Substitution of R^2=H by a methyl group enhances the steric interactions not only with the substituent R^1, which was already discussed above, but also with R^3 in the *O-s-cis* isomers I and II. The resulting *O-s-cis*→*O-s-trans* equilibrium shift manifests itself in the increase of the intensities of bands C^1 and D^1 on the expense of C^2 and D^2 if the spectrum of **10** is compared with that of **1**. With the ethyl ketone **11**, the complete disappearance of band D^2 is readily explainable by the buttressing effect in the *s-cis* rotamer but no simple explanation can be offered for the simultaneous disappearance of band C^2. This point seems to deserve a separate investigation.

The sequence of the $\nu_{C=O}$ and $\nu_{C=C}$ vibrational frequencies proposed here follows that known for other types of unsaturated ketones[3-9] but is further differentiated by taking into consideration the *O-s-cis* and *O-s-trans* rotamers. Thus, $\nu_{C=O}$(*s-cis*/*O-s-trans*) > $\nu_{C=O}$(*s-cis*/*O-s-cis*) > $\nu_{C=O}$(*s-trans*/*O-s-trans*) > $\nu_{C=O}$(*s-trans*/*O-s-cis*) > $\nu_{C=C}$(*s-trans*/*O-s-trans*) > $\nu_{C=C}$(*s-trans-O-s-cis*) > $\nu_{C=C}$(*s-cis*/*O-s-trans*) > $\nu_{C=C}$(*s-cis*/*O-s-cis*). Moreover, the wave number differences $\Delta\nu_{C=C}^{C=O}=\nu_{C=O}-\nu_{C=C}$ corroborate the regularities established by Braude and Timmons[4] and Mecke and Noack[5] enabling at the same time to more precisely classify the particular compounds according to their conformation, especially for the *s-trans* conformation. As can easily be derived from Table 1, $\Delta\nu_{C=C}^{C=O}$(*s-cis*/*O-s-trans*) = 75—85 cm^{-1}, $\Delta\nu_{C=C}^{C=O}$(*s-cis*/*O-s-cis*) = 80—100 cm^{-1}, $\Delta\nu_{C=C}^{C=O}$(*s-trans*/*O-s-trans*) = 20—30 cm^{-1} and $\Delta\nu_{C=C}^{C=O}$(*s-trans*/*O-s-cis*) = 35—50 cm^{-1}.

Experimental

4-Methoxy-3-buten-2-one (**1**), bp 53—54 °C/7 mmHg, lit,[16a] 52—53 °C/4—5 mmHg, *1-methoxy-4-methyl-1-penten-3-one* (**3**), bp 74—75 °C/7 mmHg, lit,[16a] 61—62 °C/3.5 mmHg, *1-methoxy-4,4-dimethyl-1-penten-3-one* (**4**) bp 69—70 °C/5 mmHg, lit,[16a] 61 °C/3 mmHg and *1-methoxy-2-methyl-1-penten-3-one* (**11**), bp 80—81 °C/8 mmHg, lit,[16a] 70°C/4.5 mmHg were obtained according to standard procedure described by Royals and Brannock,[16a] *viz.*, by pyrolysis of the corresponding β-ketoaldehyde dimethylacetals[16b,17] in the presence of catalytic amount of sodium methoxide. These reactions, however, were carried out under more vigorous conditions than described in order to obtain products free of starting material. This modification resulted in considerable lowering of the yield.

The same method was applied for obtaining of *1-methoxy-1-penten-3-one* (**2**), bp 65 °C/7 mmHg, lit,[18] 94 °C/15 mmHg from *1,1-dimethoxypentan-3-one*[18] and of *4-methoxy-3-methyl-3-buten-2-one* (**10**), bp 84—85 °C/10 mmHg, lit,[19b] 62—64 °C/4 mmHg, lit,[20] 83—86°C/10 mmHg from *4,4-dimethoxy-3-methylbutan-2-one*.

4-Ethoxy-3-buten-2-one(**5**): *1-Diethoxybutan-3-one*[19b] was heated with solid sodium ethoxide (3 per cent by weight) in an oil bath at 190°C while ethanol was removed by distillation at atmospheric pressure. After the distillation of ethanol has been finished (approx. 3 hr), the vacuum distillation was carried out yielding **5**, bp 87—89 °C/17 mmHg, lit,[21] 91—93° C/20 mmHg.

4-Isopropoxy-3-buten-2-one (**6**) and *1-isopropoxy-4-methyl-1-penten-3-one* (**7**) were prepared as follows:
To a solution of corresponding chlorovinylketone[22] in 2-propanol cooled to −15 °C an excess of a solution of potassium hydroxide in 2-propanol was dropped. The mixture was then allowed to reach the room temperature, stirred for 4 hr, poured out into water and extracted with ether. The ethereal layer was worked up in usual manner. The distillation *in vacuo* afforded a mixture of **6** or **7** and corresponding diisopropyl β-ketoacetal. The mixture thus obtained was heated in a distillation flask with 3 per cent by weight of solid potassium isopropoxide in an oil bath at 190—200 °C, while isopropanol distilled. After loss of 2-propanol had stopped (approx. 4 hr) the product was distilled *in vacuo*, affording **6**, bp 88 °C/15 mmHg lit,[18] 98—102 °C/12 mmHg, lit,[21] 112—118 °C/65 mmHg or **7**.

1-Isopropoxy-4,4-dimethyl-1-penten-3-one (**8**): An excess of saturated isopropanolic solution of hydrogen chloride was added to a solution of sodium salt of hydroxymethylenepinacoline (obtained from pinacoline, ethyl formate and

sodium) in 2-propanol. The mixture was then stirred for 3 hrs alkalized with 2-propanolic potassium hydroxide, poured out into water and extracted with ether. The ethereal layer was worked up in usual manner. The distillation *in vacuo* afforded a mixture of **8** and corresponding diisopropyl β-ketoacetal. The mixture was pyrolized in the same manner as described above.

1-t-Butoxy-4,4-dimethylpenten-1-one-3 (**9**) was obtained by the method analogous to that of Seifert and Schinz[23]: In a flask fitted with a reflux condenser and a water separator was placed hydroxymethylenpinacoline, equimolar amount of *t*-butyl alcohol, catalytic amount of *p*-toluenesulphonic acid and a large excess of benzene. The mixture was boiled for 16 hours while water was removed by azeotropic distillation. The mixture was then washed with aqueous sodium bicarbonate and water and benzene was removed. Vacuum distillation gave an oil which solidified immediately. Twofold sublimation of the resulting solid at 0.8 mmHg gave pure **9**.

Physical properties and analytical data for the three new compounds are given below.

Compound	Bp (°C/mmHg)	Mp (°C)	%C Calcd (Found)	%H Calcd (Found)
7	75—76/3 mmHg	—	69.19 (69.00)	10.32 (10.60)
8	71—72/2.5 mmHg	—	70.54 (70.55)	10.66 (10.63)
9	—	72	71.69 (71.74)	10.94 (11.08)

Bp and mp were not corrected.

Structures of all the compounds **1**—**11** were confirmed by NMR spectra (Table 2).

Infrared spectra were recorded on a Perkin-Elmer 325 spectrometer with a spectral slit width of 0.7—0.9 cm^{-1} and a scanning speed of 0.8 $cm^{-1} \cdot s^{-1}$. Better spectral parameters gave no better resolution. Commercial "for spectroscopy" solvents were used. The substances investigated were freshly distilled or sublimed before the measurements. Preparative thin layer chromatography was used where necessary. The spectra were calibrated with polystyrene.

NMR spectra were recorded on Varian HA-60/IL and JEOL JNM-4H-100 instruments.

The Formation of Crystalline Complexes between Inosine and Several Hydroxybenzoic Acids

Yoshihisa SUZUKI and Kentaro HARA

Central Research Laboratories, Ajinomoto Co., Inc., Suzuki-cho, Kawasaki 210

(Received June 15, 1974)

Synopsis. Inosine was found to form 1 : 1 crystalline complexes with 2,4-, 2,5-, 2,6-, 3,4-, 3,5-dihydroxybenzoic acids, and with 3,4,5-trihydroxybenzoic acid, but was found to give no crystalline complex with benzoic acid, *o*-, *m*-, *p*-hydroxybenzoic acids, 2,3-dihydroxybenzoic acid, or 2,3,4-trihydroxybenzoic acid.

Several nucleic acid bases, such as adenine and cytosine, have been known to form crystalline intermolecular complexes with benzoic acid or monohydroxybenzoic acids.[1] One of the ribonucleotides, 5′-guanylic acid, has also been known to form crystalline complexes with several hydroxybenzoic acids.[2] On the basis of these facts, ribonucleosides have also been interested to form crystalline intermolecular complexes with benzoic acid or hydroxybenzoic acids.

The present paper will deal with a study of the complex-formation of inosine or guanosine with several hydroxybenzoic acids. Inosine has been known to be a good counterpart for complex-formation with other organic substances, since only inosine, from among several ribonucleosides, has been demonstrated to form a 1 : 1 stable crystalline intermolecular complex with L-tryptophan[3,4] or with D-tryptophan.[3] On the other hand, no crystalline complex has ever been known between guanosine and other organic compounds, whereas interaction in the solution has been reported.[4]

An equimolar aqueous solution of the benzoic acid and the nucleoside was evaporated to dryness, and the resultant solid was examined by means of the X-ray powder diffraction method.

The results obtained are shown in Table 1. They are of interest, but not fully convincing. No acid—benzoic acid, *o*-, *m*-, or *p*-monohydroxybenzoic acid—showed any evidence of the complex-formation in the crystalline solid with inosine giving a mixture of the two components, whereas all of these benzoic acids are known to give crystalline complexes with adenine or cytosine.[1] The five dihydroxybenzoic acids (2,4-, 2,5-, 2,6-, 3,4-, and 3,5-), but not the 2,3-isomer and 3,4,5-trihydroxybenzoic acid, have been associated with inosine to give the corresponding crystalline complexes as is summarized in Tables 2 and 3, while 2,3,4-trihydroxybenzoic acid has not.

TABLE 1. THE FORMATION OF THE CRYSTALLINE INTERMOLECULAR COMPLEXES BETWEEN INOSINE AND SEVERAL HYDROXYBENZOIC ACIDS

Benzoic acid	−
o-Monohydroxybenzoic acid	−
m-Monohydroxybenzoic acid	−
p-Monohydroxybenzoic acid	−
2,3-Dihydroxybenzoic acid	−
2,4-Dihydroxybenzoic acid	+
2,5-Dihydroxybenzoic acid	+
2,6-Dihydroxybenzoic acid	+
3,4-Dihydroxybenzoic acid	+
3,5-Dihydroxybenzoic acid	+
2,3,4-Trihydroxybenzoic acid	−
3,4,5-Trihydroxybenzoic acid	+

The ionization constants of the benzoic acids are not available to aid in interpreting the specific capability of complex-formation between inosine and the selected benzoic acids. For example, the ionization constant of 2,3-dihydroxybenzoic acid (1.14×10^{-3})[5] exhibits no significant difference from those of the 2,4-isomer (5.16×10^{-4}),[5] the 2,5-isomer (1.3×10^{-3}),[5] and the 2,6-isomer (6×10^{-2}).[5] The information obtained in this study was that the phenolic hydroxyl groups of more than two in the benzoic acid may be important in forming crystalline complexes, and that such an arrangement in the structure as  may prevent the complex-formation with inosine. This information suggests that the hydrogen bonding may play an important role in the formation of the present crystalline molecular complexes.

The large crystals of the complexes were obtained from a dilute equimolar aqueous solution of the two components. The stoichiometry in the complexes was 1 : 1 without exception, while the number of the water of crystallization varied case by case between zero and three moles per mole of inosine (Table 2). Table 3 shows the X-ray powder diffraction data of the new complexes obtained in the present study.

Guanosine failed to form any crystalline molecular complex with any of those benzoic acids to give a mixtures of the two components. The characteristic properties of inosine to form a crystalline complex with several hydroxybenzoic acids were thus demonstrated in this study.

Experimental

Materials. The nucleosides and the benzoic acids were obtained from the Ajinomoto Co., Inc., and the Tokyo Kasei Co., respectively.

Examination of the Complex-Formation. An equimolar amount of inosine (or guanosine) and one of the benzoic acids were dissolved together in water, and the solution was evaporated to dryness in a desiccator. The resultant

solids were examined by means of the X-ray powder diffraction method, and their data were compared with those of mechanical mixtures of the two components.

The Crystallization of the Complexes. Inosine (13.4 g) was dissolved in water (160 ml) with heating, and then one of the hydroxybenzoic acids (0.05 M) was stirred, drop by drop, into this solution at 40 °C over a 2-hr period. After the mixture had then been cooled to 0—5 °C for 3 hr, the crystals precipitated were filtered and analyzed.

Analysis. Paper chromatography was carried out on Toyo-Roshi No. 51A, with the *n*-butanol—acetic acid—water (4 : 1 : 1) solvent system, and the components of the crystals were determined by comparing the UV absorption at the maximum wavelength with the standard references. The water of crystallization was determined by Karl-Fischer titration.

Dielectric Relaxation and Molecular Structure. XIV. The Dielectric Behavior of Six Isomeric Pentyl Alcohols

Hiroshi SATO, Taro KOSHII, Hiroaki TAKAHASHI, and Keniti HIGASI

Department of Chemistry, Waseda University, Shinjuku, Tokyo 160

(Received October 17, 1974)

Synopsis. The dielectric constants and losses of six isomeric pentyl alcohols have been measured in the frequency range of 1—0.35 GHz at 25 °C. The relaxation times of these alcohols decrease with an increase in the steric hindrance of the hydroxyl group.

Low-frequency measurements at room temperature showed that both the dielectric constants, ε_0, and the Kirkwood correlation factors, g, decrease with an increase in the steric hindrance of the hydroxyl groups of butanol,[1,2] heptanol,[3,4] and octanol.[5] Few repotrs are available, however, regarding the dependence of the relaxation times upon the isomeric configuration, especially in the liquid state at room temperature.[5-7] Emphasis will be placed in this report on the dielectric relaxation of six isomeric pentyl alcohols at 25 °C.

Experimental

Commercial chemicals were dehydrated by the usual methods and were fractionally distilled prior to their use. In order to check the purity of the samples, the refractive indices for the Na D line were measured with a Pulfrich refractometer. Both the boiling points and the refractive indices of the purified samples were in good agreement with the literature values[8,9]; 1-pentanol, bp=138.2—140.0 °C, n_D=1.408; 3-methyl-1-butanol, bp=131.0—131.2 °C, n_D=1.406; 2-pentanol, bp=118.8—119.2 °C, n_D=1.405; 3-pentanol, bp=113.6—115.0 °C, n_D=1.408; 3-methyl-2-butanol, bp=112.2 °C, n_D=1.407; and 2-methyl-2-butanol, bp=102.8—103.2 °C, n_D=1.403.

The dielectric constants and losses were measured at the frequencies of 0.356, 0.515, 0.601, 0.697, 0.807, and 1.00 GHz by the use of an UHF apparatus of the coaxial-slotted-line type.[10] The relaxation time, τ, and the limiting low- and high-frequency dielectric constants, ε_0 and ε_∞ respectively, were calculated on the basis of the Debye equation.[11] This is because the Debye equation has been found to be valid for the principal, low-frequency dispersion of any mono-alcohol[5,10,12,13] ever studied in the liquid state. The Kirkwood correlation factor, g,[14] was calculated by the use of ε_0 and ε_∞ in the following equation:

$$g = \frac{9kT(\varepsilon_0-\varepsilon_\infty)(2\varepsilon_0+\varepsilon_\infty)}{4\pi N\varepsilon_0(\varepsilon_\infty+2)^2\mu_0^2}$$

The g values thus obtained are denoted by $g(\varepsilon_0,\varepsilon_\infty)$, which are also compared with the $g(\varepsilon_0,n_D^2)$ values obtained by substituting n_D^2 for ε_∞. Since the exact value of the dipole moment, μ_0, in the liquid state is still unknown, we tentatively assumed the value of μ_0=1.66 D obtained by the dilute-solution method.[15]

Results and Discussion

Debye semicircles are plotted from the dielectric data obtained for six isomers of pentyl alcohols (Fig. 1). The relaxation time, τ, and the limiting low- and high-frequency dielectric constants, ε_0 and ε_∞ respectively, in the Debye equation are listed in Table 1, together with the Kirkwood correlation factor, g. The static dielectric constants, ε_0, from the literature for 1-pentanol are 13.9[16] and 14.6,[13]* for 3-methyl-1-butanol, 14.7,[16] and for 2-methyl-2-butanol, 5.82.[16] It should be noted that these values compare fairly well with the observed limiting values, which are not entirely free from error because of the large extrapolation. The relaxation time, τ, for 1-pentanol is also in fair agreement with the literature values, 7.5×10^2 ps[13]* and 7.6×10^2 ps.[17]* The differences between ε_∞ and n_D^2 are 1.1—1.3 for all the isomeric alcohols, which seems to reveal that there exists no essential difference in the high-frequency absorption.

1-Pentanol, which has the least sterically hindered OH group, has the largest ε_0, while the smallest ε_0 is found for 2-methyl-2-butanol, with the most sterically hindered OH group. The static dielectric constants decrease with an increase in the degree of steric hindrance. Of the two g values, $g(\varepsilon_0,n_D^2)$ is larger than $g(\varepsilon_0,\varepsilon_\infty)$; both $g(\varepsilon_0,n_D^2)$ and ε_0 decrease with an increase in the amount of steric hindrance of the hydroxyl group; similar trends have been observed by other workers[1-4] for other mono-alcohols.

The dielectric relaxation time, τ, decreases in the

* These values were obtained by the interpolation or extrpolation of the literature values given at different temperatures.

TABLE 1. THE RELAXATION TIMES, τ, THE LIMITING LOW- AND HIGH-FREQUENCY DIELECTRIC CONSTANTS, ε_0 AND ε_∞ RESPECTIVELY, THE DIFFERENCES, $\varepsilon_\infty - n_D^2$, AND TWO KIRKWOOD CORRELATION FACTORS, g, FOR SIX ISOMERIC PENTYL ALCOHOLS AT 25 °C

	1-Pentanol	3-Methyl-1-butanol	2-Pentanol	3-Pentanol	3-Methyl-2-butanol	2-Methyl-2-butanol
	C-C-C-C-C OH	C C-C-C-C OH	C-C-C-C-C OH	C-C-C-C-C OH	C C-C-C-C OH	C C-C-C-C OH
$\tau(\times 10^{-2}$ ps)	6.7	7.4	6.5	6.5	4.8	2.0
ε_0	14.6	14.3	13.2	13.4	12.1	5.7
ε_∞	3.2	3.0	3.0	3.1	3.3	3.1
$\varepsilon_\infty - n_D^2$	1.2	1.1	1.1	1.1	1.3	1.1
$g(\varepsilon_0, \varepsilon_\infty)$	1.8	1.9	1.7	1.7	1.4	0.5
$g(\varepsilon_0, n_D^2)$	3.3	3.2	3.0	3.0	2.7	1.1

order of: the primary pentyl alcohols (1-pentanol $\tau=6.7\times10^2$ ps, 3-methyl-1-butanol $\tau=7.4\times10^2$ ps)> secondary pentyl alcohols (2-pentanol $\tau=6.5\times10^2$ ps, 3-pentanol $\tau=6.5\times10^2$ ps, 3-methyl-2-butanol $\tau=4.8\times10^2$ ps)> tertiary pentyl alcohol (2-methyl-2-butanol $\tau=2.0\times10^2$ ps). In a preceding paper[18] we found, in contrast to this, that the relaxation time for tertiary butyl alcohol ($\tau=5.3\times10^2$ ps) is longer than that for normal butyl alcohol ($\tau=5.1\times10^2$ ps) at 25 °C. The longer relaxation time of the former than that of the latter may be associated with the considerable viscosity of the former. If we take the reduced relaxation time, τ/η, instead of τ, it will be found that τ/η decreases in the order of: primary butyl alcohols (1-butanol $\tau/\eta=2.0\times10^2$ ps/cP,** 2-methyl-1-propanol $\tau/\eta=1.9\times10^2$ ps/cP**)>secondary butyl alcohol (2-butanol $\tau/\eta=1.4\times10^2$ ps/cP***)> tertiary butyl alcohol (2-methyl-2-propanol $\tau/\eta=1.1\times10^2$ ps/cP**). For isomeric pentyl alcohols, a similar trend exists in the reduced relaxation time; *e.g.*, primary pentyl alcohol (3-methyl-1-butanol $\tau/\eta=2.0\times10^2$ ps/cP**)>secondary pentyl alcohol (3-methyl-2-butanol $\tau/\eta=1.4\times10^2$ ps/cP**)>tertiary pentyl alcohol (2-methyl-2-butanol $\tau/\eta=0.6\times10^2$ ps/cp**).

On the Melting Point of *N*-Methylacetamide–Silver Nitrate Adduct

Takaharu MATSUBARA and Toshio TANAKA*

(Received December 17, 1974)

Synopsis. The melting point of *N*-methylacetamide-silver nitrate adduct $AgNO_3 \cdot 2NMA$ was found to be 46—47 °C which is in large disagreement with that reported by Paul and Chadha. The discrepancy was interpreted to result from the tendency of the adduct to lose NMA at high temperatures or at low partial pressures of NMA.

Formation of stable solid adducts of silver nitrate with some oxygen donor ligands was reported by Paul and Chadha.[1] Of the adducts $AgNO_3 \cdot 2NMA$ (NMA: *N*-methylacetamide) was reported to have melting point (or the temperature of decomposition) at 148 °C. We also prepared[2] the adduct in an infrared absorption spectroscopic study of the interaction between photographic gelatin and silver nitrate, and found its melting point to be 46—47 °C (in sealed tubes) and not 148 °C. The purpose of the present note is to point out and discuss the discrepancy.

Our method of preparation is as follows: solid silver nitrate was dissolved in an excess (2—3 times the equivalent) of molten NMA. The solution was cooled down to room temperature to crystallize out the adduct. This method of crystallization differs from that of Paul and Chadha who added excess benzene to the solution for the purpose of crystallization, the former taking more time and giving larger and probably purer crystals. The crystal was then ground, washed several times with benzene or carbon tetrachloride to remove excess NMA and freed from the solvent in dry streaming nitrogen. The adduct was kept in a closed vessel filled with dry nitrogen because of its high deliquescence. Drying and storing in a vacuum or in the presence of desiccating agents were avoided since the adduct tended to lose NMA (effloresce) under such conditions.

The composition of the adduct thus obtained was examined by dissolving the weighed adduct in water and measuring the absorption of nitrate ions at 300 nm. The molar ratio of NMA to $AgNO_3$ was found to be 2.00 which is in very good agreement with the expected value.

Combined thermogravimetry (TG) and differential thermal analysis (DTA) were carried out at several pressures and heating rates to find out what would happen when the $AgNO_3 \cdot 2NMA$ was heated up from room temperature to the melting point of pure silver nitrate. A Chyo Balance Corporation Type $TRDA_1$–L DTA Instrument was used. The results are given in Figs. 1 and 2. Neither NMA nor silver nitrate itself decomposed, nor did they react to each other, to a significant extent within the temperature range studied, except for an eventual slight darkening of silver nitrate near its melting point.

The endothermic peak of the DTA curve around 47 °C is distinct and reproducible. The fact that there is no change in weight at this temperature shows that this is the genuine melting point of the adduct.

Between 60 and 190 °C no definite transition was observed except for an abrupt fall of the DTA curve and a knick on the TG curve at the same time. Visual observation showed that these anomalies correspond to re-solidification of the melt due to the loss of a fraction of the initial amount of NMA. The temperature at which the anomalies appeared and the composition of the solid at that stage depended considerably on

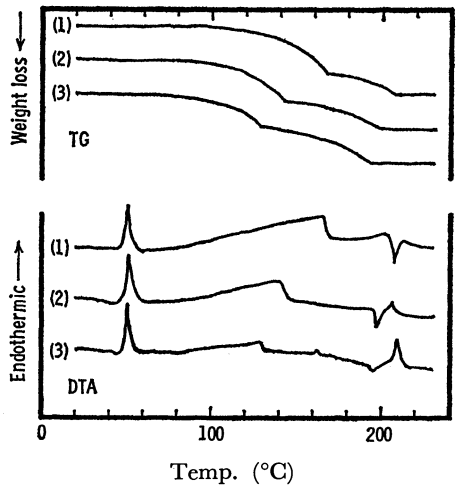

Fig. 1. TG and DTA curves of $AgNO_3$–NMA adduct at different heating rates.
Pressure: 760 mmHg. Heating rate: (1) 3.3 °C/min, (2) 1.8 °C/min, (3) 1.1 °C/min.

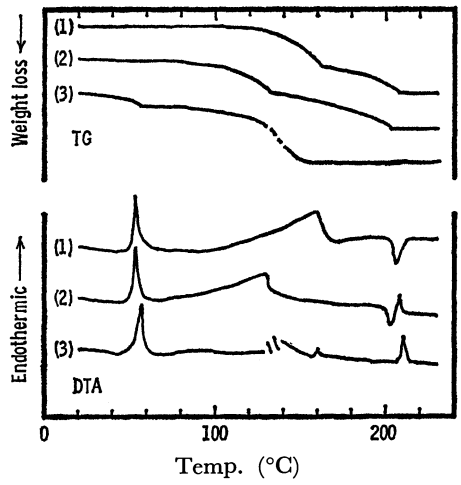

Fig. 2. TG and DTA curves of $AgNO_3$–NMA adduct at different pressures.
Heating rate: 2.6 °C/min. Pressure: (1) 760 mmHg, (2) 200 mmHg, (3) 8 mmHg.

experimental conditions. No evidence was found for the existence of another stable homogeneous phase richer in silver nitrate than the initial adduct. The cause of the knick on the TG curve would be merely the difference in the rate of vaporization of NMA from the liquid and the solid surfaces. Some DTA curves showed that the solid might contain a pure silver nitrate phase even in the presence of NMA. Traces of endothermic transition of normal silver nitrate from orthorhombic to rhombohedral structure were seen at 160 °C. (See, for example, the bottom curve in Fig. 1.)

Since we could find no "melting (or decomposition) point" at the temperature indicated by Paul and Chadha, it seems that their specimen might have lost a part of NMA during the course of drying and preservation, in particular, if the procedures had been carried out at a high temperature or at a low partial pressure of NMA, *e.g.*, in a vacuum or in the presence of desiccating agents.[3~5] On rapid heating, their specimen apparently melted at a temperature higher than the actual melting point of the adduct but lower than that of pure silver nitrate.

Attempts were made to prepare solids with NMA-content less than the adduct, by mixing powdered silver nitrate with a small amount of hot NMA and cooling the mixture rapidly in order to determine the apparent melting point of the solids in sealed tubes. Even on rapid heating, however, they melted first partly at around 50 °C, and solids coexisted with the melt. At *ca.* 140 °C generation of bubbles began to take place. This seems to correspond to the "decomposition of the adduct" mentioned by Paul and Chadha, but we consider it to be mere vaporization of NMA from the viscous melt-solid mixture.

We conclude that the actual melting point of the adduct $AgNO_3 \cdot 2NMA$ is 46—47 °C, and that the adduct is stable only at temperatures lower than this and in the presence of sufficient NMA vapor.

We are grateful to Prof. H. Hada, Kyoto University, for his kind discussions.

α,β-Unsaturated Carboxylic Acid Derivatives. VII. Reaction of Ethyl α,β-Unsaturated α-Cyanocarboxylates with Triethyl or Diethyl Phosphonate[1]

Chung-gi SHIN, Yasuchika YONEZAWA, Yasuo SEKINE, and Juji YOSHIMURA*

Laboratory of Organic Chemistry, Faculty of Technology, Kanagawa University, Rokkakubashi, Kanagawa-ku, Yokohama 221

** Laboratory of Chemistry for Natural Products, Faculty of Science, Tokyo Institute of Technology, Ōkayama, Meguro-ku, Tokyo 152*

(Received April 16, 1974)

Synopsis. The reaction of ethyl α,β-unsaturated α-cyanocarboxylates with triethyl phosphonate gave ethyl α-cyano-β-diethoxyphosphinyl-carboxylates in about 50% yields.

In a previous paper,[2] we reported that the reaction of ethyl α,β-unsaturated α-nitrocarboxylates with triethyl phosphonate gave ethyl α,β-unsaturated β-diethoxyphosphinyl-carboxylates *via* unstable 3-ethoxycarbonyl-1,2,5-oxazaphospholine derivatives.

In this paper, we wish to report the reaction of ethyl α,β-unsaturated α-cyanocarboxylates (**1**) with triethyl or diethyl phosphonate.

Results and Discussion

When compound **1a**—**d** (**a**; R=methyl, **b**; R=ethyl, **c**; R=*n*-propyl, **d**; R=*i*-propyl) was treated with triethyl phosphonate at room temperature for 30 min and then the mixture was heated at *ca.* 120 °C for 2 hr with continuous stirring, ethyl α-cyano-β-diethoxyphosphinyl-carboxylate (**3a**—**d**) was obtained in about 50% yield as a colorless oil. In the reaction of ethyl 2-cyanocinnamate (**1e**) with triethyl phosphonate, an adduct (**2e**) was obtained in a good yield. The IR spectrum of **2e** showed a strong absorption of C=C=N⁻ at 2050 cm^{-1} (Fig. 1). The compound **2e** can be repeatedly distilled (bp 152—155 °C/0.25 mmHg), but it changed gradually into **3e** at room temperature over 6 months. The stability of the intermediate, **2e**, is probably due to the resonance stabilization between its intramolecular phosphonium salt and phenyl group attached to the carbon atom at the 3-position. However, when a solution of **2e** in cyclohexane was irradiated at room temperature for 24 hr by using an external high-pressure mercury lamp, ethyl 2-cyano-3-diethoxyphosphinyl-3-phenylpropanoate (**3e**) was obtained in a good yield and ethylene was liberated. The reaction seems to proceed through the compound **2** which in turn decomposes to the compound **3** and ethylene as shown in Scheme 1. The structure of **3** was confirmed by IR spectra and an independent preparation from diethyl phosphonate and **1**. The physical properties of **3** were summarized in Table 1.

Experimental

All boiling points are uncorrected. The IR spectra were recorded with a Hitachi EPI-S2 Spectrometer. The NMR spectra were measured with a JNM-4H-100 Spectrometer using tetramethylsilane as an internal standard.

Material. Compound **1** was prepared by the reaction of appropriate aldehyde with ethyl cyanoacetate.[3,4]

*Reaction of **1a–d** with Triethyl Phosphonate.* A mixture of **1a–d** (0.05 mol) and triethyl phosphonate (0.06 mol) was stirred at room temperature for 30 min and then heated at 120—130 °C for 2 hr. The corresponding ethyl α-cyano-β-diethoxyphosphinyl-β-alkylpropanoate was obtained by distillation under reduced pressure. The physical properties are listed in Table 1.

*Reaction of **1e** with Triethyl Phosphonate.* A mixture of **1e** (0.05 mol) and triethyl phosphonate (0.1 mol) was refluxed for 5 hr. After removal of excess triethyl phosphonate, the residual syrup was distilled under reduced pressure to give an adduct (**2e**) (70.5%) as a colorless oil, bp 152—155 °C/0.25 mmHg. IR (KBr disk); 2050 (–C=C=N–), 1740 (–COOEt) and 1020 (⩾P–O–C⩽)cm^{-1}. NMR ($CDCl_3$); δ 2.40 (1H, s, C_6H_5–CH–C–).

Found: C, 58.47; H, 7.67; N, 4.12%. Calcd for $C_{18}H_{26}NO_5P$: C, 58.85; H, 7.08; N, 3.81%.

*Irradiation of **2e**.* A solution of **2e** (7 g) in dry cyclohexane (90 ml) was irradiated at room temperature for 24 hr by an external high-pressure mercury lamp. After removal of cyclohexane, the residue was purified on a silica gel column using benzene-acetone (10 : 1 V/V). After removal of the solvent, the residual oil was distilled under reduced pressure to give a colorless oil (**3e**).

*Reaction of **1a** or **1c** with Diethyl Phosphonate.* A mixture of **1a** (0.05 ml) and diethyl phosphonate (0.1 mol) was refluxed for about 5 hr. After removal of the excess diethyl phosphonate, the residual oil was distilled under reduced pressure to give a colorless oil (**3a**).

In a similar manner, **3c** was obtained as a colorless oil starting from **1c** with diethyl phosphonate.

Normal and Reverse Photochromism of 1-(β-carboxyethyl)-3,3-dimethyl-6′-nitrospiro[indoline-2,2′-2*H*-benzopyran] in Water–Dioxane

Kenryo NAMBA and Shuichi SUZUKI

Research Laboratory of Resources Utilization, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received May 18, 1974)

Synopsis. The photochromism of 1-(β-carboxyethyl)-3,3-dimethyl-6′-nitrospiro[indoline-2,2′-2*H*-benzopyran] (I) was studied in water-dioxane. It was found that (I) exhibits normal photochromism in dioxane and reverse photochromism on addition of water to the solution.

A number of derivatives of 1-alkyl-3,3′-dimethylspiro [indoline-2,2′-2*H*-benzopyran] show photoreversible color change in organic solvents. Most of them are converted from a colorless stable state into a colored metastable state by irradiation with ultraviolet light. We have found that a photochromic compound, 1-(β-carboxyethyl)-3-3-dimethyl-6′-nitrospiro[indoline-2,2′-2*H*-benzopyran] (I), synthesized for chemical modification of enzymes, showed reverse photochromism in a water–dioxane mixture.

Experimental

Compound (I) was prepared by the reaction of 1-(β-carboxyethyl)-3,3-dimethylindolenium iodide and 5-nitrosalicylaldehyde in methyl ethyl ketone in the presence of piperidine, mp. 109.5—110.5 °C.

Absorption spectra were obtained with a Hitachi Rapidscan RSP-2 Spectrophotometer, the absorbances at λ_{max} being determined with a Shimazu Spectrophotometer UV-200 equipped with a thermostated cell compartment.

Results and Discussion

Variations of the absorption spectrum in the mixed solvents are shown in Fig. 1.

A colorless dioxane solution of (I) became violet after ultraviolet irradiation. The color faded very rapidly after the cessation of irradiation. In water–dioxane (water mole fraction of 0.34), compound (I) showed a weak absorption band at 566 nm before the ultraviolet irradiation (solid line 2), the absorbance increasing after the irradiation. At mole fraction 0.88, the solution of (I) showed an absorption band at 528 nm in the dark (solid line 3), the absorbance being reduced with the ultraviolet irradiation (dotted line 3). The absorption band reappeared spontaneously in the dark.

The difference in absorbance after and before the ultraviolet irradiation was determined in various water–dioxane mixtures. The results are given in Table 1.

It is clear that the difference in absorbance after ($O.D._L$) and before ($O.D._D$) the irradiation decreased with increasing mole fraction of water. Absorption maxima shifted toward shorter wavelengths with increasing solvent polarity.

Compound (I) exhibited reverse photochromism in formamide (Dimroth's solvent polarity value : E_t, 56.6),

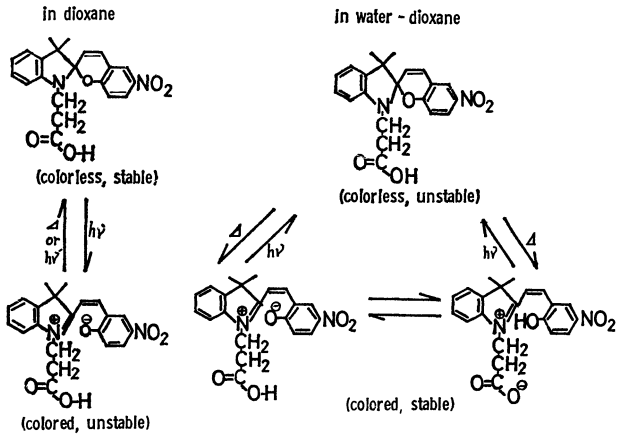

Fig. 2. Reaction Scheme of 1-(β-carboxyethyl)-3,3-dimethyl-6′-nitorospiro[indoline-2,2′-2*H*-benzopyran].

ethylene glycol (E_t, 56.3) and methanol (E_t, 55.5), but normal photochromism in other organic solvents having lower polarity such as ethanol (E_t, 51.9) and *n*-propanol (E_t, 50.7).

The results are attributed to the stabilization of ground state of the colored form due to the interaction with solvent.[1] At low mole fraction *ca.* 0.8, the ground state of the colored species was more unstable than that of the colorless species. Above 0.8, the increase of stabilization energy with the solvent might make the ground state of the colored species more stable than that of the colorless species, giving rise to reverse photochromism. The carboxyl group of (I) might play an important role in the reverse photochromism since 1,3,3-trimethyl-6′-nitrospiro[indoline-2,2′-2*H*-benzopyran] shows no remarkable effect in water–dioxane. The schemes are considered in Fig. 2.

Electronic Structures and Spectra of Quinarene Molecules

Hiroyuki YAMAGUCHI* and Takeshi NAKAJIMA
Department of Chemistry, Tohoku University, Sendai 980

(Received June 10, 1974)

Synopsis. The electronic structures and spectra of fundamental quinarene molecules, **1**—**9** (Fig. 1) and some of their diphenyl derivatives (Fig. 2) have been studied by using the variable bond-length SCF LCAO-π-MO CI method.

Although syntheses of the quinarene molecules have been attempted by many investigators, and although some derivatives have been synthesized,[1-6] the parent hydrocarbons, **1**—**9** (Fig. 1), have so far not been synthesized. Very recently, Takahashi *et al.* attempted to synthesize the 9,9-diphenyl derivative of **3**, (**3'**),[7] and the 10, 11-diphenyl derivative of **8**, (**8'**)[8] (Fig. 2).

The present note will report the results of calculations of the electronic structures and spectra of the quinarene molecules by the semiempirical LCAO MO method. Further, by comparing the calculated electronic spectra with the experimental ones, we will examine whether or not the unknown compound obtained recently by Takahashi *et al.* in an attempt to synthesize **8'** is really the **8'** molecule.

The method of calculation used is the variable bond-length SCF LCAO-π-MO CI method,[9] in which the bond lengths and, consequently, the resonance and Coulomb repulsion integrals are allowed to vary with the bond order at each iteration until self-consistency is reached. In order to discuss the electronic spectra, a configuration mixing of all the singly excited states is included.

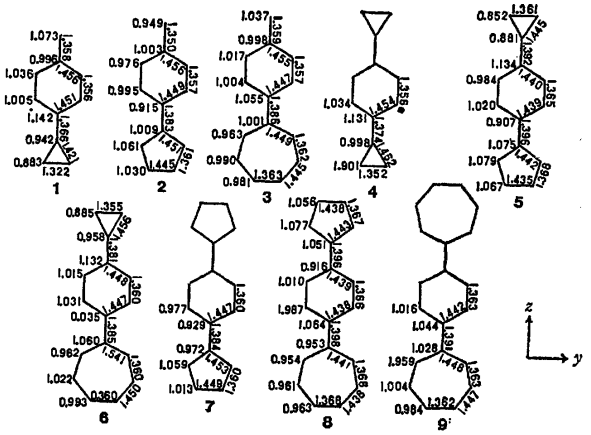

Fig. 1. Electron densities (in units of one electron) and bond lengths (in units of Å) of quinarenes.

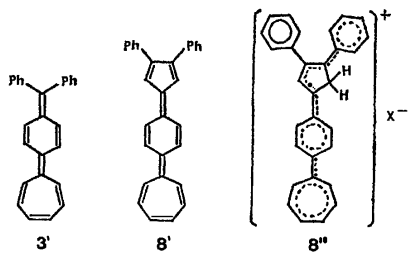

Fig. 2.

The calculated charge densities and bond lengths are shown in Fig. 1. The dipole moments of **1**, **2**, **3**, **5**, **6**, and **8** were predicted to be 5.44, 3.87, 2.94, 12.85, 4.56, and 11.08 D respectively. The dipole moments of **1** and **5** turn out to be larger than those of **3** and **8**. This means that the electron-releasing power of the 3-membered ring should be appreciably greater than that of the 7-membered ring. This fact is reflected in the appreciable dipole moment calculated for **6**, the dipolar structure of this molecule being such that the negative pole is directed toward the 7-membered ring.

The calculated transition energies and oscillator

a) Ref. 8, in chloroform.

strengths, f, for the lowest three singlet transitions are presented in Table 1. The gross spectral features of **1**—**9** should be similar to those of triafulvene, pentafulvene, heptafulvene, triafulvalene, calicene, heptatriafulvalene,[9] pentafulvalene, sesquifulvalene, and heptafulvalene[10] respectively, except for the fact that the absorption maxima for the former are predicted to shift to wavelengths longer than those for the latter.

We have also calculated the electronic spectra of **3′**. The observed electronic spectra of the pigment formed on the attempted preparation of **3′** show absorption maxima at 2.05 ($\log\varepsilon$=4.28) and 2.92 eV ($\log\varepsilon$=4.27).[7] The calculated transition energies for **3′** are 2.05 (f=0.012), 2.25 (f=2.46), 3.69 (f=0.004), and 3.84 eV (f=0.001). The pigment obtained is not expected to be **3′**, since the observed second absorption maximum is not found in the predicted spectra.

The unknown compound obtained recently by Takahashi *et al.*[8] in an attempt to synthesize **8′** seems to be either the aimed-molecule (**8′**) or the quinarenium ion of **8′** (the **8″** molecule Fig. 2). The calculated results for **8′** and **8″** are summarized in Table 2*, and compared with the observed results for the unknown compound. The experimental values for the unknown compound are in better agreement with the calculated values for **8″** than with those calculated for **8′**. From this fact, it may be concluded that the unknown compound is likely to be **8″**, not **8′**.

Abnormal Grignard Reaction of 2,4,6-Trimethylbenzophenone: An Electron-transfer Mechanism

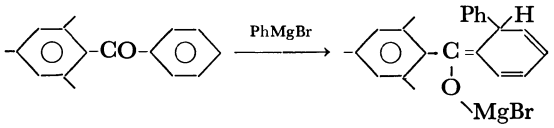
Masao Ōkubo

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honshō-chō, Saga 840

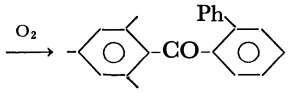
(Received June 24, 1974)

Synopsis. The reaction of 2,4,6-trimethylbenzophenone with phenyl-MgBr in tetrahydrofuran was examined by ESR technique. A high amount of the ketyl radical was detected. An electron-transfer mechanism was proposed to explain the formation of *o*-biphenylyl mesityl ketone.

2,4,6-Trimethylbenzophenone(I) undergoes nuclear phenylation in the reaction with phenyl-MgBr as reported by Fuson *et al.*[1] They explained the formation of *o*-biphenylyl mesityl ketone(III) in terms of 1,4-addition followed by air-oxidation.



(I) (II)



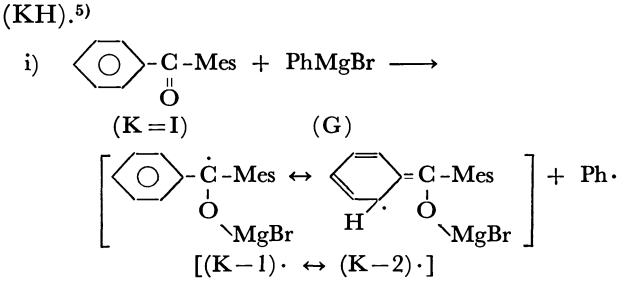
(III)

However, aeration of the ether extract of the hydrolyzed reaction mixture did not improved the yield of III. Intense red-coloration of the reaction solution seemed to indicate the presence of the ketyl radical derived from I. These results led the author to re-examine the reaction by means of ESR spectroscopy.

When ketone I was treated with five moles of phenyl-MgBr in tetrahydrofuran (THF) under vacuum at room temperature, the colorless solution turned to wine-red. A radical species was detected, its concentration increasing gradually and becoming *ca.* 30 mol% of the original ketone after four days. When the colored solution was sufficiently diluted, ESR spectrum A (Fig. 1) consisting of ninety lines evenly spaced at an interval of 0.23 gauss (total width 20.9 gauss) was obtained. When the dilution was not sufficient, the spectrum turned to one consisting of four broad lines (splitting constant 4.87 gauss, relative strength 1 : 3 : 3 : 1). Spectrum A was observed even after the solution had been allowed to stand for thirty days at room temperature.

The magnesium-ketyl prepared by the treatment of I with Mg-amalgum in THF gave a spectrum consisting of four broad lines, ascribable to the equivalent coupling of *o*- and *p*-hydrogen atoms of phenyl group with free spin.[2] However, when the treatment with amalgum was not sufficient, a spectrum identical with A was obtained. Since insufficient treatment left the original ketone mostly unchanged, spectrum A can be ascribed to a particular form of the ketyl radical existing as a dimeric or an oligomeric "aggregate" in which other neutral ketone molecules coordinate to the "monomeric" ketyl. The result of a recent work on the Grignard-ketyl of *o*-methylbenzophenone[3] suggests that "aggregate-formation" suppresses the twisting vibration of mesityl group out of the plane of benzoyl group, making it possible to observe the hyperfine splittings. The Grignard-ketyl of d_5-phenyl mesityl ketone gave a spectrum with the very small total width of 3.45 gauss, which indicates that almost all the free spin of Grignard-ketyl of I is delocalized on the phenyl group.[4] This can be explained in terms of the inhibition of conjugation due to the large twisting angle between the plane of the mesityl group and that of the benzoyl group.

As the observed radical concentration is high, most part of the original ketone may be involved in the "aggregate-formation." The main reaction should proceed in the agregate *via* an electron-transfer mechanism. The following processes can elucidate the formation of the identified products: the 1,4-adduct (II, AdH),[1] III(Ad)[1] and 2,4,6-trimethylbenzhydrol (KH).[5]



[(K−1)· ↔ (K−2)·]

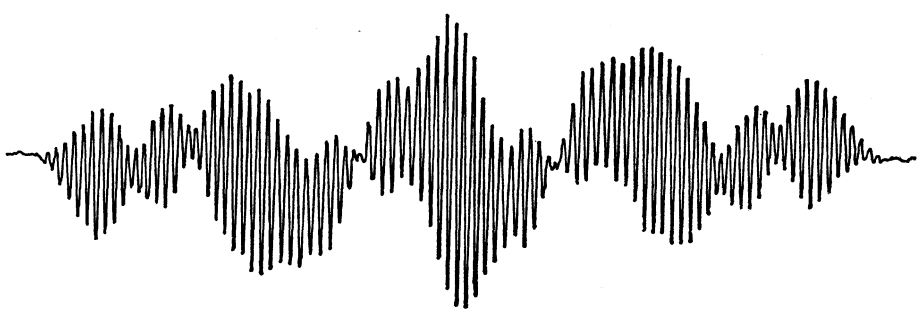


Fig. 1. ESR spectrum A obtained from the reaction of 2,4,6-trimethylbenzophenone and phenyl-MgBr.

ii) $(K-2)\cdot + (G) \rightarrow$ 
$(AdH)^{\overline{\cdot}}$

iii) $(AdH)^{\overline{\cdot}}{}^{+}MgBr + (K) \rightarrow$ 
(AdH=II)

$+ [(K-1)\cdot \leftrightarrow (K-2)\cdot]$

iv) $(AdH) + (K-2)\cdot \rightarrow$ 
(Ad)·

$+$ 
(KH-enol)

v) $(Ad)\cdot + (K) \rightarrow$ 
(Ad=III)

$+ [(K-1)\cdot \leftrightarrow (K-2)\cdot]$

(Mes=mesityl)

The five processes can explain the fact that product III(Ad) was obtained in a fair yield even if the reaction was carried out in the absence of air. Processes i), iii) and v) can also explain the presence of the high amount of ketyl radical throughout the course of reaction. The ketyl radical can be represented mainly by formula (K–2)· on the basis of the extremely high spin density on the phenyl group. The phenyl radical produced in process i) probably abstracts hydrogen from the solvent molecule.[6] Radical (K–2)·, which can be regarded as a neutral radical because of covalency of the O–Mg linkage, might reveal affinity towards another molecule of phenyl-MgBr, a nucleophile[7] (process ii). No *para*-phenylated product (*p*-biphenylyl mesityl ketone) was detected. Thus the attack of the carbanion on the *ortho*-position is favored because the position is nearer to the carbonyl-oxygen coordinating to the Mg-atom. The benzpinacol[8] was absent possibly due to the steric hindrance of the mesityl group.

Experimental

2,4,6-Trimethylbenzophenone was prepared from mesitylene and benzoyl chloride by the Friedel-Crafts method. d_5-Phenyl mesityl ketone was prepared by the same method with the use of d_5-benzoyl chloride. *o*-Biphenylyl mesityl ketone was prepared according to the reported method,[1] and *p*-biphenylyl mesityl ketone by the Friedel-Crafts method. 2,4,6-Trimethylbenzhydrol was obtained by reduction of the corresponding ketone.[5] *sym*-Diphenyldimesitylpinacol was prepared according to the method of Kharasch, Morrison and Urry.[8] The reaction products were compared with authentic samples by means of column- and thin-layer-chromatography.

The evacuated samples for ESR measurements were prepared according to the method previously reported.[9] The radical concentration was determined by the over-modulation technique with a THF solution of galvinoxyl as a standard in the same sample tube.

Photolysis of *p*-Benzoquinone in Aqueous Solution. Possibility of a Polar Mechanism in the Primary Process

Masamitsu SHIRAI, Toshio AWATSUJI, and Makoto TANAKA

Department of Applied Chemistry, Faculty of Engineering, University of Osaka Prefecture, Sakai, Osaka 591

(Received August 1, 1974)

Synopsis. The photochemistry of *p*-benzoquinone in water was investigated spectrophotometrically. The effect of *p*-nitroso-*N*,*N*-dimethylaniline as an additive confirmed a non-radical mechanism. The small positive deuterium isotopic effect suggests an electrophilic attack of the excited *p*-benzoquinone on water.

The photochemical reactions of *p*-benzoquinone (BQ) have been extensively studied in alcoholic solutions but less in aqueous solutions. In the photolysis of aqueous solutions of BQ, hydroquinone (HQ) has been isolated as the sole stable product in addition to the transient formation of benzene-1,2,4-triol (BTO) and 2-hydroxy-1,4-benzoquinone (HOBQ).[1] From the results it was suggested that the photolysis of BQ in aqueous solutions consists of a two stage process; formation of BTO from the reaction of the excited BQ with water molecule in the primary process, and dark reaction of BTO with BQ to yield HQ and HOBQ which is unstable in water in the secondary process. Kurien and Robins[2a] and Joschek and Miller[2b] proposed a radical mechanism for the primary process: the excited BQ abstracts a hydrogen atom from a water molecule forming semiquinone and a hydroxyl radical, the hydroxyl radical reacting with either the semiquinone radical or another BQ, ultimately resulting in the formation of BTO. Kano and Matsuo[3] suggested the possibility of an ionic mechanism including a cationic intermediate from the effect of micellar system on the photolysis of BQ in aqueous solutions. This paper presents some evidences supporting a polar mechanism in the primary process.

p-Nitroso-*N*,*N*-dimethylaniline(NDA), an effective hydroxyl radical scavenger,[4] was dissolved in an aqueous solution of BQ and an aqueous solution of sodium 9,10-anthraquinone-2-sulfonate(AQS), respectively. Absorption peaks of BQ and AQS were not affected by the added NDA. No direct photolysis of NDA occurred under our experimental conditions. Variation in absorbance during the course of irradiation with 313 nm light was followed at 247 nm, 255 nm, and 440 nm for BQ, AQS, and NDA, respectively. The results are shown in Fig. 1. No detectable change in the absorbance of NDA was observed in the photolysis of BQ in the BQ–NDA mixed system, while an appreciable decrease was observed in that of AQS in the AQS–NDA mixed system. The former result indicates that the photolysis of BQ takes place *via* a non-radical process. The latter result reflects a radical intermediate formation in the photolysis of aqueous AQS.[5]

The only basis for the radical mechanism[2a] was the halogen ion effect. Decrease in the quantum yield by the addition of halogen ion was ascribed to its function as radical scavenger. However, the effect

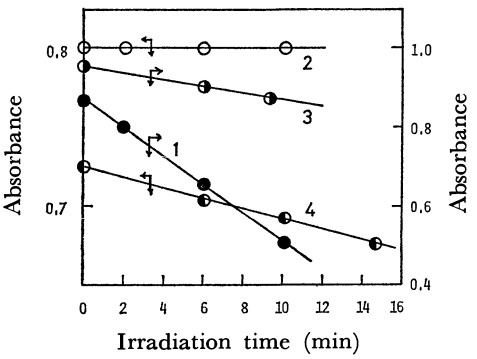

Fig. 1. Variations in the absorbance of BQ, AQS, and NDA with irradiation time.
a) BQ–NDA mixed system. $[BQ]=3.80\times10^{-5}$ M, $[NDA]=2.34\times10^{-5}$ M. Change in the absorbance; 1) at 247 nm for BQ, 2) at 440 nm for NDA.
b) AQS–NDA mixed system. $[AQS]=1.80\times10^{-5}$ M, $[NDA]=2.12\times10^{-5}$ M. Change in the absorbance; 3) at 255 nm for AQS, 4) at 440 nm for NDA.

of halogen ion should result from the quenching function as well as in the photolysis of aqueous AQS.[6] The Stern-Volmer plot for Cl^- as quencher gave a straight line.

The photochemistry of pyrimidine base in water has been investigated widely because of its significance in photobiology.[7] The photohydration of pyrimidine was suggested to occur *via* an electrophilic attack of the excited base on water. The small positive value ($k_H/k_D=1.18$) of the deuterium isotopic effect for uracil in acetonitrile–D_2O was ascribed to a secondary isotopic effect and provided strong evidence for the confirmation of an electrophilic attack mechanism.[8] The rate of photolysis of BQ in water (Fig. 2) was somewhat lower in D_2O than in H_2O. This small isotopic effect ($k_H/k_D=1.15$) suggests that the rate-determining step of the photolysis of BQ in water is

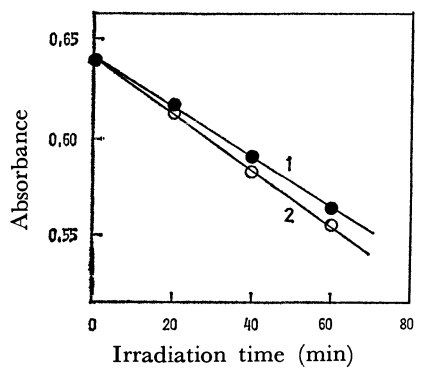

Fig. 2. Photolysis of BQ in H_2O and in D_2O.
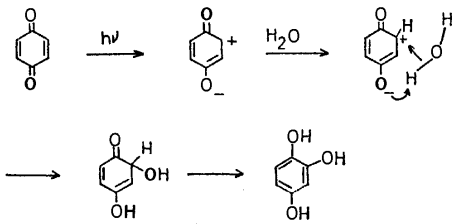
1) in D_2O, 2) in H_2O. $[BQ]=3.0\times10^{-5}$ M.

not a direct hydrogen abstraction from water but an electrophilic attack of the excited BQ on water, as well as uracil. There are several reports on the photo-induced polar reactions of cyclic enones[9] and dienones.[10] These polar reactions are explicable in terms of the contribution of polar state in the product controlling step.[11] The primary process of the photochemical reaction of BQ in water seems to pass through a polar intermediate as shown in Scheme 1.



Scheme 1.

Experimental

A Toshiba SHL-100 UV high-pressure mercury lamp was used as a light source. A combination filter, a Toshiba UV-D 25 filter, an aqueous nickel sulfate solution and a Pyrex filter were employed to obtain the light of 313 nm. The light intensity determined with aqueous potassium ferrioxalate as an actinometer was 7.1×10^{18} quanta$\cdot l^{-1} \cdot$ min.$^{-1}$ The photolysis in the presence of NDA was carried out with a light of wave length below 350 nm. The samples were irradiated in spectrophotometer cells at room temperature. The rate of photolysis for BQ was followed by the change in absorbance at 247 nm. HQ was isolated as the sole stable product but separation of HOBQ which is unstable in the dark was unsuccessful. The formation of BTO was confirmed by UV spectrum (λ_{max} 289 nm, $\varepsilon = 3300$). Spectra were measured on a Shimadzu UV-200 recording spectrophotometer. BQ was sublimed (mp 116°). NDA was recrystallized from ligroin (mp 86—87°). Water was purified by the usual method.

The Allylic Rearrangement. IV.[1] New Synthesis of 4-Hexenoic Acid

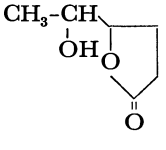
Sadao TSUBOI and Akira TAKEDA

Department of Synthetic Chemistry, School of Engineering, Okayama University, Tsushima, Okayama 700

(Received August 12, 1974)

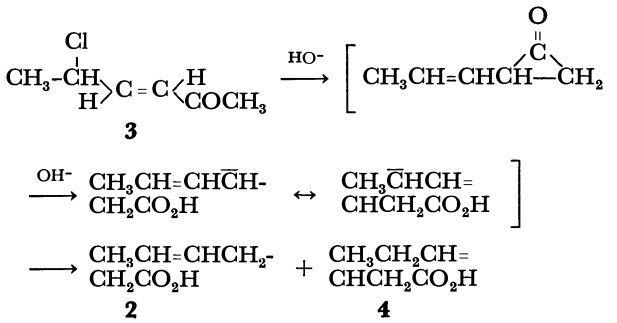
Synopsis. *trans*-4-Hexenoic acid, a useful starting material for the synthesis of racemic 4*R* : 5*S* and 4*S* : 5*R* 4,5-dihydroxyhexanoic acid γ-lactone, one component of the aroma extracts from one Californian and two Spanish flor sherries, has been conveniently prepared by the Favorskii-type rearrangement of 5-chloro-3-hexen-2-one.

The investigation of two samples of Spanish fino sherry and one sample of a California palomino flor sherry has been reported by Webb *et al.*[2] They were unable to identify two of the major high boiling components completely. Muller *et al.*[3] have isolated these components from the aroma extracts of the California palomino flor sherry, using the techniques described by Webb *et al.* and identified as (−) 4*R* : 5*R* or 4*S* : 5*S* 4,5-dihydroxyhexanoic acid γ-lactone and (+) 4*R* : 5*S* or 4*S* : 5*R* 4,5-dihydroxyhexanoic acid γ-lactone, which are diastereomeric forms of 5-(1′-hydroxyethyl)dihydro-2(3*H*)-furanone (**1**).



1

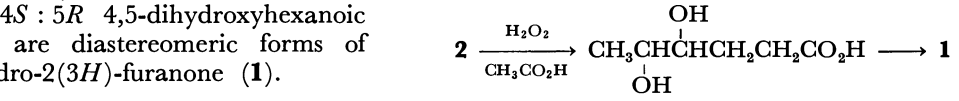
They have synthesized lactone **1** by the hydroxylation of *trans*-4-hexenoic acid (**2**), which was obtained from cyclopropyl methyl ketone *via* four steps by adaptation of the procedure reported by Julia *et al.*[4] This synthetic method of **2** seems to us less profitable for the purpose of a large scale preparation because only a mixture (approximately 1 : 1) of *trans* and *cis* isomers was obtained and gas-chromatographical fractionation was needed to isolate *trans*-**2**. We wish to report here a simple and more convenient synthesis of acid **2**, by means of the vinylogous Favorskii rearrangement[1] previously reported by us. The starting material, 5-chloro-3-hexen-2-one (**3**) was prepared by the Wittig-type reaction of 2-chloropropanal and diethylphosphonoacetone. Ketone **3** is thought to be of *trans* configuration because a large coupling constant (J=15.8 Hz) has been observed in its NMR spectrum. The treatment of ketone **3** with 15% aqueous NaOH afforded 4-hexenoic acid (**2**) in a 47% yield, with a small amount of 3-hexenoic acid (**4**). The formation of **2** can be well explained by the following mechanism involving a Favorskii-type rearrangement[1] of ketone **3**, the vinylogue of methyl α-chloroethyl ketone.



3 **2** **4**

The NMR spectrum of the product **2** exhibited a complicated pattern due to the existence of acid **4**, but its IR spectrum was identical with that of *trans*-acid **2** reported by Muller *et al.* Therefore, it is suspected that the *trans*-acid **2** obtained by Muller *at al.* also may be a mixture of the acid **2** and **4**.

trans Hydroxylation of the acid **2** with peracetic acid was done according to the Muller's procedure to give a racemic mixture of 4*R* : 5*S* and 4*S* : 5*R* 4,5-dihydroxyhexanoic acid γ-lactone (**1**) in a total yield of 29%.



Experimental

Materials. 2-Chloropropanal was prepared by the method described by us previously.[5] Diethyl phosphonoacetone was obtained by the procedure described in the literature,[6] yield 68%: bp 101—106 °C/4 mmHg (lit.[6] bp 126 °C/9 mmHg).

trans-*5-Chloro-3-hexen-2-one (**3**).* To a stirred solution of 0.96 g (0.04 mol) of sodium hydride in 60 ml of dry ether was added 7.7 g (0.04 mol) of diethyl phosphonoacetone at 0 °C. After evolution of hydrogen gas ceased, 3.7 g (0.04 mol) of freshly distilled 2-chloropropanal was added dropwise. The mixture was stirred for 30 min and then poured into a large amount of water. The ethereal extract of the organic layer was washed with water and dried over $MgSO_4$. After removal of the solvent, the residue was distilled to give 1.7 g (32%) of **3**: bp 65—70 °C/5 mmHg; IR (neat) 1695 (cisoid C=O), 1670 (transoid C=O), 1625 (C=C), 980 cm^{-1} ($\left(\text{H}\right)\text{C}=\text{C}\left(\text{H}\right)$); NMR ($CCl_4$) δ 1.65 (d, 3H, J=7 Hz, CH_3CHCl–), 2.20 (s, 3H, CH_3CO), 4.60 (doublet of quartet, 1H, J=7 Hz, CH_3CHCl–), 6.08 (d, 1H, J=15.8 Hz, –CH=CHCO–), 6.68 ppm (double d, 1H, J=7 and 15.8 Hz, –CH=CHCO–); MS (70 eV) *m/e* (rel. intensity) 132 (40, M^+, 1Cl), 117 (100, M^+-CH_3), 97 (84, M^+-Cl), 89 (75, M^+-COCH_3), 53 (75), 43 (84, $COCH_3$).

Found: C, 54.05; H, 6.81%. Calcd for C_6H_9ClO: C, 54.36; H, 6.84%.

trans-*4-Hexenoic Acid (**2**).* Ketone **3** (1.5 g, 0.011 mol) was added slowly to 15 ml of 15% aqueous NaOH with stirring at 50—55 °C. The mixture was stirred for 15 min, and washed with ether to remove neutral materials. The aqueous layer was treated with active charcoal, and then acidified with dilute hydrochloric acid. After the organic layer was extracted several times with ether, the combined etheral extract was dried over $MgSO_4$. Removal of the solvent left 0.59 g (crude yield 47%) of crude **2**. Tlc analysis[7] showed one clean spot at R_f value of 0.58: IR (neat)[8]

3500—2500 (COOH), 1710 (C=O), 1411, 1210, 1172, 968 cm^{-1} $\left(\begin{matrix}H\\ \\ H\end{matrix}\!\!>C=C<\!\!\begin{matrix}\\ \\ H\end{matrix}\right)$; NMR ($CDCl_3$)[9] δ 1.00 (t, 0.6H, $C\underline{H}_3CH_2$- of **4**), 1.63 (broad d, 3H, $C\underline{H}_3CH$=), 2.09 (m, 0.4H, $CH_3C\underline{H}_2$- of **4**), 2.37 (m, 4H, $-C\underline{H}_2C\underline{H}_2-$), 3.10 (m, 0.4H, $-C\underline{H}_2CO_2H$ of **4**), 5.50 (m, 2H, -CH=CH-), 9.57 ppm (broad s, 1.2H, CO_2H of **2** and **4**); MS (70 eV) *m/e* (rel. intensity) 114 (68, M^+), 99 (13, M^+-CH_3), 96 (13, M^+-H_2O), 68 (71), 55 (100).

*Racemic Mixture of 4R : 5S and 4S : 5R 4,5-Dihydroxyhexanoic Acid γ-Lactone (**1**).* Trans hydroxylation of **2** was carried out by the modification of the procedure of Muller *et al.*[3] A solution of 0.28 g of 30% H_2O_2 in 0.50 g of glacial acetic acid was heated for 30 min at 75 °C, and then cooled. The peracid solution was added dropwise to 0.21 g (0.0018 mol) of **2** with stirring. The solution was then heated at 40 °C for 30 min, cooled, and extracted with ether. The etheral solution was dried over $MgSO_4$, and then the solvent was removed. The residue (clean oil, 0.18 g) was analyzed by glpc.[10] The peaks, retention times (min), and integrated percentages are as follows: 1, 1.3, 11%; 2, 3.7, 37%; 3, 4.8, 12%; 4, 9.7, 40%. Component 2 was identified as the starting material **2** by comparison of the retention time. Component 4 was collected by preparative glpc and identified as **1** (yield 29%): IR (neat) 3440 (OH), 1760 (lactone C=O), 1415, 1190 cm^{-1}; NMR ($CDCl_3$) δ 1.20 (d, 3H, J=7 Hz, $-CH_3$), 2.0—3.0 (m, 4H, α- and β-H), 3.42 (s, 1H, OH), 4.10 (m, 1H, $CH_3C\underline{H}(OH)$-), 4.42 ppm (m, 1H, γ-H). Its IR and NMR spectra were identical with those of the lactone **1** reported by Muller[3]: IR (neat) 3436, 1762, 1415, 1192 cm^{-1}; NMR ($CDCl_3$) δ 1.20 (m, 3H), 2.0—3.0 (m, 4H), 3.00 (s, 1H), 4.10 (m, 1H), 4.42 ppm (m, 1H). Components 1 and 3 were not further investigated.

Potential Antitumor *N*-Carbamoyl-*N'*-methyl-*N'*-nitroso Derivatives of Amino Acids

Tomoya MACHINAMI and Tetsuo SUAMI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received October 16, 1974)

Synopsis. *N*-Carbamoyl-*N'*-methyl-*N'*-nitroso derivatives of amino acids have been prepared by treating the amino acids with methyl isocyanate followed by nitrosation with sodium nitrite in dilute acetic acid solution.

An *N*-alkyl-*N*-nitrosoureido group seems to be an essential functional group for the appearance of biological activity in streptozotocin[1] and its analogues.[2-4] In all the compounds studied so far in our laboratory, the functional group was attached to a carbohydrate residue, which does not seem to have an inconvertible role in their biological activity. Therefore, it might be possible to replace the carbohydrate moiety by other groups without losing the antitumor activity.

In the present paper, we wish to report a preparation of *N*-carbamoyl-*N'*-methyl-*N'*-nitroso derivatives of amino acids.

Potassium cyanate[5] or aryl isocyanate[6,7] have been used to prepare carbamoyl derivatives of amino acids. Under similar reaction conditions, methyl isocyanate was used to prepare *N*-carbamoyl-*N'*-methyl derivatives of glycine, alanine, aspragine, phenylalanine and methionine in the present study. The *N*-carbamoyl-*N'*-methyl derivatives of phenylalanine and methionine were obtained only as the potassium salts. Acidification of the salts resulted in an intramolecular cyclization giving hydantoin derivatives, which had large negative optical rotations.[8] Formation of hydantoin from a carbamoyl derivative under more drastic conditions has been described in a literature.[5,9-11]

Nitrosation of the *N*-carbamoyl-*N'*-methyl derivatives was performed in aqueous acetic acid solution with sodium nitrite at 0 °C, and the structure of the product was determined by PMR. The spectrum of the product had a singlet at τ 6.8—6.9 corresponding to N–CH_3 protons, clearly indicating the absence of a proton on the nitrogen atom attached to the methyl group.

The antitumor activities will be reported in the near future in an appropriate journal.

Experimental

Glycine, L-alanine, L-asparagine, L-phenylalanine and L-methionine were purchased from Asahi Kasei. Melting points were determined in capillary tubes and are uncorrected. PMR spectra were measured at 60 and 100 MHz on a Varian A-60D and a JEOL JMN-MH 100 spectrometers with reference to tetramethylsilane as an internal standard and the peak positions are given in τ values.

General Procedure for N-*Carbamoyl*-N'-*methyl Amino Acids.* The amino acid was dissolved in an equivalent molar amount of 10% potassium hydroxide solution and methyl isocyanate was added to the solution under ice cooling. The mixture was agitated overnight at room temperature and the pH was brought to 2—3 with Amberlite IR-120 (H^+ type). The solution was evaporated under reduced pressure below 30 °C to give a crude product.

N-*Carbamoyl*-N'-*methyl-glycine* (**1**). The crude crystalline product was recrystallized from methanol to give **1**, mp 147—148 °C, in 81% yield.

Found: C, 36.44; H, 6.07; N, 21.53%. Calcd for $C_4H_8N_2O_3$: C, 36.36; H, 6.10; N, 21.20%.

N-*Carbamoyl*-N'-*methyl*-L-*alanine* (**3**). The crude product was crystallized from ethanol and recrystallized from the same solvent to give **3**, mp 137—138 °C, $[\alpha]_D^{15}$ +3.0° (*c* 1.0, water), in 56% yield.

Found: C, 40.79; H, 6.74; N, 19.07%. Calcd for $C_5H_{10}N_2O_3$: C, 41.09; H, 6.90; N, 19.17%.

N-*Carbamoyl*-N'-*methyl*-L-*asparagine* (**5**). The crude product was crystallized from ethanol to give **5**, mp 142—143 °C, $[\alpha]_D^{15}$ +7.5° (*c* 1.0, water), in 66% yield.

Found: C, 38.32; H, 5.95; N, 22.44%. Calcd for $C_6H_{11}N_3O_4$: C, 38.09; H, 5.86; N, 22.21%.

Potassium Salt of N-*Carbamoyl*-N'-*methyl*-L-*phenylalanine* (**7**). The reaction mixture was evaporated without the treatment with Amberlite IR-120. The residue was crystallized from ethanol and the crystalline product was recrystallized from the same solvent to give **7** as hygroscopic needles, mp 179 °C (dec.), $[\alpha]_D^{24}$ +34.2° (*c* 1.0, water), in 69% yield.

Found: C, 47.28; H, 5.14; N, 9.67%. Calcd for $C_{11}H_{13}N_2O_3K \cdot H_2O$: C, 47.47; H, 5.43; N, 10.06%.

Potassium Salt of N-*Carbamoyl*-N'-*methyl*-L-*methionine* (**9**). The mixture was evaporated without the treatment with Amberlite IR-120. The residue was crystallized from isopropyl alcohol and the product was recrystallized from the same solvent to give **9**, mp 162—164 °C, $[\alpha]_D^{22}$ +4.7° (*c* 1.0, water), in 91% yield.

Found: C, 34.19; H, 5.46; N, 11.46%. Calcd for $C_7H_{13}N_2O_3SK$: C, 34.41; H, 5.36; N, 11.46%.

5-Benzyl-3-methyl-hydantoin (L-*Phenylalanine hydantoin*) (**11**). A 2.3 g portion of **7** was dissolved in water (20 ml) and the solution was adjusted to pH 3 with Amberlite IR-120 (H^+ type) to give an oily precipitate. Ethanol was added to the mixture until the precipitate was dissolved. The ion exchange resin was removed by filtration and the filtrate was evaporated to give a crystalline residue. The residue was recrystallized from methanol to give 1.6 g (93%) of **11**, mp 164—166 °C, $[\alpha]_D^{21}$ −103° (*c* 1.0, ethanol). PMR ($CDCl_3$): τ 7.12 (s, 3H, NCH_3).

Found: C, 64.58; H, 5.94; N, 13.79%. Calcd for $C_{11}H_{12}N_2O_2$: C, 64.69; H, 5.92; N, 13.71%.

3-Methyl-5-(methylmercapto)ethyl-hydantoin (L-*Methionine hydantoin*) (**12**). Compound **9** (6.0 g) was dissolved in water (50 ml) and the solution was adjusted to pH 3 with Amberlite IR-120 (H^+ type). The solution was evaporated under reduced pressure to give a syrup, which yielded crystals in 2-methoxyethanol at −20 °C. Recrystallization from the same solvent afforded 0.7 g (13%) of **12**, mp 88—89 °C, $[\alpha]_D^{17}$ −56.1° (*c* 1.0, ethanol). PMR ($CDCl_3$): τ 7.02 (s, 3H, NCH_3).

Found: C, 45.00; H, 6.36; N, 14.59; S, 17.33%. Calcd for $C_7H_{12}N_2O_2S$: C, 44.66; H, 6.43; N, 14.88; S, 17.03%.

General Procedure for Nitrosation. The *N*-carbamoyl-*N'*-methyl amino acid or its potassium salt was dissolved in aqueous acetic acid and sodium nitrite was added to the solution under ice cooling with agitation. The solution was settled overnight and afterwards treated with Amberlite IR-120 (H^+ type), the solution was lyophylized to give a crude product.

N-*Carbamoyl*-N'-*methyl*-N'-*nitroso-glycine (2).* The crude product was crystallized from chloroform to give **2**, mp 116—117 °C in 63% yield. PMR (C_5D_5N): τ 5.46 (d, 2H, CH_2), 6.86 (s, 3H, NCH_3); (C_5D_5N–D_2O): τ 5.32 (s, 2H, CH_2).

Found: C, 30.12; H, 4.43; N, 25.91%. Calcd for $C_4H_7N_3O_4$: C, 29.82; H, 4.38; N, 26.08%.

N-*Carbamoyl*-N'-*methyl*-N'-*nitroso*-L-*alanine (4).* The residue was crystallized from ether to give **4**, mp 85—87 °C, $[\alpha]_D^{15}$ +71° (*c* 1.0, chloroform) in 62% yield. PMR (C_5D_5N): τ 4.7—5.1 (m, 1H, CH), 6.84 (s, 3H, NCH_3); (C_5D_5N–D_2O): τ 5.08 (q, 1H, CH).

Found: C, 34.07; H, 5.16; N, 24.21%. Calcd for $C_5H_9N_3O_4$: C, 34.29; H, 5.18; N, 23.99%.

N-*Carbamoyl*-N'-*methyl*-N'-*nitroso*-L-*asparagine (6).* The crude product was crystallized from ethanol to give **6**, mp 139 °C, $[\alpha]_D^{26}$ +12°‖ (*c* 0.5, water), in 61% yield. PMR (C_5D_5N): τ 4.2—4.5 (m, 1H, CH), 6.84 (s, 3H, NCH_3); (C_5D_5N–D_2O): τ 4.49 (t, 1H, CH).

Found: C, 33.25; H, 4.70; N, 25.52%. Calcd for $C_6H_{10}N_4O_5$: C, 33.03; H, 4.62; N, 25.68%.

N-*Carbamoyl*-N'-*methyl*-N'-*nitroso*-L-*phenlalanine (8).* A 0.5 g portion of **11** and sodium nitrite (0.21 g) were dissolved in cold water (10 ml) and a mixture of glacial acetic acid (0.2 ml) and ether (10 ml) was added to the solution cooled by ice with gentle agitation. After the mixture was stirred overnight at room temperature, the etheral layer was washed with water, dried over anhydrous sodium sulfate and evaporated. The residue was crystallized from ethyl acetate–*n*-pentane to give 0.23 g (51%) of **8**, mp 97—98 °C, $[\alpha]_D^{28}$ −18° (*c* 0.2, ethanol). PMR ($CDCl_3$): τ 4.7—5.1 (m, 1H, CH), 6.82 (s, 3H, NCH_3); ($CDCl_3$–D_2O): 4.92 (t, 1H, CH)

Found: C, 52.53; H, 5.21; N, 16.71%. Calcd for $C_{11}H_{13}N_3O_4$: C, 52.59; H, 5.21; N, 16.73%.

N-*Carbamoyl*-N'-*methyl*-N'-*nitroso*-L-*methionine (10).* **9** (1.0 g) was dissolved in water (6 ml), and the solution was added to a mixture of sodium nitrite (0.48 g), glacial acetic acid (0.4 ml) and water (3 ml) under ice cooling with agitation. After standing at room temperature overnight, the solution was treated with Amberlite IR-120 (H^+ type) and extracted with chloroform. The chloroform solution was dried over anhydrous sodium sulfate and evaporated. The residue was crystallized from acetone to give 780 mg (75%) of **10**, mp 103—104 °C, $[\alpha]_D^{22}$ +17° (*c* 1.0, chloroform). PMR ($CDCl_3$): τ 4.8—5.3 (m, 1H, CH), 6.81 (s, 3H, NCH_3); ($CDCl_3$–D_2O): τ 5.19 (t, 1H, CH).

Found: C, 35.97; H, 5.63; N, 18.12; S, 13.35%. Calcd for $C_7H_{13}N_3O_4S$: C, 35.74, H, 5.57; N, 17.86; S, 13.63%.

Our thanks are due to Mr. Saburo Nakada who performed the elemental analyses and to Mr. Hitoshi Kimura who assisted in the preparations.

Syntheses of Fluorine-Containing Chromans: A Radical Cycloaddition of Phenyl Alkyl Ethers with Hexafluoropropene

Hiroshi KIMOTO, Hiroshige MURAMATSU, and Kan INUKAI

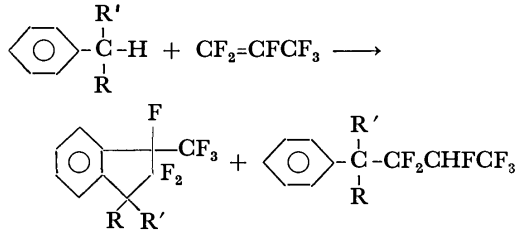
Government Industrial Research Institute, Nagoya, Hirate-machi, Kita-ku, Nagoya 462

(Received October 22, 1974)

Synopsis. Four 2-substituted 4-trifluoromethyl-3,3,4-trifluorochromans were synthesized in one step by the radical cycloaddition of phenyl alkyl ethers and hexafluoropropene in the presence of di-*t*-butyl peroxide.

Although the syntheses of compounds containing a five or six membered ring fused to an aromatic ring are established in the ionic process, such as the Friedel-Crafts ring closure and various condensation reactions, only a few investigations have been reported on the radical process, such as the radical cycloaddition reaction of aromatic compounds with olefins.

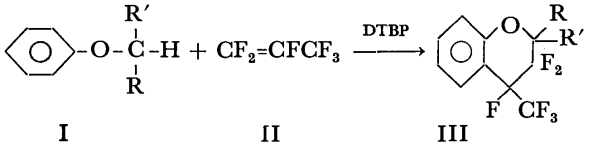
In a previous communication[1] we reported on the syntheses of 1-trifluoromethyl-1,2,2-trifluoroindanes by the radical cycloaddition reaction of alkylbenzenes with hexafluoropropene.



(R, R′ : H, CH_3)

The present work was undertaken with the aim of extending this type of cycloaddition to phenyl alkyl ethers(I), and preparing the fluorine-containing chromans(III).

Four 4-trifluoromethyl-3,3,4-trifluorochromans(III) were synthesized in one step from I and hexafluoropropene(II) in the presence of di-*t*-butyl peroxide.



I II III

(Ia, IIIa: R=R′=H; Ib, IIIb[2]: R=H, R′=CH_3; Ic, IIIc: R=R′=CH_3)

To investigate the effect of dilution with a solvent, two kinds of experimental procedure were employed: method A in which no solvent was used, and method B in which inert solvent was used. The reaction conditions and product yields are given in Table 1.

TABLE 1. THE RADICAL CYCLOADDITION REACTION OF PHENYL ALKYL ETHERS AND HEXAFLUOROPROPENE

	Phenyl alkyl ether (mol)	HFP (mol)	DTBP (mol)	Method[a]	Conversion (%)	Yield[b] (%)	Higher boiling products (g)
Ia	0.400	0.660	0.410	A	39.9	44.1	59
Ia	0.400	0.579	0.410	B	33.0	66.7	44
Ib	0.400	0.641	0.410	A	38.7	36.0	83
Ib	0.400	0.561	0.410	B	31.9	85.9	41
Ic	0.400	0.683	0.410	A	37.6	56.1	49
Ic	0.400	0.608	0.410	B	17.5	74.3	49

a) Method A: no solvent; Method B: CCl_2FCClF_2 (1.00 mol) as a solvent.
b) Yields are calculated from the amounts of the consumed phenyl alkyl ether.

As compared with the case of cycloaddition reactions of alkylbenzenes,[1] less reactive phenyl alkyl ethers afford the cycloadducts in a lower conversion, no 1 : 1 adduct, $C_6H_5OCRR'CF_2CHFCF_3$ being formed. Lack of 1 : 1 adduct formation might be due to the incapability of the intermediate radical ($C_6H_5OCRR'CF_2\dot{C}FCF_3$) to abstract a hydrogen from less reactive phenyl alkyl ethers.

Of the two methods A and B, the former is slightly better in total conversion, although a larger quantity of higher boiling products is produced. Higher yields of III were eventually obtained by method B. The yield of III was almost the same with each of the three kinds of phenyl alkyl ethers. Two stereoisomers, IIIb-1 and IIIb-2, were obtained from Ib in the ratio 1 : 3.

In order to prepare the corresponding chromen, dehydrofluorination of IIIa was attempted by treating it with an alcoholic potassium hydroxide solution, but no reaction occurred even in a reflux condition.

The structures of III were elucidated by IR, NMR and mass spectra.

In the mass spectrum, the large molecular ion peak was observed in each chroman(III). Another large ion peak of IIIa, IIIb-1 and IIIb-2 was generated by the loss of CF_3 group from the molecule, IIIc being cleaved to two fragments, *m/e* : 92 C_6H_4O and *m/e* : 192 $(CH_3)_2CCF_2CFCF_3$. Two stereoisomers, IIIb-1 and IIIb-2, gave an identical pattern of fragmentation.

The effect of temperature on the proton NMR spectra was studied in the region from −80 °C to 35 °C. No variation of the spectra was observed. Since no temperature variation was observed in ^1H NMR spectrum, it seems that most of the molecules have a fixed conformation at room temperature.[3] The predominant conformation of the dihydropyrane ring of III may be that of the half-chair form in the same manner as for cyclohexene.[4] Since the CF_3 group is bulky, the molecules are fixed in a position having the CF_3 group in the *quasi*-equatorial position. Non-equivalent *quasi*-axial and equatorial fluorines of each CF_2 group of all the chromans and protons of the CH_2 group of IIIa produced separate AB patterns, methyl groups of IIIc being also non-equivalent. Two isomers, IIIb-1 and IIIb-2, could be observed between the methyl group having a *quasi*-axial position and that having a *quasi*-equatorial one. These configurations were estimated by means of the vicinal H–F coupling constants. By irradiation on methyl protons, quartet splitting was removed from complex multiplet of their tertiary proton spectrum, leaving doublets of doublets (J=7.2 Hz, 18.4 Hz for lower

boiling isomer, IIIb-1 and $J=5.2$ Hz, 23.7 Hz for higher boiling isomer, IIIb-2). The largest doublet splitting (23.7 Hz) might be due to the vicinal coupling of *quasi*-axial hydrogen with *quasi*-axial fluorine.[5] Thus higher boiling isomer (IIIb-2), which was predominant, seems to have its methyl group in the *quasi*-equatorial position.

Characterization of the NMR spectra was made on the basis of the following rules;

(1) chemical shifts of fluorine
$\delta CF > \delta CF_2 > \delta CF_3$

(2) coupling type in the fragment H-C-C-F[5]
$J_{H^{ax}-F^{ax}} > J_{H^{eq}-F^{eq}} > J_{H^{ax}-F^{eq}}$, $J_{H^{eq}-F^{ax}}$

(3) coupling type in the fragment F-C-C-F[6]
$J_{F^{ax}-F^{eq}} > J_{F^{ax}-F^{ax}}$

(4) coupling type in the fragment F-C-C-CF_3[7]
$J_{F^{ax}-CF_3{}^{eq}} > J_{F^{eq}-CF_3{}^{eq}}$

Since signals of CH_2 and CF_2 appeared in a complex ABXY pattern in the spectrum of IIIa, it is not certain to which fluorine nuclei the CH_2 proton couples by first-order analysis. Many sets of heteronuclear and fluorine-fluorine decoupling experiments were needed in order to characterize the spectrum completely. Very weak long-range proton–fluorine couplings were indicated by the signal width.

Mass and NMR spectral data are shown in Table 2 and physical properties and analytical data in Table 3.

Experimental

Phenyl isopropyl ether (Ic) was prepared (yield 69%) from phenol and isopropyl bromide in the presence of sodium hydroxide, according to the method of Marvel and Tanenbaum.[8]

General Procedures Used in the Cycloaddition Reactions of Phenyl Alkyl Ethers(I) with Hexafluoropropene(II). *Method A*: A mixture of I (0.40 mol), II (0.64—0.68 mol) and DTBP (60 g, 0.41 mol) was heated in a 300 ml stainless steel autoclave at temperature gradually rising from 130 °C to 160 °C for about 6 hr. The products were separated by vacuum distillation.

Method B: A solution of I (0.40 mol), II (0.56—0.61 mol) and DTBP (60 g, 0.41 mol) in 1,1,2-trichloro-1,2,2-trifluoroethane (187 g, 1.00 mol) was heated in a 500 ml stainless steel autoclave, under the same conditions as used for method A. After removal of the solvent, the residue was distilled *in vacuo*.

The stereoisomers IIIb-1 and IIIb-2 were separated on preparative glc (with an aluminum column, length 6 m, dia. 10 mm, packed with 20% Silicone DC550–Celite 545).

Catalytic Transformation of Cyclohexene Hydroperoxides to Epoxy Alcohols with Vanadyl Acetylacetonate

Takashi ITOH, Kiyotomi KANEDA, and Shiichiro TERANISHI

Department of Chemical Engineering, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

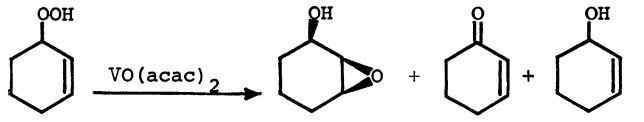
(Received November 5, 1974)

Synopsis. Cyclohexene hydroperoxide and its methyl derivatives undergo rearrangement in the presence of the vanadyl acetylacetonate catalyst to the corresponding epoxy-alcohols with high *cis*-stereoselectivity in high yields.

Hydroperoxide decomposition with transition metals can be classified mainly into homolytic decomposition (Fe, Co, Cu catalysts)[1] and heterolytic decomposition (Mo, V, W catalysts).[2] Rhodium complexes catalyze the homolytic decomposition of cyclohex-2-enyl hydroperoxide (I) to cyclohex-2-en-1-one (II) and cyclohex-2-en-1-ol (III).[3] Little information is available on the heterolytic decomposition of cyclohexene hydroperoxides.

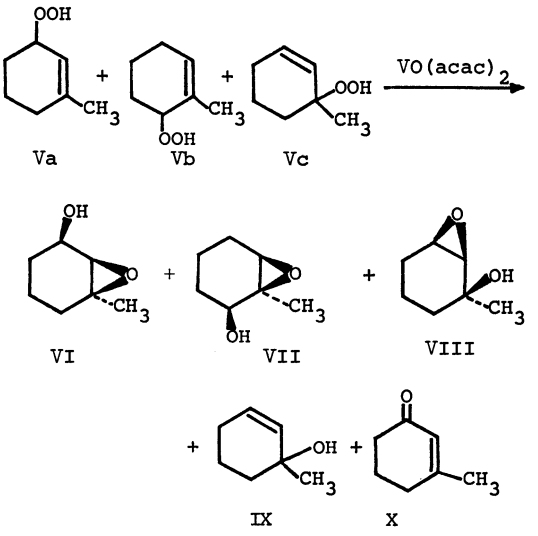
We wish to report the selective transformation of cyclohexene hydroperoxides with the $VO(acac)_2$ catalyst into *cis*-epoxy-alcohols.

The reaction of cyclohex-2-enyl hydroperoxide (I) with $VO(acac)_2$ was carried out in benzene with stirring under nitrogen atmosphere at 40 °C. After 4 hr, glc analysis of the resulting solution revealed that the main product was 2,3-epoxy-cyclohexanol (IV) (79% yield based on consumed peroxide) accompanied by a small amount of the usual decomposition products (II (8%) and III (5%)). The stereochemistry of this epoxy-alcohol was assigned to *cis*-configuration by IR and NMR spectra.[4] The presence of *trans*-isomer could not be detected by glc analysis.

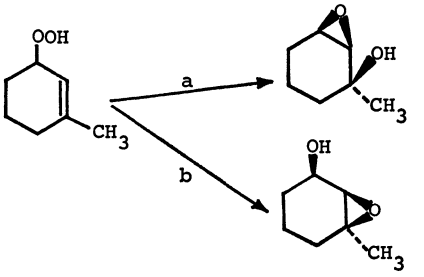


In order to ascertain the generality of this reaction and to clarify the stereochemistry of the rearrangement, hydroperoxides from an unsymmetric olefin were also investigated. Thus, a mixture of three hydroperoxides from 1-methylcyclohexene, containing 3-methylcyclohex-2-enyl hydroperoxide (Va) (51%), 2-methylcyclohex-2-enyl hydroperoxide (Vb) (34%) and 1-methylcyclohex-2-enyl hydroperoxide (Vc) (15%), was treated with $VO(acac)_2$ under the same conditions. The main products were three epoxy-alcohols, 3-methyl-*cis*-2,3-epoxycyclohexanol (VI) (46%), 2-methyl-*cis*-2,3-epoxycyclohexanol (VII) (24%) and 1-methyl-*cis*-2,3-epoxycyclohexanol (VIII) (1%).

The structures of the three epoxy-alcohols were assigned by comparison of their NMR and IR spectra and retention times with those of authentic samples prepared by the $VO(acac)_2$ catalyzed epoxidations of the corresponding methylcyclohexenols with *t*-butyl hydroperoxide.[5] *cis*-Configurations of these epoxy-alcohols were further confirmed by the reductive opening of epoxide rings with $LiAlH_4$ to the corresponding *cis*-diols.[6]



The product distribution of the above reaction showed that peroxides Va, Vb and Vc were transformed into epoxy-alcohols VI, VII and VIII, respectively. This indicates that the transformation follows reaction pattern b rather than pattern a.[7]



Scheme 1.

Thus, $VO(acac)_2$ catalyst can transform cyclohexene hydroperoxides selectively into epoxy-alcohols with a high *cis*-stereoselectivity (*cis*-isomer>99%). $V(acac)_3$ gave lower yields and selectivity. The molybdenum analogue $MoO_2(acac)_2$ was found to be a poor catalyst.

Equimolar reaction of cyclohexene hydroperoxide and $VO(acac)_2$ gave II (25%), III (63%) and a trace amount of IV. ESR study showed that the addition of hydroperoxide (I) to the benzene solution of $VO(acac)_2$ (molar ratio 1 : 1—5 : 1) causes a large reduction (85—90%) in the strength of the V^{IV} signal and no new other signals appeared. Thus, it seems that $VO(acac)_2$ can be oxidized with hydroperoxide

to higher valence species (V^v), which might act as an actual catalyst for the formation of epoxy-alcohols.

Experimental

Materials. Cyclohexene hydroperoxides, I and V, were prepared as reported previously.[3] The purity was determined by iodometric titration;[8] I (86%) and V (87%). Impurities found were the corresponding cyclohexenols and cyclohexenones. The isomer distribution of hydroperoxides (V) was determined by the area ratios of signals of vinylic protons and hydroperoxy protons in NMR spectrum.

Reaction of I. Peroxide I (10 mmol) in 5 ml dry benzene solution was added dropwise to a 25 ml dry benzene solution of $VO(acac)_2$ (0.1 mmol) at 40 °C under nitrogen atmosphere with stirring. After 4 hr, 98% of I was consumed. Three products were found by glc analysis (OV 17 at 80 °C); IV (7.7 mmol), II (0.8 mmol) and III (0.5 mmol). These compounds were identified by comparison of their NMR and IR spectra and retention times with those of authentic samples.[3,4]

Fractional distillation under reduced pressure gave IV (0.65 g); bp 86 °C/6 mmHg (Ref.,[4] 100—102 °C/12 mmHg).

Reaction of V. The same procedure as for I was used. Three epoxy-alcohols were obtained as the main products by glc analysis (PEG 6000 at 120 °C); VI (4.5 mmol), VII (2.4 mmol) and VIII (0.1 mmol). VI; IR (neat) 3400, 1092, 1034, 888 and 839 cm^{-1}. NMR (CCl_4) τ 6.13 (m, 1H), 7.00 (d, 1H), 7.9—8.8 (m, 6H) and 8.69 (s, 3H). VII; IR (neat) 3400, 1041 and 835 cm^{-1}. NMR (CCl_4): τ 6.32 (m, 1H), 6.96 (t, 1H), 7.8—8.7 (m, 6H) and 8.62 (s, 3H). VIII; IR (neat) 3400, 1143, 1100, 1087, 930, 857 and 820 cm^{-1}. NMR (CCl_4): τ 6.70 (m, 1H), 7.09 (d, 1H), 7.7—8.8 (m, 6H) and 8.66 (s, 3H). The usual decomposition products, methylcyclohexenols and methylcyclohexenones, *e.g.*, IX (0.8 mmol) and X (0.5 mmol), were minor products.

$LiAlH_4$ Reduction of Epoxy-alcohol to cis*-Diol.* VII was separated by preparative glc and then 1.0 mmol of VII was treated with 2.5 mmol of $LiAlH_4$ in 10 ml dry ether. From ethyl acetate extract of the reaction mixture, white crystals of 1-methylcyclohexane-*cis*-1,2-diol (0.08 g, 0.6 mmol) were obtained; mp 68.0—68.5 °C (Ref.,[9] 68.5 °C). NMR (C_2D_5OD): τ 5.60 (m, 1H), 8.1—8.8 (m, 8H) and 8.84 (s, 3H).

The Preparation of Aryl Heptafluoroisopropyl Ketones from Aroyl Chlorides and Hexafluoropropene in the Presence of Fluoride Ions

Nobuo ISHIKAWA and Seiji SHIN-YA

Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received November 25, 1974)

Synopsis. Aroyl chlorides and hexafluoropropene in the KF/DMF system gave aryl heptafluoroisopropyl ketones. The substituent effect on the yield was discussed.

The hexafluoroisopropyl anion prepared from hexafluoropropene (HFP) and the fluoride ion in an aprotic polar solvent is known as a useful nucleophile for heptafluoroisopropylation.[1] As for the preparation of perfluoroisopropyl ketons, $(CF_3)_2CF-CO-R_f$, Smith *et al.*[2] have obtained perfluoroalkyl heptafluoroisopropyl ketones by the reaction of this nucleophile with various perfluoroacyl fluorides. In the aromatic series, Chambers *et al.*[3] have reported on the similar formation of perfluoro(isopropyl phenyl ketone) and perfluoro-(isopropyl 4-pyridyl ketone) from pentafluorobenzoyl or tetrafluoroisonicotinoyl fluorides respectively. However, they mentioned that pentafluorobenzoyl chloride did not react with HFP under the same conditions.

We wish now to report a convenient method for the preparation of aryl heptafluoroisopropyl ketones in which aryl groups are the general substituted or unsubstituted phenyls. In this case, satisfactory yields were obtained by the reaction of aroyl chlorides with hexafluoropropene in the presence of the fluoride ion and it was not necessary to use aroyl fluorides as the starting material. The reactions were carried out in the potassium fluoride–dimethylformamide system at 120—130 °C under an autogeneous pressure. The amount of potassium fluoride must be present in excess, probably to convert the aroyl chloride into fluoride.

$$CF_3CF{=}CF_2 + F^- \rightleftharpoons (CF_3)_2CF^- \quad (1)$$

$$Ar\text{-}\underset{\underset{O}{\|}}{C}\text{-}Cl + F^- \rightleftharpoons Ar\text{-}\underset{\underset{O}{\|}}{C}\text{-}F + Cl^- \quad (2)$$

$$Ar\text{-}\underset{\underset{O}{\|}}{C}\text{-}F + (CF_3)_2CF^- \rightleftharpoons Ar\text{-}\underset{\underset{O}{\|}}{C}\text{-}CF(CF_3)_2 + F^- \quad (3)$$

For the purpose of checking the scope of this reaction, we also examined a similar reaction between substituted aroyl chlorides and HFP.

The effects of the substituents of the aroyl halides upon the yields of the heptafluoroisopropyl ketones were noteworthy. The strong electron-attractive *p*-nitro group and the strong electron-donative *p*-methoxy group both served to produce poor yields (Table 1). In the former case, it was assumed that the *p*-nitrophenyl heptafluoroisopropyl ketone formed must be very unstable thermodynamically, because the carbon atom of the carbonyl group is linked on both sides to the strong electron-attractive groups. Then the equilibrium of Eq. (3) becomes unfavorable for the formation of the ketone.

On the other hand, in the case of *p*-methoxybenzoyl halide, the electron-donative mesomeric effect of the methoxyl group increases the electron density on the carbon atom of the carbonyl group, thus making the nucleophilic attack of the heptafluoroisopropyl anion difficult. Consequently, the reaction of the *p*-nitrobenzoyl halide is controlled thermodynamically, whereas that of the *p*-methoxybenzoyl halide is controlled kinetically.

In order to improve our knowledge about the electronic effect of the $COCF(CF_3)_2$ group as a benzene substituent, we calculated the σ values for this group from ^{19}F NMR according to Taft's equation.[4] Since the chemical shifts for the aromatic fluorine atoms of *m*- and *p*-fluorophenyl heptafluorisopropyl ketones in CCl_4 from fluorobenzene were observed to be $\delta_m = -2.50$ and $\delta_P = -12.13$ ppm, the σ_R^0 and σ_I values for the heptafluoroisobutyryl group were determined to be 0.326 and 0.437 respectively. These figures suggest that the inductive and conjugative effects for the $COCF(CF_3)_2$ group are almost the same as those for the $COCF_3$ group ($\sigma_R^0 = 0.329$, and $\sigma_I = 0.455$).[4]

a) The chemical shifs are given in δ ppm from ext. PhF in CCl_4 or in neat.

Experimental

Phenyl Heptafluoroisopropyl Ketone. A mixture of benzoyl chloride (2.81 g, 0.02 mol), dimethylformamide (10 ml), and finely ground potassium fluoride (4.64 g, 0.08 mol) was put into a glass tube vessel equipped with a mechanical stirrer. At −70 °C liquefied hexafluoropropene (0.045 mol) was added, and after having been sealed the vessel was brought to room temperature. The whole was then heated for 6 hr in an oil bath kept at 120—130 °C under mechanical stirring. The reaction mixture was then poured into water and the separated oily material was extracted with diethyl ether. The extract was washed with a dilute aqueous solution of potassium hydroxide and water successively, and then dried over magnesium sulfate. After the solvent had been removed, the residual oil was subjected to a vacuum distillation. Phenyl heptafluoroisopropyl ketone (bp 80—81 °C/39 mmHg) was thus obtained in a yield of 66%.

Other substituted aryl heptafluoroisopropyl ketones were prepared in a similar manner.

A Novel Synthesis of L-Pipecolic Acid

Toshiyuki FUJII and Muneji MIYOSHI

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co. Ltd., 16-89, Kashima-3-chome, Yodogawa-ku, Osaka, 532

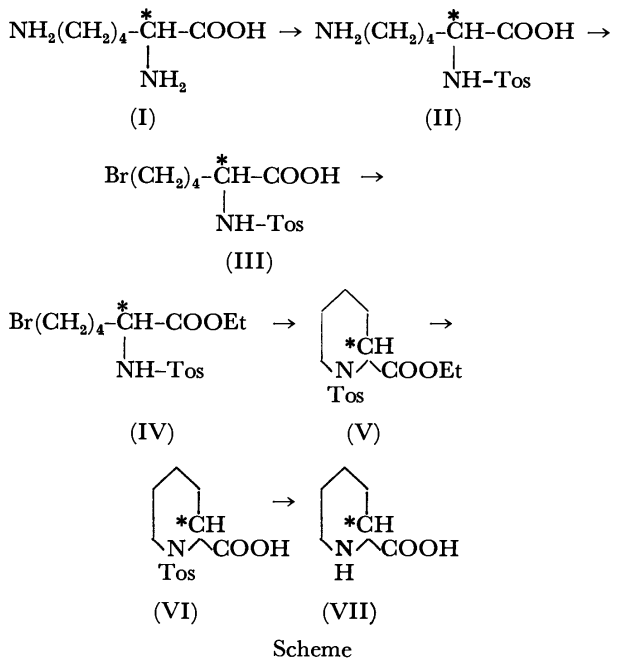
(Received December, 1974)

Synopsis. A novel synthesis of L-pipecolic acid from L-lysine is described. Bromination of ε-NH_2 group on N^{α}-tosyl-L-lysine, followed by cyclization with NaH in DMF gave *N*-tosyl-L-pipecolic acid in 45% yield.

Pipecolic acid, a non-proteinogenic amino acid, was first prepared in DL form by Ladenburg in 1891,[1] then it was resolved into optically active components by Mende.[2] Later, Morrison[3] isolated the amino acid having levo rotation from *trifolium repens* (white clover). Since then, the widespread occurrence of L-pipecolic acid in plant kingdom has attracted an interest in the metabolism of the amino acid, and several possible biosynthetic routes have also been suggested.[4] Although the full role of pipecolic acid in metabolism still remains obscure, several experiments reported so far give support that lysine may be a precursor in the biosynthesis of pipecolic acid.[5-8]

Up to date, L-pipecolic acid has been usually synthesized by reduction of 2-picolinic acid,[9] followed by resolution of the racemate. Attempts to obtain the L-form by the conversion of naturally occuring six-membered ring compounds were carried out *via* the oxidation of L-conhydrine[10] or *via* the reduction of L-baikiain.[11] The preparation of D-pipecolic acid from L-lysine by the use of Walden inversion has also been reported,[12] however, a synthetic route of L-pipecolic acid from L-lysine has not been established as yet.

In a series of our studies[13] on the conversion of L-amino acid to the optically active one, we have found a new synthesis of L-pipecolic acid from L-lysine, as shown in the scheme.



Scheme

Ring closure was performed *via* dehydrobromination by the abstraction of the NH proton at the α-position of L-lysine. Since this new route does not involve any substitution reaction on the asymmetric carbon of the starting material, full optical activity may be retained throughout the reaction.

Diazotization of N^{α}-tosyl-L-lysine (II) was investigated under several conditions: reaction temperature (0—80 °C) and the concentration of bromine ion (5—20 equivalents). Bromination of II took place with difficulty as compared with that of N^{α}-tosyl-diaminopropionic acid.[13a] It seems that the rate of substitution of the amino group with bromine at the ω-position would be decreased in proportion to the length of the alkyl chain. III was obtained as an oil, however, the esterification gave crystalline product (IV): the over-all yield of IV from II was about 45% after recrystallization.

Cyclization of IV with sodium hydride in DMF quantitatively proceeded as expected. It is noted that the ester moiety was unaffected during the cyclization reaction (IV→V) under the same condition reported previously on the synthesis of *N*-tosyl-L-azetidine-2-carboxylic acid;[13b] in that case the ester was completely saponified to the corresponding acid.

The detosylation was carried out successfully either by the treatment of V with 47% hydrobromic acid in acetic acid or by the reduction of VI with metallic sodium (4—5 equivalents) in liquid ammonia.

L-Pipecolic acid thus obtained was proved to be identical with an authentic specimen by the physical and the spectral data.

Experimental

The melting points are uncorrected. IR spectra were recorded on Shimadzu IR-27G. NMR spectra were taken at 60 MHz with tetramethylsilane as the internal standard using Hitachi R-20A.

ε-Bromo-N$^{\alpha}$-tosylamide-L-caproic acid (III). N^{α}-Tosyl-L-lysine* (60.0 g) and potasium bromide (60.0 g) were dissolved in 16% hydrobromic acid (500 ml). To the solution was added dropwise a solution of sodium nitrite (42.0 g) in water (100 ml) at 50—55 °C with vigorous stirring for 1 hr. Then, the reaction mixture was stirred for additional 1 hr at the same temperature, and the resulting oil was extracted with ether (200 ml × 3). The ether solution was washed with saturated sodium chloride solution and dried over magnesium sulfate. The dried solution was concentrated *in vacuo* to obtain an oily residue (III, 77.4 g), which was used to the following reaction without further purification.

Ethyl ε-Bromo-N$^{\alpha}$-tosylamido-L-caproate (IV). A solution

* This was prepared from L-lysine by Barrass and Elmore; mp 272—273 °C (dec.), $[\alpha]_D^{20}$ +13.9 °C (*c* 1, AcOH). [lit.[14] mp 263—264 °C (dec.)]

of III (77.4 g) in absolute ethanol (300 ml) was treated with hydrogen chloride under bubbling at 60—70 °C for 1 hr. After standing overnight at room temperature, the reaction mixture was concentrated, and the resulting oil was dissolved in ether (600 ml). The ether solution was washed with aqueous solution of 5% sodium carbonate and of saturated sodium chloride, successively. The solution was dried over magnesium sulfate and was evaporated *in vacuo*. The residual oil was crystallized from ether-petroleum ether to afford IV, which was positive to Beilstein test, 35.3 g (45% from II), mp 65—66 °C, $[\alpha]_D^{20}$ −2.3° (*c* 1, EtOH). IR (Nujol) ν_{NH}: 3280, $\nu_{C=O}$ 1740, ν_{SO_2} 1375, 1160 cm^{-1}; NMR (CCl_4, δ): 7.75—7.15 (4H, arom), 5.58—5.44 (1H, NH), 4.1—3.64 (3H, CH–CH_2), 3.39—3.18 (2H, CH_2–Br), 2.41 (3H, CH_3– ).

Found: C, 46.34; H, 5.69; N, 3.49%. Calcd for $C_{15}H_{22}NO_4SBr$: C, 45.91; H, 5.65; N, 3.57%.

Ethyl N-*tosyl*-L-*pipecolinate (V).* To a solution of IV (13.7 g) in DMF (250 ml) was added sodium hydride (1.84 g, 50% oil dispersion) at 10—15 °C, and the reaction mixture was stirred at the same temperature for 45 min. The reaction mixture was neutralized with a few drops of AcOH, and the insoluble materials were filtered. The filtrate was evaporated *in vacuo* below 40 °C, then the residue was extracted with ether and water. The ether solution was washed well with water and dried over magnesium sulfate. The dried solution was evaporated *in vacuo* to afford an oily residue (V, 11.5 g), which was negative to Beilstein test. IR (Film): $\nu_{C=O}$ 1740, ν_{SO_2} 1350, 1155 cm^{-1}.

N-*Tosyl*-L-*pipecolic Acid Dicyclohexylamine Salt (VI·DCHA).* To a solution of V (11.5 g) in methanol (100 ml) was added dropwise 2M sodium hydroxide solution (70 ml) at 15—17 °C under stirring. After 4 hr, the reaction mixture was neutralized and methanol was evaporated *in vacuo*. The residue was dissolved in sodium carbonate solution (100 ml) and the solution was washed with ether. Aqueous phase was acidified with 6M hydrochloric acid, and the resulted oil was extracted with ether. The ether solution was washed with saturated sodium chloride solution and dried over anhydrous magnesium sulfate. The dried solution was evaporated *in vacuo* to afford VI, 9.8 g. To a solution of the oily compound VI in ethyl acetate (70 ml), dicyclohexylamine (6.3 g) was added to obtain VI·DCHA salt, 13.3 g (82%), mp 166—168 °C, $[\alpha]_D^{20}$ −20.3° (*c* 1, MeOH), IR (Nujol): $\nu_{NH_2}{}^+$ 2300—2700, $\nu_{C=O}$ 1625, 1560, ν_{SO_2} 1375, 1155 cm^{-1}; NMR (DMSO-d_6, δ): 7.8—7.2 (4H, arom), 6.4—5.6 (2H, $NH_2{}^+$) 4.1—4.4 (1H, α-CH), 3.6—0.6 (30H, complex, other protons). Found: C, 64.26; H, 8.68; N, 5.97; S, 6.90%. Calcd for $C_{25}H_{40}N_2O_4S$: C, 64.63; H, 8.68; N, 6.03; S, 6.88%.

L-*Pipecolic Acid (VII).* A suspension of VI·DCHA (11.13 g) in 0.5 M sulfuric acid was vigorously shaken with ethyl acetate and the extract was concentrated *in vacuo*. The residue was detosylated with metallic sodium (2.2 g) in liquid ammonia (200 ml). After evaporation of excess ammonia, the residue was dissolved in 0.5M sulfuric acid solution, and the solution was washed with ether. The aqueous phase was treated with ion-exchange resin, Dowex 50 (H^+ form). The resin was eluted with 5% ammonium hydroxide solution, and the eluate was evaporated *in vacuo* to afford VII. Crude VII was recrystallized from methanol-ether, 2.33 g (76%), mp 259—260 °C, $[\alpha]_D^{20}$ −30.6° (*c* 1, water) [lit,[3] mp 271 °C (dec.), $[\alpha]_D^{18}$ −25.4° (*c* 5, water)]. IR (Nujol): $\nu_{NH_2}{}^+$ 2380—2500, $\nu_{C=O}$ 1615 cm^{-1}. Found: C, 55.30; H, 8.50; N, 11.02%. Calcd for $C_6H_{11}NO_2$: C, 55.77; H, 8.38; N, 10.84%.

Deoxygenation of Sulfoxides to Sulfides in an Iodine–Pyridine–Sulfur Dioxide System

Masatomo NOJIMA, Tsuyoshi NAGATA, and Niichiro TOKURA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka, 565

(Received December 5, 1974)

Synopsis. Sulfoxides were deoxygenated quantitatively in an iodine-pyridine-sulfur dioxide system under mild reaction conditions. The same reaction also occurred with bromine.

An iodine–pyridine–sulfur dioxide system was found to be effective for the dehydration reaction between carboxylic acid and amine.[1] Deoxygenation of sulfoxides to sulfides was examined in this system in order to find a convenient and selective reduction method for sulfoxides.[2]

Sulfoxides were allowed to react with 1 equiv. mole of iodine in the presence of excess pyridine–sulfur dioxide complex (1 : 1 molar ratio) using acetonitrile as a solvent at 80 °C for 2 hr. The products were isolated and characterized by comparing the physical data with those of authentic samples.

$$\mathrm{RS(O)R} \xrightarrow[\text{in acetonitrile, 80°C, 2 hr.}]{\mathrm{I_2}\ (1),\ \mathrm{SO_2}\text{-Pyridine}\ (10)} \mathrm{RSR}$$

The results obtained are summarized in Table 1. All the sulfoxides were selectively deoxygenated to give the corresponding sulfides in excellent yields. Although diphenyl sulfoxide was reduced slowly, diphenyl sulfide was obtained quantitatively when the reaction was continued for 18 hr.

TABLE 1. REDUCTION OF SULFOXIDES

Sulfoxide	Yield of Sulfide (%)	
	Reaction with Iodine[a]	Reaction with Bromine[b]
Diphenyl	20 95[c]	38
Dibenzyl	93	95
Di-*n*-butyl	84	73
Dimethyl	96	85
Tetramethylene	95	19

a) A solution of 1×10^{-3} mol of sulfoxide, 1×10^{-3} mol of iodine, 1×10^{-2} mol of sulfur dioxide-pyridine complex in 50 ml of acetonitrile was allowed to react at 80 °C for 2 hr. b) The reaction was carried out by keeping a mixture of 1×10^{-3} mol of sulfoxide, 1×10^{-3} mol of bromine and 1×10^{-2} mol of sulfur dioxide in 50 ml of acetonitrile at 80 °C for 2 hr. c) The reaction was carried out for 18 hr.

The reaction with bromine was carried out in the absence of pyridine, since in its presence α-bromination of the sulfoxide[3] competes with reduction. The reaction proceeded well, but in the case of tetramethylene sulfoxide a complex side-reaction took place.

In order to investigate the behavior of iodine we examined the UV spectra of iodine and tetraethylammonium iodide in the pyridine–sulfur dioxide–acetonitrile system.[4] No absorption of iodine was detected. An absorption considered to be that of iodosulfinate ion[5] was observed at 362 nm (ε, 7400 $\mathrm{l\cdot mol^{-1}\,cm^{-1}}$). The value is consistent with that of iodosulfinate ion in this system (ε, 8900 $\mathrm{l\cdot mol^{-1}\,cm^{-1}}$). It is reasonable to consider that iodine is dissociated into iodonium ion and iodosulfinate ion quantitatively. In the system of bromine–pyridine–sulfur dioxide, the absorption of bromosulfinate ion was also observed at 322 nm.[5]

In order to clarify the mechanism of the reaction, the following reactions were examined. When *N*-iodosuccinimide[6] or tetraethylammonium iodide was used instead of iodine, no reaction occurred suggesting the necessity of both iodonium and iodide ions for the reduction of sulfoxides. The reaction did not proceed either in the absence of sulfur dioxide. By the reaction of di-*n*-butyl sulfoxide with one third molar equiv. of iodine sulfide was obtained in 54% yield indicating that iodine works as a catalyst. No reversible reaction seems to occur in this system, since diphenyl sulfoxide was not obtained by the reaction of diphenyl sulfide with iodine in the presence of sulfur trioxide–pyridine complex.

The following scheme is considered to be the most plausible one for this novel deoxygenation reaction.

$$\mathrm{I_2} \xrightarrow{\mathrm{SO_2}} \mathrm{I^+} + {}^-\mathrm{SO_2I}$$

$$\mathrm{RS(O)R} \xrightarrow{\mathrm{I^+}} \mathrm{RS^+(O)R} \quad (\mathrm{I}) \xrightarrow{-\mathrm{SO_2I}} \mathrm{RS^{\delta+}R} \quad (\mathrm{OSO_2I^{\delta-}})$$

A

$$\mathrm{A} \longrightarrow \mathrm{RS^+R} + {}^-\mathrm{SO_3I} \quad (\mathrm{I})$$

$$-\mathrm{SO_3I} + \mathrm{SO_2\cdot Py} \longrightarrow -\mathrm{SO_2I} + \mathrm{SO_3\cdot Py}$$

Iodine ionizes to iodonium ion and iodosulfinate ion. Iodonium ion attacks sulfoxide first,[7] and then iodosulfinate ion may add to form intermediate A. Elimination of iodosulfonate ion and iodonium ion probably occurs from A to produce sulfide. Iodosulfonate ion formed would react with sulfur dioxide–pyridine complex generating again iodosulfinate ion with sulfur trioxide–pyridine complex.

Experimental

Reaction of Diphenyl Sulfoxide in the Iodine–Pyridine–Sulfur Dioxide System. In a round-bottomed flask fitted with a dry ice condenser was placed 2.52 g (0.01 mol) of iodine and 10 ml of pyridine–sulfur dioxide complex in 30 ml of acetonitrile. To this was added diphenyl sulfoxide (2.02 g,

0.01 mol) in 20 ml of acetonitrile over a period of 10 min at room temperature. The reaction mixture was kept at 80 °C for 2 hr, and then treated in the usual way. The product was analyzed with a Hitachi K-53 vpc apparatus equipped with a flame ionization detector.

Reaction of Diphenyl Sulfoxide in the Bromine-Sulfur Dioxide System. To a mixture of diphenyl sulfoxide (2.52 g, 0.01 mol) and bromine (1.6 g, 0.01 mol) in 50 ml of acetonitrile was added 5.0 ml of sulfur dioxide. The reaction mixture was kept at 80 °C for 2 hr and then extracted with ether and dried over anhydrous sodium sulfate. After removal of the solvent the product was analyzed by vpc. Diphenyl sulfide was obtained as the sole product.

The Catalytic Hydrogenation of Ethylene over Calcium Hydride and the Role of the Hydrogen of the Hydride

Masaru YAMAGUCHI, Yozaburo HIRAKI, Masatada WADA,* and Kimio TARAMA*

Faculty of Living Science, Kyoto Prefectural University, Sakyo-ku, Kyoto 606

(Received July 20, 1974)

The catalytic hydrogenation of ethylene over the non-stoichiometric calcium hydride ($CaH_{2-\delta}$) prepared by means of high-temperature evacuation was studied. The order of introducing gases had no effect on the rate of ethylene hydrogenation. The rate expressions for the initial stage were $v=k\,P_H^{0.8-1.0}\,P_E$ and $v'=k'\,P_H^{0.8-1.0}\,P_E^0$ in the lower and higher pressure ranges of ethylene respectively. The amount of hydrogen bound initially to $CaH_{2-\delta}$ and participating in the reaction was estimated from the results of the D_2–$CaH_{2-\delta}$ exchange and H_2–D_2 equilibration reactions. From these results, the mechanism of ethylene hydrogenation over calcium hydride and the role of the hydrogen of the hydride were discussed. The poisoning caused by water and acetylene was also studied. Furthermore, the catalytic activity of calcium hydride was compared with that of three metallic hydrides.

It has been established that the non-stoichiometric calcium hydride prepared by means of high-temperature evacuation has an remarkable catalytic activity for hydrogenation,[1–3] whereas metallic calcium and stoichiometric calcium hydride are far less active as catalysts of the hydrogenation of olefins. Though it has been pointed out[4] that the electrons in s-, p-, and d-bands are overlapped with each other in metallic calcium, its electronic structure is remarkably different from that of the transition metals of the 8th group, known to be excellent catalysts for hydrogenation. The distance between calcium atoms in the hydride is unusually longer (minimum distance: about 3.4 Å) in comparison with that of the transition metals of the 8th group. Also, the hydride has a highly ionic character. Therefore, it may be said that the non-stoichiometric calcium hydride is a peculiar catalyst for hydrogenation.

When the catalytic activities of calcium hydride have been studied thus far,[1–3] the investigations have been limited to the qualitative aspect of hydrogenation, the detailed mechanism has been left unsurveyed. The present investigation was undertaken in order to obtain more detailed kinetic information concerning the mechanism of the ethylene hydrogenation on this catalyst and in order to determine the role of the hydrogen bound initially to the hydride during the catalytic reaction. The experimental results will also be compared with those of the previous works on palladium black,[5] tantalum powder,[6] and titanium hydride.[7]

Experimental

Materials. The calcium hydride was obtained from the Metal Hydride Co. (purity: 98—99 %). The major impurities in this specimen were nitrogen and oxygen. It was also contaminated with trace amounts of magnesium, manganese, sodium, strontium, and iron. Noble metals, which are known as excellent hydrogenation catalysts, were not detected by emission spectrographic analysis. The hydrogen was prepared by the thermal decomposition of titanium hydride.[6,7] The deuterium (purity: D_2 97.8 %, HD 2.2 %) and the acetylene (99.6 %) in a glass ampoule were obtained from the Takachiho Trading Co.; they were used without further purification. The ethylene was purified by the conventional procedure, followed by repeated fractionations at the temperature of liquid nitrogen.

Procedure. All of the experimental runs were conducted in a closed circulating system at a constant pressure or within a constant volume. The apparatus used in these experiments was similar to that reported in a previous paper.[6] Since calcium hydride is very sensitive to the moisture, each sampling manipulation was carried out carefully in a dry box. About two grams of the powdered catalyst was placed in the reaction vessel; as a standard pretreatment, it was evacuated at 200 °C for 1 hr and finally at 450 °C under 1×10^{-5} Torr for 1 hr. After the vessel has then been cooled to the predetermined temperature, all the runs were carried out. The rate of ethylene hydrogenation was measured in the temperature range between −78 and 450 °C and in the range of total pressure between 50 and 500 Torr. The relative concentrations of ethylene and ethane in the product were estimated by a micro gas-absorption method similar to that of a previous paper;[7] these concentrations agreed with the value calculated from the volume change, thus excluding any possibility of reactions other than ethylene hydrogenation occurring. The adsorption of reactant gases to the catalyst was negligible in the rate measurements. The hydrogen isotopes were analyzed by using a CEC-21-401 mass spectrometer. The spectrum of hydrogen isotopes was taken at an ionization energy of 70 eV and at an ion-accelerating voltage of 500 V. A Shimadzu GX-3B X-ray diffractometer with copper $K\alpha$ radiation was used to obtain the diffraction diagrams of calcium hydride.

Results and Discussion

Effect of the Pretreatments of Stoichiometric Calcium Hydride on Surface Area, the Amount of Hydrogen Evolved, and the Initial Rate of Ethylene Hydrogenation. As is shown in Fig. 1, evacuation at temperatures below 200°C evolved only a slight amount of hydrogen, and the increase in the surface area was minor. No catalytic activity was observed for ethylene hydrogenation. As the temperature was raised above 250°C, the amount of hydrogen evolved and the surface area increased remarkably. The catalytic activity was considerably raised when more than ten percent of hydrogen was removed from the stoichiometric calcium hydride. Though an evaporated film of metallic calcium was formed on the wall of the evacuated reaction vessel above 450 °C,

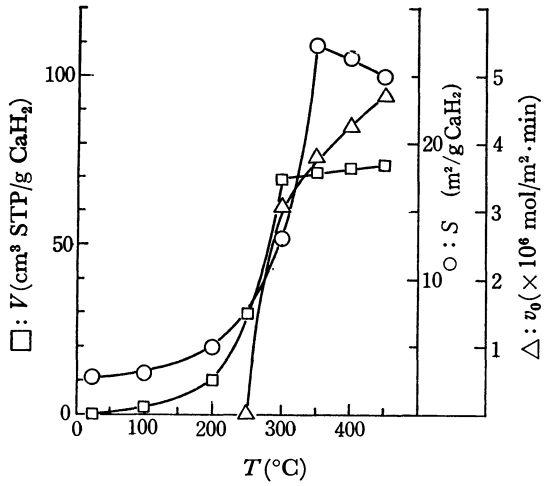

Fig. 1. Effects of the evacuation temperature (T) on the amount of hydrogen evolved (V), B.E.T. surface area (S) and the initial rate of ethylene hydrogenation (v_0).

the film revealed no catalytic activity.

It is thought that the increase in the surface area is caused by the loss of hydrogen from the crystal lattice, thus bringing about a higher porosity. Such a surface may contain many lattice defects, basic or base-like sites, metallic or metal like sites, and their interfaces.

Hydrogenation of Ethylene. Although the order of introducing gases significantly affects the rate of ethylene hydrogenation using palladium-, tantalum- and titanium hydride,[5-7] no significant differences were observed with the non-stoichiometric calcium hydride, $CaH_{2-\delta}$,* as is shown in Fig. 2. The reaction proceeds even at −40 °C; the maximum initial rate was observed at about 250 °C.

Figure 3 shows the dependence of the initial rate upon the hydrogen or ethylene pressure. From this figure, the initial rate of the ethane formation is expressed by:

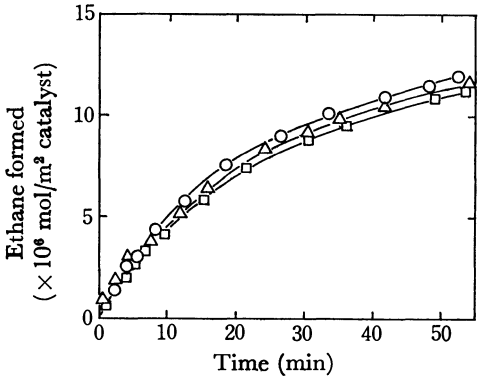

Fig. 2. Ethane formed—time plots at 0 °C (Effect of the order of introducing gases).

Each initial rate (v_0) was evaluated as follows:

Order of introduction	P_H Torr	P_E Torr	v_0 ×10⁷·mol/m²·min
○: H+E	44.1	42.7	4.88
△: H→E	41.8	44.3	5.00
□: E→H	44.7	41.1	4.68

* δ=0.35 after the standard pretreatment.

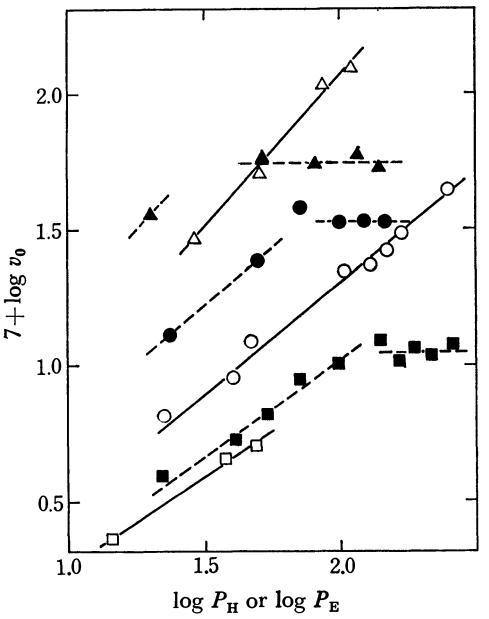

Fig. 3. Dependence of the initial rate of ethylene hydrogenation upon the pressures of ethylene and hydrogen. closed mark: dependencies upon ethylene (P_H= 48 Torr), open mark: dependencies upon hydrogen (P_E= 45 Torr), □, ■: 0°C, ○, ●: 50 °C, △, ▲: 100 °C.

$$v = kP_H^{0.8-1.0}P_E \text{ and } v' = k'P_H^{0.8-1.0}P_E^0$$

in the regions of lower and higher pressures of ethylene respectively. The apparent activation energies between 0 and 100°C were estimated to be 4.6 and 3.3 kcal/mol for k and k' respectively.

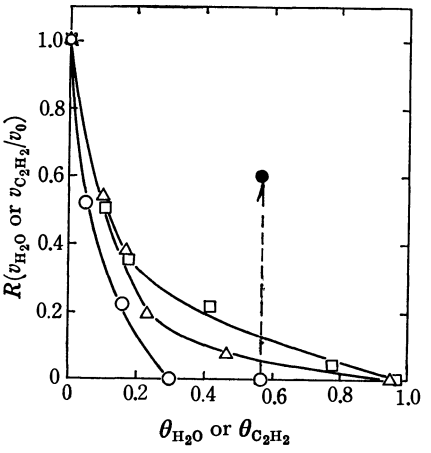

Fig. 4. Effects of the surface coverage, $\theta^{a)}$, by water or acetylene on the relative activity (R).

Pretreated substances	Reaction temperature	P_H Torr	P_E Torr
○: H_2O	100 °C	47.5	48.0
□: C_2H_2	100	52.5	49.3
△: C_2H_2	200	51.8	48.3

Closed circle shows restored relative activity after high temperature evacuation.

a) θ_{H_2O} (or $\theta_{C_2H_2}$) was estimated on the basis of the assumption that two molecules (or one molecule) of water (or acetylene) react with one atom of surface-exposed calcium: number of calcium atoms exposed on the surface was calculated from B.E.T. nitrogen surface area.

The effect of the pretreatment by water or acetylene on the catalytic activity is shown in Fig. 4. The relative catalytic activity (R), which is defined as the ratio of the initial rate of hydrogenation with the catalysts after and before the pretreatment, decreased sharply, along with the surface coverage (θ_{H_2O}) by water, falling to zero at $\theta_{H_2O}=0.3$. When this deactivated catalyst was evacuated at 650°C and when the standard pretreatment was carried out after treating it with 300 Torr hydrogen at 400°C for 1 hr, the activity was restored to some extent. The poisoning by acetylene was similar to that of water up to about $\theta_{C_2H_2}=0.1$, though the relative activity fell to zero in the vicinity of $\theta_{C_2H_2}=1$. Contrary to the case of water, the poisoning by acetylene was perfectly irreversible, regardless of the kind of treatment thereafter. When a mixture of acetylene and hydrogen was introduced into the catalyst vessel, a considerable decrease in the pressure was observed. The analysis of the remaining gas, however, revealed that the pressure decrease was caused by the adsorption or by the reaction of the acetylene with the catalyst; it was not caused by the hydrogenation.

a) $CaH_{2-\delta}$: *ca.* 2.2 g, reaction time: 30 min. The conversion of ethylene hydrogenation was about 95 % under the same condition. b) On the equilibrium constants K for $H_2+D_2 \rightleftarrows 2HD$, the values of 3.59 and 3.43 were used for 200 and 100 °C, respectively.[9)] c) The amount of hydrogen bound initially to $CaH_{2-\delta}$ and participated to the reaction.

$CaH_{2-\delta}$–D_2 Exchange and $CaH_{2-\delta}$–(H_2+D_2) Equilibration Reactions. In order to ascertain the role of the hydrogen of calcium hydride during the catalytic reaction, these two reactions were studied. The experiments were carried out when the equilibration reaction had almost been completed. The equilibrium compositions of the hydrogen isotopes, which must be composed of the hydrogen initially bound to $CaH_{2-\delta}$ and which participate in the reaction (V_{ph}), and the gas-phase hydrogen were calculated with respect to the temporal figure of V_{ph}. As is shown in Table 1 [(a) and (b), at 200°C], the observed equilibrium compositions are in good agreement with the calculated ones, in which 6.0—6.5 cm³ STP of V_{ph} was assumed. This V_{ph} value corresponds to about 0.6% of the amount of the hydrogen initially bound to $CaH_{2-\delta}$, and it roughly corresponds to half of the hydrogen in the surface monolayer (12 cm³ STP). The amount of hydrogen in the surface monolayer was estimated on the basis of the assumption that one molecule of hydrogen is attached to one atom of calcium. The V_{ph} value was very low at 100 °C compared with the values at 200 °C; it was estimated to be 0.1—0.3 cm³ STP [Table 1, (c) and (d)]. These results suggest that only a minor amount of the hydrogen of calcium hydride participates in both reactions, contrary to the results by Wright and Weller.[2)]

X-Ray Measurements. When calcium hydride of a stoichiometric composition is heated under a vacuum, the specimen is gradually changed with the rise in the heating temperature from greyish white to grey (400 °C) and to greyish black (500 °C), and a calcium mirror is formed above 450 °C at the cold parts of the vessel. These observations indicate that a part of the hydride is converted into metallic calcium. However, the X-ray diffraction analysis conducted on the powdered specimens which had been placed in a vacuum at 100, 250, 450 and 510 °C for 1 hr showed only the pattern of the stoichiometric hydride; that of metallic calcium was not detected. These results may suggest that metallic calcium is formed after the high-temperature evacuation, but it can not be detected

Table 2. Initial rate of ethylene hydrogenation on Pd-,[5)] Ta-,[6)] Ti-[7)] and Ca-hydride

Hydride	Reaction temp. °C	P_H Torr	P_E Torr	Initial rate of hydrogenation mol/g-cat·min	mol/m²-cat·min

by X-ray measurements because of its extremely fine particle size.

Comparison with the Catalytic Activity of Other Metal Hydrides. The initial rates of ethylene hydrogenation on the non-stoichiometric calcium hydride are, in Table 2, compared with those of three metallic hydrides.[5-7] The catalytic activity of non-stoichiometric calcium hydride is slightly lower than that of palladium hydride (β-phase) under similar experimental conditions. It might be higher than that of tantalum- and titanium-hydride, however, because the rates of ethylene hydrogenation at 50—100 °C on non-stoichiometric calcium hydride are of the same magnitude as the rates at 300 °C on the two hydrides mentioned above.

The Mechanism of the Hydrogenation of Ethylene and the Role of Hydrogen Bound to $CaH_{2-\delta}$. From the results of the effect of the order of introducing gases and of the dependence of the initial rate upon the pressure, it was presumed that the rate-determining step of the ethylene hydrogenation on $CaH_{2-\delta}$ is the surface reaction between adsorbed ethylene and adsorbed hydrogen on different sites. The formation of HD during the H_2–D_2 equilibration reaction strongly suggests the dissociative adsorption of hydrogen and deuterium on the catalyst surface.

From the V_{ph} values at lower temperatures ($<$ 100 °C) shown in Table 1, it can be said that the hydrogen which is initially bound to $CaH_{2-\delta}$ does not participate in the hydrogenation—only the hydrogen adsorbed from the gas phase does. At higher temperatures ($>$100 °C), on the other hand, both the hydrogen adsorbed from the gas phase and a part of the hydrogen loosely bound to calcium on the surface monolayer of $CaH_{2-\delta}$ participate in the hydrogenation. In both cases, the hydrogen in the bulk $CaH_{2-\delta}$ dose not participate. These interpretation are also supported by the results of the isomerization of butene over $CaD_{2-\delta}$.[8]

Although it is not yet certain what kind of site is catalytically active, the following suggestion may be made: the carbanion-type ethylene adsorbed on the basic or base-like sites may be able to associate with the hydrogen adsorbed on the neighboring metallic sites and may thus be converted to ethane.

The authors are grateful to Professor Shiichiro Teranishi of Osaka University and Professor Makoto Kumada of Kyoto University for their valuable suggestions. They are also thankful to Mr. Masataka Nakanishi of the Daiseru Co., Ltd., for his assistance. Thanks are further extended to Dr. Tsutomu Makita of Kyoto University for the mass spectrometric measurements.

A Study on Electronic Spectra of Organic Compounds with S-Cl Group

Tokio YAMABE, Shinichi NAGATA, Yasuo KIKUZONO, and Kenichi FUKUI

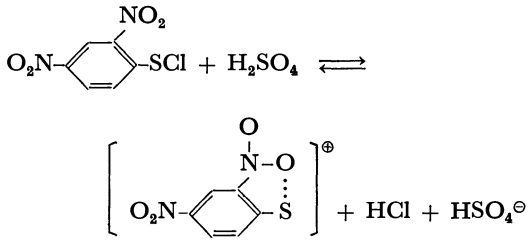
Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received August 30, 1974)

MO calculations were carried out for CH_3SCl, C_6H_5SCl, and related compounds with the S–Cl group by the CNDO/2 or the ASMO-SCF method. The absorption bands in the 300—400 nm region observed were assigned to the $\sigma^*_{S\text{-}Cl} \leftarrow n_S$ transition in view of transition energy and oscillator strength. Such characteristic bands are attributed to the extraordinarily low energy level of the $\sigma^*_{S\text{-}Cl}$ orbital.

Various organic compounds containing the sulfenyl group (S–Cl) are generally known to be highly reactive ones, often with characteristic colors (orange-red) irrespective of whether they are arylsulfenyl or alkanesulfenyl.

The first discussion on the color of such compounds was given by Kharasch *et al.*,[1] for *o*-nitrobenzenesulfenyl chloride and its derivatives which have an intensely red color, especially in sulfuric acid. They attributed this to the intramolecular π resonance formed between the sulfenium cation and the nitro group adjoining, as shown below.



The characteristic color, however, is common to *o*-nitrobenzene-sulfenyl chloride and such compounds as benzenesulfenyl chloride and methanesulfenyl chloride which have no nitro group adjacent to the S–Cl group. Studies[2,3] concerning the electronic absorption spectra of organic compounds with the S–Cl group were reported without theoretical investigation on the absorption bands of 300—400 nm common to such compounds. It seemed to be of interest to study the characteristic bands which may be closely related to formation of the S–Cl bond.

In the present study, MO calculation by the CNDO/2[4] or ASMO-SCF method[5] using the zero-differential overlap approximation were carried out for CH_3SCl, C_6H_5SCl and some related compounds containing the S–Cl bond, in order to investigate the character of the S–Cl bond. For the sake of comparison, electronic absorption spectra of methanesulfenyl and *p*-toluenesulfenyl chlorides were measured in various solvents.

Method of Calculation

Calculations of σ-electron systems such as alkanesulfenyl chlorides were carried out by the CNDO/2 method, developed by Pople *et al.*,[4] and the singlet excitation energies and oscillator strengths were calculated using the virtual orbital approximation. The atomic orbitals of sulfur atom were employed up to its 3p orbitals.* For calculations of $SOCl_2$, SO_2Cl_2, and CH_3SO_2Cl we tried to include 3d orbitals of sulfur atom having the same exponent ζ_{3d} as ζ_{3s}.[6]

In the case of benzenesulfenyl chloride, the singlet excitation energies and oscillator strengths were calculated by the ASMO-SCF method with the zero-defferential overlap approximation,[5] in order to avoid defects of the CNDO/2 method when applied to the π electron systems.** In the present calculation, the configurational interaction is not taken into account, because the transition energies of CH_3SCl and C_6H_5SCl are not changed so remarkably by the consideration of CI.

Table 1. Molecular structures of CH_3SCl, CF_3SCl, and C_6H_5SCl

Compound	Bond distance (Å)		Bond angle (deg.)
	C–S	S–Cl	∠CSCl
CH_3SCl[a]	1.815	2.014	100.39
CF_3SCl	1.829		105.4
C_6H_5SCl	1.805		103.2

a) See Ref. 7.

The assumed molecular structures of the compounds with the S–Cl group are given in Table 1. Microwave spectral analysis[7] was used for methanesulfenyl chloride, while CF_3SCl and C_6H_5SCl were estimated from both calculations and the molecular structures of $(CF_3)_2S_2$[8] and $(C_6H_5)_2S_2$,[9] respectively. For the molecular structures of all the other compounds, the observed structures were employed.[10-13]

Experimental

Methanesulfenyl chloride and *p*-toluenesulfenyl chloride were prepared by the previously reported methods[14,15] from dimethyl disulfide in 1,1,2,2-tetrachloroethane and chlorine, and from *p*-thiocresol in carbon tetrachloride and chlorine,

* Preliminary calculations including those of 3d orbitals of the sulfur atom were carried out to estimate their contribution. The results predict the unacceptable polarization of $S(\delta-)$-$Cl(\delta+)$ and the larger bond energy of E_{S-Cl} than E_{C-S} in contrast with the results obtained by restricting up to the 3p orbitals. These results are unreasonable from experimental aspects and the 3d orbitals for sulfur have thus been excluded from this study.

** For example, the π-MO of ethylene is not calculated as the highest occupied molecular orbital (HOMO) but as the next highest occupied molecular orbital (NHOMO). Furthermore, our preliminary calculation on C_6H_5SCl by the CNDO/2 gave a too large $\pi^* \leftarrow \pi$ excitation energy, *i.e.*, 12.5eV.

respectively. The products were isolated by vacuum distillation, and their electronic absorption spectra in the region 210—700 nm were measured in various solvents.

Results and Discussion

The observed electronic spectra of methanesulfenyl chloride and *p*-toluenesulfenyl chloride are shown in Fig. 1. The most stable conformation of CH_3SCl in its ground state was calculated by means of the CNDO/2 method to optimize the total energy by changing the bond distance R(S–Cl) between sulfur and chlorine atom. The optimized bond length, $R=2.064$ Å, is in good agreement with the experimental value (2.014 Å) in the gas phase. With this bond length, the transition energies were calculated to be 301.1 nm (the first band) and 203.0 nm (the second band) in the ultraviolet region. The predicted wavelength for the first band seems a little shorter than the observed one (355.0 nm). The calculated wavelengths for both bands, however, are sensitive to the change of the bond distance R(S–Cl) and shift toward the longer wavelengths by a slight elongation of the bond (Table 3).

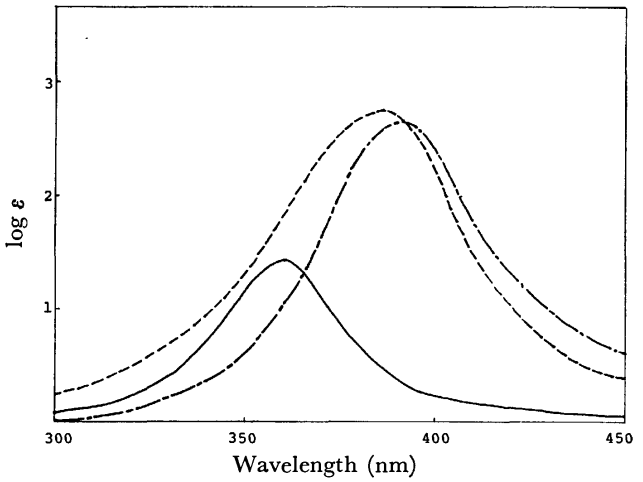


Fig. 1. Electronic absorption spectra of CH_3SCl (——), C_6H_5SCl (------), and *p*-$CH_3C_6H_4SCl$ (-·-·-) in the region of 300—450 nm.

Table 2. Observed electronic transitions of compounds with the S–Cl group

Compound	Solvent	λ_{max}(nm)	ε_{max}	Reference

Table 3. Dependence of the singlet excitation energies of CH_3SCl on the bond distance R(S–Cl)

R(S–Cl) (Å)	$\sigma^*_{S\text{-}Cl}\leftarrow n_S$ Transition energy (nm)	$\sigma^*_{S\text{-}Cl}\leftarrow n_S$ Oscillator strength	$\sigma^*_{S\text{-}Cl}\leftarrow n_{Cl}$ Transition energy (nm)	$\sigma^*_{S\text{-}Cl}\leftarrow n_{Cl}$ Oscillator strength
2.014	288.1	3.77×10^{-5}	196.9	8.07×10^{-3}
2.064	301.1	4.36×10^{-5}	203.0	3.21×10^{-3}
2.114	316.0	4.15×10^{-5}	206.7	2.90×10^{-2}
2.314	379.4	3.93×10^{-5}	239.2	5.21×10^{-2}

From the calculated results, the first band is assigned to the excitation of the lone pair electron on the sulfur atom to the lowest unoccupied orbital (LUMO), which is mainly localized in the anti-bonding MO of the S–Cl bond (σ^*_{S-Cl}). The band is thus closely related to the presence of the S–Cl bond. In fact, atom to the lowest unoccupied orbital (LUMO), which is mainly localized in the anti-bonding MO of the S–Cl

Oae, "Sulfur Bonding," Ronald Press Company (1962). b) Calculated by the CNDO/2 method excluding the 3d orbitals of sulfur atom. c) Calculated by the CNDO/2 method including the 3d orbitals of sulfur atom. d) No absorption band exists in the region 210—700 nm.

bond (σ^*_{S-Cl}). The band is thus closely related to the presence of the S–Cl bond. In fact, CH_3SH and $(CH_3)_2S$ have no absorption band above 300 nm.[16] Other possibilities of excitation of either the lone pair electron on chlorine atom or the σ-electron of the S–Cl bond might be considered. The former is assigned to the second band, but the latter is hardly acceptable since the excitation energy of the $\sigma^*\leftarrow\sigma$ transition is much larger than that of the $\sigma^*\leftarrow$n transition (*e.g.*, for $(CH_3)_2S$ $\Delta E^*_{\sigma-\sigma}$=6.2 eV $\Delta E^*_{\sigma-n}$=5.2 eV). This may be supported by the fact that methanesulfonyl chloride (CH_3SO_2Cl) without lone pairs on the sulfur atom has no absorption band in the ultraviolet and visible regions (Table 4). Moreover, the molar extinction coefficient of the $\sigma^*\leftarrow\sigma$ transition is, in general, of the order of 10^2—10^3 as ε_{max} whereas the observed one is less by one order, implying that the assignment ($\sigma^*\leftarrow\sigma$) is not reasonable for the first band.

The second band is assigned from the present calculation to be the excitation of the lone pair electron (n′) of chlorine atom to the $\sigma^*_{S\text{-}Cl}$ orbital ($\sigma^*\leftarrow$n′). The wavelength, however, is considerably longer than that of the usual alkyl chloride, *e.g.*, CH_3Cl (154–161 nm);[17] in addition the wavelength of the first band is greater than that of usual alkyl sulfides. The main reason for such large shifts toward the longer wavelength of these two bands in comparison with those of the related compounds, $(CH_3)_2S$ and CH_3Cl, may be attributed to the extraordinarily low orbital level of $\sigma^*_{S\text{-}Cl}$ in CH_3SCl. Moreover, it is seen from the increase of the S–Cl bond length that the energy level of $\sigma^*_{S\text{-}Cl}$ is greatly lowered in comparison with that of the lone pairs of sulfur and chlorine atoms (Fig. 2). Such a tendency may be connected with the color of the sulfenyl compounds. Furthermore the ratio between the calculated oscillator strengths of the two bands is in good agreement with that between the observed ε_{max}'s. Thus, it may be concluded that the first band is assigned to the σ^* (S–Cl)←n(S) transition and the second one to the σ^* (S–Cl)←n′ (Cl).

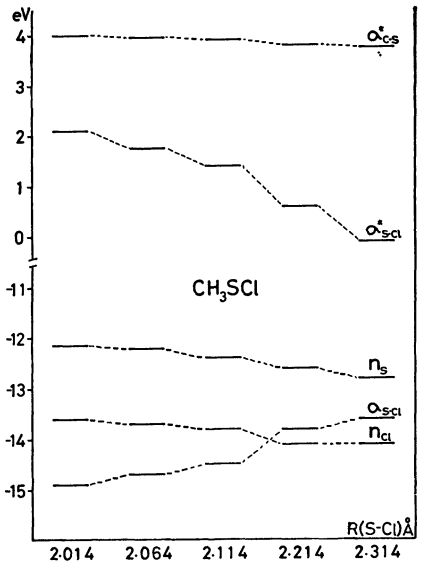

Fig. 2. The relation between the bond distance R(S–Cl) and the molecular orbital levels in CH_3SCl.

As a related compound, sulfur dichloride (SCl_2) was also studied. The results are given in Table 4. The observed absorption bands at 263 and 246 nm which have almost the same intensities as and shorter wavelengths than the $\sigma^*_{S\text{-}Cl}\leftarrow n_S$ transition of CH_3SCl were predicted to be due to the excitations of $\sigma^*_{S\text{-}Cl}\leftarrow n_S$ and $\sigma^{*\prime}_{S\text{-}Cl}\leftarrow n_S$, respectively. These assignments may be reasonable since the two σ^* orbitals of the S–Cl bond are nearly degenerate and therefore the calculated oscillator strengths for the transitions give almost the same values. For $SOCl_2$, where one oxygen atom combines with the lone pair electron of sulfur atom, its absorption band further shifts toward a shorter wavelength in comparison with that of SCl_2. This may be attributed to the stabilization of the S–Cl bond by the formation of S–O bond. The σ_{S-Cl} orbital level of $SOCl_2$ is lower than that of SCl_2 by *ca.* 1.2 eV and the corresponding σ^* orbital becomes higher accordingly. Furthermore, the absorption bands of SO_2Cl_2 and CH_3SO_2Cl, which have a sulfur atom combining with two oxygen atoms and hence no lone pair electrons, have not yet been found in the ultraviolet region. From these experimental and theoretical investigations it is demonstrated that compounds with the S–Cl group have, in general, weak absorption bands in the 350—400 nm region due to the transition between the lone pair orbital of sulfur (n_S) with small ionization potential and the low-energy anti-bonding orbital, $\sigma^*_{S\text{-}Cl}$.

Table 5. Singlet excitation energies of CF_3SCl and C_6H_5SCl

Compound	Excitation energy (nm)	Oscillator strength	Assignment
CF_3SCl[a]	290.0	4.68×10^{-6}	$\sigma^*_{S\text{-}Cl}\leftarrow n_S$
	194.0	2.40×10^{-2}	$\sigma^*_{S\text{-}Cl}\leftarrow n_{Cl}$
C_6H_5SCl[b]	372.2	5.40×10^{-3}	$\sigma^*_{S\text{-}Cl}\leftarrow n_S$

a) Calculation carried out with R(S–Cl) of 2.060 Å by the CNDO/2 method. b) Calculation carried out with R(S–Cl) of 2.070 Å by the ASMO-SCF method.

For further investigation of alkanesulfenyl chloride, CF_3SCl was studied by the same method as mentioned above and the optimized molecular structure was obtained to give a potential energy minimum at 2.060 Å of R(S–Cl). The singlet excitation energies for the optimized structure are given in Table 5. The first and second absorption bands are attributed to the excitations of $\sigma^*_{S\text{-}Cl}\leftarrow n_S$ and $\sigma^*_{S\text{-}Cl}\leftarrow n_{Cl}'$, respectively, in a manner similar to the case of CH_3SCl. These calculated results are also in fair agreement with the observed values (Table 2) not only in the wavelengths but also the intensities. The first and second absorption bands of CF_3SCl, however, shift toward shorter and longer wavelength, respectively, in comparison with those of CH_3SCl. This is also realized from a comparison of the energy levels of CH_3SCl and CF_3SCl shown in Fig. 3; in particular, the n_S orbital of CF_3SCl is largely stabilized in comparison with the $\sigma^*_{S\text{-}Cl}$ orbital.

In order to clarify such a trend, we compared the bond energy E_{AB} of CF_3SCl with that of CH_3SCl

TABLE 6. BOND ENERGIES E_{AB} (a.u.) IN CH_3SCl AND CF_3SCl CALCULATED BY THE CNDO/2 METHOD

Compound	R(S–Cl) (Å)	C–S	S–Cl
CH_3SCl	2.064	−0.612	−0.476
CF_3SCl	2.060	−0.588	−0.484

(Table 6).*** CF_3SCl has a larger S–Cl bond energy and a smaller C–S bond energy than those in CH_3SCl. This might be due to the inductive effect of fluorine atom which attracts electron on carbon atom. As a consequence, the C–S bond is weakened but the S–Cl bond undergoes no such remarkable inductive effect. From these results, it may be expected that CF_3SCl has two reactive bonds, C–S and S–Cl, which may lead to interesting chemical reactions. The shifts observed in the absorption bands of CF_3SCl in comparison with those of CH_3SCl seem to be consistent with the change of bond energies of S–Cl and C–S bonds.

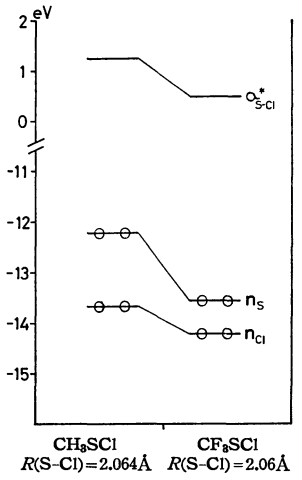

Fig. 3. The molecular orbital levels in CH_3SCl and CF_3SCl.

In the case of the arylsulfenyl chlorides, *o*-nitrobenzenesulfenyl chloride and its derivatives studied previously,[1] there may be interaction between the *ortho*-substituted nitro group and the sulfur atom to give rise to the sulfenium cation. These molecules are therefore not suitable for an investigation of the cause of the reddish color which many arylsulfenyl chlorides bear. Accordingly, benzenesulfenyl chloride which can not have such an interaction was taken as the simplest arylsulfenyl chloride.

For the calculations, the molecular structure was determined by using the CNDO/2 method; two conformations of the chlorine atom (Fig. 4, A and B) were compared. Conformation A, where the chlorine atom is on the same plane as the benzene ring, is more stable than B, where it is out of plane. The stabilization of A may be attributed to the π-conjugation effect between

*** In the CNDO/2 approximation, the total energy E_T can be expressed by the following equation, $E_T=\sum_A E_A+\sum_{A<B} E_{AB}$, where E_A and E_{AB} denote the monatomic and diatomic terms, respectively.

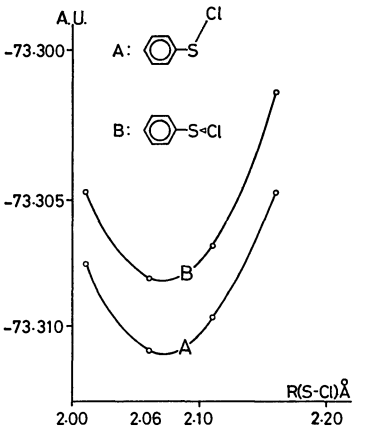

Fig. 4. Dependence of the total energies of benzenesulfenyl chloride on the parameter R(S–Cl).

the lone pair electrons on the sulfur atom and the π-electrons on the benzene ring; there is no such conjugation effect in B since the lone pair orbital is perpendicular to the π-orbitals.

Using the resulting bond distance R(S–Cl)=2.070 Å *i.e.*, the optimized bond distance of conformation A, the singlet excitation energies and oscillator strengths were calculated by the ASMO-SCF method (Table 5). It is seen that the calculated location of the absorption band of the longest wavelength (372.2 nm) is in accord with the observed one (386 nm), and that it is also due to the excitation of $\sigma^*_{S\text{-}Cl}\leftarrow n_S$ is accord with the assignment for the alkanesulfenyl chlorides.

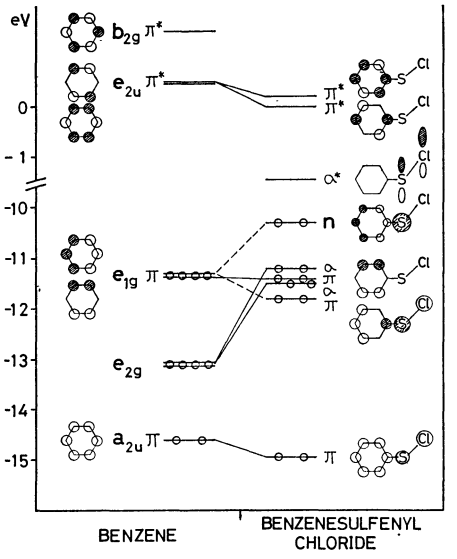

Fig. 5. The relation between the molecular orbital levels of benzene and benzenesulfenyl chloride.

In molecules having π and lone pair electrons such as carbonyl compounds, the absorption bands of the longest wavelength are generally known to be $\pi^*\leftarrow$n transitions.[18] However, the energy level of the $\sigma^*_{S\text{-}Cl}$ orbital is lower than that of the π^* orbital in this molecule, which may lead the $\sigma^*\leftarrow$n transition to be the lowest energy excitation (Fig. 5). Furthermore, the $\sigma^*\leftarrow$n transition in C_6H_5SCl is smaller than that of the alkane sulfenyl chlorides. This may be attributed to

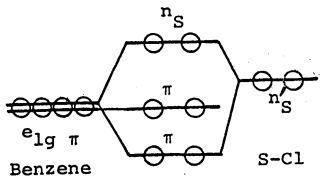

Fig. 6. Energy level of benzenesulfenyl chloride.

the participation of the lone pair orbital in the π-conjugation as follows; the n_S orbital in C_6H_5SCl is constructed from the interaction between the n_S' orbital (lone pair orbital on the sulfur atom) and degenerate π orbitals (e_{1g}) of benzene, and hence the lone pair orbital as shown in Fig. 6. This result suggests that the $\sigma^*\leftarrow$n transition in C_6H_5SCl gives a smaller excitation energy than that of alkanesulfenyl chlorides which can not have such interactions. Moreover, there is no absorption band in the region above 300 nm in $C_6H_5SC_6H_5$.[19] The calculated oscillator strength (of the order of 10^{-3}) is larger than that of CH_3SCl (of the order of 10^{-5}), and such a tendency is also found in the observed values of ε_{max} (Table 2). Thus, as in the case of the alkanesulfenyl chlorides, the observed absorption band at the longest wavelength in C_6H_5SCl is assigned to be the transition of $\sigma^*_{S\text{-}Cl}\leftarrow$n.

Conclusion

The characteristic absorption band in the ultraviolet region of organic compounds with the S–Cl group, commonly appearing at 300—400 nm, was assigned to the excitation of the lone pair electron of sulfur atom to the $\sigma^*_{S\text{-}Cl}$ orbital; the present calculation reveals that such a band at a fairly long wavelength which induces an intensely red color may be mainly due to the extraordinarily low energy level of the $\sigma^*_{S\text{-}Cl}$ orbital and the small ionization potential of 3p electron of the sulfur atom. From the present theoretical study, the high reactivity of S–Cl bond is attributed to the weakness of this bond, probably caused by the large electron repulsion between 3p electrons of sulfur and chlorine atoms.

The authors are grateful to Professor Hiroshi Kato and Mr. Katsumi Nakai for their helpful discussions.

Polarographic Reduction of Ubiquinone-10 Solubilized in Micelles

Tatsuo ERABI, Hisahide HIURA, and Masaya TANAKA
The Department of Industrial Chemistry, Faculty of Engineering, Tottori University, Tottori 680
(Received October 9, 1974)

Ubiquinone-10 solubilized in an aqueous solution containing sodium dodecyl sulfate as an anionic surfactant was polarographically investigated. Ubiquinone-10 solubilized in micelles shows a well-defined, diffusion-controlled, pH-dependent wave. Diffusion coefficient and apparent particles radii were calculated. The surfactant concentration dependence of the diffusion coefficient and of the apparent particle radii was also determined.

The electron transport system in respiratory chains and in the photosynthetic system, in which electron transfer takes place very smoothly, consists of various combinations of redox reaction. Electrochemical techniques are being developed for the analysis of the mechanism of electron transfer.

Underwood and his co-workers[1-3] investigated the electrode kinetics of NAD and its analogues by cyclic voltammetry. Takahashi *et al.*[4,5] reported that NADH produced from NAD by an enzymatic process can be anodically oxidized to NAD. Most of these studies were usually carried out in aqueous or nonaqueous media, and the difference from actual physiological conditions must be accounted for. Erabi *et al.*[6] investigated the polalographic behavior of redox components bound with chromatophores from photosynthetic bacterium, *Rhodospirillum rubrum*, under the physiological conditions, although reactions involved were not completely elucidated because of the difficulty of mass transfer.

In the photosynthetic organ, chromatophores, redox components have been arranged in good order. In such membrane systems, the usual electrochemical theory developed for homogeneous solution systems cannot be applied directly. No such development of electrochemical theory for the membrane systems have been carried out.

Hayano and Shinozuka[7-9] explained the polarographic behavior of the disperse-dyes solubilized in aqueous surfactant solutions. Westmoreland *et al.*[10] studied the polarography of *trans*-azobenzene in aqueous surfactant solutions, and discussed the boundary region between the properties of an aqueous system and those of a nonaqueous system. Micelle represents a good model for individual macromolecules and for a hydrophobic region within subcellular membrane systems. The electrochemical treatment of disperse systems is of interest not only in electrochemistry but also in biology. By accumulating the data for such disperse systems, we might obtain information on the membrane structure.

Experiments were carried out for ubiquinone-10 (UQ_{10}) solubilized in micelles, which plays an important role in the photosynthetic electron transport system.

Experimental

Materials. Pure UQ_{10} was extracted from chromatophores from photosynthetic bacterium, *R. rubrum*, by the usual method.[11] Sodium dodecyl sulfate (SDS, Marubishi Oil Co., Osaka) was washed with ether, and then recrystallized twice from ethanol. Tris(hydroxymethyl)aminomethane (Tris, Sigma Chemical Co., St. Louis) was used without further purification. Isooctane (Nakarai Chemicals Ltd., Kyoto) and other reagents (Wako Pure Chemical Industries Ltd., Osaka) were used.

Buffer solutions of various pH values were prepared with 0.12 M GTA (containing 0.04 M β-β-dimethylglutamic acid, 0.04 M Tris, and 0.04 M 2-amino-2-methyl-1,3-propandiol)–HCl and 0.12 M GTA–Tris, respectively. Water was used after five times distillation.

Apparatus. A solution containing a surfactant, 0.12 M GTA buffer solution, and UQ_{10} was irradiated with a 29kHz supersonic wave for 10 min. The solution was then stored for a day at room temperature. The equilibrium of the solution was thus attained. Excess UQ_{10} was removed by filtration through a G4 glass filter. The solid UQ_{10} remaining on the filter was dissolved with isooctane, and its quantity was determined by means of absorption spectrum at 271 nm[12] using a Hitachi Model 101 spectrophotometer. Polarographic measurements were carried out at room temperature for the filtrate, and UQ_{10} concentration in the filtrate was rechecked by the solid content on the filter. Polarograms were recorded with a high sensitive polarograph PA-202 (Yanagimoto Mfg. Co., Ltd., Kyoto).

Dissolved oxygen was removed from solutions by bubbling oxygen-free nitrogen for 2 hr.

A dropping mercury electrode (DME) was used as the working electrode, and a saturated calomel electrode (SCE) as the reference and counter electrode. The DME had the following characteristics; $m=0.93$ mg/s (in pure water at zero applied potential) and $t=3.0$ s. The height of mercury head was usually 75 cm.

The viscosity of the basic solution was measured with an Ostwald viscometer.

Results and Discussion

UQ_{10} in an Aqueous Ethanol Solution. The polarogram of UQ_{10} in an 80% (v/v) ethanolic solution showed pH-dependent wave. In the pH region pH 4.7—8.7,

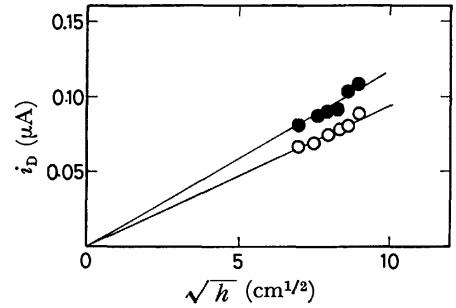

Fig. 1. Dependence of current on mercury height at pH 7.5.
●, and ○ represent the data in 80% ethanolic solution and in 4×10^{-2} M SDS solution, respectively.

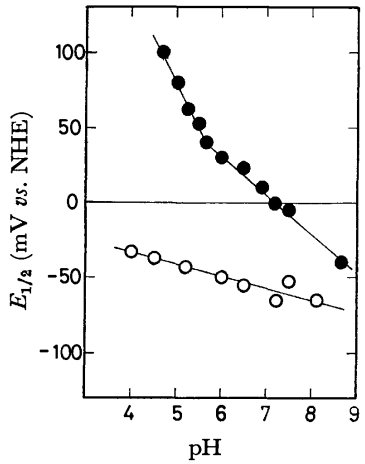

Fig. 2. Plots showing the pH dependence of the half-wave potentials for UQ_{10} reduction.
●, and ○ represent the data in 80% ethanolic solution and in 4×10^{-2} M SDS solution, respectively.

a typical well-defined cathodic wave was observed, and the limiting current was proportional to the square root of the mercury-column height as shown in Fig. 1.

The half-wave potential ($E_{1/2}$) was plotted against the solution pH (Fig. 2). The slope of the straight line for UQ_{10} was 60 mV/pH in the more acidic region than pH 5.7 and 27 mV/pH in the more basic region. When the Tafel plots and Heyrovskii-Ilkovic plots were made for the polarogram obtained, a value of $\alpha n=1.0$ (α being the transfer coefficient) was obtained, the number of electrons exchanged being presumed to be 2. The α values was thus calculated to be 0.5. The number of proton transfer was therefore estimated to be 2 in the more acidic region than pH 5.7 and 1 in the more basic region. The proportionality of the limiting current to the square root of the mercury height and to UQ_{10} concentration indicates the wave to be diffusion-controlled. The Ilkovic equation was applied to calculate the diffusion coefficient, and the value was 1.04×10^{-6} cm^2/s at pH 7.5.

UQ_{10} Solubilized in SDS Solution. The polarogram of UQ_{10} solubilized in SDS solution also showed a pH-dependent wave. A typical well-defined cathodic wave was observed and the current was also proportional to the square root of the mercury-column height (Fig. 1).

The slope of straight line for UQ_{10} solubilized in a SDS solution was 8 mV/pH in the pH region 4.0—8.2

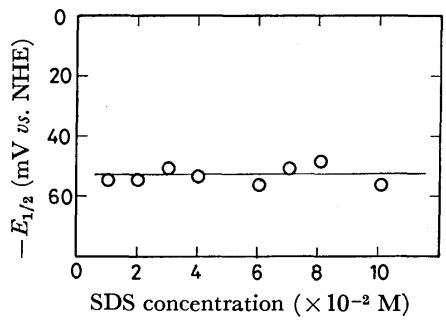

Fig. 3. Effect of surfactant concentration upon half-wave potential at pH 7.5.

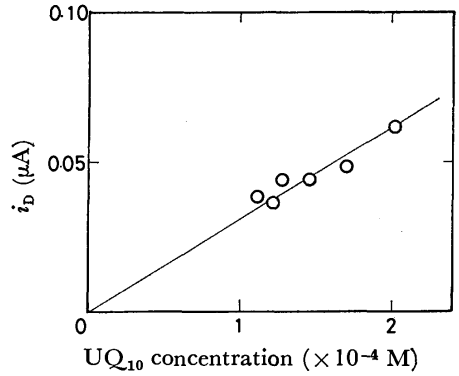

Fig. 4. Relationship of limiting current to UQ_{10} concentration at pH 7.5.

(Fig. 2). In Fig. 3 the half-wave potential for UQ_{10} reduction is shown as a function of SDS concentration. The half-wave potential was not affected by SDS concentration ($1—10\times10^{-2}$ M), that is, the solvent effect discussed by Mairanovskii[13] was not observed. Thus, UQ_{10} seems to be merely solubilized in micelles.

The dependence of the limiting current on UQ_{10} concentration is shown in Fig. 4, where a linear relationship is indicated. From the above results, it is evident that the observed waves are due to the reduction of UQ_{10} itself, and indicated to be diffusion-controlled.

The Tafel plots were drawn for the polarograms obtained at each SDS concentration, and αn values calculated from these results were plotted against the SDS concentration (Fig. 5). The αn value was not

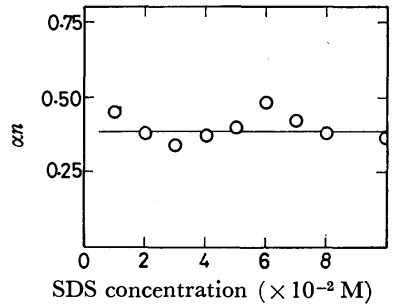

Fig. 5. Relationship of αn value to surfactant concentration at pH 7.5.

strongly affected by SDS concentration, being about 0.4 throughout the measurements in this study. Since the number of electrons exchanged for UQ_{10} in SDS solution was presumed to be 2 as well as in ethanolic medium, the α value was estimated to be 0.2. It is clear from experimental results that the diffusion particle is the micelle with UQ_{10}; this causes the diffusion current. On the one hand, adsorption and re-orientation of the surfactant molecules and micelles on the electrode were also considered to occur,[14] and micelles containing no UQ_{10} might exist in the neighborhood of the electrode. Futhermore, it was indicated by Kuta and Smoler[15] that the α value was lowered in the presence of a surface-active substance. As in the above case, the α value for UQ_{10} reduction is lowered to a greater extent in an aqueous surfactant solution than in an ethanolic one.

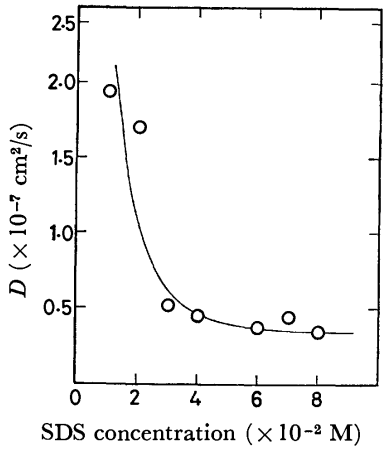

Fig. 6. Dependence of diffusion coefficient on surfactant concentration at pH 7.5.

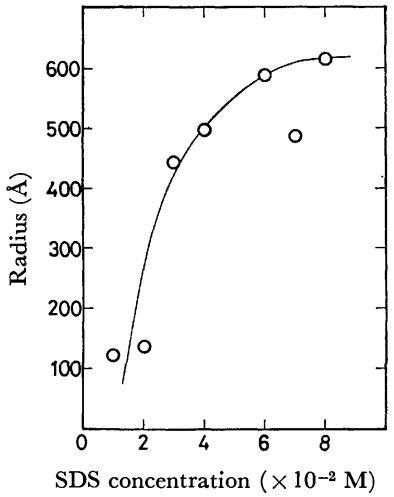

Fig. 7. Dependence of apparent mean particle radii on surfactant concentration at pH 7.5.

Since the limiting current of solubilized UQ_{10} was thought to be diffusion-controlled, the Ilkovic equation was applied to calculate the diffusion coefficient at each SDS concentration. Figure 6 shows the dependence of diffusion coefficient on SDS concentration. The apparent diffusion coefficient of solubilized UQ_{10} was about one-tenth compared with that in the ethanolic solution. Applying Stokes-Einstein's law for the diffusion coefficient (Fig. 6), the apparent mean radii of micelles were evaluated at various SDS concentrations, assuming that the micelles were perfectly spherical. The results are shown in Fig. 7. The obtained diffusion coefficients of solubilized UQ_{10} were more or less smaller than those of disperse-dyes reported by Hayano and Shinozuka.[9] However, in view of the size of a micelle which solubilized UQ_{10} containing a very long side-chain, these values seem to be appropriate. Tartar[16] and Tanford[17] reported that the theoretical micelle's radius for SDS is 16.68 Å and the aggregation number of molecules is 56. However, the radius and aggregation number of a micelle increase with increasing concentration of the electrolytes and, if a distortion in the micelle shape arises, the aggregation number of micelle increases still further. Therefore, the values for the particle radii (Fig. 7) do not seem too large if we take both existence of the electrolytes and situation of solubilized UQ_{10} into consideration.

The authors wish to express their thanks to Prof. Takekazu Horio, the Institute for Protein Research, Osaka University, for helpful assistance in the culture of photosynthetic bacterium, *R. rubrum*, and in the extraction of ubiquinone-10.

Polarography of Dialkylthallium(III) Compounds. I. Polarography of Dibutylthallium(III) Compounds

Teisuke MURAYAMA and Kenji KIKUCHI

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 432

(Received October 14, 1974)

Electrochemical reduction of three dibutylthallium(III) cations has been studied through the use of polarographic methods. Reduction at a dropping mercury electrode occurs in two steps for the di-*n*-butylthallium (DNBT) and diisobutylthallium (DIBT) cations in alkaline solutions, and for the di-*sec*-butylthallium (DSBT) cation in all pH ranges examined. The first and second waves of the DSBT cation in alkaline solutions correspond to, respectively, no-proton one-electron and two-proton two-electron processes. The DNBT and DIBT cations produce a single wave in acid solutions, consuming two protons and three electrons. On polarograms recorded with Kalousek's switching circuit a product and two kinds of intermediates were observed for the reduction of the DNBT and DIBT cations, and a product and one kind of intermediate for the reduction of the DSBT cation. A reaction scheme is proposed for the polarographic reduction of dibutylthallium cations.

Several authors have reported on the polarographic reduction of dialkyl- and diarylthallium(III) compounds. Costa studied di-*n*-alkylthallium bromides in an aqueous propanol solution,[1] and observed three waves of approximately equal heights for dipropyl- and dibutylthallium bromides. He attributed the first wave to Reaction (1) or (2), and the third to a reaction leading to the production of metallic thallium.

$$R_2Tl^+ + e \longrightarrow R_2Tl\cdot \quad (1)$$

$$2R_2Tl^+ + 2e \longrightarrow R_2Tl\text{-}TlR_2 \quad (2)$$

DiGregorio and Morris observed three waves for the diphenylthallium cation in aqueous solutions, and proposed a reduction mechanism including transmetallation with the electrode mercury.[2] Issleib *et al.* investigated five di-*n*-alkylthallium bromides in aqueous buffer solutions and dimethylformamide.[3] They obtained single waves in aqueous solutions with pH values below 7, and double waves in solutions with pH values above 7. The single step reduction was interpreted by them as follows.

$$R_2Tl^+ + e \longrightarrow R_2Tl\cdot \quad (1)$$

$$3R_2Tl\cdot \longrightarrow 2R_3Tl + Tl(Hg) \quad (3)$$

$$R_3Tl + H^+ \longrightarrow R_2Tl^+ + RH \quad (4)$$

Results of our investigation on dialkylthallium compounds indicate that the real electrode process should be more complex than any of the above-mentioned mechanisms. The present paper reports polarographic behavior of di-*n*-butyl-, diisobutyl-, and di-*sec*-butylthallium compounds. (Hereafter these are denoted as DNBT, DIBT, and DSBT compounds, respectively.) Molar conductivity data show that dimethyl, diethyl-, and diphenylthallium hydroxides are strong electrolytes.[4] By analogy dibutyl compounds may be regarded as strong electrolytes. Hence, this paper deals with the polarography of DNBT, DIBT, and DSBT cations.

Experimental

Dibutylthallium(III) chlorides were prepared by the reaction of organomagnesium compounds with thallium trichloride as described in the literature.[5] Diethyl ether was used as alkylation solvent in the preparation of DNBT chloride, but was replaced with tetrahydrofuran in the preparation of DIBT and DSBT chlorides. Nitrates were prepared from the chlorides and silver nitrate, and recrystallized three times from aqueous methanol solution. The thallium content of the products was assayed by Goddard's method.[6] Tl %: DNBT nitrate, 52.9; DIBT nitrate, 53.1; DSBT nitrate, 53.0; Calcd., 53.7. Stock solutions of dibutylthallium nitrates were made by dissolving weighed amounts.

Supporting electrolytes used were a mixture of 0.02 M sulfuric acid and 0.15 M sodium sulfate (pH 2.01), acetate buffers (pH 3.94—5.95), phosphate buffers (pH 6.34—7.64), and ammonia buffers (pH 8.71—10.16). The ionic strength of the test solutions was controlled to 0.5 with sodium sulfate by reason of solubility of dibutylthallium salts. Gelatin was used as maximum suppressor.

All solutions were prepared with redistilled water.

Test solutions were degassed with nitrogen and thermostated at 25.0±0.1 °C.

The dropping mercury electrode (DME) had the following characteristics (in 0.17 M sodium sulfate solution at zero applied potential *vs.* SCE and at mercury pressure of 800 mm): rate of flow of mercury (m), 1.401 mg/s; drop time (τ), 4.96 s; $m^{2/3}\,\tau^{1/6} = 1.64$.

The cell used was of a beaker type with a Hume and Harris type salt bridge.[7] The original design of the bridge uses an intermediate agar plug saturated with potassium chloride, of which contamination causes precipitation of dibutylthallium chloride from the test solution. To avoid this difficulty the agar plug was prepared with 1 M potassium nitrate, and its nitrate ions were replaced by sulfate ions by standing the plug in a saturated potassium sulfate solution.

DC polarograms were obtained with a Yanagimoto PB-105 polarograph operated manually. The bridge of the instrument was calibrated by a precise potentiometer. All potentials were corrected for the internal resistance (iR drop) across the cell. A simple switching circuit was used in place of Kalousek's commutator.[8] AC polarograms were recorded with a Yanagimoto PA-102 polarograph. To minimize cell impedance, the AC voltage was applied through an auxiliary platinum electrode which connected with an SCE and the positive terminal of the polarograph through a 300 μF capacitor. Coulometry was accomplished according to the method proposed by De Vries and Kroon.[9]

Results and Discussion

DC polarograms of dibutylthallium compounds exhibit slight but persistent maxima. It needed 0.05%

gelatin to suppress them. Accordingly all polarograms shown in the present paper were measured in the presence of 0.05% gelatin. The polarographic behavior of DNBT nitrate is illustrated in Fig. 1. The compound shows a reduction wave with the half-wave potential of *ca.* −0.91 V *vs.* SCE in the range of pH 3—6. The half-wave potential changes by varying concentration of DNBT nitrate as shown in Table 1. This indicates that the reversible electron transfer step is followed by a multimolecular reaction. When the pH increases above 6, the half-wave potential shifts to positive and the rising part of the wave becomes steeper. This behavior is unlike that observed for other organic compounds. It implies that a species of which existence is favorable in acid solutions hinders the easiest reaction route, and that the reduction takes place through a route with higher energy as the pH is lowered below the optimum value.

The wave splits into two at about pH 7 when the pH is increased. Although the total height of waves remains unchanged the height of the first wave decreases with increasing pH, and at pH 10 it becomes almost a third of the wave height in acid solutions. The second wave is accompanied by a maximum, even in the presence of 0.05% gelatin. The wave height in acid solutions and the total wave height in neutral and alkaline solutions increase in proportion to the concentration of DNBT nitrate and to the square root of the height of mercury column. This indicates that the limiting currents are controlled by diffusion. The variation of the half-wave potential with the mercury pressure is included in Table 1.

a) Concentration of DIBT nitrate. b) Height of mercury column. c) Since the second wave was accompanied by a maximum, only the half-wave potential of the first wave is shown.

The behavior of DIBT nitrate is much the same as that of DNBT nitrate. Figure 2 shows typical polarograms of the compound, and Table 2 the variation of the half-wave potential.

Figure 3 shows polarograms of DSBT nitrate, which undergoes a two-step reduction in all pH ranges examined. While the half-wave potential of the first

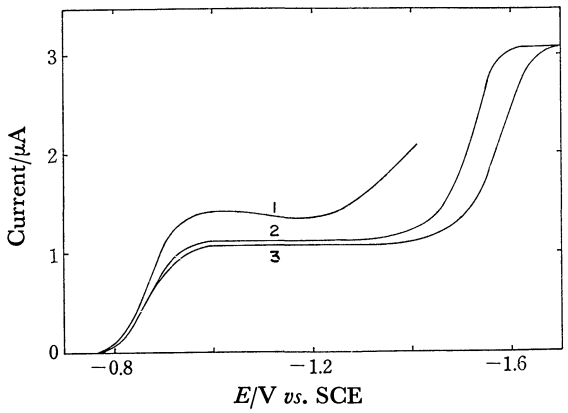

Fig. 3. Polarograms of DSBT nitrate. Concentration of DSBT nitrate, 0.424 mM. pH: 1, 3.94 (the second wave is overlapped by the hydrogen wave); 2, 8.71; 3, 10.16.

wave does not change to any noticeable extent, its limiting current decreases as much as a fifth of the wave height at pH 4 as the pH increases from 4 to 8.7. Further increase of pH, however, does not produce any appreciable change on the wave height. The limiting current of the first wave and the total wave height in alkaline solutions are in proportion to the concentration of DSBT nitrate and to the square root of the height of mercury column. This implies that the limiting currents of the first and second waves are diffusion currents. Table 3 shows the variation of the half-wave potential.

Electrocapillary curves of DNBT, DIBT, and DSBT nitrates indicate that these compounds are not adsorbed to any appreciable extent on the surface of DME.

The pH dependency of the polarograms suggests that hydrogen ions participate in the electrode processes. Amperometric titrations were carried out to establish the relation between the number of hydrogen ions and the number of electrons consumed in the electrode reaction. Figure 4 shows the change of the polarogram of DNBT nitrate during the titration with 2.02 mM sulfuric acid. The supporting electrolyte is 0.167 M sodium sulfate. The current at potentials corresponding to the limiting current region of the second wave remains unchanged until the concentration of hydrogen ions reaches a certain value, then increases from there on. The titration curve is shown in Fig. 5, where the current is measured at a potential of the limiting current region of the second wave. A similar change in the polarogram was observed for DIBT nitrate.

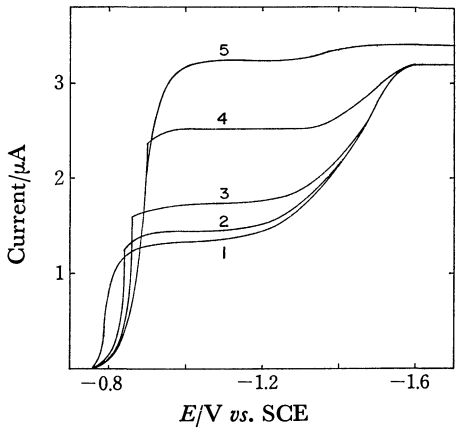

Fig. 4. Variation of the polarogram of DNBT nitrate during the titration with 2.02 mM sulfuric acid. The current was corrected for volume change. Original concentration of DNBT nitrate, 0.410 mM. Original volume of the solution, 25 ml. Supporting electrolyte, 0.167 M sodium sulfate. Volume of sulfuric acid, added: 1, 0 ml; 2, 0.5 ml; 3, 1.0 ml; 4, 2.0 ml; 5, 3.1 ml.

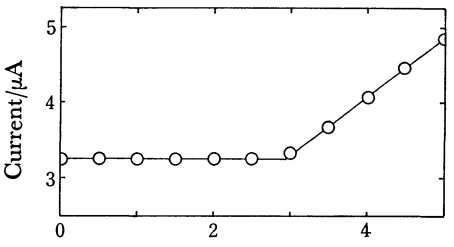

Fig. 5. Amperometric titration curve of 25 ml of 0.410 mM DNBT nitrate with 2.02 mM sulfuric acid. Titrated at −1.60 V *vs.* SCE.

When DSBT nitrate was titrated by the acid, the height of the first wave increased a little (by about a fourth of the initial height) at first and then remained unchanged, unlike that of the first wave of DNBT and DIBT nitrates. The hydrogen wave appeared at potentials between the first and second waves, and grew with increasing concentration of hydrogen ions, consuming the second wave. The titration curve is given in Fig. 6, where the current is measured at a potential of the limiting current region of the second wave.

The concentration of hydrogen ions at the end point, C_h, is related with the concentration of the dibutylthallium compound, C, by

$$I_h C_h = \frac{n_h}{n} IC \qquad (5)$$

where I is the diffusion current constant of the dibutylthallium compound, I_h the diffusion current constant of hydrogen ions, n the number of electrons involved in the electrode process, and n_h the number of hydrogen

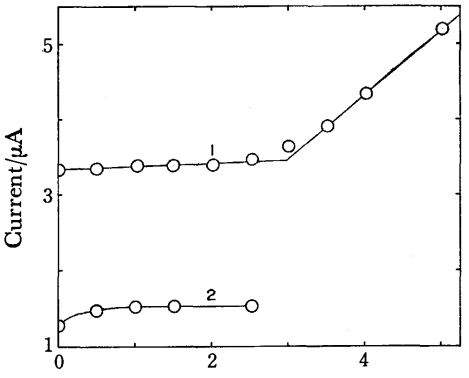

Fig. 6. Amperometric titration curves of 25 ml of 0.424 mM DSBT nitrate with 2.02 mM sulfuric acid. Curve 1, titrated at −1.80 V *vs.* SCE, of which potential lies in the limiting current region of the second wave. Curve 2, titrated at −1.10 V *vs.* SCE, of which potential lies in the limiting current region of the first wave.

ions consumed.[10] Values of the ratio n_h/n, calculated with Eq. (5) from observed values, are: 0.6_9 for DNBT nitrate, 0.6_9 for DIBT nitrate, and 0.7_2 for DSBT nitrate.

Coulometry was used for determination of the n value of DNBT nitrate reduction. The supporting electrolyte used is a mixture of 0.09 M sodium chloride and 0.01 M hydrochloric acid, where DNBT nitrate undergoes the single step reduction. A value of $n=3.0_2$ was obtained for the reduction. The n values of other reduction waves were estimated by comparison of the respective diffusion currents with the limiting current of DNBT nitrate in acid solutions.

Based on values of n and n_h/n, it was concluded that single step reductions of DNBT and DIBT nitrates in acid solutions are two-proton three-electron processes. The same reasoning was applied to the two-step reduction of DSBT nitrate. Besides, the inspection of the behavior of the first and second waves during the titration with sulfuric acid revealed that in unbuffered solutions all hydrogen ions are consumed by the electrode reaction of the second wave except a quite small fraction to be consumed by that of the first wave. Taking this and the change of height of the first wave with pH into consideration, it was concluded that the first and second waves of DSBT nitrate in alkaline solutions correspond to, respectively, no-proton one-electron and two-proton two-electron processes. In acid and neutral solutions a proton-consuming reaction proceeds to some extent at potentials of the first wave.

Figure 7 shows polarograms of DNBT nitrate recorded with Kalousek's circuit. This compound in acid solutions gives an only anodic wave at −0.4 V *vs.* SCE, of which the potential coincides with that of the anodic wave of thallium amalgam. Hence, thallium amalgam is one of the reduction products of DNBT nitrate in acid solutions where the single wave is observed on the DC polarogram. The DC polarographic wave splits into two at about pH 7 as the pH increases. Three anodic waves appear in the solution of pH 6.99 when the constant auxiliary potential (CAP) is controlled to be equal to a potential in the limiting current region

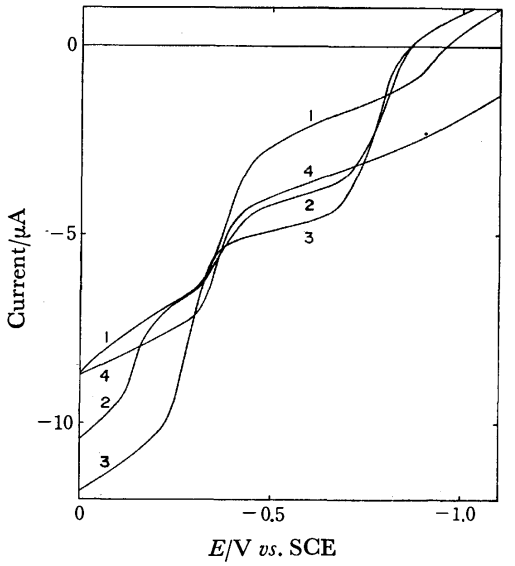

Fig. 7. Polarograms of DNBT nitrate recorded with Kalousek's circuit. Concentration of DNBT nitrate, 0.410 mM. pH and CAP (V *vs.* SCE), respectively: 1, 5.20 and −1.25; 2, 6.99 and −1.05; 3, 9.58 and −1.05; 4, 9.58 and −1.65.

of the first wave on the DC polarogram. The first and third anodic waves (counting from negative potentials to positive) decrease in height and disappear as the CAP successively becomes more negative. The second anodic wave is the dissolution wave of thallium amalgam. At pH 9.58 DNBT nitrate produces two anodic waves, namely, the first and second waves, the former disappearing with negative shift of the CAP to a potential corresponding to the limiting current region of the second wave on the DC polarogram.

DIBT nitrate produced similar polarograms when they were recorded with Kalousek's circuit.

Figure 8 shows polarograms of DSBT nitrate recorded

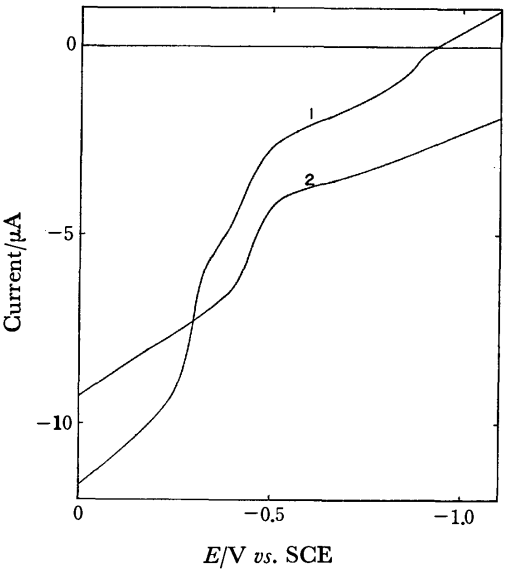

Fig. 8. Polarograms of DSBT nitrate recorded with Kalousek's circiut. Concentration of DSBT nitrate, 0.424 mM. pH and CAP (V *vs.* SCE), respectively: 1, 9.58 and −1.00; 2, 9.58 and −1.70.

with Kalousek's circuit. This compound gives two waves on the DC polarogram in all pH ranges examined. When the CAP is controlled to be equal to a potential in the limiting current region of the first wave on the DC polarogram, the compound produces two anodic waves: the dissolution wave of thallium amalgam and a wave which appears at more positive potentials and disappears with negative shift of the CAP.

The behavior of the anodic waves clearly indicates that at least two kinds of intermediates are involved in the reduction of DNBT and DIBT nitrates: one which produces the first anodic wave and of which formation does not require hydrogen ions, and the other which produces the third anodic wave and of which formation requires hydrogen ions. While the former also takes part in the reduction of DSBT nitrate (and produces the second anodic wave of this compound), participation of the latter was not proved experimentally. These conclusions were confirmed by comparison of the polarograms, recorded with Kalousek's circuit, of the three dibutylthallium nitrates in 0.167 M sodium sulfate with and without addition of sulfuric acid.

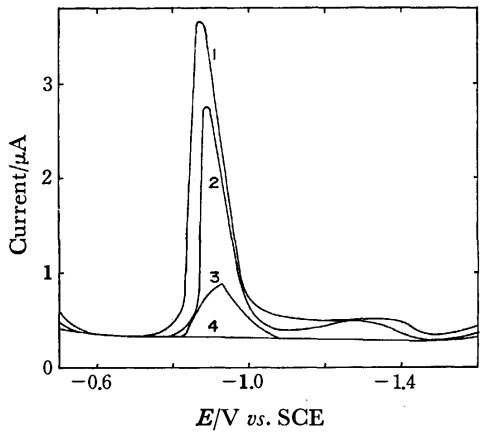

Fig. 9. AC polarograms of dibutylthallium nitrates in 0.1 M sodium hydroxide. Ionic strength was controlled to 0.5 with sodium sulfate. Curve 1, 0.410 mM DNBT nitrate; Curve 2, 0.421 mM DIBT nitrate; Curve 3, 0.424 mM DSBT nitrate; Curve 4, supporting electrolyte only.

Figure 9 shows AC polarograms of dibutylthallium nitrates in 0.1 M sodium hydroxide. It indicates that the electrode process of the first wave is most reversible for DNBT nitrate and least for DSBT nitrate. The peak heights decrease with increasing concentration of hydrogen ions, except that the peak height of DSBT nitrate does not change to any noticeable extent.

Mechanisms so far presented are not adequate enough to explain the results described above.[1-3] The following reaction scheme, accordingly, is proposed tentatively for the polarographic reduction of dibutylthallium compounds:

$$Bu_2Tl^+ + e \rightleftarrows Bu_2Tl \quad (6)$$

$$Bu_2Tl + H^+ \rightleftarrows Bu_2TlH^+ \quad (7)$$

$$2Bu_2TlH^+ \longrightarrow Bu_2Tl^+ + Tl^+ + 2BuH \quad (8)$$

$$Tl^+ + e \rightleftarrows Tl(Hg) \quad (9)$$

$$Bu_2TlH^+ + Bu_2Tl \rightleftarrows Bu_2Tl^+ + Bu_2TlH \quad (10)$$

$$Bu_2TlH + H^+ + e \longrightarrow Tl(Hg) + 2BuH \quad (11)$$

$$Bu_2Tl + Hg \longrightarrow Tl(Hg) + Bu_2Hg \quad (12)$$

$$Bu_2Tl + 2e \longrightarrow Tl(Hg) + 2Bu^- \quad (13)$$

$$Bu^- + H_2O \rightleftarrows BuH + OH^- \quad (14)$$

In the above scheme a sequence of Reactions (6)-(7)-(8)-(9) explains the single wave of DNBT and DIBT nitrates in solutions having pH values below 6. The regenerated ion Bu_2Tl^+ in Reaction (8) again enters the sequence at Reaction (6). For the species Bu_2TlH^+ it should be noted that the Tl-H^+ bond is a one-electron bond. With increase of pH another sequence of Reactions (6)-(7)-(10)-(11) becomes favorable, and is responsible for the positive shift of the wave with increase of pH in neutral solutions. Further increase of pH, however, decreases the height of the wave by making Reaction (7) difficult to proceed. The Bu_2Tl molecules that are not consumed by the reaction with Bu_2TlH^+ ions undergo transmetallation with the electrode mercury as given in Reaction (12). A two-electron reduction of the molecule is also possible by negative increase of the potential of DME. This results in a sequence Reaction (13)-(14), which corresponds to the second wave. The species Bu_2Tl and Bu_2TlH (or Bu_2TlH^+) are responsible for, respectively, the first and third anodic waves on the polarogram recorded with Kalousek's circuit.

The equilibrium constant of Reaction (7) in the reduction of DSBT nitrate does not seem to be as large as that in the reduction of DNBT and DIBT nitrates, since DSBT nitrate gives the double wave in all pH ranges examined.

(Received October 18, 1974)

The absorption spectra and the thermodynamic constants (K_{CT}, ΔH, and ΔS of formation) of the charge-transfer (CT) complexes of poly-*N*-vinylcarbazole (PVCz), the oligomers of *N*-vinylcarbazole (VCzOlig I and II, $\overline{DP}=5$ and 10 respectively), poly-*N*-carbazolylethylvinylether (PCzEVE), and the monomeric model compounds were examined in solution in order to clarify the characteristics of the complexes of polymeric donors with large pendant π-electron systems. The apparent spectra were resolved into two CT bands. The complexes of PVCz and VCzOlig II showed a lower frequency shift in the absorption maximum of the first CT band and an increase in the intensity ratio of the first to the second CT bands as compared with those of the monomeric complexes. This behavior, regarded as a kind of so-called polymer effect, seems to arise from some electronic interaction between neighboring carbazolyl groups in one polymer chain; it can be explained by variation both in the electron-donating character and in the distribution of the orientational isomers between the PVCz complexes and the others. A comparison of the observed values of K_{CT}, ΔH, and ΔS among the donors suggested that a dominant factor in determining these values is the steric hindrance rather than the small difference in the electron-donating character in the case of the structurally related polymeric complexes. The steric hindrance is important in the complexes of PCzEVE and VCzOlig I, where the electronic interaction is hardly present.

There have been many spectrophotometric investigations concerning a charge-transfer (CT) complex in which the donor consists of a polymeric species. The characteristics of CT complexes of polymeric donors can be clarified by a detailed comparison of both the absorption spectra and the thermodynamic constants (equilibrium constant (K_{CT}), and enthalpy (ΔH), and entropy (ΔS) of formation) of polymeric CT complexes with those of the corresponding monomeric ones. However, such a comparison has been made for only a few polymers.[1-6] Iwatsuki and Arai have studied the CT complexes formed between either poly-*N*-dimethylaminostyrene, copolymers of *N*,*N*-dimethylaminostyrene with styrene, or *N*,*N*-dimethyltoluidine and maleic anhydride; they have found a bathochromic shift in the CT absorption maximum and increases both in K_{CT} and in ΔH with an increase in the mean sequence length of the *N*,*N*-dimethylaminostyrene units. They have concluded that the electron-donating character of the dimethylaniline group increases with an increase in the number of groups attached to one polymer chain. This may be regarded as a kind of "polymer effect."

On the other hand, of the vinylpolymers with large pendant π-electron systems, poly-*N*-vinylcarbazole (PVCz) has been studied by two groups of investigators. Rembaum and his co-workers[4] have reported that K_{CT} values determined by the Benesi-Hildebrand method[7] were higher for the monomeric model, *N*-ethylcarbazole (ECz), than for the polymer, while Boudevska[5] have reported the opposite result for K_{CT} values determined by a modification of the successive dilution. Furthermore, the CT absorption maxima, ΔH, and ΔS have never been compared in detail between PVCz and ECz. Thus, no information about the "polymer effect" has been obtained in the case of CT complexes of the vinylpolymers with large pendant π-electron systems.

Recently, the present authors[8] have found, from the absorption spectra of the vinylpolymers, that there is some electronic interaction between pendant π-electron systems in one polymer chain in solution only for the vinylpolymers with large pendant π-electron systems connected directly to the skeletal chain. It seemed that it would be very interesting to see how the interaction affects the properties of the polymeric CT complexes. In the present series of papers, the authors have examined systematically the CT complexes of the vinylpolymers with large pendant π-electron systems and their monomeric compounds. This paper will deal with the CT complexes of PVCz and related compounds.

Experimental

Materials. The donor compounds studied were the following seven compounds containing carbazolyl (Cz) groups.

The ECz, 1,4-bis(*N*-carbazolyl)butane (DCzB), and 1,3-bis(*N*-carbazolyl)propane (DCzP) were used as monomeric model compounds of PVCz. They were prepared from purified carbazole[9] according to the literature.[10]

The oligomers of *N*-vinylcarbazole (VCz) were prepared by the HCl-initiated polymerization of VCz in acetonitrile. A 10-ml portion of acetonitrile containing 5×10^{-5} mol of dry HCl was stirred into 150 ml of acetonitrile containing 5 g of purified VCz and 2 ml of methanol at 10 °C in the dark. After half an hour, the solution was poured into 500 ml of a methanol–water (1:1) mixture. The oligomer was then filtered off, reprecipitated twice from the acetone solution with a methanol–water (7:3) mixture, and dried in a vacuum. The oligomer thus prepared (VCzOlig I) melts at 119—123 °C and has a degree of polymerization ($\overline{DP}$) of about 5. When no methanol was present in the polymerization solution, the oligomer (VCzOlig II) with a $\overline{DP}$ of about 10 and a mp of 175—185 °C was obtained.

The PVCz was prepared by the polymerization of a 0.5 M benzene solution of VCz in the presence of 1 mol % azobis-

isobutyronitrile in an evacuated sealed tube at 60 °C for 5 hr and was reprecipitated three times from the benzene solution with methanol. The polymer has $\overline{DP}$ of about 600.

The poly-*N*-carbazolylethylvinylether (PCzEVE) was used as a high molecular compound related to PVCz, in which the Cz groups are connected to the skeletal chain at a distance of about 4 Å by $-O-CH_2-CH_2-$ bonds. The polymer was prepared by the polymerization of a 0.2 M toluene solution of *N*-carbazolylethylvinylether in the presence of 3 mol % $BF_3O(C_2H_5)_2$ under a nitrogen atmosphere at −25 °C for 9 hr[11] and was reprecipitated three times from the benzene solution with methanol. The polymer has a $\overline{DP}$ of 33 and melts at 137—148 °C.

Tetracyanoethylene (TCNE), tetracyanoquinodimethane (TCNQ), *p*-chloranil (CA), 2,3-dichloro-5,6-dicyano-*p*-benzoquinone (DDQ), and 2,3,7-trinitrofluorenone (TNF) were used as acceptor compounds. The TCNE was recrystallized twice from monochlorobenzene and was subsequently sublimed in *vacuo*. The TCNQ, CA, and DDQ were recrystallized twice from acetonitrile, benzene, and methylene chloride respectively. The TNF was prepared from fluorenone according to the literature.[12]

The ethylene chloride used as a solvent was purified by the ordinary method.

Method. The absorption spectra and optical density were measured by means of two Shimadzu spectrophotometers, UV-200 and MPS-50 L, using 1-cm quartz cells and a temperature-regulated cell holder.

The K_{CT} was determined by the use of the Benesi-Hildebrand equation (1):[7]

$$[A]_0(l/A_\lambda) = (1/\varepsilon K_{CT}[D]_0) + (1/\varepsilon) \quad (1)$$

where $[A]_0$ and $[D]_0$ are the initial concentrations of the acceptor and the donor respectively; l is the path length; A_λ is the absorbance at λ due only to the complex, and ε is the molar extinction coefficient of the complex at λ. This equation is valid for a 1:1 complex when $[D]_0 \gg [A]_0$.

The K_{CT} was determined at six different temperatures from 2 °C to 30 °C. The ΔH and ΔS of formation of a CT complex were calculated by using Eq. (2),

$$\ln K_{CT}\varepsilon = (-\Delta H/RT) + (\Delta S/R) + \ln \varepsilon \quad (2)$$

Results and Discussion

The complexes with DDQ were unstable, and the CT spectra changed slowly with the time. Especially, the complexes with PCzEVE and VCzOlig I were more unstable and changes of the spectra began in a few minutes after the mixing. The other complexes were stable, and no change in absorbance with time was observed even after 12 hr. The 1:1 stoichiometry of all the complexes studied was confirmed by the continuous-variation method.

CT Absorption Spectra. The absorption spectra of the complexes with TCNE, TCNQ, CA, and DDQ are shown in Figs. 1—3. The apparent CT absorption maxima (ν_{max}) and the shifts in ν_{max} ($\Delta\nu_{max}$) as compared with that of the ECz complex are listed in Table 1.

The apparent ν_{max} appears at lower frequencies for the polymeric donors than for the monomeric ones. This is especially clear in the case of the complexes with CA or DDQ. It is well-known that there is a linear relationship between the energy of the CT transition ($h\nu_{CT}$) and the ionization potential of the donor (I_p) for a series of complexes consisting of like donors and

a common acceptor. However, in the present case, the lower frequency shift in the apparent ν_{max} should be considered not to correspond directly to a decrease in the I_p of the polymeric donors. This is because it is considered, for the following reasons that the spectra of all the complexes studied are composed of multiple overlapping bands: 1) in the spectra of the monomeric complexes, the absorption shoulders are apparently observed at frequencies lower than the apparent ν_{max}, and Klopffer has satisfactorily resolved the spectra of the complexes between *N*-isopropylcarbazole, one of the monomeric donors, and either TCNE or CA into two CT bands[13)]: 2) in the case of the polymeric donors, although the shoulders are hardly observed at all, the spectra have asymmetric bands with exceptionally large half bandwidths: 3) in the cases of CA and DDQ, although considerably shifted, the apparent absorption peaks for PVCz and VCzOlig II appear near the absorption shoulder for the monomeric donors.

Therefore, the spectra were resolved into two CT

a) Errors in ν_1, ν_2, $\Delta\nu_{12}$ and $\Delta\nu_1$ are ±100 cm^{-1} for the CA complexes of VCzOlig I, II and PVCz and ±50 cm^{-1} for the other complexes. Errors in f_1/f_2 are $\pm15\%$ for the former complexes and $\pm10\%$ for the latter ones. The parenthesized numerical values are less reliable because of either decomposition of the complex or overlapping of absorption of TNF with that of the complexes.

bands by the use of a curve-analyzer, based on the assumptions that the individual resolved CT bands were symmetrical and that the location of the second CT band was almost the same for the complexes between a series of donors and a common acceptor. These assumptions seem reasonable judging from the spectra of the complexes with poly-1-vinylpyrene and related compounds.[14] The results were satisfactory, as is shown by the examples in Figs. 4—6. The absorption maxima of the first and the second CT bands (ν_1 and ν_2), the differences ($\Delta\nu_{12}$ and $\Delta\nu_1$ ($\Delta\nu_{12}=\nu_2-\nu_1$, and $\Delta\nu_1=\nu_1-\nu_{1\cdot EC_2}$)), and the intensity ratios (f_1/f_2) of the first to the second CT bands are listed in Table 2.

As the $\Delta\nu_{12}$ values are regarded to be constant at 4100 ± 400 cm^{-1} for all the complexes studied, irrespective of the acceptors, the first and the second CT bands are considered to be due to the CT from the highest occupied and the second highest occupied levels of the donor, respectively, to the lowest vacant level of the acceptor.

There is no appreciable difference in either ν_1 or f_1/f_2 among the monomeric donors, with the exception of ν_1 for DCzP. DCzP shows a little higher frequency shift in ν_1 as compared with the ν_1 values for the other monomeric donors. This is mainly due to the weakness of the electron-donating character of the substituent group per Cz ring as compared with that of an ethyl group, and not to some interactions between the two Cz rings connected at 1,3-positions, as was found in the study concerning the UV spectra.[8] PVCz and VCzOlig II show a lower frequency shift in ν_1 (50—300 cm^{-1}), with the exception of the ν_1 values for the CA complexes, and a considerable increase in f_1/f_2, especially in the cases of CA and DDQ, as compared with those for the monomeric donors. The changes are larger for PVCz than for VCzOlig II. VCzOlig I shows no clear shift in ν_1, but a small increase in f_1/f_2 only in the case of CA. On the other hand, PCzEVE shows no appreciable change in either ν_1 or f_1/f_2 as compared with those for the monomeric donors, in spite of the high value of $\overline{DP}$.

It was thus clarified that the apparent complicated variation in the shape of the CT spectra between the monomeric and the polymeric donors results from the phenomena regarded as a kind of so-called polymer effect—namely, a lower frequency shift in ν_1 and a considerable increase in f_1/f_2 of the polymeric CT complexes as compared with those of the monomeric ones. It should be noted that the phenomena become clear with an increase in the $\overline{DP}$, although they are unobservable for the pentamer, in a series of the polymers of VCz, and that they are not observed for PCzEVE, which has Cz groups apart from the skeletal chain in spite of the high value of $\overline{DP}$ ($\overline{DP}=33$). It is interesting that the $\overline{DP}$ dependency of the shift in ν_1 mentioned above is quite different from that of the maleic anhydride complexes of poly-*N*,*N*-dimethylaminostyrene and related copolymers,[3] where the bathochromic shift results from the aminostyrene unit with a $\overline{DP}$ value of only two.

The results mentioned above are closely related to the results obtained from the UV absorption spectra concerning the electronic interaction between pendant

π-electron systems in one polymer chain.[8] The phenomena mentioned above, therefore, seem to arise from some electronic interaction between neighboring Cz groups in one polymer chain.

The increase in f_1/f_2 upon a replacement of the monomeric donors by the polymeric ones is an interesting phenomenon which has hitherto never been reported, to the knowledge of the authors. It has been suggested that the complexes between either naphthalene or substituted benzenes and TCNE in solution have isomers differing in the mutual orientations of the symmetry axes of the donor and acceptor.[15] Kuroda and his co-workers[16] have made a theoretical treatment of the CT interaction in the TCNE complexes of naphthalene and pyrene, considering the effect of the interaction of higher CT states, and have concluded that the binding energy varies little with the angle between the symmetry axes of the donor and acceptor and that the energy barrier hindering the rotation of one molecule relative to its partner is less than 1 kcal/mol. Therefore, in some complexes, the orientational isomers are considered to coexist in solution with an almost equal probability because of the ease of the rotational interconversion among them. They have also suggested that f_1/f_2 is a parameter which offers information on the orientation of the donor molecule to the acceptor one.[16] The variation in f_1/f_2 in the present case may be a result of the orientational isomers, the distribution of which is affected by a perturbation effect of neighboring Cz groups to the complex. No detailed explanation can be offered at present.

Table 3. Temperature dependence of apparent CT absorption maxima of the CA complexes of PVCz and VCzOlig II

	λ_{max} [nm][a]					
	2 °C	5 °C	10 °C	20 °C	35 °C	60 °C
VCzOlig II	590	586	585	573	556	—
PVCz	597	595	593	588	585	567

a) $[D]_0=0.156$ M (VCz unit), $[A]_0=0.007$ M in ethylene chloride.

In the complexes between either PVCz or VCzOlig II and CA, the apparent absorption maxima shifted reversibly to higher frequencies with an increase in the temperature, as is shown in Table 3. The shift was apparently due to a decrease in f_1/f_2 with an increase in the temperature and was larger for VCzOlig II than for PVCz. This suggests that the perturbation effect of neighboring Cz groups on the complex weakens according to the gradual disappearance of the local helical structure and/or the gradual ease of the internal rotation of a polymer chain with an increase in the temperature. The NMR measurements[17] have suggested that the internal rotation of the polymer chain, being restricted by neighboring bulky Cz groups, is sensitive to the temperature. In the PVCz (or VCzOlig II) complexes of TCNE and TCNQ, such a shift could not be observed, probably because of the small variation in f_1/f_2 between the PVCz and the ECz complexes.

The $h\nu_{CT}$ for a series of complexes with a common acceptor can be described by the following expressions:

$$h\nu_{CT} = (I_p - C_1) + C_2/(I_p - C_1) \quad (3)$$

$$h\nu_{CT} = aI_p + b \quad (4)$$

where C_1, C_2, a, and b are constants for a given acceptor. The first and the second ionization potentials of ECz are determined to be 7.43 ± 0.03 eV and 8.02 ± 0.04 eV respectively by the use of sets of the constants for TCNE, TCNQ, CA, and TNF.[18] These values are in agreement with those reported by Klopffer,[13] and the first ionization potential (I_{p1}) is much smaller than the previously reported values, determined from the apparent absorption maxima.[4,19,20]

The lower frequency shift in ν_1 of the PVCz complexes as compared with the ν_1 of the monomeric complexes cannot be explained by supposing an effect of insufficient solvation due to both the polymer backbone and adjacent Cz groups, because such an effect would tend to cause a higher frequency shift, if it is present at all. The lower frequency shift in ν_1 may, therefore, be attributed to a decrease in the I_{p1} value of PVCz as compared with those of ECz due to some electronic interaction between neighboring Cz groups, assuming that the ν_1 varies little with a variation in the distribution of the orientational isomers. A decrease in the I_{p1} value of PVCz is evaluated to be about 0.03 eV from the variation in the ν_1 of the TCNE complexes, which is most reliable. This value seems reasonable, because it is comparable to the value of 0.04 eV for poly-1-vinylpyrene, the CT complexes of which show no variation in f_1/f_2 as compared with that of the monomeric CT complex.[14]

Thermodynamic Constants of the Formation of CT Complexes. For all the complexes studied, fairly good straight lines of Benesi-Hildebrand plots were obtained. The thermodynamic constants are listed in Table 4. Although Livina and his co-workers[20] have reported that the values of ε in the PVCz complexes have decreased with an increase in the temperature, ε was independent of the temperature in the region from 2 °C to 30 °C with the exception of the values of the complexes between either PVCz or VCzOlig II and CA. The data for the CA complexes are less reliable because of a little variation in the spectra with the temperature.

In a series of complexes with a common acceptor, the ε_{max} values are almost constant, contrary to the results reported by Boudevska.[5] The values of K_{CT}, $-\Delta H$, and $-\Delta S$ are in the following orders: ECz$>$DCzP$\sim$PCzEVE$>$VCzOlig$\sim$PVCz for K_{CT}; ECz$\sim$PCzEVE$>$PVCz$\gtrsim$VCzOlig$\gtrsim$DCzP for $-\Delta H$, and PVCz$>$VCzOlig$\sim$PCzEVE$>$ECz$>$DCzP for $-\Delta S$.

In general, there is a near-linear correlation between K_{CT} and $-\Delta H$ as well as between $-\Delta H$ and $-\Delta S$ for a set of complexes of a common acceptor with a series of structurally related donors.[21] In the present case, this correlation holds roughly only for the complexes with ECz and DCzP, where a dominant factor in determining K_{CT}, ΔH, and ΔS is the electron-donating character rather than the steric hindrance. The steric hindrance in a series of donors is considered to be in the order of: PVCz$>$VCzOlig$>$PCzEVE$>$DCzP$>$ECz. The values of K_{CT} and $-\Delta H$ of the complexes with PVCz and VCzOlig I and II are smaller than

Table 4. Thermodynamic constants of formation of CT complexes[a)]

Donor	$[D]_0$ M	Acceptor	$[A]_0$ 10^3 M	ε_{max}[b)] (cm/M)	K_{CT} (M^{-1}) at 15 °C	$-\Delta H$ kcal/mol	$-\Delta S$ e.u.

those of ECz, in spite of a small enhancement in the electron-donating character of PVCz as compared with that of ECz. Futhermore, the value of K_{CT} of the PCzEVE complex is smaller than that of the ECz complex, in spite of no difference in the spectral properties (ν_1, ν_2, and f_1/f_2) between the former and the latter complexes. Therefore, it is clear that a dominant factor in determining K_{CT}, ΔH, and ΔS is the steric hindrance rather than a small difference in the electron-donating character in the case of the structurally related polymeric complexes. It should be noted that the situation is the same even in the case of VCzOlig I ($\overline{DP}=5$), as in the case of PVCz. This is quite different from the situation of the variation in both ν_1 and f_1/f_2 resulting from some electronic interaction between neighboring Cz groups.

The results presented above are in contrast to the results for the maleic anhydride complexes of poly-*N*,*N*-dimethylaminostyrene and related copolymers, where both K_{CT} and $-\Delta H$ increase with an increase in the $\overline{DP}$. This may be explained as follows. Poly-*N*,*N*-dimethylaminostyrene is one of the vinylpolymers with small pendant π-electron systems, although it is a fairly strong electron donor, and its electron-donating charater is to a considerable extent localized on the dimethylamino group. Therefore, the steric hindrance in forming a CT complex may not be serious in this polymer.

It is important to examine whether the interesting results for the PVCz complexes can be applied generally to the complexes of the other vinylpolymers with large pendant π-electron systems. A further study concerning the other polymeric complexes is now in progress.

This work was supported in part by a Scientific Research Grant of the Ministry of Education.

Simple and Complex Anion-radical Salts Derived from 2,3-Dicyano-1,4-naphthoquinone

Izumi MAKI, Yoshio MATSUNAGA,* Mitsuru NAKAKURA, and Akihiko NONAKA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received November 8, 1974)

Simple and complex anion-radical salts were prepared by the reduction of 2,3-dicyano-1,4-naphthoquinone with a number of onium iodides. The simple salts are green-colored, and the complex salts, with a composition of 1 : 2, are dark green or brown. The latter salts show electronic absorptions extending into the near-infrared region. The electrical resistivities are rather high—— 10^7—10^{12} ohm cm in the simple salts and 10^3—10^7 ohm cm in the complex salts. The ESR spectra characteristic of triplet excitons were observed with polycrystalline samples, and the zero-field splitting parameters and the singlet-triplet separation energies were estimated for most of the salts. The anion-radicals appeared to be in strong pair-by-pair interactions in these salts.

Extensive studies have been carried out on the synthesis and physical properties of the anion-radical salts derived from 7,7,8,8-tetracyanoquinodimethane (TCNQ); however, little attention has been paid to the possibility of finding new series derived from compounds other than TCNQ. So far, only the following compounds have been reported to form series of the onium salts: 9-dicyanomethylene-2,4,7-trinitrofluorene and -2,4,5,7-tetranitrofluorene,[1,2] 3,3′,5,5′-tetrachloro-4,4′-diphenoquinone (TCDQ), its bromo analogue (TBDQ),[3] and 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ).[4] Continuing our search for highly-conducting anion-radical salts,[3] we worked on the preparation of a new series based on 2,3-dicyano-1,4-naphthoquinone, hereafter abbreviated as DCNQ. This quinone has an electron-acceptor strength comparable with that of *o*-bromanil in terms of their complexing properties,[5,6] and it is readily reduced to the semiquinone anion by the use of the iodide ion. The solid-state spectra of some alkali salts have been described by Iida of our laboratory.[7] The anion-radical salts formed with most of the onium ions were of a 1 : 1 composition, and the complex salts, when available, were not always well-defined. Moreover, the electrical resistivities of this series were found to be discouragingly high. Nevertheless, the recent report by Gordon and Hove on triplet excitons in the four tetraalkylammonium salts of the DDQ anion-radical, which is the only other anion-radical after TCNQ which exhibits this behavior, prompted us to do a little more work and to publish the results.

Experimental

Materials. 2,3-Dicyano-1,4-naphthoquinone was prepared by the procedures reported by Reynolds and VanAllan or by Wallenfels *et al.* starting from 2,3-dichloro-1,4-naphthoquinone,[8,9] Eastman yellow label. The crude product was purified by recrystallization from toluene and then by sublimation *in vacuo*. The anion-radical salts were obtained by the reduction of the quinone dissolved in acetone with an appropriate onium iodide. All the cations employed were diamagnetic, and their iodides were taken from the stock prepared for our earlier work.[3] The precipitated salt was filtered and washed with a small amount of acetone. The salts are fairly soluble in this solvent. The composition was determined by microanalysis.

Measurements. The electrical resistivities of compressed polycrystalline samples were examined by means of a Wheatstone bridge (Yokogawa Electric Works, Type 2768) employing a cell similar to that designed by LaFlamme.[10] The electronic spectra of the solid salts in the region from 325 to 25000 nm were measured with a Beckman DK-2A spectro-reflectometer. The pulverized sample was diluted with sodium chloride in concentrations of the order of 1 weight percent in order to obtain a reasonable reflectance. The spectra were recorded as the difference in reflectance between the mixture and pure sodium chloride and were plotted using the Kubelka-Munk function $f(R)=(1-R)^2/2R$, where R is the reflectance. The ESR measurements were carried out by means of a JEOL model JES-ME-3X spectrometer in the temperature range from room temperature to 100 °C. The magnetic field scan was calibrated with Mn^{2+}-doped MgO powder (86.9 G).

Results and Discussion

The twenty-five DCNQ anion-radical salts for which the compositions could be established by microanalysis are listed in Table 1. They are of a 1 : 1 composition unless otherwise stated. The onium cations employed in the present series include ammonium, phosphonium, arsonium, quinolinium, and acridinium. The resistivities of the simple salts range from 10^7 to 10^{12} ohm cm, and those of the complex salts, from 10^3 to 10^7 ohm cm. Thus, complex salts are apparently more conducting than the simple salts, in agreement with the tendency well-established for TCNQ anion-radical salts.[11,12] However, the resistivity values, especially those of the complex salts, are appreciably greater than those of TCNQ salts and also those of the TCDQ and TBDQ salts prepared by us.

All the simple DCNQ salts are dark green, and the solid-state spectra are similar to each other. For example, Fig. 1 presents the spectra of the morpholinium and methyltriphenylphosphonium salts. They consist of three bands, located at 12.9, 20.4, and 26.3×10^3 cm^{-1}, and at 14.8, 20.0, and 27.6×10^3 cm^{-1}, respectively. Although the locations are somewhat different, the other salts including the sodium salt show essentially the same pattern. The band maxima are listed in Table 1. The low-energy bands are found in the region from 12.9 to 15.1×10^3 cm^{-1}; the middle bands, in the

Ethyldi-*n*-propyl-ammonium (1:2)	1×10^{7}	8.8, 13.5, 22.0, 24.1
Tri-*n*-propylammonium (1:2)	1×10^{7}	9.1, 13.8, ——, ——
N-Ethylquinolinium (1:2)	7×10^{3}	<4.0, —, 21.1, >30.0
Isoquinolinium (1:2)	1×10^{4}	4.8, 14.3, 20.5, 29.0

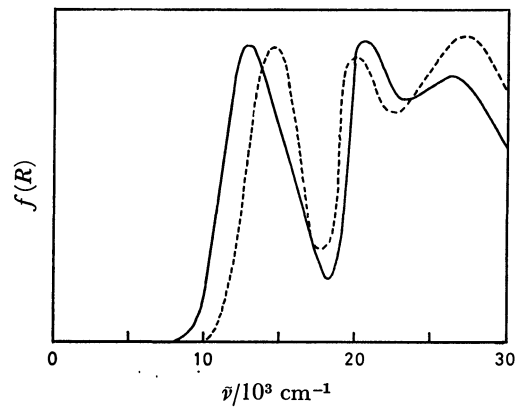

Fig. 1. Diffuse reflection spectra of the simple DCNQ salts containing morpholinium ion (——) and methyltriphenylphosphonium ion (------).

region from 19.5 to 22.8×10^3 cm^{-1}, and the high-energy bands, in the region from 25.0 to 29.3×10^3 cm^{-1}. The last location may be affected by the absorption due to the counter ion. In the case of the *N*-ethylacridinium salt, the middle band could not be determined clearly because of its breadth. These radical salts are supposed to contain columns of the semiquinone ions, which may be in an essentially pair-by-pair or more-than-by-pairs interaction. Although Iida did not identify the type of interaction in the alkali salts,[7] the observation of the triplet exciton ESR to be described later indicates that the pattern in Fig. 1 arises from the former interaction.

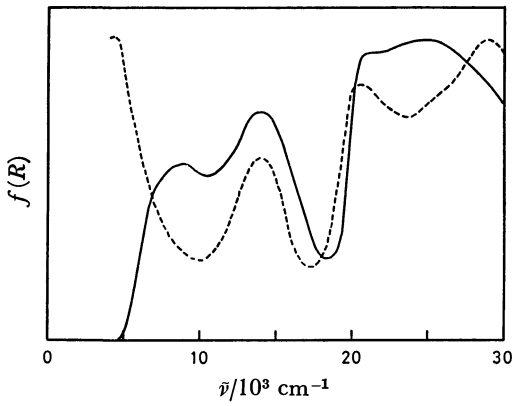

Fig. 2. Diffuse reflection spectra of the complex DCNQ salts containing tri-*n*-propylammonium ion (——) and isoquinolinium ion (------).

The complex ammonium salts are dark green, and the quinolinium salts are brown. As is shown in Fig. 2, the spectra of the complex tri-*n*-propylammonium and isoquinolinium salts consist of four bands; therefore, the whole pattern looks like the pattern of the simple salts, with an "additional" band in the near-infrared region. The location of this band depends greatly upon the kind of the onium ion. The bands in the four ammonium salts are located at energy values nearly twice as high as those in the *N*-ethylquinolinium and isoquinolinium salts. In accordance with LeBlanc's postulate that aromatic counter ions with large polarizabilities are effective in producing low resistivities of anion-radical salts,[13] the latter two may be said to be about one thousand times more conducting than the former four. The tendency for the energy of the lowest-energy band to be less as the resistivity is lower is also roughly observed in the TCDQ and TBDQ anion-radical salts studied earlier.[3] When the band shifts to a lower energy, the intensity becomes relatively higher than that of the second low-energy band. Thus, the maximum of the latter band in the most conducting *N*-ethylquinolinium salt is not observed in the spectrum. The lowest-energy absorption may be ascribed to the interaction between the DCNQ anion-radical and the neighboring DCNQ molecule, which are possibly stacked together to form a column. However, the correlation between the location of the absorption band and the resistivity suggests that the interaction is not strictly limited within such a pair.

Although the results of microanalysis were far from the values calculated for any composition, the DCNQ salts with the following cations appeared to be not simple: methyldibenzylammonium, isopropyltriphenylphosphonium, *N*-methylquinolinium, *N*-methyl-4-methylquinolinium, *N*-methylisoquinolinium, *N*-ethyl-

isoquinolinium, and *N*-methylacridinium. The resistivity values of the first two are of the orders of 10^6 and 10^4 ohm cm respectively, while those of the rest of the order of 10^3 ohm cm. These values are too low to be considered as those of the simple salts, but they fit into the range shown by the six complex salts given in Table 1. All the salts except the methyldibenzylammonium salt are dark brown in color. The spectral patterns are also characteristic of the complex salts mentioned above. The lowest-energy band in the ammonium salt is located at 7.7×10^3 cm^{-1}, and that of the phosphonium salt, at 5.8×10^3 cm^{-1}. The absorption maxima in the other salts are beyond the limits of the spectrophotometer employed—namely, below 4×10^3 cm^{-1}.

Würster's blue perchlorate and various TCNQ anion-radical salts have been known to exhibit ESR spectra from triplet spin excitons.[14-19] When a polycrystalline sample is employed for the measurement, the triplet character of the paramagnetic excitations is best manifested by the appearance of three pairs of resonance lines.[4,19] They correspond to the three principal axis splittings, which result from an anisotropic zero-field splitting of the triplet levels caused by the dipole-dipole interaction of the two electrons. All the above-mentioned salts are apparently of the class in which each radical interacts strongly with only one other free radical,[20] and they are known to exhibit rather high electrical resistivities.[16] It seems very likely that the DCNQ anion-radical salts belong mostly to such a class also. Indeed, the ESR spectra characteristic of triplet excitons could be observed with all the salts having resistivity values of 10^7 ohm cm or higher.

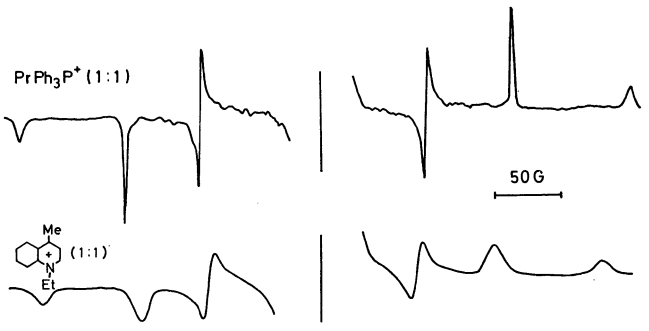

Fig. 3. First derivatives of ESR absorption spectra of the simple *n*-propyltriphenylphosphonium and *N*-ethyl-4-methylquinolinium DCNQ salts.

