiron (6.2 g, 17 mmol) suspended in it, and gentle warming was applied until the temperature rose to 42 °C in 15 min, while the yellow suspension gradually changed to dark brown in color. The almost clear solution was obtained after 10 min keeping at 42—43 °C. The dark red solution obtained after cooling to room temperature and filtration through Hyflo Super-Cel (John-Manville) afforded, on removal of the solvent under reduced pressure below 30 °C, the crude crystals of the complex (**3**), which were purified by chromatography with *n*-hexane solution. The first fraction was composed of the recovered **1** (1.5 g). The lemon yellow crystals (4.3 g, 68%) of **3** were obtained as the second, and recrystallized from *n*-pentane at −78 °C. Found: C, 26.66; Cl, 47.31%. Calcd for $C_{10}Cl_6FeO_4$: C, 26.50; Cl, 46.99%.

Tricarbonyl{*1′-2′-η-perchloro-(3,4-dimethylenecyclobutene)*}*iron (4)*. The complex **3** (1.0 g, 2.2 mmol) was dissolved in *n*-hexane (65 ml) and the solution was heated under stirring so mildly that the solution started to reflux after 45 min. Being kept for several min under refluxing, the solution was cooled, filtered and chromatographed. The recovered **1** as the first fraction weighed 260 mg. The yellow crystals (150 mg) obtained as the second were recrystallized from *n*-pentane. Found: C, 25.35; Cl, 50.73%. Calcd for $C_9Cl_6FeO_3$: C, 25.42; Cl, 50.14%.

acde-Tetracarbonyl-b-{*1-2-η-perchloro-(5-methylenecyclopentadiene)*}*iron (6)*. To the solution of perchlorofulvene (**2**) (3.0 g, 10.5 mmol) in *n*-hexane (300 ml) was added nonacarbonyl diiron (3.9 g, 10.7 mmol) and the mixture was under stirring warmed gently for 1 hr until the temperature reached 40 °C, when the suspension of carbonyl iron disappeared within several min. The solution was cooled to room temperature and filtered through a glass filter. The regular work-up afforded the recovered **2** (0.4 g) and the orange

crystals of the complex (**6**) (2.0 g, 48%), which were recrystallized from *n*-pentane at −78 °C. Found: C, 26.67; Cl, 46.94%. Calcd for $C_{10}Cl_6FeO_4$: C, 26.50; Cl, 46.99%.

Pyrolyses of the Complexes 3 and 6 to the Original Chlorocarbons. The pyrolyses of **3** (64 mg) and **6** (74 mg) were carried out in the test tubes respectively at 65—66 °C for 2 min and at 85 °C for 10 min. The partial production of **1** was confirmed by the IR spectrum in the former case and that of **2** (24 mg) by the isolation of the latter.

A Typical Example among the Oxidative Degradations of the Complexes 3—6 by Cerric Ammonium Nitrate. The solution of **6** (340 mg) in acetone (30 ml) was stirred with cerric ammonium nitrate ($Ce(NO_3)_4 \cdot 2NH_4NO_3 \cdot xH_2O$, Kishida Kagaku KK.) (400 mg) at room temperature for 15 min. The solution was then concentrated under diminished pressure and poured onto water. From the carbon tetrachloride extract, **2** (140 mg, 65%) was isolated.

Pyrolytic Formation of the Carbonylated Product, Ketone (5) from the Complex 4. The complex **4** (2.57 g) was heated without solvent very carefully to 110 °C in a flask (100 cc) equipped with a condenser. The decomposition started at 116 °C so violently that some powdery amorphous product blew up through the condenser to the top. The *n*-hexane-soluble part (400 mg) was chromatographically purified. Beside a small amount of the recovered **1**, the yellow crystals of the ketone (**5**) (60 mg) were obtained. Found: C, 27.08; Cl, 67.35%. Calcd for C_7Cl_6O: C, 26.84; Cl, 68.05%. UV: $\lambda_{max}^{n\text{-hexane}}$ 228 (3.81), 259 (4.55), 267 (4.56), 302 (4.00), 315 (4.24), 330 (4.35) and 348 (4.42); nm (log ε). IR: ν_{max}^{Nujol} 1770 (CO), 1560 and 1495 (C=C) (cm^{-1}).

The authors are indebted to Prof. M. Nakagawa, Prof. Y. Odaira, Dr. K. Sonogashira and Dr. T. Atake of Osaka University, respectively for the ^{13}C-NMR, mass- and IR measurements. They are also grateful to Mr. J. Goda of Osaka City University for the elemental analyses, and to Dr. K. Nishimoto of the same University for his helpful discussion.

Monomer-Isomerization Polymerization. XIV. Monomer-Isomerization Polymerization of 4-Methyl-2-pentene with Ziegler-Natta Catalyst

Takayuki Otsu, Kiyoshi Endo, Hiroharu Nagahama, and Akihiko Shimizu

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received January 6, 1975)

4-Methyl-2-pentene (4M2P) was found to polymerize in the presence of $TiCl_3$–$Al(C_2H_5)_3$ catalyst, and to yield a high molecular weight isotactic homopolymer of 4-methyl-1-pentene (4M1P). From the fact that the isomerizations from 4M2P to its positional isomers were also observed, it was concluded that this polymerization was induced by a monomer-isomerization polymerization mechanism, *i.e.* 4M2P isomerized first to 4M1P, which then homopolymerized. The rates of both polymerization and isomerization were affected by the Al/Ti molar ratio of catalyst system, and by the addition of transition metal compounds such as nickel acetylacetonate [Ni(acac)$_2$]. It was concluded that the maximum rates were observed at Al/Ti = 3 and Ni/Ti = 0.2 in molar ratio.

It has been well known that internal olefins do not polymerize to give high polymers in the presence of any catalysts, including Ziegler-Natta catalyst. Several years ago, however, it was found that some linear internal olefins such as 2-butene, 2-pentene, and 2-hexene polymerize with $TiCl_3$-$Al(C_2H_5)_3$ (Al/Ti$\geq$2) catalysts to give high molecular weight polymers, if allowed to react for a long time at 80 °C.[1-5]

Interestingly, the polymers thus obtained were confirmed to be homopolymers consisting of the corresponding 1-olefin units. In accordance with the observation that the isomerization from the starting 2-olefin to the 1-olefin occurs simultaneously during reaction, it was concluded that these 2-olefins isomerize first to the corresponding 1-olefins, which then homopolymerize. Since this kind of polymerization gives a new route for polymer synthesis, we have proposed that this polymerization proceeds *via* a monomer-isomerization polymerization mechanism.

These monomer-isomerization polymerizations have also been extended to the other higher internal olefins, such as 2-heptene, 3-heptene, and 2-octene.[6] In general, the monomer-isomerization polymerization involves two independent reaction steps: isomerization to the most polymerizable 1-olefin and polymerization of this 1-olefin. Accordingly, the total rate of polymerization is determined by both the rate of isomerization to 1-olefin and its concentration in an equilibrium olefin mixture. Since such a concentration in linear internal olefins is generally higher than that in branched ones, it is usually expected that the former olefins are more favorable to the monomer-isomerization polymerization than are the latter olefins.

However, it was found recently that some branched internal olefins, 4M2P, underwent monomer-isomerization polymerization in the presence of $TiCl_3$–$Al(C_2H_5)_3$ catalyst to give the homopolymer of 4M2P. The present paper describes the results of these monomer-isomerization polymerizations of 4M2P.

Experimental

Materials. 4M2P and 4M1P were purified through a fractional distillation of commercial grade samples. Purities of both monomers determined by gas chromatography were above 99.9%; here the *cis* and *trans* isomers could not be separated.

Triethylaluminum (Ethyl Corp.), titanium trichloride (Stauffer Chem.), and transition metal chelates of acetylacetonate (acac) such as Ni(acac)$_2$ and Co(acac)$_2$ (Dotite reagent) were used without further purification. Solvents were purified by ordinary methods.

Polymerization Procedure. Most polymerizations were carried out in a sealed glass tube with shaking in a thermostat for a given time. The charging of the required reagents into the tube and its sealing under vacuum were performed by methods described in the previous paper.[3] After polymerization the tube was opened and the unreacted olefin monomer was recovered by distillation in order to analyze the isomer distribution by means of gas chromatography, in which a bis(2-methoxyethyl) adipate column was used at 17 °C. The residue of the tube was then poured into a large amount of methanol containing hydrochloric acid to precipitate the polymer formed. The polymer yield was calculated from the weight of the dry polymer obtained. In these polymerizations, the polymer yield was dependent on the conditions of catalyst preparation, and seemed to contain $\pm$2% error.

Characterization of the Polymers. The structure of the resulting polymers was checked by infrared spectroscopy of their thin films. The isotacticity of the polymers was determined by the weight of the hot *n*-hexane-insoluble polymer.[7] The intrinsic viscosity ([η]) was determined from a viscosity measurement of the dilute decaline solution at 130 °C with an Ubbelohde viscometer. The number-average molecular weight ($\bar{M}_n$) was calculated from the following equation:[7]

$$[\eta] = 1.95\times10^{-4}\bar{M}_n^{0.75}$$

Results and Discussion

Polymerization and Isomerization of 4M2P with $TiCl_3$–$Al(C_2H_5)_3$ Catalyst. The results of polymerization and isomerization of 4M2P with $TiCl_3$-$Al(C_2H_5)_3$ catalyst in *p*-xylene or *n*-heptane are summarized in Table 1. As can be seen from this table, the yields of polymers in both solvents increase as a function of polymerization time, and those in *n*-heptane are somewhat higher than in *p*-xylene. Upon comparing these results with those of 4M1P under similar conditions, as shown in Table 2, the polymerization of 4M2P was found to proceed with a much slower rate.

Figure 1 shows the infrared spectra of the polymers obtained from 4M2P and 4M1P with the $TiCl_3$–$Al(C_2H_5)_3$ catalyst. From this figure, the infrared spectra of both polymers are quite identical. It is clear therefore that the polymers obtained from 4M2P and 4M1P

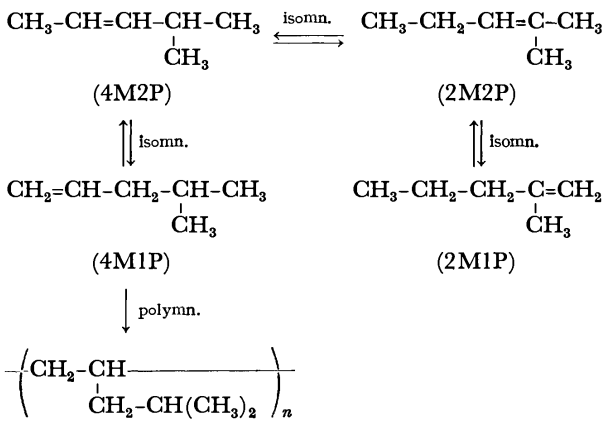
a) Polymerization conditions: $[TiCl_3]=117$ mmol/l, [4M2P]=2.7 mol/l. b) [4M2P]=3.0 mol/l.

As is also shown in Table 1, the isomerizations of 4M2P to its positional isomers are observed to proceed with a time in proportion to the polymer yield. In *n*-heptane, 2-methyl-1-pentene (2M1P) isomer was found during polymerization of 4M2P, but only a trace of this isomer was observed in *p*-xylene. Contrary to the results of the polymerization of 2-butene to poly-1-butene, the observed isomer distributions are seen to approach with a very slow rate to those in an equilibrium olefin mixture. However, it is obvious from Table 1 that the rate of isomerization to 4M1P, which is the most polymerizable isomer, is much greater than that to 2-methyl-2-pentene (2M2P), which is the most stable isomer.

Accordingly these results strongly indicate that 4M2P undergoes monomer-isomerization polymerization to give high molecular weight isotactic poly (4M1P), *i.e.* 4M2P isomerizes to 4M1P prior to polymerization and then this olefin homopolymerizes. In this case, it is interesting that 4M2P and 2M2P serve only as a diluent, and the high molecular weight homopolymer of 4M1P is obtained, although the observed concentration of 4M1P isomerized from 4M2P is as low as 0.5%. This result can be expected from the fact that the isomerization to 4M1P is sufficiently fast to replenish the consumed 4M1P.

The monomer-isomerization polymerization of 4M2P is expressed by the following reaction scheme:



More recently it has been found that both 2M2P and 2M1P also undergo the monomer-isomerization polymerization with a very slow rate to give poly (4M1P).

Table 4. Effect of Al/Ti molar ratio on monomer-isomerization polymerization of 4-methyl-2-pentene with $TiCl_3$–$Al(C_2H_5)_3$ catalyst in *p*-xylene at 80 °C for 60 hr[a]

Effect of Al/Ti Molar Ratios on Monomer-Isomerization Polymerization of 4M2P. In the monomer-isomerization polymerization of 2-butene with $TiCl_3$-$Al(C_2H_5)_3$ catalyst, it was found that the rate of polymerization was affected by the Al/Ti molar ratios used. A similar result was also reported in the polymerization of 4M1P with $TiCl_3$-$Al(C_2H_5)_3$ catalyst in which the rate went through a maximum at the Al/Ti molar ratio of 3.0.[8]

To check this point, the effects of Al/Ti molar ratio on the monomer-isomerization polymerization of 4M2P were investigated. The results are shown in Table 4, from which it is found that the maximum rates of both polymerization and isomerization are observed at a molar ratio Al/Ti of about 3.0—3.5. This finding is in agreement with that observed in the polymerization of 4M1P.[8]

From Table 4, at the Al/Ti molar ratio lower than 1.0, neither polymerization nor isomerization occured. The polymers obtained at the Al/Ti molar ratios higher than 1.0 were found to consist of poly (4M1P).

Effect of Metal Acetylacetonates [$Me(acac)_x$] on Monomer-Isomerization Polymerization of 4M2P. Since, in monomer-isomerization polymerization of 2-olefin, the isomerization to 1-olefin must occur before its polymerization,[4] the addition of isomerization catalyst is expected to accelerate this polymerizarion. As is shown in Table 5, however, the polymerizations of 4M2P slowed down in the presence of $Me(acac)_x$ in which the Me/Ti molar ratio was kept constant at 0.5. This observation is different from the observed accelerating effect on the monomer-isomerization polymerization of 2-butene.[4]

Table 6. Effect of $Ni(acac)_2$ on the monomer-isomerization polymerization of 4-methyl-2-penetene with $TiCl_3$–$Al(C_2H_5)_3$–$Ni(acac)_2$ catalyst at 80 °C in *p*-xylene for 60 hr[a]

Ni/Ti molar ratio	Yield (%)	Composition of methylpentenes recovered after polymerization, %[b]				
		2MP	4M1P	4M2P	2M2P	2M1P
0	18.5	0.9	0.5	92.0	6.3	0.3
0.06	20.9	1.9	1.2	89.3	7.0	0.6
0.15	35.6	1.4	0.8	68.2	26.8	2.8
0.20	35.9	—	—	—	—	—
0.30	18.6	1.3	2.3	70.9	22.3	3.2
0.40	3.5	0.7	4.5	78.6	13.9	2.3

Ni/Al=1/8	0.0	0.2	4.7	85.0	7.9	2.2

a) Polymerization conditions: $[TiCl_3]=117$ mmol/l, $[4M2P]=2.7$ mol/l, Al/Ti=2.0 in molar ratio. b) Determied by gas chromatography. c) In the absence of $TiCl_3$.

To test further the effect of $Me(acac)_2$, the polymerization and isomerization of 4M2P with $TiCl_3$–$Al(C_2H_5)_3$ (Al/Ti=2) catalyst in the presence of various Ni/Ti molar ratios of $Ni(acac)_2$ were investigated. The results are shown in Table 6. It is found that the rates of both polymerization and isomerization are dependent on the Ni/Ti molar ratio added, and their maximum rates are observed at an Ni/Ti molar ratio of about 0.15—0.2.

This observation seems to originate from the fact that $Ni(acac)_2$ behaves as both activator and deactivator of active sites for polymerization of 4M1P and isomerization from 4M2P to 4M1P, because $TiCl_3$ and $Ni(acac)_2$ react competitively with $Al(C_2H_5)_3$ in the catalyst system. Accordingly, it is found that at the molar ratio Ni/Ti of 0.5, the active sites for polymerization are destoroyed.

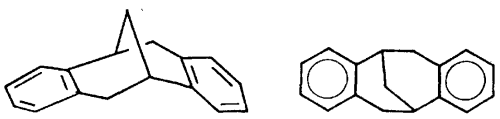
(Received January 8, 1975)

2,3 : 6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-diol was synthesized and resolved *via* (−)-menthoxyacetate. Several kinds of optically active derivatives with the same absolute configuration were prepared from the (−)-diol and their chiroptical properties were recorded. The absolute configuration of this series of compounds was determined to be 1*R*, 5*R* by a chemical correlation with (*R*)-(−)-3-phenylbutanoic acid *via* (−)-1,3-diphenylglutaric acid and (−)-2,4-diphenylpentane.

A part of the present authors (members of Faculty of Science) has studied the relationship between structure and chiroptical properties of various triptycene derivatives[1] and related compounds.[2] The absolute configuration of optically active 2,5-dimethoxy-7- or 8-substituted or 2,7-disubstituted triptycenes[1] and 1,5-disubstituted 9,10-dihydro-9,10-etheno- and ethanoanthracenes[2] have been studied by either or both X-ray analyses and chemical correlations. However, exciton theoretical analyses of their CD spectra led to antipodal absolute configurations.[2,3]

The group of title compounds, 2,3: 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (XII) and its derivatives, having fairly rigid and well-defined strainless cage structure, can be regarded as one of the most appropriate dissymmetric compounds for the study of relationship between structure and optical activity.

The other authors (members of Faculty of Engineering Science) have studied on the stereochemistry of cage compounds such as twistane and related compounds,[4] and have been interested in the preparation of 2,3: 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (XII) as a precursor of optically active dibenzotwistane.

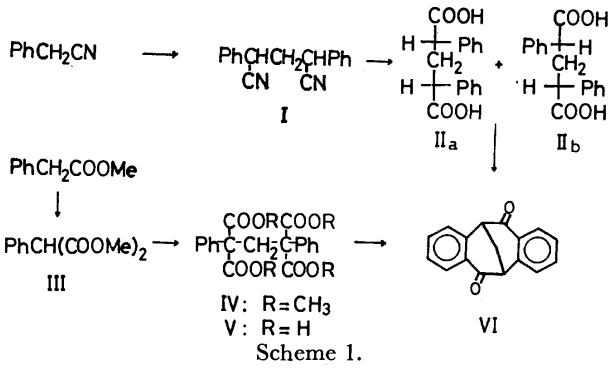


XII

The present paper deals with the synthesis, optical resolution and determination of absolute configuration by chemical means of dibenzobicyclononadiene (XII) and its derivatives.

Results and Discussion

Synthesis and Optical Resolution. The route of synthesis which followed a reported method[5] with considerable modification was outlined in Scheme 1. 1,3-Diphenylglutaronitrile (I) was prepared as a mixture of racemic and *meso* forms by the reaction of phenylacetonitrile with methylene iodide and powdered sodium hydroxide. The mixture of I was converted into a mixture of (±)- and *meso*-1,3-diphenylglutaric acids by an alkaline hydrolysis. (±)- and *meso*-1,3-Diphenylglutaric acids could be separated by repeated fractional



Scheme 1.

recrystallization from chloroform–ligroin and acetic acid. The higher-melting isomer (mp 191—192 °C) could be resolved in optical antipodes *via* quinine salt,[6] thus confirming racemic configuration (IIb). Consequently, the lower-melting isomer (mp 171.5—171.7 °C) was assigned to *meso* form (IIa). These assignments are found to be consistent with the NMR spectroscopic property of IIa and IIb. On irradiation of methine protons, triplet of methylene protons in the spectrum

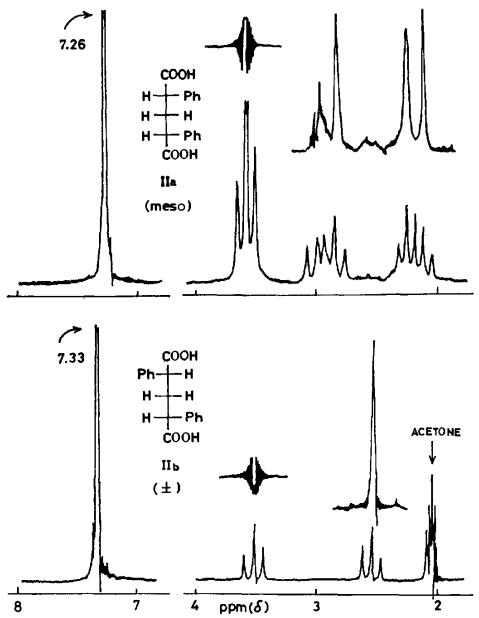


Fig. 1. 100 MHz NMR spectra of *meso*- and (±)-1,3-diphenylglutaric acids (IIa in $CDCl_3$ and IIb in acetone-d_6).

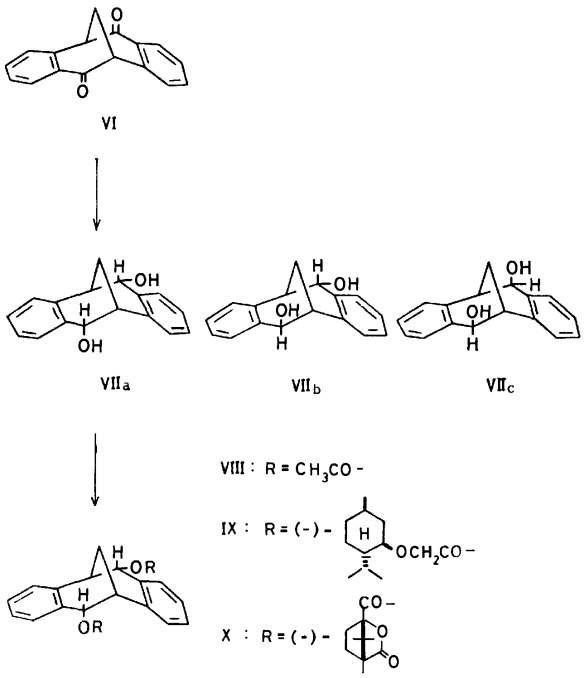
of higher-melting isomer collapsed to a singlet and multiplet of methylene protons of lower-melting isomer changed to double doublets (Fig. 1). These results indicate that the methylene protons in the higher-melting and in the lower-melting isomers situate in a magnetiacally equivalent and in an unequivalent environments, respectively. Consequently, the higher-melting isomer has a C_2 axis of symmetry passing through the methylene carbon, that is characteristic of racemic form (IIb), and the lower-melting isomer has a mirror symmetry of *meso* form (IIa). Both forms of 1,3-diphenylglutaric acid were converted into cyclic diketone (VI) with concentrated sulfuric acid. Diastereomeric mixture of the acids obtained by alkaline hydrolysis of a mixture of diastereomers of nitrile could be cyclized to the diketone (VI) directly without purification or fractionation under the same reaction conditions.

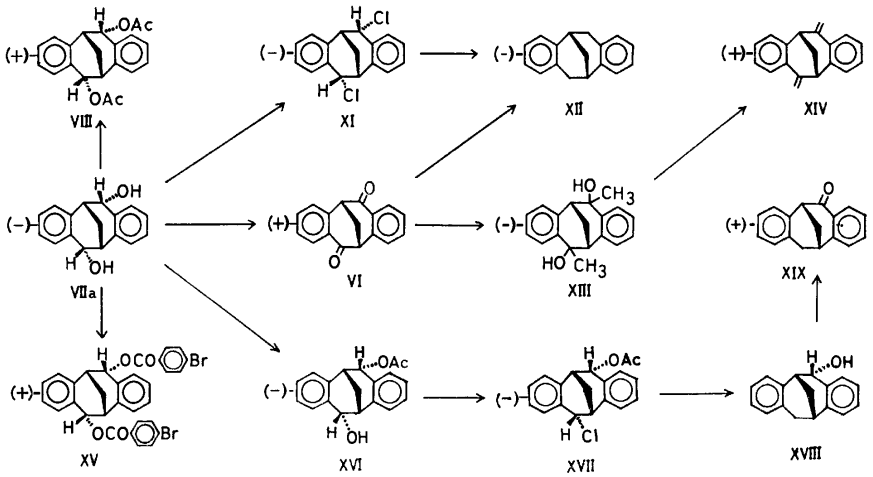
The same diketone (VI) could be prepared from methyl phenylacetate in a moderate yield *via* methyl phenylmalonate (III), methyl 1,3-diphenyl-1,1,3,3-tetracarboxylate (IV) and its hydrolysis product. The hydrolyzate consisting of mainly V was treated with polyphosphoric acid to give diketone (VI). From the diketone (VI) an identical glycol was obtained stereospecifically either by catalytic hydrogenation over platinum oxide catalyst or by reduction with lithium aluminum hydride in tetrahydrofuran. As shown in Scheme 2, three isomeric structures (VIIa,b,c) are possible in the glycol. But the formation of VIIb is excluded on the basis of NMR spectrum of the glycol and its diacetate which is prepared by a direct acetylation of the reduction product without any fractionation. The diacetate (VIII) shows doublet (J=6 Hz, 2H) at τ 3.73 (carbinyl protons) and a sharp singlet (6H) at τ 7.78 (methyl protons of acetyl groups). Therefore, the most probable structure seemed to be the one (VIIa) in which hydrogen atoms are delivered from the sterically less hindered, methano-bridge, side to generate two pseudo-axial hydroxyl groups. The inference was confirmed by the X-ray crystal structure analysis carried out on a single crystal of (+)-bis-*p*-bromobenzoate of (−)-glycol.[2)]



Scheme 2.

The optical resolution was carried out with (—)-methoxyacetyl chloride. Crude menthoxyacetate prepared from (±)-glycol (VIIa) and the chloride in pyridine was fractionally recrystallized eleven times from benzene-ethanol to give optically pure ester of (−)-enantiomer. The process of resolution could be traced by both polarimetry and IR spectroscopy. Optically pure menthoxyacetate was hydrolyzed by ethanolic potassium hydroxide to obtain optically pure (−)-glycol (VIIa). Attempts of optical resolution *via* camphanate showed poor reproducibility and the highest optical purity of (—)-glycol (VIIa) was 79.8%.

Starting from (—)-glycol (VIIa) several optically active derivatives with an identical configuration were prepared (Scheme 3). (—)-Glycol (VIIa) was oxidized by chromium trioxide-pyridine complex or by chromium trioxide in acetic acid to yield (+)-diketone (VI). The Clemmensen reduction of (+)-diketone (VI) yielded (—)-hydrocarbon (XII) in 33% yield. The same hydrocarbon was obtained quantitatively by lithium aluminum hydride reduction of (−)-dichloride



Scheme 3.

(XI) in tetrahydrofuran which is prepared from (−)-glycol (VIIa) by the usual method. The reaction of (+)-diketone (VI) with methylmagnesium iodide yielded (−)-*tert*-glycol (XIII). The configuration of carbinyl carbons could not be decided yet, but the Grignard reagent probably attacked from the side of methano-bridge to give pseudo-axial hydroxyl groups just as in the case of reduction of diketone (VI). Dehydration of (−)-*tert*-glycol (XIII) with phosphoryl chloride in pyridine gave (+)-diene (XIV) with styrene type chromophores. (−)-Glycol (VIIa) was converted into (+)-diacetate (VIII) and (+)-bis-*p*-bromobenzoate (XV) with acetic anhydride and *p*-bromobenzoyl chloride in pyridine, respectively. A single crystal of (+)-XV was submitted to the X-ray crystal structure analysis. (−)-Glycol (VIIa) was converted into (−)-monoacetate (XVI) with acetic anhydride in pyridine under a milder condition. (−)-Monoacetate (XVI) was treated with thionyl chloride in benzene to yield (−)-chloro-acetate (XVII). Lithium aluminum hydride reduction of (−)-XVII in tetrahydrofuran yielded alcohol (XVIII) which was oxidized without purification to (+)-monoketone (XIX) by the Jones reagent.

Absolute Configuration and Optical Activity. The absolute configurations of the compounds of dibenzobicyclo[3.3.1]nonadiene series were determined by chemical correlation with (*R*)-(−)-3-phenylbutanoic acid (XX).[7] The route was outlined in Scheme 4. (−)-1,3-Diphenylglutaric acid (IIb) was converted into (+)-diketone (VI) on dehydrative cyclization with concentrated sulfuric acid at 85 °C. (−)-2,4-Diphenylpentane-1,5-diol (XXIVb) was obtained by lithium aluminum hydride reduction of (−)-diphenylglutaric acid (IIb). Bis-methanesulfonate of (−)-XXIVb was reduced with lithium aluminum hydride in refluxing tetrahydrofuran to yield (−)-2,4-diphenylpentane (XXIIIb). *meso*-2,4-Diphenylpentane (XXIIIa) was obtained with essentially the same sequence of reactions from *meso*-1,3-diphenylglutaric acid (IIa). On the other hand, (*R*)-(−)-3-phenylbutanoic acid (XX) was converted into acid chloride and treated with diphenyl cadmium to give (*R*)-(−)-3-phenylbutyrophenone (XXI). The reaction of methylenetriphenylphosphorane with (*R*)-(−)-XXI gave (*R*)-(−)-2,4-diphenyl-1-pentene (XXII). Catalytic hydrogenation of (*R*)-(−)-XXII over the Adams catalyst yielded almost equimolar mixture of *meso*- and (*R*)-(−)-2,4-diphenylpentane (XXIIIa and XXIIIb) which were analyzed and identified by NMR spectroscopy.

(−)-2,4-Diphenylpentane obtained from (−)-1,3-diphenylglutaric acid (IIb) showed an identical CD spectrum with that of the mixture of XXIIIa and (*R*)-(−)-XXIIIb obtained from (*R*)-(−)-XX after correction of optical purity.

From the combined results of the above-mentioned sequence of reactions, it can be clearly concluded that all of optically active compounds shown in Scheme 4 have (*R*)-absolute configuration. The conclusion was consistent with the result of X-ray analysis carried out on a single crystal of (+)-2,3: 6,7-dibenzobicyclo[3.3.1]-nona-2,6-diene-4,8-diol-bis-*p*-bromobenzoate (XV).[8]

(+)-Diketone (VI) showed a strong positive CD band with well-developed fine structure in the longest wavelength region and a beautiful positive-negative couplet in 37000—44000 cm^{-1} region (Fig. 2). The longest wavelength band can be assigned to n→π^* transition of conjugated ketone on the basis of solvent effect and a considerably large anisotropic factor (Table 1). The strong couplet centered at near 40000 cm^{-1} was attri-

buted to an exciton couplet due to the interaction of two conjugated phenyl ketone chromophores. This compound (VI) is unique in the sense that it might be regarded as an α,β- and β,γ-unsaturated ketones at the same time. In applying the octant rule, a different conclusion came out by considering which of α,β- or β,γ-unsaturation contributed stronger to the observed optical activity.[9] It is easily shown by the Dreiding molecular model that molecular framework of this ketone (VI) brings about closely similar spatial disposition of carbonyl and phenyl groups as those in dimethylbenzsuberone and related typical β,γ-unsaturated ketone (Fig. 3).[10] Observed highly positive rotational strength of n→π^* transition is consistent with 1*R*,5*R* absolute configuration for (+)-diketone (VI) (Fig. 3). On the other hand, if the diketone (VI) is considered to be an α,β-unsaturated ketone, a small negative n→π^* Cotton effect may be expected for the above 1*R*,5*R* configuration on the ground of fairly good coplanarity of phenyl-carbonyl grouping[11] being the

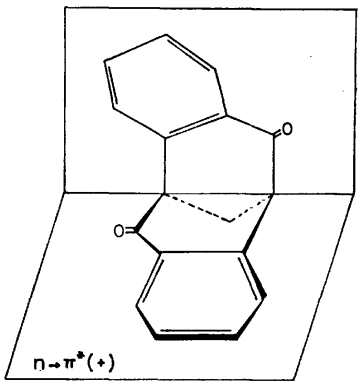

Fig. 3. Octant projection of (+)-1*R*,5*R*-2,3 : 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-dione (VI) as regarded as a β,γ-unsaturated ketone.

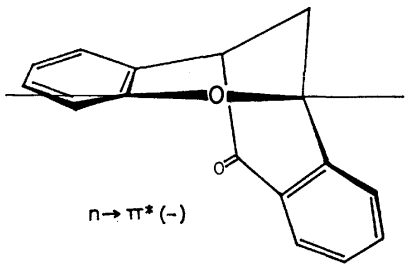

Fig. 4. Octant projection of (+)-1*R*,5*R*-2,3 : 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-dione (VI) as regarded as an α,β-unsaturated ketone.

dihedral angle of distortion less than 10 degrees as estimated from the Dreiding model (Fig. 4). We concluded that the contribution of β,γ-unsaturation is predominant and that of α,β-unsaturation is negligibly small in this ketone (VI).

With regard to the couplet in the $^1B_{1u}$ type $\pi\rightarrow\pi^*$ absorption region of (+)-diketone (VI), we assumed an exciton coupling of C_2 symmetry and the same 1*R*,5*R* configuration as shown in Fig. 5 could be deduced.

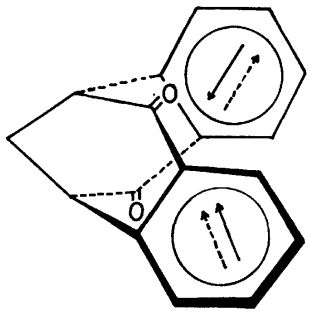

Fig. 5. Exciton coupling of $^1B_{1u}$ band of (+)-1*R*,5*R*-2,3: 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-dione (VI).

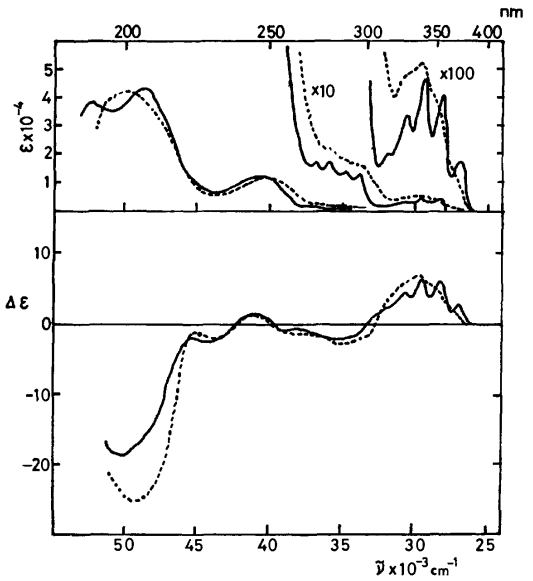

Fig. 6. UV and CD spectra of (+)-2,3 : 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene-4-one (XIX) in cyclohexane (——) and in 99% ethanol (……).

The positive and negative bands can be assigned to transitions from ground to excited states with A and B symmetry, respectively, based on usual calculations. These assignments are consistent with intensity relationship of the corresponding isotropic absorption band and the absence of a CD couplet in the n→π* band region of (+)-monoketone (XIX) (Fig. 6). In the region of $^1B_{2u}$ type absorption, the situation is not so clear. A small positive-negative couplet is similarly anticipated for the same 1*R*,5*R* absolute configuration. Observed result seems to be consistent with this prediction, if we consider that long wavelength positive band is significantly overlapped with n→π* carbonyl band (*cf.*, solvent effect, Table 1 and Fig. 2). Combining the above-stated consistent results, we concluded that (+)-diketone (VI) has 1*R*,5*R* absolute configuration.

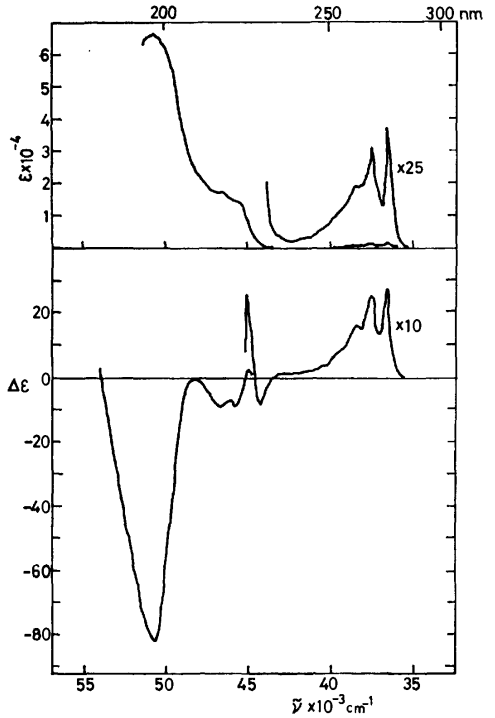

Fig. 7. UV and CD spectra of (−)-2,3 : 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (XII) in isooctane.

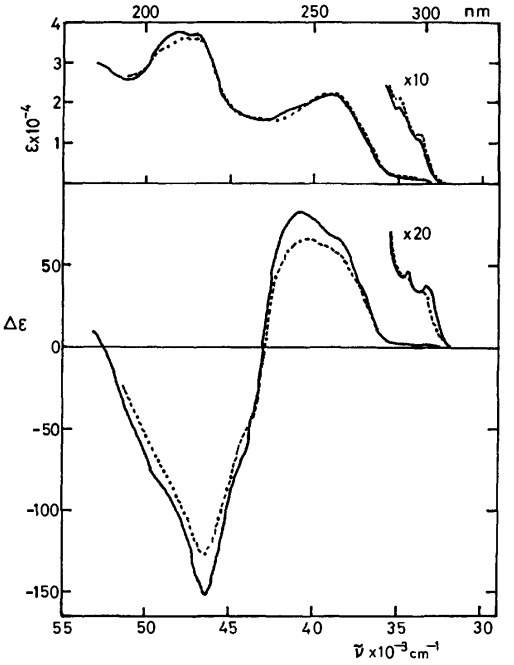

Fig. 8. UV and CD spectra of (+)-4,8-bis(methylene)-2,3 : 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (XIV) in isooctane (——) and in 99% ethanol (……).

The CD and electronic spectra of (−)-hydrocarbon (XII) are shown in Fig. 7. Complexity of the spectra might result from significant overlap of $^1B_{1u}$ and two degenerate $^1E_{1u}$ type bands and low absorption intensity of $^1B_{2u}$ band.

(+)-Diene (XIV) with styrene type chromophores showed a very interesting CD spectrum. In the π→π* spectral region, no couplet pattern could be observed (Fig. 8) in sharp contrast with (+)-diketone (VI). It is difficult to give a definite explanation, but one possible reason is that the direction of polarization of conjugation band of the styrene chromophore and position of its transition moments are considerably different from those of phenyl alkyl ketone.[12]

Experimental

The melting points were measured on a Mettler FP2 apparatus and a Shimadzu Kohfler micro hot stage, and are uncorrected. Purified and anhydrous solvents were used, unless otherwise stated. The IR spectra were obtained on a Hitachi EPI-2, EPI-G3 or a JASCO DS-301 spectrometers, electronic spectra on a Hitachi EPS-3T and a Zeiss PMQIIM4QIIId spectrometers, NMR spectra in deuteriochloroform, unless otherwise stated, on a Varian XL-100 or A-60D spectrometer using TMS as an internal standard and given in δ-unit. The optical rotations were obtained on a Yanagimoto ORD-185 spectropolarimeter or a Union Giken High Precision Polarimeter PM-71 or a JASCO DIP-SL polarimeter at 20 °C, unless otherwise stated. CD spectra were obtained on a JASCO J-20 spectrometer. Shoulders and inflections are denoted by an asterisk.

1,3-Diphenylglutaronitrile (I). Phenylacetonitrile (93.6 g, 0.799 mol), methylene iodide (107.2 g, 0.400 mol) and powdered sodium hydroxide (32.0 g, 0.800 mol) were mixed and heated to 165—170 °C for 30 min under stirring. Cooled mixture was diluted with water and extracted with ether. Combined organic layer was washed with water and concentrated undre reduced pressure. After volatile material had been removed by steam distillation (distillate, *ca.* 6 l), the residue was extracted with ether and dried over sodium sulfate. A black oil (66.1 g) obtained on concentration of the extract under reduced pressure was chromatographed on alumina (650 g) and fractions eluted with benzene (total 3.3 l) and benzene–ether (1: 1, total 1.5 l) were combined and concentrated under reduced pressure. The oily residue was crystallized from ethanol. Repeated recrystallization from the same solvent yielded analytically pure I as orange yellow crystals, mp 64.9—65.6 °C, IR (nujol mull): 2250 ($\nu_{C\equiv N}$) cm^{-1}, NMR (CCl_4): 7.33 (s, 10H, aromatic), 4.03, 3.63 (both t, J=8 Hz, 2H, methine), 2.33 (m, 2H, methylene).

The crude nitrile obtained by chromatography could be used directly for further reaction.

1,3-Diphenylglutaric Acid (II). Crude acid (II) obtained by an alkaline hydrolysis of the nitrile (I)[4] was converted into diethyl ester (see below). The purified ester was refluxed with 10% ethanolic potassium hydroxide. Colorless oil obtained on working up the reaction mixture crystallized gradually on standing, mp 147.5—163 °C (a mixture of *meso*- and *rac*-isomers), IR (Nujol mull): 1710 ($\nu_{C=O}$) cm^{-1}.

Diethyl 1,3-Diphenylglutarate. Crude carboxylic acid (II, 14.42 g) was refluxed with ethanol (100 ml) and concentrated sulfuric acid (5 ml). The reaction mixture was worked up as usual and the oily residue was distilled under reduced pressure to give pure ester, faintly yellow liquid (10.85 g, 62.8%), bp 182—186 °C/133 Pa, IR (neat): 1740, 1730 ($\nu_{C=O}$) cm^{-1}, NMR: 7.25, 7.23 (both s, 10H, aromatic), 3.88—4.33 (m, 4H, methylene of ethyl), 3.33—3.68 (m, 2H, methine), 2.58 (m, 2H, methylene), 1.17, 1.13 (both t, J=7 Hz, 6H, methyl).

meso- *and* rac-*1,3-Diphenylglutaric Acids (IIa and IIb).* Crude crystals of the acid mixture (29.7 g) were recrystallized from chloroform–ligroin. Crystals obtained (4.68 g) were recrystallized further three times from the same mixed solvent to yield colorless needles of pure racemate (IIb, 3.2 g), mp 191—192 °C, IR (Nujol mull): 1710*, 1690 ($\nu_{C=O}$) cm^{-1}, NMR (CD_3COCD_3): 7.26 (s, 10H, aromatic), 3.50 (t, of d, J=7 Hz and 1 Hz, methine), 2.52 (t, of d, J=7 Hz and 1 Hz, methylene).

Found: C, 71.70; H, 5.68%. Calcd for $C_{17}H_{16}O_4$: C, 71.82; H, 5.61%.

Crude crystals obtained by drying up the initial mother liquor *in vacuo* were recrystallized from 50% aqueous acetic acid. First crop of crystals enriched in racemate was removed by filtration. Water was added to the hot mother liquor till the mixture became 20% aqueous acetic acid solution. Precipitates obtained on cooling the mixture were recrystallized eight times from 20% aqueous acetic acid to yield pure *meso*-isomer (IIa, 1.224 g), mp 171.5—171.7 °C, IR (Nujol mull): 1710, 1700 ($\nu_{C=O}$) cm^{-1}, NMR: 7.26 (s, 10H, aromatic), 3.57 (dd, 2H, methine), 3.07—2.76 (q, 1H, methylene), 2.31—2.04 (q, 1H, methylene).

Found: C, 71.89; H, 5.66%. Calcd for $C_{17}H_{18}O_4$: C, 71.82; H, 5.67%.

Optical Resolution of rac-*1,3-Diphenylglutaric Acid (IIb).* The racemic acid (IIb, 1.204 g) dissolved in 99% ethanol (20 ml) was mixed with a 99% ethanol solution of quinine (1.374 g in 10 ml) and stood overnight at room temperature. Colorless crystals (1.578 g) deposited were collected and dried *in vacuo*, mp 215—219 °C. The mother liquor and washings were combined and concentrated under reduced pressure to give colorless residue (1.161 g).

The crystalline salt was decomposed by 3 M hydrochloric acid and extracted with ether. The extract was worked up in the usual way and concentrated under reduced pressure to yield (+)-acid (0.471 g, $[\alpha]_D$ +70.72 ° (*c* 0.2828, 99% EtOH). Enantiomeric (−)-acid (0.7068 g, $[\alpha]_D$ −48.16 ° (*c* 0.2824, 99% EtOH)) was obtained from the residue of mother liquor by the same procedure.

The quinine salt was found thermally unstable and seemed to be difficult to fractionate diastereomers by the usual recrystallization. Optically pure salt could be obtained by repetition of formation and decomposition of the quinine salt for six times at room temperature. The extent of resolution was checked by polarimetry of acid obtained from each mother liquor.

Optically pure salt (0.814 g), mp 219—223 °C (dec.), consisted of two molecules of quinine per a molecule of (+)-acid and contained one molecule of ethanol as a solvent of crystallization.

Found: C, 71.21; H, 7.21; N, 5.54%. Calcd for $C_{61}H_{76}N_4O_{10}$: C, 71.46; H, 7.47; N, 5.47%.

Optically pure (+)-1,3-diphenylglutaric acid (IIb, 0.238 g) was obtained from this salt, mp 197—198.5 °C (from chloroform–*n*-hexane), $[\alpha]_D$ +95.8 °, $[\alpha]_{546}$ +114.8 °, $[\alpha]_{436}$ +204.2 ° $[\alpha]_{405}$ +260.1 °, $[\alpha]_{365}$ +375.7 ° (*c* 0.179, 99% EtOH).

Found: C, 71.85; H, 5.66%. Calcd for $C_{17}H_{16}O_4$: C, 71.82; H, 5.67%.

Tetramethyl 1,3-Diphenylpropane-1,1,3,3-tetracarboxylate (IV). To a mixture of methanol (150 ml) and sodium methoxide (60 g) was added successively methyl phenyl acetate (150 g) and dimethyl oxalate (118 g). The mixture was allowed to stand overnight. After refluxing for 2 hr under stirring, the mixture was decomposed with water and hydrochloric acid, and extracted with ether. Combined extracts, after washing with water and drying over magnesium sulfate, were concentrated to remove solvent and volatile material. The oily residue was distilled under reduced pressure to yield dimethyl phenylmalonate (III. 178.4 g), bp 159—163 °C/3325 Pa. A mixture of dimethyl phenylmalonate (147.8 g) and methylene iodide (96.0 g) was added dropwise to a stirred solution of sodium methoxide (41 g) in methanol (180 ml), and the mixture was refluxed for 32 hr. Cooled reaction mixture was poured into water and extracted with ether. The extract, after washing and drying over calcium chloride, was concentrated, and the residue was distilled under reduced pressure to give pure tetraester (III, 67.3 g), bp 178—180 °C/133 Pa.

Found: C, 64.05; H, 5.72%. Calcd for $C_{23}H_{24}O_8$: C, 64.48; H, 5.65%.

2,3: 6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-dione (VI). From the Mixture of Racemic and Meso Forms: To 1,3-diphenylglutaronitrile (I, 40.0 g) dissolved in 99% ethanol (450 ml) was added a solution of potassium hydroxide (120 g) in water (330 ml) and the mixture was heated to 70 °C for 8 hr. The reaction mixture was mixed with water (550 ml) and washed with ether. Aqueous layer was acidified with concentrated hydrochloric acid and extracted with ethyl acetate. The extract was washed with brine and dried over sodium sulfate. Crude mixture of (±)- and *meso*-1,3-diphenylgluratic acids was obtained as a yellow oil on evaporating the solvent under reduced pressure. The mixture of acids (46.2 g) was dissolved in concentrated sulfuric acid and heated to 85 °C for 30 min. The reaction mixture was poured onto ice and extracted with benzene. The extract was washed with 3% aqueous potassium hydroxide and water successively and dried over sodium sulfate. On evaporating the solvent *in vacuo* was obtained colorless solid (24.3 g), which was recrystallized twice from

methanol to yield pure diketone (VI) as colorless needles, mp 147.7—147.8 °C, IR (Nujol mull): 1680 ($\nu_{C=O}$) cm^{-1}, NMR: 8.17—7.82 (m, 2H, aromatic protons adjacent to carbonyl group), 7.55—7.15 (m, 6H, aromatic), 4.01 (t, J= 3 Hz, 2H, bridgehead), 2.98 (t, J=3 Hz, 2H, methylene bridge).

Found: C, 81.99; H, 4.82%. Calcd for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87%.

From Racemic and Optically Active Forms (IIb): By essentially the same cyclization procedure, identical (±)-diketone (VI) was obtained from (±)-IIb in 84% yield. The (−)-acid (IIb, 0.1411 g, $[\alpha]_D$ −48.2 ° (*c* 0.2824, 99% EtOH), optical purity 50.4%) yielded (+)-diketone (VI, 0.1054 g, $[\alpha]_D$ +139.5 ° (*c* 0.02108, 99% EtOH) by the same reaction conditions. Optical purity of the (+)-diketone (VI), estimated from the values of ORD peaks and troughs, was *ca.* 45%. A minor extent of racemization seemed to occur during the course of ring closure reaction.

From meso *Form (IIa)*: The *meso*-acid (IIa) yielded the identical (±)-diketone (VI) in 77% yield under the same reaction conditions.

From Tetramethyl Ester (IV): Tetramethyl ester (IV, 14.2 g) was mixed with 5% alcoholic potassium hydroxide and refluxed for 2 hr. The mixture was diluted with water and neutral material was removed by extraction with ether. Aqueous layer was acidified with hydrochloric acid and extracted with ether. The extract was washed with water and dried over magnesium sulfate. A partly crystallized residue (V, 5.0 g) obtained on evaporating the solvent under reduced pressure was mixed with polyphosphoric acid (150 g) and heated to 100 °C under stirring for 2 hr. The reaction mixture was poured onto ice water and extracted with ether. Organic layer was washed with 5% aqueous sodium carbonate and water, and dried over magnesium sulfate. Crystalline residue obtained by evaporating the solvent *in vacuo* was recrystallized from benzene–ligroin to yield the same (±)-diketone (VI).

2,3: 6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-diol (VIIa). By Lithium Aluminum Hydride Reduction: The diketone (VI, 0.5 g) in tetrahydrofuran (8 ml) was added under stirring to an ice-cooled suspension of lithium aluminum hydride (0.63 g) in the same solvent (16 ml). After stirring for further 1 hr under ice-cooling, the reaction mixture was worked up in the usual way, and extracted with ether. The extract was washed successively with water, aqueous potassium carbonate and saturated sodium chloride, and dried over sulfate. Evaporation of the solvent under reduced pressure yielded the crude glycol (VIIa), mp 225 °C (with sublimation), IR (Nujol mull): 3280 (broad), 3550, 3575 (ν_{O-H}) cm^{-1}.

Found: C, 80.66; H, 6.35%. Calcd for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39%.

By Catalytic Reduction: The diketone (VI, 0.1228 g) in ethyl acetate (10 ml) was catalytically reduced over the Adams catalyst, yielding identical glycol (VIIa) in quantitative yield.

4,8-Diacetoxy-2,3: 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (VIII). Crude glycol (VIIa, 0.2081 g) dissolved in pyridine (3 ml) was mixed with acetic anhydride (4 ml) and heated to 90 °C for 5.5 hr. The reaction mixture was worked up in the usual way to give colorless solid (0.2247 g) which showed single spot on a silica gel TLC plate developed with benzene or benzene–ether. The solid was recrystallized from benzene–methanol to give colorless needles of VIII, mp 220.9—221.6 °C, IR (Nujol mull): 1730 ($\nu_{C=O}$) cm^{-1}, NMR: 7.32—6.87 (m, 8H, aromatic), 6.27 (d, J=6 Hz, 2H, methine), 3.55 (q, 2H, bridgehead), 2.43 (t, J=3.5 Hz, 2H, methylene), 2.22 (s, 6H, methyl).

Found: C, 74.97; H, 5.96%. Calcd. for $C_{21}H_{20}O_4$: C, 74.98; H, 5.99%.

Optical Resolution of 2,3: 6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-diol (VIIi). Via *Bis-(−)-menthoxyacetate (IX)*: (−)-Menthoxyacetyl chloride (2.18 g) was added to a stirred solution of (±)-glycol (VIIa, 1.00 g, 3.96 mmol) in pyridine (8 ml). After stirring overnight at room temperature, the mixture was poured into water and extracted with benzene. The extract was washed successively with 2 M hydrochloric acid, aqueous potassium carbonate and saturated aqueous sodium chloride, and dried over sodium sulfate. A brown solid obtained on evaporating the solvent under reduced pressure was chromatographed on silica gel (30 g). Elution with benzene–ether (4: 1) yielded light yellow solid (2.32 g), mp 179.7—189.4 °C, (Nujol mull): 1760, 1740 ($\nu_{C=O}$) cm^{-1}.

The crude bis-(−)-menthoxyacetate was recrystallized eleven times from benzene–ethanol (1: 1) to give an optically pure enantiomer as colorless needles (0.25 g), mp 215.7—216.3 °C, IR (Nujol mull): 1750 ($\nu_{C=O}$) cm^{-1}, ORD: $[\alpha]_D$ −41.4 °, $[\alpha]_{546}$ −49.7 °, $[\alpha]_{405}$ −119.4 ° (*c* 0.313, dioxane).

Found: C, 76.45; H, 8.74%. Calcd for $C_{41}H_{56}O_6$: C, 76.36; H, 8.75%.

Optically pure IX (0.217 g) thus obtained was dissolved in benzene and mixed with ethanolic potassium hydroxide (0.09 g in 5 ml). After the mixture had been refluxed for 2 hr, water was added. Precipitate formed, after being washed with water, was recrystallized from benzene to give optically pure (−)-glycol (VIIa), mp 189.5—189.8 °C, IR (Nujol mull): 3390 (ν_{O-H}) cm^{-1}, ORD: $[\alpha]_D$ −84.9 °, $[\alpha]_{546}$ −101.4 °, $[\alpha]_{500}$ −132 °, $[\alpha]_{450}$ −185 °, $[\alpha]_{436}$ −204 ° (*c* 0.4065, 99% EtOH), $[\alpha]_{405}$ −261 °, $[\alpha]_{350}$ −487 °, $[\alpha]_{320}$ −771 °, $[\alpha]_{250}$ −5400 °, $[\alpha]_{230}$ −19150 ° (*c* 0.2185, 99% EtOH), UV: $\lambda_{max}^{99\%EtOH}$ (ε) 272 (320), 269(360), 264(470), 275*(390), 255*(280), 249*(230), 244*(150), 215*(17300), 199(59100) nm, CD: see Table 1.

Via *Bis-(−)-camphanate (X)*: The crystals (0.4183 g) obtained from (±)-glycol (VIIa, 0.1754 g), (−)-camphanyl chloride (0.375 g) and pyridine (5 ml) were recrystallized five times from benzene–ligroin to give (+)-bis-camphanate (32 mg) with constant rotation, colorless needles, mp 281—285 °C, $[\alpha]_D$ +38.9 ° (*c* 0.4834, dioxane).

Found: C, 72.55; H, 6.59%. Calcd for $C_{27}H_{40}O_8$: C 72.53; H, 6.58%.

(−)-Glycol (VIIa, mp 187.9—188.3 °C (from benzene), $[\alpha]_{350}$ −388.5 ° (*c* 0.02059, 99% EtOH), optical purity 79.8%) was obtained on alkaline hydrolysis of the (+)-bis(−)-camphanate (X) with constant optical rotation.

(+)-4,8-Diacetoxy-2,3: 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (VIII). (−)-Glycol (VIIa,104.4 mg) was acetylated with acetic anhydride (2 ml) and pyridine (1.5 ml) on heating to 90 °C for 5.5 hr. The reaction mixture was worked up in the same way as racemate to give colorless crystals (129.3 mg) of (+)-VIII, which showed identical NMR spectrum and the same tlc-*Rf* value with those of the racemate. The crystals were recrystallized from methanol to give pure (+)-VIII, colorless needles, mp 242.6—243.0 °C, IR (Nujol mull): 1730 ($\nu_{C=O}$) cm^{-1}, ORD: $[\alpha]_D$ +10.7 °, $[\alpha]_{474}\approx$O °, $[\alpha]_{436}$ −12.4 °, $[\alpha]_{405}$ −31.4 °, $[\alpha]_{365}$ −83.0 ° (*c* 0.541, dioxane).

Found: C, 74.82; H, 6.03%. Calcd for $C_{21}H_{20}O_4$: C, 74.98; H, 5.99%.

(+)-2,3: 6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-dione (VI). Chromium trioxide (0.1 g) in acetic acid (1 ml) was added under stirring to an ice-cooled solution of (−)-VIIa (20.1 mg) in acetone (3 ml) and acetic acid (0.5 ml). After stirring for further 19 hr at room temperature, the mixture was worked up in the usual manner. Light brown solid (13.4 mg) obtained was dissolved in benzene

and passed through a short column of silica gel (1.5 g). The material obtained from the filtrate was recrystallized from ligroin to give (+)-VI, colorless needles, mp 194.—194.5 °C, IR (Nujol mull): 1685 ($\nu_{C=O}$) cm^{-1}, ORD: $[\alpha]_D$ +343 °, $[\alpha]_{546}$ +419 °, $[\alpha]_{436}$ +1370 °, $[\alpha]_{405}$ +2570 °, $[\alpha]_{372}$ +9140 °, $[\alpha]_{355}$ +12600 °, $[\alpha]_{341}$ +7480 °, $[\alpha]_{320}$ −9340 °*, $[\alpha]_{316}$ −23700 °*, $[\alpha]_{306}$ −29100 °, $[\alpha]_{274}$ +14600 °, $[\alpha]_{253}$ −77200 ° (*c* 0.0198, 99% EtOH), UV and CD: see Table 1.

Found: C, 82.23; H, 4.90%. Calcd for $C_{17}H_{12}O_2$: C, 82.24; H, 4.87%.

(−)-4,8-Dichloro-2,3 : 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (XI). (−)-Glycol (VIIa, 117.8 mg) in benzene (10 ml) was refluxed with thionyl chloride (1.3 ml) for 17.5 hr. The reaction mixture was treated in the usual way, and faintly yellow oil obtained on evaporating the solvent under reduced pressure was dissolved in benzene and passed through a short column of silica gel. Colorless oil (140.9 mg) obtained from the filtrate was crystallized from methanol to give pure (−)-XI, colorless leaflets, mp 130.4—132.1 °C, NMR (CCl_4): 7.30—7.10 (m, 8H, aromatic), 4.96 (d, J=2 Hz, 2H, methine), 3.52 (m, 2H, bridgehead), 2.55 (t, J=3 Hz, 2H, methylene), ORD (at 25 °C): $[\alpha]_{365}$ −428 °, $[\alpha]_{276}$ −2420 °, $[\alpha]_{271}$ −391 °* $[\alpha]_{250}$ −6770 ° (*c* 0.02148, 99% EtOH), UV: $\lambda_{max}^{99\%EtOH}$ (ε) 278(450), 273*(540), 270(580), 266*(560), 261*(500), 211.5 (26700), 206(25800), 202*(28100), 195(41700) nm, CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 278(−2.96), 270(−3.18), 264*(−1.88), 234 (+24.2), 218(+32.3), 198.5(−68.3) nm.

Found: C, 70.81; H, 4.91; Cl, 24.65%. Calcd for $C_{17}H_{14}Cl_2$: C, 70.60; H, 4.88; Cl, 24.52%.

Racemate was obtained as colorless needles, mp 173.4—174.2 °C (from methanol).

(−)-2,3: 6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene (XII).

From (−)-Dichloride (XI): (−)-Dichloride (XI, 267 mg) in tetrahydrofuran (5 ml) was added to a stirred suspension of lithium aluminum hydride (0.37 g) in the same solvent (12 ml), and the mixture was refluxed for 24 hr. The reaction mixture was worked up in the usual manner. Light yellow oil obtained was dissolved in carbon tetrachloride–benzene (1: 1) and passed through a short column of silica gel (14 g). Colorless oil (180.9 mg) obtained from the filtrate was crystallized from methanol to yield (−)-XII, colorless needles, mp 100.8—102.2 °C, NMR: 7.28—6.85 (m, 8H, aromatic), 3.52—2.55 (m, 6H, methine and methylene), 2.92 (t, J=3 Hz, 2H, methano-bridge), ORD: $[\alpha]_D$ −247 °, $[\alpha]_{404}$ −635 °, $[\alpha]_{365}$ −900 °, $[\alpha]_{282}$ −2010 °, $[\alpha]_{268}$ −987 ° (*c* 0.02188, isooctane), UV: $\lambda_{max}^{isooctane}$ (ε) 273(1480), 266(1230), 262(790), 260(770), 258*(740), 252*(430), 246*(230), 219(14450), 214(17200), 196(66100) nm, CD: see Table 1.

Found: C, 92.40; H, 7.28%. Calcd for $C_{17}H_{16}$: C, 92.68; H, 7.32%.

Racemate: mp 71.7—73.5 °C.

By the Clemmensen Reduction of (±)-VI: A mixture of (±)-diketone (VI, 218 mg), toluene (3 ml), concentrated hydrochloric acid (1.75 ml), water (0.75 ml) and granulated zinc (1.2 g) activated with mercuric chloride and diluted hydrochloric acid was refluxed for 24 hr under stirring. The reaction mixture was worked up in the usual way to yield light yellow oil. The oil in carbon tetrachloride was passed through a short column of alumina and silica gel, successively. Colorless oil (64.3 mg) obtained from the filtrate was crystallized from 99% ethanol to give pure (±)-XII, colorless plates, mp 72.1—73.5 °C, which showed identical IR and NMR spectra with those of (±)-XII obtained from (±)-VIIa.

Found: C, 92.55; H, 7.43%. Calcd for $C_{17}H_{16}$: C, 92.68; H, 7.32%.

(−)-4,8-Dihydroxy-4,8-dimethyl-2,3 : 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (XIII). To an ice-cooled solution of methylmagnesium iodide (magnesium 0.9 g, methyl iodide 5.5 g and ether 30 ml) a solution of (+)-VI (511.3 mg) in tetrahydrofuran (25 ml) was added under stirring. After 1.5 hr, the mixture was refluxed for 5 hr. Brown oil (584.4 mg) obtained on treatment of the reaction mixture in the usual manner was dissolved in benzene and passed through a short column of silica gel (3 g). Colorless solid obtained from benzene and benzene–ether eluates was recrystallized once from benzene and twice from petroleum ether to give pure (−)-XIII, mp 115.1—116.0 °C, IR (Nujol mull): 3750, 3480 (ν_{O-H}) cm^{-1}, NMR: 7.65—7.05 (m, 8H, aromatic), 3.04 (t, J=3 Hz, 2H, bridgehead), 2.57 (t, J=3 Hz, 2H, methylene), 1.65 (s, 6H, methyl), 1.63 (s, 2H, OH), ORD (at 25 °C): $[\alpha]_{365}$ −349 °, $[\alpha]_{300}$ −1040 °, $[\alpha]_{260}$ −3010 ° (*c* 0.020645, 99% EtOH), UV: $\lambda_{max}^{99\%EtOH}$ (ε) 272(240), 268(200), 262.5 (400), 275.4*(330), 252*(250), 245*(150), 218*(15050), 214* (17900), 196.5(69400) nm, CD: $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 274(+0.05), 271.5(−0.07), 265(−0.12), 256(−0.16), 251(−0.16), 216 (−35.3), 203(−85.6) nm.

Found: C, 81.27; H, 7.20%. Calcd for $C_{19}H_{20}O_2$: C, 81.39; H, 7.19%.

Racemate was prepared similarly and recrystallized twice from benzene–ligroin, mp 165.5—166.2 °C, IR (Nujol mull): 3570 (ν_{O-H}) cm^{-1}.

When just two equivalents of the Grignard reagent was added to (±)-VI, only 44.3% of (±)-XIII was obtained and a ketoalcohol, 4-hydroxy-4-methyl-2,3 : 6,7-dibenzobicyclo-[3.3.1]nona-2,6-dine-8-one, was isolated in 37.6% yield. The ketoalcohol was recrystallized three times from acetone to yield pure crystals, which contained a molecule of acetone as a solvent of crystallization, IR (Nujol mull): 3460 (ν_{O-H}), 1690, 1683 ($\nu_{C=O}$), 1712 ($\nu_{C=O}$, acetone) cm^{-1}, NMR: 7.85 (m, J_o= 7 Hz, J_m=3 Hz, J_p=1.5 Hz, 1H, aromatic *ortho* to carbonyl), 7.58—7.03 (m, 7H, other aromatic), 3.78 (t, J=3 Hz, 1H. bridgehead vicinal to hydroxyl), 3.28 (t, J=3 Hz, 1H, bridgehead vicinal to carbonyl), 2.66 (t, J=3 Hz, 2H, methylene), 2.09 (s, 6H, acetone), 1.98 (s, 1H, OH), 1.75 (s, 3H, methyl),

Found: C, 78.37; H, 6.85%. Calcd for $C_{18}H_{16}O_2 \cdot C_3H_6O$: C, 78.23; H, 6.88%.

(+)-4,8-Bis(methylene)-2,3 : 6,7-dibenzobicyclo[3.3.1]nona-2,6-diene (XIV). (−)-Dimethyl glycol (XIII, 467.4 mg) in pyridine (6 ml) was heated to 50—65 °C with phosphoryl chloride (1.8 ml) for 1.5 hr. The reaction mixture was worked up in the usual way. A benzene solution of light yellow oil obtained on evaporating the solvent under reduced pressure was passed through a short column of silica gel (7.5 g) to yield colorless crystals (231.1 mg) which were recrystallized from methanol to give pure (+)-XIV, colorless needles, mp 124.2—124.6 °C, IR (Nujol mull): 1620 ($\nu_{C=C}$) cm^{-1} NMR: 7.70—6.95 (m, 8H, aromatic), 5.44 (d, J=0.5 Hz, 2H, olefin *syn* to benzene), 5.25 (d, J=0.5 Hz, 2H, olefin *anti* to benzene), 3.88 (t, J=3 Hz, 2H, bridgehead), 2.32 (t, J=3 Hz, 2H, methylene), ORD (at 25 °C): $[\alpha]_D$ +392 °, $[\alpha]_{546}$ +703 °, $[\alpha]_{405}$ +1460 °, $[\alpha]_{365}$ +2390 °, $[\alpha]_{330}$ +4410 ° (*c* 0.01964, 99% EtOH), UV: $\lambda_{max}^{99\%EtOH}$ (ε) 296.5(1210), 286.5 (2130), 258(22100), 251*(21000), 230*(16000), 213.5(35650), 209(36000) nm, $\lambda_{max}^{isoctane}$(ε) 296.5(1130), 286.5(1930), 266* (16200), 258.5(22100), 251*(21000), 230*(16100), 213.5 (37200), 208.5(37900), 192*(27400) nm, CD: see Table 1.

Found: C, 93.20; H, 6.62%. Calcd for $C_{19}H_{16}$: C, 93.40; H, 6.60%.

Racemate: mp 81.2—81.5 °C (from *n*-pentane).

(+)-2,3 :6, 7-Dibenzobicyclo[3.3.1]nona-2, 6-diene-4,8-diol-bis-p-bromobenzoate (XV). To a stirred solution of (−)-VIIa (0.5 g) in pyridine (7 ml) *p*-bromobenzoyl chloride (0.5 g) was added at room temperature and the mixture was heated to 60 °C under stirring for 20 hr. The reaction mixture was

worked up in the usual way. A viscous oil (0.45 g) obtained was dissolved in benzene and chromatographed twice on silica gel (34 g each) very carefully. Colorless solid obtained from the benzene eluates was recrystallized from methanol to give (+)-XV, mp 212.7—213.7 °C, IR (Nujol mull): 1720 ($\nu_{C=O}$) cm^{-1}, NMR: 7.97 (d, J=8.4 Hz, 4H, *ortho* protons of *p*-bromobenzoyl groups), 7.34—6.88 (m, 8H, other aromatic protons), 6.60 (d, J=6 Hz, 2H, methine), 3.70 (q, 2H, bridgehead), 2.58 (t, J=3 Hz, 2H, methylene), ORD: $[\alpha]_D$ +192 °, $[\alpha]_{546}$ +231 °, $[\alpha]_{436}$ +424 °, $[\alpha]_{405}$ +532 °, $[\alpha]_{365}$ +753 ° (*c* 0.587, acetone), UV: $\lambda_{max}^{cyclohexane}$ (ε) 283(1410), 271* (3630), 255*(31000), 247(41200), 218*(23800), 200(116500) nm, CD: $\lambda_{max}^{cyclohexane}$ ($\Delta\varepsilon$) 287(+0.24), 284(−0.40), 278* (+2.25), 255(+46.8), 235(−3.04), 212(−63.9) nm.

Found: C, 60.44; H, 3.58; Br, 25.79%. Calcd for $C_{31}H_{22}O_4Br_2$: C, 60.21; H, 3.59; Br, 25.85%.

Single crystals of (+)-XV for the X-ray crystallographic analysis were prepared on standing an acetone solution (200 mg in 25 ml) in a loosely stoppered ground joint flask for three months in a dark place.

When the above-mentioned procedure was applied to (±)-VIIa, the (±)-diester (XV) was obtained only in 51% yield and mono-*p*-bromobenzoate was isolated in 40,6% yield.

(±)-Bis-*p*-bromobenzoate (XV): colorless needles, mp 233.7—234.4 °C (from methanol), IR (Nujol mull): 1714 ($\nu_{C=O}$) cm^{-1}.

(±)-Mono-*p*-bromobenzoate: colorless rods, mp 163.0—163.5 °C, IR (Nujol mull): 3310 (ν_{O-H}), 1728, 1718 ($\nu_{C=O}$) cm^{-1}, NMR (CCl_4): 7.79 (d, J=8.4 Hz, 2H, *ortho* protons of *p*-bromobenzoyl group), 7.46 (d, J=8.4 Hz, 2H, *meta* protons of *p*-bromobenzoyl group), 7.50—6.70 (m, 8H, other aromatic protons), 6.40 (d, J=6 Hz, 1H, methine of ester), 4.89 (q, 1H, methine of alcohol), 3.52 (m, 1H, bridgehead near to ester), 3.27 (m, 1H, bridgehead near to alcohol), 2.43 (broad s, 2H, methylene), 1.46 (d, J=12 Hz, 1H, OH, disappeared on addition of D_2O). Found: C, 66.01; H, 4.44; Br, 18.22%. Calcd for $C_{24}H_{19}O_3Br$: C, 66.22; H, 4.40; Br, 18.36%.

(−)-2,3 : 6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene-4,8-diol-monoacetate (XVI). (−)-Diol (VIIa, 3.61 g, $[\alpha]_D^{25}$ −85.2 ° (*c* 0.9240, $CHCl_3$), $[\alpha]_D^{25}$ −48.3 ° (*c* 0.4968, 99% EtOH), optical purity 56.9%) in pyridine was mixed with acetic anhydride (1.46 g) under ice-cooling. The mixture was stirred for further 2 hr at the same temperature and allowed to stand overnight at room temperature. The reaction mixture was worked up in the usual manner. Crystals of recovered (−)-diol (VIIa, 0.563 g) deposited on concentrating the extract were removed by filtration, and the filtrate was chromatographed on alumina (70 g). Recrystallization from ether of the crystals obtained from benzene eluates yielded (+)-diacetate (VIII, 0.850 g), mp 211.0—213.0 °C, $[\alpha]_D^{25}$ +25 ° (*c* 0.2469, $CHCl_3$), Found: C, 74.74; H, 5.90%.

Crystals (1.59 g) obtained from ether–methanol (95:5) eluates were recrystallized from ether to give (−)-monoacetate, mp 129.0—133.0 °C, $[\alpha]_D^{25}$ −27.7 ° (*c* 0.5340, $CHCl_3$).

Found: C, 77.53; H, 6.16%. Calcd for $C_{19}H_{18}O_3$: C, 77.42; H, 6.14%.

(+)-2,3: 6,7-Dibenzobicyclo[3.3.1]nona-2,6-diene-4-one (XIX). A mixture of (−)-monoacetate (XVI, 1.40 g), thionyl chloride (18 ml) and benzene (120 ml) was refluxed for 17 hr. The reaction mixture was worked up in the usual way and the residue obtained on evaporating the benzene extract *in vacuo* was purified by crystallization from *n*-hexane to yield (−)-8-chloro-4-acetate (XVII), mp 139.0—144.0 °C, $[\alpha]_D^{22}$ −31.0 ° (*c* 0.4974, $CHCl_3$), Found: C, 73.06; H, 5.38; Cl, 11.30%. Calcd for $C_{19}H_{17}O_2Cl$: C, 72.95; H, 5.48; Cl, 11.33%.

(−)-Chloride (XVII, 0.850 g) in tetrahydrofuran (10 ml) was added dropwise to a stirred suspension of lithium aluminum hydride (1.2 g) in the same solvent (60 ml). After the mixture had been refluxed for 24 hr, the reaction mixture was treated in the usual manner and the solvent was removed *in vacuo*. Crude alcohol (XVIII) thus obtained was submitted to oxidation without further purification. To an ice-cooled solution of crude XVIII in acetone (40 ml) was added the Jones reagent dropwise under stirring till red color of the reagent persisted for a while. The mixture was stirred for further 30 min at the same temperature and then mixed with water. Ethereal extract, after being washed and dried, was concentrated *in vacuo*, and the residue dissolved in benzene was passed through a short column of silica gel (15 g). Colorless crystals (440 mg) obtained from benzene eluates were recrystallized from benzene–*n*-hexane to give pure (+)-XIX, mp 112—114 °C, $[\alpha]_D^{22}$ +27.5 ° (*c* 0.2479, $CHCl_3$), UV: $\lambda_{max}^{99\%EtOH}$ (ε) 370*(93.5), 350*(380), 337.5(523), 326*(483), 297*(1620), 290*(1730), 278(2210), 253(11900), 201(41800) nm, $\lambda_{max}^{cyclohexame}$ (ε) 374*(164), 371(176), 355.5(410), 340(464), 326(343), 315(204), 297(1400), 287(1420), 278.5(1790), 271 (1710), 251*(11000), 247(11600), 214*(26900), 206(43050), 191.5(37900), 190(38600) nm, CD (corrected for 100% optical purity): $\lambda_{max}^{99\%EtOH}$ ($\Delta\varepsilon$) 370*(+1.50), 352.5*(+5.10), 338.5(+6.93), 327*(+6.18), 315*(+3.85), 303*(−1.50), 283(−1.96), 276*(−1.72), 260*(−1.02), 245*(+1.11), 243 (+1.21), 229(−1.71), 203.5(−25.0) nm, $\lambda_{max}^{cyclohexane}$ ($\Delta\varepsilon$) 384* (+0.05), 380*(+0.20), 377*(+1.53), 371(+2.99), 354.5 (+6.29), 339.5(+6.65), 325.5(+4.64), 315(+2.58), 303* (+0.904), 298*(+0.86), 275(−1.17), 358(−0.63), 244 (+1.31), 225(−2.61), 199(−18.5) nm.

