(Received June 16, 1975)

Synopsis. Three isomeric iodotrimethylpivalophenones and iodotetramethylpivalophenones have been prepared from the corresponding polymethylbenzenes by using the Perrier procedure of the Friedel-Crafts acylation, followed by the iodination of the resulting ketones with iodine-periodic acid dihydrate. Attempts to convert some of these hindered iodoketones to bis(pivaloyl)polymethylbenzenes *via* the Grignard reagent have failed.

In the course of our work on the non-conventional electrophilic substitution of polyalkylaromatics, some bis(pivaloyl)polymethylbenzenes are required. Several hindered aromatic ketones such as acetomesitylene, acetodurene, and acetoisodurene have been known to allow further acylation due to the lack of the coplanarity between acyl group and aromatic ring.[2)] Similar attempts to convert hindered polymethylpivalophenones to bis(pivaloyl)polymethylbenzenes, however, did not afford the desired diketones but led to the extensive deacylation, giving the complicated mixture of hydrocarbons and polymeric substances. No evidence has been obtained of the diketone formation.

As an alternative approach to the diketones, the reaction of the Grignard reagent from bromopolymethylpivalophenones with pivaloyl chloride appeared to be attractive, since 3-bromo-2,4,6-trimethylpivalophenone had been reported by Pinkus and coworkers to yield the Grignard reagent with a keto carbonyl function intact.[3)] We repeated their work and found the reaction to be slow and incomplete. Consequently, it was thought desirable to replace the bromo compound by the iodo one for the preparation of the Grignard reagent. This note describes the preparation and some properties of iodotrimethylpivalophenones and iodotetramethylpivalophenones.

Direct nuclear iodination of alkyl aryl ketones has apparently not been described to date probably because of the high propensity of the alkyl ketone moiety to react with attacking species as well as the deactivating effect of acyl group upon the aromatic ring. Iodine-periodic acid dihydrate as an iodinating agent was found to provide a simple direct route to some iodopolymethylacylophenones.[4)] Trimethylpivalophenones were readily iodinated with the above reagent to give the monoiodo derivatives in an average isolated yield of over

80%, with the ease of iodination decreasing in the order 2,4,6->2,3,4->2,4,5-. 2,3,4-Trimethylpivalophenone gave 5-iodo-2,3,4-trimethylpivalophenone, and 2,4,5-trimethylpivalophenone gave 3-iodo-2,4,5-trimethylpivalophenone as the only product. As expectedly, the *meta* position to the acyl group was preferred to *ortho* position. The position occupied by iodine atom in these systems was established by the comparison of their ^{1}H NMR spectra with those of the parent ketones.

Iodination of tetramethylpivalophenones proceeded with much ease. Of three isomeric ketones, 2,3,4,6-tetramethylpivalophenone was the most reactive, followed by 2,3,5,6-tetramethylpivalophenone and 2,3,4,5-tetramethylpivalophenone. Infrared and ^{1}H NMR spectral inspection of the crude reaction product had no indication of displacement of acyl group by iodine atom nor substitution on alkyl side-chain.

All the iodotrimethylpivalophenones and iodotetramethylpivalophenones obtained are well crystallized solids melting between 85 and 134 °C. They are moderately or readily soluble in light petroleum, benzene, carbon tetrachloride, chloroform, and hot ethanol, and are only slightly soluble in cold methanol. Yields, physical constants, and analytical data are given in Table 1.

The Grignard reagents were prepared from 5-iodo-2,3,4,6-tetramethylpivalophenone and 4-iodo-2,3,5,6-tetramethylpivalophenone, respectively, and treated with an excess of pivaloyl chloride. Ordinary work-up followed by chromatography on alumina, however, gave the parent tetramethylpivalophenones as the major product. Thick-layer chromatography of the product mixture gave some amounts of two other products, and none of these proved to be the expected bis(pivaloyl)-tetramethylbenzenes.

Experimental

All mp's are uncorrected. ^{1}H NMR measurements were made with a Varian T-60 spectrometer in deuteriochloroform solutions against internal TMS. Infrared spectra were determined in Nujol mulls on a Hitachi 215 spectrophotometer. Trimethylpivalophenones and tetramethylpivalophenones were prepared from the corresponding polymethylbenzenes by using the Perrier procedure of the Friedel-Crafts acylation.[5]

Procedure for the Preparation of Iodopolymethylpivalophenones. The general procedure is illustrated below by the reaction of 2,3,4,6-tetramethylpivalophenone.[6]

5-Iodo-2,3,4,6-tetramethylpivalophenone. A mixture of 2,3,4,6-tetramethylpivalophenone (6.45 g), iodine (3.0 g), periodic acid dihydrate (1.35 g), and 80% acetic acid (40 ml) containing several drops of concentrated sulfuric acid was kept with stirring at 70—80 °C for about 1 hr until the color of iodine disappeared. After cooling water was added, and the crystalline deposit was collected by filtration and passed over a short alumina column with light petroleum. From the eluate the iodo compound was obtained as colorless prisms, mp 92—94 °C (from methanol). Yield, 9.52 g (94%).

Attempted Conversion of Iodotetramethylpivalophenones to Bis-(pivaloyl)tetramethylbenzenes. To a solution of 5-iodo-2,3,-4,6-tetramethylpivalophenone or 4-iodo-2,3,5,6-tetramethylpivalophenone (3.38 g) in dry ether (50 ml) were added magnesium powder (0.24 g) and a small crystal of iodine, and the mixture was stirred magnetically in a tightly stoppered vessel placed in a polythene bag containing silica gel desiccant until the metal had almost disappeared. This required several days. The Grignard reagent was then added at one time to a solution of fresh pivaloyl chloride (6.0 g) in the same solvent (20 ml). After mild reaction had ceased, the mixture was hydrolyzed by pouring it into a slurry of crushed ice and hydrochloric acid. The ether layer was separated and washed with aqueous sodium hydrogencarbonate and water. The ethereal solution was dried over anhydrous sodium sulfate and evaporated to leave a light yellow oil, which on standing partly solidified to a crystalline mass. The solid product (*ca.* 1.4 g) was identified as the parent tetramethylpivalophenone by comparison with the authentic sample. Preparative thick-layer chromatography of the oily part gave three minor components. They were found to be unchanged starting material, aliphatic ketone, and alcohol of yet unidentified structure, respectively. None of the expected diketones could be isolated.

Expenses for this work were defrayed by grants from the Ministry of Education and the Saneyoshi Scientific Foundation.

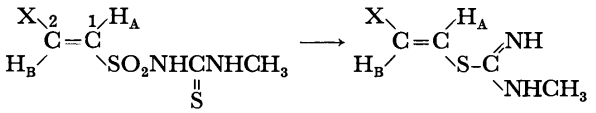
(Received April 28, 1975)

Synopsis. Treatment of *N*-(*trans*-styrylsulfonyl)- (**1**) and *N*-(4-phenyl-1,3-butadienylsulfonyl)-*N'*-methylthiourea (**2**), and the corresponding *S*-methylisothioureas (**6** and **7**), with strong base afforded the Smiles-type and Michael-type products. Effects of substituents at C-2 and nucleophiles on the products are discussed.

We recently reported that treatment of *N*-(2,2-diarylvinylsulfonyl)thioureas,[1] isoureas,[2] isothioureas[2] and *N*-(*trans*-*p*-nitrostyrylsulfonyl)thiourea[1] with base affords Smiles-type products. Matier and Comer[3] described that base-treatment of *N*-(*trans*-styrylsulfonyl)-amidines yields Michael-type and Smiles-type products. These rearrangements are facilitated by electron-withdrawing *para* substituents on the aromatic rings. However, effects of substituents at C-2 and nucleophiles on the products are not well known. This paper describes these effects by base-treatment of 2-substituted vinylsulfonylthioureas **1**—**3** and isothioureas **6** and **7**.

Results and Discussion

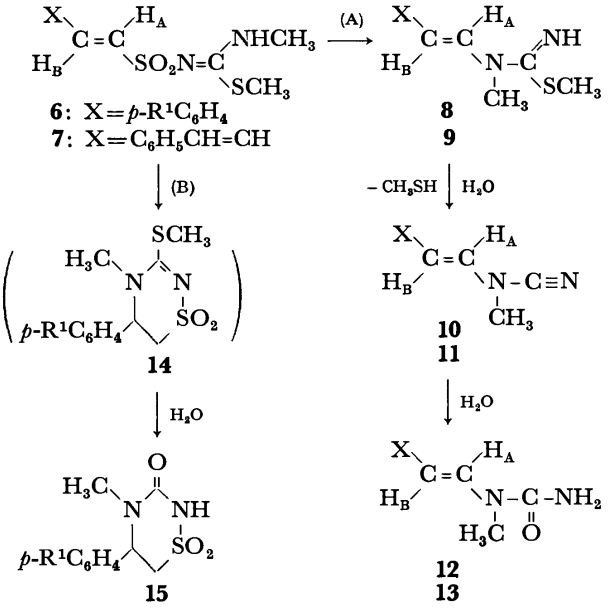
In contrast to known base-catalyzed Michael cycloaddition of *N*-(*trans*-styrylsulfonyl)thioureas[4] (**1**), -isothioureas[5] (**6**) and *N*-(4-phenyl-1,3-butadienylsulfonyl)-thioureas[6] (**2**), treatment of **1** and **2** with strong base (ten equiv. of 10M NaOH) in some solvents for 3 hr at 80 °C gave Smiles-type products, *N*-methyl-*S*-(*trans*-styryl)- (**4**) and *N*-methyl-*S*-(4-phenyl-1,3-butadienyl)-isothioureas (**5**), respectively (Table 1). No Michael cycloadducts were obtained because



1: X=*p*-R¹C₆H₄ **4**: X=*p*-R¹C₆H₄
2: X=C₆H₅CH=CH **5**: X=C₆H₅CH=CH

they were split into **1** and **2** in the strongly basic media (pH>13.30).[4] Similar treatment of *N*-(2-methyl-*trans*-styrylsulfonyl)-*N'*-methylthiourea (**3**) and *N*-(*trans*-styrylsulfonyl)-*N'*-methylurea afforded no rearranged products. The IR spectra of **4** and **5** exhibited absorption bands at 3450—3150 (NH) and 1615 (C=N) cm⁻¹.

Smiles-type rearrangement of **6** requires more vigorous reaction conditions than those of *N*-(2,2-diarylvinylsulfonyl)- and *N*-(4-phenyl-1,3-butadienylsulfonyl)-*N'*, *S*-dimethylisothioureas (**7**). Treatment of **6** with ten equiv. of aqueous 10M NaOH in DMF for 3 hr at 75 °C gave *N*-(*trans*-styryl)-*N*-methylureas (**12**) and 4-methyl-5-aryl-2,3,5,6-tetrahydro-3-oxo-1,2,4-thiadiazine-1,1-dioxides[5] (**15**) (Tables 1 and 2). Similar treatment of **7** gave the corresponding urea (**13**) and *N*-(4-phenyl-1,3-butadienylsulfonyl)-*N'*-methyurea (**16**). The Michael cycloadduct of



6: X=*p*-R¹C₆H₄ **8**
7: X=C₆H₅CH=CH **9**
14 **10**
11
15 **12**
13

7 was not obtained because of stabilization of Smiles-type intermediary carbanion.[1-3] The structures of **12**, **13**, **15**, and **16** were determined on the basis of analytical and spectral data (1650 and 1600 (C=O) cm⁻¹).

The formation of **12** and **13** would proceed through a Smiles rearrangement path (**A**) and that of **15** through a Michael cycloaddition path (**B**). Rearrangement path (A) is similar to that of *N*-(2,2-diarylvinylsulfonyl)-*N'*,*S*-dimethylisothioureas.[2] Attempts to obtain the intermediary new isothioureas **8** and **9**, and the new cyanamides **10** and **11** were unsuccessful due to their easy hydrolysis to **12** and **13** under the reaction conditions used. Under moderate reaction conditions (1N NaOH, 45 °C, 4 hr), **7** gave **9** (3%, IR: 1615 (C=N) cm⁻¹) and **11** (7%, IR: 2220 (C≡N) cm⁻¹) as yellow oils after column chromatography on silica gel, but, satisfactory analytical data were not obtained.

Tables 1 and 2 show that the rearrangements of the thioureas and isothioureas are favored by electron-withdrawing substituents on the aromatic ring, by the styryl group at C-2 and by solvents of high polarity.

Possible mechanisms for the formation of the isothioureas, **4**, **5**, **8**, and **9**, are analogous to those for the rearrangements of *N*-(2,2-diarylvinylsulfonyl)thioureas,[1] isothioureas[2] and *N*-(*trans*-styrylsulfonyl)amidines.[3] The presence of the styryl group at C-2 would stabilize the cinnamyl carbanion by resonance more than the

Studies of Surface Modification of Solids. III. Reaction of Silica with Trifluoroethanol

Kazuo Tsutsumi, Haruo Emori, and Hiroshi Takahashi

Institute of Industrial Science, The University of Tokyo, Roppongi, Minato-ku, Tokyo 106

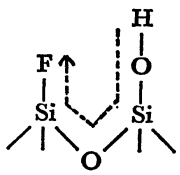
(Received August 19, 1974)

The esterification of silica was performed by reactions with 2,2,2-trifluoroethanol vapor and ethanol vapor with and without basic catalysts, such as ammonia and pyridine. The esterification with ethanol was referred to as the control. The extents of the esterifications were observed by means of infrared spectroscopy. The reactivity of the silica with trifluoroethanol was higher than that with ethanol. This is presumably because trifluoroethanol is more acidic than ethanol. The esterification was accelerated by the addition of ammonia as a base catalyst. For example, in the reaction of the silica with trifluoroethanol of 10.7 Torr at 30 °C for 3 hr, 35% of the surface silanols were esterified without any catalyst, while with the ammonia (0.2 Torr) catalyst, 98% of them was esterified. This suggests that the extraction of the proton from the hydroxyl groups of alcohol by NH_3 contributes to the esterification. The addition of pyridine influenced the reaction rate as well, but the esterification itself was disturbed by the addition of excess pyridine, because pyridine was adsorbed strongly on the surface silanol and its heterocyclic ring prevented the alcohols from adsorption. It is supposed that the physical adsorption of trifluoroethanol on the surface silanol is necessary in the first stage of the esterification. The esterified silica became hydrophobic, and it was hydrolyzed in the presence of water.

The surfaces of such metal oxides as silica and alumina are covered with hydroxyl groups, which are known to influence the adsorption properties of the surface.[1] As is well known, the hydrophilicity of silica surface originates from the silanol groups and is lost upon the esterification of the silanol groups with alcohol:[2]

$$\gtrdot\text{Si-OH} + \text{ROH} \longrightarrow \gtrdot\text{Si-O-R} + \text{H}_2\text{O} \qquad (1)$$

Hair *et al.* showed that silica treated with an ammonium fluoride solution had, in part, surface fluorine instead of silanol, and that its surface became hydrophobic. The activity of the Brönsted acid of the surface silanol was enhanced by the electronegativity of an adjacent fluorine atom, and the silica was endowed with a high catalytic activity for the cracking of cumene:[3]



In this study, the adsorption and the reaction of 2,2,2-trifluoroethanol on the silica surface were investigated by means of infrared spectroscopy. The silica used in this experiment was preheated in an electric furnace at a high temperature in advance of the esterification. By this treatment, variously reactive OH groups other than the so-called "free OH groups" or "isolated OH groups" were removed from the surface.

The rate of the reaction of 2,2,2-trifluoroethanol vapor with silica in the presence of a catalyst vapor was investigated. The reactivity of the chlorinated silica was also studied. The esterification with ethanol was also referred to.

Experimental

Aerosil-380 (Japan Aerosil Co., Ltd.) was used as the sample of silica. It was heated at 800 °C in an electric furnace under air prior to use. By this thermal pretreatment, all the molecular water and mutually-hydrogen-bonded hydroxyl groups were removde from the silica surface. In consequence, the silica surface was covered only with the isolated silanol groups and the siloxane-type groups. The trifluoroethanol, ethanol, and water were purified by repeated vacuum distillation.

The spectroscopic work was performed in a quartz cell fitted with NaCl windows[4], the cell was set in a Hitachi-EPI G3-type infrared spectrometer. The silica sample was pressed into an orbicular wafer about 10 mg/cm^2 thick. The sample was then set in a cell and heated *in vacuo* to any desired temperature. After the cell has then been cooled to room temperature under *vacuo*, the spectrum was observed. The silica was evacuated at 30 °C under 10^{-5} Torr in the cell prior to any reaction. The adsorption and the reaction studies were carried out in the same cell at various temperatures and pressures. In order to obtain the adsorption isotherm, the gaseous reactant was introduced into the cell at various pressures, and the extinction of the isolated silanols was measured at various stages during the adsorption and the reaction.

The hydroxyl group of surface silanol was exchanged also with chlorine by the use of thionyl chloride ($SOCl_2$).[5] The silica wafer pretreated in the electric furnace at 800 °C was put into $SOCl_2$ and refluxed for a total period of 14 days. The chlorinated silica was transferred quickly into the cell of the spectrometer so as not to be hydrolyzed, and then evacuated at 30 °C prior to the reaction with the reagent:

$$\gtrdot\text{Si-OH} + \text{SOCl}_2 \longrightarrow \gtrdot\text{Si-Cl} + \text{HCl} + \text{SO}_2 \qquad (2)$$

Results and Discussion

Isolated OH Groups of Silica. The heat treatment of silica at 800 °C in the electric furnace resulted in the change of the spectra shown in Fig. 1.

The absorption bands of water molecules (3500 cm^{-1}) and hydrogen-bonded hydroxyl group (3650 cm^{-1}) disappeared, and only the band of the isolated hydroxyl groups (3750 cm^{-1}) remained. The silica surface was ultimately covered with the isolated silanol and the siloxane linkages.

In the infrared spectra of silica after the reaction with trifluoroethanol, the OH stretching vibration of the silanol groups decreased and the CH_2 stretching (3000—2800 cm^{-1}), the CH_2 bending (1470 cm^{-1}), the CH_2 twisting (1440 cm^{-1}), the overtone of the CF_3

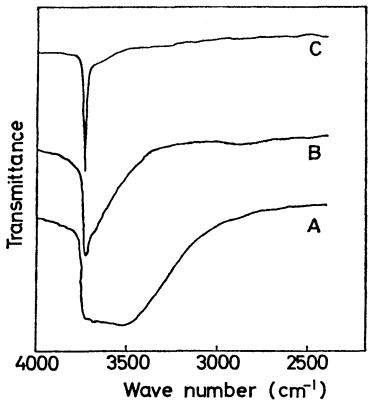


Fig. 1. Infraed spectra of silica after various treatments.
A: evacuation at 30 °C
B: evacuation at 400 °C
C: evacuation at 30 °C after heat treatment in electric furnace at 800 °C

asymmetric deformation (1360 cm^{-1}), and the CF_3 asymmetric stretching (1310 cm^{-1}) vibrations appeared (*cf.* Fig. 2).[6] The spectra indicate that the esterification occurs on the silanol according to the following equation:

$$\geqslant Si\text{-}OH + CF_3CH_2OH \longrightarrow \geqslant Si\text{-}O\text{-}CH_2\text{-}CF_3 + H_2O \quad (3)$$

The 3750 cm^{-1} band remained after the esterification. The complete esterification of all the silanols could not be attained.

The rate of the esterification of the silica with trifluoroethanol was analyzed by measuring the diminishing rate of the absorbance of the 3750 cm^{-1} band due to the isolated silanol. Since the physically absorbed alcohol has previously been desorbed by the evacuation, the diminishing rate of the 3750 cm^{-1} band corresponded to the rate of the reaction. The degree of coverage (θ) by physical adsorption at the reaction temperatures was measured by taking the spectra of the silica with the residual gas present in the cell, while the reaction was still going on. One example of the determination of the surface coverage (θ) from the infrared spectra is given in Fig. 3 for illustration. From this figure, the surface coverage (θ) of ethanol to the silanol group under the conditions of an ethanol pressure of 20 Torr at 30 °C was determined. In this figure, θ is the ratio of $\overline{OB}$ to $\overline{AB}$. The $\overline{OB}$ absorbance at the reaction time of 18 min was interpolated from the values of the absorbances at the reaction times of 10 min and 20 min respectively.

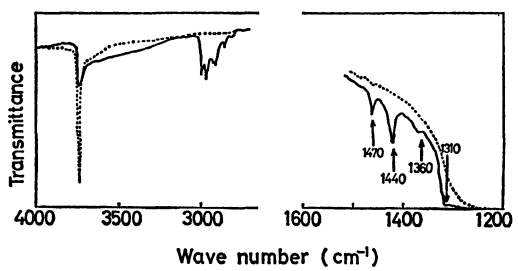

Fig. 2. Esterification of silica with trifluoroethanol (25.0 Torr).
Reaction period: 8 hr, Reaction temperature: 60 °C.
Solid line: infrared spectrum after the esterification and the successive evacuation of the residual vapor of trifluoroethanol. Broken line: infrared spectrum of original silica.

The absorbance $\overline{AB}$ was obtained by deducting $\overline{OA}$ from $\overline{OB}$. By the same manner, the values of the surface coverage of trifluoroethanol under the various conditions were determined.[7] The ratio of the extinction with the residual gas present to the interpolated value gives the fraction of hydroxyl groups not covered by physically absorbed molecules, *i.e.*, $1-\theta$. In this case, it was supposed that the fraction was independent of the degree of esterification. By the calculations of this method, the reactivity of the silica with trifluoroethanol or ethanol was investigated. The rate of the esterification with trifluoroethanol is faster than that with ethanol (*cf.* Fig. 7, Curves A and B). The hydroxylic proton of alcohol takes part in the esterification reaction, and the rate of the reaction must be controlled by the ease of the proton release. Because of the inductive effect of the electronegative fluorine atoms bonded directly to the α-carbon, trifluoroethanol releases the proton more easily than ethanol. From this point of view, the difference in the reactivities of the two alcohols seems reasonable.

Heat of Adsorption. In view of the fact that the reaction of the silica with trifluoroethanol goes on slowly at high temperatures, the esterification may be considered to take place when there is physically adsorbed alcohol on the surface silanol. As is shown in Fig. 4, the quantity of physically adsorbed alcohol

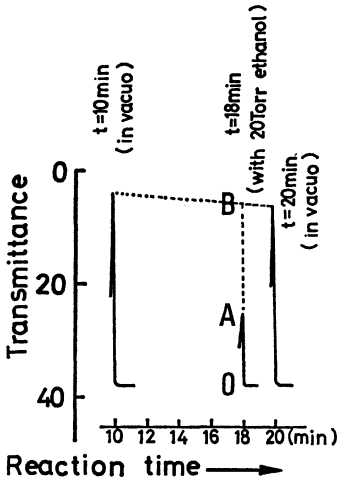

Fig. 3. Change of 3750 cm^{-1} -OH band of silica taken during the course of reaction at 30 °C, illustrating spectra used for determining the fraction of freely vibrating hydroxyl groups covered by physically adsorbed ethanol.

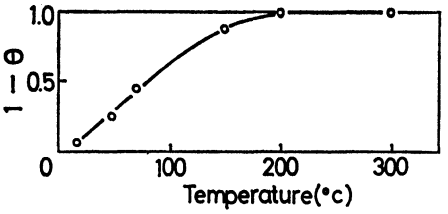

Fig. 4. Change of surface coverage of trifluoroethanol with temperature (trifluoroethanol pressure: 17.0 Torr).

Table 1. Isosteric heats of adsorption of trifluoroethanol on silica

Surface coverage (θ)	ΔH (kcal/mol)
0.1	8.0
0.2	7.0
0.3	6.4
0.4	6.8

on the surface silanol decreases with the rise in the temperature. By determining spectroscopically the amount of coverage on the freely-vibrating OH groups of the silica, it is possible to obtain the isotherms for the adsorption on these groups, independent of the adsorption at any other sites. The fraction of coverage (θ) was thus decided at various temperatures and pressures, from which the isosteric heats of the physical adsorption of trifluoroethanol on the free hydroxyl groups of the silica were derived. Some typical adsorption isotherms determined at various temperatures are given in Fig. 5. The slope of the plot relating log P to $1/T$ is proportional to the isosteric heat of adsorption, according to Clausius-Clapeyron's equation. Same typical plots are given in Fig. 6. The heats calculated from these plots are given in Table 1.

Esterification Catalyzed by Ammonia. An acid or base catalyst is normally used in the esterification.[8] Therefore, the catalytic effects of NH_3 and pyridine on the esterification were examined. In the presence of NH_3, the rate of the esterification with trifluoroethanol increased remarkably (*cf.* Fig. 7, Curves B and E). The reaction of the silica with ethanol in

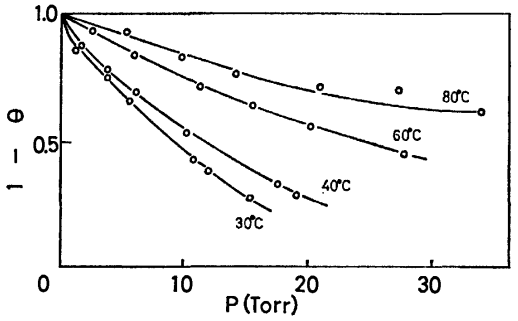

Fig. 5. Adsorption isotherms of trifluoroethanol interacted with the free hydroxyl groups on silica.

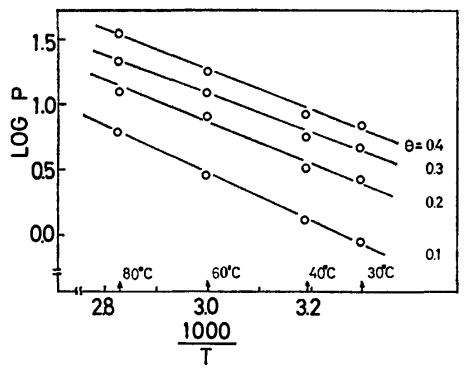

Fig. 6. Examples of the relations between log P and $1/T$ for the adsorption isotherms of trifluoroethanol on Aerosil-380.

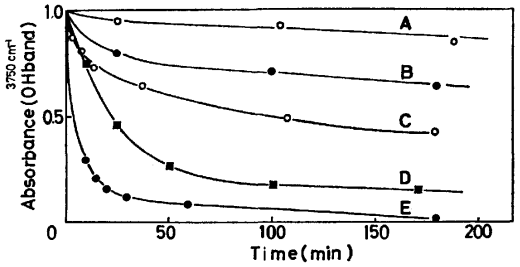

Fig. 7. Esterification rate at 30 °C under various conditions.
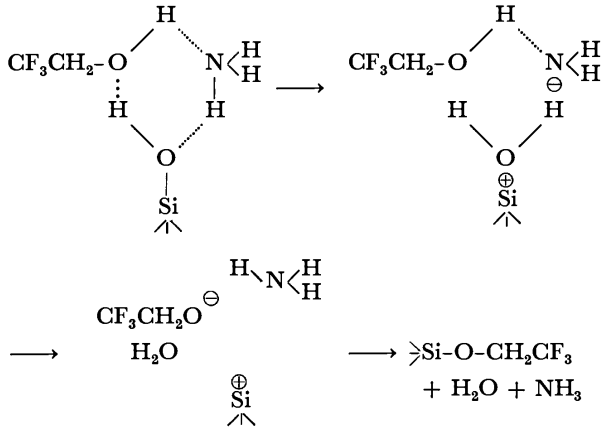
A: ethanol [7.0 Torr]
B: trifluoroethanol [11.3 Torr]
C: ethanol [7.8 Torr] and ammonia [0.2 Torr]
D: trifluornethanol [11.2 Torr] and pyridine [0.3 Torr]
E: trifluoroethanol [10.8 Torr] and ammonia [0.2 Torr]

place of trifluoroethanol was found to be accelerated by the NH_3 catalyst (Fig. 7, Curves A and C).

The mechanism of the esterification catalyzed by NH_3 can be explained as follows. In the first stage, the alcohol molecule is adsorbed on the silanol, and then ammonia containing lone-pair electrons forms a hydrogen bond with the hydroxylic proton of alcohol. On the basis of the hypothesis, the model of the adsorption of these molecules may be written as in the picture below. The reaction is completed by the formation of the ester and water. Since the ability of NH_3 to draw out the hydroxylic proton of alcohol is proportional to the acidity of alcohol, the catalytic action of NH_3 on the esterification with trifluoroethanol is more effective than on that with ethanol. No reaction between trifluoroethanol and NH_3 occurred without the silica. It is certain that NH_3 adsorbs directly on the isolated silanol. This problem will be discussed in the next paragraph.



Esterification Catalyzed by Pyridine. When pyridine was used as the catalyst, the esterification of the silica with trifluoroethanol was accelerated (*cf.* Fig. 7, Curves B and D). Since pyridine could not be completely desorbed by the evacuation at 30 °C, the effect on the esterification rate of the fraction of hydroxyl groups covered by the strongly adsorbed pyridine (θ=0.07) was considered in Curve D of Fig. 7. However, the catalytic effect of pyridine was not so remarkable as that of NH_3. It is noticeable that an excess of

Table 2. Heats of adsorption on silica

Absorbate	$\Delta H^{a)}$ (kcal/mol)	$\Delta H^{b)}$ (kcal/mol)[c]
Trifluoroethanol	7.1±0.9[a]	6.2
Ammonia	8.9±0.2[b]	9.8
Pyridine	10.8±1.0[b]	10.6

a) Obtained from Table 1. b) After Hertl and Hair.[7] c) Calculated from frequency shift by using Eq. (4).

pyridine lowers the esterification rate. This means that pyridine strongly adsorbed on the isolated silanol retards the adsorption of alcohol on it.

In Table 2, the heats of the adsorption of trifluoroethanol, NH_3, and pyridine on the isolated silanol are shown. The heat of adsorption ($\Delta H^{a)}$) is obtained by measuring the isosteric heat of adsorption in the freely vibrating hydroxyl group.[8] In the case of trifluoroethanol, the heat of adsorption ($\Delta H^{a)}$) was calculated from the data of the adsorption isotherm, as is shown in Figs. 5 and 6 by using Clausius-Clapeyron's equation. When physical adsorption takes place on the surface of the silica, it is observed that the band in the infrared spectrum attributable to the freely vibrating hydroxyl group is perturbed to lower frequencies. The heat of adsorption ($\Delta H^{b)}$) is a function of the frequency shift.

This was given by this equation:[9]

$$\Delta H^{b)} = 0.455\ (\Delta\nu\ \mathrm{cm^{-1}})^{1/2} - 2.3. \qquad (4)$$

In this equation, $\Delta\nu$ means the frequency shift of the OH stretching vibration. As is shown in Table 2, the strength of the adsorption of these molecules on the isolates silanol is in the order of: pyridine>ammonia>trifluoroethanol. The hydrogen bonding between the hydroxylic proton of the silanol and pyridine is very strong. A test showed that pyridine completely covered the surface silanols at the pressure of 4 Torr, for instance, whereas ammonia could not cover all the silanols even at 80 Torr. The infrared spectrum of the ammonia adsorbed on the silica is shown in Fig. 8. The disappearance of the isolated hydroxyl bands (3750 cm^{-1}) is accompanied by the appearance of two new bands, at 3400 and 3320 cm^{-1}. These two bands can be attributed to the asymmetric and symmetric N–H stretching vibrations. The OH vibration is shifted by about 700 cm^{-1} and is observed as a very

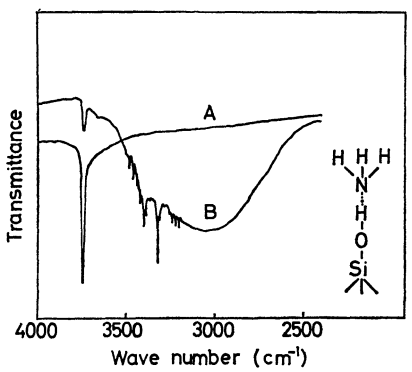


Fig. 8. Infrared spectrum of adsorbed ammonia.
A: Silica
B: Silica with ammonia (82.0 Torr)

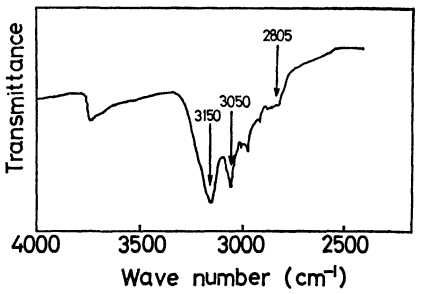

Fig. 9. Infrared spectrum of the chlorinated silica after the treatments of the esteification with trifluoroethanol in the presence of ammonia at 30 °C. (Indicated bands are assigned to ammonium chloride)

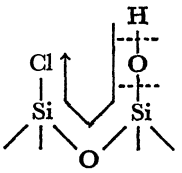
broad absorption band at about 3050 cm^{-1}. Since the intensity of the absorption band at 3750 cm^{-1} can be restored by the evacuation at 30 °C, ammonia seems to be adsorbed physically on the surface silanol.

The pyridine adsorbed on the silanol could not be removed entirely by evacuation at room temperature. When the isolated silanols are completely covered by pyridine, the esterification of the silica with trifluoroethanol is unfavorable because of the steric hindrance of the heterocyclic ring of pyridine.

Esterification of the Chlorinated Silica. The chlorination of silica was evidenced by the appearance of the infrared absorption band due to NH_4Cl molecules when the $SOCl_2$-treated silica was exposed to ammonia (*cf.* Fig. 9).[10] However, no infrared absorption bands attributable to Si–Cl bands were recognized. The reaction of the chlorinated silica with trifluoroethanol formed so few esters that they could not be observed by infrared spectroscopy. This might be because of the strengthening of the acidity of the residual silanol after about 60% of the surface OH groups has been replaced by chlorine atoms.



As a consequence, it became difficult to split the silicon atom from the oxygen which is necessary for the esterification. In the presence of NH_3 (0.8 Torr) as the catalyst, the esterification of the chlorinated silica with trifluoroethanol of 33.1 Torr at 30 °C for 25 min reached 80% of the surface OH groups.

Hydrolysis and Pyrolysis of the Esterified Silica. The nature of the silica surface was modified by treatment with trifluoroethanol and became very hydrophobic. For instance, when the modified silica wafer was immersed in water, it first floated on the surface of the water. However, the wafer floating on the water surface then began to sink very slowly. The change in the affinity of the esterified silica with water may be elucidated by the hydrolysis of the ester. As the ester (Si–O–CH_2–CF_2) possesses an oxygen atom between the silicon and the carbon atoms, it has a tendency to be hydrolyzed. The absorption of the OH stretching vibration of trifluoroethanol and that

of the water molecules appeared in the infrared spectrum of the esterified silica in the presence of water vapor. The spectrum obtained after the evacuation showed an increase in the isolated hydroxyl groups and a decrease in the $-CH_2-CF_3$ groups. When the esterified silica was placed in water vapor of 15 Torr at 30 °C for one hr, it was found that 26% of the ester was hydrolyzed. Moreover, samples which had been kept in water for one day were completely hydrolyzed. At the same time, the siloxane linkages were opened.

$$\geqslant Si\text{-}O\text{-}CH_2CF_3 + H_2O \longrightarrow \geqslant Si\text{-}OH + CF_3CH_2OH \quad (5)$$

The surface species of the esterified silica were stable up to about 200 °C. However, they were decomposed by evacuation above 300 °C.

The Ligation of Phosphine Derivatives and the Oxygen-binding Properties of the Cobalt Mesoporphyrin IX Dimethyl Ester in Toluene

Teruo TAKAYANAGI, Haruhiko YAMAMOTO, and Takao KWAN

Faculty of Pharmaceutical Sciences, University of Tokyo, Hongo, Bunkyo-ku, Tokyo 113

(Received November 5, 1974)

The coordination of phosphine derivatives and some other bases to the cobalt mesoporphyrin IX dimethyl ester in toluene has been spectrophotometrically investigated. The coordination equilibrium constants were determined for each base, and found to be of this sequence (25 °C) : $P(C_4H_9)_3 \gg P(OCH_3)_3 > P(C_6H_5)_3 > S(CH_3)_2 > As(C_6H_5)_3$. The reversible oxygenation of the penta-coordinate complexes formed as above was investigated at lower temperatures (−20——80 °C): the corresponding equilibrium constants were found to be in the following sequence (−80 °C): $P(C_4H_9)_3 > P(OCH_3)_3 > S(CH_3)_2 > P(C_6H_5)_3 > As(C_6H_5)_3$. These relations were discussed in terms of the σ-donating ability of a ligand coordinated *trans* to oxygen.

The reversible oxygenation of cobalt porphyrin has been the subject of considerable interest in recent years. EPR spectral evidence for the reversible oxygen uptake by the penta-coordinate cobalt porphyrins in a frozen organic solution at the temperature of liquid nitrogen has already been presented.[1,2] The success in the replacement of iron by cobalt in hemoglobin and myoglobin[3] particularly stimulated investigations of the amine-ligation and oxygen-binding properties of cobalt porphyrins.[4-6]

In the present work we investigated the effects of such axial ligand as $P(C_6H_5)_3$, $P(C_4H_9)_3$, $P(OCH_3)_3$, $As(C_6H_5)_3$, and $S(CH_3)_2$ on the reversible oxygenation of cobalt porphyrins. Among these bases, phosphine, phosphite, and arsine derivatives are usually considered to have not only σ-donor but also π-acceptor properties. Particularly, triphenylphosphine, a good π-acceptor, is very frequently used in the field of organometallic chemistry to stabilize the low-valent state of metal complexes. It would be interesting, therefore, to compare the effects of the ligation of phosphine derivatives on the oxygenation of cobalt porphyrins with those of the amine ligation.

In this report, we will present thermodynamic data on the ligation and oxygenation of the cobalt mesoporphyrin IX dimethyl ester in toluene solutions. The bonding properties of phosphine derivatives as well as the effect of the bases coordinated *trans* to oxygen on the oxygen-binding ability will be discussed in comparison with those of unsaturated amines.

During the course of the present work, Wayland *et al.*[7-9] reported EPR studies of tetraphenylporphyrincobalt(II) coordinated with PR_3 or $(POR)_3$, and their dioxygen complexes. The results of the EPR measurements of our cobalt porphyrin system completely agreed with those reported by these authors. Therefore, the results of our EPR measurements will be omitted.

Experimental

Materials. The mesoporphyrin IX dimethyl ester (Sigma Chemical Co.) was used without further purification. The Co(II) mesoporphyrin IX dimethyl ester (CoP) was prepared according to the established method.[10] Reagent-grade toluene was purified by the usual method and used as the solvent. The trimethylphosphite and dimethylsulfide were also distilled *in vacuo* prior to use. All the other chemicals were of a reagent grade and were used without special pretreatment.

Measurements. The coordination equilibria of CoP were measured by means of a spectrophotometric titration procedure (Hitachi spectrophotometer EPS-3T). Aliquots of a ligand solution (1—10^{-3} M in toluene) were added to 3.6 ml of a toluene solution of CoP (*ca.* 5×10^{-6} M) from a calibrated micro syringe (Terumo MS 10). The absorption spectra in the range from 350 to 400 nm were recorded after each addition of the ligand solution. The equilibrium constants of coordination (K) were derived from the changes in the absorbance at 394 nm. The constants were found to be independent of the wavelengths. Dilution corrections were kept small, and good isosbestic points were obtained. The cell temperature was controlled to ±0.2 °C in the 10—30 °C range by the use of Haake's thermostat, type "F." The temperature was measured by means of an inserted copper-constantan thermocouple.

The oxygenations were carried out in an optical cell mounted in a Pyrex Dewar. For a typical measurement, a 4-ml portion of a toluene solution containing CoP (10^{-5}—10^{-6} M) and a ligand (10^{-1}—10^{-4} M) was placed in the cell and nitrogen gas was bubbled in from a cylinder. The oxygenation temperature (−20——80 °C) was controlled by introducing cold nitrogen gas purged from the liquid-nitrogen container into the Pyrex Dewar mounted in the sample compartment of the spectrophotometer; it was kept constant within ±0.5 °C. The temperature was measured by the thermocouple attached to the outside of the sample cell.

Oxygen and nitrogen from cylinders were mixed by means of a mixing apparatus equipped with two calibrated flowmeters, and a mixture of a given composition was introduced into the solution of penta-coordinate CoP complexes. Complete spectra from 340 to 500 nm were recorded after each equilibration.

Determination of the Equilibrium Constant. The equilibrium constant, K, of the ligation of CoP, as expressed by:

$$\mathrm{CoP} + \mathrm{L} \overset{K}{\rightleftharpoons} \mathrm{CoPL} \qquad (1)$$

was determined graphically by spectrophotometric titration without direct measurements of the extinction coefficients of the complexes, using the Ketelaar method,[11] as is shown below:

$$\frac{1}{A_0 - A} = \frac{1}{K(\varepsilon_{\mathrm{CoP}} - \varepsilon_{\mathrm{CoPL}})[\mathrm{CoP}]_t[\mathrm{L}]_t} + \frac{1}{(\varepsilon_{\mathrm{CoP}} - \varepsilon_{\mathrm{CoPL}})[\mathrm{CoP}]_t} \qquad (2)$$

where

A_0: absorbance of the starting solution ([L]=0)

A: absorbance of the solution containing ligand ($[L]_t$)
ε_{CoP}, ε_{CoPL}: molar extinction coefficients of CoP, CoPL
$[CoP]_t$: molar concentration of the total CoP($[CoP]_t = [CoP] + [CoPL]$)
$[L]_t$: molar concentration of the total ligand ($[L]_t = [L] + [CoPL]$)

By plotting $1/(A_0 - A)$ against $1/[L]_t$, a straight line should be obtained. From the intercept and the slope of the straight line, K can be derived. In the concentration range of the ligand studied, hexa-coordinate complexes, $CoPL_2$, were not formed, which is in accordance with the results of EPR studies.[7]

The equilibrium constant, K_{O_2}, of the reversible oxygenation of the penta-coordinate CoP expressed by:

$$CoPL + O_2 \overset{K_{O_2}}{\rightleftharpoons} CoPL \cdot O_2 \qquad (3)$$

can be derived similarly to K from the plot of $1/(A_0 - A)$ against $1/P_{O_2}$:

$$\frac{1}{A_0 - A} = \frac{1}{K_{O_2}(\varepsilon_{CoPL} - \varepsilon_{CoPL \cdot O_2})[CoPL]_t} \frac{1}{P_{O_2}} + \frac{1}{(\varepsilon_{CoPL} - \varepsilon_{CoPL \cdot O_2})[CoPL]_t} \qquad (4)$$

The oxygenation equilibria were measured at appropriate intervals between −25 and −80 °C. When K_{O_2} was small (L=$P(C_6H_5)_3$ and $As(C_6H_5)_3$), oxygenation was investigated only near −80 °C.

Results

Ligand Binding. Figure 1 shows typical ligand-titration spectra obtained when $P(C_4H_9)_3$ was added, step by step, to a CoP solution at 11.8 °C. It is apparent from the figure that the absorbance in the Soret region (~397 nm) gradually decreases with the increase in the concentration of $P(C_4H_9)_3$ and that the spectral change is well characterized by isosbestic points. The addition of the other ligands to the CoP solution was found to cause similar changes in the Soret region. No appreciable shift was observed in the Soret band, however.

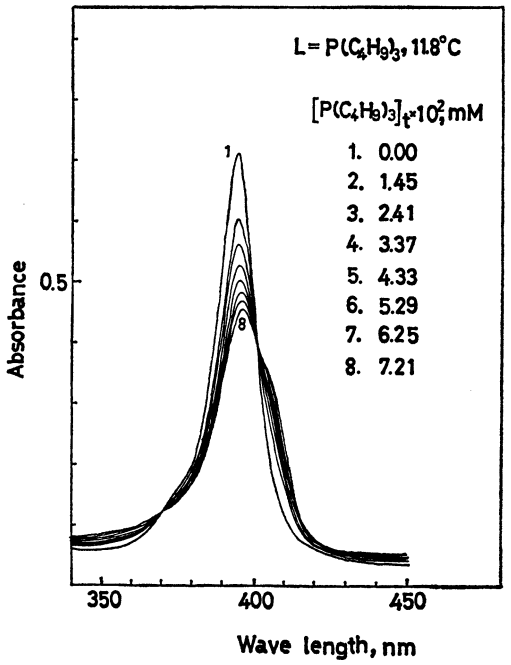

Fig. 1. The spectrophotometric titration spectrum for the determination of K at 11.8 °C for L=$P(C_4H_9)_3$. Spectrum 1 is that of 5.5×10^{-6} M Co mesoporphyrin IX dimethyl ester and 2−8 are at concentration of tri-*n*-butylphosphine added: 1.45, 2.41, 3.37, 4.33, 5.29, 6.25 and 7.21×10^{-5} M, respectively.

Figure 2 shows the plots of $1/(A_0 - A)$ (394 nm) against $1/[L]_t$ at 11.8, 15.3, and 20.5 °C respectively. Straight lines were obtained in the plots, indicating that Eq. (2) is valid. Ligand titrations were further performed with $P(OCH_3)_3$, $P(C_6H_5)_3$, $S(CH_3)_2$, and $As(C_6H_5)_3$; all were found to give rise to a similar relation. The equilibrium constant, K, of the reaction (1) was then calculated for each ligand at various temperatures. The results are summarized in Fig. 3 as well as in the third column of Table 1, where the

a) Standard State of 1 Torr O_2.

coordinated with the other ligands gave spectral changes similar to those in the case of $S(CH_3)_2$; the absorption peak of the penta-coordinate complex (deoxy form) decreased, step by step, upon oxygenation, while another absorption peak originating from the oxygenated form appeared in the longer-wavelength region. The spectral change was reversible with respect to the ambient oxygen pressure; the original spectrum was restored when nitrogen gas was bubbled into the CoPL solution.

Among the ligands studied, the oxygenation reached a saturation under 760 Torr at −80 °C with $P(C_4H_9)_3$ or $P(OCH_3)_3$ while only a partial oxygenation was observed with $P(C_6H_5)_3$, $S(CH_3)_2$, or $As(C_6H_5)_3$, even at −80 °C. Figure 5 shows the van't Hoff plots of K_{O_2}. The K_{O_2} values as well as the related thermodynamic parameters are presented in Table 2.

In the temperature range studied (−20 °C——80 °C), the K_{O_2} values for CoPL decreased in the following

order of ligands coordinated *trans* to oxygen:

$P(C_4H_9)_3 > P(OCH_3)_3 > S(CH_3)_2 > P(C_6H_5)_3 > As(C_6H_5)_3$

This order was parallel with that of the ligation capability of L except $S(CH_3)_2$ and $P(C_6H_5)_3$ were reversed. Despite the large difference in the value of K for $P(C_4H_9)_3$ ($\log K = 4.08$ at 20 °C) and $P(OCH_3)_3$ ($\log K = 1.77$ at 20 °C), the K_{O_2} values for $P(C_4H_9)_3$ ($\log K_{O_2} = -1.2$ at −50 °C) and $P(OCH_3)_3$ ($\log K_{O_2} = -2.3$ at −50 °C) were not very different from one another, suggesting that K and K_{O_2} are not determined by common factors alone.

Discussion

Ligand Binding: The importance of σ-bonding properties between ligand and metal ion has previously been recognized. Recently, it has been suggested that the π-bonding properties are also important for unsaturated amines to form a cobalt-oxygen adduct.[5,6] The importance of π-bonding properties has been well accepted for the derivatives of phosphine, leading to the stabilization of low-valent organometallic complexes.[12] Here, we shall comparatively discuss the bonding properties of unsaturated amines, phosphorous, and arsenic bases on the basis of their ligation equilibria to CoP.

We first presume that the pK_a of the conjugate acid is a measure of the σ-donor property of a base. Unfortunately, the pK_a of phosphorous and arsenic bases is little known. From the literature[13] we adopt 8.43 and 2.73 respectively as the pK_a values of $P(C_4H_9)_3$ and $P(C_6H_5)_3$. The pK_a of $P(OCH_3)_3$ was estimated to be about 3.5. The estimation was carried out on the basis of the linear relationship observed between the half-neutralization potential and pK_a for a series of tertiary phosphorous bases.[13,14] The pK_a of $As(C_6H_5)_3$ must be very low. We presumed it to be 0.0 ± 0.5 on the basis of the results of a potentiometric titration of periodic-group V_a triaryls.[15]

The log K values given in Table 1 were then plotted against the pK_a estimated as above for each base in Fig. 6a, together with the corresponding plots for unsaturated amines due to Stynes *et al.*[6] As is shown in Fig. 6a, unsaturated amines were found to stabilize their complexes more strongly than phosphorous and arsenic bases at the same pK_a, while fairly good straight lines were obtained between log K and pK_a for the two base groups. Especially, it should be noticed that the slope of the straight line ($\partial \log K / \partial pK_a$) was greater for the phosphorous and arsenic bases (0.4) than for the amines (0.1). The greater dependence of log K on pK_a must mean that the σ-donor properties of the ligand predominantly control the stability of the complex.

The ligand binding to CoP may generally be associated not only with the donation of electrons from the ligand to the cobalt atom (σ-bonding), but also with the interaction of the d-orbitals of cobalt with the π^* and/or π-orbitals of the ligand (π-bonding). Thus, it follows from Fig. 6a that unsaturated amines participate in their binding to CoP *via* the π-interacting properties more significantly than do the phosphorous and arsenic bases.

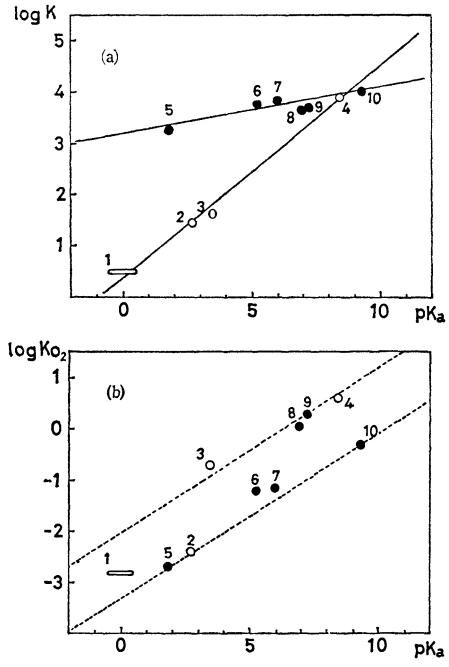

Fig. 6. The plots of pK_a of ligands against log K(a) or log K_{O_2}(b).
Open circles: $As(C_6H_5)_3$(1), $P(C_6H_5)_3$(2), $P(OCH_3)_3$ (3), $P(C_4H_9)_3$(4) Solid circles: 4-CN-pyridine(5), pyridine(6), 4-*t*-Bu-pyridine(7), imidazole(8), 1-Me-imidazole(9), 4-NH_2-pyridine(10).

Contrary to expectation, the π-bonding properties of phosphorous and arsenic bases appeared to be weaker than those of unsaturated amines. It seems that this can be explained by such factors as the contraction of the orbitals of the cobalt ion (divalent and low spin) and the expansion of the orbitals of the phosphorous atom as compared with those of the nitrogen atom. This explanation is not inconsistent with the thermodynamic observations that the binding of unsaturated amines to CoP is accompanied by larger heats and smaller entropy changes when compared with those of the phosphorous and arsenic bases.

Oxygen Binding. In the same way as in the case of ligand binding to CoP, the log K_{O_2} values were plotted against the pK_a of the ligands. The results are shown in Fig. 6b. It is apparent from Fig. 6b that the oxygen-binding properties of the complexes are promoted by larger pK_a values of the ligands, just as in the case of ligand binding, although the linear relation is only approximate. Nevertheless, it is interesting to note that the slope of the straight line for phosphorous and arsenic bases was roughly identical with that for pyridine bases, in contrast with the case for the ligand binding. In other words, the oxygen-binding properties of CoPL, in which L is the amine, seem to depend more strongly on the pK_a of L than does their ligation to CoP, suggesting that the σ-donating properties of L are important for the oxygen binding.

According to the molecular orbital model proposed by Wayland *et al.*,[8] the cobalt-oxygen binding is

considered to be principally a covalent bonding of the singly occupied cobalt(II), d_{z^2}, and the signly occupied oxygen σ-orbital that results from the splitting the π^* degeneracy: also, a ligand molecule, L, elevates in proportion to the donating ability of L, the d_{z^2} cobalt and stabilizes the cobalt-oxygen bond. The low π^*-orbital energy of oxygen will tend to localize the covalent σ pair on oxygen, causing a decline in the cobalt-oxygen $d\pi$—$p\pi$ bonding. In consequence, the π-bonding properties of L are considered to contribute to only a little to the cobalt-oxygen bonding.

The poor relationship between $\log K_{O_2}$ and pK_a may indicate that the ligands coordinated *trans* to oxygen also control oxygen-binding not only by σ-donating ability but also with other factors such as π-donating ability and/or the degree of polarization induced upon oxygenation.

We wish to thank Dr. A. Kuboyama, National Chemical Laboratory for Industry, Tokyo for our use of Haake's thermostat, type "F".

(Received November 25, 1974)

The dark- and photo-conductivities of poly-9-vinylacridine (PVAcr) were investigated in comparison with those of poly-*N*-vinylcarbazole (PVCz). The dark current was ohmic over the whole voltage region studied up to 150000 V/cm. The photocurrent showed a linear dependence on the applied voltage even in fairly high applied fields up to 130000 V/cm and a spectral dependence corresponding antibatically to the absorption spectrum. The magnitude of the photocurrent with positive electrode illumination (i_{ph}^{+}) was only 1.5—2 times larger than that with negative electrode illumination (i_{ph}^{-}), the behavior differing entirely from that in a PVCz film. The magnitude of the photocurrent of PVAcr was smaller than that of PVCz by several times for i_{ph}^{-} and by a hundred times for i_{ph}^{+}. The poor photoconductivity of PVAcr was attributed both to the high concentration of the excimer-forming site acting as an effective exciton trap and to the poor electron-donating character.

The electrical conductivity of vinylpolymers with pendant π-electron systems has been extensively investigated.[1–10] Most investigations have been done with poly-*N*-vinylcarbazole (PVCz), being used as the material for electrophotography. The large photoconductivity of PVCz is attributed both to the good efficiency of the carrier generation through the field-assisted thermal dissociation of an exciplex formed between an excited carbazolyl group and some electron-accepting impurity, and to the ease of the carrier migration through the overlap of π-orbitals of neighboring carbazolyl groups in one polymer chain.[10] In other words, it is due to the presence of the short-range electronic interaction (such as the electron exchange interaction) between neighboring carbazolyl groups in one polymer chain, which are bulky and have a fairly low ionization potential. This has been confirmed by the fact that the photoconductivity of PVCz is much superior to that of poly-*N*-carbazolylethylvinylether where carbazolyl groups are connected far apart from the skeletal chain and the short-range electronic interaction between neighboring carbazolyl groups is very weak.[11]

On the basis of investigation on both the UV spectra of a series of the vinylpolymers[12] and their NMR spectra,[13] it has been found that the vinylpolymers with large pendant π-electron systems such as poly-9-vinylacridine (PVAcr) and poly-1-vinylpyrene have also some electronic interactions between neighboring pendant chromophores in one polymer chain even in solution in a manner similar to the case of PVCz. It is, therefore, very important to investigate the photoconductivity of these polymers in comparison with that of PVCz in order to obtain information on the factors determining the photoconductivity of the vinylpolymers. This paper deals with the steady-state photoconductivity of PVAcr in a sandwich-type cell.

Experimental

PVAcr was prepared by anionic polymerization of the monomer with Na-naphthalene complex at room temperature,[14] and reprecipitated three times from chloroform (containing 1% ethanol) solution with *n*-hexane. The average molecular weight of the polymer thus prepared was determined to be 20000 with use of a membrane osmometer.

Thin films (15 or 9 μm thick) of the polymer undoped and doped with 0.5 mol% of *p*-chloranil (CA) were made on nesa-coated quartz plates from the chloroform solution. Semitransparent gold main and guard electrodes were evaporated on the film to prepare a sandwich-type cell. The cell was used for the electrical conductivity measurements without exposure to the air after the evaporation of the metal electrodes. Measurements were carried out by the DC method in a vacuum (10^{-7}—10^{-8} Torr) or in the air. A 500 W xenon lamp monochromatized by a grating monochromator was used as a light source.[10]

Results and Discussion

Dark Conductivity. PVAcr showed an ohmic dark current (specific conductivity at 60 °C, $\sigma_{60}=3\times10^{-19}\,\Omega^{-1}\,cm^{-1}$ in a high vacuum) over the whole voltage region up to 150000 V/cm. The activation energy of the dark current was 1.0 eV. The behavior differs from that in PVCz films which show a nonohmic dark current attributable to either Poole-Frenkel[2] or Richardson-Schottkey effects.[1] With doping of CA, the dark current increased by several times but the activation energy hardly varied at all.

Photoconductivity. The photocurrent showed two types of response curves (Fig. 1). Illumination with the weakly-absorbed light ($\lambda>400$ nm) induced a photocurrent of Type A, while the illumination with the strongly-absorbed light ($\lambda\leq400$ nm) induced that of Type B. The photoresponse curve of Type B seems to be attributable to the effect of space charges built up by the illumination with the strongly-absorbed light.[15] The results were obtained for the steady-state value of the photocurrent.

The voltage dependence of the photocurrent is shown in Fig. 2. The photocurrents in the films, undoped and doped with CA, were proportional to the applied voltage in the fields lower than 70000 V/cm. The superlinear dependence of photocurrent on the applied voltage, regarded as an important character of the photoconductivity of PVCz,[10] was exceptionally observed for the photocurrent induced with the light

(3) a film doped with 0.5 mol% of CA, 9 μm thick, 410 nm.

of 410 nm in fields higher than 70000 V/cm. The voltage at which the superlinearity appeared was larger for PVAcr than for PVCz by 10 times.

The photocurrent was always proportional to the light intensity (10^{12}—10^{14} photon/cm^2 s) regardless of doping of CA.

Plots of logarithm of the photocurrent *vs.* $1/T$ gave a straight line over the whole temperature range (20—130 °C). The activation energy of the photocurrent was 0.18±0.03 eV at 360—410 nm under 35000V/cm and varied little with doping of CA. The value is nearly equal to that for PVCz.

The spectral dependence of the photocurrent is shown in Fig. 3. It was obtained by normalizing the observed photocurrent values to a constant light intensity, 2×10^{13} photon/cm^2 s. It was not affected by the polarity of the illuminated electrode, applied voltage, ambient oxygen and doping of CA. The photocurrent peaks appeared at 410 and 290 nm

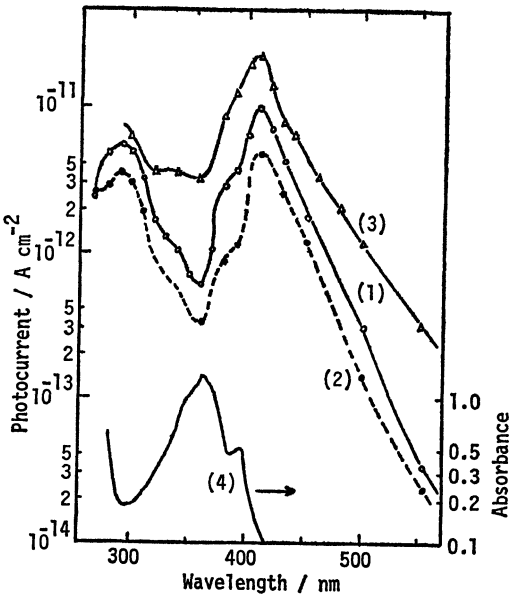

Fig. 3. Spectral dependence of photocurrent with positive electrode illumination in a PVAcr sandwich-type cell under an applied field of 33000 V/cm at a light intensity of 2×10^{13} photon/cm^2 s.

corresponding to the wavelength of the absorption edge of the ^1L_a band and the absorption minimum between the ^1L_a and ^1B_a bands, respectively. The photocurrent minimum appeared at 360 nm corresponding to the wavelength of the absorption maximum of the ^1L_a band. The spectral dependence, thus, corresponded antibatically to the absorption spectrum.

In general, for a film thick enough to absorb the light almost completely, the type of spectral dependence mentioned above appears when the carrier generation in the bulk is predominant, while the other type of spectral dependence of the photocurrent corresponding symbatically to the absorption spectrum appears when the surface carrier generation is predominant. In a PVAcr film, the latter type was not observed even under 70000 V/cm, and the photocurrent with positive electrode illumination (i_{ph}^+) was larger than that with negative electrode illumination (i_{ph}^-) only by 1.5—2 times in magnitude. These results are quite different from those for PVCz; in a PVCz film under an applied field higher than 7000 V/cm, i_{ph}^+ showed the latter type of spectral dependence, being much larger than i_{ph}^- in magnitude (*e.g.*, 20—100 times at 35000 V/cm).[10] From Fig. 4 which shows a comparison of the photocurrents observed for PVAcr and PVCz films under the same experimental condition, we see that the magnitude of the photocurrent of PVCz is larger than that of PVAcr by several times for i_{ph}^- and by a hundred times for i_{ph}^+. Judging from these results and the absence of the superlinearity of the photocurrent on applied voltage in a PVAcr film, the surface carrier generation does not seem to be predominant in

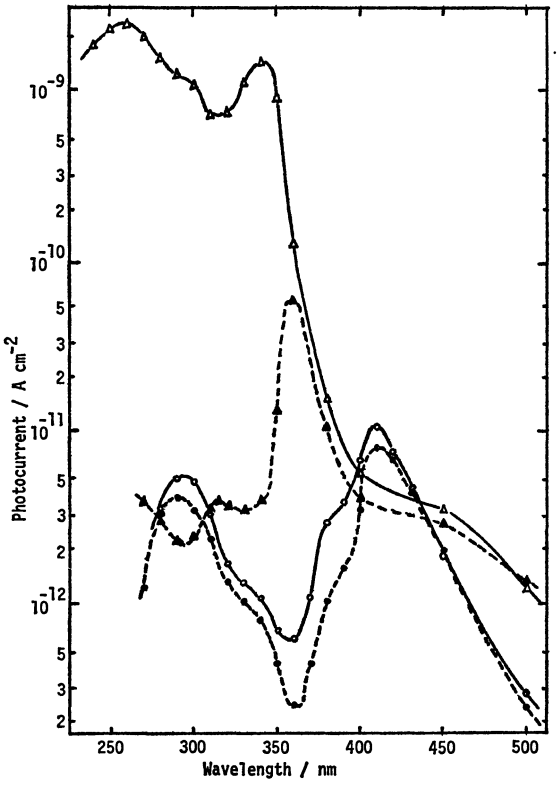

Fig. 4. A comparison of the magnitudes of the photocurrents between PVAcr and PVCz.
The photocurrents were measured in sandwich-type cells (15 μm thick) under an applied field of 33000 V/cm at 2×10^{13} photon/s in a high vacuum of 10^{-7} Torr at 20 °C.
(—○—): PVAcr, positive electrode illumination,

(—△—): PVCz, positive electrode illumination,
(--▲--): PVCz, negative electrode illumination.

a PVAcr film even under a fairly high applied field (130000 V/cm), although it has been considered to be a predominant carrier generation process in a PVCz film.

With doping of CA, the photocurrent increased over the whole wavelength region by 2—3 times with no distinct change in the spectral dependence. No new photocurrent peak was found in the charge-transfer absorption region. This is not surprising, since the charge-transfer absorption band (λ_{max}=535 nm in $CHCl_3$ solution) could hardly be found in the film (9 μm thick) doped with 0.5 mol% of CA. A film doped heavily with CA could not be used for the electrical measurements, since it easily cracked.

Although PVAcr is not considered to be inferior to PVCz as regards the electronic interaction between neighboring pendant groups in one polymer chain on the basis of their UV and NMR spectra,[12] the photoconductivity of PVAcr is greatly inferior to that of PVCz. In a PVCz film, the surface carrier generation through an exciplex formed between a singlet exciton and some electron-accepting impurity has been considered to be predominant even under a fairly low applied field. In a PVAcr film, however, such a surface carrier generation does not seem to be predominant even under a fairly high applied field. This is a reason for the poor photoconductivity of PVAcr.

A singlet exciton migrates efficiently in a polymer film and the migration is strongly affected by the inherent trapping site such as the excimer-forming site.[16] PVAcr shows exclusively excimer fluorescence not only in solid but also in a solution with no monomeric fluorescence.[17] This is probably due to the high concentration of the excimer-forming site. In this case, a singlet exciton is considered to cover only a small number of acridine rings during its life time, because its migration is limited by the excimer-forming site. As one of the most conceivable carrier generation process in an undoped PVAcr film, we can assume the field-assisted thermal dissociation of an exciplex ($(D^{\delta+}\cdots A^{\delta-})^*$) formed between a singlet exciton (D^*) and some electron-accepting impurity (A) to the ion radicals (D^+ and A^-), as is the case with PVCz[10]

$$D^* + A \longrightarrow (D^{\delta+}\cdots A^{\delta-})^* \longrightarrow D^+ + A^- \qquad (1)$$

However, the efficiency of this carrier generation might be poor for a PVAcr film because of the limitation of the exciton migration. The situation is the same as for the other extrinsic carrier generation mechanisms such as the interaction between the electrode and a singlet (or triplet) exciton. The high concentration of the excimer-forming site, therefore, may be the main cause for the poor photoconductivity of PVAcr.

In general, the efficiency of extrinsic or intrinsic photo-carrier generation increases with an increase in the electron-donating character of the aromatic rings. The situation is the same as for the carrier generation due to the dissociation of an exciplex (Eq. 1), because of an increase in the degree of charge-transfer in the exciplex state, $(D^{\delta+}\cdots A^{\delta-})^*$, with the electron-donating character. Another reason for the poor photoconductivity of PVAcr may be the poor electron-donating character of PVAcr; the first ionization potential has been determined to be 7.88 eV for PVAcr and 7.43 eV for PVCz, from the energy of the first charge-transfer absorption in chloroform solution.[18]

From the viewpoint of intensity of the electronic interaction between neighboring pendant chromophores in one polymer chain examined by the UV, CT, and NMR spectra,[12,13,18] the carrier mignation may be assumed to be as easy in a PVAcr film as in a PVCz film. The poor photoconductivity of PVAcr is, therefore, attributable mainly to the poor efficiency of carrier generation, although it remains ambiguous whether the excimer-forming site acts as an effective carrier trapping site.

The discussion mentioned above reconfirmed that the good photoconductivity of PVCz is due to both the comparatively low ionization potential of the carbazolyl groups and the low concentration of the excimer-forming sites in the polymer, in spite of the presence of the short-range electronic interactions between neighboring pendant carbazolyl groups.

ESR and ENDOR Studies of Hindered Internal Rotation of Higher Alkyl Groups in 4,4′-Dialkylbiphenyl Anion Radicals

Fujito NEMOTO, Fumio SHIMODA, and Kazuhiko ISHIZU

Department of Chemistry, Faculty of Science, Ehime University, Bunkyo-cho, Matsuyama 790

(Received January 13, 1975)

ESR and ENDOR spectra were obtained for the anion radicals of 4,4′-diisopropylbiphenyl, 4,4′-dicyclohexylbiphenyl and 4,4′-dicyclopentylbiphenyl. Both the β- and γ-proton coupling constants of the alkyl groups were precisely determined. The temperature dependence of the β-proton splittings of the alkyl groups were investigated. According to the Heller-McConnell relationship for hyperconjugation, $a_i^\beta=(B_0+B_2\cos^2\theta)\rho_i^\pi$, the positive temperature dependence of the alkyl β-proton splitting was adequately interpreted utilizing a revised model with restricted rotation. The rotational potential barrier and the energy difference of the two equilibrium states obtained were 1.2 and 0.5, 1.2 and 0.6, and 1.2 and 0.6 kcal/mol for the 4,4′-diisopropyl-, 4,4′-dicyclohexyl-, and 4,4′-dicyclopentylbiphenyl anions, respectively. The energy difference of the non-bonding interatomic interaction was calculated in terms of the Lennard-Jones 6—12 potential. Excellent agreement is found between the experimentally-determined value of the potential barrier and that calculated theoretically. ENDOR observations carried out for 4,4′-dicyclohexyl- and 4,4′-dicyclopentylbiphenyl anion radicals in solution demonstrated that γ-protons revealed two different hyperfine coupling constants. These hyperfine coupling constants were assigned to the stereochemically different γ-protons. The ratio of these γ-protons splittings suggest that hyperconjugation plays an important role in producing a spin density of the γ-protons as has been proposed for explanations of the β-proton splittings.

Restricted rotation of the alkyl groups has been extensively studied by ESR for a number of aromatic radicals.

Rotational potentials of the alkyl groups have been proposed from the analysis of the magnitudes of the β-proton coupling constants, and their temperature dependence has often been discussed based on the McConnell-Heller relationship with the aid of Boltzmann statistics.

In this work, ESR and ENDOR techniques were applied to the study of the anion radicals of 4,4′-diisopropylbiphenyl, 4,4′-dicyclopentylbiphenyl, and 4,4′-dicyclohexylbiphenyl.

Analysis of the ESR spectra, which contains complicated hyperfine structure due to the extra γ-proton splitting, was greatly simplified by ENDOR measurement, and the β-proton coupling constants of the alkyl groups and their temperature dependence were accurately determined. The temperature dependence of the β-proton splitting was theoretically investigated based on the revised model of restricted rotation. A new potential function, which has a double minimum, has been proposed,[1] and the energy barriers were calculated in terms of the rotational wave functions expanded in a Fourier series.

The potential barrier height and corresponding energy difference between the two equilibrium states were estimated by comparing the observed temperature dependence with that calculated theoretically.

On the other hand, the energy difference of the non-bonding interaction between the isopropyl group and the neighboring aromatic protons was calculated on the basis of a Lennard-Jones 6—12 potential. The maximum repulsion energy between the isopropyl and the ring protons thus calculated justified the value of the potential barrier determined experimentally.

In addition to the studies of the temperature dependence of the β-proton splittings, the dependence of γ-proton splitting was also investigated using ENDOR. A large difference between the hyperfine splitting of the two γ-protons, which have stereochemically distinct conformations, was clearly detected for the cycloalkyls. The magnitude of the γ-proton splitting is reasonably understandable under the assumption that a direct hyperconjugation is also the dominant mechanism producing the spin density of the γ-protons.

Experimental

The 4,4′-dialkylated biphenyls were prepared from the coupling of *para*-alkyl phenyl magnesium bromide in the presence of anhydrous cobaltous chloride, according to the following process.[2]

0.068 mol of freshly distilled *para*-alkyl bromobenzene was dissolved in about 30 ml of dry tetrahydrofuran (THF) and was added to magnesium chips (0.074 mol) mixed in a like amount of dry THF. To ensure the absence of any unreacted bromo-compound, the Grignard solution was refluxed for 3 hr. After reaction, the solution was dropped into a mixture of 0.05 mol of anhydrous cobaltous chloride and 0.05 mol of ethylbromide in about 30 ml of THF, and the mixture was refluxed for 4 hr. The organic product was extracted with ether. After the removal of the solvent, the residue was recrystallized from ethyl alcohol.

The materials thus obtained were all purified by silica-gel chromatography, using *n*-hexane as the solvent.

The physical constants of the white crystalline solids are listed below.

		λ_{max} nm(ε)
4,4′-diisopropylbiphenyl	mp 64.8 °C	
	UV(Hexane)	256.5 (29400)
4,4′-dicyclohexylbiphenyl	mp 204 °C	
	UV(Hexane)	258 (21300)
4,4′-dicyclopentylbiphenyl	mp 144—146 °C	
	UV(Hexane)	259.5 (22400)

The anion radicals were prepared in a solution of dimethoxyethane (DME) by reduction with potassium and sodium metal. The ESR spectra were measured in the temperature range from +20 °C to −90 °C using a Japan Electron Optics (JEOL) JES-ME-3X type spectrometer equipped with 100 kHz magnetic field modulation.

The ENDOR spectra were measured in the temperature

range from −90 °C to −50 °C using a JEOL ES-EDXI type spectrometer operating with 80 Hz magnetic field modulation.

About 150 W of continuous radio waves, frequency modulated at 6.5 kHz, were present in the cavity for NMR excitation.[3]

The magnetic field was calibrated using a perylene cation radical prepared in concentrated sulfuric acid.

Results

The ENDOR spectra of the 4,4′-diisopropylbiphenyl anion, the reference compound of the cycloalkyl derivatives, are shown in Fig. 1.

By comparison with the ENDOR signal of the biphenyl anion,[17] the signal at 14.50, 17.15 and 17.64 MHz can be assigned to the splitting due to the *meta*-, the alkyl β-, and the *ortho*-protons respectively. In addition, the splittings due to the γ-protons are recorded in the vicinity of the free proton frequency.

With elevation of the temperature, it is observed that the signals of alkyl β-protons designated by the dotted line in the figure show a higher frequency shift, that is, the positive temperature dependence of the alkyl β-protons is thus fairly well demonstrated as is in previous ESR observations.[4] The temperature dependence of the β-proton splitting of the isopropyl has been theoretically treated in terms of the restricted rotation of the alkyl group. The calculation of the β-proton splitting as a function of temperature has already been carried out with the proposed adequate potential function in a previous paper.[1]

The ENDOR spectra of the 4,4′-dicyclopentylbiphenyl anion, shown in Fig. 2, can easily be analyzed with reference to the hyperfine splittings of the 4,4′-diisopropylbiphenyl anion. Of particular interest is the fact that γ-protons of the cyclopentyl give rise to two different hyperfine splittings, although the isopropyl γ-proton produces only one hyperfine splitting. Observation of the two different γ-splittings for the cycloalkyls may be attributed to the fact that methylene groups are tightly locked in the cycloalkyl groups, while the methyl group in isopropyl undergoes free rotation.

Computer calculation of the ESR line intensities based on the hyperfine coupling constants determined by the present ENDOR measurements are in excellent agreement with the observed line intensities as shown in Fig. 3.

The ENDOR spectra of the cyclohexylbiphenyl anions (Fig. 4) are very similar to those of the cyclopentyl anions, where the equatorial and the axial γ-proton splittings are also highly resolved.

In Fig. 5, the slopes of the plots are compared for the cycloalkyls and isopropyls. A slight increase of the slope noted for cycloalkyls suggests that some modifications of the rotational function occur. A detailed analysis of the rotational potential function will be discussed in the following section.

The proton coupling constants of each derivative thus determined are summarized in Table 1.

Discussion

Alkyl β-Proton. The magnitude of the β-proton splitting can often be calculated using the following equations:

$$a_4^\beta = \langle Q(\theta)\rangle \rho_4^\pi \tag{1}$$

and

$$Q(\theta) = B_0 + B_2 \cos^2\theta \tag{2}$$

where B_0 and B_2 are empirical parameters, ρ_4^π is the spin density at the *para*-position and θ is the angle between the axis of the $2p_z$ orbital and the aliphatic C–H bond of the alkyl group, both projected on the plane perpendicular to the bond between the methylene carbon of the alkyl and the aromatic carbon.

$\langle Q(\theta)\rangle$ is the quantum mechanical average of $\cos^2\theta$ over the appropriate rotational wave functions $\psi_i(\theta)$. The β-proton splitting as a function of temperature was calculated based on Eqs. (1) and (2), with the aid of Boltzmann statistics.[6]

$$a_4^\beta = B\rho_4^\pi \langle \cos^2\theta\rangle, \qquad \theta = \alpha + \theta_0 \tag{3}$$

$$\langle \cos^2\theta\rangle = \frac{\sum_{i=0}^{\infty} \langle \psi_i(\alpha)\,|\cos^2(\alpha+\theta_0)|\,\psi_i(\alpha)\rangle e^{-E_i/kT}}{\sum_{i=0}^{\infty} e^{-E_i/kT}} \tag{4}$$

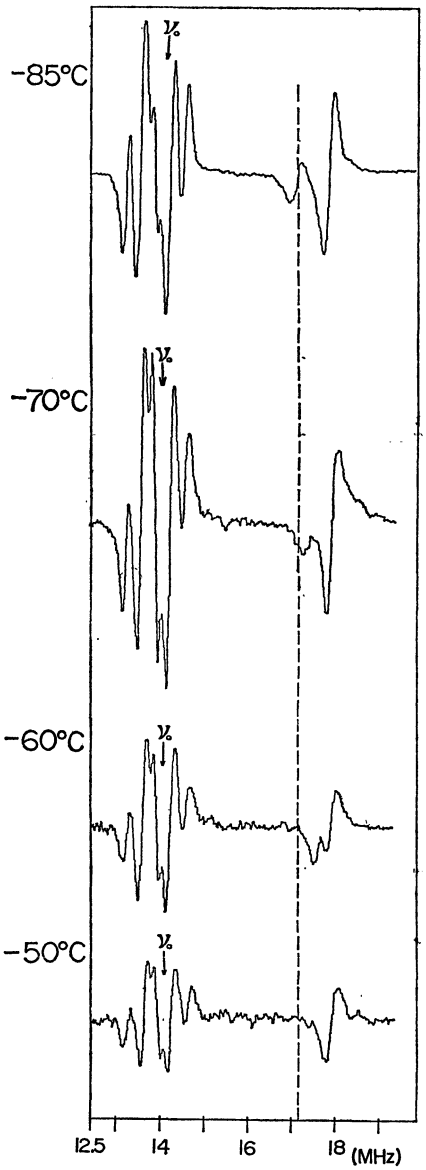

Fig. 4. ENDOR spectra of the system 4,4'-dicyclohexylbiphenyl-DME-K.

The contribution of B_0 was neglected in Eq. (2) and the value of $B\rho_4^\pi$ was estimated from the methyl proton splitting of the 4,4'-dimethylbiphenyl anion radical assuming free rotation of the methyl group, with $B\rho_4^\pi$ being 2×5.6 G.[4,8]

In Eq. (4), the wave function $\psi_i(\alpha)$ and the eigenvalue E_i are obtained by solving the following equation:

$$-\left(\frac{\hbar^2}{2I}\right)\left(\frac{d^2\psi_i}{d\alpha^2}\right) + [V(\alpha) - E_i]\psi_i = 0 \tag{5}$$

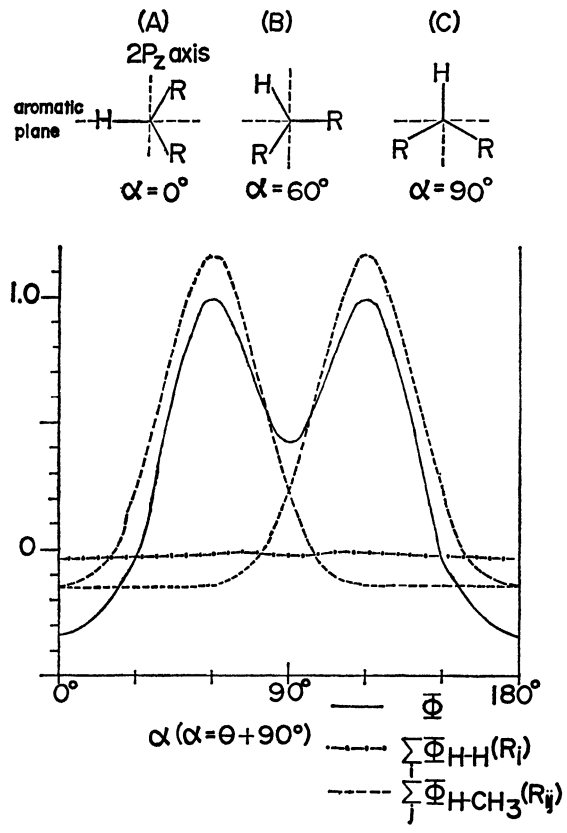

Fig. 6. Conformations of the 4,4′-diisopropylbiphenyl anion and non-bonded interaction energies between the rotating isopropyl and ring *meta* protons as a function of α.

where the moment of inertia I of the molecular fragment ϕ–R can be calculated to be 0.70×10^{-38} g·cm^2 for 4,4′-diisopropylbiphenyl, 1.90×10^{-38} g·cm^2 for 4,4′-dicyclohexylbiphenyl and 1.60×10^{-38} g·cm^2 for 4,4′-dicyclopentylbiphenyl assuming that a prefered rotation of the residual group occurs about the longer axis of the 4,4′-dialkylbiphenyl molecules.

Before solving Eq. (5) numerically, we must know the valid rotational potentials $V(\alpha)$ of the alkyl groups. For 4,4′-diisopropylbiphenyl, restricted rotation of the isopropyl group has already been discussed and the appropriate potential function obtained is illustrated in Fig. 6, as reported in a previous publication.[1] Since the principal steric repulsions occur between the γ-methyl and *meta* C–H groups of the biphenyl ring for 4,4′-diisopropylbiphenyl, and between the γ-methylene and *meta* C–H groups for the 4,4′-dicycloalkylbiphenyls, the rotational potential structures should be essentially the same in both cases. From the above considerations, the rotational potential barrier $V(\alpha)$ of each isopropyl, cyclohexyl and cyclopentyl group was approximated by:

$$V(\alpha) = V_0 \sum_{i=0}^{3} a_i \cos 2i\alpha \tag{6}$$

$$a_0 = \frac{1}{18}\left(\frac{9V_m}{V_0}+4\right),\quad a_1 = \frac{4}{9},\quad a_2 = \frac{2}{9},$$

$$a_3 = \frac{1}{18}\left(8-\frac{9V_m}{V_0}\right)$$

where V_0 and V_m are the potential energy differences between the lowest potential at state [A] and the highest potential at state [B] and that between the lowest potential at state [A] and the medium value at state [C], respectively, as is illustrated in Fig. 6. At the most stable conformation [A], the β-hydrogen of these alkyl groups is in the plane of the aromatic ring and the dihedral angle of the β-proton, θ_0 in Eq. (3), is equal to $\pi/2$. The Hamiltonian matrix $\langle i|\mathscr{H}|j\rangle$ was diagonalized by expanding the wave function in a Fourier series.

$$\psi_i(\alpha) = \sum_{j=0}^{\infty} (C_{ij}\sin j\alpha + D_{ij}\cos j\alpha) \tag{7}$$

We have calculated the temperature dependence of $\langle\cos^2\theta\rangle$ as a function of V_0 and V_m for three 4,4′-dialkylbiphenyls. For example, $\langle\cos^2\theta\rangle$ calculated for 4,4′-diisopropylbiphenyl in the temperature range

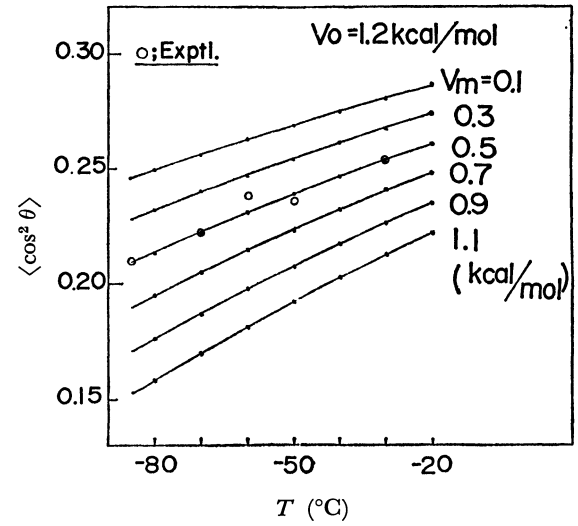

Fig. 7. Theoretical temperature dependence of $\langle\cos^2\theta\rangle$ for rotating isopropyl.
Numerical calculations were carried out taking the energy difference between the two minima, V_m, as the variable parameter, where the maximum barrier of the potential, V_0, was fixed to be 1.2 kcal/mol everywhere.

from −80 °C to −20 °C for various values of V_0 and V_m are shown in Fig. 7.

The best agreement between the calculated and experimental temperature dependences of $\langle\cos^2\theta\rangle$ is obtained with $V_0=1.2$, $V_m=0.5$, $V_0=1.2$, $V_m=0.6$ and $V_0=1.2$, $V_m=0.6$ kcal/mol for 4,4′-diisopropyl, 4,4′-dicyclohexyl and 4,4′-dicyclopentyl biphenyl.

Calculation of the Repulsive Potential Energies between the Isopropyl and the Aromatic Protons. In a previous publication,[8] calculation of the energy of the non-bonding interaction has been reported for the rotating ethyl group in the 4,4′-diethylbiphenyl, and it was found a simple calculation of the non-bonding interaction was in excellent agreement with the value determined experimentally. The interactions between the counter-cation and the radical anions had been disregarded everywhere, because it was known from conductivity measurements,[9] NMR shift observation[10] and studies of the temperature dependence of the ENDOR intersities of several alkylated biphenyl anions[11] that the radical anions may exist as solvent separated ion-pairs and may act freely under the present experimental circumstances.

In the present studies, similar calculations of the non-bonded interaction between rotating alkyl and aromatic protons are applied to the 4,4′-diisopropyl derivative using the following approximations.

[1] The methyl groups in the isopropyl are treated as a rare gas atom of Kr, since the methyl group is thought to be rapidly rotating in comparison with the motion of the isopropyl group, and not only is it non-polar in nature, but also its spherical size as given by the van der Waals radius are almost the same as those of the Kr atom.

[2] Two kinds of interatomic interactions were considered in the present calculations. The first is the interaction between the ring-*meta* protons and the alkyl β-proton, $\Phi_{H_m\text{-}H_\beta}$. The second is the interaction between the ring-*meta* protons and the methyl groups, $\Phi_{H_m\text{-}CH_3}$. All other interactions are neglected.

The total interatomic potential was calculated from a summation of the energy of interacting pairs, and each interatomic interaction was estimated using the Lennard-Jones 6—12 potential function, thus

$$\Phi_{H_m\text{-}H_\beta}(R_i) = A_{H\text{-}H}/R_i^{12} - B_{H\text{-}H}/R_i^6 \quad (8)$$

and

$$\Phi_{H_m\text{-}CH_3}(R_{ij}) = A_{H\text{-}Kr}/R_{ij}^{12} - B_{H\text{-}Kr}/R_{ij}^6 \quad (9)$$

where R_i is the interatomic distance between the ring-*meta* proton and the alkyl β-proton and R_{ij} is that between the ring-*meta* proton and the methyl group. As shown in Fig. 8, R_i and R_{ij} were calculated as functions of the rotation angle of the alkyl (α) by taking the bond angle of the tetrahedral carbons to be 109°29′ and that of the ring carbons to be 120°. The bond distances between the carbon and hydrogen atoms were estimated to be 1.09 Å everywhere, and carbon-carbon distance to be 1.52 Å for the aliphatic group, 1.45 Å for the alkyl carbon-ring carbon separation, and 1.40 Å for the aromatic ring.[12] The numerical values of parameters $A_{H\text{-}H}$, $B_{H\text{-}H}$, $A_{H\text{-}Kr}$, and $B_{H\text{-}Kr}$ in the Lennard-Jones 6—12 potential have already been established by Yasuda[13] and Oobatake.[14]

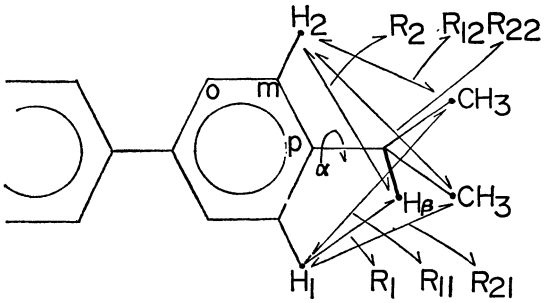

Fig. 8. Scheme of the distance R_{ij} and R_I between ring *meta* protons and methyl groups in the isopropyl and between ring *meta* protons and isopropyl β-proton.

We have already used these values to calculate of the potential barrier height of the rotating ethyl group in 4,4′-diethylbiphenyl[8] and the calculated value was in excellent agreement with the value obtained from the measurement of the temperature dependence of the β-proton splittings, using the following parameters:[13]

$$A_{H\text{-}H} = 4.7\times10^2 \text{ kcal}\cdot\text{Å}^{12}/\text{mol},$$
$$B_{H\text{-}H} = 9.2 \text{ kcal}\cdot\text{Å}^6/\text{mol}$$
$$A_{H\text{-}Kr} = 3.3\times10^4 \text{ kcal}\cdot\text{Å}^{12}/\text{mol},$$
$$B_{H\text{-}Kr} = 1.2\times10^2 \text{ kcal}\cdot\text{Å}^6/\text{mol}.$$

The interatomic potential energy Φ is given by

$$\Phi = \sum_{i=1}^{2}\Phi_{H_m\text{-}H_\beta}(R_i) + \sum_{i,j=1}^{2}\Phi_{H_m\text{-}CH_3}(R_{ij}) \quad (10)$$

In Fig. 6, we give the plot of the interatomic potential energy as a function of the rotating angle (α) of the alkyl group.

The maximum repulsion energy thus calculated was 1.4 kcal/mol when a methyl group is fixed on the aromatic ring [state (B)], while the configuration [A], in which the β-proton is in the plane of the aromatic ring, is found to be the most stable. The potential height (V_m) calculated for the configuration [C], in which the β-hydrogen is parallel with the axis of the $2p_z$ ring carbon, was 0.7 kcal/mol.

The potential function of the isopropyl thus calculated, assuming the non-bonded interatomic interaction, shows not only a double minimum but also is in satisfactory agreement with the value obtained from the measurement of the temperature dependence of the β-proton splittings.

In conclusion, the rotation of the isopropyl, cyclohexyl and cyclopentyl groups may be more or less restricted in the potential as given in Fig. 6, which have the maximum repulsion energy of ~1.2 kcal/mol, this value being slightly above the thermal activation energy at 300 K.

From these considerations, it can be said, at room temperature the isopropyl, cyclohexyl and cyclopentyl groups in para alkylated biphenyl retain fairly large degrees of freedom of rotation affected by the thermal activation, in contrast to the tight restriction of rotation of the alkyls as seen in the space-filling molecular-models.

Alkyl γ-Proton Splitting. The difference in the magnitude of the γ-proton hyperfine coupling of the cycloalkyls may be attributed to the stereochemically different γ-protons, and this offers a useful test to determine whether direct hyperconjugation is the dominant mechanism producing the spin density at these protons, as already reported by Adams *et al.*[7] In cyclohexyls, the axial and equatorial γ-protons remain stereochemically equivalent in pairs against restricted rotation of the cyclohexyl group in the rotational potential, where we assign the larger coupling (240 mG at −85 °C) to the equatorial protons, and the smaller one to the axial protons.

In Fig. 9, it is seen that the equatorial γ-proton splitting of the cyclohexyl decreases with elevation of the temperature, but the other axial γ-proton splittings exhibit only minor increases or remain constant. The similar temperature dependence of the cyclohexyl of the phenoxyl radical has already been reported,[7] and the importance of hyperconjugation of the γ-methylene group has been noted.

Hyperconjugation with a $2p_z$-orbital gives a spin density contribution at the γ-proton of the form

$$a_4^{\gamma} = (A_\gamma + B_\gamma \cos^2\theta)\rho_4^{\pi}. \qquad (11)$$

For a γ-proton, θ is the usual dihedral angle and A_γ and B_γ are empirical constants defined in the same ways as is done for β-protons. The major exchange interaction may be expected between a γ-proton and an unpaired electron in a $2p_z$-orbital on the adjacent ring carbon atoms. The interactions attributed to the other ring carbons were all neglected because the spin density of the ring *meta* carbon is about 1/10 of that of the ring *para* carbon,[15] and the distance between the γ-proton and ring *ortho* carbon is too great.

In the 4,4′-dicyclohexylbiphenyl anion, the axial and equatorial protons move on the same circle during rotations of alkyls about the C_p–C_α bond, and we can write

$$a_4^{\gamma e} = A_{\gamma e} + B_\gamma \cos^2(\theta + \theta_e^0) \qquad (12)$$

and

$$a_4^{\gamma a} = A_{\gamma a} + B_\gamma \cos^2(\theta + \theta_a^0) \qquad (13)$$

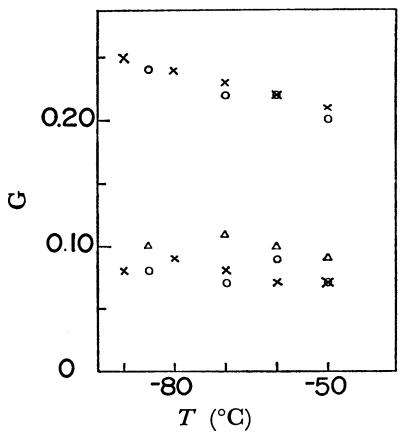

Fig. 9. Temperature dependence of the hyperfine coupling constants for the alkyl γ-protons measured by ENDOR.
△; 4,4′-Diisopropylbiphenyl, ○; 4,4′-dicyclohexylbiphenyl,, ×; 4,4′-dicyclopenthylbiphenyl.

where θ_e^0 and θ_a^0 are the equilibrium dihedral angles of the equatorial and axial protons, respectively. θ_e^0 and θ_a^0 were calculated to be 5°35′ and 54°25′ by taking the aliphatic C–H bond length to be 1.10 Å and the alicyclic C–C bond length to be 1.52 Å.[12]

A qualitative explanation of the $a_4^{\gamma e}/a_4^{\gamma a}$ ratio can be made assuming that the alkyl β-proton exchanges rapidly between state [A] and state [C] as shown in Fig. 6, and the contribution of the other state [B] is negligible. The ratio (n_A/n_C) of the populations at state [A] to that at state [C] is estimated using

$$n_A/n_C = \exp(V_m/kT) \qquad n_A + n_c = 1 \qquad (14)$$

where V_m is the energy difference between state [A] and state [C], 0.6 kcal/mol. At −85 °C, the values of n_A and n_C are estimated to be 0.87 and 0.17, respectively, and therefore the ratio $a_4^{\gamma e}/a_4^{\gamma a}$ can be calculated assuming the $|A_{\gamma e}|$ and $|A_{\gamma a}| \ll B_\gamma$, that is, that

$$\frac{a_4^{\gamma e}}{a_4^{\gamma a}} = \frac{n_A\langle\cos^2 5°35'\rangle + n_C\langle\cos^2 95°35'\rangle}{n_A\langle\cos^2 54°25'\rangle + n_C\langle\cos^2 144°25'\rangle} = 2.1. \qquad (15)$$

The calculated value of $a_4^{\gamma e}/a_4^{\gamma a}$ is nearly the same as the experimental value of 3.0.

In the case of the 4,4′-dicyclopentylbiphenyl anion, the equilibrium dihedral angles θ_0^{e1} for the pseudo-axial γ-protons and those for the equatorial γ-protons θ_0^{e2} have almost the same value, 21°, but two γ-protons in the methylene group do not move on the same circle during rotation about the C_4–C_α bond. This means that each γ-proton is separated from the ring C_4 carbon by the distinct distance of 1.51 abd 2.97 Å, respectively. Since B_γ in Eq. (11) should be represented by the exchange integral between the C_γ–H_γ bond and the $2p_z$-orbital on C_4 as discussed by McLachlan,[16] it will be a function of the distance between the $2p_z$-orbital on C_4 and the γ-proton, which is on the plane perpendicular to the nodal plane of the $2p_z$-atomic orbital. We can, therefore, assign the larger coupling to the proton taking a position closer to the ring C_4 carbon atom at a distance of 1.51 Å and that for the smaller one at a distance of 2.97 Å.

In view of the above discussion, it is seen that different hyperfine couplings observed for cyclohexyl γ-protons are attributed to the difference in the averaged value of $\cos^2\theta$. On the other hand, in cyclopentyl γ-protons, the different B_γ values produce nonequivalent γ-proton splittings.

The authors wish to thank Dr. K. Mukai for his useful discussions throughout the course of this work.

The numerical calculations were carried out on the FACOM 230-75 at the Data Processing Center, Kyoto University.

Monolayers and Built-up Films of *N,N'*-Disubstituted Dithiooxamide Cu(II) Coordination Compounds*

Asahi SUZUKI, Kuwako OHKAWA, Seiichi KANDA, Masanori EMOTO**, and Shunichi WATARI***

Department of Applied Chemistry, Faculty of Engineering, Tokushima University, Minamijosanjima, Tokushima 770

(Received February 10, 1975)

N,N'-Disubstituted dithiooxamide-Cu(II) as compound semiconductors prepared by the usual method have been liable to be an isomeric mixture of coordination polymers. Syntheses of the stereospecific coordination polymers were attempted by an interfacial technique. The dithiooxamides with two hydrophobic substituents, R's, on nitrogen atoms of a ligand molecule could be spread on a water surface to form the monomolecular film, where its possible structure is *cis* isomers of the ligands. Some coordination compounds, *i.e.* the stereospecific coordination polymers, between the *cis* isomers and Cu^{2+} ions were found to be produced at the air-water interface by employing the substrate solution containing Cu^{2+} ions. This was established by the surface pressure *vs.* area measurements for their ligand molecules with $C_6H_5CH_2$–, C_6H_{11}–, $C_{12}H_{25}$–, and $C_{12}H_{25}OCOCH_2$– as hydrophobic substituents, and by the effects of various spreading solvents, pH in substrate solutions and temperatures on their monolayers. Furthermore, built-up films of these polymers were examined for thickness.

N,N'-Disubstituted dithiooxamide–Cu(II) complex (R-DTOA-Cu) have been studied as a series of organic or metal-organic semiconductors.[1] In our study the coordination polymers were prepared by "bulk method," that is, a simple mixing of the solutions of the both components. From their chemical compositions and the properties, a two-dimensional polymeric structure has been proposed for the compounds,[2] although a linear chain structure had been proposed before.[3] However, the preparation of R-DTOA–Cu by the "bulk method" might result in the isomeric mixtures called type A because of a rotational isomerism around the central carbon-carbon bond of the ligands themselves (Fig. 1a) and the coordination isomerism in the compounds as a whole (Fig. 2). Actually all of the black precipitates show a few diffused hallows for each compound in their X-ray diffraction patterns by the powder method.[2], The discussions on electric, magnetic, and other properties, which are more or less related to the stereostructure of the molecules, would be restricted because of the isomeric irregularity.[4]

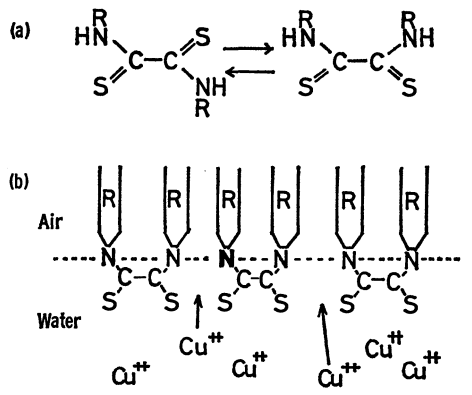

Fig. 1a. Expected rotational isomerism of the ligands.
1b. A schematic mechanism of the stereospecific synthesis of the type B compounds.

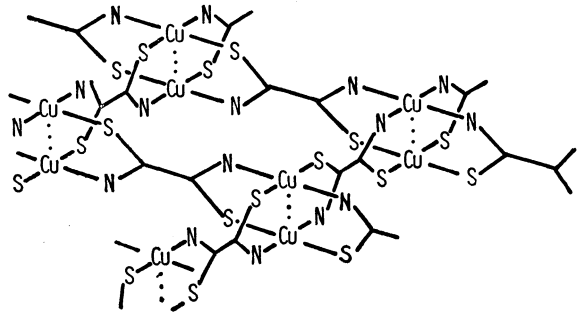

Fig. 2. Non-stereospecific two-dimensional net-work model with dimer structures of copper acetate type. For simplicity, substituents on nitrogen atoms are omitted.

For the solution of the ambiguity, the stereospecific synthesis of the polymers has been attempted by the "monolayer method" in which the ligands with the two hydrophobic substituents on the nitrogen atoms are spread on an aqueous subphase containing cupric ions (Fig. 1b) and the resultant products are called type B. The reaction yields of the type B compounds of $C_6H_5CH_2$–, C_6H_{11}–, and $C_{12}H_{25}$–DTOA-Cu seem to be more or less qualitative.[4],† On the other hand the coordination of a new ligand, dodecyl ester of $HOOCCH_2$-DTOA-H_2, with Cu^{2+} ions at the air/water interface seems to be quantitative as shown in this study, and the monomolecular film is stable. As a result, the molecular structures of the type B compounds are confirmed, and some properties of the coming built-up films might be interpreted in relation to this molecular structure.

† The preliminary study of diffraction patterns by the X-ray powder method and the presumption about the crystallinity mentioned in the previous paper (Ref. 4, pp. 91, 95) need supplemental experiments and more carefull consideration on the data.

Mallinckrodt Chemical Works, and was recrystallized from ethanol. Dodecyl ester of *N,N'*-carboxymethyl dithiooxamide, $C_{12}H_{25}OC(O)CH_2NHC(S)C(S)NHCH_2C(O)OC_{12}H_{25}$, was prepared from dodecyl alcohol and *N,N'*-bis(carboxymethyl)-dithiooxamide in the presence of a acid catalyst, H_2SO_4. The crude ester was recrystallized from acetone, mp 101 °C (uncorrected). Cupric sulfate (Special Grade Reagent, Wako Pure Chemical Industries, Ltd.) was heated for 2 hr at 350 °C in a furnace to diminish the surface active contaminations. The organic solvents (Special Grade, Wako P.C.I., Ltd.) were distilled twice. Water used for the subphase was distilled in a copper distillatory first and in a glass vessel next. Solid substrates, glass and quartz plates, were cleaned by a ultrasonic method with help of detergent followed by a treatment with hot cleaning solution ($Na_2Cr_2O_7$ in concd H_2SO_4). For the purpose of uniform deposition of the complex monolayer, each solid substrate was coated with three monolayers of Fe-stearate under the surface pressure of 29 dyn/cm.

Procedure. About 2 mg of the ligand was dissolved in 10 ml of the binary mixed solvents composed of ethanol, propanol, benzene, or hexane as shown in Figs. 3—6. The solution was spread from an Alfa micrometersyringe on water or aqueous solution in a conventional Langmuir trough ($60\times13.5\times1$ cm^3). The surface pressure (π) was measured by a automatic recording systems as a function of the surface area (A) using the hanging plate method.[5] Unless otherwise specified, the measurements were carried out at a room temperature (15—25 °C). In examining the temperature effects on complex monolayer, the temperature of the subphase was regulated at the selected values in the range of 20 to 5 °C by thermoelectric modules attached at the bottom of the trough.

Complex monolayers were transferred onto a solid substrate by the Langmuir-Blodgett method as follows. The Langmuir trough was divided into three sections for the "transfer method."[6] The ligand solution was spread on an aqueous cupric solution in the first section and was allowed to stand for 30—60 min for the complete coordination reaction. The obtained complex monolayer was transferred to the water surface in the second section for washing the non-reacted Cu^{2+} ions adsorbed beneath the complex monolayer. Furthermore the monolayer was transferred to the third section filled with pure water, where the built-up procedure was carried out. It was made by an automatic equipment with a certain speed. During the procedure, the surface pressure of monolayer was kept constant by the piston oil. The pressure of piston oil was adjusted by changing the mixing ratio of ethylmyristate and liquid paraffin. The conditions for the preparation are shown in Table 1.

Table 1. Conditions of the preparation of the built-up films of R-DTOA-Cu

Results and Discussion

Monolayer. The spread monolayers of the ligands or the complexes on an aqueous subphase were studied in order to find the structure of the molecule at the interface and the optimum conditions for the preparation of built-up films. The mechanisms of spreading of the ligand and of the coordination reactions at an air/water interface are presumed as follows. The molecules of dithiooxamides having both hydrophilic and lipophilic parts would be oriented at the surface by surface free energy, forming a monolayer. Due to internal rotation around the central carbon-carbon bond of the ligand molecule the *trans*-form, which is more stable in crystal and probably in solution,[7] is isomerized to the *cis*-form.

Equilibrium between the *trans*- and the *cis*-form of a ligand molecule at an air/water interface was studied as a first approximation by an equation, $-RT\ln([cis]/[trans]) = -RT\ln K = \Delta F^\circ = \Delta F_1 + \Delta F_2$, where K denotes the equilibrium constant; $\Delta F^\circ = F^\circ(cis) - F^\circ(trans)$, standard free-energy change in the reaction concerned; ΔF_1, the free energy change originated from an internal rotation of the isolated molecules; ΔF_2, that originated from the transfer of a hydrophobic substituent R from the water phase to the air phase. As an example, in case of R = $C_{12}H_{25}$–, the ΔF_1 was evaluated to be +1.5 kcal/mol by the measurement of the temperature variation of absorption intensities in an infrared region.[8] The ΔF_2 per $-CH_2-$ group have been estimated to be −(0.8—0.9) kcal/mol in a linear hydrocarbon chain, therefore, $\Delta F_2 = -(0.8—0.9)\times12 = -10$ kcal/mol.[9] Then the ΔF° is −(8—9) kcal/mol, and $K = [cis]/[trans]$ at the interface is greater than 10^5 approximately. Also in the case of ligands with other hydrophobic substituents, $C_6H_5CH_2$–, C_6H_{11}–, and $C_{12}H_{25}OCOCH_2$–, analogous results are expected. In conclusion virtually all the ligand molecules are expected to take the *cis*-form at the air/water interface.††

Figure 3 shows the π-A isotherms obtained for the monolayers of ligands on distilled water at a room temperature (15—25 °C). The ligands having a pair of long hydrocarbon chains as the substituents, $C_{12}H_{25}$–

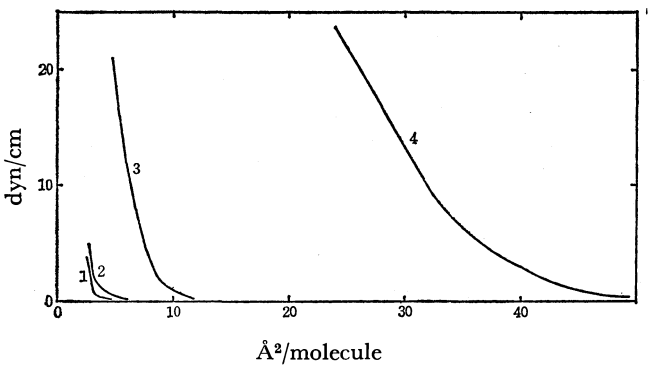

Fig. 3. Surface pressure *vs.* molecular area curves for R-DTOA-H_2 spread on pure water. Substituent, R, and spreading solvent with mixing ratio is as follows: 1) $C_6H_5CH_2$- (benzene 1, ethanol 4), 2) C_6H_{11}- (butanol 1, hexane 4), 3) $C_{12}H_{25}$- (ethanol 4, benzene 1), 4) $C_{12}H_{25}OCOCH_2$- (benzene 1, ethanol 1).

†† The more extensive study on the *cis-trans* isomerization of the ligand molecules are now in progress, and will be published elsewhere.

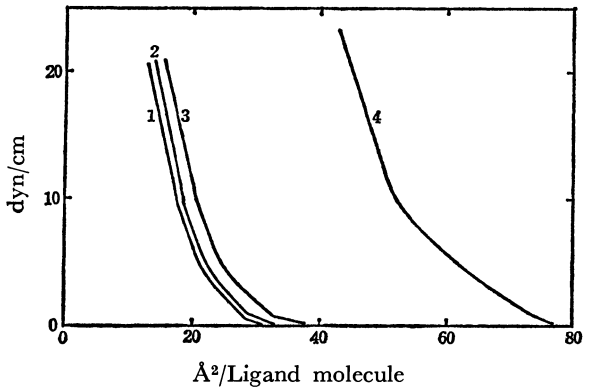

Fig. 4. Surface pressure *vs.* molecular area curves for R-DTOA-H_2 spread on 0.005 M $CuSO_4$ aqueous solution. Substituent, R, and spreading solvent with mixing ratio are as follows: 1) $C_{12}H_{25}$- (buthanol 1, hexane 4), 2) $C_6H_5CH_2$- (buthanol 1, hexane 4), 3) C_6H_{11}- (benzene 1, hexane 4), 4) $C_{12}H_{25}OCOCH_2$- (benzene 2, hexane 3).

or $C_{12}H_{25}OCOCH_2$–DTOA–H_2, form monolayers on water, whereas the others, $C_6H_5CH_2$– and C_6H_{11}–DTOA–H_2, hardly spread over a water surface due to their poor hydrophobicity; the latters might be dissolved in the subphase owing to the fair solubilities of 0.14 and 0.12 g per 100 ml of water at 25 °C, respectively.[10] The limitting areas (A_0) estimated by extrapolation of the surface pressure to zero were 7 and 38 Å²/molecule for $C_{12}H_{25}$– and $C_{12}H_{25}OCOCH_2$–DTOA–H_2, respectively. As the molecule has two hydrophobic substituents on both ends, A_0 values of the ligands should be larger than twice the value of the cross-section of a hydrocarbon linear chain, 20 Å²/chain.[11] Data for the ester is reasonable but that for another is smaller than expected; the small A_0 can be attributed to pile-up of the ligand molecules on water due to the hydrophile-lipophile unbalance and/or the dissolution owing to the solubility of 0.06 g per 100 ml of water at 25 °C.[10]

Figure 4 shows the π-A isotherms of ligands spread on 5×10^{-3} M $CuSO_4$ aqueous solutions. In this case, $C_6H_5CH_2$– and C_6H_{11}–DTOA–H_2 exhibit detectable surface pressures due to a decrease in solubility with formation of a copper compound. The complexes of the type A of these two ligands are insoluble in water though the two ligands are slightly soluble in water as mentioned previously. The A_0 values were evaluated as 25, 22, 22, and 56 A²/molecule for C_6H_{11}–, $C_6H_5CH_2$–, $C_{12}H_{25}$–, and $C_{12}H_{25}OCOCH_2$–DTOA–Cu, respectively. The former three values are smaller than that expected.

To obtain the conditions giving a reasonable limitting area, the concentration of Cu^{2+} ion, the compression speed, the spreading solvents, and the pH of the subphase were examined.††† As an example, the changes in the π-A isotherms of C_6H_{11}–DTOA–Cu complex are shown in Fig. 5a, b, c, d. In Fig. 5a, the π-A isotherms are shown as a function of Cu^{2+} ion concentration from 5×10^{-5} to 5×10^{-2} M. On the subphases of extreme cupric ion concentrations, 5×10^{-5} and 5×10^{-2} M, the results showed poor reproducibility and were found in ranges shown by the pairs of dashed and dotted lines. On the moderate concentrations, 5×10^{-4} and 5×10^{-3} M, reproducible π-A curves were obtained for both concentrations. The π-A curves observed with the various compression speeds are shown in Fig. 5b. The selected speeds were in a range of 0.33—2 cm/min (0.11—0.67 Å²/molecule·min). The A_0 did not remarkably depend on the compression speed except for the highest one, 2 cm/min.

The mixtures of benzene–hexane, chloroform–hexane, 1-pentanol–heptane, 2-pentanol–heptane, or propanol–hexane were used as the spreading solvent, the mixing ratios were 1 : 4 by volume in most cases, and the results are shown in Fig. 5c. The character of the π-A curves was not changed essentially and only displacements of the π-A curves were observed. The effect of pH of subphases was examined by adjusting pH to the values from 2.9 to 10.2 with use of hydrochloric acid or sodium hydroxide. The results found on 5×10^{-3} M $CuSO_4$ aqueous solution are shown in Fig. 5d. In the acid region, the π-A relation was not remarkably affected by the pH, whereas in the alkali region A_0 was decreased with increasing pH. The effect of pH may be attributed to the decreasing concentrations of hydrated cupric

ions, $Cu(H_2O)_{4-6}^{2+}$, as Stickland discussed.[12]

The presented results so far for the monolayer of C_6H_{11}–DTOA–Cu indicate that the limitting area was rather small, in the range of 15 to 29 Å²/molecule. Even 30 Å²/molecule is still smaller than that expected for two hydrophobic substituents on the ligand molecule in the *cis*-form. This phenomenon could be caused from the dissolution of unreacting ligand molecules into water or the stacking of the copper complex which might be too hydrophobic to form a monomolecular film. A similar reasoning may be applicable to the monolayers of $C_6H_5CH_2$– and $C_{12}H_{25}$–DTOA–Cu complexes. The A_0's for $C_{12}H_{25}OCOCH_2$–DTOA–H_2 on pure water and on the cupric aqueous solution, 38 and 56 Å²/molecule, respectively, were reproducible, and the former is reasonably related to twice the limitting area of single chain fatty acids, therefore the quantitative formation of monolayer of the ester ligand in the *cis*-form was confirmed.

The effect of temperature on the π-A curves of $C_{12}H_{25}OCOCH_2$–DTOA–Cu on a 5×10^{-3} M $CuSO_4$ solution is shown in Fig. 6.‡ By the measurements at lower temperature, 5 and 10 °C, two kinds of limiting areas, A_0^α and A_0^β in a larger (α) and a smaller (β) area region as shown in Fig. 6, were obtained. At a higher temperature A_0^α was not established clearly

‡ This operation was done mainly by Mr. Emoto.

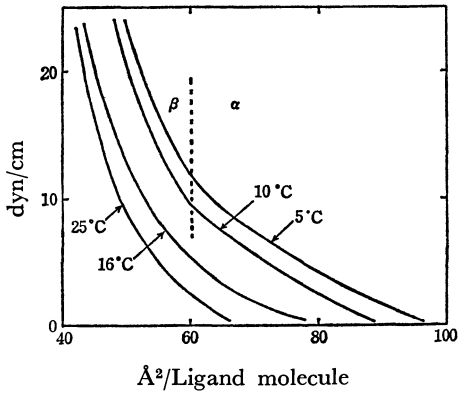

Fig. 6. The effect of temperature on π *vs.* A relation for $C_{12}H_{25}OCOCH_2$–DTOA–Cu on 5×10^{-3} M $CuSO_4$. Spreading solvent: benzene 2, hexane 3.

because of the disappearance of the α-region of the curves; the α-region might be attributed to the formation of the island structure. The A_0^β at each temperature were evaluated as follows: 52 Å² (25 °C), 56 Å² (16 °C), 60 Å² (10 °C), 64 Å² (5 °C). Contrary to the general relation between A and T, the A_0^β decreases with an increase in temperature. This unusual tendency can be explained by the slower dissolution of the unreacted ligand molecule at a lower temperature into the aqueous phase before the completion of the coordination reaction with cupric ions at a water surface. This implies that the dissolution of the ligand, even in such a slightly soluble one, should be responsible for the smaller apparent A_0 than the true value, and the same should be more probable for the more soluble other ligands. The true value of the limiting area for the ester ligand complex presumed experimentally by extrapolation might be about 65 Å² or more; this value is acceptable one if all the ligand molecules added on the water surface are assumed to exist there as the *cis* isomer and combine with cupric ions in a certain manner.

In the previous paper[4] we proposed the 'copper-acetate' type model which was a two-dimensional network for the compounds obtained by both the "bulk" and "monolayer" methods, namely the type A and B compounds. However this model is now obviously catastrophic as a model for the type B compounds by the following reasons: 1) by the calculation from the bond lengths it is concluded that this model requires only 30 Å² at most for a R–DTOA–Cu structure unit, but it is much smaller than above mentioned 65 Å², 2) 30 Å² for this model does not satisfy a condition to accomodate two hydrocarbon chains which is required in the B compounds, though the requirement is not needed in the A compounds. For the solution to the difficulty, a new model, named 'improved' model shown in Fig. 7, is proposed, and in this case a calculated area per R–DTOA–Cu unit is 60—70 Å² which agrees nicely with the observed limitting area for $C_{12}H_{25}OCOCH_2$–DTOA–Cu compound. For the type B compounds with other substituents R, we are not able to derive a suitable model from their small limitting areas experimentally obtained (22—25 Å²), however the 'improved' model

Unevenness of its plane is indicated by a arrowhead affixed to a nitrogen atom.

can be also adopted to them with a certain confidence.

Built-up films. The complex monolayer was transferred from the water surface to the solid substrate by repeated dipping and withdrawing processes, the Langmuir and Blodgett method.[13] The coating of glass or quartz slides with Fe-stearate monolayers was effective for the tight fixation of the complex monolayers.

The uniform built-up films of Y type[13] of $C_{12}H_{25}$-$OCOCH_2$–DTOA–Cu complex were obtained but the other complexes, C_6H_{11}–, $C_6H_5CH_2$–, and $C_{12}H_{25}$–DTOA–Cu, were not uniformly transferred on to the solid substrates. With latters, defects in the surface of the multilayers were often appeared and could not be recovered.

The optical density of $C_{12}H_{25}OCOCH_2$–DTOA–Cu multilayers on quartz plates was measured in the visible and the ultraviolet region. The optical density was linearly increased with the number of films transferred. It means that transfer ratio from the water surface is the same for each monolayer. The absorption maximum was observed at 380 nm for $C_{12}H_{25}OCOCH_2$–DTOA–Cu compound.

The thickness of the built-up films estimated by observing the colors by reflected skylight is listed in Table 2. The relationship between the wavelength, λ, and the thickness of film, d, is given by an equation for an interface:

$$4d(n_2^2 - n_1^2 \sin^2\beta)^{1/2} = (2m-1)\lambda$$

where n_1 and n_2 are the refractive indexes of films and air, respectively, β is the incident angle measured and m is an integer.[14] The refractive index of the films was assumed to be $n_1=1.5$. The estimated value of thickness of a layer is reasonably explained by considering the molecular model of the compound.

Table 2. The thickness of a layer of $C_{12}H_{25}OCOCH_2$–DTOA–Cu estimated from the colors of reflection from the built-up films

Number of layers	Color	Thickness of a layer (Å)
40	yellow	22.3
50	reddish yellow	19.3
62	violet	20.5
72	green	21.7

The electric resistance of the built-up films was measured and will be published elsewhere.

Part of this research was supported by a Grant-in-aid for Scientific Research from the Ministry of Education. The dithiooxamides were donated by the Mallinckrodt Chemical Works, for which we express our appreciation.

^{13}C Nuclear Magnetic Resonance Studies of the Hindered Internal Rotation and the Molecular Association of *N,N*-Dimethylacetamide

Isao ANDO, Naomi JINNO, and Atsuo NISHIOKA

Department of Polymer Chemistry, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received February 12, 1975)

The concentration and temperature dependences of the ^{13}C chemical shifts of *N,N*-dimethylacetamide (DMA) in CCl_4, H_2O, and H_2SO_4 solutions were measured by means of a ^{13}C FT-NMR spectrometer at 25.15 MHz. From the temperature dependence of the chemical-shift difference between the *cis*- and *trans*-NCH_3 carbons, the activation energy, E_a, for the hindered internal rotation about the C–N bond was obtained to be 10—17.5 kcal/mol; it was also found to be *ca.* 10 kcal/mol at an infinite dilution in a CCl_4 solution. The chemical shift of each carbon in the DMA molecule was calculated using Pople's expression under the average excitation-energy approximation by means of the CNDO/2 method. The calculated finding that each carbon in DMA appears in the order of carbonyl, *trans*-NCH_3, *cis*-NCH_3, and acetyl carbons from the low field agrees with the order assigned by McFarlane. Further, as for the molecular association in neat liquid, various models are discussed on the basis of quantum-chemical calculations, and a model is proposed which has antiparallel oriented carbonyl groups in associated states of the molecules of more than two. The observed differences between the chemical shifts of the carbonyl carbons at dilutions in CCl_4 and H_2O solutions, and between those in CCl_4 and H_2SO_4 solutions, are found to agree well with the results calculated using the model in which the DMA molecules at dilutions in CCl_4, H_2O, and H_2SO_4 exist as monomer, hydrogen-bonded DMA with H_2O, and protonated DMA respectively.

Since the first NMR study of the hindered internal rotation of the C–N bond in amide compounds was carried out by Gutowsky *et al.*,[1] many studies have been concerned with the activation energy, E_a, for the hindered internal rotation and the molecular association[2] of amide compounds through the proton chemical shift, the line shape, and the spin-lattice relaxation time. Recently a quantum-chemical study of the hindered internal rotation has been done,[3] and some interesting results have been obtained. However, the mechanisms of the molecular association have scarcely been studied at all theoretically from the viewpoint of the chemical shift, even though this approach is very interesting. From the viewpoint of the chemical shift, the proton-decoupled carbon-13 (^{13}C) NMR spectra have greater advantages than ^1H NMR because of their simplicity. In addition, the ^{13}C chemical shift can be treated theoretically by the molecular orbital method, and the observed and calculated ^{13}C chemical shifts can be compared quantitatively with each other. Therefore, these results may be of use in obtaining information on the molecular association mechanism. In this paper, we will seek to compare the observed and calculated chemical shifts of the *N,N*-dimethylacetamide (DMA) molecule, which does not form a hydrogen bond itself and which may be a much-favored dipolar model. We will be concerned with the amide-amide associate, the hydrogen-bonded amide, and the protonated amide, which correspond to the behavior in neat liquid, H_2O, and H_2SO_4 solutions respectively, and with the monomer amide, which corresponds to the behavior at an infinite dilution in CCl_4.

Experimental

Materials. The DMA, CCl_4, and H_2SO_4 were obtained from the Tokyo Kasei Co., while the H_2O was distilled.

Measurements. High-resolution natural-abundance pulsed ^{13}C FT-NMR spectra were obtained at 25.15 MHz using a Japan Electron Optics Laboratory JNM PS-100 spectrometer equipped with the PFT-100 Fourier transform system, a JEC-6 spectrum computer, a ^2D field-frequency lock, and a noise-modulated proton-decoupling system. The core memory of the computer is 12K words, and the memory of the magnetic drum used is 8K words. The length of each word is 16 bits. The observed free induction decay (FID) was sampled in 8192 points. The pulse-recycle time was chosen as 60 s, considering the *N*-methyl carbon spin-lattice relaxation time, T_1, of 14 s. However, when only the measurement of the chemical shift was required, the recycle time of 30 s was used. The FID signal was observed after a 90° pulse with a width of 20 μs.

The activation energy for the hindered internal rotation was estimated for the N–CH_3 carbon signals by the peak-separation method.[1] The temperature range of the measurements was 22.5—100 °C. The concentration range of the solution measured was 2—100%. An accumulation of 20 or 500 scans was necessary for a 100 or 2% solution respectively, but when the NCH_3 carbon signals become broad at 60 °C, the accumulations were about 2—3 times greater.

Theoretical Calculation

The magnetic shielding constant, σ_A, of any specified carbon atom, A, in a molecule can be approximately estimated by means of the sum of the following diamagnetic and paramagnetic terms:[4]

$$\sigma_A = \sigma_A^{dia} + \sigma_A^{para} \quad (1)$$

where σ_A^{dia} and σ_A^{para} are the diamagnetic and paramagnetic contributions respectively.

The approximate value of σ_A^{dia} is given as:[6]

$$\sigma_A^{dia} = 4.45\,Z^*q \quad (2)$$

where:

$$Z^* = 3.25 - 0.35\,(q-4) \quad (3)$$

in which q is the total electron density around the carbon atom, and Z^*, the "effective nuclear charge" estimated according to Slater's rule.

The paramagnetic term is estimated according to Pople's theory,[4] with the average excitation-energy (ΔE) approximation as follows:

$$\sigma_A^{para} = -(e^2\hbar^2/2m^2c^2\Delta E)\ \langle r^{-3}\rangle_{2p} \sum_{B(=A)} Q_{AB} \quad (4)$$

where:

$$Q_{AB} = \frac{4}{3}\delta_{AB}(P_{x_Ax_B}+P_{y_Ay_B}+P_{z_Az_B}) - \frac{2}{3}(P_{y_Ay_B}P_{z_Az_B}+P_{z_Az_B}P_{x_Ax_B}+P_{x_Ax_B}P_{y_Ay_B}) + \frac{2}{3}(P_{y_Az_B}P_{z_Ay_B}+P_{z_Ax_B}P_{x_Az_B}+P_{x_Ay_B}P_{y_Ax_B})$$

$$\langle r^{-3}\rangle_{2p} = \frac{1}{24a_0^3}(3.25-0.35(q-4))^3 \quad (6)$$

In these formulae, $\sum_{B(=A)}$ is a summation over all the atoms; $\langle r^{-3}\rangle_{2p}$; δ_{AB}, the Kronecker symbol; a_0, the Bohr radius, and $P_{x_Ax_B}$, the element of the bond-order matrix for the $2p_x$ atomic orbitals on the A and B atoms.

σ_A^{dia} and σ_A^{para} were estimated by the CNDO/2 method.[5] The bond lengths and bond angles used in a DMA molecule are shown in Table 1.

Table 1. The used bond lengths and bond angles of *N,N*-dimethylacetamide[a]

Bond lengths (Å)		Bond angles (°)	
C-C	1.54	C-C-H	109.5
C-N	1.32	N-C-H	109.5
C=O	1.24	C-C=O	120
C-H	1.09	N-C=O	120
		C-N-C	127

a) All the data were taken from standard bond lengths and bond angles in Ref. 5 except that the bond angles of C-C=O, N-C=O and C-N-C were taken from Ref. 7.

Results and Discussion

CCl_4 Solution. Concentration Dependence: Each carbon signal in the ^{13}C NMR spectrum of DMA in the CCl_4 solution appears in the order of carbonyl, *trans*-NCH_3, *cis*-NCH_3, and acetyl carbons from the low field, based on the assignment by McFarlane[8], where their positions appear at −73.90, 59.58, 62.67 and 66.26 ppm respectively (relative to CCl_4) in a 20% v/v CCl_4 solution at 30 °C. His assignment agrees with the calculated results for each carbon in the molecule, as will be described below.

Next, let us discuss the concentration dependence of the chemical shift for each carbon. The concentration dependences of the carbonyl carbon at 30, 60, and 80 °C are shown in Fig. 1. This carbon shows a considerable concentration dependence and shifts to a low field with an increase in the concentration of DMA. The chemical-shift change from an infinite dilution to an 80% solution is about 1.5 ppm. On the other hand, the concentration dependences of the chemical shifts for the other carbons are small, as is shown in Fig. 2. These concentration dependences do not show any large change upon a variation in the temperature except for the $COCH_3$ carbon. Further, the chemical-shift difference between the *trans*- and *cis*-NCH_3 carbons is found to increase by

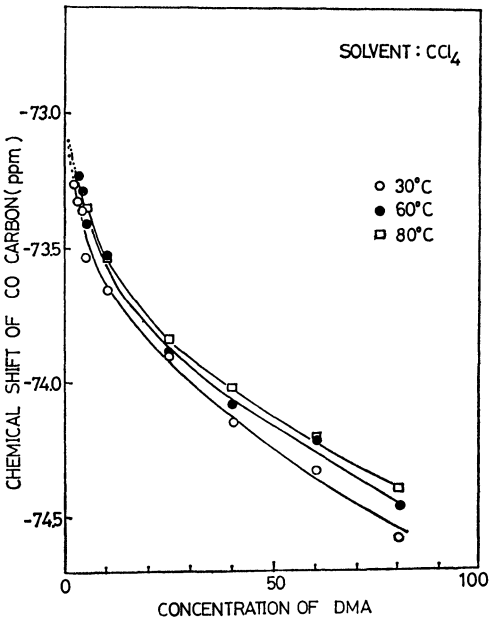

Fig. 1. Concentration dependence of the ^{13}C chemical shift of carbonyl carbon in CCl_4 solution.

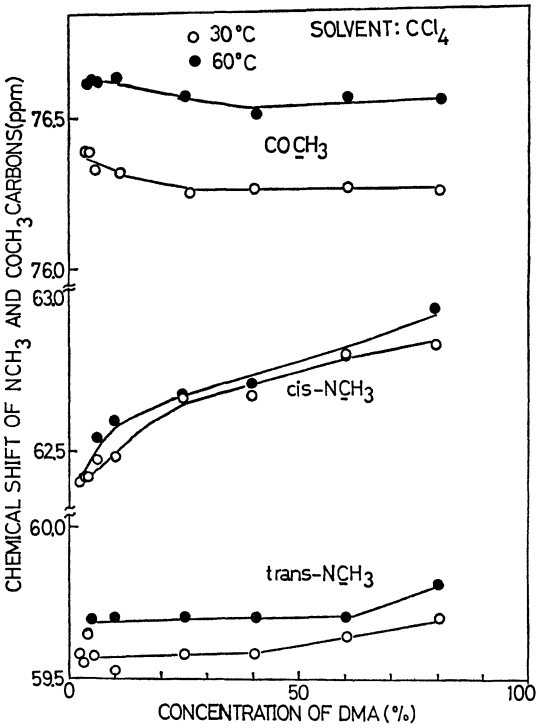

Fig. 2. Concentration dependence of the ^{13}C chemical shifts of *trans*-NCH_3 and acetyl carbons in CCl_4 solution.

about 0.3 ppm with the variation in the concentration from a 2% solution to neat liquid with an increase in the concentration, as is shown in Fig. 3. This indicates that the value of E_a increases with an increase in the concentration of DMA. A rapid increase within the range from zero to 20% corresponds well to the rapid decrease in the carbonyl carbon's shift, which suggests that the solution structure changes rapidly in this concentration range and that it may be

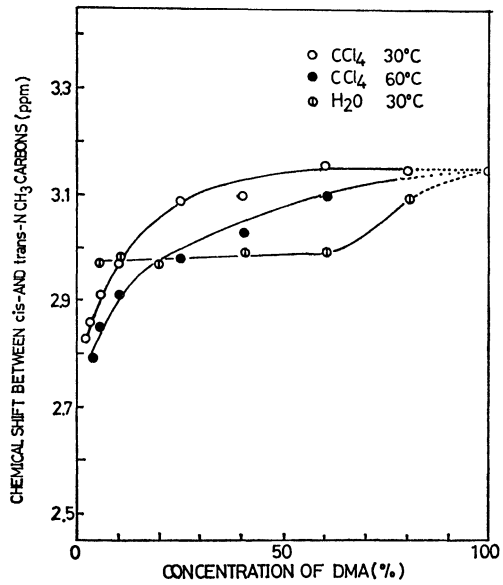

Fig. 3. Concentration dependence of the ^{13}C chemical shifts of *cis*-NCH_3 and *trans*-NCH_3 carbons in CCl_4 and H_2O solution.

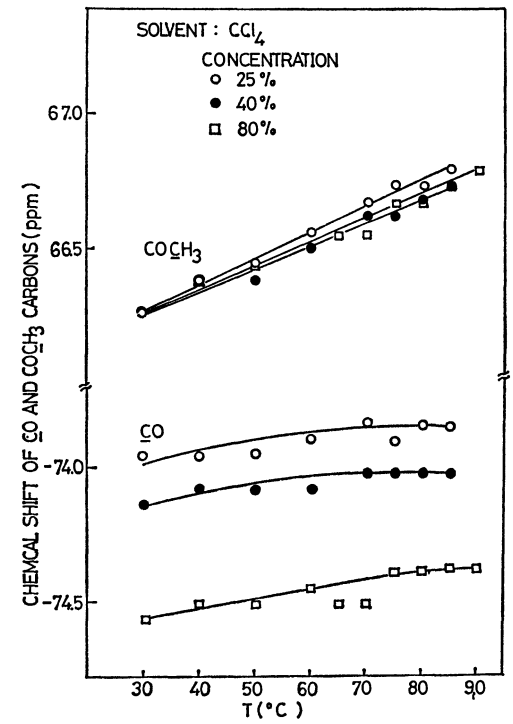

Fig. 4. Temperature dependence of the ^{13}C chemical shifts of carbonyl and acetyl carbons in CCl_4 solution.

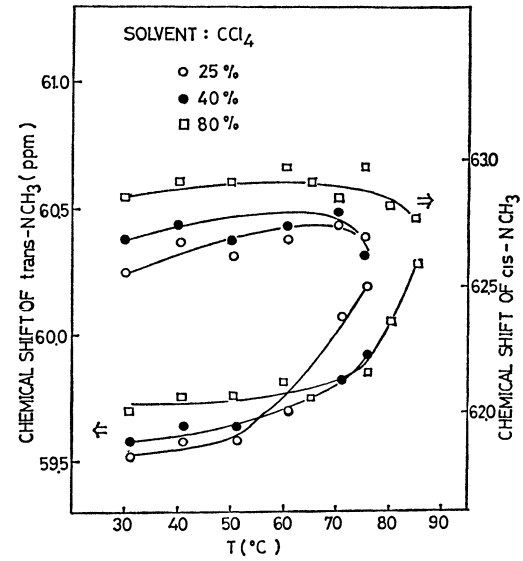

Fig. 5. Temperature dependence of the ^{13}C chemical shifts of *cis*-NCH_3 and *trans*-NCH_3 carbons in CCl_4 solution.

qualitatively interpreted in terms of an association model as well as the results of a similar study by means of ^{1}H NMR.[2h] Also, Sato *et al.*[21] have reported that the slopes of linear plots of the ^{1}H relaxation rate, $1/T_1$, against the concentration differ considerably from each other on both sides of concentration of about 3 mol/l, which corresponds to the above-mentioned concentration; these slopes have been qualitatively interpreted in terms of association.

Rabinovitz *et al.*[2h] have reported regarding the change in the ^{1}H chemical shift observed with the concentration of *N,N*-dimethylformamide in CCl_4 that a more satisfactory explanation lies in the contribution of the direct dimer shielding described in a monomer-dimer equilibrium. Therefore, it is considered that, in the monomer-dimer equilibrium, the monomer state increases with a decrease in the concentration. It is likely that the behavior of DMA in the CCl_4 solution may be described as in a monomer-dimer equilibrium. Thus, the value extrapolated using the data of low concentrations (we define this the value at an infinite dilution) may correspond to the value in a monomer state. The chemical-shift difference between the *trans*- and *cis*-NCH_3 carbons at an infinite dilution is obtained to be about 2.75 ppm, but it may possibly give a somewhat larger value than the true value at an infinite dilution because the present experiment was not done below the concentration of 2%. This value is used to compare with the calculated value.

Temperature Dependence: Next, the temperature dependences of each group in DMA at various concentrations are discussed in the temperature range from 30 to 90 °C. First, the results of the carbonyl and acetyl carbons are shown in Fig. 4. The carbonyl carbon shifts slightly by *ca.* 0.1 ppm at a high field with an increase in the temperature from 30 to 90 °C, whereas the acetyl carbon shifts linearly by *ca.* 0.5 ppm at a high field with an increase in the temperature. The former changes are smaller than those caused by the concentration. Thus, it may be predicted that the influence of the association caused by the variation in the concentration is larger than that caused by the variation in the temperature. As is shown in Fig. 5, the temperature dependence of the *cis*-NCH_3 carbon is slight, but that of the *trans*-NCH_3 carbon shifts greatly at a high field above 50 °C. Therefore, the chemical-shift difference between the two carbons decreases considerably at high temperatures. This is due to the internal rotation about the C–N bond in DMA.

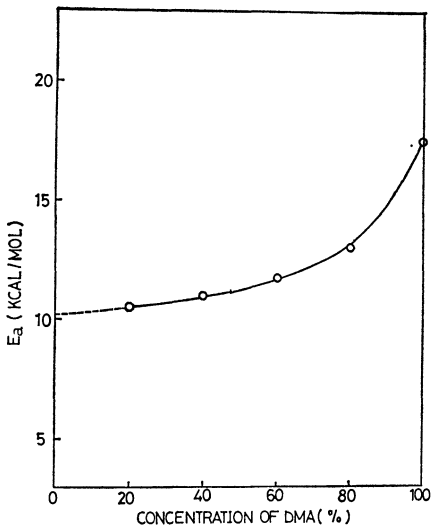

Fig. 6. Concentration dependence of activation energy E_a for the hindered internal rotation about the C–N bond in CCl_4 solution.

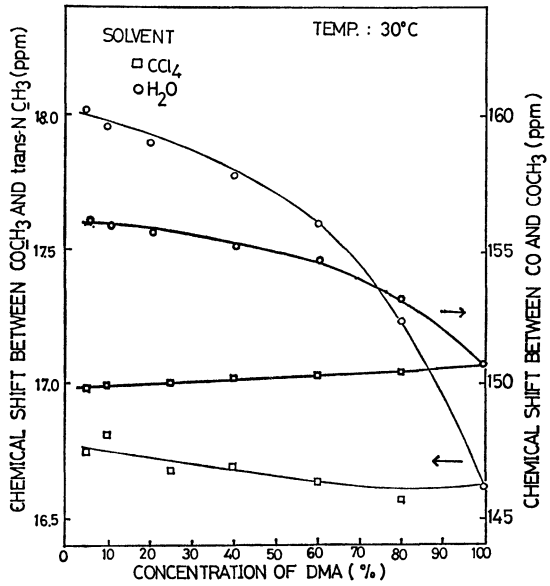

Fig. 7. Concentration dependence of the ^{13}C chemical-shift differences between carbonyl and acetyl carbons, and between *trans*-NCH_3 and acetyl carbons in CCl_4 and H_2O solutions.

From these data, the activation energies of the hindered internal rotation about the C–N bond at various contributions were obtained; they are shown in Fig. 6. The value in a neat liquid was obtained 17.5 kcal/mol, which agrees well with the value of 18.1 kcal/mol obtained from the study of ^1H NMR by Newman *et al.*[2d] Further, the value at an infinite dilution in CCl_4 is given as about 10 kcal/mol. The larger value of E_a in a neat liquid than in the CCl_4 solution may be qualitatively interpreted in terms of the association.

H_2O Solution. Concentration Dependence: The concentration dependence of the chemical-shift difference between the carbonyl and acetyl carbons in H_2O solution was found to be larger than in the CCl_4 solution, as is shown in Fig. 7. This may mainly be due to the existence of the hydrogen bond in the case of the former, while the latter case has no such bond. At an infinite dilution the difference between the two cases is about 6 ppm. On the other hand, the chemical-shift difference between the acetyl and *trans*-NCH_3 carbons in the H_2O solution was found to decrease rapidly, contrary to the case in the CCl_4 solution, as is shown in Fig. 7. Remembering that the chemical shift of the NCH_3 carbon depends hardly at all upon the concentration, this tendency shows that the acetyl carbon shifts to a low field through the formation of a hydrogen bond in an aqueous solution. At an infinite dilution in CCl_4 and H_2O solutions, the difference between the two values becomes about 1.2 ppm; this may be due to an indirect interaction through the formation of a hydrogen bond between the carbonyl group and H_2O. It is well-known that the carbonyl carbon shifts to a low field as a result of the formation of a hydrogen bond; the results shown in Fig. 7 are consistent with this.

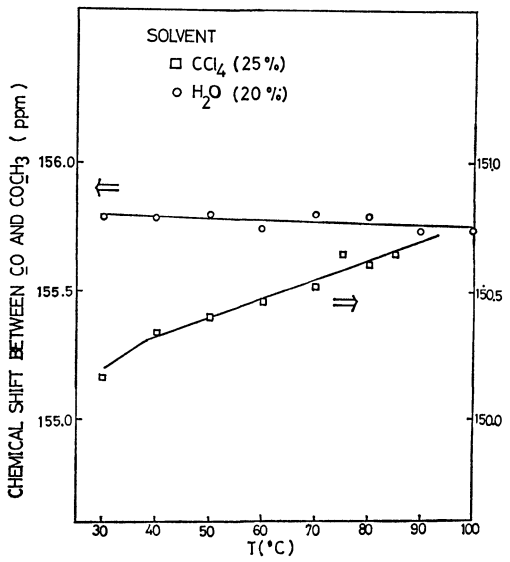

Fig. 8. Temperature dependence of the ^{13}C chemical-shift difference between carbonyl and acetyl carbons in CCl_4 and H_2O solution.

Temperature Dependence: The results of the temperature dependence of each carbon in this system are shown in Figs. 8 and 9. As may be seen from Fig. 8, the chemical-shift difference between the acetyl and carbonyl carbons in an aqueous solution is almost constant from 30 to 100°C, contrary to the case of the CCl_4 solution. This shows that probably the hydrogen bond with the H_2O molecule is stronger than the interaction between the DMA molecules and is more stable in this range of temperatures. Figure 9 shows the temperature dependence of the chemical-shift difference between the *trans*- and *cis*-NCH_3 carbons at various concentrations in an aqueous solution. These chemical-shift differences decrease with a decrease in the concentration below 60 °C. The hydrogen bonds between DMA and H_2O molecules are formed at low concentrations with the internal rotation about the C–N bond, being somewhat hindered, but at higher

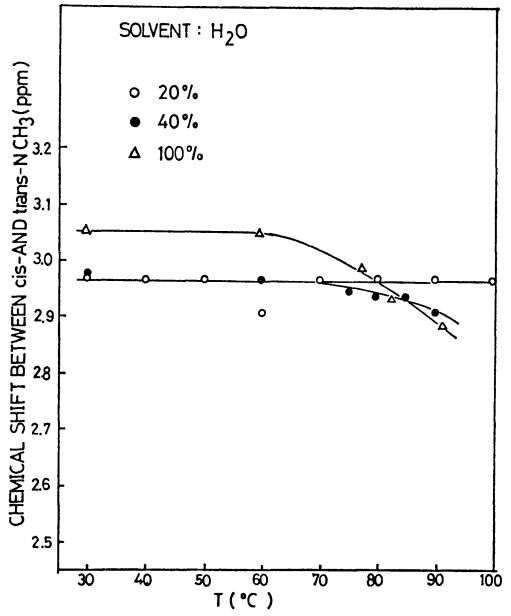

Fig. 9. Temperature dependence of the ^{13}C chemical-shift difference between *cis*-NCH_3 and *trans*-NCH_3 carbons in H_2O solution.

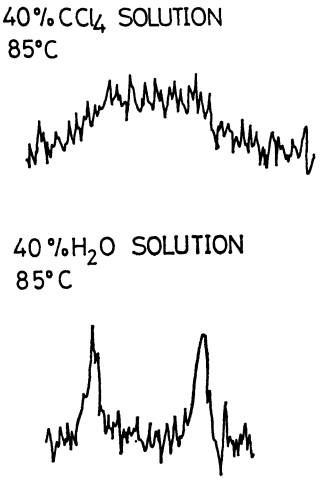

Fig. 10. ^{13}C NMR signals of NCH_3 carbons in CCl_4 and H_2O solution.

concentrations the interaction among DMA molecules becomes effective and, therefore, the rotation about the C–N bond becomes more hindered than in aqueous solutions of low concentrations. Generally, the hydrogen bond may be stronger than the interaction among the DMA molecules. The N–CH_3 carbon signals at 85 °C in 40% CCl_4 and H_2O solutions are shown in Fig. 10. From this it is clear that the rotation about the C–N bond in the H_2O solution is more hindered than in the case of the CCl_4 solution at the same concentration.

H_2SO_4 Solution. Concentration Dependence: The concentration dependence of the chemical shifts of each carbon in DMA is shown in Fig. 11. It is found particularly that the dependence of the carbonyl carbon is somewhat larger than that of the other carbons and that the carbonyl carbon shifts to a low field with a decrease in the concentration. This

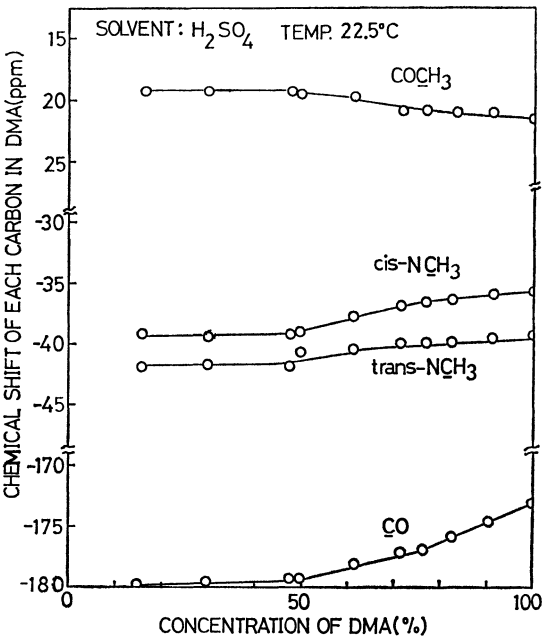

Fig. 11. Concentration dependence of the ^{13}C chemical-shifts of each carbon of *N,N*-dimethylacetamide in H_2SO_4 solution (relative to TMS).

may be due to the formation of protonated DMA molecules at the site of the carbonyl group in the H_2SO_4 solution. Further, the dependence of the *cis*-NCH_3 carbon slightly greater than that of the *trans*-NCH_3 carbon, and these carbons shift to a low field with a decrease in the concentration, contrary to the behavior of the acetyl carbon. These tendencies differ considerably from those of the aqueous solution. Therefore, it may be suggested that the influence of the protonation on the electronic state of DMA differs from that in the case of the hydrogen bond. (This tendency appears in the calculated electron-density distribution, as will be described below.)

Next, the concentration dependence of the nuclear Overhauser enhancement (NOE)[9] of the intensity of

Table 2. Concentration dependence of the enhancement of the carbonyl carbon due to ^1H decoupling in H_2SO_4 solution at 25 °C

trans-$N\underline{C}H_3$	56.26	−408.47	−352.21
$\underline{C}O$	54.77	−537.73	−480.96

The used value of average excitation energy is 5.69 eV.

the carbonyl carbon signal by the ^1H decoupling is shown in Table 2 to facilitate further study of the nature of the protonation. The enhancement increases rapidly in a 50% solution and the enhancement becomes constant. It may be considered that, when the ratio of the number of DMA's to that of protons is 1 : 1, the enhancement is at its maximum, and that even in high concentrations of H_2SO_4 the full protonation is maintained.

The observed behavior of DMA molecules in various solutions has been described above. We will now discuss this behavior theoretically.

Theoretical Considerations. We have described in a section that the DMA molecule at an infinite dilution in the CCl_4 solution can be considered as in a monomeric state. First, let us discuss this. The results of the calculated chemical shifts as a monomer DMA molecule are shown in Table 3, where, as the average excitation energy, ΔE, the value of 5.69 eV (maximum absorption of amide[10]; 208 nm) obtained by ultraviolet absorption spectroscopy, is adopted. The chemical shift of each carbon is found to be dominated mainly by the paramagnetic term. Each carbon appears in the order of acetyl, *cis*-NCH_3, *trans*-NCH_3, and carbonyl carbons; this order coincides with that of the experimental results. Also, the quantitative agreement between the two sets of results is good. Thus, the present results support McFarlane's statement that the ^{13}C resonance of the methyl group *cis* to the carbonyl group is at a higher field than that which is *trans*. As for these carbons, the observed and calculated chemical-shift differences between the two carbons are 3.09 ppm and 5.32 ppm respectively. Although the latter gives a somewhat larger value than the former, it seems natural to consider the chemical-shift difference between *trans*- and *cis*-NCH_3 carbons as being due to the contribution of the paramagnetic term; this is contrary to McFarlane's suggestion[8] that the principal contribution to this difference arises from an intramolecular electric field due to the carbonyl group.

In the neat liquid the DMA molecule has been suggested, on the basis of experimental results, to exist as the self-association state. We will now proceed to discuss its association based on the quantum-chemical calculation of the conformational energy and the ^{13}C chemical shift, and the experimental data. As has been described in the introduction, several models for the self-association of DMA molecules are possible. In Fig. 12 some models are shown, where (a) is the model of the cyclic structure proposed by Woodbrey

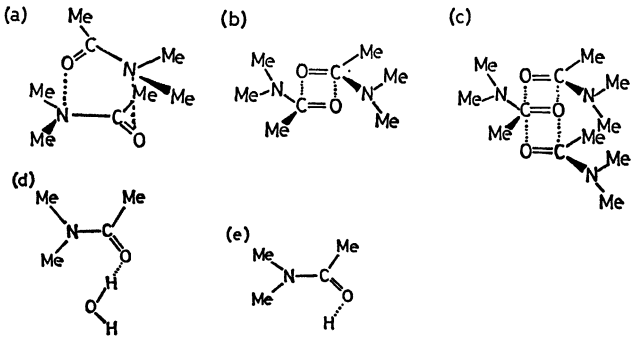

Fig. 12. Some association models (a), (b), (c), and Hydrogen-bonded (d) and protonated (e) DMA models.

et al.[2c] and Newman *et al.*,[2d] and where (b) and (c) are the dimer and trimer of an antiparallel orientation respectively, extending Saito's[12] model proposed for the acetone molecule, *etc.* to the case of the DMA molecule. For these models, the total energies were calculated by the CNDO/2 method; the results are shown in Table 4. The dimerization model (a) becomes unstable, but the (b) and (c) models become stable. The (a) model is unstable by 1.8 kcal/mol (the distance between the N and O atoms is 3 Å). The stabilization energies for the (b) and (c) models are 2.8 and 5.11 kcal/mol respectively (the distance between the C and O atoms is 3 Å). Thus, as the form of the association the (b) and (c) models may be suggested to be more appropriate than the (a) model. The total electron-density distributions of the monomer, dimer, and trimer models are shown in Table 5. As is shown in the (a) model, both N and O atoms have negative charges; therefore, this model may become unstable as a result of the electrostatic repulsion between these atoms. In the (b) and (c) models, however, the C and O atoms have positive and negative charges respectively; therefore, these models become stable as a result of electrostatic attraction between the atoms. As for the (b) model, the dependences of the total energy and the stabilization energy on the distance between the C and O atoms were calculated; the results are shown in Table 6, where the distances of 2.5,3 and 3.5 Å were used. In all of these distances, the formation of dimerization is stable; the stabilization energy at 3 Å is the largest, 2.8 kcal/mol.

Table 4. Total energies of various models in *N,N*-dimethylacetamide calculated by CNDO/2 method

These models correspond to those shown in Fig. 12. The terms "Central" and "External" correspond to the central and external *N,N*-dimethylacetamides in trimer.
a) The distance between N and O atoms is 3 Å. b), c) The distance between C and O atoms is 3 Å. d) H_7, H_{10}, and H_{13} are *trans* position relative to OC–N bond respectively.

TABLE 6. DEPENDENCE OF TOTAL ENERGY OF DIMER (b) AND TRIMER (c) MODELS IN *N,N*-DIMETHYLACETAMIDE ON DISTANCE BETWEEN C AND O ATOMS CALCULATED BY CNDO/2 METHOD

	Distance (Å)		
	2.5	3.0	3.5
Dimer			
Total energy (eV)	−3552.6799	−3552.7256	−3552.6402
Stabilization energy (kcal/mol)	−1.57	−2.82	−0.49
Trimer			
Total energy (eV)	−5329.0162	−5329.1213	−5328.9616
Stabilization energy (kcal/mol)	−2.26	−5.11	−0.53

Next, let us consider the trimer model. The dependences of the total energies and stabilization energies upon the distance between the DMA molecules at trimeric state are shown in Table 6. Just as in the case of the dimer model, the formation of the trimer is stable, and the stabilization energy at 3 Å becomes the largest value, 5.11 kcal/mol, twice the value in the dimer model. It may be suggested that the DMA molecules in a neat liquid are preferable polymerized in the antiparallel oriented form.

In order to obtain more detailed information about the associated form, let us consider the dipole moment briefly. The dipole moments calculated for various models are shown in Table 7, together with the observed results. The calculated values of the monomer and the (c) model agree well with the observed value. The (a) and (b) models have no dipole moment. Thus, in the odd *n*-mer model it is clear that the *n*-mer has a definite dipole moment. The experimental results cannot be interpreted by the dimer model; therefore, an equilibrium among the various *n*-mers, including the monomer, must exist in the neat liquid or the CCl_4 solution at high concentrations.

Next, let us discuss the value of *n* in terms of the stabilization energy. The results in Fig. 6 show that the energy difference between the hindered rotational energies at an infinite dilution in the CCl_4 solution and in the neat liquid is about 7.5 kcal/mol; this difference may be considered to be the energy due to the change from monomer to *n*-mer. As is shown in Table 6, the stacking between the DMA molecules corresponds to a stabilization energy of about 2—2.5 kcal/mol, one third of the value of 7.5 kcal/mol obtained above. Therefore, the value of *n* is about 4. Accordingly, the DMA molecule may be supposed roughly to exist in a tetramer in the neat liquid, though this is not conclusive.

Further, let us discuss the chemical shift as a continuation of the above description of the chemical shift of the monomer DMA molecule. First, we will treat the concentration dependence of the chemical shift in the CCl_4 solution on the basis of the theoretical results. As is shown in Fig. 1, the chemical shift of the carbonyl carbon shifts to a lower field with an increase in the concentration and shifts about 1.5 ppm in the range from an infinite dilution to a neat liquid. The calculated chemical shift, σ_t, of the carbonyl carbon of the monomer, which corresponds to the molecular structure at an infinite dilution, is −480.36 ppm (Table 3); the σ_t's of the dimer and the trimer, which have been suggested to exist at the neat liquid, are −483.14 ppm and −483.87 ppm for the central DMA and −483.38 ppm for the outside DMA in the trimer, as is shown in Tables 8 and 9 (in this case,

Table 7. Dipole moment of *N,N*-dimethylacetamide calculaed by CNDO/2 methoed and observed (D.U.)

Monomer	(a)model	(b)model	(c)model	DMA···H_2O	DMA···H	Obsd[a]
3.22	0.0	0.0	3.39	5.44	6.99	3.79

In (b) and (c) models the distance between C and O atoms is 3 Å.
a) Observed at 30 °C in benzene (Ref. 11).

Table 8. Dependence of chemical shift of dimer (b)model in *N,N*-dimethylacetamide on distance between C and O atoms by average excitation energy method using CNDO/2 method. σ_t (ppm)

	Distance (Å)		
	2.5	3.0	3.5
$CO\underline{C}H_3$	−317.62	−318.02	−318.13
cis-$N\underline{C}H_3$	−347.49	−348.01	−348.54
trans-$N\underline{C}H_3$	−351.99	−352.05	−352.10
$\underline{C}O$	−484.68	−483.14	−482.05

The used value of average excitation energy is 5.69 eV.

	Central[a]	External[a]
$CO\underline{C}H_3$	−317.75	−318.10
cis-$N\underline{C}H_3$	−348.07	−347.97
trans-$N\underline{C}H_3$	−351.73	−352.19
$\underline{C}O$	−483.87	−483.38

a) The terms "Central" and External" correspond to the central and external *N,N*-dimethylacetamide in trimer model.
The used value of average excitation energy is 5.69 eV.
The distance between C and O atoms is 3 Å.

the distance between the DMA molecules is 3 Å). From this, the carbonyl carbon is found to shift about 2 ppm to a lower field upon the formation of the dimer and the trimer. Therefore, this result agrees well with the observed one. The observed chemical shifts of the acetyl, *cis*-NCH_3, and *trans*-NCH_3 carbons did not depend as greatly on the concentration as in the case of the carbonyl carbon. On the other hand, the calculated chemical shifts of these carbons in the monomer, dimer, and trimer differ almost not at all from each other; this agrees with the observed results.

Next, let us concern ourselves with the behavior of DMA in the H_2O and H_2SO_4 solutions in terms of the chemical-shift calculation in addition to the above observed results. de Jeu[13] has suggested a reasonable model for the molecular structure of the acetone molecule in the corresponding solution based on his study of ^1H, ^{13}C, and ^{17}O NMR. We have adopted his model for the molecular structure of DMA which have a carbonyl group like the acetone molecule in their solutions. These corresponding models are shown in Fig. 12. The hydrogen-bonded >C=O···H–O–H amide–solvent associate (d) and protonated >C=O ···H associate (e) are formed in the H_2O and H_2SO_4 solutions respectively. Here, the ∠ >C=O···H and ∠H–O–H bond angles are set at 120° and 105° respectively, while the O–H bond length is set at 1.05 Å. The distances between the oxygen of the carbonyl group and the hydrogen atom for the cases of >C=O···H–O–H and >C=O···H are 1.34 Å and 0.985 Å respectively.[13] The electron-density distributions of these models are shown in Table 5. The protonated DMA shows a very high charge separation, as a whole, compared with the other structures. Correspondingly, as is shown in Table 7, the dipole moment is larger than that of the other structure. However, in the DMA···H_2O structure, although the charge separation does not change compared with the monomer, the dipole moment is relatively large because of the association with H_2O. If these results are confirmed experimentally, it will give important information about the DMA association in solution. Further, let us discuss the chemical shifts of these models. The carbonyl carbon is sensitively influenced by the formation of a hydrogen bond and by protonation. The difference between the carbonyl carbons at infinite dilutions in the CCl_4 and H_2O solutions is found to be about 6 ppm, as is shown in Fig. 7. These structures correspond to the monomer and the structure (d) shown in Fig. 12. From Tables 3 and 10, the corresponding calculated chemical-shift difference is found to be about 6 ppm (=487.18—480.96 ppm). This agrees well with the observed results. Also, as for the NCH_3 carbons, the observed results agree with the calculated result that the *trans*- and *cis*-NCH_3 carbons in the H_2O solution shift at a higher fileld than in the CCl_4 solution. These results suggest that the association model described above for the structure of the DMA molecule in the H_2O solution is a plausible model.

Table 10. Chemical shift of model hydrogen-bonded and protonated model in *N,N*-dimethylacet amide calculated by average excitation energy method using CNDO/2 method. σ_t (ppm)

	DMA···H_2O	DMA···H
$CO\underline{C}H_3$	−317.93	−319.07
cis-$N\underline{C}H_3$	−347.19	−340.23
trans-$N\underline{C}H_3$	−351.42	−344.06
$\underline{C}O$	−487.18	−497.05

The used value of average excitation energy is 5.69 eV.

Next, let us concern ourselves with the chemical shift of DMA in the H_2SO_4 solution. As expected for the electron-density distribution of this model, the calculated chemical shift of the carbonyl carbon occurs at a lower field than that of the hydrogen-bonded model and appears at a field lower by about 16 ppm

than that of the monomer model. However, the observed chemical shift of the carbonyl carbon at an infinite dilution in the H_2SO_4 solution appears at a field lower by only about 5 ppm than that at an infinite dilution in the CCl_4 solution; this value is smaller than the value obtained in the case of the hydrogen-bonded DMA with H_2O. Further, the calculated chemical shifts of the other carbons do not agree with the observed results. As the causes of these disagreements, the following reasons may be noted. i) the present model is not always appropriate, ii) the ΔE approximation for this case is gross, and so on. It will be necessary to study this problem in more detail in order to obtain exact information about the protonated DMA molecule.

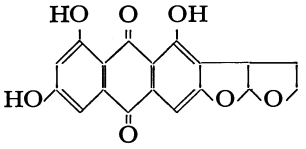
Faculty of Engineering, Tottori University, Koyama, Tottori 680

(Received February 24, 1975)

The crystal structure of versicolorin C, $C_{18}H_{12}O_7$, has been determined by the X-ray diffraction method. The crystals are monoclinic, with the space group $P2_1/a$, and with four molecules in a unit cell with dimensions of $a=24.918(7)$, $b=7.922(3)$, $c=7.003(3)$ Å, and $\beta=92.85(4)°$. The structure was refined by the least-squares method to $R=0.053$ for 1693 non-zero reflections. There are two intramolecular hydrogen bonds. A pair of molecules related by a center of symmetry forms a dimer by means of intermolecular hydrogen bonds.

Aspergillus versicolor (Vuillemin) Tiraboschi and *Aspergillus flavus* Link ex Fries produce a variety of compounds which contain a tetrahydrofuranofuran or a dihydrofuranofuran moiety. Versicolorin C, containing a tetrahydrofuranofuran moiety, was isolated as a metabolite of *Aspergillus versicolor*.[1] The crystal structures of several compounds containing a dihydrofuranofuran moiety have been determined in our laboratory. The structural investigation of the title compound is of interest in connection with the metabolites containing a dihydrofuranofuran moiety; these metabolites are believed to be toxic to animals.[2] The crystal and molecular structure of aflatoxin B_2, which has a tetrahydrofuranofuran moiety, was described in detail by van Soest *et al.*[3] As few X-ray analysis have, however, been done on the compounds involving a tetrahydrofuranofuran moiety, it seems worth carrying out the X-ray analysis of versicolorin C in order to obtain additional information about the dimensions of this moiety. Another point of interest in this analysis is to confirm the structural formula (shown below) proposed on the basis of the chemical



and spectroscopic methods.[1] This investigation has been undertaken as part of a series of systematic studies of the structures of the metabolites of the genus *Aspergillus*.[4-6]

Experimental

Versicolorin C, crystallized from an acetone solution in the form of orange red plates elongated along the b-axis. The crystal data and experimental conditions are summarized in Table 1. The intensities were collected on a Rigaku Denki computer-controlled four-circle diffractometer with a scintillation counter equipped with a pulse-height analyser. Attenuators were inserted when the maximum counting rate exceeded 8000 cps. The background was measured for 8 sec at both the start and end points of the scan range. Out of 2024 independent reflections measured up to $\sin\theta/\lambda=0.562$, 1696 reflections had a non-zero intensity. No significant variation in the intensities of the three reference reflections were observed during the data-collection process. The intensities were corrected for the Lorentz and polarization factors, but not for the absorption.

Structure Determination and Refinement

The orientation and location of the anthraquinone skeleton was determined by an interpretation of a three-dimensional Patterson map. A three-dimensional Fourier synthesis computed with the signs due to the skeleton revealed all the remaining non-hydrogen atoms. The atomic coordinates and isotropic temperature factors were refined by a block-diagonal least-squares method. By introducing anisotropic temperature factors for the non-hydrogen atoms in the refinement, the R value was reduced to 0.081. Three intense reflections, 220, 221, and 321, were rejected from the subsequent calculations. The positions of the hydrogen atoms were determined by a difference Fourier synthesis computed at this stage. The final refinement was made by including the positional parameters and isotropic temperature factors of the hydrogen atoms, using the following weighting scheme: $w=0.0$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq40$, and $w=1.0/(1.0+0.467(F_o-40))$ for $40<F_o$. The final R value was 0.053 for 1693 non-zero reflections. The final atomic parameters are listed in Table 2. A list of observed and calculated structure factors is preserved by the Chemical Society of Japan (Document No. 7517).

The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[7] The computations were performed on a TOSBAC 3400

* Faculty of Agriculture, Tottori University, Koyama, Tottori 680.

Results and Discussion

The structural formula of versicolorin C has been confirmed by this X-ray analysis. The difference-electron-density map and the numbering of atoms are shown in Fig. 1, which indicates the presence of two intramolecular hydrogen bonds, O(1)–H(1)···O(2) and O(3)–H(2)···O(2). The bond lengths and angles are shown in Fig. 2 and Table 3. In the quinonoid group, the lengths of the C(3)–C(4) and C(4)–C(5) bonds are shorter than those of the C(10)–C(11) and C(11)–C(12) bonds, and the length of the C(4)–O(2) bond is longer than that of the C(11)–O(5) bond. Such a lack of equivalence of bond lengths in the quinonoid group implies that the double-bond character at the C(11)–O(5) bond in the $\begin{matrix}C(10)\\C(12)\end{matrix}\!\!>$C(11)=O(5) system is greater than that at the C(4)–O(2) bond in the $\begin{matrix}C(3)\\C(5)\end{matrix}\!\!>$C(4)=O(2) system. These features are also found in averufin[5] and *N,N'*-diphenyl-1,8-diaminoanthraquinone.[8] As is shown in Table 4,

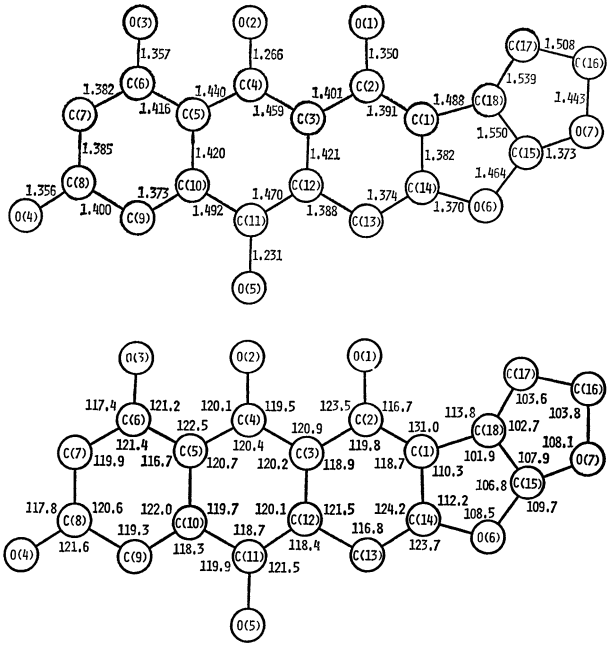

Fig. 2. The bond lengths (Å) and angles (°). The mean estimated standard deviations for the bond lengths and angles are about 0.004 Å and 0.3°, respectively.

TABLE 3. BOND LENGTHS AND ANGLES INVOLVING HYDROGEN ATOMS

The mean estimated standard deviations of the bond lengths and angles are 0.04 Å and 2°, respectively. Broken lines indicate hydrogen bonds.

C(18)	−0.027	O(7)	−0.021
C(16)[a]	0.525		

a) Not included in the least-squares calculation.

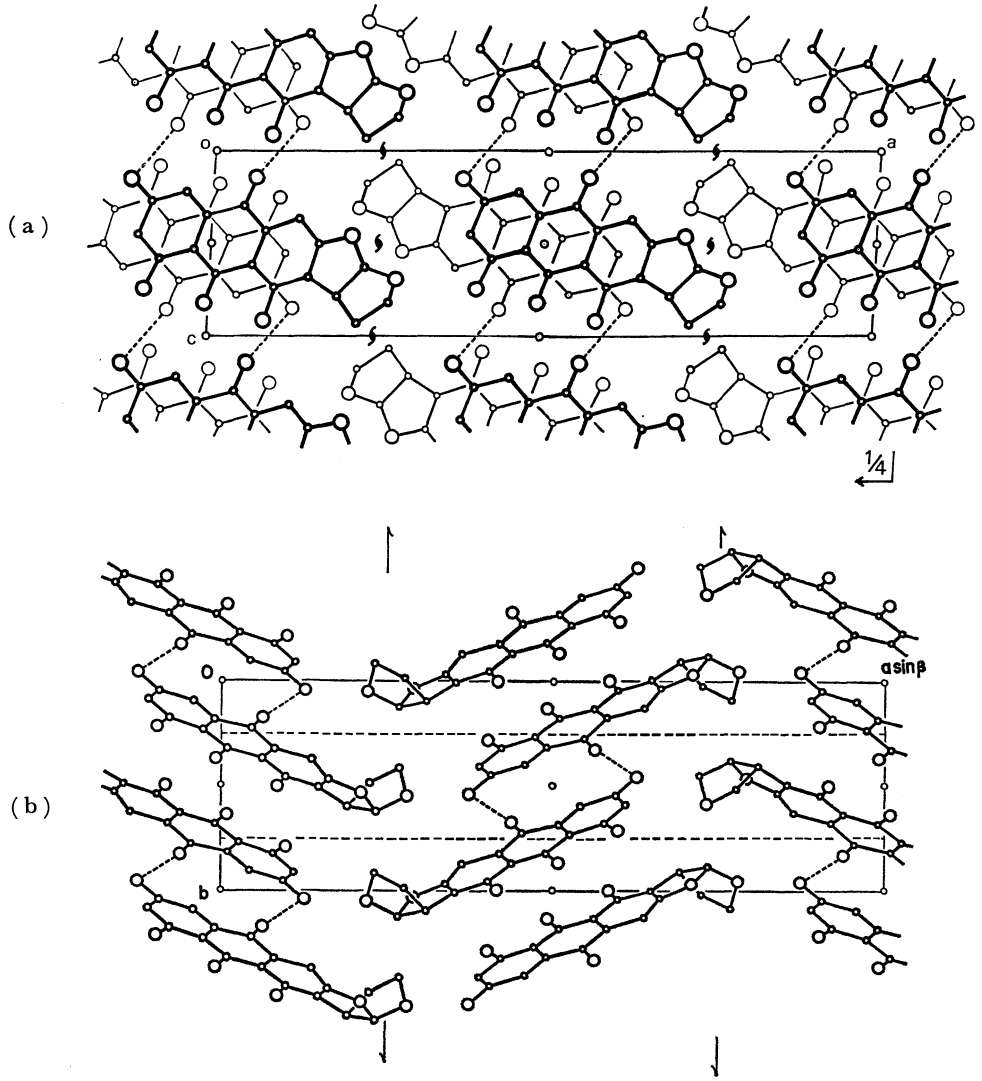

Fig. 3. The crystal structure of versicolorin C; (a) viewed along the b-axis, (b) viewed along the c-axis. Broken lines indicate intermolecular hydrogen bonds.

among the three $C(sp^3)$–$C(sp^3)$ bonds in the moiety, the length of the C(16)–C(17) bond (1.508 Å) is slightly shorter than the others (1.539 and 1.550 Å).

The least-squares planes through the anthraquinone skeleton with the O(1), O(3), and O(4) atoms and through the terminal five-membered ring except the C(16) atom are represented by these equations:

$$0.3501X - 0.8582Y + 0.3754Z = -0.4366,$$

and

$$0.2722X + 0.8409Y + 0.4678Z = 7.7470$$

respectively, where $X=ax+cz\cos\beta$, $Y=by$, and $Z=cz\sin\beta$. The dihedral angle between the above planes is 63.2°, compared with that of 62.8° in aflatoxin B_2.[3] The deviations of the atoms from these planes are listed in Table 5, which indicates that the anthraquinone skeleton is slightly twisted along the longitudinal axis of the molecule and that the terminal five-membered ring is puckered at the C(16) atom.

The crystal structure is shown in Fig. 3. A pair of molecules related by a center of symmetry are linked together by intermolecular hydrogen bonds, O(4)–H(4)···O(5) (2.857 Å), to form a dimer. The parallel dimers are held together by van der Waals

(Received February 27, 1975)

The absorption, fluorescence, and excitation spectra of 2-methyl-1-aceanthrenone (I) were investigated in several solvents in the temperature range of 77—298 K. The results show that the hydrogen-bonded (fluorescent) and non-hydrogen-bonded (very weakly fluorescent) molecules of I coexist in ethanol to a comparable extent. This is the reason why its absorption spectra are very broad in alcoholic solvents. With a decrease in the temperature, the apparent fluorescence quantum yield in ethanol at first rises to a maximum (0.37) at 197 K and then decreases. Below *ca.* 113 K, a new fluorescence band due to the non-hydrogen-bonded molecule appears. In 2-methyltetrahydrofuran (MTHF), the temperature dependence of the fluorescence quantum yield of I is significant only at low temperatures. The yield varies monotonously from 0.014 at 132 K to 0.30 at 77 K. A behavior intermediate between those in ethanol and in MTHF is observed in EPA. The rise and fall of the fluorescence quantum yield in ethanol or in EPA may be interpreted in terms of the temperature-dependent concentration change in the hydrogen-bonded molecule. From the results in MTHF, the maximum rate constant of the intersystem crossing between the $S_{1\pi\pi^*}$ and $T_{n\pi^*}$ states is estimated to be of the order of 10^{13} s^{-1}.

The way to interprete the electronic spectra of 9-anthracenecarboxaldehyde (9-CHO-A), which is distinguished from the other 9-carbonyl derivatives of anthracene by its high photochemical reactivity, is not unique,[1,2] because the diffuse nature of the electronic spectra makes impossible any accurate location of electronic states. This ambiguity has often led to very different interpretations of experimental results.[3–5] Recently, however, the present author has noted that a comparison of the electronic spectra of 9-CHO-A with those of 2-methyl-1-aceanthrenone (I), which is very similar in molecular structure to 9-CHO-A but which shows well-defined electronic spectra in all of the non-hydrogen-bonded, hydrogen-bonded, and cation forms, has made it possible to elucidate the electronic nature of the excited states of 9-CHO-A.[6]

Although such a comparison is successful in some points, as has previously shown,[6] the spectroscopic data on I and 9-CHO-A have never been adequate enough. In this paper, therefore, prominent, newly found temperature effects on the electronic spectra and the fluorescence quantum yields of I will be reported. The results obtained will not only confirm the author's earlier interpretation as to the electronic nature of the excited states of 9-CHO-A and I,[6] but will also add important experimental facts on the radiationless transition processes of 9-carbonylanthracenes.[6–11] Furthermore, compound I may be expected to serve as a model compound in interpreting unestablished spectroscopic properties of the compounds whose carbonyl groups are co-planar or almost co-planar with the parent aromatic rings.[12] For instance, the present results will point out, as may be seen below, that the interpretation of the spectroscopic properties of pyrene-3-aldehyde (3-CHO-P) and 9-CHO-A given by Förster *et al.*[1] should be re-examined.

Experimental

Materials. Compound I, obtained as one of the main photo-products of 9-α-bromopropionylanthracene,[9] was purified by column chromatography and was then sublimated twice *in vacuo*. The 9-methylanthracene (9-Me-A) was synthesized according to the well-known method[13] and recrystallized from ethanol. The 9,10-diphenylanthracene (9,10-diph-A) was obtained from the Nakarai Chem. Co., Ltd., and was used as received.

Among the solvents employed for the spectroscopic measurements, *n*-hexane and ethanol were of a spectro grade. Acetonitrile (ACN), dimethylformamide (DMF), 2-methyltetrahydrofuran (MTHF), methylenedichloride (MDC), triethylamine (TEA), isopentane (IP), methylcyclohexane (MCH), and diethyl ether were of a guaranteed grade from the Nakarai Chem. Co., Ltd., and were distilled carefully before use.

Optical Measurements. The absorption spectra were taken on a Hitachi Dual-Beam Spectrophotometer 124. For low temperature measurements, a rectangular quartz cell ($1\times1\times5$ cm, with a glass pipe 30 cm long attached on the top of the cell to facilitate handling and evacuation), each corner of which was well-fused in order to avoid cracking due to sudden cooling or warming, was held by a block made of brass, and the whole was put into a transparent Dewar vessel. The same type of cell and Dewar vessel as described above was used as a reference-cell combination. Only the sample-cell combination was cooled.

The excitation and fluorescence spectra were recorded on a Shimadzu Corrected Spectrofluorophotometer, RF 502, whose spectral characteristics have been described elsewhere.[6] For measurements at low temperatures, a Dewar vessel and a sample cell described previously[6] were employed. Correction for the spectral response of its particular cell arrangement was carried out by using a quinine bisulfate solution (5×10^{-5} M in 0.5 M sulfuric acid[14]) and an ethanol solution of anthracene as standard solutions for the fluorescence and excitation spectral measurements respectively.

In every case, the temperature of the sample was controlled by boiling liquid nitrogen using a power resister and allowing cold nitrogen gas to enter the Dewar vessel. The temperature was monitored through a thermocouple immersed in the sample cell and was recorded on a Yokogawa recorder, Type 3046. After thermal equilibrium had been reached, all the measurements were performed.

Determination of the Fluorescence Quantum Yields. In order to determine the fluorescence quantum yields as a function of the temperature, it is necessary to correct for the absorbance change with the temperature, so the absorption spectra of I were measured in MTHF, ethanol, and EPA (ether, isopentane and ethanol 5 : 5 : 2 by volume) at various temperatures. Thus, a calibration curve of the absorbance change as a function of the temperature was obtained for each solvent. A similar correction was made at 77 K for 9-Me-A,[15] which was used as a fluorescence-quantum-yield

standard of the unit yield at 77 K. The excitation of the fluorescence was performed at the 0–0 band of the $^1L_b \leftarrow {}^1A$ transition of I[6] (370 nm, band pass, 5 nm), since this band showed little spectral shift upon a decrease in the temperature.

A comparison of the areas of the corrected fluorescence spectra of I taken at various temperatures with that of 9-Me-A obtained at 77 K gave the relative fluorescence quantum yields of I at the corresponding temperatures. In correcting the relative fluorescence quantum yield, allowance was not made for variation in the refractive indices of the solvents with the temperature, since appropriate data were not available.

The relative fluorescence quantum yields of I in various solvents at room temperature were determined in a similar manner except that 9,10-diph-A was used as the fluorescence quantum-yield standard of the unit yield.[15] The change in the refractive index with the solvent was taken into account in this case.[17]

Since oxygen did not affect the present results, all these experiments were carried out without degassing. The fluorescence intensity was always measured in a dilute solution ($2—3\times10^{-5}$ M).

Results

Figure 1 shows the temperature dependence of the absorption spectra of I in ethanol. A small peak at 418 nm seen at room temperature gradually sharpened as the temperature was decreased and eventually became the main absorption band, with a peak at 425 nm at 77 K. Corresponding to this, a shoulder at 425 nm at room temperature came to form a small but clearly resolved band with a peak at 433 nm. The position of the latter band agreed approximately with the 0–0 absorption band observed for the hydrogen-bonded molecule of I formed in *n*-hexane containing a small amount of trichloroacetic acid (abbreviated as IH hereafter).[6]

In non-polar solvents, such as MCH or IP, and aprotic polar solvents, such as MTHF, however, no peak corresponding to the one at 433 nm was found at any temperature. Consequently, the small absorption peak at 433 nm found in ethanol at low temperatures can be attributed to a hydrogen-bonded molecule.

From the (g) spectrum, approximately 5—10% of I is seen to exist in a hydrogen-bonded form, even at 77 K, if the hydrogen-bonded molecule of I in ethanol is assumed to have a molar extinction coefficient of a magnitude similar to that of IH.

Figure 2 shows the effect of the temperature on the fluorescence spectra of I in ethanol. At first the spectrum was diffuse, but it gradually became structured with a decrease in the temperature. At tem-

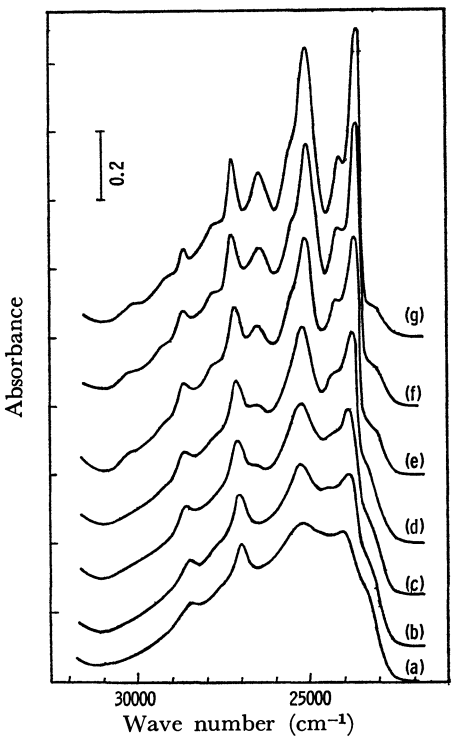

Fig. 1. Temperature effect on the absorption spectra of I (6.0×10^{-5} M) in ethanol.
(a) 290 K, (b) 250 K, (c) 233 K, (d) 190 K, (e) 160 K, (f) 125 K, (g) 77 K.
For the sake of clarity, the base line (right-hand side) of each spectrum is shifted by an appropriate amount of absorbance. The small peaks at 433 nm seen clearly in (e)—(g) are due to the hydrogen-bonded molecule of I. The decrease in the absorbance at 433 nm with a decrease in the temperature can be verified by a comparison of (d)—(g).

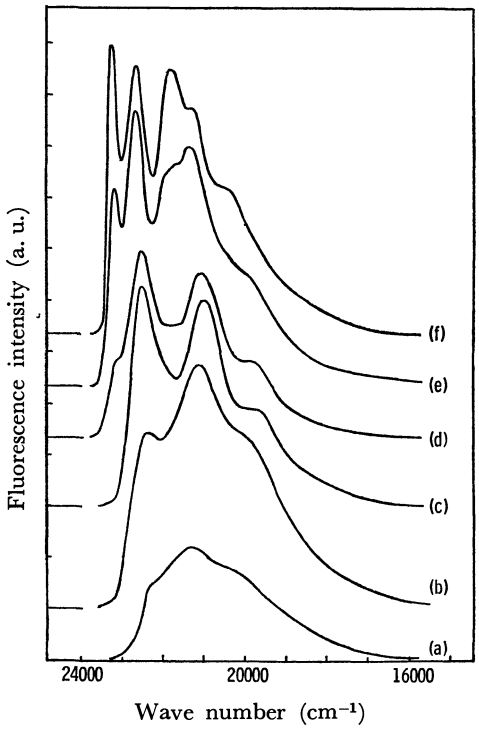

Fig. 2. Temperature effect on the fluorescence spectra of I (*ca.* 3×10^{-5} M) in ethanol.
(a) 256 K, (b) 185 K, (c) 134 K, (d) 103 K, (e) 89 K, (f) 77 K.
The excitation wavelength was 370 nm (band pass, 5 nm). The base line of emission intensity for each spectrum is shown by the solid line on the left-hand side. The fluorescence intensity of each spectrum is not parallel with the fluorescence quantum yield (for the exact value, see Fig. 5). Below *ca.* 110 K a new fluorescence band due to the non-hydrogen-bonded molecule appears on the shorter-wavelength side.

peratures near 134 K, the observed fluorescence spectrum closely resembles that of IH observed at room temperature.[6] It should be noted that the temperature effect on the shift of the fluorescence 0–0 band frequency (or the fluorescence-maximum frequency) is relatively small, reflecting a rigid molecular structure of I.[1] At temperatures below *ca.* 110 K, a new fluorescence band began to grow on the shorter-wavelength side; at 77 K this band surpassed the band at the longer wavelength.

The excitation spectra of the fluorescence of I in ethanol were also observed under similar conditions; the results are displayed in Fig. 3. In comparison with the absorption spectra shown in Fig. 1, it is quite evident that the main absorbing species is not the emitting species. The excitation spectra at low temperatures above *ca.* 110 K agreed well with those of IH, indicating that fluorescence is emitted by the hydrogen-bonded molecule. Below *ca.* 100 K, however, the excitation spectra changed significantly with the wavelength where fluorescence is observed, since, at these temperatures, two kinds of fluorescence are observable with a comparable intensity.

In Fig. 4 the fluorescence spectra of I in MTHF at low temperatures are shown. Contrary to the case in ethanol, the fluorescence spectrum in MTHF consists of only one component, which corresponds well to the component observed on the shorter-wavelength side in ethanol at very low temperatures. Evidently, the fluorescence observed in MTHF is due to a non-hydrogen-bonded molecule of I, so, of the two fluorescence components in ethanol, the one on the shorter-wavelength side can be attributed to the non-hydrogen-bonded molecule.

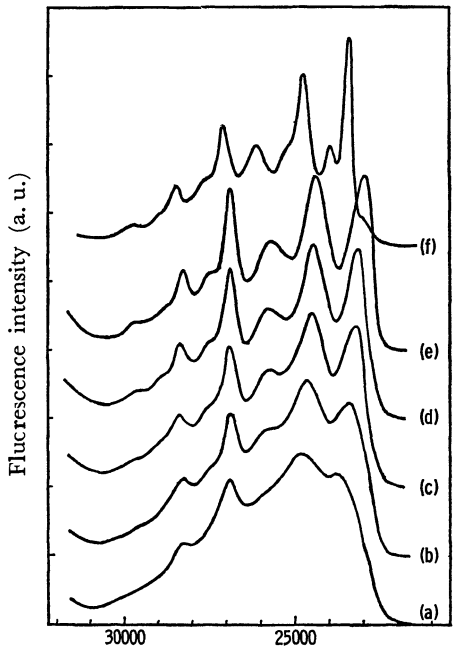

Fig. 3. Temperature effect on the excitation spectra of I (*ca.* 3×10^{-5} M) in ethanol.
(a) 290 K, (b) 236 K, (c) 185 K, (d) 148 K, (e) 106 K, (f) 77 K.
The fluorescence intensity was observed at 470 nm (the approximate fluorescence maximum of the hydrogen-bonded molecule of I) except in the case of (f), where the measurement was made at 460 nm (the approximate fluorescence maximum of the non-hydrogen-bonded molecule of I). In comparison with Fig. 1, it is evident that, except for 77 K, the excitation spectra do not accord with the absorption spectra. The coincidence of the spectra at 77 K is fortuitous.

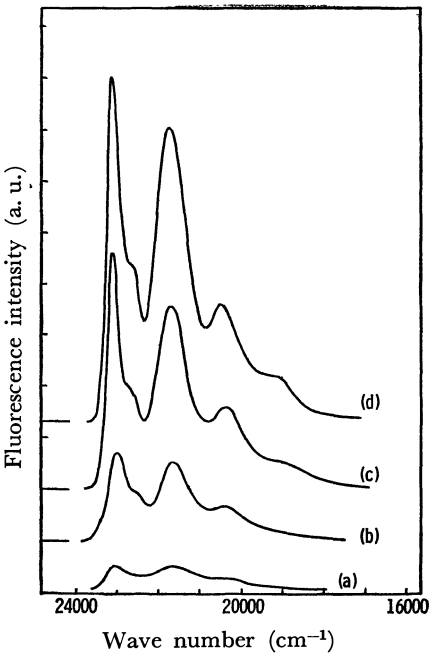

Fig. 4. Temperature effect on the fluorescence spectra of I (*ca.* 2×10^{-5} M) in MTHF.
(a) 128 K, (b) 111 K, (c) 98 K, (d) 92 K.
The excitation wavelength was 370 nm (band pass, 5 nm). The base line of the emission intensity for each spectrum is shown by the solid line on the left-hand side. The fluorescence intensity is not parallel with the fluorescence quantum yield (for the exact value, see Fig. 5). Below 92 K the fluorescence spectra are almost the same in shape.

In non-polar solvents such as MCH and IP, only a very weak fluorescence was observed. The fluorescence spectra in these solvents at 77 K were unresolved and shifted greatly to the red (λ_{max}=480 nm). In a frozen matrix of these solvents, diffuse emission spectra are frequently observed, probably because either of educed microcrystals or aggregated molecules of solutes. However, the absorption spectra of I observed in a mixed solvent of MCH and IP (3 : 1 by volume, abbreviated as MCHIP) down to temperatures as low as 77 K revealed that, at such a low concentration ($2-3\times10^{-5}$ M) as was used for the fluorescence measurements, the eduction of the solute was minute; hence, most of the solute must be dissolved homogeneously. Therefore, it may be presumed that the red-shifted weak emission observed in MCH or IP is due to educed microcrystals and that the temperature effect on the fluorescence yield of I is not appreciable in these non-polar solvents. The reason for this will be considered in a later section.

In Fig. 5 the temperature dependences of the fluores-

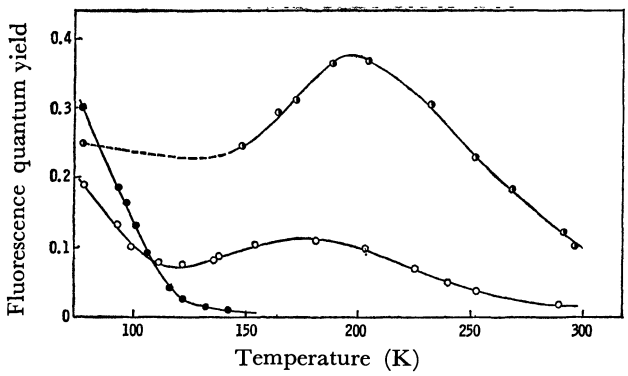

Fig. 5. Temperature dependence of the fluorescence quantum yields of I in ethanol, EPA, and MTHF.
—◑—: ethanol, —○—: EPA, —●—: MTHF.
Between 150 and 77 K a precise determination of the quantum yields in ethanol was difficult because of its unhomogeneous glassing.

cence yields of I in three media are depicted. In ethanol and EPA, the hydrogen-bonded and non-hydrogen-bonded molecules should coexist, so the obtained fluorescence yields in these media are sums of the apparent fluorescence yields from the two species. In MTHF, only at very low temperatures, the fluorescence became appreciable and the fluorescence quantum yield increased monotonously with a decrease in the temperature.

The behavior seen in EPA is intermediate between those in ethanol and in MTHF. The once-decreased fluorescence quantum yield begins rapidly to increase again near 113 K. Below this temperature, there was almost no fluorescence exhibited by the hydrogen-bonded molecule, and at 77 K no evidence for the existence of the hydrogen-bonded molecule was found in any of the absorption, excitation, and fluorescence spectra. Hence, the second increase in the apparent yield is attributable to the increase in the fluorescence quantum yield of the non-hydrogen-bonded molecule. This difference in temperature dependence between that in ethanol and that in EPA seems to reflect a difference in the hydrogen-bonding ability of these media toward I at low temperatures.

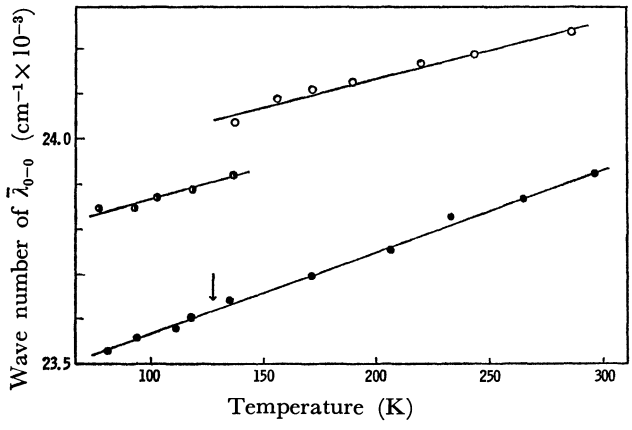

Fig. 6. Temperature-induced red shifts of the 0–0 absorption bands of $^1L_a \leftarrow {}^1A$ in MCHIP and MTHF.
—◑—: MCHIP, —○—: MCHIP, —●—: MTHF.
In MCHIP, the red shift of the 0–0 absorption band, and a large spectral change in shape were both observed as is shown in Fig. 7.

In Fig. 6 the frequencies of the 0–0 bands of the $^1L_a \leftarrow {}^1A$ transition observed in MTHF and MCHIP are plotted against the temperature. The red shift in MTHF is monotonous. In MCHIP not only the red shift but also the inversion of the absorption intensity was observed, as is represented in Fig. 7. As the temperature was lowered, a new band appeared on the longer-wavelength side of the band which was temporarily assigned as a 0–0 band at room temperature. A further decrease in the temperature inverted the absorption intensities of these two bands. In Fig. 6, therefore, the two frequencies of these two bands are plotted against the temperature. In either case, however, the magnitude of the red shift observed on cooling to 77 K is greater in MTHF than in MCHIP. Moreover, the value of $\bar{\lambda}_{0-0}$ in MTHF at the temperature where the fluorescence quantum yield of I begins to increase (indicated by the arrow in Fig. 6) is still smaller than the smallest $\bar{\lambda}_{0-0}$ (at 77 K) in MCHIP. These two facts are worth mentioning when we note that the lowering of the excited singlet-state energy is

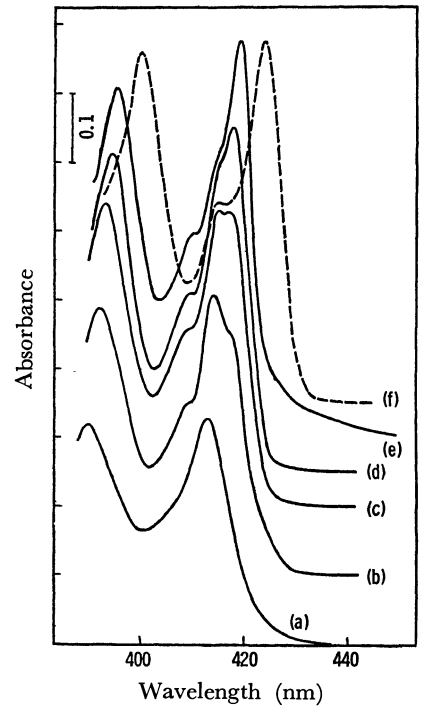

Fig. 7. Temperature effect on the absorption spectra of I (3.3×10^{-5} M) in MCHIP.
(a) 286 K, (b) 188 K, (c) 156 K, (d) 138 K, (e) 77 K, (f) 77 K (in EPA).
For the sake of clarity, the base line of each spectrum is shifted by an appropriate amount of absorbance. For comparison, the absorption spectrum in EPA (the broken line) is also shown. The broad tail seen for (e) is indicative of the existence of the educed microcrystals of I, which may be responsible for a broad weak fluorescence in this medium at 77 K. The other vibrational bands which belong to the ^1L_a or ^1L_b band did not show any marked change in shape as the temperature is lowered.

Table 1. Fluorescence quantum yields of I in various solvents

Solvent	Quantum yield[a]	Fluorescence maximum[b] ($10^{-3} \times cm^{-1}$)
n-Hexane	<0.002	22.22
TEA	<0.002[c]	—
MDC	0.016	21.65
MTHF	0.006 (0.30)[d]	21.88
DMF	0.011	21.60
ACN	0.016	21.74
EPA	0.017 (0.19)[d]	21.65
Ethanol	0.12 (0.25)[d]	21.37
n-Hexane + a small amount of trichloroacetic acid	0.78[e]	21.28[e]

a) Values at *ca.* 18 °C with reference to 9,10-diph-A. For further details, see text. b) Data on the absorption spectra of I are given in Ref. 6. c) A strong fluorescence similar to the one in MTHF at 77 K was also observed in this solvent at 77 K. The 0-0 absorption band shifted much more to the red, compared with those in the other non-polar solvents. d) The quantum yields at 77 K, with reference to 9-Me-A. e) The values for IH.

indispensable for the appearance of the strong fluorescence of I, as will be discussed later.

Relative fluorescence quantum yields of I obtained in various solvents at room temperature are collected in Table 1. It is evident from Table 1 tends to show fluorescence activation.[1] The comparatively high fluorescence quantum yield in ethanol is due to the coexisting hydrogen-bonded molecule.

Discussion

Temperature Effects on the Electronic Spectra. As is shown in Fig. 1, it is evident that, in ethanol at least, two forms of I, *i.e.*, the hydrogen-bonded and the non-hydrogen-bonded molecules, exist to a comparable extent. Thus, the present author's earlier supposition[6] that the diffuse absorption spectra of I in ethanol and acetic acid must be partly due to the coexistence of the two species has been confirmed experimentally. It is the rigid molecular structure of I that makes such experimental confirmation feasible.

In contrast to the rather rapid sharpening in the shape of the absorption and excitation spectra, the fluorescence spectra become structured less rapidly with a decrease in the temperature. On the other hand, the fluorescence spectra of IH are considerably structured, even at room temperature. From these facts, it may be inferred that the hydrogen-bonded molecule of I in ethanol does not have a definite composition and structure, but rather a loose structure composed of several solvent molecules which may be deformable upon photo-excitation.[18] Such a structure is appropriate to explain the absence of the hydrogen-bonded molecule in EPA at 77 K, in contrast to the case in ethanol.

The temperature effect on the absorption spectra of I in non-hydrogen-atom-donating polar solvents is merely a red shift. The magnitude of the red shift of I in MTHF between room temperature and 77 K (400 cm^{-1}) is larger than the corresponding values for 9-Me-A (240 cm^{-1}) and 9-propionylanthracene (9-CH_3CH_2CO-A, 200 cm^{-1}). (The latter compound shows an analogous temperature effect on the fluorescence intensity at temperatures near 77 K.) This is indicative of the greater increase in the dipole moment of the excited singlet state of I, compared with those of 9-Me-A and 9-CH_3CH_2CO-A, and also compatible with the great increase in the basicity of the carbonyl group of I at the first excited singlet state.[6]

The cause of the anomalous temperature effect seen in the absorption spectrum of I in MCHIP is not yet clear. Dissolved oxygen and moisture did not affect the spectrum. A trace amount of impurities, if any, cannot explain such a large spectral change. Since the spectra observed at temperatures below *ca.* 140 K are quite close to those in MTHF except for the larger red shift in the latter solvent, the anomalous spectrum change may be related to a structural change in I, probably occurring in the slightly strained five-membered ring. Such a structural change brought about by lowering the temperature will affect the transition moments, resulting in the reversal of the absorption intensities.[19]

Temperature Effects on the Fluorescence Quantum Yields. Since fluorescence in ethanol is emitted almost entirely from the hydrogen-bonded molecule except at very low temperatures, the rise or fall of the apparent fluorescence yield seen above 113 K must be determined by the variation in the fluorescence quantum yield of the hydrogen-bonded molecule and/or the variation in its concentration with the temperature. Since the fluorescence quantum yield of IH was determined to be close to unity (0.78), if a value with a similar magnitude is adopted for the fluorescence quantum yield of the hydrogen bonded molecule in ethanol[20] its temperature-induced increase, if any, will be too small to account for the initial three-fold increase in the apparent fluorescence quantum yield.

On the other hand, the heat of formation of IH was calculated as -12.6 kcal mol^{-1} from the temperature dependence of its formation constant. Therefore, for the hydrogen-bonded molecule formed in ethanol, we can also expect at least a negative value for its heat of formation, though it may plausibly be larger than -12.6 because of the stronger interactions between ethanol molecules compared with those of *n*-hexane, in which the heat of formation of IH was determined. Moreover, as has been calculated from the 0–0 band frequencies of the absorption and fluorescence spectra by the use of the Förster cycle, the hydrogen-bond formation constant, K, in ethanol is larger at the first excited singlet state than at the ground state. The difference in log K for the excited singlet state between at 298 and 200 K is calculated to be greater than 0.5, corresponding to more than a three-fold increase in the concentration of the electronically excited hydrogen-bonded molecule on cooling to 200 K, if the hydrogen-bonding at the excited state is completely accomplished. Hence, the initial increase in

the apparent fluorescence yield shown in Fig. 4 can most reasonably be interpreted in terms of the increase in the concentrations of the hydrogen-bonded molecules both at the ground and first excited singlet states.

At temperatures near the melting point of ethanol, however, the interactions of solvent molecules themselves come to predominate over interactions between I and ethanol molecules. As a result of this, a gradual decrease in the concentration of the hydrogen-bonded molecules, and hence a fall in the apparent fluorescence quantum yield shown in Fig. 4, are brought about. Although it may be difficult to verify quantitatively the initial increase in the concentration of the hydrogen-bonded molecule at the ground state from the absorption spectra shown in Fig. 1, the decrease in its concentration below *ca.* 190 K is definitely indicated by the absorption spectra.

In EPA, as is shown in Fig. 2 in Ref. 6, no evidence for the existence of the hydrogen-bonded molecule of I could be obtained at 77 K, indicating a prohibition of the hydrogen-bond formation at very low temperatures.[22]

A similar phenomenon, *i.e.*, the appearance of a maximum in fluorescence quantum yields when the temperature is varied, has previously been noted for 3-CHO-P by Förster *et al.*[1] It was inferred by these authors that the $\pi\rightarrow\pi^*$ and $n\rightarrow\pi^*$ excited singlet states ($S_{\pi\pi^*}$ and $S_{n\pi^*}$ respectively) are close-lying in this molecule and that a decrease in the temperature brings about a level inversion between fluorescent $S_{\pi\pi^*}$ and non-fluorescent $S_{n\pi^*}$ states, which is responsible for the rise and fall in the fluorescence quantum yield of 3-CHO-P as a function of the temperature. Although this concept is now widely accepted,[21] strong evidence supporting their proposition has not yet been obtained. Particularly, the location of the $S_{n\pi^*}$ state has not yet been established experimentally. Considering the analogous spectroscopic behavior found in three compounds—I, 9-CHO-A, and 3-CHO-P,[1,6,23] the interpretation given in the present paper for the temperature dependence of the fluorescence quantum yield of I seems also applicable to the case of 3-CHO-P.[23] In this sense, the proposition given by Förster *et al.* should be re-examined, though the complex electronic spectra of 3-CHO-P may prevent the drawing of a definite conclusion.

Mechanism of the Intersystem Crossing. Based on the facts that a high radiative electronic transition probability is expected for I because of its large molar extinction coefficient[9b] and that I does not suffer any significant photochemical reactions which affect the excitation energy dissipation processes,[6] the very low fluorescence quantum yield inherent in I must be interpreted in terms of the existence of an efficient intersystem crossing process. In the other non-fluorescent 9-carbonylanthracenes, a similar circumstance has already been met with, and the two main factors which determine the efficiency of the intersystem crossing process have previously been proposed by the present author and his co-workers.[9] One is the relative positions of the $S_{1\pi\pi^*}$ and $T_{n\pi^*}$ states, between which the intersystem crossing process is supposed to be dominant, while the other is the degree of the prohibition of the rotational motion of the carbonyl group upon photo-excitation.

Since the lowest excited singlet state of I is undoubtedly $S_{1\pi\pi^*}$, as has been discussed in Ref. 6, and since a significant structural change of I upon photo-excitation is unexpected in view of its structure, the temperature and solvent effects on the fluorescence quantum yield of I can be interpreted most reasonably in terms of these effects on the position of the $S_{1\pi\pi^*}$ state relative to that of the $T_{n\pi^*}$ state, which is expected to lie in the close vicinity of the $S_{1\pi\pi^*}$ state.[24] If the energy of the $S_{1\pi\pi^*}$ state is lowered relative to that of the $T_{n\pi^*}$ state by some cause, fluorescence will come to be emitted. In this sense, it is noteworthy that the red shift of $\bar{\lambda}_{0-0}$ with a decrease in the temperature is larger in MTHF than in non-polar solvents, where temperature-induced fluorescence enhancement was not observed. In the former solvent, moreover, the energy of the $T_{n\pi^*}$ state must be higher than those in non-polar solvents. The increase in the energy of the $T_{n\pi^*}$ state will add to the energy gap between $S_{1\pi\pi^*}$ and $T_{n\pi^*}$ state by that amount. This is the reason for the presence of a rather strong fluorescence in MTHF at very low temperatures.

It will be instructive to apply our reasoning to the case of IH. The energy of the $S_{1\pi\pi^*}$ state of IH is lower by 630 cm^{-1} than that of I in *n*-hexane, while the $T_{n\pi^*}$ state of IH is expected to shift greatly in the higher-energy direction on account of the lowering of the energy of the n-orbital of oxygen. Because of these effects, the energy gap between the $S_{1\pi\pi^*}$ and $T_{n\pi^*}$ states of IH is far greater than the corresponding gap of the non-hydrogen-bonded molecule in polar solvents. As a result, the fluorescence quantum yield of IH is considered to take a high value, close to unity.

Analysis of the Temperature Dependence of the Fluorescence Quantum Yield. When the external quenching of the fluorescence is absent, the following three processes are considered to determine the fluorescence quantum yield of I: the radiative process, the temperature-independent intersystem crossing process, probably from the $S_{1\pi\pi^*}$ state to the $T_{2\pi\pi^*}$ state, and the temperature-dependent intersystem crossing process from the $S_{1\pi\pi^*}$ state to the $T_{n\pi^*}$ state. We will represent the rate constants of these processes by k_f, k_{is}, and k'_{is} with the activation energy of E_a respectively. Then the fluorescence quantum yield, $\phi_f(T)$, at the temperature, T K, can be given by Eq. (1):

$$\phi_f(T) = \frac{k_f}{k_f + k_{is} + k'_{is}\exp(-E_a/RT)} \tag{1}$$

where k_f is assumed to be independent of the temperature and where the rate constant of the internal conversion from the $S_{1\pi\pi^*}$ state is assumed to be negligibly small, as is frequently done for anthracene derivatives.[25]

Equation (1) can also be rewritten as:

$$\ln\left(\frac{1}{\phi_f(T)} - 1 - \frac{k_{is}}{k_f}\right) = \ln\frac{k'_{is}}{k_f} - \frac{E_a}{RT} \tag{2}$$

The results in MTHF were analyzed by the use of Eq. (2). Since the value of k_{is}/k_f is not known in

our case, by putting an appropriate value of k_{is}/k_f into Eq. (2) the left-hand side of Eq. (2) was plotted against $1/T$. When $k_{is}/k_f=2.2$, the most satisfactory straight line, with a correlation coefficient of 0.998, was obtained. From the slope of the line, the activation energy was calculated as 780 cm^{-1}. From the intercept, assuming $k_f=10^8\ s^{-1}$, $k'_{is}\simeq 10^{13}\ s^{-1}$ was also obtained. Then the limiting maximum fluorescence quantum yield calculated from these values becomes 0.313, very close to that found at 77 K in MTHF.[26]

The very large value of k'_{is}, which is not unreasonably high for the rate constant of a transition between two excited states of different electronic natures, explains the very low fluorescence quantum yield of I, particularly in non-polar solvents. If a similar value can be adopted for the corresponding process of the other 9-carbonylanthracenes, its magnitude will be large enough to account for the absence of fluorescence in these compounds at the ambient temperature.[7-11]

17) J. A. Riddick and W. B. Bunger, "Techniques of Chemistry," Vol. II, ed. by A. Weissberger, Wiley-Interscience, New York (1970).

18) Since a stronger interaction between I and ethanol molecules was expected in non-polar solvents, the temperature effect on the absorption spectrum of I was investigated in IP containing 1—10% ethanol down to temperatures as low as 163 K. However, no marked spectral change indicative of a considerable amount of the hydrogen-bonded molecule was observed.

19) Such a structural change is assumed to be already occurring in MTHF.

20) To assume a high value for the fluorescence quantum yield of the hydrogen-bonded molecule in ethanol is reasonable when we take into account the apparent fluorescence quantum yield of 0.37 at 197 K, where the amount of the hydrogen-bonded molecule is estimated as 20—25%.

21) C. A. Parker, "Photoluminescence of Solutions," Elsevier Publishing Company, New York (1968), pp. 376, 433.

22) To confirm whether or not this suppression of the hydrogen-bond formation in polar solvents at low temperatures is general, the temperature effects on the concentration change of IH were studied in MCHIP (trichloroacetic acid 1.4×10^{-3} M) and EPA (trichloroacetic acid *ca.* 0.2 M). In the former medium, as expected, the concentration of IH increased continuously with a decrease in the temperature, until almost all the molecules of I had been transformed into IH (and IH_n; $1:n$ complex). In the latter, however, in spite of the much higher concentration of trichloroacetic acid, the concentration of IH was low and decreased slightly at low temperatures with a decrease in the temperature. The amount of IH formed in other polar solvents, such as ACN, DMF, and MTHF, was also minute.

23) P. Kröning, *Z. Naturforsch.*, **29a**, 804 (1974). Kröning has reported in the above paper that the monomer fluorescence quantum yield of 3-CHO-P in polar media depends considerably on the excitation wavelength, increasing steeply in the long-wave tail of the first absorption band. This phenomenon can also be interpreted in terms of the coexistence of a hydrogen-bonded (fluorescent) molecule and a non-hydrogen-bonded (non-fluorescent) molecule, without trusting to the concept of a dynamic model or local heating, as Kröning did. In fact, he found that the absorption and excitation spectra of 3-CHO-P in hydroxylic media did not accord with each other, implying the existence of two different species.

24) D. A. Warwick and C. H. J. Wells, *Tetrahedron Lett.*, **1968**, 4401.

25) J. B. Birks, "Photophysics of Aromatic Molecules," Interscience, London (1968).

26) It is not correct to employ the values of these rate constants in order to calculate the fluorescence quantum yields near room temperature, because such a single equation as Eq. (1) will not hold over a wide temperature range.

Photosensitized Decomposition of Trioxalatocobaltate (III) Ion by Organic Triplet Sensitizers

Shukichi SAKURABA, Akio KAKUTA, and Ryoka MATSUSHIMA

Department of Industrial Chemisty, Faculty of Engineering, Shizuoka University, Hamamatsu 432

(Received February 27, 1975)

Sensitized decomposition of the trioxalatocobaltate(III) ion was studied in deoxygenated aqueous solution at room temperature, using biacetyl as an n-π^* triplet sensitizer and 9-carboxyanthracene as a π-π^* triplet sensitizer. In the presence of one of these sensitizers the photodecomposition rate of the complex was increased, and the plot of the reciprocal of the sensitization quantum yield as a function of the concentration of the complex gave a straight line for each sensitization system. On the other hand, the complex quenched the phosphorescence without affecting the fluorescence of the sensitizers, indicating a triplet energy transfer mechanism. A photokinetic treatment of the data for both the sensitized photolysis and the quenching process gave a result in line with proposed mechanism for bimolecular triplet energy transfer.

The behavior of the photoproduced radical intermediates has extensively been studied for the photolysis of trioxalate complex ions of Co(III), Fe(III) and Mn(III),[1] but not the nature of the primary excited states, $*M(ox)_3^{3-}$.[2]

Sensitization and quenching methods are useful for identifying excited states whose lifetimes are very short. Thus, triplet sensitizers have been powerful tools for determining chemically reactive excited states of transition metal complexes, *e.g.*, Co(III)[3] and Cr(III).[4] In the present paper we report the results on the sensitized photodecomposition of $Co(ox)_3^{3-}$, using biacetyl as an n-π^* triplet donor and 9-carboxyanthracene as a π-π^* triplet donor.

Experimental

$K_3[Co(ox)_3^{3-}]\cdot 3H_2O$ and $K_3[Cr(ox)_3^{3-}]\cdot 3H_2O$ were prepared from the corresponding chlorides and potassium oxalate,[5,6] and were crystallized thrice. Biacetyl, 9-carboxyanthracene and organic solvents (guaranteed grade, Nakarai Chem.) were used without further purification. Water was distilled over potassium permanganate after passing through ion-exchange resins.

The light source was a 500 W high pressure mercury lamp with an attachment for obtaining a parallel light beam (Ushio Electric). Monochromatic light (366, 405 or 436 nm) was obtained by means of an interference filter or a suitable combination of glass filters. Absorption and emission measurements were carried out with a Hitachi 124-Spectrophotometer and a Hitachi 204-Fluorescence Spectrophotometer, respectively. For measurements of the emission of the sensitizers, the solutions were bubbled with purified nitrogen until there was no further increase in the phosphorescence intensity (*i.e.*, 40—60 min), and were kept air-tight with liquid paraffin and paraffin film.

Sample solutions to be photolyzed were mostly buffered at pH 3.9 with sodium acetate-acetic acid, and were irradiated at 20 °C, after deoxygenation with purified nitrogen followed by sealing. Concentrations of the Co(II) and the ox^{2-} ions formed were determined by reported methods.[7,8] Quantum yields were measured by the usual method.[9,10]

Results and Discussion

Direct Photolysis. Preliminary examination on the direct photolysis of $Co(ox)_3^{3-}$ under conditions similar to those of the sensitized photolysis showed that the molar ratios of Co(II) and ox^{2-} to the consumption of the complex, $-\Delta$[Co(III)], were independent of the extent of the reaction and the wavelength. The molar ratio, $[ox^{2-}]/[Co(II)]$ near 2.5, agreed with the mechanism previously proposed,[2] though the molar ratios of Co(II) and ox^{2-} to $-\Delta$[Co(III)] were rather small. The quantum yields of the Co(III) consumption for direct photolysis, under conditions similar to those for sensitized photolysis, depended on the temperature as well as the excitation wavelength. This indicates that the charge transfer state is the reactive state (even when the ligand field state is initially reached).[1b] The effect of the dissolved oxygen on the quantum yields was negligible for direct photolysis with light of 366 nm, while significant oxygen quenching was found for sensitized photolysis.

Biacetyl-Sensitized Photolysis. In the presence of 0.2 M biacetyl as an n-π^* sensitizer, $Co(ox)_3^{3-}$ in the concentration range 2.5×10^{-3} —1.5×10^{-4} (buffered at pH 3.9) was irradiated with a monochromatic light 366 nm at 20 °C, after deoxygenation. Under such conditions the complex absorbs the light directly up to 20% of the intensity (I_a) absorbed by the system. The number of the light quanta absorbed by the sensitizer, I_s, was estimated in proportion, *i.e.*, $I_s = I_a\varepsilon_s C_s/\sum_i \varepsilon_i C_i$. The quantum yields ($\phi$) of biacetyl-sensitized decomposition of the complex at its various concentration were determined, where photodecomposition of the complex due to its direct absorption was eliminated by calculation. The plot of $1/\phi$ as a function of 1/[Co(III)] gives a straight line with a slope, $1/K\phi_{11m}=2.1\times10^{-3}$ M and an intercept, $1/\phi_{11m}=7.6$ (Fig. 1).

9-Carboxyanthracene-Sensitized Photolysis. The quantum yields of the photosensitized decomposition of $Co(ox)_3^{3-}$ by 9-carboxyanthracene as a π-π^* sensitizer were measured at various initial concentrations of the complex in 30% aqueous acetone. The plot of $1/\phi$ as a function of 1/[Co(III)] gives a straight line with a slope, $1/K\phi_{11m}=1.28\times10^{-2}$ M, and an intercept, $1/\phi_{11m}=7.6$ (Fig. 1).

Oxygen Effect on the Sensitized Photolysis. The rate of Co(II) formation in the sensitized photolysis was depressed by the dissolved oxygen both for biacetyl- and 9-carboxyanthracene-sensitized photolyses. No significant effect was found for the rate of the direct

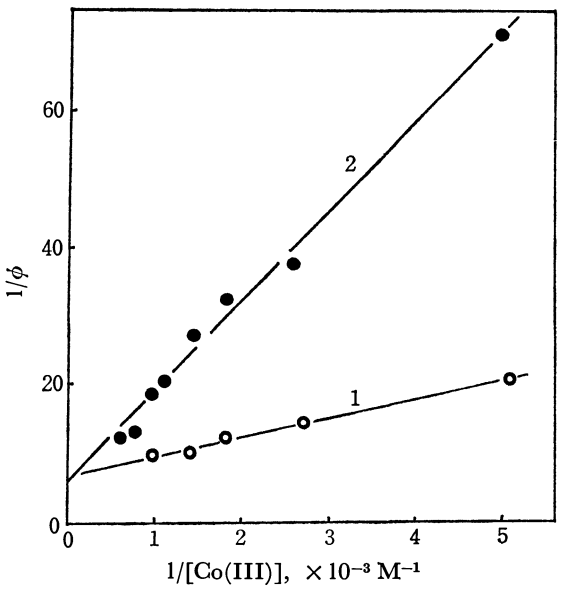

Fig. 1. Plot of $1/\phi$ *vs.* 1/[Co(III)] for organic triplet-sensitized decomposition of $Co(ox)_3^{3-}$. (1) Solvent: water (pH 3.9), sensitizer: biacetyl 0.04 M, $\lambda(h\nu)$: 366 nm. (2) Solvent: 30% aqueous acetone (pH 3.9), sensitizer: 9-carboxyanthracene 5×10^{-4} M, $\lambda(h\nu)$: 366 nm.

photodecomposition of the complex (10^{-3} M) under similar conditions. The results suggest that a bimolecular energy transfer mechanism of triplet states is involved but that the lifetime of the triplet state of the complex is too short (namely $\tau_0<10^{-9}$ s) to be significantly intercepted by the dissolved oxygen.