The triplet spectrum, particularly the outermost pair, is very weak at room temperature, and the salt starts to decompose between 80 and 110 °C; therefore, the measurements could be made only in a limited temperature range. No change in the shape and separation of the pair was detected in such a narrow range. For example, Fig. 3 shows the polycrystalline powder spectra of the *n*-propyltriphenylphosphonium and *N*-ethyl-4-methylquinolinium salts. The former spectrum was recorded at 80 °C, and the latter, at 70 °C. The central line, which may be attributed to impurities or lattice imperfections, is several orders of magnitude stronger than the triplet spectrum and becomes broader as the temperature is raised. Assuming, for the sake of simplicity, an isotropic *g* value equal to the free electron value, the principal axis splittings are related to the zero-field splitting parameters, *D* and *E*, by the following equations:[20]

$$d_1 = 2|D|$$
$$d_2 = |D| + 3|E|$$
$$d_3 = |D| - 3|E|,$$

where d_i is the measured separation. The numbering is given starting from the outermost pair of resonance lines. The parameters may be expressed in terms of the spatial distribution of the correlated spins of the triplet excitons. The values of *D* and *E* for seventeen salts, including four complex ones, are summarized in Table 2. Among the salts here, the outermost pairs in the ethyl- and *n*-propyl-dibenzylammonium salts were too weak to be accurately located, even at the highest temperature examined, 90 °C. Consequently, only the values of d_2 and d_3 were used to estimate the parameters. In addition to the salts given in Table 2, we observed the triplet spectra with the *N*-methyl- and *N*-propylmorpholinium and acridinium salts; however, these spectra were so poor that no assignment of the resonance lines could be made with confidence.

Table 2. Zero-field splitting parameters and singlet-triplet separation energies of the anion-radical salts derived from dicyanonaphthoquinone

Cation	$\lvert D\rvert$ (gauss)	$\lvert E\rvert$ (gauss)	ΔE (eV)
Sodium	111	8	0.20
Dibenzylammonium	236	19	0.35
Ethyldibenzylammonium	222	23	0.41
n-Propyldibenzylammonium	225	21	0.33
Morpholinium	238	20	0.44
N-Ethylmorpholinium	232	20	0.43
Methyltriphenylphosphonium	239	22	0.41
Ethyltriphenylphosphonium	234	19	0.45
n-Propyltriphenylphosphonium	231	21	0.41
Methyltriphenylarsonium	238	23	0.47
N-Ethyl-4-methylquinolinium	211	18	0.33
N-*n*-Propyl-4-methylquinolinium	241	25	0.37
N-Ethylacridinium	226	20	0.41
Di-*n*-propylammonium (1 : 2)	206	18	0.43
Methyldi-*n*-propylammonium (1 : 2)	165	13	0.14
Ethyldi-*n*-propylammonium (1 : 2)	203	17	0.47
Tri-*n*-propylammonium (1 : 2)	207	18	0.38

The spectra of the complex salts are exemplified by the methyldi-*n*-propylammonium and tri-*n*-propylammonium salts presented in Fig. 4. They were recorded at 30 and 80 °C respectively. The magnitude of the parameters depends on the size of exciton, which in turn may be expected to depend on the composition of the salt. As a matter of fact, both the zero-field splitting parameters in the simple TCNQ salts are about twice as large as those of the complex salts of a 1 : 2 composition, while those of a 2 : 3 composition come between them.[19] Nevertheless, the difference found with the DCNQ salts is not appreciable at all. We can see that the parameters in the complex salts are

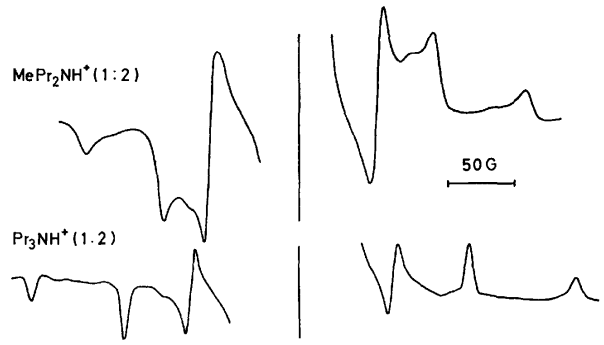

Fig. 4. First derivatives of ESR absorption spectra of the complex methyl di-*n*-propylammonium and tri-*n*-propylammonium DCNQ salts.

only slightly less than those in the simple salts. This observation may imply that the DCNQ anion-radicals in a column do not alternate with the molecules. The repeating unit might be approximated by $(DCNQ)^0$-$(DCNQ)^-$-$(DCNQ)^-$-$(DCNQ)^0$, which is analogous to a tetrad of TCNQ established by the structural analysis of triethylammonium $(TCNQ)_2$.[21] Except for the sodium and methyldi-*n*-propylammonium salts, all the salts have D values over 200 gauss and E values of about 20 gauss. Gordon and Hove have reported that the D parameter of their tetrapropylammonium DDQ salt, 231 gauss, exceeds the largest value ever recorded for the linear-chain radical salts, that is, 215 gauss for $[TMPD^+]_2[Ni(nmt)_2]^{2-}$, where TMPD is *N,N,N',N'*-tetramethyl-*p*-phenylenediamine and where nmt is the dinegative *cis*-1,2-dicyanoethylene-1,2-dithiolate anion, studied earlier by the same author.[20] The D parameter in many of the DCNQ salts matches the value in the DDQ salts or is even larger. Both the simple and complex DCNQ salts undoubtedly belong to the class of ion-radical salts with strong pair-by-pair interactions.

The integrated intensity of the ESR absorption for a triplet state is given by:

$$I \propto T^{-1}[\exp(\Delta E/kT)+3]^{-1},$$

where ΔE is the energy for the singlet-triplet separation. As the shape remains the same through the measured temperature range, the peak-to-peak intensity on the first derivative curve was taken as a measure of I. Because the separation energy was expected to be larger than kT, the following approximation was employed in the present work:

$$I \times T \propto \exp(-\Delta E/kT).$$

Plots of log IT in arbitrary unit *versus* $1/T$ give straight lines, as is demonstrated by the five salts shown in Fig. 5. The open and shaded circles represent the data taken from different pairs. The separation energies of the DCNQ salts also listed in Table 2 are generally larger than those observed with the four DDQ salts (0.19—0.30 eV) and are comparable with the value for the simple morpholinium TCNQ salt reported by Jones and Chesnut (0.41 eV) and also with that reported by Bailey and Chesnut (0.36 eV).[17,18] In this TCNQ salt, the exciton creation energy is so high that, at accessible temperatures, the exciton concentration is too low to enable one to observe any appreciable exciton-exciton

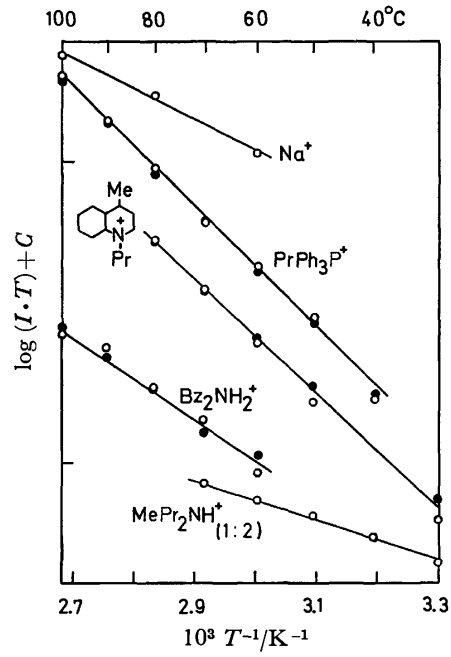

Fig. 5. Temperature dependence of ESR absorption characteristic of triplet excitons in the simple sodium, *n*-propyltriphenylphosphonium, *N*-propyl-4-methyl quinolinium, and dibenzylammonium DCNQ salts and in the complex methyldi-*n*-propylammonium DCNQ salt.

exchange.[15,17] Moreover, the resistivity at room temperature has been reported to be as high as 10^9 ohm cm.[11,12] This feature is quite similar to that of most of the DCNQ salts.

In conclusion, all the properties studied here seem to indicate that 2,3-dicyano-1,4-naphthoquinone was not a good choice for our original purpose of finding a new series of highly-conducting anion-radical salts. However, the salts may be worthwhile for a detailed study of the behavior of the triplet exciton.

An X-Ray Analysis of the Orientational Disorder of *N*-Methylphenazinium-TCNQ

Hayao KOBAYASHI

Department of Chemistry, Faculty of Science, Toho University, Funabashi, Chiba 274

(Received September 4, 1974)

The X-ray diffraction patterns of NMP-TCNQ show diffuse streaks along the c* direction. The analysis of the intensities of these streaks revealed that the orientation of NMP is one-dimensionally disordered along the c axis. The structure obtained indicates that the potential exerting on an electron moving in a column of TCNQ is not random, but can be expressed by a periodic function; this implies that NMP-TCNQ can not be regarded as a disordered one-dimensional conductor. The periodicity of the potential means that the one-dimensional energy band must be filled.

N-Methylphenazinium-7,7,8,8-tetracyanoquinodimethanide (NMP-TCNQ) is one of the highly conducting TCNQ salts. The physical properties of the salt have been intensively investigated.[1] Based on the theorem that the electronic states in any disordered one-dimensional structure are localized, Bloch, Weisman, and Varma (BWV) have explained the temperature dependence of the electrical conductivity of NMP-TCNQ.[2] Their interpretation depends on Fritchie's average structure of NMP-TCNQ[3] and the published electrical conductivity of Shchegolev *et al.*[4] NMP is located at the position of (1/2, 1/2, 1/2), whose site symmetry is $\bar{1}(C_i)$, taking either of the two possible orientations as equally probable (Fig. 1). This disorder seems to be

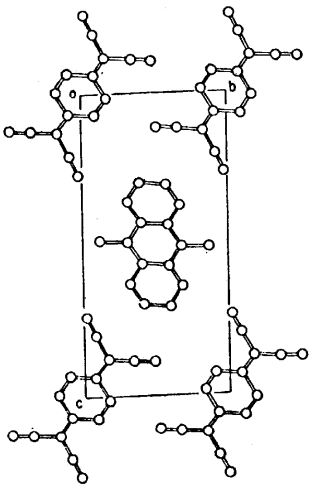

Fig. 1. The avarage structure of NMP-TCNQ.[3]

able to produce a potential which varies randomly along a TCNQ column. The low-temperature conductivity can be approximately fitted by $\ln \sigma \sim (T_0/T)^{1/2}$, derived for a disordered one-dimensional system by the application of the theories of Mott and Ambergaakar, Halperin, and Langer.[2] On the other hand, Heeger *et al.*[1,5,6] regarded NMP-TCNQ as a realization of the one-dimensional Mott-Hubbard model, with the disorder playing only a peripheral role. Their experimental study and analysis of the low-temperature conductivity of high-purity single crystals of NMP-TCNQ revealed that the plot of $\log_{10}(\sigma/\sigma_0)$ *vs.* $1/T$ shows straight-line behavior; this is not consistent with the analysis of BWV. Because of the electron-electron Coulomb repulsion, the electron localizes to from a magnetic insulator at low temperatures. The magnitude of the Hubbard gap goes smoothly to zero at *ca.* 200 K.[6] In this paper, the details of the orientational disorder will be reported in order to contribute to a better knowledge of one-dimensional conductors.

Experimental

The specimens of *N*-methylphenazinium-7,7,8,8-tetracyanoquinodimethanide(NMP–TCNQ: $C_{13}H_{11}N_2 \cdot C_{12}H_4N_4$) was kindly supplied by Ichimin Shirotani, who has paid particular

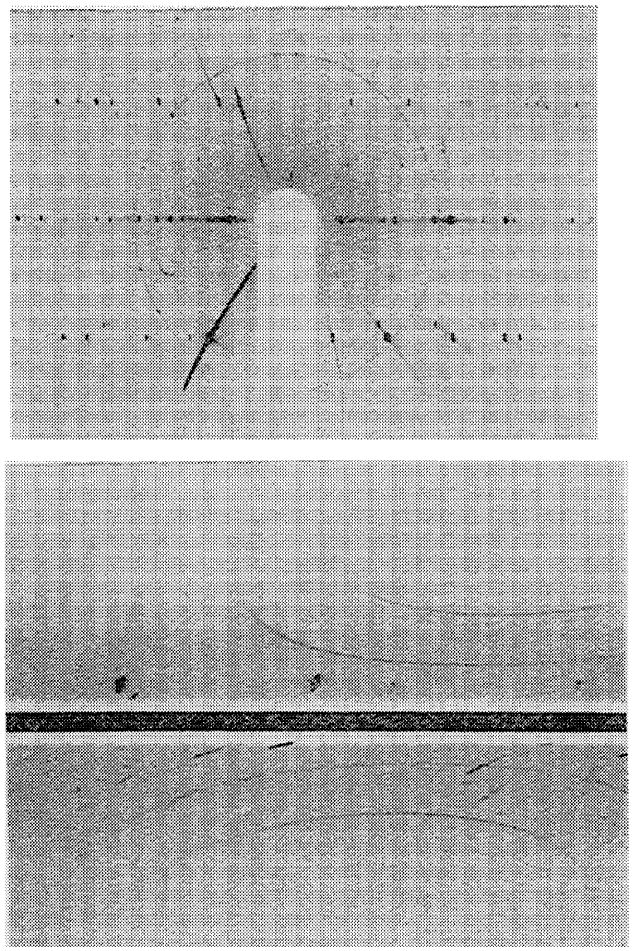

Fig. 2. (a) Oscillation photograph: weak reflections observable in the middle of the strong layer lines
(b) Weissenberg photograph (1/2, η, ζ)

attention to the purification of the samples.[7] The single crystals are black needles, with long axes parallel to the crystallographic a axis. The lattice constants has been reported to be[3]: $a=3.8682$, $b=7.7807$, $c=15.735$ Å, $\alpha=91.67$, $\beta=92.67$, $\gamma=95.38°$ (at 23 °C); space group: $P\bar{1}$. TCNQ and NMP are stacked separately along the a axis to form modadic columns.

Although oscillation and Weissenberg photographs indicated that the intensity distribution of Bragg reflections is the same as that given in Fritchie's paper,[3] a closer examination revealed that diffuse streaks occur along the c* direction in the middle of the strong layer lines around the a axis (Fig. 2). These faint X-ray scatterings were overlooked in an earlier analysis by Fritchie.[3] The streaks appear at the $(h+1/2, k, \zeta)$ position of the reciprocal space, where h and k are integers and where $(h+1/2)\boldsymbol{a}^*+k\boldsymbol{b}^*+\zeta\boldsymbol{c}^*$ is the scattering vector, $\boldsymbol{k}$. The intesities along the streaks vary slowly, and no sharp maxima were observed. Similar streaks were also observed in a Weissenberg photograph of 3/2 layer line around the a axis. All the experiments were performed at room temperature.

Analysis of the Diffuse Streaks and Discussion

The extra reflections indicate: (1) the arrangement of NMP and TCNQ is regular in each a-b layer, but each layer has no correlation to the adjacent layers, and (2) in each a-b layer, the lattice period along the a direction is twice the reported value. Thus, the Fritchie's structure must be regarded as the average structure of the one-dimensionally disordered lattice.

The probable models of the disordered structure could then be easily deduced.

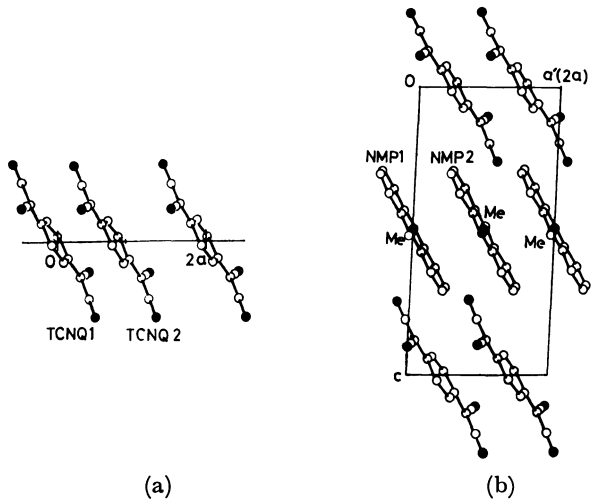

Fig. 3. The models of the molecular arrangement
(a) Model I (rejected) (b) Model II (true)

Model I: TCNQ are not stacked with an equal intermolecular spacing; rather, two different spacings appear alternately, as is found in simple salts of TCNQ[8,9] (Fig. 3a). Each TCNQ is shifted from its position in the average structure by $\varepsilon\boldsymbol{a}$ or $-\varepsilon\boldsymbol{a}$, while the orientation of NMP is disordered in the same way as in the average structure.

Model II: Two possible orientations of NMP alternate along the a axis (Fig. 2). On the other hand, the arrangement of TCNQ is the same as that given by Fritchie.

The important role of the dimeric arrangement of $TCNQ^-$ anions has been previously discussed in connection with the monomer-dimer transition of the simple salts of TCNQ[9] and a Peierls transition of one-dimensional conductors.[10,11] However, Model I can not explain the features of the X-ray diffraction patterns. Based on Model I, the intensities of the streaks are expressed as:

$$I_D(\boldsymbol{k}) = \sum_{ij}\chi_{ij}(f_1-f_2)^2 \exp(i\boldsymbol{k}\boldsymbol{R}_{ij})$$

where $\boldsymbol{R}_{ij}=\boldsymbol{R}_i-\boldsymbol{R}_j$ ($\boldsymbol{R}_i$ is the lattice vector of the i-th lattice point), $\boldsymbol{k}$ is the scattering vector $(\xi\boldsymbol{a}^*+\eta\boldsymbol{b}^*+\zeta\boldsymbol{c}^*)$, χ_{ij} is the correlation function representing the mode of the disorder of the arrangement of TCNQ, and f_1 and f_2 are the scattering factors of TCNQ shifted by $\varepsilon\boldsymbol{a}$ and $-\varepsilon\boldsymbol{a}$ respectively. $I_D(\boldsymbol{k})$ is closely related to the molecular structure factor of TCNQ, because f_1-f_2 can be written as:

$$f_1-f_2 = 2\{\sum_j f_j \cos 2\pi(\xi x_j+\eta y_j+\zeta z_j)\}\sin 2\pi\xi\varepsilon$$

where f_j is the atomic scattering factor of the j-th atom and where (x_j,y_j,z_j) is the atomic coordinate. The general features of the calculated intensity curves do not resemble those of the observed curves. Especially, according to this intensity formula, a very strong streak must be observed at the reciprocal point $(1/2,0,\zeta)$; however, the intensities were, in fact, too weak to be observed. Thus, Model I was rejected.

Using Model II, the structure factors of the disordered lattice can be written as:

$$F(\boldsymbol{k}) = \sum_j\{f_{TCNQ}+(n_j f_{NMP\uparrow}+(1-n_j)f_{NMP\downarrow})\}\exp(i\boldsymbol{k}\boldsymbol{R}_j)$$

where f is a molecular scattering factor; NMP↑ and NMP↓ indicate two types of the orientations of NMP, and n_j is the probability that the orientation of NMP in the j-th cell is that of NMP↑. The corresponding intensity is given by[12]:

$$I(\boldsymbol{k}) = |\langle F(\boldsymbol{k})\rangle|^2 + I_B + I_D$$

where

$$I_B(\boldsymbol{k}) = |\sum_j(f_{TCNQ}+f_{NMP})\exp(i\boldsymbol{k}\boldsymbol{R}_j)|^2$$

and by:

$$I_D(\boldsymbol{k}) = \sum_{jj'}\chi_{jj'}(f_{NMP\uparrow}-f_{NMP\downarrow})^2\exp(i\boldsymbol{k}\boldsymbol{R}_{jj'})$$

where $f_{NMP}=(f_{NMP\uparrow}+f_{NMP\downarrow})/2$, $\langle\ \rangle$ indicates the statistical average and where the correlation function, $\chi_{jj'}$, is expressed as

$$\chi_{jj'} = \langle(n_j-\langle n\rangle)(n_{j'}-\langle n\rangle)\rangle$$

I_B represents the reflections from the lattice with the average structure, which is the same as that derived by Fritchie[3], while I_D is due to the disorder of the crystal. Besides the methyl group, NMP is centrosymmetric. By the use of the atomic parameters of the methyl carbon given by Fritchie, $(f_{NMP\uparrow}-f_{NMP\downarrow})$ may be written simply as:

$$f_{NMP\uparrow}-f_{NMP\downarrow} = 2f_C \sin 2\pi(-0.0328\xi+0.3750\eta+0.0141\zeta),$$

where f_C is the scattering factor of a carbon atom. The correlation function of the orientation of NMP between

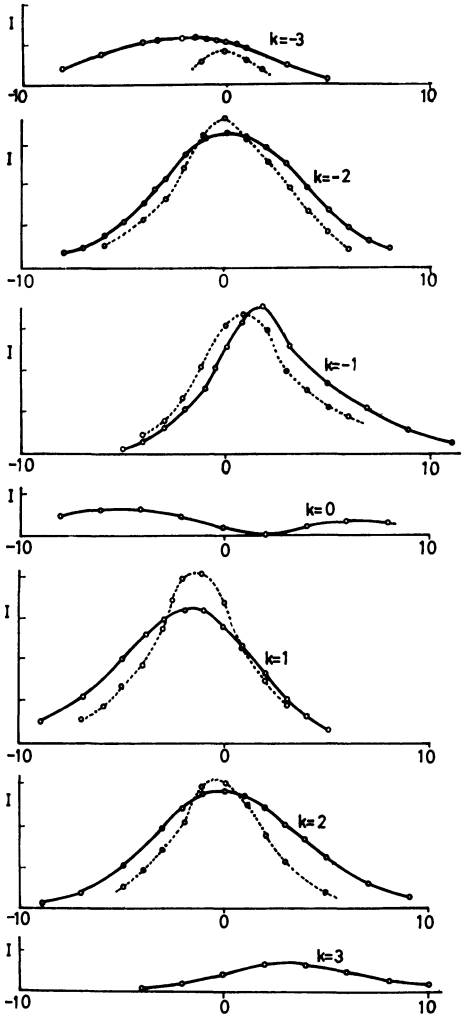

Fig. 4. The observed (broken lines) and calculated (solid lines) intensities of the streaks. The streaks were not observed ($I_{obs}=0$) for $k=0$ and 3. The intensities are plotted as ordinate and the values of ζ as abscissa. Scattering vector $\boldsymbol{k}$ is $\boldsymbol{a}^*/2+k\boldsymbol{b}^*+\zeta\boldsymbol{c}^*$.

i-th and j-th sites ($\boldsymbol{R}_{ij}=n_1\boldsymbol{a}+n_2\boldsymbol{b}+n_3\boldsymbol{c}$) is

$$\chi_{ij}=\begin{cases} 1/4 \cdots n_1=2m \text{ and } n_3=0 \\ -1/4 \cdots n_1=2m+1 \text{ and } n_3=0 \\ 0 \cdots n_3 \neq 0 \end{cases}$$

Because of the orientational disorder, the observed temperature factor of the methyl carbon is very large[3]; it was, therefore, replaced by that of the nitrogen atom of NMP in the calculation of I_D. The observed and calculated intensities of the streaks of the 1/2-layer line ($\xi=1/2$) are compared in Fig. 4. The scale of the observed intensities was adjusted so as to give the best fit to the calculated ones. The comparison was not attempted for the streaks of the 3/2-layer line because of the weakness of the intensities. Considering the roughness of the estimation of the temperature factor, the agreement is satisfactory. Therefore, we may conclude that Model II represents the real structure of NMP-TCNQ.

The molecular arrangement of NMP-TCNQ thus obtained is shown in Figs. 3b and 5. Two orientations of NMP alternate along the a axis, while one fixed orientation is repeated along the b direction. The

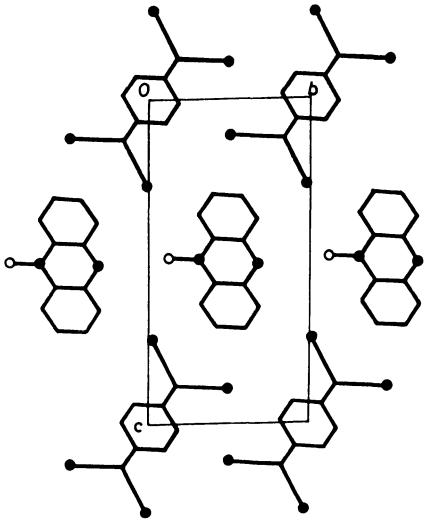

Fig. 5. A regular sequence of NMP along the b axis. This and the other arrangements of NMP with opposite orientations alternate along the a axis to form a regular *a–b* layer. Such regular layers of NMP are randomly correlated with each other along the c axis.

correlation of the orientation dose not exist between NMP, which belong to different *a–b* layers. The unusually short contact of 2.01 Å between two neighbouring methyl carbons which occur randomly in the average structure dose not exist in the real structure. The two-dimensionally ordered molecular arrangement in each *a–b* layer seems to be natural in view of the dipole-dipole interaction between NMP(Fig. 6). There is no direct intermolecular contact of NMP along the c direction. Thus, this type of one-dimensional disorder is very likely to occur in this crystal.

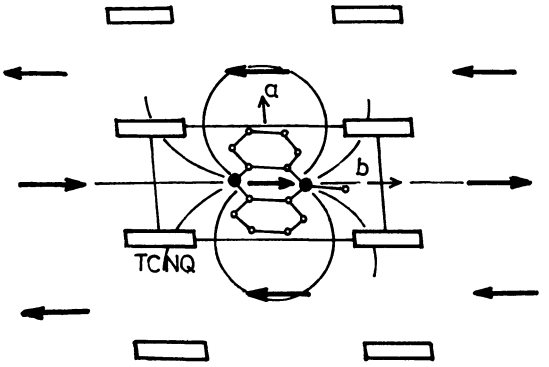

Fig. 6. Schematic drawing of the two-dimensionally ordered arrangement of NMP and TCNQ and an electric field due to a dipole moment of an NMP.

The localized model of BWV has been criticized by Heeger *et al.*,[5,6] Kurkijarvi,[13] and Suezaki.[14] Suezaki suggested the possibility that the randomness in NMP-TCNQ is insufficient to adopt the localized model, since the possible orientations of NMP are restricted in two directions, as has been shown in an earlier crystal structure analysis.[3] From the structural viewpoint, we can show evidence that the localized model of BWV is not suited for the interpretation of the electrical properties of NMP-TCNQ. Let us consider an electric potential being exerted on an electron moving along

a column of TCNQ. Within a simple noninteracting-electron approximation, the Hamiltonian can be written as

$$H(x) = -\frac{\hbar^2}{2m}\frac{\partial^2}{\partial x^2} + \sum_j V_j(x)$$

where V_j is the potential due to the ions in the j-th layer and where x is the coordinate of the electron in this column. Since all ions in each a–b layer are arranged regularly with a period of $2a$(7.736 Å), $V_j(x)$ must be a periodic function:

$$V_j(x+2a) = V_j(x).$$

Therefore, the total potential, $V(x)(=\sum V_j(x))$, is also periodic along the TCNQ column parallel to the a axis. Thus, the localized model of BWV which is based on the assumption of the random potential along the column of TCNQ can not be adopted in the interpretation of the electrical properties of NMP-TCNQ. In addition, based on this periodicity of the potential function $V(x)$, it is easy to see that there are some difficulties in the application of the one-dimensional half-filled-band Hubbard model proposed by Heeger *et al.*[1,6] Because the periodic unit is $2a$, the Bloch function $\phi(x)$ can be given as:

$$\phi(x) = \exp(ikx)u_k(x)$$
$$-\pi/2a < k \leqq \pi/2a$$

The corresponding energy band is shown schematically in Fig. 7a. There are two excess electrons in each periodic unit, so the band must be filled. Therefore, NMP-TCNQ must be semiconductive, even if the electron-electron Coulomb repulsion is small (the electron-electron Coulomb repulsion produces a Hubbard gap in a half-filled-band Hubbard model (Fig. 7b)[15]). This conclusion is qualitatively consistent with the observed low-temperature conductivities of this salt.[1]

The orientational disorder of cations has also been found in the crystals of ARD-$TCNQ_2$[11] and Q-$TCNQ_2$[16], which are also highly conducting salts. However, no X-ray diffuse streaks have been observed. The modes of the arrangement of cations in these crystals are similar to each other, but they do not resemble that of NMP-TCNQ. According to BWV, the electronic properties of these salts can also be interpreted by means of the localized model. In the crystals of ARD-$TCNQ_2$ and Q-$TCNQ_2$, the cations are stacked to form monadic columns of ARD and Q respectively. As is shown in Fig. 8, however, these columns of cations are surrounded by six TCNQ columns and have no direct contact between them. Therefore, the features of the orientational disorder in these complex salts are probably different from those in the simple NMP-TCNQ salt described above.

Electron Transfer Reaction in the Triplet State. Role of Ferrocene as an Electron Donor

Koichi KIKUCHI, Hiroshi KOKUBUN, and Masae KIKUCHI*

Department of Chemistry, Faculty of Science, Tohoku University, Aoba, Aramaki, Sendai 980

* *The Research Institute for Iron, Steel and other Metals, Tohoku University, Katahira, Sendai 980*

(Received November 20, 1974)

Quenching of the triplet state of methylene blue by ferrocene and *p*-phenylenediamine in ethanol has been investigated by an emission-absorption flash technique. The triplet dye is quenched by ferrocene and *p*-phenylenediamine at a diffusion-controlled rate, yielding the semi-reduced dye. Efficiency of the semi-reduced dye formation is 0.09 and 1.0 for ferrocene and *p*-phenylenediamine, respectively. Since the triplet level of the dye is lower than that of ferrocene, quenching of the triplet dye by ferrocene seems to occur through the charge (electron) transfer interaction.

Many triplets of aromatic compounds are quenched by ferrocence (F) at a diffusion-controlled rate.[1-3] However, the quenching mechanism has not been elucidated because the triplet level of F[4-6] remained obscure.

Fry *et al.*[1] studied the quenching rate of some triplets by F with a conventional flash technique, and presumed that quenching is due to the formation of a short-lived charge transfer complex, because they could not observe any transient absorption attributable to the addition of F.

We measured quenching rate constants by F for several triplets with levels located in the range 8000—23800 cm^{-1},[7] and studied the triplet energy transfer for the eosin-tetracene-ferrocene mixed system. It was concluded that the triplet level of F is 15000 ± 1000 cm^{-1} and the lifetime of triplet F shorter than 1 μs. Thus, it is obvious that the triplet with level higher than 15000 cm^{-1} is mainly quenched by triplet energy transfer to F and that with level lower than 15000 cm^{-1} is quenched by some other mechanism. Since the oxidation potential of F is low,[8] it is anticipated that charge transfer interaction plays an important role.

In order to show this role, quenching of the lowest triplet state of methylene blue ($^3D^+$) by F has been studied by an emission-absorption flash technique.[9] Since the dye (D^+) has a low reduction potential[10] and a triplet level lower than that of F, it is considered to be the most appropriate for the purpose. Quenching by *p*-phenylenediamine (P) has been also studied for comparison.

Experimental

Materials. Ferrocene (G. R. grade, Tokyo Kasei) was recrystallized from benzene, zone refined, and sublimated. Methylene blue (G. R. grade, Merck) was recrystallized from *n*-butanol. *p*-Phenylenediamine (E. P. grade, Tokyo Kasei) was recrystallized twice from ethanol and used immediately after sublimation. Ethanol (G. R. grade, Wako Jun-yaku) was used without further purification.

Apparatus and Procedure. Flash energy was controlled in the range 56—130 J its half duration being about 10 μs. A Toshiba V-O51 filter was used for exciting the dye only. A Q-switched ruby laser provides a 15 ns pulse of about 0.15 J. All measurements were made at room temperature. Ethanol solutions were degassed by repeating bulb-to-trap-distillation in vacuum.

Results and Discussion

Two transient absorption spectra obtained when the deaerated solution of the dye was flashed are shown in

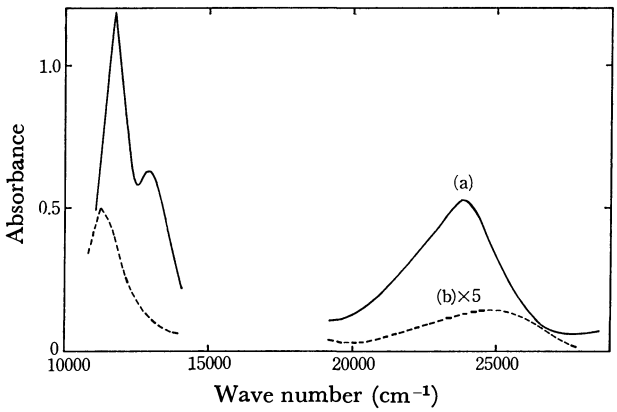

Fig. 1. Transient absorption spectra of methylene blue in deaerated ethanol (10^{-5} M). (a) triplet, (b) long-lived intermediate (5 ms after flashing).

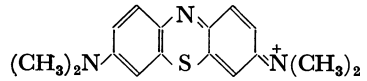
Fig. 1. Spectrum (a) is attributed to the T–T absorption of the dye because of its close resemblance to the spectrum in literature.[11,12] The decay is nearly



methylene blue (D^+)

of first order, but its rate increases with increasing dye concentration. This is apparently due to the D–D mechanism given by Koizumi *et al.*[13] The result is consistent with that of steady light illumination.[14] The observed rate constant is linear with respect to dye concentration (Fig. 2).

$$k_{obsd} = k_t = k_0 + k[D]$$

From the intercept and the slope we obtain

$$k_0 = 2.2 \times 10^3\ s^{-1}$$

$$k = 4.5 \times 10^8\ M^{-1} \cdot s^{-1}.$$

Spectrum (b) (Fig. 1) was observed after the disappearance of the T–T absorption spectrum (a) and seems to be that of the protonated semireduced dye ($DH^{\ddagger}$), since the spectral shape accords substantially with the

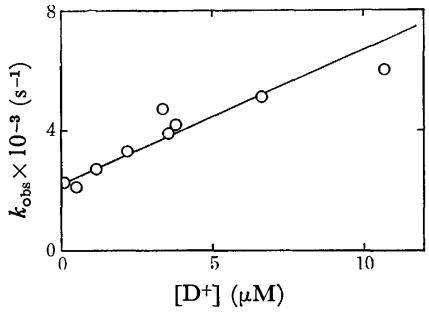


Fig. 2. The dependence of the observed first order decay constant of the triplet methylene blue on dye concentration.

reported one.[15] The decay of DH‡ is not reproducible, and the lifetime is much longer than 1 ms. The absorption spectrum of the dye changes slightly with repeated flashing.

The decay rate constant of the triplet dye increases linearly with F concentration.

$$k_{obsd} = k_t + k_F[F]$$

From the slope we obtain

$$k_F = 4.5 \times 10^9\ M^{-1} \cdot s^{-1}.$$

For F concentrations higher than 10^{-4} M (Fig. 3), quite a different spectrum (a) completely replaces the T–T absorption spectrum. The spectrum decays as a first order process to produce a long-lived absorption spectrum (b), but the decay rate is not reproducible.

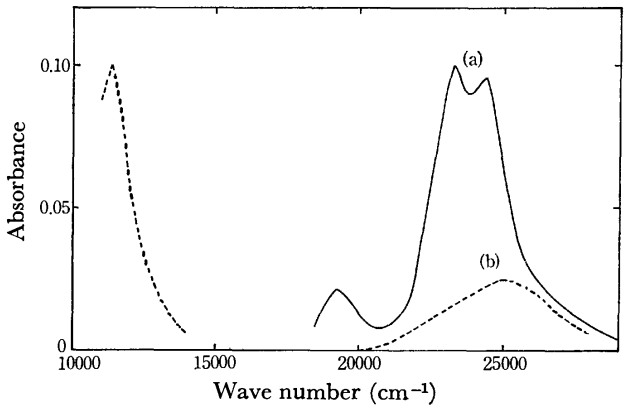

Fig. 3. Transient absorption spectra of methylene blue (5×10^{-6} M) in ethanol containing 10^{-4} M ferrocene. (a) immediately after flashing, (b) 1 ms after flashing.

With the addition of an efficient electron donor, P, the decay of the triplet dye also increases. For P concentrations higher than 10^{-4} M (Fig. 4), spectrum (a) was observed instead of the T–T absorption spectrum. The spectrum decays in first order, giving a long-lived absorption spectrum (b). The decay of the long-lived absorption is not reproducible.

The transient absorption spectrum (a) in Fig. 3 is similar to the spectrum of the semireduced dye (D·) in a basic solution.[11,15] The transient absorption spectra (a) shown in Figs. 3 and 4 resemble each other, the latter having an additional absorption peak at *ca.* 500 nm. The absorption spectrum of P cation radical (P‡)[16] was obtained by flashing the aerated ethanol

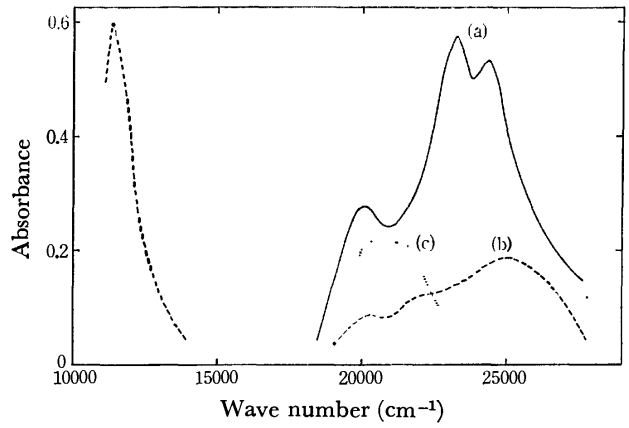

Fig. 4. Transient absorption spectra of methylene blue (5×10^{-6} M) in ethanol containing 10^{-4} M *p*-phenylenediamine. (a) immediately after flashing, (b) 1 ms after flashing. (c) The spectrum of *p*-phenylenediamine cation radical in ethanol is drawn for comparison.

solution of P (Fig. 4(c)). It is obvious that the spectrum (Fig. 4(a)) consists of the superposition of D· and P‡.

The spectra (b) shown in Figs. 1, 3, and 4 are similar to the spectrum of DH‡. Since pK_a of D· is 9.0,[15] it might be protonated in ethanol as in other basic compounds such as proflavine.[17] Thus, spectra (a) and (b) in Fig. 3 can be assigned respectively to D· and DH‡, since the contribution of F added to absorbance in this wavelength region is negligible owing to the small molar extinction coefficients of F and its cation radical (F‡).[18] The absorbance of DH‡ increases at the expense of that of D·, implying that the protonation is the main decay process of D·. The fact that the decay rate of D· is not reproducible can be interpreted as a result of unregulated proton concentration. No transient absorption was observed by flashing the aerated solution of the dye. However, the transient absorption spectra (a) in Figs. 3 and 4 were observed in the aerated solution containing F and P, respectively. These spectra decay as a second order process to reproduce the dye. The spectrum of DH$^+$ was not observed in either case. The results suggest that D· is stable against oxygen, and that DH‡ may react with oxygen as follows,

$$DH^\ddagger + O_2 \longrightarrow D^+ + HO_2\cdot$$

The absorption and fluorescence spectra are not affected by the addition of F or P. Hence, the reaction state of the dye is the lowest triplet state alone. The scheme can thus be summarized as follows.

$$\begin{aligned}
&(1)\ D^+ \xrightarrow{I_{ab}\phi_{ST}} {}^3D^+ \\
&(2)\ {}^3D^+ \longrightarrow D^+ \\
&(3)\ {}^3D^+ + D^+ \longrightarrow D\cdot + D^{\ddagger +} \quad k_t \\
&(4)\ {}^3D^+ + O_2 \longrightarrow D^+ + {}^1O_2{}^* \quad k_0[O_2] \qquad \Big\} k_{dt} \\
&(5)\ {}^3D^+ + F \longrightarrow D\cdot + F^\ddagger \quad k_F{}^r \\
&(6)\ {}^3D^+ + F \longrightarrow D^+ + F \qquad \Big\} k_F \\
&(7)\ {}^3D^+ + P \longrightarrow D\cdot + P^\ddagger \quad k_P{}^r \\
&(8)\ {}^3D^+ + P \longrightarrow D^+ + P \qquad \Big\} k_P
\end{aligned}$$

The semi-oxidized dye ($D^{\ddagger+}$) produced by process (3) has an absorption peak at *ca.* 520 nm.[11] This may interpret the fact that spectrum (b) in Fig. 1 is significantly swelled at about 500 nm compared with spectrum (b) in Fig. 3.

The yield of D· at the end of a flash is related with the total quantity of light absorbed during one flash by

$$\int d[D] \equiv [D\cdot]_0 = \phi_{ST}\cdot\frac{k_Q{}^r[Q]}{k_{dt}+k_Q[Q]}\cdot\int I_{ab}dt \qquad (1)$$

where Q indicates F or P and the subscript "0" stands for the quantity immediately after flashing. The time integrated fluorescence intensity measured at λ' during a flash is given by

$$\int I_f(\lambda')dt = \alpha\phi_f\int I_{ab}dt \qquad (2)$$

When Q is F, the transient absorption spectrum (a) in Fig. 3 is entirely attributable to D·. Thus, from Eqs. (1), (2), and the relation

$$D_0(\lambda) = \varepsilon(\lambda)[D\cdot]_0 d \qquad (3)$$

we obtain

$$\frac{\int I_f(\lambda')dt}{D_0(\lambda)} = \frac{\alpha\phi_f}{\varepsilon(\lambda)d\cdot\phi_{ST}}\cdot\frac{k_F}{k_F{}^r}\left(1+\frac{k_{dt}}{k_F}\cdot\frac{1}{[F]}\right) \qquad (4)$$

where $D(\lambda)$ and $\varepsilon(\lambda)$ are the absorbance and the molar extinction coefficient of D· at wavelength λ, respectively, and d=10 cm. When Q is P, the transient absorption is composed of D· and $P^{\ddagger}$. As the concentration of $P^{\ddagger}$ is equal to that of D·, the following relation holds instead of Eq. (3).

$$\begin{aligned} D_0(\lambda) &= \{\varepsilon(\lambda)[D\cdot]_0+\varepsilon'(\lambda)[P^{\ddagger}]_0\}d \\ &= \{\varepsilon(\lambda)+\varepsilon'(\lambda)\}[D\cdot]_0 d \end{aligned} \qquad (5)$$

where $\varepsilon'(\lambda)$ is the molar extinction coefficient of $P^{\ddagger}$ at λ. $\int I_f(720)dt$ and $D_0(420)$ were measured at various F and P concentrations. The results are given in Table 1. $\int I_f(\lambda')dt/D_0(\lambda)$ is plotted against the reciprocals of F and P concentration in Fig. 5. From the plots we have

$$k_{dt}/k_F = 7.4\times10^{-4}\,M \qquad (6)$$

$$k_{dt}/k_P = 7.3\times10^{-4}\,M \qquad (7)$$

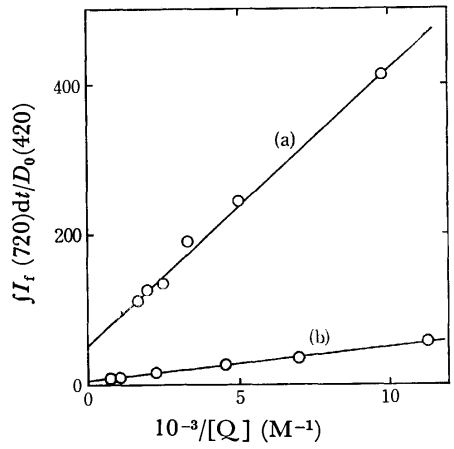

Fig. 5. The plot of $\int I_f(\lambda')dt/D_0$ (λ) *vs.* 1/[Q].
(a) Q: ferrocene, (b) Q: *p*-phenylenediamine.

The decay rate of the triplet dye in the aerated solution was measured by using a Q-switched ruby laser.

$$k_{dt} = k_t + k_0[O_2] = 3.7\times10^6\,s^{-1} \qquad (8)$$

From Eqs. (6), (7), and (8), we have

$$k_F = 5.0\times10^9\,M^{-1}\cdot s^{-1}$$

$$k_P = 5.1\times10^9\,M^{-1}\cdot s^{-1}$$

The value of k_F agrees with that (k_F=$4.5\times10^9\,M^{-1}\,s^{-1}$) obtained from the effect of F concentration on the triplet decay.

It should be noted that the yield of D· is larger for P than for F (Table 1). This indicates that the rate constant of the formation of D·, $k_P{}^r$, is larger than $k_F{}^r$, because the rate constants of the triplet quenching by P and F are nearly equal.

The efficiency of D· formation, $k_P{}^r/k_P$ and $k_F{}^r/k_F$, was estimated as follows. In the deaerated solution, the absorbance of the T–T absorption immediately after flashing is expressed by

$$\left[\frac{D_0{}^T(\lambda)}{\int I_f(\lambda')dt}\right] = \varepsilon^T(\lambda)d\cdot\frac{\phi_{ST}}{\alpha\phi_f} \qquad (9)$$

where $D^r(\lambda)$ and $\varepsilon^T(\lambda)$ are the absorbance and the molar extinction coefficient of the T-T absorption, respectively. For F concentration higher than 10^{-4} M, the T–T absorption spectrum is replaced by the spectra of D·, because the triplet dye reacts rapidly with F ($k_F[P]\gg k_{dt}$). The following relation is then obtained from Eqs. (4) and (9).

$$\frac{k_F{}^r}{k_F} = \frac{[D_0(\lambda)/\int I_f(\lambda')dt]_F}{[D_0{}^T(\lambda)/\int I_f(\lambda')dt]}\cdot\frac{\varepsilon^T(\lambda)}{\varepsilon(\lambda)} \qquad (10)$$

For P concentration higher than 10^{-4} M, we have also

$$\frac{k_P{}^r}{k_P} = \frac{[D_0(\lambda)/\int I_f(\lambda')dt]_P}{[D_0{}^T(\lambda)/\int I_f(\lambda')dt]}\cdot\frac{\varepsilon^T(\lambda)}{\varepsilon(\lambda)+\varepsilon'(\lambda)} \qquad (11)$$

The molar extinction coefficients were obtained by completely converting the dye into the triplet state or D·.

$$\varepsilon^T(825) = 1.6_5\times10^4\,M^{-1}\cdot cm^{-1}$$

$$\varepsilon(420)+\varepsilon'(420) = 1.1\times10^4\,M^{-1}\cdot cm^{-1}$$

The molar extinction coefficient of D· was estimated by correcting the absorption of P^{+}.

$$\varepsilon(420) = 9.4 \times 10^3\ M^{-1}\cdot cm^{-1}$$

$D_0(420)$ and $D_0^T(825)$ are plotted against $\int I_f(720)dt$ in Fig. 6. From the slope of the plots, we have

$$[D_0(420)/\int I_f(720)dt]_F = 0.009$$

$$[D_0(420)/\int I_f(720)dt]_P = 0.12$$

$$[D_0^T(825)/\int I_f(720)dt] = 0.18$$

From these values and the molar extinction coefficients obtained above and with the aid of Eqs. (10) and (11), we obtain

$$k_P^r/k_P = 1.0$$

$$k_F^r/k_F = 0.09$$

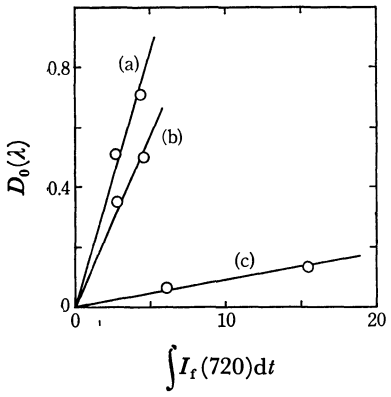

Fig. 6. The plot of $D_0(\lambda)$ and $D_0^T(\lambda)$ *vs.* $\int I_f(\lambda')d\lambda'$.
(a) $D_0^T(825)$, (b) $D_0(420)$: *p*-phenylenediamine, (c) $D_0(420)$: ferrocene.

It was suggested[7] that quenching of the triplet whose level is lower than 15000 cm^{-1} by F is due to the charge transfer interaction. However, we could not directly demonstrate quenching by the charge transfer interaction, since all the triplets studied did not give any new transient absorption in the case of quenching by F. The triplet level of the dye is 11650 cm^{-1} [19] and its reduction potential 0.008 V (*vs.* S.C.E.)[10] in aqueous solution at pH=7. The oxidation potentials of F and P in acetonitrile are 0.30[8] and 0.185 V (*vs.* S.C.E.),[20] respectively. According to the method of Rehm and Weller,[21] the changes of free enthalpy (ΔG) involved in the electron transfer reaction from F and P to the triplet dye were estimated both as $\Delta G < -20$ kcal/mol. The result suggests that the triplet dye must be quenched by F and P at a diffusion-controlled rate, which agrees well with the experimental results described above. In addition, the electron transfer reaction from F to the triplet dye, though its efficiency is small, has been confirmed. It can thus be shown that the charge (electron) transfer interaction plays an important role on the triplet quenching by F. The fact that the efficiency of electron transfer reaction from F to the triplet dye is small suggests that the lifetime of encounter complex of the triplet dye and F is too short to react. It can therefore be supposed that the triplet quenching of an aromatic compound whose triplet level is lower than 15000 cm^{-1} by F is ascribed to the instantaneous formation of the charge transfer complex.

Consequently, F can act as an electron donor for the triplet quenching by charge transfer interaction, but the efficiency of the electron transfer reaction is generally very small.

M. K. wishes to express her thanks to Professor Masao Honma for his kind guidance and encouragement in the course of the work.

The Quenching of the Cadmium Resonance Radiation at 326.1 nm by Some Aliphatic Amines and the Cadmium-sensitized Luminescence of These Amines

Shunzo YAMAMOTO and Shin SATO*

Department of Chemistry, Faculty of Sciences, Okayama University, Tsushima, Okayama 700
** Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152*

(Received November 21, 1974)

From the pressure dependence of the intensity of the 326.1 nm resonance line, the efficiencies of the quenching of the resonance line by methylamine, ethylamine, *n*-propylamine, *n*-butylamine, *sec*-butylamine, *tert*-butylamine, diethylamine, and triethylamine were estimated to be 14.2, 36.0, 58.6, 71.2, 116.7, 434.5, 69.6, and 66.0 respectively, the efficiency of ammonia being assumed to be unity. The relative values of rate constants for the formation of excited complexes between the excited cadmium atoms and the amines, and the wavelengths at the peaks of the emission bands from the complexes, were measured. The quantum yields of luminescence were also measured by comparing the integrated intensities of the emission bands with the decrease in the intensities of the resonance line at 326.1 nm upon the addition of amines. From the relationship between these values and the structure of the amines, it is concluded that the complexes are of the charge-transfer type.

In a previous study[1] of the cadmium-sensitized reaction of rare gases and nitrogen, we indicated that the $Cd(^3P_0)$ state is produced by collisions between $Cd(^3P_1)$ atoms and rare gases or nitrogen, and that, at pressures higher than a few Torr of foreign gases, an equilibrium is established between the 5 $^3P_1$ and 5 $^3P_0$ states. Therefore, in spite of the fact that Morten *et al.*[2] described the emitting species in the cadmium-sensitized luminescence of ammonia as being produced by the reaction between $Cd(^3P_0)$ atoms and ammonia, it is impossible to distinguish between $Cd(^3P_1)$ and $Cd(^3P_0)$ atoms as precursors of the emitting species.

In an earlier study of the quenching of the resonance radiation at 326.1 nm by ammonia,[3] we proposed a mechanism by which an unstabilized complex, produced from the excited cadmium atoms ($Cd(^3P_1)$ or $Cd(^3P_0)$) and ammonia, is partly decomposed to the original excited cadmium atoms and ammonia and is partly stabilized by collisions with third bodies. Since a back reaction exists, the Stern-Volmer plots for the quenching of the 326.1 nm resonance line deviate from a straight line in the low-pressure region. If other molecules more complex than ammonia can form the emitting species, and if the back reaction is not so important, we shall not be able to observe the second-order pressure dependence of the Stern-Volmer plots in the low-pressure region, as in the case of ammonia. The present paper will report the results of a study of the cadmium-sensitized luminescence of some aliphatic amines and their quenching for the 326.1 nm resonance line.

Experimental

The apparatus and procedure were the same as those previously described.[3-5] The reaction cell and the cadmium resonance lamp were kept in an electric furnace at 220 ± 1 °C. The vapor pressure of cadmium at 220 °C is 1.04×10^{-3} Torr. The lamp was operated by an alternating current (50 Hz).[1]

The cadmium metal used was high-purity cadmium (99.9999%) manufactured by the Osaka Asahi Metal Co. Pure-grade methylamine and ethylamine were used after degassing at the temperature of liquid nitrogen. Other amines (G.R. grade) were used after drying by calcium hydride and repeated trap-to-trap distillation. Pure-grade argon was used after repeated adsorption and desorption on a molecular sieve at the temperature of liquid nitrogen. In order to minimize the pressure dependence of the absorption intensity, the amines were diluted with argon, and the total pressure in the reaction cell was kept constant.

In order to estimate the quantum yields of the luminescence, the dependence of the sensitivity on the wavelength for the monochromator/photomultiplier combination was determined by using a tungsten lamp operated at 2307 K, using the emissivity data of tungsten presented by de Vos.[6]

Results

In order to estimate the efficiency of the quenching of the 326.1 nm resonance line by amines, the emission intensity at 326.1 nm was measured as a function of the pressure of amines. The Stern-Volmer plots are shown in Fig. 1, where $I_{326.1}{}^0$ and $I_{326.1}$ are the emission intensities at 326.1 nm in the absence and in the presence of amines respectively. On the assumption that 100 Torr carbon dioxide quenches the 326.1 nm resonance line completely,[1] the scattered-light intensity at 326.1 nm was estimated to be less than 0.2% of the $I_{326.1}{}^0$ and thereafter it was neglected. As the intensity, $I_{326.1}$, decreased with the increase in the irradiation time because of the influence of reaction products (one of them may be hydrogen[4]), the intensities shown in Fig. 1 were obtained by extrapolation to zero irradiation time. As has been described previously,[3] the plots obtained with ammonia do not lie on a straight line. However, the plots for the other amines from typical Stern-Volmer plots (straight lines, the intercepts of which

Ethylamine	0.350	Diethylamine	0.181
n-Propylamine	0.215	Triethylamine	0.191
n-Butylamine	0.177		

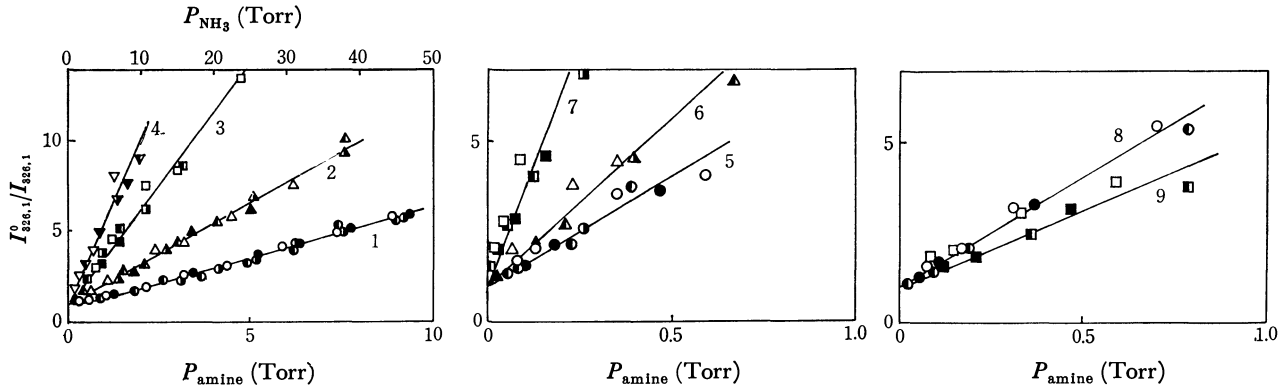

Fig. 1. Stern-Volmer plots for the quenching of the resonance radiation at 326.1 nm by amines diluted with argon. 1) ammonia; Total pressures are 208 (○), 175 (◐), 147 (◑), and 123 (●) in Torr. 2) methylamine; 106 (△), 70 (▲), 48 (▲), and 32 (▲). 3) ethylamine; 106 (□), 70 (■), 48 (■), and 32 (■). 4) *n*-propylamine; 106 (▽), 70 (▼), 48 (▼), and 32 (▼). 5) *n*-butylamine; 106 (○), 70 (◐), 48 (◑), and 32 (●). 6) *sec*-butyl-amine; 106 (△), 70 (▲), 48 (▲), and 32 (▲). 7) *tert*-butylamine; 106 (□), 70 (■), 48 (■), and 32 (■). 8) diethylamine; 80 (○), 48 (◑), and 28 (●). 9) tri-ethylamine; 80 (□), 48 (■), and 28 (■).

are equal to unity). As is shown in Fig. 1, the plots for each amine at various total pressures all lie on one straight line, and no total pressure dependence can be seen. The half-quenching pressures obtained from Fig. 1 are listed in Table 1. The efficiency of the quenching by primary amines increases with an increase in the molecular complexity.

Table 2. Wavelength at the peak of the emission band and quantum yield of the luminescence

Amine	λ (nm)	Quantum yield
Ammonia	432±2	0.67±0.10
Methylamine	449±5	0.58±0.10
Ethylamine	452±5	0.26±0.09
n-Propylamine	452±5	0.20±0.09
n-Butylamine	453±5	0.18±0.05
sec-Butylamine	453±5	0.12±0.05
tert-Butylamine	454±5	0.04±0.02
Diethylamine	longer than 460 nm	
Triethylamine	longer than 460 nm	

The emission band for ammonia was shown previously.[4] The band for the primary amines studied had the same basic shape and so will not be given here. The wavelengths at the peak of the emission band are listed in Table 2. Since the emission intensity changes with the irradiation time, the position of the peak is somewhat obscure. The wavelength at the peak for diethylamine and triethylamine could not be measured because of the interference of the scattered light of the line at 468 nm from the lamp.

According to the method of Newman *et al.*,[7] the quantum yield of the luminescence for ammonia was calculated. The ratios of the intensity of the luminescence at 432 nm to the decrease in the fluorescence intensity of the 326.1 nm line were measured at various ammonia pressures (5—50 Torr), the total pressure being kept constant. The intensity of the 326.1 nm line should be corrected for the absorption of the line on its way out of the cell. The transmission was calculated for the pure Doppler-broadening case,[8] using the known dimensions of the cell. Some typical data for

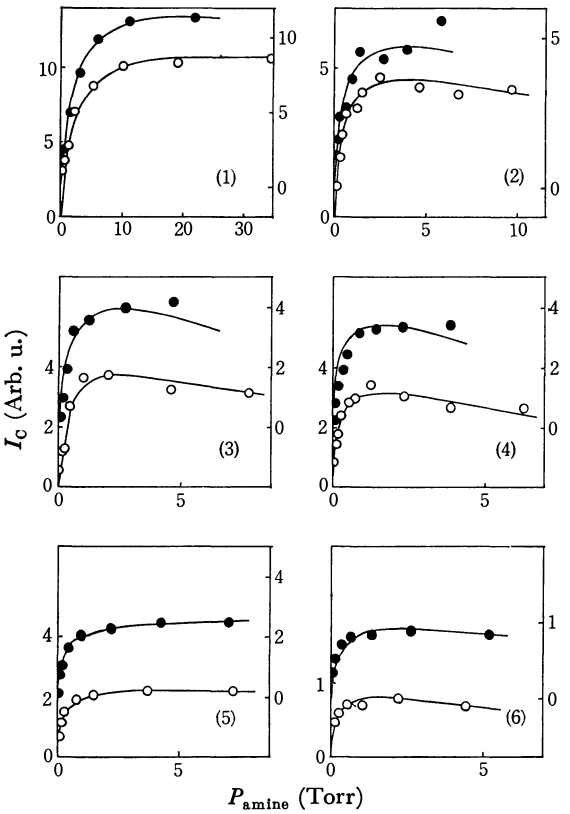

Fig. 2. The intensity at the peak of the emission band from the complex as a function of the partial pressure of amines. The total pressures are 80 (○) and 48 (●) in Torr. The plots for 48 Torr are displaced upwards for clarity. 1) methylamine; 2) ethylamine; 3) *n*-propylamine; 4) *n*-butylamine; 5) *sec*-butylamine; 6) *tert*-butylamine.

ammonia are as follows:

$$\frac{I_{432}}{\Delta I_{326.1}} = \frac{2.15}{19.31}$$

$$\frac{\text{sensitivity at 326.1 nm}}{\text{sensitivity at 432 nm}} = 0.42$$

$$\frac{\text{area under emission band}}{\text{instrumental bandwidth}} = \frac{53.4}{2.74}$$

$$\text{cell transmission at } 326.1 \text{ nm} = 0.685$$

$$\text{quantum yield} = \frac{2.15\times0.42\times53.5\times0.685}{19.31\times2.74} = 0.63$$

The mean of 25 determinations was 0.67 ± 0.10. The quantum yields for the other amines were determined by a comparison of the integrated intensity of the emission band for the amine in question with that for ammonia under the same conditions. The results are listed in Table 2.

The pressure dependence of the intensity at the peak of the emission band is shown in Fig. 2. The intensities were obtained by extrapolation to zero irradiation time. The maximum intensity is reached at a lower pressure in this order: *tert*-butylamine, *n*-butylamine, *n*-propylamine, ethylamine, *sec*-butylamine, methylamine, and ammonia. This order (except for *sec*-butylamine) is in agreement with the order of molecular complexity.

Discussion

As was described in the previous paper,[5] in the presence of foreign gases—for example, 5 Torr of Ar or 0.1 Torr of ammonia, the equilibrium between the 5 $^3P_1$ and 5 $^3P_0$ states of cadmium is readily established. Consequently, we cannot specify which state is the precursor of the emitting species. In the following treatment, therefore, we will use the symbol Cd* to express either Cd($^3P_1$) or Cd($^3P_0$).

In a manner similar to that described in a previous paper,[3] the following reaction mechanism was considered:

$$\mathrm{Cd} + h\nu \longrightarrow \mathrm{Cd}(^3P_1) \qquad I_a$$
$$\mathrm{Cd}(^3P_1) \longrightarrow \mathrm{Cd} + h\nu \qquad k_0$$
$$\mathrm{Cd}(^3P_1) + \mathrm{M} \rightleftarrows \mathrm{Cd}(^3P_0) + \mathrm{M} \qquad k_1, k_{-1}$$
$$\mathrm{Cd}(^3P_1) + \mathrm{A} \longrightarrow \text{products} \qquad k_2$$
$$\mathrm{Cd}(^3P_0) + \mathrm{A} \longrightarrow \text{products} \qquad k_3$$
$$\mathrm{Cd}^* + \mathrm{A} \rightleftarrows \mathrm{CdA_v}^* \qquad k_4, k_{-4}$$
$$\mathrm{CdA_v}^* + \mathrm{A} \longrightarrow \mathrm{CdA}^* + \mathrm{A} \qquad k_5$$
$$\mathrm{CdA_v}^* + \mathrm{Ar} \longrightarrow \mathrm{CdA}^* + \mathrm{Ar} \qquad k_5'$$
$$\mathrm{CdA}^* \longrightarrow \mathrm{Cd} + \mathrm{A} + h\nu' \qquad k_6$$
$$\mathrm{CdA}^* + \mathrm{A} \longrightarrow \mathrm{Cd} + 2\mathrm{A} \qquad k_7$$
$$\mathrm{CdA}^* + \mathrm{Ar} \longrightarrow \mathrm{Cd} + \mathrm{A} + \mathrm{Ar} \qquad k_7'$$

Here, M stands for Ar or amine, while A represents amine. CdA_v* and CdA* represent, respectively, an unstabilized and a stabilized complex between the triplet cadmium atoms and amines. In this mechanism, it is assumed that the unstabilized complex does not fluoresce.

The steady-state treatment on the assumption that the equilibration reaction between $^3P_1$ and $^3P_0$ states is very fast gives the following relation with respect to the quenching of the resonance radiation:

$$\frac{I_{326.1}}{I^0_{326.1}} = 1 + a[\mathrm{A}] + \frac{b[\mathrm{A}]}{1+c[\mathrm{M}]+d[\mathrm{A}]} \qquad (1)$$

Here, $I_{326.1}{}^0$ and $I_{326.1}$ are the emission intensities at 326.1 nm in the absence and in the presence of amines respectively. a, b, c, and d are constants; they are expressed as follows: when Cd* = Cd($^3P_1$),

$$a = \frac{1}{k_0}\left(k_2+\frac{k_1}{k_{-1}}k_3\right),\quad b = \frac{k_4}{k_0},\quad c = \frac{k_5'}{k_{-4}},$$

and $$d = \frac{k_5-k_5'}{k_{-4}}.$$

In the case of Cd*=Cd($^3P_0$), k_4 should be replaced by $(k_1/k_{-1})k_4$. If c and/or d are sufficiently large, Eq. (1) can be approximated to:

$$\frac{I^0_{326.1}}{I_{326.1}} = 1 + (a+b)[\mathrm{A}] \qquad (2)$$

The Stern-Volmer plots for amines other than ammonia in Fig. 1 are expressed by Eq. (2). The constants, $(a+b)$, were evaluated by the least-squares method; they are listed in Table 3.

The steady-state treatment of the above mechanism gives the following relation for the intensity of the emission from the complex:

$$\frac{I_{326.1}[\mathrm{A}]}{I_c} = \alpha(e+f[\mathrm{A}])\left(1+\frac{g}{h+[\mathrm{A}]}\right) \qquad (3)$$

TABLE 3. CONSTANTS INVOLVED IN EQS. (2) AND (3)

	48	34.7 ±2.1	0.038	0.0073	0.434	0.0025

Here, I_c represents the observed emission intensity from the complex at the peak. α is a proportional factor between the total emission intensity and the observed one; it depends on the geometry of the apparatus, the slit width, and the sensitivity of the photomultiplier used. e, f, g, and h are constants depending only on the total pressure:
when $Cd^* = Cd(^3P_1)$,

$$e = \frac{k_0}{k_4} + \frac{k_0 k_7'}{k_4 k_6}[M], \quad f = \frac{k_0(k_7 - k_7')}{k_4 k_6},$$

$$g = \frac{k_{-4}}{k_5 - k_5'}, \text{ and } h = \frac{k_5'}{k_5 - k_5'}[M].$$

In the case of $Cd^* = Cd(^3P_1)$, k_4 should be replaced by $(k_1/k_{-1})k_4$. These constants have been evaluated by the method described in the previous paper[3] and are listed in Table 3. The solid lines in Fig. 2 were drawn by substituting the values in Table 3 into Eq. (3).

From the relationships between the constants, $(a+b)$, αe, αf, g, and h and [M], several ratios of the rate constants can be evaluated. The results are summarized in Table 4. The lifetime (τ_0) of $Cd(^3P_1)$ has been reported to be 2.39×10^{-6} s.[9] As was mentioned in the previous paper,[1] the effective lifetime is independent of the pressure of foreign gases. Therefore, k_0 may be set equal to $1/\tau_0$ (4.19×10^5 s^{-1}). By using this value, some rate constants can be calculated. The relative values of k_4 can also be calculated by assuming that α does not depend on the kind of amine. This assumption seems reasonable, because the profile of the emission band is almost independent of the amines. These values are also listed in Table 4.

The rate constants, k_4, for the primary amines increase in this order: ammonia<methylamine<ethylamine<*sec*-butylamine<*n*-propylamine<*n*-butylamine<*tert*-butylamine. This order is in agreement with the order of the decrease in the ionization potential of amines, except for *sec*-butylamine. Figure 3 shows the correlation between the relative values of k_4 and the ionization potential of amines. Relationship of this type have also been reported in the cases of the quenching of $I(5^2P_{1/2})$[10] and $P(3^2D_j)$ and $P(3^2P_j)$.[11] This relationship indicates that the complex has the characteristics of a charge-transfer type. The tendency of the efficiency of the quenching of the resonance radiation by amines shown in Table 1 is almost the same as that of k_4. This suggests that the quenching occurs mainly through the formation of the complex (Reaction (k_4)).

The k_5/k_{-4} and k_5'/k_{-4} ratios increase generally with an increase in the molecular complexity. Thus,

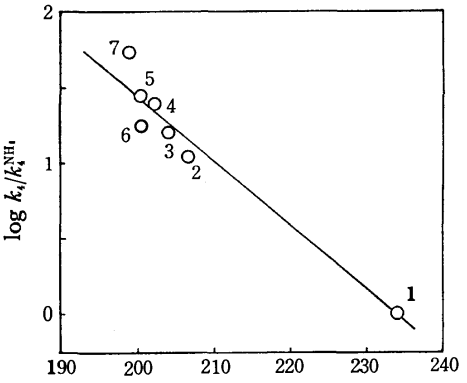

Fig. 3. Relationship between the relative values of the rate constant for the formation of complex and the ionization potential of amines.
1) ammonia; 2) methylamine; 3) ethylamine; 4) *n*-propylamine; 5) *n*-butylamine; 6) *sec*-butylamine; 7) *tert*-butylamine.

it can be said that, for the complex amines, the back reaction (Reaction (k_{-4})) is not important (c and d in Eq. (1) are large); therefore, the Stern-Volmer plots lie on a straight line.

As is shown in Table 2, the peak wavelength shifts to longer wavelengths as the ionization potentials of the amines decrease. Most of the wavelength shift occurs upon methyl substitution. These tendencies agree with the observations in the mercury-sensitized luminescence of alcohols[12] and amines.[13] These findings indicate that the complex formed between the excited cadmium atoms and amines is of the charge-transfer type, by analogy with the mercury-amines and mercury-alcohols systems. This explains why the emission band has no fine structure.

The quantum yield of the luminescence for ammonia given in Table 2 is approximately equal to that of the mercury-sensitized luminescence of ammonia. As is shown in Table 2, the quantum yield for amines decrease steadily with the increase in the molecular complexity. This tendency differs from that observed in the mercury-amines system.[13]

In the mercury-sensitized reaction, it was shown that the quenching process of $Hg(^3P_1)$ with all alcohols and amines except methylamine yields mainly Hg $(^3P_0)$.[12,13] However, in the cadmium-sensitized reaction an equilibrium between the $^3P_1$ and $^3P_0$ states is established; the quenching of the resonance radiation by amines occurs mainly through the formation of

Table 4. Rate constants and ratios between rate constants

Amine	$k_2+1.68k_3+k_4$ (or $k_2+1.68(k_3+k_4)$) (cm^3 molecule^{-1} s^{-1})	$k_4/k_4^{NH_3}$	k_5'/k_{-4} (Torr^{-1})	k_5/k_{-4} (Torr^{-1})	$10^3k_7/k_6$ (Torr^{-1})	k_7/k_7'
Ammonia	$(2.4\pm0.4)\times10^{-12}$	1.0	0.0024	0.336	4.9	1.0

n-Propylamine	$(9.9\pm0.2)\times10^{-11}$	24.9	0.0253	3.48	153.7	12.2
n-Butylamine	$(1.2\pm0.1)\times10^{-10}$	28.0	0.0649	8.93	259.0	16.4
sec-Butylamine	$(2.0\pm0.1)\times10^{-10}$	17.8	0.0195	7.81	7.0	1.0
tert-butylamine	$(7.4\pm0.4)\times10^{-10}$	53.3	0.0058	2.30	347.9	20.8

the complex, as has been mentioned above. It has been reported that, in the mercury-sensitized reaction of methylamine, the abstraction of an α-hydrogen by $Hg(^3P_1)$ atoms is important; this reaction competes with the luminescence. Therefore, in spite of the large efficiency of the quenching of $Hg(^3P_1)$ by methylamine, the quantum yield of the luminescence is very small. This explanation is supported by the fact that the quantum yield with *tert*-butylamine, which has no α-hydrogen, is large.[12] On the other hand, in the cadmium-sensitized reaction of amines the relative values of k_4 vary steadily with the decrease in the ionization potential of amines; this was taken as an indication that the relative efficiency of the formation of complex did not change markedly on going from one amine to the next. That is to say, the efficiency of the quenching can be interpreted in terms of the electron-donating ability of the nitrogen atom of amines alone.

As is seen in Table 4, the k_7/k_6 ratio increases with an increase in the molecular complexity of the amines with the exception of the case of *sec*-butylamine. If it is assumed that $1/k_6$, or the lifetime of the complex, dose not depend appreciably on the kind of amines, the above order indicates the order of the efficiency of the quenching of the complex luminescence by amines. As is shown in Table 2, therefore, the quantum yields of the luminescence decrease in this order, though the rate constants of the complex formation increase in the same order. The efficiency of the quenching of the luminescence by ammonia is very small. On the other hand, the efficiency by *tert*-butylamine is about two orders of magnitude larger than that by ammonia. This large efficiency of the quenching by *tert*-butylamine cannot be explained by the increase in the cross section of collision alone. Morten *et al.*[2] described how, at high pressures of ammonia, complexes with two or more ammonia molecules may be formed, and how the possibility of the formation of the higher complexes, which radiate at almost the same wavelength, probably provides a good explanation of the small efficiency of the quenching of the complex luminescence by ammonia. Such complexes were indeed found in the mercury–ammonia system.[14] If this explanation is correct, it can be said that the increase in the efficiency of the quenching by amines with an increase in the molecular complexity results from the difficulty in the formation of the higher complexes because of the steric hindrance of alkyl group.

The financial support for part of this work by a grant from the Ministry of Education is gratefully acknowledged.

The Micelle Formation of Mixtures of Polyoxyethylene Type Nonionic Surfactants in Aqueous Solutions

Nagamune NISHIKIDO, Yoshikiyo MOROI, and Ryohei MATUURA
Department of Chemistry, Faculty of Science, Kyushu University, Fukuoka 812
(Received November 28, 1974)

The critical micelle concentrations (CMC) of mixtures of nonionic surfactants with the same hydrocarbon, *i.e.* dodecyl group, and with various chain lengths of ethylene oxide, were determined. The observed values were compared with the values calculated by means of the equation derived from the pseudo-phase separation model on the assumption that the mixed micelle is a perfect solution. A good agreement between observed and calculated values was obtained in the mixtures of the surfactants with six or more ethylene-oxide units. However, the observed values of the two-component mixture, one component with five ethylene-oxide units, showed a small deviation from the calculated values. The difference between the above two cases was explained from the viewpoint of the most suitable packing of the first six or fewer ethylene-oxide units near the micelle core in the micelle state.

It is well known that mixtures of surfactants, either ionic-ionic, ionic-nonionic, or nonionic-nonionic, form mixed micelles in an aqueous solution. Especially, the mixed micelle formation of ionic surfactants has been widely investigated.[1,5] Also, in the work of mixed systems of ionic-nonionic surfactants, useful information has been obtained.[2,5] However, only a few studies have been made of the critical micelle concentrations (CMC) of mixture of nonionic surfactants.[3-5] Recently, using polyoxyethylene type nonionic surfactants with almost the same oxyethylene chain length, but with different hydrocarbon chain lengths, Shinoda-Nakagawa[4] and Lange[5] predicted the CMC of their mixtures by the use of a pseudo-phase separation approach, treating the mixed micelle as a perfect solution. For practical purposes, it is important to be able to predict the CMC of surfactant mixtures from the CMC of each component.

In the present work, by determining the CMC of two-, three-, and four-component mixtures of nonionic surfactants with various oxyethylene chain lengths and the same hydrocarbon chain length, we examined the CMC equation derived on the assumption that the mixed micelle behaves as a perfect solution in the pseudo-phase separation model.

Experimental

Materials. The nonionic surfactants, polyoxyethylene lauryl ethers ($C_{12}H_{25}O(CH_2CH_2O)_{\bar{n}}H$, $\bar{n}$=5, 6, 10, 15, 20, 29, 49, $\bar{n}$: the average number of ethylene oxide groups) were the same materials, supplied by the Kao Soap Co., Ltd., as those used in our previous paper.[6] The sharp distribution of the oxyethylene chain lengths could be assessed by means of the sharp breaks and the lack of, or small, minimum in the surface tension *vs.* logarithm of the surfactant concentration plots. Throughout this work, the difference in the number of oxyethylene groups between the components in mixtures was more than five units, so each component was regarded as a single species in making a good approximation for the purposes of the present work.

Method. The CMC was determined at 20 °C by the use of both the surface tension and the dye-color-change methods.[7] The details of the procedures of the former were described in a previous paper.[6] The dye used was pinacyanol chloride (Eastman Kodak Co.), and its concentration was 1×10^{-5} mol/l throughout this work. The shift of the absorption spectrum was measured with a DSB-70 spectrophotometer manufactured by the Beckman-Toshiba Co., Ltd. The procedure of direct calorimetry used to determine the standard entropy of micelle formation, ΔS_m°, was described in the previous paper.[6]

Results and Discussion

With an increase in the content of the component with a higher CMC, the extent of the minimum in the surface tension-logarithm of the concentration curve gets larger; however, we could detect distinct breaks in the curve even for four-component mixtures. These distinct breaks agreed with the CMC determined by the dye-color-change method. The CMC's of single surfactants with various lengths of ethylene-oxide chains in the aqueous solution at 20 °C are tabulated in Table 1. The CMC's of mixtures are shown in Figs. 1, 2, and Tables 2, 3, with the composition.

TABLE 1. CMC AND THE STANDARD FREE ENERGY OF MICELLE FORMATION ΔG_m^0 OF THE SULFACTANTS WITH VARIOUS ETHYLENE OXIDE CHAIN LENGTHS IN THE AQUEOUS SOLUTION AT 20 °C

Ethylene oxide chain length, $\bar{n}$	CMC (10^{-5} mol/l)	ΔG_m^0 (kcal/mol)
5	4.5	−8.15
6	6.0	−7.99
10	9.0	−7.75
15	12.0	−7.58
20	15.5	−7.43
29	26.0	−7.14
49	63.0	−6.62

Using the same pseudo-phase separation treatment as that of Lange *et al.* for two-component mixtures,[5] the equation of the CMC for multi-component mixtures of nonionic surfactants can be easily derived as follows.

In a sufficiently low concentration range, the CMC can be expressed by the mole fraction instead of by the activity in the chemical potential of the monomer. Recently, nuclear magnetic resonance studies have shown that the micelle contains some water molecules,[8] but their solubility can be neglected in a good approxi-

mation. In addition, assuming that the mixed micellar phase behaves as a perfect solution, the following equation holds for the ith-component:

$$x_i C_M = x_i^m C_i \quad (1)$$

where x_i, x_i^m: mole fraction of the ith-component in a mixture in the bulk solution and in the micellar phase respectively, C_M, C_i: the CMC (molar concentration) of a mixture and of a single system of the ith-component respectively.

The sum of the mole fractions of components in the micelle phase is unity; that is, $\sum x_i^m = 1$. Thus, Eq. (1) leads to:

$$C_M = \frac{1}{\sum_i (x_i/C_i)}. \quad (2)$$

The CMC values calculated from Eq. (2) are shown in Figs. 1 and 2 for two-component mixtures, and in Tables 2 and 3 for three- and four-component systems respectively, together with the observed values. Within the limits of experimental error, a good agreement between calculated and observed CMC's is usually obtained. However, in the case of one two-component system, $\bar{n}=5$—$\bar{n}=49$ (Fig. 2), a small disagreement is observed. The difference between the system containing $\bar{n}=5$ and the system containing $\bar{n}\geqq 6$ may be connected with the assumption made in the course of the derivation of Eq. (2). The assumption that the mixed micelle can be regarded as a perfect solution must be checked, since the other assumption, an ideal dilution in bulk solution, is sufficiently acceptable.

In order to clarify the situation, let us consider the following equation by Shinoda:[9]

TABLE 2. COMPARISON OF CALCULATED WITH OBSERVED CMC FOR THREE-COMPONENT MIXTURES AT 20 °C

○: observed, ——: calculated CMC from Eq. (2)

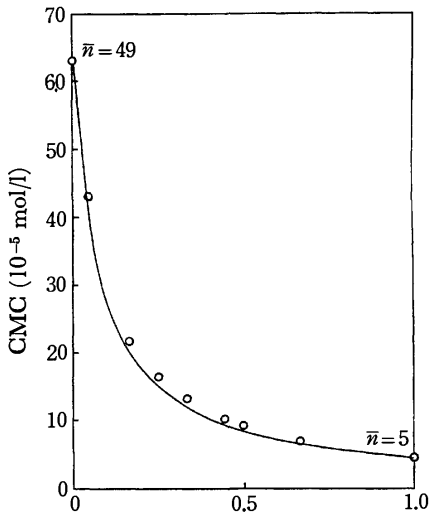

Fig. 2. Calculated and observed CMC for $\bar{n}=5$—$\bar{n}=49$ mixture at 20 °C
○: observed, ——: calculated CMC from Eq. (2)

$$\ln C = -\frac{\chi-\chi'}{kT} + \ln\frac{1000}{Nv} - 1, \quad (3)$$

where C: CMC in molarity, $\chi-\chi'$: the free energy difference of a surfactant between micellar and monomer states, N: the Avogadro number, v: the free volume of a surfactant molecule in a micelle.

In the case of nonionic surfactants,

$$\chi - \chi' = mw - \Delta,$$

where m: the number of methylene groups in a hydrocarbon chain, w: the free energy change per methylene group transferred from water into the micelle (constant value of *ca.* 1.1 kT), Δ: the free energy change of a polyoxyethylene chain between micelle and monomer states,

containing the terms of dehydration energy, configuration entropy, and oxyethylene-oxyethylene interaction energy. It is possible to evaluate this term experimentally from the ln C *vs.* ethylene-oxide chain length plots. However, it is not necessary to evaluate it experimentally or mathematically in the discussion below, so we will treat it as a parameter.

We have obtained the following equation for nonionic surfactants with the same hydrocarbon chain in the most simple form:

$$\ln C_i = -\frac{mw}{kT} + \frac{\Delta_i}{kT} + \ln\frac{1000}{Nv_i} - 1. \quad (4)$$

As each component has the same hydrocarbon chain, the assumption that the mixed micelle is a perfect solution needs an ideal mixing term, ln x_i^m, in Eq. (4):

$$\ln (x_i C_M) = -\frac{mw}{kT} + \frac{\Delta_i}{kT} + \ln\frac{1000}{Nv_i} - 1 + \ln x_i^m \quad (5)$$

Of course, we obtain Eq. (2) from Eqs. (4) and (5). In other words, in the concept of a perfect solution, the free energy difference, $mw-\Delta_i$, is not altered by mixing in a micelle. That is, the free energy difference in a mixed system is the same as that in a single system.

If the mixing process brings a small variation in mw or Δ_i in Eq. (5),

$$\ln (x_i C_M) = -\frac{mw}{kT} + \frac{\Delta_i}{kT} + \frac{\delta_i}{kT} + \ln\frac{1000}{Nv_i} - 1 + \ln x_i^m, \quad (6)$$

where δ_i is the quantity of deviation from mw or Δ_i in Eq. (5), neglecting the variation in v_i. In Eq. (6), δ_i corresponds to the heat of mixing term in the regular solution approximation, in analogy with a macroscopic solution. In Fig. 2, it may be seen that the deviation in the observed CMC's from the calculated values, *i.e.*, the ideal values, is small. Thus, Eq. (6) can be expected to be valid in this case. Alternatively and generally, by adding the excess term, ln γ_i^m, in Eq. (5), we obtain:

$$\ln (x_i C_M) = -\frac{mw}{kT} + \frac{\Delta_i}{kT} + \ln\frac{1000}{Nv_i} - 1 + \ln x_i^m \gamma_i^m \quad (7)$$

where γ_i^m is the activity coefficient of the ith-component in a mixed micelle. From Eqs. (4), (6), and (7), we obtain:

$$C_M = \frac{1}{\sum_i (x_i/C_i\gamma_i^m)} = \frac{1}{\sum_i (x_i/C_i \exp(\delta_i/kT))} \quad (8)$$

It may be seen in Fig. 2 that the observed CMC deviates positively from the ideal CMC. Then, at least, judging from Eq. (8), the activity coefficient of one component in a mixed micelle must be greater than unity. In a non-ideal macroscopic solution composed of two components, the deviation from ideality occurs in the same direction for both components. Therefore, we may conclude that the activity coefficients of both components in the mixed micelle are greater than unity. The free energy difference, $mw-\Delta_i-\delta_i$, in a mixed system is smaller than the $mw-\Delta_i$ in a single system. Thus, the micelle environments of both components are less stable than those in a single system. This conclusion is only the sufficient condition for the validity of positive deviation from the ideal CMC shown in Fig. 2. This point will be explained further in the subsequent discussions.

In the present work, the plots of the standard free energy of micelle formation, ΔG_m° ($\Delta G_m^\circ = RT \ln X_c$, where X_c represents the CMC in mole fraction) against $\bar{n}$, the number of ethylene-oxide (EO) units, yield two lines and cross around $\bar{n}=6$, *i.e.*, around the sixth unit (Table 1). In addition, the standard entropy of micelle formation, ΔS_m°, for the surfactant with 5 EO units is 41 ± 6 e.u./mol, while the values of ΔS_m° for the surfactants with 6 to 31 units are almost constant, *ca.* 52 e.u./mol in aqueous solutions at 20 °C.[6] Crook *et al.* found the similar trend for *p,t*-octylphenoxyethoxyethanol in the aqueous solution below 50 °C.[10] From the break at the sixth EO unit in the plots of the thermodymanic quantities of micelle formation against EO units, Ray and Nemethy assumed as follows:[11] in the micelle state, the first six or less EO units, near the nonpolar core of the micelle, pack together and lose some of their hydration water because of the need for close packing of the nonpolar tails, while in longer chains, the EO units beyond the sixth are located sufficiently far from each other so that their local environment is changed very little compared to that for the monomer. This picture can be applied to the present CMC data in order to explain why the deviation from the ideal mixing in the mixed micelle occurs only in the $\bar{n}=5$—$\bar{n}=49$ system.

As the steric interaction among the EO units beyond the sixth in the micelle state is not very strong, the mixing of the surfactants with six or more EO units brings little difference in the micelle environment of EO units between mixed and single micelles. In addition, as each component has the same hydrocarbon chain, the free energy difference in the hydrocarbon chain and EO units between the micelle and monomer states, $mw-\Delta_i$ in Eq. (5), is independent of the number of components in a micelle, as has already been described. Thus, the above situation leads to the concept that the mixed micelle is a perfect solution.

On the other hand, in Fig. 2, the surfactant of $\bar{n}=49$ only needs the packing of the first six EO units, while the other component has five EO units. Therefore, the positive deviation from the ideal mixing may be expected to occur only for the surfactant of $\bar{n}=49$. In this case, the activity coefficient of $\bar{n}=5$ in the mixed micelle must be unity, and that of $\bar{n}=49$ must be *ca.* 10 at 0.5 of the mole fraction in a bulk solution, in order to satisfy the experimental results in Fig. 2. However, the value of the activity coefficient, $\gamma^m=10$, corresponds to the heat of mixing term, $\delta=2.3\,kT$, which is too large to explain the small deviation from the ideal CMC. Thus, the micelle state of the surfactant of $\bar{n}=5$ in a mixed system may be also be obliged to deviate from the most suitable packing in a single system by the surfactant of $\bar{n}=49$. This deviation brings about the decrease in the free energy difference of each surfactant in a mixed system between micelle and monomer states compared to each single-component system; that is, $\delta_i>0$ in Eq. (6). Then, the surfactant with five EO units brings about the positive deviation from the ideal CMC shown in Fig. 2.

From the viewpoint of predicting the CMC, it may be concluded that the CMC's of multi-component mixtures, in which each component has six or more EO units, can be determined by means of Eq. (2).

We wish to express our hearty thanks to the Kao Soap Co., Ltd., for the supply of nonionic surfactants.

Basic Properties of Metal Phosphates and Their Catalytic Activity in the Decomposition of Diacetone Alcohol

Akio TADA

Department of Industrial Chemistry, Kitami Institute of Technology, Koen-cho, Kitami 090

(Received December 2, 1974)

The basic properties of alkali and alkaline earth metal phosphates calcined at various temperatures were investigated. The strength of the surface base was determined by the adsorption of acidic indicators from benzene solution. It was found that K_3PO_4 shows a fairly high basic strength of $H_0 \geqq 17.2$. The surface basicity was evaluated by the catalytic activity for the decomposition of diacetone alcohol, which is known to be catalyzed only by basic catalysts. Comparison of the result of the activity measurement with that of TGA indicated that the basicity of a metal phosphate reaches a maximum when dehydrated completely. The nature of the basic sites on metal phosphates is also discussed.

The surface basicities of metal phosphates have not been extensively studied as compared to the surface acidities of those. Scheidt[1] has reported that lithium phosphate, sodium orthophosphate, and calcium orthophosphate catalyze aldol condensations which are typically base-catalyzed. On the other hand, the condensation of acetaldehyde in low yield by passing the feed in the vapor phase over magnesium, zinc, strontium, cadmium, or barium phosphates has been reported by Ivanov *et al.*[2] In our preceding paper,[3] the surface of sodium and calcium orthophosphates was found to have a basic character, but that of others such as magnesium, zinc, or nickel salts an acidic character. These observations seem to be in agreement with the above results. Recently, Imanaka *et al.*[4] have reported that Li_3PO_4 has only acidic character, but Li_2MPO_4- and LiM_2PO_4- type phosphates (M=Na or K) and $Ca_3(PO_4)_2$ have both basic and acidic properties. The basic properties of metal phosphates are considered to be closely related to their structures, and it is important to clarify the relations between them. Very little work, however, has been made on such relationships. From these point of view, an attempt was made to clarify the nature or structure of the basic sites on metal phosphates calcined at various temperatures.

Experimental

Samples. The following chemicals were reagent grade, and were used without further treatment: $Ca_3(PO_4)_2$, $Na_3PO_4 \cdot 12H_2O$, K_3PO_4, Li_3PO_4, $Na_2HPO_4 \cdot 12H_2O$, $NaH_2PO_4 \cdot 2H_2O$, $Ca(H_2PO_4)_2 \cdot H_2O$, K_2HPO_4, KH_2PO_4, and $Na_4P_2O_7 \cdot 10H_2O$. $Na_2HPO_4 \cdot 12H_2O$ and $Na_3PO_4 \cdot 12H_2O$ were first calcined at about 130 °C for 6—7 hr, sieved below 100 mesh after grinding to powder and then calcined at various temperatures for 3 hr in air. The other phosphates were calcined immediately after sieving.

Measurement of Basic Property. The basicities and basic strengths of samples were measured by titrating the powder suspended in benzene with 0.1 N benzoic acid benzene solution, using bromothymol blue ($pK_a=7.1$), phenolphthalein (9.3), 2,4-dinitroaniline (15.0), and 4-chloro-2-nitroaniline (17.2) as indicators.

Measurement of Catalytic Activity. Decomposition of diacetone alcohol, which was selected as a model reaction, was carried out in the temperature range 30—55 °C, by stirring the reaction mixture in a reaction vessel containing 1.0 g of catalysts, 23.0 g of diacetone alcohol, and 2.5 g of benzene (internal standard). At an appropriate time interval, stirring was stopped and 0.15 ml of the solution was taken up through sampling rubber and analyzed by gas chromatography, after the catalyst had been removed by centrifuging. Diacetone alcohol was purified by drying with Drierite and distilling two times under 10 Torrr.

TGA and DTA. The rate of heating was maintained at 5 °C/min. The sample holder was a platinum vessel.

Results and Discussion

Basic Property. The basic color of the indicator adsorbed on the solids changes to acidic color on addition of benzoic acid but the acidic color changes again gradually to the basic color after several minutes. The results of the basic strength measurements, given in Table 1, suggests that the tertiary phosphates of sodium, potassium, and calcium as well as the secondary phosphates of sodium and potassium may be used as solid base catalysts. The basic strength of tertiary potassium phosphate is comparable to that of an alkaline earth metal oxide.[5] Although secondary potassium phosphate might show catalytic activity, its effectiveness is probably limited. Lithium phosphate is known to be a catalyst for aldol condendsation reaction,[1] but Li_3PO_4 shows no solid basicity in agreement with the result of Imanaka *et al.*[4] This fact suggests that the lithium phosphate used by Scheidt is not Li_3PO_4 but

Table 1. Basic strength of alkali and alkaline earth metal phosphates

Original metal phosphate	Calcination temp., °C	Basic strength (H_0)[a]			
		7.1	9.3	15.0	17.2
Li_3PO_4	22—400	−	−	−	−
$Na_3PO_4 \cdot 12H_2O$	22—700	+	+	−	−
$Na_2HPO_4 \cdot 12H_2O$	22— 60	−	−	−	−
	150—500	+	+	−	−
$NaH_2PO_4 \cdot 2H_2O$	22—400	−	−	−	−
$Na_4P_2O_7 \cdot 10H_2O$	22—500	−	−	−	−
K_3PO_4	22—800	+	+	+	+
K_2HPO_4	22—500	+	−	−	−
KH_2PO_4	22—400	−	−	−	−
$Ca_3(PO_4)_2$	22—600	+	+	−	−
$Ca(H_2PO_4)_2 \cdot H_2O$	22—400	−	−	−	−

a) + or − denotes yes or no.

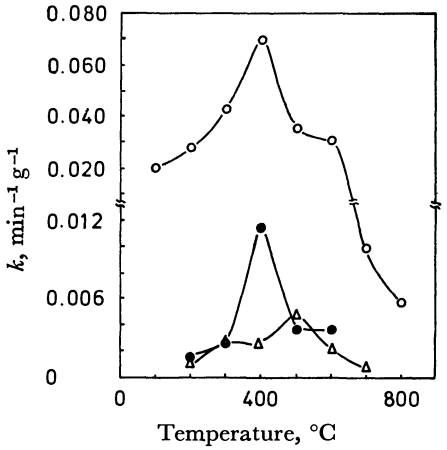

Fig. 1. The reaction rate constants over phosphates at 40 °C as a function of the calcination tempetraure.
○: K_3PO_4, ●: $Ca_3(PO_4)_2$, △: Na_3PO_4

a substituted phosphate such as $NaLi_2PO_4$. $Ca_3(PO_4)_2$ has been found to have both acidity (H_0=4.8) and basicity (7.1).[4] According to Table 1, this salt has only basicity (9.3). This inconsistency may be due to a difference in the samples.

Decomposition of Diacetone Alcohol. The only reaction product was acetone. It has been observed that the rate of decomposition of diacetone alcohol catalyzed by MgO–Al_2O_3[6] and alkaline earth metal oxides[7] is of the first order. Similarly the rate on the metal phosphates was found to be of the first order with respect to diacetone alcohol concentration. Fukuda *et al.*[7] have reported that a long induction period is observed on SrO and BaO, while it disappears by the removal of CO_2. However, no induction period was observed on the metal phosphates. The reaction rate constants over the tertiary phosphates of potassium, sodium, and calcium at 40 °C as a function of the calcination temperature are shown in Fig. 1. The catalytic activity of secondary sodium phosphate was much lower under similar conditions. Since the decomposition of diacetone alcohol is known to be catalyzed only by basic catalyst,[7] the catalytic activity is considered to be proportional to the amount of effective basic sites. Only tertiary potassium phosphate showed the catalytic activity at 30 °C. At 40 °C tertiary sodium phosphate, secondary sodium phosphate, and tertiary calcium phosphate were also found to be active, but secondary potassium phosphate inactive. These observations show that the effective basic sites at 40 °C are those having a basic strength of $H_0 \geqq 9.3$.

Arrhenius activation energies in the temperature range from 30 to 55 °C are compared to the literature values in Table 2. The activation energy for tertiary sodium phosphate is comparable with those for CaO and MgO, while the activation energies for other phosphates are comparable with those for SrO, BaO, and NaOH solution. The activation energy for tertiary potassium phosphate is considered to be rather high in view of its basic strength of $H_0 \geqq 17.2$. This may be related to the formation of light brown, unknown substance on the catalyst during the reaction.

Table 2. Activation energies of decomposition of diacetone alcohol with various catalysts

Catalyst	Calcination temp., °C	Activation energy[a] (kcal/mol)
Na_3PO_4	500	10.8
K_3PO_4	400	21.7
$Ca_3(PO_4)_2$	400	18.0
MgO	500	11.1
CaO	500	11.5
SrO	500	20.3
BaO	no heat treatment	20.3
NaOH (aq. soln.)		18.4

a) Activation energies for catalysts from MgO to NaOH are cited from Ref. 7.

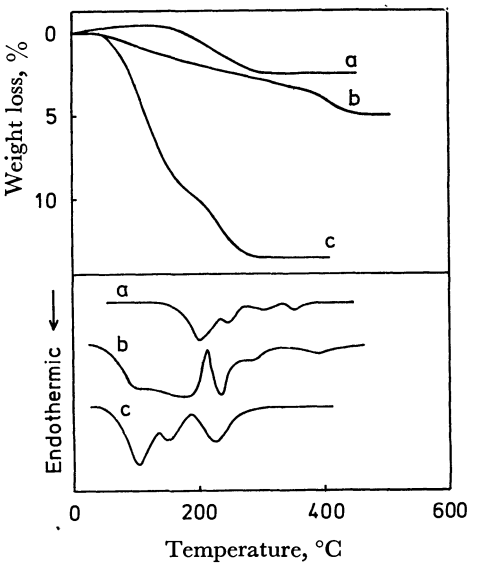

Fig. 2. TGA and DTA of K_3PO_4 (a), $Ca_3(PO_4)_2$ (b), and $Na_3PO_4 \cdot xH_2O$ (c).

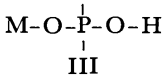
Change in Structure with Calcining. TGA and DTA curves are shown in Fig. 2. The amount of crystal water contained in metal phosphates were calculated from the TGA data by assuming the formation of anhydrides at the stage of no further detectable loss in weight. The dehydrating experiments show that tertiary sodium phosphate predried at 130 °C contains about 1.5 mol of water. The anhydride formation is detected at about 250 °C in agreement with the literature value.[8] The initial increase in weight of tertiary potassium phosphate may be attributable to the absorption of moisture during weighing, because this substance is highly hygroscopic. The water is lost at 280 °C in agreement with the result of Ben-Dor and Felner.[9] According to Fig. 2, it is obvious that $Ca_3(PO_4)_2$ contains about 1 mol of water and reaches complete dehydration at 400 °C. $Na_2HPO_4 \cdot 12H_2O$ has been reported to lose its water of hydration when heated up to 110 °C, and at 300 °C condensation to the pyrophosphate occurs.[9]

Basic Sites on Metal Phosphates. The structures of metal phosphates have been studied by many workers.[10] In hydrated metal orthophosphates, the phosphorus atoms are tetrahedrally surrounded by oxygen atoms, and the metal atoms (M) are surrounded by the oxygens

of the PO_4 groups and of the water molecules, while in anhydrous metal phosphates, the metal atoms are surrounded only by the oxygens of the PO_4 groups. Thus, the following structures I and II are considered

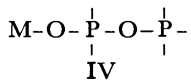
I II

to be a part of the structure of the hydrates and anhydrides, respectively. If the electron donating power of the metal atoms is adequate, the oxygen atoms in M–O linkages may be basified. Comparison of Fig. 1 with Fig. 2 indicates that the catalytic activities (basicities) of metal phosphates reach their maxima when dehydrated completely. These results are reasonably explained as follows. Since the negative charge on the oxygen of II is higher than that of I, the basicities of the anhydrides are larger than those of the hydrates, and hence the activities of the former are higher than those of the latter. In view of the valency and radius, the order of the electron donating power of alkali metal atoms is K>Na>Li and corresponds to the order of the basic strengths of tertiary phosphates: K_3PO_4>Na_3PO_4 >Li_3PO_4. A portion of the structure of an acidic phosphate is probably as given below. Since the negative charge on the oxygen of II is higher compared to that of III, the basicity of a tertiary phosphate is expected



III

to be superior to that of an acidic phosphate. Indeed, this prediction is confirmed by the results from basic property measurements and activity measurements. Ivanov *et al.*[2] have also reported that the activity of the neutral phosphates is greater than that of the disubstituted phosphates. No basicity or the very low activity[1] of a pyrophosphate can be attributed to the poorer negative charge on the oxygen atom in M–O linkages of IV, because the electron-withdrawing power



IV

of pyrophosphate ion is considered to be stronger than that of orthophosphate ion.

According to Tillmanns and Baur,[11] NaOH is built into the crystal structure of $Na_3PO_4 \cdot 12H_2O$ and its amount (0—0.25 mol) depends on the conditions under which the crystal was formed. If this is the case, it seems to deserve examination how NaOH contributes to the basicity of tertiary sodium phosphate. It was found that both NaOH and KOH initially show little basicity, but the basic colors of bromothymol blue and phenolphthalein adsorbed on the solids gradually deepen as the suspensions take up moisture. Moreover, neither dry nor wet salts converted 2,4-dinitroaniline and 4-chloro-2-nitroaniline to their conjugate bases. These results indicate that a caustic alkali is not a so-called solid base, and its concentrated solution has not so high basic strength as the surface of K_3PO_4 has. Therefore, the basic properties of metal phosphates are considered to be predominantly attributable to negatively charged oxygens on structures I—III.

Resonance Raman Spectra of Methylorange Bound to Proteins and Cationic Surfactants

Bak-Kwang Kim, Akira Kagayama, Yutaka Saito, Katsunosuke Machida, and Toyozo Uno
Faculty of Pharmaceutical Sciences, Kyoto University, Sakyo-ku, Kyoto 606
(Received December 9, 1974)

Resonance Raman spectra of methylorange were recorded for aqueous solutions containing various proteins and cationic surfactants. The base form of methylorange was found to retain its trans-azo structure on the interaction with human serum albumin and with cetyltrimethylammonium bromide. The relative intensities of the Raman bands at 1420 cm^{-1} and at 1155 cm^{-1} of methylorange change appreciably along with the shift of the absorption maximum in the visible and ultraviolet region on addition of proteins and surfactants.

Proteins and surface active agents give rise often to the anomaly in visible and ultraviolet absorption spectra and the deviation of the color-change interval of various acid-base indicators.[1-4] This phenomenon has long been the subject of extensive studies with special attention on the intermolecular interaction involved. Structure changes of indicator molecules associated with this color change may be reflected, if any, in resonance Raman spectra of the indicators in aqueous solutions in the presence of proteins and surfactants.

The absorption maximum, λ_{max}, in the visible absorption spectrum of methylorange (MO) in neutral aqueous solutions undergoes a blue shift by 20—30 nm on addition of bovine serum albumin (BSA).[2,3] Various postulates such as the change in the molecular environment[5] or the twisting around the N=N bond[6] have been forwarded to account for this shift. Carey *et al.* have recently found, based on rather small changes in the resonance Raman spectrum, that no appreciable twisting around the N=N bond occurs for MO bound to BSA.[7] Change of the λ_{max} in the visible and ultraviolet absorption spectra of MO is also known for the solutions containing human serum albumin (HSA),[5] poly-L-lysine hydrobromide (PLL)[8] and cetyltrimethylammonium bromide (CTB).[4,8] We have investigated the effects of these substances on the resonance Raman spectrum of MO with particular interest in the change of the relative band intensities.

Experimental

Reagent grade methylorange (Tokyo Kasei Co.) was recrystallized several times from water. Crystallized and lyophilized bovine serum albumin (Sigma Chem. Corp.), poly-L-lysine hydrobromide (Protein Research Foundation, Osaka) and crystallized human serum albumin (Miles Lab.) were used without further purification. Cetyltrimethylammonium bromide (Tokyo Kasei Co.) was recrystallized from ethanolic solution. The concentration of MO in the sample solutions was 1×10^{-4} M and those of proteins and surfactants were between 5% and 0.5%. The pH of these solutions was controlled by using 0.1 M HCl and the phosphate buffers, and was determined by Radiometer titrator TTT2 and combined electrode GK 2302C.

Resonance Raman spectra were recorded on a JEOL S-1 laser Raman spectrophotometer with the spectral slitwidth 12 to 15 cm^{-1}. The excitation lines at 514.5 nm, 488.0 nm and 476.5 nm were obtained from a Coherent 52G Ar^+ laser. The sample solutions were sealed in 1 mm glass capillary tubes. Band intensities were measured as the peak heights on appropriate base lines. The visible and ultraviolet spectra were recorded on a Shimadzu W-40 spectrophotometer.

Results and Discussion

In the previous work,[9] we could not detect any noticeable change in relative intensities of resonance Raman bands of the base form of MO on changing the excitation wavelength from 488.0 nm to 514.5 nm. The 1420 cm^{-1} band due to the N=N stretching vibration is always much stronger than the other bands. We found in this work, however, that the intensity ratio of the two bands at 1420 and 1155 cm^{-1}, I_{1420}/I_{1155}, in the spectra excited by the 514.5 nm line decreases appreciably on addition of BSA. It has been known that the λ_{max} of the base form of MO is at 464 nm in the neutral aqueous solution and shifts to 440—430 nm on addition of BSA up to 0.2%.[2,3] In the case of the presently used 3% BSA solution (pH 3.9—5.5), the λ_{max} of MO appears at 430 nm. Thus the change in I_{1420}/I_{1155} may be attributed to the different sensitivities of the band intensities I_{1420} and I_{1155} on the separation between the λ_{max} and the excitation wavelength. According to Ito *et al.*, the intensity of the N=N stretching band of *p*-aminoazobenzene at 1422 cm^{-1} increases much more quickly than those of two bands around 1150 cm^{-1} on changing the excitation wavelength from 632.8 to 337.1 nm.[10] In this work, a similar dependence of the relative band intensities on the excitation wavelength was observed for MO bound to BSA. As shown in Fig. 1, the ratio I_{1420}/I_{1155} increases when the excitation wavelength is

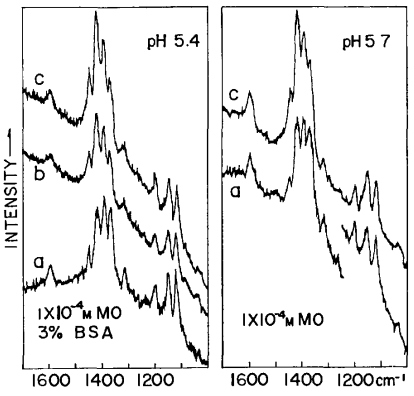

Fig. 1. Resonance Raman spectra of MO and MO–BSA solutions. Excitation wavelength: a, 514.5 nm; b, 488.0 nm; c, 476.5 nm.

shortened in the order 514.5, 488.0, and 476.5 nm. The BSA-bound molecules of MO excited by these Ar^+ lines seem therefore to be in the state of preresonance, during which the resonance effect on the stretching vibration of the N=N bond increases as the excitation line approaches the λ_{max} 430 nm. On the other hand, the unbound MO with the λ_{max} 464 nm shows no appreciable change in I_{1420}/I_{1155} on the change of the excitation line from 476.5 to 514.5 nm, probably because the band intensity I_{1420} is saturated under a rigorous resonance and is almost insensitive to the change of the excitation wavelength within the visible absorption band.

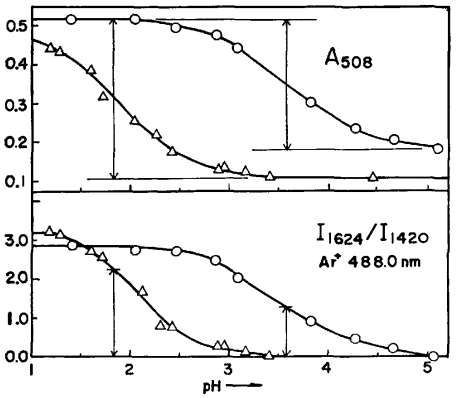

Fig. 2. The pH dependence of the absorbance (A_{508}) and the Raman intensity ratio (I_{1624}/I_{1420}): circle, 1×10^{-4} M MO; triangle, 1×10^{-4} M MO+3% BSA. The arrows indicate the pH at which the concentrations of the acid and the base forms become equal to each other.

The decrease of I_{1420} on the shift of λ_{max} from 464 nm to 430 nm is manifested in the change of the resonance Raman spectra of the bound MO and the unbound MO on the change of pH across the color-change interval. In the acidic solutions, MO is not bound to BSA, and the absorption spectrum of the acid form of MO (λ_{max}= 508 nm) dose not change on addition of BSA. The Raman band at 1624 cm^{-1} of the acid form of MO may thus be used, in the middle of the color change interval, as an internal standard to estimate the difference in I_{1420} between the bound MO and the unbound MO in the base form. In Fig. 2, the pH dependence of the ratio I_{1624}/I_{1420} is compared with that of the absorbance A_{508} for both the MO and the MO–BSA solutions. The pH's at which the concentrations of the base and the acid forms in these solutions become equal are easily determined from the sigmoid curves for A_{508}. Comparing the ratio I_{1624}/I_{1420} at these pH's, we can conclude that I_{1420} of MO bound to BSA is about 3/5 of that of the unbound MO.

Klotz *et al.* have found that the solution of MO containing HSA shows a complicated shift of the λ_{max} on the change of pH.[5] Figure 3 shows the resonance Raman spectra of the MO-HSA solution excited by the 488.0 nm and the 514.5 nm lines. The shifts of the λ_{max} on the addition of HSA and on the subsequent change of pH are not accompanied by the shift of the Raman bands, and the resonance Raman spectra of the MO–HSA solutions are entirely different from the previously reported spectrum of the acidic solution of MO.[9] This

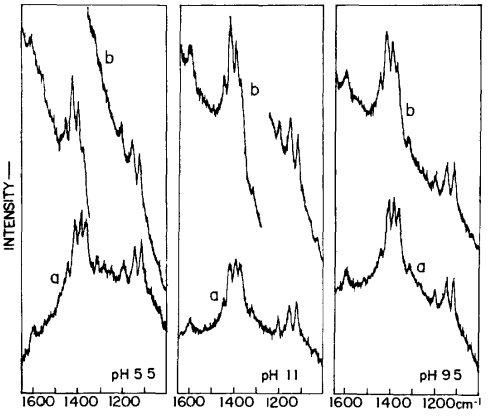

Fig. 3. Resonance Raman spectra of MO–HSA solutions (1×10^{-4} M MO+1.5% HSA) at various pH. Excitation wavelength: a, 514.5 nm; b, 488.0 nm.

result indicates that there is no proton donation from protein residues to MO bound to HSA. In the resonance Raman spectra of the MO-BSA solutions excited by the 514.5 nm line, the ratio I_{1420}/I_{1155} increases appreciably as the approach of the λ_{max} to the excitation wavelength. On the contrary, there seems to be no appreciable change in I_{1420}/I_{1155} on the change of the λ_{max} for the spectra recorded for the 488.0 nm excitation.

According to Quadrifoglio and Crescenzi, the λ_{max} of MO in the visible region undergoes a marked blue-shift to 370 nm on addition of poly-L-lysine hydrobromide (PLL).[8] These authors obtained, by using the 1×10^{-5}M solution, the absorption spectra in which no peaks were observed above 400 nm. Unfortunately, the limitation in the Raman sensitivity compelled us to use the solution 10 times as concentrated as these authors' solution, and with this concentration, we could not find the condition for eliminating a peak around 450 nm. The resonance Raman spectrum of this solution (Fig. 4) taken by the 488.0 nm excitation is the same as that of MO bound to HSA, and is thought to arise from the species responsible for the absorption at 450 nm.

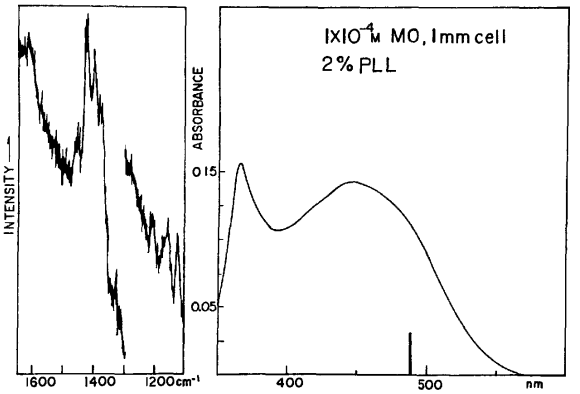

Fig. 4. Resonance Raman and visible absorption spectra of MO–PLL solution. The bar indicates the excitation wavelength (488.0 nm).

The absorption spectrum of the base form of MO changes in two steps on addition of the cationic surfactant cetyltrimethylammonium bromide (CTB). When the concentration of this surfactant is slightly lower than

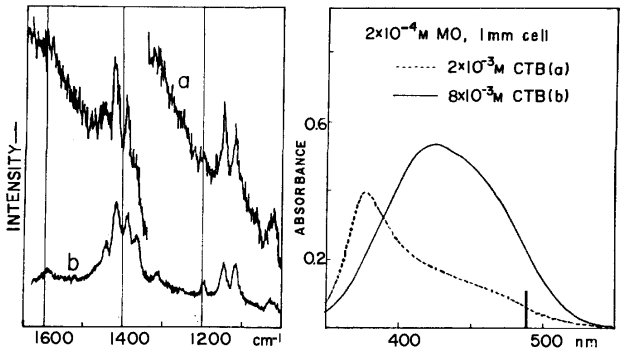

Fig. 5. Resonance Raman and visible absorption spectra of MO–CTB solutions. The bar indicates the excitation wavelength (488.0 nm).

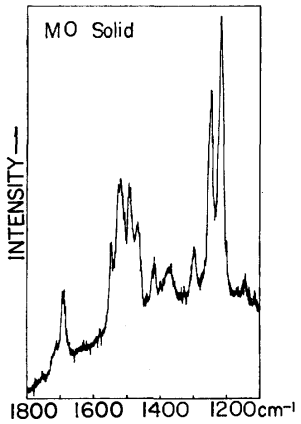

Fig. 6. Raman spectrum of solid MO excited by the He–Ne 632.8 nm line.

the critical micelle concentration (3×10^{-3} M), a peak appears at 370 nm as in case of MO bound to PLL.[8] As shown in Fig. 5a, the noise level of the resonance Raman spectrum of the MO solution containing 2×10^{-3} M of CTB is very high because the resonance effect is diminished according to the large separation between the λ_{max} and the excitation wavelength. It is recognized, however, that the intensity ratio I_{1420}/I_{1155} in Fig. 5a is appreciably smaller than that in the spectrum of the solution containing 8×10^{-3} M of CTB (Fig. 5b). In contrast to the case of the MO–PLL solution, the Raman bands shown in Fig. 5a and the λ_{max} at 370 nm are due certainly to the same species. A conformational change of the azo group from the *trans* form to the *cis* form has been postulated in order to explain the large blue-shift of the λ_{max} of MO on being bound to PLL and CTB.[8] However, the resonance Raman spectrum shows clearly that there is no possibility for such a conformational change; the *cis*-azo group is known to give the stretching frequency around 1500 cm^{-1}, about 100 cm^{-1} higher than that of the *trans*-azo group.[11] This conclusion has been drawn by Carey *et al.* for the BSA-bound MO showing the λ_{max} 430 nm.[7] When the concentration of CTB is much higher than the critical micelle concentration, the absorption spectrum of MO is similar to the case when BSA is added.[4] The corresponding Raman spectrum is identical to that of MO bound to BSA.

The difference in the sensitivities of the Raman band intensities to the excitation wavelength is reflected also on the spectra of MO in the crystalline state. As shown in Fig. 6, the Raman spectrum of the crystalline MO excited by the He–Ne 632.8 nm line gives the ratio I_{1420}/I_{1155} less than unity. According to the spectrum reported by Carey *et al.*, this ratio is much larger than unity when excited by the Ar^+ 488.0 nm line.[7] Presumably, the λ_{max} of the crystalline MO is at the shorter wavelength side of the 488.0 nm line, giving rise to the above difference in I_{1420}/I_{1155} between the 488.0 nm and the 632.8 nm excitations.

We wish to thank Professor Hisashi Tanaka for the use of the W-40 spectrophotometer in his laboraroty.

Studies of Aqueous Sodium Dodecyl Sulfate Solutions by Activity Measurements

Tsunetaka SASAKI, Michihiro HATTORI,*1 Jun SASAKI,*2 and Kenji NUKINA*3

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received December 12, 1974)

The activities of surfactant ions (a_D) and counterions (a_{Na}) were directly obtained by the EMF measurement of a concentration cell with an ion-exchange membrane and by pNa measurements respectively for aqueous solutions of sodium dodecyl sulfate (NaDS) below and above the CMC. The mean activity and activity coefficient were also calculated. From these data, together with the surface tension (γ) measured by the Wilhelmy method and the amount of adsorption (Γ) measured by the radiotracer method, the following results were obtained: (1) Mean activity was not constant, but increased with the concentration above the CMC. (2) The Gibbs adsorption isotherm was directly verified from the a_D and a_{Na} *vs.* concentration relations. (3) The decrease in γ observed above the CMC was in agreement with that calculated from the activity data. (4) The log a_D *vs.* log a_{Na} plots above the CMC showed a linear relation, indicating the validity of the charged phase separation model as the mechanism of micelle formation. The degree of the counterion attachment of the micelles was found to be 0.73 up to about 80 mmol/l. (5) The intermicellar concentrations of Na^+ and DS^- ions were calculated; the former increases, while the latter decreases with the concentration. (6) The product of the concentration with an osmotic coefficient was linear with the concentration above the CMC, tangent of the slope being about 0.7.

A number of problems remain unconfirmed as regards the properies of aqueous solutions of surface active substances, in spite of their theoretical and practical importance. For instance: 1) Surface tension of an aqueous surfactant solution usually shows aging, and empirical equations to give a correct surface tension by extrapolating it to the sufficiently long time have been proposed.[1-4] On the other hand, some are of the opinion that such aging is due to the presence of impurities and that purification largely eliminates the time effect.[5-7] 2) The formation of dimers or premicelles below the CMC and the second- and higher-order CMC's have been suggested,[8-11] but the absence of such aggregates has also been insisted on.[12,13] 3) The constancies of the activity,[14] the intermicellar concentration,[15-17] and the surface tension above the CMC have often been stated or assumed,[14] whereas a gradual decrease in the surface tension,[5,6] in the intermicellar surfactant concentration,[18,19] and an increase in the activity[6,20] have also been reported. 4) As to the micelle formation, theories based upon the mass action law[6,21,22] and the phase separation mechanism[14,23-25] have been proposed and discussed. Also, a theory covering both mechanisms has been stated.[14] The degrees of the counterion attachment of the ionic micelle thus far reported widely differ from each other according to the method of measurement.[26-28] 6) The equation for the calculation of the activity coefficient of large organic ions has been proposed,[29] but a large deviation from the calculated value has also been experimentally confirmed.[11] 7) A number of studies of the experimental confirmation of the Gibbs adsorption isotherm for an aqueous solution of the surfactant have been reported,[30-34] but no confirmation based upon the direct measurements of all the quantities involved in the isotherm, *i.e.*, the surface tension of the solution, the amount of adsorption and the activity of the surfactant, has yet been attempted as far as the present authors are aware.

The measurement of the activity of a surfactant, together with measurements of the amounts of the adsorption and surface tension of the surfactant solution, enables us not only to make a direct confirmation of the Gibbs adsorption isotherm, but also to solve most of the other problems listed above without any assumptions. The present paper will deal with these studies of an aqueous solution of sodium dodecyl sulfate.

Experimental

Materials. The surfactant used was sodium dodecyl sulfate (NaDS), which has been prepared by the sulfation of dodecanol free from its homologues with chlorosulfonic acid,[35] followed by purification by solvent extraction using ethyl ether and recrystallization from ethanol. The purity was confirmed by the absence of a minimum in the surface tension *vs.* concentration curve. The ammonium nitrate used for the agar bridges was recrystallized from a pure commercial product.

Activity Measurement. The activity of sodium ions, a_{Na} was measured by using a Hitachi-Horiba N-5 pNa meter as a sodium responsive electrode. The cell used was

pNa electrode | NaDS (a_{Na}) | NH_4NO_3 (1M) | KCl (saturate) | calomel electrode (saturate)

Sodium chloride of a known activity was used to confirm that the electrode was acting correctly according to the Nernst equation. The activity of sodium ions, a_{Na}, was then calculated according to the following equation:

$$\log a_{Na} = \frac{0.4343F}{RT}(E_{Na} - E_{Na,0}) \quad (1)$$

where E_{Na} is the EMF of the cell; F, the Faraday constant; T, the absolute temperature; R, the gas constant, and $E_{Na,0}$, a constant depending on the calomel and the glass electrodes. The $E_{Na,0}$ value was determined by extrapolating an extrapolation function;[36]

$$\Delta_{Na} = \frac{0.4343F}{RT}E_{Na} - \log C$$

to $C=0$; namely,

$$E_{Na,0} = \frac{RT}{0.4343F}\lim_{C\to 0}\Delta_{Na} \qquad (2)$$

where C is the concentration of sodium dodecyl sulfate.

As for the measurement of the activity of dodecyl sulfate ions, a_D, methods using the Hg/HgDS electrode[37] and a concentration cell using an ion-exchange membrane[28,38] or an oil-phase as a semipermeable septum[39] have been reported. However, the Hg electrode liberates Hg ions, which may influence the dissolved state of DS^- ions in an unpredictable way, and the oil-phase cell is unfavorable because of the possibility of the solubilization of the oil by the surfactant micelles. Thus, the concentration cell using an ion-exchange membrane is preferable. A cell of the following type was used in the present experiment:

calomel electd. (sat)	KCl (sat)	NH_4NO_3 (1M)	NaDS (a_D)	NaDS ($a_{D,10}$)	KCl (sat)	NH_4NO_3 (1M)	calomel electd. (sat)

Here, || indicates the anion-exchange membrane, NEOSEPTA AV-4T, the product of the Tokuyama Soda Co., Ltd.; NaDS ($a_{D,10}$), the reference solution of 10 mmol/l NaDS, and (sat), a saturated solution. A 1 M NH_4NO_3 solution was used for the agar bridges.

The ion-exchange membrane used was 0.16 cm thick. It was cut in 1.5 cm square piece and was made permeable only to dodecyl sulfate ions by soaking it in a 10 mmol/l NaDS solution for two days. Immediately before use, it was rinsed with as little water as possible and firmly supported by pressing it between two franged tubes, 5 mm in inner diameter, containing the sample and referenee solutions. The reference solution of 10 mmol/l NaDS was chosen since the electrode potential was confirmed to be almost constant near this concentration. A steady EMF value, E_D', was exhibited after 30 to 60 min, and the equilibrium value, E_D, was obtained by subtracting from E_D', the asymmetry potential measured, after each measurement of E_D', for the cell prepared by filling both sides of the membrane with the 10 mmol/l NaDS solution. To obtain reproducible results, the membrane was renewed after three successive measurements. The calculation of the activity, a_D, will be described later.

Surface Tension Measurement. The surface tension was measured by the Wilhelmy method using a Shimadzu Surface Tensiometer, ST-1. The vassel containing the solution was doubly covered with glass plates, each having a small hole at its center for the passage of a rod attached to a vertical hanging plate. Contamination from the surrounding atmosphere and the evaporation of water during the measurement were practically avoided by this device. The surface tension was automatically recorded with the time, In cases in which the surface tension decreased with the time, the steady values finally obtained or extrapolated were used for the calculation.*

The EMF and surface tension measurements were carried out at 25 °C.

Results and Discussion

Surface Tension. The surface tension *vs.* concentration relation is shown in Fig. 1. As may be seen, the surface tension decreases with an increase in the concentration and a sharp break point appears at about 7.6 mmol/l, contrary to the curve without a sharp break near the CMC reported by Mysels.[6] Above the CMC, the surface tension stays nearly constant up to about 20 mmol/l, beyond which it decreases slowly with the concentration. Since, above CMC, the surface tension does not change with the time, a gradual though slight decrease is certain, as Mysels indicated.[6] It should be noted that the constancy of the surface tension of the surfactant solution above the CMC often cited[14,17] is not always valid.

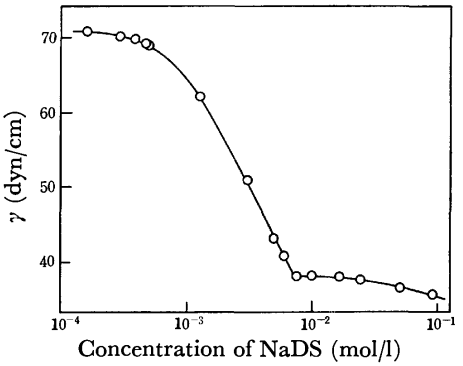

Fig. 1. Surface tension of aqueous NaDS solution.
γ: Surface tension of NaDS soln.

Activity and Activity Coefficient. The activity of Na^+ ions was calculated according to

$$\log a_{Na} = \frac{0.4343F}{RT}E_{Na} + 0.01 \quad (a_{Na} \text{ in mol/l}) \qquad (3)$$

which was obtained by putting the observed value of Eq. (2) into Eq. (1). The calculation of a_D is similar to that of a_{Na}, but it is somewhat complicated.

The EMF of the DS^- ion-concentration cell is expressed as

$$E_D = \frac{\lambda RT}{0.4343F}\log\frac{a_D}{a_{D,10}} \qquad (4)$$

where $\lambda = u_- - u_+$, and u_- and u_+ are the transport numbers of DS^- and Na^+ ions respectively in the membrane. Then the extrapolation function takes the following form:

$$\Delta_D = \frac{0.4343F}{\lambda RT}E_D - \log C \qquad (5)$$

By putting $\lambda = 1$ in Eq. (5), we obtain, similarly to Eq. (2),

$$\log a_{D,10} = -\lim_{C\to 0}\Delta_D$$

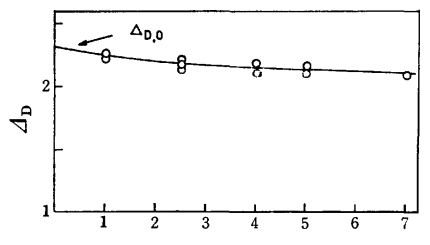

Fig. 2. Extrapolation of Δ_D function.
Δ_D: Extrapolation function (see text)
$\Delta_{D,0}$: Δ_D extrapolated to $C=0$

* As to the aging of an aqueous surfactant solution, we should like to discuss it in detail elsewhere.

The plot of Δ_D *vs.* C is shown in Fig. 2; extrapolation gave $\log a_{D\cdot 10} = -2.30$. Then, a_D was calculated, according to Eq. (4), by

$$\log a_D = \frac{0.4343F}{RT}E_D - 2.30 \quad (a_D \text{ in mol/l}) \qquad (6)$$

Here the assumption of $\lambda=1$ might be valid, considering that the value of $dE_D/d \log C$ observed is equal to the value of $RT/0.4343F$ and that Δ_D *vs.* C is linear as a whole down to a low concentration of NaDS, where the plots are expected to deviate markedly from linearity if λ is slightly less than unity.* A rough estimation shows that λ is larger than 0.99. Also, the agreement between the calculated and observed values of the amount of adsorption below the CMC, to be discussed later, indicates λ as unity.

a_{Na}, a_D: Activies of Na^+ and DS^- ions, respectively

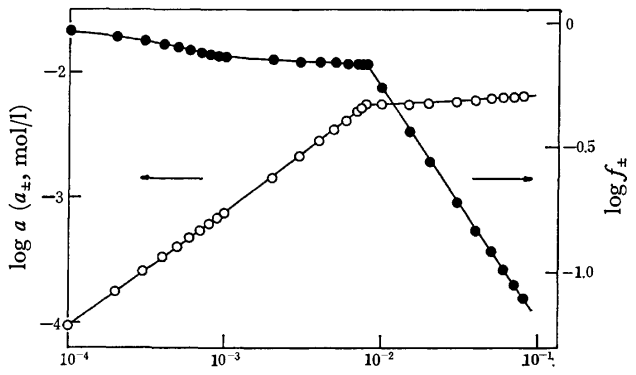

Fig. 4. Mean activity and activity coefficient of NaDS.
$a_\pm$, $f_\pm$: Mean activity and activity coefficient, respectively

The values of a_{Na} and a_D calculated according to Eqs. (3) and (6) are plotted against log C in Fig. 3. The mean activity, $a_\pm$, and the mean activity coefficient, $f_\pm$, are shown in Fig. 4. It is found that

$$\log f_\pm = -(0.033 \log C + 0.240) \quad (C \text{ in mol/l}) \qquad (7)$$

holds for the concentration region from 1×10^{-3} mol/l up to the CMC and that

$$\log f_\pm = -(0.930 \log C + 2.125) \quad (C \text{ in mol/l}) \qquad (8)$$

holds above the CMC up to about 80×10^{-3} mol/l. The coefficient of 0.033 of Eq. (7) is in accord with the estimation of Mysels.[6] However, rather unexpectedly, $f_\pm=0.68$ was obtained at the CMC. This is considerably smaller than the value of about 0.9 calculated by the modified Debye-Hückel equation, taking account of the molecular size.[29] In this connection, it is noticable that a similar value of $f_\pm=0.7$ was recently reported for cetyltrimethylammonium bromide near the CMC.[11] Whether or not this low $f_\pm$ value is due to the dimerization or premicelle formation of surfactant molecules, as has been suggested in the report, requires further study. However, it is necessary at least to check experimentally the validity of the conventional formula used for the calculation of the activity coefficients of the large organic ions mentioned above.[29]

Adsorption Isotherm below the CMC. The Gibbs adsorption isotherm is written in its general form as:

$$-d\gamma = RT\sum_i \Gamma_i \ln a_i \qquad (8)$$

where γ is the surface tension of a solution, and Γ_i and a_i, the amounts of adsorption and the activity of the i'th component of the solutes in the solution respectively. For the 1—1 electrolyte, Eq. (8) takes the form:

$$\Gamma = -\frac{d\gamma}{2RTd \ln a_\pm} = -\frac{d\gamma}{2RTd \ln f_\pm C} \qquad (9)$$

A number of studies of the verification of the Gibbs adsorption isotherm have been reported, in which the activity coefficient has been properly calculated by, for instance, using a modified Debye-Hückel equation,[29,40] or has been assumed to be unity.[41] However, in the present experiment, it is possible to confirm Eq. (8) by a direct measurement of the activity change with the concentration of NaDS without reference to the activity coefficient.

For this purpose, Eq. (8) is rewritten for an aqueous solution of NaDS as

$$\Gamma = \frac{0.4343d\gamma/d \log C}{RT(d \log a_{Na}/d \log C + d \log a_D/d \log C)} \qquad (10)$$

According to Eq. (10), the amount of adsorption can be calculated from $d\gamma/d \log C$, $d \log a_{Na}/d \log C$ and $d \log a_D/d \log C$, which are obtained from the tangents to the curves of Figs. 1 and 3. The calculated values of

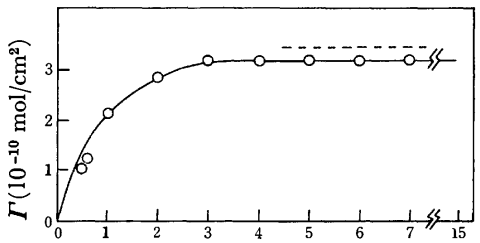

Fig. 5. Direct confirmation of Gibbs adsorption isotherm for NaDS soln.
Γ: Amount of adsorption
○: Γ calculated from steady γ value
——: Γ calculated from γ extrapolated to time zero
——: Γ observed

* A detailed discussion of λ will be made in a following paper.

Γ are plotted against C in Fig. 5 as a solid line, together with the observed amount of adsorption (open circles) obtained by the radiotracer method using tritiated NaDS.[42] The agreement is seen to be satisfactory, except for a slight deviation for dilute solutions. This is the most direct confirmation of the Gibbs adsorption isotherm in that the calculation is solely based on the observed data, without any assumptions.

It may also be pointed out that, as was mentioned above, the surface tension used for the calculation is the steady value attained after a sufficient time. The value of Γ calculated by using the surface tension extrapolated to time zero is also shown as a broken line, but it does not agree with the observed value . This is an indication that the steady value of the surface tension is better taken as an equilibrium, and the attribution of the surface aging to impurities is not valid, at least in the present case.

The agreement of the calculated and observed Γ's also indicates that λ is unity, since the introduction of a λ value of less than unity reduces the calculated Γ to $\lambda\Gamma$, resulting in a disagreement of the observed and calculated Γ's. The argument is the same for Eq. (11).

Surface Tension above the CMC. As is shown in Fig. 1, the surface tension remains nearly constant above the CMC up to about 20 mmol/l, and then it decreases with the concentration of NaDS. Since it is often stated that the surface tension above the CMC is constant and that the constancy is an indication of the micelle formation being the phase separation,[14] it is worthwhile to confirm the observed decrease in the surface tension by an independent calculation. In this connection, Mysels has made an elaborate computer calculation of the surface tension of an aqueous NaDS solution above the CMC, assuming that the micelle formation obeys the mass action law and that the activity coefficient is independent of the concentration.[6] In the present study, however, the observed $a_{\pm}$ *vs.* C relation shown in Fig. 4 makes possible a simple and direct calculation of the surface tension above the CMC without such assumptions.

Since Γ is confirmed to be constant, 3.19×10^{-10} mol/cm^2,[42] the integration of Eq. (9) above the CMC gives

$$\gamma = \gamma_8 - \frac{2RT}{0.4343}\Gamma_8[\log a_{\pm} - a_{\pm,8}] \qquad (11)$$

where γ_8, Γ_8 and $a_{\pm,8}$ denote the γ, Γ and $a_{\pm}$ values of NaDS respectively, at the concentration of 8×10^{-3}mol/l. From the observed relations of $a_{\pm}$ *vs.* C, the surface tension above the CMC was calculated according to Eq. (11). The values of γ calculated are plotted against C in Fig. 6 as open circles, together with the observed surface tension, shown by a solid line. An agreement between the observed and calculated values is seen. Here, the constancy of Γ has been confirmed experimentally up to about 15 mmol/l,[42] but the agreement seen in Fig. 5 may suggest a further constancy of Γ up to about 80 mmol/l NaDS.

Micelle Formation and Counterion Attachment. As has been mentioned, various mechanisms of micelle formation have been proposed,[14,23-25] but no satisfactory understanding has yet been obtained, at least experimentally. A similar situation prevails as to the degree of counterion attachment, r, of an ionic micelle. Various methods have been employed to estimate r; values ranging from 0.46 to 0.86 have been reported for NaDS, as shown in Table 1. The wide scattering of the data comes from the differences in the methods of measurement and in the assumptions necessary for the calculation. Also, in this case, the activity measurement enables us to give convincing answers to the questions of both the mechanism of micelle formation and the degree of counterion attachment.

According to the mass action law, the micelle formation of NaDS is expressed as a homogeneous equilibrium by[21,22]

$$p\mathrm{DS}^- + q\mathrm{Na}^+ \rightleftarrows \mathrm{Na}_q\mathrm{DS}_p^{-(p-q)}$$

and the condition of equilibrium by

$$a_M/(a_D^q \cdot a_{Na}^p) = \text{constant} \qquad (12)$$

where a_M is the activity of micelles, and p and q, the numbers of DS^- and Na^+ ions respectively forming a

micelle.

On the other hand, according to the phase separation theory,[23-25] micelles are considered as a separate microphase or pseudophase, and the micelle formation is expressed:

1) in the case of an unchanged phase separation, by

$$p\mathrm{DS}^- + p\mathrm{Na}^+ \rightleftarrows \mathrm{Na}_p\mathrm{DS}_p \quad \text{(separate phase)}$$

and the equlibrium condition by

$$a_{\mathrm{Na}} \cdot a_{\mathrm{D}} = \text{constant} \tag{13}$$

2) in the case of a charged phase separation, by

$$p\mathrm{DS}^- + q\mathrm{Na}^+ \rightleftarrows \mathrm{Na}_q\mathrm{DS}_p^{-(p-q)} \quad \text{(separate phase)}$$

and the equilibrium condition by

$$a_{\mathrm{Na}}{}^q \cdot a_{\mathrm{D}}{}^p = \text{constant}, \quad p \neq q \tag{14}$$

Eqs. (12), (13), and (14) may be summarized as

$$\left.\begin{aligned} &\log a_{\mathrm{D}} + r \log a_{\mathrm{Na}} \neq \text{constant} \qquad \text{mass action law} \\ &\log a_{\mathrm{D}} + r \log a_{\mathrm{Na}} = \text{constant} \\ &\qquad r = 1, \text{ uncharged phase separation model} \\ &\qquad r \neq 1, \text{ charged phase separation model} \end{aligned}\right\} \tag{15}$$

where $r = q/p$.

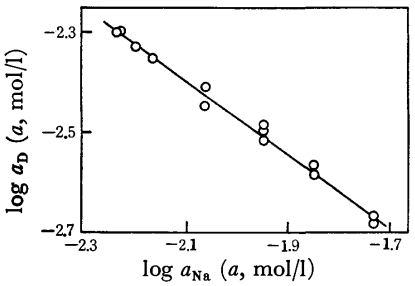

Fig. 7. Log a_{D} *vs.* log a_{Na} above CMC.
a_{D},a_{Na}: Activities of Na^+ and DS^- ions, respectively observed above CMC

As is shown in Fig. 7, the plot of log a_{D} *vs.* log a_{Na} gives a straight line expressed by

$$\log a_{\mathrm{D}} + r \log a_{\mathrm{Na}} = \text{constant} \tag{16}$$

with $r=0.73$ and the constant $=-3.94$. According to Eq. (15), Eq. (16) clearly indicates that the charged phase separation is the most probable mechanism of micelle formation; the charged micelles with the degree of counterion attachment of 0.73 are considered to form up to a concentration of about 80 mmol/l. The value of $r=0.73$ is also listed in Table 1. It may be noted that, among the widely scattered values of r, that obtained in the present study is sufficiently reliable, since it is almost free from any assumptions or approximations. It should be noticed in connection with Eq. (16) that it is the product of $a_{\mathrm{D}}{}^p \cdot a_{\mathrm{Na}}{}^q$ that becomes constant above the CMC. Since $p \neq q$ has been confirmed, $a_\pm = (a_{\mathrm{D}} \cdot a_{\mathrm{Na}})^{1/2}$ is not constant, but slowly increases with the concentration, as is shown in Fig. 4. This is not in agreement with the constancy of $a_\pm$ often stated in connection with the phase separation theory.[14,25] However, it is also contrary to the opinion that the phase separation requires a constancy of $a_\pm$ above the CMC,[20] since the charged phase separation model explains the change of $a_\pm$ above the CMC as has been described above.

The only question remaining is whether or not the aggregates bearing the net electrical charge can be separated as a phase. It may be possible only when the aggregates are separated as such a microphase as the form of micelles. For this reason, it is better called microphase separation or pseudophase separation, as has been proposed by Shinoda.[14,25] The increase in $a_\pm$ above the CMC also corresponds to the decrease in the surface tension in this region, as is shown in Fig. 1.

Equation (16) bears another implication. It is known[21,22,49] that the CMC of an ionic surfactant, C_{M}, decreases with the concentration of added salt, C_{S}, as

$$\log C_{\mathrm{M}} = -k \log (C_{\mathrm{M}} + C_{\mathrm{S}}) - m \tag{17}$$

where $C_{\mathrm{M}}+C_{\mathrm{S}}$ expresses the total counterion concentration, and k and m are constant. Here, if we replace C_{M} by a_{D} and $C_{\mathrm{M}}+C_{\mathrm{S}}$ by a_{Na}, we obtain an equation similar to Eq. (16), with k corresponding to r. This means that the application of Eq. (17) is not restricted to the solution at the CMC, but is extended above the CMC to the relation between the intermicellar activities (concentration) of single surfactant ions and counterions.

The numerical values of k and m of Eq. (17) have been reported to be 0.88 and 3.89[21] or 0.679 and 3.508[50] respectively. The constant of Eq. (16) is in close agreement with the former m value with an opposite sign, while the r value of Eq. (16) lies between the above two k's. The disagreement comes from the differences in the activity and concentration involved respectively in Eqs. (16) and (17). It is interesting to notice that the slope of Eq. (17) can be interpreted as the degree of counterion attachment from the viewpoint of mass action theory also, provided the aggregation number of the micelle (p in Eq. (12)) is large.[21,22]

The second- and higher-order CMC's could not be confirmed up to 80 mmol/l for an aqueous NaDS solution as far as the counterion attachment and activity measurements are concerned.

Intermicellar Ion Concentration. Although sugestions have been made referring the decrease in the intermicellar concentration of surfactant ions,[18,19] the constancy of the intermiceller concentration is practically assumed to be equal to C_{M} in most studies,[15-17] and its actual measurement has not been attempted.

Considering the electrical neutrality of the ions in the solution of NaDS as a whole, and the excess number of DS^- ions compared with that of the Na^+ ions in Na DS micelles, the intermicellar concentration of the DS^- ions is expected to be smaller than that of the Na^+ ions. In addition, the increase and decrease in the activities of the Na^+ and DS^- ions respectively with concentrations above the CMC may suggest an increase and a decrease in the concentration of the respective ions. The intermicellar concentration of the DS^- and Na^+ ions can be estimated from the a_{D} and a_{Na} measurenents as follows.

The activities of Na^+ and DS^- ions above the CMC are expressed by

$$a_{\mathrm{Na}} = f_{\mathrm{Na}} C_{\mathrm{Na}} \quad \text{and} \quad a_{\mathrm{D}} = f_{\mathrm{D}} C_{\mathrm{D}} \tag{18}$$

where f_{Na} and f_{D} are the true activity coefficients, and C_{Na} and C_{D}, the intermicellar concentrations of the Na^+ and DS^- ions respectively. Then we obtain from Eq.

(18)

$$a_{\pm} = f_{\pm}C_{\pm} \tag{19}$$

where

$$C_{\pm} = C_{Na}C_D \tag{20}$$

Further, we obtain from the condition of the electrical neutrality,

$$C_{Na} = (C-C_D)(1-r) + C_D \tag{21}$$

Now, if we neglect the effect of micelles on the activity coefficient above the CMC, Eq. (7) can be considered to hold above the CMC,[6] with C being replaced by $C_{\pm}$, and the following relation is obtained:

$$\log f_{\pm} = -(0.033 \log C_{\pm} + 0.240) \tag{22}$$

From Eqs. (19) to (22) with r=0.73, we obtain

$$C_D = -0.185 + 0.685[0.0729C^2 + 2.92 \times 10^{0.496+2.068 \log a_{\pm}}]^{1/2} \tag{23}$$

According to Eq. (23), the intermicellar concentration, C_D, can be calculated from the $a_{\pm}$ *vs.* C relation above the CMC as is shown in Fig. 4. The values of C_{Na} can be calculated by putting the value of C_D thus obtained into Eq. (21). The C_D and C_{Na} values thus calculated are plotted against C in Fig. 8, together with $C_{\pm}$.

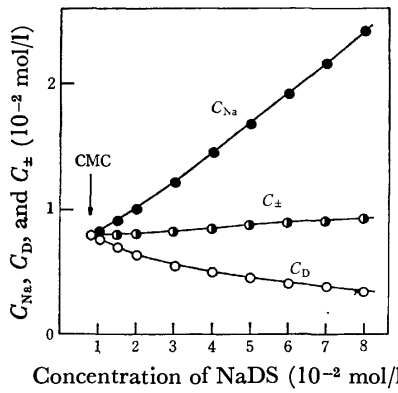

Fig. 8. Intermicellar concentrations of Na^+ and DS^- ions and $C_{\pm}$.
C_{Na},C_D: Intermicellar concentrations of Na^+ and DS^- ions, respectively
$C_{\pm}$: $(C_{Na} \cdot C_D)^{1/2}$

It may be seen that C_{Na} increases, while C_D decreases, with the increase in the NaDS concentration. The mean intermicellar concentration, $C_{\pm}$, is seen to be nearly constant or to increase only slightly with the concentration. Here, it should be noted that the actual micellar concentration, $C-C_D$, is larger than the usually assumed concentration, $C-C_M$.[15,16,21,22] However, the problem of the influence of micelles on the activity coefficient of NaDS remains unsolved; it may affect the calculation of the intermicellar concentration of the surfactant.

Osmotic Coefficient above the CMC. Brady reported that, for some surfactants, the product of the concentration, C, and the osmotic coefficient, g, plotted against C consists of two straight lines, with a break point at the CMC, and that the slope of the straight line:

$$d(gC)/dC = \beta \tag{24}$$

is proper to each substance.[51]

Applying the Gibbs-Duhem relation to Eq. (24), we obtain

$$\frac{d(gC)}{dC} = \frac{d \ln a_{\pm}}{d \ln C} = 1 + \frac{d \log f_{\pm}}{d \log C} = \beta \tag{25}$$

Eqs. (8) and (25) give β=0.07 above the CMC, which is comparable with the value of 0.06 for dodecylsulfonic acid.[52]

The Heating-rate Dependence of the Mechanical Properties of Several Polymers at Higher Temperatures

Noboru FURUSHO, Tsuyoshi KOMATSU, and Tsurutaro NAKAGAWA
Department of Polymer Science, Faculty of Science, Hokkaido University, Sapporo 060
(Received December 23, 1974)

Measurements of the mechanical properties of various polymers at higher temperatures under the conditions of several heating rates were carried out in the air using the torsional braid analysis (TBA) method. It has become apparent that the examples of the dependence of the mechanical properties upon the heating rate at higher temperatures are classified into two groups. The first is characterized by the fact that the temperature of the maximum in the logarithmic decrement remains unchanged, irrespective of any changes in the heating rate. This situation is related to the physical process. On the other hand, in the case of the second group, the TBA curves are shifted to higher temperatures with an increase in the heating rate; this is the results of chemical processes. A kinetic treatment of thermal analysis, in which kinetic parameters can be calculated from the heating-rate dependence of the characteristic point in the observed curves, was used in the present study. From this analysis, the apparent activation energies of the thermal degradation of polymers were obtained, and comparisons of these values with those from the isothermal measurements were made.

Previously, we measured the chemorheological properties of a series of polymers during thermal degradation using the torsional braid analysis (TBA) method and discussed the relationship between the mechanical behavior and the chemical processes with the aid of the results of IR spectroscopy, thermogravimetry, and calorimetric measurements. From these studies, it has become apparent that the TBA method can be used for the studies of the thermal degradation of polymers and can also be used as a convenient kinetic tool, and that the shapes of the TBA curves of the polymers can be classified into three groups according to their degradation mechanisms. Moreover, it was found that the isothermal TBA curves were superposed into one composite curve by shifting them along the axis of the logarithms of time and that activation energies were obtained from the shift factor which agree well with those estimated from the slopes of the curves of the moduli *versus* the time.[1,2]

Furthermore, from the study of the heating-rate dependence of the TBA curves of poly(acrylic acid), we found that the mechanical behavior due to the glass transition is scarcely affected at all by the heating rate and that the chemorheological behavior is shifted to higher-temperature region with an increase in the heating rate. Using the kinetic treatment in thermal analysis, in which the kinetic parameters can be derived from the plots of the logarithmic heating rate *versus* the reciprocal temperature at the characteristic point in the curves observed, the apparent activation energies of the thermal degradation of polymers were obtained. These values agree well with those obtained from the isothermal measurements.[3]

In the present study, we will report the results of studies of the heating-rate dependence of the TBA curves of several polymers at higher temperatures. For these polymers, the isothermal mechanical measurements had previously been carried out.

The purpose of this work is to examine the possibility and the validity of the classification of the mechanical properties into one group resulting from chemical processes and another resulting from physical processes on the basis of measurements of the heating-rate dependence. It was also intended to examine the general applicability of the kinetic treatment in thermal analysis, in which the kinetic parameters can be obtained from the heating-rate dependence of the characteristic point in the curves observed, and to compare the activation energies obtained from this non-isothermal analysis with those obtained from the isothermal measurements.

Experimental

The poly(methyl methacrylate) (PMMA), the poly(vinyl fluoride) (PVF), the poly(vinyl chloride) (PVC), the vinylidene chloride–vinyl chloride copolymer(PVdC-VC) with the weight ratio of 82: 18, the poly(vinyl acetate) (PVAc), the poly(methyl acrylate) (PMA), the polyacrylonitrile(PAN), and the polyacrylamide(PAAm) were all commercial materials. The polystyrene(PSt), the poly(α-methyl styrene) (PMSt), and the poly(methacrylic acid) (PMAA) were, on the other hand, synthesized in our laboratory.

The procedure of the torsional braid analysis (TBA) has been described in previous papers.[1-3] Measurements of the mechanical properties were carried out in the air using a modified TBA apparatus made by the addition of a Shinku Riko model HPC-5000 programed temperature controller. The relative shear moduli, $(1/P)^2$, were calculated from the periods, P, of damped oscillations. The logarithmic decrement $[\lambda=(1/n)\ln(A_{2n+1}/A_1)]$ is calculated from the amplitudes of the damped oscillations, where n is the number of oscillations and A_1, A_{2n+1} are amplitudes of the first and n-th oscillations respectively.

Results and Discussion

Heating-rate Dependence of the Mechanical Properties. The results of the dependence of the TBA curves of several polymers upon the heating rate are shown in Figs. 1—6. As is shown in the figures, the heating-rate dependences of the mechanical properties can be classified into two types. The first type is characterized by the fact that little change occurs in the temperature of the maximum in λ, which is accompanied by an abrupt or slight drop in the modulus. In the second type, the TBA curves are shifted to higher temperatures as the heating rate increases.

The arrows indicate the mechanical changes due to the melting. (a): 0.5 °C/min, (b): 1 °C/min, (c): 2 °C/min, (d): 5 °C/min.

First, the mechanism of the mechanical changes classified as the first type will be discussed. In the case of PVF, as is shown in Fig. 1, the temperature at which a slight drop in the moduli and the corresponding maximum in λ were found does not alter, irrespective of the change in the heating rate. Situations similar to that in PVF were found in the cases of PMSt and PMMA. That is, in PMSt (Fig. 2), the maximum in λ and the abrupt drop in the moduli at about 180 °C remain unaltered, and also in PMMA, an intense peak of λ and the slight drop in the moduli at about 230 °C are not shifted. Such phenomena, which have been discussed in our previous papers, too, may be interpreted as follows by the aid of the results of the calorimetric and other results reported by us and by other workers. First, the mechanical change at about 200 °C in PVF may be assigned to the melting.[2,4,5] Second, that at about 180 °C in PMSt is attributed to the glass transition.[6,7] Lastly, that at about 230 °C in PMMA is due to the melting.[1,8]

Wunderlich *et al.* have studied the heating-rate dependence of the glass-transition temperature (T_g) of polystyrene by means of dynamic differential thermal analysis.[9] In their results, the increase in T_g is only a few degrees in the heating-rate region from 1 to 7.6 K/min in a system in which the sample has been cooled slowly above 400 K. They compared their experimental data with the results of the theoretical considerations derived from the hole theory of liquids and calculated the activation energy at 160 kcal/mol (669 kJ/mol) from the plots of the logarithmic heating rate against the reciprocal glass-transition temperature. In PMSt, assuming that the value of the activation energy is analogous to that in PSt (probably larger than

that in PSt), the change in T_g is calculated at a few degrees from the analysis described just above. Therefore, our experimental data in PMSt are reasonable.

The above discussions have demonstrated that the slight dependence of the TBA curves upon the heating rate is a characteristic feature in the physical processes: glass transition, melting, *etc.* In order to make clear the mechanical changes in polymers in the higher-temperature region, an inspection of the heating-rate dependence of the TBA curves of PAN, PVC, PAAm, PMAA, and PSt will be made on the basis of this consideration. The nature of the processes (physical or chemical) has not yet been fully elucidated.[1-3]

In PVC, as is shown in Fig. 3, it was found that the increase in the moduli begins at about 200 °C and that the broad maximum in the λ curve at around 200 °C does not shift. In the previous paper, the origin of this change in λ (the fusion or the result of the formation of conjugated carbon–carbon double bonds) was not determined. From its slight dependence upon the heating rate in the present study, it may be concluded that this broad maximum in the λ curve is due to a physical process, presumably the fusion. This consideration agrees with the results of the measurements in the fusion of PVC by other workers.[9-11] We found, in PVC (Fig. 3), that both the increase in the moduli and the corresponding maximum in λ in the region of temperatures higher than those discussed above are shifted to higher temperatures with an increase in the heating rate. In PAN (Fig. 4), in contrast to this, slight dependence of λ at about 290 °C upon the heating rate was observed irrespective of the existence of a considerable increase in the moduli. Gillham and Schwenker have mentioned that these mechanical changes (the considerable increase in the moduli and the maximum in λ at about 290 °C) coincide in position with a exothermic peak in the differential thermal analysis.[12] This exothermic peak is assigned by Thompson to the formation of the ladder structure.[13] However, in view of the slight dependence of this maximum in λ upon the heating rate in this study, it may be concluded that the change in λ at about 290 °C is attributed to a physical process. This conclusion is supported by our finding that this exothermic peak shifts to higher temperatures with an increase in the heating rate. However, considering that this exothermic peak temperature moves below or just above the temperature of the maximum in λ according to the heating rate, it is not clear whether this change in λ is a characteristic feature in the original PAN or in the so-formed ladder polymer from PAN.

In a similar manner, the mechanism of the mechanical change above 200 °C in PAAm and PMAA is determined by the aid of the calorimetric analysis to be due to the following physical processes. First, in PAAm, the maximum of λ at about 200 °C is due to the glass transition, and that of λ at about 240 °C is due to some physical process, the details being not yet clear. Second, in PMAA, the maximum in λ at about 220 °C is attributable to the glass transition, while the peak in λ at about 270 °C is presumably due to the melting.

In the case of PSt (Fig. 5), in contrast to the cases of

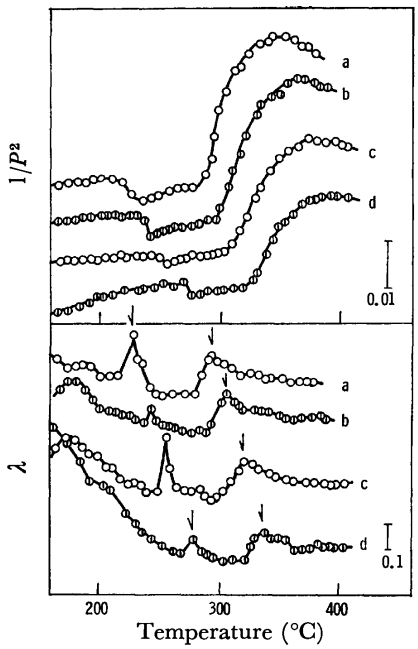

Fig. 5. The plots of $(1/P)^2$, λ *vs.* T of PSt under the several heating rates.
The arrows in left-hand side and right-hand side indicate the maxima in λ due to the chemical processes.
(a): 0.5 °C/min, (b): 1 °C/min, (c): 2 °C/min, (d): 5 °C/min.

PVC, PAN, PAAm, and PMAA, it was found that the small maximum in λ and the corresponding drop in the moduli shift from 220 °C to 280 °C with an increase in the heating rate. On the basis of the above discussions of the heating-rate dependence of the TBA curves, this mechanical change is considered to be attributable to the chemical process, not to the physical process. Considering that the weight loss during heating is slight in this temperature region, as has been reported in a previous paper,[1] and that the abrupt drop in the molecular weight at an early stage of the thermal

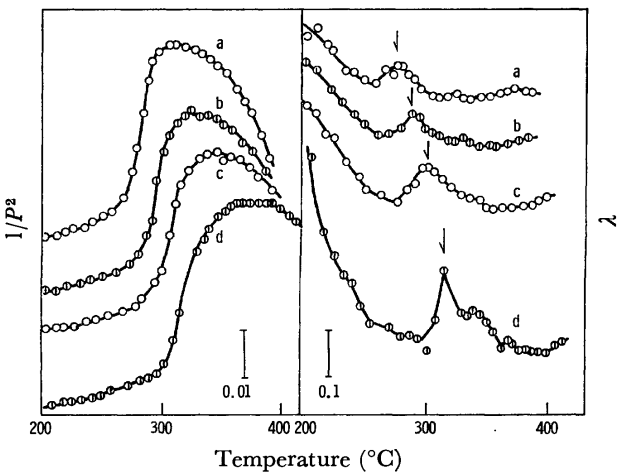

Fig. 6. The plots of $(1/P)^2$, λ *vs.* T of PVAc under the several heating rates.
The arrows indicate the maxima in λ due to the chemical process. (a): 0.5 °C/min, (b): 1 °C/min, (c): 2 °C/min, (d): 5 °C/min.

degradation of PSt was observed by Jellinek,[14] the mechanism of this mechanical change seems to be related to the abrupt drop in the molecular weight.

Here, turning the viewpoint to the mechanical changes grouped into the second type, in which the increase or decrease in the moduli and the corresponding change in the λ are shifted to higher temperatures with an increase in the heating rate (a typical example is shown in Fig. 6, the case of PVAc), the mechanism of these mechanical changes will be discussed. For PVC, it was found that the IR absorption peak of the carbon-carbon double bond becomes more intense with the progress of the reaction and that the temperature at which the weight loss occurs is near to that at which the moduli begin to increase. From these findings, it has been concluded that the increase in the moduli is attributable to the formation of the C–C double bond resulting from dehydrochlorination and the cross-linking through the double bond, while the decrease in the moduli is due to the chain scission.[2] In a similar way, in PAN, it has been shown that the formation of the ladder structures leads to an increase in the moduli.[1] For other polymers, the relationship between the mechanical change and the chemical process was demonstrated in the previous works by the aid of the results of IR spectroscopy, thermogravimetry, calorimetric study, and the results of other workers. From the above discussions, it may be concluded that a distinct dependence of the mechanical behavior upon the heating rate in these polymers is a peculiar feature of the chemorheological processes.

The considerations in this section suggest that the inspection of the heating-rate dependence of the mechanical properties can be used as a convenient tool for the identification of the nature of mechanical changes in higher-temperature regions in which not only physical processes but also chemical reaction can simultaneously occur.

Kinetic Analysis of Chemorheological Properties during Thermal Degradation. In the preceding sections, it has become clear that the heating-rate dependence of the mechanical properties can be classified into two groups. In the second group, the observed chemorheological curves shift to higher temperatures with an increase in the heating rate. A similar heating-rate dependence has been found in several kinds of thermal analysis: the thermogravimetry,[15] the mass spectrometric thermal analysis,[16] the electric thermal analysis,[17] *etc.* In these measurements, the procedures derived from the isothermal kinetic equation were used to obtain the kinetic parameters. In these procedures, the following assumptions are made. That is, the observed quantity characterizing some properties, y, is a function of a structural quantity, x; $y=f(x)$, and the change in the structural quantity obeys the Arrhenius equation; $dx/dt=A\cdot\exp(-E/RT)\cdot g(x)$, where A, E, and R are the frequency factor, the activation energy, and the gas constant respectively. Also, the same degree of change in the structural quantity leads to an equal degree of change in the properties observed. Here, a linear temperature change is also assumed; $T=T_0+ht$, where T_0 and h are the initial temperature and the heating rate respectively, and then x is integrated. The details of this calculation have been shown in the works by Ozawa and other workers.[18,19]

From the final solution of this calculation, a linear relationship between the logarithmic heating rate and the reciprocal of the temperature at the characteristic point in the observed curves is derived, and then the activation energies can be estimated from the slope of their plots. Also, it has been concluded that the superposition of the TBA curves into one composite curve is possible by their shift along the axis of the reciprocal temperatures. This kinetic treatment is extended to the systems in which the exact quantitative correlation between the observed properties and the structural quantities is not clear, assuming that conditions similar to those presented above are satisfied in such systems.[20]

In the previous paper, we attempted to apply this kinetic treatment to the chemorheological behavior in PAA and obtained reasonable activation energies, which agree well with those from the isothermal measurements. Moreover, the superposition of the isothermal TBA curves into one composite curve was successfully carried out by shifting them along the axis of the logarithmic time in all the polymers studied. In both procedures, it was assumed that the mechanical properties depend only upon their chemical structure and that the same extent of reaction leads to an equal degree of mechanical change. These assumptions are the same as those used in the kinetic procedure in thermal analysis. The success of the application of the non-isothermal kinetic treatment to the chemorheological behavior in PAA and the superposition procedure of the isothermal curves suggest that the TBA method can be used as a convenient kinetic tool in thermal analysis, despite a lack of information about the exact quantitative relationship between the mechanical properties and the chemical structures.

Below, the results of the examination of the application of this non-isothermal kinetic procedure to the chemorheological behavior during the thermal degradation of various polymers will be discussed. This was

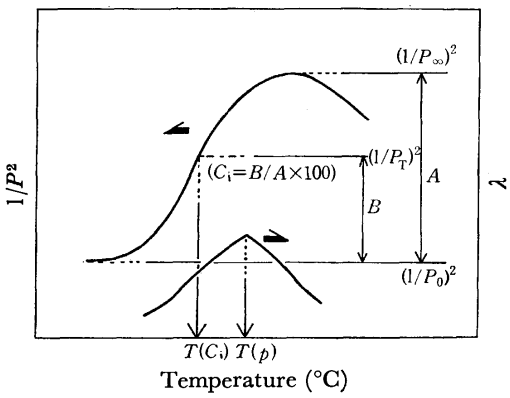

Fig. 7. The schema of the kinetic procedure.
The $(1/P_T)^2$, $(1/P_0)^2$, and $(1/P_\infty)^2$ are the values at temperature T, at minimum point, and at the maximum point in moduli, respectively.
The $T(C_1)$, $T(p)$ are the temperatures at conversion C_1 and of maximum in λ.

made by noting whether or not the following conditions are satisfied. (1) The plot of the logarithmic heating rate *versus* the reciprocal of the temperature of the maximum in λ, $T(p)$, is linear. (2) The plot of the logarithmic heating rate *versus* the reciprocal of the temperature to the same degree of conversion in the chemorheological change, $T(C_i)$, is linear. (3) The superposition of the curves of the chemorheological properties, plotted as a function of the reciprocal temperature, is possible. A schema of this procedure is shown in Fig.7.

The obvious maxima in λ which correspond to the increase or decrease in the moduli were found in PSt, PVC, PVdC–VC, PVAc, and PMA. The plots of the logarithmic heating rate against the reciprocal of the temperature of the maximum in λ are shown in Fig. 8. As is clear in the figure, these plots are linear in all the polymers mentioned above. From the slopes of these plots, the activation energies were obtained as listed in Table 1. Here, these values will be compared with those calculated from the isothermal measurements. In general, the values from these two procedures roughly agree with each other for the individual polymer.

In PMA, a good agreement similar to that in PAA reported previously[3] was found. However, in PSt, in which the increase in the moduli was controlled by the cross-linking, as in PAA and PMA, the agreement is not so satisfactory as in the above two polymers. Also, in the cases of PVC, PVdC–VC, and PVAc, in which the cross-linking is undeniable but is not the main factor affecting the chemorheological properties, as was discussed in the preceding paper, the situation is not simple. That is, a good agreement was found in PVdC–VC, but the agreement in PVC and PVAc is not so good as in PVdC-VC. This suggests that these discrepancies can not be explained by only the difference in the degradation mechanisms. In order to make clear the nature of these facts, further work is necessary.

PMA	101	92	90	—	77	67
PSt(L)[e]	96	—	—	—	—	—

a) 1J=1/4.184 cal. b) The value is estimated from the slope of the plot of the logarithmic heating rate *versus* the reciprocal of the temperature of maximum in λ. c) Assuming $dG_r/dt=k_0$, $dA_r/dt=k'_0$, and $d(\log G_r)/dt=k_{1st}$, where k_0, k'_0, and k_{1st} are the apparent rate constants of the zero order and first order reactions, respectively. The value of A_r are the relative absorbance ratio for C–C double bond and C–H group in IR spectra. d, e) In PSt(H) and PSt(L), the maxima in λ were found in the relatively higher temperature side and relatively lower temperature side, respectively.

The examination of the second point—that the plot of the logarithmic heating rate *versus* the reciprocal of the temperature to the same degree of conversion in the chemorheological change is linear—was carried out in the following manner. The degree of conversion in the chemorheological change was defined as follows:

$$C = [(1/P_T)^2 - (1/P_0)^2]/[(1/P_{00})^2 - (1/P_0)^2]$$

where $(1/P_T)^2$ is the value at a cetain temperature, T, and where $(1/P_0)^2$ and $(1/P_\infty)^2$ are the values of the minimum and maximum in the moduli respectively. Then the temperature in the degree of the conversion C_i was determined from the figure. The schema of this treatment is shown in Fig. 7. Finally, the plot of the logarithmic heating rate *versus* the reciprocal of the temperature at C_i was made. It should be added here that the determination of the value of $(1/P_0)^2$ is approximative because of the lack of a wide and flat base line of the modulus.

Some typical plots of log h *vs.* $1/T(C_i)$ are shown in Fig. 9. As is clear in the figure, in PVC the plots are linear. In the other polymers, also, similar straight lines were obtained. By means of the analysis described above, the activation energies are also obtained, as is listed in Table 2.

In PVC, the values are scarcely affected by the degree of conversion. On the other hand, in PVAc, it was found that the activation energies below C=70 % are analogous to each other, while above C=80 % the values become smaller. This fact suggests that some reaction which probably leads to the decrease in the moduli occurs simultaneously at a high degree of conversion. Similar situations have been found in

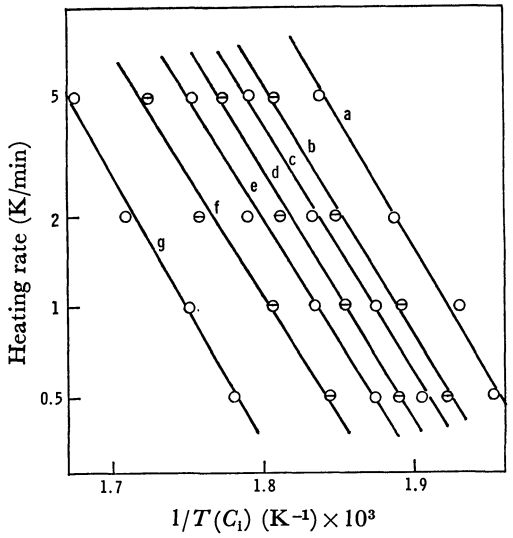

Fig. 9. The plots of the logarithmic heating rates versus the reciprocal temperatures at conversion C_i of PVC. (a): 10%, (b): 20%, (c): 30%, (d): 50%, (e): 70%, (f): 90%, (g): 100%.

TABLE 2. THE APPARENT ACTIVATION ENERGIES ESTIMATED FROM THE SLOPE OF THE PLOT OF THE LOGARITHMIC HEATING RATE VERSUS THE RECIPROCAL TEMPERATURE AT THE SAME DEGREE OF CONVERSION

Sample	The apparent activation energy (kJ/mol)[a] Degree of conversion (%)

a) 1J=1/4.184 cal.

some other polymers. However, the nature of the decrease in the activation energies at an early stage in PAAm and PMAA is not yet clear. The values at the relatively lower degrees of conversions estimated by this analysis also roughly agree with those from the isothermal kinetic treatment and agree well those from the first non-isothermal kinetic treatment described above.

Furthermore, we attempted to superpose the TBA curves plotted against the reciprocal temperature for all the polymers studied. As is shown in Fig. 10, the procedure in PVAc was carried out successfully. In the other polymers, composite curves were also obtained. The quantities of the shift along the axis of the reciprocal temperature in the two temperature regions, where the moduli increase, or decrease, do not always coincide. This situation corresponds to the fact that the relationships of a shift factor to the reciprocal temperature in the two regions, where the moduli increase or decrease, are different in the superposition procedures of the isothermal TBA curves. The quantity of the shift in this procedure was not analyzed further in the present study.

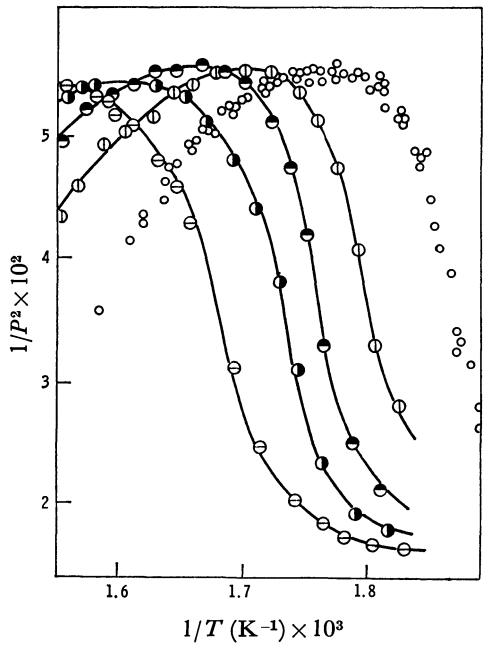

Fig. 10. The composite curve and the plots of $(1/P)^2$ *vs.* $1/T$ of PVAc under the several heating rates. ○: composite curve, ⓘ: 0.5 °C/min, ◓: 1 °C/min, ◑: 5 °C/min, ⓘ: 2 °C/min.

In the preceding sections, it has been demonstrated that the plots of the logarithmic heating rate *versus* the reciprocal of the temperature of the maximum in λ or at the conversion, C_i, are linear, and that the TBA curves observed under several heating rates can be superposed into one composite curve by means of their shift along the axis of the reciprocal temperature. These facts suggest that this kinetic treatment, in which the assumption that the same degree of change in the structural quantity leads to an equal degree of change in the observed properties was made, can be used in the kinetic studies of chemorheological behavior. However, the problem of the nature of the discrepancies between the activation energies obtained from this non-isothermal analysis and those obtained from the isothermal methods remains unsolved.

The Contribution of the Double Collision Occurring in an Atom to the Yield of the Ionization and Excitations of Noble Gases Irradiated by 100 keV Electrons

Kiyoshi OKAZAKI, Shin SATO, and Shin-ichi OHNO*

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received December 24, 1974)

Gryzinski's classical treatment of the double ionization has been used to estimate the contribution of the double-collision process to the *G*-values of the ionizations and excitations of noble gases irradiated by 100 keV electrons. Except for helium, the double collision accounted for 5—15% of the yield of electrons. The total *G*-values calculated are ultimately as follows (in the order of He, Ne, Ar, Kr, and Xe): 2.28, 2.53, 3.09, 3.41, 3.67 for *G*(electrons); 0.84, 1.37, 1.78, 1.54, 1.41 for *G*(excited singlet states); 0.17, 0.07, 0.13, 0.23, 0.39 for *G*(triplet states).

The cross sections for the formation of multiply-charged ions of atoms and diatomic molecules in collision with high-energy electrons have been measured by many investigators over the past forty years.[1-6] Recently more reliable values of the cross sections in a wide energy range of the incident electrons have been reported.[7-10] On the other hand, the theoretical treatment of the formation of the multiply-charged ions has not been developed remarkably since Gryzinski proposed the classical treatment of double ionization.[11] Although a quantum mechanical estimation of the double ionization has been proposed by Mittleman,[12] his method is at present limited in its field of application. Gryzinski's classical method has recently been modified and used by Tripathi and Rai[13] to estimate the cross section for the double ionization of He and Li^+. Their results agreed reasonably well with the experimental ones.

In a previous paper,[14] we ourselves have calculated the *G*-values of the ionizations and excitations of noble gases irradiated by 100 keV electron, using the classical binary encounter collision theory. Although the *G*-values calculated were roughly consistent with those expected from the experiment, there were a few defects in the results. One of the most serious was that the calculated *W*-value of Ne was larger than that of He. It is experimentally known that these values are reversed in magnitude. This discrepancy might result from the assumption on the basis of which the calculation was carried out. In the previous calculation, we ignored the contributions of the double ionization and the excitation from the inner shells. This might have affected the *W*-values obtained. In the present paper, we calculated the amount of the double ionization by using Gryzinski's classical method and also estimated the contributions of the double excitation and the excitations from the inner shells.

Method of Calculation

Approximations. Since the probability of the double collision of high-energy electrons in an atom is much smaller than that of the single collision, we used the following three approximations: 1) When the stopping power, $S(T)$, of a gas and the degradation spectrum, $y(T)$, of electron are calculated, the contributions of the double collision and the excitations from the inner shells are ignored; that is, the $S(T)$ and $y(T)$ previously obtained are used as they were. 2) The cross section of the double collision is formulated by Gryzinski's method.[11] The differential cross sections involved in the formulation of the double collision are, however, evaluated by the method previously used.[14] The details of the formulation will be shown later. 3) The double collision is calculated only on the electrons in the outermost shell of the atom. In order to calculate the double collision in which the electrons in the inner shells are involved, we need more parameters than are available at present. According to the estimation of Roy *et al.*,[15] the contribution of the inner shells to the double collision is much smaller than that of the outermost shell.

Formulation. Even within the treatment of the single collision we had to consider various types of collisions, such as the ionizations from all of the shells, the ionization accompanied by the exchange of electrons, and the singlet and triplet excitations. Moreover, the energy range of the incident electrons, higher or lower than the ionization potential or the energies of the excited states, had to be taken into account.[14] In the treatment of the double collision, we have to consider all of the combinations of these collisions.

Double Ionization: After the occurrence of the first ionizing collision with an incident electron, there are two types of second ionizations; one is Case A, in which the second ionization is induced by the incident electron, while the other is Case B, in which the second ionization is induced by the electron which recoiled in the first collision. According to the treatment of Gryzinski,[11] the total ionization cross section in Case A is expressed in this form:

$$Q_{ii}^{A}(T) = \frac{1}{2}\int_{I_i}^{T-I_{ii}} [\sigma_{E,\mathrm{dir}} + \sigma_{E,\mathrm{exc}}] \frac{n_e(n_e-1)}{4\pi\bar{r}^2} \times \int_{I_{ii}}^{T-E} [\sigma_{E',\mathrm{dir}}(T-E) + \sigma_{E',\mathrm{exc}}(T-E)]\mathrm{d}E'\mathrm{d}E \quad (1)$$

for $T \geq I_i + I_{ii}$. Here, n_e is the number of electrons in the outermost shell of the target atom; $\bar{r}$, the mean distance between atomic electrons; T, the initial energy of the incident electron; E, the energy loss of the incident electron in the first collision—therefore, $T-E$ is the energy of the scattered electron and $E-I_i$ is the energy

of the electron ejected from the atom in the first collision; I_i, the ionization potential of the target atom; I_{ii}, the second ionization potential of the atom; E', the energy loss in the second collision—therefore, $T-E-E'$ is the energy of the doubly scattered electron and $E'-I_{ii}$ is the energy of the electron ejected from the atom in the second collision.

As has been stated above, the differential cross sections, $\sigma_{E,\mathrm{dir}}$ and $\sigma_{E,\mathrm{exc}}$, are the same as those used in the previous paper:[14]

$$\sigma_{E,\mathrm{dir}} = \frac{\pi e^4}{T+I_i+E_i}\left(\frac{1}{E^2}+\frac{4E_i}{3E^3}\right) \tag{2}$$

$$\sigma_{E,\mathrm{exc}} = \frac{\pi e^4}{T+I_i+E_i}\left\{\frac{1}{(T+I_i-E)^2}+\frac{4E_i}{3(T+I_i-E)^3}\right\} \tag{3}$$ [16]

In a similar manner, the differential cross sections for the second ionizations are expressed as follows:

$$\sigma_{E',\mathrm{dir}}(T-E) = \frac{\pi e^4}{T-E+E_i+I_{ii}}\left(\frac{1}{E'^2}+\frac{4E_i}{3E'^3}\right) \tag{4}$$

$$\sigma_{E',\mathrm{exc}}(T-E) = \frac{\pi e^4}{T-E+E_i+I_{ii}}\left\{\frac{1}{(T-E+I_{ii}-E')^2} + \frac{4E_i}{3(T-E+I_{ii}-E')^3}\right\} \tag{5}$$

When $T<I_i+I_{ii}$, $Q_{ii}^{A}(T)$ is set equal to zero.

Similarly, the total double-ionization cross section in Case B may be expressed by:

$$Q_{ii}^{B}(T) = \frac{1}{2}\int_{I_i+I_{ii}}^{T}[\sigma_{E,\mathrm{dir}}+\sigma_{E,\mathrm{exc}}]\frac{n_e(n_e-1)}{4\pi\bar{r}^2} \times\int_{I_{ii}}^{E-I_i}[\sigma_{E',\mathrm{dir}}(E-I_i)+\sigma_{E',\mathrm{exc}}(E-I_i)]\mathrm{d}E'\mathrm{d}E \tag{6}$$

for $T\geq I_i+I_{ii}$. When $T<I_i+I_{ii}$, $Q_{ii}^{B}(T)$ is set equal to zero. A simple calculation can show that $Q_{ii}^{A}(T)=Q_{ii}^{B}(T)$.

Although, in the above treatment, Cases A and B have been formulated separately, the final states obtained through the two processes cannot be distinguished. Since we cannot specify the origin of the electron inducing the second ionization—cannot determine whether it is an incident electron or the atomic one, the total cross section of the double ionization should be a half of the sum of $Q_{ii}^{A}(T)$ and $Q_{ii}^{B}(T)$:

$$Q_{ii}(T) = \frac{1}{2}[Q_{ii}^{A}(T)+Q_{ii}^{B}(T)] = Q_{ii}^{A}(T) \tag{7}$$

Double Excitation: The above treatment of double ionization can be extended to the double excitation. In the case of excitation, we have two types; one is accompanied by a change in the spin state (SC), while the other is not accompanied by such a change (SNC). In the formulation of the double excitation, therefore, we have to consider the combination of these two types of excitations.

By referring to the formulation of the excitation shown in the previous paper, the total cross sections of all kinds of double excitations can easily be formulated. Here, only the formulation for the case of SNC-SNC will be shown. This case leads to the formation of an excited singlet state. The total cross section for this process may be described as follows:

$$Q_{ee}(\mathrm{SNC\text{-}SNC}) = \int_{E_s}^{I_i}[\sigma_{E,\mathrm{dir}}+\frac{1}{2}\sigma_{E,\mathrm{exc}}]\frac{n_e(n_e-1)}{4\pi\bar{r}^2} \times\int_{E_{s2}}^{I_{ii}}[\sigma_{E',\mathrm{dir}}(T-E)+\frac{1}{2}\sigma_{E',\mathrm{exc}}(T-E)]\mathrm{d}E'\mathrm{d}E \tag{8}$$

for $T\geq I_i+I_{ii}$. Here, E_s is the energy of the lowest excited singlet state and E_{s2} is the energy necessary for the excitation in the second collision; that is, $E_{s2}=E^{**}-E_s$, where E^{**} is the energy of the double excitation state. When $E_s+I_{ii}\leq T<I_i+I_{ii}$,

$$Q_{ee}(\mathrm{SNC\text{-}SNC}) = \int_{T-I_{ii}}^{I_i}[\sigma_{E,\mathrm{dir}}+\frac{1}{2}\sigma_{E,\mathrm{exc}}]\frac{n_e(n_e-1)}{4\pi\bar{r}^2} \times\int_{E_{s2}}^{T-E}[\sigma_{E',\mathrm{dir}}(T-E)+\frac{1}{2}\sigma_{E',\mathrm{exc}}(T-E)]\mathrm{d}E'\mathrm{d}E + \int_{E_s}^{T-I_{ii}}[\sigma_{E,\mathrm{dir}}+\frac{1}{2}\sigma_{E,\mathrm{exc}}]\frac{n_e(n_e-1)}{4\pi\bar{r}^2} \times\int_{E_{s2}}^{I_{ii}}[\sigma_{E',\mathrm{dir}}(T-E)+\frac{1}{2}\sigma_{E',\mathrm{exc}}(T-E)]\mathrm{d}E'\mathrm{d}E \tag{9}$$

When $I_i+E_{s2}\leq T<E_s+I_{ii}$, the upper limit of the second integral of Eq. (8) should be replaced by $T-E$. When $E_s+E_{s2}\leq T<I_i+E_{s2}$, the upper limit of the first integral of Eq. (8) has to be replaced by $T-E_s$, in addition to the replacement of the upper limit of the second integral by $T-E$. When $T<E_s+E_{s2}$, Q_{ee}(SNC-SNC) is set equal to zero.

Other combinations, SC–SC, SNC–SC, and SC–SNC, of the double excitation can be formulated in a similar manner by using the energies of the first triplet state (E_t) and the energy necessary for the excitation from the first excited-triplet state to the double-excitation state (E_{t2}). In the case of SC–SC, we obtain a singlet or a quintet state as the final state. However, the G-value for this process is so small that we assume that the obtained state is always a singlet state.

Ionization and Successive Excitation: This process leads to the formation of a hot ion. As in the case of the double ionization, the second collisions in this case are of two types; one is induced by the electrons scattered in the first collision, while the other is induced by the recoiled electron. The total cross sections of these two processes have the same value. Again, as in the case of the double ionization, we cannot distinguish these two processes. The total cross section, therefore, is equal to that of either of the two processes.

The following shows the case of the ionization and successive excitation without any spin change (I–SNC). A similar formulation can easily be made for the case of I–SC, which is not shown here.

$$Q_{ie}(\mathrm{I\text{-}SNC}) = \int_{I_i}^{T-I_{ii}}[\sigma_{E,\mathrm{dir}}+\sigma_{E,\mathrm{exc}}]\frac{n_e(n_e-1)}{4\pi\bar{r}^2} \times\int_{E_{s1}}^{I_{ii}}[\sigma_{E',\mathrm{dir}}(T-E)+\frac{1}{2}\sigma_{E',\mathrm{exc}}(T-E)]\mathrm{d}E'\mathrm{d}E + \int_{T-I_{ii}}^{T-E_{s1}}[\sigma_{E,\mathrm{dir}}+\sigma_{E,\mathrm{exc}}]\frac{n_e(n_e-1)}{4\pi\bar{r}^2} \times\int_{E_{s1}}^{T-E}[\sigma_{E',\mathrm{dir}}(T-E)+\frac{1}{2}\sigma_{E',\mathrm{exc}}(T-E)]\mathrm{d}E'\mathrm{d}E \tag{10}$$

for $T\geq I_i+I_{ii}$. When $I_i+E_{s2}\leq T<I_i+I_{ii}$,

$$Q_{ie}(\text{I-SNC}) = \int_{I_i}^{T-E_{s2}} [\sigma_{E,dir}+\sigma_{E,exc}]\frac{n_e(n_e-1)}{4\pi\bar{r}^2} \times \int_{E_{s2}}^{T-E} [\sigma_{E',dir}(T-E)+\frac{1}{2}\sigma_{E',exc}(T-E)]dE'dE \quad (11)$$

When $T<I_i+E_{s2}$, Q_{ie}(I–SNC) is set equal to zero.

Excitation and Successive Ionization: This process also leads to the formation of a hot ion. The formulations of Q_{ei}(SNC–I) and Q_{ei}(SC–I) can easily be made by referring to the treatments described above. Only the latter case is shown here:

$$Q_{ei}(\text{SC-I}) = \frac{1}{2}\int_{E_{t_i}}^{I_i}\left[\frac{1}{2}\sigma_{E,exc}\right]\frac{n_e(n_e-1)}{4\pi\bar{r}^2} \times \int_{E_{t_i}}^{T-E} [\sigma_{E',dir}(T-E)+\sigma_{E',exc}(T-E)]dE'dE \quad (12)$$

for $T\geq I_i+E_{ti}$, where E_{ti} is the energy necessary for the ionization from the lowest excited-triplet state to the lowest excited ion. When $E_t+E_{ti}\leq T<I_i+E_{ti}$, the I_i in the first integral should be replaced by $T-E_{ti}$. When $T<E_t+E_{ti}$, Q_{ei}(SC–I) is set equal to zero.

Inner-shell Excitation: The formulation is exactly the same as that of the single excitation described in a previous paper,[14] except that the parameters, I_i, E_i, E_s, and E_t, have to be replaced by the values corresponding to those of the inner shells. In the present calculation, the contributions of the shells more inner than 3s in Ar, 3d in Kr, and 4p in Xe are ignored.

Constants Used for Calculation

The values of E_s, E_t, I_i, and E_i are the same as those used in the previous paper.[14] Table 1 summarizes the I_i, E_s, and E_t values of the inner shells, where the last two values are assumed to be the same. Table 2 shows the mean distance between electrons in the outermost shell of each atom and the second ionization potential (I_{ii}). The mean distance was calculated by placing the electrons uniformly on a sphere the radius of which had been estimated by Slater.[17]

Table 3 shows the double-excitation energy (E^{**}) and the energy of the lowest excited state of the singly charged ion (E^{+*}). Some of these values have been experimentally obtained;[18–24] from them we can calculate E_{s2} and E_{t2}. In the case of the double excitation, we can assume that $E_{s2}=E^{**}-E_s$ and $E_{t2}=E^{**}-E_t$.

Table 1. Ionization potential (I_i) and the excitation energies to the fierst excited singlet (E_s) and the lowest triplet (E_t) states with respect to the inner shells

a) Assumed. b) Calculated on the assumption that $E^{**}=I_i+I_{ii}/2$. c) Calculated on the assumption that $E^{+*}=I_i+3I_{ii}/4$.

In the case of the ionization and successive excitation, we assumed $E_{s2}=E_{t2}=E^{+*}-I_i$.

Results

Figure 1 shows the $T\cdot y(T)\cdot Q_s(T)$ for the double collision in Ne as a function of ln T. Similar curves were also obtained in other cases —He, Ar, Kr, and Xe. All the curves for the double ionization have maxima at about twice the threshold energy of each atom and rise again as the T increases over 10^4 eV. A similar tendency was observed for the cases of the ionization and successive excitation. On the other hand, the cases of the double excitation and the excitation and successive ionization have maxima near the threshould energies and decrease rapidly as the T increases.

Tables 4 and 5 summarize, respectively, the G-values obtained for all of the double collisions and for the inner-shell excitations.

Discussion

Experimentally, the formation of the doubly charged ions is due not only to the double ionization, which we have just calculated, but also to the Auger effect. Therefore, the comparison of the calculated values with the experimental values is somewhat complicated. In the case of He, however, there is no Auger effect, so a direct comparison is possible.

Figure 2 compares the experimentally obtained total cross sections of the double ionization[6–10] with those calculated by the method described above. A serious discrepancy appears near its maximum value and at very high energies of the incident electrons. Figure 3 summarizes the He^+/He^{2+} ratios obtained both experimentally[4,6–10] and theoretically. The a curve is the present calculation, while the b and c curves are the results obtained by means of Mittleman's procedure[12] and a modification of it[25] respectively. The d curve is the result obtained by Roy and Rai.[26] Their treatment seems to be very similar to ours except for a modification which is not clear for us. Judging from the semi-quantitative agreement of the present calculation with the observed data, it may be concluded that

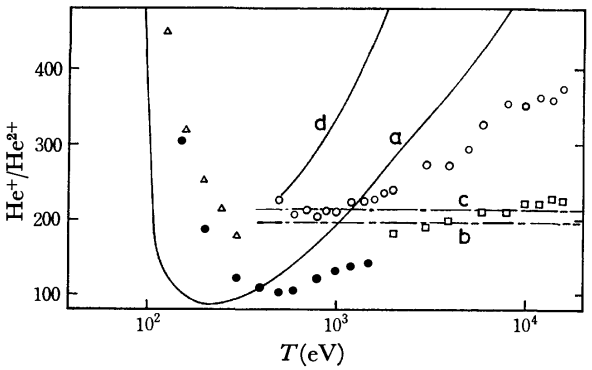

Fig. 3. The He^+/He^{2+} ratios as a function of ln T. ○, Ref. 7; □, Ref. 9; ●, Ref. 4; △, Ref. 6.

Gryzinski's treatment of the double ionization is generally correct when the yield of the doubly charged ions formed through the double collision is estimated.

Figures 4 and 5 show the ratios of M^+/M^{2+} as a function of the energy of the incident electron, where M stands for Ne, Ar, Kr, or Xe.[1–10] In the case of Ne, only the double-ionization process seems to explain the experimental data. Probably the Auger effect does not play an important role in the formation of doubly charged ions in Ne. In the cases of Ar, Kr, and Xe, on

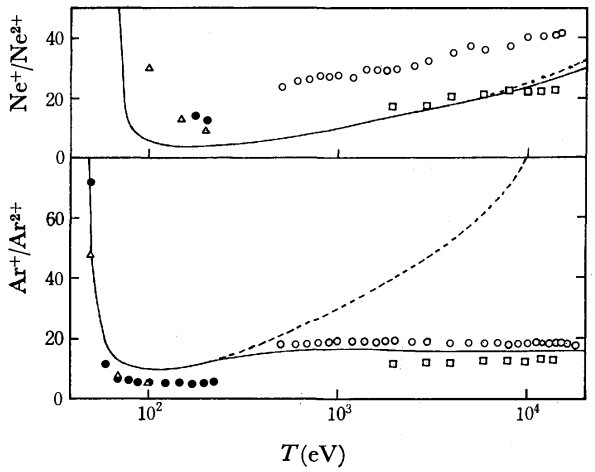

Fig. 4. The Ne^+/Ne^{2+} and Ar^+/Ar^{2+} ratios as a function of ln T. ----, calculated only on the double ionization; ——, calculated by including the Auger effect; ○, Ref. 7, 8; □, Ref. 9; ●, Ref. 1; △, Ref. 3.

the other hand, the Auger effect seems to play a principal role in the formation of the doubly charged ions at the higher energies of the incident electrons. Since the distribution of the multiply charged ions produced through the Auger effect has been reported for all of the rare gases,[27] and since the fluorescence yields have also been reported in the literature,[28] we can estimate the relative amounts of the doubly charged ions formed through the Auger effect by using the cross sections of ionizations from the inner shells.[14] Tables 6 and 7 show, respectively, the values used of the relative yields of the doubly charged ions and the fluorescence yields. The corrected M^+/M^{2+} ratios obtained by using these values are also shown in Figs. 4 and 5. The agreement with the experimental plots is satisfactory.

Table 9. The ratio of the G-value for excitation to that of electrons

	He	Ne	Ar	Kr	Xe
G_{exc}	1.01	1.44	1.91	1.77	1.80
singlet	0.84	1.37	1.78	1.54	1.41
triplet	0.17	0.07	0.13	0.23	0.39
G_{exc}/G_e	0.44	0.57	0.62	0.52	0.49

The Calculation of the G-values. When the G-values of electrons are calculated, the contribution of the double ionization, G_{ii}, should be added to the total, because the first ionization in the double ionization has already been counted as a single ionization. In the case of the ionization and successive excitation, the G-value of this process does not contribute to the increase in the G-value of the electrons, while in the case of the excitation and successive ionization, its G-value should be added to the G-value of the electrons and the same amount has to be subtracted from the G-value of the excitations.

The sum of the G-value of the double excitation and the inner-shell excitation corresponds to the G-value of the autoionization state of each atom. Some species in this state may autoionize into multiply charged ions; however, in the present calculation, we assumed that all of the autoionization states produce only singly charged ions.

Table 8 summarizes the G-values of electrons and the W-values both calculated and observed.[29] The results appear to be better than those reported in the previous paper,[14] where the double collision and the inner-shell excitation were ignored. Table 9 shows the G-values of the excitations and the ratios of the excitation and ionization. There are no remarkable differences between the values calculated here and those obtained previously.

The authors are indebted to Professor Kazuo Hisatake for estimating the fluorescence yields.

The Specific Refractive Index Increment and the Partial Specific Volume of Atactic Poly(2-vinylpyridine)

Shizuo ARICHI, Masafumi YOSHIDA, and Yoshihiro OGAWA

Chemical Laboratory, Department of General Education, Kumamoto University, Kurokami-2-chome, Kumamoto 860

(Received January 6, 1975)

The specific refractive index increment, dn/dc, of atactic poly(2-vinylpyridine) was measured in 18 solvents with 436 nm light at 25 °C. Using these data, the partial specific volume, $\bar{v}_2$, of the polymer in these solvents was then evaluated by means of the method proposed by Heller. A sufficient agreement was found between the values of $\bar{v}_2$ thus obtained optically and those determined directly by the density measurement of solutions in several solvents. It was found that $\bar{v}_2$ varies considerably with the kind of solvent and that, in some solvents, such as methanol and ethanol, it takes an extremely lower value than that of bulk crystalline isotactic poly(2-vinylpyridine). The results were discussed in terms of thermodynamic interactions between the polymer and the solvent, the molar volume, and the compressibility of the solvent molecule. The relationship between dn/dc and the refractive index of a solvent, n_1, for 436 nm light is expressed by $dn/dc = 0.900 \times (1.628 - n_1)$.

The specific refractive index increment, dn/dc, of a dilute solution of a polymer is indispensable for an investigation of the polymer in solution by light scattering. Besides, the partial specific volume of a polymer, $\bar{v}_2$, is not only a very important value, often appearing in various parameters representing thermodynamic and hydrodynamic interactions between polymer and solvent, for example, the second virial coefficient, A_2, but also $\bar{v}_2$ itself is a useful quantity, showing polymer-solvent interactions. On the other hand, the very intimate relationships between the dn/dc and the $\bar{v}_2$ of a polymer in solution have been intensively studied by many investigators.

In spite of the ever-increasing number of related papers[1-3] on the solution properties of poly(2-vinylpyridine), there has been no systematic investigation of the dn/dc and the $\bar{v}_2$ of this polymer. Because of the very strong interactions between this polymer and certain solvents,[3-5] some specific characteristics can be expected to exist in the $\bar{v}_2$ of this polymer in those solvents which may be absent in a non-polar polymer such as polystyrene dissolved in a non-polar solvent.

The objects of this work are, first, to perform the direct measurement of the dn/dc of atactic poly(2-vinylpyridine) in as many solvents as possible; the results will enable us to make a broader choice of the solvent in light-scattering measurements of this polymer, and second, to evaluate the value of $\bar{v}_2$ according to the method proposed by Heller,[6] using the dn/dc data. The values of $\bar{v}_2$ thus obtained will be compared with those measured densitometrically in several solvents, and the relationship between the $\bar{v}_2$ and various properties of the solvents will be discussed.

Experimental

Specific Refractive Index Increment. The specific refractive index increments were measured photometrically with a Shimadzu DR-3-type differential refractometer.[7] All the measurements were carried out using the blue light of Hg (436 nm). The temperature in the cell was controlled at 25±0.01 °C. The instrumental constant was carefully calibrated with the standard aqueous solutions of KCl[8] and sucrose;[9] it was agreed within the range of 1.5%. The specific refractive index increment of the standard polystyrene, obtained from the Pressure Chemicals Co., in benzene at 25 °C for the 436 nm light gave experimental values ranging from 0.109 to 0.111, within the range of values reported in the most recent literature.[7]

Refractive Index of the Solvent. The refractive index of the solvent was measured with a Pulfrich refractometer manufactured by the Shimadzu Co. with 436 nm light of Hg at 25± 0.05 °C. The calibration of the instrument was done as usual.[10]

Refractive Index of Bulk Atactic Poly(2-vinylpyridine). The refractive index of bulk atactic poly(2-vinylpyridine) was measured with an Abbe-type refractometer manufactured by the Atago Kogakukikai Co. at 25±0.05 °C with 436 nm light of Hg. A thin film of the atactic poly(2-vinylpyridine) made from a benzene solution on mercury was placed on the major prism demounted from the instrument and carefully warmed to 115 °C in a nitrogen atmosphere. That temperature was then maintained for 15 hr. As the glass-transition temperature of this polymer is 104 °C,[11] a close adherence of the film to the surface of the prism was attained, and the border line between light and shade could be recognized. After the measurements had been completed and the film on the prism had been removed by dissolving with methanol, the calibration of the instrument was done as usual.[10]

Density of Solution. Measurements of the density of the polymer solution in several solvents were made with a usual Ostwald-Sprengel-type pycnometer. For solutions in benzene and dioxane, the density was measured by means of a graduated pycnometer. The concentrations of the polymer ranged from 1×10^{-2} to 6×10^{-2} in the weight fraction of the polymer. The temperature of the bath was maintained at 25±0.002 °C.

Density of Bulk Atactic Poly(2-vinylpyridine). The density of bulk atactic poly(2-vinylpyridine) was measured with the Weld-type pycnometer, immersing the thin film in decahydronaphthalene at 20±0.002 °C. The temperature coefficient of the volume expansion of the polymer was measured with a dilatometer manufactured by Shibayama Kagakukikai Co.; thus the value of the density of the polymer at 25 °C was determined. The density of the bulk isotactic crystalline poly(2-vinylpyridine) was measured in the same way, but directly at 25 °C.

Viscosity. The limiting viscosity number, $[\eta]$, of poly(2-vinylpyridine) in a number of solvents was determined in a Ubbelohde-type viscometer at 25±0.01 °C. The values of $[\eta]$ were obtained by plotting η_{sp}/c against the concentration, c, and by extrapolating to a zero concentration.

Polymers. The polymerizations and fractionations of atactic and isotactic poly(2-vinylpyridine) were all the same

as those previously reported.[12,13] The crystallization of a fraction of isotactic poly(2-vinylpyridine) was performed by heating it at 150 °C for a night in a nitrogen atmosphere; its crystallinity was checked by the X-ray diffraction method.[13,14]

Solvents. All the solvents used in this experiment were of a reagent grade; some of them had been dried and fractionally distilled.

Results and Discussion

Recent advances in both the theory and practice of the influence of a solvent on the specific refractive index increment, dn/dc, including the proposals of Heller,[6] Bodmann,[15] and Mächtle and Fischer,[16] have been summarized in the monograph by Huglin.[7] These theories are based on the concept of the specific refraction, R, which is a constant value and is a function of the specific volume, v, and the refractive index, n, of the component. The expressions for R proposed by Gladstone-Dale, Lorenz-Lorentz, and Eykman are:[7]

$$\text{Gladstone-Dale (GD)} : R = (n-1)v \quad (1)$$

$$\text{Lorenz-Lorentz (LL)} : R = [(n^2-1)/(n^2+2)]v \quad (2)$$

$$\text{Eykman (Ey)} : R = [(n^2-1)/(n+0.4)]v \quad (3)$$

According to the theory of the mixing rule,[17] the specific refraction of a binary solution can be expressed by:

$$R_{12} = R_1 w_1 + R_2 w_2 \quad (4)$$

where R_i and w_i are the specific refraction and the weight fraction of the component, i, respectively, and where $i=1$, 2, and 12 refer to the solvent, the solute, and the solution respectively. Equation (4) is correct only when there is no volume change upon mixing in the component, when the polarizability of the components is the same before and after mixing and when the solute is spherically symmetrical isotropic.[6]

For the polymer-solvent system where the volume change of mixing cannot be neglected, Heller[6] derived an expression of the relationship between dn/dc and the partial specific volume of a polymer, $\bar{v}_2$, in solution at an infinite dilution, assuming Lorenz-Lorentz expression, Eq. (2), for the specific refraction of each component. The final expression of Heller is:

$$[dn/dc]_{c=0} = 3\bar{v}_2(B-A)/2n_1(1-A)^2 \quad (5)$$

$$A = (n_1^2-1)/(n_1^2+2)$$

$$B = (n_2^{*2}-2)/(n_2^{*2}+2)$$

where n_1 is the same as above and where n_2^* is the refractive index of the polymer in solution. Heller assumed further that the Lorenz-Lorentz relation for a single component system:

$$(\varepsilon-1)/(\varepsilon+2) = 4\pi N\alpha/3 \quad (6)$$

where ε is the optical dielectric constant; α, the polarizability, and N, the number of molecules in a unit of volume, is valid for not only a bulk polymer but also for polymer in a very dilute solution if the polarizability of the polymer does not change measurably before and after mixing, even if the volume change can not be neglected. Then the following relationship must hold:

$$R_{2,\mathrm{He}} = (n_2^2-1)/(n_2^2+2)\rho_2$$

$$= [(n_2^{*2}-1)/(n_2^{*2}+2)]\bar{v}_{2,\mathrm{op}} = \text{constant} = k \quad (7)$$

where ρ_2 is the density of the bulk polymer.

If we can obtain the values of n_2 and ρ_2 of the bulk polymer, the value of k in Eq. (7) can be determined. Then, using Eqs. (5) and (7), a series of tentative pairs of $\bar{v}_{2,\mathrm{op}}$ and dn/dc can be obtained. Thus, the true value of $\bar{v}_{2,\mathrm{op}}$ can be evaluated graphically using the experimental value of dn/dc.

Another analytical method for obtaining $\bar{v}_{2,\mathrm{op}}$ was reported by Heller[18] in his second series concerned with the optical determination of the partial specific volume of macromolecules in solution. From Eq. (5) we can obtain:

$$\bar{v}_{2,\mathrm{op}} = k/A - f(dn/dc) = R_{2,\mathrm{He}}/A - f(dn/dc) \quad (8)$$

$$f = (2/3)n_1(1-A)^2/A \quad (9)$$

From Eq. (8), $\bar{v}_{2,\mathrm{op}}$ can then be readily calculated by using our knowledge of $R_{2,\mathrm{He}}$, dn/dc, and n_1 and/or A.

The usefulness of Heller's method for the evaluation of $\bar{v}_2$ from the dn/dc data has been confirmed recently;[19] also, Scholte[20] obtained an equation identical with Eq. (5) on the same assumption as Heller's but with a rather different approach.

Another approach made by Bodmann[15] concerning the relationship between dn/dc and the $\bar{v}_2$ of the polymer at an infinite dilution established that the R_{12} should be expressed by the partial specific refractions, $\bar{R}_1$ and $\bar{R}_2$, instead of R_1 and R_2 in Eq. (4); Bodmann's final expressions for $\bar{R}_2$ for the three functions, Eqs. (1), (2), and (3) were as follows:

$$\bar{R}_{2,\mathrm{GD}} = [(n_1-1)\bar{v}_2] + (dn/dc) \quad (10)$$

$$\bar{R}_{2,\mathrm{LL}} = [(n_1^2-1)/(n_1^2+2)]\bar{v}_2 + [6n_1/(n_1^2+2)](dn/dc) \quad (11)$$

$$\bar{R}_{2,\mathrm{Ey}} = [(n_1^2-1)/(n_1+0.4)]\bar{v}_2 + [(n_1+0.84)/(n_1+0.4)^2](dn/dc) \quad (12)$$

Equations (5) and (11) are equivalent when the specific refraction, $R_{2,\mathrm{He}}$ (Eq. (7)), is equal to the partial specific refraction, $\bar{R}_{2,\mathrm{LL}}$ (Eq. (11)), because only under this condition can Eq. (5) be derived from Eq. (11).

Examinations were made into the $\bar{R}_2$ values for the three functions calculated from the data of the densitometrically determined values of n_1, dn/dc, and $\bar{v}_{2,\mathrm{d}}$ in seven solvents; the results will be discussed later.

The results of the measurement of the refractive index of a pure solvent at 25 °C with 436 nm light, all of which were used for the dn/dc measurements, are shown in the third column of Table 1.

The refractive index increment for a fraction of atactic poly(2-vinylpyridine) ($M_w = 5.5\times10^4$) in several solvents is plotted against the concentration in Fig. 1. The linearity is satisfactory in all the solvents measured. The resultant values of dn/dc in all the solvents obtained by the least-squares method are shown in the fourth column of Table 1.

The value of the refractive index of a fraction of atactic poly(2-vinylpyridine) ($M_w = 34.7\times10^4$) in bulk for 436 nm light at 25 °C was 1.622. The specific volumes of three fractions of the same polymer ($M_w = 44.7\times10^4$, 34.7×10^4, and 19.0×10^4) at 20 °C were, on the average, 0.895, 0.896, and 0.895 cm³/g respectively.

a) $\bar{v}_{2,op}$=the values obtained with Eq. (5) in combination with Eq. (7). b) Δ=per cent deviation of $\bar{v}_{2,op}$ relative to the specific volume of bulk atactic poly(2-vinylpyridine) $v_{2,a}$. c) δ=per cent deviation of $\bar{v}_{2,op}$ relative to the specific volume of bulk isotactic crystalline poly(2-vinylpyridine) $v_{2,c}$. d) κ_s=adiabatic compressibility of solvent at 25 °C and 1 atmosphere. Ref.: "Chemical Hand Books, Part II", ed. by Chem. Soc. Japan, Maruzen, Tokyo (1966), p. 485

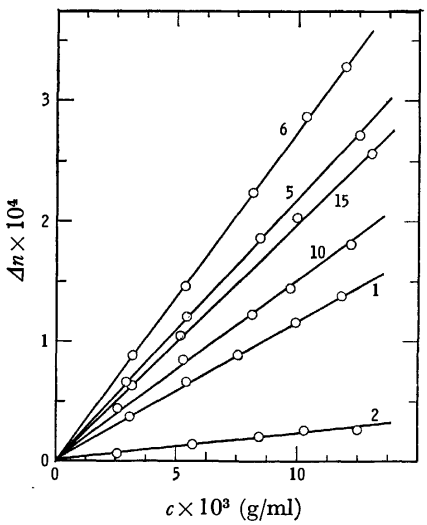

Fig. 1. Plots of the refractive index increment Δn *vs.* concentration c for atactic poly(2-vinylpyridine) at 25 °C. λ=436 nm. The numbers on the lines correspond to those in Table 1.

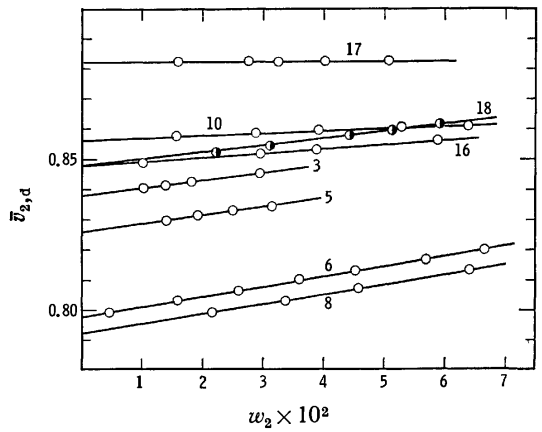

Fig. 2. Plots of the partial specific volume $\bar{v}_{2,d}$ of atactic poly(2-vinylpyridine) evaluated by densitometrically *vs.* concentration w in weight fraction at 25 °C. The numbers on the lines correspond to those in Table 2.

The mean value of these three values is 0.895 cm³/g. The volume-expansion coefficient of this polymer, as determined by dilatometry, was 3.0×10^{-4} cm³/g °C, so that the specific volume of this polymer at 25 °C was 0.897 cm³/g.

In Fig. 2 the values of the partial specific volume, $\bar{v}_{2,d}$ of the polymer at 25 °C, obtained by densitometric measurements of the solution in seven solvents, are plotted against the weight fraction of the polymer. The $\bar{v}_{2,d}$ value at each concentration was calculated, using the data of the density of a solution, with Kraemer's equation:[21,22]

$$\bar{v}_{2,d} = 1/\rho_{12}\{1-[(1-w_2)/\rho_{12}](d\rho_{12}/dw_2)\}$$

where ρ_{12} is the density of the solution, and w_2, the concentration of the polymer expressed by the weight fraction. The extrapolated values of $\bar{v}_{2,d}$ at w_2=0, which are the main interest in this investigation, are summarized in the sixth column of Table 2.

The values of the partial specific refraction, $\bar{R}_{2,GD}$, $\bar{R}_{2,LL}$, and $\bar{R}_{2,Ey}$, were calculated by fitting Eqs. (10), (11), and (12) to the data of n_1, dn/dc, and $\bar{v}_{2,d}$. The results are shown in Table 2.

As may be seen in Table 2, the deviation of the partial specific refraction from the mean value in any particular solvent is smallest in the case of $\bar{R}_{2,LL}$, and the specific refraction, $R_{2,He}$ (=0.316, Eq. (7)) of bulk atactic poly(2-vinylpyridine) is in fair agreement with the averaged value of the partial specific refraction, $\bar{R}_{2,LL}$ (=0.314, Eq. (11)). On the other hand, larger deviations are found with the corresponding specific refrac-

tions of the bulk polymer, $R_{2,GD}$ (=0.558, Eq. (1)) and $R_{2,Ey}$ (=0.724, Eq. (3)), in comparison with the mean values of the partial specific refractions, $\bar{R}_{2,op}$ (=0.542, Eq. (10)) and $\bar{R}_{2,Hy}$(=0.707, Eq. (12)).

Of course, the specific refraction, R_2, is not necessarily the same as the partial specific refraction, $\bar{R}_2$; however, the agreement between $\bar{R}_{2,LL}$ and $R_{2,He}$ is a satisfactory indication of the applicability of the Heller's method in this polymer-solvent system.

The partial specific volume of the polymer, $\bar{v}_{2,op}$, in all the solvents used in this experiment was evaluated according to the graphical scheme described previously using the value of 0.316 for $R_{2,He}$ (=k). Examples in several solvents are illustrated in Fig. 3. The $\bar{v}_{2,op}$ values in all the solvents were also evaluated from Eq. (8); they agreed very closely with those obtained graphically.

The values of $\bar{v}_{2,op}$ thus obtained are summarized in the fifth and seventh columns of Tables 1 and 2 respectively. In the eighth column of Table 2 the percent deviation of $\bar{v}_{2,op}$ from $\bar{v}_{2,d}$ defined by $[(\bar{v}_{2,op}-\bar{v}_{2,d})/\bar{v}_{2,d}]\times 100$ is shown. Except for the solution in cyclohexanone, the percentage of deviation is less than 2.4; this is almost

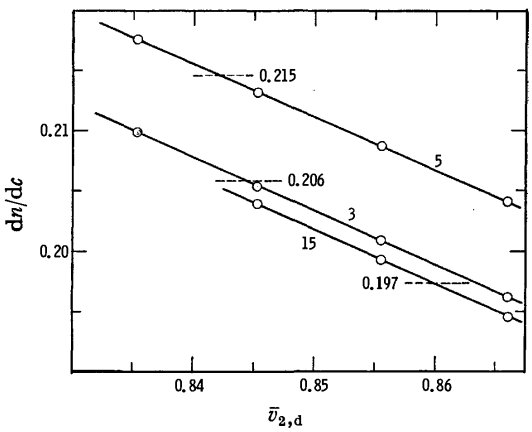

Fig. 3. Heller's plots for the tentative pairs of $\bar{v}_{2,op}$ and dn/dc obtained from Eqs. (5) and (7). The intersection of horizontal dashed lines with main plot gives $\bar{v}_{2,op}$ corresponding to experimentally obtained dn/dc. The numbers on the lines correspond to those in Table 1.

the same as the results for polystyrene reported by Heller,[6] and this is also an indication of the validity of the application of the method of Heller to this polymer-solvent system.

The values of Δ cited in the sixth column of Table 1 show the difference in $\bar{v}_{2,op}$ and the specific volume of bulk atactic poly(2-vinylpyridine), $v_{2,a}$ (=0.897 cm³/g), defined by $\Delta=[(v_{2,a}-\bar{v}_{2,op})/v_{2,a}]\times 100$. As a whole, they are larger than those reported for polystyrene.[6]

The specific volume, $v_{2,c}$ of the bulk crystalline isotactic poly(2-vinylpyridine) was 0.847 cm³/g at 25 °C for a fraction ($M_W=8.7\times 10^4$). The difference in $v_{2,a}$ and $v_{2,c}$ may be attributed to the increase in the free volume of the amorphous polymer. The apparent absolute free volume of bulk poly(2-vinylpyridine), as defined by $[(v_{2,a}-v_{2,c})/v_{2,c}]\times 100$, is 5.90%, which is comparable to the value for polystyrene:[6] 6.00—6.06%.

In the seventh column of Table 1 the apparent absolute free volumes of dissolved atactic poly(2-vinylpyridine), as defined by $\delta=[(\bar{v}_{2,op}-v_{,c})/v_{2,c}]\times 100$, are shown. Since the crystalline state is considered to be the most compact in the arrangement of the polymer segments, the negative values found in several solvents seem peculiar. The solvents which show negative values are 2-butanol, 1-propanol, 2-propanol, *n*-butanol, ethanol, and methanol, arranged in descending order of negative values. Even for a non-polar polymer such as polystyrene, a very small or slightly negative value of the apparent free volume in solution was pointed out by Heller,[6] therefore, the extremely large negative values found for this polymer in ethanol and methanol are remarkable.

In order to explain the effect of the change in the values of $\bar{v}_{2,op}$ with the nature of the solvents, we considered first the thermodynamic interactions between the polymer and the solvent. For such a thermodynamic parameter,[22] we used the values of $[(1/2-\chi_1)/V_1]$, where χ_1 is Flory's interaction parameter, and V_1, the molar volume of the solvent, as listed in the tenth column of Table 1. These values were obtained from the data of the limiting viscosity number for a fraction of atactic poly(2-vinylpyridine) ($M_W=28.7\times 10^4$) at 25 °C, assuming Flory's well-known expressions:[23]

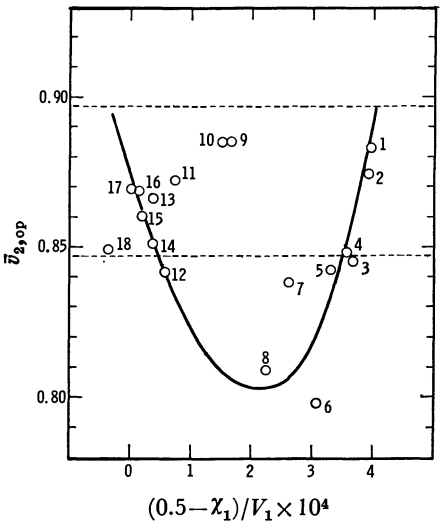

Fig. 4. Plots of the partial specific volume $\bar{v}_{2,op}$ *vs.* thermodynamic parameter $(1/2-\chi_1)/\bar{V}_1$ at 25 °C. The numbers on the points correspond to those in Table 1. The upper and lower dashed lines correspond to the specific volumes, $v_{2,a}$ and $v_{2,c}$ of bulk atactic and bulk crystalline poly(2-vinylpyridine), respectively.

$$\alpha^5 - \alpha^3 = 2C_m'(1/2-\chi_1)M^{1/2}$$

$$\alpha^3 = [\eta]/[\eta]_\theta \qquad [\eta]_\theta = KM^{1/2}$$

They are cited in the ninth column of Table 1, while $\bar{v}_{2,op}$ is plotted against them in Fig. 4. The points are rather scattered, some U-type relationship seems to exist between them. The shape of the curve is similar to that for the polystyrene-solvent system reported by Streeter and Boyer.[22] The decrease in the $\bar{v}_{2,op}$ with an increase in the solvent power may be attributed to the increase in the packing effect of the solvent molecules into the interior of the polymer coil because of the attraction between segments and solvent molecules.

As we have already shown, the interactions of poly(2-vinylpyridine) and alcohols, especially ethanol and methanol, are very strong because of the hydrogen-bonding formation.[1,4,5] The anomalous light-scattering behavior of poly(2-vinylpyridine) in methanol has been explained in terms of the extremely strong solvation of methanol to the segment-forming wire netting.[3] The peculiarity that the value of $\bar{v}_{2,op}$ is smaller than that of $v_{2,c}$ for isotactic crystalline poly(2-vinylpyridine) can also be attributed to this strong attraction between segments and solvents, which may result in a decrease in the partial specific volume of the solvent in addition to making for a closer packing of the solvent in the polymer coil.

The compressibility of the solvent molecule must also play an important role in such a case. In Fig. 5, $\bar{v}_{2,op}$ is plotted against the values of the adiabatic compressibility, κ_s, at 25 °C and one atmosphere as cited in the eleventh column of Table 1. As may be seen in this figure, there is some tendency for the value of $\bar{v}_{2,op}$ to decrease with an increase in the compressibility of the solvent. The compatibility of the large compressibility of methanol and ethanol and the large negative values of the apparent free volume of the polymer in these solvents are particularly remarkable.

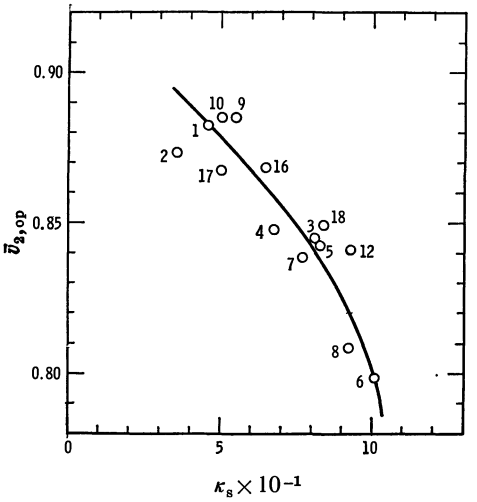

Fig. 5. Plots of the partial specific volume $\bar{v}_{2,op}$ *vs.* adiabatic compressibility of solvent κ_s at 25 °C and 1 atomsphere. The numbers on the points correspond to those in Table 1.

The tendency for them to be a rapid increase in $\bar{v}_{2,op}$ with an increase in $[(1/2-\chi_1)/\bar{V}_1]$ on the right-hand side of Fig. 4 is difficult to explain, but, it may be attributable to the crowding of the segments of different molecules in such a good solvent and to a decrease in the packing efficiency of solvent molecules. In addition, there may be some effects of the size and shape of the solvent molecule in their packing process. In Fig. 6, the values of $\bar{v}_{2,op}$ are plotted against the value of the molar volume of the solvent molecule. Although there is no definite reciprocity between $\bar{v}_{2,op}$ and V_1, some tendency for $\bar{v}_{2,op}$ to increase with V_1 is shown by the line in Fig. 6. Here again, methanol and ethanol seem to be favorable for the packing in the polymer coil because of their small volume.

Finally, for the purposes of practical use in light-scattering measurements[24,25] the empirical relation between dn/dc and n_1 for this polymer-solvent system was

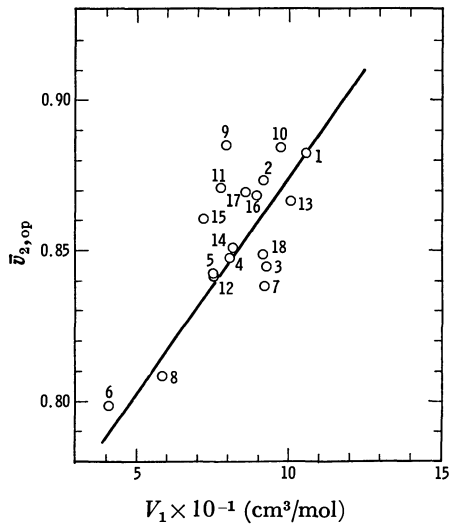

Fig. 6. Plots of the partial specific volume $\bar{v}_{2,op}$ *vs.* molar volume of solvent V_1 at 25 °C. The numbers on the points correspond to those in Table 1.

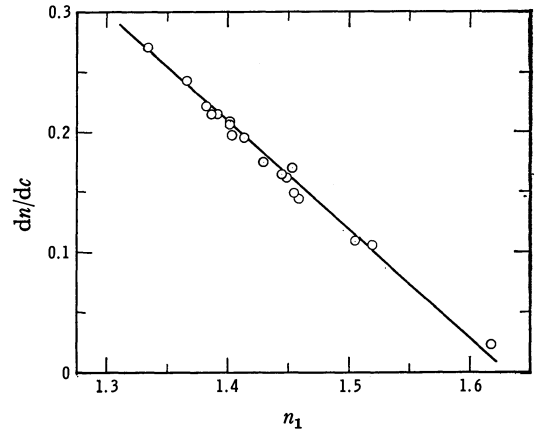

Fig. 7. Plots of specific refractive index increment dn/dc of atactic poly(2-vinylpyridine) *vs.* refractive index n_1 of solvent for 436 nm light at 25 °C.

evaluated. In Fig. 7 the values of dn/dc are plotted against the value of n_1 for 436 nm light. Their relation is represented by a linear line whose equation, as obtained by the least-squares method, is:

$$dn/dc = 0.900 \times (1.628 - n_1) \quad (13)$$

When volume additivity is assumed on the Gladstone-Dale expression for the specific refraction, Eq. (1) leads to this well-known equation:[26]

$$dn/dc = v_2(n_2 - n_1) \quad (14)$$

where each suffix is the same as before. The constants in Eq. (13), 0.900 and 1.628, agree well with the experimental values of $v_{2,a}$ (=0.897 cm^3/g) and n_2 (=1.622) presented previously.

Because the volume change on mixing the components in this polymer-solvent system is very remarkable, as has already been shown, the agreement between these values is clearly fortuitous; however, Eq. (13) can be used for predicting the value of dn/dc of atactic poly(2-vinylpyridine) within ± 0.002 in a given solvent possessing the value of n_1.

Dielectric Relaxation and Molecular Structure. XV. A Further Study of the Benzene Effect of 1,2-Dichloroethane and Related Molecules

Naoyuki SHIRATORI, Hiroaki TAKAHASHI, and Keniti HIGASI
Department of Chemistry, Waseda University, Shinjuku, Tokyo 160

(Received January 23, 1975)

The dielectric relaxation times, τ, and dipole moments, μ, of 1,2-dichloroethane (A), *cis*-1,2-dichloroethylene(B), 1,3-dichloropropane(C), *o*-dichlorobenzene(D), and 1-chloro-2-propanone(E) have been measured in two aromatic and two aliphatic nonpolar solvents. The results are as follows: both the τ and μ of (A) and (E) are exceptionally large in aromatic solvents, showing the benzene effect; (B) and (C) have large τ but normal μ values in aromatic solvents, while (D) shows normal effects of the solvent upon both τ and μ in two different sets of solvents. Finally, the intetmolecular interaction between the solute and the solvent is discussed with special regard to the origin of the benzene effect.

A previous dielectric study[1] of the solvent effects of 1,2-dichloroethane was based on the measurements on the frequencies, 1 MHz and 9.33, 24.15, and 48.00 GHz. A further investigation of the same subject by the use of millimeter waves with the frequencies of 96.3—96.6 GHz will be reported here. In addition, the results of new dielectric measurements will be discussed with regard to three dichloro-compounds (one aromatic and two aliphatic) and one ketone (1-chloro-2-propanone), which exhibits the benzene effect in dipole moments.[2]

Experimental

The samples employed were all commercially available. They were carefully purified before use. The boiling points and the refractive indices were checked against the literature values. The apparatus and the experimental technique for the dielectric measurements at 96.3—96.6 GHz were described in a preceding paper.[3] The static dielectric constants were measured by the heterodyne beat method, while the refractive indices for the Na D line were measured by the use of a Pulfrich refractometer.