(R)-(−)-3-Phenylbutanoic Acid (XX). (±)-XX, bp 134—136 °C/800 Pa, was prepared by the reaction of benzene with crotonic acid in the presence of anhydrous aluminum chloride.[13] Optical resolution was carried out with (+)-α-phenylethylamine[14] to yield (*R*)-(−)-XX, $[\alpha]_D$ −52.0 ° (*c* 0.042, benzene).

(R)-(−)-3-Phenylbutylphenone (XXI). (*R*)-(−)-XX (3.61 g) was converted into acid chloride with thionyl chloride in ether. A solution of the acid chloride in benzene (50 ml) was added under ice-cooling and stirring to a benzene solution of diphenylcadmium (*ca.* 80 ml), which was prepared from phenylmagnesium bromide (magnesium 0.61 g, bromobenzene 2.6 ml, and ether 20 ml) and anhydrous cadmium chloride (2.5 g suspended in 50 ml of ether). After being refluxed for 3 hr, the reaction mixture was worked up in the usual way. Organic layer and benzene extracts, after being washed and dried, were evaporated under reduced pressure. Viscous brown oil (3.4 g) thus obtained was found to be contanimated with considerable amount of ethyl 3-phenylbutyrate. The crude product (1.3 g) in 99% ethanol (10 ml) was mixed with potassium hydroxide (0.7 g in ethanol 20 ml and water 5 ml) and the mixture was allowed to stand at room temperature overnight. After evaporating the solvent under reduced pressure, the mixture was diluted with water and extracted with benzene. The extract was washed with 5% aqueous sodium hydrogencarbonate, and dried over sodium sulfate. (*R*)-(−)-XX (0.381 g) was recovered from the aqueous layer and sodium hydrogencarbonate washings on acidification. Light yellow oil (0.7311 g) obtained from benzene extract was carefully purified by repeated chromatography on silica gel and alumina. (*R*)-(−)-Ketone (XXI) was obtained as a colorless oil, IR (neat): 1683 ($\nu_{C=O}$) cm^{-1} NMR: 8.0—7.8 (m, 2H, *ortho* protons of benzoyl group), 7.55—7.17 (m, 8H, other aromatic protons), 3.73—3.08 (m, 3H, methylene and methine), 1.31 (d, J=6.6 Hz, 3H, methyl), UV: $\lambda_{max}^{isooctane}$ (ε) 358*(24.5), 355*(26.0), 341*(47.3), 328*(62.5), 319(64.7),

Found: C, 85.36; H, 7.18%. Calcd for $C_{15}H_{16}O$: C, 85.68; H, 7.19%.

Racemate was obtained by the same procedure in 71% yield which was recrystallized from methanol to give pure (±)-XXI, colorless leaflets, mp 70.8—71.5 °C, IR (KBr disk): 1680 ($\nu_{C=O}$), 760, 705 (δ_{CH}, monosubstituted benzene) cm^{-1}. In this case contamination with the ethyl ester was not so serious that (±)-XXI could be easily purified by chromatography on silica gel and recrystallization.

(R)-(−)-2,4-Diphenyl-1-pentane (XXII). Triphenylmethylphosphonium bromide (1.761 g) suspended in ether (30 ml) was converted into triphenylphosphinmethylene with *n*-butyllithium (3 ml of 1.65 M hexane solution).[15] (−)-Ketone (XXI, 0.774 g) in ether (70 ml) was added over 5-min period to the stirred solution of the Wittig reagent and the mixture was refluxed for 11.5 hr under stirring. Solid deposited on cooling the reaction mixture was filtered and washed thoroughly with ether. The filtrate and washings were combined and dried over sodium sulfate. Colorless oil (1.120 g) obtained on evaporating the solvent under reduced pressure was dissolved in *n*-hexane and carefully chromatographed on silica gel (40 g). Evaporation of *n*-hexane eluates gave (−)-XXII, colorless oil (0.519 g, 67.6%), IR (neat): 890 ($\delta_{=CH}$ out of plane) cm^{-1}, NMR: 7.47—7.0 (m, 8H, aromatic), 5.21 (d, J=1.6 Hz, 1H, olefinic proton *cis* to phenyl), 4.97 (m, 1H, olefinic proton *trans* to phenyl), 3.07—2.52 (m, 3H, methylene and methine), 2.87 (d, J=6.5 Hz, 3H, methyl), UV: $\lambda_{max}^{isooctane}$ (ε) 290* (77.2), 268.5 (1270), 264(2130), 240(9170), 217*(12300), 206(27000), 191.5(67640), 190(68500) nm, ORD: $[\alpha]_D$ −68.1°, $[\alpha]_{546}$ −83.1°, $[\alpha]_{436}$ −156.9°, $[\alpha]_{405}$ −196.6°, $[\alpha]_{365}$ −279.4° (*c* 1.354, *n*-hexane), CD: $\lambda_{max}^{isooctane}$ ($\Delta\varepsilon$) 271.5(−0.121), 267.5(+0.102), 264(−0.160), 235(−3.21), 210(+5.37), 192 (−39.2) nm.

Found: C, 91.90; H, 8.29%. Calcd for $C_{17}H_{18}$: C, 91.84; H, 8.16%.

A small amount of (−)-ketone (XXI, 0.131 g, 16.9%) was recovered from benzene eluate.

(R)-(−)- and meso*-2,4-Diphenylpentane (XXIIIb and XXIIIa)* Hydrogenation of (*R*)-(−)-2,4-diphenyl-1-pentene (XXII, 0.422 g) in benzene (50 ml) and ethyl acetate (50 ml) over the Adams catalyst (48 mg) yielded colorless oil (0.407 g). The material in *n*-hexane was chromatographed on silica gel. Ratio of *meso*-(XXIIIa) and (−)-isomers (XXIIIb) could be estimated to be 50.7% and 49.3%, respectively, by the intensities of methyl signals in their NMR spectra of purified reduction product, UV: $\lambda_{max}^{isooctane}$ (ε) 268(330), 264.3(346), 261 (436), 259(443), 254.5*(370), 253.5(377), 248.5(279), 243* (194), 238*(140), 217*(10000), 213*(14300), 209(17600), 205*(17500), 193(89000), 191.8(97500), 190(91800) nm, ORD: $[\alpha]_D$ −39.4°, $[\alpha]_{546}$ −49.1°, $[\alpha]_{436}$ −84.4°, $[\alpha]_{405}$ −105.2°, $[\alpha]_{365}$ −150.4° (*c* 0.5140, isooctane), CD: $\lambda_{max}^{isooctane}$ ($\Delta\varepsilon$) 271(−0.0162), 268(+0.0117), 266*(−0.0208), 263.5 (−0.0483), 257(−0.0616), 251(−0.0485), 245*(−0.0350), 239*(−0.0266), 217(−4.59) nm.

(−)-2,4-Diphenylpentane-1,5-diol (XXIVb). (−)-1,3-Diphenylglutaric acid (IIb, 0.548 g, $[\alpha]_D$ −44.1° (*c* 0.295, 99% EtOH), optical purity 46%) in tetrahydrofuran (30 ml) was added to a stirred suspension of lithium aluminum hydride (0.1464 g) in the same solvent (20 ml), and the mixture was refluxed for 5 hr. The reaction mixture was worked up in the usual manner and extracted with ether. After washing and drying, the extract was concentrated under reduced pressure. Colorless oil (0.462 g) thus obtained was crystallized from benzene to give pure (−)-XXIVb, mp 72—90 °C, IR (neat): 3350 (very broad, ν_{O-H}) cm^{-1}, NMR: 7.40—6.83 (m, 10H, aromatic), 3.45 (d, J=6.2 Hz, 4H, $C\underline{H}_2OH$), 2.68—1.77 (m, 4H, methylene and methine), 2.13 (s, 2H, OH), ORD: $[\alpha]_D$ −39.1°, $[\alpha]_{546}$ −45.1°, $[\alpha]_{436}$ −80.9°, $[\alpha]_{405}$ −99.7°, $[\alpha]_{365}$ −135.3° (*c* 0.8432, 99% EtOH).

Found: C, 79.12; H, 7.85%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%.

meso*-2,4-Diphenylpentane-1,5-diol (XXIVa).* Reduction of *meso*-1,3-diphenylglutaric acid (IIa, 0.514 g) according to the same procedure used for (−)-isomer (IIb) gave *meso*-diol (XXIVa) in a quantitative yield which was recrystallized from benzene–ligroin to give pure material, mp 116.7—117.3 °C, IR (Nujol mull): 3250, 3170* (ν_{O-H}) cm^{-1}, NMR: 7.50—7.00 (m, 10H, aromatic), 3.73 (d, J=6.6 Hz, 4H, $C\underline{H}_2OH$), 3.07—1.58 (m, 4H, methylene and methine), 1.74 (s, 2H, OH).

Found: C, 79.52; H, 7.86%. Calcd for $C_{17}H_{20}O_2$: C, 79.65; H, 7.86%.

(−)-2,4-Diphenylpentane (XXIIIb). To an ice-cooled and stirred solution of (−)-diol (XXIVb, 0.406 g, optical purity, max. 46%) in pyridine (10 ml) was added dropwise methanesulfonyl chloride (1.0 g). The mixture was stirred for further 4 hr at room temperature and then allowed to stand overnight in a refrigerator. Treatment of the reaction mixture in the usual way gave bis-methanesulfonate (0.625 g) as light brown oil. A solution of the mesylate in tetrahydrofuran (30 ml) was added to a suspension of lithium aluminum hydride (1.0 g) in the same solvent (25 ml) and the mixture was refluxed for 12 hr. The reaction mixture was worked up in the usual manner to yield crude (−)-XXIIIb, faintly yellow oil (0.300 g). A *n*-hexane solution of the crude (−)-XXIIIb was chromatographed on silica gel (20 g), yielding pure (−)-XXIIIb, colorless oil, NMR: 7.47—6.96 (m, 10H, aromatic), 2.83—2.24 (sextet, 2H, methane), 1.96—1.72 (m, 2H, methylene), 1.14 (d, J=7 Hz, 6H, methyl), UV: $\lambda_{max}^{isooctane}$ (ε) 268(372), 264(361), 261.2(473), 259(458), 255(391), 253.5 (391), 249(287), 243*(188), 237*(115), 217*(10300), 213* (14600), 209(17700), 205*(17400), 193(82300), 191.5(86800), 190(87100) nm, ORD: $[\alpha]_D$ −34.7°, $[\alpha]_{546}$ −42.3°, $[\alpha]_{436}$ −73.4°, $[\alpha]_{405}$ −91.9°, $[\alpha]_{365}$ −124.6° (*c* 0.5740, isooctane), CD: $\lambda_{max}^{isooctane}$ ($\Delta\varepsilon$) 271 (−0.0164), 268(+0.0126), 266* (−0.0203), 263.5(−0.0580), 257(−0.0696), 251(−0.0464), 245*(−0.0261), 239*(−0.0145), 217(−6.19) nm.

Found: C, 91.03; H, 9.09%. Calcd for $C_{17}H_{20}$: C, 91.01; H, 8.99%.

meso*-2,4-Diphenylpentane (XXIIIa).* *meso*-Diol (XXIVa, 0.255 g) was converted into *meso*-bis-mesylate (0.396 g) by the reaction with methanesulfonyl chloride (0.274 g) in pyridine (5 ml) performed under the same reaction condition used for the (−)-diol (XXIVb). The *meso*-bis-mesylate was reduced by lithium aluminum hydride (0.9 g) in tetrahydrofuran. Purification of crude product (0.204 g) in *n*-hexane by chromatography on silica gel (25 g) yielded *meso*-XXIIIa, colorless oil, NMR: 7.46—6.98 (m, 10H, aromatic), 2.96—2.37

(sextet, 2H, methine), 2.21—1.48 (m, 2H, aromatic), 2.21—1.48 (m, 2H, methylene), 1.21 (d, J=6.7 Hz, 6H, methyl), UV: $\lambda_{max}^{isooctane}$ (ε) 268 (312), 264.5(330), 261.1(416), 259 (432), 255*(356), 253.5(359), 248.8(256), 244*(167), 238* (103), 217(10400), 213*(14200), 209(17400), 205*(17200), 193(87300), 192(95700), 190(94000), 188.5(69200) nm.

Found: C, 90.86; H, 8.95%. Calcd for $C_{17}H_{20}$: C, 91.01; H, 8.99%.

Metal Phosphinylides and Phosphinothioylides. IV.[1] Reactions with Tetrahydrofuran

Koshiro GODA, Masaaki YOSHIFUJI, Renji OKAZAKI, and Naoki INAMOTO
Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
(Received January 14, 1975)

Diphenylphosphinic (**1**) and diphenylphosphinothioic chlorides (**2**) were allowed to react in tetrahydrofuran (THF) in the presence of metal or metal salts at 120—150 °C. In the cases of lithium and magnesium, $[Ph_2PX]^-$ (X=O, S) thus formed attacked the α-carbon of THF to give ring-opening products, which were produced by deoxygenation, sulfurization, and reaction with **1** and **2**. In the cases of iron, copper, and their salts, *O*-4-chlorobutyl diphenylphosphinate (**12**) and diphenylphosphinothioate (**13**) were obtained in a homolytic fashion. The formation mechanisms have been discussed.

In a previous paper,[2] it was reported that reactions of $[Ph_2PX]$ M (X=O, S; M=Li, FeCl) with *p*-benzoquinone gave different type compounds, depending on the metals employed. The reactions show anionic and homolytic characters in the cases of M=Li and FeCl, respectively.

It is known that lithium dimethylphosphide (Me_2PLi) reacts rapidly with tetrahydrofuran (THF) to give 4-hydroxybutyldimethylphosphine by a nucleophilic attack on the α-carbon atom of THF.[3]

In order to clarify this difference still more, reactions of diphenylphosphinic (**1**) and diphenylphosphinothioic chlorides (**2**) with THF were carried out in the presence of several metals or metal salts.

The reaction of diphenylphosphinic chloride (**1**) with lithium in THF at 150 °C gave 29% of diphenylphosphine oxide (**3**), 3% of tetraphenyldiphosphine dioxide (**4**), and a trace amount of 4-substituted butyldiphenylphosphine oxide (**5**). The structure of **5** is unknown because of difficulties of purification but it is considered to be **8** (see below) mainly from the spectral data. A similar reaction of diphenylphosphinothioic chloride (**2**) gave 13% of **3**, 46% of tetramethylene bis(diphenylphosphinodithioate) (**6**), and 16% of *S,S*-tetramethylene diphenylphosphinothioate diphenylphosphinodithioate (**7**). The formation of **3** indicates the occurrence of desulfurization during the reaction.[4]

$$\underset{\mathbf{1}}{Ph_2P(O)Cl} + Li + THF \longrightarrow \underset{\mathbf{3}}{Ph_2P(O)H} + \underset{\mathbf{4}}{Ph_2P(O)\text{-}P(O)Ph_2} + \underset{\mathbf{5}}{Ph_2P(O)(CH_2)_4Y}$$

$$\underset{\mathbf{2}}{Ph_2P(S)Cl} + Li + THF \longrightarrow \underset{\mathbf{3}}{Ph_2P(O)H} + \underset{\mathbf{6}}{Ph_2P(S)S(CH_2)_4SP(S)Ph_2} + \underset{\mathbf{7}}{Ph_2P(S)S(CH_2)_4SP(O)Ph_2}$$

Reaction of **1** with magnesium in THF at 150 °C gave 21% of 1,4-bis(diphenylphosphino)butane 1,4-dioxide (**8**) and a trace amount of **5**. A similar reaction of **2** gave 6% of diphenylphosphinic acid, 21% of diphenylphosphinodithioic acid (**9**), a trace of tetraphenyldiphosphine disulfide (**10**), and 18% of *O,S*-tetramethylene diphenylphosphinothioate diphenylphosphinodithioate (**11**). The formation of diphenylphosphinic acid and **9** also indicates the occurrence of desulfurization during the reaction.

$$\mathbf{1} + Mg + THF \longrightarrow \underset{\mathbf{8}}{Ph_2P(O)(CH_2)_4P(O)Ph_2} + \mathbf{5}$$

$$\mathbf{2} + Mg + THF \longrightarrow Ph_2P(O)OH + \underset{\mathbf{9}}{Ph_2P(S)SH} + \underset{\mathbf{10}}{Ph_2P(S)P(S)Ph_2} + \underset{\mathbf{11}}{Ph_2P(S)S(CH_2)_4OP(S)Ph_2}$$

Reactions of **1** and **2** in the presence of a catalytic amount of iron, copper, cuprous chloride, and oxide in THF at 150 °C gave *O*-4-chlorobutyl diphenylphosphinate (**12**) and diphenylphosphinothioate (**13**). In some cases, 1 : 2 product (**14**) was also obtained. These products are quite different from those in the cases with lithium and magnesium. The results are summarized in Table 1.

$$\mathbf{1}\text{ or }\mathbf{2} + \text{M or MA} + THF \longrightarrow \underset{\mathbf{12}\ X=O;\ \mathbf{13}\ X=S}{Ph_2P(X)O(CH_2)_4Cl} + \underset{\mathbf{14}}{Ph_2P(X)[O(CH_2)_4]_2Cl}$$

M=Fe, Cu; MA=Cu_2Cl_2, Cu_2O

a, X=O; b, X=S

Table 1. Yields of **12**, **13**, and **14** (at 150 °C)

1 or 2	M or MA	12 (%)	13 (%)	14 (%)
1	Fe	22	—	—
	Cu	36	—	—
	Cu_2Cl_2	23	—	4
	Cu_2O	18	—	—
2	Fe	—	27	10
	Cu	—	28	5
	Cu_2Cl_2	—	46	—
	Cu_2O	—	59	—

In order to obtain some information on the formation mechanism of **12** and **13**, **1** and **2** were allowed to react in THF in the presence of a catalytic amount of various metals and metal salts at 120 °C for 6 hr; the yields of **12** and **13** were determined by gas chromatography (glc). The results are shown in Table 2.

As seen in Table 2, copper and the salts are favorable over iron and the salts as catalyst. Moreover, Friedel-Crafts catalysts such as ferric and aluminum chlorides are not so good, except for zinc chloride.

Table 2. Yields of **12** and **13** (at 120 °C for 6 hr)

Cat.	**12** (%)	**13** (%)
none	—	—
Cu	37	8
Cu_2Cl_2	34	25
$(i\text{-PrO})_3P \cdot CuCl$	39	16
$CuCl_2$	57	28
Fe	15	4
$FeSO_4$	7	<1
$FeCl_3$	5	<1
$ZnCl_2$	36	9
$AlCl_3$	2	<1

These facts suggest that the reactions in the presence of copper, copper salts, iron, and ferrous salts proceed in a homolytic fashion, because it has been known that the reactions of cuprous and ferrous salts with carbon tetrachloride,[5] sulfonyl chlorides,[6] and *N*-chloroamines[7] generate trichloromethyl, sulfonyl, and amino radicals, respectively.

Thus, the formations of **12**, **13**, and **14** are reasonably explained as follows:

$$Ph_2P(X)Cl + M \longrightarrow Ph_2\dot{P}(X) + M^+Cl^-$$

$$Ph_2\dot{P}(X) + \square O \longrightarrow \square \overset{+}{O}\text{-}\overset{\cdot\cdot}{\underset{\cdot\cdot}{P}}(X)Ph_2 \longrightarrow$$

$$Ph_2P(X)O(CH_2)_4\cdot \xrightarrow{MCl} Ph_2P(X)O(CH_2)_4Cl \quad \mathbf{12, 13}$$

$$Ph_2P(X)O(CH_2)_4\cdot \xrightarrow{M^+} Ph_2P(X)O(CH_2)_4^+ \xrightarrow{THF} \square \overset{+}{O}\text{-}(CH_2)_4OP(X)Ph_2 \xrightarrow{Cl^-}$$

$$Cl(CH_2)_4O(CH_2)_4OP(X)Ph_2 \quad \mathbf{14}$$

Since neither addition nor polymerization occurred in the presence of acrylonitrile, styrene, vinyl acetate, and dienes under the same conditions, it is considered that the reactions are homolytic but that free radicals are not produced in these reactions.

In the above mechanisms, the second step is analogous to the reactions of alcohols with $Ph_2P\cdot$[8] and $Ph_2P(S)\cdot$ radicals.[9]

In the presence of Friedel-Crafts catalysts, the formation of **12**, **13**, and **14** is explained as follows:

$$Ph_2P(X)Cl + MCl_n \longrightarrow Ph_2P(X)^+ MCl_{n+1}^- \xrightarrow{THF}$$

$$\square \overset{+}{O}\text{-}P(X)Ph_2 \longrightarrow {}^+(CH_2)_4OP(X)Ph \xrightarrow{THF\ Cl^-} \mathbf{14}$$

$$\downarrow Cl^-$$

12 or **13**

In the cases with lithium and magnesium, the formation of products is explicable by anionic mechanisms as follows:

$$[Ph_2PO]^- + \mathbf{1} \xrightarrow{(a)} Ph_2P(O)\text{-}OPPh_2 \xrightarrow{\Delta} Ph_2P(O)P(O)Ph_2$$

$$\uparrow [O] \quad \mathbf{4}$$

$$2[Ph_2PO]^- \xrightarrow{(b)} Ph_2P(O)O^- + Ph_2P^- \xrightarrow{1} Ph_2P\text{-}P(O)Ph_2$$

$$[Ph_2PO]^- + THF \longrightarrow Ph_2P(O)(CH_2)_4O^- \xrightarrow[(c)]{[Ph_2PO]^-}$$

$$Ph_2P(O)(CH_2)_4^- \xrightarrow{1} Ph_2P(O)(CH_2)_4P(O)Ph_2 \quad \mathbf{8}$$

$$\downarrow$$

$$Ph_2P(O)(CH_2)_4Y \quad \mathbf{5}$$

$$2[Ph_2PS]^- \xrightarrow{(d)} Ph_2P^- + Ph_2P(S)S^- \quad \mathbf{9}$$

$$[Ph_2PS]^- \xrightarrow[(e)]{2} Ph_2P(S)P(S)Ph_2 \quad \mathbf{10}$$

$$\downarrow THF$$

$$Ph_2PS(CH_2)_4O^- \xrightarrow{2} Ph_2P(S)S(CH_2)_4OP(S)Ph_2 \quad \mathbf{11}$$

$$\downarrow [Ph_2PS]^- \ (f)$$

$$Ph_2PS(CH_2)_4^- \xrightarrow{2} Ph_2PS(CH_2)_4SPPh_2$$

$$2 \swarrow \quad [O] \downarrow 2$$

$$Ph_2P(S)S(CH_2)_4SP(S)Ph_2 \quad \mathbf{6} \qquad Ph_2P(S)S(CH_2)_4SP(O)Ph_2 \quad \mathbf{7}$$

The steps (a) and (e) have been discussed in a previous paper.[9] The steps (c) and (f) are deoxygenation by trivalent phosphorus.[2] The steps (b) and (d) are disproportionation involving oxygen and sulfur atoms.

Experimental

All melting and boiling points are uncorrected. The IR spectra were recorded on a Hitachi EPI-G2 spectrophotometer. NMR spectra were measured with Hitachi R-24 and R-20B spectrometers using TMS as an internal standard, and MS spectra were determined with a Hitachi RMU-6L mass spectrometer. All reactions were carried out under nitrogen in a sealed tube.

Materials. Diphenylphosphinic[10] (**1**) and diphenylphosphinothioic chlorides[11] (**2**) were prepared by the reported methods.

Reaction with 1 and Lithium. A mixture of 1.83 g (7.7 mmol) of **1** and 70 mg (10 mg-atom) of lithium metal in 5 ml of THF was heated for 24 hr at 150 °C. The reaction mixture was poured into water and extracted with chloroform. After removal of the solvent from the dried extracts, ether was added to the residue. From the solution, **3** (0.457 g, 29%) was obtained (identified by IR and NMR). The insoluble part was purified by dry column chromatography (DCC) on an alumina column with acetone to give 49 mg (3%) of **4**, which was identified by IR,[9] and a small amount of **5**, which was difficult to purify. IR (neat): 3300 (br), 1185, and 1120 cm^{-1}; NMR ($CDCl_3$): δ 1.3—1.8(m), 1.8—2.7(m), 3.2—3.8(m), and 7.2—8.0(m).

Reaction with 2 and Lithium. A mixture of 1.52 g (6 mmol) of **2** and 55 mg (7.9 mg-atom) of lithium metal in 5 ml of THF was allowed to react and treated similarly. Ether was added to the residue to crystallize 0.354 g (26%) of diphenylphosphinothioic anhydride[9] (by IR). The ether solution

was treated by DCC on silica gel with ethyl acetate to separate oily fractions. One of the fractions was identified with **3** (0.152 g, 13%) by IR but was difficult to purify. The other fractions were treated again by DCC with ether to give crystalline and oily materials. The crystals (**6**) were recrystallized from *n*-hexane–dichloromethane, yield 0.304 g (46%), mp 91—92 °C. NMR ($CDCl_3$): δ 1.60 (m, 4H, $2CH_2$), 2.85 (dd, J_{PSCH} 13.2, J_{HCCH} 6.6 Hz, 4H, 2-SCH_2), and 7.30—8.15 (m, 20H, 4Ph); Mass: *m/e* 554 (M^+) and 217 (Ph_2PS^+, 100%).

Found: C, 61.33; H, 5.19%. Calcd for $C_{28}H_{28}P_2S_4$: C, 60.63; H, 5.09%.

The oily product (**7**) was 0.128 g (16%) and also difficult to purify. IR (neat): 1197 (P=O), 1100 (P–Ph), 655, and 530 cm^{-1} (P=S); NMR ($CDCl_3$): δ 1.6 (m, 4H, $2CH_2$), 2.6—2.9 (m, 4H, 2-SCH_2), and 6.3—7.1 (m, 20H, 4Ph); Mass: *m/e* 538 (M^+).

*Reaction with **1** and Magnesium.* A mixture of 1.45 g (6.1 mmol) of **1** and 0.134 g (5.5 mg-atom) of magnesium in 5 ml of THF was heated under the same conditions. The reaction mixture was poured into water and neutralized with 2 M hydrochloric acid to give precipitates. The aqueous solution was extracted with chloroform. Evaporation of the dried extracts gave a considerable amount (0.70 g, 53%) of diphenylphosphinic acid, which was removed by filtration of the alcoholic solution through an alumina column. The eluate was purified by DCC on a silica gel column with ether to give crystalline material (**8**), which was recrystallized from 95% ethanol, mp 264—266 °C, yield 0.198 g (21%); IR (KBr): 1185 (P=O) and 1120 cm^{-1} (P–Ph); NMR ($CDCl_3$): δ 1.5—2.0 (m, 4H, $2CH_2$), 2.0—2.5 (m, 4H, $2CH_2$), and 7.3—8.0 (m, 20H, 4Ph); Mass: *m/e* 458 (M^+).

Found: C, 73.61; H, 5.90%. Calcd for $C_{28}H_{28}O_2P_2$: C, 73.35; H, 6.16%.

*Reaction with **2** and Magnesium.* A mixture of 1.70 g (6.7 mmol) of **2** and 0.162 g (6.7 mg-atom) of magnesium in 5 ml of THF was heated similarly. After removal of unchanged magnesium (91 mg), the reaction mixture was decomposed with 30% aqueous ammonium chloride, extracted with chloroform, and the extracts were dried with anhydrous magnesium sulfate. The concentration gave crystals. The crystalline part was subjected to DCC on silica gel with chloroform to give 0.180 g (21%) of **9** and 10 mg of **10**, which were identified by IR. A similar treatment of the filtrate gave 83 mg (6%) of diphenylphosphinic acid and 0.209 g (18%) of **11**, mp 72—73 °C (from ether); IR (KBr): 1100 (P–Ph), 1020 (C–O), 945 (P–O), 660, and 545 cm^{-1} (P=S); NMR ($CDCl_3$): δ 1.75 (m, 4H, $2CH_2$), 2.95 (m, J_{PSCH} 13.8 Hz, 2H, SCH_2), 3.95 (m, J_{POCH} 7.8 Hz, 2H, OCH_2), and 7.20—8.15 (m, 20H, 4Ph); Mass: *m/e* 538 (M^+). However, the analytically pure sample could not be obtained because it was difficult to make the separation of a trace of impurity.

*Reaction with **1** and Iron.* A mixture of 1.43 g (6.0 mmol) of **1** and 31 mg (0.56 mg-atom) of reduced iron powder in 5 ml of THF was heated similarly. The resulting precipitates (iron diphenylphosphinate) was filtered off, and the filtrate was treated by DCC with ether to give 0.414 g (22%) of **12** as oil; IR (neat): 1220 (P=O), 1135 (P–C), 1030 (C–O), and 970 cm^{-1} (P–O); NMR ($CDCl_3$): δ 1.9 (m, 4H, $2CH_2$), 3.53 (m, 2H, CH_2Cl), 4.05 (m, J_{POCH} 15.6 Hz, 2H, OCH_2), and 7.35—8.0 (m, 10H, 2Ph).

Found: C, 62.14; H, 5.80; Cl, 11.23%. Calcd for $C_{16}H_{18}O_2ClP$: C, 62.24; H, 5.83; Cl, 11.51%.

*Reaction with **2** and Iron.* A mixture of 1.67 g (6.6 mmol) of **2** and 53 mg (0.96 mg-atom) of reduced iron powder in 5 ml of THF was heated similarly. A similar treatment gave 0.575 g (27%) of **13**, bp 117 °C/0.05 mmHg, and 0.268 g (10%) of **14b**, which was difficult to purify.

13: IR (neat): 1120 (P–C), 1030 (C–O), 960 (P–O), 640, and 520 cm^{-1} (P=S); NMR ($CDCl_3$): δ 1.83 (m, 4H, $2CH_2$), 3.43 (m, 2H, CH_2Cl), 3.98 (m, J_{POCH} 8.4 Hz, 2H, OCH_2), and 7.25—8.05 (m, 10H, 2Ph).

Found: C, 59.29; H, 5.30; Cl, 11.48; S, 10.14%. Calcd for $C_{16}H_{18}ClOPS$: C, 59.17; H, 5.59; Cl, 10.91; S, 9.87%.

14b: IR (neat): 1435 (P–C), 640, and 520 cm^{-1} (P=S); NMR ($CDCl_3$): δ 1.73 (m, 8H, $4CH_2$), 3.40 (m, 6H, $3CH_2$), 4.03 (m, J_{POCH} 7.8 Hz, 2H, OCH_2), and 7.3—8.1 (m, 10H, 2Ph).

Found: C, 61.33; H, 6.51%. Calcd for $C_{20}H_{26}ClO_2PS$: C, 60.52; H, 6.56%.

*Copper and Cuprous Salts-catalyzed Reactions with **1** and **2**.* A mixture of **1** or **2** (about 6 mmol) and catalyst (about 0.5 mmol/mmol of one Cu atom) in 5 ml of THF was heated for 24 hr at 150 °C. The reaction mixture was filtered and the filtrate was treated by DCC to separate the reaction products (**12**, **13**, and **14**). The results are summarized in Table 1.

14a: oil: IR (neat); 1435 (C–P), 1215 (P=O), 1135 (P–Ph), and 995 cm^{-1} (P–O).

Found: C, 63.01; H, 7.13; Cl, 9.30%. Calcd for $C_{20}H_{26}ClO_3P$: C. 63.07; H, 6.83; Cl, 9.36%.

*Reactions with **1** and **2** in the Presence of Various Catalysts.* A mixture of **1** or **2** (about 6 mmol) and catalyst (about 0.1 mmol) in about 6.3 g of THF was heated at 120 °C for 6 hr. The reaction mixture was treated with methanol, concentrated, and determined by gas chromatography (column: H 523 on Diasolid at 210 °C). The results are summarized in Table 2.

This work was supported by a grant-in-aid from the Ministry of Education.

Hydrogenolyses of Halo-9,9′: 9′,9″-terfluorenyls with the Raney Nickel Catalyst

Masahiro MINABE and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Technology, Utsunomiya University, Ishii-cho, Utsunomiya 321-31

(Received January 14, 1975)

2,7-Di- and 2- halo-9,9′ : 9′,9″-terfluorenyls were treated with the Raney nickel catalyst to give 9,9′: 9′,9″-terfluorenyl isomers (mp 293 °C (dec) (I) and mp 257 °C (dec) (II)), fluorene (III), 9,9′-bifluorenyl (IV), halofluorene, and/or 1,2,3,4,4a,9a-hexahydrofluorene (V). The conformation around the C_9–$C_{9'}$ –$C_{9''}$ single bonds of these halo-9,9′: 9′,9″-terfluorenyls were concluded to be *s-cis, s-cis*, identical with those of the parent hydrocarbon I. These assignments were confirmed by hydrogenolyzing 9,9″-dideuterio-2,7-dihalo-9,9′ : 9′,9″-terfluorenyls. The chemical shifts of the 9- and 9″-methine protons in these haloterfluorenyls were explained in terms of the torsional conformations of the molecules.

The conformations of the two stereoisomers for 9,9′: 9′,9″-terfluorenyls (mp 293 °C (dec) (I) and mp 257 °C (dec) (II)) were proposed to be *s-cis, s-cis* and *s-cis, s-trans* respectively, based on the restriction of rotation around the C_9–$C_{9'}$–$C_{9''}$ single bonds.[1] These isomers were obtained simultaneously by the Michael reaction[2] of 9,9′-bifluorenylidene with fluorene (III) and by other reactions.[3]

I was converted into II by treatment with the Raney nickel catalyst (R-Ni), while II gave 9,9′-bifluorenyl (IV), III, and 1,2,3,4,4a,9a-hexahydrofluorene (V) under the same reaction conditions.[2] On the contrary, II was isomerized to I by a reaction with potassium permanganate, triton B, or other reagents.[4]

Halo-9,9′: 9′,9″-terfluorenyls were obtained in the absence of their stereoisomers by the Michael addition[5] of the corresponding fluorene to 9,9′-bifluorenylidene, by the reaction[5a-c] of the corresponding 9-lithiofluorene with 9-bromo-9,9′-bifluorenyl, and by other reactions.[6]

The present paper will describe the treatment of several halo-9,9′: 9′,9″-terfluorenyls with R-Ni; the experiments were undertaken in order to relate the conformations of these haloterfluorenyls to the conformation of I or II. In addition, 2- and 2,7-di-halofluorene and some related compounds were treated with R-Ni.

TABLE 1. HYDROGENOLYSES OF HALO-9, 9′: 9′, 9″-TERFLUORENYLS OVER RANEY NICKEL CATALYST

Reactant	React. condns. R-Ni g	Et_3N g	Time hr	Products (mol%) Monohaloterfluorenyl	I	II	Reactant recovered mol%

a) In addition, 2,7-difluoro-9,9′-bifluorenyl (15%) was isolated. b) 2-Fluoro-9,9′-bifluorenyl (44%) was additionally obtained. c) Further, a small amount of IV was isolated.

Results and Discussion

The 2,7-di- and 2-halo-9,9′: 9′,9″-terfluorenyls were treated with R-Ni at 60 °C in toluene under a dry atmosphere, as is shown in Table 1.

2,7-Diiodo-9,9′: 9′,9″-terfluorenyl[5d] produced I in a good yield, along with small quantities of III and V. Similarly, the 2-iodo analog[5d] afforded I as the main product, accompanied by small amounts of II, III, and V. 2′,7′-Dibromo-9,9′: 9′,9″-terfluorenyl[5a] gave 2′-bromo-9,9′: 9′,9″-terfluorenyl,[5e] I, II, 2-bromofluorene, III, and V.

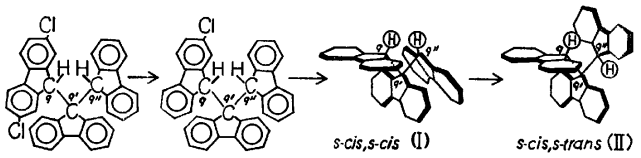
The hydrogenolysis of 2,7-dibromo-9,9′: 9′,9″-terfluorenyl[5a] yielded 2-bromo-9,9′: 9′,9″-terfluorenyl,[6] I, II, III, IV, V, and 2-bromo- and 2,7-dibromo-fluorene. The 2-bromo-9,9′: 9′,9″-terfluorenyl separated from the products was further treated with R-Ni to produce I, II, III, IV, and V. The corresponding chloro derivatives[5c] gave results similar to those of the bromo analogs.

2,7-Dichloro-9,9″-dideuterio-9,9′: 9′,9″-terfluorenyl afforded 2-chloro-9,9′ : 9′,9″-terfluorenyl, I, and II. The deuterium contents in 2,7-dichloroterfluorenyl, 2-chloroterfluorenyl, and I were of the same order: the deuterium was held at C-9 in II, but was exchanged with hydrogen at C-9″. Further, two deuterium atoms were held in I and 2-bromoterfluorenyl, which had been obtained by the treatment of 2,7-dibromo (and -iodo)-9,9″-dideuterio-9,9′: 9′,9″-terfluorenyl with R-Ni.

Accordingly, the conformations of these halo-9,9′:-9′,9″-terfluorenyls may be concluded to be identical with that of I, *i.e. s-cis, s-cis* around the central $C_{9-9'-9''}$ single bonds.

Thus, the hydrogenolysis of the aromatic carbon-halogen bonds in 2,7-dihalo-9,9′: 9′,9″-terfluorenyls occurs to form I without affecting the conformation at C-9 and C-9″ over R-Ni. For example, the reaction of 2,7-dichloro-9,9′: 9′,9″-terfluorenyl with R-Ni proceeds *via* 2-chloro-9,9′: 9′,9″-terfluorenyl to give I, which then isomerizes to II with an inversion of the conformation,[1] as is shown in Scheme 1. Small amounts of III, IV,

2,7-dichloro-, and 2-chloro-fluorene are formed by the reductive cleavage of the central $C_{9-9'}$ and/or $C_{9'-9''}$ bonds of terfluorenyls, and III is reduced to V.[2]



Scheme 1.

In general, in the dehalogenation of organic compounds by catalytic hydrogenation, the order of reactivity is: iodine>bromine>chlorine. The halide ions thus formed inhibit the halogen-hydrogen exchange.[7] In the hydrogenolysis of iodo derivatives, the further reaction of the I thus formed seems to be inhibited by the poisoning action of the iodine ion produced. On the other hand, the isomerization of I to II may follow the hydrogenolysis in the cases of chloro and bromo derivatives.

2,7-Difluoro-9,9': 9',9''-terfluorenyl[5b] gave I, 2,7-difluoro-9,9'-bifluorenyl (15% yield), 2,7-difluorofluorene, III, and V. Further, 2-fluoro-9,9': 9',9''-terfluorenyl[5b] afforded 2-fluoro-9,9'-bifluorenyl (44% yield), I, II, 2-fluorofluorene, III, and V by the same treatment.

The formations of 2,7-di- and 2-fluoro-9,9'-bifluorenyl indicate more resistance of the carbon-fluorine bond toward the hydrogenolysis, which may be attributed to the lesser polarizability of the carbon-fluorine bond and to its relatively weak affinity for the catalyst. The conformations of both fluoro-9,9': 9',9''-terfluorenyls can be identified as *s-cis*, *s-cis*, by analogy with other halo derivatives.

The hydrogenolysis of IV gave III and V, and 9,9'-bifluorenylidene yielded III, IV, and V.[8] 2,7-Di- and 2-halofluorene were treated with R-Ni to give III and V, as Table 2 shows. The tendency of these hydrogenations is similar to that of halo-9,9': 9',9''-terfluorenyls.

TABLE 2. HYDROGENOLYSES OF HALOFLUORENES WITH RANEY NICKEL CATALYST

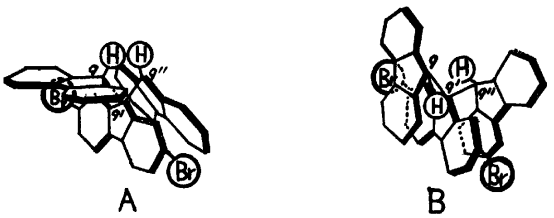
2-Cl-	5.22	5.26
2-Br-	5.20	5.26
2-I-	5.16	5.25

Table 3 shows the chemical shifts of the 9- and 9''-methine protons in halo-9,9': 9',9''-terfluorenyls.

The conformations of these halo-9,9': 9',9''-terfluorenyls are presumed to be *s-cis*, *s-cis* forms at the ground state, by analogy with the parent hydrocarbon, I.[1,2] However, the actual halomolecules are torsional conformers about the $C_{9-9'}$ and $C_{9'-9''}$ sp^3-sp^3 bonds, so that the 9- and 9''-fluorenyl rings are both twisted out from the 9'-fluorenylidene plane to release the strain within the range of the restricted degree, in the same way as with *o,o'*-substituted biphenyl. For example, *s-cis*, *s-cis*-2',7'-dibromo-9,9': 9',9''-terfluorenyl (A) may be sketched as (B) in Scheme 2.



Scheme 2.

In addition, the equal torsion of each 9- and 9''-fluorenyl plane with respect to the central dibromo-9'-fluorenylidene may be more increased than in the case of I as a result of the greater steric repulsion by the bulky dibromo-9'-fluorenylidene group. Thus, two 9- and 9''-methine protons in 2',7'-dibromoterfluorenyl are located in the shielding zone of the π electron cloud on the central 9'-fluorenylidene ring, which shifts the signal to a higher field (5.14 ppm).

However, the 9- and 9''-methine proton should be oriented differently in 2-halo- and 2,7-dihalo-9,9': 9',9''-terfluorenyls because of the different degrees of torsional and repulsive effects of the 9- and 9''-fluorenyl groups with respect to the central 9'-fluorenylidene ring. The spatial situation of the 2,7-dibromo-9-fluorenyl plane with regard to 9'-fluorenylidene in 2,7-dibromoterfluorenyl may be similar to that of the 2',7'-dibromo analog: therefore, the 9-methine proton on the 2,7-dibromo derivative appears at 5.14 ppm. At the 9''-fluorenyl group in 2,7-dibromoterfluorenyl, the degree of twisting and repulsion is probably less than that of the 2',7'-dibromo system. Thus, the 9''-methine proton

signal is observed between those of the 9-methine protons of the 2,7-dibromo system and I.

Experimental

All the melting points are uncorrected. The compounds were confirmed by mixed-melting-point determinations and by a comparison of their IR spectra with those of authentic samples.

The melting points of the deuterio-compounds in this series are identical with those of the parent compounds.

The gc analyses were run with a JGC-1100FP gas chromatograph (Japan Electron Optics Lab. Co., Ltd.), using a 1 m Sus-27 column containing 3% Silicone DC QF-1 on Chromosorb WAW (60—80 mesh). Nitrogen gas, used as a carrier, was made to flow through at an inlet pressure of 1.0 kg/cm^2; the injector and detector temperatures were maintained at 290 and 265 °C respectively. The column temperature was 95 °C (for III and fluorofluorene), 125 °C (for chloro-derivatives), and 140 °C (for bromo- and iodo-analogies). The content of each component was calculated from the average value of five chromatograms.

The IR spectra were obtained as KBr pellets (4000—400 cm^{-1}) or as suspensions in hexachlorobutadiene (3000—2800 cm^{-1}) using a IR-G spectrophotometer (Japan Spectroscopic Co., Ltd.).

The mass spectra were recorded on a RMU-6E apparatus (Hitachi, Ltd.) by means of the direct-inlet system. The chamber voltage, total emission, and target current were maintained at 80 V, 80 μA, and 23 μA respectively. The sample was evaporated at 170 °C. The number of the deuterium in the compounds was calculated from the average value of five spectra.

The NMR spectra were measured by means of a JNM-C60-HL spectrometer (JEOL) in benzene-d_6, using TMS as the internal reference.

Treatment of 2,7-Dibromo-9,9′: 9′,9″-terfluorenyl with R-Ni. Typical Procedure: A solution of 2.00 g (3 mmol) of 2,7-dibromo-9,9′: 9′,9″-terfluorenyl and 0.6 g of triethylamine in 110 ml of toluene was stirred with 10 g of R-Ni (W-4) at 60 °C for 1.5 hr. The reaction mixture was then filtered, and the catalyst was extracted with four 40-ml portions of toluene. All the toluene solution was then evaporated under reduced pressure. The residue was extracted with a 30-ml portion of boiling ethanol: the insoluble parts were recrystallized from ethyl acetate to give 0.46 g (31%) of I (mp 291—293 °C (dec)), 0.89 g of 2-bromo-9,9′: 9′,9″-terfluorenyl (mp 252—253 °C (dec)), and 0.07 g (4%) of the starting material (mp 286—287 °C (dec)).

Upon standing, the alcohol extract gave 0.06 g (total 0.95 g, 55%) of 2-bromo-9,9′: 9′,9″-terfluorenyl (mp 252—254 °C (dec)). The mother liquor was evaporated to dryness, and the residue was sublimed *in vacuo* at 180 °C. The sublimate (0.01 g) proved by means of gas chromatography to be a mixture of V (*ca.* 2.6 mg), III (*ca.* 5.7 mg), 2-bromo- (*ca.* 0.8 mg), and 2,7-dibromo-fluorene (*ca.* 0.9 mg).

Hydrogenolyses of 9,9′-Bifluorenyl (IV) and 9,9′-Bifluorenylidene. A solution of 1.32 g (4 mmol) of IV and 0.3 g of triethylamine in 110 ml of toluene was refluxed with 10.0 g of R-Ni for 3 hr.

Upon treatment in a manner similar to that described above, the residue was recrystallized from 50 ml of ethyl acetate to afford 0.69 g of IV (mp 242—243 °C). The mother liquor was evaporated to dryness, and the residue was extracted with petroleum ether. The insoluble parts yielded IV (0.02 g; total 0.71 g, 54%); mp 242—244 °C. The extract was analyzed by means of gc; the presence of 0.17 g (13%) of III and 0.33 g (24%) of V was thus confirmed.

9,9′-Bifluorenylidene (1.32 g, 4 mmol) was submitted in the same way as above: 0.85 g (64%) of IV, 0.10 g (7%) of III, and 0.35 g (25%) of V were obtained.

Hydrogenolyses of Halofluorenes. A solution of 2.5 mmol of the substrate in 15 ml of toluene was refluxed with 2.0 g of R-Ni. After each time interval, a small amount of the reaction mixture was taken out and the supernatant was examined by means of gc.

Synthesis of 2-Bromo-9,9″-dideuterio-9,9′: 9′,9″-terfluorenyl. Typical Procedure: 2-Bromo-9,9-dideuteriofluorene was prepared in a 93% yield by the method of Cram and Kollmeyer.[9] The extent of deuterium incorporation was 97%, as determined by means of the NMR spectrum.

A solution of 1.64 g of 9,9′-bifluorenylidene, 1.35 g of 2-bromo-9,9-dideuteriofluorene, and a 1-ml portion of D_2O containing 0.3 g of sodium carbonate in 14 ml of dry pyridine was placed in a sealed tube and heated at 97—100 °C for 50 hr. Upon an usual treatment,[5a] the reaction mixture afforded 0.82 g (44% yield) of 2-bromo-9,9″-dideuterio-9,9′: 9′,9″-terfluorenyl. The deuterium incorporation was calculated by means of the mass spectrum to be as follows: d_0, 1%; d_1, 12%; d_2, 87%.

Treatments of 2,7-Dihalo-9,9″-dideuterio-9,9′: 9′,9″-terfluorenyls with R-Ni. Some deuterio-compounds were treated with R-Ni in a manner analogous to those used for the parent haloterfluorenyls. The deuterium contents of the substrates and products were determined by means of the mass spectra to be as follows:

a): 2,7-Dichloro-9,9′: 9′,9″-terfluorenyl (d_0, 1%; d_1, 12%; d_2, 87%) gave a 2-chloro analog (d_0, 1%; d_1, 12%; d_2, 87%), I (d_0, 2%; d_1, 13%; d_2, 85%), and II (d_0, 12%; d_1, 88%; d_2, 0%).

b): 2,7-Dibromo derivative (d_0, 0%; d_1, 13%; d_2, 87%) yielded 2-bromo-9,9′: 9′,9″-terfluorenyl (d_0, 0%; d_1, 14%; d_2, 86%) and I (d_0, 0%; d_1, 18%; d_2, 82%).

c): I (d_0, 0%; d_1, 22%; d_2, 78%) was obtained from 2,7-diiodo-9,9′: 9′,9″-terfluorenyl (d_0, 1%; d_1, 22%; d_2, 77%).

The Facile Syntheses of Aldehydes and Aldehydic Acids from Carboxylic Acid Anhydrides Using Disodium Tetracarbonylferrate (—II)

Yoshihisa WATANABE, Masakazu YAMASHITA, Take-aki MITSUDO, Mineo IGAMI, and Yoshinobu TAKEGAMI

(Received February 6, 1975)

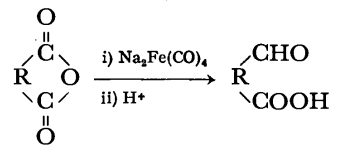
Disodium tetracarbonylferrate reacts readily with aliphatic and aromatic carboxylic acid anhydrides under mild conditions; the corresponding aldehydes are formed in high yields by quenching the reaction solution with acetic acid. Intermolecular anhydrides give aldehydes and acids, and intramolecular ones give aldehydic acids. The reaction mechanism *via* acylcarbonylferrates is assumed.

Disodium tetracarbonylferrate has been shown to be an inexpensive, versatile and selective reagent converting alkyl halides, tosylates, and acid halides into aldehydes, carboxylic acid derivatives, and ketones in high yields.[1-4] On the other hand, though aldehydes are known to be derived from various carboxylic acid derivatives such as acid chlorides, imide chlorides, thioesters, hydrazides, and nitriles,[5] there have been only a few reports describing the reduction of carboxylic acid anhydrides to aldehydes.[6,7] These reactions can be applied mainly to aliphatic acid anhydrides and are of no practical use because of the low yields of the products or of their prolonged reaction times. We now report the facile syntheses of aldehydes and aldehydic acids from carboxylic acid anhydrides in good yields using the ferrate. The preliminary report of this work was published elsewhere.[8]

Results and Discussion

Carboxylic acid anhydrides react readily with disodium tetracarbonylferrate [I] in dry tetrahydrofuran (THF) at room temperature under argon atmosphere to give reduced products, *i.e.* aldehydes or aldehydic acid, after quenching the reaction mixture with acetic acid. Intermolecular acid anhydrides give aldehydes and acids, and intramolecular ones give aldehydic acids in excellent yields.

$$(RCO)_2O \xrightarrow[\text{ii) } H^+]{\text{i) } Na_2Fe(CO)_4} RCHO + RCOOH$$



The reaction is completed in less than 20 minutes with a color change from pale yellow to dark red. The results of this reaction are shown in Table 1. This reaction can be applied to a wide variety of anhydrides, not only to aliphatic but also to aromatic ones; α,β-unsaturated carboxylic anhydrides such as maleic anhydride were not, however, reduced to the corresponding aldehydes.

The scheme of this reaction is reasonably considered as follows. One of the carbonyl groups of the anhydride is attacked nucleophilically by the ferrate to give an acyltetracarbonylferrate [II] and carboxylate, which are protonated to aldehyde and acid, as shown in Eq. (1), by quenching the reaction mixture with acetic acid. These reactions were monitored by infrared spectra. The absorption band at 1780 cm^{-1} due to the stretching vibration of the terminal carbonyls of the ferrate[9] disappeared as soon as anhydrides were added and two new bands at 1890 cm^{-1} and 1550—1600 cm^{-1} appeared. The former is attributed to the terminal carbonyls and the latter to the acyl group of [II].[10] In addition, the bands characteristic of carboxylates appeared. At this point the absorption bands of carbonyls of the anhydrides were not observed. These results support the scheme described above.

$$(RCO)_2O + [Fe(CO)_4]^{2-} \longrightarrow [RCO\text{-}Fe(CO)_4]^- + RCOO^- \longrightarrow RCHO + RCOOH \quad (1)$$

([II])

In the reaction of mixed carboxylic anhydrides, two ways for the nucleophilic attack of the ferrate to the two carbonyl groups of the anhydride are possible and thus the formation of two different aldehydes can be expected (Eq. (2)).

Table 1. Reduction of carboxylic acid anhydride using disodium tetracarbonylferrate

No.	Anhydride	Product	Yield (%)[a]
1	Propionic	Propionaldehyde	90[b]
2	*n*-Butyric	*n*-Butyraldehyde	61[b]
3	Isobutyric	Isobutyraldehyde	41[d]
4	*n*-Valeric	*n*-Valeraldehyde	67[b]
5	*n*-Caproic	*n*-Capronaldehyde	60[b]

9	Glutaric	Glutaraldehydic acid	60[c]
10	Phthalic	Phthalaldehydic acid	61[c]
11	Tetrachlorophthalic	Tetrachlorophthal-aldehydic acid	83[c]
12	1,8-Naphthalic	1,8-Naphthaldehydic acid	75[c]

a) (mol of product/mol of anhydride) × 100. b) Yields were determined by glpc. c) Isolated yields. d) Isolated yields as 2,4-DNP.

$$R^1\text{-}CO\text{-}O\text{-}CO\text{-}R^2 \xrightarrow[\text{ii) } H^+]{\text{i) } [Fe(CO)_4]^{2-}} \begin{matrix} R^1CHO + R^2COOH \\ \text{or} \\ R^1COOH + R^2CHO \end{matrix} \quad (2)$$

Several mixed anhydrides were allowed to react with the ferrate and the structural effects of anhydrides in this reaction were investigated. To make the comparison of the effects easy, benzoic acid was employed as one of the acids used as components of the anhydride. The results obtained are listed in Table 2.

Table 2. Reaction of mixed anhydrides with disodium tetracarbonylferrate in THF[a]

No.	$R^1C(=O)O(C=O)R^2$ R^1	R^2	Ratio[b] R^1CHO	R^2CHO
13	CH_3	C_6H_5	64	36
14	CH_3CH_2	C_6H_5	44	56
15	$(CH_3)_2CH$	C_6H_5	30	70

20	*p*-ClC_6H_4	C_6H_5	55	45
21	*o*-$CH_3C_6H_4$	C_6H_5	21	79
22	*o*-ClC_6H_4	C_6H_5	18	82
23	*o*-$CH_3OC_6H_4$	C_6H_5	61	39
24	*o*-$CH_3OC_6H_4$	*p*-$CH_3C_6H_4$	61	39
25	*o*-$CH_3OC_6H_4$	*p*-ClC_6H_4	59	41

a) At 25 °C for 20 min. b) Total yields of aldehydes are 60—80% in all cases.

In the reaction of benzoic aliphatic carboxylic anhydride (Exps. 13—16), the proportion of aliphatic aldehydes to benzaldehyde decreases as the alkyl groups become bulky, showing that the nucleophilic attack of the ferrate appears to be sterically affected.

In the series of benzoic substituted benzoic anhydrides (Exps. 17—23), different substituents such as Cl–, CH_3–, and CH_3O– have different effects on the reaction and distribution of the products. When the substituents are located at *meta* and *para* positions, the distribution of aldehydes is affected by their electron donating-withdrawing property: that is, an electron withdrawing group, Cl-, seems to favor the formation of substituted benzaldehyde but electron-donating groups, CH_3- and CH_3O-, are unfavorable for such formation. This shows that the nucleophilic attack is affected by the electron density on the carbon of carbonyl group of the anhydrides. In the cases in which the substituents are located at an *ortho* position, the Cl- and CH_3- groups have steric hindrance effects and disturb considerably the formation of substituted benzaldehydes. But the CH_3O– group has no such effects but on the contrary promotes the formation of *o*-anisaldehyde (Exps. 23—25). The effect of *o*-CH_3O–, quite different from that of *o*-Cl and *o*-CH_3, may be due to some interaction between the methoxy group and ion-paired disodium tetracarbonylferrate.[11]

Experimental

The carboxylic acid anhydrides shown in Table 1 were all commercial products except for *p*-toluic anhydride. The other anhydrides were prepared in the usual manner from sodium carboxylates and acid chlorides in THF or in benzene. Disodium tetracarbonylferrate, $Na_2Fe(CO)_4$, was prepared according to the method described in the literature.[2] Iron pentacarbonyl was a commercial product and used without further purification.

General Procedure for the Reaction of Intermolecular Carboxylic Anhydrides with $Na_2Fe(CO)_4$. To 11 mmol of disodium tetracarbonylferrate in THF (50 ml), 11 mmol of acid anhydride in THF (10 ml) was added with stirring at room temperature under argon atmosphere. Twenty minutes later, the reaction mixture was treated with glacial acetic acid (1.2 ml) and stirred for an additional five minutes. Then it was poured into 50 ml of water and extracted with 20 ml of pentane and 20 ml of ethyl ether, and the organic extract was submitted to glpc analysis. The aldehydes were identified by comparison of the retention time of glpc with those of authentic samples and yields were determined using internal standards.

General Procedure for the Reaction of Intramolecular Carboxylic Anhydrides with $Na_2Fe(CO)_4$. In 60 ml of THF, 11 mmol of disodium tetracarbonylferrate and carboxylic acid anhydride was allowed to react according to the above procedure. After quenching with 1.2 ml of glacial acetic acid, the reaction solvent was distilled off under a reduced pressure, and the residue was extracted with 0.5 M NaOH aqueous solution (50 ml) and filtered. The filtrate was acidified and extracted with three portions of ether (70 ml). After drying over sodium sulfate, the organic layer was evaporated and the residue was purified by recrystallization or converted into 2,4-dinitrophenylhydrazone. The products were identified by NMR, IR, elemental analyses, and by comparison with literature data or with authentic samples.

The authors would like to thank Mr. Hideo Fujiwara for his assistance in experiments.

α,β-Unsaturated Carboxylic Acid Derivatives. VIII. The Synthesis and Reaction of Esters *N*-Acyl-*N*-bromo-α-dehydroamino Acid[1)]

Chung-gi SHIN, Katsumi NANJO, Takashi NISHINO, Yoshiaki SATO, and Juji YOSHIMURA*

Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

* *Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ōokayama, Meguro-ku, Tokyo 152*

(Received February 14, 1975)

The addition of bromine to *t*-butyl 2-(*N*-acylamino)-2-alkenoate (**3**) was accompanied by the elimination of hydrogen bromide and the decomposition of the ester group to give 2-(*N*-acylamino)-3-bromo-2-alkenoic acid, while the bromination of **3** with NBS gave the corresponding *N*-bromo derivative (**7**), whose bromine atom gradually migrates to give *t*-butyl 2-(*N*-acylamino)-3-bromo-2-alkenoate. The substitution of the bromine of **7** with nucleophiles gave, successively, the corresponding *N*-methoxy, *N*-benzyloxy and *N*-cyano derivatives, while that with sodium azide gave the corresponding migration products. The structures of the new compounds were assigned.

In previous papers, we reported the new syntheses of alkyl 2-(*N*-acylamino)-2-alkenoate (**3**) by the condensation of alkyl 2-oxoalkanoate with chloroacetamide[2)] or chloroacetonitrile[3)] and by the elimination of acetic acid from alkyl 2-(*O*-acetyl-*N*-acyl-hydroxyamino)alkanoate, which had itself been derived by the acetylation of alkyl 2-hydroxyaminoalkanoate (**1**) or alkyl 2-(*N*-acyl-hydroxyamino)alkanoate (**2**).[4,5)]

Because of the possible synthetic utility of the *N*-bromo derivative of **3** in the preparation of α-dehydrohydroxyamino acids, cyclic hydroxamic acids such as mycelianamide,[6)] and other similar substances, the facile synthesis of *t*-butyl 2-(*N*-bromoacetamido)-2-alkenoate (**7**) was pursued, and it was briefly communicated that the bromination of **3** with bromine or *N*-bromosuccinimide (NBS) gave 2-(*N*-acylamino)-3-bromo-2-alkenoic acids (**5**) or **7** respectively.[7)] However, no available method of synthesizing **7** or **5** has ever been reported, except for the preparation of β-halo-*sec*- and -*tert*-enamines.[8–10)]

In the present paper, we wish to report the syntheses of **5** and **7** in detail, together with the replacement of the bromine atom of **7** with nucleophiles. A few substitutions were accompanied by the rearrangement of substituents, and the structures of the products were assigned by means of IR and NMR spectroscopies.

Results and Discussion

Bromination of 1 and 3. Attempts at the addition of bromine to ethyl 2-(*N*-acylamino)-2-alkenoate (**3**; R^1=Et) in chloroform and the subsequent elimination of hydrogen bromide under several experimental conditions were unsuccessful, except for the direct conversion of **3a,c,d** (R=CH_3, R^1=*t*-Bu: **a**; X=CH_3, **c**; X=OC_2H_5, **d**; X=Phthalyliminomethyl) into 2-(*N*-acylamino)-3-bromo-2-butenoic acid (**6a,c,d**) in an about 50% yield at room temperature for 2 days. Besides, it was found that the treatment of ethyl 2-hydroxyaminobutanoate (**1e**) with bromoacetyl bromide in benzene in the absence of an alkali such as pyridine at room temperature gave ethyl 3-bromo-2-bromoacetamido-2-butenoate (**5e**) directly, though the yield was low. It was deduced that the formation of ethyl 2-bromoacetamido-2-butenoate (**3e**; R=CH_3, R^1=C_2H_5, X=CH_2Br) *via* the corresponding hydroxamic acid ester (**2e**)[5)] was followed by the addition of bromine formed oxidatively from hydrogen bromide, and by the elimination of hydrogen bromide to afford **5e**. On the other hand, the reaction of **3** with bromine proceeded similarly through the addition of bromine and the elimination of hydrogen bromide to give **5**, which was subsequently converted into **6**.

On the other hand, the treatment of *t*-butyl 2-acetamido-2-alkenoate (**3a,b**: **b**; R=C_2H_5, R^1=*t*-Bu, X=CH_3) with NBS in tetrachloromethane at room temperature for 30 min gave **7a,b** as an unstable oily product in quantitative yield. It was found that the bromine on the nitrogen atom of **7a,b** gradually migrated at room temperature for 2 days to give **5a,b** as colorless crystals in about a 70% yield. The **5a,b** compound was composed of *E*- and *Z*-isomers, which were purely separated by chromatography on a silica gel column using benzene–ethyl acetate (5: 1 V/V). However, the unambiguous assignment of the geometric configuration of the products was difficult from only the spectroscopic data listed in Table 2.

The yields, the physical constants, and the spectral data of **5** and **7** are summarized in Tables 1 and 2 respectively.

Reactions of 7 with Nucleophiles. The treatment of **7a,b** with sodium methoxide in methanol at room temperature for 2 hr afforded *t*-butyl 2-(*N*-acetyl-*O*-methyl-hydroxyamino)-2-alkenoate (**8a,b**). Moreover, in a similar manner, compound **7a,b** reacted with sodium benzyloxide in benzyl alcohol to give the expected *t*-butyl 2-(*N*-acetyl-*O*-benzyl-hydroxyamino)-2-alkenoate (**9a,b**). On the other hand, the reaction of **7a,b** with sodium cyanide in dimethyl formamide also occurred at room temperature for 2 hr to give *t*-butyl 2-(*N*-cyanoacetamido)-2-alkenoate (**10a,b**). It was found that the products obtained were more stable than **7a,b** and that the methoxy, benzyloxy, and cyano groups on the nitrogen atom do not migrate to the carbon atom in the β-position.

On the other hand, the treatment of **7a,b** with sodium azide in dimethyl formamide at room temperature for 2 hr unexpectedly gave the *t*-butyl 2-acetamido-3-azido-2-alkenoate (**12a,b**) as a colorless syrup or as needles in a good yield. In this case, the expected *N*-substituted compound (**11a,b**) could not be isolated. However,

the preparation of **12** by the reaction of **5** with sodium azide was unsuccessful. Consequently, it was deduced that the direct formation of **12** from **7** proceeded through the rearrangement reaction of the intermediate, **11a,b**.

All of the new compounds were obtained as syrups; some of them gradually crystallized in considerably good yields after purification on a silica gel column using benzene–ethyl acetate.

The structures of all the new compounds were characterized spectroscopically and gave satisfactory results in elemental analysis. From the NMR spectra, the vinyl proton signals of **7**, **8**, **9**, and **10** showed peaks in the δ 4.12—5.01 region as quartets or triplets, while the NH proton signals of **5** and **12** showed their peaks in the δ 6.86—8.35 region as broad singlets. On the other hand, the disappearance of the NH absorption band in the IR spectrum of **3** indicates the formation of **7**, while the appearance of the NH band in the region 3150—3340 cm^{-1} seems to support the formation of

5 and **12**. From either the presence or absence of the vinyl or NH proton respectively, the structures of the above compounds were confirmed.

The above rearrangement reaction, which seems to be an intramolecular anionic 1,3-shift, and the configurational assignment of the products are now under investigation.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-S2 Spectrometer. The NMR spectra were measured with a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.), using tetramethyl silane as the internal standard.

Materials. Compounds **1e** and **3a**, **b**, **c**, **d** were prepared by a method previously reported.[4]

Reaction of 3 with Bromine A solution of bromine (0.078 mol) in chloroform (20 ml) was stirred drop by drop, into a solution of *t*-butyl 2-acetamido-2-butenoate (**3a**: 0.078 mol) in chloroform (15 ml) below 0 °C. The reaction solution was then allowed to stand at room temperature for 2 days. The colorless crystals which had thus been separated out were collected and recrystallized from acetone to give colorless tablets, which were identified as 3-bromo-2-acetamido-2-butenoic acid (**6a**); yield, 58.8%; mp 150 °C (decomp). IR (KBr): 3300, 1720, 1645, 1630 cm^{-1}.

Found: C, 32.86; H, 3.60; N, 6.37%. Calcd for $C_6H_8NO_3Br$: C, 32.50; H, 3.60; N, 6.37%.

In a similar manner, the treatment of an equimolar amount of *t*-butyl 2-(*N*-ethoxycarbonylamino)-2-butenoate (**3c**) with bromine in chloroform gave 3-bromo-2-(*N*-ethoxycarbonylamino)-2-butenoic acid (**6c**) as colorless needles; those needles were recrystallized from chloroform; yield, 59.3%; mp 154—156.5 °C (decomp). IR (KBr): 3260, 1700, 1630 cm^{-1}.

Found: C, 33.58; H, 3.98; N, 5.58%. Calcd for $C_7H_{10}NO_4Br$: C, 33.35; H, 3.97; N, 5.56%.

In a similar manner, the treatment of an equimolar amount of *t*-butyl 2-(*N*-phthaloylglycylamino)-2-butenoate (**3d**) with bromine in glacial acetic acid gave a residual reddish syrup after the removal of the excess acetic acid under reduced pressure. When a small quantity of ethanol was added to the residue, crude crystals were gradually separated out. The crystals were collected and recrystallized from glacial acetic acid to give colorless needles, which were identified as 3-bromo-2-(*N*-phthaloylglycylamino)-2-butenoic acid (**6d**); yield, 37.8 %; mp 188 °C (decomp). IR (KBr): 3260, 1735, 1680, 1630 cm^{-1}.

Found: C, 45.82; H, 3.10; N, 7.68%. Calcd for $C_{14}H_{11}N_2O_5Br$: C, 45.80; H, 3.00; N, 7.63%.

Reaction of 1e with Bromoacetyl Bromide. To a solution of ethyl 2-hydroxyaminobutanoate (**1e**: 0.027 mol) in dry benzene (20 ml), we stirred bromoacetyl bromide (0.033 mol), drop by drop at room temperature. Then the reaction solution was heated at 70—80 °C for 30 min. After cooling to room temperature, the insoluble substance which had been separated out was filtered off, and the filtrate was evaporated under reduced pressure. The residual reddish oil was purified on a silica gel column using benzene–methanol (40: 1 v/v). After the removal of the solvent, the crystals which had been separated out were collected and recrystallized from di-*n*-butyl ether to give colorless needles, which were identified as ethyl 3-bromo-2-bromoacetamido-2-butenoate (**5e**); yield, 6.7%; mp 118—119 °C. IR (KBr): 3250, 1730, 1660, 1535 cm^{-1}.

Found: C, 29.60; H, 3.40; N, 4.26%. Calcd for $C_8H_{11}NO_3Br_2$: C, 29.20; H, 3.35; N, 4.26%.

Reaction of 3 with NBS. Into a solution of **3a** (0.020 mol) in tetrachloromethane (20 ml), we stirred NBS (0.021 mol), portion by portion at room temperature. After stirring for 30 min, the succinimide which had thus been separated out was filtered off, and the filtrate was evaporated under reduced pressure to give pale yellow syrup in a quantitative yield. This syrup was identified as *t*-butyl 2-(*N*-bromoacetamido)-2-2-butenoate (**7a**).

In a similar manner, *t*-butyl 2-(*N*-bromoacetamido)-2-pentenoate (**7b**) was also obtained in a quantitative yield starting from the reaction of an equimolar amount of *t*-butyl 2-acetamido-2-pentenoate (**3b**) and NBS.

Rearrangement Reaction of 7. When **7a** (0.07 mol) was allowed to stand at room temperature for 2 days, the syrup gradually crystallized to give colorless crystals, which were composed of *E*- and *Z*-isomers. The geometric isomers were separated purely by chromatography on a silica gel column using benzene–ethyl acetate (5: 1 v/v). After the removal of the solvent under reduced pressure, *t*-butyl 3-bromo-2-acetamido-2-butenoate (**5a***E* and **5a***Z*) was obtained.

In a similar manner, *t*-butyl 3-bromo-2-acetamido-2-pentenoate (**5bE** and **5bZ**) was also obtained in a pure state by starting from **7b** through the migration of bromine atom (Table 2).

Reaction of 7 with Sodium Methoxide. After treating **7a**

(0.0151 mol) with sodium methoxide (made from sodium (0.018 mol) and methanol (30 ml)), with stirring, at room temperature for 2 hr, the reaction solution was concentrated under reduced pressure. The residual yellow syrup was dissolved in benzene (30 ml), and then the solution was washed with water twice. The benzene layer was dried over anhydrous magnesium sulfate and then evaporated under reduced pressure. The residual pale yellow syrup was purified on a silica gel column using benzene–ethyl acetate (50: 1 v/v). The effluent was then condensed under reduced pressure to give a colorless syrup, which was identified as *t*-butyl 2-(*N*-acetyl-*O*-methyl-hydroxyamino)-2-butenoate (**8a**).

In a similar manner, *t*-butyl 2-(*N*-acetyl-*O*-methyl-hydroxyamino)-2-pentenoate (**8b**) was also obtained starting from the reaction of **7b** and sodium methoxide.

Reaction of 7 with Sodium Benzyloxide. After treating **7a** (0.0151 mol) with sodium benzyloxide (made from sodium (0.018 mol) and benzyl alcohol (30 ml)), with stirring, at room temperature for 2 hr, the reaction solution was concentrated under reduced pressure. The residual yellow syrup was dissolved with benzene (30 ml), and then the solution was washed with water three times. The benzene layer was dried over anhydrous magnesium sulfate and then evaporated under reduced pressure to give a pale yellow syrup, which was subsequently purified on a silica gel column using benzene–ethyl acetate (50: 1 v/v). The effluent was evaporated under reduced pressure to give a colorless syrup, which was identified as *t*-butyl 2-(*N*-acetyl-*O*-benzyl-hydroxyamino)-2-butenoate (**9a**).

In a similar manner, *t*-butyl 2-(*N*-acetyl-*O*-benzyl-hydroxyamino)-2-pentenoate (**9b**) was also obtained starting from the reaction of **7b** and sodium benzyloxide.

Reaction of 7 with Sodium Cyanide. Into a solution of **7a** (0.010 mol) in dimethyl formamide (25 ml), sodium cyanide (0.013 mol) was stirred portion by portion at room temperature. After stirring for 2 hr, the reaction solution was poured into ice water (30 ml) and then extracted with benzene three times. The benzene extracts were washed with water twice, dried over anhydrous magnesium sulfate, and finally evaporated under reduced pressure. The residual yellow syrup thus obtained gradually crystallized to give colorless crystals, which were identified as *t*-butyl 2-(*N*-cyanoacetamido)-2-butenoate (**10a**).

In a similar manner, *t*-butyl 2-(*N*-cyanoacetamido)-2-pentenoate (**10b**) was also obtained as a syrup; the syrup was subsequently purified on a silica gel column using benzene–ethyl acetate (50: 1 v/v), starting from the reaction of **7b** with sodium cyanide.

Reaction of 7 with Sodium Azide. Into a solution of **7a** (0.010 mol) in dimethyl formamide (25 ml), sodium azide (0.013 mol) was stirred portion by portion at room temperature. After stirring for 2 hr, the reaction solution was poured into ice water (30 ml) and then extracted with benzene three times. The benzene extracts were washed with water twice, dried over anhydrous magnesium sulfate, and finally evaporated to give a yellow syrup. Purification on a silica gel column using benzene–ethyl acetate (10: 1 v/v) and the evaporation of the effluent solvent under reduced pressure gave a pale yellow syrup, which gradually crystallized and which was identified as *t*-butyl 3-azido-2-acetamido-2-butenoate (**12a**).