Quenching of the Sensitizer Emission by Complex. For clarification of the energy transfer mechanism of the sensitized reactions, quenching of the fluorescence and phosphorescence of the sensitizers by the complex were investigated. In deoxygenated aqueous solutions, $Co(ox)_3^{3-}$ quenched the phosphorescence of biacetyl without significant effect on the fluorescence.

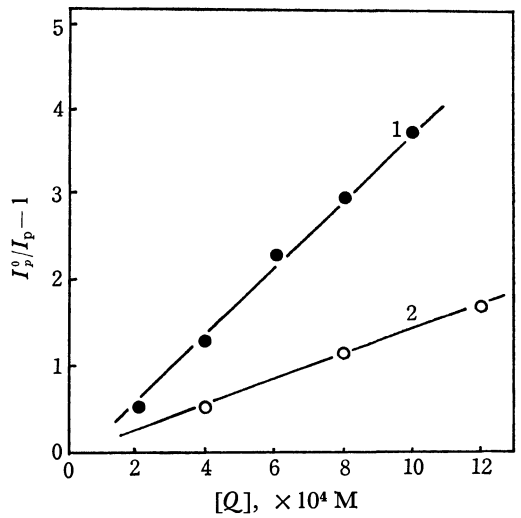

Fig. 2. Stern-Volmer plots for the quenching of biacetyl phosphosescence (512 nm peak) by (1) $Co(ox)_3^{3-}$ and (2) $Cr(ox)_3^{3-}$. Biacetyl: 0.04 M, λ(excitation): 366 nm.

The Stern-Volmer plot is given in Fig. 2. This indicates that the n-π^* triplet state is effective in the photosensitized decomposition of the complex. Form the quenching constants and the phosphorescence lifetime of biacetyl in solution at room temperature in the absence of the quenchers, $\tau_0=2.3\times10^{-4}$ s,[11] the bimolecular quenching rate constants are estimated to be $k_5=1.7\times10^7$ M^{-1} s^{-1} for $Co(ox)_3^{3-}$ and 1.0×10^7 M^{-1} s^{-1} for $Cr(ox)_3^{3-}$.

The emission of 9-carboxyanthracene in a deoxygenated aqueous alcohol solution at room temperature was only slightly affected by $Co(ox)_3^{3-}$, while in an aerated solution the emission was entirely unquenched. This implies that the energy transfer occurs from the triplet state (presumably π-π^*) of 9-carboxyanthracene.

Kinetic Analysis. A kinetic analysis of the energy transfer process for the photosensitized decomposition of $Co(ox)_3^{3-}$ will be given below.

Since the fluorescence of either biacetyl or 9-carboxyanthracene is not quenched by the complex, participation of the excited singlet states of the sensitizers is excluded. The excited singlet state of the complex is also excluded on the basis of the spin conservation rule for bimolecular energy transfer processes.[12] Direct chemical interactions between the complex and the excited state biacetyl, such as hydrogen abstraction or charge transfer, seem to be unimportant.[4b,c]

The following scheme can be assumed.

$$S + h\nu \xrightarrow{I_s} {}^1S^* \xrightarrow{\phi_{st}} {}^3S^* \quad (1)$$

$${}^3S^* \xrightarrow{k_2} S + h\nu' \quad (2)$$

$${}^3S^* \xrightarrow{k_3} S + \text{heat} \quad (3)$$

$${}^3S^* \xrightarrow{k_4,\,O_2} S + {}^1O_2^* \text{ (or } O_2+\text{heat)} \quad (4)$$

$${}^3S^* + C \xrightarrow{k_5} S + {}^3C^* \quad (5)$$

$${}^3C^* \xrightarrow{k_6} C + \text{heat} \quad (6)$$

$${}^3C^* \xrightarrow{\phi_c} Co(II) + \text{other products} \quad (7)^{2)}$$

Here, S and C are sensitizer and $Co(ox)_3^{3-}$, respectively. I_s is the light quanta absorbed by the sensitizer per unit time per unit volume, ϕ_{st} is the quantum yield of triplet formation from $^1S^*$, and ϕ_c is the quantum yield of Co(II) formation from $^3C^*$. Process (4) is included since a trace of the dissolved oxygen might be contained even after careful deoxygenation.

Since the lifetime of the triplet state of the complex $^3C^*$ seems to be short, and the bimolecular quenching rate constant k_5 is relatively small, one may assume that the unimolecular processes (6) and (7) of the complex are fast compared to (5). The steady state assumption for $^3S^*$ and $^3C^*$ leads to the following equation for the quantum yield of Co(II) formation in the sensitized reaction.

$$\frac{1}{\phi} = \frac{1}{\phi_{11m}}\left(1+\frac{1}{K[C]}\right) \quad (8)$$

$$\phi = \phi_c + \phi_{st} \quad (9)$$

$$K = k_5\tau_0 \quad (10)$$

Table 1. Rate parameters for the photosensitized decomposition of $Co(ox)_3^{3-}$ by biacetyl and 9-carboxyanthracene.

Sensitizer	ϕ_{1lm} [a]	ϕ_{st}	ϕ_c	K [b], M^{-1}	K_q, M^{-1} [c]
Biacetyl	0.13	0.99[14]	0.13	3.5×10^3	3.9×10^3
9-Carboxyanthracene	0.13	0.7—1[d]	0.13—0.19[d]	5.7×10^2	

a) From Eq. (8) and Fig. 1. b) Reciprocal of the slope of the plot of $1/\phi$ *vs.* 1/[C]. c) Quenching constant of the complex for the quenching of sensitizer phosphorscence. d) Though ϕ_{st} of 9-carboxyanthracene was not available, it is assumed to be close to unity (and hence ϕ_c to be close to 0.13), since it has been reported that the presence of the carboxyl group singificantly increases the rate of S-T intersystem crossing of aromatic hydrocarbons (*e.g.*, *J. Amer. Chem. Soc.*, **93**, 6396 (1971)).

where, $\tau_0=1/(k_2+k_3+k_4[O_2])$ is the lifetime of the triplet state of the sensitizer in the absence of the quencher (complex).

The experimental results in Fig. 1 agree with Eq. (8), supporting the assumed scheme. From the intercept and the slope of the plot of $1/\phi$ *vs.* 1/[C], ϕ_c is derived by substituting ϕ_{1lm} and ϕ_{st} into Eq. (9). These values are also given in Table 1, together with the quenching constant K_q for the quenching of the phosphorescence of biacetyl by $Co(ox)_3^{3-}$. K_q is the slope of the Stern-Volmer plot (Fig. 2) which has the following form

$$I_p^0/I_p = 1 + K_q[C] \quad (11)$$

where I_p^0 and I_p are the phosphorescence intensities of biacetyl in the absence and presence of the complex, respectively, and

$$K_q = k_5\tau_0 \quad (12)$$

From Eqs. (10) and (12), K and K_q (which were obtained from independent measurements) should be equal. The agreement of K with K_q in Table 1 might support the assumed scheme.

The upper limit of the sensitized photodecomposition quantum yield, ϕ_{1lm}, is 0.13 which is in the range of the direct photodecomposition quantum yields at its d-d band. The rate constant k_5 is a measure of the efficiency of the triplet energy transfer from the sensitizer to the complex. Though no report was found for the lifetime of 9-carboxyanthracene, it could be assumed that the π-π^* triplet lifetime is greater than the n-π^* triplet lifetime (*e.g.*, τ_0 of anthracene in solution at 20 °C is 0.026—0.035 s,[15] which is greater than that of biacetyl by two orders of manitude). Thus, the bimolecular rate constant k_5 for the triplet sensitized photolysis with 9-carboxyanthracene (as a π-π^* triplet sensitizer) is assumed to be smaller than that with biacetyl (as an n-π^* triplet sensitizer).

Photochemistry in the Adsorbed Layer. V. Effects of Surface Pretreatments upon the Photolysis of Adsorbed 2-Pentanone

Masakazu ANPO, Toshiaki WADA, and Yutaka KUBOKAWA

Department of Applied Chemistry, College of Engineering, University of Osaka Prefecture, Mozu-Umemachi, Sakai, Osaka 591

(Received March 7, 1975)

The effects of surface pretreatment upon the photolysis as well as the absorption and phosphorescence spectra of 2-pentanone adsorbed on porous Vycor glass have been investigated. The rate of propane formation (Norrish type I reaction) passes through a maximum and then decreases at higher degassing temperatures, while that of ethylene formation (Norrish type II reaction) decreases with increasing degassing temperature. Simultaneously, the phosphorescence intensity increases while the blue shift of the (n,π^*) band decreases. This suggests that with a rise in degassing temperature the triplet lifetime increases while the surface polarity decreases. Thus, the decrease in the rate of ethylene formation is attributed to destabilization of the 1,4-biradicals formed by the intramolecular hydrogen abstraction, and the decrease in the rate of propane formation to the decrease in the lifetime of the *n*-propyl radicals, the hydrogen abstraction efficiency, and the probability of α-cleavage.

Photolysis as well as absorption and phosphorescence spectra of acetone, methyl ethyl ketone, and 2-pentanone adsorbed on porous Vycor glass have been investigated recently.[1] It was shown that acetone most strongly hydrogen bonded to the surface OH groups exhibits the most efficient radiationless deactivation. It was found that in the photolysis of adsorbed 2-pentanone Norrish type I reaction occurs to a larger extent than that in the gas phase photolysis.[2]

It is well-known that the concentration of surface OH groups and their reactivity markedly change after surface pretreatment such as heat[3] or fluoridation pretreatment.[4] It is expected therefore that the interaction of alkyl ketones with the surface OH groups would be seriously affected by such surface treatment. We have investigated the effects of surface pretreatment upon the photochemistry of adsorbed 2-pentanone in order to obtain information on the nature and reactivity of the excited states.

Experimental

Details of the apparatus, procedures, and materials were described previously.[1] A conventional vacuum system was used in conjunction with a special quartz cell capable of studying the spectra and photolyses in the adsorbed layer. The specimen of porous Vycor glass which had been heated in oxygen to remove carbonaceous impurities was introduced into the cell and degassed at temperatures 100—800 °C for 7 hr. After 2-pentanone had been adsorbed on the specimen, photolysis was carried out using an ultra high pressure mercury lamp without filter. The amount of 2-pentanone adsorbed was 2.19×10^{-5} mol/g. The BET surface area[5] of the specimen remained unchanged until 500 °C, decreasing at higher temperatures from 160 m^2/g at 500 °C to 140 m^2/g at 700 °C. In the case of NH_4F pretreatment, the specimen was dried at 100 °C and then degassed at 800 °C for 7 hr. After such treatment the BET surface area was reduced to about 60% of its initial value. The IR spectra after the treatment indicate that about 60—65% of the surface OH groups was removed.

Results

Effects of Degassing Temperature upon Absorption and Phosphorescence Spectra. Figure 1 shows the blue shifts of the (n, π^*) transition of adsorbed 2-pentanone and methyl ethyl ketone against the degassing temperature. It is seen that the magnitude of the blue shift decreases with a rise in degassing temperature. It is well-known that the (n, π^*) transition of the ketones is blue shifted in polar solvents due to hydrogen bonding, its magnitude increasing with the polarity of the solvent.[6] Since alkyl ketones are adsorbed on porous Vycor glass by hydrogen bonding between the surface OH groups and C=O groups of the ketone, such a decrease in the blue shift with increasing degassing temperature is attributable to a decrease in the polarity of the surface OH groups. The change in the number of surface OH groups/g with degassing temperature obtained by Low and Ramasubramanian[3] is given in Fig. 2. A similar relative change in the number of OH groups with the degassing temperature was obtained with our specimen from the intensity measurements of the band at 3750 cm^{-1}. This suggests that the surface polarity decreases with decreasing

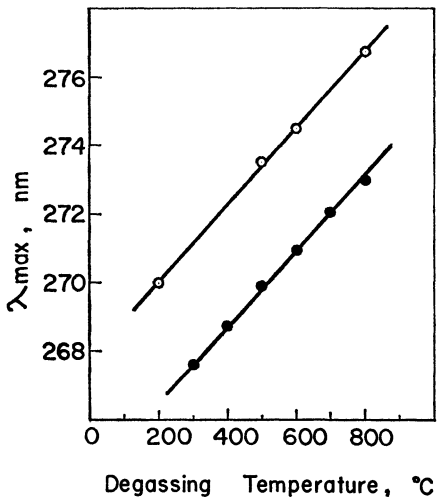

Fig. 1. Effect of degassing temperature upon the (n, π^*) transition of the ketones adsorbed. The amounts of adsorbed methyl ethyl ketone and 2-pentanone were 2.37×10^{-5} mol/g and 2.10×10^{-5} mol/g, respectively. ●, methyl ethyl ketone; ○, 2-pentanone.

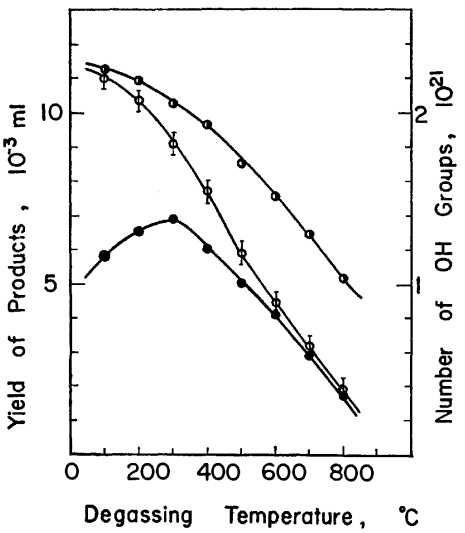

Fig. 2. Effect of degassing temperature upon the yield of products from the 2-pentanone photolysis. Amounts of adsorbed 2-pentanone was 2.19×10^{-5} mol/g. Irradiation time, 20 minutes; Temperature, 25 °C. Φ, the number of OH groups/g; ◑, ethylene; ●, propane.

TABLE 1. EFFECT OF DEGASSING TEMPERATURE UPON THE PHOSPHORESCENCE INTENSITY OF 2-PENTANONE ADSORBED

Temperature °C	Amount adsorbed 10^{-5} mol/g	Phosphoresence max. nm	Relative intensity
300	7.01	445±5	1.00
500	7.01	450±5	1.23
700	7.01	455±5	1.70
300	20.1	445±5	1.00
700	20.1	455±5	1.68

concentration of the surface OH groups.

A similar behavior has been reported by Glass and Ross[7] who found that the heat of adsorption of hydrogen sulfide adsorbed on silica gels by hydrogen bonding decreased with increasing degassing temperature, *i.e.*, with decreasing concentration of the surface OH groups.

Table 1 shows the effect of the degassing temperature upon the phosphorescence spectra of adsorbed 2-pentanone, its intensity increasing with increasing degassing temperature. Taking into account the fact that there was no change in the relative intensity of the absorption spectra with a rise in degassing temperature, such a decrease in the phosphorescence intensity is attributable to a decrease in the population of the excited triplet ketone molecules.[8] The more blue shifted, *i.e.*, the more strongly hydrogen bonded a ketone molecule is, the more efficient radiationless deactivation becomes.[1] Thus, the decrease in the concentration of the triplet molecules is attributable to the increase in the radiationless deactivation efficiency.

Effect of Surface Pretreatment upon Type I and II Reactions. The major gaseous products in the photolysis of adsorbed 2-pentanone are ethylene (type II) and propane (type I).[1] The effect of degassing temperature upon the rates of type I and II reactions is shown in Fig. 2. With increasing degassing temperature the rate of type II reaction decreases while the rate of type I reaction passes through a maximum and then decreases at higher degassing temperatures.

TABLE 2. EFFECT OF SURFACE PRETREATMENTS UPON THE PHOTOLYSIS OF 2-PENTANONE ADSORBED

Condition of pretreatment[a]	Yield of propane 10^{-2} ml/hr	Yield of ethylene 10^{-2} ml/hr	Value of propane/ethylene
No-treatment	0.88	2.00	0.44
NH_4F solution	2.09	2.01	1.04

a) The specimens were degassed at 800 °C. Amount of 2-pentanone adsorbed was 1.43—1.70 mol/g. Minor products; CO, CH_4, C_2H_6, C_6H_{12}. CH_3COCH_3 was not determined.

The results of the NH_4F treatment are given in Table 2. Taking into account a decrease in the surface area after the treatment, it is concluded that both type II and type I reactions are enhanced after the treatment, its extent being larger for the latter than for the former. According to the work of Chapman and Hair,[4] after NH_4F pretreatment the surface consists of silanol groups (Si-OH) and F atom attached to Si atoms on the surface. Owing to the electronegativity of F atoms, the weakening of the O-H bond takes place, resulting in the increase in surface acidity or surface polarity. Thus, essentially the same trend was observed for both experiments, suggesting a significant role of the polarity of the surface OH groups in determining the rates of product formation.

Discussion

Type II Reaction. Type II reactions of alkyl ketones having γ-hydrogen atoms have been investigated by many workers.[9-12] According to Yang and Elliot[9] who investigated the type II reaction of the optically active ketone, 5-methyl-2-heptanone, there seems to be no doubt that the reaction proceeds *via* 1,4-biradicals formed by the intramolecular hydrogen abstraction.

Wagner found that the type II reaction is enhanced in polar solvents in comparison with in nonpolar solvents.[10] The quantum yield of the residual singlet reaction, however, which remains after addition of sufficient amounts of diene to quench all the excited triplet ketone molecules, is the same in all solvents.[10,13] This suggests that polar solvents should increase the efficiency of type II reactions from the alkyl ketone excited triplet state. This effect has been attributed by Wagner to a decreased probability for return of the γ-hydrogen in the 1,4-biradical, formed by the intramolecular hydrogen abstraction in the excited triplet states, due to hydrogen bonding between the polar solvent and the hydroxyl group of the biradical.

The ethylene formation from adsorbed 2-pentanone decreases with increasing degassing temperature. The surface polarity or acidity decreases with increasing

degassing temperature. The following tentative conclusion may be drawn: In the photolysis of adsorbed 2-pentanone only the ethylene formation from the triplet excited states would be affected by the change in the degassing temperature. The decrease in ethylene formation with increasing degassing temperature is associated with the decrease in surface polarity which results in destabilization of the 1,4-biradicals. The photolysis of the absorbed 2-pentanone may be represented by the following scheme:

$$P + h\nu \longrightarrow {}^1P \quad (1)$$

$${}^1P \xrightarrow{k_{isc}} {}^3P \quad (isc)$$

$${}^1P \xrightarrow{k_2} P + \text{heat} \quad (2)$$

$${}^1P \xrightarrow{k_3} P + h\nu' \quad (3)$$

$${}^3P \xrightarrow{k_4} \dot{C}_3H_7 + \dot{C}OCH_3 \quad (4)$$

$${}^3P \xrightarrow{k_5} \dot{C}H_2CH_2CH_2\text{-}\underset{\underset{H}{|}}{\overset{\overset{O}{|}}{\dot{C}}}\text{-}CH_3 \quad (5)$$

$${}^3P \xrightarrow{k_6} P + \text{heat} \quad (6)$$

$${}^3P \xrightarrow{k_7} P + h\nu'' \quad (7)$$

$$\dot{C}H_2CH_2CH_2\text{-}\underset{\underset{H}{|}}{\overset{\overset{O}{|}}{\dot{C}}}\text{-}CH_3 \xrightarrow{k_8} C_2H_4 + CH_3\overset{\overset{O}{\|}}{C}\text{-}CH_3 \quad (8)$$

$$\dot{C}H_2CH_2CH_2\text{-}\underset{\underset{H}{|}}{\overset{\overset{O}{|}}{\dot{C}}}\text{-}CH_3 \xrightarrow{k_9} P + \text{heat} \quad (9)$$

(Reaction Scheme 1)

Reaction 9 is the radiationless deactivation process which proceeds *via* a return of γ-hydrogen in the 1,4-biradical. Using the steady state approximation in the excited states, the rate of type II reaction can be represented by

$$\text{Rate}_{(C_2H_4)} = \left(\frac{k_5}{k_4+k_5+k_6+k_7}\right)\left(\frac{k_8}{k_8+k_9}\right)I_p\Phi_{isc} \quad (I)$$

where I_p is the rate of light absorption by molecule P and Φ_{isc} the efficiency of the intersystem crossing.

With increasing degassing temperature the 1,4-biradical lifetime τ_b, *i.e.*, $(k_8+k_9)^{-1}$ decreases owing to an increase in k_9. The phosphorescence measurements suggest that the triplet lifetime τ_t, *i.e.*, $(k_4+k_5+k_6+k_7)^{-1}$ increases with increasing degassing temperature. The magnitude of the decrease in the biradical lifetime would be larger than that of the increase in the triplet lifetime, since the rate of ethylene formation decreases with increasing degassing temperature.

Type I Reaction. The rate of propane formation can be represented as follows: In addition to scheme 1 the following reactions are included;

$$\dot{C}_3H_7 + [H] \xrightarrow{k_{10}} C_3H_8 \quad (10)$$

$$[\dot{C}_3H_7 + \dot{C}OCH_3]_{ads} \xrightarrow{k_{11}} \text{Recombination or Disproportionation Products} \quad (11)$$

$$R_{(C_3H_8)} = k_{10}[H][\dot{C}_3H_7] = \left(\frac{k_4}{k_4+k_5+k_6+k_7}\right)\left(\frac{k_{10}[H]}{k_{10}[H]+k_{11}[\dot{C}OCH_3]}\right)I_p\Phi_{isc} \quad (II)$$

The rate of propane formation is determined by hydrogen abstraction efficiency, $k_{10}[H]$, as well as the steady state concentration of the propyl radicals. In the photolysis of acetone-d_6 adsorbed on porous Vycor glass the methane formed contained 55% of CD_3H at the amount adsorbed of 2×10^{-5} mol/g.[14] This suggests that in the case of the photolysis of adsorbed 2-pentanone the hydrogen abstraction from the surface OH groups would contribute considerably to the overall propane formation at least in the range of the small amounts adsorbed. Accordingly, the hydrogen abstraction efficiency $k_{10}[H]$ would decrease with increasing degassing temperature owing to the decrease in the concentration of the surface OH groups.

The steady state concentration of the propyl radicals is determined by the propyl radical and triplet 2-pentanone lifetime as well as by the k_4 value (Eq. (II)). The change in the radical lifetime with degassing temperature can be determined by the effect of oxygen pressure upon the propane formation,[15] by means of the Stern-Volmer relationship

$$\frac{Q_0}{Q} = 1 + \tau_r k_s[O_2]$$

where τ_r is the radical lifetime and k_s the scavenging rate constant with oxygen. Q and Q_0 are the rates of propane formation in the presence and absence, respectively, of oxygen. Assuming that the value of k_s scarcely changes with degassing temperature, the change in the radical lifetime with degassing temperature is obtained from the Stern-Volmer plots. The lifetime of propyl radicals decreases with increasing degassing temperature (Fig. 3). Remem-

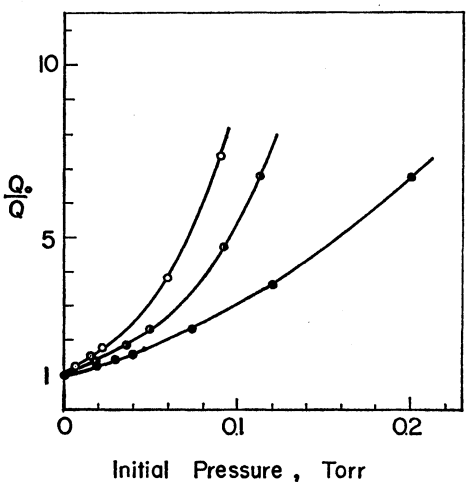

Fig. 3. Stern-Volmer plot for scavenging of the propane formation with oxygen. ○, pretreated at 300 °C; ◑, pretreated at 500 °C; ●, pretreated at 700 °C.

bering that the hydrogen abstraction efficiency $k_{10}[H]$ decreases with increasing degassing temperature, it is concluded that the increase of $(k_{10}[H]+k_{11}[\dot{C}OCH_3])$ and the decrease of $k_{10}[H]$ occurs simultaneously. This suggests that the contribution of $k_{10}[H]$ to the value of $(k_{10}[H]+k_{11}[\dot{C}OCH_3])$ is rather small. In other words, the lifetime of the propyl radicals is determined mainly by the value of $k_{11}[\dot{C}OCH_3]$, which refers to the reaction of *n*-propyl-acetyl radical pairs such as the recombination and disproportionation reactions.[16] Such an increase in the value of $k_{11}[\dot{C}OCH_3]$ with increasing degassing temperature would be expected since the magnitude of k_{11} depends upon the surface mobility of the radicals, which will increase with decreasing strength of the interaction between the radicals and the surface OH groups. The weak interaction of the radicals with the Vycor glass surface pretreated at a higher temperature was also studied by Garbutt and Gesser by means of ESR technique.[17]

Such a decrease in the strength of the interaction between the radicals and the surface with increasing degassing temperature suggests the decrease in stabilization of the radicals formed in the primary process, which would be expected to result in a decreased probability of α-cleavage, *i.e.*, a decreased k_4 value. It is concluded that the decrease in the propane formation with increasing degassing temperature is attributable to a decreased probability of α-cleavage as well as the decrease in the radical lifetime and the hydrogen abstraction efficiency. In the temperature range where no decrease in these values occurs it is expected that the propane formation increases with increasing degassing temperature owing to the increase in the lifetime of the triplet excited ketone molecules. It appears that such a situation is realized in the temperature range below 300 °C. Thus, a maximum in the propane formation is explicable.

A Conformational Study of the NO_x(x=1 or 2)-catalyzed Isomerization of *cis*-2-Butene Using the INDO-UHF Method

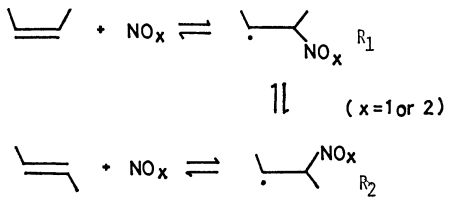
Katsutoshi OHKUBO, Hiromichi IKEBE, and Masahide OKADA

Department of Synthetic Chemistry, Faculty of Engineering, Kumamoto University, Kurokami, Kumamoto 860

(Received March 12, 1975)

The NO_x(x=1 or 2)-catalyzed isomerization of *cis*-2-butene was investigated by means of the INDO-UHF theory, with a particular view to the energetic and conformational aspects of the reaction. The NO_2-addition process to form the intermediate radical (R_1) had no appreciable activation barrier, although the NO_2-fission process from the intermediate radical (R_2) had the C–NO_2 dissociation energy of 44.6 kcal/mol. Some characteristic features of the stretched C–C bond in the intermediate radical (R_1) were; (1) r_{CC}=1.45 Å, which was roughly equal to the value (1.481 Å) in *cis*-2-butene at the transition state of its thermal isomerization; (2) a pseudo π-conjugation with a small π-character (about 13% of E^R_{CC}) in comparison with that (about 29% of E^R_{CC}) in *cis*-2-butene, and (3) approximately the same magnitude of the hfsc value (34.40—34.47 G) for the sp^2-hydrid carbon as that (experimental value of 39.07 G) for the said atom in the ethyl radical. The calculated internal-rotation barrier of the intermediate radical (R_1) around the C–C bond (1.75—3.01 kcal/mol in the two rotating directions) was smaller than that (around 4 kcal/mol) obtained from the thermodynamic estimations. The energetically most stable or unstable rotamer was found in the staggered or the eclipsed configuration respectively; a hydrogen-bonding effect on the stabilization was observed in staggered configuration, although a remarkable effect of the homoconjugation or the repulsive interaction of unpaired and lone-paired electrons can be disregarded in the present internal-rotamer.

The isomerization about the C=C double bond of olefin with free-radical catalysts, especially with NO_x (x=1 or 2), has currently received considerable attention in connection with olefin consumption in photochemical smog. In regard to the gas-phase *cis*-2-butene isomerization catalyzed by NO_x(x=1 or 2), Cundall[1] and Pitts *et al.*[2] have performed kinetic investigations of the gas-phase isomerization mechamism, and the mechanism may now be postulated qualitatively to be as follows:



In the above reaction paths, the NO_x catalyst actually diminishes the activation energy of the reaction fro 62.8 kcal/mol[3] in the thermal isomerization to 26.2 kcal/mol in the case of NO[1] or 12.1±0.3 kcal/mol in the case of NO_2.[2] It has also been established with respect to the olefin isomerization that the reaction is catalyzed by such free radicals as I,[4,5] S,[6] HS,[7] and RS.[8] The isomerization mechanism, however, is still open to question on a molecular level in view of the fact that the energetics of the reaction paths have been studied only by means of thermodynamic estimations.

On the other hand, semi-empirical calculations have recently been carried out on the thermal *cis-trans* isomerization of such olefins as 2-butene and 2-pentene with a particular view to the activation barrier of the reaction.[9] For 2-butene, there was a considerable agreement of the calculated activation energy of 56.4 kcal/mol[9] with the experimental value, 62.8 kcal/mol.[3] However, there is no literature dealing with the free-radical catalyzed isomerization of olefins on the basis of the MO theory.

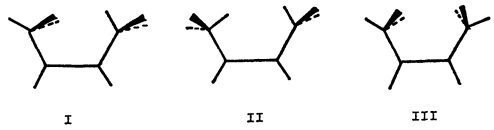
In this paper, we wish to report the application of the INDO-UHF method[10] to a conformational study of the energetics of the NO_x-catalyzed isomerization of *cis*-2-butene. The specific objectives of this study are: (1) to elucidate the mode of the interaction between the NO_x catalyst and *cis*-2-butene, (2) to provide information about the conformations of the intermediate radicals (R_1 and R_2), and (3) to discuss quantitatively the process of the internal rotation of the R_1 radical.

Method of Calculation

The following three systems were mainly investigated in this work: (a) the interacting system of NO_x (x=1 or 2) and *cis*-2-butene, involving the NO_x-addition process; (b) the intermediate radicals (R_1 and R_2), and (c) the internal rotation of the intermediate radical (R_1), augmented by the NO_x-fission process from the R_2 radical.

All the calculations on the above systems were performed by means of a semi-empirical INDO-UHF method[10] which is relatively reliable for bond angles, but less so for bond lengths.[11] The integrations and parametrizations involved in the above method will not be repeated here, because they have been described in detail in Ref. 10.

The geometries of *cis*-2-butene (r_{CC}=1.34 Å in the double bond; r_{CC}=1.54 Å in the single bond; r_{CH}=1.06 Å; ∠C=C–C=∠C=C–H=120°; ∠HCH=∠CCH=109°28′) and NO_2 (r_{NO}=1.188 Å; ∠ONO=134.1°) were obtained from a standard compendium,[12] while the bond length of NO (r_{NO}=1.159 Å) in NO was obtained as an optimum one by the INDO-UHF calculation. With regard to the optimum rotation angle of the two methyl groups in *cis*-2-butene, the INDO calculations gave the best configuration as III, which has minimum electron and nuclear repulsions, among the following three possible configurations:



The bond index of E_{AB} for the A–B bond, which is defined as the energy contribution of the A–B bond to the total energy of a molecule, was evaluated by means of a method of energy partitioning:[13,14]

$$E_{AB} = E^{R}_{AB} + E^{V}_{AB} + E^{J}_{AB} + E^{K}_{AB} + E^{N}_{AB}$$

where each energy term has the usual significance described in Refs. 13 and 14.

Results and Discussion

Interaction of the NO_x (x=1 or 2) Catalyst and cis-2-*Butene.* The ground state of NO_x(x=1 or 2) has a doublet-spin multiplicity and, hence, a free-radical character. Therefore, the SOMO (singly-occupied MO) of the NO_x, which expands predominantly around the nitrogen atom in the direction of the z-axis in Fig. 1, plays an important role in the interaction with the HOMO (highest-occupied MO) and LUMO (lowest-unoccupied MO) of *cis*-2-butene (π and π^* orbitals on the C=C double bond respectively). The interaction is favored under the maximum overlappings between the above frontier orbitals of the two reactants. In the modes of the interaction shown in Fig. 1, the bridge-type interaction was discarded because of the following reasons:

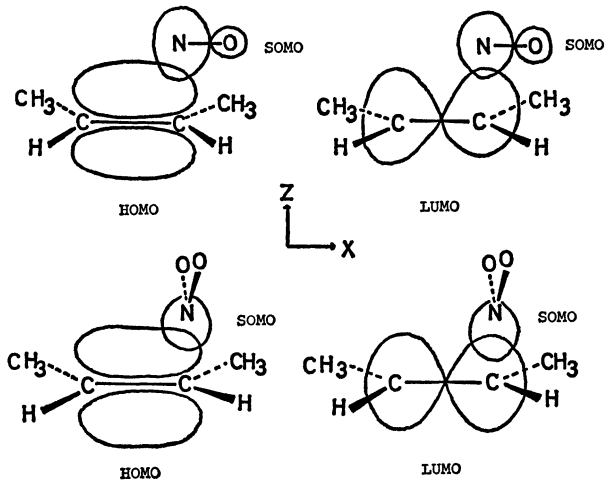


Fig. 1. Schematic representations of the modes of interaction between NO_x and *cis*-2-butene.

(a) the SOMO of the NO_x and the LUMO of *cis*-2-butene overlap unfavorably in the bridge structure; (b) the nearly equivalent rates of the exchange and isomerization reactions in such a system of di-iodoethylene and free-radical iodine atoms obviates the bridge structure,[15] even though the EPR spectroscopy of the system of *cis*-2-butene and hydrogen bromide is positive for the bridge structure,[16] and (c) the conformation of the intermediate radical formed in the isomerization of *cis*-2-butene by the sulfhydroyl radical does not favor the bridge structure.[7] In this respect,

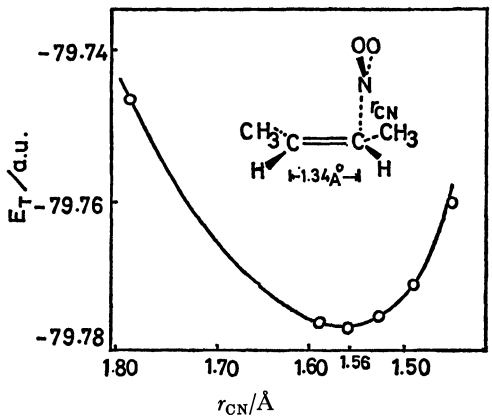

Fig. 2. Total energy of the system between NO_2 and *cis*-2-butene as a function of r_{CN}.

the present INDO-UHF calculation indicates that the two possible interacting structures mentioned above cannot be distinguished from each other only by the total energy and the overlap population[17] (0.002 at r_{CN}=3.0 Å) of the C–N bond.

Next, let us discuss the energetic aspect of the interaction system of the NO_x and *cis*-2-butene, taking NO_2 as an example. So long as the C=C double bond of *cis*-2-butene is kept constant, the NO_2 catalyst approaches *cis*-2-butene, by the least motion, in the direction of the carbon p_z-orbital expansion. As can be seen from Fig. 2, the total energy (E_T) of the above interacting system as a function of r_{CN} indicates a monotoneous stabilization of the system until r_{CN}= 1.56 Å, which is longer than the usual C–N bond length (1.47 Å[12]). With the approach of NO_2 to *cis*-2-butene, the electrons of the π-orbital of the latter flow into the former (predominantly into the two oxygen atoms) with an appreciable electron back-donation from NO_2 to the p_z-orbital of the remote carbon (not in CH_3 group) through the π-conjugation

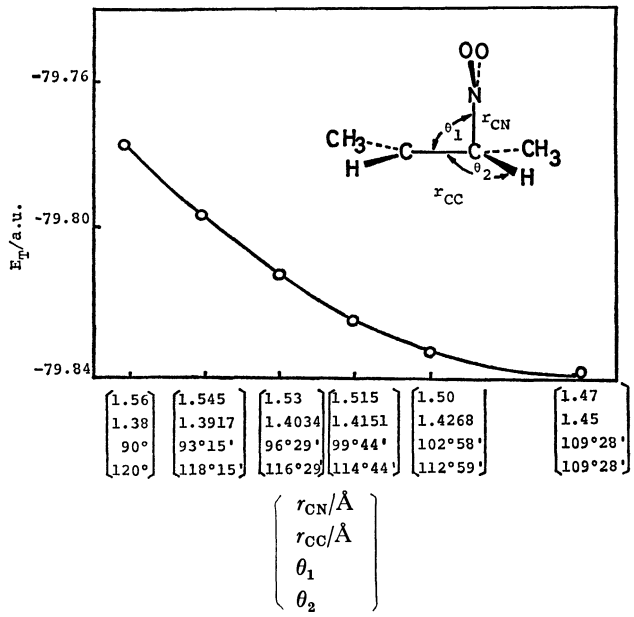

Fig. 3. Total energy for the NO_2-addition process.

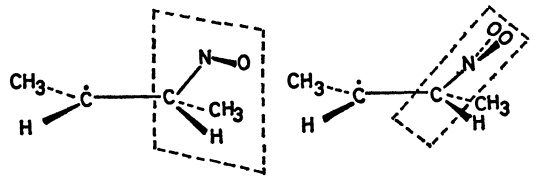
of the C=C bond. Further interaction within r_{CN}= 1.56 Å will require a stretching of the C=C bond and a change in the sp^2 hybridization of the carbon atom. We will, therefore, try to simulate the NO_2-addition process by changing the carbon hybridization=sp^2 -sp^3, r_{CN}=1.56—1.47 Å, and r_{CC}=1.34—1.45 Å (see below), with the residual part retaining its equilibrium geometries. As Fig. 3 indicates, the process has no appreciable activation barrier, although the activation energy of 12.1±0.3 kcal/mol was given for the above NO_2-addition process by Pitts *et al.*[2] The discrepancy between the INDO-UHF calculation and the experiment may be caused by the present incomplete MO-simulation; the exclusion of geometry optimizations (except for r_{CN}) in the process gave only the stabilization energy of 103.8 kcal/mol, a value which was obtained from the difference in the total energies between the intermediate radical (R_1) and the two reactants isolated.

Conformation of the Intermediate Radicals. It is necessary first to interpret the r_{CC} value of 1.45 Å for the intermediate radical (R_1) used for the MO-simulation mentioned above. Plots of the total energies (E_T) for the radical (R_1) *vs.* r_{CC} in Fig. 4 indicate that r_{CC}=1.45 Å gives the energetically most stable radical (R_1: x=1 or 2). This C–C bond length is slightly longer than that (1.430 Å[18]) of the ethylene cation, but shorter than that (1.484 Å[18]) of the ethyl cation or that (1.516 Å[18]) of the ethyl radical. Interestingly, the r_{CC} value of 1.45 Å is roughly in harmony with that (1.481 Å[9]) of 2-butene at the transition state in its thermal isomerization.

Next, we will discuss the rotation of NO_x(x=1 or 2) around the C–N bond in the intermediate radical (R_1). The rotation barrier of the C–NO ring was evaluated to be 4.08 kcal/mol, while that of the C–NO_2 ring was 1.82 kcal/mol. The former value is markedly larger than that in the methyl rotation of *cis*-2-butene (0.75 kcal/mol[19]) or of ethane (2.88 kcal/mol[20]), while the latter value of 1.82 kcal/mol is approximately of the same magnitude as the methyl rotation in *trans*-2-butene (1.95 kcal/mol[21]). At any rate, the C–NO_x (x=1 or 2) ring has indeed a restriction in rotation because its rotation barrier is essentially large as compared with the free-rotation barrier (0.6 kcal/mol at room temperature). It should be stressed here that the NO_x rotation around the C–N bond does not appreciably change the C–C bond length (1.45 Å) over 0.02 Å in the intermediate radical (R_1), because r_{CC}=1.43 or 1.47 Å makes the radical (R_1) unstable at any rotation angle in comparison with the stability of the radical (R_1) at r_{CC}=1.45 Å. The energetically most stable intermediate radical (R_1) has the following conformation:



R_1 (x=1) R_1 (x=2)

The most stable intermediate radical (R_1)

In the R_1 (x=1), the bond axes of N–O and C–H are on the same plane, and the bond angle of C–N–O is 118°, smaller by 2° than that of nitrosomethane[22]. In the R_1 (x=2), the O–O axis is perpendicular to the C–C bond axis. It is of interest here to discuss how the NO_x (x=1 or 2) rotation around the C–N bond changes the total energy and the energy-contribution terms of the radical (R_1). In Table 1, we list the total energy (E_T), and the attraction (E_I) and repulsion (E_{II} and E_N) terms as functions of some clockwise-rotation angles (θ). As can be seen form Table 1, the repulsions decrease monotonously until the R_1 takes its most stable conformation (θ=240° for NO and θ=90° for NO_2), with a normal augmentation of the attraction. It may be deduced, therefore, that the least repulsion, rather than the attraction, makes

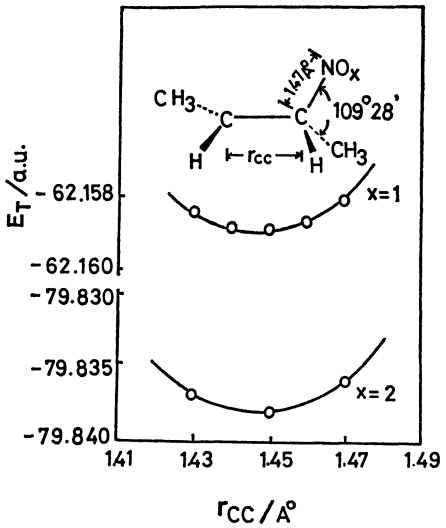


Fig. 4. Total energies of intermediate radical (R_1) as a fuction of r_{CC} (angle of C–N–O in R_1(x=1) =125°: taken from *p*-iodonitrosobenzene in M. S. Webster, *J. Chem. Phys.*, **24**, 555 (1956)).

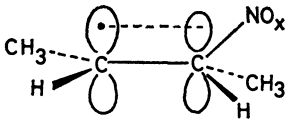
the conformation of the R_1 shown above stable. This stabilization of a rotamer is sometimes caused by the aid of hydrogen bonding,[23] the *gauche* effect,[23–26] and the interaction effect of lone-paired electrons.[27] In this respect, the hydrogen bonding seems to be expected in the hydrogen and oxygen atoms on the same plane of the R_1 ($x=1$). However, the negative overlap population does not favor such a stabilization effect.

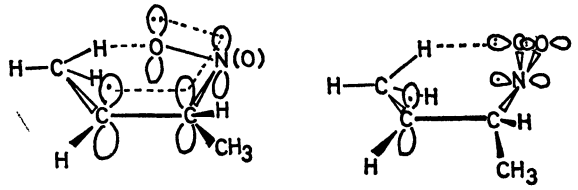
Now, let us extend the discussion to some characteristic features of the intermediate radical (R_1), paying particular attention to the C–C bond-nature and the hfsc (hyperfine splitting constant) of the sp^2-hybrid carbon. In Table 2 we list the E_{CC} and its contribution terms, together with those for *cis*-2-butene. The weakening of the C–C bond strength by the NO_x addition is well reflected in the relatively small E_{CC} and E^R_{CC} values in comparison with those in *cis*-2-butene. Interestingly, the electrostatic interaction ($E^V_{CC}+E^J_{CC}+E^N_{CC}$) becomes more repulsive in the intermediate radical (0.275 a.u.) than in *cis*-2-butene (−0.009 a.u.). This is attributable mainly to the fact that the exchange energy (E^K_{CC}) of the R_1 cannot overcompensate for the repulsion because of the diminution of the π-conjugation in the radical. It is noteworthy with respect to the π-conjugation that a weak π-conjugation (about 13% of E^R_{CC}) in the radical (R_1), as compared with that (about 29% of E^R_{CC}) in *cis*-2-butene, is possible by the aid of the following pseudo π-orbital:



Pseudo π-orbital of intermediate radical (R_1)

The pseudo π-orbital is also supported by the positive bond-order between the p_z-orbitals of the two carbon atoms (0.302 for R_1 ($x=1$) and 0.309 for R_1 ($x=2$)). In this case, the SOMO of R_1 ($x=1$ or 2) is strongly localized by the p_z-orbital of the sp^2-hybrid carbon (spin density=0.830 for R_1 ($x=1$) or 0.828 for R_1 ($x=2$)), and the interaction of this electron-unpaired p_z-orbital and the lone-pair orbitals on the oxygen atom seems to be favorably avoided in the optimum conformation of the intermediate radical (R_1). As to the hfsc values of the sp^2-hybrid carbon in the R_1, the calculated hfsc values, (+)34.47 G for R_1 ($x=1$) and (+)34.40 G for R_1 ($x=2$), are approximately of the same magnitude as that ((+)39.07 G[28]) obtained experimentally for the sp^2-hybrid carbon in ethyl radical.

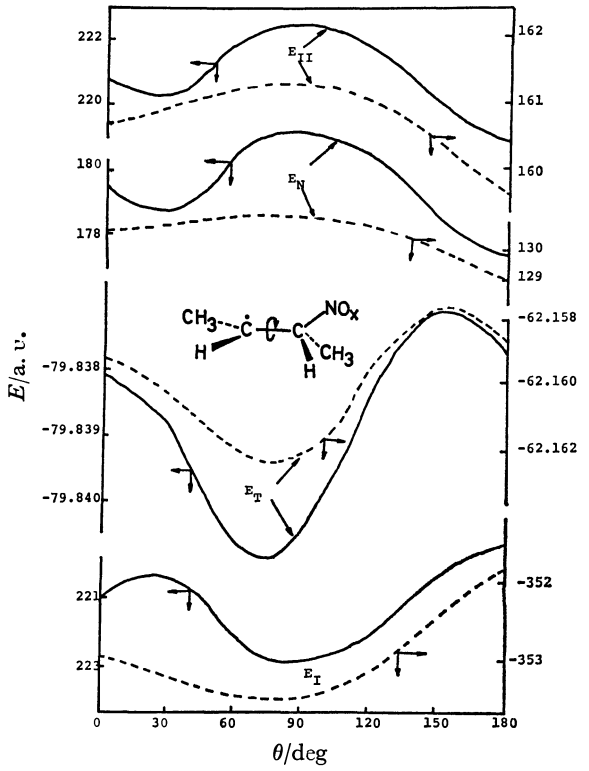
Internal Rotation of the Intermediate Radical. The intermediate radical (R_1) is transformed to the R_2 radical *via* its internal rotation around the C–C bond in two directions, *i.e.*, the clockwise and counter-clockwise rotations shown in Fig. 5. As can be seen from Fig. 5, the clockwise rotation has the energetically most stable rotamer at $\theta\simeq60°$, with the most favorable attraction (E_I), while the other rotation has the energetically best conformation at $\phi\simeq120°$, with the least repulsions ($E_{II}+E_N$). These energetically stable conformers correspond to the staggered configurations, while the most unstable ones ($\theta=150°$ and $\theta=30°$) correspond to the eclipsed configurations (see Fig. 6). As may be seen from Fig. 6, the steric repulsion of the two methyl groups seems to destabilize the rotamer, even though the size of this repulsion, 0.4 kcal/mol,[2] is relatively small. We should also discuss the stabilization effects of homoconjugation and hydrogen bonding in the rotamer and the destabilization effect of the repulsive interaction between the unpaired and lone-paired electrons. In an eclipsed configuration ($\theta=90°$), the following coplanar conformation, obtained by the NO_x ($x=1$ or 2) rotation around the C–N bond, seems to be stabilized by the aid of the homoconjugation and the hydrogen bonding.



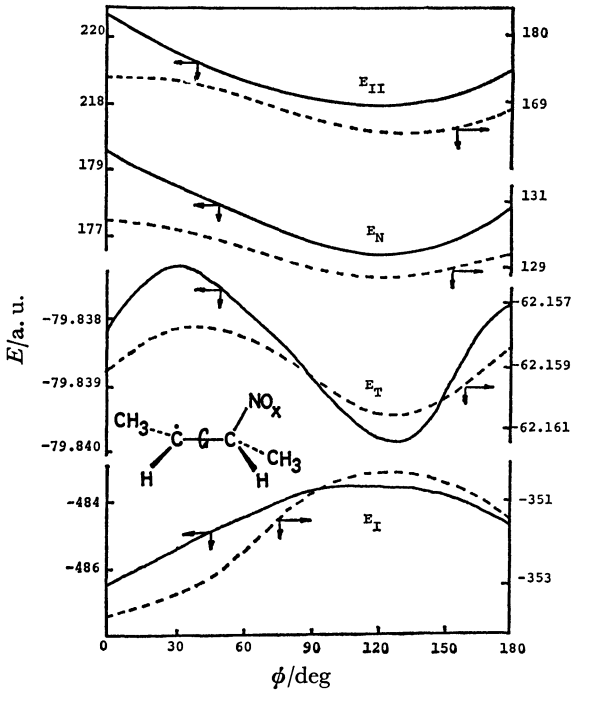
Homoconjugation and hydrogen bonding in the intermediate-radical rotamer

However, the NO_x rotation caused only electron and nuclear repulsions (augmented by the repulsion of the unpaired and lone-paired electrons), which overcome the above stabilization effects. On the other hand, the hydrogen bonding can be expected for the staggered configuration ($\theta=60°$) with a relative small interaction between the unpaired and lone-paired electrons.

Some remarks should be made with regard to the conformation of the rotamer. No change in the C–C bond length (1.45 Å) over ±0.02 Å was observed during the internal rotation of the intermediate radical (R_1), because the E_T values at $r_{CC}=1.43$ or 1.47 Å for the staggered and eclipsed conformers indicated the energetically destabilization of the rotamer. In addition, the fission of the NO_x from the intermediate radical (R_1) during the internal rotation cannot be expected in view of the fact that, at any rotation angle, the rotamer (R_1) was always more stable than the



(a) Clockwise rotation



(b) Counter-clockwise rotation

Fig. 5. Energies for the internal rotation of radical (R_1) as a function of the rotation angle (solid and dotted curves: R_1 ($x=2$) and R_1 ($x=1$) respectively).

system of the isolated NO_x and the isolated rotamer of *cis*-2-butene ($r_{CC}=1.45$ Å was used).

Now, let us discuss the activation barrier of the internal rotation of the radical (R_1). The clockwise-rotation barriers were calculated to be 3.01 kcal/mol for

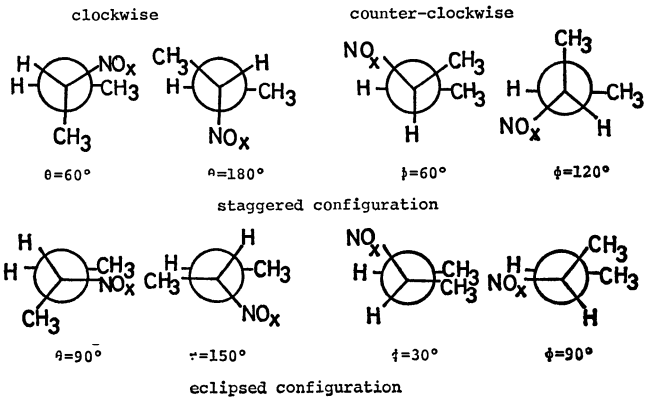


Fig. 6. Staggered and eclipsed configurations of the radical (R_1).

the R_1 ($x=1$) and 2.70 kcal/mol for the R_1 ($x=2$), while the counter-clockwise rotation-barriers were smaller, 1.82 kcal/mol for the former and 1.75 kcal/mol for the latter. The rotation barriers obtained from the present INDO-UHF calculations are relatively small as compared with those obtained from the thermodynamic estimations, 4.2 kcal/mol[29] for the R_1 ($x=1$) and 4±0.5 kcal/mol[2] for the R_1 ($x=2$). At any rate, it can be said that the NO_x ($x=1$ or 2) catalyst seems to depress extremely the activation barrier of the thermal internal-rotation of *cis*-2-butene, 62.8 kcal/mol.[3]

With regard to the intermediate radical (R_2) formed by the internal rotation of the R_1 radical, the R_2 radical is less stable by 0.36 kcal/mol ($x=1$) or 0.50 kcal/mol ($x=2$) than the R_1 radical. However, the electronic properties of the R_2 radical are not so very different from the R_1 radical in terms of the C–C and C–N bond energies ($E_{CC}=-1.158$ a.u. and $E_{CN}=-0.943$ a.u.), the spin density of the unpaired-electron orbital, and the hfsc value of the sp^2-hybrid carbon.

Finally, let us mention briefly the NO_x-fission process in the intermediate radical (R_2), taking the NO_2-fission as an example. The process was simulated much as in the case of the NO_2-addition process by changing $r_{CN}=1.47$—1.56 Å, $r_{CC}=1.45$—1.34 Å, and the hybridization of the carbon binding to NO_2= sp^3—sp^2. The monotoneous destabilization of the E_T values for the above simulated NO_2-fission process brought about a dissociation energy of 44.6 kcal/mol, a value of approximately the same magnitude as the experimental dissociation energy of the C–NO_2 bond, 60 kcal/mol.[2]

The calculations were carried out on a FACOM 230-75 at the Data Processing Center of Kyushu University.

A Formulation of Chemical Kinetics in Micellar Solutions

Keishiro SHIRAHAMA

Department of Chemistry, Faculty of Science and Engineering, Saga University, Saga 840

(Received March 19, 1975)

Reaction kinetics in the presence of micelles is formulated on the basis of a microheterogeneous reaction in accordance with a current model of micellar catalysis. The necessary molecular parameters are the radius of the hydrocarbon core of a spherical micelle, the thickness of a reaction surface layer, the surface and zeta potentials, and a distribution coefficient of a hydrophobic substrate. The derived expression was applied to the hydrolysis reaction of methylorthobenzoate in the presence of sodium dodecylsufate micelle to describe reaction properties such as a rate-surfactant concentration profile, inhibition by added electrolyte, and activation energy. The micellar effect on the reaction rate was explained by a simple concentration effect of the reactants; the stabilization of the transition state by the micellar surface potential need not be taken into consideration. Inhibition of the orthoester hydrolysis by a cationic surfactant is also predicted.

The last decade has witnessed a remarkable development in studying chemical reactions in surfactant solutions,[1-3] wherein 5- to 1000-fold acceleration of rates as well as inhibitions of various magnitudes have been reported. Most reactions are analyzed by a chemism formula akin to the Michaelis-Menten equation to obtain a rate constant at the micellar phase k_m, and one at the bulk phase k_b, separately. However, no attempt has been made to look into the physical and chemical significances of k_m, except for a few works.[4-7]

In this communication a model that has been proposed by organic chemists will be formulated and analyzed on the basis of a microheterogeneous reaction in order to give insights into the nature of micellar catalysis.

Theoretical

Now let us define $v(\boldsymbol{r})$, which may be called the "reaction density,"

$$v(\boldsymbol{r}) = k(\boldsymbol{r})C_A(\boldsymbol{r})C_B(\boldsymbol{r}) \quad (1)$$

In this equation, which is apparently that of a second order reaction, $v(\boldsymbol{r})$ is a reaction rate in an elementary volume $d\boldsymbol{u}$, $k(\boldsymbol{r})$ is a rate constant, and $C_A(\boldsymbol{r})$ and $C_B(\boldsymbol{r})$ are the concentrations of reactants A and B in the volume. It should be noted that they are all expressed as a function of the coordinate $\boldsymbol{r}$. A reaction rate in an entire reaction vessel is obtained by integrating Eq. (1) over the vessel

$$dn/dt = \int_V v(\boldsymbol{r})d\boldsymbol{u} \quad (2)$$

More specifically, consider that there are N micelles in the reaction vessel, each micelle being equivalent, and that the micellar concentration is too dilute for any two micelles to approach each other. Then this system is approximated by an assembly which consists of N subsystems, where in a subsystem it is supposed that a micelle is located at the center. The subsystem satisfies $(4/3)\pi\rho^3 = V/N$, ρ being the radius of the spherical subsystem. A reaction rate in the subsystem is expressed as

$$I = 4\pi\int_0^\rho x^2 k(x)C_A(x)C_B(x)dx \quad (3)$$

where x is the distance from the center of a spherical micelle which is very likely at concentrations not far above a critical micelle concentration (CMC). It can be further assumed that reactant A is a hydrophobic substrate, and reactant B an ionic species, without losing generality too much. Concentration profiles of these reactants around a micelle are illustrated in Fig. 1, where R is the radius of the hydrocarbon core of a micelle, and s the thickness of a surface layer around a micelle. This surface layer is presumed to be the reaction site which contains the so-called Stern layer and extends up to a plane of shear. Reactant A is partitioned in the micellar phase because of its hydrophobicity, and $C_A(x)$ decreases across the surface layer down to the bulk concentration C_{Ab}. Reactant B is concentrated around micelles by the Coulombic force if the charge is opposite to that of the micelle. The ionic reactant scarcely penetrates into the hydrocarbon core of a micelle, and, beyond the surface layer, is distributed in a diffused double layer down to the bulk concentration C_{Bb}. Then Eq. (3) is integrated in two regions: $R \leqq x \leqq R+s$, and $R+s \leqq x \leqq \rho$, respectively.

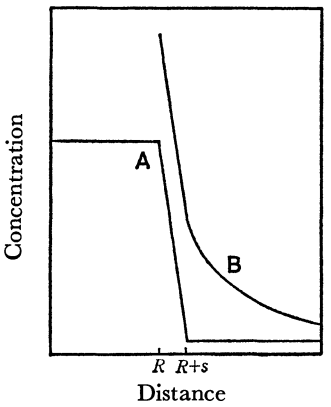

Fig. 1. Schematic representation of concentration profile around a micelle. A: a hydrophobic reactant, B: an ionic reactant.

Zeroth Approximation. It is assumed that $k(x) = k_s$, $C_A(x) = C_{As}$, and $C_B(x) = C_{Bs}$ in the surface layer, and $k(x) = k_b$, $C_A(x) = C_{Ab}$, and $C_B(x) = C_{Bb}$ in the outer layer. Then one obtains

$$I = 4\pi k_s C_{As}C_{Bs}\int_R^{R+s} x^2dx + 4\pi k_b C_{Ab}C_{Bb}\int_{R+s}^{\rho} x^2dx$$
$$= V_s k_s C_{As}C_{Bs} + V_b k_b C_{Ab}C_{Bb} \quad (4)$$

In Eq. (4), V_s and V_b are volumes of the surface and

bulk phases in a subsystem, respectively. Converting Eq. (4) into a conventional rate equation in a concentration scale, one has

$$dC/dt = (1/V)(dn/dt) = I/V_{sub} = IN/V$$
$$= \phi_s k_s C_{As} C_{Bs} + \phi_b k_b C_{Ab} C_{Bb} \quad (5)$$

where $V_{sub}=(4/3)\pi\rho^3$, and $\phi_i=NV_i/V$ is the volume fraction indicated by the respective subscript. Equation (5) is somewhat similar to equations previously reported,[4,5] but is not identical. The surface layer concentrations appearing in Eq. (5) are expressed in terms of the corresponding bulk concentrations by using the distribution coefficients K_A and K_B,

$$K_A = C_{Am}/C_{Ab} = C_{As}/C_{Ab} \quad (6)$$

where C_{Am} is a concentration of A in the micellar phase. The second identity, *i.e.*, $C_{Am}=C_{As}$ is a result of the zeroth approximation, and

$$K_B = C_{Bs}/C_{Bb} = \exp(-e\psi_0/kT) \quad (7)$$

where ψ_0 is a surface potential of a micelle. Equation (5) becomes

$$dC/dt = (\phi_s k_s K_A K_B + \phi_b k_b) C_{Ab} C_{Bb} \quad (8)$$

This equation can be expressed by the analytical concentrations of the reactants, C_A and C_B.

$$dC/dt = (\phi_s k_s K_A K_B + \phi_b k_b) C_A C_C/(\phi_m K_A + \phi_b) \quad (9)$$

where the following relations were used:

$$VC_A = (V_m C_{Am} + V_b C_{Ab}) N \quad (10)$$

and

$$C_B = C_{Bb} \quad (11)$$

In Eq. (10), V_m is a volume of the micellar region and C_{Am} a concentration of substrate A there. Equation (11) holds for a buffered species, although there is an argument suggesting the difficulty in estimating the concentration at the micellar surface.[8] Comparing Eq. (9) with the experimental expression, $v=k_2 C_A C_B$, one obtains

$$k_2 = [(\phi_s f K_A K_B + \phi_b)/(\phi_m K_A + \phi_b)] k_b \quad (12)$$

where $k_s=fk_b$ is introduced, and f implies an intrinsic micellar effect taken relative to k_b.

First Approximation. At this stage, it is assumed, based on a more realistic model, that the concentrations of the reactants decrease linearly in the surface layer, *i.e.*,

$$C_A(x) = C_{Am}[1-(K_A-1)(x-R)/K_A s] \quad (13)$$

and

$$C_B(x) = C_{Bm}[1-[1-\exp(-(\zeta-\psi_0)/kT)](x-R)/s] \quad (14)$$

In Eq. (14), the zeta potential ζ was used to denote the concentration of reactant B at $x=R+s$, or the plane of shear. Substituting Eqs. (13) and (14) into Eq. (3) for the surface layer part I_s, one has

$$I_s = 4\pi f k_b C_{Am} C_{Bm}$$
$$\times \int_R^{R+s} x^2[1-(K_A-1)(x-R)/K_A s]$$
$$\times [1-[1-\exp(-e(\zeta-\psi_0)/kT)(x-R)/s]dx \quad (15)$$

Comparing Eq. (15) with Eq. (4), one can understand that the integral in Eq. (15) corresponds to the volume of the surface layer, and it may be called the effective volume of the surface layer V_{es}. Replacing ϕ_s in Eq. (12) with $\phi_{es}=NV_{es}/V$, an effective volume fraction of the surface layer, one has

$$k_2 = k_b(\phi_{es} f K_A K_B + 1)/(\phi_m K_A + 1) \quad (16)$$

where $\phi_b=1$ was used in accordance with an assumption of very dilute micellar concentration. Equation (16) has many more detailed physicochemical contents than does the formally similar equation.[2]

Application to MOB–SDS System. Now our discussion will be confined to the hydrolysis kinetics of methylorthobenzoate (MOB) in sodium dodecylsulfate (SDS) solution, for the kinetic studies on MOB in aqueous and in SDS solutions have been fully described,[1,3,10] and since SDS is one of the most explored surfactants, the necessary molecular parameters are available.[1-3,11] First, the rate enhancement k_2/k_b at 0.01 M SDS in micellar form will be estimated according to Eq. (16). The necessary parameters are listed in Table 1. Prior to the numerical calculation, the parameters are briefly examined. Dougherty and Berg have recently reported the distribution coefficient of MOB between the micelle and the bulk phases by the ultrafiltration method.[12] The value they obtained varies with the substrate concentration, but at the concentration in the kinetic experiment (about 5×10^{-5} M), $K=1.4\times10^4$ (MOB mol fraction in micelle/MOB mol fraction in the bulk), which is converted to $K_A=C_{Am}/C_{Ab}$ [(mol of solubilized MOB/micellar volume)/(mol of MOB in the bulk/l of water)] by using the molar volume of SDS micelle=0.3 l/mol, which is between the partial molar volume of SDS micelle, 0.25 l/mol,[13] and a calculated micellar volume with a radius=$R+s$ and aggregation number of a micelle=70, 0.33 l/mol. The value of K_B, or exp $(-e\psi_0/kT)$ is taken from that calculated by Stigter and Mysels using a modified Gouy-Chapman potential, which differs by only a few milivolts from the spherical potential.[9,14] There may be various factors affecting f. The factor f should have a form $f=\exp(-\Delta G^{\neq}/RT)$, where $\Delta G^{\neq}$ is an activation free energy representing the relative stabilizations of the transition state by the hydrophobic interaction, the orientation effect, and electrostatic effects including the Coulombic as well as dipole-field interactions. For the moment $f=1$ is assumed, although there is an opinion stressing the electrostatic stabilization of the transition state,[3,15] *i.e.*, $f>1$; this is an overestimation, as will be shown later. Equation (16) gives $k_2/k_b=103$, which is com-

Table 1. Parameters to calculate the micellar effect on reaction kinetics

Quantity		Unit	Ref.

Aggregation number of a micelle	70		11

parable to a 69-fold enhancement experimentally obtained for MOB–SDS system at 25 °C.[15] Many aspects of the micellar effects on the kinetics will be explained on the basis of Eq. (16)

Inhibition of Rate Enhancement by Added Electrolyte A marked dependence of the rate on the added electrolyte can be analyzed in the following manner. Under the condition, $\phi_{es}K_A f\exp(-e\psi_0/kT) \gg 1$ at a constant micelle concentration, Eq (16) becomes

$$k_2/k_b = \phi_{es}K_A f\exp(-e\psi_0/kT) \times \text{constant} \quad (17)$$

Taking the logarithm of Eq. (17), and assuming $\phi_{es}=$ constant because it varies by less than 1% even if ψ_0 is changed from 170 to 130 mV as a result of numerical calculation, one obtains

$$\ln(k_2/k_b) = -\nu\Phi_0 + \text{constant} \quad (18)$$

where ν expresses an electrostatic effect arising from terms other than K_B, possibly from $f=\exp(-\Delta G^{\neq}/RT)$, and $\Phi_0=e\psi_0/kT$ is a reduced surface potential, which can be approximated by a simplified Gouy-Chapman potential under the pertinent condition, $|\psi_0|>100$ mV,[16]

$$\Phi_0 = \ln C_t + \text{constant} \quad (19)$$

In Eq. (19), C_t is the total counterion concentration. Combining Eq. (18) with Eq. (19), one has

$$\log(k_2/k_b) = -\nu \log C_t + \text{constant} \quad (20)$$

In Fig. 2, $\log(k_2/k_b)$ is plotted against $\log C_t$, where the kinetic data are those of Dunlap and Cordes,[15] and $C_t=cmc+$buffer concentration (0.01 M)+added salt concentration C_a. Before interpreting the features appearing in Fig. 2, it should be noted that *cmc* is remarkably diminished by the added electrolyte, and this tendency becomes approximately saturated when the added salt concentration is as much as, *e.g.*, 0.1 M.[17] Dunlap and Cordes have performed their measurement at a constant total SDS concentration of 0.01 M, and therefore the micellar concentration increases with increasing added electrolyte concentration; the fraction of micellized SDS is about 0.5 at $C_a=0$, and about 0.85 at $C_a=0.1$ M. So in accordance with the assumption of constant micellar concentration, it is the slope at the high concentration region of added electrolyte that is significant, because the micellar concentration remains nearly constant in this region of C_a. As seen in Fig. 2, the slope in the region is unity, $\nu=1$, which implies that there is no electrostatic effect other than $K_B=\exp(-\Phi_0)$ in Eq. (17). If there were any other electrostatic effect such as the stabilization of transition state,[3,15,18] a value of $\nu>1$ should be expected: in other words, $\Delta G^{\neq}$ should contain a Φ_0 term. Therefore it is considered that the carbonium ion at the transition state is stabilized by the surface potential to the same degree as the protonated MOB, a reactant of the rate-determining step, is, because of the proximity of the protonated MOB and the carbonium ion-like transition state on a reaction coordinate.[10] Thus it may be concluded that the micellar effect on MOB hydrolysis is mainly, if not solely, ascribed to the concentration effect due to the hydrophobic interaction with a micelle as well as to the electrostatic attraction of the proton.

Activation Energy. Another subsidiary piece of evidence that supports the absence of electrostatic stabilization of the transition state is obtained by examining the activation energy. The Arrhenius plot gives the activation energy in the presence of micelles, $E_m^{\neq}=11$ kcal/mol, which is about 4.5 kcal/mol smaller than the one in the absence of micelles, $E_b^{\neq}$.[10] Strictly speaking, $\Delta E^{\neq}=E_m^{\neq}-E_b^{\neq}$ arises from the temperature dependences of K_A, $K_B=\exp(-\Phi_0)$, and f, but the main part of it is certainly occupied by $\Phi_0 kT=-4$ kcal/mol ($\psi_0=-170$ mV), for the temperature dependence of the hydrophobic interaction is very small.[19] There would be no possibility for the f-factor to contribute another Φ_0 term originating from the electrostatic stabilization of the transition state to the activation energy, unless a fortuitous cancellation between the K_A and f terms occurs.

Rate-Surfactant Concentration Profile. It has been well known that there is a tri-phasic feature in the rate-surfactant concentration profile, which can be reproduced by Eq. (16), as shown in Fig. 3. It should be noted that a curve with a slight and broad maximum can be obtained only when a ψ_0 that decreases with increasing counterion concentration is employed: ψ_0 was varied from -172 mV at [M]= 0.005 M to -165 mV at [M]=0.065 M, where [M] denotes the SDS concentration in micellar form.

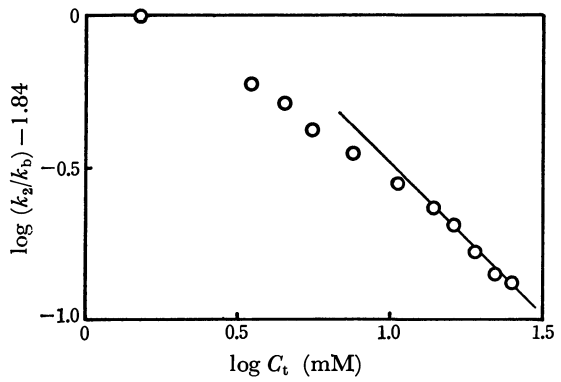

Fig. 2. Effect of added electrolyte on rate enhancement.

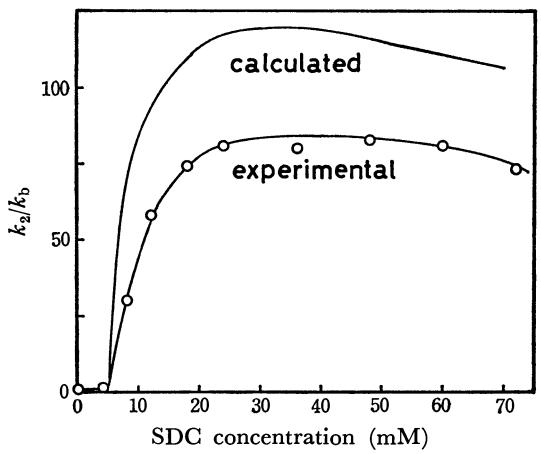

Fig. 3. Rate-SDS concentrationprofile. The experimental data from Ref. 15.

Discussion

Now let us examine the factors which are contributing to rate enhancement by means of Eq. (16). The term ϕ_{es} is numerically expressed as 0.054 [M], where [M] is a micellar concentration in SDS mol/l, and roughly evaluated by (the total SDS concentration —*cmc*), although there is some difficulty in estimating [M].[20] The numerical factor, 0.054 is an effective volume of the surface layer per one SDS molecule in l/mol. So, at [M]=0.01 M, for example, ϕ_{es}= 0.00054. Multiplied by K_A, $\phi_{es}K_A$=0.453, which is too small to explain the observed rate enhancement. Further multiplied by $K_B=\exp(-\Phi_0)$=840, $\phi_{es}K_AK_B$=380, which is divided by $(\phi_m K_A+1)$=3.52 to give 103-fold enhancement, an expected magnitude. There is a systematic discrepancy between the observed and the calculated rates, as seen in Fig. 3. A value of f=0.7 would give striking coincidence, but a deviation from unity of this size might be insignificant in view of the simplicity of the fundamental model and the consequent uncertainty in the molecular parameters. Here again it may be inferred that a simple concentration effect is the most important factor, and effects specific to micelles would be, if present, of secondary importance. In order to simulate the curve in Fig. 3, it was necessary that 15% of micellar concentration, in addition to the *cmc* and the buffer concentration, be taken as the total counterion concentration C_t: in other words, about 15% of the counterion of a micelle is shared among other micelles.

Inhibition of MOB Hydrolysis by Cationic Surfactant. Although our discussion heretofore has been restricted to the MOB–SDS system, the inhibition of MOB hydrolysis by a cationic surfactant should be briefly referred to. Hydrolysis of MOB is inhibited about 3-fold in the presence of 0.04 M cetyltrimethylammonium bromide.[21] This inhibition can be interpreted in terms of Eq. (16), in which the $\phi_{es}K_A f \exp(-\Phi_0)$ term is neglected because $\exp(-\Phi_0) \ll 1$ in this case.

$$k_2/k_b = 1/(\phi_m K_A + 1) \quad (21)$$

Equation (21) predicts about 10-fold inhibition when $\phi_m=0.3\times0.04=0.012$ and K_A=800, as a rough estimate, are substituted. Thus the inhibition is explained by the fact that MOB is localized in a micellar region by the hydrophobic interaction, while the protons are expelled out of there by the Coulombic repulsion.

The author thanks Dr. Y. Moroi of Kyushu University for his interest and discussions.

Refinement of the Crystal Structure of Sodium Hexahydroxoantimonate(V), $NaSb(OH)_6$

Takeshi Asai

Institute of Scientific and Industrial Research, Osaka University, Yamada-kami, Suita, 565

(Received March 31, 1975)

The crystal structure of sodium hexahydroxoantimonate (V), $NaSb(OH)_6$, has been refined. The previous structure given by Schrewelius was confirmed, but the positional parameters of oxygen atoms were shifted significantly. Both antimony and sodium atoms are surrounded by six oxygen atoms octahedrally. The interatomic distances are: Sb-O=1.972—1.999 Å (mean 1.98 Å), O-O=2.758—2.834 Å (2.80 Å) for an SbO_6 octahedron, Na-O=2.375—2.406 Å (2.39 Å) and O-O=3.229—3.526 Å (3.38Å) for an NaO_6 octahedron. Two types of sequences of hydrogen bonds were recognized. They were compared with the sequences of hydrogen bonds in $In(OH)_3$ and $MnSn(OH)_6$.

In the course of our NMR studies on the metal hydroxides, $In(OH)_3$, $MgSn(OH)_6$ and $NaSb(OH)_6$, accurate structural information was needed on these compounds. The crystal structure of $In(OH)_3$,[1] and that of $MnSn(OH)_6$,[2] which is isomorphous with $MgSn(OH)_6$,[3,4] have already been analyzed with single crystal X-ray diffraction data. On the other hand, the crystal structure of $NaSb(OH)_6$ was derived from powder X-ray diffraction intensities[5,6] with accordingly poor accuracy. The analysis resulted in an OH group free from hydrogen bonding and another with a very short OH···O distance (2.55 Å).

Experimental

The compound was obtained by slow evaporation of a dilute aqueous solution containing $KSb(OH)_6$ and NaCl in the molar ratio of 2 : 1. The crystals thus obtained were enclosed with one (001) and eight {111} faces.

The space group and lattice constants[5,6] were confirmed from Weissenberg and precession photographs. Crystallographic data obtained in this study are given in Table 1.

The intensity data were collected using a Rigaku automatic four-circle diffractometer with a scintillation counter and the Mo$K\alpha$ radiation. A total of 821 reflections in two octants, among which 465 reflections were independent, were measured within $\sin\theta/\lambda$ of 0.60 Å^{-1}. Ninety-six reflections with $|F_o|$ values less than 2σ, twice the estimated standard deviations based on the counting statistics, were assumed to have zero amplitudes. The whole reflections were corrected for Lorentz and polarization effects, but not for absorption nor extinction effects (μR=0.55).

Table 1. Crystallographic data

$NaSb(OH)_6$,	F. W. 246.8
Tetragonal	
a=8.029(2),	c=7.894(3) Å
U=508.9Å^3,	Z=4
D_m = 3.20 g·cm^{-3} [5]	
D_x=3.22 g·cm^{-3}	
Systematic absences:	$hk0$ with $h+k=2n+1$
	$00l$ with $l=2n+1$
Space group $P4_2/n$ (No. 86)	

From a three-dimensional Patterson synthesis, approximate positional parameters for all non-hydrogen atoms were obtained. They were refined by a block-diagonal least-squares method firstly with isotropic thermal factors and then with anisotropic ones. The final residual R was 0.063. A trial to find hydrogen positions in the difference Fourier maps was unsuccessful. The weighting scheme was; w= 1 for $|F_o|\neq 0$, and w=0 for $|F_o|=0$. Reflections of 020 and 002 were omitted in the refinement because they were seriously affected by extinction. The atomic scattering amplitudes for Sb^{5+}, Na^+ and O^- with anomalous dispersion corrections were taken from Ref. 7. All calculations were performed on a NEAC 2200/700 computer at the Computer Center, Osaka University, using UNICS programs RSSFR-5, HBLS-V and RSDA-4 with some modifications. The final parameters are given in Table 2. The final observed and calculated structure factors are listed in Table 3.

Discussion

The crystal structure is projected in Fig. 1. Interatomic distances and angles are shown in Fig. 2. The structure is in general the same as that given by Schrewelius.[6] The oxygen atoms, however, were significantly shifted (0.13—0.69 Å); as a result, his short OH···O distance (2.55 Å) increased to a normal distance of 2.859 Å, while his longer O···O distance (4.51 Å) decreased to 3.149 Å. The antimony atom is surrounded by six oxygen atoms. This coordination polyhedron is a nearly regular octahedron with the mean interatomic distances of 1.98 Å for Sb-O and 2.80 Å for O-O. The sodium ion is surrounded by six oxygen atoms belonging to six different

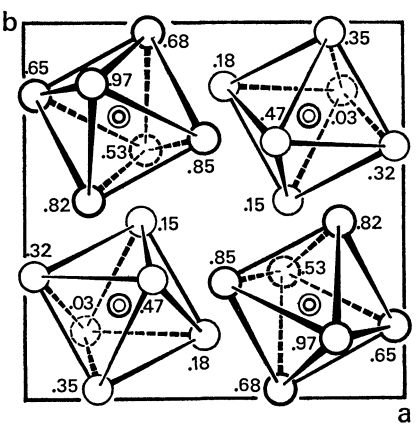

Fig. 1. The crystal structure of $NaSb(OH)_6$ projected along the [001] axis. Numbers attached to the oxygen atoms are their z-parameters.

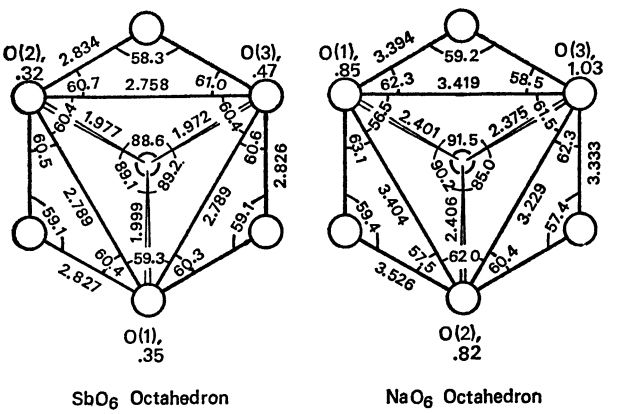

Fig. 2. Interatomic distances (l/Å) and angles (ϕ/°) for SbO_6 and NaO_6 octahedra. The e. s. d.'s are ±0.009 Å and ±0.2°, respectively. The metal atoms are situated on the center of inversion, Sb at (1/4, 1/4, 1/4) and Na at (3/4, 3/4, 3/4). Numbers attached to the oxygen atoms are their z-parameters.

SbO_6 octahedra. The coordination polyhedron is also octahedral, but the distortion is greater than that of the SbO_6 octahedron. The interatomic distances are 2.375—2.406 Å (mean 2.39 Å) for Na–O and 3.229—3.526 Å (mean 3.38 Å) for O–O.

Interatomic distances of O···O which can be associated with hydrogen bonding are given in Table 4. The table shows that all OH groups are hydrogen-bonded[8], and the OH group free from hydrogen bonding in the Schrewelius' analysis is eliminated. These hydrogen bonds extend in the whole crystal. The sequences of hydrogen bonding in $In(OH)_3$, $MnSn(OH)_6$ and $NaSb(OH)_6$ are compared schematically in Fig. 3. Squares of four hydrogen-bonded OH's

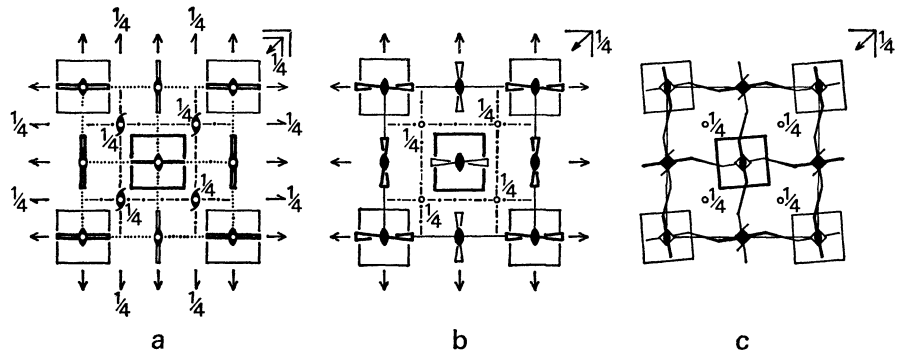

Fig. 3. Schematic sequences of hydrogen bonding viewed along the [001] axis; (a) $In(OH)_3$, (b) $MnSn(OH)_6$ and (c) $NaSb(OH)_6$. The squares at $z \simeq 0$ are shown in thin lines and those at $z \simeq 1/2$ in heavy lines. Vertical mirror planes in $In(OH)_3$ are shown in dotted lines, while the other symmetry elements are shown after the usual fashion.

Table 4. Interatomic distances associated with the hydrogen bonding

The e.s.d.'s are ±0.009 Å

$O(1)^{i}\cdots O(2)^{iv}$	2.859 Å
$O(1)^{i}\cdots O(1)^{ii}$	3.149
$O(2)^{i}\cdots O(2)^{v}$	2.738
$O(3)^{i}\cdots O(3)^{iii}$	2.787

Superscripts in this table and in the text mean the following symmetry operations to the positional parameters given in Table 2.

i	$1/2-x$,	$1/2-y$,	$1/2-z$
ii	$1/2+x$,	$1/2+y$,	$1/2-z$
iii	$1/2+y$,	$1/2-x$,	$1/2+z$
iv	$1/2-y$,	$1/2+x$,	$-1/2+z$
v	$1/2+x$,	$-1/2+y$,	$1/2-z$
vi	$3/2-y$,	$1/2+x$,	$1/2+z$

are found in $In(OH)_3$ and $MnSn(OH)_6$. Each edge of these squares affords two sites for a hydrogen atom, yielding a statistical structure of hydrogen atoms.[1,2,9] A similar hydrogen-bonded square of O(3)'s is found also in $NaSb(OH)_6$. At the same time, however, hydrogen-bonded chains of the type $\cdots O(2)^{iv}\cdots O(1)^{i}\cdots O(1)^{ii}\cdots O(2)^{iii}\cdots O(2)^{vi}\cdots$ are running along the a and b axes. These chains are found only in $NaSb(OH)_6$ among these compounds; therefore the chain structure of the hydrogen bond is a characteristic feature of this compound. Considering the symmetry, hydrogen atoms in $NaSb(OH)_6$ may also take a statistical structure.

Appearance of the chain sequences of hydrogen bonding in $NaSb(OH)_6$ can be explained well if we consider the differences in the bond nature in these $AB(OH)_6$ compounds. In $In(OH)_3$ the lattice is constructed with equivalent $In(OH)_6$ octahedra through sharing their corners, while in $NaSb(OH)_6$ it is constructed with Na^+ and $Sb(OH)_6^-$ ions. The more ionic character in $NaSb(OH)_6$ will allow an anion to take a different orientation from that of $In(OH)_6$ octahedra, yielding a distortion of $Na(OH)_6$ octahedra. The distortion in $NaSb(OH)_6$ is such that the interatomic distances of O(1)'s in the same square become longer and the distance of $O(1)\cdots O(1)^{ii}$ between the adjacent squares becomes shorter; thus a hydrogen-bonded chain is formed. A similar trend is also seen in $MnSn(OH)_6$. However, the difference between the ionic radii of Mn^{2+} and Sn^{4+} cations is much smaller than that between those of Na^+ and Sb^{5+} cations in $NaSb(OH)_6$. This means that $Sb(OH)_6^-$ octahedra must rotate much more than $Sn(OH)_6^{2-}$ octahedra in order for the lattice to accomodate A^{n+} cations in the interstices of $B(OH)_6^{n-}$ anions. Therefore, the hydrogen-bonded squares in $MnSn(OH)_6$ experience only a little distortion, while two thirds of the squares in $NaSb(OH)_6$ are forced to break and to recombine into chains.

The author is grateful to Messrs. S. Matsumoto and S. Wakano for their assistance in experiments.

The Photobleaching of Trapped Electrons and the Electron Capture of Radicals in γ-Irradiated Hydrocarbon Matrices at 77 K

Yo-ichi Ishikawa, Ko-ichi Oka, and Shin Sato

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received April 2, 1975)

The rate of the photobleaching of the trapped electrons in the 3-methylhexane and methylcyclohexane matrices at 77 K was measured by means of ESR as a function of the concentration of the 3-methylhexyl or methylcyclohexyl radicals present in the matrices. The quantum yield of the photobleaching at the wavelength of 1300 nm increased with the increase in the radical concentration. The stable products such as olefins formed during the γ-irradiation did not affect the quantum efficiency. These results support the suggestion made by Willard *et al.* that the 3-methylhexyl and methylcyclohexyl radicals capture the electrons released from the trapping sites by the irradiation of the infrared light. A comparison showed that the radicals are comparable with sulfur hexafluoride in electron capture.

The γ-irradiation of hydrocarbon glasses produces trapped electrons, radicals, and cations.[1] The increase in the radical concentration is approximately linear during the first 4×10^{20} eV g^{-1}. After *ca.* 2×10^{21} eV g^{-1} of continuous irradiation, the yield of radicals reaches a steady state.[2] On the other hand, the yield of trapped electrons has its maximum value at the point where the yield of radicals becomes saturated, and it drops to zero when the yield of radicals reaches the steady state.[3]

After complete bleaching with IR light, the irradiation of UV light at 375 nm can regenerate the trapped electrons.[4–7] This experiment suggests the following reversible reaction;

$$R + e_t^- \underset{UV}{\overset{IR}{\rightleftharpoons}} R^-$$

although the reformed trapped electrons are much fewer than originally. In the pulse radiolysis of a solution of alkali metal cations in tetrahydrofuran, the rate constant of the reaction between tetrahydrofuran radicals and mobile electrons has been reported to be 6×10^{10} mol^{-1} s^{-1}.[8]

The present study attempted to measure the rate of the electron capture of the radicals produced in the γ-irradiated, glassy 3-methylhexane (3-MHX) and methylcyclohexane (MCH) matrices. If this rate is very large, the electron capture by radicals has to be taken into account in the interpretation of the dose dependence of the formation of trapped electrons, as Willard *et al.* have mentioned.[4]

Experimental

The details of the ESR instrument, the method for the purification of 3-MHX, the set-up for photobleaching, and the actinometry of the IR light were reported in a previous paper.[9]

The MCH, purchased from the Tokyo Kasei Kogyo Co., Ltd., was degassed by freeze-thaw cycles and stored with sodium-potassium alloy. The 1-pentene, supplied by Tokyo Kasei Kogyo, was used without further purification.

A constant volume of hydrocarbons, 0.32 ml for 3-MHX and 0.25 ml for MCH, was sealed in a Suprasil quartz tube in a mercury-free vacuum system. The γ-irradiation of the samples was done at a dose rate of $0.53—0.44\times10^6$ R hr^{-1} at 77 K in the dark.

In order to obtain various concentrations of the matrix radicals, we used the following technique. The sample is γ-irradiated for various intervals, 5—150 min; we can thus obtain the trapped electrons and the 3-methylhexyl or methylcyclohexyl radicals. When this sample is irradiated with IR and visible light from a tungsten lamp (375 W) for an appropriate time interval, the trapped electrons disappear and only the matrix radicals remain. In some cases, a medium-pressure mercury lamp was used without any filter to bleach radical anions completely. This sample is again γ-irradiated for 5 min in the case of 3-MHX and for 30 min in the case of MCH. Then, we can obtain trapped electrons in the matrix, together with various concentrations of matrix radicals.

Results

Radical Concentration. For the estimation of the concentration of the trapped electrons in the 3-MHX and MCH glassy matrices, we assumed $G(e_t^-)=0.87$ for 3-MHX and 0.38 for MCH.[10] The concentration of the radicals was estimated by comparing the integrated areas of the spectrum of the radicals with those of standard samples (DPPH and Ultramarine blue). Values of G(3-MHX radicals)$=4.3\pm0.5$ and G(MCH radicals)$=4.0\pm0.5$ were obtained. When the concentration of the trapped electrons is measured by ESR, attention has to be paid to the saturation effect. Therefore, we made a calibration curve and measured the ESR spectra, usually at a constant low power of microwaves, 0.08 mW.

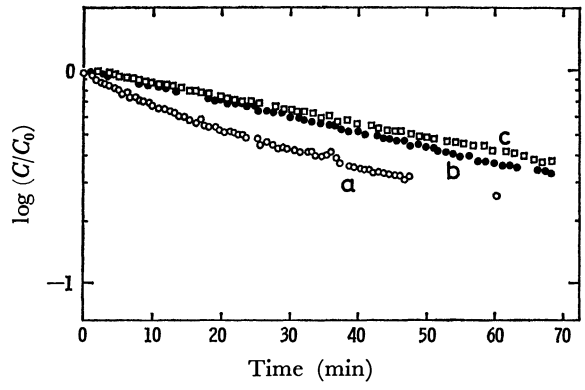

Fig. 1. Semilogarithmic plot for the decay of trapped electrons in the γ-irradiated 3-MHX glass during photobleaching at 1300 nm. The γ-irradiation dose were a) 0.27, b) 4.8, and c) 6.4×10^{19} eV g^{-1}.

Photobleaching in the Case of 3-MHX. Figure 1 shows a typical decay plot for the trapped electrons in the 3-MHX matrix during the irradiation of the IR light at 1300 nm. Apparently the decay rate is larger for a smaller initial amount of the trapped electrons. However, this is due to the non-uniformity of the light intensity in the sample tube.[9] When the concentration of the trapped electrons is high, the light absorption in the tube is not homogeneous and the apparent decay rate decreases, although the quantum yield for the decay is not affected. The details have been discussed in the previous paper.[9] Consequently, in order to study the effect of the radicals on the decay rate, we have to start with a low concentration of trapped electrons in the presence of various concentrations of the radicals.

In order to check the effect of radicals on the microwave-power-saturation phenomenon of the trapped electrons' spectrum, we made four samples containing various concentrations of the radicals in the matrix. The procedure for the preparation was described in the experimental section. Then, these samples were γ-irradiated with a constant dose of 2.57×10^{18} eV g^{-1}, and the yields of the trapped electrons were measured. Figure 2 shows the results. Here, each plot was obtained by extrapolating the microwave power to zero. The microwave-power-saturation character for the trapped electrons in 3-MHX is shown in Fig. 3. As we used the ESR instrument under fast and non-adiabatic conditions,[11] the saturation factor, Z, may be given by the following equation:[12]

$$Z = (1+2\gamma H_1^2 T_1/\pi H_m)^{-1}$$

Here, γ is the gyromagnetic ratio, H_1 is the component of the rotating magnetic field perpendicular to the direction of the external magnetic field, T_1 is the spin-lattice relaxation time, and H_m is the width of

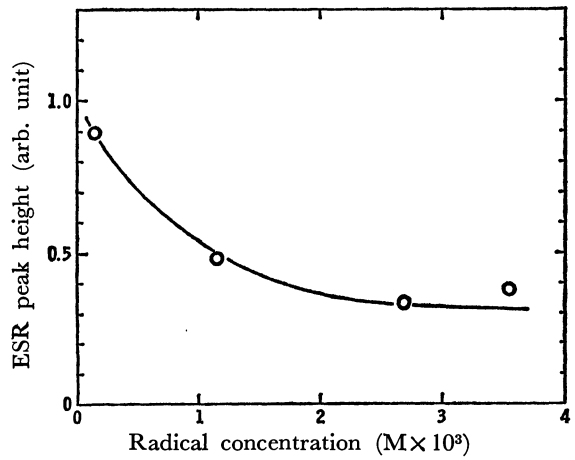

Fig. 2. The yield of trapped electrons in the γ-irradiated 3-MHX glass in the presence of various concentrations of radicals. The γ-irradiation dose for the production of trapped electrons was 0.26×10^{19} eV g^{-1}.

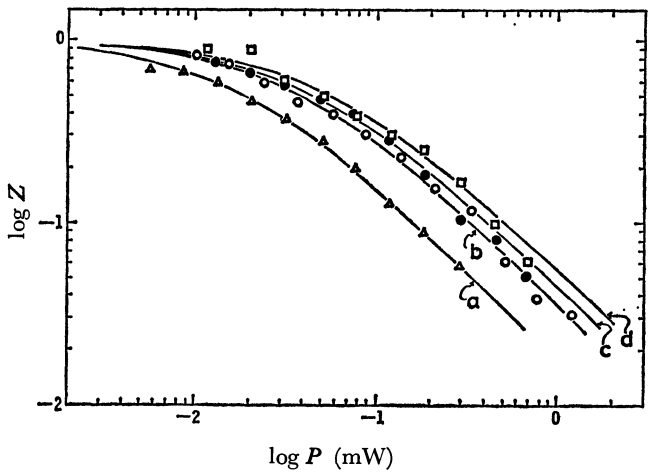

Fig. 3. Experimental values and theoretical curves for microwave-power saturation of trapped electrons in the 3-MHX glass at 77 K. P is microwave power in mW. The radical concentrations are a) 0.14, b) 1.2, c) 2.7, and d) 3.5×10^{-3} mol l^{-1}.

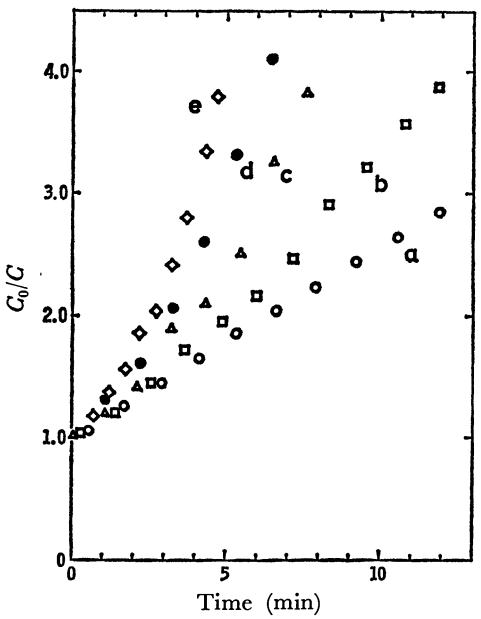

Fig. 5. The second-order decay plot for the trapped electrons in the γ-irradiated 3-MHX. The radical concentrations are a) 0.15, b) 1.2, c) 1.8, d) 2.9, and e) 3.7×10^{-3} mol l^{-1}.

the modulating magnetic field. As Fig. 3 shows, the experimental values coincide with the theoretical curves.

The results of the decay of the trapped electrons during photobleaching with various 3-MHX radical concentrations are shown in Fig. 4. Figure 5 is the second-order decay plot of the same results. Obviously the decay rate increases with the increase in the radical concentration. Moreover, when the radical concentration is small, the decay rate is of the second-order, and as the concentration increases, the decay rate becomes first-order.

In order to check the effect of the stable compounds produced by the pre-irradiation, the decay rate was measured by using samples which had been annealed to room temperature after the pre-irradiation (Fig. 6). The decay rate decreased slightly with the pre-irradiation. The stable products are some olefins and paraffins, and perhaps only olefins affect the decay rate of trapped electrons. Figure 7 shows the decay rate of the trapped electrons in the 3-MHX matrix in the presence of various concentrations of 1-pentene. These results show that the stable products do not make the decay of trapped electrons fast, but, rather, make it a little slow.

In order to obtain a completely neutralized system, we used the UV light from a mercury medium-pressure

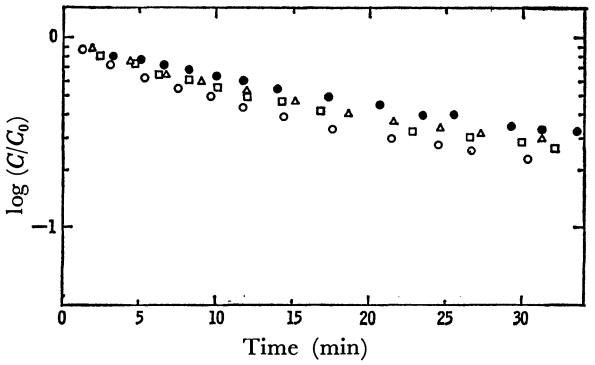

Fig. 7. The effect of the addition of 1-pentene on the decay of the trapped electrons by photobleaching. The concentrations of 1-pentene are 0(○), 5×10^{-3} (□), 6×10^{-2} (△), and 1.1×10^{-1} mol l^{-1} (●).

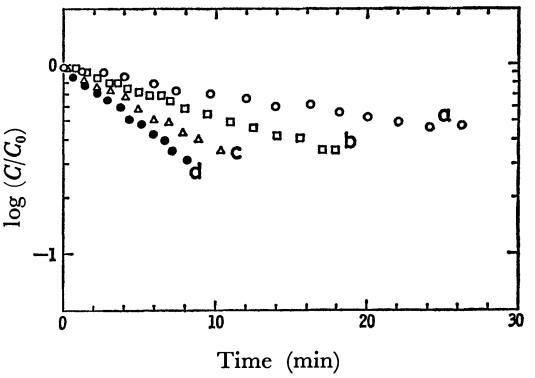

Fig. 8. The effect of UV photobleach on the decay of the trapped electrons by photobleaching at 1300 nm. The radical concentrations are a) 0.13, b) 1.7, c) 2.5, and d) 3.4×10^{-3} mol l^{-1}.

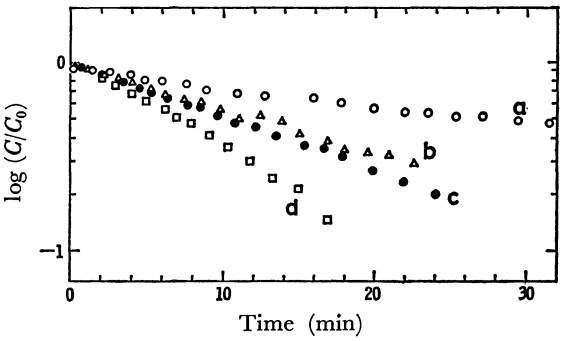

Fig. 9. Semilogarithmic plot for the decay of trapped electrons in the γ-irradiated MCH during photobleaching at 1300 nm. The dose for the production of the trapped electrons is 1.37×10^{19} eV g^{-1}. The radical concentrations are a) 0.84, b) 2.5, c) 3.3, and d) 4.1×10^{-3} mol l^{-1}.

lamp in addition to bleaching with the tungsten lamp. If all the matrix cations do not recombine with electrons by photobleaching with the tungsten lamp, the decay rate depends not only on the concentration of the radicals, but also on that of matrix cations. Irradiation with both the tungsten and the medium-pressure mercury lamps will make all the electrons recombine with cations. The peak of the absorption of the 3-methylpentyl radical anions has been reported to be at 375 nm.[4] The 3-MHX radical anions have a similar absorption spectrum. Figure 8 shows the decay curves for the trapped electrons, along with the samples thus obtained. The results are the same as those shown in Fig. 4. That is, in the present experiment, the electrons photobleached with the tungsten lamp seem to recombine completely with cations.

Photobleaching in the Case of MCH. The results are shown in Fig. 9. There was a small difference in the electron-scavenging ability, but the general tendency was almost the same between the 3-MHX and MCH matrices.

Discussion

We may draw the following conclusions from the experimental results: 1) In the matrices γ-irradiated

at 77 K, there is something which can capture the electrons released from trapping sites by the irradiation of IR light. 2) From the experiments of the thermal annealing and the addition of 1-pentene, the stable products cannot be the cause of the electron capture. 3) From the experiment of UV bleaching, the matrix cations also are not the cause of the change in the decay rate. Finally, we may conclude that the matrix radicals can capture the electrons released from the trapping sites by the irradiation of IR light.

Under a constant illumination of the IR light, the decay rate of the trapped electrons may be expressed in this form:

$$-\frac{\mathrm{d}(\log C)}{\mathrm{d}t} = \varepsilon\Phi I\bar{Q} \qquad \text{(I)}$$

Here, C denotes the concentration of the trapped electrons; ε, the molar extinction coefficient; Φ, the quantum yield by which the released electrons react with substances in the matrix and do not give the trapped electrons any more, and I, the light intensity. $\bar{Q}$ is a correction factor depending upon the optical density of the substance which absorbs the light and upon the shape of the sample tube. The details of the calculation for $\bar{Q}$ and the actinometry have been reported in the previous paper.[9] By using $\varepsilon_{3\text{-MHX}} = 2.04\times10^4$ cm^{-1} l mol^{-1} and $\varepsilon_{\text{MCH}} = 2.40\times10^4$ cm^{-1} l mol^{-1} at 1300 nm,[13] we have calculated the quantum efficiency as a function of the relative concentration of the trapped electrons. The results for 3-MHX are summarized in Fig. 10.

When the trapped electrons are released from the trapping sites by the illumination of IR light, they undergo the following three reactions: 1) Recombination with the parent cations. Since the electrons ejected by γ-irradiation are trapped around their parent cations, there should be a certain distribution for the position of the trapped electrons from their parent cations. When they are released, the electrons trapped close to their parent cations will react faster than those trapped distantly. 2) Retrapping by the trapping sites. 3) Reactions with the radicals in the matrix. The trapping sites and the radicals may be distributed homogeneously in the matrix.

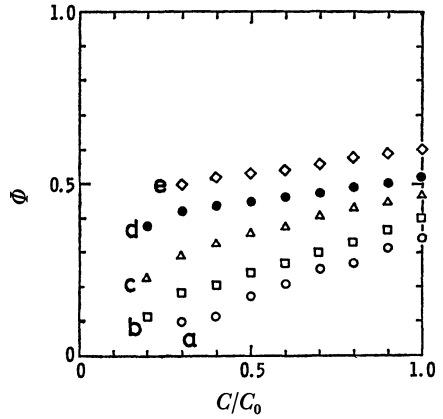

Fig. 10. The relation between the quantum yield Φ and the relative amount of the trapped electrons in the 3-MHX glass. The radical concentrations are a) 0.15, b) 1.2, c) 1.8, d) 2.9, and e) 3.7×10^{-3} mol l^{-1}.

The reaction mechanism under consideration may be described as follows:

$$\mathrm{M} \rightsquigarrow \mathrm{M}^+, \mathrm{R}, \mathrm{e_t}^- \qquad (1)$$

$$\mathrm{e_t}^- + h\nu \xrightarrow{\sigma} \mathrm{e_m}^- \qquad (2)$$

$$\mathrm{e_m}^- + \mathrm{T.S.} \longrightarrow \mathrm{e_t}^- \qquad (3)$$

$$\mathrm{e_m}^- + \mathrm{M}^+ \longrightarrow \mathrm{M} \qquad (4)$$

$$\mathrm{e_m}^- + \mathrm{R} \longrightarrow \mathrm{R}^- \qquad (5)$$

where M is the matrix molecule; R, the matrix radical; $\mathrm{e_m}^-$, the mobile electron, and T.S., the trapping site. σ is the quantum efficiency for the photo-liberation of trapped electrons from the trapping sites. The quantum yield for the photobleaching, then, may be equated in this form:

$$\Phi = \sigma\frac{k_4W + k_5[\mathrm{R}]}{k_3S_t + k_4W + k_5[\mathrm{R}]} \qquad \text{(II)}$$

Here, W is a function depending on the concentration of the cations and on the distribution of the trapped electrons. S_t is the concentration of trapping sites. With the progress of photobleaching, the spatial distribution of the trapped electrons will be changed. Consequently, W is also a function of the irradiation time.

From Eq. (II), assuming $\sigma=1$,[9] we can obtain the following equation:

$$\frac{1}{1/\Phi_i - 1} = \frac{k_4W_i}{k_3S_t} + \frac{k_5}{k_3S_t}[\mathrm{R}] \qquad \text{(III)}$$

Here, the subscript, i, attached to Φ and W means $t=0$. The left-hand side of Eq. (III) is plotted in Fig. 11 as a function of the concentration of matrix radicals. From the slopes of these plots, we could obtain:

$$k_5/k_3S_t = (0.29\pm0.06)\times10^3 \text{ mol}^{-1}\text{ l}$$

for 3-MHX and

$$k_5/k_3S_t = (0.14\pm0.06)\times10^3 \text{ mol}^{-1}\text{ l}$$

for MCH.

When sulfur hexafluoride was used as an electron scavenger in 3-MHX,[9] the following ratio was reported:

$$k_6/k_3S_t = 1.2\times10^3 \text{ mol}^{-1}\text{ l}$$

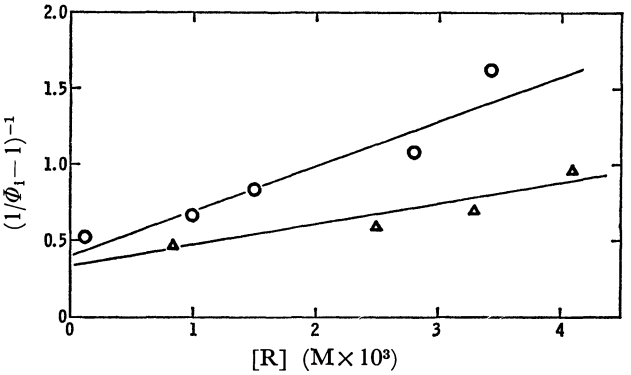

Fig. 11. The relation between $1/(1/\Phi_i - 1)$ and the radical concentration [R]. ○ for 3-MHX and △ for MCH.

Here, k_6 is the rate constant of the reaction:

$$e_m^- + SF_6 \longrightarrow SF_6^- \quad (6)$$

These values suggest that the radicals under consideration have an ability comparable with sulfur hexafluoride in the electron capture in the glassy hydrocarbon at 77 K.

Distribution of Trapped Electron-Cation Distance in γ-Irradiated 2-Methyltetrahydrofuran Glassy Matrix

Tsuneki ICHIKAWA, Hiroshi YOSHIDA, and Koichiro HAYASHI*

Faculty of Engineering, Hokkaido University, Kita-ku, Sapporo 060

(Received April 2, 1975)

An approach was presented to elucidate the distribution of trapped electron-cation distance from isothermal decay of the trapped electron by numerically solving the Smoluchowski equation and was applied to the observed isothermal decay of trapped electron at 92.2—95.0 K in 2-methyltetrahydrofuran glass irradiated by γ-rays at 77 K. The distribution curve (the probability density of finding initially the electron at the distance r) thus obtained was close to a Gaussian function.

One of the important features of radiation chemistry in condensed media is in spatial inhomogeneity of the formation of primary active entities such as electrons, ions and free radicals. It is generally accepted that the distance of an electron from its counterpart cation is smaller than average distance between pairs of the electron and the cation, and that the charge recombination process occurs mostly as an isolated event (spur reaction in liquid media). The electron-cation distance when the electron is trapped or solvated is dependent upon the kinetic energy of the secondary electron, the energy loss process and trapping or solvation process in condensed media. Distribution of the electron-cation distance was studied in liquid media by means of electron scavenge method[1-3] and electrical conductivity measurements,[4-6] and some analytical expressions were given for it. However, it is difficult to study the distribution in glassy matrices. Only average distance between the trapped electron and its counterpart cation has been estimated from the effect of electron scavenger upon the yield of the trapped electron[7-9] and also from paramagnetic relaxation measurements of the trapped electron.[10-13]

Recently we studied the isothermal decay of the trapped electron in 2-methyltetrahydrofuran (MTHF) glassy matrix irradiated by γ-rays at 77 K and found that the time profile of the decay at several temperatures above 92 K was independent of either radiation dose or temperature, if the time scale was corrected with an Arrhenius factor.[14] The results indicate that the electron is trapped close to its counterpart cation and suggest that its decay is determined solely by the electron-cation distance. This leads to the point that the time profile of the decay is correlated to the distribution of the distance and, therefore, the analysis of the decay curve may give a new approach to elucidate the distribution of the distance in glassy matrices.

The principal aim of the present paper is in reexamining the time profile of the isothermal decay of the trapped electron in MTHF glassy matrix previously reported[14] in order to show the possibility of elucidating the distribution of the distance on the basis of the Smoluchowski equation which describes the migration of electron in the matrix.

Theoretical Background

Assuming that (1) the electron migrates in the matrix as a classical particle, (2) it is formed in pairing with a cation, and (3) the mean free path of the electron is much smaller than the migration path traveled before charge recombination, the migration of the electron is regarded as the diffusion under the spherical Coulombic field due to the cation. In such circumstances, the time profile of the electron decay can be correlated with the distribution of the distance between the electron and the cation by the well known Smoluchowski equation,[15]

$$\frac{1}{D}\frac{\partial W(r,t)}{\partial t}=\frac{\partial^2 W(r,t)}{\partial r^2}+\left(\frac{2}{r}+\frac{r_c}{r^2}\right)\frac{\partial W(r,t)}{\partial t}, \tag{1}$$

where r is the distance, t time, D diffusion coefficient, $W(r,t)$ the probability density of finding the electron at r and at t, and $r_c(=e^2/\varepsilon kT)$ the Onsager length. Since the electron is presumed to disappear only in recombining with the cation, a boundary condition of the differential equation is given as

$$[W(r,t)]_{r=r_0}=0 \tag{2}$$

where r_0 is so-called recombination radius. The initial distribution is given by $W(r,0)$. On the other hand, the time profile of the electron decay, $P(t)$, is given by the spatial integration of $W(r,t)$ as

$$P(t)=\int_{r_0}^{\infty} W(r,t)4\pi r^2 dr \tag{3}$$

and $dP(t)/dt$ is given by the rate of electron flow across the spherical surface of reaction radius,

$$\frac{dP(t)}{dt}=-4\pi r_0^2 D\left[\frac{\partial W(r,t)}{\partial r}\right]_{r=r_0}. \tag{4}$$

The aim of the present study is in the derivation of $W(r,t)$ from the given $P(t)$ corresponding to the observed time profile of the electron decay. This turns out to solve Eq. (1) under the boundary conditions (2) and (4), but Eq. (1) is generally unable to be solved analytically. Several approximation methods have been invented and used, which encompass the prescribed diffusion method,[16,17] the Laplace transformation method[18] and perturbation methods.[19,20] These methods, however, are not useful for the present aim, because they derive $W(r,t)$ from a given $W(r,0)$ but not from a given $P(t)$.

One of modifications of the Smoluchowski equation is the Nernst-Einstein relationship, where the diffusion term in Eq. (1) is completely neglected.[21] On this basis, one can readily derive the initial distribution from the time profile of the electron decay:

$$W(r,0)=-\left[\frac{dP(t)}{dt}\right]_{t=t'} \tag{5}$$

* Present address: The Institute of Scientific and Industrial Research, Osaka University, Suita, Osaka 565.

where

$$t' = \frac{r^3 - r_0^3}{3Dr_C}.$$

In this case however, the calculated distribution is not very accurate because of the neglect of the diffusion term.[22]

More accurate distribution is expected to be derived by taking the diffusion term into account. This can be achieved by expanding the time profile of the observed electron decay into the Dirichlet series,

$$P(t) = \sum a_i \exp(-k_i t), \tag{6}$$

and by transforming the probability density as

$$W(r, t) = \sum R_i(r) \exp(-k_i t). \tag{7}$$

Thus the Smoluchowski equation can be transformed into ordinary differential equation:

$$\frac{d^2R_i(r)}{dr^2} + \left(\frac{2}{r} + \frac{r_C}{r^2}\right)\frac{dR_i(r)}{dr} + \frac{k_i}{D}R_i(r) = 0. \tag{8}$$

The boundary conditions of the above equation,

$$[R_i(r)]_{r=r_0} = 0 \tag{9}$$

and

$$\left[\frac{dR_i(r)}{dr}\right]_{r=r_0} = \frac{k_i a_i}{4\pi r_0^2 D} \tag{10}$$

are obtained also by transforming Eqs. (2) and (4). Equation (8) is solved, for example, by Runge-Kutta-Gill method and the initial distribution of the distance between the trapped electron and the cation is to be obtained numerically.

Observed Isothermal Decay

According to our recent study,[14] the electron trapped in the γ-irradiated MTHF glassy matrix decay rapidly in following a pseudo-first order reaction (independent of the radiation dose and the initial concentration of the electrons), when the glassy matrix is warmed to temperature higher than 92 K. This strongly suggests that an electron is trapped close to its counterpart cation and that no spatial overlapping occurs between the electron-cation pairs.

The time profile of the electron decay in the temperature range 92.2—95.0 K was observed by electron spin resonance method, and found to be superimposable on each other if the time scale was corrected by the half-life of the electrons at each temperature (the corrected time is real time devided by the half-life, $\tau = t/t_{1/2}$). The dependence of $t_{1/2}$ upon temperature followed the Arrhenius relation, which gave an activation energy of 0.8 eV in the temperature range examined. This large activation energy indicates that the charge recombination results from the migration of electron in the matrix at temperatures close to its liquifying temperature. On the other hand, the activation energy becomes smaller and approaches to zero by lowering temperature, which is consistent with the view that the charge recombination is caused essentially by quantum mechanical tunnelling of electron from its trap to the cation at low temperature.[23,24]

Quantum efficiency of photobleaching trapped electron was examined for γ-irradiated MTHF matrix at 77 K and found to be much smaller than unity.[7] This indicates that the electron photoliberated from its trap does not recombine at once with the cation, but undergoes several detrap-retrap cycles before the charge recombination. This retrapping efficiency is most probably higher at higher temperature because of the ease of reorientation of the matrix molecules to solvate the electron.

These two facts, the large activation energy and the small quantum efficiency, indicate that the lifetime of electron at elevated temperature is determined by the migration path length travelled by the electron before charge recombination and, therefore, by the number of thermal activation process (trap-detrap process). It turns out that the temperature independent time profile of the electron decay is directly correlated to the distribution of the electron-cation distance before the glassy matrix is warmed. The observed time profile of the decay to be analyzed in the following chapter is taken from the previous paper[14] and shown in Fig. 1 with open circles.

Calculation and Results

Because the diffusion coefficient D is temperature dependent, the time profile of the electron decay to be obtained from a given distribution of the electron-cation distance based on Eq. (1) is necessarily temperature dependent. However, the fundamental Smoluchowski equation is readily transformed by using the corrected diffusion coefficient

$$D_0 = Dt_{1/2} \tag{11}$$

into

$$\frac{1}{D_0}\frac{\partial W(r, \tau)}{\partial \tau} = \frac{\partial^2 W(r, \tau)}{\partial r^2} + \left(\frac{2}{r} + \frac{r_C}{r^2}\right)\frac{\partial W(r, \tau)}{\partial r}. \tag{12}$$

This differential equation gives temperature independent correlation between the distribution of the distance and the time profile of the electron decay, if the latter is plotted in the corrected time scale ($\tau = t/t_{1/2}$) and if D_0 is temperature independent. This is really the case as observed previously.[14] The temperature independent corrected diffusion coefficient implies that the migration of the electron is thermal activation process and it is controlled by thermal detrapping of electron (or thermal collapse of electron trap). The value of r_C is regarded as constant in a narrow range of temperature.

Starting from Eq. (12), Eqs. (6), (7), (8) and (10) are rewritten as follows:

$$P(\tau) = \sum a_i \exp(-k_i \tau), \tag{13}$$

$$W(r, \tau) = \sum R_i(r) \exp(-k_i \tau), \tag{14}$$

$$\frac{d^2R_i(r)}{dr^2} + \left(\frac{2}{r} + \frac{r_C}{r^2}\right)\frac{dR_i(r)}{dr} + \frac{k_i}{D_0}R_i(r) = 0 \tag{15}$$

and

$$\left[\frac{dR_i(r)}{dr}\right]_{r=r_0} = \frac{k_i a_i}{4\pi r_0^2 D_0}. \tag{16}$$

The observed time profile of the electron decay (shown in Fig. 1) was graphically analyzed and expanded

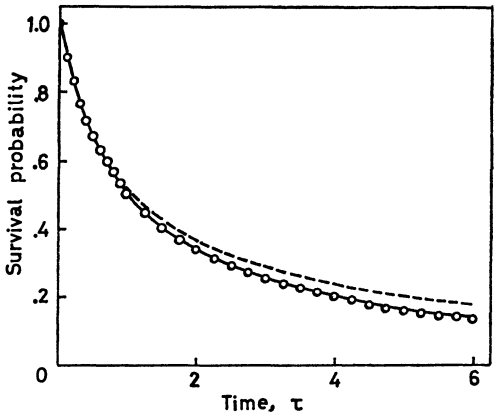

Fig. 1. Time profile of the decay of trapped electron in γ-irradiated MTHF glassy matrix (O) observed at about 93 K, (solid line) computed from the initial distribution of electron-cation distance given by open (for $r \leq 40$ Å) and filled circles (for $r \geq 40$ Å) in Fig. 2, and (dashed curve) computed from the initial distribution of the distance given by the dashed curve in Fig. 2 based on Eq. (15).

by the Dirichlet series

$$P(\tau) = 0.34 \exp(-0.15\tau) + 0.46 \exp(-0.90\tau) + 0.20 \exp(-2.85\tau). \quad (17)$$

In order to calculate numerically the initial distribution $W(r,\tau)$ from the observed $P(\tau)$ based on the differential equation (15) and the boundary conditions (9) and (16), the numerical values of r_0, r_c and D_0 should be known. The Onsager length r_c at 93 K was estimated to be 624 Å from the dielectric constant of the glassy matrix, 2.88.[25] The reaction radius r_0 was taken to be 10 Å rather arbitrarily, but the ambiguity in r_0 affects little the calculated initial distribution, because the migration of electron toward the cation is fast in its vicinity. Although there is no means to estimate the diffusion coefficient D and, therefore, the corrected diffusion coefficient D_0, the latter was arbitrarily taken to be 66 Å^2. This value gave the average initial distance between the trapped electron and the cation of about 50 Å, which seems plausible for accounting for the previous results of paramagnetic relaxation of the trapped electron in the MTHF glassy matrix.[10]

The calculated initial distribution of the distance is shown by the solid curve in Fig. 2. The oscillatory feature at large r resulted from the essential fact that the boundary value problem is not well-posed for the parabolic partial differential equation such as Eq. (12). It turns out that small errors inevitably included in the observed boundary condition (the decay curve, especially at large τ) deteriorate the calculated initial distribution of the distance at large r. If one ignores the unrealistic oscillation, the distribution curve is approximated, as shown by open and filled circles in Fig. 2, by

$$W(r, 0) = 2.5 \times 10^{-6} \exp(-r^2/1600) \quad \text{for } r_0 < r \leq 40\text{Å} \quad (18)$$

and

$$W(r, 0) = 11.5 \times 10^{-6} \exp(-r/16) \quad \text{for } r \geq 40\text{Å} \quad (19)$$

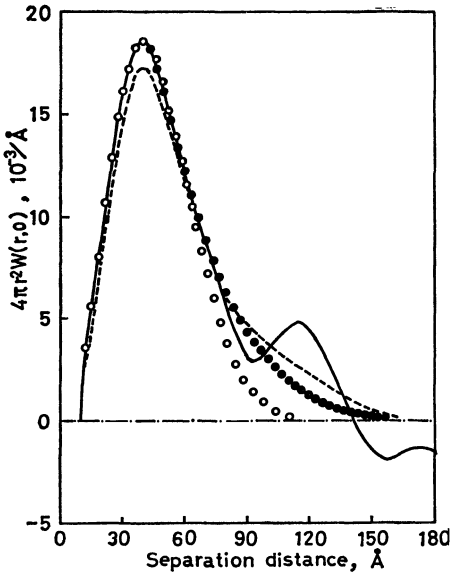

Fig. 2. Initial distribution of electron-cation distance in γ-irradiated MTHF glassy matrix derived from the time profile of electron decay shown by open circles in Fig. 1, (solid curve) on the basis of the Smoluchowski equation (15) and (dashed curve) on the basis of the Nernst-Einstein approximation (Eq. (5)). Open circles and filled ones show the smoothed distribution curve given by Eqs. (18) and (19), respectively. For $r > 40$ Å, the filled circles express the distribution better.

where r is measured in Å unit. Although the curve is not expressed by a single function, its whole shape is rather close to the Gaussian function. In order to check the validity of smoothing the oscillatory feature and that of the relationships (18) and (19), the time profile of the electron decay was reconstructed from them by using the finite difference approximation based on the Smoluchowski equation (12) (see Appendix). The result is shown by the solid curve in Fig. 1. It agrees very well with the observed time profile from which the initial distribution of the distance was derived.

Discussion

It has been shown above that the initial distribution of the distance of the trapped electron from its counterpart cation in the glassy matrix can be derived, on the basis of the Smoluchowski equation describing the behavior of electron under the spherical Coulombic field, by observing the isothermal decay of the trapped electron. The same approach may be applicable also to study the distance between solvated electron and its counterpart cation in liquid media, if the complete time profile of the prompt decay of the solvated electron becomes available by the pulse radiolysis experiments with time resolution high enough.

From mathematical point of view, the present procedure of deriving the initial distribution of the distance from the time profile of the electron decay is the translation of a boundary condition of the

Smoluchowski equation into its initial condition. The scavenger method for studying the distribution[3] is essentially one of the modification of the present method: in the scavenger method the time profile of the electron decay was obtained indirectly from the Laplace transformation of the scavenging curve.[26] However, this method presumes that electron can react with scavenger only after the thermalization (or solvation). The initial distribution of the distance was also derived from the field dependence of electric conductivity during irradiation. In this case, the probability of escaping geminate recombination and of contributing to the conductivity decreases with decreasing electron-cation distance. Therefore, this method is suitable to study the distribution only at large r. Contrary, the present method gives reliable information for small r but not for large r, because the later part of the electron decay is experimentally less accurate, which is translated into the distribution at large r.

The most direct correlation between the electron decay and the distribution of the distance is given by the Nernst-Einstein approximation (relationships (5) and (6), where t, t' and D should be replaced by τ, τ' and D_0 to analyze the decay data in Fig. 1). According to this approximation, the observed electron decay shown in Fig. 1 gave straightforwards the distribution curve shown by the dashed line in Fig. 2. The neglect of the diffusion term in the Smoluchowski equation caused a small but apparent depression of the curve for small r. Such tendency should become enhanced and the diffusion term cannot be ignored, if the distribution is very sharp and if the initial distance is as large as the Onsager length. The dashed line in Fig. 1 shows the time profile of the electron decay reconstructed from the distribution given by the dashed curve in Fig. 2 by means of the finite difference approximation based on the Smoluchowski equation (12). Here also, the contribution of the diffusion term is apparently seen from the deviation of the dashed line from the solid line.

The half-life, $t_{1/2}$, of the trapped electron was found to be temperature dependent with an activation energy of 0.8 eV (19 kcal/mol) and a pre-exponential factor of 1×10^{-42} s in the temperature range 92.2—95.0 K.[14] Based on Eq. (11) and the presumed value of 66 Å^2 for D_0 (see the preceding section), the diffusion coefficient, D, is calculated to be 10^{-7} cm^2 s^{-1} in this temperature range within the framework of the present procedure. On the other hand, Huang and Kevan measured the drift mobility of 0.055 cm^2 V^{-1} s^{-1} at 77 K for electrons photoliberated from their trap in γ-irradiated MTHF glassy matrix.[27] Assuming that the well known relationship, $\mu/D=e/kT$, between the mobility and the diffusion coefficient is valid for these electrons, we can obtain the diffusion coefficient of 3.6×10^{-4} cm^2 s^{-1}.

A big difference in the diffusion coefficient may be attributed to the difference in the mechanism of electron transport. The measurement of the drift mobility dealt with the electrons photoliberated into conduction state, which seem to have reached the collecting electrode without suffering retrapping in the matrix.[27] The electrons in the present investigation are mobilized by thermal detrapping probably due to thermal collapse of the trapping site and they seem to be more or less solvated during their migration. Therefore, it is reasonable that their diffusion coefficient is much smaller than that for the electrons in conduction state. If the big diffusion coefficient, 3.6×10^{-4} cm^2 s^{-1}, is used in deriving D_0 on trial, the observed isothermal decay of Eq. (17) gives an initial average distance between the trapped electron and its counterpart cation of more than 10^6 Å, which is unrealistically too big.

A drawback in the present approach is in the lack of the available numerical data on the diffusion coefficient D, measurements of which are highly desirable.

All numerical computations in this investigation were made by using facilities of the Computing Center of Hokkaido University.

Appendix

The Smoluchowski equation (12) is solved straightforward to give the solution $W(r,\tau)$, if the initial condition $W(r,0)$ as well as the bounday condition is given. The finite difference approximation is one of the most appropriate method to solve the equation numerically. The difference equation corresponding to the differential equation (12) is

$$W_{m,n+1} = W_{m,n} + \frac{D_0K}{H^2}(W_{m+1,n}-2W_{m,n}+W_{m-1,n}) + \frac{D_0K}{2H}\left\{\frac{2}{r_0+mH}+\frac{r_C}{(r_0+mH)^2}\right\}(W_{m+1,n}-W_{m-1,n}) \quad \text{(A1)}$$

where $W_{m,n}=W(r,\tau)$, $r=r_0+mH$ and $\tau=nK$. The time profile of the electron decay $P(\tau)=P_n$ is given as

$$P_n = \sum_{i=0}^{M} 4\pi(r_0+iH)^2HW_{i,n}. \quad \text{(A2)}$$

The upper limit of summation, M, should be so large that $4\pi(r_0+MH)^2W_{M,n}$ is vanishingly small. P_n was computed consecutively under the given initial condition $W_{m,0}$ and the boundary condition $W_{0,n}$, $W_{M,n}=0$. In the calculation, the parameters were taken as small as $H=0.6$ Å and $K=0.002$ and as large as $M=500$, which were tested to be small or large enough for the good approximate solution to be obtained.

Quantitative Estimates of π-Contact-term Contributions to the Lanthanide-induced Paramagnetic ^{1}H Shifts in Aniline and *m*-Toluidine

Masatoshi HIRAYAMA, Michihiko SATO, Makoto TAKEUCHI, and Makoto SAITO

Department of Chemistry, Faculty of Science, Ibaraki University, 2-1-1 Bunkyo, Mito 310

(Received April 4, 1975)

The paramagnetic proton chemical shifts induced by a series of Ln(FOD)$_3$(Ln=Pr, Eu, Dy, Ho, Er, and Yb) were observed for aniline and *m*-toluidine in CCl_4. In an attempt to separate the pseudo-contact(pcs) and contact shift(cs) contributions, the spin-density distributions of the π-cation radicals or the Ni(AcAc)$_2$-induced shifts were used for the cs pattern in a molecule, as well as the geometric factors for the pcs pattern. The appropriate regions of the two geometric parameters were determined by the computer-search method for the least-squares fits of the observed to the calculated shifts. Thus, the intramolecular average value of the ratio of cs-to-pcs contributions was evaluated. The variation in this ratio with an Ln ion corresponds relatively well to that of the theoretical ratio, $|\langle S_z\rangle/|\delta|$, where $\langle S_z\rangle$ has been calculated by Golding *et al.* and where δ is the relative pcs predicted by Bleaney *et al.*

There have been a number of reports showing that the contribution of the contact shift(cs) to the lanthanide-induced shifts(LIS's) may be considerable for protons as well as for ^{13}C and ^{31}P. However, most of the discussions of cs contributions have been qualitative.[1] It has recently been reported in studies of the temperature dependence of LIS's that the term proportional to $1/T$ can be separated from the term depending on $1/T^2$ on the basis of Bleaney's theory[2] and that it leads to the cs contribution for all the complexes except for those of Eu^{3+} and Sm^{3+}.[3] With a correction for the temperature effect on the equilibrium between an Ln complex(Ln=lanthanide metal) and a substrate, this method may be valuable for the determination of the cs contribution. On the other hand, the determination of the molecular structure and the conformation analysis due to the use of LIS have been made in terms of a computer search for the best fit of the calculated geometric factors to the observed paramagentic shifts.[4] These searches are based on the fact that a true pattern of pseudo-contact shifts(pcs) can be calculated if a ligand molecule includes several or more nuclei having only pcs almost entirely. Therefore, these searches are limited to the σ-compounds, in which there is a cs contribution only in some atoms close to a coordinating atom. In such a molecule, the σ-cs contribution can be calculated as the difference between the observed shift and pcs.[5] However, for aromatic molecules with cs at almost all atoms, the above procedure cannot be applied, and a relative cs(a cs pattern) in a molecule is required for a quantitative separation of the two contributions. Three possible sources of cs pattern are: (1) Gd(III)-induced shifts,[6] (2) Ni(AcAc)$_2$-induced shifts(NIS's), and (3) a theoretically estimated pattern. While (1) may not be used for ^{1}H because of the long T_1 of the electron spin,[7] an attempt has been made to use (2)[8] or (3). The results from (3) seem to be unsatisfactory.[9]

In a previous paper,[10] our procedure for estimating the cs contribution has been outlined. This report will describe in detail an attempt at separation by using the cs patterns obtained from a π-spin density distribution of a cation radical and NIS for both aniline and *m*-toluidine. In the present study, the agreement factor, *R*,[11] between the observed and calculated shifts was satisfactorily small for the adducts with all the Ln(FOD)$_3$* substances used here. In order to check the validity of our procedure for the separation of the two contributions, the relative cs contribution thus evaluated was compared to the $\langle S_z\rangle$ value reported by Golding *et al.*[12] for the six Ln chelates studied here, and a comparatively good correspondence was thus obtained. The separated pcs contribution led to a good linear relation to the relative value of Bleaney's pcs.[2]

Experimental

Aniline and *m*-toluidine were purified by vacuum distillation from zinc dust and were dried over barium oxide in the dark. CCl_4(Spectro grade) was used as the solvent without further purification. The Ln(FOD)$_3$ complexes were prepared according to the method of Springer, Jr., Meek and Sievers,[13] except for the Pr, Eu, and Yb complexes, which were obtained commercially. Particular care was taken for all the substrates used to ensure anhydrous conditions, since the observed shifts are very sensitive to traces of moisture. The solutions were *ca.* 0.5 M in the substrates. The amount of Ln(FOD)$_3$ or Ni(AcAc)$_2$ was continuously varied up to a Ln(FOD)$_3$- or Ni(AcAc)$_2$-substrate molar ratio of about 0.2. The NMR spectra were recorded with a Hitachi R-20A spectrometer at 60 MHz at a probe temperature of 34 °C, operating in the frequency-swept mode, using TMS as the internal standard.

Results and Discussion

In many lanthanide shift experiments, it has become customary to consider only one step of equilibrium with a sufficiently rapid exchange:

$$L + A \rightleftharpoons LA \qquad K_1 = \frac{[LA]}{[A]\cdot[L]} \qquad (1)$$

and to use the shift characteristic of a 1 : 1 adduct (δ_1) obtained from the linear extrapolation of $[L_0]/[A_0]=R_L$ to 1, on the basis of the idea that the observed shift is approximately equal to $R_L\cdot\delta_1$ if $R_L \ll 1$ and $K_1 \gg 1$, where A and L are a substrate and an Ln chelate respectively, and where $[L_0]$ and $[A_0]$ are the total concentrations of L and A. However, it was recently found in low-temperature experiments that two mole-

* FOD = 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyl octane-4,6-dione.

cules of $(CH_3)_2SO$ coordinate to $Eu(FOD)_3$ in CD_2Cl_2.[14] Also, considering a second equilibrium for the *n*-hexyl amine–$Eu(FOD)_3$ system in $CDCl_3$,

$$LA + A \rightleftharpoons LA_2 \qquad K_2 = \frac{[LA_2]}{[LA][A]} \tag{2}$$

an attempt has been made to determine K_1, K_2, δ_1, and the shift characteristic of a 1 : 2 adduct (δ_2) from the least-squares fits.[15]

In the present investigation, δ_2 is assumed to be approximately equal to δ_1 in magnitude;[16] consequently, if $K_1 \gg 1$ and $R_L \ll 1$, the observed LIS (S) is formulated as Eq. (3):

$$S = \delta_1 \cdot R_L \frac{1+2K_2\cdot[A_0]}{1+K_2\cdot[A_0]} \tag{3}$$

K_1 may be expected to be sufficiently large. Actually, we obtained an apparent linearity between the observed shifts and R_L at sufficiently low values of R_L in all the systems investigated in this work. The shift value

a), b), and c): See Footnotes a), c), and e) in Table 1, respectively. d) Values on the restriction of R to less than 3%. e) Values on the restriction of R to less than 3.5%. f) Values on the restriction of R to less than 4.5%.

obtained from the linear extrapolation of R_L to 1 is $\delta_1(1+2K_2[A_0])/(1+K_2[A_0])$; K_2 value is required in estimating the magnitude of δ_1. However, since the relative shift values are adequate for the estimation of the intramolecular ratio of the cs and pcs contributions, we used $\delta_1(1+2K_2[A_0])/(1+K_2[A_0])$ as S_{obs}. The S_{obs} values were corrected for the diamagnetic shifts due to complex formation (CFS's),[1e)] by using shifts induced by $La(FOD)_3$ in CCl_4; they are listed in Tables 1 and 2 for aniline and *m*-toluidine respectively,

with Ln(FOD)$_3$ (Ln=Pr, Eu, Dy, Ho, Er, and Yb). It has been presumed that the geometry of such an adduct does not vary widely with an Ln ion. From this point of view, the variation in the S_{obs} ratios with an Ln ion seen in Tables 1 and 2 clearly shows the existence of a cs contribution.

Our procedure for separating the two contributions is as follows: At first, the calculated shift is taken as $S_{cal}=S_{pcs}+S_{cs}=A\cdot R_{pcs}+B\cdot R_{cs}$, where R_{pcs} is the geometric factor; R_{cs}, the cs relative to the 2 position, and A and B, the proportionarity constants. With the R_{pcs} and R_{cs} patterns in a molecule obtained by appropriate methods, the A and B values are determined by the least-squares technique and lead to S_{cal}. In order to assess the correspondence between S_{cal} and S_{obs}, the agreement factor, R,[11] is used as a good criterion. The dependence of R on the two geometric parameters χ and r_N (Fig. 1) required for determining R_{pcs} is conveniently displayed using contour lines on a map projection. Appropriate combinations of χ and r_N values are chosen, based on the mode of minimizing the R values in the contour plot, and on the validity of the molecular structure. From the amounts of S_{cs} and S_{pcs} corresponding to these values, the average intramolecular cs contribution to the pcs contribution, $\Sigma|S_{cs}|/\Sigma|S_{pcs}|$, is calculated. Here, if $K_2[A_0]\gg 1$, $S_{cs}/2$ and $S_{pcs}/2$ are the separated shifts corresponding to the δ_1 value.

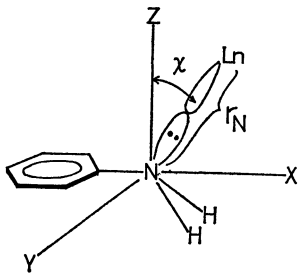

Fig. 1. Geometric parameters in the aniline adduct of Ln(FOD)$_3$.

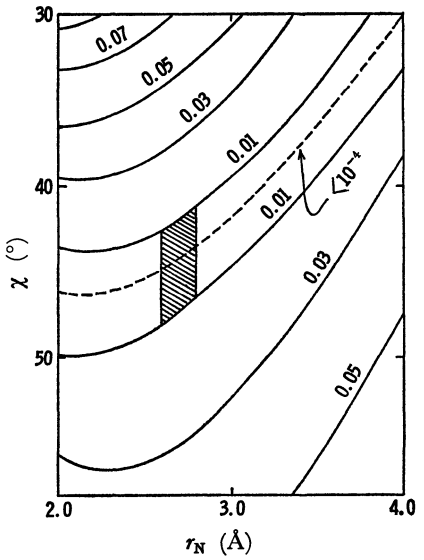
McConnell-Robertson's equation[19] for axial symmetry was used in evaluating R_{pcs}, because, for such an adduct of the lanthanide chelate, this relation has been successfully used to interpret the dipolar shifts. Thus, the geometric factors were calculated with varying amounts of two geometric parameters, χ and r_N in the chemically reasonable ranges of 20—60°[20] and 2.0—4.0 Å respectively (Fig. 1). Here, since the Ln–N vector was assumed to be co-linear with a principal magnetic axis,[21] the rotation about the N–Ln bond did not need to be considered. The effect of rotation about the N–C bond was not introduced into the pcs calculations, because the N-lone pair orbital could be expected to conjugate with the π-MO of the ring to a great extent. For CH_3 protons, R_{pcs} was averaged over those values calculated for each 10° of rotation about the C–CH_3 bond.

Since the spin induced into the N-lone pair orbital may be expected to be delocalized predominantly through the π-bonds,[22] an approximate π-spin density distribution obtained by McLachlan's method[23] was used for the calculation of R_{cs}. There are four possible R_{cs} patterns occurring from the α- and β-spins in the highest occupied π-MO [h.o(α) and h.o(β)] and from the α- and β-spins in the lowest vacant π-MO [l.v(α) and l.v(β)]. It was found from a preliminary comparison of S_{obs} and S_{cal} that only the R_{cs} due to the h.o is effective in correcting the R_{pcs} pattern. This corresponds well to the fact that the h.o is symmetric to the molecular axis and can interact strongly with an AO of the metal ion. Furthermore, this preliminary testing suggested that the electron spin introduced into the h.o has a sign opposite to that of some Ln ions. For example, the h.o(β) is particularly excellent in explaining the observed relation, $|S(\beta H)|<|S(\gamma H)|$, for the aniline adduct of Eu(FOD)$_3$. Then, an intramolecular R_{cs} pattern was calculated from the π-spin density distribution of the cation radical[24] (ρ_c^π) of each substrate and was applied to all the Ln complexes (Table 3). The map projection of R for the aniline adduct is very similar in mode for all the Ln ions used here and does not reveal a single smooth minimum in R, an example with Eu(FOD)$_3$ being shown in Fig. 2(a). However, a very deep valley in R passes through a structurally favorable region in the map and, besides, varies in shape almost not at all with an Ln ion. This suggests that the π-approximation for R_{cs} is valid; further, that there seems to be no large variation in the geometry of an adduct with an Ln ion. Also, with the R_{cs} due to NIS's (Table 3), contour plots were produced for all the Ln ions, which are very similar in pattern to one another and, further, to those formed with ρ_c^π and which include sufficiently small values of R. The map projection prepared from the Ho(FOD)$_3$-induced shifts is shown in Fig. 2(b). This leads us to conclude that the amount of S_{cs} may by considerably smaller than that of S_{pcs}. Then, by reference to the N–Ln distance in the Eu(DPM)$_3$-(Pyridine)$_2$ crystal, 2.65 Å,[25] the range of 2.6—2.8 Å was adopted as a reasonable one, and by restricting the limit of R to 1%, a reasonable area on the map was determined (Fig. 2). A possible range of $\Sigma|S_{cs}|/\Sigma|S_{pcs}|$ corresponding to this area was then evaluated, where $\Sigma|S_{cs}|/\Sigma|S_{pcs}|$ is the average value of the cs contribution relative to that of pcs in a molecule.

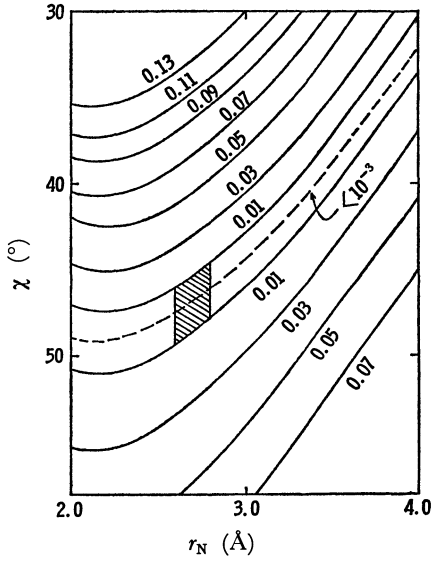
Table 3. The intramolecular relative cs[a]

Compound	Position	$R_{cs}(\rho_c^\pi)$[b]	R_{cs}(NIS)[c]
Aniline	2	1.000	1.000
	3	−0.377	−0.410
	4	1.139	1.000
m-Toluidine	2	1.000	1.000
	4	1.138	1.000
	5	−0.370	−0.402
	6	0.974	1.000
	CH_3	0.401	0.354

a) See Tables 1 and 2 on the positions. b) ρ_c^π represents the spin density distribution of α spin in the h. o (h. o(α)). Q_{CH}^H and $Q_{CCH_3}^H$ were taken as −24.0 and 27.0 gauss, respectively. c) NIS's were observed in our laboratory, but are essentially those reported in Ref. 22.



(a)



(b)

Fig. 2. Contour plots of R for the aniline adduct of $Eu(FOD)_3$ calculated by using ρ_c^π as R_{cs} (a), and of $Ho(FOD)_3$ calculated by using NIS as R_{cs} (b). Shaded parts indicate those chosen to determine a possible range of the magnitudes of S_{cs}.

The results with all the $Ln(FOD)_3$ substances are shown in Table 1, along with the ranges of χ, where the magnitudes of S_{cs} and S_{pcs} are those giving rise to the minimum of R with r_N=2.7 Å. In all the systems, the agreement between S_{obs} and S_{cal} is sufficiently good and the χ values fall within the range of 40—55°. When the limit of R can be extended to the 5% level, with the range of r_N held constant, the corresponding region of χ is fairly much expanded, but $\Sigma|S_{cs}|/\Sigma|S_{pcs}|$ does not vary so widely, except with $Dy(FOD)_3$.

Next, in order to check the above results, on the assumption of the K_2 being independent of the Ln ion, attempts were made at examining the relation of the A value to the relative pcs by Bleaney *et al.*[2] and that of the B value to $\langle S_z \rangle$ by Golding *et al.*[12] As

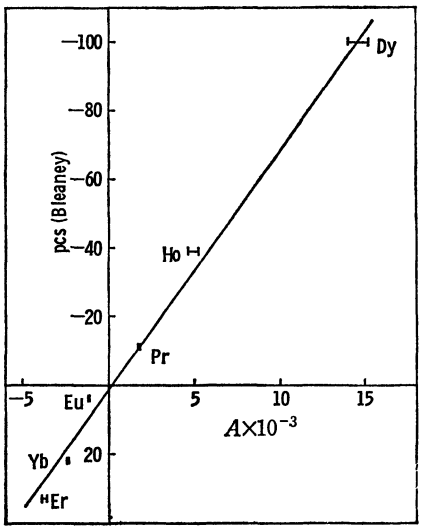


Fig. 3. Comparisons of A values for aniline (Table 1) to Bleaney's relative pcs, where A values were calculated by using ρ_c^π as R_{cs}. This figure is almost equal to that obtained with NIS as R_{cs}.

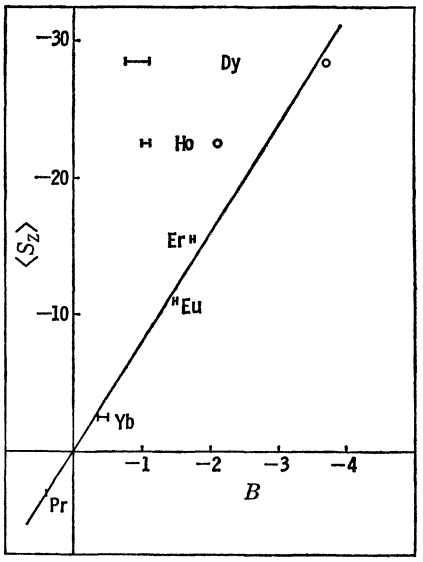

Fig. 4. Comparisons of B values for aniline (Table 1) to Golding's $\langle S_z \rangle$, where B values were calculated by using ρ_c^π as R_{cs}. This figure is similar in pattern to that with NIS as R_{cs}. (See the text) The circles show B values obtained from the expansion of allowed limit of R to 0.07.
○ (Dy): r_N=2.7 Å, χ=35°, R=0.07
○ (Ho): r_N=2.4 Å, χ=34°, R=0.07

is shown in Fig. 3, the linearity for the former is fairly good, consequently, one may consider that the above assumption regarding K_2 is acceptable. For the latter comparison, a good correspondence was obtained, as may be seen from Fig. 4, except for the values with Ho and $Dy(FOD)_3$. If a large expansion of the limit of R to 0.07 is allowable, and if the resulting decrease in χ to about 35° is not particularly noticable, for these two chelates the values of B calculated by using ρ_c^π can be improved to some extent, as may be seen

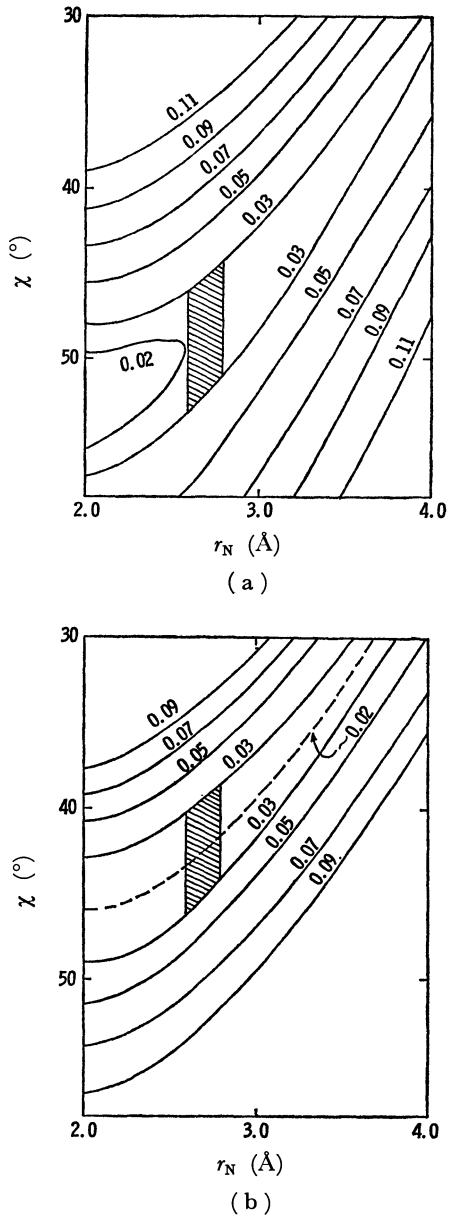

Fig. 5. Contour plots of R for the m-toluidine adduct of Eu(FOD)$_3$ calculated by using ρ_c^π as R_{cs} (a), and of Yb(FOD)$_3$ calculated by using NIS as R_{cs} (b). Shaded parts indicate those chosen to determine a possible range of the magnitudes of S_{cs}.

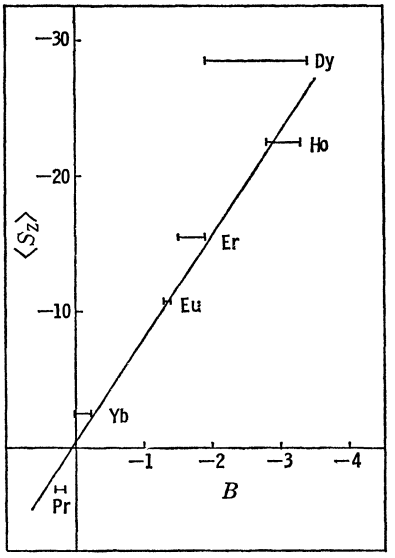

Fig. 6. Comparisons of B values for m-toluidine (Table 2) to Golding's $\langle S_z \rangle$, where B values were calculated by using ρ_c^π as R_{cs}. This figure is almost equal to that with NIS as R_{cs}.

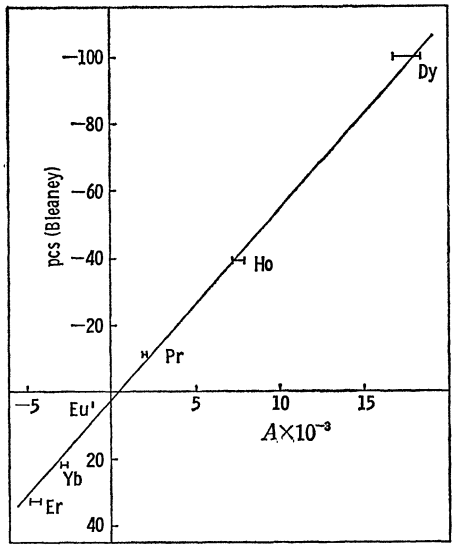

Fig. 7. Comparisons of A values for m-toluidine (Table 2) to Bleaney's relative pcs, where A values were calculated by using ρ_c^π as R_{cs}. This figure is almost equal to that with NIS as R_{cs}.

from Fig. 4, but those due to NIS's cannot be largely altered under such conditions.

The same treatments of m-toluidine adducts of Ln(FOD)$_3$ using the R_{cs} values from both ρ_c^π and NIS led to satisfactorily small values of R, though not with a valley in R so steep as in aniline, in the contour plot. We then discussed with setting the limit of R at a level between 3.0 and 4.5%. Some examples of the contour plots are shown in Fig. 5. The linear relation of the cs term to $\langle S_z \rangle$ is better than that in aniline, as is shown in Fig. 6, as is that of the pcs term to Bleaney's theoretical one (Fig. 7). Furthermore, the $\Sigma|S_{cs}|/\Sigma|S_{pcs}|$ ratios are compared with the theoretical ratios of $|\langle S_z \rangle|/|\text{pcs}|$ (Bleaney) in Fig. 8. The results for aniline are inferior to those for m-toluidine, corresponding to the comparison made separately for cs and pcs.

Thus, it may be considered that the present attempt has been roughly successful in determining the intramolecular ratio of cs and pcs contributions. However, these results may be fairly much affected by the combined inaccuracies introduced by the several assumptions and approximations included. In order to make a more accurate estimate of the cs contribution, the following investigations are in progress: (1) the variation in the angle between the Ln–N vector and the principal magnetic axis in the adduct is introduced to the computer program, and the rotation about the

Ln–N vector is simultaneously accounted for; (2) the amount of δ_2 is separated from that of δ_1 by the least-squares curve fitting for the observed shifts, and (3) a σ-cs term is added to the R_{cs} pattern.

16) As this work was in progress, it was reported by Shapiro *et al.* that δ_2 is fairly smaller than δ_1 in the cyclohexanone- and cyclohexanol-Eu(FOD)$_3$ systems in CCl_4.[17] The combination of this finding and that of the *n*-hexyl amine-Eu(FOD)$_3$ system in $CDCl_3$[15] indicates that both the difference in magnitude between δ_1 and δ_2 in each position in the molecule and the difference in the intramolecular ratio of δ_2 from that of δ_1 vary considerably with the substrate. Consequently, it may be considered that our present findings regarding cs contributions, as described in the last part in the text, are not very reliable. However, if K_2 is large, the shift value obtained from the linear extrapolation of the initial slope, R_L, to 1.0 is approximately two times δ_2, as was indicated by Shapiro *et al.*[18] From this point of view, the cs contributions estimated here are possibly those on δ_2, if the K_2 can be expected to be as large as that ($\sim$14) in the *n*-hexyl amine-Eu(FOD)$_3$ system dealt with in Ref. 15.

20) The calculation of R while varying χ from 0° to 90°

using a suitable range of r_N values showed that only the region of 20—60° in χ is needed for all the Ln ions. This suggests that the χ is slightly larger than that in the $Ni(AcAc)_2$- or $Co(AcAc)_2$-aniline adduct,[22] probably because of the steric hindrance and a different complexation.

21) The shift study on the $Eu(DPM)_3$-3-picoline system by Cramer *et al.* at low temperatures has shown that, when the $(3\cos^2\theta-1)/r^3$ term for axial symmetry is used in the calculation of dipolar shifts at room temperature, the effect of restricted rotation about the Eu–N bond should be accounted for, since the Eu–N vector may not accord with the magnetic axis. However, since the angle between the Eu–N vector and the effective magnetic axis may be expected to be very small,[5a] we roughly regard this angle as zero in the present study. See R. E. Cramer and R. Dubois, *Chem. Commun.*, **1973**, 939.

22) T. Yonezawa, I. Morishima, Y. Akana, and K. Fukuta, This Bulletin, **43**, 379 (1970).

23) A. D. McLachlan, *Mol. Phys.*, **3**, 233 (1960).

24) The values for MO parameters used were those reported by Yonezawa *et al.*,[22] and the λ value in McLachlan's equation was taken as 1.2. Although a decrease in β_{NC} corresponding to an increase in χ was introduced into the MO calculation, the pattern of contour plot was almost insensitive to the variation in β_{NC}. Therefore, β_{NC}/β was kept at 0.6.

Interpretation of Shake-up Satellites in the X-Ray Photoelectron Spectra of Small Hydride Molecules by One-Center-Expansion *ab initio* Calculation with Equivalent-Core Approximation

Takashi Fujikawa, Tomoo Aoyama, Toshiaki Ohta, and Haruo Kuroda

Department of Chemistry, Faculty of Science, University of Tokyo, Hongo, Tokyo 113

(Received April 14, 1975)

One-center-expansion *ab initio* calculations with STO basis set were carried out on H_2O, NH_3, CH_4 and BH_3, to estimate the energies and probabilities of shake-up processes accompanying the photoionization of a core level. A method based on equivalent-core approximation and that based on configuration interaction procedure were applied to obtain wave functions of core-hole ions. It is shown that the calculations by the former method yield very satisfactory results, not only for the core ionization potential, but also for the energies and intensities of shake-up satellites.

Recent development of X-ray photoelectron spectroscopy of gaseous molecules has revealed that core-electron peaks of X-ray photoelectron spectra are often accompanied by satellite bands arising from the two-electron process where a secondary excitation (shake-up) or ejection (shake-off) of an outer shell electron takes place simultaneously with the ionization of a core level.[1-5] These phenomena are of great theoretical interest since they are closely related to the relaxation accompanied with the ejection of a core electron.

Several authors[4-9] have attempted to calculate the energies and intensities of shake-up satellites on the basis of sudden approximation[10,11] where the secondary excitation (or ejection) of an outer-shell electron is treated as arising from the sudden perturbation of potential due to the removal of a core electron. On the core-hole states of small first-row molecules, Aarons *et al.*[4] carried out an *ab initio* unrestricted Hartree-Fock (UHF) calculation with Gaussian basis set, and calculated shake-up satellites of these molecules, with reasonable success. Another type of approach was done by Guest *et al.*[7] and, more recently, by Wood.[8] These authors treated the relaxed core-hole state with a configuration interaction (CI) procedure using molecular orbitals obtained by *ab initio* SCF-MO calculations on the neutral molecules. For relatively complex molecules, semi-empirical molecular orbital methods incorporated with equivalent-core approximation have been applied to calculate the energies and intensities of shake-up satellites, and found to give reasonable results.[5,6] Equivalent-core approximation[12] has been known to be a useful tool for calculating core ionization potentials. In effect, Adams and Clark[13,14] have shown that an *ab initio* calculation combined with this approximation can provide satisfactory predictions of core ionization potential. Hitherto, however, no attempt has been done to use this approximation in calculating shake-up transitions by *ab initio* molecular orbital methods.

In the present study, we carried out *ab initio* calculations by one-center-expansion method on the neutral molecules and core-hole ions of small hydrides of first-row atoms, using equivalent-core approximation, and calculated the energies and intensities of the shake-up satellites accompanying the core-electron peaks in their X-ray photoelectron spectra. The results obtained by core-hole CI method will be also given for the sake of comparison.

Methods of Calculation

According to the sudden approximation, the probability of the transition which yields the final core-hole state $\Psi_f(2n-1)$ is given by,[10,11]

$$P_f = |\langle \Psi_f(2n-1)|\Phi_0(2n-1)\rangle|^2 \quad (1)$$

where $\Phi_0(2n-1)$ is the core-hole wave function in which all molecular orbitals have been frozen as they are in the neutral molecule.[15] We may construct the ground-state wave function $\Phi_G(2n)$ of a neutral molecule from the one-electron molecular orbitals $\{\phi_i\}$.[16]

$$\Phi_G(2n) = |\phi_1\bar{\phi}_1\phi_2\bar{\phi}_2\cdots\phi_n\bar{\phi}_n| \quad (2)$$

Then, $\Phi_0(2n-1)$ can be written as follows by taking ϕ_1 as the ionizing core orbital;

$$\Phi_0(2n-1) = |\bar{\phi}_1\phi_2\bar{\phi}_2\cdots\phi_n\bar{\phi}_n| \quad (3)$$

In the present study, we obtained the one-electron molecular orbitals through one-center-expansion (OCE) *ab initio* calculation with Slater-type-orbital (STO) basis set. This method has been successfully applied by Hartmann *et al.*[17] to calculate the ground-state properties of various hydride molecules. We used 25 STO basis functions except in the case of H_2O where 19 basis functions were used; the zeta values of the used STO bases are given in Table 1.

In order to obtain the final-state wave function, we used two different methods; the equivalent-core approximation method and the core-hole CI method.

(a) Equivalent-Core Approximation (ECA) Method. In the equivalent-core approximation, it is assumed that, when a core electron is removed from an atom, the outer-shell electrons adjust themselves as if the nuclear charge of the ionized atom has increased by one unit.[13] This means that, in the case of CH_4, one can get the valence-electron orbitals of the core-hole ion by performing a calculation on the N^+H_4 system, in which the molecular geometry has been taken the same as that of CH_4 molecule, instead of directly calculating on the core-hole ion, C^*+H_4.[18] Thus, we carried out calculations on the equivalent-core models, C^+H_3, N^+H_4, O^+H_3 and F^+H_2, to obtain the relaxed valence-electron orbitals of the core-hole ions, B^*+H_3, C^*+H_4, N^*+H_3 and O^*+H_2, respectively.

In each case, the zeta values of the first five STO basis functions only were replaced with those corresponding to the change of the nuclear charge as shown in Table 1.

By using the relaxed one-electron orbitals $\{\phi_i\}$, the wave functions of the ground and excited configurations of a core-hole ion can be expressed as follows;

$$\Psi_0(2n-1) = |\bar{\phi}_1\phi_2\bar{\phi}_2\cdots\phi_n\bar{\phi}_n| \quad (4)$$

$$\Psi_{i\to j}(2n-1) = |\bar{\phi}_1\phi_2\bar{\phi}_2\cdots\bar{\phi}_{i-1}\phi_j\bar{\phi}_i\phi_{i+1}\cdots\phi_n\bar{\phi}_n| \quad (5)$$

where the core orbital ϕ_1 is assumed to be the same as ϕ_1 by adopting the frozen-core approximation. Then, the probabilities of the transition to Ψ_0 and that to $\Psi_{i\to j}$ are given as follows according to Eq. (1);[19]

$$P_0 = |\mathbf{S}_0|^4, \qquad P_{i\to j} = |\mathbf{S}_0|^2|\mathbf{S}_{i\to j}|^2 \quad (6)$$

where

$$\mathbf{S}_0 = \begin{vmatrix} \langle\phi_2 & \phi_2\rangle\cdots\cdots\langle\phi_2 & \phi_n\rangle \\ \vdots & \ddots & \vdots \\ \langle\phi_n & \phi_2\rangle\cdots\cdots\langle\phi_n & \phi_n\rangle \end{vmatrix}$$

and

$$\mathbf{S}_{i\to j} = \begin{vmatrix} \langle\phi_2 & \phi_2\rangle\cdots\cdots\langle\phi_2 & \phi_n\rangle \\ \vdots & \ddots & \vdots \\ \langle\phi_{i-1} & \phi_2\rangle\cdots\cdots\langle\phi_{i-1} & \phi_n\rangle \\ \langle\phi_j & \phi_2\rangle\cdots\cdots\langle\phi_j & \phi_n\rangle \\ \langle\phi_{i+1} & \phi_2\rangle\cdots\cdots\langle\phi_{i+1} & \phi_n\rangle \\ \vdots & \ddots & \vdots \\ \langle\phi_n & \phi_2\rangle\cdots\cdots\langle\phi_n & \phi_n\rangle \end{vmatrix} \begin{matrix} \\ \\ \\ \\ \\ \\ \\ \end{matrix} \begin{matrix} \\ \\ \\ \\ \\ \\ <i \end{matrix}$$

The relative probability of shake-up, $\bar{P}_{i\to j}=P_{i\to j}/P_0$, is given as,

$$\bar{P}_{i\to j} = |\mathbf{S}_{i\to j}|^2/|\mathbf{S}_0|^2 \quad (7)$$

For the excited states of each core-hole ion, we carried out a configuration interaction calculation, extensively taking into account singly-excited configurations. Then, the relative probability of the shake-up process which yields the k-th excited state of the core-hole ion, was obtained by the following relation by using the weight $(w^k_{i\to j})$ of each configuration;[20]

$$\bar{P}_k = \sum_{i\to j} w^k_{i\to j}\bar{P}_{i\to j} \quad (8)$$

The total probability of shake-up (P_{up}) and that of shake-off (P_{off}) are given as follows;

$$P_{\mathrm{up}} = \sum_k \bar{P}_k \cdot P_0 \quad (9)$$

$$P_{\mathrm{off}} = 1 - (P_0 + P_{\mathrm{up}}) \quad (10)$$

The procedure proposed by Adams and Clark[13] was used to estimate the core ionization potentials from the calculations by ECA method.[21]

(b) Core-hole CI (CH-CI) Method. In the core-hole CI procedure, a wave function of a relaxed core-hole ion is described as follows;

for the ground state,

$$\Psi_0(2n-1) = a^0_0\Phi_0(2n-1) + \sum_{(i\to j)} a^0_{i\to j}\Phi_{i\to j}(2n-1) \quad (11)$$

and, for the k-th excited state,

$$\Psi_k(2n-1) = a^k_0\Phi_0(2n-1) + \sum a^k_{i\to j}\Phi_{i\to j}(2n-1) \quad (12)$$

where Φ_0 and $\Phi_{i\to j}$ are the frozen-orbital wave functions of core-hole configurations and a^k_0 and $a^k_{i\to j}$ are the coefficients. Then, the probabilities of the transitions to Ψ_0 $(2n-1)$ and to Ψ_k $(2n-1)$, can be given as,

$$P_0 = |a^0_0|^2 \quad (13)$$

$$P_k = |a^k_0|^2 \qquad \text{thus} \quad \bar{P}_k = |a^k_0|^2/|a^0_0|^2 \quad (14)$$

Therefore, the energies and probabilities of shake-up transitions are obtainable through the diagonalization of CI matrix. The core ionization potential can be calculated by the following formula,

$$I_p(\mathrm{core}) = \langle\Psi_0(2n-1)|H(2n-1)|\Psi_0(2n-1)\rangle - \langle\Phi_G(2n)|H(2n)|\Phi_G(2n)\rangle \quad (15)$$

We carried out the calculations described above, using the frozen-orbital wave functions constructed from the one-electron molecular orbitals which have been obtained by the one-center-expansion *ab initio* calculations on the neutral molecules with the STO basis sets given in Table 1.

All computations were performed with HITAC 8700/8800 at the computer center of the University of Tokyo, by using the programs written by ourselves. In the present calculations, we used the observed molecular geometries of free hydrides molecules, except in the case of BH_3.

Results and Discussion

In Tables 2(a)—(d), we show the orbital energies obtained by the present calculations of the neutral molecules of H_2O, NH_3, CH_4 and BH_3. As for the virtual orbitals, we have given there only three or four lower-energy ones, omitting all others of higher energies. On these molecules, *ab initio* LCAO calculations with Gaussian basis set have been carried out by other authors,[22-24] the results of which are shown in the same table for the sake of comparison.

The ionization potentials of the molecular orbitals of H_2O, NH_3 and CH_4 have been experimentally determined by use of photoelectron spectroscopy.[25-27] These experimental values are also given in Tables 2(a)—(c). We can see that the experimental ionization potentials are smaller than the values expected from the calculated orbital energies according to Koopmans' theorem. The discrepancy is especially significant in the case of the ionization potentials of core levels. As it is known, this discrepancy is mainly associated with the electronic relaxation of core-hole state.

The values of the core ionization potential which we have calculated by CH-CI method and by ECA method

tion is much better in the cases when ECA method has been used.

The P_0 values by CH-CI method are generally larger as compared with those by ECA method. Probably, this is due to the neglect of shake-off configurations in the present CH-CI calculation. Incidentally, the P_0 values obtained by Aarons *et al.*[4] through their UHF calculations on the same molecules fall in between our values by CH-CI method and those by ECA method. It may be worthwhile to compare the above P_0 values with those by the CNDO/2 calculation with equivalent-core approximation, since the last method has been conveniently used for more complex molecules. The values which we have obtained by this method are given in Table 3. We note that the CNDO/2 calculations yielded P_0 values considerably larger than those by *ab initio* calculations. Seemingly, this is reflecting the situation that the virtual orbitals which appear in CNDO/2 calculations, are quite limited as compared with those in *ab initio* calculations.

The energies and relative intensities of shake-up satellites obtained from the present calculations are summarized in Table 4. First of all, we note that CH-CI method has given unreasonably large values for the energies of shake-up transitions. The same conclusion has been reported by Guest *et al.*,[7] who have carried out an *ab initio* calculation by core-hole CI method on similar molecules. Recently it was pointed out by Wood[8] that a good result is obtainable if the effect of valence-orbital relaxation is taken into account in a core-hole CI method.

On the other hand, our results by ECA method seem to be quite reasonable when they are compared with the reported experimental data. Recently, Siegbahn[28] observed the satellite bands accompanying the Ols peak of the X-ray photoelectron spectrum of H_2O, with a high resolution technique employing monochromatized X-ray as the stimulating radiation. The satellite spectrum reported by Siegbahn is reproduced in Fig. 1, where the shake-up transitions predicted from our calculations by ECA method are indicated as vertical lines. The calculated results are

$1e' \rightarrow 3e'$	24.6(4.26)	17.16(1.16)		

a) Relative intensities are listed in the parentheses.

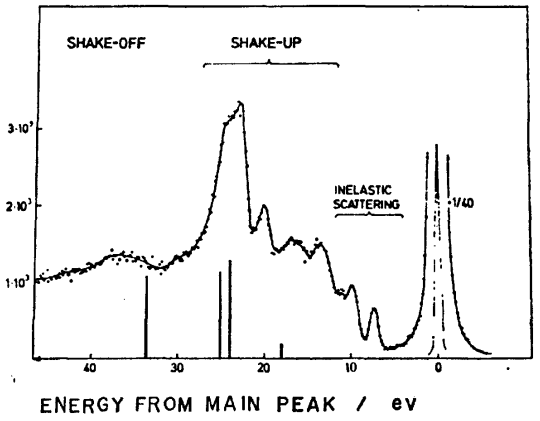

Fig. 1. Satellite bands of the Ols peak of H_2O (Siegbahn, Ref. 28). The shake-up bands predicted by the present study are shown by vertical lines.

quite satisfactory as regards the prediction of main shake-up band. In the observed spectrum, the main shake-up band is at about 24 eV from the Ols peak with an indication that it is composed of more than one components. This is in good agreement with our calculation which predicts two strong shake-up bands, at 23.98 eV ($1b_1 \rightarrow 2b_1$) and at 24.93 eV ($2a_1 \rightarrow 4a_1$). However, there is a problem concerning the interpretation of the weak satellite bands observed at lower energies. In the observed spectrum, there are three weak bands in the 11—22 eV region, their maxima being at about 13, 17 and 20 eV, respectively. All of them have been attributed by Siegbahn[28] to shake-up processes. On the other hand, our calculation predicts only one shake-up band at 17.92 eV ($2a_1 \rightarrow 3a_1$). A similar conclusion has been given by Aarons *et al.*,[4] who obtained also only one shake-up transition at 17.8 eV by UHF calculation. Seemingly, it is rather hard to explain why there are three shake-up bands in the 11—22 eV region. Siegbahn[28] attributed a broad maximum observed at about 33 eV to shake-off process. In effect, this is the energy region where we can expect a shake-off satellite. However, it should be noted also that our calculation predicts a relatively strong shake-up band at 33.22 eV ($1b_2 \rightarrow 2b_2$). Thus, there is a possibility that the 33 eV band in the observed spectrum is, at least partly, associated with a shake-up process.

For NH_3, our calculation predicts two relatively strong shake-up bands at 22.38 and 23.02 eV, which are associated with $2a_1 \rightarrow 4a_1$ and $1e \rightarrow 2e$ transitions, respectively. This is in agreement with the observation reported by Aarons *et al.*,[4] who found that the main satellite band accompanying the N1s peak of NH_3 is in the 18—25 eV region with a maximum at about 22 eV. According to our calculation, we should expect a weak shake-up band at about 14 eV. Unfortunately, however, it is difficult to judge from the reported data if there is any band corresponding to the predicted one or not.

In the case of CH_4, a relatively strong shake-up transition ($1t_2 \rightarrow 2t_2$) is predicted at 17.49 eV and a weak one ($1a_1 \rightarrow 2a_1$) at 31.17 eV. According to Aarons *et al.*,[4] the C1s spectrum of CH_4 exhibits a strong shake-up satellite at 18.1 eV, and a weak one at about 30 eV. Although they observed a weak band at about 26 eV, they attributed it to shake-off process. Seemingly, the observed spectrum is consistent with the results of our calculation.

As described above, our calculation by equivalent-core approximation (ECA) method yielded quite satisfactory results not only for the core ionization potentials, but also for the energies and intensities of shake-up satellites. On the other hand, calculations by core-hole CI(CH-CI) method failed to predict the energies of shake-up transitions correctly, while it gave reasonably good results as regards the core ionization potentials. Although we could improve the core-hole CI method by taking into account the relaxation of valence-electron orbitals as it has been proposed by Wood,[8] the equivalent core approximation method seems to have much advantage because good results are obtainable through a relatively simple computation, and, seemingly, this method can be a convenient tool for the interpretation of X-ray photoelectron spectra of molecules.

18) $C^{**}H_4$ represents the state that an electron has been removed from the core orbital (Cls) of the carbon atom of CH_4.
19) The effect of this approximation on the estimation of probability is almost negligible since $\langle \phi_1 / \phi_l \rangle \doteqdot 0 (l=2, 3, \cdots\cdots)$ and $\langle \phi_1 | \phi_1 \rangle$ is nearly equal to 1 from the calculation by use of Slater's rule.
20) Strictly speaking, $P_k = |\langle \sum_{i \rightarrow j} C^k_{i \rightarrow j} \psi_{i \rightarrow j} | \Phi_0 \rangle|^2$

$$= \sum_{(i\to j)} |C^k_{i\to j}|^2 |\langle\psi_{i\to j}|\Phi_0\rangle|^2 + 2\sum_{(i\to j)}\sum_{(l\to m)} C^k_{i\to j}C^k_{l\to m}\langle\psi_{i\to j}|\Phi_0\rangle \times\langle\psi^k_{l\to m}|\Phi_0\rangle$$

where $C^k_{i\to j}$ is the coefficient of the $(i\to j)$ excitation configuration of the k-th excited state.

However, since the second sum of the above equation was negligibly small in most cases, P_k can be expressed as follows,

$$P_k = \sum_{(i\to j)} |C^k_{i\to j}|^2 |\langle\psi_{i\to j}|\Phi_0\rangle|^2$$

On the other hand, P_0 is reasonably assumed to be $|\langle\psi_0|\Phi_0\rangle|^2$.

Thus, we obtain Eq. (8).

21) For example, the ionization potential of the Ols level of H_2O is estimated as follows;

$I_p(\text{Ols};H_2O) = E(H_2F^+) - E(H_2O) + E(O^{*7+}) - E(F^{7+}) - \delta_0$

where $E(H_2O)$ and $E(H_2F^+)$ are the total energies calculated of H_2O and the equivalent-core model (H_2F^+) of the core-hole ion, respectively. $E(O^{*7+})$ and $E(F^{7+})$ were also obtained by calculation. For the correction term δ_0, we assumed the values proposed by Adams and Clark.[12)]

The Steric Effects of Alkyl Groups on the N-H Stretching Vibrations and the Rotational Isomerism of Alkylureas

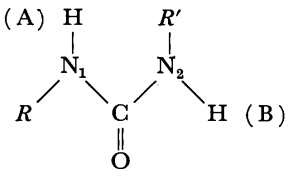
Yoshiyuki MIDO and Tamotsu GOHDA

Department of Chemistry, Faculty of Science, Kobe University, Nada, Kobe 657

(Received April 14, 1975)

The free N-H stretching vibrations of various trialkylureas, R_2UR', in dilute solutions were studied in order to resolve our questions concerning the rotational isomerism of dialkylureas. In the infrared spectrum of R_2UR', where R is isopropyl or cyclohexyl, an additional N-H band appears on the higher-frequency side of the *trans* N-H band. It was also observed that the larger the effective size of the R' group on R_2UR' is, the stronger the intensity of the additional band becomes. It was concluded, in connection with the rotational isomerism of dialkylureas, that the additional band arises from a form in which the N-H group is out of the skeletal plane.

In our previous studies of mono- and dialkylureas,[1-4] it was shown that *N,N'*-dialkylureas (*RUR'*) in solution take the configuration with the *trans-trans* relation between the C=O group and the two N-H groups; this was contrary to the interpretation by Rao *et al.*[5] However, the infrared spectrum of *sym*-di-*t*-butylurea (*s*-D*t*BU) showed a very weak N-H stretching band (3469 cm^{-1}) in addition to the *trans* N-H stretching band (3437 cm^{-1}); this suggested that the coexistence of a certain additional isomer arises as a result of the steric hindrance between the bulky alkyl group and the C=O group.[1] If this isomer, coexisting with the dominant *trans-trans* isomer, is assumed to be in the *trans-cis* configuration, the substitution of another bulky group for either of the two imino hydrogen atoms on *RUR'* having bulky groups will stabilize the *trans* form further for the following reasons.



trans-cis

The substitution of the bulky group at the A site may decrease the amount of the *cis* form about the C-N_2 axis by virtue of the steric hindrance between the substituted group and the R' group. On the other hand, the substitution at the B site does not change the *trans* form about the C-N_1 axis. Accordingly, in the spectra of trialkylureas with bulky groups, the band corresponding to the 3469 cm^{-1} band of *s*-D*t*BU is expected to be weak or absent, if the above assumption is correct.

Thus, in the present study, the N-H stretching vibrations of various trialkylureas, $R_2NCONHR'$ (R_2UR'), were investigated in order to examine whether or not the 3469 cm^{-1} band of *s*-D*t*BU arises from the *cis* form and to establish the relationships between the configurations and the N-H stretching frequencies of R_2UR'.

Experimental

Various R_2UR' substances were prepared by adding the corresponding alkylisocyanate to some dialkylamines. These crude samples were purified by repeated recrystallizations from suitable solvents, and the purified samples were identified by elementary analysis. Solvents for spectroscopy were used.

The infrared measurements were made with a Hitachi EPI-2G Infrared Grating Spectrophotometer. Samples were examined as 0.02 M solutions using 5-mm (3 μm region) and 0.5-mm cells (6 μm region). The recording conditions of the spectra were the same as in the previous study.[1]

Results and Discussion

The N-H Stretching Bands. The infrared spectra of R_2UR' in solutions will exhibit only one free N-H stretching band, if rotational isomerism is not taken into account, since R_2UR' substances have only one N-H bond. However, as is shown in Table 1 and Fig. 1, where the observed free N-H stretching bands are summarized, the spectra of ten R_2UR' derivatives (five D*i*PU*R'* and five DcHU*R'*) exhibited two free N-H bands (we will conventionally denote this type of R_2UR' as R_2UR'-II), and the spectra of the other R_2UR' derivatives showed one free N-H band (R_2UR'-I). Also, cHMUR'-type compounds, examined for comparison, exhibited only one N-H band (see the bottom of Table 1). Among the three kinds of solutions studied, the CS_2 solution showed most prominently the two N-H bands of R_2UR'-II.

From the comparisons of the band positions, the lower-frequency band of R_2UR'-II, as well as only one band of R_2UR'-I and cHMUR', is assigned to the N-H stretching vibration arising from the configuration with the *trans* relation between the N-H and C=O groups.

These N-H bands—the band of R_2UR'-I and the lower band of R_2UR'-II—appear at the positions characteristic of the substituent, R', attached to the N-H bond. Such correlations between the N-H stretching frequencies and the type of R' group correspond to the similar correlations obtained previously for the *trans* N-H stretching frequencies of *RUR'*,[1-4] although the N-H frequencies of R_2UR' are higher by ~20 cm^{-1} than those of the *trans* bands of *RUR'*.

On the other hand, the spectra of R_2UR'-II showed another free N-H band observed at the higher-(approximately 20 cm^{-1}) frequency side of the *trans* N-H band. As may be seen from Table 1, the appearance of the two free N-H bands is dependent upon the bulkiness of the R groups on R_2UR' but not on that

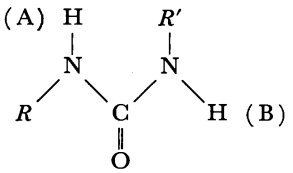
of the R' group. Even cHMUtB, with the C_6H_{11}–$\overset{CH_3}{\overset{|}{N}}$– group of a sterically medium size, exhibited only one N-H band.

Examining the band intensities of R_2UR' in Fig. 1, one can understand easily that the higher N-H band appears at the expense of the intensity of the *trans* N-H band (the lower band). Therefore, the higher band may be concluded to originate from a certain rotational isomer which is mainly caused by the steric hindrance of the R groups and the C=O group, and that this band corresponds to the very weak band at 3469 cm^{-1} of *s*-DtBU in CCl_4.

On the assumption that the 3469 cm^{-1} band of *s*-DtBU arises from the *cis* form in the *trans-cis* configuration, consider the substitution of another bulky group for either of the two imino hydrogen atoms on RUR' with the *trans-cis* configuration.



trans-cis

If the hydrogen atom at the A site is substituted for a bulky group, the steric hindrance between the substituent and the R' group may be more serious than that between the C=O and the R' groups in the case of the *trans* form. Accordingly, this substitution will favor the *trans* configuration. On the other hand, another substitution at the B site leaves the *trans* configuration. Thus, if the weak 3469 cm^{-1} band of *s*-DtBU arises from the *cis* form, the corresponding band of trialkylureas with bulky groups may be expected to be weak or absent.

Let us consider *N*-cyclohexyl-*N'*-*t*-butylurea (cHUtB) and *N*-dicyclohexyl-*N'*-*t*-butylurea (DcHUtB) as examples. We have previously reported that the spectrum of cHUtB in $CHCl_3$ shows a weak band at 3471 cm^{-1} corresponding to the 3469 cm^{-1} band of *s*-DtBU.[4] In the spectrum of DcHUtB in Fig. 1, the corresponding band appears strongly at 3478 cm^{-1} and is even stronger than the *trans* N-H band at 3451 cm^{-1}, contrary to the expectation based on the above assumption. These observations clearly indicate that the coexisting rotational isomer of *s*-DtBU in solution is not in the *trans-trans* configuration.

All the spectra of DiPUR' and DcHUR' examined in this study have a band corresponding to the 3478 cm^{-1} band of DcHUtB. As has been mentioned above, this band appears when two R groups on R_2UR' are isopropyl or cyclohexyl groups, either of which is bulkier than the other groups. Unfortunately, no R_2UR' with the bulkiest R group, *t*-butyl, could be examined.

It is quite evident from Fig. 1 that the bulkier the effective size of the R' group on R_2UR'-II is, the stronger the intensity of this band becomes at the expense of that of the *trans* N-H band. This indicates that probably the steric hindrance between the R' and the

a) I : C=O stretch (Amide I), II : C-N stretch (Amide II).

C=O groups plays an important role in determining the amount of the coexisting rotational isomer.

As for the associated N–H band of all the R_2UR' substances on the lower-frequency side of the *trans* N–H band, it may be seen that the bulkier the effective size of substituents is, the weaker the intensity of this band becomes.

From the above discussion, it may be concluded that the serious steric hindrance prevents the two R groups from leaving the skeletal plane, and that, at the same time, this effect makes the N–H bond out-of-plane, but cannot convert the N–H bond into the *cis* position. That is, the 3469 cm^{-1} band of *s*-D*t*BU arises from a form in which the N–H group is out-of-plane owing to the steric hindrance (we will call this form the *out* form hereinafter), and the rotational isomers with the *trans-trans* (dominant) and probably *out-out* configurations may coexist in solutions of *s*-D*t*BU.

In the case of R_2UR'-II, it may be seen that the amount of the coexisting *out* configuration increases with the bulkiness of the effective size of the R' group; R_2UM-II=50%, R_2UE-II=55%, R_2U*i*P-II≈R_2UcH-II=60%, and R_2U*t*B-II=65%.

The C=O and C–N Stretching Band. The C=O stretching frequencies of R_2UR' in CCl_4 and $CHCl_3$ are shown in Tables 2 and 3 respectively. The frequencies of R_2UR' in CCl_4 are higher by 24—38 cm^{-1} than those in $CHCl_3$; this indicates that the hydrogen bonding between the proton of $CHCl_3$ and the C=O group is formed in the $CHCl_3$ solution.

The C=O stretching frequencies of R_2UR' in the same solvent are similar, though those of DMUR' are somewhat higher in either solvent. However, it should be noted that the main C=O stretching band of R_2UR'-II appears at a frequency lower than that of R_2UR'-I by ~10 cm^{-1} and has a few prominences, as is shown in Fig. 2.

The C–N stretching bands of some R_2UR'-II substances in $CHCl_3$ appear at a frequency lower than those of R_2UR'-I, and others have an additional band (Table 3).

This work was supported by a grant from the Ministry of Education.

Ion Association of Some 2 : 2 Electrolytes in Water at 25 °C. I. Studies of Magnesium, Calcium, Manganese, and Tris(1,10-phenanthroline)-ruthenium(II) Sulfate Solutions with a Vapor-Pressure Osmometer*

Haruhiko YOKOYAMA** and Hideo YAMATERA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya, 464

(Received April 18, 1975)

The osmotic coefficients of aqueous solutions of magnesium, calcium, manganese, and tris(1,10-phenanthroline)ruthenium(II) sulfates were measured at 25 °C by means of a vapor-pressure osmometer. Then the ion-association constants of these electrolytes were obtained as a function of the closest distance of approach of ions from the measured osmotic coefficients as well as from the available conductivity and cryoscopy data. The *best* values of the closest distance of approach and the ion-association constant (given in Table 6) were estimated with the help of theories of ion association. The formation of triple-ions and quadrupoles and the hydration of ions are also discussed in connection with the ion-association constant.

In a previous paper,[1] we re-examined the Debye-Hückel theory[2] of strong electrolyte solutions and especially discussed ion association from the theoretical point of view. It was shown that the observed deviations from the Debye-Hückel theory could be explained without referring to ion association, but at the same time it was reported that the concept of ion association is a practical and useful convention to complement the Debye-Hückel theory. This convention can be justified at least for symmetrical strong electrolytes, irrespective of whether or not ion-pairs are actual well-defined entities.

The existing data of ion-association constants are not sufficient for comparison with our theoretical expression of ion-association constants.[1] Except in a few cases,[3-7] the literature gives only one set of values of the ion-association constant (K) and the closest distance of approach of ions (a). However, the K value to be obtained from the analysis of experimental results must be influenced by the choice of the value of a.[3-7] The theoretical expression of the ion-association constant also shows a dependence of K on a, but in a different way. Thus, it is of interest to obtain ion-association constants as a function of a and to discuss what are the *best* values of the ion-association constant and the closest distance of approach. As will be described below, we measured the osmotic coefficients of aqueous solutions of some 2 : 2 electrolytes by means of a vapor-pressure osmometer. Assuming ideal Debye-Hückel behavior of the free ions, the ion-association constants were obtained with several values of a from analyses with and without taking triple-ion formation, quadrupole formation, and ion hydration into account. Ion-association constants were also obtained as functions of a by the recalculation of the available cryoscopy and conductivity data.[3,6,8-13] These results will be shown and discussed in connection with the theories of ion association.[1,14,15]

Experimental

The osmotic coefficients of the electrolyte solutions were measured by vapor-pressure osmometry (vpo). This method has been described by many authors.[16] Thus, a brief explanation of the apparatus and the procedure will suffice.

A Hitachi Perkin-Elmer 115 molecular-weight apparatus was used in the experiment. It has a cell surrounded by double thermostats. The cell is equipped with two thermistors covered with glass, on which liquids are dropped. The thermistors are connected with a bridge circuit, which is balanced when both thermistor tops are covered with a solvent in equilibrium with its vapor. When the solvent on one of the thermistors is replaced by a solution, the solvent vapor condenses into the solution and liberates the heat of condensation. The temperature of the solution increases until an equilibrium is reached. The change in temperature is detected by the thermistor and shown as a change in the electrical resistance, ΔR. The value of ΔR is dependent on the concentration (molality), m, and the molal osmotic coefficient, ϕ, of the solute, and can be fitted to a power series of the form:

$$\Delta R = s_1(\nu m\phi) + s_2(\nu m\phi)^2 + s_3(\nu m\phi)^3 + s_4(\nu m\phi)^4 \quad (1)$$

where ν is the number of moles of ions formed from one mole of the electrolyte (for nonelectrolyte, $\nu=1$) and where s_1, s_2, s_3, and s_4 are the coefficients to be determined experimentally. We used glucose as the standard material and measured the values of ΔR on its aqueous solutions with concentrations from 0.005 to 0.18 mol kg^{-1}. Assuming $\phi=1$ for glucose in water at 25.0 °C, we obtained $s_1=4925$, $s_2=-998.7$, $s_3=13050$, and $s_4=-47920$ by the method of least-squares. The observed values of ΔR for various solutions were put into Eq. (1), and the osmotic coefficients (ϕ) were evaluated. We measured the osmotic coefficients (ϕ) of sodium chloride and obtained the approximate expression:

$$1-\phi = 0.2963m^{1/2} + 0.1036m - 1.306m^{3/2}$$

The values of ϕ predicted by this equation at several concentrations up to 0.1 mol kg^{-1} agreed with the values from e.m.f. measurements[17] within the range of experimental error. This shows that the assumption of $\phi=1$ for glucose solutions is adequate.

Materials. A reagent-grade glucose (anhydride) was used as the standard material after having been dried at about 80 °C and then kept over silica gel. A reagent-grade sodium chloride was recrystallized by concentrating its aqueous solution, and was then dried at about 600 °C. A

reagent-grade magnesium sulfate was recrystallized as the hydrate, $MgSO_4 \cdot 7H_2O$, from its aqueous solution below 48 °C and then air-dried at room temperature. Its composition was confirmed by gravimetric analyses of magnesium as magnesium pyrophosphate and of sulfate as barium sulfate. The calcium sulfate used was dihydrate of reagent grade. The number of water of crystallization was confirmed by the dehydration at about 700 °C and by the titration of the calcium ion with ethylenediaminetetraacetic acid. A stock solution of manganese sulfate was prepared by the use of a recrystallized reagent-grade hydrate. Its concentration was determined by gravimetric analysis of sulfate. Tris(1,10-phenanthroline)ruthenium(II) sulfate hydrate, $[Ru(phen)_3]SO_4 \cdot 7H_2O$, was prepared in a manner similar to that described by Dwyer.[18] The complex was synthesized by adding sodium hypophosphite as a reducing agent to a solution containing ruthenium chloride and 1,10-phenanthroline; the iodide was obtained by precipitation from the solution. Sulfate of this complex was prepared by the double decomposition of the iodide and silver sulfate, and was purified by repeated precipitations with acetone from alcoholic solutions and by a final recrystallization from an aqueous solution. It was dried over silica gel for a few days until it reached a constant weight. The number of the water of crystallization was determined to be seven—directly by the Karl-Fischer method and by the spectrophotometric analysis of HDO in a D_2O solution of the salt,[19] and indirectly by the gravimetric analysis of sulfate.

Results and Discussion

The ΔR values were measured for some 2 : 2 electrolytes in aqueous solutions at 25.0±0.03 °C. The osmotic coefficients (ϕ) were calculated from ΔR with Eq. (1) and are shown in Table 1.*** The measured ϕ values are plotted against the molal concentration of the solute, m, in Fig. 1 for $MgSO_4$ and in Fig. 2 for $CaSO_4$, together with the results from cryosocopic measurements.[3,6] These figures also give the ϕ *vs.* m curves predicted by the Debye-Hückel theory[2] with a few values assumed for the closest distance of approach of ions, a. None of the theoretical curves fits the experimental results. For any reasonable value of a, the experimental ϕ values are lower than the values predicted by the Debye-Hückel theory. A decrease in ϕ is usually considered to result from ion association.[3-6] According to this usual convention, we shall assume an ion-association equilibrium and shall estimate the ion-association constants on the basis of an analysis of the experimental ϕ values.

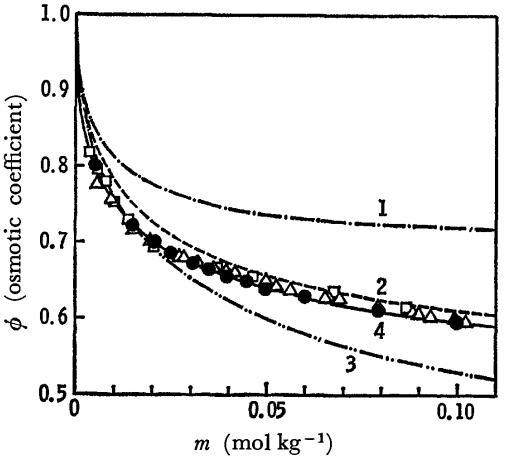

Fig. 1. Osmotic coefficients of $MgSO_4$ solutions. ●, present work at 25.0°C (vpo). △, Brown and Prue[3] at 0 °C (cryoscopy). □, Isono[6] at 0 °C (cryoscopy). Curves 1 (—·—), 2 (----), and 3 (—··—) are theoretical curves due to the Debye-Hückel theory with a=6.0, 4.0, and 3.0 Å, respectively. Curve 4 (——) is calculated with the K and K_t values in Table 2 (25.0 °C); each set of the K and K_t values gives the essentially same curve.

The ion-association equilibrium for a symmetrical electrolyte is expressed by:

$$\begin{array}{lccc} & M + A & \rightleftharpoons & MA \\ \text{concentration} & m(1-\alpha) \quad m(1-\alpha) & & m\alpha \end{array} \qquad (2)$$

*** The values of ϕ obtained for $MgSO_4$ and $MnSO_4$ around 0.1 mol kg^{-1} are, respectively, 1.6% and 3.0% smaller than those obtained by Robinson and Jones,[20] who made isopiestic vapor-pressure measurements.

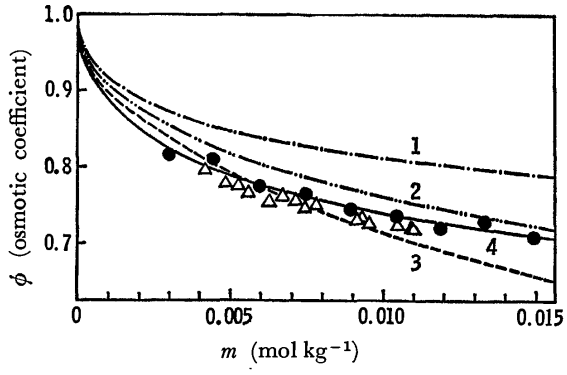

Fig. 2. Osmotic coefficients of $CaSO_4$ solutions.
●, present work at 25.0 °C (vpo). △, Brown and Prue[3] at 0 °C (cryoscopy). Curves 1 (—·—), 2 (—··—), and 3 (----) are theoretical curves due to the Debye-Hückel theory with a=6.0, 3.0, and 1.0 Å, respectively. Curve 4 (——) is calculated with the K and K_t values in Table 2 (25.0 °C); each set of the K and K_t values gives the essentially same curve.

where m denotes the molality of the electrolyte and where α is the degree of association defined by:

$$\alpha = \frac{[MA]}{m}$$

The brackets indicate the concentration of a given species. The ions, M and A, having the z_1e and z_2e charges respectively ($z_1=-z_2=z>0$), are usually considered as *free* ions in the sense that the Debye-Hückel theory can be applied to them. On the other hand, the ion-pair, MA, is presumed to behave like a non-electrolyte in dilute solutions. Therefore, the ϕ of an electrolyte solution is related to α as follows:

$$\phi = (1-\alpha)\phi_{DH} + \frac{\alpha}{2} \tag{3}$$

or

$$\alpha = \frac{\phi_{DH}-\phi}{\phi_{DH}-0.5}$$

where ϕ_{DH} is the molal osmotic coefficient expected by the Debye-Hückel theory and is given by:

$$\phi_{DH} = 1 - \frac{z^2\kappa s}{6}\sigma(\kappa a) \tag{4}$$

with the definition of the function $\sigma(x)$:

$$\sigma(x) = \frac{3}{x^3}\left[(1+x) - 2\ln(1+x) - \frac{1}{1+x}\right]$$

In Eq. (4), a is the closest distance of approach of ions, and s is a parameter equal to $e^2/\varepsilon kT$, whose value is 7.157 Å† in water at 25.0 °C with the dielectric constant (ε) of 78.30$_3$. The parameter κ is the so-called "reciprocal thickness of the ionic atomsphere" and is defined by:

$$\kappa^2 = \frac{8\pi N}{1000}z^2 s m(1-\alpha) \tag{5}$$

where N is the Avogadro number and where $m(1-\alpha)$ represents the concentration of the free ion on the molality scale. The molality can be used in place of the molar concentration, since the difference between the two values is less than the experimental error in dilute solutions up to about 0.1 mol kg^{-1}.

The values of α, κ, and ϕ_{DH} were calculated by successive approximations in the following way. The value of κ was calculated by using Eq. (5), with α=0 provisionally. The value of ϕ_{DH} was evaluated with Eq. (4), and then the value of α, with Eq. (3). This value of α was in turn put into Eq. (5) in order to recalculate the value of κ. With this κ value, the values of ϕ_{DH} and α were recalculated in the same way as before. After several cycles of the successive approximation, the parameter values were fixed. The final value of α was used for the calculation of the ion-association constant, K, with the expression:

$$K = \frac{\alpha}{(1-\alpha)^2 m\gamma_M\gamma_A}$$

where γ_M and γ_A are the activity coefficients of the free ions, M and A respectively, and are given by:

$$\ln\gamma_M = \ln\gamma_A = -\frac{z^2\kappa s}{2(1+\kappa a)} \tag{6}$$

The activity coefficient of the MA ion-pair was regarded as unity.

The ion-association constants of some 2 : 2 electrolytes were calculated with several a values assumed. The results for $MgSO_4$, $CaSO_4$, $MnSO_4$, and $[Ru(phen)_3]SO_4$ are shown in Figs. 3 to 6 respectively. Apparent linear relationships were observed between log K and m up to about 0.05 mol kg^{-1}; extrapolation to m=0 gave different log K values, depending on the a values.

In each figure for $MgSO_4$, $CaSO_4$, and $MnSO_4$, there seems to be a specific a value at which the log K value is apparently independent of the concentration, *i.e.*, a=4.2 Å for $MgSO_4$, about 4 Å for $CaSO_4$, and 3.8 Å for $MnSO_4$. However, such a situation may be incidental, since the log K values for $MgSO_4$ and $MnSO_4$ are no longer constant at concentrations higher than 0.06 mol kg^{-1}. The concentration de-

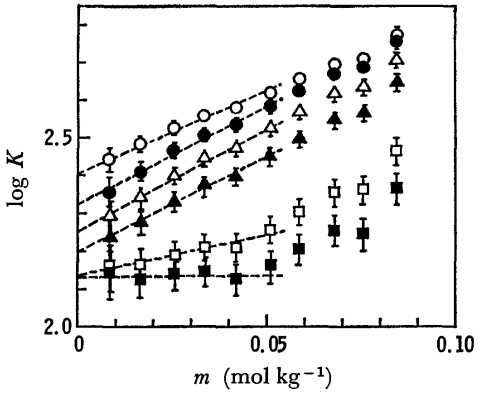

Fig. 5. log K values of $MnSO_4$. The assumed a values are 14.3 Å (○), 8.0 Å (●), 6.0 Å (△), 5.0 Å (▲), 4.0 Å (□), and 3.8 Å (■).

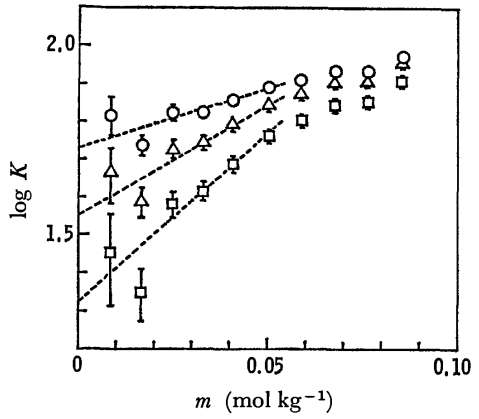

Fig. 6. log K values of $[Ru(phen)_3]SO_4$. The assumed a values are 14.3 Å (○), 11.0 Å (△), and 9.0 Å (□).

pendence of the ion-association constant may be attributed to the effects of other ion-ion interactions and ion hydration disregarded in the analysis. Below, we shall take the triple-ion formation into consideration in order to obtain better ion-association constants.

Triple-Ion Formation. When an ion approaches an ion-pair, the electrostatic interaction between the charge and the dipole will cause the formation of a so-called "triple-ion." There are two possible equilibria for the formation of a triple-ion:

$$MA + M \rightleftharpoons M_2A$$

$$MA + A \rightleftharpoons MA_2$$

Assuming an equal formation constant for the M_2A and MA_2 triple-ions, one can express the concentration of each species as follows:

$$[M] = [A] = m[1-\alpha(1+3\beta)]$$

$$[MA] = m\alpha$$

$$[M_2A] = [MA_2] = m\alpha\beta$$

where β is the parameter defined by:

$$\beta = \frac{[M_2A]}{[MA]} = \frac{[MA_2]}{[MA]}$$

Thus, the formation constant for the triple-ions, K_t, is expressed by:

$$K_t = \frac{[M_2A]\gamma_{M_2A}}{[MA][M]\gamma_M} = \frac{[MA_2]\gamma_{MA_2}}{[MA][A]\gamma_A} = \frac{\beta}{[1-\alpha(1+3\beta)]m} \quad (7)$$

where γ_{M_2A} and γ_{MA_2} are the activity coefficients of M_2A and MA_2 and are assumed to be equal to γ_M and γ_A respectively.

With the above assumptions, the osmotic coefficient of the electrolyte can be expressed by:

$$\phi = [1-\alpha(1+2\beta)]\phi_{DH} + \frac{\alpha}{2} \quad (8)$$

where

$$\phi_{DH} = 1 - \frac{z^2\kappa s}{6}\sigma(\kappa a) \quad (9)$$

Eq. (9) is apparently the same as Eq. (4), but here the parameter κ is given by:

$$\kappa^2 = \frac{8\pi N}{1000}z^2 s m[1-\alpha(1+2\beta)] \quad (10)$$

Assuming the value of K_t for a given a value and using Eqs. (7) to (10), the values of α, β, κ and ϕ_{DH} were calculated by successive approximations. With the α and β values thus obtained, the ion-association constant, K, was calculated according to the expression:

$$K = \frac{\alpha}{[1-\alpha(1+3\beta)]^2 m\gamma_M\gamma_A}$$

The value of K was thus obtained at each concentration, and then the K values were averaged. The osmotic coefficient was calculated for each concentration with the averaged value of K and used for the calculation of the standard deviation, σ_ϕ, defined by:

$$\sigma_\phi = \sqrt{\frac{\sum_{i=1}^{n}(\phi_{calcd,i}-\phi_{obsd,i})^2}{n-2}}$$

where n is the total number of points of the run and where ϕ_{obsd} and ϕ_{calcd} are the observed and calculated osmotic coefficients respectively. The σ_ϕ value was obtained as a function of K_t for a given a value. The K_t value giving the minimum value of σ_ϕ was regarded as the *best* value of K_t.

The K value was calculated at each concentration with the K_t value obtained above and was plotted against m. Fig. 7 shows the results for magnesium sulfate, assuming a few a values. For each value of a, the log K value shows a very good constancy up to about 0.1 mol kg^{-1}. In the same figure, the corresponding previous plots are reproduced from Fig. 3

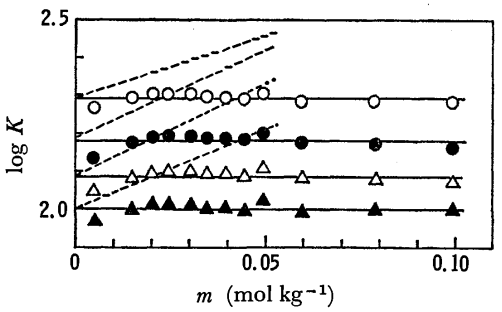

Fig. 7 Constant log K values of $MgSO_4$ obtained with the assumption of appropriate K_t values. (See the columm h=0 of Table 2.) a=14.3 Å (○), 8.0 Å (●), 6.0 Å (△), and 5.0 Å (▲).

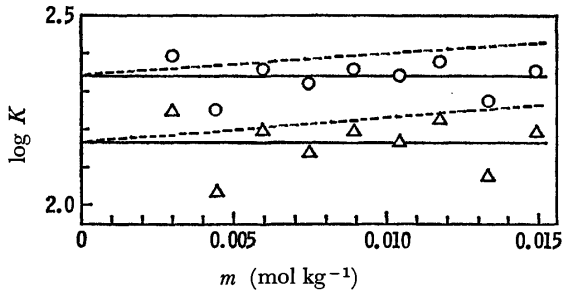

Fig. 8. Constant log K values of $CaSO_4$ with the assumption of appropriate K_t values. (See the column h=0 of Table 2.) a=14.3 Å (○) and 6.0 Å (△).

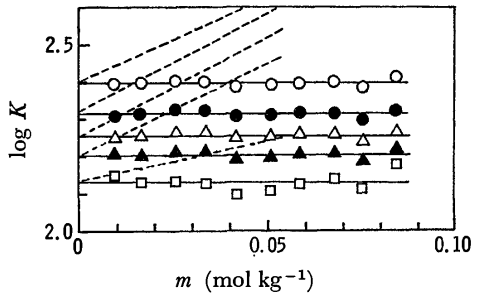

Fig. 9. Constant log K values of $MnSO_4$ with the assumption of appropriate K_t values. (See the columm h=0 of Table 2.) a=14.3 Å (○), 8.0 Å (●), 6.0 Å (△), 5.0 Å (▲), and 4.0 Å (□).

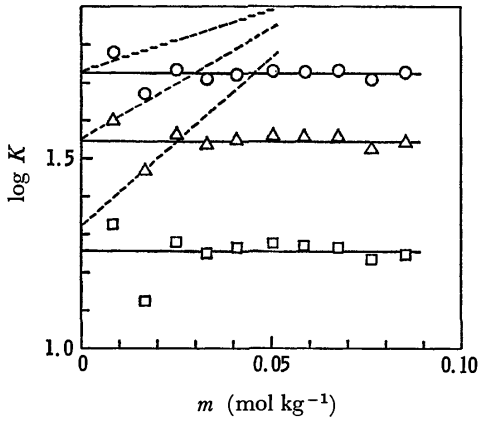

Fig. 10. Constant log K values of $[Ru(phen)_3]SO_4$ with the assumption of appropriate K_t values. (See the columm h=0 of Table 2.) a=14.3 Å (○), 11.0 Å (△), and 9.0 Å (□).

in broken lines. The constant value of log K obtained here for each of the given a values is in fairly good agreement with the value obtained by extrapolation to m=0 in the previous plot. This shows that a good enough estimation of the ion-association constant K can be made without taking the triple-ion formation into account. The same discussion also applies to Figs. 8 to 10 for the other electrolytes.

Hydration. The ion hydration causes a decrease in the concentration of the water as solvent. This decrease is equal to hm, where h represents the hydration parameter given by:

$$h = \frac{h_M[M]+h_A[A]+h_{MA}[MA]+h_{M_2A}[M_2A]+h_{MA_2}[MA_2]}{m}$$

$$= (h_M+h_A)[1-\alpha(1+3\beta)]+h_{MA}\alpha+(h_{M_2A}+h_{MA_2})\alpha\beta \quad (11)$$

where h_M, h_A, h_{MA}, h_{M_2A}, and h_{MA_2} are the hydration numbers of the M, A, MA, M_2A, and MA_2 species respectively. If the ion hydration is allowed for, the molality of the solute, m', can be expressed by:

$$m' = \frac{55.51}{55.51-hm}m = \frac{m}{1-0.0180hm}$$

and the expression for the osmotic coefficient ϕ becomes:

$$\phi = \frac{1}{1-0.0180hm}\left\{[1-\alpha(1+3\beta)]\phi_{DH}+\frac{\alpha}{2}\right\}$$

where ϕ_{DH} is given by Eq. (9). The ion-association constant, K, and the triple-ion formation constant, K_t, are expressed by:

$$K = \frac{\alpha}{[1-\alpha(1+3\beta)]^2 m'\gamma_M\gamma_A}$$

and

$$K_t = \frac{\beta}{[1-\alpha(1+3\beta)]m'}$$

If the value of the parameter h is given, the K and K_t values can be calculated by the procedure described before. Since it is difficult to estimate the hydration numbers, h_{MA}, h_{M_2A}, and h_{MA_2}, involved in the parameter h [Eq. (11)], for convenience we shall consider two extreme cases in order to learn how far the ion hydration affects the estimation of the K and K_t values.

Case (A): The hydration numbers of the ion-pair and the triple-ions are simply equal to the sums of the hydration numbers of the constituent ions.

$$h_{MA} = h_M + h_A = h_0$$
$$h_{M_2A} = 2h_M + h_A \quad (12)$$
$$h_{MA_2} = h_M + 2h_A$$

where the parameter h_0 can be determined by the measurement of the hydration number in very dilute solutions. By using Eq. (12), the parameter h in Eq. (11) is expressed by:

$$h = h_0$$

Case (B): The hydration number of the ion-pair is equal to zero and the sum of the hydration numbers of the M_2A and MA_2 triple-ions is equal to h_M+h_A:

$$h_{MA} = 0$$
$$h_{M_2A} + h_{MA_2} = h_M + h_A = h_0$$

Thus, the expression for h becomes:

$$h = h_0[1-\alpha(1+2\beta)]$$

Tentatively taking $h_0=15$,†† the ion-association constants were calculated for the two cases, (A) and (B). The case of $MgSO_4$ with $a=6.0$ Å will be taken as an example. The K_t values giving the minimum values of σ_ϕ are 3.1 and 2.7 mol^{-1} kg for (A) and (B) respectively. These K_t values are slightly greater than the value, 2.2 mol^{-1} kg, which was obtained by disregarding the ion hydration. However, the K values remained unchanged at 121 ± 5 mol^{-1} kg. The log K value for $MgSO_4$ with $a=6.0$ Å is plotted against m in Fig. 11, where the overlapping solid marks of different kinds show the unchanged K values. The log K values obtained by disregarding the triple-ion formation ($K_t=0$) are also plotted in Fig. 11. In each case, an apparent linear relationship is observed between log K and m up to about 0.05 mol kg^{-1}. The slopes are different from one another, indicating different K_t values. However, extrapolations of the lines to $m=0$ give the same intercept, showing the same log K value.

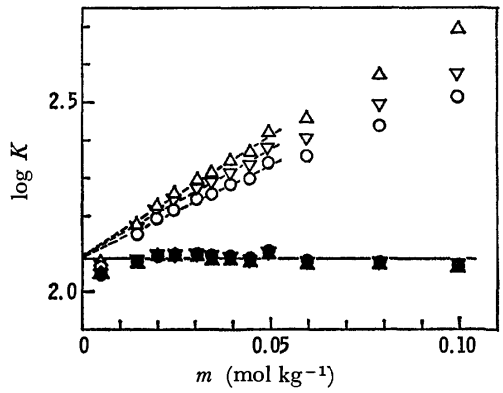

Fig. 11. log K values for $MgSO_4$ with $a=6$ Å allowing for hydration of ions.
○ and ●: $h=0$, reproduced from Figs. 3 and 7, respectively. △ and ▲: $h_0=15$, case (A). ▽ and ▼: $h_0=15$, case (B). $K_t=0$ (○, △, ▽), 2.2 (●), 3.1 (▲), and 2.7 (▼) mol^{-1} kg were assumed.

The consideration of the triple-ion formation and the ion hydration resulted in no appreciable change in the ion-association constant K from that obtained by the extrapolation of the log K *vs.* m plots in Figs. 3 to 6, where the triple-ion formation and the ion hydration were ignored. When the triple-ion formation and the ion hydration were allowed for, the value of K was practically constant up to about 0.1 mol kg^{-1}. On the other hand, the value of K_t was slightly dependent on the estimation of the hydration numbers of the ions. Table 2 gives the K values for a variety of a values, together with the K_t values. Each set of the values of a, K, and K_t can reproduce the observed osmotic coefficients within the range of experimental error. This is shown in Figs. 1 and 2. In each of the figures, the best-fitting curves for different a values coalesce into a curve (the solid line).

Fuoss and Kraus[22] have proposed a theory of the triple-ion formation. Their theory predicts K_t values of 2.6 mol^{-1} kg at $a=8.2$ Å and 3.3 mol^{-1} kg at $a=5.7$ Å for 2 : 2 electrolytes in aqueous solutions at 25 °C. These are close to the values obtained in the present work (Table 2).

Gardner and Glueckauf[5] have obtained K and K_t values for some 2 : 2 electrolytes by a reanalysis of the cryoscopic data given by Brown an Prue.[3] The manner of the analysis of the data was different from that described in the present paper. We also reanalyzed the same and other cryoscopic data[3,6] for $MgSO_4$ and $CaSO_4$ in the manner followed in the analysis of the vpo data. The results are shown in Table 3. For $a=9.25$ Å, Gardner and Glueckauf obtained $K_t=2.6$ mol^{-1} kg and $K=158$ mol^{-1} kg for $MgSO_4$ and $K_t=2.7$ mol^{-1} kg and $K=234$ mol^{-1} kg for $CaSO_4$. Their result for $CaSO_4$ is appreciably different from that given in Table 3, whereas for $MgSO_4$ the results are close to each other and also to the result of our vpo experiment (25 °C).

Quadrupole Formation. In the preceding sections, the triple-ion formation constant, K_t, was estimated disregarding the quadrupole formation. We shall now discuss how the correction for quadrupole formation will affect the values of K and K_t to be obtained.

The equilibrium for the formation of a quadrupole $(MA)_2$ is expressed by:

$$MA + MA \rightleftharpoons (MA)_2$$

The formation constant, K_q, is given by:

$$K_q = \frac{[(MA)_2]}{[MA]^2} = \frac{\delta}{m\alpha}$$

where δ is the parameter defined by:

$$\delta = \frac{[(MA)_2]}{[MA]}$$

Then, the osmotic coefficient becomes:

$$\phi = \frac{1}{1-0.0180hm}\left\{[1-\alpha(1+2\beta+2\delta)]\phi_{DH}+\frac{\alpha(1+\delta)}{2}\right\}$$

The experimental data are not good enough to estimate the values of K_t and K_q at the same time. Thus, some relation between K_t and K_q values has to be assumed if one is to estimate them by the analysis of the experimental data.

Defining K' as:

$$K' = \frac{[(MA)_2]}{[M_2A][A]\gamma_{M_2A}\gamma_A} = \frac{[(MA)_2]}{[MA_2][M]\gamma_{MA_2}\gamma_M}$$

one obtains the relation:

$$\frac{K_q}{K_t} = \frac{K'}{K}$$

K' is the ion-association constant of a kind of 2 : 2 electrolyte and can be approximated by K. Then, K_q/K_t will have a value near unity. Assuming $K_q = K_t$, we obtained the K_t, K_q, and K values for $MgSO_4$ shown in Table 4. The ion-association constants (K) given here are slightly greater than the corresponding values shown in Table 2, but the change is within the range of experimental error except when large a values are assumed. The K_t values are appreciably smaller than those shown in Table 2. Thus, it was found that a correction for the quadrupole formation would make the K_t values smaller than the values shown in Table 2, but would affect the K values very little.

Table 4. K and K_t values of $MgSO_4$ obtained with the assumption of $K_q=K_t$ at 25.0 °C (vpo)

a (Å)	K (mol^{-1} kg)	K_q (=K_t) (mol^{-1} kg) $h=0$	$h_0=15$ (B)[a]	$h_0=15$ (A)[b]
4.0	72±9	0	0.6	0.8
5.0	102±3	1.2	1.6	1.9
6.0	126±6	1.5	1.8	2.1
7.0	144±8	1.5	1.8	2.1
8.0	159±9	1.4	1.7	2.1
10.0	182±10	1.3	1.5	1.8
12.0	197±10	1.1	1.3	1.6
14.3	210±9	1.0	1.1	1.5

a) $h=h_0[1-\alpha(1+2\beta+2\delta)]$; the assumption for the hydration number of the quadrupole is similar to that described in the paragraph following case (B) on p. 2712. b) $h=h_0$; a similar assumption to that described in the paragraph following case (A) on p. 2712.

Comparison with the Ion-Association Constants Obtained from Conductivity Experiments. The electric conductivity was mesaured for $MgSO_4$ solutions by Dunsmore and James[8] and Katayama,[9] for $CaSO_4$ solutions by Inada *et al.*,[10] and for $MnSO_4$ solutions by Hallada and Atkinson[11] and Petrucci *et al.*[12] Although no conductivity measurements were made of $[Ru(phen)_3]SO_4$ solutions, the electric conductivities of $[Fe(phen)_3]SO_4$ solutions were measured by Kubota and Yokoi.[13] They analyzed the conductivity data in order to obtain the values of the ion-association constant and the closest distance of approach. However, these results have to be revised before they can be compared with the results from vpo, since different authors used different theoretical equations for the analysis of the conductivity data.