Results

The values of the slopes a_0, a', a'', a_D, and b obtained in this experiments for five compounds, (A), (B), (C), (D), and (E), in four solvents are collected in Table 1. The slopes a' and a'' were obtained on the assumption that the linear relationship of the dielectric constant, ε', and loss, ε'', with the concentration (weight fraction), w_2, is valid in dilute solutions:

$$\begin{aligned} \varepsilon' &= \varepsilon_1' + a'w_2 \\ \varepsilon'' &= \varepsilon_1'' + a''w_2 \end{aligned} \qquad (1)$$

Further, a_0, a_D, and b represent the slopes for the static dielectric constant, ε_0, the square of the refractive index, n_D^2, and the specific volume, v, against the weight fraction respectively. (Regarding the symbols and equations in detail, see the preceding papers.[1,4,5])

Table 2 records the molecular polarization, ${}_\infty P_2$, at an infinitely dilute concentration; it was obtained from a_0 and b by the use of the following equation:[5,6]

$${}_\infty P_2 = M_2\left\{\frac{3a_0v_1}{(\varepsilon_{10}+2)^2} + (v_1+b)\frac{\varepsilon_{10}-1}{\varepsilon_{10}+2}\right\} \qquad (2)$$

Table 1. THE SLOPES a_0(STATIC), a', a'' (96 GHz), a_D(OPTICAL), AND b(VOLUME) AT 20 °C

where T is the absolute temperature. It may be seen from Table 2 that both benzene and *p*-xylene give higher dipole moments for two solutes, (A) and (E), while they provide the remaining three molecules, (B), (C), and (D), with almost the same dipole moments as those in aliphatic solvents.

Discussion

The Cole-Cole equation[7] for a dilute solution is expressed in the following form:[8]

$$\frac{(a'-ia'')-a_{\infty}}{a_0-a_{\infty}}=\frac{1}{1+(i\omega\tau_0)^{1-\alpha}} \qquad (5)$$

where τ_0 is the most probable relaxation time, α is the distribution parameter, and ω is the angular frequency. Using the a' and a'' values obtained for 1,2-dichloroethane at five frequencies, 1 MHz and 9, 24, 48, and 96 GHz, three parameters, τ_0, α, and a_{∞}, of Eq. (5) were calculated for various solutions by the use of a computer. The results are shown in Table 3.

We find the distribution parameter, α, to be almost zero in non-aromatic solvents. We also find that α values are also small, but differ from zero in aromatic solvents. Using Budo's equation,[9] we are able to

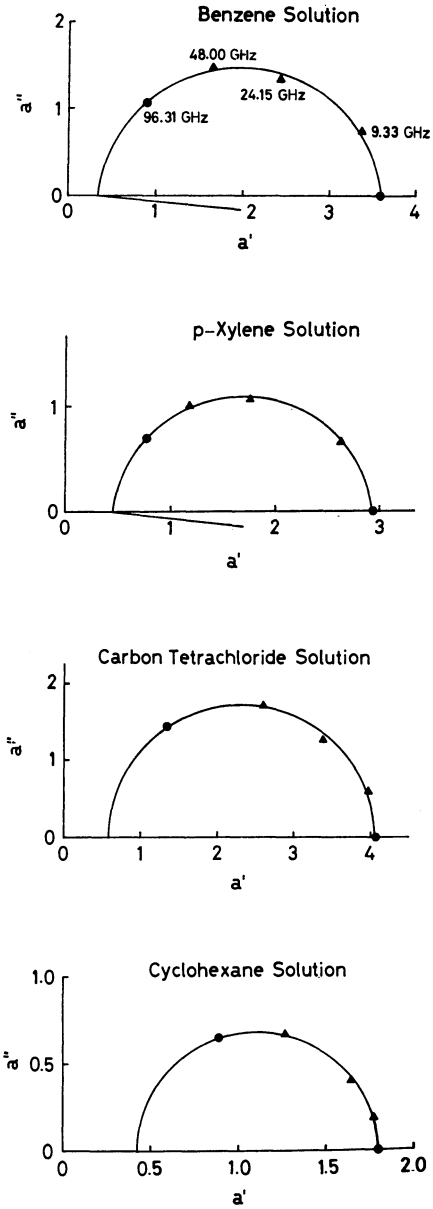

Fig. 1. The Cole-Cole plots for 1,2-dichloroethane in various solvents at 20 °C.
●: This work, ▲: A previous work (Ref. 1).

TABLE 3. THREE COLE-COLE PARAMETERS FOR 1,2-DICHLOROETHANE AT 20 °C

Solvent	a_{∞}	τ_0(ps)	α
Benzene	0.339	4.28	0.07

(E) 1-Chloro-2-propanone	4.89±0.05	5.46±0.08	3.84±0.07	2.51±0.17

as good evidence for complex formation[10] in the aromatic medium, since the observed α values are too small to make such an analysis reliable.

Another point of interest is that the slopes, a_∞, for the extremely high frequency were found to be unusually large.** In fact, the present work gives much higher values of a_∞ than those estimated roughly in the preceding paper.[1] Possibly this indicates some appreciable absorption in the submillimeter region; however, this point is not yet clear.

As has been reported in the preceding paper[1] the relaxation times of 1,2-dichloroethane are of a considerable magnitude in both benzene and *p*-xylene. That is, the τ_0 values in the aromatic solvent, 4.28 ps (benzene) and 5.67 ps (*p*-xylene), are about twice the τ_0 values in non-aromatic solvents, *viz.*, 2.96 ps (carbon tetrachloride) and 2.38 ps (cyclohexane), while the viscosities of the aromatic solvents are even smaller than those of the non-aromatic solvents (cyclohexane and carbon tetrachloride) by 32.4% (benzene) and 33.9% (*p*-xylene).

Two different approaches have been made to the benzene effect of 1,2-dichloroethane. One was made by Wada and Morino,[11] who showed that the *gauche* isomers are stabilized in the medium of benzene for an unspecified reason, resulting in a higher dipole moment. The other, by Kubo,[12] is that 1,2-dichloroethane forms a 1:1 complex with benzene, from which an increase in the relaxation time can be predicted. Morita *et al.*[10] reached Kubo's conclusion by repeating the same experiment and further confirmed that the 1:1 complex of 1,2-dichloroethane has the dipole moment of the *gauche* isomer, 2.55 D.[13]

However, there are some difficulties with the Kubo-Morita's conclusion, First. thermodynamical studies have failed in producing any evidence for the complex formation.[14] Secondly, the equilibrium constant for the complex formation has been found to depend upon the inert solvent,*** K_c (ml/mol) is 30.0 in carbon tetrachloride, 90.7 in *n*-hexane, and 139 in cyclohexane; further, the dipole moment of the complex is affected also by the solvent, μ(D)=2.54 in carbon tetrachloride, 2.11 in *n*-hexane, and 1.99 in cyclohexane.[10,15] Probably, benzene interacts with 1,2-dichloroethane in such a way that the configuration of the *gauche* isomer is more favored; however, this interaction is not strong enough to produce an aggregate with a structure rigid enough at room temperature to be unaffected by the surrounding molecules of the inert solvent.

The interaction between 1,2-dichloroethane and *p*-xylene is somewhat similar to, but stronger than, that of 1,2-dichloroethane and benzene, since the τ_0 value (5.67 ps) in *p*-xylene is larger than that (4.28 ps) in benzene—compare this change with the change in the weight factor, C_2, and its related footnote. The above findings are in accord with the changes in the equilibrium constants—*e.g.*, K_c=30.0 ml/mol in benzene and 51.0 ml/mol in *p*-xylene (in the inert solvent CCl_4).[10,15] On the other hand, the dipole moment, or the configuration itself, of the *gauche* isomer might be changed in the 1:1 complex. In fact, the polarity of the complex becomes smaller upon a change in solvent from benzene to *p*-xylene, *e.g.*, μ=2.54 D in benzene and 2.04 D in *p*-xylene (in the inert solvent CCl_4).

In Table 4 the relaxation times, τ, for five molecules, (A), (B), (C), (D), and (E), are collected. The values were all obtained by the use of the following Debye equation:

$$\tau = \frac{1}{w}\frac{a_0 - a'}{a''} \tag{6}$$

in which a' and a'' at 96 GHz are employed for the calculation.[8] In Table 4 we find the relaxation times of all the five solutes in carbon tetrachloride to be larger by 32—53% than the corresponding ones in cyclohexane. This is surprising because the two solvents have practically the same viscosity at room temperature; the two τ values should, then, be equal to each other for any solute if the usual Debye equation[18] were valid. The unusual rise in the relaxation time in carbon tetrachloride indicates, therefore, that the Debye approach is wrong. The alternative interpretation[19] after Eyring would indicate that particularly strong forces exist between all the solutes and carbon tetrachloride, by which the rotation of the solute molecules is hindered.

The skeleton of *cis*-1,2-dichloroethylene (B) is flat, and its C=C bond is slightly shorter than the C–C bond in 1,2-dichloroethane (A); the dipole moment, 1.80—1.82 D, for (B) is smaller than the *gauche* isomer of (A) 2.55 D. In other respects, however, the configuration of (B) may well compare with that the *gauche* isomer of (A). The relaxation times in the last two solvents are almost the same for the two molecules, (A) and (B). Although they differ in magnitude, the relaxation times of (B) are similarly high in aromatic solvents in spite of the fact that (A) has rotational isomers, while (B) has none. Perphaps this suggests that the relaxation

** If a_D is used instead of a_∞, we obtain a skewed arc, as has been pointed out by some Indian workers. For instance, see, for the benzene solutions, S. Chandra and R. A. Yadav, This Bulletin, **46**, 1900 (1973), and for a liquid, S. Chandra and R. A. Yadav, *J. Chim. Phys.*, **69**, 1018 (1972).

*** Similar variations in K with inert solvents were observed on charge-transfer complexes.[16,17] Possibly, the inert solvent is not ideal, but it interacts with either the solute or the solvent, or with both.

time is affected mostly by forces acting between the solute and the solvents in the first approximation.

The solvent interaction of 1,3-dichloropropane (C) with aromatic solvents is similar to, but somewhat weaker than, that of *cis*-1,2-dichloroethylene (B), while the corresponding interactions of (D) in aromatic solvents are the least pronounced of all. On the other hand, the interactions of 1-chloro-2-propanone (E) may well compare with those of 1,2-dichloroethane (A); both molecules have two rotational isomers, one strongly polar and the other nonpolar or at least less polar.

Next, we shall turn to the problem of the nature of the interaction between aromatic solvents and 1,2-dichloroethane. The mechanism of complex formation through hydrogen bonds was first proposed by Neckel and Volk[20] and later examined by Crossley and Walker[21] and Smyth.[22] However, this hypothesis of hydrogen bonding is not supported by the fact that the benzene effect in the dipole moment exists[23] even when all the hydrogen atoms of 1,2-dichloroethane are replaced by methyl groups. The alternative hypothesis is that the interaction originates from the chlorine atoms of 1,2-dichloroethane or, rather, from the C–Cl bonds. In other words, because of the large dipole moments of the C–Cl bonds and the large hyperpolarizability[24] of the aromatic solvent, the dipole-polarizability effect is possibly the origin of the benzene effect. The second explanation, however, has not yet been provided with any definitive proof.

Concluding Remarks on the Benzene Effect

The following conclusions are reached on the basis of the present investigation, together with the three preceding ones:[1,10,15]

1) 1,2-Dichloroethane and aromatic hydrocarbon molecules seem to interact in such a way as to form a loosely bound 1:1 complex in which 1,2-dichloroethane maintains its *gauche* configuration without much distortion.

2) Extra stabilization energy which cannot be explained by a simple electrostatic model[11] is gained by the *gauche* isomers in the medium of an aromatic solvent as a result of the above complex formation. Also, the Raman lines for the *gauche* isomer become stronger[11,25] in the presence of aromatic hydrocarbon molecules.

3) The apparent dipole moment of (A) becomes larger, since the number of the *gauche* isomers increases in the aromatic medium.[1] The dielectric relaxation time of (A) becomes high in the medium of an aromatic solvent because the rotation of the polar solute molecules becomes hindered in this medium.

4) The benzene effect for 1,2-dichloroethane (A) described above will be found even when another aromatic solvent is used instead of benzene. The benzene effect will also be found for some other polar molecules, *e.g.*, 1-chloro-2-propanone (E).

5) The dielectroric-relaxation-time method is useful for detecting the weakest intermolecular interaction. The dipole-polarization and other forces in the solute-solvent intraction are important in this effect.

We wish to thank the Science and Engineering Research Laboratory of Waseda University for its financial aid. We also indebted to Dr. Yoshinori Koga and Mr. Ryuichi Minami for providing us with unpublished data on the benzene effect of 1,2-dichloroethane and also for their helpful discussions.

Chemical Equilibria between a Lanthanide Shift Reagent and *n*-Hexylamine in Chloroform

Fuyuhiko INAGAKI, Mitsuo TASUMI, and Tatsuo MIYAZAWA

Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received February 18, 1975)

The $Eu(fod)_3$-induced ^1H NMR shifts of *n*-hexylamine were observed using two kinds of dilution methods. The results are analyzed in terms of the chemical equilibria among the shift reagent (L), substrate (S), 1 : 1 (LS), and 1 : 2 (LS_2) complexes. The association constants and the induced shifts intrinsic to the LS and LS_2 complexes are evaluated accurately by fitting the theoretical curves to the observed data. The values obtained are utilized to confirm the validity and usefulness of the extrapolation method proposed previously to determine the shift ratios for the LS complex.

It has been pointed out that, in order to determine the molecular structure in solution by means of the lanthanide-induced NMR shift (LIS), the ratios of shifts intrinsic to the lanthanide–substrate 1 : 1 complex (LS complex) should be used.[1-4] In a previous paper[4] we proposed an experimental method to derive the shift ratios for the LS complex and applied it to the Eu(III)–L-azetidine-2-carboxylic acid system in D_2O solution. A lanthanide chelate compound such as $Eu(fod)_3$ (fod = 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl-4,6-octanedione) induces much larger shifts to a substrate dissolved in an organic solvent than a lanthanide ion does in aqueous solution. The stoichiometric analysis can therefore be made more precisely for the system of a lanthanide chelate and a substrate in an organic solvent. In the present paper we analyze the chemical equilibria of $Eu(fod)_3$ and *n*-hexylamine in chloroform, taking into account the formation of not only the LS complex but also the LS_2 (1 : 2) complex. The results are utilized to show that the experimental method of obtaining the shift ratios for the LS complex[4] is an appropriate and useful one.

Experimental

All the NMR spectra were run on a Hitachi R-22 NMR spectrometer (90 MHz) in the frequency-sweep mode at a probe temperature of 37 °C. The shifts were measured using a frequency counter with estimated accuracy of ± 1 Hz or less.

n-Hexylamine, $Eu(fod)_3$, and deuterated chloroform containing 1% tetramethylsilane were purchased, respectively, from Tokyo Chemical Industry Co., Dojin Chemicals, and E. Merck. As a trace amount of water in the reagents was found to have a serious effect on the results of LIS mesurements, it was eliminated with special caution. *n*-Hexylamine was distilled over sodium hydroxide in the dry nitrogen atmosphere and was stored with synthetic zeolite A-4. $Eu(fod)_3$, was dried over phosphorus pentoxide in an evacuated desiccator (10^{-3}—10^{-4} mmHg) for a week.[5,6] Deuterated chloroform was mixed with active alumina which was then removed by filtration. The samples for NMR measurements were prepared in a dry box flushed with nitrogen gas. The LIS values obtained in this way were reproducible and considerably larger than those obtained without these procedures.

The LIS's of *n*-hexylamine were observed for a series of solutions prepared by the following two methods.[4] In the successive dilution method an original solution containing approximately equimolar substrate and shift reagent was diluted stepwise with the solvent. The original concentrations of *n*-hexylamine and $Eu(fod)_3$ were 0.286 and 0.272 M, respectively. On the other hand, in the incremental dilution method an original solution was diluted stepwise with the substrate solution of the same concentration as in the original solution, so that only the $Eu(fod)_3$ concentration was lowered. The original concentrations of *n*-hexylamine and $Eu(fod)_3$ were 0.097 and 0.248 M, respectively.

Method of Analysis

Chemical equilibria among a lanthanide shift reagent (L), a substrate (S), and the complexes are described by the following schemes under the assumption that the formation of complexes LS_x ($x \geqq 3$) may be neglected.

$$L + S \overset{K_1}{\rightleftharpoons} LS \quad (1)$$

$$LS + S \overset{K_2}{\rightleftharpoons} LS_2 \quad (2)$$

where K_1 and K_2 are the association constants given as

$$K_1 = [LS]/[L][S] \quad (3)$$

$$K_2 = [LS_2]/[LS][S] \quad (4)$$

If the LIS (of the ith nucleus, $i = 1$—n) intrinsic to the LS and LS_2 complexes are expressed as $\Delta_1{}^i$ and $\Delta_2{}^i$, respectively, the observed shift ($\Delta\delta^i_{obsd}$) may be given on the fast-exchange condition as

$$\Delta\delta^i_{obsd} = ([LS]/[S_0])\Delta_1{}^i + 2([LS_2]/[S_0])\Delta_2{}^i \quad (5)$$

where $[S_0]$ is the total concentration of the substrate.

The purpose of the present analysis is to obtain the most probable values of K_1, K_2, $\Delta_1{}^1$—$\Delta_1{}^n$, and $\Delta_2{}^1$—$\Delta_2{}^n$ which reproduce both sets of observed LIS data derived from the successive dilution and the incremental dilution methods. This can be done according to the following steps. (a) The values of K_1 and K_2 are assumed. (b) Equations (3) and (4) are solved for [LS] and $[LS_2]$ using the Newton-Raphson method. (c) The expected LIS value ($\Delta\delta^i_{calcd}$) is calculated by Eq. (5) with assumed values of $\Delta_1{}^i$ and $\Delta_2{}^i$. The best values of $\Delta_1{}^i$ and $\Delta_2{}^i$ can then be obtained by minimizing the sum (S) given as

$$S = \sum_{i=1}^{n} \sum_{j=1}^{N_i} w_j \{\delta^i_{obsd}(j) - \delta^i_{calc}(j)\}^2 \quad (6)$$

where N_i is the total number of observed data for the ith nucleus and w_j is the weight for the jth observed LIS value. All the values of w_j were set equal to unity. (d) The steps (a) to (c) are repeated for various sets of K_1 and K_2 until the parameters which minimize S

are finally found.

The computation outlined above was performed with the program SHIFT using a HITAC 8800/8700 system at the Computer Centre of the University of Tokyo.

Results and Discussion

By the addition of $Eu(fod)_3$ the NMR spectrum of *n*-hexylamine becomes first-order and all the resonances due to the α—ε methylene protons and the ω methyl protons are easily assigned. The results of the successive dilution and the incremental dilution methods are shown with open circles in Figs. 1 and 2, respectively. In the former method the molar ratio $\rho([L_0]/[S_0]$, the ratio of total concentrations) is kept constant (0.951), whereas

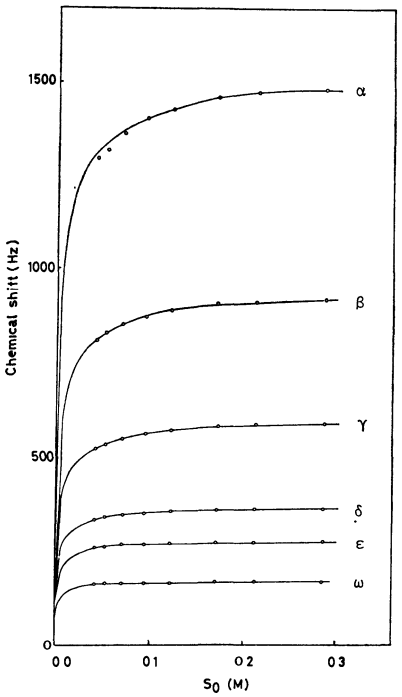

Fig. 1. $Eu(fod)_3$-induced shifts $\Delta\delta_{obsd}$ of *n*-hexylamine *vs.* total substrate concentration $[S_0]$ obtained by the successive dilution method. $CDCl_3$ solution, 37 °C, $\rho=0.95$. The observed data for α—ε methylene and ω methyl protons are shown with open circles. The curves were obtained by the calculation (see text).

TABLE 1. THE ASSOCIATION CONSTANTS (K_1 AND K_2) AND THE SHIFTS INTRINSIC TO THE LS AND LS_2 COMPLEXES (Δ_1 AND Δ_2) FOR THE $Eu(fod)_3$–*n*-HEXYLAMINE SYSTEM

Proton	Δ_1,[a] Hz	Δ_2,[a] Hz
α	1264.5 (6.8)	1373.6 (14.8)
β	793.2 (1.9)	936.7 (6.2)
γ	473.2 (1.6)	528.0 (5.3)
δ	245.5 (1.9)	304.4 (6.3)
ε	152.3 (1.5)	219.2 (4.9)
ω	89.7 (1.1)	124.4 (3.6)
	$K_1=535.5$[b]	$K_2=13.9$[b]

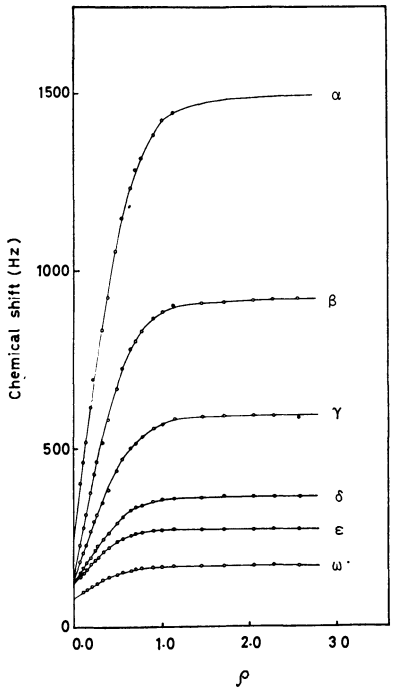

Fig. 2. $Eu(fod)_3$-induced shifts $\Delta\delta_{obsd}$ of *n*-hexylamine *vs.* ρ ($\equiv[L_0]/[S_0]$) obtained by the incremental dilution method. $CDCl_3$ solution, 37 °C, $[S_0]=0.097$ M. The observed data for α—ε methylene and ω methyl protons are shown with open circles. The curves were obtained by the calculation (see text).

in the latter method $[S_0]$ is maintained at 0.097 M. In Table 1 are given the best values of K_1, K_2, Δ_1^i's, and Δ_2^i's which were obtained by the analysis described above. The LIS values calculated using these parameters are shown by the curves in Figs. 1 and 2. The agreement between the calculated curves and the observed data is quite satisfactory.

In Figs. 3 and 4 the calculated concentration ratios $[LS]/[S_0]$, $[LS_2]/[S_0]$, and $[LS_2]/[LS]$ are shown for the successive dilution and the incremental dilution processes, respectively. As is clearly seen in these figures, the ratio $[LS_2]/[LS]$ increases rapidly to $K_2[S_0]$ as ρ approaches zero in the incremental dilution method,

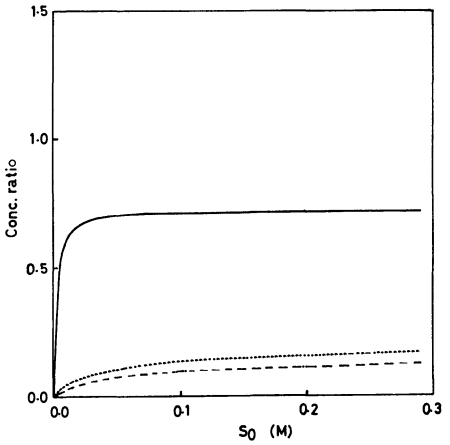

Fig. 3. The calculated concentration ratios $[LS]/[S_0]$ (——), $[LS_2]/[S_0]$ (– – –), and $[LS_2]/[LS]$ (– – – –) *vs.* $[S_0]$.

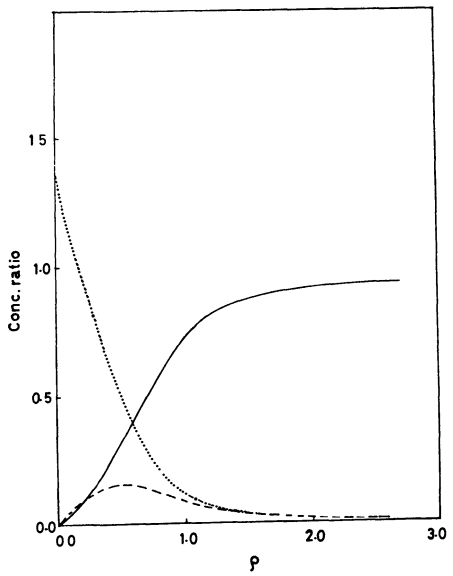

Fig. 4. The calculated concentration ratios [LS]/[S_0] (——), [LS_2]/[S_0] (— —), and [LS_2]/[LS] (– – –), *vs.* ρ.

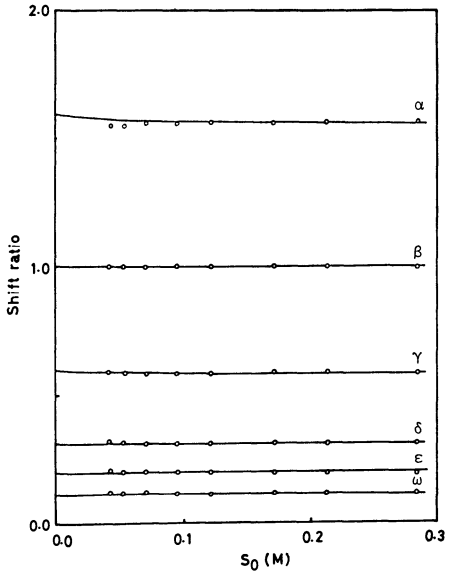

Fig. 5. The ratios of Eu(fod)$_3$-induced shifts of *n*-hexylamine *vs.* [S_0] obtained by the successive dilution method. The shift of β proton is taken as reference. The observed data are shown with open circles. The curves were obtained by the calculation (see text).

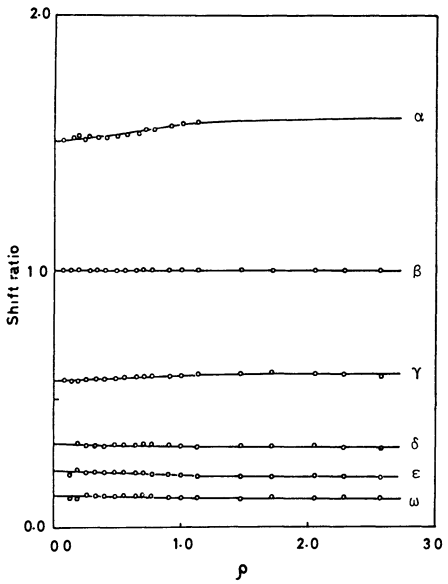

Fig. 6. The ratios of Eu(fod)$_3$-induced shifts of *n*-hexylamine *vs.* ρ obtained by the incremental dilution method. The shift of β proton is taken as reference. The observed data are shown with open circles. The curves were obtained by the calculation (see text).

whereas the ratio decreases gradually to zero as [S_0] is lowered in the successive dilution method. This point should be borne in mind in deriving the shift ratios for the LS complex. Since the successive dilution and the incremental dilution methods have quite different patterns with respect to the complex formation, a combined analysis of LIS values of the two methods enhances the reliability of the parameters listed in Table 1.

In a previous paper[4] a method of obtaining the shift ratio for the LS complex was proposed. It is interesting to apply this method to the present system. The ratio of the LIS of the ith nucleus and that of the sth nucleus is derived from Eqs. (3)—(5) as

$$\frac{\Delta\delta^i_{\mathrm{obsd}}}{\Delta\delta^s_{\mathrm{obsd}}} = \frac{\Delta_1{}^i + 2K_2[S_0]\Delta_2{}^i + 2K_2(\Delta_1{}^i - \Delta_2{}^i)[LS]}{\Delta_1{}^s + 2K_2[S_0]\Delta_2{}^s + 2K_2(\Delta_1{}^s - \Delta_2{}^s)[LS]} \quad (7)$$

The extrapolations of the shift ratio to [S_0]=0 and to ρ=0 give the following relations.

$$\lim_{[S_0]\to 0}\left(\frac{\Delta\delta^i_{\mathrm{obsd}}}{\Delta\delta^s_{\mathrm{obsd}}}\right) = \frac{\Delta_1{}^i}{\Delta_1{}^s} \quad (8)$$

$$\lim_{\rho\to 0}\left(\frac{\Delta\delta^i_{\mathrm{obsd}}}{\Delta\delta^s_{\mathrm{obsd}}}\right) = \frac{\Delta_1{}^i + 2K_2[S_0]\Delta_2{}^i}{\Delta_1{}^s + 2K_2[S_0]\Delta_2{}^s} \quad (9)$$

These equations indicate that the ratio of shifts intrinsic to the LS complex can be obtained only by extrapolating the shift ratio derived from the successive dilution method to [S_0]=0. The extrapolation of the shift ratio derived from the incremental dilution method to ρ=0 leads to a value which has also the contribution of LS_2 properties.

In Figs. 5 and 6 are shown the shift ratios obtained by the successive dilution and the incremental dilution methods, respectively. The LIS of the β proton is taken as reference. The curves in these figures indicate the shift ratios calculated using the parameters listed in Table 1. In Table 2 the observed and calculated shift ratios extrapolated to [S_0]=0 and to ρ=0 are compared. It is noted that the shift ratios extrapolated to [S_0]=0 differ significantly (*ca.* 10% for the ε proton) from those extrapolated to ρ=0 and these differences are also confirmed by the calculation. These results indicate that all the theoretical analysis and experimental procedures described above are self-consistent and useful.

It may be worthwhile to mention about the so-called "*S* value". This is often used to represent the magnitude of LIS in the conventional method of adding a

Table 2. The shift ratios extrapolated to $[S_0]=0$ and $\rho=0$

Proton	$[S_0]=0$		$\rho=0$	
	Obsd[a]	Calcd	Obsd[b]	Calcd

solid shift reagent to a substrate solution or in the incremental dilution method. Like the shift ratio extrapolated to $\rho=0$ given in Eq. (9), the S value contains the contribution of LS_2 properties. Therefore, its use may lead to some erroneous results in the structure determinations.

The Chemistry of Americium. III. The Coprecipitation of Am(III), Am(V), and Am(VI) by Some Fluorides and Phosphates

Mitsuo HARA and Shin SUZUKI

The Research Institute for Iron, Steel and Other Metals, Tohoku University, Katahira 2-chome, Sendai 980

(Received May 8, 1974)

The radiochemical behavior of americium in the coprecipitation process involving a precipitate such as lanthanum, thorium, and ceric fluorides, zirconium, and bismuth phosphates was investigated at the tracer concentrations of americium. All the precipitates except zirconium phosphate completely carried the Am(III), leaving the Am(VI) in the supernatant. The lanthanum and thorium fluorides carried portions of the Am(V) in proportion to the amounts of the metal ion of the carrier added under any given conditions. Then, the analytical conditions were established for determining the distributions of the oxidation states of americium.

The recognized oxidation states of americium in an ordinary aqueous solution are the tri-, penta-, and hexavalent states. They can usually be identified by means of spectrophotometry.[1] However, this method is not sensitive enough here because of the low molar extinction coefficients of both Am(V) and Am(VI) ions. The development of an oxidation-state separation scheme at low americium concentrations is often beset by certain inherent difficulties. The properties of a trace amount of an element (tracer) can often be observed by means only of its chemical behavior, which in most cases closely resembles the chemical behavior of the element at a macro concentration. In some cases, however, it is necessary to pay attention to such peculiarities of the tracer behavior as the radiocolloid formation, the adsorption on the container walls, and the oxidation-state perturbation caused by small amounts of impurities.

A few workers have reported methods for the separation of Am(III) and the higher oxidation states of americium at low concentrations utilizing these differences in the chemical properties: the solubility in the lanthanum-fluoride[2] and calcium-fluoride systems,[3] the adsorbability on a chromatographic column consisting of bis(2-ethylhexyl)phosphoric acid[4,5] or on a column consisting of zirconium phosphate,[6] and the extractability in liquid-liquid extraction using 2-thenoyltrifluoroacetone as the extractant.[7,8]

The methods involving the organic agents substantially perturb the oxidation states of americium in the course of the separation process, and the column operations take much time. The coprecipitation technique involving the lanthanum fluoride is based on the facts that the actinoid(III,IV) ions are carried, while the actinoid(VI) ions are not carried, by the lanthanum fluoride.[2,9] However, the behavior of the actinoid(V) ions in this system has not yet been confirmed.

In a previous work the present authors investigated the instability of Am(V) in several media and found that Am(V) at tracer concentrations was stable within a few hours after preparation in a nitric acid solution, *etc.* at 0—5 °C.[8] In order to develop the solution chemistry of the higher oxidation states of americium, it is necessary to establish a method for determining the oxidation-state distributions of americium. For this purpose, the coprecipitation technique was chosen because of its rapidity and convenience. In this work, the coprecipitation of americium by lanthanum, thorium, and ceric fluorides and by zirconium and bismuth phosphates was investigated under various conditions. The results will be discussed from the standpoints of the coprecipitation process and the oxidation-state analysis.

Experimental

Reagents. The independent solutions of Am(III), Am(V), and Am(VI) were prepared by the methods reported previously;[5,8] in some cases, they were arbitrarily mixed in order to prepare the multi-component solutions. The initial concentration of ^{241}Am was of the order of 10^{-6} M. Solutions of lanthanum, thorium, cerium(IV), bismuth, and zirconium nitrates were used as the metal ion of the carrier. The precipitants were solutions of ammonium fluoride and phosphoric acid and also, if necessary, hydrofluoric acid and ammonium dihydrogenphosphate solutions. These and other chemicals were all of a G. R. grade.

Apparatus. The experiments prior to centrifuging were carried out in an Onishi Netsu-Kagaku thermostated box at 0—5 °C. For the centrifugation, a Sakuma Model SMC 30-1 centrifuge was used. The γ-ray assay was performed by the use of a Kobe Kogyo Model PS-500 flat-type NaI(Tl) scintillation probe connected with a Kobe Kogyo Model SA-400 scaler.

Procedure. Suitable aliquots of the americium, the metal ion of the carrier, and nitric acid solutions were transferred into a polyethylene test tube; a precipitant was then added, and the volume and the acidity were adjusted to the desired values. The mixture was then shaken mechanically for enough time to obtain an apparently constant fraction of americium carried. The recommended shaking time was 10 and 30 min for the fluoride and phosphate systems respectively. The final concentration of ^{241}Am in the mixture was $(0.5-5)\times 10^{-6}$ M. By measureing the ^{241}Am activity in both the mixture and the supernatant obtained by centrifuging the mixture at about 6000 rpm for 5 min, the fraction of americium carried was determined. When thorium was used, the correction for the γ-activity from the daughters of ^{232}Th was performed, but the interference from them was negligibly small in most cases. The acidity of the supernatant was stoichiometrically calculated. In the preliminary experiments it was confirmed that no oxidation state of americium was centrifuged under the conditions examined when neither the metal ion of carrier nor the precipitant was added.

Results

The fraction of americium carried generally depended on the volume and composition of the mixture, the

amounts of the metal ion of the carrier, and the molar ratio of the precipitant to the metal ion of the carrier added. For instance, under the same conditions except for the volume, 14, 65, and 95 % of Am(III) were carried by the thorium fluoride by the use of 0.1 mg Th^{4+} per 3.5, 3.0, and 2.5 ml respectively of the mixture at an acidity of 0.1 M. Therefore, the volume of the mixture was adjusted to 2.5 ml except when otherwise noted.

Coprecipitation by the Insoluble Fluorides. The relation between the fraction of americium carried and the amounts of a metal ion of the carrier was investigated at the acidity of 0.2 M, as is shown in Fig. 1. In the range of the amounts of the thorium ion examined, more than 95 % of the Am(III) and less than 12 % of the Am(VI) were carried, but the fraction of Am(V) carried increased from 1 to 100 % with an increase in the amount of the thorium ion from 0.15 to 75 mg per 2.5 ml of the mixture. The coprecipitation behavior with the lanthanum fluoride showed a tendency similar to that with the thorium fluoride. On the other hand, in the ceric-fluoride system the fractions of Am(V) and Am(VI) carried were both very small, irrespective of the amounts of the ceric ion, while the coprecipitation of Am(III) was complete when more than 0.2 mg Ce^{4+}/ml was used.

(c) F/Ce=14: ○, Am(III); △, Am(V); □, Am(VI).
In each system, 1 mg of metal ion per 2.5 ml of the mixture was used.

The acidity dependence of the coprecipitation of americium was also studied at a constant amounts of the carrier-metal ion and at a constant molar ratio of the precipitant to the metal ion of the carrier added (F/M). The results are shown in Fig. 2. The larger fractions of americium were carried at the lower acidities, and the coprecipitation of Am(III) was less complete at the higher acidities, especially at smaller F/M values. The fractions of Am(III), Am(V), and Am(VI) carried by the insoluble fluoride under the given conditions are summarized in Table 1.

Coprecipitation by the Insoluble Phosphates. The acidity dependence of the coprecipitation of americium by the zirconium and bismuth phosphates was also investigated. The experiments with the latter were per-

formed at acidities above 0.1 M because the hydrolysis products of a bismuth ion were precipitated at lower acidities without the addition of any precipitant. Significant coprecipitation of americium took place with amounts of zirconium and bismuth ions of more than 0.3 and 0.5 mg/ml respectively. Some typical results with a constant amount of the carrier-metal ion are shown in Fig. 3. The fractions of Am(III) and Am(V) carried by the zirconium phosphate increased with a decrease in the acidity below 0.1 M, while the acidity dependence of the fraction of Am(VI) carried was small. The complete coprecipitation of Am(III) by bismuth phosphate took place at the higher acidities, at which not so much Am(III) was carried by the zirconium phosphate, while the fraction of Am(VI) carried remained constant at lower levels. The behavior of Am(V) in the bismuth-phosphate system was not investigated, since the method of preparation and the stability of the Am(V) ion have not been established at higher acidities.

The molar ratio, PO_4/M, had a remarkable effect on the coprecipitation of americium, especially in the zirconium-phosphate system. As is shown in Fig. 4, 97—100 % of the Am(III) was carried at ratios less than 20, using a constant amount of zirconium ions, but the fraction of Am(III) carried decreased strikingly when the ratio increased to more than 20. On the other hand, the variations in the fractions of Am(V) and Am(VI) carried were very small, even at ratios more than 20. The separation of the precipitate and the supernatant by centrifuging was not complete at ratios less than 2, since the fine suspension of the zirconium phosphate could hardly be centrifuged at all. The fraction of americium carried by the bismuth phosphate under the given conditions is also postulated in Table 1.

Analysis of the Multi-component Solutions. The multi-component solutions, which were prepared by mixing independent solutions of Am(III), Am(V), and Am(VI), had the following compositions with respect to the oxidation state of americium: Sample 1: Am(III) 55.4±0.3 % and Am(V) 44.6±0.2 %; sample 2: Am(III) 48.5±0.3 % and Am(VI) 51.5±0.3 %, and Sample 3: Am(III) 34.1±0.2 %, Am(V) 30.7± 0.2 %, and Am(VI) 35.2±0.2 %.

Suitable aliquots of a sample solution were simultaneously taken for the six kinds of coprecipitation experiments under the conditions presented in Table 1; the results are shown in Table 2. If the Am(III), Am(V),

a) Experimental conditions are given in Table 1.

and Am(VI) in the multi-component solution all behave independently in the course of the coprecipitation process, the fraction of americium carried under the i condition may be given as:

$$Y^i = f_{III}Y^i_{III} + f_V Y^i_V + f_{VI}Y^i_{VI}, \quad (1)$$

where Y^i_x is the fraction of Am(x) carried which is obtained in the independent system, and where f_x is the mole fraction of Am(x) in the multi-component solution. Then, the fraction of americium carried from the multi-component solution was calculated according to Eq.(1) by the use of the Y^i_x given in Table 1 and the f_x described previously; it is also presented in Table 2. The calculated values nearly agree with the observed values in all cases. Therefore, the assumption that Y^i_V in the bismuth-phosphate system is very small is reasonable.

By the way, Eq.(1) can also be written as Eq.(2), for instance, because $f_{III}+f_V+f_{VI}=1$:

$$Y^i = f_{III}(Y^i_{III}-Y^i_{VI}) + f_V(Y^i_V-Y^i_{VI}) + Y^i_{VI} \quad (2)$$

Therefore, if the Y^i_x is reproducibly established under the given condition, i, the mole fraction, f_x, in the multi-component solution can be deduced by solving two simultaneous equations like Eq.(2) with two unknowns. For instance, when two pairs of data obtained for the same sample solution in both lanthanum- and thorium-fluoride systems were analyzed, it was found that the calculated mole fractions satisfactorily agreed with those known previously, especially in the thorium-fluoride system (*cf.* Table 3).

Discussion

It has been found that the coprecipitation behavior of Am(III) and Am(VI) with lanthanum fluoride agree essentially with that reported previously.[2] On the other hand, the present work revealed the chemical behavior of Am(V) in the lanthanum-fluoride system for the first time. Portions of the Am(V) were carried by the lanthanum fluoride in proportion to the amounts of lanthanum ions of more than 0.04 mg/ml. Nearly the same results have been obtained in the thorium-fluoride system.

The processes by which the tracer is carried by a precipitate formed in the presence of the tracer have been discussed by many workers-for instance, by Bonner and Kahn[10] and by Starik.[11] The coprecipitation processes can be classified as follows:

(a) Isomorphous replacement.

(b) Adsorption. Chemical adsorption and ion-exchange adsorption.

(c) Anomalous-mixed-crystal formation.

(d) Internal adsorption.

The available information concerning the fluoro-complex formation of americium[12] or those elements whose chemical properties closely resemble those of americium, such as neptunium and plutonium,[13] suggests that the predominant species of Am(III), Am(V), and Am(VI) in the floride solutions investigated are the insoluble AmF_3, insoluble AmO_2F (or $NH_4AmO_2F_2$), and soluble $AmO_2F_4^{2-}$(and/or $AmO_2F_3^-$) respectively. The observation that both the amorphous lanthanum and thorium fluorides carried more of the insoluble and neutral species of Am(III) and Am(V) than the ionic species of Am(VI) may be explained by the adsorption process, especially by the chemical adsorption process. This mechanism is based on the phenomenon that a tracer is carried well when it forms an insoluble compound at macro concentrations. In this sense, the fluoride species of Am(V) may not be so insoluble as AmF_3, for Am(V) is less carried than Am(III). The findings obtained in the present studies with regard to the dependence of the coprecipitation of americium on the several parameters can be easily correlated to the extent to which the complex formation of americium occurs.

The coprecipitation behavior of americium in the ceric-fluoride system was considerably different from that in the other fluoride systems, and it could not be

explained by the argument presented above. Evidently the precipitate of ceric fluoride was not amorphous, but crystalline. It is known that Am(III) and Ce(IV) fluorides have a hexagonal structure.[14,15] On the other hand, if an $NH_4AmO_2F_2$ crystal is isostructural to $KAmO_2F_2$, it may be rhombohedral.[16] Therefore, it is reasonable that the ceric fluoride carries the isomorphous AmF_3 better than either the heteromorphous $NH_4AmO_2F_2$ or the ionic species of Am(VI), according to the isomorphous replacement process.

On the other hand, the behavior of americium in the zirconium-phosphate system is rather complex. All of the experiments were performed at low temperatures and within a short time, taking into account the instabilities of the higher oxidation states of americium. Such experimental conditions resulted in an ununiform and less reproducible precipitation of the zirconium phosphate. The available information concerning the phosphato-complex formation of americium,[17] neptunium,[18] and plutonium,[19] and the behavior of americium in a phosphoric acid,[20] suggests that the predominant species of Am(III), Am(V), and Am(VI) in the phosphate solutions examined are the Am^{3+} (and/or $AmH_2PO_4^{2+}$), AmO_2^+(and/or $AmO_2H_2PO_4$), and $AmO_2H_2PO_4^+$ ions respectively. It is well known that a crystal of the preliminarily-prepared zirconium phosphate has ability of ion-exchange adsorption.[6] Therefore, the coprecipitation of the ionic species of americium by zirconium phosphate must result mainly from the ion-exchange adsorption. The results obtained in the zirconium-phosphate system suggest that the adsorbability of the species decrease in this order: $Am^{3+} > AmH_2PO_4^{2+} > AmO_2^+ > AmO_2H_2PO_4^+ \gg AmO_2H_2PO_4$. The decrease in the coprecipitation of Am(III) with an increase in PO_4/Zr, as is shown in Fig. 4, can be explained by the formation of less adsorbable phosphate species.

By the way, the fine crystalline bismuth phosphate carried Am(III) completely even at higher acidities at which the zirconium phosphate did not so carry it. It seems that this finding cannot be explained simply by the ion-exchange adsorption process, but can de explained by the argument used in the case of the crystalline ceric fluoride. If this is true, Am(III) may form a phosphate compound which is isostructural to a hexagonal bismuth phosphate[21] as well as lanthanoid(III) ions.[22]

The analytical results obtained for the multi-component solutions demonstrate that the perturbation of the oxidation state in the course of the coprecipitation process was negligible, and that the fraction of americium carried by the precipitates studied was additive and constitutive. Equation (1) or Eq. (2) guarantees that the coprecipitation behavior of each oxidation state of americium must be established under the given conditions. In the lanthanum- and thorium-fluoride systems, two sets of analytical conditions have been established; they are shown in Table 1. Therefore, the distribution of the oxidation state of americium in the multi-component solutions can be approximately deduced by investigating the coprecipitation of americium by the lanthanum or thorium fluoride under the recommended conditions, followed by solving two simultaneous equations like Eq. (2). However, the sets of such conditions could not be established in the ceric-fluoride and bismuth-phosphate systems alone.

Studies on Mass Spectrometry of Metal Chelates. IV. Synthesis and Mass Spectrometry of Cobalt(III) Mixed Ligand Chelates

Yoshinori KIDANI, Shinobu NAGA, and Hisashi KOIKE*

Faculty of Pharmaceutical Sciences, Nagoya City University, Tanabe-dori, Mizuho-ku, Nagoya 467

** School of Medical Technology and Nursing, Fujita Gakuen University, Toyoake City, Aichi Prefecture 470-11*

(Received July 11, 1974)

The ligand substitution reaction of $Co(acac)_3$ proceeded with other ligands L (L=oxine, 2-Me-oxine, 4-Me-oxine, 5-Me-oxine, and 7-Me-oxine), to afford mixed ligand chelates, $Co(acac)_2(L)$ and $Co(acac)(L)_2$. Their mass spectra gave the following fragmentation patterns. The $Co(acac)_2(L)$ type chelate gave a fragment ion Co(acac)(L), produced by the loss of one molecule of acac from the molecular ion. At the same time it produced another fragment ion, $Co(acac)_2$, by the loss of L from the molecular ion. From this fragmentation pattern it was confirmed that the compound is a mixed ligand chelate having the binding ratio Co: acac: L=1: 2: 1. The $Co(acac)(L)_2$ type chelate produced a fragment ion, Co(acac)(L), by the loss of one molecule of L from the molecular ion, and another fragment ion of $Co(L)_2$ by the loss of acac from the molecular ion. From this fragmentation pattern it was confirmed that the compound is another mixed ligand chelate having the binding ratio Co: acac: L= 1: 1: 2.

In order to apply mass spectrometry to the investigation of metal chelates, the authors reported on the mass spectrometric studies of the divalent metal chelates of 8-quinolinol (oxine),[1] 8-quinolinethiol (thiooxine),[2] 2-methyl-8-quinolinol (2-Me-oxine), 4-methyl-8-quinolinol (4-Me-oxine), 5-methyl-8-quinolinol (5-Me-oxine), 7-methyl-8-quinolinol (7-Me-oxine), and 5-chloro-8-quinolinol (5-Cl-oxine).[3] As a part of this study, the authors attempted to apply mass spectrometry to the mixed ligand chelates. Cobalt(III) mixed ligand chelates with 2,4-pentanedione (acac) and oxine,[4] 2-, 4-, 5-, and 7-Me-oxine were newly synthesized, and analyses of their mass spectra, thin layer chromatogram and infrared absorption spectra were made. In this paper, syntheses of two types of Co(III) mixed ligand chelate with acac and oxine and its mono-methyl derivatives are described. From identification of the mixed ligand chelate formation by thin layer chromatography, infrared absorption spectral analyses and elementary analyses, mass spectrometry has been carried out, the fragmentations mainly being discussed. No investigation of the application of mass spectrometry to mixed ligand chelates seems to have been reported yet. The present studies suggest that mass spectrometry could well be applied to the identification of mixed ligand chelate formation and also to the determination of a binding ratio of ligand to metal.

Results and Discussion

Syntheses of Mixed Ligand Chelates. Various mixed ligand chelates were newly synthesized by means of ligand substitution reactions of tris(acetylacetonato) cobalt(III), $Co(acac)_3$, with oxine, 2-, 4-, 5-, and 7-Me-oxine. The reaction products were separated by means of column chromatography into four fractions a, b, c, and d as follows: Ia—Id for oxine, IIa—IId for 2-Me-oxine, IIIa—IIId for 4-Me-oxine, IVa—IVd for 5-Me-oxine, and Va—Vd for 7-Me-oxine.

Thin Layer Chromatography. Four fractions of five oxine derivatives. The twenty fractions separated by column chromatography were identified in comparison with thin layer chromatography of the parent metal chelates, $Co(acac)_3$, $Co(oxine)_3$, and $Co(mono\text{-}Me\text{-}oxine)_3$ (Table 1). It was confirmed that Ia, IIa, IIIa, IVa, and Va have the same R_f value as $Co(acac)_3$; Id, IId, IIId, IVd, and Vd have the same R_f value as $Co(oxine)_3$, $Co(2\text{-}Me\text{-}oxine)_3$, $Co(4\text{-}Me\text{-}oxine)_3$, $Co(5\text{-}Me\text{-}oxine)_3$, and $Co(7\text{-}Me\text{-}oxine)_3$, respectively. On the other hand, b and c fractions of I—V show characteristic R_f values, quite different from the corresponding parent metal chelates, suggesting the production of mixed ligand chelates.

Infrared Absorption Spectra. Infrared (IR) absorption spectra were measured (4000—400 cm^{-1}) by means of the KBr disc method. Infrared absorption spectra of fraction a of I—V coincided with the spectrum of $Co(acac)_3$, while fraction d of I—V gave the same IR spectra as those of $Co(oxine)_3$, $Co(2\text{-}Me\text{-}oxine)_3$, $Co(4\text{-}Me\text{-}oxine)_3$, $Co(5\text{-}Me\text{-}oxine)_3$, and $Co(7\text{-}Me\text{-}oxine)_3$, respectively. On the other hand, similar spectra were shown for Ib and Ic, IIb and IIc, IIIb and IIIc, IVb and IVc, and Vb and Vc. In addition they have characteristic absorption bands of the corresponding parent metal chelates. It thus appears that fractions b and c of I—V possess acetylacetone and either oxine or mono-Me-oxine. From a detailed investigation of the spectra between fractions Ib and Ic, it was found that in the IR spectrum of Ib the intensity of the absorption band at 1513 cm^{-1} (assignable to the C=O stretch-

TABLE 1. R_f VALUES OF MIXED LIGAND CHELATES ON THIN LAYER CHROMATOGRAM

Oxine	Ia (0.63)	Ib (0.25)	Ic (0.30)	Id (0.12)
2-Me-oxine	IIa (0.65)	IIb (0.21)	IIc (0.18)	IId (0.10)
4-Me-oxine	IIIa (0.63)	IIIb (0.29)	IIIc (0.35)	IIId (0.16)
5-Me-oxine	IVa (0.64)	IVb (0.25)	IVc (0.28)	IVd (0.16)

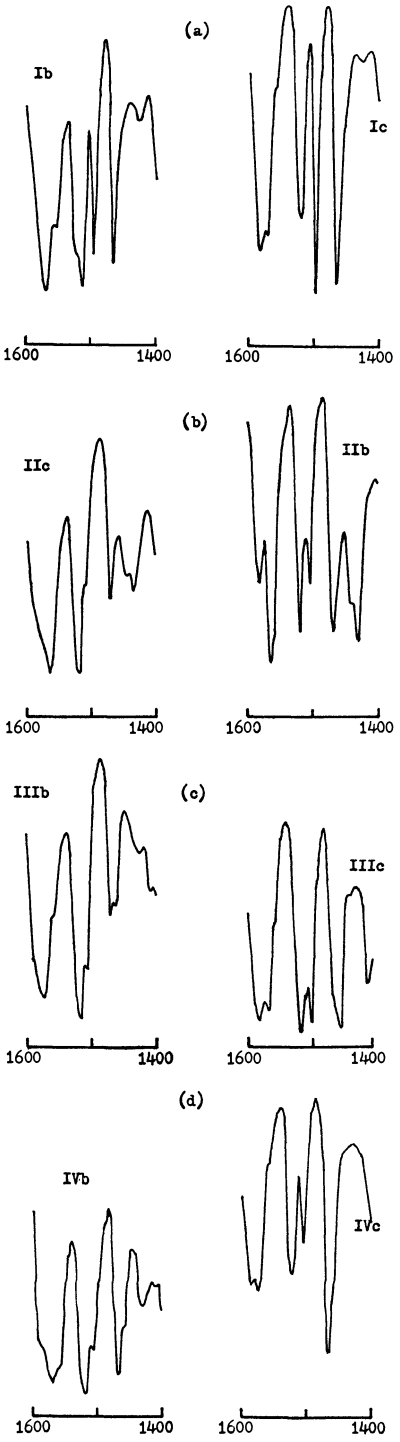
ing vibration of $Co(acac)_3$[5]) is stronger than that at 1496 cm^{-1} (assignable to the quinoline ring vibration[6]), but in that of Ic the intensity of the absorption band at 1497 cm^{-1} is stronger than that at 1520 cm^{-1} (Fig. 1-a). In the IR spectra of IIc, IIIb, IVb, and Vb, absorption bands at 1505 cm^{-1} assignable to the quinoline ring vibration are observed as a shoulder, while in those of IIb, IIIc, IVc, and Vc absorption bands with medium strength are observed (Fig. 1-b, c, d, and e). The fractions can be classified into two groups, (1) in which the quinoline ring vibration band is of low intensity (Ib, IIc, IIIb, IVb, and Vb), and (2) in which it is



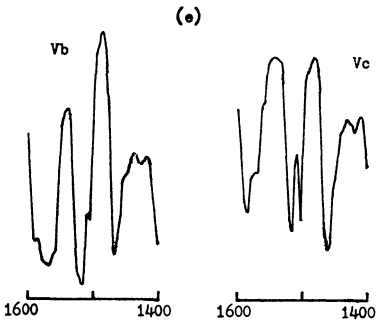


Fig. 1. IR spectra of mixed ligand chelates.
Ib; $Co(acac)_2(oxine)$, Ic; $Co(acac)(oxine)_2$, IIb; $Co(acac)(2\text{-Me-oxine})_2$ IIc; $Co(acac)_2(2\text{-Me-oxine})$, IIIb; $Co(acac)_2(4\text{-Me-oxine})$, IIIc; $Co(acac)(4\text{-Me-oxine})_2$, IVb; $Co(acac)_2(5\text{-Me-oxine})$, IVc; $Co(acac)(5\text{-Me-oxine})_2$, Vb; $Co(acac)_2(7\text{-Me-oxine})$, Vc; $Co(acac)(7\text{-Me-oxine})_2$.

of high intensity (Ic, IIb, IIIc, IVc, and Vc). It appears that the ligand substitution reaction of $Co(acac)_3$ takes place with the stepwise substitution of the acac ion in $Co(acac)_3$ with the other ligand. It is thus presumed that group (1) includes the mixed ligand chelates produced by the substitution of one acac ion in $Co(acac)_3$ with the other ligand, and group (2) the chelate produced by the substitution of two acac ions in $Co(acac)_3$ with the other ligands.

Elementary analyses of these mixed ligand chelates coincided well with the theoretical values as shown in Table 2.

Mass Spectra. Mass spectra of compounds Ib and Ic, inferred from their IR spectra, are shown in Fig. 2. They are seen to have compositions $Co(acac)_2$-(oxine) and $Co(acac)(oxine)_2$, respectively. In the

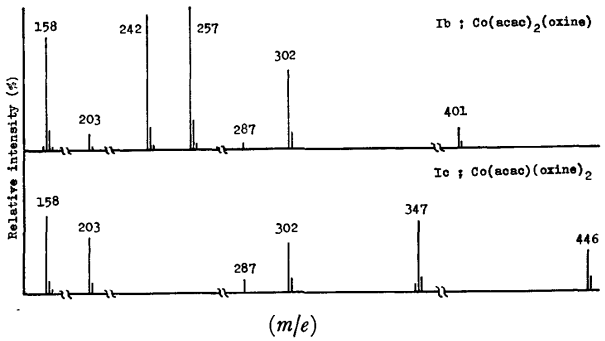

Fig. 2. Mass spectra of $Co(acac)_2(oxine)$ and $Co(acac)(oxine)_2$.

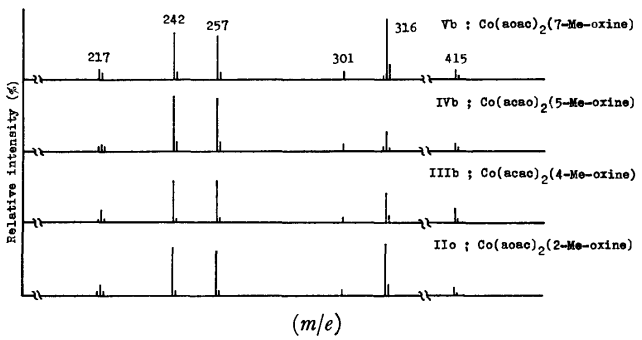

Fig. 3. Mass spectra of $Co(acac)_2$(2-Me-oxine), $Co(acac)_2$(4-Me-oxine), $Co(acac)_2$(5-Me-oxine), and $Co(acac)_2$(7-Me-oxine).

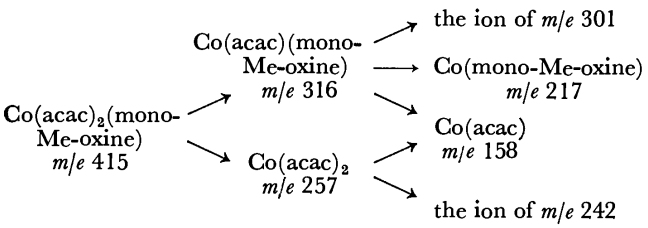
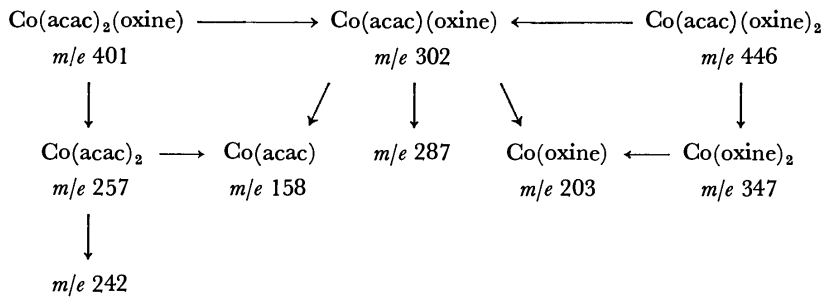
highest mass region of their spectra, the peak appears at *m/e* 401 and 446, respectively, which correspond to the respective molecular weight of the inferred mixed ligand chelates. Peaks at *m/e* 302, 287, 203, and 158 are commonly observed in both spectra. The peak at *m/e* 302 appears with a difference of 99 amu from *m/e* 401 and 144 amu from *m/e* 446. The peak at *m/e* 203 appears with a difference of 99 amu from the peak at *m/e* 302, and that at *m/e* 158 with a difference of 144 amu from the peak at *m/e* 302. The 99 amu corresponds to one molecule of acac, while the 144 amu corresponds to one molecule of oxine. Consequently, it appears that the fragment ion of *m/e* 302 has a 1: 1: 1 ratio of Co: acac: oxine, and the fragment ions of *m/e* 203 and 158 have a 1: 1 ratio of Co: oxine and Co: acac, respectively. It seems that the ion of *m/e* 287 is produced by the loss of $CH_3\cdot$ from the ion of *m/e* 302. Two peaks at *m/e* 257 and 242 are observed only in the spectrum of $Co(acac)_2(oxine)$, and they correspond to the difference between the molecular ion peak (*m/e* 401) and 144 or 144+15 amu. Accordingly, the ion of *m/e* 257 has the composition $Co(acac)_2$, while that of *m/e* 242 is produced by the loss of $CH_3\cdot$ from the ion of *m/e* 257. Since the peak at *m/e* 347 observed only in the spectrum of $Co(acac)(oxine)_2$ corresponds to the molecular ion peak (*m/e* 446) minus 99 amu, it appears that the ion has the composition $Co(oxine)_2$. The fragmentation pathways of these mixed ligand chelates are shown in Scheme 1. Based on these fragmentation patterns, the compounds were identified as the mixed ligand chelates having a 1: 2: 1 and 1: 1: 2 binding ratio of Co: acac: oxine.

Figure 3 shows mass spectra of the compounds inferred to have respective compositions $Co(acac)_2$(2-Me-oxine), $Co(acac)_2$(4-Me-oxine), $Co(acac)_2$(5-Me-oxine), and $Co(acac)_2$(7-Me-oxine). Each has a peak in the highest mass region at *m/e* 415, which corresponds to the molecular weight of the assumed compound. In the mass range lower than *m/e* 415, major peaks were observed at *m/e* 316, 301, 257, 242, 217, and 158. It appears that these peaks originate in the ion produced according to the fragmentation pathway shown in Scheme 2. The fragment ion of *m/e* 316 with the composition Co(acac)(mono-Me-oxine) is produced by the loss of one molecule of acac from the molecular ion (*m/e* 415). On the other hand, the fragment ion of *m/e* 257 with the composition $Co(acac)_2$ is produced by the loss of mono-Me-oxine (158 amu) from the molecular ion. Other fragment ions of *m/e* 158 and 217 are produced by the loss of acac and mono-Me-oxine from the ion of *m/e* 316, respectively. It seems that the ion of *m/e* 301 is produced by the loss of $CH_3\cdot$ from the ion of *m/e* 316. Based on this fragmentation pattern, it has been confirmed that these mixed ligand chelates have a 1: 2: 1 binding ratio of Co: acac: mono-Me-oxine.

Fugure 4 shows mass spectra of the compounds assumed to have respective compositions Co(acac)(2-Me-oxine)$_2$, Co(acac)(4-Me-oxine)$_2$, Co(acac)(5-Me-oxine)$_2$, and Co(acac)(7-Me-oxine)$_2$. The spectra of



Scheme 2. Fragmentation of $Co(acac)_2$(mono-Me-oxine) type mixed ligand chelate.



Scheme 1. Fragmentation of mixed ligand chelates, $Co(acac)_2(oxine)$ and $Co(acac)(oxine)_2$.

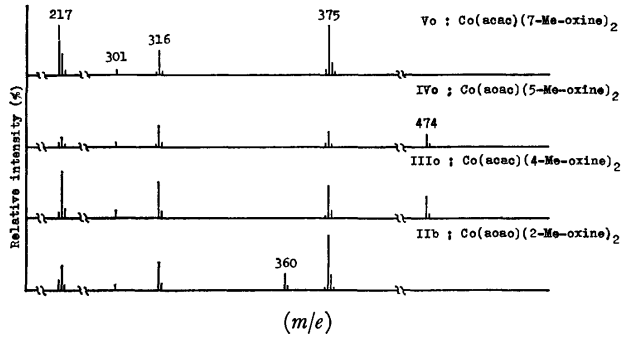


Fig. 4. Mass spectra of Co(acac)(2-Me-oxine)$_2$, Co(acac)-(4-Me-oxine)$_2$, Co(acac)(5-Me-oxine)$_2$, and Co(acac)-(7-Me-oxine)$_2$.

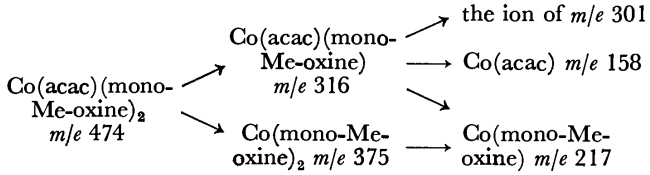
both Co(acac)(4-Me-oxine)$_2$ and Co(acac)(5-Me-oxine)$_2$ have a peak at *m/e* 474 in the highest mass region, corresponding to the molecular weight of the assumed compound, but the spectra of Co(acac)(2-Me-oxine)$_2$ and Co(acac)(7-Me-oxine)$_2$ do not give a molecular ion peak at *m/e* 474. The reason for its absence is explained by the fact that the two mixed ligand chelates have two molecules of 2-Me-oxine or 7-Me-oxine and therefore the chelates are liable to undergo steric hindrance. Thus, it may be difficult for the molecular ion produced by electron impact to exist stably. Since the peak at *m/e* 375 observed in each spectrum corresponds to the fragment ion with a difference of 99 amu (one molecule of acac) from the molecular ion peak, it appears that the peak at *m/e* 375 is a fragment ion having the composition Co(mono-Me-oxine)$_2$. The peak at *m/e* 360 can only be observed in the spectrum of Co(acac)(2-Me-oxine)$_2$. This corresponds to the ion produced by the loss of $CH_3\cdot$ from the ion of *m/e* 375, and the fragmentation pattern coincides with that of Co(2-Me-oxine)$_2$ already described by the authors.[3] The peak at *m/e* 316 appears with a difference of 158 amu (corresponding to one molecule of mono-Me-oxine) and is also observed in the spectrum of Co(acac)$_2$(mono-Me-oxine). Thus it is the peak corresponding to the fragment ion having the composition Co(acac)(mono-Me-oxine). The fragmentation pattern is shown in Scheme 3. Based on this fragmentation pattern, it has been confirmed that these mixed ligand chelates have a 1 : 1 : 2 binding ratio in Co : acac : mono-Me-oxine.

It may be suspected that each of these chelates containing either 2- or 7-Me-oxine is a mixture of Co(acac)-(mono-Me-oxine) and Co(mono-Me-oxine)$_2$, since no molecular ion peak was observed at *m/e* 474. However, the authors confirmed that all the compounds synthesized and used for the measurement of mass spectra are completely pure single substance by identification



Scheme 3. Fragmentation of Co(acac)(mono-Me-oxine)$_2$ type mixed ligand chelate.

of thin layer chromatography and elementary analyses as is shown in Table 2. Based on these facts, it seems that the spectra are not those of a mixture of Co(acac)-(mono-Me-oxine) and Co(mono-Me-oxine)$_2$.

Experimental

Reagents. Co(acac)$_3$, oxine, and 2-Me-oxine of special grade regents were used without further purification. 4-Me-oxine,[7] 5-Me-oxine,[8] and 7-Me-oxine[8] were synthesized by the reported methods. Kieselgel 60, Merck Co., and Activated Alumina, Wako Pure Chemicals Co., were used as adsorbent for column chromatography. Kieselgel H nach Stahl, Merck Co., was used as adsorbent for thin layer chromatography.

Apparatus. IR spectra were measured with a Nihon Bunko JASCO IRA-2 by means of the KBr disc method. Mass spectra were measured with a Hitachi RMU-7 mass spectrometer by introducing the samples through a direct inlet system. The other conditions were as follows; ionizing voltage 70 eV, ion accelerating voltage 1800 V, total emission current 80 μA, ion source temperature 250 °C, and sample evaporating temperature 110—240 °C.

Thin Layer Chromatography. Thin layer chromatography was carried out on plates of 0.25 mm thickness, which were activated at 110 °C for 1 hr. The solvent mixture used was benzene: methanol=95:5 v/v.

Synthesis. Tris(acetylacetonato) cobalt (III) and oxine or its methyl derivatives are dissolved in either water, methanol, or a mixed solvent of acetone and methanol and this solution in the presence of active charcoal is refluxed on a water bath. After a few minutes, the charcoal is filtered off while hot and the residue is washed well with chloroform. This washing is combined to the preceding filtrate and the solution is concentrated under reduced pressure. The concentrate thus obtained was separated by column chromatography with silica gel or alumina (eluent; chloroform or benzene).

The authors' thanks are due to Professor Akira Tatematsu, the Faculty of Pharmacy, Meijo University, for permission to use the apparatus.

Synthesis and Proton Magnetic Resonance Spectra of Some Dichloro-(picolinaldimine*)palladium(II) and -platinum(II) Complexes

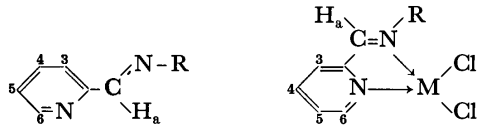
Katsuhiko KAWAKAMI, Takeshi OHARA, Gen-etsu MATSUBAYASHI, and Toshio TANAKA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

(Received October 22, 1974)

A series of dichloro(picolinaldimine)palladium(II) and -platinum(II) complexes was prepared. The PMR parameters, the chemical shifts of the ligand protons and the coupling constants between the platinum-195 nucleus and protons attached to carbons adjacent to donor nitrogens of the ligands, are discussed in the light of the metal-to-ligand bonds.

Recently we have reported that some picolinaldimines (**A**) form stable complexes with dimethyltin dichloride (**B**, M=$(CH_3)_2Sn$(IV)).[1] The ligands of this kind are interesting in that (1) the coordinating ability of the imine nitrogen atom can be altered by varying the substituent on it, (2) their configurational change from *trans* to *cis* on complex formation (**A** and **B**) is accompanied by remarkable changes in the chemical shifts of the various protons, and (3) information on the coordination bonds can be obtained through the observation of spin-spin couplings between the H_a and H_6 protons and the acceptor metal nucleus, if any, as was found in their dimethyltin dichloride complexes.[1]



(**A**) (**B**)

M=$(CH_3)_2Sn$ (IV), Pd (II), Pt (II)

This paper will report on the synthesis of a series of dichloro(picolinaldimine)palladium(II) and -platinum-(II) complexes (**B**, M=Pd(II) and Pt(II)) and on their PMR parameters in relation to the nature of the metal-to-ligand bonds.

Experimental

Materials. Na_2PdCl_4 and K_2PtCl_4 were reagent grade and were used as supplied. The picolinaldimines[1] and dichlorobis(benzonitrile)platinum(II)[2] were prepared by the literature methods.

Dichloro(picolinaldimine)palladium(II) Complexes. To a solution of Na_2PdCl_4 (0.50 g, 1.44 mmol) in C_2H_5OH (40 ml) was added dropwise a solution of *p*-tolylpicolinaldimine (0.34 g, 1.72 mmol) in C_2H_5OH (5 ml). Microcrystals were precipitated immediately. The mixture was then stirred for 1 hr at the ambient temperature. The resulting product was filtered and recrystallized from CH_2Cl_2/CH_3CN to give orange crystals of dichloro(*p*-tolylpicolinaldimine)palladium(II) (0.46 g, 85%).

Other Pd complexes were similarly obtained with the exception of the *n*-butyl derivative, which was recrystallized from CH_2Cl_2/petroleum ether.

Dichloro(picolinaldimine)platinum(II) Complexes. To a solution of $(C_6H_5CN)_2PtCl_2$[2] (0.30 g, 0.63 mmol) in 1,2-$C_2H_4Cl_2$ (30 ml) was added a solution of *p*-tolylpicolinaldimine (0.13 g, 0.64 mmol) in the same solvent (5 ml). The solution was refluxed for 4 hrs and then concentrated under reduced pressure to give an oily product, which was stirred in ether for 1 hr. The resultant precipitate was recrystallized from hot methanol to yield orange crystals of dichloro(*p*-tolylpicolinaldimine)-platinum(II) (0.17 g, 58%).

The *p*-chloro and *p*-nitro-phenyl analogs were precipitated as orange solids, which were subsequently recrystallized from hot acetonitrile.

Table 1 shows the melting points, analytical data, and molecular weights of the complexes, together with their ν(M–Cl) frequencies.

Instrumentation. The molecular weights and IR and PMR spectra were obtained as has been described elsewhere.[1] The PMR spectra were usually recorded in CH_3CN at 50 °C because of the limited solubility of the complexes at 25 °C. Little temperature effect on the PMR parameters was observed in the *n*-butylpicolinaldimine complexes of Pd(II) and Pt(II); this was assumed to be true for the other as well. The *p*-substituted picolinaldimine complexes of Pt(II) showed a limited solubility in most organic solvents, and so their spectra were obtained in *N,N*-dimethylacetamide. The solvent effect on PMR parameters in the two solvents was checked by using dichloro(*n*-butylpicolinaldimine)platinum(II) and was found to be small. Tetramethylsilane was used as the internal reference.

Results and Discussion

The analytical data (Table 1) confirm that a series of picolinaldimines forms 1:1 complexes with palladium-(II) and platinum(II) dichlorides. The molecular-weight determinations of some representative complexes showed that they were monomeric in solution. Both Pd(II) and Pt(II) complexes exhibit two ν(M-Cl) bands in the region of 360—325 cm^{-1} (Table 1). These facts indicate that the complexes adopt a square-planar configuration with the chelating ligand, as has been illustrated above in (**B**) (M=Pd(II) and Pt(II)). The chelation of the ligand is further verified in the Pt complexes from the observation of spin-spin couplings between the ^{195}Pt nucleus and the H_6, H_a, and the α-CH protons of the alkyl group on the imine nitrogen.

Table 2 shows the relevant PMR data of the picolinald imine complexes of Pd(II) and Pt(II). The H_3 and H_6 signals of these ligands occur at low fields; this is taken to be evidence for the *trans* structure (**A**), the reasons having been discussed previously in the case of *p*-anisylpicolinaldimine.[1]

On complex formation, the chemical shift of each proton may be influenced by some of the following three effects; (1) a low-field shift caused by the electron-

* Chem. Abstr. name: 2-formimidoylpyridine

a) Measured in CH_3CN at 50 °C, unless otherwise noted. b) Measured in *N*,*N*-dimethylacetamide at 25 °C. c) The values in parentheses are $\Delta\delta$ ($\delta_{complexed}-\delta_{free}$). d) Could not be obtained since the signal of the ligand was obscured by other signals. e) Could not be measured because of too weak intensity. f) Assignments for the H_3, H_4, and H_5 protons are ambiguous because of too weak intensity of the signals.

withdrawal, (2) a high-field shift caused by the disappearance of the paramagnetic effect of the imine nitrogen (to H_3)[1] and that of the ring nitrogen (to H_6 and H_a), and (3) a low-field shift caused by the paramagnetic effect of the halogen atoms[1] and/or certain d orbitals of the central metal atom[3] because of their proximity to the H_6 and α-CH protons, as has been suggested in the case of the complexes of pyridine and its derivatives with metal halides. The almost unchanged chemical shifts of the H_3 proton in all the complexes

(Table 2) are due to the two mutually opposite effects, (1) and (2), when the ligand takes the *cis* configuration (**B**) with respect to the nitrogen atom. The coordination shifts, $\Delta\delta$ ($\delta_{complex}-\delta_{free}$), of the H_4 and H_5 protons are not significantly different in the Pt and Pd complexes. The $\Delta\delta$ values of these protons are influenced only by the (1) effect, which, in turn, is a measure of the $M-N_{ring}$ bond strength if the effect of the substituent on the imine nitrogen through the azomethine group is assumed to be negligible. Thus, it may be suggested that the $Pd-N_{ring}$ bond is nearly as strong as the Pt counterpart.

On the other hand, the $\Delta\delta$ values of the H_6 proton are much larger in the Pt than in the Pd complexes; this is a result of the predominance of the (3) effect in the Pt complexes, since the (1) and (2) effects seem to be similar in the Pd and Pt complexes, as has been discussed above.

The $\Delta\delta$ values of the H_a proton in the Pt complexes are also large, whereas those of the Pd complexes are close to zero except for those of the benzyl and *p*-tolyl complexes. The $\Delta\delta$ values of the H_a proton can be explained in a manner similar to that used to explain those of the H_3 proton. Thus, in the case of the Pd complexes the (1) effect and the (2) effect of the ring nitrogen upon $Pd-N_{imine}$ coordination appear to cancel out each other. However, the large $\Delta\delta$ values of the H_a proton in the Pt complexes indicate the predominance of the former; this may be explained by assuming a stronger coordination in the $Pt-N_{imine}$ than in the $Pd-N_{imine}$ bond. In fact, the values of the α-CH protons are larger in the Pt than in the Pd complexes, although the difference in the (3) effect may be another factor.

The large values of the coupling constants, $^3J(Pt-H_a)$, $^3J(Pt-H_6)$, and $^3J(Pt-N-CH-)$, given in Table 2 confirm the presence of solid Pt–N bonds in the Pt complexes. The first value is overwhelmingly larger than the latter two. This must be due to the *trans* arrangement of the H_a proton and the ^{195}Pt nucleus with respect to the C=N bond.[4] The observation of $^3J(Pt-H_6)$ in our complexes may be the first example in the $PtCl_2$ complexes with pyridine and its derivatives; it stems from the chelation of the ligands.

(Received October 29, 1974)

Complexes formed by the reactions of nitrosylruthenium(III) with acetylacetone were investigated. The following products: $[Ru(acac)_2(hia)]$, **1**; *cis*-$[RuCl(NO)(acac)_2]$, **2**; and $[\{Ru(NO)(acac)_2\}_4]$, **3**; (acac= $C_5H_7O_2^-$ and hia=$C_5H_6NO_3^-$), were isolated as crystals and were characterized. On the basis of chemical and thermal analyses, and on the basis of observations of the magnetic properties, the conductivities, the molecular weights, the infrared spectra, and the NMR spectra, it was concluded that **1** contains the hydroxyiminoacetyl acetonato ligand, which is formed by the reaction of the coordinated nitrosyl group with acetylacetone, and that **2** contains a terminal nitrosyl group, and **3**, bridging nitrosyl groups.

The reactivity of coordinated nitrosyl has received much attention recently. The reactions of a variety of nitrosylruthenium(III) complexes with nucleophiles, such as ammonia, hydrazins, hydroxylamine, potassium azide, and potassium hydroxide, have recently been investigated.[1-7] The reactions of nitrosylruthenium-(III) halides with reducing reagents, such as tin(II) chloride and formaldehyde, have also been reported.[8,9] This paper will describe the preparation and characterization of the ruthenium complexes with the coordinated hydroxyiminoacetylacetonato or bridging nitrosyl groups obtained by the reactions of nitrosylruthenium(III) with acetylacetone.

Experimental

Preparation. Bis(acetylacetonato)hydroxyiminoacetylacetonatoruthenium(III), $[Ru(acac)_2(hia)]$, 1: To a hydrochloric-acid solution of nitrosylruthenium(III) (100 mg as Ru/10 ml) were added methanol (2 ml) and acetylacetone (2 ml). Then, the pH of the mixed solution was adjusted to 6.5 with an aqueous solution of potassium hydroxide. When the mixed solution was allowed to stand at room temperature for about a week, dark brown crystals appeared. The crystals were recrystallized from ethanol. Yield, 40 mg. Found: Ru, 23.9; C, 42.3; H, 4.75; N, 3.37%. Calcd for $[Ru(C_5H_7O_2)_2(C_5H_6NO_3)]$: Ru, 23.6; C, 42.1; H, 4.68; N, 3.28%.

Bis(acetylacetonato)chloronitrosylruthenium(III), $[RuCl(NO)(acac)_2]$, 2: To a hydrochloric-acid solution of nitrosylruthenium(III) (100 mg as Ru/10 ml) were added methanol (2 ml) and acetylacetone (2 ml). Then, the pH of the mixed solution was adjusted to 3.5 with an aqueous solution of potassium hydroxide. The solution was refluxed for 2 hr and was then allowed to stand at room temperature for several days, until dark brown crystals were separated out. The crystals were recrystallized from ethanol. Yield, 35 mg. This complex was also obtained from the filtrate of **3** when the filtrate was allowed to stand at room temperature for a long period. Found Ru, 27.4; C, 32.6; H, 3.80; N, 3.81; Cl, 9.57%. Calcd for $[RuCl(NO)(C_5H_7O_2)_2]$: Ru, 27.7; C, 32.9; H, 3.87; N, 3.84; Cl, 9.73%.

Cyclo-tetra-μ-nitrosyl-tetrakis(diacetylacetonato)ruthenium(II), $[\{Ru(NO)(acac)_2\}_4]$, 3: To a hydrochloric-acid solution of nitrosylruthenium(III) (135 mg as Ru/10 ml) were added acetylacetone (2 ml), and the pH of the solution was adjusted to 3.5 with an aqueous solution of potassium hydroxide. To this mixed solution, an equal volume of ethanol was added. The solution was refluxed for 50 min and was then allowed to stand at room temperature for about ten days, until dark green crystals were separated out. The crystals were recrystallized from a mixed solution of ethanol and benzene three times. Yield, 35 mg. Found: C, 36.2; H, 4.35; N, 4.18%. Calcd for $Ru(NO)(C_5H_7O_2)_2$: C, 36.5; H, 4.25; N, 4.25%.

Materials. Nitrosylruthenium(III) in a hydrochloric acid solution was prepared by a conventional method.[10] The nitrosylruthenium(III) chloride [^{15}N] was prepared by the method reported by Miki *et al.*[11] The palladium complexes, $[Pd(acac)_2]$ and [Pd(acac)(hia)], were prepared according to the method in the literature.[12] $[Pd(hia)_2]$ was obtained by the reaction of Pd(II) chloride with hia, which had been purchased from the Dojin Lab. (Kumamoto, Japan).

Measurements. The infrared spectra of these complexes were recorded on Leitz 221, JASCO DS-301, or Hitachi EPI-L spectrophotometers, using the KBr-pellet or Nujol-mull method. The NMR spectra were taken on a Hitachi R-22 instrument, with tetramethylsilane as the internal standard. The visible absorption spectra were recorded on a Hitachi-Perkin-Elmer 139 spectrophotometer. The conductivity and the molecular weight were measured with a Metrohm Konduktoskop E356 and with a Mecrolab Osmometer 302 respectively. The DTA and TG measurements were carried out by the use of a Rigaku TG-DTA standard-type apparatus. The measurments were made at a heating rate of 10 °C/min in atmosphere. The magnetic susceptibilities were measured by the Gouy method.

Results and Discussion

From the reactions between nitrosylruthenium(III) and acetylacetone, Complexes **1**, **2** and **3** were newly isolated. The chemical formulae of these complexes and some of their properties are shown in Table 1. The molecular weights of **1** and **3**, which were obtained in benzene by a vapor-pressure osmometry, corresponded to those of the monomeric and of the tetrameric species respectively. The molecular weight of **2** could not be measured because of an insufficient solubility in benzene, but the monomeric form of the complex can be expected from the observations of its IR and NMR spectra. All these complexes were non-electrolyte in benzene and DMF. The thermal properties of the complexes were examined by DTA and TG methods. **1**, **2**, and **3** decomposed at about 149 °C, 126 °C and 265 °C respectively, without showing any endothermic

a) In MeOH and in DMF. b) in MeOH.

peaks due to the deaquation of crystalline or coordinating water.

The structures of these complexes will now be discussed on the basis of their IR and NMR spectra and their magnetic properties.

$[Ru(acac)_2(hia)]$ (**1**): The composition of **1** is consistent with either of the following two formulae; $[Ru(acac)_2(hia)]$ and $[Ru(NO)(acac)_3]$. However, tris(acetylacetonato)nitrosylruthenium(III) was clearly excluded by the paramagnetism observed, since nitrosylruthenium(III) complexes are essentially diamagnetic. The observed magnetic moment (1.87 B.M.) is fairly close to the value, 1.73 B.M., estimated by the spin-only equation.

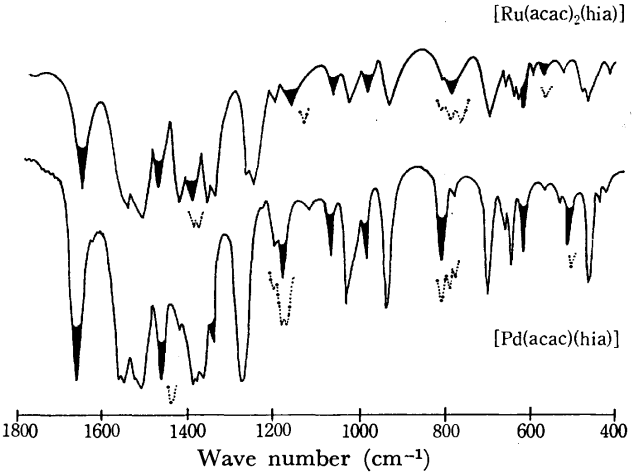

Fig. 1. Infrared spectra of $[Ru(acac)_2(hia)]$ and [Pd(acac)(hia)] (KBr disk). Painted peaks were assigned to the bands which were caused by the hia ligand. Identity of the ligand was established by a comparison of the infrared spectra of $[Ru(acac)_2(hia)]$ (**1**), $[RuCl(NO)(acac)_2]$ (**2**), $[Pd(acac)_2]$, [Pd(acac)(hia)] and $[Pd(hia)_2]$.
^{14}NO-complex, ——; ^{15}NO-complex, ·····.

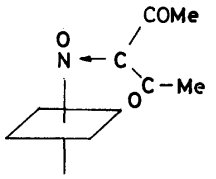

Fig. 2. Proposed structure for Complex **1**.

The infrared spectra of **1** and relevant compounds are shown in Fig. 1. The characteristic vibrations in **1** [^{14}N] and **1** [^{15}N] are summarized in Table 2. Recently, several complexes containing hia and analogous ligands were identified, by Masuda *et al.* and by White on the basis of their infrared spectra.[12,13] The spectral features observed here can be understood on the basis of the idea that one of the acetylacetonato ligands and the coordinated nitrosyl combine through the γ-carbon atom to produce the hia ligand, as is shown in Fig. 2. Evidence for the presence of the hia ligand in **1** may be found in the similarity between the infrared spectrum of **1** and that of [Pd(acac)(hia)], including their ^{15}N isotopic effects. As is shown in

Fig. 1, the bands due to the hia in both complexes were found in almost the same regions and intensities. By comparing the infrared spectrum of **1** with those of analogous complexes,[12-14] the bands at 1387, 1148, and 1660 cm^{-1} in **1** [^{15}N] can be assigned tentatively to the stretching vibrations of the C=N, N–O, and uncoordinated C=O groups of the hia ligand respectively. These bands seem to be most diagnostic for the characterization of this ligand.

cis-[RuCl(NO)(acac)$_2$] (**2**): **2** is diamagnetic. The infrared spectra of **2** [^{14}N] and **2** [^{15}N] are compared in the 200—4000 cm^{-1} region. The characteristic vibrations of both complexes are summarized in Table 2. By comparing these bands with the spectra of pentachloronitrosylruthenium(III) complexes and acetylacetonato metal chelate complexes,[15-19] the presence of the terminal nitrosyl ligand in **2** was easily verified.

Table 3. Proton magnetic resonance data (ppm) for complexes **2** and **3**

Complex	Solvent	Resonance	
		$-CH_3$	$-CH$
2, *cis*-[RuCl(NO)(acac)$_2$]	$CDCl_3$	2.05 2.14 2.24 2.29	5.47 5.73
3, [{Ru(NO)(acac)$_2$}$_4$]	$CDCl_3$	1.73 2.21	5.31

The NMR spectrum of **2** listed in Table 3 was measured in $CDCl_3$. The assignments are based on those for *cis*- and *trans*-β-diketonato complexes, which have been investigated extensively by Boucher *et al.*[20] The observed chemical shifts for the methyl and the methine protons provide proof that the complex has a *cis* arrangement of the chloride and the nitrosyl.

[{Ru(NO)(acac)$_2$}$_4$] (**3**): The molecular weight of **3** corresponded to that of a tetrameric species. X-Ray single crystal photographs of **3** showed that the cell volume of this complex was about 2598×10^{-24} cm^3 (uncalibrated film). The calculated density for two molecules per cell is 1.68 g/cm^3, and the observed density was 1.70 g/cm^3 (by floatation in CH_3Br and CCl_4). The possibility of **3** being a tri- or pentanuclear complex may thus be excluded.

The infrared spectrum of **3** is shown in Table 2. The absorption bands of the acetylacetonato moiety in **3** were identical with those of **2**, showing a chelate coordination of the ligand. No absorption band due to the nitrosyl stretching frequency of the linear or near-linear RuNO(III) group was found in the 1700—2000 cm^{-1} region. It has recently been revealed by structural investigations that a marked lowering of the nitrosyl stretching frequency reflects the presence of the NO^- ligand or the bridging nitrosyl ligand.[21-23] One of the present authors (M.M.) has reported that the infrared spectrum of a nitrosyl complex, which is believed to contain bridging nitrosyl, shows frequency shifts for the bands in the 1500, 800 and 550 cm^{-1} regions with the replacement of ^{14}N by ^{15}N.[9] ^{15}N substitution effects for **3** were observed, as is shown in Table 2. The strong band at 1573 cm^{-1} in **3** [^{14}N] was

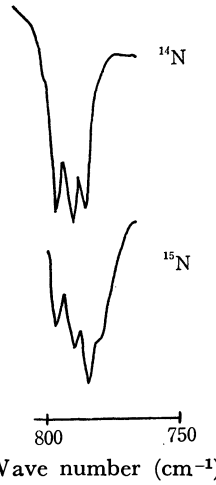

Fig. 3. IR spectra of Complex **3** at 800 cm^{-1} region (KBr).

partially split into two bands, at 1571 and 1543 cm^{-1}, in **3** [^{15}N]. The weak band at 553 cm^{-1} in **3** [^{14}N] was shifted to the lower-frequency side. As is shown in Fig. 3, a splitting of the bands was observed in the near 800 cm^{-1} region. These findings are quite similar to those found for the complex bridged with nitrosyl mentioned above,[9] suggesting that **3** contains the bridged nitrosyl group.

The NMR spectroscopy provides additional evidence for the bridged structure assumed. As is shown in Table 3, the NMR spectrum of the complex in $CDCl_3$ shows three peaks, with an area ratio of 1: 3: 3. It has been established that two methine protons in monomeric *cis*-bis(acetylacetonato)cobaltate(III), $[Co(acac)_2X_2]^-$ (X=N_3^- or OH^-), are equivalent, while the methyl protons are divided into two sets of methyl groups[20,24] A similar spectrum has also been found for di-μ-hydroxo-bis[bis(acetylacetonato)cobalt(III)],[25] $[Co_2(acac)_4(OH)_2]$. In the latter, however, quite a large methyl resonance splitting (0.48 ppm), which is thought to arise because of the hydroxo bridge and the dimeric structure,[25] has been found. The NMR spectrum observed here is identical with that of the dimeric acetylacetonato complex referred to above.

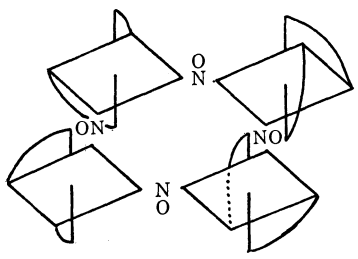

Fig. 4. Probable structure for Complex **3**

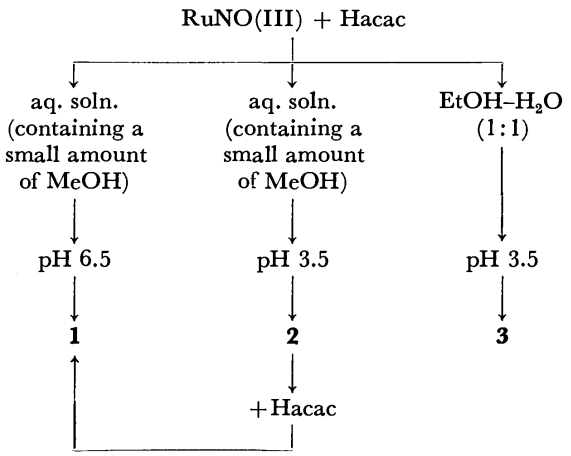
On the basis of the spectral observations, the most probable structure of **3** is thought to be the tetrameric structure bridged with nitrosyls, depicted in Fig. 4. This structure consists of four monomeric octahedral unit, Ru(NO)(acac)$_2$, containing both equivalent acetylacetonate anions and the bridged nitrosyl group.

3 is diamagnetic. The majority of nitrosylruthe-

nium(III) complexes which have a linear terminal Ru–N–O group have been considered to contain NO^+.[26] The nitrosylruthenium group in **3**, however, may be considered to be Ru(II)NO or Ru(III)NO^-. The diamagnetism of **3** may be explained using the bonding scheme applied to a complex bridged with nitrosyls, $(Me_4N)_4[Ru_2(NO)_2(SnCl_3)_2Cl_6]\cdot H_2O$, which has an analogous bridged structure.[9]

Reactions. The reactions of the nitrosylruthenium-(III) described above are summarized in the following scheme.



In a neutral solution, the coordinated nitrosyl is converted into the hia ligand under mild reaction conditions. On the other hand, **2** is formed in an acid aqueous or methanolic solution, whereas **3** is produced in an acid ethanolic solution. It should be noted that the isolation of these complexes depends on the pH of the reaction mixture and the kind of alcohol used as a solvent. **1** could also be derived by the reaction of **2** with acetylacetone in a methanolic solution. However, the formation of **1** was not observed in the reaction between RuNO(III) chloride and acetylacetone at pH 8.5—9.0. In an aqueous solution of this pH, dark brown materials were obtained in place of **1**. This is thought to be an acetylacetonato complex containing a terminal nitrosyl group([Ru(OH)(NO)$(acac)_2$]) on the basis of its composition and infrared spectrum.

The reaction of coordinated β-diketonato and analogous ligands with nitric oxide to give an oxime-type bonding has recently been reported.[12,13] However, no reaction between coordinated nitrosyl and β-diketone has yet been reported. The isolation of **1** reported here appears to be the first example of the latter reaction. The mechanism of this reaction is not clear. However, it is thought to differ from the acid-catalyzed mechanism which has been presumed for the formation of [Pd(acac)(hia)] by means of the reaction of NO on [Pd$(acac)_2$],[12] since it appears unlikely that the cleavage of Ru–NO bonding occurs under the conditions specified above. This discrepancy seems to be responsible for the difference in reactivity between coordinated nitrosyl and free nitric oxide.

The authors wish to express their thanks to Dr. Eiichi Miki of St. Paul's (Rikkyo) University for the measurement of the IR spectra. Thanks are also due to Mr. Masaaki Sakamoto and Mr. Akira Hoshi for their technical assistance. This investigation was supported in part by a grant from the Ministry of Education.

The Complexing of the Lithium Ion in Acetonitrile with Other Solvents. Investigation by the Use of a Cation-sensitive Glass Electrode

Toshio NAKAMURA

Chemistry Department, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received November 5, 1974)

The complexing of the lithium ion with other popular solvents has been studied in acetonitrile (AN) using a monovalent cation-sensitive glass electrode. A method similar to that developed to study the complexing of the sodium ion was employed.[1] Mono- and di-solvated species were formed for methanol, pyridine, formamide, methylfomamide, and HMPA. Tri-solvated species were also formed for DMF, DMA, and DMSO. In general, the complexing of the lithium ion with these solvents was more pronounced than that of the sodium ion. The formation constants for the mono-solvated lithium ion were 4.5 for methanol, 5.2 for pyridine, 16 for DMF, 20 for formamide, 25 for methylformamide, 49 for DMSO, 62 for DMA, and 2.1×10^3 for HMPA. When water was the complexing solvent, the equilibrium potential could not be obtained, probably because of the hydrolysis of the hydrated lithium ion. Prior to these experiments, the cation-sensitive glass electrode was confirmed to respond to the lithium-ion activity in different solvents by comparing its behavior with that of a lithium-amalgam electrode.

In the previous paper,[1] the author and his collaborators reported a potentiometric method which used a monovalent cation-sensitive glass electrode to obtain the formation constants of the complexing of the sodium ion in acetonitrile (AN) with several popular solvents. In this experiment, a similar method has been used to determine the formation constants (the so-called hybrid formation constants), β_x, of the complexing of the lithium ion in AN with other solvents (Eqs. (1) and (2)):

$$Li_s^+ + xD = Li_{xD}^+ \quad (1)$$

$$\beta_x = \frac{(Li_{xD}^+)}{(Li_s^+)[D]^x} \quad (2)$$

In Eqs. (1) and (2), Li_s^+ shows the lithium ion solvated only by AN, and Li_{xD}^+, that complexed by x molecules of the D solvent. (Li_s^+) and (Li_{xD}^+) are the activities of Li_s^+ and Li_{xD}^+ respectively, and [D], the concentration of the free (uncomplexed) solvent, D.

Prior to the determination of the formation constants, the glass electrode was verified to respond with a Nernstian slope to the activity of the lithium ion in different solvents. This was done by comparing the response of the glass electrode, immersed in solutions of the 10^{-3}M lithium ion in different solvents, with the response of a lithium amalgam electrode immersed in the same solutions. The formation constants were determined by the emf measurement of Cell I, in the compartment (C) of which the D solvent was titrated to a solution of 10^{-3}M $LiClO_4$+10^{-2}M Et_4NClO_4, originally in pure AN:

Ag|0.005M $AgNO_3$(AN)‖0.1M Et_4NPic(AN)‖
(A) (B)
10^{-3}M $LiClO_4$ + 0.01M Et_4NClO_4(AN-D)|glass electrode
(C)
Cell I

(D denotes the solvents added)
The following relations were used:

$$R \equiv \left\{\frac{(Li_s^+)_{AN}}{(Li_s^+)_{AN-D}} - 1\right\}/[D] = \beta_1 + \beta_2[D] + \beta_3[D]^2 + \cdots \quad (3)$$

$$(R-\beta_1)/[D] = \beta_2 + \beta_3[D] + \cdots \quad (4)$$

$$(Li_s^+)_{AN}/(Li_s^+)_{AN-D} = 10^{(E_{AN}-E_{AN-D})/59} \quad (5)$$

where $(Li_s^+)_{AN}$ and $(Li_s^+)_{AN-D}$ are the activities of Li_s^+ in pure AN and in the mixture of AN and D respectively. E_{AN} and E_{AN-D} show the potentials of the glass electrode in mV obtained in pure AN and in the AN–D mixture respectively. Assumptions similar to those in the previous paper[1] were made: (i) the (D) solvent in AN–D mixtures is monomeric; (ii) the activity of AN does not change upon the addition of D and is equal to unity; (iii) the salt-effect activity coefficient of the lithium ion, as calculated by the Debye-Hückel equation, is equal in pure AN and in AN–D mixtures; (iv) the amount of (D) solvent consumed by the solvation of the ions of an indifferent electrolyte is negligible and (v) the liquid-junction potential between the solutions in the salt bridge (B) and the compartment (C) in Cell I does not change upon the addition of D.

By this method, such formation constants for D as methanol, pyridine, DMF, formamide, methylformamide, DMSO, DMA, and HMPA were obtained. In general, the complexing of the lithium ion occurs to a fairly greater extent than that of the sodium ion. The formation constants for the hydration of the lithium ion in AN, however, could not be determined because of a peculiar behavior of the electrode potential which is probably due to the hydrolysis of the lithium ion, as will be described later.

Apparatus and Reagents

Apparatus. Most of the apparatus and experimental techniques for the determination of formation constants are the same as those in the previous report.[1] The assembly of Cell I is that Shown in Fig. 1 of Ref. (1), except that in the compartment (C) 10^{-3}M $LiClO_4$ was used instead of 10^{-3}M $NaClO_4$. The lithium-amalgam electrode was constructed by modifying the one used by Matsuura *et al.*[2]; the lithium amalgam was prepared by electrolyzing 10^{-2}M $LiClO_4$ in AN, and the concentration of lithium in the amalgam was determined to be 6.58×10^{-2}M by titration with perchloric acid. The potential of the amalgam electrode was measured with a voltameter equipped with a voltage follower with an input impedance of $10^{11}\Omega$. For the acid-base titration in AN containing a small amount

of water, a pH glass electrode, Hitachi-Horiba 1026, was used.

Reagents. Unhydrated lithium perchlorate was dried before use at 250 °C under a vacuum. The tetraethylammonium picrate, tetraethylammonium perchlorate, acetonitrile, and pyridine were the same as those in the previous work.[1] The DMF, DMSO, PC, and HMPA were purified by the conventional methods. The methylformamide was used after the purification of an analytical reagent-grade substance by fractional crystallization. The formamide was a chromatographic product. The lithium tetraphenylborate was prepared by passing an aqueous solution of sodium tetraphenylborate through a column of amberlite IR 120 exchange resin in the Li^+-form. It was dried at 50 °C under a high vacuum. The tetrabutylammonium tetraphenylborate was prepared by the method of Accascina *et al.*[3] The procedure of Cundiff and Markunas[4] was used to prepare the tetrabutylammonium hydroxide solution in a benzene–methanol (3:2) mixture. The other solvents and reagents were of an analytical reagent grade and were used without further purification.

Results

Response of the Glass Electrode to the Activity of the Lithium Ion in Different Solvents. The glass electrode used in the present study showed a slope of 57 mV to the lithium ion between 10^{-4}M and 10^{-2}M in AN–0.01M Et_4NClO_4. If corrected for the change in the salt-effect activity coefficient, the response towards pa_{Li}^+ is very near the Nernstian slope of 59 mV.

In order to confirm that the glass electrode can respond to the difference in the activity of the lithium ion in different solvents, the emf of Cell II was compared with that of Cell III. Because the reference electrode and the salt bridge in both cells are the same as each other (and as those used in Cell I), a comparison of the emf's of Cells II and III is equivalent to a comparison of the potentials of the glass electrode and the amalgam electrode.

Cell III

(D denotes AN, methanol, DMF, and DMSO)

The results are shown in Fig. 1. From these results, it may be considered that the glass electrode used in the present experiment responds to the activity of the lithium ion in those different solvents.

Complexing of the Lithium Ion in AN with Other Solvents. From the emf measurement of Cell I, the values of the formation constants (β_x) were calculated by using Eqs. (3) to (5). The results are summarized in Table 1. Figures 2 to 6 show some examples of the R–[D] and $(R-\beta_1)/[D]$–[D] relations used to obtain the formation constants.

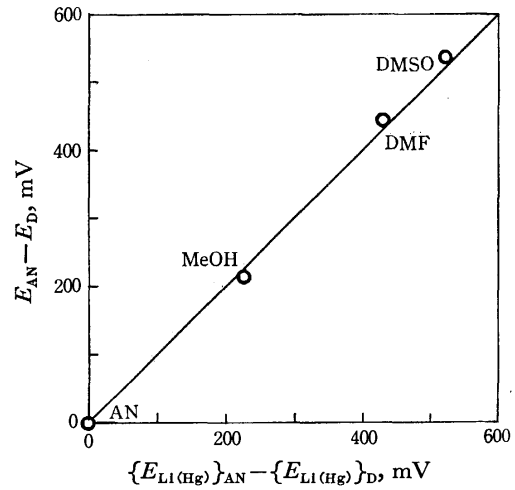

Fig. 1. Relations between potentials of the ion-sensitive glass electrode and those of the lithium amalgam electrode in various solvents, both referred to the values in AN.

When water was the complexing solvent, the equilibrium potential could not be obtained. As is shown in Fig. 7, Curve A, when water was added to the AN solution of the lithium ion, the potential shifted first to the more negative direction, but then back to the less negative direction, and it did not attain a constant value even after 60 min. (When the other solvents in Table 1 were the complexing solvents, equilibrium potentials were usually obtained soon after their addi-

tion. As example is shown in Fig. 7, Curve B, for DMSO.) Because of this behavior, hydration constants could not be obtained by the present experiment.

Discussion

From the results in Fig. 1, it seems reasonable to consider that the glass electrode can respond to the activity of the lithium ion in solvents of different species or compositions.

The formation constants in Table 1 show that the complexing of the lithium ion in AN with other solvents is generally more extensive than in the case of the sodium ion. For DMF, DMA, and DMSO, a complexing up to three solvent molecules was observed. For HMPA, however, no tri-solvated complex was formed in spite of the quite large values of β_1 and β_2. This may be

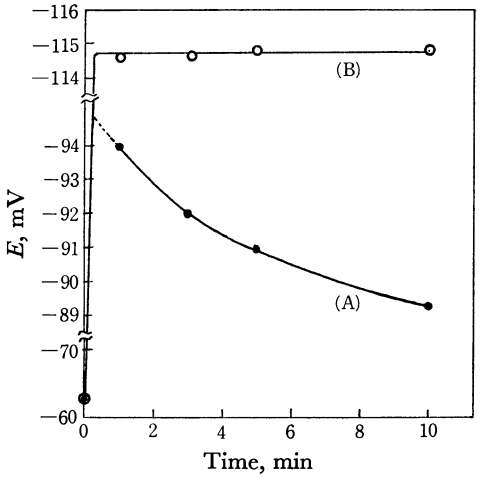

Fig. 7. Potential curves of the ion-sensitive glass electrode after the addition of complexing solvent to the AN solution of 10^{-3} M $LiClO_4$ and 10^{-2} M Et_4NClO_4. (A) H_2O, 200 μl/50 ml, (B) DMSO, 200 μl/50 ml.

because of the steric effect in the reactions between large HMPA molecules and the small lithium ion. The solvation of PC, which has a weak basic character but a large dielectric constant, occurred only weakly. From these results, it can be said that, except for the case of pyridine, the complexing of the lithium ion in AN with other solvents is more pronounced when the solvent basicity increases. The solvation of pyridine, which has a strong basic character but a small dielectric constant, occurred to only a small extent, as in the case of the sodium ion.

The values of β_1 in Table 1 seem to be reliable enough within ±10% for pyridine, DMF, DMSO, and HMPA. For protic solvents, such as methanol, formamide, and methylformamide, the reliability might be somewhat less because the junction potentials between the compartments (B) and (C) of Cell I may change during titration to a somewhat larger extent than in the case of the dipolar aprotic solvents, in which the change of the junction potential is quite small.[5]

In order to elucidate the peculiar potential change observed when water was the complexing solvent, some experiments were carried out:

(1) The lithium ion in AN has been found conductometrically to associate with the perchlorate ion, though to an extent somewhat smaller than that of the ion association between the sodium ion and the perchlorate ion.[6,7] The addition of water to the AN solution may cause the dissociation of the ion association (though the possibility of this is very small, considering the small change in the dielectric constant by the addition of water[8]) and the increase in the lithium-ion activity (the shift of the potential to a less negative direction). In order to investigate the influence of this reaction, measurements were carried out by changing the concentration of the indifferent electrolyte, Et_4NClO_4, from 0 M to 0.1 M. However, the phenomena shown in the Curve A, Fig. 7, were observed in all concentrations. The tetraphenylborate may be completely dissociated in AN, considering the case of the sodium ion.[7] Therefore, instead of the $LiClO_4$ and Et_4NClO_4 in the above experiments, $LiBPh_4$ and Bu_4NBPh_4 were used, and similar measurments were carried out. However the results did not change. From these experiments, the peculiar phenomena in Fig. 7 do not seem to be due to the effect of ion association.

(2) The hydrolysis of the lithium ion may cause behavior such as is shown in Fig. 7 if the hydrogen ion liberated by hydrolysis shifts the potential of the glass electrode to a less negative direction. Curve 1 in Fig. 8 is a acid-base titration curve obtained by titrating 10^{-3}M $LiClO_4$ in 1.2 v/v % aqueous AN–0.01M Et_4NClO_4 with Bu_4NOH (0.176M in benzene–methanol (3:2)). The pH glass electrode was a Hitachi-Horiba 1026 electrode. The titration curve of the lithium ion indicates the possibility of the lithium ion being hydrolyzed considerably in AN containing a small amount of water. The hydrolysis of the sodium ion also occurs, but to a much smaller extent; Curve 2 is the titration curve of 10^{-3} M $NaClO_4$ under the same conditions, while Curve 3 is that of the blank solution. Curve 4 in Fig. 8 is the titration curve of acetic acid with Bu_4NOH in the same solution as that of Curve 3. From Curves 1 and 4, the lithium ion can be considered as an acid, the strength of which is roughly of the same order of magnitude as that of acetic acid. When a similar titration of acetic acid was carried out by using a mono-valent cation sensitive glass electrode, Beckman 39047, Curve 5 was obtained. In this curve, the potential is almost constant before the equivalent point, but the potential change to a negative direction occurs near the equivalent; after the equivalent point, the potential changes slowly to a less negative direction.

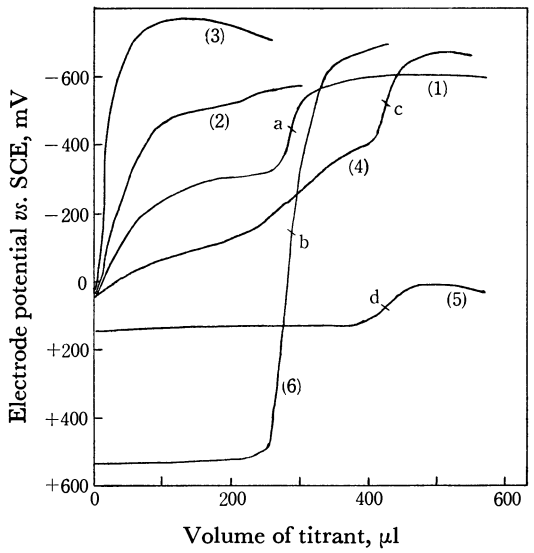

Fig. 8. Titration curves with benzene–methanol (3:2) solution of tetrabutylammoniumhydroxide (0.18 M). Curves (1) 10^{-3} M $LiClO_4$+10^{-2} M Et_4NClO_4+667 mM H_2O in 50 ml AN solution, (2) 10^{-3} M $NaClO_4$+10^{-2} M Et_4ClO_4+667 mM H_2O in 50 ml AN solution, (3) 10^{-2} M Et_4NClO_4+667 mM H_2O in 50 ml AN solution (blank), (4), (5) 10^{-2} M Et_4NClO_4+1.44 mM CH_3COOH+667 mM H_2O in 50 ml AN solution, and (6) 10^{-3} M $HClO_4$+667 mM H_2O in AN solution. The letters a,b, c, and d are the equivalent end point, respectively. For the glass electrodes used, see text.

From this, it seems reasonable to conclude that the cation-sensitive glass electrode can respond to the hydrogen ion liberated by the hydrolysis of the lithium ion in AN containing a small amount of water. Curve 6 was obtained by titrating 10^{-3} M $HClO_4$ in 1.2 v/v % aqueous AN with Bu_4NOH. From these experimental results, the peculiar behavior observed when water is the complexing solvent seems to be caused by the hydrolysis of the lithium ion and the response of the cation-sensitive glass electrode to the hydrogen ion liberated.

The author wishes to express his hearty thanks to Dr. Kosuke Izutsu of this department for his kind discussions and to Mr. Shigeo Nakajima for his experimental support.

This work was supported in part by a Grant-in-aid for Scientific Research from the Ministry of Education.

Viscosity Behavior of Coacervates of Magnesium and Calcium Highpolyphosphates[1]

Takao UMEGAKI and Takafumi KANAZAWA

Department of Industrial Chemistry, Faculty of Technology, Tokyo Metropolitan University, Fukazawa, Setagaya-ku, Tokyo 158

(Received December 6, 1974)

The viscosities of magnesium and calcium highpolyphosphate coacervates were measured in the temperature range of 20 to 90 °C. The Andrade's Equation was an approximate representation for the temperature dependence of viscosities of the coacervates. The activation energies of flow for the highpolyphosphate coacervates of magnesium and calcium were calculated to be about 7 kcal/mol and about 15 kcal/mol, respectively. The extension of the phosphate chains in coacervates was considered to be restricted, and the spinnability of the coacervates was probably originated, not by an elastic network structure, but by high viscosity of the coacervates. The viscosities of the magnesium coacervates decreased with an increase in water content and no remarkable effect of ethyl alcohol on the preparation of the coacervates was found.

Viscometric studies of dilute solutions of alkaline highpolyphosphates were carried out by Strauss, Smith, and Wineman[2] for the determination of the molecular dimensions. In the previous paper[3] viscosities of magnesium, calcium and aluminum highpolyphosphate coacervate solutions were measured in order to examine their conformational features during the dissolution into acid solvents. The viscoelasticity of the composite specimen of the magnesium highpolyphosphate coacervate and glass cloth was also determined by torsional braid analysis.[4] However, there has been no quantitative study on the viscosity behavior of the coacervates themselves.

The present paper deals with temperature dependence of viscosity at temperatures, from 20 to 90 °C, for magnesium highpolyphosphate coacervate (MPC). Moreover, the viscosities for MPC and CPC prepared according to the new methods without addition of ethyl alcohol were compared with those of the coacervates obtained by the procedures already reported,[4,5] and the viscosity change of MPC with water content was studied.

On the basis of the results on the viscometric experiments, the extension of phosphate anion chains and the complex formation in the coacervates were discussed, and viscosity behaviors of MPC and CPC were compared.

Experimental

Materials. According to the methods for synthesizing MPC and CPC[4,5] both coacervates were obtained by adding ethyl alcohol to the mixture of a 15% sodium metaphosphate solution and a 20% solution of magnesium or calcium chloride. MPC and CPC were also prepared by direct addition of $MgCl_2 \cdot 6H_2O$ (167 g) and $CaCl_2 \cdot 2H_2O$ (73.5 g), respectively, to a 20% sodium metaphosphate solution (500 g). Then all the coacervates separated became transparent in a week at room temperature.

Analysis. The coacervates were analyzed for calcium by ETA titration and for phosphorous by the vanadomolybdate colorimetry.[6] Sodium was determined by titrating a standardized HCl, which was partially neutralized by the liberated sodium ion in advance adsorbed on Amberlite IR-120 from a coacervate solution.[7] Paper chromatography of the polyphosphate ions in MPC and CPC was carried out according to the method by Kolloff.[8]

Viscosity Measurement. Shearing stresses of MPC and CPC at shear rates, from 10 to 600 s^{-1} and temperatures, from 20 to 90 °C, were measured with a rotational viscometer of cone-and-plate type (Shibayama Kagaku Co., Ltd.). The viscometer was calibrated at 20 °C by using JS 200 (1.78 P), JS 1000 (8.918 P), JS 2000 (18.14 P), 60H (497.3 P) and 200H (1683 P) as standard liquids for viscosity manufactured by Showa Oil Co., Ltd. All the above oils were assumed to be Newtonian fluid whose shearing stress is proportional to shear rate. A strain gauge was used for the measurement of torque of the cone evolved by the rotation of viscous fluid on the plate. The viscometer was so designed that the electromotive force of the strain gauge was proportional to shearing stress in the fluid. Consequently, the shearing stress was calculated from the electromotive force of the strain gauge.

Results and Discussion

From the linearity of flow curves for MPC and CPC (Figs. 1 and 2), most coacervates were recognized to be Newtonian, although the curve for MPC at 20 °C was concave upward very slightly. The non-Newtonian flow of MPC at 20 °C might be attributed to the heterogeneity of vicosity in the coacervate, which formed on coacervation and remained on viscosity measurement

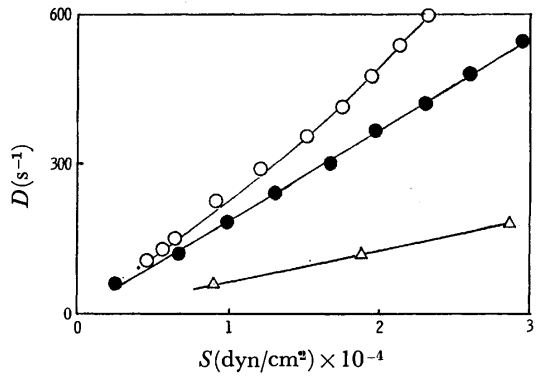

Fig. 1. Flow curves of MPC samples.
○: coacervated by $MgCl_2 \cdot 6H_2O$ powder, settled for 240 hr at 20 °C (P_2O_5 20%), ●: coacervated by $MgCl_2 \cdot 6H_2O$ powder, settled for 240 hr at 30 °C (P_2O_5 25%), △: coacervated by ethyl alcohol, settled for 912 hr at 30 °C (P_2O_5 45%)

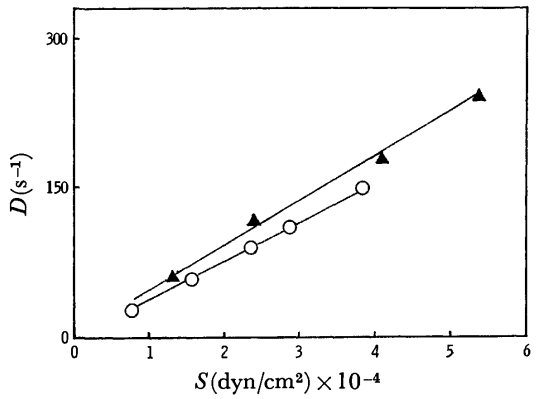

Fig. 2. Flow curves of CPC samples at 30 °C.
▲: coacervated by $MgCl_2 \cdot 6H_2O$ powder, ○: coacervated by ethyl alcohol

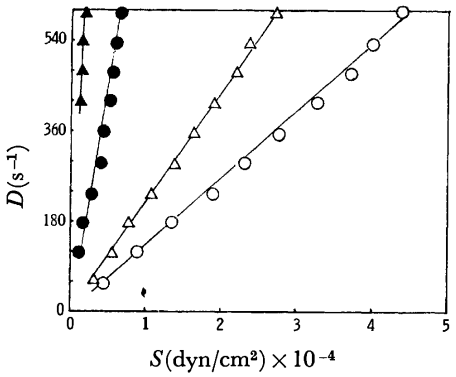

Fig. 3. Effect of the addition of distilled water to MPC on flow curve of MPC.
The ratios of MPC to water by weight are as follows: 85:15 (○), 80:20 (△), 75:25 (●), and 70:30 (▲).

at 20 °C. The viscous part remaining locally in the coacervate might act like the so-called scaffolding structure formed suspended particles in solutions.[9]

Figure 3 shows the viscosity change with water content. These samples in Fig. 3 were prepared by the mere addition of water to MPC (P_2O_5 31.8%), being settled in a week. The viscosity of MPC decreased remarkably with decrease in P_2O_5 content. For example, the addition of distilled water to MPC (P_2O_5 31.8%), in a ratio of 1:1 in weight changed the viscosity of the coacervate from 10^2 to about 2 P. Then, no degradation of highpolyphosphates upon the water addition was recognized by the paper chromatography. This viscosity change was attributed to the easily weakened interaction of various electrolytes with each other in the coacervates.

Figures 4 and 5 show the temperature dependence of viscosity for MPC and CPC, respectively. Although some flow curves of coacervates showed non-Newtonian behavior, the apparent viscosity (η) was calculated by assuming a linear relationship between shearing stress and shear rate concerning the coacervates used here. According to the Andrade's Equation ($\eta = Ae^{B/T}$, where A and B are quantities independent of temperature), a plot of the logarithmic viscosity against the reciprocal of absolute temperature should be a straight line. The apparent activation energy of flow (E) was obtained

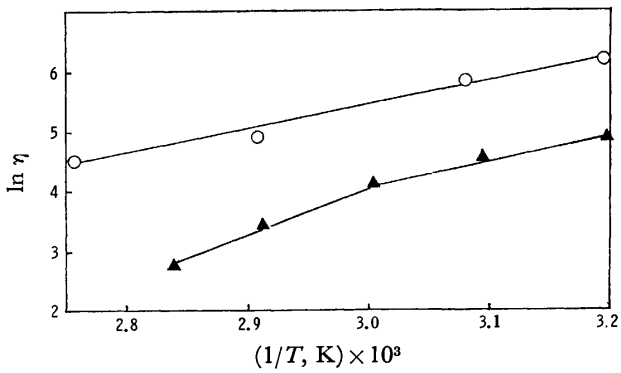

Fig. 4. Temperature dependence of viscosity of MPC.
○: coacervated by ethyl alcohol, ▲: coacervated by $MgCl \cdot 6H_2O$

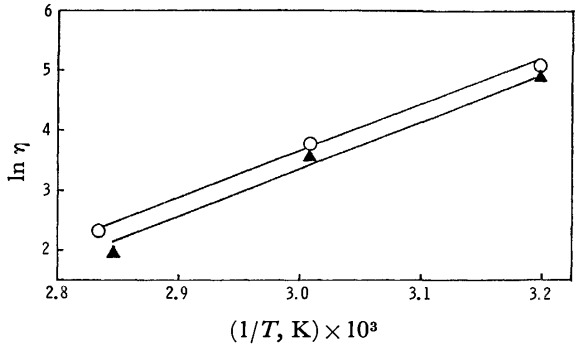

Fig. 5. Temperature dependence of viscosity of CPC.
▲: coacervated by ethyl alcohol, ○: coacervated by $MgCl_2 \cdot 6H_2O$

from the slope of the line (B) and gas constant (R) as follows: $E = B \times R = 1.986B$ (cal/mol).

The values of E for MPC and CPC calculated from the slopes in Figs. 4 and 5 are given in Table 1. The values of E for MPC were found to be 6—8 kcal/mol. This value is probably interpreted in terms of the presence of the cross-linking due to the weak bonding like a hydrogen bond in MPC, both values for MPC and water having the same order of magnitude.[10] However, the values of E for two MPC were somewhat larger than those for water. From the comparison of E for MPC with that for water, it is concluded that hydrogen bond in coacervates has a considerable effect on the viscosity of the coacervates and that the difference of the potential barriers on flow process between MPC and water is brought about by the difference in both dimension and mutual interaction of solute molecules.

Table 1. Activation energies of flow (E) of coacervates

Sample	P_2O_5 content (%)	Temperature range (°C)	E (kcal/mol)
MPC	60.1[a]	40— 90	6.4
	36.0	40— 60	8.1
CPC	63.9[a]	40— 79	16.4
	51.8	40— 80	13.9
H_2O	—	0— 20	4.61[b]
	—	50—100	3.10[b]

a) Coacervated by the addition of ethyl alcohol. b) Cited from Ref. 9.

Although MPC prepared by the addition of ethyl alcohol might contain the alcohol, the slope of $\ln\eta_i$ plot against 1/T was recognized to be almost the same as that of MPC obtained by the direct addition of $MgCl_2 \cdot 6H_2O$. Then, probably, no essential change in the configuration of highpolyphosphate ion in MPC was induced by the addition of alcohol, but in the course of the synthesis of MPC ethyl alcohol was effective only for the depression in the ionic dissociation in the mixture of sodium highpolyphosphate and magnesium chloride solutions, the dielectric constant of the mixture being reduced by the addition of alcohol.

The linearity of flow curves for most MPC indicates no remarkable conformational change of highpolyphosphate chains with an increase in shear rate. Since the values of E for MPC and water are comparable, the extension of the highpolyphosphate chains is considered to be small and the chains might be coiled spherically and somewhat tightly.

The values of E for CPC are larger than those for MPC, although the apparent viscosities for CPC are smaller or the same compared with those for MPC. Therefore, the interaction among highpolyphosphate chains in CPC is considered to be stronger than that in MPC, and the phosphate coils are extended more widely in CPC than in MPC.

The complex formation between highpolyphosphate and metal ion is well-known and sodium highpolyphosphate has been industrially utilized as a masking agent for Ca^{2+}, Mg^{2+} and other metal ions.[11] Moreover, the stability constants of some complexes were calculated from the pH lowering during the titration of highpolyphosphate ion with hydrogen ion.[11,12] It was reported that the treatment of some calcium highpolyphosphate coacervates with ammonium fluoride solution yielded no calcium fluoride, indicating that the calcium ions were strongly masked by the highpolyphosphate.[13] Then, there is no doubt about the presence of a certain stable complex between calcium and polyphosphate, even in CPC. The activation energies of flow for CPC (14—16 kcal/mol) may indicate the slight extension of the highpolyphosphate chains, and some part of the calcium-polyphosphate complex may be expected to form a network structure with the cross-linkage of the chains by calcium ions.

Erbring[14] and Nakagawa[15] found that some liquids having an elastic network structure are spinnable and some highly viscous substances (40—50 poise or more) with no anomalous structure also possess a thread-forming property. The origin of the spinnability for MPC and CPC reported in the previous paper[3] might be explained on the basis of the results on the viscosity measurement described above. The viscosity measurement of dilute solutions of the coacervates suggested the presence of the tightly coiled highpolyphosphate chains in the acid solvents.[3] On the other hand, in the coacervates themselves the extension of the highpolyphosphate chains is also supposed to be restricted from a consideration of the low activation energies of flow for coacervates compared with those for ordinary linear high molecular organic polymers. The linearity of flow curves for the coacervates used here indicates no anomalous structure, while the electron micrographs by Danno[16] and the observation with an optical microscope by Yamaguchi and Kashiwase[17] showed the network structure in such thread-forming liquids as mercury sulfosalicylate solution and potassium highpolyphosphate solution, respectively. It is concluded that the spinnability of the coacervates in this work was originated, not by an elastic network structure, but by high viscosity of the coacervates as well as that of sodium silicate solution or sugar solution with high concentration.

Conclusion

From the results of the viscometric studies on MPC and CPC, the following facts were obtained.

(1) The coacervates used here were mostly Newtonian.

(2) The Andrade's Equation was an approximate representation for the temperature dependence of the viscosities of MPC and CPC, from which the activation energies for flow process of MPC and CPC were calculated to be about 7 kcal/mol and about 15 kcal/mol, respectively.

(3) The addition of water to MPC caused the viscocity lowering, but no degradation of polyphosphate chains occurred.

(4) No essential change in the configuration of highpolyphosphate ion in MPC was induced by the addition of ethyl alcohol.

(5) The extension of the phosphate chains was restricted and the spinnability of MPC and CPC were originated, not by an elastic network structure, but by high viscosity of the coacervates.

The Coprecipitation of Strontium with Hydroxyapatite.

Osamu FUJINO

Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received December 16, 1974)

The distribution behavior of the strontium ion between hydroxyapatite and the parent solution was investigated. The hydroxyapatite was formed by the extremely slow addition of diammonium hydrogenphosphate to solutions of calcium and strontium nitrate buffered with ethylenediamine at 80 °C. The precipitate yielded a typical X-ray diffraction pattern of hydroxyapatite and had a composition in which the Ca/P molar ratio was 1.67 at pH 6.80. The strontium ion was coprecipitated in the apatite, obeying the Doerner and Hoskins logarithnmic distribution law. The distribution coefficient was scarcely affected by the strontium concentration on the pH value in the parent solution, and had a value of 0.26 ± 0.02 at 80 °C. On the other hand, the apparent distribution coefficient was a little affected by such organic anions as acetate, citrate, lactate, glycinate, and glutamate ions. The lattice constants of the precipitates prepared in the research were measured in order to confirm the formation of the solid solutions.

There is a considerably extensive literature[1] dealing with the abundance of trace elements in such geochemical samples as phosphate minerals and sediments, and in such biological samples as human bones and teeth. However, there are still very scant experimental data on the coprecipitation of trace elements with the hydroxyapatite, which is the pricipal inorganic constituent of these samples.

In previous papers we have ourselves reported data on the coprecipitation of copper[2] and zinc[3] with hydroxyapatite. The coprecipitation of strontium with the apatite is also of great interest because strontium-90 has such a long biological half life as 18000 days in bone and is well known as one of the most dangerous radioisotopes for the human body.

Experimental

Apparatus. The radioactivity countings were made with a Packard Tri-carb Liquid Scintillation Spectrometer, Model 3320. A Hitachi-Horiba pH Meter, Model F-5, was used for the pH measurements. The X-ray patterns of the hydroxyapatite samples were measured by using a Shimadzu X-ray Diffractometer, Model AZ-2A, with nickel-filtered copper radiation.

Reagents. The strontium-89 was supplied as chloride in hydrochloric acid by the Oak Ridge National Laboratory, Oak Ridge, Tennessee, U.S.A., and was diluted with 0.1 M nitric acid to make a solution of $\simeq 1$ μCi/ml. The strontium and calcium solutions were prepared from their respective reagent-grade nitrates and were standardized by EDTA titration. A standard EDTA solution containing EDTA-magnesium complex was standardized with a calcium solution which had been prepared from dry calcium oxide. A liquid scintillator for the measurement of the strontium activity was prepared by dissolving 100 mg of 1,4-bis(5-phenyloxazolyl)-benzene (POPOP), 4 g of 2,5-diphenyloxazole (DPO), and 75 g of naphthalene with dioxane and by then diluting them to 1 l with the solvent.

The other chemicals were reagent-grade materials.

Preparation of Hydroxyapatite. The following procedure was used to prepare the hydroxyapatite precipitates. Twenty milliliters of a 0.5 M calcium nitrate solution and 25 ml of 5 M ethylenediamine were placed in a one-liter Erlenmeyer flask, and the mixture was diluted to around 400 ml with water. The solution, after pH adjustment, was diluted to 500 ml. The flask equipped with a reflux condenser was placed in a thermostat, and nitrogen gas was passed through to prevent the formation of calcium carbonate. The diammonium hydrogenphosphate solution (0.1 M) was then pumped, drop by drop into the calcium solution, which was being stirred by a magnetic stirrer. The supernatent solution was pulled off by an aspirator working through a sintered glass filter, and the precipitate was washed with water repeatedly. The precipitate was then filtered and dried at 110 °C.

Chemical Analysis of Hydroxyapatite. The calcium and phosphate ions in the hydroxyapatite precipitate were determined by the EDTA titration method as follows. *Determination of calcium*: EDTA and buffer (pH 10) solutions were added to a sample solution which had been prepared by dissolving the dry sample in hydrochloric acid, and the calcium ions were determined by titrating an excess of EDTA with a magnesium standard solution, using Eriochrome Black T as the indicator. *Determination of phosphate ions*: The phosphate ions in the sample solution above were precipitated as magnesium ammonium phosphate. The precipitate was filtered and dissolved with hydrochloric acid. The phosphate ions could then be determined by titrating the magnesium with the EDTA solution.

Coprecipitation Procedure. The procedure of the coprecipitation was essentially the same as those of the hydroxyapatite preparation. The carrier and the radiotracer of strontium were added to the calcium solution in the thermostat described above. At appropriate intervals of time, an aliquot of the supernatent solution was pipetted out through a sintered glass filter. The calcium ions in the solution phase were determined by EDTA titration. The strontium ions were counted with a liquid scintillation spectrometer after the supernatent had been ashed with a mixture of perchloric, nitric and hydrochloric acids and after 4 ml of 0.1 M hydrochloric acid and 13 ml of liquid scintillator had been added to it.

The homogeneous[4,5] and logarithmic[6] distribution coefficients, K_D and K_λ, were calculated by means of the following equations:

$$\left(\frac{\text{micro-component}}{\text{macro-component}}\right)_{\text{cryst.}} = K_D \left(\frac{\text{micro-component}}{\text{macro-component}}\right)_{\text{soln.}} \quad (1)$$

$$\log\left(\frac{\text{initial quantity}}{\text{quantity left in soln.}}\right)_{\text{micro-component}} = K_\lambda \log\left(\frac{\text{initial quantity}}{\text{quantity left in soln.}}\right)_{\text{macro-component}} \quad (2)$$

Lattice Constant. Hydroxyapatite is hexagonal, with

two lattice constants, A_0 and C_0. These were determined by measuring the diffraction angles, 2θ, of the three planes—(312), (213), and (321).

Results and Discussion

Composition of Apatite Precipitate. On the apatite precipitates formed from an aqueous solution, it is well known that solid phases may be precipitated which yield X-ray diffraction patterns typical of hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$, while deviating considerably from it in composition.[7,8] Figure 1 shows the influence of the precipitation rate on the Ca/P ratio of the apatites, which were prepared by precipitating 50 per cent of calcium with a phosphate solution at pH 6.80 and 8.60. The Ca/P ratio became constant in the range of addition rates slower than 10 ml/hr. The apatite prepared at pH 6.80 gave X-ray diffraction patterns typical of hydroxyapatite, although that produced by the rapid addition of phosphate had diffraction patterns with poorly crystallized materials.

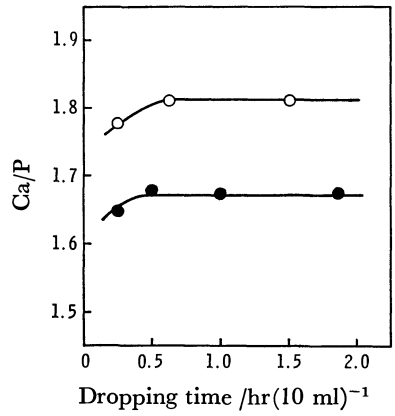

Fig. 1. The Ca/P ratio in the precipitates formed at various precipitation rates.
$Ca(NO_3)_2$, 0.02 M; ethylenediamine, 0.25 M; $(NH_4)_2HPO_4$, 0.1 M; ●, pH 6.80; ○, pH 8.60; initial volume, 500 ml; temperature, 80 °C.

In order to examine the effect of the percentage of calcium precipitation on the Ca/P ratio, the composition of the precipitates was determined; they had been prepared by changing the addition volume of phosphate. As is shown in Fig. 2, the Ca/P ratio was constant throughout the precipitation process of calcium. These precipitates showed X-ray patterns typical of hydroxyapatite.

The pH value affected the Ca/P ratio in the synthesized apatite (50% precipitation), as may be seen in Fig. 3; the Ca/P ratio decreased as the pH decreased. The Ca/P ratio in mineral bone when organic matter has been removed is between 1.57 and 1.61,[9] which implies that the apatite is a little calcium-deficient. As the value of pH 6.80 at 80 °C corresponds to about 8.0 at room temperature, the results in Fig. 3 may not be inconsistent with the fact that the accretion and resorption in bone occur around the neutral pH range.

At pH 6.80, the Ca/P ratio was 1.67; this corresponded to the composition of hydroxyapatite, $Ca_{10}(PO_4)_6(OH)_2$. This pH value was, therefore adopted throughout the experiments.

Coprecipitation of Strontium. In order to examine the influence of the precipitation rate on the coprecipitation behavior of strontium, the precipitation reaction was performed at the pumping velocities of 7, 12.2, and 65.8 ml of phosphate solutions per hour; the

concentrations of calcium, strontium and ethylenediamine were 2×10^{-2} M, 1×10^{-6} M, and 0.25 M respectively; the thermostat was regulated at 80 °C. The results are shown in Fig. 4, in which the percentages of the coprecipitated strontium are plotted against the fractions of precipitated calcium. The strontium ion was enriched in the solution phase, as is shown in Fig. 4. The homogeneous and logarithmic distribution coefficients are plotted in Fig. 5 against the percentage of calcium precipitated. In the case of the slower addition of phosphate ions, the strontium ions were coprecipitated obeying the logarithmic law (the coefficient, $K_\lambda=0.26\pm0.02$), while in the more rapid addition the distribution coefficient decreased as the amount of precipitated calcium increased. The X-ray diffraction pattern of the latter solid phase denoted that the material was a poorly crystallized one. The coprecipitation behavior of strontium at pH 6.80, 7.70, and 8.60 is shown in Figs. 6 and 7. The Ca/P ratio of the apatite was affected by the pH, as has been mentioned above, while the logarithmic distribution coefficient did not change with the pH ($K_\lambda=0.26$).

The hydroxyapatite was precipitated at pH 6.80 from solutions containing strontium ranging from 10^{-8} M to 2.5×10^{-2} M, with the other circumstances kept identical. The results are shown in Fig. 8; no significant change in the coprecipitation behavior of strontium was observed between 10^{-8} M and 5×10^{-4} M. However, the distribution coefficient in the calcium-strontium apatite system tended to decrease at higher concentrations of strontium. It was observed from the X-ray diffraction pattern that this precipitate crystallized somewhat poorly; this tendency became clearer as the strontium content increased. Calcium-strontium apatite may crystallize more slowly than the pure calcium apatite.

The effect of the concentration of ethylenediamine used as a buffering agent was examined at pH 6.80 with regard to solutions of 0.10, 0.25, 0.50, and 1.0 M ethylenediamine; the effect was found not to be

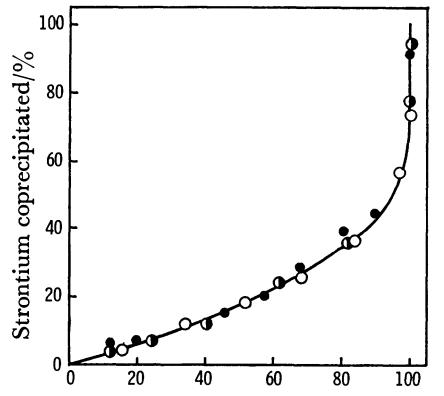

Fig. 6. The coprecipitation of strontium at different pH values.

noticeable in the range investigated. This may be caused by the fact that calcium and strontium ions do not form complexes with ethylenediamine so stable as to influence the distribution coefficient.

Calcium-strontium apatite was precipitated at 20, 55, and 80 °C. As is shown in Fig. 9, the coprecipitation behavior of strontium was identical at both 55 and 80 °C, while at 20 °C the behavior was different. The precipitate prepared at 20 °C had broad peaks in its X-ray diffraction pattern. The Ca/P mole ratio of the precipitate was 1.36 at the beginning of precipitation and decreased to 1.07 at 90 per cent precipitation. The abnormal distribution of strontium was probably caused by an incompleteness of apatite crystallization such as was observed above.

Collin prepared homogeneous solid solutions of strontium and calcium hydroxyapatite by heating precipitates formed from an aqueous solution to 950 °C,[10] and the lattice constants of these solid solutions were measured accurately. In the present apatites, the lattice constants were also measured in order to confirm the formation of the solid solutions (Table 1); the values were found to be close enough to those in Collin's paper, though there was a little error caused by the imcompleteness of crystallization.

Table 1. Lattice constants of calcium and strontium apatites

Sr/(Sr+Ca), %	A_0	C_0
0	9.417 Å	6.870 Å
14.5	9.479	6.924
20.0	9.494	6.966
42.3	9.559	7.039

It is also interesting to investigate the influence of chelating agents on the present coprecipitation system, because considerably strong chelate-forming substances should exist in the calcium-metabolism system. Acetate, citrate, lactate, glycinate, and L-glutamate ions were used as the organic anions. The results are summarized in Table 2. As is shown in the table, the apparent distribution coefficient, K_d, increases as the concentration of these organic anions increases.

Solid solutions were formed between calcium and strontium apatite by slow precipitation from a neutral or weakly basic solution at 80 °C, and the distribution coefficient of the strontium ions was about 0.26. A direct extension of these results to the processes occurring in biological systems may be difficult. However, it is possible that the very long biological half-life of strontium is caused by the formation of solid solutions.

Table 2. The effect of organic acids on the distribution coefficient

Organic acid	Concn of acid, M	K_d
Acetic acid	0	0.24_5
	0.1	0.26
	0.3	0.27_3

Studies on Electrode Processes of Oxovanadium(IV). I. Polarographic Behaviors and Photochemical Reaction in Potassium Oxalate Solution

Mitsutaka KITAMURA and Hideo IMAI

Faculty of Integrated Arts and Sciences, Hiroshima University, Hiroshima 730

(Received December 19, 1974)

Oxovanadium(IV) was found to develop a fairly stable oxidation wave as well as a reduction wave at the dropping mercury electrode in an aqueous solution containing M potassium oxalate. The predominant entity in the solution was $[VO(ox)_2]^{2-}$, and both the oxidation wave with one-electron transfer, and the reduction wave with two-electron transfer were irreversible. The anodic transfer coefficient evaluated from the logarithmic plot and Tafel plot was 0.60—0.63, and the exchange current density estimated tentatively from the Tafel plot was 1.8×10^{-6} A/cm^2. The effect of aerial oxidation of V(IV) to V(V) and the photochemical reduction of V(V) to V(IV) were investigated through the controlled potential electrolysis, absorption spectroscopy and ESR studies. The polarographic kinetic current of the oxidation process was observed under ultra-violet light irradiation. The apparent rate constant of the photochemical reduction evaluated from the kinetic current was $(0.02—0.04)/\varepsilon\phi I_0$ s^{-1}, where ε is the molecular extinction coefficient, ϕ the quantum yield and I_0 the intensity of the incident light.

Since vanadium shows various oxidation states from −1 to 5, numerous electrochemical investigations on its oxidation and reduction processes have been reported. However, only a limited number of papers refers to the oxidation process of oxovanadium (IV).

Lingane[1] has investigated the polarographic behaviors of vanadyl ion in various media, and has found the oxidation wave in a strongly alkaline medium. He has observed both the oxidation and reduction waves in an ammoniacal solution. However, the solution is very unstable and form a precipitate even in the presence of sodium sulfite added in order to avoid the oxidation. Bishop and Hitchcock[2] reported the oxidation of V(IV) in an acetate buffer of pH=4 at a platinum electrode, and suggested the possible chemical step coupled with the electrochemical oxidation. On the other hand, Dean and Herringshaw[3] have studied the oxidation of vanadyl ion by aerial oxygen. In relation to the photochemical reaction Setapathy *et al.*[4] have studied the photolysis of the aqueous suspension of V_2O_5 in oxalic acid. In general, the electrode processes of oxovanadium (IV) involve complications due to the aerial oxidation and coupled chemical and photochemical reactions.[5,6]

Our findings are that a stable polarographic oxidation wave as well as the reduction wave of oxovanadium (IV) can be observed in the solution containing M potassium oxalate, and that the oxidized entity is easily reduced by the irradiation of ultra-violet light. The kinetics of the polarographic oxidation process of oxovanadium (IV) and that of the photochemical reduction of V(V) are presented in this paper.

Experimental

The test solution was prepared by mixing the deaerated stock solution of vanadyl sulfate and M potassium oxalate solution unless otherwise noted. All reagents were of an analytical grade.

The electrochemical experiments were carried out by using a Shimadzu Model RP-50 polarograph and a Model PS-2 potentiostat. A quartz cell with a dropping mercury electrode (DME) and a saturated calomel electrode (SCE) were used for the measurement. The characteristics of the DME were as follows; the rate of flow of mercury=0.72 mg/s, the life-time=9.1 s under the head of mercury=40 cm at the applied potential of +0.15 V *vs.* SCE.

A xenon lamp (500 W) and Toshiba UV-D25 filter to pass 250—350 nm light were used for the photochemical study.

The spectrophotometric measurements were carried out by using a Shimadzu Model UV-200 dual beam spectrometer. For the ESR studies a Nihon Denki Model JES-ME ESR spectrometer was used under the following conditions; X-band microwave, modulation frequency of 100 kHz, modulation width of 6.3 gauss, the sample tubing of 1 mm diameter with 6 μl test solution.

The temperature was 28±1 °C.

Results and Discussion

Polarographic Behaviors of Oxovanadium(IV) in M Potassium Oxalate. The predominant entity of oxovanadium(IV) in M potassium oxalate solution (pH=8.4) is considered to be $[VO(ox)_2]^{2-}$.[6] It develops the polarographic oxidation wave as well as the reduction wave as shown in Fig. 1.

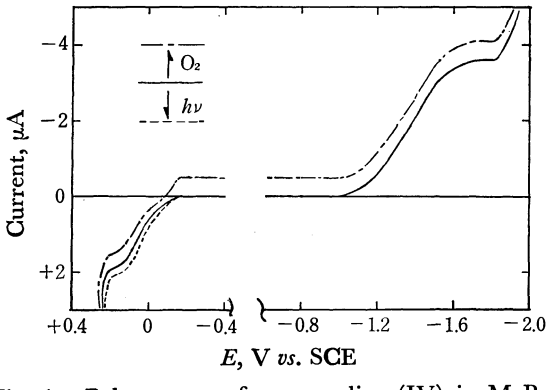

Fig. 1. Polarograms of oxovanadium(IV) in M Potassium oxalate.
—— polarogram of deaerated solution, ----- polarogram of oxidized solution, ------ polarogram of irradiated solution

The oxidation wave appeared at +0.025 V *vs.* SCE. The wave form was rather extended along with the potential axis than the well-defined reversible wave. The wave-height was approximately one half of the

reduction wave. The electrode process can be expressed as follows:

$$V(IV) - e = V(V) \quad (1)$$

Bishop and Hitchcock[2] have suggested the kinetic complication due to the coupled chemical reaction. However, no evidence could be observed so far as the effect of the mercury head on the wave-height was concerned as shown in Fig. 7.

The reduction wave of the two-electron transfer process appeared at −1.35 V *vs.* SCE. The wave form was also extended along with the potential axis, and the process was irreversible. It is noteworthy that the reduction wave showed the trend to split into two steps when the concentration of vanadyl ion was higher than 4 mM.

The dependence of the wave-height on the concentration of the vanadyl ion is illustrated in Fig. 2. Both the oxidation and reduction wave-heights showed good linear relationship with the vanadyl ion concentration. However, the linearity was no longer observed when the concentration exceeded 2 mM. The value of the diffusion coefficient estimated from the Ilkovic equation was 6.6×10^{-6} cm²/s.

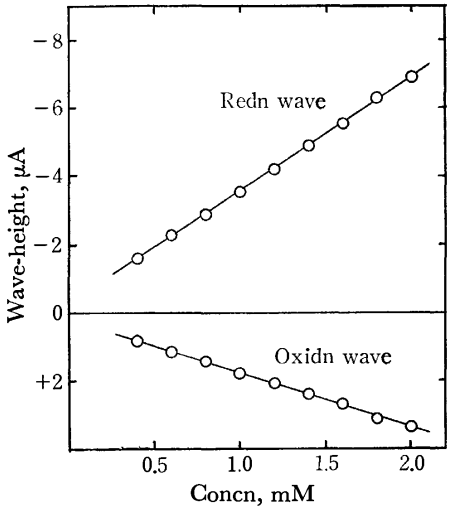

Fig. 2. Dependence of polarographic wave-height on concentration of oxovanadium(IV).

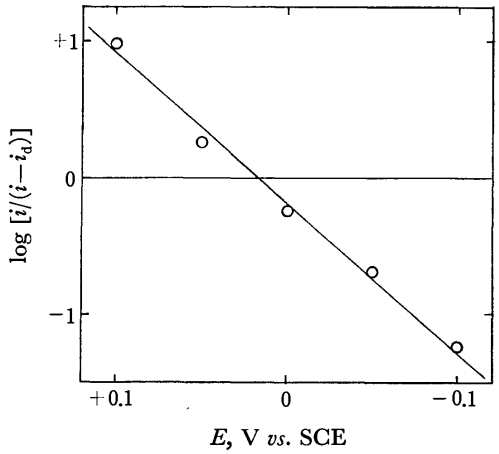

Fig. 3. Logarithmic plot of oxidation process of oxovanadium(IV).

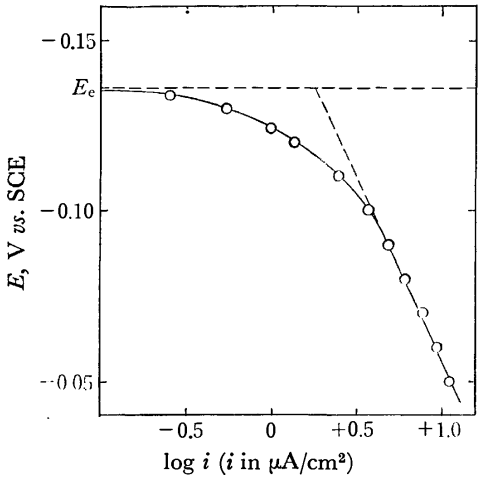

Fig. 4. Tafel plot of oxidation process of oxovanadium-(IV). E_e: equilibrium potential

Electrode Kinetics of Oxidation Process of Oxovanadium(IV). The polarographic oxidation current was recorded at each potential controlled by the potentiostat, and the $\log[i/(i_d-i)]$ *versus* the potential plot was obtained as shown in Fig. 3. From the inclination of this linear plot the anodic transfer coefficient of 0.63 was estimated.[7] On the other hand, the Tafel plot was obtained from the foot of this oxidation wave as shown in Fig. 4. The inclination of this Tafel plot gave the value of the anodic transfer coefficient as great as 0.60. Both data showed a fairly good agreement.

The value of the equilibrium potential for V(V)—V(IV) couple was tentatively evaluated assuming that the Tafel plot will be an asymptote along with the potential coordinate at the equilibrium potential as shown in Fig. 4. The exchange current density estimated from the intercept was 1.8×10^{-6} A/cm².

Oxidation of Oxovanadium(IV) by Aerial Oxygen, Electrolytic Oxidation of V(IV) and Photochemical Reduction of V(V). When dissolved oxygen was contained in the oxovanadium(IV) solution, the wave-height of the polarographic oxidation decreased and a new reduction wave appeared at −0.13 V *vs.* SCE as shown in Fig. 1. The height of the new wave was exactly equal to the decrement of the oxidation wave. The oxidation process of V(IV) by aerial oxygen in an alkaline solution was studied by Dean and Herringshaw[3] as formulated in the following;

$$O_2 + 2VO_3^{2-} + H_2O = 2VO_3^{-} + 2OH' + H_2O_2 \quad (2)$$

followed by

$$H_2O_2 + 2VO_3^{2-} = 2VO_3^{-} + 2OH' \quad (3)$$

In view of their results, the new reduction wave appeared at −0.13 V *vs.* SCE seems to be the reduction of V(V) to V(IV).

The solution color changed from light blue to light yellowish green by the aerial oxidation. A similar color change was observed by the electrolytic oxidation at the controlled potential of +0.15 V *vs.* SCE. The absorption band at λ_{max}=600 nm disappeared completely by the oxidation and the band at λ_{max}=310 nm decreased simultaneously in its intensity as shown in Fig. 5.[8,9] The ESR spectra of oxovanadium(IV) in

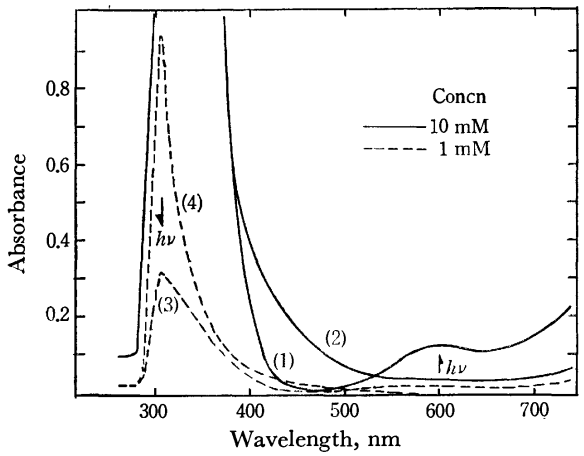

Fig. 5. Absorption spectra of oxovanadium(IV) and (V). Curves 1 and 2: 10 mM, Curves 3 and 4: 1 mM, Curves 1 and 3: deaerated or irradiated solution, Curves 2 and and 4: oxidized solution

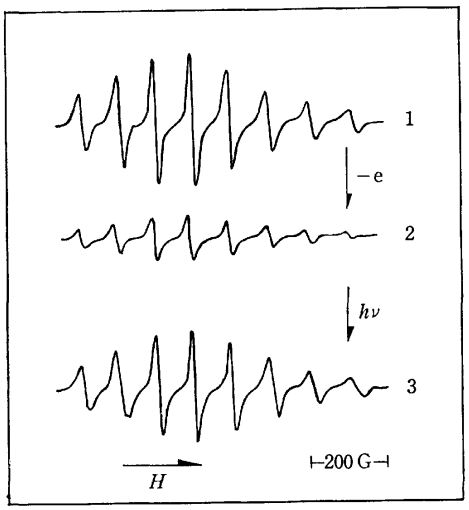

Fig. 6. ESR spectra of oxovanadium(IV). Curve 1: deaerated solution, Curve 2: oxidized solution, Curve 3: irradiated solution

M potassium oxalate solution showed eight components corresponding to the nuclear spin of 7/2 as shown in Fig. 6.[9] The ESR spectrum also decreased and disappeared in its intensity as the oxidation proceeded. It is noteworthy that vanadium of +5 oxidation state has no more spin in its d-shell. These changes in color, electronic absorption and ESR spectra were restored to the original state by the irradiation of ultra-violet light as shown in Figs. 5 and 6. The increase of the oxidation wave-height and disappearance of the new reduction wave were observed by the ultra-violet light irradiation as shown in Fig. 1. The photochemical reaction can be expressed as follows;

$$V(V) + h\nu = V(IV) - e \qquad (4)$$

and the oxidation of oxalate to form carbon dioxide seems to be coupled with Reaction (4), *i.e.*, $1/2C_2O_4^{2-} - e = CO_2$.

Kinetics of Photochemical Reduction of V(V) in M Potassium Oxalate Solution. The effect of the mercury head of the DME on the polarographic oxidation and reduction wave-heights is illustrated in Fig. 7. Both waves showed the linear increase with the square root of the mercury head. This characteristic corresponds well to the polarographic diffusion-controlled current. However, when the solution was irradiated by the ultra-violet light in the course of the polarographic oxidation, the inclination of the plot decreased slightly as shown in Fig. 7. This reveals the characteristic of the polarographic kinetic current, namely, the oxidation process of oxovanadium(IV) is coupled with the regeneration of V(IV) by the photochemical reduction of V(V), which is the product of the electrolytic oxidation. The reaction scheme is expressed by the combination of Reactions (1) and (4).

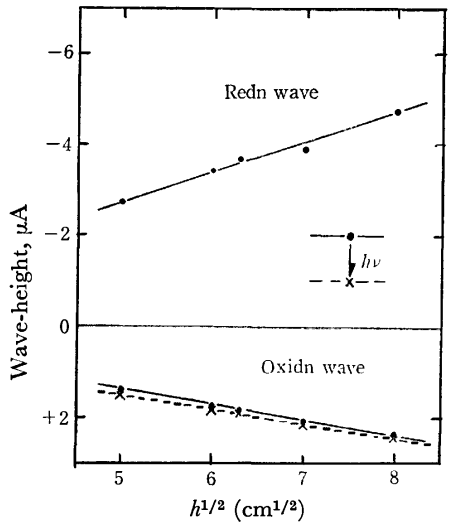

Fig. 7. Dependence of polarographic wave-height on DME mercury head.
Broken line: oxidation wave under ultra-violet light irradiation

Assuming that the Lambert-Beer's law holds for the light absorption of the V(V) species, the differential equation relating to the semi-infinite diffusion at the vicinity of the electrode-solution interface can be expressed as follows;

$$\frac{\partial C_{IV}}{\partial t} = D_{IV}\frac{\partial^2 C_{IV}}{\partial x^2} + \frac{2x}{3t}\frac{\partial C_{IV}}{\partial x} + \frac{k\phi I_0}{l}(1-e^{-\varepsilon C_V l}) \qquad (5)$$

$$\frac{\partial C_V}{\partial t} = D_V\frac{\partial^2 C_V}{\partial x^2} + \frac{2x}{3t}\frac{\partial C_V}{\partial x} - \frac{k\phi I_0}{l}(1-e^{-\varepsilon C_V l}) \qquad (6)$$

where C's are the concentration of respective species, k the rate constant of the photochemical reduction, ϕ the quantum yield, ε the molecular extinction coefficient, I_0 the intensity of the incident light, the thickness of the reaction layer and the other symbols are of the usual significance. Eqs. (5) and (6) can be simplified by the approximation that $\exp[-\varepsilon C_V l] \approx 1-\varepsilon C_V l$ and that $D_{IV} \approx D_V$.[10] The explicit equation for this case has been derived by Henke and Hans.[11] The numerical data of i_c/i_d were in the range from 1.04 to 1.10, where i_c is the mean limiting current under ultra-violet light irradiation and i_d the mean diffusion-controlled current. From the data the rate constant of the photochemical reduction, k, was evaluated as $(0.02—0.04)/\varepsilon\phi I_0\ s^{-1}$. The evaluation of the molecular extinction coefficient,

ε, the quantum yield, ϕ, and the intensity of the incident light, I_0, involves complication in this case so that it will be remained for the future.

Chemical Vapor Deposition of Tetraboron Silicide Whiskers

Seizi MOTOZIMA, Kozoh SUGIYAMA, and Yasutaka TAKAHASHI

Department of Synthetic Chemistry, Faculty of Egineering, Gifu University, Kakamigahara, Gifu 504

(Received January 6, 1975)

Growth conditions of B_4Si whiskers were investigated at the temperature range of 1000—1100 °C. Optimum composition of halides was determined as $BCl_3/SiCl_4=2$—0.5, and $BCl_3=1$—6 vol%, $SiCl_4=1$—7 vol%. Gold had an excellent impurity effect with optimum concentration of 20—50 μg/cm² on whisker growth, and gave wool like whiskers of 0.1—1 μm in thickness and 0.5—2 mm in length. B_4Si whisker growth was explained in terms of a tip VLS mechanism, for a drop-like deposit of impurity was observed on each tip.

Boron silicides are well known to have useful properties of high stability in oxygen, high elastic modulus, high mechanical strength, and so on. In the system of B–Si, a number of stoichiometric compounds, BSi, B_3Si, B_4Si, B_6Si, $B_nSi(n=10-14)$,[1] $B_{16}Si$,[2] $B_nSi(n=20-30)$,[2] and a few of nonstoichiometric compounds[3] have been prepared. Of these silicides, tetraboron silicide is the most stable and inert for oxygen up to its decomposition temperature (above 1400 °C).[4] Therefore, it is frequentry used as one of refractories[5] or coating materials of graphite to improve its oxidation resistivity.[6] On the other hand, the semiconducting properties of tetraboron silicide have been extensively studied, and are of much interest in its anisotropy.

Up to date, B_4Si has been prepared by various methods as follows: 1) solid-phase reactions between the elements,[7-10] 2) solid-vapor reactions of boron metal with silicon halides [11] and of silicon metal with boron trichloride or borane,[11] 3) vapor phase reactions in systems: $SiCl_4+BBr_3+H_2$,[12] $SiH_4+BCl_3+H_2$,[13] and $BCl_3+SiCl_4(SiHCl_3)$.[14] In these reactions, however, has never been reported the formation of B_4Si whiskers, which are expected as an excellent composite material.

In present work, B_4Si whiskers are found to grow from a vapor phase of BCl_3, $SiCl_4$, H_2, and Ar onto a quartz substrate at 1000—1100 °C and effects of various factors including gas concentration, temperature, and impurity in particular on whisker growth are examined.

Experimental

Materials. Commercial guaranteed reagent grade silicon tetrachloride, boron carbide, and chlorine gas were used without further purification. Argon was purified by passing over titanium sponge kept at 800 °C, and hydrogen was also refined by passing through active copper nets heated about 400 °C, conc sulfuric acid and phosphorus pentoxide, successively. Boron trichloride was prepared *in situ* (*vide infra*).

Preparation of B_4Si. The equipment used in this study is shown schematically in Fig. 1. The quartz tube(1) (7 mm in outside diameter and 100 mm in length), in which a SiC heater was inserted, was placed as a substrate in the center of reaction tube (quartz of 24 mm in inside diameter). The substrate was heated at 950—1200 °C dually from outside and inside. Boron trichloride (bp 12.5 °C) was prepared by chlorination of boron carbide at 800 °C, and supplied into the reaction tube. Silicon tetrachloride (bp 57.6 °C) was carried into the reactor by argon or hydrogen which was bubbled through its saturator(3) maintained at a given temperature. Hydrogen was also introduced through an upper

inlet (7) and allowed to be mixed with the streams of boron trichloride and silicon tetrachloride in the reaction zone. After the reactions had been quenched by stopping the supply of all reagent gases except argon, the furnace was allowed to cool below 200 °C to take out the substrate. The surface temperature of the substrate was measured by an optical pyrometer through a window(10), and the atmospheric temperature by an alumel–chromel thermocouple. The flow rates of each gas at room temperature were measured by an orifice type flow meter. The products formed on the surface of substrate were examined thoroughly by X-ray diffraction and an optical or electron microscope.

Whisker growth was found to be affected only when and where the substrate was painted with one of impurities such as gold, cobalt and nickel which were obtained by painting on the substrate in the form of aqueous solution of their salts: $HAuCl_4$, $CoCl_2$, and $NiCl_2$, followed by decomposition or reduction in the reactor below the reaction temperature.

Results and Discussion

When a mixture of boron trichloride, silicon tetrachloride, hydrogen and argon was introduced on a substrate(quartz) heated around 1100 °C, no deposition

was observed except formation of microcrystallites of boron metal at a condition of higher concentration of boron chloride. However, a large quantity of grayish wool-like crystals were obtained, only when the substrate was coated with gold. The X-ray diffraction profile of the crystals (Fig. 2) is consistent with that of ASTM data of tetraboron silicide,[15] and no peaks due to other products but gold were detected, even if a highly sensitive measurement was performed. In order to achieve the formation of well-formed and long crystals, the reaction conditions and impurity effects were thoroughly examined, and the results are discussed in the following sections in relation to the growth mechanism.

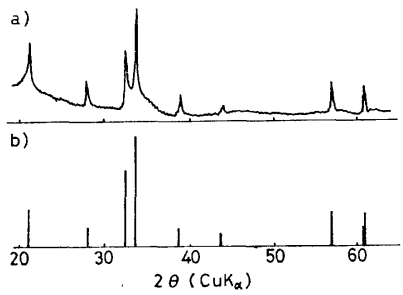

Fig. 2. X-Ray diffraction patterns.

Growth conditions. In this work, composition and concentration of reaction gas, which is considered to be the most impotant factors for whisker growth, were mainly studied.

The influences of $SiCl_4$ and BCl_3 flow rates on the whisker growth are shown in Fig. 3, where gold was used as an impurity. In this figure, it is found that optimum gas flow rates of BCl_3 and $SiCl_4$ are 0.02—0.14 cm^3/s and 0.02—0.15 cm^3/s, respectively; in other words, the growth of tetraboron silicide whisker takes place in the narrow range of molar ratio $BCl_3/SiCl_4$ of 2—0.5. In condition of an excess of boron trichloride ($BCl_3/SiCl_4 > 2$) or silicon tetrachloride ($SiCl_4/BCl_3 > 3$), whiskers of boron or silicon metal were obtained, respectively,

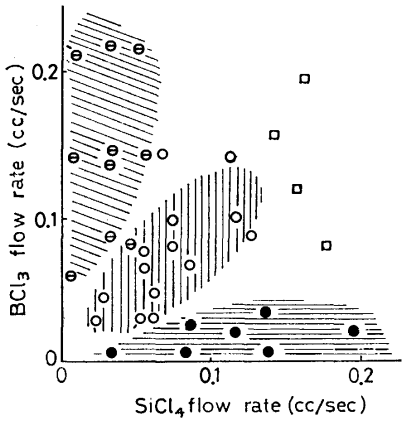

Fig. 3. Influence of $SiCl_4$ and BCl_3 flow rates on whisker growth.

Temperature: 1050 °C; total gas flow rate: 2.3 ml/s.

but tetraboron silicide was not formed. The increase of concentration of both halides could not result in deposition of the silicide, perhaps due to insufficiency of reducing agent. Although the stoichimetric ratio of chlorides in the reaction $4BCl_3+SiCl_4+8H_2=B_4Si+16HCl$, $BCl_3/SiCl_4=4$, growth experiments show the ratio to be near unity. Such a tendency that boron compound whiskers grow from a gaseous mixture of poorer boron trichloride content than that expected from stoichiometry has been found also in the case of TiB_2[16] and ZrB_2[17] whisker growth. It is supposed that such a tendency came from the difference in reactivity of halides with hydrogen on the one hand, and from the lower activity of metals such as Ti, Si, and Zr in a impurity liquid phase from which whiskers grow on the other hand.

Morphology. Figure 4 is a micrograph of B_4Si whisker typical in present experiments, where gold was used as an impurity. The appearance of whiskers was woolly and curled with dimensions of 0.5—2 mm in length and of 0.1—1 μm in diameter. The side surface of whisker was very smooth. Silicon or boron whiskers also have been obtained generally in the woolly form in contrast to a needle form of ZrB_2 or TiB_2.

Impurity effect. In Table 1, impurity effects of various metals on whisker growth at 1050 °C are shown qualitatively together with the eutectic temperature of corresponding binary system.[18-20] Although many kinds of impurities affected whisker growth of boron and silicon, for B_4Si gold alone showed an excellent effect, and Co and Ni weak effect. If vapor-liquid-solid(VLS) mechanism proposed by Wagner and Ellis[21] can be applied to B_4Si whisker growth, the impurity metal must fulfil at least following requirements: 1) the binary or ternary system among the impurity, boron and silicon has eutectic temperature lower than growth temperature, and 2) the impurity metal is stable in the corrosive atmosphere of BCl_3, $SiCl_4$, H_2, HCl, *etc.* The reason why excellent impurities such as Pd, Rh, or Pt metals for boron or silicon whisker growth are ineffective in B_4Si whisker growth is difficult to explain. However, it seems plausible that they have so strong affinity with both boron and silicon that the activities of both or one of elements in their ternary liquid may be lowered below the limit of B_4Si growth. Though the system Si–B–Au has not been reported, it may be considered from the two binary systems, that is, soluble Au–Si system and insoluble Au–B system, that the ternary system contains trace of boron in homogeneity. Therefore, growth kinetic requires fast diffusion of boron.

Whisker growth was very slow below 1000 °C, but was fast at the temperature above 1100 °C, where radial growth or branchings became striking. At the higher temperature, no deposition was observed, probably due to the following reasons: 1) activity of relevant species in Au drops is low, 2) Au disappears due to the reaction with quartz, 3) etching temperature may be attained.

In Figs. 5 and 6, the influence of Au impurity concen-

tration on growth rate of whiskers and their morphology are shown. It can be seen from Fig. 6 that the lower impurity concentration (the range of 20 to 50 μg/cm²) results in the more smooth whiskers and irregular whiskers are grown at the Au concentration of above 100 μg/cm². The lowest Au concentration for whisker growth is found to be 5 μg/cm² as seen in Fig. 5. Micrograph of the tip of typical whiskers obtained is shown in Fig. 7. There can be seen "cap" on each whisker which has a smooth surface with an apparent boundary with whisker. Rarely a hollow at the interface between the cap and crystal, and rough surface were observed (Fig. 8). The caps on the tips of whiskers look like Au or Au alloy. Accordingly, it is reasonable to consider that the wisker was grown by a tip VLS mechanism. Sometimes, whiskers with secondary growth of more thin crystals were found, too (Fig. 9), which may be attributed to a sudden fluctuation of reaction conditions such as temperature, or to precipitation during the cooling process. As shown in Figs. 7 and 9, a bright part which might be regarded as a residue of drop is frequentry observed to remain in side of the whiskers. Moreover, Fig. 10 indicates the creeping of cap material from tip to shoulder. The growing process of whiskers is shown in Fig. 11. When the quartz substrate which was painted with 2% aqueous $HAuCl_4$ solution was heated at 1050 °C in H_2 and cooled to room temperature, fine gold drops were found to be dispersed uniformly on the substrate and its size was about 0.5 μm (Fig. 11a) in diameter. This dimension is consistent with the diameter of whiskers, suggesting that the thickness of whiskers can be determined with the drop size of impurity. The number of drops per unit area quite agreed with that of whiskers (10^{7-8} per square centimeter of the substrate). Whisker growth was observed 5 minutes later after the reactant gas mixture had been introduced. This "induction time" for whisker growth may be explained in terms of a slow diffusion rate of boron, silicon and other species into the impurity drops or of the time necessary to nucleation. It can be concluded therefore that a whisker is grown from a Au-drop by the tip VLS mechanism. Although the thermodynamic data tell the gross concentrations of species in vapor phase, whiskers are grown from an impurity drop as mentioned above in which each component must be ballanced for the sake of whisker growth. Therefore, the solubility of the components to the impurity (liquid) and/or the diffusions to crystallizing sites must be more impotant factors for the growth than the concentration in vapor phase.

The Reactions of Tetrafluorobenzyne with Carboxylic Acids in Cyclic Ethers

Sei-ichi HAYASHI and Nobuo ISHIKAWA

Department of Chemical Engineering, Tokyo Institute of Technology, Meguro-ku, Tokyo 152

(Received May 2, 1974)

The reactions between tetrafluorobenzyne generated from tetrafluorobenzenediazonium-2-carboxylate and several carboxylic acids in cyclic ethers, such as THF and dioxane, were carried out. During these reactions, the cyclic ethers were cleaved and participated in the reactions to give acetate, benzoate, and salicylate esters of 4-(2′,3′,4′,5′-tetrafluorophenoxy)butanol and 2-[2′-(2″,3″,4″,5″-tetrafluorophenoxy)ethoxy]ethanol.

A number of cases have been reported of the reactions of unsubstituted or tetrahalogeno-substituted benzynes with ethers.[1,2] As for the ring cleavage of cyclic ethers during the reactions, Wolthuis *et al.* reported that tetrahydrofuran (THF) was cleaved by benzyne, thus affording a betaine intermediate, which was intercepted with water to give 23% 4-phenoxybutanol and 8% 1,4-diphenoxybutane.[3] In our own previous paper, we reported that dioxane was cleaved by tetrafluorobenzyne generated from tetrafluorobenzenediazonium-2-carboxylate and that the resulting betaine intermediate (**6**) was intercepted with bromine to give 28% 1-[2′-(2″-bromoethoxy) ethoxy]-2-bromo-3, 4, 5, 6-tetrafluorobenzene.[4]

We shall now describe further examples of this type of reaction, *i.e.*, those between tetrafluorobenzyne and carboxylic acids in the cyclic ethers, such as THF and dioxane, in which the solvents participate through their cleavage.

Results and Discussion

It is known that benzynes generated from benzenediazonium-2-carboxylate[5] or its tetrahalogeno derivatives[6–8] sometimes yield acridones by reactions with anthranilic or tetrahalogenoanthranilic acid. By analogy with these, we attempted to have tetrafluorobenzyne react with salicylic acid, expecting to obtain 2-(2′,3′,4′,5′-tetrafluorophenoxy)benzoic acid or its dehydrocyclized product, tetrafluoroxanthenone.

The reaction was carried out in THF by diazotizing tetrafluoroanthranilic acid with *n*-butyl nitrite in the presence of salicylic acid, and by subsequent refluxing for several hours. The main products were crystals with a melting point of 84—85 °C; unexpectedly, the compound contained four methylene groups. The structure of this compound was established, by means of the NMR and the mass spectra, as 4-(2′,3′,4′,5′-tetrafluorophenoxy)butyl salicylate (**4c**).

In the NMR spectrum three signals appeared at τ 5.58, 5.95, and 8.03 in a 1 : 1 : 2 ratio of strength; they are due to two $-OCH_2-$ groups and one $-CH_2CH_2-$ group. Other signals due to four protons appeared in the non-fluorinated benzene ring at τ 2.25—3.25, while signals due to a proton appeared in the fluorinated ring at τ 3.23—3.67. The signal of the OH proton appeared at an unusually lower magnetic field, τ −0.73; this may be supposed to have resulted from a strong intramolecular hydrogen bonding. The ^{19}F NMR spectrum showed the presence of four unequivalent aromatic fluorine atoms.

In the mass spectrum, the molecular ion, M^+ 358, is in agreement with the calculated value and the fragmentation is as is shown in Fig. 1. The base peak, *m/e* 149, corresponded to the tetrafluorophenyl fragment; another characteristic fragment peak, *m/e* 120, probably resulted from the elimination of 4-tetrafluorophenoxybutanol from the molecular ion. The **4c** structure was adequately

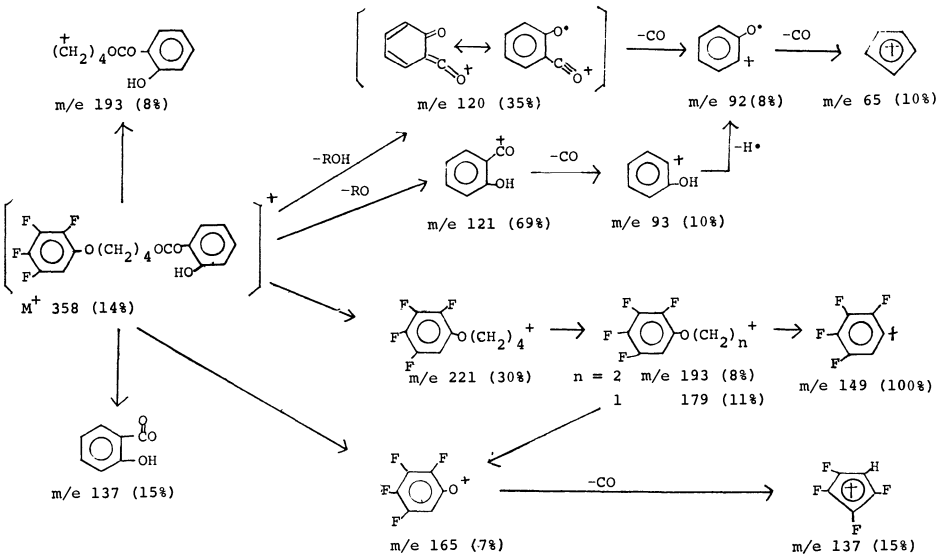

Fig. 1. MS fragmentation for **4c**.

supported by this degradation, which can be explained by the so-called ortho-effect.[9]

In this reaction it is evident that the strong electrophilic tetrafluorobenzyne initially attacked the abundant THF, prior to dilute carboxylic acid, to give **2**, followed by the ring cleavage to a betaine intermediate, **3**, which then electrophilically attacked the oxygen of carboxylic acid to give **4c**. The last two steps, **2** to **3** and **4c**, might have occurred simultaneously.

Other carboxylic acids, such as acetic and benzoic acids, were also subjected to the reaction with tetrafluorobenzyne in THF. In these cases, too, we could obtain the analogous compounds, *i.e.*, 4-(tetrafluorophenoxy)butyl acetate (**4a**) and benzoate (**4b**) respectively. The NMR spectra of these products revealed patterns similar to that of **4c** (Table 1).

The **4b** benzoate was alternately prepared by the benzoylation of 4-(2′,3′,4′,5′-tetrafluorophenoxy)butanol which had been obtained by a direct reaction between tetrafluorobenzyne and 1,4-butanediol.

Other hydroxy compounds, such as water and 3-trifluoromethylphenol, when reacted with tetrafluorobenzyne in THF gave similar results. Water yielded 4-(2′,3′,4′,5′-tetrafluorophenoxy)butanol and 2,3,4,5-tetrafluorophenol in yields of 50 and 13% respectively. The latter compound must result from the direct reaction of tetrafluorobenzyne with water, without the participation of THF.

m-Trifluoromethylphenol was chosen as the phenol to be examined, avoiding the diazo-coupling reaction

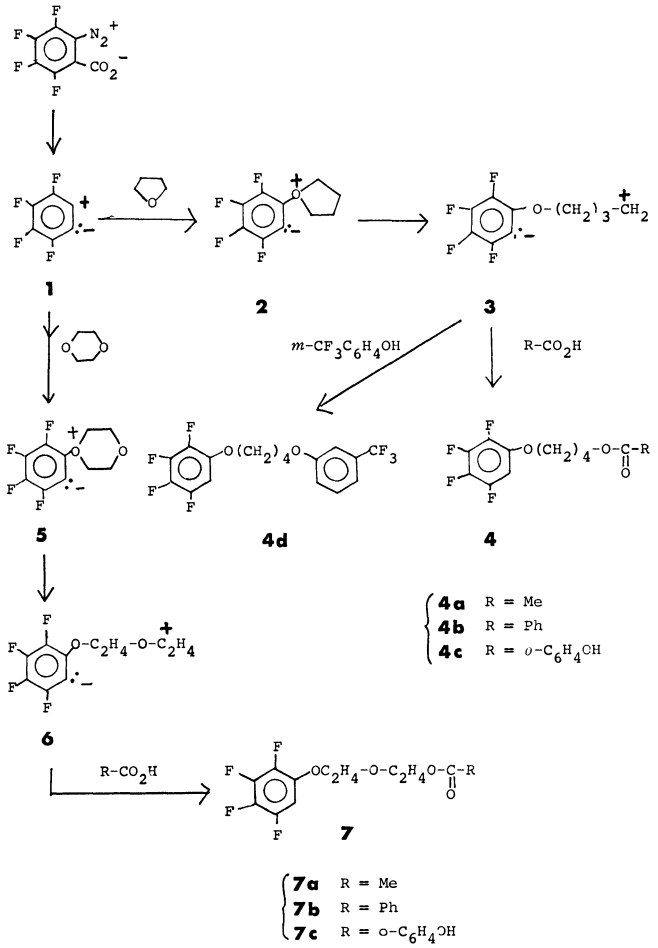
a) Similar to that of Table 1.

with tetrafluorobenzenediazonium-2-carboxylate. The phenol also gave the expected product, 4-(2′,3′;4′,5′-tetrafluorophenoxy)butyl *m*-trifluoromethylphenolate (**4d**), but in a low yield.

Since analogous reactions could be expected when using dioxane instead of THF, we reacted the carboxylic acids, such as acetic, benzoic and salicylic with tetrafluorobenzyne in this solvent. In these cases, the reaction proceeded through the betaine intermediate **6**, and the resulting products were 2-[2′-(2″,3″,4″,5″-tetrafluorophenoxy)ethoxy]ethyl acetate (**7a**), benzoate (**7b**) and salicylate (**7c**).



Compound **7b** was also obtained by the benzoylation of 2-[2′-(2″,3″,4″,5″-tetrafluorophenoxy)ethoxy]ethanol, which had been prepared from tetrafluorobenzyne and diethyleneglycol.

Experimental

4-(2′,3′,4′,5′-Tetrafluorophenoxy)butyl Salicylate (4c). A solution of tetrafluoroanthranilic acid (4.18 g, 20 mmol) in THF (40 ml) was added dropwise into a mixture of *n*-butyl nitrite (2.6 g, 25 mmol), salicylic acid (13.8 g, 100 mmol), and THF (10 ml) at 55—56 °C with stirring. After refluxing for 5 hours, the solvent was distilled out under reduced pressure and the residue was dissolved in diethyl ether. The solution was then treated with a dilute aqueous sodium hydroxide solution to remove the excess salicylic acid, washed with dilute hydrochloric acid and water successively, and dried over magnesium sulfate. After the solvent had been removed, the residue was recrystallized from methanol to give crude **4c**. Sublimation gave pure crystals; mp 84—85 °C.

IR (KBr): 3388 (OH, intramolecularly H-bonded), 1661 (C=O), 1136, 1091 cm^{-1} (C–F).

4-(2′,3′,4′,5′-Tetrafluorophenoxy)butyl Acetate (4a), Benzoate (4b) and m-*Trifluoromethylphenolate (4d).* Instead of salicylic acid in the above reaction, acetic acid, benzoic acid and *m*-trifluoromethylphenol were used. When the reactions were carried out and worked-up in the same way, they gave **4a**, **4b**, and **4d** respectively (Table 1).

The benzoate (**4b**) was also obtained by the benzoylation of (2′,3′,4′,5′-tetrafluorophenoxy)butanol. Thus, a mixture of the alcohol (2.00 g), benzoyl chloride (1.18 g), and two drops of concentrated sulfuric acid was heated until the evolution of gas ceased. Upon cooling, the reaction mixture was poured onto ice water; the precipitate was separated by filtration and washed with a dilute aqueous solution of sodium bicarbonate to remove benzoic acid, thus giving crude benzoate (2.42 g). After recrystallization from petroleum ether, a pure material (mp 42—44 °C) was obtained. No depression in mp was observed on admixture with the product described above.

4-(2′,3′,4′,5′-Tetrafluorophenoxy)butanol. A solution of anthranilic acid (2.09 g) in THF (10 ml) was dropped into a mixture of *n*-butyl nitrite (1.3 g), deionized water (10 ml), and THF (10 ml) at 60 °C, and then the mixture was refluxed for 5 hr. The reaction mixture was then worked-up as usual. In addition to the main product (1.20 g, bp 110—111 °C/3 mmHg), a small amount (0.21 g) of an alkaline-soluble material was obtained. This compound was identified as 2,3,4,5-tetrafluorophenol by means of its IR spectrum.

4-(2′,3′,4′,5′-Tetrafluorophenoxy)butanol was also alternatively obtained as follows. Into a mixture of tetrafluoroanthranilic acid (10.45 g) and 1,4-butanol (50 ml), a solution of *n*-butyl nitrite (6.5 g) in dichloroethane (10 ml) was added at 50 °C. After having been refluxed for 3 hr, the reaction mixture was worked-up as usual to give the alcohol (7.50 g, 64%).

2-[2′-(2″,3″,4″,5″-Tetrafluorophenoxy)ethoxy]ethanol. Into a mixture of *n*-butyl nitrile (2.6 g), dioxane (10 ml), and deionized water (15 ml), a solution of tetrafluoroanthranilic acid (4.18 g) in dioxane (20 ml) was added at 50 °C, and then the mixture was worked-up as usual. In addition to the alcohol (0.85 g, 17%; bp 156—157 °C/15 mmHg), 2,3,4,5-tetrafluorophenol (0.37 g, 11%; bp 143—145 °C (lit. bp 145 °C[10])) was obtained as an alkaline-soluble material.

The alcohol was also prepared by the diazotization of tetrafluoroanthranilic acid (4.18 g) in diethyleneglycol (20 ml) with *n*-butyl nitrile (2.6 g). The product (2.90 g) was identified by means of its IR spectrum.

2-[2′-(2″,3″,4″,5″-Tetrafluorophenoxy)ethoxy]ethyl Acetate (7a), Benzoate (7b), and Salicylate (7c). Instead of THF in the procedure for the preparation of **4a**—**4c** described above, dioxane was used. The results are shown in Table 2. The **7b** benzoate was also prepared by the benzoylation of the alcohol with benzoyl chloride.

Reactivity of Electrogenerated Superoxide Ion. I. Autoxidation of 9,10-Dihydroanthracene

Meguru TEZUKA, Yasukazu OHKATSU, and Tetsuo OSA

Department of Industrial Chemistry, Faculty of Engineering, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received June 18, 1974)

The superoxide ion, which was generated by means of electroreduction of the oxygen molecule dissolved in pyridine, abstracted the labile hydrogen from 9,10-dihydroanthracene and yielded anthraquinone and anthracene as the final products. From the products and their kinetics, the reaction was proposed to be a radical-chain autoxidation. Reactions with some other hydrocarbons were also carried out. The addition of ferrous or cobaltous phthalocyanine to the reaction system resulted in the increase of the reaction rate. A discussion of the effects led to the postulation of the intermediate formation of the superoxide ion-metal phthalocyanine complex.

Electrochemically an oxygen molecule is reduced by a reversible one-electron transfer to form a fairly stable species, namely a superoxide ion in common solvents such as dimethylformamide, dimethylsulfoxide and pyridine.[1-3]

$$O_2 + e \longrightarrow O_2^-$$

The superoxide ion might be a kind of an extreme form of activated oxygen molecule, which is usually observed in the adsorption on metal oxide[4,5] and in the coordination with transition metal complexes, due to the electron transfer from a low-valent metal atom.[6,7] Hence, it is interesting to investigate the reactivity of the superoxide ion, since it leads to a clearer understanding of the chemical nature of the activated oxygen.

The superoxide ion is expected to possess various reactivities to extensive organic compounds, because of its basic, nucleophilic and other properties.[8,9]

In this paper we report on the reactions of the superoxide ion with some hydrocarbons having labile hydrogens. In the case of 9,10-dihydroanthracene as a substrate, the rate equation was determined and the mechanism was proposed to be a radical-chain autoxidation. The catalytic effect of metal phthalocyanine added to this reaction system was also discussed.

Experimental

Materials. Pyridine was dried over potassium hydroxide for several days, then distilled and stored under nitrogen atmosphere. Tetraethylammonium perchlorate (TEAP) was synthesized and purified by the ordinary method.[10] 9,10-Dihydroanthracene, fluorene and diphenylmethane of reagent grade were used without any further purification. Cumene and cyclohexane were used after distillation. Ferrous and cobaltous phthalocyanines were synthesized and purified according to the method given in literature.[11]

Cyclic Voltammetry. In the solvent of pyridine, cyclic voltammograms were recorded using TEAP as a supporting electrolyte on a platinum plate of 0.40 cm^2. Potential was referred to saturated calomel electrode (SCE).

Macro-electrolysis. For controlled potential electrolysis, an H-type cell was employed in which cathodic and anodic chambers were separated from each other by a glass filter and a reference electrode was connected to the cathodic chamber with a double salt bridge. Platinum gauze of 50 cm^2 was used as a cathode. 20 ml each of the electrolytic solution containing 0.1 M TEAP was put in each chamber and vigorously stirred. The cathode potential was controlled with a Yanagimoto Type VE-3 controlled potential electrolyzer.

The consumed amount of oxygen during electrolysis was measured by means of a gas burette connected to the cell in a closed oxidation system. The temperature of the solution was kept at 20±1 °C.

Spectrometry. In the ESR study, the solution was charged into the quartz tube immediately aftet electrolysis, and then the spectra were recorded at room temperature or −196 °C with a JEOL Model JS-3BS-X spectrometer. Otherwise, the spectra were measured while electrolysis was being carried out in the cavity. The *g*-factors were determined in comparison with Mn^{2+} marker. The electronic spectra of the solution after electrolysis were recorded with a Shimadzu MPS-50L spectrophotometer.

Results and Discussion

Electrogenerated Superoxide Ion. An oxygen molecule dissolved in 0.1 M TEAP–pyridine solution was reduced on platinum to form the superoxide ion (Fig. 1). This species was re-oxidized in the reverse sweep of the potential. The peak potentials of reduction and re-oxidation were respectively −0.91 and −0.77 V. The value of 140 mV as ΔE_p shows that the electrode process is quasi-reversible.[12] In addition, the fact that the ratio of anodic current to cathodic one is substantially unity even at slow sweep rate such as 0.02 V/s means that the superoxide ion remains fairly stable in a pyridine solution.[13]

In the ESR measurement, the superoxide ion gave no signal at room temperature, but the spectrum, which possessed marked anisotropy of $g_{//}=2.069$ and $g_{\perp}=2.006$, was obtained at −196 °C (Fig. 2). These

results were identical with those reported previously.[1,3]

The superoxide ion in pyridine gave electronic spectra which had an absorption band of λ_{max}=462 nm (Fig. 3). This band became reduced in intensity as the anion radical decayed. After 20 hours at room temperature, it almost disappeared and a small absorption band at λ_{max}=375 nm appeared, due probably to the absorption of the products from the reaction of the superoxide ion with pyridine or other possible substances in the system. The band at 462 nm seems to be due not to the electronic transition in the free superoxide ion but to the charge-transfer complex, where the superoxide ion behaves as a donor and pyridine as an acceptor.[14]

Effect of Metal Phthalocyanine. In the voltammetric study, ferrous or cobaltous phthalocyanine added into the electrolytic solution gave the catalytic current to the reduction wave of oxygen and shifted the reduction potential to the positive direction (Table 1). These results suggest the intermediate formation of superoxide ion-metal phthalocyanine complex (**1**), which was concluded by Beyer *et al.* with respect to a phthalocyanine electrode.[15]

Reactions of Superoxide Ion with Hydrocarbons Having Labile Hydrogens. 9,10-Dihydroanthracene or fluorene were oxidized easily by the seperoxide ion. Figure 4a is the cyclic voltammogram of 9,10-dihydroanthracene in 0.1 M TEAP–pyridine solution with or without oxygen. In the presence of oxygen, some new reduction peaks, which were not observed in the absence of oxygen, appeared. These peaks I, II and III corresponded respectively to the reduction of oxygen, anthraquinone monoanion radical and anthracene. But the re-oxidation peak of the superoxide ion disappeared. In the second sweep the reduction peak of oxygen was remarkably diminished. In the case of fluorene, the similar phenomena were observed (Fig. 4b). The new reduction peak differed from that of oxygen was due to fluorenone. These results show that the electrogenerated superoxide ion reacted easily with 9,10-dihydroanthracene or fluorene, the species resulting from which subsequently took up oxygen molecule in the vicinity of electrode to yield anthraquinone and anthracene or fluorenone.

In order to elucidate the reaction mechanism, the consumption of oxygen during the reaction of the superoxide ion and 9,10-dihydroanthracene was pursued. The reactions were carried out by the controlled potential electrolysis of oxygen-saturated electrolytic sloution containing a certain amount of the substrate at −0.8 V which was approximately the minimum potential for the generation of the superoxide ion and at which the substrate was not reduced. When electrolysis was commenced, the absorption of oxygen

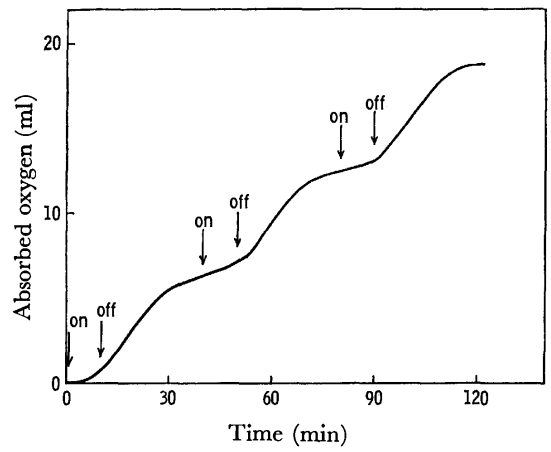

Fig. 5. Oxidation of 9,10-dihydroanthracene in 0.1 M TEAP–pyridine solution, oxygen-saturated at 20 °C, on; cathode (−0.8 V *vs.* SCE), concentration of 9,10-dihydroanthracene; 50 mM.

was observed after several minutes of induction period. Almost simultaneously the electrolytic current increased and the solution gradually became deep wine-red which seemed to be derived from anthraquinone monoanion radical since the ESR spectra of this solution gave the same signal as that of anthraquinone monoanion radical.[16] After long electrolysis, anthraquinone precipitated.

As shown in Fig. 5, when the electric circuit was opened (off) just after the beginning of oxygen absorption, the absorption went on constantly for a while and then gradually ceased. The subsequent closing of the circuit (on) recovered the absorption, preceded by the same induction period as ever.

Zinc isopropyl dithioxantate, which is a peroxy radical-trapping agent in ordinary autoxidations and is reduced at a much more negative potential than −0.8 V,[17] was added to solution, causing a remarkable prolongation of the induction period, followed by the absorption of oxygen at the same rate as that in the absence of the antioxidant. Use of 2,6-di-*tert*-butyl-4-methyphenol as another antioxidant was unsuccess, for the phenol itself was reduced and evolved hydrogen gas.

The reaction orders on substrate and oxygen partial pressure concerning the rate of oxygen absorption were determined experimentally, and the following rate equation was given in lower concentration than 2×10^{-2} M of substrate.

$$-d[O_2]/dt = k_1[RH]^{3/2}[O_2]^{1/2} \quad (2)$$

When a considerable chain length and sufficient oxygen pressure in the general elementary steps of autoxidation are present, the rate of oxygen absorption is expressed as follows, where R_i represents the rate of initiation reaction.[18]

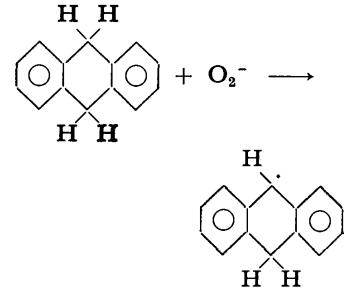
$$-d[O_2]/dt = k_2[RH](R_i)^{1/2} \quad (3)$$

Comparison of Eqs. (2) and (3) gives the rate equation of the initiation of this reaction as

$$R_i = k_3[RH][O_2] \quad (4)$$

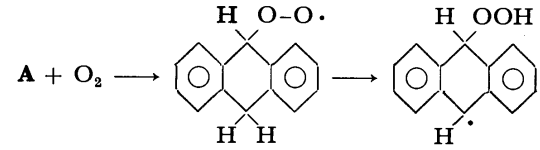
From the products and their kinetics mentioned above, the following mechanism seems to be acceptable for the initiation;

$$O_2 + e \rightleftharpoons O_2^- \quad (5)$$

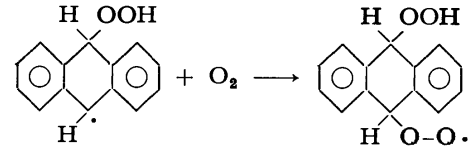


(6)

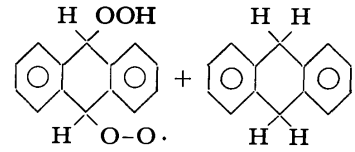
The electrogenerated superoxide ion abstracts hydrogen from 9,10-dihydroanthracene to yield radical **A**. The subsequent process may be illustrated as follows.

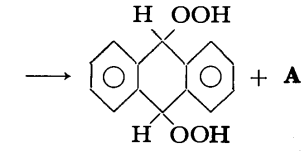


(7)



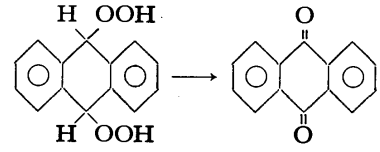
(8)





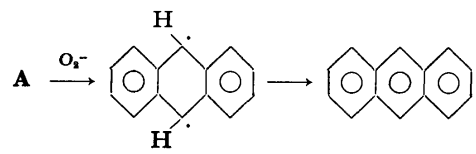
(9)

The addition of oxygen to radical **A** is followed by intramolecular hydrogen abstraction, as proposed by Hawthorne *et al.* in their study of base-catalyzed autoxidation.[19] Dihydroperoxide, one of the products in mechanism (9), is decomposed to give anthraquinone.



(10)

On the other hand, the production mechanism of anthracene seems to be as follows.



(11)

Some other compounds were also used as substrate. The results are shown in Table 2. The superoxide ion oxidized the compounds with the secondary hydrogen such as fluorene or diphenylmethane to yield ketones, that is fluorenone or benzophenone. It also oxidized cumene to yield the hydroperoxide. Moreover,

TABLE 2. OXIDATION BY ELECTROGENERATED SUPEROXIDE ION

Compounds	$-d[O_2]/dt$ ($\times 10^6$ M/s)	Main products
9,10-Dihydroanthracene	4.37	Anthraquinone: Anthracene (3: 1)
Fluorene	1.17	Fluorenone
Diphenylmethane	3.53	Benzophenone
Cumene	3.27	Cumene hydroperoxide
Cyclohexane	0.35	Unidentified

Concentration of hydrocarbons; 50 mM in oxygen-saturated 0.1 M TEAP–pyridine solution, 20 °C.

it could abstract the hydrogen of cyclohexane although its bond energy of C–H is considerably higher than those of the other substrates.[20] However, the final product could not be detected because of the slow rate of oxidation. Differing from the case of 9,10-dihydroanthracene, the oxidations of these compounds do not proceed according to the usual autoxidation, for these chain lengths were very short.

TABLE 3. EFFECT OF METAL PHTHALOCYANINE ON THE OXIDATION RATE OF 9,10-DIHYDROANTHRACENE

M–Pc	$-d[O_2]/dt$ ($\times 10^6$ M/s)
None	4.37
Fe–Pc	10.2
Co–Pc	10.4

Concentrations of M–Pc and 9,10-DHA; repectively, 1 mM and 50 mM in oxygen-saturated 0.1 M TEAP–pyridine solution, 20 °C.

It is well known that metal phthalocyanine activates oxygen molecule to initiate the autoxidation of various organic compounds such as cumene and α-methylstyrene.[21,22] In our study, ferrous or cobaltous phthalocyanine added to the macro-electrolytic solution acted as a positive catalyst and increased the reaction rate (Table 3). In the presence of ferrous phthalocyanine under 0.2 mM concentration, the rate equation was determined as follows.

$$-d[O_2]/dt = k_4[RH]^{3/2}[O_2]^{1/2}[Cat.]^{1/2} \quad (12)$$

The initiation rate is then expressed as

$$R_i = k_5[RH][O_2][Cat.] \quad (13)$$

This means that the catalyst is involved in the initiation step of Eq. 6. Addition of the catalyst gave no substantial change to the macro-electrolytic current. Therefore, it is inferred that the catalyst makes the superoxide ion more powerful in the hydrogen abstraction by the formation of complex **1** described in Eq. (1) and consequently increases the reaction rate. In the absence of a compound having labile hydrogen, complex **1** regenerates oxygen and gives the catalytic current (Table 1). However, the role of metal phthalocyanine might be more complicated, since it will deactivate the peroxy radical and decompose hydroperoxide.[23,24]

The PMR Study of the *cis-trans* Isomerization of the Dimethylaluminum Methylphenylamide Dimer, $[(CH_3)_2AlN(CH_3)(C_6H_5)]_2$

Kizuku WAKATSUKI and Toshio TANAKA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita, Osaka 565

(Received October 3, 1974)

The dimethylaluminum methylphenylamide dimer exists as an equilibrium mixture of *trans*- (I) and *cis*-isomers (II) with respect to the four-membered Al_2N_2 skeleton, and the latter involves the magnetic non-equivalence of the Al–CH_3 groups. Thermodynamic parameters for the *cis* to *trans* isomerization are obtained from the variable-temperature PMR spectra; $\Delta H = 4.47 \pm 0.09$ kJ·mol^{-1} and $\Delta S = 1.74 \pm 0.48$ J·deg^{-1}·mol^{-1}. The isomerization is markedly accelerated by adding 4-methylpyridine or tetrahydrofuran. A possible mechanism of the isomerization is proposed.

Structural studies of organoaluminum compounds have been widely undertaken by means of X-ray analysis and the PMR spectra in connection with stereospecific catalysis and the bridge-bond character in dimeric or oligomeric aluminum derivatives.[1-12]

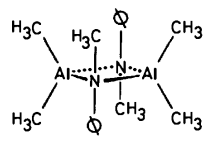
In the course of our studies of the reaction of aluminum amides with carbon disulfide,[13] we have found that the dimethylaluminum methylphenylamide dimer $[(CH_3)_2AlN(CH_3)(C_6H_5)]_2$ exists as an equilibrium mixture of *trans*- (I) and *cis*-isomers (II) with respect to the four-membered Al_2N_2 skeleton. This paper will report the PMR study of the equilibrium between the two isomers, of which the *cis*-isomer involves a magnetic non-equivalence of the terminal Al–CH_3 groups. The isomerization between the *cis*- and *trans*-isomers upon the addition of Lewis bases will also be described.

Experimental

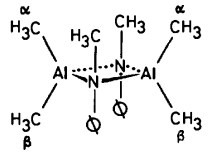
The preparation of dimethylaluminum methylphenylamide has been described elsewhere.[13] The PMR spectra were obtained at 100 MHz on a JEOL JNM-PS-100 spectrometer equipped with a variable-temperature probe. Toluene or cyclohexane was used as the internal reference. The sampling was carried out under dry nitrogen. The materials were dried over appropriate desiccants and were distilled under dry nitrogen.

Results and Discussion

The molecular-weight determination indicates the association degree of 1.96 for $(CH_3)_2AlN(CH_3)(C_6H_5)$ (Found: 319 at the 1.96 wt% solution in benzene by the cryoscopic method. Calcd for $C_9H_{14}NAl$: 163). The PMR spectrum of this compound in benzene at room temperature shows two N–CH_3 proton signals (δ 2.68 (relative intensity 4.4) and 2.64 (1.0) ppm) and three Al–CH_3 proton signals (δ −0.21 (4.4), −0.36 (2.0), and −0.54 (4.4) ppm) (Fig. 1a). The relative intensities of these signals change reversibly with the temperature. These results confirm that dimethylaluminum methylphenylamide exists essentially as an equilibrium mixture of dimeric *trans*- (I) and *cis*-isomers (II), with the mole ratio of *ca.* 1.0: 4.4 in benzene at room temperature. The mole ratio is a little solvent-dependent, such as *ca.* 1.0: 5.0 in dichloromethane at room temperature. The existence of analogous isomers has been reported for $[(C_2H_5)XAlN(H)(tert\text{-}C_4H_9)]_2$ (X = C_2H_5, Cl, Br, I) in the course of preparing this paper.[14]



I



II

The *cis*-isomer involves two kinds of Al–CH_3 groups located in magnetically different environments: α and β, while the four Al–CH_3 groups of the *trans*-isomer are equivalent. The signals at δ 2.64 and −0.36 ppm are assigned to the *trans*-isomer, while the others are assigned to the *cis*-isomer on the basis of their relative intensities. A similar non-equivalence of terminal Al–CH_3 groups has only been reported in the low-temperature PMR spectra of the dimethylcyclopropylaluminum dimer in toluene, in which the two bridging cyclopropyl groups are both bent toward the same side of the four-membered ring.[5]

Table 1. The equilibrium constants between *trans*- and *cis*-$[(CH_3)_2AlN(CH_3)(C_6H_5)]_2$ at various temperatures in dichloromethane

T(K)	296	279	268	257	244	229	216	205
K([*cis*-]/[*trans*-])	5.00	5.76	5.82	6.40	7.59	8.34	10.17	10.94

Equilibrium constants (K) measured in dichloromethane at various temperatures (T) are given in Table 1. A plot of log K *versus* $1/T$ gives $\Delta H = 4.47 \pm 0.09$ kJ·mol^{-1} and $\Delta S = 1.74 \pm 0.48$ J·deg^{-1}·mol^{-1} in the *cis*-to-*trans* isomerization. Both the enthalpy and entropy changes are fairly small compared with those in the interconversion of trimeric $[(CH_3)_2AlN(CH_2)_3]_3$ to the dimer ($\Delta H = 57.8$ kJ·mol^{-1}, $\Delta S = 168$ J·deg^{-1}·mol^{-1}).[10] This may imply that the steric effects and valence-angle strains are not very different between the two isomers of the present compound.

Figure 1 displays the PMR spectra of dimethylaluminum methylphenylamide in benzene containing varying amounts of 4-methylpyridine. When a small amount of 4-methylpyridine (4.32×10^{-2} M) was added to a benzene solution of the aluminum amide (3.93×10^{-1} M as monomer), the Al–CH_3 signals of both the *trans*- and *cis*-isomers broadened and new Al–CH_3 and N–CH_3

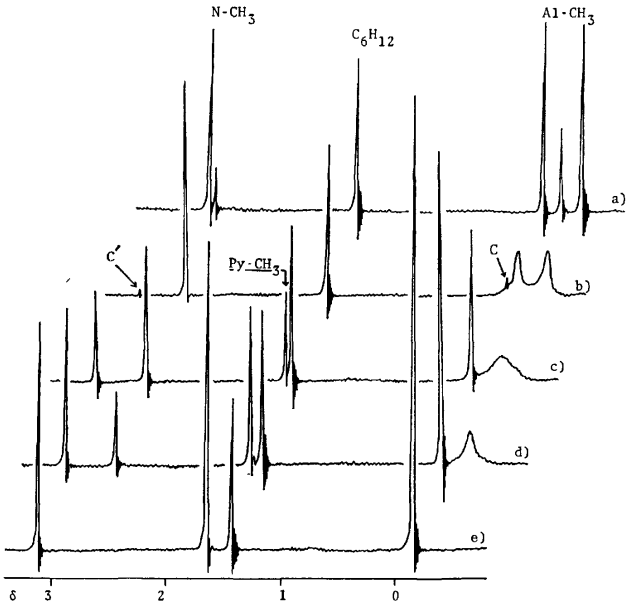


Fig. 1. The PMR spectra of $(CH_3)_2AlN(CH_3)(C_6H_5)$ (3.93×10^{-1} M) in benzene containing varying amounts of 4-methylpyridine; mole ratios of a) 1.00: 0.00, b) 1.00: 0.11, c) 1.00: 0.41, d) 1.00: 0.70, and e) 1.00: 1.37, measured at 100 MHz at 23 °C.

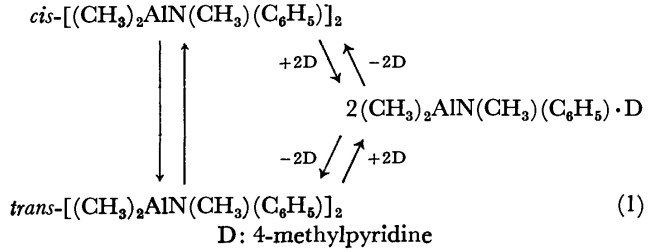
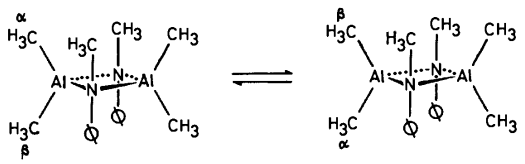
signals (denoted C and C′) occurred at δ −0.12 and 3.13 ppm respectively (Fig. 1b). The pyridine–CH_3 signal, however, was obscured by the proton signal of cyclohexane used as the internal reference in this case, probably because of their almost identical chemical shifts. This is supported by the fact that the pyridine–CH_3 signal gradually moves to a low field and is intensified as the amount of 4-methylpyridine added increases (Figs. 1c, d). The C and C′ signals were similarly strengthened when increasing amounts of 4-methylpyridine were added, and the intensity ratios of the C, C′ and pyridine–CH_3 signals were almost 2: 1: 1 up to the addition of an equimolar amount of 4-methylpyridine to the aluminum amide as a monomer. All the signals of the aluminum amide dimer disappeared in the presence of excess 4-methylpyridine (Fig. 1e). These observations suggest the formation of the 1: 1 adduct between the aluminum amide monomer and 4-methylpyridine; therefore, the C and C′ signals are assigned to the Al–CH_3 and N–CH_3 protons of the adduct respectively. In addition, the sharp and broad Al–CH_3 signals observed in Fig. 1c coalesced at about 50 °C, while the two N–CH_3 signals also merged at the same time. The spectrum was reversibly changed with the temperature. Thus, for the dimethylaluminum methylphenylamide–4-methylpyridine system the following equilibria are suggested:



(1)

The broadening of the Al–CH_3 signals of the *cis*- and *trans*-isomers (Figs. 1b—d) suggests that the *cis-trans* isomerization and the site-exchange between α- and β-CH_3 of the *cis*-isomer (shown as Eq. (2)) could be accelerated by the presence of 4-methylpyridine. It



(2)

is noted that the adduct invariably exhibits sharp Al–CH_3 and N–CH_3 signals at room temperature, irrespective of the amount of 4-methylpyridine added. This fact seems to indicate that neither the isomerization nor the site-exchange proceeds *via* the adduct formation at room temperature. At high temperatures, however, both the isomerization and site-exchange possibly occur *via* the adduct formation, since the signals of the 1: 1 adduct and the non-complexed aluminum amide coalesce at about 50 °C.

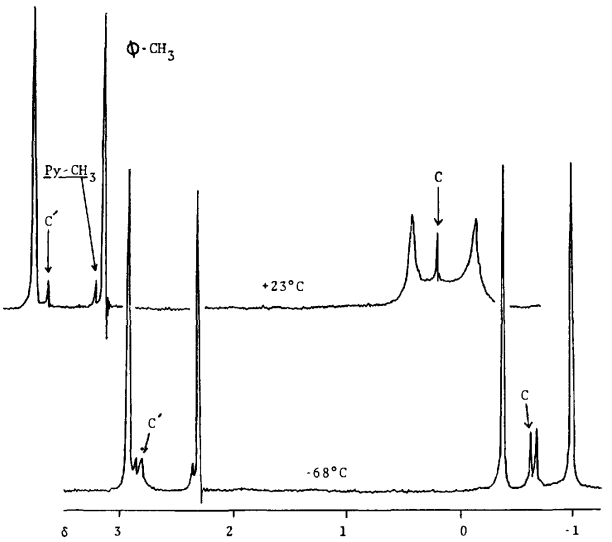


Fig. 2. The temperature-dependent PMR spectra of a mixture of $(CH_3)_2AlN(CH_3)(C_6H_5)$ (5.80×10^{-1} M) and 4-methylpyridine (7.10×10^{-2} M) measured at 100 MHz in dichloromethane.

Figure 2 shows the temperature-dependent PMR spectra of the aluminum amide (5.80×10^{-1} M as monomer) in dichloromethane containing a small amount of 4-methylpyridine (7.0×10^{-2} M). The spectral pattern observed at room temperature was similar to that in benzene, except that the Al–CH_3 and N–CH_3 signals (C, C′) of the adduct occurred very close to those of the respective *trans*-isomer. Each signal becomes sharp with a lowering of the temperature, and the spectrum at −65 °C indicates that the rates of the *cis-trans* isomerization and of the site-exchange are much slower than the NMR time scale. Tetrahydrofuran can also accelerate the *cis-trans* isomerization and the site-exchange. In the presence of less than one mol of tetrahydrofuran per mol of Al, the Al–CH_3 signals were seemingly coalesced into a broad one at room

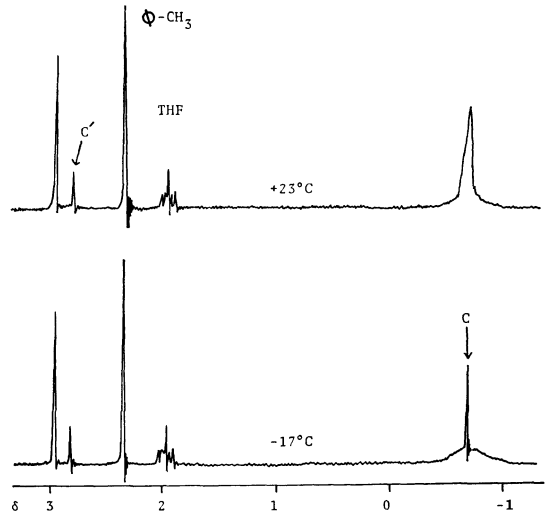

Fig. 3. The temperature-dependent PMR spectra of a mixture of $(CH_3)_2AlN(CH_3)(C_6H_5)$ (6.20×10^{-1} M) and tetrahydrofuran (1.85×10^{-1} M) measured at 100 MHz in dichloromethane.

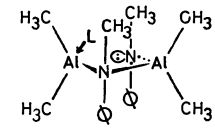
temperature, while at −17 °C the Al–CH_3 protons of the 1:1 adduct occurred as a sharp signal, as is shown in Fig. 3. The appearance of the Al–CH_3 signal at room temperature is, rather, probably due to the overlap of a sharp signal of the 1:1 adduct and a broadened signal resulting from the isomerization and site-exchange, because the N–CH_3 signal of the 1:1 adduct was observed as a sharp signal even at room temperature. Thus, the isomerization and the site-exchange in the presence of tetrahydrofuran also do not proceed *via* the adduct formation.

There are two possible mechanisms for the *cis-trans* isomerization or the site-exchange; one involves the breaking of an Al–N bond in the $(Al–N)_2$ ring, followed by the rotation-inversion of the non-bridged nitrogen atom or by the rotation of the bridged Al–N bond. The other involves simply the dissociation of the dimeric unit, followed by recombination. The former mechanism is more probable, since the breaking of two Al–N bonds requires a high energy barrier. In the presence of less than one mol of Lewis base per mol of Al, the formation of an intermediate such as III, where L is either the 1:1 adduct of the aluminum amide with a base or the base itself, may be considered to lower the



III

barrier of the isomerization and the site-exchange. The formation of such an intermediate is supported by a similar dimeric structure for $C_5H_5N\cdot Al_2(OC_3H_7\text{-}iso)_6$ tentatively proposed by Oliver and Worrall.[15]

Reduction of Nitro and Nitroso Compounds with Tetracarbonylhydridoferrate

Yoshihisa WATANABE, Take-aki MITSUDO, Masakazu YAMASHITA, and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received October 22, 1974)

An applicability of potassium tetracarbonylhydridoferrate as a reducing reagent to synthesis of primary amines from a wide variety of nitro and nitroso compounds has been examined. The reaction proceeds vigorously and exothermally at room temperature to give the corresponding amines in excellent yields. For nitroaryls, some substituents have interfering effect on the formation of amines. *o*-Nitrocinnamic aldehyde gives quinoline.

The reduction of nitro compounds using carbon monoxide, hydrogen, and/or metal carbonyls, and their derivatives has long been of interest. Transition metal carbonyls ($Fe(CO)_5$, $Fe_3(CO)_{12}$, $Ru_3(CO)_{12}$, $Co_2(CO)_8$, $[Rh(CO)_2Cl]_2$, $Ni(CO)_4$, and Cu compounds) and their derivatives have been used as reducing catalysts or reagents.[1-12] These compounds have different activities for the reduction of nitro compounds which are converted into a variety of products with groups such as –NO, –N=N–, $-NH_2$, –NCO, $\gtrless NC(=O)N\lessgtr$, and $\gtrless NOH$. Carbonylferrates, $[Fe(CO)_4]^{2-}$ and $[Fe_3(CO)_{11}]^{2-}$, are active for the formation of primary amines from nitro compounds.[1,11] Although tetracarbonylhydridoferrate among the metal carbonyls and their derivatives appears to be effective for the reduction of nitro compounds under mildest conditions, detailed reactivity of this reagent has not been clear.

The present study deals in some detail with the applicability of potassium tetracarbonylhydridoferrate to synthesis of primary amines from nitro and nitroso compounds, mainly substituted nitrobenzenes.

Experimental

Potassium tetracarbonylhydridoferrate was prepared according to the method described in a previous paper:[13] 1.8—3.7 mmol of the ferrate was used in each run. Iron pentacarbonyl, nitrobenzenes, and the other compounds employed were all commercial products.

Reaction Procedure. To the alcoholic ferrate, a certain amount of nitrobenzene or related compounds were stirred in at room temperature under argon or carbon monoxide. After a certain reaction time the reaction mixture was submitted to analysis.

Analytical Procedure. Aniline, cyclohexylamine, and quinoline were analyzed by glpc using internal standards: a column (0.3 cmϕ, 3 m) packed with 10% Versamid on Neopak 60—80 mesh. Other reaction products were isolated as amines or their salts and identified by means of infrared spectra which were recorded on a 215 Hitachi grating spectrophotometer. The products were isolated by evaporating a filtered solution exposed to air for about two days to dryness. For example, the filtered reaction mixture of *o*-nitrobiphenyl (0.95 g, 1.4 mol/mol-$KHFe(CO)_4$) was concentrated to *ca.* 2 ml, IR spectra of which had bands characteristic of *o*-aminobiphenyl, and then the solution was treated with hydrochloric acid and evaporated to dryness to give a white solid, 1.05 g (140%), IR spectra of which had bands characteristic of *o*-aminobiphenyl hydrochloride. *m*-Nitroaniline (0.70 g) gave 1,3-diaminobenzene dihydrochloride as an orange solid, 0.61 g (94%). *o*-Nitrocinnamic acid (1.0 g) gave *o*-aminocinnamic acid as a pale yellow solid, 0.45 g (65%). Carbon dioxide produced in the reaction was volumetrically determined.

Results and Discussion

The ferrate reacted with nitrobenzene to give aniline selectively. The reaction proceeded vigorously and exothermally at room temperature with an evolution of carbon dioxide (about 0.5 mol/mol-$KHFe(CO)_4$) and appeared to complete in several minutes with rapid color change from pale yellow to brown. The results are summarized in Table 1.

TABLE 1. REDUCTION OF NITROBENZENE AND RELATED COMPOUNDS WITH FERRATE[a]

Substrate[b]		Reaction time hr	Aniline[c] %
Nitrobenzene	1.6	0.5	160
Nitrobenzene	2.5	0.5	180
Nitrobenzene	4.0	0.5	180
Nitrosobenzene	4.0	0.5	210
Azobenzene	2.0	10	260
Nitrocyclohexane	2.0	1.5	140[d]

a) Room temperature under argon. b) mol/mol-$KHFe(CO)_4$. c) Based on an amount of the ferrate used. d) Cyclohexylamine.

The reducing power of one mol of the ferrate corresponds to *ca.* 1.8 mol of nitrobenzene which is selectively converted to an equimolar aniline. At this time about 2.0 mol/mol-$KHFe(CO)_4$ of carbonate, $KHCO_3$, are produced and the ferrate is oxidized to di- or trivalent. This consideration is supported by the fact that nitromethane oxidizes the ferrate in alcohol to ferric hydroxide in 12 hr.[14] Ethanol and water, and the hydrido species are hydrogen sources in this reaction but a mechanism of the hydrogen transfer is not clear.

The reaction proceeds without an absorption of carbon monoxide under carbon monoxide and is not affected by reaction atmospheres, argon and carbon monoxide. On the other hand, the reduction of olefin oxides, isoprene, and enamines with the ferrate is highly affected by the carbon monoxide atmosphere:[15] the reaction is generally accelerated under carbon monoxide with an absorption of the gas and the ferrate in the course of the reaction is converted to polynuclear ferrates, $[Fe_2(CO)_8]^{2-}$ and $[Fe_3(CO)_{11}]^{2-}$, and finally to iron pentacarbonyl. In the reduction of nitrobenzene with the ferrate, nitrobenzene acts as a powerful

oxidizing agent and then the ferrate is converted finally to higher valent states inactive to carbon monoxide.

The ferrate had also high reactivity for nitrosobenzene and moderate one for azobenzene. From these, aniline was obtained in excellent yields. Nitrocyclohexane reacted more slowly than nitrobenzene.

Although the reaction is not catalytic, this reagent appears to have a wide applicability to the reduction of nitro and nitroso compounds to primary amines.

Table 2. Reduction of substituted nitrobenzenes with ferrate[a)]

Substituted nitrobenzene	Substituted aniline (%)	Substituted nitrobenzene	Substituted aniline (%)
o-Cl	125	*o*-OH	Black solid
m-Cl	105	*m*-OH	85
p-Cl	105	*p*-OH	63
o-CH_3	120	*o*-OCH_3	85
m-CH_3	125	*o*-NH_2	Black solid
p-CH_3	120	*m*-NH_2	95
o-C_6H_5	140	*p*-NH_2	Black solid
o-COOH[b)]	70	*o*-NO_2[c)]	*o*-NH_2 10
m-COOH[b)]	60	*m*-NO_2[c)]	*m*-NH_2 45
p-COOH[b)]	30	*p*-NO_2[c)]	Black solid

a) Room temperature under argon for 30 min. Nitrobenzenes, 1.4 mol/mol-$KHFe(CO)_4$. Dinitrobenzenes, 0.7 mol/mol-$KHFe(CO)_4$. b) $K_2Fe(CO)_4$ was used. c) The ferrate was enough for the reduction of two nitro groups.

The results of the reduction of substituted nitrobenzenes are listed in Table 2. Nitrobenzenes having a variety of functional groups were readily reduced to the corresponding amines. Conditions were not optimized for these compounds. *o*-Nitrobiphenyl gave *o*-aminobiphenyl, but carbazole, which is taken as evidence for nitrene intermediate,[4,10)] was not obtained. Some functional groups can block the formation of amines and positions of the substituents in a benzene ring have a remarkable effect on the reduction. Nitrobenzenes with groups, *o*-OH, *o*-NH_2, *o*-NO_2, and *p*-NO_2 gave intractable black solids, some of which seem to be iron carbonyl-amine complexes,[16)] although further analysis of the solids was not done. These groups, however, have no interfering effect on the formation of amines when located at the *meta* position. Such substituents as –Cl, –CH_3, and –COOH have no interfering effect.

α-Nitronaphthalene and *o*-nitroacetophenone were reduced to the corresponding amines. The ferrate selectively attacked the more reactive nitro group of *o*-nitrocinnamic acid and the olefinic group remained unchanged when an amount of the ferrate used was enough only for the reduction of the nitro group. *o*-Nitrocinnamic aldehyde gave quinoline in an excellent yield, which appears to be derived *via* *o*-aminocinnamaldehyde by an intramolecular condensation.

An *N*-nitroso group had a poor reactivity for the ferrate. *N*-Nitrosodiphenylamine slowly reacted with the ferrate to give diphenylamine which seemed to be derived *via* *N,N*-diphenylhydrazine by a N–N bond cleavage. *N*-Nitrosodicyclohexylamine was recovered unchanged under the condition used. ω-Nitrostyrene had a high reactivity for the ferrate but gave an intractable, tarry material.

The Isomerization of the Stable Rotamers of 9,9′: 9′,9″-Terfluorenyls

Masahiro MINABE and Kazuo SUZUKI

Department of Industrial Chemistry, Faculty of Technology, Utsunomiya University, Ishii-cho, Utsunomiya 321–31

(Received October 24, 1974)

The conformational change of the *s-cis*, *s-trans*-9,9′: 9′,9″-terfluorenyl to the *s-cis*, *s-cis* form *via* the radical process was performed by means of a reaction with *N*-bromosuccinimide and with various oxidizing agents. A reverse change occurred on treatment with lithium aluminum hydride and with sodium bis(2-methoxyethoxy)-aluminum hydride.

Two stereoisomers (mp 293 °C (dec) and mp 257 °C (dec)) have hitherto been obtained by various reactions.[1] The conformational isomers of 9,9′: 9′,9″-terfluorenyls were inferred[2] from the results of restricted rotation around the $C_{9-9'-9''}$ single bonds: *s-cis*, *s-cis* (mp 293 °C (dec)) (**1**) and *s-cis*, *s-trans* (mp 257 °C (dec)) (**2**), both of which were stable at room temperature in solution.

1 was converted to **2** by a pyrolytic reaction[3] and by treatment with Raney nickel[2]; however, no isomer was obtained by the reverse change.

The present paper will deal with the isomerization from **1** to **2** or *vice versa*. The **2** rotamer was converted into **1** by reactions with molecular oxygen-benzyltrimethylammonium hydroxide (Triton B), with *N*-bromosuccinimide (NBS), and with such oxidants as manganese dioxide, selenium dioxide, and potassium permanganate.

Conversely, **1** was isomerized to **2** by treatment with lithium aluminum hydride. Both conformers were interconverted by refluxing with sodium bis(2-methoxyethoxy)aluminum hydride (SMAH) in benzene.

Results and Discussion

The hydrogen atoms on the 1,8, 1′,8′,1″,8″, 9, and 9″ positions are close in the overcrowded molecules, **1** and **2**. The conformation of the 9-hydrogen atom in **2** corresponds to that of *s-trans*-9,9′-bifluorenyl, and the other hydrogen on 9″-carbon is located on entering the back of the 9-fluorenyl plane, as the models indicate.[2] Therefore, the bulky 9-fluorenyl plane would tend to shield the 9″-carbon atom from an attack of approaching reagents, and it could be expected to facilitate the formation of a free radical at the less hindered 9-carbon atom.

Table 1 shows the results of the isomerization of **2** to **1** (maximum yield, 56%) by means of a reaction with NBS. 9,9′-Dibromo-9,9′-bifluorenyl,[4] 9-bromo-9,9′-bifluorenyl,[1a] fluorenone (**3**), and 9,9′-bifluorenylidene (**4**) were isolated as by-products.