In a similar manner, *t*-butyl 3-azido-2-acetamido-2-pentenoate (**12b**) was also obtained as a syrup, starting from the reaction of **7b** with sodium azide.

The authors are grateful to the Ministry of Education of Japan for its financial assistance.

Substituent Effect on the Anomeric Effect in 1,3,5-Trithiane Derivatives

Michinori Ōki, Toshiyuki Endo, and Tadashi Sugawara
Department of Chemistry, Faculty of Science, The University of Tokyo, Tokyo 113
(Received April 30, 1975)

Anomeric effect in a series of 2-alkylthio- and 2-arylthio-1,3,5-trithianes has been studied by PMR spectroscopy to investigate the substituent effect on the anomeric effect. A remarkable steric effect is found in 2-*t*-butylthio-1,3,5-trithiane: the equatorial conformer is slightly favored over the axial one. The electron-withdrawing substituent in 2-arylthio-1,3,5-trithiane enhanced the anomeric effect. The origin of the steric and electric-electronic effect has been discussed on the ground of conformational analysis.

Anomeric effect[1] has drawn attention of many investigators and, to date, various factors affecting the anomeric effect have been discussed. In contrast to the *A* values[2] of the methoxy (0.55) and the chloro (0.53) groups in cyclohexane series, the axial forms of the methoxy and the chloro groups in pyranose rings are favored over the equatorial form by 1.5[3] and 2.7 kcal/mol,[4] respectively. Pierson and Runquist have reported that the magnitude of the anomeric effect is linearly related with the Taft σ^* values of the substituents.[5] Thus the electric-electronic effect of the substituent is important in determining the extent of the anomeric effect. The enhanced axial preference of benzoates over the acetates of pyranosides may be taken as another example of this effect.[6]

In contrast to the large electric-electronic effect, the steric effect is considered to be of minor importance. The axial form of the 2-alkoxyoxanes is present to the extent of 0.77, 0.76, 0.75 and 0.70 in terms of molar fractions for methoxy, ethoxy, isopropoxy, and *t*-butoxy compounds, respectively.[7] The similar trend is also observed in alkyl tri-*O*-benzoyl-β-D-ribopyranosides.[8] The 2-alkylthiooxanes, where alkyl may be methyl, ethyl, isopropyl or *t*-butyl, give practically the same free energy difference for a given equatorial-axial pair irrespective of the size of the alkyl group.[9] Indeed, comparison of the electric-electronic effects for various substituents was possible by assuming little steric effect of the substituted alkyl part of various RO groups.[5]

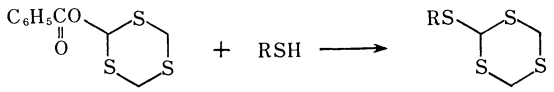
We have been interested in anomeric effect in 1,3,5-trithiane series for some time and have found that the phenylthio group exerts the stronger effect than the methylthio group: the enthalpy difference is found to be 1.3 kcal/mol in favor of the axial form for 2-phenylthio-1,3,5-trithiane in chloroform-*d*–carbon disulfide, whereas the difference is only 0.9 kcal/mol for 2-methylthio-1,3,5-trithiane.[10]

Trithiane represents a series different from those of cyclohexane and oxane. Since the bond length within the ring is one of the important factors in determining the 1,3-diaxial interaction and the steric effect exerted by the 1,3-diaxial interaction opposes the electric-electronic effect,[11] the longer C–S bond and a little flatter conformation of the trithiane ring should produce different extent of the substituent effect for a given substituent. It was felt that a systematic study would lend help in understanding the substituent effect on the anomeric effect in 1,3,5-trithianes. In addition, this kind of study may reveal the extent of the steric effect which has been neglected in the past studies.

This paper describes the results of a study on the electric-electronic effect in a series of 2-arylthio-1,3,5-trithianes and discusses the steric effect which is found in 2-*t*-butylthio-1,3,5-trithiane.

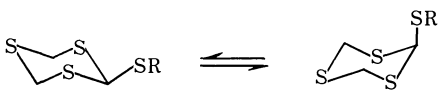
Results and Discussion

Steric Effects. It may be assumed that changing the alkyl group in 2-alkylthio-1,3,5-trithianes affects only the size of the substituent, to a good approximation, because ionization constants of alkanethiols are known to be relatively unaffected by the change of alkyl groups.[12] Thus 2-alkylthio-1,3,5-trithianes were synthesized by alkanethiolysis of 2-benzoyloxy-1,3,5-trithiane and their conformational equilibria were studied.



1: R=CH_3 **2**: R=C_2H_5
3: R=$(CH_3)_2CH$ **4**: R=$(CH_3)_3C$

PMR spectra of **1**, **2**, and **3** at room temperature show almost the same chemical shift differences, *ca.* 0.9 ppm, for the ring methylene protons (see Table 1 and Fig. 1), whereas that of **4** shows a smaller chemical shift difference. As these compounds exist as a mixture of ring-inversion isomers at room temperature, the observed chemical shift differences must be the averaged values of the individual isomers. Then almost the same chemical shift differences for compounds **1**—**3** mean that the population ratios of the equatorial and axial isomers are almost the same for these compounds, if the chemical shifts of each proton (δ_a and δ_e) are equal. The last assumption seems to be valid because the molecules are similar and the main moieties which affect the chemical shifts are equal.



Further support for the above assumption must be obtained by analyzing the population ratio in more detail. PMR spectra of these compounds at low temperatures gave two sets of signals due to ring protons and the methine proton at 2-position, respectively, as reported for the case of compound **1**.[10] These signals are assigned by taking the anisotropy effect of the C–S

Table 1. Chemical shift differences ($\Delta\delta$) between two ring methylene protons of 2-alkylthio-1,3,5-trithiane at various temperatures and equilibrium contasnts (K=a/e) in $CDCl_3$–CS_2 (1: 1 v/v)

Compound

a) Obtained by direct integration (±0.3).

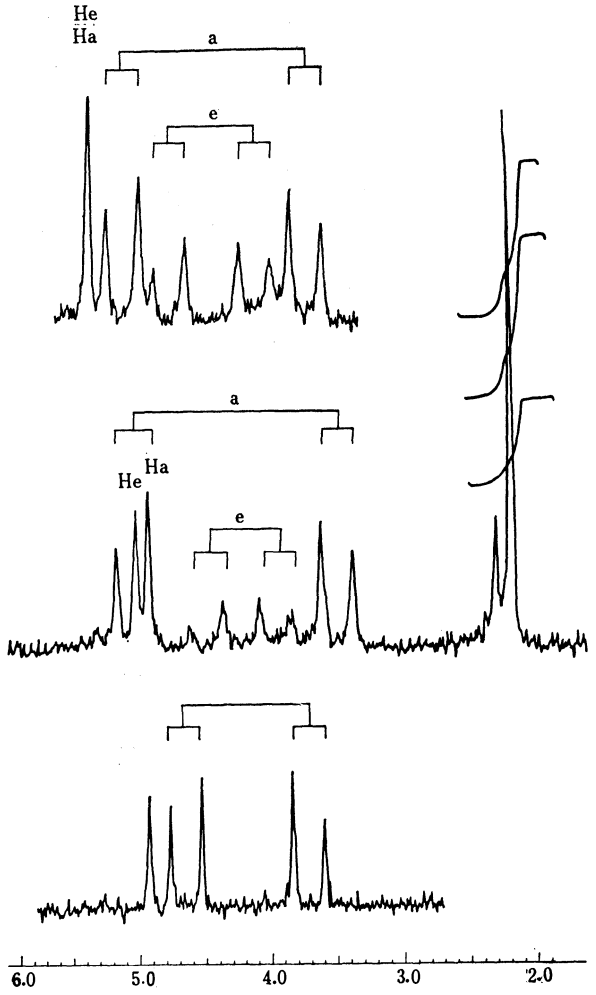

Fig. 1. PMR spectra of 2-methylthio-1,3,5-trithiane at 34 °C in $CDCl_3$–CS_2 (bottom), at −83 °C in $CDCl_3$–CS_2 (middle), and at −83 °C in $CDCl_3$–acetone-d_6 (1: 1 v/v) (top).

bond into consideration. If the C–S bond at 2-position is axially oriented, it should give the large deshielding effect to the axial protons at 4- and 6-positions. Thus the axial conformer will give a larger chemical shift difference between the equatorial and axial protons than that of 1,3,5-trithiane itself. On the other hand, the axial protons of the substituent-equatorial conformer suffer the small shielding effect from the C–S bond of the substituent to cause little change in the chemical shift difference of the AB protons from the corresponding ones in 1,3,5-trithiane.

Thus the AB protons showing the chemical shift difference of *ca.* 1.6 ppm can be assigned to the axial conformer and those with *ca.* 0.5 ppm difference to the equatorial conformer. This assignment is supported by a fact that the population of a conformer assigned to the equatorial form increases in the more polar media. Namely, the ratios of two conformers become *ca.* 1.1 in acetone-d_6 for compounds **1**—**3**, the conformer of larger chemical shift separation for the methylene being slightly favored. Compound **4** even failed to show any signals due to the conformer of larger separation of the methylene signals under the similar conditions. This solvent effect is accepted as the characteristics in anomeric equilibria and must be the result arising from the fact that the equatorial conformer is more polar than the axial.

Comparison of the peak intensities at −83 °C reveals that axial conformers are favored in the cases of **1** through **3**, whereas the equatorial conformer prevails in **4** (see Table 1). Using these chemical shifts, we may calculate the populations of the conformers at above the coalescence temperatures by the following equation.

$$\Delta\delta = N_a\Delta\delta_a + N_e\Delta\delta_e$$

where N_a and N_e are the molar fractions of axial and equatorial conformers, respectively, and $\Delta\delta$, $\Delta\delta_a$, and $\Delta\delta_e$ are the observed chemical shift difference at above the coalescence temperature, that of the axial conformer, and that of the equatorial conformer, respectively. Then the study on temperature dependence of the equilibria affords thermodynamic parameters as shown in Table 2.

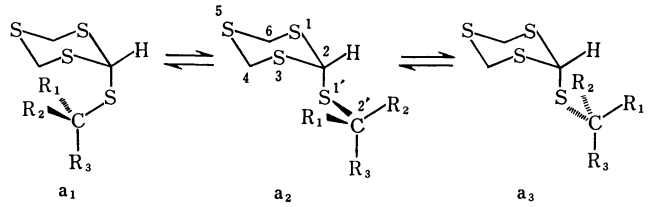
Table 2. Thermodynamic parameters for the equilibrium (a⇌e) of 2-alkylthio-1,3,5-trithiane

Compound	ΔG kcal/mol (±0.05)	ΔH kcal/mol (±0.1)	ΔS e.u. (±0.2)
1	0.44	0.9	1.5
2	0.48	1.1	2.1
3	0.46	1.3	2.8
4	−0.33	−0.12	0.6

Inspection of the data in Table 2 indicates that, while the axial conformer of **1**—**3** is more stable than the equatorial conformer by about 0.5 kcal/mol, the equatorial conformer is slightly preferred over the axial in the case of **4**. This striking contrast must be caused by combination of steric and electric-electronic effect. Although the electric-electronic effect may arise as a result of preference or rejection of one or more confor-

mers as a secondary effect, it may be considered to be almost the same for the series of compounds, to the first approximation, due to the fact that they are all 2-alkylthio-1,3,5-trithianes. Then the steric effect becomes the prime importance. We shall forcus the discussion on the steric effect and then extend to the electric-electronic effect later.

Among the axial conformers, three rotamers, a_1, a_2, and a_3, may be considered. The polarity of these compounds are equal.

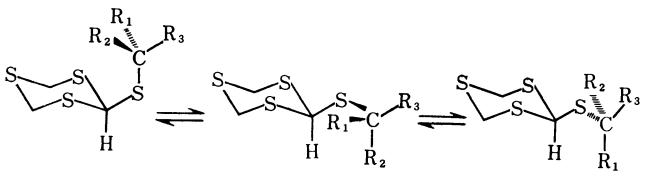


a_1 a_2 a_3

From the steric grounds, however, a_1 will be eliminated because of the severe steric effect between the *S*-alkyl group and the ring. This effect will be operative irrespective to the size of the alkyl group. In conformations of a_2 and a_3, there are two diaxial interactions if the C_2–S_1'–C_2, bonds are considered as a part of the chair ring: in a_2 conformation, C_2–S_3 and C_2'–R_1 bonds are in this relation and the relation between C_2–H and the C_2'–R_2 bonds is another case. Similarly the relation of C_2–S_1 and C_2'–R_2 bonds and that of C_2–H and C_2'–R_1 bonds are also diaxial in a_3. If the alkyl in alkylthio groups bears two hydrogens, the effect of these 1,3-diaxial interaction may be minimized by taking an appropriate conformation. Namely, the conformations a_2 and a_3 will be most stable when R_1 and R_2 are hydrogens in the case of **2**. When the alkyl group is an isopropyl, the increase in the 1,3-diaxial interaction is unavoidable. However, the severe interaction may be avoided by taking the a_2 conformation in which the C_2–H and C_2'–CH_3 bonds interact in 1,3-diaxial manner and C_2–S_3 and C_2'–H bonds interact similarly. A similar conformation is possible for a_3 also. Accordingly, it is possible for the isopropyl group in **3** to take a conformation in which repulsive force is not much higher than the corresponding methyl or ethyl compounds: in the latter two compounds also, the C–S/C–H interaction is unavoidable.

The situation of the *t*-butyl compound **4** is different from those of other alkylthio compounds. Since all the hydrogens of 2′-carbon are substituted by methyls, 1,3-diaxial interactions of the C–CH_3/C–S type become inevitable.*) The axial conformation of **4** is thus drastically destabilized as compared with other cases.

Now comparison of the energy levels of equatorial conformers becomes necessary. From the stand point of the steric effect, there seem to be some differences in the stability of the three forms, e_1, e_2, and e_3. In e_1 conformation, there are two 1,3-diaxial interactions of



e_1 e_2 e_3

the C–S/C–R type, whereas the 1,3-diaxial interactions are C–S/C–R and C–H/C–R types in e_2 and e_3. If the alkyl is either the methyl or the ethyl, the destabilization of the e_1 form due to 1,3-diaxial interaction may not become severe by taking an appropriate conformation. The e_1 form of **3** is destabilized because at least one C–S/C–C diaxial interaction is unavoidable, although this destabilization may be lessened by rotating the isopropyl group about the S_1'–C_2 bond. On the other hand, the e_1 conformation of **4** is definitely unstable due to the presence of two C–S/C–C diaxial interactions. e_2 and e_3 conformations of **1**, **2**, and **3** are neither specially stabilized nor destabilized on the steric ground, if they are compared with another conformation e_1, because they will have only C–S/C–H and C–H/C–H interactions in **1** and **2** or C–H/C–C and C–S/C–H interactions in **3** in favorable conformations. The e_2 and e_3 conformations of **4** involve C–S/C–C and C–H/C–C interactions which are less severe than the 1,3-interactions in the e_1 form.

On the electric grounds, e_1 form is most favored because the dipole formed by the substituent partly compensates that of the ring, whereas in the other forms (e_2 and e_3), the dipole made by the substituent is nearly parallel to that of the ring. At the same time, both lone pairs of electrons on the sulfur atom of the substituent are anti-parallel to the C–S bonds of the ring in e_1 conformation. This conformation is favorable for stabilization by the resonance effect.[11d]

Summarizing the steric effect and the electric-electronic effect of the equatorial forms, we may conclude that the e_1 form predominates in compounds **1**—**3**,**) whereas e_2 and e_3 forms predominate in compound **4**. Then the discussion on the stability of axial and equatorial conformers is reduced to comparison of stabilities of $a_2(a_3)$ and e_1 in the cases of **1**—**3**, whereas it is comparison of the stabilities of $a_2(a_3)$ and $e_2(e_3)$ in the case of **4**.

In the a_2 and a_3 conformations of **1** and **2**, the 1,3-diaxial interactions are C–H/C–S and C–H/C–H types, whereas those are two C–H/C–S types in e_1 conforma-

* The methyl axial-conformation is less stable than the methyl-equatorial conformation by 2.4 kcal/mol in the 1,3,5-trithiane system, as studied by equilibration of *cis* and *trans* forms of 2,4,6-trimethyl-1,3,5-trithiane. M. Fukunaga, Ph. D. thesis, The University of Tokyo, 1972.

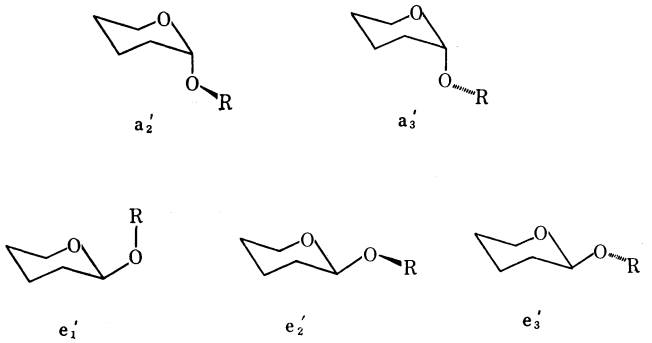
** This assumption is supported by a fact that the chemical shift of the axial 2-proton in these compounds is in a higher field than that of the equatorial. This phenomenon is contrary to the general consideration of the C–S bond anisotropy and has been attributed to the anisotropy effect of the C–S bond of the substituent in conformation e_1.[10] Similar situation occurs in 1,3-dioxane series also. The results of NOE experiment on *r*-2-methoxy-*t*-4,*t*-6-dimethyl-1,3-dioxane have been interpreted by assuming a conformation in which the methyl group in the methoxy lies nearly above the methine proton at 2-position, whereas the methoxy-methyl group of *r*-2-methoxy-*c*-4,*c*-6-dimethyl-1,3-dioxane seems to be away from the methine proton.[13]

tions of **1** and **2**. Thus a_2 and a_3 conformations of **1** and **2** are slightly favored over the e_1 form from the stand point of the steric effect in addition to the electric and electronic effects which are discussed frequently in explaining the anomeric effect. In the isopropyl compound **3**, a_2 and a_3 forms possess 1,3-interactions of C–H/C–S and C–H/C–C types, whereas e_1 has C–H/C–S and C–C/C–S types. Thus the steric effect favors the axial form in this compound. Combination of these steric, electric, and electronic factors seems to result the observed near coincidence of the difference in the stabilities of the equatorial and axial conformations.

e_2 and e_3 forms of compound **4** are disfavored from the stand point of the electric and the electronic factors and they have the steric effect due to the presence of C–C/C–S and C–H/C–C interactions. On the other hand, a_2 and a_3 forms have the same 1,3-diaxial interactions of C–S/C–C and C–H/C–C types with the e_2 and e_3 forms, although they are favored from the electric and electronic effects. The observed result that the equatorial form is more stable than the axial by about 0.12 kcal/mol may indicate that the contribution of the electronic and electric effect is considered to amount about this magnitude.

The results presented above make the striking contrast to the anomeric effect in the oxane series in a sense that the bulkiness of the alkoxy group has little effect on the distribution of the anomers.[7-9] This contrast may be attributed to the presence of heteroatoms on both sides of the electronegative substituent for the following reasons.

Since only one oxygen atom is present in the ring of oxane, the direction of dipole of the ring is not axial to the ring but is tilted. On electric grounds, this segregates two stable rotamers in oxane series, which are equivalent in trithianes. The energy levels of a_2' and a_3' of 2-alkoxyoxanes are different because two dipoles spearheaded by oxygens in a_3' are almost anti-parallel whereas those in a_2' have a definite value. Indeed, the calculated dipole moment and the observed are compared to draw a conclusion that the conformation of 2-alkoxyoxane can be taken as a_3' to the first approximation.[14]

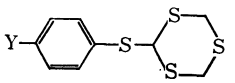


Likewise, the conformation e_2' can be taken unstable. The equatorial form can be considered to be a mixture of e_1' and e_3' from the electric factor. Since the steric factor is unfavorable in e_1', however, the e_3' form will prevail in the equatorial conformations to the first approximation.

Quantum mechanical calculation has been carried out for the conformations of methanediol as a model for the anomeric center in the pyranose.[15] The results indicate that the axial conformer has a sharp minimum at a_3' form, whereas the equatorial has two equivalent minima corresponding to conformations e_2' and e_3' with somewhat lessened O_1–C_2–O_{sub}–C_{sub} dihedral angle of 35°. This calculation is consistent with the consideration of molecular dipoles presented above.

We may now compare the stabilities of a_3' and e_3' of 2-*t*-butoxyoxane. Since there are 1,3-diaxial interactions of C–H/C–C and C–O/C–C types in both forms, the steric factor is almost equal. This will make the electric-electronic factor important to cause the preference of the axial form. The preference of the axial forms to the similar degree in *t*-butoxyoxane, compared with other alkoxyoxanes, is not surprising, because the steric factors in axial a_3' and equatorial e_3' forms of these compounds can be similar also.

Electric and Electronic Effects. The electric and electronic factors may be varied, by the introduction of various arylthio groups, without significant alteration of the steric effect. Thus a series of 2-arylthio-1,3,5-trithianes have been prepared by arenethiolysis of 2-benzoyloxy-1,3,5-trithiane.



5: X=OCH_3 **6**: X=H
7: X=Cl **8**: X=NO_2

The equilibrium constants and thermodynamic parameters were obtained as described earlier and are tabulated in Tables 3 and 4.

The results indicate that the higher is the electronegativity of the *para*-substituent, the more the axial conformer is preferred. When the free energy differences between the axial and the equatorial conformers of each compound were divided into enthalpy and entropy terms (Table 4), it has become clear that the tendency in the conformational equilibria is the result of enthalpy

Table 3. Chemical shift differences ($\Delta\delta$) between two ring methylene protons of 2-arylthio-1,3,5-trithiane at various temperatures and equilibrium constants (K=a/e) in $CDCl_3$–CS_2 (1: 1 v/v)

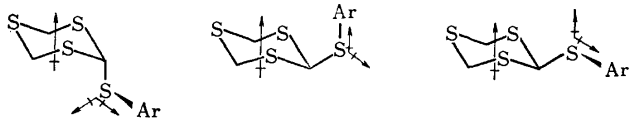
8	0.61	1.5	2.8

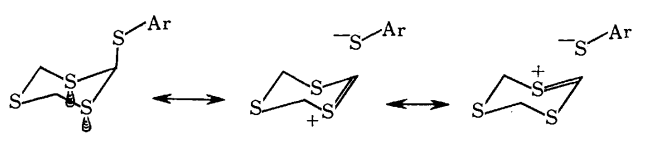
change rather than the entropy change. This result is the affirmation for the significance of the electric and electronic factors on the anomeric effect in this series.

Interpretation of the observed tendency from the stand point of the dipole-dipole interaction involves some obscureness. Estimation of the contribution of the aryl group to the dipole moment of the whole molecule is rather complicated. Putting an electronegative aryl group instead of an alkyl in the substituent of the axial form will increase the component of the dipole which is anti-parallel to the component of the trithiane ring. Thus the axial conformations seem to be stabilized more in arylthio compounds with electronegative substituents. On the other hand, in e_1 conformation of arylthiotrithianes with electronegative substituents, the dipole moment of the molecule will increase to some extent, whereas those of e_2 and e_3 conformations will decrease. Thus populations of e_2 and e_3 forms increase. These factors make it difficult to estimate the electric factor quantitatively. Although the discussion given above tends to favor the axial forms to enhance the anomeric effect, separation of the electric effect from the electronic is not possible at present.



a_2 e_1 e_2

The observed results seem to be interpreted best by consideration of the resonance effect. As the electronegativity increases, the polarity of the C_2-S_1′ increases to facilitate the donation of the lone pair electrons on sulfur atoms (S_1 and S_3). In valence bond description, hydrids of ionic structures (9b and 9c) can be



9a 9b 9c

considered in an axial conformer, because orbitals of lone pair electrons of the ring sulfur and that of the C_2-S_1′ bond are anti-parallel. The contribution of 9b and 9c becomes larger as the electronegativity of the aryl group increases, thus stabilizing the axial form. The anomeric effect becomes stronger in these cases. pK_a values of arenethiols are in accord with the consideration: pK_a's of *para*-substituted benzenethiols, as measured in 20% water-ethanol at 20 °C are *p*-methoxy 7.06, hydrogen 6.81, and *p*-chloro 6.53.[16] pK_a of *p*-nitrobenzenethiol has been measured in methanol as 8.4 when that of benzenethiol was 10.9.[17]

Hoffmann and coworkers proposed MO interpretation of the anomeric effect.[11c] According to the theory, the interaction takes place between the low-lying antibonding orbital of a polar bond and p-type orbital of the hetero atom to lower the latter level. Consequently the total energy of the molecule is lowered. This type of interaction occurs to a greater extent if the antibonding orbital is lower and the substituent is axial. The high electronegativity corresponds to the low antibonding orbital and the axial substituent means the better overlap of the orbitals concerned. The results presented here, therefore, give an experimental support to the MO interpretation.

Experimental

PMR Measurement. The PMR spectra were recorded on a Hitachi R 20B spectrometer equipped with a temperature variation accessory. Temperature was read by the chemical shift difference of methyl and hydroxy protons of methanol at the low temperature and those of ethylene glycol at room temperature or above.

Solvents. As the polarity of solvents was found to have a critical influence upon the anomeric equilibria, the solvent for measurements was picked up from a stock mixture of solvents ($CDCl_3$–CS_2 1: 1 v/v) in order to unify experimental conditions.

2-Methylthio-1,3,5-trithiane (1), mp 94—95 °C, was prepared from 2-benzoyloxy-1,3,5-trithiane and methanethiol as reported previously.[10]

2-Ethylthio-1,3,5-trithiane (2). A solution of 2 g (9 mmol) of 2-benzoyloxy-1,3,5-trithiane and 2 g (32 mmol) of ethanethiol in 30 ml of chloroform was heated for 3 hr in a reaction vessel equipped with a dry ice condenser. Benzoic acid produced during the reaction was removed by passing the solution through a potassium carbonate layer and the solvent was evaporated to give crude products (95%). This was purified by chromatography on neutral alumina. Elution with hexane–benzene (1: 1) afforded the desired product, mp 47—48 °C. Found: C, 30.56; H, 5.36; S, 64.27%. Calcd for $C_5H_{10}S_4$: C, 30.27; H, 5.08; S, 64.65%. PMR ($CDCl_3$, δ): 1.30 (t, 3H), 2.66 (q, 2H), 3.67 and 4.68 (q, J=14 Hz, 4H), 5.00 (s, 1H).

2-Isopropylthio-1,3,5-trithiane (3), mp 52—53 °C, was prepared from 2-benzoyloxy-1,3,5-trithiane and 2-propanethiol as described above. The crude product was purified by chromatography. Found: C, 34.18; H, 5.96; S, 60.15%. Calcd for $C_6H_{12}S_4$: C, 33.93; H, 5.70; S, 60.38%. PMR ($CDCl_3$, δ): 1.41 (d, 6H), 3.05 (sep, 1H), 3.69 and 4.70 (q, J=14 Hz, 4H), 5.04 (s, 1H).

2-t-Butylthio-1,3,5-trithiane (4), mp 94—95 °C, was prepared from 2-benzoyloxy-1,3,5-trithiane and 2-methyl-2-propanethiol. The crude product was purified by chromatography. Found: C, 37.21; H, 6.19%. Calcd for $C_7H_{14}S_4$: C, 37.13; H, 6.23%. PMR ($CDCl_3$, δ): 1.44 (s, 9H), 4.16 and 4.34 (q, J=14 Hz, 4H), 5.07 (s, 1H).

2-(p-Methoxyphenylthio)-1,3,5-trithiane (5), mp 129—131 °C, was prepared from 2-benzoyloxy-1,3,5-trithiane and *p*-methoxybenzenethiol.[18] The crude product was purified by chromatography. Found: C, 43.65; H, 4.28; S, 45.94%.

Calcd for $C_{10}H_{12}OS_4$: C, 43.45; H, 4.38; S, 46.39%. PMR ($CDCl_3$, δ): 3.80 (s, 3H), 3.82 and 4.68 (q, $J=14$ Hz, 4H) 5.18 (s, 1H), 6.83 and 7.50 (q, $J=8.4$ Hz, 4H).

2-Phenylthio-1,3,5-trithiane (6), mp 123.0—123.5 °C, was prepared from 2-benzoyloxy-1,3,5-trithiane and benzenethiol as reported previously.[10]

2-(p-Chlorophenylthio)-1,3,5-trithiane (7), mp 126—129 °C, was prepared from 2-benzoyloxy-1,3,5-trithiane and *p*-chlorobenzenethiol[18] and the desired product crystallized on standing. The product was purified by recrystallization from benzene. Found: C, 38.63; H, 3.15; Cl, 12.82; S, 45.44%. Calcd for $C_9H_9ClS_4$: C, 38.49; H, 2.23; Cl, 12.62; S, 45.66%. PMR ($CDCl_3$, δ): 3.83 and 4.72 (q, $J=14$ Hz, 4H), 5.31 (s, 1H), 7.33 and 7.45 (q, $J=9$ Hz, 4H).

2-(p-Nitrophenylthio)-1,3,5-trithiane (8), mp 174—175 °C, was prepared from 2-benzoyloxy-1,3,5-trithiane and *p*-nitrobenzenethiol[19] and the desired product crystallized on standing. The product was purified by recrystallization from benzene. Found: C, 37.25; H, 3.01; N, 4.74; S, 44.05%. Calcd for $C_9H_9NO_2S_4$: C, 37.00; H, 3.11; N, 4.81; S, 44.01%. PMR ($CDCl_3$, δ): 3.82 and 4.66 (q, $J=14$ Hz, 4H), 5.50 (s, 1H), 7.55 and 8.16 (q, $J=8.4$ Hz, 4H).

Chemical Studies on Tuberactinomycin. IX.[1] Nuclear Magnetic Resonance Studies on Tuberactinomycins and Tuberactinamine N[2]

Tateaki WAKAMIYA and Tetsuo SHIBA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received May 12, 1975)

Conformational analyses of peptide antibiotics tuberactinomycins were performed by NMR spectroscopy of 100 MHz. Studies on temperature dependence and deuterium exchange in amide proton resonances revealed the presence of an intramolecular hydrogen bond participated with α-amide proton of the guanidino amino acid residue in the cyclic part of each molecule. The same result was obtained in tuberactinamine N, which is the cyclopeptide moiety without amino acid side chain in tuberactinomycins N and O. The common rigid structure fixed by hydrogen bonding in the cyclic part seems to be a requisite for the exhibition of microbial activity in tuberactinomycin family.

The total chemical structures of antituberculous peptides tuberactinomycins A, B, N, and O, which were isolated from *Streptomyces griseoverticillatus* var. *tuberacticus*, were determined in our previous investigations as shown in Fig. 1.[3-8] The steric structure of tuberactinomycin O, one of the four congeners, was established by means of X-ray analysis.[4] Subsequently, Bycroft *et al.* studied on X-ray analysis of viomycin (tuberactinomycin B), applying our informations on tuberactinomycin O that the monohydrochloride-dihydrobromide of the antibiotic is adequate to crystallographic investigation.[9] From these studies, the presence of an intramolecular hydrogen bond between the α-amide proton of the guanidino amino acid residue, *i.e.*, capreomycidine (Cpd) or tuberactidine (Tbd), and the carbonyl oxygen of the serine residue (Ser(1)) neighboring the diaminopropionic acid (Dpr) residue was found in tuberactinomycin O and viomycin. This intramolecular hydrogen bond seems to be very important from the viewpoint of a relationship between the conformations of tuberactinomycins and their antimicrobial activities.

Fig. 1. Chemical structures of tuberactinomycins and tuberactinamine N.

For studies on the structure of cyclic peptide, particularly related to the intramolecular hydrogen bond, NMR is known to be highly informational. In fact, many NMR studies on biologically active cyclopeptides, *e.g.*, gramicidin S,[10] oxytocin,[11] lysine vasopressin,[11d-e,12] and stendomycin,[13] have been reported. In the present investigation, the steric conformations of four tuberactinomycins in solutions were analyzed by their NMR spectra of 100 MHz. Furthermore, we recently succeeded in isolating a cyclic peptide moiety called tuberactinamine N (Fig. 1) common to molecules of tuberactinomycins N and O by selective liberation of γ-hydroxy-β-lysine residue from tuberactinomycin N with acid treatment.[1] Tuberactinamine N was found to possess comparable antibacterial activities to those of the mother molecule against several strains of tubercule bacilli.[1] NMR study on four tuberactinomycins and one tuberactinamine indicated clearly the presence of the same intramolecular hydrogen bond in all compounds.

From the results these conformational analyses in solutions referring to the crystal structures of tuberactinomycins O and B, we assumed that the conformation of the cyclic peptide, particularly the presence of the intramolecular hydrogen bond in the cyclic part, may reflect to the biological activities of those antibiotics as a requisite.

Experimental

Spectra were recorded on a Varian Associates XL-100-15 spectrometer equipped with a Varian VFT-100 (620/L) computer. Sample solutions were measured in tubes of 5 mm o.d. and the temperature was normally kept at 37 °C. The spectra were taken with internal H^2 lock method, thus in the case of H_2O solution 20% of DMSO-d_6 being added. Chemical shifts were obtained by δ value (ppm) from DSS in aqueous media and from TMS in DMSO-d_6 solution. Proton double resonances were carried out with frequency-sweep decouplings.

Materials. The samples of tuberactinomycins A, N, and O were prepared as trihydrochloride, whereas tuberactinomycin B (viomycin) was crystallized as monohydrochloride–dihydrobromide. Tuberactinamine N dihydrochloride was obtained by the selective cleavage of γ-hydroxy-β-lysine residue from tuberactinomycin N with concentrated hydrochloric acid according to the mechanism of *N,O*-acyl migration reaction.[1] Sample concentrations in NMR measurements were 15% in D_2O (also in the case of D_2O+TFA), 10% in H_2O (pH 2.5), and 4% in DMSO-d_6.

Results and Discussion

Spectral Assignments. In the PMR spectra of tuberactinomycins in D_2O solution, some α-methine protons were concealed by HOD signal. However, on addition with trifluoroacetic acid to the solution, those protons manifested themselves entirely with the shift of HOD signal to a lower field by about 0.7 ppm. This effect enabled decoupling experiments, and thereby spectral assignments covering all protons became feasible. Since the differences in the chemical structures of tuberactinomycin family are only limited to the degree of hydroxylation at R_1 and R_2 as shown in Fig. 1, the patterns of the corresponding signals in their spectra show close resemblances to each other. Thorough comparisons in spectra of four tuberactinomycins and one tuberactinamine were very profitable for the complete assignments of all signals. Especially a relatively simple spectrum of tuberactinamine N (Fig. 2) without the branched amino acid residue gave many key informations for assignments in tuberactinomycins (Fig. 3).

In the molecule of tuberactinamine N, there are five methylene groups of three types, *i.e.*, –C–CH_2–C–, –NH–CH_2–C–, and –C–CH_2–OH. Of these groups, γ-methylene protons in six-membered pyrimidine ring of Cpd appeared at around δ 1.8 and 2.1 as non-equivalent multiplets. A multiplet of δ-methylene protons of Cpd were resonated at δ 3.32 that corresponds to normal position for –NH–CH_2–C– type methylene. On the contrary, one of two β-methylene protons of Dpr showed normal chemical shift at δ 3.30, while the another appeared at an anomalous downfield of δ 4.12 as a quartet. This assignment was confirmed by the decoupling experiment in which an irradiation at δ 3.30 caused the quartet at δ 4.12 to collapse to a doublet and *vice versa*, accompanying concurrent decoupling with α-methine proton of Dpr at δ 4.40. Such large difference between two chemical shifts of non-equivalent β-methylene protons of Dpr seems to be ascribed to an environmental difference which comes from the situation that the peptide backbone in the cyclic moiety may be fixed in a definite conformation and prohibited from free rotation.

β-Methylene protons of two serine residues showed also significant differences in their chemical shifts. One residue Ser(1) connected with Dpr appeared at δ 3.95 as a doublet coupled with a triplet at δ 4.84, while the other Ser(2) adjacent to 3-ureidodehydroalanine (Uda) residue showed double-doublets at δ 3.90 and 4.20, respectively. Thess different situations indicate that some neighboring effect may act on the latter group causing a magnetic non-equivalency of two protons likely as in the case of β-methylene of Dpr.

Although the region from δ 4.0 to 4.5 was somewhat complicated by overlapping of five protons, the decoupling study and the comparison of coupling constants enabled the complete assignment. Two quartets at δ 4.12 and 4.20 were already assigned to one of β-methylene protons of Dpr and Ser(2), respectively. A quartet centered at δ 4.32 can be assigned to α-methine proton of Ser(2) as this has the same coupling constant (J=5 Hz) with a quartet at δ 4.20. An irradiation of a quartet centered at δ 4.40 caused a multiplet at δ 3.30 to collapse to a single peak, thereby this quartet was assigned to α-methine proton of Dpr. A multiplet at

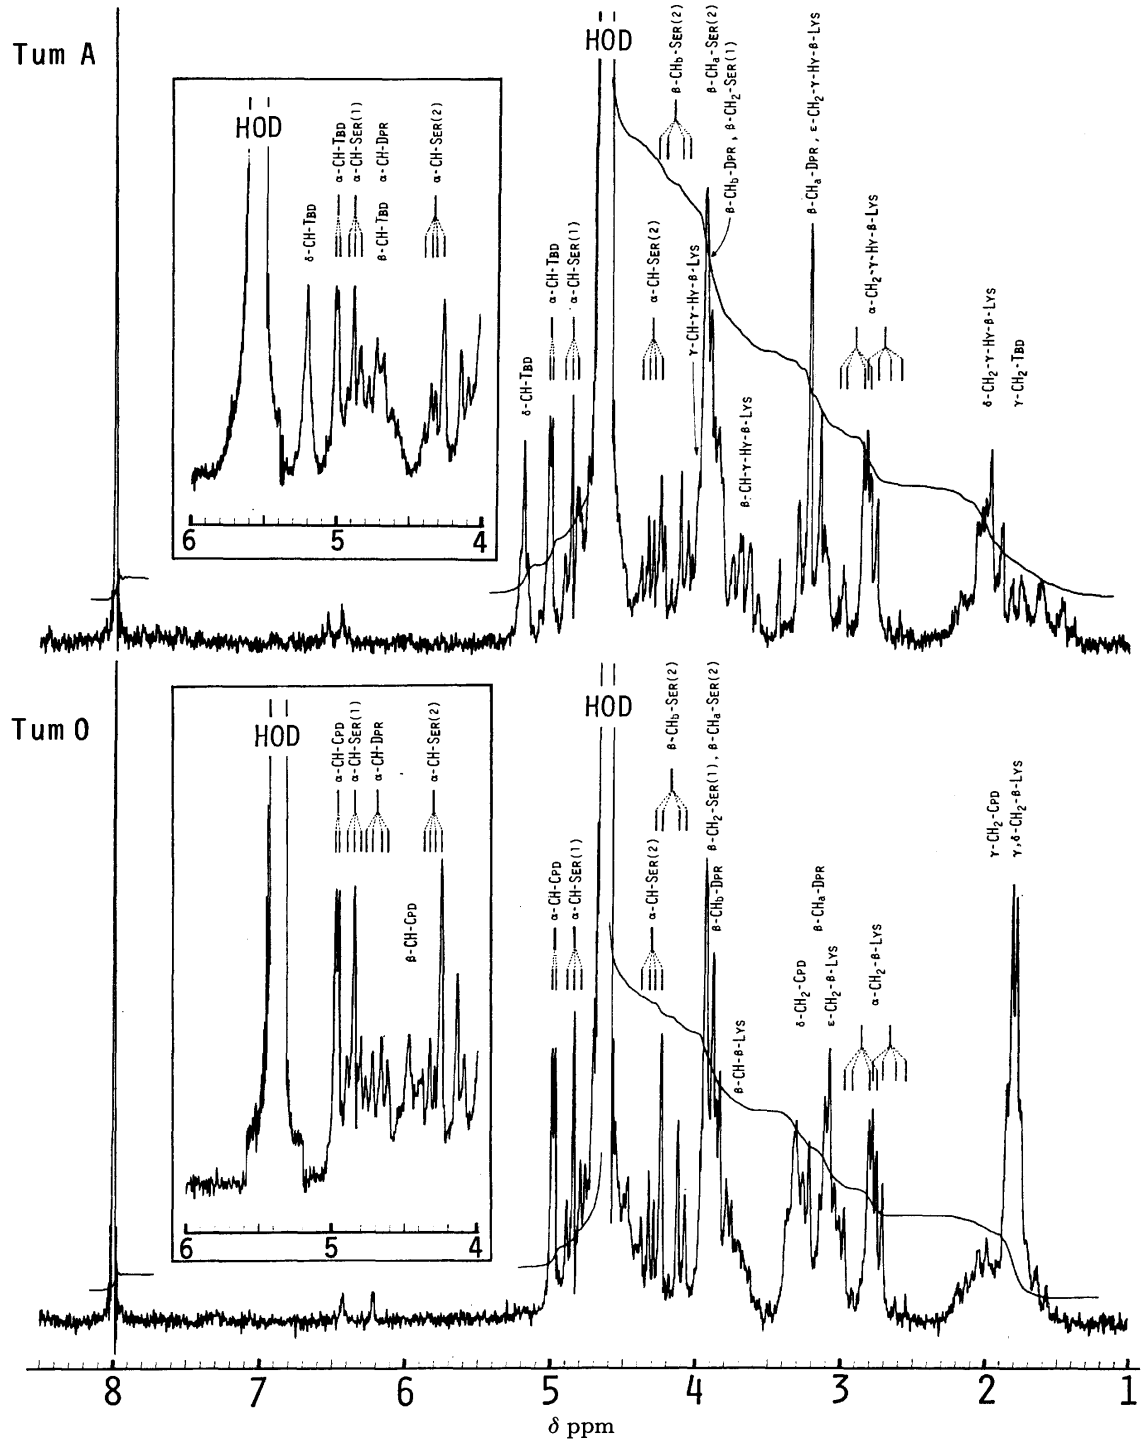

Fig. 3. NMR spectra of tuberactinomycins (Tum) A and O in D_2O. Figures in squares indicate the parts of spectra in D_2O+TFA.

δ 4.35 to 4.55 was collapsed by an irradiation of methylene protons at Cpd at δ 1.80 and 2.10. Reversely, an irradiation at δ 4.45 caused not only a change of Cpd γ-methylene as mentioned above but also of doublet at δ 5.01 of Cpd α-proton both to singlets. Thus the multiplet centered at δ 4.45 was determined to be due to β-methine proton of Cpd. A triplet at δ 4.84 and a doublet at 5.01 were necessarily assigned to α-methine protons of Ser(1) and Cpd, respectively as mentioned above already. Finally, a sharp peak at δ 8.04 was due to an olefinic proton of Uda, –C=CH-NHCONH$_2$.

Since the molecules of tuberactinomycins N and O are built up by joinings of γ-hydroxy-β-lysine and β-lysine respectively into the free α-amino group of Dpr in tuberactinamine N, simple comparisons of their spectra with that of tuberactinamine N are good enough for their assignments. However, by the effect of joining of β-amino acid with α-amino group of Dpr in tuberactinomycin N or O, the signal of the α-methine of the

latter amino acid shifted to a lower field possibly due to the decrease of electron density on its α-carbon atom.

Tuberactinomycins A and B are only distinct from N and O in terms of replacement of capreomycidine with tuberactidine. Only this difference is reflected on their spectra so that a dull singlet attributed to methine proton of δ-carbon atom of Tbd at δ 5.19 appeared in place of the corresponding δ-methylene protons of Cpd at about δ 3.3. The other minor change recognized in spectra was a slightly lower shift of β-methine proton of Tbd compared to that of Cpd owing to the substitution of hydroxyl group at δ-carbon atom. Thus, all protons attached to carbon atom in four tuberactinomycins were successfully assigned as shown in Table 1.

Next, the amide proton resonances in water at pH 2.5 were studied to obtain the informations on a backbone stereochemistry of tuberactinamine and tuberactinomycins in solutions. (Figs. 4 and 5). Tuberactinamine N in H_2O solution at 30 °C (Fig. 4) shows a triplet at δ 8.3 which could be assigned to β-NH of Dpr from its coupling mode. A doublet at δ 9.4 has the same coupling constant (J=12 Hz) to that of a doublet at δ 8.0, which is ascribed to olefinic proton of Uda, and an irradiation on one of the either peaks caused the partner to collapse to a singlet. Therefore, the lower peak was determined to be an amide proton of the ureido group attached to olefinic carbon atom. A singlet at δ 8.95 was assigned to α-NH of Uda from its chemical shift. A highest doublet at δ 7.75 (J=10 Hz) at 30 °C moved to δ 7.68 at 60 °C which was successfully decoupled by an irradiation of a peak centered at δ 4.95 (dd, J=4, 10 Hz) of α-CH of Cpd on a shoulder of H_2O signal. Therefore, the signal of δ 7.75 could be determined as α-NH of Cpd. Two doublets at δ 9.5 and δ 8.8 belong to α-amide protons of two serine residues. The lower doublet was assigned to α-NH of Ser(2) and the higher one to that of Ser(1). The three single peaks corresponding to each two protons at δ 7.4, 6.2, and 6.5 were assigned to two ring NH, *exo* NH_2 protons in guanidino group of Cpd, and primary amide protons in ureido group of Uda, respectively. The lowest signal of them was separated to two peaks with a rise in temperature from 30 °C to 60 °C.

In the spectra of tuberactinomycins A, B, N, and O (Fig. 5), α-NH of Dpr newly appeared in the slightly higher field than that of Ser(1). In the case of tuberactinamine N, the protonated α-amino proton resonance of Dpr could not be observed perhaps due to overlapping with that of water. Except this feature, both spectral patterns of tuberactinomycins N and O were substantially identical with that of tuberactinamine N. On the other hand, in the spectra of tuberactinomycins A and B, all

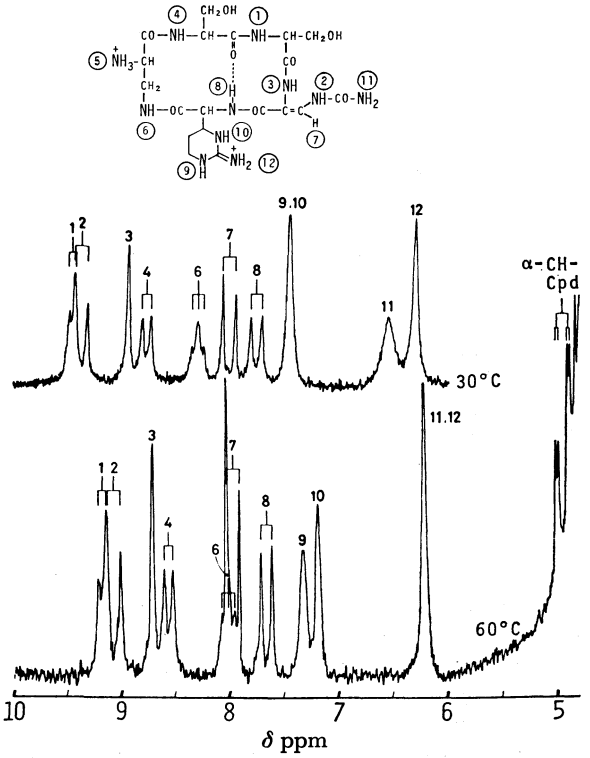

Fig. 4. NMR spectra of tuberactinamine N in low-field region in H_2O at pH 2.5.

of the guanidino proton resonances of Tbd shifted to the lower field compared with those of Cpd in the molecules of another three cyclic peptides. These shifts seem to be apparently effected by the influence of δ-hydroxyl group in Tbd. Especially, δ-NH resonance of Tbd markedly shifted to the downfield and its temperature dependence is relatively small compared with that of β-NH resonance in the same group. This tendency can serve for differentiation of two NH resonances in Cpd ring. Similarly *exo* amino proton as protonated form in Cpd or Tbd was differentiated from a primary amide proton of Uda by a smaller temperature dependence.

In addition to the experiments in H_2O solution, we also studied on spectra in DMSO-d_6 solution. In the spectrum of tuberactinamine N (Fig. 6), the complicated feature in α-methine proton region may be arised from the additional coupling with amide protons. However, the chemical shifts of them were substantially similar to those in D_2O solution. The relation between methine proton and amide proton region was examined by decoupling method on two Ser residues. Thus, an irradiation at the signal of Ser(2) α-CH of δ 4.1 caused the lowest doublet of δ 9.2 to collapse to a singlet. On the other hand, an irradiation at that of Ser(1) α-CH of δ 4.7 forced two doublets at δ 8.6 and 7.5 to collapse to a singlet. From this result, the former doublet can be assigned to that of Ser(1) α-NH, the latter to Cpd α-NH due to the concurrent decoupling with α-CH of Cpd near δ 4.7. The study in DMSO-d_6 solution has consequently supported the assignments of two serine α-NH protons in H_2O solution.

diagram of the lowfield proton resonances in H_2O solution at pH 2.5 of all compounds was given in Fig. 7. Each proton was numbered in order of increasing magnetic field, its assignment being described above. Of these protons, protons **7**, **8**, **9** and **12** showed small temperature coefficients, whereas the other protons shifted markedly to higher field with rise in temperature. Consequently, it appeared that protons **8**, **9**, and **12**, except olefinic proton **7**, were concerned more or less to either intra- or intermolecular hydrogen bond. Especially, the participation of proton **8** corresponding to Cpd or Tbd α-NH is important for comparison of the ring conformations in solutions and crystals. It should be noted that the similar result was obtained in tuberactinamine N which corresponds to the cyclic moiety of the natural peptides.

Deuterium Exchange. Deuterium exchange rates of NH resonances of tuberactinamine N in DMSO-d_6 containing 5% D_2O by volume were studied. Within 15 min after addition of D_2O, all of the resonances except protons **7** and **8** disappeared by exchange with deuteriums. Since the olefinic proton **7** can be excluded from the consideration, it is concluded that the resonance **8** corresponding to Cpd α-NH shows particularly slow exchange rate among NH protons. This proton was not replaced completely by deuteron after 2 hr and its signal remained to some extent even after allowing to stand overnight. The similar tendencies of the corresponding resonances were observed in each spectrum of four tuberactinomycins.

Consequently, it was revealed that only the α-amide proton **8** of Cpd and Tbd formed a fairly protected hydrogen bond in all compounds, while the two protons **9** and **12** may be located in somewhat crowded environment though not participating in the definite hydrogen bond. A carbonyl group as the partner to α-amide proton **8** could not be clarified unambiguously from only the above experiments. However, an intramolecular hydrogen bond was ascertained in crystals of tuberactinomycins O and B (viomycin) between the amide proton of guanidino amino acids and the carbonyl group of Ser(1) as mentioned before. In addition to this fact, taking into account a general information that many cyclic peptides form a stable β-turn structure involving the intramolecular hydrogen bond of ten membered ring, Ser(1) residue is unequivocally chosen as carbonyl partner in these cases. Furthermore the participation of Ser(1) residue in hydrogen bond made possible to understand the significant difference between the resonances of α-methine protons in two serine residues. Thus, the electron density on carbon atom of Ser(1) CO is forced to be lower by the formation of the hydrogen bond. Thereby the protons on atoms linked to Ser(1) CO, *i.e.*, Ser(1) α-CH and Ser(2) α-NH, have to show diamagnetic shift to the lower field.

The backbone conformation of cyclic moiety in crystals of tuberactinomycin O was shown in Fig. 8. The ring part in the molecule was fixed in a definite conformation with the intramolecular hydrogen bond. On the assumption that the conformation in D_2O or H_2O is the same in principle to that in crystals, one can elucidate all the observations consistently. Furthermore, the rigid conformation of tuberactinomycin O in crystals afforded useful informations for side chains in two serine residues. Thus, β-methylene group of Ser(1) was situated in the lateral direction to a nearly lined backbone chain "wall," and thereby the side chain is possible to rotate freely. On the other hand, the β-

R4:

Fig. 8. Backbone conformation of tuberactinomycin O in crystals.

methylene group of Ser(2) was located just on the upper position to the "wall" and consequently a free rotation must be prevented by steric interaction with its own carbonyl group. These magnetically different environments of both side chains made a discrimination between coupling patterns of α- and β-protons. β-Methylene protons in Ser(1) must be coupled to doublet and α-methine proton to triplet, while the both corresponding protons in Ser(2) should appear as double-doublet of ABX type as in fact. The result of this consideration seems to be consistent with the supposition that the conformations of tuberactinamine and tuberactinomycins in solution are almost the same to that in crystals. Furthermore, this conclusion was supported by the following two facts: 1) there are little changes recognized in all α-CH–NH coupling constants at several temperatures in all compounds tested: 2) most of the dihedral angles in the backbone skeleton calculated from NMR spectra in tuberactinomycin O are substantially comparable to those from the result by X-ray analysis.

Recently, Viglino *et al.* reported a NMR study of viomycin, *i.e.*, tuberactinomycin B itself.[14] However, their assignments for some NH resonances did not agree with our results. According to them the lowest signal of singlet mode in acid solution was assigned to Uda α-NH resonance from the comparison of its chemical shift with that of conjugated ureide NH, *i.e.*, –C=CH–NHCONH$_2$. Moreover, another singlet corresponding to our Uda α-NH in tuberactinomycins had been deduced to *exo* imino proton of Tbd in their paper. The guanidino moiety in acid solution must be regarded as protonated form $\begin{matrix}-NH\\-NH\end{matrix}\!\!>\!\overset{+}{C}\!-NH_2$ but not as $\begin{matrix}-NH\\-NH\end{matrix}\!\!>\!C=$ NH. Consequently, their assignment of Ser(2) α-NH in viomycin was also inconsistent with our result for tuberactinomycins.

From our studies on NMR spectra of tuberactinomycins as mentioned above, some important conclusions were drawn: 1) a strong intramolecular hydrogen bond may serve to maintain a stable and fixed conformation in ring moiety based on β-turn structure in solutions as well as in crystals; 2) such a stable and rigid conformation is common to each antibiotics in tuberactinomycin family; 3) a cyclic peptide moiety, tuberactinamine N, possesses the same conformation with the intramolecular hydrogen bond as those in tuberactinomycin molecules. These results concerning the specific conformation may not be unrelated to the exhibition of antibiotic activities since all of five cyclic peptides showed the comparable antitubercular activities. For the purpose of further investigation on the relationship between conformations of tuberactinomycins and their biological activities, studies on hydrogenated derivatives or synthetic analogues of tuberactinomycins are now in progress.

The authors are deeply indebted to Professor Yoshimasa Kyogoku, Institute for Protein Research, Osaka University, for invaluable discussions. We also wish to express our appreciations to The Research Laboratories, Toyo Jozo Co., Ltd. for the supply of the samples of tuberactinomycins.

Racemization Catalyst for Amino Acid. IV* Enantiomer Differentiating Racemization with (*S*)-2′-Nitro-5-nitroso-6,6′-dimethylbiphenyl-2-ol

Kazuhiro HIROTA

Division of Organic Chemistry, Institute for Protein Research, Osaka University, Suita, Osaka 565

(Received June 12, 1975)

The racemizations of both enantiomers of alanine were carried out with (*S*)-2′-nitro-5-nitroso-6,6′-dimethylbiphenyl-2-ol (**1**) in the presence of cupric ion. In time course studies, the apparent half-life of D-alanine is longer than that of L-alanine. Such an enantiomer differentiating ability is explained by a mechanism involving a reactive product formed from the preferred conformation of the diastereomeric cupric complexes, consisting of **1** and D- or L-alanine, respectively. Synthesis of **1** *via* the resolution of 2′-nitro-6,6′-dimethylbiphenyl-2-amine is also presented.

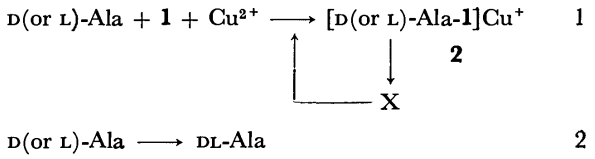
Amino acid racemases are known to catalyze the racemization of both D- and L-amino acids.[1] Studies of the enantiomer diferentiating ability of the racemases are particularly interesting, for they could provide significant stereochemical information regarding the formation of enzyme-substrate complex.

Lambert *et al.*[2] investigated the rate of racemization of alanine with racemase and found that the initial racemization rate for L-alanine is faster than that for D-alanine and that the kinetic parameters of the reaction, which would reflect the stereochemical properties of the enzyme-substrate complex, differ significantly between D- and L-alanine, regardless of the invariability of thermodynamic parameters.

Apart from the enzymatic studies, we have attempted to prepare a synthetic racemization catalyst with a chiral structure, assuming that if there are stereochemical interactions between substrate and catalyst during the reaction process, analogous to the enzyme-substrate complex in enzymatic system, the chiral catalyst should exhibit an enantiomer differentiation against the chiral substrate.

Thus, (*S*)-2′-nitro-5-nitroso-6,6′-dimethylbiphenyl-2-ol (**1**), which contains 4-nitrosophenol structure in the hindered biphenyl, has been synthesized and its enantiomer differentiating ability toward D- and L-alanine has been confirmed.[3]

The mechanism of racemization of alanine with 4-nitrosophenol derivatives has also been presented on the basis of kinetic and stereochemical studies.[4] The proposed reaction pathways are as follows:



Ala: Alanine. X: Unidentified compound.

That is, 4-nitrosophenol derivatives are decomposed into an unidentified compound (X) *via* the cupric complex (**2**) consisting of 4-nitrosophenol and alanine, the resulting X then catalyzes both reactions 1 and 2. The induced period was regarded as the time necessary to accumulate sufficient concentration of X through the decomposition of **2**, according to the reaction mechanism shown in reaction 1.

Thus, the time course of the reaction, which shows a sigmoid curve and also the effect of steric bulk of substituents surrounding the hydroxyl group of the catalyst on the induced period of the reaction, is explained by this mechanism. In the present paper, the origin of an enantiomer differentiation in the racemization process with **1** is discussed from the view point that the racemization proceeds *via* the mechanism shown in reactions 1 and 2.

Results and Discussion

Racemizations of D- and L-alanine were carried out in the presence of **1** and cupric ion. The resulting time

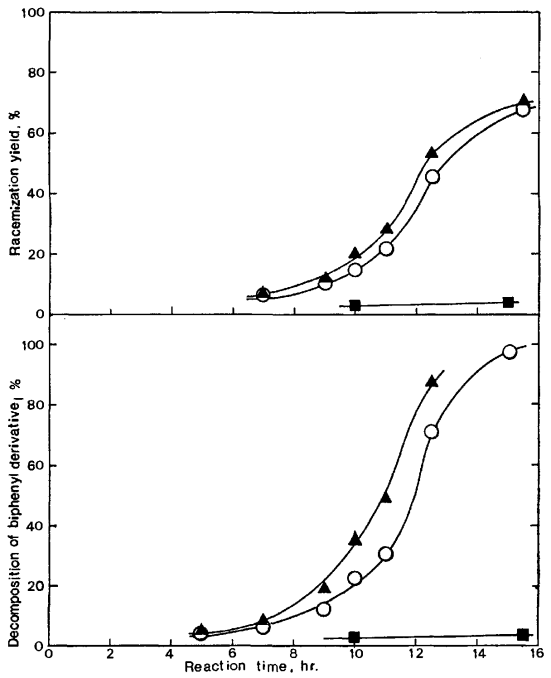


Fig. 1. The reaction mixture (0.5 ml) containing 0.5 mmol D- or L-alanine, 0.05 mmol $CuSO_4 \cdot 5H_2O$, and 0.0125 mmol the above biphenyl derivative in 0.025 M borate buffer (pH, 10.4 at 50 °C).

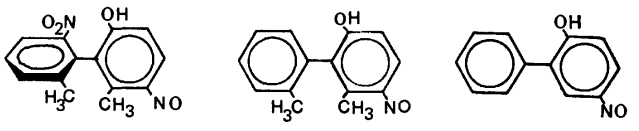
* Presented at the 30th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1974.

courses of racemization and those of the decomposition of catalysts used exhibit sigmoid curves consisting of the induced period, the acceleration and maximum rate periods, and final stage, as shown in Fig. 1.

Actually the apparent racemization half-life of D-alanine is found to be longer than that of L-alanine as the result of the enantiomer differentiating ability of **1**. However the difference of half-life does not correspond to the difference in rate constants of reaction as was found in the enzymatic reaction, but solely depends on the difference in the induced period.



1 **3** **4**

In order to make clear the relationship between the apparent half-life of racemization and the structure of the catalyst, the racemization of alanine and decomposition of the catalyst used were further studied with two representative catalysts (**3** and **4**) whose structures closely resemble that of **1** (Fig. 2). In all cases, the time courses of the reactions show similar sigmoid curves, differing however, in the length of the induced period. The apparent half-lives of racemization, and as well the lengths of the induced period, are in the order; **1**>**3**≫**4**.

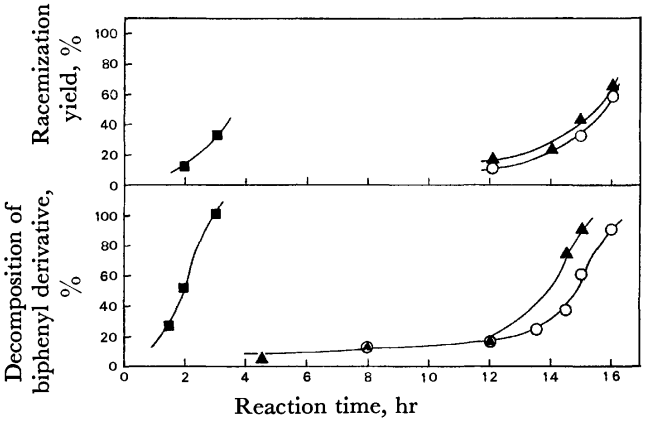


Fig. 2. The reaction mixture (0.5 ml) containing 0.5 mmol D-alanine, 0.05 mmol $CuSO_4 \cdot 5H_2O$ and 0.0125 mmol biphenyl derivatives in 0.025 M borate buffer (pH, 10.4 at 50 °C).
■: with **4**. ▲: with **3**. ○: with **1**.

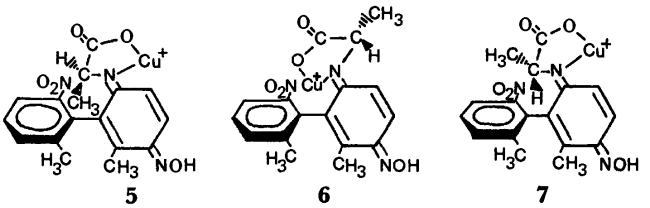
The good correlation of time course between racemizations of alanine and decompositions of 4-nitrosophenol derivatives implies that both racemization and decomposition proceed though the same intermediate consisting of 4-nitrosophenol derivatives, alanine and cupric ion as shown in **2**.

Taking into account the steric effects on the induced period, it is reasonable that the rate of formation of X is directly related to the equilibrium concentration of **2** which reflects steric effects of substituents of 4-nitrosophenol derivatives in the reaction system. Thus, the direct correlation between the induced period and the structure of **2** was made clear.[4]

The same concept can be used to explain the enantiomer differentiating ability of **1**. The different effects of D-alanine and L-alanine in the decomposition of **1** could be ascribed to the equilibrium concentrations of D-alanine-**1**-cupric complex (D-**1**-Cu) and L-alanine-**1**-cupric complex (L-**1**-Cu) since this complex is an intermediate in the decomposition of **1**. As D-**1**-Cu and L-**1**-Cu are diastereomers, the concentration of D-**1**-Cu should be different from that of L-**1**-Cu.

The apparent half-life of D-alanine is longer than that of L-alanine is also explained by the stereochemical aspects of intermediate, **2**. Actually the results are found to correspond well with predictions using the stereo model as follows: Two types of stereo models, **5** and **6**, can be proposed for L-**1**-Cu. Structure **6**, however, has much less stereo interaction between the chiral center of alanine and the biphenyl ring of **1** than structure **5**. Accordingly structure **5** must make a larger contribution to the enantiomer differentiation of **1**. Structure **7** is the corresponding version of structure **5** for D-**1**-Cu. The steric hindrance between the α-methyl group of alanine and the 2′-nitro group of **1** in **5** is less than in **7**. Hence the concentration of X would be higher for L-**1**-Cu rather than for D-**1**-Cu, resulting in shorter half-life of racemization for L-alanine than for D-alanine.

Although it is not possible to speculate on the mechanism of enantiomer differentiating ability of alanine racemase with the results obtained from **1** because of the decomposition of **1** during the reaction, the enantiomer differentiating process in the formation of enzyme-substrate complex was considered to be well simulated by the complexes **5** and **7**.



5 **6** **7**

The simulation of enantiomer differentiating racemization in the enzymatic systems with synthetic catalysts will be more feasible when the stable catalysts with a chiral structure are available. Efforts along this line are continuing.

Experimental

Melting points are uncorrected. IR spectra were determined on a Shimadzu 27-G spectrometer. NMR spectra were obtained on a Hitachi R-24 spectrometer with TMS as an internal standard.

2′-Nitro-6,6′-dimethylbiphenyl-2-amine (8). 2,2′-Dinitro-6,6′-dimethylbiphenyl[5] was reduced with sodium sulfide nonahydrate to get 2′-nitro-6,6′-dimethylbiphenyl-2-amine according to Sako's procedure.[6]

(S)-2′-nitro-6,6′-dimethylbiphenyl-2-amine (9). L-Cysteic acid monohydrate[7] (10 g) was dissolved in water (70 ml) with warming and then the solution (75 °C) was added dropwise to

a solution of **8** (12 g) in ethanol (550 ml) previously heated to the same temperature. The mixture was allowed to stand at room temperature for three hours to precipitate a white salt and chilled with ice-water for an hour. This salt was filtered by suction, washed with 90% ethanol (50 ml) and dried at 60 °C to give a white powder (11 g). It was boiled with 90% ethanol (1100 ml) and the excess L-cysteic acid which remained insoluble was filtered off. After standing at room temperature for several hours, the salt began to precipitate as a white powder and then the solution was kept in the refrigerator overnight. The precipitated salt was collected on a filter, washed with 90% ethanol and dried at 60 °C. In the successive recrystallizations, the following procedure was used in order to minimize the total volume of solvent; the salt was again dissolved in the minimum amount of boiling ethanol (80 ml) and then boiling absolute ethanol was added until the final concentration of ethanol was 90%. The yellow solution was allowed to stand overnight in the refrigerator. The white precipitate was filtered by suction and dried at 60 °C. The above recrystallization procedure was repeated four or five times. The color of the solution, during this repeated recrystallization, changed from reddish yellow to pale yellow and also the crystalline state of the salt changed from powder to white needles. Although the course of the recrystallization could be roughly monitored by observations of the above phenomena, it was accurately** followed by decomposition of the salt and measureing the optical rotation value of **9**. The salt was decomposed with 2 M sodium hydroxide to give yellow crystals, which were extracted with ether. The ether solution was washed with water and dried over sodium sulfate. After the evaporation of the ether, the residue started to crystallize almost immediately on cooling. Its specific rotation was measured on the dried sample, and the recrystallization was discontinued when there was essentially no further changes in rotation. After the resolution was complete, **9** liberated from the L-cysteic acid was recrystallized from petroleum ether to afford lustrous yellow crystals (1.8 g) in 30% yield: mp 108—109 °C (lit,[8] 108.3—109.0 °C); $[\alpha]_D$ −74° (*c* 1.0, ethanol), $[\alpha]_D$ −185° (*c* 1.0, 0.2 M HCl) (lit,[8] $[\alpha]_D$ −74.6° (*c* 1.0, 95% ethanol), $[\alpha]_D$ −187° (*c* 0.92, 0.2 M HCl)).

(S)-2-nitro-6,6′-dimethylbiphenyl-2-ol (10). **10** was prepared by the method of Angelletti,[9] but with a greatly improved yield. To a solution of 25% sulfuric acid (70 ml) was added the fine powder of **9** (1.20 g) with vigorous stirring and the diazotization performed at 0—5 °C with a solution of sodium nitrite (0.38 g) in water (1.0 ml). The resulting yellow solution was poured dropwise into continuously boiling water (20 ml) in over ten minutes. During this time, reaction took place with vigorous foaming of nitrogen and brown pitch-like material separated. After cooling, the mixture was made alkaline with 2 M sodium hydroxide and the insoluble brown materials was filtered off by suction. The filtrate was acidified with dilute sulfuric acid solution and the liberated oil was extracted with ethyl acetate. The extract was washed with water, dried over anhydrous sodium sulfate and the solvent was evaporated to give a dark colored syrupy oil containing **10**. The purification was carried out *via* acetylation as follows: The above syrupy oil was gently refluxed with acetic anhydride (5.0 ml) for forty minutes. After removal of the excess acetic anhydride under reduced pressure, the residue was dissolved in ether and the insoluble matter was filtered off. The filtrate was then washed with water, dried with anhydrous sodium sulfate, and the ether was distilled off. The brown residue was dissolved in hot ethanol (20 ml) and decolorized with charcoal.

After removal of the solvent, the residue was recrystallized from 50% ethanol to afford acetylated **10**: mp 77—78 °C, $[\alpha]_D$ +270° (*c* 1.0, ethanol), Found: C, 67.70; H, 5.04; N, 4.85%. Calcd for $C_{16}H_{15}NO_4$: C, 67.36; H, 5.30; N, 4.91%. IR(KBr): 1763 cm^{-1} (C=O) and 1530 cm^{-1} (NO_2).

The acetylated **10** (400 mg) was stirred rapidly with 2 M sodium hydroxide (30 ml) at 70—80 °C for an hour. After acidification of the reaction mixture with 2 M hydrochloric acid, the liberated oily matter was extracted with ethyl acetate (10 ml). After washing with water of the solvent, the mixture was dried over anhydrous sodium sulfate and was evaporated. The crystalline residue was recrystallized from cyclohexane to afford white crystals (0.5 g) in 41% yield from **9**: mp 109—110 °C $[\alpha]_D$ +60.0° (*c* 1.0, ethanol), Found: C, 68.55; H, 5.39; N, 5.63%. Calcd for $C_{14}H_{13}NO_3$: C, 69.12; H, 5.76; N, 5.39%. IR (KBr): 3450 cm^{-1} (OH) and 1523 cm^{-1} (NO_2).

(S)-2′-Nitro-5-nitroso-6,6′-dimethylbiphenyl-2-ol (1). **1** was prepared by the nitrosation of **10** according to the procedure described in a previous paper.[4] mp 205—208 °C, $[\alpha]_D$ −12.0 ° (*c* 1.0, ethanol), Found: C, 61.65; H, 4.22; N, 10.04%. Calcd for $C_{14}H_{12}N_2O_4$: C, 61.76; H, 4.44; N, 10.29%. IR ($CHCl_3$): 2550 cm^{-1} (OH). NMR (CD_3COCD_3): 12.5 ppm (OH), 1.96 and 2.22 ppm (CH_3).

5-Nitroso-6,6′-dimethylbiphenyl-2-ol (3). 2-Amino-6,6′-dimethylbiphenyl (4.0 g)[8] which was prepared from **8** was added to 20% sulfuric acid (50 ml) and diazotized by adding sodium nitrite (1.6 g) in water (10 ml) at 0—5 °C. The mixture was poured into boiling water (200 ml) and the resulting pitch-like material was separated by decantation of the solvent. It was stirred with 2 M sodium hydroxide (100 ml) and the insoluble material was filtered. After acidification of the filtrate with 4 M hydrochloric acid, the mixture was extracted with ether. The extract was washed with water, dried over anhydrous sodium sulfate and the solvent evaporated to afford 6,6′-dimethylbiphenyl-2-ol. The crude product was dissolved in 95% acetic acid and a solution of sodium nitrite (1.0 g) in water (30 ml) was added dropwise with stirring at 0—5 °C. The resulting brown precipitate was collected on a filter, washed with 60% acetic acid and recrystallized from 50% ethanol to afford yellow crystals (1.2 g) in 25% yield: mp 199—200 °C, Found: C, 74.47; H, 5.66; N, 6.01%. Calcd for $C_{14}H_{13}NO_2$: C, 73.99; H, 5.77; N, 6.16%.

5-Nitrosobiphenyl-2-ol (4). Biphenyl-2-ol was treated with sodium nitrite in acetic acid by the method described in the preparation of **1**. The precipitate from the reaction mixture was recrystallized from 30% ethanol to afford yellow crystals in 16% yield: mp 169—171 °C (lit,[10] mp 170—172 °C) Found: C, 72.63; H, 4.49; N, 6.84%. Calcd for $C_{12}H_9NO_2$: C, 72.35; H, 4.55; N, 7.03%.

Racemization Reaction. An aqueous solution of D- or L-alanine (0.5 mmol), cupric sulfate pentahydrate (0.05 mmol), and one of the biphenyl derivatives (0.0125 mmol) was made. The pH was adjusted to 10.4 (at 50 °C) with 1 M sodium hydroxide and diluted to a total volume of 0.25 ml. After dilution with 0.05 M borate buffer (0.25 ml, pH 10.4 at 50 °C), the mixture was shaken at 50 °C in a sealed tube. At specific time intervals the reaction was stopped by the addition of 6 M hydrochloric acid (0.25 ml).

Determination of the Ratio of D- and L-Alanine and the Recovery of Biphenyl Derivatives. The ratio of D- and L-alanine in the reaction mixture was determined by gas chromatography after conversion to *l*-menthyl D- and L-trifluoroacetylalaninates by the method described previously.[4] Careful measurements, compared with the calibrated curve, indicate an estimated

** Following the optical rotation of the salt itself could not be used as a criterion of purity due to a constant contamination of the salt with the L-cysteic acid during the procedure.

error of $\pm 0.5\%$. Biphenyl derivatives were determined spectrophotometrically after separation from reaction mixtures by thin layer chromatography according to the previously outlined procedure.[4]

The author wishes to express his thanks to Prof. Yoshiharu Izumi and Dr. Akira Tai for their continual guidance and encouragement. He also wishes to thank Prof. Shunji Kato for his valuable discussion.