For the reanalysis of the conductivity data, we used Fuoss-Hsia's equation[23] expanded by Fernández-

Prini.[24] This equation gives the equivalent conductivity, Λ, for an association system as follows:

$$\frac{\Lambda}{1-\alpha} = \Lambda_0 - S[c(1-\alpha)]^{1/2} + Ec(1-\alpha)\log[c(1-\alpha)] + J_1c(1-\alpha) - J_2[c(1-\alpha)]^{3/2} \quad (13)$$

where Λ_0 is the limiting equivalent conductivity, c is the concentration of the solute on the molar scale, and α is the degree of association. The latter is related to K by:

$$K = \frac{\alpha}{(1-\alpha)^2 c y_M y_A} \quad (14)$$

The parameters, J_1 and J_2, as well as the activity coefficients, y_M and y_A, of the free ions, M and A, are functions of the closest distance of approach of ions, a. Since measurements of the conductivity are usually made at concentrations well below 10^{-2} mol l^{-1}, c, y_M, and y_A on the molar concentration scale can be approximated by m, γ_M, and γ_A [Eq. (6)] on the molality scale respectively; the other interactions, such as triple-ion formation, described in the previous sections can be ignored.

With a given value of a and a roughly estimated value of Λ_0, K was calculated for each concentration by means of Eqs. (13) and (14). With the averaged K value, the electric conductivity at each concentration was calculated and then used to calculate the standard deviation, as defined by:

$$\sigma_\Lambda = \sqrt{\frac{\sum_{i=1}^{n}(\Lambda_{\mathrm{calcd},i} - \Lambda_{\mathrm{obsd},i})^2}{n-2}}$$

where n is the total number of points of the run and where Λ_{obsd} and Λ_{calcd} are, respectively, the observed and the calculated electric conductivity at each concentration. The averaged K value depended on the assumed Λ_0 value. The best-fitting values of K and Λ_0 for a given a value were determined by the minimization of the standard deviation, σ_Λ, and are listed in Table 5 as a function of a for each of the electrolytes. The log K values given in Table 5 show a tendency similar to that observed in Table 2 (results from vpo), and each of the K values has a magnitude similar to the corresponding one in Table 2.

Critical Discussion of the Minimum Standard Deviation as the Criterion of the Best *Values.* As a criterion of the *best* values, we used the minimum standard deviations of ϕ and Λ respectively for the determination of K and K_t from the vapor pressure osmometric measurements and for the determination of K and Λ_0 from the conductivity data. The rather sharp minima shown

by the standard deviations, σ_ϕ and σ_Λ, for each given a value made the determination of the *best* parameter values possible. In most conductivity studies, however, where the minimization of σ_Λ has been used for the simultaneous determination of the values of three parameters, K, Λ_0, and a, the minimum standard deviation is not necessarily a good criterion of the *best* parameter values. The minimum values of σ_ϕ and σ_Λ we obtained for each fixed value of a are plotted against a in Figs. 12 and 13 respectively. In the latter, the

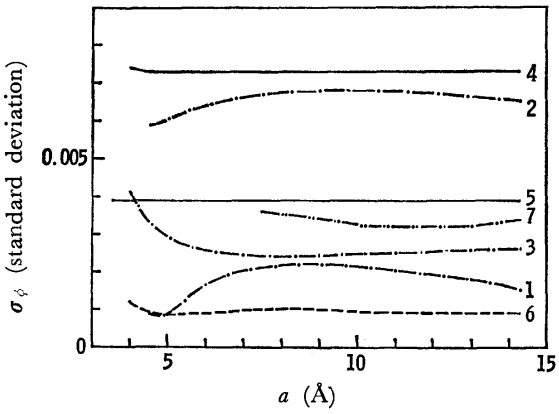

Fig. 12. The standard deviation σ_ϕ as a function of a. 1, 2, and 3: $MgSO_4$. 4 and 5: $CaSO_4$. 6: $MnSO_4$. 7: $[Ru(phen)_3]SO_4$. 1, 4, 6, and 7 are concerned with the vpo data, whereas the others with the cryoscopic data due to Isono[6] (2) and Brown and Prue[3] (3 and 5).

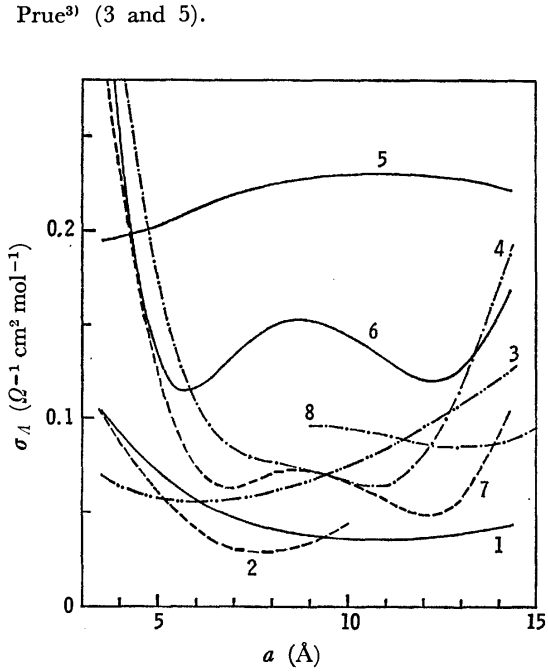

Fig. 13. The standard deviation σ_Λ as a function of a obtained from reanalysis of conductivity data. 1, 2, and 3: $MgSO_4$ (Dunsmore and James[8]). 4: $MgSO_4$ (Katayama[9]). 5: $CaSO_4$ (Inada *et al.*[10]). 6: $MnSO_4$ (Hallada and Atkinson[11]). 7: $MnSO_4$ (Petrucci *et al.*[12]). 8: $[Fe(phen)_3]SO_4$ (Kubota and Yokoi[13]). Fuoss-Hsia's equation[23,24] was used for the analysis of data, except for the cases of 2 and 3 where Fuoss-Onsager's[25] and Pitts's equation[26] were used, respectively.

results obtained for $MgSO_4$ by the use of Fuoss-Onsager's equation[25] and Pitt's equation[26] are also shown for comparison. In Fig. 13, some of the curves have two minima, while others have a shallow minimum. The a value giving the minimum σ_Λ depends not only on the experimental data, but also on the theoretical equations used for the analysis of the data. These facts imply that the minimum standard deviation cannot be a good basis for the determination of the *best a* value. Figure 12 gives hardly a clue for determining the *best a* value from the vpo data. Regarding the conductivity method, a similar discussion has also been made in detail by Hanna *et al.*[7,27] Thus, we shall try to estimate the *best a* and K values with the help of theories of ion association.[1,14,15]

Estimation of the Best *Values with the Help of Theories of Ion Association.* In a previous paper,[1] we made a refinement of the Debye-Hückel theory[2] on the basis of the purely electrostatic model and introduced a correction term into the Debye-Hückel expression for the chemical potential of a dissolved electrolyte. By connecting the correction term with the conventional concept of ion association, we derived the following expression for the ion-association constant:

$$K = \frac{8\pi N a^3}{1000} \sum_{n=1}^{\infty} \frac{b^{2n+2}}{(2n+2)!(2n-1)}$$

where b is Bjerrum's parameter as defined by $b=z^2e^2/\varepsilon kTa$. This equation gives the K value as a function of a. Since this theoretical K value decreases monotonously with the increase in a, and since the experimental K value increases with the increase in the assumed value of a, only one choice of a set of a and K values can satisfy both theory and experiment. Such sets of a and K values are given in Table 6. Each of the listed a values is somewhat greater than the sum of the crystallographic radii of the cation and the anion, r_M+r_A,††† and is plausible if hydration of the ions is taken into consideration. This can be taken as evidence for the validity of the theory.

††† The values of r_M+r_A given in Table 6 were estimated as follows. The crystallographic data of $CaSO_4\cdot 2H_2O$ and K_2SO_4[28] were used for the estimation of the radius, r_A, of the sulfate ion. Pauling's radius[29] of each cation was subtracted from the distance between the metal ion and the nearest oxygen atom of the neighboring sulfate ion; the difference, 1.3_8 Å, was obtained as the radius of the oxygen atom belonging to a sulfate ion. This oxygen radius was added to the bond length between the sulfur and the oxygen atom of a sulfate ion, 1.5_0 Å,[28,30] to obtain 2.8_8 Å as the value of r_A for the sulfate ion. Pauling's radii[29] were used as the r_M values for magnesium, calcium, and manganese ions. For $[Fe(phen)_3]^{2+}$, the data of X-ray diffraction[31] are available. They give 6.1_3 Å as the distance from the central iron atom to the most distant hydrogen atom of the coordinated 1,10-phenanthroline ligand. The r_M value of $[Fe(phen)_3]^{2+}$ was estimated as the sum of this distance, 6.1_3 Å, and the effective radius of the hydrogen atom, 0.9_5 Å, as estimated from the interatomic distance between the hydrogen atom of the ligand and the nearest oxygen atom of a tartratoantimonate ion given in the literature.[31] The r_M value for $[Ru(phen)_3]^{2+}$ was assumed to be equal to that for the iron-complex ion.

Table 6. The *best* values of a and K obtained with the help of the theoretical expression[1] for the ion-association constant (25 °C)

Electrolyte	$r_M + r_A$ (Å)	From vpo		From conductivity (recalcd)		
		a (Å)	K (mol^{-1} kg)	a (Å)	K (mol^{-1} l)	data
$MgSO_4$	3.5_3	5.4_6	110	5.4_4	111	[8]
				5.5_8	106	[9]
$CaSO_4$	3.8_7	$4{\cdot}9_2$	134	5.4_2	112	[10]
$MnSO_4$	3.6_8	4.6_4	151	5.1_4	123	[11]
				4.9_5	132	[12]
$[Ru(phen)_3]SO_4$	10.0	11.5_2	40			
$[Fe(phen)_3]SO_4$	10.0			12.3_8	36	[13]

Fuoss's theory[15] of ion association could be used in place of our theory. In that case, the results for $MgSO_4$, $CaSO_4$, and $MnSO_4$ are similar to those given in Table 6, but no value of a would simultaneously satisfy the theory and the experiment for $[Ru(phen)_3]SO_4$ and $[Fe(phen)_3]SO_4$. This disagreement between theory and experiment may substantiate our previous criticism[1] of Fuoss's theory of ion association.

Bjerrum's theory[14] could also be used to determine the values of the ion-association constant and the closest distance of approach of ions, but in a manner different from the above. Since his theory regards a cation and an anion within the critical distance q ($=z^2e^2/2\varepsilon kT$) of each other as forming an ion-pair, the substitution of q for a in the Debye-Hückel expression [Eqs. (4) and (9)] should give a K value consistent with Bjerrum's theory. Such K values are given at the bottoms of Tables 2 to 5, where the values of q (14.3 Å at 25 °C and 13.9 Å at 0 °C) are substituted for a. In Bjerrum's theory, the parameter a characteristic of each electrolyte is the closest distance of approach of the cation and the anion of an ion-pair, and the value can be calculated by the use of a relation between K and a. The values of a thus obtained from the vpo experimental results are 4.6_4 Å for $MgSO_4$, 4.3_6 Å for $CaSO_4$, 4.1_3 Å for $MnSO_4$, and 9.9_0 Å for $[Ru(phen)_3]SO_4$. These a values are smaller than those given in Table 6. Especially, the value, 9.9_0 Å, for $[Ru(phen)_3]SO_4$ is very close to the sum of the crystallographic radii of the cation and the anion, 10.0 Å. This could be taken as an indication of there being no appreciable hydration. However, in view of the fact that the salt is highly soluble in water and crystallizes as a hydrate with more than seven molecules of water, there seem to be water molecules intervening between the ions in aqueous solutions; thus, the a value of 9.9_0 Å is possibly too small. This may be caused by the unreasonable characteristic of Bjerrum's theory that the theoretical ion-association constants decrease rapidly to zero as the value of a approaches the critical distance, 14.3 Å.

The authors wish to thank the Ministry of Education for the financial support granted for this research. Thanks are also due to Nagoya University Computation Center for the use of a FACOM 230-60 computer.

Ion Association of Some 2 : 2 Electrolytes in Water at 25° C. II. Spectrophotometric Studies of the Ion Association of Magnesium, Calcium, Manganese, Copper, and Zinc Sulfates*

Haruhiko YOKOYAMA** and Hideo YAMATERA

Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464

(Received May 14, 1975)

Simple and mixed aqueous solutions of copper, magnesium, calcium, manganese, and zinc sulfates were spectrophotometrically studied in order to obtain the ion-association constants of the divalent metal ions with the sulfate ion. The ion-association constant of copper sulfate was obtained from the measured absorbances of copper sulfate solutions at 250 nm as a function of the closest distance of approach of ions. For the other metal sulfates which show a negligible absorption at 250 nm, absorbances were measured on the mixed solutions with copper sulfate, and the results were analyzed by the use of the results on copper sulfate in order to obtain the ion-association constants. The *best* values of the ion-association constant and the closest distance of approach were determined for each metal sulfate with the help of the theory of ion association. The results were compared with those obtained from the measurements of osmotic coefficients and electric conductivities. The numerical results are summarized in Table 6 of the text.

In previous papers,[1,2] we have developed a theory of ion association and have made use of it in the experimental determinations of the *best* values of ion-association constants and the closest distance of approach of ions. With the help of the theory, consistent and plausible results have been derived from vapor-pressure osmometry and conductivity measurements on 2 : 2 electrolyte solutions. In this connection, it is of interest to see if spectrophotometric studies give results consistent with the previous ones.

The absorption spectra of ion-pairs in the ultraviolet region have often been measured on solutions of metal complex salts such as hexamminecobalt(III) salts, and analyzed to obtain the ion-association constants.[3-6] The ion association of divalent ions has been observed between the Cu^{2+}, Hg^{2+}, $[CoCl(NH_3)_5]^{2+}$, and UO_2^{2+} cations and the SO_4^{2-} ion,[7-13] and between some metal cations such as Mg^{2+} and the $S_2O_3^{2-}$ ion.[14] These are considered to be special cases where spectrophotometry can be directly applied to the determination of the ion-association constant. In most electrolyte solutions, ion-pair formation causes no appreciable change in the absorption. However, even when no absorption change occurs, the ion-association constant can be indirectly determined by means of appropriate indicators.[15] For example, with the pH indicator, 2,4-dinitrophenol, the ion-association constant of $MgSO_4$ in 20% ethanol solutions has been measured by Bale *et al.*[16] This method with the pH indicator has the disadvantage, however, that the complex composition of the solution makes the analysis of the data difficult and introduces considerable uncertainty into the results.

In the present study, an attempt has been made to determine spectrophotometrically the ion-association constants of magnesium, calcium, manganese, and zinc sulfates, with copper sulfate as an indicator. Copper sulfate in aqueous solutions is known to show an intense ultraviolet absorption attributable to the formation of ion-pairs,[7-11] whereas the other four sulfates are nearly transparent in aqueous solutions and no ion-pair formation is detected spectrophotometrically. When copper sulfate is mixed with one of the four sulfates, the ion-association of the latter can be expected to be indirectly observed through the change in absorption due to copper sulfate ion-pairs. Although spectrophotometric studies of the ion association of copper sulfate have been made by several authors,[7-11] they are not sufficient for the purpose of the present investigation. Thus, a re-examination has also been made of the ion association in simple copper sulfate solutions.

Experimental

Materials. The copper perchlorate was prepared by dissolving basic copper carbonate in an aqueous solution containing an equivalent amount of perchloric acid. After the solution had then been concentrated on a water bath, the salt was crystallized with stirring at room temperature and recrystallized twice from its aqueous solution containing a very small amount of perchloric acid. The crystal was obtained as a hexahydrate after having been dried over phosphorus pentaoxide. Its composition was confirmed by the electrolytic analysis of the copper ion. A reagent-grade copper sulfate was recrystallized as a pentahydrate from its aqueous solution containing a very small amount of sulfuric acid; it was then air-dried at room temperature. Its composition was confirmed by the electrolytic analysis of the copper ion and by dehydration at about 220 °C. The magnesium and calcium sulfates used were prepared and analyzed according to the procedure described in the preceding paper.[2] The manganese sulfate used was a reagent-grade hydrate. The manganese concentration in its stock solution was determined by the titration of the manganese ion with EDTA.[17] The zinc sulfate used was a heptahydrate of reagent grade. The zinc concentration in its stock solution was determined by the titration of the zinc ion with EDTA.

Measurements. The absorption measurements were made at 250 nm with a Carl Zeiss PMQ II spectrophotometer equipped with a M4Q III monochromator, using 1-cm quartz

* Presented in part at the 24th Conference on Coordination Chemistry of the Chemical Society of Japan, Kanazawa, October, 1974.

** Present address: Department of Chemistry, Yokohama City University, 4646 Mutsuura-cho, Kanazawa-ku, Yokohama, 236.

cells. The slit width was 0.15 mm, resulting in a spectral-band width of 0.57 nm at 250 nm. The cells were maintained at 25.00±0.05 °C by the circulation of water from a thermostat to the cell holder.

Copper perchlorate solutions of 5.007×10^{-3} and 1.001×10^{-2} M were prepared by the dilution of a stock solution of 5.007×10^{-2} M copper perchlorate containing about 2×10^{-3} M perchloric acid to protect it against hydrolysis. Their absorbances, observed at 250 nm, were 0.0607 and 0.1218 respectively, which gave absorbances per mol l^{-1} of the copper ion of 12.12 and 12.16 respectively. These values are in agreement with each other within the range of experimental error; the average, 12.14, was used as the molar extinction coefficient of the free copper ions.

A stock solution of 1.000×10^{-2} M copper sulfate containing 1.01×10^{-4} M sulfuric acid was diluted with a 1.01×10^{-4} M sulfuric acid solution. Thereby, nine copper sulfate solutions with concentrations from 2×10^{-3} to 10^{-2} M at 10^{-3} M intervals were prepared; their absorbances were then measured.

A stock solution of 1.000×10^{-2} M magnesium sulfate containing 1.01×10^{-4} M sulfuric acid was mixed with the stock solution of copper sulfate, and with 1.01×10^{-4} M sulfuric acid when necessary, to make nine mixed electrolyte solutions. (The compositions of the solutions are shown in Table 3.) Similar mixed electrolyte solutions containing copper sulfate and another divalent metal sulfate were also prepared with calcium, manganese, and zinc sulfates in the same manner as in the case of magnesium sulfate. The absorbances of all the solutions were measured under the condition described above. Simple solutions containing no copper sulfate were also prepared by the dilution of the stock solutions, and their absorbances were measured as the blank values to be subtracted from the absorbances of the mixed electrolyte solutions. The blank values were nearly zero, or less than 0.001. All the solutions were prepared within an error of ±0.1% in concentration, and their transmittances were observed within an error of ±0.05%.

Results and Discussion

Determination of the Ion-Association Constant of Copper Sulfate. The observed absorbances (D) of aqueous copper sulfate solutions of various concentrations (c_M) containing 1.01×10^{-4} M H_2SO_4 are shown in Table 1, together with the absorbances per mol l^{-1} of copper sulfate (D/c_M). The corresponding values are also listed for copper perchlorate solutions containing about 2×10^{-3} M $HClO_4$. The D/c_M values of the copper sulfate solutions are very much greater than those of the copper perchlorate solutions and increase with the increase in the concentration. This phenomenon has usually been attributed to the ion association of the copper ion with the sulfate ion.[7-11] In the following, the absorption data will be analyzed in order to obtain the ion-association constant.

TABLE 1. ABSORBANCES OF AQUEOUS COPPER SULFATE SOLUTIONS CONTAINING 1.01×10^{-4} M H_2SO_4 AND OF AQUEOUS COPPER PERCHLORATE SOLUTIONS CONTAINING ABOUT 2×10^{-3} M $HClO_4$ (250 nm, 1-cm cells, 25.0 °C)

The possible ion-association equilibria between ions in the solution are:

$$M + A \rightleftharpoons MA \quad (1)$$

$$H + A \rightleftharpoons HA \quad (2)$$

where M, A, H, HA, and MA represent Cu^{2+}, SO_4^{2-}, H^+, HSO_4^-, and $Cu^{2+}SO_4^{2-}$ respectively. Since the concentration of the sulfuric acid is as low as 1.01×10^{-4} M, the formation of the $Cu^{2+}HSO_4^-$ ion-pair was ignored. The formations of the $(Cu^{2+})_2SO_4^{2-}$ and $Cu^{2+}(SO_4^{2-})_2$ triple-ions and the $(Cu^{2+}SO_4^{2-})_2$ quadrupole were also ignored. According to a previous work,[2] this approximation is good enough for the present study, where the concentrations of the solutions are lower than 10^{-2} M. The formation constants, K_{MA} and K_{HA}, of $Cu^{2+}SO_4^{2-}$ and HSO_4^- respectively are given by:

$$K_{MA} = \frac{[MA]}{[M][A]y_M y_A} \quad (3)$$

$$K_{HA} = \frac{[HA]y_{HA}}{[H][A]y_H y_A} \quad (4)$$

where y_M, y_H, y_A, and y_{HA} are the activity coefficients of Cu^{2+}, H^+, SO_4^{2-}, and HSO_4^- respectively. The activity coefficient of the $Cu^{2+}SO_4^{2-}$ ion-pair was regarded as unity. The total concentrations of Cu^{2+}, SO_4^{2-}, and H^+, denoted by c_M, c_A, and c_H respectively, are related to the concentrations of the species existing in the solution as follows:

$$\left.\begin{aligned} c_M &= [M] + [MA] \\ c_A &= [A] + [MA] + [HA] \\ c_H &= [H] + [HA] \end{aligned}\right\} \quad (5)$$

The absorption observed at 250 nm can be attributed to the free Cu^{2+} ion and the $Cu^{2+}SO_4^{2-}$ ion-pair. Thus, the absorbance, D, of each solution can be expressed by:

$$\begin{aligned} D &= \varepsilon_M[M] + \varepsilon_{MA}[MA] \\ &= \varepsilon_M c_M + (\varepsilon_{MA}-\varepsilon_M)[MA] \end{aligned} \quad (6)$$

where ε_M and ε_{MA} are the molar extinction coefficients of Cu^{2+} and $Cu^{2+}SO_4^{2-}$ respectively. Using Eqs. (3), (5), and (6), one can derive the relation:

$$P = \frac{1}{\varepsilon_{MA}-\varepsilon_M}Q + \frac{1}{K_{MA}(\varepsilon_{MA}-\varepsilon_M)} \quad (7)$$

where P and Q are variables defined by:

$$\left.\begin{aligned} P &= \frac{(c_A-[HA])y_M y_A}{(D/c_M)-\varepsilon_M} \\ Q &= (c_M+c_A-[MA]-[HA])y_M y_A \end{aligned}\right\} \quad (8)$$

If K_{MA}, ε_M, and ε_{MA} are assumed to be constant under the present experimental conditions, a linear relationship can be expected between P and Q in Eq. (7). The parameters appearing in Eq. (8) were treated as follows.

The molar extinction coefficient of the free ion, ε_M, was assumed to be equal to the absorbance (per cm) per mol l^{-1} of copper perchlorate in dilute solutions. This assumption is justified, at least at 250 nm, since the copper perchlorate solutions at this wavelength obey Beer's law, as is shown in Table 1; however, this does not exclude the possibility that ion-pairs may be formed between copper ions and perchlorate ions. The concentration of the hydrogensulfate ion, [HA], is given by:

$$[HA] = \frac{R_1 - \sqrt{R_1^2 - 4c_H(c_A - [MA])}}{2} \quad (9)$$

where R_1 is a variable defined by:

$$R_1 = c_H + c_A - [MA] + \frac{1}{K_{HA}y_A}$$

These equations were derived from Eqs. (4) and (5) on the assumption that $y_{HA}=y_H$. This assumption is acceptable for the calculation of the P and Q values with Eq. (8), since, at the low acid concentration of $c_H=2.02\times10^{-4}$ M, [HA] is very low compared with c_A. The value of K_{HA} was taken from the literature.[18] The $\log K_{HA}$ value of 1.99 was obtained by many authors by means of various experimental methods. The activity coefficients, y_M and y_A, were expressed by the Debye-Hückel expression:[19]

$$\log y_M = \log y_A = -\frac{4A\sqrt{I}}{1+Ba\sqrt{I}} \quad (10)$$

where a is a parameter representing the closest distance of approach of ions (in Å†), where A and B are constants involving the absolute temperature and the dielectric constant of the solvent ($A=0.5115$ and $B=0.3291$ in aqueous solutions at 25.0 °C), and where I is the ionic strength given by:

$$I = 2(c_M + c_A - 2[MA] - [HA]) + \frac{1}{2}c_H \quad (11)$$

The values of P, Q, and K_{MA} were calculated by the method of successive approximations in the following way. Assuming $[MA]=[HA]=0$ provisionally, the ionic strength and then the activity coefficients were estimated for a given a value. By putting the values of these parameters into Eq. (8), the values of P and Q were calculated for each solution. Assuming a linear relationship between the P and Q values, the coefficient of the first term, $1/(\varepsilon_{MA}-\varepsilon_M)$, and the second term, $1/K_{MA}(\varepsilon_{MA}-\varepsilon_M)$, of the right-hand side of Eq. (7) were evaluated by the method of least squares; the value of K_{MA} was then obtained as the ratio between them. The K_{MA} value thus obtained was used for the calculation of the [MA], [HA], I, y_M, and y_A values by means of Eqs. (3)—(5) and (9)—(11); these values were in turn used for the recalculation of the values of P and Q. Then, by the use of these values, the value of K_{MA} was evaluated again in the same way as above. In order to obtain the final value of K_{MA}, such calculations were repeated several times until the values of $1/(\varepsilon_{MA}-\varepsilon_M)$ and $1/K_{MA}(\varepsilon_{MA}-\varepsilon_M)$ in Eq. (7) became constant within 0.05% of their respective values.

The resulting plot of P *vs.* Q is shown in Fig. 1 for each value of the parameter a. In Table 2, the values of K_{MA} and ε_{MA} are shown for the several a values assumed. Figure 2 gives the plot of $\log K_{MA}$ *vs.* a. For $a=10$ Å, the result in the present work, $K_{MA}=241$ mol^{-1} l, is in essential agreement with that obtained by Davies *et al.*[9] at 240 nm, $K_{MA}=250$ mol^{-1} l,

Table 2 also gives the standard deviation of D in percentage, σ_D (%), defined by:

$$\sigma_D(\%) = \sqrt{\frac{\sum_{i=1}^{n}[100(D_{obsd,i}-D_{calcd,i})/D_{calcd,i}]^2}{n-2}}$$

where $D_{obsd,i}$, and $D_{calcd,i}$, are the observed and calculated absorbances respectively for the i-th copper sul-

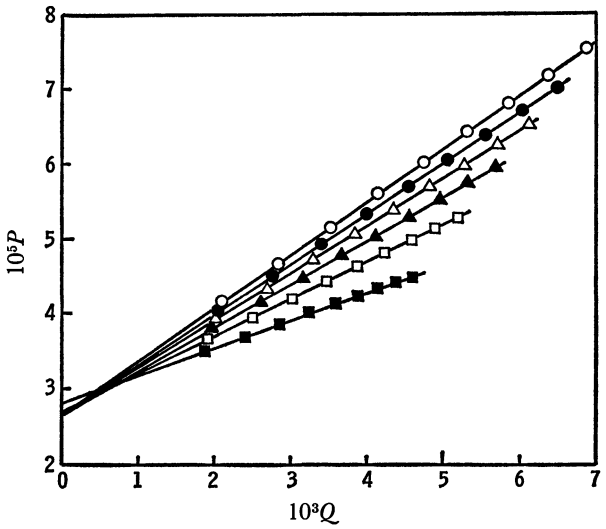

Fig. 1. Plots of P against Q. [For the definitions of P and Q, see Eq. (8).] The assumed a values are 14.3 Å (○), 12.0 Å (●), 10.0 Å (△), 8.0 Å (▲), 6.0 Å (□), and 4.0 Å (■).

fate solution. The value of $D_{calcd,i}$ was calculated by means of Eq. (6), where the ε_{MA} value given in Table 2 was used together with the connected K_{MA} value from which the [MA] value was derived. As is shown in Table 2, the $\sigma_D(\%)$ values for the a values between 4 and 14.3 Å (Bjerrum's critical distance of ion association[20]) are as small as 0.09—0.16%. This shows that the observed absorbances are reproducible within the range of experimental error with each set of the a, K_{MA}, and ε_{MA} values. The value of a which gives the minimum $\sigma_D(\%)$ might be regarded as the *best* value. A minimum was actually found around a=5 Å. However, it is a shallow minimum; therefore, there is some uncertainty as to the *best* value of a.

Determination of the Ion-Association Constants of Magnesium, Calcium, Manganese, and Zinc Sulfates from Measurements of Mixed Electrolyte Solutions. The absorbances of the mixed $CuSO_4$–$MgSO_4$, $CuSO_4$–$CaSO_4$, $CuSO_4$–$MnSO_4$, and $CuSO_4$–$ZnSO_4$ solutions containing 1.01×10^{-4} M of H_2SO_4 are shown in Table 3. A comparison of Table 3 with Table 1 shows that the addition of a second divalent metal sulfate increases the absorbance of the solution. This increase in the absorbance is attributable to the increase in the concentration of the ion-pair, $Cu^{2+}SO_4^{2-}$, caused by the increase in the concentration of the sulfate ion. However, the quantity of free sulfate ions supplied by the second metal sulfate depends on the ion-association constant of the second metal ions with sulfate ions, if the concentrations of the second components are the same. In the following paragraphs, the ion-association constant of the second metal sulfate will be estimated on the basis of an analysis of the absorption data.

We shall discuss the mixed $CuSO_4$–$MgSO_4$ solutions as an example. The third ion-association equilibrium, Eq. (12), must be considered in addition to Eqs. (1) and (2) for copper sulfate solutions:

$$M' + A \rightleftharpoons M'A \tag{12}$$

where M' represents the Mg^{2+} ion and M'A, the $Mg^{2+}SO_4^{2-}$ ion-pair. The formation constant of the ion-pair, $K_{M'A}$, is expressed by:

$$K_{M'A} = \frac{[M'A]}{[M'][A]y_{M'}y_A} \tag{13}$$

Where $y_{M'}$ is the activity coefficient of the free magnesium ion. The activity coefficient of the $Mg^{2+}SO_4^{2-}$ ion-pair is regarded as unity. The total concentrations, c_M, c_H, $c_{M'}$, and c_A, are related to the concentrations of the species existing in the solution as follows:

$$\left.\begin{aligned} c_M &= [M] + [MA] \\ c_H &= [H] + [HA] \\ c_{M'} &= [M'] + [M'A] \\ c_A &= [A] + [MA] + [M'A] + [HA] \end{aligned}\right\} \tag{14}$$

The concentration of the $Cu^{2+}SO_4^{2-}$ ion-pair can be expressed by:

$$[MA] = \frac{D-\varepsilon_M c_M}{\varepsilon_{MA}-\varepsilon_M} \tag{15}$$

which was obtained by rewriting Eq. (6). Equation (6) can also be used for the mixed electrolyte solutions, since magnesium sulfate as well as the other second components give absorbances as small as 0.001 or less in solutions of $c_{M'}=10^{-2}$ M; the small absorbance has been allowed for in obtaining each D value given in Table 3. By combining Eqs. (3) and (14), one obtains:

$$[M'A] = c_A - [MA] - [HA] - \frac{[MA]}{(c_M-[MA])K_{MA}y_My_A} \tag{16}$$

The concentration [HA] is given by:

Table 3. Absorbances of mixed aqueous solutions of divalent metal sulfates containing 1.01×10^{-4} M H_2SO_4 (250 nm, 1-cm cells, 25.0 °C)

$10^3 c_M$ (mol l^{-1})	$10^3 c_{M'}$ (mol l^{-1})	$CuSO_4$-$MgSO_4$ D	$CuSO_4$-$CaSO_4$ D	$CuSO_4$-$MnSO_4$[a] D	$CuSO_4$-$ZnSO_4$ D

a) The concentrations of $MnSO_4$($c_{M'}$) in the $CuSO_4$-$MnSO_4$ solutions were slightly higher than given in the second column. In this case, read 2.044 for 2.000, 4.088 for 4.000, 6.132 for 6.000, and 8.176 for 8.000.

$$[HA] = \frac{R_2 - \sqrt{R_2^2 - 4c_H(c_A - [MA] - [M'A])}}{2} \quad (17)$$

where R_2 is a variable defined by:

$$R_2 = c_H + c_A - [MA] - [M'A] + \frac{1}{K_{HA}y_A}$$

Equation (17) was derived from Eqs. (4) and (14) by assuming $y_{HA}=y_H$ in the same manner as in the case of copper sulfate solutions.

Then, by the use of Eqs. (13)—(17), $K_{M'A}$ can be calculated if the values of K_{HA}, K_{MA}, ε_M, ε_{MA}, y_M, $y_{M'}$, and y_A are known. As has been mentioned above, $\log K_{HA}=1.99$ is given in the literature[18] and the value of ε_M has been experimentally determined to be 12.14 (Table 1). The values of K_{MA} and ε_{MA} have already been obtained as a function of a; they are listed in Table 2. By assuming that both copper and magnesium sulfates have the same a value, the activity coefficients of the free ions, y_M, $y_{M'}$, and y_A, are given by the Debye-Hückel theory[19] as follows:

$$\log y_M = \log y_{M'} = \log y_A = -\frac{4A\sqrt{I}}{1+Ba\sqrt{I}} \quad (18)$$

where the ionic strength, I, is given by:

$$I = 2(c_M + c_{M'} + c_A - 2[MA] - 2[M'A] - [HA]) + \frac{1}{2}c_H$$

The calculation of $K_{M'A}$ was done as follows. Assuming $[M'A]=[HA]=0$ provisionally, the ionic strength, I, and then the activity coefficients, y_M and y_A, were evaluated for a given a value. [MA] was calculated by the use of Eq. (15) with the corresponding ε_{MA} value for the given a value. By putting these values into the right-hand side of Eq. (16), the value of [M'A] was obtained, and then the value of [HA] was calculated by the use of Eq. (17). The values of [M'A] and [HA] thus obtained were used for the recalculation of I, y_M, and y_A, after which [M'A] and [HA] were re-evaluated in the same way. Such a procedure was repeated several times until both the [M'A] and [HA] values became constant within 0.05% of their respective values. The values of [M'A], [HA], and y_A thus obtained were then used to evaluate the ion-association constant, $K_{M'A}$, by means of Eqs. (13), (14), and (18). The values of $K_{M'A}$ were thus obtained for the solutions of each different composition, after which the $K_{M'A}$ values were averaged. In Table 4, the averaged $K_{M'A}$ value of $MgSO_4$ as well as those of the other sulfates are shown for the several a values assumed.

Table 4. $K_{M'A}$ values of some 2 : 2 electrolytes derived from the spectrophotometric measurements on the mixed electrolyte solutions at 25.0 °C (with several a values assumed)

a (Å)	$MgSO_4$ $K_{M'A}$ (mol^{-1} l)	$CaSO_4$ $K_{M'A}$ (mol^{-1} l)	$MnSO_4$ $K_{M'A}$ (mol^{-1} l)	$ZnSO_4$ $K_{M'A}$ (mol^{-1} l)
4.0	44±15	60±17	62±16	66±18
5.0	77±10	93±14	95±12	99±14
6.0	101±7	117±14	119±11	123±13
7.0	120±6	136±14	139±11	142±12
8.0	135±5	151±14	154±11	157±12
10.0	157±5	173±14	176±11	180±12
12.0	172±5	188±14	191±11	195±12
14.3	184±6	200±14	203±11	207±13

A comparison of Table 4 with Table 2 shows that the ion-association constants ($K_{M'A}$) of $MgSO_4$, $CaSO_4$, $MnSO_4$, and $ZnSO_4$ are considerably smaller than that of $CuSO_4$ (K_{MA}) at the same a value, and that, as the assumed a value increases, $K_{M'A}$ increases in parallel with K_{MA}, with the difference kept almost constant; *i.e.*, $K_{MA}-K_{M'A}=84$—86 for $MgSO_4$, 68—70 for $CaSO_4$, 65—68 for $MnSO_4$, and 61—64 for $ZnSO_4$.

These results were derived from the data on the mixed aqueous solutions of copper sulfate and a second metal sulfate in question, assuming that the a value for the latter was the same as that for copper sulfate. Therefore, the results obtained for the second metal sulfates (Table 4) may be different from those which would be obtained from the experiments on single electrolyte solutions. This problem will be examined below.

The activity coefficient of each ionic species is expressed by:

$$\log y_i = -\frac{4A\sqrt{I}}{1+Ba_i\sqrt{I}} \quad (19)$$

where the subscript i stands for the ionic species, whether M, M', or A. Rigorously speaking, the condition $a_i=a_j$ is required in order for Eq. (19) and a similar equation for j-ions to satisfy the thermodynamical relation:[21]

$$\frac{\partial(\log y_i)}{\partial c_j} = \frac{\partial(\log y_j)}{\partial c_i}$$

As an approximation, however, Eq. (19) will be used without the condition that $a_i=a_j$.

The main ionic species existing in the mixed $CuSO_4$–$MgSO_4$ solutions are Cu^{2+}, Mg^{2+}, and SO_4^{2-}. Since the sulfate ion is the predominant anionic species, the closest distance of approach of the copper ion in the mixed electrolyte solution, a_M, can be reasonably approximated by the a value in single copper sulfate solutions. The same argument applies to $a_{M'}$ for the magnesium ion. Considering the probability of a sulfate ion colliding with each of the metal cations, we assumed the equation:

$$a_A = \frac{a_M c_M + a_{M'} c_{M'}}{c_M + c_{M'}}$$

Then the activity coefficient of each ion was calculated by the use of Eq. (19). The K_{MA} and ε_{MA} values were so chosen from Table 2 as to correspond to the assumed a_M value. Then the experimental data was analyzed in the way described above, except that different a values and, accordingly, different activity coefficients were used for different ions instead of a common a and a common activity coefficient. The values of $K_{M'A}$ were thus obtained for various combinations of the values of a_M and $a_{M'}$.

In Fig. 3, the values of $K_{M'A}$ obtained for $MgSO_4$ are plotted against the values of $a_{M'}$, with several fixed a_M values. This figure also shows, for comparison, the plot of the results given in Table 4, which was

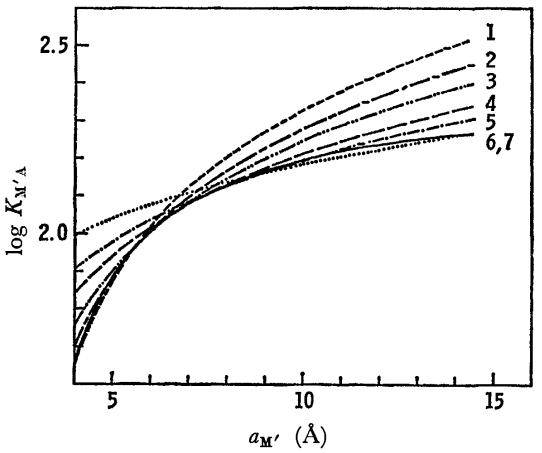

Fig. 3. log $K_{M'A}$ for $MgSO_4$ as a function of $a_{M'}$ with the assumption of several a_M values: a_M=4.0 Å [curve 1 (----)], 5.0 Å [curve 2 (— — —)], 6.0 Å [curve 3 (—··—)], 8.0 Å [curve 4 (— —)], 10.0 Å [curve 5 (—·—)], and 14.3 Å [curve 6 (·····)]. Curve 7 (——) is obtained with the assumption of $a_M=a_{M'}$ [Eq. (18)].

obtained above with the assumption that $a_M=a_{M'}$ ($=a_A$) [Eq. (18)]. The values of $K_{M'A}$ obtained with and without this assumption [Eq. (18)] are close to each other when the value of $a_{M'}$ is not very different from the value of a_M; for example, $a_{M'}$=3—7 Å for a_M=5 Å and $a_{M'}$=6.5—12 Å for a_M=10 Å. This condition is probably satisfied in view of the fact that the crystallographic radius of the magnesium ion is only slightly different from that of the copper ion (see Table 6). Thus, the $K_{M'A}$ values given in Table 4 for the special case of $a_M=a_{M'}$ approximate the $K_{M'A}$ values in the general case without the assumption that $a_M=a_{M'}$, if one reads $a_{M'}$ for a. In other words, the results obtained for $MgSO_4$ from experiments on the mixed electrolyte solutions with the assumption that $a_M=a_{M'}$ probably represent the results which would be obtained from experiments on single magnesium sulfate solutions. The same argument also applies to the cases of the other mixed electrolyte solutions investigated.

Comparison with the Vapor-Pressure Osmometry and the Conductivity Method. In the preceding paper,[2] the ion association of $MgSO_4$, $CaSO_4$, and $MnSO_4$ in aqueous solutions was studied with a vapor-pressure osmometer, and the ion-association constants were obtained. The ion-association constants of these electrolytes were also obtained by reanalyzing the literature values of the conductivity[22-26] by means of Fuoss-Hsia's equation[27] expanded by Fernández-Prini.[28] In connection with the present spectrophotometric studies, the conductivity data on aqueous $CuSO_4$ and $ZnSO_4$ solutions measured by Owen and Gurry[29] were reanalyzed in the same manner as in the previous work, and the ion-association constants were evaluated with various a values assumed. The results are shown in Table 5; the log K_{MA} for $CuSO_4$ is plotted against a in Fig. 2. In the range of a=3.0—14.3 Å, the ion-association constant of $CuSO_4$ derived from the conductivity data is not very different from that determined

TABLE 5. VALUES OF THE ION-ASSOCIATION CONSTANT K AND THE LIMITING EQUIVALENT CONDUCTIVITY Λ_0 DETERMINED BY THE REANALYSIS OF THE CONDUCTIVITY DATA[29] AT 25.0 °C WITH FUOSS-HSIA'S EQUATION[27,28] (with several a values assumed)

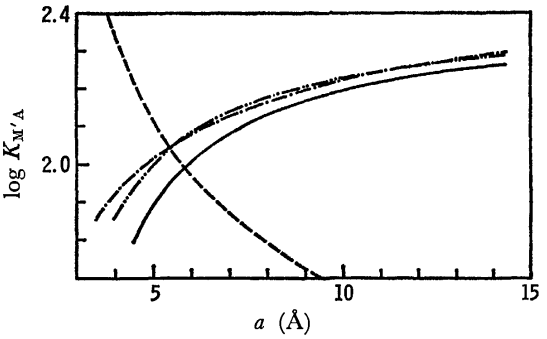

Fig. 4. log $K_{M'A}$ for $MgSO_4$ as a function of a. (——): From spectrophotometry. (—·—): From conductivity measurements (recalculation of the data due to Dunsmore and James[22]). (—··—): From vapor-pressure osmometry.[2] (— — —): Theoretical curve according to Eq. (20).

by the spectrophotometry (Table 2).

Figure 4 gives the plot of log $K_{M'A}$ *vs.* a for $MgSO_4$ as an example of the results obtained from the spectrophotometric studies of the mixed electrolyte solutions, together with those previously obtained from the vapor-pressure osmometric and conductivity studies of the single electrolyte solutions.[2] The spectrophotometric method gives slightly smaller ion-association constants than those given by the other methods.

In Fig. 5, the log K values (the subscripts, MA and M'A, are omitted) are plotted against the reciprocal of the crystallographic radii of the cations, with the assumption that a=6 Å. The log K values increase in the order: $MgSO_4<CaSO_4<MnSO_4<ZnSO_4<CuSO_4$. This order is the same as that obtained by the other methods. The same tendency was also obtained with the assumption that a=14.3 Å. Such a tendency in the magnitude of the ion-association constants seems to reflect some properties of the metal ions. In this connection, further discussions will be made in the next section.

Estimation of the Best *Value of a with the Help of the Theory of Ion Association.* In a previous work,[1]

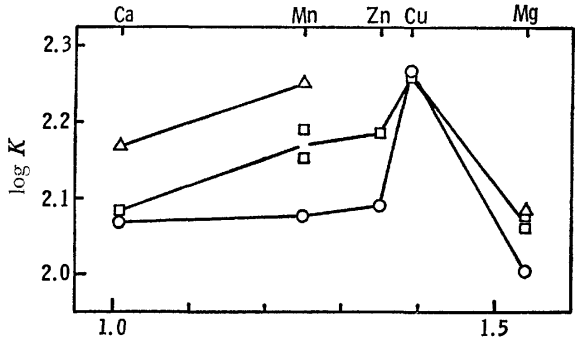

Fig. 5. log K values for divalent metal sulfates as a function of the reciprocal of crystallographic radius of the metal ion. (a=6 Å is assumed.) ○: From spectrophotometry. △: From vapor-pressure osmometry.[2] □: From conductivity measurements [recalculation of the data due to Dunsmore and James[22] ($MgSO_4$, upper), Katayama[23] ($MgSO_4$, lower), Inada *et al.*[24] ($CaSO_4$), Hallada and Atkinson[25] ($MnSO_4$, lower), Petrucci *et al.*[26] ($MnSO_4$, upper), and Owen and Gurry[29] ($CuSO_4$ and $ZnSO_4$)].

we derived an expression for the excess chemical potential of a symmetrical electrolyte in very dilute solutions. This expression has, in addition to the Debye-Hückel term, a supplementary term resulting from a more proper account of the energy of the interactions of ions existing near each other. Assuming that the contribution of ion association to the chemical potential of the electrolyte corresponds to this supplementary term, we obtained the expression for the ion-association constant:

$$K = \frac{8\pi Na^3}{1000} \sum_{n=1}^{\infty} \frac{b^{2n+2}}{(2n+2)!(2n-1)} \qquad (20)$$

where b is Bjerrum's parameter defined by $b=z^2e^2/\varepsilon kTa$. ε is the dielectric constant of the solvent, and ze is the absolute value of the charge of the ions. The log K *vs.* a curves obtained with the theoretical equation (20) are shown in Figs. 2 and 4 (broken curves) and there compared with the experimental curves. The point where the experimental curve cross the theoretical curve gives experimental a and K values consistent with the theory of ion association.[1]

The values of a and K for each electrolyte were obtained in this way; they are shown in Table 6. The magnitude of the ion-association constant increased with the decrease in a and with the decrease in the crystallographic radii of the metal ions except for the case of the magnesium ion. This general trend can be expected from electrostatic considerations. The small value of K and the large value of a for magnesium sulfate, in spite of the small crystallographic radii of the magnesium ion, can be attributed to the strong hydration of the magnesium ion.

The results given in Table 6 show that the differences between the a value of copper sulfate and those of the other electrolytes are much less than 2 Å. This satisfies the above-mentioned condition for the validity of the present treatment in deriving ion-association constants from the spectrophotometric data on the mixed electrolyte solutions.

The authors wish to thank the Ministry of Education for the financial support granted for this research. Thanks are also due to Nagoya University Computation Center for the use of a FACOM 230–60 computer.

The Formation and Collapse of Mixed Monolayers of 1-Hexadecanol and 1-Octadecanol with Interest in Evaporation Control of Water by Monolayers[1)]

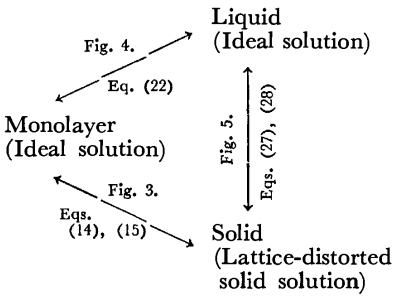
(Received April 28, 1975)

Collapse pressure, equilibrium spreading pressure, and melting points of binary mixtures of hexadecanol and octadecanol were measured in order to study the phase equilibrium among a monolayer, a solid, and a liquid and to apply the result to evaporation control of water by monolayers. Collapse pressure and equilibrium spreading pressure of solid mixtures have a maximum at a given composition, while the equilibrium spreading pressure of a liquid mixture has not a maximum. Melting points have a minimum at a given composition. From thermodynamic analysis of these phase equilibriums, it was concluded that the mixed monolayer and liquid mixture were ideal solutions, while the solid mixture was a lattice-distorted solid solution. That is, when the two components of different molecular volumes form a solid solution, the solid solution has high energy due to the distortion of the crystal lattice and consequently, it becomes easier to spread and the mixed monolayer becomes more stable against collapse. From these results, the relations between the composition of solid solution and the surface pressure, composition, and specific evaporation resistance of the mixed monolayer in equilibrium with the solid solution, were obtained.

It is said that a dusting of powdered solids of the mixed hexadecanol and octadecanol appears to meet best the purpose of the evaporation control of water by monolayers.[2)] Therefore, the effectiveness of lowering the evaporation rate by these mixed monolayers[2,3)] and the temperature dependence of the equilibrium spreading pressure[4)] have been studied in detail. But the relation between the composition of the solid mixture and the evaporation resistance of the monolayer which is in equilibrium with the solid mixture has not yet been found. The authors have shown how to get the relation between the compositions of a mixed monolayer and a bulk mixture in equilibrium with each other.[5,6)] By applying this method to the binary system of hexadecanol and octadecanol, the relation between the composition of the solid mixture and the specific evaporation resistance of the mixed monolayer in equilibrium with the solid mixture was obtained.

Theoretical

Phase equilibriums among a monolayer, a solid, and a liquid of the hexadecanol-octadecanol system are summarized in Scheme 1. The following notations are used hereafter: x is mole fraction, V is molal volume, μ is chemical potential, F is surface pressure, A is molecular area, $\bar{A}$ is partial molecular area, ΔH_v is molal heat of evaporation, ΔH_m is molal heat of fusion, and n is mole number; the subscripts 1 and 2 indicate the components 1 and 2, the subscripts e and m mean equilibrium and melting, the superscripts m, s, and l mean monolayer, solid, and liquid, and the superscript o means pure substance or standard state. R, T, and N are gas constant, absolute temperature, and Avogadro's number, respectively.



Scheme 1. Summarized relationship among three phases of a monolayer, a solid, and a liquid for the binary mixture of hexadecanol and octadecanol.

Equilibrium between a Monolayer and a Solid. It is known that the distortion energy of a crystal lattice due to the differences of size and shape of molecules contributes greatly to the heat of mixing of solids and, consequently, that it often makes the formation of a solid solution difficult.[7)] According to Scott,[7,8)] this distortion energy, ΔE_D, is given by the following equation:

$$\Delta E_D = \frac{2\delta_1\delta_2(V_1V_2)^{1/2}(V_1-V_2)^2}{x_1^sV_1^2+x_2^sV_2^2}x_1^sx_2^s, \quad (1)$$

where δ is the solubility parameter:

$$\delta = \left(\frac{\Delta H_v - RT}{V}\right)^{1/2}. \quad (2)$$

In order to simplify this equation, ω is defined as

$$\omega = 2\delta_1\delta_2(V_1V_2)^{1/2}(V_1-V_2)^2. \quad (3)$$

Assuming that the entropy of mixing ΔS and the enthalpy of mixing ΔH may be written as

$$\Delta S = -R(x_1^s \ln x_1^s + x_2^s \ln x_2^s) \quad (4)$$

and

$$\Delta H = \Delta E_D, \quad (5)$$

and from the definitions of Gibbs free energy G and chemical potential μ:

$$\Delta G = \Delta H - T\Delta S \quad (6)$$

and

$$\mu_1^s - \mu_1^{os} = \left[\frac{\partial(n_1+n_2)\Delta G}{\partial n_1}\right]_{T,P,n_2}, \quad (7)$$

we obtain μ_1^s for component 1:

$$\mu_1^s = \mu_1^{os} + RT\ln x_1^s + \frac{\omega(x_2^sV_2)^2}{(x_1^sV_1^2+x_2^sV_2^2)^2}. \quad (8)$$

Similarly, we obtain μ_2^s for component 2:

$$\mu_2^s = \mu_2^{0s} + RT\ln x_2^s + \frac{\omega(x_1^s V_1)^2}{(x_1^s V_1^2 + x_2^s V_2^2)^2}, \quad (9)$$

where μ^{os} is the chemical potential in the pure solid. Assuming that a mixed monolayer is considered as an ideal solution, in the equilibrium state of a monolayer and a solid, the following equations

$$\mu_1^{0s} + RT\ln x_1^s + \frac{\omega(x_2^s V_2)^2}{(x_1^s V_1^2 + x_2^s V_2^2)^2} = \mu_1^{0m} + RT\ln x_1^m + N\bar{F}A_1 \quad (10)$$

and

$$\mu_2^{0s} + RT\ln x_2^s + \frac{\omega(x_1^s V_1)^2}{(x_1^s V_1^2 + x_2^s V_2^2)^2} = \mu_2^{0m} + RT\ln x_2^m + N\bar{F}A_2 \quad (11)$$

can be established,[5,6] where μ^{om} is the standard chemical potential in the monolayer. For the one-component systems,

$$\mu_1^{0s} = \mu_1^{0m} + NF_{1e}A_{1e} \quad (12)$$

and

$$\mu_2^{0s} = \mu_2^{0m} + NF_{2e}A_{2e} \quad (13)$$

are derived from Eqs. (10) and (11). Substituting Eqs. (12) and (13) for Eqs. (10) and (11), we obtain the following equations:

$$RT\ln x_1^s + \frac{\omega(x_2^s V_2)^2}{(x_1^s V_1^2 + x_2^s V_2^2)^2} + NF_{1e}A_{1e} = RT\ln x_1^m + N\bar{F}A_1 \quad (14)$$

and

$$RT\ln x_2^s + \frac{\omega(x_1^s V_1)^2}{(x_1^s V_1^2 + x_2^s V_2^2)^2} + NF_{2e}A_{2e} = RT\ln x_2^m + N\bar{F}A_2. \quad (15)$$

Equilibrium between a Monolayer and a Liquid. Assuming that both the monolayer and the liquid are ideal solutions, in equilibrium with each other, the following equations

$$\mu_1^{01} + RT\ln x_1^l = \mu_1^{0m} + RT\ln x_1^m + N\bar{F}A_1 \quad (16)$$

and

$$\mu_2^{01} + RT\ln x_2^l = \mu_2^{0m} + RT\ln x_2^m + N\bar{F}A_2 \quad (17)$$

can be established.[5,6] For the one-component systems,

$$\mu_1^{01} = \mu_1^{0m} + NF_{1e}A_{1e} \quad (18)$$

and

$$\mu_2^{01} = \mu_2^{0m} + NF_{2e}A_{2e} \quad (19)$$

are derived from Eqs. (16) and (17). Substituting Eqs. (18) and (19) for Eqs. (16) and (17), we obtain the following equations:

$$RT\ln x_1^l + NF_{1e}A_{1e} = RT\ln x_1^m + N\bar{F}A_1 \quad (20)$$

and

$$RT\ln x_2^l + NF_{2e}A_{2e} = RT\ln x_2^m + N\bar{F}A_2. \quad (21)$$

Substituting Eqs. (20) and (21) for the following equation:

$$x_1^l + x_2^l = 1,$$

we obtain Eq. (22):

$$x_1^m e^{(F\bar{A}_1 - F_{1e}A_{1e}/kT)} + x_2^m e^{(F\bar{A}_2 - F_{2e}A_{2e}/kT)} = 1. \quad (22)$$

Equilibrium between a Solid and a Liquid. In the equilibrium state of a solid and a liquid, from Eqs. (10), (11), (16), and (17), we obtain Eqs. (23) and (24):

$$\mu_1^{0s} + RT\ln x_1^s + \frac{\omega(x_2^s V_2)^2}{(x_1^s V_1^2 + x_2^s V_2^2)^2} = \mu_1^{01} + RT\ln x_1^l \quad (23)$$

and

$$\mu_2^{0s} + RT\ln x_2^s + \frac{\omega(x_1^s V_1)^2}{(x_1^s V_1^2 + x_2^s V_2^2)^2} = \mu_2^{01} + RT\ln x_2^l. \quad (24)$$

Assuming that ΔC_p is independent of temperature, the following equations

$$\mu_1^{01} - \mu_1^{0s} = \Delta H_{1m}\left(1 - \frac{T}{T_{1m}}\right) - \Delta C_{1p}(T_{1m} - T) + T\Delta C_{1p}\ln\frac{T_{1m}}{T} \quad (25)$$

and

$$\mu_2^{01} - \mu_2^{0s} = \Delta H_{2m}\left(1 - \frac{T}{T_{2m}}\right) - \Delta C_{2p}(T_{2m} - T) + T\Delta C_{2p}\ln\frac{T_{2m}}{T} \quad (26)$$

are derived for the one-component systems.[9] Substituting Eqs. (25) and (26) for Eqs. (23) and (24), we obtain Eqs. (27) and (28):

$$\Delta H_{1m}\left(1 - \frac{T}{T_{1m}}\right) - \Delta C_{1p}(T_{1m} - T) + T\Delta C_{1p}\ln\frac{T_{1m}}{T} + RT\ln x_1^l = RT\ln x_1^s + \frac{\omega(x_2^s V_2)^2}{(x_1^s V_1^2 + x_2^s V_2^2)^2} \quad (27)$$

and

$$\Delta H_{2m}\left(1 - \frac{T}{T_{2m}}\right) - \Delta C_{2p}(T_{2m} - T) + T\Delta C_{2p}\ln\frac{T_{2m}}{T} + RT\ln x_2^l = RT\ln x_2^s + \frac{\omega(x_1^s V_1)^2}{(x_1^s V_1^2 + x_2^s V_2^2)^2}, \quad (28)$$

where ΔC_p is the differences in the molal heat capacities between the liquid and the solid.

Experimental

Materials. The 1-hexadecanol and 1-octadecanol used are supplied by Nihon Yushi Company. The composition of hexadecanol (abbreviated as $C_{16}OH$) was $C_{18}OH$ 0.6%, $C_{16}OH$ 99.0%, and $C_{14}OH$ 0.4% and that of octadecanol was $C_{20}OH$ 1.0%, $C_{18}OH$ 98.7%, and $C_{16}OH$ 0.3%. The melting points of hexadecanol and octadecanol were 50.0—50.5 °C (literature value[10,11] 49.3 °C) and 58.5—59.0 °C (literature value[10] 58.0 °C), respectively. The solid mixture was prepared by the methods of fusion and solution (*n*-hexane as solvent; details have been reported previously[5,6]) and used later than one month after the preparation. The water and *n*-hexane of analytical grade used were distilled twice.

Measurement of Surface Pressure. The surface pressure was measured at 20±0.1 °C using a surface trough equipped with a vertical-type surface balance described previously.[5,6] The pressure-area curve was drawn by measuring the surface pressure of the monolayer which had been compressed at nearly constant speed independently of the area and the composition of mixed monolayers. The equilibrium spreading pressure was determined as an unvaried surface pressure exerted after the solid mixture (prepared by the solution method) had been placed onto the aqueous surface. Details

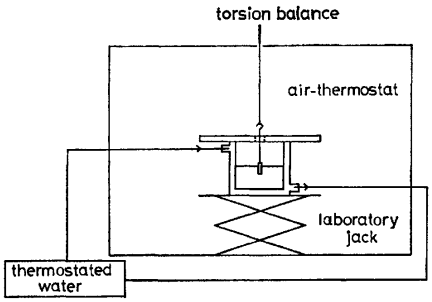


Fig. 1. The apparatus for measuring surface pressure at 65 °C.

have been described previously.[5,6]

The equilibrium spreading pressure at 65±0.2 °C was measured by means of the same surface balance in a thermostated glass cell (Fig. 1).

Measurement of Melting Points. The initial and final melting points of solid mixtures (prepared by the methods of solution and fusion) were measured with a Yanagimoto-melting point apparatus, SR-50, equipped with a polarization microscope.

Results

Collapse Pressure and Equilibrium Spreading Pressure. Figure 2 shows the pressure-area curve of a hexadecanol monolayer at 20 °C. The collapse pressure, F_c, was determined as the surface pressure unvaring with the area after the monolayer began to collapse. The collapse pressures of mixed monolayers of hexadecanol and octadecanol were likewise determined. The open circles in Fig. 3 show the relation between the collapse pressure and the mole fraction of hexadecanol in mixed monolayer, x_{16}^m. The closed circles in Fig. 3 show the relation between the equilibrium spreading pressure, F_e, and the mole fraction of hexadecanol in the solid mixture, x_{16}^s. The values of F_c and F_e have a maximum, at which F_c and F_e are 44.0 and x_{16}^m and x_{16}^s are 0.56 dyn/cm. The collapse pressure of hexadecanol, F_{16c}, was equal to the

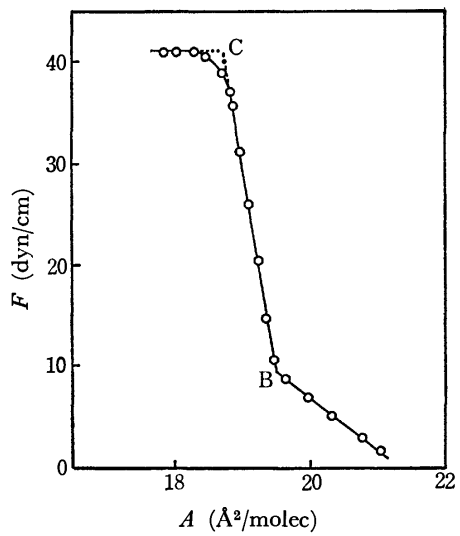

Fig. 2. The pressure-area curve of a hexadecanol monolayer at 20 °C.

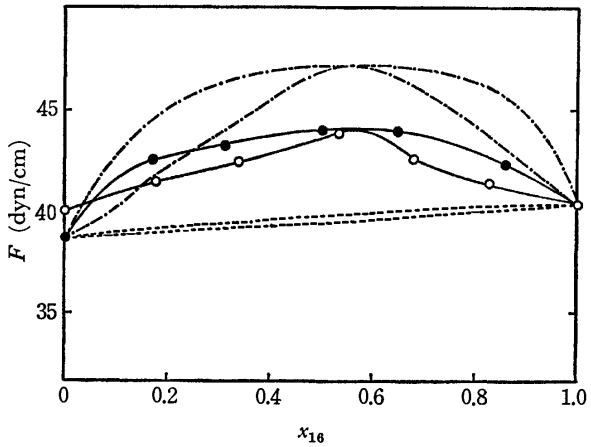

Fig. 3. Equilibrium spreading pressure and collapse pressure for the binary mixture of hexadecanol and octadecanol at 20 °C.
●: $F_e-x_{16}^s$, ○: $F_c-x_{16}^m$. —·— Curve calculated from the Eqs. (14) and (15). ---- Curve calculated from the Eqs. (32) and (33).

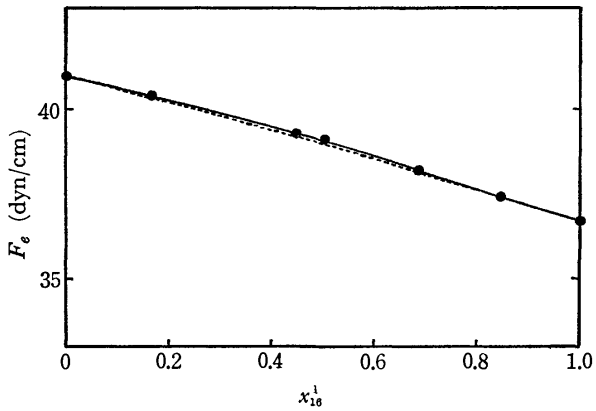

Fig. 4. Equilibrium spreading pressure for the binary system of hexadecanol and octadecanol at 65 °C.
●: $F_e-x_{16}^l$. ---- Curve calculated from the Eq. (22).

equilibrium spreading pressure, F_{16e}, while the collapse pressure of octadecanol, F_{18c}, was higher than the equilibrium spreading pressure, F_{18e}. This means that the octadecanol monolayer tends to be over-compressed. Therefore, it is suspected that the collapse pressure of octadecanol-rich mixed monolayer is also higher than the equilibrium value.

Since the value of the equilibrium spreading pressure varies greatly near the melting point,[4,11] the equilibrium spreading pressure of liquid was measured at 65 °C somewhat higher than the melting points of the mixtures. The closed circles in Fig. 4 show the relation between the equilibrium spreading pressure at 65 °C and the mole fraction of hexadecanol in the liquid mixture, x_{16}^l. In this case, it was found that the equilibrium spreading pressure did not have a maximum. The measurement of the collapse pressure at 65 °C was very hard because of the dissolution of the monolayers and the evaporation of the underlying water.

Phase Diagram of Solid-Liquid Equilibrium. The open and closed circles in Fig. 5 are initial and final

melting points of the solid mixtures, respectively. It was found that mixtures of hexadecanol and octadecanol form a complete series of solid solutions and the melting points have a minimum near $x_{16}=0.84$.

Discussion

Phase Equilibriums among a Monolayer, a Solid, and a Liquid. Equilibrium between a Monolayer and a Solid: The numerical values of ΔH_v, V_1/V_2, F_e, A_e, and $\overline{A}$ are necessary for calculating x^m and x^s at a given surface pressure from Eqs. (14) and (15). From Figs. 2 and 3, we obtain $F_{16e}=40.8$ dyn/cm, $F_{18e}=38.7$ dyn/cm, $A_{16e}=18.70$ Å^2/molec, and $A_{18e}=18.76$ Å^2/molec. $\overline{A}$ was assumed to be equal to the molecular area, A, calculated from the state equation of the solid film using Fig. 2 (straight line BC):

$$A = -0.0265F + 19.78 \quad (\text{Å}^2/\text{molec}). \tag{29}$$

ΔH_v was calculated from the experimental results of Davies and Kybett:[12]

$$\Delta H_{16v} = 47.6 - 0.0642T \quad (\text{kcal/mol}) \tag{30}$$

and

$$\Delta H_{18v} = 52.8 - 0.0716T \quad (\text{kcal/mol}) \tag{31}$$

with $T=293.15$ K. For the ratio of molar volumes, V_{18}/V_{16}, 1.118, which is the value of supercooled liquid at 20 °C,[10] was used.

Substituting these numerical values and solving the simultaneous equation of Eqs. (14) and (15) numerically, we obtain x_{16}^m and x_{16}^s at a given surface pressure. These calculated results are shown by the chained lines in Fig. 3. In addition, assuming that the solid solution is ideal *viz.*, $\omega=0$, we obtain from Eqs. (14) and (15) the following equations:

$$x_1^m e^{(F\overline{A}_1-F_{1e}A_{1e})/kT} + x_2^m e^{(F\overline{A}_2-F_{2e}A_{2e})/kT} = 1 \tag{32}$$

and

$$x_1^s = x_1^m e^{(F\overline{A}_1-F_{1e}A_{1e})/kT}. \tag{33}$$

We can calculate x_{16}^m and x_{16}^s at a given surface pressure from Eqs. (32) and (33). These calculated results are shown by the dotted lines in Fig. 3. The values calculated as an ideal solid solution are very different from the experimental values, while the values calculated as a lattice-distorted solid solution explain the features of the experimental values well. It is, however, found that ΔE_D of Eq. (1) is slightly too large.

Equilibrium between a Monolayer and a Liquid: From the experimental results of Fig. 4, we obtain $F_{16e}=36.7$ dyn/cm and $F_{18e}=41.0$ dyn/cm. The values of A_{16e}, A_{18e}, $\overline{A}_{16}$, and $\overline{A}_{18}$ at 65 °C are set equal to 24.8 Å^2/molec, the value of which is extrapolated from the data of Boyd and Schubert.[11] Substituting these values in Eqs. (22) and (20), we can calculate x_{16}^m and x_{16}^l at a given surface pressure. This result is shown by the dotted line in Fig. 4 and is in close agreement with the experimental values.

Equilibrium between a Solid and a Liquid: T_{16m} and T_{18m} are 323.20 K and 331.70 K (our values). According to Davies,[12]

$$\Delta H_{16m} = 3.6 + 0.0316T \quad (\text{kcal/mol}),$$

$$\Delta H_{18m} = 5.7 + 0.0362T \quad (\text{kcal/mol}),$$

$$\Delta C_{16p} = 0.0316 \quad (\text{kcal/mol}\cdot\text{deg}),$$

and

$$\Delta C_{18p} = 0.0362 \quad (\text{kcal/mol}\cdot\text{deg}).$$

Substituting these values for Eqs. (27) and (28), we can solve these equations numerically as a simultaneous equation. These results are shown by the chained lines in Fig. 5. Moreover, the values which are calculated from Eqs. (27) and (28) with $\omega=0$, *viz.*, as ideal solid solution, are also shown by the dotted lines in Fig. 5. The experimental values are different from the dotted lines, while they have the same tendency as the chained lines. It is, however, found that ΔE_D of Eq. (1) is slightly too large.

From the above thermodynamic treatment of phase equilibriums among a monolayer, a solid, and a liquid for the binary system of hexadecanol and octadecanol, it is concluded that a monolayer and a liquid are ideal solutions and a solid is a lattice-distorted solution, as is shown in Scheme 1. In other words, when the two components consisting of different molecular volumes form a solid solutions, the solid solution has a high energy due to the distortion of the crystal lattice; consequently, it becomes easier to spread and easier to melt and the mixed monolayer becomes more stable against collapse. These are found from the comparison of the solid lines with the dotted lines in Figs. 3 and 5.

Application to Evaporation Control of Water by Monolayers. In view of the effectiveness of lowering evaporation rate, spreading rate, and economic reasons, it is said that dusting of powdered solids of the mixed hexadecanol and octadecanol appears to meet best the purpose of evaporation control of water by monolayers.[2]

If a horizontal line is drawn at a given surface pressure in Fig. 3, the intersections of this line with the curve of the equilibrium spreading pressure (drawn through closed circles) and with the curve of the collapse pressure (drawn through open circles) give the

mole fractions of hexadecanol in the solid solution and the mixed monolayer, respectively. Therefore, if the composition of the solid solution is given, the equilibrium spreading pressure and the composition of the mixed monolayer in equilibrium are determined.

The specific evaporation resistance of the mixed monolayer, representing the effectiveness of lowering evaporation rate, can be calculated as a function of the surface pressure and the composition of mixed monolayer from the following equations:[2,3]

$$\ln r = \frac{FA^{\ddagger}}{kT} + \frac{mE^{\ddagger}_{CH_2}}{RT} + \text{constant} \qquad (34)$$

and

$$\ln r = x_1^m \ln r_1 + x_2^m \ln r_2 . \qquad (35)$$

Figure 6 shows the relation between the specific resistance and the mole fraction of hexadecanol in solid solution calculated from the data of Fig. 3, using

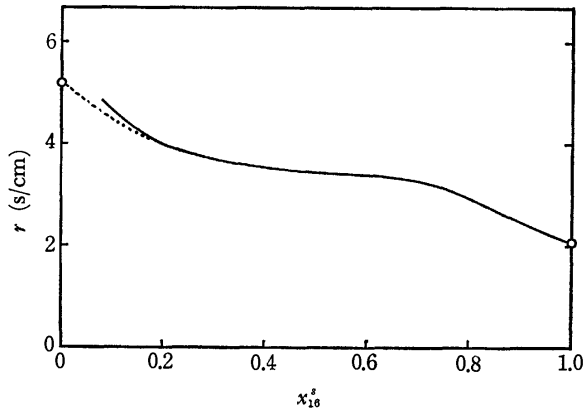

Fig. 6. The relation between the specific evaporation resistance and the mole fraction of hexadecanol in solid solution which is in equilibrium with the mixed monolayer of hexadecanol and octadecanol.

Eqs. (34) and (35). The mixed monolayer tends to be slightly overcompressed in the region where the mole fraction of octadecanol is large. It seems likely that the dotted line through the open circles represents the relation between r and x_{16}^s at equilibrium. As the result, it may be concluded that the lowering of the evaporation rate of water is expected to be more effective when a solid mixture contains more octadecanol. It is also seen from Fig. 6 that the effect remains almost unchanged when the solid mixture is varied over the compositions between 0.3 and 0.7.

The Raman Spectra and the Phase Transition of 1,2-Dibromoethane

Jiro HIRAISHI and Takako SHINODA

National Chemical Laboratory for Industry, Honmachi, Shibuya-ku, Tokyo 151

(Received May 13, 1975)

The lattice vibrations of 1,2-$C_2H_4Br_2$ and 1,2-$C_2D_4Br_2$ were measured by means of Raman spectroscopy. The temperature dependence of the frequencies and the half widths of the lattice vibrations indicates that the phase transition of the crystal is associated with the rotation of the molecule around the Br–Br axis.

The solids 1,2-dichloroethane and 1,2-dibromoethane, undergo a phase transition at 177 and 249.49 K, respectively.[1] According to the X ray diffraction studies by Lipscomb *et al.*,[2-4] the crystal of both the high (α-phase) and the low temperature phase (β-phase) of 1,2-dichloroethane is monoclinic and belongs to the space group C_{2h}^5-$P2_1/c$. A unit cell consists of two molecules. Ozora, Nakagawa, and Ito[5] studied the temperature dependence of the low frequency Raman bands of 1,2-dichloroethane and concluded that the phase transition is associated with the free rotation of the molecule about the Cl-Cl axis, which agrees with the result by Reeds and Lipscomb.[3]

On the other hand, the crystal structure and the nature of the phase transition of 1,2-dibromoethane have not been studied in detail. Pitzer[1] measured the heat capacity of the crystal and suggested that the structure of the α-phase of 1,2-dibromoethane was different from that of the β-phase. Reeds and Lipscomb[3] quoted the work by Meerman and stated that the β-phase of 1,2-dibromoethane has the same structure as that of the β-phase of 1,2-dichloroethane. In the present paper we report the temperature dependence of the low frequency Raman bands of 1,2-$C_2H_4Br_2$ and 1,2-$C_2D_4Br_2$ and discuss the nature of the phase transition of the crystal.

Experimental

A chemically pure grade reagent of 1,2-$C_2H_4Br_2$ obtained from Tokyo Kasei Co. Ltd. was further purified by means of a spinning band fractional distillation column made by Tokyo Kagaku Seiki Co. Ltd. 1,2-$C_2D_4Br_2$ purchased from Merk Darmstadt Germany was used for the measurement without further purification.

The Raman spectra were measured by use of a laser Raman spectrometer, Kawaguchi Electric Works model RL-62. The 514.5 nm line of a NEC argon ion laser model GLG2003 was used as an exciting source.

Figure 1 shows the cryostat designed in our laboratory for the measurement of the Raman spectra of liquid or solid samples in the range from liquid helium temperature to about 150 °C. About one litre of liquid helium can be contained in D. A thermal station C has an volume of about 100 ml. For measurements below 90 K the cryostat is covered by a glass vessel which contains liquid nitrogen. A sample cell, shown in Fig. 2, is made of quartz glass. The cell is hung by means of nylon cords within the adiabatic shield. The temperature was measured by use of a chlomel p-constantan thermocouple, the calibration of which was reported elsewhere.[6] A germanium resistance thermometer, which was calibrated by Cryocal. Inc., was used in the temperature range below 30 K. The temperature of the sample was held constant within ± 0.05 K during a measurement of a band.

Result and Discussions

Assignment of the Low Frequency Raman Bands of the β-Phase. Four bands at 27.7, 44.9, 56.9, and 126.5 cm^{-1} were observed for 1,2-$C_2H_4Br_2$ at 40.0 K in the frequency region below 150 cm^{-1}. 1,2-dibromoethane has two rotational isomers, the *trans* and *gauche* forms. As the molecule has a *trans* form in the crystalline state[7] and the lowest frequency[8] of the Raman active intramolecular vibrations of the *trans* form is 190 cm^{-1}, the bands observed below 150 cm^{-1} are definitely attributable to the lattice vibrations. According to Ozora, Nakagawa, and Ito,[5] the β-phase of 1,2-$C_2H_4Cl_2$ also exhibits four bands in the Raman spectra below 150 cm^{-1}. This result does not contradict the suggestion by Pitzer[1] that the crystal structure of the β-phase of 1,2-$C_2H_4Br_2$ is the same as that of the β-phase of 1,2-$C_2H_4Cl_2$.

Six rotational lattice vibrations ($3a_g+3b_g$) are expected to appear in the Raman spectrum of the β-phase. Ozora, Nakagawa, and Ito assigned the highest frequency band of the four of the β-phase of 1,2-$C_2H_4Cl_2$ to the rotational mode about the Cl-Cl axis. In order to confirm the assignments we also observed the Raman spectrum of 1,2-$C_2D_4Br_2$. The observed frequencies of 1,2-$C_2H_4Br_2$ and 1,2-$C_2D_4Br_2$ near 95 K are shown in Table 1. The transition temperature, T_c, of 1,2-$C_2D_4Br_2$ crystal was found to be about 256.0 K, from the total thermal analysis, by using the cryostat described above. As the T_c of 1,2-$C_2D_4Br_2$ is higher by about 6.5 K than that of 1,2-$C_2H_4Br_2$, the temperature for 1,2-$C_2D_4Br_2$ in Table 1 is a little higher than that for 1,2-$C_2H_4Br_2$. ν_D/ν_H and $I_D(A)/I_H(A)$ in the table represent the values of the ratios of the frequencies and the principal moment of inertia around the A axis, respectively, of 1,2-$C_2D_4Br_2$ to those of 1,2-$C_2H_4Br_2$. The values of the moment of inertia of the molecules were calculated by assuming that all of the valence angles were 109°28′ and the interatomic distances were $r_{CH}=r_{CD}=1.09$, $r_{CC}=1.54$, and $r_{CBr}=1.91$ Å.[9] The lowest frequency band observed at 27.7 cm^{-1} for 1,2-$C_2H_4Br_2$ at 40.0 K was not observed above 80 K, as the tail of the Rayleigh scattering band lapped over the band. The result of Table 1 indicates that the highest frequency band at approximately 120 cm^{-1} for 1,2-$C_2H_4Br_2$ or at approximately 100 cm^{-1} for 1,2-$C_2D_4Br_2$ should be assigned to the rotational lattice vibration about the C axis, that is, the Br-Br axis.

Temperature Dependence of the Raman Bands. Figure 3 shows the Raman spectra of the crystals at several temperatures. Below T_c three or four bands are observed for each crystal, while only one band was observed above T_c, although for the β-phase of 1,2-

Table 1. Observed frequencies near 95 K

$C_2H_4Br_2$ (93.6K)	43.6 cm^{-1}	55.4	121.4

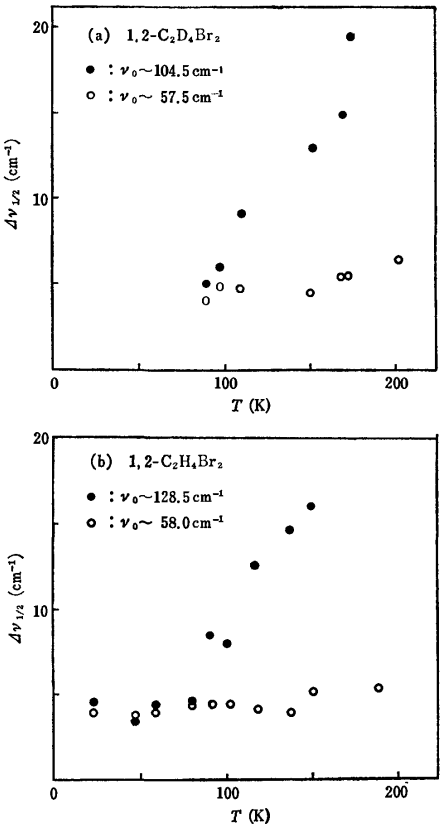

Fig. 6. The temperature dependence of the half width of the lattice vibrations.

dichloroethane two bands were reported.[5] The result may be explained in terms of a crystal structure of 1,2-dibromoethane different from that of 1,2-dichloroethane above T_c.

The widths and frequencies of lattice vibrations depend on temperature due to unharmonicity. Near T_c the crystal is expected to be very unharmonic. If there is a lattice vibration which is associated with the phase transition, the frequency of the vibration will depend on temperature much more than the other vibrations.[10] As Fig. 4 shows, the frequencies of the lattice vibrations of the crystals decreases as the temperature approaches T_c. By extrapolating the frequencies to the limit at 0 K, the values of ν_0 were estimated for each band; those are also given in Fig. 4. Figures 5 and 6 show the temperature dependence of $(\nu_0-\nu)/\nu_0$ and half width of each band. The lines in Figs. 5 and 6 represent the errors in the measurements. The frequencies of the rotational lattice vibrations about the Br–Br axis of the β-phase decrease and the half widths of the bands increases greatly with approaching Tc, as compared with the other rotational lattice vibrations. In other words, the rotational vibration about the Br-Br axis is more unharmonic than the others, which suggests that the phase transition of the crystal is associated with a rotational motion of the molecule around its Br-Br axis.

Photoelectron Spectroscopic Study of Skew Compounds. Methylhydrazine and Unsymmetrical Dimethylhydrazine

Katsumi KIMURA, Shunji KATSUMATA, and Kazuteru OSAFUNE[1)]

Physical Chemistry Laboratory, Institute of Applied Electricity, Hokkaido University, Sapporo 060

(Received June 28, 1975)

The He I photoelectron spectra of unsymmetric hydrazines CH_3HNNH_2 and $(CH_3)_2NNH_2$ have been measured and CNDO/2 calculations have been carried out, in which *gauche* (outer- and inner-skew) forms and *trans* form were taken into account for CH_3HNNH_2 and *gauche* and *trans* form for $(CH_3)_2NNH_2$. It has been found that nonbonding splittings in the photoelectron spectra are well reproduced by CNDO/2 calculations with *gauche* forms. The present results of conformation are supported by available conformational studies. The following conclusions have been obtained on orbital assignments of the photoelectron spectra: 1) The first and second bands are due to the methylated and unmethylated nitrogen lone pairs, respectively. 2) The third bands are attributed to the N–N bonding orbitals. 3) The rest of the photoelectron spectra up to 18 eV can be explained in terms of other p-type orbitals (C–N bonding, CH_3 pseudo π, and NH_2 pseudo π).

Previously, the He I photoelectron spectra of typical skew compounds, hydrazine[2)] and hydrogen peroxide,[3)] have been interpreted in terms of Walsh-type diagrams based on the CNDO/2 method. The separations of the first two photoelectron ionization bands due to nonbonding orbitals in these skew compounds have well been reproduced by CNDO/2 calculations at available dihedral angles. Recently, for a series of symmetrical dimethyl derivatives of hydrazine, hydrogen peroxide, and hydrogen disulfide, a similar analysis of He I photoelectron spectra[4)] suggested conformations that CH_3OOCH_3 has a *trans* planar form, while $CH_3HNNHCH_3$ and CH_3SSCH_3 are in *gauche* form. In connection with the previous studies,[2-4)] in the present work we have extended our photoelectron work to two kinds of unsymmetrical hydrazines in order to study nonbonding splittings as well as variations in inner valence orbitals with possible different conformations.

Nelsen and Buschek[5)] studied the nonbonding splittings of the photoelectron spectra of CH_3HNNH_2 and $(CH_3)_2NNH_2$ together with many other hydrazines, and indicated from INDO calculations that nonbonding splittings may be interpreted with a dihedral angle of 90°. Independently, Rademacher[6)] estimated the dihedral angles of various hydrazines by analyzing photoelectron nonbonding splittings. Bodar *et al.*[7)] earlier suggested in their He I photoelectron spectra of retarding-potential type for hydrazines that the nonbonding splitting reflects the skew angle.

From an entropy consideration, Janz and Russell[8)] indicated that the gaseous methylhydrazine exists predominantly as an outer-skew form. This compound can exist in either of two possible *gauche* conformations, "outer" or "inner" form. The *gauche* form with the methyl group farthest from the hydrogens of the amino group is called the outer form, while the other is known as the inner form.[8)] The outer form of methylhydrazine was later supported by an infrared and Raman study by Durig *et al.*[9)] For $(CH_3)_2NNH_2$ it was also indicated by Durig and Harris[10)] that the compound mainly exists in *gauche* rather than *trans* form.

Experimental

Measurements of He I photoelectron spectra were carried out with a high-resolution photoelectron spectrometer used previously.[2-4)] Calibration of the ionization energy scale was carried out using known ionization energies of Xe as an internal standard. Gaseous samples were introduced through a vacuum glass line with a teflon needle valve. The compounds studied are liberated from commercial hydrochloride salts in aqueous alkaline solution, and then were dehydrated by barium oxide and finally distilled in vacuum.

Results and Discussion

The He I photoelectron spectra obtained here for methylhydrazine and unsymmetrical dimethylhydrazine are shown by curves (a) and (b), respectively, in Fig. 1. Since the previous photoelectron works[11-14)] of various series of alkyl compounds have indicated that

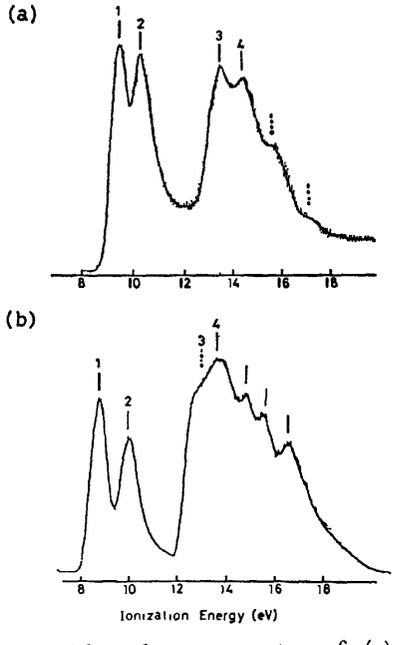

Fig. 1. He I Photoelectron spectra of (a) methylhydrazine and (b) unsymmetric dimethylhydrazine.

all photoelectron bands due to p-type localized molecular orbitals (LO's) are located below about 18 eV, the same situation may be expected to occur in the compounds studied. There are seven and nine p-type LO's in methylhydrazine and unsymmetrical dimethylhydrazine, respectively, the LO's being represented by n_N(nitrogen nonbonding), σ_{NN}(N-N bonding), σ_{CN} (C-N bonding), π_{NH_2}(NH_2 pseudo π), and π_{CH_3}(CH_3 pseudo π) orbitals. From the spectral shapes (maxima and shoulders) of the photoelectron spectra in Fig. 1, six and seven ionization bands can be identified in the region below about 18 eV. However, the remaining p-type bands are concealed under the photoelectron spectra in Fig. 1. The vertical ionization energies obtained from the photoelectron spectra in Fig. 1 are summarized in Table 1.

Table 1. Vertical ionization energies (eV) of methylhydrazine and unsymmetrical dimethylhydrazine

CH_3HNNH_2	
9.36, 10.28, 13.38, 14.32, 15.5[a], 17.1[a]	
$(CH_3)_2NNH_2$	
8.85, 10.07, 13.0[a], 13.50, 14.75, 15.40, 16.35	

a) Shoulder.

The first two vertical ionization energies slightly differ from those reported by Nelsen and Buschek (9.32 and 10.24 eV for CH_3HNNH_2; 8.88 and 10.13 eV for $(CH_3)_2NNH_2$),[5] but our separations (0.92 and 1.22 eV, respectively) are in good agreement with the reported ones (0.92 and 1.25 eV, respectively).[5] For higher ionization energies, there have been reported no high-resolution photoelectron data available for comparison.

In the present work, CNDO/2 calculations[15] were carried out for the outer, inner, and *trans* forms of methylhydrazine and for the *gauche* and *trans* forms of unsymmetrical dimethylhydrazine. Electron diffraction data of Beamer[16] were used for structural parameters. The calculated results of the p-type orbitals are illustrated in the energy level diagrams in Fig. 2, in which main characters are indicated in terms of the p-type LO's. (An ordinary 4 eV correction was made in the calculated energies.) The experimental levels based on Koopmans' theorem[17] are also compared with the calculated levels of the different conformations.

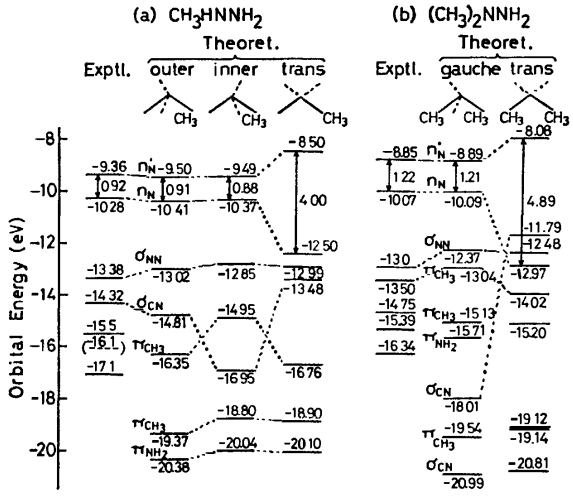

Fig. 2. Experimental and calculated (CNDO/2) energy levels for (a) methylhydrazine and (b) unsymmetric dimethylhydrazine.

Methylhydrazine. As can be seen from Fig. 2, the calculated nonbonding splittings of the outer and inner forms (0.91 and 0.88 eV, respectively) are close to the experimental one (0.92 eV), whereas the calculated splitting of the *trans* form (4.00 eV) is quite large. The comparison of the nonbonding splitting between experiment and theory therefore strongly suggests that this compound exists in the skew rather than *trans* form. This result of conformation is consistent with that of Nelsen and Buschek[5] who interpreted the nonbonding splittings of 21 hydrazines including methylhydrazine in terms of a dihedral angle of 90° using INDO calculations. According to the entropy considerations of Janz and Russell[9] and Durig *et al.*,[10] methylhydrazine mainly exists as an outer form. It would be very difficult to distinguish the outer and the inner form from each other from a photoelectron study.

The CNDO/2 results indicated that the outermost orbital is assigned to the methylated nitrogen lone pair. (Its energy level is represented by n_N' in Fig. 2.) The third and fourth photoelectron bands may correspond to the N–N and C–N bonding orbitals, respectively. It is interesting to note that the σ_{NN} level is almost independent of the dihedral angle. This tendency was previously pointed out in hydrazine.[2]

The fourth band at 14.32 eV may be due to the σ_{CN} LO, close to the 14.42-eV band of methylamine previously assigned to the σ_{CN} LO.[12] As mentioned before, there may be a concealed band in the methylhydrazine spectrum. The 15—18 eV spectrum in Fig. 1(a) should be associated with three p-type LO's (two π_{CH_3}'s and one π_{NH_2}). The position of the concealed band may be estimated on the basis of the photoelectron data of simple molecules. Using the empirical energy parameters previously proposed,[4] we have a value of —96.08 eV for the total energy sum over all the p-type LO's of methylhydrazine. On the other hand, the summation of the experimental vertical ionization energies shown in Table 1 gives rise to 79.9 eV. Therefore, the remaining photoelectron band is expected to appear around 16.1 eV (=96.0—79.9), the corresponding level being shown by a dotted line in Fig. 2. It may be concluded that the 15—18 eV spectrum consists of three ionization bands (two π_{CH_3} and one π_{NH_2}).

Unsymmetrical Dimethylhydrazine. The photoelectron nonbonding splitting again suggests that this compound may exist as a *gauche* rather than *trans* form. It is seen from Fig. 2 that the experimental nonbonding splitting (1.22 eV) is in excellent agreement with that of *gauche* form (1.21 eV). The nonbonding splitting of *trans* form (4.89 eV) is very large compared with that of *gauche* form. According

TABLE 2. COMPARISON OF NONBONDING SPLITTINGS (in eV) BETWEEN EXPERIMENT AND CALCULATION (CNDO/2)

	N_2H_4[2]	H_2O_2[3]	$(CH_3)_2O_2$[4]	CH_3HNNH_2	$(CH_3)_2NNH_2$	$CH_3HNNHCH_3$[4]	$(CH_3)_2S_2$[4]
Exptl.	0.73	1.00	1.90	0.92	1.22	0.67	0.30
CNDO/2	0.60	0.58	1.91	0.88, 0.91[b]	1.21	0.71	0.28
ϕ_0[a]	95°	111°30′	180°	90°	90°	90°	84°42′

a) The dihedral angle used in the CNDO/2 calculations. b) Inner and outer forms, respectively.

to the entropy study of Durig and Harris,[11] the compound exists predominantly as a *gauche* form.

The CNDO/2 calculations indicated that the third and fourth levels may correspond to the σ_{NN} and π_{CH_3} LO's, respectively. The third, 13.0-eV band due to the σ_{NN} LO is fairly close to the 13.38-eV band of methylhydrazine. The fourth, 13.50-eV band is considered to arise from the orbital interaction of two methyl groups.

The sum rule consideration mentioned above may help to estimate the remaining photoelectron bands. The total sum of LO energies is −124.68 eV. On the other hand, the sum of the experimental ionization energies given in Table 1 is 91.9 eV. A difference of 32.7 eV (=124.6—91.9 eV) suggests that there are two additional bands in the region 15—17 eV. In Fig. 2(b), it is not easy to correlate the experimental levels to the five deepest CNDO/2 levels of the *gauche* form which are shown by π_{CH_3}, π_{NH_2}, $\sigma_{CN(-)}$, π_{CH_3}, and $\sigma_{CN(+)}$ in this order. (These characters simply represent the largest contributions in the calculated MO's.) From our experiences,[11-14] however, the p-type LO's of this compound are considered to be $\sigma_{CN(-)}$ and $4\pi_{CH_3}$ instead of $\sigma_{CN(\pm)}$ and $3\pi_{CH_3}$, in addition to n_N', n_N, and π_{NH_2}. This conclusion was also supported by MINDO/2 calculations[18] which were also carried out in the present work. The MINDO/2 results of the *gauche* form showed that the five deepest levels mentioned above correspond to π_{CH_3}, π_{NH_2}, $\sigma_{CN(-)}$, π_{CH_3}, and π_{CH_3} in this order. The $\sigma_{CN(+)}$ orbital was indicated to give the first s-type one. (For methylhydrazine, the MINDO/2 calculations led to the same orbital assignments as the CNDO/2 calculations.) The MINDO/2 calculations were also found to give rise to somewhat smaller nonbonding splittings than the CNDO/2 calculations.

Potts *et al.*[19] indicated in their He II photoelectron spectra that s-type bands appear at 21.9 and 27.5 eV in methylamine, 20.6, 22.4, and 28.0 eV in dimethylamine, and 24.5 eV in hydrazine. The first s-type bands of the methylated hydrazines studied here are therefore expected to appear in the region 20—21 eV.

Table 2 summarizes experimental and calculated nonbonding splittings for the compounds so far studied in this laboratory. It is interesting to note that the experimental nonbonding splittings are well reproduced by CNDO/2 calculations with available skew angles.

Metachromasy. III.* Metachromatic Behavior of Trypaflavine in the Presence of Polyphosphates with Various Chain Lengths

Kiwamu YAMAOKA, Mineo TAKATSUKI, and Masaji MIURA
Faculty of Science, Hiroshima University, Higashisenda-machi, Hiroshima 730
(Received May 17, 1974)

The interaction of trypaflavine with sodium polyphosphate in aqueous solutions in the pH range 6—7 has been investigated by means of light absorption spectroscopy, conductometric titration and ultrafiltration. The metachromatic behavior of the bound dye was characterized in terms of hypso- and hypochromic effects in both visible and UV regions where no pronounced metachromasy band was observed. The effects were studied by varying the mixing ratio of polymer residue to dye, P/D, from 0.1 to 10000. They were found to be maximum in the P/D range 2–10. The effect of the chain length of polyphosphate on metachromasy was determined by use of fourteen refractionated samples with the degree of polymerization, $\bar{n}$, ranging from 8 to 158. No metachromasy appeared in samples with $\bar{n}<7$. It fully developed for those with $\bar{n}>20$, sharply depending on the chain length between 7 and 20. By conductometric titration and ultrafiltration, it was verified that the dye binds to the ionized phosphate almost at 1 : 1, and that the disappearance of metachromasy with the increase in P/D values or with the addition of salts results from two entirely different processes. The results were compared with the data for other dyes.

The physicochemical basis of metachromasy still remains to be clarified because of its extraordinary complexity.[1,2] However, it has become apparent that the metachromatic behavior of cationic dyes depends on the combination of the chemical structure of an individual dye with the conformation of a given polyelectrolyte having a specific functional group (binding site).[1,3,4] Studies of metachromasy have been directed to the interaction between biopolymers, DNA and RNA in particular, and various kinds of dyes whose structures are closely related, because of the practical application to selective staining of nucleic acids.[5–8] Such interaction is complicated due to the intricate structure of the biopolymers. Thus, in order to understand the mechanism involved in metachromasy, certain simpler polymeric models, one of which is polyphosphate, have been used.[9–12]

Metachromatic change of crystal violet (CV) occurs in the presence of sodium polyphosphate (NaPP).[1,2] The present work was undertaken with two objectives; to see whether the previous findings are confined to CV, a triphenylmethane dye, or whether they can also be observed with dyes of another class, such as cationic acridines, and also to provide basic data for a study on competitive binding to polyphosphate between two dyes of different classes.

As an acridine dye, trypaflavine (TF)—3,6-diamino-10-methylacridinium chloride—was chosen for the following reasons. The metachromatic behavior is close to that of proflavine — 3,6-diaminoacridinium chloride — but differs from that of acridine orange and its homologs, all of which have been known to interact with DNA.[3,13–15] Both TF and proflavine have been suggested to constitute a subgroup among the symmetrical 3,6-disubstituted acridines.[3,8] TF was also used together with CV in a study on competitive binding to DNA.[16] From the results obtained by means of absorption spectroscopy, conductometric titration and ultrafiltration, the metachromatic behavior of the NaPP–TF system has been compared with that of the NaPP–other related dye systems.

* Part II, Ref. 2.

Experimental

Materials. All NaPP samples are the same refractionated preparations as reported,[2] unless otherwise stated. TF in the chloride form (Chroma Gesellschaft, Schmidt & Co.) was used without further purification. The maximum molar extinction coefficient, ε, at 451 nm was found to be 42000 at 1.19×10^{-5} M.

Procedures and Measurements. Procedure for the preparation of stock solutions and polymer-dye mixtures has been reported.[2] The final concentration of TF was kept at 1.19×10^{-5} M, unless otherwise specified. Measurements of the absorption spectra and electric conductivity of NaPP-dye solutions were carried out with the precautions described previously.[2]

Ultrafiltration. In order to separate the unbound dye from the bound one in the NaPP-dye solution, a Millipore Sweenex ultrafiltration cell was used with the PSAC membrane which nominally retains molecular weights higher than 1000. Since the complete retention of a high molecular weight NaPP sample ($\bar{n}=216$) by the membrane was confirmed, this sample was used for the filtration experiments.

Results

UV and Visible Spectra of TF in the Presence of NaPP in Aqueous Solutions. The UV and visible absorption spectra of TF in the presence of a high molecular weight NaPP ($\bar{n}=216$) are shown in Fig. 1. The value of P/D as defined previously[2,17] was varied by adjusting the polymer concentration at a constant concentration of TF. The absorption maximum of TF at 451 nm was affected hypso- and hypochromically by the addition of NaPP up to P/D about unity, while the family of spectra showed two isosbestic points at 475 nm and 370 nm. The metachromatic behavior of the absorption maximum at 262.5 nm was similar to that of the 451 nm band, the isosbestic point being at 304 nm. As the P/D value increased from unity to approximately 3, the hypso- and hypochromic effects were enhanced in both UV and visible regions, no isosbestic point being observed. With the further increase in P/D value, the spectral trends reversed very slowly, three isosbestic points appearing

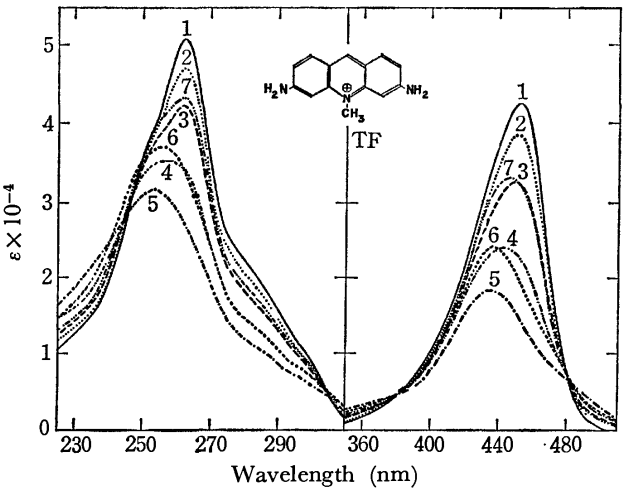

Fig. 1. Visible and UV spectra of TF in the presence of NaPP ($\bar{n}$=216) at various P/D values in aqueous solutions.
(1) pure TF (P/D=0) for comparison, (2) P/D=0.3, (3) P/D=0.5, (4) P/D=1.0, (5) P/D=3.0, (6) P/D =50, (7) P/D=850.

at 479, 374, and 307 nm. At exceedingly high P/D values, the overall spectra became almost the same as the spectrum of TF alone. It should be noted that, in contrast with the data on the NaPP-CV system,[1,2] no pronounced metachromasy band was observed for TF.

The effect of the chain length of NaPP on the UV and visible spectra of the NaPP–TF system is shown in Fig. 2. The P/D value was held at 3 (most appropriate for the metachromatic change of TF). The spectra are essentially the same as the spectrum of TF alone when the number-average degree of polymerization, $\bar{n}$, is less than 5. With an increase in the $\bar{n}$ of NaPP, the band intensity at 451 and 262.5 nm decreased, while the peak positions shifted towards the shorter wavelength. The decrease in intensity

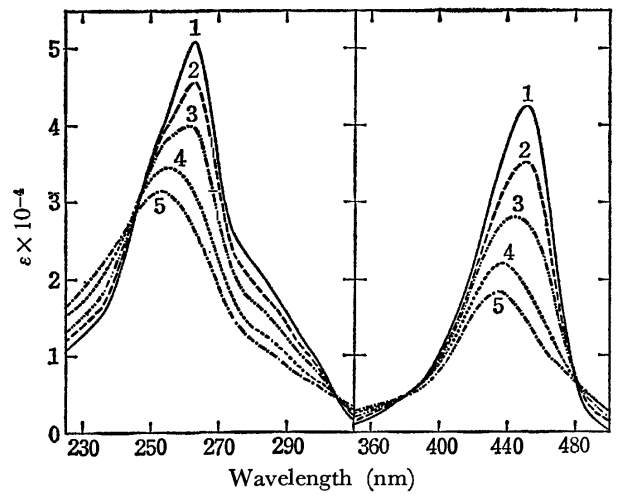

Fig. 2. Visible and UV spectra of TF in the presence of NaPP with various chain lengths at a P/D value of 3 in aqueous solutions.
(1) pure TF (P/D=0) for comparison, (2) $\bar{n}$=8, (3) $\bar{n}$=11, (4) $\bar{n}$=23, (5) $\bar{n}$=158.

occurred in a narrow region of $\bar{n}$ approximately between 7 and 20. Since the dependence of the metachromatic behavior of TF on P/D and $\bar{n}$ is characterized by hypso- and hypochromic effects, all the results are hereafter expressed in terms of both the molar extinction coefficients at 451 nm, ε_{451}, and at 262.5 nm, $\varepsilon_{262.5}$, and the wavelength shift from either the 451 or 262.5 nm maximum of TF, $\Delta\lambda=\lambda(\varepsilon_{max})-451$ or 262.5 nm. The results of the prominent shoulder at 285 nm are not included, because its change is similar to that of the 262.5 nm band.

Effect of the P/D on the Absorption of TF in the Presence of NaPP with Various Chain Lengths. In Figs. 3a and 3b, the molar extinction coefficient (open) and

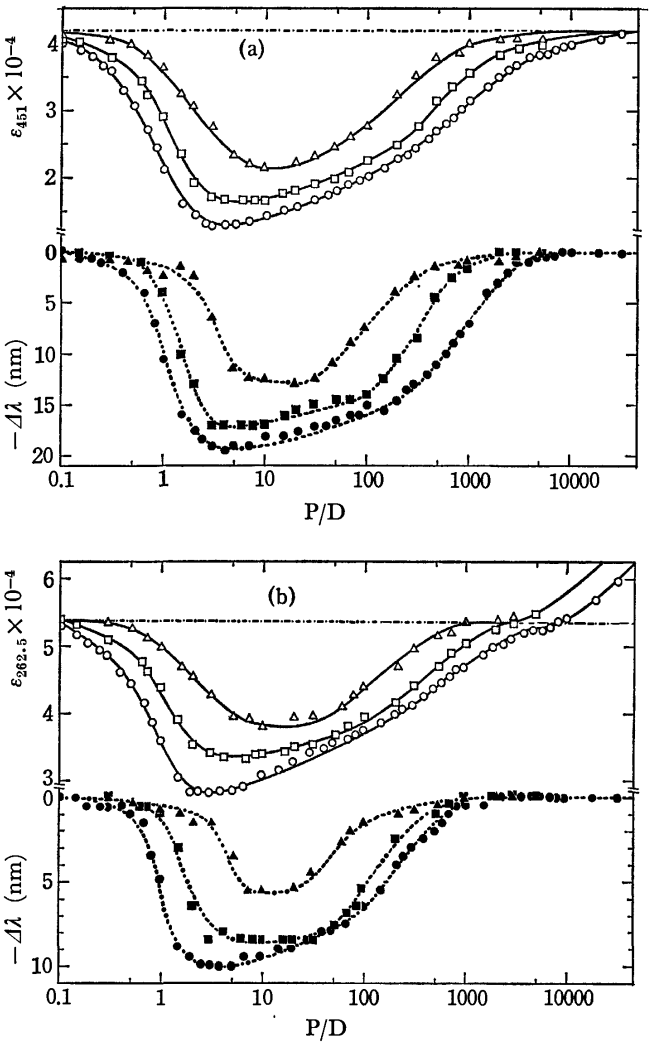

Fig. 3. The dependence of the hypo- and hypsochromisms of TF on the P/D value in the presence of NaPP with different chain lengths in the (a) visible and (b) UV regions.
Open symbols are the molar extinction coefficients of NaPP-TF at (a) 451 nm and (b) 262.5 nm (horizontal lines are those of TF alone), and filled ones are the wavelength shifts of the absorption maximum from (a) 451 nm and (b) 262.5 nm, defined as $\Delta\lambda\equiv\lambda(\varepsilon_{max})-451$ and 262.5 nm, respectively. -○- and -●- for $\bar{n}$=216, -□- and -■- for $\bar{n}$=24, -△- and -▲- for $\bar{n}$=11.

wavelength shift (filled) of TF are plotted against P/D in the presence of three NaPP samples which give rise to a small ($\bar{n}$=11), medium ($\bar{n}$=24), and large ($\bar{n}$=216) metachromatic change, respectively.[2] The intensity of the 451 and 262.5 nm bands became minimum and the corresponding wavelength shift maximum at a P/D value of approximately 7, 3, or 2 for each NaPP-TF system ($\bar{n}$=11, 24, or 216, respectively). The minimum value of ε at this P/D value depends on the chain length of the polymer.

The ε and band position of the NaPP–TF system approach those of TF alone at both extremely low and high values of P/D** (Figs. 3a and 3b). In order to see if the approach results from the dissociation of TF from the polymer site, filtration of an aqueous solution of TF in the presence of NaPP ($\bar{n}$=216) at a high P/D value of 1000, was carried out (*cf.* Experimental part). Three filtrates (3.0 ml each) were successively collected from the solution (total 15 ml). No filtrates showed the coloration of TF. In contrast, the filtrates from a NaPP–TF solution at a low P/D value of 0.6 all showed the spectrum of pure TF. It is obvious that TF is bound to the polymer site at very high P/D but partly liberated from it at low P/D.

Effect of the Chain Length of NaPP on the Absorption of NaPP–TF Solutions at Various Values of P/D. The effect of the chain length of NaPP on the metachromatic change of the NaPP–TF system is shown in Fig. 4, where the molar extinction coefficient and band shift are plotted against the chain length of NaPP. The P/D value chosen here is each responsible for a large (P/D=3), medium (P/D=30), and small (P/D=300) metachromatic change. The band intensity decrease and peak position shift toward the shorter wavelength occur in a narrow range of $\bar{n}$ between 7 and 20. Both ε and $\Delta\lambda$ leveled off, as the chain lengths of NaPP approach *ca.* 100 and over. The midpoints of those sigmoidal changes for the visible band are located at about $\bar{n}$=10 and 11 (P/D=3), $\bar{n}$=8 and 9 (P/D=30), and $\bar{n}$=11 and 19 (P/D=300), respectively (Fig. 4a). Similar changes are also noted for the UV band (Fig. 4b). It is evident that the metachromatic behavior of the TF bound to NaPP is affected by the chain length of the polymeric moiety and that the critical chain length is associated with oligomeric dimensions.

Influence of Small Ions on Metachromatic Changes. The small ions affect visible and UV bands of TF bound to NaPP ($\bar{n}$=154 and 24) at (a) P/D=3 and (b) P/D=30 (Figs. 5a and 5b). At each P/D value, the effect of the addition of sodium phosphates on the absorption spectra was negligible when the salt concentration was comparable with that of TF (10^{-5}—10^{-4} M). As the salt concentration was increased to 1×10^{-3} M, however, the effect became apparent: both ε and $\Delta\lambda$ changed hyper- and bathochromically relative to those of the low salt solution. At the exceedingly high salt concentration of the order of

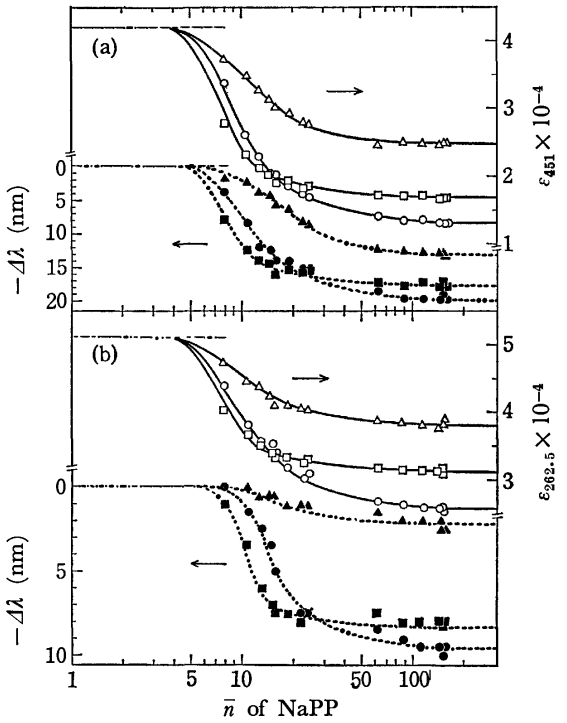

Fig. 4. The dependence of the hypo- and hypsochromisms of the NaPP-TF system on the chain lengths of NaPP at various P/D values in the (a) visible and (b) UV regions.
Open symbols are the molar extinction coefficients of NaPP-TF at (a) 451 nm and (b) 262.5 nm, and filled ones are the wavelength shifts of the absorption maximum in the presence of NaPP from (a) 451 nm and (b) 262.5 nm as defined in Fig. 3. -○- and -●- for P/D=3, -□- and -■- for P/D=30, -△- and -▲- for P/D=300.

10^{-2} M (about 1000 Na^+ ions per dye), the whole spectrum of the NaPP–TF solution was reduced to the spectrum of TF alone. In order to see if the dye is dissociated from the polymer site in the presence of the salt, ultrafiltration of an NaPP($\bar{n}$=216)–TF solution at the salt concentration and P/D of 1×10^{-2} M and 30 was carried out. Three colored filtrates (3.0 ml each) were successively collected from the NaPP-TF solution (16 ml initially). The visible spectrum of each filtrate was identical with that of free dye and that of the initial NaPP–TF solution within experimental error. The bound TF is evidently compelled to dissociate from the site in the presence of an excess of the small ions. In Figs. 5a and 5b, the midpoints of the sigmoidal changes of ε and $\Delta\lambda$ for the longer NaPP–TF solutions are displaced towards the higher salt concentrations. This indicates that more small ions are needed to dissociate the bound TF from the NaPP with a longer chain length.

Conductometric Titration of TF with NaPP in Aqueous Solutions. The results of conductometric titration of TF in aqueous solutions with three NaPP samples ($\bar{n}$=11, 24, and 154) are shown in Figs. 6a—6c. In the absence of TF the conductivity of the NaPP solution is proportional to the polymer concentration regardless of the chain length, although

** The $\varepsilon_{262.5}$ value, but not the band shift for the 262.5 nm band, exceeds that of TF at extremely high P/D. This is because polyphosphate absorbs light in this region.[18]

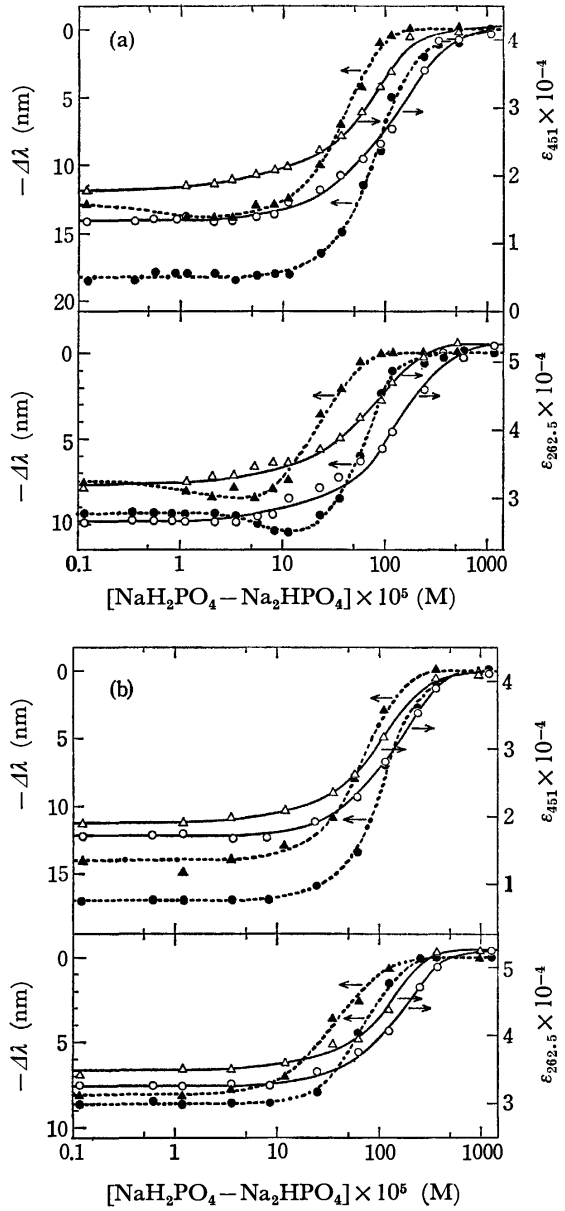

Fig. 5. The effect of sodium phosphates on the hypo- and hypsochromisms of TF in the presence of NaPP at two P/D values (a) P/D=3 and (b) P/D=30. Open symbols are the molar extinction coefficients of NaPP-TF at 451 nm (upper half) and 262.5 nm (lower half), and filled ones are the wavelength shifts of the absorption maximum from 451 nm (upper half) and 262.5 nm (lower half). -○- and -●- for NaPP with $\bar{n}=154$, -△- and -▲- for NaPP with $\bar{n}=24$.

the slope is less steep for the higher $\bar{n}$ sample. In the presence of TF, the conductivity of the titrated solution also increases linearly. However, a break occurs at a P/D value of about unity (1.2, 1.1, and 1.0) for each NaPP sample ($\bar{n}$=11, 24, and 154) as indicated by the intersection of two interpolated lines. Considering the fact that the deviation of the observed points from linearity results from the equilibrium between bound and unbound TF, the conductometric data seem to indicate that TF could be bound to the

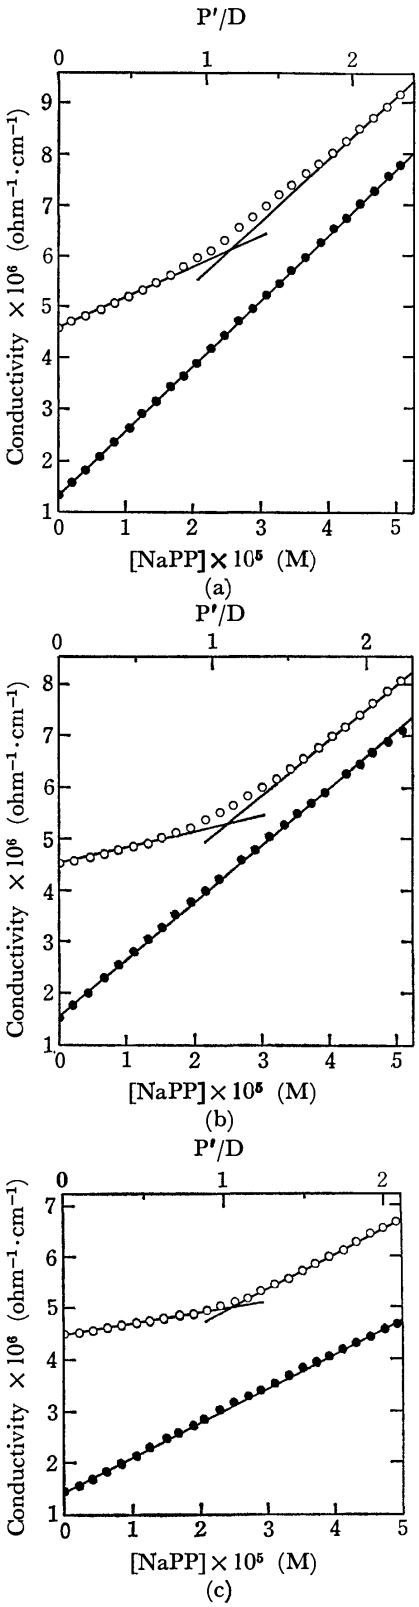

Fig. 6. Conductometric titration of TF with NaPP with various chain lengths (a) $\bar{n}=11$, (b) $\bar{n}=24$, and (c) $\bar{n}=154$.
-○- for the dye solution (the initial concentration of TF 2.26×10^{-5} M) titrated with NaPP and -●- for the blank solution titrated with NaPP for comparison. The concentration of NaPP is corrected for volume increase. P' is the concentration of the ionized group of the polymer and corrected as equal to $P(1+1/\bar{n})$ where P is the residue concentration.

ionized phosphate residue almost up to a one-to-one ratio regardless of the polymer chain length.

Discussion

Comparison of Metachromatic Behavior between TF and CV in the Presence of NaPP. The metachromatic behavior of the 451 nm band of the NaPP-TF system (Fig. 1) considerably differs qualitatively from that of the 592 nm band of the NaPP-CV system,[2] although many quantitative aspects are common to both TF and CV. The most striking difference is the appearance of a distinct metachromasy band at 506 nm in the bound CV. If such a band were also involved in the spectra of the bound TF, it would be very weak in intensity and exist in the wavelength region shorter than the 374—370 nm isosbestic point. (No apparent metachromasy band appears for either of these two dyes in the UV region). Difference is also noted for the variation of the peak positions in the presence of NaPP. The 451 nm band of TF steadily shifts hypsochromically as indicated by $\Delta\lambda$ (Figs. 1—3), whereas in the bound CV the original band at 592 nm, a shoulder at about 550 nm, and the new metachromasy band at 506 nm remain unshifted.[1,2]

Except for the differences described above, both TF and CV show the following common features. A long wavelength isosbestic point is noted at 479—475 nm for TF and at 637—639 nm for CV. The existence of such a point should imply that there is an absorption band in the wavelength region greater than that of the major band. A new long wavelength band has been observed in some triphenylmethane and acridine dyes in the solid state.[19] The P/D dependence of the metachromatic change of the two systems is also alike (Figs. 1 and 3 in Ref. 2; Figs. 1, 3a, and 3b in this article); for example, at very high and low P/D values, the absorbance of either system approaches that of the corresponding dye alone regardless of the polymer chain length. Another similarity is noted for the chain length dependence of the metachromatic change. For either dye the critical chain length of NaPP is rather short in terms of the number-average degree of polymerization. If the midpoint of the ε *vs.* $\bar{n}$ curves (Fig. 4) is taken to be a measure of the chain length dependence of metachromasy, the critical chain length is slightly shorter for TF ($\bar{n}=10$) than for CV ($\bar{n}=14$—16).[2]

For the NaPP sample whose $\bar{n}$ value is either 154, 24, or 11, a given P/D value of, say 310, signifies a polymer–dye solution containing on an average about two, thirteen, or twenty-eight polymer molecules per dye, respectively. The observed metachromatic change of TF in the solution is not abrupt but only gradual in the P/D range 100—1000 (Fig. 3). The result is best interpreted by assuming that the binding of TF to the polymer site is statistically random and essentially independent of the kind of site. If a preferential binding occurs to the dissociated secondary phosphate at the chain terminal of NaPP (only one terminal is fully dissociated at neutral pH),[20] the ε *vs.* P/D curve would show an abrupt change at a P/D value which nearly equals the $\bar{n}$ value of a given NaPP sample. Apparently this is not the case (Figs. 3a—3b). Thus, the present data on TF is not in accord with the notion that acridine orange is bound preferentially by the terminal doubly charged phosphates in the polynucleotide–acridine orange complexes.[21,22]

As observed for CV,[2] the binding of TF to NaPP is of electrostatic nature.[1,23] This is indicated from the results of the effect of small ions on metachromatic behavior (Figs. 5a and 5b) and conductometric titration (Figs. 6a—6c). It is clear from a comparison of Figs. 5a—5b with the result of the previous study on CV[2] that TF requires slightly more Na^+ ions than CV to dissociate from NaPP. The chemical structure of TF may be responsible for this result. Once bound to the polymer site, the quaternary ring nitrogen (the most probable binding locale) of TF may be shielded effectively from the small ions by two amino groups at the 3- and 6-positions, while the positively charged dimethylamino nitrogen of CV (a quaternary[24] or quinonoidal iminium ion[25]) could be exposed more to solvent and consequently susceptible to Na^+ ions.

Comparison of Metachromatic Behavior between Certain Acridine Dyes in the Presence of NaPP. Interaction with NaPP has been studied in some detail for acridine orange,[9–12] proflavine[9] and TF. The metachromatic behavior of the NaPP–proflavine system is very close to that of the NaPP-TF system. This is understandable considering the chemical structure of proflavine (protonated rather than methylated at the ring nitrogen but otherwise identical with TF). The spectral change of the visible band of the NaPP-acridine orange system differs from that of the NaPP–TF system; a broad, new band appears at 450 nm at the expense of the intensity of the principal 492 nm band as P/D values decrease.[10] This is somewhat analogous to the metachromatic behavior of the CV bound to NaPP.[2] Acridine orange possesses two dimethylamino groups, and proflavine or TF has two amino groups at the 3- and 6-positions, the pK values being 10.45, 9.65, and >12, respectively.[26] Thus, the difference and similarity of the observed metachromatic behavior should be sought from these two factors.

In spite of a qualitative variety of the spectral characteristics, the quantitative aspects of the metachromatic behavior of these acridine dyes are remarkable alike. The ε *vs.* P/D curves of acridine orange bound to NaPP indicate that the metachromatic change is maximum in the P/D range 2–20 (The Kurrol salt)[10] and 1—20 ($\bar{n}=110$),[11] and approximately 20—40 ($\bar{n}=9$)[10] and 10—40 ($\bar{n}=12$)[12] for unfractionated oligomeric samples. No metachromatic change was observed for the NaPP sample with $\bar{n}$ less than 5[10] or 3.[12] As P/D values increase to 10^4, the molar extinction coefficients of the bound dye approach the value of free acridine orange.[10] Since all the results compare favorably with the present data of the NaPP–TF system and the present work has established the fact that TF is totally bound to NaPP, acridine orange should also remain bound to NaPP even at exceedingly high P/D. The stoichiometry of the binding of the flat, symmetrical acridine dyes with substituents at

the 3- and 6-positions appears to be general for NaPP.

Closing Remarks. Together with the results with malachite green[1] and CV,[2] the present study of the interaction between NaPP and TF reveals the following. The metachromatic behavior depends on the chain length of NaPP, and the critical range of the degree of polymerization lies from 7 to 20. The dye is definitely bound to the polymer site at extremely high P/D values, irrespective of the appearance of the absorption spectra which do not appreciably differ from the free dye spectra. Although a closely resembling situation results from the addition of a great deal of the small ion to the NaPP-dye solution, the bound dye is compelled to dissociate from the polymer site because of the competition with the small ion. Thus, the resulting spectra are nearly the same in these two cases, but the underlying processes are proved to be different. It is thus concluded that the binding mode of each dye to NaPP is general and arises from complicated electrostatic interactions for which the positively charged nitrogen moiety of the dye is mostly responsible. The spectral behavior is remarkably characteristic of individual dyes, even though they belong to the same structural class.

The Franck-Condon Factor of a Polyatomic Molecule. Its Method and Application to Acetylene and Dideuteroacetylene

Isao KANESAKA and Kiyoyasu KAWAI

Faculty of Literature and Science, Toyama University, Gofuku, Toyama 930

(Received December 24, 1974)

An advanced method for the calculation of the Franck-Condon factor is reported. It is realized on the assumption of the neglect of the zero-point motions except for the three normal coordinates whose vectors are three-dimensionally orthogonal to each other. The overlap integral is given by the Cartesian displacement coordinate system in order to consider precisely the molecular structures of the ground and excited states. This coordinate system does not cause any conflicts with the above assumption. Thus, the overlap integral is defined every nucleus with one- to three-dimensional formulae to satisfy sufficiently the Franck principle, which has been considered precisely only in the case of the diatomic molecule. The method is applied to acetylene and dideuteroacetylene with very good results. The intensity factors obtained are discussed, along with the effects of the force constants and anharmonicity.

There has generally been found a wide variation in the intensity of each band in the progression of the electronic spectra of a polyatomic molecule, whose structure of the excited state changes greatly from that of the ground state. It has been found, in a progression for the $\tilde{A}\leftarrow\tilde{X}$ band of acetylene,[1] that the relative intensities vary from 1 for $v=1$ up to 285 for $v=5$. In this case, in the molecular structure of the excited state the angle of CCH is 120.2° and the distances of the H-C and C=C bonds are 1.08 and 1.383 Å respectively. Thus, it is suitable for the study of the Franck-Condon principle of a polyatomic molecule.

Ingold and King[1] have calculated the Franck-Condon factor of the progression of acetylene by the method established by Craig,[2] assuming the CH groups to be compound atoms. However, they could not explain the observed intensity distribution. In their treatment, the internal coordinate of the excited state is related one-dimensionally to that of the ground state in spite of the bent-linear transition. This is probably the reason for their failure. Smith and Warsop[3] have also calculated the Franck-Condon factor of the progression of acetylene by the method of Ansbacher.[4] However, they too could not explain the observed spectra. Their treatment of the overlap integral is based on this equation:

$$R(v,0)=\int\phi_0''(d-Q')\phi_v'(Q')\mathrm{d}Q' \tag{1}$$

where Q' is the normal coordinate of the excited state, d represents the separation of the origin of the two corresponding coordinates, and ϕ_0'' and ϕ_v' are the vibrational wave functions of the ground and excited states respectively. That is, the relation:

$$Q''=d-Q' \tag{2}$$

is assumed. The approximation of Eq. (2) is very low,[5] and, furthermore, d has not been defined clearly by the molecular structures of the ground and excited states, but estimated from the accordance of the observed with the calculated relative intensities. Though it is easy to make the observed relative intensities accord with those calculated, the value of d obtained is deficient in reliability because of its low approximation.

However, it is easily found that Eq. (1) can be applied to the diatomic molecule as it is. That is, Eq. (1) is precise if the direction of the normal coordinate of the excited state coincides with that of the ground state. In this case, the difference in d in Eq. (1) or in a frequency parameter does not cause any difficulties. On the other hand, in a polyatomic molecule a normal coordinate of the ground state does not generally coincide with that of the excited state. Therefore, Eq. (1) does not fulfill the Franck principle. That is, the value of $\phi_0''(d-Q')\phi_v'(Q')$ in Eq. (1) is correct only at a point of intersection of the two coordinates and is estimated largely at the other points. Thus, more than one-dimensional formulae is needed to estimate the correct value of the latter points. In our treatment, the vertical transition is considered sufficiently.

Method

In a polyatomic molecule, the Franck-Condon factor is generally given by:

$$R_{v'v''}=\int\phi_v'\phi_v''\mathrm{d}\tau_v \tag{3}$$

where the total wave function is given by:

$$\phi_v=\phi_1(Q_1)\phi_2(Q_2)\cdots\phi_{3N-6}(Q_{3N-6}) \tag{4}$$

where the wave function $\phi_i(Q_i)$ is given by:

$$\phi_i(Q_i)=N_{v_i}\exp\{-(\alpha_i/2)Q_i^2\}H_{v_i}(\sqrt{\alpha_i}Q_i) \tag{5}$$

where N_v is a normalization constant, $\alpha_i=4\pi^2\nu_i/h$, and $H_v(\sqrt{\alpha_i}Q_i)$ is a Hermitte polynominal of the vth degree. We will here consider the means of Eq. (4) by following the discussion of Herzberg.[6]

If only one normal vibration is excited, the total eigen-function is given by:

$$\phi_v=NH_{v_1}(\sqrt{\alpha_1}Q_1)\exp\{-(\alpha_1/2)Q_1^2-(\alpha_2/2)Q_2^2-(\alpha_3/2)Q_3^2\cdots\} \tag{6}$$

If we neglect the zero-point motion of all the other normal vibrations, we have $\phi_v=\phi_1(Q_1)$. In this case, as found from the equation:

$$\mathbf{X}=\mathbf{LQ} \tag{7}$$

where $\mathbf{X}$ is a Cartesian displacement coordinate vector, and $\mathbf{Q}$ a normal coordinate vector, the dis-

placement components of all the nuclei are proportional to Q_1. Then, the wave function conjugated with X_N is given by:

$$\psi(X_N) = \psi(Q_1) \tag{8}$$

However, actually we can not neglect the zero-point motion of the other vibration. In this case, Eq. (6) does not simplify to $\psi_1(Q_1)$ and Eq. (7) does, in general, not lead to such a simple expression for the $\mathbf{Q}$.

Departing from the discussion of Herzberg, if we use Eq. (7) as an approximation, we find that we may use $\psi_i(Q_i)$ instead of Eq. (4) as a wave function of the excited state. On the other hand, for the ground state, if the jth normal vibration is considered, we have $\psi_j(Q_j)$. If the kth normal vibration is considered, we have $\psi_k(Q_k)$, and so on. This shows, thus, that Eq. (3) can be expressed by:

$$R(v, 0) = \sum_j \int \psi_{0j}''(Q_j'')\psi_v'(Q_i')\mathrm{d}Q_i' \tag{9}$$

or

$$R(v, 0) = \sum_j \int \psi_{0j}''(d-Q_i')\psi_v'(Q_i')\mathrm{d}Q_i' \tag{10}$$

Eq. (10) is essentially equal to Eq. (1). That is, the zero-point motions different from ψ_0'' are also neglected or averaged in Eq. (1).

If we use the Cartesian displacement coordinate of each nucleus related linearly with a normal coordinate, d in Eq. (10) is defined clearly as the distance between the equilibrium positions of the nuclei of the ground and excited states. Thus, we transform Eq. (10) into the formula defined by the Cartesian displacement coordinate.

We use the $\psi(X_N)$ of Eq. (8) to resolve Eq. (10). However, $\psi_i(X_N)$ is not normalized on all Cartesian displacement coordinates of the ith normal coordinate as it is. That is shown by the consideration that the $\int\psi_i^*(X_N)\psi_i(X_N)\mathrm{d}X_N$ of a light atom such as hydrogen is larger than that of a heavy atom such as carbon. According to the reciprocal, l_N, of the $\mathbf{L}$ matrix element, a normal coordinate is expressed by:

$$Q_i = \sum_N^{Mi} l_N X_N \tag{11}$$

From the property of a normal coordinate in our approximation, there are these relations:

$$Q_i = l_1X_1 = l_2X_2 = \cdots = l_{M_i}X_{M_i} \tag{12}$$

That is, it is found that the above normalization can be settled by multiplying $\int\psi_i^*(X_N)\psi_i(X_N)\mathrm{d}X_N$ by l_N/M_i. Then, $\sqrt{|l_N|/M_i}\psi_i(X_N)$ is reasonable as the function of Eq. (9) or (10) and for the dimension of the vibrational wave function as well.

From Eq. (11) the overlap integral is given by the summation of $R_N(v,0)$ on all the coordinates. $R_A(v,0)$ is defined for every atom, and these one- to three-dimensional formulae are given by:

$$R_A(v, 0)_x = \sum_i \int \sqrt{|l_{ix}''|/M_i''}\psi_{0i}''(d_x-X') \times \sqrt{|l_{x}'|M'}\psi_v'(X')\mathrm{d}X' \tag{13}$$

$$R_A(v, 0)_{xy} = 2\sqrt{M_i''M'}R_A(v, 0)_xR_A(v, 0)_y \tag{14}$$

$$R_A(v, 0)_{xyz} = 3M_i''M'R_A(v, 0)_xR_A(v, 0)_yR_A(v, 0)_z \tag{15}$$

where the summation is carried out for all the normal coordinates of the ground state in the case of the absorption spectra. Generally, the vibrational modes expressed by the Cartesian coordinate system are not independent of each other. However, it is easily found that Eq. (12) is realized in our approximation, as has been discussed above.

In our approximation, the $\psi_i(X)$ of the ith normal coordinate would be different from zero only along the line of the Cartesian displacement coordinate. Actually, $\psi_i(X)$ is not zero outside the line, but decreases in the direction perpendicular to this line. Therefore, it is found that Eq. (13) is a very low approximation in a case such as a bent-linear transition. That is, a factor should be multiplied to Eq. (13) to satisfy the Franck principle. In our treatment, $R_A(v,0)_y$ is the factor for $R_A(v,0)_x$. Thus though Eq. (14) is a two-dimensional formula, this means the one-dimensional overlap integral and Eq. (15) has also the same mean as Eq. (14). That is, though the zero-point motions of the same axis as $R_A(v,0)_x$ are neglected in Eq. (7), those of the other axes are considered sufficiently.

By using Eqs. (13)—(15), the overlap integral of Eq. (10) is given by:

$$R(v, 0) = \sum_A R_A(v, 0) \tag{16}$$

where the sign of each term of $R_A(v,0)$ is easily determined by the displacement vector of each nucleus of the excited state, because ψ'' considered is always positive. In the case of the bent-linear transition, it is clear that the potential of the one axis, y, of the excited state is the double minimum and is symmetrical about the other, x. Then, the overlap integral of the axis becomes either double or zero. It is also possible to replace the integral for y in Eq. (14) with z. Then, Eq. (16) is rewritten by:

$$R_L(v, 0) = 4R(v, 0) \tag{17}$$

The Cartesian displacement coordinate vector is related to the normal coordinate vector by Eq. (7) in every symmetry species. Then, the values of $\psi_v'(X_N)$ of the excited state are calculated by Eq. (8), and those of $\psi_{0i}''(d-X_N)$ of the ground state by the expression:

$$\psi_{0i}''(d-X_N) = \psi_{0i}''(Q_i'') \tag{18}$$

where Q_i'' is given by:

$$Q_i'' = (d-L_N'Q')/L_{N_i}'' \tag{19}$$

where L_N is the $\mathbf{L}$ matrix element. The calculation of such an integral as Eq. (13) is carried out by the numerical calculation of $\psi_{0i}''(d-X)\psi_v'(X)$ at various values of X. Thus, the $R(v,0)$ of Eq. (16) or (17) is calculated; the square of $R(v,0)$ or $R_L(v,0)$ gives the intensity factor.

Application

Acetylene. We applied our method to the progression (C progression) of the bending vibration (1049 $\mathrm{cm^{-1}}$) of the first-excited state, ^1A_u, of acetylene.

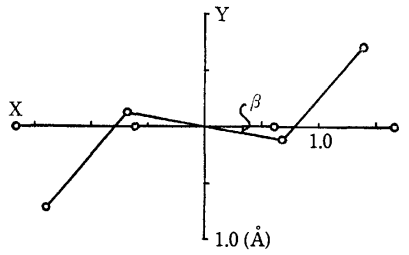

Fig. 1. The molecular structures of the ground and excited states of acetylene.

The absorption consists of a large number of very weak absorption bands, extending from 2400 to 2100 Å.[1,7] It has been determined, by an analysis of both the vibrational and rotational structures, that, in the excited state, acetylene is bent, taking the C_{2h} symmetry. The molecular structure of this excited state is shown in Fig. 1, along with that of the ground state, in which the bond lengths of the H-C and C≡C bonds are 1.064 and 1.201 Å[8] respectively. In our treatment, the principal axes of the ground and excited states should coincide as shown in Fig. 1. Thus, it is found that the relative equilibrium positions of the isomer differ considerably in the same Cartesian coordinate system, though their molecular structures are, of course, identical; we will describe dideutero-acetylene later. The intensities, expressed as the oscillator-strength, of the C progression have been measured from C_1 to C_5[1], where C_v represents the v–0 transition. They are shown in Table 1. All the fundamental frequencies of the A_g species of the excited state have been observed[1,7] at 1049, 1380, and 3000 cm^{-1}; they are assigned to the CCH bending, C=C, and C-H stretching vibrations respectively.

Table 1. The observed oscillator-strengths (f_v) and the relative intensities of C progression of acetylene

Band	C_1	C_2	C_3	C_4	C_5
$10^5 f_v$	0.0042	0.036	0.145	0.51	1.2
Relative intensities	1	8.57	34.5	121	285

The normal coordinate analysis was carried out by the computer program reported by Shimanouchi,[9] using the electronic computer, FACOM-45S, of Toyama University. The **L**S matrix obtained is expressed by:

$$\mathbf{S} = \mathbf{L}_S\mathbf{Q} \tag{20}$$

where **S** is the symmetry coordinate vector. From the $\mathbf{L}_S$ matrix, the **L** matrix is obtained by this expression:

$$\mathbf{L} = \mathbf{M}^{-1}\mathbf{B}_S\mathbf{G}\mathbf{L}_S \tag{21}$$

where the $\mathbf{M}^{-1}$ matrix consists of the reciprocal of the mass of the atom and where $\mathbf{B}_S$ and **G** are Wilson's $\mathbf{B}_S$ and **G** matrixes.[10] The **L** matrix (Set I) of Q_3' of the excited state is given in Table 2. The calculated frequencies agree completely with the observed ones. The force constants (Set I) are given in Table 3, where the H··C repulsive force constant was fixed in the least-squares adjustment. The fundamental frequencies of the ground state were quoted from a reference.[6] The **L** matrix of the ground state is also given in Table 2. The calculated frequencies agree with the observed ones. The force constants are also given in Table 3, where the interaction term between the CCH bending coordinates was taken into consideration. The calculation of Eq. (13) or Eq. (14) was carried out using the same computer mentioned above. In the summation of Eq. (14), there are two normal coordinates for y, with frequencies of 611.8(Π_g) and 729.1(Π_u) cm^{-1}, and three for x, with frequencies of 1973.8(Σ_g^+), 3287.0(Σ_u^+) and 3373.7(Σ_g^+) cm^{-1}.

It is interesting to compare the overlap integrals

of two normal coordinates for y, because only one of them has been considered. The results of Eq. (13) for hydrogen and carbon atoms are given in Table 4, where Eq. (16) is applied. The largest value of $R_A(v,0)$ is the $R_C(v,0)$ of the carbon atom of Q_4. The $R_H(v,0)$ of the hydrogen atom of Q_4 is nearly equal to that of Q_5, and both are smaller than the $R_C(v,0)$ of Q_4. The $R_C(v, 0)$ of Q_5 is negligible. It should be noticed that their large discrepancies result from the differences in the **L** matrix elements given in Table 2.

The overlap integrals for x are given in Table 5, where the results of Q_3 are omitted because they are similar to those of Q_1. In this case, the $R_H(v, 0)$ values of Q_1 and Q_2 are much larger than those in Table 4. This results mainly from the small value of d_x, 0.287 Å. The $R_C(v, 0)$ of the carbon atom of Q_2 is quite large.

From the above results, we estimated the intensity factor in two manners: (I) using only one term of Eq. (14), and (II) using all the terms of Eq. (14). Though we could not always expect a very large term

in Eq. (14), it is found in acetylene that ${}^{q_2}R_C(v,0)\cdot{}^{q_4}R_C(v,0)$ (Manner I) is much larger than the other terms. The intensity factors obtained are given in Table 6, where Eq. (17) is applied. The calculated relative intensities to C_1 are also given in Table 6. The accordances with the observed values are sufficiently satisfactory.[1)]

The oscillator-strength of the whole electronic transition is given by this relation:

$$f = f_v/R_L(v, 0)^2 \qquad (22)$$

where f_v is the observed oscillator-strength of the vth band. Then, the value of f obtained is 0.51 from v=5. This value is as large as that of an ordinary allowed electronic dipole transition.

Dideuteroacetylene. With dideuteroacetylene, in the transition to the ^1A_u state the spectra or the vibrational structures are generally similar to those of acetylene.[1,7)] That is, the C progression forms the main milestones of the spectra, with an interval of about 800 cm^{-1} between successive bands. However, the frequency intervals are so small that there is more overlapping of bands, and the band intensity is lower. Since the intensity of the C progression has not been measured, we calculate it only to compare the intensity factor of dideuteroacetylene with that of acetylene.

In this case, the equilibrium positions of the atoms of the excited state are obtained by taking β=16°40′ in Fig. 1. The fundamental frequencies of the A_g species have been reported to be at 844, 1310, and 2215 cm^{-1}. However, C_0 and C_1 have not been observed because of the low intensity, and we assumed 864 cm^{-1} as the CCD bending vibration. The normal coordinate analysis was carried out in the same manner as for acetylene. The calculated frequencies completely accord with the observed ones. The **L** matrix is given in Table 7, and the force constants in Table 8. The fundamental frequencies of the ground state are quoted from a reference.[6)] A good accordance of the observed frequencies with those calculated was obtained. The **L** matrix and the force constants are also given in Tables 7 and 8 respectively.

In the summation of Eq. (14), there are two normal coordinates for y, with frequencies at 505(Π_g) and 539.1(Π_u) cm^{-1}, and three for x, with frequencies at 2700.5(Σ_g^+), 2427.0(Σ_u^+) and 1762.4(Σ_g^+) cm^{-1}. In this instance, there are two cases of a large contribution to the overlap integral for y, while the other two

are negligibly small. The large ones are the $R_C(v, 0)$ of Q_4 and the $R_D(v, 0)$ of the deuterium atom of Q_5. They are given in Table 9, where Eq. (16) is applied. As for x of Eq. (14), all the overlap integrals are of the same order; only the values of the carbon and deuterium atoms of Q_2 are given in Table 9. They are fully considered in the calculation of the intensity factor, which is given in Table 10, where Eq. (17) is applied. The intensities relative to C_2 are also given in Table 10. The intensity factors of dideuteroacetylene are to some extent larger than those of acetylene. Since the observed band intensity of dideuteroacetylene is lower than that of acetylene, it is considered that the oscillator-strength of dideuteroacetylene is smaller than that of acetylene.

Discussion

The above results would seem to justify our method. As has been seen in the above discussion, it may be said that in Eq. (14) the wave function of the excited state is defined by the two-dimensional formula. This naturally causes overlaps with the corresponding wave functions of the ground state. A one-dimensional model of the Franck-Condon integral, that is, an explanation of Eq. (13), is given in Fig. 2, where the

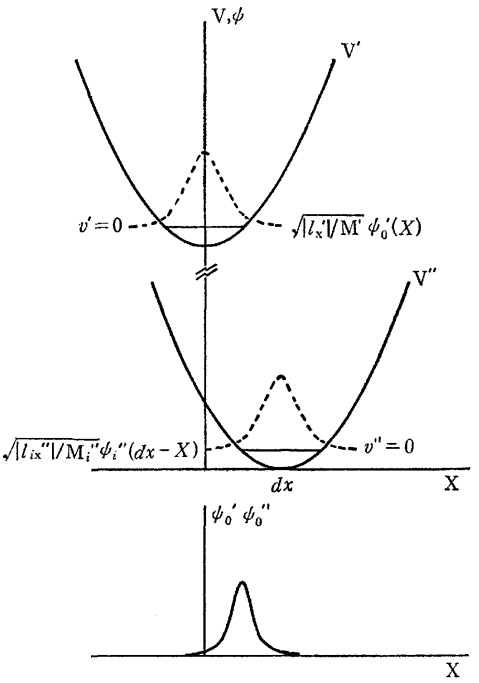

Fig. 2. One-dimensional model of the Franck-Condon integral for $R(0, 0)$.

$\psi_0''\psi_0'$ for $R(0,0)$ is also shown. The potential V' for y is similarly considered, though the V' for y is double minimum function, as has been described above. Actually V' and V'' are not generally on the same plane, as is shown in Fig. 2. That is, in the equilibrium position V' is on the plane separated by d_y perpendicular to the plane in Fig. 2. However, since the vertical transition in the Franck sense is the fundamental principle, V' and V'' should be on the same plane. In our treatment, the restriction is filled up by the overlap for y. The inverse consideration is realized. On the other hand, in Eq. (10) the above vertical transition could not be estimated precisely as it is.

The force constants of the ground state of acetylene agree satisfactorily with those of dideuteroacetylene. These values agree also with those given by Herzberg,[6] where the interaction term of the C–H with the C≡C bond is taken into consideration, *viz.*, I(C–H, C≡C)$=-0.037$ mdyn/Å in acetylene. The remaining differences are mainly due to the neglect of anharmonicity. The force constants of the excited state of acetylene are, to some extent, different from those of dideuteroacetylene. These differences may be caused mainly by using the same repulsive force constant in the isomer. Therefore, it is proper to use the other set of force constants to discuss the effect of force constants on the overlap integral; we do this for acetylene.

The new set (Set II) of the force constants of the excited state of acetylene is given in Table 3, where the repulsive force constant is assumed to be zero. The **L** matrix (Set II) of Q_3' is also given in Table 2. The intensity factors obtained by Manner I and the relative intensities are also given in Table 6. The intensity factors in Set II are, to some extent, larger than those in Set I, and the relative intensities are nearer to the observed ones. Thus, it is found that the small difference in the force constants does not have as much effect on the overlap integral.

Anharmonicity should be considered in the calculation of the overlap integral.[11] In a vibrational wave function of Morse oscillator, it is characteristic that there is asymmetry on the origin. This results in the differences of (1) the probability on both sides of the origin, and then (2) the distance from the origin at the same probability. To estimate the effect of (2) from the wave function of the harmonic oscillator, we assume this expression:

$$\alpha_v = 4\pi^2\nu_v/h \qquad (23)$$

where ν_v is the difference between the observed frequencies of the $v+1$ and vth bands.

The normal coordinate vector of Q_3' is shown in Fig. 3 by the broad solid arrow. It is generally considered that the nucleus in this phase responds to a smaller potential than in the inverse-phase. Therefore, in our assumption, the ν_v of the narrow solid arrow of the carbon atom decreases with an increase in v, and that of the broken arrow increases. In the case of the increase we assumed a regular increase of 15 cm^{-1}. The results obtained using Manner I

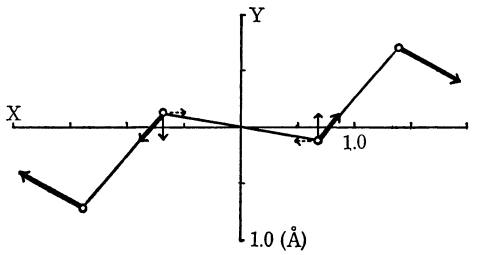

Fig. 3. The normal coordinate vector of Q_3' of the excited state of acetyleue. The vector for carbon atom is trebled.

TABLE 11. THE INTENSITY FACTORS AND THE RELATIVE INTENSITIES INVOLVING THE CONTRIBUTION OF ANHARMONICITY IN ACETYLENE

v	Intensity factors/10^{-5}	Relative intensities
0	0.00022	0.052
1	0.00424	1
2	0.0338	7.97
3	0.175	41.2
4	0.635	150
5	1.90	449

are given in Table 11. The intensity factors and the relative intensities are barely larger than those of Set I in Table 6. From Fig. 3, we can expect this to be a compensation for the increase and decrease in the overlap integrals of each coordinate. On the other hand, if the potential is the inverse of the above, results very similar to Set I in Table 6 are obtained; that is, complete compensations are found in this case. As a result, even if the precise wave function were used, a large change could not be expected in acetylene.

We wish to thank Dr. Y. Yasuda of the Faculty of Literature and Science of Toyama University for his valuable discussion of method.

Soret Coefficients and Heat of Transport of Polyvalent Electrolytes in an Aqueous Solution

Masayasu SUGISAKI

Department of Nuclear Engineering, Faculty of Engineering, Kyushu University, Fukuoka 812

(Received February 7, 1975)

The Soret coefficients of aqueous electrolytes were measured by the conductometric method for salts of K_2SO_4, Na_2SO_4, $ZnSO_4$, and $CdSO_4$ in the concentration range from 0.001 to 0.01 M at 25 °C and 35 °C. The heats of transport were calculated from the Soret coefficients. The concentration dependence of the heat of transport was ascertained to be proportional to the square root of the ionic strength, and the slopes for Na_2SO_4 and K_2SO_4 salts at 25 °C were found to be larger than those reported by Snowdon and Turner. The temperature dependence of the heat of transport was examined based on the data at 25 °C and 35 °C. The heat capacities concerning the transported entropy were found to be negative for the four salts examined.

In the basic construction of irreversible thermodynamics, Onsager's reciprocal relation plays an important role. Its validity has been checked experimentally by several investigators[1] by studying a diffusion phenomenon of a ternary system. In this phenomenon, a cross effect is due to coupling between diffusion fluxes. The another cross effect was observed in coupling of a heat flux and a diffusion flux. In this case, the concept of the heat of transport was introduced by using Onsager's reciprocal relation. There are several molecular interpretations of the heat of transport concerning the thermal diffusion of an electrolytic aqueous solution. Eastman[2] interpreted the heat of transport in terms of the interaction between ion and solvent; to his mind, the positive and negative values of the heat of transport were related to structure-forming and structure-breaking ions respectively. On the other hand, Helfand and Kirkwood[3] interpreted the heat of transport as being due to the interaction between ions; they based their consideration on the non-equilibrium statistical mechanics. They could derive the concentration dependence of the heat of transport as proportional to the square root of the ionic strength. Agar[4] studied the interaction of the ion-solvent in a hydrodynamical approximation and also derived a similar concentration dependence. In order to unify these molecular interpretations, the data in the heat of transport of an ion in several different solvents may be very useful. The temperature dependence of the heat of transport may also be expected to give important information, because the change in temperature necessarily gives rise to a change in the thermal motion of the solvent. The purposes of the present work are, first, to construct a thermal diffusion cell which can be used for the aqueous and non-aqueous electrolytes; second, to measure the temperature dependence of the heats of transport of several aqueous electrolytes, and finally, to discover some thermodynamical properties useful for the theoretical development of the molecular interpretation of the heat of transport.

Experimental

Apparatus. The arrangement of the cell is shown in Fig. 1. The solution was placed in a central cylindrical hole, 20 mm in inside diameter and 10 mm in height, drilled vertically in a polycarbonate plate. The ends of the hole

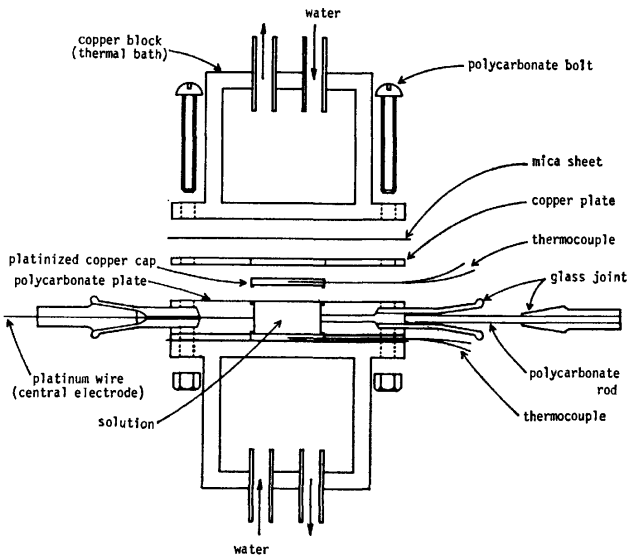

Fig. 1. Description of the cell.

are tightly covered by caps of platinized copper, which act as electrodes, secured with a small amount of epoxy resin adhesive. These platinized caps were faced to the copper blocks which were used as thermal baths, the temperature of each being maintained constant by circulating water from an external thermostat tank equipped with a mercury regulator. The temperature of each electrode was measured by means of a copper-constantan thermocouple embedded in the central part of the copper electrode. The cell was then filled, emptied, and washed out through a lateral hole, which had been closed by a polycarbonate rod during the measurement. The polycarbonate plate and the copper blocks were joined with four polycarbonate bolts. The total arrangement was especially designed to assure an uniform temperature distribution in the radial direction of a solution. This cell was set in an air thermostat and incorporated into an audio-frequency bridge with a Wagner earth operated between 900-1000 Hz/s. Thereading precision of the bridge was one part in 10^5.

Solution. Commercial extra pure salts were dried and weighed. The solution was prepared using conductivity water(specific resistance$> 10^6\ \Omega$ cm) purified by means of an ion-exchange resin column. The Na_2SO_4, $CdSO_4$, and $ZnSO_4$ were carefully dried in order to remove the water of crystallization completely.

Measurements. The concentration gradient in a solution induced by a thermal gradient was measured as a resistivity gradient of the solution. When the resistance of the

upper part of a solution is R'' and that of the lower part, R', the quantity, Y, was defined by this relation; $Y=(R'-R'')/(R'+R'')$. According to Agar and Turner[5], the Soret coefficient was calculated by means of the following relation;

$$Y_t - Y_0 = (bS\Delta T/4)[1-(32/\pi^3)\exp(-t/\theta)],$$
$$b = -[1+(\partial \ln \Lambda/\partial \ln C)].$$

Here, Y_0 and Y_t represent the initial value of Y and that at time t respectively and S the Soret coefficient; θ is called the relaxation time and is related to the interdiffusion coefficient by this equation; $\theta=a^2/(\pi^2 D)$. a is the height of the cell; D, the interdiffusion coefficient of a solution; Λ, the equivalent conductivity; C, the concentration of the solution, and ΔT, the temperature difference between the upper and lower ends of the solution. The measurements were performed as follows. First, the total cell was inversely set (*i.e.*, the lower-temperature side was upward, and the upper, downward), and the temperature gradient was applied in the solution by circulating water, the temperature of which was kept constant withinin ± 0.02 °C, into each thermal bath from the external thermostat tank. This state was held for about 1 hr to insure the stational temperature distribution in the cell. During this inverse setting the concentration gradient induced by ΔT was almost completely destroyed by the strong convective stream in the solution; the concentration of the solution was kept uniform in spite of the application of the temperature gradient. When the measurement was started, the direction of the cell was set normal by turning the cell (*i.e.*, the hot side was now up, and the cold, down); this instance was defined as time zero, t_0, and during the run of the thermal diffusion, Y_t was followed by means of the resistance bridge for a long time. The measurements were performed for the solutions of Na_2SO_4, K_2SO_4, $ZnSO_4$, and $CdSO_4$ in the concentration range from 0.001 to 0.01 M and at mean temperatures of 25 °C and 35 °C; the temperature difference, ΔT, applied across the solution was about 5 °C, which was determined within 0.01 °C for each thermal-diffusion run.

Results

Soret Coefficient. The Soret coefficient was determined from the slope of the curve of Y_t against exp$(-t/\theta)$, which is shown in the case of a 0.005 M solution of K_2SO_4 in Fig. 2. The interdiffusion coefficients, D, necessary for the calculation of the relaxation times, θ, are available in the literature at 25 °C and 35 °C for K_2SO_4[6] and at only 25 °C for Na_2SO_4.[7] Therefore for the analysis for Na_2SO_4 at 35 °C it was assumed that the D_{35}/D_{25} ratio is the same as the ratio for K_2SO_4. For the calculation of θ for $ZnSO_4$ and $CdSO_4$, the integrated interdiffusion coefficients were used; they were measured by the diaphragm-cell method for 0.01 M salt diffusing into water.[8]

In some experiments the plot of Y_t against exp$(-t/\theta)$ showed a deviation from linearity at high values of exp$(-t/\theta)$. Since such lack of a linearity resulted from convective mixing,[5] the determination of the Soret coefficient was performed by using the linear relation at lower values of exp$(-t/\theta)$. The Soret coefficients thus obtained are summarized in Table 1, while the data which were necessary for the calculation summarized in Table 2.

Heat of Transport. The heat of transport is defined by irreversible thermodynamics[1] as:

$$\hat{Q} = RT^2(\nu_1+\nu_2)\left(1+\frac{\partial \ln \gamma}{\partial \ln m}\right)S.$$

Here, $\hat{Q}$ stands for the heat of transport; ν_1, and ν_2 the stoichiometric numbers of ions of Species 1 and 2 when the salt is dissociated in a solution; γ, the activity

coefficients, and m, the molality. For the calcultaion it is necessary to have the values of $(1+\partial\ln\gamma/\partial\ln m)$, which are available in the literature for all solutions at 25 °C.[9] The data at 25 °C cited in Table 2 were also used for the analysis at 35 °C, because the experimental results show that the temperature dependence of $(\partial\ln\gamma/\partial\ln m)$ is not very large. The obtained heats of transport are summarized in Table 1.

Disscussion

Calculation of the Soret Coefficient. In the present experiment a deviation from linearity was often observed in the plot of Y_t against exp $(-t/\theta)$ in the latter half of the thermal-diffusion run when θ was calculated by using the interdiffusion coefficient data. If θ was adjusted so that the linearity of the plot of Y_t against exp $(-t/\theta)$ held, its value tended to become smaller than that calculated from the isothermal interdiffusion data. Agar and Turner[5] and Sagert and Breck[10] observed similar situations and interpreted them as being due to the convective mixing. Since such convective interference could be considered to be very small in the earlier stage of the thermal diffusion run, where the concentration gradient induced by the temperature gradient has not yet become very large, the initial linear part of the plot of Y_t against exp $(-t/\theta)$ was adopted to calculate the Soret coefficients in Table 1.

The Soret coefficients and the heats of transport of the present three salts of K_2SO_4, Na_2SO_4, and $CdSO_4$ were measured at 25 °C by Snowdon and Turner[11]; their values agree with those of the present work in the range of concentrations near 0.002 M for K_2SO_4 and 0.01 M for Na_2SO_4, but the concentration dependences do not agree with each other (see Figs. 3 and 4). These discrepancies in the concentration dependence of $\hat{Q}$ may result from the unreliable estimation of the convective interference, since we could not determine unambiguously the instant from which the convective mixing began to have appreciable influence on the construction of the concentration gradient. In fact, the Soret coefficient varied in a range of about 5 per cent depending upon the method used to estimate the linearity of the plot of Y_t against exp $(-t/\theta)$. It should be noted, however, that the precision of the reproducibility of the measurement is within 1 per cent. Therefore, the values of the Soret coefficient and the heat of transport summarized in Table 1 may involve an ambiguity of only a few per cent. In the case of the $CdSO_4$ solution, the two sets of data agree with each other, as is shown in Fig. 5. This agreement is significant because the Soret coefficient of the dilute $CdSO_4$ solution obtained by the conductivity method has been ascertained to be smoothly related to that of a higher concentration measured by a optical method.[11]

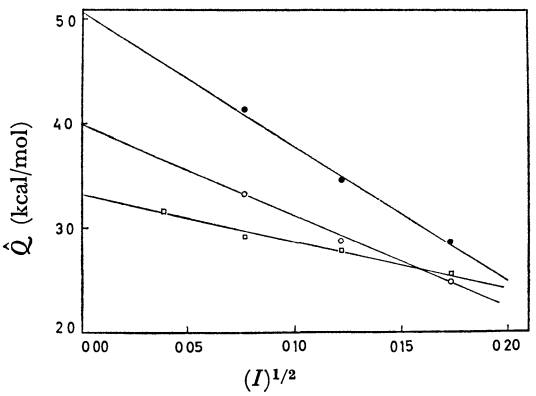

Fig. 3. The concentration dependence of the heat of transport of Na_2SO_4 solution at 25 °C and 35 °C. The open and filled circles represent the present work at 25 °C and 35 °C, respectively. The rectangles stand for the data of Snowdon and Turner at 25 °C.

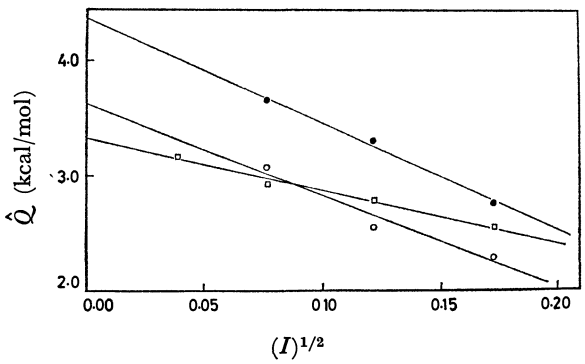

Fig. 4. The concentration dependence of the heat of transport of K_2SO_4 solution at 25 °C and 35 °C. The open and filled circles represent the present work at 25 °C and 35 °C, respectively. The rectangles stand for the data of Snowdon and Turner at 25 °C.

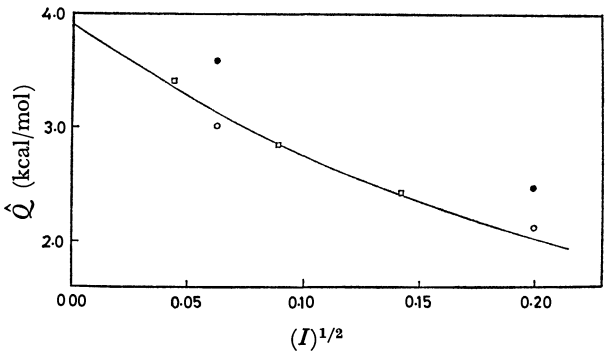

Fig. 5. The concentration dependence of the heat of transport of $CdSO_4$ solution at 25 °C and 35 °C. The open and filled circles represent the present work at 25 °C and 35 °C, respectively. The rectangles stand for the data of Snowdon and Turner at 25 °C.

Concentration Dependence of $\hat{Q}$. Agar[4] developed Eastman's idea of the molecular interpretation of $\hat{Q}$ and derived the concentration dependence of $\hat{Q}$ as proportional to the square root of the ionic strength. He could calculate the slope of the concentration dependence of $\hat{Q}$ at 25 °C in the dilute range for the 1 : 2 electrolyte as;

$$\hat{Q}_0 - \hat{Q} \approx 7500\sqrt{I}.$$

where $\hat{Q}_0$ is the value of $\hat{Q}$ at an infinite dilution, and I, the ionic strength.[4] The present results for the two alkali sulfates indicate that the $\hat{Q}_0-\hat{Q}$ varies from about $800\sqrt{I}$ for K_2SO_4 to about $900\sqrt{I}$ for Na_2SO_4. The slopes of the present results are larger than those reported by Snowdon and Turner[11] and are rather nearer to the above theoretical results. This agreement, however, must not be overestimated because of the crude approximation of the theory.

Temperature Dependence of $\hat{Q}$. The temperature dependence of $\hat{Q}$ has been studied by Alexander[12] and Agar[4] and some thermodynamical quantities has been defined. The transported entropy, $\bar{\bar{S}}$, was defined as;

$$\bar{\bar{S}} = \hat{S} + s.$$

where $\hat{S}$ stands for the entropy of transport, and s, partial molar entropy. $\hat{S}$ can be related to the heat of transport, $\hat{Q}$, by $\hat{S}=\hat{Q}/T$. The "heat capacities", $\hat{C}$ and $\bar{\bar{C}}$ were also defined as;

$$\hat{C} \equiv T(\partial\hat{S}/\partial T) = (\partial\hat{Q}/\partial T) - (\hat{Q}/T)$$

$$\bar{\bar{C}} \equiv T(\partial\bar{\bar{S}}/\partial T) = C + C_p.$$

where C_p represents the ordinary partial molar heat capacity at a constant pressure. $\bar{\bar{C}}$ can be calculated from the experimental results of the heat of transport at 25 °C and 35 °C. The C_p values for Na_2SO_4 and K_2SO_4 solutions are available in the literature.[13] The C_p values for $ZnSO_4$ and $CdSO_4$ solutions were calculated from the previously reported data of the heat capacity of the solution at 19 °C.[14,15] As the temperature dependence of the C_p of solution is not usually so large, using the data at 19 °C for the present analysis may not produce any significant error. The results are shown for the 0.01 M solution in Table 3, which shows that the values of $\bar{\bar{C}}$ are negative for all the present four salts. This result forms a striking contrast to the cases of many 1 : 1 salts summarized by Agar[4], in which the values of $\bar{\bar{C}}$ are all positive. The fact that the values of $\bar{\bar{C}}$ are positive in the cases of such alkali halides as NaCl and KCl suggests that the negative values of $\bar{\bar{C}}$ for Na_2SO_4 and K_2SO_4 may be attributed to the SO_4^{2-} ion. By summarizing many data, Tyrrell[16] showed that the contribution of the entropy of transport, $\hat{S}$, to the transported entropy, $\bar{\bar{S}}$, is relatively small as compared with the partial molar entropy, s, and that there is a good correlation between the transported entropies and the conventional partial molar standard ionic entropy except for the cases of H^+, OH^-, and SO_4^{2-}, which have larger transported entropies in spite of their small values of s relative to other cations and anions.

TABLE 3. "HEAT CAPACITIES", $\hat{C}$, C_p AND $\bar{\bar{C}}$ (cal/mol·K) FOR 0.01 M SOLUTION AT 25 °C

Salt	$\hat{C}$	C_p	$\bar{\bar{C}}$
Na_2SO_4	34.8	−42.2	−7.4
K_2SO_4	37.0	−54.7	−17.7
$ZnSO_4$	33.3	−55	−22
$CdSO_4$	36.8	−61	−24

These two exceptional aspects of the behavior of SO_4^{2-} ion may be explained in terms of the interaction between ion and solvent. The theory by Helfand and Kirkwood based on the non-equilibrium statistical mechanics may be so rigorous that it is difficult to include such a solvation effect of an ion in the theory. On the other hand, the interpretation originated by Eastman and developed by Agar, while it is phenomenological and less rigorous from the viewpoint of non-equilibrium statistical mechanics, yet has the merit of giving a simple insight into the physical significance of the approximation involved in the theory. Consequently, it would be better to examine the ion-ion contribution to the heat of transport as rigorously as possible by the theory of Helfand and Kirkwood, and to discuss the interaction between ion and solvent by the theory based on Eastman's idea: the heat of transport must be considered as a sum of those contributions.

The author would like to express his thanks to Professor Yasumichi Oishi for his useful advice in this work. Thanks are also due to Messrs. Hideyuki Moriyama, Munanori Tanemura, and Fumihiro Otsubo for their technical assistance.

Activity Measurement and Colloid Chemical Studies of Aqueous Sodium Tetradecyl Sulfate Solutions

Masakatsu KOSHINUMA* and Tsunetaka SASAKI

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received February 25, 1975)

A concentration cell using an ion-exchange semipermeable membrane as a septum for the measurement of the activities of ionic surfactants has been constructed, the method of measurement is here in described. The membranes used proved each to be exclusively permeable to one ion. The activities of both the tetradecyl sulfate ion (TS^-) and the counterion (Na^+) were determined. In the concentration region from 4.0×10^{-4} mol/l to CMC, $\log f_\pm = -(0.070 \log C + 0.283)$ held for the mean activity coefficient, $f_\pm$. The $f_\pm$ value at the CMC was found to be 0.81, considerably smaller than the value, 0.978, calculated by the Debye-Hückel equation taking account of the ionic size, 5.5 Å. Above the CMC the activity of the TS^- ion decreased, that of the Na^+ ion increased, and the mean activity slightly increased with the NaTS concentration. The Gibbs adsorption isotherm was applied for the adsorption of NaTS, using exclusively the observed data of the amount of adsorption, the surface tension, and the activities. A satisfactory agreement was obtained between the amount of adsorption observed and that calculated. The observed decrease in the surface tension above the CMC was confirmed by calculations using the Gibbs adsorption iostherm, the observed data of activity, and the amount of adsorption. The charged-phase separation model was verified as the mechanism of the micelle formation, and the degree of counterion attachment was calculated to be 0.81.

In order to elucidate various properties of the surfactants, such as the adsorption, the micelle formation, the solubilization, the dispersibility, the emulsification, and the detergency, the study of the activity of the aqueous surfactant solutions is important as a basis. However, there have been few such reports[1–5] because of the difficulty of measurement at the low concentrations where surfactants are generally used and of the inevitable error involved in the method of measurement. Amoung the various methods of measurements,[4–7] that of the electromotive force of a concentration cell with an ion-exchange membrane semipermeable to a surfactant anion has proved effective, and one of the present authors has previously applied this method to the study of sodium dodecylsulfate.[8] The activity measurement of the ionic surfactant requires those of both the surfactant ion and the counterion; in the case of the anionic surfactant, the counterion activity can be measured also by means of a pNa-responsive electrode.[8–10] The measurements of the activities of both ions by the concentration cells using anion and cation-exchange membranes are also possible.[1,2] In the present paper, the activities of both the surfactant anion and the counterion were measured for aqueous sodium tetradecyl sulfate solutions by the EMF measurement of the concentration cell with an ion-exchange membrane, which had been specially constructed to prolong the life of the membrane and to obtain reproducible results. The activity coefficients were calculated for sodium tetradecyl sulfate, which was selected as a surfactant for comparison with the sodium dodecyl sulfate (NaDS) already reported,[8] in order to study the effect of the change in the hydrophobic chain length on various properties of the aqueous solution.

The surface tension and the amount of adsorption were also measured by the Wilhelmy plate method and the radiotracer method respectively. From these results, the applicability of the Gibbs adsorption isotherm was examined with the results obtained below the CMC.[11–13] The mechanism of the micelle formation and the surface tension lowering above the CMC were also discussed. Moreover, the counterion attachment of the micelle was calculated and compared with that of NaDS.

Experimental

Materials. For the preparation of sodium tetradecyl sulfate (NaTS), 99% tetradecyl alcohol, obtained by fractional distillation and its purity checked by gas chromatography (apparatus : Yanagimoto GC G-3DH), was sulfated with chlorosulfonic acid and neutralized with an aqueous sodium hydroxide solution. The inorganic salts thus formed were removed, and the product was then recrystallized several times from ethanol. To remove the unreacted tetradecyl alcohol, extractions with ether were continued until the minimum in the surface tension *vs.* concentration curve disappeared. The tritium-labelled sodium tetradecyl sulfate used for the adsorption measurement was synthethesized much[14] as has previously been reported.[13] Deionized water was used for the EMF measurement, and thrice-distilled water, for the surface-tension and absorption measurements. The ion-exchange membranes used for the surfactant-ion and Na^+-ion activities were an anion exchanger, Neosepta AV-4T, and a cation exchanger, Neosepta CL-25T, both supplied by the Tokuyama Soda Co., Ltd.

Apparatus and Measurements. *Adsorption*: The amounts of adsorption were measured by means of a thin-window gas-flowing tube devised for soft β-ray radioactivity measurements.[15]

Surface Tension: The surface tension was measured by Wilhelmy's vertical plate method using a strain gauge as a transducer; the steady value recorded after 4 hr was regarded as an equilibrium value.[16] The error in the surface-tension measurement was ±0.05 dyne/cm for a glass plate 4 cm in perimeter.

Electromotive Force Measurement: The anion- and cation-exchange membranes used for the activity measurment were stored in an aqueous 0.5 M-NaCl solution. They were then rinsed with water and soaked in an aqueous 10.0×10^{-3}

mol/l NaTS standard solution for two or three days in order to replace all of the exchangeable ions with TS^- or Na^+ ions. The membranes were then rinsed with deionized water and immediately fixed to the cells. The concentration cell shown in Fig. 1, which had been improved from a former one, was constructed as in illustratd in Fig. 2. In this figure, a U-shaped cell, A, with flanges held an ion-exchange membrane, B, with the aid of silicon rubber washers, C. They were tightly fixed between aluminum frames, E. Water evaporation from the open edge of the ion-exchange membranes, causing craks in the film and reducing the life of the membrane, was avoided by sealing the edge with low-melting-point paraffin, as is shown by D. A sample solution and the standard NaTS solution were introduced separately into the two chambers of A, one on either side of the membrane. The aqueous 10.0×10^{-3} mol/l NaTS solution was chosen as the standard solution because the change in the concentration of the standard solution in this region gave the relative insensitivity of the EMF. Each of the two calomel electrodes, H, was connected through 1 M-NH_4NO_3 agar bridges, F, to the solutions in A. Two-percent agar was used to prepare the bridges, and NH_4NO_3 was used to avoid the direct contact of NaTS with the KCl of the calomel, which would form insoluble potassium tetradecyl sulfate. Measurements of the EMF were made by using a high-impedance electrometer, Keithly model 610 C, with an input impedance of more than 10^{14} ohm, in an air-thermostated box at 32 ± 1 °C; the EMF was recorded on a recorder of the Riken Electronic Co., Ltd., model SP-5. Both the chambers of A were filled with the same aqueous 10.0×10^{-3} mol/l NaTS solution, and they were renewed several times until the asymmetry potential (E_{as}) became constant. Each chamber was rinsed several times with each solution to be measured before the setting of the cell. Then, the solution in one chamber of A was replaced by the NaTS solution to be measured; the recording of the potential was started about 20 min after the setting. A steady EMF, E_1, was usually obtained 20 min after the setting and kept constant for about 20 min, after which it gradually decreased. The E_{as} value was confirmed to be nearly constant during each measurment. The potential, E, of the concentration cell is obtained as:

$$E = E_1 - E_{as}$$

When not in use, both chambers of the cell, A, were filled with the standard solution and the cell was placed in a vessel saturated with the vapor of the standard solution in order to avoid any evaporation of the solution in the cell and any change in the membrane properties. The membrane thus protected could be used continuously for about two weeks before the renewal of the membrane.

Results and Discussion

Calculation of Activity. The EMF of the concentration cell using a membrane permeable to the TS^- ion is given according to Nernst's equation as follows:

$$E_{TS} = (\lambda_- - \lambda_+)(2.303\,RT/F)\log(a_{TS}/a_{O,TS}) \quad (1)$$

where λ_+ and λ_- are the transport numbers of the TS^- and Na^+ ions in the membrane respectively: a_{TS} and $a_{O,TS}$, the activities of the TS^- ion in the sample and the standard solutions respectively: F, the Faraday constant: R, the gas constant, and T, the absolute temperature. To determine the activity from Eq. (1), the values of λ_- and λ_+ must be estimated. The evaluation of $\lambda_- - \lambda_+$, usually made by referring to ions of known activities, is impossible in the present experiment because no activity coefficient data are available, but we have several reasons to believe that $\lambda_- - \lambda_+$ is close to unity. First, the differenciation of Eq. (1) with respect to log C gives:

$$dE_{TS}/d\log C = (\lambda_- - \lambda_+)(2.303\,RT/F)(d\log a_{TS}/d\log C) \quad (2)$$

where C is the concentration of NaTS. In Eq. (2), since $dE_{TS}/d\log C$ is found to be nearly equal to $2.303\,RT/F$ in the concentration range from 4.0×10^{-4} to 2.0×10^{-3} mol/l, Eq. (2) gives:

$$(\lambda_- - \lambda_+)\, d\log a_{TS}/d\log C = 1$$

Since $d\log a_{TS}/d\log C$ is considered to be not larger than unity for such dilute solutions as in the present experiment, $\lambda_- - \lambda_+$ is expected to be nearly equal or larger than unity. However, from the definition, $\lambda_- + \lambda_+ = 1$. In order to satisfy both of these requirements, $\lambda_- = 1$ and $\lambda_+ = 0$ must hold, so $\lambda_- - \lambda_+$ may reasonably be taken to be close to unity. Moreover, as will be discussed below the linearity of the extrapolation function down to low concentrations of the NaTS solution, as is shown in Fig. 3, and the agreement between the calculated and observed amounts of the NaTS adsorption (Fig. 6) also indicate that $\lambda_- - \lambda_+$ may safely be taken to be unity. Thus, Eq. (1) is reduced to:

$$E_{TS} = (2.303\,RT/F)\log(a_{TS}/a_{O,TS}) \quad (3)$$

According to similar reasoning and similar observed data, the conditions of $\lambda_- = 0$ and $\lambda_+ = 1$ also hold for the cation-exchange membrane in the concentration range from 3.0×10^{-4} to 2.0×10^{-3} mol/l, and the EMF of the Na^+-ion concentration cell is given by:

$$E_{Na} = -(2.303\,RT/F)\log(a_{Na}/a_{O,Na}) \quad (4)$$

where $a_{O,Na}$ is the activity of the Na^+ ion in the solution of the standard electrode.

Experimental results of the EMF *vs.* concentration curve are expressed by Eqs. (3) and (4). In order to calculate the values of $a_{O,TS}$ and $a_{O,Na}$, the following extrapolation function, E', is constructed:[17]

$$E'_{TS} = (2.303\,RT/F)\log C - E_{TS} \quad (5)$$

The substitution of Eq. (3) into Eq. (5) gives:

$$E'_{TS} = (2.303\,RT/F)(\log C - \log a_{TS} + \log a_{O,TS})$$
$$= (2.303\,RT/F)(-\log f_{TS} + \log a_{O,TS})$$

Since $f_{TS} = 1$ for $C = 0$, the value of E'_{TS} extrapolated to $C = 0$ gives:

$$E'_{TS,C=0} = (2.303\,RT/F)\log a_{O,TS}$$

from which $a_{O,TS}$ can be calculated. The activity, $a_{O,Na}$, is similarly calculated from the corresponding function, E'_{Na}. Figure 3 shows the E'_{TS} and E'_{Na} *vs.* $C^{1/2}$ plots and their extrapolation. The activities calculated, $a_{O,TS}$ and $a_{O,Na}$, are:

$$\log a_{O,TS} = -3.018 \text{ and } \log a_{O,Na} = -2.556$$

The a_{Na} and a_{TS} values calculated according to Eqs. (3) and (4) are shown in Fig. 4, together with the mean activity calculated by means of this definition:

$$a_\pm = (a_{TS}\cdot a_{Na})^{1/2} \quad (6)$$

The activity coefficient, $f_\pm$, calculated from the $a_\pm$ thus obtained was nearly unity at the concentration of 1.5×10^{-4} mol/l, and it gradually decreased with an increase in the concentration. In the concentration region from 4.0×10^{-4} to 2.0×10^{-3} mol/l (CMC),

$$\log f_\pm = -(0.070\log C + 0.283) \qquad C;\ \text{mol/l}$$

holds. It is noted that the mean activity coefficient at the CMC was found to be 0.81, considerably smaller than the value, 0.978, calculated according to the modified equation of Debye-Hückel using the mean ionic diameter of 5.5 Å.[18] Such a difference is similar to the cases of cetyltrimethylammonium bromide[19] and sodium dodecyl sulfate.[8] It may be explained by the effect of the long hydrophobic chain in the molecule, which is neglected in the Debye-Hückel equation, or by the so-called "premicelle" formation.[20]

Above the CMC the activity of the TS^- ion was found to decrease, while that of the Na^+ ion increased with an increase in the concentration of the surfactant. As a result, the mean activity is not constant, as has been stated,[21] but slightly increases, as in the case of sodium dodecyl sulfate.[8] It should be noticed that the linearity of the extrapolation functions, E'_{TS} and E'_{Na}, observed down to a low concentration, C, proves $\lambda_- - \lambda_+$ and $\lambda'_+ - \lambda'_-$ to be unity for the anion- and cation-exchange membranes. This is because, for instance, Eqs. (1), (3) and (5) give:

$$E'_{TS} = (2.303\,RT/F)\{(1-\Delta)\log C - \Delta\log f_{TS} + \log a_{O,TS}\}$$

where $\Delta = \lambda_- - \lambda_+$. This equation means that, for $\Delta \neq 1$, the $(1-\Delta)\log C$ term becomes infinity at $C = 0$: a marked deviation from the linearity may be expected as tending to zero, but the linear plots of E'_{TS} down to low C values may exclude such a possibility. A similar argument can be made for the cation-exchange membrane.

Application of the Gibbs Adsorption Isotherm. The Gibbs adsorption isotherm was used to calculate the amount of adsorption, putting only the observed data of surface tension and activities into the isotherm; the values were then compared with the observed amounts of adsorption for NaTS at the surface of an aqueous solution. The amount of adsorption was calculated according to the Gibbs adsorption isotherm:

$$\Gamma = -(1/2.303RT)(d\sigma/d\log C)/\{(d\log a_{TS}/d\log C) + (d\log a_{Na}/d\log C)\} \quad (7)$$

by putting the $d\log a_{TS}/d\log C$, $d\log a_{Na}/d\log C$, and $d\sigma/d\log C$ values, which were obtained from Fig. 4 and from the surface tension *vs.* $\log C$ plots in Fig. 5 respectively, into Eq. (7). Figure 6 shows the calculated value of Γ by a solid line and the observed value obtained by the radiotracer method, by circles. A

satisfactory agreement was obtained between them, and the saturate value of Γ was found to be 3.21×10^{-10} mol/cm². It should be noted that the agreement obtained here is another evidence that the $\lambda_- - \lambda_+$ value for the anion-exchange membrane is unity and that the $\lambda'_+ - \lambda'_-$ value for the cation-exchange membrane is also unity, since the introduction of $\lambda_- - \lambda_+$ and $\lambda'_+ - \lambda'_-$ values less than unity reduces the calculated Γ values according to:

$$\Gamma = -(1/2.303RT)(\mathrm{d}\sigma/\mathrm{d}\log C)/\{(\mathrm{d}\log a_{\mathrm{TS}}/(\lambda_- - \lambda_+)\mathrm{d}\log C + (\mathrm{d}\log a_{\mathrm{Na}}/(\lambda'_+ - \lambda'_-)\,\mathrm{d}\log C\}$$

from that calculated by Eq. (7), and this causes a disagreement between the calculated and the observed values. That the values of λ_- and λ'_+ are unity and the observed activity of NaTS are thus confirmed to be valid.

The value calculated assuming the activity coefficient to be unity is shown as a broken line in Fig. 6. The agreement between these values and the observed ones is not so good as in the case of Γ calculated in terms of the activity data, but the deviation is not very large. Thus, the assumption of $f_\pm = 1$ often made proves invalid in this case also.

Calculation of the Surface Tension above the CMC. As is shown in Fig. 5, the surface tension of the NaTS solution above the CMC is not constant, but gradually decreases with an increase in the concentration of the surfactant. It is worthwhile to confirm the validity of the observed a_{TS} and a_{Na} values by comparing the surface tension observed and that calculted from the Gibbs adsorption isotherm using these activity data and the observed Γ values above the CMC. For this purpose, the following equation is used:

$$\sigma = \sigma_{\mathrm{CMC}} - 2.303RT\Gamma_{\mathrm{CMC}}\{(\mathrm{d}\log a_{\mathrm{TS}} + \mathrm{d}\log a_{\mathrm{Na}})_C - (\mathrm{d}\log a_{\mathrm{TS}} + \mathrm{d}\log a_{\mathrm{Na}})_{\mathrm{CMC}}\} \quad (8)$$

which is obtained by the integration of the Gibbs adsorption isotherm:

$$\mathrm{d}\sigma = -2.303\,RT\Gamma(\mathrm{d}\log a_{\mathrm{TS}} + \mathrm{d}\log a_{\mathrm{Na}})$$

from the CMC up to the C concentration, taking account of the fact that the amount of adsorption observed above the CMC, Γ_{CMC}, was constant (3.21×10^{-10} mol/cm²), as is shown in Fig. 6. The surface tension calculated according to Eq. (8) is shown by circles in Fig. 7, where the observed value is indicated by a solid line. The agreement as a whole is good, just as in the case of sodium dodecyl sulfate.[8] Thus, the observed decrease in the surface tension, together with the observed a_{Na}, a_{TS} and $a_\pm$ values above the CMC may be comfirmed as valid. It is emphasized that the calculation of σ needs no assumption such as is necessary in the case of the calculation by the mass-action law.[22]

Micelle Formation and Degree of Counterion Attachment. As has been mentioned,[8] the mechanism of micelle formation by the mass-action law[22-24] gives:

$$a_{\mathrm{M}}/(a_{\mathrm{TS}})^p(a_{\mathrm{Na}})^q = K$$

or

$$p\log a_{\mathrm{TS}} + q\log a_{\mathrm{Na}} = \log a_{\mathrm{M}}/K \neq \text{const.} \quad (9)$$

where a_{M} denotes the activity of micelles composed of p TS^- ions and q Na^+ ions.

On the other hand, the phase-separation model[25]

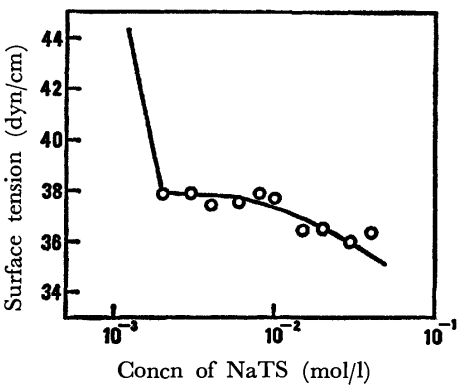

Fig. 7. Observed and calculated surface tension above CMC.
○: Surface tension calculated. ——: Surface tension observed.

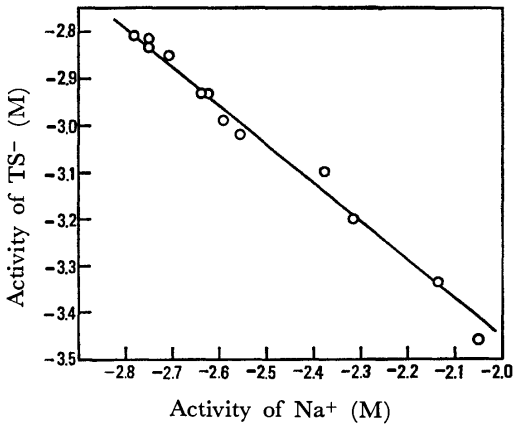

Fig. 8. $\log a_{TS}$ *vs.* $\log a_{Na}$ above CMC.

gives:

$$(a_{TS})^p(a_{Na})^q = a_M = \text{const.}$$

or

$$p \log a_{TS} + q \log a_{Na} = \text{const.} \quad (10)$$

where $p=q$ represents the uncharged-phase separation model, and $p \neq q$, the charged-phase separation model, respectively.

The plots of $\log a_{TS}$ against $\log a_{Na}$ are shown in Fig. 8. As is shown in the figure, a linear relation with $p \neq q$ is obtained; this proves that the charged-phase separation model is valid, just as in the case of sodium dodecyl sulfate.[8] The value of $p/q=0.81$ obtained as the degree of counterion attachment is somewhat larger than the latter. Though such a tendency is theoretically to be expected, it is significant that it is experimentally confirmed by reliable data. Similar results are also obtained in the system of NaTS in ethanol-water mixtures of various compositions, they will be reported in the following paper.

The gradual increase in $a_{\pm}$ with the surfactant concentration is expressed from Eqs. (6) and (10) with $p/q=0.81$ as:

$$a_{\pm} = K^{1/2}(a_{Na})^{0.095} \quad (11)$$

According to Eq. (11), $a_{\pm}$ slowly increases as a_{Na} increases, that is, with an increace in the concentration of the surfactant.

The Pressure Broadening of the Cadmium-resonance Line at 326.1 nm in Ammonia and Argon

Hironobu UMEMOTO, Shunzo YAMAMOTO, and Shin SATO

Department of Applied Physics, Tokyo Institute of Technology, Ookayama, Meguro-ku, Tokyo 152

(Received March 14, 1975)

The ratio of the collison-broadening cross-section of ammonia to that of argon for the cadmium-resonance line at 326.1 nm has been estimated to be 2.1 by comparing the experimental data of the transmission measurement with the theoretically calculated numerical table. The table shows the relation between the transmission of a resonance line passing through the system containing absorbing atoms and the ratio of the Lorentz half-breadth to the Doppler half-breadth at different values of two parameters; the optical density, and the ratio of the Doppler half-breadth of the emission line to that of the absorption line. This table may have universal importance for the study of the absorption of atomic spectra.

It is well known from experiments that atomic spectral lines have an observable breadth and are not so sharp as the simple quantum theory predicts. Such broadenings of spectral lines may be classified into four types: natural broadening, Doppler broadening, pressure broadening, and the broadening due to isotopes or hyperfine interaction. If a strong electric or magnetic field is present, the Stark and the Zeeman effects also have to be taken into account.

One of the most fundamental problems in the study of the reactions photosensitized by a certain atom is the quantitative estimation of the light intensity absorbed by the atoms. This quantity is seriously affected by the ratio of the Doppler half-breadth of the emission line to that of the absorption line. This ratio is denoted by α in the treatment of Zemansky.[1] If the optical density, $k_0(\nu_0)l$, at the maximum of the resonance line in the absence of pressure broadening is known, the intensity of the transmitted light is expressed as a function of the ratio of the Lorentz half-breadth to the Doppler half-breadth of the absorption line of the atoms in the system for a given value of α. Yang discussed this effect extensively in the particular case of mercury photosensitization.[2] Experimentally, such an effect has usually been avoided by using an appropriate actinometer or by diluting the system with a large amount of an inert gas which has a negligible quenching cross-section for the excited atoms under consideration.

In this investigation, we attacked two problems. One was the making of a numerical table of the relation between the transmission, T, and the ratio of the Lorentz half-breadth to the Doppler half-breadth at various values of α and $k_0(\nu_0)l$. This table has universal importance for the measurement of atomic spectra. The other was the determination of the collision-broadening cross-sections of ammonia and argon for the cadmium-resonance line at 326.1 nm by using the table obtained above.

Calculation

In order to discuss the pressure dependence of the transmission in terms of line broadening, it is necessary to know the shapes of the emission and absorption lines. Here, the emission line is taken to be a Doppler broadening:

$$E(\nu) = C\exp[-(\omega/\alpha)^2] \tag{1}$$

where C is a constant and where

$$\omega = 2(\nu-\nu_0)\sqrt{\ln 2}/\Delta\nu_D$$

$$\alpha = \Delta\nu_E/\Delta\nu_D$$

Here, $\Delta\nu_D$ denotes the Doppler half-breadth of the absorption line, while $\Delta\nu_E$ is that of the emission line. ν_0 is the frequency at the center of the emission line. The absorption coefficient is taken to be a type combining the Doppler broadening and the Lorentz broadening, ignoring natural broadening.[3]

$$k(\nu_0) = k_0(\nu_0)\frac{a}{\pi}\int_{-\infty}^{+\infty}\frac{\exp(-y^2)}{a^2+(\omega-y)^2}dy \tag{2}$$

where

$$a = \Delta\nu_L\sqrt{\ln 2}/\Delta\nu_D \tag{3}$$

$\Delta\nu_L$ is the half-breadth of the Lorentz broadening. $k_0(\nu_0)$ is the absorption coefficient at the maximum of the absorption line in the absence of the Lorentz broadening and may be estimated by means of the following equation.[3]

$$k_0(\nu_0) = \frac{\lambda_0^3 g_2 N}{8\pi^{3/2} g_1 \tau_0 v_0} \tag{4}$$

Here, λ_0 is the wavelength at the center of the absorption line, g_1 and g_2 are the degeneracies of the lower and upper levels, τ_0 is the lifetime, v_0 is the most probable velocity of the atoms, and N is the atomic density. Then, the transmission, T, is expressed as follows:

$$T = \frac{\int_{-\infty}^{+\infty}\exp[-(\omega/\alpha)^2]\exp\left[-k_0(\nu_0)l\frac{a}{\pi}\int_{-\infty}^{+\infty}\frac{\exp(-y^2)}{a^2+(\omega-y)^2}dy\right]d\omega}{\int_{-\infty}^{+\infty}\exp[-(\omega/\alpha)^2]d\omega} \tag{5}$$

The T values were calculated at various α, a, and $k_0(\nu_0)l$ values by using a Facom 230-75 computer. The evaluation of the numerator was carried out using Simpson's formula, with a mesh of 0.05, and the upper and lower limits of integral were taken to be ± 16. The denominator is equal to $1.7725\,\alpha$. The following is the range of parameters used for the calculations. α: 1.0~4.5, a: 0.05~7.0, and $k_0(\nu_0)l$: 0.001~99.999. A part of the results are shown in Figs. 1—4.

The general features of the calculated results may be summarized as follows:

i) The transmission, T, decreases with the increase in the optical density, $k_0(\nu_0)l$. This is a matter of course.

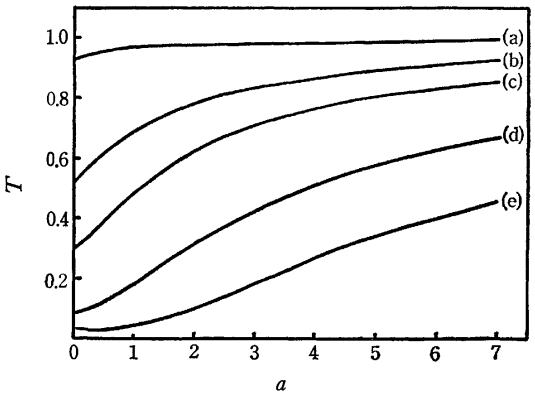

Fig. 1. Relation of the calculated transmission to the value of a with several values of optical density in the case of $\alpha=1$.
The optical density is equal to (a): 0.1, (b): 1.0, (c): 2.0, (d): 5.0, (e): 10.0.

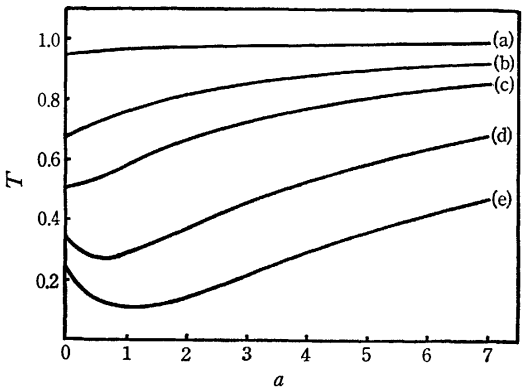

Fig. 2. Relation of the calculated transmission to the value of a with several values of optical density in the case of $\alpha=2$.
The optical density is equal to (a): 0.1, (b): 1.0, (c): 2.0, (d): 5.0, (e): 10.0.

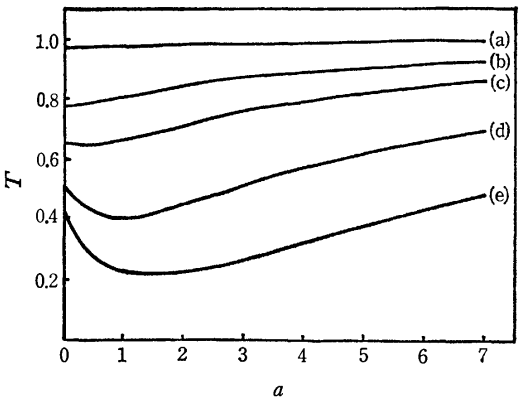

Fig. 3. Relation of the calculated transmission to the value of a with several values of optical density in the case of $\alpha=3$.
The optical density is equal to (a): 0.1, (b): 1.0, (c): 2.0, (d): 5.0, (e): 10.0.

ii) As the value of a is increased, the effect of α on the T value is reduced: *i.e.*, with the increase in the Lorentz broadening, the effect of the difference in Doppler broadening between emission and absorption lines is reduced.

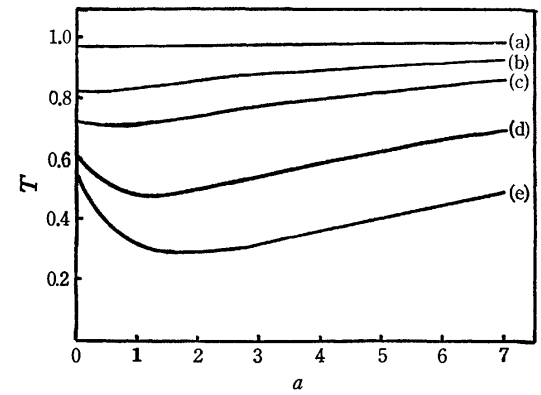

Fig. 4. Relation of the calculated transmission to the value of a with several values of optical density in the case of $\alpha=4$.
The optical density is equal to (a): 0.1, (b): 1.0, (c): 2.0, (d): 5.0, (e): 10.0.

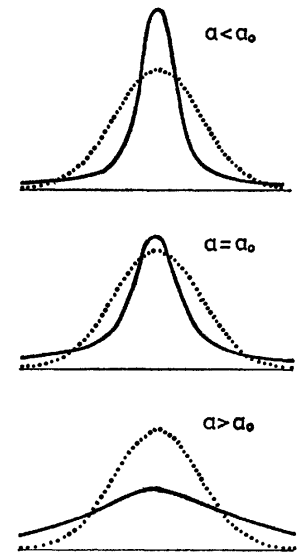

Fig. 5. The variation of the overlap between emission (dotted) and absorption (solid) lines with the increase of a. The maximum overlap is obtained at $a=a_0$.

iii) Similarly, as the α value is increased, the effect of a on the T value is reduced.

iv) On the other hand, with the increase in optical density, $k_0(\nu_0)l$, the effect of a on the T value is increased.

v) When both α and $k_0(\nu_0)l$ are large, T has a minimum at a certain value of a. This relation is qualitatively visualized in Fig. 5.

Measurements

The experimental apparatus was the same as that reported in a previous paper,[4] although the exciting resonance lamp was not used this time. The materials—cadmium, ammonia, and argon—were also the same as those described previously.[4] The furnace was maintained at 191±2 °C, while the cadmium reservoir was kept at 186±2 °C. The furnace for the resonance lamp was kept at 219±2 °C.

The results are shown in Fig. 6. The transmission n-

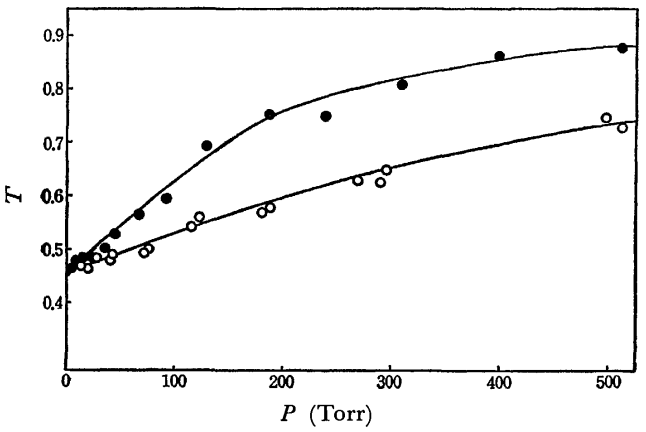

Fig. 6. The intensity of the transmitted light at 326.1 nm as a function of the pressure of argon (○) or ammonia (●).
The vapor pressure of cadmium is 1.48×10^{-4} Torr.

creased with the increase in the pressure of foreign gas. The rate of increase in ammonia was about twice that in argon. The transmission in the absence of any foreign gas, T_0, was 46.2±0.9%.

Discussion

Collision-broadening Cross-section. The $k_0(\nu_0)l$ value in the present experiment was calculated to be 2.3±0.3 by substituting the corresponding values into Eq. (4). However, this value cannot be used directly for the estimation of the collision-broadening cross-section because the presence of isotopes in natural cadmium metal has to be taken into account.

According to the work of Schüler and Westmeyer, the emission line at 326.1 nm of natural cadmium is split into three peaks.[5] Brix and Steudel demonstrated that the main peak observed by Schüler and Westmeyer is further split into three peaks.[6] Figure 7 shows the emission spectrum constructed according to the observations of Schüler and Westmeyer and those of Brix and Steudel, and by considering the Doppler broadening at 191 °C. From this figure, it may be assumed that natural cadmium consists of three imaginary isotopes, the propotions being 16 : 76 : 8.

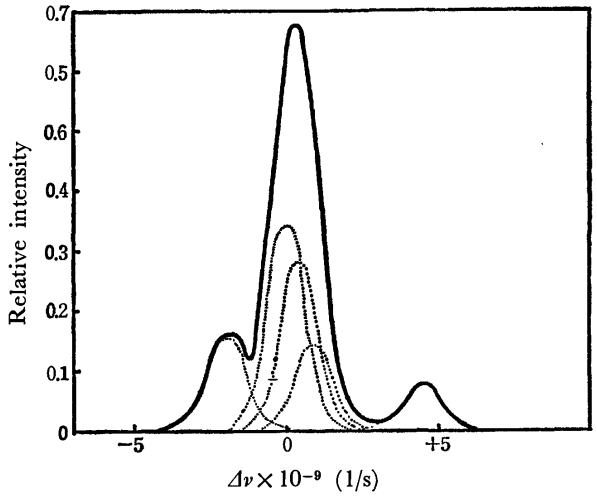

Fig. 7. Hyperfine structure of the cadmium resonance line at 326.1 nm with the Doppler broadening at 191 °C.

Unfortunately, the overlap between the two spectra due to the two imaginary isotopes (16 and 76%) is not small. In the following calculations, therefore, we assume two extreme cases. One is Case A, in which the three spectral lines are assumed not to overlap with each other at all. The other is Case B, in which the spectrum of the natural atom is assumed to consist of two separate spectra, the intensities of which are in the ratio of 92 : 8. Consequently, the true collision cross-sections of ammonia and argon will be in between the two values calculated in the two extreme cases.

In the absence of any foreign gas, the transmission, T_0, was 46.2%. The theoretical equation for this value is written as follows:

$$T_0 = \frac{\int_{-\infty}^{+\infty} \exp[-(\omega/\alpha)^2]\exp[-k_0(\nu_0)l\exp(-\omega^2)]d\omega}{\int_{-\infty}^{+\infty}\exp[-(\omega/\alpha)^2]d\omega} \quad (6)$$

The T_0 value was calculated by Horiguchi and Tsuchiya as a function of $k_0(\nu_0)l$ at different values of α.[7] This T_0 value can also be obtained from the figures shown in the previous section. Using these figures, we can estimate the α and $k_0(\nu_0)_c l$ values. Here, $k_0(\nu_0)_c l$ is the optical density corrected for the

Table 1. Calculated transmission in the absence of any foreign gas and the optical density corrected for the presence of isotopes

	3 components	2 components	α

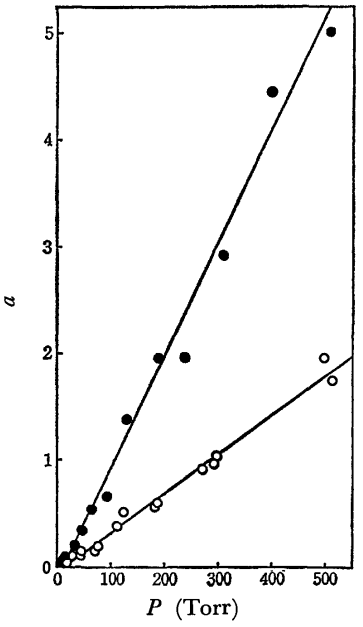

Fig. 8. The values of a as a function of the pressure of argon (○) or ammonia (●).

presence of isotopes; it may be used for the estimation of the collision-broadening cross-sections. The details of the calculation are shown in the Appendix. The results obtained are summarized in Table 1.

Once the α value and the corrected optical density are obtained, we can estimate, by using the numerical table, the value of a for each T value experimentally obtained. Thus, the a values are plotted in Fig. 8 as a function of the pressure of foreign gases. This figure is for Case A. A similar plot has also been obtained for Case B. The linear increase in the a value with the pressure is consistent with the Lorentz theory, which demands that

$$\Delta\nu_L = \frac{1}{\pi}\sigma^2 N(8\pi kT/\mu)^{1/2} \quad (7)$$

Here, σ^2 is the collision-broadening cross-section, N is the number of foreign gas molecules per cm^3, and μ is the reduced mass. Calculation by the least-squares method gives the values for σ^2. The results are listed in Table 2.

Table 2. Collision broadening cross sections (in Å^2) of argon and ammonia

	3 components	2 components
σ^2_{Ar}	49.0	72.9
σ^2_{NH3}	100.0	152.6
ratio	2.04	2.09

When we drew the spectrum shown in Fig. 7, we did not take into account any broadening other than the Doppler broadening at 191 °C. Since the resonance lamp was operated at 219 °C and contained about 3 Torr of argon as a carrier gas, the emission line should have been broadened more than that shown in Fig. 7. The α values estimated were 1.04 and 1.58 for Cases A and B respectively. These values correspond to the temperatures of 289 and 885 °C if the broadening is only due to the Doppler effect. Obviously, though, we have to consider the Stark effect in Case B. However, since we cannot estimate the broadening due to the Stark effect in the present experiment, we cannot tell which case is closer to the truth.

On the Dilution with Inert Gases. In the measurement of the quenching efficiency for excited atoms, inert gases have often been used as diluents so as to keep the broadening of the absorption line constant. In a previous paper,[4] we ourselves also used argon as a diluent gas in the measurement of the quenching efficiency of ammonia for the cadmium resonance line at 326.1 nm. One of the most severe conditions was: $k_0(\nu_0)l=0.71$ with 40 Torr of argon and 10 Torr of ammonia. The difference between the light intensity absorbed by this system and that absorbed by the system containing 50 Torr of argon without ammonia was estimated to be within 1%.

Generally speaking, the collision-broadening cross-section does not seem to depend greatly on the kind of molecule as compared with the quenching cross-section for excited atoms. Therefore, if a certain gas which has a negligible quenching cross-section for the excited atoms under consideration is found, we can probably use it as a diluent for keeping the broadening of absorption line constant.

The authors are indebted to Professor Soji Tsuchiya and Dr. Hiroyuki Horiguchi of Tokyo University for letting them use the Facom 230-75 computer and for their valuable discussions.

Appendix

The optical density for a separate spectrum, the proportion being denoted by x, is obviously $xk_0(\nu_0)l$. If the value of α is known, we can estimate the transmission, T_{ox}, for each spectrum by using the numerical table of T_0 against $k_0(\nu_0)l$. Such a relation is shown in Fig. 9. The total transmission is the average of these transmissions:

$$T_0 = \sum xT_{ox}$$

This value should be equal to the experimentally obtained value, 46.2%. Thus, the value of α was obtained by trial and error. By replacing the final value of α in Eq. (6), we can estimate the corrected optical density, $k_0(\nu_0)_c l$.

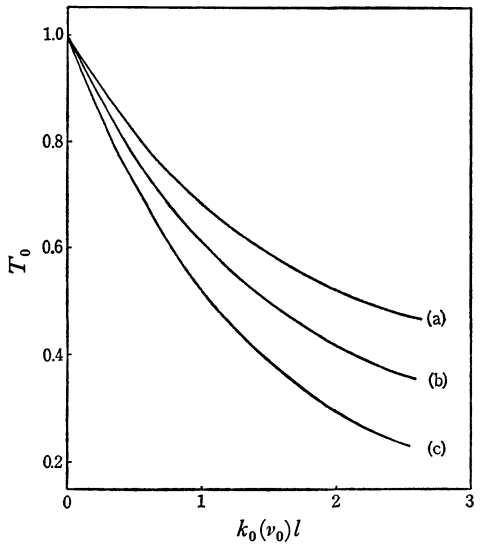

Fig. 9. Relation of the calculated transmission in the absence of any foreign gas to the optical density, $k_0(\nu_0)l$, with several values of α. (*a*): $\alpha=2.0$, (b): $\alpha=1.5$, (c): $\alpha=1.0$.

A Study of Catalysis by Uranium Oxide and Its Mixed Catalysts. IX.[1] A Catalytic Reduction of Nitric Oxide with Carbon Monoxide

Fumio NOZAKI, Fumio MATSUKAWA, and Yoshikazu MANO

Department of Industrial Chemistry, Faculty of Engineering, Chiba University, Yayoi-cho, Chiba 280

(Received March 29, 1975)

The reduction of NO with CO over the uranium oxide catalyst and its mixed catalysts with alkali metal oxide or alkaline earth metal oxide has been investigated using conventional flow and pulse reactors at temperatures of 250 to 450 °C under atmospheric pressure. The activity of the uranium oxide catalyst without any additive was higher than that of the Fe_2O_3 catalyst, although it was inferior to that of the CuO-Cr_2O_3 catalyst. The addition of alkali metal oxide or alkaline earth metal oxide to uranium oxide, particularly in the case of Cs_2O or K_2O, was effective in enhancing the catalyst activity. The W/F-conversion curves revealed that the reduction of NO to N_2 proceeds consecutively, passing through N_2O as a gas-phase intermediate. The reaction rates were formulated as $r=kP_{CO}^{1.0}P_{NO}^{0.4}$. The kinetic study suggested a redox reaction sequence. The oxidation states of the catalysts were discussed on the basis of X-ray diffractograms.

The catalytic reduction of NO with CO, H_2 or NH_3 has recently been investigated very actively as part of a comprehensive study of air pollution control, and much useful information has been presented in both fundamental study and development research.[2] In spite of the considerable number of publications on the catalysts, however, few reports have been published about the uranium oxide catalyst. Our preliminary study has revealed that uranium oxide has a high activity for NO-CO reaction.

In this paper, we will describe the behavior of uranium oxide as a catalyst and the influence of the addition of alkali metal oxide or alkaline earth metal oxide upon the catalytic activity. In addition, the results of a kinetic study and details of the catalyst structure will be given.

Experimental

Catalyst Preparation. The uranium oxide catalyst without additive (to be subsequently referred to as the U catalyst) was prepared by the method described in a previous paper.[3] The mixed catalysts with alkali metal oxide or alkaline earth metal oxide were prepared by the wet mixing method: the prescribed amount of an aqueous solution of Cs_2CO_3, KOH, NaOH, $Ca(OH)_2$, or $Mg(OH)_2$ was added to the yellow precipitate $(NH_4)_2U_2O_7$, obtained from $UO_2(NO_3)_2$ by precipitation with NH_4OH. The respective slurries were followed by drying in an air oven at the temperature of 110 °C. The resulting paste-like solid masses were well-mixed by a knead-machine for 3 hr, and were then extruded to obtain the desired pellet size. (These mixed catalysts will subsequently be referred to as the U-Cs catalyst, the U-K catalyst, *etc.*) A series of catalysts containing a certain kind of metal oxide in different proportions was prepared by the same method. The compositions of the mixed catalysts were expressed by the atomic M/(U+M) ratio, where M represents the species of the metals added to the catalyst as an oxide. All the catalysts were calcined at 500 °C for 2 hr in a stream of air before use in the catalytic tests. After calcination, the U catalyst was green-black in color; all of the mixed catalysts with alkali metal oxide or alkaline earth metal oxide were tan-orange, although their chroma was somewhat different from one another, depending upon the catalyst composition. The specific surface areas of the catalysts were determined according to the BET method, using nitrogen as the adsorbate.

In order to characterize the U catalyst, three kinds of commercial catalysts were used; the CuO-Cr_2O_3 catalyst (Nissan-Kemetron, Inc., type G-22; CuO 42%, Cr_2O_3 40%, BaO 12%), the Pt-Al_2O_3 catalyst (Nippon-Engelhard, Inc., Pt 0.5%), and the Fe_2O_3 catalyst (Shell, Inc., type 105; Fe_2O_3 93%, Cr_2O_3 5%, K_2CO_3 2%). These catalysts were also calcined at 500 °C for 2 hr in a stream of air before use.

Apparatus and Analysis. Most of the catalytic-activity measurements were carried out on a conventional flow apparatus consisting of a 18 mmϕ glass reactor. The reactor contained a packed bed consisting of 1.0 g of the catalyst and small glass-beads in the ratio of 1 : 10 by volume, thereby improving the isothermal conditions during the course of reaction. Before the start of the experiments, the catalyst was heated in a stream of helium to 500 °C for 1 hr, and then cooled to the reaction temperature. A mixture of NO and CO was admitted into the reactor at a constant rate of flow. After we had ascertained that the flow system had attained a stationary state, we began to analyze the product stream. The reaction products and the reactor feed were introduced at regular time intervals into a gas-chromatographic unit consisting of a 0.5-m column of Porapak Q and a 1-m column of Molecular Sieve 13X. The columns were operated at room temperature, with helium as the carrier gas; a detector of a thermal-conductivity type was placed between the Porapak and Molecular Sieve columns. Such a procedure permitted a satisfactory analysis of the mixture consisting of N_2, N_2O, NO, CO, and CO_2, even with the injection of only one sampling.

Considering the stoichiometry of the reaction, the conversion of NO, x_{NO}, and the selectivity, S_{N_2}, for nitrogen formation were given by:

$$x_{NO} = \frac{N_2+N_2O}{N_2+N_2O+1/2\,NO} \quad (1)$$

$$S_{N_2} = \frac{N_2}{N_2+N_2O} \quad (2)$$

In order to elucidate the reaction mechanism, some of the experiments were carried out on a conventional pulse-reaction method, using helium as the carrier gas. The gas-chromatographic unit described above served as an analytical tool.

X-Ray Diffractograms of the Catalysts. X-Ray diffraction measurements were made for the purpose of qualitatively identifying the catalysts. The X-ray diffractograms of the powdered samples were obtained at room temperature by using Ni-filtered copper radiation (Rigaku Denki Co., Geigerflex D-3F spectrometer).

Results and Discussion

Activity of the U Catalyst and the Pressure-dependency of Reaction Rates. The change in the catalyst activity during the course of the reaction was practically negligible throughout the catalytic tests.