The reaction is initiated by the abstraction of the hydrogen atom from the tertiary 9-carbon of **2** by a bromine atom; 9,9′: 9′,9″-terfluorenyl 9-radical (R) and hydrogen bromide are formed in the main reaction. The radical (R) may abstract a hydrogen atom of hydrogen bromide to form the six-membered hydrogen-bonded intermediate (A), without any homolytic cleavage of the $C_{9-9'}$ or $C_{9'-9''}$ bond, as Scheme 1 shows. Moreover, the radical reaction can be conducted so as to form the *s-cis*, *s-cis* conformer **1**, with the loss of a bromine atom from (A).

This finding may be explained in terms of the bond energies of C-H and C-Br in the crowded molecule.

TABLE 1. THE REACTION OF 9,9′: 9′,9″-TERFLUORENYLS WITH NBS

Reaction conditions					Products g(%)				Recovered g(%)
Substrate (g)	NBS g	Benzene ml	Temp. °C	Time hr	**1**	9,9′-Dibromo-9,9′-bifluorenyl	9-Bromo-9,9′ bifluorenyl[a]	**4**

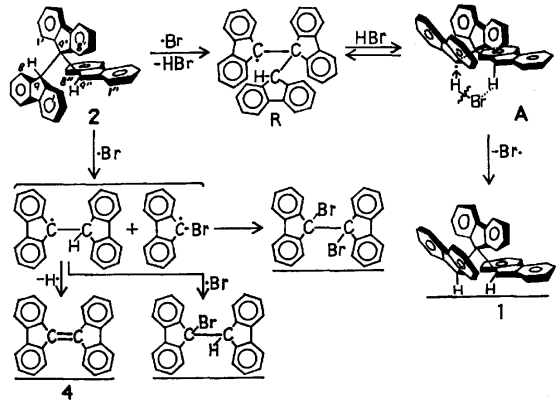
1 (1.24)	0.38 (NBA)	120	50	5					1.20 (97)

a) Yield of 9-bromo-9,9′-bifluorenyl shows the total amounts of 9-bromo-9,9′-bifluorenyl and 9-hydroxy-9,9′-bifluorenyl.
b) A trace of benzoyl peroxide was used. c) A trace amount of **3** was additionally obtained. d) NBA = *N*-bromoacetamide.

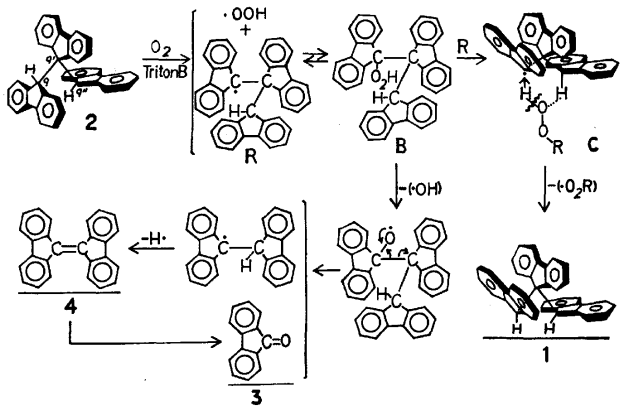


Scheme 1. (Underscored compounds were isolated.)

The molecular strain can be relieved when the radical is formed on the 9-position in **2**. Conversely, the steric compression may be increased when the crowed 9-position is occupied by a bulky bromine atom or when radical coupling takes place. Therefore, (A) is converted to **1**, or the $C_{9-9'}$ linkage in **2** dissociates partially into 9-bromofluorenyl and 9,9′-bifluorenyl radicals by an attack of the bromine atom to form stable dimerization and disproportionation products, without the formation of 9-bromoterfluorenyl.

The **2** isomerized to **1** (maximum yield, 42%) in pyridine upon treatment with molecular oxygen in the presence of a basic catalyst such as Triton B, as is shown in Table 2.

The initial radical (R) is formed along with hydroperoxide, and both species may recombine to form 9,9′:9′,9″-terfluorenyl-9-hydroperoxide (B). The **1** isomer is formed by the dissociation of the 9,9′:9′,9″-terfluorenyl-9-peroxide radical ($\cdot O_2R$) from the hydrogen-bonded intermediate (C) which is attributable to the reaction of (R) and (B), as Scheme 2 shows. The (R) and (B) intermediates can be reproduced by an attack of the radical ($\cdot O_2R$) on **2**.



Scheme 2. (Underscored compounds were isolated.)

The 9,9′-bifluorenyl radical and **3** may be formed from a part of (B) by the cleavage of the hydroxy radical. The 9,9′-bifluorenyl radical is converted into **4** by the splitting of the hydrogen atom, and **4** is oxidized finally to **3**.

The isomerization of **2** with bromine was performed under ultraviolet irradiation at room temperature; the **1** rotamer (29% yield) and 2-bromo-9,9′:9′,9″-terfluorenyl[1b] (16% yield) were thus isolated. Compound **2** was isomerized to **1** by treatment with selenium dioxide (22% yield) and with potassium permanganate (61% yield). However, no reverse isomerization occurred under the same conditions. The formation of **1** is explicable in the same way as in the reaction using NBS.

Fluorenol (1.82)	8.00	25	2			1.70 (94)	
Fluorene (1.66)	8.00	24	2			1.29 (72)	0.25 (15)

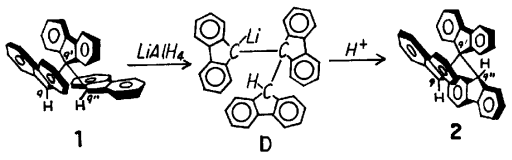
a) The reaction was carried out under nitrogen atmosphere. b) A 20 ml of pyridine was used as solvent.

The conformer **2**-9,9″-d_2[5] (or *s-cis*, *s-trans*-9,9′: 9′,9″-terfluorenyl-9,9″-dideuteride) was treated with suspended manganese(IV) dioxide in benzene to give **1**-9,9″-d_2[5] (58% yield). The deuterium contents of **1**-9,9″-d_2 and the recovered **2**-9,9″-d_2 are of the same order with that of the starting material.

It may be proposed that, under these conditions, the abstraction of 9-hydrogen in **2** by manganese dioxide may form a radical (R) and manganic oxyhydrate ($HO-Mn^{III}=O$). These are then converted to **1** and manganese dioxide through a six-membered hydrogen-bonded intermediate such as (A).

Conversely, **1** was isomerized to **2** by treatment with lithium aluminum hydride in dry tetrahydrofuran: **1**-9,9″-d_2 gave **2**-9-d[5] (36% yield) by being decomposed with ethanol and water. Moreover, **1** was allowed to react with the same reagent; subsequently it was decomposed with heavy water to give **2**-9″-d (50% yield). The **2** rotamer afforded only 9,9′-bifluorenyl (**5**) (0.3% yield) by the same reaction.

This isomerization presumably proceeds *via* 9-lithio-9,9′: 9′,9″-terfluorenyl (D), not through an intermediate such as (A) or (C), as Scheme 3 shows. Therefore, the conformation of (D) is considered to be *s-cis*, *s-trans* rather than *s-cis*, *s-cis*; (D) is then converted into **2**.



Scheme 3.

Furthermore, both rotamers were interconverted by means of a reaction with SMAH:[6] **1** into **2** (23% yield) and **2** into **1** (13% yield). The isomerization of **1** to **2** by a reducing agent may occur through 9-sodio-9,9′: 9′,9″-terfluorenyl in a way similar to that found for lithium aluminum hydride. The reverse change of **2** to **1** may be attributed to the strong basicity of SMAH, and the reaction may be proceed in analogy with the case of Triton B.

Experimental

All the melting points are uncorrected.

The compounds were confirmed by mixed-melting-point determinations and by a comparison of their IR spectra with those of authentic samples. The IR spectra were recorded as KBr-pellets using a IR-G spectrophotometer (Japan Spectroscopic Co., Ltd.).

The NMR data were obtained in a C_6D_6 solution with a JNM-C60HL spectrometer (Japan Electron Optics Lab. Co., Ltd.).

The deuterium content was confirmed from the average value of five mass spectra recorded on a RMU-6E apparatus (Hitachi, Ltd.).

Isomerization of **2** *to* **1** *by Treatment with NBS. Typical Procedure*: A solution of 1.24 g (2.5 mmol) of **2** and 0.49 g (2.7 mmol) of NBS in 120 ml of dry benzene was maintained at 50 °C for 5 hr while being stirred. The dark-red benzene solution was then evaporated to dryness under reduced pressure, and the residue was washed with hot water, dried, and recrystallized from benzene (50 ml) to give 0.34 g of **1** (mp 290—292 °C (dec)).

When the benzene mother liquor was chromatographed on alumina, the elute gave the following compounds by recrystallization from cyclohexane, cyclohexane–benzene, or benzene–ligroin: 0.20 g (total 0.54 g, 44%) of **1** (mp 292—293 °C (dec)), 0.05 g (3%) of 9,9′-dibromo-9,9′-bifluorenyl (mp 239—240 °C (dec)), and a trace amount of **4** (mp 182—184 °C).

A 0.45-g portion (35%) of 9-hydroxy-9,9′-bifluorenyl (mp 193—194 °C) was isolated from the column.[7]

Isomerization of **2** *by Treatment with Triton B and Oxygen. Typical Procedure*: To a solution of 1.24 g of **2** and 0.25 g of Triton B (10% aqueous solution) in 50 ml of pyridine, oxygen was passed gently at 23 °C for 2 hr (the color changed to black).

The reaction mixture was then diluted with 500 ml of water, and the precipitate was sublimed *in vacuo* at 140 °C to give 0.28 g (19%) of **3** (mp 82—83 °C (ethanol)). The residue after sublimation afforded 0.52 g (42%) of **1** (mp 292.5—293 °C (dec)), 0.32 g (26%) of recovered **2** (mp 256—257 °C (dec)), and 0.04 g (3%) of **4** (mp 183—184.5 °C) by recrystallization from benzene.

With Manganese Dioxide. a): A solution of 0.5 g (1 mmol) of **2**-9,9″-d_2 in 25 ml of dry benzene was refluxed with 2.5 g of manganese dioxide (E. Merck, for synthesis) for 2 hr.

Upon cooling, the reaction mixture was filtered, and the manganese dioxide was extraced with a 150-ml portion of benzene. All of the benzene solution was chromatographed on alumina; 0.29 g (58%) of **1**-9,9″-d_2 (mp 292—293 °C (dec)), 0.02 g (4%) of **5** (mp 243—244 °C), 0.11 g (20%) of **3** (mp 81—83 °C), and 0.03 g (6%) of **2**-9,9″-d_2 (mp 255-257 °C (dec)) were thus obtained.

The deuterium contents in **1**-9,9″-d_2 and the recovered **2**-9,9″-d_2 were of the same order with that of the starting **2**-9,9″-d_2, as is shown by their mass spectra: *m/e* 494 (d_0, 1%), 495 (d_1, 12%), and 496 (d_2, 87%).

b): In a similar treatment, **1** gave only **3** (2%) and recovered **1** (90%).

With Potassium Permanganate. a): Compound **2** (1.0 g, 2 mmol) was refluxed with 3.5 g of potassium permanganate in 50 ml of dry pyridine for 5 hr. After cooling, the reaction mixture was decomposed with aqueous sodium bisulfite and hydrochloric acid, and the precipitate was sublimed *in vacuo* at 120 °C.

The sublimate gave 0.28 g (26%) of **3** (mp 83—84 °C), and the residue after sublimation yielded 0.61 g (61%) of **1** (mp 292—293 °C (dec)).

When **1** was treated in a similar manner, 97% of the starting material was recovered.

b): A mixture of **2** (1.0 g), potassium permanganate (6.5 g), and aluminum sulfate (6.8 g) in dry acetone (300 ml) was refluxed for 5 hr. The reaction mixture was then treated as has been described above to afford 0.58 g (58%) of **1** (mp 292—293 °C (dec)) and 0.41 g (38%) of **3** (mp 80—82 °C).

With Selenium Dioxide. a): A mixture of 1.0 g (2 mmol) of **2**, 0.5 g of selenium oxide, and 200 ml of dry acetic acid was refluxed for 10 hr. Upon cooling, the precipitate was filtered and then recrystallized from benzene to give 0.22 g (22%) of **1** (mp 292—293 °C (dec)).

The acetic acid solution was evaporated *in vacuo*, and the residue was extracted with a 50-ml portion of benzene to give 0.62 g (62%) of **2** (mp 255—257 °C (dec)). The benzene mother liquor was chromatographed on alumina to yield 0.01 g (1%) of **3** (mp 83—85 °C).

b): The **1** isomer (1.0 g) was treated with selenium oxide (0.5 g) in dry acetic acid (200 ml) for 5 hr. 98% of the **1** (mp 292—293 °C (dec)) was recovered, accompanied by a trace

amount of **3**.

With Bromine. a): A solution of 1.0 g of **2** and 0.32 g of bromine in 130 ml of chloroform was irradiated with a 100-W high-pressure mercury lamp for 4 hr at room temperature in an atmosphere of nitrogen. The reaction mixture was then washed with a 2% sodium hydroxide solution and with water and evaporated to dryness; the residue was recrystallized from ethyl acetate: 0.19 g (16%) of 2-bromo-9,9′:9′,9″-terfluorenyl (mp 255—257 °C (dec)) and 0.29 g (29%) of **1** (mp 291—293 °C (dec)) were isolated.

b): To a solution of 1.0 g (2 mmol) of **1** and 0.01 g of anhydrous ferric chloride in 90 ml of chloroform, a 0.32-g portion (2 mmol) of bromine in 10 ml of chloroform was added, drop by drop, over a period of 1 hr at room temperature under a nitrogen atmosphere in the dark, after which stirring was continued for an additional 23 hr.

Upon treatment as above, 0.63 g (54%) of 2-bromo-9,9′:9′,9″-terfluorenyl (mp 256—257 °C (dec)) and 0.30 g (30%) of **1** (mp 292—293 °C (dec)) were obtained.

*Isomerization of **1** to **2** by Treatment with Lithium Aluminum Hydride. a)*: The **1**-9,9″-d_2 rotamer (1.0 g, 2 mmol) was refluxed with 0.76 g (20 mmol) of lithium aluminum hydride in 70 ml of dry tetrahydrofuran for 5 hr. The reaction mixture was then evaporated to dryness under reduced pressure and decomposed with a 20-ml portion of ethanol and with a 100-ml portion of 1 M hydrochloric acid. The precipitate was filtered off, dried, and recrystallized from ethyl acetate; this afforded 0.36 g (36%) of **2**-9-*d* (mp 256—257 °C (dec)), 0.03 g of **5** (mp 242—243 °C), and 0.46 g (46%) of **1**-9,9″-d_2 (mp 291—293 °C (dec)).

The deuterium content of the recovered **1** was of the same order with that of the starting material. The NMR spectrum of **2**-9-*d* showed no peak at 5.36 ppm assigned to the 9-position.

Mass spectrum for recovered **1**-9,9″-d_2: *m/e* 494 (d_0, 1%), 495 (d_1, 8%), and 496 (d_2, 91%). For **2**-9-*d*: *m/e* 494 (d_0. 25%), 495 (d_1, 74%), and 496 (d_2, 1%).

b): A solution of 1.0 g of **1** in 70 ml of dry tetrahydrofuran was refluxed with 0.76 g lithium aluminum hydride for 5 hr, Upon cooling, 14 ml of deuterium oxide containing 4% of deuterium chloride was slowly added to the resulting mixture. The precipitate was recrystallized from ethyl acetate to give 0.50 g (50%) of **2**-9″-*d* (mp 256—257 °C (dec)) and 0.15 g of **5** (mp 242—243.5 °C). The mother liquor was then evaporated to dryness, and the residue was sublimed *in vacuo* at 120 °C; the sublimate gave 0.02 g of fluorene (mp 113—114.5 °C (recrystallized from *n*-hexane)).

The signal at 4.61 ppm (9″-position) was confirmed to decrease in the NMR spectrum of **2**-9″-*d*.

Deuterium content for **2**-9″-*d*: *m/e* 494 (d_0, 81%), 495 (d_1, 16%), and 496 (d_2, 3%).

c): Compound **2** (1.5 g) was treated with 1.1 g of lithium aluminum hydride in 100 ml of dry tetrahydrofuran for 9 hr. The reaction mixture was then worked-up as has been described above to yield 1.36 g (91%) of **2** (mp 255—257 °C (dec)) and 0.004 g of **5** (mp 242—244 °C).

*Interconvertion Reactions of **1** and **2** by Treatment with SMAH. a)*: A solution of 1.0 g (2 mmol) of **1** and 8 ml of SMAH (70% benzene solution) in 50 ml of dry benzene was refluxed for 15 hr (it turned dark).

Upon cooling, the reaction mixture was washed successively with a 100-ml portion of 10% hydrochloric acid and with two 100-ml portions of water and dried over calcium chloride to yield, after the removal of the solvent, 0.23 g (23%) of **2** (mp 254—256 °C (dec)) and 0.38 g (38%) of **1** (mp 291—293 °C (dec)). Additionally, 0.17 g of **4** (mp 183—185 °C), 0.05 g of fluorene (mp 112—114 °C), and 0.04 g of **3** (mp 82—83.5 °C) were obtained.

b): The **2** isomer (1.0 g) was treated with 4 ml of SMAH in 50 ml of dry benzene for 15 hr; 0.13 g (13%) of **1** (mp 292—293 °C (dec)), 0.68 g (68%) of **2** (mp 256—257 °C (dec)), 0.18 g of **4** (mp 182—184 °C), 0.01 g of fluorene (mp 112—115 °C), and 0.07 g of **3** (mp 81—83 °C) were thus isolated.

6) Fluorenol was treated with SMAH and gave **3** (20%), **5** (0.7%), fluorene (0.06%), and recovered fluorenol (73%). This indicates that SMAH acts as oxidizing and reducing agent.

7) It is already known that 9-bromo-9,9′-bifluorenyl was converted to 9-hydroxy-9,9′-bifluorenyl by percolating through alumina. See Ref. la.

The Thermolysis and Photolysis of 6-(Benzylidenehydrazino)uracils. New Syntheses of Pyrazolo[3,4-*d*]pyrimidines. A Method to Convert Aldehydes to Nitriles

Fumio YONEDA and Tomohisa NAGAMATSU

Faculty of Pharmaceutical Sciences, Kumamoto University, Oe-honmachi, Kumamoto 862

(Received November 1, 1974)

The thermolysis of 6-(benzylidenehydrazino)uracil derivatives generally involves their oxidative cyclization to give the corresponding pyrazolo[3,4-*d*]pyrimidine derivatives. However, the thermolysis of fully methylated 6-(benzylidenehydrazino)uracils gave no pyrazolo[3,4-*d*]pyrimidines, but mixtures of the respective nitriles and 1,3-dimethyl-6-methylaminouracil. The photolysis of the fully methylated 6-(benzylidenehydrazino)uracils give the desired pyrazolo[3,4-*d*]pyrimidines.

Our interest in the pyrazolo[3,4-*d*]pyrimidine ring system,[1] bolstered by the fact that derivatives of pyrazolo[3,4-*d*]pyrimidine possess many kinds of biological activities prompted us to investigate the systematic syntheses of this ring system. Our initial efforts have been directed toward the exploration of a convenient synthesis of derivatives of pyrazolo[3,4-*d*]-pyrimidine-4,6(5*H*,7*H*)-dione, which is isomeric with xanthine. The known synthetic methods for the preparation of pyrazolo[3,4-*d*]pyrimidines have involved the construction of suitably substituted pyrazole precursors, followed by the subsequent annelation of the condensed pyrimidine ring[2,3] and the condensation cyclization of 6-hydrazinopyrimidine derivatives.[4,5] This paper will describe a new, convenient method of synthesizing pyrazolo[3,4-*d*]pyrimidine-4,6(5*H*,7*H*)-dione derivatives, a method which consists of the thermal and photochemical cyclizations of the 6-(benzylidenehydrazino)-uracils, followed by dehydrogenation.[6]

The key intermediates, the 6-(benzylidenehydrazino)-uracil derivatives (**1a**—**w**), were prepared by the treatment of the appropriate 6-hydrazinouracils with several aldehydes in ethanol at room temperature (Table 1).

a) All products were recrystallized from ethanol.

Results and Discussion

*Pyrolysis of 6-(Benzylidenehydrazino)uracils (**1a—o**).* The fusion of Compounds **1a—o** at temeratures slightly higher than their melting points for 5 to 30 min, followed by dilution with ethanol, caused a separation of the corresponding pyrazolo[3,4-*d*]pyrimidines (**2a—o**) (Table 2). The fusion of fully methylated 6-(benzylidenehydrazino)uracils (**1p—w**) took a completely different route and gave no detectable amount of pyrazolo[3,4-*d*]-pyrimidines, as will be described below. In the cases of the cyclization of **1a—d** (R=CH_3, R′=H), the

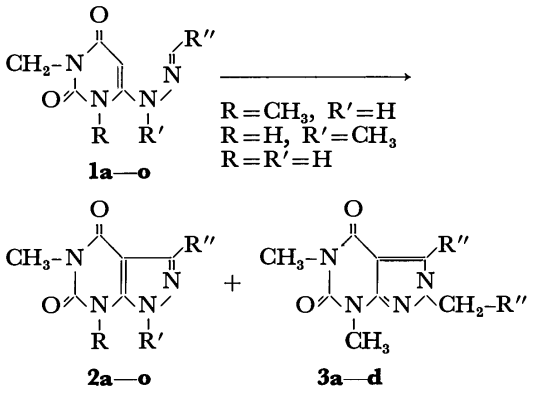
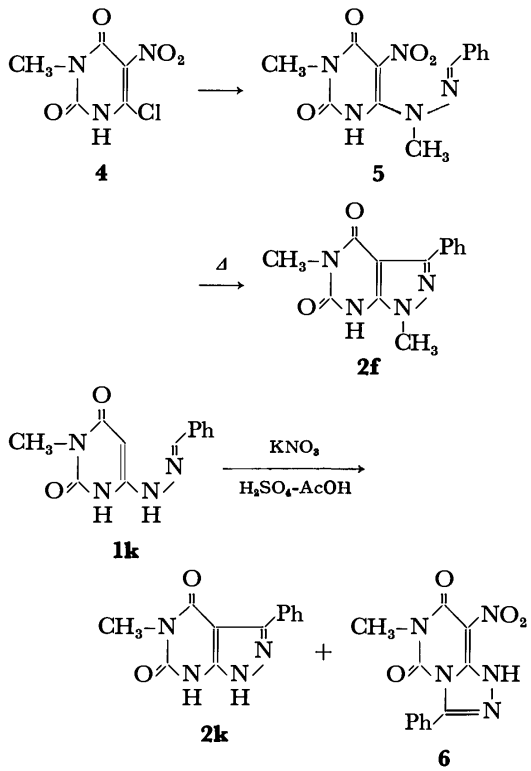
formation of 3-aryl-2-benzylpyrazolo[3,4-*d*]pyrimidine derivatives (**3a—d**) in addition to **2a—d** (see Table 3) was observed; their structures were established by unequivocal synthesis by the benzylation of **2a—d** with the corresponding benzyl halides. The mechanism of the formation of these compounds is currently under investigation.



Scheme 1.

Structural Elucidation of (2a—o) Products. The structures of **2a—o** were established by microanalyses and by the use of mass and other spectral data. Furthermore, representatives of these compounds were identified by comparison with authentic samples prepared by the following alternative routes. Some of the **2a—o** compounds were identified with the products prepared by the cyclization of the corresponding 6-benzylidenehydrazino-1,3-dimethyl-5-nitrouracils[5] in dimethylformamide. Compound **2f** was alternatively synthesized as follows: the treatment of 6-chloro-3-methyl-5-nitrouracil (**4**)[7] with benzaldehyde methylhydrazone gave 6-(benzylidene-1'-methylhydrazino)-3-methyl-5-nitrouracil (**5**); it was then converted into **2f** in 40 and 42% yields by fusion and by refluxing in dimethylformamide respectively.

The nitration of **1k** with potassium nitrate in acetic acid in the presence of sulfuric acid gave a mixture of **2k** (32%) and 5,7-dioxo-6-methyl-8-nitro-3-phenyl-1,5,6,7-tetrahydro-*s*-triazolo[4,3-*c*]pyrimidine (**6**) (15.3 %). The latter belongs to a type of compound observed previously.[7-9]



Scheme 2.

Pyrolysis of 6-(Benzylidene-1'-methylhydrazino)-1,3-dimethyluracils (1p—w). Formation of Nitriles (7p—w): As has been stated above, the thermolysis of 6-(benzylidenehydrazino)uracils constituted a convenient synthetic route to pyrazolo[3,4-*d*]pyrimidines. The reaction, however, appeared to be dependent on the presence of protons at the 1-position and/or the 1'-position of the 6-substituent. The thermolysis of fully substituted 6-benzylidenehydrazinouracils (**1p—w**) gave no pyrazolo[3,4-*d*]pyrimidines, but mixtures of the respective

nitriles (**7p—w**) and 1,3-dimethyl-6-methylaminouracil[4] in high yields and in a state of high purity. The reaction can be performed merely by heating the starting materials at temperatures slightly higher than their melting points for 10—40 min, followed by distillation, sublimation, or extraction using the ether of the reaction mixtures to give the respective nitriles (**7p—w**). The residue includes 1,3-dimethyl-6-methylaminouracil[4] exclusively (Table 4). We consider this nitrile formation as possessing a potential synthetic utility because of the good yields obtained and the neutral condition employed.

Photolysis of Compounds ***1p—w***. For the purpose of exploiting the preparative method of fully substituted pyrazolo[3,4-*d*]pyrimidine-4,6(5*H*,7*H*)-diones, photolysis of Compounds **1p—w** was carried out. The irradiation of solution of **1p—w** in benzene under aerobic condition, with a 100 W high-pressure mercury lamp at room temperature resulted in the formation of the respective pyrazolo[3,4-*d*]pyrimidines (**2p—w**) as the sole products in excellent yields (Table 5). Thus, the photolysis of fully methylated 6-(benzylidenehydrazino)uracils (**1p—w**) has been proved to offer a new method of synthesizing 1,5,7-trimethylpyrazolo[3,4-*d*]pyrimidine-4,6(5*H*,7*H*)diones (**2p—w**).

On the other hand, the photolysis of **1a—o** under the same conditions did not give **2a—o**; rather the starting materials were completely recovered.

Structural Elucidation of (2p—w) Products. The structures of **2p—w** were established by microanalyses, by molecular-weight determination by means of mass spectrometry, and by comparison with authentic samples prepared by the methylation of the corresponding 1,5-dimethylpyrazolo[3,4-*d*]pyrimidine-4,6(5*H*,7*H*)-diones (**2f—j**). The methylation of **2k** with methyl iodide gave **2r** (15.4%) and its isomeric 2,5,7-trimethylpyrazolo[3,4-*d*]pyrimidine-4,6(5*H*,7*H*)-dione (**8**) (51.3 %). Table 6 gives the ultraviolet absorption data for a series of 3-phenylpyrazolo[3,4-*d*]pyrimidine-4,6-

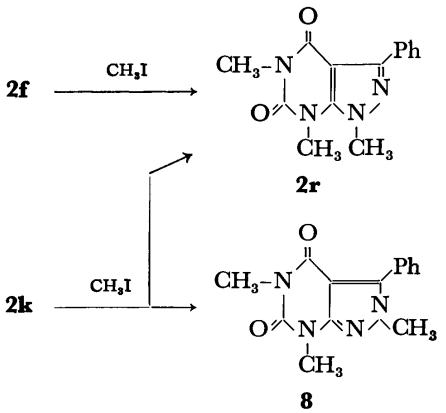
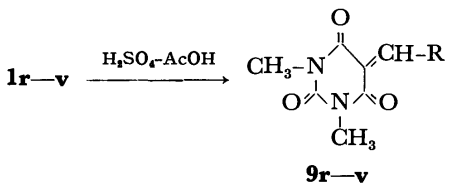
a) All products were recrystallized from ethanol.



Scheme 4.

(5*H*,7*H*)-diones. The 1,5,7-trimethyl derivative (**2r**) exhibited spectra with two intense peaks at *ca.* 230 and 260 nm, while the 2,5,7-trimethyl derivative (**8**) exhibited spectra with only one peak in the 260-nm region. It is noticeable that both **2a** and **2k** have the 2*H*-pyrazole tautomeric form in alcoholic solutions.

Reaction of ***1r—v*** *with Sulfuric Acid in Acetic Acid.* In order to find another method of cyclizing Compounds **1r—v**, we tried the reaction of **1r—v** with sulfuric acid in acetic acid. However, the products obtained were 5-benzylidene-1,3-dimethylbarbituric acid (**9r—v**) (Table 7), whose structures were established by comparison with authentic samples prepared by the condensation of 1,3-dimethylbarbituric acid with the corresponding aryl aldehydes.



Scheme 5.

Experimental

All the melting points are corrected and were determined on a Mettler FP-1 apparatus.

1,3-Dimethyl-6-hydrazinouracil,[4] *3-methyl-6-(1'-methylhydrazino)uracil,*[10] and *3-methyl-6-hydrazinouracil.*[7] These were prepared by the known procedures.

1,3-Dimethyl-6-(1'-methylhydrazino)uracil. To a solution of 6-chloro-1,3-dimethyluracil (5 g, 0.029 mol) in EtOH (60 ml), we added methylhydrazine (5.25 g, 0.114 mol), after which the mixture was stirred for 2 hr at room temperature. The crystals which separated were collected by filtration. The filtrate was evaporated *in vacuo* to give more crystals. The combined crystals were recrystallized from EtOH to give 4.47 g (84.7%) of colorless needles; mp 135—137 °C. Found: C, 45.50; H, 6.59; N, 30.23%. Calcd. for $C_7H_{12}N_4O_2$: C, 45.64; H, 6.57; N, 30.42%.

*6-(Benzylidenehydrazino)uracils (**1a—w**): General Procedure.* To a stirred solution or suspension of a 6-hydrazinouracil (0.01 mol) in 50—200 ml of EtOH, we added an aldehyde (0.015—0.02 mol) at room temperature. After stirring had been continued for 2 hr at room temperature, the product which separated was collected by filtration and recrystallized from EtOH.

*Pyrazolo[3,4-d]pyrimidine-4,6(5H,7H)-dione Derivatives (**2a—o**): General Procedure.* A 6-(benzylidenehydrazino)uracil (**1a—o**) (0.005 mol) was fused as has been described in Table 2. The reaction mixture was then dissolved in 100—200 ml of EtOH with warming. After cooling, the precipitated crystals were collected by filtration and recrystallized from EtOH.

*2-Benzyl Derivatives of **2a—d** (**3a—d**).* When Compounds **1a—d** were used as the starting materials in the above reaction, the 2-benzyl derivatives of **2a—d** (**3a—d**) were obtained by the evaporation of the filtrate, followed by the recrystallization of the residue from EtOH.

*6-(Benzylidene-1'-methylhydrazino)-3-methyl-5-nitrouracil (**5**).* To a stirred solution of 6-chloro-3-methyl-5-nitrouracil (**4**) (5 g, 0.024 mol) in EtOH (70 ml), we added methylhydrazine (1.12 g, 0.024 mol) and benzaldehyde (2.58 g, 0.024 mol) at room temperature. After stirring for 2 hr, the crystals thus precipitated were collected by filtration and recrystallized from EtOH to give 6.53 g (85.8%) of **5** as yellow prisms; mp 226—227 °C. Found: C, 51.32; H, 4.29; N, 22.84%. Calcd for $C_{13}H_{13}N_5O_4$: C, 51.48; H, 4.32; N, 23.09%.

*5-Mehtyl-3-phenylpyrazolo[3,4-d]pyrimidine-4,6(5H,7H)-dione (**2k**)* and *5,7-Dioxo-6-methyl-8-nitro-3-phenyl-1,5,6,7-tetrahydro-s-triazolo[4,3-c]pyrimidine (**6**).* A mixture of **1k** (0.5 g, 0.002 mol), potassium nitrate (0.415 g, 0.0041 mol), and sulfuric acid (0.3 g) in acetic acid (20 ml) was heated at 90—95 °C for 2 hr. After removing the undissolved inorganic substances by filtration, the filtrate was evaporated to dryness and the residue was diluted with water to precipitate crystals, which were then collected by filtration and recrystallized from

EtOH to give 0.16 g (32%) of **2k**. After the filtrate had been kept in the refrigerator, the crystals separated were collected by filtration and recrystallized from EtOH to give 0.09 g (15.3%) of **6** as pale yellow plates; mp 148—149 °C. Mass: 287 (M^+). UV λ_{max}^{EtOH} nm (log ε): 219sh (4.21), 264.5 (4.05), and 356 (3.87). IR cm^{-1} (KBr): 3470, 3375, 1733s, 1659s, 1608s, and 1340 (NO_2). Found: C, 50.08; H, 3.12; N, 24.07%. Calcd for $C_{12}H_9N_5O_4$: C, 50.18; H, 3.16; N, 24.38%.

*Pyrolysis of 6-(Benzylidene-1'-methylhydrazino)-1,3-dimethyluracils (**1p—w**). Formation of Nitriles (**7p—w**): General Procedure.* One gram of Compound **1p—w** was fused under the conditions indicated in Table 4. During the reaction, the respective nitriles (**8p—w**) were sublimed or distilled; they were then collected. After the reaction, the mixtures were extracted with ether, and the ether extracts were evaporated to give more nitriles. The residue was almost pure 1,3-dimethyl-6-methylaminouracil.[4]

*Photolysis of **1p—w**. Synthesis of 1,5,7-Trimethylpyrazolo[3,4-d]pyrimidine-4,6(5H,7H)-diones (**2p—w**).* A solution of **1p—w** (0.5 g) in benzene (600 ml) was irradiated with a 100 W high-pressure mercury lamp surrounded by a water-cooled Pyrex filter, as is shown in Table 5. The completion of the reaction was judged by tlc, using silica gel G and the appropriate mixtures of benzene, acetone, EtOH, and chloroform as the developing solvents. The removal of the solvent, followed by recrystallization from EtOH or dioxane, gave the respective pyrazolo[3,4-*d*]pyrimidines (**2p—w**).

*Methylation of 3-Substituted 1,5-Dimethylpyrazolo[3,4-d]pyrimidine-4,6(5H,7H)-diones (**2f—j**): General Procedure.* To a solution of **2f—j** (0.001 mol) in dimethylformamide (5 ml), we added methyl iodide (0.21 g, 0.015 mol) and potassium carbonate (0.2 g), after which the mixture was refluxed for 3 hr. After the reaction mixture had then been evaporated *in vacuo*, the residue was diluted with water to precipitate crystals; these crystals were collected by filtration and recrystallized from EtOH to afford **2r—v** in 50—65% yields.

*Methylation of 5-Methyl-3-phenylpyrazolo[3,4-d]pyrimidine-4,6(5H,7H)-dione (**2k**). 3-Phenyl-1,5,7-trimethylpyrazolo[3,4-d]pyrimidine-4,6(5H,7H)-dione (**2r**) and 3-Phenyl-2,5,7-trimethylpyrazolo[3,4-d]pyrimidine-4,6(5H,7H)-dione (**8**).* To a solution of **2k** (0.35 g, 0.0015 mol) in dimethylformamide (10 ml), we added methyl iodide (2.1 g, 0.015 mol) and potassium carbonate (0.7 g), after which the mixture was refluxed for 1 hr. After the reaction mixture had then been evaporated under reduced pressure, the residue was recrystallized from EtOH to give 0.2 g (51.3%) of **8** as colorless prisms; mp 204—206 °C. Mass: 270 (M^+). IR cm^{-1} (KBr): 1699s, 1662s, 1600m, 1580s, 1539m, and 1512m. Found: C, 62.01; H, 5.40; N, 20.78%. Calcd for $C_{14}H_{14}N_4O_2$: C, 62.21; H, 5.22; N, 20.73%.

The filtrate was evaporated to dryness, and the residue was diluted with H_2O to separate 0.06 g (15.4%) of **2r**.

*5-Benzylidene-1,3-dimethylbarbituric Acids (**9r—v**): General Procedure.* *A)* To a solution of **1r—v** (0.5 g) in acetic acid (10 ml), sulfuric acid (0.25 g) was added. After the mixture had been heated under stirring at 90—95 °C for 2 hr, the reaction mixture was diluted with H_2O to precipitate crystals; these crystals were then collected by filtration and recrystallized from EtOH.

B) A mixture of 1,3-dimethylbarbituric acid (1.5 g, 0.0096 mol) and aryl aldehyde (0.014 mol) in EtOH (40 ml) was refluxed for 1 hr. After cooling, the crystals which separated were collected by filtration. The filtrate was evaporated to dryness to give more crystals. The combined crystals were recrystallized from EtOH to give **9r—v**.

The Intramolecular Participation of Sulfide Linkage on the Reactivity of Carbenes and Diazoalkanes. II. Alkylcarbenes and Diazoalkanes Bearing Arylthio and Allylthio Groups on β-Carbon

Kiyosi KONDO and Iwao OJIMA

Sagami Chemical Research Center, Nishi-Ohnuma 4-4-1, Sagamihara, Kanagawa 229

(Received November 20, 1974)

β-Arylthio- and β-allylthioalkylcarbenes were generated from the corresponding ketones by a modification of the Bamford–Stevens method. Chemical evidence for the formation of novel cyclic ylides, *i.e.*, thietanonium ylides, by an intramolecular electrophilic addition of the carbene to the sulfur atom was obtained. The resulting ylides underwent various types of rearrangements to afford cyclopropyl sulfides, thiaazulenes, thietanes, and/or tetrahydrothiophenes. The mechanisms and the relative amounts of the transition energies for these rearrangements are discussed. An intramolecular cycloaddition of β-allyl- and β-crotylthioalkyldiazoalkanes is also described. The final products of the reaction were 3-thiabicyclo[4.1.0]heptanes. A thiabicyclic pyrazoline, which is presumed to be an intermediate of the cycloaddition, could be isolated in the case of the thermal decomposition of 4-allylthio-4-methylpentan-2-one tosylhydrazone.

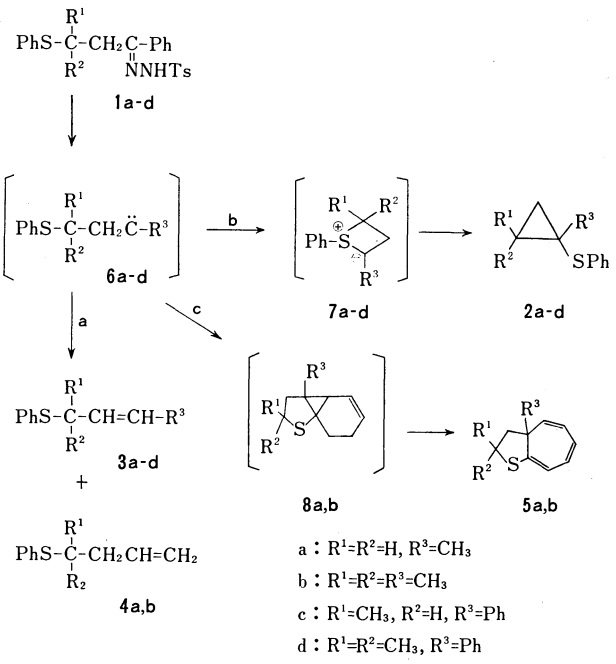
Many reports on the formation of ylides by the intermolecular electrophilic addition of carbenes to the lone-pair electrons of hetero atoms can be found in the literature.[1] The most representative patterns of these "*intermolecular reactions*" might be summarized as: i) insertion into carbon–hydrogen bonds,[1a] ii) allylic [2,3]sigmatropic rearrangement,[1b] and iii) the formation of stable ylides.[1c] On the contrary, relatively little is known about the *intramolecular* counterpart of this addition, especially in view of the ylide formation.[2,3] When a sulfide linkage is introduced into the same molecule of the carbene, it can be expected that the carbene carbon will be transformed into the ylide carbon by an intramolecular ylide formation.

In the first paper of this series,[4] we reported on the characteristic behavior of the episulfonium ylides produced by the intramolecular addition of α-alkyl and α-arylthioalkylcarbenes. The introduction of the sulfide linkage at the γ-position of the carbene may also cause the cyclization to form four-membered ring ylide. Herein we will describe the behavior of β-aryl-, β-alkyl-, and β-allylthioalkylcarbenes and will present definite evidence for the intramolecular formation of their ylides.[5]

During the course of our study of this subject, we have also found that certain diazoalkanes bearing an allylthio group on β-carbon, a precursor of the carbenes described above, underwent a facile intramolecular cycloaddition to produce bicyclic pyrazolines, which were then transformed into cyclopropanes under the present reaction conditions.[6] As the reaction may open a novel route to thiabicyclic systems, we will also touch briefly on the characteristic behavior of these diazoalkanes.

Results

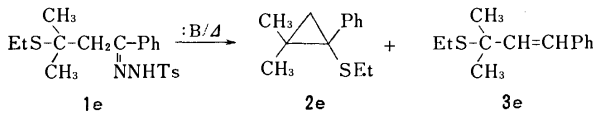
β-Phenylthioalkylcarbenes. The starting materials were prepared by the Michael addition of thiophenol to the appropriate α,β-unsaturated ketones, followed by treatment with *p*-toluenesulfonylhydrazide. The desired carbenes were generated by the thermal decomposition of the sodium salts of the resulting tosylhydrazones



Scheme 1.

(**1a—d**) in diglyme at 150—160 °C. The products were separated by column chromatography on silica gel and/or by preparative vpc. The structural assignments were based on the spectra and on the results of elemental analyses. The products caused by intramolecular reactions were olefins (**3** and **4**), cyclopropyl sulfides (**2**), and thiaazulenes (**5**). The patterns for these intramolecular carbene reactions are shown in Scheme 1. The first path, **a**, of these reactions is a usual 1,2-shift of hydrogen, and the second path, **b**, is the intramolecular ylide formation, followed by a novel rearrangement of the phenylthio group. The third path, **c**, is the addition of these carbenes to the benzene nucleus. Thiaazulene might be formed through a valence-bond isomerization of the intermediary-formed norcaradiene, **8**. This is a rare example of the cycloaddition of an alkylcarbene to a benzene nucleus. The finding that no thiaazulenes were obtained in the cases of two

carbenes, **6c** and **6d**, must be due to an inherent difference in reactivity between the arylcarbenes and the alkylcarbenes. Accordingly, **3**, **4**, and **5** are supposed to be the products from the carbene process, and **2**, from the ylide process. In order to compare the effect of the phenylthio group with that of the alkylthio group on these two competitive processes, β-ethylthio-β-methylbutyrophenone tosylhydrazone (**1e**) was decomposed under the same conditions. The product was also found to be a mixture of cyclopropylsulfide (**2e**) and olefins (**3e**) (Scheme 2).

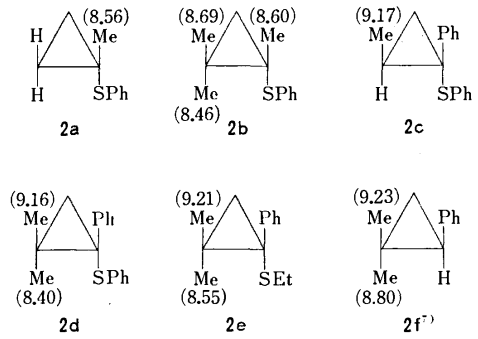


1e 2e 3e

Scheme 2.

Though the photolysis of tosylhydrazone, **1d**, afforded cyclopropyl sulfide, **2d**, in a 37% yield, the olefin, **3d**, was obtained in only 18% yield; the residue was a high-boiling intractable oil. The photolyses of other tosylhydrazones were, therefore, not attempted.

The configuration of the cyclopropyl sulfide, **2c**, was identified as *cis* with respect to the methyl and phenyl groups, based on its NMR spectrum; the methyl of this cyclopropyl sulfide was highly shielded by the *cis* phenyl group and was thus observed at τ 9.17 as a doublet. The discussion of the shielding effect of the *cis* phenyl group in cyclopropane systems advanced by Closs and Moss[7] was also found to be applicable to our systems. In the case of the cyclopropyl sulfide, **2b**, which has no *cis* phenyl group, the methyl absorption



Scheme 3.

Table 1. Intramolecular reactions of β-phenylthio- and β-alkylthioalkylcarbenes in diglyme

Carbene 6	Total yield (%)[a]	Product ratios (%)[a] 2	3	4	5
6a	81.2	5.4	77.3[c]	10.6	6.8
6b	90.0	17.4	66.0[d]	7.2	9.4
6c	93.5[b]	31.8	68.2[e]		
6d	94.0	45.5	54.5[d]		
6e	89.5	56.8	43.2[d]		

a) Yields were calculated by comparing the vpc peak area of crude products with that of pure samples using a column (1 m) packed with 20% SE-30 or 10% QF-1 on chromosorb W at 140—220 °C. b) There are also obtained 1-methyl-1-phenylthio-2-phenylcyclopropane as an insertion product of the carbene **6c** to a carbon-hydrogen bond. c) *cis*/*trans*=17/83. d) *cis*/*trans*=0/100. e) The olefin **3** (*cis*/*trans*=4/96) contained 1-methyl-3-phenylpropen-1-yl phenyl sulfide (38%), which was proved to be an isomerization product of **3c** by a controlled experiment.[8]

was observed at τ 8.69, while the cyclopropyl sulfide, **2d**, displayed an absorption at τ 9.16 which could be assigned to the *cis* methyl, as is shown in Scheme 3.

β-Allylthioalkylcarbenes Generated by the Photolyses. In order to obtain more definite evidence for the intervention of thietanonium ylide, the thermolysis and photolysis of the tosylhydrazone, **1f**, derived from β-allylthioalkylphenylketone were performed. We chose **1f** as the substrate because, once the allyl sulfonium ylide is produced, the ylide may undergo a smooth [2,3]sigmatropic rearrangement.

The photolysis of the sodium salt of β-allylthio-β-methylbutyrophenone tosylhydrazone (**1f**) in monoglyme at 10 °C afforded three products in a total yield of 68.5%. Each of the components was roughly separated by column chromatography on silica and was finally purified by preparative vpc. The identified products were 2-allyl-2-phenyl-4,4-dimethylthietane (**10a**), 2-vinyl-3-phenyl-5,5-dimethyltetrahydrothiophene (**11a**), and 1-phenyl-3-allylthio-3-methyl-1-butene (**12a**). The formation of thietane **10a** demonstrates that a definite chemical bond is formed between the carbene carbon and the sulfur; that is, there is an intervention of thietanonium ylide, **13a**. The succeeding

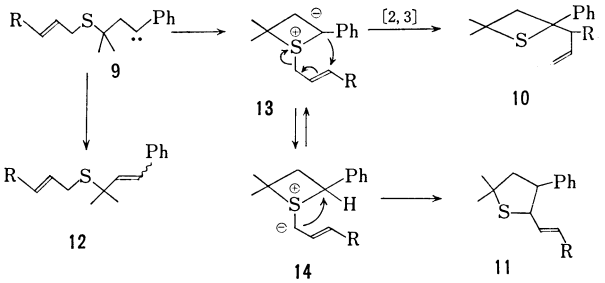
[2,3]sigmatropic rearrangement of the allylsulfonium ylide affords the thietane, **10a**, as the final product. In order to establish the [2,3]sigmatropic rearrangement and to exclude the possibility of a Stevens-type 1,2-shift of the allylic substituent, 3-crotylthio-3-methylbutyrophenone tosylhydrazone (**1g**) was photolyzed under the same conditions. The identified products were 2-(1-methylallyl)-2-phenyl-4,4-dimethylthietane (**10b**), 2-(1-propenyl)-3-phenyl-5,5-dimethyltetrahydrothiophene (**11b**), and 1-phenyl-3-crotylthio-3-methyl-1-butene (**12b**). The thietane, **10b**, was obtained as a mixture of diastereoisomers (56:44); the tetrahydrothiophene, **11b**, was also a mixture of *cis* and *trans* isomers. The facts that no 2-crotyl-2-phenyl-4,4-dimethylthietane was obtained, but **10b** was, clearly indicate the exclusive occurrence of [2,3]sigmatropic rearrangement.

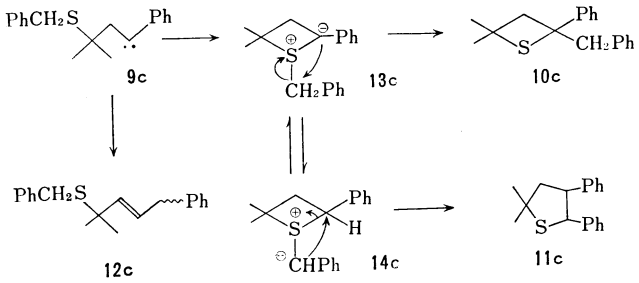
The relatively high yield production of the tetrahydrothiophenes, **11a** and **11b**, deserves to be mentioned. The formation of these five-membered ring products can also be explained by assuming the intervention of the ylide, **13**. Thus, an ylide exchange reaction of **13** to the exocyclic ylide, **14**, followed by a Stevens-type rearrangement, may constitute the ring-enlargement process. The total yield and the products ratio are listed in Table 2. In the thermolyses of the tosylhydrazones, **1f** and **1g**, an intramolecular 1,3-cycload-



Scheme 4.

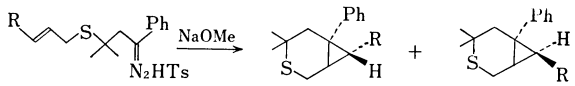
dition of a generated diazoalkane to the double bond of the allyl group was found to be the major process of the reaction; two 4-thiabicyclo[4.1.0]heptanes, **15** and **16**, were thus obtained. The details of this reaction will be discussed later.

β-Benzylthioalkylcarbenes. The ylide-exchange reaction observed in the case of β-allylthioalkylcarbene is expected to be characteristic of systems in which the intermediate cyclic ylide has an acidic hydrogen on the exocyclic α-carbon of the sulfonium function. Thus, an intramolecular reaction of the carbene-bearing benzylthio group on β-carbon was further investigated. The carbene was generated by the thermolysis or photolysis of the corresponding tosylhydrazone (**1h**). Besides the olefin, **12c**, caused by the carbenic process, two products were isolated from the reaction mixture. One was identified as the tetrahydrothiophene, **11c**, by means of its spectra and by elemental analysis; it is the expected product from the ylide-exchange reaction. The other was proved to be the thietane, **10c**, which must be formed through a Stevens-type rearrangement of the intermediate ylide, **13c**.



Scheme 5.

β-Allylthioalkyl Diazoalkanes Generated by the Thermolyses. β-Allylthio-β-methylbutyrophenone tosylhydrazone (**1f**) was thermally decomposed in diglyme in the presence of sodium methoxide at 150 °C. When the reaction mixture was chromatographed on silica, 4,4-dimethyl-6-phenyl-3-thiabicyclo[4.1.0]heptane (**15**) was obtained as the predominant product (Scheme 6). The analysis of the reaction mixture revealed that small amounts of thietane, **10a**, and the **12a** olefin were also present in the product (Table 2). Similarly, the thermolysis of β-crotylthio-β-methylbutyrophenone tosylhydrazone (**1g**) afforded 6-phenyl-4,4,7-trimethyl-3-thiabicyclo-[4.1.0]heptane (**16**) in a 44% yield, accompanied by small amounts of thietane, **10b**, tetrahydrothiophene, **11b**, and the **12b** olefin. The photolyses of these β-allylthio compounds at 10 °C underwent a completely different process, *i.e.*, a carbenic process, as has been described in the previous section. Thus, the formation of the two 3-thiabicyclo[4.1.0]heptanes, **15** and **16**, may mean that an intramolecular cycloaddition of the diazoalkane moiety to the double bond of the allylthio group and a subsequent elimination of the molecular nitrogen really do occur under the thermolysis conditions.

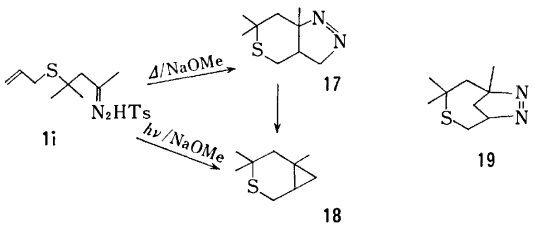


Scheme 6.

The NMR spectrum and vpc analysis of the product indicated that **16** is a mixture of *exo-* and *endo*-isomers (**16a** and **16b**) in the ratio of 74.5:25.5. The product isomer ratio was found to be constant even when the *cis-trans* mixing ratios of the starting **1g** were changed from 28/72 to 9/91. This fact indicates that the isomer ratio directly reflects the thermodynamic stabilities of the products.

Conclusive evidence for the intramolecular thermal cycloaddition of these diazoalkanes was obtained when 4-allylthio-4-methyl-2-pentanone tosylhydrazone (**1i**) was used as a substrate. That is, the thermal decomposition of **1i** in the presence of sodium methoxide at 150 °C afforded the bicyclic pyrazoline, **17**, in a 33% yield. On the other hand, the photolysis of the sodium salts of **1i** at 10 °C for two hours yielded 4,4,6-trimethyl-3-thiabicyclo[4.1.0]heptane (**18**) in a 48% yield. Furthermore, the irradiation of the bicyclic pyrazoline,

17, under the same conditions produced the same product, **18**, in a good yield.



Scheme 7.

Two orientations are possible in considering the intramolecular cycloaddition. The one possible product is **17**, and the other is **19**. The structure of the obtained product was deduced to be **17** on the basis of its NMR spectrum: the chemical shift of the C-3 methylene of the pyrazoline ring was observed at 4.31 ppm (2H) from TMS. This value is in accordance with that reported for vicinal methylenes of the azo function in a usual pyrazoline system.[9] On the other hand, the C-9 methylene of the diazabicyclononene, **19**, is expected to absorb in a much higher field.[9]

The photochemical *in-situ* generation of carbenes from tosylhydrazones has been reported to proceed through diazo precursors.[10] Therefore, it can be concluded that the intramolecular thermal cycloaddition of the diazo compound derived from **1i** is a facile process, even at 10 °C, and that the succeeding elimination of nitrogen is an effective process under photolytic conditions.

Discussion

In all the cases examined, the carbene with sulfide functions on β-carbon underwent two types of reaction: i) a normal carbene reaction, and ii) an intramolecular formation of the cyclic ylide. The relative dominance of these two processes, however, seems to be markedly affected by the nature of the substituents. The relative ratios of these two processes, along with the variation in the substituents, are summarized in Table 3.

The data on the reaction of the carbenes, **6a—6d**, clearly indicate that the ylide process is dramatically favored when the substituent on the carbene carbon is changed from methyl to phenyl and when the number of substituents on the β-carbon is increased. These phenomena can be explained as follows. The phenyl on the ylide carbon may stabilize the ylide by its inductive effect, and the methyl(s) on the β-carbon may favor the formation of the four-membered ring by their steric repulsion. From the steric and electronic points of view, it seems plausible that an alkylthio group on the β-carbon of the carbene would favor the intramolecular formation of the ylide, as compared with the phenylthio group. However, the data on the reactivities of the **6d** and **6e** carbenes tell us that there is no significant difference between these two groups. The results indicate that the basicity of the sulfur atom, as well as the steric bulk of the substituent on the sulfur, may not be at all important in determining the ratio of these two processes. On the other hand, a comparison of the data on the reactivities of the **6e** carbene with those on **9a—9c** suggests that the efficiency of the product-forming steps, *i.e.*, the rearrangement of the intermediate ylide, seems to have influence on the relative dominance of these two processes. That is, the results indicate that the ylide process gains an advantage over the carbene process when the thietanonium ylide thus formed can undergo a rearrangement with a lower transition energy (*vide infra*).

Table 3. The percentage ratios of the carbene process *vs.* ylide process

No.	R^1	R^2	R^3	R^4	Carbene (%)	Ylide (%)

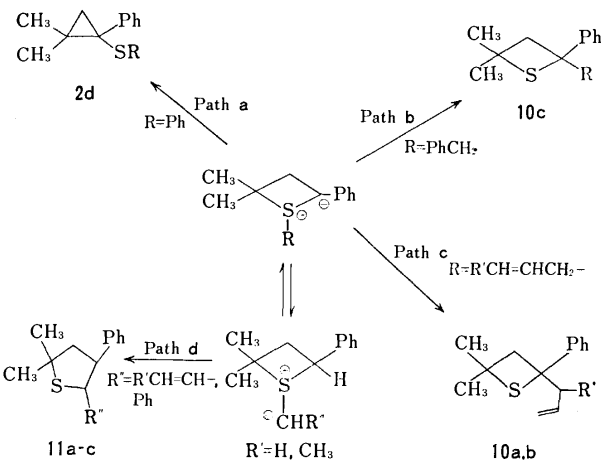
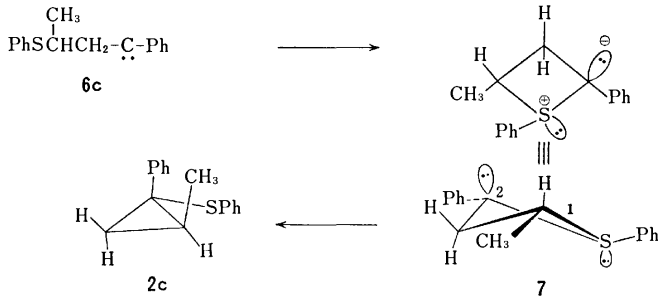


Scheme 8.

On the basis of the results collected in Tables 1 and 2, a discussion of the relative heights of the transition energies in the rearrangements of the thietanonium ylides can now be undertaken. Four different pathways of the rearrangements observed are summarized in Scheme 8. Path **a** is the rearrangement process which affords cyclopropyl sulfides. Path **b** is the Stevens-type rearrangement of the benzyl group on sulfur to give the thietane. Path **c** is the [2,3]sigmatropic rearrangement observed in the β-allylthio system, and Path **d** is the ring-enlargement process *via* the ylide-exchange reaction. In the β-allylthio and β-crotylthio systems, all four pathways are, in principle, possible. However, only two products through Paths **c** and **d** could be observed in the reaction mixture. Accordingly, the thietane formation by [2,3]sigmatropic rearrangement and tetrahydrothiophene formation by ylide-exchange reaction may have lower transition energies than those

of Paths **a** and **b**. Furthermore, the product ratios listed in Table 2 reveal that Path **d** predominates over Path **c**. In the β-benzylthio system, only Paths **b** and **d** were observed, though Path **a** was also a possible candidate for this system. Thus, it can be said that Path **a** has the highest transition energy. In conclusion, the order of the transition energies in these four processes may be as follows: Path **a**>Path **b**>Path **c**>Path **d**.

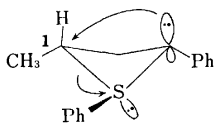
The next discussion will concern the stereospecificity of the reaction which affords the only isomer of the cyclopropyl sulfide (**2c**). An inspection of the Dreiding model indicated that the most stable conformation of the ylide might be the one that minimizes the steric repulsion between substituents and the electronic repulsion between lone pairs; this conformation has two phenyl groups and a methyl group in *pseudo-equatorial* positions, and two lone paris in *pseudo-axial* positions, as is shown in Scheme 9. Therefore, in order to accommodate the observed stereospecificity, an inversion of the configuration at C^1 or C^2 must occur during the ring contraction.



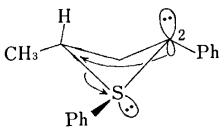
Scheme 9.

Three mechanisms (Scheme 10) can be considered for this stereospecific reaction. The first one is a concerted mechanism with an inversion of the configuration at C^1; the ylide lone pair attacks from the back side of the cleaving carbon–sulfur bond (Mechanism 1.).

Mechanism 1. Concerted process (inversion at C^1)



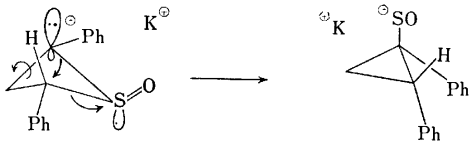
Mechanism 2. Concerted process (inversion at C^2)



Mechanism 3. Radical pair process (inversion at C^2)

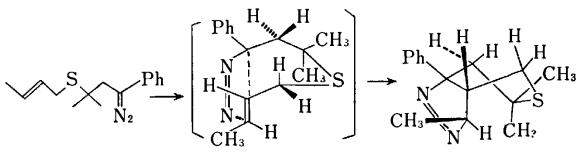
Scheme 10.

The second one is also a concerted mechanism, but with an inversion at C^2; a partially developed back lobe of the carbanion attacks C^1 from the front side, with a retention of the configuration at C^1. This mechanism has some similarity to the so-called "*double inversion mechanism*" proposed by Bordwell *et al.* in the case of the 1,3-elimination of α-halosulfones.[11] The third one is a radical-pair mechanism. This mechanism has been confirmed for the Stevens rearrangements of certain ylides[12] and is known to proceed with a retention of the configuration at the migrating carbon, C^1.[13] This means that the inversion must occur at C^2. As far as we know, however, there has never been observed such a stereospecificity at the migrating terminus in a Stevens rearrangement. On the other hand, a stereospecific rearrangement of 2,4-diphenylthietane-1-oxide to the anion of cyclopropylsulfenic acid in the presence of a base has recently been reported by Dodson *et al.*[14] They proposed that the stereospecific reaction proceeded through the most stable conformation of the anion produced and that, therefore, an inversion of the configuration should occur at the carbanion carbon.



Their observation corresponds well to the results obtained in our system and supports the concerted Mechanism 2 for the rearrangement of the thietanonium ylide, **7**.

In connection with the mechanism of the formation of the 3-thiabicyclo[4.1.0]heptanes, **15** and **16**, it is worth-while to discuss the stereochemistry of the reaction. The cycloaddition of a diazoalkane to carbon–carbon double bonds is assumed to be a stereospecific concerted process.[15] Therefore, the formation of *exo*-methylpyrazoline (A) from the tosylhydrazone bearing *trans*-crotyl group is an allowed process, while the formation of the corresponding *endo*-isomer from the same precursor is strongly forbidden.



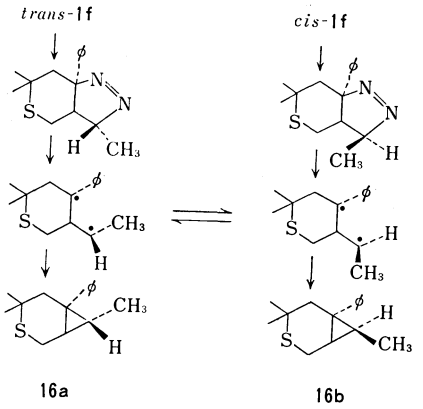
A: exo-methyl

Fig. 2.

The final product, **16**, which is produced by the nitrogen elimination of the intermediary-formed pyrazoline, dose not retain the stereochemical integrity of the starting materials. Thus, the stereochemical crossover should occur at the stage of radical recombination, as is shown in the following scheme.

The high efficiency of the *intramolecular* cycloaddition observed in the β-allylthio system is probably due chiefly to the intramolecular nature of the reaction. Another factor, however, must be considered in order to explain the results, because the addition of a diazoalkane to nonconjugated olefins is usually a very slow and difficult process.[15,16] One possible interpretation is that some kind of activating effect of the

allylic sulfur atom on the double bond is operating in these systems.[17]



Scheme 11.

Experimental

Measurements. The melting points and boiling points were uncorrected. The infrared spectra were recorded on a Hitachi-Perkin-Elmer Model 337 Infracord or a Hitachi EPI-G3 spectrophotometer, using as samples neat liquids, KBr disks, or Nujol mulls. The nuclear magnetic resonance spectra were obtained by the use of a Varian HA-100 or a Hitachi R20-B spectrometer, using TMS as the internal standard. The mass spectra were measured using a Hitachi RMU-6E spectrometer at 70 eV. Analytical gas chromatography (vpc) was carried out on a Hitachi K-53 equipped with a flame-ionization detector. The total yield and product ratios were determined by the vpc using a column packed with 20% SE-30 or 10% QF-1 on Chromosorb W. Preparative gas chromatography was performed with an Aerograph A-700 instrument or a Hitachi KGL-2B instrument using a 4 mm×1 m column packed with 3% SE-30 or 20% XF-1150 on Chromosorb W. The photolyses were carried out with the use of a 450-W high-pressure mercury lamp (Ushio Electric, Inc.).

Preparation of Tosylhydrazones. The Bamford-Stevens method[18,19] was employed for the *in-situ* generation of carbenes and diazoalkanes. Thus, the required tosylhydrazones were prepared by the condensation of the corresponding ketones with *p*-toluenesulfonylhydrazide.

*4-Phenylthio-2-butanone Tosylhydrazone (**1a**).* 4-Phenylthio-2-butanone was prepared by the addition of thiophenol to methyl vinyl ketone.[20] 4-Phenylthio-2-butanone (5 g, 0.0278 mol) and *p*-toluenesulfonylhydrazide (6 g, 0.0322 mol) were dissolved in 100 ml of ethanol, after which the solution was heated to reflux for an hour. The reaction mixture was cooled with dry ice and gradually warmed to room temperature. The precipitated colorless needles of the corresponding tosylhydrazone (**1a**) were collected by filtration. Yield: 8.24 g; 85%; mp 100—101 °C. Found: C, 58.38; H, 5.84; N, 8.15; S, 18.53%. Calcd for $C_{17}H_{21}N_2O_2S_2$: C, 58.59; H, 5.78; N, 8.04; S, 18.40%.

*4-Phenylthio-4-methyl-2-pentanone Tosylhydrazone (**1b**).* To a mixture of mesityl oxide (25 g, 0.255 mol) and thiophenol (28 g, 0.255 mol), we added a few drops of piperidine. After an initial exothermic reaction had subsided, the reaction mixture was further stirred with a magnetic stirrer overnight at room temperature. 4-Phenylthio-4-methyl-2-pentanone[21] was obtained by the distillation of the reaction mixture under reduced pressure. Yield: 42.5 g; 80%; bp 109 °C/0.35 mmHg. NMR (CCl_4): τ 8.65 (s, 6H), 7.97 (s, 3H), 7.44 (s, 2H), and 2.90—2.40 (m, 5H). The corresponding tosylhydrazone (**1b**) was prepared by a method similar to that described above. Mp 109—110 °C (colorless needles). Found: C, 60.38; H, 6.59; N, 7.37; S, 16.88%. Calcd for $C_{19}H_{25}N_2O_2S_2$: C, 60.61; H, 6.42; N, 7.44; S, 17.03%.

*3-Phenylthiobutyrophenone Tosylhydrazone (**1c**).* Phenyl propenyl ketone was prepared from crotonyl chloride and benzene employing the Friedel-Crafts method.[22] The base-catalyzed addition of thiophenol to the ketone, as has been described in the previous section, produced 3-phenylthiobutyrophenone; 86%; bp 167 °C/0.25 mmHg. Tosylhydrazone **1c**: mp 128—129 °C (colorless needles). Found: C, 64.65; H, 5.95; N, 6.43; S, 15.09%. Calcd for $C_{23}H_{25}N_2O_2S_2$: C, 64.86; H, 5.70; N, 6.60; S, 15.10%.

*3-Phenylthio-3-methylbutyrophenone Tosylhydrazone (**1d**).* Isopropylideneacetophenone was prepared from 3-methylcrotonyl chloride and benzene by the method of Smith and Engelhardt,[23] with some modifications. 3-Phenylthio-3-methylbutyrophenone was synthesized by the base-catalyzed addition of thiophenol to the ketone; 88%; bp 178—181 °C/1.0 mmHg, NMR (CCl_4): τ 8.57 (s, 6H), 6.90 (s, 2H) and 2.95—2.20 (m, 10H). Tosylhydrazone **1d**: mp 110—111 °C (colorless needles). Found: C, 65.74; H, 5.97; N, 6.45; S, 14.51%. Calcd for $C_{24}H_{26}N_2O_2S_2$: C, 65.72; H, 5.97; N, 6.39; S, 14.62%.

*3-Ethylthio-3-methylbutyrophenone Tosylhydrazone (**1e**).* The base-catalyzed addition of ethanethiol to isopropylideneacetophenone afforded 3-ethylthio-3-methylbutyrophenone: bp 127 °C/0.4 mmHg. NMR (CCl_4): τ 8.80 (t, J=7 Hz, 3H), 8.52 (s, 6H), 7.43 (quartet, J=7 Hz, 2H), 6.81 (s, 2H,) and 2.80—1.90 (m, 5H). Tosylhydrazone **1e**: mp 160—161 °C (colorless needles). Found: C, 61.55; H, 6.65; N, 7.45; S, 16.42%. Calcd for $C_{20}H_{26}O_2S_2N_2$: C, 61.51; H, 6.71; N, 7.17; S, 16.65%.

*3-Allylthio-3-methylbutyrophenone Tosylhydrazone (**1f**).* 3-Allylthio-3-methylbutyrophenone was prepared by the addition reaction of 2-propenethiol to isopropylideneacetophenone: bp 122 °C/0.3 mmHg. NMR (CCl_4): τ 8.52 (s, 6H), 6.80 (s, 2H), 6.78 (d, J=7 Hz, 2H), 5.10—4.65 (m, 2H), 4.50—3.90 (m, 1H) and 2.70—2.00 (m, 5H). The ketone was converted to the corresponding tosylhydrazone by treatment with an equimolar amount of tosylhydrazide in the presence of a catalytic amount of sulfuric acid. The use of an excess of tosylhydrazide should be avoided, as it was found that the existing allylic double bond was partially hydrogenated under such circumstances. Tosylhydrazone **1e**: mp 135—136 °C (colorless prisms). Found: C, 62.60; H, 6.26; N, 7.13; S, 15.66%. Calcd for $C_{21}H_{26}N_2O_2S_2$: C, 62.65; H, 6.51; N, 6.96; S, 15.93%.

*3-Crotylthio-3-methylbutyrophenone Tosylhydrazone (**1g**).* 2-Butenethiol was prepared from crotyl alcohol according to the standard procedure.[24] The *cis*/*trans* isomer ratio of crotyl alcohol was determined on the basis of the NMR spectrum, employing $Eu(DPM)_3$ as a shift reagent, and by vpc analysis, using a column packed with 20% XF-1150. According to the spectrum, a commercial-grade crotyl alcohol has a *trans*/*cis* ratio of 72/28. An alcohol with a *trans*/*cis* ratio of 91/9 was obtained by fractional distillation through a spinning-band column.

3-Crotylthio-3-methylbutyrophenone was synthesized from the 2-butanethiol and isopropylideneacetophenone in a manner similar to that described before: bp 142 °C/0.2 mmHg. NMR (CCl_4): τ 8.54 (s, 6H), 8.32 (d, J=4 Hz, 3H), 6.84 (d, J=7 Hz, 2H), 6.82 (s, 2H), 4.64—4.20 (m, 2H), and 2.70—2.00 (m, 5H).

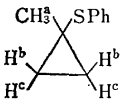
The condensation of the ketone with tosylhydrazide afforded

the corresponding tosylhydrazone (**1g**): mp 97—98 °C (colorless prisms). Found: C, 63.88; H, 6.67; N, 6.55; S, 15.77%. Calcd for $C_{22}H_{28}N_2O_2S_2$: C, 63.63; H, 6.77; N, 6.72; S, 15.39%.

*3-Benzylthio-3-methylbutyrophenone Tosylhydrazone (**1h**).* The desired tosylhydrazone was prepared from tosylhydrazide and 3-benzylthio-3-methylbutyrophenone. The latter was obtained by the addition of phenylmethanethiol to isopropylideneacetophenone in a manner similar to that described previously. 3-Benzylthio-3-methylbutyrophenone: NMR (CCl_4): τ 8.52 (s, 6H), 6.90 (s, 2H), 6.27 (s, 2H) and 2.90—2.10 (m, 10H). Tosylhydrazone **1h**: mp 93—94 °C (colorless prisms). Found: C, 65.88; H, 6.27; N, 6.24; S, 14.14%. Calcd for $C_{25}H_{28}N_2O_2S_2$: C, 66.04; H, 6.24; N, 6.19; S, 14.17%.

*4-Allylthio-4-methyl-2-pentanone Tosylhydrazone (**1i**).* The base-catalyzed addition of 2-propenethiol to mesityl oxide produced 4-allylthio-4-methyl-2-pentanone, which was then further converted to the corresponding tosylhydrazone (**1i**). 4-Allylthio-4-methyl-2-pentanone: bp 67 °C/1.0 mmHg. NMR (CCl_4): τ 8.60 (s, 6H), 7.80 (s, 3H), 7.37 (s, 2H), 6.82 (d, J=7 Hz, 2H), 5.10—4.65 (m, 2H) and 4.50—3.80 (m, 1H). Tosylhydrazone **1i**: mp 75—76 °C (colorless prisms). Found: C, 56.41; H, 6.99; N, 8.36; S, 18.84%. Calcd for $C_{16}H_{24}N_2O_2S_2$: C, 56.44; H, 7.10; N, 8.23; S, 18.83%.

*Thermal Decomposition of **1a**.* In a flask equipped with a reflux condenser a 1.04 g portion (3.0 mmol) of the **1a** tosylhydrazone was dissolved in 40 ml of diglyme, and then a 180 mg portion (*ca.* 0.35 mmol) of sodium hydride (50% suspension in mineral oil) was stirred in. After the gas evolution had ceased, the reaction flask was immersed in an oil bath heated at 180 °C. Thermolysis was monitored by nitrogen evolution, which was completed in the temperature range of 130—150 °C. The reaction mixture was heated to reflux for 15 minutes and was then left to cool at room temperature. The sodium *p*-toluenesulfinate thus precipitated was filtered off, and the filtrate was distilled under reduced pressure to remove the solvent. The residue was then submitted to column chromatography on silica (WAKO C-200), using *n*-hexane as the eluent. 1-Methylcyclopropyl phenyl sulfide (**2a**), 3a-methyl-1,2,3,3a-tetrahydro-1-thiaazulene (**5a**), and a mixture of 2-butenyl phenyl sulfide (**3a**) and 3-butenyl phenyl sulfide (**4a**) were eluted, in this order. Although the **3a** and **4a** olefins could not be completely separated by either column chromatography on silica or gas chromatography, the NMR spectrum of the mixture supported the structures. The ratio of these olefins could be calculated from the spectrum. When sodium methoxide was used as the base, cyclopropyl sulfide, **2a**, could not be detected in the product; furthermore, the total yield of the isolable product decreased. **2a**: NMR (CCl_4): τ 9.14 (H^b and H^c: ABq, J=7 Hz, 4H), 8.56 (H^a: s, 3H) and 3.00—2.70 (Ph: m, 5H).



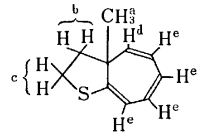
3a: NMR (CCl_4): *cis* and *trans* τ 8.43 (*cis*-H^a: d, Jad=7 Hz) and 8.35 (*trans*-H^a: d, Jad=7 Hz) (3H), 6.65—6.45 (H^b: m, 2H), 4.62—4.44 (H^c and H^d: m, 2H), and 3.00—2.65 (Ph: m, 5H). IR (neat): 958 cm^{-1} ($\delta_{HC=CH}$). Mass: 164 (M^+), 149 (M^+-CH_3), 110 ($PhSH^+$), 109 (PhS^+), 77 (Ph^+), and 55 (M^+-PhS).

$$PhSCH_2^bCH{=}^cCH{-}^dCH_3^a$$

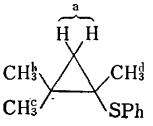
4a: NMR (CCl_4): τ 7.66 (H^b: q, Jab=Jbc=7 Hz, 2H), 7.10 (H^a: t, Jab=7 Hz), 5.10—4.65 (H^c and H^d: m, 3H), and 3.00—2.65 (Ph: m, 5H).

$$PhSCH_2^aCH_2^bCH{=}^cCH_2^d$$

5a: NMR (CCl_4): τ 9.15 (H^a: s, 3H), 7.65 (H^b: octet, 2H), 7.20 (H^c: octet, 2H), 5.01 (H^d: d, Jde=10 Hz, 1H), and 4.20—3.80 (H^e: m, 4H). Found: (a mixture of products, **2a**—**5a**): C, 73.00; H, 7.15; S, 19.25%. Calcd for $C_{10}H_{12}S$: C, 73.12; H, 7.36; S, 19.52%.



*Thermal Decomposition of **1b**.* The sodium salt of **1b** was prepared and decomposed in diglyme under the conditions described above. The crude products were chromatographed on silica, and 1,3,3-trimethylcyclopropyl phenyl sulfide (**2b**), 2,2,3a-trimethyl-1,2,3,3a-tetrahydro-1-thiaazulene (**5b**), 4-phenylthio-4-methyl-2-pentene (**3b**), and 4-phenylthio-4-methyl-1-pentene (**4b**) were eluted by *n*-hexane. The pure **3b** olefin was obtained by column chromatography, but the **4b** olefin could not be separated from the **3b** olefin. The pure sample of the **4b** olefin was, however, obtained from the reaction performed in a protic solvent. Although cyclopropyl sulfide, **2b**, and thiaazulene, **5b**, were obtained as a mixture by column chromatography on silica, further purification by preparative vpc afforded pure samples. In this case, the use of sodium methoxide as a base resulted in similar products. **2b**: NMR (CCl_4): τ 9.29 (H^a: ABq, J=5.0 Hz, 2H), 8.69 (H^b: s, 3H), 8.60 (H^d: s, 3H), 8.46 (H^c: s, 3H), and 3.20—2.80 (Ph: m, 5H). Mass: 192 (M^+, base peak), 177 (M^+-CH_3). 110 ($PhSH^+$), 109 (PhS^+), 83 (M^+-PhS), and 77 (Ph^+). Found: C, 74.78; H, 8.16; S, 16.89%. Calcd for $C_{12}H_{16}S$: C, 74.94; H, 8.39; S, 16.67%.



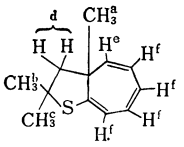
3b: NMR (CCl_4): *trans* τ 8.70 (H^a: s, 6H), 8.39 (H^b: d, Jbd=6 Hz, 3H), 5.00 (H^d: octet, Jcd=16 Hz, 1H), 4.52 (H^c: d, Jcd=16 Hz, 1H), and 2.95—2.50 (Ph: m, 5H). IR (neat): 963 cm^{-1} ($\delta_{HC=CH}$).

$$PhS{-}\overset{\overset{CH_3^a}{|}}{\underset{\underset{CH_3^a}{|}}{C}}{-}CH{=}^cCH{-}^dCH_3^b$$

4b: NMR (CCl_4): τ 8.82 (H^a: s, 6H), 7.83 (H^b: d, Jbc=6 Hz, 2H), 4.40—3.75 (H^c and H^d: m, 3H), and 2.95—2.50 (Ph: m, 5H). Found (a mixture of **3b** and **4b**): C, 74.82; H, 8.35; S, 16.66%. Calcd for $C_{12}H_{16}S$: C, 74.94; H, 8.39; S, 16.67%.

$$PhS{-}\overset{\overset{CH_3^a}{|}}{\underset{\underset{CH_3^a}{|}}{C}}{-}CH_2^bCH{=}^cCH_2^d$$

5b: NMR (CCl_4): τ 9.07 (H^a: s, 3H), 8.53 (H^b: s, 3H), 8.40 (H^c: s, 3H), 7.70 (H^d: s, 2H), 4.94 (H^e: d, Jef=10 Hz, 1H), and 4.20—3.70 (H^f: m, 4H). Found: C, 74.68; H, 8.40; S, 16.94%. Calcd for $C_{12}H_{16}S$: C, 74.94; H, 8.39; S, 16.69%.

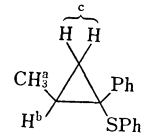


Thermal Decomposition of **1c**. The **1c** tosylhydrazone (1.49 g, 4.0 mmol) was decomposed in the presence of 220 mg of sodium methoxide in diglyme under the conditions described above. The crude products were submitted to column chromatography on silica, and 3-methyl-1-phenylcyclopropyl phenyl sulfide (**2c**), 3-phenyl-1-methylcyclopropyl phenyl sulfide (**20**), and 1-phenyl-3-phenylthio-1-butene, **3c**, (*cis* and *trans*) were eluted by *n*-hexane. Although cyclopropyl sulfide, **20**, could not be separated from cyclopropyl sulfide, **2c**, by the column chromatography, purification by preparative vpc gave a pure sample. Both *cis* and *trans* **3c** olefins were successfully isolated by column chromatography.

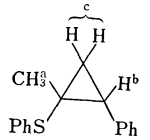
When sodium hydride was used as a base instead of sodium methoxide, 1-phenyl-3-phenylthio-2-butene (*cis*/*trans*=50/50) (**3c'**) was obtained, together with the **3c** olefin in the ratio of 38/62. Pure samples of *cis* and *trans* isomers of the **3c'** olefin were obtained by column chromatography on silica.

In a control experiment, the **3c** olefin (100 mg) was treated with 20 mg of sodium hydride in 50 ml of diglyme under reflux for 15 min.[8] The reaction mixture was concentrated under reduced pressure, dissolved in chloroform, washed with water, dried over anhydrous magnesium sulfate, and then concentrated again. A study of the NMR spectrum of the reaction mixture revealed the formation of a mixture of the **3c** and **3c'** olefins in the ratio of 60/40.

2c: NMR (CCl_4): τ 9.17 (H^a: d, Jab=6 Hz, 3H), 9.00—8.20 (H^b and H^c: m, 3H), and 3.10—2.75 (Ph: m, 10H). Mass: 240 (M^+). 225 (M^+-CH_3), 163 (M^+-Ph), 131 (M^+-PhS, base peak), 110 ($PhSH^+$), 109 (PhS^+), and 77 (Ph^+). Found: C, 79.72; H, 6.49; S, 13.60%. Calcd for $C_{16}H_{16}S$: C, 79.95; H, 6.71; S, 13.34%.

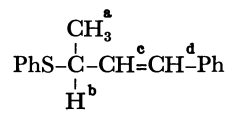


20: NMR (CCl_4): τ 9.10—8.10 (H^b and H^c: m, 3H), 8.57 (H^a: s, 3H), and 3.10—2.70 (Ph: m, 10H). Mass: 240 (M^+-CH_3), 131 (M^+-PhS, base peak), 109 (PhS^+), 91 ($C_7H_7^+$),

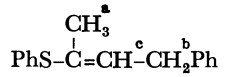


and 77 (Ph^+). Found: S, 13.44%. Calcd: S, 13.34%.

3c: NMR (CCl_4): *trans* τ 8.55 (H^a: d, Jab=7 Hz, 3H), 6.40—6.10 (H^b: m, 1H), 4.05—3.95 (H^c and H^d: m, 2H), and 3.00—2.60 (Ph: m, 10H). IR (neat): 960 cm^{-1} ($\delta_{HC=CH}$). Mass: 240 (M^+), 131 (M^+-PhS, base peak), 110 ($PhSH^+$), 109 (PhS^+), 91 ($C_7H_7^+$), and 77 (Ph^+). NMR (CCl_4): *cis* τ 8.62 (H^a: d, Jab=7 Hz, 3H), 5.82 (H^b: octet, Jbc=11 Hz, Jab=7 Hz, 1H), 4.56 (H^c: t, Jbc=11 Hz, 1H), 3.71 (H^d: d, Jcd=11 Hz, 1H), and 3.10—2.70 (Ph: m, 10H). Found: C, 79.75; H, 6.75; S, 13.46%. Calcd for $C_{16}H_{16}S$: C, 79.95; H, 6.71; S, 13.34%.



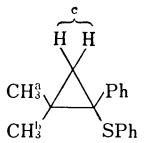
3c': NMR (CCl_4): *trans* τ 8.07 (H^a: s, 3H), 6.61 (H^b: d, Jbc=8 Hz, 2H), 4.12 (H^c: t, Jbc=8 Hz, 1H), and 3.10—2.70 (Ph: m, 10H). *cis* τ 8.11 (H^a: s, 3H), 6.40 (H^b: d, Jbc=8 Hz, 2H), 4.17 (H^c: t, Jbc=8 Hz, 1H), and 3.10—2.70 (Ph: m, 10H). Mass: 240 (M^+), 225 (M^+-CH_3), 131 (M^+-PhS, base peak), 110 ($PhSH^+$), 109 (PhS^+), 105 ($PhCH_2CH_2^+$), 91 ($PhCH_2^+$), and 77 (Ph^+).



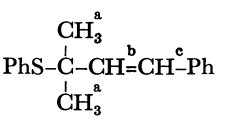
Thermolysis and Photolysis of **1d**. The sodium salt of **1d** was prepared and themally decomposed in diglyme under the conditions described above. When the crude products were chromatographed on silica, 3,3-dimethyl-1-phenylcyclopropyl phenyl sulfide (**2d**) and 3-methyl-3-phenylthio-1-phenyl-1-butene (**3d**) were obtained. The same products were obtained in similar yields when sodium methoxide was used as the base.

The photolysis of the sodium salt of **1d** (219 mg, 0.5 mmol) was carried out in 50 ml of monoglyme, using a Pyrex cell cooled with water and employing a 450 W high-pressure Hg lamp. The same treatment of the crude products described above afforded cyclopropyl sulfide, **2d** (37%), and the **3d** olefin (18%). It seems that the **3d** olefin was polymerized or decomposed under the photolytic conditions.

2d: NMR (CCl_4): τ 9.16 (H^a: s, 3H), 8.80 (H^c: ABq, J=5 Hz, 2H), 8.40 (H^b: s, 3H), and 3.10—2.85 (Ph: m, 10H). Mass: 254 (M^+, base peak), 239 (M^+-CH_3), 177 (M^+-Ph), 145 (M^+-PhS), 110 ($PhSH^+$), 109 (PhS^+), and 77 (Ph^+). Found: C, 80.50; H, 7.18; S, 12.64%. Calcd for $C_{17}H_{18}S$: C, 80.26; H, 7.18; S, 12.64%.



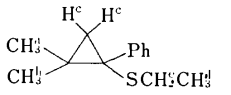
3d: NMR (CCl_4): *trans* τ 8.56 (H^a: s, 6H), 4.00 (H^b and H^c: ABq, J=16 Hz, 2H), and 3.10—2.60 (Ph: m, 10H). IR (neat): 958 cm^{-1} ($\delta_{HC=CH}$). Mass: 254 (M^+), 145 (M^+-PhS), 110 ($PhSH^+$), 109 (PhS^+), 91 ($C_7H_7^+$), and 77 (Ph^+). Found: C, 80.00; H, 7.22; S, 12.36%. Calcd. for $C_{17}H_{18}S$: C, 80.26; H, 7.14; S, 12.60%.



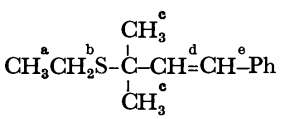
Thermal Decomposition of **1e**. The sodium salt of the **1e** tosylhydrazone was prepared from 1.56 g (4.0 mmol) of the tosylhydrazone and 240 mg of sodium hydride in mineral oil (50%), and was decomposed in diglyme under the conditions described above. When the crude products were chromatographed on silica gel, 3,3-dimethyl-1-phenylcyclopropyl ethyl sulfide (**2e**) and 3-ethylthio-3-methyl-1-phenyl-1-butene (**3e**) were obtained.

2e: NMR (CCl_4): τ 9.21 (H^a: s, 3H), 8.96 (H^c: ABq, J=5 Hz, 2H), 8.92 (H^d: t, J=7 Hz, 3H), 8.55 (H^b: s, 3H), 7.72 (H^e:

quartet, J=7 Hz, 2H), and 2.88 (Ph: 2, 5H), Found: C, 75.52; H, 8.88; S, 15.49%. Calcd for $C_{13}H_{18}S$: C, 75.67; H, 8.79; S, 15.54%.

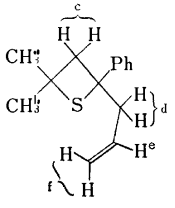


3e: NMR (CCl_4): *trans* τ 8.83 (H^a: t, J=7 Hz, 3H), 8.56 (H^c: s, 6H), 7.60 (H^b: quartet, J=7 Hz, 2H), 3.76 (H^d, H^e: s, 2H) and 3.00—2.40 (Ph: m, 5H). IR (neat): 960 cm^{-1} ($\delta_{HC=CH}$). Found: C, 75.60; H, 8.86; S, 15.52%. Calcd for $C_{13}H_{18}S$: C, 75.67; H, 8.79; S, 15.54%.

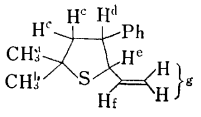


Photolysis of ***1f***. The **1f** tosylhydrazone (1.07 g, 4.0 mmol) and sodium methoxide (280 mg) were dissolved in 80 ml of monoglyme in a Pyrex photolysis vessel. After a stream of nitrogen had been bubbled into the photolysis vessel, the mixture was irradiated with a 450 W high-pressure Hg lamp for 4 hr under stirring and cooling by water. The sodium *p*-toluenesulfinate thus precipitated was filtered off. The filtrate was concentrated under reduced pressure, dissolved in chloroform, washed with water, and dried over anhydrous magnesium sulfate. The crude products were submitted to column chromatography on silica, using *n*-hexane as the eluent. 2-Allyl-4,4-dimethyl-1-phenylthietane (**10a**), 3-allylthio-3-methyl-1-phenyl-1-butene (**12a**) (*cis* and *trans*), and 2-vinyl-5,5-dimethyl-3-phenyltetrahydrothiophene (**11a**) were eluted in this order. Although the diastereoisomers of tetrahydrothiophene (**11a**) could not be separated from each other, purification by preparative vpc (20% SE-30 at 180 °C) afforded each component in the pure form. The use of sodium hydride as a base resulted in the hydrogenation of the allylic double bond.

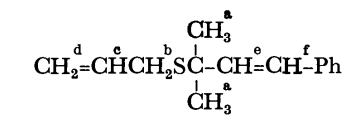
10a: NMR (CCl_4): τ 8.62 (H^a: s, 3H), 8.44 (H^b: s, 3H), 7.30 (H^d: d, J=7 Hz, 2H), 7.06 (H^c: ABq, J=12 Hz, 2H), 5.40—5.00 (H^f: m, 2H), 4.80—4.20 (H^e: m, 1H), and 3.00—2.65 (Ph: m, 5H).



11a: NMR (CCl_4): *cis* (as for phenyl and vinyl) τ 8.53 (H^a: s, 3H), 8.50 (H^b: s, 3H), 7.87 (H^c: octet, Jcc=16 Hz, Jcd=2 Hz, 6 Hz, 2H), 6.80 (H^d: octet, 1H), 6.01 (H^e: q, Jde=10 Hz, Jef=8 Hz, 1H), 5.30—5.00 (H^g: m, 2H), 4.55—4.15 (H^f: m, 1H), and 2.90—2.65 (Ph: m, 5H). *trans* τ 8.51 (H^a: s, 3H), 8.44 (H^b: s, 3H), 7.88 (H^c: octet, Jcc=12 Hz, Jcd=4 Hz, 12 Hz, 2H), 6.05 (H^e: d, Jef=7 Hz, Jde=0, 1H), 6.05 (H^d: octet, 1H), 5.30—4.95 (H^g: m, 2H), 4.75—4.20 (H^f: m, 1H), and 2.95—2.65 (Ph: m, 5H).

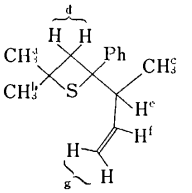


12a: *cis*: NMR (CCl_4): τ 8.76 (H^a: s, 6H), 6.85 (H^b: d, Jbc=7 Hz, 2H), 5.10—4.75 (H^d: m, 2H), 4.50—4.05 (H^c: m, 1H), 4.40 (H^e: d, Jef=12 Hz, 1H), 3.54 (H^f: d, Jef=12 Hz, 1H), and 2.90—2.70 (Ph: m, 5H). IR (neat): 1640 ($\nu_{C=C}$), 980, 910 ($\delta_{HC=CH_2}$), and 780 cm^{-1} ($\delta_{HC=CH}$). *trans* NMR (CCl_4): τ 8.56 (H^a: s, 6H), 7.01 (H^b: d, Jbc=7 Hz, 2H), 5.20—4.80 (H^d: m, 2H), 4.50—4.05 (H^c: m, 1H), 3.83 (H^e, H^f: m, 2H), and 2.90—2.60 (Ph: m, 5H). IR (neat): 1640 ($\nu_{C=C}$), 978, 910 ($\delta_{HC=CH_2}$), and 960 cm^{-1} ($\delta_{HC=CH}$) Found (a mixture of **10a**, **11a**, and **12a**): C, 76.99; H, 8.10; S, 14.43%. Calcd for $C_{14}H_{18}S$: C, 77.01; H, 8.31; S, 14.68%.



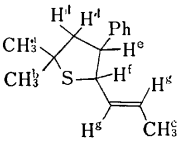
Photolysis of ***1g***. The **1g** tosylhydrazone was photolyzed in a manner similar to that described above, and the crude products were chromatographed on silica. 4,4-Dimethyl-2-(1-methylallyl)-2-phenylthietane (**10b**), 5,5-dimethyl-3-phenyl-2-(1-propenyl)tetrahydrothiophene (**11b**), and 3-crotylthio-3-methyl-1-phenylbutene (**12b**) (*cis* and *trans*) were eluted by *n*-hexane, in this order.

10b: NMR (CCl_4): diastereoisomer-(A) τ 9.34 (H^c: d, Jce=7 Hz, 3H), 8.72 (H^a: s, 3H), 8.57 (H^b: s, 3H), 7.44 (H^e: quintet, 1H), 7.04 (H^d: ABq, J=12 Hz, 2H), 5.20—4.90 (H^g: m, 2H), 4.40—4.00 (H^f: m, 1H), and 3.00—2.60 (Ph: m, 5H).

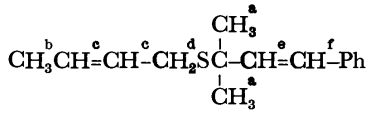


diastereoisomer-(B) τ 9.21 (H^c: d, Jce=7 Hz, 3H), 8.70 (H^a: s, 3H), 8.49 (H^b: s, 3H), 7.25—6.90 (H^e: m, 1H), 7.03 (H^d: ABq, J=12 Hz, 2H), 5.25—4.60 (H^f and H^g: m, 3H), and 3.00—2.70 (Ph: m, 5H).

11b: NMR (CCl_4): τ 8.60—8.30 (H^a, H^b, and H^c: m, 9H), 8.15—7.50 (H^d: m, 2H), 7.05—6.50 (H^e: m, 1H), 6.50—5.85 (H^f: m, 1H), 5.10—4.40 (H^g: m, 2H), and 3.00—2.60 (Ph: m, 5H).



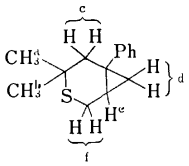
12b: NMR (CCl_4): *cis* τ 8.76 (H^a: s, 6H), 8.35 (H^b: d, Jbc=5 Hz, 3H), 6.91 (H^d: d, Jcd=6 Hz, 2H), 4.70—4.40 (H^c: m, 2H), 4.40 (H^e: d, Jef=12 Hz, 1H), 3.54 (H^f: d, Jef=12 Hz, 1H), 2.95—2.70 (Ph: m, 5H). IR (neat): 955 (δ *trans* -CH=CH-), 775 cm^{-1} (*cis* -CH=CH-). NMR (CCl_4): *trans* τ 8.58 (H^a: s, 6H), 8.40 (H^b: d, Jbc=5 Hz, 3H), 7.07 (H^d: d, Jcd=6 Hz, 2H), 4.80—4.50 (H^c: m, 2H), 3.84 (H^e and H^f: s, 2H), 2.90—2.60 (Ph: m, 5H). IR (neat): 970 (δ *trans* -CH=CH-), 955 cm^{-1} (δ *trans* -CH=CH-).



Found (a mixture of **10b**, **11b**, and **12b**): C, 77.85; H, 9.03; S, 13.88%. Calcd for $C_{15}H_{20}S$: C, 77.53; H, 8.67; S, 13.80%.

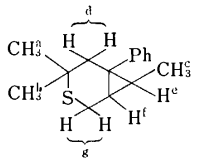
Thermal Decomposition of ***1f***. The **1f** tosylhydrazone (804 mg, 2.0 mmol) was dissolved in 50 ml of diglyme, and then we added 130 mg of sodium methoxide. Thermolysis was performed in accordance with the procedure described previously. The products were purified by column chromatography on silica. 6-Phenyl-4,4-dimethyl-3-thiabicyclo[4.1.0]-heptane (**15**) was obtained from the eluate of *n*-hexane. Yield, 196 mg (45%). The analytical vpc (20% SE-30, 200 °C) of the crude products, however, showed the formation of small amounts of thietane, **10a**, and the **12a** olefin, as is shown in Table 2.

15: NMR (CCl_4): τ 9.20—8.40 (H^d and H^e: m, 3H), 8.84 (H^a: s, 3H), 8.62 (H^b: s, 3H), 8.01 (H^c: s, 2H), 7.01 (H^f: octet, Jef=2 Hz, 4 Hz, 2H), and 3.10—2.80 (Ph: m, 5H). Found: C, 77.14; H, 8.20; S, 14.40%. Calcd for $C_{14}H_{18}S$: C, 77.01; H, 8.31; S, 14.68%.



Thermal Decomposition of ***1g***. The **1g** tosylhydrazone was decomposed at 150 °C in the presence of a slight excess of sodium methoxide, as has been described previously. Two products were observed in the analytical vpc (20% SE-30, 220 °C) of the crude product. Separation by column chromatography on silica afforded 1-phenyl-4,4-dimethyl-7-(*exo*)-methyl-3-thiabicyclo[4.1.0]heptane (**16a**) and its *endo* isomer (**16b**) in the pure form. Their structures were assigned based on the NMR spectra; the absorption peak of the methyl in the *exo*-isomer appeared at τ 9.29, while that of the *endo*-isomer was at τ 8.68.

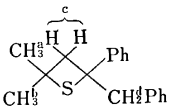
16: NMR (CCl_4): *exo* τ 9.29 (H^c: d, Jce=5.5 Hz, 3H), 9.00—8.60 (H^e and H^f: m, 2H), 8.89 (H^a: s, 3H), 8.78 (H^b: s, 3H), 8.03 (H^d: s, 2H), 6.98 (H^g: octet, Jgg=14 Hz, Jfg=1.5 Hz, 4 Hz, 2H), and 3.00—2.70 (Ph: m, 5H). *endo* τ 8.95—8.40 (H^e and H^f: m, 2H), 8.81 (H^a: s, 3H), 8.73 (H^b: s, 3H), 8.68 (H^c: d, Jce=6 Hz, 3H), 8.09 (H^d: ABq, J=14 Hz, 2H), 7.06 (H^g: octet, Jgg=13 Hz, Jfg=2 Hz, 4 Hz, 2H), and 3.10—2.70 (Ph: m, 5H). Found: C, 77.39; H, 8.87; S, 13.90%. Calcd for $C_{15}H_{20}S$: C, 77.53; H, 8.67; S, 13.80%.



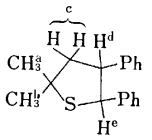
Thermolysis and Photolysis of ***1h***. The **1h** tosylhydrazone (904 mg, 2.0 mmol) was thermally decomposed in the presence of 130 mg of sodium methoxide in diglyme under the conditions described previously. The crude products were then chromatographed on silica, and 2-benzyl-2-phenyl-4,4-dimethylthietane (**10c**), 2,3-diphenyl-5,5-dimethyltetrahydrothiophene (**11c**), and 3-benzylthio-3-methyl-1-phenylbut-1-ene (**12c**, *trans*) were eluted by *n*-hexane. The tetrahydrothiophene, **11c**, was a mixture of diastereoisomers, and each component was sufficiently separated by column chromatography on silica. The isomer ratio was determined to be 50:50, based on the NMR spectrum.

The photolysis of the **1h** tosylhydrazone was performed in a manner similar to that described previously. Thietane, **10c**, tetrahydrothiophene, **11c**, and the **12c** olefin were also obtained, but the **12c** olefin was a mixture of *cis* and *trans* isomers (*cis*/*trans*=27/73).

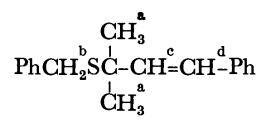
10c: NMR (CCl_4): τ 8.69 (H^a: s, 3H), 8.50 (H^b: s, 3H), 6.96 (H^c: ABq, J=12 Hz, 2H), 6.79 (H^d: ABq, J=13 Hz, 2H), and 3.40—2.80 (Ph: m, 10H). Found: C, 80.58; H, 7.26; S, 11.79%. Calcd for $C_{18}H_{20}S$: C, 80.54; H, 7.51; S, 11.95%.



11c: NMR (CCl_4) *cis* τ 8.45 (H^a: s, 3H), 8.34 (H^b: s, 3H), 7.95—7.65 (H^c: m, 2H), 6.20—5.80 (H^d: m, 1H), 5.48 (H^e: d, Jde=10 Hz, 1H), and 3.40—2.75 (Ph: m, 10H). *trans* τ 8.40 (H^a: s, 3H), 8.29 (H^b: s, 3H), 7.80—7.40 (H^c: m, 2H), 6.30—5.80 (H^d: m, 1H), 5.42 (H^e: d, Jde=7.5 Hz, 1H), and 3.40—2.75 (Ph: m, 10H). Found: C, 80.31; H, 7.24; S, 11.93%. Calcd for $C_{18}H_{20}S$: C, 80.54; H, 7.51; S, 11.95%.



12c: NMR (CCl_4): *trans* τ 8.58 (H^a: s, 6H), 6.46 (H^b: s, 2H), 3.80 (H^c and H^d: s, 2H), and 3.00—2.65 (Ph: m, 10H). *cis* τ 8.49 (H^a: s, 6H), 6.34 (H^b: s, 2H), 3.96 (H^c and H^d: ABq, Jcd=12 Hz, 2H), and 3.10—2.65 (Ph: m, 10H). Found: C, 80.26; H, 7.25; S, 12.21%. Calcd for $C_{18}H_{20}S$: C, 80.54; H, 7.51; S, 11.95%.



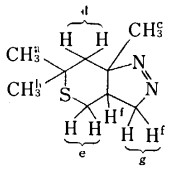
Thermolysis and Photolysis of ***1i***. The **1i** tosylhydrazone (1.70 g, 5.0 mmol) was thermally decomposed in the presence of 300 mg of sodium methoxide in diglyme. The subsequent purification of the crude products by column chromatography on silica gave 4,4,6-trimethyl-3,7,8-thiadiazabicyclo[4.3.0]-nonene (**17**), 303 mg (33%). The Δ^1-pyrazoline, **17**, is thermally stable, but sensitive to light.

The photolysis of the **1i** tosylhydrazone was performed in monoglyme in a manner similar to that described previously. The identifiable product obtained by column chromatography (silica/*n*-hexane) was found to be 4,4,6-trimethyl-3-thiabicyclo[4.1.0]heptane (**18**) (48%).

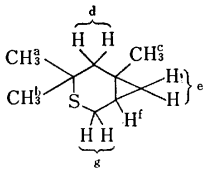
The Δ^1-pyrazoline (**17**) was irradiated in monoglyme with a 450 W high-pressure Hg lamp at room temperature, using a Pyrex filter. The solvent was evacuated off, and the residue was dissolved in carbon tetrachloride. The NMR spectrum of the reaction mixture showed the formation of 3-thiabicyclo[4.1.0]heptane **18**. The analytical vpc (20% SE-30, 140 °C) also supported the formation of the isomeric mixture of **18**.

17: NMR (CCl_4): τ 8.92 (H^a: s, 3H,) 8.85 (H^b: s, 3H), 8.67 (H^c: s, 3H), 7.88 (H^d: ABq, J=14 Hz, 2H), 7.69 (H^e: octet, Jee=14 Hz, Jef=5.5 Hz, 8 Hz, 2H), 8.35—7.80 (H^f: m, 1H), and 5.69 (H^g: octet, Jgg=17 Hz, Jfg=4 Hz, 6 Hz, 2H). Mass: 184 (M^+), 156 (M^+-N_2), 141 (156−CH_3), 123, 115,

107 (base peak). Found: C, 58.65; H, 8.90; S, 17.69%. Calcd for $C_{19}H_{16}N_2S$: C, 58.65; H, 8.75; S, 17.40%.



18: NMR (CCl_4) τ 9.75—9.10 (H^e and H^f: m, 3H), 8.95 (H^c: s, 3H), 8.87 (H^a: s, 3H), 8.72 (H^b: s, 3H), 8.35 (H^d: ABq, J=14 Hz, 2H), and 7.11 (H^g: octet, Jgg=14 Hz, Jfg=1 Hz, 2H). Found: C, 68.89; H, 10.21; S, 20.81%. Calcd for $C_9H_{16}S$: C, 69.17; H, 10.32; S, 20.52%.



The authors wish to express their thanks to the Kawakami Memorial Foundation for its partial support of this research.

A General Method for Evaluating the Resonance Energies of Monocyclic Conjugated Systems and Its Application to Heteroannulenes and Annulenones

Jun-ichi AIHARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received November 20, 1974)

The unit binding energy of a monocyclic conjugated system with an infinite number of the same unit structures can be employed as the reference energy in evaluating the resonance energy of a monocyclic conjugated system with a single unit structure. The latter system may be totally asymmetric in geometry. The resonance energy is then given as the difference between the π-energy of the system with the one-unit structure and the unit binding energy of the infinitely large system. This approach is justified by the proper prediction of the resonance energies for heteroannulenes and annulenones. The HMO theory was used in its simplest form.

Almost all compounds, even those which are obviously unstable, are known to have a significant HMO delocalization energy.[1,2] The lack of correlation between the calculated delocalization energy and the observed aromatic behavior has, though, been widely pointed out as a failure of the HMO method. Recently, Dewar, using the more elaborate PPP method, has for the first time obtained calculated resonance energies which correlate well with the experimental aromaticity for a wide range of conjugated hydrocarbons.[1] However, the important point turned out to be that he changed the reference structure relative to which aromatic stabilization was calculated. With the original HMO method, on the other hand, Hess *et al.* obtained resonance energies which correlate as well as Dewar's with the experimental properties for a wide variety of both conjugated hydrocarbons and heterocycles.[3-7]

In the calculation of the delocalization energy, the π-energy of a compound with n double bonds was compared to the π-energy of n isolated double bonds (ethylene). In the method of Hess *et al.*, modeled after Dewar's, the π-energy of a compound was compared to the π-energy of a reference structure with contributions from both single and double bonds. It is noteworthy that a considerable double-bond character was attached to the single bonds in the resonance structure of the conjugated system.[1,3] Hence, the π-energy of an acyclic compound was generally represented as an additive function of the individual π-bond energies. This fact indicates that any acyclic compound has essentially zero resonance energy, whereas cyclic compounds have been found to have a wide and continuous variation in resonance energies, from positive (aromatic) to negative (antiaromatic).[1-7] In this article, we attempted to refine this kind of resonance energies simply on the basis of the additivity of π-bond energies for nonaromatic species, and examined the aromaticity of less symmetric monocyclic compounds, such as heteroannulenes and annulenones, without referring to the individual π-bond energies. We used the HMO theory in its simplest form.

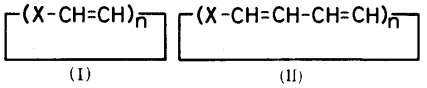
When HMO calculations are performed on conjugated compounds containing heteroatoms, appropriate corrections must be made of the Coulomb integral for each heteroatom and of the resonance integral for each carbon-heteroatom bond. A considerable amount of effort has been devoted to the determination of heteroatom parameters for such compounds.[8] Recently, Hess *et al.* evaluated the heteroatom parameters for the amine nitrogen, the ether oxygen, the thioether sulfur, and the carbonyl oxygen strictly on the basis of an experimental ground-state property, the heat of atomization.[5-7] We adopted their values, as they can be expected to be most suited to the estimation of another ground-state property, the resonance energy. They are listed in Table 1.

TABLE 1. HETEROATOM PARAMETERS

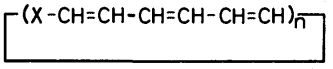
X	h_x	k_{c-x}
Amine nitrogen[5]	1.50	0.90
Ether oxygen[5]	2.00	0.34
Thioether sulfur[6]	1.00	0.68
Carbonyl oxygen[7]	0.22	0.99
sp^2-carbon	0.00	1.00

Theoretical

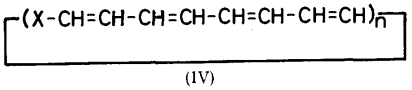
The reference energy relative to which the resonance energy of a monocyclic system is calculated is defined as follows. First, consider four hypothetical compounds of Type I-IV, in each of which n heteroatoms are periodically inserted in the cyclic chain of carbon atoms. X may be NH, O, or S. The π-energies for such systems can easily be obtained within the framework of the HMO theory.



(I) (II)



(III)



(IV)

For example, the π-energy of a compound of Type II can be obtained by solving the following secular equations:

$$a_i(\chi+h) + ke_{i-1} + kb_i = 0$$
$$b_i\chi + ka_i + c_i = 0$$
$$c_i\chi + b_i + d_i = 0$$
$$d_i\chi + c_i + e_i = 0$$
$$e_i\chi + d_i + ka_{i+1} = 0 \quad i = 1, 2, \cdots, n \tag{1}$$

where $\chi=(\alpha-E)/\beta$ and where a_i, b_i, c_i, d_i, and e_i are the Hückel coefficients of the atomic orbitals concerned on the atoms arranged in this manner:

$$\underset{d_{i-1}}{\text{—CH=CH—}}\underset{e_{i-1}}{\text{X—}}\underset{a_i}{\text{CH=CH—}}\underset{b_i}{\text{CH=CH—}}\underset{c_i}{\text{CH=CH—}}\underset{d_i}{\text{X—}}\underset{e_i}{\text{CH=CH—}}$$

These equations must be solved together with the boundary conditions:[3]

$$a_{n+1} = a_1, \quad b_{n+1} = b_1, \quad c_{n+1} = c_1, \quad d_{n+1} = d_1,$$
$$\text{and} \quad e_{n+1} = e_1 \tag{2}$$

The function

$$a_i = \sin i\lambda \tag{3}$$

automatically satisfies Eq. (2) for $i=n+1$ if

$$\lambda = \lambda_{nm} = \frac{2m\pi}{n} \qquad m = 0, 1, \cdots, (n-1) \tag{4}$$

The elimination of b_i, c_i, d_i, e_i, and e_{i-1} in Eq. (1), followed by the substitution of Eqs. (3) and (4), gives n algebraic equations of degree five:

$$\chi^5 + h\chi^4 - (2k^2+3)\chi^3 - 3h\chi^2 + (1+4k^2)\chi + (h+2k^2\cos\lambda_{nm}) = 0 \quad m = 0, 1, \cdots, (n-1) \tag{5}$$

Each of these equations possesses five real roots:

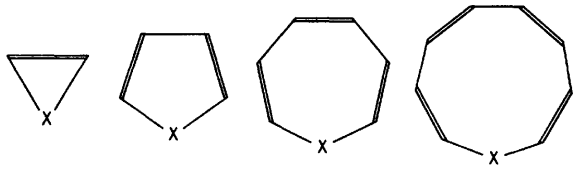
$$\chi = \chi_1(\lambda_{nm}) \leq \chi_2(\lambda_{nm}) \leq \chi_3(\lambda_{nm}) \leq \chi_4(\lambda_{nm}) \leq \chi_5(\lambda_{nm}) \tag{6}$$

Among them, the smaller three roots correspond to the π-energies of the occupied orbitals in the heterocycle in quetion. Accordingly, the π-energy of a compound of Type II can be obtained by summing the smaller three roots for every λ_{nm} over all the m's.

As may easily be seen, the unit structure of the periodic compound of Type II is composed of the two CH=CH, one CH–CH, and two CH–X bonds when the classical resonance structure is written for it. The unit binding energy corresponding to the unit structure is obtained by dividing the π-energy of the whole system by the number of the unit structures (n). It is a function of the number of the unit structures, as the π-energy might be influenced by the possible aromatic character of the smaller systems. When the n is large enough, the system can, however, be considered without difficulty as a nonaromatic species, regardless of the X. The unit binding energy of any infinitely large system should, therefore, be free from aromaticity. The unit binding energy (E_u) of an infinitely large system of Type II can be expressed in units of β as:

$$E_u(X) = -\lim_{n\to\infty}\frac{2}{n}\sum_{m=0}^{n-1}\left\{\chi_1(\lambda_{nm}) + \chi_2(\lambda_{nm}) + \chi_3(\lambda_{nm})\right\} - 2h_x$$
$$= -2\int_0^1\{\chi_1(2\pi x) + \chi_2(2\pi x) + \chi_3(2\pi x)\}dx - 2h_x \tag{7}$$

Note that it is not difficult to regard such unit binding energy as the reference energy in evaluating the aromaticity of a five-membered heterocycle of Type VI. The five-membered ring of Type VI is a special case of the compound of Type II, in which only one unit



(V) (VI) (VII) (VIII)

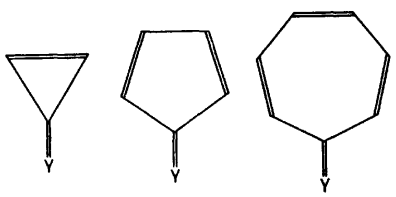
structure is present. If any compound of Type II is assumed to be absolutely nonaromatic, it should possess the same unit binding energy as the compound of Type II with $n=\infty$. Therefore, as long as the additivity of π-bond energies is assumed for the like nonaromatic systems, the unit binding energy derived from Eq. (7) can be considered as the reference energy of the five-membered heterocycle of Type VI.

In other words, the five-membered heterocycle of Type VI has the same numbers of the CH=CH, CH–CH, and CH–X bonds as the unit structure of the compound of Type II containing the same heteroatom. Furthermore, the positions of the carbon atoms relative to the position of the heteroatom in the five-membered heterocycle are exactly equivalent to those in the unit structure. The effect of the electronegative heteroatom on the nearby π-bonds in the heterocycle of Type VI is necessarily taken into account in the unit binding energy derived from Eq. (7). This explain well how that the unit binding energy of an infinitely large system represents the reference energy of the corresponding five-membered heterocycle. The resonance energy of a given heterocycle of Type VI is, then, the difference between the π-energy of the compound and the unit binding energy of the infinitely large system of Type II.

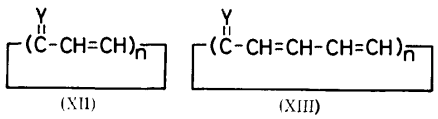
The resonance energies of the three-, seven-, and nine-membered heteroannulenes containing single heteroatoms (V, VII, and VIII) are calculated in the same manner by comparing their π-energies with the unit binding energies of the infinitely large systems of Type I, III, and IV respectively. The secular equations for these systems are analogously reduced to the following algebraic equations:

$$\chi^3 + h\chi^2 - (2k^2+1)\chi + (2k^2\cos\lambda_{nm} - h) = 0 \quad \text{for I} \tag{8}$$
$$\chi^7 + h\chi^6 - (2k^2+5)\chi^5 - 5h\chi^4 + (8k^2+6)\chi^3 + 6h\chi^2 - (6k^2+1)\chi + (2k^2\cos\lambda_{nm} - h) = 0 \quad \text{for III} \tag{9}$$
$$\chi^9 + h\chi^8 - (2k^2+7)\chi^7 - 7h\chi^6 + (12k^2+15)\chi^5 + 15\chi^4 - (20k^2+10)\chi^3 - 10h\chi^2 + (8k^2+1)\chi + (2k^2\cos\lambda_{nm} + h) = 0 \quad \text{for IV} \tag{10}$$

The unit binding energies are numerically computed

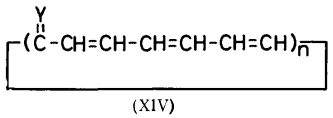


(IX) (X) (XI)



(XII)

(XIII)



(XIV)

with these equations as in Eq. (7) for the five-membered heteroannulenes.

On the other hand, the reference energies of the first three members of annulenones (IX, X, and XI; Y=O) and fulvenes (IX, X, and XI; Y=CH_2) are obtained on the basis of the following equations, which are the algebraic versions of the secular equations for the systems of Types XII, XIII, and XIV:

$$\chi^4 + h\chi^3 - (k^2+3)\chi^2 - (3h-2\cos\lambda_{nm})\chi + (k^2+2h\cos\lambda_{nm}) = 0 \quad \text{for XII} \tag{11}$$

$$\chi^6 + h\chi^5 - (k^2+5)\chi^4 - 5h\chi^3 + (3k^2+5)\chi^2 + (5h+2\cos\lambda_{nm})\chi - (k^2-2h\cos\lambda_{nm}) = 0 \quad \text{for XIII} \tag{12}$$

$$\chi^8 + h\chi^7 - (k^2+7)\chi^6 - 7h\chi^5 + (5k^2+14)\chi^4 + 14h\chi^3 - (6k^2+7)\chi^2 - (7h-2\cos\lambda_{nm})\chi + (k^2+2h\cos\lambda_{nm}) = 0 \quad \text{for XIV} \tag{13}$$

The resonance energy of a given annulenone or fulvene is the difference between the π-energy of the compound and the unit binding energy of an infinitely large system composed of like unit structures.

Results and Discussion

The resonance energies of the heteroannulenes calculated according to the above-mentioned procedure are all listed in Table 2. The most striking aspect of these resonance energies is the strong alternation between aromaticity and antiaromaticity. The alternation decreases as the ring size increases. When the heteroannulenes are $(4r+2)\pi$-electron systems, they are predicted to be aromatic, with positive resonance energies. Conversely, when they are $4r$ π-electron systems, they are predicted to be antiaromatic, with negative resonance energies. Here, r is an integer. Such a trend in the aromatic character is clearly common to all the heteroannulenes containing single heteroatoms. This fact indicates that the Hückel $(4r+2)\pi$ rule of aromaticity can still be applied to such heterocyclic systems as heteroannulenes.

It should, then, be emphasized that their chemistry is in good accord with these predictions. The three-membered rings are predicted to be strongly antiaromatic, probably because of their four π-electron systems. These compounds are correspondingly unknown as yet. On the other hand, the five-membered rings, each of which forms an aromatic sextet, are predicted to be aromatic, in line with their well-known properties.[9,10] Among them, furan is predicted to be only slightly aromatic, as is indicated by its chemistry. Furan undergoes Diels-Alder reactions readily, while pyrrole and thiophene do not.

Table 2. Calculated resonance energies of heteroannulenes

Species	n	Hückel MO π-energy (β)	Reference energy (β)	Resonance energy (β)	Resonance energy (kcal/mol)
			Aza[n]annulenes		
C_2H_2NH	3	2.0000	2.6590	−0.6590 (−0.666)	−20.224

Resonance energies given in kcal/mol were calculated with $\beta=-1.33077$ eV.[5]

The seven-membered ring systems, azepine, oxepin, and thiepin, are characterized by a cyclic array of eight π-electrons, and are predicted to be antiaromatic. Though planarity is feasible in such compounds, the maintenance of such a conformation would not be energetically preferable. X-ray studies suggest that 1H-azepines are nonplanar in the crystalline state and also, probably, in solution, so as to be liberated from antiaromaticity.[11] Azepine and oxepin are very reactive, in agreement with their calculated resonance energies.[11] Unsubstituted thiepin and the higher members of the thiaannulenes have not been reported on.

One of the nine-membered ring systems, azonine, has a positive resonance energy, which suggests that it is probably aromatic, while oxonin has a negligible resonance energy, and therefore is probably olefinic in nature. According to the experimental studies by Anastassiou *et al.*,[12] these nine-membered heterocycles are characterized in an analogous way, as azonine is considerably more stable than oxonin.

The calculated resonance energies for some annulenones and fulvenes are given in Table 3. Cyclopropenone and tropone are predicted to be aromatic, with positive resonance energies, whereas cyclopentadienone is predicted to be antiaromatic, with a negative resonance energy. The fulvenes are all predicted to be substantially

TABLE 3. CALCULATED RESONANCE ENERGIES OF SOME ANNULENONES AND FULVENES

Species	Hückel MO π-energy (β)	Reference energy (β)	Resonance energy (β)	Resonance energy (kcal/mol)
Cyclopropenone	5.0648	4.9292	0.1356 (0.126)	4.161
Cyclopentadienone	7.3811	7.4578	−0.0767 (−0.094)	−2.355
Tropone	10.0638	9.9941	0.0696 (0.053)	2.137
Methylenecyclopropene	4.9624	4.9312	0.0312	0.956
Fulvene	7.4659	7.4560	0.0099	0.304
Heptafulvene	9.9944	9.9898	0.0045	0.139

Resonance energies given in kcal/mol were calculated with $\beta = -1.33077$ eV.[5]

nonaromatic, with slight resonance energies. As was stated by Hess *et al.*,[7] their chemistry also appears to be in good accord with these predictions.

Recently, Machiguchi *et al.*[13] reported on the aromaticity of tropothione (cycloheptatrienethione), suggesting, from the carbon-13 chemical shifts, that this compound is considerably less aromatic than tropone. As the electronegativity of sulfur is presumably close to that of carbon,[8] the Coulomb integral on the thionyl sulfur might be approximated by that on the carbon atom—that is, $h \sim 0$. Consequently, the electronic structure of tropothione is likely to resemble that of heptafulvene rather than that of tropone.

On the other hand, chemical evidence of aromatic character is much easier to find in the case of tropolone (2-hydroxytropone).[14] Interaction between the neighboring hydroxy and ketone groups due to the intramolecular hydrogen bonding has been seen as a source of difference between tropone and tropolone, since the isomers of tropolone, 3- and 4-hydroxytropones, resemble tropone in their chemical properties. One of the most prominent effects arising from the intramolecular hydrogen bonding is probably that the attached proton tends to increase the effective Coulomb integral on the carbonyl oxygen within the Hückel approximation. Chemically speaking, the hydrogen bonding may be said to stabilize the classical ionic structure of tropone.

According to this scheme, we tentatively increased the Coulomb integral on the carbonyl oxygen as an effect of hydrogen bonding; we thus found that the resonance energy of tropone is a function of the Coulomb integral on the carbonyl oxygen—it increases rapidly with an increase in the h-value for the carbonyl oxygen. For example, the resonance energy amounts to 0.2108β or 6.471 kcal/mol with this set of parameters; $h=1.00$ and $k=1.00$. Such a trend in aromaticity strongly suggests that, as has long been expected, the aromatic character of troponoid compounds is attributable to the formation of an aromatic sextet in the tropenylium structure. At present, we can not determine the amount of change in the effective Coulomb integral due to the hydrogen bonding. Nevertheless, the above idea appears to give quite a possible explanation of the enhanced aromaticity of tropolone within the HMO theory.

The resonance energies presented in Tables 2 and 3 parallel fairly well those determined by Hess *et al.*,[3-7] which are placed within parentheses in the tables. In estimating these resonance energies, they classified the π-bonds according to the number of attached hydrogens, and assigned a π-energy to every π-bond type. The reference energy of a given conjugated compound is a combination of such π-bond energy terms. Therefore, the slight differences between the resonance energies determined by Hess *et al.* and those determined by us are probably due to the fact that they applied the fixed π-bond energies of carbon-carbon bonds to the conjugated hydrocarbons and to the heterocycles as well.

If the π-bond energies are universally additive in the nonaromatic compounds, the increase in the reference energy on going from a given heteroannulene to the next member of the same series must be the same as the unit binding energy of an infinitely large annulene. Both should correspond to the sum of the π-energies of the CH=CH bond and the CH–CH bond in the classical resonance structure. However, the actual increases in the reference energies, for example, for the azaannulene series (2.4967β, 2.5520β, and 2.5496β) are somewhat different from the unit binding energy of an infinitely large annulene (2.5465β).[15] The situation is the same for the other cyclic systems considered. As was suggested before, such a discrepancy should be ascribed to the electronegativity of the heteroatom or to the polarity of the carbon-heteroatom bonds. It is, hence, noteworthy that the present approach skillfully avoids this kind of difficulty by evaluating the π-energy of a group of π-bonds.

As may be seen from the above discussion, the present approach assumes, for the sake of simplicity, the planarity of the compound, and it does not take into consideration the effects of the bond alternation and the ring strain on the π-energy of the compound. Since the geometry of the reference structure is necessarily assumed to be the same as that of the compound under consideration, the rsonance energy defined by us should be regarded as a kind of vertical resonance energy. Such assumptions are analogous to those made in calculating the delocalization energy. As far as the vertical resonance energy is concerned, the distortion energy brought about in the flattened molecule is retained in the reference structure.

When there is a bond alternation in the actual conjugated compound, the same bond alternation must be present in the reference structure for the vertical resonance energy to be evaluated. Though the introduction of bond alternation is often preferable,[16-18] it can not easily be carried out, and it might cause a considerable amount of ambiguity in the obtained resonance energy. In general, the resonance energy is a very small quantity as compared to the total π-energy of the compound. To make matters worse, when the

bond alternation is considered, some other comparable terms, such as the strain energy and the σ-compression energy, must be considered at the same time.

However, the good correlation found between the calculated resonance energies and the experimental properties for various monocyclic systems definitely shows that these resonance energies are still excellent indices, much better than the delocalization energies, in predicting the stability of the compounds in the ground state.

With this aspect of the present results in mind, the stability of the actual compounds should be understood in the following manner. If the calculated resonance energy is large enough, a large portion of it will be preserved in the actual compound. On the other hand, if the calculated resonance energy is small or negative, the bond alternation will be significant in the actual system and will lower the π-energy of the compound. Especially, when the compound is predicted to be markedly antiaromatic, the bond alternation is assuredly introduced in the system, and even the planarity of the compound might be broken so as to be relieved from antiaromaticity, as in the case of azepines. The bond alternation is thus necessary to lower the absolute value of the resonance energy as well as the π-energy of the antiaromatic system. However, the sign of the resonance energy always remains unchanged upon the introduction of bond alternation. The resonance energy obtained on the assumption of constant resonance integrals hence denotes the upper limit of the absolute value of the resonance energy.

In this connection, it must be noticed that the experimental resonance energies so far published are all related to the delocalization energies; they should rather be called the "conjugation energies" in the sense that any conjugation among the formal double bonds contributes to the increase in the delocalization energy. In general, the delocalization energy is large for the large conjugated compounds, as they contain many formal single bonds. Therefore, the experimental conjugation energies should not be correlated with the present results.

In a previous paper,[15] we examined the aromaticity of some monocyclic systems, such as annulenes and radialenes, for which analytical solutions of the HMO secular equations are available. The present approach is an extension of the same procedure to less symmetric systems. In general, the unit binding energy of a monocyclic conjugated system with an infinite number of unit structures can be employed as the reference energy in evaluating the resonance energy of a monocyclic conjugated system with a single-unit structure. It should be emphasized that this approach is applicable to almost all kinds of monocyclic conjugated systems, even to those totally asymmetric in geometry. As for heteroannulenes and annulenones, the present approach gives proper values for the resonance energies which are consistent with their chemical properties. It goes without saying that the estimation of these resonance energies was made possible by the accurate heteroatom parameters determined by Hess *et al.* All the simplicity and elegance of the HMO theory remain in the present approach.

We are grateful to the Hokkaido University Computing Center for the use of their FACOM 230-60, on which all the calculations were performed.

The Reduction of Enamines with Carbonylhydridoferrates

Take-aki MITSUDO, Yoshihisa WATANABE, Masato TANAKA, Shoji ATSUTA, Kazuo YAMAMOTO, and Yoshinobu TAKEGAMI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

(Received December 11, 1974)

Enamines react with an alcoholic solution of $[FeH(CO)_4]^-$ (**1**), $[Fe_2H(CO)_8]^-$ (**2**), and $[Fe_3H(CO)_{11}]^-$ (**3**), with the absorption of carbon monoxide at room temperature, to give the corresponding saturated tertiary amines. The reduction of the pyrrolidine enamine of 2-methylcyclohexanone with **1**, **2**, and **3** gave *cis* and *trans* *N*-(2-methyl-1-cyclohexyl)pyrrolidine. The *cis*/*trans* ratio of the products were characteristic of **1**, **2**, and **3**; the values, 0.67, 1.2, and 2.1 respectively, represent the bulkiness of the hydrides. The mechanism of the reduction was discussed.

Enamines are known to be very useful starting materials for various organic syntheses, particularly for the formation of α-substituted carbonyl compounds and cyclic ones.[1] This reactivity of enamine is mainly due to the polarized carbon-carbon double bond.

On the other hand, only a few reactions of enamines with transition-metal complexes have been reported.[2] Moreover, little attention has been paid to the reaction of enamines with hydridotransition metal complexes. Previously, we briefly mentioned the reduction of enamines with $[FeH(CO)_4]^-$ (**1**).[3] This paper will deal in detail with the reduction of enamines with **1**, $[Fe_2H(CO)_8]^-$ (**2**), and $[Fe_3H(CO)_{11}]^-$ (**3**).

Experimental

The PMR spectra were obtained on a JOEL Model 3H60 NMR spectrometer. The infrared spectra were measured on a Hitachi Model 215 grating infrared spectrometer. The mass spectra were obtained with a JMS-OISG mass spectrometer.

Materials. The *N*-(1-cyclohexenyl)morpholine (**4**),[4] *N*-(2-methyl-1-propenyl) piperidine (**6**),[5] *N*-(1-phenyl-1-vinyl)-morpholine (**5**),[6] and the pyrrolidine enamine of 2-methylcyclohexanone (**7**)[7] were prepared according to the methods described in the literature and were stored in ampoules under an argon atmosphere in a refrigerator. The pentacarbonyliron, morpholine, cyclohexanone, ethyl alcohol, and other compounds employed in this study were all commercial products; their purity were checked and found to be satisfactory for the reaction. The tetrahydrofuran was dried over lithium aluminum hydride.

Preparation of Carbonylferrates. All the reactions were carried out in a 300 ml, three-necked flask equipped with a gas buret and a magnetic stirrer under an carbon monoxide or nitrogen atmosphere. $K[FeH(CO)_4]$ (**1**) and $K_2[Fe(CO)_4]$ (**1'**) were prepared according to the methods described in a previous paper.[8] Eleven mmol of each complex in 50 ml of a solvent was used in each run. The preparation of $K[FeH(CO)_4]$ is accompanied by the formation of an equivalent mole of water:[9]

$$Fe(CO)_5 + 3KOH \longrightarrow K[FeH(CO)_4] + K_2CO_3 + H_2O \quad (a)$$
(**1**)

Therefore, when a dry solution of **1** was required, the solvent of the **1** was once distilled off under a vacuum, and then 50 ml of a new dry solvent was added.

$K_2[Fe_2(CO)_8]$ (**2'**) was prepared by the method described in the literature.[10] $Fe_2(CO)_9$ (2.0 g, 5.5 mmol=11 mg-atom-Fe) was treated with 22 mmol of KOH in 50 ml of ethanol at 30 °C for 2 hr.

$[Et_3NH][Fe_3H(CO)_{11}]$ (**3**) was prepared according to the published method.[11] In each run, a 2.1 g portion of **3** (3.7 mmol=11 mg-atom-Fe) in 50 ml of ethanol was used.

General Reaction Procedures and Analysis. To the solution of the carbonylferrates described above, 33 mmol of the enamine or an equimolar mixture of a ketone and a secondary amine and an internal standard for gc analysis were added, and the mixture was agitated. After a certain reaction time, a 0.2 ml sample of the solution was taken out, oxidized with air or with an equivalent mole of iodine in ethanol for 20 s to terminate the reaction, and then submitted to gc analysis; column: SE-30 on chromosorb(I), 3 mmφ×1.5 m; Diethylene Glycol Adipate Polyester on chromosorb(II), 3 mmφ×3 m. *N*-Isobutylpiperidine(**10**), tri(*n*-butyl) amine(**13**), and *N*-propylmorpholine(**14**) were identified by gc analysis by the use of the authentic samples. The amount of $Fe(CO)_5$ was analyzed by TCD-type gas chromatography, using the latter column(II) and with benzene as the internal standard.

The amount of CO_3^{2-} was analyzed as follows. The gas evolved by the acidification of the reaction solution was collected in a gas buret; after standing for 1 hr, the gas was bubbled in aqueous KOH. The volume of the absorbed gas was regarded as the amount of CO_2. This method was verified by gc analysis; column: active carbon(III), 3 mmφ×3 m.

Reaction of Enamine (4) with 1. Enamine (**4**) (5.5 g, 33 mmol) was added to an ethanolic solution of (**1**) (11 mmol) under a carbon monoxide atmosphere, and the mixture was agitated for 4 hr at 30 °C, during which time 1.6-mol portion of carbon monoxide was absorbed. The reaction mixture was filtered in a hood and 2.6 g of *N*-cyclohexylmorpholine (**8**) was obtained by distillation (bp 100 °C/6 mmHg; Yield, 1.4 mol/g-atom-Fe). Found: C, 70.99; H, 11.21%; mol wt (Mass) 169. Calcd for $C_{10}H_{17}NO$: C, 70.96; H, 11.32% mol wt 169.26. PMR(acetone-d_6): δ 3.3(m, 4H), 2.3(m, 4H), 1.6(m, 6H), 1.1(m, 5H) ppm.

Reaction of Enamine (5) with 1. Enamine (**5**) (6.2 g, 33 mmol) was treated with an ethanolic solution of **1** (11 mmol) at 30 °C for 24 hr, during which time a 1.6 mol portion of carbon monoxide was absorbed and 3.1 g of *N*-(1-phenylethyl)-morpholine (**9**) was obtained by distillation (bp 80 °C/0.3 mmHg; Yield, 1.6 mol/g-atom-Fe). Found: C, 75.28; H, 8.89%; mol wt (Mass) 191. Calcd for $C_{12}H_{17}NO$: C, 75.35; H, 8.96%; mol wt 191.27. PMR($CDCl_3$): δ 7.0(m, 5H), 3.5 (m, 4H), 3.2(q, 1H, J=6Hz), 2.4(m, 4H), 1.3(d, 3H, J=6Hz) ppm.

Reaction of Enamine (7) with 1. This reaction was carried out in a manner similar to that described above. Gc analysis showed that two products, (A) and (B), were formed at the retention time of 8.3 and 9.9 min, respectively (Column temperature, 120 °C; carrier gas: N_2, 40 ml/min). The products, (A) and (B), were identified as *N*-(*trans*-2-methyl-1-cyclohexyl)pyrrolidine (**12**) and *N*-(*cis*-2-methyl-1-cyclohexyl)-

pyrrolidine (**11**) respectively by the use of authentic samples prepared by the reduction of enamine (**7**) with atmospheric hydrogen.[12]

Reduction of Enamine (7) with Raney Nickel.[12] Enamine (**7**) (7.6 ml) was reduced catalytically with Raney nickel (1.0 g) in dry ethyl alcohol at 30 °C under 1 atm. of hydrogen. After 2 hr, the reaction mixture was analyzes by gas chromatography. Two peaks, (A′) and (B′), were found at the same retention time of (A) and (B). The ratio of (A′) to (B′) was 27:73, the same ratio as Mitsui has reported. Five grams of the mixture of (A′) and (B′) was separated from the reaction mixture by distillation (bp 82—85 °C/9 mmHg; Yield, 63%; Found: C, 79.00; H, 12.65; N, 8.37%; mol wt (Mass) 167). The separation of (A′) and (B′) by column chromatography (Silica gel) was attempted. Pure (A′) or (B′) could not be obtained, but two mixtures, 1) (A′)/(B′)=90/10 and 2) (A′)/(B′)=14/86, were obtained. The PMR spectra of these mixtures showed that (A′) and (B′) are *trans* and *cis* *N*-(2-methyl-1-cyclohexyl)pyrrolidine, respectively.[13] PMR (CCl_4): (A′) δ 0.94(d, J=6.0 Hz, 3H), 1.4—1.1(m, 5H), 1.9—1.5(m, 8H), 2.0—2.4(m,1H), 2.8—2.4(m, 4H) ppm, (B′) 0.89(d, J=6.8 Hz, 3H), 1.4—1.2(m, 1H), 2.6—2.3(m, 4H) ppm.

Results and Discussion

Reaction of Enamines with 1. Enamines such as *N*-(1-cyclohexenyl)morpholine (**4**), *N*-(1-phenyl-1-vinyl)morpholine (**5**), and *N*-(2-methyl-1-propenyl)-piperidine (**6**) reacted with an alcoholic solution of $[FeH(CO)_4]^-$ (**1**) at 30 °C, with a rapid absorption of carbon monoxide after a certain induction period. However, no carbonylated products were detected; rather the corresponding saturated tertiary amines, *N*-cyclohexylmorpholine (**8**), *N*-(1-phenylethyl)-

morpholine (**9**), and *N*-isobutylpiperidine (**10**), were produced in high yields.

The pyrrolidine enamine of 2-methylcyclohexanone (**7**) was also reduced to *cis* (**11**) and *trans* (**12**) *N*-(2-methyl-1-cyclohexyl)pyrrolidine. The results are summarized in Table 1. The periodical change in the yields of the saturated tertiary amines and the absorption of carbon monixide in a typical reaction of **4** and **7** are shown in Figs. 1 and 2. Time plots of the *cis/trans* ratio of the isomers of the products are also shown in Fig. 2. In both cases, the plots of the yields of the products *vs.* the reaction time are very characteristic. They clearly have two steps. At first, the yield of the product increases rapidly, with a very slow absorption of carbon monoxide, and the yield amounts to 0.4—0.9 mol* in 30 min. Then the rate of the formation of the product becomes very slow for about 0.5—2 hr, after which it becomes very fast again, with a rapid absorption of carbon monoxide, and the yield of the product amounts to about 2 mol.

As the reaction proceeded, the color of the reaction solution changed from pale brown to dark red, and $[Fe_3H(CO)_{11}]^-$** and CO_3^{2-}, as well as $Fe(CO)_5$, were detected in the reaction mixture. The amount of $Fe(CO)_5$ formed is also shown in Fig. 1.

The reaction also proceeded under a nitrogen atmosphere, but the yield did not exceed 1.0 mol (Exps. 2, 3).

In the reduction of enamine (**7**), the *cis/trans* ratio of the products was 0.67 at the beginning, and it stayed constant for about 1.5 hr. Then it became large with the progress of the reduction, with a rapid absorption of carbon monoxide, reaching 0.88 at the end of the reaction. The *cis/trans* ratio of the products newly formed with the absorption of cabon monoxide was 1.1, which was easily calculated from the data at 60 min and at 190 min. These results apparently show that there are at least two different ways for the reduction of enamines; the first may be the reduction with **1** itself, while the second is that with the newly produced active species, with an absorption of carbon monoxide.

The Reaction of $K_2[Fe(CO)_4]$ with Enamine (4). When $K_2[Fe(CO)_4]$ is used instead of **1**, the rate of the reduction is slower than that in the reaction of **1**. However, the total amount of gas absorbed and the yield of the product were larger than those in the reaction of **1** (Exp. 9). In this system, $K_2[Fe(CO)_4]$ may be hydrolyzed[14] to **1**, which is active in the reduction of enamine, and a 1 mol excess of potassium hydroxide is considered to be effective for the reformation of the new hydride species.

$$K_2Fe(CO)_4 + H_2O \rightleftarrows K[FeH(CO)_4] + KOH \quad (b)$$
(1)

However, a large exess of potassium hydroxide disturbed the reduction (Exp. 10). In this case, the concentration of the active hydride (**1**) is low, and the reaction may be highly inhibited.

The Reaction of $K_2[Fe_2(CO)_8]$ with Enamines. The enamines **4** and **7** also reacted with an alcoholic solution

21	**7**+H_2O (11 mmol)	30	5	0.6	(**11**) + (**12**)	0.08	1.9
22	**7**+H_2O (11 mmol)	−60	0.25	0	(**11**) + (**12**)	0.05	1.8

a) 3.7 mmol of $[Fe_3H(CO)_{11}]^-$ was used. b) mol/g-atom-Fe. c) 11 mmol of $[Fe_3H(CO)_{11}]^-$ was used.

of dinuclear carbonylferrate, $K_2[Fe_2(CO)_8]$, with an absorption of carbon monoxide, to give saturated amines. The results are shown in Table 2 and Figs. 3 and 4. The mode of the reaction of $K_2[Fe_2(CO)_8]$ was, however, different from that of **1**. The yield of the product increased smoothly without the step which was observed in the reaction of **1**, and it amounted to 1.9—2.2 mol, *i.e.*, 3.8—4.4 mol/mol-$[Fe_2(CO)_8]^{2-}$. The induction period of the carbon-monoxide absorption was not observed; the rate of the absorption was very rapid in spite of the half concentration of the carbonylferrate complex as compared with the case of **1**, and a large amount of $Fe(CO)_5$ was formed.

The *cis/trans* ratio of the product in the reaction of enamine **7** was 1.2 at the beginning of the reaction, and it stayed constant for 1 hr, during which period 2 mol/mol-$[Fe_2(CO)_8]^{2-}$ of the product was formed; thereafter it became smaller, reaching 0.94 in 5 hr. Apparently, an active species is also reproduced during the reaction. The active species formed during the first 1 hr gave the ratio of ~1.2, which is almost the same as that observed in the reduction with the newly formed active species in the reaction of **1**.

Considering the results of the reaction of $K[FeH(CO)_4]$ and $K_2[Fe(CO)_4]$, the dinuclear hydride species, $K[Fe_2H(CO)_8]$ (**2**), which exists in the reaction system in the equilibrium:

$$K_2[Fe_2(CO)_8] + H_2O \rightleftharpoons K[Fe_2H(CO)_8] + KOH \quad (c)$$
(**2**)

may be the active species at the beginning of the reaction.

Reaction of $[Fe_3H(CO)_{11}]^-$ (3) with Enamines. An alcoholic solution of $[Fe_3H(CO)_{11}]^-$ (**3**) also reduce enamines. The results are summarized in Table 3. The mode of the reduction of the enamine (**7**) is shown in Fig. 5. The reduction of the enamine proceeded rapidly and ceased in ten min. The yield of the product was small (0.11 mol, *i. e.*, 0.33 mol/mol.$[Fe_3H(CO)_{11}]^-$), and the *cis/trans* ratio of the isomers was 2.1. The ratio stayed constant for more than 4 hr. The addition of 11 mmol of a 1M-ethanolic potassium hydroxide solution to this reaction mixture caused a dramatic change of the mode of the reaction. The yield of the product increased rapidly, with an absorption of carbon monoxide. The *cis/trans* ratio of the isomers decreased rapidly to the value of 1.0, and then it reached 0.9 by the end of the reaction. It is calculated that the *cis/trans* ratio of the isomers of the newly formed

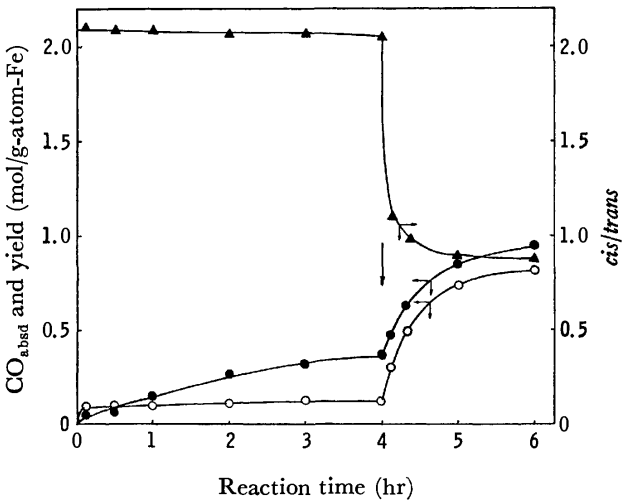

Fig. 5. Reaction of enamine (**7**) with $[Et_3NH][Fe_3H(CO)_{11}]$ in ethanol at 30 °C. ○: Total yield of *cis* and *trans* *N*-(2-methylcyclohexyl)pyrrolidine, ●: CO absorbed, ▲: *cis/trans*, ↓: 11 ml of 1 M-KOH–EtOH was added.

product is about 0.88. The effect of the mole ratio of **3** to the enamine on the *cis/trans* ratio of the products which were observed in the reduction with $LiAlH_4$[15] was small (Exp. 20). The effects of the addition of water or of the reaction temperature on the *cis/trans* ratio were also small.

Reaction of Enamine (4) with 1 in Dry THF and the Effect of the Addition of Water. In order to investigate the source of the hydrogen, the enamine (**4**) was treated with **1** in dry THF. As is shown in Fig. 6, no carbon monoxide absorption occurred, and even after a prolonged reaction time only a small amount of the product was formed. The addition of water to this reaction solution caused a rapid carbon monoxide uptake and an increase in the quantity of the product, the yield of which amounted to more than 2 mol. This result shows that the hydrogen source in the reduction of enamines is water and that carbon monoxide and water are indispensable for the reproduction of the active species of the reduction. However, a large excess of water disturbed the reduction (Exp. 11).

The Fate of the Carbon Monoxide Absorbed. The fate of the carbon monoxide absorbed was investigated. The amounts of $Fe(CO)_5$ and carbonate formed in the

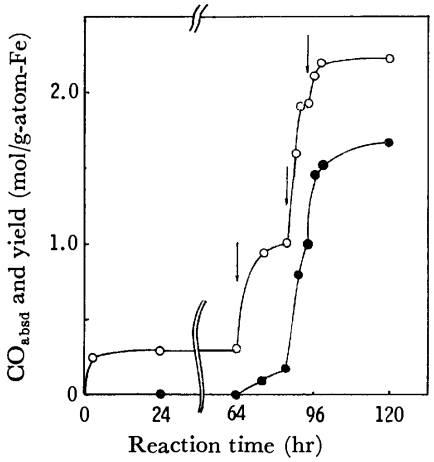

Fig. 6. Reaction of enamine (**4**) with $K[FeH(CO)_4]$ in dry THF and the effect of the addition of water. ○: *N*-Cyclohexylmorpholine, ●: CO absorbed, ↓: 1.0 mol of water was added.

Table 4. Material balance of carbon monoxide absorbed

Exp. No.	Carbonylferrate	CO_{absd}	$Fe(CO)_5$ (mol/g-atom-Fe)	CO_3^{2-}
1	$KFeH(CO)_4$	1.6	0.32	1.30
13	$K_2Fe_2(CO)_8$	2.1	0.70	1.42
17	$[Fe_3H(CO)_{11}]^-$	1.3	1.05	0.11
18	$[Fe_3H(CO)_{11}]^-$+KOH	1.7	0.41	1.31

reaction solution are summarized in Table 4. These results show that the carbon monoxide absorbed ultimately goes into $Fe(CO)_5$ and carbonate:

$$[\text{CO absorbed}] = [Fe(CO)_5] + [CO_3^{3-}] \quad \text{(d)}$$

Mechanism of the Reduction of Enamines. The mechanism of the reduction of enamines with formic acid[16] and sodium borohydride,[17] and that of the hydrolysis of enamines,[18] have been studied. The first step of both the reaction is shown to be the rapid protonation of the β-carbon atom of enamines to form the iminium salts:

$$\text{>N-CH=CHR} + H^+ \longrightarrow \text{>}\overset{+}{\text{N}}\text{=CH-CH}_2\text{R} \quad \text{(e)}$$

In our reaction, carried out in moist ethanol, it is reasonable to consider that the first step of the reduction is also the formation of iminium salt. In fact, enamine could not be detected in the reaction solution, even 10 min after the beginning of the reaction by means of gas chromatography, but iminium salt was detected by means of the IR spectra. On the other hand, enamine was detected in the reaction solution when the reduction was carried out in a dry solvent.

The fact that the iminium salt, *N*-cyclohexylidenemorpholinium perchlorate (**15**), reacts with **1**, with absorption of carbon monoxide, to give *N*-cyclohexylmorpholine (**8**) (Table 1. Exp. 12) shows that the second step is surely the nucleophilic attack of carbonylhydridoferrates on the iminium cation and the abstraction of a hydride ion from the complex.

$$\text{>}\overset{+}{\text{N}}\text{=CHCH}_2\text{R} + [HFe_m(CO)_n]^- \longrightarrow \text{>N-CH}_2\text{CH}_2\text{R} + Fe_m(CO)_n \quad \text{(f)}$$

In the reduction of iminium salts with $LiAlH_4$,[19] $NaBH_4$,[17] and formic acid,[1,16] a similar abstraction of a hydride ion has been observed.

Reproduction of Active Species. Alcoholic solutions of **1** and **2** have been known to reduce isoprene[20] and the Shiff base[21] to the corresponding monoolefins and saturated amines respectively, with absorption of carbon monoxide. The yields of the products often exceeded 1.0 mol, and the reproduction of the active species was observed. However, little has been studied on the mechanism of the reformation of the active species. The infrared spectra of the reaction solution showed too complicated absorption to resolve at 2100—1750 cm^{-1}.

In the reduction of enamines with **1** and **2**, the active species is also reproduced, with an absorption of cabon monoxide. The reduction of the enamine (**7**) with **1**, **2**, and **3** gives us some information on the reproduction of the active species. The results show that **1**, **2**, and **3** have their own ability in the reduction of enamine and have characteristic values of the *cis/trans* ratio of the products, 0.67, 1.2, and 2.1, respectively. The fact that the *cis/trans* ratios of the products stay constant for more than 1 hr in each reaction system shows that the isomerization between these isomers is negligible.

In the reduction with **1**, the *cis/trans* ratio of the newly formed product, with a rapid absorption of carbon monoxide, was 1.1, this value shows that the active species mainly reproduced is not **1**, but another active species. Considering the results of the reduction with **2**, we may suppose that the newly formed active species in the reaction of **1** is **2**. Once **2** is formed it may reduce the iminium salt catalytically, with a rapid absorption of carbon monoxide in the presence of the hydroxide ion, which is necessary for the formation of hydride species by the base reaction.[10] In this process, the formation of the carbonate may also occur. The catalytic cycle may be terminated by a lack of hydroxide ion and the formation of some such stable iron carbonyl complexes as $Fe(CO)_5$, which can not reduce the iminium salt by itself. However, to elucidate the mechanism of these reactions further studies will be required.

The Factors Which Determine the cis/trans *Ratio in the Reduction of the Enamine (7).* Considering the mechanism of the reduction of enamines with carbonylhydridoferrates discussed above the factors which determine the *cis/trans* ratio in the reduction of the

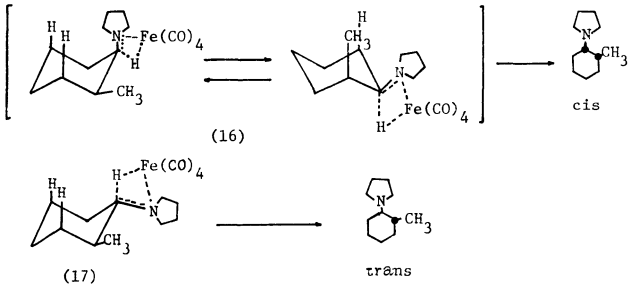
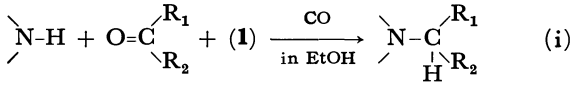
a) Solvent: EtOH: $[FeH(CO)_4]^-$: 11 mmol. b) mol/mol-$[FeH(CO)_4]^-$

enamine (**7**) are 1) the direction of the attack of the hydride complexes on the iminium salt (**16**); the axial and equatorial attack of the hydrides may give *trans* and *cis* isomers respectively, and 2) the stability of the reaction intermediates (Scheme 1). The ratios of 1.2 and 2.1 for **2** and **3** may be reasonably explained by the direction of the attack of the hydrides. The axial attack of the bulky polynuclear hydrides may be retarded by the axial hydrogens at the 3 and 5 positions, and an equatorial attack may precede. However, to explain the ratio 0.65 for **1**, another factor must be considered. It may be the stability of the intermediates. One of the possible models is a four-centered model, **16** or **17**. As **17**, in which all the axial positions are occupied by hydrogen atom, is considered to be more stable than **16**, the *cis*/*trans* ratio may become less than 1.0.

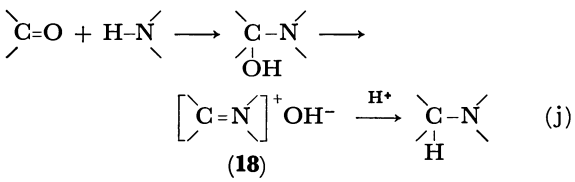


The Reductive Alkylation of sec*-Amines with* **1**. In the course of this investigation, it was found that an equimolar mixture of a secondary amine and ketone or aldehyde reacts with an alcoholic solution of **1** at room temperature, with an absorption of carbon monoxide, to give the corresponding tertiary amine:



(i)

The results are summarized in Table 5. Morpholine and cyclohexanone gave 1.4 mol of *N*-cyclohexylmorpholine, with an absorption of 1.7 mol of carbon monoxide. Acetophenone and pyrrolidine gave *N*-(1-phenylethyl)pyrrolidine. This reaction should be compared with the Leuckart-Wallach reaction.[22] The mechanism of the Leuckart-Wallach reaction of a ketone and a secondary amine has been considered to be as follows.[1] In the first step, the ketone and the secondary amine form a 1:1 adduct and then an iminium salt (**18**) is formed, which abstracts a hydride ion from formic acid or its derivatives:



(j)

In our reaction, neither ketone nor secondary amine reacts separately with **1**, and the boundary of the reaction is almost the same as that of the Leuckart-Wallach reaction. These facts strongly suggest that, in our reductive alkylation, the iminium salt (**18**) formed by the (j) equation abstracts a hydride ion from **1**; they support the mechanism of the reduction of enamines with **1** presented above.

The reductive alkylation using **1** is characterized by a low reaction temperature and the successful mono-[21] and dimethylation[23] of anilines. A full report on these reactions will be published soon.

Synthesis of Arylethylenesulfonamides and Intramolecular Rearrangement of *N*-(Arylethylenesulfonyl)thioureas

Kiyoshi HASEGAWA, Syuzi HIROOKA and Tadashi SASAKI*

Department of Industrial Chemistry, Faculty of Engineering, Toyama University, Takaoka-shi, Toyama 933

** Institute of Applied Organic Chemistry, Faculty of Engineering, Nagoya University, Furo-cho, Chigusa-ku, Nagoya 464*

(Received December 13, 1974)

The reactions of *p*- and *p'*- substituted *N*-(2,2-diarylethylenesulfonyl)- (**8**), *N*-[2-phenyl-2-(α-naphthyl)ethylenesulfonyl]- (**9**), and *N*-(*p*-nitrostyrene-1-sulfonyl)-*N'*-alkylthioureas (**12**) with bases afforded new intramolecularly rearranged *N*-alkyl-*S*-(2,2-diarylvinyl)- (**13**), *N*-alkyl-*S*-[2-phenyl-2-(α-naphthyl)vinyl]- (**14**), and *N*-alkyl-*S*-(*p*-nitrostyryl)isothioureas (**15**), respectively. *p*- and *p'*-Substituted 2,2-diarylethylene-*N*-methylsulfonamides (**6**) were treated with carbon disulfide and alkyl halides in the presence of a base to give alkyl 2,2-diarylvinyl trithiocarbonates (**17**). The order of reactivity of the sulfonylthioureas and -amides indicates that the rearrangement is retarded by electron-releasing *p*-substituents on benzene rings (Cl>H>CH_3>OCH_3).

Waldan and Pütter reported that *N*-arylnitrostyrenesulfonamide undergoes intramolecular rearrangement on C-1 to afford a sulfur free compound, stilbene derivatives.[1] The reaction requires the presence of an electron-withdrawing nitro group in the *ortho* or *para* position. In continuation of our studies on α,β-unsaturated sulfonamides,[2a-d] we have recently proposed[3] a five-membered Sn mechanism for the formation of trithiocarbonates ($(C_6H_5)_2C{=}CHSC(=S)SR$ (**17**) from 2,2-diphenylethylenesulfonamide (**5a**) ($R^1{=}R^2{=}H$) in the presence of carbon disulfide, and concluded that this rearrangement on C-1 is characteristic of **5a**, in which C-2 has two phenyl groups. However, the effect of *p*- and *p'*-substituents on the formation of **17** was not investigated. We have now studied the base treatment of thioureas **8**, **9** and **12** which were prepared as model compounds to confirm the proposed mechanism. This paper describes the mechanism for a Smiles-type reaction of the thioureas and for the formation of **17** from **6**, carbon disulfide and alkyl halides, and also describes the effect of *p*-substituents on the yield of the rearranged products.

Results and Discussion

Syntheses of α,β-Unsaturated Sulfonamides and Thioureas. The convenient sulfochlorination method of styrene[4] gave generally low yields (<10%) when applied to *p*- and *p'*-substituted 1,1-diarylethylenes (**1**). Scheme 1 shows the synthetic pathways of sulfonamides and thioureas. Compound **1** and dioxane–sulfur trioxide gave 2,2-diarylethylenesulfonates (**3**) (Table 1), which were converted into 2,2-diarylethylenesulfonyl chlorides (**4**) (Table 2). Sulfonamides **5** and **6** were pre-

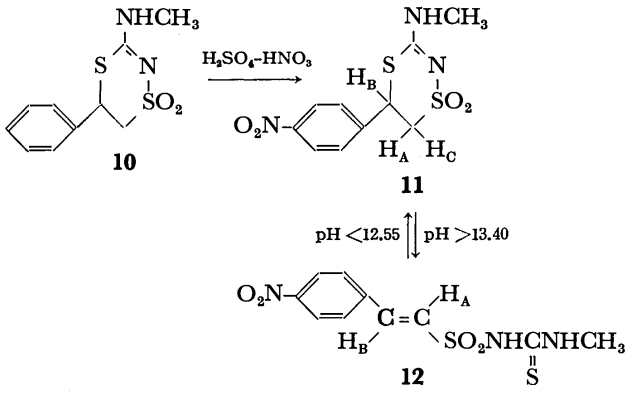
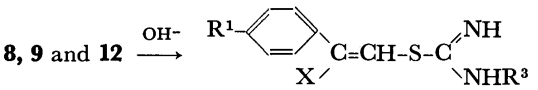
a) X=*p*-$R^2C_6H_4$. b) 80 °C, 2 hr in DMF. c) 80 °C, 15 hr in DMF. d) Purified by chromatography on silicagel using $CHCl_3$ as the eluent.

pared from them with aqueous ammonia or methylamine (Table 3). A 2-α-naphthyl derivative (**7**) was obtained by a procedure similar to that described by Culbortson and Dietz.[4] A mixture of **5**, potassium carbonate and isothiocyanates in acetone was refluxed to yield thioureas **8**. Similar treatment of **7** afforded **9** (Table 4). As a nitrated derivative, **12**, could not be formed from *p*-nitrostyrenesulfonamide and methyl isothiocyanate, it was prepared by nitration of 3-methylamino-5-phenyl-1,1-dioxo-5,6-dihydro-1,4,2-dithiazine[2a] (**10**) followed by hydrolytic cleavage of the ring C-S bond. Thiourea **12** was recyclized under weakly alkaline conditions and also by heating at 145 °C. The structures of **8**, **9**, **11** and **12** were determined on the basis of analytical and spectral data. The NMR spectrum of **11** shows that **11** consists of about a 3:2 mixture of 3-methylamino and 3-methylimino tautomers in DMSO-d_6.

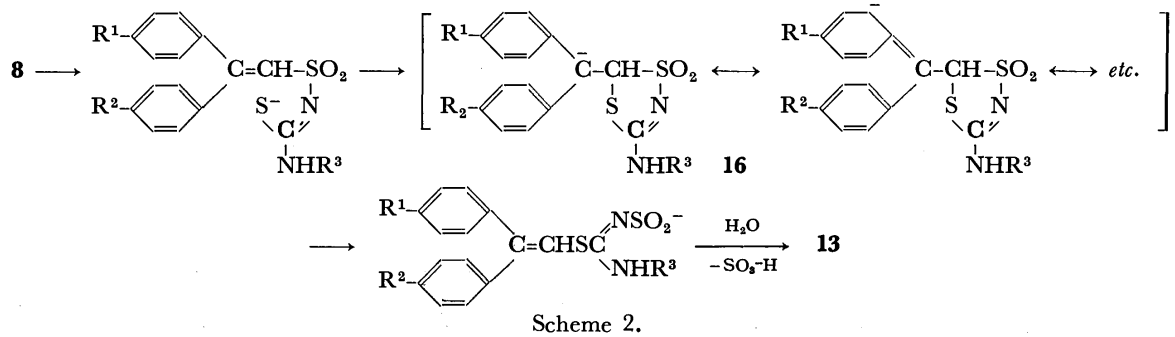


A New Intramolecular Rearrangement of Thioureas to Isothioureas. Thioureas **8** and **9** were treated with ten molar equivalents of aqueous 5 M NaOH in DMF for 2 hr at 80 °C (Method A) or for 15 hr at 80 °C (Method B) to afford rearranged isothioureas **13** and **14** respectively (Table 5).



13, X=*p*-$R^2C_6H_4$ **15**, X=H
14, X=α-naphthyl

The rearrangement was carried out with variations of the *p*- and *p'*-substituents from electron-withdrawing to -releasing groups. All of the isothioureas were resistant to hydrolytic decomposition in aqueous 10 M NaOH even for 15 hr at 80 °C. The structures of **13** and **14** were determined on the basis of analytical and spectral data. The IR spectra of **13** and **14** displayed no SO_2 bands. The formation of isothioureas has a tendency to be favored by polar solvents. For example, **13a** was obtained by Method A (2 hr, 80 °C) in the following yields: ethanol 86%, DMSO 85%, no solvent 72%, DMF 70%, diglyme 31% and dioxane 26%. More concentrated aqueous NaOH than 2 M was necessary to effect rearrangement. The yield increased with concentration of base and with aqueous 10 M NaOH **13a** was obtained in 92% yield even at room temperature after 3 days. The results of Method A shown in Table 5 indicate that the rate of rearrangement is



Scheme 2.

Table 6. 2,2-Diarylvinyl trithiocarbonates[a)]

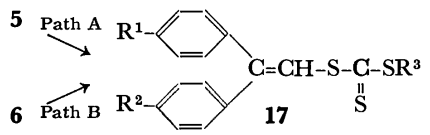
17j	OCH_3	OCH_3	CH_3	27	5	oil	59.66	5.01	26.50	59.76	4.86	26.62

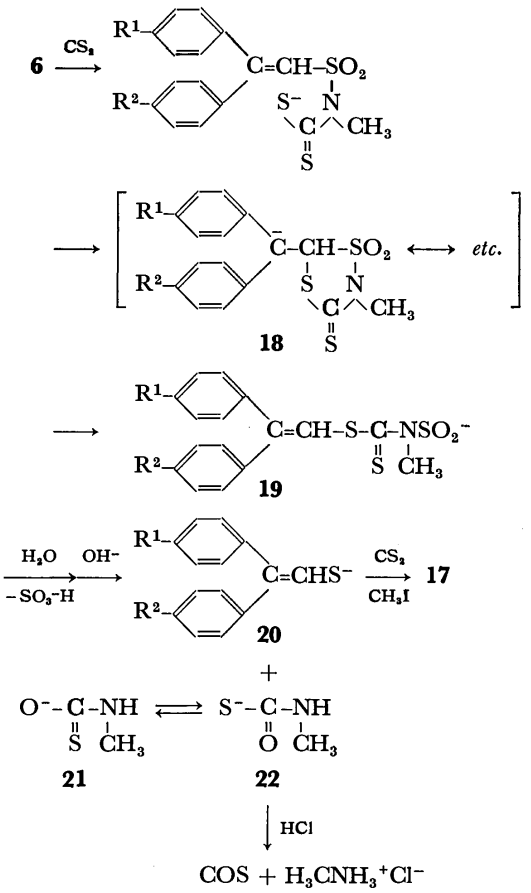
a) Purified by chromatography on silica gel using benzene–n-hexane (**17a—e** 1: 1, **17f—h** 1: 5, and **17i—j** 1: 1 v/v) as the eluent.

increased by electron-withdrawing p,p'-substituents (Cl $>$H$>$$CH_3$$>$$OCH_3$). The probable interpretation may involve the formation of a five-membered cyclic intermediate such as **16** and subsequent removal of sulfite moiety (Scheme 2). An electron-withdrawing chlorine substituent may enhance the stabilization of **16** and electron-releasing methyl and methoxy substituents would have opposite effects. In this connection, **12**, a p-nitrated derivative of N-(2-phenylethene-1-sulfonyl)-N'-methylthiourea[2a)] underwent a rearrangement in aqueous 5 M NaOH under even more moderate conditions (60 °C, 10 min) than those used with **8** to afford N-methyl-S-(p-nitrostyryl)isothiourea (**15**) in 79% yield.

Reaction of Sulfonamides with Carbon Disulfide. In the same way as reported in the formation of trithiocarbonate **17** from **5a**[3)] methylsulfonamides **6** also gave **17** from two molar equivalents of carbon disulfide and alkyl halides in the presence of base (Table 6). The



yield from **5** (Path A) or **6** (Path B) was increased by electron-withdrawing p,p'-substituents (Cl$>$H$>$$CH_3$$>$$OCH_3$). The order is in accord with that obtained in the rearrangement of thioureas. The structures of **17a—d** were characterized by comparison of their IR spectra and melting points with those of authentic samples[3)] and **17e—j** by their analytical and spectral data. The proposed mechanism for the formation of **17** from **6** is shown in Scheme 3. The mechanism is similar to that[3)] described in the formation of **17** from **5a** except that base-catalyzed hydrolysis of dithiocarbamate (**19**) is followed by degradation to diphenylvinylthiol (**20**) and N-methylthiocarbamate (**21**). Acid-catalyzed decomposition[6)] of **21** or **22** gave carbonyl sulfide and methylammonium chloride. In addition to the resonance stabilization of **18** by two phenyl groups, the stabilization of **18** by the electron-withdrawing groups, R^1 and R^2, would provide an important driving force for the thiolate anion to attack on C-1. It is a novel case[7)]



Scheme 3.

that the rearrangement could occur under moderate conditions even when R^1 and R^2 are electron-releasing groups.

Experimental

All melting points were determined on a Yanagimoto micro-melting point measuring apparatus, MP-S2, and are uncorrected. The IR spectra were recorded on a JASCO IRA-1 spectrometer. The NMR spectra were determined with a JEOL JNM-MH-100 spectrometer, using tetramethylsilane as the internal standard, and the mass spectra were recorded at

75 eV on a JEOL-O1SG-2 spectrometer. Column chromatography was performed with Wakogel C-200.

Reagents. *p*-Substituted diphenylethylenes were prepared by dehydration of the corresponding carbinols obtained from *p*-substituted acetophenone or α-acetonaphtone and phenylmagnesium bromide: 1-*p*-Chlorophenyl-1-phenylethylene, bp 136—140 °C/3 mmHg (lit,[8] 134—136 °C/1.5 mmHg); 1-*p*-tolyl-1-phenylethylene, bp 126—129 °C/3 mmHg (lit,[9] 278—294 °C); 1-*p*-anisyl-1-phenylethylene, bp 140—150 °C/2 mmHg, mp 74—75 °C (lit,[10] bp 155—170 °C/2 mmHg, mp 75 °C); 1-phenyl-1-(α-naphthyl)ethylene, mp 58—59 °C (lit,[9] 60 °C). *p,p'*-Disubstituted diphenylethylenes were prepared by dehydration of the corresponding carbinols obtained from *p*-substituted phenylmagnesium bromide (2 mol) and ethyl acetate (1 mol): 1,1-Diphenylethylene, bp 127—132 °C/10 mmHg (lit,[11] 113 °C/2 mmHg); 1,1-bis(*p*-chlorophenyl)ethylene, bp 150—158 °C/3 mmHg, mp 84—85 °C (lit,[12] mp 84—85 °C); 1,1-bis(*p*-tolyl)ethylene, bp 132—136 °C/4 mmHg, mp 61—62 °C (lit,[10] mp 62.5—63.0 °C), 1,1-bis(*p*-anisyl)ethylene, mp 141—143 °C (lit,[10] 144—145 °C).

*Sodium 2,2-Diphenylethylenesulfonate (**3a**).* Diphenylethylene was sulfonated with dioxane–sulfur trioxide by a procedure similar to that used for the sulfonation of styrene.[4] The resulting brown solution was neutralized with aqueous NaOH to give **3a**. Recrystallization from water gave monohydrate of **3a** as colorless thin plates. IR (KBr): 3050 (=CH), 1600 (C=C), and 1200 (SO_2) cm^{-1}. NMR (DMSO-d_6) δ: 6.84 (s, 1, CH), 7.33 (s, 10, $2C_6H_5$).

*2,2-Diphenylethylenesulfonyl Chloride (**4a**).* Dry **4a** (28.20 g, 0.100 mol) was treated with PCl_5 (24.99 g, 0.120 mol) similar to the procedure of chlorination of sodium 2-phenylethylene-1-sulfonate[13] to give a yellow brown oil. Recrystallization from $CHCl_3$–petroleum ether gave 19.70 g (71%) of **4a**. IR (KBr): 3060 (=CH), 1600 (C=C), 1330 and 1160 (SO_2) cm^{-1}. NMR ($CDCl_3$) δ: 7.09 (s, a, CH), 7.28±0.06 (m, 10, $2C_6H_5$). MS *m/e*: 89, 102, 152, 165, 178, 179 (base peak), 214, 243 and 278 (M^+).

Crude **4c**, **4e**, and **4f—g** were chromatographed on silica gel using benzene–*n*-hexane (**4c** and **4e** 1 : 1, **4f—g** 5 : 1 v/v) as the eluene and recrystallized from the solvents shown in Table 2.

2,2-Diphenylethylene-N-*methylsulfonamide (**6a**).* To a stirred solution of **4a** (2.78 g, 0.100 mol) in benzene (10 ml) was added dropwise a 30% aqueous methylamine (4.14 g, 0.040 mol). After stirring was continued for 1 hr at 40—50 °C the mixture was cooled and resultant precipitates were filtered to give 2.54 g (93%) of **6a**. Recrystallization from benzene gave colorless crystals. IR (KBr): 3340 (NH), 3060 (=CH), 1600 (C=C), 1315, 1150, and 1120 (SO_2) cm^{-1}. NMR ($CDCl_3$) δ: 2.42 (d, J_{NH-CH_3} = 5.0 Hz, 3, CH_3), 3.58 (broad, 1, NH), 6.64 (s, 1, CH), 7.20±0.06 (m, 10, $2C_6H_5$). MS *m/e*: 89, 102, 152, 165, 167, 178, 179 (base peak), 209 243 and 273 (M^+).

N-*(2,2-Diphenylethylenesulfonyl)*-N'-*methylthiourea (**8a**).* To a solution of **5a** (7.79 g, 0.030 mol) in acetone (20 ml) was added methyl isothiocyanate (2.63 g, 0.036 mol) and anhydrous K_2CO_3 (6.21 g, 0.045 mol), and the reaction mixture was refluxed for 10 hr with stirring. The resulting potassium salt of **8a** was filtered and washed with acetone to remove unreacted **6a**. The salt was dissolved in water (300 ml), and the solution was acidified with concd HCl to give 9.50 g (95%) of **8a**. Recrystallization from methanol gave colorless crystals. IR (KBr): 3320 (NH), 3060 (=CH), 1600 (C=C), 1570 (NH), 1380, 1180, and 1130 (SO_2) cm^{-1}. NMR (MDSO-d_6) δ: 3.00 (s, 3, CH_3), 3.40 (broad, 1, $NHCH_3$), 7.12 (s, 1, CH), 7.32±0.10 (m, 10, $2C_6H_5$), 7.80 (broad, 1, SO_2NH). MS *m/e*: 89, 102, 121, 134, 152, 165, 167, 178, 179, 195, 211, 212 (base peak), 243, 268, and 298. M^+ was not observed.

Thioureas, **8b**, **8c**, and **8d**, were obtained by evaporation of acetone from the filtrate and subsequent recrystallization of the residual oils from methanol.

*3-Methylamino-5-(*p*-nitrophenyl)-5,6-dihydro-1,4,2-dithiazine-1,1-dioxide (**11**).* To a stirred mixture of concd HNO_3 (*d*= 1.42, 40 ml) and concd H_2SO_4 (40 ml) was added 3-methylamino-5-phenyl-5,6-dihydro-1,4,2-dithiazine-1,1-dioxide (4.17 g, 0.0163 mol) portionwise at 0—5 °C. After stirring was continued for 3 hr at 5 °C, the solution was poured onto ice water (400 ml), and the solid was filtered to give 4.78 g (98%) of the crude product which was most likely contaminated with *ortho* and *meta* isomers. Repeated fractional recrystallization from methanol gave a *para* isomer (**11**) as pale-yellow crystals. IR (KBr): 3240 (NH), 1560 (N=C), 1520 (NO_2), 1340 (NO_2) and 1115 (SO_2) cm^{-1}. NMR (DMSO-d_6) δ: 2.78 (d, J_{NH-CH_3} = 4.5 Hz, 1.7H, $NHCH_3$), 2.78 (s, 1.3H, $=NCH_3$), 3.57 (q, 1, H_A), 3.83 (q, 1, H_C), 5.25 (q, 1, H_B), J_{AB} = 6.0 Hz, J_{AC} = 13.5 Hz, J_{BC} = 4.5 Hz, 7.60—8.50 (m, 4, C_6H_4), a NH proton was ambiguous. MS *m/e*: 57 (base peak), 91, 103, 120, 135, 149, 164, 166, 181, 191, 236, 255, and 301 (M^+).

N-*(*p*-Nitrostyrene-1-sulfonyl)*-N'-*methylthiourea (**12**).* When aqueous 1 M NaOH (21.0 ml, 0.0214 mol) was added to a stirred suspension of **11** (3.23 g, 0.0107 mol) in acetone (42 ml), a deep brown solution was formed. After stirring was continued for 10 min, acetone was removed *in vacuo* and the residual solution was acidified with concd HCl to give **12** (1.50 g) as brown crystals. Recrystallization from acetone gave 0.57 g (18%) of **12** as pale-yellow crystals. IR (KBr): 3330 (NH), 3040 (=CH), 1615 (C=C), 1560 (NH), 1520, 1490 and 1350 (NO_2), 1150 and 1130 (SO_2) cm^{-1}. NMR DMSO-d_6) δ: 2.74 (d, J_{NH-CH_3} = 4.0 Hz, 3, CH_3), 7.40 (d, 1, H_A), 7.94 (d, 1, H_B), J_{AB} = 15.0 Hz, 7.40—8.20 (m, 4, C_6H_4), two NH protons were ambiguous. Mass spectrum was identical with that of **11** because of ready cyclization of **12** to **11** on heating.

N-*Methyl*-S-*(2,2-diphenylvinyl)isothiourea (**13a**).* To a stirred solution of **8a** (0.40 g, 0.0012 mol) in DMF (6 ml) was added aqueous 5M NaOH (2.4 ml, 0.012 mol) and the mixture was stirred for 2 hr at 80 °C. The mixture was poured onto ice water (100 ml). The precipitates were filtered to give 0.224 g (70%) of **13a**. Recrystallization from methanol gave colorless crystals. IR (KBr): 3400, 3260 and 3180 (NH), 1605 (C=N), 1470, 1450, 1360, 1040, 770 and 695 cm^{-1}. NMR ($CDCl_3$) δ: 3.05 (s, 3, CH_3), 6.50—5.30 (broad, 2, 2NH), 6.74 (s, 1, CH), 7.24 (s, 10, $2C_6H_5$). MS *m/e*: 42, 44, 57, 77, 165, 178, 193, 212, 219, 234 (base peak) and 268 (M^+).

N-*Methyl*-S-*(*p*-nitrostyryl)isothiourea (**15**).* Similar to the synthesis of **13a**, **12** (0.36 g, 0.0012 mol) was treated with aqueous 5M NaOH (2.40 ml, 0.012 mol) in DMF (3 ml) for 10 min at 60 °C to give 0.22 g (79%) of **15**. Recrystallization from acetone gave yellow crystals. IR (KBr): 3400, 3260, and 3170 (NH), 1620 (C=N), 1510, 1470, 1370, and 1350 (NO_2), 1255, 1050, 940, 825, 800, 750, and 730 cm^{-1}. NMR ($CDCl_3$) δ: 3.30 (d, J_{NH-CH_3} = 5.0 Hz, 3, CH_3), 6.60 (d, 1, H_A), 8.18 (d, 1, H_B), J_{AB} = 15.0 Hz, 7.20—7.80 (broad, 1, NH), 8.50 (broad, 1, $NHCH_3$), 7.28—8.10 (m, 4, C_6H_4). MS *m/e*: 42, 57, 76, 89, 102, 115, 131, 136, 178, 180, 203, and 237 (M^+).

*Methyl 2,2-bis(*p*-chlorophenyl)vinyl trithiocarbonate (**17f**).* *Path A*: A solution of **5c** (0.295 g, 0.00090 mol) in DMF (3 ml) was treated with aqueous 5M NaOH (0.54 ml, 0.0027 mol), carbon disulfide (0.21 g, 0.0027 mol), and then methyl iodide (0.16 g, 0.0011 mol) by the way described by us[3] to give yellow crystals. Chromatography on silica gel to remove **5c** gave 0.220 g (66%) of pure **17f** as yellow crystals.

Path B: By using the way described in Path A, 0.241 g

(74%) of **17f** was obtained from **6c** (0.30 g, 0.00088 mol), aqueous 5M NaOH (0.52 ml, 0.0026 mol), carbon disulfide (0.17 g, 0.0022 mol) and methyl iodide (0.16 g, 0.0011 mol). Materials which were contained in the filtrate of **17f** were examined. Sulfite anion, SO_3^{-2}, in the filtrate was oxidized with H_2O_2 and detected by $BaSO_4$ precipitation. Carbonyl sulfide was confirmed with lead paper. Methylammonium chloride was converted into a red rhodamine dye exhibiting yellow green fluorescence.[14]

The authors wish to thank Mr. S. Ikeda, Mr. H. Annaka, Mr. Y. Mizukami and Mr. T. Yamamoto for assistance in preparing some of the compounds.

Charge-Transfer Complexes of Thiopyrylium Cation with Aromatic Hydrocarbons and Olefins

Zen-ichi YOSHIDA,* Toyonari SUGIMOTO, and Shigeo YONEDA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Kyoto 606

(Received December 17, 1974)

Charge-transfer (CT) interaction of the thiopyrylium cation (**1**) with aromatic hydrocarbons and olefins has been investigated by electronic spectroscopy. It is noteworthy that **1** formed a CT complex with a monoolefin. The observed CT spectra in the **1**–olefin system showed the following remarkable contrasts compared with those in the **1**–aromatic system. 1) Although one CT absorption band was observed for the **1**–aromatic hydrocarbon CT complex, while two CT absorption bands for the 1–olefin CT complex, and 2) the value of a in the equation of $\Delta E_{CT}=aIP_D+b$ was 1.04 for the former complex and 0.27 for the latter complex. A detailed discussion on the difference between the two CT complexes is presented.

Thiopyrylium cation (**1**)[1] belongs to a novel class of heterocyclic system. The question whether this system is represented by the dominant cyclic 6π aromatic structure (**1a**) or it is more accurately represented as a hybrid structure principally composed of sulfur-bridged carbonium ion structure (**1b**) is intriguing from organic as well as physicochemical view points.

1a **1b**

Our studies on the interpretation of its electronic spectrum[2] by the SCF-MO method and on its reactions with nucleophiles[3] indicated that **1** can be regarded as the carbonium ion stabilized by the (2p-3p)π conjugation with the sulfur atom. In the reactions of **1** with carbanions and amines, we expected that the reaction might proceed *via* a CT complex between **1** and the nucleophile. However, for both **1**-carbanion and **1**-amine systems such CT complex formation has not been observed by spectroscopic means because the reaction between **1** and the nucleophile with low ionization potential occurs very rapidly. This situation prompted us to investigate the CT complex formation between **1** and aromatic hydrocarbons or olefins which have higher ionization potentials than carbanions and amines. Interestingly, we observed the **1**-monoolefin CT complexes[4] as well as the **1**-aromatic hydrocarbon CT complexes, and found that **1** behaves as a strikingly different π electron acceptor from tetracyanoethylene[5] and 1,3,5-trinitrobenzene[6] in the CT complex formation with aromatic hydrocarbons and olefins. In this paper we report investigation on such an interesting CT interaction of **1** with aromatic hydrocarbon and monoolefin, and discuss difference between the two CT complexes.

Experimental

Thiopyrylium perchlorate was prepared according to the method of Degani *et al.*[1c] and purified by reprecipitation from acetonitrile–ether.

Aromatic hydrocarbons and olefins used were purified before use in the following manners. *m*-Xylene, mesitylene, 1-methylnaphthalene and 2-methylnaphthalene were purified by distillation *in vacuo*. Naphthalene, pyrene and anthracene were purified by sublimation under reduced pressure. Cyclohexene, 1-methylcyclohexene, 3-methylcyclohexene, 4-methylcyclohexene, 1-pentene, ethyl vinyl ether and *n*-butyl vinyl ether were purified by distillation *in vacuo*. Acetonitrile was dried over phosphorus pentoxide, repeatedly distilled, treated with anhydrous potassium carbonate and finally distilled without a drying agent.

The electronic spectra were recorded on a Hitachi EPS-3T type spectrophotometer at room temperature.

The pK_{R^+} value for the 1-ethylpyridinium cation was estimated from a determination of the pH of aqueous solutions of the perchlorate salt.

Results and Discussion

CT Complexes between the Thiopyrylium Cation **1** *and Aromatic Hydrocarbons.* A new absorption band was observed in the ultraviolet or visible region for the mixed solution of **1** and an aromatic hydrocarbon in acetonitrile, which is due to neither **1** nor an aromatic hydrocarbon. For example, the absorption spectrum of the **1**-mesitylene system reveals a new band at 345 nm as shown in Fig. 1. The maximum wavelengths of new bands observed for the **1**-aromatic hydrocarbon system are listed in Table 1. When the maximum

transition energies (ΔE_{CT}) of the new bands are plotted against the ionization potentials (IP_D) of aromatic hydrocarbons, a straight line with slope close to unity is obtained (Fig. 2). This demonstrates that the new bands are due to the CT complexes between **1** and aromatic hydrocarbons.

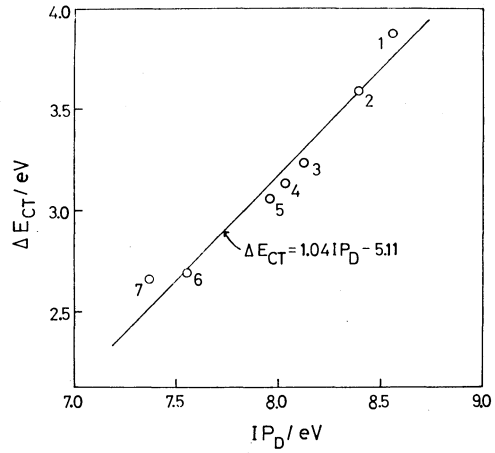

Fig. 2. Plot of the CT transition energies (ΔE_{CT}) *vs.* the ionization potentials (IP_D) of aromatic hydrocarbons: (1) *m*-Xylene, (2) Mesitylene, (3) Naphthalene, (4) 2-Methylnaphthalene, (5) 1-Methylnaphthalene, (6) Pyrene, and (7) Anthracene.

The equilibrium constant and the extinction coefficient for the **1**-mesitylene CT complex were determined to be 0.16 $l\cdot mol^{-1}$ and 2900 at 20.0°C, respectively, by the Benesi-Hildebrand equation.[7] Feldman and Winstein have observed the similar phenomenon for the tropylium perchlorate (**2**)-aromatic hydrocarbon system in acetonitrile and obtained the equilibrium constant of 0.67 $l\cdot mol^{-1}$ (25.0°C) and the extinction coefficient of 1850 for the 1:1 CT complex between **2** and mesitylene.[2,8] The value of the equilibrium constant obtained for the **1**-mesitylene CT complex is much smaller than that for the **2**-mesitylene CT complex. In contrast with these cations, the 1-ethylpyridinium cation (**3**) did not exhibit CT absorptions with aromatic hydrocarbons. This clearly indicates that abilities of their cations as electron acceptors in the CT complex formation decrease in the order of tropylium>thiopyrylium>pyridinium cations. This tendency is coincident with the reverse order of the pK_{R^+} values for their cations (**2**, +4.7;[9] **1**, +8.7;[10] **3**, +11.5). The contribution of the carbonium ion structure to the cations is closely related to their electron accepting ability in the CT complex formation.

CT Complexes between 1 and Olefins. When olefins are employed in place of aromatic hydrocarbons as an electron donor, two CT bands are observed in the ultraviolet and visible regions.[11] As one example the CT absorption spectrum of the **1**-cyclohexene system is shown in Fig. 3. The maximum wavelength of the two CT bands observed for the **1**-olefin system are listed in Table 2. Figure 4 shows that the plots of the transition energies (ΔE_{CT}) of the first (I) and the second (II) CT bands *vs.* the ionization potentials (IP_D) of olefins give straight lines with the same slope (0.27) whose value is significantly small compared with that (1.04) for the **1**-aromatic hydrocarbon CT complexes (see Fig. 2). The two absorption bands observed for the **1**-olefin system are attributed to those due to the CT complex formation between **1** and olefin.

The equilibrium constant and the extinction coefficient for the **1**-cyclohexene CT complex were determined to be 2.00 $l\cdot mol^{-1}$ and 185, respectively.

Multiple CT bands in donor-acceptor complexes

The bands, I and II, correspond to the first and the second CT absorption bands, respectively.

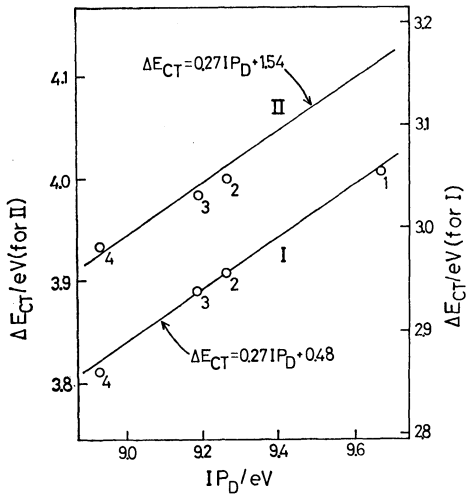

Fig. 4. Plots of the CT transition energies (ΔE_{CT}) of the first (I) and the second (II) CT absorption bands *vs.* the ionization potentials (IP_D) of olefins: (1) 1-Pentene, (2) Isobutene, (3) Cyclohexene and (4) Ethyl vinyl ether.

have been assigned to electronic transitions from two upper occupied levels in the donor[12] or to two lower unoccupied levels in the acceptor.[1,13] In the case of 1-methylpyridinium iodide[14] and 2,4,6-trimethylpyrylium iodide[15] two CT bands were once assigned to the formation of $^2P_{3/2}$ and $^2P_{1/2}$ iodine atoms in the excited state, on the basis that the separation between the two bands corresponded nearly to that expected for the formation of iodine atom in two states.[16] However, recent experimental results have indicated that the two CT bands observed in 1-methylpyridinium iodide are in fact due to the electronic transitions from the highest occupied MO of the iodide anion to the lowest and the second unoccupied π-MO's of the pyridinium cation.[17–19] Verhoeven, Dirkx and de Boer have investigated the CT interaction between the *N*-methyl-4-cyanopyridinium ions and aromatic hydrocarbons, and also observed the two CT bands which are caused by the presence of two closely located unoccupied MO's in the pyridinium cation.[20] In the case of the **1**–olefin CT complexes, the two CT bands should be assigned to the electronic transitions from the highest occupied π-MO of olefin to the lowest and the second unoccupied π-MO's of **1** as visualized in Fig. 5,

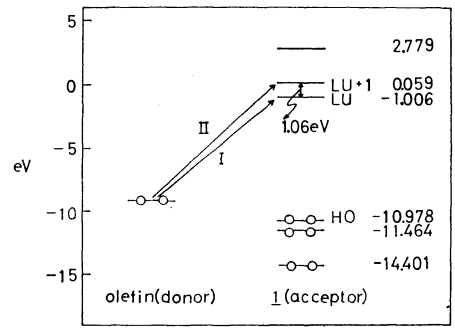

Fig. 5. Energy diagram for the **1**–olefin CT complex. I and II correspond to the first and the second CT absorption bands, respectively.

since olefin has only one occupied π-MO. From Fig. 4, the energy difference between the first and the second CT bands is almost constant independent of olefins employed and 1.06 eV. Furthermore, the observed energy difference is very close to the calculated energy difference between the lowest and the second unoccupied π-MO's of **1** by the SCF-MO method;[2] *i.e.*, 1.065 eV. The above mentioned facts lead to the conclusion that the two closely located unoccupied π-MO's of **1** play an important role in the appearance of the two CT bands for the case of the olefin complexes.

We can suggest the geometry of the **1**–olefin CT complex considering the "overlap and orientation principle."[21] The overlap between the orbitals of two component molecules will determine the resonance capability of the CT-bond and the nobond structures; that is, the relative positions of **1** and olefin molecules in the CT complex will be such as to make possible overlaps of the highest occupied π-MO of olefin with the lowest and the second unoccupied π-MO's of **1**

Fig. 6. The lowest unoccupied (LU) and the second unoccupied (LU+1) MO's of **1** calculated by the SCF-MO method.

(see Fig. 6). From Fig. 6 we can immediately illustrate only one possible configuration shown in Fig. 7 as the geometrical structure of the **1**–olefin CT complex, where olefin is located on the α-carbons of **1**. The SCF-MO calculation indicates that in this configuration the highest occupied MO of olefin overlaps more effectively with the (LU+1)MO than with the LUMO of **1**, consistent with the observation that the higher energy

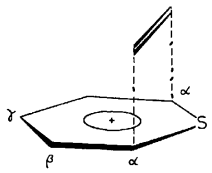

Fig. 7. Geometrical configuration for **1**-olefin CT complex.

CT band is more intense than the lower energy one (see Fig. 3).

Comparison between the 1-Aromatic Hydrocarbon and the 1-Olefin CT Complexes. The **1**-aromatic hydrocarbon and the **1**-olefin CT complexes have the folowing marked differences: (1) only one CT band is observed for the former,[22] while two CT bands for the later, and (2) the slope obtained by the plot of the CT transition energies *vs.* the ionization potentials of donors is 1.04 for the aromatic hydrocarbon complexes and 0.27 for the olefin complexes.

According to Mulliken's CT treatment of the electron donor-acceptor complexes,[23] their CT transition energy (ΔE_{CT}) depends upon the donor ionization potential (IP_D) and the acceptor electron affinity (EA_A) as expressed in Eq. (1):

$$\Delta E_{CT} = IP_D - EA_A + C_1 + \frac{C_2}{IP_D - EA_A + C_1} \quad (1)$$

The energy term C_1 mainly comprises the difference between the Coulomb attraction D^+-A^- after excitation and the van der Waals bonding energy D···A before excitation; C_2 reflects intermolecular resonance. If CT interaction is weak, the fourth term in Eq. (1) will vanish because C_2 is considered to be nearly zero. Actually, the following equation (Eq. (2))* was obtained in the **1**-aromatic hydrocarbon ($IP_D = 7.37$—8.56 eV) complexes as shown in Fig. (2). On the other hand, in the case of **1**-olefin ($IP_D = 8.93$—9.67 eV) CT

$$\Delta E_{CT} = 1.04 IP_D - 5.11 \quad (2)$$

complexes, Eqs. (3) and (4) were empirically obtained from Fig. 4 for the first and second CT absorption bands, respectively, since the C_2 term is considerably large, indicating that olefins more strongly interact with **1**.

$$\Delta E_{CT} = 0.27 IP_D + 0.48 \quad (3)$$

$$\Delta E_{CT} = 0.27 IP_D + 1.54 \quad (4)$$

This is also supported by the fact that the **1**-cyclohexene CT complex has a large equilibrium constant (2.00) compared with the **1**-mesitylene CT complex (0.16). Thus appearance of two CT bands in the **1**-olefin CT complexes is considered to be due to strong interaction between them.

* Under the assumption that C_1, C_2 and EA_A are constants for comparable CT complexes between the same electron acceptor and different electron donors of high ionization potentials,[24] Eq. (1) canbe replaced by linear expression as follows:[25]

$$\Delta E_{CT} = aIP_D + b$$

In a weak CT interaction, the value of a is nearly equal to unity because the C_2 term is nearly zero. Whereas, in a stronger CT interaction the values of a becomes smaller than unity because C_2 is not zero.

It is well known that generally π electron acceptors such as tetracyanoethylene[5] and 1,3,5-trinitrobenzene[6] form stronger CT complexes with aromatic hydrocarbons than with olefins. In marked contrast with the usual case, it is interesting that **1** forms stronger CT complex with olefin than with aromatic hydrocarbon. This is the first case in π-π type CT complexes.

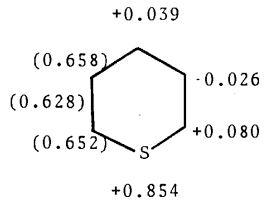

Fig. 8. Positive charge distribution and π-bond orders of **1** calculated by the SCF-MO method.

The strong CT interaction of **1** with olefin is due to the characteristic nature of **1**. It has already been suggested that the possible geometry for the **1**-olefin CT complex is one of olefin locating itself on the α-carbons of **1** (see Fig. 7), on which the positive charge localizes most as seen in the positive charge distribution calculated by the SCF-MO method[2] (Fig. 8). This geometry supplies a condition for the strong CT interaction between **1** and olefin, in which the unoccupied α-carbon 2p π-MO's of **1** overlap effectively with the occupied 2p π-MO's of olefin.

Synthetic Studies on Phosphorylating Reagent. I. The Phosphorylation of Alcohols by Means of *N*-[2-(Dihydrogen phosphoroxy)-5-nitrobenzyl]pyridinium Hydroxide

Yoshihiko TAGUCHI, Yoshitaka MUSHIKA, and Naoto YONEDA

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16–89, Kashima-3-chome, Yodogawa-ku, Osaka 532

(Received December 28, 1974)

The phosphorylation of alcohols by means of *N*-[2-(dihydrogen phosphoroxy)-5-nitrobenzyl]pyridinium hydroxide (**3**), which was prepared from 2-(chloromethyl)-4-nitrophenyl phosphorodichloridate (**1**) through two steps, was demonstrated. Alcohol with a tertiary amino group in its alkyl moiety was readily phosphorylated with **3** to afford the aminoalkyl dihydrogen phosphate in good yield. On the other hand, the phosphorylation of the usual neutral alcohol proceeded only in the presence of a strong base such as triethylamine to give the corresponding alkyl dihydrogen phosphate (**9**). Thus, several alkyl dihydrogen phosphates **9** were prepared. In this phosphorylation, the formation of alkyl 2-hydroxy-5-nitrobenzyl ether (**10**) was also observed.

In our previous papers,[1–5] we reported on the preparation of various phosphoric esters by means of 2-(chloromethyl)-4-nitrophenyl phosphorodichloridate (**1**), a phosphorylating reagent with an activatable protecting group, and demonstrated that the reagent is very useful for the preparation of alkyl dihydrogen phosphate and dialkyl hydrogen phosphate. However, the reagent could not be utilized in the phosphorylation of amino alcohol because of the complicated reaction with the basic part of the reactant.

The present study was undertaken with an aim to explore a more versatile reagent which could be used in the phosphorylation of amino alcohol. An inner salt of *N*-[2-(dihydrogen phosphoroxy)-5-nitrobenzyl]-pyridinium hydroxide (**3**), which has no active chlorine atom, was chosen as a candidate for this purpose, since, in our earlier study,[4] the inner salt of *N*-[2-(alkyl hydrogen phosphoroxy)-5-nitrobenzyl]pyridinium hydroxide was shown to retain its reactivity toward alcohol.

The inner salt **3** was obtained quantitatively by the reaction of pyridine with 2-(chloromethyl)-4-nitrophenyl dihydrogen phosphate (**2**) which was prepared by the hydrolysis of **1**. The isolation of pure crystals of **3** was somewhat difficult because of the instability upon recrystallization from aqueous ethanol. The reaction of a stoichiometric amount of 2-(*N*,*N*-diethylamino)ethanol (**4**) with **3** in pyridine at 90—95 °C afforded a mixture of the resinous compounds, which were characterized on paper chromatography (PPC) as a phenolic polymer and an inorganic polyphosphoric acid. However, when a 10-equivalent amount of **4** was used, 2-(*N*,*N*-diethyl-

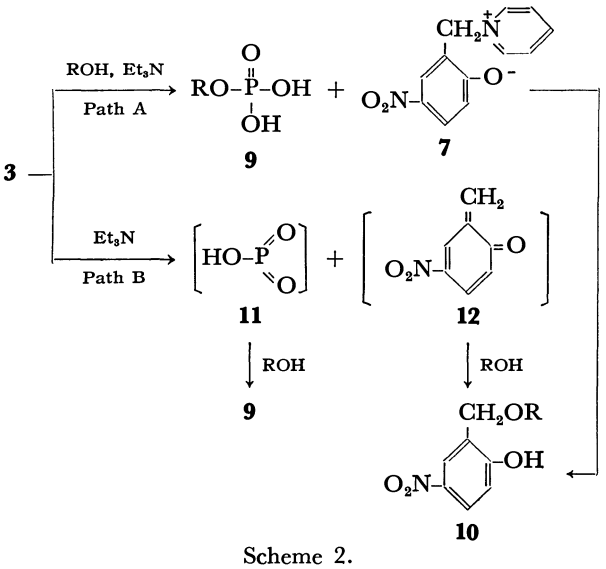
a) Alkyl dihydrogen phosphates were isolated as monoanilinium salt. b) Yields of **9** and **10** were based on 2-(chloromethyl)-4-nitrophenyl dihydrogen phosphate (**2**). c) Solvent A was used.

amino)ethyl dihydrogen phosphate (**5**) was obtained in 71% yield.

The elemental analysis and the downfield shift of the methylene protons adjacent to the phosphate group[6] in the nuclear magnetic resonance (NMR) spectrum supported the structure of the product. On the other hand, the phosphorylation of 2-aminoethanol resulted in the multiformation of intractable compounds. The reaction of an alcohol which does not contain a *tert*-amino residue, such as ethanol and benzyl alcohol, did not proceed at all under similar conditions, however, inorganic polyphosphoric acid and *N*-(2-hydroxy-5-nitrobenzyl)pyridinium hydroxide (**7**) were produced as the main products. This unexpected result could be explained by the self-condensation reaction of **3**, since the nucleophilicity of the second dissociable hydroxyl group in the phosphate group is larger than that of alcohol. An inner salt of *N*-[2-(polyhydrogen polyphosphoroxy)-5-nitrobenzyl]pyridinium hydroxide (**6**) formed would then be hydrolysed to give inorganic polyphosphoric acid (**8**) and **7** during work-up. Therefore, triethylamine was added to the reaction system in order to prevent the self-condensation.

First, the reaction with two equivalent amounts of ethanol was carried out in pyridine in the presence of three equivalents of triethylamine at 90—95 °C, however, ethyl dihydrogen phosphate (**9a**) was obtained in only 11% yield, followed by a considerable amount of the resinous phenolic polymer and inorganic polyphosphoric acid. Therefore, the reaction with ten equivalents of ethanol and three equivalents of triethylamine was attempted under the same conditions. The phosphorylation of ethanol occurred readily; ethyl dihydrogen phosphate (**9a**) was isolated in an improved yield as its monoanilinium salt, which was identified with an authentic sample on infrared (IR) spectrum. Similar results (Table 1) were obtained in the cases of other primary and secondary alcohols, such as *n*-butyl, *s*-butyl, *n*-dodecyl, cyclohexyl, and benzyl alcohol.

In these reactions, nearly equal amounts of alkyl 2-hydroxy-5-nitrobenzyl ethers (**10a-g**) to **9a-g** were isolated. The products were identified by a direct comparison with each authentic specimen, which was prepared by an alternate method.[2,7-8] It was considered that the formation of **10** is closely related to the mechanism of the phosphorylation. One conceivable mechanism (Path A) is the S_N2-type phosphorylation



Scheme 2.

with alcohol, followed by the formation of alkyl 2-hydroxy-5-nitrobenzyl ether (**10**) *via* pyridinium compound **7** formed.

However, this seemed not to be the case in view of the following results: the phosphorylation with **3** required a large excess of alcohol in order to improve the yield of the phosphate **9a-g**, whereas the same type of phosphorylation[1-3] with *N*-[2-(alkyl hydrogen phosphoroxy)-5-nitrobenzyl]pyridinium hydroxide, which probably proceeded through S_N2 mechanism, has been shown to proceed satisfactorily with a stoichiometric amount of alcohol; the formations of large amounts of inorganic polyphosphoric acid and the phenolic polymer were observed when the reaction was run with a stoichiometric amount of alcohol. Another mechanism (Path B) involves the decomposition of the reagent **3** to the quinomethide (**12**) and methaphosphoric acid (**11**) under the present reaction conditions and subsequent condensations with alcohol giving alkyl ether **10** and alkyl dihydrogen phosphate **9**, respectively. This mechanism is supported not only by the above results, but also by the formation of **9** and **10** in nearly equal amounts in all cases. The quinomethide **12** has been proposed by Horton and Koshland[9] as an active species in the reaction of 2-(bromomethyl)-4-nitrophenol with tryptophan. In view of the equivalence of the requisite structure, it seems likely that the same intermediate is generated also in the present reaction.

From these considerations, Path B is a plausible mechanism of this phosphorylation.

In conclusion, it has been shown that a new compound, *N*-[2-(dihydrogen phosphoroxy)-5-nitrobenzyl]-pyridinium hydroxide **3** has phosphorylating ability toward the alcohol in the presence of triethylamine and toward the *tert*-amino alcohol in the absence of the base. Further modification of the reagent would be necessary to improve its efficiency as a phosphorylating reagent.

Experimental

Paper chromatography was carried out by ascending technique using Toyo Roshi No. 51 paper. Solvent systems used were: isopropyl alcohol-concd NH_4OH–H_2O (7:1:2 v/v) (Solvent A) and *n*-butanol–AcOH–H_2O (5:1:4 v/v, upper layer) (Solvent B). UV lamp (254 nm) and Hanes–Isherwood reagent[10] were used for the detection of spots on paper chromatogram. Melting points are uncorrected and were determined on a Yamato apparatus MP-21. NMR spectra were determined on Hitachi Perkin-Elmer R-20A instrument (Me_4Si). IR spectra were determined on a Shimadzu IR-27G spectrometer.

Materials. Alcohols, amines, and solvents were purified and dried by the ordinary procedures.

2-(Chloromethyl)-4-nitrophenyl phosphorodichloridate (**1**) was prepared as described in the previous paper.[2]

2-(Chloromethyl)-4-nitrophenyl Dihydrogen Phosphate (2) (Improved Procedure).[2] To a solution of 3.04 g, (0.01 mol) of 2-(chloromethyl)-4-nitrophenyl phosphorodichloridate (**1**) in 15 ml of acetone was added 15 ml of cold water in one portion with stirring under ice-cooling and the stirring was continued at a temperature below 15 °C for 30 min. After concentration of the reaction mixture to dryness under reduced pressure, the residue was crystallized with $CHCl_3$ to afford 2.28 g (85%) of the phosphate **2** as a white powder; mp 137—139 °C. The product was identified with an authentic sample by the criteria of PPC and NMR spectroscopy.

Inner Salt of N-[*2-(Dihydrogen phosphoroxy)-5-nitrobenzyl*]*pyridinium Hydroxide (3).* To 16 ml (0.20 mol) of anhydrous pyridine was added 5.35 g (0.02 mol) of 2-chloromethyl-4-nitrophenyl dihydrogen phosphate (**2**) with stirring at room temperature. After being allowed to stand at room temperature overnight, the reaction mixture was diluted with 30 ml of acetone, the precipitate was then collected by filtration. The precipitate was recrystallized from 50% ethanol to afford 3.94 g (64%) of analytically pure **3** as white needles; mp 204—205 °C (decomp.); R_f 0.28 (Solvent A) and 0.61 (Solvent B); UV (H_2O, nm): 261.5 (log ε 3.90), 267.5 (3.90) and 303 (3.96); IR (Nujol, cm^{-1}): 2700—2300 (>$\overset{+}{N}$<), 1630  , 1515, 1348 (NO_2), 1280 (P=O), and 1040 (P–O–C). Found: C, 46.39; H, 3.86; N, 8.97%. Calcd for $C_{12}H_{11}N_2O_6P$: C, 46.46; H, 3.57; N, 9.03%.

2-(N,N-Diethylamino)ethyl Dihydrogen Phosphate (5).[11] To a reaction mixture containing 0.01 mol of **3**, which was prepared from 2.67 g (0.01 mol) of **2** and 20 ml of anhydrous pyridine, was added 11.7 g (0.10 mol) of 2-(*N,N*-diethylamino)ethanol (**4**), and then the mixture was heated at 90—100 °C for 7 hr with stirring. After concentration of the reaction mixture to dryness under reduced pressure, water (60 ml) was added to the residue. A water-insoluble, gummy compound was removed by filtration, and the filtrate was passed through a column (1.5 cm×60 cm) of Amberlite IR 120 resin (H^+ form). The column was washed with water until the washings became neutral to litmus. The column was eluted with 5% ammonia. The eluent was concentrated to dryness under reduced pressure, and an aqueous solution of the residue was applied to a column (1.5 cm×50 cm) of Amberlite IRC 50 resin (H^+ form). The column was sufficiently washed with water. The combined original eluent and washings were evaporated to dryness under reduced pressure, and the colorless viscous residue was crystallized with acetone to afford 1.40 g (71%) of 2-(*N,N*-diethylamino)ethyl dihydrogen phosphate (**5**) as white powder; mp 155—159 °C. Recrystallization from ethanol afforded analytically pure **5** as hygroscopic white powder; mp 159—160 °C; R_f 0.23 (Sovlent A); IR (Nujol, cm^{-1}): 2600—2330 (=$\overset{+}{N}$H–), 1270 (P=O), 1180 and 1085 (P–O–C alkyl and organic phosphoric salt); NMR (D_2O, ppm): 1.54 (t, 6H, CH_3×2), 3.36—3.73 [m, 6H, $(CH_3-C\underline{H}_2)_2N-C\underline{H}_2-$], 4.42 (m, 2H, $-CH_2O-$). Found: C, 36.20; H, 8.32; N, 7.05%. Calcd for $C_6H_{16}NO_4P$: C, 36.55; H, 8.18; N, 7.10%.

Reaction of Alcohol with 3. Typical Procedure; Reaction with Benzyl Alcohol: To a reaction mixture containing 0.01 mol of **3**, which was prepared from 2.67 g (0.01 mol) of **2** and 20 ml of anhydrous pyridine, was added 10.81 g (0.10 mol) of benzyl alcohol and 2.8 ml (0.02 mol) of triethylamine, then the reaction mixture was heated at 90—100 °C for 10 hr. After concentration of the reaction mixture to dryness under reduced pressure, an aqueous solution of the residue (H_2O, 50 ml) was extracted with three 20 ml portions of ether. The aqueous layer was passed through a column (1.0cm×50cm) of Amberlite IR 120 resin (pyridinium form), and the column was washed with water. The combined original eluent and washings were neutralized with a small amount of pyridine and were evaporated to dryness under reduced pressure. To the acetone solution of the residue was added 1.6 ml of aniline, and the precipitate was collected by filtration. The precipitate was washed with a small amount of water to remove the salt of inorganic phosphoric acid, and then the insoluble precipitate was recrystallized from 95% ethanol to afford 1.49 g (53%) of monoanilinium salt of **9 g** as white needles; mp 168—169 °C. The product was identified with an authentic specimen by a comparison of its R_f-value of PPC and the IR spectrum and by the mixed melting point test.

The combined ethereal extracts were again extracted with three 20 ml portions of 2M-NaOH. After acidification of the alkaline layer with 10% HCl, the aqueous layer was extracted with three 20 ml portions of ether. The combined ethereal extracts was evaporated to dryness, and the residue was extracted with 100 ml of a boiling mixture of benzene and *n*-hexane (1:3 v/v). After removal of an insoluble gummy substance by decantation, the solution was decolorized with charcoal and concentrated to dryness. The residue was crystallized from boiling *n*-hexane which contained a small amount of benzene to afford 1.58 g (58%) of the ether **10g** as pale yellow prisms; mp 89—91 °C. The ether **10g** was identified with an authentic specimen which was prepared by the established procedure.[8]

In a similar manner, alcohols, such as ethyl, *n*-butyl, *s*-butyl, *n*-amyl, *n*-dodecyl, and cyclohexyl alcohol, were treated with **3** in the presence of triethylamine to afford the corresponding alkyl dihydrogen phosphates **9a—f** and alkyl 2-hydroxy-5-nitrobenzyl ethers **10a—f**.

We wish to express our thanks to Professors Teruaki Mukaiyama and Tsujiaki Hata, and Drs. Takashi Takayanagi, Ichiro Chibata, Muneji Miyoshi and Ichizo Inoue for their valuable discussions and suggestions.

They have described that the phosphate **5** was a white crystal having a melting point of 118—123 °C and its crystallization was difficult. However, by improving this purification, authers obtained a hygroscopic white crystal, mp 159—160 °C, as an authentic sample.

Synthetic Studies on Phosphorylating Reagent. IV. A Novel Synthesis of Nucleoside-3′,5′ Cyclic Phosphates by the Use of 2-(*N*,*N*-Dimethylamino)-4-nitrophenyl Phosphate

Yoshihiko TAGUCHI and Yoshitaka MUSHIKA

Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., 16–89, Kashima-3-chome, Yodogawa-ku, Osaka 532

(Received December 28. 1974)

A novel method for the synthesis of nucleoside-3′,5′ cyclic phosphate has been investigated. The intermediates, nucleoside-5′ 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphates (**3a—d**), were prepared in good yields by the condensation of unprotected nucleosides with 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphate (**2**), using dicyclohexylcarbodiimide (DCC) in dimethylformamide (DMF). Treatment of the intermediates **3a—d** with acetic acid in boiling pyridine under high dilution condition gave nucleoside-3′,5′ cyclic phosphates in fairly good yields and small amount of other nucleotides, whereas nucleoside-2′,3′ cyclic phosphate was obtained by the reaction in DMF at 100 °C. An attempt at the direct synthesis of the cyclic nucleotide by refluxing the reaction mixture of unprotected nucleoside with DCC and **2** in pyridine was also successful to afford the similar results as in the stepwise procedure.

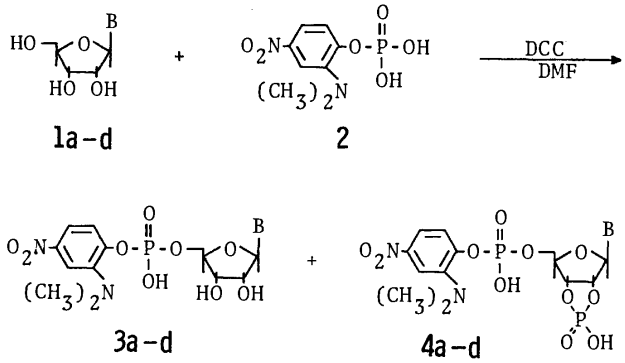
Adenosine-3′,5′ cyclic phosphate has been recognized as an intracellular second messenger of hormone action, and some of the various biological properties attributed to adenosine-3′,5′ cyclic phosphate can be explained by the stimulation of these protein kinases.

A number of procedures[1–4] have been applied to the synthesis of nucleoside-3′,5′ cyclic phosphates. Lipkin *et al.*[1] obtained adenosine-3′,5′ cyclic phosphate by the barium hydroxide-catalyzed degradation of adenosine-5′ triphosphate. Intramolecular cyclization of nucleoside-5′ phosphate was carried out by Smith *et al.*[2] using dicyclohexylcarbodiimide (DCC) in pyridine under high dilution condition. Borden and Smith[3] reported the synthesis of nucleoside-3′,5′ cyclic phosphate from nucleoside-5′ 4-nitrophenyl phosphates with potassium *t*-butoxide in dimethyl sulfoxide. Recently, Mukaiyama and Hashimoto[4] obtained nucleoside-3′,5′ cyclic phosphate in a similar manner to the method of Smith *et al.* except using triphenylphosphine and 2,2′-dipyridyl disulfide as condensation reagents.

In previous papers,[5–7] we reported that a new phosphorylating reagent, 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphate (**2**), which has an activatable protecting group, reacted with various alcohols and amino alcohols to afford the corresponding alkyl dihydrogen phosphates and amino alkyl dihydrogen phosphates, respectively. The acid catalyzed phosphorylations of unprotected nucleosides with just one equiv. of this reagent **2** gave the corresponding nucleoside-5′ phosphates selectively.

In view of our success in the direct synthesis of nucleoside-5′ phosphate from unprotected nucleoside, it was considered that the DCC coupling reaction of unprotected nucleoside with one molar equivalent of **2** would give nucloside-5′ 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphate (**3a—d**) selectively, probably because of the bulkiness of the reagent, and subsequently its intramolecular phosphorylation would afford nucleoside-3′,5′ cyclic phosphate. In this communication, we describe a new synthetic method of nucleoside-3′,5′ cyclic phosphate by the use of **2**.

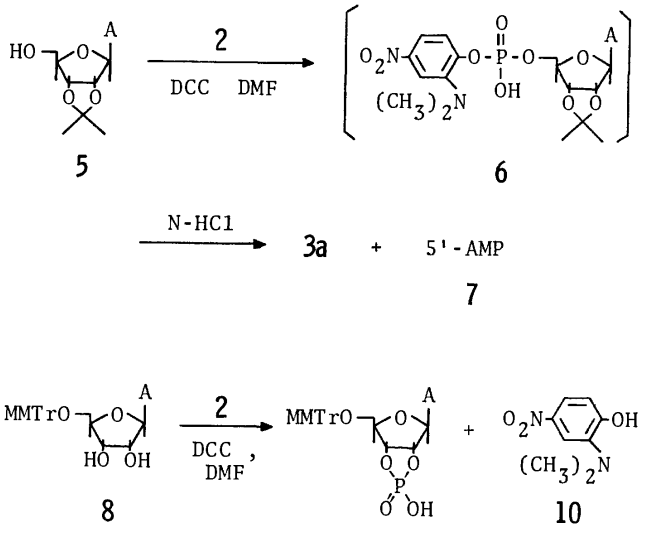
Initial attempt was carried out with adenosine. One mmole of adenosine in dimethylformamide (DMF) was allowed to react with the pyridinium salt of **2** (1.5 mmol) and DCC (2 mmol) at room temperature. After the usual work-up, the column chromatography of the reaction products using DEAE Sephadex afforded adenosine-5′ 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphate (**3a**) in 79% yield and adenosine-2′,3′ cyclic phosphate-5′ 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphate (**4a**) in 12% yield. The former product could be crystallized as calcium salt, though a good elemental analysis was not obtained. The NMR spectrum in D_2O showed the presence of the 2-(*N*,*N*-dimethylamino)-4-nitrophenyl group and the 5′-methylene protons at 4.32 ppm, which usually appears at lower field than those of the original nucleoside upon 5′-*O*-phosphorylation.[8] Comparison of the mobility in paper electrophoresis (PEP) with those of the analogous nucleotides (Table 4) also supported the assigned structure. The latter product was crystallized as lithium salt pentahydrate, mp 242—243 °C. The NMR spectrum in D_2O exhibited the 2′,3′-protons at 5.16—5.65 ppm and the 4′,5′-protons at 4.23—4.67, showing again downfield shift upon phosphorylation. In addition, the structures of both compounds were ascertained by the consideration of the following chemical reactions. Treatment of 2′,3′-*O*-isopropyl-



a, B=adenine, **b**, B=guanine
c, B=uracil, **d**, B=cytosine

Scheme 1.

ideneadenosine (**5**) with the triethylammonium salt of **2** and DCC under the same conditions gave a sole nucleotide, 2′,3′-*O*-isopropylideneadenosine-5′ 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphate (**6**), having R_f value of 0.81 in Solvent A on paper partition chromatography (PPC). Subsequent deblocking with 1M-hydrochloric acid afforded a mixture of **3a** and adenosine-5′ phosphate (**7**), which were characterized by PPC and PEP. On the other hand, when 5′-monomethoxytrityladenosine (**8**) was allowed to react with the triethylammonium salt of **2** and DCC under the same conditions, the liberation of a significant amount of 2-(*N*,*N*-dimethylamino)-4-nitrophenol (**10**) was observed, showing the occurrence of intramolecular cyclization after the phosphorylation of **8** at either the 2′- or 3′-hydroxyl group. In fact, usual work-up and DEAE Sephadex column chromatography afforded 5′-monomethoxytrityladenosine-2′,3′ cyclic phosphate



Scheme 2.

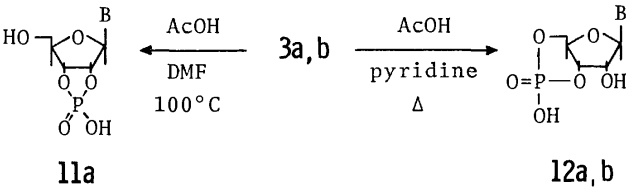
(**9**) quantitatively. This ready formation of the 2′,3′-cyclic phosphate linkage under mild conditions contrasts with the conversion of nucleoside-2′(3′) 4-nitrophenyl phosphate into the corresponding 2′,3′-cyclic nucleotide under rather vigorous conditions,[3,9] and also with the studies of Agarwal and Dhar.[10] Condensation reactions of other nucleosides underwent similarly to give the corresponding nucleotides, **3b—d** and **4b—d** (Table 1).

Table 1. Products in the reaction of nucleosides with **2**

Nucleoside	Products (Yield %)[a]		
	3	**4**	Recovered nucleoside
Adenosine	79	12	9
Guanosine	99	0[b]	1
Uridine	49	7[b]	44
Cytidine	62	6[b]	32

a) Yields were estimated from the total optical densities at their absorption maxima corresponding to the each products. b) The yields of these products were calculated from the additive optical densities of corresponding **1** and **2**.

DMF was found to be a suitable solvent for this reaction, whereas the use of pyridine resulted in the recovery of the unreacted nucleoside. Next, the intramolecular phosphorylation of **3** to nucleoside-3′,5′ cyclic phosphate was attempted in pyridine under high dilution condition. The triethylammonium salt of **3** was so soluble in anhydrous pyridine that the use of 4-morpholine-*N*,*N*′-dicyclohexylcarboxamidine was unnecessary. The cyclization was carried out by the dropwise addition of a solution of **3** and acetic acid in anhydrous pyridine to a large amount of boiling pyridine that is enough to make high dilution condition. In this reaction, acetic acid would serve as a proton catalyst, converting the dimethylamino group to the electron-withdrawing group. Thus, when **3a** was treated under these conditions, adenosine-3′,5′ cyclic phosphate (**12a**) was obtained in 61% yield, the other porducts being adenosine-5′ phosphate, adenylyl-(5′→5′)-adenosine, and dephosphorylated adenosine. These products were separated by linear gradient chromatography with DEAE Sephadex and identified with the authentic samples by the criteria of PPC and PEP. Similar result was obtained in the cyclization reaction with guanosine-5′ 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphate (**3b**) (Table 2). Further attempt was made to improve this method



Scheme. 3.

Table 2. Products composition in the cyclization of **3a,b** in pyridine

without isolation of the intermediate **3**. In a typical run, the reaction of one equivalent amount of **2** and two equivalents of adenosine with DCC was carried out in DMF at room temperature. Treatment of this reaction mixture in DMF at 100 °C under high dilution condition afforded a major product with the same PEP mobility as adenosine-(2′,3′ and 3′,5′) cyclic phosphates (**11a** and **12a**). The yield of this material was estimated spectrophotometrically to be 75%. On mechanistic consideration, it seemed likely that this product was adenosine-3′,5′ cyclic phosphate (**12a**). However, this proved not to be the case: that the product was indeed adenosine-2′,3′ cyclic phosphate (**11a**) followed from its hydrolysis properties. When the product was treated with Dowex-50 (H^+ form) in water, it was readily converted into a mixture of adenosine-(2′ and

3′) phosphates. No adenosine-5′ phosphate could be detected in the products. Reese and Khwaja[11] have observed the same phenomenon in the intramolecular phosphorylation of adenosine-5′ 2-hydroxyphenyl phosphate in pyridine, and proposed the pyridine-promoted dephosphorylation, followed by the phosphorylation of the nucleoside thus produced, as a possible mechanism. However, this would not be the case with ours, because the present reaction was run in DMF and the reagent has no participating *O*-hydroxyl group. The mechanism of this reaction remains as a matter of further investigation.

Finally, the cyclization reaction proceeded in the desired direction by high dilution treatment in boiling pyridine. Thus, after concentration of the reaction mixture, the original solvent was replaced by pyridine, and the solution was added dropwise to the boiling pyridine in the presence of acetic acid under high dilution condition. The reaction mixture was worked up as described in the Experimental section and subjected to DEAE Sephadex column chromatography with a linear gradient of triethylammonium bicarbonate to give product compositions similar to those in the stepwise procedure. All the compounds listed in the Table 3 were identified with authentic samples by PPC and PEP, and the yields were estimated spectrophotomotrically.

This reagent **2** with its high solubility and selectivity would provide a useful tool for the preparations of nucleoside-3′,5′ cyclic phosphate and nucleoside-2′,3′ cyclic phosphate.

Experimental

General Methods. Reagent grade pyridine was used after being dried over calcium hydride or Linde 4-A Molecular Sieves for several days. Solutions were concentrated to dryness at 30 to 40 °C using either a rotary evaporator or, when anhydrous conditions were required, an oil pump equipped with Dry Ice trap.

Paper chromatography was carried out using the descending technique on Toyo Roshi No. 51A paper. The solvent systems used were: isopropyl alchohol–concentrated ammonia–water (7:1:2) (Solvent A); *n*-butyl alcohol–acetic acid–water (5:2:3) (Solvent B). Paper electrophoresis was performed at pH 7.5 (0.05 M triethylammonium bicarbonate, 900 V/40 cm). Chromatographic and electrophoretic mobilities are recorded in Table 4. Melting points are uncorrected and were determined on a Yamato apparatus MP-21. The NMR spectra were determined on a Hitachi Perkin-Elmer R-20A instrument (DSS). IR spectra were determined on a Shimadzu IR-27G spectrometer, and UV spectra, on a Hitachi EPS-3T spectrometer.