Eine Ableitung aus der Hypothese über den Litheffekt

Tsuneo SUGA

Forschungslaboratorium der Konishiroku Photoindustrie AG, Hino-shi, Sakura-machi 1, Tokyo 191

(Eingegangen am 2. Juni 1975)

In früheren Arbeiten[1,2] wurde der Mechanismus der Lithentwicklung und die Hypothese über die Entstehung des Litheffekts diskutiert. Nach dieser Hypothese ist für einen bildscharfen Litheffekt eine richtige Balance zwischen der Entwickelbarkeit der stärker belichteten Bildkeime und der Oxydierbarkeit der schwächer belichteten wichtig. Damit wurde der gute Litheffekt der Chlorbromsilber-Emulsion mit hohem Chloridanteil und der Litheffekt der Bromjodsilber-Emulsion mit niedrigem Jodidanteil gut erklärt. In der vorliegenden Arbeit wurde eine steile Gradation einer Bromjodsilber-Emulsion aus der Ableitung der Hypothese versucht. Die steile Gradation der Bromjodsilber-Emulsion, die man in Gegenwart von Rhodanid im Entwickler an Stelle von Bromid erhielt, wurde der „Redox-Lith-Effekt" der Bromjodsilber-Emulsion genannt.[3]

In früheren Arbeiten[1,2] wies der Autor auf die Wichtigkeit des Oxydationseffekts der Oxydationsprodukte des Hydrochinons bei der Lithentwicklung sowie deren Beschleunigungseffekt hin. Außer den bereits zitierten Arbeiten,[2] die im Gegensatz zum Oxydationseffekt stehen, richtete neulich Austin[4] in der Revue über die Lithentwicklung auf den Oxydationseffekt wenig Aufmerksamkeit. Wie schon früher gezeigt wurde,[1] entsteht der Litheffekt aus einem Lithmaterial mit hohem Chlorsilberanteil und einem normalen Lithentwickler mit niedriger Konzentration von Sulfit. Einen guten Litheffekt erkennt man an der Grenzschärfe und der besonders steilen Gradation des zu hohen Schwärzungen ansteckend entwickelten Bildes. In der letzten Arbeit[2] wurde doch eine Oxydation der Entwicklungsbildkeime während der Induktionsperiode und noch früher[1] die Hypothese des Litheffekts vorgestellt. Nach der Hypothese ist für einen guten Litheffekt eine richtige Balance zwischen der Entwickelbarkeit der stärker belichteten Bildkeime und der Oxydierbarkeit der schwächer belichteten wichtig. Daher sind nicht alle Emulsionen dem guten Litheffekt zugänglich. Mit Hilfe der Hypothese ließ sich der gute Litheffekt der Chlorbromsilber-Emulsion sowie der schlechte der Bromjodsilber-Emulsion gut erklären.[1]

In der vorliegenden Arbeit wurde auf Grund der Hypothese versucht, einen bisher noch nicht erzielten steilen Effekt einer Bromjodsilber-Emulsion abzuleiten.

Experimentelles

Entwickler. Für die Entwicklung bei 20 °C dienten ein normaler Lithentwickler und dieser Lithentwickler mit 30 g/l Natriumsulfit. Die Entwickler enthielten Kaliumbromid oder Kaliumrhodanid unter der Konzentration von 0,02 mol/l.

Emulsion. Eine Bromjodsilber-Emulsion, die 1,5 mol% Jodsilber enthielt, und eine Chlorbromsilber-Emulsion, die 70 mol% Chlorsilber enthielt, wurden zum Versuch verwendet. Die feinkörnigen Emulsionen wurden schwefelsensibilisiert und dann auf eine Untelage gegossen. Einzelheiten der Rezepte und Versuchsdurchführung wurden schon gezeigt.[1]

Ergebnisse und Diskussion

Die Schwärzungskurven der an Halogensilberbestandteilen verschiedenen Emulsionen in Abb. 1 zeigten,

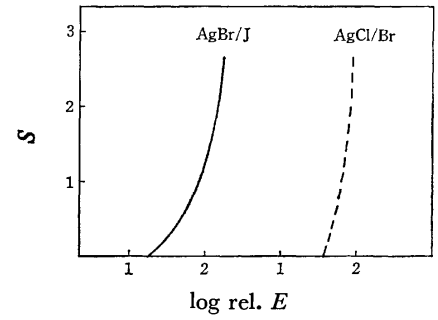

Abb. 1. Vergleich vom Litheffekt zwischen einer Chlorbromsilber-Emulsion (----) und einer Bromjodsilber-Emulsion (——) im normalen Lithentwickler, in 3 min. entwickelt.

daß die Chlorbromsilber-Emulsion einen bildscharfen Litheffekt, während die Bromjodsilber-Emulsion einen schlechten, mit einem langen Fuß auf der Schwärzungskurve darstellte.

Bei der Oxydation der Silberteilchen in der bromid- oder rhodanidhaltigen Chinonlösung wurde ein klarer Unterschied zwischen zwei Salzen schon früher mitgeteilt.[1] Dabei zeigte das erstere eine größere Wirkung als das letztere. Dies kann man aus dem Silberpotential rechnerisch voraussehen, weil die aus der Nernstschen Gleichung elektrochemisch mit den Werten der Löslichkeitsprodukte berechneten Silberpotentiale E_{Ag} gegen Normalwasserstoffelektrode bei 20 °C

$$E_{Ag}(0{,}02 \text{ mol KBr}) = 0{,}177 \text{ V}$$

$$E_{Ag}(0{,}02 \text{ mol KSCN}) = 0{,}201 \text{ V}$$

sind.

Das Verhalten der Bromjodsilber-Emulsion im bromid- oder rhodanidhaltigen Hydrochinon-Entwickler wird in den Abbildungen 2 und 3 dargestellt. Bei der Sulfit-Hydrochinon-Entwicklung in den Abbildungen 2 und 3a zeigte Rhodanid, verglichen mit Bromid, eine größere Entwickelbarkeit und eine steilere Gradation, als die gleichen Ergebnisse in gewöhnlichen Entwicklern.[5,6] In Abb. 3a wurde jedoch nichts vom einen Litheffekt bemerkt, weil Sulfit den Oxydationseffekt vernichten kann.

Die Erklärung des schlechten Litheffekts der Bromjodsilber-Emulsion wurde schon früher wie folgt vorgestellt.[1] Ihre latenten Bildkeime, verglichen mit

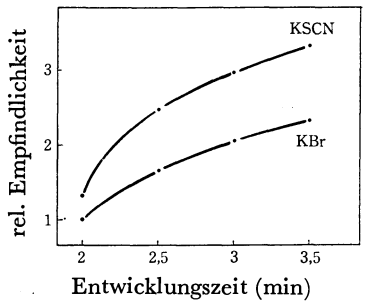

Abb. 2. Abhängigkeit der relativen Empfindlichkeit einer Bromjodsilber-Emulsion von der Entwicklungszeit in einem Sulfit-Hydrochinon-Entwickler, der KBr oder KSCN unter der Konzentration von 0,02 mol/l enthält.

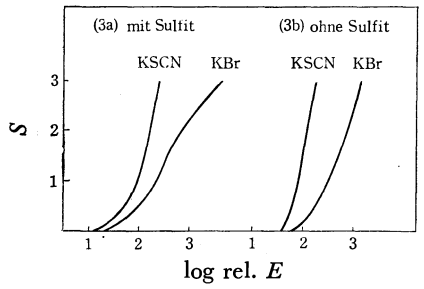

Abb. 3. Vergleich der Schwärzungskurven einer in 3 min entwickelten Bromjodsilber-Emulsion in einem Hydrochinon-Entwickler mit 30 g/l Natriumsulfit (Abb. 3a) und ohne Natriumsulfit (Abb. 3b). Die Entwickler enthalten KBr oder KSCN unter der Konzentration von 0,02 mol/l.

denen der Chlorbromsilber-Emulsion, sind an der schwächer belichteten Stelle leicht oxydierbar, und an der stärker belichteten langsam entwickelbar. Unter der Annahme der Hypothese sollte ein besserer Litheffekt der Bromjodsilber-Emulsion erhalten werden, wenn man die Oxydierbarkeit milder und die Entwickelbarkeit beschleunigender machen könnte. Aus obigen Ergebnissen folgert, daß Rhodanid dafür gelten kann. Mit anderen Worten, im Lithentwickler, in dem der Oxydationseffekt für wichtig gehalten wird, läßt wahrscheinlich Rhodanid den Oxydationseffekt an den schwächer belichteten Keimen milder und die Entwicklung der stärker belichteten beschleunigender machen. Mit dieser Absicht wurde Kaliumrhodanid an Stelle von Kaliumbromid dem Lithentwickler hinzugefügt. Dieser erwartungsvolle Versuch bewies in Abb. 3b eine sehr steile Gradation der Bromjodsilber-Emulsion. Abb.3b schildert einen Vergleich der Schwärzungskurven der im rhodanid- oder bromidhaltigen Lithentwickler behandelten Bromjodsilber-Emulsion.

In einer Rhodanid-Lösung tritt die chemische Umwandlung des Bromsilbers durch Rhodanid in Rhodansilber ein, wenn die Bedingung zwischen dem Löslichkeitsprodukt L und der Konzentration von Anionen [ ] auf die folgende Formel lautet.

$$L_{AgBr}/[Br^-] > L_{AgSCN}/[SCN^-]$$

Bei der Konzentration der SCN^--Ionen von 0,02 mol/l tritt die Umwandlung bei weniger als 0,007 mol/l Br^--Ionen rechnerisch ein. Die Messungen von Jaenicke[7] zeigten, daß das eingesetzte Rhodansilber in der Lösung von Rhodanid unter Komplexbildung als $[Ag(SCN)_2]^-$ aufgelöst wird. Klein[8] beobachtete auch die Komplexbildung mit der Konzentration des Rhodanids von 0,01 mol/l als $[Ag(SCN)_2]^-$, deren Komplexkonstante $1{,}67 \times 10^8$ bei 25 °C lagen. Daher wird angenommen, daß sich die Konzentration der Ag^+-Ionen in der Umgebung der Körner, als die aus dem Löslichkeitsprodukt berechnete, vielmehr steigen kann. Die Verminderung des Oxydationseffekts sowie die Vermehrung des Beschleunigungseffekts und die Möglichkeit[6] zur physikalischen Entwicklung, die durch Komplexbildung verursacht werden kann, scheint zusammenspielend eine günstige Wirkung zum steilen Effekt hervorzubringen.

Eine Deutung von Austin[4] lautet neulich, daß in der Lithentwicklung zwei Elementarprozesse eine große Rolle spielen. Nämlich, der Prozeß der Induktionsperiode und der von der katalytischen Beschleunigung der Oxydationsprodukte abhängige Prozeß. Wie schon erläutert wurde,[2] ist eine einheitliche Deutung des katalytischen Entwicklungsbeschleunigens für die Erklärung der Lithentwicklung nicht ausreichend.

Nach unserer Meinung ist zudem der Oxydationseffekt ein wichtiges Element bei der Lithentwicklung, besonders zu Beginn der Entwicklung. Der Oxydationseffekt, der von der oxydativen Hemmung der Entwicklung bis zum oxydativen Abbau der latenten Bildkeime führen kann, übt eine hindernde Wirkung auf die sichtbare Silberabscheidung aus.[2] Die Induktionsperiode ist eine eigentümliche Erscheinung der Lithentwicklung, welcher bei Abwesenheit von Sulfit der Oxydationseffekt in hohem Grad zugrunde liegen kann. Zum Beispiel verringerte Sulfit den Oxydationseffekt, so daß es eine kürzere Induktionsperiode[1,9] und keinen Litheffekt[1] verursachte. Mit der steigenden Konzentration von Bromid bei der Lithentwicklung, erniedrigt sich das Redoxpotential der latenten Bildkeime, um von der Oxydationsprodukte und H^+-Ionen oxydativ beeinflußt werden zu können, so daß sich dadurch die Induktionsperiode stark verlängern kann.[1]

Auf Grund der früher vorgeschlagenen Hypothese über den Litheffekt,[1] in welcher der Oxydationseffekt für wichtig gehalten wurde, ist hier der bisher noch nicht erzielte steile Effekt der Bromjodsilber-Emulsion durch eine Deutung der Redox-Vorgänge abgeleitet worden. Daher wurde dieser neue steile Effekt der „Redox-Lith-Effekt" der Bromjodsilber-Emulsion genannt, wie in dem Internationalen Kongreß der fotografischen Wissenschaften 1974 in Dresden berichtet wurde.[3]

Crystal and Molecular Structure of Potassium Acetylacetonate Hemihydrate

Shuzo SHIBATA, Shigeki ONUMA, Yukinori MATSUI, and Shoichi MOTEGI

Department of Chemistry, Shizuoka University, Oya, Shizuoka 422

(Received August 14, 1974)

The crystal structure of potassium acetylacetonate hemihydrate, $KC_5H_7O_2 \cdot 1/2H_2O$, has been determined by X-ray diffraction method. Crystals are triclinic with space group $P\bar{1}$, $a=10.86$, $b=8.74$, $c=7.45$ Å, $\alpha=90.5$, $\beta=95.8$, $\gamma=91.9°$, and $Z=4$. The final R value was 0.109 for 1589 visually estimated reflection data. Each potassium ion is surrounded by seven oxygen atoms, at distances of 2.65 to 3.05 Å, six of which belong to four acetylacetone anions and the rest is a water molecule. The bond lengths and angles of the acetylacetone anion are very similar to those of acetylacetone groups in heavy metal chelates, but differ from those of the free molecule of acetylacetone.

A number of crystal-structure determination of transition metal complexes of acetylacetone[1-6] revealed that the chelate ring is nearly planar and the molecular dimension of the ring is almost independent of the kind of the metal atom. It is, therefore, particularly interesting to compare the structure of a free acetylacetone anion with that of acetylacetone coordinated to heavy metals. The crystal structure of potassium acetylacetonate hemihydrate, $KC_5H_7O_2 \cdot 1/2H_2O$ (hereafter denoted as PAH), is described in this paper.

Experimental

The samples of PAH were prepared by mixing hot alcoholic solution of potassium hydroxide and 2,4-pentanedione,[7] and single crystals were obtained in the form of rods. They are hygroscopic; the specimens were sealed in thin-walled glass capillary tubes. The crystal was found to be triclinic from Weissenberg photographs. The unit cell dimensions were determined on the basis of the high-angle reflections on Weissenberg photographs taken with Cu$K\alpha$ radiation ($\lambda=1.5418$ Å) as follows: $a=10.86\pm0.01$, $b=8.74\pm0.02$, $c=7.45\pm0.02$ Å, $\alpha=90.5\pm0.4$, $\beta=95.8\pm0.4$, and $\gamma=91.9\pm0.4°$. They were calibrated by using the reference lines of sodium chloride ($a=5.6396$ Å). The measured density was 1.40 g cm^{-3} (flotation method in carbon tetrachloride and cyclohexane), while the calculated one was 1.39 g cm^{-3} for $Z=4$. The intensities were recorded on multiple-film equi-inclination Weissenberg photographs with Cu$K\alpha$ radiation. Intensities of the layers $hk0$–$hk4$ were collected and estimated visually. The absolute scale of the structure amplitudes for each layer was obtained at a later stage by correlating with the calculated ones. In total, 1590 reflections were observed. Corrections for Lorentz and polarization effects were applied in the usual way. Correction for absorption was neglected. The space group $P\bar{1}$ was assumed at the outset and confirmed in the course of refinement.

Structure Determination

The structure analysis was initiated on the basis of the two-dimensional heavy-atom method. The x and y coordinates of two independent potassium ions were deduced from a Patterson projection onto the (001) plane; they were overlapped in the Fourier projection on this plane. Iterative Fourier and difference-Fourier syntheses refined the x and y coordinates of K, O and C atoms. The results suggested that the acetylacetone groups are almost planar and parallel to the (001) plane. The z coordinates of the atoms were guessed from a packing consideration. With the trial and error method, all the atoms in the two planar anions and the oxygen

atom of water molecule could be located at approximately $z=1/4$, and two potassium ions at $z=0$ and 1/2, respectively.

Seven iterations of the block-diagonal least-squares refinement with isotropic thermal factors reduced the R value to 0.151. Then, anisotropic thermal factors were introduced, and the refinement was continued until all the parameter shifts became less than one tenth the estimated standard deviations. The final R value was 0.109 for nonzero reflections. A quantity $\sum w(|F_o|-|F_c|)^2$ was minimized, with $w=1.0$ if $F_o > 5.0$ and $w=0.5$ otherwise. All the data including zero reflections were used in the calculation with the exception of the reflection 100, which seemed to be seriously suffering from secondary extinction effect. The atomic scattering factors for a potassium ion, neutral oxygen and carbon atoms were taken from Ref. 8. The final positional and thermal parameters are listed in Table 1. Numbering of atoms is shown in Fig. 1. The observed and calculated structure factors are given in Table 2.

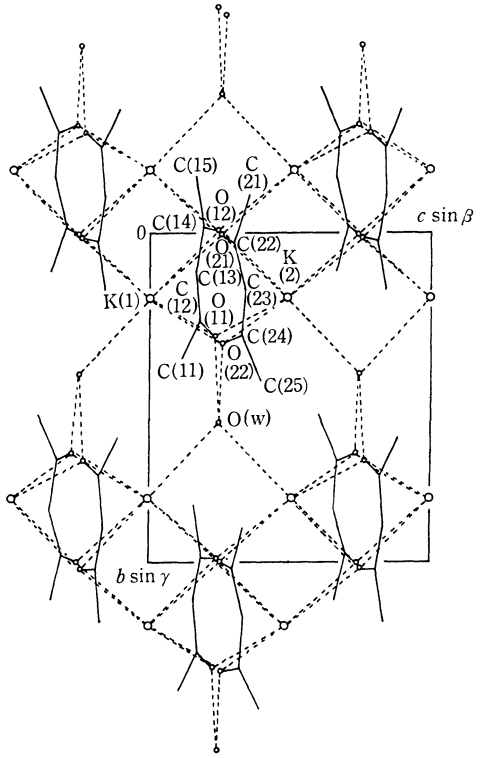

Fig. 1. Projection of the molecular skeleton along the a-axis. Solid lines indicate the acetylacetone framework and broken lines indicate the potassium-oxygen and oxygen-oxygen interactions. The numbering of the atoms refers to that in Table 1.

The space group assignment was finally checked by the distribution of the structure amplitudes.[9] The ratio of $\overline{F^2}/\overline{F}^2$ was found to be 0.631, while the theoretical values for centric and acentric distributions are 0.637 and 0.785, respectively. An $N(z)$ test[10] was also applied and indicated clearly the presence of a center of symmetry in agreement with the assigned space group.

Most of the calculations were carried out by using the UNICS programs[11] on a HITAC 8800 computer at the Computer Center of the University of Tokyo.

Results and Discussion

The crystal structure of PAH is shown in Fig. 1. Each potassium ion is surrounded by seven oxygen atoms, six of which belong to four different acetylacetone anions and the rest is a water molecule. The potassium-oxygen distances are in the range of 2.65 to 3.05 Å, as shown in Table 3.

The structures of several crystals including potassium ions in various coordination numbers were reported.

Table 3. Distances (d/Å) and angles (φ/°) with their estimated standard deviations shown in parentheses

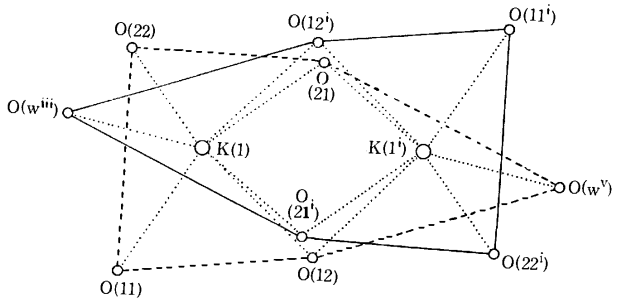

Fig. 2. Two distorted pentagons sandwiching two potassium ions.
The pentagons are shown by the solid and broken lines. The potassium ion interacts with seven oxygen atoms, as shown by dotted lines.

In potassium hydrogen bis(homophthalate),[12] the potassium ion is surrounded by four oxygen atoms at 2.76—2.80 Å. In potassium hexaiodatogermanate (IV),[13] there are two potassium ions in a tube of 18 oxygen atoms and each potassium ion is surrounded by nine oxygen atoms at 2.70—2.98 Å. In potassium hydrogen methylsuccinate,[14] the potassium ion is surrounded by a distorted tetrahedron of oxygen atoms at 2.705 to 2.763 Å and also by four oxygen atoms at longer distances of 2.956—3.085 Å. The observed K-O lengths for PAH are reasonable in comparison with these values.

The irregular seven-fold coordination of PAH can also be described, as a sandwich of two K^+ ions between two distorted pentagons shown in Fig. 2. The equation of the pentagonal plane through O(11), O(12), O(21), O(22) and O(w^{v}) is given in Table 4. The distance between the pentagonal plane is 3.7 Å. There is the crystallographically independent K^+ ion pair K(2)-K(2^{ii}), which takes the same arrangement as the K(1)-K(1^{i}) shown in Fig. 2. The distance of their pairs is about 3.4 Å.

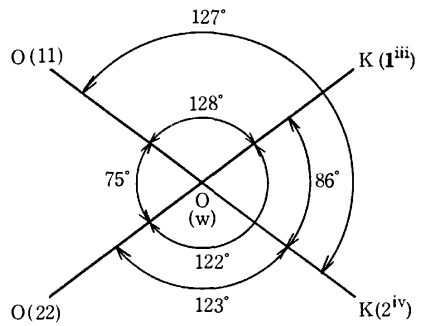

Fig. 3. Distorted tetrahedral environment of the water molecule.

The distorted tetrahedral environment of the water molecule consists of two K^+ ions and two oxygen atoms, as shown in Fig. 3. The distances of the OH···O hydrogen bonds are 2.82 and 2.72 Å. The mean values of intermolecular methyl-methyl and methyl-methylene carbon distances are 4.0 and 3.8 Å, respectively.

The mean values of bond lengths and angles in the acetylacetone anion are shown in Fig. 4. They are nearly equal to the corresponding mean values in heavy metal chelates of acetylacetone, as shown in Table 5. The skeleton of the acetylacetone anion in PAH is also nearly planar (Table 4) because of π-electron delocalization, though the methyl carbon atoms [C(11) and C(25)] are significantly out of the plane as seen in the case of the heavy metal chelates. These facts seem to suggest, though not conclusive, that the bonding between the ligand and metal atoms in heavy metal chelates of acetylacetone is rather ionic as in PAH.

Recently the molecular structure of acetylacetone was determined by gas electron diffraction.[15] It is of interest to note that the structure of the enol form, as shown in Table 5, is considerably different from the structure of acetylacetone in both PAH and the heavy metal chelates, where a heavy metal atom replaces the hydrogen atom. The greater C=O distance and the smaller CC_cC angle in the enolic acetylacetone can be

Induced Circular Dichroism of Benzyl Chromophores Bound to Helical Polypeptides

Hiroyuki NOMORI, Nobuaki TSUCHIHASHI,* Shoji TAKAGI, and Masahiro HATANO
Chemical Research Institute of Non-Aqueous Solutions, Tohoku University, Katahira, Sendai 980

(Received November 20, 1974)

Extrinsic optical activity was observed for symmetric side chain chromophores in helical polypeptides. Poly-β-benzyl-L-aspartate, poly-β-*p*-nitrobenzyl-L-aspartate and poly-γ-*p*-nitrobenzyl-L-glutamate gave induced circular dichroism in the wavelength regions corresponding to the absorption bands of the benzyl and the *p*-nitrobenzyl chromophores of the side chains in their dilute solutions. Moreover, poly-γ-benzyl-D-glutamate gave induced circular dichroism due to the benzyl chromophore in its concentrated solutions which formed a liquid crystalline phase. The extrinsic optical activity thus observed was explained as the consequence of the loss of the rotational freedom of the chromophores relative to the α-helical structure and to the cholesteric helical structure of the polypeptides.

Blout and Stryer[1] reported that extrinsic optical activity is induced in the wavelength region corresponding to the absorption band of acridine orange (AO) or acriflavine when the dye molecule becomes bound to the α-helical poly-α,L-glutamic acid (PLGA) molecule or to nucleic acids. Recently, we made more intimate investigation into the optical activity of AO bound to the carboxylate group of the side chain of PLGA in the neutral and the alkaline pH regions.[2,3]

On the other hand, it has been found that poly-γ-(1-naphthylmethyl)-L-glutamate[4] and poly-γ-(β-*N*-carbazolylethyl)-D-glutamate[5] also exhibit some circular dichroism (CD) bands in the wavelength regions corresponding to the absorption bands of their side chain chromophores when the polypeptides are dissolved in helix solvents at low concentrations, such as 10^{-3} mol of the peptide residue/l.

Loucheux and Duflot[6] reported that the nitrobenzyl chromophore in α-helical PLGA exhibits a CD band at 295 nm which they assigned to the n-π^* transition of the nitrobenzyl group. They offered for the origin of the extrinsic optical activity of the symmetric chromophore of the side chain in the α-heical polypeptide the following three mechanisms, (i) strong chromophore-chromophore interactions; in this case, the α-helix served only to hold constant the relative geometry between neighboring chromophores, (ii) local interactions between the chromophore and the dissymmetric field of the α-helix and (iii) the perturbation to the chromophore by the dissymmetric field of the chiral carbon in the peptide residue.

In our recent investigation[7] concerning the optical activity of D-phenylglycine in comparison with that of L-phenylalanine, we indicated that the perturbation by the dissymmetric field of the chiral carbon to the transition of the phenyl group in an asymmetric molecule decreases abruptly as the rotational freedom of the phenyl chromophore is increased by increase in the chiral carbon to phenyl chromophore distance, and that the perturbation is expected to be only trivial for the chromophore separated by more than four atoms from the chiral carbon atom. The perturbation by the chiral carbon to which the side chain is attached should therefore have a very small contribution to the induced circular dichroism of the benzyl chromophores bound to the α-helical polypeptides studied in this paper, unless limitation of the rotation of the chromophore is caused by some origin.

In the present paper, the extrinsic optical activity of the benzyl chromophores bound to the helical polypeptides is examined and this optical activity is correlated to the rotational freedom of the chromophore.

Experimental

Materials. Poly-β-benzyl-L-aspartate (PBLA) and poly-γ-benzyl-D-glutamate (PBDG) were prepared by the conventional polymerization of the *N*-carboxyanhydrides of the parent amino acids. Unless otherwise noted, the degrees of polymerization of these polymers were 170 and 1320, respectively. Poly-β-*p*-nitrobenzyl-L-aspartate (PNO_2BLA) and poly-γ-*p*-nitrobenzyl-L-glutamate (PNO_2BLG) were prepared by the method reported by Ledger and Stewart.[8] Ethylene chlorohydrin and tetrachloroethane were purified by ordinary methods. The other solvents were spectral grade ones and were used without further purification.

Methods. The infrared (IR) spectra were measured by a Hitachi EPI-S_2 infrared spectrometer. The cell for observation consisted of two NaCl plates separated by a 30 μm lead spacer, and the polymer solution was inserted between the plates. The absorption spectra, the CD spectra and the optical rotatory dispersion (ORD) curves were observed for the concentrated polymer solution held between two quartz plates spaced by a suitable aluminum foil. In the case of the dilute solution, a usual optical quartz cell was used. The absorption spectra were recorded on a Hitachi EPS-3T spectrometer. The CD and the ORD measurements were carried out by a JASCO J-20A dichrograph and a J-15 spectropolarimeter, respectively.

Results and Discussion

Extrinsic Optical Activity of Benzyl and p-*Nitrobenzyl Chromophores Bound to Helical Polypeptides in Dilute Solutions.* Poly-γ-*p*-nitrobenzyl-L-glutamate shows a definite negative CD band in the neighborhood of 275 nm. The CD spectrum is shown in Fig. 1. In spite of the existence of the anomalous dispersion around 275 nm in its ORD curve, we can obtain Moffitt's b_0 of −540 from the fairly linear Moffitt plot in the longer

wavelength region than 390 nm indicating the right-handed α-helical structure. As is shown in Fig. 2, we cannot detect any CD band in the wavelength region longer than 260 nm for γ-*p*-nitrobenzyl-L-glutamate and PBDG at low concentrations, such as 10^{-3} mol of glutamyl residue/l.

From these, it is deduced that the introduction of the nitro group into the side chain benzyl group of the polyglutamate intensifies the interaction between side chain groups leading to the increase of the probability of their definite orientation relative to the polypeptide main chain. This unexpected loss of the rotational freedom of the side chain chromophore causes interaction between the transition dipole moment of the nitrobenzyl chromophore and that in the α-helix main chain, and is the very reason why circular dichroism appears in the absorption region of the nitrobenzyl chromophore despite the distance between the chromophore and the polypeptide main chain.

Goodman *et al.*[9-11] reported that the nitrobenzyl group in PNO_2BLA forms a rigid side chain helix around the α-helix of the polypeptide main chain, but that the nitrobenzyl group in PNO_2BLG is not in a dissymmetric field and can rotate freely. Our above-mentioned observation of the circular dichroism or the anomalous optical rotatory dispersion ascribed to the aromatic chromophore is attained by the development of the J-20A dichrograph with a low noise-high output amplifier. Loucheux and Duflot reported that the CD spectrum of the copolymer of L-glutamic acid with *p*-nitrobenzyl-L-glutamate shows a positive peak at 296 nm in an aqueous solution at pH 4.5.[6] It is interesting that the incorporation of small amount of the γ-*p*-nitrobenzyl-L-glutamate unit into poly-L-glutamic acid results in a circular dichroism which differs both in the sign and the wavelength of the maximum from those in the homopolymer of γ-*p*-nitrobenzyl-L-glutamate.

The dilute solution of poly-β-benzyl-L-aspartate in chloroform or dichloromethane gives a weak but undoubted CD band centered at 252 nm, as is shown in Fig. 3. A large positive CD band appearing at 222 nm, means that PBLA exists in the left-handed α-helical structure.[12,13] We also observed the optical rotatory dispersion of the same chloroform solution of PBLA as is shown in Fig. 4 in comparison with that of the left-handed α-helical structure of PBDG. The feature is very similar to that reported by Blout and coworkers,[13] and shows an anomalous dispersion giving a negative Cotton effect in the absorption region of the benzyl chromophore. The extrinsic optical activity observed here is due, in similar manner to the case of PNO_2BLG, to the definite orientation of the benzyl chromophore relative to the main chain α-helix, which is brought about by the interaction between benzyl residues of PBLA whereas we have not detected any circular dichroism for the benzyl group of β-benzyl-L-aspartate. More crowded arrangement of the benzyl group in PBLA around the main chain α-helix because of the lack of one methylene group in the side chain leads to the increase in the interaction between benzyl

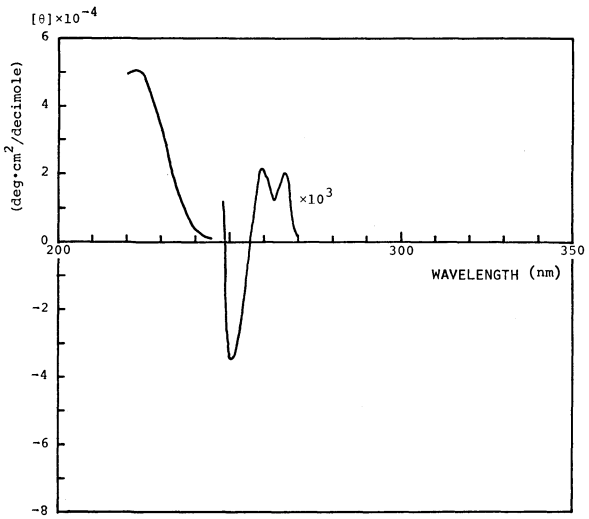

Fig. 3. CD spectrum of PBLA in chloroform ($\Delta\varepsilon/\varepsilon = -6.2\times10^{-5}$ at 252 nm); "$\times10^3$" denotes that the spectrum is magnified 10^3 times longitudinally.

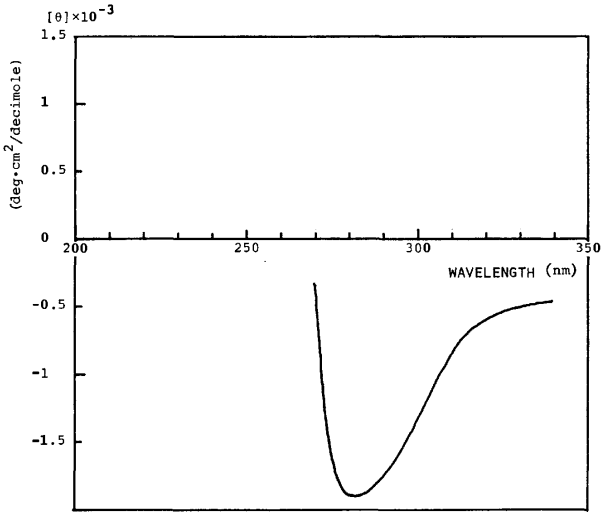

Fig. 5. CD spectrum of PNO_2BLA in *N,N*-dimethylformamide ($\Delta\varepsilon/\varepsilon = -6.9\times10^{-5}$ at 280 nm).

chromophores of PBLA, giving rise to the circular dichroism detected in PBLA while such is not the case for PBDG.

In Fig. 5 the CD spectrum of PNO_2BLA is shown. No circular dichroism is detectable in the wavelength region longer than 250 nm for β-*p*-nitrobenzyl-L-aspartate. The CD band of PNO_2BLA around 290 nm is also ascribed to its benzyl chromophore. The α-helical structure of PNO_2BLA in *N,N*-dimethylformamide has been ascertained by Goodman *et al.*[9] The molar ellipticity $[\theta]_{280}$ of PNO_2BLA is much larger than $[\theta]_{275}$ of PNO_2BLG. This again reflects the fact that the side chain in the polyaspartate is constrained in its orientation as a result of their shorter side chain length than that of the polyglutamate by one methylene group. It is remarkable that the absolute value of the optical anisotropy factor $\Delta\varepsilon/\varepsilon$ is only slightly larger in PNO_2BLA than in PBLA. The α-helical sense of PBLA is opposite to that of PNO_2BLA, so this difference in $\Delta\varepsilon/\varepsilon$ cannot be correlated in a straightforward way to the difference in the magnitude of the interaction between side chain aromatic chromophores.

It must be noticed that the size of the interaction between side chain chromophores of the above-mentioned polypeptides is no more than necessary to align the chromophores around the definite orientation relative to the main chain helices of the polypeptides and is not so strong as to cause strong chromophore-chromophore interactions mentioned in mechanism (i) by Loucheux and Duflot resulting in the Davydov splitting of the CD band.

Induced Circular Dichroism of Benzyl Chromophores Bound to Helical Polypeptides in Concentrated Solutions.

PBLG in α-helical conformation forms a cholesteric liquid crystal in its concentrated solutions (10—50 wt% of the polymer).[14] A chirality is caused by the existence of a unidirectional twist on the array of a set of equispaced parallel planes in which α-helical axes lie, nevertheless the solution forms an isotropic domain as a whole because of the random orientation of the axes of the cholesteric helix in the macroscopic domain. The extrinsic optical activity due to the side chain benzyl group is expected to occur in such a concentrated PBL(D)G solution since a regularly ordered array of the side chain chromophore may exist in such a phase.

In the concentration range of PBDG less than 0.1 mol of glutamyl residue/l in dichloromethane, no evidence of the occurrence of the higher order structure can be detected. ORD curves for such a concentration range (Fig. 4) show monotonic patterns as is encountered for the usual polypeptide solution having the α-helical structure. There is no Cotton effect observed in the wavelength region longer than 250 nm, and we get reasonable b_0 values around +650 from the good linearity of the Moffitt plot in the range of 280 nm—350 nm.

When the concentration is raised over 0.4 mol of glutamyl residue/l, it is found from the microscopic examination that the cholesteric liquid crystalline phase is formed in the system. For this system, the ORD curve, giving an anomalous dispersion near 255 nm, is quite different from those for less concentrated systems (Fig. 6), and it cannot be decided from this ORD curve whether or not the α-helical structure is retained since the Moffitt plot no longer gives a straight line and does not give a definite b_0. On the other hand, IR mesurements indicate that the α-helical structure is retained up to the concentration of 0.75 mol of glutamyl residue/l since the IR bands (amide I and amide II bands) which are ascribed to the α-helical structure appear at 1650 cm^{-1} and at 1550 cm^{-1} and a band at 1690 cm^{-1} due to the non-hydrogen bonded carbonyl group is absent.[15]

As expected from the remarkable concentration

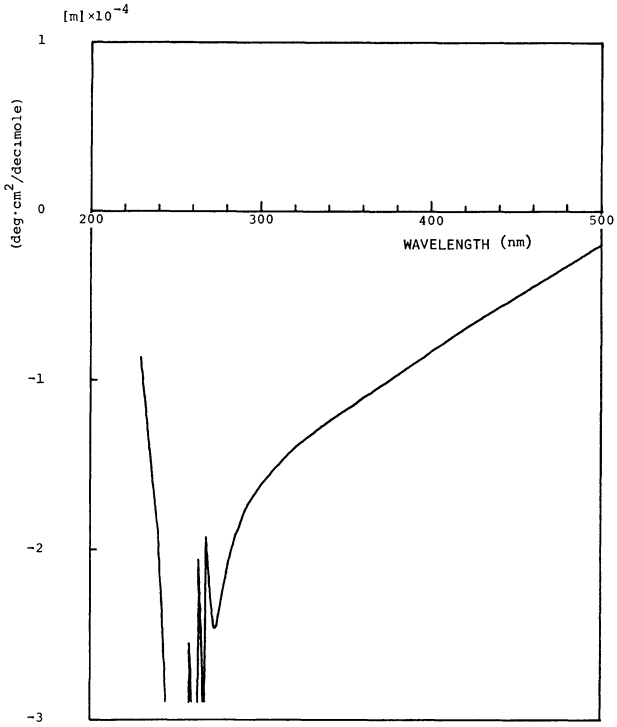

Fig. 6. ORD curve of concentrated PBDG solution in dichloromethane (0.74 mol of glutamyl residue/l).

dependence of the ORD curve, a CD band near 255 nm really appears at higher concentrations than 0.4 mol of glutamyl residue/l in dichloromethane. The cholesteric phase is also formed when PBDG is dissolved in other helix solvents such as dichloroethane and tetrachloroethane, giving similar CD bands near 255 nm, but the signs of the CD bands in these solvents are opposite to that in dichloromethane. The observed CD spectra are shown in Fig. 7. On the other hand, it has been confirmed by the polarizing microscopic observation that the nematic liquid crystalline phase of PBDG is formed when this polypeptide is dissolved in the solvent mixture of dichloromethane and dioxane (4: 1 in volume). No CD band around 255 nm appears in this nematic phase.

Extremely condensed phase is realized locally around closed-packed α-helices lying in parallel equispaced planes making up the cholesteric helix, and thus the benzyl chromophore attached to the α-helix is imposed to take a definite arrangement relative to this plane. This, in turn, means that the side chain benzyl chromophore assumes a definite orientation relative to the cholesteric helix. We can deduce, through the analogous way to that in the case of the dilute solution of PNO_2-BLG, that the extrinsic optical activity induced to the aromatic chromophore originates from the interaction between the aromatic chromophore of the polypeptide and the "helix." The solvent dependence of the sign of the Cotton effect of the benzyl chromophore of PBDG in the cholesteric liquid crystalline phase can probably be explained by the solvent dependency of the sense of the cholesteric helix reported by Robinson.[14]

No extrinsic optical activity can be observed for PBDG existing in the nematic liquid crystalline phase, while the benzyl chromophore of PBDG in such a

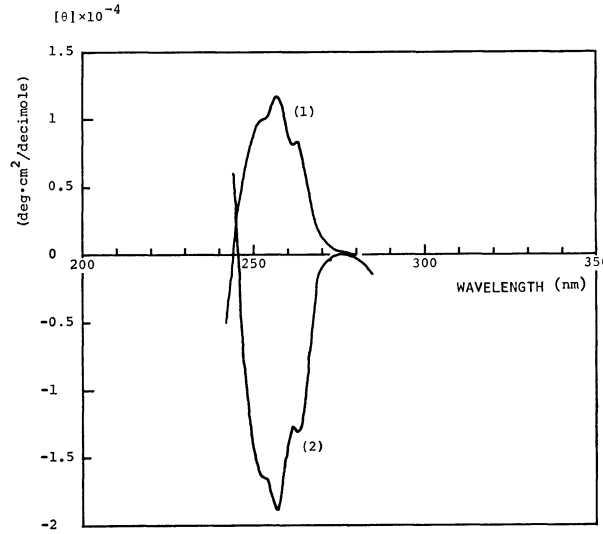

Fig. 7. CD spectra of PBDG in (1) dichloromethane (0.48 mol of glutamyl residue/l, $\Delta\varepsilon/\varepsilon = +0.014$ at 256 nm) and (2) tetrachloroethane (0.46 mol of glutamyl residue/l, $\Delta\varepsilon/\varepsilon = -0.022$ at 256 nm).

phase can be regarded as fixed in its orientation relative to the α-helix in the closed-packed structure as well as in the cholesteric phase and an extrinsic optical activity is expected to appear due to the dissymmetric field of the α-helical structure. To explain this fact, it might be necessary to assume that there exist enantiomeric arrangements of the benzyl chromophore subsisting simultaneously in the closed-packed plane of the nematic structure. This probably prevents the closed-packed plane of the nematic structure from arranging in a helical sense to form a cholesteric helical structure.

Again, as in the dilute solution of the polypeptide, there exists no Davydov pair of CD bands here, and so the benzyl chromophore of PBDG in the cholesteric liquid crystalline phase is not so closely stacked as to produce the interaction between electric transition moments in benzyl chromophores.

The optical anisotropy factor $\Delta\varepsilon/\varepsilon$ is 1.4×10^{-2} for this case, and this value is surprisingly large compared to those for PBLA, PNO_2BLA and PNO_2BLG in the dilute solutions which are -6.2×10^{-5}, -6.9×10^{-5}, and -3.8×10^{-5}, respectively. This fact is indicative that the dissymmetric field for the first case cannot be sought in the same origin as for the rest. This also supports the idea that the extrinsic optical activity of PBDG in its concentrated solutions should not be attributed to the α-helical structure of the polypeptide, but to the helical structure of the cholesteric liquid crystalline phase.

Conclusion

The dissymmetric field for the present case comes from two origins, namely the α-helical structure of the polypeptide and the cholesteric helical structure in the liquid crystalline phase of the polypeptide. The extrinsic optical activity appears when the benzyl chromophore loses its freedom of rotation to be oriented more rigidly relative to this dissymmetric field. PBLA has one less methylene group in its side chain than PBDG, realizing

more crowded arrangement of the benzyl group around the main chain α-helix. This leads to the definite orientation of the benzyl chromophore relative to the α-helix, giving rise to the extrinsic optical activity in the dilute solution of PBLA. The introduction of the nitro group into the benzyl chromophore increases the bulkiness of the side chain and the magnitude of the electrostatic interaction between side chains. This increase results in the enhancement of the probability of a definte orientation of the benzyl chromophore of PNO_2BLG relative to the α-helix of PNO_2BLG in its dilute solution or in the inversion of the left-handed α-helical sence of PBLA to the right-handed one of PNO_2BLA in the dilute solution. The benzyl chromophore of PBDG in its concentrated solution forming the cholesteric liquid crystalline phase takes a definite orientation in the closed-packed structure in the parallel equispaced planes making up the cholesteric helix.

We wish to thank Professor Akiyoshi Wada of the University of Tokyo for helpful discussions and encouragement.

The Spectroscopic Study on the Dimerization of Pyridine Derivatives on the Surfaces of MgO, CaO and SrO

Tokio IIZUKA and Kozo TANABE

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 2, 1975)

The adsorption and dimerization of pyridine derivatives on MgO, CaO, and SrO were studied by ESR and visible absorption spectrometries. Adsorbed pyridine on the oxides was found to give an ESR signal of five lines and 580 nm absorption spectrum which were attributed to dipyridyl anion radical. The deuterium isotope effects for the formation of dipyridyl anion radicals were observed on MgO and CaO, but not on strong basic oxide, SrO. Methylpyridines adsorbed on MgO gave the same species as pyridine by the irradiation of light (λ>370 nm). From these facts, the surface intermediates for the dimerization reaction were discussed. When the adsorbed species were exposed to oxygen molecule, the dipyridyl anion radicals faded away and the ESR spectra attributed to the O_2^- ion were observed.

Alkaline earth metal oxides as solid base catalysts have recently been found to show a remarkable activity and interesting selectivity for the isomerization of olefins,[1] the alkylation of phenol with methanol,[2] the conversion of benzaldehyde into benzyl benzoate,[3] *etc.* On the other hand, the formation and stabilization of negative radical ions of aromatic nitro compounds on the surfaces of MgO[4] and CaO[5] by electron transfer process are well known.

In the present work, the formation of dipyridyl anion radical by the dimerization of pyridine derivatives adsorbed on MgO, CaO, and SrO was found by ESR and visible absorption spectroscopies, and their adsorbed states were discussed.

Experimental

Magnesium oxide used in this investigation was prepared from $Mg(OH)_2$, guaranteed reagent of Kanto Chemical Co., Inc., by evacuation at different temperatures for 1 hr. Calcium and strontium oxides were from the carbonates of Merck guaranteed reagents by evacuation at 700—900 °C for 1 hr. Pyridine and α, β, γ-methylpyridines were guaranteed reagents of Wako Pure Chemical Co., Inc., distilled in a vacuum and degassed by repeating a freezing-thawing cycle several times and dried by molecular sieve. Pentadeuteropyridine was purchased from Merck Co. and purified by the same method as in pyridine derivatives.

Adsorptions were done under the vapor pressures at room temperature in a vacuum system.

A JEOL ESR spectrometer operating with 100 kHz field modulation was employed to obtain the ESR spectra. The visible absorption spectra were recorded with Shimadzu MPS-50L spectrometer by using the *in situ* quartz cell in which the pressed wafer of $Mg(OH)_2$ powder was fixed. These spectra were recorded at 20 °C.

Light irradiation was done through the pyrex glass filter by Toshiba SHL-100UH-2 ultra high pressure mercury lamp.

Results

ESR Spectra of Adsorbed Pyridine. When pyridine was introduced to MgO, CaO, and SrO evacuated at high temperature, the color of the oxide surfaces turned to purple instantly, and broad unsymmetrical ESR signals were observed as shown in Fig. 1. On MgO surface, several numbers of splittings were observed, but

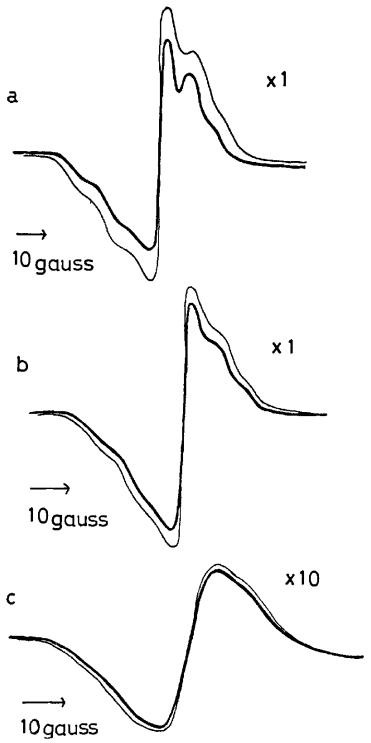

Fig. 1. ESR spectra of pyridine adsorbed on oxides. a. MgO evacuated at 600 °C, b. CaO evacuated at 700 °C, c. SrO evacuated at 900 °C, heavy line: 2 min after adsorption, weak line: 10 min after adsorption.

those splittings were obscure on CaO or SrO surface. As shown in Fig. 2, after pentadeuteropyridine (C_5D_5N) instead of pyridine adsorbed on these oxides, the sharp five splitted lines developed in the cases of MgO and CaO, but on SrO, the splitting was not clear.

From the dependence of signal shape on the microwave power change, those signals were thought to be due to one paramagnetic species, and concluded to be hyperfine structure of two equivalent ^{14}N. The hyperfine coupling constants were 8.2 for MgO, 7.4 for CaO, and 7.2 gauss for SrO.

The change of the spin concentration with adsorption time was shown in Fig. 3. On MgO surface, the broader and stronger signal was obserbed on pyridine adsorption than on the adsorption of pentadeuteropy-

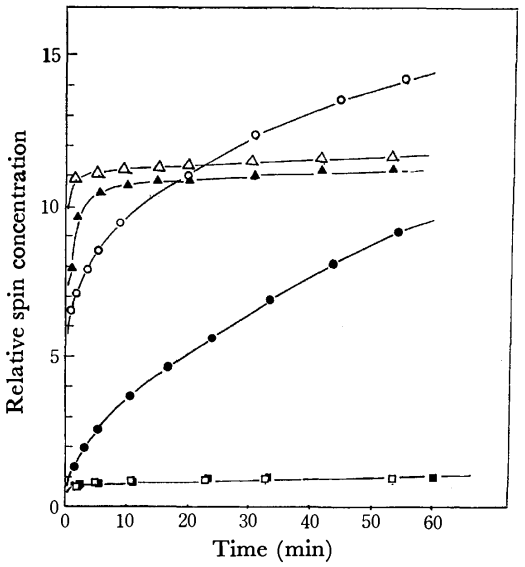

Fig. 3. Adsorption time dependence of spin concentration. ○: pyridine on MgO (evacuated at 600 °C), ●: deuteropyridine on MgO (600 °C), △: pyridine on CaO (700 °C), ▲: deuteropyridine on CaO (700 °C), □: pyridine on SrO (900 °C), ■: deuteropyridine on SrO (900 °C).

ridine. Those signals increased their intensity with adsorption time, but the shapes of two signals were very different as shown in Figs. 1 and 2.

On CaO surface, the differences in the intensity and the shape of those signals were obvious at the initial stage of the adsorption, but almost the same spectrum was observed after 20 min adsorption.

In the case of SrO, no difference was observed in the shape of spectra and spin concentration.

The Visible Spectra of Pyridine Adsorbed on MgO. The visible spectra of pyridine adsorbed on evacuated MgO were shown in Fig. 4. Those spectra had three absorption bands at 380, 470, and 580 nm.

In the reduction of pyridine by alkali metal, it is known that the formed 4,4′-dipyridyl anion radical shows the absorption at 381 and 570 nm.[6]

On MgO evacuated at high temperature, only the 580 nm band decreased remarkably. The change in 580 nm band intensity with evacuation temperature was shown in Fig. 5. It had very close correlation with the change in ESR spin density with evacuation temperature change. These facts suggest the formation of dipyridyl anion radical on MgO.

Actually, the UV spectrum of the extracted ethanol solution of adsorbed species on MgO coincided with that of 4,4′-dipyridyl.

The Visible and ESR Spectra of Methylpyridine Adsorbed on MgO. When methylpyridine adsorbed on MgO, the surface showed yellow color, but gave no ESR signal. The visible spectra of those adsorbed species

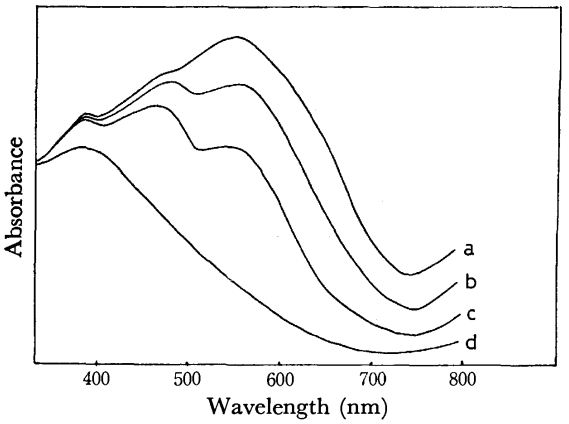

Fig. 4. Visible absorption spectra of pyridine adsorbed on MgO. a. evacuated at 600 °C, b. evacuated at 800 °C, c. evacuated at 1000 °C, d. exposed to oxygen gas.

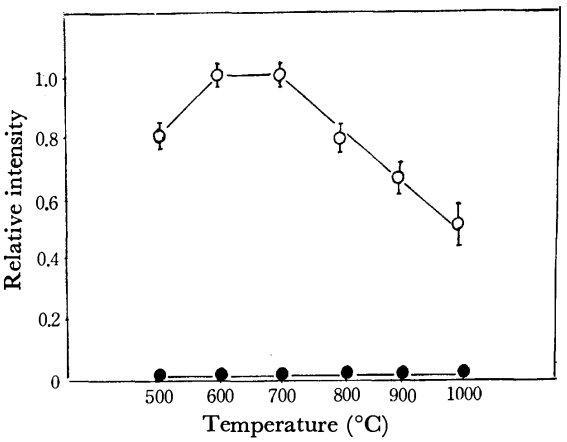

Fig. 5. Calcination temperature dependence of 580 nm band on MgO. ○: evaculated *in vacuo*, ●: heated in air.

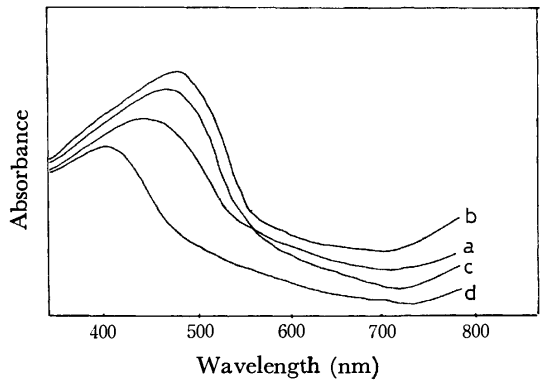

Fig. 6. Visible absorption spectra of methylpyridines adsorbed on MgO evacuated at 600 °C. a. γ-methylpyridine, b. β-methylpyridine, c. α-methylpyridine, d. exposed to oxygen gas.

are shown in Fig. 6. On any adsorbed species, only 470 nm band was observed. After the exposure to O_2 gas, this 470 nm band diminished immediately. When the methylpyridines adsorbed on MgO which showed no ESR signal were irradiated by light (λ>370 nm), those yellow surfaces turned to purple and the intense ESR signals analogous to that in pyridine adsorption were observed.

The ESR Spectra of the Adsorbed Pyridine Derivatives Exposed to Oxygen Gas. When the pyridine adsorbed on MgO was exposed to O_2 gas, the purple color and the ESR spectrum of dipyridyl anion radical disappeared and the new broad unsymmetrical ESR spectrum with g-values at g_1=2.076 and 2.060, g_2=2.008, g_3=2.001 was observed at room temperature. Those g values and the shape of this spectrum agreed well with those of the adsorbed O_2^- radical on ultraviolet irradiated MgO.[7]

On CaO surface, axial symmetrical signal with $g_{//}$= 2.082, $g_\perp$=2.005 was observed after exposure to O_2 gas. Though O_2^- ion adsorbed on CaO has never been reported, this signal would be also concluded to this ion. The O_2^- ion on SrO was not observed in spite of the disappearance of radical anion by exposure to O_2 gas. In the case of the methylpyridine adsorbed on MgO which gave no ESR signal, ESR signal of O_2^- ion appeared after the introduction of O_2 gas.

Discussion

The analysis of the ESR spectra with sharp hyperfine structure of adsorbed pentadeuteropyridine provides many informations about the electronic states of adsorbed ions, structural changes due to adsorption, and interaction with the surface. The signals shown in Fig. 2 having five line pattern are essentially due to the anisotropic interaction of the free spin of two nitrogen nuclei with each nuclear spin of unity. The Hamiltonian for this type of radical can be written in the form,

$$\mathcal{H} = \beta \cdot s \cdot \tilde{g} \cdot H + s \cdot \tilde{A} \cdot I,$$

where $\tilde{g}$, $\tilde{A}$ are tensors respectively. For axial symmetry such as an electron delocalized into a nitrogen 2p orbital, the observed hyperfine interaction α can be written as

$$\alpha^2 = [A^2 + 2AB(3\cos^2\theta - 1) + B^2(3\cos^2\theta - 1)],$$

Where A is the isotropic interaction and B is a traceless anisotropic term. If the radical is tumbling rapidly, the anisotropic interactions vanish and α becomes to A. In rigid adsorbed system, the observed hyperfine splittings can be attributed to the A and B terms, the hyperfine coupling $A+2B$ parallel to the p-orbital direction ($A_{//}$), and $A-B$ perpendicular to the p-orbital direction ($A_\perp$).

It is reasonable to consider that the outer four lines are parallel hyperfine, and the central line is the remaining parallel feature on which all the perpendicular components are overlapping.[8] Although a value for $(A+2B)$ has been measured, we must either measure $(A-B)$ or A independently to obtain values for A and B. Since the central line shows no resolution of $(A-B)$, some limiting values of A and B can be calculated assuming that $(A-B)<1/2\Delta H_{pp}$. These values (gauss) are shown in Table 1.

Table 1.

Oxide	$(A+2B)$	ΔH_{pp}	$g_{//}$	$g_\perp$	A	B	$A_{iso}N$
MgO	8.2	4.0	2.0022	2.0030	4.08	2.08	—
CaO	7.4	4.2	2.0022	2.0026	3.81	1.81	—
SrO	≃7.2	≃12	2.002	2.003	≃3.8	≃1.8	—
Solution[9]	—	—	—	—	—	—	3.64

Although the values of A and B are limiting values estimated from the equation,

$$A - B = \frac{1}{2}\Delta H_{pp}$$

so large error would not be involved, since the values of ΔH_{pp} are very small. The fact that the A value of dipyridyl on MgO is slightly larger than those of CaO and SrO is due to the difference in the ionic power or Lewis acidity of Mg^{2+}, Ca^{2+} and Sr^{2+} ions. Since the A value of the adsorbed species are almost comparable to the isotropic hyperfine coupling constant of γ,γ'-dipyridyl anion radical in solution[9] (A_{iso} N=3.64 G), the dipyridyl negative ion on the surface is not so polarized by the crystal field.

The values of A and B for the isotropic and anisotropic interactions of the nitrogen atom can be used to obtain the s and p character of the orbital of the unpaired elcetron, since those can be written:

$$A_N = a_{2s}^2 A_0,$$
$$B_N = a_{2p}^2 B_0,$$

where a_{2s}^2 and a_{2p}^2 are the populations of the nitrogen 2s and 2p orbitals. If the values of A_0=550 gauss and B_0=17.2 gauss are used for the nitrogen atom,[10] the spin population value are shown in Table 2.

There is no difference in the spectra between adsorbed pyridine and pentadeuteropyridine (C_5D_5N) on oxides, but pyridine adsorption gives larger spin density and broader spectrum than deuteropyridine adsorption on MgO. The broadening of the spectrum in this case would be caused by the dipole-dipole interaction of the

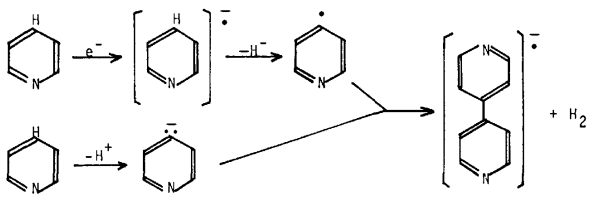
Table 2.

Oxide	a_{2s}^2	a_{2p}^2	a_{2p}^2/a_{2s}^2
MgO	0.0072	0.12	17
CaO	0.0069	0.105	15
SrO	≃0.0069	≃0.105	≃15

free spins adjoining very closely. Thus the spin density affected the shape of the spectrum. The difference in the spin density and the shape of the spectrum by the isotope labelling is evident on MgO, and this shows the isotope effect on abstraction of hydrogen or deuterium to form dipyridyl on the oxide. In the case of the adsorption on CaO, the evident isotope effect was observed in the initial stage of the adsorption, but in 20 min after the adsorption, the shape of the spectrum and the spin density became almost the same in the adsorption of pyridine or deuteropyridine. In this case, the cause of the spectrum broadening is apparently due to the increase in the spin density. On the other hand, there is no difference in the shape and spin density of adsorbed species on SrO by the isotope labelling. Since the order of the basic strength is MgO<CaO<SrO,[11] it is clear that the isotope effect becomes smaller with the increase of the basic strength, suggesting that surface oxide anion (O^{2-}) abstracts H^+ or D^+ from pyridine in the rate-determining step of the formation of dipyridyl.

The irradiation effect of light on the formation of the anion radical of phenazine on MgO was observed by Seshadri and Petrakis.[8] The anion radical formation of dipyridyl from pyridine proceeded even in dark, but the anion radical was not formed by the adsorption of methyl substituted pyridines without light irradiation. It is interesting to note that it is not necessary for the formation of the anion radical of methylpyridine dimer to irradiate with so high energy of light (λ<370 nm).

These facts suggest that both the electron transfer and H^+ abstraction are required to form dipyridyl anion radical from pyridine derivatives on alkaline earth oxides. The following scheme is proposed.



The electron transfer site on MgO was supposed to be the weakly coordinated O^{2-} ion of the surface by Che *et al.*[4b] In our scheme, the abstraction of H^+ on O^{2-} is also required. It is assured by the presence of the evident isotope effects. The abstraction of H^+ would proceed probably even on the more stabilized O^{2-} in the normal lattice than the low coordinated O^{2-} which possess electron donating ability.

On the surface of SrO, the amount of the formed dipyridyl anion radical was very small, but the isotope effect which was probably due to the abstraction of H^+ by surface O^{2-} ion was not observed.

When the adsorbed dipyridyl anion radical was exposed to oxygen gas, the anion diminished and the O_2^- ion was formed. Since the direct electron transfer to oxygen molecule on nonirradiated MgO was not observed, the expected reaction was $R^- + O_2 \rightarrow R + O_2^-$.

In the case of the exposure to O_2 gas of methylpyridine adsorbed on MgO which gave no ESR signal, the formation of O_2^- ion was also observed. From this fact, it is concluded that the adsorbed methylpyridines forms partially charge transfer complex with surface O^{2-} ion. Light facilitates this charge transfer enough to form dipyridyl derivatives through the anion radical.

Relative Determination of the Soret Coefficients of Electrolytes. V

Toshio IKEDA, Yoshihiro TAKATSUKA, and Takeshi WATANABE
Department of Chemistry, Faculty of Science, Shizuoka University, 836 Ohya, Shizuoka 422
(Received December 23, 1974)

The Soret coefficients of aqueous solutions of some transition metal chlorides were determined by use of combined thermocells. The following values (in 10^{-3} K^{-1}) were obtained in 0.005 M solutions at 25 °C: −7.01 for $MnCl_2$, −4.61 for $CoCl_2$, −2.67 for $NiCl_2$, and −3.43 for $CuCl_2$. It was concluded that ion paramagnetism does not affect thermal diffusion.

The combined thermocell method[1,2] was proved to be as useful as the most sensitive conductometric method improved by Snowdon and Turner[3] in yielding reasonable values for the Soret coefficients of a number of electrolytes. However, only a few data are reliable for the Soret coefficients so far reported of divalent salts.[2,4] Accurate Soret data are required for a great number of divalent salts. In the present work, the Soret coefficients of a series of the transition metal chlorides, MCl_2, in aqueous solutions were determined by the combined thermocell method, special interest being taken to see whether paramagnetic ions of these salts have any influence upon thermal diffusion. Combined thermocells (a cell system of a back to back combination of two thermocells consisting of common electrodes and different electrolytes without liquid junctions) of the following type were used:

$$\underset{T}{\text{Hg–HgCl}},\ \text{LiCl}(m),\ \underset{T+\Delta T}{\text{HgCl–Hg–HgCl}},\ \text{MCl}_2\left(\frac{m}{2}\right),\ \underset{T}{\text{HgCl–Hg}} \qquad (1)$$

where the concentrations of the chloride ions in the left and right halves of the cell are taken to be equivalent to each other. Lithium chloride was taken as a standard since it shows a very slight Soret effect. The Soret coefficient, σ^{MCl_2}, for MCl_2 can be calculated in terms of the σ^{LiCl} for LiCl from the resulting initial thermoelectric power, $(dE/dT)_0$, of the cell (1) by using the following approximate equation,[2] ignoring terms of the transported entropies of the chloride ion:

$$\sigma^{MCl_2} = [4t^{LiCl}_{Li^+}B^{LiCl}\sigma^{LiCl} + 2F(dE/dT)_0/RT]/3t^{MCl_2}_{M^{2+}}B^{MCl_2} \qquad (2)$$

where t is the ionic transport number of ionic species indicated by the subscripts in the solution phases indicated by the superscripts. B is defined by

$$B = (1+d\ln\gamma_{\pm}/d\ln m)_{T,P}$$

where $\gamma_{\pm}$ is the mean activity coefficient in the molality scale at a molality m, F, R, T and P having their usual meanings.

Results and Discussion

All the solutions of four transition metal chlorides, $MnCl_2$, $CoCl_2$, $NiCl_2$, and $CuCl_2$, were prepared by guaranteed reagent grade chemicals (99.8% purity, Wakō Pure Chemical Industries, Ltd.) and adjusted to a concentration of 0.01 mol dm^{-3} with respect to the chloride ions. Experimental equipments and methods are entirely the same as those reported.[2] The range of

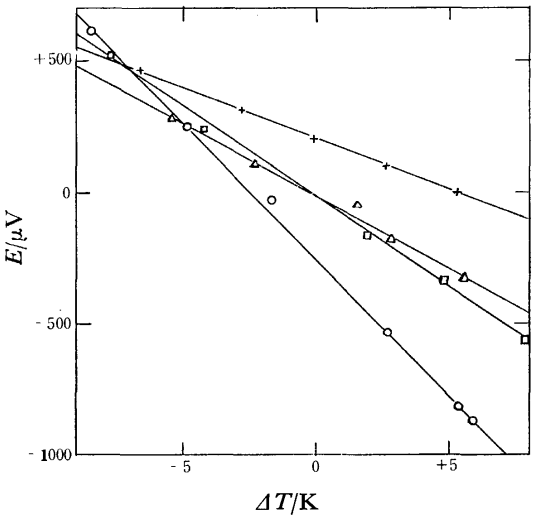

Fig. 1. Emf-plots of the combined thermocells (1) against temperature differences, ΔT: ○ for $MnCl_2$, □ for $CoCl_2$, + for $NiCl_2$, △ for $CuCl_2$.

ΔT was about 10 K around a mean temperature 25 °C, while the temperature T on the terminal electroldes was kept constant at 25 °C.

Some typical results are shown in Fig. 1. The values of the resulting initial thermoelectric power, $(dE/dT)_0$, averaged over 10—20 observations, are given in Table 1. The values of $(dE/dT)_0$ observed in the present work are accompanied by fluctuations several times larger than those ever seen in a similar work. The reason is not clear. The Soret coefficients found for the transition metal chlorides are relatively large for their small cation sizes as compared with those of the alkali and alkaline earth chlorides[2,4] which yield cations of a relatively large size. This is the reverse of the general tendency of the Soret coefficients known since the larger (the smaller) the cation size, the larger (the smaller) the Soret coefficients, and hence the stronger the ion hydration, the weaker the Soret effect. This rule seems to hold roughly so far as the elements of the same family are concerned. On the other hand, all the salts studied here are paramagnetic, and in fact the manganese chloride, which has the highest magnetic moment, showed the most predominant Soret effect, and so paramagnetism seems to have some influence on the Soret coefficient. However, this assumption might not be appropriate, since the Soret coefficients we found are not always parallel with the magnetic moments because of the one exception of cupric chloride which showed a considerable Soret effect despite the fact that the

Proton Magnetic Resonance in Some Triarylaminium Salt Free Radicals

Toshio YOSHIOKA, Kohji WATANABE,* and Hiroaki OHYA-NISHIGUCHI
Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606
**The Institute for Chemical Research, Kyoto University, Uji 611*
(Received January 6, 1975)

The static magnetic susceptibilities from 77 to 300 K and the proton NMR spectra from 1.5 to 77 K have been measured on powder samples of tris-*p*-chlorophenylaminium perchlorate and chloroantimonate, and tris-*p*-tolylaminium perchlorate and chloroantimonate. The Weiss constants have been determined to be −2.0, −40, −0.5, and −10 K respectively. A broad maximum which indicates an antiferromagnetic interaction has been observed in the electron susceptibilities of the chloroantimonates obtained from the paramagnetic shift. The magnetic behavior is interpreted assuming the linear-chain model. On the other hand, the perchlorates obeyed the Curie-Weiss law down to 1.5 K. The isotropic hyperfine coupling constants of these four aminium salts have been estimated from the proton NMR spectra, from which the cations of these crystalline aminium salts can be expected to have similar configurations.

The magnetic properties of the stable organic free radicals have been intensively investigated. A deviation from the Curie-Weiss law and a broad maximum in the susceptibilities of some ion-radical salts have been observed above the temperature of liquid nitrogen.[1] The anomalous behavior arises from the strong interaction between adjacent radicals and has been interpreted in terms of an exchange-coupled pair model or a linear-chain model. The mechanism of such a strong interaction is considered to be the charge-transfer stabilization. In the case of neutral organic radicals, an anomalous paramagnetism has often been found in the sufficiently low-temperature region and explained on the basis of a regular or alternating Heisenberg linear-chain model.[2,3] The mechanism of such a weak interaction is attributable to the overlap of $p_z\pi$-orbitals occupied by the unpaired electrons.

The series of *para*-substituted triarylaminium salts is reasonably stable in air and can be kept in the solid state for some time. Paramagnetic resonance absorption has been observed in these salts, and linewidth measurements have been reported for powder samples, together with the *g*-values.[4] However, the magnetic properties of these salts have never been studied except for the preliminary susceptibility measurements of three salts.[5] We would like to report on the magnetic behavior of four aminium salts, tris-*p*-chlorophenylaminium perchlorate and chloroantimonate (TCA·ClO_4 and TCA·$SbCl_5$), and tris-*p*-tolylaminium perchlorate and chloroantimonate (TTA·ClO_4 and TTA·$SbCl_5$), in the wide temperature range from 1.7 to 300 K. The two aminium cations, TCA and TTA, have the molecular structures shown in Fig. 1. A comparison of the infrared spectra of several tris-*p*-tolylaminium salts with those of triarylmethyl salts indicates that their cations have similar propeller-like configurations.[6] The triarylaminium radical cations are stabilized by the delocalization of the unpaired electron on the three rings.[7] Therefore, a large paramagnetic shift can be expected in the proton NMR of these salts. The proton NMR spectrum with two partially resolved lines for the TCA·ClO_4 salt have been studied at 77 K by Brown *et al.*[8] Since the paramagnetic shift is proportional to the product of the static magnetic susceptibility of the unpaired electron times the hyperfine constant, information concerning the electron susceptibility from the microscopic point of view, as well as the sign and magnitude of the hyperfine constant in the solid state, can be obtained from the nuclear magnetic resonance. The static susceptibility measurements of the four triarylaminium salts have been carried out in the high-temperature range from 77 to 300 K. The proton resonance spectra of these salts have been measured in the low-temperature range from 1.5 to 77 K in order to obtain the temperature dependence of the electron susceptibility and the hyperfine constants in the solid state. This is because some impurity effects at low temperatures encountered often in the static susceptibilities can be excluded in the case of the electron susceptibilities.

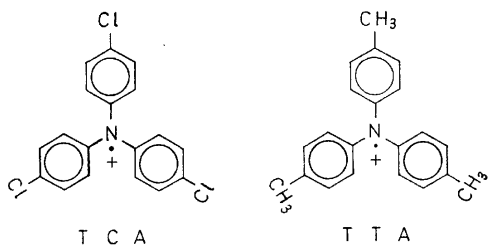

Fig. 1. The molecular structures of the triarylaminium cations, TCA and TTA.

Experimental

The tris-*p*-chlorophenylamine and tris-*p*-tolylamine were prepared by the method of Walter and were purified a few times through recrystallization. The TCA·ClO_4 and TTA·ClO_4 were prepared by the oxidation of the corresponding amine with silver perchlorate and iodine in ether by following the procedure of Walter.[9] The melting points were found to agree well with the values in the literature, and the results of the elementary analysis of the carbon, hydrogen, and nitrogen of each sample corresponded closely to the calculated values. The TCA·$SbCl_5$ was prepared by the following procedure. To a solution of the corresponding amine in chloroform, we added a chloroform solution of $SbCl_5$. A deep blue crystalline product with a metallic luster was obtained from the solution by cooling; it was then washed with chloroform and ether. This salt was found to be the most stable of the four salts. It melts sharply with decomposition at 195—196 °C. Found: C, 32.59; H, 2.09; N, 2.19; Cl, 44.35%. Calcd for $C_{18}H_{12}NCl_8Sb$: C, 33.38; H, 1.89; N, 2.16; Cl, 43.79%. The TTA·$SbCl_5$ was obtained accord-

ing to the method of Wieland,[10] mp 114—115 °C. Found: C, 42.79; H, 3.60; N, 2.29; Cl, 30.28%. Calcd for $C_{21}H_{21}NCl_5Sb$: C, 43.01; H, 3.61; N, 2.39; Cl, 30.23%.

The magnetic susceptibility measurements from 77 to 300 K were done, by means of a magnetic torsion balance described elsewhere,[11] on powder samples of about 50—100 mg in a field of 8.8 KG. The temperature was determined using a calibrated AuCo-Cu thermocouple. Manganese Tutton salt was used for the calibration of the thermometer as well as the product of the magnitude times the gradient of the magnetic field. The ESR spectra were observed at room temperature by using an X-band spectrometer PE3X of JEOLCO. The magnetic field was calibrated by the hyperfine splittings of Mn^{2+} doped in MgO. The proton NMR measurements were carried out using a Pound-Watkins-type spectrometer and a Robinson-type spectrometer at 20.0 and 35.0 MHz respectively, with an 80 Hz field modulation and a field sweep. The magnetic field was calibrated by means of the proton absorption of H_2O. A conventional cryostat was used, and the temperatures were determined using an Allen-Bradly carbon resistor calibrated against the vapor pressures of liquid helium, hydrogen, and nitrogen.