In Fig. 1, the activity and the selectivity of the U catalyst are compared with those of commercial catalysts. Figure 1 indicates that the catalytic activity decreases in this order: $CuO\text{-}Cr_2O_3 > U > Fe_2O_3 > Pt\text{-}Al_2O_3$; the $Pt\text{-}Al_2O_3$ catalyst does not begin to be active until much higher temperatures than the other catalysts, but, in such a case, the degree of reaction approches the level of 90%, the relative activity of the Pt catalyst is rather higher than those of the U and Fe_2O_3 catalysts. The selectivity, S_{N_2}, for nitrogen formation was inclined to increase with an increase in the reaction temperature in every catalyst. In the case of the U catalyst, the selectivity curve appears to have its minimum at temperatures near 300 °C. However, a steep dip as described in the literature[4,5] was not observed under the reaction conditions of this work.

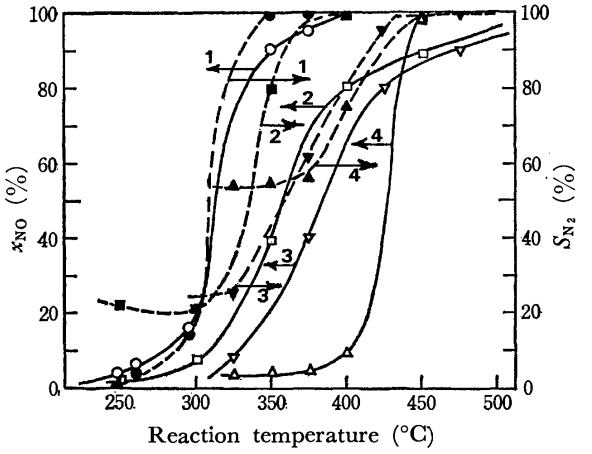

Fig. 1. Activities and selectivities of various catalysts.

Catalyst weight (W): 1.0 g, NO/CO feed ratio (m): 1.0, Flow rate of feed gas (F): 50 ml/min.

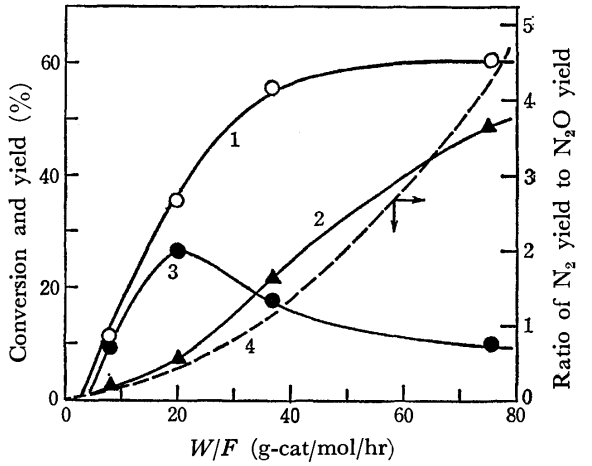

Fig. 2. Effects of W/F on the catalytic reaction.
1: x_{NO}, 2: N_2 yield ($=x_{NO} \times S_{N_2}$), 3: N_2O yield ($=x_{NO} - x_{NO} \cdot S_{N_2}$), 4: Ratio of N_2 yield to N_2O yield.
Reaction temperature (t): 310 °C, m: 1.0.

It must be noted that the U catalyst has a high activity for the NO–CO reaction; nevertheless, uranium oxide belongs to the class of heavy metal oxides which also includes MoO_3, V_2O_5, and WO_3. The MoO_3, V_2O_5, and WO_3 catalysts exhibited very little activity; the x_{NO} values were only a few %, even when the reaction temperature was raised to 500 °C. The fact that the activity of the U catalyst for the NO-CO reaction was exceptionally high for a heavy metal oxide catalyst was quite similar to the finding previously reported in the study of $CO\text{-}O_2$ reaction.[3]

Figure 2 shows the influence of W/F on the results of the reaction. The N_2O yield-W/F curve reaches a maximum. In addition, the curve of the ratio of the N_2 yield to the N_2O yield passes through the point of origin, as it increases with an increase in W/F. These facts suggest that the reduction of NO to N_2 proceeds consecutively, passing through N_2O as a gas-phase intermediate.

The rate measurements were conducted in a low range of W/F, in which one may assume the differential reactor. The reaction rate, r, can be obtained from the slopes of the linear relationship between $y_0 \cdot x_{NO}$ (y_0: mol-fraction of NO at the inlet of the reactor) and W/F. The dependence of the reaction rates on the partial pressure of NO or CO is illustrated in Fig. 3. It can be seen from Fig. 3 that the reaction rates are expressed by this equation:

$$r = kP_{CO}^{0.1}P_{NO}^{0.4} \quad (3)$$

where k is the reaction rate constant in mol/g-cat hr $atm^{1.4}$.

Influences of the Addition of Alkali Metal Oxide or Alkaline Earth Metal Oxide upon the Activity of the Uranium Oxide Catalyst. Temperature-conversion curves over the U–Cs catalysts containing cesium oxide in different proportions are shown in Fig. 4. Since the selectivity, S_{N_2}, for nitrogen formation showed a behavior similar to that in Fig. 1, the conversion datum alone is plotted in Fig. 4 as a function of the reaction temperature.

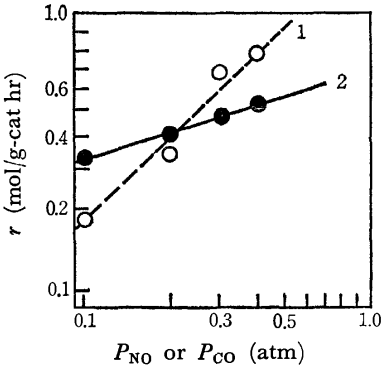

Fig. 3. Reaction rates as a function of NO or CO partial pressure.
1: Effect of CO partial pressure (P_{NO} was kept at constant pressure of 0.1 atm).
2: Effect of NO partial pressure (P_{CO} was kept at constant pressure of 0.1 atm).
Total pressure ($\pi = P_{CO} + P_{NO} + P_{He}$): 1 atm, t: 310 °C.

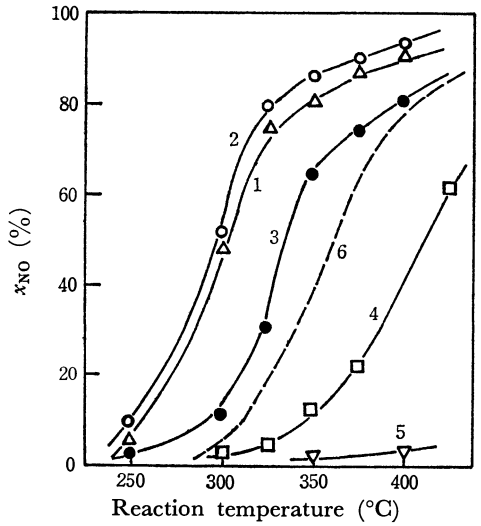

Fig. 4. Temperature-conversion curves over the catalysts containing Cs_2O in a different proportion.
Catalyst composition in atomic Cs/(U+Cs) ratio—1: 0.1, 2: 0.2, 3: 0.3, 4: 0.4, 5: 0.5, 6: 0.0 (U catalyst without Cs_2O).
Reaction conditions are the same as for Fig. 1.

Figure 4 indicates that the U–Cs catalysts with an adequate composition are much more active than the U catalyst without Cs_2O. In order to make a quantitative expression of the results, the rate constants, k_{flow}, were calculated according to a conventional manner for the ideal tubular flow reactor: at the point in the reactor where the conversion is x_{NO}, P_{NO} and P_{CO} may be written as $P_{NO}=P_{CO}=(1-x_{NO})/(2-0.5\,x_{NO})$ by taking into account the stoichiometry of the reaction and the feed NO/CO ratio of 1.0. Thus,

$$k_{flow}=\frac{y_0}{W/F}\int_0^x\frac{dx}{r}=\frac{0.5}{W/F}\int_0^{x_{NO}}\left(\frac{2-0.5x_{NO}}{1-x_{NO}}\right)^{1.4}dx_{NO} \quad (4)$$

From the series of conversion data shown in Fig. 4, the values of k_{flow} at 350 °C were evaluated by means of a graphical integral in Eq. (4) for each experimental point. The values are plotted in Fig. 5 as a function of the catalyst composition, together with the data relating to the BET surface area of the catalysts. Figure 5 shows that the catalyst activity increases with an increase in the atomic (Cs/U+Cs) ratio, passes through a maximum at about 0.2, and then almost disappears above 0.5. The k_{flow} value of the U–Cs catalyst with an atomic ratio of 0.2 was about five times that of the U catalyst without any additive. An increase in the activity upon the addition of Cs_2O was achieved in the range with a lower atomic Cs/U+Cs ratio than 0.3, and the further addition of (Cs_2O) resulted in a decrease in the activity. The correlation between the surface area of the catalysts and the composition of the catalysts leads us to the conclusion that the enhancing of activity attributable to Cs_2O addition is independent of the change in the surface area of the catalysts.

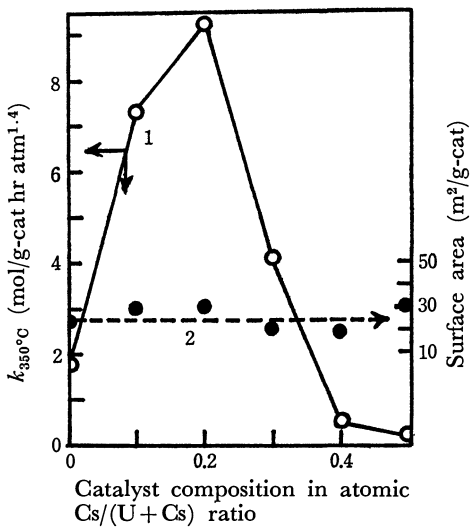

Fig. 5. Rate constant and surface area of U-Cs catalyst as a function of catalyst composition.
1: Rate constant *vs.* catalyst composition.
2: Surface area *vs.* catalyst composition.

The temperature-conversion curves over the other mixed catalysts are shown in Fig. 6. Figure 6 depicts that the addition of K_2O, Na_2O, CaO or MgO is in every cases effective in the modification of catalyst activity, although the influence of CaO and MgO upon the enhancing of activity is very slight. The effect of K_2O on activity was particularly noteworthy, by analogy with the Cs_2O addition. The modified catalysts with Cs_2O or K_2O added were superior in activity to the $CuO–Cr_2O_3$ catalyst, or at least to a catalyst of comparable magnitude. Thus, it appears established that the enhancing of the activity of the uranium oxide catalyst can be realized by the addition of small amounts of Cs_2O or K_2O, which are alkali metal oxides with lower electronegative properties.

A Plausible Reaction Mechanism. The results of an experiment in which the pulse-reaction method was employed to characterize the reduction and re-oxidation processes of the catalyst are shown in Figs. 7 and 8. Figure 7 suggests that the re-oxidation of

the reduced catalyst with NO pulses takes place more rapidly than the reduction of the catalyst with CO pulses. Figure 8, in which the facilities and regularities in the reduction of various catalysts are compared to one another, indicates that the ease of reduction decreases in this order: U-Cs>U-K>U-Na>U-Ca>U-Mg>U; this order is in accord with that of the catalyst activity. On the basis of information obtained in Figs. 7 and 8, we have speculated on a mechanism for the NO–CO reaction featuring the following reduction-reoxidation sequence:

$$\text{CAT-O} + \text{CO} \xrightarrow{\text{A}} \text{CAT} + \text{CO}_2 \qquad (5)$$

$$\text{CAT} + \text{NO} \longrightarrow \text{CAT-O} + 1/2\text{N}_2 \qquad (6)$$

where CAT-O and CAT represent an active site on the catalyst and its site as reduced by CO respectively. Provided that the rate-limiting step in the redox sequence is a reduction process of the catalyst by CO, as is shown by Eq. (5), both the results of Fig. 7 and the kinetic orders of Eq. (3) are readily understandable.

In order to make the successive order of the reduction rates of various catalysts clearer, we have analyzed the conversion data of Fig. 8 by two methods. One of the methods is to calculate the rate constant from the values of x_{CO} at the first pulse, using the rate equation for a pulse-reaction system:[6]

$$k_{\text{pulse, CAT-O+CO}} = \frac{1}{273R\,W/F} \ln \frac{1}{1-x_{CO}} \qquad (7)$$

The other method is to determine the coefficient of the variation in the CO conversion at the initial stage; $(\Delta x_{CO}/\text{pulse number})_0$ was evaluated from the conversion data of the first and second pulses for each catalyst.

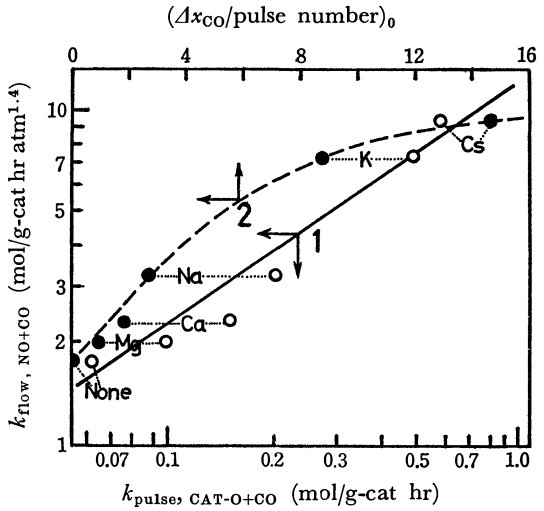

Fig. 9. Correlation between activity of the catalysts and reducibility of the catalysts.
1: $k_{\text{pulse, CAT-O+CO}}$ *vs.* $k_{\text{flow, NO+CO}}$.
2: $(\Delta x_{CO}/\text{pulse number})_0$ *vs.* $k_{\text{flow, NO+CO}}$.

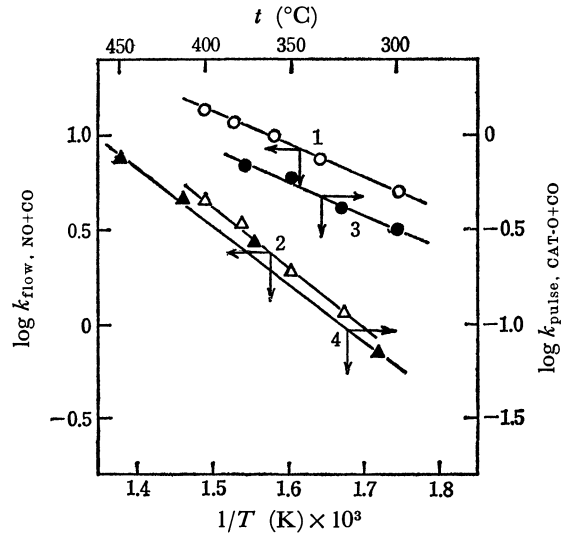

Fig. 10. Arrhenius plots for the rate constants.
1: Rate constants of NO-CO reaction over U-Cs catalyst in flow method, 2: Rate constant of NO-CO reaction over U catalyst in flow method, 3: Reduction rate constant of U-Cs catalyst in pulse method, 4: Reduction rate constant of U catalyst in pulse method.

In Fig. 9, the resulting two parameters by which the ease of reduction by CO is represented are correlated to k_{flow}. Figure 9 shows that there is a direct correlation between k_{flow} and the k_{pulse} parameter or $(\Delta x_{CO}/\text{pulse number})_0$.

Arrhenius plots of the rate constants for the U and U–Cs catalysts are illustrated in Fig. 10. Both log k_{flow} and log k_{pulse} are correlated to $1/T$ by straight lines. The apparent activation energy was found to be about 8 kcal/mol for the U–Cs catalyst and about 15 kcal/mol for the U catalyst. The finding to be emphasized here is that the activation energy observed in a flow-reaction method is entirely consistent with that of the reduction process of CAT-O by CO in a pulse-reaction method. This is suggestive of the redox mechanism which is expressed in the forms of Eqs. (5) and (6). However, a more detailed experiment, *e.g.*, tracer work labeled with an oxygen-18 isotope, is necessary to confirm the reaction mechanism. In this paper, it can only be said that all the experimental results have been interpreted satisfactorily on the basis of the redox mechanism.

X-Ray Diffractograms of the Catalysts. The X-ray diffractograms of the catalyst samples are shown in Fig. 11. Diagram 4, for the U catalyst, reveals that the sample consists mainly of U_3O_8. In contrast, Diagram 1, 2, and 3 for the catalysts containing Cs_2O, K_2O, and Na_2O respectively, show, without exception, that the definite peaks attributable to $UO_3 \cdot 2H_2O$ are present, together with minor peaks the assignment of which is unknown. The $UO_3 \cdot 2H_2O$ compound

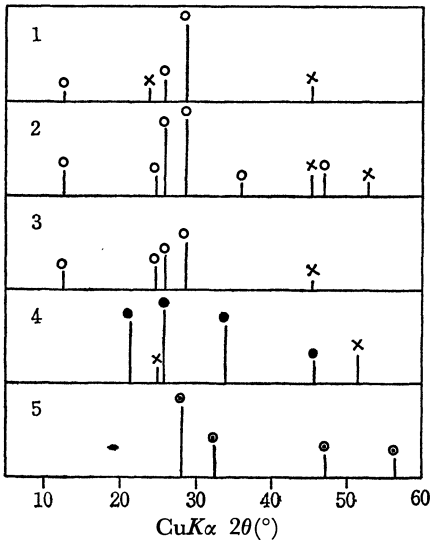

Fig. 11. X-ray diffractograms of the catalysts.

○: Peak attributable to $UO_3 \cdot 2H_2O$ (Ref. ASTM card 13—408), ●: Peak attributable to U_3O_8 (Ref. ASTM card 2-276), ⊙: Peak attributable to U_3O_7 (Ref. ASTM card 15—4), ×: Unknown peak for assignment.

results when UO_3 is allowed to stand in contact with air containing moisture; the hydrate is quickly reconverted into UO_3 by heating above 200 °C, as has previously been described.[7] The peaks attributable to $UO_3 \cdot 2H_2O$ were likewise observed in the catalysts containing CaO or MgO; however, in such cases the diffraction lines were weak in intensity.

Thus, it may be concluded that the addition of small amounts of alkali metal oxide or alkaline earth metal oxide can be used to elevate the oxidation state of U_3O_8 to UO_3. This can also readily be understood from the great difference in color between the U catalyst without any additive and the mixed catalysts; the former was green-black, characteristic of U_3O_8, whereas the latter was tan-orange, characteristic of UO_3.

The X-ray diffraction pattern of the U catalyst was entirely unchanged even after the catalyst had been used for the catalytic reaction. In contrast, the diffractogram of the U–Cs catalyst after having been used for the reaction (Diagram 5) was greatly different from Diagram 1, and the peaks were identified as belonging to those of U_3O_7. Therefore, one is forced to consider that, during the reaction, the oxidation state of uranium oxide is lower in the U–Cs catalyst than in the U catalyst. This fact is in conflict with the redox mechanism described in the previous section, because the oxidation state of the catalysts is considered to remain unaltered through the NO–CO reaction provided it proceeds *via* the sequence of Eqs. (5) and (6). This problem has not yet been completely elucidated, but it has been speculated that the U–Cs catalyst is more liable than the U catalyst to lead the formation of N_2O and that its use results in an excess of CO by unbalancing the redox reaction sequence of Eqs. (5) and (6), whereupon the reduction to the lower oxidation state takes place in the case of the U–Cs catalyst. However, a further investigation of the surface structure directly responsible for the catalytic reaction is required for a comprehensive understanding of the uranium oxide as a catalyst.

In the X-ray diffractograms of the catalysts containing alkali metal oxide or alkaline earth metal oxide, the peaks corresponding to the normal uranate and/or polyuranate structures were completely missing. The uranate K_2UO_4, which was prepared by a soaking method in a separate batch, showed only a very low activity in the NO–CO reaction.

Semi-empirical Localized MO Calculations of Saturated Carbocyclic and Heterocyclic Compounds

Gernot FRENKING, Hiroshi KATO,* Kimihiko HIRAO,** and Kenichi FUKUI

Department of Hydrocarbon Chemistry, Kyoto University, Sakyo-ku, Kyoto 606

**College of General Education, Nagoya University Chikusa-ku, Nagoya 464*

(Received April 1, 1975)

Localized MO calculations have been carried out by the "energy localization" method of Edmiston and Ruedenberg, based upon the INDO MO's, for 3-, 4-, and 5-membered cycloalkanes and their heterocycles containing one oxygen or nitrogen atom. Furthermore, LMO calculations were performed for the protonated three-membered heterocyclic compounds. The s-nature of the LMO's is discussed and correlated with the bond angle, the bond moment, the bond energy, and the bond polarity. Some LMO density maps are shown.

The usefulness of the localized molecular orbital (LMO) method has been pointed out by many authors.[1-7] Not only has the LMO method an advantage compared with the classical bond concept, but also the results which can be obtained by this method can be correlated directly with some physicochemical concepts or quantities, such as hybridization, the bond angle, and the bond moment.

In this paper, some physical and chemical properties of saturated cyclic compounds are investigated by the LMO method which was presented by Edmiston and Ruedenberg[1] based on the INDO method.[8] The compounds treated are saturated 3-, 4-, and 5-membered cycloalkanes and their heterocycles containing one oxygen or nitrogen atom. The LMO calculation for these compounds has not yet been made except for some LMO studies of three-membered heterocycles and some cycloalkanes.[5-7] Special attention is paid to the correlation between the degree of hybridization (s-nature of LMO's) in these compounds and the experimental quantities to be compared. The results of the bond polarity and the LMO charge maps are given.

Method and Details of Computation

The canonical MO's (CMO's) are obtained by the INDO method of Pople *et al.*,[8] and the LMO's, by the "energy localization" method of Edmiston and Ruedenberg.[1] In a later section, the LMO's total energy will be discussed by using the term "bond energy" presented by Parks and Parr.[2] The outline of the definition of "bond energy" may be briefly given as follows: the total energy by the LMO method, E_{el}, is given as the sum of the i-th LMO's energies, E_i's:[3]

$$E_{el} = \sum_i E_i$$

$$E_i = \langle i | F + H^c | i \rangle$$

where the summation, i, runs over all the occupied LMO's in the compound and where F and H^c denote the Fock and the core operators in the SCF Hamiltonian respectively.

The total energy, E_o, is taken as the sum of the bond energies, B_i's, where B_i belongs to the i-th two - or one-center LMO:

$$E_0 = E_{el} + E_n = \sum_i B_i$$

where:

$$B_i = E_i + E_{i\leftarrow n}$$

in which E_n is the total core repulsion energy and E_{in} is its i-th part.[2]

The geometries of the treated compounds are cited from the literature[9] if they exist. As to ethylene imine, the following values are assumed: C–N 1.488 Å; C–C 1.502 Å; C–H 1.08 Å; N–H 1.00 Å; ∠HCH 112°; as to the protonated ethylene oxide and imine, $O-H^+$ is taken as 0.96 Å and $N-H^+$ is 1.00 Å, and the bond angle between the newly formed $X-H^+$ bond (X=O, N) and the ring plane is assumed to be 56°, the other values remain unchanged. For the sake of simplicity, the rings of all the compounds, with the exception of cyclobutane, are assumed to be planar.

Results and Discussion

As a measure of the degree of localization of each LMO, Table 1 shows the sum of the squared AO-coefficients at the atoms which do not take part in the considered bond or lone pair. The values in Table 1 indicate the achievement of a high degree of localization (more than 90% in almost all LMO's); accordingly, some discussions in later sections based on the assumption of pure localization will be admissible.

In this section, the s-nature of the LMO's, the deviation of the bond angle and the bond energy, and so on, will be discussed.

s-Nature. Coulson and Moffitt[10] have pointed out the irregular degree of hybridization of small-membered cycloalkanes. In Table 2 our results are compared with the values of s% and the deviation of bond angle given by Coulson and Moffitt (C–M). The agreement between the two approaches is good. The reliability of the results by the LMO approach has also been examined by comparison between the observed $J_{C^{13}-H}$ coupling constant,[6,11a-c] and those estimated by means of the empirical formula: $J_{C-H} = 5 \times (\%s)$ cps.[11a] In Table 3 the agreement is excellent. Hence, this way of estimating the s-nature seems reasonable. The LMO's obtained by means of the INDO and *ab initio* methods have already been

** Present address: Department of Chemistry, the University of Alberta, Edmonton, Alberta, Canada.

compared by England and Gordon.[4] Our results in Table 2 are close to that of the *ab initio* LMO calculation of Newton *et al.*, which gives the deviation of the bond angle (C–C–C) as 28.4°, and the 22.9% s character in the CH bond and the 20.8% s character in the CC bond in cyclopropane.[5]

In Table 4, the values of the %s nature of various compounds are collected. From the data, it seems that there is a regular increase in s% in the CC and CX (X=N, O) bonds and the decrease in the CH and NH bonds and lone pairs with the increase in the ring size. The above tendency indicates that the 2s electrons which are highly localized in the CH bonds or the lone pairs of the small-membered ring compounds come to participate in the bonding of the CC or CX bonds with an increase in the ring size.

Since the s AO's energies are generally lower than the p AO's, a high degree of s character leads to a more stable bond. It is commonly known that a bond in the ring plane of small ring compounds is more liable to break than in the normal-size ones, and also that the CH-bond stretching frequencies become smaller with an increase in the ring size,[17] reflecting the decrease in the %s of the bond, as is shown in Table 5.

Table 4 also shows the s nature in each LMO of the protonated ethylene oxide and imine. The results reveal that the amount of %s increases at the hetero atom in the CX bond, while it decreases at the CX carbon and remains almost unchanged in the other parts, in comparison with the parent compound. Those results indicate that the change in the electronic structure by protonation is limited around the hetero

atom directly bonded to the proton.

Some attempts have previously been made to correlate the degree of hybridization to the bond angle.[12-16] We have estimated the bond angle by the vector sum of the coefficients of p AO's; the data are summarized in Table 6. The results are as follows: the bond angles in the ring plane decrease towards the tetrahedral angle with an increase in the ring size, and the deviation becomes smaller in all cases. The decrease in the bond angle is somewhat surprising and in contradiction to previous results. It indicates that there is not always a strict correlation between the hybridization and the bond angle.

Bond Energy. Parks and Parr pointed out that the additivity and the invariance of bond energy, as defined by them, hold under the assumptions that the neutral penetration term is negligible and that the bond is homopolar.[2] Hirao calculated the bond energy of various types of CH bonds with respect to hydrocarbons and pointed out that the bond energy parallels the degree of hybridization[3] and is nearly equal within the bonds of the same degree of hybridization.[19]

Table 7 lists the values of the bond energy, while their dependence on the ring size is plotted in Fig. 1. The invariance of the bond energy does not hold in these heterocyclic compounds, but the change due to the ring size is parallel to that of the s nature of the bonds or the lone pairs considered. That is, with an increase in the ring size, the energy of the CH bond and that of the lone pair become higher and those of the CC and CX bonds become lower. This tendency is roughly in accord with the values of s% in Table 3. It is interesting that the change in the CC bond energy between the three- and four-membered rings is most remarkable; this result reflects the large change in the degree of hydribization of their carbon atoms and can also be correlated to the stability of the ring.

Bond Polarity and Charge-density Contour Maps. The concept of bond polarity can be discussed directly by using the LMO results. Table 8 lists the values of the chargebond moment; μ_{AB}, which have been calculated by the following equation:

$$\mu_{AB} = 4.804\, R_m(Q_{Ai} - Q_{Bi})$$

$$Q_{Ai} = (2 \sum_{t}^{\text{on A}} C_{it}(\text{A})^2) - 1$$

where R_m is one half of the AB bond distance in units of Å and where the point of origin is the midpoint of the AB bond. Q_{Ai} is the atomic charge of the A atom in the i-th LMO, which is localized in the AB bond. C_{it} is the coefficient of the t-th AO of the A atom in the i-th LMO. The summation, t, runs over all the valence AO's of the atom A. The μ_{AB} value defined above is an approximated one. That is, this value neglects the contribution of atomic dipoles and the moments by the other parts. In spite of this approximation, the μ_{AB} values are well suited for discussing the bond polarity. It may be seen in Table 8 that the moments of the bonds of the same sort are nearly constant, and that the CX moment values are the largest (while being smaller in CN bonds than in CO bonds, as was expected), while the CC bond moments are very small. This result indicates that the polarity in the heterocycles is found only on the CX bond and that the effect of the hetero atom rapidly decreases with the distance. For reference, the AO coefficients of the LMO's in some five-membered rings are listed in Table 9; the values at the corresponding locations are nearly equal. The values of the C_2 atom in the C_1–C_2 and C_2–C_2, bonds

		C_1C_2	0.38	−0.16	0.57	0.0
		C_1H	0.36	0.32	−0.13	±0.47
	C_2	C_2C_1	0.37	0.20	−0.57	0.0
		$C_2C_{2'}$	0.36	−0.60	0.03	0.0
		C_2H	0.35	0.22	0.29	±0.48
	C_2	$C_2C_{2'}$	0.37	−0.60	0.03	0.0
		C_2H	0.34	0.22	0.29	±0.49

can be taken as examples. This indicates the same trend as in the results of the bond moments.

Figures 2(a)–(c) show the LMO density maps for the bonds in the ring plane and the lone pairs of the 3-, 4-, and 5-membered cyclic ethers. The contour lines representing the densities smaller than 1.0 A eÅ^{-3} are omitted. The figures of the LMO-charge maps in the ring bond reveal a shift of the density maxima toward the interatomic lines with an increase in the ring size. Although they indicate a significant polarity of the CO bond, the considerable change in the hybridization (s nature) with a difference in ring size is not demonstrated. This holds true also for the lone pair LMO's. It is worth noticing that the CC bonds always show two maxima, whereas the CO bonds show only one maximum, which is shifted to the oxygen atom. The figures of the cyclic imines are omitted, since they exhibit a shape very similar to that of the cyclic ethers.

Figure 2(d) shows the LMO maps of the CC bond of cyclopropane. It clearly demonstrates that the maximum of the electron density lies outside the CC line. This tendency is reduced in larger ring compounds, as can be seen from the bond-angle data in Table 3.

Figure 2(e) shows the LMO maps of the ring bonds and the lone pair of protonated ethylene oxide. There is no significant change in the shape compared to that of the neutral compound. The change in the CO bond is interesting, since more of the LMO charge

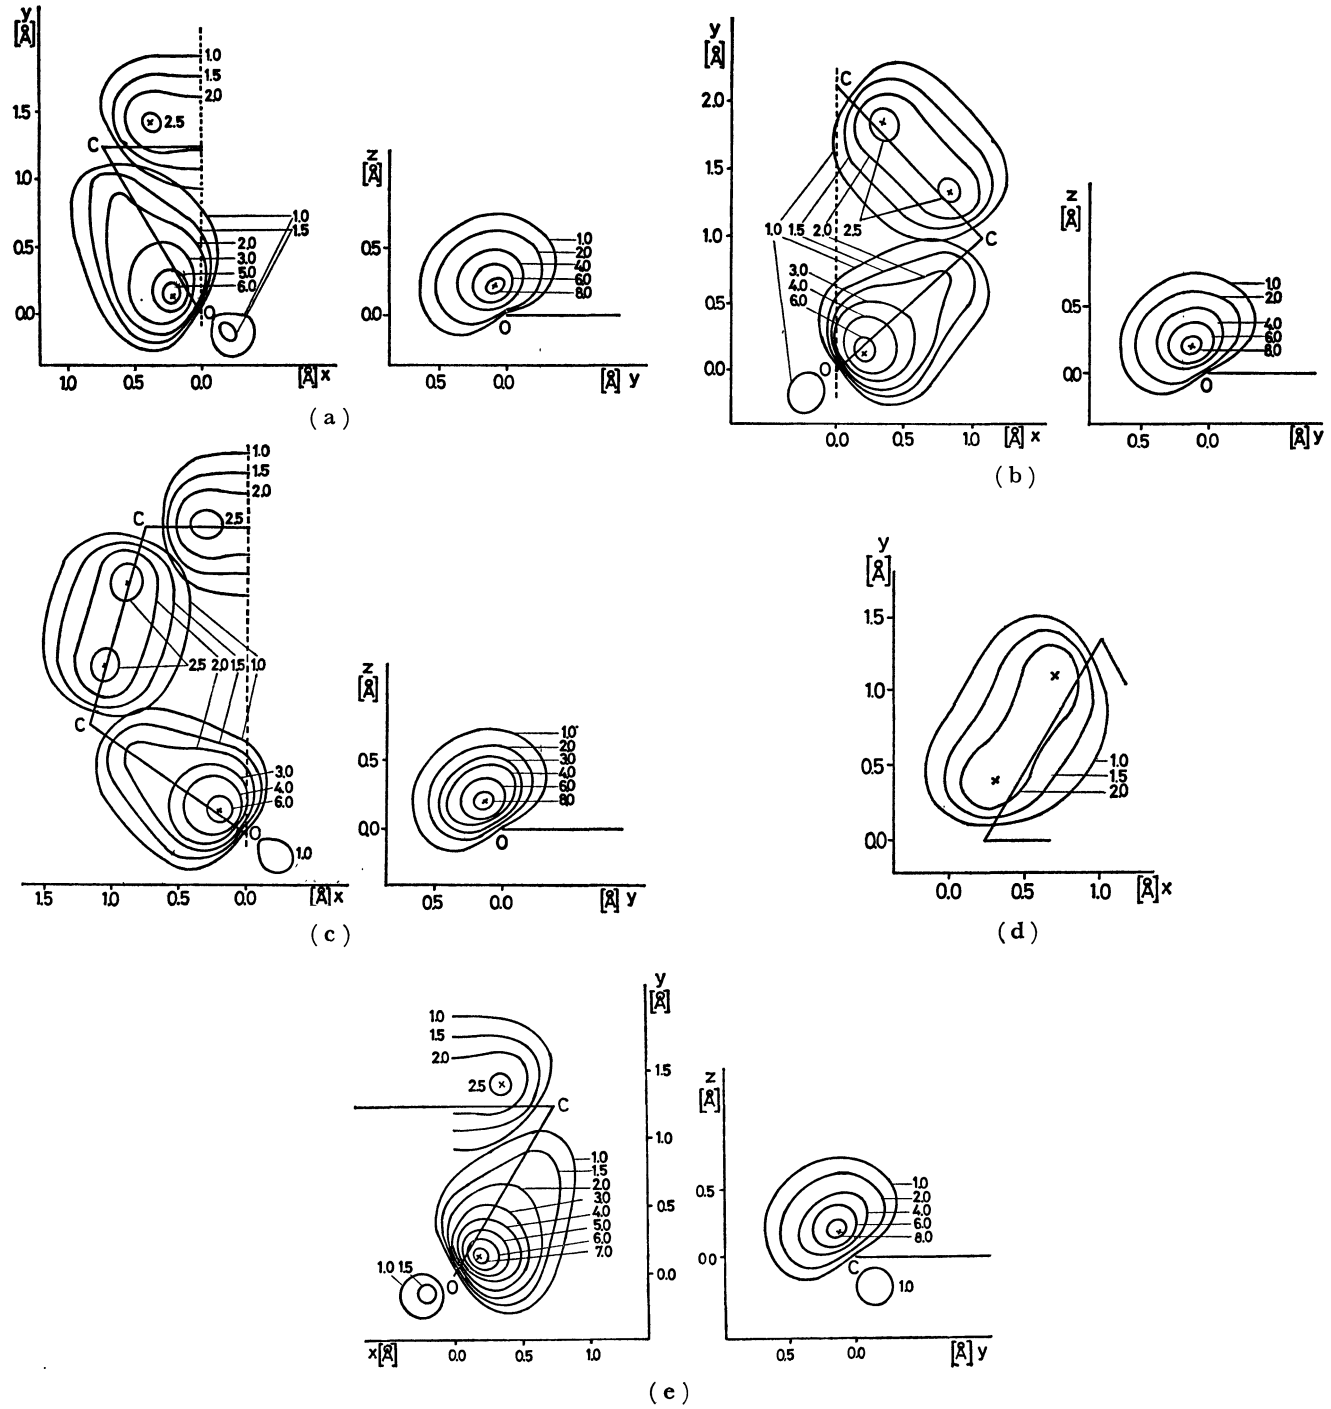

Fig. 2. LMO density maps for the ring bonds and lone pairs of ethylene oxide (a); trimethylene oxide (b); THF (c); C-C bond of cyclopropane (d); ring bonds and lone pair of protonated ethylene oxide (e). Maxima are denoted by a cross. The unit of density is $Å^{-3}$.

is shifted toward the oxygen atom, and the polarity of the CO bond becomes larger by the protonation. This trend agrees with the results of the charge-bond moment shown in Table 8.

It is interesting to visualize the characteristic features of the LMO's. We show the total-density maps of ethylene oxide and imine in Figures 3(a)–(d). The similarity between the LMO and the total-density pictures is not very clearly demonstrated. The CC bond still holds two maxima outside the ring. As to the CX bond, the maximum near the hetero atom in the LMO map is found to be the tail-off of a broad maximum nearly all around this atom. As going from the LMO picture to the total-electron-density picture, the special characteristics of the single and localized bonds given by the LMO's become more and more diffuse, as is to be expected. The differences between these two maps are produced mainly by the neglect of the overlap effect between the charges of the LMO's.

One of the authors (G.F.) is indebted to Mr. Tsutomu Minato for making available the computer programs. He also wishes to express his gratitude to the Japanese

Ultra-thin Layer of Lipids in Polymer Film and Its Electric Properties. New Sorption Method to Prepare a Model Biomembrane System

Tadayoshi Yoshida, Shin-ichiro Ogura, and Masataka Okuyama

Department of Engineering Chemistry, Nagoya Institute of Technology, Showa-ku, Nagoya 466

(Received April 8, 1975)

The ultra-thin layer of glycerol α-*cis*-9-octadecenate (glycerol α-monooleate:GMO) could be formed by impregnating nitrocellulose (NC) film with GMO and by then filling microscopically the interstices of the network structure of NC with microdrops of GMO. The dielectric dispersion characteristic of this film was found to be similar to that observed for bimolecular films. In a concentrated KCl solution (100 mM), however, an anomalous dielectric dispersion phenomenon was observed below 10 kHz. The low-frequency dispersion was attributed to surface conductance along the planes of contact between the GMO microdrops and the NC network. The ultra-thin film of di(*cis*-9-octadecenyl)phosphate (dioleyl phosphate: DOPH) could also be formed by this method. When a constant DC voltage (50 mV) was applied across the film in a 20 mM KCl solution, the electric current through the whole system changed periodically.

In a previous paper, we have reported that a stable bilayer was formed from a mixture of 1-tetradecanol and tetradecanoic acid.[1] The mixed bilayer, however, was frequently broken at higher temperatures or pH's. This could be explained by the transformation of the precursor monolayer of tetradecanoic acid from the condensed to the expanded state. Therefore, the mixed bilayer cannot be used as a model system in which a transformation of the molecular conformation in the membrane takes place.

A recent study has reported that a membrane composed of a filter paper and lipid may be used as a model system accompanying a conformational change.[2] The thickness of the model membrane, however, is *ca.* 10^4 times that of living membranes.

In the present paper, we wish to introduce a new model system that satisfies the following requirements: (1) the aggregative change (or conformational change) of the molecules constituting the model system does not result in a rupture of the film itself, and (2) the thickness and electric resistance of the model system are comparable to those of living membranes. The present model system should be useful in elucidating the molecular mechanism of excitable living membranes.

Experimental

Materials. The glycerol α-monooleate (GMO, purity> 99%) used in this study was purchased from the Gasukuro Co., Ltd. The nitrocellulose (NC; nitrogen content, 11.07%; degree of polymerization, 300) was kindly given by the Daicel Co., Ltd., while the ethylcellulose (EC;ethoxyl content, 48%; 9.5 centipoises in a 5% toluene–ethanol solution (80 : 20) at 25 °C) was obtained from the Tokyo Kasei Co., Ltd. All the solvents used in this study were reagent-grade.

Preparation of the Ultra-thin Layer of GMO. The porous NC-film (thickness, 1000—2000 Å) was prepared by the following processes prior to the formation of the ultra-thin layer of GMO: (1) A clean glass slide wad dipped in an ethylacetate solution (10 ml) containing both NC (60 mg) and EC (60 mg). (2) When the slide was taken out from the ethylacetate solution, a thin liquid layer of the solution covered the slide. (3) The slide is allowed to stand at room temperature to remove the ethylacetate. (4) Next the slide was transferred into benzene to wash out the EC from the NC–EC mixed film. (5) After an hour, when the slide was taken out from the benzene, the porous NC-film was left on the glass slide. (6) Dipping one end of the slide in water, the porous NC-film peeled off spontaneously from the glass slide within 5 minutes and floated on the water surface.

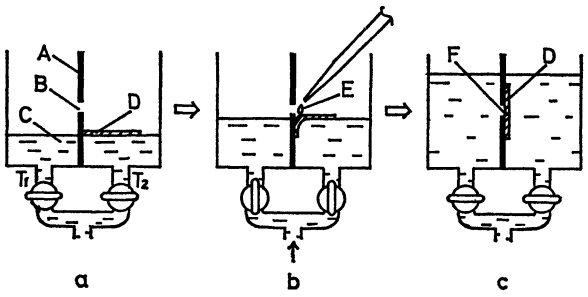

Fig. 1. Method of preparation of ultra-thin layer.
A: Teflon plate, B: Pore (0.5—1.0 mm in diameter), C: Aqueous solution, D: Porous NC-fllm, E: A drop of GMO/*n*-decane solution, F: Ultra-thin GMO-layer, T_1 and T_2: Tube.

The ultra-thin layer of GMO could be formed in the NC-film by the following procedures. (1) As is shown in Fig. 1a, two compartments of the same volume were separated by a Teflon plate (1 mm thick) with a small hole (0.5—1.0 mm in diameter) at the center. An aqueous KCl solution of the same volume was poured simultaneously into both compartments until the water surfaces were raised *ca.* 5 mm below the hole of the Teflon plate. The above-mentioned porous NC-film then floated on the water surface on the right-hand side. (2) An equal volume of the aqueous KCl solution was gradually added to both compartments through T_1 and T_2 with the two levels kept equal. In this procedure, the porous NC-film was gradually transferred to the surface of the Teflon plate as the water levels rose (see Fig. 1b). (3) When the water levels had been raised to *ca.* 1 mm below the hole of the Teflon plate, an aliquot (*ca.* 0.01 ml) of a GMO/*n*-decane solution was dropped on to the porous NC-film. The water levels were then gradually raised further until they reached *ca.* 5 mm above the hole (see Fig. 1c). In this procedure, the microdrops of GMO filled the pores of the NC-film and formed ultra-thin layers.

Measurement of Electric Properties. The electric capacitance of the whole system was measured by means of an AC bridge (Ando Electric Co., Ltd. Model TR-1C); the whole system consists of the ultra-thin GMO layer, the porous NC-film, and the adjacent aqueous solutions (see the first part of the Results and Discussion section). Measurments were carried out in the frequency range from 30 Hz to 3 MHz.

The constant potential (DC 50 mV) was applied between silver-silver chloride or platinized platinum electrodes in each compartment. The potential across the film was measured by means of an electrometer of a high-input impedance (Takeda Riken Industry Co., Ltd. Model TR-8651). The area of the film was estimated photographically. The temperature of the compartments was controlled to 20± 0.5 °C.

Results and Discussion

Our membrane system, prepared by impregnating GMO into the porous NC film, consisted of three phases; the ultra-thin GMO layer, the porous NC film, and the adjacent aqueous KCl solutions; the phases were connected in series with each other. However, the electric capacitance and resistance of the porous NC film (without GMO) in a 100 mM KCl solution were practically equal to those of an aqueous solution. Consequently. in view of the equivalent circuit, our system could be approximated by two phases: the ultra-thin GMO layer and the adjacent aqueous solution. On the other hand, a bilayer and its adjacent aqueous solution could also be approximated by two phases.[13] It is expected, therefore, that the characteristic of the dielectric dispersion of our new system is similar to that observed for the bilayer. The characteristic of the dielectric dispersion of our system in 10 mM KCl was nearly semicircular (Fig. 2). However, a marked deviation from the semicircular relation was observed below 300 Hz. The deviation became greater as the KCl solution was diluted. No such deviation was observed for bilayers.

The deviation in the low-frequency region may be attributed to the following difference in conductance between the bilayer and the thin GMO layer. In accordance with the suggestion of Hanai *et al.*,[3] the

bilayer and its adjacent aqueous solution can each be represented by a parallel combination of capacitance and conductance, connected in series with each other (Fig. 3a, C_b and G_b for the bilayer: C_a and G_a for the aqueous solution). In this electric circuit, the total conductance, G, and the capacitance, C, of the bilayer system are expressed by:

$$\frac{G}{2\pi f} = \frac{G_0}{2\pi f} + \frac{2\pi f\tau(C_0 - C_\infty)}{1+(2\pi f)^2\tau^2} \quad (1)$$

$$C = C_\infty + \frac{C_0 - C_\infty}{1+(2\pi f)^2\tau^2} \quad (2)$$

where f is the frequency, τ is $(C_a+C_b)/(G_a+G_b)$, G_0 is $G_aG_b/(G_a+G_b)$, C_0 is $(G_a^2C_b+G_b^2C_a)/(G_a+G_b)^2$, and C_∞ is $C_aC_b/(C_a+C_b)$. For the bilayer system, since G_b (*ca.* 10^{-8} ℧) $\ll G_a$(*ca.* 10^{-3} ℧) and C_b(*ca.* 10^3 pF) $\gg$ C_a (*ca.* 1 pF), the first term on the right hand side of Eq. (1) is negligibly small compared to the second term. Since the conductance of the thin GMO layer $G_u(10^{-4}$—10^{-5} ℧) $< G_a$ (*ca.* 10^{-3} ℧), the first term is not negligibly small in the low-frequency region. The first term is responsible for the deviation from the semicircular relation at low frequencies.

The combination of Eqs. (1) and (2) leads to Eq. (3):

$$G - G_0 = -\frac{1}{\tau}(C - C_0) \quad (3)$$

When G is plotted against C, therefore, a straight line should result. In fact, as is shown in Fig. 4, G and C for our system satisfied Eq. (3), which had been derived from the model of the two phases. Therefore, the capacitance of the thin GMO layer should be equal to the extrapolated value, C_0, at the low-frequency end of the semicircular curve (see Fig. 2). Assuming the thin GMO layer to be a parallel-plate condenser whose dielectric constant is 2, we find, from the above extrapolated value of C_0 (1100 pF, or 0.14 μF/cm²), that the thickness is *ca.* 150 Å, approximately 4 times that of the 1-tetradecanol bilayer.[1]

The G–C curve for our system in a 100 mM KCl solution departs from a straight line (Fig. 4). In

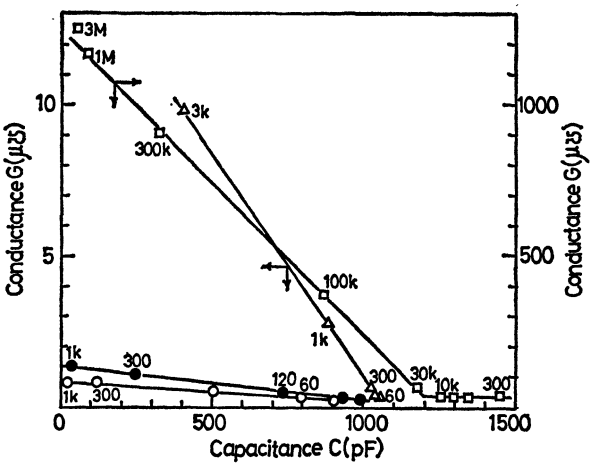

Fig. 4. Electric characteristic of a whole system.
The corresponding frequencies (Hz) are indicated beside some points.
Concentration of KCl solution, ○: 0.05 mM, ●: 0.1 mM, △: 10 mM, □: 100 mM.

the deviated region, below 10 kHz, the capacitance of the whole system increases with a decrease in the frequency, but the conductance is constant (30 μ℧, or 3.8×10^{-3} ℧/cm^2). This phenomenon at low frequencies was not observed for our system in 0.05 mM, 0.1 mM, or 10 mM KCl solutions. Since the area of the electrodes is *ca.* 100 times larger than that of the ultra-thin GMO layer, the diffusion impedance at the electrode surface is negligible. Therefore, it seemed that the above phenomenon is attributable to the property of the ultra-thin GMO-layer system itself.

When the following procedure was repeated after the formation of the ultra-thin GMO layer in the 100 mM KCl solution, the *G–C* charactristic was changed as is shown in Fig. 5. The water levels of both compartments were lowered simultaneously to *ca.* 5 mm below the hole of the Teflon plate. In this procedure, the ultra-thin GMO layer was exposed to air. Moreover, the water levels returned to the original state within one minute. The capacitance increased with the repeated exposures, and the break in the curve at low frequencies became obtuse, as is shown in Fig. 5. The increase in the capacitance should be attributed to the reduction of the GMO-layer thickness or to the quantity of GMO absorbed into the porous NC film. From the experimental results (Fig. 5) and the calculated thickness of the GMO layer (150 Å), it seemed reasonable to assume that the ultra-thin GMO layer was formed by filling the interstices of the network structure of NC with microdrops of GMO.

The form of the *G–C* curve was very similar to that observed for the suspensions of *Austerias* eggs by Cole *et al.*[4] They explained qualitatively the break in the *G–C* curve in the low-frequency region as being caused by the surface conductance at the egg–water interfaces. On the other hands, Coster[5] suggested that the double fixed-charge membrane model could account for the low-frequency dispersion. In both cases it was useful to introduce the concept of frequency-dependent elements [$C(f)$ and $G(f)$]. In our system, the surface conduction possibly occurred also at the interface of the GMO microdrop-NC network. According to Schwan *et al.*,[6] the surface conductance can be represented by a parallel combination of the capacitance, C_s, and the conductance, G_s, where C_s is inversely proportional to $\sqrt{f}$ and where G_s is proportional to $\sqrt{f}$ on the first approximation. Therefore, our system may be represented by the circuit shown in Fig. 3b. G_u and C_u indicate the conductance and the capacitance of the ultra-thin layer respectively. Curve (a) in Fig. 6 represents the calculated curve, using the equivalent circuit (Fig. 3b) with $C_a=10^{-12}$ F, $C_u=1.2\times10^{-9}$ F, $G_a=1.2\times10^{-3}$ ℧, $G_u=3\times10^{-5}$ ℧, $G_s=1.25\times10^{-8}\sqrt{f}$ ℧, $C_s=1.25\times10^{-8}/2\pi\sqrt{f}$ F. The above values of G_a and C_a correspond to those of the 100 mM KCl solution, while

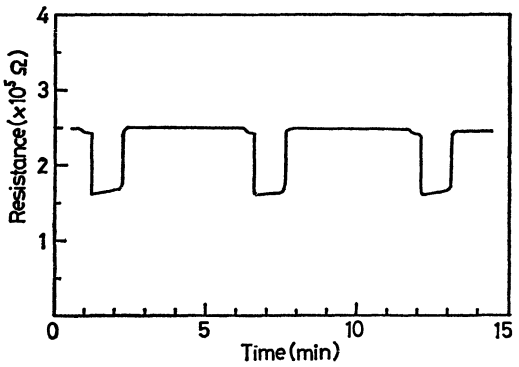

Fig. 7. Periodic change of the resistance of ultra-thin DOPH layer.

C_u is equal to the extrapolated value of C_0 at the low-frequency end of the semicircular curve in Fig. 2. Moreover, G_u is equal to the conductance at low frequencies (below 1 kHz). If we use $G_a = 1.7 \times 10^{-3}$ ℧ (the value for 10 mM KCl solution) instead of 1.2×10^{-3} ℧, Curve (b) in Fig. 6 is obtained. The bend of Curve (b) in the low-frequency region is not clear compared with Curve (a). In other words, the dilution of the KCl solution is accompanied by the disappearance of the bend in the *C–G* curve. These curves agree with the experimental results (Fig. 4)

The ultra-thin layer of dioleyl phosphate (DOPH) could also be prepared by a similar method. When a constant DC voltage (50 mV) was applied across the film in a 20 mM KCl solution, the electric current through the whole system changed periodically (Fig. 7).

Yoshida *et al.*[2] have reported that DOPH impregnated in filter paper changes its conformation discontinuously from oil droplets to bilayer films at a critical concentration of the adjacent solution and that this conformational change increases the conductance of the model membrane. On the other hand, according to Barry *et al.*,[7] the difference in transport number of ions between the membrane and the adjacent solution causes an increase in the salt concentration in the unstirred layer near the membrane surface.

In both studies, we presumed that the periodic phenomenon (Fig. 7) resulted from the following processes. If the ultra-thin layer of DOPH, as well as the ultra-thin layer of GMO, could be formed by filling the interstices of the network structure of NC with microdrops of DOPH, then the current must flow along the planes of contact between the DOPH microdrops and the NC network because of the high resistance of the DOPH microdrops. On the other hand, since DOPH possesses a negative charge, the transport number of positive ions at the planes of contact is greater than in the adjacent solution. This difference in transport number will result in an increase in the KCl concentration on one side of the thin layer-solution interfaces. If the DOPH in the NC film, as well as the DOPH in the filter paper, changes its conformation at a critical concentration of the adjacent solution, the conductance of our model membrane will increase discontinuously when the concentration at the thin layer-solution interface reaches a critical value. The periodic phenomenon (Fig. 7) disappeared in a 10 mM or 30 mM KCl solution. This fact suggests that the DOPH in the NC film changes its conformation when the concentration at the thin layer-solution interface reaches 20–30 mM. The increase in conductance is accompanied by the disappearance of the enhancement of the concentration at thin layer-solution interface. Consequently, the DOPH in the NC film returns from the transition state (bilayer) to the original state (microdrop) after *ca.* one minute (Fig. 7), and then the conductance of the whole system decreases to the original lower value. We assumed that the periodic phenomenon in Fig. 7 resulted from a repetition of the above processes. The periodic phenomenon was not observed for the ultra-thin GMO layer, which has no charged group. Therefore, it seems that the occurrence of the periodic phenomenon in Fig. 7 requires the presence of the charged group and of two conformational states of the molecule.

From the facts presented above, we may conclude that the ultra-thin layer consists of the microdrops of GMO (or DOPH) in the interstices of the network structure of NC and that the thickness of the ultra-thin layer is 150 Å.

The authors wish to thank Dr. Hirofumi Okabayashi of our laboratory for his valuable discussions. They also wish to thank Mr. Kazuo Kazikawa of the Daicel Co. for his kind supply of nitrocellulose.

Molecular Reorientational Motion of the Benzene Molecule in a Mixture of Benzene with Carbon Tetrachloride by Raman Band Spape Analysis

Hiroyasu NOMURA and Yutaka MIYAHARA

Department of Chemical Engineering, Faculty of Engineering, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 18, 1975)

The reorientational correlation times of the benzene molecule in mixtures of benzene with carbon tetrachloride were measured by the method of the Raman line shape analysis. The reorientational relaxation times τ_{OR} of C_6H_6 in solutions increased with increasing mole fraction of CCl_4. Information was also obtained on an intermolecular vibration-vibration energy transfer process which primarily affects the mean life time of the first excited vibrational state ν_2 (a_{1g}) in benzene in solutions.

Numerous investigations have been made to determine the nature of the interaction which affects the Raman spectra of molecules in solution. The measured linewidth of the Raman line provides new information about the mechanisms of intermolecular interaction in solutions.

The most accessible experimental quantity in studies of rotational molecular motion in liquids and/or solutions is the rotational correlation time τ. This value is the zero Fourier transform of the orientational time correlation function. Values of τ can be estimated from a variety of experimental techniques, for example Rayleigh-wing scattering and Raman line shape analysis.[1-4]

We estimated the reorientational correlation times of the benzene molecule in a mixture of benzene with carbon tetrachloride from the Raman line shape analysis. As a result, information has been obtained on an intermolecular vibration to vibration energy transfer process which primarily affects the mean life time of the first excited vibrational state $\nu_2(a_{1g})$ in benzene.

Experimental

We have used an argon ion laser (Coherent Radiation Co. Ltd. 2W) for the light source. The scattered light was analyzed with a double monochromator (JRS-Ul Laser Raman Spectrometer).

Raman theory and analysis

Analysis of the Raman line shape of the $\nu_2(a_{1g})$ fundamental in benzene yields information about the diffusion constant $D_\perp$. The theory has recently been summarized[5] and needs only a cursory introduction here. The mechanics of the data aquisition and analysis requires clarification, however.

All experiments were done using 90° scattering and linearly polarized incident light. With $I_\parallel(\omega)$ and $I_\perp(\omega)$ representing the strong and weak components of the scattered light, one can write

$$I_\parallel(\omega) = I_{isot}(\omega) + 4/3 I_{anis}(\omega) \quad (1)$$

$$I_\perp(\omega) = I_{anis}(\omega) \quad (2)$$

$$\rho_s = \frac{I_\perp(\omega)}{I_\parallel(\omega)} = \frac{I_{anis}(\omega)}{I_{isot}(\omega) + 4/3\, I_{anis}(\omega)} \quad (3)$$

where ρ_s is the depolarization ratio. $I_{isot}(\omega)$ represents the intrinsic vibrational line shape, whereas $I_{anis}(\omega)$ is a convolution of the vibrational line shape and the orientational spectrum. The problem is to separate the two accurately.

$I_{isot}(\omega)$ can be extracted directly from measurements of $I_\parallel(\omega)$ and $I_\perp(\omega)$. But since the depolarization ratio is very small for the band under consideration (ρ_s (991 cm^{-1}) = 0.00986±0.0005) the intrinsic vibration line shape $I_{isot}(\omega)$ and the measured line shapes $I_\parallel(\omega)$ can be considered to be the same without introducing significant errors ($I_{isot}(\omega) \simeq 0.991\ I_\parallel(\omega)$). Generally, however, the measured spectrum is a convolution of the true spectrum and the Gaussian slit function $S(\nu_i, \omega)$. One can write

$$I'_{anis}(\omega) = \int_{-\infty}^{\infty} I_{or}(\omega) I_{isot}(\omega) S(\nu_i, \omega) d\omega \quad (4)$$

and

$$I'_{isot}(\omega) = \int_{-\infty}^{\infty} I_{isot}(\omega) S(\nu_i, \omega) d\omega \quad (5)$$

where the primed and unprimed functions denote the measured and true shapes respectively. At first sight, it would appear that the order of convolution is not important and hence the slit function would cancel. This is not the case except when the line widths are very similar in magnitude. To obviate the large errors associated with this assumption, true line widths were determined directly as a function of slit width; a plot is shown in Fig. 1. For the 991 cm^{-1} line of benzene, $I_\parallel(\omega)$ can be determined directly by setting the slit 20 μ or less. In order to obtain

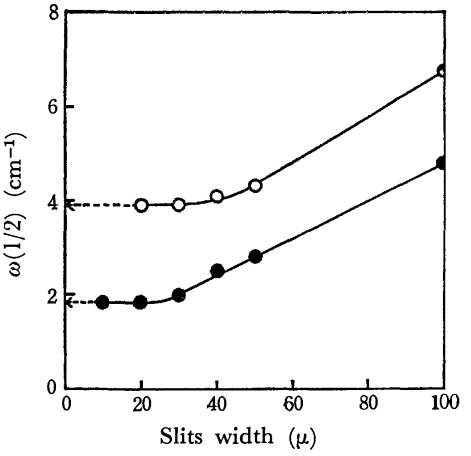

Fig. 1. Linewidth of $\nu_2(a_{1g})$ of C_6H_6 in carbon tetrachloride as a function of slit width. (37.6 mol% of benzene)
○: $\omega_{anis}(1/2)$, ●: $\omega_{isot}(1/2)$

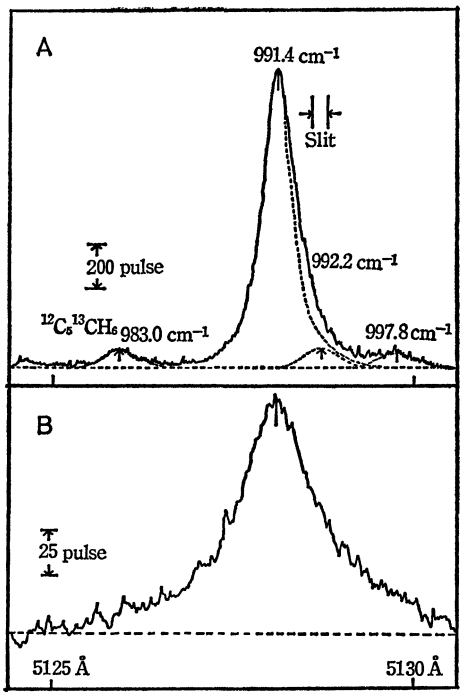

Fig. 2. A; Polarized Raman spectrum, $I_{\parallel}(\omega)$, of $\nu_2(a_{1g})$ of C_6H_6 (slit=20 μ×10 mm high, scan rate=0.5 Å/min), B; Depolarized spectrum $I_{\perp}(\omega)$(slit=25 μ×10 mm high, scan rate=0.5 Å/min) (20.0 mol% of benzene in mixtures).

$I_{isot}(\omega)$, $I_{\perp}(\omega)$ must be evaluated at the same slit width. Examples of measured $I_{\parallel}(\omega)$ and $I_{\perp}(\omega)$ are shown in Fig. 2. Errors arising from monochromator polarization response, beam convergence, light collection angles, analyzer light leak, ellipticity of the exciting light polarization, laser power fluctuations, and stray light have been minimized.

Implicit in the treatment of the data are the assumptions that $I_{isot}(\omega)$ and $I_{anis}(\omega)$ are Lorentzian and that vibrational and reorientational motions are not coupled. A test of these assumptions is shown in Fig. 3, in which $I_{isot}(\omega)$ and $I_{anis}(\omega)$, normalized to unit height, are displayed (pionts). The solid lines are calculated Lorentz functions based on the observed line width. Because $I_{anis}(\omega)$ is a convolution of

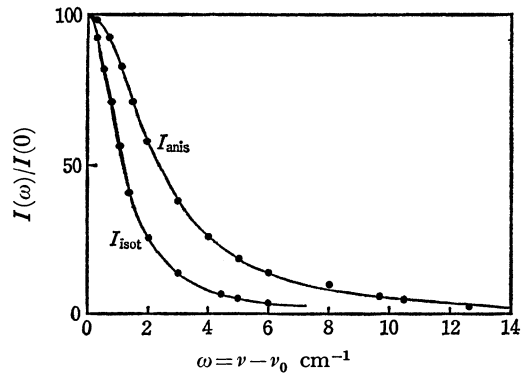

Fig. 3. Normalized line shapes of $I_{isot}(\omega)$(●) and $I_{anis}(\omega)$(○) of the $\nu_2(a_{1g})$ band of C_6H_6 in carbon tetrachloride (20.0 mol% of benzene).

$I_{isot}(\omega)$ with $I_{or}(\omega)$, the $I_{or}(\omega)$ is also Lorentzian. Accordingly,

$$\omega_{1/2}(\text{anis}) = \omega_{1/2}(\text{isot}) + \omega_{1/2}(\text{or}) \quad (6)$$

where the $\omega_1/_2$ terms are half widths. Furthermore, the reorientational correlation time is obtained as follows:

$$\tau^{-1}(\text{or}) = 2\pi c\omega_{1/2}(\text{or}) \quad (7)$$

where c is the velocity of light.

Results and Discussion

Before the measurements of the benzene–carbon tetrachloride solution were made, we measured the reorientational correlation time of pure liquid benzene together with a calibration of the Raman Spectrometer used. The values obtained by the excitation light of 4880 Å and 5145 Å wavelengths are summarized in Table 1. As is seen there, the reorientational correlation time τ from these values was in very good agreement with that obtained by Litovitz *et al.*[5] and also the values of $\omega_{1/2}$ (isot) were in good agreement with those of Griffith *et al.*[6] The line shapes of the 991 cm^{-1} Raman active fundamental of C_6H_6 are shown in Fig. 2(a). This line shape is also the same as that obtained by Griffith *et al.*[6] Several prominent features are observed. Important hot bands cause the observed bands to be skewed. The most interesting feature is that the hot band in C_6H_6 occurs on the high frequency side of ν_2. Additional Raman bands also occur in the far wings of the bands under study but they do not interfere significantly.

The dependence of the linewidth of the 991 cm^{-1} band on the mole fraction of CCl_4 is shown in Fig. 4. The reported linewidths are those obtained after

Table 1. Line width of $\nu_2(a_{1g})$ of C_6H_6 at various lights

	$\omega_{1/2}$(aniso)	$\omega_{1/2}$(isot)	$\omega_{1/2}$(or)
5145 Å	4.54 cm^{-1}	2.45 cm^{-1}	2.09 cm^{-1}
4880 Å	4.52 cm^{-1}	2.49 cm^{-1}	2.03 cm^{-1}
* Litovitz *et al.*[5]			2.0±0.5 cm^{-1}

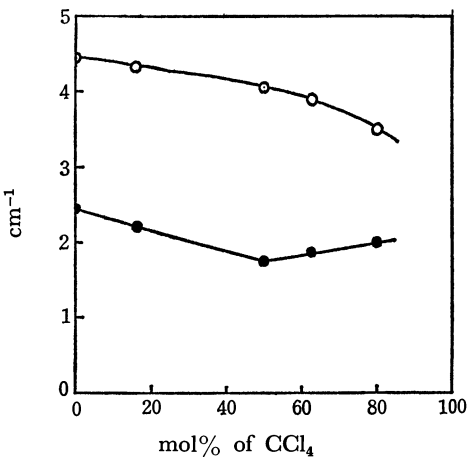

Fig. 4. Relationship between $\omega_{1/2}$(isot), $\omega_{1/2}$(anis) and the mole fraction of carbon tetrachloride.

graphical resolution of the over-all contour into the constituent $v=0\rightarrow1$ and hot band components. As is seen in Fig. 4, the $\omega_{1/2}$ (anis)'s decreased monotonously with increasing CCl_4 mole fraction. However, the $\omega_{1/2}$ (isot)'s decreased with increasing concentration of CCl_4 up to about the equimolar point and after this minimum point increased with increasing concentration of CCl_4.

Recently, the linewidths of the 991 cm^{-1} and 945 cm^{-1} bands for several mixtures of C_6H_6 and C_6D_6 were measured by Griffith *et al.*[6] They have explained their results as follows: the linewidth of the 954 cm^{-1} band of C_6D_6 is independent of the concentration, thereby supporting the initial supposition that the lack of close lying energy levels would preclude an intermolecular vibration to vibration energy transfer process from affecting the lifetime of the v'_2 state in that molecule. In C_6H_6, however, where two close lying energy levels are available, at 985 cm^{-1} and 970 cm^{-1}, the linewidth of the 991 cm^{-1} line is linearly dependent upon the concentration. As the C_6H_6 concentration decreases, the frequency of collisions between C_6H_6 molecules decreases to the same extent. If the life time of v_2 becomes longer by the mechanism for the energy dissipating process, the linewidth will be narrow and continue narrowing untill no more collisions between C_6H_6 molecules occur.

For the C_6H_6–CCl_4 mixtures, the energy dissipating process can be considered as the same mechanism. In CCl_4, there is a vibrational combination band of benzene near 991 cm^{-1} of $\nu_2(a_{1g})$; it is measured by infrared absorption spectra. We consider the following energy transfer mechanism:

$$C_6H_6(v_2') + CCl_4(v_2, v_3) \rightarrow C_6H_6(v_2) + CCl_4(v_2', v_3') + E\ (9\ cm^{-1})$$

But the linewidth broadenings by such collisions are smaller than those by C_6H_6–C_6H_6 collisions in solutions.

We consider the line broadening or narrowing mechanism of $\nu_2(a_{1g})$ of benzene in C_6H_6–CCl_4 mixtures to be that the line narrowing occurs due to the energy transfer by the collision process of C_6H_6–C_6H_6 upon increasing the mole fraction of CCl_4, but after the equimolar point the collisions between C_6H_6 and CCl_4 are predominant and then line broadening occurs due to the energy transfer in C_6H_6–CCl_4 collisions.

Following Griffith *et al.*,[6] we take the value of 1.62 cm^{-1} for the mean intrinsic linewidth of ν_2 in the absence of energy transfer collisions and we can obtain the reorientational relaxation time (τ) of C_6H_6 in solutions. We show the relationship between the τ (or) of C_6H_6 and the mole fraction of CCl_4 in Fig. 5. As is seen in Fig. 5, the τ (or) of C_6H_6 in solutions increased with increasing mole fraction of CCl_4. The reorientational relaxation times are related to the "micro-viscosity" of solution η_m as follows:

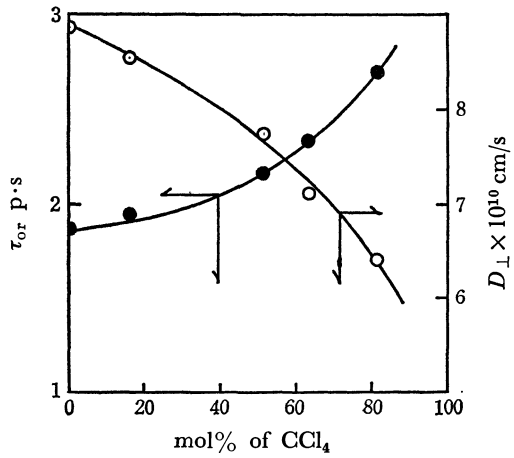

Fig. 5. Dependence of reorietntational correlation times with the mole fraction of carbon tetrachloride.

$$\tau_D = \frac{4\pi a^3}{kT}\eta_m \tag{8}$$

where a is the radius of the molecules in solution. Now assuming the micro-viscosity η_m to be equal to the viscosity η, τ_D/η should be constant. The value of τ_D/η at various mole fractions of CCl_4 is $2.96\pm0.20\times10^{-9}$ and independent of the mole fraction of CCl_4. The radius of the C_6H_6 molecules in solutions is found to be about 4.6 Å. This value is a very reasonable one.

Ion-Solvent Interaction of Tetraalkylammonium Ions in Dimethyl Sulphoxide from Electrolytic Conductivity Data

Jai Shanker JHA, Sudha SINGH, and Ram GOPAL
Chemistry Department, Lucknow University, Lucknow, U.P., India
(Received July 26, 1974)

Ion-solvent interaction of some tetraalkylammonium ions in dimethyl sulphoxide has been studied in this communication from the point of view of electrolytic conductivity and the derived Walden product. The R_4N^+ ions do not appear to interact strongly with this solvent; further, the salts examined appear to be completely dissociated in the concentration range studied here.

During the past few years, considerable interest has been shown to study the properties of the tetraalkylammonium ions (R_4N^+) in water and non-aqueous media.[1] Studies on R_4N^+–solvent interaction, using electrolytic conductivity data, in some solvents of high dielectric constant like *N*-methylformamide, *N*-methylacetamide and *N*-methylpropionamide, have been recently reported from this laboratory.[2,3] Dimethyl sulphoxide (DMSO) is an interesting solvent as it is highly polar[4] which would promote strong ion–solvent dipole interaction; it has no hydrogen bonding which distinguishes it from NMF, NMA and NMP. So it appears a little surprising that only a few studies, specially on electrolytic conductivity,[5–10] have been reported in this solvent. Electrolytic conductivities of some tetraalkylammonium halides and other salts in DMSO have been reported by Arrington and Griswold[11] at 25 °C; these studies appear to be rather sketchy, and a more detailed investigation appears very desirable. As the temperature dependence of electrolytic conductivity and the derived Walden product can be used to throw light on ion–solvent interaction, it is proposed to investigate the same in DMSO in this communication.

Experimental

DMSO (Fluka, purum) was purified by the method described in an earlier communication;[12] the purified sample was found to have conductivity $\approx 10^{-6}\Omega^{-1}\,cm^2$. Tetraalkylammonium salts (DPI, USA) were purified in the usual manner.[2] Solutions were prepared at 30 °C in a thermostat, and the concentration was corrected for the changes in volume at other temperatures from the corresponding densities which were also determined experimentally. The conductance of the solvent was taken into account while calculating the molar conductivities of the electrolytes. The conductance measurements were made with a suitably grounded Wheatstone Bridge and the cell was placed in a thermostat regulated to within ±0.01 °C in the lower temperature range and ±0.02 °C in the higher temperature range. The accuracy of measurements was checked by determining the electrolytic conductivity of some electrolytes of known conductivity.[5,11]

Results and Discussion

The plots of the molar conductivity Λ against the square root of concentration C, at different temperatures, are found to be almost straight lines. Such curves for 40 °C are given in Fig. 1. Extrapolation of the Λ *vs.* $\sqrt{C}$ curves to infinite dilution gives Λ_0-values* which are given in Table 1; from these values, the molar ionic conductivities of the R_4N^+ ions, *i.e.*, Λ_0^+, have been obtained by using the Λ_0^--values of the bromide ion, obtained from the cationic transport number of KBr[13] and its electrolytic conductivities at 25, 30, 40, and 50 °C. These data are recorded in Table 1.

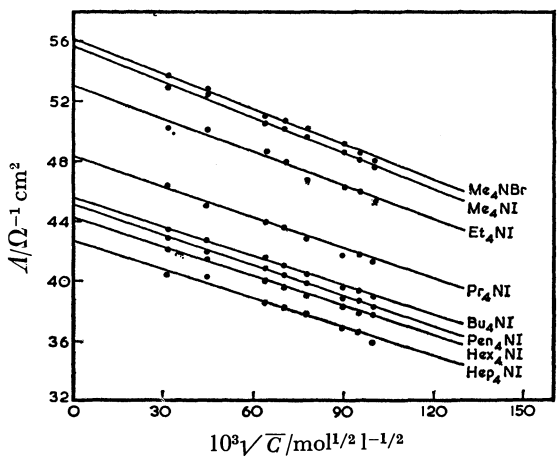

Fig. 1. Λ *vs.* $\sqrt{C}$ curves for R_4NX salt in DMSO at 40 °C.

From the Λ_0-values, the theoretical slope, S_T, of the Λ *vs.* $\sqrt{C}$ curves for different salts at 40 °C, was estimated and compared with the corresponding experimental slope, S, in Table 2. Values of the dielectric constant and viscosity, used for estimating S, are 43.97 and 1.508 $g\cdot m^{-1}\cdot s^{-1}$. respectively and have been obtained graphically from the data of Yao and Bennison.[8]

The fact that the plots of Λ *vs.* $\sqrt{C}$ gave straight lines indicates that, in dilute solution, these salts are completely ionized in DMSO. It may be noted from Table 2 that there is a good agreement between the experimental and theoretical slopes. Hence the Debye-Hückel-Onsager theory of conductivity of electrolytes in solution appears to be very closely applicable. It

* It may be mentioned that Arrington and Griswold[11] analyzed their conductivity data with the help of Fuoss-Onsager relation for unassociated electrolytes, namely,

$$\Lambda = \Lambda_0 - S\sqrt{C} + EC\log C + (J - F\Lambda_0)C$$

This analysis appears unnecessary since the electrolytic conductivity data of these workers give a reasonable straight-line Λ *vs.* $\sqrt{C}$ plot as 25 °C in different cases and this plot gives Λ_0-values in reasonable agreement with that obtained from the Fuoss-Onsager relation in most cases.

Table 1. The $\Lambda_0/\Omega^{-1}\,cm^2$ values of R_4NX salts, R_4N^+, Br^- and I^- ions at different temperatures

Salt or ion	Limiting conductivity at

Table 2. Onsager slope in DMSO at 40 °C

Salt	$S_T/\Omega^{-1}\,cm^2\cdot mol^{-1/2}\,l^{1/2}$	$S_E/\Omega^{-1}\,cm^2\cdot mol^{-1/2}\,l^{1/2}$	% Deviation $\frac{S_T-S_E}{S_T}\times 100$
Me_4NI	−74.59	−79.7	+6.85
Me_4NBr	−74.75	−77.9	+4.21
Et_4NI	−73.22	−74.2	+1.34
Pr_4NI	−70.84	−68.4	−3.44
Bu_4NI	−69.43	−65.7	−5.37
Pen_4NI	−69.22	−68.1	−1.62
Hex_4NI	−68.75	−65.8	−4.99
Hep_4NI	−67.96	−63.3	−6.85

may be mentioned that the studies on apparent molar volume of these salts in DMSO[12] appear to indicate appreciable ionic interaction at higher concentrations, but in dilute solutions, the salts appear to be completely dissociated.

The cationic Walden product, $\Lambda_0\eta^0$, of the R_4N^+ ions at different temperatures were obtained using the Λ_0-values** given in Table 1; viscosities used are: $\eta^0/g\cdot m^{-1}\,s^{-1}=1.908$(25 °C), 1.814(30 °C), 1.508 (40 °C), 1.275(50 °C). The $\Lambda_0\eta^{0+}$ *vs.* t plots are given in Fig. 2 for different R_4N^+ ions. It may be noted that the plots are straight lines with approximately zero slope, *i.e.*, $\Lambda_0\eta^0$ is almost independent of temperature. This shows that these ions neither promote nor break the structure of DMSO for the simple reason that no hydrogen-bonded structure is present originally in the pure solvent nor it can be formed. Electrostatic ion–solvent dipole interaction, if any, is not likely to be affected by a few degrees changes in temperature. It may be mentioned that similar conclusions have been arrived at for $(isoamyl)_3BuN^+$, Na^+, $B(Ph)_4^-$, ClO_4^-, SCN^-, and $CF_3SO_3^-$ ions.[8]

** Values of electrolytic conductivity at 25 °C used are those of Arrington and Griswold.[11]

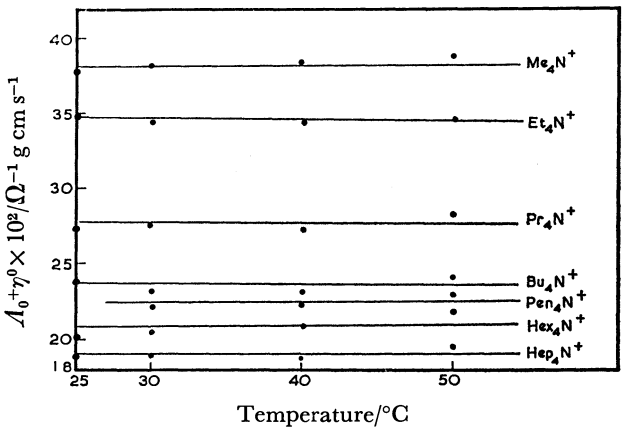

Fig. 2. Plot of $\Lambda_0\eta^0$ *vs.* temperature/°C in DMSO.

Dielectric Relaxation Studies of Trihalogenated Esters in Different Solvents at Microwave Frequency

H. D. PUROHIT, H. S. SHARMA and A. D. VYAS

Microwave Laboratory, Department of Physics, University of Jodhpur, Jodhpur, India

(Received Jannary 21, 1975)

The dielectric permittivity ε' and dielectric loss ε'' have been measured at 9.83 GHz for the solutions of four trihalogenated esters in six non-polar solvents having wide range of viscosities at 35 °C. The static permittivity ε_0 at 1 MHz and high frequency limiting permittivity $\varepsilon_\infty = n_D^2$ have also been measured at 35 °C. The normalized plots of log τ *vs.* log η for these esters are linear for non-interacting solvents only. The anomalous behaviour of these solutes in other solvents has been explained in terms of solute-solvent interactions. The distribution parameter α, the free energies of activation ΔF_τ, ΔF_η and the dipole moment μ of these esters have also been reported.

The relaxation time of a polar molecule in a non-polar solvent can be determined from the measurement of dielectric permittivity and dielectric loss. The relaxation time at a constant temperature depends upon mass and structure of the solute molecule, the intermolecular forces, viscosity of the medium and the interaction between the molecules of the solute and the solvent. As to how this relaxation time depends upon the viscosity of the medium has been a matter of considerable interest. Debye[1] considered the molecule as a sphere embedded in a continuous viscous fluid. The familiar Debye-Stoke's equation may be expressed as

$$\tau = \frac{4\pi\eta a^3}{KT}$$

in which η is the viscosity of the liquid and 'a' is the radius of the polar spherical molecule. The value of the molecular radius evaluated from the measured values of relaxation time and viscosity was considerably lower than those calculated from other sources (*viz.* van der Waals radius, molecular weight and density) for most of the cases. To overcome this discrepancy a number of modifications[2,3] in Debye equation and empirical[4,5] relations have been suggested. On the basis of present theories[6–8] it is expected that the relation between log τ and log η should be linear. This has been verified by many workers[9–11] using single solvent whose viscosity was changed by varying the temperature. The dependence of relaxation time of a polar solute in different solvents having different viscosities was studied by some workers[12,13] in a small range of viscosities. They found that the relation between log τ and log η no longer remains linear.

In present investigations dielectric relaxation time studies of four trihalogenated esters have been carried out in different solvents having wide range of viscosities with a view to study the dependence of relaxation time on the viscosity of the solvents. The esters have been selected as they are unassociated liquids and relax predominantly by overall rotation. The discrepancies have been explained in terms of solute–solvent interaction. The investigations also include determination of distribution parameter α, the free energies of activation ΔF_τ, ΔF_η and the dipole moment μ of these esters in different solvents.

Method of Measurement and Analysis of Data. The dielectric permittivity ε' and dielectric loss ε'' of solutions at microwave frequency 9.83 GHz were determined by the measurement of wavelength in dielectric and standing wave ratio using a short circuited movable plunger by the method suggested by Heston *et al*[14] adapted for short circuited termination. The following expressions were used for calculation of ε' and ε''

$$\varepsilon' = \left(\frac{\lambda_0}{\lambda_c}\right)^2 + \left(\frac{\lambda_0}{\lambda_d}\right)^2$$

$$\varepsilon'' = \frac{2}{\pi}\left(\frac{\lambda_g}{\lambda_d}\right)\left(\frac{\lambda_0}{\lambda_d}\right)^2 \frac{d\rho}{dn}$$

where ρ stands for inverse standing wave ratio.

The heterodyne beat method was used for determining the static permittivity ε_0 and ε_∞ was taken as square of the refractive index which was measured by an Abbe's refractometer. The density of the solution was found out by a pycnometer. The viscosity of the solvent was determined by an Ostwald viscometer. All the measurements were made at 35 °C and the temperature was controlled within ±0.5 °C by a thermostat.

The solutes methyl trifluoroacetate (Purum), ethyl trifluoroacetate (Puriss) and ethyl trichloroacetate (Purum) were obtained from Mr. Fluka A.G., Switzerland. These substances were used without any further purification. Methyl trichloroacetate and *n*-propyl trichloroacetate were synthesized by the usual method of esterification using trichloroacetic acid and excess of methyl and *n*-propyl alcohol respectively. The boiling points, densities and refractive indices of the synthesized compounds were found to be in good agreement with the literature values.

Benzene AnalaR grade (B.D.H., India), carbon tetrachloride guaranteed reagent (E. Merck), *n*-heptane pure grade and cyclohexane AnalaR grade (Riedel, Hungary) were used after double distillation. *p*-Dioxane AnalaR grade (B.D.H., India) and decalin pure grade (Riedel, Germany) were used as such.

The dielectric relaxation time τ and the distribution parameter α were calculated by using Higasi's single frequency measurement method.[15] The expressions for τ and α are as under

$$\tau = \frac{1}{\omega}\left(\frac{A^2+B^2}{C^2}\right)^{1/2(1-\alpha)}$$

$$1-\alpha = \frac{2}{\pi}\tan^{-1}\frac{A}{B}$$

where

$$A = a''(a_0 - a_\infty)$$

$$B = (a_0 - a')(a' - a_\infty) - a''^2$$
$$C = (a' - a_\infty)^2 + a''^2$$

a_0, a', a'' and a_∞ are the slopes defined by the relations

$$\varepsilon_0 = \varepsilon_{10} + a_0 W_2$$
$$\varepsilon' = \varepsilon_1' + a' W_2$$
$$\varepsilon'' = a'' W_2$$
$$\varepsilon_\infty = \varepsilon_{1\infty} + a_\infty W_2$$

The polarization at infinite dilution $(P_2)_\infty$ was calculated with the help of Halverstadt and Kumler equation[16] as given below

$$(P_2)_\infty = \frac{3M_2 a_0 V_1}{(\varepsilon_1+2)^2} + M_2(\beta + V_1)\frac{\varepsilon_1 - 1}{\varepsilon_1 + 2}$$

where M_2 is the molecular weight of the solute and β is defined by $V_0 = V_1 + \beta W_2$. Where W_2 represents the weight fraction of the solute, ε_1 and V_1 are the static permittivity and specific volume of solvent and ε_0 and V_0 are the static permittivity and specific volume of the solution. With this value of $(P_2)_\infty$ and accepted bond refractivities the dipole moment was evaluated.

The free energies of activation for dielectric relaxation ΔF_τ and for viscous flow ΔF_η have been calculated using Eyring's equation.[17]

Results and Discussion

The values of d, ε_0, ε', ε'' and ε_∞ for five solutions of different concentrations of methyl trifluoroacetate, methyl trichloroacetate, ethyl trifluoroacetate and ethyl trichloroacetate in different solvents and *n*-propyl trichloroacetate in cyclohexane have been measured. The values of slopes a_0, a', a'' and a_∞ and β are recorded in Table 1. The values of τ, α and μ are given in Table 2(a) and 2(b).

It is evident from Table 2(a) that the relaxation time in each solvent increases with the increase in molecular size. This shows that relaxation time of the solute molecule is sensitive to molecular size. The large value of relaxation time for each of these molecules indicates that they relax predominantly by overall rotation.

Figure 1 gives the normalized plots of log τ *versus* log η for the above mentioned esters. The plots are linear for the solvents *n*-heptane, cyclohexane and decalin. In these solvents the relaxation time increases as the viscosity of the sovlent increases and the increase is in agremment with the relation $\tau = A\eta^x$ proposed

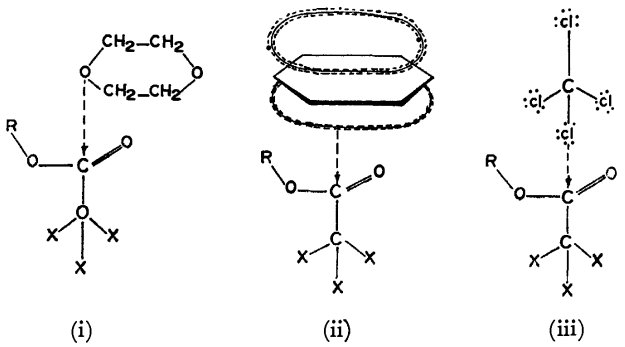
by Higasi.[6] Here x is a parameter less than unity. For spherical molecules x is very small and for non-spherical molecules x is nearly unity. The values of x obtained for these molecules lie between 0.50 and 0.85 hence these molecules are not spherical. Thus it may be concluded that the Higasi equation explains the dielectric behaviour of polar solutes in non-polar solvents of different viscosities provided the solvent molecules are inert to solute molecules.

The relaxation time for all these esters in benzene, *p*-dioxane and carbon tetrachloride shows an anomalous behaviour. The viscosity of benzene is less than that of cyclohexane whereas the relaxation time in benzene is more than that in cyclohexane. Similarly, although carbon tetrachloride and cyclohexane have nearly equal viscosity but the relaxation time in carbon tetrachloride is more than that in cyclohexane. The relaxation time in *p*-dioxane is quite large. Since the molecules have been studied in quasi-isolated state and as such the dipole-dipole interactions are negligible, this anomalous behaviour can be explained in terms of solute-solvent interactions. It is a well known fact that the ester molecule is a resonance hybrid in which carbonyl carbon assumes positive character. This positive character is further accentuated by the three electron attracting halogen atoms attached to the α carbon. This positive carbonyl carbon is liable to interact strongly with the oxygen lone-pair electrons in *p*-dioxane and π electrons of benzene ring forming complexes with these solvents resulting in large values of relaxation time. Though carbon tetrachloride is a symmetrical and non-polar molecule



yet each chlorine atom in carbon tetrachloride has three lone pairs of electrons and it can function as electron donor. Hence there is a possibility of interaction between the positive carbonyl carbon of the ester with the solvent carbon tetrachloride. Apart from the solute-solvent interactions the sticky nature of carbon tetrachloride may also play a considerable role in increasing the relaxation time of the ester molecule.

The value of dipole moment of each solute in different non-interacting solvents Table 2(b) is almost the same. The small difference may possibly be due to the solvent effect. The dipole moment of ethyl trifluoroacetate and ethyl trichloroacetate is higher than that for methyl trifluoroacetate and methyl trichloroacetate in each solvent. This is a general trend expected for members of a homologous series,[18] the effect being more pronounced for the second member of the series. This increase in moment may be attributed to the induction effects but no quantitative explanation has been advanced so far.[19] The dipole moment values for all these esters in cyclohexane, benzene and *p*-dioxane enable us to study the solute–solvent interactions in greater details. The difference $(\mu_D - \mu_C)$ and $(\mu_B - \mu_C)$, where μ_D, μ_B and μ_C refer to dipole moment of these esters in *p*-dioxane, benzene and cyclohexane respectively, are listed in Table 3.

TABLE 3. $(\mu_D - \mu_C)$ AND $(\mu_B - \mu_C)$

Solute	$\mu_D - \mu_C$ (Debye)	$\mu_B - \mu_C$ (Debye)
Methyl trifluoroacetate	0.36	0.23
Ethyl trifluoroacetate	0.33	0.13
Methyl trichloroacetate	0.30	0.21
Ethyl trichloroacetate	0.17	0.09

Table 4. The values of free energies of activation ΔF_τ and ΔF_η for trihalogenated esters

Solvents	ΔF_τ kcal/mol				ΔF_η kcal/mol
	Methyl trifluoroacetate	Ethyl trifluoroacetate	Methyl trichloroacetate	Ethyl trichloroacetate	
n-Heptane	2.03	2.27	2.13	2.30	3.01
Benzene	2.36	2.63	2.38	2.75	3.19
Cyclohexane	2.21	2.61	2.22	2.68	3.25
Carbon tetrachloride	2.31	2.75	2.34	2.84	3.22
p-Dioxane	2.49	2.79	2.49	2.96	3.27
Decalin	2.58	2.89	2.55	3.11	4.01

The difference is appreciable for all these molecules which indicates strong solute–solvent interactions. The $(\mu_D-\mu_C)$ values are higher than $(\mu_B-\mu_C)$ values which shows that the interactions of these esters with *p*-dioxane are stronger than those with benzene. It is interesting to note that difference values for fluoro compounds is more than that for corresponding chloro compounds. This is probably due to more electron attracting character of fluorine atom than chlorine atom which makes the carbonyl carbon more positive in fluoro compunds in comparison to that in chloro compounds.

The finite value of distribution parameter α calculated for these esters suggests that in these esters there are two possible relaxation mechanisms of Debye type *i.e.* overall rotation and intramolecular rotations. It is not possible to resolve the two relaxation times from single frequency measurements. If measurements are made at a number of microwave frequencies and a graph is plotted between a' and $a''\omega$ two distinct straight lines are obtained from which τ_1 and τ_2 can be evaluated. The systematic increase of α with increase of viscosity may be interpreted in terms of the disparity in two relaxation mechanisms involved in the relaxation processes. Almost regular rise of α implies that molecular relaxation time increases with viscosity where as the intramolecular does not seem to increase very much with the viscosity of the medium. It is evident from Table 2(a) that the distribution parameter increases with increase in chain-length *i.e.* from methyl to *n*-propyl trichloro esters. This increase in distribution parameter with chain length can be attributed to the number of shapes which the molecule can acquire by twisting around C-C bonds.[19] However, in case of trifluoroacetates it is observed that the distribution parameter decreases with chain-length. It is probable that addition of each CH_2 group in trifluoro esters tends to make the molecule more and more symmetric about O=C-O and thereby decreasing distribution parameter as has been suggested by Rajyam and Murty.[20] This fact needs further verification. It is expected that *n*-propyl trifluoroacetate might have a much smaller value of α, but could not be verified in this laboratory due to non-availability of this compound.

The free energies of activation ΔF_τ and ΔF_η for dielectric relaxation and for viscous flow respectively are listed in Table 4. It is evident from the table that the free energy of activation for dielectric relaxation increases with increase in molecular size. The free energy of activation for viscous flow is greater than that for the dielectric relaxation process. This is in agreement with the fact that the process of viscous flow involves greater interference by neighbours than in the case of relaxation process, because the former takes place by both rotation as well as translation where as the latter involves rotation only.[21,22]

The Thermal Decomposition Reactions of Bivalent Metal Succinates in the Solid State

Hiroko YOKOBAYASHI, Kenzo NAGASE, and Kazuo MURAISHI*

College of General Education, Tohoku University, Kawauchi, Sendai 980

**Department of Chemistry, Faculty of Science, Yamagata University, Koshirokawa, Yamagata 990*

(Received January 25, 1975)

The thermal decomposition reactions of $MC_4H_4O_4$ (M : Mg(II), Co(II), Ni(II), Cu(II), Zn(II), and Pb(II)) in nitrogen or helium were investigated by means of TG-DTA, X-ray diffraction measurements, gas chromatography, and combustion analysis for carbon. The decomposition residues of the Mg and Zn salts were composed of the corresponding metal oxides and some carbon, while those of the Co, Ni, Cu, and Pb salts were composed of the corresponding metals and some carbon. H_2, O_2, CO, CO_2, H_2O, CH_4, C_2H_2, C_2H_4, $HCOOCH_3$, $HCOOC_2H_5$, $CH_3COOC_2H_5$, $C_2H_5COOC_2H_5$, and $(CH_2CO)_2O$ were identified as the gaseous decomposition products; the compositions of the gaseous mixtures varied a great deal with the metals. Possible reaction mechanisms were discussed mainly on the basis of the decomposition products.

The thermal decomposition reactions of metal formates and oxalates have been widely investigated. In the case of metal oxalates, the primary decomposition stages was divided in three types, forming (i) metal oxide and an equimolar mixture of CO and CO_2, (ii) metal and CO_2, and (iii) metal carbonate and CO.[1] The tendency to form either metal or metal oxide is consistent with the prediction on thermodynamic grounds of the Ellingham diagram.[2]

The thermal decomposition reactions of metal salts of carboxylic acids with high proportions of both hydrogen and carbon have also been investigated by many workers, but the reactions are not well established in terms either of decomposition product or mechanism. Limited to metal succinates, only fragmentary information is available in the literature.[3-5]

In the present study, the solid and gaseous decomposition products of the anhydrous succinates of Mg(II), Co(II), Ni(II), Cu(II), Zn(II), and Pb(II) will be determined in detail, and the reaction mechanisms of these salts will be discussed on the basis of the results obtained systematically.

Experimental

Materials. The metal succinates were prepared by dissolving the corresponding metal carbonates in an aqueous solution of succinic acid. The values of the elemental analyses of C and H agreed with the calculated values within $\pm 0.3\%$ for all the salts.

Measurements. The thermogravimetric(TG) and differential thermal analytic(DTA) curves were obtained with a Shinku Riko TGD-3000 apparatus at a heating rate of 10 °C/min. In each measurement, *ca.* 20 mg of powdered sample was placed in a platinum crucible. X-Ray diffraction measurements were carried out with a Toshiba ADG-101 diffractometer in a nitrogen atmosphere. Except for the cobalt samples, Cu$K\alpha$ radiation and a nickel filter were used. Fe$K\alpha$ radiation and a manganese filter were used for the cobalt samples.

The evolved gas curves were obtained by the conductometric technique at a heating rate of 10 °C/min in a helium atmosphere. The procedure was described in a previous paper.[6] Analyses of evolved gas were performed with a Shimadzu GC-1C gas chromatograph and a Shimadzu PYR-1A pyrolyzer. A column (2 meters long) packed with 60—80 mesh active carbon was used for the analysis of nonpolar gases, and a column (2 meters long) with 60—80 mesh Gaskuro Kogyo Chromosorb-101 was used for that of polar gases. The procedure was as follows: the temperature of the pyrolysis chamber was adjusted to the peak temperature on the evolved gas curves. *Circa* 3 mg of a powdered sample in a platinum boat was introduced into the pyrolysis chamber, and it was then maintained at that temperature for 3 min. By changing the two-way valve, helium carrier gas (60 ml/min) was routed through the pyrolysis chamber so that the evolved gases were carried out into the column which was maintained at a constant temperature. The column temperatures were 100 °C for active carbon and 60, 90, and 120 °C for Chromosorb-101. The retention times were as follows: active carbon column (at 100 °C): 0.5 (H_2), 0.9(O_2), 1.1(CO), 2.0(CH_4), 3.7(CO_2), 13.5(C_2H_2), and 19.8(C_2H_4) min. Chromosorb-101 column (at 120 °C):1.2(H_2O), 2.2($HCOOCH_3$), 5.2 ($HCOOC_2H_5$), 11.7 ($CH_3COOC_2H_5$), and 27.5($C_2H_5COOC_2H_5$). The assignments were checked by using columns coated with liquid paraffin or triacetin.

Results

The TG-DTA curves of the salts of Mg, Co, Ni, Cu, Zn, and Pb in a nitrogen atmosphere are given in Figs. 1 and 2. A weight-loss beginning at 25—62 °C for the salts of Mg, Co, Ni, and Cu corresponded to the removal of the water molecules contained in these salts. The anhydrous salts of Mg, Co, and Ni just after the dehydration were amorphous, and the anhydrous salts of Mg and Co recrystallized at 306 and 272 °C respectively, with a sharp exotherm on each DTA curve. The lead salt showed an endotherm at 160 °C on its DTA curve. The endothermic passage corresponded to the phase transition from tetragonal to cubic. The details of the thermal behavior before the decomposition of the anhydrous salts will be reported elsewhere.

The decomposition of the anhydrous salts began at 237—426 °C. The decomposition temperatures (t_i) which were determined by means of the initial weight-loss temperatures, varied a great deal with the metal as may be seen in Table 1. Except for the magnesium salt, the DTA peaks splits into two or more, suggesting that these salts decomposed through multiple steps. The infrared absorption measurements at several magnitudes of the decomposition showed no presence of solid intermediates in the course of the decomposi-

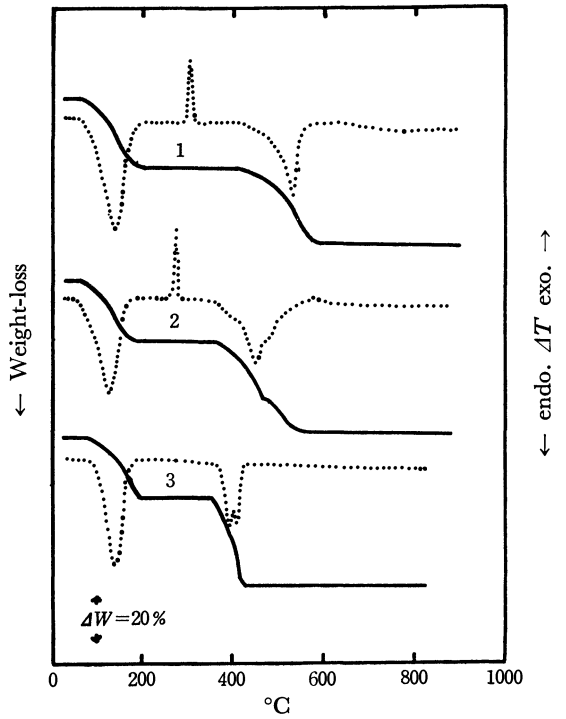

Fig. 1. TG-DTA curves of (1) $MgC_4H_4O_4 \cdot 4H_2O$, (2) $CoC_4H_4O_4 \cdot 4H_2O$, and (3) $NiC_4H_4O_4 \cdot 4H_2O$ in a nitrogen atmosphere: — indicates TG and ···, DTA.

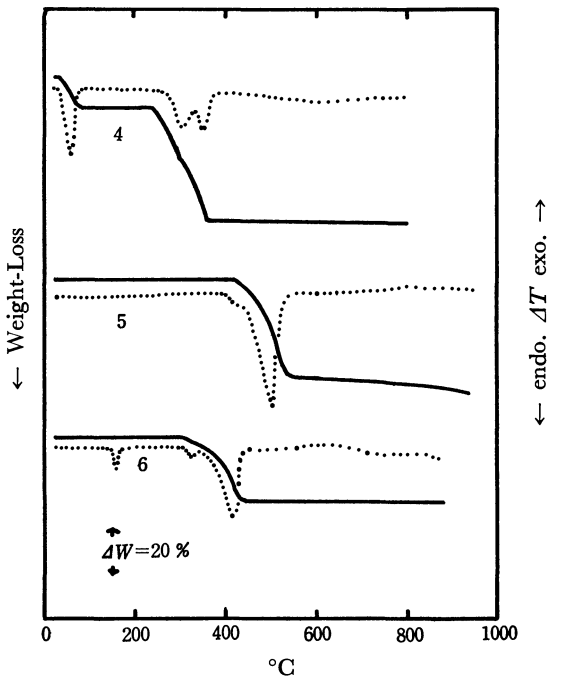

Fig. 2. TG-DTA curves of (4) $CuC_4H_4O_4 \cdot 2H_2O$, (5) $ZnC_4H_4O_4$, and (6) $PbC_4H_4O_4$ in a nitrogen atmosphere: — indicates TG and ···, DTA.

tion processes. Except for the salts of Mg, Zn, and Pb, however, the values of CO/CO_2 in the gaseous mixtures were greatly different between the primary and following steps. In the case of the copper salt, which decomposed in two steps, the CO/CO_2 ratio at the primary step was 2.3, while that at the secondary step was near zero. The salts of CO and Ni showed a similar tendency. On the other hand, the salts of Mg, Zn, and Pb predominantly evolved CO_2 over the decomposition processes.

The X-ray diffraction measurements confirmed that the final decomposition products for the salts of Co, Ni, Cu, and Pb were the metals, while those for the magnesium and zinc salts were the metal oxides. In the case of the zinc salt, however, the vaporization of zinc metal was observed above 600 °C, so no well-difined plateau for zinc oxides was seen on its TG curve, the reduction of zinc oxide probably taking place above that temperature. Although the product of the lead salt was identified as lead metal by the X-ray diffraction, it did not melt even well above the melting point of pure lead (327.3 °C). The lead metal obtained might be finely divided pyropholic lead metal, as indicated in the thermal decomposition of lead citrate[7] and tartarate.[8]

The decomposition residues for all the salts contained some carbon in addition to the metals or the metal oxides. The amount of carbon included was determined by combustion analysis (Table 1). There is possibility of the formation of the metal carbides, as has been reported in connection with the thermal decomposition of nickel malonate in a vacuum.[9] In the present work, however, no X-ray diffraction lines corresponding to the metal carbides were observed. The weight-losses (ΔW_{obsd}) agreed approximately with the values calculated (ΔW_{cald}) for the compositions which were evaluated from X-ray diffraction measurements and combustion analysis for carbon, as may be seen in Table 1.

The gas chromatograms of the salts of Mg, Co, and Cu are given in Figs. 3 and 4 as examples. They correspond to the evolved gases when the anhydrous salts were pyrolyzed at the final peak temperature of

Table 1. Initial decomposition temperatures (t_i), weight-losses (ΔW) and decomposition residues of the succinates, and heats of formation (ΔH_f°) of the metal oxides $M + 1/2O_2 \rightarrow MO$

Salt	t_i/°C	ΔW_{obsd}/%	ΔW_{calcd}[a]/%	Residue	ΔH_f°/kcal
$MgC_4H_4O_4 \cdot 4H_2O$	409	34.9	35.8	MgO+2.0C	−143.8
$CoC_4H_4O_4 \cdot 4H_2O$	356	39.3	40.2	Co+1.4C	−57.2
$NiC_4H_4O_4 \cdot 4H_2O$	351	39.6	39.7	Ni+1.5C	−58.4
$CuC_4H_4O_4 \cdot 2H_2O$	237	50.2	51.6	Cu+0.4C	−37.1
$ZnC_4H_4O_4$	426	42.9	41.9	ZnO+1.2C	−83.2
$PbC_4H_4O_4$	309	27.7	29.7	Pb+1.6C	−52.1[b]

each evolved gas curve. Although CO_2 predominated in the gaseous products for all the salts, the compositions of the gaseous mixtures varied considerably with the metals. The salts investigated could be divided in three groups. The magnesium and zinc salts, which gave similar chromatographic patterns, evolved hydrogen-rich compounds, such as H_2, CH_4, and C_2H_4, while the copper and lead salts in another group tended to evolve O_2, H_2O, $HCOOCH_3$, and C_2H_2. The latter gases are relatively oxygen-rich or hydrogen-poor compounds. Although H_2O and $HCOOCH_3$ were observed for all the salts, the latter salts were richer in them. The cobalt and nickel salts were intermediate between the two groups in the quantities of CH_4 and H_2O and were characterized as evolving a large amount of CO. All the salts gave succinic anhydride in addition to the gases shown in the gas chromatograms. Its formation was confirmed by infrared measurements.

Discussion

The values of t_i increased with the decrease in the heats of formation of metal oxide (ΔH_f°), as may be seen in Table 1, with the exception of the magnesium salt. The values of t_i for the salts of Co, Ni, Cu, and Pb, which gave the metals as decomposition residues, were correlated by a straight line with ΔH_f° (Fig. 5), suggesting that the decomposition of these salts may be initiated by electron transfer from a succinate anion to a metal cation, as has been indicated for metal oxalates and metal oxalato complexes.[10]

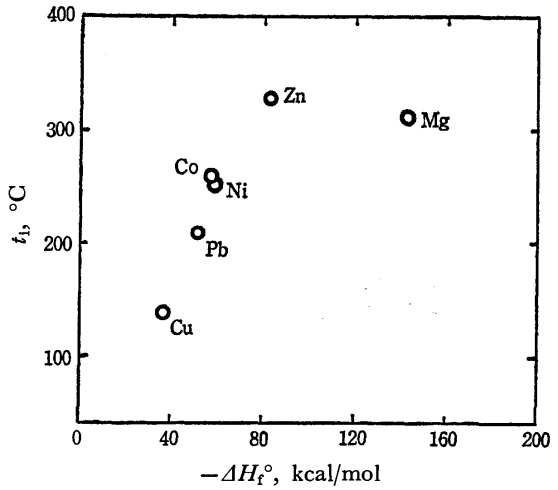

Fig. 5. Correlation of initial decomposition temperatures(t_i) of the anhydrous succinates with heats of formation(ΔH_f°) of the metal oxides.

The amounts of carbon in the decomposition residues are considered to correlate, to some extent, with ΔH_f°, since such secondary reaction as

$$MO + C \longrightarrow M + CO$$

or

$$MO + 1/2C \longrightarrow M + 1/2CO_2$$

are possible at the decomposition temperatures. In fact, the amount of carbon decreased with the increase in ΔH_f°, with a few exceptions (Table 1).

The amounts of H_2 and O_2 are also considered to correlate with ΔH_f° as a result of possible secondary reactions, such as

$$M + 1/2O_2 \longrightarrow MO$$

$$MO + H_2 \longrightarrow M + H_2O$$

In the case of the salt of Cu, which is thermodynamically most stable in the metallic state, the evolution of

H_2 was not observed. It is difficult to discuss the reaction schemes in detail, since the overall reactions might be composed of a number of elementary reactions whose contributions might vary with the reaction temperature, the decomposition pressure, and the extent of decomposition.

The Extraction Spectrophotometric Determination of Iron(III) with Eriochrome Cyanine R and Tridodecylethylammonium Bromide

Yoshio SHIJO

Department of Industrial Chemistry, Faculty of Engineering, University of Utsunomiya, Ishii-machi, Utsunomiya 321-31

(Received January 28, 1975)

A sensitive spectrophotometric procedure for the determination of iron(III) has been developed, utilizing the ternary complex system of iron-Eriochrome Cyanin R-Tridodecylethylammonium. The iron-Eriochrome Cyanin R chelate anion was extracted with tridodecylethylammonium bromide in xylene. The extracted species had an absorption maximum at 613 nm in the organic layer. The optimum pH range for the extraction was 5.8—6.5. Beer's law held for 0.2—2 μg of iron(III) in 5 ml of the organic layer. The molar absorptivity of the extracted species was 1.73×10^5 $cm^{-1}\cdot mol^{-1}\cdot l$ at 613 nm. The composition of the ternary complex was assumed to be $\{[Fe(HR)_3]^{6-}\}\cdot\{(R'-\overset{R''}{\overset{|}{N}}{}^{+}-R'')_6\}$. Lead, mercury, tin, chromium, beryllium, thorium, uranium, nitrate, iodide, thiocyanate, and perchlorate interfered with the determination of iron(III).

In the process of investigating the extraction of the metal chelate anion with tridodecylethylammonium bromide (abbreviated as TDEA) in the organic layer, we have recently described an extraction spectrophotometric method for scandium[1] and yttrium[2] as metal-Xylenol Orange chelate anions and for copper,[3] tin,[4] and aluminum[5] as metal-Pyrocatechol Violet chelate anions. These studies showed that the extracted ternary complex systems of [Metal-Ligand-TDEA] were very sensitive in their colour reactions. Eriochrome Cyanin R (abbreviated as ECR) forms water-soluble chelate anions with metal ions and has been used as a metallochromic indicator or as a colorimetric reagent for several metal ions. The interaction of metal-ECR chelate anions with quaternary ammonium salts such as cetyltrimethylammonium chloride had been applied to the spectrophotometric determination of aluminum,[6,8] beryllium,[7] iron,[8] and uranium[9]. The extraction of the metal-ECR chelate anions, however, had not been yet reported. In this paper, the fundamental conditions for the extraction spectrophotometric determination of iron (III) as the iron-ECR-TDEA ternary complex and the composition of the ternary complex extracted into xylene will be discussed. Further, the relation between highly sentitive colour reaction of the iron-ECR-CTMA complex in a micelle solution of CTMA and the extracted ternary complex of the iron-ECR-TDEA system will be described somewhat.

Experimental

Reagent. A 2.5×10^{-3} M iron(III) solution was prepared by dissolving a definite amount of ferric ammonium sulfate in 1 M hydrochloric acid. A working standard solution was prepared as needed by the dilution of the 2.5×10^{-3} M solution with deionized water to the desired concentration. Tokyo Kasei Eriochrome Cyanin R was purified following the purification method Chromazurol S.[10] 4 g of ECR were dissolved in 20 ml of deionized water, and the tetrabasic acid was precipitated by adding 20 ml of concentrated hydrochloric acid. The precipitate was filtered in a glass filter crucible, washed with a 1 : 1 hydrochloric acid solution, and dried in a vacuum over solid potassium hydroxide. The acid was reprecipitated from the solution, filtered, washed, and dried as has been described above. Further, the final product was dried to a constant weight over phosphorus pentoxide. Drying loss at 150 °C; 1.8%. Sulfur found by means of the combustion flask method; S, 6.63%, Calculated for $C_{23}H_{18}O_9S$; S, 6.81%. A 5×10^{-4} M ECR solution was prepared by dissolving the purified ECR in 0.001 M HNO_3 and by then adding 0.02% of urea. The TDEA was prepared by the reaction[11] of tridodecylamine with ethylbromide in an alcoholic solution. The salt was recrystallized from petroleum benzine. A 8×10^{-4} M TDEA solution was subsequently prepared by dissolving the above TDEA in xylene.

Apparatus. All the measurements of the absorbance were made with a Hitachi manual spectrophotometer, model Epu-2A. Matched 10-mm, 5-mm, and 2-mm absorption cells were used. The pH measurements were made with a Hitachi-Horiba model M-5 glass electrode pH meter.

Standard Procedure. Place up to 2 μg of iron(III) in a 100-ml separatory funnel and add a definite amount of 0.2 M hydrochloric acid. Add 2 ml of a 5×10^{-4} M ECR solution. Adjust the pH to 6 with a 2 ml portion of a 2 M sodium acetate buffer solution and dilute to 25 ml with deionized water. Add 5 ml of 8×10^{-4} M TDEA in xylene and extract for 2 min with vigorous shaking. After the phase have separated, draw off the aqueous layer and centrifuge the extract for 3 min at 3000 rpm. Transfer the extract into an absorption cell and measure the absorbance at 613 nm against the reagent blank obtained in the same way.

Results and Discussion

Absorption Spectra. The absorption spectra of the ternary complex extracted into xylene, of the iron (III)-ECR-CTMA complex in a micelle solution of CTMA, and of the iron(III)-ECR chelate anion in an aqueous solution are given in Fig. 1, along with that of the reagent blank. The iron(III)-ECR chelate anion had an absorption maximum at 560 nm in an aqueous solution. On the other hand, the absorption maximum of the ternary complex in xylene shifted to a longer wavelength, 613 nm, and the absorbance increased remarkably. The absorption characteristics of the iron(III)-ECR-CTMA complex in a micelle solution of CTMA were similar to those of the ternary complex. These results showed that the

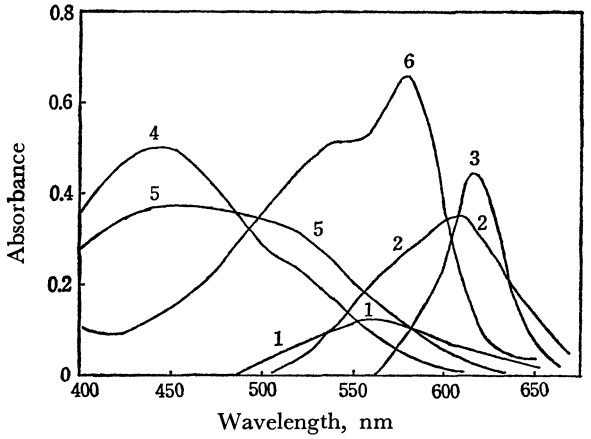

Fig. 1. Absorption spectra of the Fe-ECR-TDEA complex.
pH: 6, Volume of aq. layer $V_w=25$ ml, $[acetate]_w=0.16$ M, Volume of org. layer $V_0=5$ ml, 10 mm cell
(1) Fe-ECR in aq. soln. $[Fe]_w=2.5\times10^{-6}$ M
(2) Fe-ECR-CTMA in micelle soln. of CTMA $[Fe]_w=2.5\times10^{-6}$ M
(3) Fe-ECR-TDEA in xylene $[Fe]_o=2.5\times10^{-6}$ M.
(4) ECR in aq. soln. $[ECR]_w=3\times10^{-5}$ M
(5) ECR in micelle soln. of CTMA $[ECR]_w=3\times10^{-5}$ M
(6) ECR-TDEA in xylene $[ECR]_o=3\times10^{-5}$ M.

shift of the absorption maximum and the increase in the absorbance occurred in common with the action of long-chain quaternary ammonium salts to the iron(III)–ECR chelate anion, not only in a micelle solution of them. It was thought that the organic phases in the micelle and the extracted layer were related to the absorption characteristics of the ternary complex. The absorption maximum of ECR extracted with TDEA in xylene shifted to a longer wavelength.

Effect of pH. The effect of the pH of the aqueous phase on the absorbance was examined. The results are shown in Fig. 2. The maximum absorbance of the ternary complex was obtained at pH values from 5.8 to 6.5. The complex was extrated at considerably higher pH values, *viz.*, about 8, by the addition of glycine to the initial aqueous phase.

Organic Solvents. Several kinds of organic solvents were tested in order to achieve a quantitative extraction of iron (III). The ternary complex could be extracted into benzene, toluene, xylene, carbon tetrachloride, and *n*-buthyl acetate, but not into such polar solvents as *n*-butanol, methyl isobutyl ketone, and nitrobenzene. Xylene was chosen as the solvent.

The Effect of the ECR Concentration. The effect of the ECR concentration in the aqueous phase on the extraction of the ternary complex was examined by varying the ECR concentration, while the other variables were held constant. The absorbance of the extract was constant when the ECR in the initial aqueous phase was in the concentration range from 3.6×10^{-5} M to 4.4×10^{-5} M, as is shown in Fig. 3. The absorbance of the extract decreased suddenly upon the further addition of ECR. It was considered that a large quantity of ECR suppressed the extraction of the ternary complex, consuming the TDEA to form an ion pair with it.

The Effect of the TDEA Concentration. The effect of the concentration of TDEA in xylene on the absorbance of the ternary complex was examined. The absorbance of the extract was constant when the TDEA in xylene was in the concentration range from 7×10^{-4} M to 9×10^{-4} M, as is shown in Fig. 4. The absorbance of the extract gradually decreased upon the further addition of TDEA. However, the extraction of the ternary complex was carried out almost quantitatively in the concentration range of TDEA from 9×10^{-4} M to 1.5×10^{-3} M. The molar absorptivity of the ternary complex decreased when there was a large excess of TDEA in xylene.

a) 1 ml of 1M glycine was added as masking agent. b) 1 ml of 1 M glycine, 1 ml of 30% hydrogen peroxide, and 1 ml of 1 M potassium fluoride were added as masking agents.

The Effect of the Shaking Time. The shaking time was varied from 10s to 10 min. The absorbance of the extract was constant for the shaking times from 30 s to 10 min. A shaking time of 2 min was, therefore, selected.

Extractability and Molar Absorptivity. The extractability of the ternary complex under the optimum conditions was determined by a repetition of the extraction procedure on the same aqueous layer. When a 25-ml portion of an aqueous layer containing 1.4 μg of iron(III) was shaken with 5 ml of xylene, 97% of the iron(III) was extracted by one extraction. The molar absorptivity of the ternary complex calculated by using the percentage extraction and the absorbance was 1.73×10^5 $cm^{-1}\cdot mol^{-1}\cdot l$.

Calibration Curve. A calibration curve for the determination of iron(III) was made under the optimum conditions. A good linear relationship was obtained over the concentration range from 0.2 to 2 μg of iron(III) per 5 ml of xylene.

The Effect of Diverse Ions. The effect of foreign ions on the determination of iron(III) under the addition of 1 ml of 1 M glycine, 1 ml of 30% hydrogen peroxide, and 1 ml of 1 M potassium fluoride as masking agents to the initial aqueous phase at pH 8 was examined. The results are summarized in Table 1. Lead, mercury, tin, beryllium, thorium, and uranium interfered considerably. Of the anions tested, nitrate, iodide, thiocyanate, and perchlorate interfered seriously, giving a negative error. Chelating agents such as EDTA also interfered.

The Composition of the Ternary Complex. The results of the continuous-variation method indicated

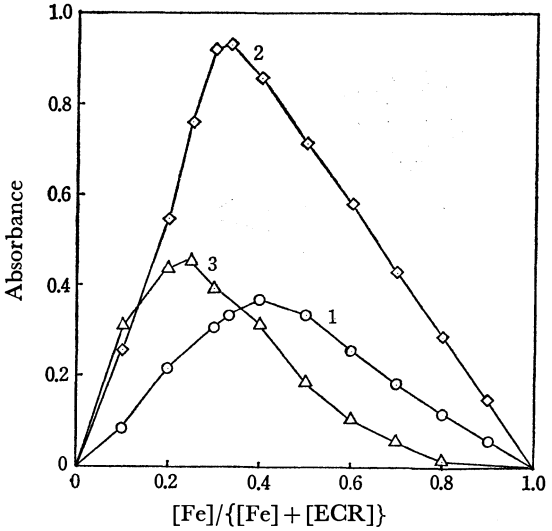

Fig. 5. Continuous variation method applied to the Fe-ECR-TDEA complex, the Fe-ECR-CTMA complex, and the Fe-ECR chelate.
pH: 6, $[acetate]_w=0.16$ M, 5 mm cell
(1) Fe-ECR chelate in aq. soln. $[Fe]_w+[ECR]_w=4\times10^{-6}$ M, 560 nm.
(2) Fe-ECR-CTMA cnmplex in micelle soln. of CTMA $[Fe]_w+[ECR]_w=4\times10^{-6}$ M,645 nm.
(3) Fe-ECR-TDEA complex in xylene $[Fe]_w+[ECR]_w=4\times10^{-6}$ M, $[TDEA]_o=8\times10^{-4}$ M, $[Glycine]_w=4\times10^{-2}$ M, 613 nm.

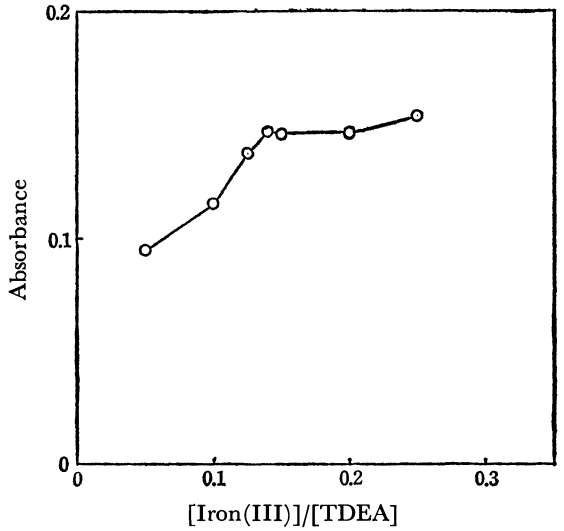

Fig. 6. Mole ratio method applied to the Fe-ECR-TDEA complex.
pH: 6, $[acetate]_w = 0.16$ M, $[ECR]_w = 4 \times 10^{-5}$ M, $[TDEA]_o = 8 \times 10^{-4}$ M, 600 nm, 2 mm cell.

that the molar ratios of iron(III) to ECR in the chelates were 1 : 1.5 in an aqueous solution, 1 : 2 in a micelle solution of CTMA, and 1 : 3 in the extracted species, as is shown in Fig. 5. The molar ratios of iron(III) to ECR increased in the micelle solution of CTMA and in the extracted species. It was thought that the increase in the combination ratio of ECR in the extracted species was due to the higher coordinated complex, it was more stable in the organic layer. The results of the mole-ratio method indicated that the molar ratio of iron(III) to TDEA in the extracted species was about 1 : 7, as is shown in Fig. 6. The bulk of ECR, however, existed as HR^{3-} [12] in the aqueous solution about pH 6, and the molar ratio of iron(III) to ECR in the extracted species was estimated to be 1 : 3. Therefore, the extracted species was assumed to be probably the ternary complex $\{[Fe(HR)_3]^{6-}\}\cdot\{(TDEA^+)_6\}$.

The Gas-chromatographic Determination of Selenium in Copper Metal and Copper Salts with 4-Nitro-*o*-phenylenediamine

Yasuaki SHIMOISHI*

Department of Chemistry, Faculty of Science, Okayama University, Tsushima, Okayama-shi, 700

(Received January 30, 1975)

The gas-chromatographic method using an electron-capture detector has a high sensitivity for the determination of selenium. Moreover, as the reaction of selenium(IV) with 4-nitro-*o*-phenylenediamine is scarcely disturbed by other elements, the chemical separation from the matrix element is not necessary. The direct determination of very small amounts of selenium in copper and copper salts has been investigated. A mixture of equal volumes of nitric acid, hydrochloric acid, and perchloric acid dissolves the copper sample and also oxidizes the selenium to the quadrivalent state quantitatively. No loss of selenium was observed upon this treatment. The proposed method can determine the selenium in copper samples in amounts as low as 0.005 μg/g.

Trace amounts of selenium are commonly present in metals and alloys. The selenium content in metals influences the mechanical strength. In some instances, small amounts of selenium are added in order to improve the property. The accurate determination of trace amounts of selenium in copper has become increasingly important in recent years. Various methods, such as the spectrophotometric method,[1,2] X-ray spectroscopy,[3] and the atomic-absorption method[4] are widely used. However, chemical separation[5-7] is usually necessary before one can analyze trace amounts of selenium.

The present author has recently proposed a far more sensitive method for determining selenium in sulfuric acid,[8] tellurium,[9] sea water,[10] and plant materials[11] by means of a gas chromatograph equipped with an electron-capture detector using 4-nitro-*o*-phenylenediamine. Cheng[1] has reported that copper is masked with EDTA in the determination of selenium using 3,3′-diaminobenzidine. However, the reaction of selenium(IV) with 4-nitro-*o*-phenylenediamine was not disturbed by a large amount of copper and selenium present in copper salts, and copper metal can be determined without any separation or masking. The present paper will describe the determination of very small amounts of selenium in copper metal and copper salts.

Experimental

Reagents. 4-Nitro-*o*-phenylenediamine dihydrochloride solution (1%): The reagent was purified by repeated recrystallizations of commercial 4-nitro-*o*-phenylenediamine from a hydrochloric-acid solution. One gram of the reagent was dissolved in 100 ml of 1 M hydrochloric acid. Selenium(IV) stock solution: A 704-mg portion of selenium dioxide was dissolved in 500 ml of distilled water. The concentration was determined gravimetrically as 0.98 mg/Se/ml. The working solutions were prepared by dilution. Oxidation mixture: Concentrated hydrochloric acid and nitric acid were mixed in equal volumes. This solution was prepared each time before use. The other reagents were of an analytical reagent grade.

Apparatus. A Shimadzu Model GC-3AE Gas Chromatograph equipped with an electron-capture detector was used. A glass column (1 m long, 4 mm bore) was packed with 15% SE-30 on 60—80 mesh Chromosorb W. The column and detector temperature was maintained at 200 °C. The nitrogen flow-rate was 36 ml/min. A Shimadzu Model 250A recorder was used at a chart speed of 5 mm/min.

Standard Procedure. Accurately weighed copper samples which have been cut into about 10-mg segments are placed in a 100 ml conical flask. Five ml of perchloric acid and 10 ml of the oxidation mixture are added, and the mixture is heated on a sand bath (200—230 °C) in a fume hood (this acid mixture is used for 1 g of copper or less). A vigorous oxidation reaction soon takes place, and a copious brown vapor is evolved. After a few minutes, the main reaction comes to an end. The solution is heated further until a white fume of perchloric acid is evolved. Then the conical flask is removed from the sand bath. After the precipitate has been redissolved with 10 ml of distilled water, the content is transferred into a 50-ml volumetric flask. The solution is diluted to the mark with distilled water. An aliquot containing 0.01—0.03 μg of selenium is transferred into a 100-ml separatory funnel containing 25 ml of 1 M hydrochloric acid which has previously been washed with toluene. A 2-ml portion of 1% 4-nitro-*o*-phenylenediamine is then added, and the solution is allowed to stand for 2 hr. Then, the 5-nitropiaselenol formed is extracted into 1 ml of toluene by shaking for 5 min and the toluene extract is washed with 2 ml of a 7.5 M hydrochloric acid solution. A 5-microliter portion of the toluene extract is injected into the gas chromatograph, and the peak height is measured.

The selenium content in copper salts is always less than that in copper metal. Consequently, in the case of copper salts, after the oxidation procedure all the contents are transferred into a 100-ml separatory funnel and washed with 1 ml of toluene. Then, the aqueous phase is transferred into another 100 ml separatory funnel. A 2-ml portion of 4-nitro-*o*-phenylenediamine is added. The following procedure is the same as that described above.

Results and Discussion

Oxidation of Selenium. Most of the selenium contained in copper metal is present in the form of selenium(II), since, on the electrolytic refining of copper, selenium can easily react with copper to form Cu_2Se. Clark[12] reported that, when a piece of thin copper film was dipped in a hydrochloric acid solution of selenite, the copper was coated with a black film of Cu_2Se. Therefore, the selenium in copper and copper salts must be oxidized to the quadrivalent state. Nitric acid is usually used in order to dissolve

and oxidize both copper and selenium. Gorsuch[13] suggested that there was not 100% recovery when a mixture of nitric acid and sulfuric acid was used for plant samples. The mixtures of nitric- and perchloric acid, hydrochloric- and nitric acid, and hydrochloric-, nitric- and perchloric acid were compared in terms of their efficiency in oxidizing selenium in both copper metal and copper salts. Only the last acid mixture can oxidize quantitatively the selenium in both samples. Thus, the mixture of hydrochloric-, nitric-, and perchloric acid was used for the dissolution of copper samples. The bromine-bromide redox buffer[8] in a sulfuric acid medium can also be used as a convenient oxidation reagent for copper salts. A gas chromatogram obtained with 500 mg of copper treated by the above-mentioned procedure is shown in Fig. 1.

Dissolution with the Mixture of Hydrochloric-, Nitric-, and Perchloric Acid. Usually, volatile compounds, such as $SeO_2 \cdot 2HCl$ and $SeOCl_2$, are formed during a dissolution in the presence of hydrochloric acid. These compounds must be responsible for the loss of selenium. In order to check whether or not there is any loss of selenium, the effects of the concentration of the oxidation mixture, the oxidation time, and the oxidation temperature were studied. As is shown in Fig. 2, the selenium in 0.5 g of copper metal could be oxidized quantitatively with more than 3 ml of the oxidation mixture in the presence of 5 ml of perchloric acid, and a good recovery was observed. If a smaller amount of the oxidation mixture is used, the back ground of the chromatogram becomes so high that the determination is not accurate. Therefore, 10 ml of the oxidation mixture and 5 ml of perchloric acid were used for the following experiments. If more than 1 g of copper metal is used for the determination, the procedure is disturbed by the deposition of the copper salt during the oxidation procedure. However, this trouble can be overcome by dissolving the precipitate with another 5 ml of perchloric acid.

The oxidation temperature was examined in the approximate range from 130 to 270 °C (sand-bath temperature). The maximum constant peak height was obtained in this region. As a longer oxidation time was needed at a lower oxidation temperature, the optimum oxidation temperature was in the approximate range from 200 to 230 °C. When the heating was continued at this temperature until the color of the solution turned pale blue, the selenium in the copper was oxidized to the quadrivalent state completely. Moreover, no selenium at the 0.1 μg level was lost by volatilization when heated for 20 min, after the evolution of white fumes of perchloric acid. Consequently, the heating was continued at about 230 °C until white fumes of perchloric acid were evolved. The whole oxidation procedure requires about 30 min.

Very small amounts of interfering substances in the distilled water used for dilution often disturb the determination, because the sensitivity of the electron-capture detector is extremely high for the unknown impurities as well as for 5-nitropiaselenol. Therefore, these interfering substances should be remove by washing with toluene. When the selenium content in copper metal is too high, the sample solution is diluted with a 1 M hydrochloric acid solution which has previously been washed with pure toluene. For the copper salts, the sample solution is washed directly with 1 ml of toluene after oxidation. Moreover, the reagent solution also contains small amounts of interfering substances; therefore, 1 ml of the toluene extract after the formation of 5-nitropiaselenol should be washed again with 2 ml of 7.5 M hydrochloric acid.

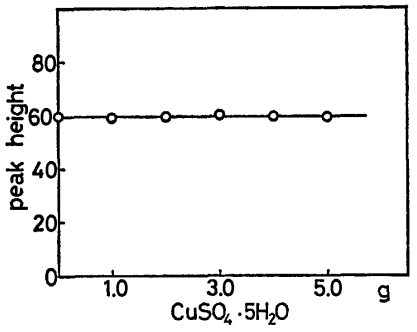

Fig. 3. Effect of copper matrix.
0.0196 μg selenium(IV) + $CuSO_4 \cdot 5H_2O$
No oxidation procedure.

Effect of the Copper Matrix. In order to check the influence of a large amount of copper ions upon the determination of selenium, 0.0196 μg Se(IV) was added to a copper-sulfate solution and determined. As is shown in Fig. 3, the selenium was recovered qunatitatively even in the presence of 5 g of $CuSO_4 \cdot 5H_2O$. Therefore, the masking or separation procedure is not necessary before the determination.

Effects of Foreign Ions. The effects of several foreign ions, such as Fe^{3+}, As^{3+}, and Pb^{2+}, were reported in the previous paper.[9] As is shown in Table 1, even if 10^3 times as many foreign ions are present, no effect is found. In particular, this method is scarcely effected by Mn^{2+} and V^{5+}. It seems that this method can be utilized for the direct determination of selenium in the presence of considerably large amounts of these elements.

Accuracy and Precision. The accuracy of the procedure was evaluated by recovery experiments using copper metal (powder). Recovery was established by dissovling the copper metal to which a known amount of selenium had been added, and by treating the samples as has been described. In all cases, theoretical recovery was obtained within the limits of experimental error (Table 2). The precision was evaluated using a copper metal (powder). The results are shown in Table 3.

Calibration Curve. The calibration curve was made with known amounts of selenous acid in a hydrochloric acid solution. The curve was coincident with that obtained from the same selenous acid by the oxidation procedure. Therefore, the curve obtained without the oxidation procedure is used for the determination. One of the calibration curves obtained at various sensitivities of the gas chromatograph is shown in Fig. 4. More than 0.005 μg of selenium can be determined.

Determination of Selenium in Copper metal and Copper Salts. Selenium can be determined successfully even in 0.1 g of copper metal or copper salts, because the ECD gas chromatograph is very sensitive to 5-nitropiaselenol. However, the values obtained in small-sample portions are dispersed widely; this implies that the distribution of the selenium is heterogeneous in copper metal and copper salts. Therefore, in many cases, 10 g or more is mixed well, and a small portion should be taken from the matrix for the determination. However, if copper powder is used, the value of the selenium content is proportional to the powder weight, because the selenium content in copper powder seems to be homogeneous. When 10 g of copper (99.999%) plate was cut into 10-mg segments, and 1—2 g of it was taken after mixing for the determination, the value obtained was reproducible. The peak height of selenium in the sample thus obtained is proportional to the sample weight, as is

shown in Fig. 5, and all the lines pass through the same point. The peak height of this point is in fair agreement with the blank value. This indicates that the oxidation is complete and that no loss of selenium occurs during the procedure.

The selenium in 1—2 g of copper metal was determined by the standard procedure; the results are shown in Table 4. The selenium in copper salts can also be determined by the standard procedure, as is shown in Table 5. The selenium in cupric sulfate seems to exist in the form of selenide, because it can not be determined without the oxidation procedure. On the other hand, the selenium in cupric nitrate and chloride may exist in the quadrivalent state, because it can be determined quantitatively without the oxidation procedure (Procedure C in Table 5). To copper metal or copper salts, a known amount (0.0098—0.49 μg) of selenium was added in the quadrivalent state, and the recovery was then examined. The results were satisfactory in all cases, within the limits of experimental error.

Table 4. Selenium content in copper metal

Material	Selenium content[a] $\times 10^{-5}$%
Copper 99% power	15.9±0.5
Copper 99.99% electrolytic (I)	8.1±0.9
Copper 99.99% electrolytic (II)	1.4±0.1

Isomerism of the Metal Complexes Containing Multidentate Ligands. VI. Geometric and Optical Isomers of the Tris(*meso*-2,3-butanediamine)-cobalt(III) Complex

Masaaki KOJIMA, Hiromi FUNAKI, Yuzo YOSHIKAWA, and Kazuo YAMASAKI
Department of Chemistry, Faculty of Science, Nagoya University, Chikusa-ku, Nagoya 464
(Received February 19, 1975)

The tris(*meso*-2,3-butanediamine)cobalt(III) complex was prepared, and four possible isomers, *mer*-Λ, *mer*-Δ, *facial*-Λ, and *facial*-Δ, were isolated by column chromatography on SP-Sephadex in the formation ratio of 1.4 : 1.4 : 1.0 : 1.0. The configurations and conformations of these isomers were proposed on the basis of the electronic, the circular dichorism, and the PMR spectra.

When unsymmetric bidentate ligands such as *R*-1,2-propanediamine(*R*-pn)[2] and 2-methyl-1,2-propanediamine(ibn)[3] coordinate to the cobalt(III) ion, geometric(*mer* and *facial*) isomers are formed by the positions of the methyl groups in addition to the optical isomers(Δ and Λ); they have been isolated and characterized. When a symmetric ligand with a *meso* structure like *meso*-2,3-butanediamine(mbn) coordinates, geometric isomers(*mer* and *facial*) are formed by the alignment of two asymmetric carbons(*R* and *S*) for each of the absolute configurations, Δ and Λ (Fig. 1). Theoretically eight(lel_3, $3lel_2ob$, $3lelob_2$, ob_3) and four (lel_3, lel_2ob, $lelob_2$, ob_3) energetically unique conformational isomers are expected for the *mer* and *facial* isomers respectively, but a rapid inversion of the chelate rings in solution will make only four isomers detectable: *mer*-Λ, *mer*-Δ, *facial*-Λ, and *facial*-Δ (Fig. 1).

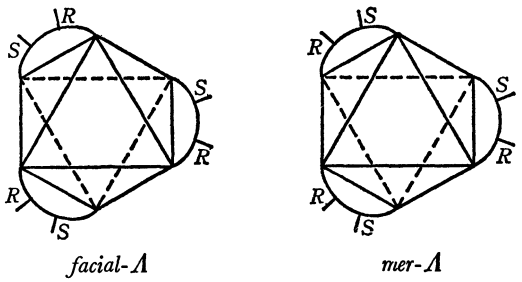

Fig. 1. Geometric isomers of Λ-$[Co(mbn)_3]^{3+}$.

The tris(*meso*-2,3-butanediamine)cobalt(III) complex was first studied by Woldbye,[4] but no geometric isomer was separated and only optical isomers with low optical activities were obtained. In the present paper the isolation of four possible isomers in a pure state and their characterization will be presented.

Experimental

Ligands. A mixture of *meso* and *racemic* 2,3-butanediamine was prepared by the reduction of dimethylglyoxime with Raney nickel in alkaline solution;[5] the isomers were then separated by the procedure of Dickey *et al.*[5]

Preparation of the Complex. *Meso*-2,3-butanediamine hydrochloride(1.3 g, 8.1 mmol) was dissolved in 5 ml of water, and the solution was adjusted to pH 8 by adding a concd. NaOH solution. To this solution, $[CoBr(NH_3)_5]Br_2$ (0.9 g, 2.3 mmol) and active charcoal (0.3 g) were added, after which the mixture was stirred for from one to three days at room temperature. The brown solution thus obtained was directly subjected to column chromatography on SP-Sephadex after the removal of charcoal.

Chromatographic Separation of the Isomers. On the top of the adsorbent layer of an SP-Sephadex column (ϕ 2.7 × 120 cm), the same SP-Sephadex, saturated in advance with a prepared solution containing about 0.4 mmol of the complex, was poured; the complex was subsequently eluted by a 0.18 M sodium $(+)_{589}$ tartratoantimonate(III) solution* at a rate of 0.75 ml per minute. The effluent was separated into fractions of 15 ml each, and the absorbance at 470 nm was plotted against the eluate volume (Fig. 2). Two separated peaks, A and B, were thus obtained, but as each peak seemed to be a mixture of enantiomers, the fractions were again adsorbed on SP-Sephadex after dilution with water, and subsequently eluted with a 0.20 M sodium $(+)_{589}$ tartrate solution. Figure 3 shows the elution curve of the fractions corresponding to the band A. Two separated peaks, A-1

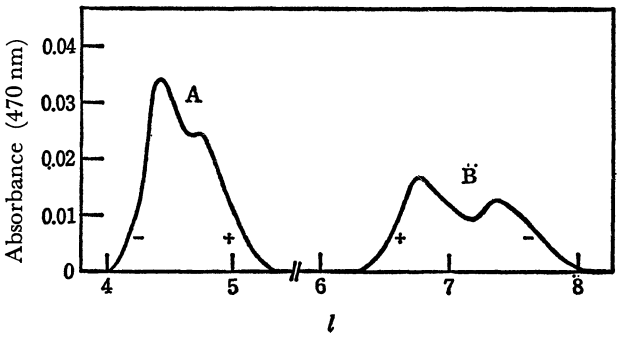

Fig. 2. Elution curve of the isomers of $[Co(mbn)_3]^{3+}$. Eluent: 0.18 M sodium $(+)_{589}$ tartratoantimonate-(III).

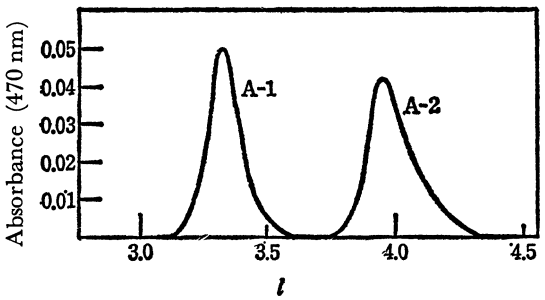

Fig. 3. Elution curve of the fractions corresponding to the band A of Fig. 2.
Eluent: 0.20 M sodium $(+)_{589}$ tartrate.

* The concentration was calculated on the basis of the formula: $[Sb_2(C_4H_2O_6)_2]^{2-}$.

and A-2, appeared. Two peaks similarly separated from the peak B were named B-1 and B-2, in the order of elution. Thus, four isomers, A-1, A-2, B-1, and B-2, were isolated. Found: A-1, C, 29.34; H, 8.56; N, 17.20%. A-2, C, 29.45; H, 8.66; N, 17.26%. B-1, C, 29.15; H, 8.63; N, 17.19%. B-2, C, 29.10; H, 8.96; N, 17.04%. Calcd for $[Co(mbn)_3]Cl_3 \cdot 3.5\ H_2O$ ($C_{12}H_{43}O_{3.5}N_6CoCl_3$): C, 29.25; H, 8.80; N, 17.05%.

Measurements. The electronic absorption(AB) and circular dichroism(CD) spectra were measured at 25 °C, as has been reported previously.[1] The 100 MHz PMR spectra were measured in D_2O by means of a JEOL JNM-MH-100 spectrometer. A small amount of a concd. NaOD-D_2O solution was added to deuterate the amine protons. DSS (sodium 2,2-dimethyl-2-silapentane-5-sulfonate) was used as the internal reference.

Results and Discussion

(1) *PMR Spectra.* Figures 4a and 4b show the PMR spectra of *N*-deuterated A-1 and B-1 isomers respectively. Although the ligand $ND_2CH(CH_3)CH(CH_3)ND_2$ in the *gauche* conformation can give rise to the eight-spin system of the $X_3AA'X'_3$ type, the spin-spin coupling constants $J_{XX'}$ and $J_{AX'}=J_{A'X}$ are considered to be approximately zero. For both isomers, the peaks at 1.1—1.4 ppm and 2.9—3.6 ppm were assigned to the methyl and methine protons respectively.

As the *facial* isomer has three equivalent chelate rings(Fig. 1), two doublet signals due to the axial and equatorial methyl protons are expected unless the chelate rings assume a symmetric envelope conformation. On the other hand, the *mer* isomer, which has no symmetry axis of rotation and which belongs to the point group C_1, should show more complicated methyl signals consisting of up to six doublets. Actually, the A-1 and B-1 isomers showed three and two methyl doublets respectively; the *mer* and *facial* forms were assigned to them.

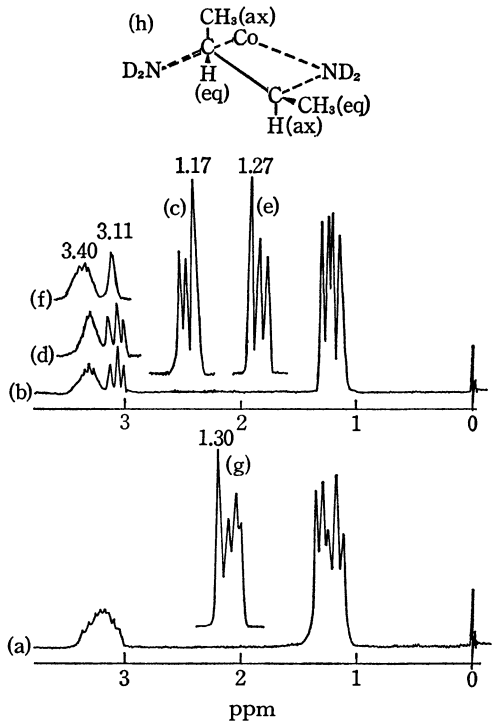

Fig. 4. 100 MHz PMR spectra of the isomers A-1 (a) and B-1 (b).
Double resonance spectra irradiated at $\delta=3.40$ ppm (c), 1.17 ppm (d), 3.11 ppm (e), and 1.27 ppm (f) of the isomer B-1. The methyl part of double resonance spectrum irradiated on the methine signal (3.15 ppm) of the isomer A-1 (g). δ-Conformation of the mbn chelate ring (h).

The methine proton signals of the *facial* isomer consist of two components, and the resonances centered at 3.11 ppm are considered as axial methine proton signals, by analogy with the methylene proton signals of $[Co(CN)_4(R\text{-pn})]^-$[6] and $[Co(pn)_3]^{3+}$.[7] The nuclear magnetic double-resonance technique was used to clarify the spin-spin coupling between methyl and methine protons(Figs. 4c—4g). For the *facial* isomer, irradiation at the methine signals (3.40 ppm) converted the methyl doublet(1.17 ppm, $J_{H\text{-}CH_3}=7$ Hz) into a sharp singlet(Fig. 4c), indicating that it originates from the axial methyl protons. Conversely, the irradiation of the doublet at 1.17 ppm made the methine signals (3.40 ppm) decouple to a still broad peak (Fig. 4d). This broadening is probably due to the spin-spin coupling between two methine protons and the strong scalar coupling with the Co-59 quadrupolar nucleus ($I=7/2$)[8] in the *gauche* conformation. Similarly, the methine signals centered at 3.11 ppm couple with the methyl protons (1.27 ppm, $J_{H\text{-}CH_3}=7$ Hz) (Figs. 4e and 4f); this doublet corresponds to the equatorial methyl group. These methyl protons have an additional bond removed from the central cobalt atom compared with the methine protons and are apparently not affected by the coupling with the Co-59 nucleus.[8]

As for the *mer* isomer, its spectrum is too complicated to be analyzed accurately. Irradiation at the methine signals (3.15 ppm) converted the lower methyl doublet (1.30 ppm) into a singlet (Fig. 4g).

It is to be noted that the $[Co(mbn)_3]^{3+}$ and $[Co(ibn)_3]^{3+}$ ions show chemichal-shift differences between the axial and equatorial methyl groups, whereas the $[Co(NH_3)_4(mbn)]^{3+}$ and $[Pt(mbn)_2]^{2+}$ ions[9] show none, giving only one sharp methyl doublet; in the latter complexes, the two methyl groups are indistinguishable upon rapid chelate ring inversion at room temperatures. However, the proton-decoupled ^{13}C-NMR spectrum of $[Co(en)_2(mbn)]^{3+}$ and $[Co(en)_2(ibn)]^{3+}$ shows two methyl signals[10] due to the axial and equatorial methyl groups. These facts indicate that the axial and equatorial methyl groups in tris(diamine)metal complexes are magnetically nonequivalent because of the unequal energy of the *lel* and *ob* conformations, even when chelate ring inversion is rapid. This chemical-shift difference[11] between axial and equatorial methyl protons was used for the conformational analysis. The difference in the B-1 (*facial*) isomer is 0.10 ppm (=1.27—1.17 ppm), slightly larger than that (0.07 ppm) of the *facial*-$[Co(ibn)_3]^{3+}$.[3] For *meso*-2,3-butanediamine-*N*,*N*,*N'*,*N'*-tetraacetatocobaltate(III), in which the diamine part is considered to be fixed in the *gauche*

Table 1. Absorption and circular dichroism spectra (in cm^{-1})

Isomer	First band		Second band		CT band	
	AB	CD	AB	CD	AB	CD
A-1 (*mer*-*Λ*)	21100(102)	20300(+2.92) 23400(−0.08)	29400(94)	28100(+0.32)	46900(24600)	45500(−34) 51800(+11)
A-2 (*mer*-*Δ*)	21100(102)	20300(−2.91) 23500(+0.08)	29400(94)	28100(−0.32)	46700(23600)	45500(+32) 52100(−10)
B-1 (*facial*-*Λ*)	21100(109)	20300(+3.28) 23400(−0.12)	29400(98)	28100(+0.36)	46900(24100)	45500(−32) 52400(+14)
B-2 (*facial*-*Δ*)	21100(106)	20300(−3.13) 23400(+0.12)	29400(96)	28100(−0.36)	46900(24700)	45700(+33) 52400(−13)

Molar extinction coefficients(ε) and $\Delta\varepsilon$ values are given in parentheses.

conformation, the chemical-shift difference has been reported to be 0.16 ppm.[12] These facts indicate that the B-1(*facial*) isomer in this case has chelate rings with non-symmetric gauche conformations.

It has been concluded for the *Λ*-$[Co(S\text{-pn})_3]^{3+}$ ion[8] that the ligands exist primarily in one conformation with the equatorial methyl group, and that the observed difference, 0.35 ppm, can be taken as the difference between the axial and equatorial methylene protons. If this result can be used to interpret the spectrum of the *facial*-*Λ*-$[Co(mbn)_3]^{3+}$ ion, the difference between the axial and equatorial methine protons, 0.29 ppm (=3.40—3.11), may suggest that the ligand mbn is primarily in the $\delta\delta\delta(lel_3)$ conformation (*cf.* (2)).

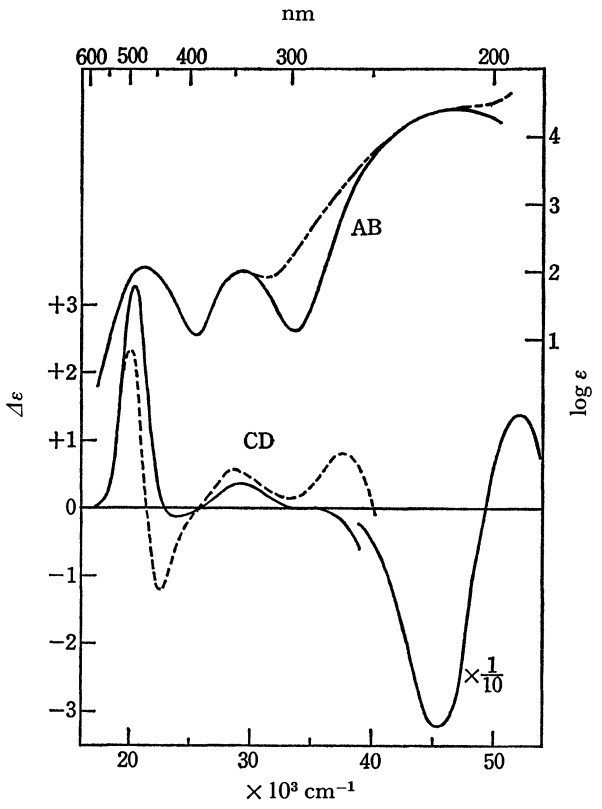

Fig. 5. AB and CD spectra of the isomer B-1(*facial*-*Λ*); —— in water, −−− and —— in 0.2 M Na_3PO_4 solution.

For the A-1(*mer*) isomer, the ligand seems to assume a more distorted conformation than for the B-1(*facial*) isomer, because: (a) the methine signals appear in a broad peak, (b) the *mer* isomer is energetically less stable than the *facial* isomer(*cf.* (3)), and (c) the A_2 component in the CD spectrum is weak(*cf.* (2)).

(2) *Absorption and Circular Dichroism Spectra.* The AB and CD spectral data are listed in Table 1. The rotations shown by the fractions corresponding to the four peaks, A-1, A-2, B-1, and B-2, are +, −, +, and − for 589 nm. The first absorption maxima of $[Co(mbn)_3]^{3+}$ (473 nm) and $[Co(ibn)_3]^{3+}$ [3] (480 nm) are in a lower energy region than that of the *Λ*-$[Co(R\text{-pn})_3]^{3+}$ ion (467 nm). The shift may be due to two methyl groups of the ligand, mbn or ibn, one of them being forced to be in the axial position regardless of the chelate ring (δ or λ).

The CD spectrum of the B-1 isomer resembles that of *Λ*-$[Co(en)_3]^{3+}$ in both the d-d and charge-transfer regions (Fig. 5). Thus, taking the PMR results into account, its absolute configuration can tentatively be determined to be *facial*-*Λ*. Similarly, the configurations of the isomers A-1, A-2, and B-2 are determined to be *mer*-*Λ*, *mer*-*Δ*, and *facial*-*Δ* respectively. The AB and CD spectra of two geometric isomers, *mer* and *facial*, are similar in shape, but the peak intensities of the former are slightly lower than those of the latter (Table 1).**

The negative CD component at 427 nm corresponding to the higher-energy band in the first absorption region is slightly weaker for the *mer* than the *facial* isomer (A-1). This peak is enhanced to the same intensity for both isomers in a 0.2 M sodium phosphate solution, and it is assigned to the $A_2(D_3)$ component. There is a general tendency for the A_2 com-

** A sample of $(+)_{589}[Co(mbn)_3]Br_3$ resolved by the fractional crystallization of the diastereoisomer with $(+)_{589}$ nitrocamphor[4] was kindly provided by Prof. F. Woldbye, which showed a small CD intensity with the constant value of $\Delta\varepsilon(20240\ cm^{-1})/\varepsilon(21200\ cm^{-1}) = 22.7\times10^{-4}$. Chromatographic separation revealed this to be a mixture of four isomers, *mer*-*Δ*, *mer*-*Λ*, *facial*-*Λ*, and *facial*-*Δ*, in the ratio 1.8 : 2.2 : 1.2 : 1.0; the composition explained the low optical activity previously reported,[4] *i.e.* the incomplete resolution.

ponent of the tris(diamine)cobalt(III) complexes to become weak as the chelate ring deviates from the *lel* conformation. The *mer* isomer has, therefore, a more distorted conformation than the *facial* isomer. In the above sodium phosphate solution, a new, weak CD peak appeared at 264 nm ($\Delta\varepsilon = +0.80$ for the *facial*-Λ isomer) as a result of the ion-pair formation, this peak is characteristic of the *lel* conformation.[13]

(3) *Formation Ratio.* If the relative abundance of geometric isomers is governed by statistics alone, the ratio of the *mer* isomer to the *facial* isomer should be 3 : 1; *i.e.*, 75% of the $[Co(mbn)_3]^{3+}$ formed should be the *mer* isomer. The actual formation ratio, as calculated from the area of the elution peaks and the extinction coefficients at 470 nm ,was A-1 : A-2 : B-1 : B-2=1.4 : 1.4 : 1.0 : 1.0; the formation of the B isomers (*facial*) was therefore more favored than the statistically calculated ratio. From the above data, the apparent free energies of the isomers at 300 K were calculated to be 0 for the *facial* isomer (B) and −0.2 kcal/mol for the *mer* isomer (A). An entropy contribution to the free energy from the 1 : 3 statistical weighting of the two configurations, *facial* and *mer*, must be taken into account. The calculated enthalpies and other entropy contributions give rise to relative energies of the following order: *facial* isomer = 0 and *mer* isomer = 0.5 kcal/mol. This value is in good agreement with the result, 0.7 kcal/mol, of the conformational analysis calculated by Niketic and Woldbye.[14]

(4) *Effects of the Eluents on the Separation Order of the Isomers.* As has been described above, when $(+)_{589}$ tartratoantimonate(III) was used as the first eluent, the isomers were eluted in the order: (A-2+A-1), (B-1+B-2) (Fig. 2), whereas with sodium $(+)_{589}$ tartrate as the eluent, four isomers were eluted in the order: (A-1+B-1), (A-2+B-2), and each peak, the mixture of the geometric isomers, was further separated by sodium $(+)_{589}$ tartratoantimonate(III). Thus, sodium $(+)_{589}$ tartratoantimonate(III) is effective in separating geometric isomers, whereas sodium $(+)_{589}$ tartrate in resolving optical isomers on an SP-Sephadex column. The geometric isomers of the $[Co(mbn)_3]^{3+}$ ion were completely separated by a 0.16 M sodium sulfate solution as well.

The X-ray determination of the absolute configuration of the *facial*-Λ-isomer is now under way in the laboratory of Professor Y. Saito, the University of Tokyo.

We are grateful to Professor F. Woldbye, the Technical University of Denmark, for providing the sample.

Derivatographic Studies on Transition Metal Complexes. XVI.[1] Thermal Chelation of Na[CoX(Hedta or Hpdta)] and [CoX(Hgly)en$_2$]X$_2$ (X=Cl$^-$ or Br$^-$) Type Complexes in Solid Phase[2]

Ryokichi Tsuchiya, Katsuhide Manzaki,* Shigeru Sekiya,** Akira Uehara, and Eishin Kyuno

Department of Chemistry, Faculty of Science, Kanazawa University, Kanazawa 920

(Received March 3, 1975)

Thermal chelation of the following two types of complexes in solid phase was investigated by means of derivatography: Na[CoX(Hedta or Hpdta)] and [CoX(Hgly)en$_2$]X$_2$ (X=Cl$^-$ or Br$^-$), where Hedta or Hpdta and Hgly designate quinquedentate ethylenediaminehydrogentetraacetate or propylenediaminehydrogentetraacetate ion and unidentate glycine molecule, respectively. The results show that all the complexes undergo characteristic thermal chelation through the dehydrohalogenation, giving an increase in ligand denticity from five to six in Na[CoX(Hedta or Hpdta)] and one to two in Na[CoX(Hgly)en$_2$]X$_2$. The reaction mechanism in the thermal chelation of each complex in solid phase was discussed in terms of the thermochemical data.

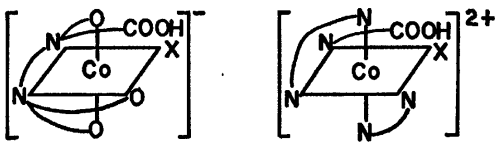
In some complexes where multidentate ligand coordinates to metal ion with its partial denticity, the potential multidenticity can be completely satisfied by further occupying the other coordination sites vacated by the escape of volatile molecule upon heating.

Such a change in which the increase of ligand denticity is involved is designated as "thermal chelation" in this paper. The situation may easily arise when the atom entering into the coordination site to form chelation in multidentate ligand resides near the escapable ligand such as H_2O or NH_3. As an example, Hertzenberg and Bailar found[3] that the unidentate sulfato complexes *cis*-[Co(SO$_4$)(H$_2$O)(NH$_3$)$_4$]X (X=ClO$_4^-$, BF$_4^-$ or 1/2PtCl$_6^{2-}$) are deaquated to form the bidentate sulfato complexes [Co(SO$_4$)(NH$_3$)$_4$]X at temperatures in the range 110—160 °C upon heating. Another example of the reaction was also reported on the quinquedentate EDTA complex [Cr(Hedta)(H$_2$O)] and on the terdentate NPDA (nitrilopropionicdiacetic acid) complex [Cr(OH)(Hnpda)(H$_2$O)$_2$]: the former was converted into sexidentate EDTA complex H[Cr(edta)] and the latter into quadridentate NPDA complex [Cr(npda)(H$_2$O)$_2$] with the increase of ligand denticity through deaquation by heating.[4]

In this paper, we deal with the thermal chelation of two additional types of complexes, Na[CoX(Hedta or Hpdta)] and [CoX(Hgly)en$_2$]X$_2$ (X=Cl$^-$ or Br$^-$), where Hedta, Hpdta and Hgly designate quinquedentate EDTA and PDTA and unidentate glycine molecule, respectively. These two types of thermal chelation are essentially distinguished from those mentioned above[3,4] with respect to the involvement of "dehydrohalogenation" in place of "dehydration".

Experimental

Preparation of Complexes. Both types of complexes used as the starting materials are characterized (Fig. 1), by the coordination of a halide ion and of quinquedentate diaminocarboxylate anion or unidentate amino acid molecule, the latter containing an uncoordinated -COOH group. They easily evolve the hydrogen halide formed from H$^+$ in -COOH and X$^-$ in the coordination sphere upon heating.



Na[CoX(Hedta or Hpdta)] [CoX(Hgly)en$_2$]X$_2$

Fig. 1. Structure of the complexes used.

Quinquedentate EDTA and PDTA Complexes: Na[CoCl(Hedta)]·2H$_2$O, Na[CoBr(Hedta)], Na[CoCl(Hpdta)]·2H$_2$O and Na[CoBr(Hpdta)]·1/2H$_2$O. They were prepared according to the procedures described in literature.[5-7]

Unidentate Glycine Complexes: [CoCl(Hgly)en$_2$]Cl$_2$ and [CoBr(Hgly)en$_2$]Br$_2$. They were synthesized by the method of Alexander and Busch[8] modified as folllows.

[CoCl(Hgly)en$_2$]Cl$_2$. *trans*-[CoCl$_2$en$_2$]Cl (2.9 g, 0.01 mol) and ethyl glycinate (1.4 g, 0.01 mol) were placed in a mortar together with water (3 ml) and diethylamine (1 ml). The mixture was triturated sufficiently to form red aggregates, which were suspended in ethanol and then collected by filtration.[9] To the ethyl glycinato complex (1 g, 0.003 mol) thus obtained was added 4 M hydrochloric acid (13 ml) to hydrolyze it and isopropyl alcohol (18 ml) was dropped into the resulting red solution, which was left to stand overnight in a refrigerator. Reddish voilet crystals were obtained and recrystallized from a minimum amount of hot water. Yield 0.5 g.

Found: C, 19.8; H, 6.2; N, 19.3%. Calcd for [Co(C$_6$H$_{21}$N$_5$O$_2$Cl)]Cl$_2$: C, 20.0; H, 5.9; N, 19.4%.

[CoBr(Hgly)en$_2$]Br$_2$. The complex was prepared by a procedure analogous to that for the above complex except that *trans*-[CoBr$_2$en$_2$]Br, triethylamine and 7 M hydrobromic acid solution were used in place of *trans*-[CoCl$_2$en$_2$]Cl, diethylamine and 4 M hydrochloric acid solution, respectively. Recrystallization was carried out from hydrobromic acid solution. From 1 g of the starting glycinato complex [CoBr(NH$_2$CH$_2$COOC$_2$H$_5$)en$_2$]Br$_2$ was obtained 0.2 g of the product.

Found: C, 14.7; H, 4.8; N, 13.9%. Calcd for [Co(C$_6$H$_{21}$N$_5$O$_2$Br)]Br$_2$: C, 14.6; H, 4.3; N, 14.2%.

Measurements. The thermal reactions of the complexes under non-isothermal conditions were observed with a MOM Derivatograph Typ-OD-102,[10] and those under isothermal conditions were measured with a Shimadzu

TM-1A thermanobalance or an Abderhalden's apparatus. The IR and UV spectra of the samples obtained at the various heating steps were measured in Nujol-mull state with JASCO model IR-E and Hitachi EPS spectrophotometers.

Results and Discussion

In order to visually grasp the thermal chelation in EDTA, PDTA and glycine complexes, experimental results obtained with Na[CoBr(Hedta)] and [CoCl(Hgly)en_2]Cl_2 are given as the typical examples.

Derivatography. Figure 2 gives the derivatograms of Na[CoBr(Hedta)] and [CoCl(Hgly)en_2]Cl_2. The TG curve of Na[CoBr(Hedta)] shows that each half mole of HBr is evolved at 53—105 °C and at 105—145 °C, respectively, the DTA curve giving two endothermic peaks in the range corresponding to the evolution of each half mole of HBr. The original bluish violet color of the complex turned violet at the final stage of dehydrobromination.

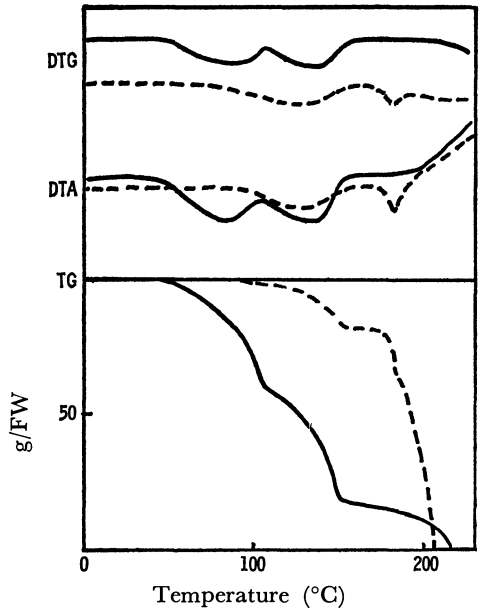

Fig. 2. Derivatograms of Na[CoBr(Hedta)](——) and [CoCl(Hgly)en_2]Cl_2(----).

In the case of [CoCl(Hgly)en_2]Cl_2, the complex releases at first a half mole of HCl at 75—150 °C and then decomposes rapidly at 175 °C as shown in its TG curve. However, a reflection and a small endothermic peak are observed in TG and DTA curves, respectively, at the point which gives the weight loss corresponding to the liberation of a further half mole of HCl. Although the formation of the stable intermediate product can not be confirmed distinctly, the color of the original complex turned orange red from reddish violet after complete dehydrobromination. The isothermal measurement also showed that the original complex brings about the complete dehydrobromination to form the bidentate glycinato-complex [Co(gly)en_2]Cl_2 upon heating at 150 °C for 10 hr.

IR Spectra. Figure 3 shows the changes of the ν_{CO} in Na[CoBr(Hedta)] and [CoCl(Hgly)en_2]-

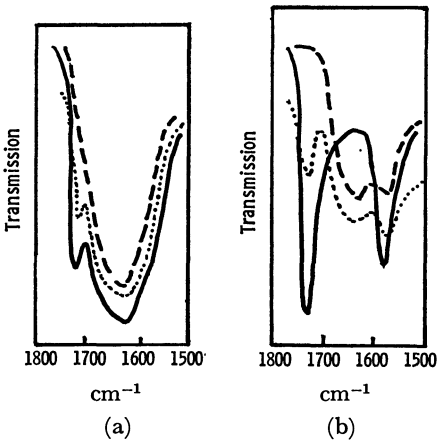

Fig. 3. (a) IR spectra of Na[CoBr(Hedta)](——) and its products obtained upon heating at 105 °C (·····) and at 145 °C (----).
(b) IR spectra of [CoCl(Hgly)en_2]Cl_2 (——) and its products obtained upon heating at 150 °C (·····) and upon heating isothermally at 150 °C for 10 hr (----).

Cl_2. Na[CoBr(Hedta)] gave a sharp band at 1730 cm^{-1} and a broad one at 1600—1700 cm^{-1} before heating, the former being assigned to $\nu_{C=O}$ of free carboxylic acid (–COOH) and the latter to that of the coordinated carboxylate group (–COO–Co).[11] The IR spectral pattern obtained in the sample heated at 105 °C does not essentially differ from that of the original one, the sharp band at 1730 cm^{-1} disappearing in the sample heated at 145 °C. This indicates that free carboxylic acid in the complex participated in coordination as a consequence of complete dehydrobromination, thermal chelation thus taking place. On the other hand, [CoCl(Hgly)en_2]Cl_2 still gave a sharp band at 1740 cm^{-1} due to the presence of free –COOH besides the band at 1580 cm^{-1} attributable to the δ_{NH_2} of glycinate ion. However, the sharp band disappeared in the sample isothermally heated at 150 °C for 10 hr, while a band due to the presence of –COO–Co appeared at 1600—1700 cm^{-1}. This suggests that the unidentate glycine complex was now converted into the bidentate glycinato-complex through complete dehydrochlorination, thermal chelation taking place.

Electronic Spectra. Figure 4 shows the electronic spectra of aqueous solutions of Na[CoBr(Hedta)], the complex heated at 145 °C and the reference complex Na[Co(edta)]·$2H_2O$ prepared by the method in literature.[12] The absorption maxima of Na[CoBr(Hedta)] heated at 145 °C appear in relatively higher frequency region as compared with those of the original complex Na[CoBr(Hedta)], and closely resemble those of the reference complex. This also indicates that the original complex was converted into Na[Co(edta)] by dehydrobromination accompanied by thermal chelation.

A similar change in electronic spectra is recognized in the case of [CoCl(Hgly)en_2]Cl_2 (Fig. 5); the complex heated isothermally at 150 °C for 10 hr gives essentially the same spectrum as that of the reference complex [Co(gly)en_2]Cl_2.[8]

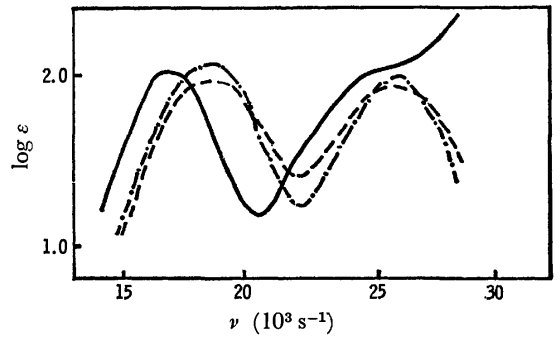

Fig. 4. Electronic spectra of Na[CoBr(Hedta)] (——), its product obtained upon heating at 145 °C (----) and the reference complex, Na[Co(edta)]·2H$_2$O (—·—).

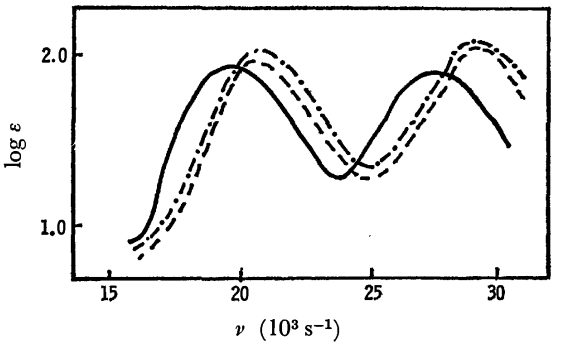

Fig. 5. Electronic spectra of [CoCl(Hgly)en$_2$]Cl$_2$ (——), its product obtained upon heating at 150 °C for 10 hr (----) and the reference complex, [Co(gly)en$_2$]Cl$_2$·H$_2$O (—·—).

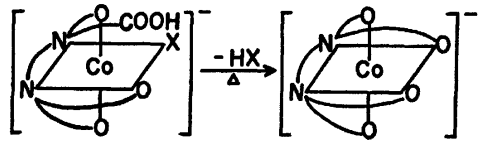
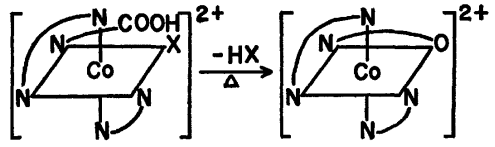


blue violet violet

(a) Na[CoX(Hedta or Hpdta)]



red violet orange red

(b) [CoX(Hgly)en$_2$]X$_2$

Fig. 6. Schemes of thermal chelation of Na[CoX(Hedta or Hpdta)] (a) and (CoX(Hgly)en$_2$]X$_2$ (b).

This is another evidence supporting the following conversion.

$$[CoCl(Hgly)en_2]Cl_2 \xrightarrow[\Delta]{} [Co(gly)en_2]Cl_2 + HCl$$

Measurement of magnetic susceptibilities showed that the cobalt ion in all the complexes remained as a tervalent state throughout the dehydrohalogenation process. The reaction seems to proceed according to the schemes shown in Fig. 6.

Thermochemical Data. Thermochemical data such as initiation temperatures, enthalpy changes (ΔH) and activation energies (E_a) were estimated in order to study the effect of kinds of ligands or counter ions on thermal chelation.

Na[CoX(Hedta or Hpdta)] Type Complexes. The enthalpy change of the reaction was estimated from the DTA peak area in the derivatograms and the activation energy from the slope of Arrhenius plots derived from the analysis of the DTA or DTG curve.[10] The numerical values of the thermochemical data are summarized in Table 1.

Table 1. Thermochemical data for thermal chelation of Na[CoX(Hedta or Hpdta)] type complexes

Complex		Init. Temp °C	ΔH kcal/mol	E_a kcal/mol
Na[CoCl(Hedta)]·2H$_2$O	1st	97	17.4	28.3
	2nd	103	17.0	57.0
Na[CoCl(Hpdta)]·2H$_2$O	1st	110	19.2	21.5
	2nd	181	18.3	116
Na[CoBr(Hedta)]	1st	53	26.4	29.2
	2nd	105	22.5	30.8
Na[CoBr(Hpdta)]·1/2H$_2$O	1st	92	20.8	40.8
	2nd	108	19.2	129

1st and 2nd denote the first (1/2 mol) and the second (1/2 mol) liberation steps, respectively, of the dehydrohalogenation.

The values of the enthalpy changes for the first and second dehydrohalogenation steps are approximately in the same order, but the value of the activation energy for the first step almost exceeds that for the second step in each complex. This suggests that the evolution of the first half mole of hydrogen halide and that of the second half mole of it proceed *via* different mechanisms though the details are still unknown.

The enthalpy changes for the bromo-complexes are relatively greater than those for the chloro-complexes and the same tendency is also recognized in the activation energies except for the second step of Na[CoCl(Hedta)]·2H$_2$O. This reflects the fact that thermal chelation of the bromo-complexes takes place with more difficulty than that of chloro-complexes. This can be understood in terms of data of the bond energies[13] as follows.

From the bond energies of O-H, 110.6, H-Cl, 103.2 and H-Br, 87.5 kcal mol^{-1}, the energy required for the bond rupture between O and H subtracted by the energy evolved in the bond formation between H and Br, ΔH=15.7 kcal mol^{-1}, is larger than the corresponding value concerning H and Cl, 7.4 kcal mol^{-1}. These two values are in line with those of the enthalpy changes in the thermal chelation of Na[CoBr(Hedta or Hpdta)] and Na[CoCl(Hedta or Hpdta)], respectively.

Comparison of the enthalpy changes and the avtivation energies for the EDTA-complexes with the corresponding data for the PDTA-complexes reveals

that the former complexes undergo thermal chelation more easily than the latter.

$[CoX(Hgly)en_2]X_2$ Type Complexes. Although the occurrence of thermal chelation could be confirmed by measurements of infrared and electronic spectra, no plateau distinctly indicating the formation of the intermediate products could be observed in the TG curve. Thus, no reliable thermal data were available from DTA and DTG peak analyses.

So far as the complexes $[CoX(Hgly)en_2]X_2$ are concerned, the activation energies for the thermal chelation were estimated by the isothermal measurement in the following manner. The sample was heated at each temperature of 140, 147, 152, and 164 °C for 150 min and the compositions of the products were determined spectrophotometrically. Since the absorbancies of the original complex $[CoCl(Hgly)en_2]Cl_2$ and the reference complex $[Co(gly)en_2]Cl_2 \cdot H_2O$ are 33.3 and 11.4 at 580 nm, and 62.5 and 106.4 at 484 nm, respectively, the composition of samples in each product by thermal chelation was calculated by means of the following simultaneous equations:

$$33.3x + 11.4y = D_{580}$$
$$62.6x + 106.4y = D_{484},$$

where x and y are the concentrations of the original complex and the complex formed by the thermal chelation, respectively, and D_{580} and D_{484} are the absorbancies at 580 and 484 nm, respectively. The chelation ratios, $[CoCl(Hgly)en_2]/[Co(gly)en_2]$ therefore, are given by $y/(x+y)$. Similar procedures were also employed for the bromo-complex. The rate constant k for thermal chelation was obtained by the chelation ratio. The activation energies were estimated from slope of the Arrhenius plots derived from the relationship of log k *vs.* $1/T$.

The values of 32.4 and 26.1 kcal mol^{-1} were obtained as the activation energies for the chloro- and the bromo-complexes, respectively. It might be said that the thermal chelation of the bromo-complex takes place more easily than that of the chloro-complex. This tendency is in contrast to that for the EDTA- and PDTA-complexes, the reason being not clear as yet.

The Decomposition of the Oxalato Complex of Manganese(IV) in Oxalate Buffer Solutions[1]

Takashi UEHIRO, Iwao TAMINAGA, and Yukichi YOSHINO

Department of Chemistry, College of General Education, The University of Tokyo, Meguro-ku, Tokyo 153

(Received March 6, 1975)

The spontaneous decomposition of the oxalato complex of manganese(IV), $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-}$, in oxalate buffer solutions is investigated photometrically. It is found that the reaction proceeds in two steps, the first step being $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-} \rightarrow [Mn^{III}(C_2O_4)_3]^{3-}$ and the second, $[Mn^{III}(C_2O_4)_3]^{3-} \rightarrow$ manganese(II) complexes. The experimental rate at pH 3.9 is written as:

$$\text{rate} = -d[Mn_2^{IV}]/dt$$
$$= \alpha[Mn^{III}] + \beta[Mn_2^{IV}]^{1/2}[Mn^{III}] + \gamma[Mn_2^{IV}]^{1/2},$$

where Mn_2^{IV} and Mn^{III} denote $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-}$ and $[Mn^{III}(C_2O_4)_3]^{3-}$ respectively. Compared with α and β terms, the contribution of the γ term is much smaller. A mechanism involving the CO_2^- radical is postulated for the reaction.

In a previous paper[2] we reported that the oxalato complex of manganese(IV) has a dimeric structure and should be formulated as $K_4[Mn_2O_2(C_2O_4)_4]\cdot 4H_2O$. It was also pointed out that the complex in an oxalate buffer solution spontaneously decomposes to give manganese(II) complex *via* manganese(III).

Since little is known about the reaction of quadrivalent manganese in solution, we have carried out a systematic study of the decomposition reaction of the oxalate complex of manganese(IV) in oxalate buffer solutions. The present paper will describe the kinetics and mechanism of the reactions of this sort.

Experimental

Materials. Potassium di-μ-oxo-tetrakis(oxalato)dimanganate(IV) tetrahydrate, $K_4[Mn_2O_2(C_2O_4)_4]\cdot 4H_2O$, and potassium tris(oxalato)manganate(III), $K_3[Mn(C_2O_4)_3]\cdot 3H_2O$ (abbreviated hereafter in rate equations, *etc.* as Mn_2^{IV} and Mn^{III} respectively) were prepared by the method described in earlier papers.[2-4] The other chemicals were all of a reagent grade and were recrystallized from water when necessary. Ordinary distilled water was purified by repeated distillation. Pyrex and Hario H-32 glass vessels were used throughout the experiment.

Kinetic Runs. The reaction was followed with a Hitachi 124 spectrophotometer, with a Hitachi 056 recorder attached. The temperature of the cell was controlled by circulating water from a Haake thermostat. In each run, a sample solution was prepared by dissolving the solid complex in a 0.05—0.5 M $K_2C_2O_4$–$H_2C_2O_4$ (2 : 1) solution of the required temperature, and then a part of the solution was transferred quickly into a 10-mm quartz cell with a joint cap. The concentration of the sample was $1—10\times 10^{-3}$ M in total manganese. The wavelengths chosen were 643 nm for $[Mn^{IV}{}_2O_2(C_2O_4)_4]^{4-}$ and 520 nm for $[Mn^{III}(C_2O_4)_3]^{3-}$. When necessary, the buffer solution was deoxygenated by nitrogen or saturated with oxygen. It was ascertained that, under these conditions, the photochemical effect on the rate of decomposition of the complex was negligibly small.

Results and Discussion

As was described in the previous paper,[2] the quadrivalent manganese complex in an oxalate buffer solution exhibits an absorption maximum at 643 nm. As the decomposition of the complex proceeds, the absorbance at 643 nm decreases, and there appear three isosbestic points—at 490, 580, and 848 nm. Therefore, during this period, the quadrivalent manganese complex can be considered to change into its conjugate colored species. It was confirmed that the spectrum observed just before the disappearance of the isosbestic points coincides with that of the tris(oxalato)manganate(III) ion, with an absorption maximum at 520 nm. Hence, it is clear that the net reaction in the first period is the reduction of the quadrivalent manganese complex to a tervalent one, $[Mn^{III}(C_2O_4)_3]^{3-}$. Thus,

$$[Mn_2^{IV}O_2(C_2O_4)_4]^{4-} + 2HC_2O_4^- + H_2C_2O_4 \rightarrow 2[Mn^{III}(C_2O_4)_3]^{3-} + 2H_2O + 2CO_2$$

After the isosbestic points disappeared, the absorbance at 520 nm decreased more slowly. In the second period it is considered that the tris(oxalato)manganate (III) is reduced to give an oxalato complex of manganese(II) (probably $[Mn^{II}(C_2O_4)_2(H_2O)_2]^{2-}$). The overall reaction may, then, be written as follows:

$$2[Mn^{III}(C_2O_4)_3]^{3-} + 4H_2O \rightarrow 2[Mn^{II}(C_2O_4)_2(H_2O)_2]^{2-} + C_2O_4^{2-} + 2CO_2$$

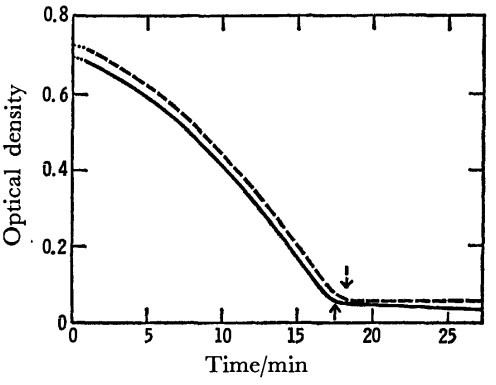

Fig. 1. Decomposition of $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-}$ at 30 °C in oxalate solution (pH 3.9). Initial concentration= 2×10^{-3} M. λ=643 nm.
——: in the absence of O_2, ----: in the presence of O_2. Change from the first period to the second occurs at the points indicated by arrows.

Figure 1 shows a typical absorbancy-time curve for the oxalato complex of manganese(IV) at 30 °C in either the absence or presence of oxygen. As may be seen in Fig. 1, the effect of oxygen on the rate in the first period is very small, while, in the second, the dissolved oxygen depresses the rate strikingly, as has been reported in the case of the decomposition of the oxalato complexes of manganese(III).[5,6] The second period corresponds to the decomposition of the tervalent manganese complex. Thus, we will hereafter be concerned only with the first period of the reaction.

Since the reaction was started by dissolving a solid sample in an oxalate buffer solution, the initial-rate method was not applicable. The rate of decomposition at time t was evaluated by reading the slope of the optical density *vs.* time curve, as may be understood from the following relation:

$$\text{rate} = -\frac{d[Mn_2^{IV}]}{dt} = -\frac{d}{dt}\left(\frac{D-\varepsilon^{III}C_0}{\varepsilon^{IV}-2\varepsilon^{III}}\right) = -\frac{1}{\varepsilon^{IV}-2\varepsilon^{III}}\frac{dD}{dt}$$

where D denotes the optical density of the solution and C_0, the total concentration of $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-}$ and $[Mn^{III}(C_2O_4)_3]^{3-}$. The ε^{IV} and ε^{III} are the molar extinction coefficients of $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-}$ and $[Mn^{III}(C_2O_4)_3]^{3-}$ respectively (at 643 nm, $\varepsilon^{IV}=440$ and $\varepsilon^{III}=12$).

The Effect of the Concentration of the Complexes. The rates of decomposition of the oxalato complex of manganese(IV) in 0.05—0.5 M oxalate buffer solutions

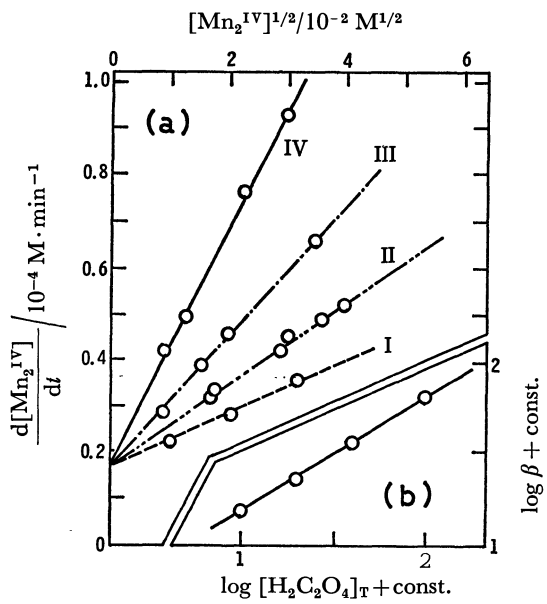

Fig. 2. Dependence of the decomposition rate of $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-}$ on the concentration of $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-}$ and buffer solution.
a) Plots of the rate at a definite concentration of $[Mn^{III}(C_2O_4)_3]^{3-}$ (3.5×10^{-3} M) *vs.* the square root of $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-}$ concentration at 20 °C in the absence of oxygen. Buffer concentrations (pH 3.9): I, 0.05 M; II, 0.1 M; III, 0.2 M; IV, 0.5 M.
b) log-log plot between the rate constant β and buffer concentration.

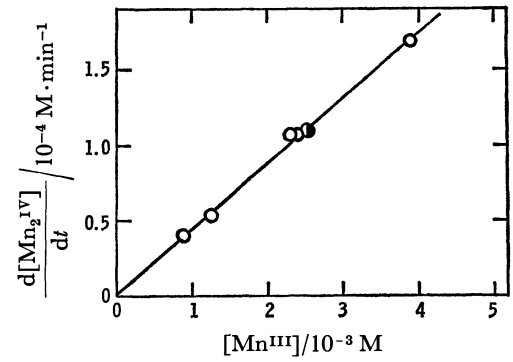

Fig. 3. Plots of the decomposition rate of $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-}$ at a definite $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-}$ concentration (1×10^{-3} M) *vs.* $[Mn^{III}(C_2O_4)_3]^{3-}$ concentration.
○: in the absence of O_2, ◑: in the presence of O_2.

(pH 3.9) were measured by varying the initial concentrations of the manganese(IV) and manganese(III) complexes. The plots of the rate at a definite concentration of the manganese(III) complex *versus* the square root of the concentration of the manganese(IV) complex give a straight line (Fig. 2). Thus, the rate at a definite concentration of the manganese(III) complex, v_{III}, may be expressed as:

$$v_{III} = a + b[Mn_2^{IV}]^{1/2} \quad (1)$$

The rate at a definite concentration of the manganese (IV) complex was plotted against the concentration of the manganese(III) complex (Fig. 3). The good straight-line relationship gives the rate, v_{IV}, as:

$$v_{IV} = c + d[Mn^{III}] \quad (2)$$

Figure 3 indicates that the value of c is very small.

The Rate Equation. By combining Eqs. (1) and (2), the following rate equation may be obtained:

$$\text{rate} = -\frac{d[Mn_2^{IV}]}{dt} = (1/2)\frac{d[Mn^{III}]}{dt} = \alpha[Mn^{III}] + \beta[Mn_2^{IV}]^{1/2}[Mn^{III}] + \gamma[Mn_2^{IV}]^{1/2} \quad (3)$$

where α, β, and γ are the apparent rate constants. From the experimental data obtained under various conditions, the values of α, β, and γ were evaluated (Table 1).

The solution of the manganese (IV) complex becomes turbid when the pH of the solution rises to *ca.* 4.5. On the other hand, $[Mn^{III}(C_2O_4)_3^{3-}]$ dissociates into $[Mn^{III}(C_2O_4)_2(H_2O)_2]^-$ in the lower pH region ($K=3.8\times10^{-3}$ at 0 °C), and it is impossible to vary the pH alone without varying the composition of the buffer. Therefore, a quantitative examination of the pH dependence of the rate was difficult to carry out. Qualitatively, the rate became slightly faster as the pH of the solution decreased.

The effect of the ionic strength was also examined by the use of Na_2SO_4, but in the range of 0.01—1.5, the ionic strength has no significant effect on the rate.

For the α term, it may be found from Fig. 2 that the rate is independent of the concentration of the buffer solutions (0.05—0.50 M). The activation energy, E_α, for the α term was calculated as 19.5 kcal/mol from the plot of log α *vs.* $1/T$.

Table 1. Apparent rate constants for decomposition of the oxalato complex of manganese(IV) in 0.1 M oxalate solution (pH 3.9) under N_2

Temperature (°C)	α (min^{-1})	β ($M^{-1/2}min^{-1}$)	γ ($M^{1/2}min$)	k_1[a] (min^{-1})
10	2.39×10^{-3}	1.1×10^{-2}	1.5×10^{-5}	
20	0.85×10^{-2}	2.74×10^{-2}	2.4×10^{-5}	0.84×10^{-2}
30	3.00×10^{-2}	3.91×10^{-2}	4.8×10^{-5}	3.01×10^{-2}
40	0.85×10^{-1}	4.56×10^{-2}	6.5×10^{-5}	

a) Rate constant for the decomposition of $[Mn(C_2O_4)_3]^{3-}$. The rate equation and mechanism for this reaction can be written as follows.[5-7]

$$-\frac{d[Mn^{III}]}{dt} = 2k_1[Mn^{III}]$$

$$Mn^{III} \xrightarrow{k_1} Mn(II) + CO_2^- + CO_2$$

$$Mn^{III} + CO_2^- \xrightarrow[fast]{} Mn(II) + CO_2$$

The behavior of the β term is rather complicated. It was found, in the 0.05—0.5 M buffer solutions of pH 3.9, that the order of the reaction is about 0.6 with respect to the buffer concentration (Fig. 2).

The Arrhenius plot of the β term did not give a straight line, but a curve which is convex upward. The apparent activation energy was estimated as *ca.* 5 kcal/mol at 30 °C and as *ca.* 13 kcal/mol at 15 °C.

The contribution of the γ term was very small. The experimental error inherent in the γ term is large, though, no detailed discussion can be given.

Reaction Mechanism. On the basis of the above observations, a plausible mechanism for the reaction involving the CO_2^- radical was proposed as follows:

$$Mn^{III} \xrightarrow{k_1} Mn(II) + CO_2^- + CO_2 \quad (1)$$

$$Mn^{III} + CO_2^- \xrightarrow{fast} Mn(II) + CO_2 \quad (2)$$

$$Mn^{IV} + CO_2^- \xrightarrow{fast} Mn(III) + CO_2 \quad (3)$$

$$Mn^{IV} + Mn(II) \xrightarrow{fast} 2Mn(III) \quad (4)$$

$$Mn_2^{IV} + ox \overset{K}{\rightleftharpoons} 2Mn^{IV} \quad (5)$$

$$Mn^{IV} + Mn(III) \xrightarrow{k_6} Mn(II) + Mn(III) + 2CO_2 \quad (6)$$

$$Mn^{IV} \xrightarrow{k_7} Mn(II) + 2CO_2 \quad (7)$$

In the above equations, the following abbreviations were used: Mn(III): any tervalent manganese complex which turns into Mn^{III} quickly; Mn(II): divalent manganese complex; Mn^{IV}: any mononuclear complex of quadrivalent manganese; ox: oxalate ion or its protonated species.

Reactions (1)-(4) in the above scheme seem to account reasonably for the α term of the rate equation. In the first step, $[Mn^{III}(C_2O_4)_3]^{3-}$ decomposes to produce Mn(II) and the CO_2^- radical (Reaction (1)). The Mn(II) or CO_2^- radical once produced successively reacts with Mn^{IV} or Mn^{III} very fast (Reactions (2)—(4)). This mechanism is supported by the following facts. The rate constant, α, is in good agreement with that of Reaction (1). Reactions (1) and (2) correspond to the mechanism widely accepted for the decomposition of $[Mn^{III}(C_2O_4)_3]^{3-}$, where Reaction (1) is the rate-determining step.[6,7] The activation energy for the α term also agrees with that of Reaction (1).[6] One piece of the experimental evidence for Reaction (4) is that we can titrate the manganese(IV) complex with the manganese(II) solution in an oxalate buffer; the formation of $[Mn^{III}(C_2O_4)_3]^{3-}$ is observed in the resultant solution. Reactions (1)—(4) indicate that, along with the decomposition of $[Mn^{III}(C_2O_4)_3]^{3-}$ according to Reaction (1), double the amount of Mn^{IV} changes into Mn(III). Accordingly, the rate equation for the α term is expressed as:

$$-d[Mn(IV)_T]/dt = -2d[Mn_2^{IV}]/dt$$
$$= 2\alpha[Mn^{III}] = 2k_1[Mn^{III}],$$

where $[Mn(IV)_T]$ denotes the total concentration of quadrivalent manganese; most of the species of quadrivalent manganese may be $[Mn_2^{IV}O_2(C_2O_4)_4]^{4-}$.

Reactions (5) and (6) correspond to the β term, which indicates that the reaction is half-order in Mn_2^{IV} and first-order in Mn^{III}. Such an order of a reaction might be explained by assuming a simple scheme involving a dimer-monomer equilibrium, that is:

$$Mn_2^{IV} \rightleftharpoons 2Mn^{IV}$$

$$Mn^{IV} + Mn(III) \longrightarrow Mn(II) + Mn(III) + 2CO_2$$

In this case, however, this simple mechanism cannot explain the buffer-concentration dependence of the rate. As has been mentioned earlier, the experimental order with respect to the buffer concentration is very close to 1/2. The scheme postulated above, Reactions (5) and (6), will account for this observation. If we assume that the (5) equilibrium is rapidly established, lying far to the left, and that Reaction (6) is slow, the rate equation for the β term may be written as:

$$-d[Mn_2^{IV}]/dt = k_6[Mn_2^{IV}]^{1/2}[Mn^{III}](K[ox])^{1/2}$$

in accord with the experimental requirements. Since we observed no significant effect of the ionic strength on the β term, it is presumed that Reactions (5) and (6) are not between charged species only, but between charged and neutral species.

As for the γ term, which corresponds to Reaction (7), the accurate determination of the rate constant was extremely difficult. We can only say that the value of the rate constant is significantly smaller than those of the α and β terms.

The oxygen effect on the decomposition rate of the oxalato complex of tervalent manganese has been explained by the formation of the $O_2CO_2^-$ (or HO_2-CO_2) radical, which is the product of the reaction between the CO_2^- (or HCO_2) radical and oxygen, O_2.[6-9] The $O_2CO_2^-$ or its derivative radical (*e.g.*, O_2^-) is known to be less active toward magnanese(III); moreover, it oxidizes manganese(II) to manganese(III). In contrast, manganese(IV), which is considered to be a stronger oxidant than manganese(III),[2] may be able to oxidize $O_2CO_2^-$ or O_2^-. That is why the decomposition rate in the first period was not affected by the dissolved oxygen, while in the second period the rate was strongly depressed.

In conclusion, the decomposition of the quadrivalent

manganese complex, di-μ-oxo-tetrakis(oxalato)dimanganate(IV), can be interpreted as an autocatalytic reaction, where Mn(III) and/or Mn(II) work as catalysts. The reaction proceeds mainly in two ways, one is the $Mn^{IV}+Mn(II)\rightarrow 2\,Mn(III)$ reaction, where Mn(II) is a decomposition product of the Mn(III). The other is a direct reaction between Mn^{IV} and Mn(III). That is to say, the oxalato complex of quadrivalent manganese is relatively stable, and its decomposition rate should be extremely slow in the absence of Mn(III) and/or Mn(II). It was actually observed that the optical density of 0.1 M buffer solution of a pure sample did not change for over 2 hr at 5 °C.

A part of the expenses of this study were defrayed by a Grant for Scientific Research of the Ministry of Education.

Kinetics of Multidentate Ligand-substitution Reactions. XVIII.* Substitution Reactions of Triethylenetetraaminehexaacetate (TTHA) with Nickel(II)–Dien, –EDMA, and –NTA Complexes

Mutsuo KODAMA

Department of Chemistry, College of General Education, Hirosaki University, Bunkyo, Hirosaki 036

(Received March 22, 1975)

The kinetics of the substitution reactions of TTHA with nickel(II) complexes of diethylenetriamine (Dien), ethylenediaminemonoacetate (EDMA), and nitrilotriacetate (NTA) were studied systematically by employing the polarographic technique. All the substitution reactions were found to have a common reaction mechanism. They were first-order with respect to TTHA and also first-order with respect to a 1 : 1-ratio nickel(II) complex of Dien, EDMA, or NTA. In all the substitution reactions, the rate constants for the reactions involving a completely-deprotonated TTHA anion were nearly identical to those for the corresponding DTPA (diethylenetriaminepentaacetate) reactions, suggesting that the TTHA reaction has the same reaction mechanism as the DTPA reaction. In the Dien system, the rate constant for the reaction of the quadrivalent TTHA anion is nearly identical to that of the quinquivalent TTHA anion, whereas, in the reactions of NTA and EDMA complexes, the reaction of the quadrivalent TTHA anion is drastically slower than that of the quinquivalent TTHA anion. These facts suggest that the proton transfer from the entering group to the leaving group plays an important role in determining the rate of the multidentate ligand-substitution reaction.

The present author has previously studied a series of substitution reactions involving metal(II)-aminopolycarboxylate complexes and has discussed their detailed reaction mechanism.[1–6] In this paper, he will also deal with the kinetics of the substitution reactions of TTHA with nickel(II) complexes of NTA, EDMA, and Dien as an extension of earlier investigations involving metal(II)-aminopolycarboxylate complexes, and will discuss the effect of the basicity of the ligand on the reaction rate. The substitution reactions of DTPA in acid and neutral media will also be studied, and their rates will be compared with those of the TTHA reaction.

Experimental

Reagents. The preparation and standardization of the nickel(II) nitrate solution were described in a previous paper.[1] Reagent-grade NTA and DTPA were recrystallized as their acid forms from their aqueous solutions. The way of purification of Dien used in this study was described in a previous paper.[2] The preparation and recrystallization of the acid forms of TTHA and EDMA were also given previously.[7,8] All the other chemicals used were of an analytical reagent grade and were used without further purification.

Apparatus and Experimental Procedures. The apparatus and experimental procedures employed were the same as those given previously.[9,10] In the EDMA system, no buffer reagent was used, because all the sample solutions always contained a large excess of uncomplexed EDMA and had a big enough buffer capacity over the entire pH range covered ($9.20<pH<10.50$, and $6.30<pH<7.65$). Phosphate ($6.00<pH<8.00$) and acetate ($4.60<pH<5.80$) buffers were used in the Dien and NTA systems respectively. All the kinetic measurements were conducted under experimental conditions in which all the reactions could be treated as pseudo first-order reactions. The rate of the substitution reaction was determined by measuring the change in the dissolution wave-height due to the uncomplexed TTHA or DTPA. The ionic strength of the sample solution was adjusted to 0.30 by adding an appropriate amount of potassium nitrate. The pseudo first-order rate constant, k_{ap}, was determined from the slope of the linear relation between log (i_0/i_t) and time, t.[1]

Results and Discussion

In this study, all the kinetic measurements were conducted under experimental conditions in which the 2 : 1 ratio nickel(II)-TTHA complex was not involved in the mixture of the reaction products. All reactions were run with several different reactant concentrations in order to determine the reaction order with respect to each reactant. Although the results will not be shown here, the rates for all the reactions studied were 1) exactly proportional to the total concentration of the nickel(II) ion, $[Ni(II)]_t$, 2) inversely proportional to $(1+K_2[X]_f/(\alpha_H)_X)$, and 3) proportional to the initial concentration of TTHA, $[TTHA]_l$, when the other experimental conditions are kept constant. These findings suggest that all the reactions studied in this paper are first-order with respect to the 1 : 1 ratio nickel(II) complex of Dien, EDMA, or NTA, and also first-order with respect to TTHA, corresponding to the following rate expression:

$$\text{Rate}=k_{ap}\cdot[TTHA]_l=k_f\cdot\frac{[Ni(II)]_t}{1+\dfrac{K_2}{(\alpha_H)_X}\cdot[X]_f}\cdot[TTHA]_l \qquad (1)$$

Here, $[X]_f$ means the concentration of uncomplexed Dien, EDMA, or NTA; K_2, the second successive formation constant of the nickel(II)–Dien, EDMA, or NTA complex, and $(\alpha_H)_X$, the (α_H) value of Dien, EDMA, or NTA, defined as $1+[H^+]/K_n+[H^+]^2/K_n\cdot K_{n-1}+\cdots+[H^+]^n/K_n\cdots K_1$, where K_i stands for the i-th deprotonation constant of H_nX^{n-m}. k_f in Eq. (1) is a function of the hydrogen-ion concentration.

Dien System. In the pH range from 8.80 to 10.00, the plot of $k_{ap}\cdot(\alpha_H)_Z\cdot(1+K_2[X]_f/(\alpha_H)_X)$ against

* Part XVII: M. Kodama, This Bulletin, **47**, 2200 (1974).

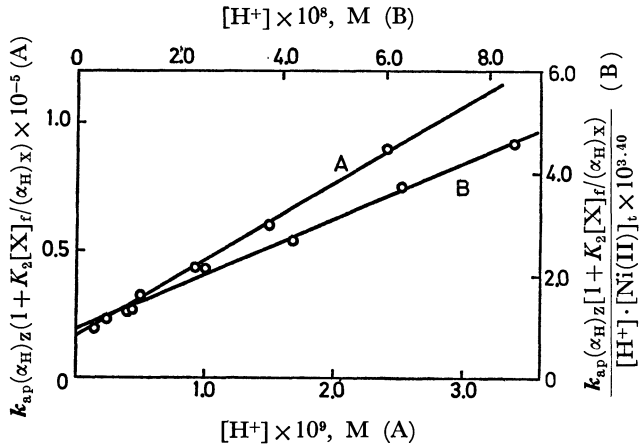

Fig. 1. The relation between $k_{ap}\cdot(\alpha_H)_Z\cdot(1+K_2[X]_f/(\alpha_H)_X)$ and the hydrogen-ion concentration, [H+], (A), and that between $k_{ap}\cdot(\alpha_H)_Z\cdot(1+K_2[X]_f/(\alpha_H)_X)/[H^+]$ and [H+] (B).
$\mu=0.30$, $[Ni(II)]_t=10.0$ mM
$[TTHA]_t=1.0$ mM
(A) Solution pH ranged from 8.80 to 10.00
25 °C, $[Dien]_f=100$ mM
(B) Solution pH ranged from 6.35 to 7.65
1.0 °C, $[Dien]_f=80$ mM

the hydrogen-ion concentration, [H+], invariably gave a straight line with an intercept of a finite value (25 °C). This indicates that the reaction proceeds through two simultaneous reaction pathways involving completely deprotonated and quinquivalent TTHA anions, Z^{6-} and HZ^{5-}. Here, $(\alpha_H)_Z$ is defined as $1+[H^+]/K_6+\cdots+[H^+]^6/K_6\cdot K_5\cdots K_1$, where K_i stands for the i-th dissociation constant of H_6Z. On the other hand, in the pH range from 6.35 to 7.65, the plot of $k_{ap}\cdot(\alpha_H)_Z\times(1+K_2[X]_f/(\alpha_H)_X)/[H^+]$ against [H+] gave a linear relation with an intercept of a finite value (1.0 °C) (Fig. 1). This fact suggests that the reaction in this pH range proceeds through two reaction pathways involving HZ^{5-} and H_2Z^{4-}. Furthermore, thermodynamic calculations using the reported equilibrium constants for the nickel(II)–TTHA and –Dien complexations reveal that the reaction product for the substitution reaction contains an appreciable amount of the protonated nickel(II)–TTHA complex, $NiHZ^{3-}$. Accordingly, the above findings lead to the conclusion that the reaction proceeds through two simultaneous reaction pathways, (3) and (4), in the pH range from 8.80 to 10.00 and in the pH range from 6.35 to 7.65 through (4) and (5), both reactions being preceded by the rapid dissociation of NiX_2^{2-2m} (2).

$$NiX_2^{2-2m} \rightleftharpoons NiX^{2-m} + X^{m-} \quad \text{rapid} \qquad (2)$$

$$NiX^{2-m} + \left\{\begin{array}{ll} Z^{6-} \overset{k_0}{\rightleftharpoons} NiZ^{4-} + X^{m-} & (3) \\ HZ^{5-} \overset{k_H}{\rightleftharpoons} NiHZ^{3-} + X^{m-} & (4) \\ H_2Z^{4-} \overset{k_{2H}}{\rightleftharpoons} NiHZ^{3-} + HX^{1-m} & (5) \end{array}\right\} \text{slow}$$

As in the case of the reaction of the nickel(II)–NTA complex with DTPA,[9] the rate constants, k_0, k_H, and k_{2H}, for the reaction of TTHA with the nickel(II)–Dien complex were determined from the intercepts and slopes of the linear relations in Fig. 1; they are listed in Table 1.

Table 1. Rate constants ($M^{-1}\,s^{-1}$, $\mu=0.30$)

	System	k_0	k_H	k_{2H}	Temp. °C
DTPA	NTA[9]	9.1×10^2	3.06×10^2	1.78	25
	EDMA[12]	1.4×10^3	2.58×10^2	—	25
		—	8.32×10^1	5.90×10^1	1.0
	Dieen[12]	7.2×10^5	9.80×10^4	—	25
		—	3.0×10^4	2.0×10^4	1.0
TTHA	NTA	2.8×10^3	9.65×10^2	1.06	25
	EDMA	4.3×10^3	2.86×10^3	4.36	25
	Dien	1.5×10^6	5.46×10^5	—	25
		—	2.7×10^4	3.0×10^3	1.0

EDMA System. In the EDMA system, all the kinetic measurements were conducted at 25 °C. in the pH range from 8.40 to 10.30, a straight line with an intercept of a finite value could be obtained by plotting $k_{ap}\cdot(\alpha_H)_Z\cdot(1+K_2[X]_f/(\alpha_H)_X\cdot)$ against [H+], whereas, in the pH range from 7.00 to 8.14, it could be obtained by plotting the $k_{ap}\cdot(\alpha_H)_Z\cdot(1+K_2[X]_f/(\alpha_H)_X)/[H^+]$ value against [H+]. Therefore, the reaction of the EDMA complex can be concluded to proceed through (3) and (4) in the former pH range and through (4) and (5) in the latter pH range. From the intercept and slope of the linear relation between $k_{ap}\cdot(\alpha_H)_Z\cdot(1+K_2[X]_f/(\alpha_H)_X)$ and [H+], the k_0 and k_H values were determined. The k_{2H} value was determined from the slope of the linear relation between $k_{ap}\cdot(\alpha_H)_Z\cdot(1+K_2[X]_f/(\alpha_H)_X)/[H^+]$ and [H+] obtained in the pH range from 7.00 to 8.14. They are also listed in Table 1. The k_H value estimated from the intercept of the linear relation at pH's lower than 8.14 agreed well with that estimated from the slope of the linear relation at pH's higher than 8.40. The influence of the phosphate buffer on the reaction rate was also investigated. No effect on the rate constant was observed that can be attributed to the buffer reagent.

NTA System. As in the case of the EDMA system, the reaction rates were determined at 25 °C. In the pH range from 8.46 to 9.50, the $k_{ap}\cdot(\alpha_H)_Z\cdot(1+K_2[X]_f/(\alpha_H)_X$ value gave a straight line with an intercept of a finite value when it was plotted against [H+], whereas, in the pH range from 4.50 to 5.70, the $k_{ap}\cdot(\alpha_H)_Z\cdot(1+K_2[X]_f/(\alpha_H)_X)/[H^+]^2$ gave a linear relation when it was plotted against [H+]. These facts indicate that the reaction proceeds through (3) and (4) in the range from 8.40 to 9.50, and through (5) and (6) in the pH range from 4.50 to 5.70.

$$NiX_2^{2-m} \rightleftharpoons NiX^{2-m} + X^{m-} \quad \text{rapid} \qquad (2)$$

$$NiX^{2-m} + H_3Z^{3-} \underset{\text{slow}}{\overset{k_{3H}}{\rightleftharpoons}} NiH_2Z^{2-} + HX^{1-m} \qquad (6)$$

The rate constants, k_0 and k_H, were determined from the intercept and slope of the linear relation between the $k_{ap}\cdot(\alpha_H)_Z\cdot(1+K_2\cdot[X]_f/(\alpha_H)_X)$ value and [H+], and the k_{2H} value from the intercept of the linear relation between $k_{ap}\cdot(\alpha_H)_Z\cdot(1+K_2\cdot[X]_f/(\alpha_H)_X)/[H^+]^2$ and [H+]. The calculation using the rate constant for

the proton-assisted dissociation of the 1 : 1 ratio nickel (II)–NTA complex determined by Kimura[11] reveals that, under the present experimental conditions, the contribution of the dissociation of the nickel(II)–NTA complex to the overall reaction rate is negligibly small. The k_H and k_{2H} values for the DTPA reactions with the nickel(II)–EDMA and –Dien complexes (1.0 °C) and with the nickel(II)–NTA complex (25 °C) were also determined by examining the effect of the solution's pH on the reaction rate. The rate constants for the DTPA reactions obtained are also listed in Table 1.

Previously, the present author determined the detailed reaction mechanism of DTPA reactions with the nickel(II)–NTA,[6] –EDMA,[3,12] and –Dien[3,12] complexes from a comparison of the observed rate constants. The substitution reaction of DTPA with the NTA complex was found to proceed through a glycinate reaction intermediate, where the leaving NTA anion and the entering DTPA anion are bonded to the nickel(II) ion through the glycinate and iminodiacetate chelate rings (glycinate reaction mechanism) respectively, while those with the nickel(II)–EDMA and –Dien complexes proceeded through an ethylenediamine reaction intermediate, in which the leaving EDMA or Dien anion and the entering DTPA anion are bonded to the nickel(II) ion through ethylenediamine (En) and glycinate (Gly) chelate rings respectively (ethylenediamine reaction mechanism). As is shown in Table 1, the k_0 values of the TTHA reactions are nearly identical to those of the corresponding DTPA reactions. This fact evidently suggests that the rates of the TTHA reaction with the NTA complex can be understood by assuming the glycinate reaction mechanism, and those with the EDMA and Dien complexes, by assuming the ethylenediamine reaction mechanism. Furthermore, the above fact indicates that, despite its large molecular size, the entering TTHA anion exerts practically no steric effect on the reaction rate. This can be cheifly ascribable to the free-bond rotation of the TTHA anion and the leaving ligand involved.

In the EDMA and NTA systems, the addition of the first proton to the TTHA anion, Z^{6-}, exerts little effect on the reaction rate, whereas the addition of the second proton to the TTHA anion remarkably diminishes the rate constant. In the Dien system, however, the second proton addition of the entering ligand causes only a small change in the reaction rate. Bohigian and Martell[13] have reported that the second protonation constant of the TTHA anion is nearly identical to its first protonation constant. This suggests that, in the quadrivalent TTHA anion, H_2Z^{4-}, two terminal nitrogen atoms are protonated. The present author has mentioned in his polarographic study of the zinc(II)–GEDTA (2,2′-ethylenedioxydi(ethylamine)-*N,N,N′N′*-tetraacetate) complex that the deprotonation of one of two terminal nitrogen atoms of the divalent GEDTA anion is required in its complexation reaction with the zinc(II) ion.[14] Similarly, in the reaction of the quadrivalent TTHA anion with the metal(II) complex ion, the deprotonation of one of the two terminal nitrogen atoms is also required. In the formation of the reaction intermediate of the multidentate ligand-substitution reaction, the protons of the entering ligand will be redistributed between it and the leaving ligand, depending on the relative basicity of their coordination sites. In the light of the structures of the reaction intermediates proposed, the free basic site of the leaving ligand, which can act as a proton acceptor in the NTA and EDMA systems, is the weakly basic carboxylate group, whereas that in the Dien system is the amino group. Therefore, in the latter system, the leaving group can accept the proton from the quadrivalent TTHA anion easily, and the ethylenediamine reaction intermediate is formed between the 1 : 1 ratio nickel(II)–Dien complex and H_2Z^{4-} without any difficulty. Thus, the second proton addition of the entering ligand, the TTHA anion, causes only a small change in the reaction rate. On the other hand, in the former systems, because of the weak basicity of the carboxylate group, the second protonation of the terminal nitrogen atom of the TTHA anion hinders the formation of the reaction intermediate and diminishes the rate constant remarkably. The rate constants obtained for the DTPA reactions listed in Table 1 also support the above explanation of the effect of the protonation of the entering ligand on the reaction rate.

The Kinetics and Mechanisms of Reaction of Iodine with Bis(*N*,*N*-diethyldithiocarbamato)dimethyltin(IV) and Related Compounds

Hidetoshi KITA, Koji TANAKA, and Toshio TANAKA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Suita, Osaka 565

(Received March 25, 1975)

The reactions of $Me_2SnL(S_2CNEt_2)$ ($L=S_2CNEt_2$ (**1**) and I (**2**)) with iodine in cyclohexane were investigated employing a stopped-flow technique. The kinetic data indicate that the reaction in the presence of a large excess of **1** or **2** proceeds *via* a charge-transfer complex of $Me_2SnL(S_2CNEt_2)\cdot I_2$, which decomposes in the rate-determining step to yield $Me_2SnI(L)$ and unstable $I(S_2CNEt_2)$. This unstable intermediate reacts with the excess **1** or **2** to afford $Me_2SnI(L)$ and tetraethylthiuramdisulfide (**3**). The reaction of **1** with a large excess of I_2 was also kinetically studied to reveal the formation of the 1 : 2 complex, $Me_2Sn(S_2CNEt_2)_2\cdot 2I_2$, as an intermediate; this intermediate then undergoes a simultaneous degradation to afford Me_2SnI_2 and **3**. The transition state in the reaction is discussed.

Several reactions of dithiocarbamato-metal complexes with halogen have been reported thus far; bis(*N*,*N*-dialkyldithiocarbamato)zinc(II), -cadmium(II) and -mercury(II) react with X_2 (X=Cl, Br, I) in the mole ratio of 1 : 1 to give adducts between MX_2 (M=Zn, Cd, Hg) and tetraalkylthiuramdisulfide, $MX_2(R_4tds)$ ($R_4tds=[R_2NC(S)S\text{-}]_2$).[1] On the other hand, *N*,*N*-dialkyldithiocarbamato complexes of Cu(I),[2] Au(I)[2] and Ni(II)[1] oxidatively add X_2 to yield $MX_2(S_2CNR_2)$ (M=Cu, Au) and $NiX(S_2CNR_2)_3$ respectively. These reactions, however, have not been studied kinetically.

Recently, we have noticed that $Me_2Sn(S_2CNEt_2)_2$ and $Me_2SnI(S_2CNEt_2)$ react with I_2 to give $Me_2SnI(S_2CNEt_2)$ and Me_2SnI_2 respectively, together with tetraethylthiuramdisulfide. This paper will report on our kinetic and mechanistic studies of these reactions as well as that of $Me_2Sn(S_2CNEt_2)_2$ with an excess of I_2 in cyclohexane. The stability constant of the charge-transfer complex between tetraethylthiuramdisulfide and iodine is also obtained.