*Adenosine-5′ 2-(*N,N*-Dimethylamino)-4-nitrophenyl phosphate (3a)* Adenosine (0.27 g, 1 mmol) and the pyridinium salt of **2** (1.5 mmol) were treated with DCC (0.41 g, 2 mmol) in DMF (50 ml) for 24 hr at room temperature. The reaction mixture was concentrated to dryness and water (500 ml) was added. After the precipitate was removed by filtration, the filtrate was applied to a 1.8×60 cm column of DEAE Sephadex (HCO_3^-) which was eluted with a linear gradient of triethylammonium bicarbonate (4 l., 0.0005—0.1 M), and the elution was followed spectrophotometrically at 260 nm. A major peak (22460 OD units, 79%) of electrophoretically and chromatographically homogeneous adenosine-5′ 2-(*N,N*-dimethylamino)-4-nitrophenyl phosphate (**3a**) was first eluted and a small peak of adenosine-2′,3′ cyclic phosphate-5′ 2-(*N,N*-dimethylamino)-4-nitrophenyl phosphate (**4a**) (3410 OD units, 12%) was followed. The pooled peak of **3a** was evaporated to dryness and coevaporated several times with methanol. The residue was dissolved in water (10 ml), and a stoichiometric amount of calcium hydroxide was added. The solution was concentrated to dryness and the residue was crystallized from aqueous ethanol to give **3a** calcium salt, in pale yellow powder; mp 187—190 °C (decomp.); $\lambda_{max}^{H_2O}$ (pH 6.85 and 12.3) 259 nm, 292 (sh); (pH 1.55) 259; NMR (D_2O) 2.73 (s, 6, N-Me_2), 4.15—5.07 (m, 5, $C_2'H+C_3'H+C_4'H+C_5'H_2$), 5.97 (d, J=5 Hz, 1, $C_1'H$), 7.10—7.64 (m, 3, Ph), 8.03 and 8.16 ppm (2 s, 2, C_2H and C_8H). The fractions containing **4a** were evaporated to dryness and the residue was dissolved with methanol. The solution was treated with lithium chloride, and precipitation with acetone gave pale yellow powder; mp 242—243 °C (decomp.); $\lambda_{max}^{H_2O}$ (pH 6.85 and 12.3) 259 (28400) nm, 292 (sh) (10800); (pH 1.55) 259 (24200); NMR (D_2O) 2.74 (s, 6, N-Me_2), 4.23—4.68 (m, 3, $C_4'H+C_5'H_2$), 5.16—5.65 (m, 2, $C_2'H+C_3'H$), 6.27 (d, J=3.2 Hz, 1, $C_1'H$), 7.06—7.71 (m, 3, Ph), 8.09 and 8.23 ppm (2 s, 2, C_2H and C_8H). Found: C, 32.07; H, 4.43; N, 14.52%. Calcd for $C_{18}H_{19}N_7O_{11}P_2Li_2 \cdot 5H_2O$: C, 32.30; H, 4.52; N, 14.63%.

*Guanosine-5′ 2-(*N,N*-Dimethylamino)-4-nitrophenyl Phosphate (3b).* Guanosine (0.28 g, 1 mmol) and the pyridinium salt of **2** (1.5 mmol) were treated with DCC (0.41 g, 2 mmol) in DMF (50 ml) at room temperature for 24 hr. The reaction mixture was concentrated to dryness and water (500 ml) was added. After the precipitates was removed by filtration, the filtrate was applied to a 1.8×60 cm column of DEAE Sephadex (HCO_3^-), which was eluted with linear gradient of triethylammonium bicarbonate (4 l., 0.005—0.1 M). A major peak (27580 OD units, 99%) of electrophoretically and chromatographically homogeneous guanosine-5′ 2-(*N,N*-dimethylamino)-4-nitrophenyl phosphate (**3b**) was eluted. The by-product **4b** was not detected in the products. The pooled peak of **3b** was evaporated to dryness and coevaporated several times with methanol. The residue was dissolved in water (10 ml) and a stoichiometric amount of calcium hydroxide was added. The solution was concentrated to dryness and the residue was crystallized from aqueous ethanol to give **3b** calcium salt, in pale yellow powder; mp 193—196 °C (decomp.); $\lambda_{max}^{H_2O}$ (pH 6.85) 254.5 nm; (pH 1.55) 258.5, 269 (sh); (pH 12.3)

257; NMR (D_2O) 2.68 (s, 6, N-Me_2), 4.05—4.48 (m, 5, $C_2'H+C_3'H+C_4'H+C_5'H_2$), 5.74 (d, J=4.5 Hz, 1, $C_1'H$), 7.02—7.66 (m, 3, Ph), and 7.76 ppm (s, 1, C_8H).

*Uridine-5′ 2-(N,N-Dimethylamino)-4-nitrophenyl Phosphate (**3c**).* The procedure described for the preparation of guanosine-5′ 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphate was applied. Uridine-5′ 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphate (**3c**) calcium salt (11900 OD units, 49%) was obtained by crystallization from aqueous ethanol; mp> 260 °C; $\lambda_{max}^{H_2O}$ (pH 6.85) 258.5 nm; (pH 1.55) 268; (pH 12.3) 257; NMR (D_2O) 2.82 (s, 6, N-Me_2), 4.19—4.40 (m, 5, $C_2'H+C_3'H+C_4'H+C_5'H_2$), 5.70 (d, J=8.2 Hz, 1, C_5H), 5.88. (d, J=3 Hz, 1, $C_1'H$) and 7.35—7.93 ppm (m, 4, Ph+C_6H).

*Cytidine-5′ 2-(N,N-Dimethylamino)-4-nitrophenyl Phosphate (**3d**).* The procedure described for the preparation of guanosine-5′ 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphate was applied. Cytidine-5′ 2-(*N*,*N*-dimethylamino)-4-nitrophenyl phosphate (**3d**) calcium salt (16300 OD units, 62%) was obtained by the crystallization from aqueous ethanol; mp>260 °C; $\lambda_{max}^{H_2O}$ (pH 6.85) 261 nm; (pH 1.55) 280; (pH 12.3) 253; NMR (D_2O) 2.87 (s, 6, N-Me_2), 4.14—4.35 (m, 5, $C_2'H+C_3'H+C_4'H+C_5'H_2$), 5.86 (d, J=7.5 Hz, 1, C_5H), 5.91 (d, J=3 Hz, 1, $C_1'H$), and 7.73—7.98 ppm (m, 4, Ph+C_6H).

Adenosine-3′,5′ Cyclic Phosphate (12a) from 3a. The triethylammonium salt of **3a** (0.2 mmol) was dissolved in pyridine (20 ml) containing acetic acid (12 mg, 0.2 mmol), and the solution was added dropwise to a boiling solution of pyridine (20 ml) over a 3-hr period. Heating was continued for further 3 hr and then the solution was concentrated to dryness. The residue was suspended in a mixture of water (10 ml) and ethyl acetate (20 ml). The aqueous layer was adjusted to pH 2 with 1M-hydrochloric acid. The solution was applied to a column of DEAE Sephadex (1.2×20 cm, HCO_3^-), which was eluted with a linear gradient of triethylammonium bicarbonate (4 l., 0.005—0.1 M) (fraction size, 20 g). Fractions containing **12a** (fractions 68—85) were concentrated to dryness. The residue was dissolved in 50% aqueous ethanol and adjusted to pH 2 with 10% hydrochloric acid. The precipitate was collected by filtration and washed with ethanol to give adenosine-3′,5′ cyclic phosphate monohydrate (43 mg, 61%), in white powder; $\lambda_{max}^{H_2O}$ (pH 2.0) 256 nm (ε 14500); (pH 7.0) 258 (14650); NMR [$D_2O+(NH_4)_2CO_3$] 4.23—5.25 (m, 5, $C_2'H+C_3'H+C_4'H+C_5'H_2$), 6.08 (s, 1, $C_1'H$), 8.09 and 8.15 ppm (2s, 2, C_2H and C_8H); ν_{max}^{nujol} 1690 (C=N), 1233 (P=O), 1202, 1081 cm^{-1} (P–O–C). This product was identified with an authentic specimen.

Guanosine-3′,5′ Cyclic Phosphate (12b) from 3b. The reaction was carried out as described for the preparation of **12a**. Guanosine-3′,5′ cyclic phosphate (1420 OD units, 55%) was isolated after the ion-exchange chromatography. This product was identified with an authentic specimen on PPC, PEP, and UV spectra; $\lambda_{max}^{H_2O}$ (pH 1.0) 256.5 nm (ε 11350); (pH 7.0) 254 (12950).

Adenosine-3′,5′ Cyclic Phosphate (12a) from Adenosine. Adenosine (2.7 g, 10 mmol) and the monotriethylammonium salt of **2** (5 mmol) were treated with DCC (2.05 g, 10 mmol) in DMF at room temperature for 24 hr. The reaction mixture was then concentrated to dryness. The residue was dissolved in pyridine (1 l) containing acetic acid (0.3 g, 5 mmol), and the insoluble dicyclohexylurea was removed by filtration. The solution was added dropwise to a boiling solution of pyridine (1 l) over a 3-hr period. Heating was continued for further 3 hr and then the solution was concentrated to dryness. The residue was suspended in a mixture of water (1 l) and ethyl acetate (500 ml). The aqueous layer was adjusted to pH 2 with 1M-hydrochloric acid. The solution was applied to a column of DEAE Sephadex (HCO_3^-, 1.5×60 cm). Elution was carried out using linear gradient with 0.005 M triethylammonium bicarbonate (2 l) in the mixing chamber and 0.1 M triethylammonium bicarbonate (2 l) in the reservoir. Fractions (20 g) were collected; adenosine-3′,5′ cyclic phosphate appeared in fractions 74—108. The combined fractions was concentrated to dryness and the solid residue was taken up in water (50 ml). The aqueous solution was evaporated to dryness to remove any residual triethylammonium bicarbonate. The residue was dissolved in 50% aqueous ethanol (10 ml) and adjusted to pH 2 with 1M-hydrochloric acid. The precipitates were filtered and washed with ethanol to give adenosine-3′,5′ cyclic phosphate (**12a**) monohydrate (1.11 g, 64%) as white powder. This product was identified with an authentic specimen.

Guanosine-3′,5′ Cyclic Phosphate (12b) from Guanosine. Guanosine (2.83 g, 10 mmol) and the monotriethylammonium salt of **2** (5 mmol) were treated with DCC (2.05 g, 10 mmol) in DMF as in the preparation of adenosine-3′,5′ cyclic phosphate. After usual work-up and ion-exchange chromatography, guanosine-3′,5′ cyclic phosphate (**12b**) (35400 OD units, 55%) was obtained in fractions 68 to 95. The product was homogeneous and identical with authentic guanosine-3′,5′ cyclic phosphate on PPC in Solvents A and B and on PEP.

Uridine-3′,5′ Cyclic Phosphate (12c) from Uridine. Uridine (2.44 g, 10 mmol) and the monotriethylammonium salt of **2** (5 mmol) were treated with DCC (2.05 g, 10 mmol) in DMF as in the preparation of adenosine-3′,5′ cyclic phosphate. After usual work-up and ion-exchange chromatography, uridine-3′,5′ cyclic phosphate (28600 OD units, 58%) was obtained in fractions 45 to 68. The nucleotide was homogeneous on PPC in Solvents A and B and on PEP.

Cytidine-3′,5′ Cyclic Phosphate (12d) from Cytidine. The procedure described for the preparation of adenosine-3′,5′ cyclic phosphate was applied. Cytidine-3′,5′ cyclic phosphate (**12d**) (14900 OD units, 32%) was obtained in fractions 45 to 72. The product was identified with an authentic specimen.

Adenosine-2′,3′ Cyclic Phosphate (11a) from Adenosine. Adenosine (5.4 g, 20mmol) and the monotriethylammonium salt of **2** (10 mmol) were treated with DCC (4.1 g, 20 mmol) in DMF (300 ml) at room temperature for 40 hr. To the reaction mixture, acetic acid 0.6 g (10 mmol) was added. The solution was added dropwise to a solution of DMF (30 ml) at 100 °C over a 3-hr period. Heating was continued for further 1 hr and the solution was concentrated to dryness. The residue was suspended in a mixture of water (1 l) and ethyl acetate (500 ml). The aqueous layer was applied to a column of DEAE Sephadex (HCO_3^-, 3.8×60 cm). Elution was carried out using linear gradient with 0.005 M triethylammonium bicarbonate (4 l) in the mixing chamber and 0.1 M triethylammonium bicarbonate (4 l) in the reservoir. The elution of nucleotides was followed spectrophotometrically at 260 nm. The fractions containing the major peak were combined and concentrated to dryness to give adenosine-2′,3′ cyclic phosphate (**11a**) monotriethylammonium salt (105140 OD units, 75.1%). This product was identified with an authentic specimen on PPC, PEP, and UV spectra.

We wish to express our thanks to Professor Yasumitsu Tamura, Drs. Takashi Takayanagi, Ichiro Chibata, Muneji Miyoshi and Ichizo Inoue for their valuable discussions and suggestions.

Intramolecular Oxypalladation. Cyclization Reaction of 2-Allylphenols with Palladium Salts

Takahiro HOSOKAWA,* Hisao OHKATA, and Ichiro MORITANI

Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560

(Received May 24, 1974)

The stoichiometric reaction of sodium salts of 2-allylphenols **1** with dichlorobis(benzonitrile)palladium(II) gives generally 2-substituted benzofurans **2** in moderate yields. The formation of cyclized products is explained by intramolecular oxypalladation followed by elimination of a palladium hydride species. The cyclization can be made catalytic by using palladium(II) acetate, cupric acetate, and oxygen.

Recently we found the intramolecular cyclization of 2-allylphenols into 2-substituted benzofurans by means of dichlorobis(benzonitrile)palladium(II).[1] The synthetic usefulness of the reaction is, however, limited by the expence of palladium salt since a stoichiometric amount of palladium salt is utilized. Accordingly, we have investigated to make the cyclization catalytic with respect to the metal salt.

The present paper describes a study of the stoichiometric and catalytic reactions of 2-allylphenols induced by palladium salts. It is also indicated that intramolecular oxypalladation intermediate plays an important role in the reaction.

Results and Discussion

Stoichiometric Cyclization Using Palladium Salts. (a) Dichlorobis(benzonitrile)palladium(II): Sodium salts of 2-allylphenols **1** were employed in the stoichiometric reaction in order to form a Pd–O bond easily *in situ*. An equimolecular amount of dichlorobis(benzonitrile)-palladium(II) was allowed to react with the sodium salts as reported previously.[1]

In general, the reaction gave 2-subsituted benzofurans **2** in moderate yields as shown in Table 1. 2,3-Dihydro-2-methyl-2-ethylbenzofuran (**3**), hydrogenated product of 2,3-dihydro-2-methyl-2-vinylbenzofuran (**2f**), was formed as a by-product in the reaction of 2-(β,γ-dimethylallyl)phenol (**1f**). The structures of products were deduced from elemental analyses and spectral data which are summarized in Tables 2. and 3. In these reactions no starting material was recovered, but polymeric residue was formed.

It was reported that the treatment of 2-allylphenol (**1a**) with palladium on charcol at 500—800 °C gave 2-methylbenzofuran (**2a**).[2] Compared with this, the present method provides a very convenient synthetic method of 2-substituted benzofurans.

The formation of 2-substituted benzofurans **2** is elucidated by the following Scheme 1** involving intramolecular oxypalladation to give the intermediate **6** followed by β-elimination of PdHCl species.[3]

In the oxypalladation intermediate **6**, where R = H or Ph, the hydrogen on the C-2 carbon is an only β-hydrogen to be eliminated with palladium. The elimination gives *exo*-methylenebenzofuran which even-

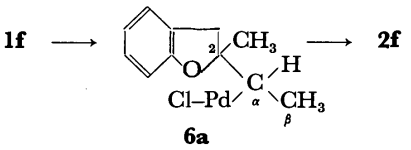
4	$C_{12}H_{14}O$	82.72	8.10	82.26	7.92	174

tually isomerizes to the thermodynamically stable 2-substituted benzofuran (**2a**—**2e**). However, exo-methylenebenzofuran **2g** is isolated in the reaction of **1g**.

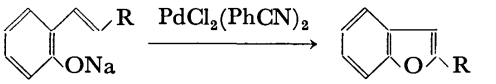
In the case of **1f**, β-hydrogen elimination is only possible from the methyl group attached to α-carbon. The elimination gives **2f** as shown below.



The product **3** can be considered to arise from hydrogenolysis of the Pd–C bond in **6a**.

In the case of **1b** (or **1h**), there are two possibilities for β-elimination of a palladium hydride in the intermediate **6** (R=CH_3). One is from the C-2 carbon leading to 2-ethylbenzofuran (**2b**), and the other from the methyl group to give 2,3-dihydro-2-vinylbenzofuran (**8a**) (*vide infra*). Similarly, dihydrobenzofuran **8b** is expected from **1h**. However, **8a** (or **8b**) would be isomerized to the thermodynamically more stable isomer **2b** (or **2h**) by the generated PdHCl species.[4] The species is known to prompt double bond isomerization.[5]

It was also found that 2-(1'propenyl)phenol (**7a**) and 2-hydroxystilbene (**7b**) gave 2-substituted benzofurans



7a, R=CH_3 **2a**, R=CH_3 17%

a) Coupling constants, J, have the unite of Hz.

2a and **2i**, respectively, but in low yields.[6]

(b) Palladium(II) Acetate: Palladium(II) acetate was found to cause the cyclization of 2-allyl phenols **1** themselves. The treatment of **1b** with an equimolecular amount of palladium(II)acetate gave **2b**(20%) and **8a** (21%). In this case, however, these two isomers were primary products because the isomerization of **8a** to the stable isomer **2b** was eliminated by the following results. 1) The amounts of both products **2b** and **8a** increased with reaction time, and the product ratio of **2b** and **8a** did not change with time. 2) The treatment of **8a** under the same conditions resulted in the recovery of **8a**. 3) Even when **8a** was added to the starting substrate in advance, the amount of **2b** did not increase under the corresponding conditions. The difference of product composition between two stoichiometric cyclizations of **1b** would be due to the difference of palladium salts used.

Moreover, the composition of products **2b** and **8a** was found to vary with the relative amount of **1b** to palladium(II) acetate. As indicated in Table 4, the ratio of **8a** to **2b** increased with increase in the relative amount of **1b** to palladium(II) acetate. Further study is required to understand the result.

Table 4. Product composition in the reaction of **1b** with palladium(II) acertate[a]

Mole ratio **1b**/$Pd(OAc)_2$	Yield on $Pd(OAc)_2$		Product ratio **8a**/**2b**
	2b, %	**8a**, %	
1	19.5	20.8	1.1
2	19.0	46.4	2.4
5	17.4	85.6	4.9
10	13.6	92.5	6.8

a) The reaction was carried out at 55°C for 30 min in methanol-water. Yields were determined by glc with biphenyl as an internal standard.

Catalytic Cyclization Using Palladium(II) Acetate.

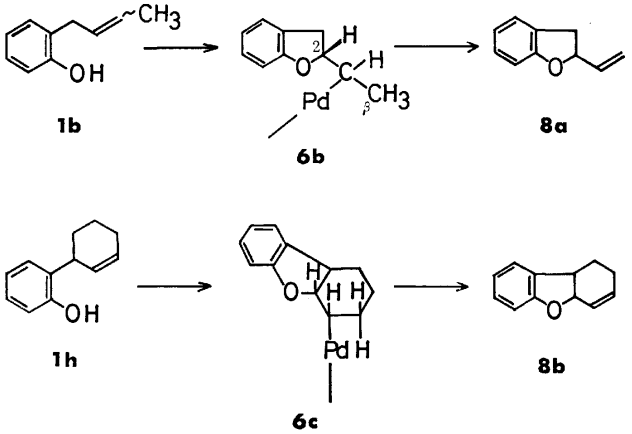
Palladium(II) acetate was found to be a convenient reagent for the reaction because it caused the cyclization of 2-allylphenols directly without using the sodium salts. Hence, the catalytic reaction was performed by use of the reagent.

Table 5. Catalytic cyclization of allylphenols with palladium(II) acetate in the presence of cupric acetate[a]

Allylphenol **1**	Product	Yield on $Pd(OAc)_2$, % (Yield on **1** used, %)	Conversion of **1**, %
1a	**2a**	1960 (34)	99
1b	**8a**	2720 (54)	99
	2b	trace	
1c	**2c**	1170 (23)	63
1d	—	—	—
1e	**2e**	786 (16)	53.5
1h	**8b**	1000 (20)	46

a) All reactions were carried out at ~55 °C for 24 hr in methanol (25 ml)-water (2 ml). Allylphenol **1** (10 mmol), $Pd(OAc)_2$ (0.2 mmol), and $Cu(OAc)_2 \cdot H_2O$ (5 mmol) were used. Yields and conversions were determined by glc and/or NMR analyses.

By considering the fact that reduced palladium metal is readily reoxidized with cupric salt and molecular oxygen as is well known in the Wacker process,[7] the reaction of 2-allylphenols **1** (10 mmol) was carried out in methanol–water solvent in the presence of a catalytic amount of palladium(II) acetate (0.2 mmol) and cupric acetate (5 mmol) under oxygen atomosphere. As indicated in Table 5, the reaction gave 2-substituted benzofurans catalytically with palladium(II) acetate, but 2-allyl-1-naphthol (**1d**) afforded polymeric material probably because of its oxidation with oxygen. In the catalytic reaction it should be noted that 2-(2′-butenyl) phenol (**1b**) gave 2,3-dihydro-2-vinylbenzofuran (**8a**) exclusively with a trace amount of 2-ethylbenzofuran (**2b**). Furthermore, 2-(2′-cyclohexenyl)phenol (**1h**) gave **8b** exclusively. (Scheme 2).



Scheme 2.

The exclusive formation of **8a** is probably due to the excess amount of **1b** to palladium(II) acetate as already shown in Table 4, although the influence of cupric salt cannot be neglected.[8] Mechanistic detail is not yet clear at present, but exclusive formation of **8a** in *the catalytic reaction* indicates that the β-hydrogen elimination occurs preferentially from the methyl group in **6b** as shown in Scheme 2. Thus, it is reasonable to suppose that the hydrogen on the C-2 carbon in **6b** is to take *trans*-configuration to palladium, since *cis*-palladium hydride eliminations are generally accepted.[9] In other words, the present catalytic reaction conceivably proceeds *via* a *cis*-oxypalladation step.

Exclusive formation of **8b** in the catalytic reaction of **1h** is also explained by the *cis*-oxypalladation followed by *cis*-elimination of a hydridopalladium species. *cis*-Oxypalladation of **1h** leads to the intermediate **6c** which bears only one *cis*-β-hydrogen to palladium as shown in Scheme 2. The elimination of the hydrogen gives only **8b**.

Experimental

2-Allylphenols 1. 2-Allylphenol (**1a**) and 2-cinnamylphenol (**1c**) were prepared by the method described in the literature.[10] 2-Allyl-1-naphthol (**1d**) and 1-allyl-2-naphthol (**1e**) were prepared by heating the corresponding allyloxynaphthalenes at 210—230 °C for 1 hr according to the method of Claisen.[11,12] 2-(2′-Cyclohexenyl)phenol (**1h**) was prepared by heating cyclohex-2-enyl phenyl ether in *N*,*N*-diethyl aniline

at 200—215 °C for 30 min.[13] 2-(α,α-Dimethylallyl)phenol (**1g**) was prepared from 3-methylbut-2-enyl phenyl ether according to the method of Vdovtsova[14] and purified by preparative glc.

2-(2′-Butenyl)phenol (**1b**) and 2-(2′-methyl-2′-butenyl)phenol (**1f**) were synthesized by C-alkylation of sodium phenoxide with crotylbromide and 1-bromo-2-methylbut-2-ene[15], respectively, according to the procedure of Hurd and Hoffman.[16] (2′-Butenyl)phenol (**1b**) was obtained in a mixture of *trans* and *cis*-isomers on a ratio of 1.9:1. 2-(2′-Methyl-2′-butenyl)phenol (**1f**) was obtained in a mixture of *trans* and *cis*-isomers on the ratio of 4.5:1. **1f** *trans-dimethyl*, NMR, δ 1.59 (broad s, 3H), 1.63 (nearly dd, $J=7$ and 1 Hz, 3H), 3.30 (broad s, 2H), 5.13 (broad s, 1H), 5.15—5.56 (m, 1H), and 6.53—7.20 (m, 4H). (Found: C, 81.04; H, 8.93%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%). **1f** *cis-dimethyl*, NMR, δ 1.62 (nearly dd, $J=1.5$ and 2.0 Hz, 3H), 1.74 (broad d, $J=7$ Hz, 3H), 3.38 (broad s, 2H), 4.82—5.10 (m, 1H), 5.48 (nearly q, $J=7$ Hz, 1H), and 6.50—7.18 (m, 4H). (Found: C, 81.00; H, 8.78%. Calcd for $C_{11}H_{14}O$: C, 81.44; H, 8.70%).

General Procedure for Stoichiometric Cyclization. A suspension of allylphenol **1** (5 mmol) and sodium methoxide (5 mmol) in dry benzene (50 ml) was stirred at room temperature under argon atmosphere. Dark green or blue coloration developed after 1—2 day's stirring. Dichlorobis(benzonitrile) palladium (5 mmol) was added into the suspension. The mixture was slowly heated to reflux for 3 hr. Palladium black gradually precipitated. After filtration of palladium black, the filtrate was concentrated *in vacuo* to leave reddish oil which was distilled under reduced pressure. Generally, distillation gave a mixture of benzonitrile and cyclized product, but the following products were separated from benzonitrile by distillation; bp **2c**, 94—95 °C/4 mmHg, **2d**, 70—72 °C/6 mmHg, and **2e**, 90 °C/8 mmHg. Analytically pure samples were obtained by preparative glc using 10% PEG 20 M–Celite or Apiezon L–Celite column. Elemental analyses and spectral data of the products are listed in Tables 2 and 3.

Cyclization of 2-(1′-Propenyl)phenol (7a) and 2-Styrylphenol (7b). 2-1′-Propenyl)phenol was prepared by isomerization of 2-allylphenol.[10] 2-Hydroxystilbene was synthesized by the procedure of Kauffman.[17]

The cyclization reaction was carried out by the same procedure described above. The yield of the product **2a** (17%) was determined by glc and NMR analyses. Sodium salt of **7b** (0.50 g, 2.5 mmol) was treated by the same procedure. The product was separated by column chromatography on alumina. Elution with benzene gave colorless crystals of **2i** (0.10 g, 20%) which was recrystallized from petroleum ether, mp 120—121 °C (lit,[18] 120 °C). (Found: C, 86.55; H, 5.10%. Calcd. for $C_{14}H_{10}O$: C, 86.57; H, 5.19%). From a fraction eluted by ether and methanol, 2-styrylphenol (0.24 g) was recovered.

General Procedure for Catalytic Cyclization. A suspension of allylphenol **1** (10 mmol) in methanol (25 ml) and water (2 ml) was stirred at ~55 °C for 24 hr in the presence of $Pd(OAc)_2$ (0.2 mmol) and $Cu(OAc)_2 \cdot H_2O$ (5 mmol) under slow stream of oxygen. After filtration, the solution was diluted with water, extracted with ether, and dried over magnesium sulfate and the solvent was removed. The cyclized product was separated by distillation under reduced pressure and was analyzed by glc and NMR analyses. In some cases, the starting phenol was removed by washing the distillate with Claisen's alkali. Analytically pure samples were obtained by preparative glc. The yields of the products and the conversions of the starting materials are given in Table 5. Specific results were described below.

Reaction of 1b. **1b** (*trans*/*cis*=1.9/1) was treated by the general procedure. The product **8a** was separated by distillation (bp 75 °C/4 mmHg). The NMR spectrum of **8a** was identical with the reported data.[19]

Reaction of 1h. **1h** was treated by the general procedure. The distillate was washed four times with Claisen's alkali, extracted with ether, washed with water, and dried over magnesium sulfate. Evaporation of ether gave a colorless oil which was only **8b** by glc analysis. Distillation gave pure **8b**, bp 109—110 °C/3 mmHg. **8b**, NMR, δ 1.4—2.4 (m, 4H), 3.28 (m, 1H), 4.85 (dd, $J=8$ and 2 Hz, 1H), 5.90 (m $J=2$ Hz, olefinic H), 6.69 (phenyl, 2H), and 6.98 (phenyl, 2H); IR, 1650 cm^{-1} (C=C); Mass *m/e* 172; Found: C, 83.44; H, 7.00%. Calcd for $C_{12}H_{12}O$: C, 83.67; H, 7.02%. The assignment of the structure **8b** was supported by double irradiation experiment in NMR. The signal of the tertiary proton (H_a) adjacent to oxygen atom (δ 4.85) was simplified by double irradiation at the signal of the other tertiary proton (H_b) to show a doublet ($J=2$ Hz). Also, the irradiation of olefinic proton (δ 5.90) simplified the signal of H_a to show clearly a doublet ($J=8$ Hz). Double irradiation of H_a proton transformed the signal of H_b from a multiplet to nearly double doublet ($J=4$ and 8 Hz). The irradiation at δ 1.99 (one of protons on cyclohexene ring) simplified the multiplet of H_b proton to show nearly triplet ($J=8$ Hz).

Reaction of 2-γ-Methylallylphenol (1b) with Palladium(II) Acetate. Palladium(II) acetate was allowed to react with various amounts of **1b** in methanol–water at 55 °C for 30 min. In each run the crude reaction mixture was analyzed by glc (flame ionization detector, 5% PEG-20M on Gas Chrom Q, lm) with biphenyl as an internal standard.

(Received July 8, 1974)

In order to characterize the intrinsic nature of 10-hydroxy-11-hydroxyimino[20]paracyclophane (Oxime-I) as being an enzyme model, the acylation reactions of Oxime-I with *p*-nitrophenyl carboxylates have been investigated in an alkaline aqueous acetone. The usual saturation-type kinetics has been observed for the reactions of *p*-nitrophenyl decanoate (PNPD), laurate (PNPL), and palmitate (PNPP) with Oxime-I. The acyl transfer reaction was consistent with the following two sequences: (1a) pre-equilibrium formation of the inclusion complex between Oxime-I and a substrate, (1b) pre-equilibrium acid dissociation of the inclusion complex, and (1c) rate-determining acyl transfer from a substrate to Oximate-I in the inclusion state; and (2a) pre-equilibrium acid dissociation of Oxime-I, (2b) pre-equilibrium formation of the inclusion complex between Oximate-I and a substrate, and (2c) rate-determining acyl transfer from a substrate to Oximate-I in the inclusion state. On the basis of the compensation correlation between enthalpy and entropy for binding process, the inclusion of a long chain carboxylate into the cavity of Oxime-I is controlled by entropy. It is interesting to note that the binding constants for the present inclusion complexes are considerably larger ($K \simeq 10^4 - 10^5\ M^{-1}$) than those for the complexes formed between phenyl esters or azo dyes and cycloamyloses ($K \simeq 10^2 - 10^3\ M^{-1}$). Thus, the paracyclophane skeleton provides an effective binding site due to the hydrophobic cavity. Since the most stable inclusion complex was formed with PNPD, the inclusion of the present esters may be not exclusively due to the hydrophobicity provided by an apolar hydrocarbon tail, but significantly due to the molecular geometry or bulkiness characterized by the folded ester molecule. This effect approves the presence of substrate specificity due to the molecular geometry for Oxime-I. In reference to the activation parameters, the acyl transfer process is controlled by entropy in a manner similar to the alkaline hydrolysis in the bulk phase and the complex formation as well. PNPP is least stabilized in the binding process due to the most unfavorable entropy effect, whereas most favorably deacylated in the acyl transfer due to the entropy factor. Consequently, the net change in the free energy is largely reflected on the entropy term. The deceleration effect observed in the reaction of PNPD with Oxime-I at a higher acetone content and the kinetic behavior of alkaline hydrolysis of the three carboxylate esters have also been discussed.

Micellar surfactants,[1] synthetic water-soluble polymers carrying various functional groups,[2] and macrocyclic compounds[3] are the three major types of enzyme models recently developed. Of these three model systems, macrocyclic compounds may exhibit several unique characters which can never be expected for other two systems: 1) a steady binding site provided by a characteristic ring conformation of hydrophobic nature; 2) a high substrate specificity brought about by the geometric requirements for binding of substrates into these macrocyclic cavities as well as by spatial geometries of substrate molecules incorporated into these cavities; and 3) a high possibility of introducing a charge relay system or a polyfunctional catalytic one, which is provided by the spatial arrangement of appropriate functional groups. Consequently, a well-designed macrocyclic compound may exhibit a catalytic ability more favorably than other types of enzyme models, providing one binding site and one catalytic function for each substrate.

From these view points, we have previously prepared two macrocyclic oximes, 10-hydroxy-11-hydroxyimino-[20]paracyclophane (Oxime-I) and 2-hydroxycyclodecanone oxime (sebacoin oxime, Oxime-II), and investigated their catalytic efficiencies for the deacylation reaction of *p*-nitrophenyl carboxylates.[4,5] The sizable cyclic cavity of Oxime-I provided an appropriate binding site as expected owing to the restricted ring conformation as well as to the hydrophobicity of paracyclophane skeleton. Oxime-I was, thus, acylated by *p*-nitrophenyl laurate (PNPL) and decanoate (PNPD), which were suitably incorporated into the Oxime-I cavity because of their relatively large molecular volume in a folded form. On the contrary, the oxime did not show any catalytic activity toward smaller esters such as *p*-nitrophenyl acetate (PNPA) or hexanoate (PNPH). Oxime-II did not undergo any reaction with all of these esters under the same conditions. In order to characterize the intrinsic nature of Oxime-I as being an enzyme model, we have employed an additional substrate having a longer alkyl chain, *p*-nitrophenyl palmitate (PNPP). On the basis of thorough thermodynamic and kinetic analyses for binding and acyl transfer processes, respectively, the substrate specificity has been elucidated for the inclusion into Oxime-I and for the subsequent acyl transfer reaction.

Experimental

Materials. Cyclic oximes, Oxime-I and -II, and two *p*-nitrophenyl carboxylates, PNPD and PNPL, were the same as those used in our previous investigations.[5] *p*-Nitrophenyl palmitate (PNPP) was commercially obtained from E. Merck, Darmstadt and used after the inspection of its purity (Found: C, 70.06; H, 9.08; N, 3.90%; mp 64.0 °C).

Kinetic Measurements. The rate of liberation of *p*-nitrophenoxide ion was measured at 400 nm either on a Hitachi 124 recording spectrometer or on a Shimadzu-Bausch & Lomb Spectronic 88 equipped with a Riken Denshi SP-G3 recorder. Reactions were initiated by the addition of a substrate dis-

solved in acetone to a reaction solution which was pre-incubated at an appropriate temperature in the thermostatted cell set in the spectrometer. The preparation of stock and reaction solutions, and the measurement procedures were essentially the same as those described previously.[5] The rate constants were checked by duplicate runs and observed to retain an accuracy within ±1%.

pH Measurements. pH-Values of the reaction solutions, which were prepared with 10.9% (v/v) aqueous acetone as the solvent, were measured and calibrated by using two separate buffer solutions in the same solvent, the pH values of which were referred to those measured in the aqueous system. The measurements were carried out either with a TOA HM-9A recording pH meter or a TOA HM-5A pH meter equipped with an attachment for expandomatic reading. Both pH meters were connected with a Metrohm EA-125 combined electrode or a set of Metrome EA-107H glass electrode and Beckman 39402 saturated calomel electrode.

Results and Discussion

As shown in Scheme 1, the present reaction system may be roughly classified into two competitive reactions: the alkaline hydrolysis of a free substrate in the bulk solution and the acyl transfer reaction occurring in the inclusion complex formed between Oxime-I and a substrate.[5] For the reactions of PNPD, PNPL,[5] and PNPP with Oxime-I, the usual saturation-type kinetics has been observed. The rate constant of alkaline hydrolysis k_{hyd} can be separately obtained from the rate measurements in the absence of Oxime-I. Kinetic results obtained for PNPD and PNPP are summarized in Tables 1 and 2, respectively.

$$\begin{array}{ccc} S + \text{Oxime-I} & \overset{K}{\rightleftharpoons} & (S\text{—Oxime-I}) \\ \downarrow k_{hyd} & & \downarrow k_{acyl} \\ P_1 & & P_2 \end{array}$$

Scheme 1.

Alkaline Hydrolysis of p-*Nitrophenyl Carboxylates.* In the absence of cyclic oximes, *p*-nitrophenyl carboxylates undergo usual hydrolytic decomposition through the hydroxide ion catalysis. The rate of alkaline hydrolysis of carboxylates having a long hydrocarbon chain was largely inhibited with increasing the chain length as previously indicated by Menger and Portnoy:[6] $k_{hyd}=4.47\times10^{-3}$ s^{-1} at pH 10.71 for PNPD, 1.41×10^{-4} s^{-1} at pH 10.31 for PNPL,[5] and 7.24×10^{-5} s^{-1} at pH 10.71 for PNPP (at 43.1 °C), respectively, among which the values for PNPD and PNPP were estimated by the aid of activation energies. A large decrease in the hydrolysis rate along with the extension of hydrocarbon chain is readily explained by the self-aggregation effect due to hydrophobic interaction. The ester carbonyl group, as being the reaction center, is presumably shielded from the attack of a nucleophile by the hydrophobic aggregation. The hydrolysis rate of these esters was retarded also with increasing the initial concentration[6] due to the similar reason. In this work, therefore, we have maintained the initial ester concentration at about 1.0×10^{-5} M, where a small change in the ester concentration gives off a

relatively minor effect on the hydrolysis rate[6] and the linearity of first-order plot is good at least for the first half-life (rate data given in Table 3).

The base-catalyzed hydrolysis rate is in general subjected to the second-order kinetics. In the present cases, however, the overall rate was not observed to depend on hydroxide ion concentration linearly as seen in Fig. 1. The rate becomes less dependent on hydroxide concentration either by decreasing the reaction temperature or by increasing the length of hydrocarbon chain of substrates. Though convincing evidence is not available at present, the self-aggregation would be favored with decreasing temperature and increasing hydrocarbon chain length, and subsequently the reaction center would be more completely encased and protected from the attack of nucleophile. As a result, the simple bimolecular mechanism with participation of hydroxide ion may be no longer observed. These effects must be reflected on the entropy of activation in terms of solvation and molecular mobility. As is clear from the apparent activation parameters listed in Table 4 for the hydrolysis of PNPD and PNPP obtained at pH 10.71, the reaction is more effectively controlled by the entropy term along with the extension

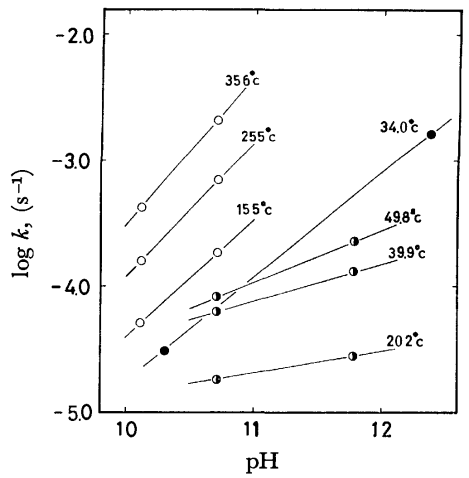

Fig. 1. pH-rate correlations for alkaline hydrolysis of PNPD (○), PNPL (●), and PNPP (◑) at various temperatures: solvent, 10.9% (v/v) aqueous acetone; μ=0.10 (KCl) (refer to Tables 1 and 2).

	11.78	20.2	0.28	29.7	51.3

a) Parameters were calculated from the data listed in Table 1 or 2 by the aid of Eq. (1). b) Data were quoted from Ref. 5. pH-Values have been reevaluated according to the present procedure. c) Values in parentheses may involve a sizable error due to computational means.

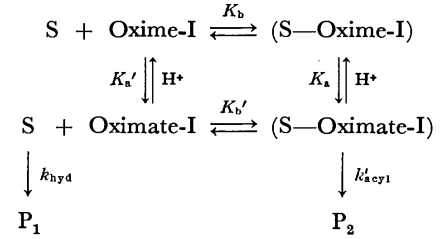
Table 4. Apparent activation parameters for alkaline hydrolysis of *p*-nitrophenyl carboxylates[a)]

Substrate	pH	$\Delta H^{\ddagger}_{hyd}$ kcal/mol	$\Delta S^{\ddagger}_{hyd}$ e.u.	$\Delta G^{\ddagger}_{hyd}$ (303 K) kcal/mol
PNPD	10.12	18.0	−14.9	22.5
	10.71	21.2	−1.7	21.7
PNPP	10.71	10.6	−44.0	24.0
	11.78	11.5	−39.7	23.6

a) Solvent, 10.9% (v/v) aqueous acetone; μ=0.10 (KCl). These apparent activation parameters were evaluated directly from the overall rate constants listed in Tables 1 and 2. The true second-order rate constants were not evaluated due to some difficulty in estimating hydroxide-ion effect (see Fig. 1).

of alkyl chain. The loss of free energy of activation ($\Delta\Delta G^{\ddagger}_{hyd}$) per methylene unit (see Fig. 3) is estimated approximately as 370 cal mole^{-1}. This value, which is due to the contribution from hydrophobic interaction,[7)] is very close to that observed for the aminolysis of phthalic anhydride with amines of long alkyl chain,[8)] where the rate enhancement was observed with increasing hydrophobic character of nucleophiles. Thus, it is clear that the hydrophobicity of an apolar hydrocarbon tail of esters gives out a large effect on their hydrolytic reactivities.

Formation of Inclusion Complex and Subsequent Acyl Transfer Reaction. In the presence of Oxime-I, the inclusion of a *p*-nitrophenyl ester of carboxylate with a long alkyl chain into the cyclic cavity takes place prior to the acyl transfer from the carboxylate to Oxime-I[5)] as represented in Scheme 1. The driving force for the inclusion of a substrate was primarily attributed to the hydrophobic interaction between the alkyl chain of a substrate and the paracyclophane skeleton of Oxime-I, which has been verified by the effects of organic solvent and added urea on the kinetic behavior.[5)]



P_1: carboxylate and *p*-nitrophenolate ions
P_2: acylated Oxime-I and *p*-nitrophenolate ion

Scheme 2.

As pointed out in our previous paper,[5)] the acyl transferring rate is dependent on pH of the medium. Thus, it seems reasonable to establish the whole reaction sequences in more critical manner as shown in Scheme 2. This means that the real nucleophile is not the neutral oxime but the oximate group of Oxime-I in the inclusion complex. As a consequence, the equilibrium constants and the specific rate constant for acyl transfer defined in Scheme 2 can be evaluated by the aid of Eq. (1), the derivation of which is given in Appendix.

$$\frac{1}{k_{obs}-k_{hyd}} = \frac{\left(\frac{1+\beta}{1+\alpha}\right)+K_b[S]_T}{\left(\frac{1}{\gamma}k'_{acyl}-k_{hyd}\right)K_b[C]_T} + \frac{1}{\left(\frac{1}{\gamma}k'_{acyl}-k_{hyd}\right)} \quad (1)$$

and $\alpha = \frac{K_a}{[H^+]}$, $\beta = \frac{K_a'}{[H^+]}$, and $\gamma = \frac{[H^+]}{K_a} + 1$,

where k_{obs} is the observed pseudo-first-order rate constant, and $[S]_T$ and $[C]_T$ stand for the total concentrations of substrate and Oxime-I, respectively. Thus, a good linear relationship must be obtained by plotting the left-hand side of Eq. (1) against the reciprocal initial concentration of Oxime-I, when the initial concentration of substrate and pH of the reaction medium are maintained constant. Since $(1/\gamma)k'_{acyl}$ is obtained as a constant value from Eq. (1), K_a and k'_{acyl} can be evaluated by Eq. (2).

$$k = \frac{\gamma}{k'_{acyl}} = \frac{[H^+]}{K_a k'_{acyl}} + \frac{1}{k'_{acyl}} \quad (2)$$

In fact, all the kinetic data were satisfactorily analyzed by the aid of Eqs. (1) and (2). This seems to validate the reaction sequences given in Scheme 2.

Table 5. Thermodynamic parameters for binding of *p*-nitrophenyl carboxylates with Oxime-I[a)]

Substrate	pH	$\Delta G^{\circ}_{303\,K}$ kcal/mol	ΔH° kcal/mol	ΔS° e.u.
PNPD	10.12	−8.01	−11.97	−13.06
	10.71	−7.96	−12.07	−13.55
PNPL	12.37	−7.50	−14.4	−22.8
PNPP	10.71	−7.65	−16.2	−28.2
	11.78	−7.32	−16.1	−28.9

a) Solvent, 10.9% (v/v) aqueous acetone; μ=0.10 (KCl).

Binding constants and the corresponding thermodynamic parameters for the combination of Oxime-I either with *p*-nitrophenyl decanoate or palmitate are listed in Tables 3 and 5, respectively, along with those for the combination of the oxime with *p*-nitrophenyl laurate previously investigated[5)] upon re-evaluation by Eqs. (1) and (2). The binding constants for these inclusion complexes are considerably larger ($K \simeq 10^4 - 10^5$ M^{-1}) than those for the complexes formed between phenyl esters[9-11)] or azo dyes[12)] and cycloamyloses ($K \simeq 10^2 - 10^3$ M^{-1}). The difference is also reflected on the respective reaction conditions: only equimolar or twice molar amount of Oxime-I relative to the substrate was used to gain a significant catalytic effect, while the cycloamyloses were required in a large excess (about 10^3 fold).[9,10)] The free energy change due to binding is in a range of −3——5 kcal mol^{-1} for the cyaloamylose system,[9,11)] while −7——8 kcal mol^{-1} for the Oxime-I system. This means that the paracyclophane skeleton provides a more favorable binding site due to the hydrophobic cavity.

The inclusion of the esters into Oxime-I is considerably dependent on the temperature: the binding constant becomes larger with decreasing the reaction temperature (negative enthalpy change). Such a negative temperature dependency of binding has also

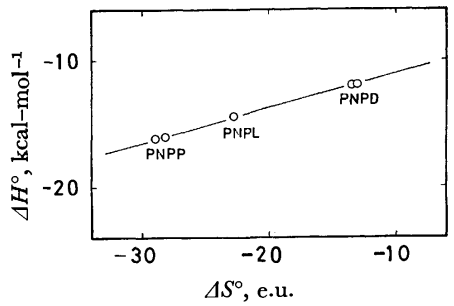


Fig. 2. Isoequilibrium relationship for binding of *p*-nitrophenyl carboxylates with Oxime-I (refer to Table 5).

been noticed for the systems of cycloamyloses[9-12] and of chymotrypsin.[13,14] A different state of affairs has been observed previously:[15,16] the hydrophobic binding increases with increasing temperature. Thus, the positive enthalpy change reported in those studies is not an intrinsic nature of hydrophobic interaction, and the binding behavior is apparently much affected by the nature of host molecules.

There exists a good linear compensation effect between enthalpy and entropy for binding as shown in Table 5 and Fig. 2. Also for the binding process, a considerably low isoequilibrium temperature (β=265 °K) was obtained. This β-value suggests that the inclusion of a long chain carboxylate into the cavity of Oxime-I is certainly controlled by entropy at ordinary temperatures[17] (see Table 5). We can see an analogous compensation effect between enthalpy and entropy in binding process of cycloamyloses with various pseudo-substrates.[18]

We have to notice that the binding stability in terms of free energy change is indicative of the strength of hydrophobic interaction and/or of the structural specificity existing between host and guest molecules. Table 5 indicates that the decanoate ester shows the largest binding stability among three carboxylates (PNPD, PNPL, and PNPP); *i.e.*, the most stable inclusion complex is formed with PNPD. If the binding force is due only to the hydrophobicity, the palmitate ester having the longest apolar tail would be expected to be most strongly bound judging from their reactivities in alkaline hydrolysis. The release of bound water from the catalyst may cause the entropy gain. A substrate molecule, which is more tightly bound with a host molecule, is expected to release more water molecules than those loosely bound, giving off the larger entropy gain. However, this is not the case for the complex formation between PNPD and Oxime-I. The relatively large enthalpy change given out in the binding process seems, therefore, not to be due to the release of bound water in the cavity of Oxime-I. These explanations lead to a conclusion that the inclusion of the present esters may be not exclusively due to the hydrophobicity provided by an apolar hydrocarbon tail, but significantly due to the molecular geometry or bulkiness characterized by the folded ester molecule[5] which is tightly fitted into the cavity. This effect approves the presence of substrate specificity due to the molecular geometry for Oxime-I. Moreover, the enthalpy of binding is evidently insensitive to the pH-value of bulk phase. This fact implies that the intrinsic binding force may be not due to electrostatic interactions such as hydrogen bonding (>C=N-OH··· O=C<) or dipole-ion interaction (>C=N-O$^-$···>C=O).

Investigations dealing with the acyl transfer *via* complex formation between acyl-substrate and nucleophilic catalyst have been recently carried out: *e.g.*, aminolysis of *p*-nitrophenyl decanoate with *n*-decylamine,[16,17] and of phthalic anhydride with various amines having a long alkyl chain.[8] The acyl transfer from a carboxylate ester to cycloamyloses involves the nucleophilic participation of an alkoxide ion derived from the secondary hydroxyl groups of the cycloamyloses.[9-11] A similar mechanistic behavior is considered to take place in the present acyl transfer reaction between a *p*-nitrophenyl carboxylate and an oxime nucleophile. However, in the case of cycloamyloses the subsequent deacylation proceeds at a significantly large rate, while hardly detected in the case of Oxime-I because of the inertness of the acylated oxime to deacylation reaction.[5] Therefore, the present acyl transfer assumes a pseudo-intramolecular mechanism as observed in some aminolysis reactions.[8,16,19]

Kinetic parameters obtained are listed in Table 6 along with their activation parameters calculated from the true rate constants for ac l transfer. Acid dissociation constants for the complexed Oxime-I, which were kinetically estimated (pK_a 10—12), are reasonable in magnitude in reference to that for acetoxime (pK_a 12.4[20]) since an additional substituent effect due to the neighboring hydroxyl group may act in favor

Table 6. Kinetic, thermodynamic, and activation parameters for acyl transfer occurring in the inclusion complexes between Oxime-I and *p*-nitrophenyl carboxylates[a]

	Temp. °C	K_a M^{-1}	pK_a	k'_{acyl} s^{-1}	$\Delta H^{\neq}$ kcal/mol	$\Delta S^{\neq}$ e.u.	$\Delta G^{\neq}$ (303 K) kcal/mol
PNPD	35.6	11.03×10^{-11}	9.99	5.52×10^{-3}			
	25.5	12.57×10^{-11}	9.90	1.86×10^{-3}	17.7	−11.5	21.2
	15.1	7.68×10^{-11}	10.11	0.82×10^{-3}

	34	4.29×10^{-12}	11.4	7.80×10^{-3}			
PNPP	49.8	2.25×10^{-12}	11.7	108×10^{-3}			
	39.9	2.14×10^{-12}	11.7	44.5×10^{-3}	17.6	−8.6	20.2
	20.2	7.62×10^{-13}	12.1	9.44×10^{-3}			

a) Kinetic and thermodynamic parameters were obtained from the data listed in Table 3 by the aid of Eq. (2).

of the liberation of oxime proton. The acid dissociation of the PNPD–Oxime-I complex is favored relative to the other, two substrate–Oxime-I system. Since the PNPD–Oxime-I complex is formed by the entropically favored inclusion process (see Table 5), this complex is presumably solvated by water molecules in a more feasible manner for the proton transfer without much destruction of the ice-berg.

On the other hand, their activation parameters show characteristic behavior: the enthalpy of activation is equal to each other among all the substrates while the entropy of activation varies in an decreasing sequence of PNPP, PNPL, and PNPD. These results suggest that the acyl transfer process in the inclusion complexes is controlled by entropy in a manner similar to the alkaline hydrolysis in the bulk phase and the complex formation as well. The palmitate ester, which is least stabilized in the binding process due to the most unfavorable entropy effect, is most favorably deacylated in the acyl transfer process due to the entropy factor.

Catalytic Effect and Substrate Specificity. Clearly from Scheme 1, the catalytic effect of Oxime-I on the acyl transfer reaction can not be simply discussed in terms of the rate ratio k_{obs}/k_{hyd}, because the acyl transfer and the alkaline hydrolysis are rather competitive reactions mutually. Therefore, the reactivity of Oxime-I is compared with that of a smaller cyclic oxime (Oxime-II), which has the same catalysis site as Oxime-I, as previously suggested.[5] The catalytic specificity of Oxime-I for the acyl transfer is defined in terms of $k_{c(Oxime-I)}/k_{c(Oxime-II)}$, where k_c is the apparent catalytic rate constant given by Eq. (3).

$$k_c = \frac{k_{obs} - k_{hyd}}{[\text{Oxime-I or -II}]} \qquad (3)$$

The catalytic specificity obtained under the controlled reaction conditions for the different carboxylate esters of *p*-nitrophenol is shown in Table 7.

Table 7. Catalytic effects of Oxime-I and -II on the *p*-nitrophenyl carboxylates[a]

[Subtrate] $\times 10^5$ M	[Oxime] $\times 10^5$ M	$k_{obs}\times 10^4$ s^{-1}	k_c $s^{-1}M^{-1}$	Rate[b] ratio
PNPA: 1.09	II: 17.5	22.8	0.86	
	II: 1.90	22.6	6.83	1.4
	I: 1.96	23.1	9.20	
PNPD: 1.03	II: 17.5	4.30	0.02	
	II: 1.90	4.30	0.15	420
	I: 1.96	16.8	62.8	
PNPL: 1.00	II: 17.5	0.77	0.05	
	II: 1.90	0.70	0.05	1420
	I: 1.96	15.3	73.2	
PNPP: 1.02	II: 17.5	0.11	0.07	
	II: 1.90	0.11	0.04	1520
	I: 1.96	12.6	62.6	

a) All runs were carried out at 23.5 °C and pH 9.23 (0.03 M $Na_2B_4O_7$) in 10.9% (v/v) aqueous acetone. The rate constants for alkaline hydrolysis of these esters were 21.3×10^{-4}, 4.27×10^{-4}, 0.69×10^{-4}, and 0.10×10^{-4} s^{-1} for PNPA, PNPD, PNPL, and PNPP, respectively, under the present reaction conditions. b) $k_{c(Oxime-I)}/k_{c(Oxime-II)}$, see text.

For a small substrate, *p*-nitrophenyl acetate, both Oxime-I and -II did not show any significant rate enhancement. On the other hand, for larger three esters, PNPD, PNPL, and PNPP, the large rate acceleration in acyl transfer has been observed with Oxime-I, particularly for the latter two esters. These rate accelerations by $1.4—1.5\times 10^3$ fold must be brought about by incorporation of the substrate into the Oxime-I cavity, which results in a pseudo-intramolecular reaction. In other words, the rate enhancement is due neither to a simple hydrophobic entanglement nor to a bimolecular reaction between the substrate and the paracyclophane oxime. Since little effect has been observed on the reaction rate even in the presence of 10 fold excess amount of Oxime-II, there is apparently no significant interaction between the substrates and the smaller cyclic oxime. Consequently, the difference in reactivity between these two cyclic oximes needs to be explained in terms of the correlations between the cavity size of a host molecule and the molecular volume of a substrate in the included state, and of their hydrophobic nature as well. When the folded substrate[5] is effectively incorporated into the cavity, the spatial orientation of the nucleophilic site in the oxime against the carbonyl carbon of the substrate is certainly an important factor to control the subsequent acyl transfer process. This orientation effect seems to be subjected to variation due to the molecular size of an incorporated substrate.

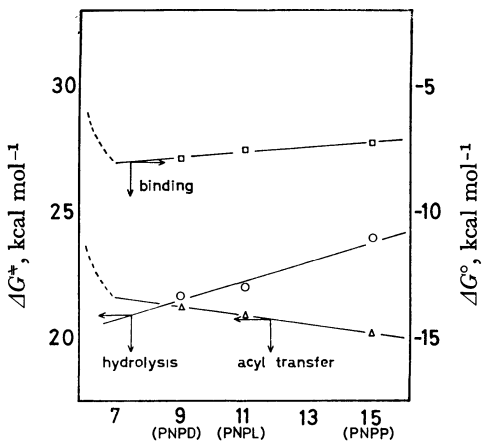

Fig. 3. Correlations between the structure of substrates and free energy changes: binding process of *p*-nitrophenyl carboxylates with Oxime-I (refer to Table 5); acyl transfer process of carboxylates to Oxime-I in the inclusion state on the basis of Scheme 2 (refer to Table 6); alkaline hydrolysis of carboxylates in the bulk solution at pH 10.71 for PNPD and PNPP and 12.37 for PNPL[5] (refer to Table 4).

It is interesting to examine the differences in reactivity in terms of thermodynamic parameters. Figure 3 shows that there are no large differences in free energies of binding among three esters examined, but that the free energy of activation for alkaline hydrolysis increases while that for acyl transfer somewhat decreases with increasing the chain length of acyl residues. A schematic representation for the correlations between relative potential energy due to free energy change and reaction

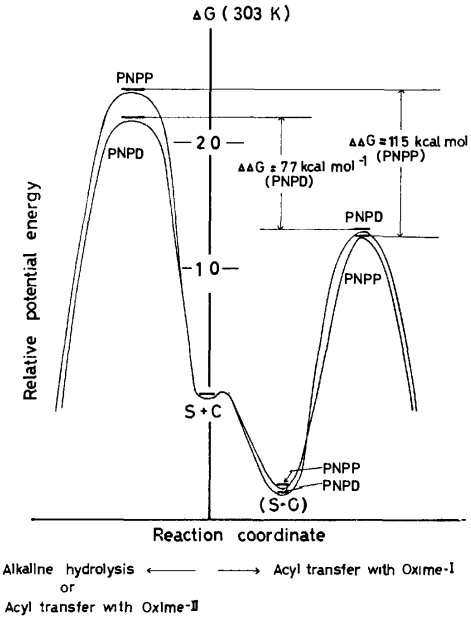

Fig. 4. Reaction coordinate diagram for alkaline hydrolysis and acyl transfer reactions of PNPD and PNPP at 303 K: relative potential energy is represented in free energy change.

coordinate for the two competitive reactions is illustrated in Fig. 4. The activation free energy values for the two carboxylate esters adopted in Fig. 4 in alkaline hydrolysis and acyl transfer reaction are based on Scheme 2 (refer to Tables 4 through 6) so that both reactions can be compared on the equal basis: the difference in $\Delta\Delta G$ between PNPP and PNPD is about 3.8 kcal mol^{-1} at 303 K and pH 10.71.

Deceleration in the Reaction of p-*Nitrophenyl Decanoate with Oxime-I.* Different from the reactions of PNPL and PNPP with Oxime-I, the liberation of *p*-nitrophnoxide ion in the case of PNPD and Oxime-I was somewhat inhibited at a higher acetone content (20.8% (v/v)) with increasing the reaction temperature as illustrated in Fig. 5. An increase in acetone content may cause the decrease in hydrophobicity of the substrate itself, which results in a rate acceleration of the alkaline hydrolysis in the bulk solution.[6] Of course, the decrease in hydrophobicity of the substrate may somehow tend to decrease the binding constant.[5] However, the effect on the binding process is not necessarily large and even some compensation effect comes into play in the subsequent acyl transfer process. As a result, the large rate enhancement for the alkaline hydrolysis in the bulk phase seems to exceed the deacylation in the Oxime-I complex. Therefore, under these circumstances substrate specificity for acyl transfer seems to be more distinctly observed. A similar inhibition phenomenon has been observed in the hydrolysis of ethyl *p*-aminobenzoate in the presence of *β*-cycloamylose.[21]

Appendix

Determination of Kinetic and Thermodynamic Parameters for Saturation-type Kinetics. The kinetic and thermodynamic parameters given in Scheme 2 have been evaluated by the aid of Eq. (1). The derivation of this equation is given below.

At the beginning, the abbreviations are made as follows:

S: a substrate species.

C: all the Oxime-I species.

CH: Oxime-I with a undissociated oxime proton.

C$^-$: Oxime-I with an anionic oximate group (Oximate-I in Scheme 2).

S–CH: a substrate–Oxime-I inclusion complex with a undissociated oxime proton (S–Oxime-I in Scheme 2).

S–C$^-$: a substrate–Oxime-I inclusion complex with an anionic oximate group (S–Oximate-I in Scheme 2).

Mass balances in consistent with Scheme 2 are established as follows.

$$[S]_T = [S] + [S\text{–}CH] + [S\text{–}C^-] \quad (4)$$

$$[C]_T = [CH] + [C^-] + [S\text{–}CH] + [S\text{–}C^-] \quad (5)$$

Relevant equilibrium constants are also given.

$$K_a = \frac{[S\text{–}C^-][H^+]}{[S\text{–}CH]} \quad (6); \qquad K_a' = \frac{[C^-][H^+]}{[CH]} \quad (7)$$

$$K_b = \frac{[S\text{–}CH]}{[S][CH]} \quad (8); \qquad K_b' = \frac{[S\text{–}C^-]}{[S][C^-]} \quad (9)$$

Through combination of Eqs. (4), (5), (6), and (8), the following relation is derived.

$$\begin{aligned}[S\text{–}C^-] &= \frac{K_a}{[H^+]}[S\text{–}CH] = \frac{K_a}{[H^+]}K_b[S][CH] \\ &= \frac{K_a}{[H^+]}K_b\{[S]_T - [S\text{–}CH] - [S\text{–}C^-]\} \\ &\quad \times\{[C]_T - [S\text{–}CH] - [S\text{–}C^-] - [C^-]\} \\ &= \frac{K_a}{[H^+]}K_b\left\{[S]_T - \left(\frac{[H^+]}{K_a}+1\right)[S\text{–}C^-]\right\} \\ &\quad \times\left\{[C]_T - \left(\frac{[H^+]}{K_a}+1\right)[S\text{–}C^-] - [C^-]\right\}\end{aligned}$$

Thus, this leads to the following expression.

$$\begin{aligned}[S\text{–}C^-] &= \alpha K_b\{[S]_T - \gamma[S\text{–}C^-]\} \\ &\quad \times\{[C]_T - \gamma[S\text{–}C^-] - [C^-]\}\end{aligned} \quad (10)$$

where $\alpha = K_a/[H^+]$ and $\gamma = ([H^+]/K_a)+1$.

On the other hand, Eqs. (5) and (7) give

$$[C^-] = \frac{K_a'}{[H^+]}[CH] = \frac{K_a'}{[H^+]}\{[C]_T - [S\text{–}CH] - [S\text{–}C^-] - [C^-]\}$$

Thus,

$$[C^-] = \beta\{[C]_T - \gamma[S\text{-}C^-]\} - \beta[C^-]$$

where $\beta = K'_a/[H^+]$.

Rearrangement results in the following relation.

$$[C^-] = \frac{\{[C]_T - \gamma[S\text{-}C^-]\}\beta}{1+\beta} \quad (11)$$

Combining Eqs. (10) and (11),

$$[S\text{-}C^-] = \alpha K_b\{[S]_T - \gamma[S\text{-}C^-]\} \times \left\{[C]_T - \gamma[S\text{-}C^-] - \frac{\beta\{[C]_T - \gamma[S\text{-}C^-]\}}{1+\beta}\right\}$$

Then,

$$(1+\beta)[S\text{-}C^-] = \alpha K_b\{[S]_T[C]_T - \gamma[S\text{-}C^-][S]_T - \gamma[S\text{-}C^-][C]_T + \gamma^2[S\text{-}C^-]^2\} \quad (12)$$

Since $[S]_T[C]_T \gg \gamma^2[S\text{-}C^-]^2$ is valid, under present experimental conditions,[22] Eq. (12) is simplified as

$$(1+\beta)[S\text{-}C^-] = \alpha K_b[S]_T[C]_T - \alpha K_b\gamma\{[S]_T + [C]_T\}[S\text{-}C^-]$$

This gives the relation as follows.

$$[S\text{-}C^-] = \frac{\alpha K_b[S]_T[C]_T}{1+\beta+\alpha\gamma K_b\{[S]_T+[C]_T\}} \quad (13)$$

The overall rate can be expressed as follows.

$$\begin{aligned} k_{obs}[S]_T &= k_{hyd}[S] + k'_{acyl}[S\text{-}C^-] \\ &= k_{hyd}\{[S]_T - \gamma[S\text{-}C^-]\} + k'_{acyl}[S\text{-}C^-] \\ &= k_{hyd}[S]_T - (k_{hyd}\gamma - k'_{acyl})[S\text{-}C^-] \end{aligned}$$

Upon rearrangement after introduction of Eq. (13) into the above equation,

$$\begin{aligned} k_{obs} - k_{hyd} &= (k'_{acyl} - k_{hyd}\gamma)\frac{\alpha K_b[C]_T}{1+\beta+\alpha\gamma K_b\{[S]_T+[C]_T\}} \\ &= \left(\frac{1}{\gamma}k'_{acyl} - k_{hyd}\right)\frac{K_b[C]_T}{\left(\frac{1+\beta}{1+\alpha}\right)+K_b[S]_T+K_b[C]_T} \end{aligned}$$

Thus, the following equation can be derived from the above reletionship.

$$\frac{1}{k_{obs}-k_{hyd}} = \frac{\left(\frac{1+\beta}{1+\alpha}\right)+K_b[S]_T}{\left(\frac{1}{\gamma}k'_{acyl}-k_{hyd}\right)K_b[C]_T} + \frac{1}{\left(\frac{1}{\gamma}k'_{acyl}-k_{hyd}\right)} \quad (14)$$

22) The first-order rate constants for the overall reaction were recalculated by the use of those evaluated kinetic parameters (K_a, K_b, and k'_{acyl}) on the basis of Eqs. (1) and (2). These calculated rate constants satisfactorily reproduced the experimental correlation between rate constant and total Oxime-I concentration.

Inositol Derivatives. 9. Lithium Aluminum Hydride Reduction of Inositol Epoxides and Their Sulfonates[1]

Tetsuo SUAMI, Seiichiro OGAWA, and Yuji FUNAKI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received September 5, 1974)

The reduction of two dianhydroinositols: 1,2:3,4-dianhydro-5,6-*O*-cyclohexylidene-*allo*-inositol (**1**) and 1,2: 5,6-dianhydro-3,4-*O*-cyclohexylidene-*allo*-inositol (**2**), and four sulfonylated anhydroinositols: 1,2-anhydro-5,6-*O*-cyclohexylidene-3,4-di-*O*-mesyl-*chiro*-inositol (**5b**), 1,2-anhydro-5,6-*O*-cyclohexylidene-3,4-di-*O*-tosyl-*chiro*-inositol (**5c**), 1,2-anhydro-5,6-*O*-cyclohexylidene-4-*O*-tosyl-*neo*-inositol (**6**) and 2,3-anhydro-4,5-*O*-cyclohexylidene-1,6-di-*O*-mesyl-*epi*-inositol (**8**), with lithium aluminum hydride has been investigated.

During a course of synthetic studies on deoxy- and dideoxy-inosadiamines,[2] it became necessary to prepare deoxy- and dideoxy-inositol derivatives. The reductive ring opening of an epoxide in sugars with lithium aluminum hydride ($LiAlH_4$) is an extensively studied reaction[3] which has been often used in a synthesis of deoxy-sugars.[4] However, few works have been done on the $LiAlH_4$ reduction of inositol epoxides.

$LiAlH_4$ reduction of 1,2-anhydro-5,6-*O*-cyclohexylidene-*chiro*-inositol (**5a**)[5] has been described to proceed regioselectively to give the 2-deoxy derivative in 87% yield,[6] and it has been suggested that the remote position in the epoxide from the *O*-cyclohexylidene group was preferentially attacked by the hydride. In the present study, the $LiAlH_4$ reduction of dianhydroinositol and sulfonyl derivatives of anhydroinositols have been attempted.

1,2: 3,4-Dianhydro-5,6-*O*-cyclohexylidene-*allo*-inositol (**1**)[5] was treated with $LiAlH_4$ in refluxing tetrahydrofuran (THF) to give a product (**3a**) in 54% yield, whose structure was established as 2,3-*O*-cyclohexylidene-1,4/2,3-cyclohexanetetrol on the basis of the following results.

Scheme 2.

Reduction of 1,2: 5,6-dianhydro-3,4-*O*-cyclohexylidene-*allo*-inositol (**2**)[5] with $LiAlH_4$ at room temperature gave predominantly 2,3-*O*-cyclohexylidene-1,2,3/4-cyclohexanetetrol (**4a**) in 66% yield. Compound **4a** was characterized by converting it into the dimesyl derivative (**4b**), which revealed two sets of quartets at τ 5.43 and 5.79 in its PMR spectrum. These signals are attributed to the H-2 and H-3 protons and the stereochemistry between C-1 and C-4 has been established as *trans*.

In general, $LiAlH_4$ reduction of a secondary sulfonyloxy group of pyranose causes desulfonylation or desulfonyloxylation to give rise to a corresponding hydroxyl or deoxy derivative. Therefore, 1,2-anhydro-5,6-*O*-cyclohexylidene-3,4-di-*O*-sulfonyl-*chiro*-inositol (**5b**: dimesylate[7] and **5c**: ditosylate[5]) were subjected to the $LiAlH_4$ reduction.

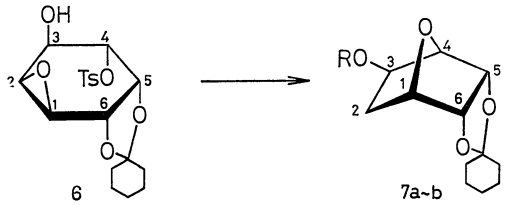
Reduction of **5b** at room temperature gave exclusively 2,3-*O*-cyclohexylidene-1-*O*-mesyl-1,4/2,3-cyclohexanetetrol (**3b**) in 70% yield, which was further converted to the acetyl (**3c**) and dimesyl derivatives (**3d**). The PMR spectrum of **3d** revealed a symmetrical multiplet (the A_2 part of the A_2X_2 system) due to the H-2 and H-3 protons at τ 5.62, which indicated a 1,4-*cis* arrangement of two mesyloxy groups, and thus the structure of **3d** was established. When the reduction was carried out at reflux temperature, **3a** was obtained predominantly in 50% yield. It was observed by tlc analysis that **3b** was formed initially in an earlier stage of the reaction and **3b** was subsequently converted into **3a** by further desulfonylation. The structure of **3a** was tentatively established by this fact.

Under the similar condition at reflux temperature, **5c** gave a monotosyl compound (**3e**) in 64% yield. It was shown that the tosyl group was less susceptible to the reduction than the mesyl group.

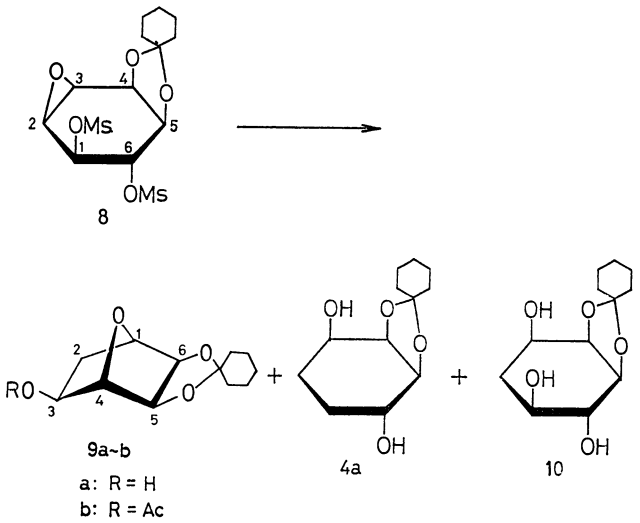
The reaction mechanism of these reductions might be explained as follows: Initially the hydride attacks exclusively on C-2 as in the case of **5a**, leading to the 2-deoxy compound. Then, a neighboring group participation of the hydroxyl group at C-1, probably by way of alumino hydride complex,[3b,8] results in a removal of the sulfonyloxy group on C-3 by a rear-side attack of the hydride giving rise to the dideoxy compounds.

In the above four compounds, the reduction occurred at the remote points from the *O*-cyclohexylidene group and this might be a reflection of the steric effect of the *O*-cyclohexylidene group.[4c,9]

The reduction of 1,2-anhydro-5,6-*O*-cyclohexylidene-4-*O*-tosyl-*neo*-inositol (**6**)[5] and that of 2,3-anhydro-4,5-*O*-cyclohexylidene-1,6-di-*O*-mesyl-*epi*-inositol (**8**)[7] afforded 1,4-anhydro-5,6-*O*-cyclohexylidene-2-deoxy-*allo*-inositol (**7a**) and -*cis*-inositol (**9a**) in 53 and 17% yield respectively.



Scheme 3.



Scheme 4.

The structure of **7a** was deduced from the elementary analysis and PMR spectrum. The C-2 *endo* proton appeared as a quartet at τ 7.29, which was remarkably deshielded by the 5,6-*endo* cyclohexylidene group. Acetylation of **7a** gave the acetyl derivative (**7b**), whose PMR spectrum showed the double doublet due to C-3 *endo* proton at τ 4.56. The formation of **7a** is reasonably explained by a mechanism involving reductive opening of the 1,2-epoxide ring at C-2 in the initial step followed by a transannular nucleophilic substitution by the C-1 hydroxyl group on the C-4 tosyloxy group.[5,10]

The structure of **9a** was also established by the elementary analysis and the well resolved PMR spectrum along with that of its acetyl derivative (**9b**) (Table 1). The coupling constants were shown to be in accordance with those reported for the related compound, *i.e.*, 2,3,5-tri-*O*-acetyl-1,4-anhydro-(2*S*)-2-hydroxyquinate.[11] In the case of **9b**, the double doublet due to the C-3 *endo* proton was upshifted by 0.76 ppm in comparison with that of **7b**, suggesting the presence of the cyclohexylidene group in the *exo* orientation.

Table 1. PMR spectral data of 1,4-anhydro-5,6-*O*-cyclohexylidene-2-deoxy-*cis*-inositol (**9a**) and its acetyl derivative (**9b**) in $CDCl_3$ at 100 MHz

a) Measured on Varian HA-100D (100 MHz) spectrometer. Chemical shifts are given in terms of τ-values, the signals being denoted by s (singlet), d (doublet), dd (double doublet), dt (double triplet), and qd (quartet of doublet). b) Values given for coupling constants are of first-order.

In the case of the reduction of **8**, **9a**, **4a** and 4,5-*O*-cyclohexylidene-2-deoxy-*epi*-inositol (**10**) were obtained in 17, 4.5 and 11% yields, respectively, after fractionation by a column chromatography. The structure of **10** was confirmed by converting it to the known 2-deoxy-*epi*-inositol (**11a**) and its derivative (**11b**).[12] The hydride might attack predominantly on C-2 of **8** to give an intermediary 2-deoxy derivative, from which the three crystalline compounds thus identified are obtained without a big contradiction in a reaction mechanism. That is, desulfonylations of the intermediate afford **10**, and desulfonylation along with desulfonyloxylation gives **4a**. Desulfonylation on the C-1 mesyloxy group and transannular displacement of the C-6 mesyloxy group by the C-3 hydroxyl group yield **9a**.

Experimental

Melting points were determined on a Mitamura Riken micro hot stage and are uncorrected. IR spectra were measured on a JASCO IR-E spectrophotometer in KBr disks. PMR spectra were obtained on a Varian A-60D (60 MHz) spectrometer in deuteriochloroform solution with tetramethylsilane as an internal standard. Chemical shifts are given in terms of τ-values and signals are denoted by s (singlet), d (doublet), dd (double doublet), t (triplet), or m (complex multiplet). All the solutions were concentrated under reduced pressure at 40—50 °C. Tlc was performed on a silica gel plate (Wako-gel B-10, Wako Pure Chemical Industries, Ltd.).

$LiAlH_4$ Reduction of 1,2: 3,4-Dianhydro-5,6-O-cyclohexylidene-allo-inositol (1).[5] To a stirred slurry of $LiAlH_4$ (0.16 g, 3 mol equiv.) in THF (20 ml), was added slowly a solution of **1** (0.30 g) in THF (5 ml), and the reaction mixture was heated under reflux for 30 min. The aluminum complex was then decomposed by addition of water (1 ml). The precipitates were removed by filtration and the filtrate was evaporated to give a crystalline residue which was pulverized with ethanol–*n*-hexane (1: 1, v/v) yielding 0.17 g (54%) of 2,3-*O*-cyclohexylidene-1,4/2,3-cyclohexanetetrol (**3a**): mp 138—139 °C. A part of the product was recrystallized from chloroform–ethanol to give an analytically pure sample, mp 140 °C.

Found: C, 63.12; H, 8.62%. Calcd for $C_{12}H_{20}O_4$: C, 63.13; H, 8.83%.

$LiAlH_4$ Reduction of 1,2: 5,6-Dianhydro-3,4-O-cyclohexylidene-allo-inositol (2).[5] To a stirred slurry of $LiAlH_4$ (80 mg, 3 mol equiv.) in THF (10 ml), a solution of **2** (150 mg) in THF (5 ml) was added, and the agitation was continued for 21 hr at room temperature. The mixture was worked up as described for **1** to give 101 mg (66%) of 2,3-*O*-cyclohexylidene-1,2,3/4-cyclohexanetetrol (**4a**), mp 98—101 °C. A part of **4a** was recrystallized from ethyl acetate–*n*-hexane (1: 2, v/v) to give an analytically pure sample, mp 101—103 °C.

Found: C, 62.91; H, 8.71%. Calcd for $C_{12}H_{20}O_4$: C, 63.12; H, 8.83%.

2,3-O-Cyclohexylidene-1,4-di-O-mesyl-1,2,3,4-cyclohexanetetrol (4b). a) Compound **2** (0.50 g) was treated with $LiAlH_4$ (0.50 g) in THF (12 ml) as described above to give a crude product of **4a**, which was, without any purification, treated with mesyl chloride (0.80 g) in pyridine (5 ml) for 4 hr at room temperature. The reaction mixture was poured into ice-water to give a crystalline product. The product was recrystallized from ethanol to give 0.56 g (65%) of **4b**, mp 151.5—153.5 °C. PMR data: τ 5.43 (dd, 1, H-2, $J_{1,2}$ 3.5 Hz, $J_{2,3}$ 5.5 Hz), 5.79 (dd, 1, H-3, $J_{3,4}$ 6.5 Hz), 6.85 (s, 3, OMs) and 6.89 (s, 3, OMs).

Found: C, 43.62; H, 6.13; S, 16.82%. Calcd for $C_{14}H_{24}O_8S_2$: C, 43.73; H, 6.30; S, 16.68%.

b) A solution of **2** (1.0 g) in ethanol (40 ml) was hydrogenated in the presence of Raney nickel T-4[13] in a Parr shaker apparatus under 3.4 kg/cm^2 of hydrogen pressure for 43 hr at room temperature. The catalyst was filtered off and the filtrate was evaporated to dryness. The residue was treated with mesyl chloride as described in a) to give 1.05 g (61%) of **4b**, mp 152—153 °C. This compound was identical with that obtained in a).

1,2-Anhydro-5,6-O-cyclohexylidene-3,4-di-O-mesyl-chiro-inositol (5b). 1,2-Anhydro-5,6-*O*-cyclohexylidene-*chiro*-inositol (**5a**)[5] (1.5 g) was treated with mesyl chloride (2.9 ml) in pyridine (30 ml) in a refrigerator for 2 days, and then at room temperature for 2 days. The mixture was poured into ice-water and the resulting crystals were recrystallized from chloroform–ethanol (1: 1, v/v) to give 1.97 g (80%) of **5b**, mp 150—152 °C.

Found: C, 42.51; H, 5.54; S, 15.84%. Calcd for $C_{14}H_{22}O_9S_2$: C, 42.20; H, 5.57; S, 16.09%.

$LiAlH_4$ Reduction of 5b. A solution of **5b** (6.0 g) in THF (50 ml) was added dropwise to a stirred slurry of $LiAlH_4$ (1.8 g, 3 mol equiv.) in THF (250 ml), and the mixture was stirred at room temperature for 2.5 hr. The mixture was worked up as described in the reduction of **1** to give, after recrystallization from ethanol, 3.18 g (70%) of 2,3-*O*-cyclohexylidene-1-*O*-mesyl-1,4/2,3-cyclohexanetetrol (**3b**), mp 135—139 °C. A part of the product was recrystallized from ethanol to give an analytically pure sample, mp 139—141 °C.

Found: C, 51.10; H, 7.16; S, 10.28%. Calcd for $C_{13}H_{22}O_6S$: C, 50.96; H, 7.24; S, 10.46%.

Compound **3b** (0.20 g) was treated with acetic anhydride (5 ml) and pyridine (5 ml) overnight at room temperature. The solution was evaporated to give a syrup which was crystallized from ethanol to give 0.15 g (65%) of the acetyl derivative (**3c**), mp 90—93 °C. PMR data: τ 5.80 (the A_2 part of A_2X_2 system, 2, H-2 and H-3), 6.86 (s, 3, OMs) and 7.91 (s, 3, OAc).

Found: C, 52.08; H, 6.95; S, 9.35%. Calcd for $C_{15}H_{24}O_7S$: C, 51.71; H, 6.94; S, 9.20%.

Compound **3b** (2.6 g) was mesylated as described in **4b** to give, after recrystallization from chloroform–ethanol (1: 2, v/v), 2.8 g (86%) of the dimesyl derivative (**3d**), mp 169—170 °C. PMR data: τ 5.03 (m, 2, H-1 an H-4), 5.62 (the A_2 part of A_2X_2 system, 2, H-2 and H-3), 6.82 (s, 6, 2OMs), and 7.94 (t, 4, methylene protons on C-5 and C-6, J 3 Hz).

Found: C, 43.45; H, 6.27; S, 16.66%. Calcd for $C_{14}H_{24}O_8S_2$: C, 43.73; H, 6.30; S, 16.68%.

$LiAlH_4$ Reduction of 5a at Elevated Temperature. A solution of **5b** (1.0 g) in THF (40 ml) was treated with $LiAlH_4$ (0.70 g, 7 mol equiv.) at reflux temperature for 2.5 hr. The reaction mixture was worked up in the usual way to give 0.31 g (55%) of **3a**, mp 124—130 °C. A part of the product was recrystallized as described in **1** to give crystals of mp 140 °C which was identical with the compound **3a** obtained by the reduction of **1**.

$LiAlH_4$ Reduction of 1,2-Anhydro-5,6-O-cyclohexylidene-3,4-di-O-tosyl-chiro-inositol (5c).[5] A mixture of **5c** (8.0 g), $LiAlH_4$ (3.5 g, 6 mol equiv.) and THF (350 ml) was treated at reflux temperature for 1 hr. The reaction mixture was worked up as described in the preparation of **3b** to give, after recrystallization from ethanol, 3.54 g (64%) of 2,3-*O*-cyclohexylidene-1-*O*-tosyl-1,4/2,3-cyclohexanetetrol (**3e**), mp 136—139 °C. Recrystallization from ethanol afforded an analytically pure sample, mp 138—139 °C.

Found: C, 59.86; H, 6.82; S, 8.35%. Calcd for $C_{19}H_{27}O_6S$: C, 59.51; H, 7.09; S, 8.38%.

Conventional acetylation of **3e** (0.15 g) gave 0.12 g (70%) of the acetyl derivative (**3f**), mp 91—92 °C. PMR data: τ 5.88 (m, 2, H-2 and H-3), 7.54 (s, 3, aryl-CH_3) and 7.95 (s, 3, OAc).

Found: C, 59.29; H, 6.68; S, 7.72%. Calcd for $C_{21}H_{28}O_7S$: C, 59.42; H, 6.65; S, 7.55%.

$LiAlH_4$ Reduction of 1,2-Anhydro-5,6-O-cyclohexylidene-4-O-tosyl-neo-inositol (6).[5] To a slurry of $LiAlH_4$ (0.23 g, 3 mol equiv.) in THF (38 ml) was added a solution of **6** (0.80 g) in THF (6 ml), and the mixture was stirred for 6 hr at room temperature. The reaction mixture was worked up as described above to give a product, which showed in tlc (2-butanone–toluene 1: 1, v/v) a presence of one major component (R_f 0.51) and two minor components (R_f 0.33 and 0.29). The crude product was recrystallized from methanol to give 0.24 g (53%) of the major product: 1,4-anhydro-5,6-*O*-cyclohexylidene-2-deoxy-*allo*-inositol (**7a**), mp 77—80 °C. PMR data: τ 7.29 (dd, 1, H-2 *endo*, $J_{1.2endo}$ 0 Hz, J_{2gem} −13 Hz, $J_{2endo,3}$ 7.5 Hz).

Found: C, 63.85; H, 7.97%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

Conventional acetylation of **7a** (0.10 g) gave the acetyl derivative (**7b**), which was recrystallized from ethanol to give an analytically pure sample (70 mg, 59%), mp 88—89 °C. PMR data: τ 4.56 (dd, 1, H-3, $J_{2endo,3}$ 7.5 Hz, $J_{2exo,3}$ 2.5 Hz, $J_{3,4}$ 0 Hz), 7.21 (dd, 1, H-2endo, $J_{1,2endo}$ 0 Hz, J_{2gem} −13 Hz) and 7.94 (s, 3, OAc).

Found: C, 62.42; H, 7.37%. Calcd for $C_{14}H_{20}O_5$: C, 62.67; H, 7.51%.

The mother liquor from **7a** was concentrated to give a syrup which was chromatographed on a silica gel column (50 g) and eluted by 2-butanone–toluene (1: 1, v/v). From the fraction

of the two minor components, 4 mg of crystals, mp 130—131 °C were obtained by recrystallization from ethanol–*n*-hexane (1:2, v/v). This product was indistinguishable from **3a** on tlc, but the IR spectrum was somewhat different from that of **3a** to suggest that the product was probably an isomer of *O*-cyclohexylidene-cyclohexanetetrol.

*$LiAlH_4$ Reduction of 2,3-Anhydro-4,5-O-cyclohexylidene-1,6-di-O-mesyl-*epi*-inositol (8).*[7] Compound **8** (4.0 g) was treated with $LiAlH_4$ (1.52 g) in THF (150 ml) at reflux temperature for 2 hr. The mixture was worked up in the usual manner to give a syrupy product (1.8 g), whose tlc showed the presence of four components: R_f 0.46, 0.38, 0.32, and 0.18 (2-butanone–toluene 2:1, v/v). The product was chromatographed on a silica gel column (100 g) with 2-butanone–toluene (2:5, v/v) as an eluent.

First fraction gave 391 mg (17%) of 1,4-anhydro-5,6-*O*-cyclohexylidene-2-deoxy-*cis*-inositol (**9a**), mp 100 °C. Recrystallization from ethanol–*n*-hexane (1:2, v/v) gave an analytically pure sample, mp 98—101 °C.

Found: C, 63.60; H, 8.00%. Calcd for $C_{12}H_{18}O_4$: C, 63.70; H, 8.02%.

Compound **9a** was acetylated in the usual manner to give the acetyl derivative (**9b**), mp 88—90 °C. Recrystallization from ethanol–*n*-hexane (1:2, v/v) gave an analytical sample, mp 90—91 °C.

Found: C, 62.36; H, 7.40%. Calcd for $C_{14}H_{20}O_5$: C, 62.67; H, 7.51%.

Second fraction gave 103 mg (4.5%) of **4a**, mp 98—100 °C, which was identified with the compound obtained from **2**.

Third fraction gave a homogeneous syrup (0.20 g, 8.7%) which was shown by tlc and IR spectrum to be an isomer of *O*-cyclohexylidene-cyclohexanetetrol. But a further structural elucidation was not attempted.

Fourth fraction gave 283 mg (11%) of 4,5-*O*-cyclohexylidene-2-deoxy-*epi*-inositol (**10**), mp 129—133 °C. Recrystallization from ethyl acetate gave an analytically pure sample, mp 133—135 °C.

Found: C, 59.02; H, 8.42%. Calcd for $C_{12}H_{20}O_5$: C, 59.00; H, 8.25%.

Compound **10** (0.20 g) was hydrolyzed in 80% aqueous acetic acid to give, after recrystallization from aqueous methanol, 33 mg of 2-deoxy-*epi*-inositol (**11a**), mp 205—215 °C (lit.[12a] mp 208 °C). (Found: C, 43.66; H, 7.36%).

Conventional acetylation of **11a** (70 mg) gave, after recrystallization from chloroform–ethanol, 140 mg (88%) of the pentaacetyl derivative (**11b**), mp 124—125 °C (lit.[12] mp 113—114 °C, 123—124 °C). PMR data: τ 7.79 (s, 3, axial OAc), 7.94 (s, 3, equatorial OAc), 7.95 (s, 3, equatorial OAc), 7.98 (s, 3, equatorial OAc) and 7.99 (s, 3, equatorial OAc). (Found: C, 51.55; H, 6.02%).

N-Alkylideneanilines. IV.[1] Kinetics and Mechanism for Site-Exchange of the Methyl Groups in *N*-Isopropylideneanilines

Hiizu IWAMURA, Michiko TSUCHIMOTO,* and Shigeo NISHIMURA*

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Tokyo 113
**Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184*

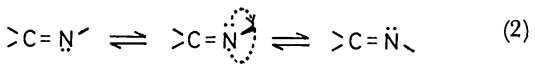
(Received October 26, 1974)

The kinetics of the site-exchange of the methyl groups in twelve *N*-isopropylideneanilines have been studied by the coalescence point analysis of their proton NMR spectra. The free energies of activation at the coalescence temperature were found to be in the range 16.5 (at 53.5 °C for *p*-nitro) ~22.4 (at 161 °C for *p*-amino derivative) kcal/mol. They give a Hammett σ^- ρ plot with ρ=2.83 (r=0.976). The results are interpreted in terms of an in-plane inversion about the imine nitrogen for the site-exchange. Noticeable deviation of the points representing *p*-chloro and *p*-bromo compounds from the linearity indicates the destabilization of the transition state by the electron-releasing resonance effect of the substituents and is consistent with the inversion mechanism.

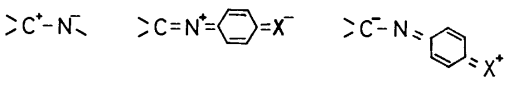
Of recent years the mechanism of interconversion of (*Z*)- and (*E*)-*N*-arylimines has been the subject of considerable debate, and has been considered in terms of either an in-plane inversion (1) or a torsional mechanism (2).[2,3] The rate of isomerization is characteristically dependent on substituents at either side of the carbon-nitrogen bond of *N*-arylimines. The application of the Hammett linear free energy relationship to the process has shown that the rate is generally less sensitive to the nature of the *C*-aryl substituents. In *N*-benzylideneanilines, for example, substituents on the phenyl rings bound to nitrogen have a much larger effect on the isomerization rate, being correlated by ρ=2.0, while the ρ-value for substitution on the aldehyde ring is only+0.4 (at 30 °C).[2c] Since the torsional mechanism is favored by contribution of a dipolar transition state (I), there should be appreciable substituent effects at both the carbon and nitrogen rings as in the rotation of amide groups. On the other hand, an inversion transition state (II) should be stabilized by resonance interaction with the electron-withdrawing *N*-substituents as in amine inversion, but may be affected to a lesser extent by the *C*-aryl substituents. Thus an inversion mechanism appears in many cases to be preferred.[3] In hexafluoroacetone *N*-arylimines, however, a Hammett plot gives the ρ value of −0.98.[2n] The result is interpreted as being the consequence of a torsional mechanism, in which the single bond character of the imine bond is considered to be favored by contribution of electron-releasing substituents (III). All of these studies concern with *N*-arylimines which carry at the imine carbon atom groups with strong inductive and/or resonance interaction with the imine moiety.

As only limited information is available for the

(1)



(2)



(I) (II) (III)

imines with the *C*-substituents of only moderate electronic effects, we wish to report here the kinetic study on the *N*-isopropylideneanilines.

Results

The temperature-dependent NMR spectra of a series of acetone *N*-arylimines[4] as dilute solutions in bromobenzene were examined. The two characteristic signals due to the (*Z*)- and (*E*)-methyl groups which are separated by 22 (for the *p*-NH_2) to 28.5 Hz (for the *m*-CF_3 derivative) were taken into account. The chemical shift differences between these two methyl signals for each imine change very little in the temperature range of −40 °C to +20 °C (in the case of *N*-isopropylidene-*p*-nitroaniline the range is −40 °C to −10 °C). As the temperature is raised, the two lines first start to broaden and then coalesce to a singlet. The coalescence temperature depends heavily on the nature of ring substituents. In a lower extreme of *N*-*p*-nitrophenylimine, it is only at 54 °C. In the other extreme it is as high as 161 °C for the *p*-amino derivative. One-point interconversion rate constants, k_c, at the coalescence temperature were obtained from the spectra using the relationship in Eq. (3) where ν_{ab} refers to the chemical shift difference of the two methyl singlets.[5] From the values of k_c and T_c thus determined, the free energy of activation at T_c, denoted $\Delta G_c^{\ddagger}$, was calculated using the Eyring equation and assuming as usual a value of unity for the transmission coefficient (Eq. (4)).

$$k_c = \pi \cdot \nu_{ab}/\sqrt{2} = 2.22\nu_{ab} \quad (3)$$

$$\ln(k/T) = \ln(k/h) - \Delta G^{\ddagger}/RT = \ln(k/h) + \Delta S^{\ddagger}/R - (\Delta H^{\ddagger}/RT) \quad (4)$$

The pertinent NMR and kinetic data are summarized in Table 1. Although it is difficult to estimate the error in such one-point rate constants, it can be shown that the value of $\Delta G_c^{\ddagger}$ is rather insensitive to the exact choice of k_c.[2e] It is desirable for the following discussion to compare the rates of interconversion at the same temperature. Strictly speaking, this can be done only with a knowledge of $\Delta S^{\ddagger}$ for each compound as seen in Eq. (4). Therefore the $\Delta G_c^{\ddagger}$ values are compared to show the substituent effects.

Table 1. NMR and kinetic data of *N*-isopropylideneanilines

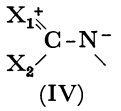
Discussion

The site-exchange of the methyl groups in *N*-isopropylideneanilines can be achieved either by an in-plane inversion at the nitrogen center or by rotation of the carbon-nitrogen bond (Eqs. (1) and (2), respectively). Both mechanisms are found to be actually operative in lower analogues; typical examples are the inversion in methyleneimine CH_2=NH and the rotation in carbodiimide HN=C=NH.[6] Attempts to choose between these mechanisms have been made by the application of the Hammett free energy relationship to the ΔG_c^* data in Table 1. On assuming a similar entropy of activation for the series of *N*-isopropylideneanilines, we note the results correspond to 10^3-fold enhancement of the rates at 25 °C on going from the *p*-amino to *p*-nitro derivatives. The increased facility of isomerization with electron-withdrawing groups on *N*-phenyl rings, as indicated by the positive slope, is consistent with a transition state of type II. A better linear correlation (ρ=2.83, r=0.976) is found when σ^- values are used in place of σ. The result suggests that the para-substituents capable of stabilizing a negative charge by resonance are especially favorable, thus providing further support for the transition state structure II. It may be argued that the same trend of $\sigma^-\rho$ correlation could also have been predicated for a rotational transition state I.[2k] However, two methyl groups are considered not to be strong enough to stabilize the positive charge on the imine carbon. In contrast to the groups such as dimethylamino, methoxy and methylthio which have unshared electron pairs on the heteroatoms that permit resonance stabilization of I, hyperconjugative effect of methyl groups are limited. The ΔG^* values for a series of *N*-phenylimines summarized in the first column of Table 2 afford an excellent insight into the effect of *C*-substituents. We note that the trasition state for the site-exchange in the acetone *N*-phenylimine under discussion is among the least stabilized. The lower free energies of activation for other *N*-phenylimines might suggest contribution of torsional character in the transition state which is stabilized as in IV, especially when the *C*-substituents X_1 and X_2 are Me_2N, MeO, and MeS. Since analyses of the *C*-aryl substituent effects,[2c,7] MO calculations,[8] and other arguments[9] have favored an inversion mechanism for the site-exchange process in these *N*-phenylimines, a torsional mechanism finds the remotest possibility in *N*-isopropylideneanilines.



(IV)

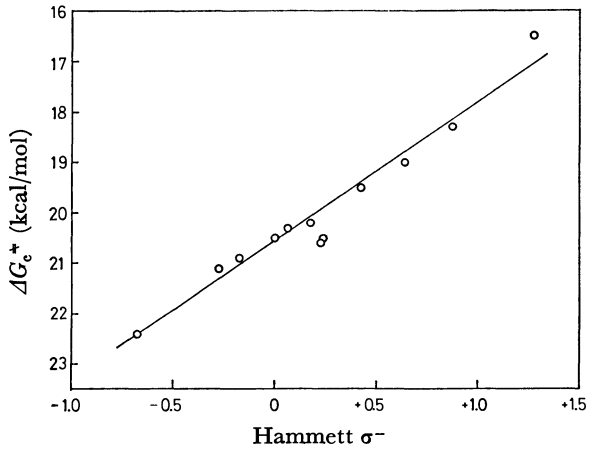


Fig. 1. The Hammett σ^- plots of $-\Delta G_c^*$ values for the site-exchange reaction.

Further inspection of the Hammett plot reveals that the points for the *p*-chloro and *p*-bromo substituents deviate considerably from the linear correlation (see Fig. 1). The errors involved in the approximation used in the coalescence point method can be a responsible factor. However, they are expected to be systematic and may not be a reason for deviation of a particular point or two. It has been shown by the results of more elaborate procedure, *e.g.*, a total line shape analysis, on the similar quinoneanils and ketimines that the relative rates of interconversion are not a sensitive function of the choice of ΔS^* which is furthermore found not to be much different from zero.[2g,2j] It is well-documented that the increase in resonance release of electron density and in inductive electron withdrawal is effective in raising the barrier to inversion of amines.[3] The observed deviation suggests that

Table 2. Hammett correlations in *N*-arylimines $X_1X_2C=NAr$

a) The rate constants at 25 °C estimated on assuming a similar entropy of activation.

both electronic substituent effects are not adequately represented by the Hammett σ^- constants. The standard Hammett σ values of 0.227 and 0.232 for the *p*-Cl and *p*-Br substituents, respectively, reflect the interplay of the electron-withdrawing inductive (σ_I; 0.348 and 0.337, respectively) and electron-donating resonance effects (σ_π; −0.070 and −0.054, respectively).[10] The fact that the rates of interconversion in *p*-Cl and *p*-Br compounds are slower than in the parent *N*-isopropylideneanilines, *i.e.*, $k_{Cl}/k_H=0.78$ and $k_{Br}/k_H=0.98$,[11] means that resonance substituent effect dominates the stability of the transition state. Precedent for the prevalence of the resonance substituent effect can be found in the pyramidal inversion of aryl *p*-tolyl sulfoxides.[12] Electronic effects on the inversion process for both series of compounds, namely, acetone *N*-arylimines and aryl *p*-tolyl sulfoxides, are quite similar.

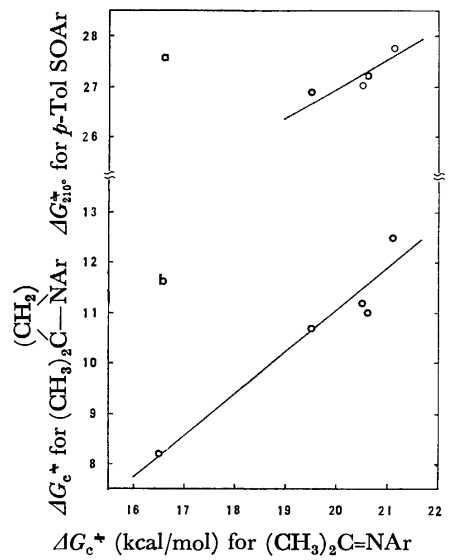

Fig. 2. Correlation of $\Delta G_c^{\ddagger}$ values for inversion of (a) aryl *p*-tolyl sulfoxides and (b) 2,2-dimethyl-1-arylaziridines *vs.* *N*-isopropylideneanilines.

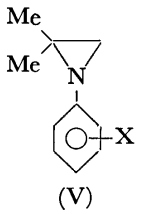
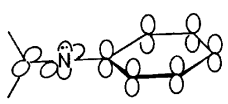
While the Hammett plots against σ^- give positive slopes as a whole, the relative rates k_{Cl}/k_H are equally less than unity (0.78, at 25 °C in the former and 0.81 at 210 °C in the latter). As a result, the $\Delta G^{\ddagger}$ values correlate very nicely between the two series as shown in Fig. 2a.

Of related interest to the inversion of *N*-arylimine nitrogen is the pyramidal inversion of 1-aryl-2,2-dimethylaziridines (V).[13] When we consider the structural similarity with respect to the unit Me_2C–N–Ar between *N*-isopropylideneanilines and V, it is not unexpected that plots of $\Delta G^{\ddagger}$ values of V *vs.* those of the former show good linear correlation (Fig. 2b). This is taken as another support for an inversion mechanism in the *N*-arylimines. The slope of the line, 0.84, may be regarded as a measure of the sensitivity of the *N*-isopropylideneanilines relative to the aziridines to electronic substituent effects. Furthermore the point for the *N*-*p*-chlorophenylaziridine conforms to the Hammett correlation defined by the other aziridines V; $k_{Cl}/k_H=1.7$ at −60 °C.[13] Thus resonance substituent effects appear not to be dominant in V. These two points, slightly diminished sensitivity to ring substituents and reduced resonance substituent effects in V, indicate that the structural analogy between *N*-arylimines and *N*-arylaziridines for inversion at the

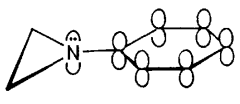


(V)

nitrogen center is only superficial. We propose as one of a number of possible origins of the more effective transmission of substituent effects in the *N*-arylimines relative to *N*-arylaziridines the difference in the nitrogen hybridization in the transition state for inversion, In the *N*-arylimines, the nitrogen center is sp hybridized and the lone pair of electrons reside in a purely *p*-charactered AO which is most favorably situated to conjugate with the benzene ring (VI). The carbon-nitrogen bonds of aziridine rings are rich in *p*-character as approximated by $sp^{4.1}$ hybridization for the cyclopropane ring orbitals in the Coulson-Moffit model.[14] As a result, the hybridized orbital in which lone pair of electrons reside has some s character to effect reluctance to delocalize into the aromatic ring (VII).

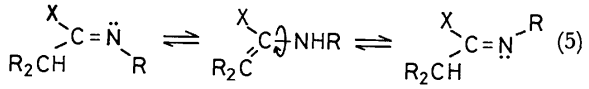


VI



VII

Recently a third mechanism in which tautomerization to the enamine (Eq. 5) has been proposed for the imines which contain a *C*-alkyl-substituent with at least



(5)

one α-hydrogen atom.[7] The mechanism has been

shown to be operative in some *N*-alkylimines in which barriers to inversion can often be high ($\Delta G^{\ddagger}\sim25$ kcal/mol).[7] The tautomerism has been shown by the deuterium incorporation experiments in methanol-d_4 to be considerably slower(10^{-5}—10^{-6} s^{-1})[1] than inversion (10^{-1}—10^{-4} s^{-1})[11] in *N*-isopropylideneanilines. Therefore the site-exchange of the methyl groups *via* imine-enamine tautomerism can be ruled out in the case of *N*-isopropylideneanilines.

Experimental

General procedure for the preparation of *N*-isopropylideneanilines:[4] 30 g of Molecular Sieve 4A were added to a solution of 0.1 mol of acetone and 0.05 mol of aniline in anhydrous ether. The mixture was kept at 10 °C for 2 to 3 days, by renewing the Molecular Sieve 2—3 times. After removing the Molecular Sieve by filtration and the solvent by application of a rotary evaporator, the residue was fractionaly distilled.

NMR spectra were obtained on a JEOL C-60HL (Japan Electron Optics Lab. Co., Ltd.) spectrometer (60 MHz), equipped with a variable temperature probe. Solutions of 0.25 mmol of *N*-isopropylideneanilines in 0.5 ml bromobenzene (25 °C——40 °C) containing TMS as internal references were employed. Temperature were calibrated by 1,3-propanediol in the region of 25 °C—160 °C, and by methanol in the region 25 °C——40 °C, and are believed to be accurate to ±1 °C. In the recording of spectra, care was taken to avoid saturation of the signal especially when the height intensity is weak near the coalescence point. Three or more spectra were recorded in the vicinity of each coalescence temperature.

Photo-addition Reaction of 1,4-Naphthoquinone with Olefins.[1] Formation of 2:1 Addition Compounds

Kazuhiro MARUYAMA, Yoshinori NARUTA, and Tetsuo OTSUKI*

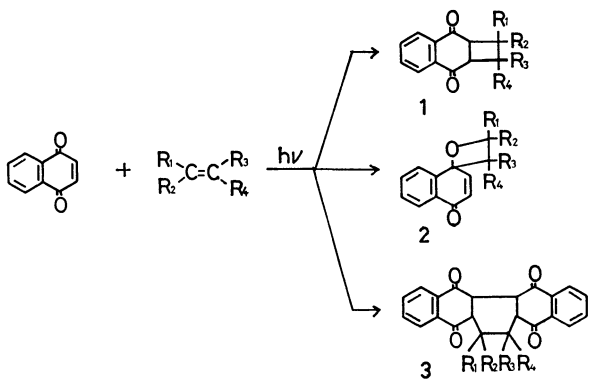
Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

** Department of Chemistry, Faculty of Home Economics, Kyoto Women's University, Kyoto 605*

(Received November 18, 1974)

A novel type of the photo-addition compound, 5,8,13,14-tetraoxo-5,5a,6, 7,7a,8,13,13a,13b,14-decahydropentaphene derivatives (**3**), consisting of two molecules of 1,4-naphthoquinone and one molecule of an olefin was obtained in the photochemical reaction of 1,4-naphthoquinone with olefins. Its structure was determined from spectral data as well as results obtained from the chemical reactions. Olefins which give this type of photo-addition compound are characterized by their bicyclo-ring systems containing considerable ring strains. The reaction mechanism for formation of the compound was discussed in terms of the ring strains of olefins and the nature of the photo-excited 1,4-naphthoquinone.

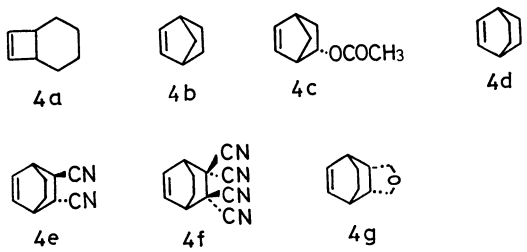
Photochemistry has provided versatile routes to many elegant compounds which otherwise are difficult to prepare.[2] From synthetic and theoretical viewpoints, elucidation of the photochemical behaviour of quinones would be fruitful since quinones and related compounds play an important role in natural environments. Several workers[3,4] have investigated the photochemical reaction of 1,4-naphthoquinone with olefins. 1,4-Naphthoquinone has been found to give 1:1 photo-addition compounds with olefins, besides the photo-reduction products of 1,4-naphthoquinone such as 1,4-naphthohydroquinone and 1,4-naphthoquinhydrones. The photo-addition compounds reported



so far were classified into structural types **1** and **2**.[3,4] We have now been able to isolate a novel type of 2:1 photo-addition compound **3** in the photochemical reaction of 1,4-naphthoquinone with olefins characterized by their bicyclo-ring systems containing considerable ring strains. The photo-addition compound was confirmed to consist of two molecules of 1,4-naphthoquinone and one molecule of an olefin and to have the structure **3** by inspection of the spectral data and from the Baeyer-Villiger oxidation of the addition compound.[1] In this report the reaction mechanism for the formation of this novel photo-addition compound **3** is discussed on the basis of product analyses and quenching experiments.

Results and Discussion

Photo-addition Compounds Obtained in the Photochemical Reaction of 1,4-Naphthoquinone with Olefins. A benzene solution of 1,4-naphthoquinone was subjected to photochemical reaction of olefins on irradiation with a high pressure Hg arc lamp. Olefins examined here were all characterized by their strained bicyclo-ring systems, such as bicyclo[4.2.0]oct-7-ene **4a**,[5] bicyclo[2.2.1]hept-2-ene **4b**, *endo*-2-acetoxybicyclo[2.2.1]hept-5-ene **4c**,[6] bicyclo[2.2.2]oct-2-ene **4d**, *trans*-2,3-dicyanobicylo[2.2.2]oct-5-ene **4e**,[7] 2,2,3,3-tetracyanobicyclo[2.2.2]oct-5-ene **4f**[8] and 4-oxatricyclo[2.2.5^{2,6}]undec-8-ene **4g**.



With olefins **4a**, **4b** and **4d**, the photochemical reaction of 1,4-naphthoquinone was found to produce the photo-addition compounds without the formation of 1,4-naphthohydroquinone or 1,4-naphthoquinhydrones. The photo-addition compounds isolated were subjected to further examination for determination of their structures. From the results the photo-addition compounds could be classified into three structural types **1**, **2** and **3**. Structure **3** was determined by the isolation of methyl ester of cyclohexane tetracarboxylic acid derivatives **5** when the photo-addition compound **3b** was subjected to oxidative degradation by perfluoroacetic acid and subsequent esterification with diazomethane.[1] The photo-addition compound **3** is outstanding, being constructed from two molecules of 1,4-naphthoquinone and one molecule of an olefin, while **1** and **2** are each composed of one moelcule of 1,4-naphthoquinone and an olefin. Compound **3** was

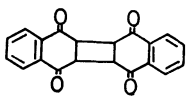
Olefin **4g** was found to react as a reducing agent due to its active hydrogen atoms to yield 1,4-naphthoquinhydrones, no photo-addition products being isolated. With olefins characterized by having electron withdrawing substituents such as **4c**, **4e** and **4f**, 1,4-naphthoquinone could not undergo the photo-addition reaction, but the photo-dimerization of 1,4-naphthoquinone proceeded to yield its dimer **6**[9)] as a sole reaction product. For elucidation of the mechanism for formation of the photo-addition compounds **1**, **2** and especially **3**, the behaviour of photo-excited 1,4-naphthoquinone was investigated.



6

Quantum Yields and Relation to Their Ring Strains in Olefins. Quantum yields of the cycloaddition were measured in the reaction of 1,4-naphthoquinone with **4b** and **4d** on irradiating (λ>300 nm) the degassed solution of 1,4-naphthoquinone and an olefin at room temperature using potassium ferrioxalate as a chemical actinometer. The results are summarized in Table 2. Although the quantum yields for the formation of **3b** and **3d** are comparable, it should be noted that the quantum yield for the formation of **1d**+**2d** is about five times greater than that of **1b**+**2b**, and the quantum yield for the formation of **2b** is about ten times greater than that of **2d**. Taking into account the fact that olefin **4a** gives none of **1a** or **2a**, we find that the formation of **1** or **2** is much influenced by the nature of olefins subjected to the reaction, particularly by the ring strains in olefins. Coupling constants of olefinic protons with ^{13}C ($J_{^{13}C-H}$) are the direct measure of the ring strains of the double bonds in olefins. They are given in Table 3 together with the % *s*-character

Table 2. Quantum yields for the formation of photo-addition compounds[a,b)]

Olefin	$J_{^{13}C-H}$	% *s*-character
4a	170 Hz	34
4b	165 Hz[a)]	33
4d	158 Hz	32

a) K. Tori, R. Muneyuki, H. Tanida, *Can. J. Chem.*, **14**, 3142 (1963).

of the C–H bonds estimated therefrom. The $J_{^{13}C-H}$ in **4d** (158 Hz) is comparable to that in cyclohexane ($J_{^{13}C-H}$=157 Hz),[10)] which is estimated to have no ring strains. It was deduced that the formation of the cyclobutane or oxetane type of compound **1** or **2** becomes less favorable as the ring strains in olefins increase; that is, none of **1a** or **2a** could be identified in the photochemical reaction of 1,4-naphthoquinone with **4a**, which has the greatest value of $J_{^{13}C-H}$ and is consequently of the greatest ring strain among the olefins examined here. On the other hand, no further chemical change could be observed on irradiating the benzene solution of **1b** in the presence of excess 1,4-naphthoquinone nor on irradiating the benzene solution of the dimer **6** in the presence of excess bicyclo[2.2.1]-hept-2-ene **4b**. From these results neither **1b** nor **6** could be the precursor of **3b**. Dependence of the yields of the photo-addition compounds **2b** and **3b** on the concentration of bicyclo[2.2.1]hept-2-ene **4b** was measured (Fig. 1). As the concentration of bicyclo-[2.2.1]hept-2-ene increases, the yields of both **2b** and **3b** increase, while the amount of the dimer **6** is depressed. Moreover, it is seen that the ratio **3b**/**2b** is nearly constant irrespective of the concentration of bicyclo-[2.2.1]hept-2-ene. The results exclude the possibility of simultaneous formation of **3b** from two molecules of 1,4-naphthoquinone and one molecule of bicyclo-[2.2.1]hept-2-ene, and suggest that the similar types of

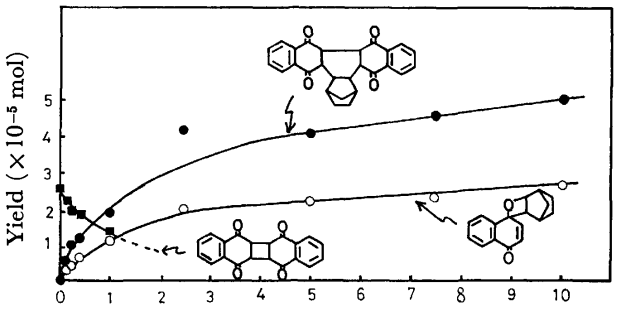

Fig. 1. Dependence of the yields of the photo-addition compounds on the concentration of bicyclo[2.2.1]hept-2-ene.
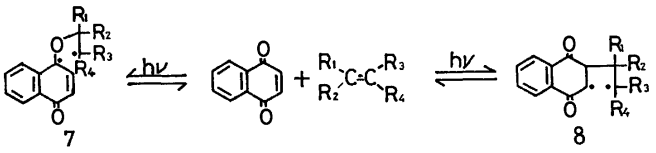
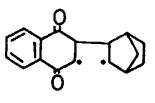
The 0.100 M-benzene solution of 1,4-naphthoquinone is submitted to the photochemical reaction (30 °C).

reaction intermediates are concerned with the formation of **2b** and **3b**. Consequently it can be deduced that the reaction intermediates for the formation of **2b** and **3b** are each composed of one molecule of 1,4-naphthoquinone and bicyclo[2.2.1]hept-2-ene as illustrated by **7** and **8**, respectively. The effects of higher



ring strains in olefin **4** on the formation of **2** might be explained, if we assume that compound **2** is produced *via* the ring closure of diradical **7** (see Tables 1 and 2), and compounds **1** and **3** *via* diradical **8**. The larger ring strains in olefins would be less favourable for the ring closure to yield **1** and **2**, because of the lack of the energy relaxation mode to bonding vibration or ring fluctuation. This would result in the longer life-time of the diradicals to meet other molecules or to decompose to the starting quinone and olefin. The fairly large steric repulsion for the ring closure may be another factor to lead to the longer life-time of the diradicals. Thus, **3** may be formed. Actually, the relative yield of **3** in each reaction is high in the order of the higher ring strain of olefins, and the cyclobutane type of **1** could be isolated only in the reaction of 1,4-naphthoquinone with **4d**, which would contain the least ring strains of the three olefins examined. The unidentified resinous matter, *i.e.* polymers produced in the highest yield of the products, may be formed on the same basis as described above. The smaller yield of **2d** compared with **2b** could result from the larger steric hindrance against the ring closure due to bulkier bicyclo[2.2.2]-oct-2-ene moiety. In the presence of fumaronitrile, however, the excess energy in **8b** would transfer to fumaronitrile to produced **1b** even if the minor portion of **8b** is concerned. Details of the photo-excited states



8b

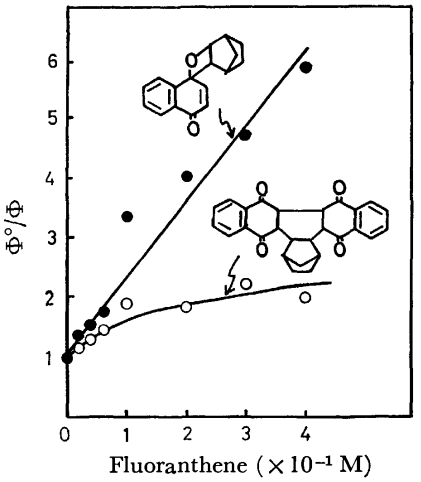


Fig. 2. Stern-Volmer plots quenched by fluoranthene in the photochemical reaction of 1,4-naphthoquinone with bicyclo[2.2.1]hept-2-ene (30 °C).

of 1,4-naphthoquinone to produce the diradical intermediates such as **7** or **8**, and subsequently to yield the photo-addition compounds are discussed in the following.

Correlation between the Reactivity and the Multiplicity of the Photo-excited 1,4-Naphthoquinone. The triplet energy of 1,4-naphthoquinone has been estimated to be 58 kcal/mol.[11] Fluoranthene could quench the triplet excited state of 1,4-naphthoquinone since E_T-value for fluoranthene has been estimated to be 54 kcal/mol.[12a] Dependence of the quantum yields for the formation of **2b** and **3b** on the concentration of fluoranthene as a quencher was estimated. The Stern-Volmer plots are shown in Fig. 2, in which the straight line for the formation of **2b** indicates that **2b** is formed through the triplet excited state of 1,4-naphthoquinone. This agrees with the findings that the oxetanes are formed *via* the triplet excited states in the photochemical reaction of benzophenone[12b] or *p*-benzoquinone[16] with olefins. Scheme 1 shows the reaction paths for the formation of oxetanes *via* diradical **7**, involving unimolecular deactivation of the excited state of 1,4-

naphthoquinone (k_f, k_d^S, k_p^T), intersystem crossing (k_{ST}), formation of diradical intermediate **7** (k_a), formation of oxetane (k_r) and dissociation of diradical intermediate **7** (k_d') and the triplet quenching of 1,4-naphthoquinone by fluoranthene (k_q). The quantum yields for the formation of oxetanes are expressed as Φ_{ox} and/or Φ_{ox}°, corresponding to whether in the presence and/or absence of quencher, respectively (Eqs. (1) and/or (2)).

$$\frac{1}{\Phi_{ox}} = \frac{1}{\Phi_{ST}}\left(1+\frac{k_d'}{k_r}\right)\left(1+\frac{k_d^T+k_q[Q]}{k_a[A]}\right) \quad (1)$$

$$\frac{1}{\Phi_{ox}^{\circ}} = \frac{1}{\Phi_{ST}}\left(1+\frac{k_d'}{k_r}\right)\left(1+\frac{k_d^T}{k_a[A]}\right) \quad (2)$$

The relative ratio $\Phi_{ox}^{\circ}/\Phi_{ox}$ can be derived from Eqs. (1) and (2) as follows.

$$\frac{\Phi_{ox}^{\circ}}{\Phi_{ox}} = 1 + \frac{k_q[Q]}{k_a[A]+k_d^T} = 1 + k_q\tau[Q] \quad (3)$$

τ: the life-time of the tripelt state of 1,4-naphthoquinone in the absence of a quencher.

From the slope and the intercept of the plots shown in Fig. 2 and $\Phi_{ox}^{\circ}=0.0056$, the following rate constants and the ratio can be evaluated; $k_a=2.0\times10^6$ $M^{-1}s^{-1}$, $k_d^T=3.0\times10^7$ s^{-1}, $k_d'/k_r=100$, assuming $\Phi_{ST}\simeq1$[13] and $k_q=5.0\times10^9$ $M^{-1}s^{-1}$ for the benzene solution at 25 °C[14]. These values are compatible to those obtained in the photochemical reaction of benzophenone with furan.[15] The state diagram estimated for the formation of oxetanes is given in Fig. 3.

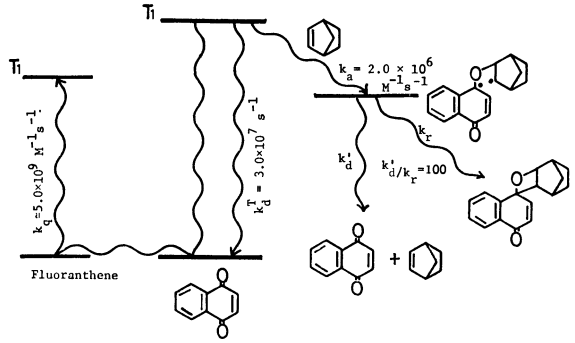

Fig. 3. The state diagram for the formation of spiro-oxetane (30 °C).

The formation of **3b**, on the other hand, is expected to proceed through both the singlet excited state and the triplet excited state of 1,4-naphthoquinone since the Stern-Volmer plots for the formation of **3b** does not give a straight line; it can be estimated that about 60% of the reaction proceeds through the singlet excited state of 1,4-naphthoquinone and the residual 40% through the triplet state since the ratio of quantum yields approaches a constant value (2.5) with increasing concentration of the quencher. It could be assumed that the singlet excited state of 1,4-naphthoquinone reacts also with olefins to give the photo-addition compound and this could be substantiated further by the following results.

Quenching of the Fluorescene of 1,4-Naphthoquinone by Olefins. The fluorescene of 1,4-naphthoquinone at 77 K and at room temperature was observed when

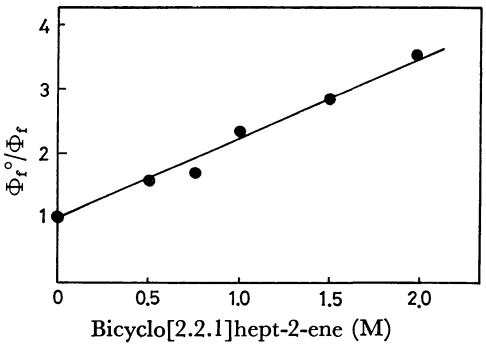

Fig. 4. Quenching of the fluorescene of 1,4-naphthoquinone by bicyclo[2.2.1]hept-2-ene (20 °C).

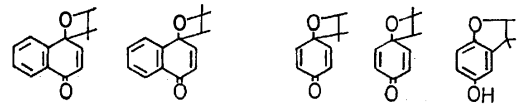
degassed solution of 1,4-naphthoquinone of ether–ethyl alcohol (vol/vol=1/1) was irradiated by light at 333 nm. The intensity of fluorescene was measured at λ_{max}=400 nm in the absence and in the presence of bicyclo[2.2.2]-hept-2-ene (Fig. 4). From the linear relationship observed, it is concluded that the singlet excited state of 1,4-naphthoquinone can be quenched by bicyclo[2.2.1]-hept-2-ene. This is consistent with the findings that the formation of **3b** proceeds partly through the singlet excited state of 1,4-naphthoquinone.

TABLE 4. QUANTUM YIELDS FOR THE FORMATION OF **2b** AND **3b** THROUGH THE EXCITATION OF n–π^* AND π–π^* TRANSITIONS (measured at 30 °C)

Photo-addition compound	Φ_{total} [a]	Φ_{333} [b]	Φ_{420} [c]
2b	8.8×10^{-3}	8.1×10^{-3}	7.0×10^{-3}
3b	5.6×10^{-3}	4.4×10^{-3}	4.4×10^{-3}

a) Excited through both n-π^* and π-π^* transitions. b) Excited through π-π^* transition with use of a Corning CS-7-54 filter. c) Excited through n-π^* transition with use of a Toshiba VY-42 filter.

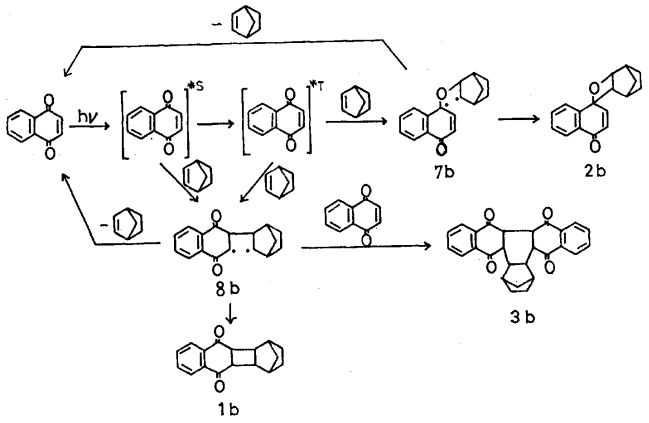
Mixing between the π-π^* Excited States of 1,4-Naphthoquinone. The benzene solution of 1,4-naphthoquinone shows two characteristic absorption bands in the region of wavelength greater than 300 nm. The bands, λ_{max}=333 nm and 420 nm, can be assigned to π-π^* and n-π^* transitions, respectively. The quantum yields for the formation of **2b** and **3b** were measured in each case when 1,4-naphthoquinone was excited through π-π^* and n-π^* transitions to react with bicyclo-[2.2.1]hept-2-ene (Table 4). The π-π^* excitation of 1,4-naphthoquinone was as equally effective as the n-π^* excitation for the formation of **2b** and **3b**. These results suggest that the lower excited singlet or triplet state would be responsible to the formation of **3b**, irrespective of the bands used for the excitation. However, the lower triplet excited state would contribute predominantly to the formation of **2b**. From the results the mixting between the π-π^* and n-π^* excited states of 1,4-naphthoquinone seems to exist to a considerable extent. This is not the case in the photo-excited states of *p*-benzoquinone. The suggestion was supported further by the following facts: in the photochemical reaction of 1,4-naphthoquinone with 2-methylbut-2-ene the oxetanes isolated are found to be a non-stereo-



9a 9b 10a 10b 11

selective mixture of **9a** and **9b** (**9a**/**9b**=1.3); in the photochemical reaction of *p*-benzoquinone with 2-methylbut-2-ene, only one isomer **10a** of the possible two isomers and its further rearrangement product **11** could be isolated stereoselectively from the reaction mixture, but none of the other isomer **10b**.[16] The lack of stereoselectivity in the photochemical reaction of 1,4-naphthoquinone with 2-methylbut-2-ene is attributable solely to the smaller degree of electron defficiency of oxygen atom in the n-π^* excited state of 1,4-naphthoquinone, *i.e.*, indication of larger mixing of the n-π^* state with π-π^* state than in the case of *p*-benzoquinone, since the stability of the diradical intermediates **7** to form **9a** and **9b**, or **10a** and **10b** could be estimated in the same order.

We can thus formulate the reaction of 1,4-naphthoquinone with bicyclo[2.2.1]hept-2-ene as shown in Scheme 2. A novel type of photo-addition compound **3** derived from the other higher strained olefins would be formed following a similar reaction scheme.



Scheme 2.

Experimental

Materials. 1,4-Naphthoquinone, *p*-benzoquinone, bicyclo[2.2.1]hept-2-ene (**4b**) and fluoranthene were used after sublimation of commercial reagents of guaranteed grade. Bicyclo[2.2.2]oct-2-ene (**4d**) and 2-methylbut-2-ene were subjected to the reaction without further purification. Bicyclo-[4.2.0]oct-7-ene (**4a**), *endo*-2-acetoxybicylo[2.2.1]hept-5-ene (**4c**), *trans*-2,3-dicyanobicyclo[2.2.2]oct-5-ene (**4e**) and 2,2,3,3-tetracyanobicyclo[2.2.2]oct-5-ene (**4f**) were synthesized according to reported method.[5-8]

*4-Oxatricyclo[2.2.5^{2,6}]undec-8-ene (**4g**)*; *endo-cis*-Bicyclo[2.2.2]-oct-5-ene-2,3-dicarboxylic anhydride[17] was treated with lithium aluminum hydride in dry ether for conversion into *endo-cis*-2,3-bis(hydroxymethyl)bicyclo[2.2.2]oct-5-ene. *p*-Toluenesulfonyl chloride (29.5 g) was added to 100 ml of pyridine solution containing 6.5 g of *endo-cis*-2,3-bis(hydroxymethyl)-bicyclo[2.2.2]oct-5-ene in an ice-cooled bath with stirring, then allowed to stand for two days at room temperature. The pyridine solution was poured into ice water (200 ml) and extracted twice with 75 ml of ether. The extract was washed twice with cold dilute hydrochloric acid solution, once with water and then dried over anhydrous sodium sulfate. Oily ditosylate was obtained after ether had been evaporated. The crude ditosylate was reduced with lithium aluminum hydride. After the work-up, the cyclic ether (**4g**) was distilled under a reduced pressure, yield: 4.0 g (76%): bp 134.5—135.6 °C (80 mmHg); mp 51—52 °C; Mass; *m/e*=149 (M^+). IR (liq. film); 3040, 2930, 1377 (C–H), 1010 cm^{-1} (C–O). PMR (CCl_4); δ: 1.34 (4H, C-10 and C-11 CH_2' s, m), 2.32 (4H, C-1, C-2, C-6, and C-7 CH's, m), 3.16 (2H, C-3 and C-5 CH's, m), 3.70 (2H, C-3 and C-5 CH's, m), 6.12 ppm (2H, C-8 and C-9 CH's, m). Found: C, 79.34; H, 9.32%. Calcd for $C_{10}H_{14}O$: C, 79.95; H, 9.39%.

General Procedures. 1,4-Naphthoquinone (1 mmol) and an olefin (2 mmol) were dissolved in dry benzene (25 ml) and irradiated in a glass tube with a high pressure Hg arc lamp (300 W) through a water layer 5 cm thick (10 °C). After the reaction was completed the photo-addition compounds were isolated by the usual work-up from the reaction mixture and subjected to further examination for structure determination.

Identification of the Photo-addition Compounds. Bicyclo-[4.2.0]octano[2',3'-h]-*5,8,13,14-tetraoxo-5,5a,6,7,7a,8,13,13a,13b,14-decahydropentaphene (**3a**)*: white needles, mp 235 °C. Found: C, 79.08; H, 5.35%. Calcd for $C_{28}H_{24}O_4$: C, 79.23; H, 5.70%. Mass: *m/e*=424 (M^+). IR (KBr disk): 1675 cm^{-1} (C=O). PMR ($CDCl_3$); δ 1.00—2.40 (12H, aliphatic protons, m), 3.43 (1H, C-7a CH, dd, J=6.0 and 11.0 Hz), 3.53 (1H, C-5a CH, dd, J=6.0 and 12.0 Hz), 4.50 (2H, C-13a and C-13 CH's, m), 7.85 (4H, aromatic protons, m), 8.16 ppm (4H, aromatic protons, m).

*Bicyclo[2.2.1]heptano[2',3': 4,5]tricyclo[6.4.0.0^{3,6}]dodeca-8,10,12-triene-2,7-dione (**1b**)*: colorless cubes from *n*-hexane, mp 113.0—114.0 °C. Found: C, 81.15; H, 6.35%. Calcd for $C_{17}H_{16}O_2$: 80.92; H, 6.39%. Mass: *m/e*=252 (M^+). IR (KBr disk); 1670 cm^{-1} (C=O). PMR ($CDCl_3$): δ; 0.80—2.00 (8H, aliphatic protons, m), 2.40 (2H, C-4 and C-5 CH's, s), 3.18 (2H, C-3 and C-4 CH's, d, J=3.0 Hz), 7.80—8.30 ppm (4H, aromatic protons, m).

4-Oxo-1,4-dihydronaphthalene-1-spiro-*2'-bicyclo[2.2.1]heptano-[2'',3'': 3',4']oxetane (**2b**)*: colorless cubes from petroleum ether, mp 101.0—102.0 °C. Found: C, 80.76; H, 6.25. Calcd for $C_{17}H_{16}O_2$: C, 80.92; H, 6.39%. Mass; *m/e*=252 (M^+). IR (KBr disk); 1668 (C=O), 977 cm^{-1} (oxetane ring). UV max ($CHCl_3$); 248 nm (ε: 1.20×10^5), 281 (5.43×10^4). PMR (CCl_4): δ: 0.80—2.90 (9H, aliphatic protons, m), 5.05 (1H, C-3' CH, dd, J=5.0 and 6.0 Hz), 6.16 (1H, C-2 CH, d, J=10.0 Hz), 7.70 (1H, C-3 CH, d, J=10.0 Hz), 7.20—8.10 ppm (4H, aromatic protons, m).

Bicyclo[2.2.1]heptano[2',3'-h]-*5,8,13,14-tetraoxo-5,5a,6,7,7a,8,13,13a,13b,14-decahydropentaphene (**3b**)*: white needles from chloroform, mp 227.5—228.5 °C. Found: C, 78.84; H, 5.39. Calcd for $C_{27}H_{22}O_4$: C, 79.00; H, 5.40%. Mass *m/e*=410; (M^+). IR (KBr disk); 1670 cm^{-1} (C=O). UV max ($CHCl_3$): 256 nm (ε: 2.35×10^4), 304 (5.40×10^3). PMR ($CDCl_3$); δ: 0.60—1.70 (8H, aliphatic protons, m). 2.03 (2H, C-6 and C-7 CH's, m), 3.13 (1H, C-7a CH, dd, J=5.0 and 12.0 Hz), 3.27 (1H, C-5a CH, dd, J=5.0 and 14.0 Hz), 4.56 (2H, C-13a and C-13b CH's, d, J=5.0 Hz), 7.70—8.24 ppm (8H, aromatic protons, m).

*Bicyclo[2.2.2]octano[2',3': 4,5]tricyclo[6.4.0.0^{3,6}]dodeca-8,10,12-triene-2,7-dione (**1d**)*: colorless cubes from benzene–petroleum ether, mp 141.5—142.3 °C. Found: C, 81.24; H, 6.76%. Calcd for $C_{18}H_{18}O_2$: C, 81.17; H, 6.81%. Mass: *m/e*=266 (M^+). IR (KBr disk); 1674 cm^{-1} (C=O). UV max ($CHCl_3$); 254 nm (ε: 1.18×10^4), 302 (1.90×10^3), 309 (2.08×10^3), 348 (1.64×10^2). PMR ($CDCl_3$); δ: 1.40—2.30 (10H, aliphatic protons, m), 2.61 (2H, C-4 and C-5 CH's, broad s), 3.37 (2H,

C-3 and C-6 CH's, d, J=6.0 Hz), 7.70—8.30 ppm (4H, aromatic protons, m).

4-Oxo-1,4-dihydronaphthalene-1-spiro-*2'-bicyclo*[*2.2.2*]*octano*[*2'', 3'': 3',4'*]*oxetane* (**2d**): assignment of the structure was confirmed by IR and UV spectra which were in good agreement with those of **2b**: IR (CCl_4 solution); 1670 (C=O), 980 cm^{-1} (oxetane ring). UV max ($CHCl_3$); 253, 281 nm.

Bicyclo[*2.2.2*]*octano*[*2',3'*-h]-*5,8,13,14-tetraoxo-5,5a,6,7,7a,8, 13,13a,13b,14-decahydropentaphene* (**3d**): white needles from benzene–petroleum ether, mp 245 °C (decomp.). Found: C, 79.15; H, 5.58%. Calcd for $C_{28}H_{24}O_4$: C, 79.21; H, 5.70%. Mass; m/e=424 (M^+). IR (KBr disk); 1675 cm^{-1} (C=O). UV max ($CHCl_3$); 258 nm (ε: 2.31×10^4), 300 (4.13×10^3), 308 (4.56×10^3). PMR ($CDCl_3$); δ: 1.35 (12H, aliphatic protons, m), 3.30 (2H, C-5a and C-7a CH's, m), 4.50 (2H, C-13a and C-13b CH's d, J=4.0 Hz), 7.77 (4H, aromatic protons, m), 8.08 ppm (4H, aromatic protons, m).

4-Oxo-1,4-dihydronaphthalene-1-spiro-*2'-3',3',4'-trimethyloxetane* (**9a**) *and 4-Oxo-1,4-dihydronaphthalene-1*-spiro-*2'-3',4',4'-trimethyloxetane* (**9b**): these two isomers were isolated as a mixture. The relative ratio of the isomer content (**9a**/**9b**) was estimated to be 1.3/1.0 through integration of the PMR signals due to the methine protons of the oxetane ring. They appeared at δ=4.74 ppm (C-4' CH, q, J=6.0 Hz) for **9a** and 2.86 ppm (C-3' CH, q, J=6.0 Hz) for **9b**, respectively; colorless oil. Mass; m/e=228 (M^+). IR (liq. film); 1670 (C=O), 960 cm^{-1} (oxetane ring).

Measurement of the Quantum Yields. Light of wavelengths in the range 300—400 nm (filters, Corning CS 7–54 and usual glass, 2 mm thick) was used. The quanta absorbed by the reaction mixture were calibrated using potassium ferrioxalate as a chemical actinometer.[18] The benzene solution of 1,4-naphthoquinone (0.100 M) and an olefin (0.200 M) in a quartz cell was degassed and subjected to measurement. After the reaction was over the reaction mixture was purified by thin layer chromatography on silica gel, the amount of photoaddition compounds produced being estimated by their absorptions in the UV region.

Part of the work was carried out with research funds of the Ministry of Education (No. 943019) and the Takeda Science Fundation.

(Received November 25, 1974)

When 3-formxlguaiazulene was heated at 200 °C for 1 hr, three new compounds were isolated in addition to *S*-guaiazulene (formed by loss of the formyl group). They were shown to be 2-formylguaiazulene, produced by migration of the formyl group, and dimers produced from two molecules of the starting material through dehydration between the formyl and the aromatic methyl groups. The observed elimination or migration of the formyl group was analogous to the behavior of 3-acylguaiazulenes which had been studied earlier. On the other hand, the extent of the loss of the acyl group and the formation of the dimers was peculiar to this substance. Moreover, migration of the formyl group was not reversible at 200 °C, but was at 250 °C.

In the previous papers[1-3] dealing with the thermal reaction of 3-acylguaiazulene at 200—260 °C, it was shown that *S*-guaiazulene, 2-acylguaiazulene and 1-acyl-7-isopropyl-3,4-dimethylazulene were formed by the loss of the acyl group, migration of the acyl group, or by the interchange of the acyl and methyl groups in the five-membered ring of the azulene nucleus, respectively. On the other hand, a discrepancy among the reactions due to differences of the carbonyl components was also noted:[3] the main reaction in such a ketone as acetylguaiazulene or benzoylguaiazulene is migration of the acyl group, while that in a methyl ester is interchange of the ester and the methyl groups in the five-membered ring, and reduction of an acyl group is observed only in the benzoyl compound.

In an effort to determine the effect of a formyl substituent on the thermal reaction of 3-acylguaiazulene, the behavior of 3-formylguaiazulene was studied.

Results and Discussion

3-Formylguaiazulene (I) was heated at 200 °C for 1 hr or 2 hr, and compounds III—V were isolated in addition to *S*-guaiazulene (II), the main product, formed by loss of the formyl group.

a) 2-Formylguaiazulene (III): A dark red crystalline product (mp 80—81 °C) isolated in the next highest yield had the same molecular formula, $C_{16}H_{18}O$, as I. The existence of a formyl group was indicated by the appearance of a $\nu_{C=O}$ band at 1666 cm^{-1} and ν_{C-H} bands at 2710 and 2795 cm^{-1} in the IR spectrum, and by presence of a singlet at 10.58 ppm attributable to the formyl proton in the NMR spectrum.

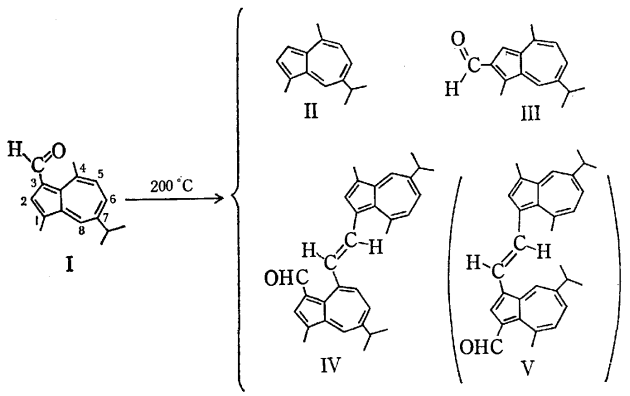

Chart 1.

Moreover, the NMR spectrum (*cf.* Experimental section) showed, besides the formyl-proton signal, signals due to one isopropyl-, two aromatic methyl-, and four aromatic ring hydrogens, a pattern of which is quite similar to that of I. The compound is, therefore, thought to be a positional isomer of I.

The visible absorption spectrum of this compound had two maxima of nearly equal intensities at 660 and 705 nm, and bore a marked resemblance to that of 2-acetylguaiazulene (VI).[1]

These facts lead us to conclude the present compound to be 2-formylguaiazulene (III). In agreement with this deduction, this compound gave VI when treated with diazomethane.[4,5]

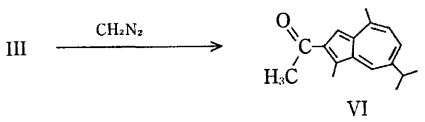

Chart 2.

b) trans-1,2-(1,4-Diazulyl)ethene Derivative (IV). A purple crystalline substance (mp 160—161 °C), the third reaction product, was also an aldehyde, since it exhibited a $\nu_{C=O}$ band at 1620 cm^{-1} in its IR spectrum and a formyl signal at 10.68 ppm in its NMR spectrum. It also gave semicarbazone (mp 192—194 °C). The visible absorption maximum of the compound (513 nm) exhibited, however, an ε value larger than that of I or III by a factor of about twenty, and this is not consistent with the structure of an ordinary formylguaiazulene.

Based on the molecular ion of the mass spectrum, this compound is thought to have a composition, $C_{32}H_{34}O$ (MW, 434), made up through dehydration from two molecules of I ($C_{16}H_{18}O$, 226). This deduction was supported by the observation in the NMR spectrum (*cf.* Experimental section) that the signals ascribed to 34H were recognized.

In the methyl region of the NMR spectrum there were three aromatic methyl signals in addition to two isopropyl ones. Among them, two aromatic methyl signals (2.58 and 2.62 ppm) adjacent to one another

corresponded to Me_1 of I, and a down-field signal (3.08 ppm), to Me_4 of I (*cf.* Experimental section). The appearance of only one signal (3H) corresponding to Me_4 indicates that the formyl group of one molecule of I was condensed with methyl group at 4-position of a second molecule. Consequently, the present compound was postulated to be a diazulylethene derivative (IV).

On the other hand, this compound could possibly be a condensation product of I and III or of III and III, since III was also found in the reaction mixture. This possibility was, however, excluded because IV was isolated as a by-product in preparing I through formylation of II, where no III was obtained.

As to geometrical isomerism, IV was determined to have a *trans* configuration on the basis of the following three reasons: i) According to the NMR spectrum, the coupling constant for the olefinic protons was found to be 15.5 Hz, the value of which fits with a *trans* configuration.[6] ii) From a model examination, a fully conjugated system of two azulene rings and an olefinic bond may hardly be attainable in the *cis* form of IV. Thus, the configuration cannot explain the extremely large ε value in the visible spectrum of IV. iii) IV is expected to take a thermally stable configuration, since it is a thermal reaction product.

c) 1,2-(1,3-Diazulyl)ethene Derivative (V). This substance was isolated as a purple oil, but was not well characterized because of its poor yield and instability. On the basis of the observation in the NMR spectrum that the signals from two isopropyl and three aromatic methyl groups existed and that the pattern of an aromatic proton region was close to that for IV, this compound is thought to be another dimer V formed from two molecules of I through dehydration of the formyl group and the methyl group at 1-position.

Sequence of the Reaction. As is obvious from the above arguments, the heating of 3-formylguaiazulene (I) yielded two monomers, which were formed by elimination or migration of a formyl group, and two dimers, generated by condensation of two molecules of I.

In Table 1 are listed the yields (%) of the products obtained by a reaction time of 1 hr. The yield of IV was found to increase almost linearly with increasing reaction time, while no change in the yield of II and a decrease in that of III were observed. This kind of dehydration is well known in the presence of an appropriate dehydrating reagent,[7] and is apparently characteristic of formyl compounds.

With regard to the acyl migration 2-formylguaiazulene (III) afforded no appreciable product when heated at 200 °C for 1 hr but gave II and I by heating at 250 °C for 1 hr. Thus the acyl migration is concluded to be reversible at the higher temperature, the same as alkyl- and phenyl-migration[8,9] which were investigated at a temperature above 250 °C.

Table 1 also includes the yields (%) of the reaction products formed from the three 3-acylguaiazulenes studied before.[1-3] As is obvious from the Table 1, the thermal exchange between the acyl and the methyl groups was not observed in the case of 3-formylguaiazulene, while it was common to the other acylguaiazulenes. Another feature of the thermal reaction of the 3-formyl compound is that elimination of the acyl group, less important in the other acylguaiazulene, is a major reaction.

In order to clarify the reasons for the observed differences in the reactions, further work is in progress in our laboratory on the reactions of phenyl esters having a variety of electron releasing- or withdrawing-groups at the *p*-position.

Experimental

All melting points are uncorrected. The UV and the visible absorption spectra (VS) were taken in a cyclohexane solution. The IR spectra were obtained as KBr disks, and the mass spectra (MS), at 70 eV. Unless otherwise stated, the NMR spectra were measured at 60 MHz using deuteriochloroform as the solvent: the chemical shifts are given in ppm using TMS as an internal standard, and the coupling constants in Hz. The thin-layer chromatography (tlc) was conducted by the use of silica gel-G (Merck), and the gas chromatography (vpc), using a column (1 m in length) of Chromosorb W impregnated with Silicone SE-30 (1.5%) under a 20 ml/min flow of helium.

3-Formylguaiazulene (I). This compound was synthesized by a Vilsmeier-Haack formylation of *S*-guaiazulene (II).[10] The recrystallization of the product from *n*-hexane gave dark reddish-brown needles [mp 86.0—86.1 °C (mp 85—86 °C[10])], which showed a single brown spot (R_f, 0.16) in tlc (benzene). VS: nm (ε), 573 (539), 600 sh (453), 618 sh (404), 678 (297) [571 (501), 680 (118)[10]]. UV: nm (log ε), 247.5 (4.35), 277.5 (4.05), 310.5 (4.50), 316.5 (4.58), 366 sh (3.71), 385 (3.98), 400 (4.07). IR: 1608 cm^{-1} (C=O). NMR: 1.37/3.05 (d, 6H/m, 1H, J=6.8; *i*-Pr), 2.58 (s, 3H; Me_1), 3.12 (s, 3H; Me_4), 7.40 (d, 1H, J=12.0; H_5), 7.65 (dd, 1H, J=2.0 and 12.0; H_6), 8.25 (s, 1H; H_2), 8.32 (d, 1H, J=2.0; H_8), 10.63 (s, 1H; CHO). NMR (CF_3COOH)[11]: 1.52/3.47 (d, 6H/m, 1H, J=7.2; *i*-Pr), 2.60 (s, 3H; Me_1), 3.23 (s, 3H; Me_4), 8.25 (s, 1H; H_2), 8.35 (s, 2H; $H_{5,6}$), 8.73 (s, 1H; H_8), 9.12 (s, 1H; $=C<^{O}_{H}$).

Table 1. Yields (%) of the thermal reaction products

Products	Carbonyl components			
	HCO	CH_3CO[1,2]	C_6H_5CO[3]	CH_3OCO[3]
S-Guaiazulene	9.1	1.4	1.8	0.8
2-Acylgauaiazulene	6.1	16.4	11.3	0.08
1-Acyl-7-isopropyl-3,4-dimethylazulene	—	7.0	5.7	5.3
2-Benzylguaiazulene	—	—	2.5	—
Diazulylethene derivatives	0.3	—	—	—

Thermal Reaction of 3-Formylguaiazulene (I). *a) Determination of the Reaction Temperature*: Three glass tubes, each containing 50 mg of I, were sealed under a nitrogen atmosphere and heated at 150 °C, 200 °C and 250 °C for 1 hr, respectively. The reaction mixture was, after being dissolved in a small amount of benzene, investigated by tlc (benzene) and vpc (200 °C). The ratio of the reaction products relative to the recovery of I was of 0.8, 15.7 and 108% corresponding to the temperatures of 150, 200 and 250 °C, respectively, on the basis of the vpc. Contrary to these data, in the case of 250 °C we observed tlc spots of degradation products which were spread out over a whole region or did not move from the original point, while those were scarcely apparent in the other cases.

b) The Case of 1 hr Heating. I (1.0255 g) was heated in a sealed tube at 200 °C for 1 hr. The reaction mixture was eluted through a silica-gel column with petroleum ether, subsequently with benzene, and separated into the following three fractions.[12]

petroleum ether:

Fr. 1 blue oil (106.9 mg)···*S*-guaiazulene (II) (93.5 mg)

benzene:

Fr. 2 greenish-brown oil (140.9 mg)···
- 1,2-(1,3-diazulyl)ethene derivative (V) (0.15 mg)
- 2-formylguaiazulene (III) (62.25 mg)

Fr. 3 violet crystals (301.1 mg)···
- *trans*-1,2-(1,4-diazulyl)ethane derivative (IV) (2.74 mg)
- 3-formylguaizulene (I) (277.4 mg) (recovered)

c) The Case of 2 hr Heating. I (3.36 mg) was heated at 200 °C for 2 hr. By treating the reaction mixture as described for (b), each product was obtained in the following yield:

II (262.4 mg), V (0.6 mg), III (58.6 mg), IV (21.0 mg).

S-Guaiazulene (II). This compound was obtained as a blue oil which showed a single blue spot (R_f, 0.46 in tlc (petroleum ether)). It was identical with an authentic specimen[13] in tlc and vpc (180 °C).

1,2-(1,3-Diazulyl)ethene Derivative (V). The greenish brown oil from Fr. 2 exhibited violet and blue spots (R_f, 0.37 and 0.34) overlapping each other in tlc (benzene). By means of repeated benzene–silica-gel elution chromatography, it was roughly separated into a red oil (V portion) and a blue oil (III portion), corresponding to each spot in tlc. The red oil, still containing some of the III portion, was then chromatographed on an aluminum oxide column with a mixed solvent of petroleum ether–benzene (7:3); R_f, 0.29]. NMR (90 MHz, accumulated 34 times): 1.28 (d, 6H, J=6.8; *i*-Pr), 2.57, 2.80 and 3.02 (each s, 3H; Me), 6.90—8.43 (10H; aromatic- and vinyl protons), 10.23 (s, 1H; CHO).

2-Formylguaiazulene (III). The blue oily portion described above was purified by repeated benzene–silica-gel elution chromatography to give III as dark red needles, which showed a single blue spot (R_f, 0.34) in tlc (benzene). After being recrystallized from ethanol, it showed a mp of 80.0—81.0 °C. IR: 1666 cm^{-1} (C=O), 2710 and 2795 cm^{-1} (CH: aldehyde). UV: nm (log ε), 251.2 (4.37), 286.5 (4.47), 304.5 (4.58), 312 sh (4.47), 347 (3.74), 361.5 (3.78), 374 (3.41). VS: nm (ε), 392 (223), 416 (70), 570 sh (277), 616 sh (495), 660 (675), 705 (697). NMR: 1.38/3.07 (d, 6H/m, 1H, J=6.9; *i*-Pr), 2.83 (s, 3H; Me_1), 2.90 (s, 3H; Me_4), 7.00 (d, 1H, J= 2.1 and 10.4; H_5), 7.46 (dd, 1H, J=2.1 and 10.4; H_6), 7.60 (s, 1H; H_3, 8.35 (d, 1H, J=2.1; H_8), 10.58 (s, 1H; CHO). MS: *m/e* 226 (M, $C_{16}H_{18}O$; 96.4%), m/e 225 (M−H; 11.1%), *m/e* 211 (M−CH_3; base peak), *m/e* 197 (M−CHO: 13.1%).

Reaction of 2-Formylguaiazulene (III) with Diazomethane. To a solution of III (32.00 mg) in ether (1 ml), was added an ethereal solution (2 ml) of diazomethane prepared from nitrosomethylurea (0.4 g); the solution was then kept at room temperature for 25 days. After the remaining reagent was decomposed by adding a few drops of formic acid, the reaction mixture was submitted to benzene–silica gel elution chromatography to afford VI (3.90 mg) as green crystals and the recovery of III (11.56 mg) as dark red crystals. VI, thus obtained, was idetical with an authentic specimen[1] in tlc (benzene) and vpc (195 °C).

Thermal Reaction of 2-Formylguaiazulene (III). III was sealed in three glass tubes (*ca.* 50 mg in each ampoule), and heated at 150, 200 and 250 °C for 1 hr, respectively. The reaction mixture, dissolved in a small amount of benzene, was investigated by tlc (benzene) and vpc (195 °C). The formations of II, I and an unknown substance were observed in the case of 250 °C, while only unchanged III was detected in the cases of 150 °C and 200 °C. The yield of each compound at 250 °C (III; 46.2 mg) was estimated on vpc (195 °C) to be 7.5 (II), 2.5 (I), 13.7 (unknown) and 76.4% (III; recovered). Successively the reaction mixture was subjected to benzene–silica-gel elution chromatography to be separated into II (15.78 mg), I (1.15 mg) and unchanged III (12.71 mg). These compounds were identical with the authentic specimens in tlc and vpc.

trans-*1,2-(1,4-Diazulyl)ethene Derivative (IV).* *a) By Thermal Reaction of 3-Formylguaiazulene (I).* The violet crystals from Fr. 3 were chromatographed on a silica-gel column with a mixed solvent of benzene–ether (49:1), and separated into purple crystals of IV and reddish-brown crystals of I (recovered). The former showed a single violet spot (R_f, 0.19) in tlc (benzene), and had a mp of 160.0—160.1 °C after being recrystallized from *n*-hexane. IR: 1620 cm^{-1} (C=O). UV: nm (log ε), 256 (4.40). 262 (4.40), 310 (4.44). VS: nm (log ε), 403 (4.00), 513 (4.21). NMR (90 MHz, accumulated 41 times): 1.36 and 1.42 (each d, 6H, J=7.0; 2*i*-Pr), 2.58 and 2.62 (each s, 3H; $2Me_1$), 3.08 (s, 3H; Me_4), 6.97—8.20 (8H; aromatic protons), 7.88 and 8.32 (each d, 1H, J=15.5; vinyl protons), 10.68 (s, 1H; CHO). MS: *m/e* 434 (M, 16.5%), *m/e* 211 (M−CH=CH; base peak).

The semicarbazone of this compound was obtained as a dark brown powder in a usual manner. After being recrystallized from ethanol, it showed a mp of 192.0—194.0 °C.

b) As a By-product in the Preparation of 3-Formylguaiazulene (I). *S*-Guaiazulene (II) (10.0 g) was formylated with a mixed reagent of dimethylformamide (65 ml) and phosphorous oxychloride (8.7 g).[10] The reaction mixture was submitted to benzene–silica-gel elution chromatography giving I (3.05 g) and IV (13.32 mg). The IV obtained thereby was identical with that from (a) (thermal reaction product) in tlc and in IR spectrum.

The authors wish to thank Professor Shûichi Hayashi of Hiroshima University for the mass spectral measurements, Professor Yûho Tsuno of Kyushu University for the measurements of the accumulated NMR spectra, and to Professor Arthur G. Anderson, Jr., University of Washington, U.S.A., for assistance in preparing the manuscript. Thanks are also due to the Ministry of Education, Japanese Government, for a Scientific Research Grant-in-Aid.

Autoxidation of Toluic Acids Catalyzed by Cobalt and Bromide Ions in Acetic Acid

Yoshio KAMIYA and Toshisuke USHIBA

Department of Reaction Chemistry, Faculty of Engineering, University of Tokyo, Hongo 113

(Received December 25, 1974)

The effect of toluic acid concentration on the rate of autoxidation of toluic acids catalyzed by cobalt acetate and sodium bromide was elucidated. *p*-Toluic acid has shown a similar reactivity against oxidation to *m*-toluic acid, but a much different one from *o*-toluic acid. Although the rate of oxidation of *p*-toluic acid at 0.023 M cobalt increased with increasing *p*-toluic acid concentration and appeared to reach a limiting value, it was of first order with respect to the substrate concentration over wide range of concentration in the presence of 0.058 M cobalt. While, the rate of oxidation of *o*-toluic acid has shown higher values than the other toluic acids at substrate concentrations below 1.5 M and a maximum value at substrate concentration 0.75 M, suggesting that *o*-toluic acid can be oxidized easily but retards the catalysis by cobalt bromide. It was found that benzenecarboxylic acids remarkably retard the catalysis by cobalt and bromide ions, and the rate of oxidation of toluic acids is higher than that of toluene at such a low substrate concentrations as 0.34 M. The ease of oxidation of toluic acids can be attributed to the smaller rate constant of termination of carboxy benzyl peroxy radicals according to the polar and steric effects.

Although the rate of oxidation of alkylbenzenes[1-3] in acetic acid catalyzed by cobalt and bromide ions is of first order with respect to substrate concentration as in the cases of ordinary autoxidation reaction, that of *p*-toluic acid was reported to be independent of toluic acid concentration according to Ravens,[4] Bawn and Wright.[5] There has never been presented any successful explanations for this interesting result on *p*-toluic acid. Previously,[6] we have shown that the relative reactivity of substituted toluenes in this catalysis can be correlated by the polar effect of the substituent and is largely different from the relative rate of oxidation of single component. We intended to clarify the effect of benzenecarboxylic acids on the catalysis by cobalt and bromide ions and also to make clear the substituent effect on the rate of oxidation of substituted toluenes.

Experimental

Acetic acid, sodium bromide, cobaltous acetate $Co(OAc)_2 \cdot 4H_2O$, benzoic acid, phthalic acid, and three isomers of toluic acids were of reagent grade and used as received.

The oxygen absorption apparatus has been described elsewhere.[6]

Results and Discussion

The oxygen absorption curves in Fig. 1 shows that the rate of oxidation of toluic acids catalyzed by cobalt and bromide ions in acetic acid reaches a maximum and steady value within ten minutes of reaction.

In the cases of *m*- and *p*-toluic acids, the rate of oxidation slowly decreased after the absorption of considerable amount of oxygen and the solution became turbid indicating the formation of insoluble dibasic acids. The decrease in the rate of oxidation can be attributed to the decrease in the concentration of bromide ion, since it has been accepted[3,8,9] that bromide ion is slowly converted to an inactive form of organic bromide in the autoxidation of alkylbenzenes catalyzed by cobalt bromide.

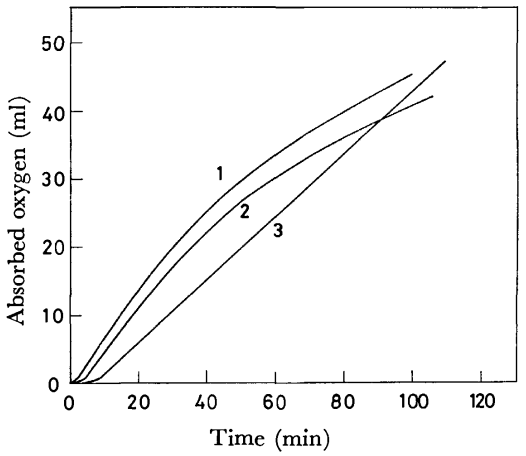

Fig. 1. Oxygen absorption curves of 2.4 M toluic acids in the autoxidation catalyzed by 0.023 M $Co(OAc)_2$ and 0.046 M NaBr in acetic acid at 85 °C.
1: *p*-Toluic, 2: *m*-Toluic, 3: *o*-Toluic acids.

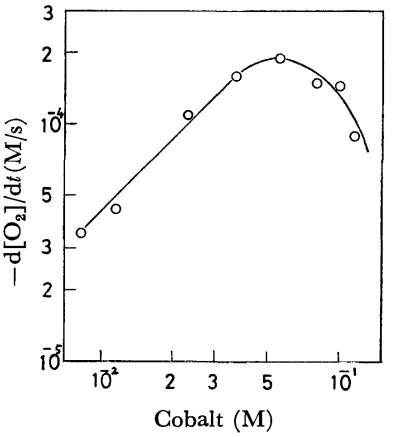

Fig. 2. The rate of oxidation of 0.65 M *p*-toluic acid catalyzed by cobaltous acetate and sodium bromide in acetic acid as a function of the concentration of cobalt acetate at the molar ratio of cobalt to bromide ion 2 and 85 °C.

However, in the case of *o*-toluic acid the oxygen absorption curve has shown a complete straight line for a long time. This might be due to the slower formation of organic bromides from the bromide ion than the other toluic acids, since Nakayama[7] observed a very small amounts of organic bromides in the oxidation of *o*-xylene to *o*-phthalic acid.

The steady rate of oxidation of *p*-toluic acid was nearly of first order with respect to cobalt concentration below 0.05 M in the presence of twice concentration of sodium bromide, as shown in Fig. 2. And the rate of oxidation was increased with increasing bromide ion until the ratio of cobalt to bromide ion became two. Hence, the oxidation was carried out at cobalt concentrations below 0.058 M and at the ratio of cobalt to bromide ions 2.

The steady rate of oxidation of three toluic acids as a function of substrate concentration is shown in Figs. 3, 4

and 5. When 0.023 M of cobalt acetate was used, the rates of oxidation of *p*- and *m*-toluic acids increased with increasing toluic acid concentration at concentrations below 1.0 M, and approached to a limiting value. The reactivity of *p*-toluic acid seems entirely the same as that of *m*-toluic acid. On the other hand, *o*-toluic acid has shown a maximum rate at 0.75 M and started to decrease as the substrate concentration was further increased.

o-Toluic acid was oxidized faster than *p*- and *m*-toluic acids by a factor of two, but it seems to deactivate the catalyst remarkably.

When the concentration of cobalt acetate was increased from 0.023 M to 0.058 M, the rate of oxidation of *p*-toluic acid showed an almost linear relation against the substrate concentration over a wide range of concentration, suggesting that *p*-toluic acid suppressed the catalytic effect due to cobalt and bromide ions. The retardation effect due to *o*-phthalic and benzoic acids on the oxidation of *o*-toluic acid was further studied as shown in Table 1. The addition of 0.54 M *o*-phthalic acid has shown a considerable retardation effect, but further addition of phthalic acid higher than 1.0 M presented no additional retardation effect according to the low solubility in acetic acid.

It was confirmed that isophthalic and terephthalic acids have no effect on the rate of oxidation of toluic acids because of very low solubility.

In contrast, benzoic acid, which was quite stable against oxidation, has shown a quite clear retardation effect on the cobalt bromide catalysis. The rate of oxidation of *o*-toluic acid decreased by factors of two and three in the presence of 1.28 and 2.44 M of benzoic acid, respectively.

Since the rate of oxidation is nearly first order with respect to cobalt, 1.28 M of benzoic acid can be considered to deactivate 0.01 M cobalt ion.

As reported previously,[6] cobaltous acetate bromide was oxidized by 2-cyano-2-propyl peroxy radical quantitatively in acetic acid solution, yielding cobaltic

Table 1. Retardation effect of benzenecarboxylic acids on the rate of oxidation of *o*-toluic acid in acetic acid solution at 85 °C

o-Toluic acid (M)	0.75	0.75	0.75	0.75	0.67	0.67	0.75
Benzoic acid (M)	0	1.28	1.86	2.44	—	—	—
o-Phthalic acid (M)	—	—	—	—	0	0.54	0.91
$Co(OAc)_2$ (M)	0.023	0.023	0.023	0.023	0.023	0.023	0.023
NaBr (M)	0.046	0.046	0.046	0.046	0.023	0.023	0.046
$-d[O_2]/dt$ (M/s) $\times 10^4$	1.70	0.84	0.83	0.58	1.20	0.89	1.39

ion. It was confirmed that the rate of formation of cobaltic ion by peroxy radical decreased by a factor of three in the presence of 2.4 M benzoic acid.

Coordinated benzoic acid to cobaltous ion may retard the reaction of cobalt with peroxy radical and the formation of cobaltic ion because of steric hindrace, and so retard the successive oxidation of toluic acid.

In order to exclude the retardation effect due to toluic acids, the relative rate of oxidation of toluic acids at concentration of 0.34 M is compared with the other rates of substituted toluenes as shown in Table 2. It is surprizing that toluic acids are apparently more reactive than toluene or methoxy toluene.

Table 2. Relative rate of oxidation of substituted toluenes catalyzed by 0.023 M $Co(OAc)_2$ and 0.046 M NaBr in acetic acid at 85 °C

Substituted toluene (0.34M)	Relative rate of oxidation
Toluene	1.00
p-Xylene[a)]	1.96
p-Methoxytoluene[a)]	0.96
p-Chlorotoluene[a)]	1.05
o-Chlorotoluene[a)]	1.03
p-Toluic acid	1.10
m-Toluic acid	1.15
o-Toluic acid	2.30

a) Ref. 6.

Apparently, the rate of oxidation of toluene was much higher than those of toluic acids at higher substrate concentration, for example, it was about 2.4 times as fast as those of *m*- and *p*-toluic acids at concentration of 2.4 M and 85 °C.

Previously,[6)] we have shown that the relative rates of autoxidation of substituted toluenes were quite different from the relative reactivities obtained by the competitive oxidation and we ascribed these results to the difference in the rate of termination reaction between substituted benzyl peroxy radical. An electron withdrawing substituent such as carboxyl group will decrease the rate of hydrogen abstraction step as in the case of ordinary free radical reaction, but it seems also to reduce considerably the rate of bimolecular reaction of benzyl peroxy radicals. Although we can not present any measured values about the termination rate constant of substituted toluenes, the polar effect seems to be a good explanation for the results given in Table 2. In addition, the bimolecular reaction of 2-carboxy benzyl peroxy radical can be expected to be slower than that of 4-carboxy benzyl peroxy radical because of steric hindrance. However, the steric effect of chlorine atom on the rate of termination seems not so large as the carboxyl group.

In order to elucidate the steric effect of carboxyl group, the mixing effect of toluic acids was studied and shown in Table 3. The rate of oxidation of an equimolar mixture of *m*- and *p*-toluic acids was nearly equal to those of twice amount of single components, because the rates of oxidation of 0.68 M and 1.22 M *p*-toluic acid were 1.10×10^{-4} and 1.50×10^{-4} M/s, respectively, and those of 0.68 M and 1.22 M *m*-toluic acid were 1.12×10^{-4} and 1.43×10^{-4} M/s.

It can be concluded that *m*- and *p*-toluic acids have similar reactivities in the autoxidation reaction. On the other hand, the rate of oxidation of 0.34 M *o*-toluic acid decreased from 1.30 to 1.21 or 1.18×10^{-4} M/s by the addition of 0.34 M *m*-toluic or *p*-toluic acids. These results can only be explained on the basis of cross termination between two different peroxy radicals as in the case of cumene and tetralin.[10)] The retardation effect due to *m*- and *p*-toluic acids should be much smaller than by *o*-toluic acid according to Figs. 3—5.

The higher rate of oxidation of *o*-toluic acid than *p*-toluic acid can be attributed to the smaller termination rate constant (k_t) of the derived peroxy radical. However, in the presence of *p*-toluic acid, the cross termination between different peroxy radicals will be predominant and the rate constant of cross termination will be larger than k_t of *o*-toluic acid and similar to k_t of *p*-toluic acid, since no more significant steric effect can be expected in the bimolecular reaction between different peroxy radicals. Thus, a mixture of *o*- and *p*-toluic acids will present a similar rate of oxidation as a mixture of *m*- and *p*-toluic acids.

Incidentally, we observed similar antagonistic effect in the oxidation of a mixture composed of *p*-toluic acid and toluene, that is, the rate of oxidation of 0.86 M toluene catalyzed by 0.023 M $Co(OAc)_2$ and 0.046 M NaBr just increased from 1.35 to 1.43×10^{-4} M/s by adding 0.34 M *p*-toluic acid.

Table 3. Mixing effect of toluic acids on the rate of oxidation at $Co(OAc)_2$ 0.023M, NaBr 0.046 M and 85 °C in acetic acid

p-Toluic acid (M)	0.34	0.68	1.22	—	—	—	—	0.34	0.34	0.61	—	—

Carbon-Carbon Bond Formation by Selective Coupling of Alkylthioallylcopper Reagent with Allylic Halides

Koichiro OSHIMA, Hisashi YAMAMOTO, and Hitosi NOZAKI
Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606
(Received January 30, 1975)

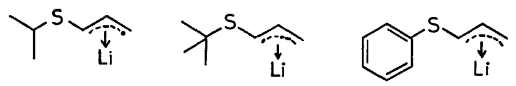
The reaction of 1-alkylthioallylcopper reagents with allylic halides affords the S_N2' type substitution product in excellent yield. The more synthetically useful reagent, 1,3-bis(methylthio)allylcopper reagent behaves in the same fashion. Attempts to hydrolyze the vinyl sulfide moiety to an aldehyde unit is successful only in the latter case. Yomogi alcohol is synthesized stereospecifically in the light of these results.

The remarkable regio- and stereospecificity of simple organocopper derivatives, *e.g.*, CuR or $LiCuR_2$, where R=alkyl, vinyl, or aryl, to form carbon-carbon bond with organic halides[2] raises the question whether the specific reactivity of more stable carbanionic intermediates could be enhanced by copper(I) ion.[3] The answer to the question is of particular interest for the 1-alkylthioallyl anions since the reaction of these systems has substantial synthetic utility. Moreover, the recent development of effective methods for converting allylic sulfides to 1-alkylthioallyllithium species[4] has made 1-alkylthioallylcopper(I) derivatives readily available for synthetic studies.

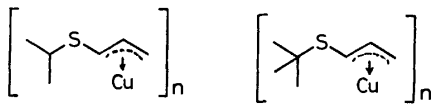
1-Alkylthioallyl anion is synthetically equivalent to either the 1-oxopropyl anion ($-COCH_2CH_3$) or 3-oxopropyl anion ($-CH_2CH_2CHO$). It was already

known that aryl- or alkylthioallyllithium undergoes reaction with organic halides to introduce an alkyl group specifically on the carbon α to the alkylthio group and not γ to the sulfur atom.[4] In this study we have synthesized alkylthioallylcopper(I) derivatives and have examined their behavior as potential synthon of 3-oxopropyl anion. We have also examined 1,3-bis(methylthio)allylcopper(I) as a synthon of 3-oxopropenyl anion ($-CH=CHCHO$).

A solution of 1-alkylthioallyllithium **1**—**3** in ether or tetrahydrofuran was prepared from the corresponding allyl sulfide and *sec*-butyllithium at −25 °C for 30 min. Treatment of the ethereal solution of organolithium derivative **1** or **2** with slightly excess cuprous iodide (CuI) at −78 °C for 15 min furnished a gray to white suspension which by analogy with the previous work[5] probably due to the polymeric organocopper derivatives **4** and **5**, respectively.



1 2 3



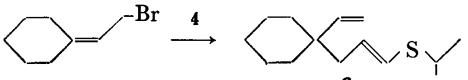
4 5

These suspensions were stable at −78 °C for 1 hr but decomposed gradually at −25 °C to form a black precipitate.[6] Although the similar complex could be formed in tetrahydrofuran, the resulting complex was found to decompose much faster. Thus, alkylthioallylcopper derivatives should be prepared in ether at −78 °C in a period of 15—30 min. It is noteworthy, however, that similar treatment of **3** with CuI failed to produce analogous monoalkylcopper derivatives but only a black tar.

Attempted preparation of lithium di(alkylthioallyl)-cuprate derivatives failed. After addition of a half equiv of CuI to the lithium derivative **1** a black precipitate formed, the behavior of which was quite similar to that of **1**. From the previous observation,[6b] it would appear that the tendency of metal cuprate species to undergo specific reaction is retarded by the presence of carbon ligand which could form reasonably stable anion.

$$R_2Cu^- \rightleftharpoons RCu + R^-$$

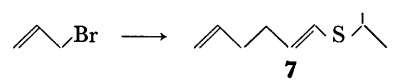
The reaction of 2-cyclohexylideneethyl bromide (1.0 equiv) with isopropylthioallylcopper (2.0 equiv) in ether at −78 °C for 4 hr produced the substitution product **6** in 92% yield;>96% pure by glpc and NMR assay.



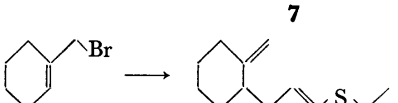
6

The reaction appears to be a pure S_N2' type displacement of bromine by isopropylthioallyl group. In addition this ambident anion undergoes alkylation exclusively γ to sulfur atom in high yield: thus, the alkylthioallylcopper reagent did behave as a synthon of 3-oxopropyl anion. Although the S_N2' type displacement of allylic or propargylic acetate by metal dialkylcuprate reagent have been shown previously,[7] the present reaction offers the advantage of high regio selectivity to a unique degree.

In a similar experiment, allyl bromide and 1-cyclohexenylmethyl bromide gave the sulfides **7** and **8** in 88% and 87% yields, respectively.



7

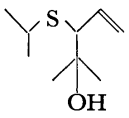


8

Further study is required before the stereochemical and mechanistic details of these reactions can be

undestood. However, we could assume the involvement of a radical type intermediate for this reaction on the basis of the following results. Treatment of benzyl bromide with the copper complex **4** at −78 °C for 2 hr produced bibenzyl in a moderate yield. Similarly benzhydryl chloride gave 1,1,2,2-tetraphenylethane as a major product. These observations are possibly indicative of the presence of benzyl radical or benzhydryl radical in the course of the reaction, since both of which are known to be dimerized easily to form the isolated coupling products.[8]

Alkylthioallylcopper also reacts with substances other than allylic halides. The isopropylthio complex **4** reacts with acetone in ether at −78 °C to yield **9** as a major product. Thus, the behavior of carbonyl compounds toward the copper derivative **4** contrasts sharply with that of allylic halides as those appearing above.

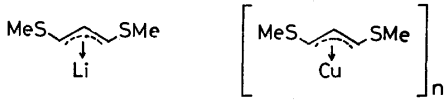


9

Finally, we examine the possibility of Michael reactions including the addition of **4** or **5** to mesityl oxide. In no case, however, did the presence of excess copper(I) derivatives in the reaction mixture have any substantial effect on the rate or product distribution of the Michael reaction.

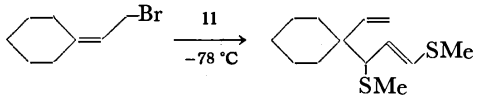
The experimental procedure generally used for hydrolysis of vinyl sulfides with mercuric chloride[9] was applied to the product **6** without any success. Only minimal conversion to the corresponding aldehyde was observed, and the major products constitute a complex mixture, possibly as a result of acid-catalyzed cyclization followed by rearrangements. The relative difficulties associated with δ,ε-unsaturated aldehyde synthesis led us to explore the following route starting from 1,3-bis(methylthio)propene.

1,3-Bis(methylthio)allyllithium (**10**) was readily prepared by metallation of 1,3-bis(methylthio)propene with *sec*-butyllithium in ether at −25 °C, a procedure superior to previous methods[10] for our present purpose in that **10** is formed in high yield in the absence of secondary amine. Although a solution of the lithio derivative **10** was reported to be purple, a pale yellow solution was obtained in the absence of diisopropylamine. Treatment of this solution with CuI at −78 °C and stirring for 15 min produced the corresponding copper derivative **11** which behaved similarly as isopropylthioallylcopper in the following reaction with allylic halides.



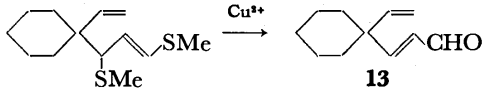
10 11

Thus, 2-cyclohexylideneethyl bromide was treated with the copper reagent **11** at −78 °C to furnish the expected S_N2' type substitution product **12** in almost quantitative yield.



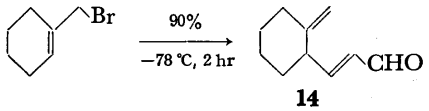
12

Previously, the hydrolysis of 1,3-bis(methylthio)-propene derivatives to α,β-unsaturated carbonyl compounds has been effected by mercury(II) ion.[10] Seeking a milder hydrolysis procedure, we investigated the use of cupric ion in ethanol[11] and found that this ion afforded very high yields of pure aldehydes. The process is devoid of the cationic cyclization of **11** as well as other side reactions.



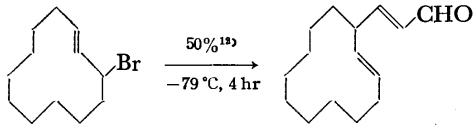
13

The δ,ε-unsaturated aldehyde **13** was obtained in 92% over-all yield from the cyclohexylideneethyl bromide. Similarly, the reaction of 1,3-bis(methylthio)-allylcopper with several allylic halides in ether as solvent, followed by cupric ion catalyzed hydrolysis, led to efficient cross coupling as indicated below.



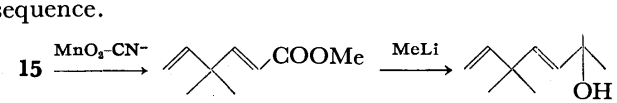
14

15



16

The observed regio- and stereoselectivity of our new reaction portends its broad synthetic application in the field of natural product chemistry. As an example, Yomogi alcohol, (*E*)-2,5,5-trimethyl-3,6-heptadien-2-ol (**17**),[13] was prepared regio- and stereoselectively when the aldehyde **15** was subjected to the following two-step sequence.



18 **17**

The aldehyde **15** was converted to the corresponding carboxylic ester **18** stereospecifically in good yield by manganese dioxide-cyanide ion method.[14] The homogeneity of the ester **18** was indicated by tlc and glpc analysis. In addition, the NMR and infrared spectra of **18** were entirely analogous to those of the corresponding ethyl ester.[13] The ester so obtained was alkylated by the treatment of excess methyllithium[13] at −25 °C for 30 min to yield Yomogi alcohol (**17**) in 75% yield. The NMR, infrared, and mass spectra of **17** were identical with those of the natural alcohol **17**.[13]

The authors acknowledge with pleasure the financial support by the Grant-in-aid administered by the Ministry

of Education, Japanese Government. We are also grateful to Dr. Y. Kato, Teijin Limited, for the exact mass spectral data.

Experimental

IR spectra were determined on a Shimadzu IR-27-G spectrometer, mass spectra on a Hitachi RMU-6L mass spectrometer, glpc analyses on a Yanagimoto GCG-550F, and NMR spectra on a JEOL-C-60-H or Varian EM-360 spectrometer; chemical shifts are given in δ with TMS as the internal standard. Analyses were carried out by Mrs. K. Fujimoto at Prof. Kawanisi's Laboratory and by the staffs at the Elemental Analyses Center of Kyoto University. High resolution mass spectra were taken on a JMS-D100 mass spectrometer operating at 75 eV. All experiments were carried out under an atmosphere of dry nitrogen, preparative thin layer chromatography (plc) on silica gel PF-254 (Merck) plates with hexane or benzene as a developing solvent, and preparative column chromatography on silica gel WAKO-gel C-100 (Wako).

Preparation of Allyl Alkyl Sulfides. A mixture of alkyl mercaptane (0.27 mol), sodium ethoxide (20 g, 0.30 mol), and ethanol (200 ml) was heated at reflux and treated with a solution of allyl bromide (37 g, 0.30 mol) in ethanol (20 ml) dropwise over 30 min. The mixture was heated at reflux for 1 hr, and allowed to cool to room temperature. The reaction was quenched by the addition of water and the separated organic layer was dried. Fractional distillation through a 20 cm Vigreux column afforded NMR-pure allyl sulfides in 60—80% yield.

Allyl isopropyl sulfide: bp 127—128 °C (760 mmHg); IR (neat) 1640, 1250, 1230, 990, 910 cm^{-1}; NMR (CCl_4) δ 1.20 (d, J=7, 6H), 2.82 (dq, J=7, 1H), 3.12 (d, J=8, 2H), 4.85—5.27 (m, 2H), 5.45—6.10 (m, 1H); mass *m/e* (%) 116 (38), 74 (80), 59 (35), 43 (42), 41 (100).

Allyl *tert*-butyl sulfide: bp 60 °C (43 mmHg); NMR (CCl_4) δ 1.29 (s, 9H), 3.0—3.3 (m, 2H), 4.8—6.3 (m, 3H); mass *m/e*: 130 (M^+).

Generation of Isopropylthioallylcopper **4** *and* tert-*Butylthioallylcopper* **5**. Allyl isopropyl sulfide or allyl *tert*-butyl siulfide (2.0 mmol) was dissolved in dry ether (15 ml). The solution was cooled to −78 °C and treated with *s*-butyllithium in pentane (2.0 ml of 1.02 M solution). After stirring for 30 min at −26 °C, the resulting organge or pale yellow solution was recooled to −78 °C. Solid cuprous iodide (2.4 mmol) was added. A white precipitate formed immediately and the mixture was stirred at the same temperature for 15 min before subsequent treatments described below.

Reaction of **4** *with Cyclohexylideneethyl Bromide.* A solution of cyclohexylideneethyl bromide (1.9 g, 10 mmol) in either (10 ml) was added at −78 °C to a solution of **4** prepared from allyl isopropyl sulfide (2.4 g, 20 mmol), ether (70 ml), *s*-butyllithium (20 ml of 1.02 M solution in pentane), and cuprous iodide (5.0 g, 26 mmol). The mixture was kept at −78 °C for 4 hr. The resulting black mixture was filtered through a pad of Celite 545 and the filter cake was washed with ether. The filtrate and washings were combined, washed with water, dried, and freed of the solvent. The residual liquid was separated through a column chromatography on silica gel (100 g) with hexane–benzene as an eluant. The less polar fraction (tlc R_f 0.50 (hexane)) provided the sulfide **6** (2.1 g, 92% yield): bp 145 °C (bath temp., 3 mmHg); IR (neat) 1640, 1242, 945, 912 cm^{-1}; NMR (CCl_4) δ 1.25 (d, J=7, 6H), 1.40 (bs, 10H), 2.03 (d, J=7, 2H), 3.00 (dq, J=7, 1H), 4.96 (dd, J=2 and 17, 1H), 5.09 (dd, J=2 and 12, 1H), 5.60 (dt, J=7 and 15, 1H), 5.70 (dd, J=12 and 17, 1H), 6.02 (d, J=15, 1H); mass *m/e* (%) 224 (5), 181 (16), 116 (20), 115 (100), 73 (70); Anal. Found: C, 75.2; H, 11.0. Calcd for $C_{14}H_{24}S$: C, 74.9; H, 10.8. The more polar fraction (tlc R_f 0.15 (hexane)) afforded the dimer of allyl isopropyl sulfide (0.48 g, *m/e* 230 (M^+)) which was not identified completely.

Reaction of **4** *with 1-Cyclohexenylmethyl Bromide.* A solution of **4** prepared from allyl isopropyl sulfide (0.23 g, 2.0 mmol) was treated with 1-cyclohexenylmethyl bromide (0.18 g, 1.0 mmol) at −78 °C and stirred at −78 °C for additional 4 hr. The orange liquid obtained on extractive work-up was submitted to preparative tlc on silica gel with hexane as an eluant. The band at R_f 0.4—0.6 provided the sulfide **8** (0.18 g, 87% yield) as a colorless liquid: bp 130 °C (bath temp., 3 mmHg); IR (neat) 1645, 1240, 945, 905, 890 cm^{-1}; NMR (CCl_4) δ 1.25 (d, J=7, 6H), 2.95 (dq, J=7, 1H), 4.58 (bd, J=7, 2H), 5.63 (dt, J=7 and 15, 1H), 5.90 (d, J=15, 1H); mass *m/e* (%) 210 (24), 167 (92), 134 (44), 116 (76), 115 (100). Found: C, 73.9; H, 10.4%. Calcd for $C_{13}H_{22}S$: C, 74.2; H, 10.5%.

Reaction of **4** *with Allyl Bromide.* A solution of **4** prepared from allyl isopropyl sulfide (0.23 g, 2.0 mmol) was treated with allyl bromide (86 μl, 1.0 mmol) at −78 °C. The resulting solution was kept at −78 °C for 4 hr, and the color of the solution was turned black at the end of the period. Tetralin (100 μl, 97 mg) was injected and the entire mixture was filtered through a pad of Celite 545 and washed with ether. The filtrate was washed with dilute hydrochloric acid, water, and dried. The resulting organic phase was submitted directly to glpc to obtain the yield of the sulfide **7** using tetralin as the internal standard: 88% yield. The analytical sample was prepared by preparative tlc and bulb to bulb distillation: bp 110 °C (bath temp., 45 mmHg); IR (neat) 1640, 1240, 990, 940, 910 cm^{-1}; NMR (CCl_4) δ 1.30 (d, J=7, 6H), 2.02—2.38 (m, 4H), 2.98 (dq, J=7, 1H), 4.75—5.16 (m, 2H), 5.40—6.05 (m, 3H); mass *m/e* (%) 156 (8), 115 (51), 113 (18), 84 (14), 73 (100); Found: C, 69.2; H, 10.2%. Calcd for $C_9H_{16}S$: C, 69.2; H, 10.3%.

Reaction of **4** *with Benzyl Bromide.* Benzyl bromide (0.17 g, 1.0 mmol) was treated with the complex **4** (2.0 mmol) in ether (13 ml) at −78 °C for 2 hr. The preparative tlc separation of the crude reaction mixture gave bibenzyl (71 mg, 78% yield) as the major product; it was identical in all respects with an authentic sample.

Reaction of **4** *with Benzhydryl Chloride.* Benzhydryl chloride (0.20 g, 1.0 mmol) was treated with the complex **4** (2.0 mmol) in ether (10 ml) at −78 °C for 2 hr. After the concentration of the dried extracts *in vacuo*, a white solid was obtained. Recrystallization from benzene-hexane (1: 1) gave pure 1,1,2,2-tetraphenylethane (0.12 g, 70%) as colorless crystals; the product was identical in all respects with an authentic sample.

Reaction of **4** *with Acetone.* A solution of **4** prepared from allyl isopropyl sulfide (0.23 g, 2.0 mmol) was treated with acetone (1.0 ml) at −78 °C and kept there for 1 hr. The mixture was filtered through a pad of Celite 545 and washed through with ether. The filtrate was washed with dilute hydrochloric acid and water, dried, and concentrated *in vacuo*. The residual liquid (0.31 g) was submitted to glpc; α-adduct/γ-adduct=20: 1 by comparison with an authentic sample.[15]

Generation of 1,3-bis(Methylthio)allylcopper **11**. *sec*-Butyllithium in pentane (1.02 M, 2.0 ml, 2.0 mmol) was added to a solution of 1,3-bis(methylthio)propene (2.0 mmol) in ether (15ml) with stirring under nitrogen at −78 °C and kept at −26 °C for 30 min. The resulting orange solution was recooled to −78 °C and treated with cuprous iodide (2.4 mmol) and stirred at that temperature for 15 min before subsequent

treatments described below.

*Reaction of **11** with Cyclohexylideneethyl Bromide.* A solution of **11** derived from 0.27 g (2.0 mmol) of 1,3-bis(methylthio)propene was treated with cyclohexylideneethyl bromide (0.19 g, 1.0 mmol) at −78 °C. The color of the solution turned brown rapidly and black after stirring for additional 2 hr. The liquid (0.35 g) obtained on extractive work-up was treated with cupric chloride (0.44 g, 3.0 mmol) and cupric oxide (0.24 g, 3.0 mmol) in ethanol (20 ml) at 25 °C for 1 hr. The mixture was filtered through a pad of Celite 545 and the filter cake was washed with ether. The ethereal solutions were washed with dilute hydrochloric acid and water and concentrated *in vacuo*. The residual liquid was submitted to preparative tlc with benzene as an eluant. The band at R_f 0.5—0.6 provided the aldehyde **13** (0.15 g, 92% yield) as a colorless liquid: bp 120 °C (bath temp., 18 mmHg); IR (neat) 1685, 1625, 1110, 980, 915, 850 cm^{-1}; NMR (CCl_4) δ 1.2—2.1 (m, 10H), 4.7—5.8 (m, 2H), 5.95 (dd, J=7 and 15, 1H), 6.6 (d, J=15, 1H), 9.45 (d, J=7, 1H); mass *m/e* (%) 164 (12), 135 (67), 121 (24), 107 (36), 81 (64), 79 (70), 67 (100); Mol wt. Found: 164.1170. Calcd for $C_{11}H_{16}O$: 164.1201.

*Reaction of **11** with 1-Cyclohexenylmethyl Bromide.* A solution of **11** derived from 1,3-bis(methylthio)propene (0.27 g, 2.0 mmol) was treated with 1-cyclohexenylmethyl bromide (0.18 g, 1.0 mmol) at −78 °C and kept there for 2 hr. After extractive work-up, a mixture of residual liquid, cupric chloride (0.40 g, 3.0 mmol), and cupric oxide (0.24 g, 3.0 mmol) in ethanol (20 ml) was stirred under nitrogen at 25 °C for 1 hr. The black suspension was filtered through a pad of Celite 545 and the filter cake was washed with ether. The ethereal solutions were washed with water, dried, and freed of the solvent. The remaining oil was submitted to preparative tlc on silica gel with benzene as an eluant. The band at R_f 0.45—0.60 provided the aldehyde **14** (0.14 g, 90% yield) as a colorless liquid: bp 100 °C (bath temp., 18 mmHg); IR (neat) 1690, 1645, 1150, 1120, 980, 890 cm^{-1}; NMR (CCl_4) δ 4.5—4.65 (bd, 2H), 6.0 (dd, J=7 and 15, 1H), 6.8 (dd, J=8 and 15, 1H), 10.1 (d, J=7, 1H); mass *m/e* (%) 150 (21), 135 (33), 121 (62), 107 (65), 93 (39), 81 (94), 79 (100); Anal. Found: C, 79.8; H, 9.65%. Calcd for $C_{10}H_{14}O$: C, 80.0; H, 9.39%.

*Reaction of **11** with 4-Bromo-2-methyl-2-butene.* A solution of **11** prepared from 1,3-bis(methylthio)propene (0.27 g, 2.0 mmol) was treated with 4-bromo-2-methyl-2-butene (0.15 g, 1.0 mmol) at −78 °C for 2 hr. Ethereal extracts were washed with water, dried, and concentrated. Powdered cupric chloride (0.40 g, 3.0 mmol) and cupric oxide (0.24 g, 3.0 mmol) were sequentially added to a solution of the remaining liquid (0.25 g) in ethanol (20 ml). The heterogeneous reaction mixture was stirred under nitrogen at 25 °C for 1 hr. Extractive workup furnished a liquid which was submitted to preparative tlc with benzene as an eluant. The band at R_f 0.5—0.65 provided the aldehyde **15** (0.18 g, 72% yield) as a colorless liquid: IR (neat) 1690, 1160, 1110, 986, 920, 785 cm^{-1}; NMR (CCl_4) δ 1.25 (s, 6H), 4.95 (dd, J=2 and 20, 1H), 5.02 (dd, J=2 and 10, 1H), 5.80 (dd, J=10 and 20, 1H), 5.95 (dd, J=7 and 16, 1H), 6.7 (d, J=16, 1H), 9.5 (d, J=7, 1H); mass *m/e* (%) 124 (13), 109 (85), 81 (90), 79 (64), 67 (100); Mol wt. Found: 124.0843. Calcd for $C_8H_{12}O$: 124.0889.

*Reaction of **11** with 2-Cyclododecenyl Bromide.* A solution of **11** prepared from 1,3-bis(methylthio)propene (0.27 g, 2.0 mmol) was treated with 2-cyclododecenyl bromide (0.24 g, 1.0 mmol) at −78 °C. The color of the solution changed very slowly to brown and then the solution was maintained at −78 °C for 4 hr. The similar procedure afforded the aldehyde **16** (0.11 g, 50% yield) as a colorless liquid: bp 140 °C (bath temp., 0.1 mmHg); IR (neat) 1690, 1630, 1130, 975 cm^{-1}; NMR (CCl_4) δ 1.2—2.2 (m, 19H), 5.1—5.7 (m, 2H), 6.95 (ddd, J=16, 7, and 1.5, 1H), 7.65 (dd, J=7 and 16, 1H), 9.41 (d, J=8, 1H); mass *m/e* (%) 220 (25), 135 (17), 121 (28), 107 (50), 95 (70), 81 (100); Mol wt. Found: 220.1862. Calcd for $C_{15}H_{24}O$: 220.1830.

*Generation of Yomogi Alcohol from the Aldehyde **15**.* The aldehyde **15** (0.26 g, 2.1 mmol) was stirred with a mixture of sodium cyanide (0.40 g), acetic acid (0.16 g), and manganese dioxide[16] (5.0 g) in methanol (25 ml) for 12 hr at 25 °C. The remaining liquid on extractive work-up after filtration was subjected to preparative tlc with benzene as an eluant. The band at R_f 0.6—0.8 provided the ester **18** (0.24 g, 76% yield) as a colorless liquid: IR (neat) 1725, 1655, 1190, 1165, 1010, 985 cm^{-1}; mass *m/e* (%) 154 (6), 139 (12), 125 (10), 123 (12), 111 (16), 95 (100), 79 (44), 67 (38); Found: C, 70.2; H, 9.23%. Calcd for $C_9H_{14}O_2$: C, 70.1; H, 9.15%.

The ester **18** (0.15 g) was treated with methyllithium (5 ml of 1.5 M solution in ether) in ether at 0 °C and kept at 25 °C for an additional 1 hr. The reaction mixture was poured into ice-cold water and the product was extracted with ether repeatedly. The combined ethereal extracts were washed with water, dried, and freed of the solvent. The remaining oil was submitted to preparative tlc on silica gel with dichloromethane as an eluant to yield the desired Yomogi alcohol as a colorless liquid, identical in all respects with the authentic sample.

Steric Requirements in Base-Promoted Elimination Reactions

Akio ISHIZAWA

Department of Chemistry, Faculty of Science, Kyoto University, Sakyo-ku, Kyoto 606

(Received February 24, 1975)

The effect of the steric requirement of the attacking base in base-promoted elimination reactions was studied using a variety of pairs of diastereoisomeric bases. The pairs of diastereoisomeric alkoxide bases examined gave difinitely different *cis*-olefin to *trans*-olefin ratios from elimination reactions of secondary alkyl bromides and tosylates in dimethyl sulfoxide. The results indicate unambiguously that the steric requirement of the attacking base is an important controlling factor in determining the olefinic product distribution in these elimination reactions. The structural effect of the solvent molecule was also investigated using pairs of diastereoisomeric alcohols in base-promoted elimination reactions. Under a variety of conditions the effect upon the product distribution observed was rather small, as compared with those observed for the diastereoisomeric bases, to be an important contributing factor on the product distribution.

Extensive studies on the base-promoted elimination reactions have revealed that the olefinic product distribution (positional and geometrical isomers) is affected by various factors such as the structure of the substrate, the nature of the leaving group, the strength and the structure of the attacking base, and the nature of the reaction medium.[1] Since the structure of the substrate can be varied independently to the other variables such as the base, the solvent and the leaving group, the importance of this factor has easily been tested and clearly evidenced experimentally.[1] The effect of the base, on the other hand, are much more complicated because these must depend both on the structure and on the strength of the base and an ambiguity of many experimental works attempting to separate the factors arises mainly from the fact that the strength of the base is not an independent variable to the structure of the base. Moreover, since the effect of the base depends strongly on the solvent used, it is very difficult to separate the effects on the product distribution that are caused by intrinsic properties of the base from those they are the result of solvent effects. A metal alkoxide dissolved in the corresponding alcohol is the most common reagent for bringing about elimination reactions, so that much of the data available are on the results of simultaneous change in the base and the solvent.

Intramolecular non-bonded interactions such as eclipsing effects are effectively able to alter the relative stereochemical stabilities between the possible conformers at the transition state in elimination reactions, so that it is reasonably anticipated that the intermolecular interactions between reactants or between reactants and the environment (such as the solvent molecule), though lesser extent than the intramolecular by virtue of the greater freedom with the intermolecular, will constitute a contributing factor on the product distribution.

To understand the effect of the attacking base on the product distribution in base-promoted elimination reactions, it is, therefore, desired to determine the effects of the strength and of the structure of the attacking base separately. The present work was undertaken to make this point clear, and also to examine the effect of the molecular structure of the solvent as one of the effects of the environment in elimination reactions.

For the examination of the structural effect of the base it is necessary to use such bases that the variation of the structure should have little effect upon the base strength. A pair of diastereoisomeric alkoxide bases that differ only in the spatial alignment of the substituents around the basic center would satisfy the requisite, because the electronic effect of the substituents may cause little differences in the base strength between the pair. With such a pair of bases, the transition states are diastereoisomeric in each other, so that they should give different product distributions.

In a similar sense, the parent diastereoisomeric alcohols can also be utilized as solvent for the elucidation of the structural effects of the environment in elimination reactions.

Results and Discussion

Effects of Diastereoisomeric Alkoxide Bases. The effect of pairs of diastereoisomeric alkoxides, the conjugate bases of *dl-threo-* and *dl-erythro*-alcohols, **1**—**6**, was examined for the product distribution from base-promoted elimination reactions of secondary alkyl

bromides and tosylates. Since the nature of the transition state is affected by the solvent, the steric requirement of the attacking base must also be dependent on the nature of the solvent used. With changing the polarity the influence of the solvent upon the steric requirement of the base was first examined using two pairs of alkoxides, **1** and **2**, and the results are given in Table 1. The solvents used in these runs were mixtures of the solvent in question and 3-methyl-3-pentanol which was added to make all the base solutions easily homogeneous. Though the reaction temperatures were different, little differences were observed in the product distributions between a pair of the diastereosiomeric alkoxides **1** or **2** in dimethyl sulfoxide-methylpentanol system (Table 1) and in the pure dimethyl sulfoxide system (Table 3),[2] so that the equilibrium between an alkoxide

base and the added alcoholic component, $ROH+R'O^- \rightleftharpoons RO^-+R'OH$, seems to contribute little in the mixed solvent systems.[3] Though the factors attributable to the apparent trend in the product distribution were not clear, the results indicated that the larger the polarity of the solvent used, the larger the difference in the product distribution between a pair of the diastereoisomeric alkoxides. Hence dimethyl sulfoxide was the prefered solvent throughout the studies of the structural effect of the attacking base.

The product distributions from elimination reactions of 2-, 3-pentyl and 4-heptyl bromides and tosylates with pairs of diastereoisomeric sodium alkoxides, **1**—**6**, in dimethyl sulfoxide are given in Tables 2 and 3. In these runs the results are much less complicated than those in Table 1, because neither an alcoholic cosolvent was present nor the polarity of the solvent varied. The remarkable feature of the results is that all the pairs of diastereoisomeric alkoxides examined gave definitely different product distributions. With 4-heptyl systems the *erythro*-alkoxides always produced larger *cis* to *trans* ratios than the *threo*-alkoxides except for the diastereoisomeric diphenylpropoxides **6** with which the ratios were just the opposite to those for the other members.[4] Generally the larger the steric bulk of the attacking base, the larger the difference in the product distribution between the pair of diastereoisomeric bases. By comparing the results of 2- and 3-pentyl systems with those of 4-heptyl system, the alkyl substituents on the α and the β' carbons of the substrate seems to play a certain role in controlling the steric interactions between the substrate and the attacking base, that is, the larger the alkyl substituents on the substrate, the larger the ratio of $(cis/trans)_E$ to $(cis/trans)_T$ with a given pair of diastereoisomeric alkoxides.

As mentioned, since the base strength should be of little difference between a pair of diastereoisomeric bases, it must contribute little to the variation of the product distribution, so that a steric factor must be the controlling one. The relationship generally observed between the reactivity and the selectivity[5] will also ascertain steric factors to be responsible for the variation of the product distribution. Though, strictly speaking, the comparison of the product distributions should be limited within a given pair of diastereoisomeric bases only where the strength of the bases is held constant, the apparent trend of the change in the product distribution with different pairs of bases is opposite

to that predicted by the change in the base strength, that is, the variation of the alkyl substituents R^1 or R^2 in the alkoxide from methyl to ethyl to *n*-butyl (from **1** to **2** to **3** or from **2** to **4** to **5**) should make the alkoxide base stronger, so that a decrease in selectivity (expressed in $(cis/trans)_E/(cis/trans)_T$) would be anticipated in this order. The selectivity observed, however, is just the opposite (Table 3).

The contribution of the parent alcohol produced during reaction to the variation of the product distribution appears to be negligible, since no effect of a pair of diastereoisomeric alcoholic solvent was observed when a large amount of dimethylformamide, as a cosolvent, was present (see below).

Recent studies on the stereochemistry of the base-promoted elimination reactions have revealed that a *syn-anti* dual mechanism of elimination prevails a wide range of conditions of the base and the solvent properties and the substrate structure.[6] In general, a *syn* mechanism appears to become important when the substrate carries large alkyl substituents on the both α positions to the leaving group and a poor leaving group such as trimethylammonio, and when the elimination is effected by a bulky and strong base in a poor ion dissociating solvent such as *tert*-butoxide in *tert*-butanol or in benzene. With the systems examined here, incursion of a *syn* mechanism seems unlikely to be a significant factor to the *cis* to *trans* ratio. A *syn* mechanism accounts for only 10 per cent of the overall reaction in the reaction of 5-decyl tosylate with *tert*-butoxide in *tert*-butanol,[6f] and even smaller contributions of the mechanism with the same substrate have been reported when a good ion dissociating solvent was used (5.2 and 4.2 per cent of the overall reaction with *tert*-butoxide in dimethylformamide[6f] and in dimethyl sulfoxide[6i] respectively). With secondary alkyl bromides the mechanism seems to contribute to the *cis* to *trans* ratio even lesser extent than with secondary alkyl tosylates.[6g]

These results confirm unambiguously that the steric requirement of the attacking base to be an important contributing factor to the product distribution in base-promoted elimination reactions.

Effects of Diastereoisomeric Solvents. Using pairs of diastereoisomeric alcohols **1**, **2** and **3** as solvent, the olefinic product distributions from elimination reactions of 4-heptyl bromide and tosylate were examined under a variety of conditions, and the results are collected in Tables 4 and 5. As anticipated, the effect of the diastereoisomeric solvent, *i.e.*, the steric requirement for solvation, upon the product distribution was less pronounced compared to that of the diastereoisomeric attacking base in Tables 2 and 3. From the Tables it is clearly seen that the effect of the steric requirement for solvation upon the product distribution changes in a complex manner by the nature of the reaction medium and by the attacking base. With the bicyclic amine base known as a very efficient dehydrohalogenating agent,[7] the difference in the product distribution, *i.e.*, the selectivity, between a given pair of diastereoisomeric solvents gradually decreased with increasing the steric bulk of the solvent molecule, whereas complex changes in the product distributions were observed with phenoxide base. In the presence of 18-Crown-6 ether which has been believed to make an alkoxide base reactive by dissociating ion paired species,[6g,6h] a maximum selectivity was observed in the diastereoisomeric phenylheptanols **3**. When 25 volume per cent of dimethylformamide was present as a cosolvent,[8] a maximum selectivity was obtained from the eliminations of the bromide in the diastereoisomeric phenylpentanols **2**. The tosylate, though only two pairs of diastereoisomeric alcohols **1** and **2** were examined, showed a similar change to that of the bromide. In the presence of 50 and 75 volume per cent of the cosolvent, no selectivity between a given pair of diastereoisomeric solvents could be observed from elimination reactions of either the bromide and the tosylate.

Neither the stereochemistry of these elimination reactions nor the details of the interactions between the reactants and the solvent molecules are known, but these results show definitely that it is necessary to take into account the structural effects of the solvent molecule as well as the polarity of the solvent,[9] when

the solvent effects upon the product distribution in the elimination reactions are considered.

Experimental

Materials. *2-Pentyl, 3-Pentyl, and 4-Heptyl Bromides*: The bromides were prepared by treating the corresponding alcohols with triphenyl phosphite dibromides at −10—0 °C.[10] 2-Pentyl bromide, bp 117—118 °C, n_D^{20} 1.4409 (lit.,[9a] bp 58.4—58.8 °C/100 mmHg, n_D^{20} 1.4412); 3-pentyl bromide, bp 47 °C/60 mmHg, n_D^{20} 1.4454 (lit.,[9a] bp 59—59.5 °C/100 mmHg, n_D^{20} 1.4444); 4-heptyl bromide, bp 64—65 °C/24 mmHg, n_D^{20} 1.4501 (lit.,[11] bp 75—75.5 °C/38 mmHg, n_D^{25} 1.4478).

2-Pentyl, 3-Pentyl, and 4-Heptyl Tosylates: The tosylates were prepared by the standard method.[12] 2-Pentyl tosylate, n_D^{20} 1.5008 (lit.,[9e] n_D^{20} 1.4995); 3-pentyl tosylate, mp 44.6—44.8 °C (lit.,[9a] mp 42—44 °C); 4-heptyl tosylate, n_D^{20} 1.4978. Found: C, 62.33; H, 8.44%. Calcd for $C_{14}H_{22}O_3S$: C, 62.20; H, 8.20%.

18-Crown-6 Ether: This macrocyclic polyether was prepared according to Greene.[13] mp 39.7—40.7 °C, PMR ($CDCl_3$) δ 3.7 (s) (lit.,[13] mp 39.5—40.5 °C, PMR ($CDCl_3$) δ 3.67 (s)).

1,8-Diazabicyclo[5.4.0]undec-7-ene: A commercial sample was dried over potassium hydroxide and distilled under reduced pressure. bp 96—97 °C/3 mmHg.

Diastereoisomeric Alcohols, 1—6: The alcohols **1**, **2**, **4**, and **6** were prepared and separated into the diastereomers according to Cram *et al.*[14] The alcohol **3** obtained by the action of *n*-butyl-magnesium bromide upon 2-phenylpropionaldehyde, bp 137—140 °C/14 mmHg (lit.,[15] bp 156—160 °C/30 mmHg), was separated into the diastereomers *via* their ester derivatives. 4-Phenyl-3-octanone obtained by *n*-butylation of ethyl benzyl ketone, bp 142—145 °C/14.5 mmHg, semicarbazone, mp 105—106 °C (lit.,[15] bp 147—150 °C/16 mmHg, semicarbazone, mp 104—105 °C) was reduced to **5** by sodium borohydride, bp 146.5—147.5 °C/15 mmHg. The diastereomers were separated *via* their ester derivatives. The properties of the alcohols and their derivatives are collected in Table 6.

Purification of Solvents. Dimethyl sulfoxide was distilled from calcium hydride under reduced pressure. Dimethylformamide was first dehydrated by distilling with anhydrous benzene, dried over Driereit and then redistilled under reduced pressure. Acetonitrile was distilled from phosphorus pentoxide. Diethyleneglycol dimethyl ether was distilled from lithium aluminum hydride under reduced pressure. 3-Methyl-3-pentanol was purified by distilling twice from sodium metal.

Preparation of Base Solutions. A. Sodium hydride (Ventron Co., dispersed in mineral oil) was washed three to four times with anhydrous *n*-pentane, weighed and dissolved in an appropriate amount of anhydrous dimethyl sulfoxide or a solvent mixture. The resulting solution was converted into the desired alkoxide solution by adding a slightly excess of the calculated amount of an alcohol.

B. Phenoxide solutions were prepared by dissolving sodium hydride into an appropriate solvent mixture containing a calculated amount of phenol. All the preparations were operated under dry nitrogen atmosphere.

Procedure for Elimination Reactions. An appropriate amount (2 to 5 ml) of the base solution was pipetted into an ampoule with a serum stopper under dry nitrogen atmosphere. The substrate was added by a syringe through the stopper just before the reaction. The ampoule was sealed and reacted in a thermostated bath.

Analysis of the Reaction Mixtures. The reaction mixture was poured into about 100 ml of cold water and extracted with 1 to 1.5 ml of *n*-pentane when the reaction was fast. With slow reactions 1 ml of *n*-pentane was added to the reaction mixture and the low boiling fractions were distilled into a dry ice-acetone trap under reduced pressure (about 30 mmHg) at room temperature. The pentane solutions were analyzed for the olefins produced by glpc on JEOL Model JGC 20K or JGC 1100 instruments. The pentenes were analyzed on a 3 m×3 mm column of silver nitrate in *p*-methoxybenzyl cyanide on Celite 545 at 25 °C. The heptenes were analyzed on a 2 m×3 mm column of silver nitrate in benzyl cyanide on Celite 545 at 35 °C (JGC 1100) or on 3 m×3 mm column of silver nitrate in *p*-nitrobenzyl cyanide on Celite 545 at 35 °C (JGC 20K). The *cis* to *trans* ratios obtained from the peak heights were calibrated by the standard curves prepared by analyzing the *cis-trans* mixtures of known compositions under the same conditions.

Control Experiments. Neither synthetic *cis*- nor *trans*-3-heptenes were isomerized on exposure to the reaction condition, 0.2 M of sodium 3-phenyl-2-butoxide (a mixture of *threo*- and *erythro*-isomers) in dimethyl sulfoxide at 35 °C for 60 min.

No isomerizations between the pairs of diastereoisomeric alkoxides could be detected for the recovered alcohols, **1** and **2**, from the elimination reactions carried out in dimethyl

The Segregation of Sodium Ions in KCl Minute Crystals

Yoshihiro SENSUI and Kenji TOMURA

Institute for Atomic Energy, Rikkyo University, Yokosuka, Kanagawa 240-01

(Received February 7, 1975)

The surface accumulation of solute sodium ions in KCl crystallites was measured as a function of the annealing temperature, 250—450 °C. The minute crystals were baked out under 3×10^{-7} Torr, and their surface layers were dissolved successively with anhydrous ethyl alcohol. The contents of sodium and potassium were determined by instrumental neutron-activation analysis with the aid of a 50 cc-Ge(Li)-4K gamma spectrometer.

In a solid solution of ionic crystals with a common anion, quantitative measurements of the distribution coefficients of cations between the surface and the bulk are of interest in relation to the surface distortion[1] and the surface reactivity of the solids.[2,3] However, few experimental works have been reported even for such a simple system as alkali chloride, ACl/BCl. Kummer and his co-workers investigated the system of the Ca impurity in NaCl minute crystals[4] by the dissolution method using acetone, and that of Cs in KCl minute crystals by isotopic exchange techniques[5] using an acetone-solution/KCl-solid system. In these works, their attention was principally in the first surface layer of crystals in connection with the surface reactivity. According to the gas/solid-isotopic exchange reaction studied by the present authors[2,3] and theoretical works by Benson *et al.*,[1] the structure and properties of the surface change gradually in the range from the first layer to the fifth. With this in view, the present paper will study the accumulation of the sodium impurity in the surface layers of KCl crystals. The solubility of NaCl in KCl is rather high,[6] for they have the same type of structure. This situation differs very much from that in the previously studied systems.[4,5]

Experimental

Materials and Procedure. The KCl (Merck reagent, item No. 4933) used as a starting material contains 2.4 ppm of an Na impurity, as determined by radio-activation analysis. The precipitates of KCl, doped with Na amounting to 300—900 ppm, were prepared by a modified Marshall method.[7] The precipitates were washed twice with fresh ethanol. After the supernatant ethanol phase had been replaced completely with ethyl ether, the precipitates were transferred, together with ether, into a vessel connected to a vacuum system. Both the ethanol and ethyl ether used were dehydrated with CaO baked at 1100 °C for 12 hr and then distilled *in situ*. The precipitates were carefully dehydrated and degassed by baking then in a vacuum, 3×10^{-7} Torr. The baking temperature was raised, step by step, to 450 °C over a 140 hr period and then kept at that temperature for 48 hr. The crystallites thus obtained had a surface area of about 1.5 m^2/g, as determined by krypton adsorption at 77 K and electronmicrography showed that the faces exposed were the {100} planes as well as the crystallites used by Kummer *et al.*[5]

After pretreatment at 450 °C, the crystallites were annealed at a temperature between 250 and 450 °C for 48 hr at 3×10^{-7} Torr in order to establish the equilibrium distribution of the impurity at that temperature. Then, the surface regions of the crystals were dissolved successively with a small amount of anhydrous ethanol under atmospheric pressure. The solubility of NaCl in absolute ethanol at 20 °C is 1.149 mg/ml,[8] while that of KCl is 1.1624 mg/ml.[9] Because of these small solubilities, it is usually possible to remove several monolayers of the crystal surfaces in a batch-by-batch fractionation. The amounts of Na and K in each fraction were determined as follows. The alcoholic sample solution was irradiated with thermal neutrons, amounting to 1.08×10^{16} n/cm^2, by means of the TRIGA II reactor of Rikkyo University. The gamma rays of 1524.7 keV from ^{42}K and 1368.4 and 2753.6 keV from ^{24}Na in the samples concerned were measured by the use of a 50 cc-Ge(Li)-4K gamma spectrometer.

Results and Discussion

Figure 1 illustrates the relationship between the surface accumulation of sodium and the layer number as a function of the sodium concentration in the crystals. The sodium concentration in the surface region is very high as compared with that in the bulk, but far lower than the solubility limit, judging from the phase diagram of the NaCl/KCl solid solution.[6,10] Let us define the accumulation coefficient, $C_A(n)$, by the quantity $([Na]/[K])_n/([Na]/[K])_{bulk}$, where n designates

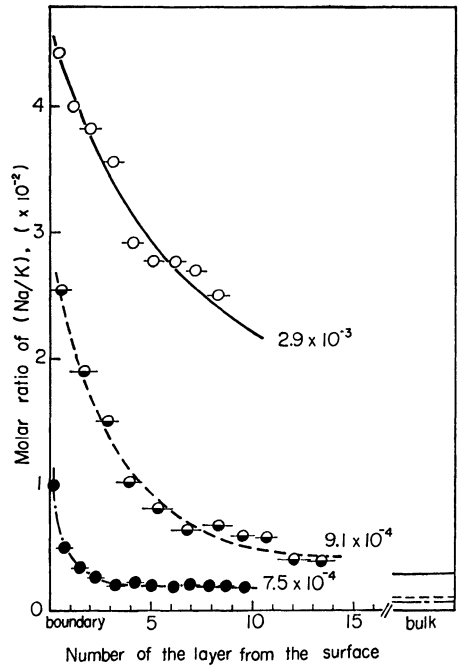

Fig. 1. The concentration dependence of the surface accumulation of sodium in potassium chloride crystallites at 300 °C.
○, ◒ and ● for the molar ratio of $(Na/K)=2.9\times10^{-3}$, 9.1×10^{-4} and 7.5×10^{-4}, respectively.

the numbering of the layer from the surface. Then, $C_A(n)$ may be independent of $([Na]/[K])_{bulk}$ as long as the impurity concentration is very low and far from the solubility limit. The present data may, then, be interpreted under these conditions. Figure 2 shows a typical profile of $C_A(n)$ as a function of the annealing temperature. The curves seem to converge to unity, but the rate of convergence is very low, *i.e.*, about 1/3—1/4 times that expected from the isotopic exchang reaction between chlorine gas and alkali chloride crystals.[2,3] This discrepancy may be attributed to the fact that the process of surface dissolution cannot be so well controlled as to remove strictly the specified n-th layer from various crystallites. The surface accumulation increases with the rise of the temperature. The value of C_A (1) is determined from the smoothed curve in Fig. 2, and its logarithms are plotted against the reciprocal of the temperature in Fig. 3. We obtain a straight line, though the figure shows some scatter of points. If an equilibrium is established, the slope of the line gives, as the enthalpy difference, ΔH, and the intercept of the coordinate at $1/T=0$ gives the entropy difference, ΔS, when sodium atoms segregate into the first layer from the bulk. We obtain $\Delta H=4.9\pm1.0$ kcal/mol and $\Delta S=13\pm1.6$ e.u. The values for both ΔH and ΔS are considerably large compared with the values predicted from the thermodynamic data of the NaCl/KCl solid solution.[6] These values cannot be explained on the basis of simple statistical thermodynamics; further detailed studies of various samples is, therefore, desired.

Next, let us discuss the rate of the eluilibriation of the impurity distribution in minute crystals of alkali

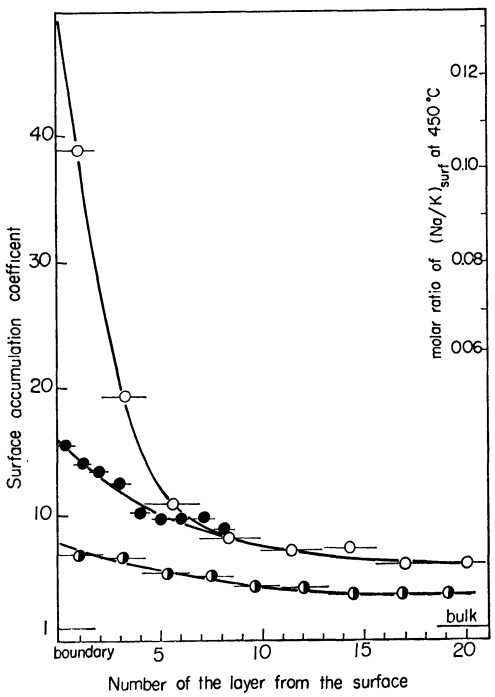

Fig. 2. The temperature dependence of the surface accumulation coefficients of sodium in potassium chloride crystallites.

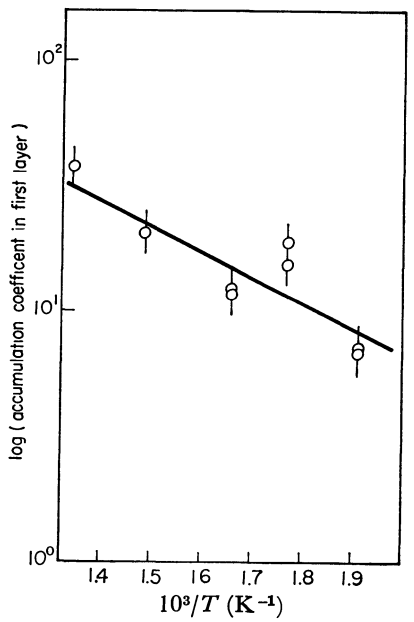

Fig. 3. Arrhenius plots of the accumulation coefficient of the surface first layer.

chloride. According to Kummer *et al.*,[4,5] it takes longer than thirty hours to eliminate step-dislocation on the surface of KCl crystallites doped with cesium at 600 °C.[5] On the other hand, Voss *et al.*[11] proposed that the equilibrium was easily established in the system of NaCl/KCl minute crystals, even while cooling the crystals from 350 °C to room temperature. The present results support the idea that it takes a long time to attain an equilibrium distribution of the Na^+ impurity. If the latter view is true, the two curves referred to 300 and 450 °C in Fig. 2 may be reduced to the same curve.

Finally, we must discuss the phase separation, fissures, and dislocation, the existence of which makes the analysis of the results complex. According to Barret *et al.*[6] and Tichelaar,[10] no macroscopic-phase separation takes place in the concentration range of sodium used at 250—450 °C. Even if a minute amount of NaCl crystals arises on the surface of KCl crystals during the preparation of the precipitates, it is considered that the NaCl phase is dissolved and removed by ethanol washing, as has been mentioned before. This results from the solubilities of the chlorides concerned in ethanol.[8,9] On the other hand, if crystals contain fissures and dislocations, the impurity accumulates along them as well as on the surface region; furthermore, these regions are selectively etched. Thus, fissures and dislocations remarkably disturb the study of the surface accumulation of impurities if their density is high. The present authors believe that the influence of fissures and dislocations in KCl minute crystals disapper upon the pre-baking treatment used in the present experiment. This view is supported by a comparison between the self-diffusion of Cl^- ions in large NaCl single crystals reported by Morrison *et al.*[12] and that in minute crystals reported earlier by the present authors.[3] Consequently, it can safely be concluded that the present results are a connected with the surface accumulation of impurities.

The authors would like to express their grateful acknowledgement to Professor Tetsuo Takaishi of Rikkyo Unviersity for his valuable suggestions.

Role of Chlorine in β-FeOOH on Its Thermal Change and Reactivity to Sulfur Dioxide

Tatsuo ISHIKAWA and Katsuya INOUYE

Department of Chemistry, Faculty of Science, Chiba University, Chiba 280

(Received January 8, 1975)

The state of Cl in β-ferric oxide hydroxide (β-FeOOH) was examined by X-ray diffraction, IR absorption, chemical analysis, DTA, and TGA. The adsorption of SO_2 was determined as a measure of the surface activity. No influence of Cl contained in the crystal appeared in the X-ray diffraction patterns and surface area. The absorption bands at 640 and 840 cm^{-1} in IR spectra showing the deformation vibration of OH group diminished with the decrease of Cl content. It was shown that the path for β-FeOOH to transform into α-Fe_2O_3 by heating differentiates from the sample including more than 11.5% Cl/Fe to one including less than 11.5% Cl/Fe. This critical Cl content is equal to the amount of Cl when Cl fills up the characteristic tunnels existing in the β-FeOOH crystal. Cl in β-FeOOH interferes both its transformation into α-Fe_2O_3 and the recrystallization of resultant α-Fe_2O_3. These effects were explained by the stabilization of the β-FeOOH structure by Cl in tunnels and the bonding between Cl and Fe. The amount of chemisorbed SO_2 was lowered by Cl which was adsorbed on outer surfaces.

It has been known that β-FeOOH is formed in the presence of Cl^- ions. It results in the fact, for example, that the corrosion products of steel, formed in marine environments, contain β-FeOOH amounting to 20—30 %.[1] The β-FeOOH sample prepared by the hydrolysis of an $FeCl_3$ solution also contains a certain amount of Cl and the Cl content varies with the conditions of preparation and subsequent treatments.[2] Mackay[3] asserted that β-FeOOH has the hollandite ($BaMn_8O_{16}$) or α-MnO_2 structure[4] and presumed that Cl^- ions and H_2O molecules fill the positions which in hollandite are occupied by Ba^{2+} ions and that Cl^- ions are replaced by H_2O molecules on washing, accompanied by the conversion of OH^- to O^{2-} to maintain the electrical neutrality. This structure of β-FeOOH was confirmed recently by means of neutron diffraction.[5] Chlorine in β-FeOOH is believed to affect some properties of β-FeOOH, *e.g.*, the thermal transformation into α-Fe_2O_3 and the surface activity. Hofer, Peebles, and Deiter[6] investigated the catalytic activity of various ferric oxides and oxide hydroxides in the Fisher-Tropsh synthesis but concluded that β-FeOOH is inactive. However, the present authors found that β-FeOOH shows higher reactivity to SO_2[7] and higher heat of immersion in water[8] than those of α-FeOOH and γ-FeOOH.

In the present work, β-FeOOH samples containing different amounts of Cl were examined by X-ray diffraction, infrared absorption, thermal analyses (DTA and TGA), chemical analysis, and the adsorption of SO_2 to reveal the influence of Cl on the reactivity of crystal surface.