Results and Discussion

The diamagnetic correction was made using Pascal's constants. The value of the diamagnetic susceptibility for $SbCl_5^-$ was taken to be -1.24×10^{-4} cgs emu/mol, following Kainer and Hausser.[12] The paramagnetic susceptibilities of the four salts follow the Curie-Weiss law in the high-temperature range from 77 to 300 K. The values of the Curie constant and the Weiss constant were determined by plotting the inverse paramagnetic susceptibility against the temperature, and then the radical concentration was estimated from the Curie constant. The chloroantimonates have relatively large negative Weiss constants, indicating the presence of an antiferromagnetic exchange interaction between the unpaired electrons, while the perchlorates have small negative Weiss constants. The diamagnetic susceptibility, the Curie constant, the Weiss constant, and the radical concentration for each salt are summarized in Table 1.

Table 1. Results from susceptibility measurements

Compound	Diamagnetic susceptibility 10^{-6} (cgs emu/mol)	Curie constant (K·cgs emu/mol)	Weiss constant (K)	Radical concentration (%)
TCA·ClO_4	−246	0.358	-2.0 ± 0.5[a]	95
TCA·$SbCl_5$	−336	0.329	-40 ± 10	87
TTA·ClO_4	−230	0.281	-0.5 ± 0.2[a]	75
TTA·$SbCl_5$	−320	0.354	-10 ± 2	94

a) The values estimated from the paramagnetic shift in the low-temperature region.

The ESR absorption spectrum for each sample, as measured at room temperature, show a symmetrical single line. The linewidth, which was taken to be the peak-to-peak linewidth of the first derivative of the absorption spectrum, and the g-value are shown in Table 2. The ESR data indicate that each aminium salt is a monopositive cation radical salt.

Table 2. Results from ESR measurements

Compound	Linewidth (Gauss)	g-value
TCA·ClO_4[a]	4.6	2.0045
TCA·$SbCl_5$	4.0	2.0042
TTA·ClO_4[a]	2.3	2.0029
TTA·$SbCl_5$	1.4	2.0029

a) Ref. 4.

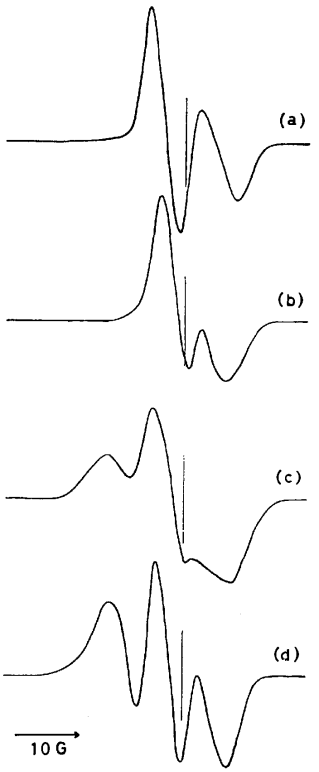

Fig. 2. Proton magnetic resonance absorption derivative curves (a) of TCA·ClO_4, (b) of TCA·$SbCl_5$, (c) TTA·ClO_4, (d) of TTA·$SbCl_5$, measured at 35.0 MHz, 77 K. The vertical lines show the free-proton position.

The 77 K proton resonance spectra of powder samples of the four salts measured at 35.0 MHz are shown in Fig. 2. The spectrum for TCA·ClO_4 agrees well with the results reported by Brown *et al.*[8] The spin Hamiltonian for a free radical in which one proton interacts with one unpaired electron can be described by the following equation:

$$\mathcal{H} = -g_N\beta_N\boldsymbol{H}\cdot\boldsymbol{I} + a_H\boldsymbol{S}\cdot\boldsymbol{I} + \boldsymbol{S}\cdot\boldsymbol{D}\cdot\boldsymbol{I} \quad (1)$$

The meanings of the symbols have been described in a previous paper.[13] In the paramagnetic state, the proton sees only a time-averaged local field proportional to the mean value, $\langle S_z\rangle$, of the electron spin component because of the exchange interaction between the unpaired electrons. In polycrystalline samples, the third term of Eq. (1), which is due to the electron-nuclear dipolar interaction, produces a distribution of the proton resonance shift and broadens the proton resonance, but it does not shift the resonance center of gravity signifi-

cantly.[8,13] In polycrystalline samples, therefore, the proton-resonance-signal shift from the free-proton position to a higher field can be approximately described by the following equation:

$$\Delta H = -a_H \chi H / g\beta g_N \beta_N \quad (2)$$

Thus, ΔH is proportional to the isotropic hyperfine coupling constant, the static susceptibility, χ, and the resonance frequency. Further, the more the resonance line is shifted, the broader the linewidth becomes because of the third term of Eq. (1). The isotropic hyperfine constant, a_H, of a proton attached to a carbon atom is related to the π-electron spin density on the carbon atom by the so-called McConnell relation, $a_H = Q\rho$.[14,15] The Q value for aromatic C–H fragment has been semiempirically determined as $Q(CH) = -22.5$ G. In the proton resonance of TCA·ClO_4 and TCA·$SbCl_5$ measured at 77 K, the upper-field line and the lower-field line are attributable to the *ortho* protons attached to the carbon atoms with positive spin densities, and to the *meta* protons attached to the carbon atoms with negative spin densities, respectively, following the results of Brown *et al.*[8] The fact that the two lines for TCA·ClO_4 are shifted from the free-proton position more than those for TCA·$SbCl_5$ can be ascribed to the difference in the magnitude of the magnetic susceptibility, for TCA·$SbCl_5$ has a much larger negative Weiss constant than TCA·ClO_4. One upper-field line and two lower-field lines have been observed in the spectra of TTA·ClO_4 and TTA·$SbCl_5$. The proton hyperfine coupling constant of a methyl group attached to an aromatic carbon atom is related to the π-electron spin density of the carbon atom. In this case, the Q value has been empirically estimated to be +27.2 G. Therfore, the line with the largest lower-field shift is attributable to the protons of the methyl groups attached to the carbon atoms with positive spin densities situated at the *para* positions. The upper-field line and the other lower-field line can be assigned to the *ortho* protons and to the *meta* protons respectively. The spectrum for TTA·ClO_4 apparently includes an unshifted line arising from the diamagnetic impurities due to the radical decomposition, as will be shown below.

On the basis of the assignment of the polycrystalline NMR spectra, the isotropic hyperfine constants in the crystalline state have been evaluated by using the susceptibility results. The results are tabulated in Table 3, together with the ESR results in solution.[7] The a_H values of TCA radical salts do not agree with those in solution. The disagreement may be due to the inadequacy of the ESR simulation or to some other effect. From the results, the unpaired electron distribution on the three aryl groups can be expected to be equal to each other, even in the crystalline state. Probably, the crystalline aminium salts have similar D_3 propeller-like configurations, as is to be expected from the infrared spectra.[6] The three protons of the methyl group have identical isotropic hyperfine constants; this suggests that the methyl group rotates freely about the C–C bond in solution and even in the crystalline state at 77 K. Further, the proton NMR data indicate that the paramagnetism of the chloroantimonates observed in the susceptibility measurements arises from the aminium cation, and that the antimony pentachloride in the salts has a diamagnetic formula. Kainer and Hausser have suggested the formula of $(SbCl_4^- + SbCl_6^-)/2$ for the complexes of diphenylamine derivatives.[12]

When the temperature was lowered from 77 K, the paramagnetic shift of the perchlorates increased con-

TTA (solution)[b]	9.45	2.06	1.03	3.89

a) Ref. 8, b) Ref. 7.

tinuously down to 1.5 K, following the Curie-Weiss law. By plotting the reciprocal of the paramagnetic shift *vs.* the temperature, the Weiss constants of TCA·ClO_4 and TTA·ClO_4 were determined to be −2.0 and −0.5 K respectively. The 4.2 K spectra measured at 20 MHz are shown in Figs. 3(a) and (c). The broadening of the shifted lines is due to the existence of an anisotropic hyperfine coupling coming from the third term of Eq. (1), which could lead to an asymmetric line shape for our polycrystalline samples. In the spectrum of TTA·ClO_4, only the absorption line of the *meta* protons shifted to the lower field can be detected; the lines of the *ortho* and methyl protons broaden out to the upper field and the lower field respectively. In addition to the shifted lines, an unshifted line was observed. In the measurements of TCA·ClO_4 after a month, we observed an increase in the intensity of the unshifted line, compared with that of the shifted lines. As the radical is not so stable and gradually decomposed, the diamagnetic impurities due to the radical decomposition are probably responsible for the unshifted line. The weak signal of the protons arising from the background is also attributable to the unshifted line.

A broad maximum in the paramagnetic shift of TCA·$SbCl_5$, which indicates an antiferromagnetic interaction, has been observed at about 40 K. The 4.2 K spectrum measured at 35.0 MHz shows an asymmetrical line at the free-proton position, as is shown in Fig. 3(b). However, a quantitative treatment is difficult since the magnitude of the shift is not very large.

The temperature dependence of the relative electron susceptibility of TTA·$SbCl_5$ obtained from the paramagnetic shift is illustrated in Fig. 4. In the spectra, the paramagnetic shift was defined as the distance between the free-proton position and some shifted lines which was proportional to the resonance frequency. When the temperature was lowered from 15 K, the paramagnetic shift deviated from the Curie-Weiss law and reached a broad maximum at 6.0 K. The 4.2 K spectrum measured at 35.0 MHz is shown in Fig. 3(d). The absorption line of *meta* protons was observed as the shoulder of the unshifted line arising from the radical decomposition. The absorption due to the methyl protons involves two lines at least, for the methyl protons are no longer equivalent at 4.2 K. This means that the methyl group is either completely locked or rotates rather slowly.[16] When the temperature is lowered from 4.2 K, the shifted line becomes so broad that the paramagnetic shift can not be estimated below 3.0 K.

The data of the paramagnetic shift can be interpreted by means of the one-dimensional Heisenberg model based on Bonner and Fisher's calculation,[17] rather than by means of the well-known pair model. The kT_m/J ratio is 1.282 for the one-dimensional Heisenberg model, where T_m is the temperature at which the susceptibility reaches its maximum value and where J is the exchange coupling constant. The J value for TTA·$SbCl_5$ is estimated to be −4.7 K from the T_m value obtained experimentally. In Fig. 4, the relative electron susceptibility obtained from the paramagnetic shift is compared

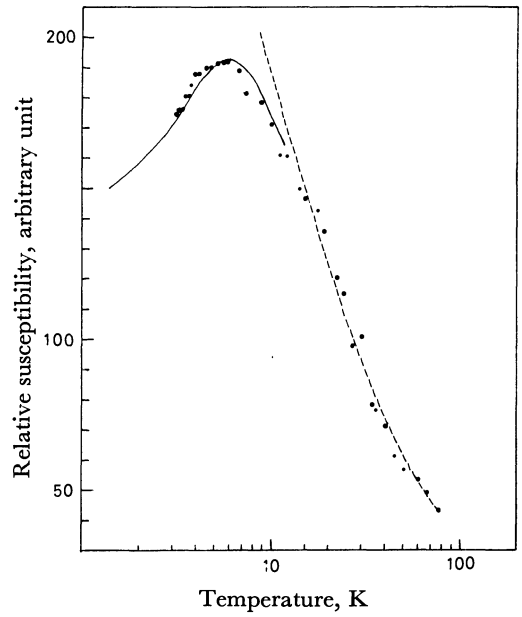

Fig. 4. The relative susceptibility of TTA·$SbCl_5$ obtained from the paramagnetic shift as a function of temperature. The solid line is the theoretical curve for one-dimentional Heisenberg model of $J=-4.7$ K, which is fitted at the temperature T_m. The dashed line represents the curve for the Curie-Weiss law, with the Weiss constant $\theta=-10$ K.

with the theoretical curve for the one-dimensional Heisenberg model of $J=-4.7$ K, which is fitted at the temperature of T_m. The broadening of the shifted lines below 4.2 K can no longer be explained by the third term of Eq. (1). Their behavior is perhaps attributable to an increase in the correlation time of the exchange motion because of the short-range magnetic ordering below the temperature of the susceptibility maximum.[18] Taking the results for the neutral organic radicals into account,[2,3] the mechanism of such a week interaction may be considered to be due to the overlap of π-orbitals occupied by the unpaired electron rather than to the charge-transfer stabilization. Although the interpretation, in which it is assumed that the cation radicals form chain-like arrays of molecules, is tentative, for lack of data on the crystal structure, the data of the paramagnetic shift are consistent with the linear Heisenberg antiferromagnetic exchange model.

On the other hand, the perchlorates exhibit a very small exchange interaction. The crystal structure of triphenylmethyl perchorate has been determined, and it has been reported that the carbonium ion is propeller-shaped, with a three-coplanar central bond, and that triphenylmethyl tetrafluoroborate is isomorphous with the perchlorate.[19] Provided that the aminium perchlorates have a crystal structure similar to that of triphenylmethyl perchlorate, they may be expected to form a three-dimensionally interacting spin-system rather than a one- or two-dimensionally interacting spin-system. Therefore, it is possible that the aminium perchlorates go into a three-dimensionally ordered antiferromagnetic state if the temperature is lowered below 1.5 K.

The authors are much obliged to Professor Yasuo Deguchi for his continuous encouragement throughout this work.

Studies of the Solvent Dyeing of Poly(ethylene terephthalate) with Disperse Dyes from Trichloroethylene and Isooctane

Zenzo MORITA, Shinji HIRAOKA,* Toshiyasu YAMAMORI, and Hiromi MOTOMURA

Department of Textiles and Polymer Science, Faculty of Engineering, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

(Received February 8, 1975)

The diffusion of 1,4-dihydroxyanthraquinone and C. I. Disperse Orange 3 in poly(ethylene terephthalate) (PET) from the trichloroethylene (TRI) and isooctance (ISO) dyebath was investigated by the method of the cylindrical film-roll. The stability of PET in TRI and ISO at high temperatures was also examined. The degradation of PET by solvents was in the following order: water>TRI>tetrachloroethylene (TCE) and ISO. The diffusion coefficients of Orange 3 from various solvents at 90 °C were in the order: TRI>TCE>water>ISO. The activation energy of diffusion from ISO was much larger than that from TRI, the latter being nearly identical to that from TCE. The Arrhenius plots of the diffusion coefficients in PET indicated some transitions. The glass transition temperature of PET in TRI was lower than that in TCE. The diffusion coefficient and the surface concentration of Orange 3 from ISO were increased by the addition of water, while those from TRI were not changed within the range of experimental error.

Solvent dyeing with disperse dyes from ISO has been studied by Schuler,[1] that from *n*-octane, by Kojima,[2] and that from TRI, by Parkins and Hall recently.[3,4] A bimodal relation between the effects of the solvents on PET and the solubility parameter, δ, has also been observed.[5,6] According to Ribnick *et al.*, the bimodal relation suggests that the specific groups of PET molecules interact differently with two types of solvents. One maximum, near $\delta=10$, is due to the interaction between the solvent and the hydrophobic group of PET, while the other one, near $\delta=12$, is due to that between the solvent and the hydrophilic ester group of PET. The difference between the solubility parameters of TCE and TRI is small, while that between the dyeing characteristics of these solvents is large.

There are also large differences in the diffusion coefficients of the disperse dyes from the solvents used in the present study, though all the solvents have a hydrophobic character. The diffusion coefficients from TRI and TCE are larger than that from water, though that from ISO is smaller.

The addition of water to the ISO and TCE dyebath has given rise to an increase in the diffusion coefficients and the equilibrium adsorption of the disperse dyes.[1,7] The addition of water to the TRI dyebath, however, has not yet been reported.

In the present paper, we wish to examine the diffusion of disperse dyes in PET from the TRI and ISO dyebath and the effect of water added to the solvent dyebath by means of the cylindrical film-roll method. The results and the transition phenomena of the PET-TRI system will be discussed and compared with those of the PET–water and PET–TCE systems reported earlier.[8,9]

Experimental

Materials. Biaxially oriented PET films (Mylar C-25. du Pont), TRI (commercial grade—Toa Gosei Kagaku Kogyo Co., Ltd.), and ISO (reagent grade) were used. 1,4-Dihydroxyanthraquinone (reagent grade) and C. I. Disperse Orange 3 recrystallized from ethanol were used as penetrants.

* Present address: Fuji Spinning Co., Ltd., 2-3 Nihonbashi-Ningyo-cho, Chuo-ku, Tokyo 103, Japan.

Stability of PET in TRI and ISO. The film was wound on a stainless steel rod ($\phi=1$ cm) in TRI or ISO so that there were no bubbles between the consecutive film layers, and the film end was fixed. The film-roll was then treated by TRI or ISO in the same dyeing bottle as before under definite conditions.[9] After drying, the viscosities of the PET films treated were measured by means of a Cannon-Fenske viscosimeter at 20 °C in the same manner as before.[9]

Diffusion. The biaxially oriented PET film treated by water at 160 °C for 1 hr was wound on glass tubing ($\phi=1$ cm) in the experiment with a glass diffusion bottle or on a stainless steel rod in the ISO system above 135 °C with a high-pressure diffusion bottle, in the same solvents as in the dyeing. The diffusion experiments were carried out in the same manner as before under the conditions shown in Tables 1—3.[9] The experiments above or near the boiling point of the dyeing solvent were done under pressure using a high-pressure diffusion bottle.

Before beginning the diffusion experiment, the diffusion bottle was inserted into a thermostat set at a given temperature to dissolve the water, if necessary, and then the dye for a long time (*cf.* Table 3). After that, a film-roll was immersed in the bottle. In the case of a high-pressure diffusion bottle, a test tube in which a given weight of the dye and a little of the dyeing solvent had been added and a film-roll were placed in the bottle in which the dyeing solvent was put. The bottle was kept at a given temperature for a prescribed time to dissolve the dye in the test tube and was then quickly turned upside down several times in order to mix completely the solution in the test tube with the dyeing solvent. The time when the solution began mixing was regarded as the initial time of diffusion. After diffusion and drying, the optical densities of the dyed film were measured by means of a Shimadzu MPS-50L recording spectrophotometer at the wavelength of maximum absorption. The concentration of dyes on the film was confirmed to obey Beer's law under the present experimental conditions.

The diffusion coefficients and surface concentrations were calculated by the Sekido-Matsui method from the concentration profile obtained experimentally.[10]

Results and Discussion

The Effect of Solvent on PET. The solution viscosities of PET treated by TRI and ISO are shown in Fig. 1. The treatment of PET with ISO at 180 °C for

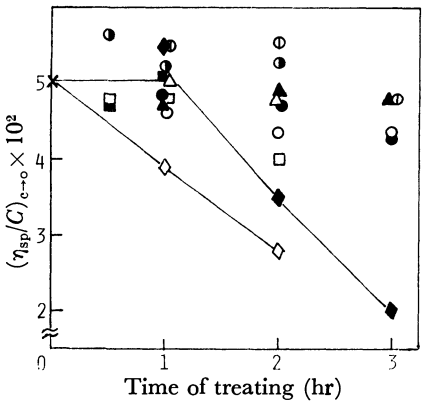

Fig. 1. Change of viscosity by treating with some solvents at high temperature (*m*-cresol: phenol=1: 1 (wt), 20 °C).

no treatment	×		

2 hr and with TRI at 180 °C for 1 hr brought about almost no change in the viscosity. However, during the treatment of PET with TRI at 180 °C for 2 hr, the TRI turned brownish and smelled offensively, and the film-roll could not be opened. No coloration of TRI was observed below 160 °C. On the other hand, the treatment of PET with water at 160 °C for more than 1 hr brings about a profound decrease in the viscosity.[8] That with TCE at 180 °C for less that 2 hr produces no change in the viscosity, but there is the decomposition of TCE above 180 °C, and the film-roll of PET treaed with TCE even at 200 °C for 1 hr could be opened.[9] Therefore, the degradation (in molecular weight) of PET by the solvents is in the following order: water>TRI>TCE and ISO. The order of TCE and ISO could not be determined by viscometry.

Diffusion from the TRI and ISO Dyebath. The diffusion coefficients, D, and the surface concentrations, C_0, of Orange 3 and 1,4-dihydroxyantraquinone from the TRI and ISO dyebath are shown in Tables 1 and 2 and in Fig. 2 as the Arrhenius plots. It is well known that the diffusion of penetrants in a polymer correlates with the intrinsic mobility of polymer molecules.[11] However, in the case of the diffusion in a polymer which is in a swelling equilibrium with a solvent, such as in dyeing, it also correlates with the swelling or plasticization of the polymer by the solvent.[8,9,12] The diffusion coefficients of Orange 3 from various solvents at 90 °C were in the order: TRI>TCE>water>ISO (Table 1). This order, therefore, is considered to be due to the plasticization effect of the solvents on PET or to the solvent-polymer interaction.

Orange 3 is one of the few kinds of dyes which can be dyed from various solvents. In the case using the ISO dyebath, the diffusion of even a small penetrant may be difficult below 100 °C. The activation energies for the diffusion of Orange 3 from the TRI dyebath and that of quinizarine from the ISO one were 30 (60—85 °C) and 80 kcal/mol (135—145 °C) respectively. That from ISO was very much larger than that from TRI, the

latter being nearly identical with that from TCE.[9]

The surface concentrations from the TRI and ISO dyebaths, shown in Tables 1 and 2, decreased with an increase in the temperature.

Transition Phenomena. A transition region was found above 145 °C in the Arrhenius plots of the diffusion coefficient from ISO (Fig. 2). In those from TRI, it was considered that there were three transitions—above 85 °C, between 50 and 60 °C (a shoulder), and below 40 °C. According to Ribnick, the glass-transition temperature, T_g, of PET has been reduced to a lower temperature by TRI than by TCE.[6] In a previous paper, a transition point at 60 °C and two transition regions between 95 and 110 °C and below 50 °C have been observed in the diffusion of C.I. Disperse Violet 1 from the TCE dyebath (*cf.* Fig. 2).[9] In comparison with the case from the TCE dyebath, it can be concluded that the transition region below 40 °C is the T_g of PET swollen by TRI, though the upper limit of T_g is reduced to 40 °C. A transition region between 50 and 60 °C, appearing as a shoulder in Fig. 2, may correspond to the transition at 60 °C from the TCE dyebath, though the lower limit is reduced to 50 °C.

The transition correlated with the maximum crystallization rate of PET[13] was observed as a trasition region above 145 °C in the diffusion in PET from the ISO dyebath and as a transition region above 85 °C in that from the TRI one. It has been observed as a transition region between 125 and 145 °C in water[8] and as one between 95 and 130 °C in TCE.[9] The lower limit of this transition in ISO was higher than that in water and TCE, while that in TRI was lower. Therefore, ISO has no capability to affect the properties of PET, the transitions in PET-ISO system being considered to be nearly identical with those of PET in the dry state. On the other hand, TRI has a more profound effect on PET than do water and TCE.

TABLE 3. DYEING OF C. I. DISPERSE ORANGE 3 FROM THE TRI AND ISO DYEBATH (0.2 g dye/100 ml solvent) IN ADDITION WITH WATER

Dyebath		Diffusion time (min)	D (cm²/min)	C_0 (g dye/kg PET)
Solvent (Temp.)	Water added (ml)			
TRI (70°C)	0	120—150	3.34×10^{-8}	2.18
	0.1	120—150	3.33×10^{-8}	2.38
	0.3	120—150	3.58×10^{-8}	2.30
	0.5	120—150	3.45×10^{-8}	2.20
	1.0	120—150	3.47×10^{-8}	2.36
ISO (90°C)	0	12870	3.07×10^{-11}	6.47
	0.1	12860	3.50×10^{-11}	10.5
	0.3	12860	3.75×10^{-11}	9.20
	0.5	12865	3.84×10^{-11}	9.41

Standing times in the TRI system for dissolving water and dye added were about 1 and 1—2 days, respectively. Those in the ISO system were 28 and 20 hrs, respectively. Glass-stoppered diffusion bottles were used to keep the dyebath from evaporation.

Mean values were shown in the diffusion coefficient and surface concentration of the TRI system.

Dyebath	D	C_0
ISO (at 90 °C)	△	▲
TRI (at 70 °C)	○	●

The Effect of Water Added to the Solvent Dyebath. The effect of the addition of water to the ISO dyebath on the diffusion and adsorption of Orange 3 at 90 °C is shown in Fig. 3 and Table 3. The solubility of water in ISO can be estimated from the data reported by Englin *et al.* to be about 0.3 wt% at 90 °C.[14] The diffusion coefficients and surface concentrations of Orange 3 from ISO increased with an increase in the addition of water to the dyebath. On the other hand, it has been observed that the water added to the TCE dyebath has the capability of accelerating the diffusion of disperse dyes.[7] In the solvent dyeing of nylon 6, the diffusion of C. I. Disperse Violet 1 from the TCE dyebath has been slower than that from the aqueous one.[15] The water added to the TCE dyebath, however, has accelerated the diffusion in nylon. These facts show that the water added to the TCE and ISO dyebath promotes the diffusion of disperse dyes in PET and nylon.

In order to elucidate these phenomena, the effect of the addition of water on diffusion and adsorption from the TRI dyebath has been examined. The solubility of water in TRI at 90 °C can be estimated from McGovern's data to be 0.15 g water/100 g TRI.[16] The results in Fig. 3, however, show that the diffusion coefficients and the surface concentrations of Orange 3 did not change within the range of experimental error when water was added to the TRI dyebath. It may be considered that, as TRI with an active hydrogen atom is adsorbed on both the hydrophilic and hydrophobic groups of PET and the water added to the TRI dyebath on the former, the adsorption of water brings about a decrease in that of TRI as a result of their competition. In the TRI system, therefore, there may be no addition effect of water. The effect of the addition of water to the TCE dyebath on the diffusion and adsorption of some disperse dyes in PET is more complicated than

that investigated in the present study; it is currently under investigation.

The authors should like to thank Prof. Kiichiro Sakaoku for his helpful discussions. Acknowledgements are also due to Nippon Kayaku Co., Ltd. for its staff's assistance in the preparation of this paper.

The Enthalpy of Vitreous Beryllium Fluoride

Seiichi TAMURA and Toshio YOKOKAWA
Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060
(Received February 12, 1975)

The enthalpy increments of beryllium fluoride were measured by the drop method in the glassy and liquid states from 450 to 914 K. The other thermodynamic functions were also calculated. The estimated configurational entropy of the supercooled liquid showed its temperature dependence to be small compared with those of nearly all other glass-forming liquids. The theory of Adam and Gibbs was applied to explain both the present enthalpy data and the Arrhenius viscosity behaviour over an unusually wide temperature range. The similarity between beryllium fluoride and silicon dioxide was also shown with respect to the heat capacities of the glassy and supercooled liquid states.

Beryllium fluoride has been considered to be the low-temperature model of silicon dioxide. Similarities between them are observed in many respects, for instance, in the crystal structure, the structure of the vitreous state, and the low-temperature heat capacities.

On the other hand, silicon dioxide differs from nearly all other glass-forming liquids, which exhibit marked and rather abrupt increases in their heat capacities from the glassy to the liquid state. Since this glass transition occurs in most liquids at a viscosity of approximately 10^{13} poise, it should be realized around 1430 K for silicon dioxide.[1,2] The best calorimetric data on vitreous silicon dioxide indicate the heat capacity to show a smooth and monotonous temperature dependence in this temperature region.[3,4] As for beryllium fluoride, the glass transition temperature can be expected from the viscosity data to be about 580 K.[5,6] However, the enthalpy increments or the heat capacities of the vitreous beryllium fluoride have not yet been measured in this temperature region because of the spontaneous devitrification.[7,8]

Recently, the rates of crystallization were measured in our laboratory for vitreous samples of beryllium fluoride which had various different thermal histories.[9] The results showed that the glass which has been prepared by quenching, as in the previous calorimetric study described above, certainly crystallizes abruptly, but that when the glass or, more correctly, the supercooled liquid has not been brought to room temperature, it does not crystallize, not even at the most appropriate temperature for crystallization, *i.e.*, 740 K, in the case of beryllium fluoride, within the time scale of the calorimetric experiments (say, one or two hours). This is related to the nucleation process. Therefore the enthalpy of the vitreous sample can be measured in the temperature region that the previous work could not cover. The purpose of the present work is to measure the enthalpy increments and to calculate the other thermodynamic functions of vitreous beryllium fluoride in the temperature range in which the glass transition may be observed. Further, the enthalpies of the glasses at 298.15 K were measured by solution calorimetry in order to detect any effect of the heat treatments. The results of the enthalpy of the vitreous state are compared with those for silicon dioxide and other glass-forming substances.

Experimental

Materials. The beryllium fluoride used for this study was prepared from a commercial beryllium fluoride (Mitsuwa Kagaku Co., Ltd.) which was approximately 99.5 moles per cent pure. The sample was heated at about 380 K, and then the remaining water was removed by gradually raising the temperature to about 900 K over a 2-day period. The above preparation was performed in a nitrogen atmosphere. All the containers were made of platinum tubes 8 mm in diameter, 45 mm in height, and 0.2 mm thick (2 to 2.5 g). Samples of 1.5 to 2.5 g were loaded into the sample containers, after which the tops of the containers were sealed by arc-welding in a glove-box filled with nitrogen.

Drop Calorimetry. The calorimeter used for this study was a high-temperature calorimeter of the Calvet type described previously.[10] The assembly of the apparatus for the present work is identical to that used in the previous work[8] except that the thermostat maintained at 298.15 K is now replaced by an electric furnace and that liquid mercury is used instead of coarse silver powder in the calorimeter cells. The electric furnace is shown in Fig. 1. The samples were held at the A position to be maintained at 903 K and then taken down to the B position to be maintained at the measuring temperature, T, in the electric furnace. It took 40 to 70 min for the samples to achieve the thermal equilibrium, and the average cooling rates ranged from 10 to 40 K min^{-1}. Then the samples were dropped into the calorimetric receiver at room temperature. The measureing temperatures ranged from 450 to 914 K. The temperatures were measured with a calibrated chromel–alumel thermocouple in terms of IPTS-68. The energy equivalent of this calorimeter was determined by the drop method, using a calorimetric standard, synthetic sapphire, provided by the National Bureau of Standards. As a preliminary check on the accuracy of the calorimetric systems, the enthalpy increments of gold were measured at several temperatures in the temperature range of the main measurements. The enthalpy results did not deviate more than ± 0.6 per cent from the values in Kelley's table, and so the calorimetric system was assumed to be working satisfactorily.

Solution Calorimetry. The calorimeter used was of a CM-502 model micro-calorimeter (LESCA, Ltd.). Two types of glassy samples were used in this solution calorimetry. One was "quenched glass" which had been prepared by heating the sample at various temperatures above the melting point, and by then dropping it into a silver crucible at room temperature for rapid cooling. The other was "slowly cooled glass" which had been cooled slowly from 903 K to several temperatures below the melting point and then quenched in the same manner as in the drop-calorimetry experiment.

These samples (about 0.5 g) were crushed to the grain sizes in order to dissolve them easily in the solvent which contained 47 g of sodium acetate in one liter of 0.1M acetic acid solution. Calorimetric calibration was performed electrically by means of the heater in the calorimeter.

Results

The results obtained by the drop method, including the data of the glass and liquid, are listed in Table 1 and are depicted in part in Fig. 2. These enthalpy increments are referred to the enthalpy of glass at 298.15 K, H (glass, 298.15 K). However, because of their very nature, the enthalpies of the glasses at room temperature might differ from each other according to the temperatures before dropping. This point was not cleared up in the previous work by Taylor and Gardner.[7] The heat of solution measurements were carried out in order to ascertain whether H (glass, 298.15 K) varies from one sample to the other. The results of the measurements are given in Table 2. From the results, the enthalpy differences, H (glass, 298.15 K) $-H$ (α-q-BeF_2, 298.15 K), in all runs appeared to have a nearly constant value, (1070 ± 60) $cal_{th}\,mol^{-1}$.* This value is in good agreement with what had been obtained by the transposed-temperature drop calorimetry where the glassy sample was prepared by quenching the melt from 903 K.[8] The investigation by the X-ray diffraction method also did not reveal any difference between the X-ray diffraction halos of glassy samples with different thermal histories. Furthermore, in order to ascertain whether the crystallization was completely prevented and whether a particular experimental value of the enthalpy suffered from the heat effect of premelting or pretransition, the so-called Shomate plot[11] was applied to the enthalpy increments, which included the present results as well as those of the glass below 630 K and the liquid from the melting point to 1083 K obtained previously.[8] The Shomate plot gives a straight line, as is depicted in Fig. 3. No crystallization effect exceeding the experimental error could be detected by this plot. Further, since any glass transition is accompanied by a heat-capacity increase around the glass-transition temperature, this plot will be bent around this temperature. A tentative plot with the increase of 0.4 $cal_{th}\,K^{-1}\,mol^{-1}$ at 580 K for this system shows a clearly distinguishable bending at this temperature; this is in contrast with the fact. Therefore, no distinction between glass and supercooled liquid is appreciable in the present system. The least-squares treatment gives the following equation

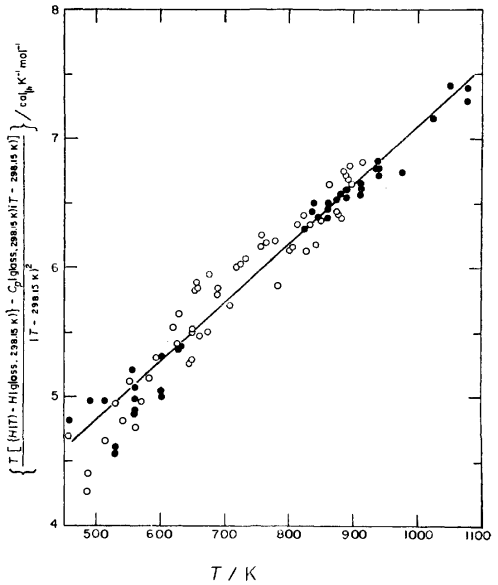

Fig. 3. Shomate plot of enthalpy increments.

a) $H^\circ(\text{glass, 298.15 K})-H^\circ$ (α-q, 298.15 K) = 1135 cal_{th} mol^{-1} from Ref. 8 is used. b) estimated from the entropy of β-quartz form of BeF_2 at the melting point[8] and the present enthalpy data of the liquid.

The standard deviation is 39 cal_{th}mol^{-1}. The enthalpy increments calculated from Eq. (1) and the deviations are listed in Table 1. Some thermodynamic functions were derived from Eq. (1) with well-known equations; they are tabulated in Table 3. Fig. 4 shows the derived heat capacities as well as those of other phases.

Discussion

The present experimental results indicate two interesting facts: (1) the glass transition was not observed, and (2) the heat capacity and the temperature dependence of the entropy of the supercooled liquid are quite similar to those of the crystal. Figure 5 illustrates the entropies of the crystalline, glassy, and liquid forms as functions of the temperature. Here the entropy of fusion, ΔS_f°, was quoted from our previous work,[8] while the residual entropy of the glass at 0 K, S_{res}°, was quoted from Ref. 12. The heat capacity data of the crystal and glass at low temperatures were also quoted from the literature.[7,13] For a closer examination, the data of the residual entropy, the entropy of fusion, and the heat-capacity differences between the liquid and glassy states of various glass-forming liquids are tabulated in Table 4. The first column shows the heat-capacity differences between the liquid and glassy states as a basis for a later discussion of the glass transition. The second column is the value of $\Delta C_p/n$, where n is the number of beads defined as the smallest molecular units, whose movements may change the molecular configuration.[14] Though it is a concept devised for chain polymers, it is tentatively set at 2 for beryllium fluoride. The fact

·····: have not been measured.

that the heat capacity of the supercooled liquid of beryllium fluoride is quite similar to that of the crystal is reflected in the similarity of the entropy trends, as may be seen in Fig. 5. ΔS_f° (T_m) is kept nearly constant down to S_{res}° at 0 K. These facts seem to be closely related to the viscosity-temperature curve of this system.

As is well known, the viscosities of liquids in a temperature range considerably above their melting points obey a two-parameter Arrhenius equation of this form:

$$\eta = A \exp(E_\eta/RT) \tag{2}$$

where η is the viscosity, A is a constant, R is the gas constant, and E_η is the activation energy of the viscous flow. However, this equation is not applicable to the group of liquids with high viscosities or to the supercooled liquids with a glass-forming tendency. For these liquids, Fulcher[15] and Tammann and Hesse[16] found an empirical equation of the form:

$$\eta = B \exp\{C/(T-T_0)\} \tag{3}$$

where B, C, and T_0 are constants.

Meanwhile, according to Adam and Gibbs,[17] the temperature dependence of such transport properties as viscosity is given by an equation of this form:

$$\eta = D \exp(\Delta\mu s_c^*/kTS(T)^{config}) \tag{4}$$

where D is a temperature-independent factor, k is Boltzmann's constant, $\Delta\mu$ is the potential energy barrier impending over the cooperative rearrangement, s_c^* is the critical configurational entropy, and $S(T)^{config}$ is the configurational entropy of liquids. Since the temperature dependence of $\Delta\mu$ is so small as to be safely neglected,[17] the above equation explicitly explains the temperature dependence of the viscosity (Eqs. 2 and 3) in terms of the configurational entropy of the glass-forming liquids. From the standpoint of the modern lattice theory of the liquid state,[18,19] any thermodynamic function of the supercooled liquid may be separated into two terms: vibrational and configurational. Thus, the entropy of the liquid, $S(T)^{liq}$, is given by $S(T)^{liq} = S(T)^{vib} + S(T)^{config}$, and since $S(T)^{vib}$ is approximately equal to the entropy of the crystal, $S(T)^{cryst}$, at the same temperature, the following equation is obtained:

$$S(T)^{config} \approx S(T)^{liq} - S(T)^{cryst} \equiv \Delta S_f(T) \tag{5}$$

It is very interesting to note that Kishimoto, Suga and Seki compared the T_0 (dynamic) in Eq. 3 with the T_2 (static) estimated in their study and found a consistency between these values.[20] Here T_2 is the temperature, as proposed by Gibbs and DiMarzio,[21] at which the configurational entropy, $S(T_2)^{config}$, of a liquid would vanish *via* a second-order thermodynamic transition if it were possible to cool the liquid in a metastable equilibrium state to T_2.

On the other hand, beryllium fluoride is also different from nearly all other glass-forming liquids in that the viscosity shows Arrhenius behaviour over a wide range of more than 10 orders of magnitude, as is shown in Fig. 6.[5,6] This behaviour is analogous to that of silicon dioxide.[1,2] This unusual viscosity behaviour of beryllium fluoride can be understood when the configura-

tional entropy of a liquid is independent of the temperature, as in the present work (see ΔC_p in Table 4); then Eq. 4 turns into Eq. 2. In other words, it is very difficult to estimate T_2 because $S(T)^{\text{config}}$ shows little temperature-dependence. If T_2 were estimated, it might be quite low. It is also difficult to estimate T_g because the entropy of fusion is small, comparable with the residual entropy. The small entropy of fusion implies that the structure of the liquid is not very different from that of the crystal. Thus, any heat-capacity increase at the glass-transition temperature would be negligibly small.

In conclusion, the present data, if coupled with the heat of fusion and the unusual viscosity behaviour, suggest that the structures of the crystal, glass, and liquid states are similar to each other. This is consistent with the similarities of their spectroscopic data.[22,23] No distinction between glass and the supercooled liquid of beryllium fluoride is appreciable in the present work.

A Photoconductivity Study of Trapped Ionic Species in γ-Irradiated Ethylcyclohexane Glass at 77 K

Noriyuki KATO, Kenji FUEKI, and Zen-ichiro KURI
Department of Synthetic Chemistry, Nagoya University, Chikusa-ku, Nagoya 464
(Received February 27, 1975)

A photoconductivity study has been made of trapped ionic species in γ-irradiated ethylcyclohexane glass at 77 K. The photocurrent peak initially increases with an increase in the dose, reaches a maximum, and then decreases with a further increase in the dose. The experimental results indicate that the photocurrent *vs.* dose curve is probably affected by the radiolysis products. The photocurrents of γ-irradiated ethylcyclohexane–cyclopentane and 3-methylpentane glasses were also measured in the presence of biphenyl. It has been observed that electrons can be transferred almost reversibly between the biphenyl molecules and solvent traps. An analysis of the experimental data shows that only a very small fraction of the trapped electrons are responsible for the observed photoconductivity. A procedure is developed for estimating the lifetime of mobile electrons in glassy matrices.

Since the investigation of ionic processes became one of the main subjects in radiation chemistry, a great many efforts have been made to investigate the properties of trapped ionic species in glassy matrices by the techniques of ESR and optical absorption spectroscopy.

Electrical conductivity techniques have, on the other hand, been used mostly in the radiolysis of liquids. They are particularly useful, since even those ionic species can be measured which are not observable by means of ESR and optical absorption spectroscopy. In previous studies, photoconductivity studies have brought information on the energy levels of trapped electrons in the glassy matrices of MTHF,[1] 3-methylhexane,[2] and alkaline ice,[3] while thermal conductivity studies have been made on the thermal behavior of trapped ionic species in the glassy matrices of 3-methylpentane,[4,5] and of TEA[6] after γ-irradiation. The present paper will report on the photoconductivity of trapped ionic species in glassy hydrocarbon matrices.

Experimental

Materials and Sample Preparation. The ethylcyclohexane (ECH), cyclopentane (CP), and biphenyl were Tokyo Kagaku Seiki standard pure and were used as received. The Aldrich 3-methylpentane (3MP) was purified by passing it through an activated silica gel column.

The sample preparation was carried out by distilling the proper solvent, dried over calcium hydride *in vacuo*, into a conductivity cell.

Photoconductivity Apparatus. The photoconductivity cell is of a rectangular type with suprasil windows, as is shown in Fig. 1a. The electrodes of stainless steel mesh are separated from each other with a quartz ring spacer 1 mm thick.

The electric circuit is shown schematically in Fig. 1b. A series of 90 V dry batteries were used as the voltage supply. The electric current was measured with a Toa Electronics Ltd. PM-18C electrometer and recorded with a Toa Electronics Ltd. EPR-2T recorder. The lower limit of the measurable current value was of the order of 10^{-12} A.

The light sources for photobleaching were a Toshiba 500 W lamp for the IR region and a Toshiba medium-pressure mercury lamp for the UV region.

Results and Discussion

Photoconductivity of ECH Glasses. A typical photocurrent profile of the γ-irradiated and IR bleached ECH glass at 77 K is shown in Fig. 2. The photocurrent

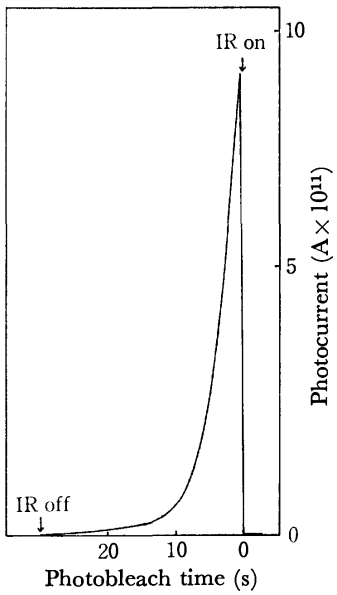

Fig. 2. Typical photocurrent profile for γ-irradiated (2×10^{19} eV/g) ECH glass at 77 K with an applied electric field of 4.5 kV/cm.

rises instantaneously within the response time of the apparatus and decays at a rate which differs slightly from one hydrocarbon matrix to another. The magnitude of the photocurrent per cm^2 is given by the following equation;

$$I = en\mu\tau E \quad (1)$$

where e is the electronic change, n is the number density of current carriers photoexited into the conduction band per second, μ is the mobility of the current carriers, τ is the average lifetime of the carriers, and E is the applied field. Since μ and τ are normaly independent of the applied field, Eq. (1) indicates that the photocurrent is linearly proportional to the applied field; this is called Ohm's law. The observed voltage-dependence of the initial photocurrent on the ECH glass was almost linearly proportional to the applied field up to 5.4×10^3 V/cm. The measurement of the photocurrent was carried out in this ohmic region.

Dose Dependence of the Photocurrent. The dose dependence of trapped electrons in γ-irradiated hydrocarbon glasses at 77 K has been previously investigated by ESR[7] and IR[8] absorption techniques. Those studies indicate that the yields of trapped electrons reach a maximum at a dose of from 1 to 2 Mrads.

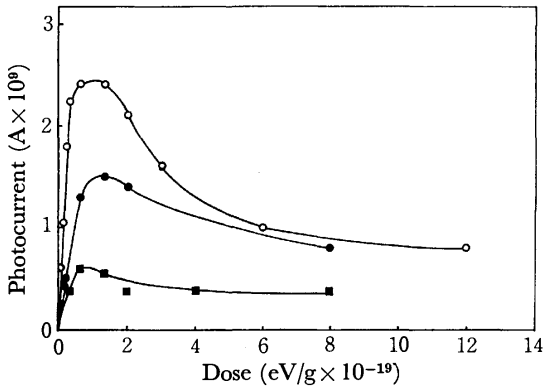

Fig. 3. Dose dependence of initial photocurrent for ECH glass at 77 K: ○, fresh sample; ●, the same sample preirradiated with a dose of 2.57×10^{20} eV/g; ■, the same sample preirradiated with a dose of 3.81×10^{20} eV/g.

The photocurrent peak *vs.* dose curves on ECH glasses at 77 K are shown in Fig. 3. The curves show two characteristic dose dependences: (a) they have a maximum value at a dose of about 0.1 Mrad, much lower than the 1 Mrad reported for 3 MP;[7] (b) they suffer from the effect of preirradiation, *i.e.*, the photocurrents diminish in intensity each time a sample is repeatedly melted, freezed, and irradiated after the previous experiment. The (b) result indicates the influence of some impurities formed by the γ-irradiation. This may be supported by the following experiment. The photocurrent-dose curve for ECH glass containing 0.04% biphenyl is shown in Fig. 4.[12] This curve is close in the shape and magnitude of the current to those for samples preirradiated with high doses (Fig. 3). The plateau of the current in an ECH-biphenyl system starts at about the same dose as that at the maximum current in pure

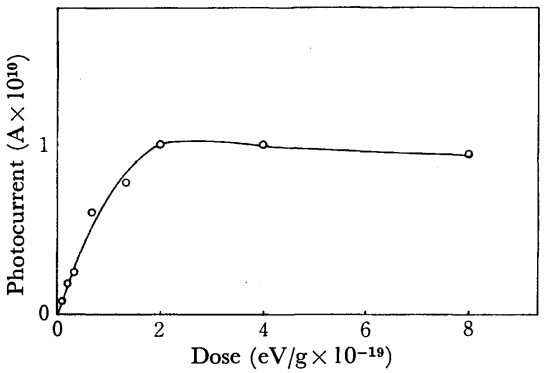

Fig. 4. Dose dependence of initial photocurrent for ECH glass containing 0.04% biphenyl at 77 K.

ECH, as is shown in Fig. 3. However, the impurities formed by radiolysis are yet unknown. Treatment with concentrated sulfuric acid could not eliminate them.

The appearance of the photocurrent maximum mentioned in the (a) result is at present a well-known phenomenon except that the dose at the maximum is much lower than that in the literature.[7,8] The decrease in the yield of trapped electrons with an increase in the dose has been interpreted in terms of the reactions of trapped electrons with trapped positive ions and radicals.[7] The (a) result may be explained by this hypothesis, but the influence of molecular products other than radicals and ionic species may also be significant, because the value of the maximum current is lowered every time the γ-irradiation is repeated.

The photocurrent profile in Fig. 2 may be represented as follows Eq. (1);

$$A = \int I dt = n_t e\mu\tau E = n_t e w \quad (2)$$

where A is the area under the photocurrent curve, n_t ($=\int n dt$) is the total number of electrons per unit of volume released by bleaching, and w is the average distance of carrier movement.

The electrons contribute to the photocurrent when they are trapped far from parent ions where the Coulomb potential is very weak. Then, n_t can be expressed as follows;

$$n_t = G_{fl}^{p}\frac{D}{100}V \quad (3)$$

where G_{fl}^{p} is the yield per 100 eV of the electrons mentioned above, D is the dose (eV/g), and V is the volume between the electrodes.

In the region of a linear current-dose relation for the fresh sample (Fig. 3), the following numerical relation was obtained from Eqs. (2) and (3), with V taken as 0.1 cm^3 and D as 5×10^{18} eV/g;

$$5.7\times10^{-9} = G_{fl}^{p}\times0.8\times10^{-3}\times w \quad (4)$$

If all of the free electrons are assumed to travel over the distance between the electrodes, w becomes 0.1 cm and G_{fl}^{p} is calculated as 7.1×10^{-5}. It should be noted that this value is at the lower limit for G_{fl}^{p}.

By further putting μ=0.1 $cm^2/V\cdot s$[9] and $E=4.5\times10^3$ V/cm into $\mu\tau E=w$, τ is obtained as 2.2×10^{-4} s. However, flash photobleaching is necessary for the

measurement of the precise value of τ, which will be carried out in a subsequent work.

Photoconductivity of Hydrocarbon Glasses in the Presence of Biphehyl. ECH glass has some cracks at 77 K, but an ECH-cyclopentane (CP) mixture (50 : 50 in volume) forms a very transparent glass. However, the photocurrent shows the same value as that for pure ECH.

ECH-CP glass containing 0.04% biphenyl yields both trapped electrons and biphenyl anions under γ-irradiation.

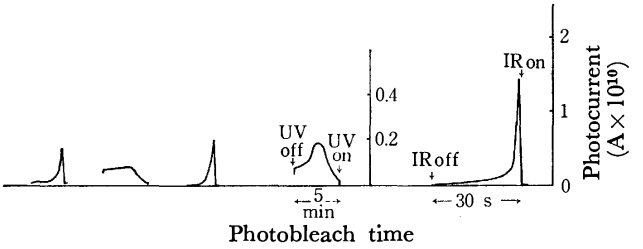

Fig. 5. Photocurrent profile for ECH–CP (50: 50 in volume) glass containing 0.04% biphenyl illuminated alternately with IR and UV light.

The photoconductivity profile of the sample illuminated alternately with IR light with $\lambda>900$ nm and UV light with $\lambda<340$ nm is shown in Fig. 5. The profile indicates that electrons can be transferred back and forth between the matrix and biphenyl molecules with little loss due to neutralization with positive ions. 3MP glass containing 0.04% biphenyl illuminated alternately with IR light and UV light showed the same photocurrent profile as the ECH–CP glass containing 0.04% biphenyl in Fig. 5. The results are the same as those found for MTHF[10] and 3MP[11] glasses spectroscopically.

The number of electrons photobleached is almost equal in each bleaching cycle except for the first cycle. The decrease in the photocurrent in the first cycle is presumably to be attributed to the recombination of electrons with positive ions in the neighborhood. The following relation may be deduced from Eq. (2);

$$\frac{A_2}{A_1} = \frac{n_t e\mu\tau_2 E}{n_t e\mu\tau_1 E} \qquad (5)$$

where the subscripts 1 and 2 stand for the bleached electrons from the solvent traps and those from the biphenyl anions respectively.

The A_2/A_1 ratio obtained from the bleaching profile is equal to the ratio of the lifetimes of the electrons, τ_2/τ_1, in the conduction state; it is 1.1×10^2.

The value of 1.1×10^2 for τ_2/τ_1 implies that the electrons detached from biphenyl anions have a mean free path, $\bar{l}$, 1.1×10^2 times as large as that for the electrons from the solvent traps, since the lifetime is represented as $\tau=\bar{l}/\mu E$. It is conceivable that this difference in lifetime is due to the difference between the average energy of electrons optically released from the biphenyl anions and that of electrons released from the solvent traps.

Photoconductivity due to Carbanions. As has been stated above, only a very small fraction of the trapped electrons are responsible for the observed photoconductivity. A major fraction of them may be captured by impurities and/or radicals and neutralized by cations. As is the case with the biphenyl anions in the above section, electrons can be photoionized from carbanions by UV light shorter than 340 nm, as is shown in Fig. 6. Such a phenomenon has already been seen by Willard *et al.* on 3MP and 3EP glass by means of optical absorption spectroscopy.[7]

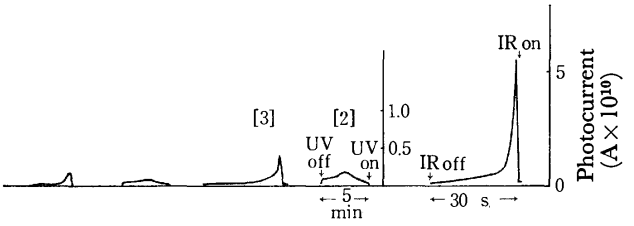

Fig. 6. Photocurrent profile for ECH–CP (50: 50 in volume) illuminated alternately with IR and UV light.

The photocurrent areas, [2] and [3], in Fig. 6 are almost equal. This might idicate that the solvent radicals have nearly the same trapping rate for mobile electrons as the solvent traps under the present experimental conditions.

Dielectric Relaxation in Substituted Benzaldehydes

B. SINGH and J. K. VIJ
Department of Physics, Punjabi University, Patiala-147002, India
(Received December 23, 1974)

The measurements of the relative permittivity at frequencies of 1 MHz and 9.274 GHz and of the refractive index at sodium D-line have been carried out at 30 °C for *o*-chlorobenzaldehyde (A), *m*-chlorobenzaldehyde (B), *p*-chlorobenzaldehyde (C), *o*-nitrobenzaldehyde (D), *m*-nitrobenzaldehyde (E), and *p*-nitrobenzaldehyde (F), in dilute solutions of benzene, cyclohexane, carbon tetrachloride, *p*-dioxane and Nujol. The dielectric relaxation times for the overall rotation and the electric dipole moments for these molecules have been calculated. These results have been used to calculate the dipole moment for the internal rotations, possibly of the CHO-group, in the molecule. The results are analyzed in terms of the solute-solvent interactions for these molecules. The bonding between the hydrogen atom of the aldehyde group and the oxygen atom of the dioxane molecule seems to be fairly weak. The comparative behavior of the chlorobenzaldehydes and the nitrobenzaldehydes has also been discussed.

In the past decade, attempts have been made to detect intramolecular rotations of the polar group in the organic molecules by using the dielectric dispersion techniques.[1,2] Several interesting results have been obtained especially when one of the hydrogen atoms of the benzene ring is replaced by any of the groups namely, -OH, $-OCH_3$, $-NH_2$, $-CH_2Cl$. In some cases, the results have led to the quantitative interpretations about the mechanisms of the intramolecular rotations. Measurements have been made on a particular molecule over several decades of frequency. The results have been analyzed using either the Cole-Cole[3] plot or the Scaife's polarizability[4] plot in terms of the molecular relaxation time, τ_1, the intramolecular relaxation time, τ_2, and their respective contributions to the observed dielectric dispersion.

Recently,[5,6] an attempt has been made to analyze the data in terms of two arbitrary dielectric relaxation times defined by the equations given below:

$$\tau(1) = \frac{a''}{w(a'-a_\infty)} \tag{1}$$

$$\tau(2) = \frac{a_0-a'}{wa''} \tag{2}$$

where w is the pulsatance, a_0, a', a'', a_∞ are defined in linear range by the equations,

$$\left.\begin{aligned} \varepsilon &= \varepsilon_1 + a_0 w_2, \\ \varepsilon' &= \varepsilon_1' + a' w_2, \\ \varepsilon'' &= a'' w_2, \\ \varepsilon_\infty &= \varepsilon_{1\infty} + a_\infty w_2. \end{aligned}\right\} \tag{3}$$

Subscript 1 refers to the pure solvent, 2 to the solute and the subscript ∞ refers to the values of the relative permittivity at infinite frequency. w_2 is the weight fraction of the solute. The analysis reported in the paper[6] has shown that $\tau(1)$ is dependent on τ_1,τ_2 and on the relative contribution of τ_2 to the observed dielectric loss, C_2. It has also been shown that for certain cases, $\tau(2)$ leads to τ_1. It has also been proved[7] that $\tau(1)$ is approximately equal to the dielectric relaxation time, $\tau_{G.K.}$, determined using the Gopala Krishna method.[8] It follows, therefore, that $\tau_{G.K.}$ depends on τ_1,τ_2 and C_2. As a consequence the value of $\tau_{G.K.}$ provides only with an indication of the presence of the intramolecular rotations in the molecule. The presence of these rotations is concluded only when $\tau(2)$ and $\tau_{G.K.}$ differ significantly from each other.

The following parameters, however, are introduced to quantify these rotations. First we calculate $\tau(2)$ using Eq. (2) and then we calculate a_∞ from Eq. (1) on the assumption that $\tau(1)$ is equal to $\tau(2)$. Then the parameter a_∞ would correspond to those rotations of the molecule to which the value of $\tau(2)$ corresponds. For simplification, this parameter is designated as a_{∞_2}. Now the parameter governing the slope of a_∞ *versus* concentration curve is differentiated from a_{∞_2} and is designated as a_{∞_1}. The difference between a_{∞_2} and a_{∞_1} is suggested to provide us with the magnitude of the residual dipole moment taking part in the internal rotations of the molecule.

To our knowledge, no systematic work on the measurements of the substituted benzaldehydes is available in literature. However, the values of $\tau_{G.K.}$ are reported[9] for some of the molecules in *p*-xylene solution. In this paper, we report the results of the measurements on the *o*-, *m*- and *p*-chlorobenzaldehydes and of the nitrobenzaldehydes in the dilute solutions of benzene, cyclohexane, carbon tetrachloride, *p*-dioxane and Nujol at the temperature of 30 °C. These measurements are of relevance because the results can help in advancing the understanding of the dielectric relaxation mechanism of the methoxy compounds which are being studied in Professor Walker's laboratory.[10] A methoxy or an aldehyde group when attached to the benzene ring should have similar dielectric relaxation mechanisms. The paper also deals with examining the possibility of detecting the solute-solvent interactions of the aldehydes with the solvent molecules. This is important particularly when the carbonyl groups are known to have interactions with the π-orbital electrons of the benzene molecule.

Materials and the Dielectric Measurements

The name and the specifications of the materials, as given by the manufactures, are given in parentheses of the particular sample.

1. *o*-chlorobenzaldehyde (Fluka A.G., purum).
2. *m*-chlorobenzaldehyde (Koch Light, pure grade).
3. *p*-chlorobenzaldehyde (Koch Light, pure grade).
4. *o*-nitrobenzaldehyde (Koch Light, puriss).

5. *m*-nitrobenzaldehyde (B.D.H., L. R.).
6. *p*-nitrobenzaldehyde (Koch Light, pure grade).

The materials mentioned above, with the exception of the *m*-nitrobenzaldehyde, were used without further purification. *m*-Nitrobenzaldehyde was crystallised in methanol and was thereafter vacuum-dried to remove traces of the solvent. The materials with serial number 3—6 were checked for their melting points. The refractive indices for the materials 1 and 2 were measured. For the cases studied, the agreement between the measured value and its literature value was good.

The solvents namely benzene, cyclohexane, carbon tetrachloride, *p*-dioxane and Nujol were of the same purity specifications as already given.[11] These solvents were treated similarly for further purification. The measurements of the relative permittivity at the frequency of 9.274 GHz and of the refractive index at wavelength of the sodium D-line were made in the same way as already described.[11,12] The relative permittivity measurements at frequency of 1 MHz were taken using the dielectrometer based on the principle of heterodyne beat method.[13] This piece of equipment was assembled to the same specifications as already reported in the paper by one of the authors (JKV). The Rohde and Schwarz[14] two terminal dielectric cell (Type KMF BN 5721) was used. The capacitance between the inner and the outer electrode is measured to be 37.09 pF. Both the terminals of the dielectric cell are properly screened from each other.

Results

The values of a_0, a', a'', of the so called slopes, defined by Eq. (3), are given in Table. a_D is defined as given below:

$$n_D^2 = n_{1D}^2 + a_D w_2.$$

These slopes have been determined by fitting the appropriate data of the appropriate equation using the multiple regression program on the IBM 360/44 digital computer. The standard errors of estimate, as obtained, are given with their coefficients. An examination, of the coefficients and of their standard deviations, indicates that the errors in a_0, a', a'' and a_D are of the order of 2%, 3%, 4% and 5%, respectively. Bearing in mind that the total number of observations in each case is only 7 and also taking into account the errors involved in the measurement of a particular parameter, one leads to the conclusion that Eq. (3) are valid within the experimental range of the solute concentration in dilute solutions. The range of the solute concentration by weight is approximately 7% of the solvent in each case.

The experimental data is analyzed by determining $\tau(2)$. Hereinafter this parameter would be denoted as the dielectric relaxation time for the overall rotations,

τ. For reasons given in the introduction, this value of τ is plugged into Eq. (1) to calculate a_{∞_2}. Equation (1) is written as

$$a_{\infty_2} = a' - \frac{a''}{w\tau} \tag{4}$$

Under these conditions, the physical significance of a_{∞_2} is that it is the slope of the relative permittivity when plotted against concentration. The relative permittivity values are measured at frequency such that the electric dipole taking part in the molecular rotations ceases to follow the alternations of the field. In other words, for frequencies higher than this limit, only the dipole moment for the internal rotations can contribute to the dielectric loss in the liquid.

Now the magnitude of the dipole moment involved in the internal rotations is calculated as follows.

The parameter a_0 in the modified Higasi's equation[15] is replaced by the parameter a_{∞_2}, determined as outlined above. Higasi's equation for the dipole moment of the internal rotations is written as:

$$\mu_{\text{int.rot.}} = B\sqrt{(a_{\infty_2} - a_{\infty_1})}, \tag{5}$$

where

$$B = \frac{1}{2(\varepsilon_1+2)}\sqrt{\frac{27kTM_2}{\pi N_A d_1}}$$

and ε_1 is the relative permittivity of the solvent, k is the Boltzmann constant, T is the absolute temperature of the material, N_A is the Avogadro's number and d_1 is the density of the solvent.

The parameter a_{∞_1} is calculated from the parameter a_D by the equation

$$a_{\infty_1} = a_D + \Delta a_D$$

whereas Δa_D is calculated using the following equation suggested by Higasi *et al.*[16]

$$\frac{\Delta P_E}{P_E} = \frac{3a_D}{(\bar{n}_{2D}^2+2)(\bar{n}_{2D}^2-1)}$$

on putting

$$\frac{\Delta P_E}{P_E} = 0.05$$

where

$$\bar{n}_{2D}^2 = n_{1D}^2 + a_D$$

The subscript 1 refers to the solvent and 2 refers to the solute.

The electric dipole moment of these molecules in the dilute solutions of the non-polar solvents is calculated using the modified Higasi's equation[15] given below:

$$\mu = B\sqrt{(a_0 - a_{\infty_1})} \tag{6}$$

where the constant B is the same as in Eq. (5).

Discussion

The experimental dipole moment for *p*-chlorobenzaldehyde as shown in Table 2 agrees well with its literature value. There does not seem to be any literature value available for *o*-chloro- and *m*-chlorobenzaldehydes based on measuring the static relative permittivity in solutions. There seems to be a constant difference of 0.2 D in the moments for *o*- and *m*-nitrobenzaldehydes when compared to their literature values, a point worth noting. An experimental error of this magnitude seems to be unlikely.

The dielectric relaxation times for *o*-nitrobenzaldehyde and *p*-nitrobenzaldehyde in *p*-xylene and for *o*-chlrobenzaldehyde in *p*-dioxane have been determined by Mehrotra and Saxena[9] at a temperature of 22 °C, using the Gopala Krishna (G.K.) method.[8] The method adopted over here is different, for reasons already stated. The viscosity of *p*-xylene when compared to benzene is within 1%. A comparison of the τ values in the two solvents determined by the same method is therefore of interest. By using the G.K. method, our data yields the $\tau_{\text{G.K.}}$ values for *o*-nitrobenzaldehyde and for *p*-nitrobenzaldehyde in benzene solution as 14.1 ps and 10.8 ps respectively. On the basis of the standard errors of estimates in the parameters a_0, a', a'', and a_D, given in Table 1, the standard error in the estimate of the τ values is 10%. The agreement in the τ values is reasonably good when a temperature difference of 8 °C and a change in the nature of the solvent is considered. The τ value for *o*-chlorobenzaldehyde is 19.2 ps/30 °C when compared to its literature value of 16.6 ps/22 °C. Obviously, there is no explanation for the disagreement. The authors have not quoted the accuracy in their determination of the τ value.

The remarks made in the previous section lead us to the conclusion that the τ values given in Table 2 correspond either to those for the overall rotation or to that of the longest relaxation time of the molecule. The results also indicate that these molecules have a higher frequency dipolar absorption. This is evidenced by a large difference between the a_{∞_2} and the a_{∞_1} values, given in Table 2. The difference between the a_{∞_2} and a_{∞_1} values has also been thought of in terms of the dipole moment for the internal rotations ($\mu_{\text{int.rot}}$) of these molecules. From the structural considerations of these molecules alone, one would not expect any moment for the internal rotations for the chlorobenzene or the nitrobenzene molecules. This is because rotations of the chloro or the nitro group along their respective bonds to the carbon atom of the molecules do not give rise to a change in the direction of the dipole moment. But the situation is, however, different when the -CHO group is attached to the benzene ring. The dipole makes an angle of 55° with the C-C bond. The rotations of the -CHO group along the C-C bond of these molecules as shown

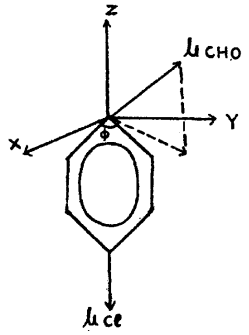

Fig. 1. *p*-Chlorobenzaldehyde.

a) These literature values are for τ in *p*-xylene solvent and are calculated using the Gopala Krishna method.

in Fig. 1, can be depicted by resolving the dipole moment, in three components along the Cartesian axes. The problem is illustrated by considering the case of *p*-chlorobenzaldehyde as shown in Fig. 1.

Let θ be the angle between the μ_{CHO} and the C–C bond and ϕ be the angle that the projection of μ_{CHO} on the X–Y plane, makes with the x-axis.

$$\mu_x = \mu_{CHO} \sin\theta \cos\phi$$
$$\mu_y = \mu_{CHO} \sin\theta \sin\phi$$
$$\mu_z = \mu_{CHO} \cos\theta - \mu_{C-Cl}$$

On the basis of free rotations of the groups, the total dipole moment and the dipole moment for internal rotations in these molecules can, therefore, be written as

$$\mu = (\mu_{CHO}^2 + \mu_{C-Cl}^2 - 2\mu_{CHO}\cdot\mu_{C-Cl}\cdot\cos\theta)^{1/2}$$
$$\mu_{\text{int.rot.}} = \mu_{CHO} \sin\theta$$

The determined values of $\mu_{\text{int. rot.}}$ are nearly consistent with the model. However, the difference is that the angle θ comes out to be of the order of 45 °C. There are several approximations made in calculating the resultant dipole moment of the molecule. One of them is that an addition of another group to the benzaldehyde molecule leads to a change in the angle which the dipole of the –CHO group makes with the C–C bond. Secondly, the magnitude of the group moment of the –CHO group changes with an addition of another polar group to the molecule due to the phenomenon of mesomerism. It may be desirable to mention here that the dipole moment studies of the nitrobenzaldehydes[17)] reveal that the dipole of the –CHO group makes an angle of 36.5° with the C–C bond.

The dependence of the magnitude of $\mu_{\text{int. rot}}$ on the solvent can be interpreted in terms of its interactions with the –CHO group. A lower value possibly indicates hindrances to free rotations of the –CHO group. One notices that the values of the $\mu_{\text{int. rot.}}$ in cyclohexane, particularly for *o*-chlorobenzaldehyde and *o*-nitrobenzaldehyde, are higher when compared to other solvents. Therefore there is a possibility of the interaction of the remaining solvents with the benzaldehyde group. These observations are extended further by considering a plot of log τ *versus* log η, shown in Fig. 2, for these molecules. Firstly, one

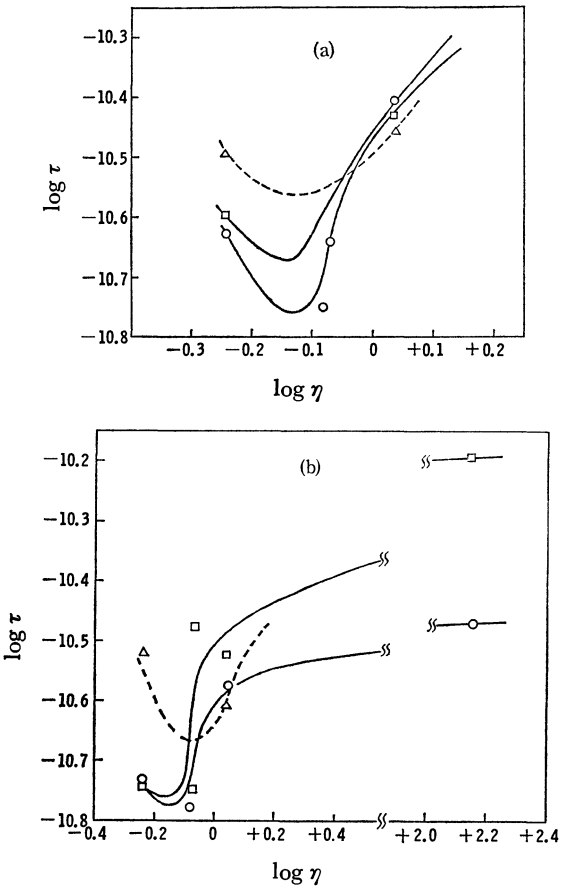

Fig. 2. Plot of $\log \tau$ *vs.* $\log \eta$.
(a) ○: *o*-Nitrobenzaldehyde, □: *m*-nitrobenzaldehyde, △: *p*-nitrobenzaldehyde.
(b) ○: *o*-Chlorobenzaldehyde, □: *m*-chlorobenzaldehyde, △: *p*-chlorobenzaldehyde.

notices that the τ values for the molecules increase from the *o*- to *p*-substituents through the *m*-position for both the chlorobenzaldehydes and nitrobenzaldehydes. Secondly, the τ values for the isomers of the nitrobenzaldehyde are larger than the corresponding isomer of the chlorobenzaldehyde. This trend is repeated by nearly all the solvents. The first observation is in line with our ealier studies[11] on the chloroanilines, and is thought of arising due to the shape of the molecule. Possibly, this indicates that the greater the departure from the spherical shape, the longer is the dielectric relaxation time for the molecule. In the case of the *p*-substituent the molecule is elongated in comparison with the *o*- and *m*-substituents and therefore the dielectric relaxation time appears to increase in the following order, *o*-, *m*-, and *p*-substituent. The second observation can be explained on the basis of the molecular volumes. The molecular volume for the nitrobenzaldehydes is approximately 20% higher than the value for the chlorobenzaldehydes.

One of the interesting features of these studies is that the dielectric relaxation time in benzene, τ_B, for the molecules under study seems to be larger than anticipated because of the low viscosity of benzene when compared with the values in other solvents. It is suggested that these molecules could be undergoing an interaction with the benzene molecules. The effect seems to be independent of the isomer and appears to be a result of the aldehyde group only. There is a possibility of transfer of π-electrons from the benzene ring to the C=O bond resulting to the formation of a complex. This could account for the increase in the dielectric relaxation time of the molecules in benzene and in a decrease of the dipole moment for the internal rotations of the –CHO group. Similarly, the dielectric relaxation times in carbon tetrachloride for the three molecules A, B and D, are larger by about 30% of the τ values of these molecules in cyclohexane. The viscosity of carbon tetrachloride over cyclohexane is only 3% greater. The anomalous behavior of the carbon tetrachloride follows a general trend exhibited by a number of molecules. This is thought of being due to the 'sticky' nature of the carbon tetrachloride which arises possibly from the fairly large short range forces between the molecules of the solute and of the carbon tetrachloride. The effect is further evidenced by comparatively small magnitude of the dipole moment for internal rotations of the –CHO group in carbon tetrachloride. The dielectric relaxation times in *p*-dioxane when compared to those in other solvents are expected on the basis of its viscosity alone. There is no great difference in the total dipole moment values of the molecules in dioxane and in benzene. These observations are in contrast to those already reported on anilines.[13,18] One would have normally expected a hydrogen bonding between the hydrogen atom of the –CHO group and the oxygen atom of the dioxane molecule. The findings suggest that such a bonding, if at all there, is fairly weak. Possibly, the oxygen atom of the –CHO group does not allow formation of the intermolecular bond. It is suggested that a qualitative experimental study of these system should be made in order to verify these predictions.

The work was financed by the Department of Atomic Energy, Government of India, to which the authors are thankful. The authors are grateful to Professor B.S. Sood, for administering the research project. One of the authors (B. Singh) is thankful to Mr. I. Krishan for his help in the measurements.

The Crystal Structure of Monoaquobis(1,10-phenanthroline)-copper(II) Nitrate, $[Cu(H_2O)(phen)_2](NO_3)_2$

Hisayoshi NAKAI* and Yoshito DEGUCHI

Department of Chemistry, Faculty of Science, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received February 28, 1975)

The crystal structure of the title compound has been determined from three-dimensional X-ray data collected on Weissenberg photographs, using Cu$K\alpha$ radiation. The intensities were estimated visually with a standard scale. The structure was solved by the heavy-atom method and refined by the least-squares method. The final R value was 0.118 for 1835 observed reflections. The space group is C2/c, with $a=22.58(2)$, $b=7.23(1)$, $c=16.58(2)$ Å, $\beta=123.6(1)°$, and $Z=4$. The crystal is composed of $[Cu(H_2O)(phen)_2]^{2+}$ cations with C_2-symmetry and NO_3^- anions. The copper atom is surrounded by four nitrogen atoms of the two phenanthroline ligands (average Cu–N=2.01 Å) and a water-oxygen atom (Cu–O=2.18 Å) in a distorted trigonal-bipyramidal arrangement. One oxygen atom and two nitrogen atoms of two different phenanthroline ligands are coplanar with the central copper atom, and lines linking the copper atom with each of the axial nitrogen atoms make angles of about 10°, with the normal to the basal N–N–O plane. The electronic reflectance spectrum of this complex shows a characteristic band at about 12.5×10^3 cm^{-1}, which is analogous to that of $[CuI(bipy)_2]I$.