Experimental

Materials. Bis(*N*,*N*-diethyldithiocarbamato)dimethyltin(IV), $Me_2Sn(dtc)_2$ ($dtc=S_2CNEt_2$), was obtained as has been described in a previous paper.[3] *N*,*N*-Diethyldithiocarbamatodimethyliodotin(IV), $Me_2SnI(dtc)$, was prepared by the reaction of $Me_2SnCl(dtc)$ with a large excess of NaI in acetone in the manner described previously;[3] it was then recrystallized from ligroin; mp 124 °C. Found: C, 19.82; H, 4.04; N, 3.50%. Calcd for $C_7H_{16}NS_2ISn$: C, 19.84; H, 3.81; N, 3.31%.

Iodine was purified by sublimation five times. Commercially available tetraethylthiuramdisulfide, Et_4tds ($tds=\rangle NC(S)S\cdot SC(S)N\langle$), was recrystallized from ligroin; mp 70 °C. Cyclohexane used as a solvent in the kinetic experiments was purified in the usual manner.[4]

Reactions. (i) A solution of I_2 (1.02 mmol) in benzene (20 ml) was added to $Me_2Sn(dtc)_2$ (2.38 mmol) in the same solvent (20 ml) at room temperature. The solution was stirred for 30 min, and then evaporated to dryness under reduced pressure. The resulting solid was recrystallized from ligroin to afford white crystals of $Me_2SnI(dtc)$ (1.87 mmol). The filtrate after recrystallization was evaporated to dryness again to give Et_4tds (0.84 mmol).

(ii) A benzene solution (20 ml) containing I_2 (0.5 mmol) and $Me_2SnI(dtc)$ (1.9 mmol) was stirred for 1 hr at room temperature; the subsequent application of the procedure described above gave Me_2SnI_2 (0.6 mmol).

(iii) A benzene solution (20 ml) of $Me_2Sn(dtc)_2$ (2.3 mmol) was added to the excess of I_2 (4.5 mmol) in the same solvent (20 ml) at room temperature. The solution was then stirred for 3.5 hr, filtered, and evaporated to a small volume. The precipitate which appeared was collected by filtration and recrystallized from petroleum ether to afford $Me_2SnI(dtc)$ (0.3 mmol). The filtrate was evaporated to give a solid product, from which Me_2SnI_2 (1.5 mmol) was obtained.

Spectra. The electronic spectra were recorded on a Hitachi 124 spectrophotometer. The infrared spectra were measured in Nujol mulls on a Hitachi EPI-L spectrophotometer.

Kinetics. Kinetic experiments were carried out under pseudo-first-order conditions at 25 °C, using at least a ten-fold excess amount of either iodine or the tin compound. The rate of reaction was followed by monitoring the transmittance at a fixed wavelength in the electronic spectra of the reaction mixture, using a Union RA-1100 stopped-flow spectrophotometer equipped with a 1-cm quartz cell. The measurements were usually made over a period of 3 half-lives of the reaction. Pseudo-first-order rate constants, k_{obsd}, were obtained from the semi-logarithmic plots of $\ln(A_t-A_\infty)$ against time, where A_t and A_∞ are absorbances at a given wavelength at time t and at the end of the reaction respectively. Rapid scanning spectra were measured on a Union RA-1300 stopped-flow reaction analyzer in order to determine the wavelength of which the reaction could best be followed.

Results and Discussion

Stoichiometry of the Reaction. The reaction of I_2 with excess $Me_2Sn(dtc)_2$ rapidly proceeds to give $Me_2SnI(dtc)$ and Et_4tds in good yields. Iodine also reacts with $Me_2SnI(dtc)$ to afford Me_2SnI_2 and Et_4tds; this reaction is reversible. The forward and backward reactions require a few minutes and several days respectively to come to an equilibrium. Thus, the stoichiometry for the reaction of $Me_2Sn(dtc)_2$ with I_2 may be expressed as follows:

$$Me_2Sn(dtc)_2 + \frac{1}{2}I_2 \xrightarrow{\text{fast}} Me_2SnI(dtc) + \frac{1}{2}Et_4tds \quad (1)$$

$$Me_2SnI(dtc) + \frac{1}{2}I_2 \underset{\text{very slow}}{\overset{\text{slow}}{\rightleftharpoons}} Me_2SnI_2 + \frac{1}{2}Et_4tds \quad (2)$$

Stability Constant of the Charge-transfer Complex between I_2 and Et_4tds. By analogy with the formation of a stable charge-transfer complex between I_2 and

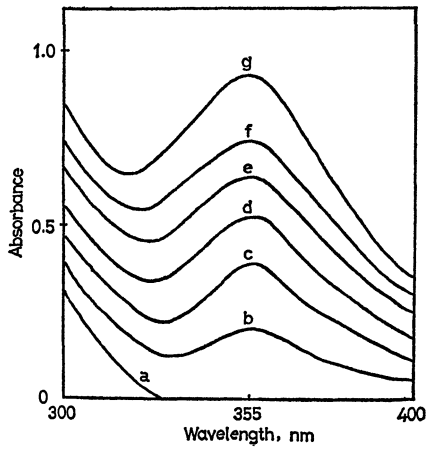

Fig. 1. Absorption spectra of Et_4tds in cyclohexane (1.0×10^{-4} M) containing varying amounts of I_2: (a) 0, (b) 1.0×10^{-3}, (c) 2.0×10^{-3}, (d) 3.0×10^{-3}, (e) 4.0×10^{-3}, (f) 5.0×10^{-3}, (g) 8.0×10^{-3} M (25 °C).

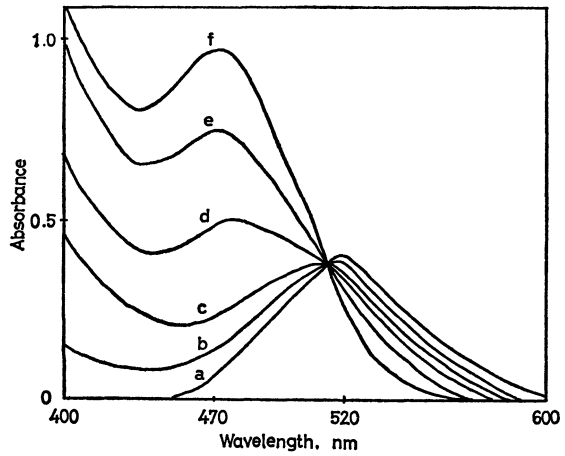

Fig. 2. Absorption spectra of I_2 in cyclohexane (8.0×10^{-4} M) containing varying amounts of Et_4tds: (a) 0, (b) 8.0×10^{-4}, (c) 1.6×10^{-3}, (d) 4.0×10^{-3}, (e) 8.0×10^{-3}, (f) 1.6×10^{-2} M (25 °C).

N-methylthioacetamide,[5] *N*-methylthiocarbamate[5] or other sulfur containing compounds,[5,6] I_2 may be expected to form a complex with Et_4tds, which is the reaction product between I_2 and $Me_2Sn(dtc)_2$ or $Me_2SnI(dtc)$. In accordance with this, cyclohexane solutions containing Et_4tds and I_2 exhibit an absorption at 355 nm, which is intensified with an increase in the amounts of I_2, as is shown in Fig. 1. Thus, the 355 nm band can unequivocally be assigned to the CT transition from Et_4tds to I_2. Figure 2 shows the electronic spectra of I_2 in cyclohexane containing varying amounts of Et_4tds. The 520 nm band due to I_2 is shifted to a short wavelength (470 nm) by adding Et_4tds, and an isosbestic point is observed at 515 nm. The continuous-variation method at 470 nm revealed that the composition of the CT complex is 1 : 1. Thus, the following equilibrium takes place in solution:

$$I_2 + Et_4tds \rightleftharpoons I_2\cdot Et_4tds \quad (3)$$

The equilibrium constant, as calculated from the absorbances at 470 nm ($\varepsilon_{max}=2.14\times10^3$) by means of the Rose-Drago equation,[7] was $K=3.75\ (\pm0.01)\times10^2$ in cyclohexane at 25 °C.

Reaction of I_2 with Excess $Me_2Sn(dtc)_2$ or $Me_2SnI(dtc)$. The rapid scanning spectra for the reaction of I_2 with excess $Me_2Sn(dtc)_2$ are depicted in Fig. 3, which reveals that a strong band appears at 386 nm immediately after mixing and that the band decays with a half-life of about 200 ms. An almost identical half-life of decay was found at the 520 nm band. The reaction of I_2 with excess $Me_2SnI(dtc)$ also showed the decay of the 386 nm band with a half-life of about 40 s. However, the CT band due to $I_2\cdot Et_4tds$ at 355 nm was not observed at all.

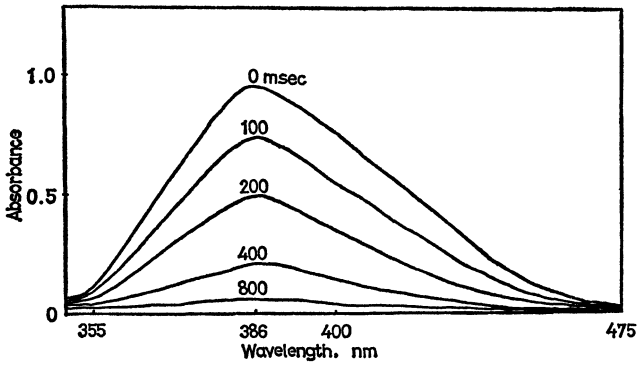

Fig. 3. The decay of the electronic spectrum after mixing I_2 (1.7×10^{-3} M) with $Me_2Sn(dtc)_2$ (3.0×10^{-2} M) in cyclohexane at 25 °C.

The rate of reaction was followed by measuring the transmittances at 386 and 520 nm of a solution right after the mixing of I_2 with excess $Me_2Sn(dtc)_2$. The Guggenheim plots showed a good linear relationship between $\ln(A_t-A_\infty)$ and the time. Thus, the reaction apparently obeys the first-order kinetics with respect to I_2. The apparent first-order rate constants, k_{obsd}, obtained at various concentrations of $Me_2Sn(dtc)_2$ are collected in Table 1.

Plots of the rate constants obtained from the decay of the transmittances at 386 and 520 nm against the concentration of $Me_2Sn(dtc)_2$ showed a good linearity, as may be seen in Fig. 4; this indicates that the reaction is first-order in both I_2 and $Me_2Sn(dtc)_2$.

Taking into account this result and the fact that I_2 can form CT complexes with various sulfur-containing compounds,[5,6] the band at 386 nm may be

Table 1. Apparent rate constants for the reactions of $Me_2Sn(dtc)_2$ with I_2 at various mole ratios in cyclohexane at 25 °C. $[I_2]=3.0\times10^{-4}$ M

[Sn]/[I_2]	10	20	30	40	50	60	80
k_{obsd} (386 nm)	0.263	0.527	0.846	1.08	1.32	1.57	2.24
k_{obsd} (520 nm)	0.268	0.555	0.761	1.02	1.32	1.63	2.16

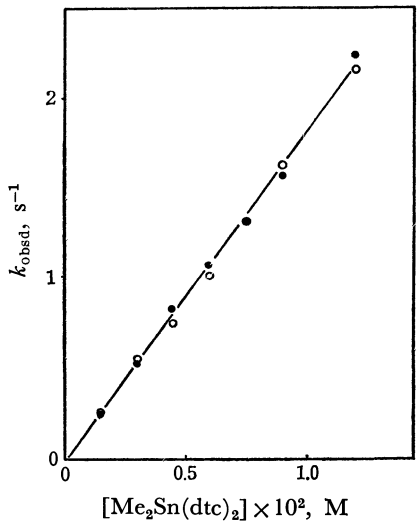

Fig. 4. Plots of the apparent rate constant against the $Me_2Sn(dtc)_2$ concentrations; ● 386 nm, ○ 520 nm.

assigned to the CT complex formed between I_2 and $Me_2Sn(dtc)_2$ in the initial process. The addition of Et_4tds to the reactant solution caused no appreciable decrease in the rate of reaction. Thus, the following pathways for the reaction may reasonably be suggested:

$$Me_2Sn(dtc)_2 + I_2 \overset{K_1}{\rightleftharpoons} Me_2Sn(dtc)_2 \cdot I_2 \quad (4)$$

$$Me_2Sn(dtc)_2 \cdot I_2 \overset{k_1}{\longrightarrow} Me_2SnI(dtc) + I(dtc) \quad (5)$$

$$I(dtc) + Me_2Sn(dtc)_2 \overset{fast}{\longrightarrow} Me_2SnI(dtc) + Et_4tds \quad (6)$$

Reaction (5) represents the rate-determining step, producing unstable I(dtc). Although there is no evidence for the formation of I(dtc) as an intermediate, a somewhat analogous species, ISCN, has been reported to exist in the following equilibrium:[8]

$$I^- + (SCN)_2 \rightleftharpoons I(SCN)_2^- \rightleftharpoons ISCN + SCN^- \quad (7)$$

It may be possible that the two molecules of I(dtc) produced in Eq. (5) react with each other to afford I_2 and Et_4tds, but this reaction dose not seem to occur, since no band was observed at 355 nm (due to $I_2 \cdot Et_4tds$) at all in the presence of excess $Me_2Sn(dtc)_2$. Instead, I(dtc) must react rapidly with excess $Me_2Sn(dtc)_2$ to give $Me_2SnI(dtc)$ and Et_4tds, as is shown in Eq. (6). According to this reaction scheme, k_{obsd} can be expressed by Eq. (8):

$$k_{obsd}^{(1)} = \frac{k_1K_1[Me_2Sn(dtc)_2]}{1+K_1[Me_2Sn(dtc)_2]} \quad (8)$$

If $K_1[Me_2Sn(dtc)_2]$ is negligibly small compared with unity, $k_{obsd}^{(1)}$ is reduced to $k_1K_1[Me_2Sn(dtc)_2]$. This expression is consistent with the plots of k_{obsd} against the concentration of $Me_2Sn(dtc)_2$ with a zero intercept (Fig. 4). Thus, k_1K_1 is obtained as 1.84×10^2 M^{-1} s^{-1}.

Kinetic experiments on the reaction of $Me_2SnI(dtc)$ with I_2 were carried out by monitoring the transmittance only at 386 nm, since there was no marked change in the transmittance at 520 nm in this system because of the low solubility of $Me_2SnI(dtc)$ in cyclohexane. The k_{obsd} values obtained at various concentrations of $Me_2SnI(dtc)$ are listed in Table 2, which shows the reaction to be first-order in both $Me_2SnI(dtc)$ and I_2.

Table 2. Apparent rate constants for the reaction of $Me_2SnI(dtc)$ with I_2 at various mole ratios in cyclohexane at 25 °C. $[I_2] = 3.3 \times 10^{-4}$ M

$[Sn]/[I_2]$	23	28	38	47
$k_{obsd} \times 10^2$ (386 nm)	1.10	1.24	1.59	2.08

By analogy with the $Me_2Sn(dtc)_2$–I_2 system, the following pathways may be postulated, where $k_2K_2 = 1.37$ M^{-1} s^{-1}:

$$Me_2SnI(dtc) + I_2 \overset{K_2}{\rightleftharpoons} Me_2SnI(dtc) \cdot I_2 \quad (9)$$

$$Me_2SnI(dtc) \cdot I_2 \overset{k_2}{\longrightarrow} Me_2SnI_2 + I(dtc) \quad (10)$$

$$I(dtc) + Me_2SnI(dtc) \overset{fast}{\longrightarrow} Me_2SnI_2 + Et_4tds \quad (11)$$

Since both K_1 and K_2 are unknown, k_1K_1 and k_2K_2 have been difficult to analyze quantitatively.

Reaction of $Me_2Sn(dtc)_2$ with Excess I_2. The rate of reaction was determined from the decay of the transmittance at 386 nm. A good linear relationship between the $\ln(A_t - A_\infty)$* and the time was observed, except for the final short period, in which the 355 nm band arising from the product of $I_2 \cdot Et_4tds$ is intensified and the tail of this band is overlapped with the 386 nm band. Plots of k_{obsd} *vs.* the square of I_2 concentrations gave a straight line in the presence of a large excess of I_2, while a significant deviation from it was observed in the presence of a small excess of I_2, as is shown in Fig. 5. These results may be interpreted by assuming the reaction pathways shown in Scheme 1.

One of the pathways involves the formation of the 1 : 2 adduct between $Me_2Sn(dtc)_2$ and I_2, which

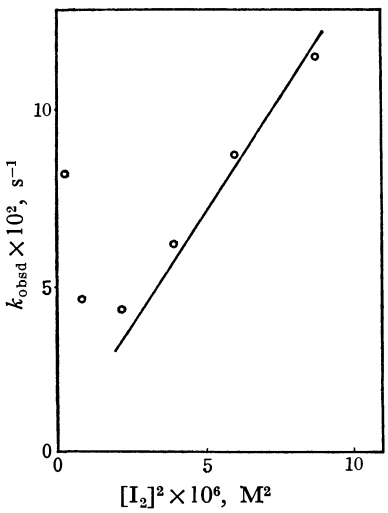

Fig. 5. Plots of the apparent rate constant against the square of the I_2 concentrations; $Me_2Sn(dtc)_2$ 5.1×10^{-4} M.

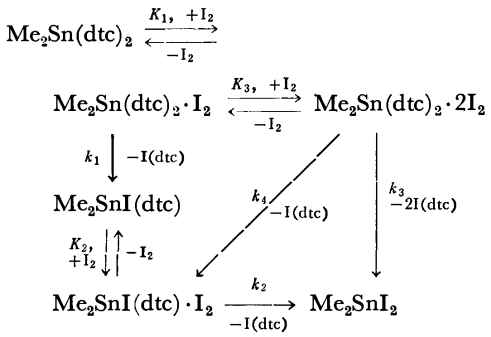
* Here, A_∞ was assumed to be zero.



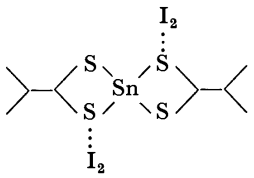
Scheme 1.

undergoes either consecutive (k_4 and k_2 in Scheme 1) or simultaneous (k_3) degradation to yield Me_2SnI_2 and $I_2 \cdot Et_4tds$. These processes can well explain the second-order dependence of the I_2 concentration. Taking into account the result that the reaction is much faster than that of I_2 with excess $Me_2SnI(dtc)$, the simultaneous degradation of the 1 : 2 adduct is preferable to the consecutive one. Another route is the successive formation of two 1 : 1 adducts, $Me_2Sn(dtc)_2 \cdot I_2$ and $Me_2SnI(dtc) \cdot I_2$, followed by degradation such as has been described above. This pathway leads us to the assumption that the reaction obeys the first-order kinetics in the I_2 concentration, because $k_1K_1 \gg k_2K_2$. It may, therefore, be assumed that, in the presence of a small excess of I_2, the processes *via* both the 1 : 1 and 1 : 2 adducts take place. Thus, in the presence of a large excess of I_2, the rate constant can be expressed by Eq. (12):

$$k^{(2)}_{obsd} = \frac{k_3K_1K_3[I_2]^2}{1+K_1K_3[I_2]^2} \qquad (12)$$

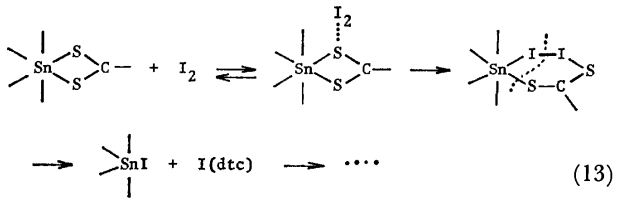
If $K_1K_3[I_2]^2$ is negligibly small compared with unity, one can obtain $k^{(2)}_{obsd}=k_3K_1K_3[I_2]^2$, which coincides with the experimental data, and $k_3K_1K_3=1.34\times 10^4\ M^{-2}\ s^{-1}$.

There are two possible mechanisms to form the unstable 1 : 2 adduct between $Me_2Sn(dtc)_2$ and I_2. One is a nucleophilic attack of two I_2 molecules on the tin atom. This is, however, not likely to occur, since no eight-coordination of tin is common. The other mechanism is an electrophilic attack of I_2 on the sulfur of separate dithiocarbamato ligands in a given complex, such as is shown in **a**. This can be assumed on the basis of the fact that I_2 forms CT complexes with various sulfur-containing compounds.[5,6]



a

In conclusion, we propose that the reaction proceeds through a transition state involving a six-membered ring formed by the electrophilic attack of I_2 on the sulfur as follows: This mechanism predicts that the



(13)

stronger Sn-S bond would be, the less reactive toward I_2. This is consistent with the present result that the rate of the reaction of $Me_2SnI(dtc)$ with I_2 is slower than that of $Me_2Sn(dtc)_2$, since the ν(Sn-S) frequency of $Me_2SnI(dtc)$ (393 cm^{-1}) is fairly higher than that of $Me_2Sn(dtc)_2$ (366 cm^{-1}).

The authors are grateful to the Ministry of Education for a Science Research Grant-in-aid. They are also indebted to Professor Shin-ichi Kawaguchi, Osaka City University, for letting them use the rapid-scan spectrophotometer.

Metal Chelates of 9-Hydroxy-1-phenalenone

Yoichi DEMURA, Toshio KAWATO, Hajime KANATOMI, and Ichiro MURASE

Laboratory of Chemistry, College of General Education, Kyushu University, Ropponmatsu, Chuo-ku, Fukuoka 810

(Received April 11, 1975)

Metal chelates of 9-hydroxy-1-phenalenone(9-hydroxyperinaphthenone) have been prepared. Metal-ligand compositions were 1 : 2 for Cu(II), Ni(II), Co(II), Mn(II), Zn(II), Mg(II), UO_2(II), and Be(II) chelates and 1 : 3 for Fe(III) and Al(III) chelates. The structure of the Cu(II) chelate was determined to be square-planar by the spectral analogy to copper(II) acetylacetonate. The Ni(II), Co(II), Mn(II), Zn(II), and Mg(II) chelates were octahedral with further coordination of two moles of water. The structure determination dealt at first with the Ni(II) chelate by means of its electronic spectrum and magnetic property; the others were studied using the similarity of their X-ray diffraction diagrams to that of the Ni(II) chelate. The Fe(III) and Al(III) chelates were also octahedral and probably have D_3 symmetry. Infrared spectra were studied for the free ligand and the metal chelates and the assignment of the carbonyl and metal-oxygen stretching vibrations was discussed by comparison with those of metal acetylacetonates.

9-Hydroxy-1-phenalenone (abbreviated as HPNA), which was first synthesized by Laudon,[1] carries a hydroxyl group at a *peri* position to a carbonyl group and can be regarded as a cyclic analogue of an enol form of acetylacetone. Although metal chelates of acetylacetone have been studied extensively, those of HPNA have not been reported so far. The chemical behavior of HPNA is anomalous as a ketone or a phenol because the hydroxyl group is neither acetylated nor methylated and the carbonyl group affords no oxime or Schiff bases. This is assumed to be due to a very strong conjugated hydrogen bonding between the functional groups and it is evidenced by the fact that HPNA exhibits no absorption due to the OH stretching vibration and shows anomalous carbonyl stretching frequency in its infrared spectrum. In this respect the metal chelate formation of this compound as a bidentate ligand will be worth investigating. In this paper, we deal with the synthesis of the metal chelates and their structure determination and will discuss the infrared assignment of the carbonyl and metal-oxygen vibrations in comparison with those of metal acetylacetonates.

Experimental

Infrared absorption spectra were taken by a Koken Model DS-301 with NaCl prism for the 4000—700 cm^{-1} region and by a Hitachi EPI-G2 grating spectrophotometer for the 700—400 cm^{-1}. Electronic reflectance spectra were measured with a Hitachi EPS-3T spectrophotometer. NMR spectra were recorded at 60 MHz in $CDCl_3$ with a Hitachi Model R-24 spectrometer. The chemical shifts are quoted as τ values relative to TMS. X-Ray diffraction diagrams were obtained with a Rigakudenki Geigarflex and magnetic moments were measured by a Faraday method at room temperature.

9-Hydroxy-1-phenalenone(HPNA) was prepared according to the method of Laudon[1] and purified by vacuum sublimation followed by repeated recrystallization from methanol: yellow plates, mp 199—200 °C.

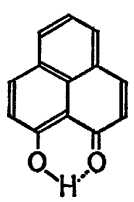
Metal Chelates were prepared by the following general procedure: one mol of HPNA was dissolved in hot ethanol and to this was added 1/2 mol of a divalent metal salt or 1/3 mol of a trivalent metal salt in minimum amount of dilute ethanol. The mixture was heated in a water bath for 30 min and the resulting precipitates were filtered after cooling and washed with ethanol. The crude metal chelates were recrystallized from butanol for those of Ni(II), Co(II), Mn(II), Zn(II), and Mg(II) or from pyridine for those of Cu(II), UO_2(II), Be(II), Al(III), and Fe(III), and dried *in vacuo* at room temperature. When the Ni(II) and Co(II) chelates were recrystallized from pyridine, the dipyridinate complexes were obtained. The metal salts employed in the reactions were acetates, except for beryllium nitrate, potassium alum, and ferric chloride hexahydrate. The sodium salt was prepared by adding excess sodium ethoxide in ethanol to the absolute ethanol solution of HPNA. The elemental analyses of these metal chelates are summarized in Table 1.

Results and Discussion

It has been found that 9-hydroxy-1-phenalenone (HPNA) showed fairly strong chelating tendencies, yielding chelates with a wide variety of metal ions. The elemental analyses revealed that the metal-ligand composition was 1 : 2 for the bivalent metal chelates and that they carried two moles of water, except for the Cu(II) and Be(II) chelates.

Because of their low solubility in ordinary organic solvents, the spectroscopic study of these metal chelates had to be done in the solid state. Figure 1 shows a reflectance spectrum of the Cu(II)-chelate, in which one can observe at least two and probably three d-d transition bands at 18.5×10^3, 15.6×10^3, and 14.5×10^3 cm^{-1}. The spectral pattern is similar to that obtained for bisacetylacetonatocopper(II),[2] whose structure has been established to be square-planar by X-ray crystallography.[3] It is obvious, therefore, that the Cu(II)-chelate has a similar square-planar structure.

The Ni(II) dihydrate complex was paramagnetic (μ_{eff}=3.48 B.M.) and the waters could be replaced by two pyridine molecules by recrystallization from the solvent; the dipyridinate complex was also



HPNA

paramagnetic (μ_{eff}=3.05 B.M.). The reflectance spectrum of the dihydrate complex as well as the dipyridinate complex exhibits d-d transitions around 8×10^3 and 18×10^3 cm^{-1} as seen in Fig. 1. It is due to a partial overlap with a tail-off from the π-π^* transition of the phenalenone ring that the absorption bands are not well defined. They are, however, essentially similar to those for octahedral Ni(II)-complexes such as bisacetylacetonatonickel(II) dihydrate and bis-salicylaldehydatonickel(II) dihydrate.[4] Judging from the magnetic and spectral evidence, an octahedral configuration is most probable for the Ni(II) dihydrate and dipyridinate complexes.

The water and pyridine molecules in the Ni(II)-complexes could be eliminated by heating at 150 °C *in vacuo*. The resulting anhydrous Ni(II)-chelate still showed an appreciable magnetic moment (μ_{eff}= 1.5 B.M.). This value is, however, too low to be reliable evidence for adopting a polymeric octahedral structure in which the planar unit is linked by sharing a lone pair of the oxygen atoms. This is probably due to contamination by the paramagnetic dihydrate complex species, because the crystals were fairly hygroscopic and the magnetic moment increased to 2.05 B.M. after standing in air for a while. The chelate which resulted from the dipyridinate complex was identical to the anhydrous one in its electronic spectral pattern, as seen in Fig. 1. The absorption due to the d-d transition, which appears at 15×10^3 cm^{-1} and is absent at lower frequencies, is normally associated with a square-planar configuration.[5]

For the structural determination of other bivalent metal chelates, X-ray powder diffraction diagrams were drawn for the dihydrate complexes of Co(II), Zn(II), Mn(II), and Mg(II), and compared with that of the Ni(II) dihydrate complex. As seen in Fig. 2, all patterns are identical; they are therefore isomorphous and the configurations are all similar to the Ni(II) dihydrate complex. Thus they are octahedral.

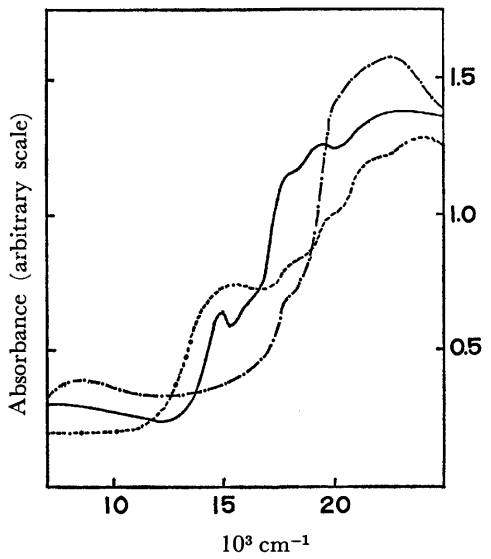

Fig. 1. Reflectance spectra of metal-chelates of HPNA: (----), Cu(II); (——), Ni(II); (—·—), Ni(II)·$2H_2O$.

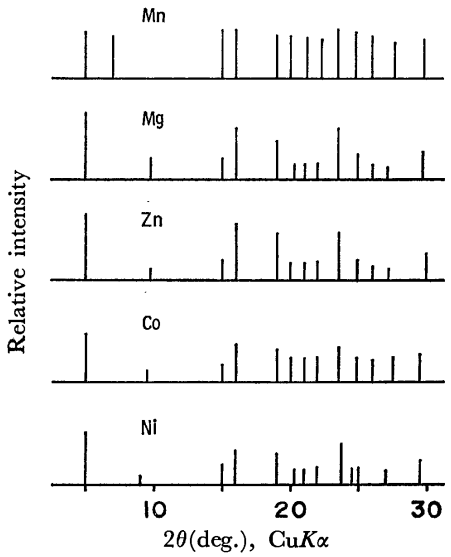

Fig. 2. X-ray powder diffraction diagrams of Mn(II), Mg(II), Zn(II), Co(II), and Ni(II) dihydrate complexes of HPNA.

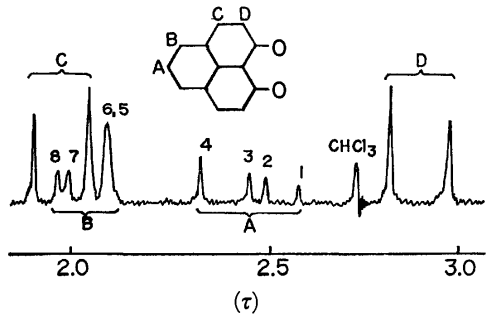

Fig. 4. PMR spectrum of HPNA in $CDCl_3$.

As has been revealed by the elemental analyses, the metal-ligand composition of the Fe(III) and Al-(III) chelates was 1 : 3; therefore, they undoubtedly take an octahedral configuration with coordination of three moles of the ligand.

The infrared absorption spectrum of HPNA shown in Fig. 3 exhibits no OH stretching band in the solid state or in benzene or chloroform. This implies the presence of a very strong intramolecular hydrogen bonding with the carbonyl oxygen. The PMR spectrum of the phenalenone ring protons is shown in Fig. 4, in which assignment of the peaks is also illustrated. The spectral pattern can be explained as an $AB_2CC'DD'$ system, providing no spin-spin coupling occurs between B and C protons ($J_{BC}=0$) and $\Delta\nu_{AB}/J_{AB}=2.7$.[6] This leads to two doublets for C(C') and D(D') protons, which appear at τ 2.02 and τ 2.92 respectively with $J_{CD}=10$ Hz. For the AB_2 system there are theoretically eight peaks, as numbered in the spectrum. Peaks 5 and 6 are not resolved in this instance. Consequently the molecule has a C_{2v} symmetry and the two carbon-oxygen bonds are equivalent so far as the PMR spectrum is concerned. The hydroxyl proton resonance appears at very low magnetic field (τ 5.90), which indicates the proton is located in a strong hydrogen bonding evironment.

In the carbonyl region of the IR spectrum the first and the second bands appear at 1637 and 1590 cm^{-1} with similar intensity. In general, the carbonyl frequency of aromatic ketones and quinones is lowered by 20—50 cm^{-1} by intramolecular hydrogen bonding, some examples of which are illustrated in Table 2. Judging from these facts, the PMR evidence, and comparison of the carbonyl vibration with that of phenalenone (1637 cm^{-1}), the band at 1590 cm^{-1} is tentatively assigned to the carbonyl band. The extremely low frequency for a carbonyl stretching vibration is assumed to be due to the high conjugation with the phenalenone ring associated with the intramolecular hydrogen bonding.

Upon metal chelate formation, the spectral patterns became sharp and new bands appeared, along with strengthening of some original bands, as illustrated for the Cu(II)-chelate in Fig. 3. The assignment of the principal absorption bands of the free ligand and the metal chelates are summarized in Table 3.

Nakamoto and Martell assigned the bands in the 1500 cm^{-1} region to the C=O vibration of the metal acetylacetonates from a calculation based on a normal coordinate analysis.[14,15] Providing the degree of the resonance of the metal chelate ring is proportional to the stability of the complex, the more the stability increases, the lower the C=O frequency will become. Although no simple relation existed between the C=O stretching frequency and the stability in a series of metal acetylacetonates, the band which was sensitive to the change in metal ions could be assigned to the C=O absorption. In the present case, the bond order of the carbonyl linkage is intrinsically decreased even in the free ligand by the resonance contribution through the phenalenone ring. In this respect the influence of metal chelate formation against the bond order is assumed to be negligible. Thus the band around 1500 cm^{-1} which was sensitive to the change in metal ions was chosen for the C=O absorption in a series of the metal chelates. The increasing order of the wave number is:

Cu(1525 cm^{-1}) < Ni(1531) < Co(1547) < Zn(1548) < Mg(1550)

a) Dihydrate complexes. b) U=O stretching. c) U-Py?

The earlier work of Nakamoto and Martell has revealed that the bands near 400 cm^{-1} were due to a M–O stretching vibration for metal acetylacetonates.[14,15] The decreasing order of the vibration was the same as the stability order: Cu(455 cm^{-1})> Ni(452)>Co(422)≈Zn(422) for the bivalent metal chelates. Nakamoto and coworkers extended the observation of the IR spectra to a lower frequency region and confirmed the M–O stretching mode assignment by using a metal isotope technique.[16] The bands which showed a large isotope shift were 455.0 and 290.5 cm^{-1} for the ^{63}Cu chelate and 421.1 and 228.6 cm^{-1} for the ^{58}Ni chelate, and they were in agreement with the assignment based on a normal coordinate analysis, in which the latter bands were due to a pure M–O stretching vibration.[17] Although we could not use the isotope technique and did not cover the 200 cm^{-1} region, two metal sensitive bands were observed in 400—500 cm^{-1} in each metal chelate. Since the M–O stretching mode is similar to that of metal acetylacetonates, it can be inferred that the strength of the coordinate bond in each transition metal chelate is comparable to that of the corresponding metal acetylacetonate, providing the lower frequency band in Table 3 is taken as the M–O stretching vibration. The markedly different M–O frequency of the Be(II)-chelate will be attributed to the light mass of the beryllium atom and the short Be–O distance.

Conclusion

Judging from the IR and PMR evidence, HPNA is a highly conjugated and symmetrical molecule including the two carbon-oxygen bonds and there exists very strong hydrogen bonding between the two oxygen atoms. The Cu(II) and the anhydrous Ni(II) chelates are monomeric in the solid state and square-planar, while the dihydrate complexes of Mn(II), Ni(II), Co(II), Zn(II), and Mg(II) are octahedral. The two water molecules probably coordinate axially to the chelate plane, as pictured in Fig. 5. The Fe(III) and Al(III) chelates are octahedral and probably have D_3 symmetry like those of acetylacetonates. It is also concluded in the IR band assignment of the metal chelates that the first two bands in the double bond region are due to the skeletal C=C vibration of the phenalenone ring, because similar frequency bands are found in the free ligand and they do not move on metal chelate formation. Consequently, the second band at 1590 cm^{-1} in the free ligand is an overlap with the carbonyl stretching vibration.

(Received May 7, 1975)

Palladium(I) species were produced by the polarographic reduction of palladium(II)–oxinate and –acetylacetonate complexes in a *N,N*-dimethylformamide solution. These species were unstable and decomposed into electro-inactive species through an irreversible following chemical reaction. The rate constants were obtained from the fundamental and second harmonic AC polarograms, which were obtained at two different frequencies of the AC potential, 55.8 and 173.6 Hz, at 22.5 °C as 5.5 ± 1.0 s^{-1} for the oxinate complex and as 50 ± 10 s^{-1} for the acetylacetonate complex.

Many palladium(II) complexes are irreversibly reduced to a palladium amalgam at a dropping mercury electrode in an aqueous solution.[1] However, it has been found that Pd(I) is detected as a product of the following chemical reaction in the case of $[Pd(CN)_4]^{2-}$.[2]

Such a lower-valence state has been proven to be produced in an aprotic dipolar solvent by the polarographic reduction of bipyridine complexes of iron, cobalt, and other metal ions.[3,4] The palladium *o*-phenylenediamine complex can also exist as a low-valent species in an acetonitrile solution.[5] These results seem to suggest that the π-bonding nature between the central ion and the ligand stabilizes the lower-valence state and that Pd(I) may be observed in the polarographic reduction of the oxinate and acetylacetonate complexes of palladium.

In this study, the polarographic reduction of the palladium(II)–oxinate and –acetylacetonate complexes was studied in a *N, N*-dimethylformamide(DMF) solution. Low-valent species(Pd(I)) were detected as unstable intermediates. The life-times of the intermediates were obtained quantitatively by the fundamental and second harmonic AC polarography.

Experimental

Material. The palladium(II) complexes were prepared according to the usual method and were recrystallized. The DMF was treated with K_2CO_3 and distilled. The tetraethylammonium perchlorate (TEAP) was recrystallized five times from water.

Measurements. The DC polarogram was taken with a Yanagimoto Polarograph, Model P-8. The oscillo- and AC polarograms were taken with apparatuses constructed in this laboratory. The details of the measurements were the same as those given in previous papers.[6,7] An H-type cell was used with a reference electrode (saturated calomel electrode(SCE), Yanagimoto Model MRP). The flow rate of the mercury was 0.67 mg/s at the mercury column height of 40 cm in a 1 M KCl solution at an open circuit. All the measurements were carried out at (22.5 ± 0.5) °C. All the potentials were referred to the SCE.

The calculations of the simulation curves were based on the expanding plane model.[8,9] The following chemical reactions were assumed to be irreversible (See Results and Discussion). A computer simulation was performed with a HITAC 8700/8800 system, the Computer Center, the University of Tokyo, using the FORTRAN program of Smith.[8,9]

Results and Discussion

DC Polarography. The oxinate complex, [Pd(oxine)$_2$], was reduced through two waves (first at -1.39 V and second at -1.8 V). The first wave gave a diffusion controlled current. The second wave was very drawn out. The acetylacetonate complex, [Pd(acac)$_2$], was reduced through one wave at -1.17 V. This wave was also diffusion controlled and corresponded to the reduction of Pd(II) to a palladium amalgam.[10]

Oscillopolarography. The oscillopolarograms of these complexes are shown in Fig. 1-(A, B).

In the system of [Pd(oxine)$_2$]–0.5 M TEAP, the (1) and (5) waves correspond to the two waves of the DC polarogram. The (2) wave is the reoxidation wave of the reduced product of the (1) wave. This wave refers to the presence of the low-valent species. If the first reduced form is the palladium amalgam, it is difficult for the palladium to be reoxidized before the dissolution of mercury starts.[11] The (5) wave is irreversible. Hence, it is attributed to the reduction to the palladium amalgam. The (1), (2), and

(A) [Pd(oxine)$_2$]=0.27 mM
(B) [Pd(acac)$_2$]=1.28 mM.

(5) waves suggest that $[Pd(oxine)_2]$ is first reduced to the Pd(I) species and then to the amalgam.

In the system of $[Pd(acac)_2]$-0.5 M TEAP, the (1′) wave corresponds to the wave of the DC polarogram. The reoxidation wave (2′) suggests that a low-valent species (Pd(I) or Pd(0)) is present. The (3′) and (4′) waves did not appear when the sweep range was reduced so that the reduction of $[Pd(acac)_2]$ did not occur. Therefore, these waves are assumed probably to be due to the oxidation and reduction of mercury by the free acetylacetonate anion,[10] which has been liberated by the reduction of $[Pd(acac)_2]$.

same parameters as Fig. 2, except frequency$=173.6$ Hz.

In the system of $[Pd(oxine)_2]$-0.5 M TEAP, the (3) and (4) waves appeared only when the reduction of $[Pd(oxine)_2]$ occurred. When only the (1) wave appeared, these waves were also observed, but were as small as one-third of those in Fig. 1. These wave forms were different from the normal redox wave. This is probably because of the adsorption of the species which participate in the redox reaction of mercury by the oxinate anion.

AC Polarography. Figures 2 and 3 show the AC polarograms of $[Pd(oxine)_2]$ corresponding to the first wave of the DC polarogram. Though the phase angles of the fundamental and second harmonic AC polarograms were almost consistent with that of the reversible electrode reaction, the amplitudes were considerably smaller than that expected from the diffusion coefficient, which was calculated from the DC polarogram. The peak potential(E_p) of the fundamental harmonic AC polarogram was not equal to the zero-current potential (E_{min}) of the second harmonic AC polarogram. These features are typical of a reversible electrode reaction coupled with a following chemical reaction. As was seen in the preceding paragraph, the following chemical reaction was a decomposition reaction and was assumed to be irreversible. In the case of an irreversible following chemical reaction, the presence of the zero-current potential and the small cathodic peak height compared with the anodic one in the second harmonic AC polarogram indicate that the following chemical reaction is slow and so is inoperative in the AC polarographic sense. Figures 2 and 3 correspond to this case. This conclusion coincides with the fact that the cotangent of the phase angle of the second harmonic AC polarogram was almost equal to -1.[9] From the half-width of the fundamental harmonic AC polarogram, the number of electrons transferred(n) was found to be one. Therefore, the life-time of the Pd(I) species is assumed to be long in the AC polarographic sense. From the computer simulation, which was carried out at two frequencies, the rate constant of the following chemical reaction was estimated to be 5.5 ± 1.0 s^{-1}; *i.e.*, the life-time was about 0.18 s.

Figures 4 and 5 show the AC polarograms of $[Pd(acac)_2]$. In the fundamental harmonic AC polarogram, another small peak was observed at -1.65 V. These results seem to suggest that $[Pd(acac)_2]$ is also reduced through two steps. The observed second wave was irreversible; hence, it was attributed to the reduction to the amalgam. The Pd(I) species was also detected in this system. The two waves were so close together that the DC polarogram apparently showed only one wave. The first AC wave was also typical of an electrode reaction coupled with a following chemical reaction. When the rate constant of

same parameters as Fig. 4, except frequency=173.6 Hz.

the following chemical reaction increases and/or that of the charge transfer reaction decreases, the phase angle of the second harmonic AC polarogram deviates from the value of a reversible electrode reaction, and the cathodic peak of the second harmonic AC polarogram becomes remarkably small. The system of

Table 1. Polarographic data of Pd(II)-0.5 M TEAP System

	$E^r_{1/2}$ or Pd(II)/Pd(I) (*vs.* SCE)	k_s (α=0.5)	k_f of Pd(I)
[Pd(oxine)$_2$]	−1.46$_2$ V	>1 cm/s	(5.5±1.0)/s
[Pd(acac)$_2$]	−1.29$_2$ V	(0.07±0.03) cm/s	(50±10)/s

T=(22.5±0.5)°C, k_s; the standard rate constant of a charge transfer reaction, k_f; the rate constant of a following chemical reaction.

[Pd(acac)$_2$] corresponds to this case. From the computer simulation assuming an irreversible following chemical reaction and assuming that the transfer coefficient of the charge transfer reaction(α) was 0.5, it was found that n was 1 and that the rate constant of the following chemical reaction and the standard rate constant of the charge transfer reaction were 50± 10 s^{-1} and 0.07±0.03 cm/s respectively; *i.e.*, the lifetime of the Pd(I) species was about 0.020 s. The parameters of these complexes can be summarized as is shown in Table 1.

In conclusion, these complexes were first reduced to mono-valent species. These complexes may have the same configuration as the starting complexes. These mono-valent species were unstable, decomposed, and liberated the ligands. These mono-valent species were also reduced irreversibly to palladium amalgams, and liberated the ligands.

The k_s of the Pd(II)/Pd(I) couple was larger in the [Pd(oxine)$_2$] system than in the [Pd(acac)$_2$] system. The rate constant of the decomposition was slower in the [Pd(oxine)$_2$] system than in the [Pd(acac)$_2$] system. These results show that the bi-valent species is reduced to the mono-valent species more easily in the oxinate complex than in the acetylacetonate complex, and that the mono-valent species is more stabilized as the oxinate complex than as the acetylacetonate complex.

From the ESR study of γ-ray irradiated Pd(I) complexes,[12] the covalency of the palladium-ligand σ bond has been found larger in [Pd(I)(oxine)$_2$]$^-$ than in [Pd(I)(acac)$_2$]$^-$. Therefore, the stabilization of Pd(I) may be due to the delocalization of the highest occupied energy level of Pd(I) complexes.

The product of the decomposition reaction is unknown. However, from the second harmonic AC polarogram, the regeneration of Pd(II) species can not be considered.[13] As there seems to be no species which can stabilize the mono-valent species, the decomposition reaction may be the reduction to palladium metal. In both systems with the higher frequency of the AC potential, humps were observed in the second harmonic AC polarogram. These are probably due to the adsorption of the complex preceding the reduction. In the data analysis for the following chemical reaction, this effect was neglected. In the simulation program, the diffusion coefficients of the first reduced form and the product of the following chemical reaction are assumed to be equal to each other. This condition was not applicable in these systems. However, this discrepancy was as-

sumed not to be very serious. The effect of a spherical diffusion was also not considered.

Reaction of Nickel Ion Fixed on the Ion Exchange Resin with 2-Thenoyltrifluoroacetone

Kunio OHZEKI, Tooru TAMURA, and Tomihito KAMBARA

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received June 7, 1975)

The reaction of nickel ions fixed on the ion exchange resin with 2-thenoyltrifluoroacetone was investigated in various organic solvents. In the presence of pyridine, nickel ions were quantitatively extracted from the resin into the organic phase in the form of the adducts of nickel(II) chelate with pyridine. The synergistic effect of a series of pyridine bases on the removal of the metal ions from the resin decreased in the order : pyridine> γ-picoline> β-picoline> α-picoline.

Several studies on the conversion of a metal ion fixed on the ion exchange resin to a chelate compound based on the ion exchange reaction in organic medium have been investigated in our laboratory. The authors have reported the quantitative removal of iron(III)[1] and copper(II)[2] ions fixed on Amberlyst 15 by acetylacetone with the aid of a small amount of pyridine–water mixture. In this work, the reaction of the nickel ions fixed on Amberlyst 15 with 2-thenoyltrifluoroacetone(Htta) was investigated in benzene, carbon tetrachloride, chloroform, and ethyl alcohol, and the effects of pyridine bases on the quantitative removal of the nickel ions were discussed.

Experimental

Apparatus and Reagents. Absorption measurements were carried out by the aid of a Shimadzu Spectronic 88 spectrophotometer and a Hitachi 356 two-wavelength double-beam spectrophotometer with 10 mm cells. A Hitachi 508 atomic absorption spectrophotometer was used for the nickel absorption measurement at 231.4 nm in air-acetylene flame. 2-thenoyltrifluoroacetone and β-picoline were obtained from Wako Chemical Inc. and used without further purification. Pyridine, α-picoline, γ-picoline, and all other materials used were of guaranteed grade.

Preparation of Nickel(II)-Form Resin. The resin used was sulfonic acid cation exchanger, Amberlyst 15, with a macroreticular structure. The commercially available Amberlyst 15 was crushed and shieved to a fraction of 60—80 mesh. The resin was converted to Ni(II)-form by treatment with 0.1 mol dm^{-3} solution of nickel nitrate. The resulting Ni(II)-form resin was washed with water until the washings showed no color reaction with dimethylglyoxime and dried over silica gel. The ratio of exchange capacity of nickel ion to proton was 0.996, and that the nickel ions are expected to be adsorbed on the resin in the form of Ni^{2+}. When the air dried Ni(II)-form was dried at 110 °C for 3 hours, the weight loss was found to be about 24%. The infrared spectrum of the resin showed the existence of a small amount of water. The water on the oven dried resin was determined by the method described in the previous paper[2] and it is supposed that two water molecules are coordinated to a nickel(II) ion on the resin, such as $(RSO_3)_2Ni\cdot 2H_2O$. In the following experiments, the air dried resin was used without oven drying.

Determination of Nickel Ions on the Ni(II)-Form Resin. The nickel ions on the air dried Ni(II)-form resin were eluted by 4 mol dm^{-3} hydrochloric acid solution and determined by EDTA titration. It was found that 2.95±0.02 meq of nickel ions were adsorbed onto 1.00 g of the air dried Ni(II)-form resin.

Reaction of Ni(II)-Form Resin. A portion of 5 ml of 0.1 mol dm^{-3} Htta in organic medium was poured onto the 25 mg of air dried Ni(II)-form resin in a test tube and varying amounts of pyridine and/or pyridine–water mixture were added. The mixture was shaken mechanically for 10 min at room temperature (around 19 °C) and for equilibrium study, it was allowed to stand for 24 hours with occasional shakings. After filtration, the resin was washed with ethyl alcohol and water. The nickel ions remaining on the resin were eluted by 4 mol dm^{-3} hydrochloric acid solution and determined by atomic absorption spectrophotometry.

Results and Discussion

Effect of Pyridine. Any portion of the nickel ions fixed on the resin could not be removed by Htta alone into organic medium. But the addition of a small amount of pyridine or pyridine–water mixture was highly effective, as Fig. 1 shows. Upon addition of pyridine to Htta solution in contact with the Ni(II)-form resin, green color was developed in the organic phase, indicating the formation of $Ni(tta)_2py_2$. More than 99% of nickel ions can be removed from the resin by the addition of the 30 : 1 to 100 : 1 pyridine–water mixture, where Htta dissolved in chloroform in 4—14% (v/v) is employed. The resin floated up to the surface of the solvent as the reaction proceeded.

Effect of Solvents. Figure 2 shows the effect of the solvents on the removal of nickel ions from the resin. More than 99% of the nickel ions are extracted into benzene and carbon tetrachloride by the

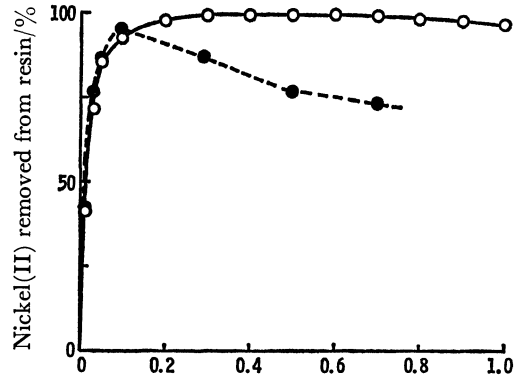

Fig. 1. Effect of the addition of pyridine (●), and pyridine-water (50 : 1) mixture (○) on the removal of nickel ions from the resin with 5 ml of 0.1 mol dm^{-3} Htta solution in chloroform.

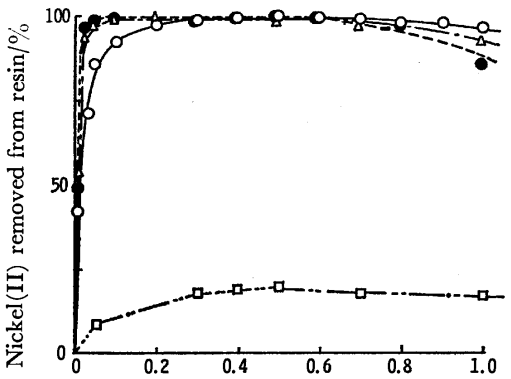

Fig. 2. Removal of nickel ions from the resin with 5 ml of 0.1 mol dm^{-3} Htta solution in various solvents. Ethyl alcohol (□), chloroform (○), benzene (△) and carbon tetrachloride (●).

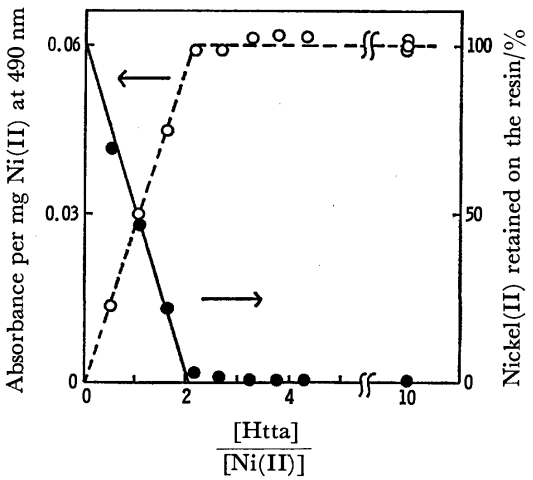

Fig. 3. Effect of Htta concentration in chloroform containing 1.14 mol dm^{-3} pyridine-water (50 : 1) mixture. The absorbance measurement of the organic extract (○), and nickel retained on the resin (●).

addition of pyridine as well as pyridine-water mixture. The poor extraction of nickel ions in ethyl alcohol is due to a probable interaction of the solvent and Htta.

Ion Exchange Extraction Constant. The composition of the complex in chloroform medium was determined by the mole ratio method. The nickel ions remaining on the resin were eluted by 4 mol dm^{-3} hydrochloric acid solution and determined by atomic absorption spectrophotometry and the absorbance of the solution was measured at 490 nm against chloroform. Consequently the composition of the Ni(II)-Htta complex was estimated to be Ni(II) : Htta=1 : 2 as shown by Fig. 3. It is reported that Ni(II)-Htta complex adds two moles of pyridine at high concentration of pyridine[3] and it is reosonable to expect that pyridinium ion is adsorbed on the resin instead of nickel ion[1]. Consequently the following ion exchange extraction equilibrium is proposed.

$$(RSO_3)_2Ni + 2\,Htta + 4\,py \rightleftharpoons 2\,RSO_3Hpy + Ni(tta)_2py_2 \quad (1)$$

where R denotes the resin matrix.

Now we can define the ion exchange extraction constant K_{ex}^{r} as

$$K_{ex}^{r} = \frac{[Ni(tta)_2py_2]_o[pyH^+]_r^2}{[Ni^{2+}]_r[Htta]_o^2[py]_o^4} \quad (2)$$

where the subscripts r and o denote the chemical species on the resin and in the organic phase, respectively. In this case, the distribution ratio of nickel is shown by

$$D = \frac{[Ni(tta)_2py_2]_o}{[Ni^{2+}]_r} \quad (3)$$

Introducing the ion exchange extraction constant shown by the Eq. (2) into the Eq. (3), one obtains.

$$\log D[py]_o^{-4} = \log K_{ex}^{r} + 2\log[Htta]_o[pyH^+]_r^{-1} \quad (4)$$

Consequently a plot of $\log D[py]_o^{-4}$ against $\log [Htta]_o[pyH^+]_r^{-1}$ should give a straight line of slope 2. The result is given in Fig. 4. The values of $\log K_{ex}^{r}$ obtained are 1.96 in chloroform, 4.81 in benzene, and 4.91 in carbon tetrachloride. In all calculations, the concentration of the species on the resin is expressed as mole per gram of Ni(II)-form resin.

Effect of Pyridine Bases. The relationship between the percentage of nickel ions removed from the resin and the shaking time was examined with various pyridine bases. It is found that picolines are less effective than pyridine and it takes several hours to remove more than 99% of nickel ions from the resin as Fig. 5 shows. The synergistic effect of the pyridine bases on the removal of the nickel ions from the resin decreased in the order of pyridine>γ-picoline>β-picoline>α-picoline. On the other hand, it is reported that the synergistic effect decreases in the order of γ-picoline>β-picoline>pyridine>α-picoline in the solvent extraction of nickel ions with Htta.[3] The disagreement of the results between ion exchange

extraction and solvent extraction may be caused by the steric influence of the resin matrix with methyl group of the picolines.

Comparison of Chelating Reagents. The removal of nickel ions from the resin into benzene with benzoylacetone(Hba) was investigated in the presence of pyridine as the function of the shaking time as Fig. 6 shows. It is found that the reaction rate is much

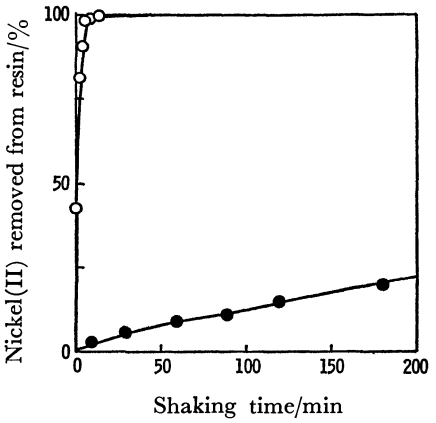

Fig. 6. Comparison of reaction rates.
Htta (○) and Hba (●) in benzene in the presence of pyridine.

slower in the case of Hba than Htta. This may be due to the difference in the acidity of the chelating reagents, Hba (pK_a=9.8), Htta (pK_a=5.7).

An Electron Spin Resonance Study of Some Quadridentate Schiff Base Complexes of Copper(II)

David J. Cookson, Thomas D. Smith, and John R. Pilbrow*
Chemistry Department, Monash University, Clayton, Victoria, Australia 3168
**Physics Department, Monash University, Clayton, Victoria, Australlia 3168*
(Received June 16, 1975)

The X-band ESR spectra of a series of quadridentate Schiff base complexes of copper(II) have been examined in frozen xylene and chloroform solutions. Well resolved triplet state spectra were observed both at *g ca.* 2 and *g ca.* 4 due to dimeric forms of these complexes which exist in frozen solution. Magnetic and structural parameters have been determined by computer simulation of the triplet state spectra based on a lower than axial symmetry model for the copper(II) pair system.

The structural features of Schiff base compounds have been the subject of numerous investigations and more recently ESR spectroscopy has been used to study the dimeric forms of several copper(II) Schiff base complexes in frozen solution.[1-6] The application of a dipole-dipole coupled model to copper(II) dimers of low symmetry has enabled the ESR spectra to be analysed by computer simulation and has yielded values for the copper(II)-copper(II) separation, r, and the angle ξ (Fig. 1). In some cases it has been possible to compare structural data deduced from X-ray diffraction studies with similar information obtained from ESR spectra.[1,7]

Crystallographic studies on the dimeric forms of copper(II) Schiff bases indicate that the symmetry is monoclinic. However the host lattice relevant to the X-ray crystallographic studies is quite different from that involved in ESR measurements which are confined to isolated interacting pairs of copper(II) ions in solvent mixtures and it is possible that the stereochemistry of the dimers formed in solution may be dependent upon solvent effects.

Chikira and Isobe[2] concluded from computer simulations of the observed ESR lineshapes that the dimeric structure of bis(*N*-salicylidenemethylaminato)-copper(II), [Cu(MeSal)], in frozen toluene solution was similar to that found for the γ-form crystals as determined by X-ray methods. Furthermore it was found necessary to take into account the non-coincidence of the principal axes of the g tensor with those of the fine structure tensor in order to estimate such dimeric structures.[2]

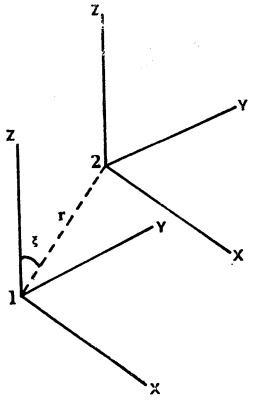

Fig. 1. Orientation of g tensor principal axes and internuclear axis for centrosymmetric metal ion dimers.

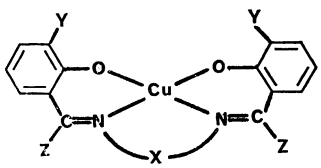
A more recent investigation by Chikira *et al.* involved a study of the triplet state ESR spectra due to the dimeric forms of the copper(II) complexes of some bidentate and quadridentate Schiff bases.[3] The spectra were analysed on the basis of the previously obtained results concerning the non-coincident g and fine structure tensors.[2] Their results indicated that the angles between the $g_{\parallel}$ axis and the copper-copper axis of the dimers of the quadridentate Schiff base complexes were considerably smaller than those of the bidentate ones. The lineshapes and the magnetic parameters of the bidentate Schiff base complexes were characterized by non-coaxial g and fine structure tensors whereas the quadridentate complexes were thought to show ESR spectra indicative of near coaxial g and fine structure tensors. It was concluded from this argument that the difference between the solid state and frozen solution dimeric structure of *N,N'*-ethylenebis-(salicylideneiminate)copper(II), [Cu(Salen)], was due to the fact that, in frozen solution the $g_{\parallel}$ axis almost coincides with the copper–copper axis.

These results are in direct conflict with the previously reported results of Toy *et al.*[1] who estimated the copper–copper distance and the angle between the $g_{\parallel}$ axis and the copper–copper axis for Cu(Salen) dimers in chloroform at 4.55±0.05 Å and 40±5° respectively. It was later claimed by Chikira *et al.* that the spectral patterns for the $\Delta Ms=\pm1$ transition of Cu(Salen) could not be reproduced by the use of such non-coincident g and spin-dipole interactions.[3] The magnetic and structural parameters determined by Toy *et al*[1]. were obtained by computer simulation of the low field ($\Delta Ms=\pm2$) components of the spectra only since, in all cases, the observation of the corresponding $\Delta Ms=\pm1$ spectrum at *g ca.* 2 proved difficult due to masking in



X = $\underset{\underset{CH_3}{|}}{CHCH_2}$ (pn), $(CH_2)_3$ (tn)
Y = H, OCH_3
Z = H, CH_3

Fig. 2. Structural formulae of copper(II) Schiff base complexes.

that region by a strong signal due to the monomer species. On the other hand, the parameters determined by Chikira *et al.*[3] were based on computer simulation of the $\Delta Ms=\pm1$ spectra only and no data relevant to the $\Delta Ms=\pm2$ transitions was presented.

The present investigation involves the determination of structural and magnetic parameters of a number of copper(II) Schiff base complexes which include *N,N'*-isopropylenebis(salicylideneiminato)copper(II), Cu(Salpn); *N,N'*-propylenebis(salicylideneiminato)copper(II), Cu(Saltn); *N,N'*-isopropylenebis(3-methoxysalicylideneiminato)copper(II), Cu(3MeO-Salpn); *N,N'*-propylenebis(3-methoxysalicylideneiminato)copper(II), Cu(3MeO-Saltn); *N,N'*-isopropylenebis(7,7'-dimethylsalicylideneiminato)copper(II), Cu(7,7'Me_2Salpn) and *N,N'*-propylenebis(7,7'-dimethylsalicylideneiminato)copper(II), Cu(7,7'Me_2Saltn). The structural formulae of these complexes are shown in Fig. 2.

The results obtained are based on computer simulation of both the $\Delta Ms=\pm1$ and $\Delta Ms=\pm2$ transitions in the ESR spectra due to the dimeric forms of the Schiff base complexes, and indicate that the *g* and fine structure tensors are in fact non-coincident.

Experimental

ESR spectra were recorded by means of a Varian E12 spectrometer. Cu(Salpn), Cu(Saltn), Cu(3MeO-Salpn) and Cu(3MeO-Saltn) were prepared by refluxing in ethanol the salicylaldehyde or 3MeO-salicylaldehyde complex of copper(II) with the appropriate diamine. Cu(7,7' Me_2Salpn) and Cu(7,7' Me_2Saltn) were prepared by refluxing in ethanol, copper(II) acetate, *o*-hydroxyacetophenone and the appropriate diamine.

In all cases the composition of the products was established by elemental analysis.

Results

Chikira *et al.*[3] calculated the magnetic parameters for a wide range of quadridentate Schiff base complexes, including Cu(Salpn), from the triplet state ESR spectra, at *g ca.* 2, arising from frozen toluene solutions of the complexes. However, even under these conditions, the ESR spectra included contributions from the doublet spectra due to monomeric forms of the Schiff bases.

Ideal conditions for computer simulation of triplet state ESR spectra arise when there is complete conversion to dimer and where the signals due to the $\Delta Ms=\pm1$ and $\Delta Ms=\pm2$ transitions are easily discerned and the resolution of their peaks is good enough to compare with computed lineshapes. A solvent which was found to provide these requirements was xylene. The ESR spectrum, at −140 °C, due to a xylene solution of Cu(Salpn) is shown in Fig. 3. Similar spectra were observed in the case of xylene solutions of Cu(Saltn), Cu(7,7' Me_2Salpn) and Cu(7,7' Me_2Saltn).

The ESR spectra of Cu(3MeO-Salpn) and 3MeO-Saltn) in xylene, at −140 °C, consisted of single broad lines, (approx. 150 gauss from peak to peak), indicative of the formation of aggregate forms of the Schiff bases under these conditions. The best circumstances for the observation of triplet state spectra were provided by chloroform, although monomer spectra of comparable intensity were also observed. The ESR spectrum, at −140 °C, due to a chloroform solution of Cu(3MeO-Salpn) is shown in Fig. 4. A chloroform solution of Cu(3MeO-Saltn) gave rise to a similar spectrum.

No triplet state spectra were obtained from chloroform solutions of the other Schiff bases although at sufficiently high concentrations (*ca.* 10^{-1} M), weak signals at *g ca.* 4 were observed due to small concentrations of dimer in solution. The ESR spectrum due to a solution of Cu(Saltn) in chloroform, at −140 °C, is shown in Fig. 5. The copper(II) Schiff base complexes are soluble in polar solvents such as ethanol and pyridine but under these circumstances triplet state ESR spectra are not observed.

It was found that Ni(Salpn) could readily be doped with Cu(Salpn) thus providing the conditions for diamagnetic dilution. The ESR spectrum at −140 °C due to Cu(Salpn) under these circumstances is shown in Fig. 6.

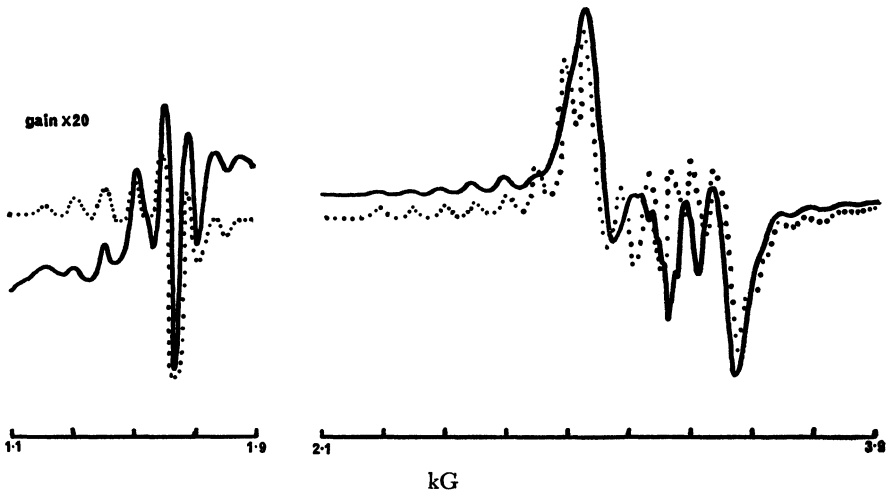


Fig. 3. X-Band ESR spectrum due to a xylene solution of Cu(Salpn) (1.0×10^{-2} M) at −140 °C; microwave frequency 9150 MHz. The dotted curves represent the computer simulation of the experimental spectrum using the parameters listed in Table 1. Baseline drift ignored in $\Delta Ms=\pm2$ spectrum.

Quantitative Treatment of Results and Discussion

Observation of the ESR spectrum, shown in Fig. 3, for a frozen xylene solution of Cu(Salpn) indicates that negligible amounts of monomeric species are present under these conditions.

The low field (*g ca.* 4) component of the spectrum is attributed to $\Delta Ms=\pm2$ transitions in the triplet state arising from magnetic dipole-dipole coupling of the copper(II) ions in a dimeric form of Cu(Salpn) while the signal at *g ca.* 2 is attributed to the corresponding $\Delta Ms=\pm1$ transition.

The intensity pattern of peaks in the $\Delta Ms=\pm2$ signal is indicative of a monoclinic arrangement of the copper(II) ions in the pair system[7] and the structural and magnetic parameters obtained by computer simulation of the experimental lineshape using this symmetry model are listed in Table 1.

Theoretical considerations involved in the computer simulation of an ESR spectrum using this model for the copper(II) pair system have been described previously.[7] The results of Chikira *et al.*[3] are in agreement with those of Lund and Hatfield.[6] who determined the magnetic parameters for a series of copper(II) dimers and concluded for Cu(Salen), that the principal axes of the *g* and fine structure tensors were coincident. However, as has been shown in a recent review,[8] Lund and Hatfield[6] omitted necessary terms in the Hamiltonian for lower than axial symmetry dimers and were therefore unable to reconcile their ESR results with known structural data. This has been discussed previously by two of the authors.[8] On the other hand Boyd *et al.*,[7] in examining many of the same systems in terms of a theoretical model which included all necessary terms for low symmetry dimers, did, in fact obtain very sensible agreement between X-ray and ESR structural parameters.

The effect of low symmetry on calculated spectra shows that the intensity pattern and field positions of

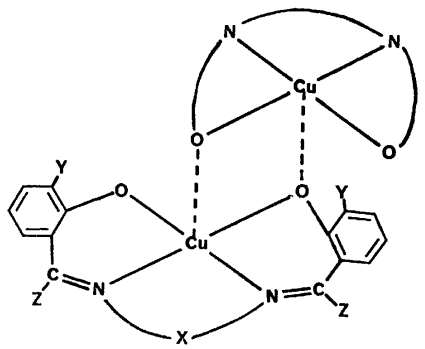

Fig. 7. Proposed structure for the dimeric forms of the copper(II) Schiff base complexes, present in frozen solution.

the lines in the low field ($\Delta Ms=\pm2$) region in particular, are affected considerably by variation in ξ.[7,8] This indicates the necessity of obtaining a well resolved low field spectrum before any conclusion about the symmetry of the copper(II) pair system can be made and unique set of structural and magnetic parameters determined.

The ESR spectrum due to a chloroform solution of Cu(3MeO-Salpn) at −140 °C is the result of the presence of a mixture of monomeric and dimeric species in solution. However the triplet state spectrum, due to the dimer, is still easily discerned at both *g ca.* 2 and *g ca.* 4 and the parameters obtained from computer simulation of this spectrum as well as that of Cu(3MeO-Saltn) in chloroform, are summarised in Table 1. A structure which meets the symmetry requirements as outlined in Table 1 is shown in Fig. 7 and involves a value of ξ of about 35°.

The ESR spectrum of Cu(Saltn) in $CHCl_3$ at −140 °C indicates the formation of a monomeric species only. The predominant feature of this spectrum, as well as those of Cu(Salpn), Cu(7,7' Me_2Salpn) and Cu(7,7'-Me_2Saltn) in chloroform, is the appearance of extra hyperfine splitting in addition to that due to copper. Each line is split into approximately fourteen additional lines although the exact number is difficult to ascertain because of a certain degree of overlap. The separation of the lines is 7 G. Interaction of the unpaired electron on copper with two equivalent nitrogen nuclei each having a nuclear spin of 1, would be expected to result in the splitting of each copper hyperfine line into five lines with intensity ratios 1 : 2 : 3 : 2 : 1, and spacing between adjacent lines of 14—15 G. It is possible therefore that the lineshape may be the result of either the superposition of two or more monomer spectra or, that interactions with atoms other than nitrogen are occurring.

The signal observed at *g ca.* 4 in the ESR spectrum due to Cu(Salpn) doped into Ni(Salpn) indicates the formation of a dimeric species under these conditions, although only in small concentrations. The lineshape of the low field component of the spectrum again points to a monoclinic symmetry of the copper(II) pair system and the calculated magnetic and structural parameters from this spectrum are listed in Table 1. It can be seen from the similarity of these parameters to those obtained from frozen solution measurements, that the structural features of the copper(II) Schiff base are unchanged despite the gross change in host lattice.

Chikira *et al.* have studied the equilibrium between monomeric and dimeric forms of the copper(II) Schiff bases and have estimated equilibrium constants for the conversion of monomer to dimer by comparing the spectral intensities of the two species.[3] Their calculations concerning the quadridentate Schiff base complexes indicated that the K values (K is the equilibrium constant for the reaction $2M \rightleftharpoons M_2$, where M is the monomer) were not changed by branching methyl groups at the ethylene bridge. Contrary to their results however we have shown that when the iminoic nitrogens are bridged by a timethylene group, as in Cu(Saltn), the distribution of dimer in solution is unaltered and readily detectable triplet state ESR spectra are observed. A similar situation arises when

there is a methyl group on the imine carbon in the Schiff bases derived from *o*-hydroxyacetophenone and, once again, increasing the size of the bridging group from two to three carbon atoms produced no noticeable effect on the ESR spectra of these complexes. No evidence for dimer formation involving the complex with a tetramethylene bridge could be detected due to the low solubility of this complex in common organic solvents.

The effect of substituents on the phenyl ring is more noticeable. The tendency to dimerise is greater in the substituted complexes as can be seen by comparing the ESR spectra of Cu(Saltn) and Cu(3MeO-Saltn) in frozen chloroform. In xylene or toluene the substituted complexes aggregate further whereas the unsubstituted complexes are essentially dimeric in these solvents. This result indicates that solvent effects also play an important part in the dimerization and polymerization of the copper(II) Schiff base complexes in frozen solution. In all cases association was more marked in xylene than in chloroform presumeably due to the greater solvating tendencies of the latter.

The Australian Research Grants Committee is thanked for a grant for the purchase of the Varian E-12 ESR Spectrometer. D.J.C. acknowledges receipt of a Commonwealth Post Graduate Award.

Non-isothermal Studies of Adduct Molecules of Metallic Halides with Oxo Compounds in Solid State. III.

N. Ray Chaudhuri and S. Mitra

Inorganic Chemistry Laboratory, Indian Association for the Cultivation of Science, Calcutta 700032, India

(Received December 23, 1974)

Non-isothermal studies of some adduct molecules of metallic halides with ethylene glycol dimethyl ether of the type $MX_2(EGDME)_y$ in solid state were carried out with a derivatograph, where M=Mn(II), Co(II), Ni(II), Cu(II) or Cd(II), X=Cl^- or Br^-, EGDME=ethylene glycol dimethyl ether and y=0.5—1. These adduct molecules lost ethylene glycol dimethyl ether in single or multiple steps upon heating. Thermally stable intermediate products were isolated and characterised by elemental analysis and IR spectral measurement. The activation energy for each step of decomposition of the adduct was evaluated from the analysis of TG, DTG and DTA curves of the respective derivatograms. Enthalpy change was evaluated from the DTA peak area and the order of reaction was found to be unity for each step of decomposition. Thermal parameters for the above adducts were compared with those for the corresponding type of adducts with oxo-compounds like dioxane or tetrahydrofuran.

Works on the adduct molecule with ethylene glycol dimethyl ether were carried out by several groups of workers,[1-11] but they only prepared and characterised some adduct molecules of metallic halides with ethylene glycol dimethyl ether. Ludwig and Schroer[12] carried out thermal decomposition of ethylene glycol dimethyl ether adducts of some metal halides. They investigated the thermal properties of the adducts by thermogravimetry and differential thermal analysis but not by the measurement of DTG, and they did not evaluate the activation energy, order of reaction and enthalpy change for each step of decomposition of the adducts. In continuation of our previous works[13,14] on dioxane and tetrahydrofuran, the present paper deals with thermal decomposition of ethylene glycol dimethyl ether adducts of some metal halides to evaluate the activation energy for decomposition of the adducts from the results by simultaneous TG, DTG, and DTA measurements as well as the order of reaction(n) from the TG curve and ΔH from the DTA peak area. This paper gives a comparative picture on the thermal properties of adducts similar in composition and a discussion on the thermal properties relating the other oxo-compounds studied earlier.[13,14]

Experimental

All the adducts were prepared by a method similar to that described previously[13,14] and characterised by elemental analysis and IR spectral measurement. The ethylene glycol dimethyl ether used was sufficiently purified according to the standard procedure.[8]

The following adducts of the metal halides were prepared

1. $MnCl_2 \cdot 0.5EGDME$
2. $MnBr_2 \cdot 1EGDME$
3. $CoCl_2 \cdot 0.5EGDME$
4. $CoBr_2 \cdot 1EGDME$
5. $NiCl_2 \cdot 1EGDME$
6. $NiBr_2 \cdot 1EGDME$
7. $CuCl_2 \cdot 0.5EGDME$
8. $CuBr_2 \cdot 1EGDME$
9. $CdCl_2 \cdot 1EGDME$
10. $CdBr_2 \cdot 1EGDME$

where EGDME represents ethylene glycol dimethyl ether.

A Paulik-Paulik-Erdey type MOM derivatograph was used for thermal analysis. The particle size of the sample was within 150—200 mesh. Heating rate was about 1.5 °C/min. The volume of the sample in each case was the same. Platinum crucible was used. All the experiments were conducted in static air.

Results

Adducts of $MnBr_2$, $NiBr_2$, $CuBr_2$, $CdCl_2$ and $CdBr_2$ with ethylene glycol dimethyl ether are similar in composition with one another and lose ethylene glycol dimethyl ether in a single step upon heating as indicated by their respective derivatogram in Figs. 1 and 2. A similar single step decomposition is observed in the adduct of $CuCl_2$ although its composition is not similar to that of the former adducts. The adducts of $MnCl_2$ and $CoCl_2$ are similar to one of $CuCl_2$ in composition and they lose ethylene glycol dimethyl ether on heating in different fashion (Fig. 3); *i.e.*, $MCl_2 \cdot 0.5EGDME \rightarrow MCl_2 \cdot 0.25EGDME$; $MCl_2 \cdot 0.25EGDME \rightarrow MCl_2$, where M=Mn(II) or Co(II). The adduct of $NiCl_2$ though it is similar to the adduct of $NiBr_2$ in composition loses ethylene glycol dimethyl ether upon heating in the following way as shown in Fig. 4; $NiCl_2 \cdot 1EGDME \rightarrow NiCl_2 \cdot 0.25EGDME \rightarrow NiCl_2$. The intermediate product *i.e.*, $NiCl_2 \cdot 0.25EGDME$ is not stable. The adduct of $CoBr_2$ which is similar in composition to the major number of adducts described earlier loses ethylene glycol dimethyl ether in multiple steps upon heating as shown in Fig. 4. None of these intermediate products are stable enough to be isolated. Its derivatogram indicates its decomposition in three steps and the intermediate products are very unusual in composition.

The decomposition of all the adducts shows endotherm. Temperature ranges of decomposition and the DTG peak temperatures for the adducts are listed in Table 1. Enthalpy change for each step of decomposition of the adducts was evaluated by the method of Sano[15] using copper sulfate pentahydrate as the standard. When the two DTA curves are too much overlapped with each other, the ΔH values are evaluated from the overall area of the DTA peaks concerned.

The activation energy for each step of decomposition of the adduct molecules was evaluated (Table 1) from the analysis of the TG curves using Freeman and Carroll's[16] equation. The plots of $\Delta\log(dw/dt)/\Delta\log W_r$ *vs.* $\Delta T^{-1}/\Delta\log W_r \times 10^3$ from TG curves are shown in Fig. 5. The order of reaction for each step of decomposition is found to be unity.

Activation energy for each step of decomposition was also evaluated from the analysis of the DTG curve

A Ethylene glycol dimethyl ether. a) Evaluation of activation energy not possible due to too much overlapping of the corresponding curves. b) Overall enthalpy change. c) Evaluation of activation energy and enthalpy change not possible due to very weak resolution of the curve.

Discussion

The adduct of $MnCl_2$ was known as $MnCl_2 \cdot 1EGDME$.[8] On repeated preparation we could not isolate an adduct of similar composition. Recently Hengge and Zimmermann[11] isolated the adduct of $MnCl_2$ like ours. Its composition and nature of thermal decomposition are similar to the corresponding adduct with tetrahydrofuran.[14] It is observed that thermal stability of $MnCl_2 \cdot 0.5EGDME$ is greater than the corresponding tetrahydrofuran adduct, whereas its intermediate product, $MnCl_2 \cdot 0.25EGDME$, is thermally less stable than the corresponding tetrahydrofuran adduct. It is also noted that values of activation energies for decomposition of $MnCl_2 \cdot 0.5EGDME \rightarrow MnCl_2 \cdot 0.25EGDME$ and $MnCl_2 \cdot 0.25EGDME \rightarrow MnCl_2$ are less than those for the corresponding tetrahydrofuran adduct.

The adduct of $MnBr_2$ is similar in composition to the corresponding adduct with tetrahydrofuran and dioxane we isolated.[13,14] The thermal stability of $MnBr_2 \cdot 1EGDME$ is higher than the corresponding adduct with tetrahydrofuran and less than the corresponding adduct with dioxane. The value of activation energy evaluated for the decomposition of $MnBr_2 \cdot 1EGDME \rightarrow MnBr_2$ is less than that for the corresponding adduct with dioxane.

The adduct of $CoCl_2$ was isolated as $CoCl_2 \cdot 1EGDME$.[12] Ludwick and Schroer[12] carried out its thermal decomposition and DTA study. In their studies the

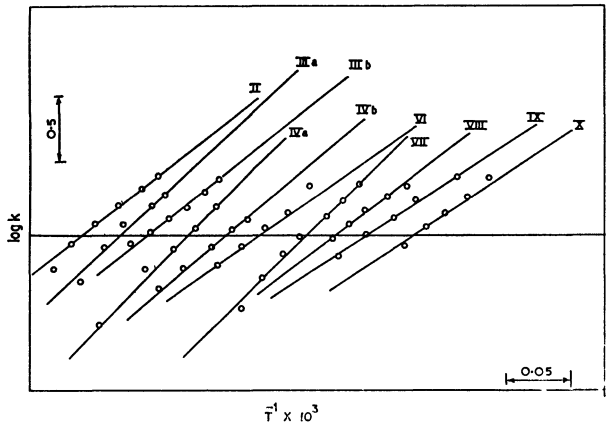

Fig. 6. Arrhenius plots of $\log k$ *vs.* $T^{-1} \times 10^3$, from DTG for the decomposition of $MnBr_2 \cdot 1$EGDME → $MnBr_2$(II), $CoCl_2 \cdot 0.5$EGDME→$CoCl_2 \cdot 0.25$EGDME (IIIa), $CoCl \cdot 0.25$EGDME → $CoCl_2$ (IIIb), $CoBr_2 \cdot 1$EGDME → $CoBr_2$. 0.74EGDME (IVa), $CoBr_2 \cdot 0.65$EGDME→$CoBr_2$ (IVb), $NiBr_2 \cdot 1$EGDME→$NiBr_2$ (VI), $CuCl_2 \cdot 0.5$ EGDME→$CuCl_2$ (VII), $CuBr_2 \cdot 1$EGDME→$CuBr_2$ (VIII), $CdCl_2 \cdot 1$EGDME→$CdCl_2$ (IX) and $CdBr_2 \cdot 1$EGDME→$CdBr_2$ (X).

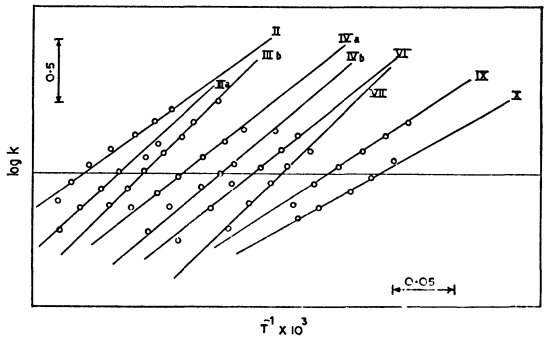

Fig. 7. Arrhenius plots of $\log k$ *vs.* T^{-1}, from DTA for the decomposition of $MnBr_2 \cdot 1$EGDME → $MnBr_2$ (II), $CoCl_2 \cdot 0.5$EGDME→$CoCl_2 \cdot 0.25$EGDME (IIIa), $CoCl_2 \cdot 0.25$EGDME→$CoCl_2$ (IIIb), $CoBr_2 \cdot 1$EGDME → $CoBr_2 \cdot 0.74$EGDME (IVa), $CoBr_2 \cdot 0.65$EGDME→ $CoBr_2$ (IVb), $NiBr_2 \cdot 1$EGDME → $NiBr_2$ (VI), $CuCl_2 \cdot 0.5$EGDME→$CuCl_2$ (VII), $CdCl_2 \cdot 1$EGDME→$CdCl_2$ (IX) and $CdBr_2 \cdot 1$EGDME → $CdBr_2$ (X).

existence of $CoCl_2 \cdot 0.5$EGDME was observed from the TG curve and the two overlapped endothermic peaks of the DTA curve. We could not isolate the adduct of the composition described above.[8,12] The adduct $CoCl_2 \cdot 5$EGDME we isolated is similar in composition to that of the adduct with tetrahydrofuran and dioxane, its nature of thermal decomposition being also similar to that of the adduct of $MnCl_2$ and the corresponding adduct with tetrahydrofuran. $CoCl_2 \cdot 0.5$D being similar to the corresponding adduct with ethylene glycol dimethyl ether in composition loses dioxane in a single step. The existence of $CoCl_2 \cdot 0.25$EGDME, $MnCl_2 \cdot 0.25$EGDME and corresponding adduct with THF is indicated by their respective derivatograms. The thermal stability of $CoCl_2 \cdot 0.5$EGDME is equal to the corresponding adduct of $MnCl_2$ and the activation energy for the decomposition of $CoCl_2 \cdot 0.5$EGDME→ $CoCl_2 \cdot 0.25$EGDME is greater than that for the decomposition of $MnCl_2 \cdot 0.5$EGDME→$MnCl_2 \cdot 0.25$-EGDME. On the other hand the thermal stability of $CoCl_2 \cdot 0.25$EGDME is higher than that of the corresponding adduct of $MnCl_2$. However, the thermal stability, activation energy and enthalpy change of this intermediate product are practically equal to that of tetrahydrofuran adduct.[14] The thermal stability of the adduct $CoCl_2 \cdot 0.5$EGDME is lower than the corresponding similar adduct with dioxane but greater than the corresponding tetrahydrofuran adduct. The activation energy for the first step of decomposition of $CoCl_2 \cdot 0.5$EGDME is higher in comparison to the corresponding similar adducts with dioxane and

tetrahydrofuran

The adduct $CoBr_2 \cdot 1EGDME$ we isolated is similar in composition to the adducts isolated by Fowles *et al.*[8] and Ludwig and Schroer.[12] DTA study of $CoBr_2 \cdot 1EGDME$[12] shows that the decomposition takes place in two steps and the intermediate product is very unstable. In our case the nature of decomposition is somewhat different. This is probably due to the very small rate of heating in comparison with that in the earlier work.[12] Though the intermediate products are unstable, we obtained three endothermic peaks in the DTA curve. The weight loss of the second step is very small. Though the composition of the adduct of $CoBr_2$ with ethylene glycol dimethyl ether is similar to that of the corresponding adduct with dioxane, the nature of thermal decomposition of the two differs. The adduct $CoBr_2 \cdot 1D$ loses dioxane in a single step. The thermal stability of $CoBr_2 \cdot 1D$ is lower than that of the corresponding adduct with ethylene glycol dimethyl ether. Activation energy is smaller in case of dioxane adduct.

The composition of the adduct of $NiCl_2$ we isolated differs from that of the corresponding adduct with dioxane and tetrahydrofuran.[13,14]

The adduct of $NiBr_2$ was isolated as $NiBr_2 \cdot 2EGDME$.[12] Its TG and DTA studies indicate multiple steps of decomposition. Ludwig and Schroer could not isolate the adduct as $NiBr_2 \cdot 1EGDME$ thermally. However, Ward[10] isolated the same recently. $NiBr_2 \cdot 1EGDME$ we isolated is similar in composition to the corresponding dioxane adduct[13] but not similar to the corresponding adduct with THF.[14] The nature of thermal decomposition of the adduct $NiBr_2 \cdot 1EGDME$ is similar to the corresponding dioxane adduct, $NiBr_2 \cdot 1D$. With respect to the thermal stability and activation energy of decomposition the ethylene glycol dimethyl ether adduct is less stable than the dioxane adduct in the case of $NiBr_2$.

The adduct $CuCl_2 \cdot 0.5EGDME$ we isolated was reported earlier.[8,12] Although the composition of the adduct of this salt with dioxane and tetrahydrofuran differs from this adduct, the nature of decomposition of this adduct and the adduct of dioxane is the same.

Ethylene glycol dimethyl ether adduct of $CuBr_2$ we isolated is similar in composition to the corresponding adduct with tetrahydrofuran. The dioxane adduct of similar composition is observed as an intermediate during the thermal decomposition of $CuBr_2 \cdot 2D$. Thermal stability and activation energy of $CuBr_2 \cdot 1EGDME$ are equal to those of the corresponding adduct with THF but the adduct $CuBr_2 \cdot 1EGDME$ is thermally more stable than the corresponding dioxane adduct.

Preparation and characterisation of the adduct of $CdCl_2$ and $CdBr_2$ with ethylene glycol dimethyl ether were carried out by Fowles *et al.*[8] We isolated the adducts of $CdCl_2$ and $CdBr_2$ as $CdCl_2 \cdot 1EGDME$ and $CdBr_2 \cdot 1EGDME$ which are similar in composition to their adducts and also similar to the corresponding adduct with tetrahydrofuran but not similar to the corresponding adduct with dioxane in the case of $CdCl_2$. Dioxane forms the adduct of $CdCl_2$ as $CdCl_2 \cdot 0.5D$. The nature of the decomposition of the adducts of both $CdCl_2$ and $CdBr_2$ with ethylene glycol dimethyl ether is similar to the adducts of other oxo-compounds such as tetrahydrofuran and dioxane.[13,14] The thermal stability and activation energy of the decomposition of $CdCl_2 \cdot 1EGDME$ are lower than those of the corresponding tetrahydrofuran adduct. The adduct $CdBr_2 \cdot 1EGDME$ is thermally less stable than the corresponding adduct with dioxane and more stable than that of adduct with tetrahydrofuran. The activation energy of decomposition of ethylene glycol dimethyl ether adduct of $CdBr_2$ is lower than that of the corresponding adduct with tetrahydrofuran or dioxane.

Thermal stability of the adducts of the type $MBr_2 \cdot 1EGDME$, where M=Mn(II), Co(II), Ni(II), Cu(II) and Cd(II) increase in the order: Cu>Mn>Cd>Ni=Co. The thermal stability, activation energy and enthalpy change of decomposition of $CdCl_2 \cdot 1EGDME$ and $CdBr_2 \cdot 1EGDME$ are nearly the same. Such similarities are not observed between the corresponding tetrahydrofuran adducts of $CdCl_2$ and $CdBr_2$.

In general the later step of decomposition gives larger ΔH value and activation energy than the earlier step. But such a tendency is not observed in the decomposition of all the adducts.

The authors wish to express their hearty thanks to Prof. P. C. Dutta of this Institute for his kind help in the work.

Synthesis of 2,3,6,7-Tetramethylnaphthalene from 2,3-Dimethylsuccinic Anhydride and *o*-Xylene

Yasuhiko Dozen and Masato Hatta

Government Industrial Research Institute, Osaka, Ikeda-shi, Osaka 563

(Received October 24, 1974)

2,3,6,7-Tetramethylnaphthalene (**7b**) was prepared from 2,3-dimethylsuccinic anhydride (**1**) and *o*-xylene in five steps, and the configurations of their intermediates were studied. The higher-melting isomer (*threo* form) of **1** gave higher-melting products in each step, while the lower-melting isomer (*erythro* form) of **1** gave lower-melting ones. The configurations of the intermediates were confirmed by the MNR spectral data of tetramethyltetralines (**6b**). Similar reactions were carried out with 3-benzoyl-2,3-dimethylpropionic acid (**2a**) in order to learn the configurations of the intermediates. 3-Aroyl-2,3-dimethylpropionic acids (**2**) gave 2,3-dimethyl-4-aryl-3-buten-4-oildes (**3**) upon heating with hydrochloric acid.

In the course of the investigation of thermally stable polyimide polymers derived from naphthalenetertacarboxylic acid anhydrides and aromatic diamines, we realized the necessity of a convenient method of synthesizing 2,3,6,7-naphthalenetetracarboxylic acid. The anhydride of this acid has been prepared by the dehydrogenation of 1,2,3,4,5,6,7,8-octahydronaphthalene-2,3,6,7-tetracarboxylic acid dianhydride[1-3] with bromine.[4,5] 2,3,6,7-Tetramethylnaphthalene, which is oxidizable to the tetracarboxylic acid, has been synthesized by Mosby[6] and Rieke *et al.*[7] but these procedures are inadequate for obtaining the acid in quantity. 4-Arylbutyric acids, which give rise to naphthalene derivatives by cyclization, have been prepared by the Clemmensen reduction of 3-aroylpropionic acids[8] or by catalytic hydrogenation over palladium in acetic acid.[9-11] A partial hydrogenation of 3-benzoylpropionic acid over palladium in alcoholic ammonia gives 4-phenylbutyrolactone.[12]

The present paper will deal with the synthesis of 2,3,6,7-tetramethylnaphthalene (**7b**) from 2,3-dimethylsuccinic anhydride (**1**) and *o*-xylene in five steps, as is shown in Scheme 1, where the *threo* isomer has been designated as an example. A mixture of the diastereoisomer of the starting material could be used for the synthesis of **7b**. When optically inactive *threo* **1** was used, the products of each step in Scheme 1 were of the *threo* form, with a retention of the configuration. Similarly, *erythro* **1** gave *erythro* products. Similar reactions with **2a** were carried out as an adjunct for the investigation of the configuration. The intermediates reported here are new compounds.

Results and Discussion

3-Aroyl-2,3-dimethylpropionic Acids (*2*). In the Friedel-Crafts reaction of **1** with benzene alone or with *o*-xylene in tetrachloroethane, the higher-melting isomer (*threo* form) of **1** gave predominantly the higher-melting isomer of **2a** or **b**. On the other hand, the lower-melting isomer (*erythro* form) of **1** gave the lower-melting isomer of **2a** or **b**. These results suggest that the configuration is retained in the reaction.[13] The NMR and IR spectral data of **2** are summarized in Table 1.

The *threo* **2a** was insoluble in carbon tetrachloride, whereas the *erythro* isomer was soluble. On the other hand, *threo* and *ertyhro* **2b** could not be separated into two diastereoisomers by solvent extraction; rather, they were characterized on the basis of the NMR spectra. The *threo* or *erythro* **2a** was converted to a mixture of nearly equal amounts of them in a strong alkaline solution, while in a weak alkaline solution only a small portion of *threo* **2a** was epimerized, as is shown in Table 2.

2,3-Dimethyl-4-aryl-3-buten-4-olides (*3*). On the Clemmensen reduction of *threo* **2a**, compounds **3a** (racemate) and **4a** (*threo* and *erythro* mixture) were obtained in a molar ratio of 37 : 63, while a mixture of *threo* and *erythro* **2b** (about 1 : 1) gave **3b** (racemate) and **4b** (*threo* and *erythro* mixture) in a 62 : 38 ratio. Refluxing a mixture of **2** and hydrochloric acid gave racemic **3**[14] (Table 3). The IR and NMR spectral data of **3** are shown in Table 4.

Table 2. Epimerization of **2a** in aqueous alkaline solution

Reactant		Product, %		
Compound	Base	Yield	*threo*	*erythro*
threo	KOH	91	53	47
threo	Na_2CO_3	94	>91	<9
erythro	KOH	92	42	58

Table 3. Lactonization of **2** to **3** with hydrochloric acid

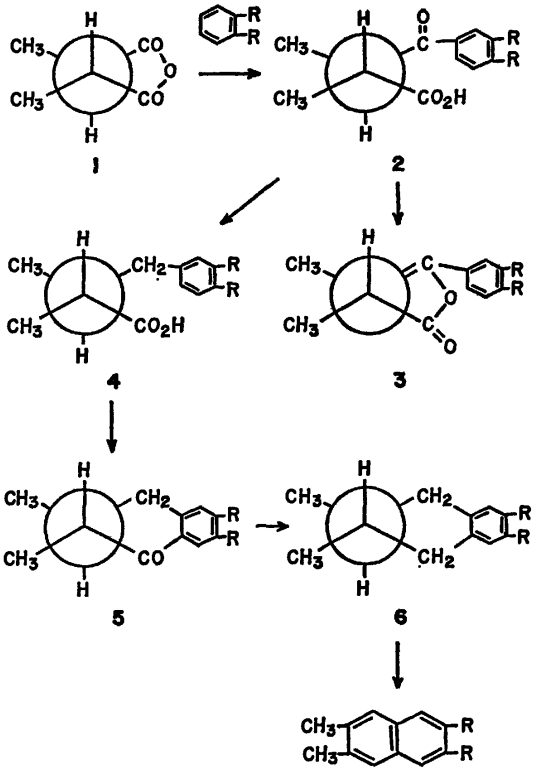
Reactant **2**	Recovered **2**, %	Product **3**, %
a *threo*	6	83
erythro	4	82
b *threo*	4	88

The aliphatic methyl hydrogen signal which appeared upfield in the NMR spectra of racemic **3a** and **b** has triplet bands, while that downfield has a sextet. The downfield signal was changed to a triplet by decoupling with the methine proton. The splitting into a triplet can not be explained at present.

An attempt to esterify the racemic **3b** with methanol in the presence of sulfuric acid failed, and the lactone was recovered. The Clemmensen reduction of racemic **3b** for 10 hr gave a mixture of *threo* and *erythro* **4b** in a 13.5% yield, and 76% of the racemic **3b** was recovered. The hydrolysis of racemic **3b** with potassium hydroxide in aqueous ethanol gave a mixture of the diastereoisomers of **2b**. A reddish color was observed at the initial stage of the hydrolysis, in analogy with angelicalactone.[15]

4-Aryl-2,3-dimethylbutyric Acids (*4*). On the catalytic hydrogenation with palladium on carbon in glacial acetic acid, the higher-melting isomers (*threo* form) of **2a** and **b** gave higher-melting ones of **4a** and **b** respectively, and the lower-melting isomers (*erythro* form) of **2a** and **b** were converted to the lower-melting ones of **4a** and **b**, as is shown in Table 5. The NMR and IR data are summarized in Table 6. It is interesting to note that the carbonyl band of *threo* **4** in the IR spectra appeared at a lower frequency than that of *erythro* ones.

Tetralones (*5*). The cyclization of the acid chloride of *threo* **4a** with anhydrous aluminum chloride in tetrachloroethane gave predominantly the higher-melting isomer of **5a**, while *erythro* **4a** and **b** gave



Scheme 1. *threo*-Isomer.

lower-melting ones of **5a** and **b** respectively, as is shown in Table 7. The cyclization of *threo* or *erythro* **4a** and **b** with polyphosphoric acid (PPA), on the other hand, gave a mixture of the diastereoisomers of **5a** and **b** respectively. The ratio of *threo* and *erythro* **5a** and **b** could be determined by fractional crystallization from petroleum ether or methanol. After heating the *erythro* **5b** with PPA at 115 °C for 1 hr, the recovered tetralone (mp 65—95 °C) was composed of a mixture of nearly equal amounts of the diastereoisomers of **5b**. These results suggest that the configuration is retained during the cyclization by the Friedel-Crafts reaction. It is assumed that the configuration is retained at the cyclization step with PPA, but the tetralone obtained is rapidly epimerized through the enolization catalyzed by the proton.

The NMR data of **5** are summarized in Table 8. The aliphatic methyl proton signals of *threo* and *erythro* **5** overlapped, but they could be distinguished from each other. The methylene and 3-methyl proton

signals in **5** and **6** exhibited similar chemical shifts, whereas the 2-methyl proton signal of **5** was shifted to a lower field as compared with that of **6** (see Table 10) as a result of the deshielding by the carbonyl group. The lower-field shift of the signal of 8-H as compared with that of 5-H in **5b** may also be attributed to deshielding by the carbonyl group.

Tetralines (**6**). The catalytic hydrogenation of *threo* **5a** and **b** over palladium on carbon in glacial acetic acid at 70—80 °C gave predominantly higher-melting isomers of **6**, as is shown in Table 9. The ratios of the *threo* and *erythro* isomers were determined by means of the aliphatic methyl proton signals in the NMR spectra. The NMR spectral data of **6** summarized in Table 10 support the theory that the two methine protons in the higher-melting isomer are axial and hence the aliphatic methyl groups are equatorial, and that the methine protons in the lower-melting isomer are one axial and one equatorial.[16] Therefore, it may be concluded that the higher-melting isomers in each step have the *threo* (*trans*) configuration, while the lower-melting isomers have the *erythro* (*cis*) one.

2,3,6,7-Tetramethylnaphthalene (**7**) *and -Naphthalenetetracarboxylic Acid.* The diastereoisomer of **6a** and **b** was dehydrogenated with palladium on carbon at 300 °C to 2,3-dimethylnaphthalene and 2,3,6,7-tetramethylnaphthalene respectively. The tetra-

methylnaphthalene was then oxidized to the corresponding naphthalenetetracarboxylic acid with aqueous sodium bichromate at 275 °C for 20 hr under an autogeneous pressure in the presence of pyridine to avoid the sublimation of hydrocarbon.

Experimental

All the melting points are uncorrected. The compounds described here are optically inactive. The IR spectra were recorded with a JASCO IR-G Spectrophotometer. The NMR spectra were measured with a JEOL JIM PS 100 apparatus (with TMS as the internal standard).

2,3-Dimethylsuccinic Anhydride (1). Diethyl 2-cyano-2,3-dimethylsuccinate[18,19)] was hydrolyzed with hydrochloric acid to give a mixture of *threo* and *erythro* 2,3-dimethylsuccinic acids. *erytho* (*cis*, *meso*) Acid was obtained by recrystallization from diluted hydrochloric acid[20)]; mp 205 °C (decompn.) (lit, mp 209 °C[20,21)]). The *threo* (*trans*, *racemic*) isomer was isolated from the original mother liquors by extraction with ether; mp 119 °C (lit, mp 127 °C,[20)] 129 °C,[21)] and 128—130 °C[22)]). These acids were then converted to the corresponding acid anhydrides (**1**) by treating them with acetyl chloride.[23)] *threo* **1**: bp 115—120 °C/8—10 mmHg, mp 81—82 °C (lit, mp 89 °C[21)]), NMR (δ, ppm) C**H** 2.68, m in 5% CCl_4, 2.78, m in 2% $CDCl_3$ (lit, 2.76 in $CDCl_3$[21)]) and CH_3 1.41, d, J=7 Hz in 5% CCl_4 1.46, d in 2% $CDCl_3$ (lit, 1.40 in $CDCl_3$[21)]). *erythro* **1**: bp 102—104 °C/7 mmHg, mp 36—37 °C (lit, mp 39—40 °C[20)]), NMR (δ) C**H** 3.18, m in 10% CCl_4, 3.24, m in 2% $CDCl_3$ (lit, 3.23 in $CDCl_3$[21)]) and CH_3 1.26, d, J=7.5 Hz in 10% CCl_4, 1.30, d in 2% $CDCl_3$ (lit, 1.30 in $CDCl_3$[21)]). These acid anhydrides (**1**) exhibited slightly lower melting points than the literature values, but they were NMR spectroscopically pure substances. Therefore, **1** was used in the subsequent reactions without further purification.

3-Aroyl-2,3-dimethylpropionic Acids (2). A mixture of *threo* **1** (24.0 g, 0.188 mol) and anhydrous aluminum chloride (50.5 g, 0.376 mol) in 200 ml of benzene was stirred for 0.5 hr in an ice-water bath, heated for 1 hr at 50 °C, and then poured into 200 ml of ice water containing 30 ml of concd. hydrochloric acid. The precipitate was filtered and washed with benzene. The solid was dissolved in sodium carbonate (8.0 g) in 200 ml of hot water, treated with active carbon, and then acidfied with hydrochloric acid to give 26.7 g of *threo* **2a**; mp 147—148 °C. The benzene solution was extracted with 7.0 g of sodium carbonate in 150 ml of water. The aqueous solution was acidified with hydrochloric acid, and the solid was recrystallized from 40 ml of carbon tetrachloride (treated with active carbon) to give 1.9 g of *threo* **2a**; mp 145—147 °C. The removal of the solvent gave 2.3 g of *erythro* **2a**; mp 69—80 °C. The total yield of **2a** was 28.6 g (79.6%), and the ratio of the *threo* and *erythro* isomers was 92.6 : 7.4. Pure *threo* **2a** was obtained by recrystallization from methanol; mp 148.5—149.5 °C. Found: C, 69.94; H, 6.98%. Calcd for $C_{12}H_{14}O_3$: C, 69.89; H, 6.84%.

A mixture of *erythro* **1** (26.0 g, 0.203 mol) and anhydrous aluminum chloride (54.5 g, 0.408 mol) in 200 ml of benzene was treated as above. The benzene solution was then extracted with 14.0 g of sodium carbonate in 200 ml of water. After the acidification of the aqueous solution, the separated oily material was extracted with ether. The subsequent removal of the solvent gave 37.8 g (90.4%) of *erythro* **2a**; mp 75—78 °C. Found: C, 69.67; H, 6.89%.

o-Xylene (16.6 g, 0.156 mol) was added to a solution of *threo* **1** (20.0 g, 0.156 mol) and anhydrous aluminum chloride (42.0 g, 0.315 mol) in 150 ml of tetrachloroethane chilled with an ice-water bath, after which the reaction mixture was treated as above. *threo* **2b** was obtained from the aqueous alkaline extract; 27.1 g (59.4%); mp 110—113 °C. Recrystallization from aqueous ethanol (1 : 1 vol) gave a pure sample; mp 116.5—117.5 °C. Found: C, 71.51; H, 7.56%. Calcd for $C_{14}H_{18}O_3$: C, 71.75; H, 7.74%.

From the reaction product of *o*-xylene and *erythro* **1**, pasty *erythro* **2b** was obtained in a 92.1% yield.

Epimerization of 2a. A mixture of 10.3 g of *threo* or *erythro* **2a**, 4.5 g of potassium hydroxide (or 3.8 g of sodium carbonate), and 100 ml of water was heated at 85 °C for 3 hr. The solution was then acidified with hydrochloric acid, filtered, and dried over soda lime under a vacuum. The solid was heated with 100 ml of carbon tetrachloride to separate the undissolved *threo* isomer. The *erythro* isomer was obtained from the mother liquors (Table 2).

Clemmensen Reduction of **2**. After the Clemmensen reduction of *threo* **2a** (40 g) for 10.5 hr, the product was extracted with benzene. The removal of benzene gave a pasty product; bp 157—160 °C/5 mmHg; 29.9 g. The distillate was added to aqueous sodium carbonate and extracted with benzene. Racemic **3a** was obtained from the benzene solution; bp 149 °C/4 mmHg; 8.3 g (29%). A mixture of *threo* and

erythro **4a** was obtained by the acidification of the aqueous solution; bp 143—144 °C/2.5 mmHg; 17.0 g (49%). The molar ratio of **3a** : **4a** was 33 : 67. Similarly, a mixture of *threo* and *erythro* **2b** was reduced for 12 hr to give **3b** (racemate) and **4b** (*threo* and *erythro* mixture) in a molar ratio of 62 : 38.

The racemic **3b** was recrystallized from methanol to give a pure sample; mp 66.5—67.5 °C. Found: C, 77.50; H, 7.51%. Calcd for $C_{14}H_{16}O_2$: C, 77.75; H, 7.46%.

Lactonization of **2** *to* **3**. A mixture of *threo* (or *erythro*) **2a** (16.0 g) 80 ml of concd. hydrochloric acid, and 20 ml of water was heated at 150 °C for 1 hr. The product was then treated as above to separate lactone (**3**) and ketonic acid (**2**)) Table 3).

Catalytic Hydrogenation of **2** *to* **4**. Compound (**2**) was hydrogenated to **4** with 5% Pd/C in glacial acetic acid at 60—80 °C for 1 hr under an initial pressure of hydrogen of 60—80 kg/cm² in an autoclave. The product, which was contaminated with 2–5% of ring-hydrogenated compound, was filtered and washed with methanol. After the removal of the solvent, the residue was recrystallized from petr. ether or distilled under a vacuum to give **4** (Table 5). *threo* **4a**: Found: C, 74.61; H, 8.51%. Calcd for $C_{12}H_{16}O_2$: C, 74.97; H, 8.39%. An analysis of NMR spectra of *erythro* **4a** showed it to contain 18% of the *threo* isomer. *threo* **4b**: Found: C, 76.07; H, 9.38%. Calcd for $C_{14}H_{20}O_2$: C, 76.32; H, 9.15%. *erythro* **4b**: Found: C, 75.96; H, 9.42%.

The catalytic hydrogenation of racemic **3** required a higher temperature (*ca.* 115 °C) than that of **2**, and the product was comtaminated with 20—40% of a ring-hydrogenated compound.

Cyclization of **4** *to* **5**. *A)*: A mixture of 15.0 g (0.078 mol) of *threo* or *erythro* **4**, 15 g of thionyl chloride, and 30 ml of benzene was heated in an oil bath at 90 °C for 2 hr. The excess thionyl chloride and solvent were then removed under reduced pressure. The resulting acid chloride, dissolved in 30 ml of tetrachloroethane, was added to 10.4 g of anhydrous aluminum chloride in 60 ml of tetrachloroethane chilled with an ice-water bath. Stirring was continued for 0.5 hr at this temperature and then for 1 hr at 60—70 °C. The product was subsequently treated in the usual manner. Fractional crystallization from methanol or petr. ether gave pure *threo* and *erythro* **5b** (Table 7). *threo* **5a** (mp 33.5—34.5 °C): Found: C, 82.49; H, 8.05%. Calcd for $C_{12}H_{14}O$: C, 82.72; H, 8.10%. *threo* **5b** (mp 112.5—113.0 °C): Found: C, 83.41; H, 9.11%. Calcd for $C_{14}H_{18}O$: C, 83.12; H, 8.97%. *erythro* **5b** (mp 51.5—52.5 °C): Found: C, 83.34; H. 9.12%.

B): *threo* or *erythro* **4** (10.0 g) was added to PPA (prepared from 50 ml of 85% phosphoric acid and 60 g of phosphorous pentoxide) at 120 °C. The mixture was stirred for 50 min at this temperature and then poured into 200 ml of ice water. The product was extracted with 100 ml of benzene, and the organic layer was washed with aqueous sodium hydroxide. After the removal of the solvent under reduced pressure, the residue was treated as above to give **5** (Table 7).

Catalytic Hydrogenation of **5** *to* **6**. *threo* **5b** (15.0 g, 0.075 mol) was hydrogenated to give 12.9 g of **6b** in glacial acetic acid (150 ml) in the presence of 5% Pd/C (0.7 g) at 70—80 °C for 1—2 hr under an initial pressure of 60 kg/cm². Subsequent recrystallization from methanol gave a pure sample (mp 104—105 °C); IR (Nujol), 856 cm^{-1} (aromatic one free hydrogen). Found: C, 89.55; H,11.03%. Calcd for $C_{14}H_{20}$: C, 89.29; H, 10.71%.

erythro **5b** was hydrogenated to give *erythro* **6b**, contaminated with the *threo* isomer, in a 93—98% yield. Fractional crystallization from petr. ether gave a pure sample; mp 51.5—52.5 °C.

threo **5a** (2.9 g) gave *threo* **6a**; mp 34—35 °C.

Dehydrogenation of **6** *to* **7**. *threo* **6b** (40.0 g) was dehydrogenated to **7b** in the presence of 3.3 g of 5% Pd/C and 10 ml of α-methylnaphthalene at 290—300 °C for 6 hr. The product was extracted with 500 ml of hot benzene and then filtered. The subsequent removal of the solvent gave 35.0 g (89%) of **7b**; mp 192—193.0 °C (from benzene) (lit, mp 191.2—191.8 °C[6] and 188—190 °C[7]). IR (Nujol): 894 cm^{-1} (aromatic one free hydrogen). NMR (δ. ppm in 2% CCl_4): 2.41 (12H, s, Ar-CH_3) (lit, $\tau=7.66$[7] and 7.64[24]) and 7.44 (4H, s, CH) (lit, $\tau=2.63$[7]).

Similarly, *erythro* **6b** gave **7b** in an 82.5% yield. *threo* **6a** gave **7a** in an 83% yield; mp 103.5—104.5 °C (from methanol).

Oxidation of **7b** *to 2,3,6,7-Naphthalenetetracarboxylic Acid.* A mixture of 9.2 g (0.05 mol) of **7b**, 75 g (0.25 mol) of dihydrate of sodium bichromate, 10 ml of pyridine, and 150 ml of water was stirred in an autoclave (300 ml) at 275 °C for 20 hr under autogeneous pressure (40—50 kg/cm²). The product was filtered while hot, and the filtrate was acidified with hydrochloric acid to give 10.1—11.2 g (67—74%) of 2,3,6,7-naphthalenetetracarboxylic acid. The tetramethyl ester had a mp of 184.0—185.0 °C (from 3 : 1 vol methanol/benzene) (lit, mp 181—183 °C[5]). IR (Nujol): ν_{co} 1734 cm^{-1} (lit[5], 1740 cm^{-1})

The authors would like to thank Mr. Jun Iyoda for his helpful determination and discussion of the decoupling of the NMR spectra.

Effects of Solvents and Added Amines on the Selective Hydrogenation of 2-Naphthol over Urushibara Nickel and Cobalt Catalysts

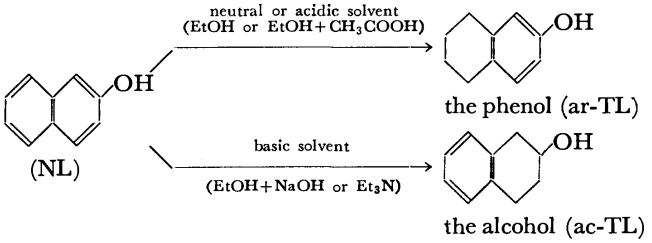
Masatsugu KAJITANI, Yoshio WATANABE, Yutaka IIMURA, and Akira SUGIMORI

Department of Chemistry, Faculty of Science and Technology, Sophia University, Kioi-cho, Chiyoda-ku, Tokyo 102

(Received November 16, 1974)

The selective hydrogenation of 2-naphthol (NL) was investigated with Ni (U-Ni-B, U-Ni-A, and R-Ni) and Co (U-Co-B, U-Co-A, and R-Co) catalysts in various solvents at elevated temperatures and pressure (50 kg/cm²). U-Ni-B and U-Ni-A exhibited a high selectivity for the formation of 1,2,3,4-tetrahydro-2-naphthol (ac-TL), expecially in alcoholic solvents, while the hydrogenation with R-Ni in Et_2O, *i*-PrOH, and benzene solvents gave preferentially 5,6,7,8-tetrahydro-2-naphthol (ar-TL). The ar-TL formation over Ni catalysts decreased in the following order, irrespective of the catalysts. *i*-PrOH>EtOH>MeOH and Et_2O>benzene. However, the selectivity over Co catalyst was influenced to a lesser extent by the solvents. The addition of amines promoted the hydrogenation of NL to ar-TL in the following order: prim->*sec*->*tert*-amine in EtOH over Ni and Co catalysts. In general, Ni catalysts are more susceptible to the effects of solvents and added amines than Co catalysts.

The partial hydrogenation of 2-naphthol (NL) over nickel and cobalt catalysts gives predominantly either the alcohol 1,2,3,4-tetrahydro-2-naphthol (ac-TL) or the phenol 5,6,7,8-tetrahydro-2-naphthol (ar-TL). Musser and Adkins reported that R-Ni gave the alcohol (ac-TL, 55%), decahydro-2-naphthol (20%), and tetrahydronaphthalene (8%) at 140 °C and 100—200 kg/cm² of hydrogen pressure, and Cu-Cr oxide gave higher yields of the alcohol (ac-TL) than was obtained with R-Ni.[1] Stork found that the hydrogenation of 2-naphthol (NL) is influenced by the acidity of the solvent used, as shown below.[2]



Adkins and Kusek reported that the use of R-Ni in EtOH gave ac-TL (*ca.* 10%) and ar-TL (*ca.* 80%), but the use of R-Ni in EtOH containing a small amount of NaOH or Et_3N gave ac-TL in more than 60% yield.[3]

Thus, the selective hydrogenation of 2-naphthol has been investigated mainly by changing the solvent acidity, while the solvent effect has been largely ignored.

In this study, the selective hydrogenation of 2-naphthol with Urushibara nickel, Urushibara cobalt, Raney nickel, and Raney cobalt catalysts in various neutral solvents and in ethanol containing various amines was investigated. The characteristic differences between Ni and Co catalysts, especially with respect to the effects of solvents and added amines, are discussed.

Experimental

Material and Solvents. 2-Naphthol (Wako Pure Chemical Industries, GR) was recrystallized from H_2O-EtOH (v/v=1/3). Solvents were purified according to the standard methods described in the literature.[4]

Commercial guaranteed reagent grade amines were used without further purification.

Catalysts. Urushibara nickel and cobalt catalysts were prepared by simplified methods.[5] R-Ni (W-7 type) and R-Co catalysts were prepared by the method of Adkins and Billica:[6] To a well-stirred solution of 2 g of sodium hydroxide in 10 ml of distilled water was added 2 g of Raney nickel or cobalt alloy (Al-Ni or Co, w/w=1/1) at such a rate as to maintain the temperature (for *ca.* 30 min) at 50± 2 °C. After the addition was completed the mixture was digested at 50 °C for an additional 50 min with gentle stirring. Ordinarily the W-7 R-Ni catalyst, after digestion, is washed with water three times by decantation, but the Raney catalysts were washed with distilled water until the washings were neutral to phenolphthalein.

When the solvents were immiscible with water, the catalysts were first washed with *i*-PrOH to remove the water and then with the solvent specified.

Each catalyst thus prepared contained about 1 g of Ni or Co metal. Urushibara nickel-cobalt catalyst (U-Ni, Co-B) contained 0.5 g of Ni and 0.5 g of Co.

Hydrogenation. 2-Naphthol (3.6 g; 0.025 mol) was hydrogenated with the catalyst in 25 ml of solvent at an elevated temperature under the initial hydrogen pressure of 50 kg/cm² in an autoclave (Nitto Hannoki; 100 ml) at an agitation rate of 450—500 rpm. The reaction temperature was raised from room temperature at the rate of 4±1 °C/min.

Analysis of Reaction Mixtures. After the reaction, the catalyst was filtered off, and the filtrate was analyzed by gas chromatography using the Yanagimoto GC 550T equipped with a column of 5% Silicone OV-17 on Uniport B (Gaschro Kogyo) (ϕ 3 mm×220 cm; glass column, column temp. 180 °C, carrier gas He; 7 ml/min).

Results and Discussion

Selectivity (S value). The main products obtained by the hydrogenation of 2-naphthol (NL) were 1,2,3,4- and 5,6,7,8-tetrahydro-2-naphthols (ac-TL and ar-TL). Since the sums of the yields of decahydro-2-naphthol and tetralin were less than about 5% in most cases, the selectivity in the hydrogenation of 2-naphthol is discussed with respect to the formation of tetralols (ac-TL and ar-TL). The selectivity (S) of the hydrogenation is expressed by

$$S = [\text{ar-TL}/(\text{ac-TL}+\text{ar-TL})] \times 100.$$

Solvent Dependence of Selectivity. The results of

the hydrogenation of 2-naphthol over Ni and Co catalysts prepared by various methods are shown in Tables 1 and 2.

The different selectivities of U-Ni-B, U-Ni-A, and R-Ni in the various solvents are more clearly seen in Fig. 1.

The selectivities over Ni catalysts changed over a wide range from 22% (U-Ni-B, MeOH) to 81% (R-Ni, *i*-PrOH or Et_2O) with the combinations of catalysts and solvents. In general, the hydrogenation

ar-TL: 5,6,7,8-Tetrahydro-2-naphthol

of the phenol ring occurred preferentially over R-Ni and that of the benzene ring over U-Ni-B. The selectivity over U-Ni-A was intermediate between those over U-Ni-B and the R-Ni and *S* values over the catalyst were widely distributed with different solvents, as seen in Fig. 1.

Although the *S* values differed widely with the catalysts, the effects of the solvents with respect to *S* were similar, irrespective of the catalysts, as seen in Fig. 1. Thus, the ar-TL formation over Ni catalysts decreases in the following order: *i*-PrOH>EtOH> MeOH and Et_2O>benzene. The *S* values in ethers were generally greater than those in hydrocarbons.

The hydrogenation over U-Co-B was influenced to a lesser extent by the solvents used than that over U-Ni-B; all the *S* values over U-Co-B were about 50%, as seen in Table 2-1. U-Ni, Co-B catalyst exhibited a greater similarity to U-Ni-B than to U-Co-B. The selectivities by U-Co-A and R-Co catalysts

a) Ni, 0.5 g; Co, 0.5 g.

were practically similar to those by U-Co-B. Compared with Ni catalysts, Co catalysts were not very susceptible to the solvent effects on the selectivity.

It is widely recognized that a solvent containing oxygen atoms often acts as a catalyst poison, because of the strong affinity of the oxygen atom to the catalyst surface. Orito and Imai showed that the solvent effect is a critical factor in the hydrogenation of benzene and toluene over Ni catalysts; hydrocarbons are good solvents for rapid hydrogenation, but solvents containing oxygen atoms, particularly primary alcohols and dioxane, strongly restrain the hydrogenation.[7)]

In the hydrogenation of 2-naphthol over Ni catalysts, primary alcohols tended to suppress the hydrogenation of the unsubstituted benzene ring, whereas secondary alcohol, ether, and hydrocarbon solvents gave greater *S* values than the primary alcohols. However, it is still not clear why the selectivity of hydrogenation depends on the solvents or why the solvent effect of Ni catalyst differs from that of Co catalyst.

The selectivity may depend on the reaction temperature, the amount of hydrogen uptake, or the presence of H_2O. However, it was confirmed that the reaction temperature and the amount of hydrogen uptake influenced the selectivity to only a small extent (less than about 5%), as seen in Tables 1-1 and 2-1. In the hydrogenation over U-Ni-B in *i*-PrOH containing H_2O, added H_2O tends to promote the formation of ac-TL. The selectivity over U-Co-B was only slightly affectes by the addition of H_2O.

Effects of Added Amine on the Selectivities. The effects of added amine (the amount of amine added: 5 ml) on the hydrogenation in 20 ml of EtOH were investigated. The results with Ni and Co catalysts are shown in Tables 3 and 4, respectively.

It has so far been thought that amines promote the hydrogenation of NL to ac-TL. Stork[2)] and Adkins and Kusek[3)] reported that the addition of Et_3N in EtOH solution over R-Ni catalyst also promotes this reaction.

However, as shown in Tables 3 and 4, the effects of added amines on the selective hydrogenation depend on the nature of the amines: the primary amines tend to increase the yield of ar-TL. On the other hand, the addition of tertiary amines promoted slightly the formation of ac-TL with Ni catalysts and was of

TABLE 3. EFFECTS OF ADDED AMINES ON THE SELECTIVITY OF THE HYDROGENATION OF 2-NAPHTHOL OVER Ni CATALYSTS

2-naphthol(NL): 0.025 mol, solvent: EtOH 20 ml + amine 5 ml, Ni content of catalysts: 1 g, Selectivity: $S=100\times$ ar-TL/(ar-TL+ac-TL).

TABLE 4. EFFECTS OF ADDED AMINES ON THE SELECTIVITY OF THE HYDROGENATION OF 2-NAPHTHOL OVER Co CATALYSTS

2-naphthol(NL): 0.025 mol, solvent: EtOH 20 ml + amine 5 ml, Co content of catalysts: 1 g, Selectivity: $S=100\times$ ar-TL/(ar-TL+ac-TL).

Catalyst	Amine	React. Time (min)	React. Temp. (°C)	Recov. NL (%)	Selectivity (*S*)(%)
U-Co-B	Et_3N	35	r.t.—154	28	57
	O N-Et	40	—132	49	59
	Et_2NH	40	—148	49	62
	i-$PrNH_2$	45	—156	43	63
	n-$BuNH_2$	45	—180	0	65
R-Co	Et_3N	30	—120	21	55
	O N-Et	30	—120	21	52
	Et_2NH	25	—90	47	51
	i-$PrNH_2$	35	—106	14	59
	n-$BuNH_2$	70	—184	22	62

little effect in the case of Co catalysts. Thus, the selectivities (*S*) decreased in the following order: primary amine>secondary amine>tertiary amine.

Furthermore, it is noteworthy that the *S* values over Ni catalysts are influenced in a wide range by the addition of various amines, as compared with Co catalysts: *e.g.*, from 70% with *n*-$BuNH_2$ to 33% with Et_3N over U-Ni-B and from 65% with *n*-$BuNH_2$ to 57% with Et_3N over U-Co-B. Thus, concerning the amine effects, the characteristic differences between Ni and Co catalysts are similar to those of the solvent effects discussed above.

The rate of hydrogenation both over Ni and Co catalysts decreased with increasing selectivity (*S*). The effects of the amines to depress the rate of hydrogenation were in the following order: prim-amine> *sec*-amine> *tert*-amine. The order is parallel to that

of the adsorption strength of the amines.

Usually, it has been thought that hydrogenation of a phenol proceeds *via* an intermediate cyclohexanone, which in some cases can be isolated. Stork reported that palladium on charcoal in basic media (*N*-ethylmorpholine) can be used as a good catalyst for the hydrogenation of 2-naphthol to 2-tetralone.[8]

In the present work, however, the formation of 2-tetralone could not be observed, even when the hydrogenation was carried out in the presence of amine with Ni and Co catalysts, respectively. This may be plausible because the conversion of 2-tetralone to 2-tetralol (ac-TL) would be rapid over Ni and Co catalysts.

Stork has reported that the accelerating effects of Et_3N on the formation of ac-TL might be attributed to the shift of equilibrium toward the ketonic tautomer of 2-naphthol.[8] Though this idea may account for the effect of Et_3N, it does not explain how prim- or *sec*-amines promote the formation of ar-TL. Owing to lesser steric hindrance, prim- or *sec*-amines would be more strongly adsorbed onto the catalyst surface than tertiary amines.[4] The results obtained suggest that the presence of strongly adsorbed amines on the catalyst surface might inhibit the adsorption of the phenol ring more than that of the benzene ring of 2-naphthol.

Selective Homogeneous Hydrogenation of 3-Oxo-1,4-diene Steroids. III.[1] On the Formation of Saturated 5α-Ketone in the Hydrogenation Catalyzed by Dichlorotris(triphenylphosphine)ruthenium

Shigeo NISHIMURA, Tomio ICHINO, Akira AKIMOTO, Kiyoshi TSUNEDA,* and Hiromu MORI*

Department of Industrial Chemistry, Tokyo University of Agriculture and Technology, Koganei, Tokyo 184

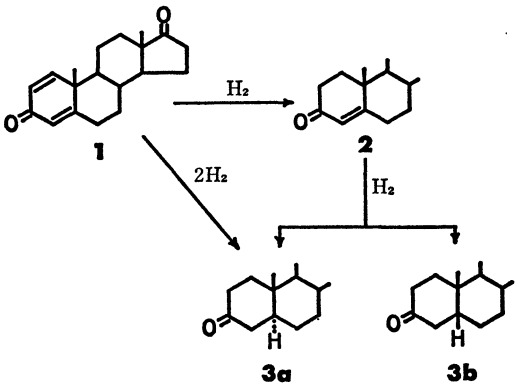
(Received December 5, 1974)

Hydrogenation of 1,4-androstadiene-2,17-dione (**1**) with $RuCl_2(Ph_3P)_3$ gives some saturated 5α-ketone together with 4-androstene-3,17-dione (**2**). The ratio of **2** to the saturated ketone formed increases almost in proportion to hydrogen pressure. The rate dependence upon hydrogen pressure has been shown to be first-order for formation of **2** and zero-order for formation of the saturated ketone. A mechanism which involves a 1,5-hydride shift at an intermediate species is proposed for the stereoselective formation of the 5α-ketone.

In previous papers,[1,2] it was shown that 1,4-androstadiene-3,17-dione (**1**) is hydrogenated selectively to 4-androstene-3,17-dione (**2**) with dichlorotris(triarylphosphine)rutheniums as catalysts. Although hydrogenation of **2** to saturated ketones (**3a** and **3b**) was very slow with the ruthenium complex some saturated 5α-ketone was found to arise directly from **1**.[2] This was in contrast to the hydrogenation catalyzed by chlorotris(triphenylphosphine)rhodium[3,4] where saturated ketones were all produced consecutively through **2**.[2]



Scheme 1. Hydrogenation pathways of 1,4-androstadiene-3,17-dione (**1**).

This paper describes further studies which were undertaken to get an insight into the mechanism of formation of the saturated 5α-ketone in the ruthenium complex catalyzed hydrogenation.

Experimental

Material. 1,4-Androstadiene-3,17-dione (**1**) was obtained from the Kikkoman Shoyu Co. and used without further purification, mp 138—139 °C.

Catalyst. Dichlorotris(triphenylphosphine)ruthenium was prepared as described previously.[1]

Hydrogenation and Analysis of the Products. The hydrogenation apparatus and the method of analysis of the products were the same as those described previously.[1] **1** (500 mg) was hydrogenated with 50 mg of the ruthenium complex in 10 ml benzene at 50 °C under various hydrogen pressures. During each hydrogenation the hydrogen pressure was kept almost constant. The reaction time was varied from 505 min for the hydrogenation at the lowest pressure (2.2 kg/cm²) to 60 min for that at the highest pressure (101 kg/cm²). The conversion of **1** ranged from 16% to 42% by hydrogenations. The pseudo-first-order rate constants were calculated from the compositions of reaction mixtures employing the integrated form of Eq. (1).

Results

Figure 1 shows the effect of hydrogen pressure on the ratio of **2** to saturated ketone formed in the hydrogenation of **1** in benzene at 50 °C. Hydrogenation of **2** to saturated ketones **3a** and **3b** was extremely slow under these conditions and this ratio was, therefore, practically independent of the conversion of **1** at a given hydrogen pressure. As described previously,[2] the saturated ketone formed here is predominantly 5α-androstane-3,17-dione (**3a**) and this is also indicative that the saturated ketone was not formed through **2**, because hydrogenation of **2** gave an about 2 : 1 mixture of **3a** and **3b**. As is seen from Fig. 1, the ratio of **2** to the saturated ketone increases

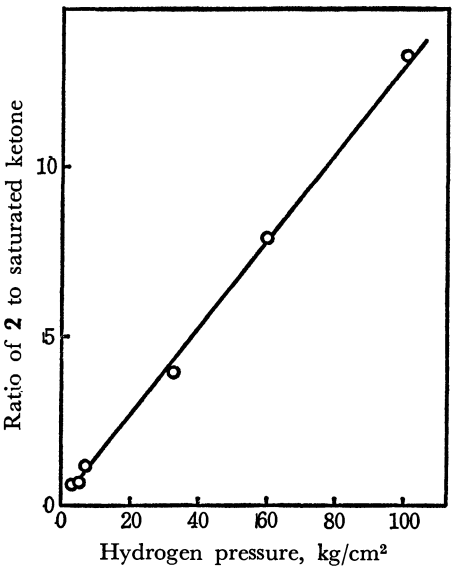


Fig. 1. Effect of hydrogen pressure on the ratio of 4-androstene-3,17-dione (**2**) to the saturated ketone formed in the hydrogenation of **1**. **1** (500 mg) was hydrogenated with 50 mg of $RuCl_2(Ph_3P)_3$ in 10 ml benzene at 50 °C. Each hydrogenation was performed at nearly constant pressure.

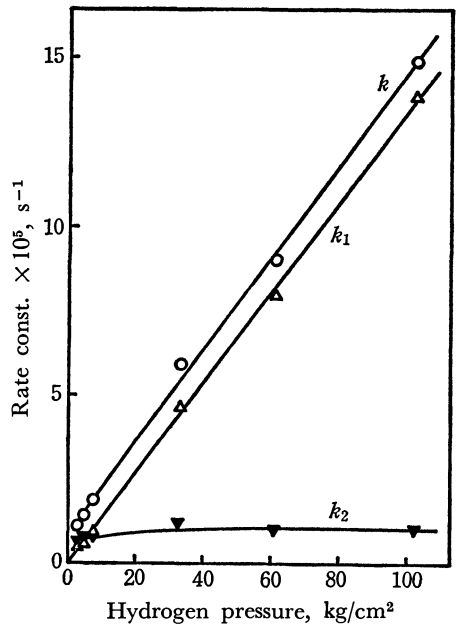

Fig. 2. Effects of hydrogen pressure on the conversion of **1**, the formation of **2** and the formation of saturated ketone. k, k_1, and k_2 are pseudo-first-order rate constants defined by Eq. (1). For experimental conditions, see the footnote of Fig. 1.

almost in proportion to the hydrogen pressure in a wide range of 2 to more than 100 kg/cm².

Figure 2 shows the effect of hydrogen pressure on a pseudo-first-order rate constant k defined by Eq. (1).[5] The rate constant k can be separated into the

$$-\frac{d[\mathbf{1}]}{dt} = k[\mathbf{1}] = (k_1+k_2)[\mathbf{1}] \quad (1)$$

two rate constants k_1 and k_2 for formation of **2** and the saturated ketone, respectively, from the results shown in Fig. 1. From the effects of hydrogen pressure on k_1 and k_2 thus obtained (Fig. 2), it is concluded that the rate of formation of **2** is first-order in hydrogen pressure while that of the saturated ketone is independent of hydrogen pressure. At low pressures, however, k_2 appears to decrease with decreasing hydrogen pressure.

From the plots of the log of the ratio **2**: saturated ketone *vs.* the reciprocal of reaction temperature

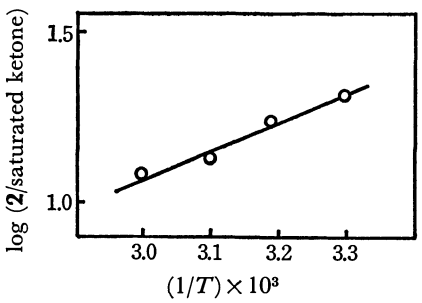

Fig. 3. Effect of reaction temperature on the ratio of **2** to the saturated ketone formed in the hydrogenation of **1**. **1** (500 mg) was hydrogenated with 50 mg of $RuCl_2(Ph_3P)_3$ in 10 ml benzene at 100 kg/cm² hydrogen pressure.

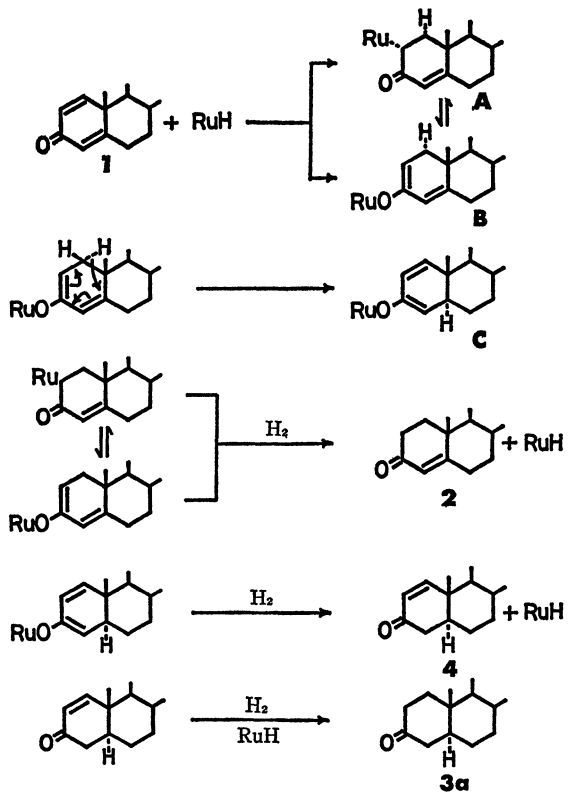
(Fig. 3), we know that the apparent activation energy for formation of saturated ketone is 3.8 kcal/mol higher than for formation of **2**. Thus a better selectivity for **2** is obtained in the hydrogenation at a low temperature.

Discussion

The active species in the hydrogenation catalyzed by dichlorotris(triphenylphosphine)ruthenium is considered to be the hydrido complex $RuClH(Ph_3P)_3$ formed by the hydrogenolysis of the dichloro complex.[6,7] The first step of the hydrogenation of **1**, therefore, will be the addition of the hydrido complex (abbreviated as RuH) to **1**, probably from the α-face.[4] Although the mode of addition of RuH to an α,β-unsaturated ketone is not certain, it might be presumed to occur in the following ways: *1,2* to the C_1–C_2 double bond to give **A** or *1,4* to give **B** as shown in Scheme 2.[8] If we assume that isomerization of **B** to **C** by a 1,5-hydride shift at the cyclic conjugated diene system would occur during the hydrogenation of **A** or **B**,[9] the stereoselective formation of saturated 5α-ketone **3a** could be accounted for because such hydride shifts would be expected to occur without difficulty between quasi-axial 1α and axial 5α positions, assisted by the cyclic conjugated system.[10] The observed zero-order dependence of the rate of formation of **3a** upon hydrogen pressure will not be in conflict with this mechanism if we assume that the hydride shift is rate-controlling in the course of hydrogenation leading to the formation of **3a**. The driving



Scheme 2. A mechanism for formation of 4-androstene-3,17-dione (**2**) and saturated 5α-ketone (**3a**) in the ruthenium complex catalyzed hydrogenation of 1,4-androstadiene-3,17-dione (**1**).

force for the isomerization of **B** is presumed to be the decrease of electron density at the C-5 carbon atom, which would be caused by the coordination of the enolate anion to ruthenium.[11] The hydrogen chloride liberated by the hydrogenolysis of the dichloro ruthenium complex may contribute to this decrease of electron density by interacting with the triphenylphosphine ligand. The effect of the addition of triethylamine to depress the formation of the saturated ketone[1] may give a support for this consideration, because the degree of the depression caused by the addition of triethylamine was so great (from 10.5% to 1.7%), and such a great effect would be difficult to explain by an only twofold increase in the rate of hydrogenation with addition of the amine alone.

From the observed dependencies of the rates on hydrogen pressure, it seems that **C** and **4** are hydrogenated faster than those species which afford **2** on hydrogenation. It is suggested that **C** and **4**, which both have the 5α configuration, will be less hindered than **A** and **B** for the hydrogenation from the α-face, because the 5α species are in a flatter conformation regarding the rings A and B than the Δ^4 species such as **A** and **B**. This is supported by the fact that 5α-1-androstene-3,17-dione (**4**) is hydrogenated more easily than **1** with the ruthenium complex under comparable conditions.[12]

The authors are grateful to Professor J. A. Marshall of Northwestern University for his valuable suggestion concerning the 1,5-hydride shift.

8) A similar mode of addition to α,β-unsaturated carbonyl compounds has been suggested by Goetz and Orchin in the cobalt hydrocarbonyl catalyzed hydrogenation [*J. Amer. Chem. Soc.*, **85**, 2782 (1963)]. Alternative reverse addition of RuH would be less probable because of an increased steric interaction between the Ru moiety and 9α-hydrogen in the resulting species.
9) For the preference of 1,5- over 1,3-hydrogen shift, see R. T. Morrison and R. N. Boyd, "Organic Chemistry," 3rd ed., Allyn and Bacon, Inc., New York (1973), p. 954.
10) The saturated 5α-ketone formed in the deuteration of **1** at about 40% conversion, on treatment with methanolic sodium hydroxide, gave 5α-ketone-d_2 as the predominant product. This result suggests that no exchange occurred at the C-6 carbon during the deuteration and excludes the mechanism involving the C-6 hydrogen, e.g., enolization of **1** prior to hydrogenation, which may well explain the stereospecific 5α-ketone formation.

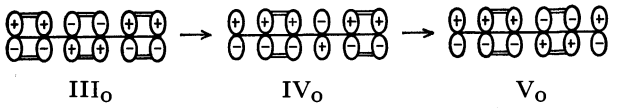
12) **4** was completely hydrogenated to **3a**, compared with only 84% conversion of **1** under the same conditions (unpublished results; see also Ref. 2)

II→I, should proceed also concertedly through the bonding interaction between χ_4 and $\psi_1'^*$: in which χ_4 and χ_3 face the phase in the same direction, and χ_3 and χ_2 in the inverse direction. Orbital χ_1 which becomes vacant in II is always in the same, invariable phase. When the process I→II→I is concerted, it can be represented by the following scheme (Scheme 1).[13,14]

In the following concerted reaction of hexatriene which is considered to comprise a butadienic and an additional ethylenic system,

$$\begin{array}{l} CH_2{=}CH{-}CH{=}CH{-}CH{=}CH_2 \\ \qquad\qquad \text{III} \\ \quad \psi_1 \quad\quad \psi_2 \quad\quad \psi_3 \\ \quad \psi_1^* \quad\quad \psi_2^* \quad\quad \psi_3^* \\ \longrightarrow \overset{+}{C}H_2{-}CH{=}CH{-}\overset{-}{C}H{-}CH{=}CH_2 \\ \qquad\qquad \text{IV} \\ \qquad\quad \psi_1' \quad \chi_4 \quad\quad \psi_3 \\ \chi_1 \quad\quad \psi_1'^* \quad\quad\quad \psi_3^* \\ \longrightarrow \overset{+}{C}H_2{-}CH{=}CH{-}CH{=}CH{-}\overset{-}{C}H_2 \qquad (2) \\ \qquad\qquad \text{V} \\ \qquad\quad \psi_1' \quad\quad \psi_2' \quad\quad \chi_6 \\ \chi_1 \quad\quad \psi_1'^* \quad\quad \psi_2'^* \end{array}$$

the orbital representation of this process can be given as follows (Scheme 2):[15]



Scheme 2.

The first step, III→IV, is the same as that of I→II in Eq. 1, and the second step, IV→V, is equivalent to the reverse process, II→I, in Eq. 1. If these two steps(III→IV and IV→V) are included in one concerted process, *viz.*, the process III→V proceeds concertedly, the phase of χ_6 in V_o should be dependent upon that of χ_1 (or χ_2). Each elementary step in Eqs. 1 and 2 can be considered to be a sort of nucleophilic substitution analogous to S_N2 reaction. Thus, the conversion of III to V may be a sequential nucleophilic substitution process. The phase correlation of AO's in such concerted processes as shown above can be expected to hold also for σ-systems.

In general, from a non-cyclic system (S_α) with n-two-center MO's (σ and/or π, n=2,3,4,⋯) by sequential nucleophilic process, a new non-cyclic system (S_ω) can be obtained which is composed of an unoccupied nonbonding MO (χ_1) and an occupied nonbonding MO (χ_{2n}) in the two terminals, and of new ($n-1$)-two-center MO's between the two nonbonding MO's (*vide infra*). If this system forms a pericyclic system, the unoccupied orbital χ_1 should be situated in the position adjacent to the occupied orbital χ_{2n}. So long as the reaction proceeds concertedly, the phase of χ_{2n} is determind by that of χ_1. When the positive overlapping between χ_1 and χ_{2n} in S_ω is possible, an additional two-center bond is formed by χ_1 and χ_{2n}, making the pericyclic reaction allowable. On the other hand, when the overlapping between χ_1 and χ_{2n} is negative or antibonding, the two-center bond between the two terminals can not be formed, thus the reaction is forbidden.

$$\begin{array}{l} \qquad\qquad \text{Sequential Nucleophilic Process} \\ S_\alpha \longrightarrow S_\omega \\ \psi_1 \ \psi_2 \ \psi_3 \cdots\cdots \psi_n \qquad \psi_1' \ \psi_2' \cdots\cdots \psi'_{n-1} \ \chi_{2n} \\ \psi_1^* \ \psi_2^* \ \psi_3^* \cdots\cdots \psi_n^* \qquad \chi_1 \ \psi_1'^* \ \psi_2'^* \cdots\cdots \psi'_{n-1}{}^* \end{array}$$

χ_1, χ_{2n} in S_ω	Pericyclic Rection
Bonding	Allowable
Antibonding	Forbidden

The phase relationship (bonding or antibonding) between χ_1 and $\chi_{2\omega}$ in S_ω should change according to the number and the relative configuration of the two-center bonds included in the pericyclic system. For example, when II_o and V_o are shown in the cis-bent form, it can easily be predicted that the reaction butadiene→cyclobutene is conrotatory, and that the reaction hexatriene→cyclohexadiene is disrotatory (Fig. 2).

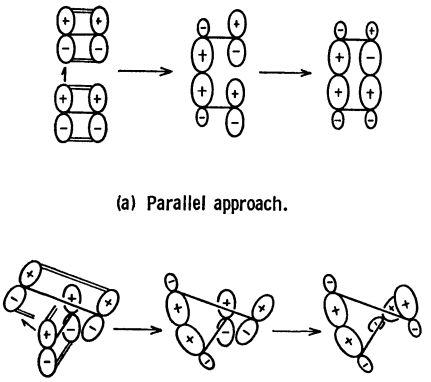


Fig. 1. Mutual cycloaddition of ethylenes.

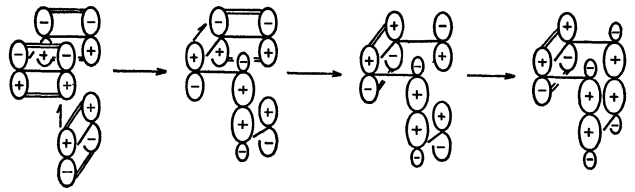
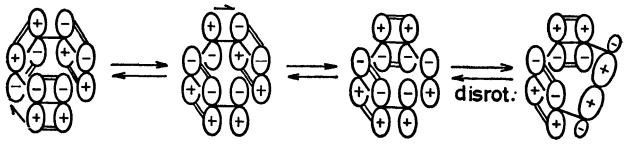
The analysis of reaction based on this argument is well demonstrated by the examples in Fig. 1. The mutual cycloaddition of ethylene in parallel approach gives the antibonding interaction between the terminals in the final step, which indicates that the reaction is forbidden. On the other hand, the bonding interaction between the terminals can be obtained in orthogonal approach, which means that the reaction is allowable. Other examples of allowed reactions are given in Fig. 2.

When the reaction system contains an odd number of AO's as in the case of carbanion or carbonium ion, the following treatment is reasonable.

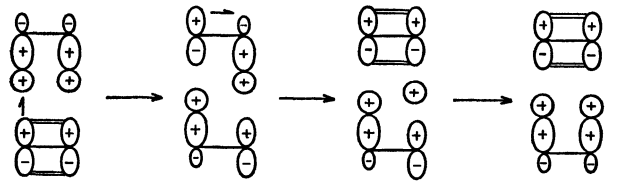
System Involving an Occupied Nonbonding MO. In the following reaction,



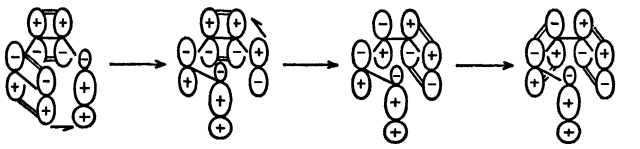
(a) Diels-Alder reaction.



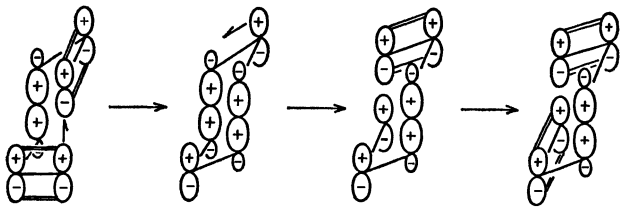
(b) Electrocyclic reaction (⟶ cyclization; ⟵ ring opening).



(c) Group transfer reaction ($CH_2=CH_2+CH_3-CH_3 \rightarrow CH_3-CH_3+CH_2=CH_2$).



(d) Superfacial [1,5] shift of a hydrogen atom.



(e) Cope rearrangement (with chair-type transition state).

Fig. 2. Examples of allowed reaction.

$$\underset{\text{VI}}{\bar{C}H_2-CH=CH-CH=CH_2} \rightarrow \underset{\text{VII}}{CH_2=CH-\bar{C}H-CH=CH_2}$$

χ_0 $\quad$ ϕ_1 $\quad$ ϕ_2 $\quad$ ϕ_0' $\quad$ χ_2 $\quad$ ϕ_2

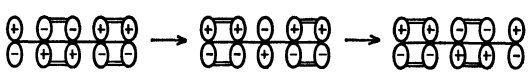
$\quad\quad$ ϕ_1^* $\quad$ ϕ_2^* $\quad\quad$ $\phi_0'^*$ $\quad\quad$ ϕ_2^*

$$\rightarrow \underset{\text{VIII}}{CH_2=CH-CH=CH-\bar{C}H_2} \qquad (3)$$

ϕ_0' $\quad$ ϕ_1' $\quad$ χ_4

$\phi_0'^*$ $\quad$ $\phi_1'^*$

the orbital-array representations of each step are given as follows (Scheme 3):



VI_o $\quad\quad$ VII_o $\quad\quad$ $VIII_o$

Scheme 3.

Since the two ethylenic π-systems and one negative center in VI are regarded as being independent of each other, the phase of AO's between these three systems can be taken arbitrarily. Similarly to Eqs. 1 and 2, reaction VI→VII is initiated through the interaction between χ_0 and ϕ_1^*, two new two-center bonds and an occupied nonbonding center at another terminal being obtained in VIII.

In general, by sequential nucleophilic process, from a noncyclic system (S_α) consisting of an occupied nonbonding MO(χ_0, the lone-pair center) at the beginning terminal and n-two-center MO's($n=1,2,3\cdots\cdots$),[16] a new system (S_ω) can be obtained which is composed of new n-two-center MO's and a new lone-pair center (χ_{2n}) at the end terminal.

$$S_\alpha \xrightarrow{\text{Sequential Nucleophilic Process}} S_\omega$$

χ_0 $\quad$ ϕ_1 $\quad$ ϕ_2 $\quad\cdots\cdots$ ϕ_n $\quad\quad$ ϕ_0' $\quad$ ϕ_1' $\quad\cdots\cdots$ ϕ'_{n-1} $\quad$ χ_{2n}

$\quad\quad$ ϕ_1^* $\quad$ $\phi_2^*\cdots\cdots$ ϕ_n^* $\quad\quad$ $\phi_0'^*$ $\quad$ $\phi_1'^*\cdots\cdots$ ϕ'^*_{n-1}

When this system forms a pericyclic system, the unoccupied orbital $\phi_0'^*(=\chi_0-\chi_1)$ is to be situated in the position adjacent to the occupied orbital χ_{2n}. So long as the reaction proceeds concertedly, the phase of χ_{2n} is determined by that of χ_0. Thus, if the positive overlapping between χ_{2n} and χ_0 in $\phi_0'^*$ is possible, χ_{2n} can interact with $\phi_0'^*$ in a bonding manner; in this case, this pericyclic reaction is allowable.

Alternatively, this type of reaction can be treated in the same way as that of systems with an even number of AO's by regarding χ_0 as a two-center MO with a ghost unoccupied AO. (*Cf. Participation of Lone-pair Orbital*).

System Involving an Unoccupied Nonbonding MO. In the following reaction,

$$\underset{\text{IX}}{CH_2=CH-\overset{+}{C}H-CH=CH_2} \rightarrow \underset{\text{X}}{\overset{+}{C}H_2-CH=CH-CH=CH_2}$$

ϕ_0 $\quad\quad$ ϕ_2 $\quad\quad$ ϕ_1 $\quad$ ϕ_2

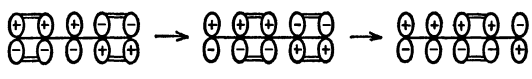
ϕ_0^* $\quad$ χ_2 $\quad$ ϕ_2^* $\quad\quad$ χ_0 $\quad\quad$ ϕ_1^* $\quad$ ϕ_2^*

$$\rightarrow \underset{\text{XI}}{\overset{+}{C}H_2-\overset{+}{C}H-CH=CH-\bar{C}H} \qquad (4)$$

ϕ_1' $\quad$ χ_4

χ_0 $\quad$ χ_1 $\quad\quad$ $\phi_1'^*$

the orbital-array representations of each step can be given as follows (Scheme 4):



IX_o $\quad\quad$ X_o $\quad\quad$ XI_o

Scheme 4.

As in the case of I_o, III_o, and VI_o, the phase of AO's between three systems (two ethylenic π-systems and one nonbonding center) in IX_o can be taken arbitrarily. The phase of the unoccupied nonbonding MO is adjusted to that of ϕ_0 so that the bonding interaction may arise between them in the process $IX_o \rightarrow X_o$; the treatment corresponds to that of each elementary step in Scheme 1—3. The first nucleophilic process

(IX→X) is not of substitution, and the second process (X→XI) is equivalent to I→II in Eq. 1.

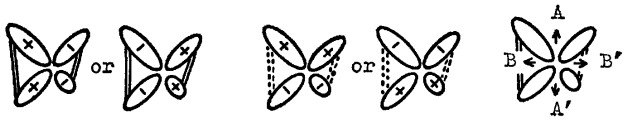
For this type of reaction system, the following general, schematic expression can be given:[16]

$$S_\alpha \xrightarrow{\text{Seq. Nuc. Process}} S_\alpha' \longrightarrow S_\omega$$

$$\psi_0 \quad \psi_2 \cdots \psi_n \qquad \psi_1 \ \psi_2 \cdots \psi_n \qquad \psi_1' \cdots \psi'_{n-1} \ \chi_{2n}$$
$$\psi_{0*} \ \chi_2 \ \psi_2^* \cdots \psi_n^* \quad \chi_0 \ \psi_1^* \ \psi_2^* \cdots \psi_n^* \quad \chi_0 \ \chi_1 \ \psi_1'^* \cdots \psi'^*_{n-1}$$

In the concerted process, the phase of χ_{2n} is determined by that of χ_0(or χ_1) in ψ_0 of $S_\alpha(\psi_0=\chi_0+\chi_1)$. Therefore, when the positive overlapping between χ_0 and χ_{2n} in S_ω is possible, the pericyclic reaction is allowable.[17]

Cheletropic Reactions. Cheletropic reactions are a specific type of pericyclic reaction. As an example, the addition reaction of singlet carbene to ethylene is discussed. The carbene species has two localized MO's; one is occupied sp^2 (σ orbital) and the other unoccupied p(p orbital).[18] In order to avoid introducing a qualified nucleophilic and electrophilic center into the reaction process, these two orbitals are dealt with as their combination in terms of LCMO. Thus, the new bonding and antibonding MO are given as follows:



$\sigma+p \quad -(\sigma+p)$ Bonding MO $\qquad \sigma-p \quad -(\sigma-p)$ Antibonding MO

The bonding MO should be occupied, having its maximum extension in the direction of B; the antibonding MO should be unoccupied, having its maximum extension in the direction of A. Consequently, carbene species should direct side B toward the ethylene π system in its pseudo-nucleophilic(PN) approach to ethylene (*vide infra*), and side A toward the π system in its pseudo-electrophilic(PE) approach according to the HOMO-LUMO maximum overlapping principle.[19] In view of the fact that the extensions B-B' and A-A' can be considered alternatively to be the σ and the p MO of carbene, respectively, the merit of π approach of carbene in addition to olefin[20] can be interpreted easily.

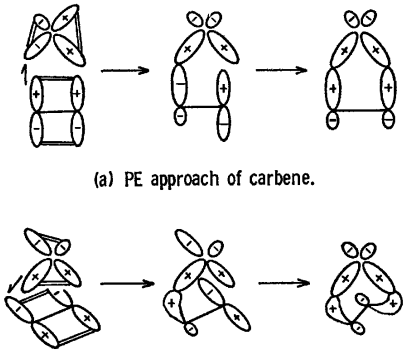


Fig. 3. Addition of carbene to ethylene.

Thus, the addition of singlet carbene to ethylene can be illustrated as in Fig. 3, in which the MO's of carbene can be treated in the same manner as that of olefinic π MO.[21] The process through PE approach of carbene to ethylene is allowed, while the reaction through PN approach is impossible because of steric reasons though the process is formally allowed. By this MO representation, it can be easily understood that carbene functions in an antarafacial manner in PE approach, namely in non-linear cheletropic reaction, and that it acts in a suprafacial fashion in PN approach, namely in linear cheletropic reaction.

Interpretation of Secondary Effects. The secondary conformational effects in concerted cyclo-addition or sigmatropic reactions have been interpreted in terms of the HOMO-LUMO[1,2] or the NHOMO-NLUMO interaction.[2] The present approach can also provide an analogous interpretation for the effects. As an example, the endo selectivity in the Diels-Alder reaction of two butadiene molecules is explained in the following way (Fig. 4). The reaction is represented by the process: from C_6 to C_1, from C_2 to C_3, and from C_4 to C_5(C_6→C_1; C_2→C_3; C_4→C_5, Route I). An alternative process, however, can proceed via [C_2→C_7; C_6→C_1, (Route II)] to afford a four-membered cyclic transition species. In this transition species, C_4 and C_5 are still interactive, so that it changes to the Diels-Alder adduct *via* [C_4→C_5; C_8→C_7; C_2→C_3,

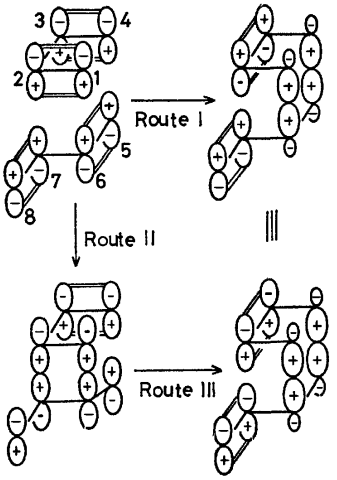

Fig. 4. Diels-Alder reaction of two butadiene molecules

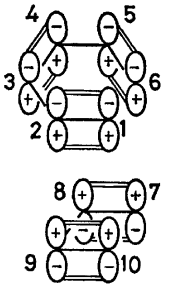

Fig. 5. MO representation of the endo approach of [4+6] cycloaddition between butadiene and hexatriene.

(Route III)]. That is to say, the MO bonding interaction, $C_2 \rightarrow C_7$ and $C_6 \rightarrow C_1$, may decrease the energy of the endo transition state, and promote the formation of cyclohexene ring. In contrast, in a [4+6] cyclo-addition (Fig. 5), an allowed process, $C_2 \rightarrow C_3$; $C_4 \rightarrow C_5$; $C_6 \rightarrow C_7$; $C_8 \rightarrow C_9$; $C_{10} \rightarrow C_1$, can be followed to give the [4+6] cyclo-adduct. However, an alternative process *via* $C_5 \rightarrow C_8$; $C_9 \rightarrow C_2$ is possible to give easily a six-membered cyclic transition species, in which the orbitals of C_1 and C_{10}, and of C_6 and C_7 become antibonding with each other, respectively. Consequently, the endo approach of the reactants may prevent the [4+6] cycloaddition. The preference of chair type transition state in the Cope rearrangement can be interpreted also in the same way.

Participation of Lone-pair Orbital to Pericyclic Systems. In nucleophilic non-cyclic concerted reactions with amines, the lone-pair orbital (n orbital) of nitrogen should function as the HOMO. When a hetero-atom such as nitrogen, oxygen, or halogen is contained in a pericyclic reaction system, its n orbital can also participate, at least formally, as a HOMO in the MO interaction.[22,23]

Isomerization of isoxazoline to *C*-acylaziridine[24] can be analyzed as an allowed [1,3] sigmatropic reaction with inversion at nitrogen. For this reaction, an alternative allowable process can be represented with participation of the nitrogen n orbital (Fig. 6), in which the configuration of nitrogen of the product is identical with that of the former process. By steric requirement, the latter process might be favorable. In this type of process, an n orbital should be regenerated with retention of orbital phase at the hetero-atom for allowed reactions (Fig. 6). By taking up the participation of 3p-n orbital of chlorine, a cyclic concerted scheme can be illustrated formally for S_Ni reaction of alkyl chlorosulfite.

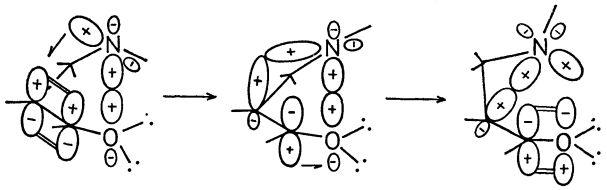

Fig. 6. Isomerization of isoxazoline to acylaziridine with participation of nitrogen lone-pair orbital.

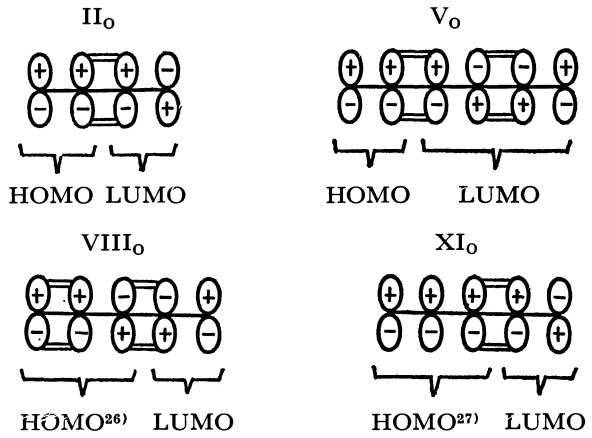
Discussion

Pericyclic reactions in ground states can be followed by the present procedure (Fig. 2). The acutal reactions proceed neither stepwise nor via the so-called nucleophilic substitution scheme. However, according to Fukui, "a stepwise recognition of concerted reactions may be more reasonable than an attempt to understand each concerted multi-center reaction as a simultaneous change."[2] The feasiblity of stepwise recognition of concerted multi-center reactions might be related to the fact that delocalized MO's can be derived from localized MO's in terms of LCMO.[25] If a multi-center cyclic reaction proceeds concertedly, each consituent elementary step should be a concerted process(*vice versa*).

The orbital arrays of II_o, V_o, $VIII_o$, and XI_o are the same as those of the HOMO-LUMO interaction method(Scheme 1—4):



So far as the orbital phase alteration is concerned, the process through nucleophilic substitution scheme represents the delocalized LUMO: for example, in systems with an even number of AO's, the first nucleophilic process induces the localized HOMO to the localized LUMO, and the next and further processes will give the delocalized LUMO through the procedure corresponding to the LCMO method. This relationship can afford a theoretical ground to the present method.

Transformation between canonical forms of a conjugate system in classical molecular formula is to be taken as an intramolecular nucleophilic process. In Hückel systems, the two Kekulé formulas of [4N+2] annulene can be converted into each other by the present procedure, but not those of [4N] annulene; on the other hand, the principle should be the reverse in Möbius systems. This situation can give an alternative indirect reasoning for the present method in view of the aromaticity of transition state of pericyclic reactions in the Hückel-Möbius concept.[3,4]

Although the present method is somewhat roundabout, it can in a unified manner be applied also to the systems with low symmetry and to those in which the delocalized HOMO and LUMO can not easily be represented. This method is inapplicable to the systems with delocalized or three- or multi-center bonds. Since reaction systems are represented with localized MO's, the exact nature of molecules, especially of conjugate systems, can not be expressed. π and σ bonds are not differentiated from each other, and the analysis of reaction is carried out merely qualitatively. This method can not estimate the facility of reaction, but only whether a reaction can proceed concertedly or not.

For reactions in excited states, the present procedure does not afford any prediction, since it is based essentially on nucleophilic substitution process. Formally, however, a modification in which the antibonding representation is adopted for the initial nucleophilic center instead of the bonding one can give selection rules for reactions in excited states. This procedure corresponds to the SOMO-LUMO interaction scheme,[2]

but has no theoretical grounds within the scope of the present consideration based on nucleophilic processes.

Electroorganic Chemistry XVIII[1] Anodic Oxidation of Substituted Cyclopropanes

Tatsuya SHONO and Yoshihiro MATSUMURA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received February 6, 1975)

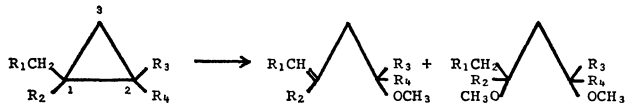
The anodic oxidations of polyalkyl-substituted cyclopropanes (**1**—**3**) and spiro[2.n]alkanes (**4**—**6**) were carried out in methanol. Monomethoxyolefin and dimethoxy compound resulted from the selective cleavage at the most substituted carbon–carbon bond. The decrease in the oxidation potential brought about by the substitution of the one methyl group was observed to be about 0.3 V *vs.* SCE. The analysis of the products and oxidation potentials of the cyclopropanes suggested that the σ-electron transfer from cyclopropane to the anode may be the initiation process and that the stereochemistry at the surface of the solid electrode plays an important role in this anodic oxidation.

The electrochemical oxidation of a cyclopropane ring seems quite interesting because of its olefin-like character. In a previous study,[2] we have reported the first evidence that the carbon–carbon single bond in a cyclopropane ring could be anodically oxidized to yield ring-opened products which may be synthesized by other methods only with difficulty.

In the present study, we wish to report the effect of an alkyl substituent and some specific selectivity on the anodic ring cleavage of cyclopropanes.

Results

Product Study. The anodic oxidations of polyalkyl-subsituted cyclopropanes (**1**—**3**) and spiro[2.n]alkanes (**4**—**6**) were carried out in methanol containing tetraethylammonium *p*-toluenesulfonate (Et_4NOTs) as a supporting electrolyte (Eqs. (1) and (2)). Compounds **1**—**5** gave monomethoxy and dimethoxy products, which resulted from the cleavage of the most highly substituted carbon–carbon bond, although **3a** and **5a** were not isolated because of their further oxidation. Interestingly, spiropentane (**6**) was anodically stable.



1:	$R_1=H$, $R_2=R_3=R_4=CH_3$	**1a**	**1b**
2:	$R_1=R_4=H$, $R_2=R_3=CH_3$	**2a**	**2b**
3:	$R_1=CH_3$, $R_2=CH_2CH_3$, $R_3=R_4=H$	**3a**	**3b**

2a': $R_1=R_4=H$, $R_2=R_3=CH_3$

TABLE 1. PRODUCT YIELDS[a] AND CURRENT EFFICIENCIES OF ANODIC OXIDATIONS OF **1**—**5**

Cyclopropane	Product yields (%)		Current efficiencies (%)
	Monomethoxy	Dimethoxy	
1	**1a** (47)	**1b** (24)	71
2	**2a** (11)	**2b** (10)	21
3	**3a** (—)[b]	**3b** (12)	12
4	**4a** (1)	**4b** (5)	6
5	**5a** (—)[b]	**5b** (26)	26

a) Yields were calculated at the time when 2F/mol of electricity had been passed. b) The corresponding monomethoxy product could not be isolated.

All products were identified by spectroscopic and elemental analysis. Yields and current efficiences are shown in Table 1.

Oxidation Potential and Current–Potential Relationship. In order to evalute the effect of alkyl substituents on the oxidation potentials of cyclopropanes, they were measured in acetonitrile containing tetraethylammonium tetrafluoroborate as a supporting electrolyte. All cyclopropanes gave one oxidation wave, showing the lowering of the oxidation potential in proportion to the increase in the number of alkyl substituent. Table 2 lists the oxidation potentials of cyclopropanes together with those of the corresponding olefins.

The current–potential relationship was measured under the condition of the preparative oxidation of cyclopropane. As the number of alkyl substituents increases, the current–potential curve becomes more cathodic, indicating a lowering of the oxidation potential of the cyclopropane.

Acid-catalyzed Methanolysis of Cyclopropanes. It has been well known[3] that, owing to its olefin-like character, the cyclopropane ring may be able to be cleaved by the attack of an electrophile to yield ring-opened products. It seems interesting to compare

Table 2. Oxidation potentials[a] of cyclopropanes and olefins

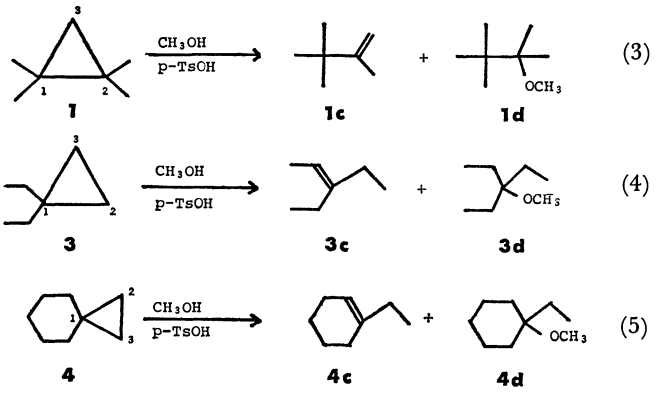
Cyclopropane	+E (V *vs.* SCE)	Olefin	+E (V *vs.* SCE)
(**7**)	>2.5		
(**2**)	2.30		1.96
(**1**)	2.05		1.74
(**4**)	2.38		
(**8**)	2.40		2.26

a) Average of three measurements; solvent, CH_3CN; supporting electrolyte, Et_4NBF_4.

the mode of the anodic ring cleavage of cyclopropane with that observed in the acid-catalyzed methanolysis.

The reflux of a methanolic solution of **1** containing a catalytic amount of *p*-toluenesulfonic acid gave ring-opened products (**1c** and **1d**) as shown in Eq. (3). The similar treatment of compound **3** yielded **3c** and **3d** (Eq. (4)), and compound **4** gave **4c** and **4d** (Eq. (5)).

In contrast to the bond cleavage in the anodic oxidation, the 1,3-bond (compound **1**) or 1,2-bond (compounds **3** and **4**) was cleaved in the acidic methanolysis.

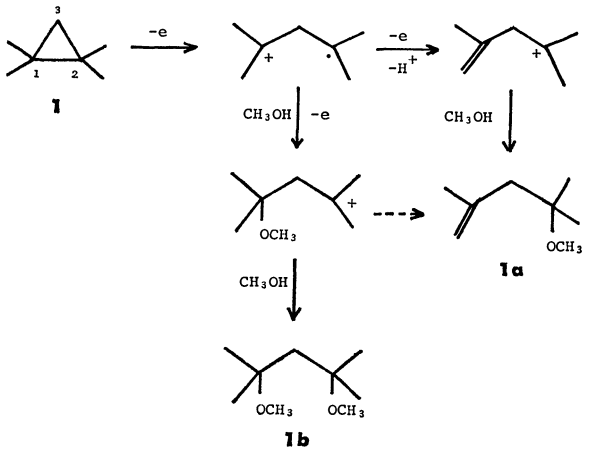


(3) (4) (5)

Discussion

Reaction Mechanism. As was pointed out in the previous study,[2] a direct σ-electron transfer from cyclopropane to the anode may be the initiation process of this anodic oxidation. The oxidation wave and the current–potential relationship support this proposal, which leads to the following reaction pathway (Scheme I):

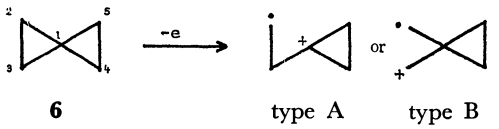
In the anodic electron transfer from the cyclopropane σ-bond, the electron must be ejected from the most strained σ-bond, where the ionization potential would be the lowest. In the cation radical generated from **1**, the free rotation of the bond between C-1 and C-3 may be hindered owing to the steric restriction brought about by the surface of the solid electrode. This stereochemical hindrance may be the reason why the unsaturated ether of type **1a'** was not formed in the oxidation of **1**.



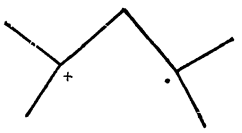
Scheme 1.

On the other hand, the attack of the proton in the acid catalyzed methanolysis occurs on the less hindered side, which is in disagreement with the selectivity of bond cleavage observed in the anodic reaction.

Oxidation Potential. The increase in the oxidation potential was observed in the order of **1**<**2**<**7**; this can be explained from the notion that the substitution of an alkyl group stabilizes the intermediate, whereas it increases the energy of the starting compound owing to the steric strain. The decrease in the oxidation potential brought about by the substitution of one methyl group was about 0.3 V *vs.* SCE (Table 2), and this amount is comparable to that which results from the substitution of an alkyl group into the olefinic system. In view of the strain energy, the oxidation of spiro[2.2]pentane (**6**) was expected to give a relatively high current efficiency. The disagreement of this prediction with the experimental observation may be explained by the instability of the intermediate.



The intermediate of type A is analogous to a cyclopropyl cation, whose instability has been demonstrated by the solvolytic study.[4]



type C

Furthermore, the intermediate of type B may not be stabilized by the interaction with the neighboring cyclopropyl group since the direction of the vacant p-orbital of the cation may be orthogonal to the plane

of the cyclopropane ring if the C_1-C_3 bond is not able to rotate freely at the time when the electron transfer from the C_2–C_3 σ-bond takes place on the surface of the anode. The absence of such free rotation is supported by the fact that **1a** was the only unsaturated ether from the intermediate of type C.

Experimental

Materials. Compounds **1**,[5] **2**,[6] **3**,[7] **4**,[7] and **6**[8] were prepared by the reported methods. Compound **5** was prepared by the Simmons-Smith method[9] from methylenecyclobutane[10] and identified spectroscopically by comparison with an authentic sample[11] (yield 28%).

Preparative Electrolysis of Cyclopropane. General: Into a 100 ml electrolysis cell equipped with a magnetic stirrer and two carbon electrodes were poured a solution of 0.05 mol of cyclopropane and 0.01 mol of Et_4NOTs in 0.50 mol of methanol. The electrolysis was carried out under the constant potential condition until 2F/mol of electricity had been passed. The reaction mixture was poured into water, extracted with three portions of ether, dried on magnesium sulfate, filtered, and concentrated successively. The residue was distilled to give the oxidized products.

1,1,2,2,-Tetramethylcyclopropane (**1**) was electrolyzed at the anode potential of 1.45 V *vs.* SCE and gave 2,4-dimethyl-4-methoxy-1-pentene (**1a**) and 2,4-dimethyl-2,4-dimethoxypentane (**1b**) in 47.2 and 24.2% yields respectively after 2F/mol of electricity was passed. **1a**: IR 3070 (olefin), 2820 (ether), 1640 (olefin), 1075 cm^{-1} (ether); NMR (CCl_4) τ 5.4 (d, 2, $C\underline{H}_2$=), 6.85 (s, 3, $OC\underline{H}_3$), 7.85 (s, 2, $C\underline{H}_2$), 8.20 (s, 3, $CC\underline{H}_3$), 8.87 (s, 6, $C\underline{H}_3$); (Found: C, 74.95; H, 12.57%. Calcd for $C_8H_{16}O$: C, 74.94; H, 12.58%). **1b**: IR 2820, 1075 cm^{-1} (ether); NMR (CCl_4) τ 6.90 (s, 6, $OC\underline{H}_3$), 8.37 (s, 2, $C\underline{H}_2$), 8.80 (s, 12, $C\underline{H}_3$); (Found:, C, 67.04; H, 12.70%. Calcd for $C_9H_{20}O_2$: C, 67.45; H, 12.57%)

1,1,2-Trimethylcyclopropane (**2**) was electrolyzed at the anode potential of 1.6 V *vs.* SCE and yielded 2-methyl-4-methoxy-1-pentene (**2a**) (contaminated with a small amount of unknown products) and 2-methyl-2,4-dimethoxypentane (**2b**) in 10.7 and 9.9% yields respectively. **2b** was spectroscopically identified with the sample which was prepared by the methoxylation of hexylene glycol. **2a**: IR 3080, 1640 cm^{-1} (olefin); NMR (CCl_4) τ 5.30 (broad s, 2, $C\underline{H}_2$=), 6.85 (s, 3, $OC\underline{H}_3$), 6.6—7.0 (m, 1, $C\underline{H}$), 7.8 (d, 2, =C–$C\underline{H}_2$), 8.3 (s, 3, $C\underline{H}_3$), 8.9 (d, 3, $C\underline{H}_3$), mass spectrum parent peak, *m/e* 114. (Found: C, 73.79; H, 12.54. Calcd for $C_7H_{14}O$: C, 73.63; H, 12.36%). **2b**: IR 2840, 1090 cm^{-1} (ether); NMR (CCl_4) τ 6.6 (m, 1, $C\underline{H}$), 6.80 (s, 3, $OC\underline{H}_3$), 6.90 (s, 3, $OC\underline{H}_3$), 8.90 (s, 6, $C\underline{H}_3$), 8.95 (d, 3, $C\underline{H}_3$). (Found: C, 65.43; H, 12.68%. Calcd for $C_8H_{18}O_2$: C, 65.74; H, 12.41%).

1,1-Diethylcyclopropane (**3**) yielded 3-ethyl-1,3-dimethoxypentane (**3b**) in a 11.7% yield. **3b**: NMR (CCl_4) τ 6.65 (q, 2, $C\underline{H}_2$), 6.70 (s, 3, $OC\underline{H}_3$), 6.90 (s, 3, $OC\underline{H}_3$), 8.2—8.8 (m, 6, $C\underline{H}_2$), 9.20 (t, 6, $C\underline{H}_3$).

Spiro[2.5]octane (**4**) was electrolyzed at the anode potential of 2.30 V *vs.* SCE and yielded 1-(1-cyclohexenyl)-2-methoxyethane (**4a**) and 1-(1-methoxycyclohexyl)-2-methoxyethane (**4b**) in 1.1 and 4.8% yields respectively. 1,1-Dimethoxymethylcyclohexane was not detected; **4a**: IR 3050, 1630 (olefin), 2845, 1120 cm^{-1} (ether); NMR (CCl_4) τ 4.63 (broad s, 1, C=C$\underline{H}$), 6.70 (t, 2, $C\underline{H}_2O$), 6.75 (s, 3, $OC\underline{H}_3$), 7.7—8.7 (m, 10, $C\underline{H}_3$). mass spectrum parent peak, *m/e* 140. **4b**: IR 2840, 1115 cm^{-1} (ether); NMR (CCl_4) τ 6.7 (t, 2, $C\underline{H}_2$), 6.75 (s, 3, $OC\underline{H}_3$), 6.95 (s, 3, $OC\underline{H}_3$), 8.0—9.0 (m, 12, $C\underline{H}_2$). (Found: C, 71.58; H, 11.76%. Calcd for $C_{10}H_{20}O_0$: C, 77.09; H, 11.50%).

Spiro[2.3]hexane (**5**) was electrolyzed at the anode potential of 2.25 V *vs.* SCE and yielded 1-(1-methoxycyclobutyl)-2-methoxyethane (**5b**) in a 25% yield. **5b**: IR 2840, 1120 cm^{-1} (ether); NMR (CCl_4) τ 6.70 (t, 2, $C\underline{H}_2O$), 6.70 (s, 3, $OC\underline{H}_3$), 6.93 (s, 3, $OC\underline{H}_3$), 7.80—8.60 (m, 8, $C\underline{H}_2$), (Found: C, 66.33; H, 11.06%. Calcd for $C_8H_{16}O_2$: C, 66.63; H, 11.18%).

Spiro[2.2]pentane (**6**) yielded no detectable products.

Acid Catalyzed Methanolysis of Cyclopropane. General: A solution of 0.05 mol of cyclopropane in 0.50 mol of methanol containing 0.01 mol of *p*-toluenesulfonic acid was refluxed for one or two days.

After cooling, the solution was poured into water and extracted with ether. The ethereal layer was shaken with aqueous carbonate and water and dried on magnesium sulfate. After the magnesium sulfate was filtered and the ether was removed, the residue was distilled to give products.

1,1,2,2-Tetramethylcyclopropane (**1**) gave 2,3,3-trimethyl-1-butene (**1c**) and 2,3,3-trimethyl-2-methoxybutane (**1d**) in 6 and 60% yields respectively.

1c was identified spectroscopically by comparison with an authentic sample.[12] **1d**: IR 2840, 1080 cm^{-1} (ether); NMR (CCl_4) τ 6.85 (s, 3, $OC\underline{H}_3$), 8.90 (s, 6, $C\underline{H}_3$), 9.10 (s, 9, $C\underline{H}_3$). (Found: C, 73.98; H, 13.69%. Calcd for $C_8H_{18}O$: C, 73.78; H, 13.92%).

1,1-Diethylcyclopropane (**3**) yielded 3-ethyl-2-pentene (**3c**) and 3-ethyl-3-methoxypentane (**3d**) in 57 and 10% yields respectively. **3c**: IR 3020 cm^{-1} (shoulder, olefin); NMR (CCl_4) τ 4.85 (q, 1, C=C$\underline{H}$), 7.70—8.20 (m, 4, $C\underline{H}_2$), 8.4 (d, 3, $C\underline{H}_3$), 9.0 (double triplet, 6 $C\underline{H}_3$). Compound **3c** was also identified spectroscopically by comparison with an authentic sample.[13] **3d**: NMR (CCl_4) τ 6.97 (s, 3, $OC\underline{H}_3$), 8.40—8.80 (m, 6, $C\underline{H}_2$), 9.25 (t, 9, $C\underline{H}_3$).

Spiro[2.5]octane (**4**) yielded 1-ethylcyclohexane (**4c**) and 1-ethyl-1-methoxycyclohexane (**4d**) in 42 and 3% yields respectively. **4c**: IR 1630 cm^{-1} (olefin); NMR (CCl_4) τ 4.63 (broad s, 1, =C$\underline{H}$), 7.70—8.60 (m, 10, $C\underline{H}_2$), 9.00 (t, 3, $C\underline{H}_3$). **4c** was also identified spectroscopically by comparison with an authentic sample.[14] **4d**: IR 2840, 1080 cm^{-1} (ether); NMR (CCl_4) τ 6.97 (s, 3, $OC\underline{H}_3$), 8.10—8.80 (m, 12, $C\underline{H}_2$), 9.23 (t, 3, $C\underline{H}_3$); mass spectrum parent peak, *m/e* 142.

Oxidation Potential. The data were obtained at room temperature in dry acetonitril containing 0.1 M tetraethylammonium tetrafluoroborate[15] in a three-electrode polarography system (Yanako P8DP).

Oxidative Cleavage of Aromatic Methoxy Compounds with Photo-excited Aromatic Nitro Compounds[1-2]

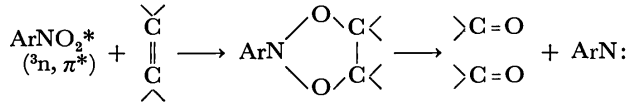
Isao SAITO, Masaaki TAKAMI, and Teruo MATSUURA

Department of Synthetic Chemistry, Faculty of Engineering, Kyoto University, Kyoto 606

(Received February 10, 1975)

Photochemical addition of the aromatic nitro group with aromatic methoxy compounds leading to the cleavage of the aromatic ring was studied. The oxidative cleavage occurs selectively at 1,2-bond with respect to a methoxy group of methoxybenzenes and methoxynaphthalenes. Aromatic nitro compounds having the lowest π,π^* triplet are more effective to the oxidative ring cleavage of the methoxynaphthalenes than those having the lowest n,π^* triplet. A mechanism involving charge-transfer complex is proposed. The scope and limitation on the use of these photochemical reactions are discussed.

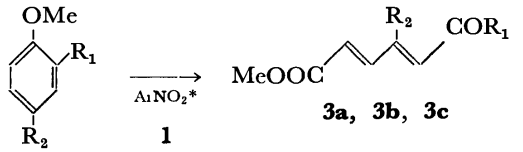
The photochemical addition of the aromatic nitro group to alkenes[3-4] and alkynes[3-5] has received considerable attention. Recent work by de Mayo and co-workers[4a] has shown that aromatic nitro compounds having the lowest $^3n,\pi^*$ state undergo photocycloaddition with alkenes to give 1,3,2-dioxazolidines which decompose readily at room temperature to yield two carbonyl fragments.



From our interest in the oxidative cleavage of aromatic nuclei in relation to the biological oxidation of aromatic compounds,[6] we investigated the photochemical reaction of aromatic nitro compounds with aromatic methoxy compounds. We now report that aromatic nitro compounds having either $^3n,\pi^*$ or $^3\pi,\pi^*$ state could react photochemically with aromatic methoxy compounds to yield ultimately 1,2-cleavage products, providing a useful method for the selective 1,2-cleavage of an aromatic ring. The scope and limitation on the use of this type of photochemical reactions are also discussed.

Results and Discussion

Photoreaction of Nitrobenzenes with Methoxybenzenes. We first examined the photochemical reaction of *m*-chloronitrobenzene (**1**) and nitrobenzene, known to have the lowest $^3n,\pi^*$ state,[3] in the presence of methoxybenzenes. A solution of **1** and a methoxybenzene in benzene was irradiated with a high pressure mercury lamp through a Pyrex glass under nitrogen atmosphere at room temperature. Products were separated from polymeric tars by column chromatography or distillation under reduced pressure, and their structures were assigned on the basis of spectral and chemical evidences. In a typical run, when a solution of **1** (0.086 M) and veratorole (**2a**) (0.516 M) in benzene was irradiated, dimethyl *trans,trans*-muconate (**3a**) was obtained in 8% yield (basid on reacted **1**) along with *m*-chloroaniline (**4**) (4%) and polymeric tars. Irradiation of a solution of **1** with 1,4-dimethoxybenzene (**2b**) gave the corresponding 1,2-cleavage product **3b** (14%) and **4** (7%). Similarly, irradiation of **1** in anisole (**2c**) gave **3c** (6%), phenol (5%) and 3,3'-dichloroazobenzene (**5**) (trace) (Table 1).

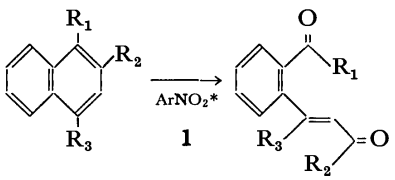


2a: R_1=OMe, R_2=H
2b: R_1=H, R_2=OMe
2c: $R_1=R_2$=H

3a, 3b, 3c + $ArNH_2$ + ArN=NAr
4 **5**
Ar=*m*-Cl-Ph-

The photoreaction of methoxybenzenes with nitrobenzene was found to proceed much less efficiently, but the products were essentially the same in both cases (Table 1). Although the yields of ring cleavage products (**3a**, **3b**, **3c**) are relatively low, it should be noted that the oxidative cleavage occurs selectively at 1,2-bond with respect to a methoxyl group.

Photoreaction of m-Chloronitrobenzene with Methoxynaphthalenes. Methoxynaphthalenes react much faster with photo-excited *m*-chloronitrobenzene to give the cleavage products in good yield than methoxybenzenes (Table 1). As an example, irradiation of 1,4-dimethoxynaphthalene (**6a**) (0.545×10^{-2} M) and **1** (0.673×10^{-2} M) in benzene gave the corresponding 1,2-cleavage product **7a** (70%), **4** (5%), **5** (13%) and *m*-chloroformanilide (**8**) (7%). The results of other methoxynaphthalenes (**6b**, **6c**) are given in Table 1.



6a: $R_1=R_3$=OMe, R_2=H
6b: R_1=OMe, $R_2=R_3$=H
6c: $R_1=R_3$=H, R_2=OMe

7a, 7b, 7c + $ArNH_2$ + ArN=NAr + ArNHCHO
4 **5** **8**
Ar=*m*-Cl-Ph-

Although the fate of the reacted **1** in these reactions is complicated and appears to depend upon the starting methoxy aromatics, it is very probable that the azobenzene **5** and formanilide **8** result from the corresponding nitrene or its precursor, since the photoreaction of **1** without methoxy compounds gave neither **5** nor **8**, but only **4**.

Photoreaction of 1-Nitronaphthalene with Methoxynaph-

Table 1. Photoreaction of aromatic nitro compounds ($ArNO_2$) with aromatic methoxy compounds (ArOMe) in benzene

	ArOMe	$ArNO_2$	Products (yield)[b]			
1	**2a**	**1**	**3a** (8%)	**4** (4%)		
2	**2a**	Nitrobenzene[a]	**3a** (2%)	azobenzene (trace)		
3	**2b**	**1**	**3b** (14%)	**4** (7%)		
4	**2b**	Nitrobenzene[a]	**3b** (5%)	azobenzene (trace)

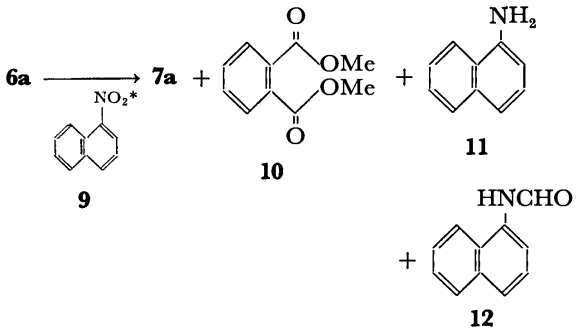
a) Used as solvent. b) Yields were based on reacted starting materials.

thalenes. It has been reported that 1-nitronaphthalene (**9**) or 2-nitrobiphenyl, which has the lowest $^3\pi,\pi^*$ state,[7-8] does not undergo cycloaddition with alkenes after prolonged irradiation.[4a] We have observed that photo-excited **9** is much more effective to the oxidative ring cleavage of the methoxynaphthalenes. When a solution of **9** (4.68×10^{-2} M) and **6a** (4.25×10^{-2} M) in benzene was irradiated, the reaction proceeded rapidly and **7a** (58%) was obtained along with dimethyl phthalate (**10**) (20%), 1-naphthylamine (**11**) (14%) and 1-formaminonaphthalene (**12**) (43%). Yields of **7a** (or **10**) and **11** (or **12**) were based on the reacted **6a** and **9**, respectively. The results are shown in Table 1. The photoreaction of **9** differs from that of **1** in the following respect; (1) The reaction of **9** proceeds much faster than that of **1**. (2) Considerable amounts of **10**, which results most likely from the 1,4-addition of **9** to **6a**, is obtained in the reaction of **9** with **6a**.



Mechanism of Reaction. Since 1,4-dimethoxynaphthalene (**6a**) showed the highest reactivity toward the photo-excited **9** and both **7a** and **10** were obtained in good yield, we examined the photoreaction of **9** with **6a** in some detail.

Solvent Effect

The rate of disappearance of **6a** is highly sensitive to solvent and temperature. At room temperature the photoreaction proceeds at an appreciable rate in benzene, ether, *n*-hexane and acetone, but much more slowly in more polar solvents such as methanol and acetonitrile (Table 2). When the reaction was carried out in ether solution at −78 °C, the rate of the reaction increased considerably as compared to that at room temperature, suggesting that an initially formed adduct collapses thermally to the starting compounds **6a** and **9**.

Table 2. Solvent effect on the rate of disappearance of **6a**

Solvent	Relative rate of disappearance of **6a**[a]
n-Hexane	0.8
Benzene	1.0
Ether	1.4
Acetone	0.2
Methanol	0.02
Acetonitrile	0.02

a) Solutions of **6a** (4.00×10^{-3} M) and **9** (5.80×10^{-3} M) in each solvent were irradiated simultaneously in a merry-go-round apparatus. The relative rate was determined by glc analysis at *ca.* 20% conversion of **6a**.

We also observed that the product ratio **10**/**7a** is sensitive to temperature, solvent, and degree of conversions of **6a**, the product ratio not being reproducible in some cases. However, the addition of a trace organic acid such as benzoic acid or acetic acid to the reaction system considerably changes the ratio. The presence of these acids completely inhibited the formation of **10**, and the 1,2-cleavage product **7a** was obtained almost exclusively (Table 3).

Table 3. Effects of acids on the product ratio **10**/**7a** in the photoreaction of **6a** with **9** in benzene

Product ratio	Acetic acid[a]		Benzoic acid[b]	
	None	2.33×10^{-2} M	None	6.85×10^{-3} M
10/**7a**[c]	0.48	0.03	0.63	0.02

a) [**6a**]=[**9**]=4.89×10^{-3} M. b) [**6a**]=[**9**]=5.55×10^{-3} M. c) The ratio was determined by glc analysis at *ca.* 50% conversion.

Excited State and Multiplicity

Questions concerning the mechanism of the reaction include those on the excited state and multiplicity of the nitro aromatics. In order to ascertain whether the lowest triplet state of **9** is involved in the reaction, we carried out quenching experiments. Quenching effects of piperylene and oxygen on the formation of **7a** and **10** in the reaction of **6a** with **9** are shown in Table 4.

Table 4. Quenching effects of piperylene and oxygen on the rate of formation of **7a** and **10**[a]

Quencher (equiv. mol)	Relative rate of formation	
	7a	**10**
0	1.0	1.0
100	0.55	0.52
300	0.34	0.37
O_2 (saturated)	0.65	0.68

a) [**6a**]=[**9**]=2.56×10^{-3} M.

The formation of **7a** and **10** was inhibited considerably by added piperylene. Considering the relatively high efficiency of the intersystem crossing of **9**,[9] it is very likely that the lowest triplet state (π,π^*) of **9** is involved in the reaction.

In order to elucidate the excited state of the nitro compound involved in the reaction, we examined the photochemical reaction of **6a** with various nitro compounds, whose lowest excited triplet states are well characterized, using a merry-go-round apparatus with light through Pyrex glass. Relative reactivity of the nitro compounds with respect to nitrobenzene as a standard (1.0) is given in Table 5. Although the relative reactivity indicates only the efficiency of the reaction for a preparative mean and does not mean the absolute quantum efficiency of the reaction, it is interesting to note that both an $^3n,\pi^*$ and a $^3\pi,\pi^*$ state of the nitro compounds could participate in the photoaddition and that the $^3\pi,\pi^*$ state seems to be more reactive than the $^3n,\pi^*$ state. Solvent effects on the reaction of **1** ($^3n,\pi^*$) and **9** ($^3n,\pi^*$) with **6a** are essentially the same, suggesting that the same mechanism operates in both cases (Table 6).

The photoreaction of **9** with **6a** could proceed at a moderate rate under irradiation with visible light at 435 nm or even at 545 nm. At this wavelength (545 nm) neither **9** nor **6a** absorbs the light. The results suggest a mechanism involving a charge-transfer complex. A new absorption band located at *ca.* 430 nm was observed in the electronic spectrum of a solution of **9** (0.05 M) and **6a** (0.05 M) in benzene (Fig. 1). However, no spectroscopic evidence for the formation of such ground state complex between **9** and **6b** or **6c** has been observed.

As a further indication for the charge-transfer complex mechanism, solutions of **9** in the presence of various aromatic methoxy compounds were irradiated simultaneously, and the relative rates of disappearance of the methoxy compounds were determined. The relative rates were obtained with respect to 1,4-dimethoxybenzene (**2a**) as a standard (1.0). The results are shown in Table 7. If a charge-transfer like transition state is involved in the reaction, then increase of electron availability in the methoxy aromatic system should be expected to increase the rate of reaction. The aromatic methoxy compounds with more powerful electron-donating properties are more reactive to photo-excited **9**. The result can best be explained by a donor-acceptor mechanism involving a charge-transfer complex, although an alternative mechanism involving an electrophillic attack of a short-lived triplet

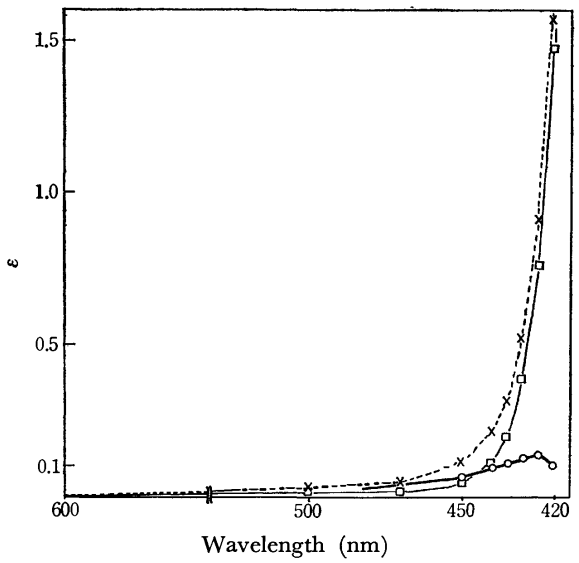


Fig. 1. The UV spectra of **9** and **6a** in benzene.
—□— **9** (0.05 M), --×-- **9** (0.05 M)+**6a** (0.05 M), —○— calculated absorption spectrum of a complex (**9**···**6a**).
In this region (600—420 nm) there is no absorption of **6a**.

Table 5. Photoreactivity of aromatic nitro compounds ($ArNO_2$) toward **6a**[a]

Lowest excited triplet state	n,π^*				π,π^*		
$ArNO_2$ (Ar=)	*m*-Cl-Ph-[7], **1**	*m*-CN-Ph[7],	Ph-[7],	*p*-MeO-Ph-[10],	1-Napht-[8], **9**	2-Napht-,[8]	3-Cl-1-Napht-[8]
Relative rate of disappearance of **6a**	0.8	1.0	1.0	1.3	7.7	10.8	6.1

a) Solution of an equimolar amount of a nitro compound ($ArNO_2$) and **6a** (5.0×10^{-3} M) in benzene was irradiated in a merry-go-round apparatus. The relative rate of disappearance of **6a** with respect to that of nitrobenzene (1.0) was determined by glc analysis.

Table 6. Solvent effects on the photoreactions of 1 and 9 with 6a in the presence of acid[a]

Solvent	$ArNO_2$ (Ar=)	
	m-Cl-Ph-(**1**) (n, π^*)	1-Napht-(**9**) (π, π^*)
Benzene	1.00	1.00
Methanol	0.16	0.02
Acetonitrile	0.25	0.02

a) Solutions containing $ArNO_2$ (2.78×10^{-3} M), **6a** (2.78×10^{-3} M) and benzoic acid (5.55×10^{-3} M) were irradiated simultaneously. The rate of disappearance of **6a** was determined by glc analysis.

Table 7. Relative reactivity of aromatic methoxy compounds (ArOMe) toward photo-excited 9

ArOMe	Rel. reactivity
1,4-Dimethoxybenzene (**2b**)	1.0
1,2,4,5-Tetramethoxybenzene	1.5
2-Methoxynaphthalene (**6c**)	2.6
1-Methoxynaphthalene (**6b**)	7.3
1,4-Dimethoxynaphalene (**6a**)	20.6

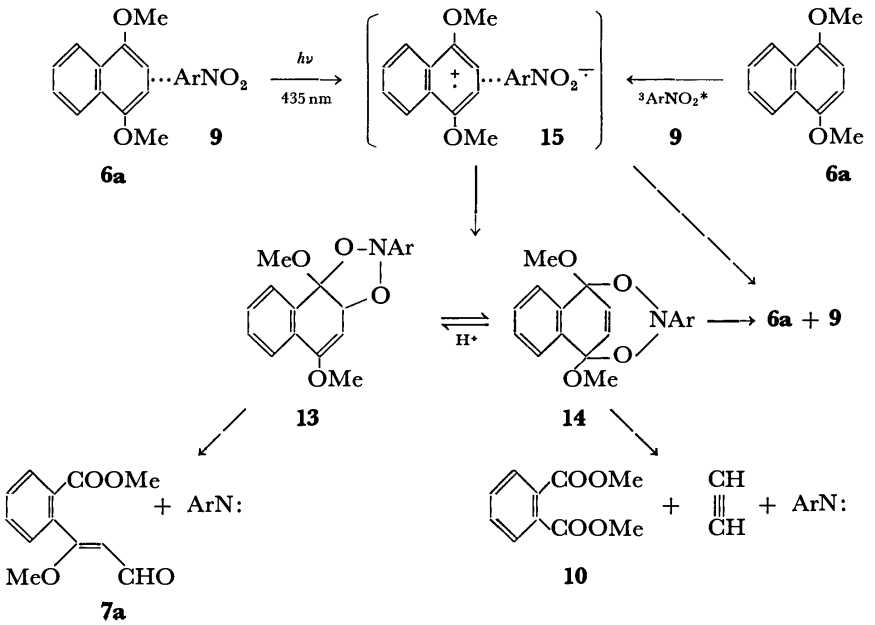
of **9** on the methoxy compound[4a] cannot be ruled out rigorously.

Reaction Sequence

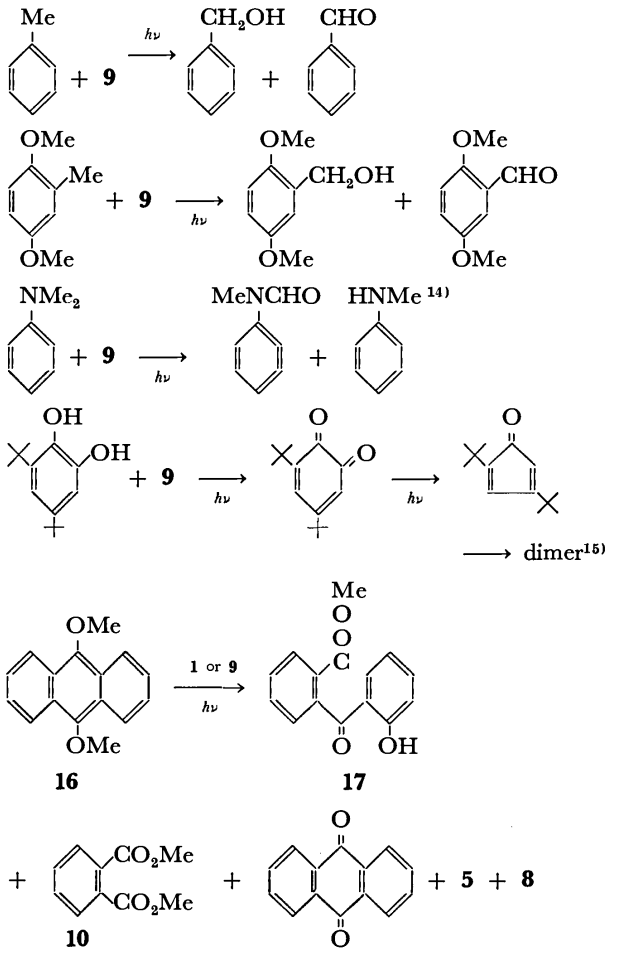
The ultimate formation of two carbonyl fragments **7a** and **10** can be interpreted by a mechanism involving a thermal and prototropic equilibrium mixture of 1,2- (**13**) and 1,4-cycloadduct (**14**), formed *via* a triplet excited complex **15**. The excited complex **15**, a key intermediate in the mechanism, might be formed either by the excitation of the ground-state complex (435 nm) or by the interaction between $^3\pi, \pi^*$ state and ground state **6a**. The complex **15** thus formed could collapse to the cycloadducts **13** and **14** or decay to ground state **9** and **6a**. It may be considered that both of the processes have solvent dependence, the latter process becoming predominant in polar solvents such as methanol.

The 1,2-cycloadduct (**13**), a 1,3,2-dioxazolidine derivative, would thermally decompose to the corresponding carbonyl product **7a** with the elimination of an aryl nitrene. The 1,4-cycloadduct (**14**) could decompose photochemically[11] or thermally to yield **10**, acetylene and an aryl nitrene. In an attempt to isolate such cycloadducts, we carried out the photoreaction at low temperature. However, such intermediates were too unstable to be detected even at −78 °C. While the fate of the aryl nitrene is not fully elucidated, it could account satisfactorily for the formation of the corresponding azo[12] and amino[13] compounds. In order to confirm whether the aryl nitrene could be a precursor for the formamino compound (**8** or **12**), we examined the photochemical reaction of *m*-chlorophenyl azide with **6a** in benzene. However, the reaction only gave **5** (10%) and **4** (trace), no trace of the corresponding formanilide **8** being detected. This suggests that the formamino compound is formed by an unknown side reaction which still remains to be clarified (Scheme 1).

Scope and Limitation. We also examined the photoreaction of aromatic nitro compounds with several other aromatic compounds. These were methyl-, dimethylamino-[14] and hydroxy-substituted benzenes. The reactions of these compounds with photo-excited nitro compounds resulted in the hydrogen abstraction from these groups, no product resulting from the oxidative ring cleavage being observed (Scheme 2). However, 9,10-dimethoxyanthracene (**16**) was found to react smoothly with the photo-excited **1** to give similar types of products **17** (36%), **10** (14%), 9,10-anthraquinone (22%), **5** (5%) and **8** (26%).



Scheme 1



Scheme 2

Experimental

IR spectra were recorded on an IRA-1 spectrometer, NMR spectra on a Varian T-60 with TMS as an internal standard, and UV spectra on a Shimadzu UV-200. Light source was a high pressure mercury lamp (Ushio 400 W or 100 W) through Pyrex glass. Yields were based on reacted starting materials.

Photolysis of m-*Choronitrobenzene (**1**) with Veratrol (**2a**).* A solution of **1** (4.074 g, 25.9 mmol) and **2a** (21.381 g, 155 mmol) in 300 ml benzene was irradiated with a 400 W high pressure mercury lamp (Pyrex filter) under nitrogen atmosphere at room temperature for 35 hr. The resulting red brown solution was concentrated and the residue was distilled *in vacuo* to give the unreacted starting materials (19.71 g of **2a**, 3.05 g of **1**). Preparative glc (Silicon DC 550, 170 °C) of the residue gave *m*-chloroaniline (**4**) (0.041 g, 4%) and colorless crystals (mp 155—156 °C, 0.101 g, 8%) which was identical with an authentic sample of dimethyl *trans,trans*-muconate (**3a**).

*Photolysis of Veratrol (**2a**) in Nitrobenzene.* A solution of **2a** (1.00 g, 7.25 mmol) in 20 ml nitrobenzene was irradiated externally for 30 hr. After removal of the solvent, the residue was chromatographed on silica gel (52 g). Elution with PE-benzene (1 : 1) gave azobenzene (0.002 g). Elution with benzene gave unreacted **2a** (0.496 g). Elution with $CHCl_3$ and subsequent preparative glc (Silicon DC 550, 190 °C) yielded **3a** (0.020 g, 2%).

Photolysis of m-*Chloronitrobenzene (**1**) with 1,4-Dimethoxybenzene (**2b**).* A solution of **1** (4.0 g, 25.4 mmol) and **2b** (8.0 g, 58.0 mmol) in 300 ml benzene was irradiated for 24 hr under the same conditions. Unreacted starting materials (3.07 g of **1**, 6.412 g of **2b**) were removed by distillation *in vacuo*. Preparative glc (Silicon DC 550, 170 °C) of the residue gave **4** (0.086 g, 7%) and **3b** (0.22 g, 14%), mp 85—86 °C; IR (Nujol): 1725, 1660 cm^{-1}; UV (EtOH): 289 nm (ε 16000), 218 nm (ε 13800): NMR ($CDCl_3$); τ −0.10 (1H, d, J=6.0 Hz), 2.10 (1H, d, J=15 Hz), 3.40 (1H, d, J=15 Hz), 4.37 (1H, d, J=6 Hz), 6.17 (3H, s), 6.20 (3H, s); MS *m/e* 170 (M^+).

Found: C, 56.77; H, 6.08%. Calcd for $C_8H_{10}O_4$: C, 56.46; H, 5.90%.

*Photolysis of 1,4-Dimethoxybenzene (**2b**) in Nitrobenzene.* A solution of **2b** (4.03 g, 28.2 mmol) in nitrobenzene (82 g) was irradiated for 55 hr under the same conditions. After removal of the solvent, the residue (0.996 g) was chromatographed on a silica gel column (25 g). Elution with PE-benzene (1 : 1) gave azobenzene (0.005 g). Elution with benzene yielded unreacted **2b** (0.042 g). Further elution with $CHCl_3$ gave a black solid which on recrystallization from benzene-*n*-hexane gave **3b** (0.052 g, 5%). The remaining polymeric tars (0.81 g) was eluted with acetone.

Photolysis of m-*Chloronitrobenzene (**1**) in Anisole (**2c**).* A solution of **1** (1.497 g, 9.5 mmol) in 200 ml anisole was irradiated for 31 hr. After removal of the solvent, the residue was chromatographed on silica gel (100 g). Elution with PE-benzene (1 : 1) afforded red crystals of 3,3′-dichloroazobenzene (**5**) (mp 107 °C, 0.005 g). Further elution with the same solvent yielded unreacted **1** (0.695 g). Elution with benzene gave phenol (0.125 g, 5%). Elution with $CHCl_3$ gave a black mass which on crystallization from benzene-*n*-hexane yielded **3c** (0.147 g, 6%), mp 82 °C; IR (Nujol): 1730, 1675 cm^{-1}; NMR ($CDCl_3$): τ 0.33 (1H, d, J=8 Hz), 2.57 (1H, d d, J=12, J'=15 Hz), 2.84 (1H, d d, J=12, J'=15 Hz), 3.59 (1H, d d, J=8, J'=15 Hz), 3.71 (1H, d, J=8 Hz), 6.17 (3H, s). This compound was identical with an authentic sample.[16]

Photolysis of m-*Chloronitrobenzene (**1**) with 1,4-Dimethoxynaphthalene (**6a**).* A solution of **1** (0.53 g, 3.36 mmol) and **6a** (0.512 g, 2.72 mmol) in 500 ml benzene was irradiated for 22 hr. After removal of the solvent, the residue was chromatographed on silica gel (35 g). Elution with PE-benzene (1 : 1) gave **5** (0.031 g, 12.5%). Further elution with the same solvent gave a mixture of unreacted starting materials **1** (0.22 g) and **6a** (0.116 g). Eluiton with benzene yielded **4** (0.013 g, 5.2%). Elution with $CHCl_3$ and subsequent preparative glc (Silicon DC 550, 190 °C) gave *m*-chloroformanilide (**8**) (0.020 g, 6.6%) and **7a** (0.302 g, 69.5%), mp 43 °C; IR (Nujol): 1730, 1650, 1600 cm^{-1}; NMR ($CDCl_3$): τ 0.88 (1H, d, J=8 Hz), 2.00 (1H, m), 3.47 (2H, m), 3.63 (1H, m), 4.45 (1H, d, J=8 Hz), 6.17 (3H, s), 6.18 (3H, s); MS *m/e* 191 (M^+−CHO).

Found: C, 65.78; H, 5.36%. Calcd for $C_{12}H_{12}O_4$: C, 65.44; H, 5.49%.

Photolysis of m-*Chloronitrobenzene (**1**) with 1-Methoxynaphthalene (**6b**).* A solution of **1** (1.104 g, 7.02 mmol) and **6b** (1.014 g, 6.42 mmol) in 500 ml benzene was irradiated for 36 hr. After removal of the solvent, the residue was chromatographed on silica gel (40 g). Elution with PE-benzene (1 : 1) gave **5** (0.03 g, 12.6%) and unreacted starting materials **1** (0.797 g) and **6b** (0.761 g). Elution with benzene gave **4** (0.045 g, 18.1%). Elution with $CHCl_3$-benzene (1 : 1) yielded a black mass which on recrystallization from benzene-*n*-hexane gave colorless crystals of **7b** (0.123 g, 33.2%), mp 47 °C; IR (nujol): 1725, 1680 cm^{-1}; NMR ($CDCl_3$): τ 0.30 (1H, d, J=8 Hz), 1.62 (H, d, J=15 Hz), 2.04 (1H, d, J=7 Hz), 2.36 (1H, dd, J=7, J'=2 Hz), 2.49 (1H, m), 2.60 (1H, m), 3.52 (1H, dd, J=15, J'=8

Hz), 6.09 (3H, s); MS *m/e* 161 (M^+-CHO).

Found: C, 69.81; H, 5.41%. Calcd for $C_{11}H_{10}O_3$: C, 69.46; H, 5.30%. Elution with $CHCl_3$ gave **8** (0.046 g, 15%).

Photolysis of m-*Chloronitrobenzene (**1**) with 2-Methoxynaphthalene (**6c**).* A solution of **1** (0.750 g, 4.75 mmol) and **6c** (0.660 g, 4.18 mmol) in 500 ml benzene was irradiated for 47 hr. After removal of the solvent, the residue was chromatographed on silica gel (40 g). Elution with PE-benzene (1 : 1) gave **5** (0.005 g, 3%). Further elution with the same solvent gave a mixture of starting materials **1** (0.537 g) and **6c** (0.566 g). Elution with benzene yielded **4** (0.02 g, 12%). Elution with $CHCl_3$-benzene (1 : 1) and subsequent preparative glc (Silicon DC 550, 170 °C) yielded **7c** (0.035 g, 13.6%), mp 82 °C: IR (Nujol): 1730, 1605 cm^{-1}; NMR ($CDCl_3$): τ −0.27 (1H, s), 1.49 (1H, d, J=16 Hz), 2.14 (1H, m), 2.40 (3H, m), 3.36 (1H, d, J=16 Hz), 6.18 (3H, s); MS *m/e* 161 (M^+-CHO). This compound was prepared independently by esterification of the corresponding acid.[17] Elution with $CHCl_3$ and subsequent glc separation (Silicon DC 550, 170 °C) yielded **8** (0.042 g, 10%).

*Photolysis of 1-Nitronaphthalene (**9**) with 1,4-Dimethoxynaphthalene (**6a**).* A solution of **9** (0.405 g, 2.34 mmol) and **6a** (0.400 g, 2.12 mmol) in 50 ml benzene was irradiated with a 100 W high pressure mercury lamp for 12 hr. After removal of the solvent, the residue was chromatographed on silica gel (26 g). Elution with PE-benzene (1 : 1) gave a mixture of unreacted starting materials **6a** (0.059 g) and **9** (0.071 g). Benzene eluted 1-aminonaphthalene (**11**) (0.39 g, 14%) and dimethyl phthalate (**10**) (0.074 g, 20%). Elution with $CHCl_3$ and subsequent glc separation (Silicon DC 550, 200 °C) yielded **7a** (0.247 g, 58%) and 1-formaminonaphthalene (**12**) (0.141 g, 43%).