Experimental

Materials. β-FeOOH was precipitated by heating 0.1 M $FeCl_3$ solution for 5 hr at 96—99 °C. The resultant precipitate was washed by the following method in order to change the Cl content. The sample A-1 was obtained by washing the precipitate with distilled water until no Fe^{3+} ions were detected, and A-2 by electrodialyzing the sample A-1 at 10 V/cm for 10 hr. A-3 was obtained by washing the original precipitate with 1 M NH_4Cl solution till free of Fe^{3+} ions, with 1 M NH_4OH solution to remove Cl^- ions, and finally with distilled water. The electrodialysis of A-3 at 10 V/cm for 10 hr gave A-4. A-5 was obtained by dispersing A-3 in 1 M NH_4OH for 3 day, followed by filtering and washing with distilled water. Another kind of β-FeOOH was prepared by heating 500 ml of 0.1 M $FeCl_3$ solution containing 30 g urea at 96—99 °C for 5 hr. The sample U-1 was obtained by washing the resultant precipitate with distilled water (500 ml) till free of Fe^{3+} ions and U-2 with 4 l distilled water. Each sample was dried in an air oven for 2 hr at 100 °C.

Procedure. The SO_2 adsorption was measured at 30.0 °C by use of a quartz spring balance. The samples were pretreated by outgassing under 10^{-5} Torr for 14 hr at 110 °C. The BET surface area was determined by N_2 adsorption measurement at liquid nitrogen temperature. The X-ray diffraction examination was carried out by the powder method by use of Mn-filtered FeKα at 30 kV and 10 mA. The differential thermal analysis (DTA) was done in air using α-Al_2O_3 as a reference sample at a heating rate of 10 °C/min, and the thermogravimetric analysis (TGA) by means of a quartz spring at a heating rate of 10 °C/min. Infrared absorption spectra were taken by the KBr disk method with JASCO IR-G spectrophotometer. Cl and Fe contents of the sample were determined according to the procedures described in the previous paper.[9]

Results

The Cl content expressed in atomic % Cl/Fe (Table 1) could not be reduced below 7% by the washing procedures used in this work. The X-ray diffraction patterns and the surface area were almost identical regardless of the Cl content. IR spectra (Fig. 1) changed with the Cl content; the absorption bands at 640 and 840 cm^{-1} shifted to higher frequencies and their absorbance increased with the Cl content. Müller[10] reported that β-FeOOH prepared from $FeCl_3$ solution shows IR spectra having two bands at 690 cm^{-1} and 840 cm^{-1} due to the OH deformation vibration, but the 840 cm^{-1} band disappears on treating with alkali bicarbonate or carbonate. In our spectra, the 640 cm^{-1} and 840 cm^{-1} bands diminished with the removal of Cl. It is accordingly speculated that the bands at 640 cm^{-1} and 840 cm^{-1} are due to the deformation vibration of the OH^- which become O^{2-} to maintain the electrical neutrality when Cl^- ion is replaced by H_2O molecule.

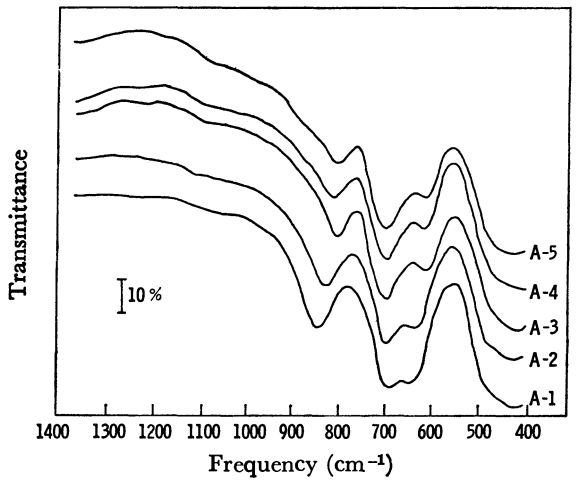

Fig. 1. Variations of IR spectrum with Cl content.

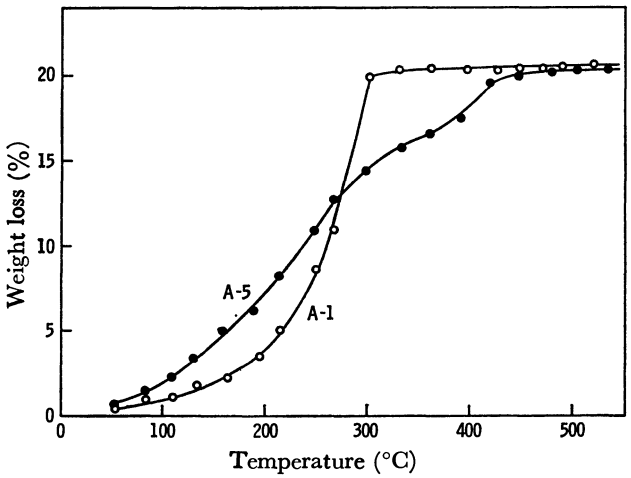

Fig. 2. TGA curves of A-1 and A-5.

TGA curves of samples A-1 and A-5 are shown in Fig. 2. The weight loss up to 270 °C of A-5 sample of 7% Cl/Fe was larger than that of A-1 of 17% Cl/Fe, but a gradual weight loss up to 420 °C was observed for A-5. The weight loss is considered to be caused by the dehydration of hydroxyl group ($2FeOOH \rightarrow Fe_2O_3 + H_2O$), the release of HCl, and the sublimation of $FeCl_3$. Then, the water content was calculated by subtracting the amount of released Cl and Fe from the weight loss between 110 and 500 °C in TGA curves. The water content thus obtained (Table 1) was still larger than the theoretical dehydration value (10.1 wt %). This result indicates that β-FeOOH embraces some more water molecules in addition to hydroxyl groups which produce

Table 1. Surface area and composition of samples

Sample	Surface area (m^2/g)	Cl (Cl/Fe, %)	Fe (mmol/g)	H_2O molecule (wt %)	(H_2O/Fe, %)
A-1	35	17	11.1	12.5	12.5
A-2	34	12	11.5	12.7	13.1
A-3	32	7.7	10.7	13.5	18.2
A-4	32	7.4	11.4	13.8	18.6
A-5	32	7.0	10.6	13.8	20.0
U-1	33	10	10.7	12.9	15.0
U-2	31	9.4	10.6	13.0	15.7

the "crystallization water" on dehydration.[11] As Mackay suggested,[3] this excess water seems to exist in tunnels parallel to the c-axis of the crystal. The amount of these water molecules, calculated by subtracting the theoretical dehydration value (10.1 wt %) from the water content, increases with the decrease of Cl content (Table 1). This result shows that Cl in β-FeOOH is replaced by H_2O molecule in the course of washing with water. The larger weight loss of A-5 below 270 °C will be due to the release of such water molecules.

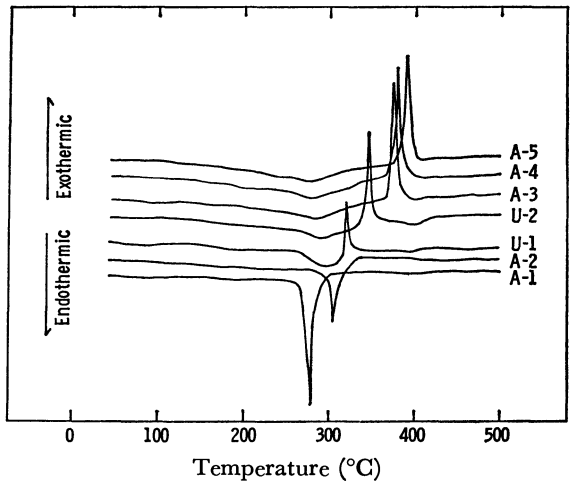

Fig. 3. Variations of DTA curve with Cl content

Variations of DTA curve with the Cl content are illustrated in Fig. 3. The sample A-1 of 17% Cl/Fe showed an endothermic peak at 280 °C, whereas A-5 of 7% Cl/Fe showed a broad endothermic peak at 275 °C and a sharp exothermic peak at 390 °C.

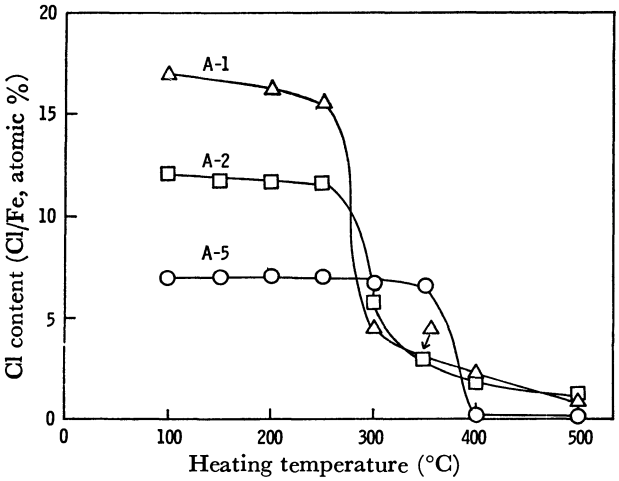

Fig. 4. Relation between Cl content and heating temperature.

The curves expressing the relationship between the Cl content and heating temperature (Fig. 4) showed the steep drop of Cl content at different temperatures. This temperature fell with the increase in the original Cl content. The sublimation of $FeCl_3$ was observed for A-3, A-4, and A-5 and the evolution of HCl was observed for A-1 and A-2 at each temperature corresponding to the sudden decrease of Cl.

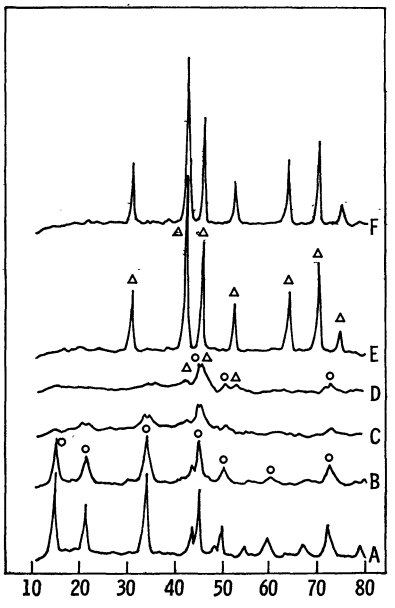

Fig. 5. X-ray diffraction patterns of A-1 at various heating temperatures: ○, β-FeOOH; △, α-Fe_2O_3; A, 100 °C; B, 200 °C; C, 300 °C; D, 350 °C; E, 400 °C; F, 500 °C.

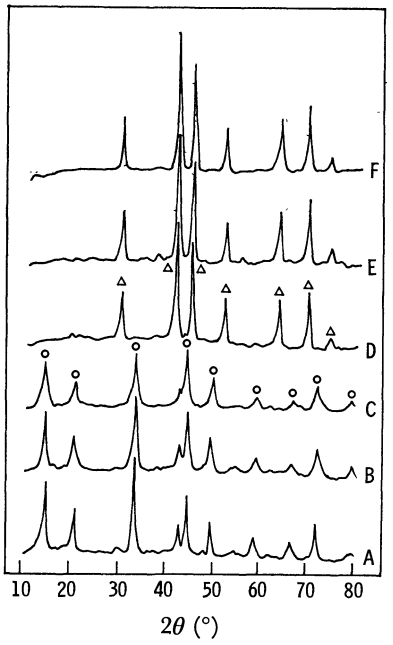

Fig. 6. X-ray diffraction patterns of A-5 at various heating temperatures: ○, β-FeOOH; △, α-Fe_2O_3; A, 100 °C; B, 200 °C; C, 250 °C; D, 300 °C; E, 400 °C; F, 500 °C.

Variations of X-ray diffraction patterns of A-1 and A-5 with heating up to various temperatures are shown in Figs. 5 and 6. A-1 was converted into an amorphous mixture of β-FeOOH and α-Fe_2O_3 at the temperature range 300—350 °C, whereas A-5 was transformed from β-FeOOH to α-Fe_2O_3 at 300 °C. Above 400 °C all the samples were completely transformed into α-Fe_2O_3. The crystallite size, calculated by the Scherrer equation for the (301) pattern of β-FeOOH at 2θ of 50.2 ° and

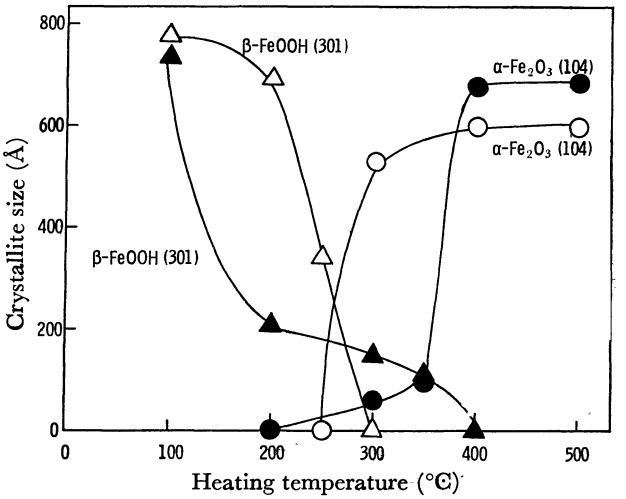

Fig. 7. Relation between crystallite size and heating temperature: △ and ○, A-1; ▲ and ●, A-5.

for the (104) pattern of α-Fe_2O_3 at 2θ of 41.9 °, is given in Fig. 7 for A-1 and A-5 as the function of heating temperature. The β-FeOOH structure of A-5 must be more liable to be destroyed on heating than that of A-1.

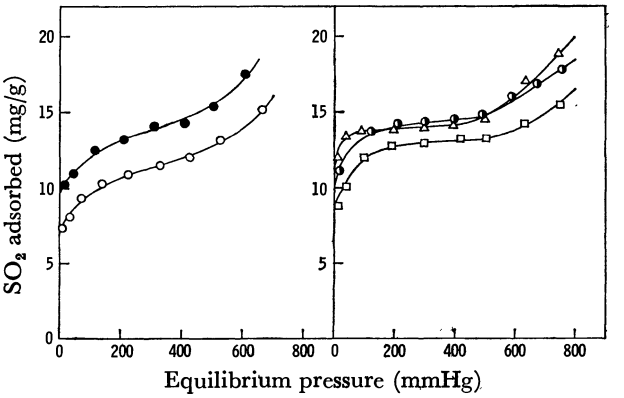

Fig. 8. SO_2 adsorption isotherms: ○, A-1; ●, A-2; △, A-3; ◑, A-4; □, A-5.

TABLE 2. AMOUNTS OF ADSORPTION (A_m and A_c) OF SO_2 ON β-FeOOH AND THE C CONSTANT OF THE BET EQUATION

Sample	Cl content (Cl/Fe, %)	A_m (mg/m²)	A_c (mg/m²)	A_c/A_m	C constant
A-1	17	0.31	0.25	0.8	390
A-2	12	0.38	0.34	0.9	390
A-3	7.7	0.40	0.40	1.0	520
A-4	7.4	0.44	0.43	1.0	720
A-5	7.0	0.45	0.46	1.0	1100

All the SO_2 adsorption isotherms are the BET-II type as shown in Fig. 8. However, the C constant of the BET equation, representing the adsorption strength in the first adsorption layer, increases with the decrease of Cl content. The monolayer adsorption capacity (A_m) calculated by the BET equation and the amount of the chemisorbed SO_2 (A_c) determined by the desorption under 10^{-5} Torr at 30.0 °C for 24 hr increased as the Cl content lowered (Table 2). The A_c/A_m ratio

also increased up to unity as the Cl content decreased. These results indicate that the adsorption force for A-3, A-4, and A-5 is stronger than that for A-1 and A-2.

Discussion

Structure of β-FeOOH and the existence of Cl. The unit cell of β-FeOOH crystal contains two tunnels parallel to the c-axis (Fig. 9), in which water molecules and Cl^- ions can be accomodated.[3] If we assume that the unit cell includes one Cl^- ion, the Cl content is 1/8=12.5% Cl/Fe, since a unit cell has eight Fe atoms. The H_2O/Fe ratio (Table 1) and the atomic ratio (Cl+H_2O)/Fe obtained by the chemical analysis and TGA are plotted against the Cl content in Figs. 10 and 11, respectively. The values of (Cl+H_2O)/Fe (Fig. 11) and H_2O/Fe (Fig. 10) amount to about 25% and 12.5%, respectively, at 12.5% Cl/Fe on each abscissa corresponding to the Cl content postulated from crystal structure as discussed above. It is therefore likely that tunnels and outer surfaces are to be filled up with Cl^- ions and H_2O molecules of equal amounts. As the crystal surfaces of β-FeOOH consist of a—c or b—c planes, the amount of Fe existing in the surface, estimated from the surface area obtained by N_2 adsorption and the unit cell area of a—c or b—c plane (31.7 Å^2), is 6.5% of the total Fe atoms. Therefore, the amount of Fe in the bulk is 93.5%. The Cl content in the crystal, which is overwhelmingly the amount of Cl in tunnels, is calculated as 11.7% Cl/Fe from the Cl/Fe ratio 12.5% and the Fe content 93.5%. The ratio (Cl+H_2O)/Fe for the samples containing more than 12 or less than 9 atomic % is over 25% as shown in Fig. 11. As the tunnels in the 17% Cl/Fe sample are filled with H_2O molecules and Cl^- ions, the Cl^- ions of 17 minus 11.7% appear to exist on the crystal

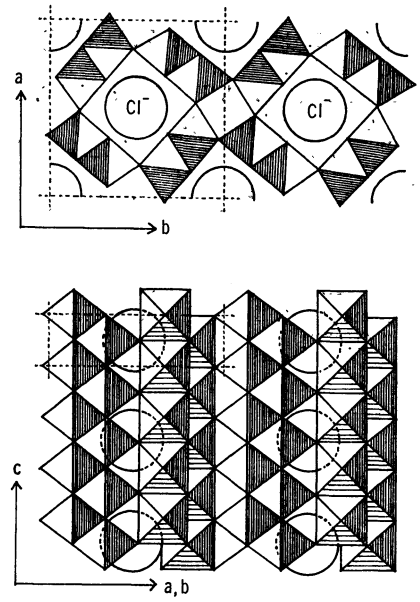

Fig. 9. Crystal structure of β-FeOOH. O^{2-} and OH^- ions are to be imagined at the corners of each octahedron and an Fe^{3+} ion at its center. β-FeOOH has a tetragonal lattice with the following unit cell dimensions: $a=b=10.48$ Å, $c=3.02$ Å.

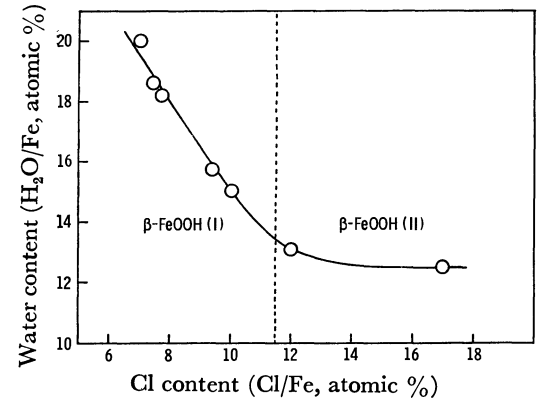

Fig. 10. Variation of H_2O content with Cl content.

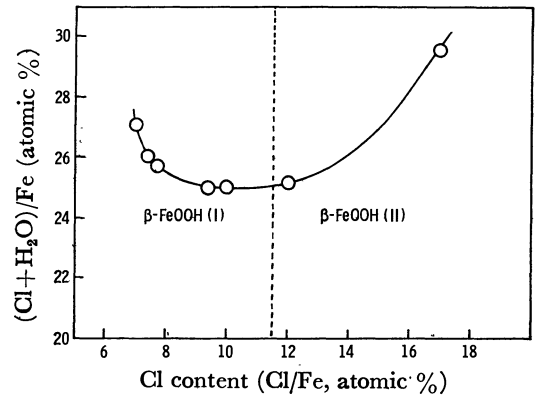

Fig. 11. Variation of (Cl+H_2O)/Fe with Cl content.

surfaces. The large value of (Cl+H_2O)/Fe for the 7% Cl/Fe sample is considered to be due to the accumulation of H_2O molecules in the tunnels by replacing Cl^- ions.

The broad endothermic DTA peaks at 275—295 °C observed for A-3, A-4, A-5, U-1, and U-2 correspond to the conversion of β-FeOOH to the mixtures of β-FeOOH and α-Fe_2O_3. The sharp exothermic peaks at 345—390 °C correspond to the recrystallization of less-crystalline α-Fe_2O_3 produced from β-FeOOH at lower temperatures. On the other hand, A-1 and A-2 show only one endothermic DTA peak in the temperature region around 300 °C. It is confirmed by the X-ray diffraction and the chemical analysis of Cl that in cases of A-1 and A-2 the transformation of β-FeOOH into α-Fe_2O_3, the crystallization of resultant α-Fe_2O_3, and the Cl elimination occur simultaneously around 300 °C. The peak temperatures in those DTA curves are plotted against the Cl content in Fig. 12, where the following three areas are defined; the region of β-FeOOH, region of a mixture of β-FeOOH and α-Fe_2O_3, and region of α-Fe_2O_3. The three lines intersect each other at a point of 11.5% Cl/Fe. The Cl content of 11.5% Cl/Fe is nearly equal to the amount of Cl filling up the tunnels (11.7%). The samples containing Cl of less than 11.5% Cl/Fe and more than 11.5% Cl/Fe are denoted in Figs. 10, 11, and 12 as β-FeOOH(I) and β-FeOOH(II), respectively. The α-Fe_2O_3(II) transformed from β-FeOOH(II) contains an appreciable amount of Cl and is less crystalline than the α-Fe_2O_3(I) transformed from β-FeOOH(I).

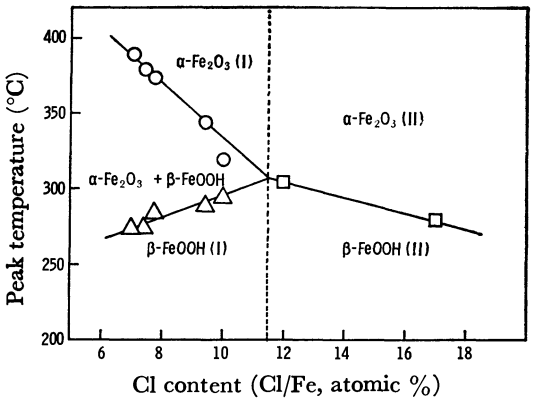

Fig. 12. Relation between peak temperature of DTA curve and Cl content in the original crystals: ○, exothermic peak; △ and □, endothermic peaks.

Cl in β-FeOOH(I). TGA curves (Fig. 2) show that H_2O molecules in the tunnels in A-5 (β-FeOOH(I)) are easily released by heating at temperature below 250 °C, so that the β-FeOOH structure of A-5 is more easily destroyed by heating than that of A-1 (β-FeOOH-(II)) as shown in Fig. 7. β-FeOOH(I) is not completely transformed into α-Fe_2O_3 until Cl is removed as $FeCl_3$, though it changed into the mixture of less-crystalline β-FeOOH and α-Fe_2O_3. This fact suggests the roles of Cl in β-FeOOH: Cl inhibits both its transformation into α-Fe_2O_3 and the recrystallization of less-crystalline α-Fe_2O_3. The inhibitory effect of Cl on the transformation into α-Fe_2O_3 will be due to the stabilization of the β-FeOOH structure by Cl. The recrystallization of α-Fe_2O_3 seems to be obstructed by the bonding between Cl and Fe.

Cl in β-FeOOH(II). Fig. 7 indicates that A-1 (β-FeOOH(II)) is thermally more stable than A-5 (β-FeOOH(I)) up to 250 °C, probably because Cl^- ions on the surface interfere the release of H_2O molecules. However, the transformation of β-FeOOH(II) into α-Fe_2O_3 occurs abruptly at the temperature of release of Cl. The evolution of HCl was observed at the transformation temperature of β-FeOOH(II) into α-Fe_2O_3. It is presumed from this fact that Cl^- ions on the surface produce HCl on heating according to the formula; $OH^- + Cl^- \rightarrow O^{2-} + HCl$. The resulting HCl may accelerate the formation of α-Fe_2O_3 by destructing β-FeOOH crystal structure.

SO_2 adsorption. The monolayer adsorption capacity (A_m) and the amount of chemisorbed SO_2 (A_c) decrease with the increase of Cl content. Furthermore, A_c/A_m value approaches unity and the C constant in the BET equation increases as the Cl content decreases. From these results, we can conceive that Cl in β-FeOOH interferes the SO_2 adsorption, especially the chemisorption of SO_2. The chemisorption sites for SO_2 are presumably the O^{2-} ions in β-FeOOH. The surface is covered with Cl^- ions as the Cl content increases, The estimation of the surface coverage with Cl^- ions. using the diameter of Cl^- ion (3.6 Å) and the surface area obtained by N_2 adsorption, shows that the surface of the 17% Cl/Fe sample is completely covered by the monolayer of Cl^- ions, and suggests that the chemisorption does not occur. However, Table 2 indicates that the sample of 17% Cl/Fe chemisorbs a considerable amount of SO_2, which is nearly equal to half A_c of 7% Cl/Fe sample adsorbing no Cl^- ions on the surface. This conflict can be understood by assuming that SO_2 binds with a half O^{2-} ions, pushing Cl^- ions aside. According to the structure of a—c or b—c plane constituting the crystal structure, there are two kinds of surface O^{2-} ions; O^{2-} ion bound with one Fe atom and O^{2-} ion bound with two Fe atoms. The former O^{2-} ions are considered to have stronger affinity with sulfur in SO_2 than the latter O^{2-} ions.

The authors wish to thank Dr. K. Sato (Fundamental Res. Inst., Nippon Steel Corp.) for IR spectra measurements.

This work was partly supported by the Science Research Fund of the Ministry of Education.

Transfer Hydrogenation and Transfer Hydrogenolysis VII. The Mechanism of Hydrogen Transfer from 2-Propanol to Olefins Catalyzed by Dihydridotetrakis-(triphenylphosphine)ruthenium(II)

Hideaki IMAI, Takeshi NISHIGUCHI, Masaki KOBAYASHI, and Kazuo FUKUZUMI

Department of Applied Chemistry, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received January 16, 1975)

The dihydride complex, $RuH_2(PPh_3)_4$, has been found to be an excellent catalyst for the hydrogen transfer from 2-propanol to olefins. For cyclohexene in toluene solution, the rate law at 80°C was:

$$\text{Rate} = \frac{0.04[C]_0[D]}{1+24[P]}$$

where $[C]_0$, [D] and [P] are the concentration of the catalyst, 2-propanol and triphenylphosphine, respectively. It is pressumed that active intermediates of the reaction are not Ru(IV)-species but Ru(0)-species. The rate-determining step of the reaction is inferred to be the dehydrogenation of 2-propanol, that is, the hydrogen transfer from the alcohol to Ru(0)-complex to form a hydride complex by oxidative addition.

We have reported previously that cyclic ethers,[1] amines[2] and 2-propanol[3] donate hydrogen to olefins in the presence of $RhCl(PPh_3)_3$ or $RhH(PPh_3)_4$. In these transfer hydrogenations or in other homogeneous catalytic hydrogenations with molecular hydrogen, hydride complexes of transition metals have been considered as active intermediate.[4] Thus, hydride complexes may be expected to have high catalytic activity. Moreover, they seem to have good solubilities in organic solvent.

We have studied the catalytic nature of the monohydride complex, $RhH(PPh_3)_4$,[3] for the hydrogen transfer from alcohol to olefins, and now have undertaken to study that of the dihydride complex, $RuH_2(PPh_3)_4$. It has been reported that $RuH_2(PPh_3)_4$[5] and $RuH_4(PPh_3)_3$[6] have activity for hydrogenation of olefins and $RuH_2(PPh_3)_4$ gives $RuH_4(PPh_3)_3$ in the reaction with hydrogen.[7] Further, $RuClH(PPh_3)_3$ and $RuCl_2(PPh_3)_3$ are thought to catalyze the hydrogenation of olefins *via* Ru(IV)-species.[4] So, which of the Ru(0)-, Ru(II)- and/or Ru(IV)-complex is a reaction intermediate in the transfer hydrogenation is of interest.

Results and Discussion

Measurement of Initial Rates. Unless otherwise noted, the transfer hydrogenation was carried out in any instance under the standard condition that $RuH_2(PPh_3)_4$ (0.01 mol·l^{-1}), cyclohexene (0.5 mol·l^{-1}) and 2-propanol (1.0 mol·l^{-1}) were heated in toluene at 80°. The reaction proceeded stoichiometrically without side reactions, for the amount of the dehydrogenation product, acetone, was equal to that of the formed cyclohexane and the total amounts of the cyclohexene and cyclohexane were equal to the amount of the charged cyclohexene within experimental error. The conversion of the olefin to paraffin was proportional to reaction time until 30% conversion. However, the linearity did not hold at higher conversion, perhaps because the formed acetone competes with the olefin for a vacant coordination site of the catalyst though the initial rate of the reaction, which was derived from the linear part, is independent of the olefin concentration as described later.

Table 1. Effect of solvents on the initial rate[a]

Solvent	Rate×10^4 (mol·l^{-1} min^{-1})
Dimethylsulfoxide	0.0
Acetic acid	0.1
Chlorobenzene	0.1
N,N-Dimethylacetamide	1.0
Anisole	3.6
Toluene	4.0
Benzene	4.1

a) Cyclohexene (0.5 mol·l^{-1}), 2-propanol (1.0 mol·l^{-1}) and $RuH_2(PPh_3)_4$ (0.01 mol·l^{-1}) were heated at 80°C in the solvent.

Initial rates of the transfer hydrogenation in several solvents were measured and the results are summarized in Table 1. Some solvents, which have high polarity and strong coordinating power, dissolved the catalyst easily but the reaction in those solvents was slow. This may be explainable by the fact that highly polar solvents make the coordination of other reagents difficult. In a few aromatic solvents, such as toluene and benzene, the catalyst dissolved well at room temperature and the reaction proceeded rapidly. Toluene was used as a solvent in this kinetic study.

The rate of the hydrogenation of several cycloolefins is given in Table 2. The rate was not so varied by the

Table 2. Effect of olefine on the initial rate[a]

Olefin	Rate×10^4 (mol·l^{-1}·min^{-1})	Product
Cyclopentene	3.1	Cyclopentane
Cyclohexene	4.0	Cyclohexane
Cycloheptene	3.5	Cycloheptane
Cyclooctene	3.4	Cyclooctane
Norboranadiene	0.5	Norbornene
1,3-Cyclooctadiene	0.0	
1,5-Cyclooctadiene	0.0	

a) Olefin(0.5 mol·l^{-1}), 2-propanol (1.0 mol·l^{-1}) and $RuH_2(PPh_3)_4$ (0.01 mol·l^{-1}) were heated at 80°C in toluene.

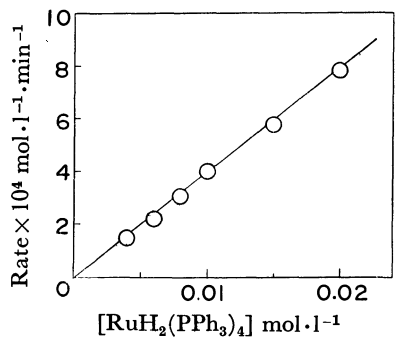

Fig. 1. Dependence of the rate of hydrogenation of cyclohexene on catalyst concentration in toluene at 80 °C, with 0.5 mol·l^{-1} cyclohexene and 1.0 mol·l^{-1} 2-propanol.

kinds of cyclomonoenes. As for dienes, norbornadiene was slowly hydrogenated to norbornene and cyclooctadienes were not reduced. Perhaps the difficulty in reduction of these dienes may be understandable by the fact that they are bidentate ligands and have strong coordinating power.

Figure 1 shows the dependence of the rate on the catalyst concentration. In the region of the catalyst concentration higher than 0.004 mol·l^{-1}, the rate was first-order in the catalyst concentration. Extrapolation of the line to lower catalyst concentration passes through the origin.

The initial rate of the hydrogenation was independent of the cyclohexene concentration in the range, examined. The zero-order dependence may be interpreted either by the assumption that the coordination of olefins to the metal occurs after the rate-determining step or by the assumption that though the olefin coordinates before the rate-determining step, the coordination occurs so completely that the intermediate olefin complex concentration is not greately changed over the range of 0.05 to 1.30 mol·l^{-1}. The former assumption seems to be more plausible on the basis of spectroscopic data described later.

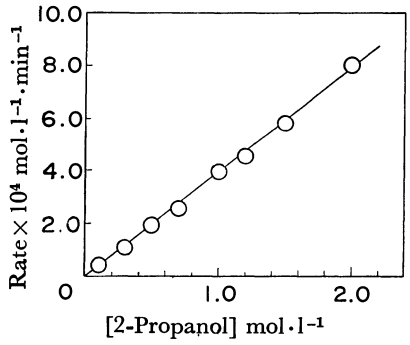

Fig. 2. Dependence of the rate of hydrogenation of cyclohexene on 2-propanol concentration in toluene at 80 °C, with 0.01 mol·l^{-1} $RuH_2(PPh_3)_4$ and 0.5 mol·l^{-1} cyclohexene.

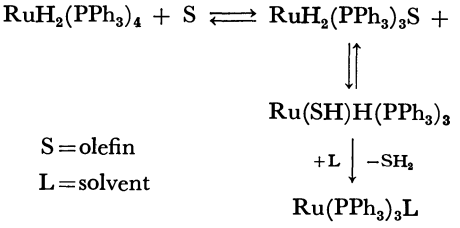
As shown in Fig. 2, the rate of the reduction showed a good linear dependence on the concentration of 2-propanol.

Initial rates were measured at 70, 80, 90 and 100°C and a good linear plot of $\log_{10}$ (Rate) against $1/T$ was obtained, from which a value for activation energy, E_a of 31.4 kcal mol^{-1} is obtained; $\Delta H^{\ddagger}$ being 30.7 kcal mol^{-1}. The obserbed rate constant provides a value of 20 e.u. for $\Delta S^{\ddagger}$.[8]

Reaction between $RuH_2(PPh_3)_4$ and Olefins. When cyclohexene (0.5 mol·l^{-1}) and $RuH_2(PPh_3)_4$ (0.03 mol·l^{-1}) in toluene were kept at 20°C for 1 day in the absence and in the presence of 2-propanol (1.0 mol·l^{-1}), 0.01 mol·l^{-1} of cyclohexane was formed. In the reaction of 1-hexene and $RuH_2(PPh_3)_4$ (0.01 mol·l^{-1}) under the same condition, 0.33 mol·l^{-1} of internal hexenes was obtained in addition to 0.007 mol·l^{-1} of *n*-hexane. The hydrogen transfer from $RuH_2(PPh_3)_4$ to olefins at room temperature has also been reported by Komiya *et al.*[5] The transfer hydrogenation did not take place at room temperature. This fact suggests that the first step of the overall transfer hydrogenation is the transfer of hydride ligands of the metal complex to olefins. The hydrogen transfer from the catalyst to olefins is considered as Scheme 1.



Scheme 1.

Isotopic Study. When octadeutero-2-propanol was used instead of 2-propanol at 80°C, the initial rate was 1.5×10^{-4} mol·l^{-1} min^{-1}, while in the case of 2-propanol the rate was 4.0×10^{-4} mol·l^{-1} min^{-1}. Moreover, in the reaction of octadeutero-2-propanol GC-MS spectroscopic study revealed that cyclohexane-d_1 and -d_2 were major product and cyclohexane-d_0, -d_3 and -d_4 were minor. The result proved clearly that hydrogen atoms transferred from the alcohol to cyclohexene and double bond migration of the olefin scarcely take place during the hydrogenation.

The value of the kinetic isotope effect, $R_H/R_D=2.7$, shows that a hydrogen transfer step is rate limiting.

The IR spectrum of the ether solution of $RuH_2(PPh_3)_4$ (0.03 mol·l^{-1}) and octadeutero-2-propanol (1.0 mol·l^{-1}), which had been heated at 100°C for 2 hr, showed no peaks assignable to –OH and C=O, and that of the recovered complex was identical with that of the original complex, $RuH_2(PPh_3)_4$, having no absorption attributable to Ru–D bond. As no hydrogen exchange occurred between 2-propanol and $RuH_2(PPh_3)_4$, tetrahydride species are not the reaction intermediate in this transfer hydrogenation.

Effect of Added Acetone. By the addition of 1.0 mol·l^{-1} acetone to the reaction system, the rate was decreased to one-eighth. The retarding effect is explained by the fact that acetone was hydrogenated to 2-propanol in tetralin, so it competes for the coordination sites of the metal complex with other reagents. From this point of view, when the total concentration of acetone and cyclohexene was kept constant (2.0 mol·l^{-1}) and the ratio of acetone against cyclohexene was changed, the reciprocal of the rate against [acetone]/

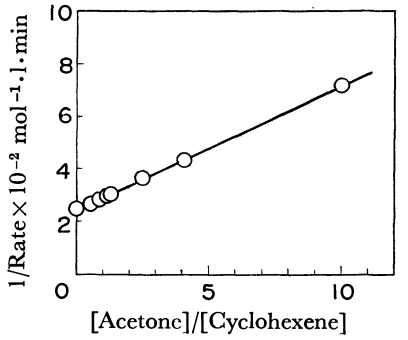


Fig. 3. Plot of the reciprocal of the rate of hydrogenation of cyclohexene *vs.* the ratio of [acetone]/[cyclohexene] in toluene at 80 °C, with 0.01 mol·l^{-1} $RuH_2(PPh_3)_4$, 0.5 mol·l^{-1} cyclohexene and 1.0 mol·l^{-1} 1-propanol.

[cyclohexene] was linear with a positive intercept on y-axis, as shown in Fig. 3.

Effect of Added Triphenylphosphine. The rate was decreased by the addition of excess triphenylphosphine to the reaction system, as in cases of the hydrogenation by molecular hydrogen catalyzed by transition metal complexes.[9-11] The plots of the reciprocal of the rate against the added triphenylphosphine concentration was linear with a positive intercept on y-axis, as shown in Fig. 4.

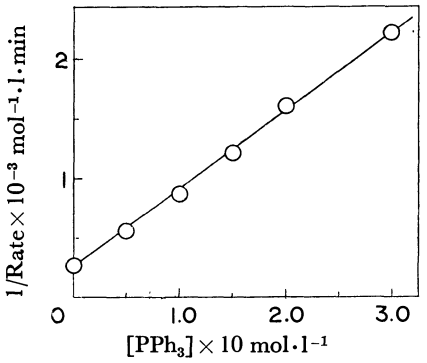

Fig. 4. Plot of the reciprocal of the rate of hydrogenation of cyclohexene *vs.* the concentration of added triphenylphosphine in toluene at 80 °C, with 0.01 mol·l^{-1} $RuH_2(PPh_3)_4$, 0.5 mol·l^{-1} cyclohexene and 1.0 mol·l^{-1} 2-propanol.

Reaction Intermediate. The infrared spectrum of a toluene solution of 0.03 mol·l^{-1} catalyst, 1.0 mol·l^{-1} 2-propanol and 0.5 mol·l^{-1} cyclohexene, which had been heated at 100 °C for 1 hr, showed no peaks assignable to the hydride ligands. The residual solid obtained from the solution had peaks at 1380 cm^{-1} and 3250 cm^{-1} (broad) in infrared spectrum (KBr). These absorption bands are attributable to 2-propanol and the ones assignable to cyclohexene or acetone were not detected. To evaluate the numbers of coordinated triphenylphosphine, diethylene glycol dimethyl ether (0.0134 g) was added as an internal standard into $CDCl_3$ solution of the residual solid (0.200 g). The NMR spectrum showed three multiplets centered at τ 2.7, τ 8.8 and τ 6.4 and a singlet at τ 6.7, with 50: 1: 38: 29 area. The peak at τ 2.7 are assignable to phenyl protons, the peaks at τ 6.4 and τ 6.7 are due to diethylene glycol dimethyl ether and the peak at τ 8.8 is due to 2-propanol, respectively. The peaks which are assignable to cyclohexene and acetone were not obserbed. Though methyl groups of free 2-propanol show a doublet, the doublet might be changed to the multiplet by the hindrance of the rotation of the methyl groups on account of the coordination on the metal. As the number of coordinated triphenylphosphine molecules, the value of 3.1 was obtained from the ratio of the area of peak at τ 2.7 to the one at τ 6.4 or at τ 6.7. This value is not contradictory to the result of elemental analysis of the residual solid. (Found: C, 73.12; H, 5.08%. Calcd for $Ru(PPh_3)_4$ C, 75.05; H, 5.21%; for $Ru(PPh_3)_3$ C, 72.89; H, 5.06%; for Ru(2-propanol)-$(PPh_3)_4$ C, 74.28; H, 5.65%; and for Ru(2-propanol)-$(PPh_3)_3$ C, 74.44; H, 5.62%;)

These result shows that $Ru(PPh_3)_3$ is the major species and $Ru(PPh_3)_4$, Ru(2-propanol)$(PPh_3)_4$ and Ru(2-propanol)$(PPh_3)_3$ are minor. When this recovered complex was used as a catalyst, the initial rate of the reaction was 3.5×10^{-4} mol·l^{-1} min^{-1}, which is roughly equal to that of the reaction in which $RuH_2(PPh_3)_4$ was used. The fact that Ru(0)-species were isolated and they had catalytic activity suggests that the Ru(0)-complex existed in the reaction process as a major intermediate and the first step of this reaction is the hydrogen transfer from catalyst to olefin to give Ru(0)-species.

Rate-determining Step. The observed kinetic isotope effect, $R_H/R_D=2.7$, distinctly shows that a hydrogen transfer step is rate limiting. There may be three hydrogen transfer steps in this transfer hydrogenation, that is; (1) hydrogen transfer from the coordinated alcohol to the Ru(0)-complex to give the Ru(II) species, (2) hydride transfer to the coordinated olefin to give the Ru(II)-alkyl complex and (3) hydrogenolysis of the Ru(II)-alkyl complex by a coordinated hydride to yield the paraffin.

The isomerization of the terminal olefin (involving step (2)) and the hydrogenation of olefins by molecular hydrogen (involving steps (2) and (3)) occurred at room temperature in the absence of 2-propanol. As the steps (2) and (3) are inferred to occur fast at the reaction temperatures of the transfer hydrogenation, these steps may not be rate limiting. Therefore, the dehydrogenation of 2-propanol to give acetone, that is step (1), is inferred be rate limiting.

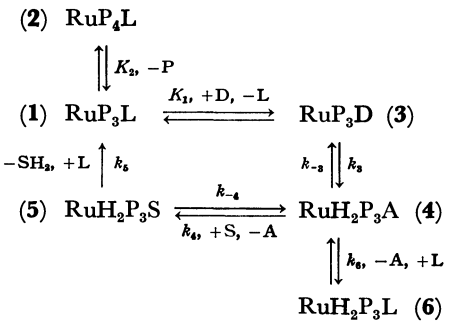
Kinetic Discussion

The first step of this transfer hydrogenation was as shown in Scheme 1. So upon the results described earlier and the facts described in the literature,[1-9] we should like to propose the following reaction scheme for the catalytic cycle of transfer hydrogenation.

Based on the proposed scheme and the assumption described later, the rate (R) is expressed as follows;

$$R=\frac{k_3k_4k_5K_1[D][S][C]_0}{(k_{-3}k_{-4}[A]+k_4k_5[S])(1+K_1[D]+K_2[P])} \quad (1)$$

where K_1 and K_2 are equilibrium constants and k_3, k_{-3}, k_4, k_{-4} and k_5 are rate constants, and [D], [S], $[C]_0$, [A]



where,

P=PPh_3 S=olefin D=2-propanol
A=acetone L=solvent, PPh_3 or 2-propanol

and [P] are the concentrations of the hydrogen donor, the olefin, the added catalyst, acetone and triphenylphosphine, respectively. The assumption is that the dihydride species, **4**, **5** and **6** are so active as steady state treatment to be applied. This assumption seems not so unreasonable, because the spectroscopic study of this reaction system showed no sign of the existence of hydride species as described before.

Equation (1) accommodates the effect of the added acetone. At initial stage of the hydrogenation, the concentration of the added acetone may approximately be regarded as the total acetone concentration in the reaction system. So the dependence of the rate on [A]/[S] is derived from Eq. (1);

$$\frac{1}{R} = \frac{k_{-3}k_{-4}(1+K_1[D]+K_2[P])}{k_3k_4k_5K_1[D][C]_0}\cdot\frac{[A]}{[S]} + \frac{1+K_1[D]+K_2[P]}{k_3K_1[D][C]_0} \quad (2)$$

As free phosphine concentration is negligible compared with acetone and olefin concentration, Eq. (2) is identical in form to that obtained from Fig. 3. When acetone was not added, the initial rate was independent on the olefin concentration. Therefore, the numerator of the first term of Eq. (2) must be zero. This may be realized by the fact that at the initial stage of the reaction the amount of the formed acetone is negligible. This reasoning is supported by the fact that in the presence of added acetone the initial rate depended on the olefin concentration. Then the rate expression is reduced to;

$$R = \frac{k_3K_1[C]_0[D]}{1+K_1[D]+K_2[P]} \quad (3)$$

As described earlier, the rate had the first order dependence on the concentration of 2-propanol. This fact requires $1+K_2[P] \gg K_1[D]$, that is, $[1]+[2] \gg [3]$. This assumption seems to be not so unreasonable from the results of the isolation of reaction intermediate described previously. Therefore, Eq. (3) is reduce to;

$$R = \frac{k_3K_1[C]_0[D]}{1+K_2[P]} \quad (4)$$

This expression is found to accommodate most of the other experimental observations; (a) The dependence of the rate on the catalyst concentration should be linear, and this agrees with the experimental result shown in Fig. 1. From this figure, 4.0×10^{-4} min^{-1} was obtained as the value of $k_3K_1/(1+K_2[P])$. (b) The dependence of the rate on the donor concentration should be linear, and this agrees with Fig. 2. From this figure, 4.0×10^{-4} min^{-1} was obtained as the value of $k_3K_1/(1+K_2[P])$. (c) When triphenylphosphine was added to the reaction system, the concentration of the added triphenylphosphine may approximately equal to the total phosphine concentration in the reaction system. The dependence of the rate on the phosphine concentration is;

$$\frac{1}{R} = \frac{K_2}{k_3K_1[C]_0[D]}[P] + \frac{1}{k_3K_1[C]_0[D]} \quad (5)$$

which is in agreement with experimental observation. From Fig. 4, the value for gradient, 6.0×10^4 $mol^{-2}\cdot l$ min and the value for the intercept, 2.5×10^3 $mol^{-2}\cdot l$ min were obtained, respectively. By using these values $K_2=24$ $mol^{-1}\cdot l$ and $k_3K_1=0.04$ $mol\cdot l^{-1}\cdot min^{-1}$ were obtained, as the values at 80 °C. Then the overall rate expression at 80 °C may be formulated as;

$$R = \frac{0.04[C]_0[D]}{1+24[P]} \quad (6)$$

The intercept of Fig. 3, $(1+K_1[D]+K_2[P])/k_3K_1[D][C]_0 = 2.5\times10^{-3}$ $mol^{-1}\cdot l$ min, is in good agreement with the intercept of Fig. 4, $(1+K_2[P])/k_3K_1[D][C]_0=2.5\times10^{-3}$ $mol^{-1}\cdot l$ min. This suggests that the reduction of Eq. (3) to Eq. (4) is feasible. Moreover, both Figs. 1 and 2 gave 2.5×10^{-3} $mol^{-1}\cdot l$ min as the value of $(1+K_2[P])/k_3K_1[D][C]_0$. This value also agrees well with the one obtained from Fig. 4. (d) In Eq. (4), k_3 is the only rate constant and the most important step, so the dehydrogenation step, **3**—**4**, may be rate limiting in the transfer hydrogenation. This supposition is supported by the results of the kinetic isotope effect which has a value of 2.7 and the experimental observations described earlier.

Experimental

Materials. The experimental techniques, together with the methods of purification of the materials have been given previously.[3] Dihydridotetrakis(triphenylphosphine)-ruthenium(II) was prepared by a method given in the literature.[12] The complex was identified as follows; ν_{Ru-H} 2080 cm^{-1} (lit,[13] 2080 cm^{-1}), mp 180 °C (lit,[13] 180 °C).

An Example of Kinetic Runs. Hydrogenation were carried out in a Pyrex glass tube. The sealed tube was prepared by the following procedure. Catalysts, alcohols and olefins were put into Pyrex glass tubes which had been sealed an one end. Into the mixture, solvent was added and the total volume of the solution was made 1.0 ml. The tube was sealed under vacuum after two freeze-pump-thaw cycles at 10^{-3} Torr on a vacuum line and liquid nitrogen bath. Five samples, prepared by the method described above, were heated in the polyethylene glycol-bath kept at 80±1 °C for 15, 30, 45, 60, and 90 min. The reaction mixture were submitted to glc analysis.

Isolation of a Reaction Intermediate. Toluene was added to the mixture of $RuH_2(PPh_3)_4$ (0.0345 g, 0.03 mmol), 2-propanol (0.0600 g, 1.00 mmol) and cyclohexene (0.0410 g, 0.50 mmol), and the total volume of the solution was made 1.0 ml. This sample was heated at 100 °C for 1 hr. After cooling the solution, the volatile compounds were evaporated

from this solution *in vacuo* and the residual solid was washed with ether twice and dried *in vacuo* for 48 hr. This residual solid was submitted to IR, NMR and elemental analysis.

Lanthanide-Induced Nuclear Magnetic Resonance Shifts and Molecular Structure of L-Azetidine-2-Carboxylic Acid. II. Determination of Molecular Conformation

Fuyuhiko INAGAKI, Seizo TAKAHASHI, Mitsuo TASUMI, and Tatsuo MIYAZAWA

Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received January 30, 1975)

Lanthanide-induced shifts (LIS) in ^{1}H NMR spectra of L-azetidine-2-carboxylic acid were observed in D_2O solution using Pr(III), Nd(III), and Eu(III) nitrates as shift reagents. By taking the LIS of one of the protons as reference, the shift ratios for the other four protons were calculated. The shifts ratio obtained were nearly constant for the three lanthanide ions, except for that with respect to the α proton which is located closest to the lanthanide ion. This indicates that the contribution of the contact shift is appreciable only for the observed LIS of the α proton and is negligible for the LIS's of the β and γ protons. The constancy of shift ratios assures, in addition, that the magnetic tensor is axially symmetric. Therefore, the LIS's of the β and γ protons may be used for the structure determination. For the β and γ protons, the ratios of LIS's intrinsic to the lanthanide-substrate 1 : 1 complex were corrected for the contribution of diamagnetic shifts due to complex formation which were estimated by the use of La(III) nitrate. The line broadening induced by Gd(III) was also observed. The structure analysis based on these data shows that the four-membered ring of L-azetidine-2-carboxylic acid is puckered with the dihedral angle of 25° and the carboxylate is in the equatorial position.

In order to utilize the lanthanide-induced nuclear magnetic resonance shift (LIS) to the quantitative discussion of molecular structure in solution, it seems to be a good practice to follow the procedures outlined below.

(a) The observed LIS may be a weighted average of those intrinsic to various stoichiometric complexes. The presence of a lanthanide-substrate 1 : 2 complex (abbreviated as LS_2) in addition to a 1 : 1 complex (LS) has been established in some cases.[1-3] The LIS intrinsic to the LS complex should be evaluated for the structure determination. In a preceding paper we discussed this problem and proposed an extrapolation method useful for evaluating the ratios of LIS's intrinsic to the LS complex.[3]

(b) The position of a nucleus (i) in the substrate molecule coordinated to a lanthanide ion may be determined by the use of the following equation, provided that the observed shifts arise solely from the dipolar interaction and that the magnetic tensor is axially symmetric.

$$\Delta\nu_i/\nu_0 = K\langle(3\cos^2\theta_i - 1)/r_i^3\rangle \qquad (1)$$

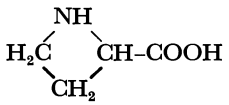
where ν_0 is the probe frequency, ν_i is the observed value of LIS, r_i is the length of the vector joining the lanthanide ion with the i th nucleus, and θ_i is the angle between this vector and the unique magnetic axis. Although two different expressions have been given to K by McConnel and Robertson[4] and by Bleaney *et al.*,[5] K can be treated as a constant characteristic of a lanthanide ion in applying this equation for the structure determination. Then, the ratios of observed LIS's of different nuclei should be nearly constant for various lanthanide ions, if the observed LIS's are predominantly due to the dipolar interaction[6] and the magnetic tensor is axially symmetric. This constancy of shift ratios for various lanthanides should be checked experimentally.[5]

(c) The correction for diamagnetic shifts induced by the complex formation should be made by observing the shifts with a diamagnetic lanthanoid La(III) or Lu(III).[5]

(d) The line broadening caused by Gd(III) should also be observed to supplement the LIS data.[5,7,8]

Recently Barry *et al.* applied these procedures to the structure determination of adenosine-5'-monophosphate[9] and cyclic 3',5'-adenosine monophosphate.[10] We have applied them to L-azetidine-2-carboxylic acid (abbreviated as Az acid) in D_2O solution and have obtained satisfactory results which will be reported in this paper.

Az acid is a naturally occurring cyclic imino acid (see below) and is known to inhibit various reactions in



many biological systems. The inhibitory action of Az acid is related to its incorporation into some proteins, where it replaces an equivalent amount of proline. The references dealing with biological activities of Az acid may be found in the paper by Berman *et al.*[11] in which the crystal structure of this compound has been reported. The information on the molecular structure of Az acid in aqueous solution will be of use in elucidating the molecular basis of its biological activities.

Experimental

^{1}H NMR spectra were observed in a similar way as described in the previous paper.[3] For the purpose of comparing the ratios of LIS's for various lanthanide ions, the successive addition of solid lanthanide nitrates to a substrate solution was employed, because it is experimentally simpler than either the successive dilution or the incremental dilution.

The structure analysis based on the LIS data was carried out by the programs PCS-I and II prepared in our laboratory.

Results and Discussion

Shift Ratios. As described above, it is important,

before applying Eq. (1) to the structure determination, to check if the ratios of LIS's observed of different protons are constant for various lanthanide ions. For this purpose the LIS's of Az acid were observed in D_2O solution using the nitrates of praseodymium, neodymium, and europium as shift reagents.[12] Since Pr(III) and Nd(III) induced greater line broadening than Eu(III) did, the measurements with Pr(III) and Nd(III) were confined to the region of small ρ ($\equiv[L_0]/[S_0]$, where $[L_0]$ and $[S_0]$ are the total molar concentrations of the lanthanide ion and the substrate, respectively). This precluded the detailed analysis as applied previously to the results of the successive dilution and incremental dilution methods for the Az acid-Eu(III) system.[3] Therefore, in the present study, the results obtained by the successive addition method shown in Figs. 1—3 were compared. The LIS of proton A is taken as reference in these figures. It is noted that the shift ratio of proton E changes markedly for the three lanthanide ions, whereas the shift ratios for protons B, C, and D remain essentially constant.

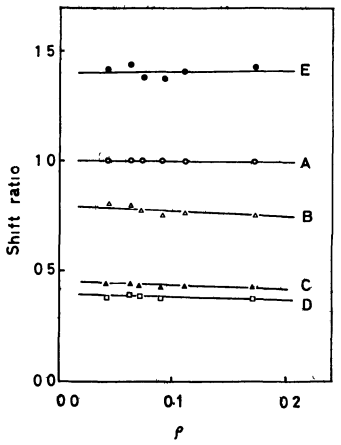


Fig. 1. The ratios of Pr(III)-induced shifts of L-azetidine-2-carboxylic acid observed by the successive addition method.
○, A; △, B; ▲, C; □, D; ●, E.

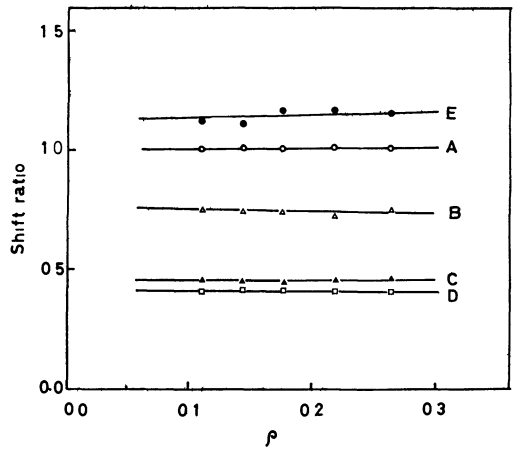

Fig. 2. The ratios of Nd(III)-induced shifts of L-azetidine-2-carboxylic acid observed by the successive addition method.
○, A; △, B; ▲, C; □, D; ●, E.

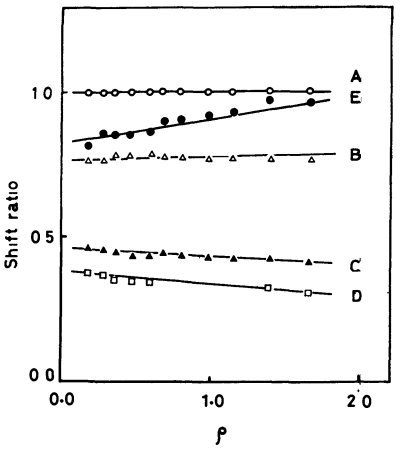

Fig. 3. The ratios of Eu(III)-induced shifts of L-azetidine-2-carboxylic acid observed by the successive addition method.
○, A; △, B; ▲, C; □, D; ●, E.

From these results it may be concluded in the first place that the contact shift makes a sizable contribution only to the observed LIS of proton E. The shift due to a contact mechanism is not expressed by Eq. (1). Accordingly, if the observed LIS's consist of contact and dipolar interaction terms, the shift ratios are not expected to be constant for various lanthanide ions. The contribution of a contact term to the shift of proton E may be explained by the fact that proton E is assigned to the α proton which is located nearest to the coordination site of the lanthanide ion;[3] the number of bonds between the α proton and the coordination site is smaller than that separating the β or γ proton from the coordination site.

In the second place the present results contain information on the axial symmetry of magnetic tensor. According to La Mar *et al.*[13] the shifts arising from the dipolar interaction may be expressed for the case with nonaxially symmetric magnetic tensor as

$$\Delta\nu/\nu_0 = k_1\langle(3\cos^2\theta-1)/r^3\rangle + k_2\langle(\sin^2\theta\cos 2\phi)/r^3\rangle \quad (2)$$

where r, θ, and ϕ are the polar coordinates of the nucleus under consideration, the Cartesian coordinates being taken along the principal magnetic axes with the lanthanide ion at the origin. If the observed LIS's are in accord with this equation, the shift ratios are expected to change their values for Pr(III), Nd(III), or Eu(III) which have different k_1 and k_2 values.[14] However, this is contrary to the results obtained for the shift ratios of protons A, B, C, and D. Therefore, it seems reasonable to conclude that the LIS's of these four protons are satisfactorily accounted for by Eq. (1) which is applicable to the axially symmetric case.

Correction for Diamagnetic Shifts Due to Complex Formation

Observed LIS's usually consist of the diamagnetic as well as paramagnetic terms. In the present case the contribution of the diamagnetic term due to complex formation was found small compared with that of the paramagnetic term. However, the diamagnetic shift should be subtracted from the observed LIS's before an accurate structure determination is attempted. The contribution of the diamagnetic shift may be estimated by measuring the shift with a diamagnetic ion such as

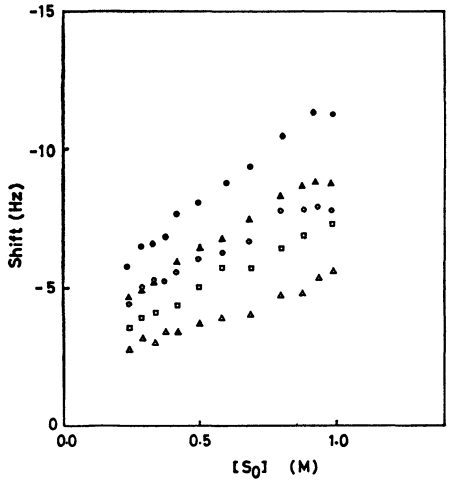

Fig. 4. La(III)-induced shifts of L-azetidine-2-carboxylic acid observed by the successive dilution method *vs.* total substrate concentration ([S_0]). D_2O solution, 37 °C, $\rho=1.01$.
○, A; △, B; ▲, C; □, D; ●, E.

○, A; △, B; ▲, C; □, D; ●, E.

La(III). The assumption underlying this method is that the complex formed with La(III) has a structure almost identical to those formed by other lanthanide ions. The diamagnetic shifts observed by the successive dilution method for the Az acid-La(III) system are shown in Fig. 4. The low-field shifts were observed for all the protons. Using the results given in Fig. 4, the Eu(III)-induced shifts were corrected for the diamagnetic contributions. The shift ratios calculated from these corrected values for the Az acid-Eu(III) system are shown in Fig. 5. For the structure determination described below, the shift ratios of protons A, B, C, and D extrapolated to $[S_0]=0$ in this figure (1.00, 0.79, 0.48, and 0.42, respectively) will be used. These values correspond to the ratios of dipolar interaction terms in LIS's intrinsic to the LS complex.

Structure Analysis and Assignment of ^1H NMR Spectrum

As the number of observed LIS data is rather limited,

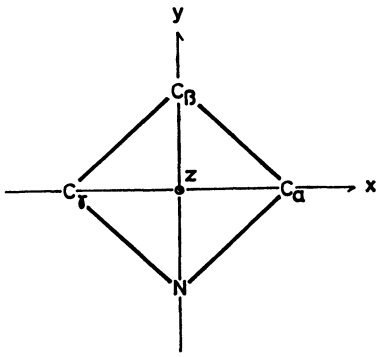

Fig. 6. The four-membered ring of L-azetidine-2-carboxylic acid and the coordinate system.

only the L-C_α distance and the ring-puckering coordinate are chosen as structural variables to be determined. The puckering mode of a four-membered ring can be best described by the coordinate (z) introduced by Chan *et al.*[15] The coordinates of atoms forming the azetidine ring (Fig. 6) are given as

$$\begin{aligned} x_\alpha &= -x_\gamma = [(x_\alpha^\circ)^2-2z^2]^{1/2} \\ y_\alpha &= y_\gamma = 0 \\ z_\alpha &= z_\gamma = z \\ x_\beta &= x_N = 0 \\ y_\beta &= [(y_\beta^\circ)^2-2z^2]^{1/2} \\ y_N &= -[(y_N^\circ)^2-2z^2]^{1/2} \\ z_\beta &= z_N = -z \end{aligned} \tag{3}$$

where α, β, γ, and N represent the α, β, and γ carbons, and the nitrogen, respectively. When the molecule is planar, the α and γ carbons are located on the x axis and the β carbon and the nitrogen on the y axis. x_α°, y_β°, and y_N° refer to the corresponding coordinates in the planar conformation. It is assumed that the four-membered ring always has a plane of symmetry (yz). The puckering mode described by Eq. (3) occurs without changing either the CC or CN bond length. The lengths of CC and CN bonds in the ring and the geometry around the α carbon and the carboxylate group are transferred from the structural parameters determined for this molecule in crystal.[11] As for the geometry around the β or γ carbons, it is assumed that the CH bond length and the HCH bond angle are 1.08 Å and 109°28′, respectively, and four CCH angles are all equal.

As for the coordination site of the lanthanide ion in the LS complex and the direction of symmetry axis of the magnetic tensor, it is most reasonable to assume that the lanthanide ion is on the bisector of the OCO angle and that the symmetry axis is collinear with the bisector.[16] This is in analogy with the lanthanide-mononucleotide complex where both the lanthanide ion and the symmetry axis are on the bisector of the OPO angle.[7,9,10] The shift ratios can now be calculated using Eq. (1).

On the other hand, four combinations (I-IV) are possible regarding the assignments of protons A, B, C, and D to *β-cis*, *β-trans*, *γ-cis*, and *γ-trans*, as given in Table 1 (*cis* and *trans* refer to the position of a proton

Table 1. Assignments of protons A, B, C, and D[a)]

Proton	Assignment			
	I	II	III	IV
A	*β-cis*	*β-cis*	*β-trans*	*β-trans*
B	*β-trans*	*β-trans*	*β-cis*	*β-cis*
C	*γ-cis*	*γ-trans*	*γ-cis*	*γ-trans*
D	*γ-trans*	*γ-cis*	*γ-trans*	*γ-cis*

a) *Cis* and *trans* refer to the positions of protons with respect to the carboxylate group.

with respect to the carboxylate group). For each one of these four assignments the agreement factor (R) defined as[17-19]

$$R=\left[\left\{\sum_i\left[\left(\frac{A_1^i}{A_1^s}\right)_{obs}-\left(\frac{A_1^i}{A_1^s}\right)_{calc}\right]^2\right\}\Big/\left\{\sum_i\left(\frac{A_1^i}{A_1^s}\right)^2_{obs}\right\}\right]^{1/2} \quad (4)$$

has been calculated for various values of the L-C_α distance and the z coordinate, so that a contour map as shown in Fig. 7 is obtained. This map shows that, for Assignment III, R is minimized only if the L–C_α distance is taken so short (2.3 Å) that the lanthanide ion partially penetrates into the carboxylate group. This indicates clearly that Assignment III should be discarded. The contour map obtained for Assignment IV is essentially the same as that shown in Fig. 7. Thus, Assignment IV is also discarded.

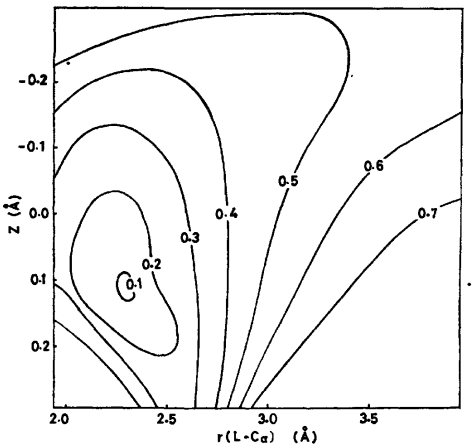

Fig. 7. The contour map of the agreement factor (R) for Assignment III.

Since only Assignments I and II remain acceptable, the assignments of β protons are now established; *i.e.*, A and B are assigned, respectively, to the *β-cis* and *β-trans* protons. The contour maps obtained for Assignments I and II are shown in Figs. 8 and 9, respectively. The minimum in the contour map in Fig. 8 corresponds to a conformation in which the ring is almost planar ($z\sim0$, Conformation I). On the other hand, the molecular structure corresponding to the minimum in the contour map in Fig. 9 has a puckered ring ($z=-0.125$ Å and the dihedral angle=25 °) with the carboxylate group in the equatorial position (Conformation II). (From the present analysis no information can be obtained about the internal-rotation angle around the C_α–CO_2^- bond.) It seems rather difficult

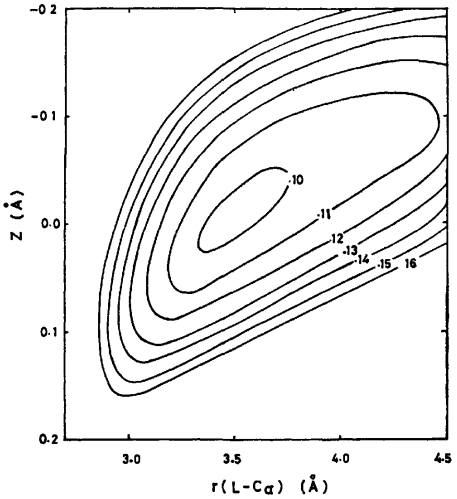

Fig. 8. The contour map of the agreement factor (R) for Assignment I.

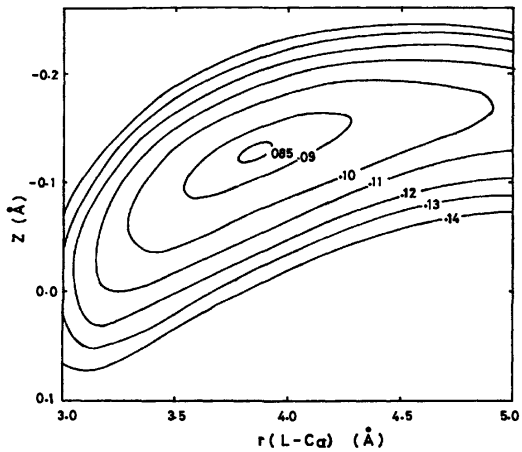

Fig. 9. The contour map of the agreement factor (R) for Assignment II.

to decide, from these results alone, which of the two conformations (therefore, which of Assignments I and II) is more probable, though the L–C_α distance in Conformation I (3.5 Å) is slightly shorter than the value (~4 Å) normally accepted.

The line broadening induced by Gd(III) has been found useful for solving the above-mentioned problem. Since the Gd(III)-induced line broadening is proportional to $1/r^6$ and independent of θ, the line-width data obtained for protons C and D are expected to be useful for determining which of these protons are closer to Gd(III). In Conformation I the distances from Gd(III) to C and D are 5.3 and 6.2 Å, respectively, whereas in Conformation II they are 6.5 and 6.3 Å, respectively. The ratios of the line broadening expected for protons, A, B, C and D in both conformations are given in Table 2. The spectra observed after adding extremely small amount of Gd(III) are shown in Fig. 10 for the lines assignable to almost pure transitions related to protons A, B, C, and D. Although the concentration of Gd(III) was not precisely determined, it was about 10^{-6} M for Fig. 10(b) and twice and three times of that for Figs. 10(c) and (d), respectively. The ratios

Table 2. The ratios of Gd(III)-induced line broadening[a)]

Proton	Calcd		Obsd
	Conformation I	Conformation II	
A	11.1	7.0	>3
B	2.8	2.5	>2
C	2.5	0.8	0.9
D	1.0	1.0	1.0

a) The broadenining of a line due to the transition of proton D is taken as reference.

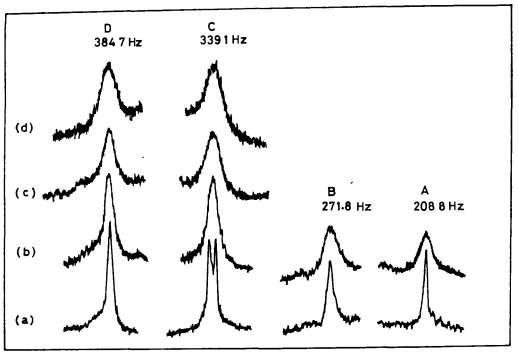

Fig. 10. Gd(III)-induced broadening of the lines assigned to the pure transitions of protons A, B, C, and D of L-azetidine-2-carboxylic acid. The concentration of Gd(III) is zero in (a), *ca.* 10^{-6} M in (b), twice and three times of *ca.* 10^{-6} M in (c) and (d), respectively.

of the line broadening thus observed are also given in Table 2. It is clear in this table that the observed ratios are in agreement with those expected for Conformation II. Thus, it may be concluded that Conformation II (therefore, Assignment II) is the real one.

It was found that the R value for Conformation II could be made as small as 0.038 by changing the bond angles N–C_α–COO^- and C_β–C_α–COO^- to 115.5 ° and 118.4 °, respectively, from the crystal data 117 ° and 113 ° with all the other parameters fixed as before. This changes the overall molecular conformation only slightly.

Conclusion

In utilizing the lanthanide-induced shifts and line broadening to the determination of molecular structure in solution, it has been shown necessary and rewarding to follow all the procedures outlined in the introductory part. In weakly acidic aqueous solution the four-membered ring of L-azetidine-2-carboxylic acid has a puckered conformation with a dihedral angle of 25 °, which compares with the angle of 11 ° as determined for this molecule in crystal.[11] The carboxylate group is in the equatorial position. This molecular structure is depicted in Fig. 2 of the preceding paper.[3]

The authors are grateful to Dr. H. Sugano of Research Laboratory of Applied Biochemistry, Tanabe Seiyaku Co., Ltd., for supplying the sample of L-azetidine-2-carboxylic acid. Thanks are also due to Dr. K. Tori of Shionogi Research Laboratory, Shionogi & Co., Ltd., and Dr. M. Kainosho of Central Research Laboratories, Ajinomoto Co., Inc., for helpful discussions.

Infrared Spectra and Structures of Copper(II) and Zinc(II) Complexes of Glycylglycine in Aqueous Solution

Mitsuo TASUMI, Seizo TAKAHASHI, Toshio NAKATA, and Tatsuo MIYAZAWA

Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received January 21, 1975)

The infrared spectra of the Cu(II) and Zn(II) complexes of glycylglycine were observed in D_2O at various pD values. Large spectral changes in going from acidic to neutral solution were interpreted in terms of the equilibria among free and complexed forms of glycylglycine. In the Cu(II) complex formed for $3<pD<5$ the metal-ligand bonding occurs through the amino nitrogen and peptide oxygen. As pD is increased further, the structure of the Cu(II) complex changes into a form in which the metal-ligand bonding occurs through the amino nitrogen, peptide nitrogen (deprotonated), and carboxyl oxygen. In contrast to the Cu(II) complex, no change of structure is found for the Zn(II) complex. The Zn(II) complex formed for $pD>5$ is similar to the Cu(II) complex present for $3<pD<5$.

The interaction between metal ions and peptides is an important subject not only in the chemistry of coordination compounds but also from biological viewpoint. In this and subsequent papers we study the structures of metal(II) complexes of some dipeptides in aqueous (or deuterium oxide) solution of various pH (or pD) and discuss, on this basis, the role of metal ions in the hydrolysis of dipeptides.

The structure of Cu(II) complex of glycylglycine, the simplest dipeptide, has been studied by many authors in crystal[1-3] and in aqueous solution.[4-8] The most interesting feature derived from the previous studies is the change of complex structure with the increase in pH (or pD). All the authors seem to agree that the peptide group is deprotonated in going from acidic to neutral solution and that in neutral solution the metal-ligand bonding occurs through the amino nitrogen, peptide nitrogen (deprotonated), and carboxyl oxygen. As for the structure in acidic solution, two different forms have been proposed with respect to the metal-ligand bonding. We discuss this matter through the analysis of infrared spectra of this complex in deuterium oxide solution. The structure of the Zn(II) complex in aqueous solution is also examined by referring to the Cu(II) complex case.

Experimental

Materials. Glycylglycinatocopper(II) trihydrate[Cu-GG·$3H_2O$[9]], glycylglycinatocopper(II) chloride monohydrate[Cu(HGG)Cl·H_2O], bis(glycylglycinato)zinc(II) dihydrate[$Zn(HGG)_2\cdot 2H_2O$], and glycylglycinatozinc(II) hemihydrate[Zn(HGG)Cl·$0.5H_2O$] were prepared from glycylglycine and corresponding metal(II) chloride or nitrate according to the methods described in references 10—12.

Infrared Absorption Measurements. The infrared spectra were recorded for *ca.* 0.2 M D_2O solutions using a Hitachi EPI-G3 spectrophotometer and a pair of cells made of As_2Se_3 (sample layer thickness 0.05 mm). The amino and peptide protons were deuterated by conventional method before preparing the D_2O solution. The pD value was adjusted by adding suitable amount of the 1 M D_2O solution of DCl or NaOD. The pD value was determined using a Hitachi-Horiba pH-meter F-7 with a combination electrode and a set of pH test paper, and no correction for the obtained values was made.

Results and Discussion

Infrared Spectra and Structures of the Cu(II) Complexes. The spectrum of the D_2O solution of CuGG·$3D_2O$ was essentially the same as that of Cu(DGG)Cl·D_2O under common pD values. So, the structure of complexed glycylglycine in both solutions must be identical. The infrared spectra in the region between 1800 and 1200 cm^{-1} of Cu(DGG)Cl·D_2O are shown in Fig. 1. The results shown in this figure agree well with those obtained previously by Kim and Martell[5] for the mixture of the Cu(II) ion and glycylglycine in D_2O.

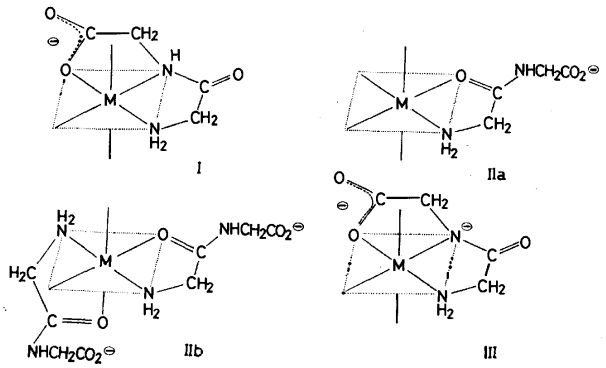

Fig. 2. Structures of the metal-glycylglycine complexes.[15]

Although Kim and Martell observed only the 1800—1500 cm^{-1} region, the region below 1500 cm^{-1} also gives useful information as will be described shortly. By comparing the spectra in Fig. 1 with pD variation of the spectra of glycylglycine itself,[13,14] it is clear that no complex is formed in the pD range below *ca.* 3. The band at 1630 cm^{-1} which appears only in the pD range between 3 and 5 was assigned by Kim and Martell[5] to the amide I vibration of Complex I shown in Fig. 2.[15] The formation of Complex I in acidic solution was later supported by a potentiometric analysis.[7] However, the present infrared results are better accounted for by assuming Complex IIa of Fig. 2 on the following grounds.

The amide II band which is located at about 1560 cm^{-1} in the spectra of simple peptides is known to shift, on deuteration, to about 1480 cm^{-1} (amide II').[16] The amide II' band is clearly seen at 1502 cm^{-1} in the spectrum of deuterated solid complex Cu(DGG)Cl·D_2O[17] (Fig. 3), whereas no corresponding band is found in the spectrum of deuterated solid complex $CuGG \cdot 3D_2O$ (Fig. 4). Since the peptide group in the latter complex is deprotonated, the normal modes would be different from those of ordinary peptide bond. So, it is reasonable that no band is found around 1500 cm^{-1} for $CuGG \cdot 3D_2O$. In D_2O the amide II' band of free glycylglycine is found at 1483 cm^{-1}. In the spectra of Cu(II) complexes in D_2O at pD 3, the presence of this band indicates, together with

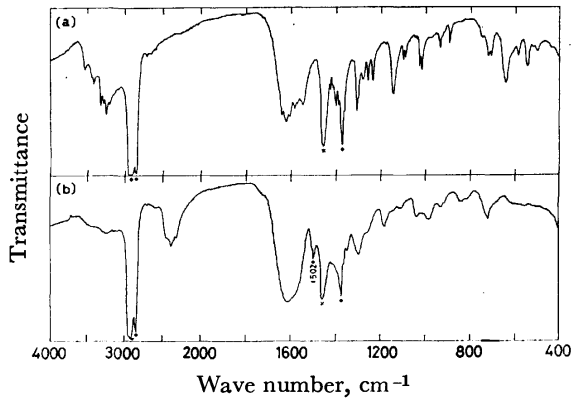

Fig. 3. Infrared spectra of solid (a) Cu(HGG)Cl·H_2O and (b) Cu(DGG)Cl·D_2O (Nujol mull).
The absorptions due to Nujol are indicated by asterisk.

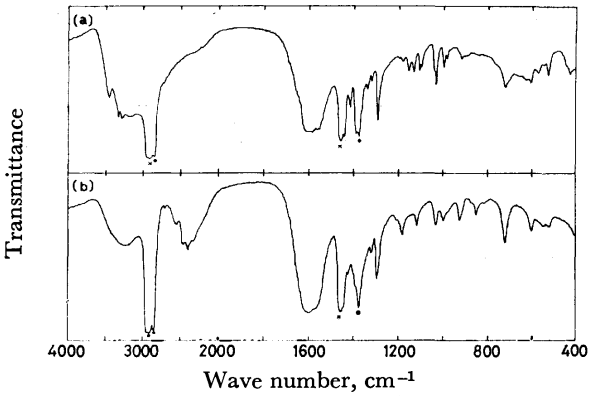

Fig. 4. Infrared spectra of solid (a) $CuGG \cdot 3H_2O$ and (b) $CuGG \cdot 3D_2O$ (Nujol mull).
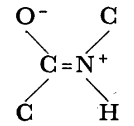
The absorptions due to Nujol are indicated by asterisk.

other evidence, that the complexes are dissociated in this low pD range. In the pD range between 3 and 5 where the 1630 cm^{-1} band is observed, another band appears at 1508 cm^{-1} in addition to the 1483 cm^{-1} band. The 1508 cm^{-1} band can be assigned to the amide II' vibration of complexed glycylglycine. The shift of amide II' band to higher frequency is related to the increase in bond order of the peptide C-N linkage; in other words, the contribution of the resonance form



increases with the complex formation. This type of change can be expected for Complex IIa but not for Complex I (Fig. 2). In the latter the bond order of the peptide linkage would be reduced through the increased contribution of sp^3 configuration of the nitrogen atom.

The infrared analysis given above indicates that complex IIa and free glycylglycine coexist in the range $3<pD<5$. The presence of Complex IIa in acidic solution was first proposed by Rabin[4] from potentiometric studies and later supported by calorimetric[6] and kinetic[8] analyses. The X-ray diffraction analysis of Cu(HGG)Cl·H_2O crystallized from acidic solution gave a structure analogous to Complex IIa.[3]

In neutral solution with $pD>5$ new bands are observed at 1610, 1443, and 1295 cm^{-1}, whereas the bands at 1630 and 1508 cm^{-1} disappear. The spectra measured at pD values between 5 and 11 were essentially the same as that of Fig. 1(e). The new bands are undoubtedly due to Complex III shown in Fig. 2. The 1610 cm^{-1} band may be assigned to the C=O stretching and the latter two bands are probably associated with the C–N^- stretching vibration. The conversion of complex structure in going from acidic to neutral solution and the presence of Complex III in neutral solution are unanimously accepted.[4-8] In this complex the terminal CO_2^- group is also coordinated to the metal. In fact, the CO_2 symmetric stretching band is shifted to 1384 cm^{-1} [Fig. 1(e)] from 1394 cm^{-1} of free CO_2^- [Fig. 1(b), (c), and (d)].

The assignments of bands observed in the region

Table 1. Assignments of the infrared bands of the D_2O solution of the Cu (II) complex in the region between 1750 and 1440 cm^{-1}.[a)]

Obs. freq., cm^{-1} [a)]	Assignment
1725 (1725)	C=O str. of terminal COOH
1675 (1675)	Amide I of free $D_3N^+CH_2CONDCH_2CO_2^-$
1630 (1640)	(1) Amide I of free $D_2NCH_2CONDCH_2CO_2^-$ (2) Amide I of Complexes IIa and IIb
1610	C=O str. of Complex III
1595 (1595)	Antisym. str. of free and complexed CO_2^-
1508 (1500)	Amide II′ of Complexes IIa and IIb
1483 (1483)	Amide II′ of free $D_3N^+CH_2CONDCH_2CO_2^-$
1443	$C-N^-$ str. of Complex III[b)]
1394 (1394)	Sym. str. of free CO_2^-
1384	Sym. str. of complexed CO_2^-

a) This table is also applicable to the D_2O solution of the Zn (II) complex. The observed frequencies for the D_2O solution of the Zn(II) complex are given in parentheses. b) The 1295 cm^{-1} band also may be assigned to a mode which has a considerable contribution of the $C-N^-$ stretching.

between 1750 and 1300 cm^{-1} are given collectively in Table 1.

Infrared Spectra and Structures of the Zn(II) Complexes. The infrared spectrum of the D_2O solution of Zn-$(DGG)_2 \cdot 2D_2O$ was not much different from that of $Zn(DGG)Cl \cdot 0.5D_2O$ under common pD values. The structure of complexed glycylglycine in both solutions must therefore be identical. The infrared spectra in the region between 1800 and 1200 cm^{-1} of $Zn(DGG)Cl \cdot 0.5D_2O$ in D_2O are shown in Fig. 5. The examination of these spectra shows that no complex is formed for pD<4. In this pD range the amide II′ band at 1483 cm^{-1} of free glycylglycine is observed similarly as in the case of the D_2O solution of the Cu(II) complexes for pD<3. The bands at 1640 and 1500 cm^{-1} begin to appear at pD about 5 and become stronger for higher pD values until the precipitation of the complex begins from alkaline solution with pD about 9. At pD 7.6 the amide II′ band of free glycylglycine is observed as a very weak shoulder. This indicates that Complex IIa and /or Complex IIb are the predominant species in this pD range. In both of these complexes the metal-ligand bonding occurs through the amino nitrogen and peptide oxygen. Complex IIb is consistent with the structure determined for the crystal of $Zn(HGG)_2 \cdot 2H_2O$ by X-ray diffraction.[2)] It is interesting to note that no conversion of complex structure takes place for the Zn(II) complex in going from acidic to neutral solution.

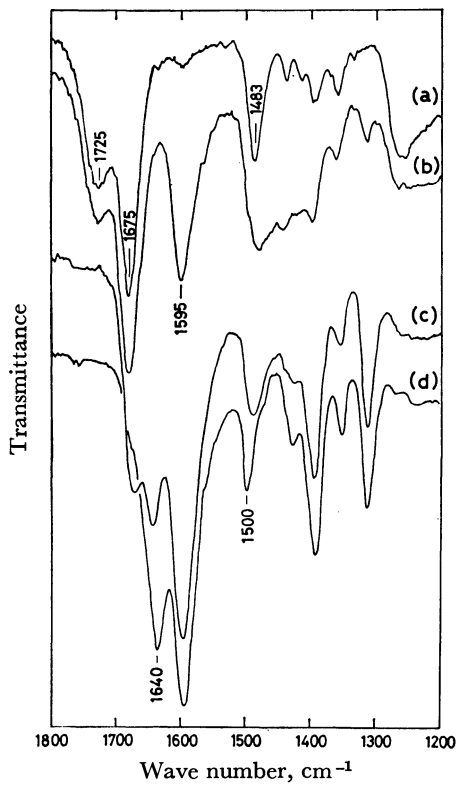


Fig. 5. Infrared spectra of the D_2O solution of the Zn(II) complex at various pD values.
Concentration, *ca.* 0.2 M; sample layer thickness, 0.05 mm. (a), pD 0.8; (b), pD 3.2; (c), pD 6.0; (d), pD 7.6.

Conclusion

The analysis of the infrared spectra of the Cu(II) complex of glycylglycine in D_2O shows that, for 3< pD<5, a complex is formed in which the metal-ligand bonding occurs through the amino nitrogen and peptide oxygen. As pD is increased, the structure of complex changes. In the complex which is present predominantly for pD>5 the metal-ligand bonding occurs through the amino nitrogen, peptide nitrogen (deprotonated), and carboxyl oxygen.

The behavior of the Zn(II) complex of glycylglycine is considerably different from that of the Cu(II) complex. No structure change of the complex is observed with increasing pD. In the complex formed for pD>5 the metal-ligand bonding is of the same type as found for the Cu(II) complex for 3<pD<5. Such structural information is useful in analysing the catalytic activities of these two metal ions in the hydrolysis of peptide bond. This point will be treated in a subsequent paper.

The authors wish to thank Miss Hideko Ito for the assistance throughout this work.

Metal(II)-Ion Promoted Hydrolysis of Glycylglycine

Toshio NAKATA, Mitsuo TASUMI, and Tatsuo MIYAZAWA

Department of Biophysics and Biochemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received January 31, 1975)

The hydrolysis of glycylglycine was studied in the presence of Cu(II) and Zn(II) at various pH values between 3.4 and 6.3. Glycine produced by the hydrolysis and remaining glycylglycine were trimethylsilylated and their relative quantities were determined by gas-liquid chromatography. The reaction is promoted by both metal ions. In the presence of Cu(II) the pH-rate profile has a maximum at pH *ca.* 4.4, whereas in the presence of Zn(II) the rate increases as pH becomes higher. These kinetic results are discussed in terms of the structures of metal(II)-glycylglycine complexes in aqueous solution.

Some metal ions are known to have catalytic activities in the hydrolysis of peptide bond.[1,2] Grant and Hay[2] have studied the hydrolysis of glycylglycine in the presence of Cu(II) and have found that the reaction rate is clearly dependent upon pH, showing a maximum at pH 4.2. The purpose of the present study is to examine more quantitatively the pH dependence of catalytic activities of Cu(II) and Zn(II) in the hydrolysis of glycylglycine and to discuss the relationship between the reactivity and structure of the metal(II)-glycylglycine complex. The structures of Cu(II) and Zn(II) complexes of glycylglycine in aqueous solution have been reported in a previous paper.[3]

Experimental

Materials. Glycylglycinatocopper(II) chloride monohydrate [Cu(HGG)Cl·H_2O][4] and glycylglycinatozinc(II) chloride hemihydrate [Zn(HGG)Cl·0.5H_2O] were prepared from glycylglycine and corresponding metal(II) chloride according to the method of Bair and Larsen.[5]

Bis(trimethylsilyl)trifluoroacetamide (BSTFA) was synthesized by adding trimethylsilyl chloride to a mixture of trifluoroacetamide and trimethylamine. The product was purified by distillation.[6] Bp 52.5 °C (30 mmHg).

Reaction. The hydrolysis of glycylglycine was studied for 0.01 and 0.1 M solutions of Cu(HGG)Cl·H_2O and Zn(HGG)Cl·0.5H_2O. The samples were dissolved in sodium acetate–acetic acid buffer solution. The total concentrations of acetate ion plus acetic acid were 0.2 and 1 M, respectively, for the sample concentrations of 0.01 and 0.1 M. Sealed reaction tubes containing 5 ml solutions were kept in an oil bath at 85 °C for 100 hr. After the reaction each solution was diluted with several ml of water, treated with hydrogen sulfide, and then freed of hydrogen sulfide with a stream of nitrogen. The precipitate (CuS or ZnS) was removed after centrifugation (2000 g, 10 min).

Thin-layer Chromatography. The solution thus obtained was analysed qualitatively by thin-layer chromatography, using phenol–water–ammonium hydroxide (3:1:trace) mixture as solvent and a 20×20 cm TLC plate covered with microcrystalline cellulose. Glycine produced by the hydrolysis and glycylglycine were both identified by the coloration with ninhydrin, R_f values being 0.37 and 0.57, respectively.

Trimethylsilylation. Trimethylsilylation of glycine and glycylglycine was carried out in order to obtain volatile derivatives which could be analysed by gas–liquid chromatography. By adjusting the pH value of the solution (from which metal sulfide was already separated) to about 2.5 with 1 M hydrochloric acid, sodium acetate was converted to acetic acid, which was then removed by freeze-drying. After dissolving the remaining solid substance in a small amount of water (1 ml), an aliquot (100—200 μl) was put into a vial for trimethylsilylation (purchased from Pierce Co., Ltd. in Rockford, Illinois, U.S.A.). The solution in the vial was frozen and evaporated completely to dryness in a vacuum desiccator over phosphorus pentoxide. To this dry sample were added 150 μl of dry acetonitrile and 150 μl of BSTFA. The vial was sealed with a silicon-lined cap and heated for 15 min at 125—130 °C. Under such a condition both glycine and glycylglycine were trimethylsilylated to a satisfactory degree. However, two kinds of trimethylsilylated derivatives were obtained as described later.

Gas-liquid Chromatography. Gas-liquid chromatographic analysis was carried out with a Shimadzu gas chromatograph GC-4BM equipped with a flame ionization detector. Glass columns of 2.0 m×4 mm i.d. containing 5.0% w/w SE-30 coated on 80/100 mesh AW-DMCS Chromosorb W were used. The flow rate of carrier gas (nitrogen) was 60 ml/min and the temperature was elevated from 100 °C to 220 °C at a programmed rate of 5 °C/min.

Mass Spectrometry. The characterization of trimethylsilylated derivatives was carried out by mass spectrometry. A Hitachi RM 50 (combined GLC-MS instrument) was used with the temperature of ion source and manifold 220 °C, accelerating voltage 3 kV, and ionizing energy 70 eV.

Results

Analysis of Trimethylsilylated Glycine and Glycylglycine by Gas-liquid Chromatography. By the reaction with BSTFA both glycine and glycylglycine gave two kinds of trimethylsilylated (TMS) derivatives as shown below.

(1) $H_2NCH_2COOH + CF_3CON[Si(CH_3)_3]_2 \longrightarrow$ TMS-$NHCH_2COO$-TMS (Di-TMS-glycine, TG-1) + $(TMS)_2NCH_2COO$-TMS (Tri-TMS-glycine, TG-2)

(2) $H_2NCH_2CONHCH_2COOH + CF_3CON[Si(CH_3)_3]_2 \longrightarrow$ TMS-$NHCH_2CONHCH_2COO$-TMS (Di-TMS-glycylglycine, TGG-1) + $(TMS)_2NCH_2CONHCH_2COO$-TMS (Tri-TMS-glycylglycine, TGG-2)

This was proved by GLC-MS analysis. The results of our GLC-MS analysis for trimethylsilylated glycine were in agreement with those reported by Bergström *et al.*[7] Both di-TMS- and tri-TMS-glycylglycine have fragmentation patterns very similar to di-TMS- and tri-TMS-glycine, respectively. Tri-TMS-glycine(M=348) gave the following fragment ions: *m/e* 333, $[(M-CH_3)^+]$; *m/e* 174, $[(TMS)_2N^+=CH_2]$; *m/e* 147, $[TMS-O^+=Si(CH_3)_2]$; *m/e* 102, $[TMS-N^+H=CH_2]$; *m/e* 86, $[(CH_3)_2Si=N^+=CH_2]$; *m/e* 73, $[TMS^+]$; *m/e* 59,

$[HSi^+(CH_3)_2]$; *m/e* 45, $[H_2Si^+CH_3]$.

It was found that trimethylsilylation of glycine at 100 °C for 15 min gave TG-1 alone, whereas the addition of trimethylsilyl chloride besides BSTFA yielded only TG-2 under the same reaction condition. Using fluorene as internal standard, the relative molar sensitivity of TG-1 and TG-2 for the flame ionization detector used in this experiment was determined to be 1.00: 1.39. In a similar manner the relative molar sensitivity of TGG-1 and TGG-2 was determined to be 1.00: 1.40. Various mixtures of glycine and glycylglycine were trimethylsilylated at 125 °C for 15 min, and the ratios of peak areas of TG-1 and TGG-1 were plotted against the molar ratio of glycine and glycylglycine. A linear relationship was obtained and from the slope the relative molar sensitivity of TG-1 and TGG-1 was determined to be 1.87: 1.00. Consequently, the relative molar sensitivity of TG-1, TG-2, TGG-1, and TGG-2 was 1.87: 2.60: 1.00: 1.40.

Hydrolysis of Glycylglycine. The solutions (0.01 and 0.1 M) of glycylglycine, $Cu(HGG)Cl\cdot H_2O$, and $Zn(HGG)Cl\cdot 0.5H_2O$ having various pH values were kept at 85 °C for 100 hr. The percentage of hydrolysis (ρ) was calculated by the following equations and the results are given in Tables 1 and 2 and Fig. 1.

$$\rho(\%) = \left\{1-\frac{[\text{Glygly}]_{100}}{[\text{Glygly}]_0}\right\}\times 100 = \left\{1-\frac{[\text{Glygly}]_{100}}{[\text{Glygly}]_{100}+(1/2)[\text{Gly}]_{100}}\right\}\times 100 = \left\{\frac{1}{2([\text{Glygly}]_{100}/[\text{Gly}]_{100})+1}\right\}\times 100 \quad (1)$$

where [Glygly] and [Gly] denote the concentrations of glycylglycine and glycine, respectively, and suffix indicates the reaction time (hr). The ratio $[\text{Glygly}]_{100}/[\text{Gly}]_{100}$ can be obtained from the gas-liquid chromatographic analysis as follows.

$$\frac{[\text{Glygly}]_{100}}{[\text{Gly}]_{100}} = \frac{A_{\text{TGG-1}}+(1/1.40)A_{\text{TGG-2}}}{(1/1.87)A_{\text{TG-1}}+(1/2.60)A_{\text{TG-2}}} \quad (2)$$

where $A_{\text{TG-1}}$, $A_{\text{TG-2}}$, $A_{\text{TGG-1}}$, and $A_{\text{TGG-2}}$ denote the peak areas of TG-1, TG-2, TGG-1, and TGG-2, respectively.

Discussion

The kinetic results obtained above may be summarized as follows.

(1) In the absence of the metal ion, glycylglycine is hardly hydrolysed under the present experimental conditions (Table 1).

(2) Both the Cu(II) and Zn(II) ions promote the hydrolysis of glycylglycine (Tables 1 and 2).

(3) In the presence of Cu(II) the pH-rate profile is a "bell-shape" having maximum at pH *ca.* 4.4. In contrast to this, the rate increases as pH becomes higher in the presence of Zn(II) (Fig. 1). The pH-rate profile in this case may be called "half bell-shape." (The pH range beyond 6.3 was not examined due to the lack of suitable buffer solution.)

(4) The rate of hydrolysis is greater for the solution having higher initial concentration (0.1 M *vs.* 0.01 M).

The bell-shaped pH-rate profile for the Cu(II)-glycylglycine system is in good agreement with the results reported previously by Grant and Hay[2] using an analytical method (ninhydrin technique) quite different from ours.

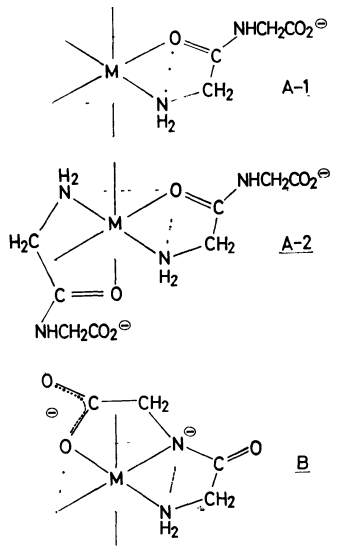

Fig. 2. Structures of metal(II)-glycylglycine complex.

An interesting aspect of the results obtained above is the correlation between the rate of hydrolysis and the structure of metal(II)-glycylglycine complex in aqueous solution. Previously we have studied the infrared spectra of D_2O solutions of the Cu(II) and Zn(II) complexes of glycylglycine and have derived the following conclusions on their structures.[3] (a) In the Cu(II) complex formed in the pD range between 3 and 5 the metal-ligand bonding occurs through the amino nitrogen and peptide oxygen (Structure A-1 of Fig. 2). (b) As pD is increased further, the structure of the Cu(II) complex changes into a form in which the metal-ligand bonding occurs through the amino nitrogen, peptide nitrogen (deprotonated), and carboxyl oxygen (Structure B of Fig. 2). (c) In contrast to the Cu(II) complex, the Zn(II) complex is formed for pD>5. Its structure is similar to the Cu(II) complex formed for 3<pD<5, the metal-ligand bonding ocurring through the amino nitrogen and peptide oxygen (Structure A-1 and/or A-2 of Fig. 2). A correlation between the rate and the complex structure is then obvious; *i.e.*, the hydrolysis occurs through the complex in which the peptide oxygen is coordinated to the metal ion (Structure A-1 and/or A-2). This suggests that the mechanism of hydrolysis might be described as follows. Due to the coordination of peptide oxygen to the metal ion, the double bond character of peptide C=O decreases. Although the bond order of peptide C–N increases somewhat at the same time,[3] the net effect of coordination results in the decrease of electron density around the peptide carbon atom. The electron-deficient carbon atom is susceptible to nucleophilic attack of the water molecule which will induce the scission of peptide bond. On the contrary, the electron density around the peptide carbon atom of Structure B would not be reduced (in comparison with free glycylglycine) due to the presence of negative charge on the nitrogen atom. Accordingly, the complex with Structure B is not as susceptible to nucleophilic attack of the water molecule.

It is interesting to compare our results with the peptidase activity of carboxypeptidase A (CPA).[8] Native CPA which has Zn(II) at its active site shows a bell-shaped pH-rate profile with maximum at pH 7.5. It is established that the peptide oxygen of the substrate molecule is coordinated to Zn(II) in the enzyme-substrate complex. If Zn(II) is replaced by Cu(II) (CuCPA), the enzymatic activities are lost. Our present results seem to suggest that a complex analogous to Structure B is formed between CuCPA and the substrate peptide. It is not surprising that this type of complex is inactive to hydrolysis. Although much more studies are needed, the investigation of the properties of metal-substrate complexes may supply useful information in delineating fundamental aspects of metalloenzyme activities.

Sum Rule Consideration of Molecular Photoelectron Spectra. Substituted Ethylenes

Tomoko YAMAZAKI and Katsumi KIMURA

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received February 24, 1975)

The ionization-energy sum rule previously proposed has been applied to photoelectron spectra of three series of chloro-, bromo-, and methyl-substituted ethylenes $C_2H_{4-m}X_m$ ($m=1$ and 2; X=Cl, Br, and CH_3) in the He(I) region. The total sums of ionization energies were obtained in the p-type region and the partial sums of ionization energies were interpreted in terms of in-plane and out-of-plane molecular orbitals. The following conclusions have been deduced: (1) The experimental total and partial sums are almost constant in the *cis*-, *trans*-, and *iso*-di-substituted ethylenes. (2) The experimental total and partial sums linearly increase with increasing number of the substituents, the slopes leading to useful informations about orbital energies. (3) Such linear relationships are supported by CNDO/2 and MINDO/2 calculations. (4) The experimental total and partial sums are approximately reproduced in terms of several appropriate localized-molecular-orbital energies based on the photoelectron data of simplest molecules.

Molecular photoelectron spectroscopy provides a variety of vertical ionization energies associated with valence molecular orbitals.[1] Total and partial sums of vertical ionization energies in the He(I) region in various alkyl halides,[2-4] alcohols and amines[5] have previously been interpreted by Kimura *et al.* in terms of empirical energy values of appropriate p-type localized molecular orbitals (LO's) under Koopmans' theorem. A similar sum rule consideration has also been applied to ionization energies associated with out-of-plane orbitals in many planar skeletal unsaturated compounds,[6] and further extended to the He(II) region including all the valence molecular orbitals in mono-, di-, and tri-methylamine.[7] These sum rule considerations of ionization energies have been found to be very helpful for interpreting molecular photoelectron spectra.[2-8]

In the present paper we wish to report an application of the sum rule to chloro-, bromo-, and methyl-substituted ethylenes in the He(I) region, placing special emphasis on the total sum of ionization energies over all the p-type LO's and on the partial sums of ionization energies corresponding to the in-plane and out-of-plane LO's.

Photoelectron spectroscopy studies of substituted ethylenes have so far been carried out by many other workers.[1,9-16] The resulting photoelectron spectra, vertical ionization energies, and orbital assignments have been published in considerable detail. In the present sum rule consideration therefore we use the available complete sets of ionization energies.

Sum Rule Consideration

In the present work we consider all the p-type LO's in the substituted ethylenes $C_2H_{4-m}X_m$ ($m=1$ and 2; X=Cl, Br, and CH_3). As previously done,[2-8] the p-type LO's used are: (1) nonbonding orbitals, n_{Cl} and n_{Br}; (2) bonding orbitals, $\pi_{C=C}$, σ_{C-Cl}, σ_{C-Br}, σ_{C-C}, and $\sigma_{C=C}$; and (3) the pseudo π orbitals of the methyl and methylene groups, π_{CH_3} and π_{CH_2}. The numbers of p-type LO's in the substituted ethylenes studied are

Table 1. Numbers of *p*-type LO's in $C_2H_{4-m}X_m$

Number of subst. (m)	In-plane (a′)				Out-of-plane (a″)		Total number of LO's
	$\sigma_{C=C}$	π_{CH_2}	n_X[a]	σ_{C-X}[a]	$\pi_{C=C}$	n_X[a]	
0	1	2			1		4
1	1	1	1	1	1	1	6
2 {*cis*, *trans*}	1		2	2	1	2	8

a) When X is the methyl group, n_X and σ_{C-X} represent π_{CH_3} and σ_{C-C} respectively.

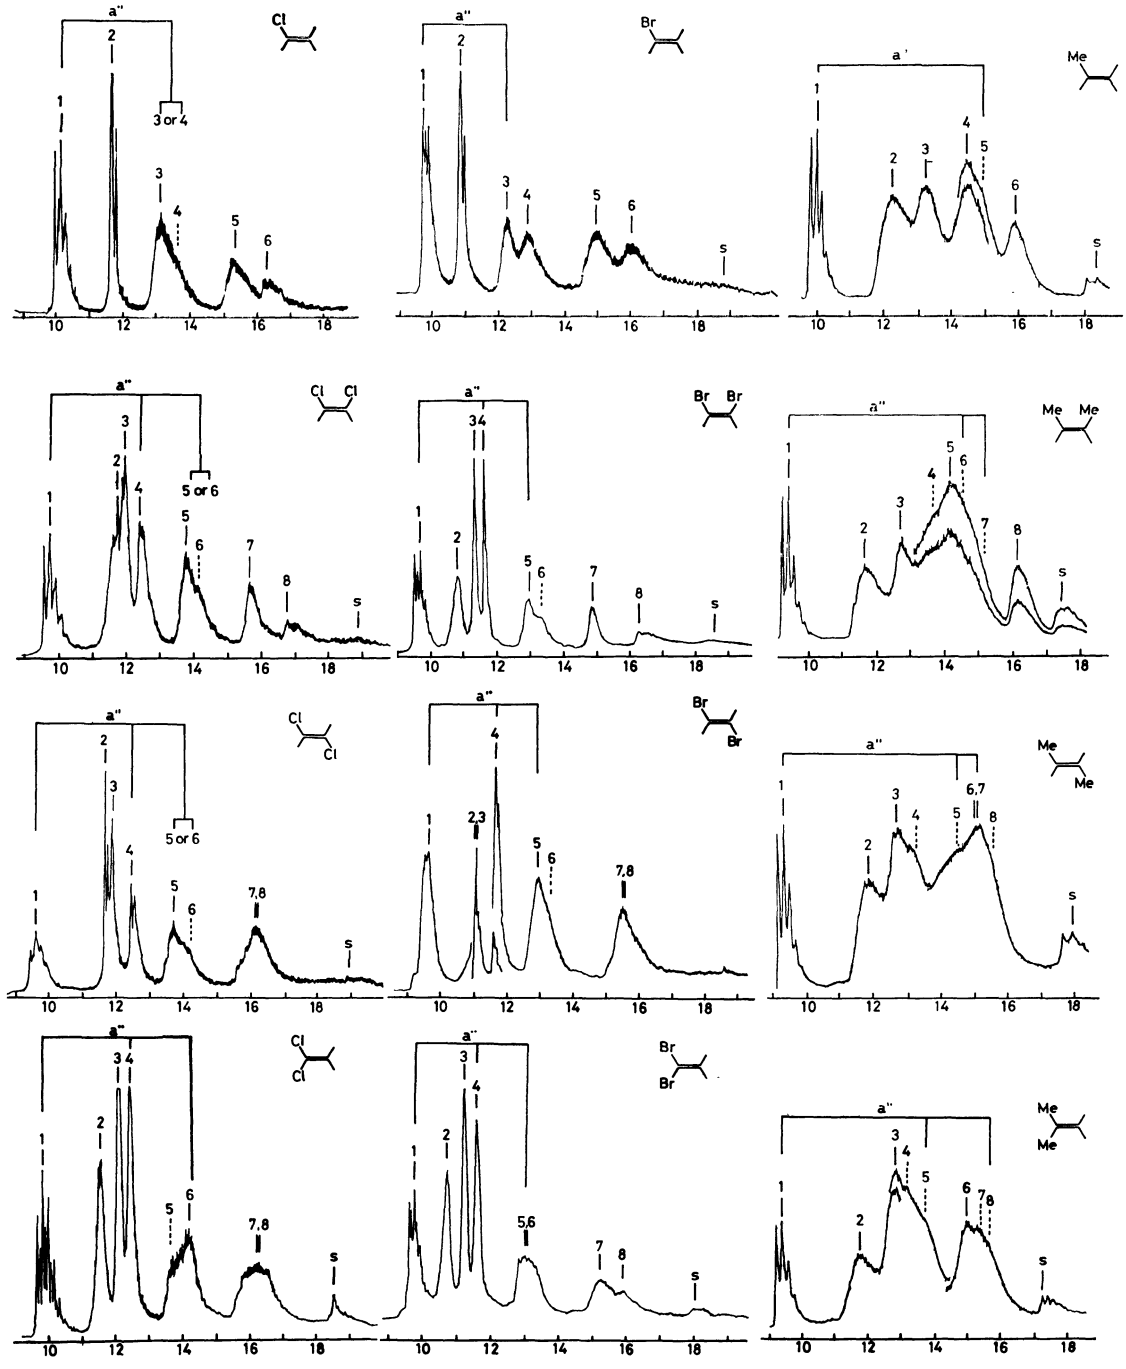

Fig. 1. Numbering of *p*-type ionization bands in He(I) photoelectron spectra of chloro-, bromo-, and methyl-substituted ethylenes.
The spectra of the chloro- and bromo-ethylenes are those reported by Wittel and Bock (Ref. 14) and the spectra of the methyl-substituted ethylenes are those reported previously by Kimura *et al.* (Ref. 6).
Out-of-plane bands are represented by a″ and s-type bands are by letters.

summarized in Table 1, indicating four, six, and eight p-type LO's in the un-, mono-, and di-substituted ethylenes, respectively. The present authors have previously indicated from several studies of alkyl compounds that all the photoelectron bands associated with p-type LO's lie below about 17—18 eV.[2-8] In order to show the numbering of the individual ionization bands, we illustrate the photoelectron spectra taken from the literatures in Fig. 1. The spectra of the series of chloro- and bromo-ethylenes in Fig. 1 are those from the paper of Wittel and Bock,[14] slightly modified in the numbering of the bands. The Wittel-Bock I_7 bands in *trans*- and *iso*-dichloroethylene and *trans*-dibromoethylene are designated as I_7 and I_8 in Fig. 1. The same numbers of ionization bands as those of p-type LO's can be recognized in the available photoelectron spectra in the region below about 17 eV in Fig. 1.

The vertical ionization energies used in the sum rule treatments are summarized in Table 2, in which the data for the chloro-, bromo-, and methyl-substituted ethylenes are those reported by Lake and Thompson,[9] by Wittel and Bock,[14] and by the present authors,[6] respectively. The values for I_8 in *trans*- and *iso*-dichloroethylene are set equal to those for I_7. The values in parentheses correspond to the shoulders which are indicated by vertical broken lines in Fig. 1.

Experimental Total and Partial Sums. The total sums of vertical ionization energies are taken over all the p-type region by

Table 4. Average α values (in eV) obtained with the experimental total and partial sums

Series		α	α'	α''
$C_2H_{4-m}Cl_m$	(m=0—2)	−26.44±0.07	−13.34±0.01	−13.11±0.06
$C_2H_{4-m}Br_m$	(m=0—2)	−23.24±0.01	−11.48±0.04	−11.78±0.06
$C_2H_{4-m}(CH_3)_m$	(m=0—2)	−26.82±0.06	−12.54±0.05	−14.26±0.01

$$T_{expt} = -\sum_{i}^{all} I_i \quad (1)$$

and the experimental partial sums associated with the in-plane and out-of-plane LO's, P' and P'', respectively, are obtained by

$$P'_{expt} = -\sum_{i}^{a'} I_i \text{ and } P''_{expt} = -\sum_{i}^{a''} I_i \quad (2)$$

which are based on the available symmetry assignments. The results of the experimetal total and partial sums obtained by Eqs. (1) and (2) are summarized in Table 3. Since different kinds of orbital assignments have been proposed for the chloro- and bromo-ethylenes,[12,14,17,18] we took two kinds of possible combinations of I_i into account in the partial sums as shown in Table 3.

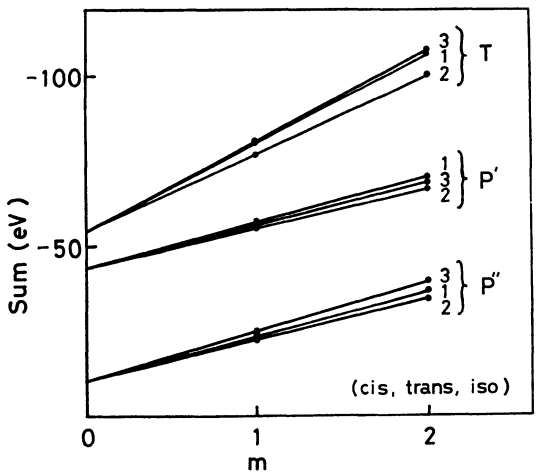

Fig. 2. Plot of the experimental total and partial sums of vertical ionization energies against the number of substituents in series of (1) chloro-, (2) bromo-, and (3) methyl-substituted ethylenes.

In Fig. 2 the experimental values for T, P', and P'' are plotted against the number (m) of substituents, indicating excellent linear relationships. The straight lines (solid lines) in Fig. 2 are drawn so as to fit the experimental data. The slope of the straight lines represents the variation of the total and partial sums with increasing number of substituents.

Calculated Total and Partial Sums. As shown previously,[2-8] the total and partial sums in the substituted ethylenes may be expressed in terms of empirical LO energies as follows,

$$T_{calc} = P'_{calc} + P''_{calc} \quad (3)$$

$$P'_{calc} = m\varepsilon_{n(X)} + m\varepsilon_{\sigma(C-X)} + (2-m)\varepsilon_{\pi(CH_2)} + \varepsilon_{\sigma(C=C)} \quad (4)$$

$$P''_{calc} = m\varepsilon_{n(X)} + \varepsilon_{\pi(C=C)} \quad (5)$$

When X is the methyl group, n(X) and σ(C-X) in Eqs. (4) and (5) represent $\pi(CH_3)$ and σ(C–C), respectively. From Eqs. (4) and (5), therefore the successive differences α' and α'' in the partial sums may be expressed as follows

$$\alpha' = \varepsilon_{n(X)} + \varepsilon_{\sigma(C-X)} - \varepsilon_{\pi(CH_2)} \quad (6)$$

$$\alpha'' = \varepsilon_{n(X)} \quad (7)$$

On the other hand, the successive differences in T, P', and P'' may be experimentally obtained from the slopes of the straight lines shown in Fig. 2. The resulting average values for α, α', and α'' are summarized in Table 4, the upper combination of I_i being used in the case in which two possible combinations of I_i are shown in Table 3.

Table 5. Empirical energies of p-type LO's (in eV)

a′ (in-plane)			
n_{Cl}= −13.05	n_{Br}= −11.89	π_{CH_3}= −14.30	π_{CH_2}= −14.36
σ_{C-Cl}= −14.70	σ_{C-Br}= −13.82	σ_{C-C}= −12.58	$\sigma_{C=C}$= −14.66
a″ (out-of-plane)			
n_{Cl}= −13.05	n_{Br}= −11.89	π_{CH_3}= −14.30	$\pi_{C=C}$= −10.51

The values for ε's used in the sum rule treatments are summarized in Table 5, which were selected on the basis of the vertical ionization energies of simple molecules as follows. The energies of n(Cl) and n(Br) were taken from the mean values of the first and second ionization energies of molecular chlorine and bromine, respectively.[19] The energies of π(C=C) and σ(C=C) were taken from the first and third ionization energies of ethylene, respectively.[11] The energy of $\pi(CH_2)$ was taken from the mean value of the second and fourth ionization energies of ethylene.[11] The energy of $\pi(CH_3)$ was determined from the ionization energies of methyl halides as described previously.[2] The energies of σ(C–Cl), σ(C–Br), and σ(C–C) were deduced by Eq. (6) from the experimental α' values shown in Table 4.

With all these energy parameters the total sums (T) and the in-plane and out-of-plane partial sums (P' and P'') were calculated by Eqs. (3)—(5), the results being compared with the experimental results in Table 3.

Discussion

The following three points may be pointed out on the experimental total and partial sums. (1) Good linear relationships can be seen between the sums (T, P', and P'') and the number of substituents. (2) The total and partial sums of the *cis*-, *trans*-, and *iso*-isomers in each series are very close to one another. (3) The effects of the chloro-, bromo-, and methyl-substitutions on the total and partial sums are very similar, as seen from Fig. 2.

Previously,[8] a good linearity was indicated between such total sums and the number of chlorine atoms in a

series of chloroethanes $C_2H_{6-m}Cl_m$ ($m=0$—6), and a value of -14.90 eV was deduced for σ(C–Cl), differing slightly from the value of -14.70 eV found here in the chloroethylenes. In the present work, the linearities have been found not only for the total sums but also for the partial sums.

From Eq. (7) it is seen that the successive difference α'' is equivalent to $\varepsilon_{n(X)}$, so that the α'' values of -13.11, -11.78 and -14.26 eV in Table 4 may be regarded as the orbital energies for n(Cl), n(Br), and $\pi(CH_3)$, respectively. It is interesting to note that these values are very close to those given in Table 5 which were determined from the photoelectron data of the simple molecules.

In the previous study of alkyl alcohols and amines (ROH and RNH_2; R = methyl to *n*-butyl),[5] we obtained an average difference of -26.04 eV in the total sums for the successive substitution of the CH_3 group. A similar value $\alpha_{av.}=-26.07$ eV was obtained in a series of alkyl halides (RX: R=methyl to *n*-butyl; X=Cl, Br, and I).[2] Furthermore, using available ionization energies of several alkanes (methane, ethane, propane, isobutane, and neopentane),[20] we may obtain a value of $\alpha_{av.}=-26.0$ eV. In these saturated alkyl compounds, therefore, the differences in T by the successive CH_3 substitutions are found to be -26.0——-26.1 eV, close to the sum of -11.75 eV and -14.30 eV which have previously been proposed for σ_{C-C} (in alkyl compounds) and π_{CH_2}, respectively.[2-5] For the methyl-substituted ethylenes studied here, however, we obtained a value of $\alpha_{av.}=-26.82$ eV which leads to a value of -12.58 eV for σ_{C-C} involving the sp^2 carbon as given in Table 5.

The α value of -26.44 eV in the series of chloroethylenes is fairly close to that (-26.69 eV) previously obtained in a series of chloroethanes.[8] The energies of -14.70 and -13.82 eV deduced for σ_{C-Cl} and σ_{C-Br}, respectively, in the present work are fairly close to those (-14.45 and -13.52 eV, respectively) previously estimated from the second ionization energies of methyl chloride and bromide, respectively.[2] As seen from Eq. (7), the α'' values of -13.11, -11.78, and -14.26 eV in Table 4 are equivalent to $\varepsilon_{n(Cl)}$, $\varepsilon_{n(Br)}$, and $\varepsilon_{\pi(CH_3)}$, respectively, in excellent agreement with those (-13.05, -11.89, and -14.30 eV, respectively) determined from the simple molecules.

From the present study it has been found that the experimental total and partial sums of the *iso*-isomers are almost the same as those of the *cis*- and *trans*-isomers. Equation (4) however does not hold for the *iso*-compounds. One of three LO's associated with the carbon sp^2 orbitals in the CCl_2 group in 1,1-dichloroethylene should be of s-type. In calculating P', therefore, one of the three in-plane p-type LO's (two σ(C–Cl) and one σ(C=C)) should be removed as an s-type LO. It is not unambiguous however to decide which one is of s-type. As shown in the combinations of LO's in Table 3, we removed one σ(C–Cl) in 1,1-dichloroethylene and σ(C=C) in 1,1-dibromoethylene and isobutene. The numbers of in-plane p-type LO's in the *iso*-isomers are of course the same as those in the *cis*- and *trans*-isomers.

Only the ionization energy data shown in Table 2 were used in the present sum rule considerations. Other complete sets of ionization energies reported for the chloroethylenes by Jonathan *et al.*[10] and Wittel and Bock[14] and for the bromoethylenes by Chadwick *et al.*[12] were also employed, and it was found that essentially the same results as above on the total and partial sums may be obtained.

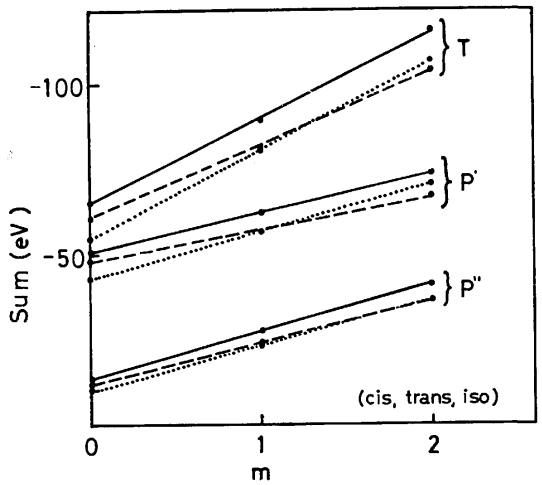

Fig. 3. Plot of theoretical total and partial sums obtained by CNDO/2 method against the number of chlorine atoms in a series of chloroethylenes.
The results multiplied by 0.85 (solid lines) and the results of the 4-eV correction (broken lines) are compared with the experimental ones (dotted lines).

In the present work we also investigated the relationship between the total (and partial) sums and the number of substituents using CNDO/2 method[21] and MINDO/2 method[22] under the Koopmans' theorem. The CNDO/2 results of T, P', and P'' for the series of chloroethylenes are plotted against the number of chlorine atoms in Fig. 3, the solid lines indicating the results multiplied by 0.85. The broken lines in Fig. 3 show the results reduced by 4 eV in each orbital. It is interesting to note in Fig. 3 that good linear relationships between the sum and the number of chlorine

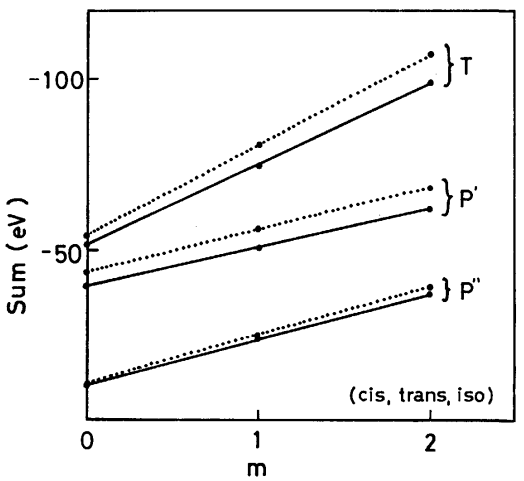

Fig. 4. Plot of theoretical total and partial sums obtained by MINDO/2 method against the number of CH_3 groups in a series of methyl-substituted ethylenes.
Dotted lines represent the experimental results.

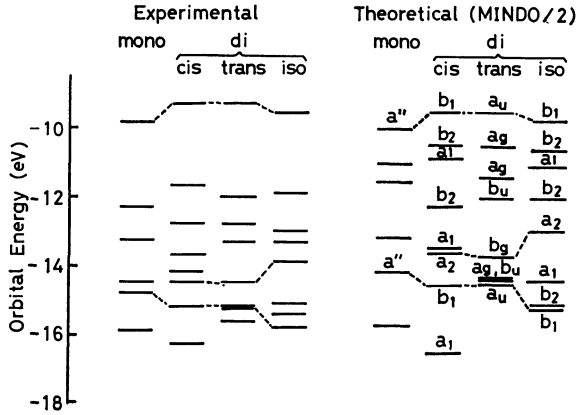

Fig. 5. Experimental and theoretical orbital level diagrams of the methyl-substituted ethylenes.

atoms can be seen and that the calculated results multiplied by 0.85 are approximately parallel to the experimental lines (dotted lines). The MINDO/2 results of T, P', and P'' for the methyl-substituted ethylenes are shown in Fig. 4, again indicating good linearities and parallelisms between calculation and experiment. The linearities between the partial sums and the number of substituents have been found for the first time in the present work.

Theoretical orbital energy diagrams obtained by the MINDO/2 method for the methyl-substituted ethylenes are shown in Fig. 5, compared with those of the experimental diagrams. The out-of-plane levels in Fig. 5 are connected by broken lines. As can be seen from Fig. 5, it may be pointed out that the variation of the out-of-plane levels in going from ethylene to *iso*-butylene is well reproduced by the MINDO/2 calculations.

Finally, the following point should be mentioned in connection with Koopmans' theorem. Koopmans' theorem has been assumed in the present orbital energy considerations using the experimental ionization energies. However, if we consider each empirical value in Table 5 (without the negative sign) as a hypothetical ionization energy of an electron from the original unperturbed p-type LO, the present sum rule consideration may be thought as an "additivity rule of ionization energy." In such a standpoint, Koopmans' theorem is unnecessary. Potts *et al.*[23] have indicated that the total sums of ionization energies associated with s- and p-type photoelectron bands in many aliphatic compounds may be reproduced in terms of atomic energy parameters on the basis of an idea of additivity rule. Most striking difference between the present sum rule consideration and the additivity rule consideration of Potts *et al.*[23] is that the former depends on the LO's whose energies are based on the molecular photoelectron spectra of simplest molecules, whereas the latter depends on the atomic parameters.

The Thermal Changes in Gels of the SiO_2–Al_2O_3–In_2O_3–H_2O System

Mitsuhiro KASAI, Yoshiyuki KUDO, and Shuichi HAMADA

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received March 7, 1974)

The synthesized coprecipitated gels in the SiO_2–Al_2O_3–In_2O_3–H_2O system showed an allophane-like pattern in the DTA except for the indium-rich gels. The exothermic peak temperature in the DTA was lowered from 980 to 940 °C with an increase in the indium content, while that on mixed gels was scarcely lowered at all. A new small exothermic peak around 880 °C in the DTA was observed in the coprecipitated gels with more than 11.93 wt% of In_2O_3; it was considered to be due to the structural change in the gels which arose from the formation of the indium (III) oxide. The firing products of the coprecipitated gels were identified as mullite, indium (III) oxide, and indium (III) silicate. The mullite formed in the coprecipitated gels included indium ions at 900 °C, accompanied by an increase in its unit cell volume, while the indium ions were almost entirely removed from the mullite lattice at 1200 °C.

The thermal properties of coprecipitated gels, the SiO_2–Al_2O_3–Fe_2O_3–H_2O[1] and the SiO_2–Al_2O_3–Ga_2O_3–H_2O[2] systems, have been studied. It has been found that aluminum ions are replaced by iron (III) or gallium ions in the allophane structure of the coprecipitated gels. The thermal properties of the gels in the SiO_2–Al_2O_3–In_2O_3–H_2O system have not been studied, while phase diagrams of the In_2O_3–Al_2O_3[3] and the In_2O_3–Ga_2O_3[4] systems have been reported.

In this work, the thermal properties of the coprecipitated gels in the SiO_2–Al_2O_3–In_2O_3–H_2O system were studied in order to determine the role of trivalent cations in a silicoalumina-gel structure.

Experimental

Materials. The samples were prepared by means of a method similar to that described in previous papers:[1,2] indium-coprecipitated gels were obtained by boiling mixed solutions of aluminum sulfate, indium(III) sulfate, and sodium silicate at a pH of about 4.5, a pH value obtained by adding hexamethylenetetramine. The $In_2O_3/(Al_2O_3+In_2O_3)$ molar ratio in the mixed solutions was varied from zero to 1.0 at a constant molar ratio of 2.0 as $SiO_2/(Al_2O_3+In_2O_3)$. The gels thus coprecipitated were washed by decantation and then air-dried for three weeks. They were identified as amorphous from their X-ray powder diffractograms. The indium-mixed gels were prepared by mixing a synthesized allophane, free from indium, and an amorphous hydrated indium(III) oxide in order to compare the properties of the coprecipitated gels. The hydrated indium(III) oxide was prepared by using ammonia water at pH 4.0. The gel thus obtained was identified as amorphous from its X-ray powder diffractogram, though the gels obtained at pH 5.3 and 7.0 contained crystalline InOOH.[5-7]

Procedure. The contents of SiO_2, Al_2O_3, and $H_2O(\pm)$[8] in the samples were estimated gravimetrically, and that of In_2O_3,[9] polarographically.

The differential thermal analysis for the sample was carried out at the heating rate of 10 °C/min in the temperature range from room temperature to 1000 °C with a Rigaku Denki Thermoflex, model 8002, differential thermal analyzer.

The X-ray powder diffractogram of the sample was taken by using an X-ray diffractometer, model JDX-5P, from the Japan Electron Optics Laboratory Co. The sample, in a quartz tube, was heated at 800, 900, 1000, 1100, and 1200 °C for 5 hr, and at 1300 °C for 1 hr, in an electric furnace. The firing products were identified, and their relative amounts were estimated by using the diffraction peaks at (120) and (210) of the mullite, that at (101) of the cristobalite, and those at (222) and (400) of the indium (III) oxide. The unit-cell dimensions of the mullite and the indium (III) oxide, the firing products of the samples, were calculated by using the peaks at (121), (230), (400), (041), (331), and (002) of the mullite and those at (222), (400), and (440) of the indium (III) oxide. The diffraction angles were calibrated with those of silicon.

Results and Discussion

The chemical compositions of the indium-bearing gels are shown in Table 1. The molar ratios of $SiO_2/(Al_2O_3+In_2O_3)$ in the coprecipitated gels were smaller than those of $SiO_2/(Al_2O_3+Ga_2O_3)$ in the gallium-coprecipitated gels[2] obtained from the mixed solutions with the same molar ratio of 2.0, except for the In-12C sample. These small values of the molar ratios were considered to arise from the condition of a higher acidity for precipitation than that for the gallium-coprecipitated gels, or from the nature of the indium (III) ion.

The Differential Thermal Analysis of the Samples. The DTA patterns of the gels are shown in Fig. 1. The In-0 sample, free from indium, was identified as an allophane from its DTA pattern, attributable to allophane. The exothermic peak temperature was lowered from 980 to 940 °C as the indium content increased, except for the In-8C and -9C samples, in contrast to the small shift in the mixed gels. This peak was not observed in the gels with more than 38.22 wt% of In_2O_3 (the In-10C and -11C samples). The tendency of the peak temperature in the indium-coprecipitated gels to lower was considerably less than that in the gallium-coprecipitated gels.[2]

The apparent activation energy, E_a, for the exothermic change around 980 °C was estimated by means of the Kissinger equation.[10] The E_a values of the exothermic change in the coprecipitated gels decreased with an increase in the indium content, while those in the mixed gels were nearly equal to that in the In-0 sample, as is shown in Table 2.

A new, small, broad exothermic peak around 880 °C in the DTA was observed in only the coprecipitated gels with more than 11.93 wt% of In_2O_3 (from the In-3C to -12C samples); the mixed gels did not show it.

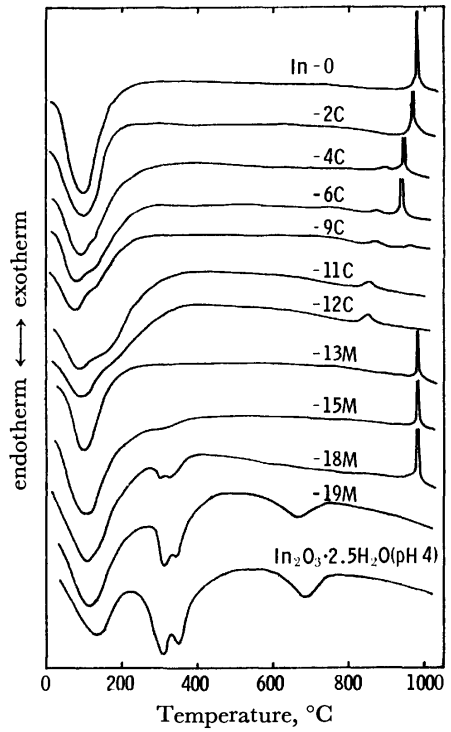

Fig. 1. DTA curves of indium-bearing samples.

This exothermic peak temperature was also lowered continuously with an increase in the indium content.

In the indium-rich mixed gels, the endothermic peaks based on the amorphous hydrated indium (III) oxide were observed besides the endo- and the exothermic peaks around 100 and 980 °C.

The Variation in the Firing Products in the Samples during the Heat Treatment. The crystalline phases formed

in the samples heat-treated at 800, 900, 1000, 1100, and 1200 °C for 5 hr, and at 1300 °C for 1 hr were identified by X-ray powder diffractometry as mullite, indium (III) oxide, and a new phase, as Table 3 shows.

The indium (III) oxide formed below 1000 °C in the coprecipitated gels with more than 11.93 wt% of In_2O_3 (from the In-3C to -11C samples) showed broad X-ray powder diffraction peaks; their spacings were smaller than those of the indium (III) oxide with the usual unit-cell dimensions.[11] This contraction of the crystal lattice was considered to arise from the replacement with aluminum ions.

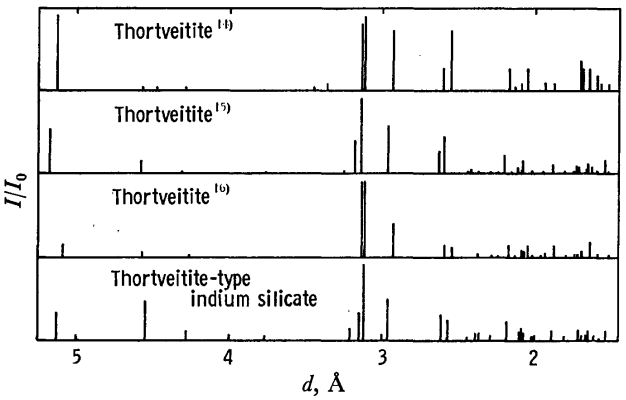

Fig. 2. X-ray powder diffraction patterns of thortveitite and thortveitite-type indium silicate.

New X-ray diffraction peaks were observed in the firing products above 1100 or 1200 °C of the indium-bearing gels, except for those of the In-17M and -18M samples, and the aluminum-free samples. This X-ray diffraction pattern, without the diffraction peaks of the known materials, was found to resemble closely that of thortveitite, $Sc_2Si_2O_7$, as is shown in Fig. 2. In the coprecipitated gels of the SiO_2–Al_2O_3–Sc_2O_3–H_2O system, a large portion of their scandium component was confirmed to separate out as thortveitite upon heating.[12] In this system, cristobalite was not found as a firing product, except in the In-1C sample, just as in the system of SiO_2–Al_2O_3–Sc_2O_3–H_2O. In the iron (III)- and the gallium-bearing systems,[1,2] excess amounts of such trivalent cations as iron (III) and gallium ions separated out as hematite and β-gallia with the formation of cristobalite at higher temperatures. Judging from the above facts and a similarity in their ionic radii (In^{3+}: 0.81 and Sc^{3+}: 0.73 Å[13]), the new phase was considered to be a thortveitite-type indium (III) silicate; it has not been found in nature, but only as a synthesized mineral. It is assumed that the crystal structure of the new phase is the same as that of thortveitite (monoclinic); the unit-cell dimensions were calculated by means of the least-squares method, using all the observed spacings (27 spacings up to 1.58 Å), as is shown in Table 4. The spacings and their Miller indices of the indium (III) silicate are shown in Table 5. It can be concluded from the results presented in Tables 4 and 5 that the new phase found in this work is thortveitite-type indium (III) silicate; however, it could not be identified chemically because it could not be isolated. The SiO_2/In_2O_3 molar ratio in the indium-rich mixed gels and the aluminum-free gels in this system were considered not to be effective in the formation of indium (III) silicate upon heating.

The cause of the exothermic peaks around 980 and 880 °C in the DTA was examined as follows: the In-0, -1C, -9C, -12C, and -15M samples were preheated in the DTA equipment up to temperatures just below and above their peak temperatures. The phases of the preheated samples were found by X-ray powder diffractometry to be as are shown in Table 6. While the exothermic changes around 980 and 880 °C were found to be related to the formations of the mullite and the indium (III) oxide, it could not be confirmed whether or not both the exothermic peaks themselves depended on the formations of the mullite and the indium (III) oxide. They might be caused by the same structural changes[2] in the coprecipitated gels which brought about the formations of the mullite and the indium (III) oxide.

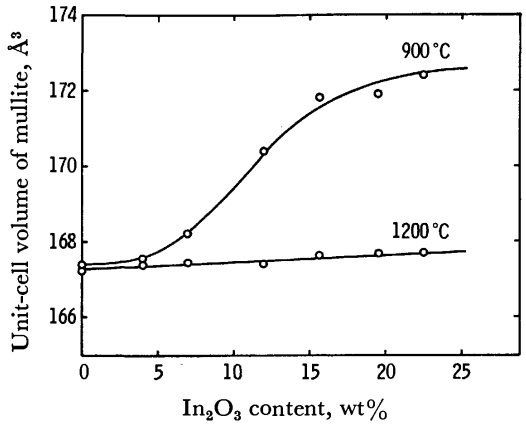

Fig. 3. Plot of unit-cell volume of mullite formed in coprecipitated gels against indium content.

The Unit-cell Volume of the Mullite Formed in the Heat-treated Samples. The unit-cell volumes of the mullite formed in the coprecipitated gels at 900 and 1200 °C for 5 hr were estimated to be as are shown in Fig. 3; those in the gels with more than 25 wt% of In_2O_3 could not be estimated because of the weak intensity of their diffraction peaks. The unit-cell volume of the mullite formed at 900 °C increased with the increase in the indium content when the indium (III) ions were included, while those in the mixed gels scarcely changed at all.

On the contrary, the unit-cell volume of the mullite decreased at 1200 °C as the crystallization proceeded with the removal of the indium (III) ions; then it became nearly equal to that in the indium-free coprecipitated gels. The exclusion of the indium (III) ions at 1200 °C from the mullite lattice was considered to arise from its large ionic radius, though the gallium ions were included in the mullite in fairly large quantities, even at 1200 °C.[2)]

(Received January 6, 1975)

The relations between the structures and thermal behaviors of the succinates of Mg(II), Co(II), Ni(II), Cu(II), Zn(II), Cd(II), and Pb(II) were studied. In the case of the copper salt, the dehydration of its dihydrate began easily at room temperature. However, the tetrahydrates of Mg, Co, and Ni held their waters more tightly, and changed from crystalline to amorphous state in the course of dehydration which began at 50—60 °C. The anhydrous salts of Mg and Co recrystallized at 306 and 272 °C, respectively, with a sharp exotherm on each DTA curve. The cobalt salt showed stepwise color changes, pink $\xrightarrow{\text{dehydration}}$ bluish violet $\xrightarrow{\text{recrystallization}}$ pink. $PbC_4H_4O_4$ exhibited a phase transition from tetragonal to cubic at 160 °C with $\Delta H=2.5$ kJ/mol and $\Delta S=5.9$ J/deg·mol. The phase transition was reversible and seems to be accompanied with a conformational change of the succinate ion.

The structures of the copper salts of α,ω-dicarboxylic acids, $HOOC(CH_2)_{n-2}COOH$ with $n=2-10$ have been investigated by means of magnetic[1] and infrared measurements,[2] and it was found that, when n is even, the carbon chain assumes the *trans* conformation.[2] The structures of α,ω-dicarboxylates of other metals, on the other hand, have been determined in the case of the oxalates of Mg(II), Mn(II), Fe(II), Co(II) and Ni(II) by X-ray analyses, and it was found that two water molecules contained in the salts coordinate to the metals and the oxalate ion acts as a quadridentate ligand.[3]

This work was undertaken to obtain detailed information on the compositions and structures of the various bivalent metal succinates by means of infrared and diffuse reflectance spectroscopies and thermal analysis.

In the course of the TG-DTA measurements, heat changes without any weight-loss were found for magnesium, cobalt and lead succinates. It was considered to be worthwhile to investigate the nature of the heat changes, since a conformational change of succinate ion or a change of coordination structure is expected to occur.

Experimental

Materials. The metal succinates were prepared by the reaction of the corresponding metal carbonates with succinic acid. The results of the elemental analyses for C and H agreed with those calculated within $\pm 0.3\%$ (Table 1).

Apparatus and Procedure. Infrared absorption spectra were measured from 4000 to 250 cm^{-1} by KBr disk method with a Hitachi 215 spectrophotometer. The spectra at elevated temperatures were recorded with the apparatus equipped with a standard heating cell. Diffuse reflectance spectra were measured with a Hitachi EPS-3T spectrophotometer using a standard integrating sphere attachment; in the case of heated samples, they were cooled to room temperature and brought to measurements.

Powder X-ray diffraction diagrams at room temperature and those at elevated temperatures were obtained with a Toshiba diffractometer ADG-101 equipped with a standard high temperature sample holder. Fe Kα radiation and a manganese filter were used for cobalt salts, and Cu Kα radiation and a nickel filter for all other salts.

Thermogravimetric (TG) and differential thermal analytical (DTA) curves were obtained with a Shinku Riko TGD-3000 apparatus at a heating rate of 10 °C/min in an atmosphere of nitrogen flowing at 50 ml/min. About twenty milligrams of powdered sample in a platinum crucible were used in each measurement. Calorimetric measurements were carried out with a Rigaku Denki 8002 CS differential scanning calorimeter at a heating rate of 5 °C/min in an atmosphere of nitrogen flowing at 40 ml/min. The apparatus was calibrated against the transition heat of KNO_3.

Results and Discussion

In general, water molecules in inorganic salts gives symmetric and antisymmetric O–H stretching bands at 3500—3000 $cm,^{-1}$ and it is well known that ν(O–H) of crystal water appears at a higher frequency than that of coordinated water. The values of ν(O–H) of the hydrated succinates of Mg, Co, Ni and Cu are given in Table 1. The value of the copper salt is considerably higher (by *ca.* 300 cm^{-1}) than those of the other salts which are similar with each other. This result seems to suggest that the water in the copper salt is crystal water (or very weakly coordinated water), while that in the other salts is commonly coordinated water.

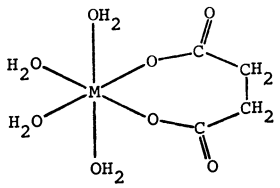
Table 1. Stretching frequencies of water (ν(O–H)), initial dehydration temperatures (T_{H_2O}) and weight-losses (ΔW) for various metal succinates

Formulas	ν(O–H)/ cm^{-1}	T_{H_2O}/ °C	ΔW_{obsd}/ %	ΔW_{calcd}/ %
$MgC_4H_4O_4\cdot 4H_2O$	3100	62	31.2	33.9
$CoC_4H_4O_4\cdot 4H_2O$	3075	53	27.8	29.2
$NiC_4H_4O_4\cdot 4H_2O$	3050	61	28.8	29.2
$CuC_4H_4O_4\cdot 2H_2O$	3370	25	14.8	16.7
$ZnC_4H_4O_4$	—	—	—	—
$CdC_4H_4O_4$	—	—	—	—
$PdC_4H_4O_4$	—	—	—	—

Dehydration temperature gives information about the

dissociation energy of the metal-coordinated water bonding. Assuming an electrostatic model, it is expected that the bond energy increases with the increase of $1/r$, where r means ionic radius of metal. The initial dehydration temperatures (T_{H_2O}) of the hydrated succinates are also given in Table 1, together with the corresponding weight-loss. For the salts of Mg, Co and Ni, the change of T_{H_2O} with $1/r$ is reasonable, but T_{H_2O} of the copper salt is too much lower than the value expected from the ionic radius of copper. Thus, the thermal data also support the view obtained from the IR study.

In the frequency region of 4000—250 cm^{-1}, the infrared absorption patterns of the salts of Mg, Co and Ni were very similar with each other, suggesting that the bonding structures of these salts are identical. The diffuse reflectance spectra of the cobalt and nickel salts indicated that the metals are surrounded octahedrally by six oxygen atoms. Since all of four water molecules contained were found to be the same kind of coordinated water, the structure represented by [**A**] seems to be most probable for these salts, although other possibilities can not be ruled out. According to Kuroda and Kubo,[2]



[**A**]

the succinate ion in the copper salt assumes the zigzag chain form resulting from the *trans* conformation about the $-CH_2-CH_2-$ bond. It is expected that the succinate ion forming the chelate ring in [**A**] will give more complicated spectral pattern in the frequency region of methylene group than that of the *trans* conformation. The comparison of the spectral pattern of the cobalt salt (Curve 1 in Fig. 2) with that of the copper salt (Curve 3 in Fig. 6) seems to support this expectation. The spectral pattern of succinic anhydride in the frequency region of methylene group was also found to resemble that of the cobalt salt.

Except for the copper salt, the anhydrous salts obtained by heating the corresponding hydrates at 170 °C, gave no X-ray diffraction lines, and their infrared absorption bands were broad, compared with those of their hydrates. In the case of the copper salt, on the other hand, the X-ray diffraction and infrared absorption patterns remain almost unchanged by dehydration. This difference is probably due to the fact that, in the former case, the removal of coordinated water will alter not only the crystal lattice but also the coordination structure. In fact, striking color changes, pink→bluish violet for the cobalt salt and bluish green→yellow for the nickel salt, were observed in the course of the dehydration.

The anhydrous salts of Mg and Co gave a sharp exotherm at 306 and 272 °C, respectively, on the DTA curves which are shown in Fig. 1, together with the TG curves. The X-ray diffraction, infrared absorption and diffuse reflectance data of the cobalt salts before and after the exothermic process are shown in Figs. 2, 3 and 4, respectively, together with those of its hydrate. The X-ray results indicate that the anhydrous salt is

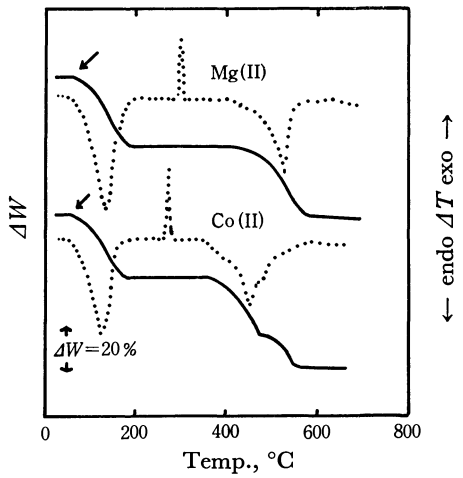


Fig. 1. TG-DTA curves of $MgC_4H_4O_4 \cdot 4H_2O$ and $CoC_4H_4O_4 \cdot 4H_2O$ in a flowing nitrogen atmosphere:
—— indicates TG; ····· DTA.
Points corresponding to T_{H_2O} are indicated with arrows.

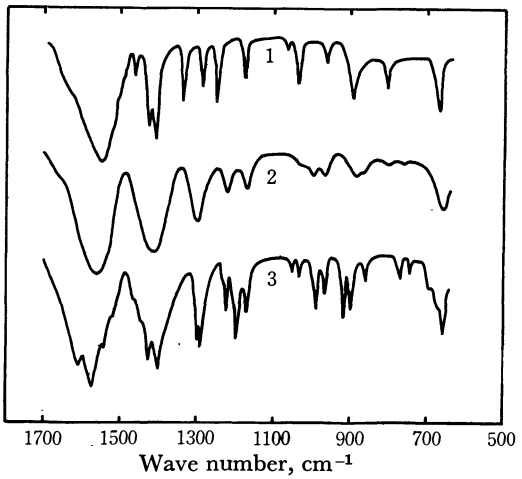

Fig. 2. Infrared absorption spectra of cobalt salts:
(1) $CoC_4H_4O_4 \cdot 4H_2O$, (2) and (3) $CoC_4H_4O_4$ heated up to 170 and 300 °C, respectively.

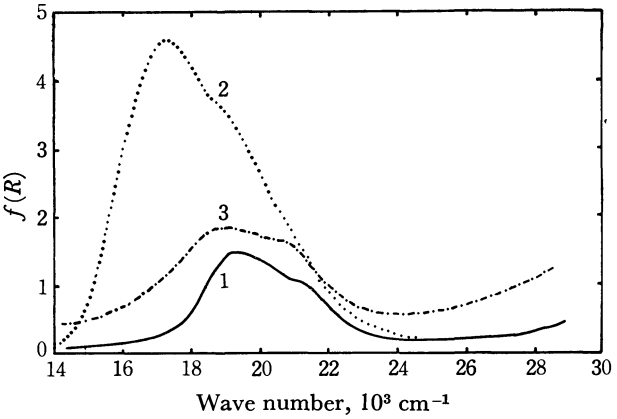

Fig. 3. Reflectance spectra of cobalt salts:
(1) $CoC_4H_4O_4 \cdot 4H_2O$, (2) and (3) $CoC_4H_4O_4$ heated up to 170 and 300 °C, respectively.

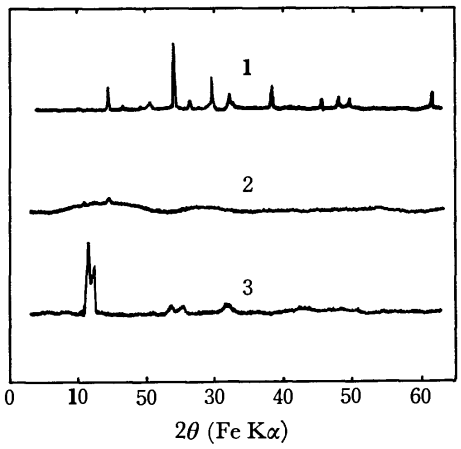

Fig. 4. X-ray diffraction patterns of cobalt salts: (1) $CoC_4H_4O_4 \cdot 4H_2O$, (2) and (3) $CoC_4H_4O_4$ heated up to 170 and 300 °C, respectively.

converted from amorphous to crystalline state through the exothermic process.[4] The infrared absorption bands become thereby remarkably sharper, showing that the crystallized salt has a rigid bonding structure. Along with these changes, the salt becomes pink again, and its reflectance spectrum shows that it has an essentially octahedral coordination structure, just as in the case of the hydrate, so that the formation of weak Co–O bonds between the coordinated oxygen atoms and adjacent Co ions must be postulated. Except for the absence of color change, the magnesium salt gave data which are similar to those of the cobalt salt. Therefore, the nature of the exotherm of the magnesium salt seems to be identical with that of the cobalt salt. By the DSC measurements, the enthalpy changes corresponding to the exothermic processes were obtained: $\Delta H = -10.0$ kJ/mol (cobalt) and -10.9 kJ/mol (magnesium). The entropy changes calculated were -18.3 J/deg·mol (cobalt) and -18.8 J/deg·mol (magnesium), respectively.

The succinates of Zn, Cd and Pb which were crystallized from the corresponding aqueous solution, were anhydrous. The infrared absorption patterns of the salts of Zn and Cd were similar to that of the copper salt in the frequency region of the methylene group, while that of the lead salt was similar to that of the hydrated cobalt salt. The TG-DTA curves of the salts of Zn, Cd and Pb were also measured, and only

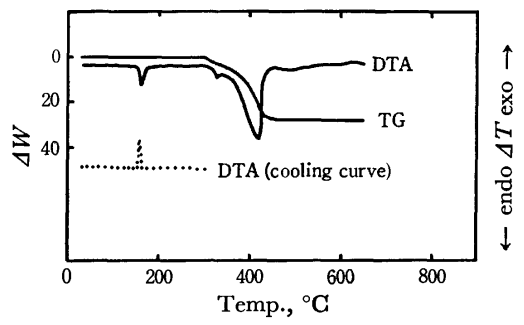

Fig. 5. TG-DTA curves of $PbC_4H_4O_4$: ……indicates cooling curve.

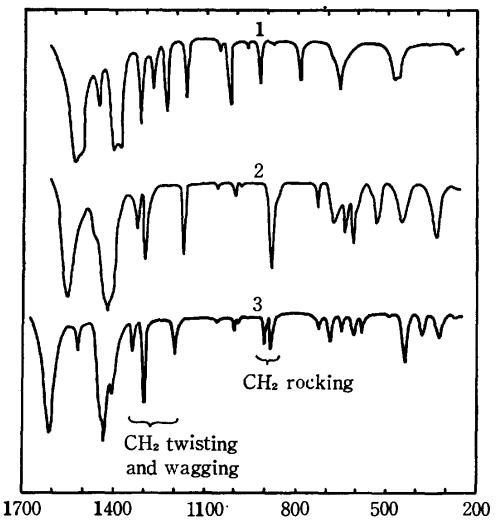

Fig. 6. Infrared absorption spectra of (1) $PbC_4H_4O_4$ at room temperature, (2) $PbC_4H_4O_4$ at 200 °C, and (3) $CuC_4H_4O_4$.

the lead salt gave an endotherm at 160 °C on the DTA curve without any weight-loss. The curves of the lead salt are given in Fig. 5, together with the cooling curve. An exotherm is observed at 153 °C on the cooling curve, and so the heat change is reversible. ΔH and ΔS of the endothermic process were 2.5kJ/mol and 5.9J/deg·mol, respectively. The analyses of the X-ray diffraction lines before and after the heat change indicated that the crystals of the lead salt changed from tetragonal to cubic at about 160 °C. The lattice constants calculated were $a=b=15.2$ and $c=14.6$ Å for the tetragonal (low temperature) form, and $a=b=c=15.2$ Å for the cubic (high temperature) form.

The phase transition of the lead salt was accompanied with a considerable change of the infrared spectrum. In Fig. 6, the infrared spectra at room temperature and at 200 °C are given. The spectral change is also reversible, *i.e.* the spectrum at 200 °C reverts to its original shape when the sample is cooled to room temperature. The spectrum at 200 °C is simpler than that at room temperature in the frequency region of the methylene group; while the latter is similar to that of the cobalt salt hydrate, the former is similar to that of the copper salt. Thus the phase transition seems to be accompanied with a conformational change of the succinate ion, and its possible structures below and above 160 °C can be represented by **[C]** and **[B]**, which can be changed into each other by rotating the chain around the $-CH_2-CH_2-$ bond.

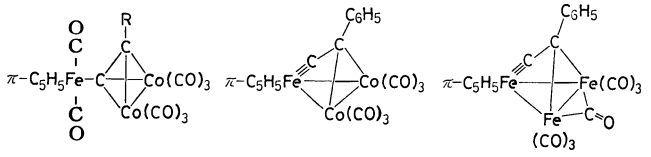
Crystal and Molecular Structure of $(\pi\text{-}C_5H_5)Fe_3(CO)_7C_2C_6H_5$ Obtained from $(\pi\text{-}C_5H_5)Fe(CO)_2C{\equiv}CC_6H_5$ with $Fe_2(CO)_9$[1)]

Katsutoshi YASUFUKU, Katsuyuki AOKI, and Hiroshi YAMAZAKI
The Institute of Physical and Chemical Research, Wako-shi, Saitama 351
(Received March 7, 1975)

The crystal structure of $\pi\text{-}C_5H_5Fe_3(CO)_2(C_2C_6H_5)$ obtained from the reaction of $\pi\text{-}C_5H_5Fe(CO)_2C_2C_6H_5$ with $Fe_2(CO)_9$ has been determined from single crystal X-ray diffraction data. The space group is $P\bar{1}$ and the cell constants are $a=12.635$, $b=9.457$, $c=9.033$ Å, $\alpha=94.64$, $\beta=109.10$, and $\gamma=99.60$ °, and $Z=2$. The refinement was carried out using block-diagonal least-squares calculation including anisotropic thermal factors for the non-hydrogen atoms and isotropic thermal factors for the hydrogens. The final R value for 2488 reflections is 0.035. The molecular configuration consists of an isosceles triangle of the three iron atoms, each two of which bonds to three terminal carbonyl groups and one bonds to the cyclopentadienyl ring. The phenylethynyl group is disposed above the iron plane and is σ-bonded to one iron atom with three carbonyls and π-bonded symmetrically to the other two iron atoms. The seventh carbonyl group is bridged asymmetrically between these two iron atoms, below the iron plane. The characteristic shortening in the Fe-C σ-bond and in the acetylenic C–C bond was observed.

Some interesting reactions of transition metal acetylides with organic reagents are known.[2)] However, reactions of these acetylides with organometallics have been little studied. Recently, the acetylides with organometallics have attracted attention from a viewpoint of metal cluster preparation. We have briefly reported[3)] the reactions of some transition metal acetylides with metal carbonyls giving new mixed transition metal complexes. Also, Bruce *et al.*[4)] have reported the reactions of cupper acetylides with halometal complexes to be an expedient route to clusters.

In a previous paper,[3)] we reported the reaction of ethynyldicarbonyl-π-cyclopentadienyliron (**1**), $\pi\text{-}C_5H_5Fe(CO)_2C{\equiv}CR$, with octacarbonyldicobalt which gave $\pi\text{-}C_5H_5Fe(CO)_2(C_2R)Co_2(CO)_6$ (**2a**), when $R=CH_3$, but gave $\pi\text{-}C_5H_5Fe(C_2C_6H_5)Co_2(CO)_6$, when $R=C_6H_5$. A speculative structure **2b** was presented for the product, however later remeasurement of the mass spectra of the product with various conditions revealed that the composition was incorrect but should have been **2a**($R=C_6H_5$). Thus, the reaction of **1** with $Co_2(CO)_8$ gave unequivocally **2a** irrespective of the nature of R($R=CH_3$, CO_2CH_3, and C_6H_5).



2a **2b** **3a**

It is interesting to determine the structure of $\pi\text{-}C_5H_5Fe_3(CO)_7C_2C_6H_5$ (**3**) [which was obtained by us[3)] from the reaction of **1** with $Fe_2(CO)_9$ and later also by Bruce[5)] from the reaction of $[\pi\text{-}C_5H_5Fe(CO)_2C_2Ph\cdot CuCl]_2$ with $Fe_2(CO)_9$], because the structure **3a** proposed on the basis of an analogy with **2b** is now somewhat doubtful, although metal carbine complexes, $X(CO)_4M{\equiv}CR$, have been obtained by Fischer *et al.*,[6)] recently.

Here we report the X-ray determination of the structure of **3**.

Experimental

Monoclinic and triclinic brown crystals were obtained from hexane solution. Preliminary examination of Weissenberg photographs showed that the triclinic crystals were more suitable for further examination than the monocilinic crystals because of large cell constant of the latter, $b\sim55$ Å. (The IR spectrum of the triclinic crystal was identical to that of **3** before growing the crystals.) The diffraction data for the triclinic crystal were collected on automated Phillips PW-100 Single Crystal Diffractometer using monochromatic Mo Kα radiation. The cell constants and the orientation matrix of the triclinic crystal were determined from least-squares refinements of the setting angles for high-angle reflections. These dimensions and other crystal data are given in Table 1. For collection of intensity data, the ω-2θ scan technique with a scan rate of 4.0 °/min was used and 2685 independent reflections up to a maximum 2θ value of 50 ° were measured.

TABLE 1. CRYSTAL DATA FOR $\pi\text{-}C_5H_5Fe_3(CO)_7C_2C_6H_5$

Formula wt 529.8	Triclinic $P\bar{1}$
$a=12.635$ Å	$\alpha=94.64°$
$b=9.457$ Å	$\beta=109.10°$
$c=9.033$ Å	$\gamma=99.60°$
$V=994.98$ Å^3	$Z=2$
Mo Kα radiation	$\mu=22.56$ cm^{-1}
$d_x=1.77$ g/cm^3	d_m[a)] $=1.75$ g/cm^3

a) Measured by floatation in an aqueous zinc bromide solution

The intensities of three reflections were measured every 123 reflections as a check on crystal and electronic stability. A correction for Lorentz and polarization factors but no correction for absorption was applied to the data. In the structural refinement the 2488 reflections with $Fo>3\sigma(Fo)$ were used.

The approximate positions of the three Fe atoms were determined from a sharpened Patterson function. From a three-dimensional Fourier synthesis calculated with all terms phased by the Fe atoms, all non-hydrogen atoms of the molecule were located. At this stage, the value of R was 0.353. After five cycles of block-diagonal least-squares refinement with isotropic thermal parameters and five further cycles with anisotropic thermal parameters, (minimizing the function $[\sum w||F_o|-|F_c||^2/\sum w|F_o|^2]^{1/2}$) the R value decreased to 0.045. A weighting scheme, $w=1$, was used. Scattering factors were

The B is defined by: $\exp[-B(\sin\theta/\lambda)^2]$.

taken from the International Tables.[7] The anomalous dispersion effect was included in the calculated structure factors for iron using $\Delta f'=0.4$ and $\Delta f''=1.0$.[8]

A difference Fourier map then revealed the positions of all the hydrogen atoms. Four cycles of refinement with isotropic thermal parameters for hydrogen and anisotropic thermal parameters for non-hydrogen atoms were carried out, giving a final R of 0.038. The atomic coordinates and anisotropic thermal parameters with estimated standard deviations (esd's) for the non-hydrogen atoms are given in Table 2. The coordinates and isothermal parameters for the hydrogens are given in Table 3.

Description of the Structure and Discussion

The bond distances (with esd's) are shown in Table 4 and the bond angles (with esd's) are listed in Table 5. Important least-squares planes and dihedral angles are shown in Table 6. Fig. 1 shows the packing of the two molecules of **3** in the unit cell. The shortest intermolecular contacts are 2.970(6) Å between O(2) and O(6) at (−x, −y, −z) and 3.082(6) Å between O(5)

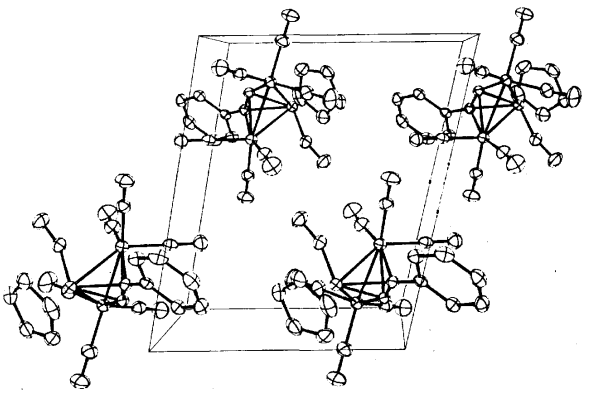

Fig. 1. View of the structure along the c axis showing crystal packing.

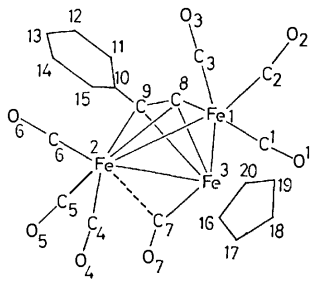

Fig. 3. Numbering scheme for the molecule.

and O(6) at (1−x, −y, −z). All other intermolecular contacts between non-hydrogen atoms are >3.34Å.

The perspective view of **3** without the hydrogens showing thermal vibration with 20% electron density is shown in Fig. 2 and the numbering scheme for the atoms in Fig. 3. The three iron atoms form a triangle in which the distance, Fe(2)–Fe(3)=2.524(1) Å, is slightly shorter than the other two Fe–Fe distances, Fe(1)–Fe(2)=2.639(1) and Fe(1)–Fe(3)=2.632(1) Å. The six carbonyls bond to the Fe(1) and Fe(2) atoms as terminal carbonyls: Two of the three carbonyls on Fe(1) and one of the three on Fe(2) are nearly in the plane of the iron atoms. The terminal carbonyl Fe–C bonds range from 1.738 to 1.829 Å (average 1.801 Å). The seventh carbonyl group is located between the Fe(2) and Fe(3) atoms as an asymmetric bridge[9] [Fe(2)–C(7)=2.273(6) Å and Fe(3)–C(7)=1.788(5) Å, ∠Fe(2)–C(7)–O(7)=126.35(46)° and ∠Fe(3)–C(7)–O(7)=157.63(56)°] below the iron plane. The dihedral angle between the iron plane and the Fe(2)C(7)Fe(3) plane is 106.95°. An IR band, $\nu_{C\equiv O}$= 1870 cm^{-1}, corresponds to this asymmetrically bridged CO. The cyclopentadienyl ring attached to Fe(3) is almost perpendicular to the iron plane: Fe(3) is 1.730 Å from the ring.

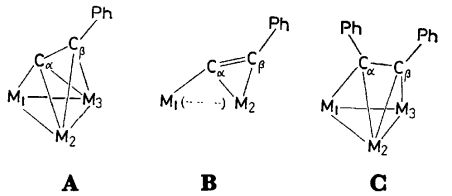

Fig. 4. Schematic geometry of the related σ,π-coordinated ethynyl complexes.

The phenylethynyl group is located above the iron plane: Fe(1)–C(8)=1.829(6), C(8)–C(9)=1.299(9), Fe(2)–C(8)=2.040(4), Fe(3)–C(8)=2.006(9), Fe(2)–C(9)=2.081(5), Fe(3)–C(9)=2.031(5) Å. The dihedral angle between the iron plane and the Fe(2)C(8)Fe(3) plane is 51.97° and that between the iron plane and the Fe(2)C(9)Fe(3) plane is 99.28°. These distances and angles show that the phenylethynyl group, originally σ-bonded to the Fe(3) atom, is now σ-bonded to the Fe(1) atom and π-bonded symmetrically to both the Fe(2) and Fe(3) atoms through the C(8)–C(9) triple bond. The configuration about the three iron atoms and the phenylethynyl group is shown in Fig. 4 (Type **A**) (in which C(α) and C(β) correspond to C(8) and C(9)). $Ru_3(CO)_9H(C_2Bu^t)$ (**4**) has been reported[10] to have a very similar configuration to **3**. Some complexes in which a σ-bonded acetylide is π-bonded to one metal (type **B**) have also been reported.[11,12] The geometries of these related complexes are summarized in Table 7.

A similarity around the C(α)–C(β) moiety in both **3** and **4** is evident when the difference (~0.1 Å) in the M–C distances for the terminal carbonyls (the average Fe–C in **3** is 1.801 and Ru–C in **4** is 1.91 Å), and in the M(1)–C(α) distances in [π-$C_5H_5Fe(CO)_2C_2Ph$·CuCl]$_2$[12] and π-$C_5H_5Ru(PPh_3)_2C_2Ph$·CuCl[5a] is assumed also to be due solely to the difference between Fe and Ru covalent radii.

The distance C(α)–C(β) in **3** is markedly shorter than the acetylenic C–C distances found in the usual dinuclear monoacetylene complexes, *e.g.* (π-$C_5H_5)_2Ni_2$-(PhC_2Ph)[13] 1.35(3), $Co_2(CO)_6(PhC_2Ph)$[14] 1.46, and (π-C_5H_5)$NiFe(CO)_3(Ph_3PC_2H)$[15] 1.37(3) Å. The C(α)–C(β) distance in the type **B** complexes are a little shorter than that in **3**, whereas the Fe(1)–C(α) distance

a) as shown in Fig. 4. b) This work, c) Ref. 10. d) Ref. 11, e) Ref. 12, f) Ref. 5a, g) Ref. 17, h) ∠C(α) C(β) C(of Bu^t), i) These two complexes have no M_1–M_2 bond and the M_1–C=C–Ph moiety has *cis* configuration.

in **3** is a little shorter than that in the type **B** compounds. The shorter distances, M(1)–C(α) and C(α)–C(β), in **3** may reflect an additional interaction between the Fe(1) and C(α) or among Fe(1), C(α), and C(β), although the decrease in the Fe(1)–C(α) distance is not so great as the decrease between carbene and carbin complexes: $(Co)_5CrC(OCH_3)C_6H_5$ 2.04(3) and $(CO)_4ICrCCH_3$ 1.69(1) Å.[16]

The shortening of the Fe(1)–C(α) and C(α)–C(β) bonds may be emphasized also by comparison with $Fe_3(CO)_9(PhC_2Ph)$[17] (**5**) (type **C**) in which the C(α) atom has more phenyls than the C(α) atom in **3**. Another difference between **3** and **5** is that the phenyl plane in **3** is almost parallel to the Fe(1)C(α)C(β) plane (dihedral angle = 9.33°), whereas the phenyls in **5** are not.

The C(β)–(phenyl) distance and ∠C(α)–C(β)–(phenyl) are in good agreement with those in $(\pi$-$C_5H_5)_2Ni_2(PhC_2Ph)$,[13] average 1.45 Å and 140°, and in $Co_2(CO)_6(PhC_2Ph)$,[14] average 1.43 Å and 138°.

Preparation of Reinforcing Fillers from Japanese Acid Clays with Lime and by Calcination. III. Elucidation of the Reinforcing Effects Based on the Investigation of Changes in the Structure, Physicochemical Properties and Morphology of N Hard Clay

Hideki RAI and Junkichi YAMADA*

The Institute of Industrial Science, The University of Tokyo, Minato-ku, Tokyo 106

(Received November 5, 1974)

In order to elucidate the reinforcing effects of the fillers prepared from Japanese acid clay with hydrated lime and by calcination and mechanical disintegration, **N** hard clay (CaO 3—60%; calcination 400—800 °C, 1—1.5 hr; wet ball-milling 18 hr) derived from Nakajo acid clay (**N**) were investigated on the structure, physicochemical properties and morphology in comparison with those of **N**, Dixie Clay and Silene EF. X-Ray diffraction, infrared spectroscopy and electron micrography were applied to the examination of the structural and morphological features. The physicochemical properties were determined on the surface properties such as hygroscopicity, pH and DPG adsorption together with the specific gravity and bulk density. The following results were obtained: (1) Treatment under the optimum conditions (CaO 6%, calcination 600 °C, 1.5 hr; wet milling 18 hr) caused a favorable change in the structure of the prepared filler, resulting in controlling the surface properties, reduction in the particle size and its distribution, a decrease in the specific gravity and an increase in the bulk density. (2) Deviation from the conditions, *e.g.*, calcination at 400 °C for 1.5 hr remained too much residual adsorptivity to improve the great surface activity of **N**, whereas treatment at 800 °C for 1—1.5 hr afforded sintering, collapse and/or fusion yielding too hard aggregates to be disintegrated as well as a serious breakdown or complete loss in the effective functional groups involved.

Previously we reported the studies of the availability of some Japanese acid clays such as Nakajo (**N**), Matsune (**M**) and Kuramitsu (**K**) origins for the preparation of a reinforcing filler of elastomers,[1] the optimum conditions for producing good hard clays from **M** and **N**, and their reinforcing properties.[2]

Further investigations were carried out in order to elucidate the reinforcing effects in connection with the characteristics of structure, morphology and physicochemical properties of the fillers prepared. The **N** hard clay derived from **N** were investigated on the structure and morphology by means of X-ray diffraction, infrared spectroscopy and electron micrography. The physicochemical properties such as hygroscopicity, pH, DPG adsorption, specific gravity and bulk density were determined as described before. The features of the structure, morphology and physicochemical properties were compared with those of reference fillers, Dixie Clay, Silene EF, and dried or calcined **N** without lime treatment beforehand. Valuable information elucidating the characteristics of **N** hard clay with relation to the reinforcement was obtained.

Experimental

Materials. The **N** hard clay prepared under the various conditions of treatment (CaO 3—60%; calcination 400—800 °C, 1—1.5 hr; wet ball-milling 18 hr) described in the preceding paper[2] were put to use.

Dixie Clay, Silene EF and Nakajo acid clay **N**, dried in air (24 hr), in oven (110 °C, 2 hr) or calcined (400—800 °C, 1 hr) without the lime treatment and mechanical disintegration, were used as references.

Determination of Structure, Morphology and Physicochemical Properties. The same apparatus and conditions of measurement as mentioned before[1] were followed in the investigation of changes in the structure, morphology and physicochemical properties of the fillers prepared.

* Present address: AA Chemical Co., Ltd., Shibakoen, Minato-ku, Tokyo 105.

Results and Discussion

Treatment of the original acid clay with hydrated lime follwed by calcination and mechanical disintegration caused noticeable changes in the structure, physicochemical properties and morphology of the fillers obtained.

(1) Structural Changes. (a) X-Ray Diffraction Patterns: Figures 1(a)—(c) illustrate the X-ray powder diffraction patterns of **N** hard clay showing the structural changes in comparison with those of the dried or calcined **N** without the lime treatment beforehand.

It is apparent that all the hydrated lime (4.90 and 2.63 Å)[3] added to **N** has disappeared as a result of the reaction during the treatment.

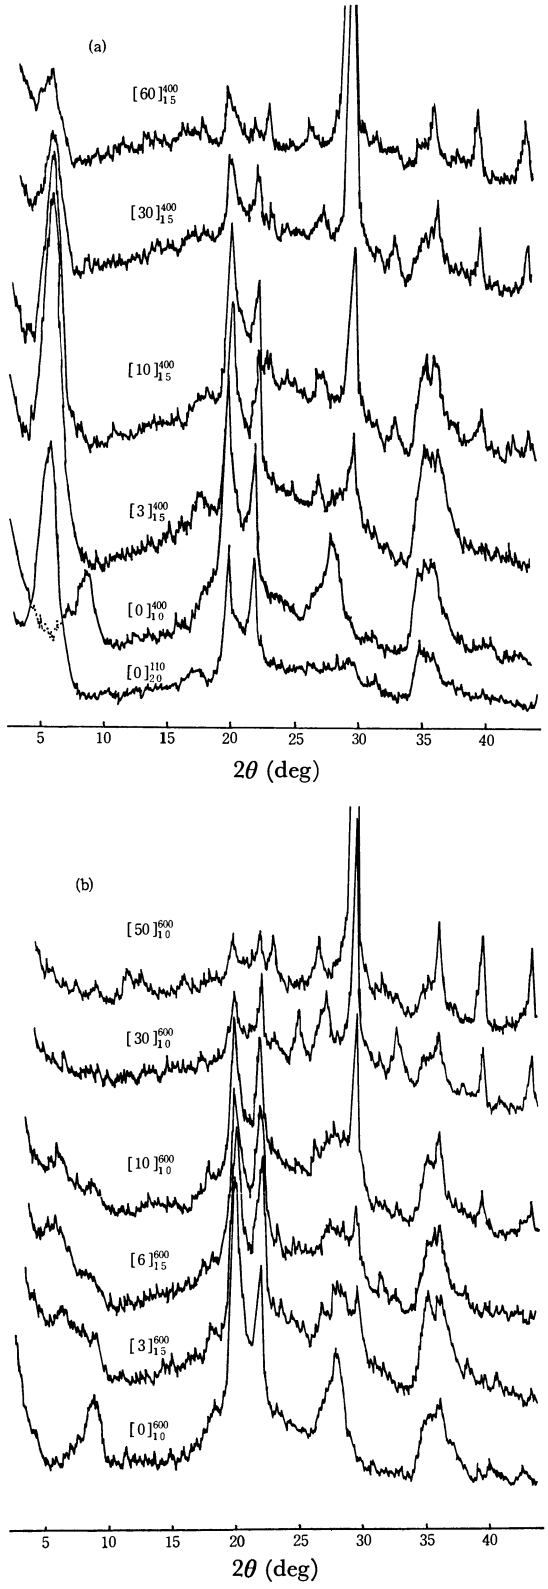
An increase in the amount of alkali and the temperature of calcination for the prepared fillers resulted in some basal shift of an irreversible contraction along the c-axis of montmorillonite lattices as well as the diminution or even disappearance of the prominent basal reflection (15.77 Å (001))[4] of the montmorillonites, normal and abnormal,[1] in the air-dried **N**.

Coincidently an almost proportional decrease in the intensity of excess silica α-cristobalite (4.04 Å (101))[5] occurred in the fillers as the amount of alkali increased.

New reflections also appeared approximately in proportion to an increase in the amount of alkali. They were ascribed to calcium silicate hydrates of tobermolite group (CSH I, II and G; 2.90—3.08, 2.78—2.85 and 1.80—1.85 Å)[6,7] and calcite (3.86, 3.04, 2.50, 2.28 and 2.09 Å).[8] The former was generated by the reaction of hydrated lime with the excess silica

covering the external and internal surfaces of the montmorillonite crystallites or existing in an isolated state, and the latter by the carbonation of the alkali liberated during the courses of mixing raw materials followed by filtration, drying, calcination and mechanical disintegration.

(i) Calcination at 400 °C for 1—1.5 hr (Fig. 1 (a)). The basal reflection (15.77 Å) of the air-dried **N** shifted



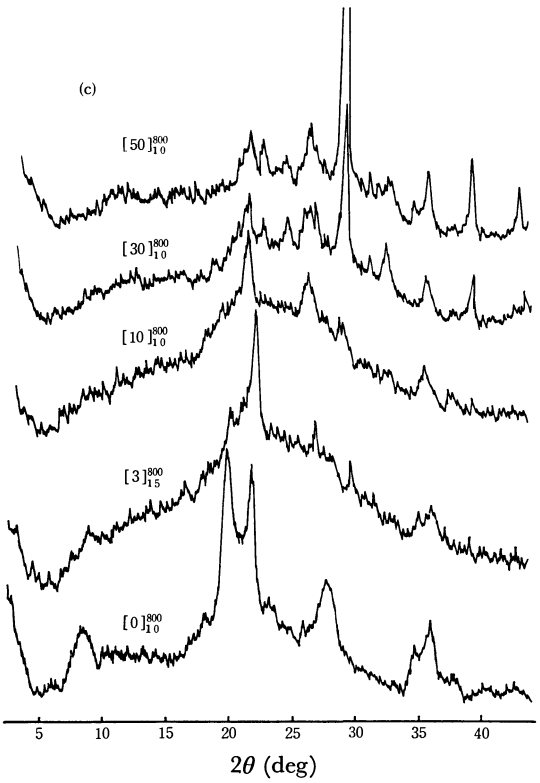


Fig. 1. X-ray diffraction patterns of **N** hard clay (CaO 3—60%; calcination 400—800 °C, 1—1.5 hr; mechanical disintegration 18 hr) in comparison with those of Nakajo acid clay **N**, dried (110 °C, 2 hr) or calcined (400—800 °C, 1 hr) without further treatment. Inscriptions are as follows. (a): CaO 3—60%; calcination 400 °C, 1—1.5 hr; wet milling 18 hr. (b) CaO 3—50%; calcination 600 °C, 1—1.5 hr; wet milling 18 hr. (c): CaO 3—50%; calcination 800 °C, 1—1.5hr; wet milling 18 hr.

* Number in brackets indicates the amount of alkali used, and the superscript and subscript numbers of the brackets denote the temperature and time of calcination, respectively.

towards 10.04 Å and decreased the intensity as much as 72.1% by the calcination at 400 °C for 1 hr without the lime treatment and mechanical disintegration.

Irrespective of the change in the amount of alkali (CaO 3—60%), the fillers prepared without the calcination showed a nearly constant shift (about 2 Å) in the basal reflections as a result of the formation of Ca-montmorillonite. The intensity of the basal reflection first increased with less than 10% CaO and then decreased with more than 30% CaO. The increase in the intensity of the basal reflection is considered to be based on the saturation of the Ca^{2+} ion interposed between the interlayers of the montmorillonites, and the decrease on the erosion initiated from the edges and outer surfaces of the crystallites with the hydrated lime. These reactions should be accelerated mechanochemically during the course of mixing raw materials, especially by the wet ball-milling.

The subsequent calcination at 400 °C for 1.5 hr and by the wet milling for 18 hr gave a considerable diminution (24.5, 39.6, 72.3 and 83.7% for 3, 10, 30 and 60%

CaO, respectively) in the basal reflection as well as a slight shift (1.97, 1.75 and 1.53 Å for 3, 10—30 and 60% CaO, respectively).

In view of the changes in the intensities and shifts of the basal reflections of the calcined **N** and the fillers prepared without such a calcination as mentioned above, the decrease in the basal shift of the fillers with an increase in the amount of alkali suggests that the formation of CSH as well as the erosion would proceed on the lamellae surfaces of the montmorillonite crystallites. The remained intensity (75.5—16.3% for 3—60% CaO) and the relatively small shift (less than 2 Å) of the basal reflection indicate that noticeable capabilities of rehydration and rehydroxylation[9-11] were still reserved in the fillers obtained. Consequently the inherent, great surface activity of the original acid clay **N** was restrained insufficiently by this procedure, which would be discussed in detail in connection with the physicochemical properties later.

(ii) Calcination at 600 °C for 1—1.5 hr (Fig. 1 (b)). The calcined **N** (600 °C, 1 hr) prepared without the lime treatment and mechanical disintegration gave an irreversible contraction (5.90 Å) in the montmorillonite lattices as well as a noticeable diminution (81.2%) in the intensity of the basal reflection, which were greater than those of the calcined **N** (400 °C, 1 hr) described above. Nevertheless, exhaustive dehydroxylation or the formation of anhydrous modification[12,13] could not be observed in the crystallites.

The treatment with hydrated lime (3—50% CaO) followed by calcination at 600 °C for 1 or 1.5 hr and the same mechanical disintegration as above afforded a further shift (2.59, 1.75 and 1.05 Å for 3, 6 and 10% CaO, respectively) and a greater diminution (91.2, 89.9 and 93.1% for 3, 6 and 10% CaO, respectively) than the corresponding values of the foregoing fillers (CaO 3—60%; 400 °C, 1.5 hr; wet milling 18 hr) or even resulted in the disappearance (for more than 30% CaO) of the basal reflection in the prepared fillers.

The intensity of α-cristobalite also decreased with an increase in the amount of alkali.

The reactions including thermal dehydration and dehydroxylation, fixation and substitution with Ca^{2+} ion, erosion by free alkali and the formation of CSH proceeded so extensively in the crystallites that the capability of rehydration and rehydroxylation during the wet milling decreased noticeably. However, the minute crystallites still persisted the montmorillonite lattices, even though they were eroded considerably.

The results obtained indicate that as the calcining temperature increased, the irreversible contraction along the c-axis of the montmorillonite lattices increased especially with a less amount of alkali, and that an increase in the amount of alkali resulted in the moderation of the thermal contraction. The moderation should be attributed mainly to the formation of CSH on the lamellae surfaces of the minute crystallites.

The treatment with alkali more than 10% CaO followed by calcination at temperatures higher than 600 °C for more than 1 hr gave the formation of calcium aluminate hydrates (CAH) (7.7 and 5.6 Å ascribable to C_4AH_{13})[6,7,14] and the appearance of some peaks of unknown significance (5.6, 4.94 and 3.36 Å for 50% CaO and 5.11, 3.57 and 3.28 Å for 30% CaO).

(iii) Calcination at 800 °C for 1—1.5 hr (Fig. 1 (c)). The calcined **N** (800 °C, 1 hr) prepared without the lime treatment and mechanical disintegration afforded an irreversible contraction (5.73 Å) of the montmorillonite lattices and a noticeable diminution (83.02%) in the intensity of the basal reflection. The basal spacing (10.04 Å) is slightly greater than those of the calcined **N** (600 °C, 1 hr; 9.87 Å) described above as well as the dehydrated layer (9.5 Å)[4] of montmorillonite, indicating the occurrence of an appreciable expansion of the crystallites.

The most serious structural changes appeared in the fillers treated with hydrated lime (3—50% CaO) followed by calcination at 800 °C for 1 or 1.5 hr and mechanical disintegration for 18 hr; all reflections of the montmorillonites disappeared completely in almost of the fillers obtained. Especially those prepared with less than 10% CaO accompanied very diffused and broadened reflections due to amorphous phases, indicating the appearance of sintering or partial fusion of the minute crystallites besides the collapse in the montmorillonite lattices. The less the amount of alkali and the higher the temperature of calcination, the greater the effect on the structural changes in the fillers prepared. In view of the appearance of relatively less intensities of CSH and calcite than in the cases of the lower-temperature calcination described above, a greater part of the alkali should be incorporated into the montmorillonite lattices.

(b) Infrared Spectra: Figures 2 (a)—(c) give the infrared spectra of the prepared fillers in comparison with those of **N**, dried or calcined without the lime treatment. The diagnostic bands[15] of montmorillonite in **N** varied with the treatment with hydrated lime followed by calcination and mechanical disintegration, and those of the new minerals appeared.

(i) Calcination at 400 °C for 1.5 hr (Fig. 2 (a)). The band at 3650 cm^{-1} (νO–H, free) observable in the dried **N** decreased with an increase in the amount of alkali added to the fillers prepared (CaO less than 10%; calcination 400 °C, 1.5 hr; wet milling 18hr), and disappeared with more than 30% CaO as a result of the formation of Ca-montmorillonite and CSH as confirmed by X-ray diffraction. Whereas the calcination without the lime treatment and mechanical disintegration remained the band up to 600 °C, although the intensity decreased with an increase in the temperature of calcination.

The bands at 914 (δAl^{3+}–O–H)[16] and 836 cm^{-1} (δFe^{3+}–O–H)[17] completely disappeared in the fillers prepared with more than 30% CaO. Whereas the calcined **N** (400 °C, 1 hr) which had excluded the lime treatment still reserved the former band slightly. The both bands were barely lost by the calcination over 600 °C for 1 hr.

Among the bands of layer silicates in the region 900—1200 cm^{-1} (νSi–O), the band at 1081 cm^{-1} related to colloidal silica[18-20] and ion saturation[21] as well as the band at 796 cm^{-1} (δSi–O) related to hydrated amorphous silica[18-20] gradually decreased the

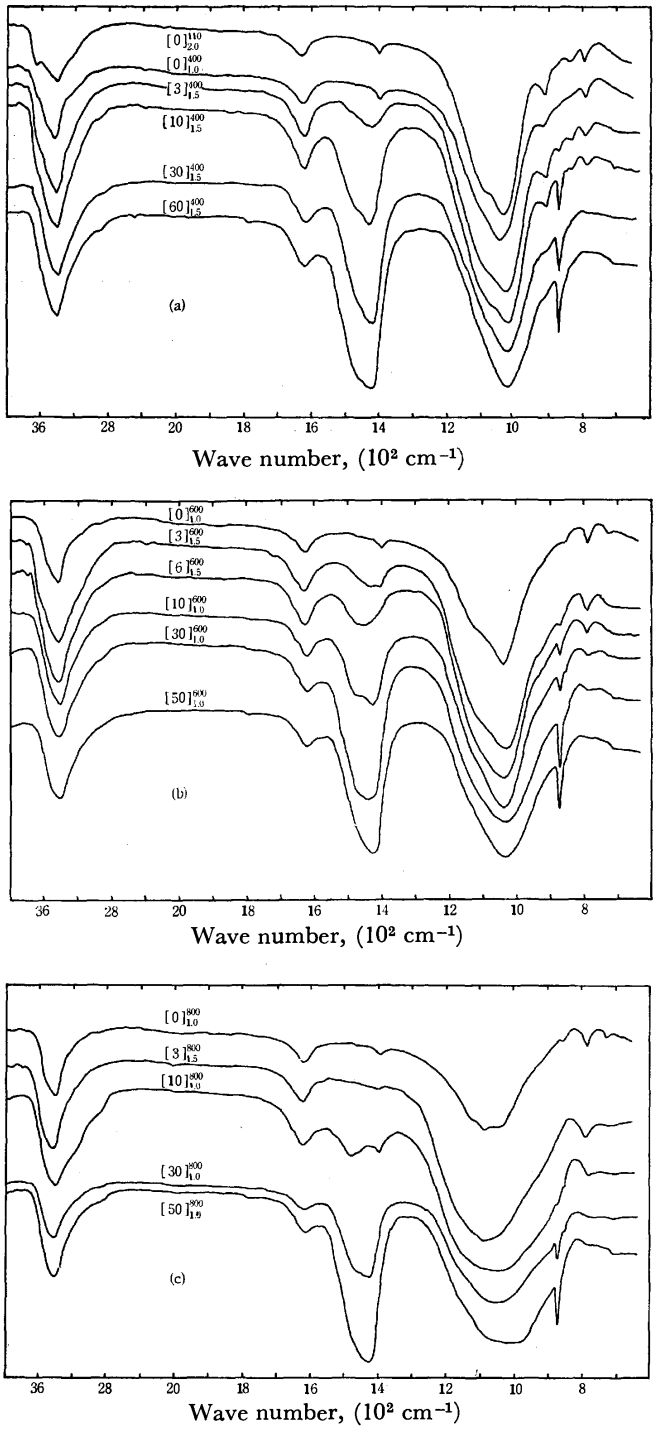

Fig. 2. Infrared spectra of **N** hard clay (CaO 3—60%; calcination 400—800 °C, 1—1.5 hr; mechanical disintegration 18 hr) in comparison with those of Nakajo acid clay **N**, dried (110 °C, 2 hr) or calcined (400—800 °C, 1 hr). The same inscriptions as in Fig. 1 are applied.

intensities as the amount of alkali increased. The latter was barely lost with more than 60% CaO in accordance with the consumption of the excess silica α-cristobalite observable in the foregoing X-ray diffraction. The abnormally great deviation in the amount of alkali required for the complete reaction with the excess silica (13%)[1] involved suggests that considerable amounts of hydrated lime were consumed by carbonation, fixation or trapping in the interior of the crystallites, substitution and some other reactions with Ca^{2+} ion in the tetrahedrons and octahedrons of the montmorillonites. The formation of calcite, CSH, CAH and some other calcium salts resulted consequently. The band at 1035 cm^{-1} related to the skeletal vibrations of the tetrahedrons of montmorillonite slightly shifted towards a lower frequency at 1025 cm^{-1} with appreciable broadening[21] with more than 30% CaO, verifying the above suggestion.

The bands ascribable to the newly formed minerals, CSH (1480 and 855 cm^{-1})[22,23] and calcite (2520, 1790, 1430, 876, and 715 cm^{-1}),[24,25] in the fillers increased with an increase in the amount of alkali.

The bands at 3410 and 1630 cm^{-1} in the calcined **N** decreased in proportion to an increase in the temperature of calcination. They are related to the waters adsorbed on the surfaces and among the interfaces of the minute crystallites and those hydrated with the exchangeable cations interposed between the interlayers of the montmorillonites. Irrespective of the calcination at 400 °C for 1.5 hr, they increased the intensities noticeably in the fillers as the amount of alkali increased. This can be explained in terms of the residual adsorptivity of the montmorillonites inducing considerable rehydration and rehydroxylation. The crystal water of CSH, remained after the calcination and rehydrated during the course of the wet milling for 18 hr, also contributed additionally.

(ii) Calcination at 600 °C for 1—1.5 hr (Fig. 2 (b)). The band at 3650 cm^{-1} was lost by degrees in the fillers treated with more than 10% CaO followed by the calcination (600 °C, 1—1.5 hr) and the same disintegration.

The bands at 914 and 836 cm^{-1} disappeared completely in those prepared with more than 3% CaO or even by the calcination (600 °C, 1 hr) alone without the lime treatment in advance.

The bands at 1081 and 796 cm^{-1} decreased more slowly with an increase in the amount of alkali than in those of the fillers calcined at 400 °C for 1.5 hr, and barely disappeared with more than 50% CaO. Diminution in the reactivity of the excess silica with alkali can be attributed mainly to more favorable polycondensation and/or the crystallization of the amorphous silica and α-cristobalite at 600 °C rather than 400 °C on the basis of a noticeable increase in the sharpness of the corresponding peaks in the X-ray diffraction patterns (Fig. 1 (a) *cf.* (b)). The phenomena of crystallization of silica gels, analogous to the natural aging of gels to hyalite and so on, are extensively studied by X-ray diffraction and other methods,[26,27] and are well known to be accelerated by thermal treatment.[28,29]

A new phase ascribable to pyrophillite dehydroxylate (864, 795, and 730 cm^{-1})[9] appeared in the fillers treated with less than 3% CaO, suggesting the occurrence of appreciable transformation as well as exhaustive dehydroxylation in the montmorillonite lattices.

As the amount of alkali increased, the band at 1035 cm^{-1} progressively shifted towards a higher frequency at 1042 cm^{-1} overlapping the adjacent band

at 1081 cm^{-1} with 6% CaO, and then towards a lower frequency at 1030 cm^{-1} with 50% CaO, giving one single, broader band. This suggests that more Ca^{2+} ions reacted with the tetrahedrons of the montmorillonites.

The bands at 3410 and 1630 cm^{-1} decreased with an increase in the amount of alkali but remained moderately, indicating the presence of preferable hygroscopicity or an appropriate surface activity as well as the formation of CSH.

For the same composition of alkali, the amount of CSH estimated from the intensities of the bands at 855 and 1480 cm^{-1} was found to be greater than in the corresponding filler calcined at 400 °C for 1.5 hr, whereas that of the calcite (1425, 875, and 715 cm^{-1}) formed fairly less. Therefore the thermal treatment (600 °C, 1—1.5 hr) is considered to be more advantageous for the production of CSH than in the lower-temperature calcination. The formation of CSH on the lamellae surfaces of the montmorillonites could restrain the excessive contraction, sintering and/or partial fusion of the minute crystallites induced by the calcination (600 °C, 1—1.5 hr). Thus the facilitation of disintegrating the calcined products resulted in the reduction of both the particle size and its distribution of the fillers prepared.

(iii) Calcination at 800 °C for 1—1.5 hr (Fig. 2 (c)). The bands at 3650, 914 and 835 cm^{-1} disappeared completely in the fillers prepared with or without alkali followed by the calcination (800 °C, 1—1.5 hr) and mechanical disintegration.

No phase attributable to the pyrophillite dehydroxylate, which was observed in the calcined **N** (600—800 °C, 1 hr), appeared in the fillers treated with hydrated lime (3—50% CaO) and by the subsequent calcination (800 °C, 1—1.5 hr) and mechanical disintegration. The restraint of forming the pyrophillite dehydroxylate might be resulted from the presence of the CSH distributed on the lamellae surfaces of the montmorillonites.

As the amount of alkali increased, the band at 796 cm^{-1} decreased with noticeable broading and still remained the intensity even with 50% CaO. Further polycondensation of the excess silica can be suggested under the conditions of preparation.

The bands at 1081, 1033 and 914 cm^{-1} overlapped each other, giving a very broad band around 1020 cm^{-1}. A considerable amount of Ca^{2+} ion might be incorporated into the octahedrons as well as the tetrahedrons of the montmorillonites by the calcination. Under such a high-temperature calcination, sintering or partial fusion of the minute crystallites should coincidently be accompanied in the fillers treated with higher composition of alkali. This should result in lowering the pulverizability of the prepared fillers due to the formation of too hard aggregates to be disintegrated.

The bands ascribable to CSH (1480 and 855 cm^{-1}) showed the intermediate intensities of the respective peaks observable in the fillers calcined at 400 and 600 °C for 1—1.5 hr, whereas the amount of calcite decreased noticeably with less than 30% CaO. A partial decomposition of calcite and the migration of CO_3^{2-} ion into the lattices of the newly formed minerals may be suggested.

The results obtained substantially agreed with those investigated by X-ray diffraction.

(2) Physicochemical Properties. (i) Hygroscopicity: Figure 3 (a) demonstrates obviously that the more the amount of alkali and the higher the temperature of calcination, the greater the effect of lowering the hygroscopicity of the fillers obtained.

A hyperbolic decrease in the hygroscopicity with an increase in the amount of alkali appeared in those treated with hydrated lime (CaO 3—60%) followed by the calcination (400—600 °C, 1—1.5 hr) and mechanical disintegration. The decreasing rate with respect to the change of the same amount of alkali was found to be greater in those calcined at the lower temperature, though the difference was relatively small.

Those prepared with more than 3% CaO and by the subsequent calcination (600 °C, 1—1.5 hr) and mechanical disintegration gave the hygroscopicity smaller than half of that (15.08%) of the dried **N**. Even those treated with more than 25% CaO followed by the calcination (400 °C, 1.5 hr) and mechanical disintegration would afford the values less than that (8.4%) of Silene EF.

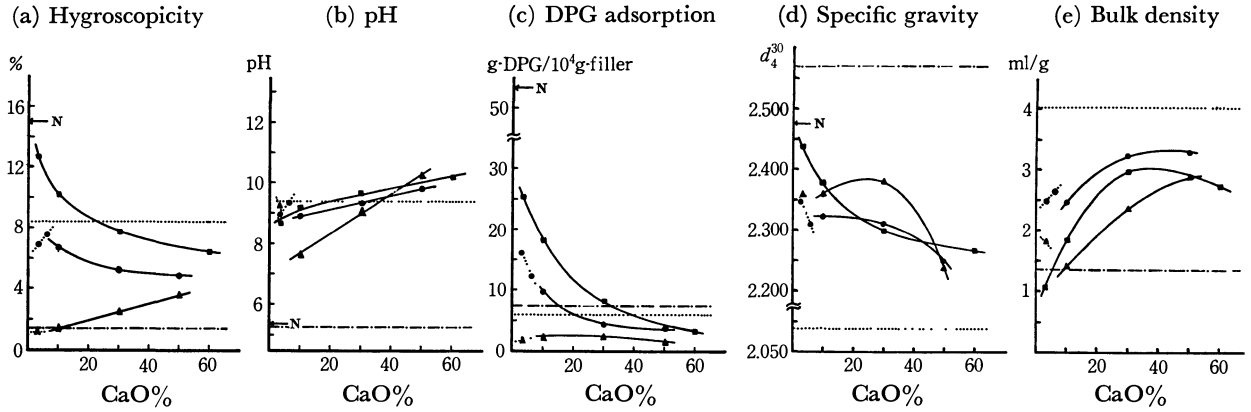

Fig. 3. Physicochemical properties of **N** hard clay (CaO 3—60%; calcination 400—800 °C, 1—1.5 hr; mechanical disintegration 18 hr) as compared with those of Dixie Clay, Silene EF and dried **N**. (a): Hygroscopicity, (b): pH, (c) DPG adsorption, (d) Specific gravity, (e): Bulk density.
▲·····▲ 800 °C, 1.5 hr; ●·····● 600 °C, 1.5 hr; ■——■ 400 °C, 1.5 hr; ▲——▲ 800 °C, 1 hr; ●——● 600 °C, 1 hr; -·-·-·- Dixie Clay; ····· Silene EF.

A noticeably-decreased hygroscopicity comparable to that (1.46%) of Dixie Clay was obtained in those prepared with less than 10% CaO and by the subsequent calcination (800 °C, 1—1.5 hr) and mechanical disintegration. Whereas the values conversely increased in proportion to an increase in the amount of alkali up to 50% CaO. The peculiar phenomenon may be attributed to the formation of some basic calcium salts (CaO/SiO_2 and/or $CaO/Al_2O_3>1$) during the course of the high-temperature calcination: A remarkable increase in pH, the lowest values in DPG adsorption and changes in the specific gravity and bulk density discussed later are considered to be the verifications in reference to the results investigated into the fillers by the X-ray diffraction and IR spectroscopy.

(ii) pH: Figure 3 (b) illustrates changes in the pH of **N** hard clay. The pH (5.40) of the dried **N**, slightly greater than that (5.30) of Dixie Clay, varied noticeably with the treatment with alkali (CaO 3—60%) followed by the calcination (400—800 °C, 1—1.5 hr) and mechanical disintegration (wet milling 18 hr), and resulted in the pH values comparable to that (9.45) of Silene EF in the fillers prepared.

Those treated with alkali (CaO 10—60%) and by the subsequent calcination (400—600 °C, 1—1.5 hr) and mechanical disintegration gave a proportional increase in the pH values with an increase in the amount of alkali. For the same composition of alkali, a high-temperature-calcined product showed a smaller value (about 0.3) than in the one treated by a lower-temperature calcination. This indicates that the higher-temperature calcination (600 °C, 1—1.5 hr) caused a further fixation of dissociative Ca^{2+} ions in the minute crystallites of the fillers.

Those prepared with alkali (CaO 10—50%) followed by the calcination (800 °C, 1 hr) and mechanical disintegration afforded an abrupt but proportional increase in the pH values as the amount of alkali increased. Formation of some basic calcium salts in the matrix can also be suggested on the basis of the followings; (1) a basic calcium salt, which generally exhibits a greater pH value than that of a normal one, is easily produced under the conditions of treatment with more alkali and by higher-temperature calcination, (2) no signal related to $Ca(OH)_2$ was observed in the fillers by means of X-ray diffraction and IR spectroscopy and (3) the results investigated on the structural changes previously described.

In the case of those produced with 3% CaO followed by the calcination (400—800 °C, 1.5 hr) and mechanical disintegration, the pH values appeared in a reverse order as compared with those treated with more than 10% CaO mentioned above. Although the difference of pH among the fillers were relatively small, they increased the values with an increase in the temperature of calcination. Presumably the formation of localized basic salts might be predominant under the conditions of preparation with such a little amount of alkali as 3% CaO followed by the calcination at a sufficiently high temperature.

(iii) DPG Adsorption: Figure 3 (c) shows changes in the DPG adsorption of **N** hard clay. A hyperbolic decrease in the DPG adsorption analogous to the hygroscopicity described above appeared in the fillers (CaO 3—60%; calcination 400—600 °C, 1—1.5 hr; wet milling 18 hr). The higher the temperature of calcination, the greater the effect of decreasing the DPG adsorption or the surface activity of the filler obtained. However, the decreasing rate with respect to the change with the same amount of alkali was found to be greater in the filler prepared with a less amount of alkali followed by calcination at a lower temperature.

The great DPG adsorption of the dried **N** (53.44 g DPG/10^4 g filler) would diminish to the degree comparable to or even less than those of Dixie Clay (6.05 g DPG/10^4 g filler) and Silene EF (5.08 g DPG/10^4 g filler) by the treatment with more than 15 (or 35)% CaO and by the subsequent calcination at 600 (or 400) °C for 1—1.5 hr and mechanical disintegration.

Those prepared with alkali (CaO 3—50%) followed by the calcination (800 °C, 1—1.5 hr) and mechanical disintegration decreased the values as low as 1/2 of that of Silene EF. They remained the values nearly unchanged irrespective of the variation in the amount of alkali. This indicates that the surface activity of the fillers disappeared almost completely.

(iv) Specific Gravity and Bulk Density: Figures 3 (d) and (e) give changes in the specific gravity and bulk density of **N** hard clay, respectively.

A hyperbolic decrease in the specific gravity and a maximum value with about 35% CaO in the bulk density appeared in the fillers (CaO 3—60%; calcination 400 °C, 1.5 hr; wet milling 18 hr).

For the same composition of alkali, however, those prepared with hydrated lime (3—50% CaO) followed by the calcination (600 °C, 1—1.5 hr) and the same mechanical disintegration as above afforded a lower specific gravity and a greater bulk density than those of the former fillers.

The higher the temperature of calcination, the greater the increase in the specific gravity and the decrease in the bulk density of the fillers prepared.

Consequently those treated with alkali (3—50% CaO) and by the subsequent calcination (800 °C, 1—1.5 hr) and mechanical disintegration showed a maximum value in the specific gravity with about 25% CaO and smaller values of the bulk density which increased almost linearly up to 50% CaO. This suggests that sintering occurred in the minute crystallites of the fillers.

The specific gravity (2.3110) and the bulk density (2.65 cc/g) of the best reinforcing filler[2] derived from **N** were found to be corresponded to the intermediates of the respective values of Dixie Clay (2.5684; 1.38 cc/g) and Silene EF (2.0989; 4.05 cc/g).

(3) Morphology. The prepared hard clays showed small, irregular flake-shaped crystallites, mostly in aggregates, which differ from those[30] of Dixie Clay and Silene EF; the former being well-formed hexagonal flakes of kaolinite[31] and the latter being spheroidal-colloid particles in clusters with some elongated lath-shaped units as given in Fig. 4 Plates 2 and 3, respectively.

Plate 1 illustrates the best **N** hard clay (CaO 6%; calcination 600 °C, 1.5 hr; wet milling 18 hr) with the

smallest average particle size and its distribution as compared with those prepared under the conditions deviated from the optima. The filler exhibited comparable tensile strength and higher elongation than those of Dixie Clay, though its modulus and hardness were found to be lower than those of the latter.[2)]

The average particle size and its distribution of the prepared fillers and the contents of newly formed minerals, CSH, CAH and calcite, were intimately related to the conditions of treatment with hydrated lime followed by calcination and mechanical disintegration besides the mineralogical composition of the original acid clay. A detailed report will be made in comparison with the morphology of **M** hard clay in the next paper.

Conclusion

On the basis of the foregoing investigations on the structure, morphology and physicochemical properties of the fillers together with the results investigated on the reinforcing properties described in the previous paper,[2)] it can be unequivocally concluded that the effect on the reinforcement of SBR-1502 compounds agreed precisely with the reduction in both the particle size and its distribution of the fillers.

The treatment with an optimum amount (CaO 6%) of hydrated lime and by the subsequent calcination at an appropriate temperature (600 °C) for a proper time (1.5 hr) and sufficient mechanical disintegration (wet milling 18 hr) caused a favorable change in the structure of **N**. This resulted in an increase in the bulk density and an decrease in the specific gravity of the prepared filler. It simultaneously contributed to restrain the surface properties such as hygroscopicity, pH and DPG adsorption, which were modified to the extent closing to those of Dixie Clay and/or Silene EF.

The treatment with an appropriate amount of hydrated lime followed by proper calcination contributes not only to the formation of CSH and/or CAH on the surfaces of the montmorillonite lamellae, but also to the restraint of thermal effects inducing the excessive, irreversible contraction, unfavorable collapse, sintering and/or partial fusion of the minute crystallites due to the interposition of the newly formed minerals. The collapse, sintering and partial fusion of the calcined products resulted in the formation of too hard aggregates to be disintegrated and the occurrence of a serious breakdown or complete loss in the effective functional

groups involved. The inferior reinforcing properties[2] of the fillers treated by the calcination at 800 °C for 1—1.5 hr can be attributed to those reasons.

The authors wish to thank the late Prof. T. Kuwata for his constant interest and encouragement during this work, Prof. J. Kumanotani for his help and valuable discussion, and Mr. Y. Sugawara, the President of Mizusawa Industrial Chemicals Co., Ltd., for providing the sample of Nakajo acid clay.

The Radical Formation of Polyethylene by Tesla Discharge

Akira YOKOHATA, Katsuyuki HARAKON, Kazuto TAKIMOTO, and Satoru TSUDA
Department of Chemistry, Faculty of Engineering, Hiroshima University, Senda-machi, Hiroshima 730
(Received March 14, 1974)

Synopsis. The ESR spectra of polyethylene discharged by a Tesla coil in an atmosphere of various gases were observed. An alkyl radical showing a six-line spectrum was formed in the Tesla discharge at 77 K, whereas a polyenyl radical was mainly produced by the discharge with an increase in the duration time; these facts showed that the effects of the Tesla discharge were similar to the γ-irradiation up to a high dose.

Many studies of the radical formation of polyethylene by γ-irradiation have been done.[1-6] The results of these works have revealed that at least three kinds of radicals are produced in polyethylene irradiated at room temperature. A radical with a short life-time gives a sextet spectrum and is identified with the alkyl radical, $-CH_2-\dot{C}H-CH_2$. A radical with a longer life-time shows a septet spectrum and is assigned to the allyl radical, $-CH_2-\dot{C}H-CH=CH-CH_2-$. The third radical has a very long life-time and gives a singlet spectrum, identified with the polyenyl radical, $-CH_2-\dot{C}H(-CH=CH)_n-CH_2-$. The alkyl and allyl radicals are the main products in γ-ray irradiation, whereas in the case of a high-dose irradiation the polyenyl radical is mainly formed.

On the contrary, the mechanism of the radical formation of polyethylene in a discharge has not been revealed. Our purpose in this work is to confirm that it is reasonable to interpret discharge chemistry from the standpoint of radiation chemistry.

H_2, N_2, and Ar gases with a high purity were used without further purification. The He gas was purified according to Polley's cold-charcoal-trap method.[7] The polyethylene used in these experiments was HZ 5000p, supplied by the Mitsui Petroleum Chemical Co. as powder. This powder sample was evacuated for 50 hr *in vacuo*. After the introduction of each gas (0.3 Torr), the sample tube was cut off. γ-Irradiation at a dose rate of 3×10^3 r/hr and a discharge by using a Tesla coil were carried out in the Pyrex-glass part of the sample tube at 77 K, while the ESR spectra were measured in the quartz-glass part at the same temperature. The ESR spectra were observed by using a Japan Electron Optics Laboratory JES-3BS-X-type spectrometer at a microwave frequency of 9400 MHz, with a 100 kHz field modulation. The gas products from irradiated and discharged polyethylene were measured by using a Hitachi-RMU-6D mass spectrometer.

It is well known that the alkyl radical formed by the γ-irradiation of unstretched polyethylene shows a six-line spectrum. It is interpreted as resulting from the abstraction of a hydrogen atom from the middle of a linear polyethylene[8] and from the apparent equal coupling of the unpaired electron to α-and β-hydrogen.[9,10]

Figure 1 shows the first derivative curve and the integrated curve of the ESR spectrum of the radical produced by Tesla discharge in an atmosphere of H_2 gas (0.3 Torr). The ESR spectrum with a hyperfine coupling constant of 30 gauss is similar to that of γ-irradiated polyethylene.[11] Furthermore, the absorption-peak intensity ratio of the sextet in the integrated curve was 1:4:11:10:4:1. This ratio is in good agreement with the theoretical ratio for the alkyl radical, 1:5:10:10:5:1. Thus, it can be concluded that, in the Tesla discharge, the alkyl radicals are mainly formed, as in radiolysis. In an atmosphere of N_2, He, and Ar gasses, the same spectra were observed, although the peaks differed in sharpness.

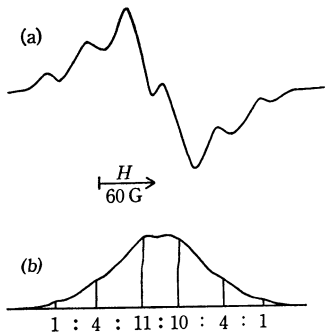

Fig. 1. ESR spectrum of radical produced by Tesla discharge at 77 K.

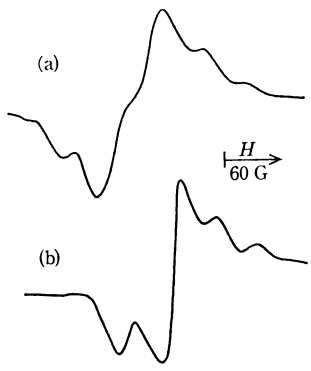

Fig. 2. Transformation of polyethylene radical generated by the dischage to peroxy radical.
(a): After the immersion into a dry-ice bath for 60 s.
(b): After exposure to air for 60 s in a dry-ice bath.

When polyethylene discharged at 77 K was exposed to air at its temperature, the ESR spectrum was almost the same as the original. Figure 2(a) shows the ESR spectrum of the discharged polyethylene after immersion into a dry-ice bath for 60 s. Although there was an appreciable loss in signal, there was little or no change in line shape. The spectrum in Fig. 2(b) represents the behavior of the alkyl radical when exposed to air for 60

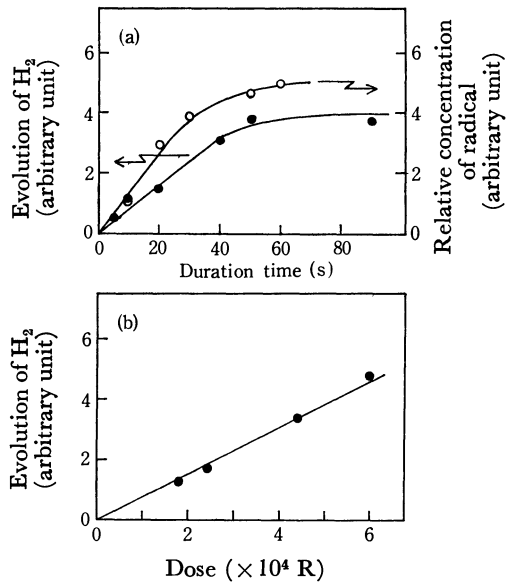

Fig. 3. Evolution of H_2 gas *vs.* duration time and dose. (a): Discharge, (b): γ-Irradiation.

s under the same conditions. It has been found that many of the polymer radicals react with oxygen to form peroxy radical.[11] Thus, the singlet line in the central part of the spectrum, which is superimposed on the spectrum attributable to the alkyl radical, represents the peroxy radical.

A relatively major quantity of H_2 gas and a trace amount of CH_4 gas were detected from the discharged polyethylene, whereas only the H_2 gas was observed from the γ-irradiated polyethylene. Lawton *et al.* have revealed the mechanism of H_2-gas evolution in γ-irradiated polyethylene.[12] Figure 3 shows the amount of H_2 gas evolved against the duration time and the irradiation dose. In the case of discharge, the amounts remained constant 50 s. The relative concentration of the alkyl radical also similarly became constant. On the contrary, in the case of γ-irradiation the amount of H_2 gas increased linearly with an increase in the irradiation dose. Figure 4 shows the ESR spectra of polyethylene with an increase in the duration time of discharge and in the irradiation dose of the γ-rays. The ESR spectrum of polyethylene discharged for 120 s ill-resolved, and the overall line-width of the spectrum of polyethylene discharged for 300 s is smaller than that in Fig. 4(b), suggesting that the alkyl radical is transformed with the dose to another radical, probably one with a singlet absorption. In the polyethylene irradiated with high dose γ-rays, the spectrum containing a six-line (4(d)) is transformed to a singlet with a smaller overall line width (4(e)). The latter spectrum is assigned to the polyenyl radical.[13] Thus, the ESR spectrum of polyethylene discharged for a long duration time is presumed to be attributable to the polyenyl radical, as in radiolysis. Although we could not find any precise correspondence between the Tesla discharge and the γ-irradiation, from these results it was semiquantitatively ascertained that their effects were similar to each other up to a high dose.

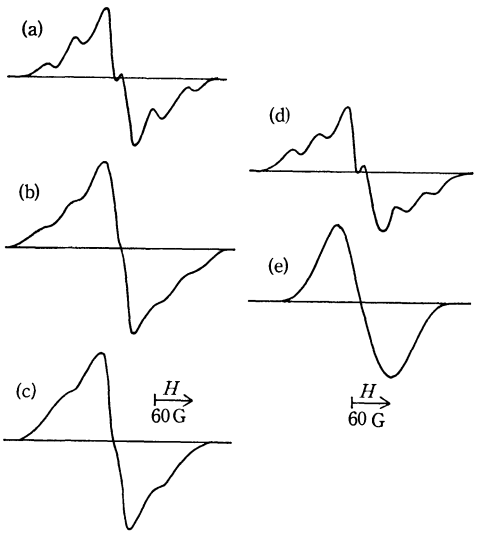

Fig. 4. ESR spectra of polyethylene discharged and irradiated with an increasing duration time and dose. (a): Discharge for 10 s, (b): 120 s, (c): 300 s, (d): γ-Irradiation with 8 MR, (e): 1000 MR.

The Radiation-induced Dehalogenation of Dichloromethane and Dibromomethane in Methanol Solutions

Hajime OGURA, Takashi FUJIMURA, Takaaki UNNAI,, and Masaharu KONDO
Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received October 26, 1974)

Synopsis. The scheme of the radiation-induced dehalogenation of dichloromethane and dibromomethane was investigated in deaerated methanol. The relative rate constants of those solutes toward e^-_{sol} were determined by competition kinetics, using a N_2O scavenger.

Organic halides are generally radiosensitive, and the main reaction in the radiolysis is usually dehalogenation, producing readily determinable halide ions. Therefore, a number of studies concerning the radiation chemistry of organohalogen compounds and their aqueous or alcohol solutions have appeared in the literature.[1-9]

In previous work,[10-12] we ourselves have determined the reactivities of monochlorobenzene and its derivatives toward the solvated electron in alcohols. We now wish to extend those studies to simple aliphatic halogen compounds, such as dichloromethane and dibromomethane, in methanol systems and to elucidate the scheme of the radiation-induced dehalogenation of these methylene halides in methanol solutions.

Experimental

The methanol was purified according to the procedure proposed by Imamura *et al.*[13] The dichloromethane and dibromomethane were treated successively with dilute sulfric acid and a 0.1 M K_2CO_3 solution and washed repeatedly with distilled water. They were subjected to fractional distillation after being dried over $CaCl_2$. A deaerated solution (5 ml) prepared by the conventional vacuum technique with freeze and thaw cycles was sealed in a glass cell. ^{60}Co γ-irradiation was carried out at a dose rate of 1.34×10^{18} eV ml^{-1} h^{-1}. The halide ions were determined by potentiometric titration. The formaldehyde was determined spectrophotometrically by the use of chromotropic acid. The amounts of hydrogen and nitrogen were determined by gas chromatography, using a Molecular Sieve 5A column and argon as the carrier gas.

Results and Discussion

Figure 1 shows the yields of halides ions as a function of the methylene dihalide concentration in deaerated methanol solutions. $G(Cl^-)$ reaches a plateau value of 3.6 at concentrations above 0.07 M CH_2Cl_2. The significantly high yield of $G(Br^-)$, which is, for example, 54 at 0.07 M CH_2Br_2, indicates the occurrence of a chain reaction.

Figure 2 shows the yields of bromide ions and formaldehyde as a function of the absorbed dose in a 0.07 M CH_2Br_2 solution under the three following experimental conditions; (1) deaerated, (2) aerated, and (3) sealed. The experimental condition is designated as "sealed" when the irradiation ampoule is filled with an aerated solution up to a ground-glass joint stopper. Under this condition, only the oxygen initially dissolved in a solution can participate in the reaction. The condition is designated as "aerated" when the solution is equilibrated with the oxygen present in the air above a solution in a stoppered vial during irradiation. As is illustrated in Fig. 2, the yields of Br^- and H_2CO from the sealed and the aerated systems are initially the same (that is, $G(Br^-)=5.7$ and $G(H_2CO)\simeq4$), but on further irradiation, the yields from the sealed system rise very sharply at doses over 10^{22} eV l^{-1}. This might be due to a progressive depletion of the oxygen content in solutions, because the yields after the break are very close to those in deaerated solutions, that is, $G(Br^-)=54$ and $G(H_2CO)=50$, indicating that the dissolved oxygen inhibits the chain reaction.

The species initially produced by the irradiation of methanol are usually presented as follows:

$CH_3OH\rightsquigarrow e^-_{sol}$, H, CH_2OH, $CH_3OH_2^+$ and molecular products (0)

The solvated electrons and H atoms are likely to react

with dihalogeno methane as follows:

$$e^-_{sol} + CH_2X_2 \longrightarrow CH_2X + X^- \quad (1)$$

$$H + CH_2X_2 \longrightarrow CH_2X + HX \quad (2)$$

$$\searrow CHX_2 + H_2 \quad (2')$$

X is Cl or Br depending on the solute. In deaerated methanol solutions of CH_2X_2 above 0.05 M, the observed $G(H_2)$ is almost equal to the molecular yield of hydrogen, $G_{H_2}=1.7$, so Reaction (2') may be excluded in the present system.[14] Our finding that, in a deaerated CH_2Cl_2 solution, $G(Cl^-)$ is 3.6 and very close to $Ge^-_{sol}+G_H$, taking $Ge^-_{sol}=2.0$ and $G_H=1.7$, indicates that all the Cl^- results from Reactions (1) and (2), while CH_2OH dose not contribute to Cl^- formation in this system. Otherwise, $G(Cl^-)$ would have to be equal to the total radical yield, $G(R)=Ge^-_{sol}+G_H+G_{CH_2OH}=6.5$. The high yields of Br^- and H_2CO from deaerated CH_2Br_2 solutions suggest that these products are formed by the following chain mechanism, similar to that proposed for the radiolysis of carbon tetrachloride in alcohols:[15]

$$CH_2OH + CH_2Br_2 \longrightarrow CH_2Br + H_2CO + HBr \quad (3)$$

$$CH_3OH + CH_2Br \longrightarrow CH_2OH + CH_3Br \quad (4)$$

Since $G(Br^-)$ and $G(H_2CO)$ are very close to each other, as is shown in Fig. 2, these products are likely to be formed by the same reactions. Although the yield of CH_3Br in Reaction (4) has been determined only qualitatively at the present time, its presence may support this view. On a thermochemical basis, Reaction (4) is exothermic ($\Delta H=-2$ kcal mol^{-1}), while it is endothermic ($\Delta H=4$ kcal mol^{-1}) when $X=Cl^-$. Moreover, in the 0.07 M CH_2Cl_2 solution, the observed $G(H_2CO)$ was only about 2,[14] close to the molecular yield of H_2CO in pure methanol, so the chain dehalogenation of CH_2Cl_2 is unlikely to occur. These considerations can explain the marked difference between $G(Cl^-)$ and $G(Br^-)$. In an aerated system, the chain breaking may be due to the reaction of dissolved oxygen with CH_2OH and CH_2Br.

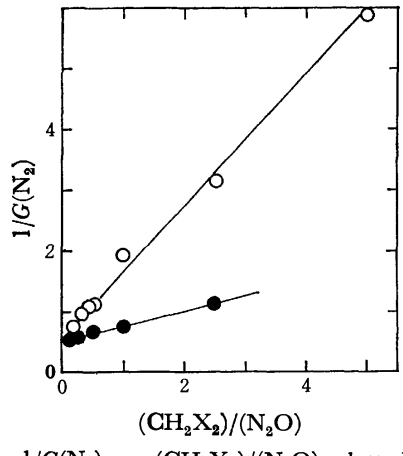

Fig. 3. $1/G(N_2)$ *vs.* $(CH_2X_2)/(N_2O)$ plotted according to Eq. (1). ●: CH_2Cl_2, ○: CH_2Br_2

When nitrous oxide is present in a deaerated system, Reaction (5) will compete with Reaction (1) for the solvated electron:

$$e^-_{sol} + N_2O \longrightarrow N_2 + O^- \quad (5)$$

On the basis of simple competition kinetics, one can formulate:

$$\frac{1}{G(N_2)} = \frac{1}{Ge^-_{sol}}\left[1+\frac{k_1(CH_2X_2)}{k_5(N_2O)}\right] \quad (I)$$

where k_1 and k_5 represent the rate constants of Reactions (1) and (5) respectively. Plots of $1/G(N_2)$ *vs.* $(CH_2X_2)/(N_2O)$ are seen to give straight lines in Fig. 3. From the slopes of the lines and the intercept, one can obtain $k_1/k_5=0.50$ for CH_2Cl_2 and $k_1/k_5=2.15$ for CH_2Br_2. Taking 1.3×10^{10} M^{-1} s^{-1} for k_5,[16] k_1 is estimated to be 6.5×10^9 M^{-1} s^{-1} for CH_2Cl_2 and 2.9×10^{10} M^{-1} s^{-1} for CH_2Br_2.

A Study on Anode Effect in KF-2HF System. I. ESCA Spectra of Carbon and Graphite Anode Surfaces

Hiroki IMOTO, Tsuyoshi NAKAJIMA, and Nobuatsu WATANABE

Department of Industrial Chemistry, Faculty of Engineering, Kyoto University, Yoshida, Sakyoku, Kyoto 606

(Received November 7, 1974)

Synopsis. The ESCA spectra of carbon and graphite electrodes, used as an anode in the molten KF-2HF system at 100 °C, indicated that a $(CF)_n$ film was formed on the surface of the electrodes. This may give strong support to the assumption that the anode effect in molten KF-2HF is caused by the formation of $(CF)_n$ on the carbon and graphite electrodes.

Fluorine gas is produced by the electrolysis of molten KF-2HF by using a carbon anode. The electrolysis current density is in the range 0.1—0.18 A/cm^2,[1] since the anode effect takes place when the current density is higher than this, and electrolysis must be stopped. It is, therefore, necessary to study the anode effect to increase the operating current density. It has been claimed that the anode effect is caused by a decrease of the wettability of an anode surface with electrolyte, KF-2HF, owing to the formation of a $(CF)_n$ film which has very low surface energy.[2-7] The investigation confirmed this mechanism.

Experimental

Six kinds of carbon and graphite samples were prepared in the following manner. Five electrode samples were anodically polarized under various conditions and the surface of the other electrode was treated with fluorine gas.[8] Their ESCA spectra were obtained with a Du Pont 650 Electron Spectrometer. The cubic carbon and graphite electrodes which were covered with Teflon tape except for one side were fixed at the end of a brass rod coated with Teflon. A Pt rod was used as a reference electrode. The molten KF-2HF system was dehydrated by pre-electrolysis using a carbon electrode.