It is well known that 1,10-phenanthroline (=phen) forms a number of bis-phenanthroline copper (II) complexes with the general formula $Cu(phen)_2X_2\cdot nH_2O$.[1] In this case, however, the two phenanthroline molecules can not assume a square-coplanar arrangement about the copper atom because of the steric repulsions between the hydrogen atoms on the 2- and 9-carbon atoms of one molecule and the corresponding ones in the other.[2] Several investigations[3–5] have been made of the coordination geometry of these complexes, but the detailed structure has not yet been established. Jørgensen,[3] and James *et al.*,[4] have independently suggested, from their spectral studies, that the bis-phenanthroline copper(II) complexes take a *cis*-octahedral configuration in an aqueous solution. On the other hand, Faye[5] used the elementary ligand-field theory to interpret the absorption spectra of those complexes in an acetone medium, and concluded that they probably have a trigonal bipyramidal structure.

One of the present authors (H. N.) has been attempting the crystal structure analyses of bis-bipyridine and bis-phenanthroline copper(II) complexes.[6,7] This paper will describe the crystal structure of $Cu(phen)_2(NO_3)_2\cdot H_2O$.

Experimental

The green crystals of $Cu(phen)_2(NO_3)_2\cdot H_2O$ were easily prepared by adding a methanol solution of 1,10-phenanthroline (20 mmol in 30 cm^3 of the solvent) to an aqueous solution of cupric nitrate (10 mmol in 30 cm^3 of water), and were recrystallized from a water–methanol mixture. Found: C, 50.80; H, 3.27; N, 14.34%. Calcd for $Cu(phen)_2(NO_3)_2\cdot H_2O$: C, 50.93; H, 3.21; N, 14.85%.

The crystal symmetry was determined from preliminary Weissenberg photographs, which showed a Laue symmetry of 2/m and systematic absences of hkl for $h+k=2n+1$ and of $h0l$ for $l=2n+1$. Hence, the space group is C2/c or Cc. The centro-symmetric choice, C2/c, was initially taken on the basis of intensity statistics;[8] it was subsequently verified by the successful refinements of the derived structure. Cu$K\alpha$ radiation ($\lambda=1.5418$ Å) was used throughout the diffraction study. The lattice parameters were obtained by the least-squares refinement of the data from the higher-angle reflections of the $h0l$ and $hk0$ Weissenberg photographs, on which aluminium powder lines were superimposed for calibration. The density was measured by the flotation technique using a mixture of benzene and bromoform. The crystal data are listed in Table 1.

Table 1. Crystal data

$[Cu(H_2O)(phen)_2](NO_3)_2$
F.W.=566.0
Monoclinic
$a=22.58(2)$ Å
$b=7.23(1)$
$c=16.59(2)$
$\beta=123.6(1)°$
$V=2256$ Å^3
$Z=4$
$D_x=1.66$ g·cm^{-3}
$D_m=1.65$ g·cm^{-3}
$\mu=20.9$ cm^{-1} (for Cu$K\alpha$)
Space group: C2/c

The intensity data of $h0l$ to $h4l$ and $hk0$ to $hk8$ were collected by the multiple-film equi-inclination technique from two cylindrically shaped crystals with approximate dimensions of $0.2\times0.2\times0.8$ mm. The intensities of 2102 independent reflections were visually estimated by comparison with a standard scale; 267 of them were too weak to be measured and so were assumed to be zero. After the intensity data has been corrected for Lorentz-polarization, spot-extension, and absorption effects, the structure factors were placed on a common arbitrary scale by the least-squares method.

The reflectance spectrum of this compound was also measured, using a Hitachi 139 spectrophotometer fitted with a standard reflectance attachment.

Structure Determination

As described above, the space group of this compound is C2/c, and the number of the complex molecules in the unit cell is four. Therefore, the copper and oxygen

atoms in the complex cation $[Cu(H_2O)(phen)_2]^{2+}$ must be situated at a special position, and the two phenanthroline ligands as well as the two nitrate ions are equivalent.

The position of the copper atom was readily determined from a three-dimensional Patterson map, which lies on the two-fold axis. The Fourier synthesis phased with the Cu atom gave positions of about a half of the lighter atoms; the remaining non-hydrogen atoms were obtained from the subsequent Fourier and difference Fourier maps. The structure was refined by the block-diagonal least-squares method, using the HBLS-IV program.[9] The weighting scheme used was:

$$w = 0.2 \text{ when } F_0 = 0$$

and

$$w = 1.0 \text{ when } F_0 > 0.$$

The atomic scattering curves were taken from the International Tables for X-ray Crystallography, Vol. III,[10] the real part of the anomalous dispersion correction ($\Delta f'=-2.1$) being applied for the neutral copper atom. Three cycles of refinements with anisotropic thermal parameters for the copper atom and isotropic for the remainder reduced the R value to 0.15 for 1835 non-zero reflections. A further two cycles of refinements with anisotropic thermal parameters for all the non-hydrogen atoms improved the R value to 0.118. In the last cycle of the calculations, the shift in any parameter was less than one-tenth of its estimated standard deviation. The final atomic coordinates and temperature factors are listed in Table 2. A comparison of the observed and calculated structure factors is given in Table 3**.

** Table 3 has been deposited at the Office of the Chemical Society of Japan, Document No. 7520.

Results and Discussion

The crystal consists of the $[Cu(H_2O)(phen)_2]^{2+}$ cations and the nitrate anions. Figure 1 shows the b-axis projection of the crystal structure. The bond lengths and bond angles, with their estimated standard deviations, are given in Table 4.

Figure 2 shows a schematic drawing of the complex cation $[Cu(H_2O)(phen)_2]^{2+}$, where only two nitrogen atoms of each phenanthroline ligand are shown. As is shown in Fig. 2, the complex cation has a two-fold axis passing through the oxygen atom O(4) of the coordi-

a) Estimated standard deviations, shown in parentheses, are right-adjusted to the last digit of the preceding number. b) Atoms with primes are related by two-fold symmetry to the corresponding unprimed atoms (see Fig. 1 for labelling of atoms).

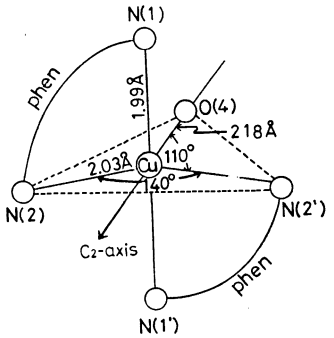

Fig. 2. A schematic drawing of the complex cation $[Cu(H_2O)(phen)_2]^{2+}$.

nated water molecule. The coordination geometry about the copper atom is a distorted trigonal bipyramid; the axial positions are occupied by N(1) and N(1′), while the Cu, N(2), N(2′), and O(4) atoms lie on the trigonal plane. The axial Cu–N bonds are 1.99 Å long and are slightly shorter than the equatorial Cu–N bonds (2.03 Å). The N(1)–Cu–O(4) angle is 85.5°; thus, the axial Cu–N bonds are not perpendicular to the trigonal plane. The angles between those axial bonds and that normal to the trigonal plane are about 10°. The angles of O(4)–Cu–N(2) and N(2)–Cu–N(2′) in the trigonal plane are 110.0 and 139.6° respectively. The N–Cu–N angles in chelate rings are 83.0°, normal for metal-phenanthroline complexes.[11–15] An analogous stereochemistry with the chromophore $[CuN_4O]$ has been found in $[Cu(NO_3)(bipy)_2]NO_3 \cdot H_2O$, where the bipy is the 2,2′-bipyridine molecule. Although these two complexes have such an analogous stereochemistry and both have the general formula of $Cu(chelate)_2(NO_3)_2 \cdot H_2O$ (chelate=phen or bipy), it must be noted that the coordinating group in the fifth position is different.

The phenanthroline ligands are planar within a maximum deviation of 0.04 Å (Table 5). The dihedral angle between the best planes of these two phenanthro-

O(2)	0.003	O(3)	0.004
Plane formed by Cu, N(1), and N(2)			
$0.006X + 0.930Y + 0.366Z = 4.01$			

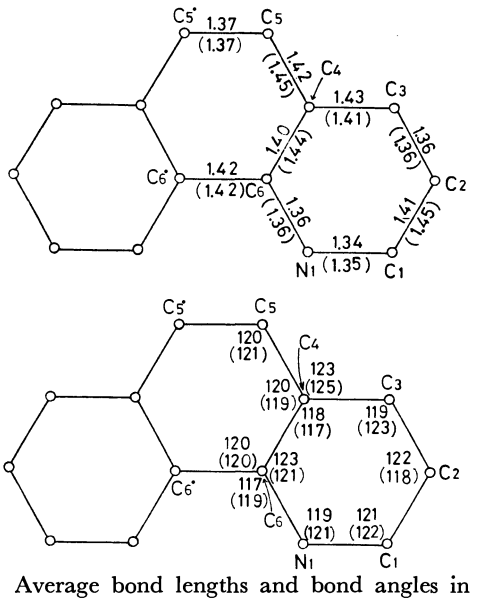

Fig. 3. Average bond lengths and bond angles in the phenanthroline ligand (values in parentheses are corresponding ones in $[Cu(phen)_3](ClO_4)_2$).

line ligands is about 40°. The bond lengths in the phenanthroline ligands range from 1.33 (2) to 1.44 (2) Å in C–C and from 1.34 (1) to 1.37 (1) Å in C–N (Fig. 1 and Table 4). Assuming that the phenanthroline ligand has a C_{2v}-symmetry, the average bond lengths and bond angles are as given in Fig. 3, where the values in parentheses are the corresponding ones in $[Cu(phen)_3](ClO_4)_2$.[11] As is shown in Fig. 3, the C(2)–C(3) and C(5)–C(5′) bond lengths are shorter than the others by 0.3—0.7 Å; the same trend has been observed in $[Cu(phen)_3](ClO_4)_2$. All the average bond lengths and angles are in good agreement with those in the $[Cu(phen)_3]^{2+}$ in view of the standard deviations.

The nitrate anions are planar (Table 5) and are linked to the water molecule in $[Cu(H_2O)(phen)_2]^{2+}$ by hydrogen bonds, which are indicated by the dotted lines in Fig. 1 (O(3)···O(4)=2.77 Å). This value is comparable to the $O(NO_3^-)\cdots O(H_2O)$ distance (2.79 Å) found in $Cu(NO_3)_2\cdot 5/2H_2O$.[16]

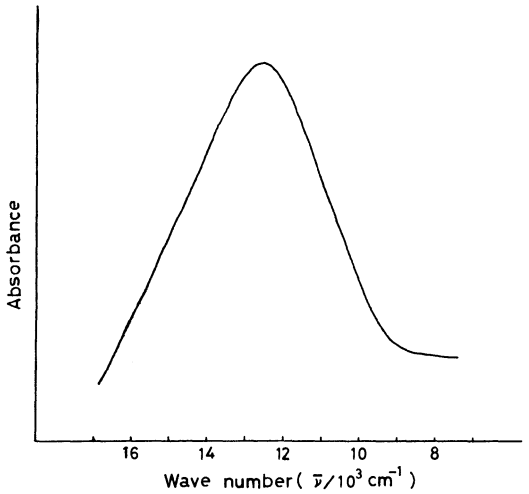

Fig. 4. Electronic reflectance spectrum of $[Cu(H_2O)(phen)_2](NO_3)_2$.

The electronic reflectance spectrum of this compound was also measured at room temperature (Fig. 4); it shows a single peak at 12.5×10^3 cm^{-1}. This is quite similar to those of $[CuI(bipy)_2]I$ and $[Cu(NH_3)(bipy)_2]X_2$ (X=ClO_4 or BF_4), but is clearly different from the spectrum of the trigonal-bipyramidal $[Cu(NO_3)(bipy)_2]^+$.[17] On examining the crystal structure of $[Cu(NO_3)(bipy)_2]NO_3\cdot H_2O$ in detail,[6] we can recognize, however, two more oxygen atoms at a distance of 2.8—3.0 Å from the copper atom.

The authors wish to express their thanks to Professor Hisao Kuroya and Dr. Shun'ichiro Ooi for their kind discussions throughout the present work.

Ion-exchange Chromatographic Studies of the $[Co(N)_4(O)_2]^+$-type Complexes

Kazuhiro KOBAYASHI and Muraji SHIBATA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received March 20, 1975)

The following complexes of the $[Co(N)_4(O)_2]^+$ type have been prepared: $[Coox(tn)_2]^+$, *u-fac-*, *s-fac-*, and *mer*-$[Coox(NH_3)(dien)]^+$, *cis-* and *trans*-$[Coox(NH_3)_2(en)]^+$, *u-fac-* and *s-fac*-$[Co(ida)(NH_3)(en)]^+$, *fac*-$[Co(ida)(NH_3)_3]^+$, and *cis*(O)*trans*(N)*cis*(NH_3)-, *cis*(O)*cis*(N)*cis*(NH_3)-, and *cis*(O)*cis*(N)*trans*(NH_3)-$[Co(gly)_2(NH_3)_2]^+$. The geometrical structures have been determined on the basis of the PMR spectra, the absorption spectra, *etc.* Including these new complex species, twenty-six species of the $[Co(N)_4(O)_2]^+$ type have been investigated through ion-exchange chromatographic separation. The elution orders obtained have been discussed in connection with the geometrical configurations.

Recent years have seen a dramatic development in the application of ion-exchange chromatography to the preparation of isomeric complexes of cobalt(III), in particular that of isomeric complexes of the $[Co(N)_4(O)_2]^+$ type consisting of polydentate ligands. In contrast to such practical separations of the isomeric complexes, only a little attention has been focused on the relationship between the order of the chromatographic separation and the geometrical configuration; a few works[1] were, though, once undertaken in order to establish the elution order of such simple complexes as diacidotetraamminecobalt(III) ions. Very recently, a wide variety of cobalt(III) complexes were investigated by means of high-speed liquid chromatography.[2]

In the present work, experiments were designed, in the first place, to prepare some complexes of the $[Co(N)_4(O)_2]^+$ type in order to undertake the work systematically. All the complexes including the new ones were classified into several series according to their geometrical structures. Then the order of elution was determined among the complexes of each series. The comparison between the series was done by using suitable complexes as the markers.

Experimental

Preparations. The new complexes designed in this work were prepared by the methods to be described below.

a) Oxalatobis(trimethylenediamine)cobalt(III) Chloride, $[Coox(tn)_2]Cl$. To a suspension of 6.3 g (0.02 mol) of *trans*-$[CoCl_2(tn)_2]Cl$[3] in 20 ml of water, we added 3.7 g (0.02 mol) of potassium oxalate monohydrate, after which the mixture was stirred at 50 °C for 10 min. After an insoluble material had been removed by filtration, the filtrate was kept in a refrigerator overnight. The purple-red crystals thus deposited were filtered and washed with ethanol and ether. The yield was 3 g.

b) Oxalatoamminediethylenetriaminecobalt(III) Chloride, $[Coox(NH_3)(dien)]Cl$. Method 1: To a solution of 25 g (0.1 mol) of $K[Co(CO_3)_2(NH_3)_2]\cdot H_2O$[4] in 200 ml of water, we added 35.7 g of the solid material which had been isolated by saturating an aqueous diethylenetriamine with carbon dioxide; thereafter the mixture was stirred at room temperature for a day. To the resulting red solution oxalic acid was added until the solution showed a pH of *ca.* 3. The solution was again stirred at room temperature for a day. After the removal of insoluble white precipitates by filtration, the filtrate was found to be contain three geometrical isomers of the desired complex, their formation ratio being estimated to be *u-fac*: *s-fac*: *mer*=59: 6: 35 by means of ion-exchange chromatography (the symbols *s-* and *u-* indicate the structures with and without a plane of symmetry respectively).

Method 2: To a solution containing 0.7 g (0.005 mol) of ammonium oxalate in 50 ml of 2.8% aqueous ammonia, we added 1.3 g (0.005 mol) of *mer*-$[CoCl_3(dien)]$;[5] the mixture was then stirred at room temperature for 1.5 hr. The mixture contained mainly two geometrical isomers of the complex, their formation ratio being estimated to be *u-fac*: *mer*=8: 92.

c) Oxalatodiammineethylenediaminecobalt(III) Chloride, $[Coox(NH_3)_2(en)]Cl$. This complex was prepared from *trans*(NH_3)-$[CoCl_2(NH_3)_2(en)]Cl$.[6] A solution containing 3.0 g (0.015 mol) of the dichloro complex and 2.2 g (0.015 mol) of potassium oxalate monohydrate in 20 ml of water was warmed at 60 °C for 30 min. When the warm solution was allowed to stand at room temperature for some time, pink precipitates appeared. The substance was filtered and washed with ethanol and ether. The yield was 0.8 g. When the filtrate was kept in a refrigerator, red crystals were deposited, along with a small amount of the pink precipitates. The yield of this crude product was 1.2 g. The product was recrystallized twice from water. The pink complex was identified as the *cis*(NH_3) isomer, and the red one, as the *trans*(NH_3) isomer, from their absorption and PMR spectra.

d) Iminodiacetatoammineethylenediaminecobalt(III) Chloride, $[Co(ida)(NH_3)(en)]Cl$. To a green solution of tricarbonatocobaltate(III)[4] $(Co(NO_3)_2\cdot 6H_2O$, 0.1 mol scale) we added a mixture of 16 g (0.12 mol) of iminodiacetic acid and 20 ml of concd aqueous ammonia; the mixture was then stirred at 50 °C for 10 min. To the resulting blue solution we added 7.2 g (0.12 mol) of ethylenediamine and 1 g of activated charcoal. The mixture was stirred vigorously at room temperature for a day. After the charcoal had then been filtered off, the filtrate was acidified with aqueous perchloric acid until the solution showed a pH of *ca.* 3, and then again filtered to remove the precipitated material. The solution thus obtained contained *u-fac* and *s-fac* isomers in the formation ratio of 88: 12.

e) Iminodiacetatotriamminecobalt(III) Chloride, $[Co(ida)(NH_3)_3]Cl$. To a green solution of tricarbonatocobaltate (III)[4] $(Co(NO_3)_2\cdot 6H_2O$, 0.1 mol scale) we added a mixture of 16 g (0.12 mol) of iminodiacetic acid and 20 ml of concd aqueous ammonia, after which the whole was stirred at 50 °C to give a blue solution (*ca.* 10 min). Twenty ml of concd aqueous ammonia and 1 g of activated charcoal were then added to the solution, and the mixture was stirred again at 50 °C for 2 hr. After the charcoal has subsequently been removed by filtration, the deep red filtrate was neutralized with aqueous hydrochloric acid and then kept in a refrigerator overnight. The red crystals thus deposited were collected and washed with ethanol and ether. The yield was 10 g. This complex was characterized as the *fac* isomer on the basis of its spectral data.

f) Bis(glycinato)diamminecobalt(III) Chloride, $[Co(gly)_2(NH_3)_2]Cl$. This was readily prepared by modifying the method for the corresponding ethylenediamine complex $[Co(gly)_2(en)]Br$.[7] A solution of 10 g (0.042 mol) of cobalt(II) chloride hexahydrate in 10 ml of water was added to another solution containing 20 ml of concd aqueous ammonia and 6.4 g (0.085 mol) of glycine in 30 ml of water. After the addition of 10 g of lead dioxide, the solution was heated on a water-bath for 30 min. The reaction was completed by adding 10 more grams of lead dioxide and by then warming the solution for an hour. After having been cooled in a refrigerator overnight, the solution was filtered. The red solution thus obtained contained three *cis*(O) isomers; the formation ratio was found to be *cis*(O)*trans*(N)*cis*(NH_3): *cis*(O)*cis*(N)*cis*(NH_3): *cis*(O)*cis*(N)*trans*(NH_3)=46: 49: 5.

The other known complexes used in this work were as follows: $[CoCO_3(NH_3)_4]Cl$, $[CoCO_3(en)_2]Cl$, $[Coox(NH_3)_4]Cl$, $[Coox(en)_2]Cl$, $[Comal(NH_3)_4]NO_3$, $[Comal(en)_2]I$, α-$[Coox(trien)]Cl$, β-$[Coox(trien)]ClO_4$, $[Co(ida)(dien)]Cl$ and $[Co(gly)_2(en)]Cl$. They were all prepared according to the known methods.

Elution. The columns used in this work were those containing 100—200 mesh Dowex 50W- X 8 in sodium form (diameters, 2.0—7.0 cm; resin heights, 10—50 cm). The elutions were carried out with 0.3—0.4 M NaCl aqueous solutions at rates in the range of *ca.* 0.3—1.2 ml/min. The complexes were classified into several series, and the chromatographic separation was carried out with each series.

Resolution. The optical resolution of the *cis*(O)*trans*(N)*cis*(NH_3) isomer of the $[Co(gly)_2(NH_3)_2]^+$ complex was carried out successfully by means of ion-exchange chromatography; the complex dissolved with a small amount of water was charged on a column of Dowex 50W- X 8 resin (100—200 mesh, Na-form, 2.5×50 cm). When being eluted by an aqueous solution of sodium antimony $(+)_{589}$-tartrate (0.25 M) at the rate of 0.3 ml/min, a band adsorbed on the top of the column was clearly separated into two bands. The first band corresponded to the $(-)_{589}$-antipode, and the second band, to the $(+)_{589}$-antipode.

Measurements. The absorption spectra were measured with a Hitachi EPU-2A spectrometer. The circular dichroism spectrum (CD) was recorded on a JASCO Model ORD/UV-5 spectrometer with a CD attachment. The proton magnetic resonance spectra (PMR) were recorded on a JEOL JNM-PS-100 MNR spectrometer at about 22 °C, using D_2O or a mixture of D_2O and 30% D_2SO_4 as the solvent. The values of the chemical shifts were determined in relation to the sodium D_4-trimethylsilylpropionate (TMSP) used as an internal reference.

Results and Discussion

Characterization of Complexes. The results of the elemental analysis and numerical data of the absorption spectra for the new complexes are summarized in Table 1. The geometrical structures of these complexes were determined mainly on the basis of their absorption and PMR spectra. For convenience, the PMR spectra will be discussed in the succeeding section.

The possible geometrical forms regarding the present complexes are shown in Fig. 1: There are three isomers for the $[Coox(NH_3)(dien)]^+$ complex. Among those, the *u-fac* isomer was easily characterized by its PMR spectrum, but the *s-fac* and *mer* isomers were not by their PMR spectra. However, we have found that the preparation from the *mer*-$[CoCl_3(dien)]$ complex produced one isomer predominantly. Considering this fact, the *mer*-form was tentatively assigned to that isomer obtained in a predominant yield.

Two isomers may be expected for the $[Coox(NH_3)_2(en)]^+$ complex. The complexes obtained were characterized by comparing their PMR spectra.

a) Because of the poor yield, no elemental analysis was carried out.

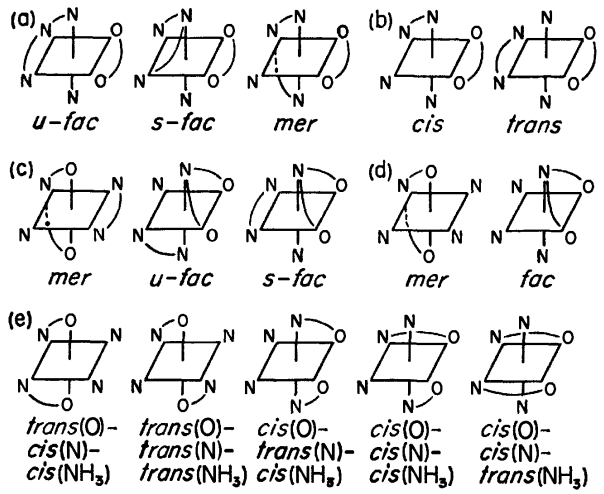

Fig. 1. Possible geometrical isomers.
(a) $[Coox(NH_3)(dien)]^+$ (b) $[Coox(NH_3)_2(en)]^+$
(c) $[Co(ida)(NH_3)(en)]^+$ (d) $[Co(ida)(NH_3)_3]^+$
(e) $[Co(gly)_2(NH_3)_2]^+$.

The $[Co(ida)(NH_3)(en)]^+$ complex can exist in three geometrical isomers. In the absorption spectrum of the *mer* isomer of the $[Co(ida)(NH_3)(en)]^+$ complex, a clear splitting of the first absorption band is to be expected from the *trans*(O) structure. In the spectrum of the known $[Co(ida)(dien)]^+$ complex,[8] the separation of the split of the first band is estimated to be about 2900 cm^{-1}. In the spectra of the present two compounds, no such remarkable separation is observed, as may be seen in Fig. 2. This suggests that both the compounds are of facial forms. It is well known that the ida chelating in the *mer*-position is very strained.[8,9] This suggests the preferential chelation of the ida in the facial configuration for the present compounds.

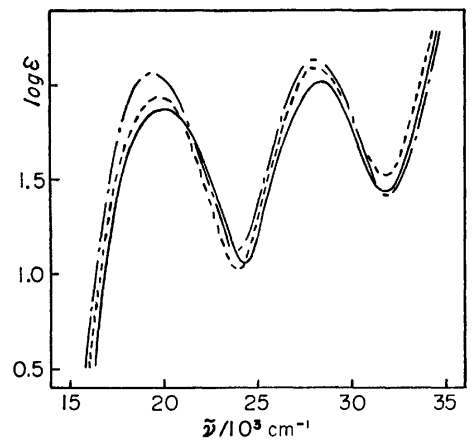

Fig. 2. Absorption spectra of iminodiacetato complexes.
———: *u-fac*-$[Co(ida)(NH_3)(en)]^+$
— · —: *s-fac*-$[Co(ida)(NH_3)(en)]^+$
------: *fac*-$[Co(ida)(NH_3)(en)]^+$.

With the $[Co(ida)(NH_3)_3]^+$ complex, two geometrical isomers can exist, but only one was actually obtained; it was identified as having the *fac* form on the basis of the absorption spectrum (Fig. 2).

Five geometrical isomers can exist for the $[Co(gly)_2(NH_3)_2]^+$ complex. Much as in the absorption spectra of the above ida complexes, the spectra of the three isomers show no splittings in their first absorption bands (Fig. 3); therefore, they may be regarded as the *cis*(O) isomers. With the related $[Co(gly)_2(en)]^+$ complex, its *trans*(O) isomer and *cis*(O) isomers were isolated,[7] but with the present diammine complex no *trans*(O) isomers were obtained. One of the three *cis*(O) isomers, *cis*(O)-*cis*(N)*cis*(NH_3), was easily assigned on the basis of its PMR spectrum. Of the other two isomers, the *cis*(O)-*trans*(N)*cis*(NH_3) isomer can be resolved into antipodes. In fact, the resolution was successful using a chromatographic method. Accordingly, the distinction between the resolvable *cis*(O)*trans*(N)*cis*(NH_3) isomer and the unresolvable *cis*(O)*cis*(N)*trans*(NH_3) isomer was made on the basis of such resolution experiments. The CD spectrum of the antipode eluted earlier is shown in Fig. 3. The spectrum shows a lower-energy negative component ($\Delta\varepsilon = -1.23$, 19300 cm^{-1}) and a higher-energy positive component ($\Delta\varepsilon = +0.41$, 22000 cm^{-1}) in the region of the first absorption band.

PMR Spectra. *a)* *[Coox(NH$_3$)(dien)]Cl*: Figure 4 shows the PMR spectra of the three isomers. The spectrum of one of the two *fac* isomers shows a small peak at 6.78, two small peaks at 4.68 and 4.50, and a sharp peak at 3.63 ppm, with an integrated ratio of 1: 2: 2: 3. The spectrum of the other *fac* isomer exhibits a small peak at 6.9, a somewhat large peak at 4.94 and a sharp peak at 3.50 ppm, with a ratio of 1: 4: 3. The spectrum of the *mer* isomer exhibits a small peak at 6.27, a rather large peak at 4.90, and a sharp peak at 3.20 ppm, with a ratio of 1: 4: 3. From an inspection of the intensities, the peaks at 6.2—7.0 ppm are assignable to the NH proton resonances, the ones at 4.2—5.2 ppm, to the NH_2 proton resonances, and the ones at 3.1—3.7 ppm, to the NH_3

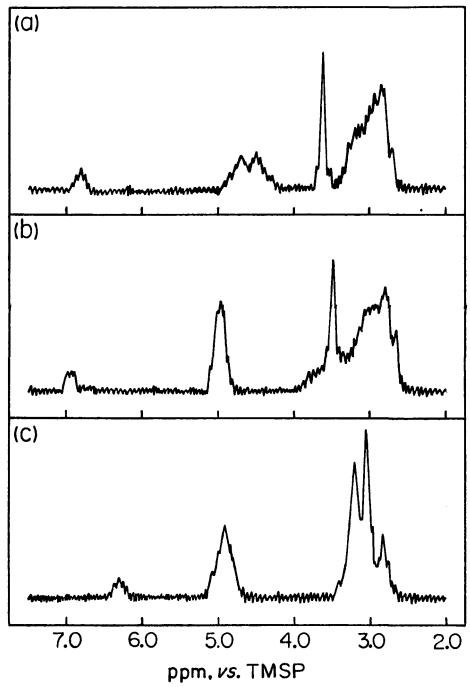

Fig. 4. PMR spectra of $[Coox(NH_3)(dien)]^+$.
(a) *u-fac* (b) *s-fac* (c) *mer* (D_2O–30% D_2SO_4).

(a) *cis* (b) *trans* (D_2O–30% D_2SO_4).

proton resonances. The peaks due to the C_2H_4 groups appear at 2.6—3.4 ppm. On this basis, the *u-fac* configuration, with two non-equivalent NH_2 groups (Fig. 1), can be assigned to the complex whose spectrum shows the two peaks due to the NH_2 groups.

b) $[Coox(NH_3)_2(en)]Cl$: The PMR spectra of the two isomers are shown in Fig. 5. The spectrum of one of the two isomers shows a broad peak at 4.2—5.2 ppm, and two sharp peaks at 3.64 and 3.06 ppm, in which the integrated ratio is 4: 3: 3. The spectrum of the other isomer exhibits a broad peak at 4.94 and a sharp one at 3.51 ppm, with a ratio of 4: 6. From the intensities, the peaks at 4.2—5.2 ppm can be assigned to the NH_2 proton resonances, and those at 3.0—3.7 ppm, to the NH_3 proton resonances. The resonances due to the C_2H_4 groups appear at 2.5—3.0 ppm. The structures illustrated in Fig. 1 suggest that both the NH_2 and the NH_3 proton resonances split into two for the *cis*(NH_3) isomer. On this basis, the former complex is identified as the *cis*(NH_3) isomer. In the spectrum of the latter complex, each peak appears, in accord with the *trans*-(NH_3) structure.

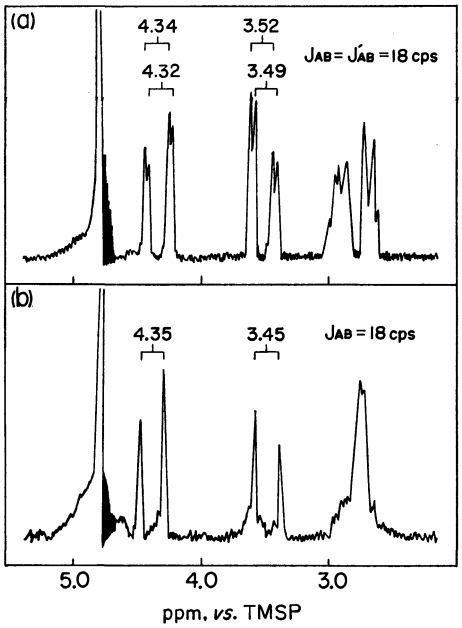

Fig. 6. PMR spectra of $[Co(ida)(NH_3)(en)]^+$.
(a) *u-fac* (b) *s-fac* (D_2O).

c) $[Co(ida)(NH_3)(en)]Cl$: The PMR spectra of the two isomers are shown in Fig. 6. The peaks due to the CH_2 proton resonances of the acetate rings of the ida appear at a lower field (3.3—4.5 ppm) than the C_2H_4 proton resonances of the en (2.6—3.0 ppm) because of the combined deshielding effects on the acetate protons from the carboxylate and amine groups.[8] When the geminal acetate protons are in magnetically different situations, the spectrum shows symmetrical AB quartets due to two spin-coupled protons. One of the two *fac* isomers exhibits two overlapping AB quartets, indicating that the two CH_2 groups are in slightly different environments, while the other isomer exhibits one quartet (Fig. 1). On this basis, the former complex is assigned to the *u-fac* isomer, and the latter, to the *s-fac* isomer.

In the spectrum of the *u-fac* isomer thus assigned, the

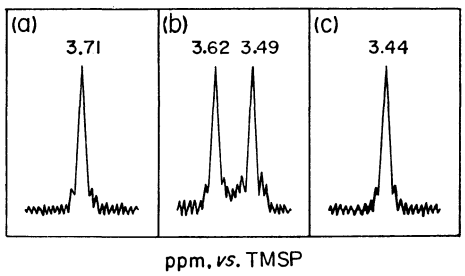

Fig. 7. PMR spectra of $[Co(gly)_2(NH_3)_2]^+$.
(a) *cis*(O)*trans*(N)*cis*(NH_3) (b) *cis*(O)*cis*(N)*cis*(NH_3)
(c) *cis*(O)*cis*(N)*trans*(NH_3) (D_2O).

C_2H_4 protons of the en give two complicated peaks because of the inequality of the two CH_2 groups, while in the spectrum of the *s-fac* isomer the C_2H_4 protons give a symmetrical peak because of the equality of the two CH_2 groups.

d) $[Co(gly)_2(NH_3)_2]Cl$: The PMR spectra of the three *cis*(O) isomers show only peaks due to the CH_2 protons of the glycinate rings (Fig. 7); one of the three isomers shows two peaks, at 3.62 and 3.49 ppm, indicating different situations of the CH_2 groups, while the other two isomers exhibit only one peak each, at 3.71 and 3.44 ppm respectively. On this basis, the *cis*(O)-*cis*(N)*cis*(NH_3) configuration can be assigned to the former one.

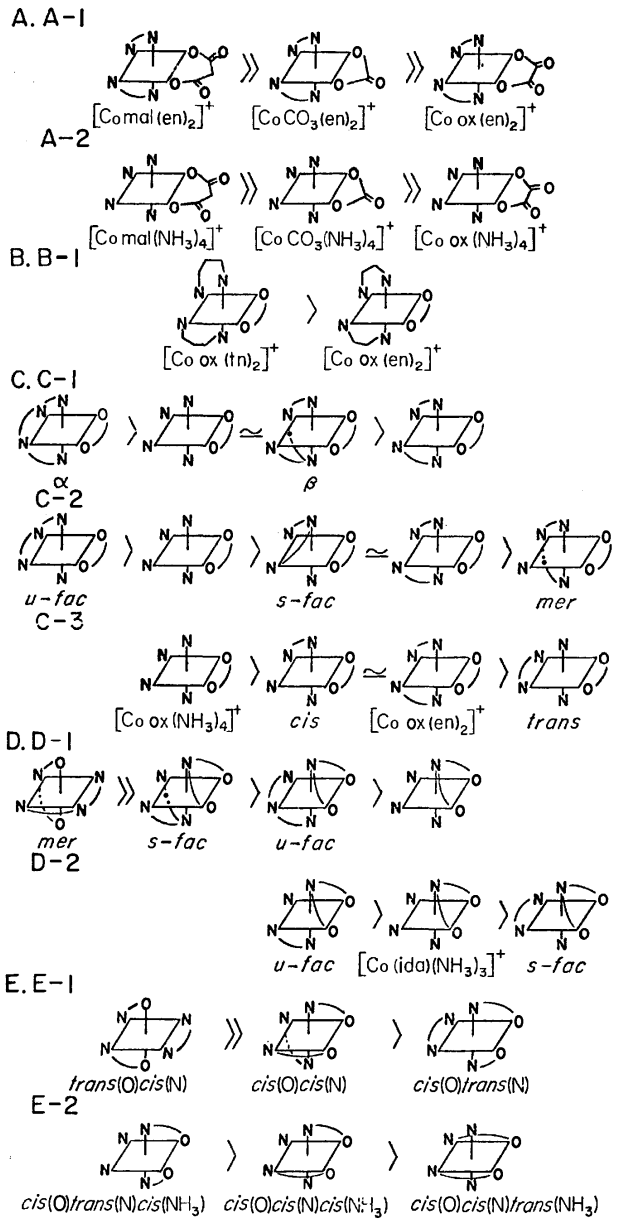

Fig. 8. Elution orders.

D. D-1: $[Co(ida)(dien)]^+$ D-2: $[Co(ida)(NH_3)(en)]^+$
E. E-1: $[Co(gly)_2(en)]^+$ E-2: $[Co(gly)_2(NH_3)_2]^+$.

Elution Order. The elution orders were investigated with the series classified A—E. The results are summarized in Fig. 8, where the $>$notation indicates an earlier elution of a complex species written on the left side than that on the right side ($\gg$indicates a separation with a long distance, and$\simeq$means nearly the same order of elution).

In the A series, the carbonato, oxalato, and malonato complexes of a tetraammine type were compared. In the B series, the oxalato–ethylenediamine, and –trimethylenediamine complexes were compared. In the C series, the ox ligand was fixed and the other ligands were varied, being trien in the C-1, NH_3+dien in the C-2, and $2NH_3$+en in the C-3 series. In addition, the $[Coox(NH_3)_4]^+$ and $[Coox(en)_2]^+$ complexes were used as markers in order to compare the elution orders among the series. In the D series, the ida ligand was fixed and the other ligands were varied, being dien in the D-1 and NH_3+en in the D-2 series. In the E series, the *bis*-(glycinato)-en (E-1) and -diammine (E-2) complexes were examined.

In both the *bis*(ethylenediamine) and tetraammine complexes (A-1 and A-2), the elution order was found to be malonato$\gg$carbonato$\gg$oxalato. This fact indicates that such a variety of dicarboxylate ions makes the separation of the complexes may clear. In the B series, the elution order was found to be tn$>$en; the more bulky tn complex was eluted earlier. Between the two markers used in the C series, the $[Coox(en)_2]^+$, with two en chelate rings, was eluted later than the $[Coox(NH_3)_4]^+$, which has no such chelate rings, while the $[Coox(trien)]^+$, with three such chelate rings, was eluted faster than the $[Coox(en)_2]^+$.

In both D-1 and E-1, the *trans*(O) isomers, *mer*-$[Co(ida)(dien)]^+$ and *trans*(O)*cis*(N)-$[Co(gly)_2(en)]^+$, were eluted faster than the corresponding *cis*(O) isomers. The same results have previously been reported by other workers[7,8]; this order is in accordance with the general tendency found in the *cis* and *trans* isomers of the simple complexes.[1]

So far as the elution order of the *cis*(O) isomers is concerned, only a little discussion has been done; Legg and Cooke[8] stated that, in the $[Co(ida)(dien)]^+$ complex, the *u-fac* isomer was eluted later than the *s-fac* one because of more unsymmetrical charge distribution. This explanation is applicable to the present C-1 and D-1 series. However, in the C-2, C-3, D-2, and E series, their *cis*(O) isomers, in which more symmetrical change distributions are to be expected, were eluted later.

It is well known that a chelated dien ring situated in the *mer*-position is very distorted.[10] It is considered that, in the present C-2 series, the *mer* isomer is in such a strained configuration. In the D-1 series, the *u-fac* isomer is known to have a strained configuration because of steric repulsion between the amine substituent of the chelated ida and the $-CH_2-$ protons of the chelated dien.[8] In the D-2 series, the *s-fac* isomer may have the most strained structure for the same reason. Corresponding to these strained structures, the last eluted species in each series was the isomer mentioned above.

It is noticeable that a partial reverse in the elution orders between the E-1 and E-2 series was observed; the *cis*(O)*cis*(N) isomer was eluted faster than the *cis*(O)-*trans*(N) isomer in the E-1 series,[7] but the corresponding two isomers of the E-2 series were eluted in the reverse order.

Neutron-activation Analysis of Selenium, Osmium and Ruthenium in Rocks, Sediments and Biological Materials by Successive Distillations with Three Kinds of Strong Phosphoric Acid Reagents*

Kikuo TERADA, Ken MATSUMOTO, and Toshiyasu KIBA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Ishikawa 920

(Received May 22, 1975)

A new separation scheme is presented for the neutron-activation analysis of selenium, osmium and ruthenium in solid samples such as rocks, sediments and biological materials. A neutron-irradiated sample accompanying the carriers of the three elements was heated with the bromide-SPA reagent to 250 °C, whereupon selenium came out as gaseous selenium tetrabromide. The second distillation was performed by heating the residual sample with Ce(IV)-SPA reagent till 285 °C to separate osmium as osmium tetroxide gas. The last distillation of ruthenium as ruthenium tetroxide followed under heating the residue with the Cr(VI)-SPA reagent till 245 °C. Each distillate was absorbed in an appropriate absorbing solution from which selenium metal, osmium thiourea chromithiocyanato complex, and ruthenium metal were respectively recovered and they were submitted to γ-counting by means of a Ge(Li) detector coupled with a multi-channel pulse height analyzer. The chemical recoveries of the added carriers were found to be about 80% for selenium and above 90% for osmium and ruthenium.

Because of its excellent decomposing power against various insoluble solid samples, strong phosphoric acid(SPA) is very useful in chemical analysis to avoid tedious treatments for samples such as fusion with flux or dissolution by acids.[1] The SPA treatment of samples can be done in a closed system throughout the analysis, therefore losses of the elements upon the decomposition can be prevented, and the method might be most effectively employed in the activation analysis of various solid samples.

Previously[2] the present authors reported the chemical separation and determination of osmium and ruthenium in the neutron-irradiated samples such as rocks, sediments, and biological materials, where two kinds of strong phosphoric acid reagents, Ce(IV)-SPA and Cr(VI)-SPA, were employed successively. In spite of the excellent results for the separation of the two elements, it was found in the distillation of osmium tetroxide some radioactive nuclides were apt to be accompanied in the distillate: those were selenium, iodine, bromine, mercury and arsenic. Among them Se-75 had to be removed prior to the distillation of osmium because, if it came in the distillate, its photopeaks of 121.0 keV and 136.6 keV locate too close to distinguish from those of 129.4 keV and 139.0 keV of Os-191. In order to make the separation of selenium feasible in the same SPA medium, various reagent-SPA systems were examined, and finally ammonium bromide-SPA reagent has been found most preferable for the purpose.[3] By heating the sample with this ammonium bromide-SPA, selenium(IV) and (VI) can be evolved as selenium tetrabromide in gaseous state, while osmium and ruthenium are not affected at all. Accompaniment of arsenic, iodine, bromine, and mercury to the selenium tetrabromide distillate seemed unavoidable, but these do not interfere the radiochemical determination of selenium. Therefore, the distillation of selenium is well suited as the treatment preceeding the Ce(IV)-SPA treatment for osmium and the Cr(VI)-SPA treatment for ruthenium. Thus, three successive distillations for selenium by ammonium bromide-SPA, for osmium by Ce(IV)-SPA, and for ruthenium by Cr(VI)-SPA could finish the complete separation of the three elements taking only one specimen from the sample.

* Part of this work was done at the Research Reactor Institute, Kyoto University.

Experimental

Reagents. *Strong Phosphoric Acid (SPA)*: SPA was prepared from orthophosphoric acid of extra-pure reagent grade as described previously.[2,3]

Standard Selenium Solution (1 mg/ml): Anhydrous sodium selenite of guaranteed reagent grade was dissolved in 0.1 M hydrochloric acid, and the solution was standardized by iodimetric titration.

Osmium Standard Solution (2 mg/ml) and Ruthenium Standard Solution (2.5 mg/ml): Their trichlorides of guaranteed reagent grade were dissolved in 2 M hydrochloric acid, respectively. They were standardized gravimetrically as thiourea chromithiocyanato complex for osmium and as metal for ruthenium.

Radioactive Tracers: Se-75, Re-186 and Os-191 were prepared by irradiation of each pure metal of them in the KUR, Research Reactor Institute, Kyoto University. On the other hand, As-74, Br-82, Fe-59, Hg-203, I-131, Ir-192, Ru-106, Sb-124, and Sn-113, those purchased from the Radiochemical Centre (England), New England Nuclear Corp. (U.S.A.), Union Carbide Corp. (U.S.A.), Japan Atomic Energy Research Institute (Japan) and Dainabot RI Lab. (Japan). Tc-99 m was obtained by milking of Ultratechnecow which was purchased from Mallincrodt Chemical Works (U.S.A.). Other chemicals were of guaranteed reagent grade.

Apparatus. A well-type γ-ray scintillation counter, Kobe Kogyo Co., Model STL-200 and a 2-cm^3 Ge(Li) detector, ORTEC Model 8100-45 having a resolution of about 2.5 keV for the 1335-keV gamma-peak of Co-60 were used, being coupled with a 400 channel pulse-height analyser, TMC Model 401D, and a printer Model 500P, to determine the radioactivity.

The reaction vessel and the absorption tubes were all the same as those recommended in the previous report.[3]

Procedure. Each 0.5—1.0 g of the finely-ground rocks, sediments or biological materials was accurately weighed and sealed in a clean silica tube. For the standard, about 0.01 ml of 500-ppm standard selenium solution, 10-ppm standard osmium solution and 10-ppm standard ruthenium solution were placed in separate small silica tubes by microsyringe,

respectively, then weighed, dried and sealed. The samples and the standards were irradiated with a thermal neutron flux of 4.65×10^{13} n·cm^{-2}·sec^{-1} for 80 hr at Research Reactor Institute, Kyoto University.

After cooling for 4—5 days, the sample was transfered into the SPA reaction vessel together with non-radioactive carriers of the elements in question, *i.e.*, 10 mg of Se(IV), 4 mg of Os(III), and 10 mg of Ru(III).

About 30—40 g of SPA and about 0.1—0.2 g of ammonium bromide were added to the reaction vessel. The vessel was connected with the absorption tubes which contain each 10 ml of a 1: 1 v/v mixture of 0.3 M hydrochloric acid and 0.6 M perchloric acid. The air was sucked slowly from the last outlet tube with a pump and the reaction vessel was heated with an electric heater to start the reaction. Within 30—50 min the temperature of the contents in the vessel was raised to 250 °C. After the distillation, the heating was stopped and all the connections were disconnected. The absorbing solutions and washings were combined in an Erlenmeyer flask (100 ml), and the solution was made about 6 M in hydrochloric acid, heated on the water-bath, added with about 3 ml of 10% tin(II) chloride solution (in concentrated hydrochloric acid) and digested for 1 hr. The precipitate was filtered off on a previously weighed glass-fiber filter paper (Toyo Roshi, GB-60), washed successively, with 6 M hydrochloric acid, distilled water and ethyl alcohol, then dried at 110 °C and weighed. The final precipitate was wrapped in a "Mylor" film or paraffin-waxed paper and the 136.0 or 264.6 keV photopeaks of Se-75 (121 d) was counted with a Ge(Li) solid-state detector coupled with a 400 channel pulse-height analyser.

After the separation of selenium as described above, about 4 g of cerium(IV) sulfate was put into the reaction vessel which must be cooled to below 100 °C after the selenium distillation. The vessel must be cooled whenever the reagent is added, to make the dissolution of the reagent uniform in the SPA medium. The osmium was distilled by heating the reaction vessel to 285 °C within 30—40 min. The absorbing solution was 1: 1 v/v 2% thiourea and 2 M hydrochloric acid mixture. After distillation the absorbing solution and washings were transfered into a beaker (100 ml) to make the volume about 50 ml. One milliliter of 40% potassium chromithiocyanate solution[4] was added and the contents were stirred vigorously until precipitation was complete. The precipitate was filtered as described in the selenium determination, and washed several times with distilled water, dried at 105 °C for 1 hr, then weighed. Finally, the 129.4 keV photopeak of Os-191 (14.6 d) was counted as same as for selenium.

After the second distillation about 2 g of potassium dichromate (in 2 or 3 portions) was put into the vessel, in the same way for osmium. The ruthenium was distilled by heating the reaction vessel to 240 °C within 30—40 min. The absorbing solution was 1: 1 v/v 6 M hydrochloric acid and ethyl alcohol mixture. After distillation the absorbing solution and the washings were transfered into an Erlenmeyer flask (100 ml) and was diluted with distilled water to about 1 M in hydrochloric acid. About 1.3 g magnesium powder was put little by little into the flask to reduced Ru(III) to Ru(0), followed by heating to coagulate the precipitate on a water-bath. The excess of magnesium was dissolved by a drop-wise addition of concentrated hydrochloric acid to be required and the solution was heated gently. The ruthenium metal thus obtained was collected on a glass-fiber filter paper, and washed several times with hydrochloric acid, distilled water, ethyl alcohol and ethyl ether, successively. The precipitate was dried at room temperature for 2 hr under reduced pressure, and weighed. The 215.8 keV photopeak of Ru-97 (2.88 d) was counted with a Ge(Li) solid-state detector.

Nuclear Data

Naturally occurring selenium consists of six isotopes, Se-74(0.87%), Se-76(9.02%), Se-77(7.58%), Se-78 (23.52%), Se-80(49.82%) and Se-82(9.19%). Some of these isotopes give rise to radionuclides when subjected to the irradiation with thermal neutrons, these are as follows:

$$^{74}\mathrm{Se}(n,\gamma)^{75}\mathrm{Se} \xrightarrow[t=121\,\mathrm{d}]{\mathrm{EC}} {}^{75}\mathrm{As}$$

$$^{78}\mathrm{Se}(n,\gamma)^{79m}\mathrm{Se} \xrightarrow[t=3.91\,\mathrm{m}]{\mathrm{IT}} {}^{79}\mathrm{Se} \xrightarrow[t=6.5\times10^{4}\,\mathrm{y}]{\beta^-} {}^{79}\mathrm{Br}$$

$$^{80}\mathrm{Se}(n,\gamma)^{81m}\mathrm{Se} \xrightarrow[t=57\,\mathrm{m}]{\mathrm{IT}} {}^{81}\mathrm{Se} \xrightarrow[t=18\,\mathrm{m}]{\beta^-} {}^{81}\mathrm{Br}$$

$$^{82}\mathrm{Se}(n,\gamma)^{83}\mathrm{Se} \xrightarrow[t=23\,\mathrm{m}]{\beta^-} {}^{83}\mathrm{Br} \xrightarrow[t=2.40\,\mathrm{h}]{\beta^-} {}^{83}\mathrm{Kr}$$

Among them Se-75 is the most useful nuclide to estimate the total amount of selenium in the present study.

Osmium consists of seven isotopes, Os-184(0.01%), Os-186(1.59%), Os-187(1.64%), Os-188(13.3%), Os-189(16.1%), Os-190(26.4%) and Os-192(41.0%). The nuclear data are as follows:

$$^{184}\mathrm{Os}(n,\gamma)^{185}\mathrm{Os} \xrightarrow[t=94\,\mathrm{d}]{\mathrm{EC}} {}^{185}\mathrm{Re}$$

$$^{190}\mathrm{Os}(n,\gamma)^{191m}\mathrm{Os} \xrightarrow[t=14\,\mathrm{h}]{\mathrm{IT}} {}^{191}\mathrm{Os} \xrightarrow[t=15\,\mathrm{d}]{\beta^-} {}^{191}\mathrm{Ir}$$

$$^{192}\mathrm{Os}(n,\gamma)^{193}\mathrm{Os} \xrightarrow[t=31\,\mathrm{h}]{\beta^-} {}^{193}\mathrm{Ir}$$

Osmium was determined in terms of the nuclide Os-191-(15 d) in all cases, and in some cases in terms of the nuclide Os-185 (31 hr).

Naturally occurring ruthenium consists of seven isotopes: Ru-96(5.57%), Ru-98(1.91%), Ru-99(12.7%), Ru-100(12.0%), Ru-101(17.0%), Ru-102(31.5%) and Ru-104(18.5%). The production and the decay of the radionuclides are represented by the following sequences:

$$^{96}\mathrm{Ru}(n,\gamma)^{97}\mathrm{Ru} \xrightarrow[t=2.88\,\mathrm{d}]{\mathrm{EC}} {}^{97m}\mathrm{Tc}$$

$$\xrightarrow[t=91\,\mathrm{d}]{\mathrm{IT}} {}^{97}\mathrm{Tc} \xrightarrow[t=2.6\times10^{6}\,\mathrm{y}]{\mathrm{EC}} {}^{97}\mathrm{Mo}$$

$$^{102}\mathrm{Ru}(n,\gamma)^{103}\mathrm{Ru} \xrightarrow[t=39.8\,\mathrm{d}]{\beta^-} {}^{103m}\mathrm{Rh} \xrightarrow[t=57\,\mathrm{m}]{\mathrm{IT}} {}^{103}\mathrm{Rh}$$

$$^{104}\mathrm{Ru}(n,\gamma)^{105}\mathrm{Ru} \xrightarrow[t=4.5\,\mathrm{h}]{\beta^-} {}^{105m}\mathrm{Rh}$$

$$\xrightarrow[t=45\,\mathrm{s}]{\mathrm{IT}} {}^{105}\mathrm{Rh} \xrightarrow[t=36.5\,\mathrm{h}]{\beta^-} {}^{105}\mathrm{Pd}$$

Taking into consideration of possible interferences from the nuclear reactions: U(n,f)^{103}Ru, U(n,f)^{105}Ru and U(n,f)^{106}Ru, Ru-97 was used for the determination of ruthenium.

Results and Discussion

Distillation Recovery of Selenium. Various solid chlorides and bromides were tested for the SPA decom-

position and distillation, and the amount of selenium distilled was determined radiometrically in every cases. As the results, ammonium bromide was found the most useful for the purpose. The following reactions might take place simultaneously[5]:

$$H_2SeO_3 + 4HBr \longrightarrow SeBr_4 + 3H_2O$$

$$H_2SeO_4 + 2HBr \longrightarrow H_2SeO_3 + Br_2 + H_2O$$

Consequently, in the presence of bromide Se(IV) and Se(VI) can evolve themselves as gaseous selenium tetrabromide from a solid matrix such as rocks, sediments, and biological materials, by heating the samples with ammonium bromide in strong phosphoric acid. Under the condition, elemental selenium and selenide were not affected at all, however, these species could react with bromide after converting them to selenite state by adding 40—50 mg of potassium iodate in the SPA medium as reported previously.[3]

Ammonium bromide together with potassium iodate was found not to react with osmium and ruthenium, and their tetroxide did not appear at all in the absorbing solution as shown in Table 1 which exhibits also the recoveries of selenium, osmium and ruthenium at various temperatures of the SPA media. It is seen that selenium is completely distilled till the temperature reached about 250 °C.

Table 1. Recovery of selenium, osmium and ruthenium at various temperatures of the SPA medium

Reagent (g/30 g SPA)	Temp. °C	Recovery after distillation, %		
		Se	Os	Ru
NH_4Br (0.1) + KIO_3 (0.04)	220	83—85	0	0
	240	93—95	0	0
	250	98—99	0	0
	260	98—99	0	0
	270	94—96	0	0
$Ce(SO_4)_2$ (4)	210		60—70	0
	250		85—90	0
	280		98—99	0
	285		99	0
$K_2Cr_2O_7$ (2)	180			95
	210			99
	230			100
	240			100

Carriers added: Se(IV): 10 mg, Os(III): 4 mg
Ru(III): 10 mg.

Furthermore, the time taken to raise the temperature to 250 °C seemed affect the recovery of selenium tetrabromide. Too fast and too slow heating gave poor recovery of the element. The heating to 250 °C should be done for 30 to 50 min.

Next, various kinds of absorbing solutions were examined for quantitative trapping of the distilled selenium tetrabromide. A 1: 1 v/v mixture of 0.3 M hydrochloric acid and 0.6 M perchloric acid was found to give the best results.

Distillation Recovery of Osmium. The osmium should be oxidized to Os(VIII) and evolved as the tetroxide from the matrix. Spectrophotometric method with thiourea and radioisotopic tracer method were used to find a suitable reagent for the oxidation of osmium. The results show that osmium in various forms, *e.g.*, metal, sulfide, tetrahydroxide and tetroxide, could be distilled quantitatively by means of Ce(IV)-SPA. Ruthenium did not react with cerium(IV) sulfate and not evolve its tetroxide. This fact was explained by Rao's experiments for the formal redox potentials in phosphoric acid of increasing concentrations.[6] The results indicate that cerium(IV) sulfate behaves as a less powerful oxidant than potassium dichromate in SPA contrarily the order of their ordinary oxidation potentials in an aqueous solution. In Table 1, the recovery of osmium is given as a function of temperature. It is seen that the heating to 280 °C or more bring the quantitative recovery of osmium.

Osmium tetroxide evolved could be absorbed in alkaline solution or a mixture of 6 M hydrochloric acid and ethyl alcohol (1: 1 v/v), plus 1 ml of 10% thiourea solution.[2] But in the present study 2% thiourea and 2 M hydrochloric acid mixture (1: 1 v/v) was preferably employed as an absorbing solution for the convenience of the subsequent precipitation of $Os(NH_2 \cdot CS \cdot NH_2)$-$Cr(SCN)_6$. In the presence of ethyl alcohol in the absorbing solution no precipitate appears because the complex can be easily dissolved in ethyl alcohol. The chemical yield is generally 90—95%.

Distillation Recovery of Ruthenium. As described in the previous report[2] potassium dichromate was found the most suitable oxidizing reagent for ruthenium in SPA medium. Ruthenium can be distilled quantitatively by heating with Cr(VI)-SPA to 240 °C and absorbed in 1: 1 v/v mixture of 6 M hydrochloric acid and ethyl alcohol (Table 1).

The time required for completion of reaction was examined and the results showed that the chloride was the most easily decomposed, taking only about 5 min, but sulfide and metallic ruthenium were more resistant, since it took about 30 min to complete the distillation of ruthenium tetroxide.

Table 2. Distillation of various elements by SPA method

Element	Recovery, %		
	Br^--SPA (250 °C)	Ce(IV)-SPA (285 °C)	Cr(VI)-SPA (245 °C)
As(III)	>95	0— 2	0— 2
Br^-	>95	>95	>95
Cl^-	>95	>95	>95
Fe(III)	0	0	0
Hg(I, II)	>95	0—10	10—20
I^-	>95	>95	>95
Ir(IV)	0	0	0
Mn(II)	0	0	0
Os(III)	0	100	100
Re(VII)	0	0	0
Ru(III)	0	0	100
Sb(III, V)	~2	40—60	30—40
Se(IV, VI)	100	0	0
Sn(II, IV)	~3	0	0
Tc(VII)	0	10—20	10—20
Te(IV, VI)	~10	0	0

Behavior of Other Elements. Other elements giving their volatile bromides, oxides as well as volatile acids are believed to be released from their acidic solutions by heating.[7] Table 2 shows that more than 95% of As(III), Br^-, Cl^-, I^- (as hydrohalogenic acid), Hg(I, II), and a few per cent of Sb(III, V), Sn(II, IV) and Te(IV, VI) are driven off from Br^--SPA medium by heating. On the other hand, distillation of As(III) and Hg(I, II) do not exceed a few per cent and 20%, respectively, from Ce(IV)-SPA and Cr(VI)-SPA. In conclusion, not only selenium but other volatilizable elements are almost distilled off on the first Br^--SPA distillation, and hence they do not appear in the absorbing solutions of the second and third distillation with Ce(IV)-SPA and Cr(VI)-SPA. Thus osmium and ruthenium could be separated quantitatively without contaminations except some of technetium species which might be produced secondary from molybdenum [$^{98}Mo(n,\gamma)^{99}Mo \xrightarrow{\beta^-} {}^{99m}Tc(t=6.04\ hr)$ and $^{100}Mo(n,\gamma)$-$^{101}Mo \xrightarrow{\beta^-} {}^{101}Tc(t=14.0\ min)$]. In the present study the interferences by these nuclides were found to be neglible.

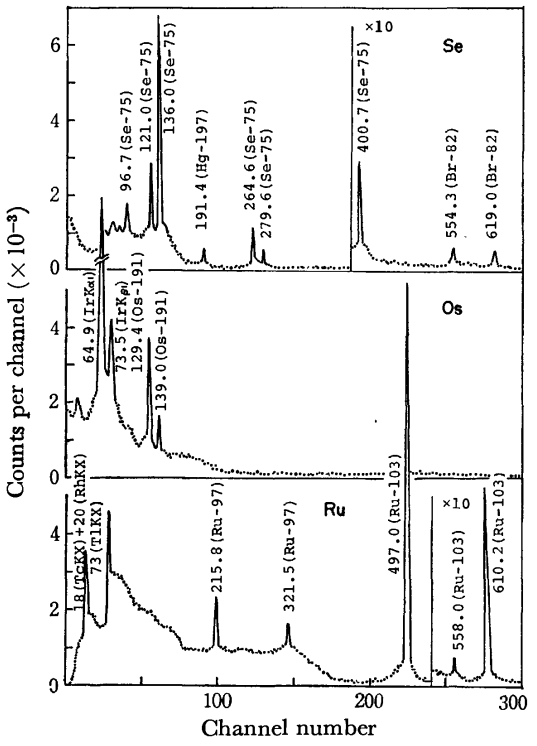

Fig. 1. Gamma-spectra of selenium-, osmium- and ruthenium-fractions after the separation by SPA method (Marine sediment, Japan Sea).

Successive Distillations for Selenium, Osmium and Ruthenium. Successive distillations were tried for marine sediment samples which were collected from the bottoms of Japan Sea, and of Pacific Ocean. One gram of the dried sample was irradiated and processed by the present method as described above, and the final counting samples were submitted to γ-counting. The typical γ-spectra of each fraction separated by the method are shown in Fig. 1. From these spectra, the selenium fraction after Br^--SPA treatment is seen to be contaminated with some of the other nuclides, mainly with Hg-197(65 hr) and Br-82(35.87 hr). However, these radionuclides do not interfere the determination of selenium. On the other hand, the osmium and ruthenium fractions after the Ce(IV)-SPA and then Cr(VI)-SPA treatment were not contaminated with any other radionuclides. In the γ-spectrum of the ruthenium fraction a large photopeak of 497.0 keV appear and it seems to be attributed to mainly Ru-103 produced by fission of uranium existing in the sediment sample. Fission product Ru complicates seriously the determination of ruthenium by the activation analysis. In several sediment samples, ruthenium was characterized by radiation from Ru-103 only and no Ru-97 component could be identified from γ-spectra. According to Gijbels,[8] when the U/Ru ratio is unity the error caused by simply measuring Ru-103 is *ca.* 12%. However, when U/Ru ratio is higher as in the case of marine sediments (10^3—10^4), the ruthenium determination *via* Ru-103 poses a significant problem. It is thus necessary to measure the Ru-97 activity to obtain the reliable results.

TABLE 3. SELENIUM, OSMIUM AND RUTHENIUM CONTENTS OF THE STANDARD ROCKS AND MARINE SEDIMENTS

	Se, ppb	Os, ppb	Ru, ppb
Standard rock			
JG-1 (5)	2.7±0.2	2.7±0.2	n.d.
JB-1 (5)	26 ±2	1.9±0.2	n.d.
Marine sediment			
0°00′00″ N 150°04′07″ E (3)	470	1.0	n.d.
0°48′08″ N 163°59′05″ E (3)	870	9.8	3.6
37°24′ N 132°03′ E (3)	2600	16	8.2
38°33′ N 131°01′ E (3)	910	17	4.3

Determination of Selenium, Osmium and Ruthenium in Rocks and Marine Sediments. The separation and determination of selenium, osmium and ruthenium in standard rock samples and marine sediments were tried by the proposed method. The results are shown in Table 3. Selenium and osmium contents in the standard rocks, JG-1 and JB-1 are the average of five determinations, respectively. Ruthenium was not identified in the present condition. The values for marine sediments are the average of three determinations, respectively. Some sediments were found to contain measurable amount of selenium, while osmium and ruthenium could not be determined, therefore these analytical results are omitted in the table.

The chemical recoveries of the added carriers were in the range 80—85%, 90—95% and 90—95% for selenium, osmium and ruthenium, respectively, within the error of ±10%. The time required for the completion of the radiochemical separation of a sample was about 3 hr.

It will be expected that the present SPA method is applicable for the simultaneous determination of selenium, arsenic, mercury, and bromide from a single

sample and the technique will be described elsewhere.

The authors are much indebted to the members of the Research Reactor Institute of Kyoto University for their help with the activation of the samples and radiochemical treatment. Support of a part of this work by the Ministry of Education is gratefully acknowledged.

Mixed Ligand Copper(II) Complexes of Amino Acids and Related Compounds with Possible Ligand-Ligand Interactions

Osamu YAMAUCHI, Yasuo NAKAO, and Akitsugu NAKAHARA

Institute of Chemistry, College of General Education, Osaka University, Toyonaka, Osaka 560

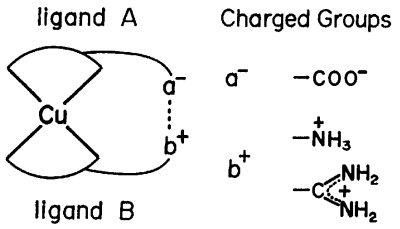
(Received June 12, 1975)

Ternary systems composed of copper(II) and two ligands, each with an oppositely charged uncoordinated group in the side chain, have been investigated by synthetic and spectral methods. The absorption and circular dichroism(CD) spectra in the d-d region were measured at various pH values for the binary and ternary systems, $Cu(B)_2$ and Cu(A)(B), where A refers to ethylenediamine-*N*-monoacetic acid(EDMA), glycylglycine(Gly·Gly), glycyl-β-alanine(Gly·β-Ala), ethylenediamine(en), or glycine(Gly), and B to D- and L-arginine (D- and L-Arg), L-ornithine(L-Orn), L-lysine(L-Lys), L-alanine(L-Ala), or L-valine(L-Val), and the following complexes containing ligands with polar side chains were isolated as crystals: $[Cu(EDMA)(L\text{-}Arg)]ClO_4 \cdot H_2O$; $[Cu(EDMA)(L\text{-}Orn)]ClO_4 \cdot 1/2H_2O$; $[Cu(EDMA)(L\text{-}Lys)]ClO_4$; $[Cu(Gly\cdot Gly)(L\text{-}Arg)] \cdot 3/2H_2O$. From comparison of the CD magnitudes expressed in terms of the relative magnitude which assumes half the value for $Cu(B)_2$ as unity, the magnitude enhancements observed for the systems Cu(EDMA)(D- and L-Arg), Cu(EDMA)(L-Orn), Cu(EDMA)-(L-Lys), and Cu(Gly·β-Ala)(D- and L-Arg) in water and in 50% aqueous ethanol have been inferred to be due to the intramolecular electrostatic interactions between the charged groups in the side chains of ligands A and B.

Transition metal ions in the biological systems are most probably in the forms of various mixed complexes. Thus, the enzyme–metal–substrate complex, formed as an intermediate in the enzymatic reaction in the presence of a metal ion, is a kind of mixed ligand complex, and the reaction itself is regarded as a ligand-ligand interaction assisted by the cooperative action of the central metal ion. A well known example is the carboxypeptidase A–peptide complex whose crystal structure has been disclosed by X-ray analysis.[1] What appeared most interesting to us is that it has electrostatic or hydrogen bondings between the guanidinium group of arginine 145 of the enzyme and the carboxylate terminus of its substrate. Since such an interaction serves as a driving force for the enzyme-substrate complex formation, we considered it to be of fundamental importance to work out reasonable model systems based on the carboxypeptidase A-peptide complex and investigate, as a chemical counterpart of the enzymatic reactions, the possibilities of ligand-ligand interactions within mixed ligand complex molecules.

Studies have been reported for the stereoselective effects of the interactions between coordinated ligands in various cobalt(III) complexes, where, for example, the uncoordinated carboxylate group around the central atom interacts with the adjacent coordinated amino group through hydrogen bonding. Such interactions have been concluded to give rise to stereoselectivity in the formation of the diastereoisomers.[2–5] Wellman and Wong[6] observed favored formation of the L-histidinol-containing mixed ligand complexes of copper(II), whose circular dichroism(CD) spectra suggested the interaction between the imidazole group of L-histidinol and the amino group of the other ligand. Angelici *et al.*[7,8] reported the stereoselectivity exhibited by (*N*-carboxymethyl-L-valinato)copper(II) toward optically active amino acids and ascribed it to the interference between the amine hydrogens of the two ligands in the resulting complexes. However, mixed ligand systems involving explicit electrostatic interactions within a molecule have not been reported yet.

As an approach to the biological systems, we studied the properties of the mixed ligand copper(II) complexes of the type shown in Scheme 1 in expectation of intramolecular electrostatic ligand-ligand interactions that would occur between the oppositely charged, uncoordinated groups of the side chains of ligands A and B.



Scheme 1.

We selected for this purpose such pairs of A and B as would exhibit the mentioned interactions, as well as the pairs without possible interactions, and investigated isolation and absorption and CD spectral properties of the copper(II) complexes of type Cu(A)-(B), which are to be described in the following sections. For convenience, ethylenediamine-*N*-monoacetic acid (EDMA), glycylglycine(Gly·Gly), glycyl-β-alanine (Gly·β-Ala), ethylenediamine(en), and glycine(Gly) will be referred to as A ligands, and D- and L-arginine (D- and L-Arg), L-ornithine(L-Orn), L-lysine(L-Lys), L-alanine(L-Ala), and L-valine(L-Val) as B ligands.

Experimental

Materials. L-Arginine, L-ornithine hydrochloride, L-lysine dihydrochloride, and L-alanine were purchased from Nakarai Chemicals, Ltd., and L-valine and glycine from Wako Pure Chemical Industries, Ltd. D-Arginine hydrochloride was obtained from Fluka AG. Glycylglycine was obtained from Protein Research Foundation, Osaka, and glycyl-β-alanine was prepared according to the literature.[9] The dihydrochloride of EDMA was prepared by the method of Fujii *et al.*,[10] and the purity was checked by elemental analysis and potentiometric titration.

All the chemicals used were of reagent grade or of highest grade available.

Synthesis of Mixed Ligand Copper(II) Complexes. [*Cu(EDMA)(L-Arg)*]$ClO_4 \cdot H_2O$: EDMA dihydrochloride hydrate (1.05 g, 5 mmol), L-arginine (0.87 g, 5 mmol), and copper(II) perchlorate hexahydrate (1.85 g, 5 mmol) were mixed in water, and the pH of the resulting solution was adjusted to 8 with aqueous sodium hydroxide. The chloride ions were removed from the reaction mixture by passing it through a column of Amberlite IRA-400 in perchlorate form. The blue oily residue obtained after concentration *in vacuo* was mixed with methanol and kept at room temperature for a few days, when it gradually crystallized. Recrystallization from aqueous methanol–ethanol and drying *in vacuo* over silica gel gave deep blue crystals. Found: C, 25.40; H, 5.35; N, 17.80%. Calcd for $C_{10}H_{23}N_6O_8ClCu \cdot H_2O$: C, 25.43; H, 5.34; N, 17.79%.

[*Cu(EDMA)(L-Orn)*]$ClO_4 \cdot 1/2H_2O$: A neutralized solution (pH 7) of EDMA dihydrochloride hydrate (1.05 g, 5 mmol), L-ornithine hydrochloride (0.84 g, 5 mmol), and copper(II) chloride dihydrate (0.85 g, 5 mmol) in water was treated in the manner described above to give deep blue crystals. Found: C, 25.84; H, 5.22; N, 12.88%. Calcd for $C_9H_{21}N_4O_8ClCu \cdot 1/2H_2O$: C, 25.87; H, 5.22; N, 13.29%.

[*Cu(EDMA)(L-Lys)*]ClO_4: This was prepared in a similar manner from EDMA dihydrochloride hydrate (1.05 g, 5 mmol), L-lysine dihydrochloride (1.10 g, 5 mmol), and copper(II) chloride dihydrate (0.85 g, 5 mmol). The deep blue crystals were recrystallized from methanol–water and dried *in vacuo* over P_4O_{10} at 60 °C. Found: C, 28.18; H, 5.56; N, 12.77%. Calcd for $C_{10}H_{23}N_4O_8ClCu$: C, 28.17; H, 5.44; N, 13.14%.

[*Cu(Gly·Gly)(L-Arg)*]$\cdot 3/2H_2O$: An aqueous solution containing Gly·Gly (1.3 g, 10 mmol), L-arginine (1.7 g, 10 mmol), and copper(II) perchlorate hexahydrate (3.7 g, 10 mmol) was made alkaline (pH 10) with aqueous sodium hydroxide, stirred for 1 hr at room temperature, and filtered. Ethanol was added to the filtrate to give deep blue crystals, which were recrystallized from aqueous methanol-ethanol. Found: C, 30.41; H, 5.88; N, 21.28%. Calcd for $C_{10}H_{20}N_6O_5Cu \cdot 3/2H_2O$: C, 30.57; H, 5.60; N, 21.42%.

Measurements of Spectra. Absorption spectra were recorded on a Union Giken SM-401 High-Sensitivity recording spectrophotometer and CD spectra on a JASCO MOE-1 spectropolarimeter. The spectra were measured for most of the systems with Cu(II): A: B ratios of 1: 2: 0, 1: 0: 2, and 1: 1: 1 at various pH values in the ranges 350—750 nm (absorption spectra) and 350—800 nm (CD spectra). The measurements were made at a constant copper(II) concentration of 5.0×10^{-3} M in four different media: (i) water (ionic strength (μ) not adjusted (μ=variable)); (ii) water (μ=0.1 ($NaClO_4$)); (iii) water (μ=0.5 ($NaClO_4$)); (iv) 50% aqueous ethanol. The pH values of the solutions were roughly adjusted with aqueous sodium hydroxide and dilute perchloric acid and finally determined immediately after the spectral measurements. The values described are meter readings with no corrections for difference in the medium.

The above measurements were made at room temperature.