*Photolysis of 1-Nitronaphthalene (**9**) with 1-Methoxynaphthalene (**6b**).* A solution of **9** (0.552 g, 3.19 mmol) and **6b** (0.481 g, 3.04 mmol) in 500 ml benzene was irradiated for 13 hr. After removal of the solvent, the residue was chromatographed on silica gel (30 g). **6b** (0.104 g), **9** (0.163 g), **11** (0.044 g, 16%), **7b** (0.172 g, 60%), **12** (0.114 g. 25%) and phthalic anhydride (0.030 g, 14%) were obtained (Table 1).

*Photolysis of 1-Nitronaphthalene (**9**) with 2-Methoxynaphthalene (**6c**).* A solution of **9** (0.414 g, 2.39 mmol) and **6c** (0.475 g, 3.0 mmol) in 400 ml benzene was irradiated for 33 hr. Products were separated by column chromatography (silica gel, 30 g). **6c** (0.369 g), **9** (0.151 g), **7c** (0.036 g, 28%), **12** (0.015 g, 4%) and **11** (trace) were obtained (Table 1).

*Effects of Acids on the Product Ratio **10**/**7a**. Acetic acid*: A solution of **6a** (19.2 mg) and **9** (15.1 mg) in 18 ml benzene was divided into two parts, one of which contained 25 mg of acetic acid. These two solutions were irradiated simultaneously in a merry-go-round apparatus for 30 min. The product ratio **10**/**7a** was determined by glc analysis (Table 3). *Benzoic acid*: A solution of **6a** (22 mg) and **9** (17.3 mg) in 18 ml benzene was divided into two parts, one of which contained 15 mg of benzoic acid. The solutions were irradiated as descrived above. The result is shown in Table 3.

Quenching Experiments. Solutions containing **6a** (2.56×10^{-3} M), **9** (2.56×10^{-3} M) and varying amounts of piperylene in benzene was irradiated in a merry-go-round apparatus. The relative rates of formation of **7a** and **10** were determined by glc analysis (Table 4).

*Photolysis of 1-Nitronaphthalene (**9**) in Toluene.* A solution of **9** (0.080 g) in toluene (20 ml) was irradiated externally for 8 hr. After removal of the solvent, the residue was analyzed by glc and NMR. The results indicates that it contains benzaldehyde and benzyl alcohol (1 : 4). The products were separated by preparative glc and identified by IR.

*Photolysis of 1-Nitronaphthalene (**9**) with 2,5-Dimethoxytoluene.* A solution of 2,5-dimethoxytoluene (0.322 g, 2.12 mmol) and **9** (0.44 g, 2.54 mmol) in 600 ml benzene was irradiated for 31 hr. After removal of the solvent, the residue was analyzed by glc and tlc. Glc of the residue showed two peaks corresponding to 2,5-dimethoxybenzyl alcohol and 2,5-dimethoxybenzaldehyde (6 : 1). The products were identified by IR.

*Photolysis of 1-Nitronaphthalene (**9**) with* N,N-*Dimethylaniline.* A solution of *N,N*-dimethylaniline (0.140 g, 1.16 mmol) and **9** (0.200 g, 1.16 mmol) in 50 ml benzene was irradiated for 6 hr. The resulting yellow solution was concentrated and the residue was chromatographed on silica gel (11 g). Elution with PE-benzene (1 : 1) gave unreacted **9** (0.016 g). Further elution with the same solvent and subsequent glc separation yielded *N*-methylaniline (0.010 g, 8%), *N*-methylformanilide (0.053 g, 31%), and 1-aminonaphthalene (0.033 g, 37%). Elution with $CHCl_3$ gave formanilide (0.040 g, 23%).

*Photolysis of 1-Nitronaphthalene (**9**) with 3,5-di-*t*-Butylcatechol.* A solution of 3,5-di-*t*-butylcatechol (0.130 g, 0.59 mmol) and **9** (0.102 g, 0.59 mmol) in 70 ml benzene was irradiated for 25 hr. The resulting red brown solution was concentrated. Preparative glc of the residue yielded 2,4-di-*t*-butylcyclopentadienone dimer (0.070 g, 60%), which was identified by comparison of its IR spectrum with that of an authentic sample.[15]

*Photolysis of 9,10-Dimethoxyanthracene (**16**) with* m-*Chloronitrobenzene (**1**).* A solution of **16** (0.204 g. 0.86 mmol) and **1** (0.430 g, 2.73 mmol) in 250 ml benzene was irradiated for 39 hr. After removal of the solvent, the residue was chromatographed on silica gel (20 g). Elution with PE-benzene (1 : 1) gave **5** (0.005 g, 5%). Further elution gave a mixture of starting materials **16** (0.041 g) and **1** (0.311 g). Elution with benzene and subsequent preparative tlc yielded anthraquinone (0.035 g, 22%) and **17**[18] (0.70 g, 36%), which were identified by comparison of their IR spectra with those of authentic samples. Elution with $CHCl_3$-benzene (4 : 1) gave **10** (0.020 g, 14%). Elution with $CHCl_3$ yielded **8** (0.031 g, 26%).

(Received February 14, 1975)

The photoamination of sodium 1-amino-4-bromoanthraquinone-2-sulfonate (I) by ammonia or alkylamines in acrated 4 : 1 2-propanol–water was investigated. No effect on the reaction was observed by the addition of Rose Bengal as the addition of the triplet quenchers. The reciprocal of the quantum yield was proportional to the reciprocals of both the partial pressure of oxygen and the concentration of the amine. The peroxide was produced as the photoamination proceeded, and the simultaneous photodecomposition took place in a constant ratio to the photoamination. This reaction scheme for the photoamination of (I) was proposed: the exciplex was formed by the excited (I) (^{1}CT) and the ground-state oxygen, followed by the nucleophilic attack of the amine.

While many detailed studies have been made of the photochemical behavior of anthraquinone derivatives, especially the photoreduction by a hydrogen abstraction reaction in their excited $n\pi^*$ triplet states, few examples of the photosubstitution reaction of anthraquinones have been known.[1,2] However, recently many reports have been written on the photochlorination, the photoamination, and the photohydroxylation of anthraquinone derivatives.[3–15] Richards and his co-workers proposed an interesting reaction scheme for the photohydroxylation of 1-methoxyanthraquinone in which the reaction product was formed by the attack of a hydroxyl ion on the photochemically generated semiquinone radical anion. We also have found that the bromine atom of sodium 1-amino-4-bromoanthraquinone-2-sulfonate (I) is replaced by ammonia or alkylamines under the irradiation of visible light.[16] In a previous paper we reported that: 1) the presence of the oxygen molecule is essential for the photoamination of (I); 2) the effect of the addition of the oxidizer suggests that the dissolved oxygen does not act as a smiple oxidizing agent, but plays a more complicated role in the photoamination; 3) any reaction scheme including the photoreduction of (I) can be excluded; 4) the reaction is induced by the absorption of the light corresponding to the first absorption band of (I), and 5) the solvent effect suggests the presence of a polar intermediate in the reaction.[17] On taking account of the role of oxygen in the photoamination of (I), the following several reaction schemes are possible.

Scheme A: The oxygen molecule participates in the photoamination as a singlet oxygen.

Scheme B: The photoamination of (I) proceeds through some interaction between the excited (I) and the ground-state oxygen as follows.

a) The oxygen enhances the intersystem crossing between the lowest excited singlet and triplet states of (I). The latter state is assumed to be active in the photoamination

b) The photoamination proceeds through the exciplex between the excited (I) and the ground-state oxygen, such as:

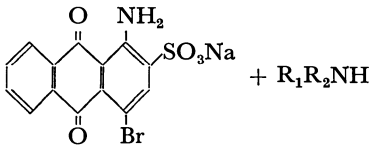
$$AQ^* + O_2 \rightarrow [AQ^{\delta+} \cdots\cdots O_2^{\delta-}]$$

$$[AQ^{\delta+} \cdots\cdots O_2^{\delta-}] \rightarrow AQ + O_2$$

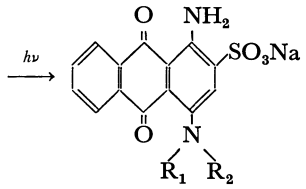
$$[AQ^{\delta+} \cdots\cdots O_2^{\delta-}] \xrightarrow{\text{Amine}} \text{Amination}$$

where AQ* denotes the excited (I).

In the present paper we will report the results obtained by photochemical studies of the photoamination of (I) and propose that the best reaction scheme is Scheme B-b), including the exciplex formation between (I) in its excited singlet state and the ground-state oxygen.



(I)



(II)

Experimental

The sodium 1-amino-4-bromoanthraquinone-2-sulfonate (I) and 2-propanol were purified as has been reported previously.[17] Shimadzu UV-200 spectrophotometer was used for the measurement of the visible and UV spectra. The quantum yield of the photoamination of (I) was determined by the use of a potassium ferrioxalate chemical actinometer according to the method recommended by Hatchard and Parker.[18] A quantitative analysis of the peroxide produced in the reaction system was carried out by the colorimetric iodide method.[19] The reaction mixture was irradiated by meas of a 500 W xenone lamp (USHIO UXL-500DXO) or a 100 W high-pressure mercury lamp (Eikosha) through the following filter system: a Toshiba interference filter KL-47 and a glass filter VY-45 were used for the monochromatic light (λ=468 nm) irradiation, soda glass for the irradiation of λ>300 nm, and a Toshiba glass filter VO-57 for the irradiation for λ>550 nm.

Results and Discussion

Effect of the Oxygen. If the singlet oxygen participates in the reaction of the photoamination of (I), a promotive effect can be expected upon the addition of Rose Bengal as a singlet oxygen sensitizer. Solutions of (I) (1.000×10^{-4} mol/l) and ammonia

Table 1. Effect of the addition of Rose Bengal on the photoamination of (I) by ammonia

[Rose Bengal] (mol/l)	Yield of the aminated product (%)[a]
0	31.0
5×10^{-6}	21.5

a) 15 min irradiation of $\lambda>300$ nm by Xe 500 W lamp.

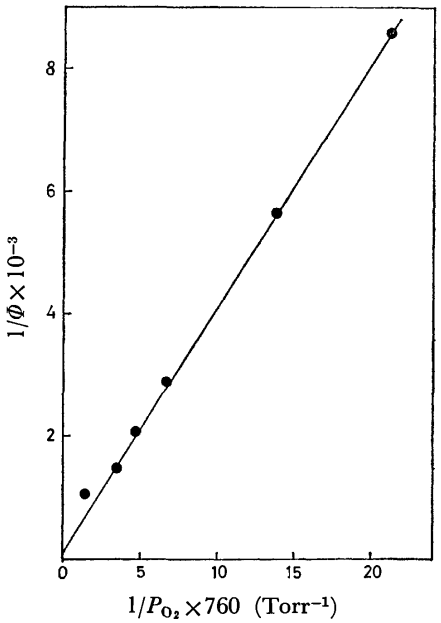


Fig. 1. Effect of the partial pressure of the oxygen on the quantum yield Φ of the photoamination of (I). [I]$\sim1.00\times10^{-4}$ mol/l, [NH_3]$\sim5.00\times10^{-2}$ mol/l in 4 : 1 2-propanol-water, irradiation of $\lambda=468$ nm.

(5.00×10^{-2} mol/l) in aerated 4 : 1 2-propanol–water with and without Rose Bengal (5.00×10^{-6} mol/l) were irradiated by the light of $\lambda>300$ nm or $\lambda>550$ nm. In the case of the irradiation of $\lambda>300$ nm, which excites both (I) and Rose Bengal, no promotive effect was observed upon the addition of Rose Bengal. The retardative results shown in Table 1 can be attributed to the inner-filter effect of Rose Bengal. Moreover, no amination was observed upon the irradiation of $\lambda>550$ nm, which excites only Rose Bengal. These results probably exclude the reaction scheme including the singlet-oxygen formation. Consequently, the other reaction scheme, including the interaction between the excited (I) and the ground-state oxygen, is probable. As is shown in Fig. 1, a plot of the reciprocal of the quantum yield of the photoamination of (I) *vs.* the reciprocal of the partial pressure of the oxygen in the reaction cell gave a good straight line. This strongly suggests that the photoamination proceeds through the collision process between the oxygen molecule and a transient intermediate such as the excited (I).

Formation of the Peroxide. The addition of acetic acid and a 20% aqueous solution of potassium iodide to the irradiated reaction mixture of (I) (1.00×10^{-4} mol/l) and ammonia (5.00×10^{-2} mol/l) in aerated 2-propanol–water increased the absorption intensity

Table 2. Peroxide formation during the photoamination

([I]$\sim1.00\times10^{-4}$ mol/l in 4 : 1 aerated 2-propanol-water)

Irradiation time[a] (min)	NH_3 (mol/l)	Yield of the aminated product (mol/l)	Peroxide in the reaction system (mol/l)
0	5.00×10^{-2}	0	0
7	5.00×10^{-2}	10.6×10^{-6}	2.34×10^{-6}
13	5.00×10^{-2}	29.5	7.8
30	5.00×10^{-2}	48.3	10.6
20	0	0	0

a) Irradiation of $\lambda>300$ nm by Xe 500 W lamp.

Table 3. Peroxide formation in the case of various amines

Amine	NH_3	CH_3NH_2	$C_2H_5NH_2$	n-$C_4H_9NH_2$
[Peroxide]$\times10^6$ (mol/l)	10.6	132	138	166
Conversion of I (%)	48.3	43.6	43.5	43.0

at 357 nm. The enhancement of the absorption intensity at 357 nm, which is characteristic of the triiodide ion, I_3^-, shows the formation of peroxide. Hence, the amount of peroxide produced in the reaction system was estimated by means of the difference in the absorption intensity at 357 nm between the irradiated and the unirradiated solutions, because the absorption intensity of the unirradiated reaction mixture is unchanged by the addition of acetic acid and a potassium iodide aqueous solution.[20] As is shown in Table 2, the peroxide was produced as the photoamination of (I) proceeded. When ammonia was absent, no photoamination could occur and the peroxide was not produced at all. These results indicate that the peroxide is formed in the course of the photoamination of (I). When alkylamines were used in place of ammonia, the peroxide was also produced in the same manner. The amounts of the peroxide produced in the reaction system in the case of various amines at nearly the same conversion of (I) are compared in Table 3. If a formation of the exciplex such as [$AQ^{\delta+}\cdots O_2^{\delta-}$] is assumed in the photoamination, it seems reasonable that the super oxide ion O_2^- and, consequently, the peroxide are produced as the reaction proceeds.

Effect of the Triplet Quencher. In order to clarify the multiplicity of the reactive excited state in the photoamination, the effect of the triplet quenchers on the reaction was studied. The solution of (I) (1.00×10^{-4} mol/l) and ammonia (5.00×10^{-2} mol/l) in aerated 4 : 1 2-propanol–water with or without a triplet quencher (*ca.* 10^{-2}—10^{-4} mol/l) such as naphthalene (E_T=60.9 kcal/mol), anthracene (E_T=42.0 kcal/mol), or naphthacene (E_T=29.3 kcal/mol), was irradiated by the monochromatic light of $\lambda=468$ nm which excites only (I). In no case was any quenching effect observed. Since it has been reported that anthraquinones have their $n\pi^*$ triplet states in *ca.* 62—3 kcal/mol and 1-aminoanthraquinone has

TABLE 4. THE VALUES OF THE RATIO OF THE INTERCEPT TO THE GRADIENT IN THE PLOT OF $1/\Phi$ *vs.* 1/[amine] ([I]$\sim 1.00\times10^{-4}$ mol/l in aerated 4 : 1 2-propanol-water, irradiation of $\lambda=468$ nm by Xe 500 W lamp)

Amine	CH_3NH_2	$C_2H_5NH_2$	$C_6H_5CH_2NH_2$	NH_3	n-$C_4H_9NH_2$	CH_2-$(CH_2)_4$-NH	$(n$-$C_4H_9)_2NH$
pK_a	10.62	10.63	9.34	9.21	10.43	11.22	11.25
Intercept / Gradient ($mol^{-1}\cdot l$)	89	72	75	68	51	43	42

its intramolecular CT triplet state between 47.1 kcal/mol and 42.1 kcal/mol[21], the above fact indicates that the excited singlet state of (I) is the active one in the photoamination. As has previously been reported, the amination is induced by the absorption of the light corresponding to the first absorption band, which inherently has an intramolecular CT nature. Thus, it may be concluded that the photoaminatuin of (I) proceeds through the lowest excited singlet CT state of (I) and that Scheme B-a), in which the lowest excited triplet state is the active one, can also be excluded.

Effect of the Concentration of the Amine. The effect of the concentration of the amine on the quantum yield of the photoamination was studied. A representative, good linear plot of the reciprocal of the concentration of ammonia against the reciprocal of the quantum yield is shown in Fig. 2. A similar relationship was also found in every alkylamine, such as methylamine, ethylamine, *n*-butylamine, benzylamine, di-*n*-butylamine, and piperidine. These results strongly suggest the presence of a collisional process between the amine and a transient intermediate in the course of the photoamination. The values of the intercept divided by the gradient in the plot of $1/\Phi$ *vs.* 1/[amine] and the value of pK_a of each amine are compared in Table 4.

Simultaneous Photodecomposition. As has been reported previously, the photoreaction of (I) with ammonia in an aerated 4 : 1 2-propanol–water mixture by the irradiation of the visible light gave only one colored product (II).[17] However, as is shown in Table 5, the conversion (%) of (I) was not equal to the yield (%) of (II) and the ratio of the yield to the conversion had an almost constant value of 0.62 during the course of the photoreaction,—that is, about 40% of the conversion of (I) was the yield of the other compound, which has no absorption band in the visible region. From the paper-chromatogram of the concentrated reaction mixture, a pale yellow, unknown compound was indeed isolated; it has no absorption band in the region of $\lambda>400$ nm. The pH measurement of the reaction system ([I]$\sim 1.00\times10^{-4}$ mol/l, [NH_3]$\sim 5.00\times10^{-2}$ mol/l in 4 : 1 2-propanol–water) indicated that the amount of OH^- did not exceed more than 1×10^{-4} mol/l. When the amine was absent, (I) and the reaction product (II) alone did not decompose at all upon the irradiation of visible light and only a slight photodecomposition occurred in the presence of OH^- (1×10^{-4} mol/l). Consequently, it may be concluded that the photoamination proceeds competitively with the photodecomposition of (I). Moreover, the fact that the ratio of the yield to the conversion has a constant value during the course of the photoamination strongly suggests that the photoamination and the simultaneous photodecomposition proceed through a common intermediate in a certain ratio. Similar phenomena

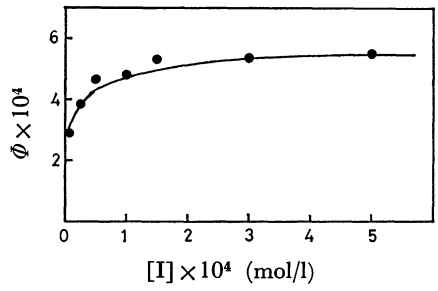

Fig. 4. Effect of the concentration of (I) on the quantum yield Φ of the photoamination of (I). [NH_3]~5.00×10^{-2} mol/l in aerated 4 : 1 2-propanol-water, irradiation of $\lambda=468$ nm.

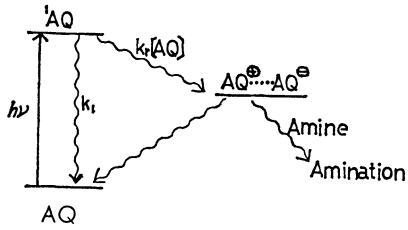
were also observed in other amines; the various ratios of the yield to the conversion in the amines are compared in Table 6.

Effect of the Intensity of the Incident Light. As is shown in Fig. 3, the quantum yield was constant, independent of the intensity of the incident light. This clearly indicates that the photoamination of (I) requires only one photon and that any reaction scheme which requires two photon is invalid.

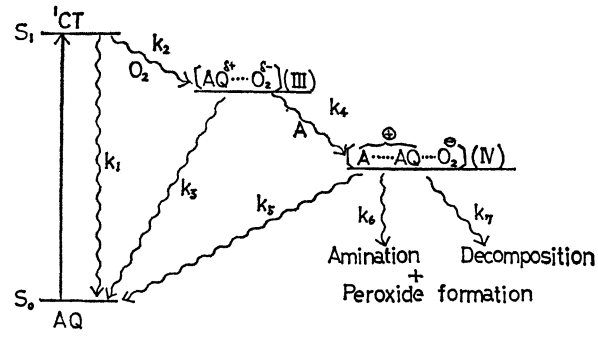
Effect of the Concentration of (I). Figure 4 shows that the quantum yield increased gradually with the increase in the concentration of (I). This suggests that the second molecule of (I) participates in the photoamination of (I). A linear relationship between $1/\Phi$ and $1/[I]$ was approximately obtained; the ratio of the intercept to the gradient in the plot was estimated to be about 10^5 mol$^{-1}\cdot$l. If the photoamination of (I) proceeds through the D-D scheme[22], which has been reported in the photofading of the xanthene dyes as Scheme C:



Scheme C

where k_1 denotes the deactivation rate constant of the excited (I) and k_r, the rate constant of the reaction between the excited (I) and the second (I), k_r/k_1 can be estimated as 10^5 mol$^{-1}\cdot$l. As k_r is smaller than the diffusion-controlled rate constant (10^{10} mol$^{-1}\cdot$l s^{-1}), k_1 should be smaller than 10^5 s^{-1}; that is, the excited (I) should have rather long lifetime of $\tau\gtrsim$ 0.01 ms. However, the actual lifetime of the excited (I) (^{1}CT) is much shorter than 0.01 ms; hence, the D-D scheme can also be excluded.

Reaction Mechanism of the Photoamination. The experimental results presented above exclude the reaction schemes of both A) and B-a), which was stated in the Introduction, and also Scheme C. Eventually, then, the following reaction scheme, B-b), for the mechanism of the photoamination of (I) including the CT interaction between (I) in its excited singlet state and the ground-state oxygen, comes to be the most probable one:



Reaction Scheme B-b)

In the above scheme, AQ and A denote (I) and the amine respectively. (I) in its lowest excited singlet CT state interacts with the ground-state oxygen to form the exciplex (III) (k_2). The exciplex (III) deactivates into (I) and the oxygen in the ground state (k_3) or is attacked by the amine to form the intermediate (IV) (k_4), in which a complete one-electron transfer from (I) to the oxygen molecule can occur. The deactivation (k_5), the amination (k_6), and the decomposition (k_7) take place from the intermediate (IV) at a constant ratio, along with the production of the superoxide ion, O_2^-, and the consequent formation of the peroxide. Hence, by applying the steady-state approximation for the respective intermediates, the quantum yield, Φ, of the photoamination of (I) is expressed as:

$$\Phi = C\cdot\left(\frac{k_2[O_2]}{k_1+k_2[O_2]}\right)\left(\frac{k_4[A]}{k_3+k_4[A]}\right)\left(\frac{k_6}{k_5+k_6+k_7}\right) \quad (1)$$

and the reciprocal of Φ is:

$$1/\Phi = 1/C\cdot\left(1+\frac{k_1}{k_2[O_2]}\right)\left(1+\frac{k_3}{k_4[A]}\right)\left(\frac{k_5+k_6+k_7}{k_6}\right) \quad (2)$$

where k_i denotes the rate constant of each process shown in the scheme and where C denotes the efficiency of the production of the aminated product (II) from the intermediate (IV). Linear relationships between $1/\Phi$ and both $1/[O_2]$ and 1/[amine] are found in Eq. (2). If Eq. (2) is rewritten as Eq. (2′), it is obvious that the efficiency of the formation of the exciplex,

$k_2[O_2]/(k_1+k_2[O_2])$, can be given by the product of the quantum yield, Φ, and the intercept (f) in the linear plot of $1/\Phi$ against $1/[O_2]$:

$$1/\Phi = f\cdot\left(1+\frac{k_1}{k_2[O_2]}\right) \quad (2')$$

When ammonia (5.00×10^{-2} mol/l) was used in aerated 4 : 1 2-propanol–water, the quantum yield of the photoamination Φ was 4.8×10^{-4} and the value of the intercept in Fig. 1 was 102. Consequently, the efficiency of the exciplex (III) formation in the aerated 4 : 1 2-propanol–water mixture should be 4.9×10^{-2}; that is, the small values of the quantum yield of the photoamination of (I) are mainly ascribable to the low efficiency of the exciplex (III) formation.

Equation (2) also shows that the ratio of the intercept to the gradient in the plot of $1/\Phi$ *vs.* 1/[amine] is equal to k_4/k_3. As k_3 is the rate constant of the deactivation process of the exciplex (III) and can reasonably be assumed to be independent of the variation in the amine, the values of k_4/k_3 compared in Table 4 are proportional to the rate constant of the reaction process between the exciplex (III) and the amine. The values of k_4/k_3 of the primary amines were roughly in the order of their basicities, but the secondary amines have smaller values of k_4/k_3 than those of the primary amines. Therefore, it seems that the order of the reactivity of each amine can be explained by the basicity and steric factors and it seems reasonable that a nucleophilic attack by the amine on the exciplex (III) takes place.

The amount of the peroxide produced in the case of the alkylamines is more than ten times larger than that in the case of ammonia (Table 3). One possible explanation for this result is as follows. In the case of ammonia used as a nucleophile, the super oxide ion, O_2^-, or the peroxide may be formed in the processes giving the amination and the decomposition products from an intermediate (IV). On the other hand, in the case of alkylamines used as a nucleophile the super oxide ion, O_2^-, or the peroxide may also be formed in the deactivation process of the intermediate (IV) by an electron transfer from the alkylamine to the oxygen, since alkylamines have much lower ionization potentials than does ammonia (NH_3: I_p=10.154 eV, CH_3NH_2 : I_p=8.97 eV, $C_2H_5NH_2$: I_p=8.86 eV, and n-$C_4H_9NH_2$: I_p=8.71 eV respectively).

The fate of the superoxide ion, O_2^-, produced in the course of the reaction is considered to be as follows: hydrogen peroxide is produced by the dismutation of $HO_2\cdot$, and the hydroperoxide is also produced as:

$$O_2^- + H^+ \rightleftharpoons HO_2\cdot \begin{cases} \nearrow\ 1/2\ H_2O_2 + 1/2\ O_2 \\ \xrightarrow[\text{Amine}]{}\ \text{Hydroperoxide} \end{cases}$$

The super oxide ion, O_2^-, may react with the amine to give the corresponding nitric oxide:[23]

$$R_1R_2NH + O_2^- \longrightarrow R_1R_2NO + OH^-.$$

Moreover, the super oxide ion, O_2^-, and $HO_2\cdot$ may participate in the decomposition process of (I) (k_7) in an oxidative manner. On the whole, the simultaneous formation of the peroxide with the photoamination can be reasonably explained, but a quantitative explanation is difficult at present.

It seems that the second molecule of (I) participates in the process after the formation of the intermediate (IV), though the role of the second molecule of (I) is not clear. The quantitative explanation of the peroxide formation and the role of the second molecule of (I) will lead to a complete elucidation of the mechanism after the formation of the intermediate (IV).

Chemical Structure and Some Properties of Roseoflavin

Sabu KASAI, Retsu MIURA, and Kunio MATSUI

Division of Biology, Research Institute for Atomic Energy, Osaka City University, Sumiyoshi-ku, Osaka 558

(Received February 22, 1975)

Roseoflavin (I) is identified as 7-methyl-8-dimethylamino-10-(1'-D-ribityl)-isoalloxazine (IX) by comparing I with four diastereoisomers of 7-methyl-8-dimethylamino-10-D-*n*-pentitylisoalloxazine, which were synthesized from 2-dimethylamino-4-amino-toluene, D-pentoses, and violuric acid. The coincidence of chemical and physical properties—elemental analysis, UV-visible absorption spectrum, melting point, optical rotation, R_f value in thin layer chromatography, and NMR spectrum—of free and acetylated I with those of the free and acetylated IX, respectively, verified the identity. Some of the properties of I and acetylated I (pK_a, oxidation-reduction, absorption spectra, and extinction coefficients of various ionic species, and photosensitivity) are also described.

Recently many derivatives of riboflavin have been found to be consitituents of coenzymes. In most cases, 8-CH_3 of riboflavin is modified, for example, to >N-CH_2-,[1] -S-CH-,[2,3] or 8-CH_3 is substituted with an HO-group.[4] Otani *et al.*[5] isolated an antibacterial red pigment, roseoflavin (I), from a culture medium of a *Streptomyces* strain No. 768, and it was revealed that in I, 8-CH_3 of riboflavin is substituted with a $(CH_3)_2N$-group. In this report we describe the details of the determination of the chemical structure and some properties of I.

Results and Discussion

Properties of I. I forms dark reddish-brown fine needles, which are slightly soluble in water producing a grenadine red solution. The UV-visible absorption spectrum in water, shown in Fig. 1 (curve 1), is analogous to that of 8-hydroxyflavin[4] and dissimilar to that of riboflavin in water. I is not fluorescent in water in contrast with riboflavin and 8-hydroxyflavin. The results of mp, $[\alpha]_D$, and elemental analyses are shown in Table 1. The molecular weight is estimated to be 405 from the molecular ion peak in the mass spectrum. This value coincides with the molecular weight of $C_{18}H_{23}N_5O_6$.

As described in a previous communication,[6] I was oxidized with periodate forming 7-methyl-8-dimethylamino-10-formylmethylisoalloxazine $C_{15}H_{15}N_5O_3$. From this fact it is deduced that the 10-side chain should be tetrahydric pentityl chain. I was acetylated by the usual method with acetic anhydride producing tetraacetate (Ia).

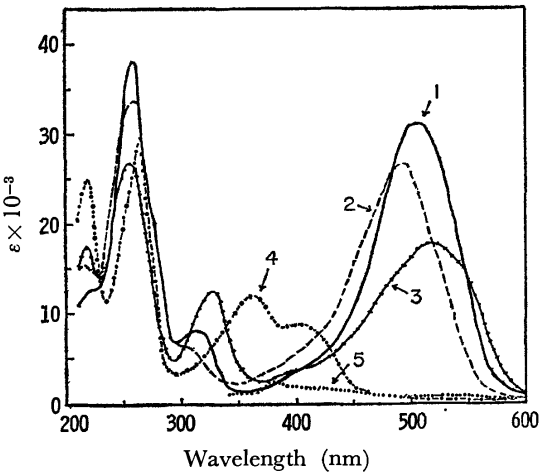

Fig. 1. UV-Visible absorption spectra of I and IX. Curve 1, I in water and IX at pH 6.99; curve 2, IX at pH 11.99; curve 3, IX at pH 0.60; curve 4, IX in 11 M HCl; curve 5, reduced IX in $Na_2S_2O_4$ solution (2.5 g/100 ml).

Properties of Ia. Ia was recrystallized from ethanol (dark reddish-brown fine needles). The results of mp, $[\alpha]_D$, and elemental analyses are shown in Table 1. The observed values coincide with those calculated for $C_{26}H_{31}N_5O_{10}$ which corresponds to a tetraacetyl compound. The molecular weight ob-

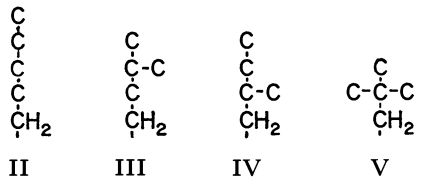
Solvent, $CDCl_3$. The chemical shifts are expressed in ppm with tetramethylsilane as an internal standard.



II III IV V

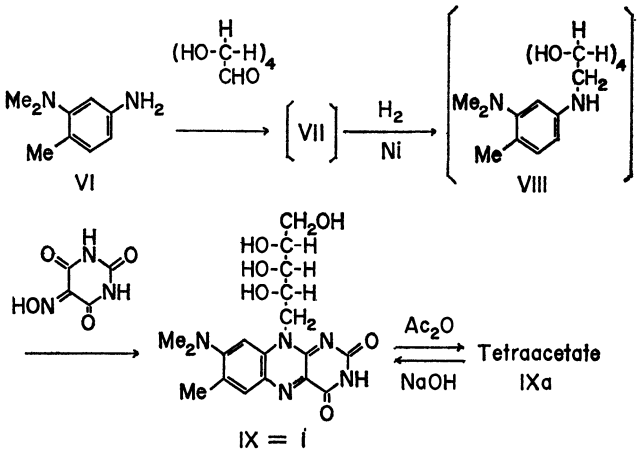
Scheme 1.

tained from mass spectrometry was 574, which coincide with the value calculated for the above compound. UV($CHCl_3$), λ_{max} (ε_{mM}): 260 (40.7), 500 nm (40.9).

The chemical shifts of the protons in Ia are shown in Table 2. Twelve protons were assigned to (CO–CH_3)$_4$, 3 to C–CH_3, 6 to N(CH_3)$_2$, 2 to the H linked to the aromatic nucleus, and one to acidic H. Seven unassignable protons were found in the range from 4.23 to 5.70 ppm. These results agree with the structure of 7-methyl-8-dimethylamino-10-*n*-pentityl-isoalloxazine tetraacetate. The NMR spectrum shows 4 different shifts for the protons of CO–CH_3 (the ratio of the intensity of the signals being 1 : 1 : 1 : 1). This suggests that the pentityl side chain is unbranched, because among the possible structures of the pentityl side chain (scheme 1), II satisfies three requirements: (1) optical activity, (2) the formation of a formylmethyl compound by oxidation with periodate and (3) the formation of tetraacetate having the characteristic NMR spectrum described above.

The *n*-pentityl structure is consistent with the peaks of the fragment ions in the mass spectrum of I. In addition to the peak of the molecular ion (*m/e* 405), small peaks for *m/e* of 388, 374, 344 and 314, and large peaks at 284, 271 and 270 were observed. They are assumed to be residual fragments deprived of –OH, $-CH_2OH$, $-(CHOH)_2-H$, $-(CHOH)_3-H$, $-(CHOH)_4-H$, $-CH_2-(CHOH)_4-H(+H)$ and $-CH_2-(CHOH)_4-H$, respectively.

*Synthesis of 7-methyl-8-dimethylamino-10-*n*-pentitylisoalloxazine and Its Tetraacetates.* *n*-Pentitylisoalloxazine has eight diastereoisomers. We synthesized four D-isomers and their tetraacetates for comparison with I and Ia. The process is shown in Scheme 2. VI[7] was condensed with D-ribose to VII, for which the structure was not confirmed, but is assumed to be ribopyranoside.[8] VII was reduced with H_2 in the presence of Raney nickel to VIII. As VII and VIII were too labile to be isolated in pure states, the reaction mixtures were subjected to succeeding steps as



Scheme 2.

soon as possible without purification. VIII was condensed with violuric acid to isoalloxazine IX (Piloty's alloxazine synthesis[9]), which was purified through acetate, *i.e.*, IX was acetylated with acetic anhydride and pyridine producing tetraacetate (IXa), which was recrystallized from ethanol and hydrolyzed with 1 M NaOH forming IX.

Three other D-diastereoisomers and their tetraacetates, D-arabinityl- (X, Xa), D-xylityl- (XI, XIa), and D-lyxityl- (XII, XIIa), were synthesized in the same way as IX.

Comparison of I and Ia with Synthesized Isoalloxazines and Their Acetates. Of the four synthetic isoalloxazines (IX—XII) only IX coincides with I for all three properties (mp, $[\alpha]_D$, and elemental analyses) and of the four tetraacetates (IXa—XIIa) only IXa coincides with Ia (Table 1). Mixed examinations of the mp of I–IX and Ia–IXa also demonstrated the identities of I–IX and Ia–IXa.

For NMR (Table 2), the chemical shifts of protons of Ia coincide with those of IXa. For thin-layer chromatography, the R_f value of I (0.45) coincides with that of IX (0.45) and not with those of X, XI and XII (0.37, 0.24 and 0.29, respectively) (the solvent being acetone–water 9 : 1 by volume; Merck's Precoated TLC Plate Silica Gel 60F-245). UV-visible absorption spectrum of I in water was coincident with that of IX at a pH of 6.99 (neutral species, Fig. 1) and those in 6 M HCl and in 0.1 M NaOH (not shown in Fig. 1) also coincide with those of IX under the

same conditions. However, the differences in absorption spectra of the diastereoisomers of IX are so small that this does not provide definite proof of the identification of diastereoisomer.

Therefore, I was identified to be 7-methyl-8-dimethylamino-10-(1'-D-ribityl)-isoalloxazine (Scheme 2).

The identification of I as 7-methyl-8-dimethylamino-10-(1'-D-ribityl)-isoalloxazine using physicochemical methods was consistent with bacteriological data, *i.e.*, IX was antibacterially as active as I and more active than the other diastereoisomers.[10]

The mp of I recrystallized from water was 274—276 °C as described above. However, in a previous paper,[5] the authors reported that the mp of I was 276—278 °C. It was ascertained by repeated experimentation that this discrepancy was caused by the presence of water of crystallization, that is, the previous sample was dried over P_2O_5 *in vacuo* at 110 °C and the sample used in this paper was dried over $CaCl_2$ *in vacuo* at room temperature and contained one mole of water of crystallization.

Other Properties of I and IX. Some properties of I are analogous to those of riboflavin and 8-hydroxyflavin, *e.g.*, pK_a, reducibility-autoxidizability, and photosensitivity. pK_a was measured spectrophotometrically using IX. The observed values, 10.8 and 1.6, correspond to those of riboflavin, 10.2 and 1.7,[11] and of 8-hydroxyflavin, 11.5 and 0.7.[4] The absorption spectra of IX at pH 11.99, 6.99, and 0.60 (Fig. 1) show these for the anion, the neutral species, and the cation. When the solution was acidified to less than pH 0.1, the absorption spectrum changed even more (see, for example, absorption curve 4 (11 M HCl) shown in Fig. 1). Therefore, IX should have another $pK_a<0.1$, and in this range IX should be protonated doubly. The absorption properties are as follows: λ_{max} (ε_{mM}): (pH 6.99, neutral species) 225 sh (12.7), 259 (38.2), 275 sh (20.3), 314 (8.0), 505 nm (31.1); (pH 0.60, cation) 219 (17.3), 255 (26.6), 328 (12.5), 519 nm (17.8): (11 M HCl, divalent cation) 219 (24.8), 265 (29.4), 364 (12.1), 402 nm (8.8), (pH 11.99, anion) 215 (15.2), 259 (33.7), 308 (6.0), 492 nm (26.6).

I was reducible with sodium dithionite to a yellow substance, which was autoxidizable to the original form. During the reduction with dithionite, no color of the intermediate (semiquinone) was recognized in contrast with riboflavin. The visible absorption spectrum of the reduced form is shown in Fig. 1. The oxidation-reduction potential of I, E_{m7}, was estimated to be −0.466 V, while that of riboflavin to be −0.428 V (*vs.* SCE, 20 °C, by the polarographic method). These values indicate that I is more difficult to reduce than riboflavin.

I was photosensitive as is riboflavin. When an alkaline solution of I was illuminated, the solution turned yellow and fluoresced. Two of the photolytic products of I were identified as 7-methyl-8-methylamino-10-(1'-D-ribityl)-isoalloxazine (a demethylated compound) and 7-methyl-8-dimethylaminoalloxazine. The details have been published elsewhere.[12]

Some properties of I are qualitatively different from those of riboflavin, for example, the absorption spectra. The neutral species of I has only one absorption peak (505 nm) in the range from 350 to 600 nm, while riboflavin has two (375 and 445 nm). The cation of I has one peak (509 nm) similar to that of riboflavin (396 nm). However, the divalent cation of I (in 11 M HCl) has two peaks (364 and 402 nm). In fluorescence, I was different from riboflavin. The neutral species of I does not fluoresce in water and ethanol, while that of riboflavin is fluorescent. However, Ia is apparently green fluorescent in chloroform, at a λ_{max} (emission) of 534 nm (uncorrected), as is riboflavin tetraacetate. However, it is curious that I was not fluorescent while Ia was fluorescent, and moreover, that other 8-dialkylamino-isoalloxazine tetraacetates were not fluorescent in chloroform (from unpublished data). The λ_{max} for excitation of Ia was 494 nm, which does not coincide with the λ_{max} for absorption of Ia (500 nm). Therefore, it would be reasonable to assume that the Ia preparation was fluorescent because of some impurity (or impurities).

Otani[13] reported that I inhibited the growth of *Lactobacillus casei* by competing with riboflavin. I has similar and dissimilar properties to riboflavin—this could be the cause of the antibacterial activity of I.

Experimental

Materials and Methods. I from *Streptomyces* strain No. 768 was provided by Mr. Takatsu of Nissin Food Products Co., Ltd.[5] As necessary, it was recrystallized from water. 2-Dimethylamino-4-aminotoluene[7] (VI) was prepared from *N*-dimethyl-*o*-toluidine by nitration and reduction with $SnCl_2$.

Absorption spectra, extinction coefficients, and fluorescence emission spectra were measured with a Hitachi recording spectrophotometer EPS-2U, fluorescence excitation spectra with a Jasco spectrofluorometer FP-4, specific rotation with a Jasco recording spectropolarimeter J-20, proton NMR spectra with a JEOL NMR spectrometer C-60 HL (60 MHz) (by Dr. Kinoshita), mass spectra with a Hitachi mass spectrometer RM-50 (direct injection method), oxidation reduction potential with a Yanaco Polarograph P-8 (by Mr. Ichimura), and pH with a Corning digital pH meter model 109.

Roseoflavin Tetraacetate (Ia). I (85 mg) was suspended in pyridine (10 ml) and dissovled by adding acetic anhydride (2 ml). The mixture was left standing overnight at room temperature. After the addition of cold water (about 30 ml) with ice cooling, the reaction mixture was evaporated in a rotary evaporator. The product was recrystallized from ethanol five times. Yield, 60.7 mg, reddish dark brown fine needles with metallic luster. Mp, elemental analysis, $[\alpha]_D$, see Table 1; NMR, see Table 2.

Synthesis of Flavins. 7-Methyl-8-dimethylamino-10-(1'-D-ribityl)isoalloxazine (IX): D-Ribose (3.0 g) and 3.3 g of freshly distilled VI were suspended in 6 ml of absolute methanol. The suspension was refluxed to dissolve the materials, and after complete dissolution the reflux was further continued for 2 hr. Immediately after cooling, the reaction mixture was transferred into an autoclave and mixed with 8 g of freshly prepared Raney nickel. After hydrogenation at 100 °C at a pressure of 120 atm for 1 hr, the catalyst was removed by filtration. The solvent was removed in a rotary evaporator, and the residual syrup was again dissolved in

10 ml of methanol. The solution was poured into a hot solution of violuric acid (3.2 g in 50 ml of methanol). After reflux for 2 hr, the reaction mixture was chilled in a refrigerator overnight. The deposited crystals were filtered and washed with cold methanol. The filtrate, combined with washings, was evaporated and the residue was extracted with hot water. The second crop from the concentrated extract was recrystallized from water-methanol. The combined crystals (first and second crops) were further recrystallized from water. Yield, 4.4 g, 50%.

The purest material was obtained by hydrolysis of the recrystallized IXa (see following). IXa (3.0 g) was dissolved in 30 ml of 1 M NaOH, and after 10 min, the solution was neutralized with acetic acid (about 3 ml). The precipitates were filtered and washed with water. If necessary, it was recrystallized from water. Yield, 2.0 g, 90% of dark reddish-brown fine needles with metallic luster. Mp, elemental analysis, $[\alpha]_D$, see Table 1.

IX Tetraacetate (IXa): IX (2.0 g) dissolved in 20 ml of pyridine was mixed with 8 ml of acetic anhydride. After stirring at room temperature for several hours, the reaction mixture was evaporated to dyrness in a rotary evaporator. The residue was dissolved in chloroform, and washed with water. The chloroform layer was dried over anhydrous magnesium sulfate, and was then evaporated. The product was recrystallized from ethanol. Yield, 2.0 g, 74% of dark reddish-brown fine needles with metallic luster. Mp, elemetal analysis, $[\alpha]_D$, see Table 1; NMR, see Table 2.

7-Methyl-8-dimethylamino-10-(1'-D-arabinityl)-isoalloxazine(X): This compound was prepared from 3.0 g of D-arabinose, 3.3 g of VI, and 3.2 g of violuric acid (yield of crude preparation, 4.4 g, 50%), and purified through tetraacetate in the same way as IX. Yield, 2.0 g from 3.0 g of Xa, 90% of dark reddish-brown fine needles with metallic luster. Mp, elemental analysis, $[\alpha]_D$, see Table 1.

X Tetraacetate (Xa): This substance was prepared by acetylation of X in the same way as IXa. Yield, 2.0 g from 2.0 g of X, 74% of dark reddish-brown fine needles with metallic luster. Mp, elemental analysis, $[\alpha]_D$, see Table 1; NMR, see Table 2.

7-Methyl-8-dimethylamino-10-(1'-D-xylityl)-isoalloxazine (XI): This compound was prepared from 3.0 g of D-xylose, 3.3 g of VI, and 3.2 g of violuric acid (yield of crude preparation, 4.3 g, 48%), and purified through tetraacetate in the same way as IX. Yield, 2.0 g from 3.0 g of XIa, 87% of dark reddish-brown fine needles with metallic luster. Mp, elemental analysis, $[\alpha]_D$, see Table 1.

XI Tetraacetate (XIa): This compound was prepared by acetylation of XI in the same way as IXa. Yield, 1.9 g from 2.0 g of XI, 75% of dark reddish-brown fine needles with metallic luster. Mp, elemental analysis, $[\alpha]_D$, see Table 1: NMR, see Table 2.

7-Methyl-8-dimethylamino-10-(1'-D-lyxityl)-isoalloxazine (XII): This compound was prepared from 3.0 g of D-lyxose, 3.3 g of VI, and 3.2 g of violuric acid (yield of crude preparation, 4.6 g, 53%), and purified through tetraacetate in the same way as IX. Yield, 2.0 g from 3.0 g of XIIa, 88% of dark reddish-brown fine needles with metallic luster. Mp, elemental analysis, $[\alpha]_D$, see Table 1.

XII Tetraacetate (XIIa): This compound was prepared by acetylation of XII in the same way as IXa. Yield, 1.9 g from 2.0 g of XII, 75% of dark reddish-brown fine needles with metallic luster. Mp, elemental analysis, $[\alpha]_D$, see Table 1; NMR, see Table 2.

The authors thank Prof. S. Otani of Koshien University for encouragement, Mr. M. Takatsu of Nissin Food Products Co., Ltd. for the I, and Dr. Kinoshita and Mr. Ichimura of Osaka City University for the NMR spectra and polarographic measurements, respectively.

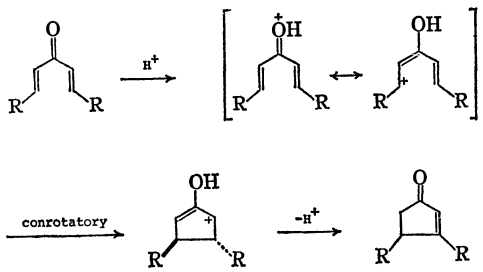
The Role of Nucleophilic Solvents in the Acid-Catalyzed Cyclization of a Cross-Conjugated Cycloalkadienone

Ryoji NOYORI, Yasushi OHNISHI, and Masao KATÔ
Department of Chemistry, Nagoya University, Chikusa, Nagoya 464
(Received February 25, 1975)

In acetic acid or methanol containing a trace amount of H_2SO_4, 2,8-cyclononadienone cyclizes readily to give bicyclic ketones; the mechanism including the role of the nucleophilic media is discussed.

The acid-catalyzed cyclization of cross-conjugated dienones to produce cyclopentenones is known as the Nazarov cyclization.[1] Woodward and coworkers analyzed the reaction with *di*-1-cyclohexenyl ketone and concluded the transformation as occurring through conrotatory ring closure of the protonated dienone–hydroxypentadienyl cation resonance hybrid (Scheme 1).[2] As might be expected, common and medium-sized cycloalkadienones in an oxygen-protonated form are thermally stable, because the symmetry-allowed electrocyclization is sterically prohibited by the presence of a methylene chain which links the β and β' carbons. This paper describes an example where a combination of an acid and certain nucleophiles can facilitate the so far restricted cyclization of a medium-sized cyclic dienone.



Scheme I.

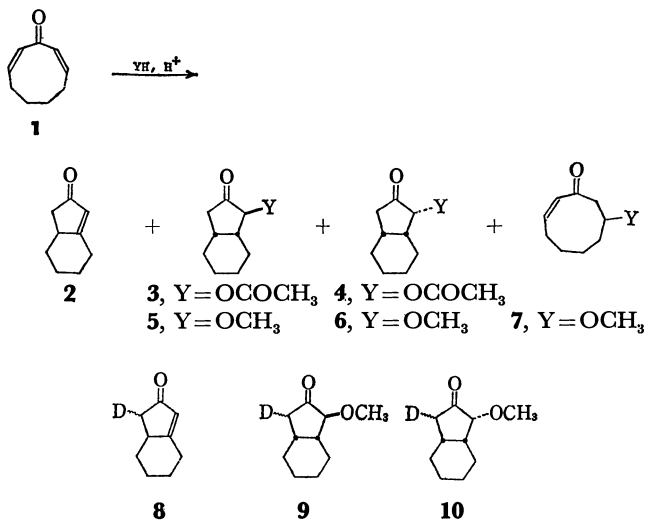
2,8-Cyclononadienone (**1**) in 97% H_2SO_4 or FSO_3H exists in a protonated form as indicated by spectral data (NMR and UV)[3,4] and remains unchanged for an extended period below room temperature. The dienone is also inert in acetic acid below 30 °C. Remarkably, however, when a drop of H_2SO_4 was added to an acetic acid solution of **1**, spontaneous reaction took place at room temperature yielding the bicyclic enone **2** (25%) and the epimeric acetoxy ketones **3** and **4** (40% combined yield).

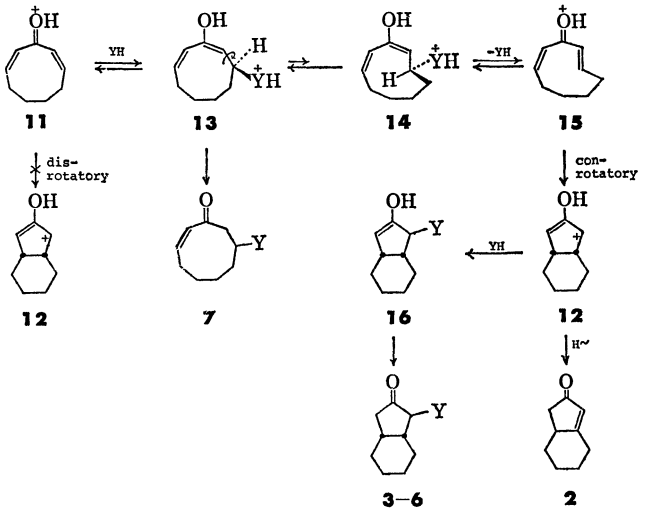
No reactions were observed when **1** was allowed to stand in methanol solution at room temperature. Again, rapid reaction was caused by the addition of a drop of H_2SO_4, and there was obtained a mixture of **2** (6%), the bicyclic methoxy ketones **5** and **6** (72%), and the monocyclic methoxy ketone **7** (7%). These products **2**—**7** were stable under the present reaction and workup conditions.

The reaction in methanol-*O*-*d* as solvent gave the deuterium-incorporated bicyclic products **8**—**10**. The mass spectral analysis showed that these consisted mainly (69—85%) of d_1 material and contained some d_0 and d_2 products. The NMR spectra indicated that the deuterium atoms are located specifically at position α to carbonyl group but randomly with respect to stereochemistry, the *exo* to *endo* ratio being approximately 1 : 1. Control experiments showed that **2** suffers protium-deuterium exchange to some extent under the present reaction conditions.

The observed reactions forming the bicyclic ketones are characteristic of the nine-membered dienone **1**. With seven-, eight-, and twelve-membered cross-conjugated dienones, only mixtures of monocyclic solvent-incorporated products were obtained.

Apparently the presence of both acidic and nucleophilic species is a necessary condition for promotion of the β,β' bond-forming reaction of **1**. Although

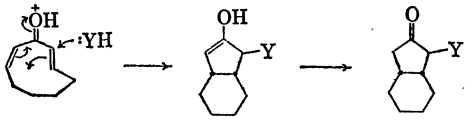




YH=CH_3COOH or CH_3OH

Scheme II.

there may be a variety of possible mechanisms conceivable, the most likely seems to be a pathway which involves solvent-assisted *cis-trans* isomerization of **1** in a key step as outlined in Scheme II. The protonated *cis, cis* dienone **11** cannot undergo unimolecular electrocyclizations; the disrotatory ring closure to the bicyclic hydroxyallyl cation **12** is symmetry-forbidden, while the alternative conrotatory cyclization to the *trans*-fused bicyclic system is unlikely due to the high strain energy involved in the transition state as indicated by molecular models. Reaction of **11** with the nucleophilic solvent YH at the electron-deficient β carbon produces the dienol adduct **13**.[5] Reketonization gives the monocyclic adduct **7**. If the conformational change, **13**→**14**, followed by elimination of YH occurs prior to ketonization, then the key intermediate, protonated *cis, trans* dienone **15**,[6] is formed, which in turn undergoes conrotatory ring closure to give **12**. Its proton reorganization affords the bicyclic enone **2**, while nucleophilic trapping with YH and subsequent ketonization produces the epimeric bicyclic solvent adducts **3**—**6**. Patterns of the deuterium incorporation observed for the reaction in methanol-*O-d* solvent are also consistent with the mechanism of Scheme II. The conformational change of type **13**→**14**, an essential process for the formation of the reactive *cis, trans* dienone, would be feasible only with the nine-membered dienone **1**; with the lower homologs, the form corresponding to **14** could hardly be accomodated in the conformational equilibrium. With twelve-membered dienones, the *cis-trans* isomerism in the protonated form also seems possible. Neither *cis, cis* nor *cis,trans* isomer, however, is strained enough to undergo the unimolecular electrocyclization to give bicyclic hydroxypentadienyl cations.



15 **16** **3—6**

Scheme III.

Photochemically generated *cis, trans*-2,8-cyclononadienone is known to undergo the cyclization in protic solvents with or without added Brönsted acids.[7] Under the present reaction conditions, **3**—**6** may also be derived *via* bimolecular reaction of **15** and YH as illustrated in Scheme III. An alternative mechanism involving direct, bimolecular reaction between the *cis,cis* dienone **11** and YH is unlikely to be operating, since it could not explain the profound ring-size effect on the reaction course.

Experimental

General. NMR spectra were taken in CCl_4 solution using a JEOLCO Model C-60 H instrument. IR spectra were obtained on a JASCO Model DS-402 G spectrometer. A Hitachi Model RMU-6C mass-spectrometer was used for mass spectral analysis. Gas-liquid partition chromatography (glpc) was done with a Yanagimoto Model G-8 chromatograph equipped with a 2-m column of 5% poly(ethylene glycol succinate) on Celite 545. Product ratio was determined using C_{12}—C_{16} hydrocarbons as internal standard. Thin-layer chromatography (tlc) was carried out on silica gel (E. Merck GF_{254} silica gel). 2,8-Cyclononadienone (**1**) was prepared by the method of Garbisch.[8]

Reaction of 2,8-Cyclononadienone (1) in Nucleophilic Solvents Containing H_2SO_4. A solution of **1** (492 mg, 3.64 mmol) in acetic acid (5 ml) containing one drop of 96% H_2SO_4 was stirred at room temperature for 20 min. The mixture was diluted with water, neutralized with sodium bicarbonate, and extracted with ether. The ethereal solution was washed with water, dried over $MgSO_4$, and concentrated *in vacuo* to give a crude oil (514 mg). Glpc analysis (150 °C) of the oil indicated the formation of bicyclo[4.3.0]non-6-en-8-one (**2**) (25% yield), *exo*-7-acetoxy-*cis*-bicyclo[4.3.0]nonan-8-one (**3**) and *endo*-7-acetoxy-*cis*-bicyclo[4.3.0]nonan-8-one (**4**) (5 : 2 ratio, 40% combined yield). Each compound was separated by preparative tlc (1 : 1 *n*-hexane-ether) and identified by comparison of the NMR and IR data with those of an authentic sample.[4,7]

Similarly, when a 10% methanol solution of **1** containing a trace amount of H_2SO_4 was allowed to stand for 20 min at room temperature, a mixture of the enone **2** and the methanol adducts was obtained. Glpc analysis (140 °C) of the crude product showed the formation of **2** (6%), *exo*-7-methoxy-*cis*-bicyclo[4.3.0]nonan-8-one (**5**) and *endo*-7-methoxy-*cis*-bicyclo[4.3.0]nonan-8-one (**6**) (5 : 2 ratio, 72%), and 8-methoxy-2-cyclononenone (**7**) (7%).[7] The identity of these compounds was established by comparison with authentic specimens.

Reaction of 1 in Methanol-O-d *Containing D_2SO_4.* The dienone **1** (129 mg, 0.96 mmol) was dissolved in methanol-*O-d* (1 ml, E. Merck, deuterium content >99%) containing a trace amount of 97% D_2SO_4 (E. Merck, deuterium content >99%). The resulting solution was stirred at room temperature for 20 min, diluted with dichloromethane (10 ml), and washed with water three times. The organic layer was dired by being passed through a short Na_2SO_4-silica gel column and concentrated *in vacuo* to leave a crude oil (156 mg), which contained the solvent adducts as the major components. In order to minimize loss of deuterium atom from the products, the reaction mixture was worked up as quick as possible. About 10 min were required for this work-up procedure. Preparative tlc with a 1 : 1 *n*-hexane-ether mixture (2 developments) afforded bicyclo-[4.3.0]non-6-en-8-one-9-*d* (**8**) (13 mg), *exo*-7-methoxy-*cis*-bicyclo[4.3.0]nonan-8-one-9-*d* (**9**) (73 mg), and *endo*-7-methoxy-*cis*-bicyclo[4.3.0]nonan-8-one-9-*d* (**10**) (56 mg). The deuterated derivative of **7** could not be isolated in a pure state. The structures were deduced from thier NMR spectra. The spectra taken in CCl_4 solution with the added $Eu(fod)_3$ shift reagent indicated that deuterium atom in these products was incorporated at the carbonyl α position, where the *exo* to *endo* ratio was approximately 1.0. The molecular ion peaks in the mass spectra appeared at *m/e* 137 for **8** and 169 for **9** and **10**. Comparison of the intensities with those of the neighboring peaks showed the extent of deuterium incorporation: **8** 15% d_0, 69% d_1, and 16% d_2; **9** 17% d_0, 82% d_1, and 1% d_2; **10** 13% d_0, 85% d_1, and 2% d_2. The enone **2** recovered after treatment with methanol-*O-d* containing D_2SO_4 at room temperature for 20 min contained deuterium atoms; 29% d_0, 54% d_1, and 17% d_2.

New Syntheses of Fervenulin (1,3-Dimethyl-7-azalumazine) and Analogs

Fumio YONEDA and Tomohisa NAGAMATSU

Faculty of Pharmaceutical Sciences, Kumamoto University, Oe-honmachi, Kumamoto 862

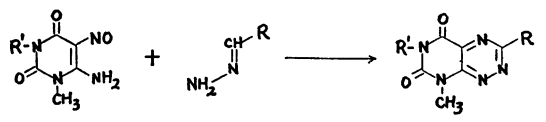
(Received March 3, 1975)

A new, convenient method for the synthesis of fervenulin and its derivatives on the basis of the condensation of 6-amino-5-nitrosouracils and aldehyde hydrazones is described. A transformation of toxoflavins into fervenulins *via* 1-demethyltoxoflavins is also described. The alkylation of 1-demethyltoxoflavin with several alcohols in the presence of diethyl azodicarboxylate and triphenylphosphine gave the corresponding fervenulin homologs.

Fervenulin, an antibiotic having pyrimido[5,4-*e*]-*as*-triazine ring system, was first synthesized in 1958 by Pfleiderer and Schündehütte.[1] Since then there has been considerable interest in the synthesis and the reaction of pyrimido[5,4-*e*]-*as*-triazine derivatives.[2] This paper will describe a new, convenient method for the synthesis of fervenulin and its derivatives on the basis of the condensation of 6-amino-5-nitrosouracils and aldehyde hydrazones; additionally, we wish to describe a transformation of toxoflavins into fervenulins *via* 1-demethyltoxoflavins and the synthesis of homologs of fervenulin by the alkylation of 1-demethyltoxoflavin.[3]

Reaction of 6-Amino-5-nitrosouracils with Aldehyde Hydrazones

Stirring a suspension of 6-amino-1,3-dimethyl-5-nitrosouracil (**1**) in aprotic solvents, such as dimethylformamide or dimethyl sulfoxide, with an equimolar amount of 37% aqueous formaldehyde and hydrazine hydrate under cooling, followed by a mild refluxing of the mixture, resulted in the formation of fervenulin (**2a**) in about a 40% yield. The product was found by IR and elemental analysis to be identical with an authentic sample prepared by an alternative route.[1] Similarly, the heating of **1** with other aldehydes and hydrazine hydrate in dimethylformamide or dimethyl sulfoxide gave the corresponding 3-substituted fervenulins (6- substituted 1,3-dimethyl-7-azalumazines) (see Table 1).



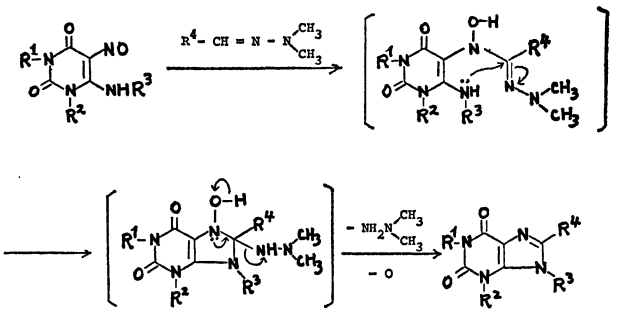
1 R′=CH$_3$ **2a-p** R′=CH$_3$
3 R′=H **4a,b** R′=H

Scheme 1.

The reaction essentially involves **1** and the aldehyde hydrazones, since aldehydes and hydrazine hydrate react immediately to give the hydrazones. In fact, the yields of the 3-substituted fervenulins increased when **1** was allowed to react with the aldehyde hydrazones.

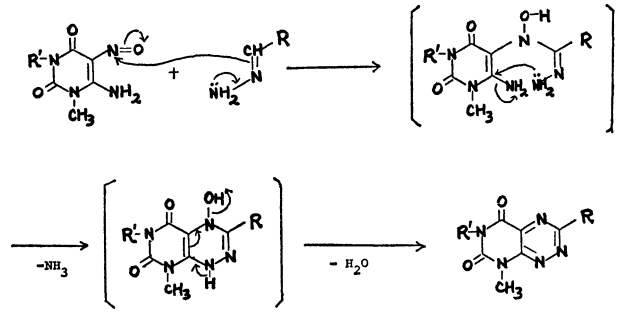
6-Amino-1-methyl-5-nitrosouracil (**3**) also gave the corresponding 7-azalumazine derivatives by the condensation with aldehyde hydrazones. For instance, the heating of **3** with formaldehyde and benzaldehyde hydrazones in dimethylformamide gave 1-methyl-7-azalumazine (**4a**) and 1-methyl-6-phenyl-7-azalumazine (**4b**) respectively. These 7-azalumazines gave the corresponding fervenulins (**2a**, **b**) by treatment with methyl iodide in dimethylformamide in the presence of potassium carbonate.

It is interesting to note that the heating of 6-amino-5-nitrosouracils with aryl aldehyde 1,1-dimethylhydrazones (instead of aryl aldehyde hydrazones) in dimethylformamide gave 8-arylxanthines. This purine synthesis can be explained as is depicted in Scheme 2.[4]



Scheme 2.

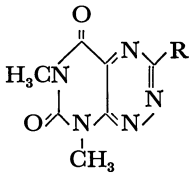
From the above facts, the reaction of the new fervenulin synthesis seems to proceed by the initial nucleophilic attack of the electron-rich-α-carbon of the hydrazones on the nitroso group of the uracils to form hydroxylamine intermediates, which are then converted into fervenulins by the elimination of the ammonia and water.



Scheme 3.

Another explanation of the mechanism would be initial transamination of the 6-amino-5-nitrosouracils by the aryl aldehyde hydrazones. It is possible that the previously formed 6-benzylidenehydrazino-5-nitrosouracils undergo intramolecular cyclization to give fervenulins. However, this mechanism seems unlikely, because the transamination of 6-amino-5-nitrosouracils with amines usually requires more drastic conditions

TABLE 1. SYNTHESIS OF FERVENULINS BY THE REACTION OF 6-AMINO-1,3-DIMETHYL-5-NITROSOURACIL (1) WITH ALDEHYDES AND HYDRAZINE HYDRATE



Aldehyde	3-Substituent (R) in product	Mp (°C)	Yield (%)	Formula	Analysis (%) Calcd (Found) C	H	N

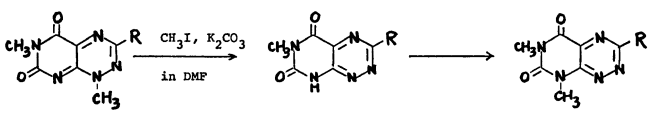
The Transformation of Toxoflavins into Fervenulins

Toxoflavin,[6,7] another antibiotic with pyrimido-[5,4-*e*]-*as*-triazine ring system, is isomeric with fervenulin. We are the first to have succeeded in the transformation of toxoflavin and its derivatives into fervenulin and its derivatives respectively. Heating toxoflavin (**5a**) under reflux with methyl iodide in dimethylformamide containing anhydrous potassium carbonate for 2 hr gave fervenulin (**2a**) in a moderate yield in a single step. Similarly, heating other toxoflavin derivatives with methyl iodide in dimethylformamide in the presence of potassium carbonate led to the formation of the corresponding 3-substituted fervenulins (Table 2).



5a-c, i, n **6** **2a-c, i, n**

Scheme 4.

The reaction essentially involves the demethylation of the toxoflavins (**5**) to 1-demethyltoxoflavins (**6**), and the subsequent methylation of **6** with methyl iodide. Both heating **5** with excess methyl iodide in dimethylformamide in the absence of potassium carbonate, and heating **5** alone in dimethylformamide in

TABLE 2. CONVERSION OF TOXOFLAVINS INTO FERVENULINS

3-Substituent (R) of starting materials (Toxoflavins)	3-Substituent (R) of products (Fervenulins)	Yield (%)
Hydrogen (**5a**)	Hydrogen (**2a**)	35

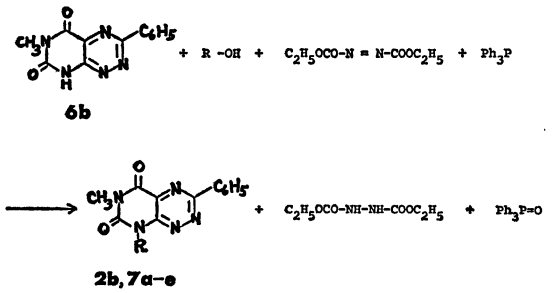
the presence of potassium carbonate yielded only the corresponding **6** in almost quantitative yields.[8]

The Alkylation of 1-Dimethyltoxoflavins

Mistunobu *et al.*[9] have reported a convenient alkylation of phthalimide with alcohols in the presence of equimolar amounts diethyl azodicarboxylate (DAD) and triphenylphosphine. We have extended this reaction to the alkylation of **6**,[8] which was easily prepared by the demethylation of **5** with dimethylformamide.

Refluxing a mixture of 3-phenyl-1-demethyltoxoflavin (**6b**) and an alcohol in dioxane in the presence of DAD and triphenylphosphine gave the corresponding 1-alkyl-3-methyl-6-phenyl-7-azalumazines (Table 3). Some of these compounds were identified with the authentic samples prepared by the alkylation of **6b** with the corresponding alkyl halides. When **6b** and ethylene glycol were used in this reaction, 1-(2-hydroxyethyl)-3-methyl-6-phenyl-7-azalumazine (**7e**) was obtained.



Scheme 5.

Experimental

The melting points were determined on a Yanagimoto Micro-melting Point apparatus and are uncorrected. The infrared spectra were determined on a Japan Spectroscopic Co., Ltd., spectrophotometer, Model IR-I A, from samples mulled in Nujol.

*Fervenulin (1,3-Dimethyl-7-azalumazine) (**2a**).* To a cooled suspension of 6-amino-1,3-dimethyl-5-nitrosouracil (**1**) (1.8 g, 0.01 mol) in DMF (50 ml), we added 37% formaldehyde (0.8 g, 0.01 mol) and 100% hydrazine hydrate (0.5 g, 0.01 mol). The mixture was stirred for about 10 min under cooling with ice water and then refluxed for 3 hr. After the solvent had been evaporated to dryness, the residue was extracted with chloroform. The chloroform extracts were evaporated, and the resulting residue was treated with 50% aqueous MeOH to cause the separation of 0.76 g (40%) of **2a** which was identical in all respects with an authentic sample.[1]

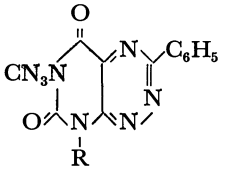
*3-Substituted Fervenulins (**2b-p**); General Procedure*: A mixture of **1** (0.01 mol), an aryl aldehyde (0.01 mol), and 100% hydrazine hydrate (0.01 mol) in DMF (50 ml) was refluxed for 3—5 hr. The reaction mixture was then evaporated to dryness, and the residue was diluted with EtOH in order to precipitate a crude product, which was recrystallized from EtOH to give the 3-arylfervenulin as yellow needles.

Sometimes a small amount of a by-product, the corresponding 8-aryltheophylline, was isolated from the mother liquor.

*7-Methyl-7-azalumazine (**4a**).* To a suspension of 6-amino-1-methyl-5-nitrosouracil (**3**) (2 g, 0.012 mol) in DMF (50 ml), we added 37% formaldehyde (0.96 g, 0.012 mol) and 100% hydrazine hydrate (0.6 g, 0.012 mol) under cooling in ice water with continuous stirring, after which the mixture was refluxed for 4 hr. The reaction mixture was then concentrated *in vacuo*, and the residue was diluted with EtOH to precipitate crystals, which were subsequently recrystallized from EtOH to give 1.25 g (58%) of pale brown crystals; mp>260 °C (decomp.). MS *m/e* 179 (M^+). Found: C, 40.20; H, 2.77; N, 38.87%. Calcd for $C_6H_5N_5O_2$: C, 40.23; H, 2.81; N, 39.10%.

*7-Methyl-6-phenyl-7-azalumazine (**4b**).* A mixture of **3** (2 g, 0.012 mol), benzaldehyde (1.25 g, 0.012 mol), and 100% hydrazine hydrate (0.6 g, 0.012 mol) in DMF (50 ml) was refluxed for 5 hr. After the DMF had been evaporated, the residue was treated with EtOH to precipitate crude **4b**, which was collected by filtration and recrystallized from

TABLE 3. PREPARATION OF 1-ALKYL-3-METHYL-6-PHENYL-7-AZALLMAZINES



1-Alkyl (R)	Mp (°C)	Yield (%)	Appearance	Formula	Analysis (%) Calcd (Found) C	H	N

Ethyl (**7a**)	228	60	yellow prisms	$C_{14}H_{13}N_5O_2$	59.35(59.31)	4.63(4.70)	24.72(24.50)
n-Propyl (**7b**)	214	67	yellow needles	$C_{15}H_{15}N_5O_2$	60.59(60.57)	5.09(5.01)	23.56(23.60)
i-Propyl (**7c**)	226	76	yellow needles	$C_{15}H_{15}N_5O_2$	60.59(60.48)	5.09(5.08)	23.56(23.54)
Allyl (**7d**)	213	78	yellow needles	$C_{15}H_{13}N_5O_2$	61.01(61.09)	4.44(4.48)	23.72(23.79)
2-Hydroxyethyl (**7e**)	215	95	yellow prisms	$C_{14}H_{13}N_5O_3$	56.18(56.37)	4.38(4.36)	23.40(23.50)

DMF+EtOH to give 1.45 g (47%) of yellow crystals; mp> 280 °C (decomp.). MS *m/e* 255 (M^+). Found: C, 56.38; H, 3.67; N, 27.23%. Calcd for $C_{12}H_9N_5O_2$: C, 56.47; H, 3.55; N, 27.44%.

In the mother liquor, a trace of 3-methyl-8-phenylxanthine[10] was detected.

*Methylation of **4b** with Methyl Iodide.* A mixture of **4b** (0.5 g, 0.002 mol), CH_3I (1.4 g, 0.01 mol), and K_2CO_3 (0.7 g, 0.005 mol) in DMF (20 ml) was refluxed for 2 hr. The reaction mixture was then concentrated *in vacuo*, and the residue was diluted with H_2O to precipitate 0.3 g (56%) of 3-phenylfervenulin, which was found by IR to be identical with the **2b** prepared by the above method.

Conversion from Toxoflavins into Fervenulins; General Procedure: To a mixture of CH_3I (0.05 mol) and K_2CO_3 (0.01 mol) in DMF (50 ml), we added a toxoflavin (0.005 mol), after which the mixture was refluxed for 2—3 hr. After the solvent had been evaporated *in vacuo*, the resulting residue was diluted with H_2O to separate yellow crystals. Recrystallization from EtOH gave the corresponding fervenulin.

*Alkylation of 3-Phenyl-1-demethyltoxoflavin (**6b**) General Procedure:* To a suspension of **6b** (0.002 mol) and triphenylphosphine (0.03 mol) in dioxane (30 ml), we added diethyl azodicarboxylate (0.004 mol) and an alcohol (0.01—0.02 mol), after which the mixture was refluxed for 3 hr. The reaction mixture was then evaporated *in vacuo*, followed by dilution with benzene or EtOH to precipitate a crude sample, which was collected by filtration and recrystallized from EtOH to give the corresponding homologs of fervenulin (1-alkyl-3-methyl-7-azalumazines).

*Ethylation of **6b** with Ethyl Iodide.* A mixture of **6b** (1.5 g, 0.005 mol), C_2H_5I (3.9 g, 0.025 mol), and K_2CO_3 (3.5 g, 0.025 mol) in DMF (50 ml) was refluxed for 2 hr. After the insoluble material had been filtered off, the filtrate was concentrated to dryness *in vacuo* and the residue was diluted with H_2O to give crystals. Recrystallization from EtOH gave 1 g (71%) of 8-ethyl-3-methyl-6-phenyl-7-azalumazine (**7a**), which was found by IR and elemental analysis to be identical with the product prepared as has been described above.

Synthesis of [4-5,4′-5′-Bis(δ-Aminovaleric Acid)]-Gramicidin S[1]

Shōsuke SŌFUKU, Ichiro MURAMATSU, Kazuki OKADA, and Akira HAGITANI

Department of Chemistry, College of Science, Rikkyo (St. Paul's) University, Nishi-Ikebukuro, Tokyo 171

(Received March 26, 1975)

An analog of gramicidin S, [4-5,4′-5′-bis(δ-aminovaleric acid)]-gramicidin S, was synthesized, in which both of the two residues of D-Phe-L-Pro of gramicidin S (GS) were replaced with δ-aminovaleric acid residues (δAva). The spectra of optical rotatory dispersion (ORD) and circular dichroism (CD) of this analog suggest that its conformation in solution at room temperature is a random structure by comparison with that of GS. This analog has no antimicrobial activity. The linear peptide H-(Val-Orn-Leu-δAva-)$_2$-OH also has no activity and its ORD and CD are nearly the same as those exhibited by the random structure of the polypeptide. These results indicate the importance of the presence of D-Phe-L-Pro in GS for the maintenance of the specific conformation.

In order to investigate the contribution of amide bonds in peptides to their activity and conformation, we have synthesized analogs of gramicidine S (GS) containing δ-aminovaleric acid residue (δAva). In a previous paper,[1] it was reported that the synthetic analog, [δAva$^{4-5}$]-GS, had antimicrobial activity and showed a type of opitical rotatory dispersion (ORD) and circular dichroism (CD) spectra similar to that of GS. Proton magnetic resonance data[2] indicated that the secondary structure of this analog was similar to that of GS.

In this paper, we describe the synthesis of [δAva$^{4-5,4'-5'}$]-GS, in which both of the residues of D-Phe-L-Pro of GS were replaced with δAva, as well as the results of the antimicrobial assay and the ORD and CD measurements of this analog.

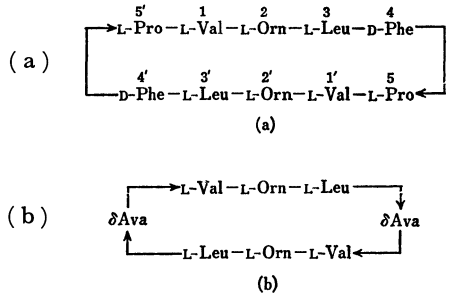

Fig. 1. Structures of gramicidin S (a), and [δAva$^{4-5,4'-5'}$]-GS (b).

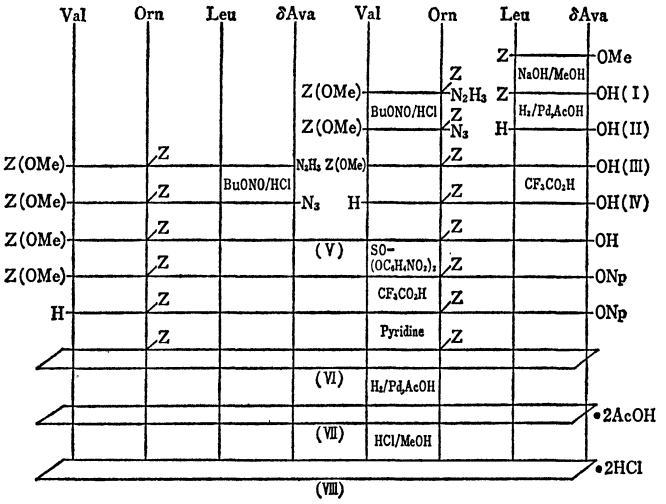
The route of the synthesis of this analog is shown in Scheme 1. The synthesis of *p*-methoxybenzyloxycarbonyl-L-valyl-N^{δ}-benzyloxycarbonyl-L-ornithyl-L-leucyl-δ-aminovaleric acid hydrazide has been reported in the previous paper.[1] The azide derived from the hydrazide was coupled with IV. The resulting linear octapeptide (V) was used for cyclization reaction, which was carried out in the same manner as in the cyclization described in the previous paper. The cyclic peptide (VI) was obtained in 32% yield, which was inferior to that of the cyclization of the peptide containing one residue of δAva in the case of [δAva$^{4-5}$]-GS. This result might indicate that the yield of cyclization depends on whether the conformation of the active ester is such as to be favorable for the cyclization or not. [δAva$^{4-5,4'-5'}$]-GS diacetate (VII) was obtained by hydrogenolysis of the benzyloxycarbonyl groups on the ornithine residues of VI in the presence



Scheme 1.

of acetic acid. VII was coupled with 1-dimethylaminonaphthalene-5-sulphonyl chloride (DNS-Cl).[3] After the hydrolysis of this DNS derivative, only N^{δ}-DNS-ornithine was detected in thin layer chromatography.[1] This result proves that VII has a cyclic form. The antimicrobial activity of this analog toward several microorganisms was tested for, but none could be found.

The related linear octapeptide, H-(Val-Orn-Leu-δAva-)$_2$-OH·3HCl (IX),[4] was prepared from V by hydrogenolysis of its N-protecting groups in the presence of hydrogen chloride. This peptide also did not exhibit any antimicrobial activity.

ORD and CD spectra of the cyclic peptide dihydrochloride (VIII) were measured. These spectra are different from those of GS and some of its biologically active analogs[1,5] as shown in Figs. 2 and 3. The minimum value of ORD of the analog (VIII) is observed at 208 nm, this represents a conspicuous difference from the spectrum of GS (232 nm). The CD spectrum of this peptide has a trough at 198 nm. In methanol also the trough of the CD at room temperature appeared at 199 nm.

ORD and CD spectra of the linear peptide (IX) in Figs. 2 and 3 show that it has a random structure.

Thus, the conformation of VIII in solution at room temperature is presumed to be a random structure,[6,7] while those of GS[8] and [δAva$^{4-5}$]-GS[1] are ordered.

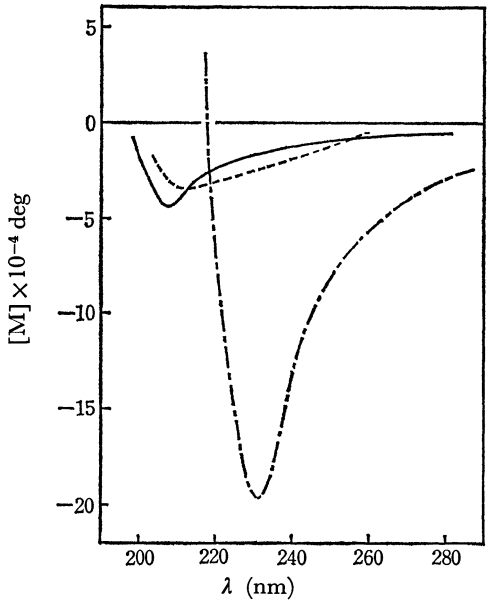


Fig. 2. Optical rotatory dispersion spectra of [δAva$^{4-5,4'-5'}$]-GS·2HCl (VIII), linear peptide (IX), and gramicidin S·2HCl (GS) in water; VIII (——), IX (----), and GS (———). Measurments were made using a 1 mm quartz cell at room temperature.

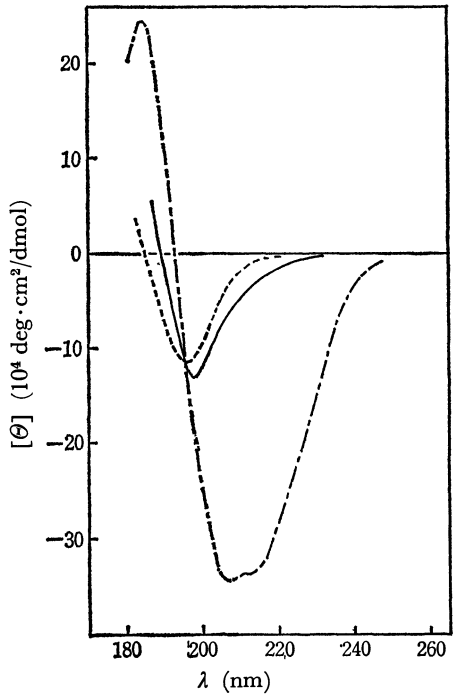

Fig. 3. Circular dichroism spectra of [δAva$^{4-5,4'-5'}$]-GS·2HCl (VIII), linear peptide (IX), and gramicidin S·2HCl (GS) in water; VIII (——), IX (----), and GS (———). Measurments were made using a 0.5 mm quartz cell at room temperature.

These results indicate that the cyclic structure of GS is retained not only by the formation of hydrogen bonds but also by the presence of D-phenylalanyl-L-prolyl residue in the β-turn.[9]

Experimental[10]

ORD and CD spectra were measured with a JASCO model J-20 spectrometer and represented by the values of molar optical rotation and molar ellipticity, respectively. The molecular weight was determined with a Hitachi molecular weight apparatus model 115, using methanol. Thin layer chromatography (tlc) was carried out on silica gel and the spot was detected with ninhydrin reagent. N-protected compounds were also detected with ninhydrin after deblocking with concd hydrobromic acid. The following solvent systems (V/V) were used in tlc: Solv. 1, $CHCl_3$–MeOH–AcOH (95 : 5 : 3); Solv. 2, $CHCl_3$–MeOH (9 : 1); Solv. 3, *n*-BuOH–AcOH–pyridine–H_2O (4 : 1 : 1 : 2); Solv. 4, *n*-BuOH–EtOH–concd NH_3 (6 : 1 : 3). Amino acid analyses were performed with a JEOL automatic amino acid analyzer, after hydrolyzing samples with 6 N HCl in evacuated sealed ampoules for 20 hr at 110 °C.

Benzyloxycarbonyl-L-leucyl-δ-aminovaleric Acid (I). Z-L-Leu-δAva-OMe (12.5 g, 33 mmol)[11] was saponified in methanol (90 ml) with 1 M NaOH (34 ml) at 38 °C for 2 hr. The reaction solution was acidified with 1 M HCl on cooling and evaporated *in vacuo*. The oily residue was dissolved in ethyl acetate and extracted with 5% sodium bicarbonate. This solution was acidified with 1 M HCl and extracted with ethyl acetate. The organic phase was dried over sodium sulfate and evaporated *in vacuo*. Upon recrystallization from ethyl acetate and *n*-hexane the product (10.18 g) was obtained in 84.6% yield. Mp 70—72 °C; $[\alpha]_D^{20.5}$ −15.4° (*c* 1.0, ethanol); tlc; R_f 0.42 (Solv. 1).

Found: C, 62.35; H, 7.80; N, 7.57%. Calcd for $C_{19}H_{28}N_2O_5$: C, 62.62; H, 7.74; N, 7.69%.

L-Leucyl-δ-aminovaleric Acid Acetate (II). I (4.38 g, 12 mmol) in ethanol (50 ml) and glacial acetic acid (2.5 ml) was hydrogenolyzed in the presence of palladium black for 4 hr. After removal of the catalyst and concentration of the filtrate *in vacuo*, an oily product was obtained in the theoretical yield.

p-Methoxybenzyloxycarboxyl-L-valyl-N$^\delta$-benzyloxycarbonyl-L-ornithyl-L-leucyl-δ-aminovaleric Acid(III). Z(OMe)-L-Val-L-Orn(δ-Z)-$NHNH_2$[11] (6.53 g, 12 mmol) was suspended in DMF (100 ml), followed by the addition of 1.81 M dry HCl in THF (26.51 ml) at −30 °C. After the addition of *n*-butyl nitrite[12] (1.45 ml) the reaction mixture was stirred at −20——30 °C for 15 min. To this azide solution, Et_3N (6.68 ml) and a solution of II(12 mmol) and Et_3N (1.67 ml) in DMF (20 ml) were added dropwise at −60 °C. The stirring was continued at −20 °C for 1.5 hr and at 0 °C for 2 days. After the addition of water (1 l) into the reaction mixture, the precipitate was filtered and washed with 5% citric acid and water. The crude product was recrystallized from DMF and ethyl ether. Yield, 6.24 g (70.1%); mp 177—180 °C; $[\alpha]_D^{24}$ −14.6° (*c* 1.0, DMF); tlc: R_f 0.72 (Solv. 2).

Found: C, 61.33; H, 7.56; N, 9.39%. Calcd for $C_{38}H_{55}N_5O_{10}$: C, 61.52; H, 7.47; N, 9.44%.

L-Valyl-N$^\delta$-benzyloxycarbonyl-L-ornithyl-L-leucyl-δ-aminovaleric Acid Trifluoroacetate(IV). III (5.94 g, 8.0 mmol) was dissolved in trifluoroacetic acid (30 ml) containing anisole (2.56 ml) in an ice-salt bath. After 20 min, the reaction solution was concentrated *in vacuo* at 0 °C. White crystals produced by trituration of the oily residue with ethyl ether were collected by filtration, and after drying weighed 5.30 g (95.8%). Mp 88—90 °C; $[\alpha]_D^{20}$ −17.0° (*c* 1.0, ethanol); tlc: R_f 0.8 (Sov. 3).

p-Methoxybenzyloxycarbonyl-L-valyl-N$^\delta$-benzyloxycarbonyl-L-

ornithyl-L-leucyl-δ-aminovaleryl-L-valyl-N$^{\delta}$-benzyloxycarbonyl-L-ornithyl-L-leucyl-δ-aminovaleric Acid (V). Z(OMe)-L-Val-L-Orn(δ-Z)-L-Leu-δAva-NHNH$_2$[1] (5.30 g, 7.0 mmol) and IV (4.92 g. 7.1 mmol) were subjected to the same treatment as was used for III. After the reaction mixture was stirred for 3 days at 0 °C, water was added to it. The resulting precipitate was separated by centrifugation and washed with 5% citric acid and water. Recrystallization of the dried crude product from DMF and ethyl ether gave 4.96 g (54.4%) of the pure product. Mp 254—257 °C (decomp.); $[\alpha]_D^{20}$ +17.7 °C (*c* 0.1, DMF); tlc: R_f 0.81 (Solv. 1).

Found:,C, 61.22; H, 7.66; N, 10.74%. Calcd for $C_{67}H_{100}N_{10}O_{16}$: C, 61.83; H, 7.74; N, 10.76%.

cyclo-L-*Valyl-N$^{\delta}$-benzyloxycarbonyl-L-ornithyl-L-leucyl-δ-aminovaleryl-L-valyl-N$^{\delta}$-benzyloxycarbonyl-L-ornithyl-L-leucyl-δ-aminovaleryl (VI).* The reaction of V (1.96 g, 1.5 mmol) and di-*p*-nitrophenyl sulfite (4.87 g, 15 mmol) in a mixture of DMF (200 ml) and pyridine (50 ml) at room temperature for 45 hr gave the *p*-nitrophenyl ester of V. In the same manner as described in Ref. 1, the removal of Z(OMe)-group of this ester and the cyclization (1.5×10^{-3} M in pyridine, at 58—60 °C) were carried out. After evaporation of the reaction solution and treatment through columns, Dowex-1 (OH^- form) and Dowex-50 (H^+ form), the effluent was concentrated to dryness *in vacuo* and a white crystalline product was obtained in 33.4% yield. It was recrystallized from aqueous methanol. Yield, 540 mg (32.2%); mp 209—210 °C; $[\alpha]_D^{20}$ −71.7° (*c* 0.3, methanol); tlc: R_f 0.35 (Solv. 1), 0.6 (Solv. 2); mol wt. Found: 1090 (Calcd for $C_{58}H_{90}N_{10}O_{12}$:1119).

cyclo-L-*Valyl-L-ornithyl-L-leucyl-δ-aminovaleryl-L-valyl-L-ornithyl-L-leucyl-δ-aminovaleryl Dihydrochloride (VIII).* The acetate (VII) was dissolved in excess dry methanolic hydrogen chloride (*ca.* 1M) at room temperature. After the solution had been evaporated *in vacuo*, the residue was lyophilized in water. The product was obtained in the theoretical yield. Mp 200—202 °C (decomp.); $[\alpha]_D^{28}$ −63.1 °C (*c* 0.15, ethanol).

Found: C, 50.62; H, 8.93; N, 13.60%. Calcd for $C_{62}H_{80}O_8N_{10}Cl_2\cdot4H_2O$: C, 50.64; H, 8.90; N, 14.06%.

L-*Valyl-L-ornithyl-L-leucyl-δ-aminovaleryl-L-valyl-L-ornithyl-L-leucyl-δ-aminovaleric Acid Trihydrochloride (IX).* V (1.0 g, 0.77 mmol) was hydrogenolyzed in DMF (120 ml) containing concd HCl (1.0 ml) in the presence of palladium black (610 mg) for 22 hr. After removal of the catalyst, the filtrate was concentrated to dryness *in vacuo*. The product was isolated from this crude preparation by countercurrent distribution (0.01 M HCl/*n*-butanol = 10/10 ml, ten transfers). The aqueous layers (No. 3—7) were concentrated to dryness *in vacuo*. The pure product was obtained by recrystallization from methanol and ethyl ether in 60.3% yield (470.3 mg). Mp 221—225 °C; $[\alpha]_D^{26}$ −44.3° (*c* 0.3, ethanol). Paper electrophoresis: migration distance −13.5 cm, *cf.* −10.8 cm for GS dihydrochloride (the same conditions in the case of VII). Amino acid ratios: Val, 0.86; Orn, 1.08; Leu, 1.07; αAva, 0.98.

Found: C, 49.58; H, 9.02; N, 14.17; Cl, 12.66%. Calcd for $C_{42}H_{83}N_{10}Cl_3\cdot H_2O\cdot1/2HCl$: C, 49.71; H, 8.49; N, 13.80; Cl, 12.22%.

Peptides VIII and IX did not exhibit antimicrobial activity toward the microorganisms *Bacillus subtilis, Staphylococcus aureus, Micrococcus flavus, and Sarcina lutea* in concentrations below 100 mcg/ml by the agar dilution method.

The authors are indebted to the members of the Research Laboratories of Toyo Jozo Co., for their elemental analyses and microbiological assays.

(Received March 31, 1975)

α,β-Dibromo-β-diethoxyphosphinylalkane (**2**) was obtained as a stereo-isomeric mixture (erythro : threo= 50 : 50) by the bromination of β-diethoxyphosphinyl-α-alkene, composed of the *E*-isomer and the *Z*-isomer (50 : 50). It was found that the reaction of **2** with sodium azide proceeded stereoselectively to give only the *E*-isomer of α-bromo-β-diethoxyphosphinyl-α-alkene, which could then be converted into α-azido-β-diethoxyphosphinyl-α-alkene (**4**), and α-azido-β-diethoxyphosphinyl-β-alkene, whose configuration was determined by the coupling constants between the phosphorus atom and the vinyl protons. Moreover, the irradiation of **4** yielded a new type of β-diethoxyphosphinyl-α-alkene-α-imine, which later rearranged into the corresponding nitrile.

Although there have been fairly many reports on the synthesis and reaction of the saturated phosphinylalkane, only a little attention has been paid to the unsaturated phosphinyl derivative. We ourselves have reported the synthesis of β-diethoxyphosphinyl-α-alkene and ethyl β-diethoxyphosphinyl-α-alkenoate (**1**) by the reaction of α-nitro-α-alkene or ethyl α-nitro-α-alkenoate with triethyl phosphonate in one step.[2,3]

Because of the pharmacological and structural interest of phosphinyl-2*H*-azirene, aziridine,[4-6] or other phosphinyl derivatives,[7,8] the replacement of the dibromo derivative of **1** (**2**) with sodium azide and the photochemical transformation of the azido derivatives thus obtained will be examined in this paper.

Results and Discussion

*Reaction of **2** with Sodium Azide.* The addition of bromine to 2-diethoxyphosphinyl-1-butene (**1a**), 2-diethoxyphosphinyl-3-methyl-1-butene (**1b**), and ethyl 3-diethoxyphosphinyl-2-pentenoate (**1c**) in chloroform at room temperature for a day gave the corresponding dibromo derivatives, 1,2-dibromo-2-diethoxyphosphinylbutane (**2a**), 1,2-dibromo-2-diethoxyphosphinyl-3-methylbutane (**2b**), and ethyl 2,3-dibromo-2-diethoxyphoshpinyl-pentanoate (**2c**), in good yields.

The ratio of the geometric isomers (*E*-isomer : *Z*-isomer=50 : 50) in **1**, as determined from the intensity of the olefinic proton signals, was maintained in the diastereomers (*erythro* : *threo*=50 : 50) in **2**.

Since the dehydrobromination of **2a**, **b** with triethylamine scarcely proceeded at, all a solution of **2a** in dimethylformamide was treated with sodium azide with stirring at 40—45 °C for 24—35 hr to give 1-bromo-2-diethoxyphosphinyl-1-butene (**3a**) as the main product, together with a small amount of 1-azido-2-diethoxyphosphinyl-2-butene (**5a**). The similar treatment of **2b** gave 1-azido-2-diethoxyphosphinyl-3-methyl-2-butene (**5b**) as the main product, along with a small amount of 1-bromo-2-diethoxyphosphinyl-3-methyl-2-butene (**3b**). Compound **3a** was also obtained in a good yield by the reaction of **2a** with liquid ammonia in a sealed tube at room temperature for 2 days. The treatment of **3a** or **3b** with sodium azide with stirring at 50—55 °C for 45—50 hr gave 1-azido-2-diethoxyphosphinyl-1-butene (**4a**) or 1-azido-2-diethoxyphosphinyl-3-methyl-1-butene (**4b**) respectively in a good yield. On the contrary, the dehydrobromination of **2c** proceeded smoothly with triethylamine to give ethyl 2-bromo-3-diethoxyphosphinyl-2-pentenoate (**3c**); ethyl 2-azido-3-diethoxyphosphinyl-2-pentenoate (**4c**) could not be obtained. This fact may be attributed to the inactivity of the α-bromo atom of the α, β-unsaturated carboxylic ethyl ester. Compounds **3**, **4** and **5** were separated by distillation under reduced pressure or by chromatography on a silica-gel column, using benzene-acetone as the eluent. It is interesting that **3**, **4** and **5** are all composed of only one geometric isomer. The yields, physical constants, and spectral data are summarized in Tables 1 and 2.

The stereochemical assignment of **3**, **4** and **5** was made on the basis of elementary and spectroscopic analyses. The IR spectra of **3** and **4** showed a weak band of the carbon-carbon double bond in the 1575—1618 and 1610 cm^{-1} regions respectively, and strong bands of the diethoxyphosphinyl group in the 1240—1260 (≫P=O) and 1020—1025 (≫P-O-C) cm^{-1} regions, while that of **5** showed a band of the carbon-carbon double bond at 1625—1630, ≫P=O in the 1235—1250 region, and ≫P-O-C at 1025 cm^{-1}. The absorption pattern of **3**, **4** and **5** is essentially the same as that of the starting material (**1**) except for the characteristic strong azido band of **4** and **5** appearing in the 2100—2110 cm^{-1} region. The NMR spectra of **3**, **4** and **5** showed a vinyl hydrogen signal in the α- or γ-position with regard to the β-phosphorus atom in lower magnetic fields, and with smaller coupling constants ($J_{P,H}$=12.0—23.0 Hz), in comparison with those of the *E*-isomer ($J_{P,H}$=22.3—23.0 Hz) and the *Z*-isomer ($J_{P,H}$=48.0—59.0 Hz) of **1**[3] and others appearing in the literature.[9] From the above results, it may be deduced that the dehydrobromination of **2** proceeded stereoselectively to give only an *E*-isomer and that the configuration was retained in the subsequent substitution of the bromine atom of **3** with the azido group.

*Irradiation of **4a** and **5b**.* A solution of **4a** in cyclohexane was irradiated in a stream of nitrogen by means of an external high-pressure mercury lamp for

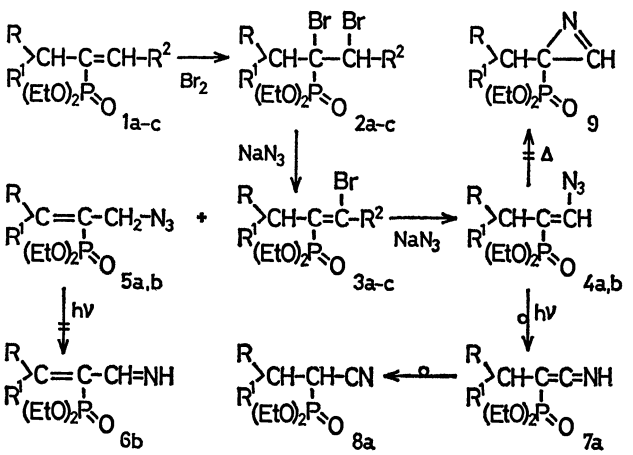
a day until the azido band at *ca.* 2100 cm^{-1} had disappeared at room temperature; the chromatographic separation of the resultant solution gave 2-diethoxyphosphinyl-1-butene-1-imine (**7a**) in a 30% yield and a small amount of 2-diethoxyphosphinyl-butanenitrile (**8a**), instead of the expected 1-ethyl-1-diethoxyphosphinyl-2*H*-azirene (**9**). Since the irradiation of the isolated **7a** gave **8a** in a 17% yield, it was concluded that **8a** was derived from **7a** by the 1,3-shift of hydrogen.[10] On the other hand, the irradiation of **5b** in cyclohexane in a stream of nitrogen by means of a high-pressure mercury lamp gave several kinds of products, none yielding the expected 2-diethoxyphosphinyl-3-methyl-2-butene-1-imine (**6b**). The structures of the products are now under investigation.

The IR spectrum of **7a** showed a characteristic strong band at 2070, and that of **8a** showed a weak nitrile band at 2250 cm^{-1}, causing the band at



a; R=CH_3, R^1=R^2=H b; R=R^1=CH_3, R^2=H c; R=CH_3, R^1=H, R^2=COOEt

Scheme 1.

2070 cm^{-1} to disappear. On the other hand, the NMR spectrum of **7a** showed the imino proton signal at δ 4.80. These spectral data support the structures of **7** and **8**.

Experimental

All the boiling points are uncorrected. The IR spectra were recorded with a Hitachi EPI-S2 Spectrometer. The NMR spectra were measured with a JNM-4H-100 Spectrometer (Japan Electron Optics Laboratory Co., Ltd.), using tetramethylsilane as the internal standard.

Material. Compounds **1a—c** were prepared by the method previously reported.[3]

*Reaction of **1a** and **1b** with Bromine.* Into a solution of **1a** (19.2 g, 0.1 mol) in chloroform (70 ml), a solution of bromine (16 g, 0.1 mol) in chloroform (30 ml) was stirred portion by portion, at room temperature. The resultant solution was sealed tightly in a vessel (200 ml) and allowed to stand overnight at room temperature, and then the solution was concentrated. The residual oil was distilled under reduced pressure to give **2a** as a colorless oil.

In a similar manner, equimolar amounts of **1b** and bromine were reacted to give **2b** as a colorless oil after standing for 2 days.

*Reaction of **1c** with Bromine.* Into a solution of **1c** (7.5 g, 0.03 mol) in chloroform (30 ml), a solution of bromine (4.8 g, 0.03 mol) in chloroform (10 ml) was stirred at room temperature. After having been heated in a sealed tube at 100 °C for 12 hr, the reaction solution was concentrated. The residual syrup was purified on a silica-gel column, using benzene–acetone (10 : 1 V/V) as the eluent; the eluent solvent was then evaporated under reduced pressure to give **2c** as a colorless syrup which could not be distilled.

*Reaction of **2a** and **2b** with Sodium Azide.* Into a mixture of sodium azide (3.9 g, 0.06 mol) in dry dimethylformamide (50 ml), we stirred a solution of **2a** (7.04 g, 0.02 mol) in dimethylformamide (5 ml), portion by portion, at room temperature. After continuous stirring at 40 °C for 25 hr, the reaction solution was poured into ice water (300 ml), and then the aqueous solution was stirred for 1 hr. The solution was extracted well with benzene (100 ml) three times. The benzene extracts were washed with water twice, dried over anhydrous sodium sulfate, and then evaporated under reduced pressure to give a yellow oil. The purification of the oil on a silica-gel column, using benzene–ethyl ether (20 : 1 V/V) as the eluent, and the evaporation of the eluent solvent under reduced pressure gave **3a** from the first fraction and **5a** from the last fraction, both as colorless oils.

In a similar manner, Compound **2b** was reacted with sodium azide in dimethylformamide to give **3b** and **5b**.

*Reaction of **2a** with Liquid Ammonia.* Compound **2a** (7.04 g, 0.02 mol) was dissolved in liquid ammonia (15 ml), and then the solution was allowed to stand in a sealed tube at room temperature for 2 days. To the reaction solution, dry chloroform (20 ml) was then added. After the removal of the ammonium bromide deposited, the chloroform solution was concentrated. The residual oil was purified on a silica-gel column, using benzene–ethyl ether (20 : 1 V/V), to give **3a** as a colorless oil in a 67.5% yield.

*Reaction of **3a** and **3b** with Sodium Azide.* Into a mixture of sodium azide (6.5 g, 0.1 mol) in dry dimethylformamide (70 ml), a solution of **3a** (3.8 g, 0.014 mol) in dimethylformamide (5 ml) was stirred, portion by portion, at room temperature. After continuous stirring at 50 °C for 56 hr, the reaction solution was poured into ice water (300 ml), and then the aqueous solution was stirred for 1 hr. The solution was extracted well with benzene (100 ml) three times. The benzene extracts were washed with water twice, dried over anhydrous magnesium sulfate, and finally evaporated under reduced pressure to give a yellow syrup. Purification on a silica-gel column, using benzene–ethyl ether (10 : 1 V/V), and the evaporation of the eluent solvent under reduced pressure gave **4a** as a colorless syrup.

In a similar manner, Compound **4b** was obtained as a colorless syrup by the reaction of **3b** with sodium azide in dimethylformamide.

*Reaction of **2c** with Sodium Azide.* Into a mixture of sodium azide (3.9 g, 0.06 mol) in dry dimethylformamide (50 ml), we stirred, portion by portion, a solution of **2c** (8.2 g, 0.02 mol) in dimethylformamide (5 ml) at room temperature. After continuous stirring at room temperature for 15 hr, the reaction solution was poured into ice water (300 ml), and then the aqueous solution was stirred for 1 hr. The solution was extracted well with benzene (100 ml) three times. The benzene extracts were washed with water twice, dried over anhydrous magnesium sulfate, and then finally evaporated under reduced pressure to give a yellow syrup. The purification of the syrup on a silica-gel column, using benzene–acetone (7 : 1 V/V), and the evaporation of the eluent solvent under reduced pressure gave **3c** as a colorless syrup which could not be distilled.

*Irradiation of **4a**.* A solution of **4a** (2.0 g, 0.0086 mol) in cyclohexane (50 ml) was irradiated in a stream of nitrogen by means of a 500 W high-pressure mercury lamp at room temperature for 6 hr. After the removal of the solvent under reduced pressure, the residual syrup was purified on a silica-gel column, using carbon tetrachloride–acetone (5 : 1 V/V), and then the eluent solvent was evaporated to give **7a** in a 30% yield from the first fraction and **8a** in a 7% yield from the last fraction, both as colorless syrups. **7a**; IR (KBr disk): 2080 (C=C=N), 1635 (C=C), 1243 (P=O), and 1225 (P–O–C) cm^{-1}. NMR ($CDCl_3$): δ 4.80 (1H, broad s, NH) and 1.72—2.24 (2H, m, $CH_3\underline{CH_2}-C=$). The structure of **7a** was confirmed by means of the spectral data and by its conversion into **8a**. **8a**; IR (KBr disk): 2230 (C≡N), 1260 (P=O), and 1220 (P–O–C) cm^{-1}. NMR ($CDCl_3$): δ 2.70—3.14 (1H, m, $-CH_2\underline{CH}-C\equiv$).

Found: N, 6.58%. Calcd for $C_8H_{16}NO_3P$: N, 6.83%.

*Isomerization of **7a** to **8a**.* A solution of **7a** (0.2 g, 0.00086 mol) in dry tetrahydrofuran (30 ml) was irradiated in a stream of nitrogen by means of a 500 W high-pressure mercury lamp at room temperature for 10 hr. After the subsequent removal of the solvent under reduced pressure, the residual syrup was purified on a silica-gel column, using benzene–acetone (5 : 1 V/V), and then the solvent was evaporated under reduced pressure to give **8a** in a 17% yield.

The authors are grateful to the Ministry of Education, Japanese Government, for its financial support of this work.

Aminocyclitols. 32. Synthesis of Inosadiamine-1,4[1]

Tetsuo SUAMI, Kinnichi TADANO, and Sumio HORIUCHI

Department of Applied Chemistry, Faculty of Engineering, Keio University, Hiyoshi, Yokohama 223

(Received April 15, 1975)

Three new inosadiamines have been prepared by nitromethane cyclization of dialdehyde, followed by catalytic hydrogenation. Their structures were established to be *scyllo*-1,4, *myo*-1,4, and *epi*-inosadiamine-3,6 by PMR spectra.

Nitromethane cyclization of dialdehydes is a well known and well studied reaction in a field of carbohydrate chemistry.[2] The first successful application of this reaction to a carbohydrate was accomplished by Sowden and Fischer[3] in 1944 and later Grosheintz and Fischer[4,5] extended this reaction to intramolecular cyclization to prepare nitrodeoxyinositols. These reactions were extensively studied by several investigators.[6–10]

In connection with the preceding paper of this series,[11] we have attempted to prepare an inosadiamine-1,4 by means of the nitromethane cyclization of dialdehydes. In the present article, we wish to report the synthesis of three new inosadiamines: *scyllo*-1,4, *myo*-1,4, and *epi*-inosadiamine-3,6.

The starting material: 1,4-di-*O*-acetyl-2,3-*O*-cyclohexylidene-(1,4/2,3,5-5)-acetamide-1,2,3,4-cyclopentanetetrol (**1**) was prepared by the method of Ahluwalia *et al.*[12] Mild hydrolysis of **1** in 80% aqueous acetic acid afforded 1,4-di-*O*-acetyl-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol (**2**).[13] The 1,4-di-*O*-benzoyl derivative (**3**) was prepared by the analogous reaction process.

Compound **2** was oxidized by periodate in an aqueous solution to give 3-acetamido-2,4-di-*O*-acetyl-2-deoxy-*xylo*-pentodialdose (**4**) as a syrup. Compound **4** was treated with nitromethane under the presence of sodium methoxide. The product was hydrogenated in the presence of Raney nickel under a hydrogen atomosphere and subsequently acetylated. The product was fractionated by means of recrystallization and column chromatography to give three new hexaacetyl inosadiamines (**7**), (**8**) and (**9**) in 3.5, 39, and 1.3% yields, respectively.

In the case of the reactions starting from the di-*O*-benzoyl derivative **3**, the analogous results were obtained.

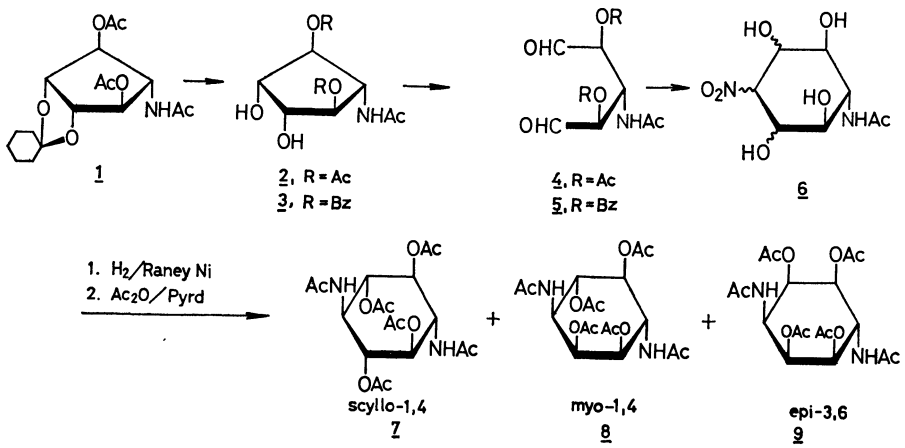
TABLE 1. CHEMICAL SHIFTS OF THE ACETYL METHYL PROTONS IN DMSO-d_6 (60 MHz) IN τ-VALUE

Compound		Acetoxy		Acetamido	
		ax.	eq.	ax.	eq.
7	*scyllo*-1,4		8.07(12H)		8.22(6H)
8	*myo*-1,4	7.82(3H)	8.05(3H)		8.20(3H)
			8.09(3H)		8.23(3H)
			8.10(3H)		
9	*epi*-3,6	7.88(6H)	8.13(6H)		8.17(3H)
					8.24(3H)

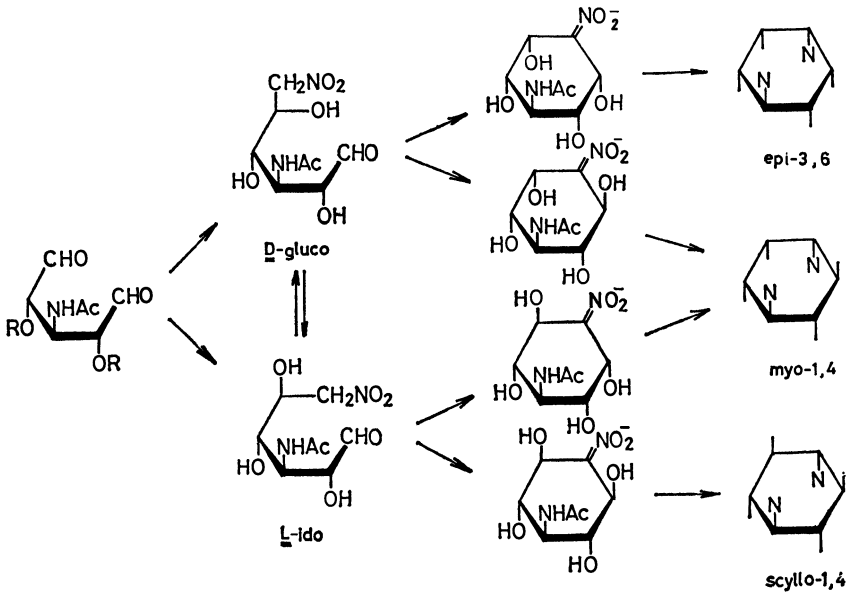
There are fourteen theoretically possible isomers in inosadiamine-1,4 and five ones are already described in the literatures.[14–17] The three inosadiamines obtained in the present experiment are not identical with any one of these known isomers. In the present reaction, three new chiral centers are introduced in the products and therefore, six isomers are conceivable. Among these six isomers, *muco*-3,6[16] and *chiro*-inosadiamine-1,4[15] are known isomers.

Compound **7** should be one of the remaining four unknown compounds. The PMR spectrum of **7** revealed a simple pattern of the signals due to the acetyl methyl protons and this was only compatible with hexaacetyl *scyllo*-inosadiamine-1,4.

The PMR spectrum of **8** revealed six sharp signals with a same intensity of three protons. The two signals at τ 8.20 and 8.23 are attributed to the two equatorial acetamido groups and the signal at τ 7.82 is due to an axial acetoxy group.[19] The other three signals are attributed to the equatorial acetoxy groups



Scheme 1.



Scheme 2.

and therefore, **8** was assigned as hexaacetyl *myo*-inosadiamine-1,4.

Compound **9** showed four sharp signals in its PMR spectrum. The signal at τ 7.88 is attributed to the two axial acetoxy groups and the two signals at τ 8.17 and 8.24 are due to the two equatorial acetamido groups. Hence, **9** was assigned to be hexaacetyl *epi*-inosadiamine-3,6.

Besides the above described three inosadiamines, another minor product was detectable on tlc, but the structural assignment of this product was unsuccessful owing to a poor yield.

The reaction mechanism of nitromethane cyclization has been well studied by Kovar and Baer[6] using 6-deoxy-3-*O*-methyl-6-nitro-D-glucose and -L-idose. The present experiments are coincident with their results.[6]

In the present reaction, the initial step of the reaction is an addition reaction between nitromethane and one of the two aldehyde groups in **4** to give two diastereomers: D-*gluco* and L-*ido* type intermediates. The second step of the reaction is intramolecular cyclization of the intermediates to give *myo*-1,4 and *epi*-3,6 type compounds from the D-*gluco*, and *myo*-1,4 and *scyllo*-1,4 type compounds from the L-*ido* *via* corresponding nitronate salts.

Exeprimental

All melting points were determined in capillary tubes and are uncorrected. Solutions were evaporated under diminished pressure below 40 °C. Acetylation was carried out with acetic anhydride in pyridine. PMR spectra were measured at 60 MHz on a Varian A-60D in dimethyl sulfoxide-d_6 (DMSO-d_6) with reference to tetramethylsilane as an internal standard and the peak positions are given in τ values.

*3-Acetamido-2,4-di-*O*-acetyl-3-deoxy*-xylo-*pentodialdose* (**4**). 1,4-Di-*O*-acetyl-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol (**2**) was prepared by the method of Suami *et al.*[13] from 1,4-di-*O*-acetyl-2,3-*O*-cyclohexylidene-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol.[12] Compound **2** (6.0 g) was dissolved in cold water (60 ml) and sodium metaperiodate (5.13 g) was added to the solution under ice cooling with agitation. The solution was stirred overnight at room temperature and neutralized with sodium hydrogencarbonate. Methanol (60 ml) was added to the solution and the mixture was settled overnight in a refrigerator. The mixture was filtered and the filtrate was evaporated. The residue was extracted with a mixture of ethanol and ethyl acetate (1 : 1, v/v) and the extract was evaporated to give a crude product of **4** (6.7 g) as a pale yellow syrup. The product showed a positive Fehling test and a spot on tlc at R_f 0.3 in benzene–ethanol (5 : 1, v/v) solvent system.

*3-Acetamido-2,4-di-*O*-benzoyl-3-deoxy*-xylo-*pentodialdose* (**5**). 2,3-*O*-Cyclohexylidene-(1,4/2,3,5)-5-acetamide-1,2,3,4-cyclopentanetetrol[13] (1.37 g) was acylated with benzoyl chloride (1.8 ml) in pyridine (25 ml). After the mixture was agitated for 2 hr, the mixture was poured into ice cold water (600 ml) to give crystals. The crystals were collected by filtration to give 2.40 g (99%) of 1,4-di-*O*-benzoyl-2,3-*O*-cyclohexylidene-(1,4/2,3,5)-5-acetamide-1,2,3,4-cyclopentanetetrol, mp 187—188 °C.

Found: C, 67.92; H, 6.13; N, 2.77%. Calcd for $C_{27}H_{29}NO_7$: C, 67.63; H, 6.10; N, 2.92%.

The above described product (2.5 g) was heated in 80% aqueous acetic acid (70 ml) under reflux for 3 hr and the solution was evaporated to give a crystalline residue. The residue was recrystallized from a mixture of ethanol and ethyl acetate (1 : 5, v/v) to give 1.61 g (72%) of 1,4-di-*O*-benzoyl-(1,4/2,3,5)-5-acetamido-1,2,3,4-cyclopentanetetrol (**3**), mp 177—178 °C.

Found: C, 62.95; H, 5.41; N, 3.35%. Calcd for $C_{21}H_{21}NO_7$: C, 63.15; H, 5.30; N, 3.51%.

Compound **3** (7.64 g) was dissolved in ethanol (200 ml) and a solution of sodium metaperiodate (7.01 g) in cold water (300 ml) was added to the solution under ice cooling with agitation. After stirred overnight at room temperature, the mixture was neutralized with sodium hydrogencarbonate. The mixture was filtered and the filtrate was evaporated to give 7.14 g (94%) of **5** as a crude syrup. The product showed a positive Fehling test and a spot on tlc at R_f 0.7 in benzene–ethanol (5 : 1, v/v) system.

Nitromethane Cyclization of **4**. To a mixture of **4** (6.7 g), nitromethane (2.4 ml) and methanol (30 ml), 2.2 M methanolic sodium methoxide (20 ml)was added under ice cooling

with agitation. After settled overnight in a refrigerator, the reaction mixture was adjusted to pH 6 with glacial acetic acid and evaporated to give a brown residue (11.9 g).

Hexaacetyl scyllo-*Inosadiamine-1,4 (7).* The crude nitromethane cyclization product (11.9 g) was hydrogenated in water (25 ml) under the presence of Raney nickel T-4 catalyst[18] in 3.4 kg/cm^2 hydrogen atomosphere for 12 hr. After the catalyst was removed by filtration, the solution was evaporated to give a dark residue (11.5 g). The residue was acetylated overnight at room temperature to give a dark product. The product was recrystallized two times from ethanol to give 120 mg of **7**, mp above 290 °C. The mother liquor was evaporated and the residue was recrystallized from ethanol to give another crop of **7** (207 mg). Total yield was 327 mg (3.5% from **4**).

Found: C, 49.95; H, 6.03; N, 6.52%. Calcd for $C_{18}H_{26}N_2O_{10}$: C, 50.23; H, 6.09; N, 6.51%.

Hexaacetyl myo-*Inosadiamine-1,4 (8).* The ethanolic mother liquor of **7** was evaporated and the residue was recrystallized from a mixture of benzene and ethanol (5 : 1, v/v) to give 2.50 g of **8**. The mother liquor was evaporated and the residue was fractionated on a silica gel column (Wakogel C-300, 80 g, 30×400 mm) with benzene-ethanol (5 : 1, v/v) as an eluating solvent. The fractions which showed a single spot on tlc at R_f 0.28 in the same solvent system were collected and evaporated to give another crop of **8** (1.14 g). The product was recrystallized from ethanol to give 3.63 g (39% from **4**) of **8**, mp 258—259 °C.

Found: C, 50.39; H, 6.11; N, 6.47%. Calcd for $C_{18}H_{26}N_2O_{10}$: C, 50.23; H, 6.09; N, 6.51%.

Hexaacetyl epi-*Inosadiamine-3,6 (9).* Another product was obtained from the column chromatography by collecting the fractions which showed a single spot at R_f 0.26 on tlc in the same solvent. The product was recrystallized from a mixture of benzene and ethanol (5 : 1, v/v) to give 121 mg (1.3% from **4**) of **9**, mp 228—230 °C.

Found: C, 50.07; H, 6.05; N, 6.51%. Calcd for $C_{18}H_{26}N_2O_{10}$: C, 50.23; H, 6.09; N, 6.51%.

The mother liquor was evaporated and the residue was recrystallized repeatedly from a mixture of acetone, benzene and ethyl acetate (1 : 10 : 1, v/v) to give 5 mg of hexaacetyl inosadiamine, mp 278—280 °C. The product showed practically a single spot at R_f 0.20 on tlc in a benzene-ethanol (5 : 1, v/v) solvent system and gave a correct analysis for hexaacetyl inosadiamine (Found: C, 50.37, H, 6.26; N, 6.71%).

Nitromethane Cyclization of **5**. To a mixture of **5** (8.5 g), nitromethane (10 ml) and methanol (200 ml), 2.2 M methanolic sodium methoxide (30 ml) was added under ice cooling with agitation. The reaction mixture was worked up as described in the case of **4** to give compounds **7**, **8** and **9** in 4.1, 32 and 1.6% yields, respectively.

The authors express their sincere thanks to Mr. Saburo Nakada for his elementary analyses.

The Hydroxyphenylation of Methylstyrenes with Phenylpalladium Chloride

Hiroshi HORINO and Naoto INOUE

Department of Chemistry, College of General Education, Tohoku University, Kawauchi, Sendai 980

(Received April 16, 1975)

The reaction of α- or β-methylstyrene with phenylpalladium chloride in aqueous acetone were studied. From *cis*- or *trans*-β-methylstyrene, a mixture of *erythro* and *threo* isomers of hydroxyphenylation products PhMeCHCHOHPh (VIa, VIb) and chlorophenylation products PhMeCHCHClPh (IVa, IVb) were obtained accompanying the phenylated olefins (I, II, and III). The main reaction product was the tertiary alcohol $PhCH_2C(OH)MePh$ (V). The reaction of α-methylstyrene with phenylpalladium chloride gave V exclusively. Phenylpalladium acetate and phenylpalladium bromide were used as phenylating agents. The yields of hydroxyphenylation products are in decreasing order: chloride > bromide > acetate.

Recently, Heck reported a new arylation of olefins with the reactive organopalladium compounds prepared *in situ* from organomercurials and palladium salts to give the arylated olefins.[1)]

When the Heck reaction was applied to some conjugated benzocycloalkenes with phenylpalladium chloride in protic solvents, the phenyl group and an anion part of the protic solvent were found to add to the olefins simultaneously (Oxyphenylation)[2a,b)] The formation of the oxyphenylation products was illustrated by solvolysis of the organopalladium intermediate in which *cis*-elimination of hydridopalladium moiety is prevented by the *cis* configuration between a vicinal phenyl group and the palladium atom.[2b)]

In order to study the general applicability of the oxyphenylation reaction and clarify the reason why the *trans* isomer is obtained exclusively in the reaction of conjugated benzocycloalkenes, we extended our studies to acyclic olefins conjugated to a benzene ring.

In this paper, we describe the reaction of styrene, α- and β-methylstyrene with phenylpalladium chloride in an aqueous acetone.

Results and Discussion

The reaction of *cis*-β-methylstyrene with an equivalent amount of phenylpalladium chloride gave a complicated mixture of products which produced seven peaks in its gas chromatogram. Identification of these compounds was carried out by gas chromatographic analyses (glc) and also isolation by elution column chromatography. They are numbered I, II, III, IV, V and VI in the order of their appearance in the gas chromatogram. (Table 1). Although compounds I and II were unable to be isolated due to their poor yield, they were determined by glc analysis to be *cis*-1,2-diphenyl-1-propene[3)] and 2,3-diphenyl-1-propene,[3)] respectively.

Column chromatography succeeded in isolating the other products. Three crystalline products III (mp 79 °C), IVa (mp 138 °C) and IVb (mp 44 °C) were obtained upon elution with *n*-hexane. Compound III was identified as *trans*-1,2-diphenyl-1-propene.[3)] Further elution with a mixture of benzene and *n*-hexane (1 : 1) produced crystals with a mp of 50 °C (V), whose IR spectrum showed the presence of a carbinol moiety at 3600—3500 cm^{-1} and 1100 cm^{-1}. The structure of V was determined to be 1,2-diphenylpropan-2-ol by comparison with an authentic sample.[5)]

Elution with benzene gave an oily substance VI having absorption bands at 3500—3300 cm^{-1} and 1030—1000 cm^{-1} (carbinol). However, the comparison of the NMR spectrum of VI with those of authentic samples[3)] indicate that VI is a mixture of *erythro*- and

a) In a mixture of acetone and water (1 : 1) at 30 °C for 2 hr. b) *c*-MS; *cis*-β-methylstyrene. *t*-MS; *trans*-β-methylstyrene. α-MS; α-methylstyrene. c) Determined by glc analysis (PEG 20M, 180 °C) using α-methylstilbene as the external standard. d) As the decomposition of IVb occurred during glc analyses, the net yield of IV (17%) and the ratio of *erythro* to *threo* IVa/IVb (30/70) was determined independently by column chromatography. e) Only the *erythro* isomer IVa was detected. f) The ratio of *erythro* to *threo* isomer VIa/VIb (47/53) (NMR). g) VIa/VIb (34/66) (NMR).

threo-1,2-diphenylpropan-1-ol (VIa and VIb). The doublet peaks centered at 1.07 and 1.35 ppm were assigned to the methyl protons of VIa and VIb, respectively. The NMR spectrum shows that VI consists of VIa and VIb in a ratio of 47 : 53.

Both IVa and IVb showed the same gas chromatographic peak. The patterns of the NMR spectra of IVa and IVb were very similar to those of VIa and VIb, respectively, and their elemental analyses correspond to $C_{15}H_{15}Cl$. The treatment of VIb with thionyl chloride produced two chlorides which were found to be identical with IVa and IVb. Since the chemical shift of the methyl protons of the *erythro* isomer VIa is located at higher magnetic field than that of the *threo* isomer VIb, the doublet peak centered at 1.17 ppm for IVa and that of 1.54 ppm for IVb were assigned to the methyl protons of *erythro* and *threo*-1,2-diphenylpropyl chloride, respectively. This is the first example of chloride formation in the Heck reaction without cupric chloride. Attention should be called to the glc analysis (PEG 20 M, 180 °C) in which the *threo* chloride IVb decomposed to give olefines I (5.6%), II (4.4%) and III (76%). On the other hand, the *erythro* isomer IVa decomposed to III only in a 12% conversion with the recovery of IVa.

The product distribution in the reactions of *trans*-β-methylstyrene under the same conditions was different from that of *cis*-β-methylstyrene in the following points: 1) the amount of chloride IV from the *trans* olefin was considerably greater than that from the *cis* olefin, 2) only the *erythro* chloride IVa was isolated in the reaction with the *trans* olefin, and 3) the ratio of *erythro* alcohol VIa to the *threo* isomer VIb was determined to be 34 : 66, whereas the *cis* olefin gave a ratio of 47 : 53.

The reaction of α-methylstyrene with phenylpalladium chloride under the same conditions gave the tertiary alcohol V (91.9%) accompanying a small amount of olefins I and III. Styrene reacted with phenylpalladium chloride under the same conditions to give a mixture of *trans*-stilbene (88%) and 1,2-diphenylethanol[6] (6%).

Isolation of the chlorides IVa and IVb is based on the assumption that the hydroxyphenylated product, *e.g.*, the alcohols VIa and VIb, may be derived from IVa and IVb. With the view of confirming this possibility, the chlorides IVa and IVb were treated with a mixture of lithium chloropalladite and mercuric chloride in 50% aqueous acetone at 30 °C for 2 hr. The *threo* isomer IVb gave a mixture of VIa and VIb (34 : 66) with a conversion of 76.3%. On the other hand, the *erythro* isomer VIa was unchanged under the same conditions. This fact indicates that a part of the secondary alcohols VIa and VIb was formed *via* *threo*-1,2-diphenylpropyl chloride IVb.

Heck[1b] proposed step by step and stereospecific reaction mechanisms consisting of the *cis* addition of the phenylpalladium compound to the olefins and subsequent *cis* elimination of the hydridopalladium species. The phenylated olefins I, II and III were obtained in the reaction of *cis*-β-methylstyrene with phenylpalladium acetate. (PhPdOAc in place of PhPdCl in Fig. 1). However, II and III cannot arise from the direct *cis* elimination of hydridopalladium

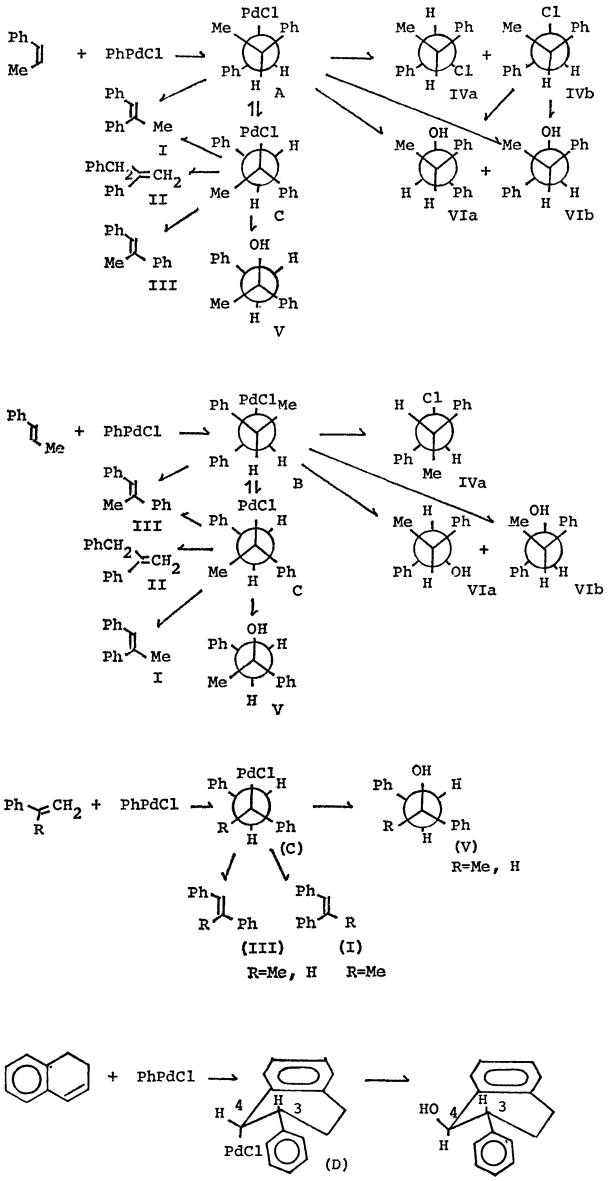

Fig. 1

acetate (HPdOAc) from the initially formed intermediate (A). To explain the formation of II and III, he proposed the formation of a rearranged intermediate (C) which is able to produce the olefins by the *cis* elimination of HPdOAc. The complex C was also used to illustrate the formation of the unexpected olefins I and II from *trans*-methylstyrene.

Henry[7] has studied the stereochemistry of the acetoxypalladation of cyclohexene. He suggested that the reaction intermediate, the *trans* acetoxypalladium compound, was decomposed by the chloride ion *via* the S_N1 mechanism to give the *trans* chloroacetate (with retention of configuration), while *cis* diacetate was produced by reaction with the acetate ion in S_N2 fashion (with inversion of configuration).[8]

Applying the mechanism proposed by Heck and Henry, our experimental results can be explained by the reaction scheme shown in Fig. 1. A *cis* addition of phenylpalladium chloride to *cis* and *trans*-β-methylstyrenes produced the organopalladium intermediates

A and B, respectively. Phenylated olefins I and III are formed by the *cis* elimination of HPdCl from A and B, respectively, while C explains the formation of II and III from *cis*-methylstyrene, or the production of I and II from the *trans* olefin. The secondary chlorides (IVa and IVb) and the secondary alcohols (VIa and VIb) are produced by S_N1-type substitution with the chloride ion and S_N1-type hydrolysis of A and B.

The ratio of *erythro* to *threo* IVa/IVb (30/70) from *cis*-methylstyrene shows that IVb is the main product in S_N1-type substitution of A with the chloride species. However, the failure to isolate IVb from *trans* methylstyrene may be attributed not only to the sensitivity of IVb to hydrolysis under the reaction conditions but also to the small quantity of IVb in this S_N1-type substitution of B. The retention of configuration tendency in the chloride formation is consistent with Henry's conclusion mentioned above. Also, unsuccessful isolation of the expected tertiary chloride from C may be due to its higher reactivity, even if it is produced.

The formation of the tertiary alcohol V from either A or B is unimaginable. The rearrangement of A and B to the tertiary intermediate C is necessary to explain the formation of V. In a protic solvent, the carbon-palladium bond of A, B and C may be somewhat ionic, since the carbon atom bearing the palladium atom is located at a benzylic position liable to solvolysis. On the assumption that the stability of A, B and C is based only on the structure of the benzylic carbon, the tertiary intermediate C is more favorable to the secondary A and B. If an equilibrium between A or B and C exists,[1b] the higher reactivity of C increases the amount of V at the expense of IV and VI. This is supported by the exclusive formation of V from α-methylstyrene. The yield of V is higher than VIa and VIb in the reaction of both *cis* and *trans* β-methylstyrenes.

In previous papers,[2] the authors reported that the oxyphenylation of conjugated benzocycloalkenes gave large quantities of the *trans* alcohols. The elimination of hydridopalladium species between C_3 and C_4 from D (Fig. 1) is difficult because of its *trans* configuration. The exclusive formation of the *trans* alcohol was interpreted on the basis of the prevention of *cis* S_N1-type attack at C_4 by *cis* phenyl group at C_3. However, the corresponding hydroxyphenylation products from methylstyrenes were a mixture of *erythro* and *threo* isomers (VIa and VIb). In the case of acyclic A or B, it is possible to rotate around the carbon-carbon bond of A or B to give the most favorable conformation for S_N1-type solvolysis. Therefore, S_N1-type substitution is rather general for the palladium intermediate in hydroxy- or oxyphenylation.

In order to examine the effect of a chloride ion, the reactions of methylstyrene with phenylpalladium acetate were carried out in the same conditions as in the case of phenylpalladium chloride. The glc and IR analyses of the reaction products indicate the absence of alcohols, but the phenylated olefins I, II and III were obtained in good yields (Table 1).

The reaction of methylstyrenes with phenylpalladium bromide in aqueous acetone gave predominantly phenylated olefins (I, II and III). A trace of the tertiary alcohol V in the reaction of β-methylstyrene suggests the characteristic distinction between bromide and chloride ions (Table 1). However, α-methylstyrene reacted with phenylpalladium bromide producing predominantly V. It is not clear why the ligands of the palladium complexes and the position of the methyl groups on the substrate play a significant role in controlling the direction and extent of the hydroxyphenylation.

Experimental

All melting points and boiling points are uncorrected. Glc analyses were performed using a Shimadzu GC 5A on a 2 m column packed with 5% PEG 20 M. IR and NMR spectra were measured with a Hitachi 215 grating infrared spectrometer by the KBr method, and with a Hitachi R22 in carbon tetrachloride or deuteriochloroform using TMS as the internal standard.

Materials. *cis*-β-Methylstyrene[9] and *trans*-β-methylstyrene[9] were synthesized by decarboxylation of α-methylcinnamic acid and by reduction with cinnamic chloride with lithium aluminum hydride. Styrene and α-methylstyrene of commercial grade were used for distillation before use. Phenylmercuric chloride was prepared by treating commercial phenylmercuric acetate with lithium chloride.

Standard Samples. According to the appropriate references, the following standard samples were synthesized, with which the reaction products were compared by glc analyses, mixed-melting-point tests and spectroscopic techniques.

cis-1,2-diphenyl-1-propene I, mp 46—48 °C (lit,[3] mp 47—48 °C; Found: C, 92.71; H, 7.32%); *trans*-1,2-diphenyl-1-propene III, mp 81—82 °C (lit, [3,5] mp 81—82 °C; Found: C, 92.85; H. 7.41%); 2,3-diphenyl-1-propene II, bp 113—114 °C/4 Torr (lit,[4] 140—143 °C under reduced pressure; Found: C, 92.62; H, 7.38%); *erythro*-1,2-diphenylpropan-1-ol VIa, mp 49—51 °C (lit,[3] mp 50—51 °C; Found: C, 84.20; H, 7.56%); *threo*-1,2-diphenylpropan-1-ol VIb, mp 27 °C (bp 136—137 °C/1—2 Torr. Reported as an oily substance[3]; Found: C, 84.88; H, 7.70%); *p*-nitrobenzoate of VIb, mp 142—143 °C (lit,[3] mp 143—144 °C; Found: C, 73.20; H, 5.42; N, 3.78%); 1,2-diphenylpropan-2-ol V, mp 50 °C (lit,[5] mp 50—51 °C; Found: C, 84.88; H. 7.65%).

erythro- *and* threo-*1,2-Diphenylpropyl Chloride IVa and IVb.* Thionyl chloride (0.72 g, 6 mmol) was added to a cooled solution of VIb (1.06 g, 5 mmol) in dry ether (20 ml) with stirring. The solution became turbid when pyridine (0.2 ml) was introduced. The reaction mixture was stirred for 30 min, and then refluxed for 2 hr. After evaporation of the solvent by suction, the residue was recrystallized from *n*-hexane to give 25 mg of VIa, mp 132—133 °C. Concentration of the mother liquor yielded 955 mg of IVb, mp 48—50 °C. Recrystallization of IVa and IVb was carried out from *n*-hexane and *n*-pentane, respectively. IVa, mp 138 °C. Found: C, 78.09; H, 6.53%. Calcd for $C_{15}H_{15}Cl$: C, 78.09; H, 6.55%. IVb, mp 55 °C. Found: C, 78.29; H, 6.75%. Calcd for $C_{15}H_{15}Cl$: C, 78.09; H, 6.55%.

General Procedure for the Reaction of Methylstyrenes with Phenylpalladium Chloride. To a solution of palladium chloride (1.78 g, 10 mmol) and lithium chloride (0.85 g, 20 mmol) in aqueous acetone (50%, 200 ml), the olefin (12 mmol) and then phenylmercuric chloride (3.13 g, 10 mmol) were added. The mixture was stirred for 2 hr at 30 °C, and then poured into a saturated solution of sodium chloride. The resulting oil was extracted with benzene, dried over

sodium sulfate, and then evaporated under reduced pressure. The residue was diluted with ether to provide a sample solution for glc analysis. After the solvent was replaced with *n*-hexane, the solution was chromatographed on a silica gel column (Wako gel C 200, 60 g). Each volume of these eluted fractions was maintained below 60 ml, some of which were analysed by glc and also checked by IR spectra. Elution with *n*-hexane gave crystals of III, IVb and IVa successively in the order of separation. No depression was observed in the mixed-melting-point tests of III, IVa and IVb with *trans*-1,2-diphenyl-1-propene, *erythro*- and *threo*-1,2-diphenylpropyl chloride, respectively. Evaporation of the benzene-*n*-hexane (1 : 1) eluent produced an oily substance, a part of which was distilled under reduced pressure to give crystals of V. This was identified to be 1,2-diphenylpropan-2-ol from a comparison of the mixed-melting-point test and IR spectrum with those of the authentic sample.[5] Elution with benzene produced another oily substance which, although it possessed a single peak in its gas chromatogram, was found to be a mixture of VIa and VIb from its NMR spectrum. Their structure was determined by comparison of their glc and NMR spectra with those of the standard samples. The ratio was confirmed by comparison of the area of the methyl protons in the NMR spectrum.

Reaction of Methylstyrenes with Phenylpalladium Bromide or Phenylpalladium Acetate. These experiments were carried out in a manner similar to that described above, except for the use of a bromide or an acetate for all anions in the reactions.

Reaction of Styrene with Phenylpalladium Chloride. To a solution of lithium chloropalladite (3 mmol) in a mixture of acetone and water (1 : 1), styrene (345 mg, 3.3 mmol) and phenylmercuric chloride (940 mg, 3 mmol) were added successively. The reaction mixture was treated in the same way as in the reaction of methyl-styrenes. By column chromatography on silica gel, *trans*-stilbene (225 mg) and 1,2-diphenylethanol (20 mg)[6] were eluted with *n*-hexane and benzene, respectively. They were identified by the mixed-melting-point test and the comparison of IR spectra with authentic samples.

Solvolysis of IVa and IVb. A solution of lithium chloropalladite (1 mmol) and mercuric chloride (270 mg, 1 mmol) in aqueous acetone (50%, 20 ml) was added to IVa or IVb (230 mg, 1 mmol), and stirred for 2 hr at 30 °C. The reaction mixture was diluted with an aqueous solution of sodium chloride and extracted with ether. The extract was analyzed by the glc method and then chromatographed on a silica gel column. A mixture of VIa and VIb (42 mg) was prepared and the recovery of IVb (166 mg) were performed, however, no alcohol formation was observed with the quantitative recovery of IVa from the glc and IR analyses of the solvolysis of IVa.

The authors wish to express their thanks to the Kawaken Fine Chemicals Co. Ltd., for its gift of palladium chloride.

Aromatic Solvent-induced Shift(ASIS). I. An Interpretation Based on the Dipole-Quadrupole Interaction[1)]

Kunio NIKKI, Naoya NAKAGAWA, and Yoshito TAKEUCHI*

The University of Electro-Communications, Chofu, Tokyo 182

**Department of Chemistry, College of General Education, University of Tokyo, Komaba, Meguro-ku, Tokyo 153*

(Received April 17, 1975)

Two general theoretical ways of estimating aromatic solvent-induced shifts(ASIS), which are based on the dipole (solute)-induced diple(solvent) interaction [(μ-μ')interaction] or the dipole(solute)-quadrupole(solvent) interaction [(μ-Q) interaction], are proposed. Solvent shifts can occur by means of the magnetic anisotropy of solvent molecules, which take specific orientations due to those electro-static interactions. As an example, we calculate the ASIS of a hypothetical spherical molecule, a model for camphor, with a dipole near the center and covered with protons, immersed in benzene. The estimated ASIS based on (μ-μ') interaction is much too small to account for the shifts normally observed, while those based on (μ-Q) interaction agree well with the observed ASIS in respect to both its magnitude and angular dependency (*e.g.*, the carbonyl plane rule). More specifically, the theoretical and experimental ASIS for methyl protons of camphor are compared.

It is well known that large chemical-shift differences are often incurred by the proton resonance of organic molecules if the medium is changed from a solvent such as cyclohexane or carbon tetrachloride to an aromatic solvent like benzene. This phenomenon is frequently referred to as the aromatic solvent-induced shift (ASIS).[2-5)]

Various explanations have been put forward to explain the ASIS. These have been based on a kind of hydrogen-bonding,[6)] the 1 : 1 complex formation between the solute and the solvent, particularly of the specifically oriented one,[7-9)] the dipole-induced dipole interaction,[10)] the time-averaged 1 : n cluster formation,[5)] *etc.* Several years ago one of the present authors suggested that the interaction between the permanent dipole of the solute and the permanent quadrupole of the aromatic solvent might cause ASIS.[12)] The purpose of this paper is to give quantitative evidence for this interaction.

Theoretical

It is noteworthy that ASIS are observed for those molecules having a permanent dipole. Hence, whatever the origin of the ASIS, the permanent dipole of the solute should be responsible for the solute-solvent interaction which causes the ASIS. There are various possible modes of electrostatic interaction between the solute and the solvent, in which the solute permanent dipole plays an important role. These modes are the dipole(solute)-dipole(solvent) interaction, the dipole(solute)-induced dipole(solvent) interaction [hereafter specified as the (μ-μ') interaction], the dipole(solute)-quadrupole(solvent) interaction [hereafter specified as the (μ-Q) interaction], and interactions of higher orders. The first will not be considered here since a benzene molecule has no permanent dipole; also, the last need not be taken into consideration, as their magnitude must be very small. Now, these two (μ-μ') and (μ-Q) interactions will be compared.

When molecules with a permanent dipole are dissolved in benzene, the orientation of benzene molecules surrounding a solute molecule is less random than that of pure benzene molecules; they take a specific orientation due to the electric field caused by the permanent dipole. The situation is best represented in Figs. 1a and 1b. As is indicated, the orientation is, as a whole, determined by the assumed interaction, (μ-μ') or (μ-Q), between the solute and the solvent. The ASIS should reflect the orientation involved. The calculation of the ASIS will be carried out in the following manners.

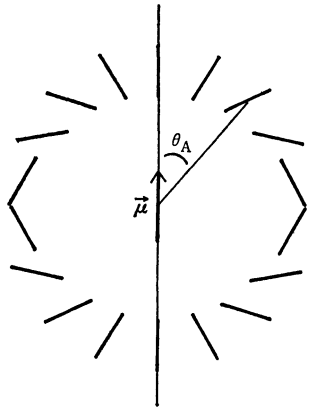

Fig. 1a. Orientation of benzene molecules in the least stable direction based on the (μ-μ') interaction. —— is a six-fold axis of symmetry of benzene.

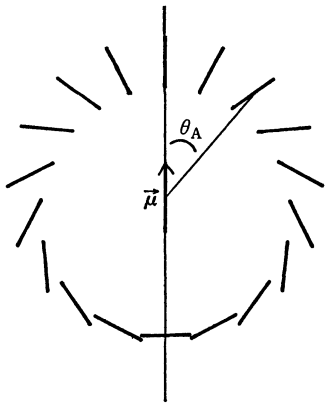

Fig. 1b. Orientation of benzene molecules in the most stable direction based on the (μ-Q) interaction.

ASIS Caused by the Dipole-induced Dipole (μ-μ') Interaction. First, the energy of the (μ-μ') interac-

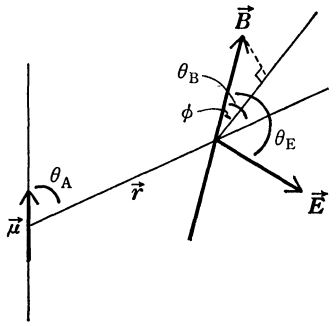

Fig. 2. A benzene molecule in a permanent dipole field of a solute molecule.

tion between one solute and one solvent is carried out. In Fig. 2 the parameters required for the calculation are defined: $\vec{\mu}$ is the permanent dipole of the solute located at the point of origin, $\vec{r}$ is the distance from the origin to the center of a solvent molecule, and θ_A is the angle between $\vec{\mu}$ and $\vec{r}$. The orientation of a benzene molecule is conveniently defined by the direction of its six-fold axis $\vec{B}$, rather than by its plane. θ_B is the angle between $\vec{B}$ and $\vec{r}$. ϕ is the dihedral angle between the plane containing $\vec{\mu}$ and $\vec{r}$ and that containing $\vec{r}$ and $\vec{B}$. $\vec{E}$ represents the electric-field vector at the benzene molecule caused by the $\vec{\mu}$ of the solute, and $|\vec{E}|$ is defined by Eq. (1):

$$E = |\vec{E}| = |\vec{\mu}|\sqrt{1+3\cos^2\theta_A}\cdot r^{-3} \tag{1}$$

θ_E is the angle between $\vec{B}$ and $\vec{E}$; it is related to θ_A, θ_B, and ϕ as is shown in Eq. (2):

$$\cos\theta_E = (\cos\theta_A\cos\theta_B - \sin\theta_A\sin\theta_B\cos\phi)/\sqrt{1+3\cos^2\theta_A} \tag{2}$$

An induced dipole, $\vec{\mu}'$, is caused in a benzene molecule when it is placed in the electric field, $\vec{E}$, as defined by Eq. (3):

$$\vec{\mu}' = \alpha\cdot\vec{E} \tag{3}$$

where α is the electric polarisability of a benzene molecule.

The energy of interaction between $\vec{\mu}$ and $\vec{\mu}'$ is given by Eq. (4):

$$U_{\mu\text{-}\mu'} = -\vec{\mu}'\cdot\vec{E} = -(1/2)\{\alpha^{\parallel}(E\cdot\cos\theta_E)^2 + \alpha^{\perp}(E\cdot\sin\theta_E)^2\} \tag{4}$$

By substituting Eqs. (1) and (2) in Eq. (4), Eq. (5) is obtained:

$$U_{\mu\text{-}\mu'} = -\mu^2\{(\alpha^{\parallel}-\alpha^{\perp})(2\cos\theta_A\cos\theta_B - \sin\theta_A\sin\theta_B\cos\phi)^2 + \alpha^{\perp}(1+3\cos^2\theta_A)\}\cdot r^{-6} \tag{5}$$

where $\alpha^{\parallel}$ and $\alpha^{\perp}$ are the parallel and perpendicular components of the electric polarisability of a benzene molecule in respect to its axis of symmetry.

As a result of this solute-solvent interaction, benzene molecules will be oriented around the solute with a decreased randomness of orientation.

As an aromatic solvent has an anisotropy of magnetic susceptibility, the shift $\delta(\mu\text{-}\mu')$ observed for a proton of the solute due to one benzene molecule at the one position is given by:

$$\delta(\mu\text{-}\mu') = \frac{\int_{\theta_B}\int_{\phi}\Delta\chi(1-3\cos^2\xi)(3R^3)^{-1}\exp(-U_{\mu\text{-}\mu'}/kT)\sin\theta_B d\theta_B d\phi}{\int_{\theta_B}\int_{\phi}\exp(-U_{\mu\text{-}\mu'}/kT)\sin\theta_B\, d\theta_B\, d\phi} \tag{6}$$

where $\Delta\chi(=\chi^{\parallel}-\chi^{\perp}=\chi^{\perp}-\chi^{\perp *})$ is the diamagnetic anisotropy of benzene, ξ is an angle between the axis $\vec{B}$ and $\vec{R}$, and $\vec{R}$ is the distance from the center of benzene to the proton in question (see Fig. 3).

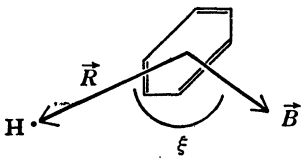

Fig. 3. Relationship between a benzene molecule and a proton in question.

By difinition, the ASIS, $\sigma(\mu\text{-}\mu')$, is the sum of the effect of all the benzene molecules around the solute; thus,

$$\sigma(\mu\text{-}\mu') = \int\rho\delta(\mu\text{-}\mu')\,d\tau \tag{7}$$

where ρ is the specific density of benzene. The integration is carried out throughout the space except for the excluded volume of the solute (as $\rho=0$). The excluded volume was defined as the region surrounding a solute molecule into which the center of a solvent molecule cannot enter.

ASIS Caused by the Dipole-Quadrupole(μ-Q) Interaction. The calculation of the ASIS caused by the interaction between the permanent electric dipole moment of a solute molecule and the permanent electric quadrupole moment of a benzene molecule was performed in the following manner. The molecular quadrupole moment along a principal axis is defined by:[13]

$$Q_{\alpha\alpha} = \frac{|e|}{2}\sum_n Z_n(3\alpha_n^2 - r_n^2) - \frac{|e|}{2}\langle 0|3\alpha_i^2 - r_i^2|0\rangle \tag{8}$$
$$\alpha = x,\ y,\ z$$

where e is the unit electric charge, Z_n is the atomic number of the n-th nucleus, α_n and α_i are the nuclear and the electric coordinates, and the summation is over the n nuclei and i electrons. $\langle 0|\ |0\rangle$ indicates the electric ground-state average value. A quadrupole tensor of a benzene molecule, calculated from the magnetic anisotropy, is given by:[13]

$$Q = \begin{vmatrix} 2.8\pm1.4 & 0 & 0 \\ 0 & 2.8\pm1.4 & 0 \\ 0 & 0 & -5.6\pm2.8 \end{vmatrix} \times 10^{-26}\ \text{esu} \tag{9}$$

The electrostatic energy of a molecular quadrupole at the position of r from the dipole is given by:

$$U_{\mu\text{-}Q} = qq'\left(\frac{2}{r_1} - \frac{1}{r_2} - \frac{1}{r_3} - \frac{2}{r_4} + \frac{1}{r_5} + \frac{1}{r_6}\right) \tag{10}$$

where q is the electric charge of the bar-dipole (solute) with the length of $2a$, where q' is the electric charge of a bar-quadrupole (solvent) with the length of $2b$, and where r_1^{-1}, r_2^{-1}, r_3^{-1}, *etc.* are given by:

$$r_1^{-1} = r^{-1}(1-2\cos\theta_A \cdot ar^{-1}+a^2r^{-2})^{-1/2}$$
$$= r^{-1}\{1+\cos\theta_A \cdot ar^{-1}+(1/2)(3\cos^2\theta_A-1)\cdot a^2r^{-2}$$
$$+ (1/2)(5\cos^3\theta_A-3\cos\theta_A)\cdot a^3r^{-3}+\cdots\cdots\} \quad (11)$$

$$r_2^{-1} = r_1^{-1}\{1+(\cos\theta_B\cos\delta-\sin\theta_B\sin\delta\cos\phi)\cdot 2br_1^{-1}+b^2r_1^{-2}\}^{-1/2}$$
$$= r_1^{-1}[1-(\cos\theta_B\cos\delta-\sin\theta_B\sin\delta\cos\phi)\cdot br_1^{-1}+$$
$$(1/2)\{3(\cos\theta_B\cos\delta-\sin\theta_B\sin\delta\cos\phi)^2-1\}\cdot b^2r_1^{-2}-$$
$$(1/2)\{5(\cos\theta_B\cos\delta-\sin\theta_B\sin\delta\cos\phi)^3-$$
$$3(\cos\theta_B\cos\delta-\sin\theta_B\sin\delta\cos\phi)\}b^3r_1^{-3}+\cdots\cdots] \quad (12)$$

$$r_3^{-1} = r_1^{-1}\{1-(\cos\theta_B\cos\delta-\sin\theta_B\sin\delta\cos\phi)\cdot 2br_1^{-1}+b^2r_1^{-2}\}^{-1/2}$$
$$= r_1^{-1}[1+(\cos\theta_B\cos\delta-\sin\theta_B\sin\delta\cos\phi)\cdot br_1^{-1}+$$
$$(1/2)\{3(\cos\theta_B\cos\delta-\sin\theta_B\sin\delta\cos\phi)^2-1\}\cdot b^2r_1^{-2}+$$
$$(1/2)\{5(\cos\theta_B\cos\delta-\sin\theta_B\sin\delta\cos\phi)^3-$$
$$3(\cos\theta_B\cos\delta-\sin\theta_B\sin\delta\cos\phi)\}\cdot b^3r_1^{-3}+\cdots\cdots] \quad (13)$$

etc., where δ is the angle between $\vec{r}$ and $\vec{r}_1$; then $\sin\delta = a\cdot\sin\theta_A/r_1$ (see Fig. 4).

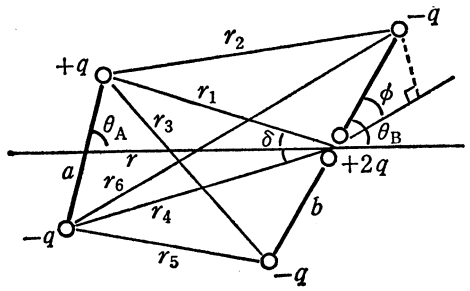

Fig. 4. Electrostatic interaction between bar-dipole and bar-quadrupole. q is the electric charge of the dipole. q' is the electric charge of the quadrupole.

The substitution of Eqs. (11), (12), (13), *etc.* into Eq. (10) and the use of the point-dipole and -quadrupole approximations, ($r \gg a$, $r \gg b$ and $\delta=0$), will give the orientation energy by means of:

$$U_{\mu\text{-Q}} = -6qq'ab^2r^{-4}\{\cos\theta_A(1-3\cos^2\theta_B)$$
$$+ 2\cos\theta_B\sin\theta_B\sin\theta_A\cos\phi\}$$
$$= -(3/2)\mu Q_{zz}r^{-4}\{\cos\theta_A(1-3\cos^2\theta_B)$$
$$+ 2\cos\theta_B\sin\theta_B\sin\theta_A\cos\phi\} \quad (14)$$

where Q_{zz} is the principal value of the quadrupole moment on the six-fold axis of a benzene molecule.

Thus, the shift, $\delta(\mu\text{-Q})$, observed for a proton of a solute molecule caused by one solvent molecule at one position is given by:

$$\delta(\mu\text{-Q}) = \frac{\int_{\theta_B}\int_{\phi} A\chi(1-3\cos^2\xi)(3R^3)^{-1}\exp(-U_{\mu\text{-Q}}/kT)\sin\theta_B d\theta_B d\phi}{\int_{\theta_B}\int_{\phi}\exp(-U_{\mu\text{-Q}}/kT)\sin\theta_B d\theta_B d\phi} \quad (15)$$

The $\sigma(\mu\text{-Q})$ ASIS can be estimated in the manner described in the previous section.

Calculation

Point-dipole (-quadrupole) approximations are employed for calculating the electrostatic interaction between the solute and the solvent. Thus, both the electric polarization of a solute molecule and the induced polarization of a benzene molecule are approximated as a point dipole, whereas the electric distribution in a benzene molecule (molecular quadrupole) was approximated as a point quadrupole at the center of the molecule. Unless the solvent molecule is in contact with the solute molecule, the dielectric constant of the medium should be considered. In our calculation, however, it was assumed to be unity for all the distances.

The energies of the dipole-induced dipole interaction and the dipole-quadrupole interaction are given by Eqs. (5) and (14) respectively. The maximum and the minimum energy of the two interactions are plotted against the distance, r, in Fig. 5. As in our calculation, the difference between the maximum and the minimum energy due to the (μ-Q) interaction at the one position at any value of r larger than 4.45 Å, the closest possible distance between the solute and benzene, was about 14 times as large as that due to the (μ-μ') interaction. This indicates that the (μ-Q) interaction is almost exclusively responsible for the orientation of the benzene molecules around the solute.

In order to obtain a general perspective as the magnitude of the ASIS caused by two interactions, a spherical-model molecule, with a diameter of 2.9 Å and a permanent dipole of 3.1 D which is located 1.5 Å

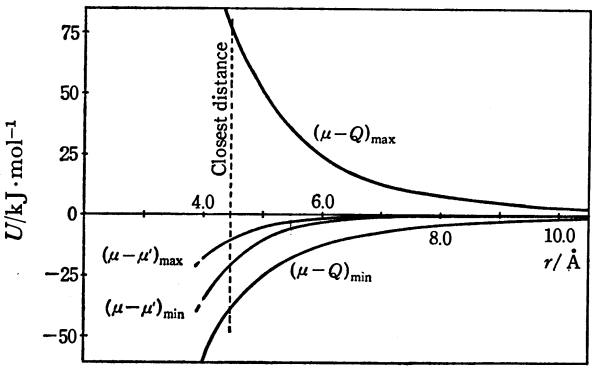

Fig. 5. The maximum energy and the minimum energy of the dipole-induced dipole interaction and the dipole-quadrupole interaction.

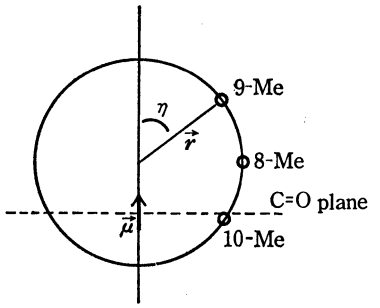

Fig. 6. A spherical "model" molecule. ↑ is the dipole, and ○ is a center of a "methyl" group on the sphere.

apart from, and pointed toward, the center of the sphere (Fig. 6), was introduced. The "average" position (proton point) of the three protons of each methyl group of camphor was on the surface of the sphere, when the dipole of camphor is superimposed on the dipole of the model. For the benzene molecule we assumed a sphere with a van der Waals radius of 1.85 Å. The values used for the calculation were as follows:

$\Delta\alpha$ (benzene): -60×10^{-25} esu

$\Delta\chi$ (benzene): -0.9×10^{-28} esu

Q_{zz} (benzene): -5.6×10^{-26} esu

ρ (benzene): 0.00679 molecule/Å^3

van der Waals radius of H: 1.2 Å.

In the computation of $\delta(\mu\text{-}\mu')$ and $\delta(\mu\text{-Q})$, the $\int_{\theta_B}\int_{\phi} f(\theta_B, \phi)d\theta_B d\phi$ integration is approximated by a double summation:

$$\sum_{\theta_B=0}^{180^\circ}\sum_{\phi=0}^{360^\circ} f(\theta_B, \phi)\Delta\theta\Delta\phi$$

with $\Delta\theta_B=10^\circ$ and $\Delta\phi=10^\circ$.**

In a similar manner, $\int\rho\delta(\mu\text{-}\mu')d\tau$ and $\int\rho\delta(\mu\text{-Q})d\tau$ are approximated by the triple summation:

$$\sum_{\theta_A=0}^{180^\circ}\sum_{\phi=0}^{360^\circ}\sum_{r=4.45\text{Å}}^{10.5\text{Å}} f(\theta_A, \phi, r)\Delta\theta_A\Delta\phi\Delta r$$

where $\Delta\theta_A$ and $\Delta\phi$ are taken as 10°† and Δr as $0.1r$. θ_A and ϕ varied from 0° to 180° and from 0° to 360° respectively, whereas r varied from 4.45 Å, which corresponds to the smallest possible distance between a benzene molecule and a solute molecule (closest distance), to 10.5 Å.††

The calculated ASIS for the model molecules based on $(\mu\text{-}\mu')$ or $(\mu\text{-Q})$ interactions are plotted against an angle in the model molecule (see Fig. 6) in Fig. 7.

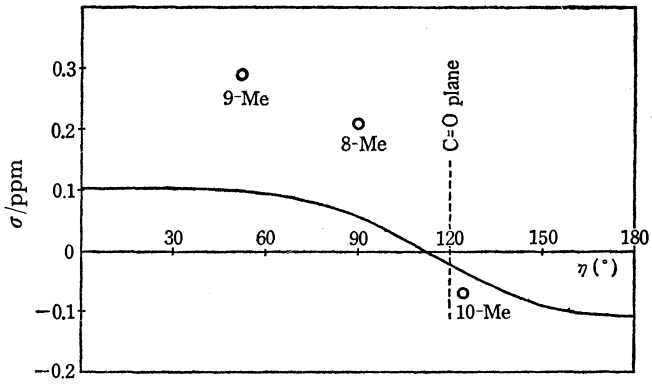

Fig. 7. The angular dependency of ASIS. η is an angle between $\vec{\mu}$ and $\vec{r}$ (a distance of a proton from the center of the sphere). A solid line represents calculated values, $\sigma(\mu\text{-}Q)$, and ○ represent observed values of ASIS of methyl groups of camphor.

Discussion

It is surprising that no quantitative calculation has ever been attempted to assess the ASIS caused by the $(\mu\text{-}\mu')$ interaction, although most, if not all, of the proposed interpretations have been based on this interaction.

Our calculations indicate that the energy of the $(\mu\text{-}\mu')$ interaction is so small that no appreciable orientation is incurred in benzene molecules. Hence, the ASIS caused by this interaction is negligibly small. On the contrary, the $(\mu\text{-Q})$ interaction seems to cause a noticeable orientation; hence, the ASIS caused is at least hundred times as large. For example, the observed ASIS for three methyl groups of camphor are plotted in Fig. 7. The locations of the proton points were estimated from the geometry of the camphor, as determined by the HGS molecular model. The agreement between the calculated and observed values proves that our assumption is qualitatively correct. In our preliminary paper,[1] we took only three possible orientations of benzene molecules into consideration, for the sake of simplicity, instead of all the possible ones as we have done in this paper. The estimated ASIS under that approximation was twice as large as the present estimation.

Far more important in predicting the ASIS is its sense (its upfield or downfield shift, as compared with the chemical shifts in a neutral solvent). This is particularly the case with carbonyl compounds where the observed ASIS is quite dependent on the relative geometry of the proton(s) in question and on the carbonyl dipole, as summarised by the so-called carbonyl plane rule.[11] According to this rule, protons lying in front of (or behind) the carbonyl plane (a plane perpendicular to $\vec{\mu}$ and through the carbonyl carbon) exhibit a positive (negative) ASIS, while protons on the plane show virtually no ASIS. This empirical rule is in good agreement with our calculated results.

Thus, for a polar solute molecule the dipole-quadrupole interaction model is a much better approximation of the ASIS than the dipole-induced dipole interaction model in estimating its magnitude and "sense." This electrostatic interaction model is now being used in our laboratories to study the solvent shifts caused by other solvents, including hexafluorobenzene and carbon disulfide.

** Much the same results were obtained with $\Delta\theta_B$ and $\Delta\phi=5^\circ$.

† Calculations were also carried out with $\Delta\theta_A$ and $\Delta\phi=5^\circ$; these results were much the same as those, given in the text.

†† At this distance, δ is almost 1/4000 of that at the closest distance.

α-Thiocarbonyl-stabilized Triphenylphosphonium Ylides: Preparation, Structure, and Alkylation Reactions

Hiroshi YOSHIDA, Hironori MATSUURA, Tsuyoshi OGATA, and Saburo INOKAWA

Department of Synthetic Chemistry, Faculty of Engineering, Shizuoka University, Johoku, Hamamatsu 430

(Received April 21, 1975)

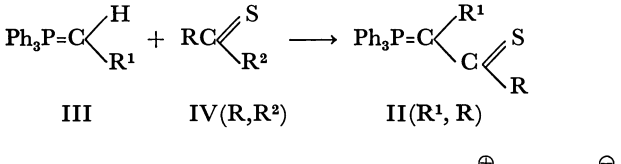
A number of α-thiocarbonyl-stabilized ylides II were prepared in moderate yields, and their alkylation reactions were studied. II(H, MeO), II(H, EtO), II(H, i-PrO), and II(H,H) were mixtures of *cis* and *trans* isomers, and the II_{cis}/II_{trans} ratios were solvent-dependent. II(H, Ph), II(H, Me_2N), II(H, MeS), and II(H, EtS) were composed of only *cis* isomers. All these ylides II with alkyl iodide gave S-alkylation products in good yields.

The physical and chemical properties of carbonyl-stabilized phosphonium ylides (I) have been widely studied in recent years.[1] In this report we will discuss the structure and alkylation reactions of thiocarbonyl-stabilized triphenylphosphonium ylides (II).

Results and Discussion

Preparation of II(R^1,R). The reaction of triphenylphosphonium alkylide (III) with *S*-alkyl thiolcarboxylates yields phosphonium acylalkylides in good yields.[2]

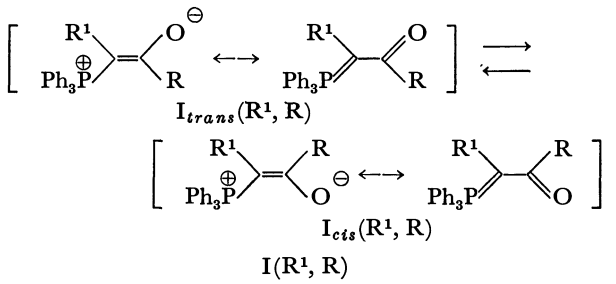
The treatment of III with a two-fold excess of thionocarboxylate (IV) was performed in benzene under a nitrogen atmosphere at room temperature or under ice-water cooling. The product was then purified by crystallization. The results are collected in Table 1.



III IV(R,R^2) II(R^1, R)

Structure of II(R^1,R) and Alkylation Reaction. The NMR spectra of carbonyl-stabilized phosphonium ylides (I) have been widely studied in recent years. The NMR spectra of ester-stabilized ylides I(H, Alkyl-O) have been shown to be a mixture of *cis* and *trans* isomers;[3] however, keto-stabilized ylides I(R^1, Alkyl or Aryl) are only *cis* isomers[4] unless R is large and R^1 is strongly electron-withdrawing.[5] Keto-stabilized ylides I(Cl, Ph) and I(I, Ph) have been shown to be *cis* by X-ray studies.[6,7]

It is known that ester-stabilized ylides I(R^1, Alkyl-O) undergo alkylation with alkyl halides to give normal C-alkylation products,[8] whereas alkylation with triethyloxonium fluoroborate yields a mixture of C- and



$I_{trans}(R^1, R)$ $I_{cis}(R^1, R)$ $I(R^1, R)$

Table 1. Preparation of II(R^1, R) and their physical properties

a) Taken from Ref. 3. Recorded at −10—0 °C. b) Recorded at 34.5 °C.

O-alkylation products (O-rich).[9] Keto-stabilized ylides I(R^1, Alkyl or Aryl) react with alkyl halides to give O-alkylation products.[10] Contrary to these results, the alkylation of II with alkyl iodides takes place exclusively at sulfur and easily at room temperature to give salts V in quantitative yields (Table 2).

The stereochemistry of the products was assigned on the assumptions that the protons of the R group *cis* to the phosphorus are shielded by the phenyl rings and that they appear at a higher field than the R *trans* to the phosphorus.

The variable-temperature NMR study of I(H, MeO) shows the methyl protons as a singlet above the coalescence temperature (T_c=35±3 °C for I(H, MeO)) and an unsymmetrical doublet at a lower temperature.[4] The NMR spectra of II(H, Alkyl-O) at 34.5 °C gave clean peaks of two groups corresponding to the *cis* and *trans* isomers (Table 1). These results indicate that the T_c for II (H, Alkyl-O) may be higher than the T_c for I(H, Alkyl-O). However, the rotation for II is not restricted, since II (H, Alkyl-O) reached equilibrium fairly rapidly in any solvent and the II_{cis}/II_{trans} ratio was nearly constant during the reaction with alkyl halides.

In a previous communication[11] we have reported on the effect of solvents on the II_{cis} (H, Alkyl-O)/II_{trans} (H, Alkyl-O) isomer ratios and on the effect of alkylating reagents on the V_{cis}(H, Alkyl-O, R')/V_{trans} (H, Alkyl-O, R') products ratios. Here, only representative data are collected in Table 3.

It is clear that $P^{\oplus}/O^{\ominus}$ or $P^{\oplus}/S^{\ominus}$ attraction is maximized in I_{cis} or II_{cis}. For ester-stabilized ylides I, it has been reported that a large R and an increasing solvent aggregation about the ester carbonyl favor a relatively high population of the *trans* form.[3] The regular variation in I_{cis}/I_{trans} found for ylides I is interpreted as a result of steric inhibition of solvation.[3] As is shown in Table 3, both I(H, Alkyl-O) and II(H, Alkyl-O) show similar properties. The smaller *cis*/*trans* value for II than for I seems to show a higher solvent aggregation around thiocarbonyl than that around carbonyl. This result clearly reflects the higher mesomeric character of the thiocarbonyl than the carbonyl group. This trend is especially marked in the chloroform solvent, with which negative oxygen or sulfur associates by hydrogen-bonding interaction.[3]

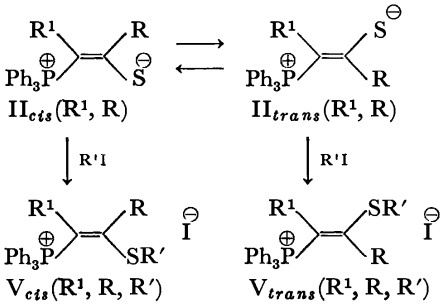
The ylides II(H, Ph), II(H, Me_2N), II(H, MeS), and II(H, EtS) gave only a single *cis* isomer. The structure was confirmed as follows.

The methylation of II(H, MeS) with methyl iodide gave needles whose NMR spectrum showed two *S*-methyl peaks, at δ 2.39 and 2.92 in $CDCl_3$. The ethylation of II(H, MeS) with ethyl iodide gave needles with a mp of 167—169 °C, which showed only one *S*-methyl signal, at δ 2.85. II(H, EtS) reacted with methyl iodide to give needles (mp 125—127 °C) which showed one *S*-methyl signal, at 2.38. Thus, these alkylation products were confirmed to be V_{cis}(H, MeS, Me), V_{cis}(H, MeS, Et), and V_{cis}(H, EtS, Me). These products were stable for more than 20 hr at 80—90 °C

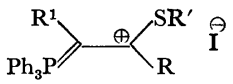
Table 4. NMR data for II(H, H), II(Me, H) and their methylation products in $CDCl_3$.

Compound	δ_{R^1}	δ_R	J_{R^1R}	$J_{PCR'}$(Hz)	J_{PCCR}(Hz)	δ_{SMe}
II_{cis}(H, H)	5.17	9.34	8.1	30.2	45.0	
II_{trans}(H, H)	5.94	8.69	14.8	26.0	15.3	
V_{cis}(H, H, Me)	6.80	8.73	12.0	15.9	44.0	2.54
V_{trans}(H, H, Me)	a)	a)				2.81
II_{trans}(Me, H)	2.21	8.66		13.7	18.6	
V_{trans}(Me, H, Me)	2.11	7.19		13.7	21.1	2.55

a) Signals were appered in the phenyl proton region.



in $CDCl_3$, and they showed no isomerization. However, on irradiation with a high-pressure mercury lamp for 6 hr in $CDCl_3$, V_{cis}(H, MeS, Et) and V_{cis}(H, EtS, Me) gave the same 1 : 1 mixture of V_{cis}(H, MeS, Et) and V_{cis}(H, EtS, Me). These results indicate that the structure of the ylides II(H, MeS) and II (H, EtS) was *cis* and that alkylation products have a structure of a vinylphosphonium salt like V, not that of a carbonium ion like VI.



VI

The NMR spectrum of the methylation product V(H, Ph, Me) of II (H, Ph) with methyl iodide showed signals at δ 1.91 (s, MeS) and 6.41 (d, J=21.8 Hz, methine). The compound gave new peaks at 2.87 (s, MeS) and 6.38 (d, J=14.1, methine) on ultraviolet irradiation. The results show that the ylide II(H, Ph) is *cis* and that the methylation product is V_{cis}(H, Ph, Me), which gives V_{trans}(H, Ph, Me) on ultraviolet irradiation. The equilibrium ratio, V_{cis}(H, Ph, Me): V_{trans}(H, Ph, Me), was 6 : 4 after 6 hr.

The ylide II (H, Me_2N) gave an isomer on methylation, but the product showed no change on ultraviolet irradiation for 10 hr. Although we have no direct evidence, the structure of II(H, Me_2N) was assumed to be *cis* judging from the kinetic studies of methylation reaction (see the next section).

Formylmethylenetriphenylphosphorane I(H, H) exists as a mixture of *cis* and *trans* isomers, whose ratio (about 1 : 1) is constant in any solvent,[1,12,13] but I(Me, H) gives only the *trans* isomer.[1]

The NMR spectrum of II(H, H) was shown to be a mixture of *cis* and *trans* isomers, while II(Me, H) gave only *trans* (Table 4). Interestingly, II(H, H) showed a solvent dependence like that of ester-stabilized ylides I(H, Alkyl-O) and II(H, Alkyl-O); however the small solubility of II(H, H) inhibited precise studies. A sample crystallized from benzene gave a *cis*-rich product of *cis*/*trans*=7, one of *cis*/*trans*=1.1 from nitrobenzene, and one of *cis*/*trans*=0.23 from chloroform. These data were obtained by the analysis of the NMR spectra of samples in the $CDCl_3$-Et_3N (5%) solvent. A sample from benzene attained equilibrium quickly (*cis*/*trans*=0.23) without the addition of any dry sodium carbonate (in 3—5 min); with the addition of dry sodium carbonate, attaining equilibrium took rather longer (about 60 min). However, the sample attained equilibrium slowly (about 25 hr) in the $CDCl_3$–Et_2N solvent. These results indicate that the acid-catalyzed *cis-trans* isomerization is a lower energy process than the thermally induced one, as has been reported in connection with the ester-stabilized ylides I (H, Alkyl-O).[1,3]

Table 5. Second-order rate constants for the methylation of II with methyl benzenesulfonate in $CDCl_3$ at 34.5 °C

II	$k_2 \times 10^3$ l/mol·s	
	cis	*trans*
II(H MeO)	1.60	3.59
II(H, EtO)	1.77	4.13
II(H, *i*-PrO)	2.12	4.36
II(H, Ph)	11.2	
II(H, Me_2N)	24.1	
II(H, MeS)	3.45	

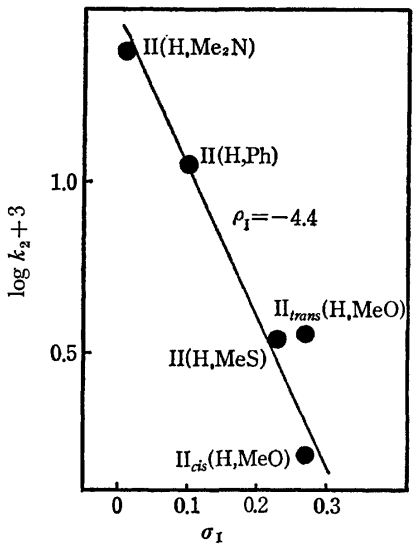


Fig. 1. The relation between σ_I and $\log k_2$.

Kenetic Studies of the Methylation of II with Methyl Benzenesulfonate. Since the reaction of II with methyl iodide was too fast to follow by means of the NMR spectra (within one min), methyl benzenesulfonate was used as the methylating reagent. The reaction gave good second-order rate constants (k_2), first-order with II and benzenesulfonate respectively. The results are shown in Table 5 and Fig. 1. The large negative ρ_I value seems to indicate that, in the transition state of the reaction, the negative charge is highly localized on the thiocarbonyl sulfur (*i.e.*, the betaine form).

As was observed on II(H, Alkyl-O), the *trans* isomer showed nearly twice as much reactivity with methyl benzenesulfonate as the *cis* isomer. The ylide II(H, Me_2N) was supposed to be *cis*, since there was a much deviation of II_{trans}(H, MeO) from the line (Fig. 1).

Experimental

Preparation of II. A suspension of triphenylmethylphosphonium bromide (5.0 g, 14 mmol) and sodium amide (1.5 g) in 50 ml of dry benzene was stirred for 12 hr in a stoppered flask at room temperature. After the separation of the precipitate, the ammonia was removed *in vacuo* to give a yellow solution of triphenylphosphonium methylide. After the solution had then been cooled in an ice-water bath, methyl methylxanthate (1.7 g, 14 mmol) in 10 ml of benzene was added in one portion, and the resulting mixture was allowed to stand for 1 hr at room temperature. The mixture was then treated with charcoal and condensed *in vacuo* to give an oil. The oil was washed several times with petroleum ether, II(H, MeO) was then obtained in a 38% yield from benzene–petroleum ether.

Similarly several other II were prepared in moderate yields; the results are collected in Table 1.

Alkylation of II. A solution of II(H,Ph) in chloroform was treated with twice as much methyl iodide at room temperature. The subsequent evaporation of the solvent *in vacuo* afforded needles (mp 198—200 °C) in a quantitative yield.

The similar treatment of II(R^1,R) with alkyl iodide (R'I) gave V(R^1,R,R') in a good yield (Table 2).

The photo-isomerization of V(H,Ph,Me), V(H,MeS,Et), and V(H,EtS,Me) in $CDCl_3$ was performed in NMR tubes (Pyrex), following at suitable time intervals by observing NMR spectral change.

Kinetic Studies. A solution of II and methyl benzenesulfonate in $CDCl_3$ was sealed in an NMR sample tube. The rate was followed at suitable time intervals by analyzing the NMR spectra of the *O*-methyl and *S*-methyl groups. The results are collected in Table 5.

Determination of Amino Acid Sequence of Peptides by the Combination of Mass Spectrometry and Edman Degradation. Alternate Use of *p*-Chloro- and *p*-Bromophenylisothiocyanate Followed by Modification of Shortened Peptide

Asao MURAI and Yoko TAKEUCHI

Central Research Laboratories, Ajinomoto Co. Inc., Suzuki-cho, Kawasaki-ku, Kawasaki 210

(Received April 30, 1975)

It was shown that the alternate use of *p*-chloro- and *p*-bromophenylisothiocyanate for Edman degradation makes it possible to determine the amino acid sequence of peptides more unambigously by mass spectrometry, *i.e.*, by the doublet molecular ions of phenylthiohydantoin derivatives of amino acids with the intensity ratio inherent to the natural abundance of each halogen atom. The amino acid sequence of the shortened peptide could also be surely determined by the deuterium labeled mixed acylation by shifting the "sequence determining peaks" to higher mass region where no interfering peaks for the interpretation of the mass spectra would appear as well as labeling them as doublets with equal intensities by the distance of 2 mass units. Two examples, a dodecapeptide H-(Pro-Pro-Gly)$_4$-OH, and an octapeptide angiotensin II, were presented.

In recent years, the combination of Edman degradation[1] with mass spectrometry is well recognized as a useful method for the determination of amino acid sequence of peptides.[2] The advantages of the method might be considered as follows; the phenylthiohydantoins produced from the sequential degradation of peptide with phenylisothiocyanate are the most desirable derivatives for the unambigous identification of amino acids by mass spectrometry, and after suitable modification the residual shortened peptide can readily be determined the amino acid sequence in one step by mass spectrometry.[3,4] Thiohydantoin derivatives of amino acids can also be identified by gas chromatography-mass spectrometry.[5,6] An automatic sequenator using Edman degradation with reaction and inlet device directly connected to mass spectrometer has already been reported.[7]

Tschesche, Wachter[8] and Weygand, Obenmeier[9] reported that the N-terminal amino acids could be more clearly identified by converting to their *p*-bromophenylthiohydantoin [PTH(Br)] derivatives by mass spectrometry because the doublet molecular and fragment ions appear on their mass spectra with approximately equal intensities by the distance of two mass units due to the isotopic bromine atoms, ^{79}Br and ^{81}Br.

It seems that the alternate use of *p*-bromo- and *p*-chlorophenylisothiocyanate [PIT(Br) and PIT(Cl), respectively] for the sequential Edman degradation followed by mass spectrometric identification of the products [amino acid-PTH(Br) or PTH(Cl)] allows more unambigous sequence determination by checking the intensity ratio of their molecular and fragment ion pairs inherent to the natural abundances of each halogen atom. This is especially advantageous for the cases where the extraction of PTH derivative is incomplete or the application to the peptides in which the same amino acid neighbours with each other.

The authors also wish to report the method for the determination of amino acid sequence of peptides shortened by the consecutive Edman degradations; mixed acylation of peptide with normal and deuterium labeled long chain acyl groups to discriminate the "sequence determining peaks" (due to the cleavages of CO-N bonds with positive charges on each carbonyl group) by marking with doublet as well as shifting them to higher mass region where no undesirable contaminant peaks would appear.

Results and Discussion

Alternate Edman Degradation with PIT(Cl) and PIT(Br). A dodecapeptide, H-(Pro-Pro-Gly)$_4$-OH, was applied to the alternate sequential Edman degradations with PIT(Cl) and PIT(Br) followed by acylation and permethylation of the shortened peptide. Series of mass spectra of the PTH(Cl or Br) derivatives obtained from first through sixth Edman degradation are illustrated in Fig. 1. The mass spectrum of the derivative of the N-terminal amino acid indicates the clear molecular ion pair at *m/e* 266 and 268 with an intensity ratio of 3 : 1 and this readily leads to identification the N-terminal amino acid as proline. The spectrum of the second Edman degradation products clearly indicates the second amino acid as proline, too, by the molecular ion pair at *m/e* 310/312 with the equal intensity ratio of proline-PTH(Br). The mass spectrum of the third Edman degradation products using PIT(Cl) exibits three doublet peaks of molecular ions. One pair of the doublet at *m/e* 226/228 with the intensity ratio of 3 : 1 must be the molecular ion of the third amino acid-PTH(Cl), glycine. Another doublets at *m/e* 266/268 (3 : 1) and *m/e* 310/312 (1 : 1) should be attributed to the first and second amino acid, proline and proline, by the incomplete extraction of the PTH derivatives in the first and second stage of the Edman degradations. A similar result can be deduced from the spectrum of the fourth Edman degradation products using PIT(Br), in which the new pair of doublet at *m/e* 310/312 (1 : 1) is indicative of the fourth amino acid, proline. The same procedures of identification of amino acid-PTH derivatives by the alternate Edman degradations resulted the determination of the sequence from first to sixth amino acid as Pro-Pro-Gly-Pro-Pro-Gly. The residual shortened peptide was then acetylated, esterified and permethylated by the method

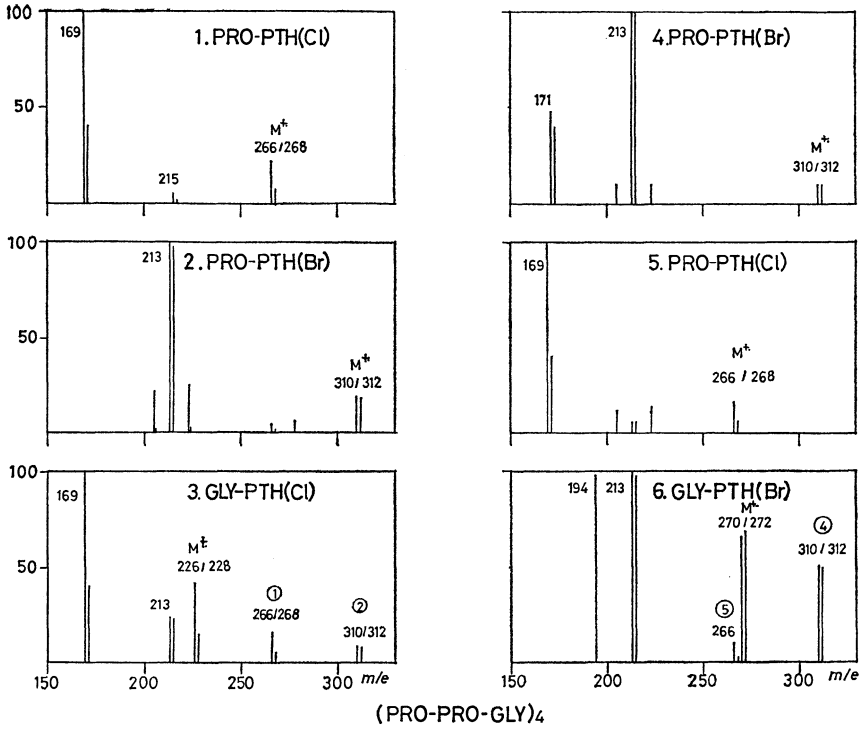

Fig. 1. Series of mass spectra of amino acid-PTH (Cl or Br) derivatives from 1st to 6th Edman degradations of (Pro–Pro–Gly)$_4$. The peaks under encircled numerals represent the molecular ions of the PTH derivatives from corresponding order of degradation.

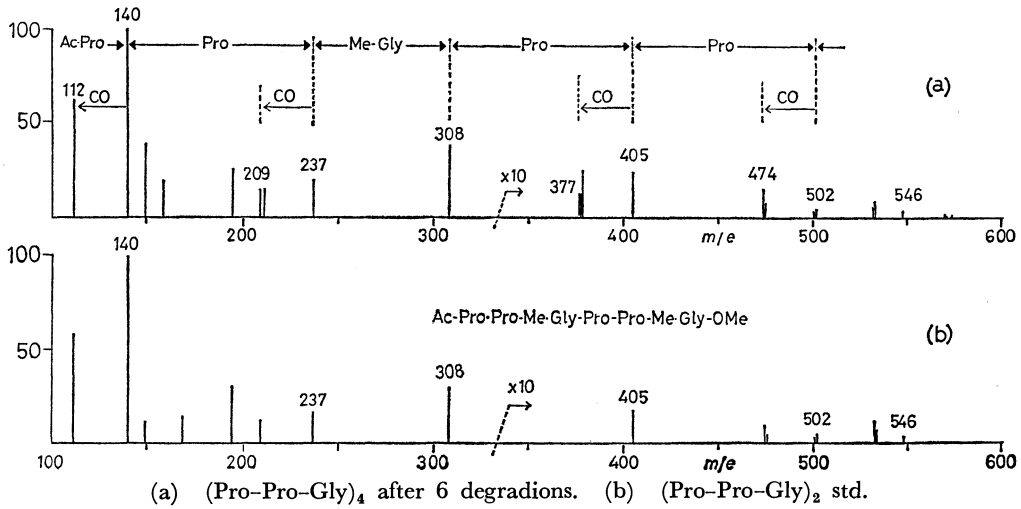

(a) (Pro–Pro–Gly)$_4$ after 6 degradions. (b) (Pro–Pro–Gly)$_2$ std.

Fig. 2. Mass spectra of the N-acetylated and permethylated peptides.
Upper: residual peptide after 6 degradations of (Pro–Pro–Gly)$_4$, lower: standard peptide (Pro–Pro–Gly)$_2$.

of Vilkas and Lederer[10] and determined the amino acid sequence by its mass spectrum as Pro–Pro–Gly–Pro-Pro–Gly. The mass spectra of the modified shortened peptide after six degradations and the standard peptide, H–(Pro–Pro–Gly)$_2$–OH, are shown in Fig. 2. The complete amino acid sequence of this dodecapeptide was then ascertained by combining with the results from alternate Edman degradation as H–(Pro–Pro–Gly)$_4$–OH

Mixed Long-chain Acylation with Unsaturation or Deuterium Labeling. Consecutive Edman degradation procedures often accumulate undesirable by-products or other artifacts by which the mass spectra are contaminated at the mass region of lower "sequence determining peaks" ($\sim m/e$ 300) of an acetylated peptide derivatives. It seems that the interpretation of mass spectra for the sequence determination must be much simplified by introducing the mixture of saturated and unsaturated acyl groups to the peptides not only because the molecular and fragment peaks would be marked by doublets by the distance of two mass units but because they would be shifted to the higher mass region where no peaks from contamination would appear. Mixed acylation

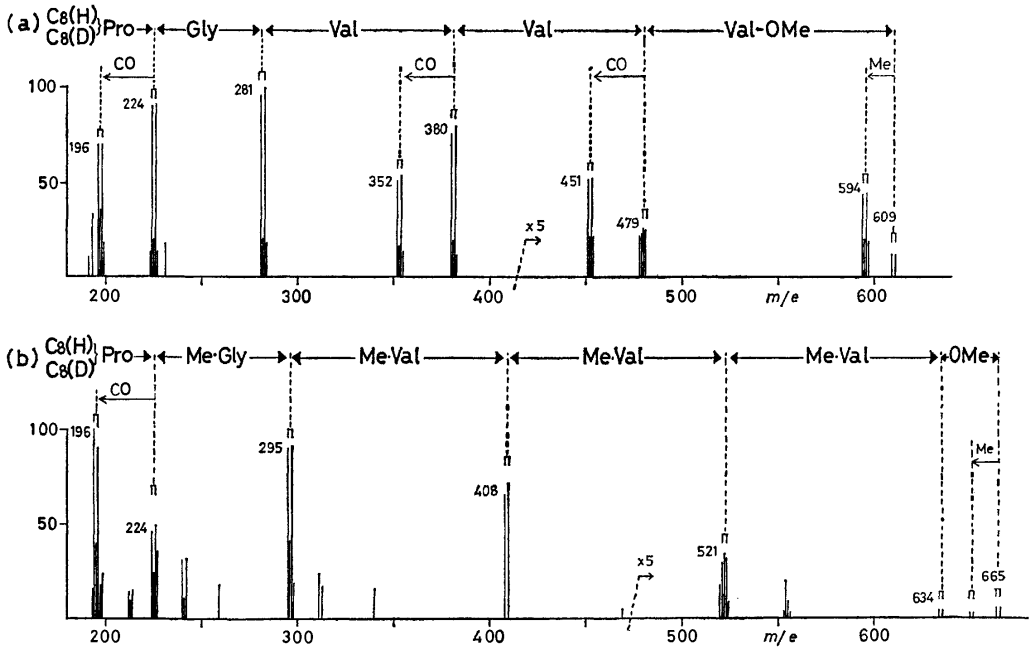

Fig. 3. Mass spectra of mixed acylated Pro-Gly-Val-Val-Val methyl ester with(b) and without(a) permethylation. $C_8(H) = C_7H_{15}CO$, $C_8(D) = C_7H_{13}D_2CO$

of peptides with C_2H_5COCl/C_2H_3COCl, $C_7H_{15}COCl/C_7H_{13}COCl$, and $C_{17}H_{35}COCl/C_{17}H_{33}COCl$ were investigated. A C_8-mixed acylation was sufficient for the "sequence determining peak" shifting. The intensity ratio of the doublets, however, differed significantly among the peaks of the molecular and fragment ions within a spectrum and moreover, the ratio varied not only with vaporization temperature but with peptide to peptide. Similar results were obtained from C_3- or C_{18}-mixed acylation.

Marking the molecular and sequence peaks by doublets was successful by the acylation of peptides with equivalent mixture of *n*-octanoyl chloride and *n*-octanoyl-3,3-d_2 chloride. Figure 3 shows the mass spectra of deuterium labeled-acylated Pro-Gly-Val-Val-Val methyl ester with (b) and without (a) permethylation. The lowest "sequence determining peaks" appear at *m/e* 224/226 (acylprolyl ion). The fragment ions appearing in higher mass region than that of the acylprolyl ion were enough simple and clear for the interpretation of sequence determination.

Permethylation of long-chain acylated peptide esters usually lowers the relative intensities of the molecular ions and does not seem to give an additional advantage on the spectra for the interpretation of sequence determination. The vaporization temperature, however, is lowered by 30—40° by permethylation.

Combination of Alternate Edman Degradation and Deuterium Labeled Long-chain Acylation of the Residual Peptide. A typical example for the sequence determination of peptides by sequential Edman degradation followed by esterification and deuterium labeled long-chain acylation of the shortened peptides is shown in Fig. 4. An octapeptide, angiotensin II, was easily proved its amino acid sequence after six alternate Edman degradations followed by deuterium labeled acylation.

There can be the case where the shortened peptide, even in the case of tripeptide such as Val-Val-Val, is extracted together with the PTH derivative by ethyl acetate by the usual separation procedures[5,6] in Edman degradation. As in these cases, the mixture of the extracted PTH derivative and the residual peptide was directly applied to esterification and *N*-acylation, then the mass spectra of the mixture were recorded at the suitable vaporization temperatures at which the PTH and peptide derivatives were separately evaporated. Alternatively, PHT derivatives can be well and selectively extracted from the residual peptides with toluene–ethyl acetate (1 : 1) instead of ethyl acetate.

Experimental

Peptides. H-(Pro-Pro-Gly)$_2$-OH, H-(Pro-Pro-Gly)$_4$-OH, and angiotensin II were purchased from Protein Research Foundation.

n-*Octanoic-3,3-d_2 Acid.* A similar method of synthesis of *n*-heptanoic-3,3-d_2 acid by Katoh *et al.*[13] was used with the starting material of *n*-hexanoic acid in place of *n*-valeric acid.

Edman Degradation. Sequential degradation of peptides with PIT (Cl or Br) was done by the method of Tschesche and Wachter.[8] PIT(Cl) and PIT(Br) were synthesized by the method described elsewhere.[11]

Peptide Modification. The shortened peptide (1—5 mg) was esterified with HCl-saturated methanol (10 ml) at room temperature for 2 hr and the excess reagents were evaporated off. To the residue, 2 ml of dried pyridine containing acid chloride 1.2—2 molar equivalent to the free amino groups was added and the solution was allowed to stand for 2 hr at room temperature. After the solvent was evaporated, the residue was dissolved in chloroform and was washed with

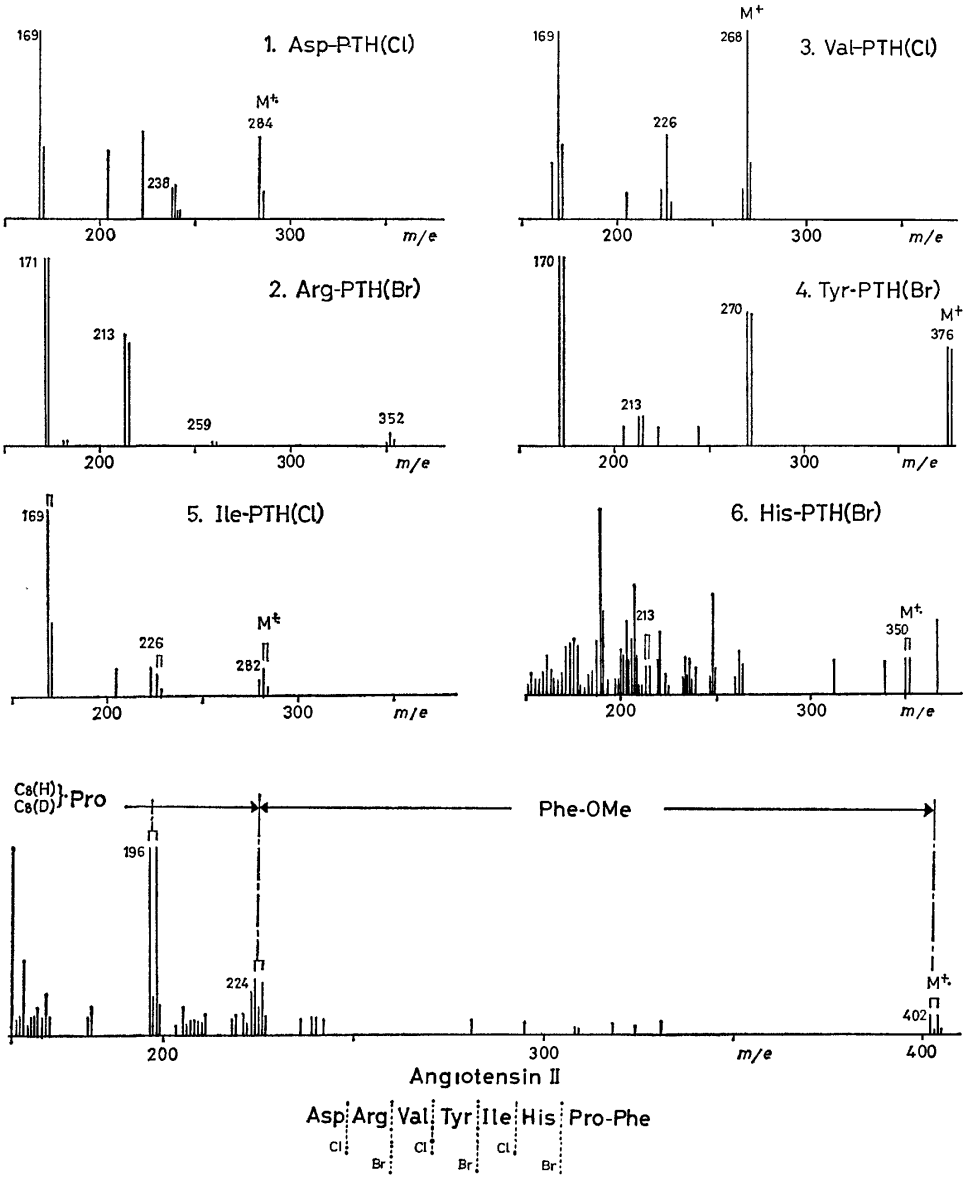

Fig. 4. Mass spectra of PTH(Cl or Br) derivatives from 1st to 6th Edman degradations of angiotensin II and residual peptide after esterification and deuterium labeled mixed acylation.

aqueous $NaHCO_3$ solution. The chloroform layer was then dried over anhydrous Na_2SO_4, and the solvent was evaporated. The oily residue was directly introduced into the ion source of mass spectrometer. Permethylation, if necessary, was carried out according to the method of Thomas[12] or Vilkas.[10]

Mass Spectrometry. A Hitachi RMU-6E Mass Spectrometer with 70 eV ionizing energy, 80 μA of emission current, and ion source temperature of 220° was used.

The Synthesis of 1,3,4-Oxadiazolo[3,2-*b*]isoquinoline and 1,3,4-Thiadiazolo-[3,2-*b*]isoquinoline Derivatives from Homophthalic Anhydride

Masahiko TAKAHASHI, Takamitsu SHINODA, Hideshi OSADA, and Toshio NAKAJIMA

Department of Industrial Chemistry, Faculty of Engineering, Ibaraki University, Hitachi, Ibaraki 316

(Received May 2, 1975)

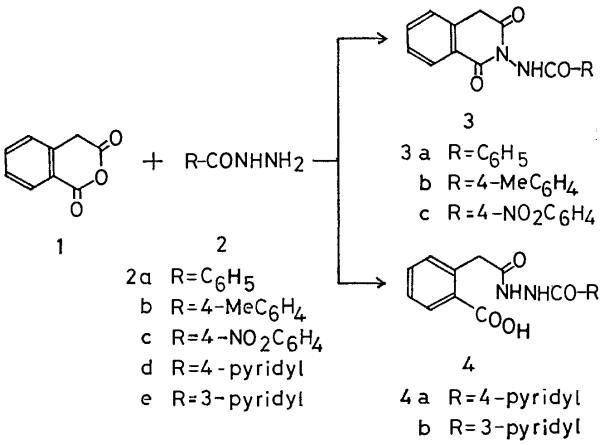
The synthesis of 1,3,4-oxadiazolo[3,2-*b*]isoquinoline and 1,3,4-thiadiazolo[3,2-*b*]isoquinoline derivatives is described. The reaction of homophthalic anhydride (**1**) with acylhydrazines (**2**) afforded 2-acylamino-1,2,3,4-tetrahydroisoquinoline-1,3-diones (**3**) or 1-(*o*-carboxyphenylacetyl)-2-acylhydrazines (**4**). The treatment of **3** or **4** with polyphosphoric acid gave 2-substituted 1,3,4-oxadiazolo[3,2-*b*]isoquinolin-5(5*H*)-ones (**5**) in quantitative yields. The treatment of **3** or **4** with phosphorus pentasulfide gave 2-substituted 1,3,4-thiadiazolo[3,2-*b*]-isoquinoline-5(5*H*)-thiones (**6**). 2-Phenyl-1,3,4-oxadiazolo[3,2-*b*]isoquinoline-5(5*H*)-thione (**9**) was obtained by the reaction of **5a** with phosphorus pentasulfide.

Homophthalic anhydride is a readily-available cyclic anhydride,[1] which is considered to be a useful starting material for the synthesis of various condensed isoquinoline derivatives. Homophthalic anhydride (**1**) has been condensed with *o*-phenylenediamine to give benzimidazo[1,2-*b*]isoquinoline derivatives.[2-5] On the other hand, *o*-aminobenzenethiol has been treated with 5-substituted homophthalic anhydride to form 2-substituted benzylbenzothiazoles, which were then cyclized to 9-substituted isoquinolino[3,2-*b*]benzothiazolones.[6] Thiazolo[3,2-*b*]isoquinoline derivatives[7] were similarly obtained from 2-aminoethanethiol and **1**. In the reaction of **1** with 1,2-dimethylhydrazine, 2,3-dimethyl-1,2,3,4-tetrahydro-5*H*-2,3-benzodiazepine-1,4-dione[8] has been isolated. The reaction of **1** with *S*-alkylisothiosemicarbazides has been reported to give 2-alkylthio-*s*-triazolo[1,5-*b*]isoquinolin-5-ones, and their reactions have been studied.[9] *s*-Triazolo[1,5-*b*]isoquinolin-5-ones[10,11] have also been synthesized from **1** and amidrazones.

In this paper we wish to report the synthesis of two groups of heterocycles which have new ring systems.

Results and Discussion

When **1** was treated with acyl hydrazines (**2**) in boiling acetic acid, the products isolated were 2-acylamino-1,2,3,4-tetrahydroisoquinoline-1,3-diones (**3**) or 1-(*o*-carboxyphenylacetyl)-2-acylhydrazines (**4**).



Scheme 1.

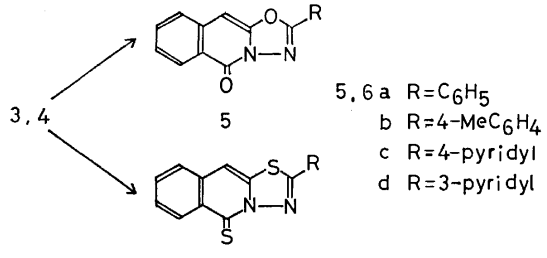
Thus, the reaction of **1** with benzohydrazide (**2a**) gave 2-benzamido-1,2,3,4-tetrahydroisoquinoline-1,3-dione (**3a**) in a 92% yield. The IR spectrum of **3a** showed an NH absorption at 3250 cm^{-1} and three carbonyl absorptions at 1735, 1695, and 1660 cm^{-1}. The reaction of **1** with (**2b**) and (**2c**) proceeded in a similar manner to give (**3b**) and (**3c**). However, the products obtained from (**2d**) and (**2e**) were 1-(*o*-carboxyphenylacetyl)-2-acylhydrazines (**4a**) and (**4b**). The physical properties and spectral data, shown in Table 1, are consistent with the structure assigned.

TABLE 1. PHYSICAL PROPERTIES AND SPECTRAL DATA OF **3** AND **4**

Compound	Reaction time (hr)	Yield (%)	Mp (°C) Solvent	Found (%) (Calcd (%)) C	H	IR (KBr, cm^{-1})	UV (λ_{max}^{MeOH} nm (log ε))
3a	4	92	190—191 MeOH	68.54 (68.56	4.48 4.32)	3250, 1735, 1695, 1660	238(4.13), 280(sh, 3.36) 290(sh, 3.23), 310(sh, 2.93)
3b	4	74	206—208 AcOH	69.19 (69.37	4.61 4.80)	3220, 1730, 1695, 1650	243(4.43), 282(sh, 3.51) 292(sh, 3.41), 310(sh, 3.30)
3c	10	76	210—211 MeOH	58.94 (59.08	3.67 3.41)	3280, 1743, 1700, 1665	251(4.33)
4a	5	66	112—115 MeOH	60.06 (60.19	4.56 4.38)	3430, 3160, 2920, 2820, 1735, 1700 1663	242(4.20), 310(sh, 3.49)
4b	16	35	166—169 EtOH	60.27 (60.19	4.66 4.38)	3540, 3160, 2980, 1730, 1670	243(4.21), 290(sh, 3.24) 310(sh, 2.86)

The dehydration of **3** with polyphosphoric acid proceeded smoothly to give the desired products (**5**) in quantitative yields. Thus, **3a** was heated with polyphosphoric acid at 125—130 °C, and the reaction mixture was treated in the usual manner to give 2-phenyl-1,3,4-oxadiazolo[3,2-*b*]isoquinolin-5(5*H*)-one (**5a**). The IR spectrum of **5a** showed no NH absorptions, only one C=O absorption at 1685 cm^{-1} and a new C=N absorption at 1652 cm^{-1}. The olefinic proton resonance of **5a** in the NMR spectrum was observed at δ 6.49 ppm. The elemental analysis and the mass-spectral molecular ion at *m/e* 262 also supported the assigned structure. A similar cyclization by polyphosphoric acid occurred in one step in the case of **4**. The **5** compounds showed characteristic IR absorptions at 1683—1685 (C=O) and 1648—1652 (C=N) cm^{-1}. The physical properties and spectral data are summarized in Table 2. The **5** compounds are heterocycles with a new ring system.

When **3** or **4** was heated with phosphorus pentasulfide in refluxing pyridine, 2-substituted 1,3,4-thiadiazolo[3,2-*b*]isoquinoline-5(5*H*)-thiones (**6**) were obtained; these heterocycles also belong to a new ring system. 2-Phenyl-1,3,4-thiadiazolo[3,2-*b*]isoquinoline-5(5*H*)-thione (**6a**) showed no NH or C=O absorptions in the IR spectrum. The NMR spectrum exhibited a signal of an olefinic proton at δ 7.31 ppm. The molecular-ion peak at *m/e* 294 and the other fragment-ion peaks in the mass spectrum were also consistent with the structure. The physical properties and spectral data of the other compounds of **6** are summarized in Table 2. These compounds show similar absorption maxima in the UV and visible spectra.



Scheme 2.

Some reactions of these new heterocycles **5** and **6** were attempted. The hydrolysis of **5a** in refluxing aqueous methanol containing sodium hydroxide afforded a crystalline product (**7**). The characteristic absorptions of the carboxyl group were observed at 2620—3340 (OH) and 1705 (C=O) cm^{-1} in the IR spectrum. The NMR spectrum of **7** indicated the presence of a methylene group at δ 4.13 ppm. From the above data, the structure of **7** was assigned to 2-(*o*-carboxybenzyl)-5-phenyl-1,3,4-oxadiazole. A similar treatment of **6a** with alkaline afforded a product (**8**). The characteristic absorption of the carboxyl group were observed at 2340—3440 and 1688 cm^{-1} in the IR spectrum. **8** was also shown to be the ring-opened product 2-(*o*-carboxybenzyl)-5-phenyl-1,3,4-thiadiazole.

When **5a** was treated with phosphorus pentasulfide

TABLE 2. PHYSICAL PROPERTIES AND SPECTRAL DATA OF 5 AND 6

Compound	Reaction time	Yield (%)	Mp (°C) Solvent	Found (%) (Calcd (%)) C	H	IR (KBr, cm^{-1})	UV (λ_{max}^{MeOH} nm (log ε))
5a	40 min	100	236—238 Pyridine	73.50 (73.27	3.78 3.84)	3040, 1685, 1652, 1610	245(sh, 4.51), 256(sh, 4.59), 263(4.61), 290(sh, 4.13), 354(sh, 3.83), 370(3.92), 385(sh, 3.79)
5b	40 min	100	290—292 Pyridine	73.72 (73.90	4.14 4.38)	3040, 1685, 1652, 1610	251(sh, 4.47), 268(4.63), 354(sh, 3.88), 368(3.95), 385(sh, 3.80)

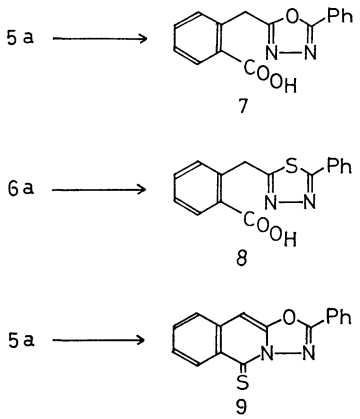
6a	4 hr	48	217—218 Pyridine	65.34 (65.30	3.65 3.43)	3040, 1600, 1530, 1472	230(4.45), 270(4.61), 294(4.51), 347(sh, 3.87) 443(4.01), 465(3.97)
6b	5 hr	49	178—180 Pyridine	66.55 (66.23	4.11 3.92)	3040, 1665, 1605, 1532	232(4.53), 274(4.57), 299(4.60), 348(sh, 3.87), 440(4.06), 463(4.03)
6c	5 hr	39	269—273 Pyridine	61.27 (61.02	3.28 3.07)	3030, 1603, 1530, 1475	225(4.42), 266(4.65), 290(4.37), 330(3.99), 350(sh, 3.93), 467(3.92)
6d	5 hr	50	251—252 Pyridine	61.12 (61.02	3.04 3.07)	3030, 1600, 1533, 1469	227(4.39), 266(4.58), 292(4.45), 326(3.94), 349(sh, 3.90), 450(3.96), 470(3.92)

in refluxing pyridine, yellow needles (**9**) were obtained in a quantitative yield. The IR spectrum of **9** showed no C=O absorption, but the C=N absorption band which was characteristic of the **5** compounds remained at 1652 cm^{-1}. The absorption maxima observed in the UV and visible spectrum were similar to those of **5a**. These spectral data and the satisfactory analytical value accorded with the structure of **9** as 2-phenyl-1,3,4-oxadiazolo[3,2-*b*]isoquinoline-5(5*H*)-thione.



Scheme 3.

Experimental

All the melting points are uncorrected. The IR, UV, and NMR spectra were measured with a JASCO Model IRA-2, a Shimadzu Model MPS-501, and a Hitachi Model R-20 spectrometer respectively. A Shimadzu Model UM-3B apparatus was used for the elemental analysis.

*2-Benzamido-1,2,3,4-tetrahydroisoquinoline-1,3-dione (**3a**).* A mixture of **1** (724 mg, 4.5 mmol) and **2a** (618 mg, 4.5 mmol) in acetic acid (10 ml) was refluxed for 4 hr. After the concentration of the solution *in vacuo* and subsequent cooling, the crystals were filtered to give **3a** (1.15 g, 92% yield). Recrystallization from methanol afforded white crystals; mp 190—191 °C.

The other derivatives, **3b**, **3c**, **4a**, and **4b** were obtained according to methods similar to those described in the case of **3a**.

*2-Phenyl-1,3,4-oxadiazolo[3,2-b]isoquinolin-5(5H)-one (**5a**).* A mixture of **3a** (840 mg, 3.0 mmol) and polyphosphoric acid (2.7 g) was heated at 125—130 °C with gentle stirring for 40 min. After cooling, the mixture was poured into water (30 ml) and the resulting precipitates were filtered to give **5a** in a quantitative yield. Recrystallization from pyridine afforded yellow plates; mp 236—238 °C. NMR ($CDCl_3$): δ 6.49 (s, 1H, =CH–), 7.2—8.7 (m, 9H, aromatic H). Mass *m/e* (%): 262 (M^+, 100), 131 (57), 103 (57).

The other derivatives, **5b**—**5d**, were obtained from **3** or **4** according to methods similar to those described in the case of **5a**.

*2-Phenyl-1,3,4-thiadiazolo[3,2-b]isoquinoline-5(5H)-thione(**6a**).* A mixture of **3a** (560 mg, 2.0 mmol) and finely powdered phosphorus pentasulfide (450 mg. 2.0 mmol) in pyridine (3.0 ml) was refluxed for 4 hr. The insoluble materials were then filtered off from the hot solution, and the filtrate was cooled. The precipitates were filtered to give **6a** (227 mg, 48% yield). Recrystallization from pyridine afforded orange needles; mp 217—218 °C. NMR ($CDCl_3$): δ 7.31 (s, 1H, =CH–) 7.5—8.2 (m, 9H, aromatic H). Mass *m/e* (%): 294 (M^+, 100), 266 (17), 250 (44), 191 (23), 159 (40), 147 (98), 146 (65), 121 (63).