Results and Discussion

Figure 1 shows the ESCA spectra of the carbon 1s electron in the samples which were prepared as follows.

(A) Anodically polarized at 5 V *vs.* Pt for 30 min.

(B) Anodically polarized at 10 V *vs.* Pt for 30 min.

(C) Anodically polarized at a current density of 350 mA/cm^2, the circuit being opened immediately after onset of the anode effect.

(D) Anodically polarized at a constant current density of 350 mA/cm^2, and polarized further at 20 V *vs.* Pt for 5 min after onset of the anode effect.

(E) Conditions are the same as for (D) except for polarization of 30 min after onset of the anode effect.

(F) The carbon and graphite samples were directly treated with fluorine gas under the following conditions. (I) F_2 pressure; 200 mmHg, temp.; 450 °C, time; 2 hr. (II) F_2 pressure; 110 mmHg, temp.; 450 °C, time; 0.5 hr. $(CF)_n$ was formed on the surface of the samples.

(G) The original carbon and graphite samples.

When the carbon and graphite electrodes were polarized at various controlled potentials, the current densities

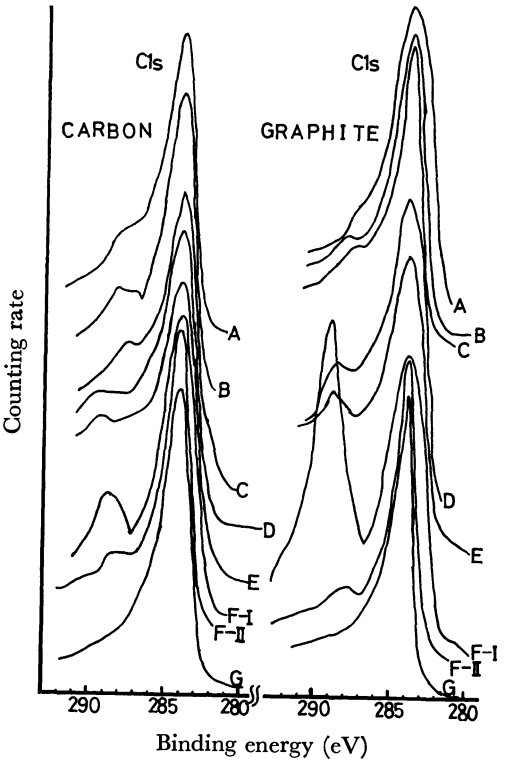

Fig. 1. ESCA spectra of carbon and graphite (C 1s).

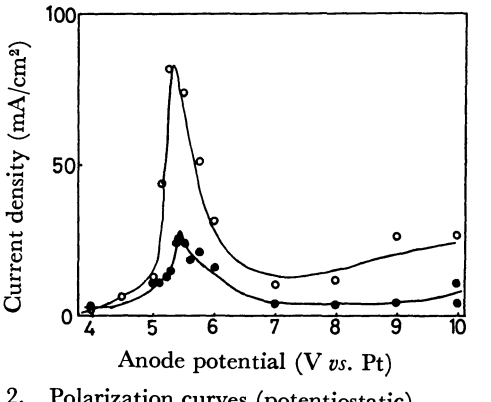

Fig. 2. Polarization curves (potentiostatic).
○: Carbon, ●: Graphite.

reached stationary values. Figure 2 shows the relation of these values against their potentials; electrode (A) was prepared under conditions of normal electrolysis, (B) under conditions of the anode effect. The latter conditions, however, are milder than those of (D) and (E). Anodic polarization of carbon and graphite electrodes with a constant current density of 350 mA/cm^2 gave rise to the anode effect within five seconds. The spectra of the original carbon and graphite samples (G) indicated

only one peak at 284 eV. This peak may correspond to the binding energy of the carbon 1s electron in cases where the carbon atom has the C–C bond. On the other hand, the spectra of samples (F) fluorinated by fluorine gas indicated two peaks at 284 and 289 eV. The peak at 289 eV may be assigned to the binding energy of the carbon 1s electron in cases where the carbon atom has the C–F bond. If the carbon atom is combined with the fluorine atom which is the most electro-negative element, the chemical shift of the binding energy of the carbon 1s electron must be large and positive. The spectra of samples (A), (B), (C), (D), and (E) indicated the same peaks as those of sample (F), that is, at 284 eV and 289 eV (the latter became a shoulder or appeared to slightly approach the peak at 284 eV as it was much smaller than this peak). Consequently, it was proved that the $(CF)_n$ film was formed on the surface of the carbon and graphite anodes not only during the anode effect but also under normal electrolysis conditions. From the results described above, it can be considered that the following reactions may occur on the anode surface, when the molten KF–2HF is electrolyzed by using the carbon or graphite anode.

$$2F^- \longrightarrow F_2 + 2e^- \quad (1)$$

$$nC + nF^- \longrightarrow (CF)_n + ne^- \quad (2)$$

When a $(CF)_n$ compound is formed on the anode surface during the evolution of fluorine, the wettability of the anode surface with the molten KF–2HF decreases markedly because of the very low surface energy of the $(CF)_n$ compound and the carbon and graphite surfaces do not come directly into contact with the electrolyte. If a large part of the anode surface is covered with the $(CF)_n$ conpound, the anode reaction does not proceed and only a small arc current flows through the interface at the anode under higher voltages. This is called the anode effect. However, since the following reaction (Eq. (3)) is considered to take place simultaneously, the net formation reaction rate of $(CF)_n$ during the fluorine evolution reaction depends upon the reaction rates of Eqs. (2) and (3).

The decomposition reaction of the $(CF)_n$ film.

$$(CF)_n \longrightarrow C + CF_4 + C_2F_6, \textit{ etc.} \quad (3)$$

In conclusion, the previous explanation that the cause of the anode effect is the formation of a compound which has a very low surface energy on the carbon and graphite electrodes has been confirmed experimentally by ESCA analysis.

ENDOR Studies on the Hindered Alkylbiphenyl Anion Radicals

Kazuhiko Ishizu, Fujito Nemoto, Kazuo Mukai, Masahiro Kohno,* and Hideo Hasegawa*

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

** Japan Electron Optics Laboratory, Akishima, Tokyo 196*

(Received November 8, 1974)

Synopsis. ENDOR observations were carried out for the anion radicals of 2,2′-bitolyl, 2,2′-diethylbiphenyl, and 2,2′-diisopropylbiphenyl. The spin densities obtained from the ring protons at the *ortho*-positions showed a depression in the order of the spherical bulkiness of the substituents, and the degrees of the steric hindrance of the biphenyl ring were estimated based on McLachlan's MO calculation. ENDOR experiments demonstrated that methyl groups undergo free rotation, but it is greatly hindered in each higher alkyl derivative.

Recently, ENDOR tequniques have often been applied to conformational studies of the aromatic free radicals. In particular, the multiple hyperfine components of the complex molecule have been successfully resolved, and the structures of the radicals have been discussed in detail on the basis of the accurate analysis of the spin densities.[1-3] In our previous ESR studies of the 2,2′-dialkylbiphenyl anion radicals, we have proposed that the coplanarity of the biphenyl ring would be enhanced by the delocalization of the unpaired electron and that the free rotation of the higher alkyl groups would be greatly hindered by the steric hindrance caused by the anomalous coplanarity of the biphenyl rings.[4]

In the present communication, we wish to report the ENDOR studies of the anion radicals of several hindered alkylbiphenyls, such as *o,o′*-bitolyl, 2,2′-diethylbiphenyl, and 2,2′-diisopropylbiphenyl. The validity of the ring-proton splittings assumed by ESR measurements was reconfirmed. In addition, the present ENDOR observations offered new experimental evidence to support the fact that the rotation of the ethyl and isopropyl groups at the *ortho*-position is nearly locked, while the methyl group of *o,o′*-bitolyl undergoes free rotation.

Experimental

The alkylbiphenyls used in this experiment were synthesized in the manner described in a previous paper.[5] The anion radicals were prepared by reduction with potassium metal in dimethoxyethane (DME) at the temperature of dry ice and aceton. The ENDOR spectra were recorded by a JEOL-type ES-EDX-1 spectrometer under operating conditions similar to those described elsewhere.[6] The ESR intensity began to saturate at a microwave output of about 2 mw on the dial scale of a JES-ME-3 ESR spectrometer, and the ENDOR spectra were successfully recorded in the temperature range from −65 to −85 °C.

Results and Discussion

Figure 1 shows the ENDOR spectra of the biphenyl (a), *o,o′*-bitolyl (b), 2,2′-diethylbiphenyl (c), and 2,2′-diisopropylbiphenyl (d) anion radicals. The ENDOR spectrum of the *o,o′*-bitolyl anion radical can be easily analyzed in terms of absorptions due to the *meta*-ring (14.21, 14.55 MHz), the *ortho*-ring and methyl (17.04 MHz) and the *para*-ring protons (21.26 MHz), in comparison with the ring-proton absorption of the biphenyl anion radical (*meta*: 14.37, *ortho*: 17.58 and *para*: 21.34 MHz). In the previous ESR studies of the 2,2′-diethylbiphenyl anion radical, we assumed that the methylene protons of the ethyl group reveal an equivalent splitting.[7] The ENDOR spectrum of the 2,2′-diethylbiphenyl anion radical (Fig. 1-(c)) was, however, clearly resolved into two kinds of different absorptions due to non-equivalent β-ethyl protons at 15.48 and 17.16 MHz.

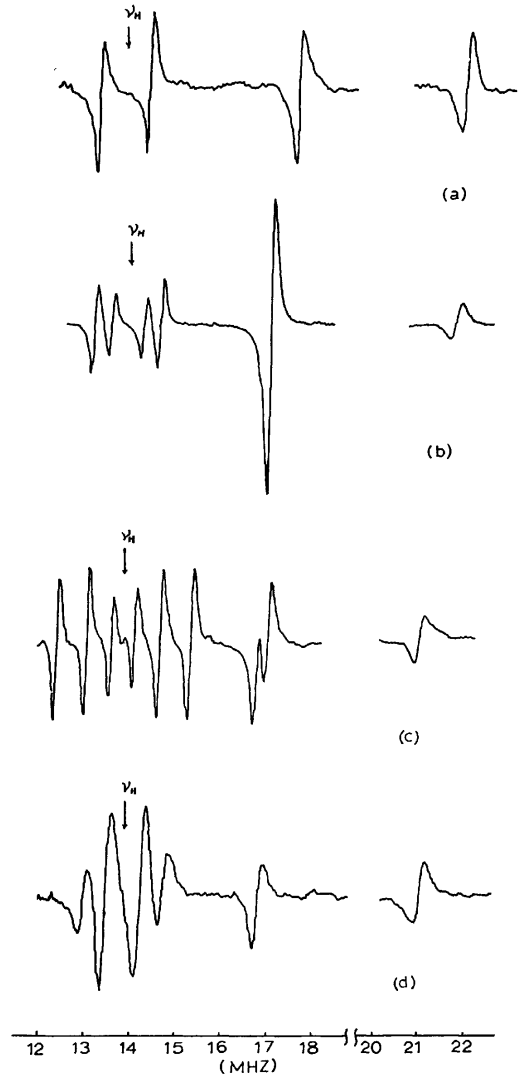

Fig. 1. The higher frequency half of the ENDOR spectra recorded at −85 °C.
(a) biphenyl, (b) *o,o′*-bitolyl, (c) 2,2′-diethylbiphenyl
(d) 2,2′-diisopropylbiphenyl, ν_H: free proton frequency

Table 1. Coupling constants of the hindered dialkylbiphenyls (G)

Position	2	3	4	5	6
Biphenyl	2.66	0.38	5.34	0.38	2.66
o,o'-Bitolyl	2.27	0.26	5.21	0.51	2.27
2,2'-Diethyl	2.29 1.07	0.19	5.20	0.59	2.11
2,2'-Diisopropyl	0.28	0.28	5.16	0.57	1.96

It is important to note here that each of the absorption frequencies of the ring protons (*meta*: 14.18, 15.40, *ortho*: 16.90 and *para*: 21.15 MHz) is nearly comparable with that of the *o,o'*-bitolyl anion radical. A similar conformational dependence of the spin-density distribution can be seen in 2,2'-diisopropylbiphenyl, but the splitting of the isopropyl-β-proton is greatly reduced and its absorption overlaps with one of the *meta* proton absorptions (14.25 MHz) in the vicinity of the free-proton frequency. The proton-coupling constants of the 2,2'-dialkylbiphenyls are summarized in Table 1. It is interesting that the experimental spin densities decrease with the order of the spherical bulkiness of the substituents.

This probably means that the higher alkyl groups bring a larger steric hindrance into the biphenyl ring than that in the methyl derivative. A quantitative estimation of the twisting angle (θ) of the phenyl rings for the higher alkyl derivatives needs elaborate MO calculations, and the hyperconjugative effect of the higher alkyl groups should be rigorously taken into account.

In a qualitative approach, however, the θ-values for higher alkyl derivatives can be estimated using the results calculated for the methyl derivative, since a perturbation of the ring-spin density due to the hyperconjugation of the higher alkyls is usually small. As is shown in Fig. 2, the θ-values of the ethyl and the isopropyl derivatives would be in the range from 40 ° to 50 °.

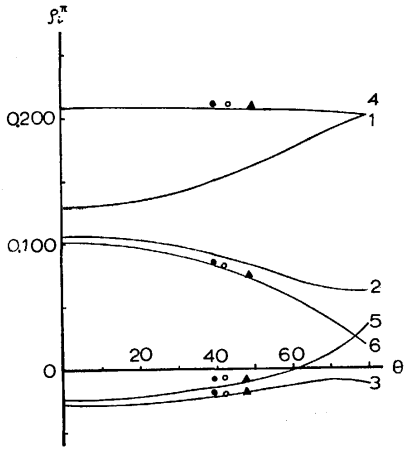

Fig. 2. Dependence of theoretical spin density of ring carbon atoms on twisting angle θ between the phenyl ring in 2,2'-bitolyl anion radical. Experimental values are shown in the figure using the following notation.
●···: *o,o'*-bitolyl, ○···: 2,2'-diethylbiphenyl, ▲···: 2,2'-diisopropylbiphenyl
Twisting angles θ of the higher alkyl derivatives were tentatively estimated based on the figure calculated for bitolyl anion radical. The Coulson and Crawford's parameters of the hyperconjugation were used in the calculation of the methyl group.[10]

In the previous paper, we proposed that the rotation of the higher alkyl groups at the *ortho*-positions may be seriously hindered and that the alkyl groups behave as torsional oscillators rather than as free rotators.[7] According to the present ENDOR experiments, this is indeed true; the *ortho*-methyl proton splitting in *o,o'*-bitolyl was found to be equivalent, while the methylene protons of the ethyl group exhibited non-equivalent splittings. Futhermore, the methine proton of the isopropyl group revealed an exceptionally small value.

The dihedral angles of the ethyl methylene-protons at the equilibrium conformation were calculated to be $\varphi_1 = 54$ ° and $\varphi_2 = 66$ ° respectively, using the McConnell-Heller equation[8] with $B_0 \approx 0$; that is, $A^H = [B_0 + B_2 \langle \cos^2\varphi \rangle] \rho_i^\pi \approx B_2 \langle \cos^2\varphi \rangle \rho_i^\pi$ (1), where $B_2 = 50$ G.

The ρ_2^π (0.0908) of *o,o'*-bitolyl, estimated from Equation (1), is in excellent agreement with the theoretical value, 0.0913 ($\theta = 40$ °), predicted by the MO calculation based on the free rotation of the methyl group, that is, $\langle \cos^2\varphi \rangle = 1/2$.

In the case of the ethyl derivative, however, the ρ_2^π·(exp) value, 0.129, obtained from Equation (1) using $\varphi_1 = 54$ ° and $\varphi_2 = 66$ ° is considerably larger than the theoretical value (0.0913). Recently, the importance of the B_0 term contributing to the β-proton splitting of the higher alkyls has been demonstrated by an ENDOR study of the *p,p',p''*-triisopropyl trityl radical.[9] The discrepancy in the experimental values between the methyl and the ethyl derivatives is probably attributable to the neglect of the B_0-term.

If $B_0/B_2 = +0.06$ is tentatively assumed, the following values of ρ_2^π, which seem to be more reliable, are obtained: ρ_2^π(methyl) = 0.081 and ρ_2^π(ethyl) = 0.094.

The large diminution in the isopropyl methine-proton splitting also indicates a tight lock of the rotation of the alkyl group. The dihedral angles of the methine proton with the twisting angle of $\theta = 50$ ° ($\rho_2^\pi = 0.0822$) are calculated to be 89 °, assuming the B_0/B_2 ratio to be +0.06. This means that the isopropyl methine-proton is fixed in a position close to one of the aromatic planes of the twisted biphenyl.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (5), 1637—1638 (1975)

A Semi-empirical Calculation of the Substituent Effect on the ^{1}H Chemical Shift of Benzene[1)]

Jun NIWA

College of General Education, Nagoya University, Chikusa, Nagoya 464

(Received November 25, 1974)

Synopsis. The applicability of a semi-empirical expression for obtaining the relative ^{1}H chemical shifts in substituted aromatic side-chains, which was presented in the preceeding paper (J. Niwa, This Bulletin, **48**, 118 (1975)), has been examined for ring protons of monosubstituted benzenes.

In the preceeding paper,[1)] we derived a semi-empirical expression for obtaining the relative chemical shifts (in ppm) of protons in substituted aromatic side-chains by considering the "ring-current" effect ($\sigma^{A,\,ring}$) in addition to the diamagnetic contribution of the hydrogen atom, A, in the C–H bond of interest (σ_{dia}^{AA}) and that from its bonded carbon, B(σ_{dia}^{AB}):

$$\delta_{calcd}(\equiv \Delta\sigma^{A}) = \Delta\sigma_{dia}^{AA} + \Delta\sigma_{dia}^{AB} + \Delta\sigma^{A,ring} \quad (1)$$

$$= a\Delta q^{A} + b\Delta q^{B} - 0.4f(\rho, z)|\sigma_{\pi}| \quad (2)$$

where the $\Delta q'$ s are the increments in electron densities on specified atoms, where a and b are, respectively, the constants particular to the hydrogen atom and the C–H bond, and where the third term is the modified Johnson and Bovey ring-current shift. We showed that Eq. (2) could correctly reproduce the relative chemical shifts of protons in substituted aromatic side-chains. In the present paper, we will examine to what degree of accuracy Eq. (2) can reproduce the relative chemical shifts observed for the ring protons of monosubstituted benzenes. In evaluating the first and second terms of Eq. (1), we have used the CNDO/2 formalism.

In order to calculate the local diamagnetic term (σ_{dia}^{AA}) of the hydrogen atom, the expression (Eq. (3)) given by Kajimoto and Fueno[2a)] was applied to the case of the ring protons:

$$\sigma_{dia}^{AA} = 17.75(-0.3q_H^2 + 1.5q_H) \quad (3)$$

The calculated value of σ_{dia}^{AA}, relative to the unsubstituted compound, is linearly correlated with the increment in the electron density on the hydrogen atom:

$$\Delta\sigma_{dia}^{AA} = 16.0\Delta q^{A} \quad (4)$$

In the preceeding paper,[1)] we showed that the diamagnetic contribution from the bonded carbon (σ_{dia}^{AB}) can be expressed as:

$$\sigma_{dia}^{AB} = (e^2/3mc^2)r_{AB}^{-1}q^{B} \quad (5)$$

where r^{-1} is the inverse distance of the A atom from the point charge on the B atom and where q is the total (2s and 2p) electron density on the B atom. In the case of benzene, too, the contribution can be calculated in the same way as in the case of the olefinic proton,[1)] because the ring proton also bonds to the sp^2-hybridized carbon atom and the C–H bond length is taken to be 1.08 Å. Thus, the σ_{dia}^{AB} term, relative to the unsubstituted compound, becomes:

$$\Delta\sigma_{dia}^{AB} = 8.70\Delta q^{B} \quad (6)$$

The paramagnetic term, σ_{para}^{AB}, calculated according to Pople's expression,[2b)] remains almost constant for the series of monosubstituted benzenes so long as we assume the same average excitation energy and the same value of the integral $\langle r_{AB}^{-3}\rangle$.

In order to calculate the contribution of the "ring-current" effect relative to the unsubstituted compound, Eq. (7) derived by Yamada, Tsuno, and Yukawa[2d)] can be applied, just as it is, to all the ring protons in the present case:

$$\Delta\sigma^{A,ring} = -0.4f(\rho, z)|\sigma_{\pi}| \quad (7)$$

where the value of $f(\rho,z)$ is -1.50 ppm.[3)]

Using Eqs. (4), (6), and (7), we obtain the following equation for the relative chemical shifts of the ring protons:

$$\delta_{calcd} = 16.0\Delta q^{A} + 8.70\Delta q^{B} + 0.6|\sigma_{\pi}| \quad (8)$$

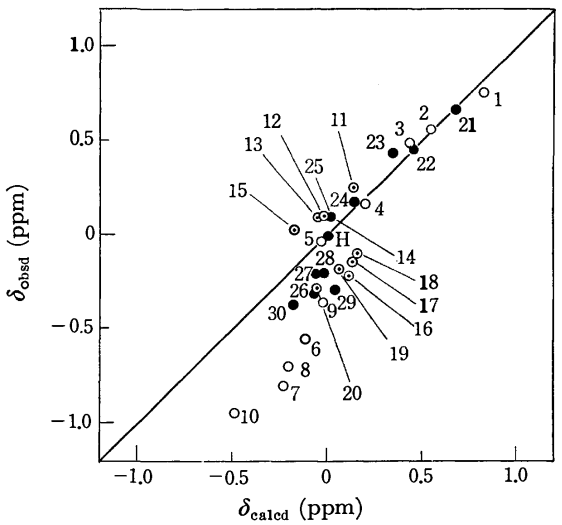

Fig. 1. Plots of δ_{obsd} against δ_{calcd} for ring protons of monosubstituted benzenes.
Numbered points correspond to entries in the Table 1.
○: *ortho*-substituent, ⊙: *meta*-substituent, ●: *para*-substituent.

The chemical shifts calculated by Eq. (8) are compared in the table with those observed for monosubstituted benzenes. In the figure, plots of the observed chemical shifts are shown against the calculated shifts. As may clearly be seen in the figure, the calculated chemical shifts can semi-quantitatively reproduce the trend of the substituent effects on the chemical shifts for protons at the position *para* to the substituents. This reveals that the three terms of Eq. (2) constitute the most important

factors determining the relative chemical shifts in the case of *para*-protons remote from the substituent. In the protons at the positions *meta* and *ortho* to the substituents, however, the correlation between the observed and the calculated chemical shifts collapses appreciably. The cause of the deviations in the case of *meta*-protons may be mainly ignoring the magnetic contributions from carbon atoms neighboring the B atom. In the case of *ortho*-protons, especially in carbonyl and nitro derivatives, one reason that the calculated chemical shifts do not well reproduce the observed shifts may be ignoring the magnetic anisotropy of substituent groups which cause a low-field shift in the proton.[4)]

The CNDO/2 calculation was carried out on a FACOM-230 computer at the Nagoya University Computation Center.

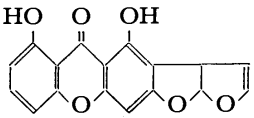
(Received December 5, 1974)

Synopsis. The crystal structure of sterigmatin has been determined by single-crystal X-ray analysis. The crystals are triclinic; space group P1, $Z=2$, with $a=14.392(4)$, $b=14.120(4)$, $c=4.256(2)$ Å, $\alpha=78.22(3)$, $\beta=100.42(3)$, $\gamma=56.90(3)$ °. The structure was refined to an R value of 0.039 for 1961 reflections. There are two intramolecular hydrogen bonds in each of the crystallographically independent molecules.

Sterigmatin was isolated as a metabolite of *Aspergillus versicolor* (Vuillemin) Tiraboschi, and its structural formula was shown to be as follows.[1]



As part of a program of research on the structures of metabolites of this mold,[2,3] the structure of sterigmatin has been studied by means of the X-ray diffraction method.

Sterigmatin was crystallized from acetone in the form of pale yellow needles elongated along the c-axis. The crystals are triclinic; space group P1, $Z=2$, with $a=14.392(4)$, $b=14.120(4)$, $c=4.256(2)$ Å, $\alpha=78.22(3)$, $\beta=100.42(3)$, $\gamma=56.90(3)$ °. The intensities were collected on a Rigaku Denki computer-controlled four-circle diffractometer using Ni-filtered Cu-$K\alpha$ radiation. The ω-2θ scan technique was employed, with a scan speed of 2 ° min^{-1} in ω. The background was measured for 5 s at both the start and end points of the scan range. A total of 1968 intensities were collected, with $\sin\theta/\lambda<0.562$. The crystal used was so small (*ca.* $0.06\times0.07\times0.25$ mm) that the intensities were corrected only for the Lorentz and polarization factors.

The orientations of the xanthone skeletons of the crystallographically independent molecules were easily determined by the application of the convolution molecule method.[4] Since the origin could be arbitrarily chosen for the P1 space group, the Fourier synthesis based on the phases due to one of the xanthone skeletons revealed the other xanthone skeleton. The structure obtained by successive Fourier syntheses was refined by a block-diagonal least-squares method. Seven intense reflections with low-order indices were omitted from the refinement and difference Fourier synthesis because of the extinction effect. The difference electron density map revealed all the hydrogen atoms. The refinement was continued by including the hydrogen atoms until the R value of 0.039 for 1961 reflections. The unit weight was applied for all reflections. The final atomic parameters of the two molecules (A and B) are listed in Tables 1 and 2. The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[5] The computations were performed on a TOSBAC-3400 computer at the Tottori University Computing Center and on a NEAC 2200-N700 computer at the Computation Center of Osaka University.

Since the corresponding bond lengths and angles of the two crystallographically independent molecules do not differ significantly, we may use the mean values given in Fig. 1 and Table 3 for the discussion of the

Table 1. Final atomic parameters and e.s.d.'s ($\times10^4$) for non-hydrogen atoms

The anisotropic temperature factors are of the form: $\exp(-\beta_{11}h^2-\beta_{22}k^2-\beta_{33}l^2-\beta_{12}hk-\beta_{13}hl-\beta_{23}kl)$.

structure. The mean value of the C(4)–O(2) bond lengths is 1.267 Å, which is longer than the accepted value of the C–O double bond length. Such an elongation has also been found in averufin.[2] The bond lengths of C(3)–C(4) and C(4)–C(5) are 1.440 and 1.438 Å respectively; they are considerably longer than the mean

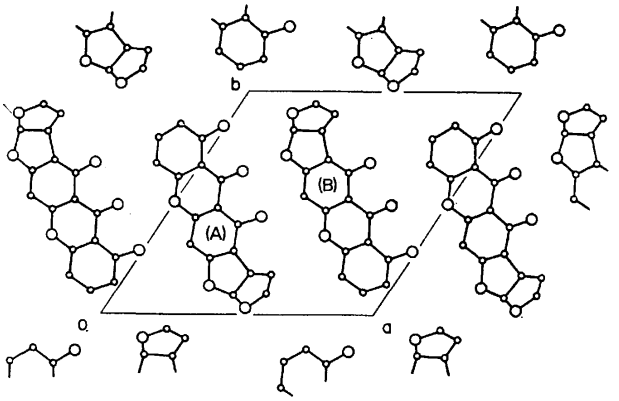

Fig. 2. The crystal structure of sterigmatin projected along the c*-axis.
The large circles indicate oxygen atoms and the small ones carbon atoms. The hydrogen atoms are omitted in the figure.

C–C bond length (1.390 Å) in the benzenoid rings. There are two intramolecular hydrogen bonds, O(1)–H(1)·····O(2) and O(3)–H(2)·····O(2). In each molecule the xanthone skeleton and terminal five-membered ring are planar within ±0.06 Å and ±0.02 Å respectively. The dihedral angles between the planes are 67.3 ° in the A molecule and 65.0 ° in the B molecule.

The crystal structure projected along the c* axis is shown in Fig. 2. Although the closest intermolecular contact (2.86 Å) of non-hydrogen atoms is found between O(A1) and O(B5), the difference electron density map calculated using the final atomic parameters showed no peak in the region between these two oxygen atoms. Therefore, there is no intermolecular hydrogen bond between the O(A1) and O(B5) atoms. The other intermolecular distances require no special comment.

The authors wish to thank Mr. Isao Tanaka of Nagoya University for his permission to use the program of the convolution molecule method.

Electron-transfer Kinetics of Transition-metal Complexes in Lower Oxidation States. Part III.[1] Electrochemical Rate Constants for the Fe(II)/Fe(I) Redox Systems

Tetsuo SAJI, Tamaki YAMADA, and Shigeru AOYAGUI*

Faculty of Engineering, Tokyo Institute of Technology, Ohokayama, Meguro-ku, Tokyo 152

(Received December 12, 1974)

Synopsis. The standard rate constants for the redox systems Fe(II)/Fe(I) are measured. They are about one tenth of those for the systems Fe(III)/Fe(II) and Cr(I)/Cr(0). The difference in the kind of molecular orbital occupied by the excess electron of the reductant species can account for the difference in the rate constant.

Transition-metal complexes in lower oxidation states have been widely studied from the structural chemical, magnetochemical, spectroscopic and kinetic points of view. Although electrochemical studies have also been made, they have been almost limited to polarographic ones. Eelctrode kinetic parameters have been measured so far only on two redox systems in lower oxidation states: one is the $Co(bipy)_3^{2+}/Co(bipy)_3^{+}$ system[2] and the other the $Cr(bipy)_3^{+}/Cr(bipy)_3$ system.[1] The standard rate constant of the latter system was discussed in comparison with the second order rate constant of the corresponding homogeneous homonuclear electron-transfer reaction.[3] It was pointed out that each of the electrochemical and the homogeneous electron-transfer reactions of this system fell into a class of the fastest reaction. Its electronic configuration differing by one in the number of electrons in metal t_{2g}-orbitals was considered to account for the high reaction rate.

This note treats the measurements of the standard rate constants of the redox systems $Fe(bipy)_3^{2+}/Fe(bipy)_3^{+}$ and $Fe(bipy)_2(CN)_2/Fe(bipy)_2(CN)_2^{-}$. According to our recent polarographic investigations,[4,5] the excess electron of a reductant complex of these systems occupies a ligand π^*-orbital.

Experimental

Each electrolytic solution contained a 2 mM electroactive species, *i.e.*, $Fe(bipy)_3^{2+}$, $Fe(bipy)_2(CN)_2$ or 2,2′-bipyridine in *N,N*-dimethylformamide (DMF). Supporting electrolyte was 0.2 M tetra-*n*-butylammonium perchlorate (TBAP). Either a platinum spherical electrode or a dropping mercury electrode (DME) was used as the working electrode. The standard rate constant (k°) was assumed to be identical with the rate constant at the half-wave potential ($E_{1/2}$). It was measured with the aid of the galvanostatic double-pulse method with the *in situ* generation of a reductant complex at the half-wave potential of the redox system. Measurements were made at 25±2 °C. Details of the experiments were described in a separate paper.[6]

Results and Discussion

Results obtained are listed in Table 1. They are summarized as follows: (1) a partial subtitution of a ligand bipy with a CN^- does not affect the rate constant, (2) the rate constant does not depend much on the material of the working electrode, platinum or mercury, (3) the rate constants are smaller about one order of magnitude than the rate constant for the $Cr(bipy)_3^{+}/Cr(bipy)_3$ system,[1] 1.0 cm s^{-1}, and (4) the rate constants for the Fe(II)/Fe(I) systems are nearly equal to the rate constant for the bipy/$bipy^-$ system. Feature (1) forms a striking contrast to findings obtained for Fe(III)/Fe(II) systems:[6] the apparent standard rate constants for $Fe(bipy)_3^{3+}/Fe(bipy)_3^{2+}$, $Fe(bipy)_2(CN)_2^{+}/Fe(bipy)_2(CN)_2$, $Fe(bipy)(CN)_4^{-}/Fe(bipy)(CN)_4^{2-}$ and $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ become smaller in this order from about 1 cm s^{-1} to 0.2 cm s^{-1}. Features (3) and (4) may be consistent with the previous conclusion that the electron transferred in the course of electrochemical oxidation of Fe(I) complexes occupies a ligand π^*-orbital[4] and that of Fe(II) complexes a metal t_{2g}-orbital.[7] These facts may suggest that the electronic configuration of a redox species can be a predominant factor determining the electrochemical electron-transfer rate. It is known that the rate constant of a homogeneous electron-transfer reaction depends on the electronic configuration of the reactants. Such a dependence has been discussed on electrode reactions by Vlček[8] and later by Marcus[9] who has pointed out that when a reductant species loses a metal e_g-electron on oxidation, the rate is slower than when it loses a t_{2g}-electron. This has been interpreted on the basis of his theory[10] as follows: a t_{2g}-electron transfer, compared with an e_g-electron transfer, requires a lesser change in bond lengths or bond geometry and in its turn smaller energy of reorganization of the inner coordination shell.

Further support for the conclusion of this note will be furnished in a separate paper[11] by the same kind of experiments on more than twenty redox systems of tris-

An ESR Study of Diborane Anion Radicals in the Adsorbed State

Kunihisa SOGABE, Akinori HASEGAWA, and Masaji MIURA

Department of Chemistry, Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730

(Received January 16, 1975)

Synopsis. The ESR spectra were examined for diborane anion radicals, $B_2H_6^-$, formed when diborane adsorbed on several kinds of adsorbents was irradiated with γ-rays at 77 K or diborane adsorbed at 77 K on adsorbents pre-irradiated with γ-rays at 77 K. The radicals in the adsorbed state were compared with those in an argon matrix, previously reported.

The ESR spectra of two kinds of radicals have been investigated in connection with diborane. When the solid of diborane was irradiated with γ-rays, the ESR spectrum of neutral diboranyl radicals formed by extracting one of the two bridging hydrogens of diborane was observed. The radical was investigated in detail by means of both ESR measurements with an irradiated single crystal of diborane[1] and theoretical calculations.[1,2] On the other hand, when an argon matrix containing diborane and sodium was irradiated with UV light at 4.2 K, an electron on the sodium atom was transferred to diborane and the ESR spectrum of diborane anion radicals was observed.[3] Kasai *et al.*[3] interpreted the anion radical as having a bridging structure with an unpaired electron in a b_{3g} orbital given by an antibonding combination of the 2p orbitals of the two borons perpendicular to the plane defined by the four terminal hydrogen atoms. However, Claxton *et al.*[4] recently proposed, on the basis of the results of *ab initio* UHF calculations, that the anion radical favors a staggered structure rather than the bridged D_{2h} structure of the parent molecule. They also said that the neutral diboranyl radical is presumably formed by proton loss from the cation radical of diborane, $B_2H_6^+$.

Several kinds of radicals have been revealed by ESR spectroscopy to be produced upon the irradiation of specimens adsorbed on the surfaces of solids; for example, cation radicals of benzene[5] and toluene,[6] anion radicals of O_2, CO_2, SO_2 and TCNE,[7] and neutral radicals from methane[8] and ethane[9] were observed on the surface of silica gel.

Thus, it may be of interest to investigate what kind of radical species is produced by the irradiation of diborane in such an adsorbed state.

Diborane, B_2H_6, and deuterodiborane, B_2D_6, were prepared by a method described elsewhere.[1] The silica gel, alumina, magnesium oxide, mordenite (HZ type), and zeolite (MgY type) used as the adsorbents for diborane were outgassed in a vaccum of 10^{-5} Torr at 550 °C for *ca.* 30 hr, while the adamantane was evacuated at room temperature for 1 hr. Diborane gas was introduced into ESR sample tubes containing these adsorbents through breakable seals at room temperature, except for the case of pre-irradiation, where the gas was introduced at 77 K. The irradiation with γ-rays was carried out at 77 K for 2 hr at a does rate of *ca.* 6×10^5 rad/hr from a ^{60}Co source, and the ESR spectra were measured at 77 K with an ESR spectrometer described elsewhere.[1]

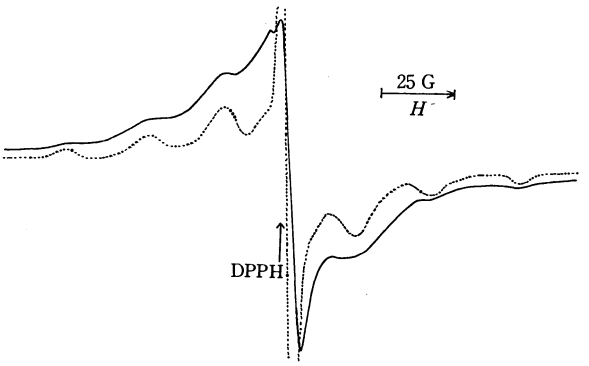

Fig. 1. ESR spectra of anion radicals of B_2H_6 (solid line) and B_2D_6 (dotted line) adsorbed on silica gel.

The ESR spectrum observed after the irradiation of diborane adsorbed on silica gel is shown in Fig. 1. The spectrum consists of a broad spectrum with seven peaks attributable to two equivalent boron atoms ($I=^3/_2$) and a spectrum of trapped electrons in the central region of the spectrum. These seven peaks could be explicitly distinguished when deuterodiborane was used, as is shown by a dotted line in Fig. 1. These observed spectra, except for that of the trapped electron, are very similar to those of the diborane anion radical, $B_2H_6^-$, and the deuterated anion radical, $B_2D_6^-$, observed in an argon matrix at 4.2 K,[3] while they are quite different from those of diboranyl radicals observed in the polycrystalline states of diborane and deuterodiborane.[1] No transformation of the observed spectrum to that of diboranyl radicals was detected during storage at 77 K under room light for several days.

In order to determine whether the cation radical or the anion radical was produced, the effect of the pre-irradiation on the radical production was investigated. The ESR spectrum of electrons trapped by defects in silica gel was observed with silica gel irradiated with γ-rays at 77 K. When diborane gas was adsorbed on the pre-irradiated silica gel, the intensity of the ESR spectral line of the trapped electrons was reduced; the same spectrum with seven peaks as that observed in the case of the post-irradiation appeared simultaneously. This observation may mean that the trapped electron on the surface silica gel is transferred to the diborane, which is well-known to be an electron-deficient molecule. The formation of the anion radical in the adsorbed state may be interpreted as arising from the electron transfer from the adsorbent to the diborane, as in the cases of the anion radicals of O_2, CO_2, SO_2, and TCNE adsorbed on silica gel.[7] Accordingly, it may be concluded that the anion radical was produced by the irradiation of diborane adsorbed on silica gel and by the adsorption of diborane

on pre-irradiated silica gel.

The ESR spectra of the anion radical of diborane in the adsorbed state were examined not only with adsorbents of metal oxides, alumina, magnesium oxide, mordenite, and zeolite, but also with the recently discovered organic adsorbent, adamantane.[10] All of the observed spectra of the anion radicals were interpreted by analogy with the analysis of the spectrum by Kasai and Mclood.[3] The parallel components of the hyperfine couling of the two boron atoms were easily determined from the spectra observed with deuterodiborane, whereas the perpendicular components for the two boron atoms and the proton coupling were not explicitly evaluated from the observed spectra. Accordingly, the parallel components for the boron atoms, $A_{//}(^{11}B)$, observed with different kinds of adsorbents were evaluated to be as follows:

Silica gel	25.0 *G*	Mordenite	25.4 *G*
Alumina	25.4 *G*	Zeolite	24.6 *G*
Magnesium oxide	24.7 *G*	Adamantane	19.0 *G*

Except for the case of adamantane, the parameters are in close agreement with that reported previously.[3] The value observed with adamantane is considerably smaller than those with the other adsorbents. For the anion radical in the argon matrix at 4.2 K, Kasai and Mclood.[3] gave these ESR parameters: $A_{//}$ (^{11}B)$=24.5\pm0.5$ *G*, $A_{\perp}$ (^{11}B)$=2.5$ *G* and $A(H)\leq 15$ *G*. Claxton *et al.*,[4] however, estimated the coupling of six hydrogens to be $A_{//}(H)=A_{\perp}(H)=7$ *G* by the use of a curve resolver. On the basis of a comparison between the estimated values of $a(^{11}B)$ and $a(H)$ and the results of their *ab initio* calculation, Claxton *et al.*[4] concluded that the anion radical of diborane has not a bridge structure, but a staggered conformation. Thus, the present authors attempted to observe the proton coupling directly by means of ENDOR.

The ENDOR spectra of the anion radical adsorbed on silica gel and adamantane were measured at 77 K with a JEOL type ES-EDX-1 spectrometer. Unfortunately, no ENDOR signal except for the ENDOR signals due to the electron trapped in the cavity of adamantane[11] was observed, in spite of careful measurements. Therefore, the attempt to check experimentally the proposed staggered conformation of the diborane anion radicals from proton couplings was unsuccessful, and the discussion of the structure of the anion radicals in the adsorbed state could not be advanced beyond the staggered conformation discussed by Claxton *et al.*[4] However, the small coupling of $A_{//}(^{11}B)$ observed with adamantane may suggest that some distortion of the staggered conformation arises from the existence of the radical in the cavity of a molecule of adamantane.

It may be mentioned that the method using an adsorbent is very much more convenient for producing the anion radicals of diborane compared with that using an inert gas matrix containing sodium at 4.2 K.[3]

The authors would like to express their gratitude to Professor Kazuhiko Ishizu of Ehime University for measuring the ENDOR spectra and to Professor Junkichi Sohma of Hokkaido University for his valuable discussions.

Effect of Inorganic Electrolytes on the Cloud Point of Polyoxyethylene Dodecyl Ether

Fumikatsu TOKIWA and Tadao MATSUMOTO

Research Laboratories, Kao Soap Company, 2-1-3 Bunka, Sumida-ku, Tokyo 131

(Received January 21, 1975)

Synopsis. The cloud points of polyoxyethylene dodecyl ether in the presence of different types of inorganic electrolytes have been determined. The cloud points can be expressed by the empirical equation: $(C.P.)_s/(C.P.)_0=1+A\sqrt{C_s}+BC_s$ where $(C.P.)_s$ and $(C.P.)_0$ are the cloud points with and without an electrolyte, respectively, C_s is the electrolyte concentration, and A and B are constants.

When an aqueous solution of a polyoxyethylene-type nonionic surfactant $RO(CH_2CH_2O)_pH$ with a relatively small number of p is heated, it becomes cloudy reversibly at the temperature of incipient phase separation called the cloud point. The cloud point is rather insensitive to the concentration of the surfactant itself, but is highly dependent on the kind and the concentration of an added electrolyte.[1,2] Most of inorganic electrolytes depress the cloud point of a nonionic surfactant owing to their salt-out effect, while some electrolytes such as nitrates, iodides and thiocyanates, raise the cloud point. In addition, the cloud point is in general more influenced by the anions of added electrolytes than by the cations. However, the nature of the interaction of a nonionic surfactant with an added electrolyte (or the interaction through a change in the structure of water by an added electrolyte) is not necessarily well understood.

This note describes a systematic study on the effect of various types of inorganic electrolytes on the cloud point of polyoxyethylene dodecyl ether (abbreviated to C_{12}-POE) and proposes an empirical equation to express the cloud point as a function of an added electrolyte.

Experimental

The nonionic surfactant C_{12}POE was prepared from dodecyl alcohol of high purity by addition of ethylene oxide and purified by molecular distillation. The average number of oxyethylene units per molecule for the purified sample was found to be 6.3 from its hydroxyl value. The inorganic electrolytes examined were of guaranteed reagent grade and used without further purification.

Cloud points were photometrically measured of 2.0% C_{12}POE solutions containing electrolytes in the concentration range of 0.01—0.5 m with the apparatus shown in Fig. 1a. The transmittance of light through a sample solution and the temperature of this solution were plotted on a X–Y recorder connected with the apparatus. The solution was heated or cooled at a rate of 0.4 °C per minute across the cloud point. Fig. 1b shows the transmittance *vs.* temperature curves for the 2.0% C_{12}POE solution in the absence of an electrolyte, which were obtained by heating from below the cloud point and by cooling from above; the two curves are superimposed. The cloud point was determined as a temperature at 50% transmittance. Similar curves were obtained for other sample solutions containing electrolytes. The data were reproducible within an accuracy of ±0.05 °C.

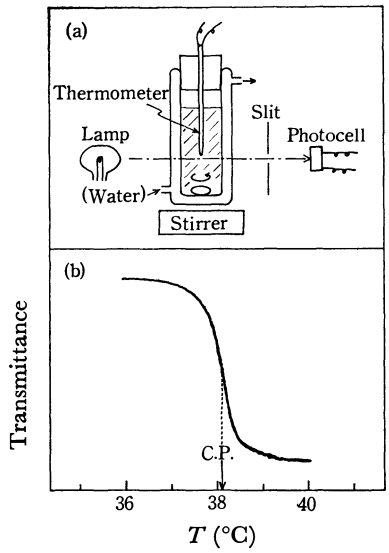

Fig. 1. (a) The apparatus used for measurement of cloud points. (b) An example of transmittance *vs.* temperature curves.

Results and Discussion

Figure 2 shows some typical examples of the effects of added electrolytes on the cloud point of the 2.0% C_{12}-POE solution. The cloud point much depends on the species of anions than on the species of cations.

Here, the present authors propose the following empirical equation, which was arrived at by analysis of the data, to describe systematically the relation of the cloud

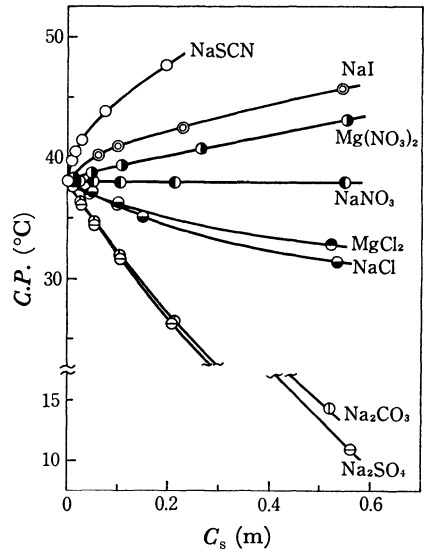

Fig. 2. Some examples of the effects of added electrolytes on the cloud point of 2.0% C_{12}POE solution.

point with the concentration of an added electrolyte.

$$(C.P.)_s/(C.P.)_0 \equiv \theta = 1 + A\sqrt{C_s} + BC_s \quad (1)$$

or $$(\theta-1)/\sqrt{C_s} = A + B\sqrt{C_s} \quad (2)$$

where $(C.P.)_s$ and $(C.P.)_0$ are the cloud points expressed, by absolute temperature with and without an electrolyte respectively, C_s is the electrolyte concentration in molality, and A and B are constants. If the quantity of $(\theta-1)/\sqrt{C_s}$ is plotted against $\sqrt{C_s}$, according to Eq. (2), a straight line is obtained for each electrolyte in the range of concentrations lower than about 0.25 m, as shown in Fig. 3. With chlorides and nitrates, linear relations are maintained up to a concentration of 0.5 m. The values of the constants A and B derived from the intercept and the slope of each straight line are summarized in Table 1.

According to the magnitudes of A and B, the electrolytes examined may be classified into the following two types. *Type I—carbonates, sulfates, and chlorides.* These electrolytes have negative values of A and B, as given in Table 1, and only small differences in A are seen among the electrolytes. The constant B varies, depending on the species of anions rather than cations. *Type II—nitrates, iodides, and thiocyanates.* The values of A for these electrolytes are positive, or negative but very close to zero. The values of B are slightly positive.

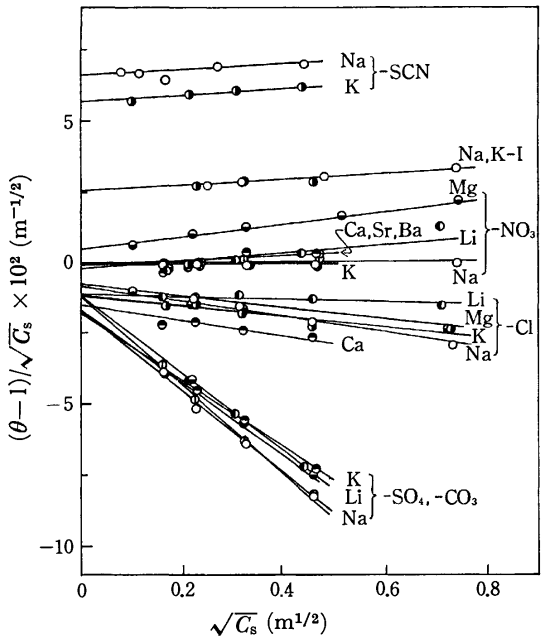

Fig. 3. Plots of $(\theta-1)/\sqrt{C_s}$ *vs.* $\sqrt{C_s}$ for various electrolytes.

Table 1. Values of A and B for various electroytes

Type I			Type II		
Electrolyte	$A\times10^2$ (m$^{-1/2}$)	$B\times10^2$ (m^{-1})	Electrolyte	$A\times10^2$ (m$^{-1/2}$)	$B\times10^2$ (m^{-1})
Na_2CO_3	−1.2	−16.2	$LiNO_3$	−0.2	1.3
K_2CO_3	−1.2	−13.5	$NaNO_3$	0	0.1
Li_2SO_4	−1.7	−12.9	KNO_3	0.1	0.1
Na_2SO_4	−1.7	−14.3	$Mg(NO_3)_2$	0.5	2.1
K_2SO_4	−1.8	−11.8	$Ca(NO_3)_2$	−0.1	0.9
LiCl	−1.1	−0.4	$Sr(NO_3)_2$	−0.1	0.9
NaCl	−0.9	−2.6	$Ba(NO_3)_2$	−0.1	0.9
KCl	−1.2	−1.7	NaI	2.6	1.0
$MgCl_2$	−0.7	−1.8	KI	2.6	1.0
$CaCl_2$	−1.5	−2.7	NaSCN	6.6	1.1
			KSCN	5.7	1.1

The solubility of nonionic surfactants in solutions of electrolytes may be discussed in terms of two factors: i) hydration of the ions, with a consequent change in the water structure nearby, which affects the affinity of the water molecules to the ether oxygens of the surfactant, and ii) binding of the ions or salts of polyvalent metals to the ether oxygens *via* cation complexation at high concentrations, resulting in an increase in solubility of the surfactant.

The structure of water in electrolyte solutions has been discussed from viscosity[3,4] and NMR[5] data with the conclusion that the effectiveness in destrusturing water around anions is in the order of $I^->NO_3^->Cl^->SO_4^{2-}>CO_3^{2-}$, in which CO_3^{2-} and SO_4^{2-} ions are rather structure-forming. Their conclusion is in accordance with the magnitude of B shown in Table 1. These results would suggest that the constant B has some close relation to the extent of destructure of water by added electrolytes, although differences in B between iodides and nitrates, and between sulfates and carbonates, are not so distinctive. Probably, added electrolytes, especially their anions, would affect the solubility of the nonionic surfactant through changes in the structure of water around them, depending on their structure-breaking or -forming ability.

The difference in A between electrolytes of the types I and II cannot be explained at the present stage: the constant A might be concerned with a factor not being related to the structure of water, presumably, with an interaction of ions (or salts) with the ether oxygens of the nonionic surfactant. Interpretation of the constant A requires additional information.

According to current views, thiocyanate ions are destructive of water,[6,7] and unassociated water hydrates nonionic surfactant molecules better than hydrogen-bonded, associated water, which results in raising the cloud point. Therefore, the positive values of B for thiocyanates could also be ascribed to their destruction of water structure. The large values of A are to be noted, which seem to be related to an increase in cloud point although the detailed mechanism is not clear.

The behavior of cations in nonionic surfactant solutions may be discussed in terms of complex formation.[8] For example, differences in A and B between $NaNO_3$ and $Mg(NO_3)_2$ could be explained in part by the complex formation of Mg^{2+} ions with the ether linkages of the surfactant.

A Gel-state Liquid-membrane Iodide-ion Electrode

Yoshio SHIJO

Department of Industrial Chemistry, Faculty of Engineering, University of Utsunomiya, Ishii-machi, Utsunomiya 321-31

(Received April 19, 1974)

Synopsis. A new liquid-membrane iodide-ion electrode has been developed. The liquid membrane of the electrode consists of poly vinyl chloride gel containing a nitrobenzene solution of tridodecylethylammonium iodide as an ion exchanger, a lead wire is inserted directly into the gel. The properties of the electrode, such as the response time, the effect of the temperature, the reproducibility of the preparation, and the selectivity, have been determined.

Recently, a number of studies of the simplification of the construction of liquid-membrane ion electrodes have been carried out. James *et al.*[1] developed coated-wire ion-selective electrodes with a fine platinum wire covered with poly vinyl chloride film containing an ion-association complex. Ruzicka and Rald[2] developed a simple liquid-state ion electrode, named selectrode, consisting of a graphite rod impregnated with the liquid-membrane, it was put in a Teflon tube. A stainless steel wire screwed into the graphite rod served as a lead to an electronic voltmeter. We prepared a simple liquid-membrane ion electrode consisting of a gel-state liquid-membrane and a lead wire inserted directly into the gel phase. Further, the effects of various conditions on the properties of the gel-state liquid-membrane were examined.

Experimental

A Hitachi-Horiba Model F-7 SS pH meter was used for the potential measurements. The tridodecylethylammonium bromide (TDEA) was prepared according to the method of a previous paper.[3]

The electrode body consisted of a glass tube, 8—10 mm in diameter and fitted with rubber and cork stoppers, as is shown in Fig. 1. A stainless steel wire 2 mm in diameter inserted into the gel membrane served as a lead to an electronic voltmeter. The ion-association complex solution was prepared by repeatedly shaking a nitrobenzene solution of 1×10^{-4} M TDEA with an aqueous solution of 1×10^{-3} M potassium iodide. The gel-state liquid-membrane was prepared by the following procedure. A 5 ml portion of the ion-associate solution was mixed with 0.9 g of poly vinyl chloride (PVC) in a test tube. The mixture was heated to 100 °C in an oil bath and stirred until the PVC has been completely dissolved. This solution was then poured into the B part of the electrode body and gelatinized by cooling to room temperature. The gel-state liquid-membrane electrode was preserved over nitrobenzene in a bottle fitted with a cork stopper. All the potentials were measured against a saturated calomel electrode as the reference electrode at 25.0±0.1 °C. The gel-state liquid-membrane electrode was dipped in the ion-associate solution for 1 s before use.

Results and Discussion

The variation in the potential of the gel-state liquid-membrane electrode with the concentration of the iodide ions is shown in Fig. 2. The calibration curve is linear down to 1×10^{-5} M iodide. The response of this gel-state liquid-membrane electrode was fairly fast and attained an equilibrium potential after a 2-min dipping of the electrode into the test iodide solution beyond 1×10^{-5} M. Below 1×10^{-6} M iodide, however, the equilibrium potential was attained only after 10 min. The effects of the concentration of the ion associate in nitrobenzene on the potential were examined. Four electrodes with varying concentrations of TDEA in nitrobenzene were made by the above-mentioned procedure. The variation in the potential with the concentration of iodide for each electrode is shown in Fig. 3. A better linearity of the potential variation and a higher sensitivity were obtained for the electrode with the membrane of the concentration of the ion associate of 1×10^{-4} or 7×10^{-5} M.

The surface of the gel-state liquid-membrane gradually became softer with the rise in the temperature and was

Table 1. Summary of the properties of iodide-responsive electrodes

Electrode	Ion exchanger	Slope (mV/log a)	Concn range of linear response	Selectivity ratios (NO^-_3)
Gel state liquid membrane electrode	Tridodecylethylammonium salt	56.0	10^{-1}—10^{-5}	0.058
Coarted wire[1] electrode	Tricaprylmethylammonium salt	60.0	10^{-1}—10^{-4}	0.11
Liquid membrane[5] electrode	Tricaprylmethylammonium salt	59.0	10^{-1}—10^{-3}	0.19

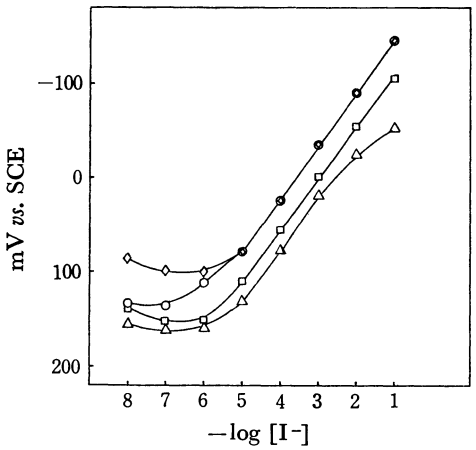

Fig. 3. Effect of concentration of the ion associate in nitrobenzene on potentials
Ion associate: △; 1×10^{-5} M, □; 7×10^{-5} M, ○; 1×10^{-4} M, ◇; 1×10^{-3} M.

deformed a little beyond 40 °C. The variation in the potential was small below 30 °C, but the potential dropped suddenly above 35 °C. Therefore, the temperature of the test solution must be kept constant below 30 °C. The pH variation in the test solution showed that the potential did not change over the pH range of 3—9. The reproducibility of the preparation of the electrode was also examined. Five pieces of electrodes were made by the above-mentioned procedure. The potentials of the electrodes for the same concentration of the iodide solution were fairly different, but the slopes of the potential variation for all the electrodes were nearly the same in the concentration range of iodide of 1×10^{-5}—1×10^{-1} M.

The gel-state liquid-membrane deteriorated on exposure to air because of the evaporation of the solvent. Therefore, the electrode should be stored over nitrobenzene in a bottle fitted with a cork stopper. If the electrode was dipped in a 1×10^{-4} M ion-associate solution before employment, the electrode could be used for two months. The influence of foreign anions on the determination of iodide was examined by adding various salts to the 1×10^{-4} M iodide solution. The selectivity ratios, as calculated by the same procedure as that of Rechnitz,[4] were 56 for perchlorate, 2.8 for thiocyanate, 0.058 for nitrate, 0.013 for cyanide, and 0.0047 for bromide.

The properties of the gel-state liquid-membrane electrode are compared with those of other, similar iodide electrodes in Table 1.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48 (5), 1649—1650 (1975)

The Magnetic Susceptibility of Two Coupled Dimers Consisting of S=1/2 Spins

Shuji EMORI, Tadashi TOKII, and Yoneichiro MUTO

Department of Chemistry, Faculty of Science and Engineering, Saga University, Honjo-machi, Saga 840

(Received September 2, 1974)

Synopsis. Tetramers consisting of two coupled dimers were classified as (a) linear, (b) cyclic, (c) rhombic, or (d) tetrahedral. The magnetic susceptibility for each tetramer model consisting of S=1/2 spins was obtained as an analytical equation. For the linear tetramer, the susceptibility equation was calculated numerically and compared with the observed values.

It has been found that many compounds have spin-spin interactions among their magnetic ions, so they may be regarded magnetically as composed of clusters such as a dimer and a trimer. Some of them may also have interactions among such clusters.[1-6] These interactions increasing to a certain extent, the compounds may be regarded as composed of larger complicated clusters. While such interactions are weak, the effects can be taken into consideration approximately by modifying the equation of the original cluster—for example, as the magnetic susceptibility of the modified dimer model.[7] Hatfield and Inman, Jr., tried to obtain an exact expression[5] of a tetramer consisting of two coupled dimers, the Hamiltonian of which was:

$$\mathcal{H} = -2J(S_1S_2+S_3S_4)-2J'S_2S_3 -2J''(S_1S_3+S_2S_4)-2J'''S_1S_4 \quad (1)$$

where the S_i's are spin operators, J is the exchange integral of intradimer interaction, and J', J'', and J''' are the exchange integrals of the interdimer interactions. The magnetic expression thus obtained, however, was not completely an analytical equation because of the complexity of the problem.

For a tetramer which has interaction between only the adjacent ends of two dimer units, the problem has been simplified; the Hamiltonian appropriate for this problem (Fig. 1a) is:

$$\mathcal{H} = -2J(S_1S_2+S_3S_4+\gamma S_2S_3) \quad (2)$$

Here γ is the ratio of the exchange integrals of the interdimer to the intradimer interactions. This Hamiltonian is, of course, a special case of the first (Eq. 1). Using

TABLE 1. NON-ZERO MATRIX ELEMENTS

$$(\phi_1\mathcal{H}\phi_1) = (\phi_{10}\mathcal{H}\phi_{10}) = -J\left(1+\frac{\gamma}{2}\right)$$
$$(\phi_2\mathcal{H}\phi_2) = (\phi_3\mathcal{H}\phi_3) = (\phi_7\mathcal{H}\phi_7) = (\phi_8\mathcal{H}\phi_8) = (\phi_9\mathcal{H}\phi_9) = (\phi_{12}\mathcal{H}\phi_{12}) = (\phi_{13}\mathcal{H}\phi_{13}) = (\phi_{16}\mathcal{H}\phi_{16}) = -J\gamma/2$$
$$(\phi_4\mathcal{H}\phi_4) = (\phi_5\mathcal{H}\phi_5) = J\left(1-\frac{\gamma}{2}\right)$$
$$(\phi_6\mathcal{H}\phi_6) = (\phi_{11}\mathcal{H}\phi_{11}) = (\phi_{14}\mathcal{H}\phi_{14}) = (\phi_{15}\mathcal{H}\phi_{15}) = 3J\gamma/2$$
$$(\phi_2\mathcal{H}\phi_3) = (\phi_4\mathcal{H}\phi_7) = (\phi_5\mathcal{H}\phi_7) = (\phi_6\mathcal{H}\phi_7) = (\phi_8\mathcal{H}\phi_9) = (\phi_{11}\mathcal{H}\phi_{12}) = (\phi_{13}\mathcal{H}\phi_{14}) = (\phi_{15}\mathcal{H}\phi_{16}) = -J$$
$$(\phi_4\mathcal{H}\phi_6) = (\phi_5\mathcal{H}\phi_6) = J$$

the same spin functions (products of the eigenfunctions of a dimer system consisting of S=1/2 spins) as in the literature,[5] the elements of an energy matrix are found to be as in Table 1. Diagonalizing this matrix, 6 kinds of eigenvalues (1 quintet, 3 triplets, and 2 singlets) are obtained as:

$$J\left(-1-\frac{\gamma}{2}\right) \quad \text{for S = 2}$$

$$J\left(1-\frac{\gamma}{2}\right),\ J\left(\frac{\gamma}{2}+\sqrt{1+\gamma^2}\right),\ J\left(\frac{\gamma}{2}-\sqrt{1+\gamma^2}\right) \quad \text{for S = 1}$$

$$J\left(1+\frac{\gamma}{2}+\sqrt{4-2\gamma+\gamma^2}\right),\ J\left(1+\frac{\gamma}{2}-\sqrt{4-2\gamma+\gamma^2}\right) \quad \text{for S = 0}$$

The Van Vleck susceptibility expression yields:

$$\chi = \frac{Ng^2\beta^2}{2kT}\frac{\begin{array}{l}5\exp\{J(2+\gamma)/kT\}+\exp(J\gamma/kT)\\+\exp\{J(1+\sqrt{1+\gamma^2})/kT\}\\+\exp\{J(1-\sqrt{1+\gamma^2})/kT\}\end{array}}{\begin{array}{l}5\exp\{J(2+\gamma)/kT\}+3\exp(J\gamma/kT)\\+3\exp\{J(1+\sqrt{1+\gamma^2})/kT\}\\+3\exp\{J(1-\sqrt{1+\gamma^2})/kT\}\\+2\cosh(J\sqrt{4-2\gamma+\gamma^2}/kT)\end{array}} \quad (3)$$

where differences in g-value among the 4 spins are neglected.

Figure 2 shows the results of the numerical calculations of the susceptibility for an antiferromagnetically interacting tetramer with γ=0—2. In the case of γ=0, this model represents a dimer model. If γ increases infinitely, the model tends to indicate an admixture of a dimer and two monomers. Some of the copper(II) alkanoate complexes with *N*-alkylsalicylideneimines (HSal=N–R) have been postulated to have such a linear tetramer structure.[8] The observed susceptibility for the $Cu_2(Sal{=}N{-}CH_3)(OH)(C_2H_5COO)_2$ compound does not show a maximum; perhaps it appears at lower temperatures. However, the differences among various models are already sufficiently clear in the lower part of

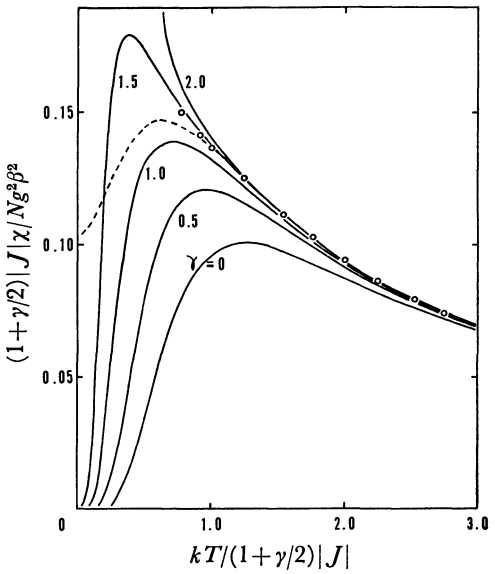

Fig. 2. Magnetic susceptibility of a linear tetramer with $\gamma=0-2$.
Broken curve is drawn for a one-dimensional Heisenberg model. The observed values of $Cu_2(Sal{=}N{-}CH_3)(OH)(C_2H_5COO)_2$ are plotted for the choice of the parameters $J(1+\gamma/2)/k=-100$ K, $g=2.17$, and $N\alpha=60\times10^{-6}$ emu/mol.

this experimental temperature range (77—300 K). The observed values agree well with the equation of a linear tetramer model, but not with that of a dimer model ($\gamma=0$) or a one-dimensional Heisenberg model, the curve of which is extrapolated to a higher temperature than in the literature.[9]

If a linear tetramer has an interaction between the remaining ends as well, a cyclic tetramer (Fig. 1b) will be formed. The Hamiltonian for this problem is:

$$\mathcal{H}=-2J\left(S_1S_2+S_3S_4+\frac{\gamma}{2}S_2S_3+\frac{\gamma}{2}S_1S_4\right) \tag{4}$$

The equation of the magnetic susceptibility can be obtained in a similar manner as for a linear tetramer:

$$\chi=\frac{Ng^2\beta^2}{2kT}\frac{\begin{array}{l}5\exp\{J(2+\gamma)/kT\}+1\\+\exp(J\gamma/kT)+\exp(2J/kT)\end{array}}{\begin{array}{l}5\exp\{J(2+\gamma)/kT\}+3\\+3\exp(J\gamma/kT)+3\exp(2J/kT)\\+2\cosh(J\sqrt{4-2\gamma+\gamma^2}/kT)\end{array}} \tag{5}$$

Considering a diagonal interaction also in a cyclic tetramer, the problem varies to that of a pseudo-rhombic tetramer (Fig. 1c), the Hamiltonian of which is:

$$\mathcal{H}=-2J\left(S_1S_2+S_3S_4+\frac{\gamma}{3}S_2S_3+\frac{\gamma}{3}S_2S_4+\frac{\gamma}{3}S_1S_4\right) \tag{6}$$

The susceptibility equation obtained in a manner similar to that above is:

$$\chi=\frac{Ng^2\beta^2}{2kT}\frac{\begin{array}{l}5\exp\{J(2+\gamma)/kT\}+\exp(J\gamma/3kT)\\+2\exp\left\{J\left(1+\frac{\gamma}{3}\right)/kT\right\}\\\times\cosh\left(J\sqrt{1-\frac{2}{3}\gamma+\frac{2}{9}\gamma^2}/kT\right)\end{array}}{\begin{array}{l}5\exp\{J(2+\gamma)/kT\}+3\exp(J\gamma/3kT)\\+6\exp\left\{J\left(1+\frac{\gamma}{3}\right)/kT\right\}\\\times\cosh\left(J\sqrt{1-\frac{2}{3}\gamma+\frac{2}{9}\gamma^2}/kT\right)\\+2\cosh\left(J\sqrt{4-2\gamma+\frac{1}{3}\gamma^2}/kT\right)\end{array}} \tag{7}$$

If the ends of a dimer unit interact with either end of the other dimer, the resulting molecule is a pseudo-tetrahedral tetramer (Fig. 1d) with this Hamiltonian:

$$\mathcal{H}=-2J\left(S_1S_2+S_3S_4+\frac{\gamma}{4}S_1S_3+\frac{\gamma}{4}S_2S_4+\frac{\gamma}{4}S_1S_4+\frac{\gamma}{4}S_2S_3\right) \tag{8}$$

The susceptibility equation thus obtained is:

$$\chi=\frac{Ng^2\beta^2}{2kT}\frac{\begin{array}{l}5\exp\left\{J\left(1+\frac{\gamma}{2}\right)/kT\right\}\\+2\exp(-J/kT)+\exp\left\{J\left(1-\frac{\gamma}{2}\right)/kT\right\}\end{array}}{\begin{array}{l}5\exp\left\{J\left(1+\frac{\gamma}{2}\right)/kT\right\}\\+6\exp(-J/kT)+3\exp\left\{J\left(1-\frac{\gamma}{2}\right)/kT\right\}\\+\exp\{J(1-\gamma)/kT\}+\exp(-3J/kT)\end{array}} \tag{9}$$

The Back-extraction Behavior of Chelate Compounds. II.* Some Aspects of the Secondary Dithizonate of Copper

Takaharu HONJO, Toshiyuki UNEMOTO, and Toshiyasu KIBA

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa, Ishikawa 920

(Received November 18, 1974)

Synopsis. The behavior of secondary copper dithizonate in carbon tetrachloride, chloroform, 1,2-dichloroethane, benzene, monochlorobenzene, *o*-dichlorobenzene, and nitrobenzene has been investigated by a kinetic study of the back-extraction of the copper ion in order to clarify the extraction mechanism and to ascertain the chemical form of this chelate.

Dithizone (diphenylthiocarbazone, H_2Dz) forms an extractable, colored chelate with about twenty metals by replacing one or both hydrogen atoms, yielding the primary and the secondary dithizonate.[1,2] The primary dithizonate of copper ($Cu^{II}(HDz)_2$ type)[3] is formed in an acidic solution and appears as red-purple, while a secondary complex of a yellow-brown color ($Cu^{II}Dz$,[3] $Cu^{I}(HDz)$,[4,6] or $Cu^{II}_2(Dz)_2$[5] type) is formed in a basic solution or in the presence of a deficit of dithizone. The extraction mechanism and the structure of the secondary dithizonate of copper have not yet been fully elucidated.[1-6]

Experimental

The secondary dithizonate of copper in an organic solvent containing no free dithizone was prepared around pH 11 under the so-called substoichiometric conditions by adding an excess of copper ions over the equivalent amount of dithizone. After the phase separation, the organic phase was shaken with the same volume of an acidic aqueous solution adjusted to a desired pH with 0.1 M acetic acid. The aqueous phase was separated from the organic phase by centrifugation, and then the pH was checked again. The concentration of copper ions back-extracted into the aqueous solution was determined by atomic absorption spectrophotometry. The amount of the initial secondary complex was also determined by atomic absorption spectrophotometry after all the copper has been extracted into 6 M hydrochloric acid. All the extractions were carried out in a thermostatic room at 20 °C.

Results and Discussion

The change in the absorption spectra in the course of the back-extraction of the secondary copper dithizonate in carbon tetrachloride at pH 3.0 was determined; the results are shown in Fig. 1(a), in which No. 1 is the spectrum before the back-extraction. The spectra gradually change to No. 2, that of the primary copper dithizonate after a few hours' shaking; there are two isosbestic points—at 497 and 615 nm. The spectrum of dithizone in carbon tetrachloride is also shown in Fig. 1(a) (No. 3). Moreover, an extraction reaction between the primary complex in carbon tetrachloride and copper ions took place at pH 3.0; the change in the absorption spectrum of the secondary and primary complexes with the shaking time were determined at 450 nm and 550 nm respectively. The results are shown in Fig. 1(b). From these results, it is clear that the extraction equilibrium between the secondary copper dithizonate and the primary copper dithizonate in carbon tetrachloride is reversible under the present conditions:

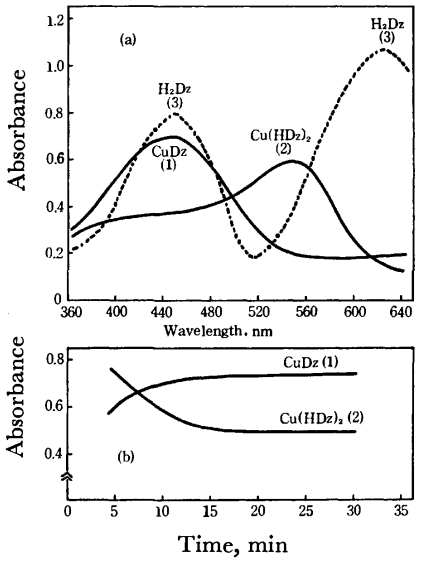

Fig. 1. (a) The change of the absorption spectra of copper dithizonate in carbon tetrachloride with the formation of $Cu(HDz)_2$ from CuDz by back-extraction at pH 3.0
(1) $(CuDz)_{initial}=3.3\times10^{-5}$ M (2) $Cu(HDz)_2=2.5\times10^{-5}$ M (3) $H_2Dz=4.0\times10^{-5}$ M
(b) The change of the absorbance of CuDz at 450 nm and $Cu(HDz)_2$ at 550 nm in carbon tetrachloride by the formation of CuDz from $Cu(HDz)_2$ and Cu^{2+} at pH 3.0
$(Cu(HDz)_2)_{initial}=5\times10^{-5}$ M, $(Cu^{2+})_{initial}=5\times10^{-5}$ M
(1) CuDz (2) $Cu(HDz)_2$

$$2CuDz + 2H^+ \rightleftarrows Cu(HDz)_2 + Cu^{2+} \quad (1)$$

Fig. 2(a) shows that the amount of copper ions increased in an aqueous phase with the shaking time in the relation of a hyperbolic curve, when the reaction was performed in carbon tetrachloride. The following two relations have been found to hold from the results after the determination of copper ions.

$$(Cu(HDz)_2)_0 = (Cu^{2+}) \quad (2)$$

For the remaining secondary dithizonate,

$$(CuDz)_0 = (CuDz)_{initial} - (Cu(HDz)_2)_0 - (Cu^{2+}) = (CuDz)_{initial} - 2(Cu^{2+}) \quad (3)$$

* T. Honjo, K. Ameno, M. Horiuchi, and T. Kiba, This Bulletin, **47**, 1799 (1974), Part I.

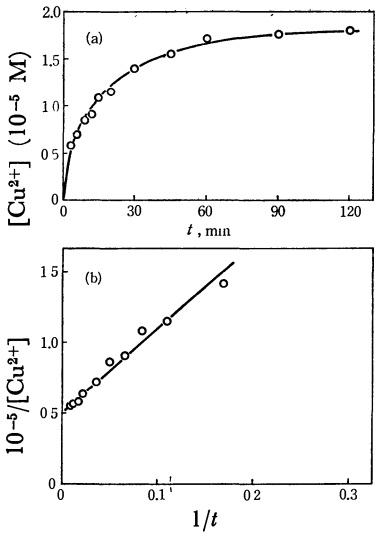

Fig. 2. The effect of the reaction time on stripping of Cu^{2+} from CuDz in carbon tetrachloride at pH 2.93. $(CuDz)_{initial}=8.6\times10^{-5}$ M

where ( ) and ( )$_0$ designate the concentration of chemical species in the aqueous and the organic phase respectively. The term of $(CuDz)_{initial}$ indicates the concentration of the secondary dithizonate at the start of the reaction. The kinetic study of the reaction shows that the increasing rate of the copper ion in the aqueous phase is the pseudo-second order reaction.

$$d(Cu^{2+})/dt = k(CuDz)_0^2 \quad (4)$$

$$d(Cu^{2+})/dt = k\{(CuDz)_{initial}-2(Cu^{2+})\}^2 \quad (5)$$

$$1/(Cu^{2+}) = 1/\{k(CuDz)_{initial}^2 t\} + 2/(CuDz)_{initial} \quad (6)$$

This equation shows that the reciprocal of the concentration of the copper ion is proportional to the reciprocal of the reaction time, that is, the shaking time, t. As is shown in Fig. 2(b), the $1/(Cu^{2+})$ *vs.* $1/t$ plot is linear at pH 2.93. This fact indicates that the treatment of the back-extraction mechanism of the secondary copper dithizonate in carbon tetrachloride is valid. The back-extraction of the secondary copper dithizonate in other solvents, such as 1,2-dichloroethane, benzene, monochlorobenzene, *o*-dichlorobenzene, and nitrobenzene, was also investigated by shaking a solution of them with an aqueous solution of pH 2.90—2.95. In the case of the complex in a chloroform solution, the back-extraction at pH 1.46 was examined because a distinct back-extraction reaction in the pH region mentioned above was observed. The wavelengths of the maximum absorptions of the secondary dithizonate in the seven solvents against the dielectric constants of the solvents are given in Table 1, together with those of dithizone. The plots of $1/Cu^{2+}$ *vs.* $1/t$ obtained with these solvents are shown in Fig. 3. This shows that the primary complex which had been formed by Reaction (1) acted with a proton to effect the following reaction:

$$Cu(HDz)_2 + 2H^+ \rightleftharpoons 2H_2Dz + Cu^{2+} \quad (7)$$

Dithizone was released as a matter of course. The solvents showing the break in the line have relatively high dielectric constants. This fact is compatible with the general rule that the polar solvents have stronger effects on the solutes than the non-polar solvents. It

Table 1. The dielectric constant, ε, of the organic solvents and the wavelength of the absorption maximum, λ_{max}, of the secondary copper dithizonate and dithizone in these solvents

Solvent	ε	λ_{max}, nm	
		CuDz	H_2Dz
Carbon tetrachloride	2.24	450	450 627
Chloroform	4.81	448	441 610
1,2-Dichloroethane	10.36	450	450 620
Benzene	2.28	454	454 627
Monochlorobenzene	5.62	454	457 629
o-Dichlorobenzene	9.93	458	457 629
Nitrobenzene	34.82	448	441 610

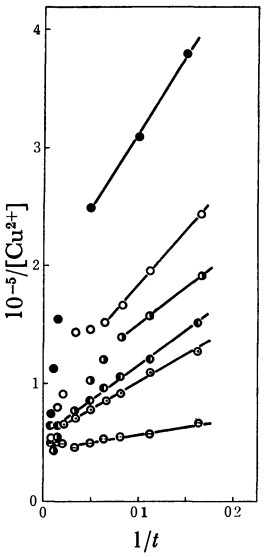

Fig. 3. The effect of the reaction time on stripping of Cu^{2+} from CuDz in various organic solvents at pH 2.90—2.95.

Solvent	$(CuDz)_{initial}$	pH
—●— chloroform	4.9×10^{-5} M	1.46
—○— 1,2-dichloroethane	9.5×10^{-5} M	2.92
—◐— benzene	7.7×10^{-5} M	2.90
—⊙— monochlorobenzene	9.7×10^{-5} M	2.90
—⊖— *o*-dichlorobenzene	8.0×10^{-5} M	2.90
—◑— nitrobenzene	5.5×10^{-5} M	2.95

is clear from these results that the extraction equilibrium between the secondary copper dithizonate and the primary dithizonate is reversible and that the secondary copper dithizonate is of the $Cu^{II}Dz$ type.

(Received January 29, 1975)

Synopsis. Five triple mixed Co(III) complexes with one 1,1,1-tris(aminomethyl)ethane and one aminocarboxylato and one ammine ligand were prepared. The glycinato complex was optically resolved and three L-aminocarboxylato complexes were chromatographically separated into their diastereomers. The circular dichroism spectra of the complexes were discussed.

1,1,1-Tris(aminomethyl)ethane (tame) is a typical tripod ligand and coordinates facially to a Co(III) ion; then three coordination sites remain to be occupied by other ligands. A new type of chirality due to the arrangement of three different groups is expected for such tame complexes, for example, $[Co(gly)NH_3(tame)]^{2+}$ (Fig. 1). This paper deals with the preparation, optical resolution and diastereomer separation of the tame complexes, $[Co(am)NH_3(tame)]^{2+}$, where am =glycinate (gly), L-alaninate (L-ala), L-serinate (L-ser), L-valinate (L-val) and L-isoleucinate (L-ileu). The absorption and circular dichroism (CD) spectra of the complexes are reported and discussed.

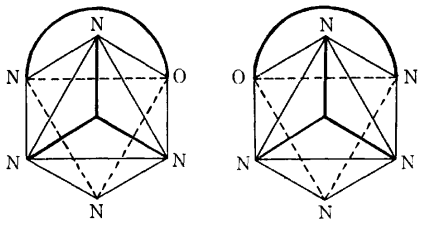

Fig. 1. Optical isomers of $[Co(gly)NH_3(tame)]^{2+}$.

Experimental

1,1,1-Tris(aminomethyl)ethane was prepared by the method of Fleischer *et al.*[1]

(−)$_{589}$-[Co(gly)NH$_3$(tame)]Cl$_2$·3H$_2$O. The mixture of *cis*-$K[Co(CO_3)_2(NH_3)_2]\cdot H_2O$[2] (10 g), tame·3HCl (8.5 g) and sodium hydroxide (4.5 g) in 100 ml of water was stirred at 70 °C for about 2 hr. The product was poured into a column containing cation exchange resin (Dowex 50W×8, Na^+ form) and eluted with 1.0 M NaCl solution. The red eluate was condensed and a crystalline complex was isolated after repeated removal of NaCl deposited out. Anal. Found: C, 22.47; H, 6.67; N, 18.01%. Calcd for $[Co(CO_3)NH_3(tame)]Cl\cdot 1.5H_2O = C_6H_{21}N_4O_{4.5}ClCo$: C, 22.83; H, 6.71; N, 17.75%. To a solution of $[Co(CO_3)NH_3(tame)]Cl\cdot 1.5H_2O$ (2 g) in 20 ml of water about 1.0 g of glycine was added and the mixture was heated at 70 °C for about 2 hr. The solution was poured into a cation exchange column of SP-Sephadex C-25 (Na^+ form) and eluted with 0.15 M NaCl solution. The orange colored eluate was concentrated in a vacuum evaporator. The crude product thus obtained, $[Co(gly)NH_3(tame)]Cl_2$, was recrystallized from as little hot water as possible.

The glycinato complex was resolved by using $K_2[Sb_2(d\text{-tart})_2]\cdot 3H_2O$ as resolving agent. The racemic glycinato complex chloride (0.5 g) was completely dissolved in 5 ml warm water (60 °C) and to the solution 0.5 g of the resolving agent was dissolved. The less soluble diastereomer gradually crystallized when the solution was kept in a refrigerator. Anal. Found: C, 20.43; H, 3.90; N, 7.88%. Calcd for (−)$_{589}$-[Co(gly)NH$_3$(tame)][Sb$_2$(*d*-tart)$_2$]·4H$_2$O = $C_{15}H_{34}N_5O_{18}CoSb_2$: C, 20.59; H, 3.92; N, 8.01%. The diastereomer was converted to optically active chloride by using an anion exchange resin (Dowex 1×8, Cl^- form). Anal. Found: C, 21.69; H, 7.15; N, 17.99%. Calcd for (−)$_{589}$-$[Co(gly)NH_3(tame)]Cl_2\cdot 3H_2O = C_7H_{28}N_5O_5Cl_2Co$: C, 21.44; H, 7.20; N, 17.86%.

The L-aminocarboxylato complexes were prepared by the method similar to that used for the racemic glycinato complex chloride, using L-alanine, L-serine, L-valine or L-isoleucine instead of glycine. Anal. Found: C, 24.56; H, 7.29; N, 18.05%. Calcd for $[Co(L\text{-ala})NH_3(tame)]Cl_2\cdot 2H_2O = C_8H_{28}N_5O_4Cl_2Co$: C, 24.75; H, 7.27; N, 18.04%. Found: C, 29.68; H, 7.48; N, 17.17%. Calcd for $[Co(L\text{-val})NH_3(tame)]Cl_2\cdot 1.5H_2O = C_{10}H_{31}N_5O_{3.5}Cl_2Co$: C, 29.57; H, 7.69; N, 17.24%. Found: C, 31.74; H, 7.68; N, 17.11%. Calcd for $[Co(L\text{-ileu})NH_3(tame)]Cl_2\cdot H_2O = C_{11}H_{32}N_5O_3Cl_2Co$: C, 32.05; H, 7.82; N, 16.99%. Found: C, 25.37; H, 6.68; N, 18.50%. Calcd for $[Co(L\text{-ser})NH_3(tame)]Cl_2\cdot 0.5H_2O = C_8H_{25}N_5O_{3.5}Cl_2Co$: C, 25.28; H, 6.68; N, 18.57%. These analytical values of each the complex are for a mixture of two diastereomers. Each the complex except L-serinato one was separated into the two diastereomers by column chromatography of SP-Sephadex C-25 (3×30 cm, Na^+ form) by using 0.075 M $Na_2[Sb_2(d\text{-tart})_2]\cdot 2H_2O$ solution as eluent. The lavels F1 and F2 denote the isomer separated earlier and later, respectively. It was confirmed that the F1 dominates over the F2 in quantity. The separation of L-serinato diastereomers was unsuccessful. The CD spectra of these diastereomers were measured with the eluates, and the concentrations were calculated from the determination of optical densities refering those of the diastereomeric mixtures (It was assumed that the two diastereomers of each the complex have identical molar absorption coefficients).

Results and Discussion

Figure 2 shows typical electronic absorption and CD spectra of the present tame complexes. These complexes can be assigned safely as $[Co^{III}(O)(N)_5]$ type[3] from their first (log ε=1.92 at 20600 cm^{-1}) and second (log ε=2.05 at 28900 cm^{-1}) absorption bands. The optical isomer of the glycinato complex, (−)$_{589}$-$[Co(gly)NH_3(tame)]^{2+}$, which was obtained from the less soluble diastereomer, shows two CD bands ($\Delta\varepsilon$=+0.016 at 18400 cm^{-1} and $\Delta\varepsilon$=−0.44 at 20500 cm^{-1}) in the first absorption band region and two weak CD bands ($\Delta\varepsilon$=−0.037 at 27500 cm^{-1} and $\Delta\varepsilon$=+0.029 at 30100 cm^{-1}) in the second absorption band region (Fig. 3). The configurational CD contribution arised from the chirality due to the arrangement of glycinate and NH_3 is considerably small

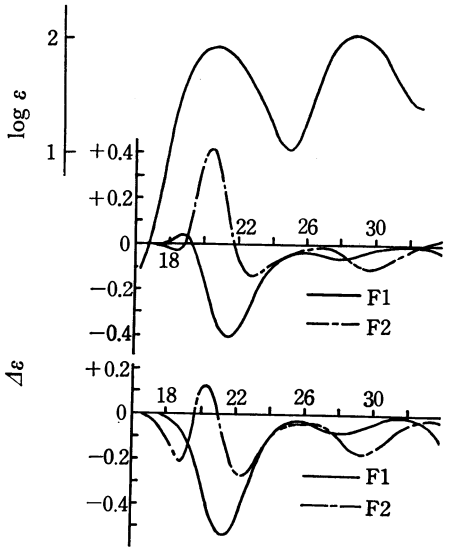

Fig. 2. Upper: Absorption and CD spectra of [Co(L-ala)-NH_3(tame)]$^{2+}$. Lower: CD spectra of [Co(L-val)NH_3-(tame)]$^{2+}$.

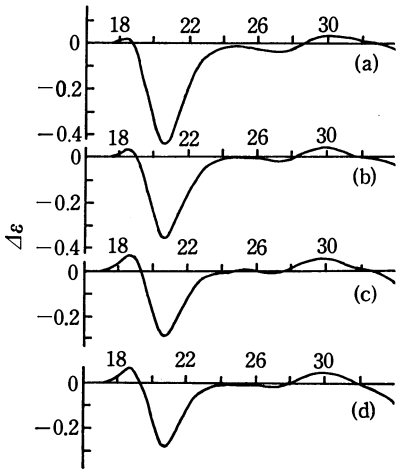

Fig. 3. CD curve of $(-)_{589}$-[Co(gly)NH_3(tame)]$Cl_2 \cdot 3H_2O$ (a), and calculated configurational effect curves, $1/2 \times \{\Delta\varepsilon(F1) - \Delta\varepsilon(F2)\}$; (b) [Co(L-ala)$NH_3$(tame)]$^{2+}$, (c) [Co(L-val)$NH_3$(tame)]$^{2+}$, and (d) [Co(L-ileu)$NH_3$-(tame)]$^{2+}$.

in comparison with those of the complexes of bis or tris chelate type.[4] The CD curves of L-alaninato, L-valinato and L-isoleucinato diastereomers deviate considerably from that of the $(-)_{589}$-glycinato isomer. However, applying the additivity rule of the configurational and vicinal contributions[5] to the CD curves of each the diastereomeric pair, a configurational CD curve similar to that of $(-)_{589}$-glycinato isomer is produced by subtracting the CD of F2 from that of F1 (Fig. 3). On the other hand, the calculated vicinal CD curves are similar to those of the corresponding [Co(L-am)$(NH_3)_4$]$^{2+}$ complexes[6] (Fig. 4). This fact points out that all three F1 isomers have the same absolute configuration and this is also the same as that of $(-)_{589}$-glycinato isomer.

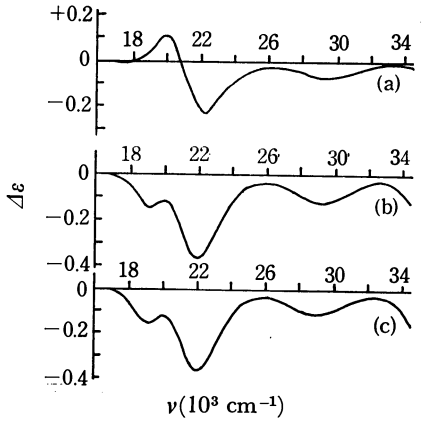

Fig. 4. Calculated vicinal effect curves: $1/2 \times \{\Delta\varepsilon(F1) + \Delta\varepsilon(F2)\}$; (a) [Co(L-ala)$NH_3$(tame)]$^{2+}$, (b) [Co(L-val)-$NH_3$(tame)]$^{2+}$, and (c) [Co(L-ileu)$NH_3$(tame)]$^{2+}$.

Catalytic Activities of Pyridoxal Analogues. I. The Catalytic Effects of Pyridoxal, Pyridoxal Methochloride, and Pyridoxal *N*-Oxide on the Racemization of L-Glutamic Acid

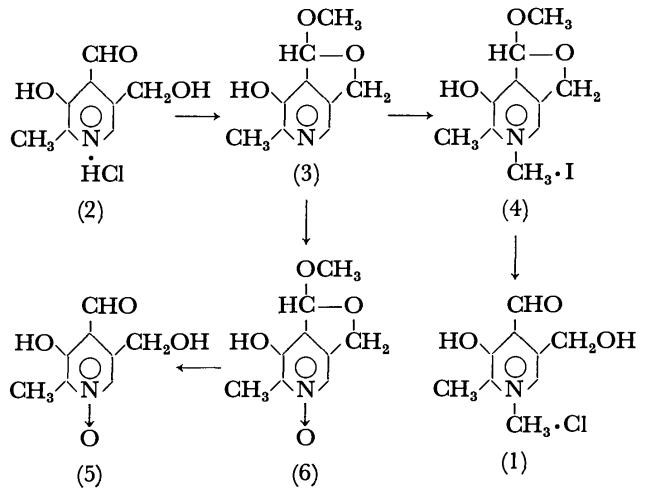
Makoto ANDO and Sakae EMOTO

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received July 4, 1974)

Synopsis. An improved method for the syntheses of pyridoxal methochloride (**1**) and pyridoxal *N*-oxide (**5**) was investigated. Further, the catalytic activities of pyridoxal, **1**, and **5** on the racemization of L-glutamic acid in the presence of cupric ions were studied.

In the presence of a metal ion, pyridoxal (PAL) catalyzes many reactions of amino acid, including racemization[1] and transamination.[2] Catalytic activities are also observed for the racemization with salicylaldehyde (SAL) derivatives, the benzene analogue of PAL.[3] In a previous paper, it has been reported that an electron-attracting substituent, introduced on the benzene ring of SAL derivatives, promoted the catalytic activity on the racemization of L-glutamic acid (L-Glu) in the presence of cupric ions at pH 10 and at 80 °C.[4] The catalytic activity may be expected to be more powerful when the PAL derivatives, which have a substituent on the ring nitrogen in order to increase the electron affinity of the pyridine ring, are used than when PAL itself is used.



Scheme 1

Anhydrous PAL methochloride (**1**) had been synthesized from PAL hydrochloride (**2**) in a 21% yield *via* PAL monomethyl acetal (**3**) and then PAL monomethyl acetal methiodide (**4**).[5] When the synthetic conditions were improved, **1** monohydrate was prepared in a 42% yield. PAL *N*-oxide (**5**) had also been obtained from pyridoxine *via* pyridoxine *N*-oxide.[6] In tetrahydrofuran (THF), **3** was oxidized with *m*-chloroperbenzoic acid (CPA) to PAL monomethyl acetal *N*-oxide (**6**),[7] which was then easily hydrolyzed to **5**.

According to the precedents,[3,4,8] the racemization of L-Glu was carried out in the presence of cupric ions at pH 10, where it is known that side reactions, such as transamination, proceed scarcely at all. Theoretically, $(\log \alpha_t - \log \alpha_0)/t$ should be a constant, where t is the time and α_t is the observed rotation at t. Table 1 shows that the catalytic activities of **1**, **2**, and **5** were gradually lowered as the reaction proceeded at 80 °C; a similar phenomenon had been observed with **2** by Yoshikawa *et al.*[8] At 25 °C, however, the racemization catalyzed by **2** and **5** was found to obey a psudo-first-order reaction at an early stage of the reaction. Though **1** was unstable even at 25 °C, the most active catalyst was **1**, followed by **5** and **2**; this order agreed with the one expected from their molecular structures. The decrease in the catalytic activity was parallel to that in the absorption maximum of the alkaline racemization mixture at around 380 nm, attributed to the chelation of the Schiff base of Glu with **1**, **2**, or **5** and cupric ion.[9] Therefore, in these cases, the catalytic activity is seemingly lowered by the decomposition of the cayalyst. Fukui *et al.* reported that, in β-elimination and transamination, the catalytic activity of **5** was inferior to that of **2** at pH 4—5,[10] where **2** forms pyridinium salt; consequently, the electron affinity of **2** is larger than that of **5**. Although the Braunstein-Snell mechanism of the non-enzymatic reactions of amino acid catalyzed by PAL, such as racemization, transamination, and β-elimination, is generally accepted,[11] the details of the

TABLE 1. CATALYTIC ACTIVITIES

	PNO	11	37	63	83

intermediates are still uncertain, and it has not been completely elucidated whether racemization, transamination, and β-elimination proceed with the same mechanism. As far as the order of the catalytic activity is concerned, the results of Fukui are consistent with those of our racemization.

No optimum pH was found for the racemization system, containing L-Glu, SAL derivatives (0.02 mole) equivalents), and cupric ions (0.02 mole equivalents) at 80 °C.[3,8] On the other hand, an optimum pH was found at around pH 10 for the racemization of L-alanine with **2** (equimolar) in the presence of cupric or aluminum ions (0.1 mole equivalents) at 100 °C for 10 min.[1] Therefore, we investigated the effect of the pH on the racemization of L-Glu under our conditions. As Table 2 shows, in a lower-pH solution, the catalytic activities decreased in the order of **1**, **5**, and **2** as was to be expected from their molecular structures, whereas, in a higher-pH solution, the order was reversed because of the unstabilities of the catalysts. In all the cases tested except the case of **1** at 80 °C, in the higher-pH solutions faster racemizations were observed. Without exception, no optimum pH was found under our conditions, in contrast to Snell's observations.[1]

It was concluded that the more powerful catalytic activities of PAL derivatives, as well as of SAL derivatives, were observed when a larger electron affinity was introduced on the aromatic ring; however, a catalyst for the racemization should be stable in an alkaline solution.

Experimental

All the mps are uncorrected. The IR spectra were recorded by means of a Shimadzu IR-27G instrument in KBr disks. The absorption spectra of the diluted alkaline racemization mixture were measured by means of a Hitachi 124 spectrophotometer.

PAL Methochloride (1). A mixture of a benzene solution of PAL monomethyl acetal (**3**), prepared from PAL hydrochloride (**2**) (8 g),[5] and CH_3I (12 ml) was refluxed for 72 hr while being stirred; during the reaction, additional 3 ml portions of CH_3I were added every 12 hr. Treating the mixture in a way similar to Heyl's method[5] gave a crude PAL monomethyl acetal methiodide (**4**) (6.1 g), which melted at 167—169 °C (decomp.) (lit,[5] mp 178—179 °C (decomp.)). Its IR spectrum showed the presence of a carbonyl group resulting from the partial hydrolysis of acetal. The crude **4** was converted to **1** as has been described in the literature.[5] Drying the final product over silica gel at room temperature under atmospheric pressure afforded 3.9 g of **1** monohydrate (42% based on **2**), which partly melted at around 100 °C and then gradually decomposed above 160 °C, as has been described in the literature.[5] IR 1660 cm^{-1} (C=O).

Found: C, 45.74; H, 5.92; N, 6.07; Cl, 15.25%. Calcd for $C_9H_{14}O_4NCl$: C, 45.86; H, 5.99; N, 5.94; Cl, 15.04%.

PAL Monomethyl Acetal N-Oxide (6). To a solution of **3** (5 g) in THF (500 ml), a solution of CPA (5.4 g; 85% purity) in THF (50 ml) was stirred at 0—5 °C over a period of 90 min; soon a precipitate resulted. The mixture was stirred for another 30 min at 0—5 °C and then left to stand overnight at room temperature. The separation of the precipitate gave 3.9 g of **6** (72%); mp>280 °C.

Found: C, 54.88; H, 5.64; N, 6.98%. Calcd for $C_9H_{11}O_4N$: C, 54.82; H, 5.62; N, 7.10%.

PAL N-Oxide (5). A solution of **6** (3.9 g) in boiling water containing a few drops of conc. HCl was cooled in an ice-water bath to precipitate 3.2 g of **5** monohydrate (80%), which melted at 120 °C (decomp.) (lit,[6] mp 120 °C (decomp.)).

Procedure of Racemization.[3] PAL was used in the form of hydrochloride; **1** and **5** monohydrates were used without drying. In a tightly stoppered test tube, a mixture of a pH-adjusted solution (2 ml) of sodium L-glutamate (2 mmol) and $CuSO_4$ (0.04 mmol) and a pH-adjusted borate buffer solution (2 ml) of the catalyst (0.04 mmol) was kept at 80 °C or 25 °C. After the required time, 6 M HCl (5 ml) was added immediately to the cooled mixture. The optical rotation of the solution was measured by means of a Perkin-Elmer 141 polarimeter; the racemization yield was calculated as follows:

$$100(\alpha_0-\alpha_t)/\alpha_0$$

The authors wish to express their thanks to Dr. Haruo Homma and his staff of this Institute for their elemental analyses and to Miss Kimiko Oguchi for her technical assistance. They also wish to acknowledge a Reaserch Grant of Life Sciences given by this Institute, which partially supported this work.

The Reaction of Acetylenecarboxylic Acid with Amines. XVII.[1] The Addition of Dialkyl Acetylenedicarboxylates to Several Carcinogens

Yasuo IWANAMI

Department of Chemistry, Sasaki Institute, Kanda-Surugadai, Chiyoda-ku, Tokyo 101

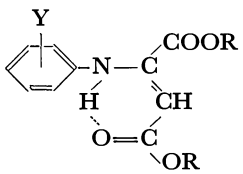
(Received July 9, 1974)

Synopsis. Hazardous carcinogens, α-naphthylamine (I), benzidine (II), 2′,3-dimethyl-4-aminoazobenzene (*o*-aminoazotoluene) (III), 2-amino-1-naphthol (IV), and 4-methylaminoazobenzene (V), easily reacted with esters of acetylenedicarboxylic acid (VI and VII) to give addition products, whose carcinogenicity could possibly be changed.

Since Rehn noticed, in 1895, three men with bladder tumors who all worked in the same dyestuffs factory, many cases of the hazards of handling α-naphthylamine (I), benzidine (II), and other aromatic compounds have been reported.[2] 2′,3-Dimethyl-4-aminoazobenzene (III), [3] 2-amino-1-naphthol (IV),[4] and 4-methylaminoazobenzene (V)[5] have also been established as carcinogenic substances.

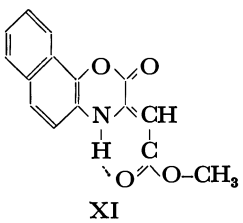
We have attempted the chemical modification of these hazardous compounds. It is conceivable that one can lessen or eliminate such a dangerous property by modification.

Dimethyl or diethyl acetylenedicarboxylate (VI or VII) reacted easily on admixture with these compounds. An addition reaction of an amino group onto the triple bond taking place, the primary amines, I, II, and III, gave the following fumarate-type compounds (VIII, IX, and X):



VIII: R=Methyl; Y=Benzo[*b*]
IX: R=Ethyl; *p,p′*-Linked dimer
X: R=Ethyl;
Y=*o*-Methyl-*p*-(*o′*-methylphenylazo)

In the reaction of IV, cyclocondensation followed the addition, forming a naphthoxazinone derivative (XI):



XI

Instead of the fumarate derivative, the secondary amine, V, afforded a compound of the succinate type (XII) upon the addition of two moles of V to the acetylenic bond. Except for XII, all the products are characterized by an intramolecular hydrogen bonding, as is evidenced by the IR (an absorption of ester carbonyl in the region 1674—1650 cm^{-1}) and NMR spectra.[6] Not only VIII, IX, and X, but also XI is similarly hydrogen-bonded between the ester carbonyl of the side chain and the amino group of the dihydrooxazine ring. This is one of the main structural changes as the carcinogenic amines (I, II, III, and IV) turn into the corresponding products.

All the reactions gave the adducts in high yield, proving themselves to be fit for the present purpose. These products are all new compounds; a carcinogenicity examination of them is awaited.[7]

Experimental

All the melting points are uncorrected. The IR spectra were recorded on a Nippon Bunko DS-301 or a Hitachi EPI-G3 spectrophotometer, while the NMR spectra were measured on a Hitachi H-60 spectrometer, using TMS as the external standard.

Dimethyl N-*(α-Naphthyl)aminofumarate (VIII).* Into a solution of I (0.3 g) in ethanol (10 ml), VI (0.3 g) was dropped with stirring. An exothermic reaction took place immediately, and the temperature of the reaction mixture rose to 25 °C from room temperature (21 °C). After the mixture had stood overnight, a small amount of water was added until it was turned turbid by yellow precipitates. The mixture was then left to stand in a freezer for several weeks. The crystals thus formed in an almost quantitative yield (0.6 g) were recrystallized from toluene to give pale yellow prisms; mp 69—70 °C. IR (nujol): 3242 (NH), 1736 (C=O), 1674 (chelated C=O), and 1612 (C=C) cm^{-1}. NMR (DMSO-d_6, δ): 3.57 (OCH_3), 3.72 (OCH_3), 5.41 (=CH–), and 10.17 (NH) ppm.

Found: C, 67.17; H, 5.30; N, 4.84%. Calcd for $C_{16}H_{15}O_4N$: C, 67.36; H, 5.30; N, 4.91%.

Tetraethyl Benzidine-N,N′-*difumarate (IX).* Obtained from II and VII in a similar manner. Yield, 91%. Yellow (dark) prisms from ethanol; mp 150—151 °C. IR (KBr): 3295 (NH), 1736 (C=O), 1662 (chelated C=O), and 1614 (C=C) cm^{-1}.

Found: C, 64.34; H, 6.08; N, 5.79%. Calcd for $C_{28}H_{32}N_2O_8$: C, 64.11; H, 6.15; N, 5.34%.

Diethyl 2′,3-Dimethyl-4-aminoazobenzene-N-*fumarate (X).* Obtained from III and VII. Yield, 87%. Orange prisms from methanol; mp 81—82 °C. IR(KBr): 3307 (NH), 1735 (C=O), 1662 (chelated C=O), and 1615 (C=C) cm^{-1}.

Found: C, 66.47; H, 6.40; N, 10.31%. Calcd for $C_{22}H_{25}O_4N_3$: C, 66.82; H, 6.37; N, 10.63%.

*3-(Methoxycarbonylmethylene)-3,4-dihydro-2*H-*naphtho*[*1,2*-b]-*1,4-oxazin-2-one (XI).* Obtained from IV and VI. Yield, 93%. Yellow fluorescent needles from methanol; mp 183—183.5 °C. IR (nujol): 3240 (NH), 1764 (lactone C=O), 1650 (chelated C=O), and 1623 (C=C) cm^{-1}. NMR (DMSO-d_6, δ): 3.77 (OCH_3), 5.69 (=CH–), and 10.91 (NH) ppm.

Found: C, 67.08; H, 4.36; N, 5.51%. Calcd for $C_{15}H_{11}O_4N$: C, 66.91; H, 4.12; N, 5.20%.

Dimethyl 2,3-Bis[*methyl(*p-*phenylazophenyl)amino*]*succinate*

(XII). Obtained from V and VI. Yield, 82%. Dark yellow crystals; mp 109—110 °C. IR (KBr): 1740 (C=O) cm^{-1}.

Found: C, 67.98; H, 5.82; N, 15.32%. Calcd for $C_{32}H_{32}O_4N_6$: C, 68.07; H, 5.71; N, 14.89%.

Some of the instruments used in this study were obtained by a grant-in-aid from the Ministry of Education, Japan, and a grant from the Anna Fuller Fund, U.S.A.

Thanks are due to Mr. T. Inagaki, Nitto Chemical Industry, Co., for the measurement of the NMR spectra.

The Photolysis of α-Haloketones. II. The Intramolecular Reactions of 9-α-Bromopropionylanthracene

Tamotsu MATSUMOTO, Masanori SATO, and Satoshi HIRAYAMA[1)]

Faculty of Textile Science, Kyoto Technical University, Matsugasaki, Sakyo-ku, Kyoto 606

(Received July 18, 1974)

Synopsis. The main photolysis products of 9-α-bromopropionylanthracene were identified as 2-methyl-1-aceanthrenone and 9-vinylanthryl ketone. The yield of 9-bromoanthracene was very small. A significant solvent and temperature dependence was noted on the yields of these products. The photolysis at −196 °C resulted in the formation of almost 100% of 9-vinylanthryl ketone.

In a previous paper,[2)] we reported that 9-ω-bromoacetylanthracene (I) undergoes new intramolecular photochemical reactions, yielding mainly 1-aceanthrenone (II) and 9-bromoanthracene (III). In this note, we will describe an extension of these photochemical reactions to 9-α-bromopropionylanthracene (IV), an analogue of I. Besides the three features noted for the photochemistry of I,[2)] several new facts, including a photoelimination reaction peculiar to IV, were found and will be reported herewith.

Experimental

According to the method of May and Mosettig,[3)] IV was synthesized by brominating 9-propionylanthracene and was recrystallized from ligroin. For spectroscopic measurements, it was purified further by sublimation *in vacuo*. (UV: (ethanol), λ_{max} ($\varepsilon\times10^{-3}$), 350 nm (4.36), 366 (6.20), 384 (6.03).)

The fluorescence spectra were recorded on a Shimadzu Spectrofluorophotometer Model RF 502, and the absorption spectra were taken with a Hitachi Spectrophotometer Model 124.

To analyze the photo-products, an ethanol solution of IV (*ca.* 200 mg/250 ml) was irradiated for 2 hr in a reaction vessel previously described.[2)] The reaction vessel was kept cooled to dry ice-ethanol temperatures during irradiation. The photo-products thus obtained were separated by column chromatography on silica gel. Elution with benzene gave III, unreacted IV, 9-vinylanthryl ketone (V), 2-methyl-1-aceanthrenone (VI), and anthraquinone. V, NMR: 5.63—7.10 ppm (m, ABX type, 3H), 7.27—8.03 (m, aromatic, 8H), 8.40 (s, aromatic meso-H, 1H). Found: C, 87.44; H, 5.36%. Calcd for $C_{17}H_{12}O$: C, 87.90; H, 5.21%. IR: 1663 cm^{-1} (C=O). UV: (ethanol), λ_{max} ($\varepsilon\times10^{-3}$), 329 nm (2.65), 345 (4.72), 362 (6.53), 381 (5.92). VI, mp 88—89 °C. NMR: 1.46 ppm (d, CH_3-CH, 3H, J=7.5 Hz), 3.25 (q, CH_3-CH, 1H), 7.11—7.91 (m, aromatic, 6H), 8.31 (s, aromatic meso-H, 1H), 8.93 (m, aromatic α-H, 1H). Found: C, 88.00; H, 5.14%. Calcd for $C_{17}H_{12}O$: C, 87.90; H, 5.21%. IR: 1703 cm^{-1} (C=O). UV: (cyclohexane), λ_{max} ($\varepsilon\times10^{-3}$), 349 nm (3.86), 368 (7.83), 390 (9.71), 413 (9.97); (ethanol), λ_{max} ($\varepsilon\times10^{-3}$), 351 nm (3.71), 369 (6.80), 397 (7.67), 418 (7.16).

The irradiation source and filters used for the spectrophotometric studies of the photochemical reactions have also been described previously.[2)] The product yields were, unless otherwise stated, always determined in the photolysis of dilute solutions (*ca.* 10^{-4} M) by the use of the molar extinction coefficients reported here.

Results and Discussion

The main photolysis products of IV were identified as V and VI. Dissolved oxygen was ascertained to have no significant effect on the qualitative nature of the photochemical reactions of IV.

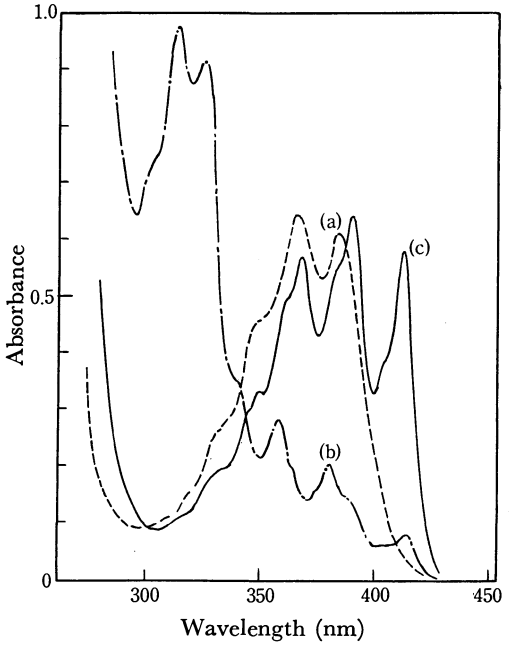

Fig. 1. Photolysis of IV in degassed *n*-hexane.
(a) ----: reactant, (b) ——: after 15 min irradiation with the filter UV-39 at room temperature, (c) ——: final products obtained by the dark reaction after irradiation (see the text).
A detailed description on the electronic spectra of VI is given in Ref. 4.

Figure 1 shows the absorption spectra of IV in degassed *n*-hexane before and after illumination. After about 15 min irradiation at room temperature through the UV-39 filter, which absorbs all light below 344 nm from a high-pressure mercury-arc lamp, a stable intermediate with the absorption band with a peak at 314 nm (Curve b) appeared. A very similar absorption band of the intermediate has been observed in the photolysis of I, indicating the formation of an analogous intermediate.[2)] The intermediate gradually underwent a thermal reaction to yield VI and finally gave the absorption spectrum represented by Curve c (two days later). When the intermediate was irradiated through the UV-DIB filter, which transmits light of 313, 334, and 366 nm, VI was formed immediately.

In ethanol the intermediate was not stable at room temperature. It was confirmed, however, that the intermediate could exist stably at dry ice-ethanol temperatures, as is shown in Fig. 2. The absorptions (Curve b) at around 314 nm and in the 340—400 nm region are due to the intermediate and to V respectively;

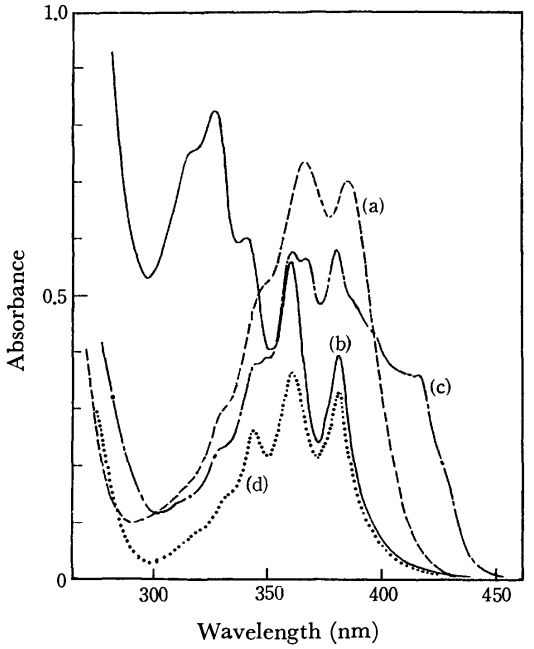

Fig. 2. Photolysis of IV in aerated ethanol.
(a) ——: reactant, (b) ——: after 30 min irradiation with the filter UV-39 at dry ice–ethanol temperatures, (c) —·—: final products obtained immediately after warming the solution in the dark (Curve b) to room temperature, (d) ·····: the absorption spectrum of V.

no absorption due to VI is seen. On the other hand, the formation of III could easily be revealed by observing the fluorescence spectrum of the solution with the absorption spectrum b.[5] When this solution was allowed to warm to room temperature in the dark, the absorption of the intermediate disappeared rapidly and the absorption due to VI built up, as is shown by Curve c. Thus, it is evident that the process to form the intermediate and those to form III and V are different and that only VI is formed from the intermediate. In this respect, the photochemistry of IV is closely similar to that of I. Thus, the reaction scheme to give III, V, and VI can be summarized as follows;

$$\text{IV} \xrightarrow{h\nu} \text{III } (ca.\ 4\%)$$
$$\text{IV} \xrightarrow{h\nu} \text{Intermediate} \xrightarrow[\text{or } \Delta]{h\nu'} \text{VI } (43\%)$$
$$\text{IV} \xrightarrow{h\nu} \text{V } (42\%).$$

Different pathways are given for the formation of III and V, because the yields of these two products show a very different temperature dependence, as will be shown below. The yields obtained in an aerated ethanol solution at dry-ice–ethanol temperatures are shown in parentheses. The value for III was determined by fluorometric measurements. In contrast to the case of the photolysis of I, the yield of III is very small.

Photolysis at Low Temperatures. The ratio of the yield of VI to that of V was found to depend significantly on the solvent and the temperature. As the temperature decreased, the ratio decreased from 4.0, 2.6, and 1.2 at 0 °C to zero at −196 °C in isopentane, EPA, and ethanol respectively.[6] The yield of V reached almost 100% at −196 °C in all these solvents. It was also confirmed by fluorometric measurements that the yield of III decreased to zero when the temperature was lowered. The retardation of the photochemical reaction of IV to give III by lowering the temperature was evidenced even more clearly by the temperature effect on the photochemical reactions of I, where the yield of III is of the order of 30% at dry ice–ethanol temperatures.[2] At first the amount of III increased against that of II as the temperature decreased (*ca.* 72% in ethanol at −145 °C), since the reaction to give II was more rapidly retarded. However, as the temperature was decreased further, the irradiation time needed to complete the reaction of I became logner and longer, and at last no photochemical reaction could be observed at −196 °C. Thus, the retardation of the reaction by lowering the temperature can be said to increase in the order of the reactions to give V, III, and VI (or II). The occurrence of the photolysis of IV at −196 °C is one of the most prominent differences in behavior between I and IV.[7]

Cause of the Great Decrease in the Yield of III. The IR absorption spectrum of a streching mode of the carbonyl group of I shows a clear splitting (1729 and 1700 cm^{-1}) characteristic of α-haloketones; this indicates the existence of two distinct conformations of the bromine atom to the carbonyl group. On the other hand, the corresponding IR absorption spectrum of IV shows no splitting (1703 cm^{-1}), suggesting that there are not two distinguishable conformations.

Since the IR and UV spectra of I and IV reveal that the plane of the carbonyl group is almost perpendicular to the anthracene ring, in one of the two conformations of I the bromine atom is expected to take a position where non-bonding electrons of the bromine atom lie just above the *p*-orbital of 9-carbon atom. If the photorearrangement mechanism proposed for 9-nitroanthracene is referred to,[8] such a conformation can be expected to be suitable for the formation of III. On the other hand, in the photolysis of IV the yield of III greatly decreased. This may, therefore, reflect either the circumstance that the allowed conformation of IV is unfavorable for such an interaction between the bromine atom and 9-carbon atom or the fact that the reaction rates to give V and VI are faster than that to give III.

The Cycloaddition Reaction of Isobenzofuran with Fulvenes: The Formation of an *endo*-(6+4)π Adduct

Hitoshi TAKESHITA, Akira MORI, Sansei SANO, and Yutaka FUJISE*

Research Institute of Industrial Science, Kyushu University, Hakozaki, Fukuoka 812

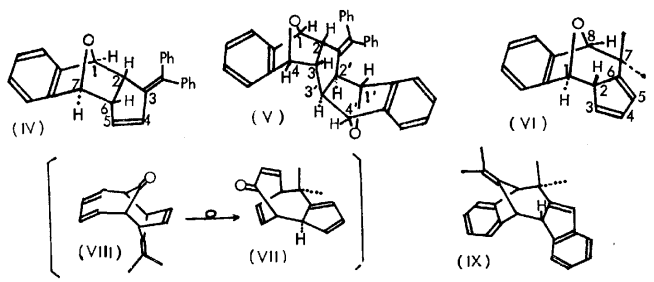
** Department of Chemistry, Tohoku University, Aramaki-Aoba, Sendai 980*

(Received July 25, 1974)

Synopsis. Isobenzofuran (I) was shown to react at 160 °C with 6,6-diphenylfulvene to give two *endo*-(2+4)π cycloadducts, an *endo*-1:1-adduct and an *endo-anti-endo*-1:2-adduct. On the other hand, I and 6,6-dimethylfulvene gave an *endo*-(6+4)π cycloadduct at room temperature.

Recently, we have reported the results on the cycloaddition reaction of isobenzofuran (I) with some typical tropones.[1] To extend the study to the reaction of I with other possible 6π-dienophiles, we have now carried out experiments with fulvenes, 6,6-diphenylfulvene (II), and 6,6-dimethylfulvene (III).

When II was placed to react with I, which has been generated at room temperature, it caused no change and resulted in the quantitative recovery of II. At higher temperatures (160—165 °C), however, a smooth reaction occurred to give two crystalline products, IV (48.1%) and V (14.9%). The structure of IV was, on the basis of the NMDR [δ: 3.77 (H_6, ddd, J=7.5, 5.5, 2.5 Hz), 4.19 (H_2, dd, J=7.5, 5.5 Hz), 4.83 (H_1, d, J=5.5 Hz), 5.38 (H_7, d, J=5.5 Hz), 5.63 (H_5, dd, J=6.0, 2.5 Hz), 5.79 (H_4, d, J=6.0 Hz) and 6.65—7.4 (14H, m)] spectral evidence, identified as an *endo*-(2+4)-π cycloadduct. The other compound, V, was shown to be a 1:2-cycloadduct, and was independently proven to be formed from I and IV, having at least one *endo*-configuration. Furthermore, its NMR [δ: 2.43 (2H, dd, J=9.0, 5.3 Hz), 2.93 (2H, dd, J=9.0, 5.3 Hz), 4.35 (2H, d, J=5.3 Hz), 5.23 (2H, d, J=5.3 Hz) and 6.8—7.4 (18H, m)] spectrum indicated the presence of an element of symmetry, ruling out two isomers of the *endo-anti-exo*- and *endo-syn-exo*-configurations. From the remaining two isomers (*endo-anti-endo*- and *endo-syn-endo*-adducts), the former must represent the structure, since it is impossible to construct the molecular frame with the latter. Accordingly, the observed chemical shifts of the methine protons are interpreted in terms of an up-field shift caused by the induced ring current from the aryl group of the other half of the molecule.[2] Obviously, the absence of the (6+4) π cycloaddition process to give a *gem*-diphenyl derivative may be a result of the steric hindrance.



Chart

On the other hand, when III was treated with I at room temperature, a 1:1-adduct (VI), a colorles liquid, was formed in a 25.0% yield. The NMR spectrum of VI showed the presence of a *gem*-dimethyl group and three olefinic protons [δ: 1.22 (3H, s), 1.50 (3H, s), 5.56 (H_5, dddd, J=1.9, 1.4, 0.6, 0.5 Hz), 6.14 (H_3, ddd, J=5.5, 1.4, 1.0 Hz) and 6.20 (H_4, dd, J=5.5, 1.9Hz)], together with three methine protons and aromatic protons [δ: 3.46 (H_2, ddd, J=5.2, 1.0, 0.5 Hz), 4.59 (H_8, br. s), 5.48 (H_1, d, J=5.2 Hz), and 6.7—7.2 (4H, m)], indicating it to be a (6+4) π cycloadduct. Interstingly, the vicinal coupling constant between the two methine protons (H_1 and H_2), measured as 5.2 Hz, was in the range for the magnitude of the *endo*-adduct, while the *exo*-adduct was estimated to have a smaller coupling constant.[3] No other product was detected in the reaction of I with III.

The occurrence of this rather rare *endo*-(6+4)π cycloaddition is neteworthy. The cross-conjugated 6π-arrangement of the fulvene ring might be less effective in determing the stereospecificity than the linearly oriented 6π-dienophiles because of orbital overlapping, and, according to a molecular model, the *exo*- and *endo*-(6+4) π adducts show no significant difference in steric hindrance, yet the results show a throughly inverted stereospecificity. As we have shown in the cycloaddition of tropones with I,[1] the *exo*-(6+4)π adducts are derived from the *endo*-(2+4)π adduct; one should consider the possibility that VI is also formed from a thermodynamically less stable adduct, for which, only the *exo*-(2+4)π adduct can be taken into account in this case. However, (2+4)π adducts were obtained under more severe conditions, and their structures were unrelated *endo*-(2+4)π as can be seen in the formation of IV and V. Therefore, VI is probably not a secondary cycloadduct. In this regard, Paddon-Row and Warrener[4] have recently suggested that the *exo*-(6+4)π cycloadduct[5] obtained from the reaction of III with tropone could be formed afterwards by a [3,3]-sigmatropy of another initially formed *exo*-(4+6)π adduct (VIII), which was regarded as thermodynamically unstable. Thus, the stereospecificity of the formation of VII should be inherited after that of a linearly arranged (4+6)π adduct. Interestingly, dimethylisobenzofulvene has been shown to form an *endo*-(6+4)π cyclodimer (IX)[6] which, like VI, includes a non-linear 6π component; it could not be derived from a (4+2)π precursor.

Experimental

Reaction of Isobenzofuran (I) and 6,6-Diphenylfulvene (II) at a Higher Temperature. The adduct (1.24 g)[1] obtained

from tetracyclone and 7-oxabenzonorbornadiene was dissolved in cellosolv acetate (15 ml), together with II (566 mg), and the mixture was heated at 160—165 °C for 4 hr. The mixture was then poured into ice water and extracted with benzene. After the removal of the solvent, the residual mass was separated by silica gel column chromatography; from the less polar fraction eluted with benzene, recovered II (217 mg) and tetraphenylbenzene were isolated, and subsequently, from a benzene-ether (1:1) mixture, colorless crystals (IV), (mp 160—161 °C; 254 mg (Found: C, 89.16; H, 5.79%. Calcd for $C_{26}H_{22}O$: C, 89.62; H, 5.79%. λ_{max}^{MeOH}: 295 nm (ε: 27300)), and colorless crystals (V) (mp 250—251 °C, 106 mg (Found: C, 87.81; H, 5.82%. Calcd for $C_{34}H_{26}O_2$: C, 87.52; H, 5.62%)) were obtained.

Reaction of IV and I: Formation of V. IV (50 mg) was similarly allowed to react with I at 160—165 °C for 2 hr. Then, a similar work-up afforded colorless crystals (30 mg) (mp 250—251.5 °C), which were identical with the authentic V obtained from the preceeding experiment (IR and NMR spectral and mixed mp comparisons).

Reaction of I and 6,6-Dimethylfulvene (III) at Room Temperature. 3,6-Diphenyltetrazine (1.13 g) and III (500 mg) were dissolved in dichloromethane (60 ml), to which a dichloromethane (10 ml) solution of 7-oxabenzonorbornadiene (677 mg) was then added, drop by drop; the mixture was then kept 3.5 hr at room temperature with stirring. Then, the solvent was removed *in vacuo*, and the residue was fractionated by silica gel column chromatography. The first few fractions (from *n*-hexane) gave the recovered III (145 mg). The next few fractions, eluted by benzene, afforded an oily adduct VI (188 mg (*m/e*: 224 (M^+). λ_{max}^{MeOH}: 256 nm (ε: 3100), 264 (2600), 270.5 (2000). IR 1340, 1160, 755, 725 cm^{-1}). The more polar fraction gave two crystalline compounds, the *exo-exo*-adduct of 7-oxabenzonorbornadiene with I (mp 262—264 °C (lit,[7] 264—265 °C)) and the *exo-endo*-isomer (mp 174—175 °C (lit,[7] 175—176 °C)).

The Catalytic Hydrogenolysis of Alkyl-substituted Aziridines

Yoshihiro SUGI,* Mitsuru NAGATA, and Sekio MITSUI

Department of Applied Science, Faculty of Engineering, Tohoku University, Aramaki aza Aoba, Sendai 980

(Received August 13, 1974)

Synopsis. Alkyl-substituted aziridines were hydrogenolysed, mainly at the less-substituted C–N bonds over Raney Ni, to yield β-amines. This hydrogenolysis occurred with the retention of the configuration. The differences in behavior between aziridines and oxiranes may be ascribed to the difference in polarisation between C–N and C–O bonds in the transition state of the hydrogenolysis.

Previous publications from our laboratory[1,2] have shown that 2-phenylaziridines undergo selective hydrogenolyses at the benzylic C–N bonds. However, there has no systematic work on the hydrogenolysis of 2-alkylaziridines. This paper will present our results for the hydrogenolysis of some 2-alkyl and 2-benzylaziridines over Raney Ni. One aspect of this investigation has been an examination of the differences in effect between alkyl and phenyl groups and in behavior between aziridine and oxirane.

Results

The results of the hydrogenolysis of 2-alkyl and 2-benzylaziridines are listed in Table 1. 2-Methyl (I), 2-ethyl (II), and 2,2-dimethyl (III) aziridines underwent rapid hydrogenolyses to yield β-amines**: *iso*-propyl, *sec*-butyl, and *t*-butylamines respectively. Karabinos and Seigen,[3] and Campbell, Sommers, and Campbell[4] have also reported the selective formation of *t*-butylamine in the hydrogenolysis of III over Raney Ni. I and II yielded small amounts of α-amines: *n*-propyl and *n*-butylamines respectively, in addition to β-amines. 1-Methyl-7-azabicyclo[4.1.0]heptane (IV) was also hydrogenolysed to a mixture of 1- and *trans*-2-methylcyclohexylamines in a ratio of 4: 1, and scarcely any *cis*-2-methylcyclohexylamine was obtained. The hydrogenolysis of 2-benzylaziridine (V) gave 1-methyl-2-phenylethylamine (82%) and 3-phenylpropylamine (18%).

Discussion

Aziridines undergo facile hydrogenolyses even under mild conditions because of their strains. 2-Alkyl and 2-benzylaziridines (I—V) were mainly hydrogenolysed at the less-substituted C–N bonds to yield β-amines. This is quite different from the hydrogenolysis of 2-phenylaziridines.[1,2] This difference may be ascribed to the fact that the latter can form π-benzyl complexes by the C–N bond fission, while the former can not.

The hydrogenolysis of IV gave *trans*-2-methylcyclohexylamine (20%) in addition to 1-methylcyclohexylamine. This suggests that the aziridine, which has no phenyl group adjacent to the ring, will be hydrogenolysed with the configurational retention over Raney Ni.

Because of the tetrahedral character of the nitrogen, the aziridine **1** will be adsorbed inclined cornerwise on the catalyst, and the nucleophilic attack to the carbon atom from the catalyst will occur to form two α,γ-diadsorbed species, **2** and **3**.[1,2] The Cα-atom*** has a

*** The C_α-atom is the less-substituted one; the alternative is the C_β-atom.

larger positive charge than the Cβ-atom, and it is also less hindered than the Cβ-atom because of the steric hindrance of the alkyl group. Moreover, the α,γ-diadsorbed species **2** may be more stable than the alternative **3**, because the stability of the carbon–metal bond is usually in this order: primary>secondary>tertiary.[5]† The result of these effects is that the Cα–N bond fission predominates over the Cβ–N bond fission.

2-Methyl-1,2-epoxyoctane (VI) was hydrogenolysed at the Cβ–O bond to yield an almost equimolar mixture of α-alcohol†† and 2-methyloctane, while the isomeric β-alcohol was obtained in a trace.[6] The hydrogenolysis of 1,2-epoxyoctane (VII) led to the formation of α- and β-alcohols in a ratio of 3: 2.[6] These results are in contrast with those of the aziridines (I—III). These differences we may ascribe to the difference in electronegativity between the nitrogen and oxygen atoms. The hydrogenolysis of the oxiranes VI and VII will proceed *via* carbonium ions, and the direction of the C–O bond fission will be governed by the relative stabilities of the carbonium ions: tertiary≫secondary>primary.[6] Howevev, it is unreasonably that the hydrogenolysis of the aziridines (I—V) occurs *via* the carbonium ions because more than 80% of the β-amines were obtained, in contrast with the oxiranes VI and VII. The polarisation of the C–N bond in the transition state of the hydrogenolysis may be lower than that of the C–O bond, because the nitrogen atom has a lower electronegativity than the oxygen atom. The direction of the C–N bond fission will be governed by such factors as the positive charge on the carbon, the steric hindrance of the alkyl group, and the stability of the α,γ-diadsorbed species, as has been discussed above.

† When R_1 is phenyl, **3** will be more stable than **2**, as has previously been discussed.[1,2]

†† α-Alcohol is the less-substituted one.

Experimental

Materials. The 2-methyl (I), 2-ethyl (II), and 2,2-dimethyl (III) aziridines were prepared by the procedure of Campbell *et al.*[4] The 2-benzylaziridine (V) was obtained by the Brois method[7] from 3-phenyl-1-aminopropanol-2.

1-Methyl-7-azabicyclo[4.1.0]heptane (IV). Methyl *N*-(1-methyl-*trans*-2-iodocyclohexane)carbamate was obtained by the procedure of Hassner *et al.*[8] The carbamate, without isolation, was treated with a NaOH solution in water. The usual work-up gave IV; bp 58—64 °C/25 mmHg.

Hydrogenolysis. The hydrogenolyses of I, II, and III were conducted over W-4 Raney Ni at 25 °C and 1 atm of hydrogen, using *n*-BuOH as a solvent. IV and V were hydrogenolysed in EtOH under similar conditions. The reaction mixtures were analysed by gas chromatography (liquid phase: Carbowax 4000 dispersed on firebrick†††).

Pyrolysis of 1,2-Epithiocyclohexane

Shodo INOUE and Shigeru OAE*

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo-ku, Tokyo 112

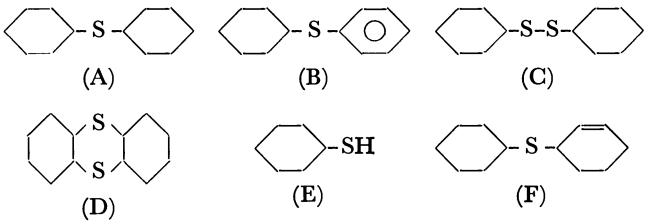
** Institute of Chemistry, The University of Tsukuba, Sakura-mura, Niihari-gun, Ibaraki 300-31*

(Received October 31, 1974)

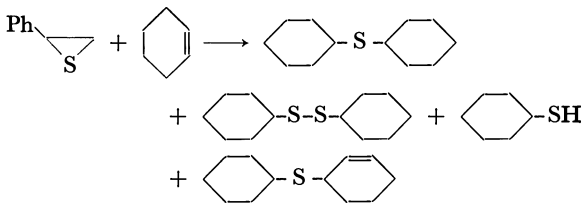
Synopsis. Dicyclohexyl sulfide, cyclohexyl phenyl sulfide, dicyclohexyl disulfide, 2,3,5,6-bis(tetramethylene)-1,4-dithiane, cyclohexanethiol and cyclohexyl cyclohexenyl sulfide were obtained by the pyrolysis of 1,2-epithiocyclohexane apparently *via* the attack of sulfur radical species, formed by the pyrolysis of 1,2-epithiocyclohexane, on the double bond of cyclohexene.

Certain thiiranes are known to split off sulfur upon pyrolysis to give the corresponding olefins.[1] A recent report indicates that sulfur-containing products are formed by the pyrolysis of thiiranes.[2] Nevertheless, little is known about the reaction of olefins with sulfur extruded from thiiranes.[1,3]

We have carried out the liquid phase pyrolysis of 1,2-epithiocyclohexane and examined products formed in this reaction in the hope of sheding light on the reaction of cyclohexene with sulfur species[4] which would be formed by the pyrolysis of 1,2-epithiocyclohexane. The pyrolyzed products were found to consist of six gas-chromatographically separable components (A,B,C,D, E,F). From mass and NMR spectroscopic data and by comparison with authentically synthesized samples, the pyrolyzed products were identified as dicyclohexyl sulfide (A), cyclohexyl phenyl sulfide (B), dicyclohexyl disulfide (C), 2,3,5,6-bis(tetramethylene)-1,4-dithiane (D), cyclohexanethiol (E) and cyclohexyl cyclohexenyl sulfide (F).

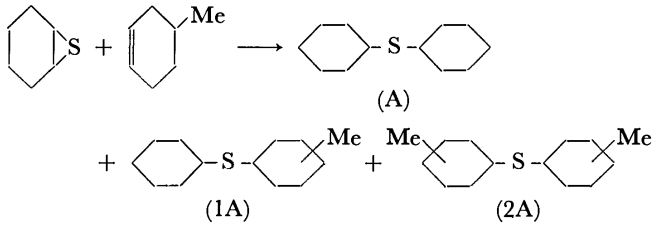


A small amount of benzene was formed apparently by the hydrogen abstraction of cyclohexene with the sulfur species formed initially.[5] The formation of hydrogen sulfide was also observed but none of elemental sulfur. When 1,2-epithiocyclohexane was heated at 210 °C for one hour in a sealed tube, compounds A,B,C,D and E were formed in 22, 4, 12, 1, and 6% yields respectively. Compound F was formed only at an early stage of the reaction but might give a compound such as B after abstraction of allylic hydrogens of F by the sulfur species. Actually, B is formed upon heating F with elemental sulfur. However, it cannot be formed by the reaction of the episulfide with benzene which is formed by the hydrogen abstraction of cyclohexene, since compound B was not formed upon heating 1,2-epithiocyclohexane in benzene. When a mixture of 1,2-epithiocyclohexane and ten equimolar amount of cyclohexene was heated at 210 °C for one hour in a sealed tube, the yield of A increased while F was also formed. This suggests that the hydrogen abstraction from F by the sulfur species is depressed by excess cyclohexene. In this case, the yields of A,C,E, and F based on the amount of episulfide used, were found to be respectively 63, 2, 2, and 7%. When a mixture of excess cyclohexene and stilbene episulfide was heated under the same conditions, compounds A,C,E, and F were similarly formed, their yields being respectively 57, 1, 2, and 8%. When a similar mixture of cyclohexene and styrene episulfide was heated, compounds A,E, and F were formed in respective yields of 26, 1, and 5%. A similar result was obtained upon heating a mixture of excess cyclohexene and 1,2-butene episulfide. These experiments suggest that a sulfur radical species produced by the pyrolysis of a certain episulfide attacks the double bond of cyclohexene as in the pyrolysis of 1,2-epithiocyclohexane.



An interesting problem in the pyrolysis of episulfide is whether the two carbon-sulfur bonds of episulfide are cleaved simultaneously or consecutively, eventually yielding the corresponding olefin and sulfur. In order to clarify the mode of the C–S bond cleavage, we carried out the following experiments. An equimolar mixture of cyclohexene and 4-methylcyclohexene containing the same amount of styrene episulfide was heated in a sealed tube. Dicyclohexyl sulfide (A), cyclohexyl methylcyclohexyl sulfide (1A) and dimethyldicyclohexyl sulfide (2A) were formed in the molar ratio 1:2:1. This is the statistical ratio, since the sulfur species, formed by the pyrolysis of the styrene episulfide, will attack cyclohexene and 4-methylcyclohexene with equal ease and hence the amount of 4-methylcyclohexyl cyclohexyl sulfide formed will be twice that of dicyclohexyl or di-4-methylcyclohexyl sulfide in this reaction. The products containing one methyl group, *viz.* 3-methylcyclohexyl and 4-methylcyclohexyl sulfides, were formed nearly in the same yields. When an equimolar mixture of 1,2-epithiocyclohexane and 4-methylcyclohexene was heated in a sealed tube, compounds A, 1A, 2A, were formed in the molar ratio 1:2.3:1.2. This is similar to the results in the former case, suggesting that the sulfur species is formed by the pyrolysis of 1,2-epithiocyclohexane and attacks both the cyclohexene formed by the pyrolysis and 4-methylcyclohexene with equal ease; thus, 1,2-epithiocyclohexane seems to give sulfur and cyclohexene upon pyrolysis and not the stable thiyl

radical. When 1,2-epithiocyclohexane and 4-methylcyclohexene were heated in the molar ratio a: b, the ratio of products A, 1A, and 2A was found to be represented approximately by a^2: 2ab: b^2. However, the formation of compound A is usually slightly smaller than the calculated amount. This is because 4-methylcyclohexene, being present in the system form the beginning, will have a slightly greater chance of being attacked than cyclohexene on account of the small amount of cyclohexene formed in the early stage of the reaction.



(A) (1A) (2A)

There is a possibility that compounds 1A and 2A are formed in the reaction of 4-methylcyclohexene with some other reaction products. A small amount of 1A was formed upon heating a mixture of cyclohexanethiol and 4-methylcyclohexene, but neither A nor 2A was formed. When a mixture of A and 4-methylcyclohexene was heated, 1A and 2A were obtained besides unreacted A, but the molar ratio of compounds A, 1A, and 2A was found to be 100: 9: 2. Compound 2A was not obtained in a large amount. In another experiment, a mixture of compound C and 4-methylcyclohexene was heated but no sulfide was formed. Futhermore, when an equimolar mixture of 1,2-epithiocyclohexane and 4-methylcyclohexene was heated for 4 min, the initial reaction products A, 1A, and 2A were formed in the molar ratio 1: 10: 17. Thus, 2A was formed in a large amount in the early stage of the reaction, This suggests that the sulfur species released from 1,2-epithiocyclohexane mainly attacks 4-methylcyclohexene, since there is little cyclohexene formed in the early stage of the pyrolysis. Thus it is clear that 1A and 2A are formed in the early stage of the reaction and other products such as the thiol, sulfide and disulfide which are formed in the course of the reaction would rarely undergo decomposition and recombination with 4-methylcyclohexene; therefore, the molar ratio of the products A, 1A, and 2A, 1: 2: 1, does not result from the reaction of cyclohexene and 4-methylcyclohexene with other products but from the reaction with the sulfur species. From an overall picture of the whole process, these experimental results suggest that at the relatively high temperature we employed (210 °C) the two carbon–sulfur bonds of 1,2-epithiocyclohexane may be cleaved simultaneously, resulting in the formation of cyclohexene and sulfur species. If only one of two carbon-sulfur bonds of 1,2-epithiocyclohexane were cleaved to form a highly stable biradical intermediate, compounds A and 2A would not be formed in this reaction.

Experimental

Materials. 1,2-epithiocyclohexane, styrene episulfide and 1,2-butene episulfide were prepared from the corresponding epoxy compounds with potassium thiocyanate.[6] Stilbene episulfide was obtained by reacting stilbene oxide with thiourea.[7] Dicyclohexyl sulfide, cyclohexyl phenyl sulfide and cyclohexyl cyclohexenyl sulfide were synthesized by the reaction of the corresponding bromide with the thiol in the usual way. Dicyclohexyl disulfide and cyclohexylcyclohexenyl disulfide were synthesized by heating the corresponding chloride with sodium disulfide.[8] 4-methylcyclohexyl cyclohexyl and 3-methylcyclohexyl cyclohexyl sulfides were prepared by treating 4-methylcyclohexyl and 3-methylcyclohexyl bromides with cyclohexanethiol.

Reactions. A typical run was carried out as follows. 1,2-epithiocyclohexane (0.3 g) or a mixture of 1,2-epithiocyclohexane and cyclohexene was heated at 210 °C for one hour in a vacuum sealed tube. After completion of the reaction, evolved gas was admitted into a solution of cupric sulfide and hydrogen sulfide was identified by trapping it as cupric sulfide. The liquid products of the reaction mixture were analyzed by vpc, NMR and mass spectroscopies. Their mass spectra indicate that the cracking patterns of the six compounds are similar and all of them have the cyclohexyl ring. Their parent peaks are given at *m/e* 198, 196, 192, 230, 228, 116. Since both 2,3,5,6-bis(tetramethylene)-1,4-dithiane and cyclohexyl cyclohexenyl disulfide should give the same parent peak of 228, cyclohexylcyclohexenyl disulfide was synthesized independently but was not found to be the reaction product by vpc. Compounds A, C, and E were obtained in sufficient amounts to enable their identification by NMR spectroscopy. The NMR spectrum of A gave a broad singlet at τ-value of 7.2 and a multiplet centered on a τ-value of 9.4. C and E gave similar spectra.

The Reaction of *N*-Hydroxylamino Compounds with Triphenylphosphine and CCl_4

Takehisa OHASHI[1] and Rolf APPEL

Institute of Inorganic Chemistry, University of Bonn, 53 Bonn, West Germany

(Received November 15, 1974)

Synopsis. In the reaction of triphenylphosphine with *N*-*p*-toluene-*N*-hydroxylamine and CCl_4, *p*-azotoluene and *p*-azoxytoluene were formed as the main products. On the other hand, in the reaction using *N*-*p*-toluenesulfonyl-*N*-hydroxylamine, sulfonyliminophosphorane was obtained.

In conjunction with our studies[2-8] of the ternary system phosphine/CCl_4/ammonia derivatives, we wish to report a new method of synthesizing azo and azoxy compounds by the reaction of *N*-*p*-toluene-*N*-hydroxylamine (A) with Ph_3P and CCl_4 and a new method of synthesizing sulfonyliminophosphorane by the reaction of *N*-*p*-toluenesulfonyl-*N*-hydroxylamine (B) with Ph_3P and CCl_4. It was found that *p*-azotoluene (**1**) and *p*-azoxytoluene (**2**) could easily be obtained in the reaction of (A) with Ph_3P and CCl_4 as is shown in Reaction (1).

$$\underset{\text{(A)}}{MeC_6H_4NHOH} + Ph_3P + CCl_4 \xrightarrow{(Et)_3N}$$
$$MeC_6H_4N{=}NC_6H_4Me\ (\mathbf{1}) + MeC_6H_4\overset{+}{N}{=}NC_6H_4Me\ (\mathbf{2})\ (O^-)$$
$$+ Ph_3PO\ (\mathbf{3}) + MeC_6H_4NH_2\ (\mathbf{4})$$
$$+ (Ph_3P^+CH_2Cl)Cl^-\ (\mathbf{5}) + CHCl_3 + (Et)_3NHCl \quad (1)$$

In this reaction, the formation of $CHCl_3$ was observed under several conditions (yields: 35—40%); besides the main products, two by-products, **4** and **5**, were obtained, and triphenylphosphine oxide (**3**) was isolated in high yields. However, no *N*-*p*-tolueneiminotriphenylphosphorane was found in this reaction. The results are presented in Table 1. On the other hand, *N*-*p*-toluenesulfonyliminotriphenylphosphorane (**1′**) was obtained as the main product of the reaction of (B) with Ph_3P and CCl_4 (Reaction (2)).

$$\underset{\text{(B)}}{MeC_6H_4SO_2NHOH} + Ph_3P + CCl_4 \longrightarrow$$
$$MeC_6H_4SO_2N{=}PPh_3\ (\mathbf{1'}) + (\text{Adduct of } Ph_3PO \text{ and } MeC_6H_4SO_2NHOH)\ (\mathbf{2'}) + Ph_3PO\ (\mathbf{3'}) + CHCl_3$$
$$+ (Ph_3P^+CH_2Cl)Cl^-\ (\mathbf{4'}) \quad (2)$$

Results obtained in Reaction (2) are described in Table 2.

In all the reactions described in Table 2, the formation of $CHCl_3$ was also observed, and the yield of $CHCl_3$ in the reaction using 2 mol of triphenylphosphine to (B) was higher (51.5%) than that (40.5%) observed in the reaction using an equimolar triphenylphosphine. Besides the main product (**1′**), the (**2′**) compound, triphenylphosphine oxide (**3′**) and chloromethyltriphenylphosphonium chloride (**4′**) were isolated, but no triphenylphosphine oxide was formed when triphenylphosphine equimolar to (B) was used. The new compound (**2′**) was estimated to be a hydrogen-bonded adduct, as is shown below:

Table 1. The reaction of *p*-tolyl-NHOH with Ph_3P and CCl_4

MeC_6H_4NHOH (mmol)	Ph_3P	CCl_4	Et_3N	Solvent[b]	Yields of products[a] %						
					1	**2**	**3**[c]	**4**	**5**[d]	**6**	**7**

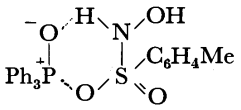
10.7	21.4	10.7	B	60	60	62.3	11.0	41.0	20.1
10.7	21.4	10.7	A	40	150	69.3	4.0	46.9	24.5

a) **1′** : $MeC_6H_4SO_2N{=}PPh_3$, **2′**: Adduct of Tosyl-NHOH and Ph_3PO, **3′**: Ph_3PO, **4′**: $(Ph_3P^+CH_2Cl)Cl.^-$ b) A: CH_2Cl_2, B: 1,2-Dichloroethane. c) Yields of **1′**, and **2′** were calculated based on Tosyl-NHOH used. Yields of **3′** were calculated based on Ph_3P used. Yields of **4′** were calculated based on CCl_4 used.



It was confirmed that the same compound can be obtained quantitatively by the reaction of triphenylphosphine oxide with (B). Similar hydrogen-bonded interactions have recently been reported[9] in the study of 1:1 adducts obtained in the reaction of triarylphosphines with *p*-toluenesulfonamide.

It is supposed that the first step in the reactions of *N*-hydroxylamino compounds with Ph_3P and CCl_4 is the formation of the intermediate phosphonium compounds (I-a) and (I-b) resulting from the reaction of (A) or (B) with the Ph_3P–CCl_4 complex,[2-8] as is shown in Reaction (3):

$$\mathrm{RNHOH\ (A) + (Ph_3P^+Cl)CCl_3^-} \longrightarrow \begin{cases} (\mathrm{Ph_3P^+Cl,\ ^-ONHR}) \\ \text{or} \\ (\mathrm{Ph_3P^+Cl,\ ^-N(OH)R}) \end{cases} + \mathrm{CHCl_3} \quad (3)$$

I-a (R; MeC_6H_4) I-b (R; $MeC_6H_4SO_2$)

In the reaction of (A) with Ph_3P and CCl_4, the nucleophilic attack of (A) on the nitrogen of the intermediate (I-a) can be assumed to be as is shown in Reaction (4):

$$\mathrm{I\text{-}a + MeC_6H_4NHOH} \xrightarrow[(A)]{} \begin{cases} \mathrm{MeC_6H_4N{=}NC_6H_4Me + Ph_3PO + HCl + H_2O} & \text{(Path a)} \\ \mathrm{MeC_6H_4NO + MeC_6H_4NH_2 + Ph_3PO + HCl} & \text{(Path b)} \end{cases} \quad (4)$$

Azotoluene was supposed to be formed *via* Path a, while azoxytoluene was estimated to be formed *via* the reaction of nitrosotoluene, which is formed *via* Path b, with Ph_3P, as has been reported by Cadagon[10] and *via* the reaction of nitrosotoluene with (A), as has been reported by Bamberger.[11] The deoxygenation of azoxytoluene[12] with Ph_3P did not occur under the mild conditions used in this investigation.

On the other hand, in the reaction of (B) with Ph_3P and CCl_4, the nucleophilicity of (B) is not so strong; therefore, the nucleophilic attack of triphenylphosphine on the nitrogen of the intermediate (I-b) was assumed to form the **1′** compound and triphenylphosphine oxide. Further, triphenylphosphine oxide reacts simultaneously with (B) to form the adduct (the **2′** compound in Reaction (2)).

Experimental

Materials. *N-p*-Toluene-*N*-hydroxylamine (A) was prepared as has been reported by Bamberger.[13] *N-p*-Toluenesulfonyl-*N*-hydroxylamine (B) was prepared as has been reported by Meyer.[14]

General Procedure of the Reaction of A with Ph_3P and CCl_4. Into a solution (solvent: acetonitrile or 1,2-dichloroethane) of A and CCl_4, a solution of Ph_3P and triethylamine was stirred, drop by drop, under an atmosphere of argon at room temperature; a slight exothermic reaction was observed. The solution was then heated at 55 °C for an additional 1 hr. The solvent was subsequently evaporated, and the semi-solid or oily residue was analysed by fractional crystallization and NMR analysis. The formation of chloroform was confirmed qualitatively and quantitatively from the NMR spectra of the distillates. The 4,4′-azotoluene, *p*-azoxytoluene, triphenylphosphine oxide, *p*-toluidine, and (chloromethyl)triphenylphosphonium chloride were identified by comparing them with the authentic compounds.

General Procedure of the Reaction of B with Ph_3P and CCl_4. A turbid dichloromethane or 1,2-dichloroethane solution of B and Ph_3P was warmed to 35—40 °C, and then CCl_4 was added to the solution. The mixture was stirred under an atmosphere of argon, keeping the temperature at 40 °C (in dichloromethane) or 60 °C (in 1,2-dichloroethane). From the reaction mixture, *N-p*-toluenesulfonyliminotriphenylphosphorane, triphenylphosphine oxide, and (chloromethyl)triphenylphosphonium chloride were isolated and identified by comparison with authentic compounds. When the reaction was carried out in the presence of triethylamine, for example, in the reaction using 2 mol of Ph_3P, CCl_4 and triethylamine equimolar to B, the same products as in the reaction without triethylamine were obtained, but the yields of the **1′** compound were low (13%).

Adduct of Triphenylphosphine Oxide and N-p-*Toluenesulfonyl*-N-*hydroxylamine.* After the removal of the **1′** compound from the reaction mixture, the residue was dissolved in benzene at 60 °C and filtered. A white precipitate obtained on cooling the filtrate was washed with ether and recrystallized from benzene. Mp 158 °C. IR: 3140, 2880, 1440, 1340, 1180. 1155, 730 and 548 cm^{-1}. NMR: (τ in CD_3OD) 2.10—2.70 (m, 19H) and 7.63 (s, 3H). ^{31}P NMR: (δ in MeOH) −31.3 ppm (relative to H_3PO_4). Found: C, 64.78; H, 5.20; N, 3.08; O, 13.42; P, 6.21; S, 7.12%. Calcd for $C_{25}H_{24}NO_4PS$: C, 64.51; H, 5.20; N, 3.01; O, 13.75; P, 6.44; S, 6.89%.

The Authors wish to thank Alexander von Humboldt-Stiftung for his help with our research.

Photochemistry of *N*-(4-Dimethylaminobenzylidene)aniline[1]

Hiroyuki OHTA and Katsumi TOKUMARU

Department of Chemistry, Faculty of Science, The University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 30, 1974)

Synopsis. Irradiation of *N*-(4-dimethylaminobenzylidene)aniline, contrary to an earlier report, does not give *cis*-4,4′-bis(dimethylamino)stilbene and azobenzene, however, its triplet state has, exceptionally as an acyclic imine, enogh lifetime at 77 K to exhibit phosphorescence.

Recently increaseing attention has been paid to photochemistry of carbon-nitrogen double bonds.[2] For the irradiation of several imines in alcoholic solvents to give the reduced products, once the excited states of the imines were supposed to abstract hydrogen atoms from the solvents, but it is now accepted that carbonyl compounds present as impurities or as hydrolysis products are responsible for initiating the reaction on irradiation.[3] Cyclic imines, whose excited triplet states have longer lifetimes than the most acyclic imines, are still unreactive towards hydrogen atom abstraction probably on account of high π, π^* character of their triplet states.[4] Most imines are also photochemically unreactive in unimolecular cleavage except those carrying heteroatoms adjacent to carbon–nitrogen double bonds,[5] azirines[6] and acyclic imines substituted with benzyl groups.[7] The unreactive nature of the most imines in photochemical cleavage is attributable to the too short lifetimes of their excited states owing to their facile radiationless deactivation accompanid by syn-anti isomerization. Many carbonyl compounds in the n,π^* excited states and olefins in the π,π^* excited states are well known to undergo cycloaddition to unsaturated bonds.[8] On the other hand, imines have not been reported to add to unsaturated compounds except the following cases. One exception is recent finding by Koch and Rodehorst on capability of cyclic imines with conjugated carbonyl groups for addition to vinyl ether.[9] The other one, with which the present work concerns, is Searles and Clasen's report in 1965 that irradiation of *N*-(4-dimethylaminobenzylidene)aniline (I) in ether gave *cis*-4,4′-bis(dimethylamino)stilbene (II) and azobenzene (III) probably through cycloaddition between the imine to give diazetidine intermediate followed by its cleavage into the products.[10]

$$2\,\mathrm{ArCH{=}NPh} \xrightarrow{h\nu} \underset{\text{(I)}}{\mathrm{ArCH{-}NPh}\ \mathrm{ArCH{-}NPh}} \longrightarrow \underset{\text{(II)}}{\textit{cis}\text{-ArCH=CHAr}} + \underset{\text{(III)}}{\mathrm{PhN{=}NPh}}$$

(Ar: p-$Me_2NC_6H_4$)

Since most benzylideneanilines were known not to undergo this type of reaction, this report prompted us to explore the nature of the excited state of the imine (I) and the mechanism with which this excited state would be so reactive contrary to the most imines. This photochemical reaction was reinvestigated in several conditions as described below, but their results were not reproducible in our experimental conditions. However, the triplet state of this imine was found to have enough long lifetime at 77 K to phosphoresce in contrast with the most acyclic imines.

Results and Discussion

The imine (I) was irradiated in ether and in methanol with a high or a low pressure mercury lamp. The results are summarized in the Table. It indicates that after the irradiation most of the imine was recovered and a part of the imine was converted into 4-dimethylaminobenzaldehyde (IV) and aniline (V) but the reported products, II and III, were not found among the products. Thus, irradiation of I in 0.02 M ether solution with a high pressure mercury lamp or in 0.04 M ether with a low pressure mercury lamp did not afford the reported products. Use of concentrated solution (0.16 M) which would favour the bimolecular cycloaddition still failed in giving the reported products. Irradiation was also undertaken at solid carbon dioxide–ethanol temperature, but the reported products were not produced. Replacement of solvent from ether to methanol gave no effect on the reaction. A control experiment showed that II was not consumed on irradiation with the imine in ether. Therefore, we are forced to conclude that, in our experimental conditions, the imine (I) does not lead to the products earlier reported, and the reported products seem to have arisen in an adventitious or a limited condition.

Formation of IV and V in the irradiation are supposed to be due to hydrolysis of the imine by trace amount of water eventually present. Since the solution of the imine, on being kept in the dark, did not afford the hydrolysis products, the observed hydrolysis appears to be promoted by the irradiation as was reported by Furey and Kan for unsubstituted benzyldeneaniline.[11]

$$\mathrm{ArCH{=}NPh} + \mathrm{H_2O} \xrightarrow{h\nu} \mathrm{ArCHO} + \mathrm{PhNH_2}$$

To our knowledge, acyclic imines have never been reported to phosphoresce. It is therefore remarkable to have found that I exhibited phosphorescence in EPA at 77 K with maxima at 435 and 455 nm with lifetime of 0.4 sec. However, it did not fluoresce at room temperature and at 77 K. A possibility that the observed phosphorescence would result from the triplet state of IV eventually present as an impurity or as hydrolysis product of the imine is ruled out, because IV showed phosphorescence with a maximum at 465 nm in EPA and the maximum of the phosphorescence excitation spectrum of I, 345 nm, or IV, 335 nm, corresponded nearly to the respective absorption maximum, 345 or 339 nm. So, it is evident that the observed phosphorescence originates from the triplet state of I. The above result indicates that the triplet state of the imine (I) lies 63

Table 1. Products from the irradiation of *N*-(4-dimethylaminobemzylidene) aniline (I) in ether

I used (mmol)	Sovent (ml)	Lamp[b] (W)	Time (hr)	Products (%) [d,i]

7.77	400[a]	H 100[c]	68	*ca.* 80	h	h

a) methanol; b) H and L: a high or low pressure mercury lamp, respectively; c) immersion-type lamp; d) based on I used; e) recovered; f) 4-dimethylaminobenzaldehyde; g) aniline; h) present but not determined; i) IV and V were determined by vpc and I was isolated by column chromatography and weighed.

kcal mol^{-1} above the ground state and its long lifetime suggests that the triplet state is abundant in π,π^* or intramolecular charge transfer electronic configuration.[12]

Experimental

N-(4-Dimethylaminobenzylidene)aniline (I) was prepared according to literature.[13]

Irradiation was carried out for runs using 200—400 ml solution with a Riko immersion-type high or low pressure mercury lamp under nitrogen. For a concentrated ethereal solution of the imine in a Pyrex tube kept under argon atmosphere, external irradiation was done with a Riko high pressure mercury lamp. For a run at low temperature, the ethereal imine in a Pyrex tube under argon was kept in a solid carbon dioxide–ethanol in a Dewar vessel and irradiated with a high pressure lamp placed in the same bath. The irradiated mixture was analyzed by vpc with a Hitachi 063 gas chromatograph with a FID detector using a 2 m SE-30 column at 200 °C. 4-Dimethylaminobenzaldehyde (IV) and aniline (V) were determined with the use of nitrobenzene as an internal standard, however, *cis*-4,4′-bis(dimethylamino)stilbene (II) and azobenzene (III) were not detected. The mixture was concentrated under vacuum and the residue was chromatographed over well-washed silica gel to give the recovered imine together with IV and V.

The emission was measured with a Hitachi MPF 2A spectrofluorometer together with an attachment for phosphorescence observation.

The authors thank Professor O. Simamura for his stimulating discussion and the Ministry of Education for partial support of this work.

Photochemical Reactions of 3,3-Bis(dialkylamino)acrylophenones and 3-Dibenzylaminopropiolophenone

Hiromu AOYAMA, Tadashi HASEGAWA, Takehiko NISHIO,* and Yoshimori OMOTE*

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Tokyo 112

* *Department of Chemistry, University of Tsukuba, Niihari, Ibaraki 300-31*

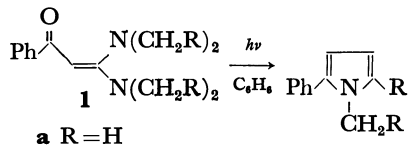
(Received December 4, 1974)

Synopsis. The photolysis of 3,3-bis(dialkylamino)-acrylophenones **1a**, **b**, and **c** gave the **3a**, **b**, and **c** pyrroles respectively. 3-Dibenzylaminopropiolophenone (**2**) reacted with water upon irradiation to give *N,N*-dibenzylbenzoylacetamide (**5**), whereas the addition of acetic acid to **2** proceeded without irradiation.

Recently, we reported the photochemical cyclization of 3-dialkylaminoacrylophenones.[1] This paper will be concerned with the photochemical reactions of 3,3-bis(dialkylamino)acrylophenones (**1a**, **b**, and **c**) and 3-dibenzylaminopropiolophenone (**2**).

The **1a**, **b**, and **c** ketones were prepared by the condensation of 3,3-dichloroacrylophenone (**4**) with the corresponding secondary amines according to the method in the literature.[2] On the other hand, the reaction of **4** with dibenzylamine yielded the ynaminoketone **2**.

The irradiation of **1a**, **b**, and **c** in benzene by means of a high-pressure mercury lamp gave the **3a**(trace), **3b**(25%) and **3c**(8%) pyrroles respectively. The structures of the pyrroles were confirmed by direct comparison (IR, NMR, tlc) with samples obtained in the photochemical reactions of 3-dialkylaminoacrylophenones.[1] These reactions also proceeded in *n*-hexane, but did not proceed in methanol or acetonitrile. The mechanism of these reactions is not clear at present.

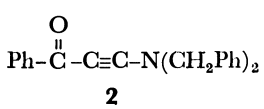


1

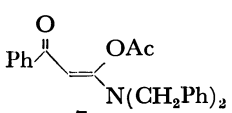
a R=H
b R=Et
c R=*n*-Pr

3

The ynaminoketone **2** was inert toward photolysis in dry benzene, whereas the irradiation of **2** in benzene containing water yielded *N,N*-dibenzylbenzoylacetamide (**5**). The structure of **5** was confirmed by an unequivocal synthesis from ethyl benzoylacetate and dibenzylamine. The formation of **5** can be easily explained in terms of the addition of water, followed by ketonization. The reaction did not take place in the dark. On the other hand, the addition of acetic acid to **2** proceeded without irradiation[3,4] to give an adduct **7**.



2



7

Experimental

All the melting points are uncorrected. An Ushio 450 W high-pressure mercury lamp was used as an irradiation source.

3-Dibenzylaminopropiolophenone (2). To dibenzylamine (25 g), 3,3-dichloroacrylophenone (3.5 g) was added, drop by drop. The temperature rose to 74 °C and then slowly fell to room temperature. After the addition of dry ether (50 ml), the mixture was refluxed for 24 hr and then stirred at room temperature for an additional 24 hr. The mixture was filtered to remove the dibenzylamine hydrochlororide, and the filtrate was evaporated *in vacuo*. On the addition of a small amount of petroleum ether to the residue, a crystalline solid was deposited; this was later recrystallized from benzene–petroleum ether to give 2.6 g of **2**; mp 109—110 °C; IR (KBr) 2300, 1610, 1570 cm^{-1}; UV λ_{max}^{EtOH} 254 (ε, 10500), 323 nm (16000); NMR ($CDCl_3$) δ 4.32 (s, 4H, CH_2), 7.20—7.45 (m, 13H, aromatic), 7.50—7.73 (m, 2H, aromatic).

Found: C, 84.83; H, 5.88; N, 4.34%. Calcd for $C_{23}H_{19}NO$: C, 84.89; H, 5.89; N, 4.30%.

General Procedure for the Photochemical Reaction of 1a, b, and c. A solution of **1** (200 mg) in benzene (70 ml) was irradiated in a Pyrex vessel under nitrogen for 30—50 hr. After the removal of the solvent, the residue was chromatographed on silica gel. Elution with benzene yielded **3**.

N,N-*Dibenzylbenzoylacetamide (5).* A solution of **2** (100 mg) in benzene (50 ml) containing a small amount of water was irradiated in a Pyrex vessel under nitrogen for 30 hr. After the removal of the solvent, the residue was chromatographed on silica gel (benzene–ethyl acetate 2: 1) to give 80 mg of **5**; mp 79—80 °C; IR (KBr) 1690, 1630, 1570 cm^{-1}.

Found: C, 80.18; H, 6.43; N, 4.08%. Calcd for $C_{23}H_{21}NO_2$: C, 80.44; H, 6.16; N, 4.08%.

The amide **5** was also prepared by heating a solution of ethyl benzoylacetate (6.1 g) and dibenzylamine (5.7 g) in xylene (7.5 ml) to 140 °C (yield, 79%).

3-Dibenzylamino-3-acetoxyacrylophenone (6). A solution of **2** (200 mg) and acetic acid (1 ml) in benzene (10 ml) was stirred for 2 hr at room temperature. After the removal of the solvent, the residue was chromatographed on silica gel (benzene–ethyl acetate 20: 1) to give 225 mg of **6**; mp 72—73 °C; IR (KBr) 1770, 1650, 1610 cm^{-1}; NMR ($CDCl_3$) δ 2.32 (s, 3H, CH_3), 4.55 (d, 4H, CH_2), 6.43 (s, 1H, olefinic), 6.80—7.80 (m, 15H, aromatic).

Found: C, 78.09; H, 5.99; N, 3.73%. Calcd for $C_{25}H_{23}NO_3$: C, 77.90; H, 6.01; N, 3.63%.

A New Synthesis of 2-Pyrones

Taeko IZUMI and Akira KASAHARA

Department of Applied Chemistry, Faculty of Engineering, Yamagata University, Yonezawa, Yamagata 992

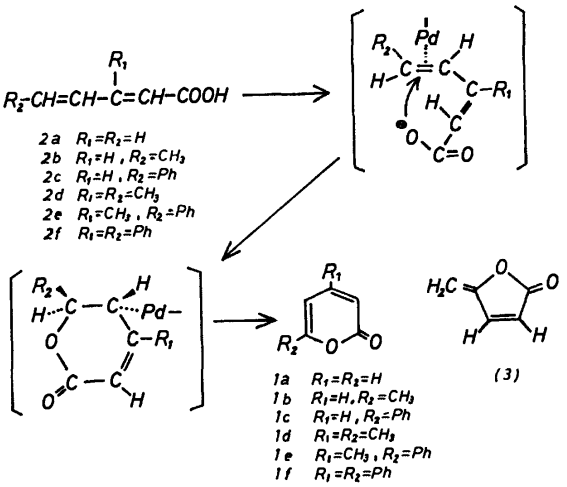
(Received December 9, 1974)

Synopsis. The reaction of sodium salt of penta-2,4-dienoic acids with lithium chloropalladite in a polar solvent such as water led to the formation of 2-pyrone derivatives.

Numerous reports on the synthesis of 2-pyrones (**1**) have appeared in the literature.[1] However, no direct cyclization of penta-2,4-dienoic acids (**2**) into **1** has yet been reported. In this report, we wish to describe an intramolecular cyclization of **2** to **1** with lithium chloropalladite in moderate yields.

The solution of sodium salt of penta-2,4-dienoic acid (**2a**) in water was stirred with lithium chloropalladite under reflux to produce 2-pyrone (**1a**) in a 72% yield. The experiment in a mixture of dioxane and water (1:1) gave also **1a** in a 67% yield. In the conversion of **2a** to **1a** with palladium(II) salt, no formation of the five-membered-ring product [protoanemonin (**3**)] was observed.

Similarly, 6-methyl- and 6-phenyl-2-pyrone (**1b** and **1c**) were synthesized from sorbic acid (**2b**) and 5-phenylpenta-2,4-dienoic acid (**2c**) respectively. The reactions carried out are summarized in Table 1. In the presence of palladium(II) salt, the reaction of nucleophile with olefins has received considerable attention;[2] however, only a few reports are known in the field of intramolecular oxypalladation.[3] Henry and Ward.[4] have reported that the reaction of olefins with palladium(II) acetate gave products which were consistent with a *trans* acetoxypalladation, followed by a *cis* elimination of hydridopalladium. Recently, Hosokawa *et al.*[5] have reported that, in the reaction between 2-γ-methylallylphenol and palladium(II) acetate, the processes of both *cis*- and *trans*-oxypalladations are involved. However, in the reaction of **2** with palladium(II) salt, the reaction is explained only by a *trans*-oxypalladation, since a *cis*-palladium-hydride elimination is a general process.[4,6]



Experimental

Materials. All the melting points are uncorrected. The following compounds were synthesized by the methods described in the literature: penta-2,4-dienoic acid (**2a**),[7] 5-phenylpenta-2,4-denoic acid (**2c**)[8], 3,5-dimethylpenta-2,4-dienoic acid (**2d**),[9] 3-methyl-5-phenylpenta-2,4-dienoic acid (**2e**),[9] and 3,5-diphenylpenta-2,4-dienoic acid (**2f**).[9] Sorbic acid (**2b**) of a commercial grade was used without further purification.

General Procedure for the Preparation of 1. A solution of 10 mmol of **2** and 5 mmol of sodium carbonate in water (50 ml) or dioxane–water (1: 1, 50 ml) was stirred with 10 mmol of lithium chloropalladite under reflux for 4 hr. The reaction mixture was then extracted with ether. The ether layer was washed with water and then dried over anhydrous magnesium sulfate. After the evaporation of the solvent, the product was isolated by distillation or by column chromatogram on silica gel. The structures of the products were confirmed by a

Table 1. Reaction of penta-2,4-dienoic acid (**2**) with lithium chloropalladite

Lactone Carboxylic Acids. IX.[6] Base-Catalyzed Rearrangement of Ethyl α-Hydroxyaminoaconate Leading to the Formation of Isoxazolines

Sigeru TORII, Masasi UKIDA, and Hideo TANAKA

Department of Industrial Chemistry, School of Engineering, Okayama University, Okayama 700

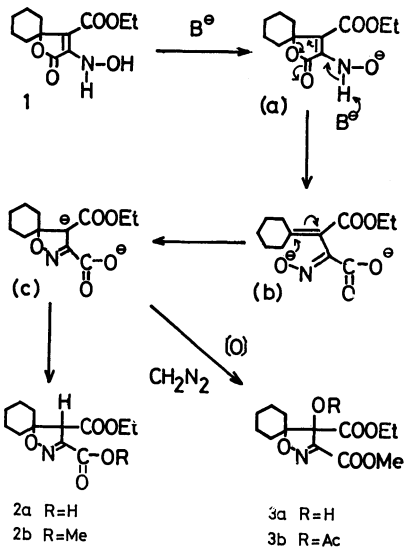
(Received December 27, 1974)

Synopsis. The syntheses of 4-ethoxycarbonyl-3-methoxycarbonyl-5,5-pentamethylene-Δ^2-isoxazoline (**2b**) and its 4-hydroxy and 4-acetoxy derivatives (**3a** and **3b**) by the base-catalyzed rearrangement of ethyl γ,γ-pentamethylene-α-hydroxyaminoaconate (**1**) were described.

Several attempts have been made to find the synthetic way in obtaining appropriate Δ^2-isoxazoline-3-carboxylic acids by the reaction of hydroxamic acid with α-ketosuccinic esters,[1] by 1,3-cycloaddition of α-carbonitrile oxides[2] or nitrone esters[3] to olefins, by the condensation of nitroacetic esters,[4] and others.[5] Such compounds are of interest as potential intermediates for the preparation of useful chemicals.[2b,2d,5] We wish to report here a base-catalyzed rearrangement of ethyl γ,γ-pentamethylene-α-hydroxyaminoaconate (**1**)[6] giving the corresponding Δ^2-isoxazolines (**2b**, **3a**, and **3b**).

The reaction of ethyl α-hydroxyaminoaconate (**1**) with one equivalent of *n*-butyl lithium in THF at −78 °C afforded the isoxazoline ester **2b** in 84% yield after treating the crude acid **2a** with excess diazomethane and a small amount of **3a** (5.9%). On the other hand, the reaction of two equivalents of *n*-butyl lithium with **1** resulted in **3a** in 63% yield. The hydroxy isoxazoline **3a** could be converted into the corresponding acetate **3b** by the treatment with a mixed solution of acetic anhydride and pyridine. The structures of **2b**, **3a**, and **3b** after purifyng by column chromatography are elucidated by PMR, ^{13}C NMR, infrared, and mass spectral analyses together with elemental analyses. The ^{13}C NMR spectra of **2b**, **3a**, and **3b** (Fig. 1) provided effective evidences for their structural assignment. The ^{13}C NMR spectrum of **2b** displayed characteristic three bands at δ 149.5 (C=N), 160.7 (carbonyl attached to methoxy group), and 167.0 (carbonyl attached to ethoxy group) and, in addition, the peaks at δ 60.5 (or 61.6) and 93.1 are accounted for the C_4 and C_5 carbon atoms of **2b**. The ^{13}C NMR spectrum of **3a** was almost similar to that of **2b** except for a downfield shift of *ca.* 25 ppm for C_4 of **2b**. The structural relationship between **3a** and **3b** could be assigned reasonably, since the ^{13}C NMR spectrum of **3b** showed two new peaks at δ 21.0 and 164.8 accounted for the acetyl group.

A tentative mechanism for the formation of the isoxazolines **2a** and **3a** is outlined in Scheme 1. The mode of the base-catalyzed rearrangement of **1** is assumed to be migration of the electron on nitrogen atom as shown in (**a**) to produce (**b**), which would occur by abstraction of the hydrogen atom attached to the imino group with the



Scheme 1.

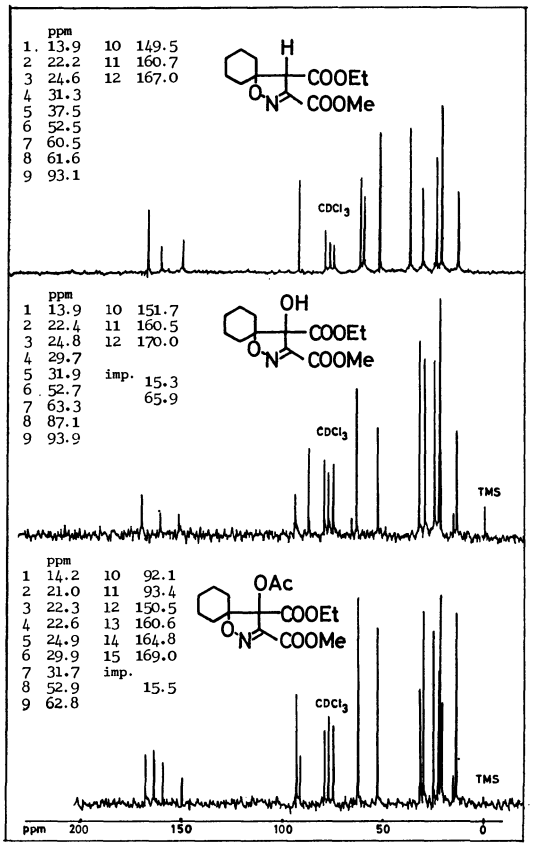


Fig. 1. The ^{13}C NMR spectra of **2b**, **3a**, and **3b** ($CDCl_3$) determined at 15.0 MHz under conditions of proton noise decoupling; scale, parts per million relative to carbons of TMS.

base. The following recyclization of the oxime anion of (**b**) would lead to a dianion (**c**), which is considered to be stable thermodynamically. Thus, the final products formed in this process seem to be similar to those produced in the acid-catalytic acyllactone rearrangement.[7]

Although the reason of the formation of **3b** is not certain, it seems likely that the formation of **3a** takes place when two equivalents of the base were used, suggesting that the dianion (**c**) may be oxidized with oxygen dissolved in the solvent.[8]

Experimental

Melting points and boiling points are uncorrected. PMR spectra were recorded on a Hitachi R-24 instrument. ^{13}C NMR spectra were recorded on a JEOL FX-60 instrument. IR spectra were determined with Hitachi EPI-S2, with only major absorptions being cited. Mass spectral analysis was carried out with a Hitachi RMS-4 spectrometer at 70 eV. Wako gel C-200 silica gel was used for elution chromatography. Elemental analysis was performed by Mr. Tsutomu Okamoto of our Laboratory.

Reaction of Ethyl γ,γ-Pentamethylene-α-hydroxyaminoaconate (1) with One Equivalent of n*-Butyl Lithium.* To a stirred solution of **1** (66.0 mg, 0.25 mmol) in THF (0.5 ml), 0.2 ml (0.25 mmol) of 1.3 M *n*-BuLi in ether was added at −78 °C. The reaction mixture was allowed to warm slowly to room temperature during 2 hr and the stirring was continued for additional 2.5 hr. The mixture was poured into ice-cold diluted HCl (0.5 ml) and extracted with $CHCl_3$. The extracts were washed with water, dried (Na_2SO_4), and concentrated *in vacuo* to give 94.5 mg of a yellow oil. Treatment of this oil with an excess amount of diazomethane and subsequent chromatography using *n*-hexane–$ClCH_2CH_2Cl$ gave 56.5 mg (84%) of **2b**: bp 105—107 °C/1.0 mmHg; IR (neat) 1726 (ester C=O), 1590 (C=N) cm^{-1}; PMR (CCl_4) δ 1.28 (t, J=7.0 Hz, 3H, CH_3), 1.20—2.10 (broad s, 10H), 3.69 (s, 1H, H_β), 3.81 (s, 3H, CH_3O), 4.16 (q, J=7.0 Hz, 2H, CH_2O); Mass *m/e* (%) 269 (M^+, 2), 253 (9), 196 (83), 154 (62), 59 (100). Found: C, 57.74; H, 7.06%. Calcd for $C_{13}H_{19}NO_5$: C, 57.98; H, 7.01%.

From the following elution with $ClCH_2CH_2Cl$ 4.0 mg (5.9%) of **3a** was obtained: bp 117—120 °C/1.0 mmHg; IR (neat) 3475 (OH), 1740 (ester C=O), 1589 (C=N) cm^{-1}; PMR (CCl_4) δ 1.30 (t, J=7.0 Hz, 3H, CH_3), 1.00—2.20 (m, 10H), 3.59 (s, 1H, HO), 3.82 (s, 3H, CH_3O), 4.26 (q, J=7.0 Hz, 2H, CH_2O); Mass *m/e* (%) 212 (28), 127 (52), 99 (100), 81 (97). Found: C, 54.99; H, 7.03%. Calcd for $C_{13}H_{19}NO_6$: C, 54.73; H, 6.71%.

Reaction of **1** *with Two Equivalents of* n*-Butyl Lithium.* To a stirred solution of **1** (66.0 mg, 0.25 mmol) in THF (1.0 ml), 0.62 ml (0.56 mmol) of 0.9 M *n*-BuLi in ether was added at −78 °C under nitrogen. The reaction mixture was allowed to warm slowly to room temperature for 2 hr and the stirring was continued for additional 2 hr. The reaction mixture was worked up as the standard manner to afford an oil. Treatment of the oil with excess diazomethane gave a yellow oil, whose tlc showed the presence of 2 spots at R_f 0.30 and 0.12 (Merck PF_{254}, benzene–EtOAc: 15/1). The column chromatography using benzene–EtOAc gave 44.8 mg (63.0%) of **3a** and 3.7 mg (3.45%) of an unknown crystal.

Preparation of the Acetate **3b** *from* **3a**. A solution of the alcohol **3a** (14.5 mg, 0.051 mmol) in Ac_2O (0.5 ml) and dry pyridine (0.5 ml) was stirred at 65 °C under nitrogen for 12 hr. The solvent was roto-evaporated to give 28.5 mg of a dull reddish material. The crude product was chromatographed using benzene and benzene–EtOAc to give 12.3 mg (74.1%) of **3b**; bp 119.5—122.5 °C/1.0 mmHg; IR (neat) 1756 (ester C=O), 1595 (C=N) cm^{-1}; PMR ($CDCl_3$) δ 1.30 (t, J=7.0 Hz, 3H, CH_3), 0.70—2.30 (broad s, 10H), 2.13 (s, 3H, CH_3CO), 3.85 (s, 3H, CH_3O), 4.28 (q, J=7.0 Hz, 2H, CH_2O); Mass *m/e* (%) 327 (M^+, 0.4), 212 (75), 127 (53), 99 (100), 81 (69). Found: C, 55.04; H, 6.54%. Calcd for $C_{15}H_{21}NO_7$: C, 55.04; H, 6.47%.

From the second elution 3.3 mg (22.8%) of **3a** was recovered.

The Photocycloaddition of 2-Cyclohexenone and Maleic Anhydride to $\Delta^{9,10}$-Octalin

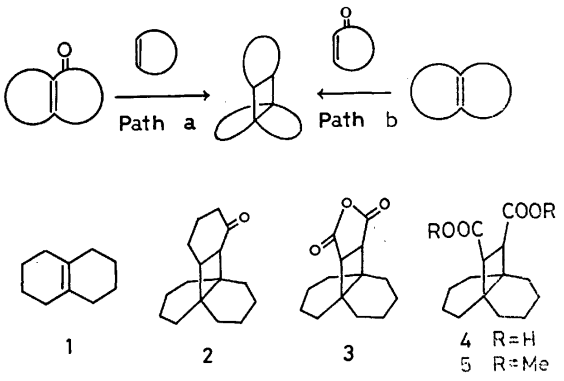
Atsutaka KUNAI, Koji KIMURA, and Yoshinobu ODAIRA

Department of Petroleum Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received December 28, 1974)

Synopsis. The photocycloaddition to $\Delta^{9,10}$-octalin (**1**) was investigated. Both 2-cyclohexenone and maleic anhydride reacted with **1** to afford the corresponding photocycloadducts, **2** and **3** respectively.

From the viewpoint of the synthesis of interesting cyclic compounds, increasing attention has been shown in the study of the photocycloaddition of cyclic enones to olefins.[1] Especially, for the synthesis of propellanones, the photocycloaddition of bicyclic enones to olefins has been generally employed as a convenient method.[2] More recently, we reported the photochemical synthesis of a new type of tetracyclic propellanone according to the above method (Path a).[3] Although the photocycloaddition of appropriate substances to bicyclic olefins, which have a central double bond, can be assumed to be an alternative method, no such study has yet been reported (Path b). In an extension of our study of the photochemical preparation of a variety of propellane derivatives, we wish to report here our preliminary finding concerning the photocycloaddition of some cyclic substrates to $\Delta^{9,10}$-octalin (**1**).



First, we examined the photocycloaddition of 2-cyclohexenone to **1**. When a neat mixture of 2-cyclohexenone and a 6-molar excess of **1** was irradiated through a Pyrex filter, a cross cycloadduct **2** was given, along with 2-cyclohexenone dimers. The yield of **2** was estimated by glpc analysis to be 13% based on the quantity of **1** reacted. The structure was determined to be **2** on the basis of the spectral data and by elemental analysis, and also, most especially, by the fact that no hydrogenation occurred when the palladium-charcoal catalyst was used.[4]

Next, we examined the photocycloaddition of maleic anhydride to **1**. When an ethereal solution of maleic anhydride and a 2-molar excess of **1** was irradiated through a Pyrex filter, a cross cycloadduct **3** was given, along with a considerable amount of the maleic anhydride dimer. When **3** was chromatographed on silica gel, spontaneous hydrolysis occurred and an acid (**4**) was isolated in a 24% yield, based on the quantity of **1** reacted. By treatment with ethereal diazomethane, **4** was changed into an ester (**5**).

As has been described above, 2-cyclohexenone and maleic anhydride easily reacted with **1** to afford the corresponding tetracyclic [4.4.2]propellanone derivatives. In connection with the above study, we have also obtained some information about the attempted photocyclodimerization of **1**. Attempts at photosensitized cyclodimerization with acetone, benzophenone, and phenanthrene were unsuccessful, but photosensitization with triphenylene gave a cyclodimer, albeit in a low yield. A detailed study of the photocyclodimerization of **1** is now in progress.

Experimental

Generals. All the melting points and boiling points are uncorrected. The IR spectra were recorded with a JASCO IR-G spectrometer. The NMR spectra were recorded for a 5% solution in carbon tetrachloride or deuterochloroform, with tetramethylsilane as the internal standard, on a JEOL JNM-3H-60 spectrometer. All the irradiations were carried out using a 500-W high-pressure mercury arc under a nitrogen atmosphere at room temperature. Analytical glpc was carried out on a Hitachi 063 gas chromatograph employing the following columns: a) 20% PEG-20M, b) 3% SE-30, c) 20% DC-550, and d) 10% FFAP.

Reagents. The $\Delta^{9,10}$-octalin (**1**) was prepared by the method of Dauben and was purified by nitrosyl-chloride treatment.[5] The maleic anhydride and the 2-cyclohexenone were purified by distillation before use. The triphenylene was recrystallized from methanol.

Photocycloaddition of 2-Cyclohexenone to 1. A neat mixture of 2-cyclohexenone (1.60 g, 16.7 mmol) and **1** (14.0 g, 103 mmol) was irradiated through a Pyrex filter for 3 hr. The photolysate was vacuum-distilled to give 13.3 g of recovered **1** (bp 60—65 °C/10 mmHg) and 2.32 g of viscous oil (bp 140—180 °C/10^{-3} mmHg). The latter was chromatographed on silica gel (200 mesh, 50 g) and was eluted initially with petroleum ether (400 ml) and then with ether (400 ml). The concentration of the latter eluate afforded 1.2 g of an oil which consisted of the cross adduct **2** and two cyclohexenone dimers.[6] The yield of **2** was estimated by glpc analysis to be 13% on the basis of **1** reacted. Preparative glpc using Column a) and d) gave an analytical sample; IR (neat) 1705 cm^{-1} (C=O); NMR (CCl_4) δ 1.00—2.80 (m); Mass *m/e* 232 (M^+); Found: C, 82.41; H, 10.39%. Calcd for $C_{16}H_{24}O$: C, 82.70; H, 10.41%; 2,4-dinitrophenylhydrazone, mp 161—163 °C. By treatment with a 5% palladium–charcoal catalyst under hydrogen, **2** was not hydrogenated (in methanol, room temp., 1 atom).[4]

Photocycloaddition of Maleic Anhydride to 1. A solution of maleic anhydride (5.4 g, 55 mmol) and **1** (15.0 g, 110 mmol) in dry ether (130 ml) was irradiated through a Pyrex

filter for 60 hr. The maleic anhydride dimer which was thus precipitated from the reaction mixture was removed by filtration, and then the ether was evaporated. The residual oil was vacuum-distilled to give 8.8 g of recovered **1** (bp 53 °C/3 mmHg) and 7.0 g of a viscous oil (bp 145—150 °C/10^{-3} mmHg) showing two characteristic IR absorptions ascribable to **3** at 1860 and 1790 cm^{-1}. The anhydride fraction was chromatographed on silica gel (200 mesh, 185 g). Elution with benzene–ether (95: 5, 10 l) brought about spontaneous hydrolysis to give 2.80 g of the acid **4** in a 24% yield, based on the quantity of **1** reacted. Recrystallization from aq. methanol provided an analytical sample; mp 181—182 °C; IR (KBr) 1700 cm^{-1} (COOH); NMR ($CDCl_3$) δ, 11.35 (s, 2H, COOH), 1.0—3.0 (m, 18H, others); Mass *m/e*, 234 (M^+-H_2O), 135; Found: C, 66.37; H, 7.99%. Calcd for $C_{14}H_{20}O_4$: C, 66.64; H, 7.99%. By treatment with ethereal diazomethane, **4** was changed into the dimethyl ester **5**, which showed an IR absorption at 1715 cm^{-1} and an NMR absorption at δ 3.70 (methyl ester).

A New Synthesis of Pyrimido[4,5-*e*][1,2,4]triazines from 5,5-Dibromopyrimidines

Takashi SUGIMOTO and Sadao MATSUURA

College of General Education, Nagoya University, Chikusa-ku, Nagoya 464

(Received February 3, 1975)

Synopsis. A new method for the synthesis of pyrimido-[4,5-*e*][1,2,4]triazines from 5,5-dibromopyrimidines was studied. Condensation of dibromopyrimidines (**1a, b**) with aminoguanidine or its analogues gave the 6,8-dioxo series (**5**) of the pyrimidotriazine, and aminodibromopyrimidines (**2a, b**) gave the 6-amino-8-oxo series (**6**).

An approach to a pyrimido[4,5-*e*][1,2,4]triazine from a pyrimidine may usually find difficulties in introducing a hydrazino group into the 5-position of the pyrimidine nucleus. In continuing our investigation in the synthesis of pyrimido[4,5-*e*][1,2,4]triazines as a potential antiviral agent,[1] we studied a new synthetic method of the series starting from 5,5-dibromopyrimidines.

The dibromopyrimidine(**1b**)[2] condensed with 1-amino-3-methylguanidine(**3d**) to give a guanylhydrazone(**4q**); this cyclized to 3-methylamino-5,7-dimethylpyrimido[4,5-*e*][1,2,4]triazin-6,8-dione (**5q**)[1] when heated with aqueous ammonia. The analogous treatments of **1b**[2] with **3c** or **3e** gave the corresponding pyrimitriazines(**5p,r**); similarly, their 5,7-demethyl homologues(**5i,j,k**)[1] were made from **1a** and the respective aminoguanidine(**3c,d**, or **e**). The 3-ethylthio- and 3-benzyltio-pyrimidotriazines(**5s;t**) were made from **1b** and *S*-ethyl or *S*-benzyl isothiosemicarbazide(**3f,g**); the use of pyridine in stead of ammonia in the cyclization step gave better yields.

Then, we extended this method to the preparation of 6-aminopyrimidotriazin-8-ones(**6**), which could not be made by other method.[1] The required dibromopyrimidines(**2a,b**) were obtained by the action of bromine on 2-amino(or dimethylamino)-5-nitrosopyrimidin-4,6-dione in ice-cold water. The aminopyrimidine(**2a**), on condensation with **3f** or **3g** in DMF and subsequent cyclization in boiling pyridine, afforded the expected products(**6n,o**); also the dimethylaminopyrimidine(**2b**) and **3d** yielded a pyrimidotriazine (**6q**). The ethylthio ether(**6n**) readily underwent aminolysis to give the 3-amino analogues(**6i,j,k,l**) on heating with an appropriate amine. Similarly, **6o** and hydrazine gave the 3-hydrazino derivative(**6m**); the hydrazino group was easily removed from **6m** by silver oxide[3] to give the 3-unsubstituted 6-aminopyrimidotriazin-8-one(**6h**).

Experimental

The analyses were done by the Analytical Section, Meijo University, Nagoya; the UV spectra were measured with a JASCO model ORD/UV-5 spectrophotometer and the λ_{max} are given in nm with a log ε in parentheses.

*3-Methylamino-5,7-dimethylpyrimido[4,5-*e*][1,2,4]triazin-6,8-dione (5q) and its analogues (5p, r).* A solution of **1b**[2] (2.8 g) and **3d**·2HCl (1.6 g) in HOAc (50 ml) was stirred at 20 °C for 30 min, then boiled for 5 min. After cooling, the needles were collected and crystallized from 1M-HCl to give **4q**·HCl (3.5 g), mp>300 °C (Found: C, 33.6; H, 4.9; N, 29.4%. Calcd for $C_9H_{14}N_6O_3HCl \cdot 0.5H_2O$: C, 33.6; H, 4.9; N, 29.4%). Refluxing of **4q** (3.0 g) in 1% ammonia (150 ml) for 3 hr gave **5q** (1.3 g), mp 290—291 °C (from water) (lit.[1] mp 290—291 °C). The same treatments of **1b** with **3e** gave **4r** (79%), mp >300 °C (Found: C, 35.5; H, 5.6; N, 27.7%. Calcd for $C_9H_{14}N_6O_3HCl \cdot 0.5H_2O$: C, 35.6; H, 5.45; N, 27.7%); **4r** was converted to **5r** (31%), mp 267—268 °C (from MeOH) (lit,[1] mp 267—268 °C). In the analogous manner, **5p** was obtained in 37% yield, mp>300 °C (lit,[4] mp 363—365 °C dec.) (Found: C, 40.0; H, 3.2; N, 40.3%. Calcd for $C_7H_8N_6O_2$: C, 40.4; H, 3.9; N, 40.4%); λ_{max}^{MeOH}: 221 (4.57), 247 (4.14), and 329 (3.99).

*3-Aminopyrimido[4,5-*e*][1,2,4]triazin-6,8-dione (5i) and its analogues (5j, k).* These compounds were made from **1a**[2] and the respective aminoguanidines (**3c, d, e**) by an analogous method as above in 40, 55, and 34% yields respectively; all gave satisfactory elemental analyses and were identified with the authentic samples.[1]

*3-Ethylthio(and benzylthio)-5,7-dimethylpyrimido[4,5-*e*][1,2,4]-triazin-6,8-diones (5s, t).* A suspension of **1b** (0.60 g) and **3f**·HBr (0.50 g) in HOAc (20 ml) was treated as above. Evaporation under reduced pressure gave a yellow solid; this compound was heated in pyridine (40 ml) under reflux for 20 min. Evaporation and recrystallization from water gave **5s** (0.30 g), mp 146.5—147.5 °C (lit,[5] mp 146—147 °C); λ_{max}^{MeOH}: 237 (4.32), 260 (sh., 4.06), and 340 (4.00). A similar treatment of **1b** with **3g** gave **5t** (85%), mp 201—202 °C (from H_2O–EtOH) (Found: C, 53.4; H, 3.95; N, 22.5%. Calcd for $C_{14}H_{13}N_5O_2S$: C, 53.3; H, 4.15; N, 22.2%); λ_{max}^{MeOH}:

238 (4.36), 260 (sh., 4.13), and 339 (4.05).

*6-Amino-3-ethylthio(and benzylthio)pyrimido[4,5-e][1,2,4]triazin-8-ones (**6n**, **o**).* Bromine (26 g) was added dropwise to a vigorously stirred suspension of 2-amino-5-nitrosopyrimidin-4,6-dione (12 g) in ice-cold water (50 ml) during 30 min. The colorless solid (17.2 g) was collected, washed with water, and dried over P_2O_5. The product could not be purified satisfactorily for elemental analysis owing to its instabilities. A solution of the dibromopyrimidine (9.0 g) and **3f**·HBr (6.5 g) in DMF (100 ml) was stirred at 20 °C for 30 min. The solution was diluted with pyridine (100 ml) and refluxed for 2 hr, followed by filtration while hot. The filtrate, on evaporation under reduced pressure and subsequent trituration with water, gave **6n** (3.2 g), mp>300 °C (by reprecipitation)(Found: C, 37.6; H, 3.4; N, 37.75%. Calcd for $C_7H_8N_6OS$: C, 37.5; H, 3.6; N, 37.5%); pK_a 6.72±0.06; λ_{max} at pH 4.1: 261 (4.48) and 353 (3.99); at pH 10.4: 253 (4.53) and 352 (3.99).

Replacing **3f** by **3g** in the foregoing condensation gave **6o** (73%), mp >300 °C (by reprecipitation) (Found: N, 28.4%. Calcd for $C_{13}H_{10}N_6OS$: N, 28.2%); pK_a 6.72±0.03; λ_{max} at pH 4.0: 261 (4.47) and 354 (4.03); at pH 11: 255 (4.54) and 354 (4.04).

*6-Dimethylamino-3-methylaminopyrimido[4,5-e][1,2,4]triazin-8-one (**6q**).* 5,5-Dibromo-2-dimethylaminopyrimidin-4,6-dione (**2b**) was made from its 5-nitroso precursor and bromine in 70%. The dibromopyrimidine (**2b**) and **3d**, on treatments in a similar way for the 2-oxy analogue (**5j**), gave **6q** (37%), mp>300 °C (from water) (Found: C, 43.6; H, 5.0; N, 44.2%. Calcd for $C_8H_{11}N_7O$: C, 43.4; H, 5.0; N, 44.3%); pK_a 7.60±0.02; λ_{max} at pH 4.0: 247 (4.62) and 352 (4.02); at pH 10.0: 238 (4.56), 265 (sh., 4.04), and 368 (4.11).

*3,6-Diaminopyrimido[4,5-e][1,2,4]triazin-8-one (**6i**) and its 3-alkylamino analogues (**6j**, **k**, **l**).* A solution of **6n** (0.50 g) in 30% ammonia (10 ml) was heated in a sealed tube at 140 °C for 10 hr. Evaporation and subsequent trituration with dil. formic acid gave **6i** (0.30 g), mp >300 °C (from water) (Found: C, 33.5; H, 2.8%. Calcd for $C_5H_5N_7O$: C, 33.5; H, 3.2%); pK_a 8.05±0.05; λ_{max} at pH 4.0: 232 (4.54) and 346 (3.91); at pH 10.2: 227 (4.46), 245 (sh, 4.25), and 339 (4.00). The use of methylamine, ethylamine, or dimethylamine in the foregoing aminolysis gave the corresponding analogues: **6j** (93%), mp >300 °C (Found: C, 36.55; H, 3.5; N, 49.2%. Calcd for $C_6H_7N_7O\cdot0.2H_2O$: C, 36.6; H, 3.8; N, 49.8%); pK_a 7.86±0.05; λ_{max} at pH 4.1: 241 (4.59) and 345 (3.90); at pH 12: 237 (4.63) and 347 (3.99). The 3-ethylamino derivative (**6j**) was obtained in 76% yield, mp >300 °C (Found: C, 39.8; H, 4.4; N, 45.4%. Calcd for $C_7H_9N_7O\cdot0.3H_2O$: C, 39.55; H, 4.55; N, 46.1%); pK_a 8.08±0.04; λ_{max} at pH 11.0: 249 (4.60) and 346 (3.98). The 3-dimethylamino analogue (**6l**), obtained in 65% yield, had mp >300 °C (Found: C, 40.05; H, 4.3; N, 46.5%. Calcd for $C_7H_9N_7O\cdot0.2H_2O$: C, 39.9; H, 4.5; N, 46.5%); pK_a 7.94±0.02; λ_{max} at pH 4.0: 250 (4.50), 270 (sh., 4.19), 353 (3.77), and 380 (sh., 3.68); at pH 10.1: 242 (4.58) and 351 (3.87).

*6-Aminopyrimido[4,5-e][1,2,4]triazin-8-one (**6h**).* A mixture of **6o** (1.5 g), hydrazine hydrate (10 ml), and pyridine (100 ml) was refluxed for 6 hr. Chilling gave a solid (0.70 g), which was stirred with silver oxide (4 g) in water (300 ml) at 30 °C for 10 hr. Filtration and concentration to *ca.* 30 ml gave **6h** (0.18 g), mp >300 °C (from water) (Found: C, 32.7; H, 2.7; N, 45.6%. Calcd for $C_5H_4N_6O$: C, 33.0; H, 3.3; N, 46.1%); pK_a 6.37±0.03; λ_{max} at pH 4.1: 277 (3.90) and 332 (3.68); at pH 10.4: 258 (4.15) and 339 (3.73).

(Received November 16, 1974)

Synopsis. Electric dipole moments at 25 °C in benzene have been measured for *cis*-2-styrylfurans and -styrylthiophenes which are chloro- and nitro-substituted in 2′-, 3′-, 4′-position. Results of dipole moment analyses in conjunction with UV spectroscopic data have been discussed in terms of preferred conformations for these compounds.

Recent studies on 1,2-diarylethylenes have led to the isolation of stable *cis*-isomers of unsymmetrical derivatives bearing two distinct aryl groups.[1-5] In these works the assignment of configuration was made by means of IR, UV, and NMR spectroscopy. Information about the conformational properties of these molecular systems, however, is still lacking in the literature.

We therefore report here the results of dipole moment measurements (benzene, 25 °C) for a number of derivative compounds of the series *cis*-2-styrylfuran (**1**)—(**7**) and -styrylthiophene (**8**)—(**14**). Their preferred molecular solute conformations are discussed on the basis of comparison between the observed and calculated dipole moments.

Experimental

Materials. The *cis*-2-styrylfurans (**1**)—(**7**) and -styrylthiophenes (**8**)—(**14**) were prepared as previously described.[1-3] Each compound, just before dipole moment determination, was crystallized or distilled under reduced pressure when liquid to constant mp or bp and ε_{max}. Each sample examined was at least 99% in the pure *cis* isomer, as checked by glc.

Physical Measurements. Dielectric constants of benzene solutions were measured at 25±0.01 °C using a Dipolmeter WTW DMO1 apparatus. Specific volumes and refractive indexes of solutions were determined using experimental techniques described in detail elsewhere.[6]

The total solute polarization $P_{2\infty}$ was evaluated using the Halverstadt-Kumler[7] method. The distortion polarization P_e+P_a was assumed to be 1.05 R_D, where R_D is the experimental molar refraction.

The probable error in μ was estimated not to exceed ±0.03 D for each compound examined.

Experimental results are summarized in Table 1.

TABLE 1. POLARIZATION DATA AND DIPOLE MOMENTS OF *cis*-2-STYRYLFURANS (**1**)—(**7**) AND -STYRYLTHIOPHENES (**8**)—(**14**) IN BENZENE AT 25 °C

Results and Discussion

In order to predict dipole moments for the various conformations of the compounds studied, the first task is estimating the direction of action of the resultant moment μ_X of the unsubstituted molecules (**1**), (**8**). The data in Table 1 show that the experimental dipole moment values for *cis*-2-styrylfuran (**1**) and -styrylthiophene (**8**) are fairly close, at less than ±0.08 D, to those of furan (0.67 D[8]) and thiophene (0.53 D[8]), respectively. On this basis we assume that: (i) the interaction moment between the phenyl and the heterocyclic ring can be neglected; (ii) the resultant μ_X can be taken as equal to the individual moment of furan or thiophene molecule; (iii) μ_X acts from the ring to the hetero-atom along the bisector of the C–X–C angle.[9]

In the calculations the following group moments were used:[10] μ_{NO_2}=3.98 D; μ_{Cl}=1.58 D.

The rotational conformations of the molecules dealt with are defined by the angles θ and ϕ described by the phenyl and furan (or thiophene) rings in clockwise and *anti*-clockwise direction, respectively, starting from the planar structure shown in Fig. 1.

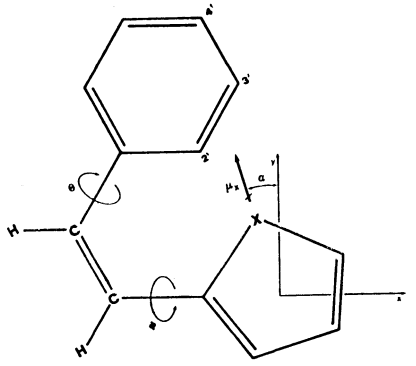

Fig. 1.

* To whom all correspondence should be addressed.

By reference to this model, the total moment was calculated using the relation (1)

$$\mu = (\mu_x^2+\mu_y^2+\mu_z^2)^{1/2}, \quad (1)$$

in which the component moments μ_x, μ_y, and μ_z along the co-ordinate axes are given as a function of θ and ϕ by Eqs. (2)—(4)

$$\mu_x = \pm\mu_R \cos 60° \cos\beta - \mu_R \sin 60° \sin\beta \cos\theta - \mu_x \sin\alpha \quad (2)$$

$$\mu_y = \mp\mu_R \cos 60° \sin\beta - \mu_R \sin 60° \cos\beta \cos\theta + \mu_x \cos\alpha \cos\phi \quad (3)$$

$$\mu_z = \mu_R \sin 60° \sin\theta + \mu_x \cos\alpha \sin\phi \quad (4)$$

In Eqs. (2)—(4) μ_x is the moment of the hetero-ring and μ_R is the group moment of the substituent; the angle α takes the values 18.5° for X=O and 11.8° for X=S, as can be calculated using the given geometries for furan[11] and thiophene.[12] The above equations are in general valid for all compounds examined by substituting β=300° and lower signs for 2′-substituted derivatives; β=300° and upper signs for 3′-substituted derivatives; β=180°, θ=0° and lower signs for 4′-substituted derivatives.

Results of computations show that for each 2′- and 3′-substituted derivative numerous combinations (ϕ,θ) are possible for which the predicted dipole moment agrees with the experimental value. Therefore the most probable conformation within the ranges (ϕ,θ) indicated cannot be decided with certainty. However, the number of possible conformations can be restricted by assuming that the ϕ angles found in the 4′-Cl derivatives **4** and **11** are preserved in all the 2′- and 3′-substituted compounds with slight distortions due to steric factors. Computations produce a value of ϕ=78° for **4** and ϕ=89° for **11**, thus indicating that non-bonded repulsive interactions, due to crowding, essentially operate to force the hetero-ring out from coplanarity with the ethylenic fragment. On the other hand, it seems highly unlikely that the angles ϕ=0° and ϕ=43° found for the 4′-NO_2 derivative compounds **7** and **14**, respectively, are retained in *cis*-2-styrylfurans and -styrylthiophenes. The powerful electron withdrawing group in 4′-position is, in fact, a factor determining a coplanarity-favoring conjugative interaction which tends to minimize ϕ in these particular derivatives.

In Table 2 are given the possible conformations (ϕ,θ) obtainable, on the basis of the above assumptions, from our calculations.

Use of scale molecular models shows that the conformations denoted by II are sterically more favorable. The general preference in both series for these conformations can be clearly understood in terms of repulsive steric interactions which determine the arrangement of the phenyl ring with the 2′- or 3′-substituent group as far as possible from the heterocyclic nucleus. A combined mesomeric effect, moreover, is the factor determining the preference for structures in which the phenyl ring is coplanar to the ethylenic fragment, *i.e.* for conformations having a ϕ value near 180°.

Table 2. Preferred conformations of *cis*-2-styryl-furanes and -styrylthiophenes

	Compound	Conformation I ϕ	I θ	II θ
2	*cis*-2-(2′-Chlorostyryl)furan	78°	36°	186°
3	*cis*-2-(3′-Chlorostyryl)furan	78°	30°	198°
5	*cis*-2-(2′-Nitrostyryl)furan	78°	26°	200°
6	*cis*-2-(3′-Nitrosrytyl)furan	78°	32°	192°
7	*cis*-2-(4′-Nitrostyryl)furan	0°	—	—
9	*cis*-2-(2′-Chlorostyryl)thiophene	89°	8°	192°
10	*cis*-2-(3′-Chlorostyryl)thiophene	89°	348°	212°
12	*cis*-2-(2′-Nitrostyryl)thiophene	89°	—	210°
13	*cis*-2-(3′-Nitrostyryl)thiophene	89°	35°	168°
14	*cis*-2-(4′-Nitrostyryl)thiophene	43°	—	—

An interesting feature of the UV spectroscopic data available[1-4] is that the conjugation band of each *cis*-2-styrylfuran derivative compound is shifted to shorter wavelengths in the corresponding derivative of thiophene series. This fact suggests that the tendence for aryl rings to be coplanar with the ethylenic group is in general more reduced in *cis*-2-styrylthiophenes. The present dipole moment results are therefore consistent with these deductions in that the twisting angle values found (see Table 2) are correspondingly greater in the derivatives of the thiophene series.

Base-catalyzed Oxygenation of 2,6-Di-*t*-butylphenols. A Convenient Method for Preparation of *p*-Quinols

Akira NISHINAGA, Toshio ITAHARA, and Teruo MATSUURA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received January 13, 1974)

Synopsis. The oxygenation of 4-alkyl-2,6-di-*t*-butylphenols in diethylamine containing sodium amide under mild conditions afforded the corresponding *p*-quinols in excellent yields.

The synthesis of *p*-quinols has been developed by the oxidation of the corresponding phenols involving Co(II)–Schiff's base complex catalyzed oxygenation[1] and thallium triperchlorate oxidation,[2] and also by the reduction of the appropriate *p*-benzoquinones with alkyllithium compounds.[3] The reduction of hydroperoxides formed from appropriate phenols by oxidation with O_2[4] or hydrogen peroxide-molybdenum complex[5] also affords *p*-quinols. No attempt has been made for a one-step synthesis of such *p*-quinols by simple oxygenation. We previously reported that the oxygenation of *t*-butylated phenols in *t*-BuOH or aprotic solvents such as DMF, DMSO, and HMPA containing *t*-BuOK leads to the exclusive formation of epoxyquinols, intramolecular decomposition products of the corresponding hydroperoxides.[6,7]

a; R=Bu^t, **b**; R=Pr^i, **c**; R=Et, **d**; R=Me

TABLE 1. THE FORMATION OF *p*-QUINOLS BY OXYGENETION OF **1**.

1	Solvent	Base	Base/1 mol/mol	Reaction time (hr)	Conversion (%)	**1** Yield (%)[a]
1a	$HNEt_2$	$NaNH_2$	5	4	100	**2a**, 86
	NEt_3	$NaNH_2$	5	6	30	90
	$HNEt_2$	*t*-BuOK	5	6	35	80
1b	$HNEt_2$	$NaNH_2$	5	6	100	**2b**, 92
1c	$HNEt_2$	$NaNH_2$	5	6	100	**2c**, 94
1d	$HNEt_2$	$NaNH_2$	5	6	100	**2d**, 95
	NEt_3	$NaNH_2$	5	6	40	90
	Me_2S	$NaNH_2$	5	6	20	90
	Me_2S	*t*-BuOK	5	6	20	90

a) Yields by isolation.

We now find that the oxygenation of 2,6-di-*t*-butylphenols in $HNEt_2$ containing $NaNH_2$ affords the corresponding *p*-quinols in excellent yields. This provides a convenient method for one-step synthesis of such *p*-quinols (**2**). The phenols (**1**) were dissolved in $HNEt_2$ containing excess $NaNH_2$ and bubbled with oxygen at room temperature. The products (**2**) could be isolated in crystalline form upon diluting the reaction mixture with ice-cooled water and were identified with authentic samples (IR and NMR). The results are summarized in the Table. Since the hydroperoxides (**3**) separately synthesized are easily reduced in $HNEt_2$ to **2**, the formation of **2** by oxygenation should proceed *via* the hydroperoxide intermediate. Replacement of the solvent with NEt_3 or of the base with *t*-BuOK reduces the reactivity (Table 1). Dimethyl sulfide is a good reducing reagent for **3** to **2** but the oxygenation of **1** in this solvent is largely inhibited (Table 1) probably due to competition of oxidation of the solvent itself.

Experimental

*Oxygenation of **1** in Diethylamine Containing Sodium Amide.* The phenols (1 mmol) were dissolved in diethyl amine (20 ml) containing sodium amide (5 mmol). Oxygen was bubbled through the solutions at room temperature for appropriate periods (see Table 1). The reaction mixtures were then poured into a large amount of ice-cooled water to give the *p*-quinols (**2**) as crystals, which were identified with authentic samples[1] (IR and NMR).

Products of the Palladium-catalyzed Dehydrogenation of *o*-Cyclohexylphenol. A Correction

Kimiaki IMAFUKU

Department of Chemistry, Faculty of Science, Kumamoto University, Kurokami, Kumamoto 860

(Received November 18, 1974)

Previously, we reported,[1] on the basis of vpc analysis, that the dehydrogenation of *o*-cyclohexylphenol (I) over palladium-on-charcoal gave *o*-phenylphenol (II), dibenzofuran (III), and diphenyl ether (IV'). However, we have now confirmed that the structure of the compound which was previously assumed to be diphenyl ether (IV') is really diphenyl (IV); confirmation was made by its isolation and on the basis of its spectral data. It was found that the diphenyl was produced by the hydrogenolysis of *o*-phenylphenol (II) in the presence of the same catalyst.

The procedure was as follows. A mixture of *o*-cyclohexylphenol (I) (5 g) and 5% palladium-on-charcoal (1 g) was heated at 220—230 °C for 3 hr under a nitrogen atmosphere. The reaction mixture was then dissolved in benzene, and the catalyst was filtered off. The filtrate was chromatographed on a silica gel column (Wakogel C-100, 500 g) with chloroform. The resulting solid from the first fraction was recrystallized from ethanol, giving diphenyl (IV) (370 mg, 8.5%) (mp 69—70 °C (mixed mp 68.5—70 °C)). Its spectral data were also consistent with those of the authentic material.

In addition, a mixture of *o*-phenylphenol (II) (2 g) and 5% palladium-on-charcoal (0.4 g) was heated at 220—230 °C for 3 hr under a hydrogen atmosphere and treated such as above, thus giving diphenyl (IV) (260 mg, 14%).

(Recieved December 27, 1974)

Twelve force constants in the general quartic force field of carbon disulfide have been determined by a least-squares method from the available spectroscopic data on four isotopic species of carbon disulfide: $^{12}C^{32}S_2$, $^{13}C^{32}S_2$, $^{12}C^{32}S^{34}S$, and $^{13}C^{32}S^{34}S$. A reasonable set of force constants is obtained together with a set of the third-order parameters λ_1, λ_2, λ_3, and δ which appear in Fermi coupling off-diagonal matrix elements. From the converged set of force constants, l-type doubling constants for a few π-vibrational states are calculated through a direct numerical diagonalization method of vibrational Hamiltonian matrix. They agree well with the observed l-type doubling constants.

In a process of extending the numerical diagonalization technique of vibrational Hamiltonian matrix[1] to the anharmonic treatment of linear symmetric triatomic molecules, it was required to obtain the most reliable set of force constants of CS_2 up to the fourth order. The general quartic force field of CS_2 has previously been studied by Smith and Overend[2] and by Giguere, Wang, Overend, and Cabana.[3] More recently, however, two high resolution infrared studies have been reported on this molecule by Maki[4] and by Blanquet and Courtoy.[5] The study of Maki covers a number of 'hot transitions' in $^{12}C^{32}S_2$ and gives the information of levels which are not directly accessible from the ground state. The study of Blanquet and Courtoy consists of the high resolution measurements of a number of $^{13}C^{32}S_2$ bands. Both studies provide very important pieces of information on the determination of anharmonic force constants of CS_2. Like CO_2, CS_2 is one of a few fundamental molecules, on which the validity of various model potential functions is tested:[6] One of the criteria for this test is whether they can reproduce the values of force constants in the general quartic force field reasonably well or not. It is, therefore, desirable to determine these force constants as precisely as possible. We have carried out such new anharmonic calculations: twelve force constants in the general quartic force field and four third-order parameters, which appear in Fermi coupling off-diagonal matrix elements of $v_1=2v_2$ type, are adjusted simultaneously to fit the presently available spectroscopic data of $^{12}C^{32}S_2$,[3,4,7-10] $^{13}C^{32}S_2$,[5] $^{12}C^{32}S^{34}S$,[11-13] and $^{13}C^{32}S^{34}S$.[11] The l-type doubling constants of $^{12}C^{32}S_2$ and $^{13}C^{32}S_2$ are also obtained from the π-π transitions.[4,5] From the refined set of force constants, the corresponding l-type doubling constants are calculated which can be compared with experimental values quite well.

Determination of Anharmonic Force Constants

A general method for the determination of force constants in the general quartic force field was described in the preceding papers[14,15] and it is not repeated here. However, our program of anharmonic calculations has been improved so as to handle 'hot transitions' directly. This is particularly useful when the spectroscopic constants associated with a given hot transition ($v_0'-v_0''$, $B'-B''$) are determined more accurately than those in the lower state (v_0'', B'').

The potential functions of linear symmetric triatomic molecules may be expanded in terms of curvilinear internal coordinates through quartic terms and

$$\begin{aligned} V = {} & K_{11}(R_1^2+R_3^2) + K_{13}R_1R_3 + K_{22}R_2^2 \\ & + K_{111}(R_1^3+R_3^3) + K_{122}(R_1+R_3)R_2^2 \\ & + K_{113}(R_1+R_3)R_1R_3 + K_{1111}(R_1^4+R_3^4) \\ & + K_{1113}(R_1^2+R_3^2)R_1R_3 + K_{1133}R_1^2R_3^2 \\ & + [K_{1122}(R_1^2+R_3^2) + K_{1223}R_1R_3 + K_{2222}R_2^2]R_2^2, \end{aligned} \quad (1)$$

where R_1 and R_3 are two stretching coordinates and R_2 is the bending coordinate.[16]

Fermi Resonance in CS_2. The vibrational levels of most non-hydride linear triatomic molecules are more or less affected by Fermi resonance through non-vanishing matrix elements $\langle v_1, v_2, l_2, v_3|v_1-1, v_2+2, l_2, v_3\rangle$. To the third order of approximation in perturbation treatment, this matrix element is expressed as

$$\begin{aligned} & (1/2)[-k_{122}/\sqrt{2}+\lambda_1 v_1+\lambda_2(v_2+2)+\lambda_3(v_3+1/2) \\ & \qquad +\delta J(J+1)][(v_2+2)^2-l_2^2]^{1/2}v_1^{1/2} \end{aligned} \quad (2)$$

The λ's and δ represent the third order vibrational and rotational effects on the matrix elements,[17] which cannot be ignored in the determination of the general quartic force field of most linear triatomic molecules.[2,3,15,18] The effect of δ on the perturbed rotational constant in each vibrational state is also taken into account. In the present calculation we are able to treat the third-order parameters of the ^{12}C- and ^{13}C-species separately,[19] thus the total number of independent parameters is twenty.

Spectroscopic Data Used in Computations. The spectroscopic data used in the refinement of twelve general quartic force constants and eight third-order parameters are listed in Table 1 along with the corresponding weights. References are also given in the last column in Table 1. The present system for the weighting is based on the fact that the band centers are usually determined within a few thousandths of a wave number and that the errors in the ΔB values are in the order of 10^{-7} cm^{-1}. The spectroscopic data associated with the transitions from the 02^20 level of $^{12}CS_2$ as well as those from the 01^10 level in $^{13}CS_2$ are used directly, since the spectroscopic constants of the lower states are known less accurately. We employed $r_e=1.5562$ Å for the equilibrium bond distance,

Table 1. Observed and calculated vibrational levels (in cm^{-1}) and rotational constants (in 10^{-4} cm^{-1}) for $^{12}C^{32}S_2$, $^{13}C^{32}S_2$, $^{12}C^{32}S^{34}S$, and $^{13}C^{32}S^{34}S$

S[c]	0.25		0.35					

a) The units of force constants are: mdyn/Å for K_{11} and K_{13}, mdyn·Å/rad² for K_{22}, mdyn/Å² for K_{111} and K_{113}, mdyn/rad² for K_{122}, mdyn/Å³ for K_{1111}, K_{1113}, and K_{1133}, mdyn/Å rad² for K_{1122} and K_{1223}, and mdyn·Å/rad⁴ for K_{2222}. The third order parameters λ's and $\delta\times10^4$ are given in cm^{-1}. In order to retain good reproducibility of the calculated values, four or three significant numbers beyond the decimal point are given, even when the corresponding dispersions are considerably larger than that. b) Dispersions, shown in parentheses, apply to the last digits of the quantity. c) The weighted sum of squared deviations for a given set of force constants and the third order parameters. d) The corresponding force constants of CO_2 (Ref. 15).

Results and Discussion

The converged sets of the anharmonic force constants and the third-order parameters are listed in Table 2 with the corresponding previous results on CS_2 and CO_2. In preliminary calculations the differences of the third-order parameters due to isotopic substitutions were neglected, and the converged set for the sixteen parameter problem is given in column (ii). It was found, however, that the fit in frequency and rotational constant is much improved by allowing the third-order parameters vary for the ^{12}C- and ^{13}C-species, and the twenty parameter problem seems to be stable enough to give a good converged set which is listed in the column (i) of Table 2. The harmonic frequencies ω_i, the anharmonicity constants x_{ij}, the vibration-rotation constants α_i, and the cubic and quartic force constants in dimensionless normal coordinates k_{ijk} and k_{ijkl} are calculated for the four isotopic species of CS_2 from the sets (i) and (ii), their values are listed in Table 3.

Values of Force Constants. The force constants of CS_2 thus determined have the features expected for linear triatomic molecules: (1) They show a dis-

tinctive positive-negative-positive pattern for the quadratic, cubic and quartic force constants. (2) Off-diagonal force constants are one order of magnitude smaller than the corresponding diagonal force constants. In addition, the overall feature of the potential function is very close to that of CO_2 which is quite reasonable. In Table 4 three diagonal stretching force constants are listed and compared with the corresponding constants of CS[20] and OCS.[21] The ratios $a_1=K_{111}/K_{11}$, $a_2=K_{1111}/K_{11}$, and $a_2^*=7a_1^2/12$ are also listed in the table. Within the limits of present approximation, the Morse type potential function[22] seems to be a good model for the CS stretching mode, since the relationship $a_2=a_2^*$, which holds strictly in the Morse potential function, is nearly realized in this molecule. We may also estimate the dissociation energy of $CS_2\rightarrow CS+S$ from an assumption that the stretching potential is of Morse type. Then we have $D_e=K_{11}/a_1^2=6.8$ eV. As far as we are aware, no experimental data seem available for this process, but the value is close to that of 7.2 eV for diatomic CS.[23]

Although the least-squares dispersions for the third-order parameters λ's are relatively large, it is gratifying that the converged values are very close to those obtained on purely experimental basis. The isotopic ratios seem also reasonable. The values of harmonic frequencies, anharmonicity constants, vibration-rotation constants, and third-order parameters for $^{12}C^{32}S_2$ are collected in Table 5 from different sources: (1) calculated from the set (i) in the present work, (2) obtained by Blanquet and Courtoy[24] who made the direct least-squares fit of the experimental data to the analytical expressions of the energy levels and the rotational constants, (3) calculated from the force constants given in Ref. 3, and (4) obtained by the same authors by applying the Amat-Pimbert method to experimental data.[25] The agreements (or disagreements rather) in their values indicate, in a way, the precisions of the general quartic force constants and of some spectroscopic constants of the CS_2 molecule. As seen in Table 5, the final set of force constants yields the spectroscopic constants which are very close to those obtained experimentally. This seems to guarantee the consistency of the present anharmonic calculation.

Unperturbed Energy Levels. Fermi resonances in CS_2 are not so strong as those in CO_2. Nevertheless, the effects are seen on most of energy levels. The unperturbed and perturbed energy levels and rotational constants are calculated from the set (i) in Table 2 and are listed in Table 6 for a few typical Fermi polyads. Shifts of 7—20 cm^{-1} are usually observed. It is also seen that Fermi resonances in $^{13}C^{32}S_2$ are stronger than those in $^{12}C^{32}S_2$, as is expected from the lowering of the ν_2 frequency on the ^{13}C-substitution.

l-Type Doubling Constants. From the analyses of the π-π transition bands, the l-type doubling constants have been determined for a few vibrational states of $^{12}C^{32}S_2$ and $^{13}C^{32}S_2$.[4,5] The dependence of l-type doubling constants on vibrational quantum numbers has previously been explored by Nakagawa and Morino who used the contact transformation method.[26] The l-type doubling in linear molecules arises essentially from the Coriolis Hamiltonian term which connects

with the $l=\pm 1$ levels through a common $l=0$ level. The effect of vibrational anharmonicities on l-type doubling constants may be evaluated if the perturbed vibratioanl wave functions are known. This is most easily done by solving the vibrational Hamiltonian matrix numerically. The eigenvectors indicate the mixings of the basis harmonic wave functions through the vibrational anharmonicity.[1] The l-type doubling constant for a given π-state may then be calculated numerically from the perturbed wave functions.[27] In Table 7, the l-type doubling constants calculated from the converged set (i) are listed and compared with the experimental values. In most cases the calculated constants are slightly smaller than the observed, however, differences are small and they show a remarkably similar trend in their dependence on vibrational quantum numbers as well as on isotopic substitutions.