Results and Discussion

Synthesis of the Mixed Ligand Complexes. Out of the mixed ligand systems investigated, [Cu(EDMA)(L-Arg)]ClO_4, [Cu(EDMA)(L-Orn)]ClO_4, [Cu(EDMA)-(L-Lys)]ClO_4, and [Cu(Gly·Gly)(L-Arg)] have been isolated as crystals under the conditions employed. The pH of the reaction mixture was so adjusted as to keep the most basic group of the α-amino acid protonated.

The compositions of the isolated complexes indicate that each complex involves a ligand with a negatively charged uncoordinated group and a ligand with a positively charged one. The behavior of these particular systems may be correlated with the stereoselectivity reported for cobalt(III) complexes.[2-5] In the present cases, ligand-ligand interactions, which should be electrostatic in nature, are reasonably expected to occur between the charged groups of the side chains (Scheme 1).

Absorption Spectra. The absorption spectra in the d-d region were measured in water (μ=variable, 0.1, and 0.5) and in 50% aqueous ethanol at various pH values. The shifts of the absorption maxima of the binary and ternary systems due to the increase of ionic strength were small (*ca.* 2—4 nm toward shorter wavelength), and their intensities remained virtually constant at different ionic strengths except that they slightly increased in 50% aqueous ethanol. Table 1 shows the absorption spectral data for various binary systems at μ=0.1. The data for the ternary Cu(A)(B) systems at μ=variable are summarized in Table 2.

The absorption maxima of the ternary systems containing EDMA, Gly·Gly, Gly·β-Ala, or Gly as ligand A fall in the region 610—640 nm at pH>9 where Cu(A)(B) is expected to be the major complex species

present. As we see from the data for Cu(A)(L-Orn) and Cu(A)(L-Lys), some of the spectra exhibit shifts to longer wavelengths at pH>10, probably due either to apical coordination by the δ- or ε-amino group or to formation of hydroxy complexes. This point will be referred to again in connection with the CD spectra.

CD Spectra. In the d-d spectral region, the binary and ternary systems containing optically active amino acids exhibited CD extrema due to the vicinal effect of the asymmetric carbon. Figs. 1 and 2 illustrate the spectra for the systems involving L-arginine and L-ornithine, respectively. The spectral data in water (μ=variable) at selected pH are listed in Table 3. Usually a negative extremum, which is shifted to longer wavelengths at μ=0.1 and 0.5, is observed in the region 570—610 nm with a weak positive peak at >700 nm.

a) The data (pH, λ_{max} (nm), $\Delta\varepsilon$) for Cu(EDMA)(L-Arg) at higher concentrations are as follows: (i) at 0.05 M, 8.2, 603, −0.11; (ii) at 0.1 M, 9.0, 604, −0.11.

The magnitudes of the negative peaks are small in acid solution (pH 3—5) and increase with pH up to their maximum at pH 9—10, which indicates the chelation by the amino acid is almost complete at this pH. That the CD spectra observed for the ternary systems are due primarily to Cu(A)(B) and not to the binary $Cu(B)_2$ is substantiated by the wavelengths of their extrema which are significantly different from those of the binary ones. Except for the L-ornithine series, the systems Cu(EDMA)(B), Cu(en)(B), and Cu(Gly)(B) at pH>7 have their peaks at 600—612, 580—616, and 600—630 nm, respectively, and the wavelengths do not shift greatly with pH. On the other hand, the systems with Gly·Gly or Gly·β-Ala as ligand A have negative bands around 570—600 nm, which are shifted to shorter wavelengths with the increase of pH. The behavior may be due to the deprotonation of the peptide NH group and the concomitant change of the donor atom from oxygen to nitrogen.

A sign inversion of the main peak was observed for $Cu(L\text{-}Orn)_2$ and every Cu(A)(L-Orn) system studied, and there appeared a positive peak in the region 610—650 nm at pH 9—10. The same spectral changes have been reported by Wellman *et al.*[11] and Wilson *et al.*[12] for the systems Cu(Gly)(L-Orn)[11,12] and Cu(en)-(L-Orn).[12] It was concluded from their studies that the change is due to apical coordination by the δ-amino group of L-ornithine in these systems. The present observation that the sign inversion coincides with the acid dissociation of the δ-amino group (pK_a=10.67[13]) supports their conclusion, and apical coordination by this group is inferred to occur in all the L-ornithine-containing systems studied. The shifts of the absorption maxima to longer wavelengths at high pH correspond with those observed for copper(II)–ammine complexes.[14] Apical coordination by the ε-amino group of L-lysine, if at all, seems to be negligible, because the absorption and CD spectral changes exhibited at pH 8—10 are small.

CD Magnitude and Intramolecular Ligand-Ligand Interaction. Of utmost interest is the fact that the CD magnitudes shown in Table 3 have a distinct trend which seems to reflect the differences in the environments where the amino acids are located. In order to make a clearer comparison of the magnitudes of the negative extrema in the region 570—620 nm, we tentatively expressed a series of magnitudes related to an amino acid in terms of the relative magnitude which assumes half the magnitude ($\Delta\varepsilon/2$) of the binary complex of that amino acid as unity. Table 4 displays the relative magnitudes calculated in this way for various systems in water (μ=variable) at pH as indicated. The values for L-ornithine series were calculated at pH 7 where its apical coordination does not take place appreciably. It is now apparent that the systems Cu(EDMA)(L-Arg), Cu(EDMA)(L-Orn), Cu(EDMA)(L-Lys), and Cu(Gly·β-Ala)(L-Arg) have significantly larger relative magnitudes than unity, while the others have values close to 1.

Although attempts have been made to interpret the CD spectral patterns of copper(II) complexes in the d-d region and to correlate them with the structures around copper(II),[15—22] it is still necessary to determine experimentally whether or not the relative CD magnitudes as defined above can be compared between different systems or, in other words, whether the additivity of the CD magnitude holds in complexes with differentcombinations of ligands. Tsangaris and Martin[23] reported the magnitude additivity observed for copper(II)–dipeptide complexes. In the present studies, the donor atoms of A ligands are two nitrogens(2N) or a nitrogen and an oxygen(1N1O), and simple additivity may not hold owing to the differences in the environments. However, we see from Table 4 that the relative magnitudes observed for the Cu(en)(B) and Cu(Gly)-(B) series, where the donor atoms are 2 N and 1N1O, respectively, are 0.8—1.1 irrespective of B ligands.[24] Also, the ternary systems containing L-alanine or L-valine as B have magnitudes of 0.8—1.2 for all combinations with A. These results clearly indicate that the relative CD magnitude is approximately equal to 1 and accordingly additive unless both ligand A and ligand B have respectively a negatively charged and a positively charged group in their side chain. In addition, we may infer from this that the mode of coordination of the simple α-amino acids in the ternary systems studied is the same as in the binary systems. As α-amino acids are effective bidentate ligands, the carboxylate group of EDMA, Gly·Gly, or Gly·β-Ala are probably dis-

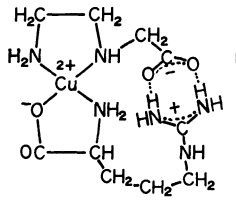
a) Relative CD magnitude is the magnitude relative to $\Delta\varepsilon/2$ of $Cu(B)_2$ as unity. b) Numerals in parentheses refer to the pH values where the comparison was made.

placed from the tetragonal plane upon formation of Cu(A)(B) (**1a** and **1b**).

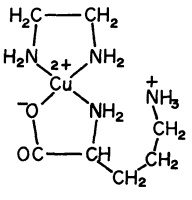
Considering that the magnitude enhancement is observed only for the combination of A and B with oppositely charged side chains and that the CD measurements have been performed at a copper(II) concentration of 5.0×10^{-3}M, we may take the enhancement as an indication of the presence of an intramolecular ligand-ligand interaction which adds to rigidity of the complex. The enhancement of the CD magnitude and the sign inversion have been reported for the Cu(bipyridyl)(L-amino acid) systems,[25] which are quite different in nature from the present ones.

Molecular models for Cu(EDMA)(L-Arg), Cu(EDMA)(L-Orn), and Cu(EDMA)(L-Lys) corroborate the favorable steric requirements for the assumed intramolecular hydrogen bonds as shown for Cu(EDMA)(L-Arg) (**2**). According to this structure, the imino nitrogen of EDMA can be asymmetric if it is fixed around copper(II) by hydrogen bonding. For the systems without charged pairs, such as Cu(en)(L-Orn) (**3**) and Cu(EDMA)(L-Ala) (**4**), no intramolecular hydrogen bonding is possible, and the observed CD magnitudes are expectedly close to **1**.



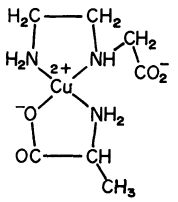
Cu(EDMA)(L-Arg)

2



Cu(en)(L-Orn)

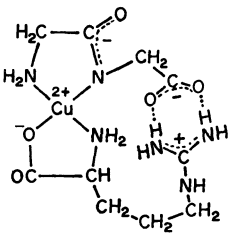
3



Cu(EDMA)(L-Ala)

4

As regards the Cu(Gly·Gly)(B) and Cu(Gly·β-Ala)(B) systems except Cu(Gly·β-Ala)(L-Arg), the relative magnitudes are 0.8—1.2 and apparently contradictory to the ligand-ligand bondings as are expected from the molecular models of the structures like **5**. Table 3 indicates that in the peptide series the positive peak found at >700 nm is shifted to shorter wavelength with the increase of pH, probably inducing the cancellation of the two Gaussian curves with signs opposite to each other. This may explain the unexpectedly small relative magnitudes. Space-filling models do not reveal explicitly the stereochemical difference between Cu(Gly·Gly)(L-Arg) and Cu(Gly·β-Ala)(L-Arg) of



Cu(Gly·Gly)(L-Arg)

5

which the latter has a significantly larger magnitude of 1.5 than that of the former.

From the CD spectral behavior of Cu(EDMA)(D-Arg), the CD patterns for the other D-amino acid series are expected to be the same as those observed for the corresponding L-series with the signs inverted.

If the assumed electrostatic ligand-lagand bonding as illustrated in **2** and **5** is real and has influence on the CD spectra, the relative magnitude should then be affected by the ionic strength and the polarity of the solvent. The results of the spectral measurements in water at $\mu=0.1$ and 0.5 are compared with those at $\mu=$variable in Table 5, which discloses that the enhanced values for Cu(EDMA)(L-Arg), Cu(EDMA)(L-Orn), and Cu(EDMA)(L-Lys) at $\mu=$variable decrease to nearly normal values with the increase of ionic strength, while those for Cu(EDMA)(L-Ala), Cu(EDMA)(L-Val), and Cu(en)(B) remain unaffected. On the other hand, the data obtained in 50% aqueous ethanol indicate that the ionic strength-dependent values are further increased up to 2.1—2.7 by lowering the polarity of the solvent with ethanol. Interestingly, the CD patterns of Cu(EDMA)(L-Arg) at concentrations as high as 0.05 M (pH 8.2) and 0.1 M (pH 9.0) were the same as the pattern observed at 0.005 M (Table 3, footnote). This points to the fact that the molecular environment in the complex is not affected by the concentration of the solution in the range studied.

Taken together, the observations may provide evidence that there exists, at least in solution, an intramolecular electrostatic bonding in a certain pair of oppositely charged ligands constituting a mixed ligand copper(II) complex and that it affects the CD magnitude under favorable conditions.

We wish to acknowledge the helpful comments and

Table 5. Relative CD magnitudes in various media at pH 7—10

Ligand B	Cu(EDMA)(B)				Cu(Gly·Gly)(B)[a]				Cu(en)(B)

The Acid-catalyzed Reaction of Cycloalkanones with Formaldehyde

Fukumi HIRANO and Shoji WAKABAYASHI

Department of Chemistry, Faculty of Science, Okayama College of Science, Okayama 700

(Received January 14, 1975)

The acid-catalyzed reactions of several cycloalkanones, such as cyclopentanone (**1a**), 2-methylcyclopentanone (**1b**), cyclohexanone (**1c**), 2-methylcyclohexanone (**1d**), and 2-isopropyl-5-methylcyclohexanone (**1e**), with formaldehyde were investigated. These reactions involved an aldol condensation analogous to the Prins reaction, and they afforded methylol derivatives and cyclic ethers. It was found that the formation of the products is strongly influenced by the skeletal structure and by the substituent on the cycloalkanones. That is, **1a**, **1c**, and **1d** gave mainly 1,3-dioxanes, while **1b** and **1e** formed only methylol derivatives. The reaction of cycloalkanone enol esters with formaldehyde was also studied.

The base-catalyzed reaction of cycloalkanones with formaldehyde has already been studied by many workers.[1-4] However, only a few papers have been reported on the acid-catalyzed reaction. For example, Olsen[5] has shown that cyclohexanone in sulfuric acid gave mono- and *bis*-1,3-dioxanes. Lumma[6] has recently reported the formation of methylol derivatives in the reaction of 2-methylcyclohexanone in trifluoroacetic acid. However, the details of the products have not been described.

In this investigation, the reaction of cycloalkanones and their enol esters with formaldehyde in the presence of an acid-catalyst was examined in considering the effects of the skeletal structure and of the substituents on the cycloalkanones.

Results and Discussion

These reactions were mainly carried out in a mixture of acetic acid and acetic anhydride in the presence of phosphoric acid.

The reaction of cyclopentanone (**1a**) with formaldehyde gave 2-hydroxymethylcyclopentanone (**2a**), the acetate (**2'a**), 2-[(acetoxymethoxy)methyl]cyclopentanone (**4'a**), and 2,4,8,10-tetraoxatricyclo[4.4.3.0^{1,6}]tridecane (**6a**) as the main products.

TABLE 1. REACTANTS AND PRODUCTS IN THE ACID-CATALYZED REACTION OF CYCLOALKANONES WITH FORMALDEHYDE

Reactants	Products
1a	**2a, 2'a, 4'a, 6a**
1b	**2b, 2'b, 3b, 3'b**
1c	**2c, 2'c, 4'c, 5c, 6c, 7c**
1d	**2d, 2'd, 3'd, 4'd, 6d, 7d**
1e	**2e, 2'e, 3e, 3'e**

The reaction of 2-methylcyclopentanone (**1b**) with formaldehyde yielded 2-hydroxymethyl-2-methylcyclopentanone (**2b**), the acetate (**2'b**), 5-hydroxymethyl-2-methylcyclopentanone (**3b**), and the acetate (**3'b**) mainly. In this reaction, no formation of a bis-1,3-dioxane, such as **6a**, was detected.

The reaction of cyclohexanone (**1c**) with formaldehyde afforded 2-hydroxymethylcyclohexanone (**2c**), the acetate (**2'c**), 2-[(acetoxymethoxy) methyl] cyclohexanone (**4'c**), 2,4-dioxa-7-oxospiro[5.5]undecane (**5c**), 2,4,8,10-tetraoxatricyclo[4.4.4.0^{1,6}]tetradecane (**6c**), and 2,4,12,-14-tetraoxatricyclo[8.4.0.0^{1,6}]tetradecane (**7c**) mainly.

Similarly, the reaction of 2-methylcyclohexanone (**1d**) gave 6-methyl-2,4,12,14-tetraoxatricyclo[8.4.0.0^{1,6}]-tetradecane (**7d**), along with small amounts of 2-hydroxymethyl-2-methylcyclohexanone (**2d**), the acetate (**2'd**), 6-acetoxymethyl-2-methylcyclohexanone (**3'd**), 2-[(acetoxymethoxy)methyl]-2-methylcyclohexanone (**4'd**), and 11-methyl-2,4,8,10-tetraoxatricyclo[4.4.-4.0^{1,6}]tetradecane (**6d**).

The reaction of 2-isopropyl-5-methylcyclohexanone (**1e**) with formaldehyde gave 2-hydroxymethyl-2-isopropyl-5-methylcyclohexanone (**2e**), the acetate (**2'e**) 6-hydroxymethyl-2-isopropyl-5-methylcyclohexanone (**3e**), and the acetate (**3'e**) as the main products. Methylol derivatives (**2e** and **3e**) when heated to 160—210 °C decomposed to **1e** and formaldehyde. A similar treatment of the acetates (**2'e** and **3'e**) yielded 2-isopropyl-5-methyl-1-cyclohexenyl acetate and formaldehyde.

The methanolysis of bis-1,3-dioxanes (**6c** and **7d**) gave the methylol compounds, (**2c** and **2d** respectively).

The spectral data of these products are summarized in Tables 2 and 3.

Effect of the Skeletal Structure. The reaction products in the condensation of **1a** and of **1c** with formaldehyde were compared. The reaction of **1c** afforded a spiro-type 1,3-dioxane (**5c**), along with a bis-1,3-dioxane (**6c**), in good yields. On the contrary, in the case of **1a**, the yield of bis-1,3-dioxane was remarkably less than that in the case of **1c**, and a spiro-type 1,3-dioxane was not formed at all. These

results indicate that the formation of a 1,3-dioxane ring involving the adjacent two carbon atoms of cyclopentane and that of a spiro-type 1,3-dioxane involving the α-carbon atom to the carbonyl group of cyclopentanone are attended with various difficulties, because of the consequent internal strain and the steric hindrance respectively.

Effect of the Substituent. In the reaction of **1d**, which has the methyl group in the α-position to the carbonyl group, with formaldehyde, bis-1,3-dioxane (**7d**) was produced in a greater yield than in the case of **1c**, but no spiro-type 1,3-dioxane such as **5c** was formed. On the other hand, the α-substituted cyclopentanone (**1b**) did not give any 1,3-dioxane derivatives. Moreover, the reaction of **1e**, with a bulky substituent such as an isopropyl group, also did not give 1,3-dioxanes at all. These results suggest that a methyl or isopropyl substituent attached at the α-position of cycloalkanones plays an important role in the formation of the 1,3-dioxane ring, in combination with the effect of the skeletal structure.

Effect of the Reaction Temperature. In all cases, the reactions carried out at temperatures between 40 and 60 °C provided products in good yields. At temperatures below 30 °C, these reactions scarcely proceeded at all. Above 90 °C, the reaction mixture gave a large amount of a polymer, along with the other products which could be isolated with difficulty from the reaction mixture.

Effect of the Catalyst. The effects of catalyst in these reactions were examined using several inorganic and organic acids, and also such Lewis acids as zinc chloride. Phosphoric acid and *p*-toluene sulfonic acid were found to be most effective catalysts. The use of hydrochloric acid, sulfuric acid, and *d*-10-camphorsulfonic acid gave rise to the polymerization of reactants, resulting in the formation of the products in lower yields. Lewis acids had little catalytic effect. The effect in the reaction of **1d** with formaldehyde is shown in Fig. 1 as an example.

Effect of the Solvent. It was found that the ratio and constitutions of the products are largely dependent on the solvents employed. The results shown in Tables 4

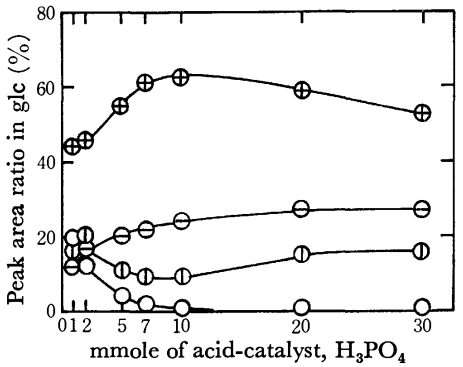

Fig. 1. Effect of supported amount of acid-catalyst, H_3PO_4 in the reaction of **1d** with formaldehyde Reaction conditions: Reactants, **1d** 10 mmol; $(CH_2O)_n$ 30 mmol; Solvent, AcOH 10 ml; Reaction temperature, 60 °C; Time, 15 hr.

25.0	75.0	C_6H_6–Ac_2O (125—25)	4.2	7	9	91

Reaction conditions: Reaction temperature, 70 °C; Catalyst, PTS.

and 5 indicate that the reaction is affected markedly by the character of the solvents. Especially, the use of aliphatic alcohol caused a remarkable reduction in the yields of the products. When the reaction was carried out in halogen-substituted alkanes under reflux, the only products were 1,3-dioxanes. The reaction proceeded hardly at all in the same solvents at a lower temperature. In acetonitrile, lower aliphatic acids, and ethers, the reaction gave 1,3-dioxanes mainly.

Reaction of Cycloalkanone Enol Esters with Formaldehyde. The acid-catalyzed reaction of cycloalkanone enol esters (acetates and propionates) with formaldehyde was investigated under the same reaction conditions as those used for cycloalkanones. The reactions of cycloalkanones and of its enol esters with formaldehyde afforded quite similar products, but in the latter reaction the yields of 1,3-dioxanes increased remarkably. Especially, the reaction of the enol esters of cycloalkanones (**1c** and **1d**) with formaldehyde led preferentially to the formation of 1,3-dioxanes, even under milder reaction conditions. Therefore, it may be considered that the 1,3-dioxane derivatives are produced through the enolization of cycloalkanone, followed by a mechanism analogous to the Prins reaction.

Experimental

All the melting points are uncorrected. The IR spectra were measured with a JASCO Model IR-G spectrometer. The NMR spectra were recorded on a JEOL LMN-MH-60 II spectrometer (60 MHz) in CCl_4, using TMS as an internal standard.

Materials. *2-Methylcyclopentanone (**1b**)* was prepared by the method of van Rysselberge[7] from adipic acid. bp 138.0—138.5 °C; d_4^{25} 0.9127; n_D^{25} 1.4330. *2-Isopropyl-5-methylcyclohexanone (**1e**)* was prepared by the oxidation of 2-isopropyl-5-methylcyclohexanol with sodium bichromate,[8] bp 66—67 °C/4 mmHg; d_4^{25} 0.8950; n_D^{25} 1.4499; α_D^{25} −26.62 °. The other cycloalkanones, solvents, and catalysts were commercial materials.

The enol acetates of cycloalkanones were prepared by the method of Goodman *et al.*[9] *1-Cyclopentenyl acetate*: bp 47—49 °C/15 mmHg; d_4^{25} 1.0115; n_D^{25} 1.4480. *2-Methyl-1-cyclopentenyl acetate*: bp 62.5—63.0 °C/9 mmHg; d_4^{25} 0.9864; n_D^{25} 1.4476. *1-Cyclohexenyl acetate*: bp 178—179 °C; d_4^{25} 1.0082; n_D^{25} 1.4547. *2-Methyl-1-cyclohexenyl acetate*: bp 67—68 °C/14 mmHg; d_4^{25} 0.9901; n_D^{25} 1.4568. *2-Isopropyl-5-methyl-1-cyclohexenyl acetate*: bp 88—90 °C/3 mmHg; d_4^{25} 0.9465; n_D^{25} 1.4550; α_D^{25} +66.35 °.

The enol propionates of cycloalkanones (**1c** and **1d**) were prepared by the method described in the literature.[10] *1-Cyclohexenyl propionate*: bp 194—195 °C; d_4^{25} 0.9783; n_D^{25} 1.4548. *2-Methyl-1-cyclohexenyl propionate*: bp 73—75 °C/3 mmHg; d_4^{25} 0.9649; n_D^{25} 1.4539.

*Reaction of Cycloalkanones (**1a—1e**) with Formaldehyde.* To a mixture of paraformaldehyde (0.30 mol), acetic anhydride (0.10 mol), glacial acetic acid (1.00 mol), 85% phosphoric acid (0.05 mol), and cycloalkanone (0.10 mol) was added in several portions, under moderate cooling, after which the mixture was stirred at 40 or 60 °C for 10 or 15 hr. The reaction mixture was poured into cold water (30 ml), neutralized with 5% sodium carbonate, and then extracted with ether. After the ether had been evaporated, the residual oil was subjected to fractional distillation under reduced pressure. From these fractions, the individual products were isolated by preparative glpc using a DEGSP column at 160 °C.

The reaction of the enol ester of cycloalkanone with formaldehyde was carried out similarly.

The structures of the products were identified on the basis of the elemental analysis, and the MS, IR, and the NMR spectra. Tables 2 and 3 show some pertinent spectral data on the products.

*2-Hydroxymethylcyclopentanone (**2a**)*: Bp 95—96 °C/10 mmHg (lit,[11] 104 °C/13 mmHg); d_4^{25} 1.0823; n_D^{25} 1.4629; MR: 29.042. Calcd for $C_6H_{10}O_2$: 29.244. MS: *m/e* 114 (M^+).

Found: C, 63.10; H, 9.00%. Calcd for $C_6H_{10}O_2$: C, 63.13; H, 8.83%.

*2-Acetoxymethylcyclopentanone (**2'a**)*: Bp 100—102 °C/10 mmHg (lit,[11] 120—121 °C/15 mmHg); d_4^{25} 1.0886; n_D^{25} 1.4502; MR: 38.570. Calcd for $C_8H_{12}O_3$: 38.609. EV: 359. Calcd 359.3.

Found: C, 61.54; H, 7.94%. Calcd for $C_8H_{12}O_3$: C, 61.52; H, 7.75%.

*2-[(Acetoxymethoxy)methyl]cyclopentanone (**4'a**)*: Bp 109—110 °C/5 mmHg; d_4^{25} 1.1136; n_D^{25} 1.4513; MR: 45.046. Calcd for $C_9H_{14}O_4$: 44.870. EV: 296. Calcd: 301.3. MS: *m/e* 186 (M^+).

Found: C, 57.91; H, 7.49%. Calcd for $C_9H_{14}O_4$: C, 58.05; H, 7.58%.

*2,4,8,10-Tetraoxatricyclo[4.4.3.0^{1,6}]tridecane (**6a**)*: Bp 102—102.5 °C/10 mmHg: d_4^{25} 1.1920; n_D^{25} 1.4741. MR: 43.907. Calcd for $C_9H_{14}O_4$: 43.734. MS: *m/e* 186 (M^+).

Found: C, 58.02; H, 7.61%. Calcd for $C_9H_{14}O_4$: C, 58.05; H, 7.58%.

*2-Hydroxymethyl-2-methylcyclopentanone (**2b**)*: n_D^{25} 1.4677 (lit,[12] n_D^{20} 1.4681).

Found: C, 65.54; H, 9.45%. Calcd for $C_7H_{12}O_2$: C, 65.59; H, 9.44%.

*2-Acetoxymethyl-2-methylcyclopentanone (**2'b**)*: Bp 194—195 °C*; d_4^{25} 1.0558; n_D^{25} 1.4485. MR: 43.196. Calcd for $C_9H_{14}O_3$: 43.277. EV: 327. Calcd: 329.7.

Found: C, 63.50; H, 8.23%. Calcd for $C_9H_{14}O_3$: C, 63.51; H, 8.29%.

(Received February 17, 1975)

A new type of cyclization reaction of α-(*N*-acyl-hydroxyamino) acid esters to imidazolidine-4-one derivatives and the synthesis of several 2,5-piperazinedione derivatives are described. The treatment of β-methoxy-α-(*N*-chloroacetyl- or *N*-phthaloylglycyl-hydroxyamino) acid esters with ammonia gave 2-carbamoyl-2-(1-methoxy)alkyl- or aralkyl-imidazolidine-4-ones, while a similar cyclization of α-(*N*-haloacetylamino) or α-(*N*-haloacyl-hydroxyamino) acid esters with ammonia or hydroxylamine gave 2,5-piperazinedione, 1-hydroxy-2,5-piperazinedione or 1,4-dihydroxy-2,5-piperazinedione derivatives. The difference in the formation mechanisms between the imidazolidine-4-one and 2,5-piperazinedione and their structural assignment were discussed.

In previous papers, we have reported that the cyclization of newly synthesized ethyl α-(*N*-chloroacetylamino)-α-alkenoate (**8**)[2] with alcoholic ammonia generally gave 3-alkylidene- or 3-arylidene-2,5-piperazinediones,[3] while a similar cyclization of ethyl β-methoxy-α-(*N*-chloroacetyl- or *N*-phthaloylglycyl-hydroxyamino)alkanoates (**4**) with ammonia afforded 2-carbamoyl-2-(1-methoxy)alkyl-imidazolidine-4-ones (**10**).[4] However, it was later found that the same cyclization of the *O*-acetyl derivative of **4d** (**5d**; ethyl 2-(*O*-acetyl-*N*-chloroacetyl-hydroxyamino)-3-methoxy-3-phenylpropanoate)[5] gave the normal cyclization products, 3-(1,1-dialkoxy)benzyl-2,5-piperazinediones (**15** and **16**).

In this paper, we wish to report in detail on the conversion of **4** into **10**, and on the difference in the mode of cyclization between **4** and **5**. Moreover, it has been confirmed that the cyclization of ethyl 2-(*N*-bromoacetyl-hydroxyamino)-3-phenylpropanoate (**3d**), which has no methoxy group in the alkyl moiety, with ammonia and hydroxylamine gives the corresponding 1-hydroxy and 1,4-dihydroxy-2,5-piperazinediones (**17** and **18**), as reported by Cook and Slater.[6]

Results and Discussion

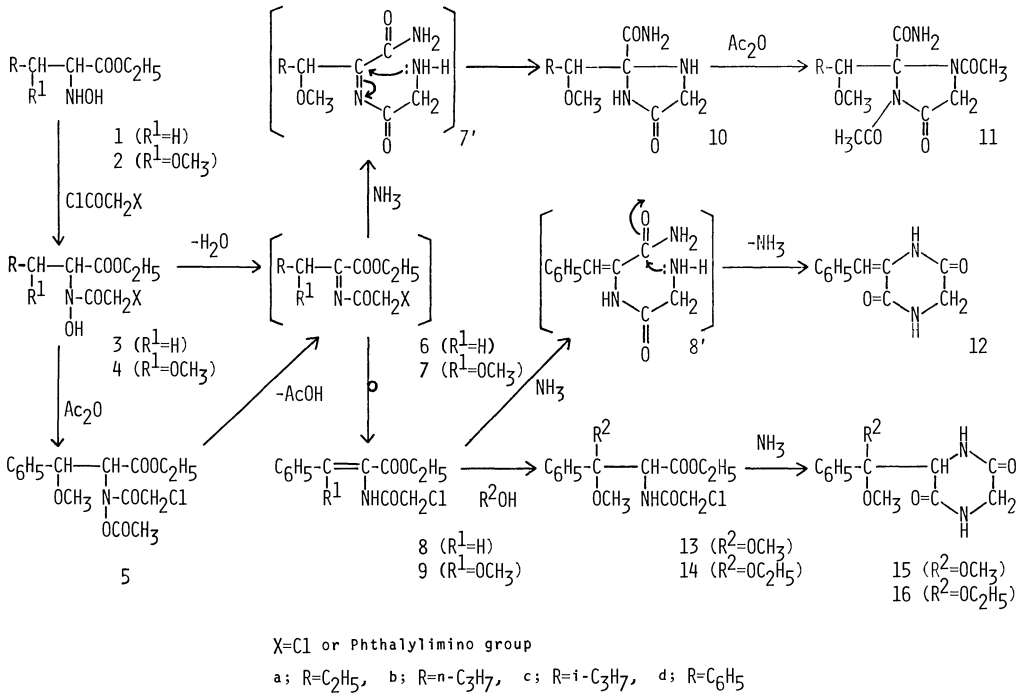
As the starting materials, ethyl α-(*N*-haloacetyl-hydroxyamino)-β-phenylpropanoate (**3d**; X=Cl and X=Br) and **4** (X=phthalylimino: **a**; R=C_2H_5, **b**; R=*n*-C_3H_7, **c**; R=*i*-C_3H_7, **d**; R=C_6H_5. X=Cl: **d**; R=C_6H_5) were synthesized by the acylation of ethyl α-hydroxyaminoalkanoate (**1**) or ethyl α-hydroxyamino-β-methoxyalkanoate (**2**)[7] with haloacetyl halide or phthaloylglycyl chloride respectively.

When an ethanol solution of **4** was saturated with ammonia at room temperature, an unexpected compound, **10** was obtained in a 23—51% yield. The structure of **10** was confirmed by elementary analysis, by the spectral data, and by the acetylation of **10**. The infrared spectrum showed the absorption bands of the amide and cyclic imino groups in the 3180—3360 region and that of the carbonyl groups in the 1665—1700 cm^{-1} region. The acetylation of **10** with acetic anhydride under reflux afforded 2-carbamoyl-1,3-diacetyl-2-(1-methoxy)alkyl-imidazolidine-4-one (**11**) in a good yield.

A similar treatment of ethyl 2-(*N*-chloroacetyl-hydroxyamino)-3-phenylpropanoate (**3d**; X=Cl) with ammonia yielded 3-benzylidene-2,5-piperazinedione (**12**) in a 30% yield, instead of the expected **17** or 2-benzyl-2-carbamoyl-imidazolidine-4-one. On the other hand, the same reaction of the **5** obtained by the acetylation of **4** with acetic anhydride[2] with methanolic or ethanolic ammonia gave 3-(1,1-dimethoxy) (**15**)- or 3-(1-ethoxy-1-methoxy)benzyl-2,5-piperazinedione (**16**) respectively, though the yields were poor.

In a previous paper,[5] we have reported that the treatment of **5** with alkali in benzene gave ethyl 2-(*N*-chloroacetylamino)-3-methoxy-3-phenyl-2-propenoate (**9**) *via* the corresponding imino derivative (**7**). Consequently, the formation of **15** and **16** indicates that ethyl 2-(*N*-chloroacetylamino)-3,3-dimethoxy (**13**)- or 3-ethoxy-3-methoxy-3-phenylpropanoate (**14**) is formed by the addition of alcohols to **9** and that it subsequently cyclizes to give **15** or **16** respectively. In fact, the treatment of **5** with methanol or ethanol in the presence of 3 M-potassium hydroxide at room temperature gave **13** or **14** respectively in a good yield. When the cyclization of the **13** or **14** isolated with alcoholic ammonia was performed at room temperature, the expected **15** or **16** was also obtained in a good yield.

From the above facts, it seems that the cyclization reaction of the β-methoxy compound (**4**) may proceed through an imino intermediate (**7**→**7′**) formed by the dehydration of **4** to give **10**, while, in the case of **3**, the corresponding imino intermediate (**6**) readily isomerizes to the tautomeric enamine (**8**→**8′**)[8] and then cyclizes to give **12**. It may be deduced that **7** is more stable, because of the influence of the methoxy group in the 3-position, than **6**, the prototropy of which readily takes place from the carbon in the 3-position to the nitrogen atom. Furthermore, on the other hand, it may be postulated that the difference in the reaction products between **4** and **5** depends upon their relative rate of dehydration from **4** and the elimination of acetic acid from **5**.[5] It may safely be concluded that the structures of the products in these cyclization are determined by the relative rate of elimination (**3,4**→



Scheme 1.

6,7 and **5**→**7**), the substitution of the halogen atom (X) with ammonia (X→NH_2), and the addition of alcohol to enamine (**8** and **9**). If the substitution of the halogen atom is faster than the elimination of water, as in the case of **4**, the newly formed amino group easily attacks the electron-deficient imino carbon to give a five-membered imidazolidine derivative. Even though the isomerization from **6** or **7** into **8** and **9** proceeds smoothly, **15** and **16** will be produced when the addition of alcohols to enamines (**8** and **9**) proceeds readily.

The infrared spectra of **13** and **14** showed the absorption band of NH at 3380 and the carbonyl group at 1700 cm^{-1}, while that of **15** and **16** showed them at 3080 and 3200 and in the 1680—1695 and 1660—1670 cm^{-1} regions, essentially as in ordinary 2,5-piperazinedione derivatives.

The physical constants, the yield, and the spectral data of the **10** and **11** and of **12**, **15**, and **16** obtained above are summarized in Tables 1 and 2 respectively.

When a solution of **3d** (X=Br) in ethanol was

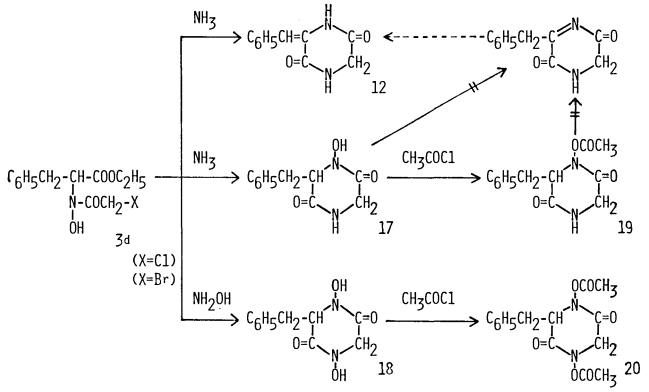
a) Ref. 3.

saturated with ammonia at room temperature, according to the Cook and Slater method,[6] Compound **17** was obtained, while the reaction with hydroxylamine gave **18** in a good yield. However, as has been mentioned above, Compound **17** and **18** could not be derived from **3d** (X=Cl).

From the above results and from facts previously reported,[6] it is evident that **3d** (X=Cl) reacts with ammonia to give **12** after dehydration into **6**, whereas **3d** (X=Br) cyclizes without the dehydration to give **17** and **18**. These results indicate the difference in the reactivity of chlorine and bromine atoms with ammonia or hydroxylamine.

Compounds **17** and **18** gave a deep violet coloration with methanolic ferric chloride, indicating the presence of the cyclic hydroxamino-acid structure. Moreover, for the purposes of the structural assignment, **17** or **18** was treated with excess acetyl chloride under reflux to give 3-benzyl-4-acetoxy (**19**)- or 3-benzyl-1,4-diacetoxy-2,5-piperazinedione (**20**) respectively, in a good yield; the characteristic coloration with the ferric chloride was not found. The attempted conversion of **17** or **19** into **12** by the dehydration or the elimination of acetic acid in methanolic ammonia *via* the pyrazine derivative was unsuccessful.



Scheme 2.

Experimental

All the melting points are uncorrected. The IR spectra were recorded with a Hitachi EPI-S2 Spectrometer. The NMR spectra were measured with a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.), using tetramethyl silane as the internal standard.

Materials. The ethyl 2-hydroxyamino-3-phenylpropanoate (**1d**)[5] and ethyl α-hydroxyamino-β-methoxyalkanoate (**2**)[7] were prepared by the methods previously reported.

Ethyl α-(N-Haloacetyl-hydroxyamino)-β-phenylpropanoate (3d). Into a solution of **1d** (0.027 mol) and pyridine (0.027 mol) in dry benzene (40 ml), we stirred, drop by drop, a solution of acetyl chloride or bromide (0.027 mol) in dry benzene (15 ml) at room temperature. After stirring for 3 hr, the resulting solution was washed successively with water, an aqueous solution of sodium hydrogencarbonate, 3 M-hydrochloric acid, and then finally with water. The benzene layer was dried over anhydrous magnesium sulfate and then evaporated. The reddish residual syrup was purified by chromatography on a silica gel column using benzene–ethyl acetate (X=Cl; 10: 1 or X=Br; 20: 1 in v/v) and the effluent solvent was evaporated under reduced pressure to give a pale yellow syrup (**3d**; X=Br) or colorless crystals (**3d**; X=Cl), which were then recrystallized from benzene–petroleum ether to give colorless needles. Ethyl 2-(*N*-chloroacetyl-hydroxyamino)-3-phenylpropanoate: yield, 41%; mp 64—65 °C. IR (KBr): 3200, 1730, 1640 cm^{-1}. NMR ($CDCl_3$): δ 7.54 (1H, bs, OH), 7.33 (5H, s, aromatic H), 5.42 (1H, t, J=8.2 Hz, $-CH_2-\underline{C}H-$), 4.23 (2H, s, $-COCH_2-$), 3.22 (2H, d, J=8.2 Hz, $-\underline{C}H_2-CH-$). Found: C, 54.79; H, 5.67; N, 4.85%. Calcd for $C_{13}H_{16}NO_4Cl$: C, 54.64; H, 5.65; N, 4.90%. Ethyl 2-(*N*-bromoacetyl-hydroxyamino)-3-phenylpropanoate: yield, 46%. IR (KBr): 3200, 1730, 1620 cm^{-1}. Found: C, 47.58; H, 5.02; N, 4.11%. Calcd for $C_{13}H_{16}NO_4Br$: C, 47.29; H, 4.89; N, 4.24%.

Ethyl α-(N-Chloroacetyl- or Phthaloylglycyl-hydroxyamino)-β-methoxyalkanoate (4). Compound **4** was prepared by the methods previously reported.[5,7] Ethyl 2-(*N*-chloroacetyl-hydroxyamino)-3-methoxy-3-phenylpropanoate (**4d**; X=Cl); colorless needles from benzene–petroleum ether; yield, 58%; mp 108—109°C. IR (KBr): 3100, 1740, 1640 cm^{-1}. NMR ($CDCl_3$): δ 7.40 (1H, s, OH), 7.27 (5H, s, aromatic H), 5.35 (1H, d, J=7.0 Hz, $-\underline{C}H-OCH_3$), 4.88 (1H, d, J=7.0 Hz, $-\underline{C}H-N-$), 4.22 (2H, s, $-COCH_2-$). Found: C, 53.10; H, 5.73; N, 4.30%. Calcd for $C_{14}H_{18}NO_5Cl$: C, 53.25; H, 5.71; N, 4.44%.

2-Carbamoyl-2-(1-methoxy)alkyl-imidazolidine-4-ones (10). When a solution of **4a**—**d** (0.02 mol) in ethanol (20 ml) was saturated with dry gaseous ammonia under cooling and then allowed to stand overnight at room temperature, colorless crystals were separated out. The crystals were collected and washed with methanol twice. Recrystallization from methanol gave **10a**—**d** as colorless needles. The melting points of all the new compounds decomposed.

In an analogous manner, **4d** (X=Cl) also reacted with ammonia to give **10d** (Table 1).

2-Carbamoyl-1,3-diacetyl-2-(1-methoxy)alkyl-imidazolidine-4-ones (11). A suspension of **10a**, **c**, **d** (0.002 mol) in acetic anhydride (4 ml) was heated at 120—130 °C until the crystals dissolved. The reaction solution was then concentrated under reduced pressure to dryness, giving a crystalline residue. The crystalline product was collected and recrystallized from boiling water to give **11a**, **c**, and **d** as colorless prisms (Table 1).

Ethyl α-(N-Chloroacetylamino)-β,β-dialkoxy-β-phenylpropanoate (13 and 14). To a solution of **5d** (0.005 mol, an unstable syrup, which was assigned by means of the IR spectrum (the $OCOCH_3$ band appeared at 1800 cm^{-1}) and which had no coloration with methanolic ferric chloride, derived by the reaction of **4d** (X=Cl) with excess acetic anhydride by a method previously reported[5]) in methanol (20 ml), with stirring, we added, drop by drop, a solution of potassium hydroxide (0.23 g) in methanol (10 ml) at room temperature. After continuous stirring for a day, the reaction solution was poured into benzene (20 ml) and washed with 3M-hydrochloric acid twice and with water. The benzene layer was dried over anhydrous magnesium sulfate and then evaporated under reduced pressure. The residual syrup thus obtained gradually crystallized. The crystalline product was collected and recrystallized from di-*n*-butyl ether to give **13** as colorless prisms; yield, 58%; mp 92—94 °C. IR (KBr): 3380, 1740, 1700, 1505 cm^{-1}. Found: C, 54.62; H, 6.06; N, 4.38%. Calcd for $C_{15}H_{20}NO_5Cl$: C, 54.64; H, 6.11; N, 4.25%.

In an analogous manner, Compound **14** was also obtained as a colorless syrup by the reaction of **5d** with ethanol, its structure was confirmed by means of the IR spectrum and by its conversion into **16**. Yield, 75%. IR (KBr): 3380, 1740, 1700, 1505 cm^{-1}.

Reaction of 13 or 14 with Ammonia. A solution of **13** (0.005 mol) in ethanol (20 ml) was saturated with dry gaseous

ammonia under cooling. When the resultant solution was allowed to stand at room temperature, a crystalline substance was precipitated. The ethanol was evaporated under reduced pressure, and the residual crystals were collected and washed successively with water and with ethanol. Subsequent recrystallization from glacial acetic acid gave **15** as colorless needles.

In an analogous manner, Compound **14** also reacted with ammonia to give **16** as colorless needles from acetic acid.

*Reaction of **4d** (X=Cl) with Ammonia.* A solution of **4d** (0.005 mol) in ethanol (20 ml) was saturated with dry gaseous ammonia under cooling. When the resultant solution was allowed to stand at room temperature for a day, colorless crystals were precipitated. The crystals were collected, washed with ethanol, and then recrystallized from glacial acetic acid to give **16** as colorless needles. The product was identical, in melting point and IR spectrum, with the sample obtained from **14**. Yield, 28%.

*Reaction of **3d** (X=Cl) with Ammonia.* When a solution of **3d** (0.005 mol) in ethanol (20 ml) was saturated with dry gaseous ammonia under cooling and then allowed to stand overnight at room temperature, colorless crystals were separated out. These crystals were collected and washed successively with water and with ethanol. Subsequent recrystallization from glacial acetic acid gave **12**. The product was identical, in melting point and IR spectrum, with the sample obtained by the method previously reported.[2]

*Reaction of **3d** (X=Br) with Ammonia.* A solution of **3d** (0.005 mol) in ethanol (30 ml) was saturated with dry gaseous ammonia under cooling. When the resultant solution was allowed to stand at room temperature overnight at room temperature, a crystalline product was precipitated. The precipitates were collected and washed with ethanol. The ethanol filtrate was condensed under reduced pressure to give a colorless powder, which was consistent with the first crystals obtained. Subsequent recrystallization from methanol gave **17** as colorless needles.

*Acetylation of **17** with Acetyl Chloride.* A mixture of **17** (0.001 mol) and acetyl chloride (3 ml) was refluxed at *ca.* 80 °C for 30 min until the crystals dissolved. The reaction solution was concentrated under reduced pressure to give a crystalline residue, which was collected and then washed with dry benzene twice. Recrystallization from benzene gave **19** as colorless needles. NMR ($CDCl_3$): δ 7.02—7.38 (6H, m, aromatic H and NH), 4.49 (1H, t, J=3.7 Hz, $-CH_2-\underline{C}\underline{H}-$), 3.23 (2H, d, J=3.7 Hz, $-C\underline{H}_2-CH-$), 2.58, 3.07 (2H, AB q, J=17.5 Hz, $-C\underline{H}_2-NH-$), 2.25 (3H, s, $-OCOCH_3$).

*Reaction of **3d** (X=Br) with Hydroxylamine.* A solution of **3d** (0.0066 mol) and hydroxylamine (made from hydroxylamine hydrochloride (0.6 g) and sodium (1.8 g)) in ethanol (150 ml) was refluxed for 3 hr. The reaction solution was then concentrated under reduced pressure. The residual syrup was dissolved in water (10 ml), and the aqueous solution was acidified with 3M-hydrochloric acid and then allowed to stand overnight in a refrigerator. The colorless crystals which were then separated out were collected and washed successively with water and ethyl ether. Recrystallization from ethyl acetate gave **18** as colorless tablets.

*Acetylation of **18** with Acetyl Chloride.* A mixture of **18** (0.001 mol) and acetyl chloride (3 ml) was refluxed at *ca.* 80 °C for 1 hr. After the removal of an insoluble substance, the reaction solution was condensed under reduced pressure to give a crystalline residue. The crystalline product was collected, washed with petroleum ether, and then recrystallized from benzene–petroleum ether to give **20** as colorless prisms. NMR ($CDCl_3$): δ 7.10—7.45 (5H, m, aromatic H), 4.67 (1H, t, J=4.0 Hz, $-CH_2-\underline{C}\underline{H}-$), 3.33 (2H, d, J=4.0 Hz, $-C\underline{H}_2-CH-$), 3.21, 3.93 (2H, AB q, J=16.0 Hz, $-CH_2-N-$), 2.21, 2.28 (6H, two s, $-OCOCH_3$).

Syntheses of Photosensitive Poly(amino acids)

Masato NANASAWA and Hiroyoshi KAMOGAWA
Faculty of Engineering, Yamanashi University, Tadeka, Kofu 400

(Received February 28, 1975)

New poly(amino acids)(L-glutamic acid, L-tyrosine and L-lysine) containing photosensitive acryloyl, methacryloyl, and cinnamoyl groups in their side chains were synthesized from the corresponding amino acid NCAs. Their photosensitivities under UV irradiation were also investigated as to kind of functional group and the skeleton portion of the poly(amino acids). As regards the effect of the former, the sensitivities were in the order: acryloyl≃methacryloyl>cinnamoyl; as regards the effect of the latter, the sensitivities were in the order: poly-glutamate>poly-lysine>poly-tyrosine.

Many basic studies of the syntheses and properties of poly (amino acids) have been reported. Furthermore, these polymers have been used as synthetic fibers with characterstics similar to those of natural polypeptide fibers, leather, and surface-coating agents, and have also been utilized as models for natural peptides in the field of biochemistry. In recent years, some functinal polymers containing the naphthalene,[1] carbazole,[2] and cinnamyl[3] groups at the γ-position of poly-glutamate, and photochromic groups[4] at the ω-position of poly-tyrosine have been synthesized with the intention of keeping the steric regularities of poly(amino acids). This paper will describe the syntheses of characteristic photo resins carrying photosensitive groups at the ω-positions of the side chains of the poly(amino acids) in the light of the properties of poly(amino acid) films, which possess a high vapor permeability and thermal stability and which are edible.

The polymers were derived from the following L-amino acid derivatives previously synthesized: γ-acryloyloxyethyl-L-glutamate (**1a**), γ-methacryloyloxyethyl-L-glutamate (**2a**), γ-cinnamoyloxyethyl-L-glutamate (**3a**), *O*-acryloyl-L-tyrosine (**4a**), *O*-methacryloyl-L-tyrosine (**5a**), *O*-cinnamoyl-L-tyrosine (**6a**), ε-*N*-acryloyl-L-lysine (**7a**), ε-*N*-methacryloyl-L-lysine (**8a**), and ε-*N*-cinnamoyl-L-lysine (**9a**). These derivatives were transformed into the corresponding amino acid *N*-carboanhydrides by treatment with phosgene, followed by polymerization with tertiary amine in dichloromethane. The routes of the syntheses were as follows:

$$\mathrm{RCOOCH_2CH_2OH} + \text{L-glutamic acid} \xrightarrow{H_2SO_4}$$

$$(\mathbf{1a}\text{—}\mathbf{3a}) \xrightarrow{COCl_2} \text{NCA } (\mathbf{1b}\text{—}\mathbf{3b}) \xrightarrow{Bu_3N}$$

$$\left[\mathrm{RCOOCH_2CH_2OOC(CH_2)_2CH}\begin{matrix}\diagup\mathrm{CO}\\ \diagdown\mathrm{NH}\end{matrix}\right]_n \quad (\mathbf{1c}\text{—}\mathbf{3c})$$

$$\mathrm{RCO}\diagdown \\ \quad \mathrm{O} + \text{O-Na-L-tyrosine-Cu} \longrightarrow (\mathbf{4a}\text{—}\mathbf{6a})\text{-Cu} \\ \mathrm{RCO}\diagup$$

$$\xrightarrow{H_2S} (\mathbf{4a}\text{—}\mathbf{6a}) \xrightarrow{COCl_2} \text{NCA } (\mathbf{4b}\text{—}\mathbf{6b}) \xrightarrow{Bu_3N}$$

$$\left[\mathrm{RCOO}\text{-}\langle\bigcirc\rangle\text{-}\mathrm{CH_2CH}\begin{matrix}\diagup\mathrm{CO}\\ \diagdown\mathrm{NH}\end{matrix}\right]_n \quad (\mathbf{4c}\text{—}\mathbf{6c})$$

$$\mathrm{RCO}\diagdown \\ \quad \mathrm{O} + \text{L-lysine-Cu} \longrightarrow (\mathbf{7a}\text{—}\mathbf{9a})\text{-Cu} \\ \mathrm{RCO}\diagup$$

$$\xrightarrow{H_2S} (\mathbf{7a}\text{—}\mathbf{9a}) \xrightarrow{COCl_2} \text{NCA } (\mathbf{7b}\text{—}\mathbf{9b}) \xrightarrow{Bu_3N}$$

$$\left[\mathrm{RCONH(CH_2)_4CH}\begin{matrix}\diagup\mathrm{CO}\\ \diagdown\mathrm{NH}\end{matrix}\right]_n \quad (\mathbf{7c}\text{—}\mathbf{9c})$$

R; CH_2=CH- (**1**, **4**, **7**), CH_2=C(CH$_3$)- (**2**, **5**, **8**), -CH=CH- (**3**, **6**, **9**)

The films made of the resulting photosensitive poly(amino acids) were crosslinked by irradiation from a UV lamp, the solubilities of the films being compared as to the kind of functional group and amino acid.

Experimental

The IR spectra were measured on a Hitachi EPI-G spectrophotometer. The elemental analyses were carried out by the use of a Perkin-Elmer 240 apparatus. The melting points were measured by a capillary method and were not corrected. The double-bond contents of the polymers were determined by the pyridine-sulfate dibromide method.[5] Materials of a reagent grade were used without further purification; all the solvent were of the highest purity commercially available and were used after dehydration over a molecular sieve.

γ-Acryloyl(methacryloyl)oxyethyl-L-glutamate (1a, 2a). Into a mixture of 8.5 g (58 mM) of L-glutamic acid, 25 ml (232 mM) of 2-hydroxyethyl acrylate, and 0.2 g of hydroquinone, concentrated sulfuric acid was dropped with stirring at 25 °C until the mixture was in solution. After then standing for five days, the reaction mixture was vigorously stirred into 200 ml of ether. The ether layer was discarded, the remaining viscous crude ester-sulfate being washed once with ether and dissolved in 150 ml of ethanol. The solution was then neutralized with *n*-tributylamine. The crude ester was isolated by filtration, washed with ethanol, and dried *in vacuo*. The product was then dissolved in 50 ml of water and then stored in a refrigerator overnight. The remaining L-glutamic acid thus crystallized was filtered; the filtrate was precipitated into a large quantity of ethanol, and then dried *in vacuo*. **1a**: Yield, 52.6%. Mp 145—147 °C. Found: C, 47.95; H, 6.39; N, 5.71%. Calcd for $C_{10}H_{15}NO_6$: C, 48.98; H, 6.12; N, 5.71%. **2a**: Yield, 55.6%. Mp 152 °C. Found: C, 49.80; H, 6.89; N, 5.67%. Calcd for $C_{11}H_{17}NO_6$: C, 50.88; H, 6.56; N, 5.40%.

γ-Cinnamoyloxyethyl-L-glutamate (3a). 2-Hydroxyethyl-cinnamate was prepared from cinnamic acid and ethyleneglycol in the presence of *p*-toluenesulfonic acid; bp 130—131 °C/0.5 mmHg (lit,[6] 186—189 °C/10 mmHg). A mixture of 3.53 g (24 mM) of L-glutamic acid, 23 g (120 mM) of 2-

hydroxyethylcinnamate, and 4 ml of conc. sulfuric acid was stirred at 90 °C for 10 min. After then standing for two days at 25 °C, the reaction mixture was warmed up to 40 °C over a 4 hr period and then vigorously stirred into 100 ml of ether. The ether layer was discarded, and the remaining viscous crude ester-sulfate was washed with ether and dissolved in 50 ml of water. The solution was then neutralized with dil. aqueous ammonia and cooled in a refrigerator overnight. The ester thus crystallized was filtered, washed with cold water, and dried *in vacuo*. Yield, 10.2%. Mp 167—168 °C. Found: C, 59.27; H, 5.85; N, 4.13%. Calcd for $C_{16}H_{19}NO_6$: C, 59.81; H, 5.91; N, 4.36%.

O-*Acryloyl(methacryloyl)*-L-*tyrosine (4a, 5a)*. Acrylic (methacrylic) anhydride was prepared from the corresponding acid with triethylamine and phosgene by a conventional method.[7] Compounds **4a** and **5a** were prepared from acid anhydrides and L-tyrosine Cu-complex as in the case of the preparation of *O*-acetyl-L-tyrosine in an alkali solution.[8] **4a**: Yield, 67.5%. Mp 211—214 °C (dec.). Found: C, 61.38; H, 5.94; N, 5.48%. Calcd for $C_{12}H_{13}NO_4$: C, 61.21; H, 5.53; N, 5.95%. **5a**: Yield, 56.7%. Mp 228—230 °C (dec.). Found: C, 62.62; H, 6.09; N, 5.65%. Calcd for $C_{13}H_{15}NO_4$: C, 62.58; H, 6.02; N, 5.62%.

O-*Cinnamoyl*-L-*tyrosine (6a)*. L-Tyrosine (4.5 g, 25 mM) was dissolved in 50 ml of 1 M sodium hydroxide, followed by the addition of 3.43 g (10% excess) of cupric sulfate. The solution was stirred at 60 °C for 30 min, then cooled to 30 °C and filtered. To the filtrate, 13.92 g (50 mM) of cinnamic anhydride in 100 ml of DMF was added dropwise. The mixture was stirred at 50 °C for 3 hr, and then cooled to room temperature, filtered, and washed with water. The *O*-cinnamoyl-L-tyrosine-Cu thus obtained was washed with hot benzene. The finely powdered **6a**-Cu was decomposed with hydrogen sulfide in 0.5 M hydrochloric acid, followed by filtration. The filtrate was neutralized with dil. aqueous ammonia and cooled overnight. The product thus crystallized was isolated by filtration, washed with cold water and then with ethanol, and dried *in vacuo*. Yield, 57.0%. Mp 238—241 °C (dec.). Found: C, 69.32; H, 5.51; N, 4.50%. Calcd for $C_{18}H_{17}NO_4$: C, 69.38; H, 5.46; N, 4.50%.

ε-N-*Acryloyl (methacryloyl)*-L-*lysine (7a, 8a)*. L-Lysine-Cu (4.63 g, 13 mM) was suspended in 80% THF containing 2.82 g (30 mM) of sodium acrylate; 3.93 g (31.2 mM) of acrylic anhydride was then added dropwise to the mixture in an ice bath. The mixture was stirred in an ice bath for 2 hr, then stirred at 25 °C overnight and refluxed for 4 hr. The product (**7a**-Cu) was isolated by filtration and washed with cold water. The **7a**-Cu and **8a**-Cu thus obtained were decomposed with hydrogen sulfide in 50 ml of water and then filtered. The filtrates were concentrated *in vacuo* below 50 °C. The residues were recrystallized from 90% ethanol. **7a**: Yield, 45.8%. Mp 213—216 °C (dec.). Found: C, 53.99; H, 7.95; N, 13.72%. Calcd for $C_9H_{16}N_2O_3$: C, 53.92; H, 7.99; N, 13.98%. **8a**: Yield, 42.6%. Mp 218—225 °C (dec.). Found: C, 55.66; H, 8.49; N, 13.98%. Calcd for $C_{10}H_{18}N_2O_3$: C, 55.98; H, 8.40; N, 13.07%.

ε-N-*Cinnamoyl*-L-*lysine (9a)*. The molar ratio of L-lysine-Cu, cinnamic anhydride, and sodium cinnamate was equal to that of the above preparation. A mixture of the three compounds in 100 ml of 80% THF was refluxed for 12 hr with stirring, filtered while still hot, and washed with water. The **9a**-Cu thus obtained was decomposed with hydrogen sulfide in 100 ml of warm 0.5 M hydrochloric acid, and then filtered. The filtrate was neutralized with dil. aqueous ammonia and cooled in a refrigerator. The resulting solid was isolated by filtration, washed with cold water, and dried *in vacuo*. Yield, 38.5%. Mp 225—228 °C (dec.). Found: C, 65.31; H, 7.29; Calcd for $C_{15}H_{20}N_2O_3$: C, 65.31; H, 7.24; N, 10.13%.

Preparation of NCA and Polymerization. A dry and finely powdered amino acid derivative (4 mM) was suspended in 25 ml of abs. THF and stirred at 50—55 °C. A 12 mM portion of phosgene (30% in carbon tetrachloride) was then added dropwise to the mixture, and the mixture was stirred at that temperature for 1 hr. The unreacted phosgene was taken off by passing through dry nitrogen gas. The reaction mixture was concentrated to a 2—3 ml volume *in vacuo*, followed by precipitation into dry petroleum-ether cooled in a dry ice methanol bath. The crude amino acid NCA thus obtained was subjected to chromatographic purification with 10 g of a molecular sieve (type 3A) column[9] in dichloromethane. The NCA solution was then concentrated to 5 ml and precipitated into petroleum ether. NCA (2 mM) was dissolved in 15 ml of dichloromethane to afford a 2—3% (wt/vol) solution, which was then polymerized with 0.4 mM of dry *n*-tributylamine at 25 °C with stirring. The solution was stirred for 3 hr, allowed to stand for three days, and then precipitated into ether to isolate a solid polymer. Polymer films were made from dichloromethane solution on cover glass plates so as to afford 30—35 mg of the polymer (by weight), left overnight, and then dried *in vacuo* for 2 hr. The polymer films were crosslinked upon irradiation for 15 min by the use of a mercury lamp (Toshiba SHL 100UV-2) placed at a distance of 15 cm; the films crosslinked being immersed in chloroform overnight; they were then dried *in vacuo* for 2 hr to determine their weight loss.

Results and Discussion

Syntheses of ω-Derivatives of L-*Amino Acid*. Ester (**1a**—**3a**) were synthesized using sulfuric acid as the esterification catalyst. The yield of **3a** was lower than those of the others (**1a** and **2a**) because of the gelation of the reaction mixture at room temperature. When the reaction is prolonged at 90 °C, the ester and double bond of 2-hydroxyethyl cinnamate might be broken. With other acidic catalysts such as *p*-toluenesulfonic acid, however, the yield was very little, so, for this direct esterification, the method with sulfuric acid was adopted. The IR spectra indicated the NH-bond at 3350 cm^{-1}, $COO^-NH_4^+$ at 2600—3200 cm^{-1}, the C=O band of the ester at 1740 cm^{-1}, NH_4^+ at 1610 cm^{-1}, COO^- at 1590 cm^{-1} and the double bond of the corresponding ester at 900—1000 cm^{-1}. Compounds **1a** and **2a** were soluble in water and 50% ethanol; **3a** was slightly soluble in hot water and hot ethanol. *O*-Acetyl-L-tyrosine was directly prepared from L-tyrosine and acetyl chloride without the protection of the α-amino group of the former.[10] In this experiment, however, drastic conditions are unsuitable since double bonds are present in the reaction mixture and should be affected by the reaction; the direct use of acid chloride would cause low yield. In the synthesis of **6a**, the reaction mixture gradually turned brown, presumably due to the decomposition of a certain amount of the Cu-complex. The IR spectra indicated the phenyl group of tyrosine at 1900 and 840—850 cm^{-1} besides the absorption noted above. Compounds **4a** and **5a** were freely soluble in water and were slightly soluble in hot ethanol. Compound **6a** was slightly soluble only in hot water, but its hydrochloride was freely soluble in water

and ethanol. ε-*N*-Derivatives of L-lysine were prepared by the so-called aminolysis of L-lysine with the methyl ester in conc. aqueous ammonia.[11] With an acrylic or methacrylic ester, however, the possibilities of the formation of α-derivatives of L-lysine and the occurrence of a Michael reaction are present, so aminolysis is not suitable. The yield of the product prepared with L-lysine-Cu and acid anhydride in an aqueous solution was about 20% lower than those of tyrosine derivatives (**4a**—**6a**). Sodium salt was used to prevent the decomposition of the Cu-complex under basic conditions,[12] although a long reaction time at a high temperature as in the case of the preparation of **9a** caused a certain amount of decomposition. The IR spectra indicated amide I at 1650 and amide II at 1510 cm^{-1}, besides the absorption of amino acid and the double bond noted above. Compounds **7a** and **8a** were soluble only in water; **9a** was slightly soluble in hot water.

Syntheses of Polymer from ω-Derivatives of Amino Acid. Amino acid *N*-carboanhydrides (NCA) were prepared by a general method with phosgene from the corresponding ω-derivatives of amino acid, and were purified by reprecipitation and by column chromatography carried out with a 3A sieve. The chlorine contents and the purity were not determined. The NCAs (**1b**—**3b**) were poorly crystallized because of the presence of two ester bonds; they melted between 55 and 70 °C and were soluble in conventional organic solvents except petroleum ether. The solubility in dichloromethane was decreased in the order of the *O*-derivatives of tyrosine NCA and the ε-*N*-derivatives of lysine NCA. The melting points of the NCAs were about 100 °C lower than those of the preceding amino acid ω-derivatives: **4b**, 98 °C; **5b**, 111 °C; **6b**, 118 °C; **7b**, 98—100 °C; **8b**, 110—115 °C; **9b**, 120—123 °C. The IR spectra in dichloromethane indicated the absorption of NCA at 1860—1870 and 1790 cm^{-1} besides the absorption of the functional groups in the ω-position and the double bonds described above. Amino-acid NCAs, even without drying, were polymerized with *n*-tributylamine in dichloromethane. When the solubility of NCA in dichloromethane was low, an α-helix solvent such as DMF was added until cleanness was reached. Table 1 shows the results of the analysis of the polymer thus prepared. The values of the double-bond content less than 100% may be accounted for by the some precipitates were formed during the pyridine-sulfate-dibromide titrations of the polymer solutions in dichloroacetic acid (DCA), thereby causing errors in analysis due to heterogeneity. The degrees of polymerization were low in the case of the polymers carrying sterically large cinnamoyl groups at the ω-position. The solubility in an α-helix solvent was large when polymers contained two ester groups as in the case of **1c**—**3c**, and decreased in the order of substituted poly-lysine and poly-tyrosine. The IR spectra indicated NH at 3280 cm^{-1}, the ester at 1720—1740 cm^{-1}, amide I and amide II at 1650 and 1530 cm^{-1} respectively (**7c**—**9c** overlapped), and the double bonds in the side chains at 900—1000 cm^{-1}. Table 2 shows the results obtained in the crosslinking experiments effected for polymer films. To compare the effect of the kind of sensitizer, the weightloss by solvent extraction was determined for **2c**; none, 74.8%; methylene blue, 66.1%; 1% chlorophyll, 67.0%; 1% methylene blue and 5% benzoyl peroxide (BPO), 14.0% and 1% chlorophyll and 5% BPO, 4.3%. The last combination was used for the crosslinking experiments shown in Table 2. As regards the effects of functional groups in polymers, the degree of crossliking was in the order: acryloyl≃methacryloyl>cinnamoyl. No differences in effect were observed between the acryloyl and the methacryloyl groups. The photodimerizable cinnamoyl groups caused a very low degree of crosslinking, presumably because of steric hindrance.

TABLE 1. THE RESULTS OF ANALYSIS OF PLOY(AMINO ACID) ω-DERIVATIVES

Polymer No.	Yield[a] %	$[\eta]$[b] dl/g	Double bond[c]	Elemental analysis Found (Calcd), % C	H	N	Solubility[d] Soluble	Insoluble

a) Based on amino acid ω-derivatives. b) **1c**—**3c** in DMF at 25 °C, **4c**—**9c** in DCA at 25 °C. c) mol % based on theory by the method of pyridine-sulfate-dibromide. d) Determined woithut drying of polymers, DCM, dichloromethane; CF, chloroform; AC, acetone; W, water.

Table 2. Crosslinking of polymer films[a,b]

Polymer	Sensitizer None	Present[c] I	Present[c] II	Appearance[d]
1c	64.5	2.4	2.7	Swelling
2c	74.8	4.3	10.9	Swelling
3c	74.7	24.8		Swelling
4c	73.5	46.8	29.3	Swelling
5c	59.2	28.5	9.7	Swelling
6c	90.1	83.1	83.5	Almost dissolved
7c	68.8	11.6	26.3	Swelling
8c	61.6	28.1	39.1	Swelling
9c	86.1	69.8	66.8	Almost dissolved

a) 15 min-irradiation at 15 cm from Hg lamp. b) Weight loss % due to the immersion in $CHCl_3$ overnight after irradiation. c) 1% chlorophyll and 5% BPO based on polymer. I, weightloss in $CHCl_3$; II, after immersion in $CHCl_3$ (I), weightloss in DCA determined in the same manner as in I. d) For the irradiated polymer films containing the sensitizers.

As regards the effect of the skeleton portion of poly amino acid, the degree of crosslinking was in the order: poly-glutamate>poly-lysine>poly-tyrosine. The substituted poly-tyrosine have a sterically large phenyl groups adjacent to the ester group, thereby causing a low extent of crosslinking; while poly-glutamates carrying photosensitive functional groups at the ends of long flexible side chains were crosslinked to a large extent.

This work was supported in part by a grant from the Alumni Association of Yamanashi University.

Restricted Rotation Involving the Tetrahedral Carbon. XVI. Isolation of Stable Rotamers about an sp^3-sp^3 Carbon Bond[1,2]

Gaku YAMAMOTO, Mikio NAKAMURA, and Michinori ŌKI

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received June 5, 1975)

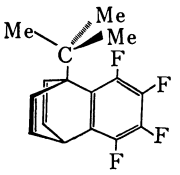
Both antiperiplanar and synclinal rotamers resulted from the restricted rotation about a C–C single bond between the bridgehead *t*-alkyl group and the skeleton of 9-(1,1-dimethyl-2-phenylethyl)-11-methoxycarbonyl-9,10-dihydro-9,10-ethenoanthracene-12-carboxylic acid are isolated. Optical resolution of the synclinal rotamer is successfully performed by way of the mono-(−)-menthyl esters and a pair of enantiomers of the acid, $[\alpha]_D^{32} \pm 24.7°$, are isolated as stable entities. Activation energy for the interconversion between the rotamers of dimethyl esters is found to be 33.2 kcal/mol with a frequency factor of $10^{13.3}$ s^{-1}.

Isolation of stereoisomers originated from the restricted rotation about a single bond, *i.e.*, atropisomerism,*[3] has been one of the challenging problems for organic chemists. In substituted biphenyl and styrene derivatives, in which both of the two carbon atoms constructing the bond in quenstion is sp^2 hybridized, plenty of examples of realization of atropisomerism have been reported[4] with the first example of optical resolution of 6,6′-dinitrodiphenic acid as far back as 1922.[5]

As for the bond between two sp^3 hybridized carbon atoms, the situation is quite different. It had long been believed that the rotation about a saturated carbon bond is completely free, and it was not until 1949 that the concept of the energy barrier to rotation about the C–C bond in ethane with the staggered forms as the most stable conformations was definitely established.[6] Since then many investigations have been performed on the internal rotation in ethane derivatives making use of infrared and microwave spectroscopies as well as thermodynamic methods. Toward the end of 1950s nuclear magnetic resonance spectroscopy, especially so-called dynamic NMR, became available to this area of investigation and a vast number of reports have appeared since then. Several review articles have been published.[7]

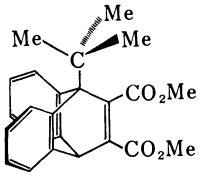
At the outset of this investigation, all the compounds yet examined by DNMR had an energy barrier to rotation of less than 20 kcal/mol and no example had been recorded in which the rotation was still slow on the NMR time scale at the highest temperature attained. In order that the atropisomerism is realized at room temperature, the energy barrier to rotation about the bond in question should be higher than 23 kcal/mol assuming the mean lifetime of 1 hr at 25 °C and the frequency factor of 10^{13} s^{-1}.**

The energy barrier to internal rotation of a *t*-butyl group attached to a flexible residue could not exceed 12 kcal/mol,[10] but when a *t*-butyl group is attached to the bridgehead position of a rigid framework, the barrier rises considerably. First of such cases was reported by Brewer *et al.* in an ethenonaphthalene derivative **1**.[11] Although the authors did not give the

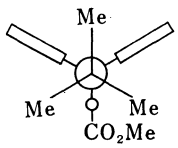


1

definite value, the energy barrier of about 20 kcal/mol is estimated, based on the chemical shift (*ca.* 0.2 ppm) and the coalescence temperature (between 120 °C and 180 °C). In one of the preceding papers of this series, a 9-*t*-butyl-9,10-dihydroethenoanthracene derivative **2** has been shown to exist in a staggered conformation shown by the Newman projection **3** and to have an extraordinarily high barrier to rotation about the axis bond (more than 25 kcal/mol), from the observation that the methyl signals of the *t*-butyl group remained 2:1 doublet even at 180 °C without any indication of line broadening.[12]

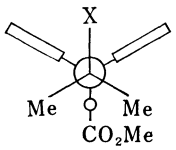


2

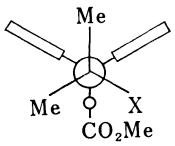


3

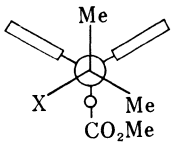
If one of the methyls of the *t*-butyl group of **2** is replaced by a suitable group X of similar bulkiness, the resulting three staggered conformations **4**, **5a**, and **5b** should exist as atropisomers, which are stable at room temperature.



4: *ap*



5a: *P-sc*



5b: *M-sc*

* We confine the discussion in this article only to carbon-carbon single bonds.

** Realization of atropisomerism at low temperatures does not necessarily require the high barrier to rotation. Certain compounds are known to be conformationally pure in the crystalline state. Crystals of *gauche* and *trans* conformations of 1,1,2,2-tetrabromoethane were independently obtained depending on the way of crystallization.[8] The equatorial conformer of chlorocyclohexane was purely isolated not only in the crystalline state but also in solution at −150 °C.[9] In these compounds the energy barrier is lower than 15 kcal/mol and naturally the conformational equilibrium is immediately attained in solution at room temperature.