*2-(o-Carboxybenzyl)-5-phenyl-1,3,4-oxadiazole (**7**).* A solution of **5a** (262 mg, 1.0 mmol) in a mixture of aqueous sodium hydroxide (1 M, 5.0 ml) and methanol (5.0 ml) was refluxed for 5 hr. After the removal of the solvent, water (15 ml) was added to the residue, and the solution was neutralized with dilute hydrochloric acid. The resulting precipitates were filtered to give **7** (191 mg, 68% yield). Recrystallization from methanol afforded white needles; mp 174—175 °C. Found: C, 68.76; H, 4.37%. Calcd for $C_{16}H_{12}O_3N_2$: C, 68.56; H, 4.32%. IR (KBr): 3360, 3040, 2960, 2740, 2620, 1705, 1608, 1555 cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 280 (4.32). NMR (DMSO-d_6): δ 4.13 (s, 2H, $-CH_2-$), 7.4—8.3 (m, 9H, aromatic H).

*2-(o-Carboxybenzyl)-5-phenyl-1,3,4-thiadiazole (**8**).* A solution of **6a** (147 mg, 0.50 mmol) in a mixture of aqueous sodium hydroxide (1 M, 2.5 ml) and methanol (15 ml) was refluxed for 24 hr. After the subsequent evaporation of the solvent, water (15 ml) was added to the residue; the small amount of insoluble materials was then filtered off. The filtrate was neutralized with dilute hydrochloric acid, and the resulting precipitates were filtered to give **8** (111 mg, 75% yield). Recrystallization from methanol afforded white needles; mp 193—194 °C. Found: C, 64.87; H, 4.04%. Calcd for $C_{16}H_{12}O_2N_2S$: C, 64.87; H, 4.08%. IR (KBr): 3440, 2860, 2760, 2680, 2455, 2370, 1688, 1597, 1459 cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 272 (4.22).

*2-Phenyl-1,3,4-oxadiazolo[3,2-b]isoquinoline-5(5H)-thione (**9**).* A mixture of **5a** (500 mg, 2.0 mmol) and phosphorus pentasulfide (440 mg, 2.0 mmol) in pyridine (10 ml) was refluxed for 8 hr. The insoluble materials were filtered off from the hot solution, and then the filtrate was concentrated *in vacuo* to one-half volume. After cooling, the precipitates were filtered to give **9** (542 mg, 100% yield). Recrystallization from ethanol afforded yellow needles; mp 205—206 °C. Found: C, 69.44; H, 3.62%. Calcd for $C_{16}H_{10}ON_2S$: C, 69.06; H, 3.62%. IR (KBr): 3040, 1652, 1610, 1572, 1535, 1472 cm^{-1}. UV λ_{max}^{MeOH} nm (log ε): 218 (4.34), 259 (4.64), 282 (4.61), 310 (sh, 4.02), 415 (4.02), 436 (4.03).

The authors wish to express their thanks to Dr. Masatoshi Hirayama for the NMR measurements and to the Sankyo Co., Ltd., for the mass measurements.

Oxidation of Cyclopropylamines and Aziridines with Lead Tetraacetate

Tamejiro HIYAMA, Hiroshi KOIDE, and Hitosi NOZAKI

Department of Industrial Chemistry, Kyoto University, Yoshida, Kyoto 606

(Received May 6, 1975)

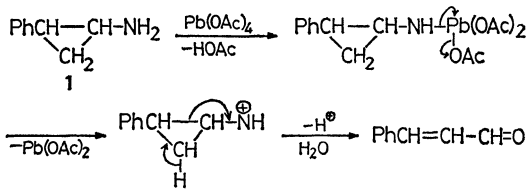
The title reaction of 2-phenylcyclopropylamine gives cinnamaldehyde, while that of the 1-phenyl isomer produces benzonitrile and ethylene. The similar treatment of 2-phenylaziridine provides benzaldehyde as the only isolable product. These reactions are explained by assuming the common intermediacy of nitrenium ions such as  respectively. The assumption is confirmed by the oxidation of the corresponding amines with sodium hypochlorite. Entention of the reaction to 2,3-polymethyleneaziridines with R group on C-2 afforded R–CO–$(CH_2)_n$–C≡N type products (R=H, alkyl, phenyl) in preparative yields. This provides a novel method of C=C bond cleavage of cycloalkenes.

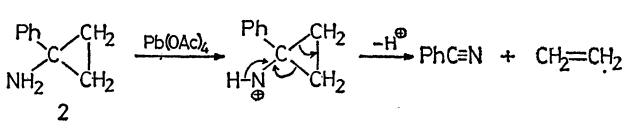
Information on reactive metastable species has been accumulating.[1] Among them much attention has been focused on the oxidation of amines with metal salts in higher valency.[2] The species involved in the oxidation are nitrenium ions, nitrogen radicals,[3] and nitrenes.[4] We wish to report that the lead tetraacetate oxidation of cyclopropylamines and aziridines proceeds *via* nitrenium ion intermediates.[5]

The *trans* isomer of 2-phenylcyclopropylamine (**1**) in dichloromethane was treated with equimolar lead tetraacetate at −78 °C to afford *trans*-cinnamaldhyde. The oxidation of the *cis* isomer of **1** gave the same product. The regioisomer, 1-phenylcyclopropylamine (**2**), reacted in a completely different way to produce benzonitrile and ethylene, the latter being ascertained by obtaining 1,2-dibromoethane.

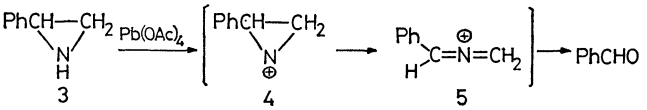
Nitrene intermediates in these reactions are excluded on the basis of the following facts. Thermal decomposition of cyclopropyl azides results in the ring expansion to yield 1-azetines.[6] This transformation involves cyclopropylnitrene intermediates.[6c] In contrast, however, fragmentation to olefins and nitriles is observed when appropriately substituted cyclopropyl azides are decomposed.[7] The choice of either ring expansion or fragmentation seems to depend upon the substituents on the cyclopropane ring. The fragmentation is particularly favored in the one that partial positive charge being developed in the transition state resides on the remaining nitrogen upon the extrusion of nitrogen molecule.[7]

More appropriately the above oxidation can be explained by assuming the intermediacy of nitrenium ions.[8] In order to confirm this, the amines *trans*-**1** and **2** were treated successively with sodium hypochlorite and with silver perchlorate. The products obtained under such nitrenium ion producing conditions[9] were the same as in the above oxidation, *i.e.*, cinnamaldehyde from *trans*-**1** and benzonitrile from **2**.

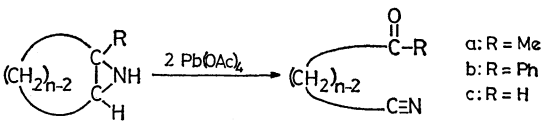




Oxidation of 2-phenylaziridine (**3**) gave benzaldehyde as a sole isolable product. Possibly the reaction involves nitrenium ion intermediate **4**[10] and the 2-azaallene cation **5**,[11] which is then oxygenated to benzaldehyde. With this observation in hand we examined lead tetraacetate oxidation of aziridines fused with medium and large rings.



The aziridine **6a** dissolved in dichloromethane was treated with lead tetraacetate under a nitrogen atmosphere at −40 °C. Stirring for 1 hr at −40 °C, warming up to room temperature during 2 hr and work-up gave 12-cyano-2-dodecanone (**7a**). Best results were obtained upon the use of two molar equivalent of lead tetraacetate. The structure of the product was unambiguously confirmed by the alternative synthesis of **7a**. Namely, ethyl acetoacetate was alkylated with 1,9-dibromononane and the resulting product was heated in aqueous dimethyl sulfoxide containing sodium cyanide. Both decarboxylation[12] and substitution of cyano group for bromine were attained in this single operation yielding **7a**. The oxidation was extended to aziridines **6b**, **6c**, **8a**—**c**, and to the nonamethylene homologue **11a**. The yields as well as the physical properties of the products are listed in



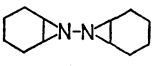


Table 2. In contrast to the above results, 7-azanorcarane (**10c**) was recovered unchanged under the typical condition, but the reaction at reflux of dichloromethane gave a product tentatively assigned as 7,7'-bi-7-azanorcarane (**13**).

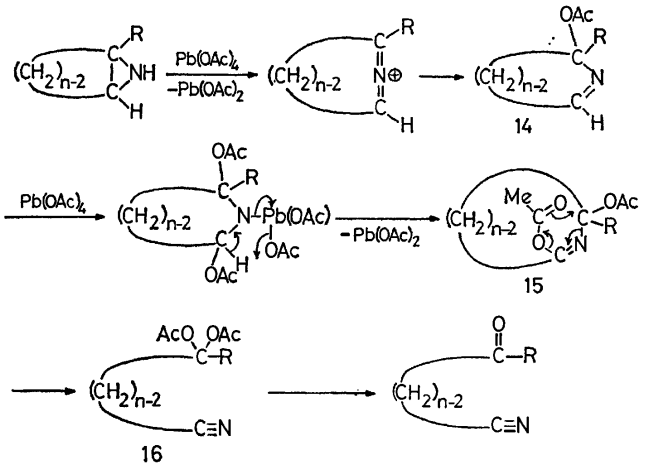
The mechanism of the novel transformation can be understood by the following scheme involving two moles of lead tetraacetate. A cyclic 2-azaallene cation is readily susceptible to nucleophilic attack of acetate anion to give **14**. Addition of lead tetraacetate on the C=N bond in **14** followed by elimination yields **15**. Facile thermal rearrangement affords a *gem*-diacetate **16**, characterized by the spectrometry of the crude product (1735—1744 cm^{-1}, δ~2.0 (singlet)). Purification upon silica gel tlc induces the hydrolysis of **16** to give the corresponding ω-cyano carbonyl compound. Obviously **10c** should give a nitrenium ion which can not be isomerized to a seven-membered azaallene cation due to the strain. This accounts for the formation of **13**.

The transformation of an olefin into an ω-cyanoaldehyde has been previously achieved by the addition of nitrosyl chloride and the following Beckmann rearrangement.[13] The present method is more generally applicable, as the 2-substituted aziridines are easily obtained from cyclic ketone oximes by means of the Neber reaction[14] proceeding in the presence of Grignard reagents or organolithiums.



Experimental

IR spectra were recorded on a Shimadzu IR-27 G spectrometer, mass spectra on a Hitachi RMU-6L machine, and PMR spectra on a Varian EM 360 spectrometer (60 MHz) in carbon tetrachloride solution. All the temperatures recorded are uncorrected.

Oxidation of Amines ***1***, ***2***, *and* ***3*** *with Lead Tetraacetate. A General Procedure.* To a solution of lead tetraacetate (490 mg, 1.1 mmol) in dichloromethane (20 ml) an amine (1.0 mmol) dissolved in dichloromethane (5 ml) was added dropwise under a nitrogen atmosphere at −78 °C. The mixture was then gradually warmed up to room temperature in *ca.* 10 hr. Isolation of the product was accomplished by concentration of the reaction mixture, followed by preparative tlc. The product was identified by the comparison of its spectral data with those of the authentic specimen. The results are summarized in Table 1. The yields were estimated either by the isolation or glc assay as indicated.

Table 1. Oxidation of **1**, **2**, and **3**

Amine	Oxidant	Product	Yield (%)
trans-**1**	$Pb(OAc)_4$	PhCH=CHCHO	79[a]
trans-**1**	NaOCl	PhCH=CHCHO	34[a]
cis-**1**	$Pb(OAc)_4$	PhCH=CHCHO	84[a]
2	$Pb(OAc)_4$	PhC≡N[c]	69[b]
2	NaOCl	PhC≡N	21[b]
3	$Pb(OAc)_4$	PhCHO	42[b]

a) Isolation yield. b) Estimated by gas chromatographic assay. c) The accompanying ethylene was identified as 1,2-dibromoethane.

Oxidation of Amines trans-***1*** *and* ***2*** *with Sodium Hydrochlorite.* An amine (0.6 mmol) was added to ice-cooled commercially available aqueous sodium hypochlorite (5% content, 5.2 g) at 0 °C. The mixture was stirred at 0 °C for 10 min and then at room temperature for 1 hr. Extractive work-up with ether gave a crude product which was treated with silver perchlorate (166 mg) in acetone (5 ml) for a night. The results are listed in Table 1.

Oxidation of 2,3-Polymethyleneaziridines. A Typical Procedure: Aziridine **6a** (197 mg, 1.0 mmol) dissolved in dichloromethane (4 ml) was added to a solution of lead tetraacetate (1.00 g, 2.3 mmol) in dichloromethane (15 ml) under a nitrogen atmosphere at −40 °C. Precipitation of lead diacetate immediately occurred. The mixture was gradually warmed up to room temperature in 6 hr and then concentrated *in vacuo*. The product **7a** (171 mg, 82% yield) was separated from lead diacetate by preparative tlc on silica gel (*n*-hexane/ether 3 : 1, R_f 0.4). The yields and the physical properties of the products are collected in Table 2.

*1-Methyl-13-azabicyclo[10.1.0]tridecane (****6a****).* A methylmagnesium iodide solution prepared from methyl iodide (11.4 g, 80 mmol) and magnesium (2.0 g, 82 mmol) in ether (20 ml) was diluted with toluene (20 ml) and then cyclododecanone oxime (3.94 g, 20 mmol) was added. Ether was removed by heating the mixture and the remaining toluene solution was heated to reflux overnight. The mixture was poured into ice-cooled aqueous ammonium chloride and extracted with benzene. Work-up and distillation at 89—90 °C/0.1 mmHg gave the aziridine **6a** (2.19 g, 56% yield), mp 33.0—33.5 °C (*n*-hexane). IR (neat): 3250, 888 cm^{-1}, PMR: δ 0.9—2.4 (m+s (δ 1.17), methylenes, methyl and methine), mass: *m/e* 195 (M^+), 194 (M^+-1), 180 (M^+-15). Found: C, 79.8; H, 13.2; N, 7.4%. Calcd for $C_{13}H_{25}N$: C, 79.9; H, 12.9; N, 7.2%

*1-Phenyl-13-azabicyclo[10.1.0]tridecane (****6b****).* Cyclododecanone oxime (5.91 g, 30 mmol) and toluene (70 ml) were added to an ethereal solution of phenyllithium (prepared from lithium dispersion (1.75 g) in ether (50 ml) and bromobenzene (18.8 g, 120 mmol)). The resulting suspension was concentrated to remove ether and heating was continued for 24 hr (bath temperature 140 °C). Work-up and column chromatography (silica gel, *n*-hexane/ether 1 : 1) afforded **6b** (6.19 g, 80%), mp 55—56 °C (*n*-hexane). IR (Nujol): 3230, 1604, 1580, 763, 701 cm^{-1}, PMR: δ 0.5 (br s, 1H, NH), 0.8—2.2 (m, 21H, methylenes and methine), 7.10 (s, 5H, Ph). Mass: *m/e* 257 (M^+), 256 (M^+-1), 148 (100%). Found: C, 83.8; H, 10.8; N, 5.7%. Calcd for $C_{18}H_{27}N$: C, 84.0; H, 10.6; N, 5.4%.

*13-Azabicyclo[10.1.0]tridecane (****6c****).* A mixture (*ca.* 1 : 1) of *cis*- and *trans*-cyclododecene (1.66 g, 10 mmol) was treated with silver isocyanate (2.0 g, 13 mmol) and iodine (2.54 g, 10 mmol) in tetrahydrofuran (20 ml) in a similar

Table 2. Lead tetraacetate oxidation of aziridines **6**, **8**, **10** and **11**, and the physical properties of the products

manner as the reported procedure[15] to obtain methyl 2-iodocyclododecanecarbamate, mp 108—109.5 °C (*n*-hexane), IR (Nujol): 3200, 1692, 1536 cm^{-1}. Found: C, 45.9; H, 7.2; N, 3.7%. Calcd for $C_{14}H_{26}INO_2$: C, 45.8; H, 7.1; N, 3.8%.

The carbamate (1.11 g, 30 mmol) was heated in methanol (40 ml) and water (8ml) containing sodium hydroxide (2.4 g, 60 mmol) for 2 hr. Work-up followed by distillation at 120—130 °C (bath temperature)/0.2 mmHg gave the aziridine **6c** (490 mg, 90% yield), mp 46.5—47.5 °C (*n*-hexane), IR (neat): 3250, 969, 874 cm^{-1}. Found: C, 79.4; H, 12.9; N, 7.8%. Calcd for $C_{12}H_{23}N$: C, 79.5; H, 12.8; N, 7.7%.

*1-Methyl-9-azabicyclo[6.1.0]nonane (**8a**).* Cyclooctanone oxime (2.82 g, 20 mmol) was treated with methylmagnesium iodide (*ca.* 80 mmol) in toluene (10ml) and ether (25 ml) in a similar manner as **6a** to give **8a** (l. 92 g, 51% yield), bp 54 °C/4 mmHg. IR (neat): 3250, 830 cm^{-1}, PMR: δ 1.0—2.4 (m+s (δ 1.15)), mass: *m/e* 139 (M^+), 138 (M^+-1). Found: C, 77.3; H, 12.5; N, 9.8%. Calcd for $C_9H_{17}N$: C, 77.6; H, 12.3; N, 10.1%.

*1-Phenyl-9-azabicyclo[6.1.0]nonane (**8b**).* The aziridine was obtained in 62% yield, bp 103—105 °C/0.1 mmHg. IR (neat): 3230, 1601, 1496, 931, 809, 760, 742, 701 cm^{-1}, PMR: δ 0.7—2.7 (m, 14H), 7.0—7.7 (m, 5H), mass: *m/e* 201 (M^+), 200 (M^+-1). Found: C, 83.4; H, 9.7; N, 6.7%. Calcd for $C_{14}H_{19}N$: C, 83.5; H, 9.5; N, 7.0%.

*Aziridines **8c** and **10c**.* The aziridines were prepared according to the literature.[16]

*1-Methyl-12-azabicyclo[9.1.0]dodecane (**11a**).* The aziridine was obtained by the similar method from cycloundecanone oxime in 71% yield, bp 160—165 °C/22 mmHg. IR (neat): 3250, 894 cm^{-1}, PMR: δ 0.2—0.7 (br. s, 1H), 0.7—2.3 (m+s (δ 1.18), 22H), mass: *m/e* 181 (M^+). Found: C, 79.5; H, 12.8; N, 7.7%. Calcd for $C_{12}H_{23}N$: C, 79.4; H, 12.9; N, 7.6%.

*Alternative Preparation of 12-Cyano-2-dodecanone (**7a**).* Ethyl acetoacetate (1.30 g, 10 mmol) was added to sodium hydride (10 mmol) suspended in dimethoxyethane (20 ml). After the evolution of hydrogen gas ceased 1,9-dibromononane (2.86 g, 10 mmol) was added to the resulting pale yellow solution. Stirring at room temperature for two days, followed by chromatographic separation of the crude product, gave 12-bromo-3-ethoxycarbonyl-2-dodecanone (0.62 g, 54% yield based on the consumed dibromide). The alkylate was dissolved in 95% aqueous dimethyl sulfoxide (10 ml) containing sodium cyanide (9.50 g), and the solution was heated at 160—165 °C for 3 hr. Extractive work-up and the subsequent purification by preparative tlc (silica gel, ether/*n*-hexane 1 : 3, R_f 0.4—0.5) afforded **7a** (0.11 g, 28% yield). All the spectral data were identical with those of the oxidation product.

Stereospecific [2π+2π+2π] Cycloaddition Reaction of Norbornadiene[1]

Iwao TABUSHI*, Kazuo YAMAMURA, Zen-ichi YOSHIDA,** and Atsushi TOGASHI**

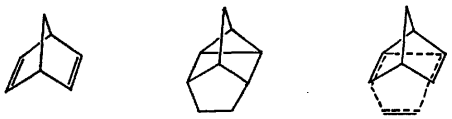
Faculty of Pharmaceutical Sciences, Kyushu University, Fukuoka 812

***Department of Synthetic Chemistry, Kyoto University, Kyoto 606*

(Received May 27, 1975)

[2π+2π+2π] cycloaddition reaction of *cis*- or *trans*-disubstituted olefinic dienophiles (**4a–4e**) to bicyclo-[2.2.1]hepta-2,5-diene (**1**, norbornadiene) was found to be stereospecific. The cycloadducts obtained, 4,5-disubstituted tetracyclo[4.2.1.0.^{2,9}0^{3,7}]nonane (**5,6**) conserved the original stereochemistry in the dienophiles, strongly suggesting the presence of *homo*-conjugation in **1**. A striking contrast between cycloaddition reaction of quadricyclane (a valence bond isomer of **1**) and that of norbornadiene was understood by application of the principle of orbital symmetry conservation to these cycloadditions.

[2π+2π+2π] cycloaddition reaction of norbornadiene (**1**) with dienophiles are known as *homo*-Diels-Alder reaction in several cases,[2] giving tetracyclo-[4.2.1.0.^{2,9}0^{3,7}]nonanes (**2**). The unique and very interesting mode of these cycloadditions of **1** may be interpreted by means of a six-membered transition state (**3**).



1 **2** **3**

It was suggested by Hoffmann *et al.*[3] that there exists a (through-space) conjugation between the two double bonds in the ground electronic state of **1**, and several physico-chemical investigations (photoelectron spectroscopy,[4] photoionization spectroscopy[5]) or quantum chemical studies[3,4b] afforded good evidences for the suggestion.

If the unusually effective *homo*-conjugation in **1** also strongly contributes to the assumed transition state (**3**), the cycloadducts must conserve the original stereochemistry of the starting dienophiles. No investigation appeared so far, which showed that the *homo*-Diels-Alder reactions are concerted ones, except for crotononitrile which is reported to conserve the substituents' configuration, *cis* or *trans*, in the cycloadducts.[2f] If these reactions are concerted, the difference in the symmetry of the highest occupied molecular orbital (HOMO) between norbornadiene (SA) and quadricyclane (AS) could be attributed to the striking difference in regiospecificity of the cycloaddition reactions between these two valence bond isomers.[8]

Now we wish to report stereochemistry in *homo*-Diels-Alder cycloadditions of **1** with several *cis*- and *trans*-disubstituted olefinic dienophiles (**3a**—**3e**). These cycloaddition reactions were concluded to be completely stereospecific, based on results of chemical and spectroscopic studies of the adducts, therefore, it seems to be concerted, suggesting that the *homo*-conjugation in **1** is very important to control its cycloaddition reactions.

Results and Discussion

Dimethyl fumarate (**4b**) was treated with excess amount of norbornadiene (**1**) in a sealed tube at 180 °C for 50 hr, in the presence of hydroquinone (2% to **4b**) as an inhibitor to radical polymerizations. Distillation under the reduced pressure gave an oily product (bp 120—125°/5 mmHg) in 78% yield. Determination of the product's structure was made chemically (*vide infra*) and spectroscopically. The mass spectrum of the product showed molecular peak (M^+, 236 *m/e*) and expected fragment peaks (M^+—HCO_2CH_3, 176 *m/e* and M^+—HCO_2CH_3—CO_2CH_3, 117 *m/e*). Infrared spectrum of **5b** exhibited an absorption at 800 cm^{-1}, characteristic to nortricyclane skeleton,[7] and nuclear magnetic resonance spectrum showed absorptions of two protons α to methoxycarbonyls (δ 3.42, 3.22), two protons β to methoxycarbonyls (δ 2.40, 2.32), C_7-H proton[8] (δ 2.04, 1H), and cyclopropane ring protons (δ 0.9—1.3, 3H), which also strongly supported the structure **5b**.

a) R_1R_2=-COOOC-; R_3=R_4=H
b) R_1=R_4=CO_2CH_3; R_2=R_3=H
c) R_1=R_2=CO_2CH_3; R_3=R_4=H
d) R_1=R_4=CN; R_2=R_3=H
e) R_1=R_2=CN; R_3=R_4=H

4,5-*trans*-Dicyanotetracyclo[4.2.1.0.^{2,9}0^{3,7}]nonane (**5d**) was obtained in 69% yield, when fumaronitrile (**4d**) was treated at 120 °C with norbornadiene in a similar manner to that described above. The structure **5d** was again supported by mass spectrum (Table 1), IR spectrum (2240 and 800 cm^{-1}), and NMR spectrum (Table 2), the latter strongly resembled to that of *trans*-dicarboxylate, **5b**, in every detail (chemical shifts and coupling patterns) except for the chemical shifts of H_{4x} and H_{5n}.

Two *homo*-Diels-Alder stereoisomers, *endo-cis*- (**5**) and *exo-cis*-4,5-disubstituted, were obtained from each of maleic anhydide (**4a**), dimethyl maleate (**4c**), and maleonitrile (**4e**) additions to **1**. The NMR spectrum of each cycloadduct (**5a**, **6a**, **5c**, **6c**) exhibited characteristic absorptions of symmetrical two α protons ($H_{4,5}$) and two β protons ($H_{3,6}$) to the substituents, CO_2X, together with absorptions of isolated bridgehead proton (H_7) and three cyclopropane ring protons, again strongly supporting the products' structure of tetracyclo-

a) Relative intensities are in parentheses.

[4.2.1.0.^{2,9}0^{3,7}]nonane skeleton. Based on all of spectral data, NMR (*vide infra*), IR, and/or mass spectra, and chemical conversion cited below, it was concluded that cycloadducts, **5a**—**5d**, **6a**—**6d** differ only in substituents or in stereochemistry at C_4 and C_5.

Product distribution in dienophiles' addition to **1** were carefully determined by means of gas liquid phase chromatography (glpc) and the results are shown in Table 3. In each case of addition of a *trans*-disubstituted olefin (**4b** and **4d**) to **1**, no or little corresponding *cis*-4,5-disubstituted isomer was produced within the precision of glpc detection (0.3%) (runs 3 and 7). It was also shown by glpc analysis of crude products that, in the cases of additions of the *cis*-disubstituted olefins (**4c** and **4f**), corresponding *trans* isomers were not detected for **4c** (run 4) or produced only in a trifling amount (5%, run 8) for **4e**. From the present results, therefore, it was concluded that the cycloadducts conserved the original stereochemistry, *cis* or *trans*, of the dienophiles.

Table 3 shows that the stereospecificity mentioned

a) Not detected. b) The conversion was less than 2%.

above holds under the conditions of the controlled reaction temperatures for cases of *cis*-disubstituted dienophiles' additions to **1**. Thus, 35% and 11% of the *trans* isomers isomerized were produced in additions at higher temperature; from *cis* olefin **4c** at 200 °C (run 5) and **4e** at 120 °C (run 9), respectively.

Since maleonitrile (**4e**) was unstable (to isomerize to fumaronitrile, **4d**) at the higher temperatures than 130 °C, the addition reaction of **4e** with **1** was followed at 120 °C up to *ca.* 2% conversion. Glpc analysis of the crude mixture gave a product ratio : **5e** : **6e** : **5d**=73 : 16 : 11. Products **5e** and **6e** could be purified through a preparative glpc, whose IR spectra exhibited absorptions at 2230 and 800 cm^{-1}, demonstrating the presence of nortricyclane skeleton and the cyano substituents.

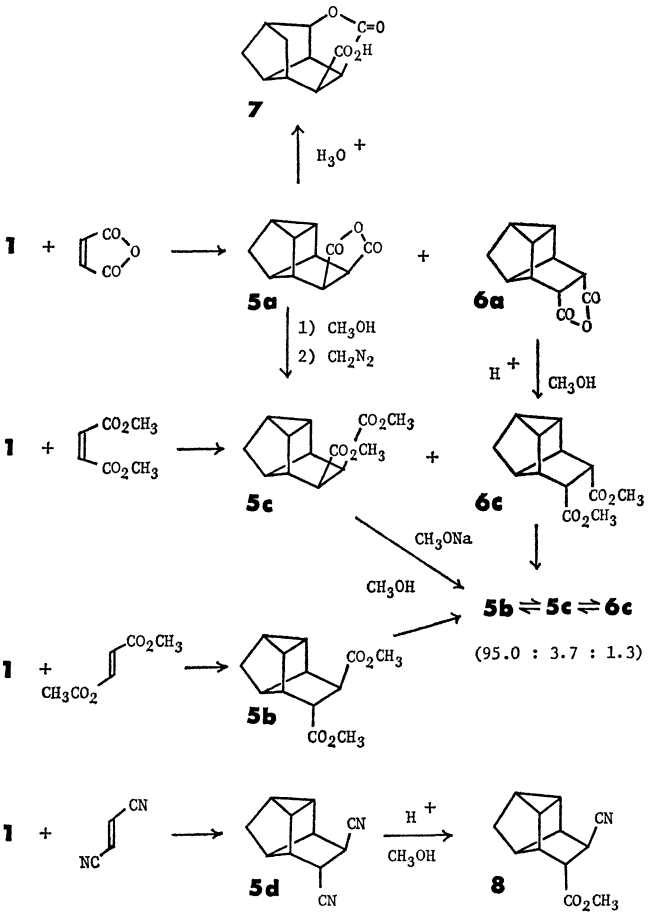
Chemical Conversion of the Cycloadducts. Two stereoisomers, tetracyclo[4.2.1.0.^{2,9}0^{3,7}]nonane-*endo-cis*-4,5-dicarboxylic anhydride (**5a**) and *exo-cis*-dicarboxylic anhydride (**6a**), were obtained in the ratio of 66 : 34,*** when maleic anhydride was treated with excess amount of norbornadiene at 200 °C (Table 3).

The *endo* anhydride (**5a**) was converted to the corresponding half ester on treatment with methanol, followed by estirification with diazomethane giving *endo-cis*-4,5-diester (**5c**) exclusively. Acid catalyzed esterification of the *exo* anhydride (**6a**) in HCl methanol led to the *exo-cis*-4,5-dicarboxylate (**6c**). Dicarboxylates thus obtained, **5c** and **6c**, were identical with those obtained in the reaction of dimethyl maleate (**4c**) with **1**, respectively in every detail (NMR and IR spectra, glpc retention times, see Experimental Section).

It is noteworthy that an equilibrium was attained between the three isomeric dicarboxylates (**5b** : **5c** : **6c**=95.0 : 3.7 : 1.3), when any pure sample of the three was treated with sodium methoxide in methanol at 30 °C for 10 hr.

The conversion of the *trans* dinitrile (**5d**) to the *trans* dicarboxylate (**5b**) was attempted by refluxing a solution of **5d** in HCl acidic methanol for *ca.* 8 hr. However, 4-*endo*-cyano-5-*exo*-methoxycarbonyltetracyclo[4.2.1.0.^{2,9}0^{3,7}]nonane (**8**) was isolated instead of **5b**. NMR spectroscopic evidence (next paragraph), nevertheless, strongly supported that the *trans* dinitrile (**5d**) had the same skeletal structure as the *trans* dicarboxylate (**5b**), and therefore, it was concluded that the cycloadducts (**5a**—**5d**, **6a**, and **6c**) differ only in substituents (with the same stereochemistry) or in stereochemistry (with the same substituent). Structural correlations are shown in Scheme 1.

Stereochemistry and NMR Spectra of the Cycloadducts. Careful examinations of chemical shifts data in Table 2 reveal a very characteristic trend : the δ values of the *endo* protons at C_4 (C_5) were somewhat smaller (0.05—0.25 ppm) than those of the *exo* protons at C_4 (C_5). For example, in *trans* diester **5b** (*trans* dinitrile **5d**), the chemical shift of H_{5n} was δ 3.22 (δ 3.07) and that of H_{4x} was δ 3.42 (δ 3.21). A similar trend



Scheme 1.

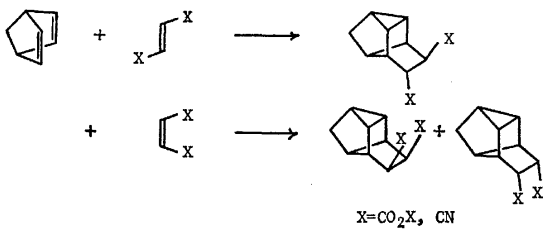
is well known in norbornanes[9] or norbornenes,[10] where the resonances of *exo* protons were observed at somewhat lower field than those of *endo* protons. These were mainly explained as the result of C–C shielding effect.[11]

The chemical shift, δ 3.50 (δ 3.20), of α protons of **5a** (**5c**) was larger than that of α protons, δ 3.25 (δ 3.15), of **6a** (**6c**). This strongly indicated that **5a** (**5c**) and **6a** (**6c**) have *exo* protons and *endo* protons, respectively, in good agreement with the structures assigned on the basis of chemical conversions.

NMR decoupling experiments of the *trans*-dicarboxylate (**5b**) (*trans*-dinitrile, **5d**) were carried out, which made it possible to calculate $J_{3,4x}$, $J_{6,5n}$, or $J_{4,5x}$ (Table 2). Apparently there observed a large coupling of the *exo* proton (H_{4x}) with the bridgehead proton ($J_{3,4x}$=4 Hz), whereas coupling between the *endo* proton (H_{5n}) and the corresponding proton (C_6-H) was not appreciable. Therefore, the appreciable coupling constants, J=3 Hz and J=2 Hz, of the resonances of α protons of **5a** and **5c**, respectively, again strongly supported that these α protons are *exo*, in good agreements with the assigned structures.

Regiospecificity and Stereospecificity of homo-*Diels-Alder Reaction.* Based on the assigned structures of the cycloadducts, it was concluded that the *homo*-Diels-Alder reaction is stereospecific as shown in Scheme 2. The regiospecificity and stereospecificity observed implies that the reaction is concerted and allowed, giving

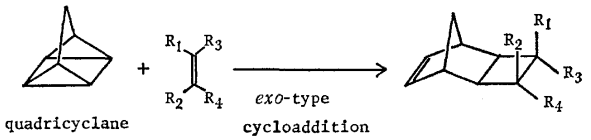
*** Cookson *et al.*[2d] isolated only the *endo-cis* isomer (**5a**), the structure of which was determined by the fact that **5a** could be converted to lactone **7** (Scheme 1).



Scheme 2.

a strong evidence for the *homo*-conjugation in **1** on a reactivity ground.

The present results make a striking contrast to the [2σ+2σ+2π] cycloaddition reaction of quadricyclane reported by the authors,[6] where another type of regiospecificity (*exo*-type addition) together with stereospecificity were observed.



These regiospecificities and stereospecificities in Scheme 3 required a presence of an effective interaction between the two cyclopropane ring bonds in a transition state. Consideration of the usual orbital correlation diagram[12] (Fig. 1) suggests that the *homo-endo*-type cycloaddition to norbornadiene is allowed, whereas the *exo*-type addition, shown in Scheme 3, is forbidden. Thus, the present experimental results are in good agreement with the orbital symmetry consideration.

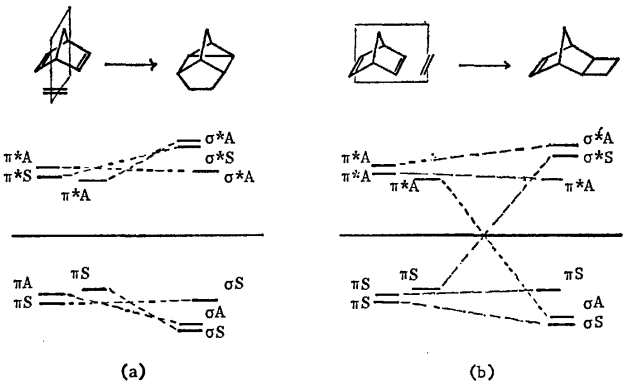


Fig. 1. Orbital correlation diagram.
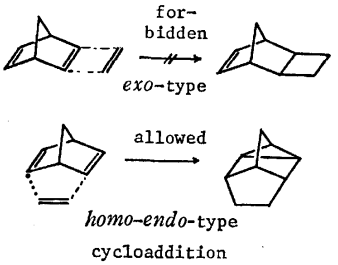
(a) *homo-endo*-type cycloaddition; (b) *exo*-type cycloaddition.



Scheme 3.

On the other hand, for quadricyclane, *exo*-type cycloaddition is allowed and *homo-endo*-type cycloaddition is forbidden. Again experimental results[6] are in good agreement with the prediction from the orbital symmetry consideration.

It is concluded, therefore, that the striking difference in regiospecificity of the cycloaddition reaction between quadricyclane and norbornadiene is attributable to the differed orbital symmetry of these two valence bond isomers.

Experimental

Measurements of nuclear magnetic resonance spectra were performed on Varian T-60, JEOL 60-H, or JEOL 100-H spectrometer. Infrared spectra were obtained with a Hitachi model 215 infrared spectrometer. Elemental analyses were performed by Microanalysis Laboratory in Faculty of Pharmaceutical Sciences, Kyushu University or by Microanalysis Center of Kyoto University. Measurements of mass spectra were performed by Analysis Laboratory of Faculty of Pharmaceutical Sciences, Kyushu University or of Department of Synthetic Chemistry, Kyoto University.

For the determination of the product distribution, glpc analyses were carried out with Shimadzu model GC 4B-IT on two different liquid phases: Silicone DC 550 and polyethylene glycol 20 M. Retention times are shown below.

*Reaction of **1** with Dimethyl Fumarate (**4b**).* A mixture of 1.00 g (6.9 mmol) of dimethyl fumarate (**4b**) and 10 ml (*ca.* 97 mmol) of norbornadiene (**1**) and 10 mg of hydroquinone was sealed in a Pyrex tube (30 ml volume). The sealed tube was heated at 180 °C in a bath for 50 hr. After the evaporation of excess of norbornadiene *in vacuo*, the residue was distilled at the reduced pressure: (**5b**); bp 120—130 °C/5 mmHg; 1.27 g (78%); IR (neat) 3080, 2950, 1735 ($\nu_{C=O}$), 1435, 1180—1200, 1038, 1015, 800, 786 cm^{-1}; Found C, 65.94; H, 6.94%. Calcd for $C_{13}H_{16}O_4$ C, 66.08; H, 6.83%.

*Reaction of **1** with Dimethyl Maleate (**4c**).* A mixture of 1.0 g (6.9 mmol) of dimethyl maleate (**4c**) and 10 ml (97 mmol) of **1** and 10 mg of hydroquinone was sealed in a Pyrex tube and heated at 200 °C for 24 hr. After the distillation off the excess of **1** *in vacuo*, the residue was distilled at the reduced pressure: bp 120—140 °C/5 mmHg; **5c** : **6c** : **5b**=41 : 24 : 35. **5c** : IR (neat) 3060, 2960, 2875, 1740 ($\nu_{C=O}$), 1438, 1200, 818, 794 cm^{-1}; glpc retention time, 18.2 min on 2 m polyethylene glycol (190 °C, H_2, 1.7 atm); Anal. Calcd for $C_{13}H_{16}O_4$ C, 66.08; H, 6.83%. Found; C, 65.45; H, 6.90%. **6c**: IR (neat) 3060, 2960, 2870, 1740 ($\nu_{C=O}$), 1438, 1120, 1195, 818, 792 cm^{-1}; glpc retention time 16.1 min on 2 m polyethylene glycol (190 °C, H_2, 1.7 atm); Found C, 65.75; H, 6.60%. Calcd for $C_{13}H_{16}O_4$: C, 66.08; H, 6.83%.

*Reaction of **1** with Maleic Anhydride (**4a**).* A mixture of 0.50 g (5.1 mmol) of maleic anhydride (**4a**) 1.0 g (*ca.* 11 mmol) of **1**, and 30 mg of hydroquinone was heated in a sealed Pyrex tube at 130 °C for 5 hr. Glpc analysis of the crude mixture on a 2.5 m column of polyethylene glycol at 230 °C (H_2, 3.0 atm) revealed that two products were formed: **5a**, 79% (retention time, 8.8 min) and **6a**, 21% (6.7 min). The product ratio at 200 °C was also shown in Table 2. Purifications of **5a** and **6a** were carried out through preparative glpc. **5a** : IR (KBr) 2980, 1860, 1780, 1220, 1080, 906, 895, 830, 800 cm^{-1}; **6a** : IR (KBr) 2960, 1860, 1780, 1212, 980, 908, 896, 830, 800 cm^{-1}. The NMR chemical shifts of the *endo* anhydride (**5a**) were identical with the values reported by Cookson *et al.*[2d]

Reaction of ***1*** *with Fumaronitrile (****4d****).* A mixture of 1.00 g (12.8 mmol) of fumaronitrile (**4d**), 10 ml of norbornadiene, and 10 mg of hydroquinone was heated in a sealed tube at 120 °C for 50 hr. After the excess of **1** was distilled off at the reduced pressure, the residue was distilled at 10 mmHg : **5d**; 1.5 g (69%); bp 165 °C/10 mmHg; mp 77—77.5 °C (from methylene chloride or methanol); IR (neat) 3070, 2950, 2240 ($\nu_{C\equiv N}$), 1305, 1210, 800 cm^{-1}; glpc retention time, 1.75 min (polyethylene glycol, 1 m, 190 °C, H_2, 1 atm); Found C, 77.83; H, 5.81%. Calcd for $C_{11}H_{10}N_2$ C, 77.62; H, 5.92%.

Reaction of ***1*** *with Maleonitrile (****4e****).* A mixture of 0.75 g (9.6 mmol) of maleonitrile (**4e**), 4 ml (43 mmol) of **1**, and 10 mg of hydroquinone was heated in a sealed tube at 100 °C for 17 hr. Glpc analysis on polyethylene glycol (1 m, 190 °C, H_2, 1 atm) showed two peaks (3.1 and 4.0 min) and a ratio of 15 : 85. IR spectrum of each product exhibited characteristic absorptions at 2240 and 800 cm^{-1}.

Chemical Conversion. ***5a*** *to* ***5c***: After 100 mg of **5a** was dissolved in 5.0 ml of methanol at 50 °C, excess methanol was distilled off *in vacuo*. Then 10 ml of ether was added and the solution was treated with etheral solution of diazomethane. After the evaporation of ether, the residue was analyzed by glpc, IR and NMR spectra.

6a *to* ***6c***: A mixture of 100 mg of **6a**, 5 ml of methanol, two drops of concentrated HCl was heated at 60 °C for 3.0 hr. The methanol solution was condensed to one third and then poured into ice cooled water, to which was added an aqueous solution of sodium bicarbonate to neutralize hydrochloric acid. The aqueous solution was extracted with 25 ml of ether twice, and the glpc analysis of the etheral solution revealed that the product was the *endo-cis*-diester (**6c**).

5d *to* ***8***: A mixture of 50 mg (0.29 mmol) of **5d**, a drop of concentrated hydrochloric acid, and 10 ml of dry methanol in a 25 ml flask was stoppered and heated at 80 °C for 8 hr. After the solution was neutralized with an aqueous solution of sodium bicarbonate, the product was extracted with chloroform. Evaporation of chloroform gave an oily product, and the product was identified as **8** by means of glpc analysis and the identical infrared spectrum with an authentic compound. **8** : retention time, 9.5 min on polyethylene glycol 20 M (2 m, 190 °C, H_2, 1 atm); IR (neat) 3070, 2948, 2240, 1740, 1438, 818, 799 cm^{-1}.

Stereoselective Synthesis of 1,4,4a,9a-Tetrahydro-9-fluorenone Bearing *trans* Angular Substituents

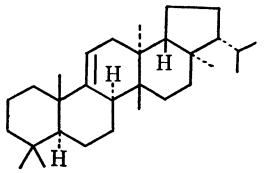
Takenori KUSUMI, Kiyoto IMAYE, and Hiroshi KAKISAWA

Department of Chemistry, Tokyo Kyoiku University, Otsuka, Bunkyo, Tokyo 112

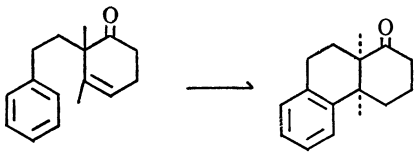
(Received May 31, 1975)

An intramolecular Friedel-Crafts reaction of 2-methyl-1-phenyl-1,2,3,6-tetrahydrophthalic anhydride **6** followed by methylation afforded new types of fluorenones bearing *trans* angular substituents, 4a-carbomethoxy-*trans*-9a-methyl-1,4,4a,9a-tetrahydro-9-fluorenone **7** and 3-hydroxy-*trans*-9a-methyl-9-oxo-1,2,3,4,4a,9a-hexahydrofluoren-*cis*-4a-carboxylic anhydride **10**.

A number of triterpenes are found to have polycyclic systems bearing *trans* substituents at the angular positions, as exemplified by the C/D ring system of fernene **1**.[1] A few reports have appeared concerning the methods for building up such *trans* fused cyclic systems, *e.g.*, hydrocyanation,[2] olefinic cyclization,[3] and the cleavage of a cyclopropane ring.[4] In the preceding paper[5] we have reported upon the acid-catalyzed cyclization of the cyclohexenone **2**, which gives rise to the *cis*-dimethylphenanthrenone **3**.



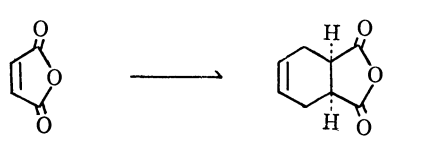
1

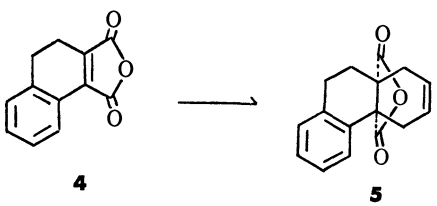


2 **3**

We report here a new method for the stereoselective synthesis of a tricyclic system carrying *trans* angular substituents using a Diels-Alder reaction and an intramolecular Friedel-Crafts reaction.

The Diels-Alder reaction of maleic anhydride and butadiene is well known to produce stereoselectively *cis*-1,2,3,6-tetrahydrophthalic anhydride. The same reaction of the anhydride **4** and butadiene affords the hydrophenanthrene derivative **5**,[5] in which the two functional groups are also oriented in a *cis* sense at the ring junctions. Thus, the cycloaddition reaction is suitable for synthesis of alicyclic compounds with two functional groups in a *cis* relation. We have devised the synthesis of polycyclic compounds having *trans* angular substituents from the *cis*-intermediate produced by a Diels-Alder reaction.





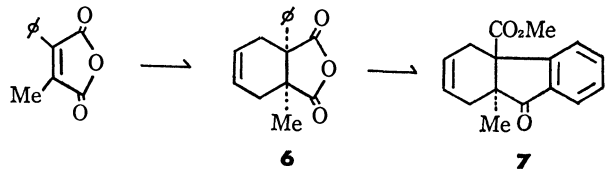
4 **5**

Results and Discussion

A Diels-Alder reaction of phenylmethylmaleic anhydride[6] and butadiene (or 3-sulfolene[7]) at 200 °C afforded the adduct **6** (mp 99.5—100 °C). Treatment of the anhydride **6** with aluminum chloride in carbon disulfide, followed by methylation with diazomethane, afforded the fluorenone **7** in 40% yield accompanied by three reaction products, the structures of which will be clarified later. The NMR spectrum of **7** shows two singlets at 1.05 (3H, angular methyl) and 3.48 (3H, $-COOCH_3$), in addition to a broad singlet at 5.8 (2H, olefinic protons) ppm. The IR (1710 and 1600 cm^{-1}) and UV (245 and 288 nm) spectra are consistent with the indanone chromophor of **7**. The structure was also verified by a further transformation; the ester **7** was reduced with lithium aluminum hydride in ether to give the diol **8**. The benzylic hydroxyl group was selectively oxidized on treatment with manganese dioxide[8] in methylene chloride to afford the crystalline hydroxy ketone **9**, which gives analytical datum and spectroscopic properties consistent with the proposed structure.

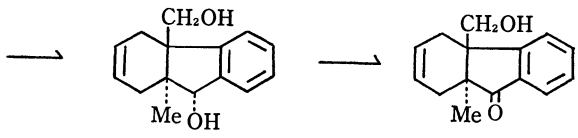
The angular substituents in these compounds (**7**–**9**) are necessarily located in the *trans* relationship because of the *cis* arrangement of the two carbonyls in the anhydride **6**.

Three other crystalline substances were also isolated from the Friedel-Crafts reaction products of the an-



6 **7**

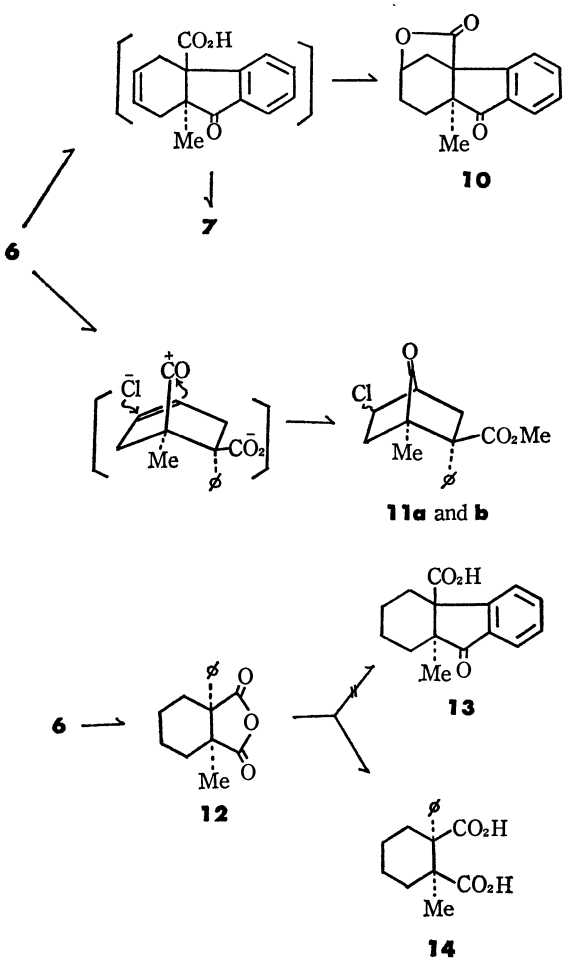
+ Three products



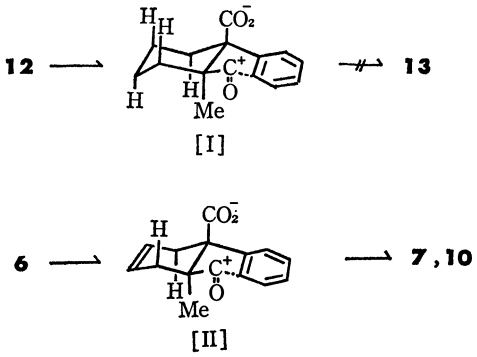
8 **9**

hydride **6**. The IR spectrum of the first crystals (40% from **6**) shows bands at 1765 and 1712 cm^{-1} and the UV spectrum exhibits absorption maxima at 247 and 290 nm, suggesting the presence of a γ-lactone and an indanone chromophor. The NMR spectrum exhibits a sharp singlet at 1.22 due to an angular methyl group and a 1H-multiplet at 4.95 ppm attributable to the proton attached to the carbinyl carbon atom of the lactone. From these properties the structure **10** was assigned for the first crystals, and this was further supported by physicochemical analyses.

The second and third crystals (7% and 2% from **6**) were found to be isomers having molecular formula $C_{16}H_{17}O_3Cl$ from the consideration of their mass spectra (*m/e* 264, M^+-CO; 266, M^++2-CO [32% height of the 264 peak]) and analytical data. The presence of chlorine atom in each compound was also detected by a Beilstein test. The IR spectra of each substance gave a pair of carbonyl bands at around 1776 (strained carbonyl) and 1720 (ester) cm^{-1}; the NMR spectra suggest the presence of a quaternary methyl (1.48/1.34 ppm, s, 3H), methoxy (3.42/3.41 ppm, s, 3H), and monosubstituted phenyl (7.29/7.28 ppm, s, 5H) groups. The signal ascribable to the proton attached to the carbon bearing chlorine atom appears around 4.5 ppm, as a multiplet. The structures **11a** and **b** can be assigned to the isomeric pair which are formed by the attack of the acyl cation to the double bond, as shown in the following scheme.



It is noteworthy that the dihydroanhydride **12**, obtainable by hydrogenation of **6** on platinum oxide, does not give rise to the hexahydrofluorenone **13** by treating with aluminum chloride, but affords the diacid **14**. The molecular models indicate that interactions between the angular substituents and hydrogens destabilize the intermediate I. On the other hand, the absence of two hydrogen atoms at C-4 and 5 makes the intermediate II more stable and easier to cyclize.



Experimental

NMR spectra were obtained with a Hitachi H-60 instrument using TMS as an internal standard. All the infrared spectra were taken on a Hitachi EPI-3T spectrophotometer. Ultraviolet spectra were taken on a Hitachi EPS-3T. Melting points and boiling points are uncorrected.

2-Methyl-1-phenyl-1,2,3,6-tetrahydrophthalic Anhydride ***6***. A solution of phenylmethylmaleic anhydride (3.76 g) and butadiene (10.8 g) in dry dioxane (12 ml) containing a small amount of hydroquinone was heated at 200 °C in a sealed tube for 65 hr. The tube was cooled in a Dry Ice–acetone bath and opened. The solvent was evaporated to afford a yellow residue, which was chromatographed on silica gel (200 g). Elution with benzene–hexane (4 : 6) gave the adduct **6** (1.24 g) followed by the recovered phenylmethylmaleic anhydride (0.87 g). The analytical sample of **6** was obtained by recrystallization from ethanol as needles, mp 99.5—100 °C; ν (KBr): 1855, 1780, 1210, 970, 760, 700 cm^{-1}; δ ($CDCl_3$): 0.98 (3H, s), 6.04 (2H, br. s), 7.28 (5H, s) ppm. Calcd for $C_{15}H_{14}O_3$: C, 74.36; H, 5.83%. Found: C, 74.16; H. 5.80%.

Intramolecular Friedel-Crafts Reaction of the Tetrahydrophthalic Anhydride ***6***. Finely powdered aluminum chloride (4.37 g) was added to a solution of the anhydride **6** (1.81 g) in dry carbon disulfide (500 ml) during 30 min with vigorous stirring under an atmosphere of nitrogen. The deep purple mixture was stirred at room temperature for 34 hr, and the solvent was removed on a rotary evaporator at 30 °C. Cold dilute hydrochloric acid (200 ml) was added to the dark red residue and the resulting light yellow oil was taken up in ether. The organic layer was separated and washed with aqueous sodium bicarbonate solution (150 ml), and dried over sodium sulfate. The ether was evaporated to give the crude γ-lactone **10** which was recrystallized from benzene (712 mg); mp 175—176 °C; ν (KBr): 1765, 1712 cm^{-1}; δ ($CDCl_3$): 1.22 (3H, s), 2.60 (2H, ABX, J_{AB}=12 Hz, J_{AX}= 5 Hz), 4.95 (1H, br. t, J=5 Hz), 7.1—7.9 (4H, m) ppm. Calcd for $C_{15}H_{14}O_3$: C, 74.36; H, 5.83%. Found: C, 74.09; H, 5.83%.

The aqueous layer was acidified with concentrated hydrochloric acid and extracted with several portions of ether.

The ethereal layer was washed with brine and dried over sodium sulfate. Removal of the ether under reduced pressure gave a brown oil; ν ($CHCl_3$): 3500—2400, 1770, 1730, 1700, 1605 cm^{-1}. The oil was dissolved in ethyl acetate–ether (1 : 2; 50 ml) and treated with excess diazomethane at 0 °C. After 3 hr the polymethylene was filtered away, and the filtrate was concentrated to afford a brown oil. Chromatography on silica gel (50 g) using benzene as eluent produced the ester **7** (700 mg) as a colorless oil; ν (film): 1730, 1710, 1600 cm^{-1}; δ ($CDCl_3$): 1.05 (3H, s), 3.48 (3H, s), 5.8 (2H, br. s), 7.0—8.0 (4H, m) ppm. Found: *m/e* 256.110. Calcd for $C_{16}H_{16}O_3$: 256.110.

Further elution with benzene gave the isomers **11a** and **b** as slightly yellow crystals; **11a** (155 mg); mp 125.5 °C; ν (KBr) 1776, 1732 cm^{-1}, δ ($CDCl_3$) 1.48 (3H, s), 3.42 (3H, s), 4.6 (1H, m), 7.29 (5H, m) ppm. Found: C, 65.59; H, 5.83%. Calcd for $C_{16}H_{17}O_3Cl$: C, 65.64; H, 5.85%. **11b** (40 mg); mp 140—141 °C; ν (KBr): 1776, 1713 cm^{-1}; δ ($CDCl_3$): 1.34 (3H, s), 3.41 (3H, s), 4.15 (1H, m), 7.28 (5H, s) ppm. Found: C, 65.59; H, 5.85%. Calcd for $C_{16}H_{17}O_3Cl$: C, 65.64; H, 5.85%.

4b-Hydroxymethyl-8a-methyl-4b,5,8,8a-tetrahydro-9-fluorenone ***9***.

Lithium aluminum hydride (4 g) was added to a solution of the ester **7** (393 mg) in dry ether (100 ml), and the reaction mixture was refluxed overnight. The excess hydride was decomposed with water followed by the addition of 10% sodium hydroxide solution. After the precipitates were removed by filtration, the filtrate was concentrated into an oil (347 mg); ν ($CHCl_3$): 3560, 3430, 1180, 1070 cm^{-1}; δ ($CDCl_3$): 0.71 (3H, s), 3.50 (2H, ABq, J_{AB}=10 Hz), 5.09 (1H, s), 5.74 (2H, br. s), 6.9—7.6 (4H, m) ppm. The crude diol (250 mg) was dissolved in methylene chloride (50 ml) and stirred with active manganese dioxide (3 g) at room temperature for 3 hr. The manganese dioxide was removed by filtration and the filtrate was concentrated. The residual oil was crystallized with benzene to give needles (200 mg); mp 122—126 °C; δ ($CHCl_3$): 1.00 (3H, s), 3.48 (2H, s), 5.76 (2H, br. s), 7.0—8.0 (4H, m) ppm. Found: C, 78.90; H, 7.12%. Calcd for $C_{15}H_{16}O_2$: C, 78.92; H, 7.06%.

1-Methyl-2-phenyl-1,2,3,4,5,6-hexahydrophthalic Anhydride ***12***. A solution of the anhydride **6** (193 mg) in ethyl acetate (15 ml) was hydrogenated in the presence of platinum oxide (18 mg). After the catalyst was filtered away, the ethyl acetate was evaporated to give a crystalline residue (190 mg); mp 110—115 °C (cubes from benzene); ν (KBr): 1870, 1855, 1780 cm^{-1}. Found: C, 73.93; H, 6.66%. Calcd for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60%.

Attempted Cyclization of the Hexahydrophthalic Anhydride ***12***. A solution of the anhydride **12** (73 mg) and aluminum chloride (200 mg) in nitrobenzene (2 ml) was stirred at room temperature for 24 hr. Cold hydrochloric acid was added and the mixture was extracted with ether. Evaporation of the ether and removal of the nitrobenzene afforded the starting anhydride (20 mg). Continuous extraction of the aqueous layer with ether afforded the diacid **14** as a white powder (20 mg); ν (KBr): 3500—2400 (br.), 1710, 1695 cm^{-1}. The structure of the diacid **14** was confirmed by heating it with acetic anhydride for 4 hr. A quantitative yield of the anhydride **12** was obtained.

Sesquiterpenes from *Acorus calamus* L.

Masatake NIWA, Atsuko NISHIYAMA, Masanobu IGUCHI, and Shosuke YAMAMURA*

Faculty of Pharmacy, Meijo University, Showa-ku, Nagoya 468

(Received June 3, 1975)

Three new sesquiterpenes, acoragermacrone (**1**), acolamone (**2**), and isoacolamone (**3**) were isolated from *Acorus calamus* L., and their structures were elucidated. In particular, acoragermacrone, a ten-membered ring sesquiterpene, is the most important precursor of the other sesquiterpenes included in the same plant. Acoragermacrone was converted into shyobunone, epi-shyobunone, preisocalamendiol, acolamone, and isoacolamone.

Many sesquiterpenes have been isolated from the plant *Acorus calamus* L. (Japanese name "Shyobu") growing in Japan.[1] However, such a key intermediate as acoragermacrone (**1**) has not been isolated. From a biogenetic point of view, our considerable efforts have been made to search for such an important precursor as **1**, and led us to the isolation of the expected ten-membered ring sesquiterpene, named "acoragermacrone", and two selinane-type compounds, acolamone (**2**) and isoacolamone (**3**). In this paper, we wish to describe the isolation and structures of these new sesquiterpenes. Furthermore, chemical correlation among them, including thermal and acid- or base-catalyzed isomerizations of acoragermacrone **1**, is also reported.

The Structures of Acoragermacrone (1). The pluverized raw rhizomes of *Acorus calamus* L. were carefully extracted with *n*-hexane to give a brown oil, which was directly chromatographed on silica gel. Rapid elution with *n*-hexane–ether (3 : 1) afforded a mixture of two ten-membered ring sesquiterpenes after elution of shyobunone and its isomers. Further separation of this mixture was successfully carried out by repeated preparative tlc using alumina in *n*-hexane–benzene (2 : 1) to give acoragermacrone **1** and preisocalamendiol (**4**) in 6 and 18% yields, respectively.[2]

Acoragermacrone **1** is a monocyclic sesquiterpene with a molecular formula $C_{15}H_{24}O$. The presence of an α,β-unsaturated cisoid carbonyl system (Me–C(=)CH–C(=)O) can be confirmed by its IR and UV spectra (ν_{max} 1680 and 1607 cm^{-1}; λ_{max} 242 nm (ε, 6590)] coupled with NMR spectrum which has two prominent signals at δ1.97 (3H, d, J=1.0 Hz) and 5.33 ppm (1H, q, J=1.0 Hz).[3] As found in the case of preisocalamendiol **4**,[1] furthermore, this new sesquiterpene also has an isopropyl group [δ 0.94 (3H, d, J=5.7 Hz) and 1.02 ppm (3H, d, J=5.7 Hz)] as well as a methyl group attached to a trisubstituted double bond [δ 1.12 (3H, d, J=1.5 Hz) and 4.60 ppm (1H, m)[4]]. In particular, the appearance of the methyl signal in unusually higher magnetic field (δ 1.12 ppm) seems to be due to the anisotropy effect of the α,β-unsaturated carbonyl system. This fact was supported by the following chemical evidence. When treated with sodium methoxide in MeOH (room temp., 30 min), acoragermacrone **1** was readily converted into the corresponding methoxy-ketone (**5**) in 48% yield, $C_{16}H_{28}O_2$ [*m/e* 252 (M^+)], which was proved to have a partial structure [Me–C(OMe)–CH_2–C(=)O] on the basis of its spectral data [ν_{max} 1705 cm^{-1}; δ 1.41 (3H, s), 2.46 (1H, d, J=17.7 Hz), 2.93 (3H, s) and 3.03 ppm (1H, d, J=17.7 Hz)]. Furthermore, it should be noted that the methyl signal at δ 1.12 ppm in **1** is shifted to δ 1.53 ppm in **5**.

From the above spectral and chemical data it is clear that acoragermacrone must be the most important ten-membered ring sesquiterpene (**1**) that has been expected to be present in the plant. Finally, the structure of acoragermacrone including its stereostructure (**1**) was established on the basis of some chemical evidences, namely thermal and base-catalyzed isomerizations.

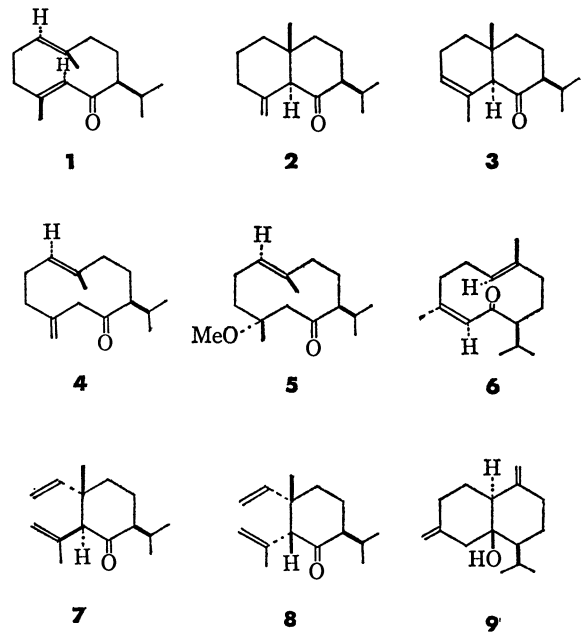

Fig. 1.

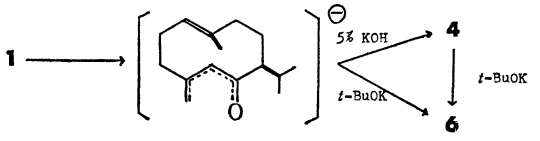
Base-catalysed Isomerization. As described earlier, action of MeONa on acoragermacrone **1** converted it into the corresponding addition product (**5**). When treated with *t*-BuOK in *t*-BuOH under N_2 (room temp., 30 min), **1** was readily converted into the known isomer (**6**)[5] in 95% yield through an enolate anion [A], as shown in Scheme 1. On the other hand, **1** reacted with 5% aq. KOH in *t*-BuOH (room temp., 24 hr) to give preisocalamendiol **4** in 84% yield, whose stereostructure had been already established in connection with shyobunone (**7**).[1] Further action of *t*-BuOK in *t*-BuOH on **4** also converted it into the most stable ten-membered ring compound, isoacoragermacrone (**6**), in almost quantitative yield.

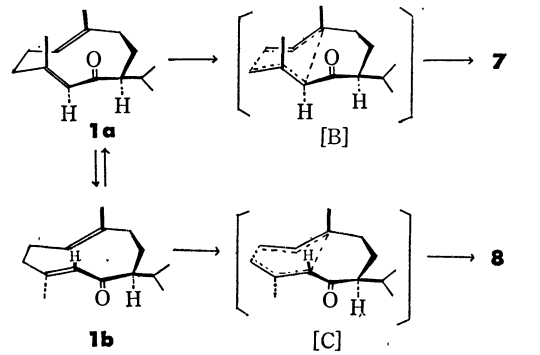


[A]

Scheme 1. Base-catalysed isomerization of acoragermacrone.

Thermal Isomerization of Acoragermacrone (1). In the cases of germacrones having an (*E,E*)-1,5-cyclodecadiene system, most of them have been known to adopt a crossed conformation.[6] In connection with the Cope rearrangement, conformations of these 1,5-cyclodecadienes have been also discussed by Takeda *et al.*[7]

The variable-temperature NMR spectrum of acoragermacrone was measured using benzene-d_6 as a solvent (24—106 °C). At 106 °C, it showed the new signal corresponding to those of shyobunone **7** in addition to the own signals, indicating that the Cope rearrangement took place to give **7**. When heated in a sealed tube at 110 °C for 30 min, acoragermacrone was completely converted into a mixture of shyobunone **7** and epi-shyobunone (**8**) (relative ratio **7**/**8**=21/4). In these experiments, shyobunone and epi-shyobunone both must be directly produced from acoragermacrone **1**, because these two elemene-type sesquiterpenes are quite stable under the same conditions. Therefore, this fact indicates that **1** has two possible conformational isomers (**1a** and **1b**) at least at higher temperature than 110 °C. Of two conformers, shyobunone **7** must be formed from the crossed conformer (**1a**) through a chair-like transition state [B], whereas epi-shyobunone **8** can be derived from the parallel one (**1b**) *via* a boat-like transition state [C]. In the above case, the chair-like one is much preferred as usual. However, it should be noted that the latter [C] leading to the formation of **8** can not be discarded, as shown in Scheme 2.[8] Under more vigorous conditions, in Scheme 2, the retro-Cope rearrangement of the elemene-type compounds takes place, leading to the formation of acoragermacrone **1** again, from which preisocalamendiol **4** and dehydroxyisocalamendiol (**9**) are readily produced.[1,5,9]



Scheme 2. Thermal isomerization of acoragermacrone (**1**).

The Structures of Acolamone (2) and Isoacolamone (3).[10] According to essentially the same procedure as that of acoragermacrone **1**, the *n*-hexane extracts were chromatographed repeatedly on different kinds of silica gel to afford acolamone **2** and isoacolamone **3** in each *ca.* 1.6% yield (from the *n*-hexane extracts) before elution of shyobunone **7** and its isomers.

Acolamone and isoacolamone both are bicyclic ketones ($C_{15}H_{24}O$; ν_{max} 1715 cm^{-1} in **2** as well as in **3**), and can be regarded as double bond isomers to each other on the basis of their NMR spectra, as shown in Table 1.

Table 1. NMR spectra of acolamone (**2**) and isoacolamone (**3**)

2	**3**
0.76(3H, s)	0.74(3H, s)
0.87(3H, d, J=6.5 Hz)	0.89(3H, d, J=6.3 Hz)
0.90(3H, d, J=6.5 Hz)	0.93(3H, d, J=6.3 Hz)
	1.76(3H, d, J=1.8 Hz)
2.90(1H, s)	3.10(1H, br. s)
5.00(1H, br. s)	
	5.42(1H, br. s)
5.95(1H, br. s)	

In the comparison of the NMR spectra between **2** and **3**, the former has two protons attached to an exocyclic double bond (δ 5.00 and 5.95 ppm), whereas **3** has one proton and the methyl group, both of which must be attached to a tri-substituted double bond (δ 5.42 and 1.76 ppm). The remaining signals are almost identical in both compounds. Furthermore, the structural relationship between acolamone and isoacolamone was established by the following thermal isomerization.

When heated in a sealed tube at 190 °C for 5 hr, acolamone **2** was converted into a mixture of two α,β-unsaturated ketones[11], whose spectral data were fairly close to each other [**10** (relative retention 2.30), ν_{max} 1690 and 1635 cm^{-1}; λ_{max} 248 nm (ε, 5600). **11** (relative retention 2.79), ν_{max} 1685 and 1638 cm^{-1}; λ_{max} 252 nm (ε, 4300)], in 60 and 27% yields, respectively. The former was completely identical with the selinane-type compound (**10**), which has been already derived from isoacoragermacrone **6** in several steps,[12] in respect of the glc and IR spectra. The compound (**10**) has also been derived from ajanol.[13] In the case of isoacolamone **3**, a mixture of **10** and **11** was also obtained in the same ratio as that of acolamone. Finally, the stereostructures of acolamone and isoacolamone were established as discussed below.

The ORD curve of acolamone showed a weak positive Cotton effect ($[\phi]^{P}_{325nm}+9°\times10^2$, $[\phi]^{T}_{280nm}-4°\times10^2$, $A=+13$), whereas that of isoacolamone has a weak negative Cotton effect ($[\phi]^{T}_{314nm}-10°\times10^2$, $[\phi]^{P}_{283nm}+7°\times10^2$, $A=-17$). In these cases, however, it is pretty dangerous to apply the octant rule to such $\beta\gamma$-unsaturated ketones as **2** and **3**. Therefore, the stereochemistry at C_5-position should be discussed in the case of the corresponding dihydro-compound (**12**, $C_{15}H_{26}O$, ν_{max} 1715 cm^{-1}),[14] which was readily

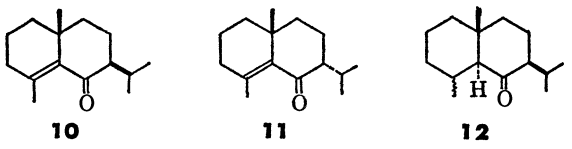


Fig. 2.

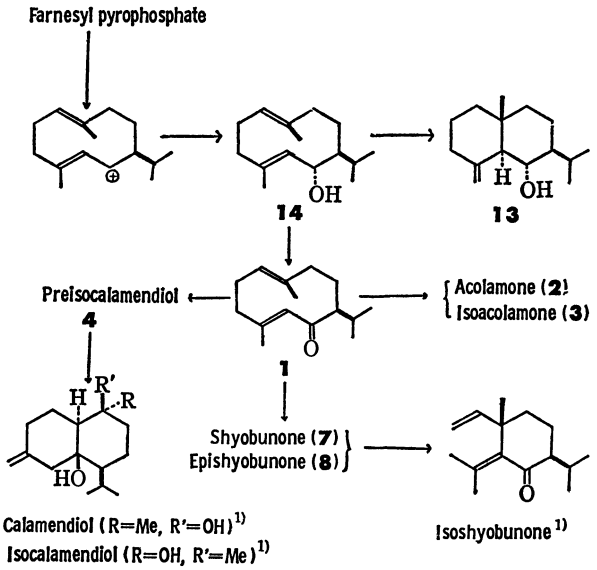
produced from acolamone as well as from isoacolamone on catalytic hydrogenation (H_2/PtO_2 in AcOEt) and has a positive Cotton effect in its ORD curve ($[\phi]^{P}_{312nm}+19°\times10^2$, $[\phi]^{T}_{274nm}-13°\times10^2$, $A=+32$), indicating that acolamone and isoacolamone should have the stereostructures (**2**) and (**3**), respectively.

From a structural view point, particularly, acolamone **2** is regarded as the higher oxidation product of junenol (**13**)[15], which must be derived from a plausible precursor (**14**). However, in consideration of the co-occurrence of acoragermacrone **1**, acolamone **2** and isoacolamone **3** both must be derived from **1** *in vivo*, as shown in Scheme 3. Thus, these two sesquiterpenes (**2** and **3**) were directly produced from acoragermacrone **1**.[16]

When treated with $AlCl_3$ in dry ether (0 °C, 1 hr), acoragermacrone afforded a pale yellow liquid, from which acolamone **2** and isoacolamone **3** were successfully separated, in each pure state, by preparative tlc in 55 and 23% yields, respectively.



Scheme 3. Biogenesis of acoragermacrone and related sesquiterpenes.

Experimental

All mps are uncorrected. Relative retentions *vs.* calamenene as an internal standard were recorded on Shimadzu GC-1C (flame-ionizer detector) [stationary phase: 5% PEG 20M on Celite 545 (100 mesh); column [ϕ 3 mm× 1.5 m (stainless steel)] temp.: 90 °C; carrier gas: nitrogen (85 ml/min); inlet pressure: 1.2 kg/cm²], unless otherwise stated. The IR spectra were recorded on a Hitachi-215 spectrophotometer. The UV spectra were recorded on a Hitachi 124 spectrophotometer using MeOH as solvent. The NMR spectra were recorded on a Varian Associates HA-100, a Varian A-60 or a Nihondenshi JNM-C60H NMR spectrometer using $CDCl_3$ as solvent, unless otherwise stated. Chemical shifts are given in ppm relative to internal TMS, and only prominent signals are cited (d, doublet; m, multiplet; q, quartet; s, singlet; t, triplet). The mass spectra were obtained on a Hitachi RMU-6D mass spectrometer operating with an ionization energy (70 eV). The ORD curves were recorded on a JASCO ORD/UV-5 spectrophotometer using MeOH as solvent.

Isolation of Acoragermacrone (1). As expected from the previous paper,[1] such ten-membered ring compounds as preisocalamendiol **4** and isoacoragermacrone **6** seem to be more polar than those of shyobunone and its isomers. Thus, our attentions were focused on searching for the much polar fraction similar to that of preisocalamendiol **4**.

Raw sliced rhizomes of *Acorus calamus* L. (7 kg) growing in Aichi-ken, which were collected late in November, were pluverized with a mixer, and immersed in *n*-hexane (*ca.* 35 l) at room temperature for two weeks, and then filtered. The filtrates were concentrated under reduced pressure below 35 °C to leave a brown residue. The above procedure was repeated three times, and total weight of the *n*-hexane extracts so far obtained is 92 g (*ca.* 13% yield). The brown oil (20 g) was chromatographed on silica gel (Kanto Chemical Co. Ltd., 100—200 mesh) (250 g), and eluted very rapidly with *n*-hexane -Et_2O (3 : 1). The first fraction eluted with the mixed solvent (*ca.* 400 ml) afforded a mixture of shyobunone, acolamone and their isomers and undetermined hydrocarbons. Further elution with the same solvent system (*ca.* 200 ml) gave the slightly brown oil (8.4 g) corresponding to the spot of preisocalamendiol on a tlc plate. This oil (150 mg) was directly separated by repeated preparative tlc using alumina [GF_{254} (Type E), E. Merck A. G., Darmstadt] in *n*-hexane–benzene (2 : 1). From the less polar fraction, preisocalamendiol (64 mg) was obtained. From the more polar fraction, acoragermacrone (22 mg) was isolated, whose physical data were shown below.

Acoragermacrone (1). A colorless liquid; ν_{max} (film) 1680 and 1607 cm^{-1}; λ_{max} 242 nm (ε, 6590); $\delta(C_6D_6)$ 0.94 (3H, d, J=5.7 Hz), 1.02 (3H, d, J=5.7 Hz), 1.12 (3H, d, J=1.5 Hz), 1.97 (3H, d, J=1.0 Hz), 4.60 (1H, br. m) and 5.33 ppm (1H, q, J=1.0 Hz); *m/e* 220 (M^+), 215, 177 and 150 (Found: *m/e* 220.1786. Calcd for $C_{15}H_{24}O$: *m/e* 220.1825).

Reaction of Acoragermacrone with MeONa. To a solution of acoragermacrone (22 mg) in anhydrous MeOH (1 ml) was added MeONa (6 mg) with stirring. The resulting solution was further stirred at 20 °C for 30 min, and then diluted by addition of water (1 ml) and extracted with *n*-hexane. The extract was washed with water and dried over anhydrous Na_2SO_4. Evaporation of the solvent afforded a colorless liquid (21 mg), which was purified by preparative tlc [Alumina (GF_{254} (Type E), E. Merck A. G., Darmstadt); *n*-hexane–benzene (4 : 1)] to give a colorless liquid (12 mg) of the methoxy-ketone (**5**); ν_{max} (film) 1705 and 1640 cm^{-1}; δ (C_6D_6) 0.79 (6H, d, J=6.0 Hz). 1.41 (3H, s), 1.53 (3H, s), 2.46 (1H, d, J=17.7 Hz), 2.98 (3H, s), 3.03 (1H, d, J= 17.7 Hz) and 5.40 ppm (1H, br. m); *m/e* 252 and 220 (Found: *m/e* 252.2137. Calcd for $C_{16}H_{28}O_2$: *m/e* 252.2088).

Action of t-BuOK on Acoragermacrone. To a solution of acoragermacrone (22 mg) in *t*-BuOH (1.5 ml) was added *t*-BuOK (11 mg) under N_2. The resulting solution was further stirred at room temperature for 30 min, and then diluted with saturated aqueous NaCl solution (5 ml) and extracted with *n*-hexane. The extract was washed with water, and then dried over anhydrous Na_2SO_4. Removal of the solvent under reduced pressure afforded a colorless liquid (21 mg),

an analytical tlc of which showed one spot corresponding to that of isoacoragermacrone **6**[5] (tlc and IR spectrum).

Conversion of Preisocalamendiol into Isoacoragermacrone. To a solution of preisocalamendiol (47 mg) in *t*-BuOH (2 ml) was added *t*-BuOK (24 mg) under N_2 with stirring. The resulting solution was continuously stirred at room temperature for 30 min and then extracted with *n*-hexane after addition of saturated aqueous NaCl solution (10 ml). The *n*-hexane extract was washed with water, and then dried over anhydrous Na_2SO_4. Removal of the solvent gave a colorless liquid (45 mg), which was identical with the authentic sample of isoacoragermacrone **6** (tlc and IR spectrum).[5]

Conversion of Acoragermacrone into Preisocalamendiol. To a solution of acoragermacrone (25 mg) in *t*-BuOH (2.5 ml) was added 5% aqueous KOH (0.5 ml). The resulting solution was stirred at room temperature for 24 hr, and then extracted with ether after addition of water (10 ml). The ethereal extract was washed with water and dried over anhydrous Na_2SO_4, and then concentrated under reduced pressure to give a colorless liquid (25 mg), whose glc showed two peaks (relative ratio; 84 : 16). The former was completely identical with preisocalamendiol **4**, (glc, tlc and IR spectrum).

Thermal Isomerization of Acoragermacron. Acoragermacrone **1** was heated in a sealed tube under various conditions as shown in Table 2, and the thermal reaction was stopped after the starting material was completely consumed.

Table 2. The Cope rearrangement of acoragermacrone

Temp. (°C)[a]	Time (min)	Relative ratio (%)[b]	
		7	**8**
110	30	83.8	16.2
120	25	82.6	17.4
130	12	81.9	18.1
140	6	80.5	19.5
150	3	80.1	19.9
160	2	77.5	22.5

a) Under more vigorous conditions, the retro-Cope rearrangement takes place, leading to the formation of acoragermacrone **1**, from which preisocalamendiol **4** can be produced.[1,5] b) Peak area of gas-liquid chromatogram (5% PEG 20 M on Celite 545, 95 °C, N_2) was served as an approximate value of content (%).

*Isolation of Acolamone (**2**) and Isoacolamone (**3**).* The *n*-hexane extract (36 g), which was described in the case of acoragermacrone **1**, was directly chromatographed on silica gel (Katayama Chemical Co. Ltd., 100—200 mesh) (500 g), and eluted rapidly with petroleum ether–Et_2O (9 : 1). After elution of a mixture of hydrocarbons (8.0 g), further elution with the same solvent system (*ca.* 240 ml) afforded a fraction (9.0 g) containing sesquiterpenic ketones as the main component, which was rechromatographed on silica gel (Kanto Chemical Co. Ltd., 100—200 mesh) (240 g), and eluted with *n*-hexane–benzene (1 : 1). After elution of hydrocarbons (1.0 g), a mixture of two new ketones (1.2 g) was obtained from the second fraction, which was checked by analytical tlc. Further elution with the same solvent afforded shyobunone (1.6 g), epishyobunone (0.7 g) and other undetermined ketones. The mixture of the second fraction (1.2 g) was carefully chromatographed on silica gel (Mallinckrodt, 100 mesh) (50 g) and eluted with *n*-hexane–benzene (1 : 1) to give acolamone (560 mg) and isoacolamone (570 mg), in each pure state*. Their physical data are shown below.

*Acolamone (**2**).* A colorless liquid; relative retention 2.70; λ_{max} (film) 1715 and 1645 cm^{-1}; *m/e* 220 (M^+), 205, 177 and 149 (Found: *m/e* 220.1825. Calcd for $C_{15}H_{24}O$: *m/e* 220.1825).

*Isoacolamone (**3**).* A colorless liquid; relative retention 2.30; ν_{max} (film) 1715, 1660 (w) and 1640 (w) cm^{-1}; *m/e* 220 (M^+), 205, 177 and 149 (Found: *m/e* 220.1863. Calcd for $C_{15}H_{24}O$: *m/e* 220.1825).

Thermal Isomerization of Acolamone. Acolamone (30 mg) in a sealed tube was heated at 190 °C for 5 hr, and then cooled. The resulting viscous oil was separated by preparative tlc [Wakogel B-5F; *n*-hexane–benzene (1 : 1)]. From the less polar fraction, an $\alpha\beta$-unsaturated keton (**10**) (18 mg) was obtained. On the other hand, an isomer (**11**) (8 mg) was separated from the more polar fraction.

10. A colorless liquid; relative retention 2.79; ν_{max} (film) 1690 and 1635 cm^{-1}; λ_{max} 248 nm (ε, 5600); δ 0.92 (3H, d, J=6.7 Hz), 0.97 (3H, d, J=6.7 Hz), 0.98 (3H, s) and 1.74 ppm (3H, s); *m/e* 220 (M^+), 205 and 178 (Found: *m/e* 220.1821. Calcd for $C_{15}H_{24}O$: *m/e* 220.1825).

11. A colorless liquid; relative retention 2.79; ν_{max} (film) 1685 and 1638 cm^{-1}; λ_{max} 252 nm (ε, 4300); δ 0.87 (3H, d, J=5.8 Hz), 0.93 (3H, d, J=5.8 Hz), 1.00 (3H, s) and 1.75 ppm (3H, s), *m/e* 220 (M^+), 205 and 178 (Found: *m/e* 220.1823. Calcd for $C_{15}H_{24}O$: *m/e* 220.1825).

Thermal Isomerization of Isoacolamone. Under the same conditions as that of acolamone, isoacolamone (30 mg) was heated in a sealed tube, and then the resulting viscous oil was proved to be a mixture of **10** and **11** in the same ratio as that of acolamone by its glc.

Catalytic Hydrogenation of Acolamone as well as of Isoacolamone. Catalytic hydrogenation of acolamone (30 mg) in AcOEt (3 ml) was carried out over PtO_2 (4 mg) at room temperature overnight, and then filtered to remove the catalyst. The filtrate was concentrated under reduced pressure to give a colorless liquid (30 mg) of the dihydro-compound (**12**), which was also obtained, in almost quantitative yield, from isoacolamone **3** under the same conditions as that of **2**.

12. A colorless liquid; relative retention 2.32; ν_{max} (film) 1715 cm^{-1}; δ 0.86 (3H, d, J=6.8 Hz), 0.91 (3H, s), 0.92 (3H, d, J=6.8 Hz) and 1.15 ppm (3H, d, J=6.9 Hz); *m/e* 222 (M^+), 207, 138, 137 and 109 (Found: *m/e* 222.1980. Calcd for $C_{15}H_{26}O$: *m/e* 222.1982).

*Conversion of Acoragermacrone into Selinane-type Sesquiterpenes (**2** and **3**).* To a solution of acoragermacrone (50 mg) in anhydrous ether (2 ml) was added a solution of $AlCl_3$ (30 mg) in anhydrous ether (1 ml), with stirring, at 0 °C. The resulting solution was further stirred at 0 °C for 1 hr. and then diluted with ice–water and extracted with ether. The ethereal extract was washed with water, and then dried over anhydrous Na_2SO_4. Removal of the solvent afforded a pale yellow liquid (50 mg), which was separated by preparative tlc [Wakogel B-5F; *n*-hexane–benzene (1 : 1)] to give acolamone (22 mg) and isoacolamone (9 mg) in addition to the starting material (10 mg). These compounds were identified by comparing their tlc and IR spectra with those of the corresponding authentic samples.

The authors wish to thank Professor Yoshimasa Hirata (Nagoya University) for his invaluable suggestion, and Mr. Bunichi Eziri for collection of the plant.

* Analytical glc of the original *n*-hexane extract has the peaks corresponding to those of these two ketons.

Thanks are also due to Professor Akira Tatematsu (Meijo University) for measurements of high resolution mass spectra and to Dr. Yoshikazu Shizuri (Nagoya University) for measurements of NMR spectra. This research has been supported in part by grants from the Ministry of Education, to which greatful acknowledgement is made.

Ungewöhnliche Wichterle-Reaktionen. Eine Neue Synthese von Phenalenonen

Makoto KOBAYASHI und Takeshi MATSUMOTO

Chemisches Institut, Naturwissenschaftliche Fakultät der Hokkaido Universität, Sapporo 060

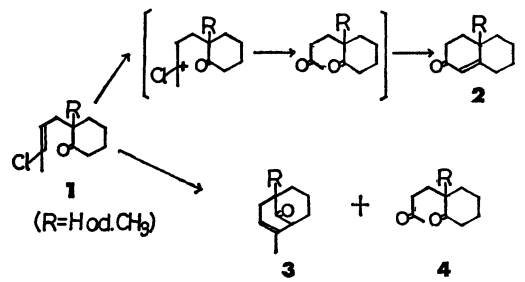
(Eingegangen am 9. Juni 1975)

Beim Erhitzen von 1-Methyl-1-(3-chlor-2-butenyl)-5-methoxy-2-tetralon(**10**) in HCO_2H in Gegenwart von $HClO_4$ wurde 4,7-Dimethyl-1-phenalenon(**11**) erhalten, während das Desmethoxy-Analogon, 1-Methyl-1-(3-chlor-2-butenyl)-2-tetralon(**5**) ein Phenanthren-Derivat ergibt. Es wurde gezeigt, dass die Bildung von Phenalenon über die Zwischenprodukte 2,3,9,9a-Tetrahydro-7,9-dimethyl-4-methoxy-1-phenalenon(**13**) und 2,3-Dihydro-4,7-dimethyl-1-phenalenon(**17**) verläuft. Unter den gleichen Bedingungen wurde 1-(3-Chlor-2-butenyl)-5-methoxy-2-tetralon(**21**) über 2,3-Dihydro-7-methyl-4-methoxy-1-phenalenon(**23**) in 7-Methyl-4-methoxy-1-phenalenon(**24**) umgewandelt.

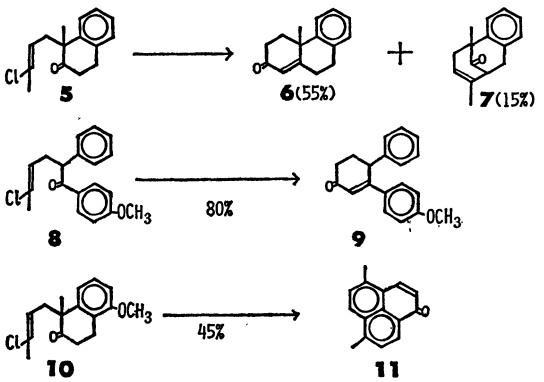
In einer früheren Mitteilung haben wir über eine Modifizierung der Wichterle-Reaktion berichtet und gezeigt,[1] dass beim Erhitzen von an 2-C 3-Chlor-2-butenylierten Ketonen wie z. B. 2-Alkyl-2-(3-chlor-2-butenyl)-cyclohexanon(**1**) in HCO_2H in Gegenwart von $HClO_4$ als Katalysator Δ^2-Cyclohexenone von Typ **2** entstehen.[2] Im Gegensatz dazu lieferten die Chlor-ketone unter konventionellen Reaktionsbedingungen die verzweigten Bicyclen **3** als Hauptprodukte (Schema-1).[3] Versuche zur Übertragung der modifizierten Bedingungen auf die arylierten, 2-(3-Chlor-2-butenyl)-ketone haben einen neuen Zugang zu Phenalenonen aufgedeckt, über den wir hier berichten.[4]

Aus 1-Methyl-1-(3-chlor-2-butenyl)-2-tetralon (**5**) und 1-(3-Chlor-2-butenyl)-1-phenyl-4'-methoxy-acetophenon(**8**) wurden je die erwarteten Cyclohexenone **6** bzw. **9** erhalten(Schema-2). Im Gegensatz dazu führte die gleiche Behandlung von 1-Methyl-1-(3-chlor-2-butenyl)-5-methoxy-2-tetralon(**10**) nicht zum Hydrophnanthren-Derivat, sondern zu einem stark gelb gefärbten Produkt, $C_{15}H_{12}O$, Schmp. 118.5—119 °C. Im NMR-Spektrum dieser Substanz erscheinen zwei Singuletts für aromatisch gebundene Methylgruppen bei 2.69 und 2.78 ppm sowie drei AB-Systeme zwischen 6.6—8.5 ppm.[5] Das erste mit Dubletts bei 6.65 und 7.95 ppm ist durch eine Kopplungskonstante $J=10$ Hz charakterisiert und wird den *cis*-ständigen *vic*-Protonen eines α,β-Enon-Systems zugeordnet. Das Dublett beim tiefsten Feld(8.45 ppm)gehört zum zweiten AB-Muster mit dem breiten Dublett bei 7.48 ppm ($J=7.5$ Hz), welches durch „Long-Range" Kopplung mit einer Methylgruppe fein aufgespaltet ist. Das dritte, von aromatischen *vic*-Protonen herrührende AB-System wird durch die Dubletts bei 7.38 und 8.02 ppm ($J=8.5$ Hz) angezeigt. Die IR-Absorption der Carbonylgruppe bei 1640 cm^{-1} sowie das UV-Spektrum weisen darauf hin,[6] dass diese gelbe Verbindung ein stark konjugiertes System enthält. Auf Grund dieser spektroskopischen Befunde sowie mechanistischer Überlegungen (siehe weiter unten) folgt für das gelbe Produkt die Konstitution eines 4,7-Dimethyl-1-phenalenons(**11**).

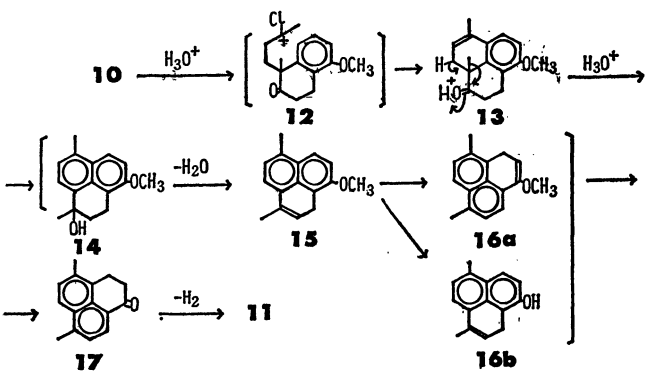
Ein denkbarer Bildungsmechanismus für **11** ist in Schema-3 wiedergegeben. Zuerst wird das Ausgangsmaterial zum Carbonium-Ion **12** protoniert, das durch eine intramolekulare Friedel-Crafts Alkylierung zum Tetrahydro-Derivat **13** cyclisiert. Aus **13** führen die Wanderung einer Methylgruppe und die nachfolgende Wasserabspaltung zum Phenalen **15**, das über **16a** gefolgt von **16b** oder über **16b** gefolgt von **16a** in den Dihydrokörper **17** übergeht. Zuletzt muss **17** unter Dehydrierung in das Phenalenon **11** umgewandelt werden,[7] weil Phenalenone troz des 12π-konjugierten Systems aromatische Stabilität zeigen.[4] Das hier angenommene Reaktionsbild konnte in der Tat, wie folgt, bestätigt werden. Die Behandlung des Chlorketons **10** mit 90% H_2SO_4 lieferte nicht ein Hydro-



Schema 1.

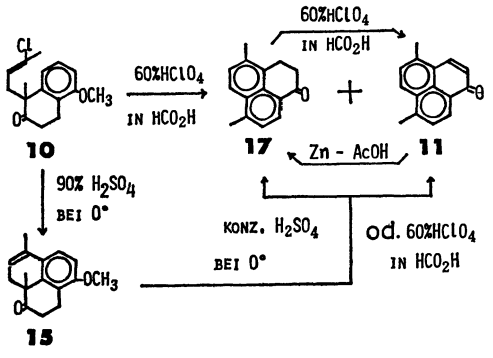


Schema 2.



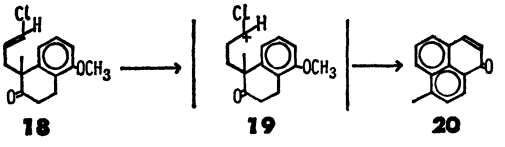
Schema 3.

phenanthren-Derivat,[8] sondern das oben als Zwischenprodukt postulierte Tetrahydro-dimethyl-methoxy-phenalenon **13**, Schmp. 78—79 °C, mit 80%-Ausbeute. Die Einwirkung von konz. H_2SO_4 (Raumtemp. 6 h.) ergab das 2,3-Dihydro-phenalenon **17**, neben dem Hauptprodukt **11**. Bei längerer Behandlung von **10** mit konz. H_2SO_4(Raumtemp. 20 h.) fand sich nur noch das Phenalenon **11** mit 30%-Ausbeute. Ausserdem wurde **13** durch Erhitzen in HCO_2H in Gegenwart von $HClO_4$ in das Phenalenon **11** und Dihydro-phenalenon **17** übergeführt. Bei kürzerer Behandlung des Chlorketons **10** mit $HClO_4$–HCO_2H wurden auch 7% der Dihydrokörper **17** neben 38% **11** erhalten. Die Konstitution der Zwichenprodukte **13** und **17** gehen aus den Analysen und spektroskopischen Daten hervor. Das NMR-Spektrum von **13** zeigt ein Singulett bei 1.15 ppm für die tertiäre Methylgruppe, ein Dublett (J=1.5 Hz)bei 1.99 ppm für die olefinische Methylgruppe, ein Singulett bei 3.78 ppm für die Methoxygruppe, ein AB-Signal bei 6.50 and 7.00 ppm (J=9 Hz) für die *o*- und *m*- Protonen des Anisolteils und ein breites Triplett bei 5.55 ppm ($J\approx$6 Hz) für das olefinische Proton, das mit der olefinisgebundenen Methylgruppe allylisch koppelt. Die Carbonylgruppe von **13** ist nicht konjugiert (1715 cm^{-1}); nach dem UV-Spektrum mit λ_{max} bei 237 nm ist die Doppelbindung zum Anisolring konjugiert.[9] Im NMR-Spektrum von **17** waren erkennbar : zwei Singuletts für aromatische Methylgruppe bei 2.49 und 2.61 ppm, ein bei 2.9 und 3.3 ppm zentriertes angenährtes A_2B_2-Muster für die Äthylengruppe, ein AB-Signal bei 7.37 und 8.11 ppm (J=7.5 Hz) für zwei aromatische *vic*-Protonen und ein zusätzliches AB-System bei 7.40 und 7.86 ppm (J= 9 Hz) für zwei weitere aromatische *vic*-Protonen. Die Carbonylgruppe ist mit dem Arylrest konjugiert (1685 cm^{-1}). In Übereinstimmung mit der Konstitution **17** und dem postulierten Reaktionsmechanismus, liess sich das Dimethyl-phenalenon **11** mit Zn-AcOH in guter Ausbeute zum Dihydro-phenalenon **17** reduzieren, das durch Erhitzen in HCO_2H mit $HClO_4$ wieder in **11** zurück verwandelt werden konnte[10] (Schema-4).



Schema 4.

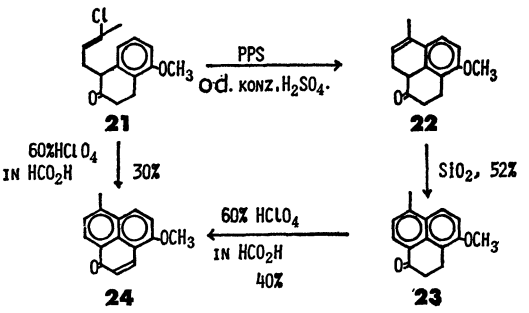
Um den Anwendungsbereich und die Grenzen dieser neuen Phenalenon-Synthese zu untersuchen, wurden nachfolgende Reaktionen durchgeführt. Nicht durch Erhitzen in HCO_2H mit $HClO_4$,[11] sondern nur durch Behandlung mit konz. H_2SO_4 bei 50—60 °C oder mit FSO_3H bei Raumtemp. lieferte 1-Methyl-1-



Schema 5.

(3-chlor-2-propenyl)-5-methoxy-2-tetralon(**18**) u.a. 7-Methyl-1-phenalenon(**20**), allerdings, in sehr schlechter Ausbeute (<7%).[12] Dieses Resultat zeigt, dass offensichtlich für die Phenalenon-Bildung die Stabilität der intermediären Carbonium-Ionen wie **19** sehr wichtig ist(Schema-5), und dass die Methylgruppe der Chlor-butenylgruppe in **10** für die Stabilisierung von **12** eine grosse Rolle spielt. Dadurch könnte der Anwendungsbereich auf alkylierte Phenalenone beschränkt werden.

Die Behandlung von 1-(3-Chlor-2-butenyl)-5-methoxy-2-tetralon (**21**), bei dem die anguläre Methylgruppe durch ein Wasserstoffatom ersetzt ist, liefert mit $HClO_4$–HCO_2H ein neues Phnalenon **24**, Schmp. 138—139.5 °C (zers.), in 30%-Ausbeute.[13] Das NMR-Spektrum von **24** zeigt zwei Singuletts bei 2.71 (aromatische $-CH_3$) und 4.02 (aromatische $-OCH_3$) ppm, sowie drei AB-Systeme. Das erste, zwei Dubletts bei 6.57 und 8.09 ppm, ist durch J=10 Hz charakterisiert (CH=CH–CO); das zweite bei 7.12 und 8.04 ppm (J=9.5 Hz, *o*- bzw. *m*-ständiges Proton am Anisolteil); das dritte bei 8.44 und 7.32 ppm (J=8 Hz, *o*- bzw. *m*-ständiges Proton am Toluolteil). Die Carbonylgruppe von **24** ist stark konjugiert (1633 cm^{-1}). Dem neuen Produkt kann somit die Konstitution eines 7-Methyl-4-methoxy-1-phenalenon (**24**) zugewiesen werden. Ein möglicher Mechanismus(Schema-6) für die Genese von **24** aus **21** wurde, wie folgt, bestätigt. Das NMR-Spektrum vom durch Behandlung von **21** mit Polyphosphorsäure[14] oder konz. H_2SO_4 erhaltenen Rohprodukt zeigt u.a. die folgenden Signale: ein breites Singulett bei 2.00 ppm (olefinische $-CH_3$), ein Singulett bei 3.80 ppm (aromatische $-OCH_3$), ein breites Quartett bei 5.70 ppm (Proton am cyclischen Olefin; koppelt mit der olefinischen $-CH_3$), und ein bei 6.17 und 7.09 ppm (J=8 Hz, *o*- bzw. *m*-ständiges Proton am Anisolteil) zentriertes AB-System. Das Hauptprodukt ist demgemäss 2,3,9,9a-Tetrahydro-7-methyl-4-methoxy-1-phenalenon(**22**). Bei der Säulenchromatographie des rohen **22** an SiO_2 fand aber eine Dehydrierungsreaktion statt und danach wurde nur



Schema 6.

2,3-Dihydro-7-methyl-4-methoxy-1-phenalenon (**23**) isoliert. Im NMR-Spektrum von **23** erkennt man ein Singulett bei 2.70 ppm(aromatische $-CH_3$), ein Singulett bei 3.98 ppm(aromatische $-OCH_3$), das 4H-Multiplett bei 2.9—3.3 ppm, bei 7.26 und 7.93 ppm (J=9.5 Hz, *o*- bzw. *m*-ständiges Proton am Anisolteil) zentriertes AB-Signal und zwei Dubletts bei 7.25 und 8.08 ppm (J=7.5 Hz, *o*- bzw. *m*-ständiges Proton am Toluolteil) eines zusätzlichen AB-Systems. Der Tetrahydrokörper **22** konnte sogar durch Dünnschichtchromatographie nicht rein erhalten werden. Schliesslich liess sich der Dihydrokörper **23** durch Behandlung in HCO_2H in Gegenwart von $HClO_4$ zu **24** mit 40%-Ausbeute überführen. Die modifizierte Wichterle-Reaktion erweist sich somit als eine neue Darstellungsmethode für 4,7-Dialkyl- sowie 7-Alkyl-4-methoxyphenalenon.

Experimenteller Teil

Die IR-Spektren wurden mit dem Jasco. IR-S und die UV-spektren in Äthanol mit dem Hitachi EPS-III gemessen. Die NMR-Spektren wurden in $CDCl_3$ oder CCl_4 mit den Geräten Hitachi R-20B oder JEOL. PS-100 aufgenommen. Die chemischen Verschiebungen sind in ppm (interner Standard; TMS=0) angegeben. Die Mass-Spektren (Abk: MS)wurden mit dem Hitachi RMU-6E oder RMS-4 erhalten. Die Schmp. wurden in einer Kapillare bestimmt und sind korrigiert. Für die Säulenchromatographie(SC) verwendete man Silikagel der Kanto Chemischen Industrie. Die Dünnschichtchromatogramme(DC) wurden auf Kieselgelplatten 60.PF_{254}, der Firma Merck ausgeführt.

Darstellung der Ausgangsverbindungen ***5***, ***8***, *und* ***10***. Ein Gemisch von aromatischem Keton(5.3 mMol) und NaH(50% ölsuspension, 6.9 mMol, verwendet ohne Waschen mit *n*-Hexan) in 10 ml Benzol wurde 1 h. unter Rückfluss, Rühren und N_2-Atomosphäre erhitzt. Nach Abkühlen auf Raumtemp. wurde 1,3-Dichlor-2-buten(*cis-trans* Gemisch, 6.9 mMol) in 10 ml Benzol zugetropft und dann die Lösung 1.5 h. gekocht. Nach der üblichen Aufarbeitung und Entfernung des Lösungsmittels chromatographierte man das Rohprodukt an der 30-fachen Menge SiO_2 mit Benzol und erhielt das ölige Chlor-keton mit 70—80%-Ausbeute.

1-Methyl-1-(3-chlor-2-butenyl)-2-tetralon (***5***): IR (Film): 1715, 1666 cm^{-1}; NMR ($CDCl_3$): 1.44 (3H, s), 1.96 ((3H, d, J=1.5 Hz), 5.70 (1H, q. t, J=1.5, 7 Hz), 7.18 (4H,m); MS : 248, 250 (M^+).

1-(3-Chlor-2-butenyl)-1-phenyl-4'-methoxy-acetophenon (***8***): IR (Film) : 1675, 1600, 1260, 1245 cm^{-1}; NMR ($CDCl_3$) 2.01 (3H, d, J=1.5 Hz), 2.75 (2H, m), 3.78 (3H, s), 4.56 (1H, t, J=7 Hz), 5.40 (1H, q. t, J=1.5, 7 Hz), 7.21 (5H, s), 6.79, 7.84 (2H, AB-q, J=8.5 Hz); MS : 314, 316 (M^+).

1-Methyl-1-(3-chlor-2-butenyl)-5-methoxy-2-tetralon (***10***); IR (Film): 1715, 1665, 1590, 1265 cm^{-1}; NMR (CCl_4) : 1.34 (3H, s), 1.94 (3H, d, J=1.5 Hz), 2.3—3.1 (6H, m), 3.78 (3H, s), 5.52 (1H, q. t, J=1.5, 7 Hz), 6.5—7.1 (3H, m); MS : 278, 280 (M^+).

Analog wurde mit 1,3-Dichlor-2-propen(*cis-trans* Gemisch) *1-Methyl-1-(3-chlor-2-propenyl)-5-methoxy-2-tetralon* (***18***) als Öl erhalten: IR(Film): 1719, 1633, 1590, 1263 cm^{-1}; NMR (CCl_4) : 1.35, 1.38 (3H, anguläre $-CH_3$), 2.1—3.3 (6H, m), 3.80 (3H, s), 5.05—5.95 (2H, olefinische Protonen), 6.5—7.3 (3H, m); MS : 264, 266 (M^+).

1-(3-Chlor-2-butenyl)-5-methoxy-2-tetralon (***21***). Eine Lösung des Pyrrolidin-enamins von 5-Methoxy-2-tetralon[15] (10 mMol) und 1,3-Dichlor-2-buten (50 mMol) in 15 ml Dioxan wurde 15 h. unter N_2-Atomosphäre gekockt. Nach Abkühlen auf Raumtemp. wurde die Lösung mit 2 ml AcOH und 8 ml H_2O versetzt und weiter 4 h. unter Rückfluss erhitzt. Die übliche Aufarbeitung und Reinigung durch SC mit Benzol als Elutionsmittel ergaben das ölige Chlorketon **21**(*ca.* 50%). Dieses Substanz ist sehr labil und zersetzt sich bei Raumtemp. innerhalb 24 h. vollständig; IR (Film): 1720, 1665, 1590, 1278 cm^{-1}; NMR ($CDCl_3$): 2.01 (3H, d, J=1.5 Hz), 3.08 (3H, s), 5.39 (1H, q. t, J=1.5, 7 Hz).

2,3,4,4a,9,10-Hexahydro-4a-methyl-phenanthren-2-on (***6***) *und 2,5-Dimethyl-6,7-benz-bicyclo*[3.3.1]*-2-nonen-9-on* (***7***). Eine Lösung von 150 mg Chlor-keton **5** in 10 ml HCO_2H wurde mit 1 ml $HClO_4$ versetzt und 1.5 h. under Rückfluss gekocht. Nach Abkühlen auf Raumtemp. wurde das Reaktionsgemisch auf 90 ml gesättigte $NaHCO_3$-Lögung gegossen und dann mit AcOEt extrahiert. Nach Entfernung des Lösungsmittels wurde der Rückstand an SiO_2 mit Benzol→Benzol/AcOEt (9 : 1) chromatographiert, und man erhielt 70 mg **6** (55%) und 20 mg **7** (15%). Die Konstitution von **6** wurde durch Vergleich mit den Daten in der Literatur bestätigt.[16]

7; Schmp. 81.5—82° (*n*-Hexan-Isopropyläther); IR(Nujol): 1715, 1670 cm^{-1}; NMR (CCl_4) 1.42 (3H, s). 1.70 (3H, d, J=2 Hz), 2.42 (2H, b), 2.8 (1H, m), 3.15 (2H, m), 5.15 (1H, m), 7.0 (4H); MS : 212 (M^+), 197 (M^+-15); Gef : C, 84.78; H, 7.61%. Ber. für $C_{15}H_{16}O$: C, 84.87; H, 7.60%.

4-Phenyl-3-(4'-methoxy-phenyl)-cyclohexenon(***9***). Zu 90 mg Chlor-keton **8** in 7 ml HCO_2H fügte man 0.7 ml $HClO_4$ und kochte 1.5 h. unter Rückfluss. Nach der Aufarbeitung wie oben wurde das Rohprodukt durch DC[Laufmittel : *n*-Hexan-Benzol (1 : 3)] gereinigt, und man erhielt 63 mg **9**(80%); Schmp. 113—114 °C (MeOH-Isopropyläther); IR (Nujol): 1660, 1575, 1253 cm^{-1}; NMR ($CDCl_3$): 2.47 (4H,m), 3.73 (3H, s), 4.29 (1H, m), 6.64 (1H, s), 7.21 (5H, s), 6.76, 7.40 (2H, AB-q, J=8.5 Hz); MS: 278 (M^+); Gef; C, 81.82; H, 6.52%. Ber. für. $C_{19}H_{18}O_2$: C, 81.98; H, 6.52%.

4,7-Dimethyl-1-phenalenon (***11***). *a) Aus* ***10***: Eine Lösung von 90 mg Chlor-keton **10** und 0.9 ml $HClO_4$ in 9 ml HCO_2H wurde 1.5 h. unter Rückfluss gekocht. Nach Abkühlen auf Raumtemp. wurde die Lösung auf gesättigte $NaHCO_3$-Lösung gegossen und mit $CHCl_3$ extrahiert. Die organischen Phasen wurden zweimal mit gesättigter $NaHCO_3$-Lösung und zweimal mit gesättigter NaCl-Lösung gewaschen. Nach Entfernung des Lösungsmittels wurde das Rohprodukt durch präparative DC gereinigt. Man erhielt 30 mg (45%) von Dimethyl-phenalenon **11** als gelbe Kristalle; Schmp. 118.5—119 °C (CH_2Cl_2-Isopropyläther); IR(Nujol) : 1640, 1618, 1589, 1559 cm^{-1}; NMR($CDCl_3$) : 2.69 (3H, s), 2.78-(3H, s), 6.65, 7.95(2H, AB-q, J=10 Hz), 7.48, 8.45(2H, AB-q, J=7.5 Hz), 7.38, 8.02(2H, AB-q, J=8.5 Hz); UV : 255(Schulter), 260.5(ε=30000), 332(ε=5300), 396(ε=11800)nm; MS : 208(M^+), 180(M^+-28), 165(M^+-43); Gef : C, 86.62; H, 5.87%. Ber. für $C_{15}H_{12}O$: C, 86.51, H, 5.87%. *b) Aus* ***17***: Zu einer Lösung von 20 mg Dihydrophenalenon **17** in 2.5 ml HCO_2H fügte man 0.2 ml $HClO_4$ und erhitzte 1 h. auf 90°. Die übliche Aufarbeitung ergab 12 mg **11** (60%).

2,3,9,9a-Tetrahydro-7,9a-dimethyl-4-methoxy-1-phenalenon (***13***). 200 mg Chlor-keton **10** wurde mit 5 ml von 90% H_2SO_4 bei 0 °C versetzt. Nach 1.5 h. wurde das Reaktionsgemisch auf Eis gegossen und mit $CHCl_3$ extrahiert. Nach der üblichen Aufarbeitung und Reinigung durch SC[Elutionsmittel: *n*-Hexan-Benzol(1 : 3)] wurde das ölige Rohprodukt aus *n*-Hexan-Isopropyläther-MeOH kristallisiert; Schmp. 78—79°; IR(Nujol): 1715, 1600, 1585, 1255 cm^{-1}; NMR-($CDCl_3$): 1.15(3H, s), 1.99(3H, d, J=1.5 Hz), 3.78(3H, s), 5.55(1H, b. t, J~6 Hz), 6.50, 7.00(2H, AB-q, J=9 Hz); UV: 273(ε=13700) nm; MS: 242(M^+); Gef: C, 79.04;

H, 7.70%. Ber. für $C_{16}H_{15}O_2$: C, 79.31; H, 7.49%.

*2,3-Dihydro-4,7-dimethyl-1-phenalenon (**17**).* *a) Reduktion von **11** mit Zn-AcOH*: Eine Lösung von 20 mg **11** in 2.5 ml AcOH wurde mit 110 mg Zn-Pulver versetzt und bei 80—95 °C unter N_2-Atmosphäre gerührt. Nach der üblichen Aufarbeitung und Reinigung durch präparative DC[Laufmittel: Benzol] erhielt man 16 mg **17**(80%). Nach Kristallisieren aus CH_2Cl_2-Isopropyläther schmolz die Substanz bei 82.5—83.5 °C; IR(Nujol): 1685, 1610, 1575 cm^{-1}; NMR($CDCl_3$): 2.49(3H, s), 2.61(3H, s), 2.9(2H, m), 3.3(2H, m), 7.37, 8.11(2H, AB-q, J=7.5 Hz), 7.40, 7.86 (2H, AB-q, J=9 Hz); UV: 221(ε=52500), 251(ε=32800), 345(ε=9450) nm; MS: 210(M^+), 195(M^+−15), 167(M^+ −43); Gef: C, 85.48; H, 6.70%. Ber. für $C_{15}H_{14}O$: C, 85.68; H, 6.71%.

*b) Aus **10***: Eine Lösung von 370 mg **10** in 17 ml HCO_2H wurde mit 3 ml $HClO_4$ versetzt und 12 h. bei Raumtemp. stehengelassen, dann langsam bis zu Siedepunkt erwärmt, und zuletzt 1 h. unter Rückfluss gekocht. Die Trennung des Rohprodukts durch SC[Elutionsmittel: $CHCl_3$] ergab 20 mg **17**(7%) und 105 mg **11**(38%).

*c) Durch Behandlung von **13** mit konz. H_2SO_4*: Eine Lösung von 100 mg **13** in 0.2 ml CH_2Cl_2 wurde bei 0 °C mit 0.3 ml konz. H_2SO_4 versetzt und 6 h. bei Raumtemp. gerührt, 8 mg **17**(9%) und 25 mg **11**(29%) wurden abgetrennt.

*d) Aus **13** mit $HClO_4$-HCO_2H*: Zu 56 mg **13** in 5 ml HCO_2H fügte man 0.5 ml $HClO_4$ und erhitzte die Lösung 1.5 h. auf 90—95°, wobei 6 mg **17**(12%) und 10 mg **11**(21%) erhalten wurden.

*7-Methyl-1-phenalenon (**20**).* Zu 90 mg Chlor-keton **18** in 0.2 ml CH_2Cl_2 fügte man 0.5 ml FSO_3H und rührte 2 h. bei Raumtemp. Nach Aufarbeitung erhielt man 45 mg als Rückstand. Die Auftrennung des Rohproduckts durch DC[Laufmittel: $CHCl_3$] lieferte 5 mg(*ca.* 7%) nicht völlig reines Monomethyl-phenalenon **20**; IR($CHCl_3$): 1643, 1623, 1585, 1565 cm^{-1} NMR($CDCl_3$): 2.82(3H, s), 6.66(1H, d, J=9.5 Hz), 7.5—7.8 (4H), 8.19(1H, m) 8.49(1H, d, J= 7.5 Hz); MS: 194(M^+), 166(M^+ − 28).

*2,3-Dihydro-7-methyl-4-methoxy-1-phenalenon (**23**).* Zu Polyphosphorsäure aus 1.7 g P_2O_5 und 1.2 ml H_3PO_4 fügte man eine Lösung von 100 mg **21** in 0.3 ml CH_2Cl_2 und rührte 1.5 h. bei Raumtemp. Danach wurde die Lösung unter Eiskühlung mit 50 ml Wasser verdünnt und wurde mit $CHCl_3$ extrahiert. Die Reinigung durch SC[Elutionsmittel: $CHCl_3$]lieferte 45 mg **23**(52%); Schmp. 87—87.5 °C (CH_2Cl_2-*n*-Hexan-Isopropyläther); IR(Film): 1680, 1614, 1583, 1270 cm^{-1}; NMR ($CDCl_3$): 2.70(3H, s), 2.9(2H), 3.3(2H), 3.98(3H, s), 7.26, 7.93(2H, AB-q, J=9.5 Hz), 7.25, 8.08(2H, AB-q, J=7.5 Hz); UV: 228(ε=52000), 253(ε=35000), 322(ε=5500), 358(ε=8700) nm; MS: 226(M^+), 211(M^+ −15), 195(M^+ −31), 183(M^+ −43); Gef: C, 79.30; H, 6.37%. Ber. für $C_{15}H_{14}O_2$: C, 79.62; H, 6.24%. Das reine Tetrahydro-Derivat **22** liess sich nicht isolieren. Die Behandlung von **21** mit konz. H_2SO_4 ergab eine niedrigere Ausbeute an **23**.

*7-Methyl-4-methoxy-1-phenalenon (**24**).* *a) Aus **21***: Eine Lösung von 155 mg **21** in 10 ml HCO_2H wurde mit 1.5 ml $HClO_4$ versetzt, allmählich erwärmt und zuletzt 1 h. unter Rückfluss gekocht. Nach der üblichen Aufarbeitung und Abtrennung erhielt man 40 mg **24**(30%), die durch Sublimation(100°/3 Torr)gereinigt wurden; Schmp. 138—139.5° (zers.); IR(Nujol): 1633, 1589, 1578, 1270 cm^{-1}; NMR ($CDCl_3$): 2.71(3H, s), 4.02(3H, s), 6.57, 8.09(2H, AB-q, J=10 Hz), 7.12, 8.04(2H, AB-q, J=9.5 Hz), 7.32, 8.44(2H, AB-q, J=8 Hz); UV: 266(ε=21000), 331.5(ε=4500), 433 (ε=11300) nm; MS: 224(M^+), 209(M^+ −15), 196(M^+ −28), 181(M^+ −43); Gef: C, 79.06; H, 5.62%. Ber. für $C_{15}H_{12}O_2$: C, 80.33: H, 5.39%.

*b) Aus **23***: Zn einer Lösung von 18 mg **23** in 1.8 ml HCO_2H fügte man 0.15 ml $HClO_4$ und erhitzte 1.5 h. unter Rückfluss. Die übliche Aufarbeitung lieferte 7 mg **24** (40%).

Wir danken Herrn Prof. Dr. H. Musso (Universität Karlsruhe) für die Durchsicht des Manuskripts.

Preparation and Application of Some New Disperse Anthraquinone Dyes

Saoud A. M. METWALLY* and Karl BREDERECK**

Chemistry Department, Faculty of Science, Assiut University, Assiut, Egypt

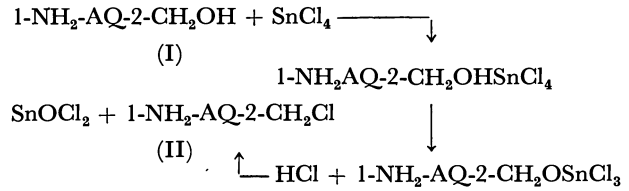
(Received October 3, 1974)

A series of anthraquinone derivatives free from water-solubilising groups were prepared. These compounds were found to be valuable for dyeing synthetic fibers with different shades of good fastness properties.

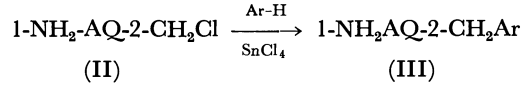
Anthraquinone dyes remain as the most important and pre-eminent class of all dyes because of their outstanding all-round fastness. On the other hand, disperse dyes are very useful and represent the main class of dyes for coloring synthetic textile materials.

In a previous note[1] we have reported that hydroxymethylanthraquinones could be used as alkylating agents for aromatic compounds using Friedel-Crafts catalysts. This paper gives the results of some experiments in regard to the reaction course and new examples are expressed.

(Hydroxymethyl)anthraquinones (I) react with aromatic hydrocarbons in the presence of aluminium chloride or tin tetrachloride to give the corresponding (arylmethyl)anthraquinones (III).[1] An equimolecular mixture of freshly fused tin tetrachloride and 1-amino-2-(hydroxymethyl)anthraquinone gave an addition product at 60 °C and heating of the addition product at 90—95 °C yielded the corresponding chloride (II). A determination of the hydrogen chloride evolved by heating of the addition product leads to the view that the reaction proceeds in the following steps.



If aromatic hydrocarbon and more than equimolar amounts of tin tetrachloride are used, reaction with 1-amino-2-(chloromethyl)anthraquinone (II) yields III.



Heating of the addition product with aromatic hydrocarbon in the absence of the catalyst gave no III, indicating the necessity of two moles of tin tetrachloride to complete the reaction.

Reaction of toluene with 1,4-dihydroxy-2-(hydroxymethyl)anthraquinone gave 1,4-dihydroxy-2-(4′-methylbenzyl)anthraquinone.[1] The mass spectrum of this product is different from that of 1,4-dihydroxy-2-(2′-methylbenzyl)anthraquinone which was prepared by a modified Marschalk's method.[2] The molecular ion in the former isomer is the base peak, while that in the latter one is 57.8% as relative abundance.

Loss of water molecule from molecular ions is more intense in case of 1,4-dihydroxy-2-(2′-methylbenzyl)-anthraquinone. This may be explained by the formation of the stable six-membered ring ion resulted from the loss of hydroxyl group in the 1-position and the hydrogen atom from the *ortho* methyl group. All these steps are indicated by metastable peaks and accurate mass measurements.

1-Amino-2-(4′-hydroxybenzyl)anthraquinone has been prepared using concentrated sulfuric acid as a catalyst.[2] Our trials to obtain this product according to the patent specification gave very low yield and also different side products. The side products were identified as 1-aminoanthraquinone, 1-aminoanthraquinone-2-carbaldehyde beside a red product

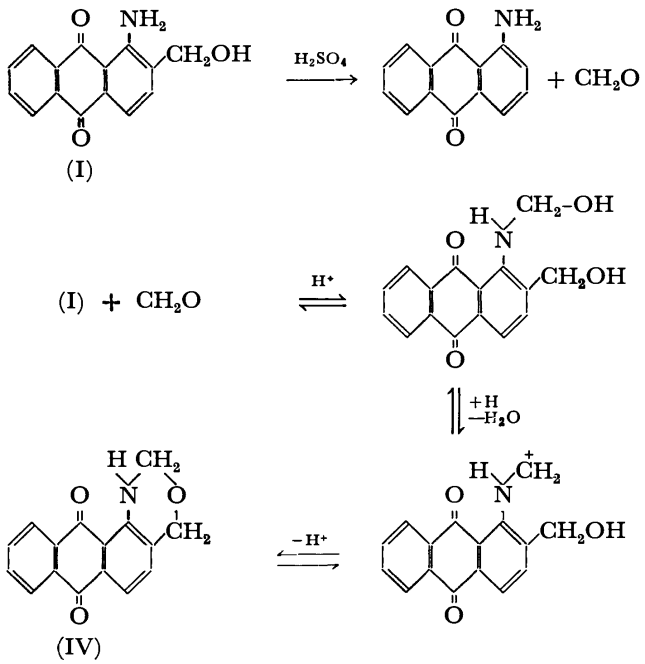
($C_{16}H_{11}NO_3$) which indicates the presence of a secondary amino group and a bathochromic schift of 20 nm in its ultraviolet spectrum as compared with the starting 1-amino-2-(hydroxymethyl)anthraquinone. Molecular weight of the red product was 265 by the mass spectrum.

Table 1 indicates the mass spectrum of this compound (*cf.* Scheme A). The molecular ion undergoes the loss of hydrogen atom to give the base peak which can lose H_2CN *via* an α, γ-proton schift to give anthraquinonecarbaldehyde cation radical. The latter loses carbon monoxide yielding the parent anthraquinone[3]. These steps were proved by accurate mass measurements and metastable peaks determinations. According to these facts, this compound was formulated as 1,2-dihydro-4*H*-anthra[1,2-*d*][1,3]oxazine-7,12-dione (IV).

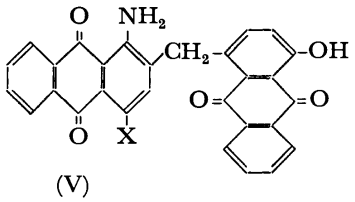
Compound IV was also prepared by the action of 70% sulfuric acid on 1-amino-2-(hydroxymethyl)-anthraquinone.



Reaction of 1-amino-2-(hydroxymethyl)anthraquinone with formaldehyde in presence of dilute hydrochloric acid gave IV quantitatively.

The formation of the 1-aminoanthraquinone-2-carbaldehyde may be due to self oxidation of the starting (hydroxymethyl)anthraquinone derivatives in acidic medium.

The (arylmethyl)anthraquinone derivatives[1] have colors ranging from yellow, orange, red, magenta and blue. The work was extended for the preparation of green disperse dyes. This was done by alkylation of a yellow anthraquinone. An example for such preparation is 1,4-diamino-2-[(4'-hydroxyanthraquinon-1-yl)methyl] anthraquinone(Vb) which was prepared by heating 1,4-diamino-2-(hydroxymethyl)-anthraquinone with 1-hydroxyanthaquinone in an inert solvent and in the presence of freshly fused tin tetrachloride.



(V)

a, X=H
b, X=NH_2

The visible spectra of such green dyes are characterized by the presence of two bands, one in the yellow and the other in the blue region of the spectra.

Experimental

Melting points are uncorrected. Infrared spectra were measured on a Perkin-Elmer Model 21 spectrophotometer, ultraviolet and visible spectra were measured on a Unicum 1800 spectrophotometer. Mass spectra were obtained using an AEI MS9 mass spectrometer operating at 70 eV. Samples were introduced through a heated inlet system at *ca.* 185 °C.

Preparation of 2-(Chloromethyl)anthraquinones. (Hydroxymethyl)anthraquinone (I) (0.5 mol) was added to freshly fused tin tetrachloride (0.5 mol) in dioxane, but only a trace of hydrogen chloride evolved. On heating, the solid product began to melt at 85—90 °C and hydrogen chloride was given off freely. About 0.5 mol of hydrogen chloride was collected at 95 °C for 2 hr. The reaction mixture was added to ice-cold water and the precipitates were washed throughly with water and dried. Some examples are summarized in Table 2.

Preparation of (Arylmethyl)anthraquinones. A mixture of (hydroxymethyl)anthraquinone (1 mol), 1-hydroxyanthraquinone (1 mol) and freshly fused tin tetrachloride (2 mol) was heated in dioxane under reflux for about one hour. The reaction mixture was poured into excess 4 M sodium hydroxide solution. The precipitated product was washed with excess water, dried and recrystallized from dimethylformamide.

Vb; yield 78%; mp 235 °C; λ_{max}^{PhH} 412 nm (log ε 3.86) and 585 nm (log ε 3.25). Found: C, 73.28; H, 3.84; N, 6.12%. Calcd for $C_{29}H_{18}N_2O_5$: C, 73.41; H, 3.79; N, 5.90%

Preparation of other derivatives was reported previously.[1]

Preparation of 1,2-Dihydro-4H-anthra[1,2-d][1,3]oxazine-7, 12-dione(IV). 1-Amino-2-(hydroxymethyl)anthraquinone (0.53 g), 30% aqueous formaldehyde solution (1 ml) and concentrated hydrochloric acid (0.5 ml) were dissolved at room temperature in dioxane (100 ml). The mixture was left for 30 min and then warmed at 45 °C for 15 min. The reaction mixture was poured into ice-cold water and the precipitated red product was washed with water and dried. It was crystallized from benzene into red fine needles, mp 162 °C, yield 0.52 g.

λ_{max}^{PhH} 490 nm (log ε 3.72); IR 3252, 1592, 1660, and 1630 cm^{-1}. Found: C, 72.55; H, 4.16; N, 4.94%. Calcd for $C_{16}H_{11}NO_3$: C, 72.45; H, 4.15; N, 5.28%.

Application of Disperse Dyes to Synthetic Fibers. These disperse dyes were applied to polyamide fibres by immersing the textile materials in a dyebath containing the aqueous dispersion of these dyes and an anionic surface-active reagent. The dyeing process was done at the boil for 45 min. Table 3 indicates the fastness properties of such dyes on Nylon-66.[4]

Appreciation is expressed to the Alexander von Humboldt-Stiftung, West Germany for a grant supporting this work.

Electric Dipole Moment of Pyrrole and Molecular Interaction in Solution

A. N. SRIVASTAVA and V. K. JOSHI

Chemistry Department, University of Jodhpur, Jodhpur-342001, India

(Received April 26, 1975)

Literature[1] reports two values for μ_s/μ_v namely 1.06 and 0.9 for pyrrole in benzene solution. Our orientation polarisation data on pyrrole discussed in terms of Higasi's theory favours the former. Further we observe that in benzene the solute forms donor-acceptor complexes, while in carbon tetrachloride it undergoes association through hydrogen bonding.

The moment values of pyrrole both in vapour and solution state cited earlier[2] are widely divergent. A survey of literature[1,3-7] shows that though Buckingham and others have carried much work on pyrrole, yet they have shown considerable variation in apparent moment. The discrepancy may be attributed to the specific interaction in solution. Consequently the purpose of the present investigation was to re-examine the apparent moment values and then to understand the interaction operating between solute and solvent from the data so obtained, with reference to theory of Earp and Glasstone.[8]

Experimental

The practical work essentially involves the measurements of dielectric constant and density of various solutions containing different mole fractions of the solute. The method and techniques have been described elsewhere.[9]

Pyrrole[12] (Fluke A.G., Buchs S. G., Switzerland) was distilled twice in a quickfit apparatus, where there was no possibility for the liquid to be in contact with atmospheric moisture and carbon dioxide. The fraction boiling at 128 °C was used.

The solution moment value μ_s has been determined by the method of Halverstadt and Kumler.[13] The constants α, β, ε_1 and V_1 in Halverstadt and Kumler equation have been evaluated by the method of least square. Electronic polarization P_e is the same as the molecular refraction for sodium D-line and has been taken from the literature.[14] Atomic polarization P_A has not been taken into consideratoin as suggested by Debye[15] namely that the electronic polarisation calculated from the sodium D-line partly compensates the neglect of atomic polarisation for which there is still no good method of evaluation.

The excess polarisation P^E needed for the present study, has been evaluated from the expression,

P^E = (Solution polarisation) − (Total polarisation)

The solution polarisation P_{12} is given by

$$P_{12} = \frac{\varepsilon_{12}-1}{\varepsilon_{12}+1} \cdot \frac{M_1 f_1 + M_2 f_2}{d_{12}}$$

and total polarisation $= P_1 f_1 + P_2 f_2$

where P_1 and P_2 are the molar polarisation of the solvent and the solute respectively and f_1 and f_2 are their respective mole fractions.

Results and Discussion

The values available in literature for μ_s/μ_v of pyrrole in benzene are 1.06 and 0.9. However we observe that the μ_s value of pyrrole in benzene is slightly greater than that in cyclohexane. This is in agreement with the positive solvent effect (*i.e.* $\mu_s > \mu_v$) as suggested by Higasi.[16-18] Consequently our observed data in benzene favours the value 1.06 for the ratio μ_s/μ_v. The experimental data has been shown in Table 2.

The molecular interaction in solution has been discussed in terms of the theory of Earp and Glasstone.[8]

Accordingly we observe that no chemical interaction takes place in the mixture since the variation of

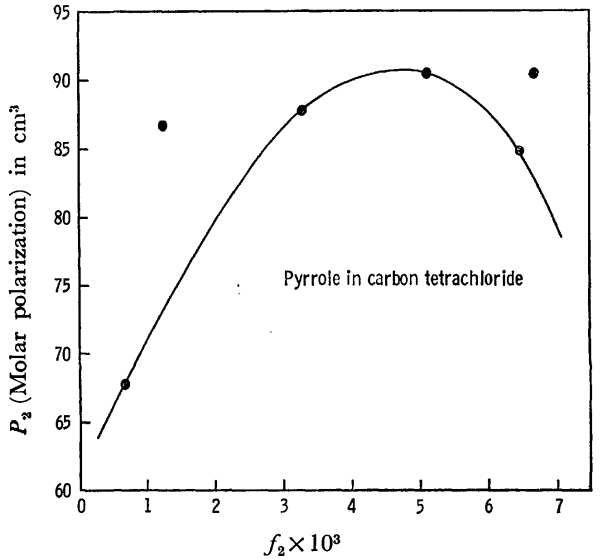

Fig. 2.

$\{(\varepsilon_{12}-1/\varepsilon_{12}+1)\}^2$ with P_{12} is linear. Further the values of P^E (the excess polarisation) in benzene and cyclohexane being positive (Table 3) eliminate the possibility of dipole association as well.

However the variation of P^E with $f_1 f_2$ (Fig. 1) for the system (pyrrole+benzene) is linear and passes through the origin. This shows the formation of charge-transfer complexes in solution. The specific interaction according to Goats and Sullivan[19] in benzene appears to be of donor-acceptor type. Literature[20] reports that pyrrole is practically non-basic and its hydrogen atom is acidic in nature. It seems probable therefore that pyrrole accepts the π electrons through its hydrogen atom from benzene. This is supported from the complex formation between benzene (donor) and carbon tetrachloride reported recently.[21] The possibility of complex formation in cyclohexane does not arise as it has no π electrons. Our experimental data fully demonstrate this fact.

The negative values of P^E in carbon tetrachloride (Table 3) suggest that pyrrole undergoes association through hydrogen bonding in this solvent. To ascertain this view, the graph between P_2 and f_2 (Fig. 2) has been plotted, which shows a maxima.[9,22] This observation is further supported from the study of infrared spectra[23,24] of pyrrole in carbon tetrachloride. A lower value of pyrrole in carbon tetrachloride suggests head to head association. There seems to be the following two possibilities during association.

Friedel-Crafts Benzylation of Toluene with Benzyl Chloride Catalyzed by Metal Oxides

Kazushi ARATA, Norio AZUMI, and Hiromitsu SAWAMURA
Hokkaido University of Education, Hachiman-cho, Hakodate-shi 040

(Received May 26, 1975)

Synopsis. Metal oxides were found to catalyze significantly the Friedel-Crafts type benzylation of toluene with benzyl chloride with a selectivity similar to that occurring with metal sulfates.

The benzylation of toluene with benzyl chloride, which is a typical example of Friedel-Crafts alkylations and is known to proceed over Lewis-type catalysts such as anhydrous aluminum chloride and gallium bromide,[1] has been found to be catalyzed by metal sulfates: $NiSO_4$, $MnSO_4$, etc.[2] Iron sulfates especially showed an unexpected effectiveness for this reaction.[3,4] The selectivity, however, of these studied catalysts was almost the same, indicating the analogous reaction mechanism. In order to extend the scope of this reaction, we have examined the catalytic activity as well as the selectivity of these metal oxides: ZnO, TiO_2, ZrO_2, and TiO_2-ZrO_2.

Experimental

Experiments which do not overlap with those reported in the previous paper[4] are described here.

Preparation of Catalysts. ZnO was prepared by calcining its hydroxide in air at 400 °C for 3 hr. The hydroxide was precipitated by adding 2 M aqueous ammonia to an aqueous solution of zinc chloride (1 M), followed by washing thoroughly with water until no chloride ion was detected in the filtrate and drying at 120 ° for 24 hr. TiO_2, ZrO_2, and TiO_2-ZrO_2 (molar ratio=1 : 1) were prepared by calcining H_4TiO_4, $Zr(OH)_4$, and H_4TiO_4-$Zr(OH)_4$, respectively, in air at 500 °C for 3 hr. These materials were precipitated by heating a mixed aqueous solution (5 l of 0.2 M) of titanium tetrachloride, zirconium oxychloride, or both chlorides and an excess amount of urea (300 g) on a boiling water bath for 6—9 hr, followed by thorough washing and drying at 110 °C for 30 hr.

Results and Discussion

As observed in the case of metal sulfates, the initial part of the HCl evolution was linear with time after a slight period of induction, and the over-all reaction followed first order reaction kinetics with respect to the benzyl chloride concentration.

Table 1 summarizes the initial rates and the relative rates, together with the pertinent data taken from our previous study.[2] It is shown that the present metal oxides, solid acid catalysts,[5,6] are quite active for this Friedel-Crafts reaction, especially TiO_2-ZrO_2, which is more than 400 times as active as $NiSO_4$. The products were very similar in distribution with an almost negligible amount of polymer, as shown in Table 2. This product distribution is quite similar to that by sulfates of Ni, Mn, and other metals.[2-4] This similarity of selectivity implys that the catalytic actions upon this benzylation are the same on those studied catalysts: that is, the catalytic mechanism is independent of the species of catalyst and reaction rate. Since an induction period, which is presumably the period of HCl adsorption on the catalyst surface, was observed in every reaction, it is supposed that the adsorbed HCl acts as a true catalyst. This model is attractive in explaining the similarity of the catalytic action. However, $AlCl_3$, a typical Lewis catalyst, gave a quite different selectivity (10.2% *ortho*-, 69.0% *meta*-, and 20.8% *para*-isomer) under the heterogeneous reaction condition.[2] Therefore, it is concluded that solid acids such as metal sulfates and oxides give the same selectivity arising from the same catalytic actions for the Friedel-Crafts type benzylation.

TABLE 1. CATALYTIC ACTIVITIES OF METAL OXIDES FOR BENZYLATION OF TOLUENE WITH BENZYL CHLORIDE AT 100 °C

Catalyst	Initial rate (mol/l·min·g)	Relative rate (ZnO=1)
ZnO	0.036	1.00
TiO_2	0.30	8.3
ZrO_2	0.11	3.1
TiO_2-ZrO_2	0.48[a]	13.3
$MnSO_4$[b]	0.0073	0.2
$NiSO_4$[b]	0.0012	0.03

The Electronic Absorption Spectra of UV Irradiated Anilines Adsorbed on Porous Vycor Glass

Tadayoshi SAKATA, Toshihiro OKAI,* Hiroaki SUGIMOTO,** and Hiroshi TSUBOMURA
Department of Chemistry, Faculty of Engineering Science, Osaka University, Toyonaka, Osaka 560
(Received February 8, 1975)

Synopsis. Cation radicals of aniline and its derivatives were formed on porous Vycor glass plates by UV-irradiation. One of the absorption bands appearing in the visible region is assigned to the transition to the first excited state of the cation radical by comparison with the reported photoelectron spectrum. The charge resonance band of the dimer cation was also observed in the near infrared region in most cases.

The electronic absorption spectra due to the transition to the first electronic excited states of the cation radicals of anilines do not seem to have been observed, although they are expected to exist in the visible or near infrared region both from theoretical calculation[1] and photoelectron spectra (PES)[2-4] of anilines.

The porus Vycor glass (PVG) which adsorbed a large amount of anilines was exposed to ultraviolet (UV) light at 77 K by using a 250 W high pressure mercury lamp and a Toshiba glass filter UV-D25, transparent in the region from 200 to 400 nm.

The electronic absorption spectra obtained after UV-irradiation of aniline (AN), *N*-methylaniline (NMA) *N,N*-dimethylaniline (DMA), *N,N*-diethylaniline (DEA) *N,N*-dimethyl-*p*-toluidine (DMT), and *m*-phenylenediamine (MPD) are shown in Fig. 1. The peak positions of the visible strong bands obtained for the cation radicals of anilines are given in Table 1, together with those reported by others.[5] They agree fairly well with each other, though the absorption shape is rather broader in our case. The reason for this broadening might be attributed to the effect of adsorption or the high concentration of anilines. ESR (electron spin resonance) spectra were observed for the irradiated specimens containing NMA and DMA, which decayed above ~150 K. The electronic absorption spectra also changed remarkably above the same temperature. All these facts suggest that the obtained visible absorption bands are those of the cation radicals of anilines. Besides these bands there appear one or two weak bands at the longer wavelength as seen in Fig. 1.

In order to assign them, we estimated the energies of the first and second excited states of the cation radicals from the results of photoelectron spectroscopy (PES). The results are compared with ours in Table 2, showing that the peak positions of the new bands agree fairly well with those estimated from PES for AN, NMA, and MPD, each having only one new band. Therefore, the first absorption bands of these compounds seem to be attributable to the first excited state of the cation radical.[6]

There appear two new bands in each of the case of DEA, DMA, and DMT as seen in Fig. 1. The first excited state of the cation radical estimated from PES seems to correspond well to the weak absorption band observed at 500—700 nm in these cases. Then, what is the origin of the near infrared band in these cases? To clarify this, the change of intensity with temperature from 77 K was followed for the visible band (2.65 eV), the near infrared band, and the ESR absorption of DMA cation. As shown in Fig. 2, all shows similar temperature dependency, indicating that the cation radical of DMA begins to decompose at about 150 K and almost disappears at 270 K[7]. The possibility that these bands are due to solvated electrons can be denied because they do not change by the irradiation in the visible or near infrared region.

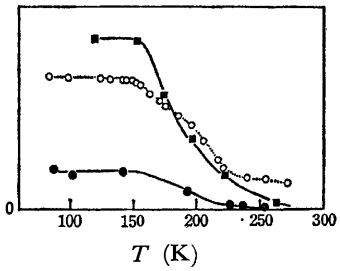

Fig. 2. The temperature dependence of the intensity on the visible band (2.67 eV) (○), the near infrared band (●), and the ESR absorption (■).
As for ESR the ordinate shows the intensity of ESR absorption multiplied by temperature, so that it represents the number of paramagnetic species.

Since in our experiments a large amount of anilines were adsorbed on PVG and only their small part is photoionized, this band can be most reasonably assigned to the charge resonance band of the dimer cation formed between the cation radical and its neutral molecule,[8] not to the charge transfer band of the cation dimers. The weakness of the charge resonance bands can be attributed to the small concentration of the dimer cations.

It is possible in the cases of AN and NMA that similar charge resonance bands exist in the energy region of the first excited band of the cation. Therefore, the observed IR bands for these cases might be a superposition of the cation band and the charge resonance band. This assumption seems fairly reasonable because the charge resonance interaction is thought to be stronger in these cases than in the other three compounds, taking account of the steric hindrance of the methyl group. If one assumes further that the IR bands consist mostly of the charge resonance bands, the excitation energies of these bands are in reasonable sequence as regarded to be the charge resonance bands for all compounds, decreasing in the order, AN, NMA, DMA, DEA, DMT, parallel to the increasing steric hindrance. From the excitation energy of these resonance bands, the intermolecular resonance integrals are estimated to be from 0.4 to 0.5 eV for these dimer cations which seem resonable. For MPD, the corresponding charge resonance band might be located in the longer wavelength region.

The authors would like to express their gratitude to Prof. T. Shida of Kyoto University for informing us his unpublished spectral data of the cation radicals of AN and DMA.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(10), 2947—2948 (1975)

The Crystal and Molecular Structure of Emericellin, A Metabolite of *Aspergillus nidulans*

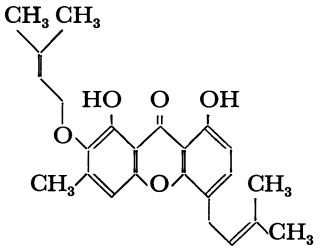
Keiichi FUKUYAMA, Tomitake TSUKIHARA, Shunji KISHIDA, Yukiteru KATSUBE, Masayoshi ISHIDA,* Takashi HAMASAKI,** and Yuichi HATSUDA**

Faculty of Engineering, Tottori University, Koyama, Tottori 680

(Received March 26, 1975)

Synopsis. The crystal and molecular structure of emericellin has been determined by the X-ray diffraction method. The compound crystallizes in the space group $P\bar{1}$, with $a=8.667$, $b=14.665$, $c=9.157$ Å, $\alpha=88.29$, $\beta=113.10$, and $\gamma=91.61°$. The structure was refined to an R value of 0.086 for 2151 non-zero reflections. There are two intramolecular hydrogen bonds.

Emericellin was isolated as a new metabolite of *Aspergillus nidulans* (Eidam) Winter.[1] The isolation and the chemical structure (shown below), proposed on the basis of the chemical and spectroscopic data, have been reported previously.[1] In order to confirm this, an X-ray structure analysis has been undertaken as part of the investigation of the metabolites of the genus *Aspergillus*.[2,3]



Emericellin crystallized from an ethanol solution in the form of yellow prisms. Preliminary oscillation and Weissenberg photographs showed that the crystals were triclinic and that there was no significant reflection in the region of $2\theta>110°$ (Cu $K\alpha$ radiation). Measurement was made by manually operating a Toshiba four-circle diffractometer. The cell constants were obtained by least-squares fits of the θ values for 49 reflections. Crystal data: $C_{25}H_{28}O_5$, $M=408.5$, triclinic, $P\bar{1}$, $a=8.667(5)$, $b=14.665(7)$, $c=9.157(5)$ Å, $\alpha=88.29(9)$, $\beta=113.10(9)$, $\gamma=91.61(9)°$, $V=1070$ Å^3, $Z=2$, $D_o=1.28$ g/cm^3, $D_x=1.27$ g/cm^3. The intensities of 2584 independent reflections were measured with Ni-filtered Cu $K\alpha$ radiation up to $\sin\theta/\lambda=0.531$ from a specimen with dimensions of *ca.* $0.21\times0.15\times0.06$ mm. The stationary-crystal stationary-counter method was used, with a counting time of 30 seconds. The background for each reflection was taken from plots of the background as a function of 2θ. The intensities were corrected for Lorentz and polarization factors, but not for absorption.

The structure was deduced from an interpretation of the three-dimensional Patterson map, followed by successive Fourier syntheses. The coordinates and isotropic temperature factors of all the non-hydrogen atoms were refined with the carbon scattering factor. Five oxygen atoms were assigned by an inspection of the temperature factors. When an R value reached 0.12 by further refinement with anisotropic temperature factors, the positions of all the hydrogen atoms were derived from a difference Fourier synthesis. The final refinement, made by including the hydrogen atoms, used the following weighting scheme: $w=0.0$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq17$, and $w=1.0/(1.0+0.3(F_o-17))$ for $17<F_o$. The final R value is 0.086 for 2151 non-zero reflections. The final atomic parameters are given in Tables 1 and 2.

The atomic scattering factors were taken from the International Tables for X-ray Crystallography.[4] The computations were performed on a TOSBAC-3400 computer at the Tottori University Computing Center and on a NEAC 2200-N700 computer at the Computation Center of Osaka University.

The structural formula of emericellin has been confirmed by the present X-ray analysis. A stereo-

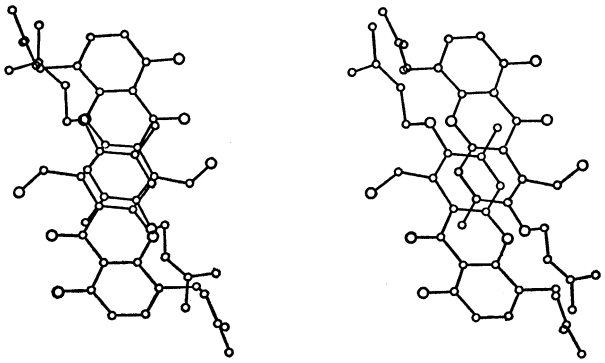

Fig. 1. Stereoscopic view of a pair of melecules.

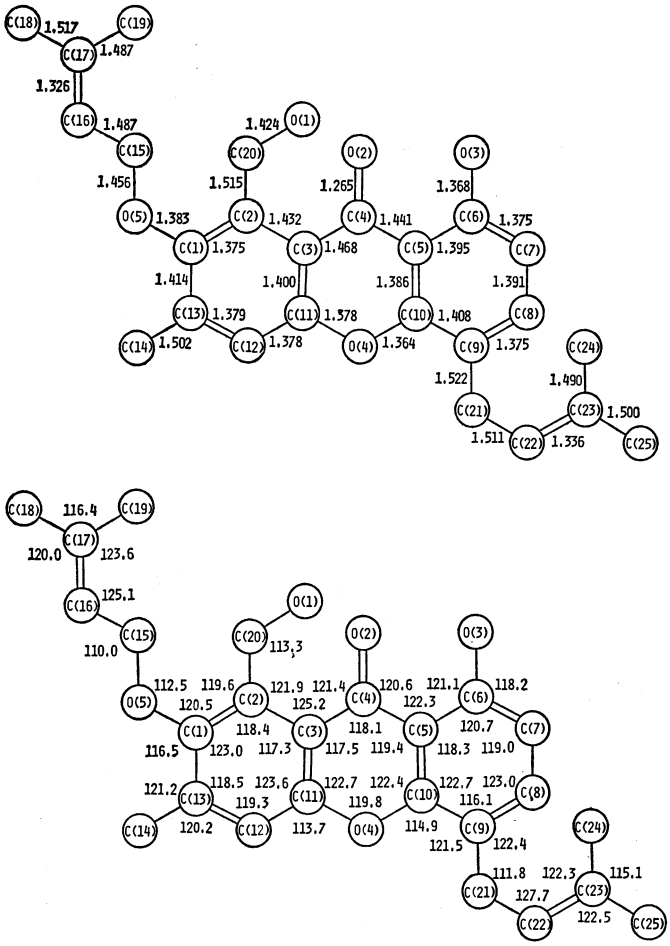

Fig. 2. Bond lengths (Å) and angles (°) for non-hydrogen atoms.
The e. s. d.'s of bond lengths and angles are about 0.008 Å and 0.5° respectively.

scopic view of the pair of molecules is shown in Fig. 1. The bond lengths and angles for non-hydrogen atoms are shown in Fig. 2. The bond lengths and angles in the xanthone skeleton are comparable with those found in sterigmatin.[2] There is a screw-like twist along the longitudinal axis of the skeleton; the twist angle between the two outer benzenoid rings is about

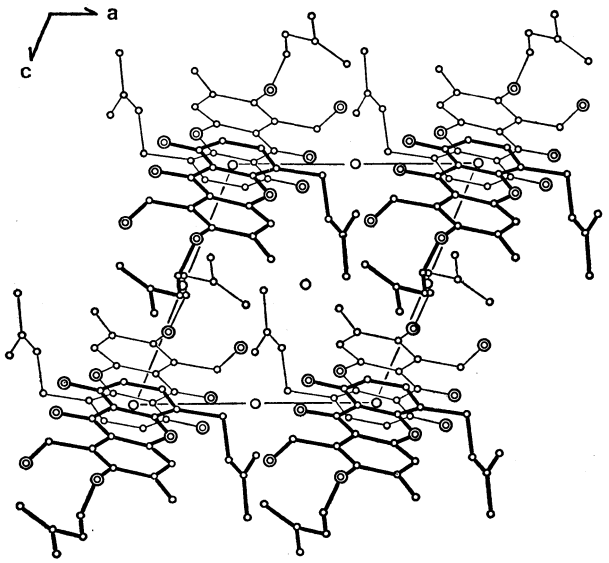

Fig. 3. The crystal structure of emericellin viewed along the b axis. The hydrogen atoms are omitted in the figure.

3°. The C(20) atom is largely displaced from the least-squares plane passing through the 14 ring atoms in the skeleton. The corresponding bond lengths and angles in the two isopentenyl groups are similar to each other. There are two intramolecular hydrogen bonds, O(1)–H(18)·····O(2) and O(3)–H(19)·····O(2). The distances of O(1)·····O(2) and O(3)·····O(2) are 2.736 and 2.575 Å respectively, while the angles of O(1)–H(18)·····O(2) and O(3)–H(19)·····O(2) are 122° and 154° respectively.

The crystal structure viewed along the b axis is shown in Fig. 3. There are only three kinds of close contacts; plane to plane contact of the xanthone skeletons around (0, 0, 0), contact between the isopentenyl group and the xanthone skeleton around (0, 0, 1/2), and head-to-tail contact between the molecules related by unit translation along the a axis. Except for these contacts, the crystal consists of a loose-packed array, and there is no intermolecular hydrogen bond. These are in accordance with the relatively low density of the crystal.

The authors wish to thank Professor Tamaichi Ashida of Nagoya University for his permission to use the block-diagonal least-squares program.

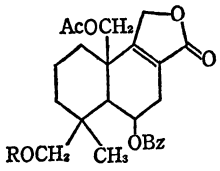
(Received May 6, 1975)

Synopsis. The structure of a bromo-derivative of parasiticolide A, $C_{26}H_{29}O_8Br$, has been determined by single-crystal X-ray analysis. The compound crystallized in the space group $P2_12_12_1$, with $a=14.658$, $b=15.323$, and $c=11.181$ Å. The absolute configuration of the molecule was determined using the anomalous dispersion effect of the bromine atom for Cu$K\alpha$ radiation.

Parasiticolide A (I) was isolated as a new metabolite from a strain of *Aspergillus parasiticus* Speare IFO 4082, which produces a small amount of carcinogenic aflatoxins.[1] Although the structural formula of parasiticolide A had been determined by means of chemical and spectroscopic methods,[1] the three-dimensional structure and the absolute configuration of this compound remained unsolved. Therefore, a bromo-derivative of parasiticolide A (II) has been studied by the X-ray diffraction method in a series of works on the structures of the metabolites of the genus *Aspergillus*.[2-4]



(I) R: CH_3CO-
(II) R: $BrCH_2CO$-

The bromo-derivative of parasiticolide A was prepared by the acylation of a partial hydrolysis product of parasiticolide A and bromoacetylbromide. The compound crystallized from acetone solution in the form of colorless prisms elongated along the b-axis. The cell dimensions were obtained by the least-squares fits of the Bragg angles of forty-nine reflections measured by a Toshiba four-circle diffractometer. The crystal data were as follows: $C_{26}H_{29}O_8Br$, $M=549.4$, mp 206—208 °C, orthorhombic, space group $P2_12_12_1$, $a=14.658(6)$, $b=15.323(6)$, $c=11.181(5)$ Å, $V=2511.4$ Å^3, $Z=4$, $D_o=1.45$ g/cm^3, $D_x=1.45$ g/cm^3. The intensities were measured from a specimen with dimensions of *ca.* $0.36\times0.16\times0.14$ mm on a diffractometer with a scintillation counter equipped with a pulse-height analyzer. The stationary-crystal stationary-counter method was used, with a counting time of 30 seconds. The intensities of 1782 independent reflections were measured up to $\sin\theta/\lambda=0.53$ with Ni-filtered Cu $K\alpha$ radiation. The background for each reflection was taken from plots of the background as a function of 2θ. The intensities were corrected only for the Lorentz and polarization factors.

The structure was solved by the heavy-atom method and refined by a block-diagonal least-squares method. In the early stage of the refinement, all the lighter atoms were assumed to be carbon atoms. Eight oxygen atoms were assigned on the bases of the temperature factors and of the chemical sense. The refinement with anisotropic temperature factors reduced the R value to 0.079. The absolute configuration of the molecule was determined using the anomalous dispersion effect of the bromine atom ($\Delta f'=-0.9$ and

$\Delta f''=1.5$) for Cu $K\alpha$ radiation. A comparison of the intensities between the Friedel-pair of reflections is given in Table 1. Including hydrogen atoms with fixed parameters and the anomalous dispersion effect of the bromine atom, the final refinement reduced the R value to 0.062 for 1772 reflections. The weighting scheme adopted in the final calculation was $w=0.3$ for $F_o=0$, $w=1.0$ for $0<F_o\leqq 20$, and $w=1.0/(1.0+0.5(F_o-20))$ for $20<F_o$. The final atomic parameters are given in Table 2. The absolute configuration of the molecule is correctly represented by the coordinates in Table 2 if the right-handed coordinate system is adopted. All the atomic scattering factors were taken from the International Tables for X-ray Crystallography.[5] The computations were performed on a TOSBAC-3400 computer at the Tottori University Computing Center, and on a NEAC 2200 N700 computer at the Computation Center of Osaka University.

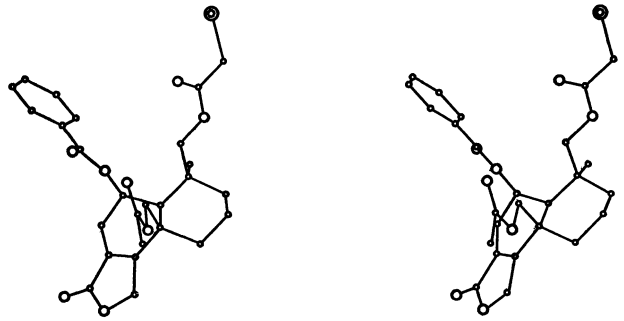

Fig. 1. Stereoscopic view of the molecule.

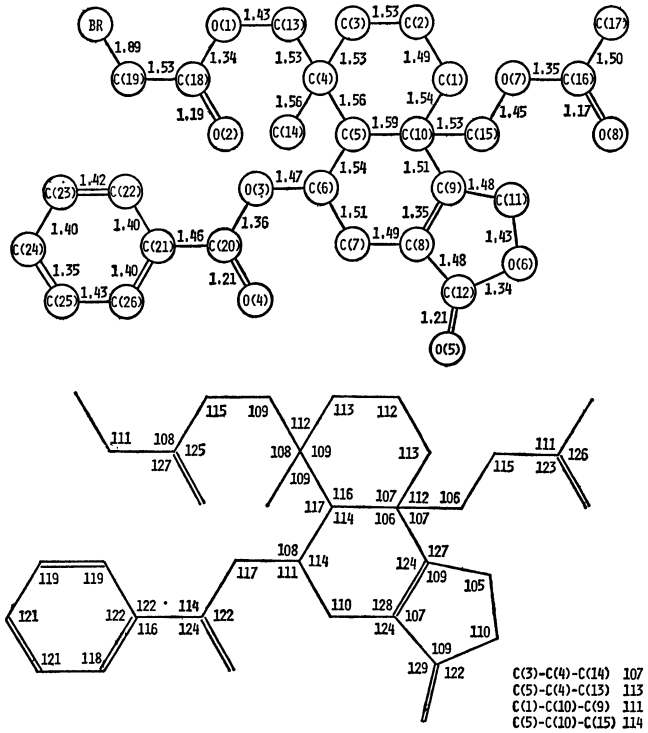

Fig. 2. Bond lengths (l/Å) and angles (φ/°) for non-hydrogen atoms. The mean estimated standard deviation of bond lengths is 0.012 Å, and that of bond angles is 0.7°.

The present analysis has established the three-dimentional structure and the absolute configuration of the bromo-derivative of parasiticolide A. A stereoscopic view of the molecule is shown in Fig. 1, which is drawn with the correct absolute configuration. The bond lengths and angles for non-hydrogen atoms are given in Fig. 2. Two six-membered rings are joined through two equatorial-type bonds. The two acetoxymethyl groups and one benzoyloxy group show a 1,3-diaxial relationship. As a consequence, the bond angles, C(4)–C(5)–C(6), C(4)–C(5)–C(10), C(6)–(5)–C(10), and C(5)–C(10)–C(15), may be widened from the regular tetrahedral angle to release these groups from crowding. The remaining bond lengths and angles seem to be normal for the respective bond types. The details of the stereochemistry of parasiticolide A itself will be published later.

The authors wish to thank Professor Tamaichi Ashida of Nagoya University for his permission to use the block-diagonal least-squares program.

The Apparent Solvent Effect on the Fluorescence Efficiency of 9-Methyl-10-(chloromethyl)anthracene

Fujio TANAKA and Jiro OSUGI

Department of Chemistry, Faculty of Science, Kyoto University, Kyoto 606

(Received March 28, 1975)

Synopsis. 9-Methyl-10-(chloromethyl)anthracene (I) is immediately transformed into 9-methyl-10-(ethoxymethyl)-anthracene (II) in ethanol, and a very strong fluorescence of II is observed. While I is practically nonfluorescent, II fluoresces strongly in all solvents. These facts explain well a phenomenon misinterpreted by Melhuish as a remarkable solvent effect on the fluorescence efficiency of I.

It was reported by Melhuish that the fluorescence yield of 9-methyl-10-(chloromethyl)anthracene (I) was 0.09 in benzene and 0.73 in ethanol.[1] This remarkable difference has received some attention as a typical example of solvent effects on fluorescence yields.[2] However, the origin of this interesting phenomenon is not yet well understood. The present authors re-examined the behavior of the fluorescence of I in the course of their studies of the environment effects on the fluorescence yields of anthracene and its derivatives.

As reported by Melhuish, all alcoholic solutions of I fluoresce very strongly, while I is practically nonfluorescent in all solvents except alcohols.[3] To clarify the mechanism of the high-fluorescence efficiency in alcoholic solvents, first the spectroscopic nature of I in ethanol and benzene was investigated. The absorption spectrum of an ethanol solution of I shifts toward wavelengths shorter by *ca.* 10 nm relative to that of a benzene solution. This shift is too large compared with the corresponding values (3—4 nm) for anthracene and most derivatives. Therefore, the change in the absorption spectrum suggests the occurrence of a solvolytic reaction in ethanol. Indeed, the residue of an ethanol solution of I was identified as 9-methyl-10-(ethoxymethyl)anthracene (II) by PMR (signals of ethyl group) and mass spectrometry (M^+=250). II fluoresces strongly in both ethanol and benzene. Melhuish also reported in the same paper that the fluorescence yields of II are 0.68 in ethanol and 0.71 in benzene.[1] As a matter of course, an ethanol solution of II shows the same absorption and fluorescence spectra as an ethanol solution of I. The absorption and fluorescence spectra of I and II in ethanol and benzene are shown in Fig. 1. It is also clear from the similar changes in the absorption spectra that I is transformed into the corresponding alkoxy-compounds in other alcoholic solvents. Accordingly, the following conclusion may be drawn: the high-fluorescence efficiency in alcoholic solutions of I is not due to the solvent effect on the fluorescence efficiency of I itself, but to the transformation of I into II in alcoholic solvents.

Further, the above conclusion is confirmed by the fluorescence behavior of I in the acetonitrile-water system, where a solvolytic reaction is likewise possible. Although I is nonfluorescent in acetonitrile, a strong fluorescence appears upon the addition of some water. The residue from this solution was identified as 9-methyl-10-(hydroxymethyl)anthracene (III) by mass spectrometry (M^+=222). III also fluoresces strongly in all solvents.

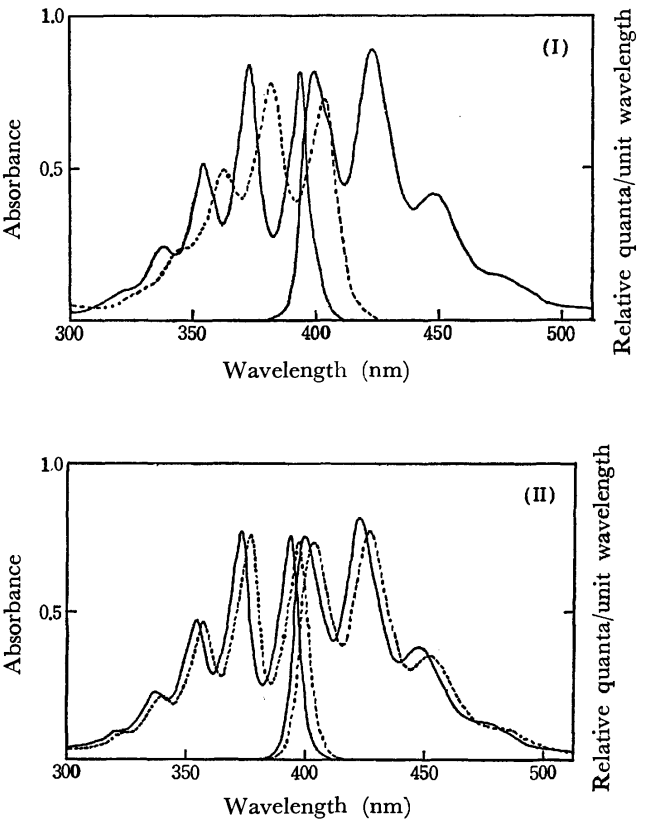

Fig. 1. Absorption and fluorescence spectra of (I) and (II) in ethanol (——) and benzene (----); 8×10^{-5} mol/l for absorption and 8×10^{-6} mol/l for fluorescence. The fluorescence spectra are normalized to the absorption spectra at the 0-0 band.

In conclusion, then, the nonfluorescent character of I is an interesting problem. A photolytic process of the C-Cl bond may be considered as the main deactivation process.

Experimental

I was prepared by the chloromethylation[4] of 9-methylanthracene[5] and was recrystallized three times from benzene. The ethanol and benzene are of a spectroscopic grade. The absorption and fluorescence spectra were measured with a Shimadzu spectrophotometer, UV 200, and a Shimadzu corrected fluorospectrophotometer, RF 502, respectively.

The Reaction of Water Vapor and Carbon Vapor Produced by Laser Irradiation

Pil Hyon KIM, Ko TAKI,* and Susumu NAMBA

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

**Faculty of Industrial Hygiene, Kitasato University, Sagamihara-shi, Kanagawa 228*

(Received January 31, 1975)

Synopsis. The carbon vapor produced by laser irradiation was found to react with the water vapor. The main products were carbon monoxide, hydrogen, and acetylene, the last of which is not found in the water-gas. Acetylene is considered to be formed by the reaction of the C_2 species of the carbon vapor.

The present authors have previously studied the reactions of gaseous substances with the vapor of the solid target produced by laser heating.[1,2] In these cases, only a small region of the target is heated rapidly by the irradiation of the pulsed laser beam, and the gaseous substances can react with the vaporized species produced at high temperatures. Moreover, because of the localized heating and the short-pulse heating, the gaseous products are prevented from thermal decomposition.

In the reaction of hydrogen or hydrocarbons with the carbon species vaporized from the graphite carbon target,[1] acetylene was obtained as the main product; it had been assumed that the C_2 species played the main role in the product-forming step. From the above results, the carbon vapor produced by laser heating can be expected to react with the water vapor, which is most simple and easily obtainable hydrogen compound, to produce hydrocarbons as gaseous fuel.

It is well known in the fuel and coal-product industries that the reaction of heated carbon and water vapor gives a water-gas[3] which contains hydrogen and carbon monoxide as the main components, plus a small quantity of methane and carbon dioxide, but no acetylene. However, the reaction of the water vapor with the carbon vapor produced by the laser heating has never been reported.

This paper will describe the reaction of the water vapor with the carbon vapor produced from the graphite carbon target by the irradiation of the pulsed laser beam.

Experimental

The graphite carbon target and a small amount of water ($\sim 10^{-2}$ g) were placed in a 7-cm^3 Pyrex cell, as is shown in Fig. 1. The cell had been preheated to increase the vapor pressure of water ($\sim$100 Torr). Then, the target was irradiated by means of a ruby laser beam focused by a lens 35 mm in focal length. The ruby laser used was a normal laser, the output energy and pulse duration of which were about 3 J and 1 ms respectively. The temperature of the irradiated region ($\sim 10^{-3}$ cm^2) is estimated to be above 3000 K, and the carbon vapor produced is considered to be the C_1, C_2, C_3 . . . species.[4] After 5—7 pulse irradiations, the reaction products were analysed by gas chromatography using silica gel and squalane columns and by mass spectroscopy.

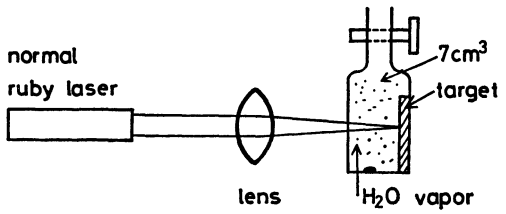

Fig. 1. Experimental block diagram.

Results and Discussion

The product yields in the reaction of water vapor with the carbon vapor produced by six pulse-laser irradiations are shown in Table 1. The yields are proportional to the number of laser irradiations. For a comparison of the product yields, the product ratios of the water-gas[3] produced by conventional heating are also shown in Table 1. In laser irradiation, the main products are carbon monoxide, hydrogen, and acetylene, the last of which is not contained in the water-gas.

TABLE 1. PRODUCT YIELD IN THE REACTION OF WATER VAPOR WITH CARBON VAPOR AFTER 6 PULSE LASER IRRADIATIONS AND RELATIVE YIELD IN WATER-GAS

Product	Yield (10^{-6} mol) in laser irrad.	Relative yield (%) in water-gas
CO	6	30—42
H_2	5	44—52
C_2H_2	2	
CO_2	$\sim 10^{-2}$	2— 8
CH_4	$\sim 10^{-2}$	0.5—1.0
C_2H_4	$\sim 10^{-2}$	
N_2		2— 6

In the case of water-gas, it has been considered that monatomic carbon reacts with water vapor to give carbon monoxide and hydrogen as the main products. In laser irradiation of the carbon target, the reaction of the C_1 species of the carbon vapor with water vapor may also give carbon monoxide and hydrogen. As has been described in a previous paper,[1] acetylene may be formed by the reaction of the C_2 species of the carbon vapor in this system. Therefore, as in the reaction of C_2 species with hydrogen or hydrocarbons, the elementary formation processes of acetylene may be considered to be as follows:

1) $C_2 + H_2O \longrightarrow \cdot C_2H + \cdot OH$

2) $\cdot C_2H + H_2O \longrightarrow C_2H_2 + \cdot OH$

By the addition of about 100 Torr NO to the reaction system, the yield of acetylene was decreased to about one-tenth, but that of carbon monoxide increased about 1.5 times. In this case, NO may scavenge the acetylene precursor, C_2, to give carbon monoxide, because it has also been reported that the C_2H radical is not affected by this scavenger.[5] Moreover, by the addition of about 100 Torr oxygen, the yield of acetylene decreased to a trace.

The reaction of the C_2 species with the hydrogen produced may also give acetylene. However, the contribution to the yield is considered to be smaller than that of the reaction with water vapor, because the partial pressure of the hydrogen produced is several Torr for about a hundred Torr of water vapor.

The two reasons for the formation of acetylene in the laser irradiation are considered to be as follows: one is that the carbon vapor produced by laser irradiation contains a considerable amount of the C_2 species, and the other is that the acetylene produced is prevented from thermal decomposition because the laser heating features rapid heating and rapid quenching.

Micellar Effect of Alkylammonium Propionates on Reaction Rate of Keto-Enol Tautomerism in Cyclohexane

Kijiro KON-NO, Kiyoshi MIYAZAWA, and Ayao KITAHARA

Department of Industrial Chemistry, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received May 31, 1975)

Synopsis. The rate of keto-enol transformation of acetylacetone or acetoethyl acetate was spectroscopically measured in the cyclohexane solutions in the presence of primary, secondary or tertiary alkylammonium propionate. The rate was enhanced by micelle formed. The order of effectiveness of the surfactants was that primary≫secondary> tertiary. The order coincides with the number of protons in the ammonium ion of the surfactants and the aggregation number of micelle.

Reversed micelle of oil-soluble surfactants in apolar solvents which involves polar region or ion-pairs in the interior is expected to provide active sites for reactions. Because reversed micelle is more analogous to an enzymatic model than aqueous micelle as pointed out by Fendler *et al.*,[1] micellar catalysis in apolar media seems to be more interesting than that in water media. Furthermore, reversed micellar catalysis is possible to be modified by solubilization of polar substances such as water, acids, alcohols and amines and the solubilization has been considerably studied.[2]

Enhancement of the rate constant of mutarotation of 2,3,4,6-tetramethyl-α-D-glucose and decomposition of Meisenheimer complex in benzene in the presence of alkylammonium carboxylates has been recently reported by Fendler *et al.*[3,4] They have attributed the rate enhancement to the orientation of the reactants in the micelle and the transfer of proton from the ammonium ion of the surfactant to the reactant. However, such a system has little been studied.[5] The present authors have also studied the catalytic effect of alkylammonium carboxylates on hydrolysis of *p*-nitrophenyl esters.[6]

For the further investigation on the effect of proton of surfactant molecules of ammonium type, the rate of keto-enol transformation is now studied in the presence of a surfactant of primary, secondary or tertiary ammonium type in a nonpolar solvent.

Experimental

Materials: Dodecylammonium propionate (DAP), didodecylammonium propionate (DDAP) and cetyldimethylammonium propionate (CDAP) were used as oil-soluble surfactants. The preparation and purification were described in the previous paper.[6] They were further dried under reduced pressure at 50 °C immediately before use. Cyclohexane used as the solvent was purified by the process reported[7] and dried with Molecular Sieves 4A. Acetylacetone (AA) and acetoethyl acetate (EA) used as the substrates were of the chemical grade.

Methods: The rate was measured by following UV-absorption spectra of the keto-form with the Spectrophotometer UV-200 of the Shimadzu Manufacturing Co. The absorption peaks of the keto-form used for calculation of the rate constant were 275, 285 and 304 nm for EA in the DAP solution, EA in the DDAP solution and AA in the DAP solution, respectively.

All of the rates of transformation were the pseudo-first order and the apparent rate constants (k_ψ) were obtained by the Guggenheim method.[8] In pure cyclohexane, 43% of EA or 88% of AA is present as the enol-form.[9] The initial concentration of the enol-form used throughout the present measurements was 2.5×10^{-5} M and 5.0×10^{-5} M for EA and AA, respectively. Temperature of the solutions in the cell was kept at 30 °C.

The measurement of aggregation number and critical micellar concentration (CMC) or critical aggregating concentration (CAC) were carried out with a vapor pressure osmometer, the Hitachi-Perkin-Elmer Molecular Weight Apparatus, as reported previously.[10]

Results and Discussion

The equilibrium concentration of the enol- or keto-form of EA or AA in cyclohexane is considerably different from that in water. Hence water present in the cyclohexane solution may affect the rate of the shift reaction. Hence, the reaction rate of EA was measured by varying the quantity of water in the DAP solution. The result was shown in Fig. 1. Further experiments were carried out below the 0.5 molar ratio.

Transformation reaction from enol-form to keto-form for EA and AA occurred in all of the surfactant solutions used, though the reaction did not appear in pure cyclohexane. The increasing rate constant (k_ψ) of the keto-form of EA and AA was depicted as a function of surfactant concentration in Fig. 2, with the inserted small figure enlarging lower concentration range. The aggregating number (n) and CMC or CAC obtained experimentally were listed in Table 1.

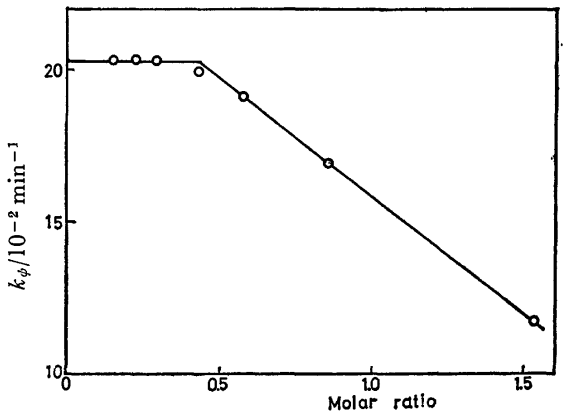

Fig. 1. Rate constant (k_ψ) of transformation to the keto-form of EA *vs.* the amount of water (molar ratio of water to the surfactant) added in the DAP solution (50 mM).

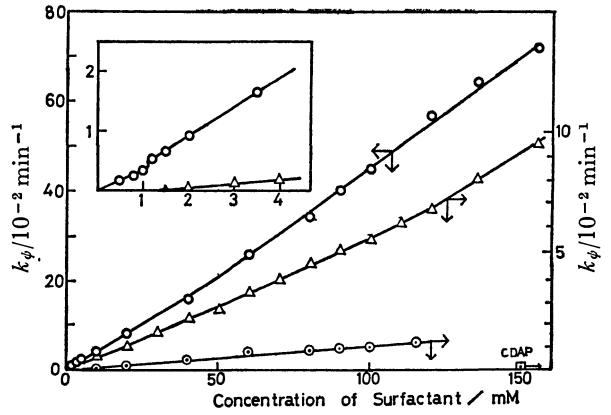

Fig. 2. Rate constant (k_ψ) of transformation to the keto-form *vs.* concentration of surfactants.
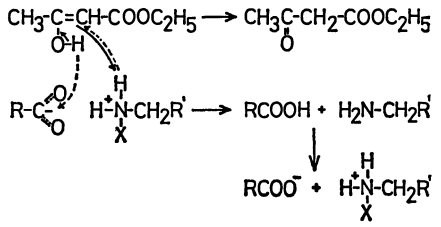
—○—: EA in the DAP solution, —△—: AA in the DAP solution, —⊙—: EA in the DDAP solution, ⊡: EA in the CDAP solution.

Table 1. The values of CMC or CAC and aggregation number (n) of surfactants (Dry systems, 30 °C)

Surfactants	CMC or CAC (mM)	n	Number of protons in ammonium ion
DAP	1.8	3.8	3
DDAP	4.4	1.2	2
CDAP	0.78	1.2	1

Combination of Fig. 2 and Table 1 elucidates the following effect of micelle on the reaction rate. Below CMC or CAC, transformation to the keto-form was too slow to calculate k_ψ for AA in the DAP solution and EA in the DDAP solutions, though k_ψ was obtained for EA in the DAP solution. That is, it can be seen that transformation to the keto-form is more enhanced by micelle than monomer, except for EA in the CDAP solution in which k_ψ was too small to be depicted in the Fig. 2 over the whole range of concentration measured. This may be due to concentration of polar groups by micelle formation which increases interaction with the substrate. It is also evident from Fig. 2 that effectiveness of the surfactant micelle on the k_ψ-values is the order of DAP≫DDAP>CDAP. The order coincides with the number of protons or hydrogen atoms in the ammonium ion and the aggregation number shown in Table 1, though the difference of n between DDAP and CDAP is ambiguous. Hence it is concluded that the surfactant having more protons and aggregation number shows the more effectiveness on the reaction rate.

It is considered from the above facts that keto-enol transformation is induced by proton transfer from the ammonium ion to the substrate. The consideration may propose a following scheme for the reaction mechanism similar to the proposition by Fendler *et al.*[3] As an example, for EA:



R: $CH_3(CH_2)_2$
R': $CH_3(CH_2)_{10}$
X: $CH_3(CH_2)_{11}$ or H

The inhibition effect of water shown in Fig. 1 may be due to hydration to ammonium and/or carboxylate.

The Redox Acidity Function, R_0(H) in Glycols and Their Aqueous Mixtures

V. Srinivas Rao and C. Kalidas*

Department of Chemistry, Indian Institute of Technology, Madras-600 036, *India*

(Received February 3, 1975)

Synopsis. The variation of the redox acidity function, R_0(H), based on ferrocene redox couple has been studied at 25 °C as a function of solvent composition in diethylene glycol-water and ethylene glycol-water mixtures and compared with the H_0 variation in these solvents. Further, the redox function for sulfuric acid has been reported upto 6 molal in 50 wt% diethylene glycol-water mixture as the solvent.

The indicator acidity functions have been the most extensively studied[1] among the acidity functions. However, it has been well established in recent years,[1] that these functions are not satisfactory as an index of the proton activity of the medium as they are known to vary with the nature of the indicators employed in such measurements. Strehlow and Wendt[2] proposed an alternate acidity function, the redox function, R_0(H), based on redox systems of large size of the charge type, $0/1^+$, such as ferrocene couple. Although this function has been studied in aqueous solutions,[2] practically no measurements have been reported in non-aqueous media,[3] especially in amphiprotic solvents and their aqueous mixtures. In continuation of our earlier work[4-6] on this subject in glycolic solvents, the present investigation deals with a study of the variation of R_0(H) in diethylene glycol–water and ethylene glycol–water mixtures at 0.01 mol/kg perchloric acid as also the determination of R_0(H) for sulfuric acid in 50wt% diethylene glycol as solvent.

Experimental

The purification of ethylene and diethylene glycols has been described[4,7] elsewhere. Ferrocene (E. Merck) was sublimed twice under vacuum and the resulting pure orange crystals were employed. Perchloric acid (E. Merck, Proanalysi, 70 wt %) was used in measurements in aqueous mixtures involving variation of solvent composition while methanesulphonic acid (Fluka), purified by distillation, was used in the pure organic solvents. Aqueous SCE was the reference electrode in these studies. A.R. Sulfuric acid was used in measurements in 50 wt % diethylene glycol as solvent. Mercury, mercurous sulphate electrode was employed as the reference in these measurements.

The determination of R_0(H) function is based on the evaluation of the EMF of the cell.

$$\text{Pt, } H_2(\text{g, 1 atm})\,/\,\frac{\text{acid in the given solvent}}{}\,\frac{\text{FOC, FiC}^+}{(1:1)}\,/\,\text{Pt} \qquad (1)$$

in the solvent and water and was obtained by a combination of the polarographic $E_{1/2}$ of ferrocene *vs.* SCE or mercury, mercurous sulphate electrode as reference and the EMF of the hydrogen–calomel or hydrogen–mercury, mercurou sulphate cell using the same experimental solution for both the measurements. Further details of the determination of the EMF of the cell (1) are given[8] elsewhere.

Results and Discussion

The redox function, R_0(H), is defined by

$$R_0(\text{H}) = \frac{E_s - E^\circ_w}{2.303\,RT/F} \qquad (2)$$

where E_s refers to the EMF of the cell (1) in the solvent and E°_w is the standard EMF of the cell in water which has a value of +0.400 V at 25 °C as reported[2] earlier. The EMF's of cell (1) at 0.01 mol/kg perchloric acid in various diethylene glycol–water and ethylene glycol–water mixtures and the R_0(H) data in these media at 25 °C are recorded in Table 1. The H_0 data obtained in these solvents at 0.01 mol/kg perchloric acid according to the method described[4] previously, using *p*-nitroaniline as indicator are also recorded in this table for comparison.

Table 2 presents the EMF's of cell (1) and R_0(H) data at various molalities of sulfuric acid in 50 wt% diethylene glycol as solvent.

Assuming that the neutral component of the transfer free energy of ferricinium ion is equal to that of ferrocene and neglecting the small electrostatic transfer free energy of the ferricinium ion, which is justifiable in view of the larger size of ferricinium ion (r_{fic^+} = 3.3 Å,)[9] the R_0(H) can be related to the proton activity of the medium by

$$R_0(\text{H}) = -\log\,(m_{\text{H}^+}\,{}_w\gamma_{\text{H}^+}) \qquad (3)$$

where m_{H^+} is the molality of the H^+ ion and ${}_w\gamma_{\text{H}^+}$ is the activity coefficient of the same ion on the aqueous standard state. It is seen from Table 1 that R_0(H) increases continuously with increasing additions of diethylene glycol, passes through a maximum at about 90 wt% organic solvent and then decreases. A similar result is observed in ethylene glycol–water mixtures although the maximum occurs at 95 wt% organic solvent in this case. This implies that in both organic solvent–water mixtures the proton activity of the medium initially decreases, passes through a minimum at about 90—95 wt% organic solvent and then increases. Evaluation of the proton medium effect employing the ferrocene redox couple as reference in these solvents showed[8] a variation similar to R_0(H) and thus the basicity of the medium increases with increasing addition of the organic solvent at fixed acid concentration upto 90—95 wt% organic solvent and then decreases in the pure solvent, which can be explained on the basis of the structural theory of ion solvation proposed by Feakins and Watson.[10] It is also noted from Table 1 that R_0(H) and H_0 vary similarly in these solvent mixtures with good agreement in the composition of maximum basicity region in diethylene glycol–water mixtures while it is somewhat

Table 2. R_0(H) of sulfuric acid in 50 wt% diethylene glycol at 25 °C

Molality of H_2SO_4	EMF of cell (1) in V	R_0(H)
0.1178	0.4644	1.09
0.2335	0.4251	0.43
0.4710	0.4107	0.18
1.00	0.3945	−0.09
2.00	0.3553	−0.76
3.60	0.3171	−1.40
6.00	0.2155	−3.12

poor in ethylene glycol–water mixtures, Further, R_0(H) is generally greater than H_0 at a given solvent composition (from the data in diethylene glycol–water mixtures), the difference being given by

$$R_0(\mathrm{H}) - H_0 = \log_{w}\left(\frac{\gamma_B}{\gamma_{BH^+}}\right) \quad (4)$$

where the γ_B and γ_{BH^+} represent the activity coefficients of the indicator base and its conjugate acid on the aqueous standard state. Equation (4) was checked in diethylene glycol–water mixtures by calculation of the activity coefficient ratio from the indicator data (unpublished results) on *p*-nitroaniline in these mixtures. For this purpose, the medium effect of the indicator was obtained from solubility measurements and that of its conjugate acid was realised through the application of the ferrocene assumption to the pK data on the indicator and fair agreement was indeed observed.

It is seen from Table 2 that R_0(H) of sulfuric acid in 50 wt% diethylene glycol decreases with increasing acid concentration indicating that the proton activity of the medium is enhanced with acid concentration. The R_0(H) of an aqueous sulfuric acid solution is more negative[2] than R_0(H) in 50 wt% diethylene glycol at a given acid concentration which shows that aqueous acid solutions have higher proton activity than those in 50 wt% diethylene glycol. This indicates that this solvent is more basic than water, a result in agreement[8] with the conclusions arrived from the proton medium effect in this solvent.

One of us (V.S.R.) thanks the C.S.I.R.(India) for the award of a Senior Research Fellowship.

Hydration of Perchlorate Anion in Nitrobenzene by Means of Cryoscopic Measurements

Takao TARUI

Department of Chemistry, Faculty of Science, Hiroshima University, Hiroshima 730

(Received December 21, 1974)

Synopsis. By means of cryoscopic measurements, hydration of the perchlorate anion in nitrobenzene was examined and the value of the first hydration constant was determined.

Tris(1,10-phenanthroline)iron(II) chelate cation is well extracted into nitrobenzene with certain anions.[1] As the size of anions increases, extractability increases. At the same time, a small amount of water was found to be transferred into nitrobenzene accompanied by the anions.[2,3] However, it is not as yet clear whether or not the water molecule transferred with the ion pair is associated with the ions in the organic phase. Cryoscopic measurements were carried out in order to estimate the first hydration constant of the perchlorate anion. The results were compared with those obtained by isopiestic measurements.[4]

Experimental

Preparation of the crystal of tris(1,10-phenanthroline)-iron(II) perchlorate was carried out according to the method reported previously, and its purity was checked by analysis.[4] The crystal was dehydrated by heating at 120 °C for a day just before use. Nitrobenzene was purified by washing with concentrated sulfuric acid and water successively, then dried over anhydrous calcium chloride and filtered with a filter paper. The resulting product was distilled under reduced pressure.

An appropriate amount (85—425 mg) of $Fe(phen)_3(ClO_4)_2$ was added to 20 ml of nitrobenzene solution containing various amounts of water, the freezing point depression being measured with a Beckmann thermometer. Since moisture in the air seriously affects the measurements, the amount of water was checked before and after the cryoscopic measurements and necessary correction made. Stoichiometric concentration of water was determined by means of the Karl Fischer titration.

Results and Discussion

The cryoscopic constant determined by the use of water as a solute is 6.815. The value is similar to that reported previously.[5] Some authors pointed out the occurrence of self-association of water in nitrobenzene,[6,7] but we have ignored it since the concentration of water is very low. The mixture of water and tris(1,10-phenanthroline)iron(II) perchlorate shows a smaller freezing point depression than expected from the additivity, thus indicating the occurrence of association.

From conductivity measurements, the ion pair of tris(1,10-phenanthroline)iron(II) perchlorate is considered to be completely dissociated in nitrobenzene.[8] Moreover, the amount of water co-extracted into nitrobenzene decreased with the increase[2,3] in anion size. The water co-extracted into nitrobenzene is considered to be attached to anions.

Now let us consider the degree of hydration. Since the concentration of water is very low (below 0.05 mol/l), the concentration of highly hydrated species such as di- or tri-hydrated species is assumed to be negligibly small. The mean hydration number $\bar{n}$ is described as follows:

$$\bar{n} = \frac{[ClO_4\cdot H_2O]}{[ClO_4]+[ClO_4\cdot H_2O]} = \frac{\beta_1[H_2O]_f}{1+\beta_1[H_2O]_f} = \frac{[H_2O]_{total}-[H_2O]_f}{[M]}$$

or

$$\frac{\beta_1}{1+\beta_1[H_2O]_f} = \frac{[H_2O]_{total}-[H_2O]_f}{[H_2O]_f}\cdot\frac{1}{[M]} \quad (1)$$

where $[M]=2\,[Fe(phen)_3^{2+}]=[ClO_4]$, and β_1 denotes the first hydration constant. Strictly speaking, the depression of freezing point at a certain concentration of salt might not be the linear function of the concentration of water. However, as a first approximation, the concentration of free water not associated with the perchlorate ion can be represented by the use of an apparent cryoscopic constant. The approximation is equivalent to the description that the amount of hydrated water is proportional to the stoichiometric concentration of water, and is considered to be valid from the data relating to the change of mean hydration number with free water. $[H_2O]_{total}/[H_2O]_f$ can thus be represented by K_f/K_1, where K_f is the cryoscopic constant of nitrobenzene and K_1 the apparent cryoscopic constant of nitrobenzene containing salts. Substituting the above relation into Eq. (1) we have

$$\frac{\beta_1}{1+\beta_1[H_2O]_f} = \frac{K_f-K_1}{K_1}\cdot\frac{1}{[M]}$$

If we assume that $\beta_1[H_2O]_f$ is negligibly smaller than unity, we get the following equation.

$$\frac{K_f-K_1}{K_1}\cdot\frac{1}{[M]} = \beta_1 \quad (2)$$

The results calculated by means of Eq. (2) are given in Table 1. Measurements were carried out at tem-

Table 1. Hydration constants of the perchlorate ion in nitrobenzene

M	K_1	β_1
0.00498	6.49 ±0.12	5.1±2.9
0.00999	6.270±0.094	4.5±1.4
0.0151	6.068±0.095	4.2±1.0
0.0257	5.493±0.204	4.7±1.1

peratures near 5.5 °C, the term β_2 being neglected in the treatment of data. The values of β_1 estimated at different concentration of salt are similar to each other, a mean value 4.5 being obtained within experimental errors. The constant β_1 was determined to be 1.5 ± 0.1 from the isopiestic study,[4] where the measurements were carried out at 25 °C. The results seem to be reasonable, when we take the difference of conditions of the two experiments into consideration. We can conclude that all the excess water transferred by the solvent extraction of ion pair is hydrated to the anions. This indicates that the water molecule is chemically bound to the perchlorate ion in nitrobenzene phase.

The author would like to thank Professor Yuroku Yamamoto for his helpful discussion and comments.

An Equilibrium Study of the Formation of Mixed-Ligand Nickel(II)–Aminopolycarboxylate Complexes

Mutsuo KODAMA

Department of Chemistry, College of General Education, Hirosaki University, Bunkyo, Hirosaki 036

(Received March 22, 1975)

Synopsis. The equilibria for the formation of 1 : 1 : 1 ratio mixed-ligand complexes of nickel(II)–NTA, HIDA, and -ethylenediamine-*N*,*N*′-diacetate (EDDA) complexes with the glycinate (Gly), glutamate (Glut), and aspartate (Asp) anions were studied by determining the effects of the Gly, Glut, and Asp anions on the rates of the substitution reactions of nickel(II)–NTA, -HIDA, and -EDDA complexes with EDTA-OH or DTPA.

Recently the importance of the formation of mixed-ligand complexes has been recognized, and a large number of studies have been carried out for a better understanding of the mixed-ligand complex formation.[1–3] The present author has also studied the equilibria for the formation of mixed-ligand complexes between ammonia and metal (II)-aminopolycarboxylate complexes.[4,5] In this paper, the mixed-ligand complex formation equilibria between the nickel(II)–aminopolycarboxylate complexes and the Gly, Glut, and Asp anions will be studied by investigating their effects on the rates of the substitution reactions of nickel(II)–aminopolycarboxylate complexes.

Experimental

Reagents. The EDDA, NTA, Glut, Gly, Asp, EDTA-OH, and DTPA used in this study were recrystallized as their acids from their aqueous solutions. The preparation and recrystallization of the acid form of HIDA were described previously.[6] The other chemicals used were of analytical reagent-grades and were used without further purification.

Apparatus and Experimental Procedures. The polarographs and the dropping mercury electrode (DME) used for the measurement of the DC current-voltage curves and the current-time curves were the same as those described previously.[6,7] The pH of the solution was measured with a glass electrode in combination with a pH meter (Hitachi-Horiba Model F-7). All the experimental procedures used in the kinetic study have been described previously.[8] In this study, all the measurements were conducted in solutions with an ionic strength of 0.30 ($NaClO_4$) at 25 °C. No buffer reagent was used, because the sample solutions always contained a large excess of uncomplexed aminopolycarboxyfate and had a sufficient buffer capacity in the pH range studied ($9.00<pH<10.00$). The reaction rates were determined by observing the change in the dissolution wave due to the uncomplexed DTPA or EDTA-OH under the experimental conditions where all the reactions could be treated as pseudo first-order reactions. The forward apparent rate constant, k_{ap}, was determined from the slope ol the linear relation between log (i_0/i_t) and time, t.[9]

Results and Discussion

Previously,[7] the present author reported that the rate of the reaction of EDTA with the nickel(II)–EDDA complex is reduced appreciably by the addition of Gly; he ascribed this to the formation of a mixed-ligand complex involving the Gly anion. As in the case of the EDTA reaction with the nickel(II)–EDDA complex in the presence of the Glut or Asp anion also gave a k_{ap} value which was independent of the concentrations of the uncomplexed DTPA and EDDA, but proportional to the total concentration of the nickel(II) ion$[Ni(II)]_t$. Furthermore, the Glut and Asp anions reduced the reaction rate and the plot of k_{ap}^{-1} against the uncomplexed Glut or Asp concentration, $[A^{m-}]$, invariably gave a straight line, with an intercept of a finite value (Fig. 1). In view of the conclusion obtained in the EDTA reaction with the nickel(II)–EDDA complex in the presence of the Gly anion, these findings suggest that the Glut and Asp anions also form a 1 : 1 : 1 ratio mixed-ligand complex with the nickel(II)–EDDA complex and that the rapid dissociation of the Glut or Asp anion from the mixed complex precedes the slow reaction of the DTPA anion with the 1 : 1 ratio nickel(II)–EDDA complex. Thus, the k_{ap} at a given pH should be given by the following relation:

$$k_{ap} = k\cdot[Ni(II)]_t/(1+K^{A}_{MxA}\cdot[A^{m-}]) \quad (1)$$

where K^{A}_{MxA} means the equilibrium constant for the formation of a mixed-ligand complex from the nickel-(II)–EDDA complex and the Glut or Asp anion. Therefore, the K^{A}_{MxA} value can be determined from

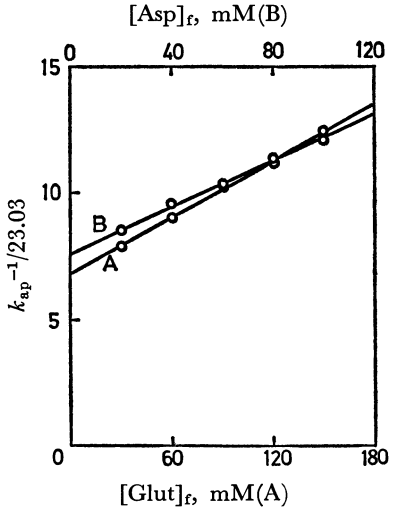

Fig. 1. The plot of the reciprocal of k_{ap} for the reaction of nickel(II)–EDMA complex with DTPA against the concentrationof uncomplexed Gly or Asp.
$\mu=0.30$, 25 °C, pH=9.35, $[DTPA]_l=1.0$ mM
$[EDDA]_f=10.0$ mM, $[Ni(II)]_t=10.0$ mM
A) $[Gly]_f$ ranged from 30 to 150 mM.
B) $[Asp]_f$ ranged from 20 to 100 mM.

the ratio of the slope to the intercept of the linear relation between k_{ap}^{-1} and $[A^{m-}]$. Although no experimental result is shown here, k in Eq. (1) could be determined to be $(k_\alpha+k_\beta\cdot[H^+])/(\alpha_H)_Y$[9] from a systematic investigation of the pH effect on the reaction rate. The K^A_{MXA} values obtained from the slope and intercept of the linear relation in Fig. 1 are listed in Table 1, together with that for the EDDA~Gly system.[7] The reactions of DTPA with the nickel(II)–NTA complex and of EDTA-OH with the HIDA complex in solutions containing the Gly, Glut, or Asp anion also showed kinetic profiles quite similar to that of the DTPA reaction with the nickel(II)-EDDA complex in the presence of Glut or Asp. In these reactions, the reaction rates of the Gly, Glut, and Asp anions were also appreciably reduced, and the plot of k_{ap}^{-1} *versus* the concentration of the Gly, Glut or Asp anion, $[A^{m-}]$ at a given pH invariably gave a straight line with an intercept of a finite value. A typical result obtained for the Asp system is reproduced in Fig. 2. In the light of the coordination natures of the nickel(II) ion and the NTA and HIDA anions, the above fact also suggests the formation of a 1 : 1 : 1 ratio mixed-ligand complex involving the Gly, Glut, or Asp anion, which is in a rapid equilibrium with the 1 : 1-ratio NTA or HIDA complex involved in the rate-determining steps. With the NTA and HIDA anions, the nickel(II) ion forms a 1 : 2 ratio complex. Therefore, the k_{ap} value for the NTA and HIDA systems should be given by $[Ni(II)]_t\cdot k/(1+K_2'\cdot[X]_f+K^A_{MXA}\cdot[A^{m-}])$ in place of Eq. (I). Here, K_2' denotes the conditional second successive formation constant of the nickel(II)–NTA or –HIDA complex, and $[X]_f$, the concentration of uncomplexed NTA or HIDA. Then, the K^A_{MXA} values for the NTA and HIDA systems were determined from the ratio of the slope to the intercept of the linear relation between k_{ap}^{-1} and $[A^{m-}]$, with the aid of the $K^A_{MXA}=(1+K_2'\cdot[X]_f)\times$slope/intercept relation. In the case of the HIDA system, no confirmative evidence which suggests the formation of a mixed-ligand complex involving the Gly anion could be obtained under the present experimental conditions. The K^A_{MXA} values obtained for the NTA and HIDA systems are also listed in Table 1. In all the systems studied in this paper, the K^A_{MXA} values determined at various solution pH's showed a satisfactory agreement with each other.

Table 1. The K^A_{MXA} values (μ=0.30, 25 °C)

System	log K^A_{MXA}	System	log K^A_{MXA}
EDDA-NH_3	1.62[11]	NTA-Gly	3.68
EDDA-Gly	1.12[8]	NTA-Glut	3.57
EDDA-Glut	1.32	NTA-Asp	3.92
EDDA-Asp	1.30	HIDA-Glut	4.84
		HIDA-Asp	4.86

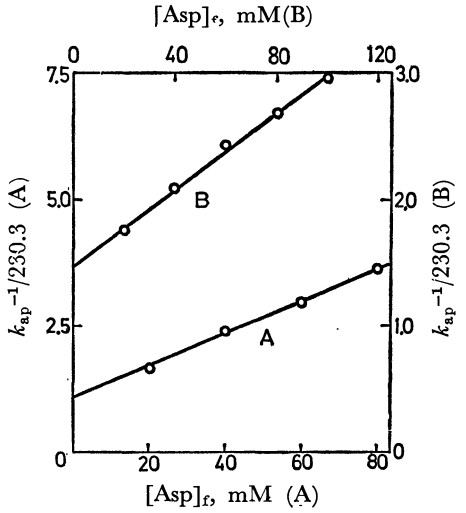

Fig. 2. The effect of aspartate on the rates of the reactions of the nickel(II)-NTA complex with DTPA and of the nickel-HIDA complex with EDTA-OH. μ=0.30, 25 °C, $[Asp]_f$ ranged from 20 to 100 mM
A) NTA system pH=9.73, $[NTA]_f$=20.0 mM $[Ni(II)]_t$=10.0 mM, $[DTPA]_l$=1.0 mM.
B) HIDA system pH=9.58, $[HIDA]_f$=28.0 mM $[Ni(II)]_t$=6.0 mM, $[EDTA\text{-}OH]_l$=0.6 mM.

Ho *et al.*[10] reported in their NMR study of mixed 1 : 1 : 1 EDDA complexes of the nickel(II) ion with the Glut and Asp anions that the mixed-ligand complex has the trans-form, and that the Glut and Asp anions in the complex are bonded to the nickel(II) ion through the glycinate chelate ring. The finding that the K^A_{MXA} value for the Gly~EDDA system is nearly identical with those for the Glut~ and Asp~ EDDA systems may support their conclusion. As is shown by the data in Table 1, the K^A_{MXA} values for the Gly, Glut, and Asp systems are slightly smaller than that for the 1 : 1 : 1 mixed complex of ammonia.[11] This is probably ascribable to the unfavourable entropy change due to the formation of the charged mixed complex from the neutral parent complex. The mixed 1 : 1 : 1-ratio NTA and HIDA complexes with the Gly, Glut, and Asp anions also have almost the same K^A_{MXA} values. This may also indicate that all three aminoacid anions in the mixed-ligand complex coordinate to the nickel(II) ion through a Gly chelate ring.

The Solubilities and the Solubility Parameter of Heptasulfur Imide

Shuichi HAMADA, Yoshiyuki KUDO, and Masako KAWANO

Department of Chemistry, Faculty of Science, Science University of Tokyo, Kagurazaka, Shinjuku-ku, Tokyo 162

(Received March 31, 1975)

Synopsis. The solubilities of heptasulfur imide in eleven organic solvents were measured. The solubility parameter of heptasulfur imide was estimated to be 12.$_7$ at 25 °C from the solubilities and the activity deduded from the enthalpy of the fusion; we assumed the solutions to be regular.

The structure of heptasulfur imide, S_7NH, closely resembles that of cycloocta-sulfur; one of the sulfur atoms in it is, however, replaced by an NH group.[1] Only a few solubilities of heptasulfur imide have been reported—for example, those for carbon disulfide[2] and carbon tetrachloride.[3] In this work, the solubilities and the solubility parameter of this compound will be estimated.

Experimental

Materials. The heptasulfur imide was prepared by the method described by Heal;[4] the disulfur dichloride was reacted with an ammonia at −10 °C by passing the ammonia into its dimethylformamide sulution. A crude product wa; extracted with an ethyl ether, and then the heptasulfur imide was isolated chromatographically from the by-products by using a silica-gel column. The pure heptasulfur imide was obtained as pale yellow crystals by recrystallization from a benzene solution. Eleven organic solvents were used to estimate the solubilities, as Table 1 shows. All the solvents were purified in the usual ways.

Procedure. Suitable amounts of the heptasulfur imide and an organic solvent were put into a three-necked flask and were then stirred continuously for 2 hr at the temperature range from 20 to 40 °C (from 10 to 30 °C for the *n*-pentane), with a precision of ±0.03 °C. An aliquot of the solution was withdrawn through a fine Teflon tube with a glass filter by applying excessive pressure in the flask. The concentration of the solution was estimated from its optical absorbances at the range from 320 to 365 nm, after the solution has been diluted to a suitable concentration. The molalities of the solutions were estimated by using the working curves for the respective solvents previously determined by means of a double-beam spectrophotometer, model UV-200, from Shimadzu Seisakusho. The solubility was estimated repeatedly (at least three times) under the same conditions; its deviation from the average value was less than ±1.5%. The partial molar volume of the heptasulfur imide was estimated from the benzene solutions at 25 °C with a precision of ±0.01 °C by using a modified Lipkin-Davison-type pycnometer. The molar enthalpy of the fusion of the heptasulfur imide was estimated with a differential scanning calorimeter, model DSC-1B, from Perkin-Elmer. The enthalpy of the fusion was calibrated by using that of a metallic indium (0.781 kcal/mol at 156 °C).

Results and Discussion

The heptasulfur imide was isolated chromatographically three times because it could not be completely separated from the by-products by only one run. The X-ray powder diffractogram[1] and the IR spectrum[5] of the sample showed patterns attributable to heptasulfur imide only. The melting point of the sample was determined microscopically to be 113.5 °C; this value agreed with that of the purified heptasulfur imide.[6]

The solubilities, X_2 (mole fraction), at 25 °C of the heptasulfur imide in various solvents are shown in Table 1. The logarithms of the mole fractions in the saturated solutions for the respective solvents showed good linearities against the reciprocals of the absolute temperatures except for those in the acetone solution. The enthalpies of solution, ΔH^d, were estimated from the linear relationship between $\log X_2$ and $1/T$ with an accuracy of ±0.1 kcal/mol, as Table 1 shows. The solubility of the heptasulfur imide decreased abruptly with an increase in the enthalpy of solution except for that in the methanol. Though the solubilities for the acetone at 20 and 30 °C were estimated to be 1.3×10^{-2} and 1.8×10^{-2} respectively, the sulfur was detected as a decomposition product in the solution at 40 °C by means of thin-layer chromatography.

TABLE 1. SOLUBILITIES, ENTHALPIES OF SOLUTION, AND SOLUBILITY PARAMETERS OF HEPTASULFUR IMIDE AT 25 °C

Solvent	X_2 ($\times10^3$)	ΔH^d kcal/mol	δ_1[a]	δ_2
Methanol	4.1	5.7		
n-Pentane	0.45	7.7	7.1	12.$_4$
n-Hexane	0.67	7.9	7.3	12.$_4$
n-Heptane	0.81	7.8	7.5	12.$_5$
Cyclohexane	2.0	7.3	8.2	12.$_8$
Cyclooctane	4.3	7.3	8.55	12.$_7$
Benzene	14	6.4	9.15	12.$_7$
Toluene	18	5.9	8.9	12.$_3$
Chlorobenzene	14	6.3	9.5	13.$_0$
Chloroform	9.6	6.4	9.3	13.$_0$
Carbon tetrachloride	3.8	7.3	8.6	12.$_9$

a) The solubility parameters of the solvents, δ_1, were those at 25 °C.[7]

Therefore, the data are not presented in Table 1. The absorption peaks in the UV spectra of the heptasulfur imide were observed at approximately 270 and 225 nm in all the solvents except for those with strong absorption bands near 270 and 225 nm. The UV spectra of the heptasulfur imide in all the solvents did not change over a period of three days, while the color of the acetone solution at 40 °C turned light yellow.

If it is assumed that these solutions are regular solutions,[7] the following equation can be obtained:[8]

$$RT\ln a_2 = RT\ln X_2 + V_2\phi_1^2(\delta_1-\delta_2)^2 \quad (1)$$

where a_2 is the activity of the solute based on its supercooled liquid state at a given temperature; V_2, the molar volume of the solute in the liquid state; ϕ_1, the volume fraction of the solvent; δ_1 and δ_2, the solubility parameters of the solvent and the solute, and R, the gas constant. The activity of the solute can be calculated by means of the following equation:[7]

$$\ln a_2 = -\frac{\Delta H^f}{R}\left(\frac{T_f - T}{T_f T}\right) \quad (2)$$

where ΔH^f is the molar enthalpy of the fusion, and T_f, the melting point of the solute.

The molar enthalpy of the fusion of the heptasulfur imide was estimated to be 4.5 kcal/mol at its melting point by using the differential scanning calorimeter. The activity of the heptasulfur imide was calculated to be approximately 1.8×10^{-1} at 25 °C. The molar volume, V_2, of the heptasulfur imide in the supercooled liquid state was deduced from the partial molar volume (127 cm^3/mol), which was itself estimated from the benzene solutions at 25 °C.

By using the values of a_2, X_2, V_2, ϕ_1, and δ_1,[7] the solubility parameter, δ_2, of the heptasulfur imide at 25 °C was calculated from Eq. (1); the results are shown in Table 1.

The solubility parameter of the heptasulfur imide at 25 °C was estimated to be $12._7$ as an average value. This value agreed with that of cyclooctasulfur (12.7).[9]

Kinetic Studies of the Electron Transfer Reaction in Iron(II) and Iron(III) Systems. VII. The Electron Transfer Reaction in Solid Dimethyl Sulfoxide[1]

Goro WADA and Mikiko TABIRA

Department of Chemistry, Nara Women's University, Nara 630

(Received March 31, 1975)

Synopsis. The electron transfer reaction between Fe(II) and Fe(III) in dimethyl sulfoxide (DMSO) was investigated in the solid phase, and compared with the case in the liquid. In the temperature range between the freezing point (T_M) and the eutectic point (T_E), the reaction actually proceeds in the liquid phase where the reactants are concentrated due to the partial separation of pure DMSO solid, while below T_E the reaction occurs in the solid phase at considerable reaction rates, with a lower activation energy, 4 kcal/mol, than that in the liquid. This indicates a different probable mechanism in solid DMSO.

It has been proved that the electron transfer reaction between iron(II) and iron(III), Fe(II)+*Fe(III)=Fe(III)+*Fe(II), in aqueous media in the absence of catalytic ligand proceeds *via* a hydrogen atom transfer mechanism through a Grotthuss type conduction along the extended chains of the hydrogen bonds between the oriented solvent molecules.[2-4] As one proof of this mechanism, the occurrence of the reaction in solids of protic solvents was observed in the cases of ice[5-7] and of very concentrated perchloric acid,[8] although the reactants are frozen with no freedom of translational mass transfer in the solids of such media.

Dimethyl sulfoxide (DMSO) is typical of the aprotic solvents for which the hydrogen atom transfer mechanism is difficult. In fact, the reaction was shown to proceed not *via* the hydrogen atom transfer but rather *via* an inner-sphere mechanism in liquid DMSO.[9-11] Consequently, it seems to be of interest to test whether the reaction can proceed in solid DMSO or not.

Experimental

The procedure of determination of the rate constant was similar to that already described,[9-11] except for several points indicated below. Soon after the initiation of the reaction by mixing the two solutions of iron(II) and ^{59}Fe-labeled iron(III), equal amounts of the reaction solution were quickly delivered into eight glass tubes of the same shape and size in a thermostat at 20 °C, followed by simultaneous cooling to −78 °C. The solutions were solidified within several seconds at this temperature. Then the tubes were set in a bath at a fixed reaction temperature. The reaction temperatures adopted were −28, −48, −68, and −78 °C, which were attained by freezing mixtures of dry-ice with carbon tetrachloride, chloroform, or ethanol, according to the temperature adopted. At appropriate time intervals, one of the tubes was taken out of the bath and the quenching solution was quickly added. It took only about twenty seconds to complete dissolving the solid and quenching the reaction by using a vibrator. The concentration of perchloric acid was always 0.005 M.

For the sake of simplicity, the phase diagram of the binary system $Fe(ClO_4)_3$+DMSO was studied in the very low concentration range of $Fe(ClO_4)_3$.

Results and Discussion

As have been seen in the liquid system, McKay's plots of $\log(x_e-x)$ against time in the solid phase were also linear: here x and x_e stand for the specific radioactivities of iron(II) at reaction time t and at infinite time, respectively.[12] Thus, the rate constant k of the electron transfer reaction can be obtained from the half period of the reaction $t_{1/2}$.

$$k = \frac{0.693}{([Fe(II)]+[Fe(III)])t_{1/2}} \quad (1)$$

The Arrhenius plot of log k against reciprocal temperature is drawn in Fig. 1. The activation energy in the liquid phase is E_{liq}=9.2 kcal/mol, which is in agreement with the values in the literature.[9,11] On the other hand, the activation energy obtained from the temperature range of the solid state appears to be approximately E_{solid}=4 kcal/mol, which is much smaller than E_{liq}.

The phase diagram of the $Fe(ClO_4)_3$–DMSO binary system in the low concentration range of $Fe(ClO_4)_3$ is shown in Fig. 2. When a liquid DMSO solution of $Fe(ClO_4)_3$ at low concentration is continuously cooled, it reaches its freezing point, T_M, below which an equilibrium between pure solid DMSO and concentrated liquid solution is established. As the cooling goes on, the liquid phase becomes more concentrated with $Fe(ClO_4)_3$ due to the progressive separation of solid DMSO, until the system arrives at the eutectic temperature, T_E, approximately −45±3 °C, where the concentrated solution itself freezes as a solid solution.

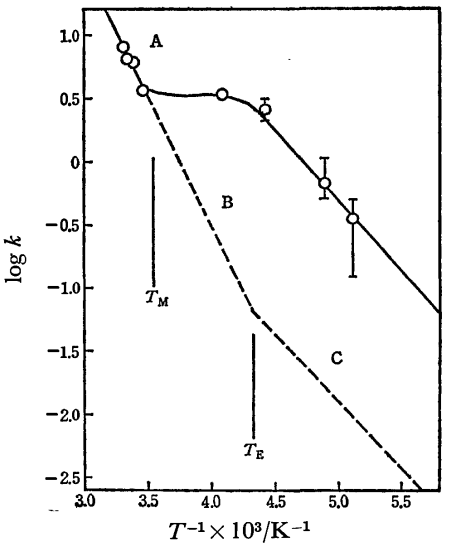

Fig. 1. Arrhenius plot for liquid and solid phase reaction,

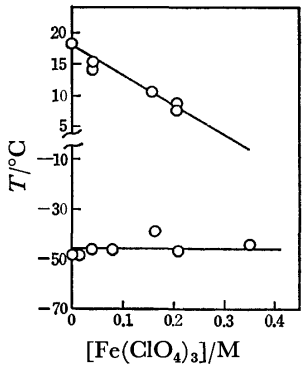

Fig. 2. Phase diagram of $Fe(ClO_4)_3$-DMSO binary system.

In the present reaction system, the phase diagram must be more complicated than this, but the fundamental tendency appearing in this simple system would be similarly valid: the concentration phenomenon of the dissolved species in the liquid phase and the eutectic freezing of the concentrated liquid would also occur.