Concluding Remarks. We believe that the general quartic force constants and the third-order parameters determined in the present work are as good as the corresponding constants in the CO_2 molecule.[15] In order to secure their reliability, however, more experimental works should be needed especially on low-lying vibrational levels of the ^{13}C- and ^{34}S-species. The measurements along this line is being planned.

The present author wishes to express his gratitude to Dr. G. Blanquet who has provided the results of the measurements for $^{13}C^{32}S_2$ prior to publication.

Molecular Structure of Trimethylene Sulfide as Studied by Gas Electron Diffraction with Joint Use of Rotational Constants

Ken-ichi KARAKIDA and Kozo KUCHITSU

Department of Chemistry, Faculty of Science, The University of Tokyo, Bunkyo-ku, Tokyo 113

(Received March 5, 1975)

The molecular structure of trimethylene sulfide (thietane) has been determined by an analysis of electron diffraction intensities combined with the rotational constants determined by microwave spectroscopy by Harris *et al.*: r_g(C–S) = 1.847±0.002 Å, r_g(C–C) = 1.549±0.003Å, r_g(C_α–H) = 1.09±0.02 Å, r_g(C_β–H) = 1.12±0.04 Å, ∠C–S–C(r_{av}) = 76.8±0.3°, ∠H–C_α–H(r_{av}) = 112±4°, ∠H–C_β–H(r_{av}) = 114±5° and the dihedral angle, ∠C_2SC_4–$C_2C_3C_4$(r_{av}) = 26±2°. The uncertainties represent estimated limits of error. The definitions of the geometrical parameters have the usual physical significance except that the normal coordinate representing the large-amplitude ring-puckering motion is extrapolated to its equilibrium position. The conventional formula used in the joint analysis has been modified to account for the large-amplitude vibration.

The ring-puckering motion of trimethylene sulfide (Fig. 1) has been studied in detail by spectroscopy[1,2] by Harris *et al.*, and the potential function is found to have a double minimum with a barrier of 274 cm^{-1} at the planar configuration. The bond distances and angles in this molecule were not determined with high accuracy, however. The present study was undertaken to determine the molecular structure by electron diffraction for a quantitative comparison with those of related molecules.

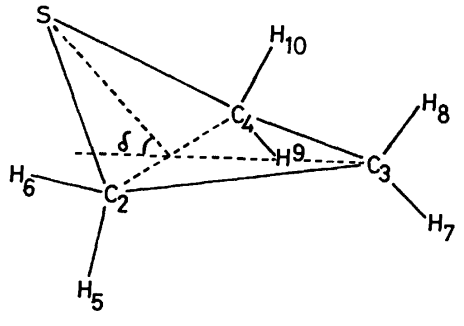

Fig. 1. Trimethylene sulfide.

The C–C, C–S and the weighted average of C–H distances were determined uniquely from electron diffraction intensities[3]. However, since the two ring diagonal distances, r(C···C) and r(C···S), are closely spaced and constitute a single peak in the radial distribution curve, it is difficult to resolve the distances with high accuracy from the electron diffraction data alone. In addition, the diffraction data has strong correlation between the hydrogen parameters in the α and β positions. Spectroscopic rotational constants A and B provide information on the r(C···C) and r(C···S) distances, respectively, and on the hydrogen parameters. Therefore, the diffraction intensities and the rotational constants have been used jointly in the present study[4]. The conventional formula used in the analysis has been modified to account for the large-amplitude ring-puckering vibration.

Experimental

The sample (bp 94 °C/752 Torr) used for the short camera length was prepared[5] in the laboratory of Professor I. Tabushi at Kyoto University. The infrared, NMR and mass spectra, and gas chromatographic analysis indicated that the sample was free from any significant impurities. The sample used for the long camera length was purchased from Tokyo Kasei Co., Ltd. (purity over 96%). Since the major impurities of the sample were solid polymers with negligible vapor pressures, it was used without further purification.

Electron diffraction photographs were taken[6] with an r^3-sector at the camera lengths of 107.73±0.02 and 243.29±0.02 mm. The electron wavelength (about 0.06 Å) was calibrated with reference to the r_a(C=O) distance of carbon dioxide (1.164_6 Å) measured under the same experimental conditions. The sample gas was maintained in thermal equilibrium with its liquid phase at room temperature. The pressure of the sample gas was about 30 Torr, and the exposure times were about 100 and 60 s for the short and long camera lengths, respectively. Other experimental details are described elsewhere.[6,7] The optical densities (0.17—0.62) were assumed to be proportional to electron intensities. The observed molecular intensity covering the range of s = 3.5—37.7 $Å^{-1}$ was used in the analysis. The data taken with the short and long camera lengths[8] were linked at s = 9.4 $Å^{-1}$. The elastic and inelastic scattering factors and the phase shifts were taken from the tables[9] prepared by

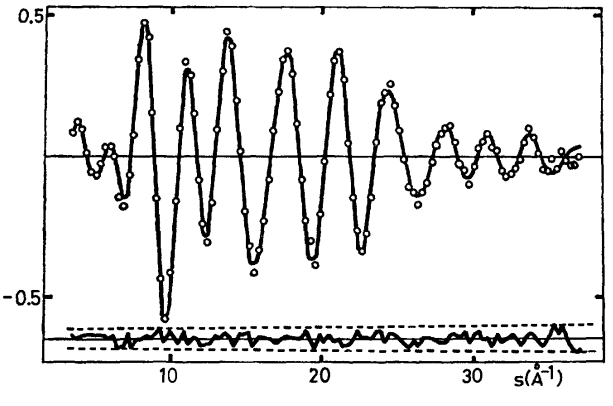

Fig. 2. Experimental and theoretical molecular intensities for trimethylene sulfide.
Typical observed $sM(s)$ values are shown in open circles, and the best-fit theoretical is shown in the solid curve. The indices of resolution are 0.84±0.03 and 0.96±0.03 for the long and short camera regions, respectively. The lower solid and broken curves represent the residuals and the error limits in the $sM(s)$ to a fractional error of 1×10^{-3} of the original photocurrent, respectively.

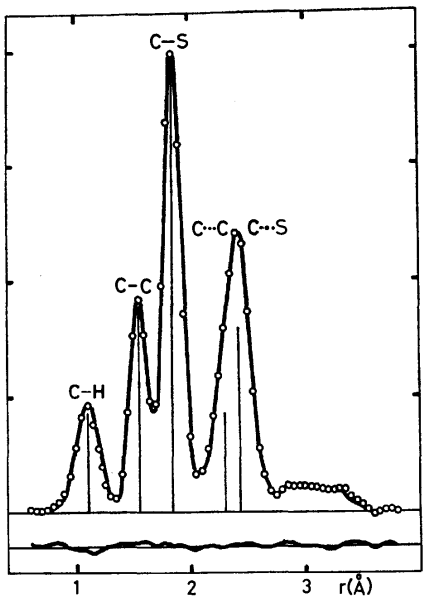

Fig. 3. Experimental (open circles) and theoretical radial distribution curves for trimethylene sulfide. The lower curve represents residuals. Vertical bars correspond to principal internuclear distances. A damping factor, $\exp(-0.0019 s^2)$, was used.

Schäfer *et al.* The molecular intensity is illustrated in Fig. 2, and the corresponding radial distribution curve is given in Fig. 3. Most of the calculations were carried out on a HITAC 8800/8700 operating system in the Computer Center of the University of Tokyo.

Analysis

Analysis of Diffraction Intensities. The C–S, C–C and the weighted average C–H distances and their mean amplitudes were determined without assumptions or constraints.[3]

In order to get further information on the rest of the structural parameters, the following assumptions were made in the analysis:

a) The average positions of the hydrogen atoms are such that the H–C–H plane is perpendicular to the plane defined by one carbon and two adjacent ring atoms, and the angle bisectors are colinear.

b) The C_α–H and C_β–H distances are equal.

c) The H–C_α–H and H–C_β–H angles in the r_α^0 structure are equal to the corresponding angles in trimethylene oxide,[10] 110.3° and 110.7°, respectively.

Since this molecule has a large-amplitude motion, the conventional formulas based on infinitesimal vibrational amplitudes have to be modified to calculate the mean amplitudes and vibrational corrections. The zero-point average structure in the present study is defined as the r_α^0 structure[11] where the normal coordinate representing the large-amplitude ring-puckering motion (Q) takes its equilibrium value (Q_e). Mean amplitudes and vibrational corrections for bonded pairs are calculated from the conventional formulas[11] but contributions from the large-amplitude vibration are not included.

The mean amplitude for a nonbonded pair is calculated by[12]

$$l^2 = (\langle r_e(Q)^2\rangle_T - \langle r_e(Q)\rangle_T^2) + \langle \Delta z^2\rangle'_T \quad (1)$$

where T denotes thermal average at T kelvin and the prime outside the bracket denotes the sum of contributions from all the small-amplitude modes, and r_e is an instantaneous distance for the nonbonded pair when all the small-amplitude coordinates take their equilibrium positions. The r_g distance for a nonbonded pair is defined as

$$r_g = \langle r_e(Q)\rangle_T + \langle \Delta r\rangle'_T \quad (2)$$

which can be rewritten by use of a diatomic approximation[13,14] as

$$r_g \cong \langle r_e(Q)\rangle_T + \frac{3}{2}a_3\langle \Delta z^2\rangle'_T \quad (3)$$

The r_g distance is assumed to satisfy the equation,

$$r_g = r_a + \frac{l^2}{r_a} \quad (4)$$

where r_a is directly derived from the diffraction intensities. Since the radial distribution of the principal nonbonded pairs in trimethylene sulfide are practically Gaussian as shown in Fig. 3, Eq. (4) appears to be a sufficient approximation. The r_α distance for a nonbonded pair is defined as

$$r_\alpha = r_e(Q_e) + \langle \Delta z\rangle'_T \quad (5)$$

where Q_e is an equilibrium value of the large-amplitude coordinate. Equation (5) can be rewritten by use of a diatomic approximation as

$$r_\alpha \cong r_e(Q_e) + \frac{3}{2}a_3\langle \Delta z^2\rangle'_T - \frac{\langle \Delta x^2\rangle'_T + \langle \Delta y^2\rangle'_T}{2r_e(Q_e)} \quad (6)$$

The r_α parameters can be extrapolated to zero kelvin (r_α^0) by using a diatomic approximation for the bonded parameters and neglecting temperature dependence of the angle parameters.[11] From Eqs. (3), (4) and (6), the vibrational correction, $d = r_a - r_\alpha$, is given by

$$d = [\langle r_e(Q)\rangle_T - r_e(Q_e)] - \frac{l^2}{r_a} + \frac{\langle \Delta x^2\rangle'_T + \langle \Delta y^2\rangle'_T}{2r_e(Q_e)} \quad (7)$$

Since neither the force constants nor the vibrational frequencies for trimethylene sulfide were available except for the puckering motion, the contributions from the small-amplitude modes to the terms in Eqs. (1) and (7) were calculated from the Urey-Bradley force constants listed in Table 1 transferred from ethylmethyl sulfide,[15] diethyl sulfide[15] and thietanone-3.[16] The contributions from the large-amplitude mode were calculated from the following molecular model: The ring-puckering motion causes a change in the dihedral angle, $\delta = \angle C_2SC_4$–$C_2C_3C_4$, and a deformation of $\alpha = \angle$C–S–C angle, but retains the C–S, C–C, C–H distances and H–C–H angles constant. The dependence of α on δ is assumed to satisfy the following relation derived from the microwave study:[1]

$$\rho = [r(C\cdots S) - r^0(C\cdots S)]/[r(C\cdots C) - r^0(C\cdots C)] = 0.54 \quad (8)$$

where r^0 is a nonbonded distance at the planar configuration ($\delta = 0°$). The potential function for the puckering motion is taken from Ref. 1.

The mean amplitudes and vibrational corrections for bonded pairs were calculated from the force constants listed in Table 1, and their uncertainties were

a) Observed mean amplitudes derived from diffraction intensities. b) Mean amplitudes calculated from the force constants listed in Table 1 and the molecular model described in the text. The uncertainties were estimated from those in the force constants and the model. c) Vibrational corrections calculated from the force constants and the model described in the text. The uncertainties for the nonbonded pairs mainly originate from those in the model.

estimated to be ±10%. The mean amplitudes and vibrational corrections for nonbonded pairs consisted of the contributions from the small-amplitude and large-amplitude modes. The former contributions were calculated from the force constants and were estimated to have uncertainties of ±20%, while the latter contributions calculated classically and numerically from the model were estimated to have uncertainties of ±30%. The quoted errors for l_{calcd} and $r_a - r_\alpha$ in Table 2 represent these uncertainties. The asymmetry parameters[12] κ for the C–H, C–C and C–S bonds were estimated to be 1.2×10^{-5}, 2.7×10^{-6} and 2.7×10^{-6} Å^3, respectively, from the anharmonicity parameters[14] a_3 for CH, CC and CS assumed to be 1.98, 2.13 and 1.95 Å^{-1}, respectively. The κ parameters for nonbonded pairs were ignored since the observed radial distribution peaks of the nonbonded pairs were symmetric within estimated experimental error.

A least squares analysis was carried out with an empirical diagonal weight matrix.[17] The C–H, C–C and C–S distances, ∠C–S–C and dihedral angles, mean amplitudes for C–H, C–C, C–S, C···C and C···S pairs and the indices of resolution for the long and short camera regions were taken as independent variable parameters. The mean amplitudes fixed in the analysis are shown in Table 3 with vibrational corrections for the corresponding pairs. The r_α^0 parameters determined in the analysis are shown in Table 4, and the observed mean amplitudes are compared in Table 2 with the calculated values.

Systematic errors originating from slight modifications in assumptions b) and c) above had negligible effects on the structural parameters. The uncertainty in the vibrational corrections for the C···C pair caused a systematic error in the C–S–C angle, ±0.1°, and those for the other atomic pairs were unimportant compared to the random errors in the structural parameters. The uncertainty in the r_α to r_α^0 conversion was also negligible. The nonbonded mean amplitudes fixed at the calculated values (Table 3) in the analysis were estimated to have uncertainties of ±20% as mean values. Changing the value by that fraction caused a significant systematic variation only in the dihedral angle, ±2°. The fixed κ parameters caused no significant systematic errors in the distances. The error limits quoted in Table 4 include 2.5 times the

standard deviations plus the systematic errors estimated above.

In the next step the rotational constants determined[1] in the microwave study were combined[4] with the diffraction intensities in order to obtain more accurate angle parameters and hydrogen parameters for the α and β positions.

Joint Analysis of Diffraction Intensities and Rotational Constants. The rotational constants A, B and C for the ground and excited states (up to $v=4$) have been determined by microwave spectroscopy[1] by Harris *et al.* They expressed the rotational constants as a power series in the coordinate of the large-amplitude mode,

$$A = 10013.44 + 17.52Q^2 - 0.088Q^4 \quad (9a)$$

$$B = 6670.78 + 5.01Q^2 - 0.76Q^4 \quad (9b)$$

$$C = 4335.74 + 19.15Q^2 - 0.087Q^4 \quad (9c)$$

This procedure is based on the fact that the vibration-rotation interactions in this molecule are given simply by the quantum mechanical averaging of the rotational constant over the puckering motion, and Coriolis interactions are relatively unimportant.[1,2] The potential function for the vibration has been determined[1] by numerically fitting the experimentally determined rotational constants to the power series without assumptions on the details of the vibrational motion,

$$V(Q) = 7.0207Q^4 - 87.7581Q^2 \text{ cm}^{-1} \quad (10)$$

which has a minimum at $Q=Q_e=2.500$ (amu)$^{1/2}$ Å. Substitution of Q by Q_e in Eq. (9) leads to the rotational constants for the ground vibrational state (A'_0, B'_0 and C'_0) where the normal coordinate representing the large-amplitude motion takes its equilibrium value. A similar treatment has been applied to the rotational constants of trimethylene oxide by Chan *et al.*[10] in order to obtain a set of structural parameters corresponding to the equilibrium or nonvibrating values for the large-amplitude mode. The rotational constants A'_0, B'_0 and C'_0 were conventionally transformed into the average rotational constants[18] A_z, B_z and C_z by subtracting the vibration-rotation interactions for all the small-amplitude modes.

The uncertainties in A_z, B_z and C_z were estimated from the following sources: a) Uncertainties in the corrections for the large-amplitude mode were estimated from the deviations[1] of the observed rotational constants from the values calculated by use of Eq. (9) to be ±1, ±3 and ±1 MHz for A_z, B_z and C_z, respectively. b) Uncertainties in the corrections for all the small-amplitude modes were estimated to be $\pm10\%$ of the corrections, or ±4, ±2 and ±0.5 MHz for A_z, B_z and C_z, respectively. The A_z, B_z and C_z are compared in Table 5 with the rotational constants A^0_α, B^0_α and C^0_α calculated from the r^0_α parameters determined in the foregoing electron diffraction analy-

TABLE 5. ROTATIONAL CONSTANTS FOR TRIMETHYLENE SULFIDE[a] (MHz)

a) k_1, k_2=indices of resolution for the long and short camera regions, respectively, $x_1=r$(C-S), $x_2=r$(C-C), $x_3=r(C_\alpha\text{-H})$, $x_4=r(C_\beta\text{-H})$, $x_5=\angle$C-S-C, $x_6=\delta$, $x_7=\angle H\text{-}C_\alpha\text{-H}$, $x_8=\angle H\text{-}C_\beta\text{-H}$, $l_1=l$(C-S), $l_2=l$(C-C), $l_3=l$(C···S) and $l_4=l$(C···C). Units ($\times10^{-4}$) for the distances and mean amplitudes are Å, those for the angles are rad, and those for the indices are dimensionless.

sis. The diffraction and spectroscopic constants agree within the experimental error of the former.

The rotational constants A_z, B_z and C_z were combined with the diffraction intensities into a joint least squares analysis, where the assumptions b) and c) made in the analysis of diffraction intensities were excluded. The mean amplitudes for C_α–H and C_β–H pairs were fixed at the calculated values. The relative weight for the rotational constants were adjusted empirically so that 2.5 times the standard errors in the rotational constants were nearly equal to their uncertainties. The weights used in the analysis were 1.5×10^6, 1.5×10^6 and 2×10^7 for A_z, B_z and C_z, respectively, where a unit weight was assigned to the molecular intensities from $s=6.3$ to 26.7 Å^{-1} taken at $\pi/10$ intervals. A typical error matrix is shown in Table 6.

The r_{a_v} structure listed in Table 4 agrees with the r_α^0 structure derived from the electron diffraction data alone except that the angle parameters are appreciably more accurate. The final r_g structure derived from the r_{a_v} structure is shown in Table 4. The structural parameters of this molecule determined earlier by the visual method of gas electron diffraction[19–21] are in good agreement with the present results to within their uncertainties: r(C–S)$=1.85_1\pm$ 0.02 Å, r(C–C)$=1.54_9\pm0.03$ Å, ∠C–S–C$=78\pm1°$ and ∠C–C–C$=97\pm5°$.

The dihedral angle determined in the present study is nearly equal to that estimated by Harris *et al.*,[1,2] 28°. The skeletal structure of trimethylene sulfide was compared[3] with those of analogous molecules. Sulfur-carbon bond lengths in 4-membered rings are clearly longer than in other environments, a trend also observed among carbon-carbon bond lengths.[22]

The authors are indebted to Professor Iwao Tabushi, Dr. Yoshinao Tamaru and Mrs. Kazumi Mizuno for preparation of the sample and to Professor Robert K. Bohn for helpful comments.

The Crystal and Molecular Structure of *trans*-Bis(trimethylphosphine)propynyl-1-(4′-dicyanomethylene-cyclohexa-2′,5′-dien-1-yliden)-3,3-dicyano-2-methyl-prop-2-en-1-ylplatinum, a Reaction Product of *trans*-Bis(trimethylphosphine)bis-(propynyl)platinum and 7,7,8,8-Tetracyanoquinodimethane

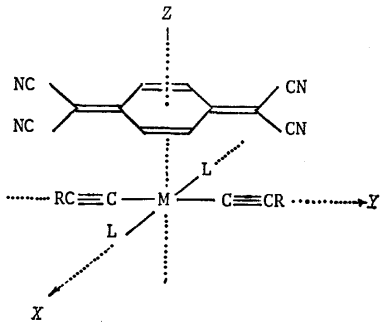
Ken-ichi ONUMA, Yasushi KAI, Noritake YASUOKA, and Nobutami KASAI

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received March 17, 1975)

The molecular structure of the title complex has been determined from three-dimensional X-ray diffraction data. The crystal belongs to the monoclinic system, space group $P2_1/c$, $a=14.934(2)$, $b=8.997(1)$, $c=20.221(3)$Å, $\beta=97.44(2)°$, $Z=4$. The molecular structure showed that the tetracyanoquinodimethane (TCNQ) molecule has reacted with one of the propynyl groups of *trans*-$\{(PMe_3)_2Pt(C{\equiv}CMe)_2\}$: part of the TCNQ is bonded to the α-carbon atom and the other part to the β-carbon of the propynyl ligand. The platinum atom has a square-planar geometry; Pt–P=2.302(5) and 2.290(5), Pt–C(C≡CMe$_3$)=2.009(15) and Pt–C(reacted)=2.057(15) Å.

Recently, it has been found that *trans*-bis(tertiary-phosphine)dialkynyl complexes of transition metals (Ni, Pd or Pt) react with 7,7,8,8-tetracyanoquinodimethane (TCNQ) to form stable complexes.[1] Spectroscopic studies suggested that these might be charge-transfer complexes although no other π-acceptors such as tetracyanoethylene, chloranil, bromanil or pyromellitic dianhydride show the charge-transfer interaction with the transition metal complexes mentioned above. This peculiar property of the TCNQ was explained by the possible overlapping of π system of the TCNQ and ethynyl ligands. The structure shown below has been proposed.[1]



(1) M=Pt, L=PMe$_3$, R=H,
(2) M=Pt, L=PMe$_3$, R=Me,
(3) M=Pt, L=PEt$_3$, R=Me.

In order to verify this hypothesis, an X-ray crystallographic study of [*trans*-$\{(PMe_3)_2Pt(C{\equiv}CMe)_2\}\cdot$(TCNQ)] (2) has been carried out. However, as the crystal suffered from an X-ray damage, the standard deviations for all variable parameters were high and consequently the structure is not well-defined.

Experimental

Crystal Data. $C_{21}H_{28}N_4P_2Pt$, *F.W.*=629.56, monoclinic, $a=14.934(2)$, $b=8.997(1)$, $c=20.221(3)$ Å, $\beta=97.44(2)°$, $U=2694.0(7)$ Å^3, $D_m=1.56$ g·cm^{-3} (by flotation), $Z=4$, $D_c=1.55$ g·cm^{-3}, $F(000)=1232$, Space group $P2_1/c$, Mo$K\alpha$ radiation ($\lambda=0.71069$ Å), μ(Mo)=56.14 cm^{-1}.

The crystals are purple-black and long prismatic. Initially, a freshly prepared crystal (approximate dimensions 0.17×0.19×0.17 mm) was used. Accurate cell parameters were obtained by least-squares refinement of 22 high angle reflections. Intensity data were collected on a Rigaku automated, four-circle diffractometer using the θ-2θ scan technique[2] with Zr-filtered Mo$K\alpha$ radiation.

A total of 2666 (2332 non-zero) independent reflections was collected at room temperature. Intensities of three standard reflections, 060, 500, and 006, were measured every 50 reflections, and these were used to detect any crystal decay or mispositioning. The magnitudes for the structure factors of these reflections decreased at an approximately linear rate with time. At the end of the data collection ($(\sin\theta)/\lambda \leqq 0.458$) they were 85.2% of the original values and a linear decay correction was applied. Another set of 1011 (887 non-zero) higher order reflections ($0.457 \leqq (\sin\theta)/\lambda \leqq 0.527$) was collected with a second crystal (*ca.* 0.23×0.17×0.23 mm) with standard reflections decreasing by 2.7%. A linear decay correction was also applied. All these data were placed on the same scale as the first set by collecting common 1117 non-zero reflections ($(\sin\theta)/\lambda \leqq 0.350$). The interset scale factor was 1.157. No absorption correction was applied to either set of data.

Structure Solution and Refinement

The structure was solved and refined using the intensity data from the first crystal. Three-dimensional Patterson synthesis revealed the positions of platinum and phosphorous atoms. All the nonhydrogen atoms were found from subsequent Fourier and difference electron density syntheses. Block-diagonal least-aquares refinement of positional and thermal parameters was carried out using HBLS-V program[3] in three steps: three cycles of isotropic, three cycles of partial anisotropic (Pt and P), and four cycles of anisotropic parameters for nonhydrogen atoms. The second data set was then added and the refinement continued. After the final three cycles, the R was 0.060 (R_2=0.071) for non-zero reflections.

The positional and thermal parameters are given in Tables 1 and 2, respectively. The observed and calculated structure factors are listed in Table 3.[4] Throughout the refinement, neutral atomic scattering factors were taken from those given by Hanson and co-workers.[5]

Results and Discussion

A perspective view of the molecule is given in Fig. 1 with the numbering system of atoms. A stereographic drawing of the molecule is shown in Fig. 2.

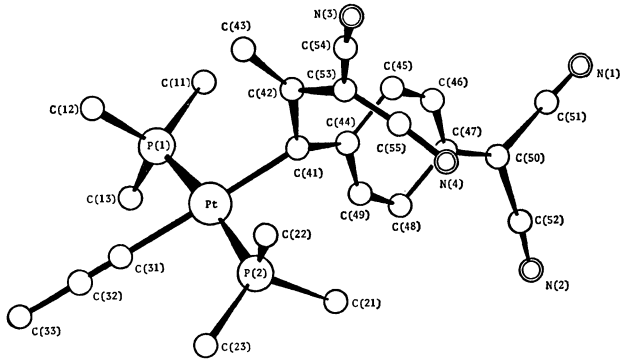

Fig. 1. Perspective view of the molecule with the numbering system of atoms.

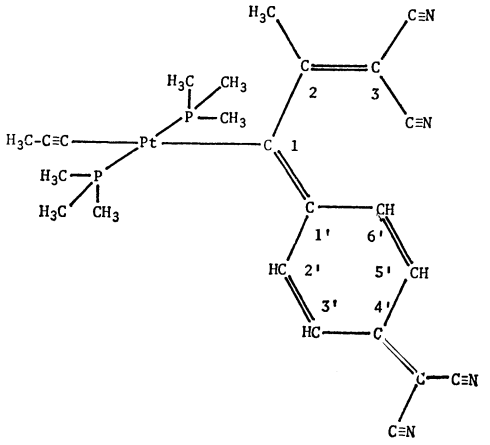
The molecular structure determined is entirely different from that proposed[1] as no charge-transfer complex had been formed. The TCNQ molecule had reacted with one of the propynyl groups of *trans*-{$(PMe_3)_2Pt(C{\equiv}CMe)_2$} (Pt-complex), and, as a result, part of the TCNQ is bonded to the α-carbon atom (C(41)) and the remaining part to the β-carbon (C(42)) of the propynyl ligand. The product is, therefore, *trans*-bis (trimethylphosphine) propynyl-1-(4′-dicyanomethylene-cyclohexa-2′,5′-dien-1′-yliden)-3,3-dicyano-2-methyl-prop-2-en-1-ylplatinum.

Bond distances and bond angles are listed in Table 4. The environment of the platinum atom is essentially square-planar and the phosphine groups are mutually *trans*. The Pt–P distances observed [2.290(5) and 2.304(5) Å] are normal as found in the related platinum(II) complexes.[6,7] Both the Pt–C(31)(sp) and Pt–C(41)(sp^2) distances [2.009(15) and 2.057(15)Å] are equal to the respective sum of the covalent radii [Pt–C(sp)=2.00 and Pt–C(sp^2)=2.07 Å]. However, the former is longer than the Pt–C(CNR) distances in *cis*-{$PtCl_2(PEt_2Ph)(C{\equiv}NEt)$} [1.83(4) Å][8] and *cis*-{$PtCl_2(C{\equiv}NPh)_2$} [av. 1.986(16) Å],[9] and it is also longer than the Pt–C(CO) distance in *trans*-{$PtCl(CO)(PEt_3)_2$} [1.78 Å].[10] This may be caused by the reduced basicity of the σ-bonded carbon atoms. The C(31)–C(32) distance of the unreacted propynyl ligand [1.15(3) Å] is shorter than in *trans*-{$(PEt_3)_2Ni(C{\equiv}CPh)_2$}[11] [1.22(2) Å] although the difference is not fully significant.



The skeleton around the resulted propyl group is shown in Fig. 3. The C(41)–C(42) and C(42)–C(43) links [1.50(2) and 1.52(3) Å] are single bonds, while the C(41)–C(44) and C(42)–C(53) [both 1.35(2) Å] are double bonds. The sum of bond angles around the C(41) and C(42) atoms are both equal to 360° within the range of experimental error. These facts suggest that both the C(41) and C(42) are sp^2 carbon atoms. The significant distortions of Pt–C(41)–C(42) and Pt–C(41)–C(44) angles from 120° [111.9(10) and 127.3(12)°] are probably due to the Pt...C(44) non-bonded interaction, and the concomitant steric strains are relieved by the distortion of the cyclohexadiene ring.

The geometry around the C(41), C(42), C(44) and C(53) atoms suggests that the C(41), C(42) and C(43) atoms are from the original propynyl ligand of the Pt-complex and the remaining C(44) to C(55) and N(1) to N(4) from the TCNQ. Of the two possibilities to arrange a triple bond of the Pt-complex and a double bond of the TCNQ approximately parallel the scheme (1) in Fig. 4 is supported from the structure determined. The charge-transfer complex proposed by Masai and co-workers[1] may be considered as an

intermediate. However, it is inconclusive whether both or one of the ethynyl bonds interact with a double bond of the TCNQ. The unreactivity of the other π-acceptors with the Pt-complex is supposed partly due to the steric hindrance of phosphine groups attached to the platinum atom.

Bond distances and bond angles in two dicyanomethylene groups are similar to those in TCNQ.[12]

A perspective drawing of the crystal structure along the b axis is shown in Fig. 5. No close intermolecular atomic contact less than the sum of the van der Waals radii is observed.

Computations throughout the present study were carried out on a NEAC 2200-700 computer at Osaka University. Figures 2 and 4 were drawn on a NUMMERICON 7000 system at Osaka University with a local version of ORTEP.[13]

The Effect of the Hydrostatic Pressure on the Hydrogen-bond Formation between Phenol and Dioxane in Hexane*

Keizo SUZUKI and Masao TSUCHIYA**

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603

(Received September 24, 1974)

The near-UV absorption spectra of phenol-dioxane in *n*-hexane were observed under hydrostatic pressures up to 1480 atm and at 30 °C. With an increase in the pressure, the spectra shift toward the longer wavelength side and the amount of the hydrogen-bonded phenol increases. The equilibrium constant for -OH + O  O ⇄  -OH···O O was obtained, and the volume change accompanying the hydrogen-bond formation was estimated to be −3.0——3.4 cm³/mol.

The effect of the hydrostatic pressure on the hydrogen-bond formation has been investigated by Shishkin and Novak,[1] Fishman and Drickamer,[2] and Osugi and Kitamura[3] on the basis of IR-absorption measurements. Shishkin and Novak[1] studied the system of phenol and some alcohols in carbon tetrachloride under pressures up to 3200 kg/cm². A pressure rise of 90—130 kg/cm² is found to have the same effect as a temperature drop of 1 °C. Using this result, Hamann[4] estimated the volume change accompanying the hydrogen-bond formation, ΔV, to be −4.5——6 cm³/mol. Fishman and Drickamer[2] investigated the association of *n*-butyl alcohol in carbon disulfide up to 11300 atm. The ΔV values estimated were −4.64 cm³/mol in the range from 1 to 5820 atm, and −2.47 cm³/mol in the range from 5820 to 11300 atm. The system of *n*-butyl alcohol in carbon disulfide was studied up to 8000 atm by Osugi and Kitamura.[3] Assuming the association numbers to be 2, 3, and 4, the ΔV was estimated to be −2.20, −4.31, and −5.74 cm³/mol respectively. The high concentration of solute used in these experiments seems to permit a higher degree of association due to hydrogen bonding. The number of solute molecules participating in the association is not necessarily certain, so that it seems difficult to estimate the ΔV value per mol H-bond exclusively from these data.[3]

Using the molecular model of hydrogen bonding, the ΔV has been calculated theoretically by Hamann.[4,5] Assuming that the distance between the α and β oxygen atoms in the hydrogen bonding ($\overset{\alpha}{O}$–H···$\overset{\beta}{O}$) is contracted by about 0.9 Å, and that this contraction occurs along the axis of a cylinder having a radius equal to the van der Waals radius of the oxygen atoms, he estimated the ΔV to be about −3.8 cm³/mol.

The purposes of the present paper are to observe the near-UV absorption spectrum of phenol–dioxane in *n*-hexane, where the concentration of phenol is very dilute and where the only hydrogen-bonded complex is  -OH···O O, under hydrostatic pressures up to 1480 atm, and to estimate the ΔV value accompanying the hydrogen-bond formation. A series of excellent studies of the same system has been performed at atmospheric pressure by Baba and Nagakura,[6,7] Nagakura and Baba,[8] and Nagakura.[9] The pressure effect on the hydrogen-bond formation, however, has never been studied on the basis of UV-absorption measurements.

Experimental

Materials. All the reagents, of an extra pure grade, were used after the following purification. The *n*-hexane was purified as has been described previously[10,11] (bp 68.9 °C) and was optically transparent to 230 nm. The phenol was purified twice by vacuum distillation (mp 40.5±0.5 °C). The dioxane was refluxed with sodium metal for two days and then fractionally distilled (bp 101.3 °C).

Apparatus. A Shimadzu model MPS-501 double-beam spectrophotometer was used to measure the absorption spectra. Figure 1 shows schematically the clamp-type optical cell used to measure the absorption spectra under high pressures. The optical cell, which was constructed from cobalt alloy (HAYNES alloy No.25, manufactured by the Mitsubishi Metal Mining Co., Ltd.), was designed so as to be set in the sample space of the spectrophotometer after the pressure had been raised. The windows of sapphire permitted measurement to wavelengths of about 230 nm. The pressure generated in the cell was calibrated against the readings of the Bourdon-tube gauge of the oil press by

means of a manganine gauge, which was inserted in the cell instead of the window. The accuracy of the pressure was ±2.7% at 1400 atm.

Procedures. The measurement of the absorption spectra under pressure was carried out at 30 °C by the following procedures. The sample solution was admitted into the cell directly using a glass pipet before a piston was inserted into the cylinder. The piston was pushed into the cylinder by an oil press until the desired pressure was generated. Then the piston was fixed by a clamp nut to keep the pressure constant after the press load had been released. The absorption spectra were measured, with air as the reference, and the base line, which was not affected by the pressure, was subtracted. No optical contamination was observed throughout the experiment. The concentration of the solution under pressure was corrected from the compressibility data of *n*-hexane.[12]

Results and Discussion

Figure 2-1 shows the pressure effect on the absorption spectrum of phenol and dioxane (0.15 mol/l) in *n*-hexane. The a and c arrows and the b and d arrows in the figure represent the absorption bands of free phenol and hydrogen-bonded phenol respectively at atmospheric pressure.[6-9] Figures 2-2 and 2-3 show the absorption spectra corrected by the compressibility of *n*-hexane.[12] Figures 3-1 and 3-2 also show the pressure effect on the absorption spectra of the solution with a different concentration of dioxane (0.10 mol/l). Two characteristic points are noticeable from these figures: (1) the spectrum shifts toward a longer wavelength. As is shown in Fig. 4, the results of the red shift, $\Delta\lambda$, for the a-band and c-band of phenol as a function of the pressure are in good agreement with those obtained by Robertson *et al.*[13] A similar shift is found for the b-band and d-band of hydrogen-bonded phenol, though the bands are so broad that it is hard to determine $\Delta\lambda$ precisely. Many authors

●: this work, ○: Robertson *et al.*[13]

have indicated that such a red shift is attributable to an increase in the intermolecular interaction of the London–van der Waals type between the solvent and solute molecules upon an increase in the pressure, and that the energy level of the excited state is lowered.[13,14]
(2) The ratio of the absorbance of the hydrogen-bonded-phenol band to that of the free-phenol band increases with an increase in the pressure. This shows that the hydrogen-bonded phenol increases with an increase in the pressure. From these spectral data, the equilibrium constant at each pressure and the volume change accompanying the hydrogen-bond formation can be obtained.

The following equilibrium is assumed to be established in *n*-hexane:

(1)

Here, the concentration of phenol is so dilute that the self-association of phenol[15,16] and the formation of 2-mol hydrogen bonds for a dioxane molecule[7]

are eliminated. The equilibrium constant, K, is represented as follows:

$$K = \frac{C_H}{C_P C_D} \tag{2}$$

where C_P, C_H, and C_D are the concentrations of free phenol, hydrogen-bonded phenol, and dioxane respectively. According to Lambert–Beer's law, C_P and C_H are given as follows:

$$C_P = \frac{\beta(\alpha\varepsilon_b' - \varepsilon_a')}{(\alpha\varepsilon_b' - \varepsilon_a') + (\varepsilon_a - \alpha\varepsilon_b)} \tag{3}$$

$$C_H = \frac{\beta(\alpha\varepsilon_b - \varepsilon_a)}{(\alpha\varepsilon_b - \varepsilon_a) + (\varepsilon_a' - \alpha\varepsilon_b')} \tag{4}$$

Here, β is the total concentration of phenol, which is a sum of C_P and C_H, α is the ratio of the absorbances of the a-band and the b-band, ε and ε' are the molar absorption coefficients of free phenol and hydrogen-bonded phenol, and the subscript denotes each absorption band. When we insert Eqs. (3) and (4) in Eq. (2), K is represented as:

$$K = \frac{\varepsilon_a - \alpha\varepsilon_b}{C_D(\alpha\varepsilon_b' - \varepsilon_a')} \tag{5}$$

Similar expressions can be deduced for the c-band and the d-band. The following values were obtained in this experiment for each molar absorption coefficient ($\times10^{-3}$ l/mol): $\varepsilon_a=2.102$ and $\varepsilon_a'=1.670$ at 270.9 nm, $\varepsilon_b=1.134$ and $\varepsilon_b'=1.922$ at 273.2 nm, $\varepsilon_c=2.030$ and $\varepsilon_c'=1.318$ at 277.5 nm, $\varepsilon_d=0.650$ and $\varepsilon_d'=1.604$ at 279.8 nm. The ε' values were decided at 0.80 mol/l of dioxane, where the spectral change became to level. On the right-hand side of Eqs. (3)—(5), all the values except α are known. Therefore, C_P, C_H, and K can be calculated by using the experimental value of α. The results at atmospheric pressure are shown in Table 1, in which the K value is held approximately constant, at least in the lower concentrations cited here.[17]

The total concentration of phenol: 5.000×10^{-4} mol/l.

Assuming that the absorbance observed under high pressures follows Lambert-Beer's law, and that the molar absorption coefficient and the optical path length do not change with the pressure, Eqs. (3)—(5) hold also under high pressure. The concentration of a solution is, of course, corrected from the compressibility data of *n*-hexane.[12] The free-energy change, ΔG°, and the volume change, ΔV, accompanying the hydrogen-bond formation are given by:

$$\Delta G^\circ = -RT \ln K \tag{6}$$

$$\Delta V = -RT\left(\frac{\partial \ln K}{\partial P}\right)_T \tag{7}$$

Table 2. Effect of pressure on the equilibrium of hydrogen-bond formation (30 °C)

Pressure (atm)	α	$C_P \times 10^4$ (mol/l)	K (l/mol)	$-\Delta G^\circ$ (kcal/mol)
a-band/b-band, dioxane: 0.15 mol/l				
1	1.036	1.286	19.3	1.78
600	1.019	1.169	20.4	1.82

Enthalpies of Combustion of Organic Compounds. I. 8-Quinolinol.

Minoru SAKIYAMA, Toshiro NAKANO, and Syûzô SEKI

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received November 1, 1974)

A rotating-oxygen-combustion bomb calorimeter equipped with a platinum lined bomb has been constructed and calibrated. The enthalpy of combustion of 8-quinolinol(c) was determined. Thermodynamic quantities obtained are as follows: $\Delta E_c^\circ = -4458.90 \pm 1.60$, $\Delta H_c^\circ = -4460.76 \pm 1.60$ and $\Delta H_f^\circ = -81.24 \pm 2.00$ kJ mol^{-1} for the crystalline state and $\Delta H_f^\circ = 27.6 \pm 2.6$ kJ mol^{-1} for the gaseous state.

Measurement of enthalpy of combustion is the standard experimental method in organic thermochemistry. It provides not only fundamental chemical-thermodynamic quantities but also the most reliable experimental means for determination of the total intramolecular energy if the enthalpy of vaporization or sublimation data are available. The usual static bomb calorimeter is sufficient for compounds containing carbon, hydrogen, oxygen and nitrogen. It is well-known that the use of a rotating bomb calorimeter is required in order to get accurate results for compounds containing halogen, sulfur or metal besides the above-mentioned elements. By rotating the bomb after the combustion reaction the internal bomb-wall is washed out thoroughly with bomb-liquid so that a thermodynamically well-defined state is established.

We have constructed an isoperibol, rotating-bomb calorimeter in order to carry out the measurement of enthalpy of combustion for various kinds of compounds with high precision and accuracy. In the present paper we report the construction, operation and calibration of the calorimeter as well as the enthalpy of combustion of 8-quinolinol. The idealized combustion reaction which the energy and enthalpy of combustion given in this paper refer to is as follows:

$$C_9H_7ON(c) + 10.25\ O_2(g) = 9\ CO_2(g) + 3.5\ H_2O(l) + 0.5\ N_2(g).$$

All the quantities refer to the reference temperature 298.15 K.

Experimental

Apparatus. The rotating-bomb calorimeter is similar in design to that used by Hubbard *et al.*[1,2] The principal calorimeter was based upon the design of the Argonne National Laboratory, U.S.A. (CAPE-432) with some modifications made by ourselves. The calorimetric apparatus consists of a calorimeter vessel surrounded by a jacket with a constant air gap of 10 mm width. The whole system is kept in a measuring-room thermostatted at 23.0±0.3 °C.

The jacket, 47 cm in diameter and 33 cm in height, is made of brass except for portions which face the calorimeter vessel and which are made of copper. The outer surface of the jacket is chromium-plated and polished. The jacket is filled with distilled water of *ca.* 46 dm^3 which is stirred by two stirrers positioned symmetrically. Two centrifugal pumps are installed at the base of the stirrers. The double walled jacket lid is divided into two parts, and a pump circulates the jacket water through each half. Each pair of stirrer and pump is driven simultaneously by an induction motor. A cold water nozzle, a manganin heater (30 V, 36 W) and a thermistor probe for temperature regulation are located at the upper, middle and lower portions, respectively, of a cylinder made of brass which surrounds the stirrer. A pipe heater (100 V, 1000 W) is attached to the bottom of the jacket for rapid heating of the jacket-water.

The calorimeter vessel is made of copper and is of a novel shape in order to minimize the heat capacity. The outer surface is chromium-plated and brightly polished to minimize heat transfer by radiation. The combustion bomb is placed in the vessel with the base upward in order to protect the bomb lid from possible damage due to the high temperature flame during combustion of the sample. The vessel is filled with 2850 g of water while the measurement is going on. The stirrer for circulation water is driven at the rate 200 rpm by a synchronous hysteresis motor attached to the lid of the jacket. The combustion bomb is driven by another synchronous hysteresis motor. The rotation motion of the combustion bomb can be stopped with a plug actuated by a solenoid if desired, after the bomb-drive-motor is switched off. The stirrer and the bomb-drive shaft are connected with each motor via Nylon couplers in the air gap space between the jacket and the vessel. The combustion bomb rotates around two axes perpendicular to each other. The modes of rotation are a spinning motion about the bomb axis at $4\,^4/_{17}$ rpm and an end-over-head motion at 10 rpm. A blade and a spring switch both made of phosphor bronze electrically connect the bomb with an outer AC power source for ignition of the sample contained. The calorimeter-water is heated up to a predetermined temperature with a cartridge heater (DC 22 V, 22 W). A quartz thermometer probe is inserted into the calorimeter can through tubing at the top of the vessel. The probe is in intimate contact with the jacket-lid by a metal-to-metal contact device. All the openings on the upper portion of the vessel are closed with rubber bushing, cork stopper and oil seals in order to minimize the possible evaporation of calorimeter-water.

A Parr 1004C stainless steel combustion bomb with platinum-lining *ca.* 0.5 mm thick was used. A platinum-10% rhodium dish (*ca.* 11.14 g in weight) is placed on a gimbal and its ring. Ignition current flows between an insulated electrode and the bomb proper *via* a platinum-ignition-wire (diam. 0.1 mm). Two needle valves are attached to the lid of the bomb, one for introduction and the other for discharge of a gas. One end of a cotton fuse is connected with the ignition wire and the other with the sample. On the outer wall of the bomb proper, miter gears and ball bearings are attached for the biaxial rotational motion mentioned above. It was found from separate experiments that rotation energy is 0.0505 J s^{-1}.

The temperature of the jacket is maintained at 25.300±0.003 °C throughout the experiment by regulating the electrical current through the jacket heater against a constant flow of cold water from outside. The electrical current is regulated in proportional mode by a vacuum tube regulator similar in principle to that used by Skinner *et al.*[3] The jacket-water is recycled with a rate of *ca.* 20 cm^3 min^{-1} by a metering pump through a spiral copper tube immersed in an ice bath. The temperature of the jacket is monitored

by a Beckmann thermometer having the finest division of 0.001 K in its scale.

A sample is ignited by heating the platinum wire to red with AC current supplied from a transformer, with output voltage 4 V and current capacity of the secondary coil 10 A. Under these conditions, ignition can be carried out without fusion of the platinum wire in most cases. The ignition energy is measured by an integrating ammeter, which is similar in principle to that used by Mackle and O'Hare[4] but designed for use of integrated circuits. It was found from calibration-experiments that the full deflection of the meter corresponds to 9.03 J. For the measurement of temperature of the calorimeter a Hewlett-Packard model 2801A quartz thermometer with a model 2850 D sensor was used. The temperature is measured with a 0.000 01 K resolution at constant intervals of *ca.* 101.5 s with the use of an option M40 and is recorded on a Hewlett-Packard model 562 A digital printer.

Experimental Procedure. In the case of solid material, the pelletted sample, cotton fuse and platinum dish are weighed separately. The pelletted sample is tied to one end of the fuse, and measurement is then made of the total weight of the sample and fuse contained in the dish. Buoyancy correction is made to the final weight. The dish with the sample and fuse is attached to the gimbal ring of the bomb, the platinum ignition wire being tied to the other of the fuse. A predetermined amount of water is then added to the bomb and finally the bomb is closed tightly. The bomb is flushed with *ca.* 3.5 dm^3 oxygen at the rate of *ca.* 400 cm^3 min^{-1}. Combustible impurities in the oxygen are removed by passing it over Deoxo M (0.5% Pt on γ-alumina) kept at 150 °C. Water and carbon dioxide formed are removed by Ascarite (NaOH on asbestos), Dehydrite ($Mg(ClO_4)_2$) and phosphorus pentoxide, contained in a train of purification-tubes. The bomb is then charged with oxygen up to 3.040 MPa at 25 °C. The bomb is weighed on a large chemical balance (measurable up to 20 kg with *ca.* 3 mg resolution). The combustion bomb is set up in an inverted position in the calorimeter vessel, 2850 g of distilled water is added to the vessel and the total weight is measured. After the outer surface is wiped clean with chamois-leather, the can is fixed on pegs in the hollow of the jacket and then the ignition and heater wires are connected. The calorimeter is heated up to 22.80 °C with the cartridge heater. It is then subjected to a gradual temperature-rise by heat exchange with the surrounding jacket wall and stirring. When it reaches 23.00 °C, the recording of the temperature is started. The temperature rise in the main period is *ca.* 1.8 °C, when the calibration experiment with the standard benzoic acid is carried out under standard bomb conditions (see next section). In combustion experiments mass of a sample is adjusted so that the temperature rise may be as equal as possible to that in the calibration experiments. The anticipated initial temperature T_i of the main period is chosen so that the final temperature of the main period is close to 25 °C. The sample is ignited around T_i and the deflection of the integrating ammeter is recorded. Twenty readings of temperature preceding the ignition compose the initial period. After forty readings following the ignition are recorded, the bomb is taken out from the calorimeter. The bomb surface and external accessories are burst with a hot blaster in open air in order to dry them completely. The bomb is then placed in a sealed-metal-tank which is evacuated ($\sim$ 0.1 Pa) by an oil rotary pump for an hour. After the gas is released, the bomb is opened and the internal wall together with the fittings are washed thoroughly with distilled water. After collecting the washings, which is adjusted to 100 cm^3, the nitric acid formed as a by-product of combustion from a nitrogen containing sample and/or the nitrogen remaining in oxygen is analyzed with 0.02 M sodium hydroxide solution.

Establishment of the Standard Calorimeter System. The energy equivalent of the calorimeter ε°(calor.) is determined by the combustion of benzoic acid (Standard Reference Material 39 i, National Bureau of Standards, U.S.A.). The certificated value for the energy of combustion of the benzoic acid is $26434 \pm 3\ Jg^{-1}$ under standard bomb conditions[9] where the uncertainty is the uncertainty interval.[11] Deviation from the standard bomb conditions is made as small as possible and correction is made for it by the expression given by Jessup.[5] The energy equivalent is defined for the total system consisting of the calorimetric vessel containing 2850.00 g of water and the bomb where the gimbal and platinum ignition wire are installed. Total weight of the calorimetric system is *ca.* 10682 g in the case of calibration.

Material: 8-Quinolinol (Kishida Chemicals Co.) was used without further purification. The sample was prepared as the organic micro-analytical standard substance. The makers assert that the sample is purified by recrystallization (three times) using two kinds of solvents or solvent mixtures. It is certificated by the subcommittee of organic micro-analysis of the Japan Society for Analytical Chemistry. The substance is known to have four crystalline modifications with melting points of 73.5, 65, 57—58, and 38—39.5 °C.[6] The present sample was examined with a Perkin-Elmer DSC-1B and no thermal anomaly was detected below 73 °C. It is therefore considered to have the most stable modification. Horton and Wendlandt[7] reported the sublimation pressure of 8-quinolinol. The maximum amount of 8-quinolinol lost by flushing with 10 dm^3 of oxygen was *ca.* 2.7×10^{-5} g at 300 K, corresponding to *ca.* 0.003% of the sample burnt. It was decided to burn the sample pellet without enclosing it in a polyester bag.

Calculations

Corrected Temperature Rise. The corrected temperature rise $\Delta T (= T_f - T_i - \Delta T_c)$, where T_i and T_f are the initial and final temperatures of the main period, respectively, and ΔT_c the temperature rise during the main period due to heat absorbed from the jacket wall and to that caused by stirring (and bomb-rotation), was calculated in the following way.

Temperature readings in the initial and the final periods are fitted to the following integrated form of Newton's cooling law: $T = T_\infty - (T_\infty - T_0)\exp[-k \cdot (t - t_0)]$, where T is the temperature at time t, T_0 the temperature at a reference time t_0, k the cooling constant (thermal leakage modulus), and T_∞ the convergence temperature. The fitting procedures were made as follows: (1) An appropriate practical value for k, a mean value ($= 3.734 \times 10^{-5}\ s^{-1}$), was first assumed from preliminary analyses. Linear least-square analysis between T and $\exp[-k(t - t_0)]$ was then carried out for the initial and final periods separately. In this case the time of onset of the initial period and that of the final period are taken as the reference time t_0. A curvature correction is applied since the temperature reading of the quartz thermometer shows a mean value during 100 s before display. The effect of rest periods (*ca.* 1.5 s) between each sample period

(100 s) is not taken into consideration in order to conform with the procedure adopted for the main period. From the values of T_∞ and T_0 thus obtained, temperatures $\bar{T}_i$ and $\bar{T}_f$ and the rates of temperature rise G_i and G_f are calculated for the time midway in the initial period and that in the final period, respectively. New values of k and T_∞ are obtained by the expressions: $k=(G_i-G_f)/(\bar{T}_f-\bar{T}_i)$ and $T_\infty=(G_i\bar{T}_f-G_f\bar{T}_i)/(G_i-G_f)$. (2) By using the newly derived values of k, the same linear least-squares analysis described above is carried out again and new values of k and T_∞ are obtained. (3) The temperatures T_i and T_f are calculated as the ending temperature of the initial period and the beginning temperature of the final period from the final set of k and T_∞ by taking the reference time midway in the initial period and that in the final period, respectively.

In each case examined, the variation in k was found to be less than 1×10^{-9} s^{-1} and that in T_∞ less than 1×10^{-5} K, after the procedure in stage (1) had been adopted.

The temperature rise ΔT_c during the main period due to heat exchange with the jacket and the heat of stirring (and rotation) is calculated by: $\Delta T_c=k\int_{t_i}^{t_f}(T_\infty-T)dt$, where t_i and t_f are the beginning and ending times, respectively, of the main period. Calculation is simple as the temperature readings are mean temperatures during 100 s before display. In the main period it is difficult to estimate the effect of the rest periods on ΔT_c. However, the effect is estimated to be negligible and is not taken into consideration for the final determination of ΔT_c.

Determination of the duration of the main period should satisfy the following requirements:[8] 1) attainment of a state in which the effect of evolution of heat due to combustion is no more detectable, and 2) minimization of heat exchange as well as heat of stirring correction which may be a cause of experimental error. The corrected temperature-rise was calculated by increasing the length of the main period from eight to twenty readings. A compromise between the two contradictory requirements has been found to be twelve readings both in calibration (using benzoic acid) and in combustion experiments. Thus, twenty readings after the main period have been assigned to the final period.

Energy Equivalent and Energy of combustion. The energy equivalent of the standard calorimetric system $\varepsilon°$(calor.) was calculated by the procedure described by Coops *et al.*[9] The mean and standard deviation of the mean for the energy equivalent was found to be 15162.8 ± 1.3 J K^{-1} from six calibration experiments interspersed between combustion experiments, where uncertainty is the standard deviation of the mean. The standard energy of combustion $\Delta E_c°$ was calculated by the method of Hubbard *et al.*,[10] the final overall precision of the $\Delta E_c°$ mean values being estimated as recommended by Rossini[11] following the scheme presented by Bjellerup.[12] All procedures in the calculation of ΔT, $\varepsilon°$(calor.) and $\Delta E_c°$ were incorporated in a Fortran program*, the computations being carried out with a NEAC 2200 computer of Osaka University.

Table 1. Auxiliary quantities used in the calculation of energy of combustion

Substance		ρ / g cm^{-3}	C_p / J K^{-1} g^{-1}	$(\partial E/\partial P)_T$ / J kPa^{-1} g^{-1}
8-Quinolinol	C_9H_7ON	1.57	(1.21) [a]	(−1.19) [a]
Fuse	$CH_{1.860}O_{0.930}$	1.50	1.70	−2.94

a) Estimated value.

The standard energy of combustion of the cotton fuse $\Delta E_c°$(fuse) was determined by separate combustion experiments and found to be -16507 J g^{-1}.

Auxiliary Quantities. Molecular weight were computed from the 1961 Table of Relative Atomic Weights. Auxiliary data necessary for calculating weights *in vacuo* from weights in air, for correcting the energy of bomb reaction to that of an isothermal reaction at 25 °C and for making the reduction to standard states are given in Table 1. The density and specific heat capacity of the dish (Pt–Rh alloy) were estimated to be respectively 20.50 g cm^{-3} and 0.1464 J K^{-1} g^{-1}.

Results and Discussion

The results of six combustion experiments on 8-quinolinol are given in Table 2. Symbols in the table are similar to those used by Hubbard *et al.*[10] except for $\Delta m(H_2O)$, ΔE_{rot}, and ΔE(std. state). $\Delta m(H_2O)$ is the mass of excess water in the calorimeter can, ΔE_{rot} the energy evolved by the rotation of the bomb and ΔE(std. state) the sum of items 81—86, 87—89, 91 and 93—94 designated by Hubbard *et al.*[10] From these results the following thermodynamic quantities were derived: $\Delta E_c°(c) = -4458.90\pm1.60$, $\Delta H_c°(c) = -4460.76\pm1.60$, $\Delta H_f°(c) = -81.24\pm2.00$ and $\Delta H_f°(g) = 27.6\pm2.6$ kJ mol^{-1}, where the uncertainties are uncertainty intervals defined by Rossini.[11] The standard enthalpy of combustion $\Delta H_c°$ has been calculated by the use of the expression: $\Delta H_c° = \Delta E_c° + \Delta n_g RT$, where Δn_g is the increase in moles of gaseous species in an idealized combustion reaction and R is the gas constant. In the calculation of the standard enthalpy of formation, CODATA key values[13] for $\Delta H_f°(CO_2,g)$ and $\Delta H_f°(H_2O, l)$ and the enthalpy of sublimation value of Horton and Wendlandt[7] for 8-quinolinol have been used. These values are as follows: $\Delta H_f°(CO_2, g) = -393.51\pm0.13$ and $\Delta H_f°(H_2O, l) = -285.830\pm0.042$ kJ mol^{-1}, where uncertainties are those at 95% confidence level and $\Delta H_{subl} = 108.8\pm1.7$ kJ mol^{-1}, where uncertainty is the uncertainty interval.

Combustion experiments were carried out with and without the rotation of the combustion bomb after ignition. No significant difference was found in $\Delta E_c°$ values for both modes. In some experiments nitric acid was analyzed separately for the solutions formed on the side wall and on the upper and lower walls of the bomb. The results in an experiment are 5.6×10^{-4} and 2.1×10^{-4} mol for the solutions on the side

* The Washburn correction portion of the program was rewritten with a slight modification from an ARGOL program supplied by courtesy of Professor S. Sunner, University of Lund, Lund, Sweden.

Mean and standard deviation of the mean = -30716.9 ± 4.4 J g^{-1}

wall and on the upper and lower walls, respectively. Judging from the relative availability of water on both portions, nitric acid is more concentrated in the solution on the side wall. The nitric acid solution on the side wall is formed by the reaction of nitrogen oxides with water from the sample. The fact that nitric acid is more concentrated on the side wall is in good agreement with the observation of Armstrong and Marantz[14] that most of nitrogen oxides from the combustion of organic nitrogen compounds not containing hydrogen may not be absorbed by bomb water effectively unless a device to vaporize the water after the combustion is made. The localization of nitric acid in the bomb, however, does not cause a significant systematic error in the determination of the standard energy of combustion because the contribution of the energy of dilution of nitric acid to the total energy is not significant and in addition the energy of dilution does not depend seriously on the concentration in the range 5—10%.

The enthalpy of combustion of 8-quinolinol was reported only briefly by Sullivan and Hunt[15] and Wood and Jones.[16] A large difference of *ca.* 12 kJ·mol^{-1} (*ca.* 0.3%) was found between their values. Our value does not agree with either of them within the assigned uncertainty intervals, but agrees fairly well with the mean of these values ($\Delta H_c^\circ = -4458.9$ kJ·mol^{-1}) cited as a selected value by Domalsky.[17]

This work was carried out with the support of a scientific research fund from the Ministry of Education.

Kinetic Studies of the Aggregation of Acridine Orange onto Poly-(α,L-glutamic acid)

Motoyuki TSUDA†

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received November 5, 1974)

The aggregation process of acridine orange (AO) onto the helical poly-α,L-glutamic acid (PLGA) was studied by means of a stopped-flow and rapid-scan spectrophotometer. After the flow stop, a rapid spectral change was observed in which the α-band and the β-band fell, and the γ-band and the polymer band rose. A mechanism of the process was proposed by which after a rapid nucleative process, AO molecules are cooperatively bound to form a dimer and that then the dimer grows to the oligomer and to the polymer of AO which has the form of a super-helix around the core of the α-helix of PLGA.

The main feature of the binding of a number of cationic dyes to polyanions is the so-called metachromasia,[1-3] an effect which has been recognized as due to different binding modes of the dye molecules exhibiting different absorption spectra in the visible region. The absorption bands show that the dye molecules bind to the polyanion in their monomeric forms, or interact with each other on the polyanion to form dimers or aggregates similar to those existing in concentrated aqueous solutions.[4-7] Various theories with regard to the phenomena have been proposed and have been rigorously tested by studying the equilibria[8-19] and the dynamic properties[20-26] of the dye-polymer interaction in aqueous solutions. So far, however, the phenomena have not been able to be interpreted in terms of a generally accepted mechanism.

The interaction of acridine orange (AO) with poly-α,L-glutamic acid (PLGA) has been extensively studied.[18-20] Since PLGA exists predominantly as the α-helix in aqueous solution below about pH 5 and as a random coil above pH 7,[27-28] the role of the structure of the polyanion in the dye-PLGA interaction can be discussed.

Hammes and Hubbard[20] reported kinetic studies of the interaction of AO and PLGA at pH 4.7 and pH 7.5. They proposed a mechanism in which an AO binds very rapidly to a site on the polymer, followed by a slower intramolecular rearrangement. Their results suggested that the same general mechanism appears to be operative for both the helical and random coil forms of PLGA. On the other band, Schwartz and his co-workers[23] proposed a cooperative binding mechanism for the association of AO with PLGA on the basis of thermodynamic and kinetic analyses. Since their measurements, however, followed only the decay of the absorbance of the α-band (monomeric form of AO), the mechanism could not interpret the processes of the formation of the other aggregates.

The associations of AO with itself and with PLGA are both very rapid processes, so the temperature-jump method has been used in most kinetic measurements.[20,23] This method, however, requires an ionic strength of about 0.1 M for the maintenance of the resistance of the solution at an appropriate value. The overall association constant for the AO and PLGA complexes has been reported to be markedly decreased as the ionic strength is increased.[11-14] Because of the above facts, the strong binding processes of the complex cannot be observed in the conventional temperature-jump method. Although the time of observation is limited by its relatively long dead time (slightly less than 1 ms), the stopped-flow method has an advantage in its applicability to a wide range of salt concentrations.[25]

A rapid-scan spectrophotometer was used for the measurement of the change in the spectral pattern after the flow stop. The fall and rise of several spectral bands of the AO and PLGA complexes could successfully be observed by means of this apparatus. In this investigation, the aggregation process of AO onto PLGA was studied in the various ionic atmosphere to clarify the mechanism.

Experimental

The AO was purified according to the following method. An aqueous solution of commercial AO (2 g) purchased from the Merck Co. was titrated with 0.1 M NaOH to pH 10.5. The suspension was then filtered, and the residue was washed with 100 ml of 3×10^{-3} M EDTA. This procedure was repeated. The residue was then dried at 100 °C and dissolved in absolute ethanol. The solution was neutralized with ethanolic HCl, refluxed for 1 hr, and filtered to remove the NaCl formed. The filtrate was passed through an 8× 40 cm acid-washed alumina column in ethanol. The elute comprising the main fraction was then filtered to remove any alumina particles present. The AO–HCl was precipitated from the filtrate by the addition of ether, collected by filtration, and dried under a vacuum. The melting point of the compound was sharp at 181 °C (Ref. 5, 180—181 °C), and the molar extinction at the absorption maximum (492 nm) extrapolated to zero concentration is 6.3×10^4 (6.1×10^4 after Zanker[5]). Generally we prepared a stock solution of 1 mM AO by weighing it in a dry polyethylene bottle. The concentration of AO was determined from the absorbance at 492 nm according to the extrapolated equation[11] for a dilute solution.

The sodium poly-α,L-glutamate was purchased from the Protein Research Foundation (Osaka); it had a weight-average molecular weight of 60,000. The poly-α,L-glutamic acid solution was made by the deionization of the salt with 0.1 M HCl and was dialyzed against frequent changes of the deionized distilled water.[27] Each solution of AO and PLGA was prepared in 2 mM sodium acetate-acetic acid (pH 4.7), adding sodium chloride to adjust the ionic strength to the chosen value. The final pH was maintained approximately

† Present address: Department of Physics, Sapporo Medical College, Sapporo 060.

at pH 4.7 throughout the experiments. In this pH region, PLGA exists predominantly as the α-helix in an aqueous solution.[27,28] All the experiments were performed at 25 °C.

The optical absorption spectra were taken with a recording spectrophotometer (Hitachi EPS-3T). The kinetics of the AO-PLGA reaction was studied using a rapid-scan spectrophotometer equipped with a stopped-flow apparatus (UNION RA-1300). After equal volumes of AO and PLGA solution had been rapidly mixed, the spectral patterns were measured by means of an image detector with a maximum speed of 300 nm/ms and were memorized by a transient recorder. The device contains five channel transient memories. Each digitizes a transient signal with an 8-bit resolution and stores it in a 512-word MOS shift-resister memory. Its sweep time can be varied between 1 ms and 10 s. An analog replica of the original can be recorded on a X-Y recorder as spectral patterns of the transmittance, absorbance, or time resolution difference spectra.

For the kinetic measurements, an absorption or fluorescence stopped-flow apparatus was used. The fluorescence was observed from the right angle to the excitation beam (492 nm), through an interference filter of 552 nm.

Results and Discussion

AO aggregates in an aqueous solution.[5] It is thought that there are at least three types of species; they may be defined as monomers, dimers, and oligomers[5-7] and their absorption bands are located at 492 nm(α-band), 464 nm(β-band), and 445 nm(γ-band), respectively. When AO is mixed with a polyanion in a dilute aqueous solution, the color of either the monomer or the aggregates may appear, depending upon the ionic strength, the pH, and the relative amounts of polymer and dye (P/D ratio).[8-18]

Figure 1 shows the visible absorption spectra of the AO (2.0×10^{-5} M) and PLGA complex at the P/D ratio of 10 while the ionic strength is changed. As the ionic strength is lowered, the shape of the spectrum is continuously changing; that is, the absorbance of the α-band decreases relative to that of β-band, and both the bands fall, while the absorbance of the γ-band and the band around 535 nm rise.

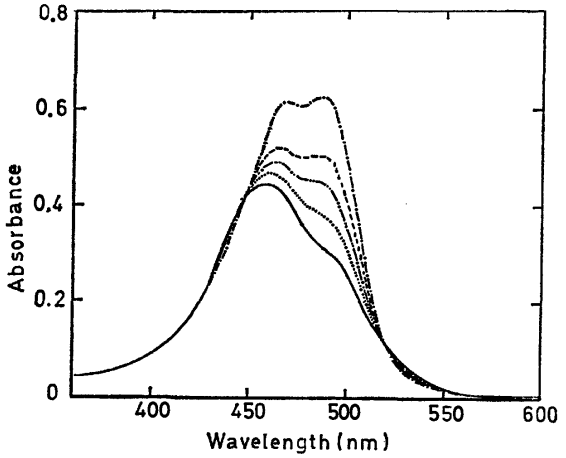

Fig. 1. Effect of ionic strength upon visible absorption spectra of AO-PLGA solutions. Solvent is 0.002 M sodium acetate-acetic acid (pH 4.7) and the ionic strength is adjusted by NaCl. The molarities of AO and PLGA are 2.0×10^{-5} M and 2.0×10^{-4} M, respectively. —— =0.005, ····· =0.01, —·—· =0.05, ---- =0.10, —·— =0.20.

The results suggest that the aggregation of dye was brought about at a low ionic strength.

The formation of these aggregates upon mixing of AO with PLGA at a low ionic strength was measured with the rapid-scan spectrophotometer. Figure 2(a) shows the results on the rapid spectral change in the reaction mixture at the times of 0, 10, 100, and 400 ms after the flow stop, the scanning speed being constant at 150 nm per 1 ms. The abrupt change in the spectra before and after the flow stop shows that almost all of the reaction occurred during the dead time (about 1 ms). After the flow stop, the α-band and the β-band fall, but the change in the other bands is not clear. To clarify the change in these absorption bands, we observed the time resolution difference spectra, which were obtained using the analog device by subtracting the absorbance at an appropriate time from the corresponding absorbance immediately after the flow stop. The results are illustrated in Fig. 2(b); they show that the α-band and β-band fall but γ-band and the band around 535 nm appear slightly. The above facts suggest that the reaction between AO and PLGA does not proceed in a single step, rather, spectrally different steps may be involved.

The mechanism of the binding processes of AO

onto PLGA was studied by means of the stopped-flow apparatus. The decrease in the AO monomer in the species was observed by means of fluorescence quenching,[5] and the formation of the aggregates was followed by the change in the absorbance of the α-band (490 nm), the β-band (435 nm), and the band around 535 nm. Figure 3 shows a replica of the transient-memory recordings of some typical kinetic data. For each absorption band and emission band, a plot of the logarithms of the amplitude of the light intensity change *vs.* time was curved. The non-linear relaxation spectra thus obtained suggest that a cooperative binding of the dye over the polymer or some aggregation processes may take place.

The mean relaxation time (τ^*) of the non-linear relaxation spectra can be obtained in a good approximation during an initial period, with more or less appreciable deviations later on. Accordingly, τ^* was conveniently determind from the pertinent experimental curve.

To make the aggregation processes clear, the effect of the salt concentration on the relaxation time of each spectral band was studied, for the association is thought to involve electrostatic interaction between the oppositely charged dye and residue of the polymer in addition to nonelectrostatic interaction. According to the transition-state theory and the Debye-Hückel theory,[30] the relation between the rate and the ionic strength is given for dilute solutions by;

$$\log k = \log k_0 + 1.02 \cdot Z_a Z_b \sqrt{I} \qquad (1)$$

where Z_a and Z_b are the numbers of the charges on the ion and where k and k_0 are the rate constants at a finite and at an infinite dilution respectively in a given solvent. The mechanism for the overall reaction is not clear now, so we assume that the apparent

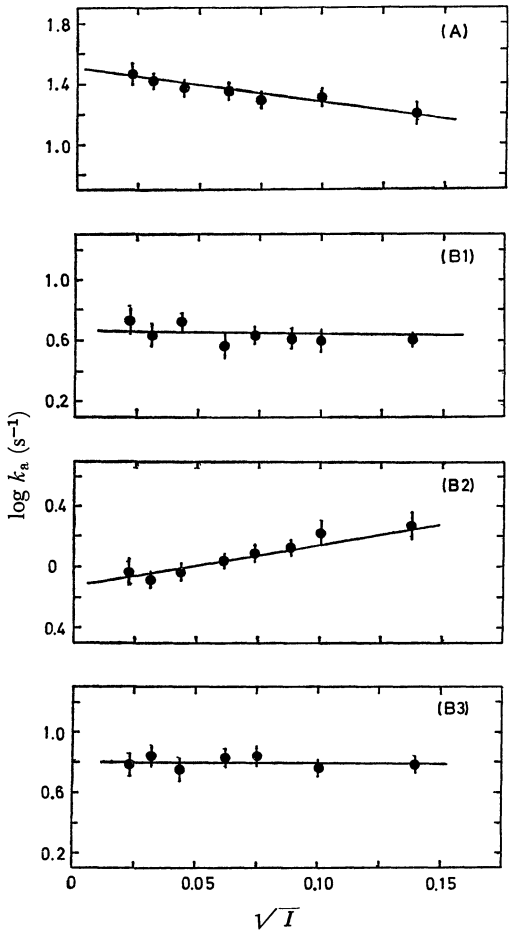

Fig. 4. Plots of $\log k_a$ against the square root of the ionic strength obtained with each spectral band as shown in Fig. 3. The curve number and the reaction conditions except ionic strength are the same as those in Fig. 3.

rate constant is approximately linear to the reciprocal relaxation time at a constant concentration. Equation (1) predicts a linear relationship if $\log k_a$ is plotted against the square root of the ionic strength with a slope proportional to the $Z_a Z_b$ product. Figure 4 shows plots of the apparent rate constants over the range of ionic strength from 5.0×10^{-4} to 2.0×10^{-2}. The results of fluorescence observation give a negative value for the $Z_a Z_b$ product. This shows that the reactants are oppositely charged. As AO is ionized to be cationic at pH 4.7, with its pK_a of 10.45,[5] the other reactant may be the negatively charged site of PLGA. The charge of the site of PLGA can be derived -1.3 ± 0.4 from the values of the product of $Z_a^* Z_b = -1.6 \pm 0.5$ and the effective charge†† of $Z_a^* = +1.2$. The result is consistent with the fact that the side-chain of PLGA is the mononegative

†† The differnce in binding affinity to the charged site of PLGA between the monomer and the dimer of the AO cation is not known. Assuming that Coulombic force may play an important role in the binding force, the effective charge, Z_a^*, of the free AO in the reaction mixture can be estimated for a given reaction. At concentration of AO used (2.0×10^{-5} M), the fraction of the dimer in free AO is estimated to be *ca.* 10%.

anion of the carboxyl group at pH 4.7.

The rate for the decrease in the absorbance of α-band was independent of the ionic strength. This suggests that two or more cationic AO molecules were associated at the occupied site of PLGA, where the negatively charged carboxyl group of the polypeptide had been neutralized by a cationic AO molecule and formed a dimer or oligomers of AO outside the complex. The close resemblance in the magnitude of the rates and the Z_aZ_b products between the rise of the band around 535 nm and the fall of the α-band and β-band indicates that the process of the decay of dimeric AO is the rate-limiting step for the rise of the band around 535 nm. Therefore, the appearance of the band around 535 nm may be due to formation of polymeric AO along the axis of the α-helix of PLGA.

The positive sign of Z_aZ_b observed at the γ-band suggests that both of the reactants are similarly charged ions. It seems reasonable to consider that the cationic AO molecules bind to the similarly charged site of PLGA, where more than two cations have been bound to a carboxylate anion of the side chain of the polypeptide. The effective charge of the Z_a* of the free AO in the reaction mixture can be estimated as $+0.9$, as the similarly charged ions associate with each other in this process. As the value of the $Z_a{}^*Z_b$ product was given as 3.2 ± 0.4 from the results, the charge of the binding site of PLGA can be estimated as 3.5 ± 0.5. These facts show that the residue of PLGA is occupied by four or five cationic AO molecules and that the oligomer bound in the outside of the helical PLGA.

Although the aggregation theory successfully explains the monomer-dimer equilibrium, the nature of the higher aggregates is not yet clear. Schwartz[7] assumed that the spectra of the γ-band is independent of the length of the oligomer. The present work shows that the γ-band appears with the association of five or six AO molecules and that the formation of the further aggregates gives rise to a polymer band around 535 nm. This polymer band of AO has also been confirmed by the CD study of Hatano *et al.*[19]

The results suggest that the primary process of the reaction mechanism is one in which the AO cation binds very rapidly to the carboxyl anion of PLGA and the charge of the binding site is neutralized. This process may be followed by the cooperative binding of a cationic AO molecule to an unoccupied site adjacent to the occupied site of PLGA and by the formation of an oligomer and polymer of AO onto the helical PLGA.

We wish to express our thanks to Dr. M. Yoneyama of Hokkaido University for reading the manuscript. This investigation was supported by the Matsunaga Science Foudation.

Apparent Viscosities of Ferric Oxide–Water Suspensions

Noboru MORIYAMA

Research Laboratories, Kao Soap Company, Minatoyakushubata, Wakayama 640-91

(Received July 11, 1974)

The effects of various types of anionic surfactants and inorganic phosphates on the apparent viscosities of ferric oxide–water suspensions of high pigment concentrations are examined. The additions of surfactants or inorganic phosphates to the suspensions cause depressions in their apparent viscosities from values of more than 10000 centipoise (cP) to about 10 cP. The concentration of the surfactants or the inorganic phosphates required to depress the apparent viscosity, which is designated as C_0, is highly dependent upon the alkyl-chain length of the 1-1-type surfactants, the degree of the polymerization of the surfactants of the type of the vinyl copolymers and the degree of the condensation of the surfactants of the type of the formalin condensates or inorganic phosphates. With the 1-1-type surfactants, the values of the C_0 decrease with the increases in the alkyl-chain length, and the surfactants with much shorter alkyl-chain lengths, such as Na octyl sulfate, linear-chain Na hexylbenzene sulfonate, and Na butyl-naphthalene sulfonate, have no marked viscosity depression effects. With the formalin condensates and the inorganic phosphates, the values of C_0 decrease with the degree of condensation. With the vinyl copolymers, the C_0 show smallest values at the appropriate degree of polymerization, *e.g.*, about 10—40 for the Na salt of polyacrylic acid. Both the absolute value of the zeta potential and the amount of adsorption increase remarkably in the concentration regions showing marked viscosity depressions. The viscosity depressions of the suspensions upon the additions of the surfactants or inorganic phosphates can be qualitatively explained by taking into account the contributions of the zeta potential values and concentrations to the dispersion-coagulation of the pigment particles.

It has been well known that the additions of surfactants or electrolytes to pigment–water suspensions with high pigment concentrations and with apparent viscosities of more than 10000 centipoise (cP) show the apparent viscosities to be depressed to about 10 cP.[1-9] The viscosity depressions caused by the additions of surfactants or electrolytes have been widely used as a measure of the dispersibility of surfactants.[5,10]

Many studies of the pigment–water suspensions of high pigment concentrations have been reported from the view-point of viscometric behavior,[6-9] but these few studies have been from the view point of surface chemistry, such as zeta potential and adsorption. Marked viscosity depressions have been observed in the aqueous suspensions of various sorts of inorganic pigments, such as ferric oxide, titanium dioxide, zinc oxide, and carbon black. In the present paper, ferric oxide was used as the inorganic pigment, which had no special meaning.

The present paper will describe the effects of the alkyl-chain length of 1-1-type anionic surfactants, the degree of the polymerization of vinyl copolymers, and the degree of the condensation of formalin condensates or inorganic polyphosphates on the apparent viscosities of 50 wt% ferric oxide suspensions, and will discuss these effects in relation to the zeta potential, adsorption, and the pH data.

Experimental

Materials. All the surfactants used were prepared according to a procedure described earlier.[11] Their chemical compositions, degrees of polymerization or condensation, and abbreviations are listed in Table 1. The orthophosphates (NaH_2PO_4 and Na_3PO_4), pyrophosphates ($Na_2H_2P_2O_7$ and $Na_4P_2O_7$), and tripolyphosphate ($Na_5P_3O_{10}$) were of a reagent grade. The tetrapolyphosphate ($Na_6P_4O_{13}$) was a specially prepared commercial product. The phosphates were obtained from the Wako Pure Chemicals Co. Most of the surfactants and inorganic phosphates described above are known to have dispersing power and are used widely.[10]

Pigments. Ferric Oxide (Toda Color 130R) obtained from the Toda Industries Co., which had not been treated, was washed with water until there was no change in the conductivity of the filtrate. The surface area, as determined by the B.E.T. method using nitrogen at −195 °C, was 7.0 m^2/g. The average particle radius, calculated from electron microscopic observation, was 0.2 μm. The particles have a sphere-like form. The isoelectric point of ferric oxide, determined according to the method of Parks *et al.*,[12] is 5.5.

Apparent Viscosity Measurements. Aqueous solutions of the materials, which refer to the surfactants or inorganic phosphates, were prepared by dissolving the desired quantities of the materials in distilled water of 500 ml. Into a beaker with a 750-ml capacity, a 400-ml portion of the material solutions thus prepared was poured, and maintained at 25± 0.1 °C in a water bath. The desired quantities of ferric oxide were then added to the material solutions. After the above ferric oxide–material solution suspensions had been stirred with a Homomixer, TK type (Tokushu Kiki Industries Co.), for five minutes, the apparent viscosities were determined using a Viscometer (Tokyo Kiki Manuf. Co. Type BM, rotor 60 rpm).

Sedimentation Velocity Measurements. Suspensions containing 1 wt% ferric oxide were prepared by the dilution of the desired quantities of the same suspensions used for the apparent viscosity measurements in supernatant solutions of their suspensions obtained by removing the ferric oxide particles with a refrigerated-automatic Ultracentrifuge, Serval Model RC-2B. Into graduated test cylinders with a 30-ml, capacity and 30 cm in height, 30 ml portions of the suspension thus prepared were poured, and the mixtures were maintained at 25 °C in the thermostat. The cylinders were turned end-over-end ten times and then allowed to stand. By the sedimentation of the pigment particles, a sedimentation boundary was formed between the material solution and the suspension. The positions, h, of the sedimentation boundaries were read periodically and were plotted *vs.* the standing time, t. The time (designated as the sedimenting time, $T_{1/2}$) during which h falls from a 30-cm height to a 15-cm height is calculated from the h *vs.* t curves and used as a measure of the sedimentation velocity.

Sedimentation Volume Measurements. Suspensions containing 5 wt% ferric oxide were prepared by the dilution of

the desired quantities of the suspensions used for the apparent viscosity measurements into supernatant solutions of their suspensions obtained by the method described above. Into graduated test cylinders with a 30-ml capacity and 30 cm in height, 30-ml portions of the suspensions thus prepared were poured, and the mixtures were maintained at 25 °C in the thermostat. The test cylinders were turned end-over-end ten times, and then allowed to stand. The positions of the sedimentation boundary between the material solution and the suspension, formed by the sedimentation of ferric oxide particles, were lowered with the standing times. After the rates of their lowerings became almost zero, the positions of the sedimentation boundaries were measured and the sedimentation volumes of ferric oxide particles were calculated from these data.

Average Radius of the Particle Measurements. The average radius of the particle was calculated by means of microscopic observation by the dilution of a quantity of the suspensions used for apparent viscosity measurements into supernatant solutions of their suspensions.

Electrophoretic Mobility Measurements. The mobility measurements of ferric oxide particles were made using a Zeta-Meter (Zeta-Meter, Inc.) by the dilution of a quantity of the suspensions used for the apparent viscosity measurements into supernatant solutions of their suspensions.

Adsorption Measurements. The amounts of the adsorption of the materials onto ferric oxide particles were calculated from measurements of the difference in concentrations of the material solutions before and after preparing the suspensions. The material solutions after preparing the suspensions described above refer to the same supernatant solutions as those used for sedimentation velocity measurements. The concentrations of the surfactants having benzene ring or naphthalene ring in the molecule, among the surfactant solutions, were calculated by measuring the intensity of the absorption band at about 260 nm using a Shimadzu Spectrophotometer, UV-200. On the other hand, those having no benzene ring or naphthalene ring in the molecule were measured with a TOC Meter, Toshiba-Beckman Model 102, which determined the amount of carbon dioxide generated by firing the solutions at 950 °C, using CoO as the catalyst. The concentrations of orthophosphate and polyphosphate solutions were measured according to the directions of Nakahara.[13]

pH Measurements. The pH values of the suspensions used for the apparent viscosity measurements were measured with a pH meter, TOA Electronics, Ltd. The pH values of the suspensions were controlled by adding an aqueous sodium hydroxide solution or an aqueous hydrochloric acid solution to the suspensions.

Results and Discussion

In Fig. 1, the apparent viscosities of ferric oxide–water suspensions containing 30, 50, 60, and 70 wt% ferric oxide are plotted as a function of the concentration of PA-33. Figure 1 shows that the additions of PA-33 to the ferric oxide–water suspensions with apparent viscosities of more than 10000 cP have their viscosities depressed to about 10 cP, and that the concentrations of PA-33 required to depress the vis-

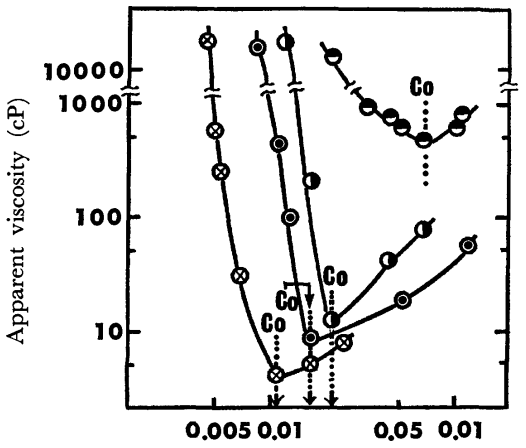

Fig. 1. The effects of the concentrations of PA-33 on the apparent viscosities of ferric oxide–water suspensions containing 30(⊗), 50(⊙), 60(◑) and 70(◓) wt% ferric oxide at 25 °C.
The initial concentrations of PA-33 refer to the mole concentrations expressed per monomer unit.

cosities up to about 10 cP, which are designated as C_0, increase with the increase in the pigment concentrations of the suspensions. As the concentrations of PA-33 approach C_0, the apparent viscosities of the suspensions decrease remarkably, but they increase gradually above C_0. These results suggest that the values of C_0 can be used as a measure of the apparent viscosity depression effects.

The values of C_0 and the apparent viscosities at C_0 for ferric oxide–aqueous-surfactant or inorganic phosphate-solution (weight ratio of 50/50) suspensions are listed in Table 2. Both the values of C_0 and the apparent viscosities at C_0 for 1-1-type anionic surfactants tend to decrease with the increases in the alkyl-chain length of the surfactants. The viscosity depression effects of the surfactants with a short alkyl-chain length, such as C_8S, $C_{10}S$, C_6BS, C_8BS, and C_4NS, are small,

a) Concentrations (mol/l) of vinyl copolymers and formalin condensates are expressed in those of monomer unit of them, respectively. b) Measured at 40 °C because of insolubility of $C_{14}S$ at 25 °C.

as may be seen in Table 2. These results show that the viscosity depression effects of 1-1-type anionic surfactants have a correlation with the critical micelle concentration (CMC) values of the surfactants, and that the surfactants with large CMC values have not marked viscosity depression effects. The values of C_0 for the formalin condensates decrease with the increases in the degree of condensation. The C_0 for PA series becomes smallest at a degree of polymerization of about 33. However, the changes in the degree of the polymerization from 12 to 33 have only a little influence on the values of C_0. As may be seen in Table 2, there exist only small differences in the values of C_0 among the vinyl copolymers except PA-64 and PA-146. These polymers have degrees of polymerization from 7.5 to 33, and the C_0 values are expressed in monomer units. Therefore, it can be concluded that the C_0 values undergo only a little influence by the changes in the chemical composition of the polymers, whereas they are greatly influenced by the changes in the degrees of polymerization. The C_0 values for polyphosphates are small compared with those of the surfactants described above, and tend to lower with the degree of the condensation of polyphosphates. With orthophosphates, on the other hand, no viscosity depression effects can be found.

In Fig. 2, the apparent viscosity, $T_{1/2}$, the sedimentation volume, and the average radius of pigment particles for the suspensions are plotted as functions of the concentration of PA-33, NSF-3.7, and $Na_5P_3O_{10}$ respectively. As may be seen in Fig. 2, a correlation can be found among the apparent viscosity, $T_{1/2}$, the

A dotted line refers to the apparent viscosity *vs.* log concentration, *C*, curve for $C_{12}BS$ at a controlled pH of 8.0.

sedimentation volume, and the average radius of the particle data. These results suggest that the viscosity changes in the suspensions are based upon the dispersion-coagulation of the ferric oxide particles.

Figure 3 shows the effects of the alkyl-chain length of linear-chain Na alkylbenzene sulfonate on the apparent viscosities, and their relations with the zeta potential, the adsorption, and the pH data. The calculation of the zeta potential, ζ, on the basis of the electrophoretic-mobility, u, measurements is done using the Helmholtz-Smoluchwski equation for the systems of $\kappa a \geq 200$,[14] where κ is the reciprocal of the thickness of the double layer, and a, the particle radius:

$$u = \frac{E\zeta\varepsilon}{4\pi\eta} \qquad (1)$$

where η and ε are the viscosity and the dielectric constant of the medium respectively, and where E is the applied electric field.

Both the absolute values of the zeta potential and the amounts of adsorption for $C_{10}BS$ and $C_{12}BS$ increase remarkably in the concentration regions showing marked viscosity depressions, as may be seen in Fig. 3. The absolute values of the zeta potential and the amounts of adsorption for C_8S are very small compared with those for $C_{10}S$ and $C_{12}S$ in all the concentrations tested.

The viscosity changes in the suspensions are due to the dispersion-coagulation of the ferric oxide particles, as has been described above. Therefore, the viscosity changes in the suspensions may be explained by taking into account the contributions of the zeta potential values and the thickness of the double layer, $1/\kappa$*), to the dispersion-coagulation of the particles, that is, by applying the DLVO theory.[16] With 1-1-type anionic surfactants, the contributions of the zeta potential and $1/\kappa$ to the dispersion-coagulation of the particles increase with the increases in the zeta potential values, and decrease with the increases in the concentrations of the surfactant ions. As may be seen in Fig. 3, the amount of adsorption is in the order of $C_{12}BS > C_{10}BS > C_8BS$ at the same initial concentration, which shows that the equilibrium concentration at the same initial concentration is in the order of $C_8BS > C_{10}BS > C_{12}BS$. Accordingly, the negative contributions of the concentrations to the viscosity depressions increase in the order $C_8BS > C_{10}BS > C_{12}BS$. The apparent viscosities for C_8BS decrease up to about 600 cP at very high concentrations, as may be seen in Fig. 3. Perhaps this viscosity depression is related to the contribution of the zeta potential. In the high concentrations, however, precise electrophoretic mobility measurements cannot be made, because electrolysis may occur between the anodic and cathodic electrodes. Therefore, the calculation of the zeta potential cannot be made at high concentrations. As may be seen in Fig. 3, the apparent viscosities for $C_{10}BS$ and $C_{12}BS$ show considerable increases at very high concentrations. This may be due to the increase in the negative contribution of the concentration to the viscosity depression.

Generally, the stabilities of lyophobic colloids and the suspensions depend upon the pH of the systems.[17,18,11] Figure 3 shows that the pH values of the suspensions dispersed with each surfactant of C_8BS, $C_{10}BS$, and $C_{12}BS$ become almost the same at the same concentration, and undergo very little changes with an increase in the concentration, except for those in the region of low concentrations. The dotted line in Fig. 3 refers to the viscosity *vs.* concentration curve for $C_{12}BS$ at a controlled pH of 8.0. The dotted line is nearly in accord with the solid line of $C_{12}BS$, for which the pH is not controlled, this shows that the pH changes of the suspensions accompanied by changes in the concentrations have no appreciable influences on the viscosities.

It can be concluded from these results that the viscosity depression data can be explained by the zeta potential and the adsorption data. The weak viscosity depression effects of 1-1-type anionic surfactants with short alkyl chain lengths, such as C_8S and C_6BS, shown in Table 2 may be due to the lack of the amounts of adsorption and their contributions to the zeta potential.

Figure 4 shows the effects of the degree of the condensation of the formalin condensates on the apparent

where e is the elementary charge, z_i, the valency, n_i, the number of ions of the species, i, per cubic centimeter, K, Boltzmann's constant, and T, the absolute temperature.[15]

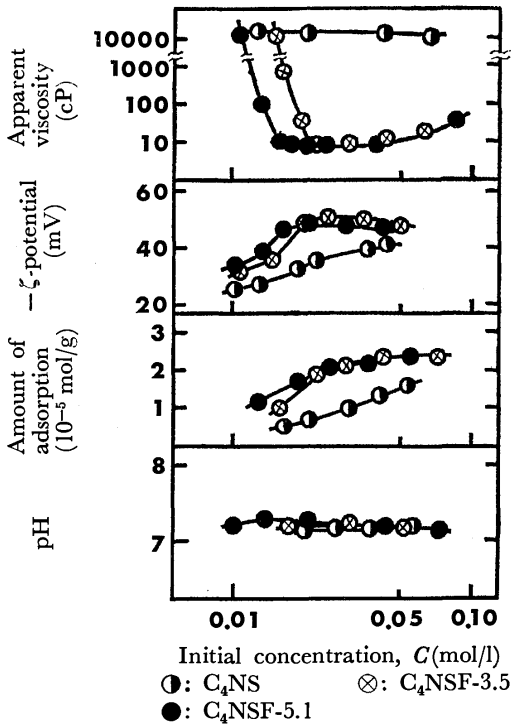

Fig. 4. The effects of the degree of the condensation of alkylnaphthalene sulfonate formalin condensates on the apparent viscosities of 50 wt% ferric oxide suspensions, and their relations with zeta potential, adsorption and pH data.

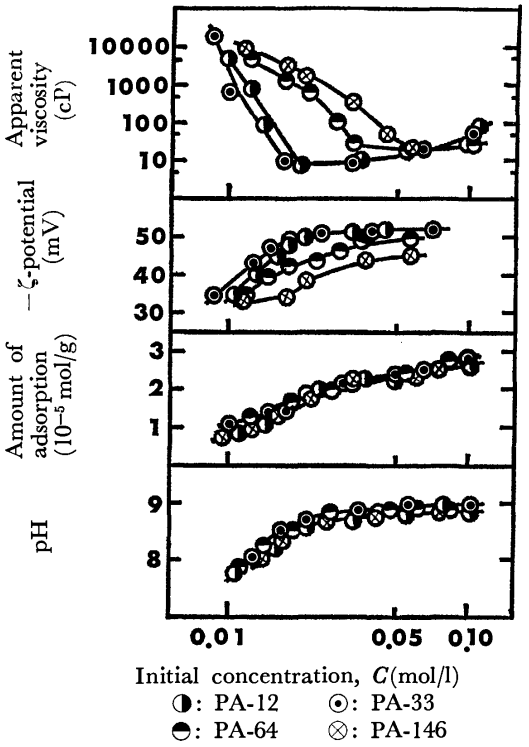

Fig. 5. The effects of the degree of the polymerization of Na salt of polyacrylic acid on the apparent viscosities of 50 wt% ferric oxide suspensions, and their relations with zeta potential, adsorption and pH data.

viscosities, and their relations with the zeta potential, the adsorption, and the pH data. With C_4NS, no marked viscosity depression effects are observed. With C_4NSF-3.5 and C_4NSF-5.1, on the other hand, marked viscosity depression effects are observed, and the value of C_0 for C_4NSF-5.1 is smaller than that for C_4NSF-3.5. That is, the viscosity depression effects are highly dependent upon the degree of condensation. As may be seen in Fig. 4, the zeta potential and the adsorption data are closely correlated with the viscosity data. The pH of the suspensions dispersed with each surfactant of C_4NS, C_4NSF-3.5, and C_4NSF-5.1 show almost the same values at the same concentration. These results suggest that the degrees of the condensation of the formalin condensates have great influences on the viscosity depression effects, and that their effects are due to the marked increases in the absolute values of the zeta potential and the amounts of adsorption with the increases in the degree of condensation.

Figure 5 shows the effects of the degree of the polymerization of the Na salt of polyacrylic acid (PA) on the viscosities, and their relations with the zeta potential, the adsorption, and the pH data. Figure 5 shows that PA with low degrees of polymerization, such as PA-12 and PA-33, show marked viscosity depressions in the region of low concentrations, whereas those with high degrees of polymerization, such as PA-64 and PA-146, show small viscosity depressions in the region of low concentrations. The absolute values of the zeta potential for the PA series increase remarkably in the concentration regions showing marked viscosity depressions, and the order of C_0 corresponds to the order of the zeta potential. Similarly, the amounts of adsorption for the PA series increase in the concentration regions showing viscosity depressions. However, no pronounced differences in the amounts of adsorption for the PA series are observed, although the amounts of adsorption may be expected to increase with the degree of polymerization. The absolute values of the zeta potential for high degrees of polymerization are small compared with those for low degrees of polymerization; this suggests that the contributions of the amounts of adsorption to the zeta potentials decrease with the increases in the degree of polymerization. In other words, the concentration of PA on the pigment surface, *i.e.*, the parts of PA which contribute to the zeta potential, decrease with an increase in the degree of polymerization. This may be attributed to the difference in the adsorption conformation among the PA on the pigment surface. Generally, the bridging action of polymers increases with an increase in the degree of polymerization,[19,20] and serves to promote coagulation. However, in the case of the PA tested the bridging action is negligible, because the degree of polymerization is not large enough to have a large bridging action.

The pH values of the suspensions dispersed with each PA show almost equal values at the same concentration; this shows that the pH's of the suspensions are not dependent upon the degrees of polymerization.

Figure 6 shows the effects of the degree of the condensation of inorganic phosphates on the viscosities, and their relations with the zeta potential, the adsorption, and the pH data. Sodium dihydrogen phosphate

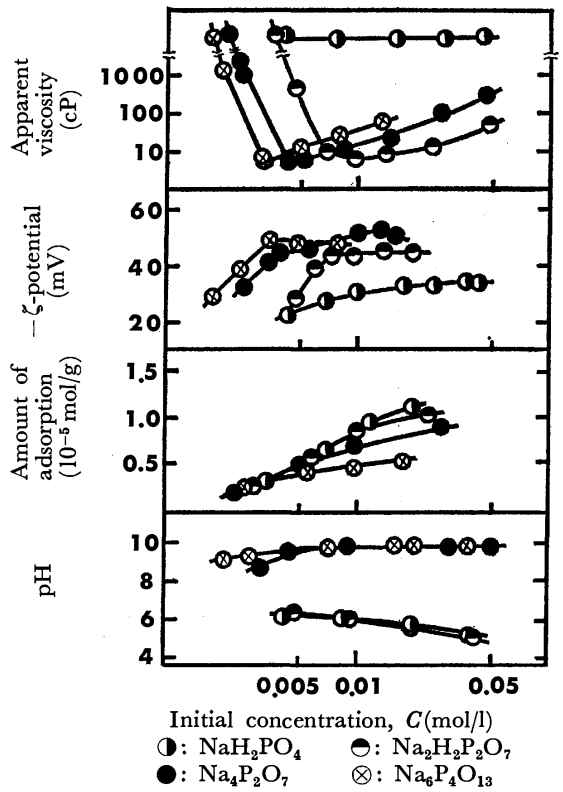

Fig. 6. The effects of the degree of the condensation of inorganic phosphates on the apparent viscosities of 50 wt% ferric oxide suspensions, and their relations with zeta potential, adsorption and pH data.

(NaH_2PO_4) has no marked viscosity depression effects, whereas acid sodium pyrophosphate ($Na_2H_2P_2O_7$), sodium pyrophosphate ($Na_4P_2O_7$), and sodium tetrapolyphosphate ($Na_6P_4O_{13}$) have such effects. The values of C_0 are in the order of $Na_6P_4O_{13}<Na_4P_2O_7,<Na_2H_2P_2O_7$. The zeta potential data are closely related with the viscosity data, whereas the adsorption data are not necessarily related with the viscosity data. The pH's of the suspensions dispersed with each phosphate of NaH_2PO_4 and $Na_2H_2P_2O_7$ show almost the same values lower than the isoelectric point (pH 5.5) of the ferric oxide particles at very high concentrations. Similarly, the pH's of the suspensions dispersed with each phosphate of $Na_4P_2O_7$ and $Na_6P_4O_{13}$ show almost the same values, much higher than the isoelectric point of the particles. In the pH range below the isoelectric point, where the pigment particle has positive charge, the anionic phosphate ion adsorbs on the particle and cancels the charge. On a further increase in adsorption, the particle comes to have a negative charge.[13] The pH's of an aqueous solution of $Na_2H_2P_2O_7$ and NaH_2PO_4** are lower than the isoelectric point of the particle. Therefore, the phosphate ion may be consumed to cancel the positive charge of the particle in the region of low concentrations. The absolute values of the zeta potential for $Na_2H_2P_2O_7$ are much smaller than those for $Na_4P_2O_7$ and $Na_6P_4O_{13}$ in the region of low concentrations, whereas the amounts of adsorption for $Na_2N_2P_2O_7$ and NaH_2PO_4 are larger than those for $Na_4P_2O_7$ and $Na_6P_4O_{13}$. These may be explained in relation to the isoelectric point of the particle described above. The zeta potential and the adsorption data show that the contributions of the amount of adsorption to the zeta-potential values increase with an increase in the valency of the phosphate ions. The pH's of the suspensions dispersed with $Na_2H_2P_2O_7$ and NaH_2PO_4 show somewhat higher values than the isoelectric point of the pigment particle in the region of low concentrations. This may be because the majority of the phosphate ions are adsorbed upon the particles.

It can be concluded from these results that the viscosity depression effects increase with the increase in the degree of the condensation of the phosphates, and have close relations with the zeta potential, the adsorption, and the pH data, especially the isoelectric point of the pigment particle.

According to the DLVO theory,[16] the total potential energy, V, between the two sphere particles (ferric oxide particles) for a system in which $\kappa a \gg 1$ and $H \ll a$ is given by:

$$V/a = \frac{\varepsilon\zeta^2}{2} \ln (1+e^{-\kappa H}) - \frac{A}{12H} \qquad (2)$$

where A is the Hamaker constant, and H, the shortest distance between the two particles.

Using the value of A (4.5×10^{-13}) calculated by Fowkes,[21] the value of V/a can be calculated from Eq. (2). The value of V/a depends upon the absolute value of the zeta potential and the value of $1/\kappa$, *i.e.*, the thickness of the double layer. The thickness of the double layer is inversely proportional to the square of the valency of the material ion and the concentration of the material ion, as has been described above. Accordingly, the value of V/a increases with the absolute value of the zeta potential and decreases with the increase in the concentration and the valency of the material ion.

The values of V/a for aqueous 50 wt% ferric oxide suspensions dispersed with 1-1-type surfactants such as $C_{12}BS$ have been calculated from Eq. (2) and plotted as a function of H in Fig. 7. In this figure, the apparent viscosity *vs.* $\log C$ curve is also shown to facilitate examination of the correlation of the V/a data with the apparent viscosity data. The abscissa in Fig. 7 is expressed in terms of the initial concentration of the surfactant. The calculation of V/a is made by using the equilibrium concentration of the surfactant, which was measured for the 50 wt% suspension. The values of V/a become positive over certain ranges of H for the concentrations of the numbers of 2 and 3, showing the suspensions with low apparent viscosity values. In other words, in the suspensions of the numbers of 2 and 3, repulsive forces enough to disturb the coagulation of the particles work between the particles. Therefore, the apparent viscosities of the suspensions may have small values. On the other hand, the values of V/a become negative in all the H values for the concentration of the number of 1, showing suspensions of very high viscosity values. In other words, in this suspension no repulsive force enough to disturb the coagula-

** The pH's of aqueous solutions of $Na_2H_2P_2O_7$ and NaH_2PO_4 change from 4.7 at 0.0045 mol/l to 4.18 at 0.45 mol/l, and from 4.98 at 0.0042 mol/l to 4.65 at 0.042 mol/l, respectively.

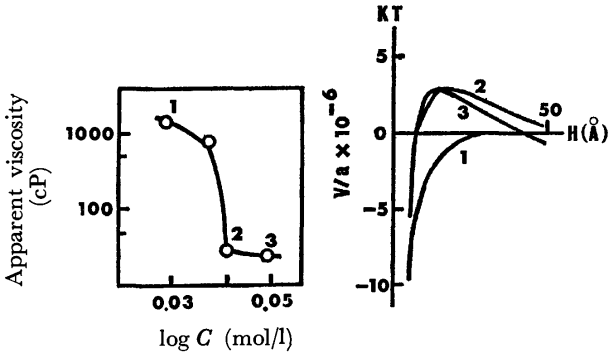

Fig. 7. The relations between V/a and apparent viscosity data for $C_{12}BS$.
1: initial concentration; 0.0287 mol/l

tion of the particles works between the particles. Therefore, the particles coagulate, and the apparent viscosity of the suspension may have a large value. A relation similar to that found for the systems of $C_{12}BS$ is also found for the systems of C_8BS and $C_{10}BS$. These results show that the viscosity changes of 50 wt% ferric oxide suspensions upon the addition of surfactants can be explained by taking into account the zeta potential value, the valency, and the concentration of the surfactants, *i.e.*, the application of DLVO theory. Not only the viscosity changes in ferric oxide suspensions, but also the viscosity changes in other pigment suspensions, such as titanium dioxide and zinc oxide, can be explained qualitatively by the DLVO theory. This will be reported in a forthcoming paper.

The author wishes to express his thanks to Professor Sei Hachisu of the Institute for Optical Research, Kyoiku University for his valuable suggestions, and to Dr. Takashi Takeuchi and Dr. Kunihiko Nagase of the Research Laboratories for their encouragement and the permission to publish this paper.

The Adsorption of the Ampholytic Surfactant and the Anionic Surfactant at the Nitrogen-Solution Interface from the Mixed Aqueous Solution

Akio NAKAMURA

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya-ku, Tokyo 158

(Received November 8, 1974)

The amounts of adsorption of an ampholytic surfactant, *N*-dodecyl-*β*-alanine(NDA), and an anionic surfactant, sodium alkylsulfate(SAS), at nitrogen–solution interface from aqueous equimolar mixtures of them were measured directly by the radiotracer method, using tritiated and non-tritiated samples of NDA and ^{35}S-labeled and non-labeled samples of SAS: sodium tetradecylsulfate(STS), sodium dodecylsulfate(SDS), and sodium decylsulfate(SDeS). The adsorption of both components of the mixed systems was observed at concentrations lower than those for the systems containing each component alone. A stronger adsorption of NDA than that of SAS was observed for all mixed systems. The overall area per alkyl chain at the maximum adsorption was about 26 Å^2 for each system, showing the adsorbed layer to be in a highly condensed state. Electrophoresis measurements, together with surface tension measurements of NDA-SDS systems and the elemental analysis of the precipitates from concentrated NDA-SDS solutions, suggested the presence of a 1 : 1-complex formed between NDA and SDS. The Gibbs adsorption isotherm for the binary system was derived. The calculated amounts of adsorption agreed with the observed values. A linear relationship was found to hold between the logarithm of the constants of complex formation and the number of carbon atoms of SAS. A free energy of the complex formation of −0.50 kcal per mole of the methylene group was found.

A number of studies have been made of the interaction between organic cations and anions in solutions, such as surfactant–surfactant[1–6] and surfactant–dye[7–11] systems, where the formation of ion pairs or association complexes may occur. Especially in an aqueous solution containing anionic and cationic surfactants, surface tension depression and micelle formation[1,6] have been observed at lower concentrations than in single-surfactant solutions, suggesting the formation of a complex with high surface activity and a mixed micelle.

Similar effects can be expected to occur in an aqueous mixture of ampholytic and ionic surfactants. However, studies of such mixtures are rather rare.[12] In the present study, the measurements of the adsorption of the ampholytic surfactant, *N*-dodecyl-*β*-ananine (NDA), and anionic surfactants including sodium tetradecylsulfate(STS), sodium dodecylsulfate(SDS), and sodium decylsulfate(SDeS) from equimolar aqueous solutions of them were made by the radiotracer method, together with measurements of the surface tension of these systems. The Gibbs adsorption isotherm for an aqueous system containing two surfactants and an equimolar complex was derived and was confirmed to be applicable to the system. The formation of a complex between two solute species was inferred, and the equilibrium constants of complex formation and the free energy of complex formation per methylene group of surfactants were estimated.

Experimental

Materials. Tritiated NDA was synthesized from tritiated dodecylamine and *β*-propiolactone and was purified as has been reported.[13] The specific activity of the sample was about 16 Ci/mol. ^{35}S-labeled sodium alkylsulfate, STS, SDS, and SDeS were synthesized by allowing them to react the corresponding alcohols with ^{35}S-labeled sulfuric acid, were purified by repeated recrystallization from ethanol, and were dried *in vacuo*. The specific activity of the samples was about 1 Ci/mol. The water used was prepared by refluxing ordinary distilled water with acid permanganate, then by distilling it from an alkaline permanganate solution, and finally by distilling twice using a Hysil flask.

Methods. The radiotracer method of adsorption measurement was similar to that reported previously.[14] Two solutions of the same composition were prepared, one containing ^{3}H-NDA and SAS, and the other, ^{35}S-SAS and NDA, in order to measure the amounts of the adsorption of both components for a given solution separately. The surface tension was measured by the Wilhelmy plate method. The time dependence of the surface tension was self-recorded, and the curve was extrapolated to an infinite time in order to obtain an equilibrium value. All the measurements were made at 30 °C in the neutral pH region, where NDA molecules have been confirmed to be in the zwitterionic state.[15]

Results and Discussion

Surface Tension. Figure 1 shows the surface tension *vs.* concentration curves of NDA and equimolar mixtures of NDA and SAS's of 4 to 14 carbon

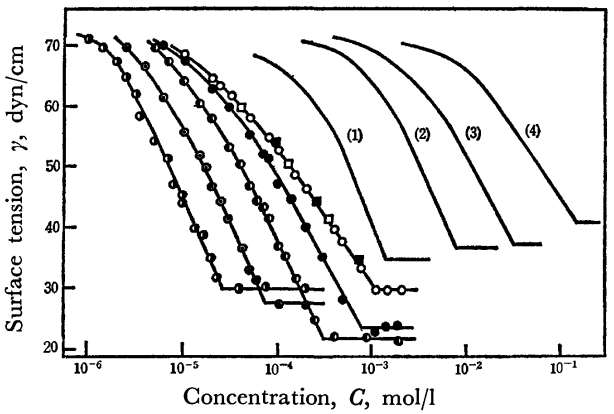

Fig. 1. Surface tension *vs.* concentration of NDA-SAS, NDA and SAS solutions.
○: NDA solution
mixed solution of NDA and
◑: STS, ⊙: SDS, ◐: SDeS, ●: sodium octylsulfate
□: sodium hexylsulfate, ■: sodium butylsulfate
SAS solution: (1) STS, (2) SDS, (3) SDeS, (4) sodium octylsulfate

atoms in a molecule. The abscissa shows the concentration of each component of the mixed solutions. The surface tension of SAS is also shown for the sake of comparison.[16] It is noticeable that DNA shows a lower critical micelle concentration and a smaller slope than those of SAS. The surface tension of NDA–SAS mixtures in an equimolar ratio is generally far lower than that expected from the surface tensions of solutions containing each component alone.

Thus, a synergistic effect of surface activity was confirmed. The effect increases with the increase in the surface activity of SAS's. This suggests some kind of interaction between NDA and SAS's, depending on the hydrocarbon chain length of the latter.

Adsorption. Figures 2, 3, and 4 show the observed amounts of the adsorption of both NDA and SAS from their equimolar mixtures for the systems of NDA–STS, NDA–SDS, and NDA–SDeS respectively. The amount of adsorption is larger for NDA than for SAS, and the amounts of the adsorption of NDA and SAS increase at a nearly constant ratio with the increase in the concentration, tending toward saturation. The amount and the molar fraction of the adsorption of SAS in the mixed systems increase with the increase in their alkyl chain length.

The adsorbed layers observed in the present study show an overall area of about 26 Å^2 per molecule and are highly condensed compared with those of each of the components, which show the values of 43 Å^2 per molecule for NDA[13] and 52 Å^2 for SDS[14] at their saturated adsorption. The value of 26 Å^2 is even smaller than that of the mixed solution containing anionic and cationic surfactants, *i.e.*, 30 Å^2.[4] These facts also suggest the interaction of NDA with SAS in the adsorbed layer.

As regards the interactions between oppositely charged organic ions in a bulk solution, the formation of a complex with a 1 : 1-molar ratio has been reported for surfactant–surfactant and surfactant–dye systems by many investigators on the basis of studies of conductometry,[2,8,9] spectrophotometry,[3,11] the elemental analysis of precipitates,[3,5,8] and polarography.[10] Similar interactions of NDA with SDS in an acid solution, and with dodecyltrimethylammonium bromide in an alkaline solution, have been investigated.[12] However, the interaction between an anionic surfactant such as SAS and the zwitterionic NDA in the near neutral pH region[15] has not yet been experimentally confirmed.

In order to confirm whether or not a 1 : 1-complex forms in the present case, the electrophoresis of NDA in an aqueous SDS solution, elemental analysis of the precipitates obtained from NDA–SDS mixtures were carried out. A surface tension *vs.* composition curve was also constructed in order to examine the complex formation.

Electrophoresis. As is shown in Fig. 5, a U-tube 0.7 cm in diameter and 30 cm in length, with an opening with a rubber stopper 10 cm from a porous plate at the bottom, was used for this purpose. Platinum electrodes were put in both arms of the tube. An equimolar solution of 4×10^{-5} mol/l ^{3}H-NDA and

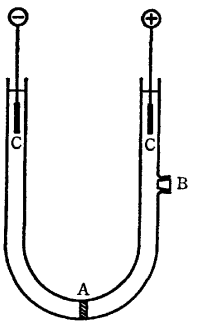

Fig. 5. Apparatus for electrophoresis.
A: porous plate, B: small opening with rubber stopper, C: platinum electrodes

SDS was introduced into the left arm while the same solution without radioactivity was introduced in the right arm. Then, a 200-volt DC current was applied between the electrodes about 30 cm apart through the solution; the migration of ^{3}H-NDA into the right arm was detected by measuring the radioactivity of a sample of about 1 μl of the solution taken out by means of a microsyringe through the rubber stopper. When the left electrode was made negative as shown, the radioactivity began to be detected several minutes after applying the DC voltage. In the absence of SDS, the migration of NDA was not detected even after a prolonged time. This indicates no net charge in the NDA, that is, the zwitterionic state of NDA in the solution without SDS and the net negative charge of NDA in the mixed solution, which would be evidence of NDA–SDS complex formation. Here, the size of the complex formed may not be so large as an ordinary micelle, since the concentration is sufficiently below the breakpoint of the surface tension *vs.* concentration curve shown in Fig. 1.

Elemental Analysis. When NDA and SDS solutions of concentrations sufficiently higher than that used for surface tension measurements were mixed at about 20 °C, a white precipitate appeared. The results of the elemental analysis of the precipitates are shown in Table 1. The molar ratio of NDA to SDS was conventionally estimated from the nitrogen-to-carbon ratio as shown in the last column. The values are found to be nearly unity for the wide range of SDS : NDA molar ratios of the solutions studied. Thus, the 1 : 1-complex formation can be confirmed, at least in the state of the precipitate, suggesting that 1 : 1-complex ions may also exist in the solution.

Surface Activity. Figure 6 shows the surface tension plotted against the molar ratio of NDA to SDS plus NDA in the solution with the total concentration kept constant at 2×10^{-5} mol/l (Curve 1), together with its deviation from the surface tension calculated assuming the additivity of the surface tension depression for each component (Curve 2). Curve 2 exhibits a distinct maximum at the molar ratio of 1 : 1. Again, this suggests a complex formation in the aqueous solution between NDA and SDS at this ratio.

TABLE 1. ELEMENTAL ANALYSIS OF PRECIPITATES FROM NDA-SDS SOLUTIONS

Composition of solution		Composition of precipitate		Molar ratio of precipitate
SDS	NDA	nitrogen	carbon	NDA/SDS

The Gibbs Adsorption Isotherm for the Binary System of the Surfactants. The Gibbs adsorption isotherm giving the amount of each component adsorbed from the mixed aqueous solution of ampholytic and anionic surfactants was derived. The Gibbs adsorption isotherm is written, in its general form, as:[17]

$$-\mathrm{d}\gamma/RT = \sum_i \Gamma_i \,\mathrm{d}\ln a_i \qquad (1)$$

where γ denotes the surface tension, and Γ_i and a_i, the surface excess and the activity of the i'th solute in the solution respectively. Equation (1) is rewritten for a solution containing the ampholytic (NDA) and the anionic (SAS) surfactants as:

$$-\mathrm{d}\gamma/RT = \Gamma_\mathrm{D}\,\mathrm{d}\ln C_\mathrm{D} + \Gamma_\mathrm{Na}\,\mathrm{d}\ln C_\mathrm{Na} + \Gamma_\mathrm{A}\,\mathrm{d}\ln C_\mathrm{A} + \Gamma_\mathrm{C}\,\mathrm{d}\ln C_\mathrm{c} \qquad (2)$$

where the activities are replaced by concentrations, since the concentration of the surfactants used is of the order of magnitude of 10^{-5} mol/l; subscripts D, Na, A, and C refer to the alkylsulfate, the sodium, the ampholyte, and the complex ions respectively. Here, as has been mentioned above, we have sufficient reason to assume the 1 : 1-complex formation between NDA and SAS. Therefore, the following equation can be expected to hold:

$$C_\mathrm{C}/C_\mathrm{A}C_\mathrm{D} = K \qquad (3)$$

where K is the equilibrium constant of the complex formation. We also obtain the following equation from the condition of electrical neutrality in the adsorbed phase:

$$\Gamma_\mathrm{Na} = \Gamma^\mathrm{D} \qquad (4)$$

From Eqs. (2), (3), and (4), we obtain:

$$-\mathrm{d}\gamma/RT = \Gamma^\mathrm{D}(\mathrm{d}\ln C_\mathrm{D} + \mathrm{d}\ln C_\mathrm{Na}) + \Gamma^\mathrm{A}\,\mathrm{d}\ln C_\mathrm{A} \qquad (5)$$

where $\Gamma^\mathrm{A}=\Gamma_\mathrm{A}+\Gamma_\mathrm{C}$ and $\Gamma^\mathrm{D}=\Gamma_\mathrm{D}+\Gamma_\mathrm{C}$ are the total amounts of the adsorption of NDA and SAS respectively. In order to obtain Γ^D and Γ^A, we should derive two equations from Eq. (5). For this purpose, Eq. (5) is differentiated under two appropriate conditions. First, we differentiate Eq. (5) with respect to the logarithm of the equimolar concentration, keeping the molar ratio of NDA to SAS constant at unity:

$$-[\mathrm{d}\gamma/RT\,\mathrm{d}\ln C]_{1:1} = \Gamma^\mathrm{D}[(\mathrm{d}\ln C_\mathrm{D}/\mathrm{d}\ln C)_{1:1} + (\mathrm{d}\ln C_\mathrm{Na}/\mathrm{d}\ln C)_{1:1}] + \Gamma^\mathrm{A}(\mathrm{d}\ln C_\mathrm{A}/\mathrm{d}\ln C)_{1:1} \qquad (6)$$

where C denotes the concentration of the equimolar mixture given by:

$$C = C_\mathrm{A} + C_\mathrm{C} = C_\mathrm{D} + C_\mathrm{C} = C_\mathrm{Na} \qquad (7)$$

From Eqs. (3) and (7), we obtain, for the equimolar mixture:

$$(\mathrm{d}\ln C_D/\mathrm{d}\ln C)_{1:1} = (\mathrm{d}\ln C_A/\mathrm{d}\ln C)_{1:1}$$
$$= (C/C_A)(\mathrm{d}C_A/\mathrm{d}C)_{1:1}$$
$$= 2KC/(1+4KC-\sqrt{1+4KC}) \quad (8)$$

From Eqs. (6), (7) and (8), we obtain:

$$I_{1:1} = (p+1)\Gamma^D + p\Gamma^A \quad (9)$$

where:

$$I_{1:1} = -(\mathrm{d}\gamma/RT\,\mathrm{d}\ln C)_{1:1}$$
$$p = 2KC/(1+4KC-\sqrt{1+4KC})$$

Next, we differentiate Eq. (5) with respect to the logarithm of the total concentration of SAS, keeping the total concentration of NDA constant:

$$-[\mathrm{d}\gamma/RT\,\mathrm{d}\ln C^D]_{C^A} = \Gamma^D[(\mathrm{d}\ln C_D/\mathrm{d}\ln C^D)_{C^A}$$
$$+ (\mathrm{d}\ln C_{Na}/\mathrm{d}\ln C^D)_{C^A}]$$
$$+ \Gamma^A(\mathrm{d}\ln C_A/\mathrm{d}\ln C^D)_{C^A} \quad (10)$$

where:

$$C^A = C_A + C_C, \quad C^D = C_D + C_C = C_{Na} \quad (11)$$

By substituting Eq. (11) into Eq. (3) and differentiating with respect to C^D, while keeping C^A constant, the following equations are obtained:

$$(\mathrm{d}C_D/\mathrm{d}C^D)_{C^A} = (KC_D+1)/(2KC_D+KC^A-KC^D+1)$$
$$(\mathrm{d}C_A/\mathrm{d}C^D)_{C^A} = -KC_A/(2KC_A+KC^D-KC^A+1)$$

which, give at $C^D=C^A$:

$$(\mathrm{d}C_D/\mathrm{d}C^D)_{C^A,C^D=C^A} = (KC_D+1)/(2KC_D+1) \quad (12)$$
$$(\mathrm{d}C_A/\mathrm{d}C^D)_{C^A,C^D=C^A} = -KC_A/(2KC_A+1) \quad (13)$$

Further, we obtain from Eqs. (3) and (11), with $C^D=C^A$:

$$(C^D/C_D) = (C^D/C_A) = 2KC^D/(-1+\sqrt{1+4KC^D}) \quad (14)$$

By putting Eqs. (12), (13), (14) and $(\mathrm{d}\ln C_{Na}/\mathrm{d}\ln C^D)_{C^A}=1$ (from Eq. (11)) into Eq. (10),

$$I_{A,1:1} = (q+1)\Gamma^D - r\Gamma^A \quad (15)$$

is obtained, where:

$$I_{A,1:1} = -[\mathrm{d}\gamma/RT\,\mathrm{d}\ln C^D]_{C^A,C^D=C^A}$$
$$q = KC^D(1+\sqrt{1+4KC^D})/(1+4KC^D-\sqrt{1+4KC^D})$$
$$r = KC^D/\sqrt{1+4KC^D}$$

Equations (9) and (15) finally give:

$$\Gamma^A = [(x^2+6x+1)/2(x+1)^2]I_{1:1} - [(3x+1)/(x+1)^2]I_{A,1:1} \quad (16)$$

$$\Gamma^D = [(x-1)/2(x+1)]I_{1:1} + [1/(x+1)]I_{A,1:1} \quad (17)$$

where

$$x = \sqrt{1+4KC^D}$$

By using Eqs. (16) and (17), Γ^A and Γ^D can be calculated for each system. The values of $I_{1:1}$ in Eqs. (16) and (17) can be obtained from the slopes of the curves for the mixed systems shown in Fig. 1. The values of $I_{A,1:1}$ can be obtained from the slopes of the surface tension *vs.* C^D curves at $C^D=C^A$. The curves obtained for NDA–STS, NDA–SDS, and NDA–SDeS systems are shown in Figs. 7 and 8. The arrows in the figures indicate the equimolar concentration of $C^D=C^A$, where the slopes give the respective values of $I_{A,1:1}$ for these systems. Using these data of $I_{1:1}$ and $I_{A,1:1}$, the values of K were determined so as to obtain the best fit between the calculated and observed Γ^A's and Γ^D's.

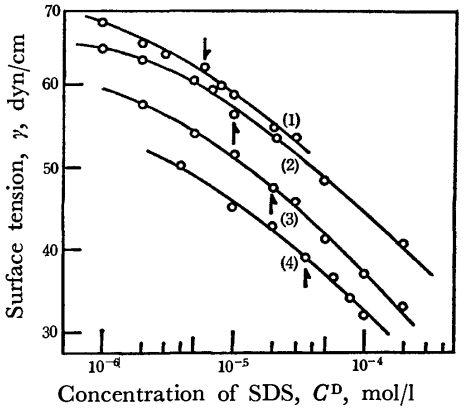

Fig. 7. Surface tension of mixed system *vs.* concentration of SDS.
concentration of NDA (10^{-5} mol/l)

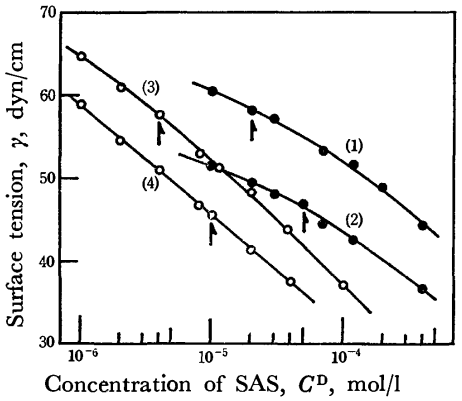

Fig. 8. Surface tension of mixed system *vs.* concentration of SAS.
(●: SDeS, ○: STS).
concentration of NDA (10^{-5} mol/l)
(1): 2.0, (2): 5.0, (3): 0.4, (4): 1.0

The best-fit Γ's thus calculated are shown, together with the observed values, in Figs. 2, 3, and 4.

The values of K were found to be 3.36×10^5, 6.54×10^4, and 1.32×10^4 mol/l for NDA–STS, NDA–SDS, and NDA–SDeS systems respectively. In the case of the interaction of SDS with a cationic surfactant(dodecyltrimethylammonium bromide) with the same hydrocarbon chain length as NDA, the equilibrium constant of complex formation has been determined by conductometry to be 1.67×10^4 mol/l.[2] The overall agreement of those results with ours suggests that the interaction between SAS and the ampholyte NDA is roughly the same in magnitude as that between SAS and the cationic surfactant. The fractions of complex formation in the solution as expressed by C_C/C^D were calculated to be 0.42, 0.55, and 0.70 for NDA–SDeS, NDA–SDS, and NDA–STS systems respectively at a concentration slightly less than the breakpoints of the curves in Fig. 1.

The Free Energy of Complex Formation. Figure 9 shows the relationship between ln K and the number of carbon atoms in the hydrocarbon chain of SAS. A linear relationship with a positive slope is found to hold. This result shows that the interaction between

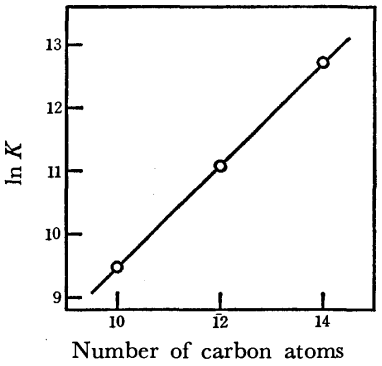

Fig. 9. ln K *vs.* number of carbon atoms in hydrocarbon chain of sodium alkylsulfate.

hydrocarbon chains affects the complex formation in addition to the electrostatic interaction. The free energy change in the complex formation calculated according to the $\Delta G^\circ = -RT \ln K$ relation is found to decrease by 0.50 kcal/mol for each increase in the methylene group of SAS. The value can be regarded as the free energy of hydrophobic interaction per mol of the methylene group of the surfactants, since the value is of the same order of magnitude as has been evaluated for amino acid side chains, *i.e.*, -0.5 to -0.6 kcal/mol for the hydrophobic bond.[18] These facts support the 1 : 1-complex formation between NDA and SAS molecules due to ionic and hydrophobic interactions.

The author expresses his hearty thanks to Professor Tsunetaka Sasaki of Tokai University for his kind discussions and suggestions.

The Reflection Spectra of Complex Salts of the Tetracyanoquinodimethane Anion Radical

Yukako Oohashi and Tadayoshi Sakata*

The Institute for Solid State Physics, The University of Tokyo, Roppongi, Minato, Tokyo 106

(Received November 11, 1974)

Reflection measurements of the pressed pellets of two 2 : 3 complex salts and six 1 : 2 complex salts of the tetracyanoquinodimethane (TCNQ) anion radical were carried out over the 5000—43000 cm^{-1} range by the use of Avery's method. The polarized normal-incidence reflection was measured for the $Ph_3PCH_3(TCNQ)_2$ single crystal. The observed results were examined on the basis of the composite-system method. For 2 : 3 salts, the transition energy and the oscillator strength are interpreted by the use of the N-A-A model (N: $TCNQ^0$ and A-A: TCNQ anion dimer); it is concluded that the interaction between the two components, N and A-A, is weak. In the solid-state spectra of 1 : 2 salts, the assignments were made by the use of the polarization results of the normal-incidence reflection of the $Ph_3PCH_3(TCNQ)_2$ crystal. Besides the four transitions corresponding to those of 2 : 3 salts, two new CT bands with weak intensities were observed and assigned. Except for quinolinium$(TCNQ)_2$, a spectral change correlative to the electrical conductivity was found in the 1 : 2 salts and discussed in relation to the extent of the delocalization of the negative charge of $(TCNQ)_2^-$. The spectrum of quinolinium$(TCNQ)_2$ exhibits a remarkable intensity decrease compared with those of the other 1 : 2 salts.

It is known that anion radical salts of 7,7,8,8-tetracyanoquinodimethane (TCNQ) exhibit interesting physical properties. The 1 : 2 complex salts, $M^+(TCNQ)_2^-$, and the 2 : 3 complex salts, $(M^+)_2(TCNQ)_3^{2-}$, have been especially extensively investigated with respect to their structure[1-5] and their magnetic,[6-12] electrical,[13-16] and optical[17-22] properties. Previously, we measured the reflection intensity of the simple salts of the TCNQ anion radical, and discussed three typical types of crystalline electronic states and the correlation between the intensity of the interradical charge-transfer (CT) band and the singlet-triplet splitting of the ground state.[22] On the basis of this knowledge of the electronic structures of the simple salts, we aimed to investigate the electronic states of the complex salts containing formally-neutral TCNQ ($TCNQ^0$) besides the anion radical ($TCNQ^-$). In the present study, we measured the polarized normal-incidence reflection for a single crystal of methyltriphenylphosphonium$(TCNQ)_2$, $Ph_3PCH_3(TCNQ)_2$ and discussed the character of each electronic transition on the basis of these polarization results. Furthermore, we measured the reflection of the pressed pellets of eight complex salts of the TCNQ anion radical and obtained the oscillator strength (f) for each transition. On the basis of these experimental results (peak positions and oscillator strengths) and the knowledge of the electronic structures of the simple salts, we discuss the electronic structure of complex salts, together with its relation to the electrical and the magnetic data.

Experimental

Materials. The samples used in this experiment were prepared by the method described in the literature.[13] The eight complex salts investigated were morpholinium$_2(TCNQ)_3$ ($Mor_2(TCNQ)_3$), $Cs_2(TCNQ)_3$, $(CH_3)_3NH(TCNQ)_2$, $Ph_3PCH_3(TCNQ)_2$, $(C_2H_5)_3NH(TCNQ)_2$, *N*-ethylquinolinium $(TCNQ)_2$(EtQ$(TCNQ)_2$), bipyridinium$(TCNQ)_2$ (Bip$(TCNQ)_2$), and quinolinium$(TCNQ)_2$ (Q$(TCNQ)_2$). Large single crystals suitable for the measurement of the polarized normal-incidence reflection were obtained for $Ph_3PCH_3(TCNQ)_2$.[13]

Measurements and Analysis. The reflection intensities were usually measured with pressed pellets of the samples over the range from 5000 to 43000 cm^{-1}. The experimental details are the same as those described in a previous paper.[23] The polarized normal-incidence reflection of the single crystal was measured for $Ph_3PCH_3(TCNQ)_2$ over the range from 5000 to 37000 cm^{-1}. The analysis of these reflection data was carried out by Avery's method for the pressed pellets, and by Kramers-Kronig transformation for the single crystal. The treatment of the inaccessible spectral regions in the Kramers-Kronig analysis follows the method of Roessler.[24] The A and B values of the approximate equation of:

$$\theta(\omega_0) = A \ln\left|\frac{a+\omega_0}{a-\omega_0}\right| - \frac{1}{\pi}\int_a^b \ln\sqrt{R(\omega)}\,\frac{\mathrm{d}}{\mathrm{d}\omega} \times\left(\ln\left|\frac{\omega+\omega_0}{\omega-\omega_0}\right|\right)\mathrm{d}\omega + B\ln\left|\frac{b+\omega_0}{b-\omega_0}\right|$$

were determined from the observed reflectivities in the zero-absorbing region, the observation being carried out in the spectral region from a to b. The refractive index (n) and the extinction coefficient (k) were thus determined, and the oscillator strength (f) for each transition was calculated by means of this equation: $f = \frac{m}{e^2 n_0}\int 4n(\nu)k(\nu)\nu\mathrm{d}\nu$, where n_0 is the number of the molecules in a unit volume and where ν is the frequency of the incident light. In the figures of the present paper, the $4\pi n(\nu)k(\nu)/2.303\,\lambda C$ value (ε') will be plotted to show the wave-number dependence of the absorption intensity of the solid-state spectrum (C: molar concentration; λ: wavelength of the incident light).

Results and Discussion

In the crystal of $Ph_3PCH_3(TCNQ)_2$ at room temperature, tetrads of TCNQ molecules with the interplanar spacings of 3.22 Å, 3.24 Å and 3.22 Å compose a one-dimensional column.[5] The interplanar spacing between tetrads is 3.57 Å. In a tetrad, molecules are overlapped with a shift along the long axis of the TCNQ molecule (Y axis), and there are two crystallographycally independent molecules (II-I-I'-II'). The small difference observed between the

* Present address: Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka.

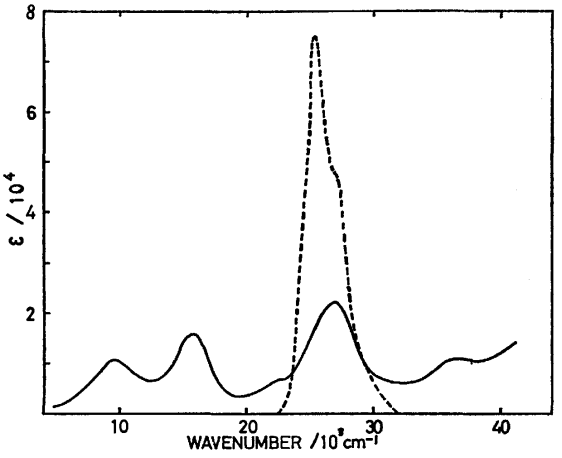

Fig. 1. The absorption spectrum of TCNQ in acetonitrile and the solid-state spectrum of NH_4TCNQ.

molecular structures of I and II suggests that the negative charge is slightly localized on the I molecule. Therefore, we will at first investigate the electronic structure of $Ph_3PCH_3(TCNQ)_2$ by the use of the simple model of N-A-A-N (A and N designate $TCNQ^-$ and $TCNQ^0$ respectively).

Figure 1 shows the absorption spectra of $TCNQ^0$ in an acetonitrile solution and of NH_4TCNQ in the solid state.[22] From the SCF-LCAO-MO-CI calculation of $TCNQ^0$ by the use of the molecular structure[25] in the TCNQ crystal, the lowest electronic transition observed at 25.3×10^3 cm^{-1} ($f=1.01$) is assigned to the 8→9 locally-excited (LE) electronic transition polarized parallel to the Y axis. The 8 and 9 molecular orbitals are the highest occupied and the lowest vacant ones respectively. In the previous paper, the peaks at 9.5×10^3, 16.0×10^3, and 26.9×10^3 cm^{-1} of NH_4TCNQ solid were assigned to the 9→9′ CT transition between $TCNQ^-$ and $TCNQ^-$, the 8→9 LE transition, and the 9→10 LE transition of $TCNQ^-$ respectively.[22] These LE transitions are polarized parallel to the Y axis. The analysis of the solid-state spectrum revealed that the NH_4TCNQ solid contains the dimer (A-A) of $TCNQ^-$. Therefore, the superposition of the two spectra in Fig. 1 gives the tentative absorption spectrum of the above-mentioned N-A-A-N model without any interaction between N and A.

Polarized Normal-Incidence Reflection of the $Ph_3PCH_3(TCNQ)_2$ Single Crystal. Figure 2 shows the normal-incidence reflections of the (100) face with the polarized lights along four directions ($b_{//}$, $b_\perp$, $c_{//}$, $c_\perp$) over the range from 5×10^3 cm^{-1} to 37.0×10^3 cm^{-1}. Table 1 shows the square of the direction cosine of the component of the molecular axis projected on (100) to the polarization direction. I and II designate the two crystallographycally independent TCNQ's. Iida suggested the assignment of the transition observed in the infrared region as a CT transition between $TCNQ^-$ and $TCNQ^0$, or as a direct transition to the electrical conduction state.[19] Since $Ph_3PCH_3(TCNQ)_2$ exhibits an intermediate conductivity, we adopted the former assignment. The transition moment of the CT transition is parallel to the I-II direction in Table 1; therefore, the former assignment sug-

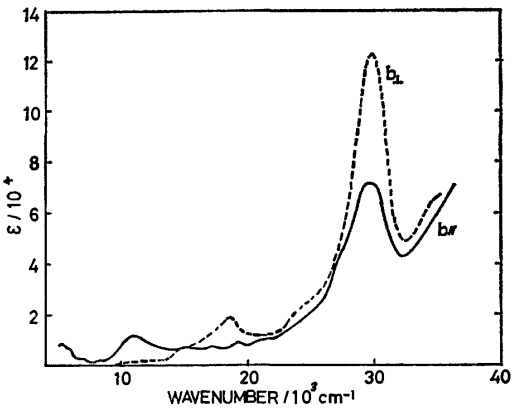

Fig. 3. The absorption spectra obtained from Kramers-Kronig analysis on (100) face of $Ph_3PCH_3(TCNQ)_2$ single crystal. The solid and the dashed curves were obtained with the incident light polarized parallel and perpendicular to the *b* axis.

gests that the infrared band is not found in the polarized spectrum perpendicular to the b axis ($b_\perp$). Therefore, the $b_\perp$ polarized reflection spectrum can be analysed by the equation of Roessler ($A=0.012$ and $B=-0.18$). The obtained spectrum is shown in Fig. 3. As may be seen from Table 1, for the other three polarization directions the infrared band has intensity and the zero-absorbing region is not found. Since the A and B values depend on the respective electronic transitions below 5×10^3 cm^{-1} and above 37.0×10^3 cm^{-1}, and since the former transition is ascribed to a CT transition between $TCNQ^-$ and $TCNQ^0$, and the latter, mainly to the LE transitions, the following relations can be estimated from Table 1:

$$B(c_{//})<B(b_\perp)<B(b_{//})<B(c_\perp)$$
$$A(b_{//})<A(c_\perp)<A(c_{//})<A(b_\perp)$$

Under these conditions, the A and B values were parametrized so as not to give the negative extinction coefficient. The obtained spectra are shown in Figs. 3 and 4. Since the absolute intensity is sensitive to the values of the parameters, no detailed discussion of the absorption intensity is carried out for the single crystal.

From the above polarization results, the I and II bands can clearly be assigned to the CT transitions, and the IV and VIII bands, to the LE transitions polarized parallel to the Y axis (LE(Y)). Although the other, weak peaks are not discussed in detail, it is noticeable that the V and VII bands were assigned with the CT polarization. In comparison with the tentative spectrum of the N-A-A-N model, the I and II bands are assigned to the 9→9′ CT transition from $TCNQ^-$ to $TCNQ^0$ and 9→9′ CT transition between $TCNQ^-$ and $TCNQ^-$. The IV and VIII bands are assigned to the 8→9 LE transition of $TCNQ^-$ and the superimposed transition of the 9→10 LE transition of $TCNQ^-$ and the 8→9 LE transition of $TCNQ^0$. Since the peak of the lowest transition (I) was reported at $2.9-3.3\times10^3$ cm^{-1} by Iida,[19] the energy separations between the I and V bands and between the II and VII bands are about 16×10^3 cm^{-1}; this value nearly coincides with the transition energy of the 8→9 LE transition of $TCNQ^-$. Therefore, the CT bands, V and VII, can possibly be assigned to 8→9′ CT transitions from $TCNQ^-$ to $TCNQ^0$ and to the 8→9′ CT transition between $TCNQ^-$ and $TCNQ^-$ (Table 2). Sakai *et al.* reported that the reversible pressure-induced absorption band was found at around 20×10^3 cm^{-1} at high pressures with respect to $(C_2H_5)_2NH(TCNQ)_2$ and $Q(TCNQ)_2$.[20] This experimental result is explained by the intensity increase of these new CT bands. The present assignments are consistent with those by Iida[19] for the I, IV, and VIII bands; also, the ambiguity of the assignment of the II band is excluded by this polarization measurement.

The Solid-state Spectra of the Pressed Pellets. The solid-state spectra and the refractive index, n, of the pressed pellets of the eight complex salts are shown in Figs. 5—8. Since four predominant transitions are observed in this spectral region, they are designated by CTI, CTII, YI, and YII in the increasing order of the transition energy; they correspond to the I,

II, IV, and VIII bands of the $Ph_3PCH_3(TCNQ)_2$ crystal respectively. The origin of the two or three weak peaks observed at 20—23×10^3 cm^{-1} of the 2 : 3 complex salts and some 1 : 2 complex salts is not clear, but these peaks are reproducible. For all

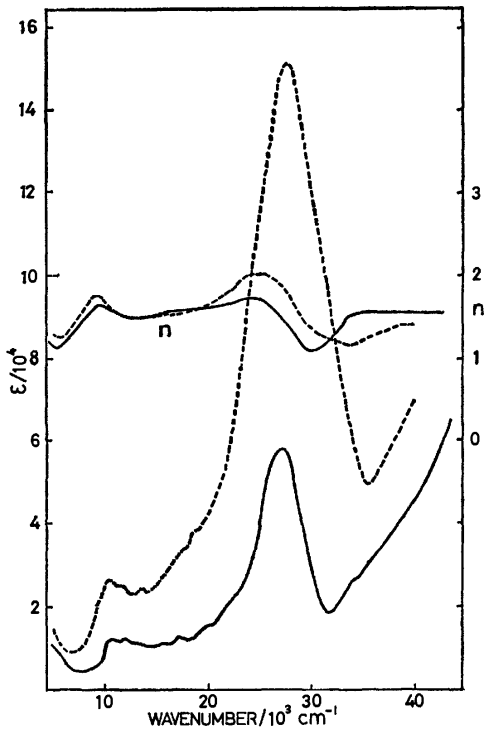

Fig. 8. The solid-state spectra and the refractive index n of $Bip(TCNQ)_2$ (----) and $Q(TCNQ)_2$ (——).

the 1 : 2 complex salts except for $Q(TCNQ)_2$, a weak peak was observed at about 14×10^3 cm^{-1}; it corresponds to the III band in the polarized crystalline spectrum of $Ph_3PCH_3(TCNQ)_2$. The III band exhibits polarization behavior a little different from that of the YI band (Figs. 3 and 4) and can be observed clearly when the YI band becomes obscure ($EtQ(TCNQ)_2$ and $Bip(TCNQ)_2$). Therefore, this peak is considered to have a different electronic origin from the YI band. The peak positions and the oscillator strengths are tabulated in Table 3, together with the solid-state results of NH_4TCNQ (Group A) and RbTCNQ-II (Group B) of the simple salt[22] and the electronic transition of $TCNQ^0$ in acetonitrile.

The crystal structures have been reported for the five complex salts investigated in this study.[1-5] In all cases, the TCNQ molecules compose a one-dimensional column. In the case of the 2 : 3 complex salts ($Mor_2(TCNQ)_3$[4]) and $Cs_2(TCNQ)_3$[1]), TCNQ molecules in a column form a triad which consists of two $TCNQ^-$ and one $TCNQ^0$. Among the 1 : 2 complex salts, $Ph_3PCH_3(TCNQ)_2$[5] and $(C_2H_5)_3NH(TCNQ)_2$[2] contain a tetrad unit which consists of two $TCNQ^-$ and two $TCNQ^0$. However, in the $Q(TCNQ)_2$ crystal,[3] the TCNQ column is composed of equally spaced TCNQ molecules and one electron per two TCNQ molecules is completely delocalized.

The 2 : 3 Complex Salts. As have been mentioned above, the TCNQ column of the 2 : 3 complex salts is represented as a repeat of N(1/2)-A-A-N(1/2). N(1/2) means that the N's on both sides half belong to this repeating unit. Therefore, we will discuss the electronic states of this repeating unit by the

method of the composite molecule, the components of which are A-A and N. In this unit, the TCNQ radicals (A-A) overlap each other with a shift along the short axis of the TCNQ radical. This packing is the same as that for the anion dimer of Group A of the simple salts. Therefore, the electronic states of the anion dimer of NH_4TCNQ (Group A)[22] and $TCNQ^0$ in acetonitrile are used as component states.

To discuss the electronic states in the energy region treated in this study, it is sufficient to take into account the following excited states of the components: the 8→9 (LEI) and the 9→10 (LEII) excited states of $TCNQ^-$, the 8→9 LE state of $TCNQ^0$ (LEN), and the CT excited state between $TCNQ^-$ (9) and $TCNQ^-$ (9′) (CTA). Furthermore, the CT configuration between two components (CTN) is considered. Therefore, the electronic configurations are as follows:

$$G = G_{AA}\cdot G_N$$
$$AYI^{\pm} = LEI^{\pm}\cdot G_N$$
$$AYII^{\pm} = LEII^{\pm}\cdot G_N$$
$$NY^{\pm} = G_{AA}\cdot LEN^{\pm}$$
$$CTA^{\pm} = CT^{\pm}\cdot G_N$$
$$CTN^{\pm} = 1/2[\{|8_A\bar{8}_A9_A8'_A\bar{8}'_A\bar{9}'_N| - |8_A\bar{8}_A\bar{9}_A8'_A\bar{8}'_A9'_N|\} \pm \{|8_A\bar{8}_A9_N8'_A\bar{8}'_A\bar{9}'_A| - |8_A\bar{8}_A\bar{9}_N8'_A\bar{8}'_A9'_A|\}]\cdot G_N$$

and

$$G_{AA} = 1/\sqrt{2}\{|8_A\bar{8}_A9_A8'_A\bar{8}'_A\bar{9}'_A| - |8_A\bar{8}_A\bar{9}_A8'_A\bar{8}'_A9'_A|\}$$
$$G_N = |8_N\bar{8}_N|$$
$$LEI^{\pm} = 1/2[\{|8_A\bar{9}_A9_A8'_A\bar{8}'_A\bar{9}'_A| - |9_A\bar{8}_A\bar{9}_A8'_A\bar{8}'_A9'_A|\} \pm \{|8_A\bar{8}_A9_A9'_A\bar{8}'_A\bar{9}'_A| - |8_A\bar{8}_A\bar{9}_A8'_A\bar{9}'_A9'_A|\}]$$
$$LEII^{\pm} = 1/2[\{|8_A\bar{8}_A10_A8'_A\bar{8}'_A\bar{9}'_A| - |8_A\bar{8}_A\overline{10}_A8'_A\bar{8}'_A9'_A|\} \pm \{|8_A\bar{8}_A9_A8'_A\bar{8}'_A\overline{10}'_A| - |8_A\bar{8}_A\bar{9}_A8'_A\bar{8}'_A10'_A|\}]$$
$$LEN^{\pm} = 1/2[\{|8_N\bar{9}_N| - |\bar{8}_N9_N|\} \pm \{|8'_N\bar{9}'_N| - |\bar{8}'_N9'_N|\}]$$
$$CT^{\pm} = 1/\sqrt{2}\{|8_A\bar{8}_A9'_A8'_A\bar{8}'_A\bar{9}'_A| \pm |8_A\bar{8}_A9_A8'_A\bar{8}'_A\bar{9}_A|\}$$

where i_N, i_A, i'_A, and i'_N designate the molecular orbitals of N, A, A′, and N′ respectively of the N(1/2)-A-A-N(1/2) model. The ± signs denote the symmetric and the antisymmetric properties with respect to the symmetric center. The doubly occupied molecular orbitals 1—7 are neglected. The configuration interactions are:

Symmetric	C	0					
	CTN^+	$\sqrt{2}\beta(9_A9_N)$	E^+_{CTN}				
	CTA^+	$2\beta(9_A9'_A)$	0	E^+_{CTA}			
	AYI^+	0	0	$-\sqrt{2}\beta(8_A9'_A)$	E^+_{AYI}		
	$AYII^+$	0	$\beta(10_A9_N)$	$\sqrt{2}\beta(9_A10'_A)$	0	E^+_{AYII}	
	NY^+	0	$-\beta(9_A8_N)$	0	0	0	E^+_{NY}
Asymmetric	CTN^-	E^-_{CTN}					
	NY^-	$\beta(9_A8_N)$	E^-_{NY}				
	CTA^-	0	0	E^-_{CTA}			
	AYI^-	0	0	$\sqrt{2}\beta(8_A9'_A)$	E^-_{AYI}		
	$AYII^-$	$-\beta(10_A9_N)$	0	$\sqrt{2}\beta(9_A10'_A)$	0	E^-_{AYII}	

where $\beta(i_A j_N) = \int i_A(1)\ H(1)\ j_N(1)\ d\tau_1$ and where H(1) is the one-electron Hamiltonian of the crystal. The asymmetric configuration matrix almost splits into two parts, and the 3×3 part is the same as the configuration matrix of the anion dimer.[22]

Really, except for a new band, CTI, based on the CT transition between two components, the observed spectra of the 2 : 3 salts are similar to the superposed spectrum of the two components, with a small blue shift caused by the stabilization of the ground state due to the interaction with CTN^+. The observed oscillator strengths of YI(0.5) and YII(2.5) of $Mor_2(TCNQ)_3$ agree with the calculated values (YI: 0.5 and YII: 2.1) for the N(1/2)-A-A-N(1/2) model without any interaction between A and N, using the solid-state spectrum of NH_4TCNQ for A-A and the acetonitrile spectrum of $TCNQ^0$ for N. These results reveal for the 2 : 3 salts that the interaction between the two components is weak in the excited states. For $Cs_2(TCNQ)_3$, a weak hyperchromism was observed.

The singlet-triplet (S-T) splittings of the ground state reported by the magnetic measurements are 0.31 eV for $Mor_2(TCNQ)_3$[11], 0.14 eV or 0.16 eV for $Cs_2(TCNQ)_3$,[6,9] and 0.16—0.29 eV for Group A of the simple salts.[6,7,12] In the present treatment of the composite system, the stabilization of the singlet ground state becomes larger by the interaction with the low-energy ^SCTN configuration for the 2 : 3 salts than for the anion dimer. However, since the triplet ground state is also stabilized by the interaction with ^TCTN for the 2 : 3 salts, it is reasonable that the S-T splitting of the 2 : 3 salts is not very different from that of the anion dimer (Group A of the simple salts).

The 1 : 2 Complex Salts. To discuss the electronic structure of the 1 : 2 salts, we can at first adopt the simple model of N-A-A-N.[26] The electronic configurations are analogous to those of the 2 : 3 complex salts. The difference in the configuration energies between the 2 : 3 and the 1 : 2 complex salts is considered to be not very large with respect to the LE and CTA configurations, because the changes in the interplanar spacings and the molecular structure are small. However, the configuration energy of CTN is lower for the 1 : 2 salts than for the 2 : 3 salts because of a difference in the electrostatic repulsion between anion radicals. This is consistent with the observed red shift of the CTI band and the small changes of three other band positions of the 1 : 2 salts compared to those of the 2 : 3 salts.

The CTII bands of the 1 : 2 salts show the vibrational structure. Since the vibrational frequency (1300—1500 cm^{-1}) agree well with that (1600 cm^{-1}) observed for the 11.8×10^3 cm^{-1} band of the $TCNQ^-$ monomer, the assignment of the CTII band to LE transition has been proposed.[19] However, as the CT character of the CTII band was determined by our polarization experiment, the vibrational structure is attributed to a small quantity of the $TCNQ^-$ monomer. The magnetic susceptibility measurement also reported the $TCNQ^-$ monomer as an intrinsic impurity.[9]

Our previous work on the simple salts[22] showed that the separations between the CTII and YI bands are larger for the salts of Group B than for the salts of Group A, as may be seen from Table 3 (6500 cm^{-1} for NH_4TCNQ and 9300 cm^{-1} for RbTCNQ-II). This was explained by the difference in the configuration interaction between the CTA and AYI configurations. A symmetry consideration of the molecular orbitals reveals that the CTA and AYI configurations interact for the A-A overlapping form of Group B (an overlap with a shift along the Y axis) and not for that of Group A (an overlap with a shift along the X axis). The overlapping form between anions of the 1 : 2 salts is the same as that of Group B, and that between anions of the 2 : 3 salts, the same as that of Group A. However, the corresponding CTII-YI separations in the spectra of the 1 : 2 salts range from 4.3 to 6.6×10^3 cm^{-1} and are not so large as those of the 2 : 3 salts (4.3 and 5.7×10^3 cm^{-1}). From the polarized reflection analysis, the CTN configuration from the 8 orbital of A to the 9 orbital of N is located just above the AYI configuration. The interaction between these two configurations based on $\beta(9_A 9_N)$ removes the YI band to the lower-energy side, so it is reasonable that the separation between the YI and CTII bands becomes not so large.

The observed transition energies and the oscillator strengths are shown in Table 3 in the decreasing order of electrical resistivity. As may be seen from Table 3 and Figs. 6—8, the solid-state spectra of the 1 : 2 salts are divided into three main groups. The first salt, $(CH_3)_3NH(TCNQ)_2$, exhibits no CTI band and a weak CTII band; this reveals the small CTN and CTA contributions in the ground state. The YI band appears at a position intermediate between those of the first LE transitions of the $TCNQ^-$ monomer and the $TCNQ^-$ dimer in the aqueous solution, and the YII band shows the same 1700 cm^{-1} shoulder as the LE band of $TCNQ^0$ in acetonitrile. These two features show weak $TCNQ^-$–$TCNQ^-$ and $TCNQ^-$–$TCNQ^0$ interactions in the excited states. The second group contains $Ph_3PCH_3(TCNQ)_2$, $(C_2H_5)_3NH(TCNQ)_2$, $EtQ(TCNQ)_2$, and $Bip(TCNQ)_2$. These salts exhibit a gradual spectral change as the electrical resistivity decreases; the dispersion of the refractive index near 5000 cm^{-1} becomes larger, which reflects the intensity increase in the CTI band: the intensity of the CTII band increases, the YI band becomes more obscure, and the oscillator strength and the half-width of the YII band increase. The increase in the absorption intensity of the two CT bands reveals the increase in the electron delocalization in the ground state; this is consistent with the tendency of the electrical property. The absolute absorption intensities of the YI and YII bands becomes nearly double the intensities calculated from the solid-state data of the simple salts and the solution data of $TCNQ^0$. In the range corresponding to these LE transitions of $TCNQ^-$ and $TCNQ^0$, several CT bands were estimated. However, the intensities of these bands are not enough large for us to interpret the remarkable hyperchromism of the YII band. Therefore, it is considered that the electron delocalization also makes an important contribution. It is noticeable that the effect of the elec-

tron delocalization is found not only in CT transitions, but also in LE transitions for the 1 : 2 salts.

The S-T splittings of the ground state have been reported for $(CH_3)_3NH(TCNQ)_2$ (>0.2 eV),[9] Ph_3PCH_3-$(TCNQ)_2$ (0.062 eV),[6] and $(C_2H_5)_3NH(TCNQ)_2$ (0.034 eV)[6] on the basis of magnetic measurements. This remarkable difference between the salts belonging to the first and second groups can be explained by the difference in the extent of delocalization of the negative charge of $(TCNQ)_2^-$. The previous discussion showed that the contribution of the CTN^+ configurations to the ground state is smallest for $(CH_3)_3$-$NH(TCNQ)_2$ in the 1 : 2 salts investigated here, therefore, the negative charge is located almost entirely on one TCNQ. However, for the two salts of the second group, the delocalization of the negative charge occurs to some extent. This delocalization makes the CT transition between A and A less important than the CT transition between A and N; therefore, the part of the S-T splitting due to the stabilization of the singlet ground state by the interaction with the ^{S}CTA configuration becomes less important.

The third group contains only $Q(TCNQ)_2$. The solid-state spectrum of $Q(TCNQ)_2$ is very different from those of the other 1 : 2 salts (Fig. 8). Its characteristics are as follows; the absorption tail near 5×10^3 cm^{-1} becomes clear, the intensity of the YII band becomes remarkably small, and the intensity as a whole becomes smaller than those of the other 1 : 2 salts. The relatively strong intensity of the absorption near 20×10^3 cm^{-1} makes the YI band obscure. The fact that $Q(TCNQ)_2$, with the highest electrical conductivity among the eight complex salts investigated here, exhibits the clearest tendency for the intensity to increase near 5×10^3 cm^{-1} is consistent with the results of the other optical study. An infrared study of $Q(TCNQ)_2$ at 1.5 K reported that the broad absorption beginning from 500 cm^{-1} with the absorption maximum near 3000 cm^{-1}, was the transition to the electrical conduction band,[21] and that the increase in the intensity of this band is accompanied by an increase in the electrical conductivity.[18] On the other hand, a study of the crystal structure reported the complete delocalization of the negative charge of $(TCNQ)_2^-$ in the ground state.[3] The delocalization of the negative charge makes the chance of the A-A pair occurrence less than that of the A-N pair occurrence. Since the CTA transition and CTN transition are based on the above pair structure, the oscillator strength ratio of CTI to CTII is expected to become larger than in the other 1 : 2 complex salts. As is seen in Fig. 8, this tendency is consistent with the experimental results. Furthermore, the charge delocalization transforms the molecular structure[3] and, as a result, changes the oscillator strengths of the LE transitions. This is considered one of the reasons for the intensity decrease in the LE transitions of $Q(TCNQ)_2$. The relatively strong intensity near 20×10^3 cm^{-1} also supports the large extent of the delocalization.

The authors would like to express their deep gratitude to Professor Saburo Nagakura of this Institute for giving them the chance to do this work and for his helpful discussions and critical reading of the manuscript. Our thanks are also due to Dr. Suehiro Iwata of the Institute of Physical and Chemical Research for his kindness in putting his computer program at our disposal and to Dr. Michiko Konno of this Institute for her X-ray determination of the crystal face of $Ph_3PCH_3(TCNQ)_2$.

26) For the case of $(C_2H_5)_3NH(TCNQ)_2$, the interplanar spacing in a tetrad are 3.24, 3.32 and 3.24 Å, and that between the neighbouring tetrads in 3.30 Å.[2] However, the model of N-A-A-N is also applicable to this case, because the interaction between N's is weak in comparison with that between A's.

The Intramolecular Dynamic Behavior of Tetraaryl Allyl Radicals

Kohji WATANABE

Laboratory of Solid State Chemistry, Institute for Chemical Research, Kyoto University, Uji, Kyoto 611

(Received November 29, 1974)

The electron spin resonance (ESR) and the electron nuclear double resonance (ENDOR) spectra of tetraaryl allyl radicals have been observed. A comparison of the ENDOR spectra of α,α,γ,γ-tetraphenyl allyl, α,α-diphenyl-γ,γ-dianisyl allyl, and α,α,γ,γ-tetraanisyl allyl revealed that the four aryl groups are not equivalent, but are apparently to be classified into two types with different conformations in their molecular frameworks. The molecular orbital calculations on the basis of this model have shown a fairly good agreement with the observed spectra. The temperature dependence of the ENDOR spectra at −60∼−110 °C were analyzed, assuming mutually different twisting angles for the allyl skeleton. The activation energy of the torsional vibration of the allyl skeleton is estimated to be about 2.5 kcal/mol. The ESR spectra of α,α,γ,γ-tetraphenyl allyl and α,α-diphenyl-γ,γ-diphenylene allyl change drastically with the temperature at around +115 °C and show a marked line-width alternation effect. It is concluded from the results that the torsional vibration becomes vigorous with an increase in the temperature and that the allyl skeleton begins to rotate internally at high temperatures. The activation energy of the internal rotation of the allyl skeleton has been estimated to be about 15∼20 kcal/mol. The temperature-dependent hyperfine splitting of the methine proton has also been explained by assuming a model of the internal rotation of the allyl skeleton.

Anomalously large proton hyperfine splittings have often been observed for the radicals which possess twisted π-systems in their molecular frames.[1,2] The present author and his co-workers[3] also observed similar phenomena in the ESR spectra of the tetraaryl allyl radicals. Such an extraordinarily large proton hyperfine splitting can be successfully explained by the following modified McConnell relation:

$$A_\beta^H = |Q_{CH}^H| \cdot \rho_{C\beta} + |B_{t-\pi}^H| \{\cos^2(90-\theta) \cdot \rho_{C\alpha} + \cos^2(90-\phi) \cdot \rho_{C\gamma}\} \quad (1)$$

where Q_{CH}^H is −22.5∼−29.0 G and where $\rho_{C\alpha}$, $\rho_{C\beta}$, and $\rho_{C\gamma}$ are the 2pπ spin densities on the α-carbon (Cα), β-carbon (Cβ), and γ-carbon (Cγ) atoms respectively. Here, Cα and Cγ are the carbon atoms on the two sides of Cβ in the allyl molecule, and $B_{t-\pi}^H$ is a proportionality constant for the twisted π-radical, where the magnitude of B^H for the neutral radical is usually estimated to be 50∼60 G.[4-6] The θ and φ angles are the mean values of the twisting angles of the $2p_z$-*orbitals* on Cα and Cγ respectively. From Eq. (1) and McLachlan's molecular orbital (MO) calculation assuming $\theta \approx \phi$, the twisting angles (θ, φ) of the $2p_z$-*orbitals* on both α- and γ-allyl carbons were estimated to be about 28° for α,α,γ,γ-tetraphenyl allyl (TPA).[3]

Of particular interest is the fact that the methine-proton splitting of TPA shows a marked positive temperature dependence (Fig. 1). Carter *et al.*[7] interpreted the temperature-dependent splitting of the methylene proton in terms of the restricted rotation and a simple harmonic oscillator model based on the Stone-Maki theory.[8]

In order to explain the temperature dependence of the methine-proton splitting observed here, the detailed conformational analysis of these radicals is necessary. Hence, the electron-nuclear-double-resonance (ENDOR) and electron-spin-resonance (ESR) experiments have been carried out over a wide temperature range (from −110°C to +210 °C) in order to investigate the dynamic behavior of molecular motion. The most interesting result established by the ENDOR experiments at low temperatures is that the four phenyl groups in TPA are not equivalent each other, but are apparently to be classified into two different kinds of paired groups. On the other hand, the ESR results demonstrated that, in the higher-temperature region, the torsional vibration of the allyl skeleton  becomes vigorous and the allyl skeleton begins to rotate internally. As the result, the four phenyl rings of TPA become almost equivalent because of the averaging effect of the rapid internal rotation of the allyl skeleton. These phenomena observed in the ESR spectra can be well treated by means of the following modified Bloch equation:[9,10]

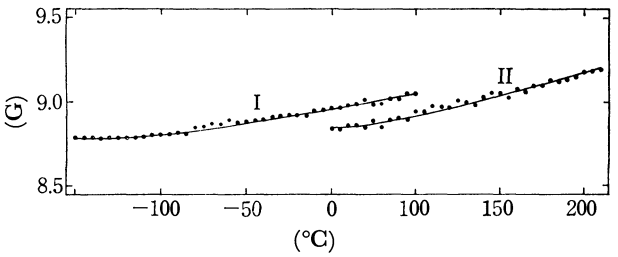

Fig. 1. Temperature dependence of the splitting constant A_β^H of TPA.
(I): in toluene, (II): in liquid paraffin.

$$G = \frac{i\omega_s M_0 \tau \sum_{s=1}^{N} f_s}{N[1 - \sum_{s=1}^{N} f_s]} \quad (2)$$

where $f_s = (N + \alpha_s \tau)$, $\alpha_s = (1/T_{2s}) - i(\omega_s - \omega)$, G: the complex transverse magnetization; ω_s: the resonance frequency for the species, s; M_0: the equilibrium value of polarization, M_z; τ: the mean life time; N: number of species; $1/T_{2s}$: transverse relaxation time, and ω: angular frequency. The results obtained from the computer simulation will be given in the following section. In this paper the author will report the results of the analyses of the temperature-dependent ESR and ENDOR spectra and will discuss in some detail the dynamic behavior of the molecular frameworks of the tetraaryl allyl radicals.

Experimental

The materials were TPA, α,α-diphenyl-γ,γ-dianisyl allyl (DPDAA), α,α,γ,γ-tetraanisyl allyl (TAA), α,α-diphenyl-γ,γ-diphenylene allyl (DDA), α,α,γ,γ-bisdiphenylene allyl (BDA), α,α,γ,γ-bisdiphenylene-β-azo allyl (BDAA), and α,α,γ,γ-bisdiphenylene-β-phenyl allyl (BDPA) (Fig. 2). They were prepared by following the process described in Refs. 11, 12, 13, 14, and 15.

The toluene and liquid paraffin used as solvents were well purified, dehydrated, and degassed. The ESR spectra were measured with a JEOL Model PE-3 X-band ESR spectrometer; an aqueous solution of peroxylamine disulfonate was used as standard of the magnetic field.[16] The ENDOR spectra were measured by means of a JEOL ES-EDX 1 spectrometer operating with a 80-Hz magnetic-field modulation in the temperature range from −110 to −40 °C for the toluene solutions and from 55 to 80 °C for the liquid paraffin solutions. The 150-watt CW RF field (6.5 KHz frequency modulation) was introduced into the coil inside the cavity for the NMR excitation. The hyperfine splitting constant was determined by averaging the values obtained from two or three measurements. The simulation of the spectra and the MO calculations were carried out at the Kyoto University Computer Center.

Results and Discussion

ENDOR Spectra. Tetraphenyl Allyl-type Radicals: The ENDOR spectra of TPA, DPDAA, and TAA are shown in Fig. 3. It is obvious that the absorption lines near the free-proton frequency are due to the methoxy protons. The line at around 26 MHz was undoubtedly identified as the one due to the methine proton by reference to the ESR measurements. The two

lines at 15.5 MHz and 16.5 MHz for TAA are assumed to arise from the *ortho*-protons of the *interior* (**B**, **C**) and *exterior* (**A**, **D**) aryl groups respectively (see Fig. 4). From similar considerations, the absorptions at around 15.5 MHz and 16.5 MHz for TPA and DPDAA are attributed to the overlapping line arising from the *ortho*- and *para*-protons of the *interior* and *exterior* phenyl groups respectively. It should be remembered here that the *ortho*- and *para*-protons have hyperfine splitting constants of nearly the same magnitude, as is often the case with neutral aromatic free radicals.[17] The other absorptions observed at about 14.7 MHz are probably due to the *meta*-protons. The two kinds of hyperfine splitting constants observed for the methoxy protons in DPDAA and TAA imply that the methoxy-protons splitting constants on the *interior* rings are different from those on the *exterior* rings. This supports the previous assumption that the splitting of the *ortho*-proton of the *exterior* aryl groups is different from that of the *interior* groups. As has been described in a previous paper,[3] these tetraaryl allyl-type radicals have a twisted allyl skeleton, in which the distance between the rings of **B** and **C** (*interior* rings) is much closer than that between the rings of **A** and **D** (*exterior* rings) or of **A** and **B**. This model offers a reasonable theoretical basis for the present ENDOR experiments, in which a

S : Not confirmed. *: Methoxy proton. a) In toluene. b) Calculated splitting constants are obtained using the 50, $\theta=\phi=28°$, where ρ_{Ci} are spin densities obtained by McLachlan's calculation using the following param-

nonequivalent spin distribution was observed between the *exterior* and the *interior* rings. This model also gives a good agreement between the observed and the calculated hyperfine splitting constants of the ring protons if one assumes $\theta=\phi=28°$, $\Omega_1=35°$, and $\Omega_2=15°$ (see Fig. 4). Based on this model, the theoretical spin density on each carbon atom was calculated by means of McLachlan's MO method;[18] the results are given in Table 1, together with the hyperfine splitting constants calculated by the McConnell relation. The hyperfine splittings of the ring protons may be classified into three groups: the *ortho*- and *para*-protons of the *exterior* rings, those of the *interior* rings, and the *meta*-protons of all the rings. In the previous paper,[13] the four phenyl rings of TPA were assumed to be nearly equivalent. However, it is more reasonable to assume the above-mentioned molecular structure (Fig. 4) in order to account for the ENDOR and the ESR spectra on the same basis.

Bisdiphenylene Allyl-type Radicals: Since BDA and BDAA are partially dimerized in a solution at low temperatures,[19] the ENDOR spectra of these radicals were not observed in toluene solutions in the temperature region suitable for this solvent. The ENDOR spectra for BDA, BDAA, and BDPA in liquid paraffin solutions are shown in Fig. 5. The smallest hyperfine splitting group of BDPA, which has never been observed in the ESR spectra, was clearly identified as being

S: Not confirmed. *: Splittings of nitrogen. **: Splittings of phenyl proton. a) In liquid paraffin. b) Calculated splitting constants are obtained using the formula $A^{H}_{Ci}=|Q^{H}_{CH}|\cdot\rho_{Ci}$, $Q^{H}_{CH}=-27.0$ (i) $A^{H}_{\beta}=|Q^{H}_{CH}|\cdot\rho_{C\beta}+|B^{H}_{t-\pi}|\{\cos^2(90-\theta)\cdot\rho_{C\alpha}+\cos^2(90-\phi)\cdot\rho_{C\gamma}\}$, $|B^{H}_{t-\pi}|=50$, $\theta=\phi=37°$ (ii) $A^{N}_{\beta}=Q_1\cdot\rho_{N\beta}+Q_2(\rho_{C\alpha}+\rho_{C\gamma})$, $Q_1=+30.9$, $Q_2=-2$, where ρ_{Ci} are spin densities obtained by McLachlan's calculation using the following parameters $\lambda=1.2$, $\alpha_N=\alpha+1.2\beta$, $\beta_{C-N}=0.9\beta$, $\theta=\phi=37°$, and in BDPA the tilted angle of the phenyl attached to the Cβ is assumed to be 30°.

due to the proton in the phenyl group attached to the β-carbon.[20,21] The multiple absorption lines at *ca.* 16.5 MHz vary as the temperature rises and collapse into a single line in the temperature region at around −65 °C, as is shown in Fig. 5-c. The proton hyperfine splitting constants thus obtained are shown in Table 2, where the assignment of the hyperfine splitting constants is based on the results of the MO calculations. From this table it may be seen that there are four kinds of equivalent protons in the biphenylene groups of each radical and that the splitting constants due to the corresponding protons in these radicals are almost equal.

In the BDA-type radicals, the two phenylene groups attached to the α- or the γ-carbon are fixed in the same plane and have no degree of free rotation, although this is not the case for the TPA-type radicals. Thus, if the two twisting angles of the allyl skeleton (θ and ϕ) were nearly equal, the spin-density distributions in the four aryl rings would be approximately equivalent. However, the temperature dependence of these ENDOR spectra (Fig. 5-c) indicates that the two twisting angles of the allyl skeleton will not be equal probably. On the other hand, the MO calculations show that if the difference in the two twisting angles ($\theta\sim\phi$) is tentatively assumed to be 10°, the difference between $A^{H}_{1,3}$ and $A^{H}_{1',3'}$ is 0.5 G, while there is no noticeable difference between $A^{H}_{2,4}$ and $A^{H}_{2',4'}$. This result implies that the spectra which reflect the difference between θ and ϕ would be observed only at quite low tem-

peratures because of the torsional vibration of the allyl skeleton ($C^{\theta}C^{\phi}C \rightleftarrows C^{\phi}C^{\theta}C$). However, this is not the case at ordinary temperatures because of the fast torsional vibration rate of the allyl skeleton. Thus, the several lines near 16.5 MHz collapse into a single line, while the two lines near 14.5 MHz remain unchanged, as is shown in Fig. 5. Similar phenomena were also observed in TPA-type radicals (Fig. 3-b). For such a temperature dependence of ENDOR spectra, Hyde *et al.*[22] used the Arrhenius equation rearranged as:

$$\log_{10} 1/\tau\delta\omega = \log_{10} 2\nu_0/\delta\omega - \Delta E/2.3RT \quad (3)$$

$$1/\tau\delta\omega = 2^{-1/2}[1-(\delta\omega_e/\delta\omega)^2]^{1/2} \quad (4)$$

where τ is the lifetime of a proton in a particular site; $\delta\omega$, the separation of the two lines within the limits of slow exchange (assumed to be 0.34 MHz); ν_0, the frequency factor; ΔE, the activation energy of the torsional vibration of the allyl skeleton; R, the gas constant; T, the absolute temperature, and $\delta\omega_e$, the experimentally observed separation (Fig. 5-d). As an example, the Arrhenius plot obtained for BDPA from Eqs. (3), (4), and from the assumed value of $\delta\omega$, is shown in Fig. 6, from which the activation energy (ΔE) of the torsional vibration of the allyl skeleton ($C^{\theta}C^{\phi}C \rightleftarrows C^{\phi}C^{\theta}C$) is estimated to be about 2.5 kcal/mol. Judging from the fairly small magnitude of ΔE for the present radicals, the torsional vibration rate of the allyl skeleton may be very sensitive to the temperature variation.

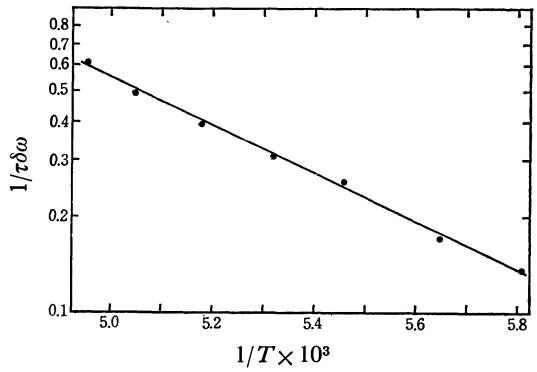

Fig. 6. Temperature dependence of the torsional vibration rate of the allyl skeleton of BDPA in toluene.

Temperature-dependent ESR Spectra and Molecular Dynamics. Tetraphenyl Allyl: As Fig. 7 shows, the hyperfine structure of the ESR spectra of TPA changes markedly with the temperature. The spectra at low temperatures (Fig. 7a-1) were analyzed assuming the three non-equivalent hyperfine components ($A^H_{o,p}$, $A^H_{o',p'}$, and $A^H_{m,m'}$), as has been established by the ENDOR measurements. The hyperfine splitting constants thus determined are listed in Table 3. As the temperature increases, the spectral pattern changes remarkably; at around 115 °C (Fig. 7a-3) it becomes a seven-line pattern with the line separation of ($A^H_{o,p}+A^H_{o',p'}$). This hyperfine pattern can be interpreted in terms of a typical line-width alternation, as has been discussed in the Introduction, and its intensity ratio coincides well with that to be expected from the theory for an extremely broadened case (the doublet of 1 : 36 : 225 : 400 : 225 : 36 : 1). The line-width alternation effect observed here may be attributed to the exchange of the *interior* and *exterior* rings due to the internal rotation of the allyl skeleton of TPA, shown in Fig. 8. At low temperatures, the rate of the internal rotation is slow, and the $A^H_{o,p}$ and $A^H_{o',p'}$

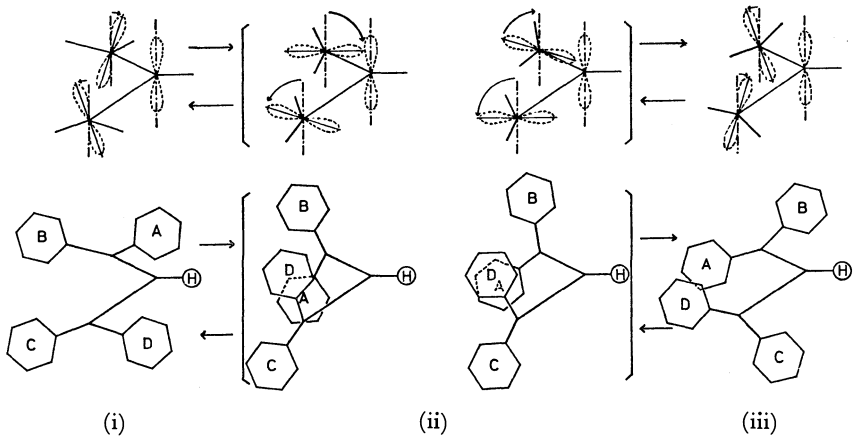

Fig. 8. Model of the internal rotation of the allyl skeleton.
Here, the interchange between the tilted angles of phenyl rings (Ω_1, Ω_2) is also considered to take place cooperative with the internal rotation of the allyl skeleton.

values are separately observed. At higher temperatures, however, the internal rotation is so rapid that it is not possible to distinguish the *interior*-phenyl protons from the *exterior*-phenyl ones because of the rapid exchange between the two states. This rate process may be analyzed by using a modified Bloch equation for the two-jump model*. The computer-simulated ESR spectra obtained on the basis of this model are compared with the observed spectra in Fig. 7. Here, the small temperature changes in the hyperfine splitting constants were ignored and the hyperfine splitting constants determined by the ENDOR measurements were used as those at the limit of the slow exchange rates. By applying the estimated lifetime (τ) to the following Arrhenius relation, the activation energy, *Ea*, of the internal rotation was evaluated:

$$k = 1/\tau = k_0 \exp(-Ea/RT), \quad (5)$$

where k is the rate constant of the internal rotation, and k_0, the frequency factor. A plot of $\log_{10} 1/\tau$ against $1/T$ is shown in Fig. 9, from which *Ea* and k_0 were calculated to be 13.4 kcal/mol and $2.3 \times 10^{14}\ s^{-1}$ respectively.

DPDAA and TAA showed merely broadened ESR spectra, as is shown in Fig. 10. The reason why these spectra do not split more clearly may owe to the unresolved small hyperfine splittings of the methoxy protons. This reasoning was confirmed by the ENDOR measurements. If these ESR spectra were well-resolved, the line-width alternation effects would be

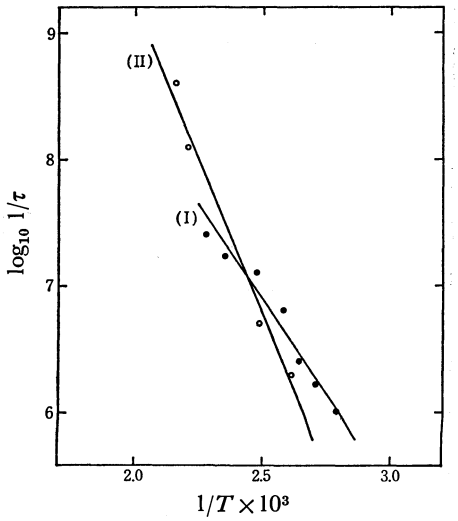

Fig. 9. Plots of $\log_{10} 1/\tau$ against $1/T$ 10^3.

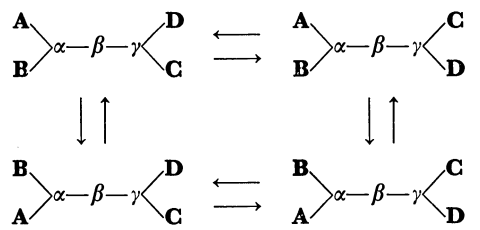
observed as well.

Bisdiphenylene Allyl: As is shown in Fig. 11, the hyperfine patterns of the ESR spectra of BDA are not temperature-dependent. Each phenylene ring of BDA has no degree of free rotation; therefore, there may be little difference between the *interior* and *exterior* proton splittings in the biphenylene group. This was confirmed by the results of the ENDOR measurements. Because of the equivalency of the two kinds of the

* Strictly speaking, the internal rotation of the allyl skeleton must be expressed by the following four-jump model:



However, since only the two kinds of interconversion at the sites of α and γ are expected to be cooperative, it seems to be enough to assume merely the two-jump model.

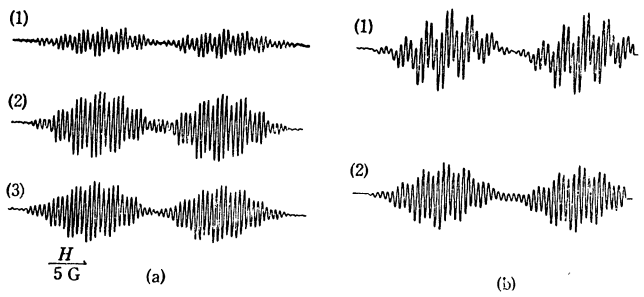


Fig. 11. ESR spectra of BDA in liquid paraffin.

aryl rings in BDA, there is no line-width alternation effect in the ESR hyperfine pattern. However, the slope of the plots of the A_β^H *vs.* temperature (Fig. 12) is similar to that for TPA. This suggests that the internal rotation of the allyl skeleton might also take place in BDA, as will be discussed later.

Diphenyl Diphenylene Allyl: The ENDOR spectrum of this radical has not been observed; therefore, its hyperfine splitting constants were analyzed with reference to the analyses of the observed ESR spectra for BDA and TPA. From the result of the computer simulation, the hyperfine splitting constants of the proton of DDA were assigned as shown in Table 4. The increase in $A_{1,3}^H$ with the temperature shows that the delocalization of an odd electron to the biphenylene group may be more favorable than that to the two phenyl rings, because with a rise in the temperature the conjugation of the biphenylene group with the allyl framework may become more favorable than that of the

two phenyl rings, which undergo restricted rotation. Furthermore, at low temperatures evidences were obtained for inequivalent phenyl rings (*interior* and *exterior*) in DDA, while, on warming, the allyl skeleton begins to rotate internally. Hence, the interconversion between the two phenyl rings must be the origin of the complex temperature dependence of the ESR spectral pattern shown in Fig. 13. Therefore, the two-jump model was tentatively applied in the manner described for TPA. The activation energy for an interconversion of the two phenyl rings (=internal rotation of the allyl skeleton) thus estimated is about 22.3 kcal/mol, and the frequency factor (k_0), about 1.4×10^{19} s^{-1} (Fig. 9).

Temperature Dependence of A_β^H. The temperature dependence of A_β^H of TPA is shown in Fig. 1.

The slopes of the plots of the A_β^H *vs.* the temperature at high temperatures are nearly independent of the solvents. In addition, the ESR hyperfine patterns of toluene solutions at 90—100 °C are essentially the same as those of liquid paraffin solutions at 115—135 °C. This suggests that the temperature dependence of A_β^H is caused by the intramolecular dynamics of the allyl skeleton. Similar results were obtained for both BDA and DDA, as is shown in Fig. 12. The observed A_β^H at lower temperatures are likely to be constant. This is related to the fact that the torsional vibration of the allyl skeleton is very slow at very low temperatures, as was confirmed by the ENDOR analyses of the BDA-type radicals. At such temperatures, the internal rotation of the allyl skeleton does not take place; also, the two twisting angles of the allyl skeleton are different from each other. As the allyl skeleton begins to rotate internally with a rise in the temperature, the two $2p_z$-*orbitals* on both the α and γ carbon atoms tend to overlap with the ls-*orbital* of the methine proton (Fig. 8). Hence, A_β^H must reach a maximum in the state of Fig. 8-(ii)**. When the internal rotation rate is slow (that is, when the τ-values are large), the probability of finding the state of Fig. 8-(ii) may be small, resulting in a small A_β^H. On the other hand, when the internal rotation becomes faster (that is, when the τ-values are smaller), the probability of finding the state of Fig. 8-(ii) may increase, making A_β^H larger and larger.

Conclusion

1. At low temperature the allyl skeleton of the tetraaryl allyl radicals oscillates very slowly.
2. The torsional vibration becomes larger with an increase in the temperature, and the allyl skeleton begins to rotate internally at high temperatures.
3. Line-width alternation effects have been observed in TPA and DDA, the activation energies of their internal rotations being 13.4 kcal/mol and 22.3 kcal/mol respectively.
4. The temperature dependence of A_β^H is interpreted by means of the mechanism of the internal rotation of the allyl skeleton.

** Here, the author assumes that an odd electron distribution on the allyl skeleton is kept almost constant with temperature variation. (*cf.* sections of TPA and BDA)

The author wishes to thank Professor Yasuo Deguchi, Professor Kazuhiko Ishizu, Professor Saburo Kako, Dr. Hiroaki Ohya-Nishiguchi, Dr. Jun Yamauchi, and their collaborators for their helpful advices and discussions. He is also indebted to Professor Toshio Takada and Professor Hideo Takaki for their continual encouragements during this work. Thanks are also due to the attendants of the 13th ESR symposium who stimulated the author with useful discussions.

CNDO/2 Calculations on the Configurations of the Ion-molecule Complexes. The NH_4^+–CH_4, H_3O^+–CH_4 and NH_4^+–H_2 Systems

Kazuyoshi TANAKA, Tokio YAMABE, Hiroshi KATO,* and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Faculty of Engineering, Kyoto University, Sakyo-ku, Kyoto 606

**College of General Education, Nagoya University, Chikusa-ku, Nagoya 464*

(Received December 16, 1974)

The optimized configurations of several ion-non polar molecule complexes (NH_4^+–CH_4, H_3O^+–CH_4 and NH_4^+–H_2) have been discussed by the use of the CNDO/2 method. The results for NH_4^+–CH_4 and H_3O^+–CH_4 turn out to be quite different from those previously proposed by the calculations based on the classical electrostatic model. It may be demonstrated that these systems are stabilized by a kind of hydrogen bond where the charge transfer effect from a neutral molecule to a cation plays an important role, according to the configuration analysis.

In the field of intermolecular forces, there has been recent progress in the theoretical development of weak interactions, such as hydrogen bonds or ion-molecule bonds, based on *ab initio* calculations or fairly reliable semi-empirical calculations.[1,2]

Of these, ion-molecule bonds consist of interaction between ions and neutral molecules in the singlet ground state. Such bonds have usually been investigated in order to comprehend the solvation process of ions in polar solvents, such as H_2O and NH_3.[1a,1b] In contrast with the extensive studies of these ion-polar molecule complexes, there have been only a few studies of ion-non polar molecule complexes.

Recently it has become possible to obtain direct thermodynamical data on some ion-non polar molecule complexes in the gaseous state through the mass spectrometry of ion beams at low temperatures. Bennett, Field, and Beggs have obtained the equilibrium constants and thereby evaluated the ΔG_{300}, ΔH^0 and ΔS^0 values of the following reactions:[3-5]

$$CH_5^+ + CH_4 \rightleftharpoons CH_5^+\text{-}CH_4 \quad \Delta H^0 = -4.14 \text{ kcal/mol}$$

$$NH_4^+ + CH_4 \rightleftharpoons NH_4^+\text{-}CH_4 \quad \Delta H^0 = -3.59 \pm 0.11 \text{ kcal/mol}$$

$$CF_3^+ + CH_4 \rightleftharpoons CF_3^+\text{-}CH_4 \quad \Delta H^0 = -4.55 \pm 0.05 \text{ kcal/mol}$$

$$H_3O^+ + CH_4 \rightleftharpoons H_3O^+\text{-}CH_4 \quad \Delta H^0 = -8.0 \text{ kcal/mol}$$

The $-\Delta H^0$ means the interaction energy needed to stabilize such an ion-molecule complex. They have also calculated the classical electrostatic interaction energy in order to discuss the stable configurations of these complexes.

Geometries suggested by the popular semi-classical electrostatic model[6] are often consistent with the experimental results or those calculated by MO method[7] for small ion-non polar molecule complexes, such as H_5^+ and He–H_3^+. It is, however, questionable whether this method yields reliable results for larger complexes such as the NH_4^+–CH_4 system, since it quite neglects the effect of charge transfer, which seems to play an important role in stabilizing these complexes. Indeed, the models proposed by the experimentalists are far from those conjectured from the reliable geometries of the H_3O^+–H_2O and NH_3–NH_3 systems.[1a,1b]

It may, therefore, be worthwhile to discuss the geometries of some typical ion-non polar molecule systems. In this paper, we will calculate the interaction energies in order to predict the stable configurations of the NH_4^+–CH_4, H_3O^+–CH_4 and, additionally, NH_4^+–H_2 systems by means of the CNDO/2 method.** This method has yielded considerably reliable results on the interaction energies and stable configurations for neutral molecule systems and for cationic systems as well.[8] Furthermore, we will carry out the configuration analysis by expanding the MO of the optimized configuration in order to show the contribution factors which stabilize each complex.

Method of Calculation

The bond distances and angles in the isolated cations and molecules are optimized individually by the CNDO/2 calculation; they are shown in Table 1.

TABLE 1. BOND DISTANCES AND ANGLES USED FOR ISOLATED SYSTEMS

Species	Bond	Distance (Å)	Angle	Size. deg
CH_4	C-H	1.115	H-C-H	109°28′
H_2	H-H	0.741[a]	—	—
NH_4^+	N-H	1.077	H-N-H	109°28′
H_3O^+ [b]	O-H	1.045	H-O-H	114°45′

a) Assumed. b) Pyramidal form.

For the NH_4^+–CH_4 system, in which both NH_4^+ and CH_4 have the C_2 axis and the C_3 axis, ten different kinds of configurations within the probable symmetries have been selected. The optimized configuration is determined for each interacting system by changing the intermolecular distance between NH_4^+ and CH_4; subsequently, several prominent parameters are optimized in the order of their magnitudes for the interaction energy.

For the H_3O^+–CH_4 system and the NH_4^+–H_2 system, details will be described later.

The method of configuration analysis[9] is applied to the most optimized configuration of each complex. Here we will briefly outline a CI wavefunction:

$$\Psi = C_0\Psi_0 + \sum_i^{occ}\sum_l^{uno} C_{i\to l}\Psi_{i\to l} + \sum_k^{occ}\sum_j^{uno} C_{k\to j}\Psi_{k\to j} + \sum_i^{occ}\sum_j^{uno} C_{i\to j}\Psi_{i\to j} + \sum_k^{occ}\sum_l^{uno} C_{k\to l}\Psi_{k\to l} + \cdots\cdots \quad (1)$$

** As to CF_3^+–CH_4 and CH_5^+–CH_4 systems, it is doubtful whether the CNDO/2 method is suitable to treat CF_3^+ and CH_5^+ isolated systems. Thus the reliable MO calculation results of these systems are of further indices.

where i, j, k, and l represent the i-th occupied MO of an isolated system, A, the j-th unoccupied of A, the k-th occupied of B, and the l-th unoccupied of B respectively, and where the sign $i \rightarrow l$ indicates the one-electron shift from MO i to MO l and so on. We can thus make the CI wavefunction of the complexes if the coefficients are known. In order to see the contributing factors to the stabilization of the complexes, we construct a wavefunction:

$$\begin{aligned}\Psi = C_0\Psi_0 &+ [\sum_i^{occ}\sum_l^{uno}(C_{i\rightarrow l})^2]^{1/2}\Psi(A^+\cdot B^-) \\ &+ [\sum_k^{occ}\sum_j^{uno}(C_{k\rightarrow j})^2]^{1/2}\Psi(A^-\cdot B^+) \\ &+ [\sum_i^{occ}\sum_j^{uno}(C_{i\rightarrow j})^2]^{1/2}\Psi(A^*\cdot B) \\ &+ [\sum_k^{occ}\sum_l^{uno}(C_{k\rightarrow l})^2]^{1/2}\Psi(A\cdot B^*) + \cdots\cdots \quad (2)\end{aligned}$$

where, for instance, $\Psi(A^+\cdot B^-)$ and $\Psi(A^*\cdot B)$ represent all of the one-electron transferred configurations from A to B, and all of the one-electron excited configurations in A, respectively.

Results and Discussion

The NH_4^+–CH_4 System. The selected configurations are shown in Fig. 1, while the changes in the interaction energies with varying the distance between NH_4^+ and CH_4 are drawn in Fig. 2. The optimized configuration turns out to be (A). The starred hydrogen atom in (A), (B), and (C) seems to play an important role in binding the systems. The values of the net charge of the hydrogen atoms are as follows; (A)+0.300, (B)+0.296, and (C)+0.289. It can easily be seen that the (A) configuration is the most advantageous for bonding, since the positively charged hydrogen contributes to bind the system as a bridging center through Coulomb interaction with the carbon atom in CH_4. Henceforth, it may be said that the optimized configuration for the ion-molecule complex is mainly guaranteed by the existence of a positively charged hydrogen atom in the cation situated on the bonding axis of the complex as a bridging center. Furthermore, the neutral molecule retains its highest

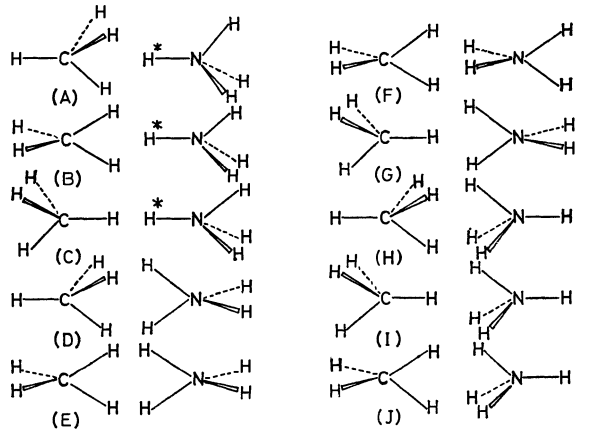

Fig. 1. The selected configurations for the NH_4^+-CH_4 system.

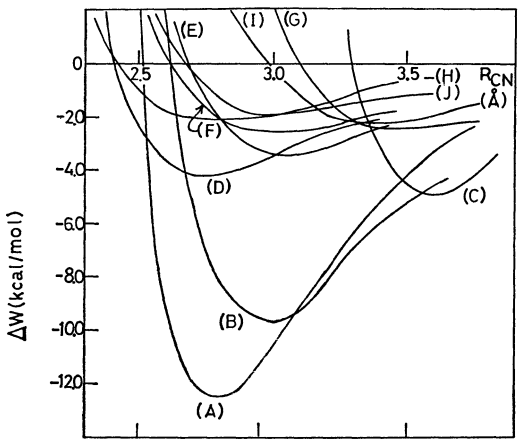

Fig. 2. Potential curves of the selected configurations for the NH_4^+-CH_4 system. The 90° rotation of either fragment along the C–N axis in (B), (D), (G), and (J) and 180° rotation in (A) yield no energy change within an error.

symmetry and avoids the form in which a hydrogen atom in the molecule confronts the positively charged hydrogen atom in the cation. Such a tendency coincides with the previous calculation results as to, for instance, the H_3O^+–H_2O and the H_2O–H_3O^+–H_2O systems.[1a]

The (A) configuration is next treated so as to be optimized with other parameters. The optimized (A) configuration in Fig. 3 shows that R_{6N7H} stretches toward 1C as far as 1.117 Å and that ∠3H1C4H *etc.* open a little to be 112°. Thus, the optimized energy of this system is 14.49 kcal/mol (experimental: 3.59 kcal/mol). We need not further optimize the (B) configuration and those following in Fig. 1, since they would not exceed the optimized (A) in Fig. 3 in interaction energy. Interestingly, the configuration in Fig. 4 proposed by Bennett and Field[5] is converse in the direction of the CH_4 and NH_4^+ from the optimized

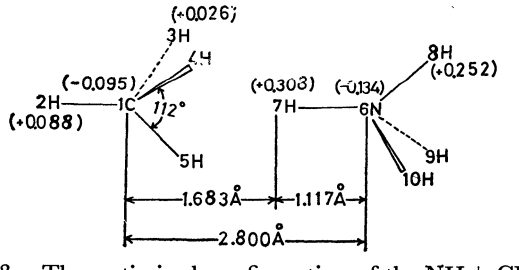

Fig. 3. The optimized configuration of the NH_4^+-CH_4 system. R_{4H7H}=1.729 Å and other bond distances remain unchanged.

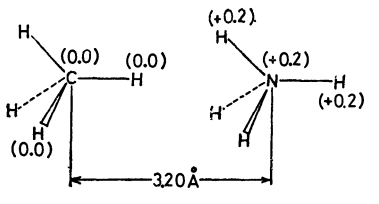

Fig. 4. Bennett and Field's model for the NH_4^+-CH_4 system.

configuration predicted here. The E_{AB} analysis in the CNDO/2 method shows that the E_{1C7H} and E_{6N7H} attractive energies have the largest effect in stabilizing the complex among the other attractive and repulsive energies. In fact, the eclipsed form yields the same $-\Delta W$ as that of the staggered form in Fig. 3. Therefore, in this configuration, CH_4 and NH_4^+ seem to rotate along their bonding axis. The values of atomic net charge are also given in Fig. 3; the quantity of the transferred charge from CH_4 to NH_4^+ is estimated to be -0.071.

The H_3O^+–CH_4 System. For this system, five kinds of configurations are treated. The (A) configuration in Fig. 5 is selected by the criterion noted above, and others that have C_{3v} geometries in both fragments are compared with (A). In Fig. 6 the optimized configuration is shown to be (A), as was expected. The other configurations are far less stable than (A) in spite of their symmetries. A further optimized form of (A) is shown in Fig. 7, where R_{6O7H} stretches toward 1C to be 1.115 Å and where ∠3H1C4H *etc.* in CH_4 open until 114°. This is also quite the same pattern as in the NH_4^+–CH_4 system in Fig. 3. The calculated interaction energy gives 31.56 kcal/mol (experimental: 8.0 kcal/mol). The configurations in Fig. 8, previously proposed by Bennett and Field,[4] are quite different from the most optimized one predicted here.

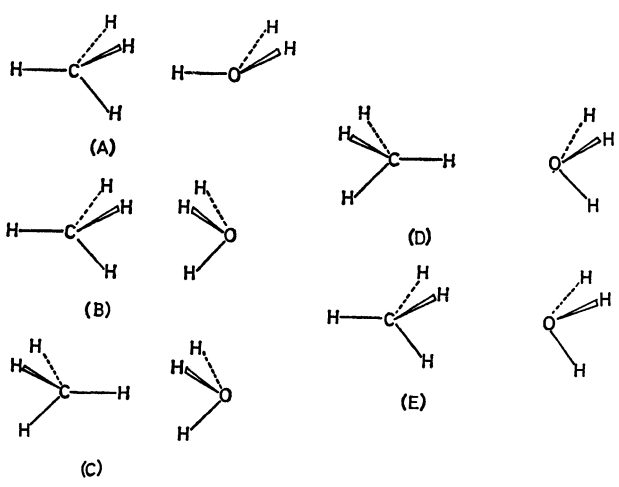

Fig. 5. The selected configurations for the H_3O^+–CH_4 system.

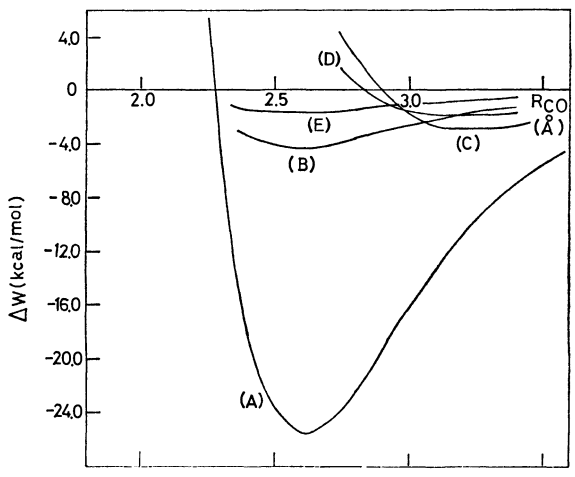

Fig. 6. Potential curves of the selected configurations for the H_3O^+–CH_4 system. The 90° and 180° rotation of either fragment along the C–O axis in (A) yields no energy change within an error.

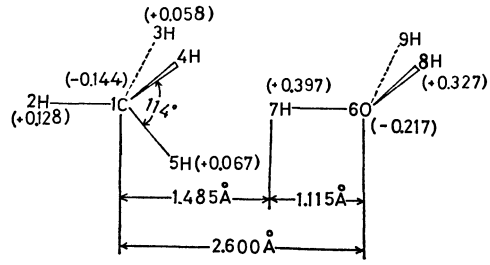

Fig. 7. The optimized configuration for the H_3O^+–CH_4 system. $R_{4H7H} = 1.619$ Å and other bond distances remain unchanged.

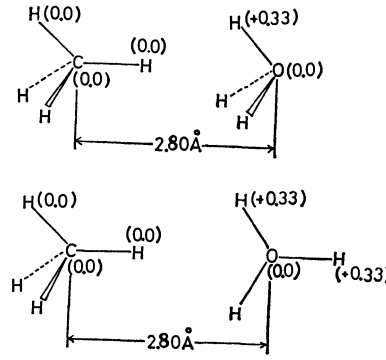

Fig. 8. Bennett and Field's model for the H_3O^+–CH_4 system.

As to the E_{AB} values, E_{1C7H} and E_{6O7H} are the dominant attractive energies, and the 90° and 180° rotations of either fragment along the C–H–O axis yield no energy change as in the NH_4^+–CH_4 system. Therefore, this system should also rotate freely along the C–H–O axis. The quantity of the transferred charge from CH_4 to H_3O^+ is -0.166, which is considerably larger than that in the NH_4^+–CH_4 system.

The NH_4^+–H_2 System. This system is considered to be a simple model of the ion-molecule complexes, although there are no previous experimental data available. Therefore, it seems that it would be

TABLE 2. THE INTERACTION ENERGY OF THE NH_4^+-H_2 SYSTEM

Configuration	Parameters		Interaction energy (kcal/mol)
(A) Configuration	R_{6H7H}[a]	=0.641 Å	−7.45 (Repulsive)
		0.741 Å	3.07
		0.841 Å	2.45
	R_{1N2H}	=0.977 Å	−9.98 (Repulsive)
		1.077 Å	3.07
		1.117 Å	−3.70 (Repulsive)
(B) Configuration	R_{6H7H}	=0.721 Å	1.57
		0.741 Å	2.13
		0.761 Å	2.13
		0.781 Å	1.51
	R_{1N2H}	=1.067 Å	1.88
		1.077 Å	2.13
		1.087 Å	2.26
		1.097 Å	2.20

a) 7H is fixed.

interesting to predict the interaction energy and the optimized configuration for this system by MO theoretical treatment. In order to do so, four kinds of configurations were selected and their maximum interaction energies were calculated. The selected configurations and the potential curves are shown in Fig. 9 and Fig. 10 respectively. The interaction energy, $-\Delta W$, of the optimized (A) configuration is 3.07 kcal/mol, while that of the secondary optimized (B) configuration is 2.13 kcal/mol. Since these values are very close, both (A) and (B) should be further optimized. The results, presented in Table 2, show that the $-\Delta W$ in (A) remains unchanged, while that in (B) becomes 2.26 kcal/mol. Therefore, the (A) configuration is still most stable. In Fig. 11 the detailed form of the (A) configuration is presented. The quantity of the transferred charge from H_2 to NH_4^+ is −0.013, much less than those of the NH_4^+-CH_4 and the H_3O^+-CH_4 systems, and it produces less stabilization energy. The result that the difference in $-\Delta W$ values between (A) and (B) is only 0.81 kcal/mol, which is the same order as kT at room temperature, implies that H_2 rotates in the space near NH_4^+. Furthermore, the experimental data of $-\Delta H^0$ of this system, if any, would be about 0.5~0.75 kcal/mol, referring that the calculated $-\Delta W$ values for both the NH_4^+-CH_4 and the H_3O^+-CH_4 systems are four times the respective experimental values. If so, the $-\Delta W$ values for the (A), (B), (C), and (D) configurations will become closer, and (A) may change into (B), (C) or (D) in rapid succession, at least in the range of room temperature.

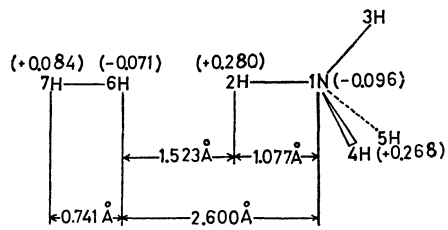

Fig. 11. The optimized configuration for the NH_4^+-H_2 system.

Thus, the NH_4^+-H_2 system is far from being a rigid complex. The two fragments, NH_4^+ and H_2, retain most of their individual integrity in the cluster. H_2 should be considered as distributed on a sphere about NH_4^+, with only a slight maximum probability at the calculated equilibrium configuration.

Configuration Analysis. Table 3 shows the results of the configuration analysis for the optimized configurations of the above systems. The values represent the weights (*i.e.*, the square of the coefficients in Eq. (2)) of the wavefunctions of various configurations. It can easily be seen that the more the weights of the charge transfer terms increase and that of the ground state decreases, the larger the stabilization energy appears, namely, the NH_4^+-H_2, the NH_4^+-CH_4, and the H_3O^+-CH_4 system, in order. The percentage contribution of the charge transfer term from the neutral molecule to the cation is particularly remarkable—that is, 1.47%, 7.22%, and 15.44% in the NH_4^+-H_2, NH_4^+-CH_4, and H_3O^+-CH_4 systems respectively, compared with the contributions from the other configurations. The weight of the polarization term of the cation is larger than that of the neutral molecule in the NH_4^+-CH_4 and H_3O^+-CH_4 system, while for the NH_4^+-H_2 system the weight in H_2 is 0.0030, surpassing that of NH_4^+.

In conclusion, it turns out that the previous results for these complexes obtained by the classical electrostatic method are deficient, since that method apparently

TABLE 3. THE WEIGHTS OF VARIOUS CONFIGURATIONS FOR EACH SYSTEM

Configurations	NH_4^+-CH_4	H_3O^+-CH_4	NH_4^+-H_2
Ground state	0.9130	0.8048	0.9797
Neutral→Cation charge transfer	0.0722	0.1544 (0.0074)[a]	0.0147
Cation→Neutral charge transfer	0.0049	0.0058	0.0022
Polarization of neutral molecule	0.0031	0.0089	0.0030
Polarization of cation	0.0044	0.0140	0.0002
Sum of the above values	0.9977	0.9964[b]	0.9999

a) Two-electron transfer configuration. b) All contributions from two-electron transfer are added.

neglects the charge transfer, which has a significant effect in stabilizing the complexes. On the contrary, the MO treatment allows us to predict the optimized configurations and display the essential factors which stabilize the complexes, as has been mentioned above. Lastly, it is interesting that the ion-molecule complexes reported here are held by a kind of hydrogen bond, X···H–Y, in which X represents a carbon atom, and Y, a nitrogen or an oxygen atom. Since the H bears most of the positive charge in the cation, this X···H–Y bond is strong enough to hold the complex, and it yields a larger interaction energy than those of the ordinary hydrogen bond systems. Either fragment of the systems treated here is able to rotate freely along the axis of the X···H–Y because of the dominance of the E_{XH} and E_{HY}-attractive energies, which are isotropic with regard to this type of rotation. Furthermore, in the NH_4^+–H_2 system H_2 would rotate three-dimensionally near NH_4^+, according to the CNDO/2 calculation. In the present calculation we have used the convenient semi-empirical MO method. An *ab initio* MO treatment for these complexes would be further expected.

One of the present authors (K.T.) is grateful to Mr. Shigeki Kato and Mr. Tsutomu Minato for their helpful advice on performing the MO calculation. We also wish to express our gratitude to the Data Processing Centre of Kyoto University for its generous permission to use the FACOM 230-60 Computer.

The Effects of Anionic and Cationic Surfactants on the Ion Flotation of Cd^{2+}

Koichi KOBAYASHI*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received November 16, 1974)

The ion flotation of Cd^{2+} ions has been investigated from the surface chemical point of view in comparison with the case of Cu^{2+} ions reported previously.[1] The effects of the change in the pH, the anionic and cationic surfactants, and bentonite on the flotation rate have also been studied. Sodium α-sulfolaurate proved to be one of the best surfactants among the anionic surfactants used for removing Cd^{2+} ions, showing as high as a 97% removal. About 97% of the Cd^{2+} ions could be floated in the region of pH 11.3 when a cationic surfactant was used with bentonite, regardless of the exact surfactant used. The addition of bentonite reduced the foam formation and liquid hold-up, resulting in effective bubble flotation. This behavior was as a whole similar to that of Cu^{2+} ions.[1] However, in all the flotation systems tested, the flotation rate increased sharply at about pH 8, and the flotation rate *vs.* pH curve for Cd^{2+} shifted towards a more alkaline region than that for Cu^{2+}, because of the stronger basic nature of the former. Also, the flotation rate of Cd^{2+} ions for the Cd^{2+}-anionic surfactant systems attained a steady value after about 7 min, longer than the 2-min gas flow required in the case of Cu^{2+} ion flotation. The adjustment of the pH using ammonia gave a lower rate of flotation than in the case of flotation using sodium hydroxide.

The importance of the process of ion flotation[2,3] is well known, as has already been mentioned in a previous paper reporting the bubble flotation of Cu^{2+} ions.[1]

The flotation of Cd^{2+} ions has become an important problem in connection with water pollution and sewage treatment.[4–6] As regards the flotation of Cd^{2+} ions, however, only a limited number of papers have been reported. Ferguson *et al.* have reported the removal of CdS using hexadecyltrimethylammonium bromide.[7] Shimoiizaka *et al.* have studied the removal of Cd^{2+} ions from mine water by using xanthates.[5] Also, this problem is of surface chemical interest, since Cd^{2+} ions are a stronger base and are fairly different chemically compared with the Cu^{2+} ions previously studied.

The present paper will report a study of the bubble flotation of cadmium ions by anionic and cationic surfactants with bentonite in order to find the condition of most efficient ion flotation, to make clear the mechanism of flotation, and to compare it with the case of Cu^{2+} ion flotation.

Experimental

Materials. A stock solution containing 1.78×10^{-4} mol l cadmium ions (Cd^{2+}) and with a pH of 2.7 was prepared by dissolving Cd metal of a 99.999% purity (obtained from the Wako Pure Chemical Co., Ltd.) in nitric acid. The surfactants used were sodium *n*-dodecylsulfate (SDS), sodium laurate (LNa), sodium *n*-dodecylbenzenesulfate (DBS), and sodium α-sulfolaurate (α-SLNa) (obtained from the Kao Soap Co., Ltd.) as anionic surfactants, and *n*-dodecyltrimethylammonium chloride (DTAC) (obtained from the Tokyo Kasei Industrial Co., Ltd.), hexadecyltrimethylammonium chloride (HTAC) and octadecyldimethylbenzylammonium chloride (OBAC) (obtained from the Kao Soap Co., Ltd.) as cationic surfactants. The bentonite powder used as an ion exchanger was obtained from the Wako Pure Chemical Co., Ltd. The methods of the purification of the materials were the same as have previously been described[1] except for the case of OBAC. The commercial product of OBAC was recrystallized twice from acetone. The surfactants were kept in a desiccator. The pH of the solution was controlled by using special-grade sodium hydroxide and ammonia.

The triply distilled water used was free from Cd^{2+} ions, as detected by means of an atomic absorption spectrometer.

Apparatus and Procedure. The flotation apparatus and method were the same as those described previously.[1] Nitrogen gas humidified with water vapor and controlled to a constant rate of gas flowing was bubbled through a glass filter of No. 4 into a flotation cell containing 10 ml of the sample solution.

To prepare a sample solution of Cd^{2+} ions, 2 ml of the stock solution of Cd^{2+} ions, a proper amount of sodium hydroxide or ammonia to adjust the pH, 2 ml of the surfactant solution, and 2 ml of bentonite solution in the case of a cationic surfactant were introduced into a 20-ml measuring flask. The total volume of the solution was made up to 20 ml with water. A part of the solution was used to measure the initial pH (pH_i) and the Cd^{2+} ion concentration (C_i mol/l). A 10-ml portion of the remaining solution was transferred into the flotation cell, and the gas flow was started. After a definite time of flotation, about a 7-ml portion of the solution was taken out in order to determine the final pH (pH_f) and Cd^{2+} ion concentration (C_f mol/l), the latter being calculated from the absorbance measured at 2288 Å and at pH 2.6 using an atomic absorption spectrometer (Techtron Pty., Ltd., Model-AA-100).

The gas-flow rate was kept constant at 10 ml/min throughout the experiments. The gas-flow time was kept at 7 min unless otherwise stated. The measurements were carried out at room temperature (about 25 °C).

Results and Discussion

In the present work, the effects of the flotation rate on the gas-flow time, the bentonite concentration, the surfactant concentration, and the pH were studied.

The flotation rate (F) of Cd^{2+} ions is conventionally given by:

$$F = (1 - C_f/C_i) \times 100\ \%$$

Experiments were mainly run under the conditions of bubble flotation, mainly flotation using only ascending bubbles, without the aid of foam formation. Since most of the solution after flotation was used for the measurement of C_f, the flotation rate calculated expresses substantially the percentage of Cd^{2+} ions removed from the total solution.

Flotation of Cd^{2+} Ion by Anionic Surfactants. Relation between Flotation Rate and Gas-flow Time: In order to study the optimum gas-flow time of various surfactants, flotation experiments were run at the optimum condition of flotation at around pH 11.2. Figure 1 shows the effects of the gas-flow time at the gas-flow rate of 10 ml/min on the flotation rate for the Cd^{2+}–α-SLNa, –DBS, and –SDS systems. It can be seen that the flotation rate attains a steady value after about 7 min, longer than the 2-min gas flow required in the case of Cu^{2+} ion flotation.[1]

Relation between pH and Flotation Rate. Figure 2 shows the effect of the pH on the flotation rate for the Cd^{2+}–SDS system. As may be seen, the flotation rate begins to increase from zero at around pH 8 for the 1.78×10^{-5} mol/l SDS concentration. The pH value is higher than pH 6 in the case of Cu^{2+} ions because of the stronger basic nature of Cd^{2+} ions. When the pH is adjusted using sodium hydroxide, a maximum flotation rate of about 85% was observed at pH 11.3, while the flotation rate was less in the case of the pH adjusted by using ammonia. In the former case, cadmium hydroxide, probably in the form of polynuclear Cd^{2+} ions,[8] is attracted and floated by SDS, whereas in the latter case, the formation of polynuclear Cd^{2+} ions is prevented to a certain extent by the formation of an ammine complex such as $Cd(NH_3)_4^{2+}$, which adsorbs less efficiently than the polynuclear ions. At the large SDS concentration of 8.90×10^{-5} mol/l, a stable foam layer forms and Cd^{2+} ions are floated even below pH 8, showing flotation rates of about 40% for systems with the pH adjusted by both sodium hydroxide and ammonia. This may be explained by the simple adsorption of Cd^{2+} ions on the surface of ascending bubbles, which persist as a stable foam layer and concentrate the Cd^{2+} ions. Thus, the flotation is considered to be an ion-adsorption flotation. Between pH 8 and 10, Cd^{2+} ion flotation is considered to take place either by ion adsorption and precipitation or by ion adsorption and a hindered precipitation mechanism, according to whether sodium hydroxide or ammonia is used to adjust the pH. Beyond pH 10, the curve for the system adjusted by sodium hydroxide shows a maximum and a subsequent decrease due to the competition between OH^- and DS^- ions for Cd^{2+} in the high pH region, while the curve ends before the appearance of a maximum for the system controlled with ammonia due to the weak basicity of ammonia. The flotation was carried out further for the Cd^{2+}–DBS system. A result similar as a whole to Fig. 2 was obtained except that a maximum F value of 95% was obtained at about pH 11.3 for the system containing 1.78×10^{-5} mol/l DBS and the pH adjusted using sodium hydroxide. In other pH regions, however, the flotation rates were less than those of the SDS system. Figure 3 shows the flotation rates for the Cd^{2+}–LNa system, ammonia being used to adjust the pH. In this system, the flotation rate begins to increase at about

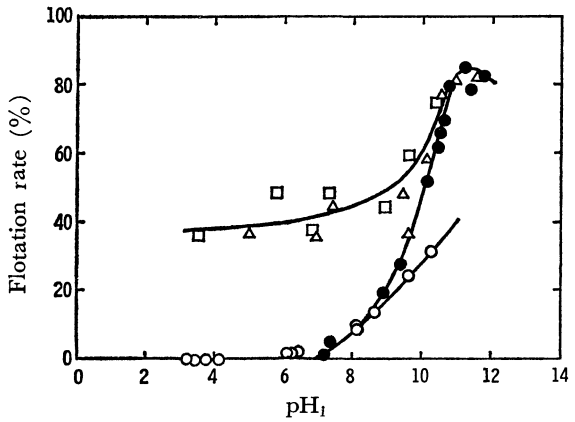

Fig. 2. Flotation rate *vs.* initial pH for Cd^{2+}–SDS system.
Cd^{2+}: 1.78×10^{-5} mol/l, SDS: 1.78×10^{-5} mol/l (○: NH_3, ●: NaOH), 8.90×10^{-5} mol/l (□: NH_3, △: NaOH).

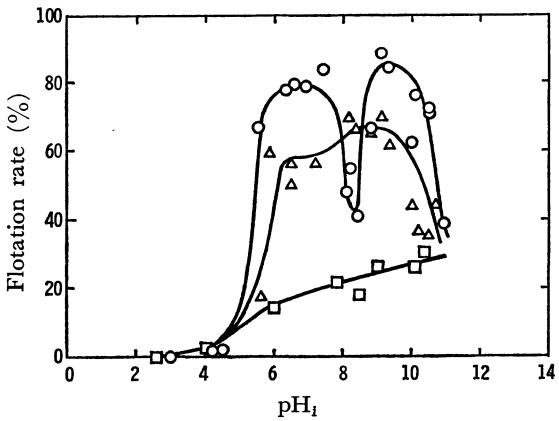

Fig. 3. Flotation rate *vs.* initial pH for Cd^{2+}–LNa system.
Cd^{2+}: 1.78×10^{-5} mol/l, LNa (□: 1.78×10^{-5} mol/l, △: 3.90×10^{-5} mol/l, ○: 1.78×10^{-4} mol/l), pH adjusted by NH_3.

pH 5.5 and sharply decreases at about pH 10.5, at least for the two systems studied. In the acid solution, LNa is hydrolyzed to form uncharged lauric acid, and the flotation may be explained by the Cd^{2+} ions being trapped in or adsorbed by the lauric acid floc. The sharp minimum or the slight step observed in the *F vs.* pH curve near pH 8 also suggests that the precipitation flotation takes place in the region of pH values larger than 8.

Figure 4 shows the *F vs.* pH_i curve for Cd^{2+}–α-SLNa systems of varying surfactant concentrations. The flotation rate increases sharply at around pH 8 and reaches a maximum at around pH 11 for all the systems observed. A maximum *F* value of 97% was observed for the 3.56×10^{-4} mol/l α-SLNa system with its pH adjusted by sodium hydroxide. The flotation rates remain far below those for the system with its pH adjusted by ammonia. The reason for this is the same as has been presented above. The decrease in *F* at higher pH values may be due, in addition to the ionic competition mentioned above, to the formation of $Cd(OH)_4^{2-}$ and $Cd(OH)_5^{3-}$.[9]

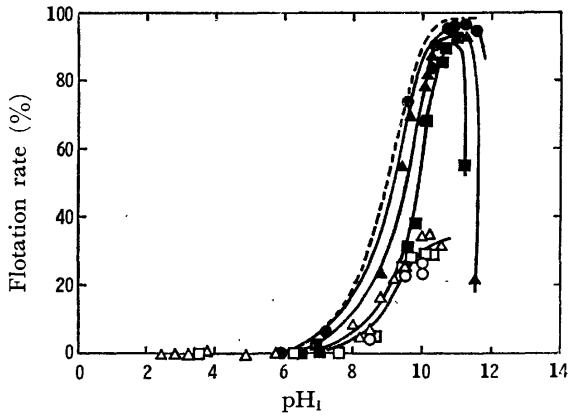

Fig. 4. Flotation rate *vs.* initial pH for Cd^{2+}–α-SLNa system.
Cd^{2+}: 1.78×10^{-5} mol/l, α-SLNa: 8.90×10^{-5} mol/l (△: NH_3, ▲: NaOH), 1.78×10^{-4} mol/l (□: NH_3, ■: NaOH), 3.58×10^{-4} mol/l (○: NH_3, ●: NaOH, ----: ultracentrifugation of cadmium solution (20000 rpm × 20 min).

Further, as may be seen in Fig. 4, the effect of the α-SLNa concentration on *F* was found to be rather small in the region of concentrations studied. It is noticeable that a larger increase in the α-SLNa concentration does not produce foam formation; only the bubble flotation of the precipitate takes place. Thus, the best condition of Cd^{2+} ion flotation is provided by the α-SLNa molecule having both carboxylic and sulfonic groups. The situation is very similar to the case of Cu^{2+} flotation.[1] These results are further evidence for the view stated previously[1] that α-SLNa forms a strongly surface-active Cd salt by the carboxylic group, while the sulfonic group protects the salt from precipitation.

It is further shown that the optimum pH of flotation roughly agrees with the pH 11 of the complete removal of Cd^{2+} as hydroxide, which is confirmed by the centrifugal separation, as is also shown in Fig. 4. It was

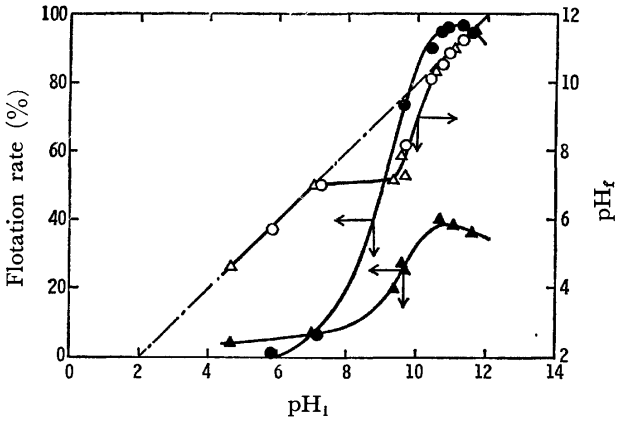

Fig. 5. Initial pH *vs.* final pH and flotation rate for Cd^{2+} and Cd^{2+}–α-SLNa systems.

inferred that the existence of a foam layer was not essential for precipitation flotation, although foam formation enhances the ion-adsorption flotation.

Mechanism of Flotation of Cd^{2+} Ions by Anionic Surfactant. The final pH after flotation is plotted as a function of the initial pH in Fig. 5. The *F vs.* pH curves with and without α-SLNa are also shown in Fig. 5. As may be seen in this figure, a plateau appears in the pH region from about 7 to 9 as a result of the liberation of H^+ ions by the formation of insoluble polynuclear species such as are expressed by:

$$n\mathrm{Cd^{2+}} + (n-1)\mathrm{H_2O} \rightarrow {}^{+}\mathrm{Cd(OCd)}_{n-2}\mathrm{OCd^{+}} + 2(n-1)\mathrm{H^{+}}$$

much as in a previous report.[1] Again, this is evident that large amounts of Cd^{2+} ions are removed in a polynuclear form by a small amount of a surfactant. A slight flotation was observed by the adsorption or adhesion of polynuclear species on ascending bubbles without any surfactant, but the best flotation was obtained by adding an anionic surfactant. The decrease in the flotation rate below pH 8 seems to be due to the competition between H^+ and Cd^{2+} ions for the anionic surfactant.

Flotation of Cd^{2+} Ion by Cationic Surfactants. Effect of the Time of Gas Flow: Cd^{2+} ions can be floated by a cationic surfactant through a bridge of macromolecular anions like bentonite.

The flotation was carried out for a solution containing 1.78×10^{-5} mol/l Cd^{2+} ions, 1.78×10^{-4} mol/l HTAC, and 0.01% bentonite at pH 11.3. About 98% of the *F* was obtained after a 2-min gas-flow time. It was found that the addition of bentonite markedly reduced the time of gas flow and increases the *F* compared with the case of the Cd^{2+}-anionic surfactant systems of Fig. 1. Thus, the cationic surfanctant-bentonite system is superior to the anionic surfactant system in this respect.

Relation between pH and Flotation Rate. Figure 6 shows the results of the flotation of the Cd^{2+}–bentonite–OBAC system with the gas-flow time of 7 min and with the pH being controlled with sodium hydroxide and ammonia. The flotation rate increases sharply at around pH 8 and shows a maximum of $F=93\%$ at pH 11.3 for the system of pH adjusted by sodium hydroxide,