Table 1. PMR data of the atropisomers **7** and **8**[a]

Protons	*ap*-Isomer (**7**)		*sc*-Isomer (**8**)	
	$CDCl_3$	C_6D_6	$CDCl_3$	C_6D_6
C–Me	1.78 (6H, s)	1.90 (6H, s)	1.83 (6H, br, s)[b]	1.83 (3H, s) 1.97 (3H, s)
O–Me	3.65 (3H, s) 3.72 (3H, s)	3.25 (3H, s) 3.39 (3H, s)	3.72 (3H, s) 3.75 (3H, s)	3.28 (3H, s) 3.43 (3H, s)
CH_2	3.75 (2H, s)	3.70 (2H, s)	3.64 (2H, q: J_{AB}=13.8 Hz, δ_{AB}=18.1 Hz)	3.90 (2H, q: J_{AB}=14.4 Hz, δ_{AB}=4.9 Hz)
10-H	5.57 (1H, s)	5.70 (1H, s)	5.56 (1H, s)	5.69 (1H, s)
aromatic[c]	6.9—7.6(11H, m)	6.7—7.5(11H, m)	6.7—7.6(11H, m)	6.6—7.6(11H, m)
peri	8.0 (2H, m)	8.0 (2H, m)	7.7 (1H, m) 8.0 (1H, m)	7.7 (1H, m) 8.0 (1H, m)

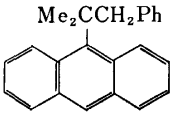
a) Obtained for *ca.* 10% (w/v) solution at 34 °C and 60 MHz, and given in ppm relative to internal tetramethylsilane. b) Appearent singlet with a half width of 2.1 Hz, suggesting the overlap of two slightly shifted singlets. c) Excluding the *peri*-protons.

We report here the successful manifestation of this prediction in a case where X is a benzyl group in the following sequence of procedures***: stereoselective synthesis of the antiperiplanar or meso form (**4**), isomerization of **4** to the equilibrium mixture of the atropisomers, isolation of the racemic synclinal form (**5a** and **5b**), and optical resolution of the *sc*-form† through mono-(−)-menthyl ester of the acid.

Enantiomeric atropisomerism, or optical activity due to the restricted rotation, involving an sp^3-sp^3 carbon bond is completely unprecedented, although realization of diastereomeric atropisomerism has been claimed by several groups of investigators without "convincing" evidence.[14]

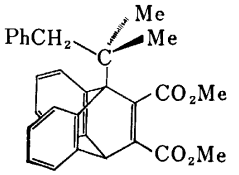
Results and Discussion

Stereoselective Synthesis of the Antiperiplanar Isomer. 9-(1,1-Dimethyl-2-phenylethyl)anthracene (**6**) was synthesized by treatment of 1,1-dimethyl-2-phenylethylmagnesium chloride with anthrone followed by dehydration with phosphorus pentoxide.

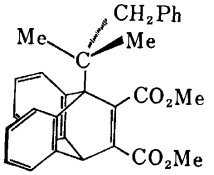


6

Heating **6** with dimethyl acetylenedicarboxylate in toluene under reflux for 5 hr gave colorless needles, mp 200—201 °C, in a spectral yield of *ca.* 85%. PMR data (Table 1) as well as those of MS and elemental analysis of the product clearly showed that it was a 1:1 Diels-Alder adduct with 9,10-dihydro-9,10-ethenoanthracene skeleton. The benzylic methylene as well as the geminal dimethyl groups appeared as a singlet and the *peri*-protons (protons at 1- and 8-positions of the skeleton), which appeared at δ *ca.* 8.0 separated from the other aromatic protons (δ 6.9—7.6), showed a two-proton multiplet indicating the magnetic equivalence of the two *peri*-protons. Although these NMR features could be understood assuming that the internal rotation of the bridgehead *t*-alkyl group were fast on the NMR time scale, such an interpretation is not consistent with the slow rotation of the *t*-butyl group in compound **2**. The most reasonable interpretation will be that the product has the antiperiplanar conformation (**7**) and the rotation about the axis bond is hindered at room temperature.



7



8

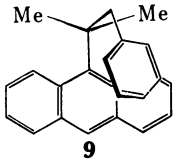
Careful inspection of the reaction mixture by PMR revealed the existence of *ca.* 15% of another product, spectral properties of which were consistent with the other atropisomer of the synclinal conformation (**8**).†† Separation of **8** from the reaction mixture seemed laborious and time consuming because of the small quantity and the similar chromatographic behavior as that of **7**. Thus the isolation and characterization of **8** was performed by another way described in the next section. No other products than these two were identified in the reaction mixture. The selective formation of the *ap*-isomer (**7**) in the Diels-Alder reaction is not the result of thermodynamic control as is shown later and therefore must be the result of kinetic origin. This means that the approach of the dienophile from the opposite direction to the benzyl group is favored. Since the *peri*-protons to the *t*-alkyl group in **6** give PMR signals at δ 8.0 in contrast to those in 9-*t*-butylanthracene (δ 8.4), the *peri*-protons in **6** are considered to be within the shielding cone of the benzyl-phenyl group. Although this does not necessarily mean that the conformation is fixed in such a form, the population of the folded conformation (**9**)

*** The benzyl group was chosen because of the synthetic convenience.

† Nomenclature of conformations used here is in accord with that proposed by Cahn, Ingold and Prelog.[13]

†† One of the enantiomers, the *P*-*sc* form, is illustrated.

must, at least, be significant. In conformation **9**, the attack of the dienophile from the benzyl side may effectively be blocked. This type of stereoselectivity has been observed in the Diels-Alder reaction between 9-*t*-alkylanthracenes and dienophiles such as dimethyl acetylenedicarboxylate[15] and benzynes.[16]



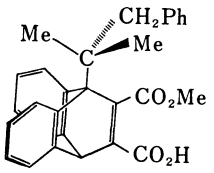
9

Equilibration of the Rotamers and Isolation of the Synclinal Isomer. The *ap*-isomer (**7**) was thermally quite stable at room temperature both in solution and in the crystalline state. Upon heating in chlorobenzene at 150 °C, however, **7** gradually isomerized to give an equilibrium mixture in which **7** and an isomerization product existed in a ratio of 1 : 3. The major component was isolated as colorless granules, mp 149—151 °C, upon chromatography on silica gel and was concluded to be the *sc*-atropisomer (**8**) from the data of PMR (Table 1) together with those of MS and elemental analysis. Two singlets for *gem*-methyls, an AB quartet for the methylene and the nonequivalent *peri*-protons suggested the chiral structure of the compound and are consistent with **8**. And these spectral features of **8** are the same as those of the minor product in the Diels-Alder reaction.

Reversible nature of the interconversion of these two atropisomers was confirmed by the equilibration experiment starting from the *sc*-isomer: upon heating in chlorobenzene at 150 °C, **8** afforded the same equilibrium mixture as that attained from the *ap*-isomer (**7**).

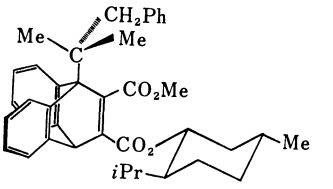
Kinetics of the equilibration and thermodynamics of the equilibrium are described in later section in some detail.

Optical Resolution of the Synclinal Isomer. Treatment of the synclinal dimethyl ester **8** with alcoholic potassium hydroxide afforded an isoluble crystalline mass which upon acidification gave a monocarboxylic acid. The acid was shown by PMR to have retained the synclinal conformation regarding the axis bond. Although no definite conclusion has yet been available as to which of the two methoxycarbonyl groups was hydrolyzed, structure **10** was tentatively assigned from the consideration of steric effects on hydrolysis.†††

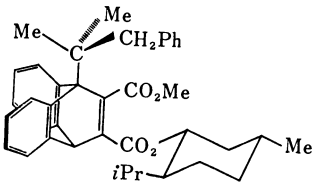


10

Attempts to obtain crystalline salts of **10** with alkaloid bases such as strychnine, quinine, cinchonine, and brucine gave no successful results. Thus resolution of **10** by way of the ester with a chiral alcohol was attempted. The racemic carboxylic acid **10** was converted to the corresponding acid chloride and treated with (−)-menthol to afford *ca.* 1 : 1 mixture of two diastereomeric (−)-menthyl esters **11** and **12** as an oil. Upon dissolution of the oil in hexane, one of the diastereomers (tentatively named as **A**) selectively crystallized out, leaving *ca.* 1 : 5 mixture of **A** and the other diastereomer (named as **B**) in the mother liquor. The glass obtained



11



12

upon evaporation of the mother liquor resisted crystallization, andvarious attempts to isolate pure **B** were unsuccessful.

Alkaline hydrolysis of the distereomerically pure **A** gave a crystalline monocarboxylic acid, $[\alpha]_D^{32}$ −24.6°, whose PMR spectrum was identical with that of the racemic acid. The obtained acid ((−)-**10**) showed poorer solubility (for example in benzene) than (±)-**10**, and the IR spectrum of (−)-**10** in Nujol mull was essentially the same as that of the racemic acid. These observations suggested that (±)-**10** formed a conglomerate rather than a racemate or a racemic solid solution. The fact that the specific rotation of (−)-**10** did not change by further recrystallization together with the observations mentioned above suggested that (−)-**10** was obtained optically pure.

Similar saponification of the glassy mixture (1 : 5) of **A** and **B** afforded another crystalline carboxylic acid, $[\alpha]_D^{32}$ +24.8°, which showed the same PMR and IR spectra as those of (±)-**10**. The poorer solubility of (+)-**10** compared to the racemic acid seemed to help to isolate the pure dextrorotatory form.

Equilibration and Its Kinetics. Interconversion of the atropisomers is most reasonably assumed to occur through the rotation about the axis bond, although possibility of alternative mechanisms such as retro-Diels-Alder reaction and bond fission-recombination mechanisms involving biradical or zwitterionic intermediates could not be definitely eliminated. Thus kinetics of equilibration of the *ap*-isomer (**7**) was studied using PMR in order to obtain the energy barrier to interconversion between the atropisomers (**7** and **8**).

TABLE 2. KINETIC DATA OF EQUILIBRATION OF THE *ap*-ISOMER (**7**)[a]

$ap \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} sc$: $K = k_1/k_{-1}$

Temperature (°C)	k_1 (s^{-1})	τ (hr)	K
111	2.5×10^{-6}	114	3.0
126	1.1×10^{-5}	24	3.0
138	3.7×10^{-5}	7.5	3.0
152	1.6×10^{-4}	1.7	3.0

a) Measured in *ca.* 10% solution in chlorobenzene.

††† The remaining methoxycarbonyl group severely resisted hydrolysis.

Detailed method is described in the experimental section. First order rate constants k_1 (*ap*→*sc*) and equilibrium constants K were obtained at four temperatures in the range of 111—152 °C and shown in Table 2 along with the mean lifetime τ.

Arrhenius and Eyring plots of k_1's gave the good linear relationship and thermodynamic parameters were obtained as shown in Table 3.‡ Extrapolation of the data gives the mean lifetime of 18 days at 100 °C, 7 months at 80 °C, and 2600 years at 25 °C.

Table 3. Thermodynamic parameters of equilibration of the *ap*-isomer (**7**)

$E_a = 33.2$ kcal/mol	$\Delta H^{\ddagger} = 32.4$ kcal/mol
$\log A = 13.3$	$\Delta S^{\ddagger} = -0.4$ eu

Kinetics of the equilibration starting from the *sc*-isomer (**8**) was studied at 138 °C, and gave the rate constant k^{-1} of 1.1×10^{-5} s^{-1} and hence k_1 ($= K \times k^{-1}$) of 3.3×10^{-5} s^{-1} which agreed well with $k_1 = 3.7 \times 10^{-5}$ s^{-1} obtained from the forward reaction.

Ratio of *sc*- to *ap*-isomers at equilibrium remained constant at 3.0 throughout the temperature range examined. This means that there is little enthalpy difference between the isomers and the entropy term is in favor of the *sc*-isomer by 2.2 eu due to entropy of mixing and some other factors.

The barrier obtained here represents the third highest barrier to rotation about an sp^3-sp^3 carbon bond yet reported, following 37.7 kcal/mol for 9,10-bis(1-cyano-1-methylethyl)triptycene (**13**)[17] and 33.6 kcal/mol for 2,3-dichloro-9-(1,1-dimethyl-2-phenylethyl)-triptycene (**14**).[16]

Experimental

Melting points were uncorrected. PMR spectra were recorded on a Hitachi R-20B spectrometer at 60 MHz and 34 °C, and tetramethylsilane was used as an internal reference. Mass spectra were measured on a Hitachi RMU-6L mass spectrometer, IR spectra on a Hitachi EPI-G2 grating spectrophotometer, and optical rotations on a JASCO DIP-SL automatic polarimeter using a 10 mm quartz cell.

9-(1,1-Dimethyl-2-phneylethyl)anthracene (6). To a chilled Grignard reagent prepared from 67.5 g (0.4 mol) of 1,1-dimethyl-2-phenylethyl chloride according to the procedure of Brown *et al.*[19] was added 19.4 g (0.1 mol) of anthrone powder in small portions during the course of 1 hr. The reaction mixture was allowed to stand overnight at room temperature and decomposed with a saturated aqueous solution of ammonium chloride. The ethereal solution was evaporated and heated *in vacuo* at 100 °C to remove low boiling substances. The residual oil, mainly composed of 9-(1,1-dimethyl-2-phenylethyl)-9-hydroxy-9,10-dihydroanthracene‡‡ and anthrone, was dissolved in 200 ml of carbon tetrachloride and heated under reflux for 5 hr in the presence of 30 g of phosphorus pentoxide. The carbon tetrachloride solution was filtered and evaporated. The residue was chromatographed through alumina column with the use of hexane containing 5% of benzene as an eluent to give **6** as pale yellow fluorescent crystals, mp 125—127 °C, in 15% yield. (Found: C, 93.04; H, 7.32%. Calcd for $C_{24}H_{22}$: C, 92.86; H, 7.14%). PMR (CCl_4): δ 1.74 (6H, s), 3.68 (2H, s), 7.01 (5H, s), and 6.9—8.2 (9H, m). The presence of mineral acids easily induced the decomposition of **6** into anthracene and (2-methyl-1-propenyl)benzene.‡‡‡

ap-9-(1,1-Dimethyl-2-phenylethyl)-11,12-bis(methoxycarbonyl)-9,10-dihydro-9,10-ethenoanthracene (7). A mixture of 2.80 g (9 mmol) of the anthracene **6** and 2 ml of dimethyl acetylenedicarboxylate in 30 ml of toluene was heated under reflux for 5 hr. Recrystallization of the product from chloroform–methanol gave 2.79 g (70%) of colorless needles, mp 200—201 °C. (Found: C, 79.78; H, 6.18%. Calcd for $C_{30}H_{28}O_4$: C, 79.62; H, 6.24%). MS (*m/e*): 452 (M^+, 1.5), 361 (61), 301 (44), 273 (68), 260 (33), 243 (50), 242 (48), 241 (33), 203 (33), 202 (39), and 91 (100).* IR (Nujol): 1735 and 1715 cm^{-1}.

(±)-sc-9-(1,1-Dimethyl-2-phenylethyl)-11,12-bis(methoxycarbonyl)-9,10-dihydro-9,10-ethenoanthracene (8). The *ap*-isomer **7** was heated at 150 °C for 10 hr in *o*-dichlorobenzene. After evaporation of the solvent, the equilibrated mixture was chromatographed on silica gel (Wakogel C-200) and eluted with benzene. Although the separation was poor, the *sc*-isomer was eluted slightly faster than the *ap*-isomer and repeated chromatographic operation of the fractions containing both of the two isomer enabled us to isolate **8**. Recrystallization of **8** from methanol gave colorless granules, mp 149—151 °C. (Found: C, 79.54; H, 6.42%. Calcd for $C_{30}H_{28}O_4$: C, 79.62; H, 6.24%). MS (*m/e*): 452 (M^+) (Essentially the same fragmentation pattern as that of the *ap*-isomer was obtained). IR (Nujol): 1742 and 1725 cm^{-1}. Recrystallization of **8** from solvents containing benzene or chloroform resulted in the inclusion of the solvent into the crystals.

(±)-sc-9-(1,1-Dimethyl-2-phenylethyl)-11-methoxycarbonyl-9,10-dihydro-9,10-ethenoanthracene-12-carboxylic acid (10). A solution of 420 mg (0.93 mmol) of the dimethyl ester **8** in 20 ml of ethanol was mixed with a solution of 200 mg of potassium hydroxide in 10 ml of ethanol and allowed to stand overnight at room temperature. The resulted crystalline mass was collected by filtration, acidified with dilute hydrochloric acid, and extracted with ether. The ethereal solution, upon evaporation of the solvent followed by recrystallization from chloroform–carbon tetrachloride, afforded 298 mg (73%) of white crystals, mp 188—190 °C (dec.). Found: C, 79.13; H, 5.69%. Calcd for $C_{29}H_{26}O_4$: C, 79.43; H, 5.98%. PMR ($CDCl_3$): δ 1.84 (6H, br s), 3.63 (2H, q, $J_{AB} = 14.8$,

‡ The parameters obtained here correspond to the pathway through the anticlinal transition state. Information on the synperiplanar transition state would be obtained by the study of racemization behavior of the optically active *sc*-isomer, which is left for future study.

‡‡ This alcohol was not isolated but its formation was recognized by the PMR spectrum (CCl_4) of the reaction mixture: δ 0.62 (6H, s), 2.60 (2H, s), and 3.82 (2H, q: $J_{AB} = 19$, $\delta_{AB} = 24$ Hz).

‡‡‡ The acid-catalyzed decomposition of 9-*t*-butylanthracene to anthracene and isobutylene was reported.[19]

* Fragmentation peaks with the intensity of more than 30% are cited.

δ_{AB}=16.7 Hz), 3.72 (3H, s), 5.55 (1H, s), 6.8—8.1 (13H, m), and 11.7 (1H, br s); (C_6H_6): δ 1.82 (3H, s), 1.97 (3H, s), 3.39 (3H, s), 3.90 (2H, br s), and 5.68 (1H, s). IR (Nujol): 1735 and 1685 cm^{-1}.

ap-9-(1, 1-Dimethyl-2-phenylethyl)-11-methoxycarbonyl-9, 10-dihydro-9, 10-ethenoanthracene-12-carboxylic acid, mp 223—225 °C (dec.), was similarly prepared from the *ap* diester (**7**). Found: C, 79.77; H, 6.32%. Calcd for $C_{29}H_{26}O_4$: C, 79.43; H, 5.98%. PMR ($CDCl_3$): δ 1.76 (6H, s), 3.63 (3H, s), 3.72 (2H, s), 5.52 (1H, s), 6.9—8.1 (13H, m), *ca.* 8.1 (1H, br s). IR (Nujol): 1735 and 1675 cm^{-1}.

(−)-Menthyl esters of the carboxylic acid ***10***. A solution of 710 mg (1.6 mmol) of the carboxylic acid **10** and 0.5 ml of thionyl chloride in 50 ml of benzene was heated under reflux for 1 hr in the presence of a catalytic amount of pyridine. Complete convertion of **10** to the corresponding acid chloride was checked by PMR of the reaction mixture: δ 1.77 and 1.88 (*gem*-Me_2), 3.30 (OMe), 3.78 (q, J_{AB}=14, δ_{AB}=8.5 Hz, CH_2Ph), and 5.69 (bridgehead). The reaction mixture was evaporated and the residual oil, without purification, was heated with 500 mg of (−)-menthol in 50 ml of pyridine at 100 °C for 2 hr. Evaporation of the solvent followed by chromatography on silica gel with benzene afforded a glass, which was shown to be *ca.* 1: 1 mixture of two diastereomeric esters by PMR. One of the diastereomers (Diastereomer **A**) crystallized out upon dissolution of the glass in hexane. Recrystallization from tetrahydrofuran–methanol gave 133 mg (15%) of colorless granules, mp 199—200 °C. $[\alpha]_D^{25}$ −77.0° (c=5.7, $CHCl_3$). PMR (C_6H_6): δ 1.84 and 2.02 (*gem*-Me_2), 3.51 (OMe), 3.87 (q, J_{AB}=14.1, δ_{AB}=9.1 Hz, CH_2Ph), and 5.87 (bridgehead). MS (*m/e*): 576 (M^+). IR (Nujol): 1735 and 1715 cm^{-1}.

Evaporation of the mother liquor gave a glass which was found by PMR to be *ca.* 1: 5 mixture of **A** and the other diastereomer (**B**). The latter showed the following PMR signals (C_6H_6): δ 1.87 and 1.96 (*gem*-Me_2), 3.51 (OMe), 3.98 (br s, CH_2Ph), and 5.87 (bridgehead).

(−)-sc-9-(1, 1-Dimethyl-2-phenylethyl)-11-methoxycarbonyl-9, 10-dihydro-9, 10-ethenoanthracene-12-carboxylic acid. A solution of 330 mg (0.57 mmol) of Diastereomer **A** in 20 ml of ethanol containing 200 mg of potassium hydroxide was heated at 60 °C for 3 hr and allowed to stand overnight at room temperature. The solution was evaporated *in vacuo* and the residue was acidified with dilute hydrochloric acid and extracted with chloroform. The chloroform solution was dried over magnesium sulfate and evaporated. The resulting solid mass was washed twice with small amounts of benzene to remove (−)-menthol. Recrystallization from chloroform–benzene gave 210 mg (84%) of colorless crystals, mp 188—190 °C (dec.). $[\alpha]_D^{32}$ −24.6 ° (c=2.4, $CHCl_3$). Found: C, 79.25; H, 6.08%. Calcd for $C_{29}H_{26}O_4$: C, 79.43; H, 5.98%.

(+)sc-(1, 1-Dimethyl-2-phenylethyl)-11-methoxycarbonyl-9, 10-dihydro-9, 10-ethenoanthracene-12-carboxylic acid. Similar treatment of 182 mg of the glassy mixture (1: 5) of **A** and **B** with potassium hydroxide followed by recrystallization from chloroform–benzene afforded 58 mg of colorless crystals, $[\alpha]_D^{32}$ +24.8° (c=1.2, $CHCl_3$).

Kinetics. A solution of the *ap*-isomer (**7**) in chlorobenzene (*ca.* 10% (w/v)) was sealed in a PMR sample tube and dipped in a boiling solvent bath. At appropriate intervals the sample tube was taken out from the bath and rapidly cooled to room temperature. The PMR spectrum was measured at 34 °C. Careful integration of methyl signals of the methoxycarbonyl groups of the *ap*- and *sc*-isomers afforded the relative population of both isomers.

The rate law for a first order reversible reaction is given[20] by

$$\log\left[1-\left(1+\frac{1}{K}\right)\frac{x}{a}\right] = -\frac{k_1}{2.303}\left(1+\frac{1}{K}\right)t$$

where a is the initial concentration of the *ap*-isomer, x the quantity of the *sc*-isomer formed at time t, and K the equilibrium constant [*sc*]/[*ap*]. The left side of the equation was calculated from the PMR integration data and the plot against t gave a good straight line, the slope of which afforded the rate constant k_1. This procedure was performed at four temperatures using the following solvents as a bath: toluene (111 °C), diethyl carbonate (126 °C), *p*-xylene (138 °C), and cumene (152 °C).

Thermodynamic parameters were obtained from the least square analysis of the following equations:

$$\log k_1 = \log A - \frac{E_a}{4.576}\cdot\frac{1}{T} \quad \text{(Arrhenius plot)}$$

$$\log\frac{k_1}{T} = \left(\frac{\Delta S^{\ddagger}}{4.576}+10.319\right) - \frac{\Delta H^{\ddagger}}{4.576}\cdot\frac{1}{T} \quad \text{(Eyring plot)}$$

Degradation of Polyacrylamide Molecules in Aqueous Solutions by High-speed Stirring

Waichi NAGASHIRO, Teruo TSUNODA, Makoto TANAKA, and Mitsuru OIKAWA
Central Research Laboratory, Hitachi Ltd., Kokubunji, Tokyo 185

(Received January 21, 1975)

Synopsis. The viscosity of polyacrylamide aqueous solutions decreases as a result of high-speed stirring, due possibly to the degradation of the molecules.

It has been observed that the viscosity of the polyacrylamide (PAM) solution decreased with increased high-speed stirring time. This decrease is assumed to be due to a change in the dissolved state and/or the degradation of the PAM molecules. It was experimentally found that the molecular weight decreased, implying that the PAM molecules were degradated.

Experimental

PAM solutions were placed in a type M (Tokushu Kika) Homo-Mixer and subjected to high-speed stirring for various periods of time. Care was taken that the blades were immersed to the same level in the liquid in each case in order to ensure identical stirring conditions. The viscosities of these solutions were then measured by a type B viscometer (Tokyo Keiki).

The intrinsic viscosities $[\eta]$ (reduced viscosity at zero concentration) were obtained by extrapolating the measured values for a 0.1—1.0 g/dl concentration. The molecular weights M were calculated from the intrinsic viscosities by using the Staudinger equation, $[\eta]=KM^{\alpha}$. The constants K and α in the equation are given, for PAM in water at 25 °C, as 0.631×10^{-4} and 0.8, respectively.[1)]

Results and Discussion

The high-speed stirring effect on the viscosity of PAM solutions is shown in Fig. 1. The figure indicates that the viscosities of the solutions decrease initially, and then saturate as the stirring time is increased. The saturated values depend on the stirring speed.

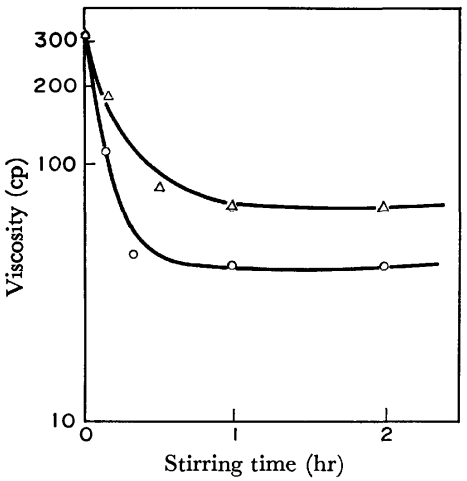

Fig. 1. Viscosity decrease of PAM solutions by high-speed stirring at 25 °C.
(—○—: 7000 rpm, —△—: 4000 rpm)

Two assumptions were made to explain this phenomenon. One is that the dissolved state of PAM solutions changes due to stirring. From various investigations, however, this assumption was found to be invalid.

The other assumption is that the PAM molecules degradate by high-speed stirring. Figure 2 shows the graph of reduced viscosity η_{sp}/C against the concentration C for PAM solutions at various stirring speeds. Here, these solutions are three days after stirring was completed. The figure shows the linear relationship between η_{sp}/C and C as well as the decrease in $[\eta]$ as the stirring speed is increased. The molecular weight cal-

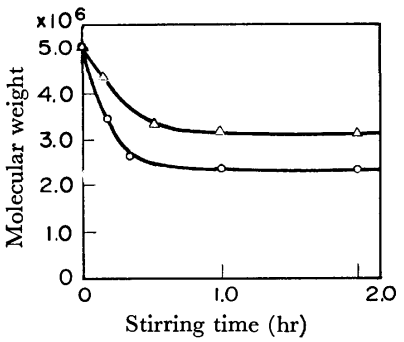

Fig. 3. Molecular weight decrease of PAM by high-speed stirring.
(—○—: 7000 rpm, —△—: 4000 rpm)

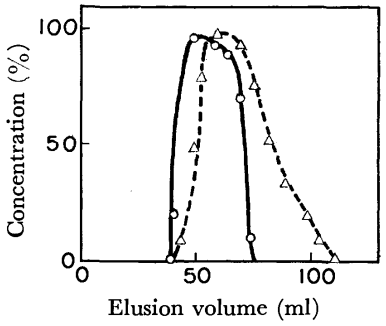

Fig. 4. GPC elusion curve of PAM solution.
(—○—: before stirring, ---△---after stirring)

culated from $[\eta]$, with respect to the stirring time, is given in Fig, 3. The figure shows that the molecular weight reduced to about a half of the initial value after stirring at 7000 rpm at 25 °C. The distribution of molecular sizes measured by gel permeation chromatography (GPC) is shown in Fig. 4. It is evident from the figure that the molecular size of PAM was reduced after stirring. It can be concluded that the decrease in the viscosity of the PAM solution by high-speed stirring is due to degradation of the PAM molecules.

The degradation mechanism of vinyl polymer has been widely described. Our degradation results for PAM molecules can be explained by employing the formula given by Jellinek,[2]

$$dB_i/dt = k(P_i - 1)n_i \quad \text{for } P_i > P_1$$
$$dB_i/dt = 0 \quad \text{for } P_i \leqq P_1$$

where B_i is the number of shear degradation, P_i is the degree of polymerization, P_i is the limiting degree of polymerization, n_i is the number of molecules, k is the rate constant, and t is the time. The solution of Jellinek's equation, together with the experimental results, are shown in Fig. 5. The agreement is good, indicating the applicability of Jellinek's theory.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (9), 2599—2600 (1975)

Measurement of Singlet-Triplet Absorption Spectrum of Pyridazine by a Sensitized-Phosphorescence Excitation Method

Kohzaburo YAMAMOTO, Takeshi TAKEMURA, and Hiroaki BABA

Division of Chemistry, Research Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received March 5, 1975)

Synopsis. The $S_0 \rightarrow T$ absorption spectrum of pyridazine was measured by means of sensitized-phosphorescence excitation in EPA rigid-glass solution at 77 K. Its intensity was found to be much lower than that of the corresponding spectrum of pyrazine.

The phosphorescence of pyridazine has not been observed as yet, although its intersystem-crossing quantum yield is of the same order of magnitude as the yields of strongly phosphorescent pyrazine and pyrimidine.[1] It may be presumed that a slow rate of radiative decay of the triplet state, compard with its radiationless decay, is responsible for the non-phosphorescent property of pyridazine.

Hochstrasser and Marzzacco[2] measured $S_0 \rightarrow T$ absorption of pyridazine crystal at 4.2 K, where S_0 and T denote the ground singlet and excited triplet states respectively, and they evaluated the rate constant for the radiative triplet decay (k_p). According to their results, the k_p value for pyridazine is of the same order of magnitude as those for pyrazine and pyrimidine, and the 0–0 band of the $S_0 \rightarrow T$ absorption of pyridazine is located at 412.5 nm. Recently, however, Innes *et al.*[3] reported that pyridazine vapor gives $S_0 \rightarrow T$ absorption with the 0–0 band at 445 nm.

In the present study, the $S_0 \rightarrow T$ absorption of pyridazine in rigid-glass solution was measured by a method based on sensitized-phosphorescence excitation (SPE). In the SPE method, a triplet energy donor and an acceptor are used. Only the donor molecule is excited, and an excitation spectrum is obtained by monitoring the sensitized phosphorescence emitted from the acceptor triplet produced by triplet-triplet energy transfer. The SPE spectrum thus obtained corresponds to the donor absorption spectrum. Note that the SPE spectrum can be measured even when the donor gives no phosphorescence, and that the SPE method has a high sensitivity compared with the absorption method. In this study pyridazine was used as energy donor and naphthalene-d_8 as acceptor.

Experimental

Pyridazine (Nakarai Chemical Co.) was carefully purified by repeated vacuum distillation. Pyrazine (Nakarai Chemical Co.) and naphthalene-d_8 (E. Merck Co.) were purified by vacuum sublimation. EPA (5: 5: 2 parts by volume of ethyl ether, isopentane, and ethyl alcohol) was used as solvent. The acceptor concentration was fixed, while the donor concentration was widely changed. All the sample solutions were degassed by repeated freeze-thaw cycles.

The SPE spectra were measured at 77 K with a high-resolution, high-sensitivity emission spectrophotometer equipped with a photon-counting detector and a phosphoroscope. The SPE spectra were corrected for the spectral intensity of the light source and monochromator system.[4]

The quantum yield of the donor triplet is either equal to or less than unity according as the donor molecule is photoexcited in the wavelength region of $S_0 \rightarrow T$ or $S_0 \rightarrow S$ absorption; in the latter case the yield is identical with the intersystem-crossing yield. Allowance was made for this difference in quantum yield[5] to obtain the SPE spectrum which, throughout the two wavelength regions, has an intensity proportional to the absorption intensity represented by the molar extinction coefficient (ε). The intensity of the excitation spectrum at a certain wavelength in the $S_0 \rightarrow S$ absorption region was then equated to the ε value at that wavelength to convert the excitation spectrum to the absorption spectrum.

Results and Discussion

In order to confirm the validity of the present method, we first observed the SPE spectrum for a system of pyrazine (donor) and naphthalene-d_8 (acceptor). The resulting absorption spectrum of pyrazine is compared in Fig. 1 with the absorption spectrum derived from the usual phosphorescence excitation (PE) spectrum which was measured with pyrazine alone. The two spectra are in good agreement with each other.

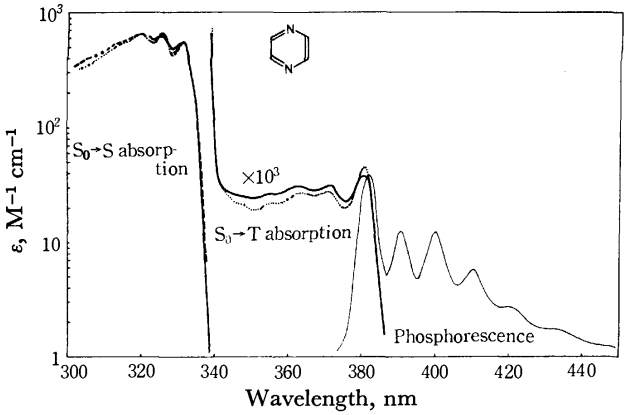

Fig. 1. Absorption and phosphorescence spectra of pyrazine in EPA at 77 K. Solid and dotted lines depict the absorption spectra derived from SPE and PE spectra, respectively. Broken line shows the usual $S_0 \rightarrow S$ absorption spectrum. Scale of intensity in the phosphorescence spectrum is linear.

An example of the SPE spectrum obtained for the system of pyridazine and naphthalene-d_8 is given in Fig. 2 with solid lines (a). The PE spectrum which was measured under the same conditions (except for the absence of pyridazine) as in the measurement of the SPE spectrum (a) is also shown in Fig. 2 with dotted lines (b). The PE spectrum (b) ranging from 385 to 470 nm corresponds to the $S_0 \rightarrow T$ absorption of naphthalene-d_8. Comparison of the spectra (a) and (b) shows

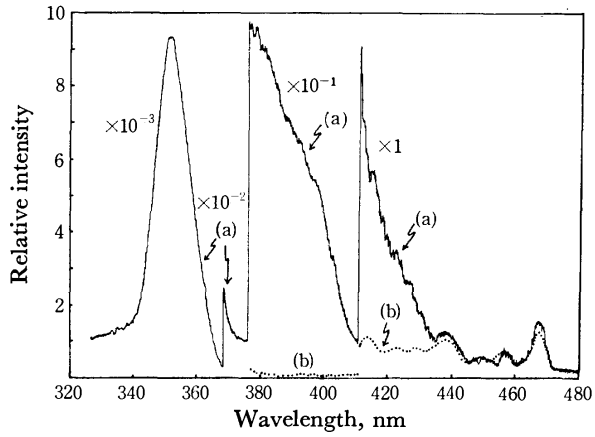

Fig. 2. Uncorrected chart of SPE and PE spectra.
(a) SPE spectrum of 0.1 M pyridazine and 0.06 M naphthalene-d_8 pair in EPA at 77 K; (b) PE spectrum of naphthalene-d_8 under the same conditions.

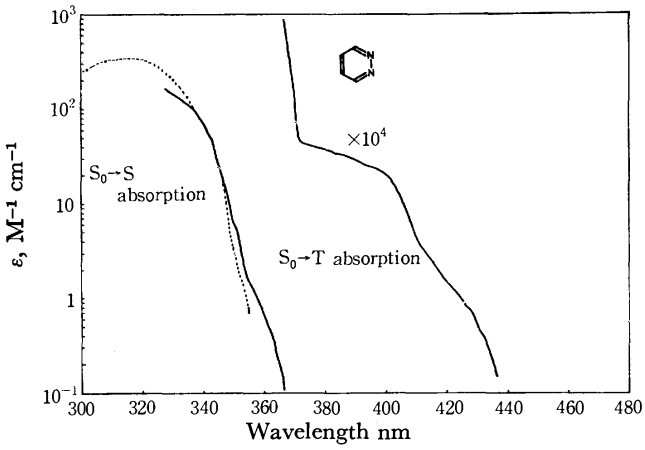

Fig. 3. Absorption spectrum of pyridazine in EPA at 77 K. Solid line, spectrum obtained by the SPE method; broken line, the usual $S_0 \rightarrow S$ absorption spectrum.

that the SPE spectrum between 435 and 470 nm originates actually from the direct $S_0 \rightarrow T$ excitation of naphthalene-d_8. Subtraction of the spectrum (b) from the spectrum (a) yields the true SPE spectrum, which in turn leads to the absorption spectrum of pyridazine through the procedure described before; the results are shown in Fig. 3.

In Fig. 3 the absorption occurring in a region of 370—440 nm can be assigned to an $S_0 \rightarrow T$ transition. Alternatively, one may imagine that it consists of two transitions which are to be called $S_0 \rightarrow T_1$ and $\rightarrow T_2$ in order of increasing energy. Theoretically, $^1A_1 \rightarrow {}^3B_1(n, \pi^*)$ and $^1A_1 \rightarrow {}^3A_2(n, \pi^*)$ transitions are possible for the C_{2v} pyridazine molecule.[2,3] The $S_0 \rightarrow T_1$ transition may then be related to the 445 nm absorption reported by Innes *et al.*,[3] and the $S_0 \rightarrow T_2$ to the 412.5 nm absorption by Hochstrasser and Marzzacco.[2] The values of ε_{max} for the $S_0 \rightarrow T_1$ and $\rightarrow T_2$ transitions are about 5×10^{-5} and 2×10^{-3} M^{-1} cm^{-1}, respectively. In either case the ε_{max} value is much smaller than the corresponding value for pyrazine (3×10^{-2} M^{-1} cm^{-1} from Fig. 1).[6] If, in this way, the $S_0 \rightarrow T$ absorption of pyridazine involves two transitions, the phosphorescence must originate from the lower triplet state, T_1. Then, it follows from the intensity of the $S_0 \rightarrow T_1$ absorption that k_p of pyridazine is as small as 0.16 s^{-1}. It may be noted that k_p of pyrazine is estimated to be 110 s^{-1} from its $S_0 \rightarrow T$ absorption intensity.

The lack of phosphorescence in pyridazine may thus be attributed, at least in part, to the fact that its lowest excited triplet has a relatively small k_p value.

Kinetics of Reduction of Mercury(II) Chloride to Mercury(I) Chloride Induced by the Decomposition of Trioxalatocobaltate(III) in Acid Aqueous Solutions

Toshiro SATO and Masaru KIMURA*

Department of Applied Chemistry, Yamagata University, Yonezawa 992

**Department of Chemistry, Nara Women's University, Nara 630*

(Received May 15, 1975)

Synopsis. The decomposition reaction of trioxalatocobaltate(III) complex in the presence of mercury(II) chloride in acid medium induces the reduction of the latter to mercury(I) chloride (calomel). The results are accounted for by a sequence of a chain reaction which is initiated by the intramolecular redox decomposition of trioxalatocobaltate(III). The formation rate of mercury(I) chloride is expressed as half order with respect to the concentrations of oxalic acid, mercury(II) chloride, and trioxalatocobaltate(III). Mechanisms and kinetics are presented to account for these facts.

The light-initiated reduction of mercury (II) chloride by oxalate in a neutral medium has long been known as Eder's reaction after its discovery.[1] The photochemical reactions of this reaction have been studied by many investigators. Recently, Kimura *et al.*[2] have reported that the slow addition of a trace of a strong oxidizing agent to dilute oxalic acid solutions in dilute sulfuric acid causes the formation of free radicals which can bring about the reduction of mercury (II) chloride to mercury (I) chloride, and also reported briefly that a similar reaction occurs upon the thermal decomposition of trioxalatocobaltate (III) complex in an acid medium. In the present paper, the kinetics of the reduction of mercury (II) chloride to mercury (I) chloride according to the decomposition reaction of trioxalatocobaltate (III) is studied in the acid aqueous solutions.

Experimental

The potassium trioxalatocobaltate(III) was prepared following the directions of Sörensen.[3] All chemicals were of the guaranteed reagent grade. Pure nitrogen gas was bubbled through the reaction mixture. All experiments were carried out in the dark at a given temperature. The amount of mercury(I) chloride formed was determined by weighing after filtering through a glass-sintered crucible, washing, and drying at 80 °C. In order to compare conveniently the amount of mercury(I) chloride with the concentrations of the other species such as oxalic acid, mercury(II) chloride, and so forth, the amount of mercury(I) chloride formed is expressed as molarity which refers to the volume of the reaction mixture. After removal of mercury(I) chloride by filtration, concentrations of trioxalatocobaltate(III) in the filtrates were determined by means of the absorption spectra at 600 nm.

Results and Discussion

The relative efficiency of trioxalatocobaltate (III) in initiating the reaction increases with increasing concentrations of oxalic acid and mercury (II) chloride. Table 1 illustrates this effect over the range 0—0.4 M in oxalic acid, in 0.1 and 0.2 M in mercury (II) chloride at varying the reaction time. The concentration of trioxalatocobaltate (III) decreases in accordance with the first order expression, $-d[Co(C_2O_4)_3^{3-}]/dt=k_0[Co(C_2O_4)_3^{3-}]$ which is the same as that reported in the previous paper.[4] Concentrations of trioxalatocobaltate (III) decomposed are also listed in Table 1. The temperature effect on the formation of mercury (I) chloride was investigated in an initial composition of 0.1 M in oxalic acid, 0.1 M in mercury (II) chloride, and 10^{-3} M in potassium trioxalatocobaltate (III). The data obtained at various temperatures are listed in Table 2. Similarly as in Table 1, the concentrations of trioxalatocobaltate (III) decomposed were determined. But the data are omitted in Table 2. In all the instances, the amount of mercury (I) chloride formed was many times greater than that of trioxalatocobaltate (III) decomposed.

Table 2. Temperature dependence on the formation of mercury(I) chloride[a)]

Temp., °C	Reaction time, hr			
	1	2	3	4
	$[Hg_2Cl_2]_{formed} \times 10^3$, M			
25	0.74	2.3	3.4	
30	2.1	4.7	4.9	7.9
35	4.6	7.5	10.3	12.0
40	8.5	12.1	16.0	16.5

a) Initial solutions 1.0×10^{-3}M in potassium trioxalatocobaltate(III), 0.1 M in oxalic acid, 0.1 M in mercury (II) chloride, and 0.1 M in sulfuric acid; The other conditions are the same as in Table 1.

Therefore, a chain reaction must occur. The initiation reaction is probably the intra-molecular redox decomposition of trioxalatocobaltate (III).[4)]

$$Co(C_2O_4)_3^{3-} \longrightarrow Co(II) + 2C_2O_4^{2-} + CO_2 + CO_2^{\cdot-} \quad (1)$$

$$Co(C_2O_4)_3^{3-} + H^+ \longrightarrow Co(II) + 2C_2O_4^{2-} + H^+ + CO_2 + CO_2^{\cdot-} \quad (2)$$

The radical which is formed in the above reactions may be either $CO_2^{\cdot-}$ or $C_2O_4^{\cdot-}$. An approximate theoretical calculation[5)] indicates that the latter radical is more stable, but the two forms do not appear to be distinguishable on the basis of kinetic or spectroscopic evidence.[6)] Conveniently we write $CO_2^{\cdot-}$ in this paper. In this paper, in which all the experiments were carried out in acid media, considerations must be taken of the protonated and dissociated forms of the anion species. According to the data by Fojtik *et al.*,[7)] the acid dissociation constant for the reaction $HCO_2^{\cdot} \rightleftarrows CO_2^{\cdot-} + H^+$ is $pK_a = 3.9$. Therefore, in 0.1 M sulfuric acid solutions such as in Tables 1 and 2, a predominant species of radicals is assumed to be $HCO_2^{\cdot}$. By a similar calculation for the protonated and dissociated forms of oxalate, $H_2C_2O_4$ is assumed as a predominant species. Consequently, in subsequent equations $HCO_2^{\cdot}$ and $H_2C_2O_4$ are written rather than $CO_2^{\cdot}$ and $C_2O_4^{2-}$.

Following after the initiation reactions (1) and (2), reactions, (3), (4), and (5) constitute a chain reaction.

$$HgCl_2 + HCO_2^{\cdot} \longrightarrow Hg(I) + H^+ + 2Cl^- + CO_2 \quad (3)$$

$$H_2C_2O_4 + Hg(I) \longrightarrow Hg + HCO_2^{\cdot} + CO_2 + H^+ \quad (4)$$

$$HgCl_2 + Hg \longrightarrow Hg_2Cl_2 \quad (5)$$

Termination presumably occurs mainly *via*

$$Hg(I) + HCO_2^{\cdot} \longrightarrow Hg + CO_2 + H^+ \quad (6)$$

Assumption of the steady state concentrations for HCO_2, Hg (I), and Hg, together with the assumption that the chain is long, leads to the following equation.

$$[Hg_2Cl_2]_{formed} = \sqrt{\frac{k_0 k_3 k_4 [HgCl_2][H_2C_2O_4][Co(C_2O_4)_3^{3-}]}{2k_6}}\ \tau \quad (7)$$

where k_0 indicates an overall decomposition-rate constant of trioxalatocobaltate (III), k_n, the rate constant of reaction (n), and τ, the reaction time. When the initial concentrations of oxalic acid and mercury (II) chloride are much larger than the concentrations of mercury (I) formed, the former concentrations remain approximately constant during the reaction time. Under these circumstances, Eq. (7) predicts a linear relation between $[Hg_2Cl_2]_{formed}/[Co(C_2O_4)_3^{3-}]^{1/2}$ and τ. This relation was found experimentally at all the experiments. Several examples obtained at the various temperatures are given in Fig. 1. The slopes of the straight lines in Fig. 1 correspond to the apparent-overall rate constants, *i.e.*, $k_{app} = \{k_0 k_3 k_4/(2k_6)\}^{1/2}$. From Arrhenius plots with respect to k_{app} and k_0, activation energies for the overall and initiation reactions were determined to be $E_{app} = 28$ kcal/mol, and $E_0 = 39$ kcal/mol, respectively. From the relation between the overall rate constant and the rate constants for the separate steps in the reaction scheme, the activation energy of the overall reaction constitutes a function with the activation energies for the separate steps in reaction, *i.e.*, $2E_{app} = E_0 + E_3 + E_4 - E_6$. If the activation energy for the termination reaction (6) is assumed to be negligibly small, the activation energy for the chain propagation steps is calculated to be $E_3 + E_4 = 17$ kcal/mol.

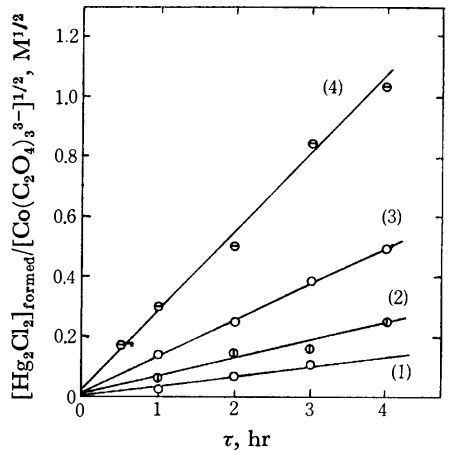

Fig. 1. Plot of $[Hg_2Cl_2]_{formed}/[Co(C_2O_4)_3^{3-}]^{1/2}$ *vs.* τ. Conditions as in Table 2. Temperatures are 25 °C (1), 30 °C (2), 35 °C (3), and 40 °C (4).

Note on the Preparation and Catalytic Properties of Dichlorotris[tris(*p*-methoxyphenyl)phosphine]ruthenium

(Received October 14, 1974)

Synopsis. The procedure for the preparation of $RuCl_2[(p\text{-}MeOC_6H_4)_3P]_3$ was improved, resulting in a higher catalytic activity. The complex was thirteen and five times as active as $RuCl_2(Ph_3P)_3$ in the hydrogenation of 1,4-androstadiene-3,17-dione (I) and 4-androstene-3,17-dione (II), respectively, indicating that the methoxy complex is more selective for formation of II in the consecutive hydrogenation pathway of I.

In the preceding paper,[1] it was shown that the catalytic activity of dichlorotris(triarylphosphine)-ruthenium was enhanced by *p*-methoxy and *p*-methyl groups and reduced by *p*-fluoro group when the complex was used in the presence of an optimal amount of triethylamine. During this study it has been noticed that the complex with *p*-methoxy substituent prepared by the same procedure as for the preparation of dichlorotris-(triphenylphosphine)ruthenium[2] was often of different color and showed different catalytic activity depending on preparation. Since tris(*p*-methoxyphenyl)phosphine is much less soluble in ethanol than triphenylphosphine, it seemed that the amount of ethanol used (120 ml for 1 g of $RuCl_3 \cdot 3H_2O$ and 6 molar equivalents of the phosphine) would be too small for the preparation of the methoxy complex. The complex formed in this amount of ethanol might be contaminated with free phosphine or its hydrochloride, which would be harmful to the catalytic activity of the resulting complex.[3] From this point of view the ruthenium complex was prepared using a larger amount of ethanol and the precipitate filtered off before the reaction mixture was cooled to room temperature.[4] By this simple improvement, however, the catalytic activity of the complex was greatly increased. A rather long refluxing time (*ca.* 6 hr) was also favorable for the catalytic activity. The *p*-methoxy complex thus prepared gave satisfactory C, H, and Cl analyses corresponding to the formula $RuCl_2[(MeOC_6H_4)_3P]_3$. Application of this improvement to the preparation of the *p*-methyl complex resulted in only a moderate increase in catalytic activity and no increase in the case of the complex without substituent, as might be expected from the higher solubilities of the corresponding phosphines in ethanol. For the same reason it is advisable to use a lesser amount of ethanol for the preparation of the complex with tris(*p*-fluorophenyl)phosphine because of its much higher solubility in ethanol.

Stoichiometrically the amount of triarylphosphine required for the preparation of the ruthenium complex must be 4.5 molar equivalents if the reaction occurs by the equation:

$$RuCl_3 + \frac{9}{2}Ar_3P + \frac{1}{2}H_2O \longrightarrow RuCl_2(Ar_3P)_3 + \frac{1}{2}Ar_3P{=}O + Ar_3P \cdot HCl$$

The complexes prepared with use of 5 molar equivalents of the phosphine, however, were slightly less active than those obtained with 6 molar equivalents. Blum and Becker[5] prepared triarylphosphine ruthenium complexes by refluxing ruthenium chloride and triarylphosphine in methanol. We also prepared the complexes according to their procedure, but the resulting complexes were less active than those obtained in ethanol by the improved procedure. They describe the colors of the methoxy and methyl complexes as apparently the same, but those of our preparations are definitely different from each other (dark brown for the methoxy complex and brown for the methyl complex).

In Table 1 are summarized the results of the hydrogenation of 1,4-androstadiene-3,17-dione (I) and 4-androstene-3,17-dione (II), using the complexes obtained

TABLE 1. HYDROGENATION OF 1,4-ANDROSTADIENE-3,17-DIONE (I) AND 4-ANDROSTENE-3,17-DIONE (II) WITH DICHLOROTRIS(TRIARYLPHOSPHINE)RUTHENIUM[a]

Compound	Catalyst X in $RuCl_2[(p\text{-}XC_6H_4)_3P]_3$	Reac. time (min)	Composition of reac. mixture (mol%)			$10^4 k_x$[c] (s^{-1})	k_x/k_H[c]
			I	II	III[b]		
I	OMe	20	3.7	90.0	6.3	27.5	13.1
I	Me	40	6.8	87.1	6.1	11.2	5.3
I	H	180	10.3	85.8	3.9	2.1	1.0
II	OMe	360	—	86.9	13.1	0.065	5.0
II	H	490	—	96.1	3.9	0.013	1.0

a) The compound (500 mg) was hydrogenated in 10 ml benzene in the presence of 0.026 mmol of the ruthenium complex and 0.034 mmol of triethylamine at 50 °C under a hydrogen pressure of 100 kg/cm². b) 5α- and 5β-androstane-3,17-dione. c) k_x and k_H denote the pseudo-first-order rate constants for the hydrogenations catalyzed by the ruthenium complexes with *p*-substituent X and with no substituent, respectively.

by the improved procedure. Pseudo-first-order rate constants were calculated by assuming that the rate of hydrogenation is first-order in the concentration of I and II.[6] It is seen that the catalytic activity of dichlorotris(triphenylphosphine)ruthenium is enhanced definitely more by the *p*-methoxy substituent than by the *p*-methyl to such an extent as would be expected from its substituent constant in the Hammett equation.

The *p*-methoxy complex is only five times as active as the complex with triphenylphosphine in the hydrogenation of II compared to thirteen times in the hydrogenation of I. Thus the ratio of the rate of hydrogenation of I to that of II is much greater for the *p*-methoxy complex. Accordingly, the *p*-methoxy complex will be more selective than the triphenylphosphine complex for formation of II in the consecutive hydrogenation pathway: I→II→saturated ketones. On the other hand, the amount of the saturated ketone formed directly from I[1,2] appears slightly increased with the methoxy complex. Therefore it is recommended to use the highly active methoxy complex at a lower temperature (*e.g.* 30 °C) to obtain a high yield of II by hydrogenation of I.

Experimental

Preparation of Dichlorotris[tris(p-methoxyphenyl)phosphine]ruthenium. A mixture of 0.425 g of $RuCl_3 \cdot 3H_2O$ (obtained from the Nippon Engelhard Co.), 3.43 g of tris(*p*-methoxyphenyl)phosphine (6 molar equivalents) and 80 ml ethanol was refluxed for 6 hr under the atmosphere of nitrogen. The crystals were filtered off before the reaction mixture was cooled to room temperature, and washed with ethanol and then with a small amount of ether. The yield was 1.83 g (92%) (Found: C, 61.37; H, 5.14; Cl, 5.96%. Calcd for $C_{63}H_{63}Cl_2O_9P_3Ru$: C, 61.56; H, 5.18; Cl, 5.77%). The same procedure is also applicable to the preparation of $RuCl_2[(p\text{-}MeC_6H_4)_3P]_3$ and results in a slightly lower yield.

The authors are grateful to the Mitsubishi Chemical Industries Co. for the analysis of chlorine.

The Reaction of 1,2,4,5-Tetrazines with 2-Phenyl-1-azirine. The Synthesis of 2*H*-1,2,4-Triazepine Derivatives

Masahiko TAKAHASHI, Norimoto SUZUKI, and Yoshihiko IGARI

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi, Ibaraki 316

(Received December 19, 1974)

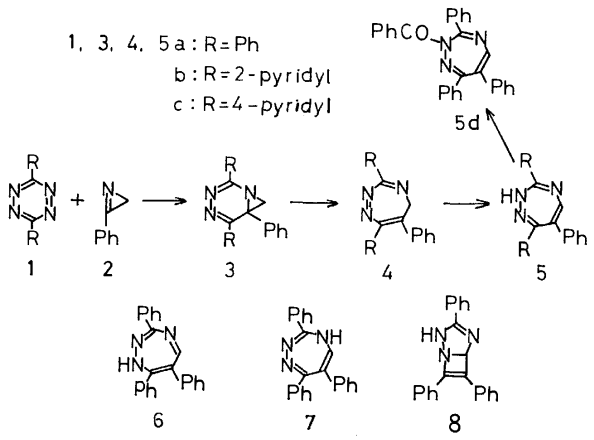
Synopsis. The Reaction of 3,6-disubstituted 1,2,4,5-tetrazines (**1a**—**c**) with 2-phenyl-1-azirine (**2**) afforded 3,7-disubstituted 6-phenyl-2*H*-1,2,4-triazepines (**5a**—**c**) in good yields.

The thermal and photochemical reactions of 1-azirines have been extensively investigated in recent years. Some examples of the Diels-Alder reaction of 1-azirines with cyclic dienes have been reported to yield cycloadducts or their ring-expanded products. The reaction of 1-azirines with cyclopentadienones[1,2] gives strained cycloadducts, which undergo a loss of carbon monooxide to yield azanorcaradienes, followed by ring enlargement to form 3*H*-azepine derivatives. The reaction of the benzo analogue of cyclopentadienones[3] has also been reported to form condensed azepine derivatives. The reaction of diphenylisobenzofuran[4,5] has been reported to yield cycloadducts and to be subjected to subsequent ring expansion to isoquinoline and azanorcarane derivatives.

The reaction of 1,2,4,5-tetrazines with cyclopropenes is a simple and convenient diene synthesis of substituted 5*H*-1,2-diazepines.[6] A similar reaction of 1,2,4,5-tetrazine with 1-azirine suggests a useful method for the synthesis of 1,2,4-triazepines. As an extension of our studies of the synthesis of triazepine derivatives,[7] we examined this reaction. Recently, Anderson *et al.*[8] and Johnson *et al.*[9] have reported that the same cycloaddition reaction gives 2*H*-1,2,4-triazepines. We wish to report our independent results[10] on the sunthesis of 2*H*-1,2,4-triazepines.

A toluene solution of 3,6-diphenyl-1,2,4,5-tetrazine (**1a**) and 2-phenyl-1-azirine (**2**) was refluxed for 26 hr. A product was obtained in a 58% yield as orange needles. The IR spectrum of the product showed a NH absorption at 3320 cm^{-1} and a C=N absorption at 1635 cm^{-1}. The mass spectrum of the product showed the following significant peaks: *m/e* 323 (M^+, 41%), 322 (M^+-1, 52%), 296 (M^+-HCN, 42%), 220 (M^+-PhCN, 100%), and 178 ($PhC{\equiv}CPh^+$, 19%). From the above data and the elemental analysis, the structure of the product was considered not to be triazanorcaradiene (**3a**) or its [3,3]sigmatropically rearranged product (**4a**), but rather the 2*H*-1,2,4-triazepine derivative (**5a**) or its 1*H* isomer (**6**), which seemed to be the result of the [1,5]sigmatropical shift of the C-5 hydrogen of **4a**. However, it was thought that **6** was more unstable than **5a** because of the sterical crowding of the C-6 and C-7 phenyl groups. Similar examples have been described in the case of the isomerization of 2*H*-azepines to 3*H*-azepines.[1,2] The possibility of the 4*H*-1,2,4-triazepine structure (**7**) is small, because **7** seemed to be the product of the 1,5-hydrogen shift of **6**. The signal of the vinyl proton resonance is probably contained in the region of aromatic protons at δ7.0—8.1 ppm, as is observed in the case of azepines.[1,2] Although 5*H*-1,2-diazepine derivatives were thermally isomerized into diazabicyclo [3,2,0]heptadiene,[6] another possibility of a bicyclic structure (**8**) of the present product was eliminated on the basis of the absence of bridgehead methine proton resonance at *ca.* δ 3.1—4.1 ppm such as observed for the photoisomers of azepines and oxepines.[11] The results cited above indicate that the structure of the product is probably 3,6,7-triphenyl-2*H*-1,2,4-triazepine, **5a**. Other derivatives, **5b** and **5c**, were similarly obtained in good yields.

The reaction **5a** with benzoyl chloride afforded a bezoate (**5d**) in a 35% yield. The IR spectrum of **5d** showed no NH absorption, but it did show a C=O absorption at 1685 cm^{-1}. Although the parent peak at *m/e* 427 was not observed in the mass spectrum, the other peaks were analogous to those of **5a**.



Experimental

All the melting points are uncorrected. The IR, UV, and NMR spectra were measured with a JASCO Model IRA-2 spectrometer, a Shimadzu Model MPS-501 spectrometer, and a Hitachi Model R-20 spectrometer respectively. A Shimadzu Model UM-3B apparatus was used for the elemental analysis.

3,6,7-Triphenyl-2H-1,2,4-triazepine (5a). A mixture of 0.80 g (3.4 mmol) of 3,6-diphenyl-1,2,4,5-tetrazine[12], **1a**, and 0.90 g (7.7 mmol) of **2**[13] in 60 ml of toluene was refluxed for 26 hr. After the subsequent concentration of the solution *in vacuo* and cooling, the resulting precipitates were filtered to afford 0.65 g (58% yield) of **5a**. It was recrystallized from ethanol to give orange needles; mp 208—210 °C. Found: C, 81.43; H, 5.24%. Calcd for $C_{22}H_{17}N_3$: C, 81.71; H, 5.30%. IR (KBr): 3320, 3050, 3020, 1635 cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 234 (4.59), 271 (4.67), 360 sh (3.50). NMR (DMSO-d_6): δ 7.00—8.10 (m, aromatic and olefinic H). Mass *m/e* (%): 323 (41), 322 (52), 297 (10), 296 (42), 295 (18), 221 (18), 220 (100), 219 (20), 191 (17), 189 (17), 178 (19), 165 (17),

118 (8.3), 104 (11), 90 (13), 77 (17).

*3,7-Bis(2-pyridyl)-6-phenyl-2*H-*1,2,4-triazepine (5b).* A mixture of 2.58 g (11 mmol) of 3,6-bis(2-pyridyl)-1,2,4,5-tetrazine,[14] **1b**, and 2.11 g (18 mmol) of **2** in 140 ml of toluene was refluxed for 16 hr. A treatment of the mixture similar to that described for **5a** afforded 2.25 g (63% yield) of **5b**. It was recrystallized from methanol to give orange needles; mp 190—192 °C. Found: C, 73.97; H, 4.62%. Calcd for $C_{20}H_{15}N_5$: C, 73.83; H, 4.65%. IR (KBr): 3330 (NH), 3042, 1640 (C=N) cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 232 (4.21), 281 (4.34), 383 sh (3.34). NMR ($CDCl_3$): δ 6.90—8.70 (aromatic and olefinic H).

*3,7-Bis(4-pyridyl)-6-phenyl-2*H-*1,2,4-triazepine (5c).* A mixture of 710 mg (3.0 mmol) of 3,6-bis(4-pyridyl)-1,2,4,5-tetrazine,[15] **1c**, and 420 mg (4.2 mmol) of **2** was refluxed for 20 hr. After the evaporation of the solvent *in vacuo*, the solid residue was washed with a small amount of methanol to afford 812 mg (83% yield) of **5c**. It was recrystallized from methanol to give orange needles; mp 218—219 °C. Found: C, 73.27; H, 4.58%. Calcd for $C_{20}H_{15}N_5$: C, 73.83; H, 4.65%. IR (KBr): 3320 (NH), 3050, 3020, 1626 (C=N) cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 232 (4.44), 268 (4.42). 385 sh (3.07).

*2-Benzoyl-3,6,7-triphenyl-2*H-*1,2,4-triazepine (5d).* A solution of 407 mg (1.3 mmol) of **5a** and 247 mg (1.8 mmol) of benzoyl chloride in 10 ml of tetrahydrofuran was refluxed for 21 hr. The solvent was removed *in vacuo* to give an oily residue, which was then dissolved into 10 ml of methanol and crystallized by cooling. The precipitates were filtered to afford 190 mg (35% yield) of **5d**. It was recrystallized from the mixed solvent of benzene and methanol to give white needles; mp 145—146 °C. Found: C, 81.55; H, 4.99%. Calcd for $C_{29}H_{21}ON_3$: C, 81.48; H, 4.95%. IR (KBr): 3040, 3020, 1685, 1595 cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 228 (4.58), 282 sh (4.02). NMR ($CDCl_3$): δ 7.20—8.60 (m, aromatic and olefinic H). Mass *m/e* (%): 323 (43), 322 (6.3), 296 (6.3), 295 (8.0), 221 (3.6), 220 (2.7), 219 (3.6), 191 (8.0), 189 (13), 165 (5.4), 105 (100), 77 (72).

The authors wish to express their thanks to Dr. Masatoshi Hirayama for the NMR measurements and to the Sankyo Co., Ltd., for the mass measurements.

Friedel-Crafts Reaction of 1,3,5-Trialkylbenzenes with Sulfur Monochloride and *N*-Chlorodimethylamine

Masaaki YOSHIFUJI, Susumu TANAKA, and Naoki INAMOTO

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113

(Received January 14, 1975)

Synopsis. The reaction of sulfur monochloride gave 2,4,6-tri-*t*-butylchlorobenzene (**3**) from 1,3,5-tri-*t*-butylbenzene (**1**), but gave the corresponding sulfide and disulfide from mesitylene (**2**). The reaction of *N*-chlorodimethylamine gave **3**, 2-chloro-3,5-di-*t*-butyltoluene and 2,4,6-trimethylchlorobenzene from **1**, 3,5-di-*t*-butyltoluene and **2**, respectively. The reaction of *N*-chlorodimethylamine with benzene gave chlorobenzene or *N,N*-dimethylaniline in 1-nitropropane or nitromethane.

The Friedel-Crafts reaction of sulfur monochloride gives diphenyl sulfide from benzene,[1] and diaryl sulfide and disulfide from substituted benzene.[2] Similarly, *N*-chlorodimethylamine gives *N,N*-dimethylanilines in reactions with benzene and substituted benzenes.[3] We have found that the Friedel-Crafts reaction of 1,3,5-tri-*t*-butylbenzene (**1**) with phosphorus trichloride gave an abnormal product, *t*-butyl-3,5-di-*t*-butylphenylphosphinic chloride.[4]

Therefore, the Friedel-Crafts reaction of 1,3,5-tri alkylbenzenes with sulfur monochloride or *N*-chlorodimethylamine was investigated.

Reaction with Sulfur Monochloride in the Dark. In the case of **1**, 2,4,6-tri-butylchlorobenzene (**3**) was always obtained (Table 1). Use of aluminum chloride as a catalyst gave a yellow tarry material and the yield of **3** was lower than when iron powder was used. The reaction of mesitylene (**2**) in the presence of iron powder at 0 °C gave a mixture or dimesityl sulfide (**4**) and disulfide (**5**); their yields were 64 and 15%, respectively, by gas chromatography (glc).

Reaction with N-*Chloromethylamine.* Compounds **1**,**2**, and 3,5-di-*t*-butyltoluene (**6**) were allowed to react in the presence of anhydrous aluminum chloride in nitromethane, nitrobenzene, or 1-nitropropane as solvents. Reaction with **1** gave always **3** (Table 2). The best result was obtained in 1-nitropropane by use of five molar amounts of *N*-chlorodimethylamine (Run 4). This method is applicable to the preparation of **3**, because **3** has been prepared from **1** through nitration, reduction, diazotization, and then Sandmeyer reaction.[5]

The reaction of **2** with five molar amounts of *N*-chlorodimethylamine in nitropropane at room temperature gave 60%[1] of 2,4,6-trimethylchlorobenzene (**7**), a trace of 2,4-dichloromesitylene (**8**), and 3% of 3,3′-dichloro-2,4,6,2′,4′,6′-hexamethylbiphenyl (**9**). A similar reaction of **6** at 60 °C gave 65% of 2-chloro-3,5-di-*t*-butyltoluene (**10**).

The reaction of **2** in nitromethane gave **7** (38%), bimesityl (**11**, 4%), and 2,4,6-trimethylbenzonitrile (**12**, 2.6%). The nitrile (**12**) was also obtained from the Friedel-Crafts reaction of **2** with nitromethane.[6]

Since **2** gave chloride (**7**), the reaction with benzene[3] was re-examined. The reaction in 1-nitropropane gave only chlorobenzene, but the reaction in nitromethane gave *N,N*-dimethylaniline. This difference is very interesting, but the reason for it is still obscure.

Table 1. Friedel-Crafts reaction of **1** with S_2Cl_2 in CS_2

1 (mmol)	S_2Cl_2 (mmol)	Cat.	(mmol)	Temp.	Time (hr)	**3** (%)
40	44	Fe	0.23	r.t.	6.0	57,[a] 12[b]
17	25	Fe	0.42	0 °C then r.t.	7.5 24	76,[c] 16[b]
20	25	$AlCl_3$	3.2	0 °C	5.8	39,[a] 10[b]

a) Determined by NMR. b) Isolated yields.
c) Contained a trace of sulfur.

Experimental

All boiling and melting points are uncorrected. All reactions were carried out under nitrogen.

Materials. 1,3,5-Tri-*t*-butylbenzene (**1**)[7] (mp 73—74.5 °C), 3,5-di-*t*-butyltoluene (**6**)[8] (mp 29.5—31 °C), and *N*-chlorodimethylamine[3] (bp 43—44 °C) were prepared by the reported methods.

Reaction of **1** *with Sulfur Monochloride (***13***).* A typical procedure is described below. To a stirred mixture of **1** (9.91 g, 40 mmol) and iron powder (13 mg, 0.23 mg-atom) in CS_2 (10 ml) was added dropwise **13** (5.9 g, 44 mmol) in CS_2 (5 ml) over 1.5 hr, and the mixture was stirred for an additional 4.5 hr. The reaction mixture was poured into water and extracted with ether and then CH_2Cl_2. The combined extracts were washed with water and dried with $MgSO_4$. After evaporation of solvent, ether was added to the residue to leave sulfur (1.65 g, 51.5 mg-atom). The filtrate was evaporated to leave 9.21 g as a residue, which was recrystallized three times from MeOH to give 1.31 g (12%)

Table 2. Reactions of **1** with *N*-chlorodimethylamine

Run	**1** (mmol)	$AlCl_3$ (mmol)	Me_2NCl (mmol)	Solvent	(mmol)	Temp. (°C)	Time (hr)	**3** (%)
1	20	19	15	$MeNO_2$	200	80	4	35,[a] 7.4[b]
2	20	16	15	$PhNO_2$	161	80	4	24,[a] 8[b]
3	20	16	15	$PrNO_2$	201	80	4	35,[a] 27[b]
4	20	23	100	$PrNO_2$	201	65—70	1	79[b]

a) Determined by NMR. b) Isolated yield.

of **3**, mp 156.5—160 °C (lit,[5] 162 °C).

Reaction of ***2*** *with* ***13***. To a stirred mixture of **2** (30.2 g, 252 mmol) and iron powder (20.5 mg, 0.37 mg-atom) was added dropwise **13** (3.38 g, 25 mmol) in CS_2 (3 ml) over 1.5 hr at 0 °C. The mixture was stirred at room temperature for one day. After a similar treatment, distillation gave 5.4 g of a yellowish brown substance, bp 174 °C/3 mmHg, which was fractionally recrystallized five times from EtOH to give 1.1 g (15%) of **5**, mp 123.5 °C (lit,[9] 123—124 °C), and 1.0 g (15%) of **4**, mp 90—91 °C (lit,[10] 91—92 °C). The yields of **4** and **5** were estimated to be 64 and 15% by glc.

Reaction of ***1*** *with* N-*Chlorodimethylamine (****14****)*. To a stirred solution of **1** (5.01 g, 20 mmol) in 1-nitropropane (13.5 ml) was added $AlCl_3$ (3.0 g, 22.5 mmol) and then **14** (7.96 g, 100 mmol) in 1-nitropropane (4.5 ml) dropwise at 0 °C. The mixture was stirred at 65—70 °C for 1 hr and poured into ice-water. The reaction mixture was made alkaline with aq. NaOH and extracted with CH_2Cl_2. After drying, distillation *in vacuo* gave crude **3** (5.62 g, 98%), mp 153—156 °C, which was recrystallized from MeOH, mp 161—162 °C, yield 4.50 g (79%).

Reaction of ***2*** *with* ***14***. *a) In 1-Nitropropane*: To a stirred mixture of **2** (4.84 g, 40 mmol), 1-nitropropane (3.58 g), and $AlCl_3$ (5.5 g, 41 mmol) was added dropwise **14** (15.9 g, 200 mmol) at 0 °C. The mixture was stirred at room temperature for 3 hr. After a similar treatment, distillation under vacuum gave **7** (3.73 g, 60%), bp 39—40 °C/1 mmHg (lit,[11] 51—52 °C/1.5 mmHg). The residue was chromatographed on silica gel with *n*-hexane to give 35 mg (0.5%) of **8**, mp 58.3—59.8 °C (lit,[12] 59 °C), and 180 mg (3%) of **9**, mp 131.1—131.9 °C (lit,[13] 130—131.5 °C).

b) In Nitromethane: A mixture of **2** (9.62 g, 80 mmol), $AlCl_3$ (4.0 g, 30 mmol), **14** (1.59 g, 20 mmol), and nitromethane (4.88 g) was stirred for 5 hr at 80 °C. After a similar treatment, distillation under vacuum recovered **2** (3.53 g, 37%). The residue was chromatographed on silica gel. Elution with *n*-hexane gave 1.18 g (38%) of **7** and 207 mg (4%) of **11**, mp 101.5—102 °C (from EtOH) (lit,[14] 101—102 °C). Elution with CCl_4 gave 308 mg (2.6% based on **2** used) of **12**, mp 48—48.5 °C (from EtOH) (lit,[15] 50—52 °C); IR (KBr): 2200 cm^{-1}.

Reaction of ***6*** *with* ***14***. A mixture of **6** (3.39 g, 16.6 mmol), **14** (6.43 g, 81 mmol), $AlCl_3$ (2.2 g, 16.5 mmol), and 1-nitropropane (14.3 g) was stirred for 3 hr at 60 °C. After a similar treatment, the residue of the distillation was chromatographed on silica gel with *n*-hexane to give 2.57 g (65%) of **10**, bp 113 °C/2.5 mmHg. NMR (CCl_4): δ 1.30 (s, 9H, *t*-Bu), 1.50 (s, 9H, *t*-Bu), 2.36 (s, 3H, Me), 6.99—7.05 (d, J_{HCCCH} 3 Hz, 1H, Ar-H), and 7.20—7.26 (d, J_{HCCCH} 3 Hz, 1H, Ar-H). Found: C, 75.39; H, 9.68; Cl, 15.09%. Calcd for $C_{15}H_{23}Cl$: C, 75.45; H, 9.71; Cl, 14.85%.

Reaction of Benzene with ***14***. A solution of benzene (6.26 g, 80 mmol) in 1-nitropropane (7.15 g), $AlCl_3$ (4.0 g, 30 mmol), and then **14** (1.58 g, 20 mmol) were mixed under stirring at −10 °C, and stirred at 80 °C for 5 hr. The reaction mixture was treated similarly. *N,N*-Dimethylaniline could not be detected by glc. After drying, the distillation gave 701 mg (31%) of chlorobenzene, bp 130—133 °C.

A mixture of benzene (5.27 g, 67.5 mmol), $AlCl_3$ (3.3 g, 24.7 mmol), nitromethane (4.08 g), and **14** (1.38 g, 17.4 mmol) was stirred for 5 hr at 80 °C; a similar treatment gave 625 mg (30%) of *N,N*-dimethylaniline, bp 40 °C/1.8 mmHg.