At temperatures between T_M and T_E, the reaction system is a heterogeneous mixture of liquid solution and solid DMSO, and the reaction takes place only in the liquid phase, where the reactants are concentrated according to the reaction temperature. This results in an apparent increase in k, because the true [Fe(II)] and [Fe(III)] in the concentrated liquid phase must be larger than those used in Eq. (1). When the apparent and the true rate constants are denoted by k and k_0 respectively, k is apparently enlarged by a factor of p.

$$k = p\,k_0 \qquad (2)$$

The lower the temperature, the larger the p value. In Fig. 1, the straight line above T_M (A) is extrapolated into the T_M-T_E range, where the liquid phase reaction still continues to occur with an unchanged activation energy E_{liq}. Consequently, this extended straight line (B) gives the corrected true rate constant k_0 at the respective temperatures.

At temperatures below T_E, the reaction occurs truely in the solid phase, where p no longer varies with temperature but is a constant. Thus, another straight line (C) can be drawn in parallel with the observed one with an equal slope corresponding to E_{solid}, as is done by the broken line in Fig. 1. From the vertical shift of the straight line C from the apparent one, the p value below T_E could be roughly estimated as p=40.

Since the glass tubes containing the reaction solution were cooled far below the eutectic point as quickly as possible, the geometric sizes of the crystalline particles of both pure DMSO and solid solution might be very small, and it is likely that there remains some local heterogeneity of concentration of the reactants and that heterogeneous catalysis on the mosaic interfaces between the solid particles may affect the reaction rate. However, if the probabilities of these heterogeneous effects are small and the reaction is simply supposed to occur homogeneously in the solid phase, the averaged distance between iron(II) and iron(III) is calculated to be about 50 Å in our present case. Since in the solid phase the medium is too viscous for the reactants to diffuse so that the electron transfer reaction may proceed not through the migration of the reactants carrying electrons but through the tunnelling of electrons for long distances over several medium molecules. The extension of wave functions of the electrons is suitable for such a transfer.[13] In such a case, the low activation energy observed as E_{solid} to be 4 kcal/mol would seem to be reasonable.

In the case of aqueous media, the reaction mechanism is the same indifferent to whether in the liquid or in ice: *via* the hydrogen atom transfer along the bridges of the hydrogen bonds between water molecules. Therefore, the activation energy is also the same for both phases.[5,6] On the other hand, in the case of DMSO, the reaction mechanism must differ in going from liquid to solid, with a consequent variation in the activation energies.

According to our present study, the true rate constant of the reaction in solid DMSO at −78 °C is approximately of the order of $10^{-2}\,M^{-1}\,s^{-1}$, which roughly coincides with $7\times10^{-3}\,M^{-1}\,s^{-1}$ in a liquid mixed solvent of water : DMSO=3 : 2,[14] although the reaction mechanisms might be completely different from each other. At any rate, looking at the cases of aqueous, aqueous-DMSO, and pure DMSO media together, one problem yet remains unsolved: whether electrons can be transferred not only *via* the hydrogen atom transfer mechanism but also *via* an alternative mechanism, probably *via* electron tunneling over a considerably long distance.

The Responses of the Monovalent Cation-sensitive Glass Electrode to the Cationic Activities in Different Solvents

Toshio NAKAMURA

Chemistry Department, Faculty of Science, Shinshu University, Asahi, Matsumoto 390

(Received April 9, 1975)

Synopsis. The responses of the glass electrode to the cationic activities in different solvents have been studied for several monovalent cations in several dipolar aprotic and protic solvents by comparing the potentials of the amalgam electrode with those of the glass electrode.

The Nernstian responeses of cationic glass electrodes to cations in partially aquated solvents[1,2] and in non-aqueous systems[1,3,4] have been well established. Cations are known to have quite different activities according to the solvent in which they are dissolved, and there have been some investigations in methanol[1] and hydro-organic madia[5] which confirm that the cationic glass electrodes can also respond to such a solvent effect on the cationic activities. In the present report, the potentials of the monovalent cation-sensitive glass electrode immersed in solutions of various monovalent cations were compared, in a variety of solvents, with the potentials of the corresponding amalgam or metal electrodes. To carry this out, the emf's of the following two cells were measured:

$$\text{Glass electrode} \mid \underset{(A)}{10^{-2}\,\text{M}\ \text{Et}_4\text{NClO}_4,\ x\text{M}\ \text{M}^+\text{ClO}_4^-\ (\text{D})} \parallel_{J_1} \underset{(B)}{0.1\,\text{M}\ \text{Et}_4\text{NClO}_4\ (\text{AN})} \parallel \underset{(C)}{5\times10^{-3}\,\text{M}\ \text{AgNO}_3\ (\text{AN})} \mid \text{Ag}$$

Cell I

$$\text{M(Hg)}^* \mid \underset{(A)}{10^{-2}\,\text{M}\ \text{Et}_4\text{NClO}_4,\ x\text{M}\ \text{M}^+\text{ClO}_4^-\ (\text{D})} \parallel_{J_2} \underset{(B)}{0.1\,\text{M}\ \text{Et}_4\text{NClO}_4\ (\text{AN})} \parallel \underset{(C)}{5\times10^{-3}\,\text{M}\ \text{AgNO}_3\ (\text{AN})} \mid \text{Ag}$$

Cell II

(* Ag wire for $M^+=Ag^+$)

In these cells, D shows such solvents as 1,2-dichloroethane (DCE), acetonitrile (AN), propylene carbonate (PC), methanol, water, dimethylformamide (DMF), and dimethyl sulfoxide (DMSO), and M^+, such monovalent cations as lithium, sodium, potassium, cesium, thallium, and silver ions. The concentrations of $M^+ClO^-_4$ in the compartments (A) are shown in Table 1. It should be noted that the salt bridge (B) and the reference electrode (C) in Cells I and II are always the same as each other.

TABLE 1.

	Concentration of metal in amalgam (M)	Concentration of the ion[a] in Cells I and II[b]; x values
Lithium	6.58×10^{-2}	1.00×10^{-3}
Sodium	3.02×10^{-2}	1.00×10^{-3}
Potassium	2.25×10^{-2}	5.000×10^{-4}
Cesium	1.03×10^{-2}	5.000×10^{-4}
Thallium	1.84×10^{-2}	5.00×10^{-4}
Silver	Wire	1.00×10^{-4}

a) When the solvent was DCE, saturated solution of each ion was used, and methanol solution of the cesium ion was also saturated solution. b) See text.

Experimental

Apparatus. The glass electrode was a Beckman 39047. The constructions of the cell and the amalgam electrodes have been described previously.[6,7] The reference electrode was a silver wire immersed in 5×10^{-3} M silver nitrate in AN. The salt bridge consisted of 0.1 M tetraethylammonium perchlorate in AN instead of the 0.1 M tetraethylammonium picrate in AN used in the previous report.[6,7] Except when the D solvent was water, the junction potentials of J_1 and J_2 changed by only several millivolts upon the change in the salt bridge electrolyte.[8] When the D solvent was water, the change in the junction potential was somewhat larger. The test solution in Cell II were deoxygenated by bubbling in nitrogen gas. The metal contents in the amalgams were determined titrimetrically: the amalgams were decomposed in an excess of a 0.1 M perchloric acid solution, and then the excess acid was titrated with a standard sodium carbonate solution. For the emf measurements, a Hitachi-Horiba pH meter, model F-7ss (for Cell I), and a voltmeter equipped with a voltage follower with an input impedance of $10^{11}\Omega$ (for Cell II) were used.

Reagents. The potassium perchlorate of an analytical-reagent-grade substance was recrystallized. The cesium perchlorate was prepared from cesium carbonate and perchloric acid. These perchlorates were dried at 150 °C under a vacuum. The thallium perchlorate was prepared by passing an aqueous solution of thallium formate through a column of Amberlite IRA 411 exchange resin in the OH^- form and by then neutralizing it with perchloric acid. It was dried at 70 °C under a vacuum. The silver perchlorate and silver nitrate were of an analytical-reagent-grade substance and were used after drying. The lithium perchlorate, sodium perchlorate, and tetraethylammonium perchlorate were the same as those in previous papers.[6,7] The 1,2-dichloroethane was purified by the method of Coetzee and Lok.[9] The acetonitrile, dimethylformamide, dimethyl sulfoxide, propylene carbonate, and methanol were purified by conventional methods.

Results and Discussion

The relations between the potentials of the glass electrode and those of the metal amalgam or silver wire electrodes in various solvents are shown in Fig. 1. Except for the case of the silver ion, the values of the potentials were referred to those in AN. In deaerated solutions, the potentials of the amalgam electrodes soon reached their equilibrium values and were stable

enough during the period of the measurements. When oxygen was introduced, however, the potential changed, especially when the measurements were carried out in methanol. Generally, the response of the glass electrode was slower than that of the amalgam electrodes. To reach the equilibrium potentials, it usually took about fifteen to twenty minutes. For various cations in water and for the silver ion in AN, the stabilizations of the glass electrode potentials needed a longer time, however. In Fig. 1, the potentials of the glass electrode for the cesium, and the thallium ions in water and the sodium ion in 1,2-dichloroethane deviate somewhat from the values of the amalgam electrodes. The potential change for the silver ion in 1,2-dichloroethane, propylene carbonate, and particularly in AN also deviates from the change in the potential of the silver wire electrode. Except for these exceptional cases, though, the correspondences of the potential changes of the glass electrode with those of the amalgam or silver wire electrodes are good enough for the cations investigated in this work.

In conclusion, if we consider that the amalgam or silver wire electrodes always make Nernstian responses to the solvent effects on the activities of monovalent cations, the glass electrode can also be considered in many cases to respond in the same ways. However, it should be remembered that there exist exceptional cases in which the Nernstian response cannot be obtained.

The author wishes to express his hearty thanks to Professor Kosuke Izutsu of this department for his kind suggestions and discussions.

This work was supported in part by a Grant-in-aid for Scientific Research from the Ministry of Education.

A Study of Optically Active (Benzoin-α-oxime)dichlorocopper(II)

Tomikatsu KUDO, Sumio KAIZAKI, Jinsai HIDAKA,* and Yoichi SHIMURA

Department of Chemistry, Faculty of Science, Osaka University, Toyonaka, Osaka 560

(Received April 24. 1975)

Synopsis. An optically active complex, [(*S*)-benzoin-α-oxime]dichlorocopper(II), was prepared and its absorption and circular dichroism spectra were investigated in organic solvents.

(Benzoin-α-oxime)dichlorocopper(II), $[CuCl_2(cuprH_2)]$,[1] was prepared by Jennings *et al.*[2] and studied magnetochemically by Rindorf,[3] who established its monomeric nature from the effective magnetic moment of 1.91 μ_B in contrast to the polymeric subnormal 1 : 1 complex $\{Cu(cupr)\}_x$ (0.80 μ_B at 294 K). In the present paper, the dichloro complex with optically active (*S*)-benzoin-α-oxime is reported.

Experimental

Preparation. $(+)_{589}$-(S)-*Benzoin-α-oxime*: Hydrogen phthalate of benzoin was obtained from the reaction of racemic benzoin and phthalic anhydride in trimethylamine, and resolved with $(+)_{589}$-quinidine by a modified method of Kenyon *et al.*;[4] the powdered solid of phthalic anhydride was used instead of its suspension in pyridine. $(+)_{589}$-(*S*)-Benzoin was obtained by the hydrolysis of hydrogen phthalate. $[\alpha]_{589}=+119.2°$ (*c*, 0.0105, in acetone). (lit,[4] $[\alpha]_{589}=+118.4°$). $(+)_{589}$-(*S*)-Benzoin-α-oxime was prepared by the oximation of $(+)_{589}$-(*S*)-benzoin. mp 163—164 °C. $[\alpha]_{589}=+3.0°$ (*c*, 0.0472, in chloroform). Found: C, 74.02; H, 5.71; N, 6.14%. Calcd for $C_{14}H_{13}NO_2$: C, 73.99; H, 5.76; N, 6.16%.

(Benzoin-α-oxime)dichlorocopper(II): This was prepared by a new method as follows. To 30 ml of 2,2′-dimethoxypropane was added 2.7 g (0.0158 mol) of $CuCl_2\cdot 2H_2O$ with stirring. The yellow mixture obtained was kept at room temperature, stirring for 30 min. When 3.6 g (0.0159 mol) of $cuprH_2$ was added to it, the mixture turned immediately to a green solution. A pale-green fine precipitate deposited after standing at room temperature for about 10 min. The product was filtered off, washed with methanol, and then air-dried. Found: C, 45.53; H, 4.72; N, 3.60%. Calcd for $[CuCl_2(cuprH_2)]\cdot CH_3OH=C_{15}H_{17}NO_3Cl_2Cu$: C, 45.76; H, 4.35; N, 3.57%. The complex which was recrystallized from methanol, ethanol, acetone, or acetonitrile had one molecule of the solvent. The solvent of crystallization was removed by air-drying for several days. Found: C, 45.98; H, 3.71; N, 3.87%. Calcd for $[CuCl_2(cuprH_2)]=C_{14}H_{13}NO_2Cl_2Cu$: C, 46.49; H, 3.62; N, 3.87%.

[(+)$_{589}$-(S)-Benzoin-α-oxime]dichlorocopper(II): To 20 ml of 2,2′-dimethoxypropane was added 2.1 g (0.0123 mol) of $CuCl_2\cdot 2H_2O$ with stirring. After 30 min, 2.8 g (0.0123 mol) of (*S*)-$cuprH_2$ was added to this mixture; the mixture immediately turned into a green solution. In this case, however, the desired complex did not appear because of its high solubility. To the solution was added 20 ml of methanol and the resulted solution was concentrated to half of its original volume in a vacuum rotary evaporator at about 30 °C. After 80 ml of ether was added to it, the solution was kept in a refrigerator for a week. Bright emerald-green needle crystals were obtained. The complex had one molecule of methanol as solvent of crystallization, but lost it easily. Found: C, 45.46; H, 4.29; N, 3.47%. Calcd for $[CuCl_2\{(S)\text{-}cuprH_2\}]\cdot CH_3OH=C_{15}H_{17}NO_3Cl_2Cu$: C, 45.76; H, 4.35; N, 3.56%. Found: C, 46.07; H, 3.71; N, 3.79%. Calcd for $[CuCl_2\{(S)\text{-}cuprH_2\}]=C_{14}H_{13}NO_2Cl_2Cu$: C, 46.49; H, 3.62; N, 3.87%.

Tetraethylammonium trichlorocuprate(II): An aqueous solution containing $CuCl_2\cdot 2H_2O$ and $[N(C_2H_5)_4]Cl$ (1 : 1) was concentrated by evaporation to dryness. The brick red crystals obtained were recrystallized from acetone. Found: C, 31.07; H, 6.51; N, 4.41%. Calcd for $[N(C_2H_5)_4]CuCl_3=C_8H_{20}NCl_3Cu$: C, 32.01; H, 6.71; N, 4.67%.

Measurement. Visible and ultraviolet absorption spectra were measured with a Shimadzu spectrophotometer QR-50 or UV-200. Diffuse reflectance spectra were obtained by a Hitachi spectrophotometer EPU-2. CD spectra were recorded on a JASCO MOE-1 spectropolarimeter, and optical rotation were checked by a JASCO ORD/UV-5 spectropolarimeter.

Results and Discussion

The absorption and CD data of $[CuCl_2\{(S)\text{-}cuprH_2\}]$ in various organic solvents are shown in Figs. 1 and 2. The spectral behavior in the visible region depends remarkably upon the kind of solvents, which can be classified into three groups, [A], [B], and [C].

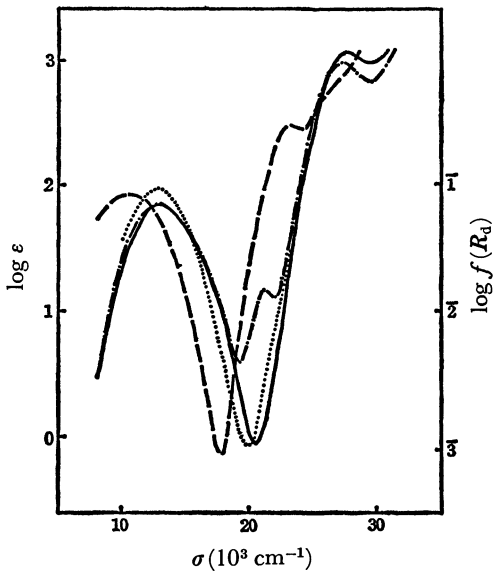

Fig. 1. Absorption curves of $[CuCl_2(cuprH_2)]$ in organic solvents (10^{-2} M): - - - Dimethylformamide ([A] group), —— Chloroform ([B] group), —·— Acetone ([C] group), and ····· Diffuse reflectance spectra (the right ordinate).

* Present address: Department of Chemistry, The University of Tsukuba, Ibaraki, 300—31.

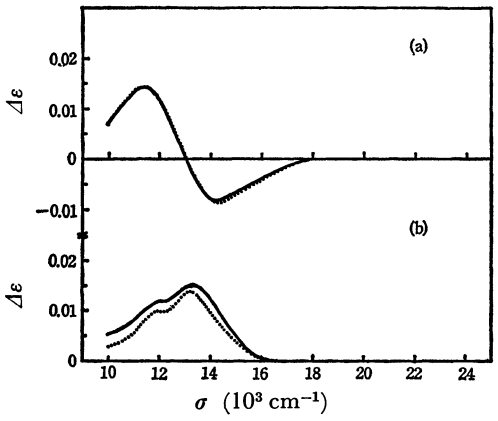

Fig. 2. CD curves of $[CuCl_2\{(S)\text{-}cuprH_2\}]$ in organic solvents; (a) Chloroform ([B] group), (b) Acetone ([C] group), (—— 10^{-2} M, ·····10^{-3} M solution).

The d-d absorption band in [A] group solvents differs markedly from those in [B] or [C] solvents (Fig. 1), and no CD band appears in the visible region. It seems that the [A] group solvents, dimethyl sulfoxide, dimethylformamide, and pyridine, coordinate strongly to copper(II) ion; accordingly, the coordinated (*S*)-$cuprH_2$ may be substituted by the solvent employed.

In the [B] group solvents, chloroform, dichloromethane, methanol, and ethanol, the complex shows a broad but relatively strong ligand field absorption band at about 13000 cm^{-1}, which obeyed Beer's law in the range 10^{-2}—10^{-4} M. The absorption spectra in [B] group solvents resemble closely the powder diffuse reflectance spectrum of the complex (Fig. 1). In the d-d absorption band region, two CD components, (+) and (−) from the lower frequency side, were observed and the net CD sign was positive.

In the [C] group solvents, acetone, acetonitrile, acetophenone, ethyl acetate, and tetrahydrofuran, a sharp absorption band appeared at about 21000 cm^{-1} in addition to the d-d band at about 13000 cm^{-1}. The intensity of the former band depends markedly upon the concentration of the solution (Fig. 3). Two positive CD bands were obtained in the d-d absorption band region, but the CD intensity also depends upon the concentration of the solution (Fig. 2). No CD band appeared in the 21000 cm^{-1} band region. The 21000 cm^{-1} absorption band was intensified by the addition of $[N(C_2H_5)_4]Cl$ to the solution. An intense d-p_π charge transfer band was observed at 21000 cm^{-1} for $[N(C_2H_5)_4]CuCl_3$ dissolved in acetone: the absorption bands appear at 8600 cm^{-1} ($\log \varepsilon_{max}=0.89$), 11000 (1.93), and 21000 (3.18). Manahan and Iwamoto[5] reported a stability constant study of the Cu^{2+}–Cl^- system in organic solvents and showed that the main species is $CuCl_3^-$. Indeed, the intensity of the 21000 cm^{-1} band of $[N(C_2H_5)_4]CuCl_3$ decreases with addition of $[N(C_2H_5)_4]Cl$ and a new band appears at 24300 cm^{-1}. The band at about 24000 cm^{-1} has been attributed to a charge transfer transition of the $CuCl_4^{2-}$ species.[6,7] In conclusion, the 21000 cm^{-1} band is ascribed to the charge transfer band of a small amount of the $CuCl_3^-$ species which is the dissociation product of $[CuCl_2(cuprH_2)]$ in the [C] group solvents.

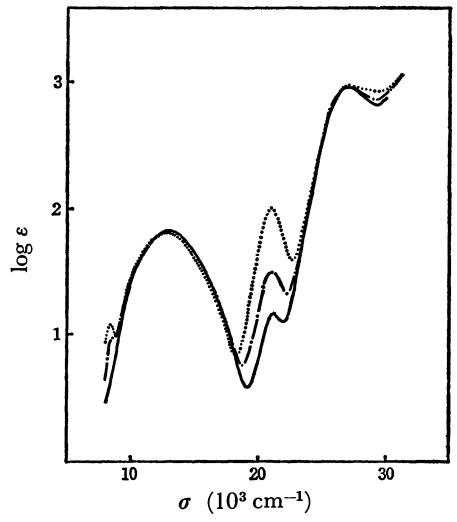

Fig. 3. Absorption curves of $[CuCl_2(cuprH_2)]$ in Acetone; —— 10^{-2} M, —·— 10^{-3} M, ····· 10^{-4} M.

The CD intensities of $[CuCl_2\{(S)\text{-}cuprH_2\}]$ in Fig. 2 are comparable to those of the (*S*)-α-amino acidato copper(II) complexes and the net CD sign is positive both in the [B] and [C] group solvents. It has been well established that the copper(II) complexes of ordinary (*S*)-α-amino acids,[8,9] their amides,[10] and simple peptides[11] have a net negative CD sign in the d-d absorption band region, and this negative Cotton effect has been explained from a true vicinal contribution[9] of the (*S*) asymmetric carbon atom, from a conformational contribution[12] of the δ chiral chelate ring, or from a regional contribution[11] of the large substituent on the (*S*) asymmetric carbon atom. A molecular model examination of the interaction between the two phenyl groups in the present ligand (*S*)-benzoin-α-oxime shows that the ligand prefers axial disposition of the phenyl group attached to the asymmetric carbon atom, producing a λ chiral chelate ring. Thus, it is concluded that the net positive CD of the present copper(II) complex is due to the regional contribution of the axial phenyl group and/or the conformational contribution of the λ chelate ring.

Kinetics and Mechanism of the Reaction of Copper(II) with Hydroxylamine in the Presence of Bathocuproine Disulfonate

Taira IMAMURA and Masatoshi FUJIMOTO

Department of Chemistry, Faculty of Science, Hokkaido University, Sapporo 060

(Received May 6, 1975)

Synopsis. The stoichiometry and the mechanism of the electron-transfer reaction of Cu(II) with hydroxylamine are investigated by measuring a fast complex formation of Cu(II) with bathocuproine disulfonate. The data are evaluated for the rate-determining step involving a radical species.

Hydroxylamine acts as a reducing agent on various metal ions,[1] the stoichiometry of the reaction being dependent on the metal species and on the acid concentration of the medium.[2]

Bathocuproine disulfonate (4,7-diphenyl-2,9-dimethyl-1,10-phenanthroline disulfonate; abbr. BCDS) was used as a specific chelating agent for copper(I) forming a very stable complex of intense color.[3] The corresponding complex of the bivalent copper has not been reported owing to its low stability due to the steric hindrance of the ortho-methyl groups of the ligands in the square planar complex.

We report here the stoichiometry and the kinetics of the reaction between copper(II) and hydroxylamine. The copper(I) formed in the reaction was measured by stopped-flow method as a colored 1 : 2 complex of BCDS. The very fast complex formation of univalent copper ion was found to be useful as an indication of the slow redox reaction.

Experimental

Reagents. Reagent grade chemicals were used. The stock solution of copper(II) sulfate (Koso) was titrated with EDTA. Hydroxylammonium sulfate (Wako) was dissolved in distilled water free from oxygen, and stored in a refrigerator under nitrogen atmosphere. The concentration of the stock solution was determined with potassium permanganate. Disodium bathocuproine disulfonate (Dojindo) was dissolved in water to prepare a 1.00×10^{-3} M stock solution.[4] The ionic strength was adjusted at 0.15 with potassium sulfate (Koso).

Stoichiometry. The composition of the complex species was confirmed using the absorption peak of the copper(I)-BCDS complex at 483 nm ($\varepsilon_{max}=1.27\times10^4$). The stoichiometry of the reaction of copper(II) with hydroxylamine was also determined spectrophotometrically at 483 nm.

Kinetics. The reaction of copper(II) with hydroxylamine was followed spectrophotometrically at 483 nm using a Yanagimoto SPS-1 stopped-flow apparatus. Reservoirs of the reagent solutions were kept under nitrogen atmosphere to avoid air oxidation. Kinetics was studied in the acid region under the condition $[NH_2OH]_0 \gg [BCDS]_0 > [Cu(II)]_0$, $\mu=0.15$ (K_2SO_4), and at 25.0±0.2 °C.

Results and Discussion

Stoichiometry. The parent compound bathocuproine (4,7-diphenyl-2,9-dimethyl-1,10-phenanthroline) has been known to form a 1 : 2 complex with copper(I). We confirmed by the mole ratio method that the BCDS also forms a 1 : 2 complex with copper(I) as shown in Fig. 1.

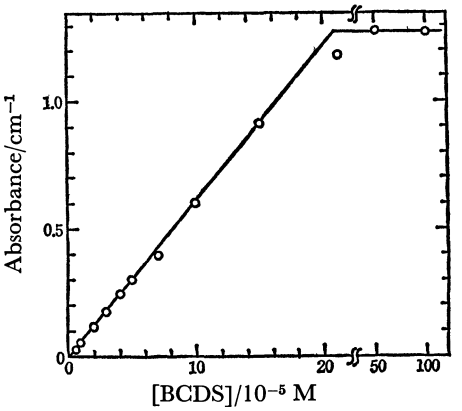

Fig. 1. Mole ratio method for the formation of Cu(I)-BCDS complex.
$[Cu(II)]_0=1.008\times10^{-4}$ M, $[NH_2OH]_0=1.23\times10^{-2}$ M, pH=4.0 (acetate buffer), $\mu=0.15$ (K_2SO_4), 25 °C.

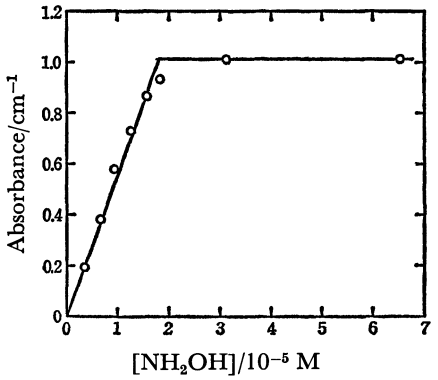

Fig. 2. Stoichiometry of the reaction of Cu(II) with hydroxylamine.
$[Cu(II)]_0=4.03\times10^{-5}$ M, $[BCDS]_0=5.08\times10^{-4}$ M, $\mu=0.15$ (K_2SO_4), pH≃5.7, 25 °C.

Figure 2 indicates that one mole of hydroxylamine reduces two moles of copper(II) to copper(I).[5]

Kinetics. Since no difference in the reaction rate was observed between two combinations of the mixing of the reactants, (A) {NH_2OH+BCDS}+{Cu(II)} and (B) {NH_2OH}+{BCDS+Cu(II)}, the combination A was mainly used to follow the kinetics. The very fast increase in the absorbance at 483 nm on mixing the solution {Cu(II)+NH_2OH} with BCDS indicates a much higher rate of the complex formation of copper(I) with BCDS than that of the redox reaction between copper(II) and hydroxylamine.

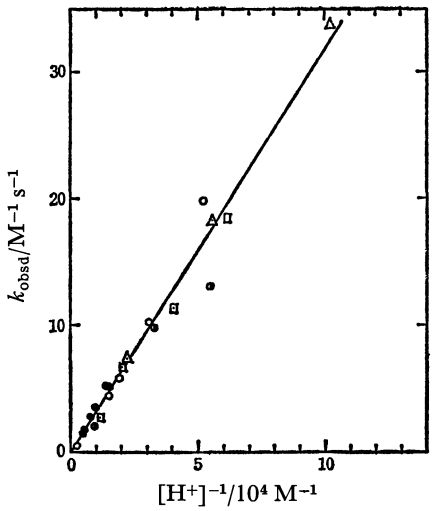

Fig. 3. Plot of the second-order rate constant k_{obsd} against $[H^+]^{-1}$ at 25 °C.
$[Cu(II)]_0$, $[BCDS]_0$, and $[NH_2OH]_0$ are, ◑: 5.04×10^{-6}, 2.03×10^{-4}, 6.10×10^{-2}; ⊡: 5.04×10^{-6}, 2.03×10^{-4}, 4.58×10^{-2}; △: 2.52×10^{-6}, 2.03×10^{-4}, 3.05×10^{-2}; ○: 5.04×10^{-6}, 2.03×10^{-4}, 1.83×10^{-2}; ●: 2.01×10^{-5}, 4.06×10^{-4}, 1.00×10^{-1} M, respectively.

Linear semi-logarithmic plot of the absorbance at 483 nm *vs.* time indicates the first-order dependence on the [Cu(II)] under the conditions $[NH_2OH]_0 \gg [BCDS]_0 > [Cu(II)]_0$. The second-order rate constant k_{obsd} thus obtained depends on the acidity, increasing with $[H^+]^{-1}$ as shown in Fig. 3.

Following rate law of the redox reaction is thus derived.

$$\frac{1}{2}\cdot\frac{d[Cu^I(BCDS)_2]}{dt} = -\frac{1}{2}\cdot\frac{d[Cu(II)]}{dt}$$
$$= k_{obsd}[NH_2OH][Cu(II)]$$
$$= \frac{k_a}{[H^+]}\cdot[NH_2OH][Cu(II)].$$

The apparent rate constant k_a is evaluated to be $3.1\times10^{-4}\ s^{-1}$ from the slope of the straight line in Fig. 3.

The acid dissociation constants for the aquo copper(II) ion and the hydroxylammonium ion are in the same order of magnitude as $K_H=[CuOH^+][H^+]/[Cu^{2+}]=10^{-6.47}$ [6] and $k_a=[NH_2OH][H^+]/[NH_3OH^+]=10^{-5.96}$ [7] at 25 °C.

Although direct evidence for the formation of the complexes of copper(II) with hydroxylamine was not obtained, it would be reasonable to assume the fast formation of copper(II) complex with hydroxylamine followed by the redox reaction, since the observed redox reaction is very slow in comparison with the complex formation of aquo copper(II) ion in general.

The formation of short-lived radical species was reported in the reaction of hydroxylamines with one-electron abstracting oxidants such as cerium(IV).[8] Though in the reaction with bivalent copper we have no direct evidence as for the radical formation, we derived the following reaction scheme involving radicals to interpret the above reaction stoichiometries.

$$\begin{array}{ccc} CuSO_4 & NH_3OH^+ & \\ \downarrow\uparrow K_1 & +H^+ \uparrow\downarrow K_2(=K_a) & \\ Cu^{2+} + NH_2OH & \overset{K}{\rightleftharpoons} & Cu^{II}\cdot NH_2OH \\ \uparrow\downarrow K_3(=K_H) & & \downarrow k_1 \\ CuOH^+ + H^+ & & \end{array}$$

$$Cu(I) + NH_2O\cdot + H^+ \quad (1)$$

$$2Cu(II) + 2NH_2O\cdot \xrightarrow{k_2}$$
$$2Cu(I) + N_2O + H_2O + 2H^+ \quad (2)$$

$$Cu(I) + 2BCDS \xrightarrow{fast} Cu^I(BCDS)_2. \quad (3)$$

The overall reaction is thus summarized as,

$$4Cu(II) + 2NH_2OH + 8BCDS \longrightarrow$$
$$4Cu^I(BCDS)_2 + N_2O + H_2O + 4H^+. \quad (4)$$

In the radical reaction (2), k_2 is postulated to be much larger than k_1K. Thus the k_{obsd} is approximated as follows:

$$k_{obsd} = \frac{k_a}{[H^+]} = \frac{k_1K}{[H^+]\{K_1[SO_4^{2-}]+1\}+K_3}.$$

Under the experimental conditions, $[H^+]\{K_1[SO_4^{2-}]+1\} \gg K_3$, and $[SO_4^{2-}]=0.1$ M.

The value of k_1K is evaluated to be $6.2\times10^{-3}\ s^{-1}$ at 25 °C. The small values of k_a and k_1K may be attributed to the small complex formation constant K.

Organische Metallkomplexe. VIII.* Notiz über die Kupfer(II)- und Nickel(II)chelate der *N,N'*-Bis(2-phenylhydrazono-1-methyläthyliden)-α,ω-alkandiamine

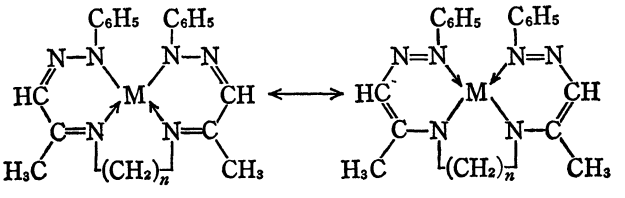
Hiroshi OHTA, Yasushi KODERA, Fumie MORI, Mitsue KOYAMA, und Sumie ISHIBASHI
Chemisches Institut der Fukuoka Universität, 814 Fukuoka, Nishi-ku, Nakaduma 11

(Enigegangen am 6. Mai 1974)

Synopsis. Es wurden die Synthesen der neuen Chelatbildner, *N,N'*-Bis(2-phenylhydrazono-1-methyläthyliden)-1,2-äthandiamin und -1,3-propandiamin sowie ihrer Kupfer(II)- und Nickel(II) chelate beschrieben.

Glyoxal-, Methylglyoxal-(Pyruvinaldehyd-) und Dimethylglyoxal (Biacetyl)phenylhydrazone wurden schon früher dargestellt und charakterisiert.[1-3] Aus den Molekularmodellen erscheinen sie als N.O-Chelatbildner mit den Schwermetallionen Chelate zu bilden. In Wirklichkeit jedoch, trotz verschiedener Versuche konnten wir aus ihnen keine Metallchelate erhalten. Die schwache Acidität der am Benzolkerne haftenden NH-Gruppe im Phenylhydrazon-Reste und die stärkere Elektronegativität des Sauerstoffatoms der C=O-Gruppe erscheinen die Ursache dafür zu sein.

In Rücksicht auf die Tatsache, daß die Formazane mit den Schwermetallionen beständige Metallchelate liefern, haben wir versucht, die anderen Carbonylgruppen in die Azomethine überzüfuhren. Als Carbonylverbindungen lieferten sie alle mit den Carbonylreagenzien normale Kondensationsprodukte. So konnten wir aus ihnen die Phenylhydrazone (Phenylosazone), Oxime, Semicarbazone, und die Schiffschen Basen mit Alkanaminen und Alkandiaminen erhalten. Die Versuche, aus diesen Metallchelate darzustellen, ergaben, daß nur die Schiffschen Basen mit Alkandiaminen Metallchelate liefern, und zwar *N,N'*-Bis(2-phenylhydrazono-1-methyläthyliden)-1,2-äthan-diamin und -1,3-propandiamin beständige Kupfer(II)-und Nickel(II)chelate geben. Ferner haben wir gefunden, daß mit der Zunahme der Methylengruppe die Metallchelate schwerer zugänglich werden. Aus diesen Resultaten konnten wir einen Schluß ziehen, daß in diesen beiden Schiffschen Basen zwei NH-Gruppen und zwei C=N-Gruppen eine begünstigte Lage für die eintretenden Metallione nehmen und so daß diese Basen als 4N-Chelatbildner fungieren.



M=Cu, Ni n=2, 3

Aus den Betrachtungen der Molekularmodelle ist die tetraedrische Anordnung der Liganden um das zentrale Kupfer- bzw. Nickelatom schwierig; dagegen ist die plane Anordnung spannungsfrei. Die magnetischen Momente der Nickel(II)chelate haben darauf hingedeutet, daß in ihnen eine ebene oder fast ebene Struktur vorliegt. Man könnte daher annehmen, daß auch den Kupfer(II)chelaten die gleiche Anordnung der Liganden zukommt.

Aus dem Vergleich der Stabilität und der Absorptionsmaxima im sichtbaren Bereich der ebenen (oder fast obenen) Kupfer(II)chelate haben Nakahara *etal.*[4] festgestellt, daß innerhalb einer bestimmten Reihe von den orthokondensierten tricyclischen Kupfer(II)-chelaten, das 6-5-6-Chelatringsystem stabiler als 6-6-6-System ist, und die stabileren Chelate stets im kürzeren Wellenbereich die Absorptionsmaxima haben als die instabileren und umgekehrt. Wir haben gefunden, daß die Nakahara-sche Regel auch für unsere Kupfer(II)chelate gilt.

Beschreibung der Versuche

Die Schmelzpunkte sind nicht korrigiert. Die Absorptionsspektren im sichtbaren Bereich wurden mit dem Hitachi-Gerät, Modell 124 aufgenommen. Die magnetischen Messungen wurden mit der Gouy-schen Waage im pulverisierten Zustand bei Zimmertemperatur ausgeführt.

Darstellung der Chelatbildner.

N,N'-Bis(2-phenylhydrazono-1-methyläthyliden)-1,2-äthandiamin (PMÄ-H_2). Man fügt zur warmen Lösung von 3.2 g Methylglyoxal-al-phenylhydrazon in 10 ml Äthanol 0.9 ml 1,2-Äthandiamin zu, und erhitzt das Gemisch auf dem Wasserbade etwa 20 Min under Rückfluß. Nach dem Erkalten kristallisiert man die erhaltene kristallinische Masse aus Äthanol um. Gelbe Kristalle, Schmp. 193—94 °C. Zur Analyse und Darstellung der Metallchelate wurde eine Substanzprobe verwendet, die durch einstündiges Erhitzen unter vermindertem Druck über P_2O_5 bei 90 °C getrocknet wurde.

Gef.: C, 68.74; H, 6.91; N, 24.36%. Ber.($C_{20}H_{24}N_6$): C, 68.95; H, 6.92; N, 24.12%.

N,N'-Bis(2-phenylhydrazono-1-methyläthyliden)-1,3-propandiamin (PMP-H_2). Man stellt die Verbindung in derselben Weise wie beim PMÄ-H_2 aus 3.2 g Methylglyoxal-al-phenylhydrazon gelöst in 10 ml warmem Äthanol und 1 ml 1,3-Propandiamin dar. Gelbe Kristalle, Schmp. 145—46 °C. Zur Analyse und Darstellung der Metallchelate wurde eine Substanzprobe verwendet, die durch mehrstündiges Erhitzen unter vermindertem Druck über P_2O_5 bei 110—30 °C getrocknet wurde.

Gef.: C, 69.46; H, 7.19; N, 23.04%. Ber. ($C_{21}H_{26}N_6$): C, 69.59; H, 7.23; N, 23.18%.

Kupfer(II)chelate. *PMÄ-Cu(II)*: Man fügt zur warmen Lösung von 350 mg PMÄ-H_2 in 35 ml Äthanol eine Lösung von 220 mg Kupfer(II)acetat(Monohydrat) in 10 ml Äthanol zu. Die Farbe der Lösung schlägt sofort nach schwärzlichem Purpur um, und die glänzenden purpurroten Platte scheiden sich ab. Man kristallisiert sie aus Äthanol um.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(10), 2975—2976 (1975)

Nitrosylrhodium (^{14}NO and ^{15}NO) Compounds Containing Triphenylphosphine

Eiichi MIKI,* Kunihiko MIZUMACHI, and Tatsujiro ISHIMORI

Department of Chemistry, College of Science, Rikkyo University, 3-Chome, Nishi Ikebukuro, Toshima-ku, Tokyo 171

(Received May 14, 1975)

Synopsis. The oxidation states of the NO group and the geometries for the nitrosylrhodium compounds were investigated on the basis of the ^{15}N-isotopic shifts of the N–O stretching vibrations and the frequencies of the Rh–NO stretching ones. $RhCl(NO_2)(NO)(PPh_3)_2$ was found to react with NO to give $RhCl(NO_2)_2(PPh_3)_2$.

It has been reported that the oxidation states of the metal atom and the NO group in transition-metal nitrosyl complexes significantly influence the isotopic shifts of the vibrational bands due to the metal–N–O skeleton upon ^{15}NO-substitution, and control the region where these bands are observed.[1-3] Such a view may be connected with the concept of "Stereochemical Control of Valence": that the geometry of NO group is determined by the stereochemistry of the ligands attached to the metal.[4]

On the basis of these facts, the authors measured the isotopic shifts of the following nitrosylrhodium compounds: $Rh(NO)(PPh_3)_3$ (PPh_3=triphenylphosphine), $RhX_2(NO)(PPh_3)_2$, and $RhX(NO_2)(NO)(PPh_3)_2$ (X=Cl and Br), which have been the subject of great interest as homogeneous catalysts of olefin hydrogenation.[5]

Experimental

Syntheses. The examined compounds were prepared in accordance with Ref. 6—8. One of the starting materials, rhodium(III) bromide, was prepared from $RhCl_3 \cdot 3H_2O$ by heating it with concentrated hydrobromic acid on a boiling water bath to dryness. The ^{15}NO-complexes were prepared in a vacuum line by the use of *ca.* 5 mmol of ^{15}NO (^{15}N atom %=95.5—96.8) on the same scale as that used for preparing the ^{14}NO-complexes. The elementary analyses and IR spectra showed that the desired products were obtained. All of these compounds were diamagnetic.

$RhCl(NO_2)_2(PPh_3)_2$: A 6-mmol portion of NO was trapped in a reaction vessel containing 1 mmol of $RhCl(PPh_3)_3$ in 70 ml of chlorobenzene by cooling with liquid nitrogen. Then the solid solution was melted under running water and was allowed to stand for more than 2 days, changing from dark red to yellow through green. The yellow solution was condensed to less than 5 ml by the use of liquid nitrogen to give a yellow product. Yield, 150—300 mg. Found: C, 56.98; H, 3.95; N, 3.71; Cl, 4.82%. Calcd for $RhCl(NO_2)_2(PPh_3)_2$: C, 57.29; H, 3.98; N, 3.71; Cl, 4.70%. χ_g (at 291 K)$=-0.46\times10^{-6}$ (cgs).

Measurements. The magnetic susceptibility was measured by the Gouy method at room temperature. The IR spectra were measured in the region 200—4000 cm^{-1} as Nujol and hexachlorobutadiene mulls using JASCO DS-402 G and JASCO model IR-F infrared spectrophotometers. The reproducibility was about ±0.5 cm^{-1} in the region 200—2400 cm^{-1}. The Raman spectra of the powdered samples were measured in the region 100—700 cm^{-1} on a Narumi 750 Z-1200 double monochrometer equipped with a He-Ne laser.

Results and Discussion

From the comparison of the observed isotopic shifts with the calculated ones, the following rules were established:[1-3] the observed isotopic shift of the N–O stretching vibration for NO^+ complex is 36—44 cm^{-1}, while that for the NO^- one is 25—28 cm^{-1}; the metal-NO bending vibration is observed in the region 450—650 cm^{-1}, and its isotopic shift is 10—15 cm^{-1} for both NO^+ and NO^- complexes; the metal–NO stretching vibration for the NO^+ complex is observed in the region 500—650 cm^{-1}, while that for the NO^- one is seen in the region *ca.* 300 cm^{-1}, and their isotopic shifts are 2—6 cm^{-1}. The bands due to the RhNO group were assigned on this basis.

The wave numbers, isotopic shifts, and assignments of IR and Raman bands for the examined compounds are shown in Table 1.

The N–O stretching vibration of $Rh(NO)(PPh_3)_3$ was observed at 1610 cm^{-1} and shifted downwards by 49 cm^{-1} upon ^{15}NO-substitution. In the region where skeletal vibrations due to metal-NO groups have been usually observed, only a weak absorption band at 410 cm^{-1} shifted downwards by 18 cm^{-1}. This band may be assigned to the Rh–NO bending vibration. Another skeletal vibration, the Rh–NO stretching one, may be considered to overlap with the strong bands due to the coordinated PPh_3 groups. The Raman bands in the region 200—700 cm^{-1} showed no isotopic shifts. The isotopic shift of the N–O stretching vibration supports the view that the oxidation state of the NO group is I, and that of the rhodium atom, −I. The concept of "Stereochemical Control of Valence" will support the view that this compound is not a square planar one with a strongly bent RhNO group but a tetrahedral one with a linear RhNO one, if this compound is a NO^+ one,[4]

The N–O stretching vibration of $RhX_2(NO)(PPh_3)_2$ was observed in the region *ca.* 1630 cm^{-1}; the isotopic shift was 28 cm^{-1}. The band at *ca.* 590 cm^{-1} shifted downwards by *ca.* 15 cm^{-1}, and the 339 cm^{-1} band for the bromide shifted downwards by 2 cm^{-1}. The former band can be assigned to the Rh–NO bending vibration, and the latter one to the Rh–NO stretching one. The Rh–NO stretching vibration of the chloride could not be observed because of the overlapping with the strong band due to the Rh–Cl stretching one. The Rh–Cl band was observed as a single band on both IR and Raman spectra. This suggests that the two chloride ions are in a *trans* position to each other in this compound.

* Present address: Department of Chemistry, The University of Texas at Austin, Austin, Texas 78712.

Table 1. Wave numbers, observed isotopic shifts, and assignments of IR and Raman bands[a]

Assignments	$Rh(NO)(PPh_3)_3$	$RhCl_2(NO)(PPh_3)_2$	$RhBr_2(NO)(PPh_3)_2$
NO str	1610 vs (49)[b]	1632 vs (28)	1631 vs (28)
Rh-NO bend	410 w (18)	591 s (15), 598[c] (14)	586 s (15)
Rh-P str	450 s	456 s	460 s
Rh-NO str	not obsd.	not obsd.	339 m (2)
Rh-X str		341 vs, 347[c]	271 vs

Assignments	$RhCl(NO_2)(NO)(PPh_3)_2$	$RhBr(NO_2)(NO)(PPh_3)_2$
NO str	1659 vs (29), 1632 w (28)	1653 vs (28), 1625 w (29)
Rh-NO bend or NO_2 wag	577 m, br (15); 560 s (13)	573 m (17), 554 w (14)

Rh-NO str	341 m (1)	320 m (2)
Rh-X str	318 vs	280 m, br

a) The bands which are characteristic of PPh_3 and the nitro group are eliminated. b) The wave numbers in parentheses indicate the observed isotopic shifts. c) Raman band.
Abbreviations: vs=very strong; s=strong; m=medium; w=weak; br=broad; str=stretching vibration; bend=bending vibration; wag=wagging vibration.

For $RhX(NO_2)(NO)(PPh_3)_2$, two N–O stretching vibrations were observed in the region 1630—1660 cm^{-1}, and these shifted downwards by 28—29 cm^{-1}. The ^{15}N-isotopic shifts of the bands which are characteristic of the nitro group were comparable to those of $[Rh(NO_2)(NH_3)_5]Cl_2$.[9] The two bands observed in the region 550—580 cm^{-1} are considered to be assigned to the wagging vibration of the NO_2 group and the Rh–NO bending vibration. These bands, however, could not be assigned distinctly because their isotopic shifts are almost equal to each other. The 320 cm^{-1} band of the bromide shifted downwards by 2 cm^{-1}, and can be assigned to the Rh–NO stretching vibration. The 341 cm^{-1} band of the chloride is considered to be the Rh–NO stretching vibration. The oxidation state of the NO group for $RhX_2(NO)(PPh_3)_2$ and $RhX(NO_2)(NO)(PPh_3)_2$ is considered to be −I, that of the rhodium atom, III. If these compounds are NO^- ones, the concept of "Stereochemical Control of Valence" will support the view that the geometries of these five-coordinate compounds are tetragonal pyramids with an apical NO^-.[4]

It is established that the metal–NO stretching vibration for the NO^- complex is in the region *ca.* 300 cm^{-1}, as observed for the nitrosylplatinum complexes such as $M_2[PtX_5(NO)]$.[2]

For $RhCl(NO_2)_2(PPh_3)_2$, no absorption bands could be observed in the region where the N-O stretching vibration has been usually observed, but the absorption bands and their ^{15}N-isotopic shifts, which are characteristic of the coordinated nitro group, could be observed in addition to the bands due to PPh_3. The IR bands and the elementary analyses show that this new compound is $RhCl(NO_2)_2(PPh_3)_2$. The reaction of NO with a square-planar d^8 complex of rhodium, such as $RhCl(PPh_3)_3$, has been reported to give a five coordinate derivative, $RhCl(NO_2)(NO)(PPh_3)_2$.[8] It was found from this study that the nitro-nitrosyl compound further reacts with NO to give the dinitro compound, $RhCl(NO_2)_2(PPh_3)_2$. The apical NO^- ion of the nitro-nitrosyl compound is considered to react with NO to give NO_2^- ion and N_2O.

$$RhCl(NO_2)(NO)(PPh_3)_2 + 2NO \longrightarrow RhCl(NO_2)_2(PPh_3)_2 + N_2O.$$

A Structural Investigation of the 2-Methylthiophene Trimer and Its Related Compounds†

Akira ISHIGAKI and Toshiyuki SHONO*

Nara Technical College, Yata, Yamato-Kōriyama-shi, Nara 639-11

**Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamada-kami, Suita-shi, Osaka 565*

(Received November 30, 1974)

Synopsis. A structural investigation of the 2-methylthiophene trimer and its crystalline oxidation product has been performed. These compounds have been found to be identical with 2,4-bis(5′-methyl-2′-thienyl)-2-methylthiolane and its sulfone derivative.

Thiophene and alkylthiophen react under the catalytic action of phosphoric acid to give their oligomers. The reaction was investigated by Meisel *et al.* in 1950.[1] Noting the presence of trimers in the reaction products, they proposed a reaction mechanism and elucidated the structure of the thiophene trimer, 2,4-bis-2′-thienylthiolane [**1**]. However, no structural description of the alkylthiophene trimers was undertaken.

In a previous paper,[2] the present authors investigated an oligomerization of 2-methylfuran and elucidated the structure of the 2-methylfuran tetramer. 2-Methylfuran reacts under the catalytic action of phosphoric acid to give its tetramer in a good yield. However, no trimeric compounds are found in the reaction product. Our interest in preparing the 2-methylfuran tetramer led us to reinvestigate the trimerization of thiophene and 2-methylthiophene. In this paper, the authors will try to elucidate the structure of the 2-methylthiophene trimer [**2**] and its related compounds, novel crystalline derivatives of **1** and **2**.

Experimental

*Preparation of **1** and **2**.* Reagent-grade thiophene was used after fractional distillation. The 2-methylthiophene was prepared by the ordinary method[3,4] and was used after fractional distillation; bp 112 °C (750 mmHg). The preparations of **1** and **2** were carried out by the method of Meisel *et al.*

Thiophene trimer [**1**]: bp 181—183 °C (2 mmHg); n_D^{20} 1.6455 (lit,[1] bp 167—170 °C (1 mmHg); n_D^{20} 1.6450).

2-Methylthiophene trimer [**2**]: bp 190 °C (2 mmHg); n_D^{20} 1.6103 (lit,[1] bp 190—193 °C (0.8 mmHg); n_D^{20} 1.6104).

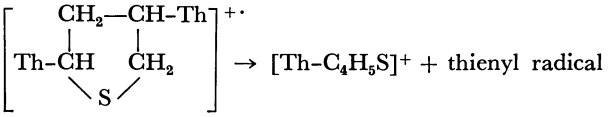
*Preparation of the Crystalline Derivatives of **1** and **2**.* To 20 ml of glacial acetic acid we added 1.5 g (6 mmol) of **1**, followed by 20 ml of an aqueous solution of potassium permanganate (2.6 g, 8 mmol). The solution was stirred at 40—50 °C for 30 min. The resulting solution was treated with sodium hydrogen sulfite to dissolve the precipitated manganese dioxide. The solution was then extracted with two portions of ether. The combined ethereal layers were washed with a saturated sodium hydrogen carbonate solution and then successively twice with water. The ethereal extract was dried over anhydrous magnesium sulfate and concentrated. The residue was crystallized from ethanol to give 0.57 g of a crude product; mp 129.3 °C. The product was treated with active carbon in ethanol and then recrystallized to afford 0.37 g of a colorless crystalline product [**3**]; mp 133.3 °C. Found: C, 50.74; H, 4.27%, mol wt, 285.3 (measured in dioxane by means of a vapor-pressure osmometer). Calcd for $C_{12}H_{12}S_3O_2$: C, 50.67; H, 4.25%; mol wt, 284.4.

The crystalline derivative of **2** was prepared following the method of the preparation of **3**. From 1.0 g of **2**, 0.1 g of colorless fine crystals [**4**] was obtained; mp 146.5 °C. Found: C, 55.15; H, 5.68%; mol wt, 325.1. Calcd for $C_{15}H_{18}S_3O_2$: C, 55.17; H, 5.55%; mol wt, 326.5.

Results and Discussion

The NMR spectrum of **1** in CCl_4 reveals a signal at δ 6.7—7.1 (m, 6H). This signal is assigned to the protons of the two thienyl groups. This fact supports the structure of **1** proposed by Meisel *et al.*—2,4-bis-2′-thienylthiolane. Following the structure, the other signals are assigned to the six protons on the thiolane ring; the thiolane ring protons of the 2-position (δ 4.6—5.0, m, 1H), the 3-position (δ 2.0—2.5, m, 2H), the 4-position (δ 3.6—3.9, m, 1H), and the 5-position (δ 2.6—3.5, m, 2H).

The mass spectrum of **1** reveals a metastable ion at *m/e* 112. The presence of the metastable ion at *m/e* 112 (calcd: $(168)^2/252=112.0$) supports the following fragmentation process:



M^+ of **1**, *m/e* 252 *m/e* 168 (rel. intensity 98.8%)

Th; thienyl group

These NMR and mass spectral data are useful for investigating the unknown structure of **2**. If the trimerization of 2-methylthiophene occurs by means of the same reaction mechanism as that proposed by Meisel *et al.*, the following two kinds of structural formulas may be expected: 2,4-bis(5′-methyl-2′-thienyl)-2-methylthiolane or 2,4-bis(5′-methyl-2′-thienyl)-5-methylthiolane.

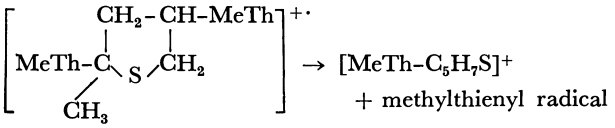
The remarkable resemblance between the NMR spectra of **1** and **2** indicates the structural resemblance between them. Thus, the signal at δ 6.3—6.8 (m,4H) is assigned to the protons of the two disubstituted thiophene nuclei, while the signal at δ 2.36 (s, 6H) is assigned to the two methyl groups substituted on the thiophene nuclei. The other signals are, then, assigned to the eight protons on the methylthiolane nucleus: the thiolane ring protons of the 3-position (δ 2.1—2.7, m, 2H; overlapped with a broad singlet at δ 2.36),

† Presented in part at the 30th Annual Meeting of the Chemical Society of Japan, Osaka, April, 1974.

the 4-position (δ 3.5—4.0 m, 1H) and the 5-position (δ 2.8—3.4, m, 2H), and the methyl protons attached to the 2-position of the thiolane ring (δ 1.8, s, 3H).

The presence of the singlet methyl signal at δ 1.8 shows that one of the two thienyl groups must be attached to the 2-position of the thiolane ring. The other thienyl group must, then, be attached to the 4-position of the thiolane ring. The structure of the two methylthienyl groups probably corresponds to that of the 5′-methyl-2′-thienyl groups, because the α and α' positions of the thiophene nucleus are actually more reactive than the β and β' positions. Therefore, the structure of **2** is identified with 2,4-bis(5′-methyl-2′-thienyl)-2-methylthiolane.

The mass spectrum of **2** reveals a metastable ion at *m/e* 131. This metastable ion supports the following fragmentation process (calcd=(196)²/294=130.6):

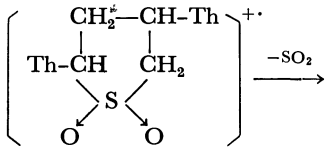


M⁺ of **2**, *m/e* 294 *m/e* 196 (rel. intensity 80.9%)
Meth; methylthienyl group

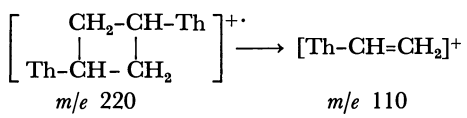
The NMR spectral pattern of **3** closely resembles that of **1**, and the two IR bands of **3** correspond to the characteristic bands due to the sulfone group: NMR ($CDCl_3$) δ 2.5—3.0 (m, 2H), 3.3—3.8 (m, 2H), 3.8—4.2 (m, 1H), 4.6—4.9 (m, 1H) and 6.9—7.4 (m, 4H); IR 1315 ($\nu_{as}SO_2$) and 1135 cm^{-1} ($\nu_{s}SO_2$). These facts support the structure of **3** as a sulfone derivative of **1**: 2,4-bis-2′-thienylthiolane 1,1-dioxide.

The structure of **4** was also identified as 2,4-bis(5′-methyl-2′-thienyl)2-methylthiolane 1,1-dioxide by the NMR and IR spectral data, and by elemental analysis: NMR ($CDCl_3$) δ 1.86 (s, 3H), 2.44 (s, 6H), 2.5—2.9 (m, 2H), 3.1—3.4 (m, 2H), 3.5—4.0 (m, 1H) and 6.5—7.0 (m, 4H); IR 1300 ($\nu_{as}SO_2$) and 1130 cm^{-1} ($\nu_{s}SO_2$).

No metastable ion peaks are found in the mass spectra of **3** and **4**. These spectral data suggest a quite different fragmentation process from those of **1** and **2**. The mass spectrum of **3** reveals the molecular ion peak at *m/e* 284 and some major peaks: *m/e* 110 (rel. intensity 100%), 220 (10%), and others. The presence of these ion peaks suggests the following possible fragmentation process for **3**:

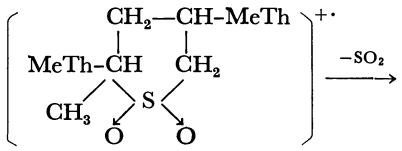


M⁺ of **3**, *m/e* 284

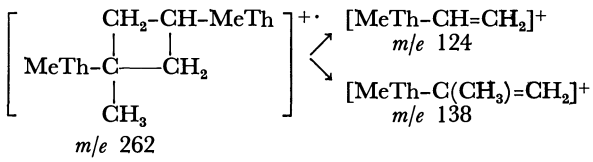


m/e 220 *m/e* 110

The mass spectrum of **4** lacks the molecular ion (*m/e* 326). However, the presence of several ion peaks at *m/e* 262 (rel. intensity 3%), 138 (100%) and 124 (21%) supports the following fragmentation process similar to that discussed in connection with the fragmentation of **3**:



M⁺ of **4**, *m/e* 326



m/e 262

A Theoretical Model for the Hydrogen Migration of Butyl Alcohol

Tsutomu TAKAGI and Masayoshi OIWA

Department of Applied Chemistry, Faculty of Engineering, Kansai University, Suita-shi, Osaka 564

(Received December 20, 1974)

Synopsis. The hydrogen-migration mechanism of the fragmentation of *n*-butyl alcohol in a mass spectrometer is discussed from the standpoint of the bonding interaction energy, as estimated by an all-valence electron semi-empirical SCF-MO treatment (CNDO/2-UHF), assuming the following models I and II:

$CH_2CH_2CH_2CH_2$-OH $\rightarrow$ $C_4H_8^{+}$ + H_2O (I)

H.....

$CH_3CHCH_2CH_2$-OH $\rightarrow$ $C_4H_8^{+}$ + H_2O (II)

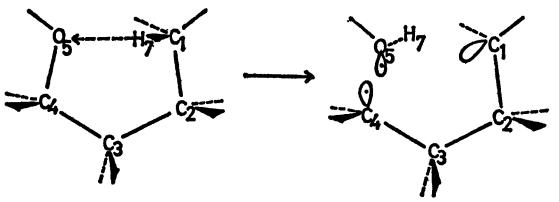
H.....

Finally, Model I is suggested to be energetically favorable.

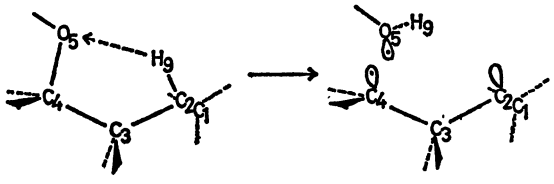
The elimination of H_2O from *n*-butyl alcohol[1] in the fragmentation by electron impact was suggested to be due to the intramolecular migration of a hydrogen atom from the γ- or δ-carbon to oxygen. However, the precise mechanism of the migration has not yet been elucidated, but only speculated from the mass spectra data.

The present paper is concerned with a discussion of the hydrogen migration mechanism in a mass-spectrometric fragmentation of *n*-butyl alcohol from the standpoint of the theory of the partition of the total energy.[2]

The models in the hydrogen migration are schematically represented in view of the least-motion path from the origin of migration to the terminus. It should be considered that the lengths and angles of each bond change with the migration steps of the hydrogen migration, and that the breaking of the carbon-oxygen bond requires more precise electronic structure calculations. However, in the calculations, the conformation of the molecule was already assumed to be the optimal ground state, as determined from the standard table.[3] Four steps were also chosen to form a path representing the hydrogen migration. The bond distances between the migration hydrogen (H_7 or H_9 in the two models respectively) and oxygen (O_5), and the energy profile along the migration steps, which was estimated by CNDO calculations, have also been listed in Table 1.



Model I



Model II

E^K	−75.246	−74.752	−74.962	−75.549
E^V	−5714.770	−5814.251	−5814.445	−5820.285
E^N	3043.687	3126.999	3131.315	3141.743

a) E^U is the total one electron AO energy of the electrons on atom A. E^R is the contribution of the resonance integral to the energy of the AB bond and is the main feature of the covalent bond. E^J is the repulsion of the electrons of the atoms A and B. E^K is the corresponding term of the electronic exchange interactions. E^V is the potential energy of the electrons on atom A in the field of nucleus B plus that of the electrons on atom B in the field of nucleus A. E^N represents the nuclear repulsion energy of the nuclei A and B.

Here, the driving factor for the migration was interpreted by using the partition method for the total energy. The total energies of both models increase with the hydrogen migration. The variation in the total energy in Model I is, however, smaller than that in Model II. The resonance energy term (E^U+E^R) decrease with the hydrogen migration in both models. It can be suggested that the decrease in the energy is due to the resonance effect and that the increase in the total energy results from the steric effect.

Now, the changes of the E_{AB} of each bond due to migration will be employed to estimate the bond length and the bond order.[4] The E_{AB} of the C_1–H_7

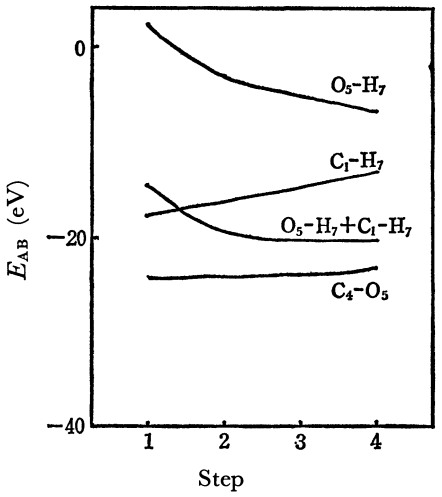

Fig. 1. Variation of E_{AB} of each bond due to migration through the least motion path in the model I.

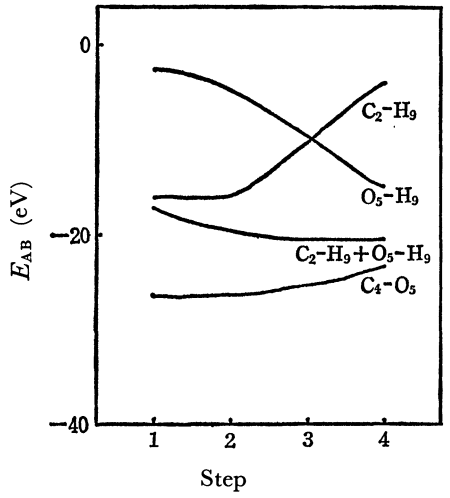

Fig. 2. Variation of E_{AB} of each bond due to migration through the least motion path in the model II.

bond becomes smaller and the E_{AB} of the O_5–H_7 bond becomes larger in Model I, as is shown in Fig. 1. Therefore, the sum of the E_{AB} values of the two bonds is significant. The sum of the E_{AB} values of the two bonds decreases along the migration steps. On the other hand, in Model II, as is shown in Fig. 2, the C_2–H_9 bond also becomes smaller, while the O_5–H_9 bond becomes larger. In the case of Model II, the sum of the E_{AB} values of the two bonds decreases with the hydrogen migration, the same tendency as in Model I. The decrease in the sum of the E_{AB} values of the two bonds implies that the bonding interaction between O_5 and the leaving hydrogen becomes strong along the coordinates representing the migration of hydrogen to O_5.

As is shown in Figs. 1 and 2, the bonding interaction energies of the C_4–O_5 bonds decrease with the approach of hydrogen to oxygen. In other words, the bonding interaction between C_4 and O_5 is weakened by the hydrogen migration. The variation in the bonding interaction of the C_4–O_5 bond in Model I was, however, smaller than that in Model II. Also, the E_{AB} values of the other carbon-carbon bonds are larger than that of the C_4–O_5 bond; the E_{AB} values of the C_4–O_5 bonds of Step 4 in Models I and II were calculated to be −23.753 eV and −23.376 eV respectively. Moreover, the E_{AB} values of the C_1–C_2, C_2–C_3, and C_3–C_4 bonds were found to be −29.124 eV, −28.497 eV, and −29.260 eV in Model I.

On the other hand, the E_{AB} values of the C_1–C_4 and C_2–C_4 non-bonds were found to change from 0.147 eV to 0.041 eV and from −0.015 eV to −0.255 eV respectively. The interaction between non-bonded carbon atoms (between C_1 and C_4 in Model I and between C_2 and C_4 in Model II) tends to change from the non-bonding to a weakly bonding state, *i.e.*, the sequence of ring formation.

Thus, these results may be related to the ease of the cleavage from the molecular ion (M ion) to the M-H_2O ion in the rearrangement reaction. Moreover, although the possibility of the hydrogen migration in Model II can not always be eliminated, the hydrogen migration *via* Model I may be estimated to be energetically favorable, judging from the variation in the total energy and the small steric effect compared with those of Model II. The simple models described in the present paper can provide sufficient information as the rearrangement reaction of *n*-butyl alcohol.

All the calculations were performed using a NEAC 2200 MODEL 700 computer at Osaka University.

A Convenient Method for the Preparation of Aryl and Alkyl Isothiocyanates Using Amines, Carbon Disulfide, and a Grignard Reagent

Shizuyoshi SAKAI, Tatsuo FUJINAMI, and Toshiyuki AIZAWA

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

(Received January 7, 1975)

Synopsis. The thermal decomposition of bromomagnesium *N*-aryl- or *N*-alkyl-*N*-bromomagnesio-dithiocarbamate (**3**), prepared *in situ* from amines, carbon disulfide, and a Grignard reagent, is a new and convenient method for the preparation of aryl or alkyl isothiocyanate.

The reported methods for the preparation of isothiocyanates from amines have usually involved the decomposition reactions of dithiocarbamate derivatives.[1-4] However, these methods are inconvenient, because a poisonous reagent, such as a heavy metal or a phosgene derivative, is used as the starting material. In view of this, we have already described a new method, which consists of the decomposition reaction of lithium *N*-lithio-dithiocarbamate prepared *in situ* using butyllithium. Grignard reagent appears also to have an interesting synthetic potential in isothiocyanate preparation. In this report, we will describe a more convenient and alternative approach for isothiocyanate synthesis using a Grignard reagent, and will compare this new method with that using an organolithium compound.

Aromatic amines were treated with two equivalents of ethylmagnesium bromide in tetrahydrofuran under a nitrogen atmosphere to form bis(bromomagnesio)-aniline (**2**; R=Aryl); then excess amounts to carbon disulfide were added below room temperature to give bromomagnesium *N*-aryl-*N*-bromomagnesio-dithiocarbamate (**3**; R=Aryl) *in situ*. The characteristic band of the ν_{NCS} of isothiocyanate could not be detected after the reaction mixture had been refluxed for 1 hr. After the evaporation of the mixture of tetrahydrofuran and excess carbon disulfide, the distillation residue was heated at 120—140 °C to decompose (**3**), thus affording aryl isothiocyanate (**4**; R=Aryl). The results for other amines are designated by 'Direct Method' in Table 1.

$$\underset{\mathbf{1}}{RNH_2} \xrightarrow[-2EtH]{+2EtMgBr} \underset{\mathbf{2}}{RN(MgBr)_2} \xrightarrow{+CS_2} \underset{\mathbf{3}}{RN(MgBr)CS_2MgBr} \xrightarrow[-(BrMg)_2S]{} \underset{\mathbf{4}}{RNCS} \quad (1)$$

The by-product, '$(BrMg)_2S$', could not be characterized, but it reacted violently with water to evolve hydrogen sulfide gas.

Bis(bromomagnesio)anilines are well known to be formed by the reaction of aromatic amines with a Grignard reagent.[6] However, the dimetallation reaction of primary aliphatic amines by organomagnesium is difficult to complete; therefore, the yields of alkyl isothiocyanates by the 'Direct Method' are rather low, except for cyclohexylamine (Table 1). To improve the yield of alkyl isothiocyanate, an alternative approach was tried; in it we treated alkylamine with the Grignard reagent and carbon disulfide, step-by-step, in the way described in Eq. (2) ('Step-by-step Method' in Table 1).

$$\underset{\mathbf{1}}{RNH_2} \xrightarrow[-EtH]{+EtMgBr} \underset{\mathbf{5}}{RNHMgBr} \xrightarrow{+CS_2} \underset{\mathbf{6}}{RNHCS_2MgBr} \xrightarrow[-EtH]{+EtMgBr} \mathbf{3} \xrightarrow[-(BrMg)_2S]{} \mathbf{4} \quad (2)$$

The temperature required to decompose the *N*-alkyl-*N*-bromomagnesio-dithiocarbamate (**3**; R=

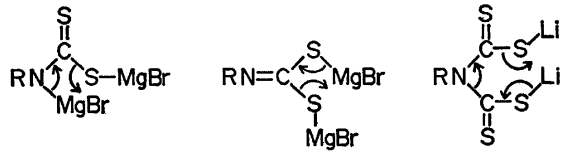
α-Naphthyl-NH_2	30	—	—	125—127/0.5	2090
β-Naphthyl-NH_2	40	—	—	118—119/0.1	2110

a) Two mol of CS_2 and EtMgBr were used per one mol of amine through the reaction (1), and the reaction mixture prepared *in situ* was decomposed at 120—140 °C. b) The temperature where the carbamate (**3**) began to decompose. c) Refluxing temperature of tetrahydrofuran solution.

Alkyl) thus prepared was substantially lower than that needed for the corresponding *N*-aryl derivative (**3**; R=Aryl). The dithiocarbamate (**3**; R=Alkyl) was decomposed for 1 hr at the refluxing temperature in tetrahydrofuran, thus affording a good yield of **4**.

Contrary to the case of isothiocyanate synthesis using butyllithium, where two equivalents of carbon disulfide per mole of amine were essentially required,[5] the 'direct' and 'step-by-step' methods using the Grignard reagent needed only one equivalent of carbon disulfide. Although mechanistic comparisons of these reactions are now in progress, a four-centered scheme (**7a** or **7b** in Fig. 1) for the reaction using the Grignard reagent and a six-centered scheme (**8**) *via* a lithium intermediate can tentatively be suggested to explain the different amounts of carbon disulfide needed.



7a **7b** **8**

Fig. 1. Tentative schemes for isothiocyanate formation.

In conclusion, the Grignard reagent is superior to butyllithium both in purity and in yield of isothiocyanate obtained, except for the lower yield of isothiocyanate from sterically hindered amines such as *tert*-butylamine and α-naphthylamine.

Experimental

All the boiling points are uncorrected. The IR and NMR spectra were determined with a JASCO Model IRA-1 spectrometer and a Hitachi Perkin-Elmer Model R-24 spectrometer respectively. The tetrahydrofuran, carbon disulfide, and amines were dried using metallic sodium, diphosphorous pentoxide, and pellets of sodium hydroxide respectively, and were distilled before use. Some standard examples of the preparation of aryl and alkyl isothiocyanates are given below.

Thermal Decomposition of Bromomagnesium N-*Bromomagnesio*-N-*Phenyldithiocarbamate (**3**; R=Ph) (Direct Method).* In a flask equipped with a mechanical stirrer, a condenser, a dropping funnel, and a nitrogen inlet, ethylmagnesium bromide (110 mmol) was prepared in the usual manner from a magnesium ribbon (2.68 g; 110 mmol) and bromoethane (*ca.* 115 mmol) in dry tetrahydrofuran (80 ml) under a dry nitrogen atmosphere. To the solution we then slowly added aniline (4.66 g; 50 mmol) in dry tetrahydrofuran (5 ml), followed by 4 hrs' refluxing to form bis(bromomagnesio)aniline. The resulting suspension was treated slowly with excess amounts of carbon disulfide (7.61 g; 100 mmol) in tetrahydrofuran (5 ml) below room temperature. A violent heat evolution was observed in the reaction at room temperature; therefore, the mixture had to be cooled by mean of a water bath. The solution of the reaction mixture was heated for 1 hr and was then transferred into a distillation apparatus. After the solvent and excess carbon disulfide had then been recovered by distillation, the residue[7] was heated for 1 hr at 120—140 °C to decompose the bromomagnesium *N*-bromomagnesio-*N*-phenyldithiocarbamate (**3**; R=Ph), thus affording phenyl isothiocyanate (**4**; R=Ph). The product was redistilled *in vacuo* to separate **4** (R=Ph); yield 5.54 g (82% based on the aniline used); bp 105—107 °C/20 mmHg (Ref,[5] 96—98 °C/15 mmHg); IR(neat) ν_{NCS} 2070 cm^{-1}. The NMR and IR spectra were in good agreement with those of the authentic sample prepared by the published method.[5]

Even when an equivalent amount of carbon disulfide (3.81 g; 50 mmol) was used in the reaction with bis(bromomagnesio)aniline, phenyl isothiocyanate was obtained in a slightly lower yield (75%). However, excess amounts (two equivalents) of carbon disulfide were used in most cases; the results are summarized in Table 1.

Hydrogen sulfide was violently evolved by the addition of water to the distillation residue.

Thermal Decomposition of Bromomagnesium N-*Bromomagnesio*-N-*butyldithiocarbamate (**3**; R=Bu) (Step-by-step Method).* A solution of *n*-butylamine (3.66 g; 50 mmol) in tetrahydrofuran (5 ml) was added, drop-by-drop, to a solution of ethylmagnesium bromide (55 mmol) in tetrahydrofuran (50 ml) under dry nitrogen in the apparatus described above. After refulxing for 1 hr, the solution of **5** (R=Bu) was treated with an equivalent amount of carbon disulfide (3.81 g; 50 mmol) in tetrahydrofuran (5 ml) under cooling by water, to form the *N*-butyl-dithiocarbamate salt (**6**; R=Bu). Heat evolution was observed during this procedure at room temperature. The solution thus prepared *in situ* was treated again with ethylmagnesium bromide (55 mmol) to give bromomagnesium *N*-bromomagnesio-*N*-butyldithiocarbamate (**3**; R=Bu) and ethane. After the reaction mixture had then been heated with stirring for 1 hr under reflux, the characteristic band of isothiocyanate at 2090 cm^{-1} appeared in the IR spectrum of the product mixture. The tetrahydrofuran was recovered by distillation, and the residue was heated for 1 hr at 120—140 °C. Butyl isothiocyanate was obtained by distillation *in vacuo*; yield 4.89 g (85%); bp 64—66 °C/20 mmHg (lit,[5] 47—48 °C/10 mmHg); IR(neat) ν_{NCS} 2090 cm^{-1}.

In separate experiments, an additional amount of carbon disulfide (3.81 g; 50 mmol) was added to the solution of **3** (R=Bu), but no heat evolution was ever observed. The treatment of the reaction mixture in the same manner as has been described above afforded an 86% yield of BuNCS.

The Reaction of *N*-Phenylsulfonyl Thione *S*-Imide with Acyl Halides[1)]

Seizo TAMAGAKI, Keishi SAKAKI, and Shigeru OAE[2)]

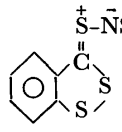
Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received January 21, 1975)

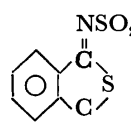
Synopsis. Thiocarbonyl *S*-imide of 1,2-dithiole-3-thione reacted with various acyl halides producing the corresponding *N*-phenylsulfonyl-1,2-benzodithiole-3-imine and elemental sulfur. The reaction was found to proceed *via* initial acylation on the nitrogen of the imide and was essentially acyl halide-catalyzed with regard to rearrangement.

The authors have shown previously that the *N*-phenylsulfonyl thione *S*-imide(I) underwent rearrangement accompanied by desulfurization producing product(II) either by heating in neat[3)] or by treating with various nucleophiles such as amines[4)] and mercaptans.[5)]

We have now extended the investigation to the reaction of I with several electrophilic reagents and it has been found that the *S*-imide(I) produces the corresponding *N*-phenylsulfonyl imine(II) in good yield upon treatment with a variety of acyl halides. This paper describes a detailed account of the reaction.



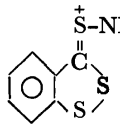
(I)



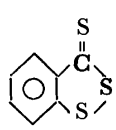
(II)

Results and Discussion

When the imide(I) was allowed to react with an equimolar amount of trichloroacetyl chloride at room temperature in CH_2Cl_2, yellowish elemental sulfur followed by a trace of hydrochloride(III) of the imide(I) precipitated from the solution within minutes, and then the imine(II) was isolated in a 75% yield along with a small amount of the reduction product, benzotrithione(IV), by preparative layer chromatography. The hydrochloride(III) seems to be produced by the reaction of imide(I) with the hydrochloric acid inevitably present or generated in normal reacting systems containing acyl halides.



Cl⁻ (III)



(IV)

As is seen from Table 1, only less than one-half an equimolar amount of trichloroacetyl chloride is sufficient to complete the reaction. This indicates clearly that the reaction is essentially acyl halide-catalyzed with regard to the rearrangement reaction, where the halide is utilized repeatedly during the reaction. In fact, after completion of the reaction with an equimolar amount of trichloroacetyl chloride, 75% of the halide remained unchanged.

The reactions with aroyl chlorides were likewise found to produce both the rearranged product and a trace amount of benzotrithione. The reaction times required for benzoyl chlorides bearing electron-donating substituents are longer than those with electron-capturing substituents. This implies that acylation of the nitrogen atom of the imide(I), leading to an intermediate(V), is the key step in the reaction. Meanwhile, both thionyl and sulfinyl chlorides can also react in a similar manner to produce the imine(II).

Thus, based on these results and intuitive considerations, the outline of the reaction scheme may be written as follows:

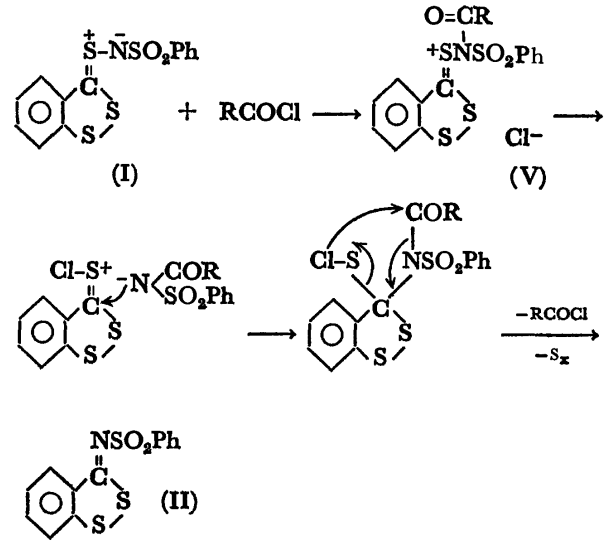


TABLE 1. ACYL HALIDE-CATALYZED REARRANGEMENT OF I IN CH_2Cl_2 AT ROOM TEMPERATURE

Halide	Mole ratio[a)]	Reaction time[b)]	Isolated yield, % II	IV

a) Ratio of I to acyl halide. b) Required time for the change in color of the solution from red to yellow. c) The amount of the remaining halide was determined as 75% using the IR absorption band at 1795 cm^{-1} due to the carbonyl group in trichloroacetyl chloride. d) For *p*-nitrophenylsulfonyl thione *S*-imide. e) for *p*-methylphenylsulfonyl thione *S*-imide. f) The low yield was mainly due to the formation of III. g) No yield was determined.

Experimental

A typical run is as follows. To *S*-imide(I) (339 mg, 1 mmol) in CH_2Cl_2 well-dried over $CaCl_2$ one equivalent of trichloroacetyl chloride dissolved in the same solvent was added at room temperature. After 5 min the solution turned yellow. The solvent was evaporated under reduced pressure and then the residue was separated b preparative tlc using benzene as the eluent. The yields thus obtained are listed in Table 1.

Kinetic Studies of the Thiol-catalyzed Rearrangement of *N*-Phenylsulfonyl Thione *S*-Imide[1)]

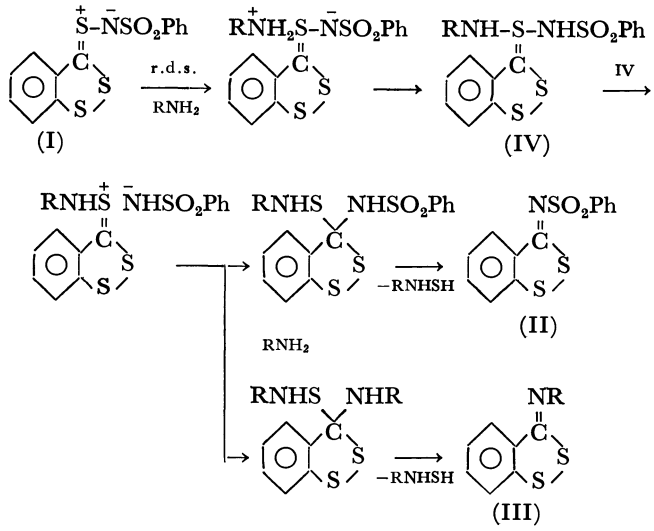
Seizo TAMAGAKI, Keishi SAKAKI, and Shigeru OAE[2)]

Department of Applied Chemistry, Faculty of Engineering, Osaka City University, Sugimoto-cho, Sumiyoshi-ku, Osaka 558

(Received January 27, 1975)

Synopsis. The *N*-phenylsulfonyl thione *S*-imide(I) of 1,2-dithiole-3-thione reacted catalytically with various thiols to afford the corresponding rearranged *N*-phenylsulfonyl-1,2-benzodithiole-3-imine(II) with the extrusion of the elemental sulfur together with a minor amount of reduced benzotrithione. A kinetic study of the rearrangement of I with thiobenzoic acid was performed, and a plausible mechanism is discussed.

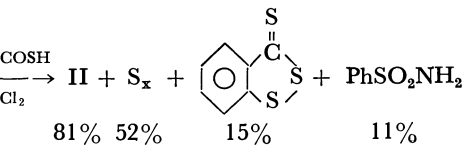
Recently we reported the reaction of I with a variety of amines to give the corresponding rearranged(II) and amine-exchanged(III) products. A detailed kinetic study of this reaction suggested that the rate-controlling step is the attack of amine on the tetravalent sulfur atom rather than on the carbon-3 of the thione *S*-imide(I) to give the addition complex(IV), which, in the subsequent step, yields an ion-pair that eventually collapses to give the products outlined below:



In this paper we wish to report our findings on an interesting rearrangement in which the thione *S*-imide(I) readily reacts catalytically with various thiols to afford mainly the same rearranged product(II) as in the amine-catalyzed rearrangement; however, the reaction was found to be quite different in its reaction mechanism from that with amines.

Results and Discussion

When I was treated with various inorganic sulfides, organic thiols, and thioacetic or thiobenzoic acid in CH_3CN or CH_2Cl_2 at room temperature, the precipitation of a yellowish, elemental sulfur was observed; furthermore, the rearranged product(II), benzotrithione, and the sulfonamide could be obtained.



The results of the product analyses are collected in Table 1. In order to focus our attention especially on the rearrangement of this hitherto unknown type, a kinetic study of the reaction between I and thiobenzoic acid was carried out in CH_3CN at about 20 °C. At the given initial thiobenzoic acid concentrations in the range of $1—5\times10^{-5}$ mol/l, the reaction was found to follow strictly first-order kinetics with regard to the thione *S*-imide (I) up to more than half-lives.

The plot of the pseudo-first-order rate constants (k_{obsd}) thus obtained against the thiobenzoic acid concentrations showed a fairly good straight line in the $1—5\times10^{-5}$ mol/l range, as shown in Fig. 1, while in the concentrations below this range the plot was found to shift the straight line upward. It seems likely that, in the range of high concentrations of thiobenzoic acid, the over-all reaction follows second-order kinetics essentially and that the reaction rate is not much affected by the occurrence of the reduction leading to the formation of benzotrithione and the

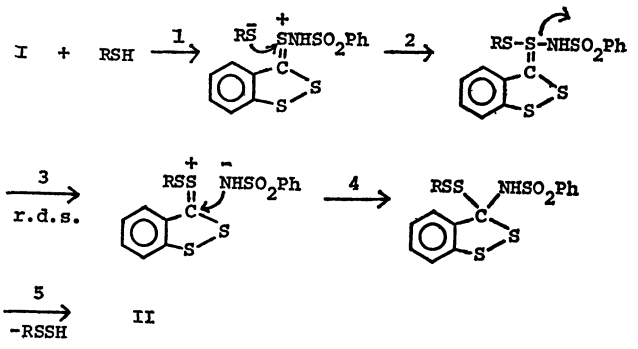
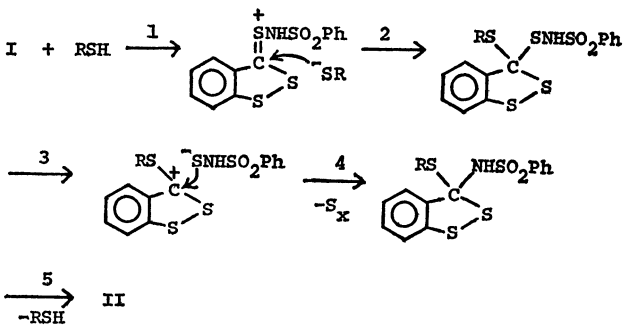
sulfonamide. The fact that I was recovered in a appreciable yield when I was treated with less than a one-fifth equiv. of thiobenzoic acid implies that the added acid was completely consumed by a side-reaction before the rearrangement was completed.

In order to clarify the mechanism, especially the rate-determining step of the reaction, the effects of the substituent and temperature on the rate were examined in CH_3CN as a solvent at the thiobenzoic acid concentration of 5×10^{-5} mol/l; the results are listed in Tables 2. An inspection of the data reveals that the *rho* values (ρ_X and ρ_Y) for the para-substituents, X in I and Y in thiobenzoic acid, are both positive, *i.e.*, 1.06 and 0.7 respectively. In sharp contrast to the previously reported reaction with amines ($\rho_X=+0.13$)[3] and phosphines ($\rho_X=+0.08$),[4] where the attack of the nucleophiles on the sulfur atom is considered to be rate-determining, the rate is very sensitive to the nature of the substituent(X). Thus, the fairly large value of ρ_X is fully consistent with Pathway I, as is shown below, when the reaction proceeds *via* the initial addition of thiobenzoic acid to the S–N moiety of I prior to the rate-controlling S–NSO_2 bond cleavage, eventually leading to the products *via* an ion-pair.

Another pathway involving the rate-determining nucleophilic attack of RS^- on the sulfur atom can readily be ruled out, since the activation energy for the reaction involving the rate-determining addition



Path I.



Path II.

(Step 2 in Path I) would be low; it is estimated to be around 5 kcal/mol based on the activation energeis of 4±1 and 3±2 kcal/mol for the reactions with amines and phosphines respectively.

The large ρ_X value offers strong evidence against Pathway II, which proceeds through the rate-determining carbon attack. The HASB principle also seems to support the above conclusion, since a soft nucleophile(RS^-) tends to attack a soft electrophilic sulfur center rather than a hard electrophilic carbon center.[5]

Hence, the study of the effects of substituent and temperature on the rearrangement shows that both the large ρ_X value and an energy of activation as large as 12 kcal/mol are in accordance with the mechanism involving the S–N bond breaking in the rate-determining step.

Experimental

A typical run is as follows: to the imide(I)(339 mg, 1 mmol) in CH_2Cl_2, an equivalent thiol dissolved in the same solvent was added at room temperature. After 5 min, the solution turned yellow. The solvent was evaporated under reduced pressure, and then the residue was separated by preparative tlc using benzene. The yields thus obtained are listed in Table 1. The rate constants (k_{obsd}) were determined spectrophotometrically by the usual procedure.

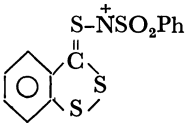
(Received March 17, 1975)

Synopsis. *N*-Phenylsulfonyl thione *S*-imide(I) was reduced with tetra-*n*-butylammonium bromide and iodide in the presence of trichloroacetic acid to yield benzotrithione and the sulfonamide in good yields. The kinetics of the reaction was performed, and the mechanism was discussed in detailed.

Earlier we reported[1] the isolation and characterization of the thione *S*-imide(I) formed in the reaction of chloramine-B with 1,2-benzodithiole-3-thione (benzotrithione).



(I)

Our primary interest in this new type of the compound was to elucidate the mechanism of its formation. Previously,[2] the reaction of diphenyl sulfide with chloramine-T was found to be acid-catalyzed and to take place through an initial chlorination of the sulfur atom to give the chlorosulfonium ion, followed by nucleophilic displacement with the sulfonamide anion; the rate-limiting step is the former rather than the latter step.

Quite contrary to the rate of common sulfilimide formation, the thione *S*-imide formation did not allow us to determine its rate because the rate of the reaction was too fast for us to employ the usual techniques even at a neutral pH. The object of the present study was to examine the reduction of the thione *S*-imide with halide, since although the rate of the formation could not be followed by our usual means, as has been stated above, an examination of the reduction should clarify the mode of its reverse reaction, *i.e.* the formation, according to the microscopic reversibility principle.

Results and Discussion

When the thiocarbonyl *S*-imide(I) was treated with an equimolar amount of tetra-*n*-butylammonium bromide (Br^-) or iodide in CH_3CN containing a five-fold excess of trichloroacetic acid (H^+) at room temperature for 20 min, benzotrithione and benzenesulfonamide were both obtained in excellent yields.

The reaction was catalyzed essentially by acids with pH values of a moderate strength. In fact, a weak acid such as acetic acid with a pH of 4.76 did not catalyzed the reduction, not even in a neat acetic acid solution.

The kinetic study of the reaction of *S*-imide with bromide was carried out in some detail by adding a large excess of acid and by monitoring the increase in the absorbance due to the reduced trithione appearing at 445 nm. At high acid concentrations, as the UV spectra indicate, all the *S*-imide has been protonated on the nitrogen atom; that is, the protonated *S*-imide is the only predominant species at the initial stage of the reaction. Indeed, there is an isosbestic point at 443 nm between the benzotrithione produced and what appears to the protonated *S*-imide (Fig. 1). The data for the substituent effect on the rate are collected in Table 1, where k_0 is the observed first-order-rate constant of the reaction, which follows simple first-order kinetics.

First, we attempted to determine the kinetic order with regard to both the acid and bromide concentrations. At a large excess of acid concentrations relative to the *S*-imide, additional protic acid did not play any important role in accelerating the rate, as is shown in Fig. 2. Under these reaction conditions, kinetic experiments at different initial concentrations of bromide salt were performed and showed that the rate constants(k_0) thus determined did not follow the usual first-order kinetics with regard to the bromide concentrations, but gave a correlation represented by a down-concave curvature, as is shown in Fig. 3.

In the initial range of the plot the rate appears to obey first-order kinetics, while at the higher bromide concentrations the rate appears to be essentially independent of the bromide concentration. It thus seems clear that the reaction is indeed consistent with

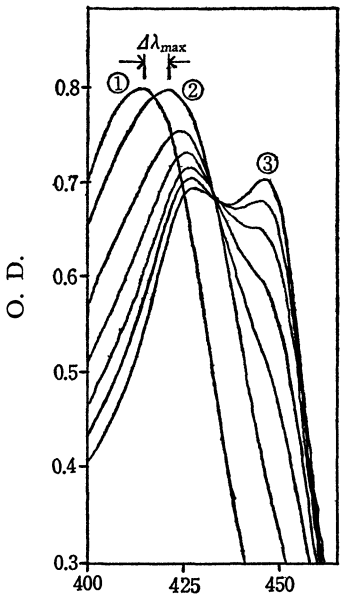


Fig. 1. Reduction of I with Br^- in the presence of Cl_3CCOOH.

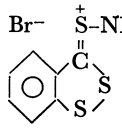
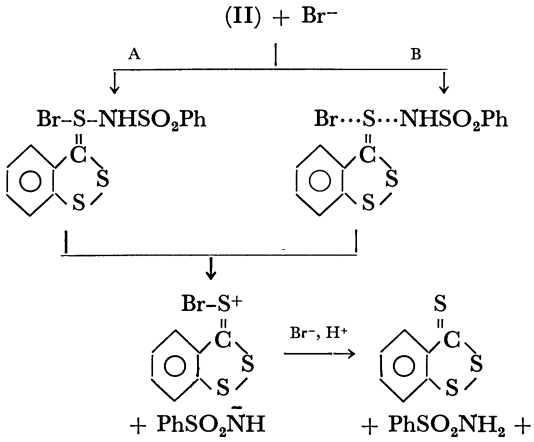
step-by-step processes involving the buld-up of at least one Br^--containing intermediate, which we assumed to be an intimate ion-pair(II).



ion-pair (II)

In Fig. 3 a plot of the change of the UV maxima against varying bromide concentrations is also shown. An inspection of Fig. 3 reveals that the change in the absorption maximum by varying the bromide concentration gives a good parallelism with the change in the rates. This observation can best be accounted for by a specific solute-solute interaction between the protonated *S*-imide and Br^-; that is, the reduction takes place *via* the formation of quite a stable intimate ion-pair intermediate(II).

The Hammett plot of the data(Table 1) gives the best linear correlation with the σ_p values for the para-substituted *S*-imide. The direction of the substituent effect is shown by the large, positive value of $\rho=0.9$ indicating that, in the rate-determining step, the S-NSO_2 bond cleavage apparently takes place. The two reaction mechanisms, A and B, fit the experimental data thus obtained.



Both the activation energy and entropy, 13 kcal/mol and −25 eu respectively, at $[Br^-]=8.01\times10^{-4}$ M and $[H^+]=1.21\times10^{-1}$ M are well consistent with these mechanisms. The first one (A) involves the addition-elimination of the nucleophilic Br^- ion on the sulfur atom, followed by the rate-determining N-S bond cleavage, leading to a bromonium salt and eventually giving the reduced trithione. Meanwhile, the (B) mechanism resembles that outlined for a usual S_N2 reaction on a carbon atom; this process requires a one-step displacement of the leaving sulfonamide anion by the bromide anion.

Based on only the limited data available it is difficult to decide whether or not this reduction involves an discrete addition intermediate. However, a more plausible mechanism would be the process like A which includes the intervention of an addition complex in which the entering and leaving groups are bonded to the central sulfur atom. Such a hypervalent intermediate has been documented in other substitution reactions[3] and, in some cases, isolated.[4] In fact, quite a structurally similar planar compound has recently been synthesized.[5]

Finally, it should be emphasized that the Br^--reduction itself is the reverse of the formation of the

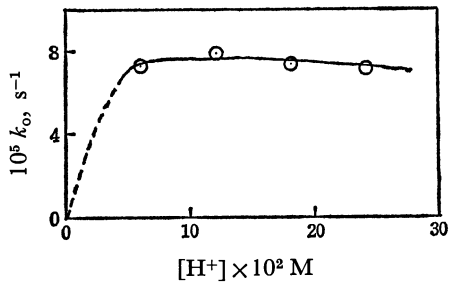


Fig. 2. Plot of the rate constant against acid concentration at 25 °C in CH_3CN. $[Br^-]=8.01\times10^{-4}$ M, $[I]=1.00\times10^{-4}$ M.

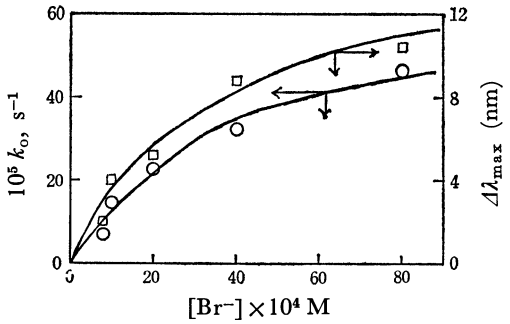

Fig. 3. Plots of the rate constant and $\Delta\lambda_{max}$ against Br^- concentration in the presence of a large excess of acid at 25 °C in CH_3CN. $[CCl_3COOH]=1.21\times10^{-1}$ M, $[I]=1.00\times10^{-1}$ M.

S-imide from the trithione and chloramine-B. From a consideration of the microscopic reversibility, it can be said that the *S*-imide is probably produced not by the mechanism involving the initial halogenation as the rate-controlling step, but rather, by the rate-determining attack of the sulfonamide anion on the halogenated trithione in sharp contrast to the mechanism of the formation of the sulfilimide where the halogenation is the rate-determing step.[2]

Experimental

Kinetics. The rates were determined spectrophotometrically by employing the usual techniques.

Products. The *S*-imide (339 mg) was treated with an equimolar amount of tetra-*n*-butylammonium bromide and a five-fold excess of Cl_3CCOOH in CH_3CN at room temperature. After 20 min, the solvent was evaporated *in vacuo* and the residue was treated with a dilute $Na_2S_2O_3$ solution. Extraction with ether, the evaporation of the ether, and the chromatographic separation of the extract on silica plates, using benzene as the eluent, gave benzotrithione (85.9%) as well as benzenesulfonamide (91.1%)

Synopsis. The reaction of penicillin *S*-oxides (**1a,b**) with *N*-bromosuccinimide afforded sulfinyl bromides (**2a,b**) in high yields. The bromides were converted into cephalosporin *S*-oxides (**4a**, **4b**, **6a**, and **7a**) in fairly good yields.

It is well known that sulfenic acid is generated by a thermal sigmatropic rearrangement of penicillin *S*-oxide. The highly reactive sulfenic acid has been trapped by several methods.[1,2] We have also investigated a method for trapping sulfenic acid with the objective of the preparation of a useful intermediate for the synthesis of cephalosporin analogues. In this paper the reaction of penicillin *S*-oxides with *N*-bromosuccinimide (NBS) is described and a few examples of the conversion of the produced sulfinyl bromides into cephalosporin *S*-oxides are noted.

The reaction of methyl 6-phthalimidopenicillinate 1-oxide (**1a**) with 1 equivalent of NBS in boiling CCl_4 afforded sulfinyl bromide (**2a**) in high yield. The NMR spectrum of **2a** resembles closely that of the corresponding sulfinyl chloride, prepared by the reaction of **1a** with sulfuryl chloride according to the method of Kukolja *et al.*[3] The structural assignment of **2a** is also supported by the reaction of **2** with aniline; readily reacted with 2 equivalents of aniline to give sulfinamide (**3a**).

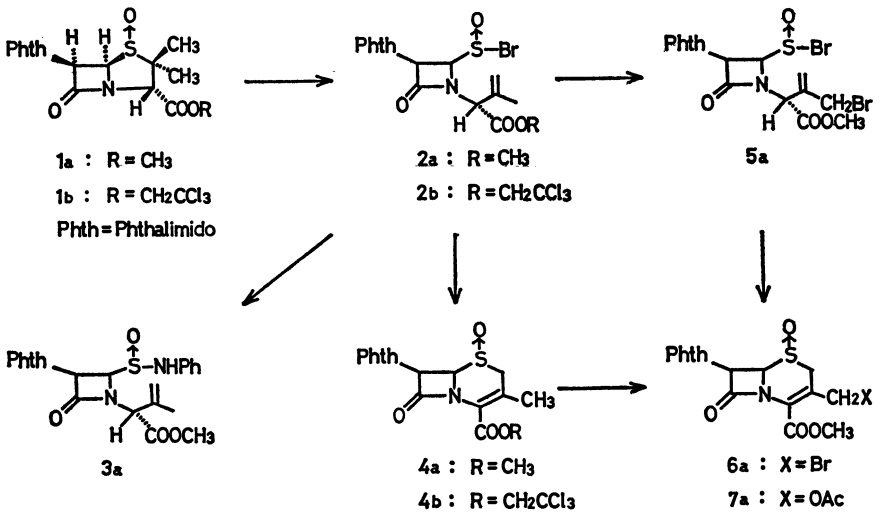
A noteworthy fact is that **2a** was successfully converted into cephem *S*-oxide by the action of 1 equivalent of tertiary amine. When **2a** was treated with triethylamine in CCl_4, the ring-closed product **4a** was obtained in 47% yield. In a similar manner, trichloroethyl ester *S*-oxide (**1b**) was transformed into the corresponding cephem *S*-oxide (**4b**).

In connection with the above results, we examined the preparation of 3-bromomethyl cephem *S*-oxide (**6a**) and 3-acetoxymethyl cephem *S*-oxide (**7a**). The reaction of **2a** with NBS in the presence of benzoyl peroxide (BPO) in boiling CCl_4 provided **5a** (not isolated), which, on subsequent treatment with triethylamine, gave **6a** in 33% yield. The direct bromination of **4a** with excess NBS in the presence of BPO in boiling benzene also afforded **6a**. The bromide **6a** was then acetoxylated by the action of AgOAc in AcOH to give **7a** in 45% yield.

Experimental

Preparation of Methyl 3-Methyl-2-(2-bromosulfinyl-4-oxo-3-phthalimido-1-azetidinyl)-3-butenoate (2a). A mixture of methyl 6-phthalimidopenicillinate 1-oxide (**1a**) (376 mg, 1 mmol) and NBS (178 mg, 1 mmol) in 15 ml of CCl_4 was refluxed for 1.5 hr under N_2. The precipitated succinimide was removed by filtration and the filtrate was evaporated to afford a yellow amorphous solid. This product was found from its NMR spectrum to be a 2 : 1 mixture of the two diastereomers of the compound **2a** which were epimeric at sulfur.[4] Yield, 442 mg (97%). NMR ($CDCl_3$): major component, δ 1.96 (3H, br. s), 3.84 (3H, s), 5.03 (2H, br. s), 5.20 (1H, br. s), 5.85 (1H, d, J=5 Hz), 6.08 (1H, d, J=5 Hz), 7.83 (4H, m); minor component, δ 2.00 (3H, br. s), 3.84 (3H, s), 4.90 (2H, br. s), 5.12 (1H, br. s), 5.82 (1H, d, J=5 Hz), 6.08 (1H, d, J=5 Hz), 7.83 (4H, m).

Reaction of 2a with Anilline. Into the solution of **2a** in CCl_4, prepared from 1 mmol of **1a** by the above procedure, anilline (232 mg, 2.5 mmol) was added with stirring at 0 °C. The mixture was then diluted with CH_2Cl_2, washed with water, and dried ($MgSO_4$). The evaporated residue was purified by silica gel chromatography using C_6H_6-AcOEt (2 : 1) as the eluent to give the pale yellow amorphous solid of methyl 3-methyl-2-(2-anilinosulfinyl-4-oxo-3-phthalimido-1-azetidinyl)-3-butenoate (**3a**) (389 mg, 83% yield). Softening point 100—120 °C. UV (EtOH): λ_{max} 207 nm (ε 40700), 221 (50400), and 290 (2400). IR (KBr): 1790 (β-lactam) and 1065 cm^{-1} (S=O). NMR ($CDCl_3$): δ 1.92 (3H, br. s),



3.59 (3H, s), 4.73 (1H, br. s), 4.82 (1H, br. s), 5.02 (1H, br. s), 5.86 (1H, d, J=5 Hz), 6.29 (1H, d, J=5 Hz), 6.80 (5H, m), 7.63 (1H, s), 7.81 (4H, m). Found: C, 59.21; H, 4.67; N, 8.52%. Calcd for $C_{23}H_{21}N_3O_6S$: C, 59.09; H, 4.53; N, 8.99%.

Reaction of ***2a*** *with Triethylamine.* Into the solution of **2a** in CCl_4, prepared from 1 mmol of **1a** by the above procedure, triethylamine (120 mg, 1.2 mmol) was added at 0 °C. After stirring for 20 min, the mixture was diluted with CH_2Cl_2, washed with water, and dried ($MgSO_4$). The evaporated residue was chromatographed on silica gel using AcOEt as the eluent to afford methyl 3-methyl-7-phthalimido-3-cephem-4-carboxylate 1-oxide (**4a**) (175 mg, 47% yield); mp 212—214 °C (dec) (from MeOH) (lit,[3] 215 °C (dec)). UV (EtOH): λ_{max} 221 nm (ε 40700) and 264 (4900). IR (KBr): 1795 (β-lactam) and 1055 cm^{-1} (S=O). NMR ($CDCl_3$): δ 2.35 (3H, s), 3.49 (1H, d, J=16 Hz), 3.84 (3H, s), 4.13 (1H, d, J=16 Hz), 4.65 (1H, d, J=5 Hz), 6.03 (1H, d, J=5 Hz), 7.79 (4H, m). Found: C, 54.34; H, 3.75; N, 7.37%. Calcd for $C_{17}H_{14}N_2SO_6$: C, 54.54; H, 3.77; N, 7.48%.

*Preparation of Trichloroethyl 3-Methyl-7-phthalimido-3-cephem-4-carboxylate 1-Oxide (****4b****).* In a procedure similar to that described above, **4b** was obtained in 54% yield. Mp 200—202 °C (dec) (from MeOH). UV (EtOH): λ_{max} 221 nm (ε 50900) and 271 (5700). IR (KBr): 1800 (β-lactam) and 1055 cm^{-1} (S=O). NMR ($CDCl_3$): δ 2.44 (3H, s), 3.67 (1H, d, J=16 Hz), 4.19 (1H, d, J=16 Hz), 4.68 (1H, d, J=5 Hz), 4.90 (2H, s) 6.07 (1H, d, J=5 Hz), 7.81 (4H, m). Found: C, 44.20; H, 2.72; N, 5.97%. Calcd for $C_{18}H_{13}N_2O_6SCl_3$: C, 43.96; H, 2.66; N, 5.70%.

*Preparation of Methyl 3-Bromomethyl-7-phthalimido-3-cephem-4-carboxylate 1-Oxide (****6a****).* *Method A*: A mixture of **1a** (3.76 g, 10 mmol) and NBS (1.78 g, 10 mmol) in 150 ml of CCl_4 was heated at refluxing temperature for 1.5 hr under N_2. After cooling to room temperature, NBS (2.67 g, 15 mmol) and BPO (300 mg) were added and the mixture was refluxed for 3 hr under N_2. The reaction mixture was then chilled in an ice bath, and triethylamine (1.50 g, 15 mmol) was added. After stirring for 20 min, the mixture was diluted with CH_2Cl_2, washed with water, and dried ($MgSO_4$). The evaporated residue was purified repeatedly by chromotography on silica gel using C_6H_6-AcOEt (2 : 1) as the eluent to give the amorphous solid of **6a** (1.40 g, 33% yield). Softening point 130—140 °C. UV (EtOH): λ_{max} 221 nm (ε 43200) and 278 (8500). IR (KBr): 1800 (β-lactam) and 1045 cm^{-1} (S=O). NMR ($CDCl_3$): δ 3.68 (1H, d, J=16 Hz), 3.92 (3H, s), 4.23 (1H, d, J=16 Hz), 4.55 (2H, s), 4.73 (1H, d, J=5 Hz), 6.08 (1H, d, J=5 Hz), 7.85 (4H, m). Found: C, 45.29; H, 2.94; N, 6.26%. Calcd for $C_{17}H_{13}N_2O_6SBr$: C, 45.05; H, 2.89; N, 6.18%.

Method B: A solution of **4a** (374 mg, 1 mmol), NBS (445 mg, 2.5 mmol), and BPO (50 mg) in 20 ml of benzene was refluxed for 3 hr. The reaction mixture was worked up in a similar procedure to that described above to give **6a** (80 mg, 18% yield).

*Preparation of Methyl 3-Acetoxymethyl-7-phthalimido-3-cephem-4-carboxylate 1-Oxide (****7a****).* To a solution of **6a** (453 mg, 1 mmol) in 4 ml of AcOH, a suspension of AgOAc (200 mg, 1.2 mmol) in 4 ml of AcOH was added with stirring; the stirring was continued for 1 hr. The reaction mixture was filtered to remove the silver salts, and the filtrate was diluted with AcOEt. The solution was then washed successively with water, 3% $NaHCO_3$, and water. After drying over $MgSO_4$, the solvent was evaporated and the residue was purified by chromatography on silica gel using C_6H_6-AcOEt (1 : 1) as the eluent to give the colorless amorphous solid of **8a** (178 mg, 45% yield). Softening point 105—125 °C. UV (EtOH): λ_{max} 221 nm (ε 45100) and 267 (5600). IR (KBr): 1800 (β-lactam) and 1045 cm^{-1} (S=O). NMR ($CDCl_3$): δ 2.10 (3H, s), 3.58 (1H, d, J=16 Hz), 3.89 (3H, s), 4.14 (1H, d, J=16 Hz), 4.68 (1H, d, J=5 Hz), 4.91 (1H, d, J=14 Hz), 5.79 (1H, d, J=14 Hz), 6.06 (1H, d, J=5 Hz), 7.82 (4H, m). Found: C, 52.92; H, 3.77; N, 6.46%. Calcd for $C_{19}H_{16}N_2O_8S$: C, 52.77; H, 3.73; N, 6.48%.

The authors wish to express their sincere appreciation to Mr. Osamu Sakanaka for his assistance.

Cryptate Chemistry. I. The Reaction of Potassium Alkanoates with Alkyl Halides in the Presence of 4,7,13,16,21,24-Hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane

Sadatoshi AKABORI and Michiko OHTOMI

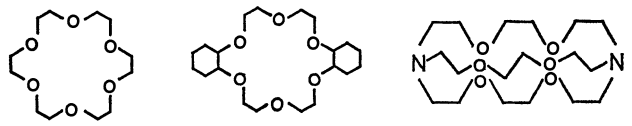
(Receieved April 19, 1975)

Synopsis. Potassium alkanoates reactes with organic halides in the presence of bicyclopolyether (III) in benzene to give esters in high yields.

In recent years, many papers[1-3] have been published reporting that such crown ethers as I and II increase the solubility of salts and the reactivity of anions in aprotic solvents. For example, Sam and Simmons[4] have reported that the complexes of potassium halide and potassium hydroxide with dicyclohexyl-18-crown-6 (II) show strong nucleophilic and basic properties.



(I) (II) (III)

Liotta *et al.*[5] have observed that potassium fluoride and the potassium acetate complex of 18-crown-6 (I), which he termed the "naked anion" in non-polar aprotic solvents, have shown unusual properties and reactivities. Dietlich *et al.*[6-7] have reported the preparation and properties of a number of macrobicyclic polyethers with bridgehead nitrogens, such as 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]-hexacosane (III). It was shown that these compounds form stable complexes, cryptate, with alkali, alkaline earth, and other cations, and that the complexing ability of the cryptates could be correlated with the number of ligand sites, the approximate cavity size of the bicyclopolyether, and the relative cation radius in question. Our interest in the reactivities of these cryptates in aprotic solvents led us to examine the reactivities of the potassium salts of acids with some halides in the presence of III in benzene.

Nucleophilic substitution was carried out by the following method. The carboxylate complex of III was prepared by dissolving a catalytic amount of III in 7 ml of dry benzene and by then adding an appropriate amount of dry potassium salts of acids. After the heterogenious system had then been stirred for 30 min, the alkyl halide was added all at once and the mixture was stirred for a further 3 hr at 15 or 83 °C. Table 1 summarizes the results.

The data in the table clearly show that the cryptates prepared by mixing III with potassium alkanoates in benzene are sufficiently reactive to form organic esters from organic halides at an appropriate temperature. Indeed, in the absence of III, no reaction takes place under the same conditions. Benzyl bromide gives less than 2% benzyl acetate after 10 hr at room temperature when it is treated with potassium acetate in the absence of III, whereas benzyl acetate is formed quantitatively within 3 hr when III is present. The reaction of the cryptate complex from potassium propionate with 1,2-dibromoethane afforded a mixture of ethylene dipropionate and 2-bromoethyl propionate. The ratio of the two substances is dependent upon which reagent is present in excess. Another

$BrCH_2CH_2Br$ (0.500)	CH_3CH_2COOK (2.00)	(0.133)	83	89 11	$CH_3CH_2COOCH_2CH_2OCOCH_2CH_3$ $BrCH_2CH_2OCOCH_2CH_3$

a) The values are those obtained by glc. b) All products show the same retention time with authentic sample and mass spectra were consistent with the proposed structure. Reaction of *n*-octyl bromide with potassium alkanoates afforded octene in less than 0.3% yield.

feature of the reaction with the aid of the cryptate is the low degree of the formation of the olefin. *n*-Octyl bromide afforded less than 0.3% of 1-octene.

The main conclusions to be drawn from these results are as follows: 1) cryptate carboxylate can be used as an extremely valuable reagent in the preparation of alkyl esters in non-polar aprotic solvents such as benzene, and 2) cryptate carboxylate is a powerful nucleophile but a weak base.

Experimental

The gas chromatograms were obtained on a Hitachi K 23 apparatus using the following column; 10% FFAP on Chromosorb W AW/DMCS 1 m×3 mm. The mass spectra were recorded on a gas-chromatography mass spectrometer, Shimadzu LKB 9000, at an ionizing voltage of 70 eV.

Materials. Compound (III) was prepared according to the procedures described in the literature.[6] Potassium alkanoates of the Tokyo Kasei Kogyo Co., Ltd., were used without further purification. *n*-Octyl bromide and benzyl bromide of the Tokyo Kasei Kogyo Co., Ltd., were purified by distillation prior to use.

Solvent. The solvent used was purified by distillation.

General Procedure. To a solution of III in 7 ml of benzene, we added potassium alkanoate, after with the mixture was stirred for 30 min at room temperature. To the mixture we then added organic halide and continued stirring for a further 3 hr at 15 °C or 83 °C. At the end of the reaction, the organic layer was analyzed by gas chromatography and gas-chromatography mass spectrometer.

The authors wish to express their gratitude to Professor Michinori Ōki, the University of Tokyo, for his valuable discussions and suggestions.

Synthesis and NMR Spectra of *para*-Substituted Benzyl Hydrodisulfides and Related Compounds

Shunichi KAWAMURA, Toyokazu HORII, Takeshige NAKABAYASHI, and Masayuki HAMADA

Radiation Center of Osaka Prefecture, Shinke-cho, Sakai, Osaka 593

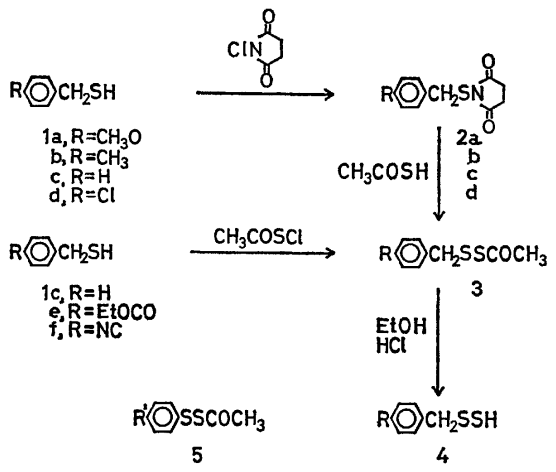
(Received May 29, 1975)

Synopsis. The titled compounds were synthesized and their NMR spectra were measured. The chemical shifts of benzyl hydrodisulfides were not related to σ or σ_R, while those of the corresponding thiols were related to σ.

In an NMR study of *para*-substituted phenyl hydrodisulfides, we have found a novel correlation for the chemical shifts of the mercapto protons.[1] The correlation, $\tau_{SSH}=0.263\sigma_R+6.653$ ($r=0.993$),[2] includes the chemical shift which is only related to the resonance term, and includes also a large positive ρ value. It has thus been postulated that the substituent effect in the *para*-substituted phenyl hydrodisulfides is conducted to the terminal protons anisotropically.

In the present work, the synthesis of *para*-substituted benzyl hydrodisulfides through a slightly modified route has been attempted, and the NMR spectra of the compounds have also been measured. The chemical shifts of mercapto and methylene protons of the compounds are interesting, because different correlations for the two kinds of protons are anticipated; the chemical shifts of mercapto protons should be related to σ_R, and those of methylene, to σ.

α-Toluenethiols having methoxy, methyl, or chlorine at the *para*-position (**1a, 1b**, and **1d**) were allowed to react with *N*-chlorosuccinimide, giving *N*-(*p*-substituted benzylthio)succinimides in 22—35% yields (**2a, 2b**, and **2d**).[3] By the condensation of the *N*-aralkylthiosuccinimides with thioacetic acid, acetyl *p*-substituted benzyl disulfides (**3a, 3b**, and **3d**) were obtained in moderate yields. This reaction is an application of the synthesis of thiolsulfonates from *N*-(arylthio)-succinimides and arenesulfinic acids.[4] Acetyl disulfides **3e** and **3f** were prepared by the reactions of **1e** and **1f** with acetylsulfenyl chloride, respectively.[5] Compound **3c** could be obtained by both methods mentioned above. The acetyl *p*-substituted benzyl disulfides obtained were ethanolyzed in the presence of hydrogen chloride. Of the resulting hydrodisulfides, **4b, 4d**, and **4e** were distilled under high vacuum to give products in 18—54% yields. However, **4a** and **4f** were unstable on distillation; in the case of **4a**, only 2.5% of the product was isolated and no product was obtained for **4f** (see experimental). The hydrodisulfides **4a—f** were stable in solvents such as carbon tetrachloride and chloroform.



The chemical shifts of the benzyl hydrodisulfides and related compounds are shown in Table 1. The chemical shifts of mercapto protons of *p*-substituted α-toluenethiols fit the thermodynamic relationship, $\tau_{SH}=-0.149\,\sigma+8.496$ ($r=0.978$). The ρ value (−0.149) is about a half of that for benzenethiols,[6] which is reasonable because it has been demonstrated that the insertion of methylene carbon atom into a side chain (in the present case, R-C_6H_4-CH_2-SH) diminishes ρ to 1/2—1/3 of its original value.[7] For the methylene protons of the α-toluenethiols, $\tau_{CH_2}=-0.103\,\sigma+6.330$ ($r=0.929$) was obtained. The correlation coefficient is not sufficiently large, and ρ is too small for protons of R-C_6H_4-CH(SH)-**H**. These facts imply that some other effects, *e.g.*, a stereochemical effect as well as an electronic effect, reflect the chemical shift of the protons.

The chemical shifts of protons (both SSH and CH_2) of *p*-substituted benzyl hydrodisulfides **4** were related

neither to σ nor to σ_R, the correlation coefficients did not exceed 0.90. It should be noted that even the chemical shifts of the methylene protons of the hydrodisulfides were not represented by the Hammett equation. These complicated results remind us of the restricted rotation of the sulfur-sulfur bond.[8] If it is true that the sulfur-sulfur group in the phenyl hydrodisulfide was almost fixed in the same plane as the benzene ring, the CH_2-S-S-H group would be relaxed in motion owing to its methylene carbon, and this relaxation would bring about a deviation from a correlation with the chemical shift.

The chemical shifts of acetyl disulfides **3** and **5** were also measured in connection with the above compounds. The shifts of methyl protons of **5** showed no relation for σ or σ_R. A similar relaxation of the restricted rotation of S-S bond can be also seen in this case. The differences among the chemical shifts of the methyl protons of **3a**—**f** are small; these protons seem too distant from the substituents for any substituent effect to be detected. Also, the methylene protons of these compounds were not connected to the character of the substituents.

Experimental

Melting points are corrected. NMR spectra were recorded on a JEOL MH-100 Spectrometer using carbon tetrachloride or deuteriochloroform as solvent and TMS as internal lock. Chemical shifts were determined by use of a frequency counter. The chemical shifts reported in Table 1 were values at infinite dilution, which were obtained by extrapolation of four concentrations (2.5, 5, 7.5, and 10 w/v%).

Benzyl hydrodisulfide[5] and acetyl *p*-substituted phenyl disulfides[1] were obtained by the procedures described previously.

*N-(p-Substituted benzylthio)succinimides (**2a**, **2b**, and **2d**)* were prepared by the reaction[3] of *N*-chlorosuccinimides with *p*-substituted α-toluenethiols.[9] Two recrystallizations from ethanol (70 °C) gave **2a**, mp 139.2—140.2 °C (22%); **2b**, mp 180.7—181.3 °C (26%); **2d**, mp 188.2—189.5 °C (35%).

Found for **2a**: C, 57.18; H, 5.21; N, 5.27; S, 12.11%. Calcd for $C_{12}H_{13}O_3NS$; C, 57.35: H, 5.21; N, 5.57; S, 12.76%.

Found for **2b**: C, 61.37; H, 5.56; N, 5.73; S, 13.19%. Calcd for $C_{12}H_{13}O_2NS$: C, 61.25; H, 5.57; N, 5.95; S, 13.62%.

Found for **2d**: C, 51.75; H, 3.89; N, 5.30; S+Cl, 25.57%. Calcd for $C_{11}H_{10}O_2ClNS$: C, 51.67; H, 3.94; N, 5.48; S+Cl, 26.40%.

Acetyl p-Substituted Benzyl Disulfides. *A. Procedure for **3a**—**d***: These compounds were obtained by a method similar to that of thiolsulfonate synthesis from *N*-(*p*-tolylthio)-succinimide and *p*-toluenesulfinic acid.[4] A mixture of **2a** (7 mmol), thioacetic acid (7.35 mmol, 5% excess), and benzene (30 ml) was stirred for 2 hr at room temperature. The mixture was allowed to stand overnight. The white precipitate of succinimide formed was filtered off. The filtrate was evaporated under reduced pressure. Crude **3a** was crystallized out from the solution of the residue in petroleum ether by cooling (−18 °C, then 2 °C). Immediate pumping out of the solvent after recrystallization from petroleum ether (2 °C) produced 77% yield of **3a** with mp 22 °C. Disulfides **3b** and **3d** were prepared similarly. Disulfide **3c** obtained by Procedure A showed mp 54.5—56 °C (*cf.* by Procedure B, mp 54—55 °C). The analytical data is summarized in Table 2.

*B. Procedure for **3e** and **3f***: To a solution of *p*-ethoxycarbonyl-α-toluenethiol (10 mmol) in ether (20 ml) was added a solution of acetylsulfenyl chloride (10 mmol) in carbon tetrachloride with stirring and cooling (−2 °C to −5 °C) for 10 min. After 1 hr, the solution was evaporated *in vacuo*. To the residue 3 ml of petroleum ether was added, and then the treatment described in A was followed. Disulfide **3e** was obtained in a good yield. Disulfide **3f** was prepared similarly; its analytical data as well as those for **3e** are listed in Table 2.

p-Substituted Benzyl Hydrodisulfides. A mixture of acetyl *p*-substituted benzyl disulfide (**3a**, **3b**, **3d**, **3e**, or **3f**, 0.5 g) and 0.83 M ethanolic hydrogen chloride (6 ml) was stirred at 26—28 °C under a nitrogen atmosphere. After several hours (4 hr for **3a**, **3b**, and **3d**, 5 hr for **3e**, and 7 hr for **3f**), the resulting solution was evaporated under reduced pressure. The oil obtained was distilled under vacuum. On distillation, *p*-methoxybenzyl hydrodisulfide **4a** was unstable and its major portion decomposed. *p*-Cyanobenzyl hydrodisulfide **4f** was quite unstable and decomposed immediately after its formation, unless it was dissolved in solvents such as carbon tetrachloride and chloroform.

Such being the case, the NMR spectrum of **4f** was measured using a carbon tetrachloride solution of a neat sample without distillation. It was confirmed with all the other hydrodisulfides mentioned here that the differences between the chemical shifts of a sample obtained from distilled hydrodisulfide and those without distillation were within 0.5 Hz (av. 0.2 Hz).

The yields and boiling points of the hydrodisulfides were as follows: **4a** 2.5%, *ca.* 90 °C, decomp/0.01 mmHg; **4b**, 38%, 91—96 °C/0.02 mmHg; **4d**, 54%, 90—95 °C/0.01 mmHg; **4e**, 18%, 117—120 °C/0.01 mmHg.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(10), 2995—2996 (1975)

Diels-Alder Reaction of 2-Methyl-2-cyclohexenone and Substituted Butadienes[1)]

Isao NAGAKURA, Haremi OGATA, Masako UENO, and Yoshio KITAHARA*

Department of Chemistry, Faculty of Science, Tohoku University, Aramaki, Aoba, Sendai 980

(Received June 16, 1975)

Synopsis. Diels-Alder adducts of 2-methyl-2-cyclohexenone and substituted butadienes were obtained in a high yield in the presence of catalytic aluminum chloride.

Eremophilane type sesquiterpenoids possess the basic skeleton (I) and syntheses of these compounds have been reported.[2-5)] One of the important problems for elaboration of eremophilane type skeleton is a construction of *cis* fused six-membered rings. Diels-Alder reaction is expected to be a useful method for synthesis of these *cis* fused rings. Although Diels-Alder reactions of 2-methyl-2-cyclohexenone with substituted butadienes have been reported,[6-8)] the addition products were generally formed in a low yield. It has been known that some of the Diels-Alder reactions are catalyzed by Lewis acids,[9)] but dienes are unstable under these acidic conditions. Now we found that in the presence of catalytic aluminum chloride, Diels-Alder reaction afforded the adducts in a satisfactory yield (Table 1).

The reaction between 2-methyl-2-cyclohexenone and butadiene proceeded smoothly at room temperature in the presence of one tenth mole of aluminum chloride to dienophile in methylene chloride and adduct (II) was obtained in a good yield (95%). A small amount of hydroquinone was added to prevent polymerization of diene. Under the same reaction condition, however, both reactions of 3-methyl-2-cyclohexenone and 2,3-dimethyl-2-cyclohexenone with butadiene did not give any addition products. On the other hand, the reaction of 2-methyl-2-cyclohexenone with isoprene or piperylene in methylene chloride gave the adducts (III or IV) in a poor yield and a resinous material was obtained. The reason may be due to that the rate of the polymerization of diene is faster than that of the addition of diene to dienophile. In benzene, the adduct, III or IV, was obtained, but the reaction was very slow. When this reaction was carried out in the presence of one forth mole of aluminum chloride to dienophile in benzene, the reaction took place smoothly, and the adducts III and IV were obtained in a high yield. Structures of the adducts described above were determined by NMR.

These results seem to be of considerable utility for building up *cis* fused rings of eremophilane type sesquiterpenoids and several examples of the successful total syntheses have been reported.[9)]

Experimental

General Procedure. To an ice cooling suspension of $AlCl_3$ in solvent was added dropwise dienophile. $AlCl_3$ was dissolved to give a colored solution, to which hydroquinone was added. The reaction flask was provided with a dry ice condenser, and then butadiene was absorbed in the reaction mixture. After the reaction flask was closed with stoppers, the mixture was stirred at room temperature for several days. The reaction process was traced by gas chromatography. After excess butadiene was recovered, the mixture was extracted with CCl_4. The organic layer was washed with water, dried and concentrated. The residue was distilled to give the adduct.

Reaction of 2-Methyl-2-cyclohexenone and Butadiene. To

* To whom all correspondences should be addressed.

a suspension of 6.5 g (0.048 mol) of powdered anhydrous $AlCl_3$ in 650 ml of CH_2Cl_2 was added 55 g (0.5 mol) of 2-methyl-2-cyclohexenone and then 100 g of butadiene. The mixture was stirred for 4 days. Work-up as described gave 75.5 g (93%) of adduct (II), bp 80—90 °C/5 mmHg (lit,[7b] bp 58—65 °C/0.4 mmHg). IR(neat): 3020, 1725, 1655, 925 cm^{-1}. NMR(CCl_4): 1.08 (s, 3H), 5.58—5.62 ppm (m, 2H).

Reaction of 2-Methyl-2-cyclohexenone and Isoprene. 2-Methyl-2-cyclohexenone (11 g, 0.1 mol) was added to a suspension of 3.3 g (0.025 mol) of $AlCl_3$ in 120 ml of dry benzene. $AlCl_3$ was gradually dissolved to form a paste, to which was added dropwise with ice cooling 20 ml of isoprene. After the mixture was stirred for 2 days, 20 ml of isoprene was added again. Up to the end of the reaction after additional 3 days, a heterogeneous mixture became homogeneous reddish brown. Work-up as described gave 15.6 g (88%) of the adduct (IIIa). IR(neat): 3010, 1705, 995, 920 cm^{-1}, NMR ($CDCl_3$): 1.13 (s, 3H), 1.70 (s, 3H), 5.36 ppm (m, 1H).

Reaction of 2-Methyl-2-cyclohexenone and Piperylene. The adduct (IV) was prepared from 2.2 g (20 mmol) of 2-methyl-2-cyclohexenone, 0.66 g (5 mmol) of $AlCl_3$ and 5 ml of piperylene in 24 ml of benzene. The reaction mixture was stirred for 2 days. After work-up in usual way, the residue was chromatographed on silica gel with CH_2Cl_2 and gave 2.7 g (76%) of IV. The IR and NMR spectra of the mixture of (IVa) and (IVb) matched the published data of that mixture.

BULLETIN OF THE CHEMICAL SOCIETY OF JAPAN, VOL. 48(10), 2997—2998 (1975)

Metal Derivatives of Amidoximes. VII. Synthesis of Bis(1,3,5,2-Oxadiazaborol-2-yloxy)tetrabutyldistannoxanes

A. B. GOEL and V. D. GUPTA
Chemistry Department, Rajasthan University, Jaipur-302004, India

(Received March 24, 1975)

Synopsis. Bis(1,3,5,2-oxadiazaborol-2-yloxy)tetrabutyldistannoxanes have been synthesized by the reaction of amidoxime, boric acid and dibutyltin oxide. A probable structure for the dimeric species has been proposed on the basis of molecular weight and IR spectral data.

Industrial importance of polymers like silicones[1] has given impetus to the study of metalloboroxanes containing B-O-M linkage.[2] In continuation to our earlier report[3] we briefly communicate here the synthesis and characterization of the dibutylstannoxy boron derivatives containing amidoxime ring.

Bis(1,3,5,2-oxadiazaborol-2-yloxy)tetrabutyldistannoxanes (I) have been synthesized from the mixture of dibutyltin oxide, boric acid and amidoxime by removing water azeotropically with benzene.

$$2Bu_2SnO + 2H_3BO_3 + 2R\underset{NH_2}{\overset{NOH}{C}} \xrightarrow{C_6H_6}$$

$$\left[\begin{array}{l} N\!-\!O \\ \| \quad\quad B\text{-}O\text{-}SnBu_2\text{-} \\ R\text{-}C \quad\quad\quad\quad -O \\ \quad\; N \\ \quad\; H \end{array}\right]_2 + 5H_2O$$

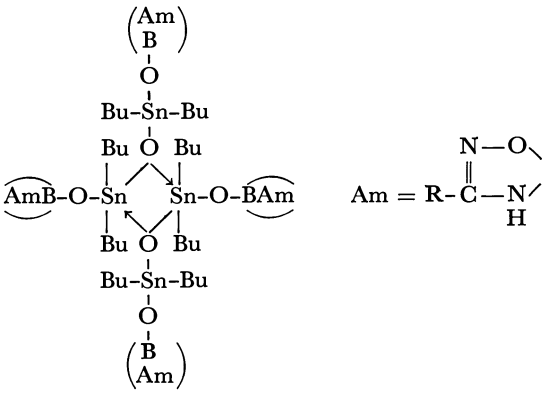
(I)

(R=Me, Et, Pr or Ph)

The reactivity of dibutyltin oxide with amidoxime[4] and boric acid[5] in refluxing benzene indicates that probably amidoxime reacts preferentially with boric acid with the formation of $[R(HN)C{=}N\text{-}OB\text{-}]_2\text{-}O$ (II) which with dibutyltin oxide gives the final product (I). This has been substantiated by the interchange reaction of II[6] with dibutyltin oxide which furnishes I.

These products are white crystalline solids re-crystallizable from hot benzene and are dimeric in refluxing benzene as revealed by molecular weight data.

Infrared spectrum of I shows the characteristic bands[7] due to νNH in the region 3250—3350 cm^{-1}, νC=N at 1646±5 cm^{-1} and νN–O at 920±10 cm^{-1}. Bands at 1275±5 and 1240±10 cm^{-1} due to νB–O (–Sn) and at 595 and 565±5 cm^{-1} due to ν(Sn–O–Sn) indicate the possibility of ladder type structure[8] for these products (I).



The more detailed structural work is in progress.

Experimental

Dibutyltin oxide (Nitto Kasei) and boric acid were used as supplied. Amidoximes were prepared by standard methods.[9] Boron, tin and nitrogen were estimated by the methods reported earlier.[3] Infrared spectra were recorded on Nujol on Perkin-Elmer 337 spectrophotometer in the range 4000—400 cm^{-1} using KBr optics. Molecular weights were determined on an ebulliometer (Gallenkamp).

a) With decomposition.

Reaction between Dibutyltin Oxide, Boric Acid and Amidoxime. Removal of water azeotropically with benzene (~60 ml) from an equimolar mixture of dibutyltin oxide, boric acid and amidoxime left a clear solution. After removing the solvent *in vacuo*, the product (I) is obtained as white solid recrystallizable from benzene. The details are given in Table 1.

Reaction between II(R=Ph) and Dibutyltin Oxide. A mixture of II,[6] R=Ph (0.98, 3.23 mmol) and dibutyltin oxide (1.61 g, 6.47 mmol) was refluxed in benzene (~40 ml) for about 9 hr leaving a clear solution. On removing excess benzene a white product (2.36 g, 90% yield, mp 90—92 °C) crystallized out. Found: B, 2.62; Sn, 29.5; N, 7.30%. Calcd for I (R=Ph), B, 2.69; Sn, 29.5; N, 7.47%.

One of the authors (A.B.C.) is grateful to UGC New Delhi for a Junior Research Fellowship.

The Volatilization of Cadmium from Polyvinyl Chloride–Cadmium Mixtures on Heating

Ryoichi TSUNODA

Industrial Research Institute of Kanagawa Prefecture, Showa-machi, Kanazawa-ku, Yokohama-shi 236

(Received February 17, 1975)

Synopsis. The volatilization of cadmium from a PVC–cadmium stearate mixture on heating was studied by the X-ray diffraction analysis of the products volatilized, which were identified as $CdCl_2$ in air metal Cd and $CdCl_2$ in N_2.

In papers dealing with the decomposition of PVC, there have been much discussion of the effects of metal soaps, but no attention has been paid to the volatilization of metal elements from metal soaps in PVC compositions.[1–6]

About 1.2 mg of cadmium stearate was weighed, sandwich-like, into a platinum sample dish (5 mm $\phi \times$ 5 mm) containing about 40 mg of PVC, mixed well by tapping the bottom and side of the dish lightly, and heated at a heating rate of 5 °C/min in a small electric furnace. The electric furnace, shown in Fig. 1, was a Rigaku Denki Thermoflex, the heating unit of which was employed as the heating apparatus.

The products volatilized after the decomposition of the PVC-cadmium stearate were trapped on the wall of a quartz tube placed in the furnace and were examined by X-ray diffraction analysis by means of an X-ray diffractometer, Rigaku Denki Geigerflex, using Ni filter-CuKα radiation. The residues, heated in platinum sample dishes, were oxidized with sulfuric and nitric acids, and the Cd was determined by atomic absorption spectrometry by means of an atomic absorption spectrometer, Perkin Elmer 403, at a wavelength of 2288 Å.

The percentage of cadmium retained and the X-ray diffraction diagrams of the products volatilized from PVC–cadmium stearate on heating are shown in Figs. 2 and 3 respectively, from which the difference in the volatilization processes of cadmium between that in air and that in nitrogen was observed.

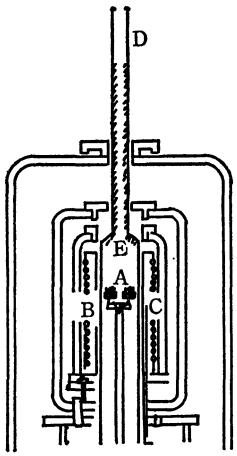

Fig. 1. Electric furnace.
A: Platinum sample dishes, B: heater, C: CA thermocouple, D: Quartz tube, E: Position where volatilized products were trapped.

By the way, the generation of metal chloride by the interaction of metal carboxyrate with pyrolytically eliminated hydrogen chloride was previously reported,[1] but not that of metal. In order to ascertain the formation and volatilization of metal Cd, the cadmium

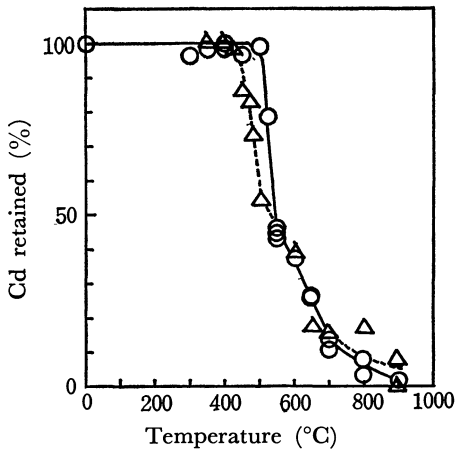

Fig. 2. Percentage of Cd retained in PVC–cadmium stearate on heating.
△: in N_2, ○: in air.

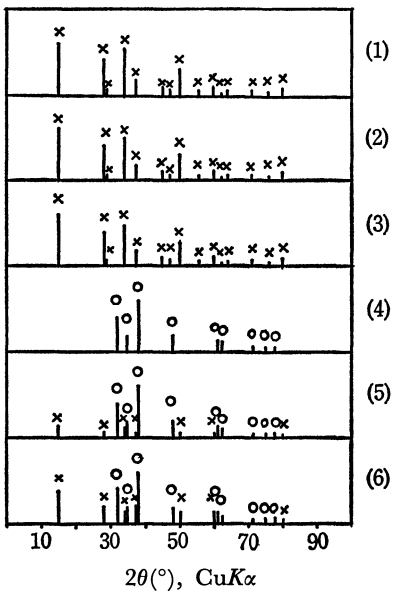

Fig. 3. X-Ray diffraction diagrams of products volatilized from PVC–cadmium stearate on heating up to:
(1) 550 °C, (2) 700 °C, (3) 900 °C in air
(4) 500 °C, (5) 550 °C, (6) 900 °C in N_2
×: $CdCl_2$, ○: Cd.

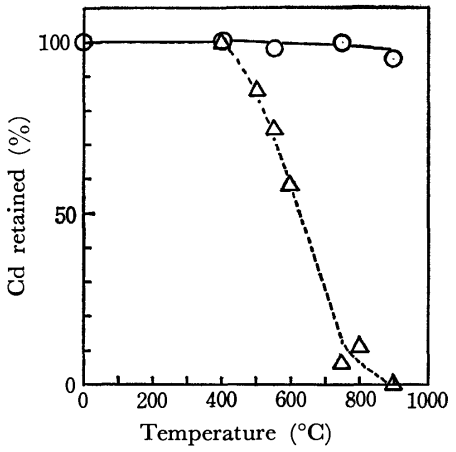

Fig. 4. Percentage of Cd retained on heating of cadmium stearate.
△: in N_2, ○: in air.

stearate was heated in N_2 or in air and subsequently examined in the same way. This showed the volatilization and existence of metal Cd in the residues heated in N_2. The percentage of Cd retained is shown in Fig. 4.

These results show that, in air, the cadmium in PVC–cadmium stearate was volatilized as $CdCl_2$[7] above *ca.* 500 °C, while in nitrogen the cadmium was volatilized as metal Cd[8] above *ca.* 400 °C, and as a mixture of metal Cd and $CdCl_2$ above *ca.* 500 °C.

(Received April 25, 1975)

Whatever the merit of the combined application of a FE-treatment and the hole/particle formalism, proposed by Basu[1] for the calculation of the electronic spectra of all-*cis* cyclic polyenes containing n π-electrons in a perimeter system of at least D_{nh} symmetry, the experimental results known to date do *not* constitute proof that the predicted convergence limit for the $^1L_b \leftarrow {}^1A$ transition does exist. In fact they agree much better with the assumption that for $n\rightarrow\infty$ the difference $\Delta E = E(^1L_b) - E(^1A)$ does not differ much from zero. The limit of ΔE for $n\rightarrow\infty$ is definitely much smaller than suggested by Fig. 1 of Ref. 1, which is based on wrong or inadequate data.[2]

Many-electron SCF treatments including configuration interaction[2,3] indicate that ΔE for the longwave $^1L_b \leftarrow {}^1A$ transition of all-*cis* cyclopolyenes satisfying Hückel's rule should depend on n according to $\Delta E \propto \sin(\pi/n)$. Using the data given in Ref. 2 for cyclic π-systems with n=6, 10, 14, 18 we find

$$\Delta E = [(-1.47\pm1.93) + (85.99\pm6.57)\sin(\pi/n)]\times 10^3\ \mathrm{cm}^{-1}$$

a regression line which does not miss the origin $\sin(\pi/\infty)=0$ significantly. (Predicted 90% security confidence limits for n=22 : 8.8 to $12.8\times10^3\ \mathrm{cm}^{-1}$; n=26 : 6.7 to $11.1\times10^3\ \mathrm{cm}^{-1}$; n=30 : 5.1 to $9.9\times10^3\ \mathrm{cm}^{-1}$). Of course linear extrapolation beyond $n\approx30$ is dangerous, because of higher order terms which are not accounted for, if one uses the transformation of the independent variable n into the new variable $\sin(\pi/n)$. However, the analysis clearly indicates that the value of the upper limit of ΔE for $n\rightarrow\infty$ must be at best of the order of $5\times10^3\ \mathrm{cm}^{-1}$, especially if the lack of planarity of some of the reference systems is taken into account. This value is close to the highest frequency vibrational modes and thus "zero" for all practical purposes.

(Received December 2, 1974)

The relative absorption intensities of the scissoring vibration bands of *trans*- and *gauche*-1,2-dibromoethanes were measured in pure liquid and in solutions of *cis*-1,2-dichloroethylene or tetrachloroethylene at various concentrations. The relative populations of the rotational isomers were determined from the intensity data. An attempt was made to describe quantitatively the observed concentration-dependence of the relative population on the basis of a semi-molecular theory of dipole-interaction. An equation is proposed for the averaged interaction energy of a molecule with its surrounding molecules, which is expressed in terms of the dipole moments and the polarizabilities of the solute and the solvent molecules.

The problem of rotational isomerism has been one of the major subjects in the field of physical chemistry.[1-3] Many investigations have been concerned with the determination of the energy difference, ΔE, between rotational isomers. In doing so, one uses the van't Hoff's relation and plots the logarithms of the relative intensities (either absorption or scattering) of two isomers against $1/T$, where T is the absolute temperature, and obtains ΔE from the slope of the plot. There remain two problems, however. One is that a straight-line relation is assumed in the plot. This means that ΔE is assumed to be independent of the temperature or, more generally, of intermolecular interactions. Although the assumption holds effectively in many cases, the present authors[4] recently showed that ΔE depends on the temperature in the case of liquid 1,2-dibromoethane. The other problem is that, in general, only the relative intensities, and not the relative populations, can be known from spectroscopic measurements. If one wants to discuss the equilibrium properties of rotational isomers, however, the relative populations must be known experimentally. Fortunately, the present authors[4] succeeded in obtaining the relative populations at several temperatures from the relative intensities of Raman lines in the case of liquid 1,2-dibromoethane. This permits one to discuss the equilibrium property of liquid 1,2-dibromoethane in some detail.

The present investigation concerns the quantitative description of the concentration-dependence of the relative populations of *trans*- and *gauche*-1,2-dibromoethanes. The solvents used were *cis*-1,2-dichloroethylene and tetrachloroethylene: they were chosen because the former is strongly polar, while the latter is nonpolar. *gauche*-1,2-Dibromoethanes and *trans*-1,2-dibromoethanes are also characterized by their dipole moments; the former is strongly polar, while the latter is nonpolar. The effects of intermolecular dipole-interactions on ΔE are estimated in this paper; a good agreement is obtained between the calculated and observed concentration-dependencies of the relative populations of *trans*- and *gauche*-1,2-dibromoethanes.

Experimental

All the chemicals used in the present study were commercial products. Purchased samples showed no trace of impurity in the infrared spectra covering the range of 400—4000 cm^{-1} and were used without further purification. Solutions of 1,2-dibromoethane in *cis*-1,2-dichloroethylene or in tetrachloroethylene were prepared just before the observations so as to obtain the appropriate concentrations by measuring the weight of each component. On determining the mole percents and the molar concentrations, the density data from a standard table[5] were used. The additivity of the volumes of the components was assumed in this process.

The infrared absorption spectra were measured for the scissoring vibration of 1,2-dibromoethane (ν_{15} of the *trans* form, and ν_3 and ν_{13} of the *gauche* form) in pure liquid and in solutions by the use of a Perkin-Elmer 112G single-beam infrared spectrometer. The spectrometer was operated under a resolution of about 1 cm^{-1} and at room temperature (25 °C). The effects of a finite slit-width on the observed band shapes and on the intensities were ascertained to be very small. The observed spectra were reduced to the absorption-index curves, $k(\nu)$'s.[6] It is known that the effects of the refractive index often spoil the observed relative intensity data when the absorption bands are strong.[7] In the present case, however, all the absorption bands observed was very weak, so no special correction for the observed intensity data was made.

The observed spectra, as is shown in Figs. 1 through 3, contain two absorption bands arising from the *trans* and the *gauche* isomers of 1,2-dibromoethane. We separated the two slightly overlapping bands by the method of least-squares,

I_t/I_g is the relative intensity of the scissoring vibration bands. Numbers in parentheses indicate the standard deviations. n_t/n_g is the relative population obtained from $\ln(I_t/I_g)$ (see the text). H is calculated through Eq. (15). The sixth column is the sum of the fourth and the fifth columns. a) See Ref. 4.

assuming a Lorentzian band shape, and estimated the relative values of the integrated intensities. The separated bands are illustrated by the broken lines in Figs. 1 through 3. Table 1 contains the relative intensity at each concentration thus obtained. The standard deviations attached to the relative intensities in Table 1 were estimated from the deviation between the observed and the calculated absorption curves.

The logarithmic relative population, $\ln(n_t/n_g)$, differs from the corresponding logarithmic relative intensity, $\ln(I_t/I_g)$, only by a constant which is independent of the concentration, if the absolute intensities of the *trans* and the *gauche* isomers do not change in the concentration-variation.[8] The constant was determined so as to make $\ln(n_t/n_g)$ in pure liquid equal to

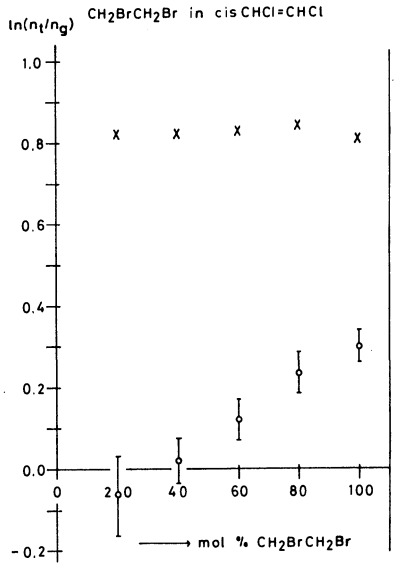

Fig. 4. Concentration-dependence of the relative population of *trans*- and *gauche*-1,2-dibromoethanes in *cis*-1,2-dichloroethylene solution. Open circles; experimental values of the relative population. Crosses; values of the relative population corrected for the effect of dipole interaction (see the text). Vertical lines show the standard deviations.

0.300, the value of which had previously been determined by the present authors.[4] The value of $\ln(n_t/n_g)$ was determined at each concentration from the corresponding $\ln(I_t/I_g)$ by substracting the constant. The results are shown in Table 1 and Figs. 4 and 5.

Theory

Usually the enrgy difference, ΔE, and the relative population, n_t/n_g, are related by the van't Hoff equation:

$$\ln(n_t/n_g) = A + (\Delta E/kT) \tag{1}$$

where A is a constant, k is the Boltmann's constant, and T is the absolute temperature. Let us consider the effect of intermolecular interaction on the magnitude of ΔE. The effect is, in principle, a function of the temperature, the concentration, and other parameters characterizing the system. We may write:

$$\Delta E = \Delta E^\circ + H \tag{2}$$

and

$$\ln(n_t/n_g) = A + (\Delta E^\circ/kT) + (H/kT) \tag{3}$$

where ΔE^0 means the intrinsic energy difference or the energy difference of the rotational isomers when they are well isolated from other molecules, and where H is the effect of intermolecular interactions.

From the microscopic point of view, the *gauche* and the *trans* isomers are considered to differ only in that the former possesses a dipole moment, while the latter does not. The other physical properties may be regarded as almost identical for the two isomers. H, then, arises from the dipole-interaction of a *gauche* isomer with other molecules. In the following, we will focus our attention on a special *gauche* isomer, which will be designated as "central", and try to find the energy of its dipole interaction with the surrounding molecules. It may be expedient to distinguish here the following four types of dipoles which interact with the central *gauche*-dipole; (1) the dipole moments of other *gauche* molecules, (2) the dipole moments of solvent molecules (if any), (3) the dipole moments of other molecules of 1,2-dibromoethane (*gauche*+*trans*) induced by the central *gauche*-dipole, and (4) the dipole moments of solvent molecules induced by the central *gauche*-dipole. The reason why we do not distinguish the *trans* and the *gauche* isomer in (3) is that the refractive index, and hence the polarizability, is known only for the equilibrium mixture of the *trans* and the *gauche* isomers.

Let the polar coordinates of the central *gauche*-dipole, $\boldsymbol{\mu}_g$, of another dipole, $\boldsymbol{\mu}$, and of the radius vector, $\boldsymbol{r}$, pointing from $\boldsymbol{\mu}_g$ to $\boldsymbol{\mu}'$, be (θ_g, φ_g), (θ', φ'), and (θ_r, φ_r) respectively. $\boldsymbol{\mu}'$ can be any one of the aforementioned four types of interacting dipoles. The dipole, $\boldsymbol{\mu}'$, induces an electric field at the point of $\boldsymbol{\mu}_g$. The component of the field along the direction of $\boldsymbol{\mu}_g$ is written as:[11]

$$F = -\frac{\mu'}{r^3}(A+B+C+D+E+F) = -\frac{\mu'}{r^3}\Omega \tag{4}$$

where A, B, C, D, E, and F are expressed in terms of the spherical harmonic with respect to polar coordinates, (θ_g, φ_g), (θ', φ'), and (θ_r, φ_r),[11] and where Ω means the sum of these six terms. Similarly, $\boldsymbol{\mu}_g$ induces an electric field in the surroundings and produces an induced moment, $\boldsymbol{\mu}_i$:

$$\mu_i = -\frac{\alpha\mu_g}{r'^3}\Omega' \tag{5}$$

where α is the polarizability of the molecule in the surroundings. The primes on r and Ω in Eq. (5) show that r Ω of Eq. (5) are not necessarily the same as those in Eq. (4). The induced moment, $\boldsymbol{\mu}_i$, in turn induces and electric field on the position of $\boldsymbol{\mu}_g$. The component of the field along the direction of $\boldsymbol{\mu}_g$ is, according to Eq. (4):

$$F = \frac{\alpha\mu_g}{r'^6}\Omega'^2 \tag{6}$$

Now we can write the induced field at the position and along the direction of the central $\boldsymbol{\mu}_g$:

$$F_1 = -\frac{\mu_g}{r_g^3}\Omega_g \tag{7a}$$

$$F_2 = -\frac{\mu_s}{r_s^3}\Omega_s \tag{7b}$$

$$F_3 = \frac{\alpha_m\mu_g}{r_m^6}\Omega_m^2 \tag{7c}$$

$$F_4 = \frac{\alpha_s\mu_g}{r_s^6}\Omega_s^2 \tag{7d}$$

where all the quantities suffixed with g, s, or m, except for the μ_g in Eq. (7c) or (7d), which stands for the dipole moment of the central *gauche* isomer, are related with the surrounding *gauche* isomers. the solvent molecules, or the mixture of the *trans* and the *gauche* isomers, respectively. The total interaction energy, $\mathcal{H}$, of the central *gauche* isomer is, then:

$$\mathcal{H} = \mu_g(F_1+F_2+F_3+F_4) \tag{8}$$

To obtain H of Eq. (2) or (3), one must average Eq. (8) over all the possible orientations and distances of the interacting pair. In doing so, it must be considered that the relative orientation of two dipole moments is distributed according to their interaction energy; that is, energetically more stable configurations are distributed more than the less stable configurations. This concept is considered in the averaging process by introducing the Boltzmann distribution function:

$$W = w\exp(-\mathcal{H}/kT) \tag{9}$$

where w is a constant which is to be determined by the normalization condition:[12]

$$w\int_v d\tau = n \tag{10}$$

where v indicates a sphere of the unit volume, at the center of which the central *gauche*-dipole is situated, where $d\tau$ is the volume element:

$$d\tau = r^2\sin\theta d\theta d\varphi dr \tag{11}$$

and where n is the number of molecules in v. Now, the average way be expressed in terms of an integral:

$$H = \sum_i w_i\int\mu_g F_i\exp(-\mu_g F_i/kT)d\tau \tag{12}$$

where the suffix i corresponds to the four terms of Eq. (7). In Eq. (12), it is assumed that the averages of the four terms of Eq. (8) can be taken independently. In other words, the orientational correlation between neighbour dipoles is assumed to have no effect on the interaction of the dipoles with the central *gauche*-dipole.

To calculate the integral in Eq. (12), we expand the exponential and neglect the higher terms than the second:[13]

$$H = \sum_i w_i \int \mu_g F_i [1 - (\mu_g F_i / kT)] \mathrm{d}\tau \qquad (13)$$

Integration over orientations is performed by the use of the orthonormality of the spherical harmonics, which results in:[13]

$$\int \Omega \mathrm{d}\tau' = \int \Omega^3 \mathrm{d}\tau' = 0$$

and

$$\int \Omega^2 \mathrm{d}\tau' = \frac{128}{3}\pi^3 \qquad (14)$$

where $\mathrm{d}\tau'$ is the angular part of the volume element. A lower limit, a_0, must exist for the integration over the distance; the meaning of this is that two molecules can not come closer than a_0. We estimated the a_0 from the density and the molecular weight, assuming a rigid sphere for each molecule.[14] The result is:

$$H = -\frac{4\pi^2}{27}\frac{\mu_g^4}{kT}\frac{\rho}{W_m}c_m\frac{N_a^2}{1+(n_t/n_g)} - \frac{4\pi^2}{27}\alpha_m\mu_g^2\frac{\rho}{W_m}c_m N_a^2 - \frac{32\pi^2}{27}\left(\frac{\mu_g^2\mu_s^2}{kT}+\alpha_s\mu_g^2\right)\frac{c_{ms}N_a^2}{\left[\left(\frac{W_m}{\rho}\right)^{1/3}+\left(\frac{W_{ms}}{\rho_s}\right)^{1/3}\right]^3} \qquad (15)$$

where N_a is Avogardo's number, where W_m, ρ, and c_m are the molecular weight, the density, and the molar concentration (mol/cm^3) respectively of the solute, and where the same symbols suffixed with s refer to those of the solvent molecule.

Results and Discussion

Figures 4 and 5 show the experimental values of the relative populations of *trans*- and *gauche*-1,2-dibromoethanes in solutions. It may be seen from the figures that the population varies on going from pure liquid to dilute solutions: it increases in a tetrachloroethylene solution. In other words, the numbers of the *gauche* isomer increase as the polarity of the environment increases.

To see whether or not the model of dipole interaction, developed in the last section, is appropriate, we calculate H/kT from Eq. (15) at each concentration and subtract it from the observed value of $\ln(n_t/n_g)$. The resultant value should be $A+(\Delta E^0/kT)$, as may be seen from Eq. (2), and should remain constant over all concentrations. In the calculation, α_m and α_s were estimated from the values of the refractive indices[5] using the Lorentz-Lorenz formula, the densities were taken from a standard table,[5] and μ_g and μ_s (of *cis*-1,2-dichloroethylene) were taken to be 2.20 D[15] and 1.89 D[16] respectively. The results of the subtraction are shown in Table 1 and in Figs. 4 and 5. It may be seen from the table and the figures that the resultant value remains almost constant for all the concentrations; this indicates the validity of the model used in the calculation. Thus, it may be concluded that the equilibrium properties of the *trans*- and *gauche*-1,2-dibromoethanes in solutions are fully described by the model of dipole-interaction, Eq. (15).

Incidentally, Eq. (15) tells us that the energy difference, ΔE, should change in value according to the change in temperature as well as that in concentration. The temperature-effect data of the reference[4] can also be explained by the use of Eq. (15).

It should be noted that, in the present calculation, we are considering the environments to be built up of gas-like molecules dispersed in a vacuum to give the actual density, instead of looking them as continuous dielectrics. The latter model yields the famous reaction field of Onsager.[17] The present approach has a close resemblance to the latter in concept, but it has resulted in a quite different equation which is expressed in terms of the dipole moment and the polarizability instead of the dielectric constant, a very macroscopic quantity. The present theory is not, however, a fully molecular theory in the sense that the polarizability is calculated from such macroscopic quantities as the refractive index and the density through the Lorentz-Lorenz formula, and in that the molecular radius is estimated in the same way as in Onsager.[14,17] A comparison of the numerical results of the present equation with those based on the reaction field shows that the two approaches do not give the same results for the averaged electric field acting on a molecule.[4] It can be said at the same time that the present model can well describe the magnitude of the change in the averaged electric field in the concentration- or temperature-variation. To clarify the difference existing between the two approaches is interesting and may be a problem for the future.

The authors are indebted to all the members of the Shimanouchi laboratory for their helpful correspondence about this work. They are particularly grateful to Professor Takehiko Shimanouchi of the University of Tokyo for giving them the opportunity of publishing this work.

8) In the discussions of the text, it is assumed that the absolute intensity of a *gauche* or a *trans* isomer does not change in dilution. This assumption, however, is not strictly true. The authors are going to show, in a subsequent paper,[9] tha the absolute intensities of the infrared absorption bands may change, in some cases about a factor of two, on going from a pure liquid to a dilute solution. An equation is to be presented to describe the intensity change: the basic concept is that the transition moment, m_1, differs in liquid media from that of an isolated molecule, μ_1:

$$m_1 = \mu_1 + \alpha_1 \langle \mathscr{F} \rangle_{av}$$

where α_1 is the transition polarizability and where $\langle \mathscr{F} \rangle_{av}$ is the averaged field acting on the absorbing molecule. The most contributing term in $\langle \mathscr{F} \rangle_{av}$ is, in the case of liquid 1,2-dibromoethane;

$$\frac{4\pi^2}{27} N_a \frac{\mu_g^2}{kT} \left(\frac{\rho}{W_m} \right)^2 \frac{1}{1+(n_t/n_g)}$$

where the notations are the same as in the text. We must remember that, among the two scissoring vibrations of *trans*-1,2-dibromoethane, one (b_u) is Raman-inactive ($\alpha_1=0$) and the other (a_g) is infrared-inactive ($\mu_1=0$). Therefore, one might expect that the absolute intensity of the scissoring vibration of the *trans* isomer does not change. On the other hand, the two scissoring vibrations (*a* and *b*) of the *gauche* isomer are active in both the infrared and Raman spectra, so one must consider the intensity-change in this case. The results of the present measurement, combined with the value of the relative population in Table 1, yield 504 cm^2/mol for the absolute intensity of the scissoring vibration band (*a* and *b* combined) of the *gauche* isomer, after the Polo-Wilson correction.[10] This corresponds to m_1 of 0.0449 D. If α_1 is assumed to be 0.1 $Å^3$, which might be unrealistically large for this vibration, then μ_1 becomes 0.0441 D and the corresponding intensity is 487 cm^2/mol. Therefore, the change in the absolute intensity is only about 3.5% even for the large value of α_1, on going from a pure liquid to a very dilute solution in nonpolar solvents. Thus, the intensity-change does not exceed the experimental errors in the present work.

12) More precisely, Eq. (10) should be written as:

$$w \int_v \exp(-\mathscr{H}/kT) d\tau = n.$$

However, the higher-order terms than the first, in the expansion of the exponential, yield only very small contributions to the result, and so Eq. (10) is justified.

13) The next nonvanishing term in the expansion of H can be calculated by the use of this relation:

$$\int \Omega^4 d\tau' = \frac{1536}{25} \pi^3.$$

Calculation showed that the contribution from the next nonvanishing term is, at most, about 1% of Eq. (15) in the case of 1,2-dibromoethane in solutions.

14) In principle, one must use a radial distribution function in the integration of the radial part in Eq. (13). The radial distribution function can not, however, be used for large molecules. The present assumption is identical with putting the radial distribution function equal to unity for $r \geqq a_0$ and to 0 for $r < a_0$.

Coagulation-dispersion and Precipitation-flotation Behavior of Bentonite and Cadmium-ion Flotation

Toyono INAKAZU,* Koichi KOBAYASHI,** and Tsunetaka SASAKI***

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 158

(Received December 9, 1974)

The states of dispersion and the precipitation-flotation behavior of bentonite particles in an aqueous solution of hexadecyltrimethylammonium chloride (HTAC) were studied, and the effect of the HTAC on the coagulation and dispersion was discussed in connection with its adsorption on bentonite. The coagulation precipitation of bentonite began to occur at the ratio of the adsorbed amount to an exchange capacity, A/T, of about 0.05. It changed to coagulation flotation in the vicinity of $A/T=1.2$. The change was very sharp. The results suggest that the change from precipitation to flotation is produced by the adsorption of HTAC a little in excess of the first-layer formation, where a slight hydrophilization begins. It seems likely that, in the above state, the bubbles are easily accessible to bentonite particles because the agglomerates assume an open structure. The redispersion occurred near the point of sufficient hydrophilization of bentonite particles because of the adsorption of the second layer of cationic surfactant molecules.

There have been a number of studies of the coagulation and redispersion of suspension by the addition of inorganic electrolytes, macromolecular substances, and surfactants.[1-4] Thus, the sensitizing and stabilizing action of gelation on hydrophobic sol; the addition to the colloidal suspension of an electrolyte with a polyvalent ion with the charge opposite to that of the colloidal, particle, known as the irregular series, is a popular instance.[5] The effect of the addition of ionic[4,6] and nonionic surfactants[7] on the flocculation-deflocculation behavior of sulfathiazole and other suspensions, in particular the bentonite suspension, has also been reported. In such cases, the suspension often foams and the suspended particles coagulate and float. However, such phenomena have not received much attention,[2,8] though they are properly suitable to the removal of many different ions from solutions.

In the present paper, the coagulation and redispersion, accompanied by the precipitation and flotation upon the addition of a cationic surfactant, will be described for the bentonite suspension. The adsorption of the surfactant on bentonite was also studied, and the mechanisms of the coagulation, flotation, and redispersion of bentonite will be discussed in connection with its adsorption on bentonite. Further, the ion flotation of Cd^{2+} ions will be studied in parallel with the bentonite flotation.

Experimental

Materials. The bentonite used was of a commercial grade (origin; Gunma, Japan, montmorillonite type) and was supplied by the Wako Pure Chemical Co., Ltd; the fraction passing through a 350-mesh sieve was collected. A stock suspension of bentonite was prepared first by dispersing the bentonite in distilled water; then it was allowed to stand for 24 hr after shaking. Then, the supernatant solution was taken in the visking dialysis tube and dialyzed while the suspension was being stirred by passing nitrogen gas through it. The dialysis was continued for 5 days, frequently exchanging the outer water with fresh ion-exchange water. The dialysis of the bentonite suspension was continued until a constant specific conductivity of about 10^{-5} Ω/cm was reached. The stock suspension of about 10000—20000 ppm bentonite thus obtained was well shaken before use. A preliminary experiment showed that the bentonite suspension thus prepared scarecely sedimentated at all within a week, but no solution aged longer than a week was used. Pure-grade hexadecyltrimethylammonium chloride (HTAC), supplied by the Kao Soap Co., Ltd., was dried under reduced pressure and kept in a desiccator containing silica gel. The sodium octadecylsulfate (SOS) used for titrating HTAC was obtained from the Kao Soap Co., Ltd., and was used without further treatment.

A stock solution of Cd^{2+} ions of a 1.78×10^{-4} mol/l concentration was prepared by dissolving in nitric acid pure metals (purity>99.99%) kindly supplied from the Laboratory of General Chemistry of our department.

Water was refluxed overnight with a mixture of sulfuric acid and potassium permanganate and then triply distilled using a borosilicate glass apparatus.

All the experiments were carried out at room temperatures from 25 to 27 °C.

Measurement of the Coagulation and Redispersion of Bentonite. Varying amounts of the bentonite suspension and of the HTAC solution were placed in a test tube with a ground-glass stopper, 1.5 cm in inner diameter and 13 cm in length, and the total volume of the solution was made up to 10 ml with water. The pH values of suspension thus prepared ranged from 5.7 to 6.4. The test tube was turned upside down 3 times, then shaken by hand for 10 s again turned upside down 3 times, and finally allowed to stand for 30 min. The appearances of the dispersion, coagulation precipitation, coagulation flotation, and redispersion of the suspension were judged by the naked eye, and the regions of the compositions of systems showing these phenomena were plotted as a diagram.

Measurement of the Adsorption of HTAC on Bentonite. In the ground test tube, a fixed amount of the dialyzed bentonite suspension and varying amounts of the HTAC solution were placed. The volume of the solution was made up to 10 ml with water. After shaking the test tube for 10 s or by turning the test tube upside down 20 times with a 2-min period, bentonite particles were removed from the solution by (a) centrifugation, (b) ultrafiltration, or (c) electrodialysis

as the case required. The concentration of HTAC remaining in the solution was titrated with a SOS solution of a known concentration, with the addition of dilute hydrochloric acid and of bromophenol blue as an indicator.[9]

The amount of HTAC adsorbed on the bentonite was calculated from the difference between the HTAC concentration before and after adsorption. (a) Centrifugation. A suspension containing bentonite particles was centrifuged for 10 min at about 2500 rpm. The aqueous supernatant thus obtained was used for the determination of the HTAC concentration. (b) Ultrafiltration. The aqueous suspension was filtered using a visking membrane supported by a glass filter with a porosity of No. 4 under reduced pressure. The filtrate was then used for the determination of the HTAC concentration. (b) Electrodialysis. Electrodialysis was carried out for a stable suspension containing concentrated HTAC; neither method, (a) or (b), could be applied. The apparatus used for the electrodialysis is shown in Fig. 1.[10] In this figure, a glass tube, A, with a semipermeable visking membrane, E, closing its bottom and a glass U-tube, B, were filled with the solution of a stable bentonite suspension to be dialysed. The tube, A, was adjusted so that the membrane just touched the surface of the solution in the tube, B. The solution in A was renewed after being allowed to stand for 30 min. The electrodialysis was then carried out for 2 to 3 hrs applying a 200-V DC between two platinum electrodes inserted in the solution, as is shown in Fig. 1. The electrodes were 27 cm apart from each other along the axis of the tubes. After the electrodialysis, a transparent layer of the solution was obtained in the tube, B, just below the membrane, which was then carefully taken out for the determination of the HTAC concentration.

Measurement of the Total Base Exchange Capacity of Bentonite.[11] A suspension containing about 4 g of bentonite in 100 ml of a 0.1 M aqueous $BaCl_2$ solution was prepared, and the mixture was stirred for 4 hrs. The precipitates of Ba-bentonite, thus obtained were removed by centrifuging (2500 rpm for 20 min), and the precipitates separated were dispersed in triply distilled water. The free $BaCl_2$ remaining was then removed by dialysis, and the precipitates of Ba-bentonite were again dispersed in a 2: 1 (vol) water–ethanol mixture. The suspension thus obtained was conductometrically titrated with a 0.2 M $MgSO_4$ solution, and the total base exchange capacity of the bentonite was determined from the amount of Mg^{2+} ions added until a sudden increase in the conductance appeared.

Measurement of the Flotation of Cd^{2+} Ions by HTAC. The apparatus and procedure used in the present experiment were the same as have been described in a previous paper.[12] Nitrogen gas humidified with water vapor and controlled to a constant rate of gas flowing was bubbled through a glass filter (No. 4) into a flotation cell containing 10 ml of the sample solution. The concentrations of Cd^{2+} ions before and after flotation were determined by using an atomic absorption spectrometer (Techtron Pty., Ltd., Model-AA-100).

The flotation rate (F) of Cd^{2+} ions is conventionally given by:

$$F = (1 - C_f/C_i) \times 100\%$$

where C_i and C_f denote the concentrations of the Cd^{2+} ions before and after flotation respectively.

Results and Discussion

Coagulation-dispersion Behavior of Bentonite upon the Addition of HTAC. The change in the dispersion state of the bentonite suspension upon the addition of the cationic surfactant HTAC is shown in Fig. 2. As may be seen in the figure, each region—dispersion, coagulation precipitation, coagulation flotation, and redispersion— is distinct.

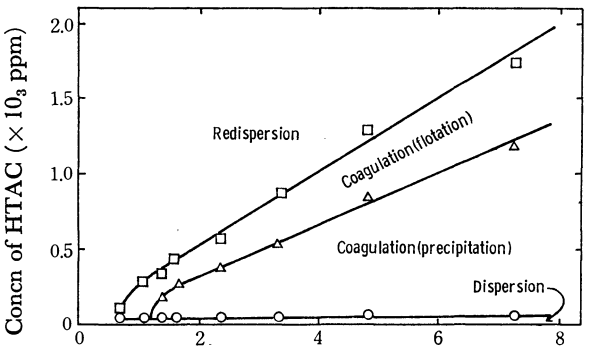

Fig. 2. Effect of HTAC on bentonite suspension.

Dispersion Region. Immediately after the preparation of the solution, the aggregates form slightly, but after shaking they disappear and the suspension is stable even after 30 min. The amount of HTAC is thus insufficient to produce coagulation in this region.

Coagulation Precipitation Region. On an increase in the amount of HTAC, with the amount of bentonite kept constant, fluffy aggregates begin to precipitate. The sedimentation volume increases with a further increase in the amount of HTAC, and a turbid supernatant gradually changes to a clear one.

Coagulation Flotation Region. On a further increase in the amount of HTAC, a sharp point is arrived at which aggregates change suddenly the state of precipitation to that of flotation, while the bentonite particles are still in an aggregated state. In this region, the suspension is readily coagulated by shaking and the coagulates quickly rise to the aqueous surface, leaving a transparent solution below.

Redispersion Region. On continuing the addition of HTAC, the state is arrived at in which the aqueous phase begins to become turbid; this turbidity increases with an increase in the amount of HTAC, while the amount of bentonite floated decreases until the coagulates completely disappear. The foam formation is observed for a sufficiently concentrated solution of HTAC.

The above observation of the change in the dispersion state with an increase on the amount of HTAC leads to the consideration that the coagulation-redispersion and precipitation-flotation phenomena are closely related to the nature of the outermost surface of the bentonite particles modified by the increasing adsorption of HTAC with the concentration. The increase in the amount of adsorption is considered to change the surface properties gradually from those favorable for coagulation precipitation through coagulation flotation to redispersion. To confirm such a reasoning, the following measurements were carried out.

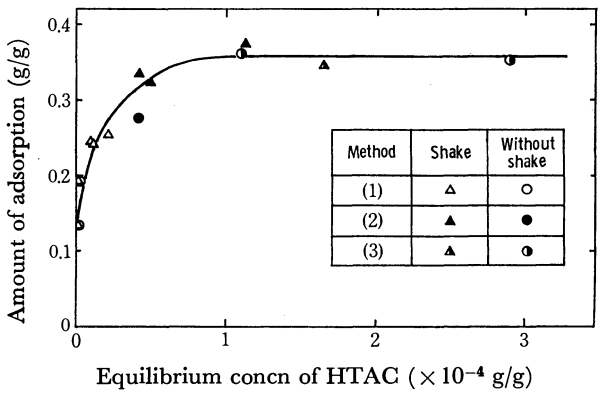

Fig. 3. Adsorption isotherm of HTAC on bentonite.
(1) centrifuge, (2) dialysis, (3) ultrafiltration

Amount of the Adsorption of HTAC. The amount of HTAC adsorption of bentonite is plotted against the equilibrium concentration in Fig. 3. The values obtained by the various methods mentioned above may be seen to agree with each other. A sharp initial increase in the amount of adsorption and the saturated adsorption at a low HTAC concentration show the almost complete adsorption of added HTAC on the bentonite up to saturation. Such behavior is indicative of the exchange adsorption being rapid and quantitative. The saturated adsorption is obtained in the region of equilibrium HTAC concentrations larger than 1×10^{-4} g/g water. The fact that the amount adsorption is independent of the shaking also shows that the adsorption of HTAC on air bubbles is negligible.

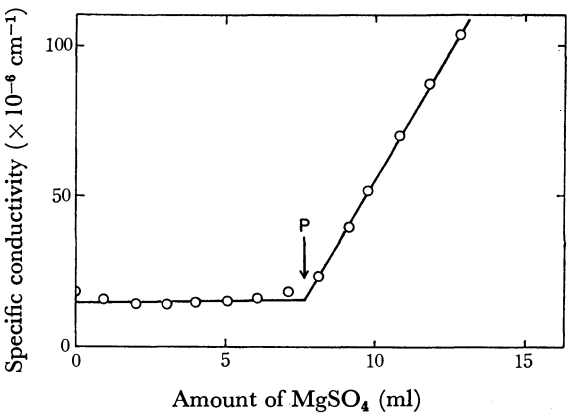

Fig. 4. Conductometric titration of Ba-bentonite. P: total exchange capacity of bentonite.

Total Base Exchange Capacity of Bentonite. In order to measure the exchange capacity of bentonite, the conductance of the Ba-bentonite suspension is plotted against the volume of $MgSO_4$ added in Fig. 4. The exchange capacity, as calculated from the break point corrected for the moisture content of the bentonite, is 42.5 m. e./100 g dry bentonite. The value obtained is somewhat smaller than the value from 60 to 100 m. e./100 g previously reported for bentonite.[13]

Effect of the HTAC Adsorption on Coagulation and Redispersion. In order to study the relation between the adsorption of HTAC and the coagulation-redispersion behavior of bentonite shown in Fig. 2, the amount of adsorption of HTAC on the bentonite was calculated for the system corresponding to the points on the line of Fig. 2. The amount of adsorption, Γ, can be calculated as the intersection of the isotherm, Γ *vs.* C, shown in Fig. 3 and the straight line where M and m denote the

$$M = m\Gamma - CV$$

total amount of HTAC and the amount of bentonite taken up respectively, and V, the volume of the solution, all of which are known constants corresponding to a given point in Fig. 2. The amount of adsorption thus calculated is shown in Table 1, together with the ratio of the adsorbed amount (A) to the exchange capacity (T).

Table 1. Effects of HTAC adsorption on coagulation—dispersion and precipitation—flotation

Concn of bentonite (ppm)	Coagulation precipitation		Coagulation flotation		Redispersion	
	A[a]	A/T[b]	A[a]	A/T[b]	A[a]	A/T[b]
3000	0.016	0.12	0.154	0.13	0.236	1.75
4000	0.009	0.07	0.162	1.19	0.243	1.79
6000	0.007	0.05	0.165	1.21	0.245	1.80

a) Minimum amount of adsorption. b) Ratio of minimum amount of adsorption (A) to exchange capacity (T).

It may be seen that coagulation begins at a very low A/T ratio of about 0.05 and that the coagulation precipitation changes to the coagulation flotation at about $A/T=1.2$, *i.e.*, at an amount of adsorption slightly above the exchange capacity, and that the redispersion begins at an A/T ratio larger than about 1.8. On the basis of these experimental results, the state of the adsorption of the cationic surfactant on the bentonite to produce coagulation and redispersion is illustrated in Fig. 5.

In this figure, (a) and (b) show the HTAC adsorption on the single bentonite particle and the state of aggregation of such particles respectively in each concentration range of Fig. 2. At a very concentration of HTAC, the bentonite is dispersed despite the adsorption of the

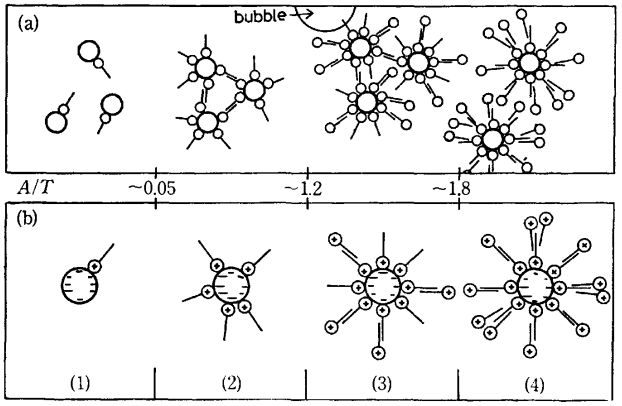

Fig. 5. Adsorption of HTAC and state of dispersion of bentonite (a) and adsorption of HTAC on a bentonite particle (b). (1) dispersion, (2) coagulation precipitation, (3) coagulation flotation, (4) redispersion.

cationic surfactant. With an increase in the concentration of the cationic surfactant, the surface of the particles is rendered hydrophobic by the increasing amount of the adsorption of HTAC, with its hydrophobic tail directed outward, and the coagulation of particles is promoted by the hydrophobic binding of these adsorbed molecules. Since there are no sufficient molecules available for adhering to bubbles, coagulated particles precipitate. As the amount of adsorption increases and comes slightly to exceed the exchange capacity, namely, $A/T>1.2$, double-layer adsorption takes place, as is shown in Fig. 5, and the coagulates assume an open structure favorable for bubble attachment, resulting in coagulation flotation. At A/T ratios larger than 1.8, the double-layer adsorption is nearly completed and the bentonite particles are rendered hydrophilic, resulting in a redispersion of the particles. In this state, the bentonite particles have sufficient positive charges as a result of the adsorption of the cationic surfactant.[14] This reversl. of the charge was also confirmed by electrodialysis measurements.

Flotation of Cd^{2+} Ions by HTAC and Bentonite. There are various possible types of methods of ion flotation.[15] The combined use of bentonite and a cationic surfactant is especially effective for the removal of both anion and cations in the solution.[16] From this fact, together with the phenomena of coagulation flotation and precipitation mentioned above, the bentonite-cationic surfactant system is considered to be suitable for the flotation of ions in an aqueous solution. Here, cadmium ions are selected as the ions to be floated. The flotation was carried out for a solution containing 1.78×10^{-5} mol/l Cd^{2+}, 1000 ppm bentonite, and varying concentrations of HTAC under a gas-flow rate and a time of 10 ml/min and 7 min respectively and at pH 11.2. The results are shown in Fig. 6.

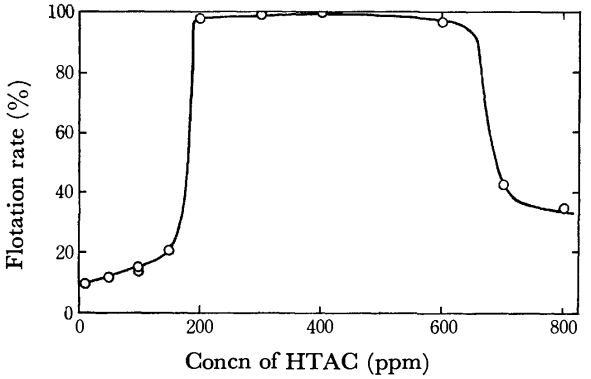

Fig. 6. Rate of Cd^{2+} ion flotation *vs.* concn of HTAC. Cd^{2+}: 1.78×10^{-5} mol/l, bentonite: 1000 ppm, pH: 11.2, gas-flow time: 7 min, gas-flow rate: 10 ml/min, pH adjusted by NaOH.

As may be seen, the flotation rate, F, increases rapidly at an HTAC concentration of about 150 ppm, shows a flat maximum of about 98% in the region of HTAC concentrations from 200 ppm to 600 ppm, and decreases at concentrations of HTAC larger than about 600 ppm. In the region of HTAC concentrations from 200 ppm to 600 ppm, the solutions after flotation look quite transparent, while in the other region of HTAC concentrations they look opaque. These facts indicate that the region of coagulation flotation shown in Fig. 2 corresponds to the optimum region of ion flotation, although the former does not coincide with the latter, perhaps because of difference in the pH at which the flotation measurements were carried out. A rapid decrease in the flotation rate above 600 ppm HTAC may be explained by a redispersion of the bentonite in addition to the replacement of the Cd^{2+} ions on the bentonite by HTAC. It was further confirmed that a stable foam layer was produced for the bentonite concentrations larger than about 400 ppm.

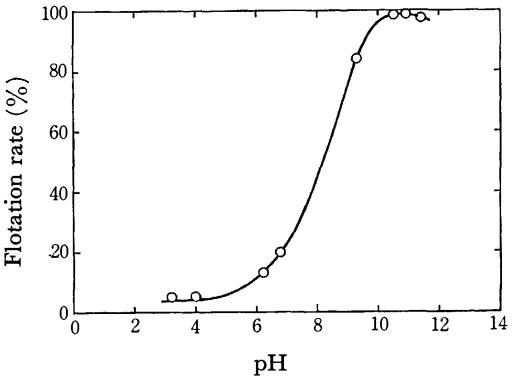

Fig. 7. Rate of Cd^{2+} ion flotation *vs.* pH. Cd^{2+}: 1.78×10^{-5} mol/l, bentonite: 600 ppm, HTAC: 200 ppm, gas-flow time: 7 min, gas-flow rate: 10 ml/min, pH adjusted by NaOH.

Figure 7 shows the flotation rate *vs.* pH curve under the optimum conditions specified in the figure. As may be seen, the flotation rate begins to increase from almost zero at around pH; the maximum flotation rate of 99% was observed at about pH 11. From these experiments, it may be concluded that the optimum conditions for the bubble flotation of Cd^{2+} ions exist in the region of coagulation flotation and that the region is relatively wide with respect to the amount of HTAC, while it is rather narrow for hydrogen-ion-concentration change, as expressed by the pH. Since the bentonite and the HTAC are confirmed to be removed together with the Cd^{2+}, the above conditions are also the optimum ones for these additives.

Surface Dilational Properties of Adsorbed Monolayers of Aqueous Sodium Dodecyl Sulfate Solutions

Masao NAKAMURA*

Department of Chemistry, Faculty of Science, Tokyo Metropolitan University, Setagaya, Tokyo 156

(Received January 6, 1975)

The surface pressure relaxation of a freshly formed surface and the surface area creep at a constant surface pressure have been studied for aqueous surface of sodium dodecyl sulfate solutions. It was found that the area stress after the formation of a fresh surface undergoes relaxation according to the generalized Maxwell model, and that the surface area viscosity is not constant during the process but increases with the surface area. The concept of two-dimensional open system rheology was introduced and the observed phenomena were discussed. A surface equation of state applicable under such dynamic conditions has been derived.

Numerous studies[1-3] have been carried out on the adsorption kinetics of surface-active solute from aqueous solutions onto their surfaces in connection with the variation of surface tension with time. For such studies, it is necessary to change the measured surface tension (pressure) data into the amount of solute absorbed at each moment. However, there is no non-equilibrium surface equation of state that can be applied during the course of adsorption.

The rheological properties of the surface containing adsorbed surfactants have often been the cause of the stability of dispersion.[4] Four independent surface rheological paramenters are taken into consideration, surface shear viscosity and elasticity, and surface dilational (or area) viscosity and elasticity. The surface area modulus, the reciprocal of surface compressibility, is zero at equilibrium for the adsorbed surface, when the equilibrium surface tension of surfactant solution is constant, independent of the area at a constant temperature. The surface viscosity and elasticity contribute to foam drainge *via* surface transport phenomena.[5] The surface area viscosity seems to influence the damping of ripples a great deal.[6] As regards the measurement of the surface area viscosity, only a few reports have appeared for surfactant solutions.[7]

The expansion or contraction of the surface in equilibrium produces an area strain, and the corresponding stress changes the surface pressure (or tension) from the equilibrium value. Under the action of surface area viscosity, the surface pressure usually returns to its equilibrium value. This seems to be due to the relaxation of area stress. The change of surface tension after the formation of a fresh surface is a special case.

The process of the change of surface area under a constant surface pressure differing from the equilibrium value corresponds to the creep of the area strain under a constant stress, and under the action of the surface area viscosity. In the present paper, the relaxation and creep processes for the aqueous surface containing adsorbed film in contact with bulk of the solution were studied. Aqueous sodium dodecyl sulfate solutions were chosen for this purpose.

Experimental

Sodium dodecyl sulfate (SDS) was prepared by the reaction of pure dodecanol with chlorosulfonic acid in ether followed by neutralization with sodium hydroxide. The product was purified twice by addition of active charcoal to its hot saturated ethanol solution followed by recrystallization from the cold solution.[8] The product was sufficiently pure, showing no minima in the surface tension *vs.* concentration curve.

The surface pressure against pure water was measured within an error of ± 0.02 dyn/cm by the Wilhelmy method using a vertical glass plate, peripheral length 4.790 cm.[9] The glass plate was cleaned by immersing it in concentrated aqueous alkaline–alcohol solution overnight, dipping in a hot chromic acid mixture for *ca.* 1 hr, and rinsing with water.

The stock solution of SDS was prepared and subjected to aging for *ca.* 17 hr before each measurement, since the variation of surface tension with time is considered to depend upon age. The water used for dissolving SDS was freshly distilled and boiled for *ca.* 1 hr to remove dissolved gas, which otherwise formed bubbles on the paraffin-coated walls during the course of measurement.

A Langmuir type trough of $60 \times 15 \times 1$ cm size coated with paraffin was used. Water from a thermostat was circulated beneath the trough, and the solution was maintained at 30 ± 0.3 °C. The trough and the tensiometer, contained in a closed chamber of air thermostat at 30 ± 1 °C, were protected from atmospheric contaminations. For measurements under a constant area, glass barriers coated with paraffin were used to clean and to provide a specified surface area. For measurements under a constant surface pressure, one of the barriers was driven by a motor to change the surface area continuously.

Reproducible surface pressure could be obtained after allowing the solution to stand in the trough for 1 hr and then sweeping its surface at least 10 times with three barriers. The error of the surface pressure measurement due to the fall of water level produced by the surface evaporation during the course of measurement was confirmed to be negligible as compared with the overall error.

Results and Discussion

Relaxation Process under a Constant Area Strain. Figure 1 shows the variation of surface pressure π with time t after the formation of fresh surface for aqueous SDS solutions of varying concentrations under a constant area *ca.* 400 cm^2, and pH *ca.* 6. Since the surface pressure did not attain a constant value except for a very dilute solution (1×10^{-4} mol/l), the equilibrium surface pressure π_e was obtained by extrapolating plot π *vs.* $1/t$ to $1/t = 0$.[10]

From a rheological point of view, the process shown in

* Present address: Department of Chemistry, Faculty of Science, Tokai University, Hiratsuka, Kanagawa 259-12.

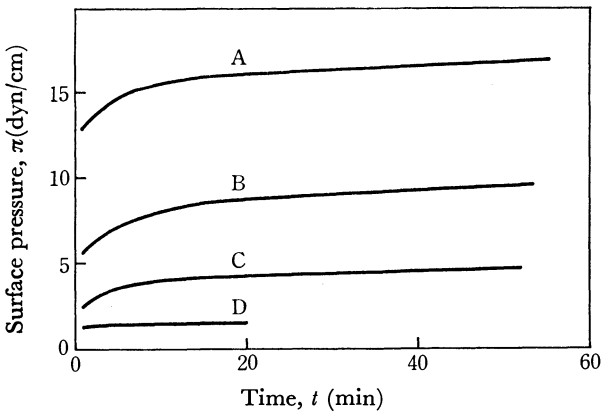

Fig. 1. Surface pressure *vs.* time plot for aqueous SDS solutions at 30 °C. Surface area: 400 cm².
Concn of SDS: A,2.02; B, 1.05; C, 0.52; D, 0.10×10^{-3} mol/l.

Fig. 1 is regarded as one in which the stress

$$\Delta\pi = \pi_e - \pi \tag{1}$$

produced by a constant area strain undergoes relaxation according to the generalized Maxwell model as given by

$$\Delta\pi = \sum_i^n K_i e^{-t/\tau_i}, \tag{2}$$

where K_i and τ_i are constants. At $t=0$, Eqs. (1) and (2) give

$$\sum_i^n K_i = \pi_e \tag{3}$$

since $\pi=0$ at $t=0$.

As regards the τ_i and K_i values, the largest value, τ_1, with the corresponding K_1 value can be determined from the linear part of the plot log $\delta\pi$ *vs.* t for sufficiently large value of t, and the next largest value, τ_2, with the corresponding K_2 value can be obtained from the linear part of the plot log $(\delta\pi - K_1e^{-t/\tau_1})$ *vs.* t. Figure 2 shows such a plot. The values obtained (Table 1) express the curves in Fig. 1 within ±0.05 dyn/cm. It is the shorter relaxation time τ_2 which should be compared with thin

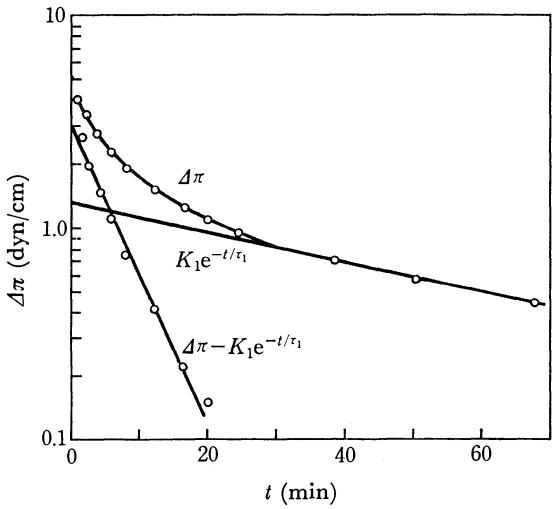

Fig. 2. $\Delta\pi$, K_1e^{-t/τ_1}, and $\Delta\pi - K_1e^{-t/\tau_1}$ *vs.* t plot.
Concn of SDS: 2.02×10^{-3} mol/l.
Surface area: 400 cm².

Table 1. Relaxation times (τ_1, τ_2) and initial stresses (K_1, K_2) for the freshly formed surfaces of aqueous SDS solutions and their equilibrium surface pressures (π_e) at 30 °C

	Concn (mol/l) $\times10^{-3}$	π_e (dyn/cm)	τ_1 (min)	τ_2 (min)	K_1 (dyn/cm)	K_2 (dyn/cm)
A	2.02	17.20	63	6.1	1.31	3.10
B	1.05	10.40	39	4.5	2.31	2.65
C	0.52	5.45	82	3.4	1.67	1.78

film relaxation times of the order of minutes, measured by Razouk and Mysels[11] for the aqueous SDS solutions.

In all the cases, K_1+K_2 is not equal to the equilibrium surface pressure π_e. This means that the value of surface pressure (Fig. 1) extrapolated to $t=0$ is not zero and suggests the existence of at least one more relaxation element something like "semi-dynamic surface tension" postulated by Bouteric and Berthier[12] and Ross.[13] The presence of two relaxation elements has been reported,[14] when the relaxation was measured after expanding the lamellae of bovine hemoglobin solution.

Equations (1) and (2) give

$$\pi = \sum_i^n K_i(1-e^{-t/\tau_i}). \tag{4}$$

The two longest relaxation times of τ_i were thus determined. The remaining shorter relaxation times can not be measured by the vertical plate technique. They might be detected by a more rapid measurement, such as the jet method.

Creep Process under a Constant Stress. The change of surface area A under a constant surface pressure was determined with time t for solutions whose area stress relaxation had been measured. The results are shown in Fig. 3. Measurements were made first by sweeping the surface with a paraffin-coated glass barrier to form a fresh surface and then with a motor-driven barrier to expand the surface in order to keep the surface pressure within 0.5 dyn/cm of the predetermined value of π_s. Surface area A thus obtained was plotted against time t.

Since the rate of area strain is expressed by $(1/A)(dA/dt)$ and the stress by $\delta\pi=(\pi_e-\pi_s)$, the area viscosity η_A is defined by

$$\Delta\pi = \eta_A \frac{1}{A}\cdot\frac{dA}{dt}, \tag{5}$$

according to Boussinesq.[15] By integration under the assumption that $\delta\pi$ and η_A are constant, we have

$$\ln A - \ln A_i = \frac{\Delta\pi}{\eta_A}\cdot t, \tag{6}$$

where A_i is the value of A at $t=0$. Thus, log A should change linearly with t. However, this was not the case actually, the dependence of η_A on A or t being shown. Equation (5) combined with the $A(dt/dA)$ *vs.* A relation gives

$$\frac{\eta_A}{\Delta\pi} = \frac{rA}{1+qA} + s, \tag{7}$$

where q, r, and s are constants.

The fact that η_A increases with area is in line with the result of van Voorst Vader's experiments in which $(1/A)$

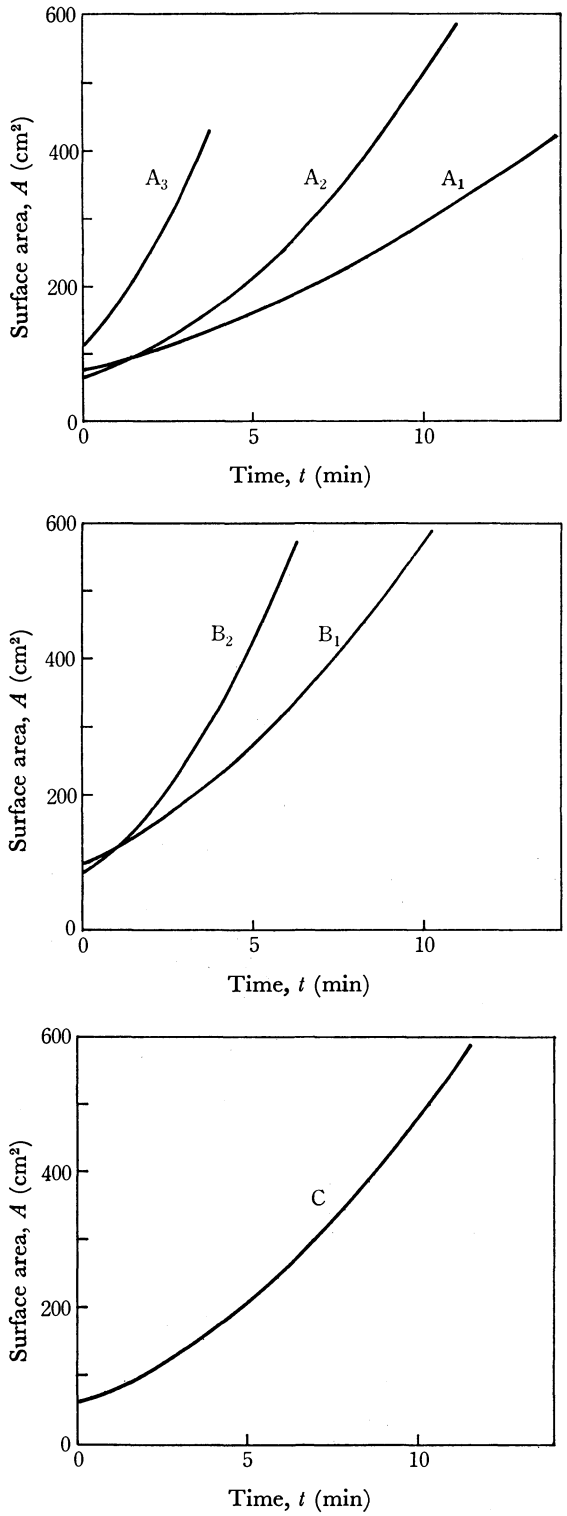

Fig. 3. Surface area *vs.* time plot under constant area stress.

	A_1	A_2	A_3	B_1	B_2	C
Concn of SDS ($\times 10^{-3}$ mol/l)	2.02	2.02	2.02	1.05	1.05	0.52
Area stress, $\Delta\pi$ (dyn/cm)	2.02	2.68	3.34	3.14	3.80	1.13

(dA/dt) is kept constant.[7] We see that the relation of $\delta\pi$ *vs.* $(1/A)(dA/dt)$ at a given A of the same solution (A_1, A_2, and A_3, or B_1 and B_2 in Fig. 6) gives a relation similar to the curve in the steady state obtained by van Voorst Vader *et al.*[7] The area viscosity obtained can be separated into two parts, if two Maxwell elements are considered. It would be reasonable to divide η_A into two portions in a ratio of τ_1K_1 and τ_2K_2, since

$$\eta_{Ai} = \tau_i\varepsilon_{Ai}, \tag{8}$$

in which ε_{Ai} is the area elastic modulus of the i'th element, to which K_i is proportional. Since K_1 and K_2 are of the same order of magnitude (Table 1), η_{A1} and η_{A2} would be roughly proportional to τ_1 and τ_2. If there are more relaxation elements as given by Eq. (2), area viscosity should be separated into more than two elements.

Rheology of Two-dimensional Open System. The system treated here differs essentially from the ordinary rheological system in that the number of molecules involved in the system changes in the former (open system), and remains constant in the latter (closed system). In the rheology of a two-dimensional system, the open system treatment is required when the area of liquid surface with its soluble adsorbed film changes. The above four rheological parameters are similarly defined for both open and closed systems, but the molecular behavior brought about by an area strain is quite different for the two systems. Thus, in the closed system, the stress relaxation after area strain is due to the change in the rearrangement, orientation, conformation and/or other chemical change of the molecules in the system, while in the open system the relaxation involves the transfer of the molecules into or out of the system, *i.e.*, the adsorption from or desorption into bulk of the solution, in addition to the above changes of the closed system. As a result, the area viscosity is much more significant in the mechanical behavior of the two-dimensional open system than the volume viscosity of the three-dimensional closed system.

The surface film flows and the adsorbed molecules in the surface generally rearrange themselves by the pressure gradient due to the compression or expansion of the surface. Since the surface shear viscosity is sufficiently below the order of magnitude of 10^{-4} surface poise for an adsorbed film of pure SDS,[16] the surface flow would rapidly follow the surface expansion in the creep experiment and the surface might be regarded to be uniform as a whole. The rate of orientation of adsorbed molecules on the water surface is also considered to be fairly rapid in a dilute solution of SDS, similar to that of water molecules on the surface, though the exact rate is not known.[17] The measured rheological properties might be governed mainly by the transfer of molecules from bulk of the solution to the surface.

In such a case, when the rate of adsorption is constant and the rate of desorption simply depends upon the surface pressure, the relaxation due to the process would be rather simple. On the other hand, when an unstirred diffusion layer of certain thickness exists just below the surface, several exponential terms should be taken into account in order to elucidate the relaxation mechanism, regardless of the presence of energy barrier at the surface, as Sutherland suggested.[18] The relation between relaxation and creep observed might be discussed as rheology of an open system.

Since the adsorption of surfactant molecules is the

principal cause common to both the relaxation of area stress and the creep of area strain observed as an open system, a certain relation might be expected to exist between these phenomena. Because of the lack of exact equation of state available for the adsorbed film under such dynamic conditions, surface pressure is first assumed to be proportional to the surface density of adsorbed SDS molecules, namely, an ideal gas type equation is assumed to hold:

$$\pi A = nkT, \tag{9}$$

where n is the total amount of adsorbed SDS, k the Boltzmann constant, and T absolute temperature. Thus at a given moment of surface area expansion, the relation between creep and relaxation is given by

$$A\left(\frac{\partial\pi}{\partial t}\right)_A = \pi\left(\frac{\partial A}{\partial t}\right)_\pi. \tag{10}$$

This is derived by differentiation of Eq. (9) with respect to time t keeping π or A constant. In order to examine the validity of Eq. (10), $(\partial A/\partial t)\pi$ and $(\partial\pi/\partial t)_A$ obtained by drawing tangents to the curves shown in Figs. 3 and 4, respectively, are used. However, both sides of Eq.

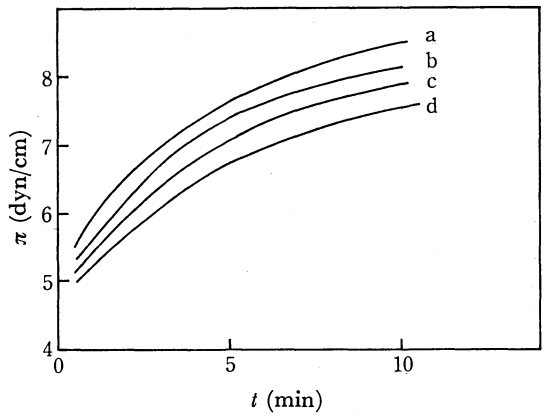

Fig. 4. Area effect on π *vs.* t curve for aqueous SDS solution.

(10) calculated differed from each other by about one order of magnitude. It was also found that Amagat's type of equation of state does not hold in the present case. We assume a surface equation of expanded film type

$$(\pi+\pi_0)(A-A_0) = nkT, \tag{11}$$

where π_0 and A_0 are constants. A similar calculation gives the following equation:

$$(A-A_0)\left(\frac{\partial\pi}{\partial t}\right)_A = (\pi+\pi_0)\left(\frac{\partial A}{\partial t}\right)_\pi. \tag{12}$$

Neither Eq. (12) nor Eq. (11) holds, since π_0 found was not constant but increased in proportion to π. However, we found at least experimentally that the relation

$$A - A_0 = p\pi_s\left(\frac{\partial A}{\partial t}\right)_{\pi_s}\left(\frac{\partial t}{\partial\pi}\right)_A \tag{13}$$

holds as a whole with constants A_0=25 cm² and p=0.13 (Fig. 5) for the systems of B_1 and B_2 under a constant π_s. The original state of equation corresponding to Eq. (13)

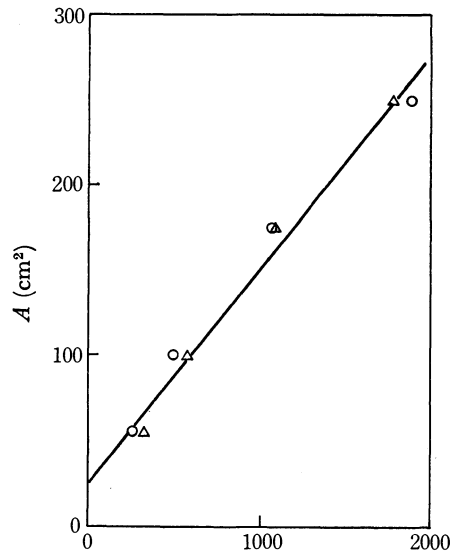

Fig. 5. A *vs.* $\pi_s\left(\frac{\partial A}{\partial t}\right)_{\pi_s}\left(\frac{\partial t}{\partial\pi}\right)_A$ plot.
○: B_1, △: B_2.

would then take the form

$$\pi(A-A_0)^p = \alpha n, \tag{14}$$

where α is a constant. We see that π decreases rapidly with increasing A in the region of small A with an asymptote at $A=A_0$ while the decrease is small in the region of large A as compared with π *vs.* A relation for ideal gas film. This suggests that the curve π *vs.* A shifts towards the region of larger area than that of ideal gas film, and that a large apparent repulsive force prevails. The ionic nature and steric factor are also considered to have certain relations.

The values $(\partial\pi/\partial t)_A$ at sufficiently large A were calculated by means of Eq. (14) and compared with the observed values. According to Eq. (13), we have

$$\left(\frac{\partial\pi}{\partial t}\right)_A = p\pi_s\left(\frac{\partial A}{\partial t}\right)_{\pi_s}\Big/(A-A_0). \tag{15}$$

In order to obtain an empirical formula for $(\partial A/\partial t)\pi_s$, a trial and error method was attempted and the following relation was found to hold (Fig. 6):

$$A\left(\frac{\partial t}{\partial A}\right)_{\pi_s} = \frac{rA}{1+0.002A} + s. \tag{16}$$

The values of r and s are given in Table 2. Substituting $(\partial A/\partial t)\pi_s$ of Eq. (16) into Eq. (15), the value $(\partial\pi/\partial t)_A$ at infinite A is obtained as

$$\left(\frac{\partial\pi}{\partial t}\right)_{A_\infty} = p\pi_s q/r, \tag{17}$$

where q=0.002 cm^{-2}. The values $(\partial\pi/\partial t)_{A\infty}$ calculated by means of Eq. (17) are given in Table 2 together with the observed values obtained at π_s from Fig. 1.

The values agree as a whole, although the disagreement is not small in some cases. The discrepancy might come from the nature of Eq. (14) for the open system under dynamic conditions, together with the fact that the states of the film in an immediate vicinity of the

barrier and rim of the trough differ from those in the main part of the film. It may be further inferred that A_0 in Eq. (14) when expressed per molecule seems to correspond to the co-area of Amagat's equation, but it may involve contribution of some other factors, which reduce the area effective for adsorption.

The author wishes to express his hearty thanks to Professer Tsunetaka Sasaki for his encouragement and guidance.

Heat Capacity Changes of Alkyl-substituted Ammonium Chlorides in Aqueous Solutions

Kunio TAMAKI, Satoru YOSHIKAWA, and Mitsuyoshi KUSHIDA
Department of Chemistry, Yokohama City University, Kanazawa-ku, Yokohama 236
(Received January 21, 1975)

The changes in the heat capacity for the dissolution in water, ΔC_p°, of *n*-alkylammonium chlorides (methyl to hexyl), di-*n*-alkylammonium chlorides (methyl to butyl), and tri-*n*-alkylammonium chlorides (methyl to propyl) at the room temperature were determined from measurements of the relation between the heats of solution of these salts in water and the temperature, and the results were compared with the ΔC_p° values for tetraalkylammonium salts in the literature. It was found that the effect of the coordination of the charge-bearing nitrogen atom by alkyl groups was definitely reflected in the ΔC_p° values. In the cases of $MeNH_3Cl$, $EtNH_3Cl$, Me_2NH_2Cl, and Me_3NHCl, the ΔC_p° values are negative, while in the cases of other higher homologues, the ΔC_p° values are positive; the increments in the ΔC_p° values per methylene group are discussed in terms of the hydrophobic hydration and the steric effect of alkyl chains.

Recently, studies of the behavior of electrolytes with attached nonpolar groups, particularly of tetraalkylammonium salts, R_4NX, have been extensively carried out by various experimental methods.[1-5] Measurements of the heat capacities of aqueous electrolytes solutions produce useful information about the influences of ions on the structure of solvent water.[6] The changes in the heat capacities for the dissolution in water of simple salts indicate negative values, whereas the changes in the heat capacities for the dissolution in water of nonpolar solutes indicate positive values. This characteristic relation has been applied to the study of R_4NX salts in water, and the behavior of R_4NX salts has been discussed in terms of the modification of the water structure around the nonpolar parts.[6-12] To elucidate the role of the alkyl groups on the coordination of the charge-bearing nitrogen atom, it seems of great interest to study the behavior of incompletely alkylated ammonium salts in water.

In this paper, we will report our experimental results on the changes in the heat capacity for the dissolution in water of *n*-alkylammonium chlorides RNH_3Cl (methyl to hexyl), di-*n*-alkylammonium chlorides R_2NH_2Cl (methyl to butyl), and tri-*n*-alkylammonium chlorides R_3NHCl (methyl to propyl); we will discuss the results in terms of the balance of two types of hydration-namely, electrostrictive hydration due to the ionic part and hydrophobic hydration due to the nonpolar part.

The change in the heat capacity for the dissolution at infinite dilution, ΔC_p°, may be obtained from the relation between the heat of solution at infinite dilution, ΔH_s°, and the temperature, T:[13]

$$d\Delta H_s^\circ/dT = \Delta C_p^\circ = \bar{C}_p^\circ - C_p \quad (1)$$

where $\bar{C}_p^\circ$ is the partial molal heat capacity of the solute at infinite dilution, and C_p the heat capacity of the pure salt.

Experimental

NH_4Cl was a commercial sample of a G. R. grade. The other organic chemicals were obtained from Tokyo Kasei Kogyo Co. RNH_3Cl salts were the same samples as have been described elsewhere.[14] Pr_2NH_2Cl, Bu_2NH_2Cl, and Pr_3NHCl were prepared by the neutralization of the respective amines with gaseous hydrogen chloride in benzene. All the organic salts were recrystallized from suitable solvents: ethanol for Me_2NH_2Cl, Et_2NH_2Cl, Pr_2NH_2Cl, and Me_3NHCl; ethyl acetate for Pr_3NHCl; and ethanol–ethyl acetate mixtures for Bu_2NH_2Cl and Et_3NHCl. Water was redistilled from an alkaline permanganate solution.

The heats of solution were measured by means of a twin conduction microcalorimeter (Model CM-204D1 of Ōyodenki Kenkyujo) described in a previous paper.[15] The uncertainties of the heat-of-solution data obtained in this work were estimated to be within 0.03 kcal/mol at 10—25 °C and 0.05 kcal/mol at 30—45 °C. The concentration of the measured solution was 0.01 M, and the heat of dilution from a solution at 0.01 M to one at a large dilution is about $-0.03 \sim -0.04$ kcal/mol for NH_4Cl, $MeNH_3Cl$, Me_2NH_2Cl, and Me_3NHCl.[16] In view of this situation, the mean values of the heats of solution repeatedly measured at 0.01 M are presented in this paper. The ΔC_p° values are obtained by assuming that the change in the heat capacity at 0.01 M is equal to that at infinite dilution.[15]

Results

The heats of solution obtained for three homologous series of RNH_3Cl, R_2NH_2Cl, and R_3NHCl are listed in Table 1. The ΔH_s° values at 25 °C reported by Krishnan and Friedman[17] for RNH_3Cl salts, Me_2NH_2Cl, Bu_2NH_2Cl, and Me_3NHCl are also included in Table 1. Except for Bu_2NH_2Cl, the heats of solution obtained in this work at 25 °C are in fairly good agreement with those reported by Krishnan and Friendman.[17] Taking account of the experimental uncertainties described above, the heats of solution can be regarded as approximately a linear function of the temperature over the range studied. The approximate linear relation between the heat of solution and the temperature in the range of room temperature has sometimes been reported.[10] The mean ΔC_p° values in the range of measurements are obtained from the average slope of the linear plots of the heats of solution against the temperature: the results are listed in Table 2. For comparison, the ΔC_p° values at room temperature reported for R_4NBr salts in the literature[7,10] are also included in Table 2. As will be explained below, the difference in ΔC_p° values due to the variation in halide ions for the same cation is very small. Therefore, the ΔC_p° values of R_4NBr salts may well be

used in place of R_4NCl salts for the purpose of considering the effect of alkyl chains on the behavior of alkyl-substituted ammonium salts in water.

Discussion

The $\Delta\bar{C}_p^\circ$ Value as the Ion-solvent Interaction Parameter. The $\bar{C}_p^\circ$ value is of thermodynamical importance for the study of electrolyte solutions.[18] The $\bar{C}_p^\circ$ value can be obtained by the measurement of the heat capacities of solutions at dilute concentrations.[18] There have been reports about the $\bar{C}_p^\circ$ values for methyl- and ethylammonium chlorides by Rüterjans, Schreiner, Sage, and Ackermann,[19] for a series of *n*-alkylammonium bromide by Leduc, Fortier, and Desnoyers.[20] and for some di-*n*-alkylammonium chlorides by Cobani, Conti, Martinelli, and Matteoli.[21] Alternatively, if the C_p value is known, the $\bar{C}_p^\circ$ value can be obtained by adding the C_p and ΔC_p° values by means of Eq. (1). Furthermore, it is assumed that the $\bar{C}_p^\circ$ value consists of two contributions; the first is the intrinsic heat capacity of the ions in the absence of ion-solvent interactions, while the second is the contribution arising from the influence which the ions exert on the solvent structure:[11]

$$\bar{C}_p^\circ = \bar{C}_p^\circ(\text{int}) + \bar{C}_p^\circ(\text{solv}) \quad (2)$$

Thus, in order to discuss the interaction of ion with solvent using the data of the $\bar{C}_p^\circ$ value, we must obtain the $\bar{C}_p^\circ$ (solv) value by substracting the appropriate value of the $\bar{C}_p^\circ$(int) value from the $\bar{C}_p^\circ$ value. For the $\bar{C}_p^\circ$(int) value, Visser and Somsen[11,12] adopted the hypothetical liquid state of the salt. On the other hand, Leduc, Fortier, and Desnoyers[20] assumed two limiting cases for the $\bar{C}_p^\circ$(int) value; one is as the liquid state, and the other is as the solid crystalline.

If we regard $\bar{C}_p^\circ$(int) as the capacity of the solid crystalline, ΔC_p° in Eq. (1) corresponds to $\bar{C}_p^\circ$(solv) in Eq. (2). In other words, the ΔC_p° value is a measure of ion-solvent interactions if the standard state of the salt is taken as the solid state.

A variety of simple salts show negative $\bar{C}_p^\circ$ values in water, which may be interpreted in terms of electrostrictive hydration.[22] For example, the $\bar{C}_p^\circ$ values for NaCl, NaBr, and NaI are −22.1, −23.3, and −23.4 cal/K mol at 25 °C respectively.[23] If we use 11.9, 12.5, and 13.0 cal/K mol for the corresponding C_p values at 25 °C in the literature,[24] the ΔC_p° values become −34.0, −35.8, and −36.4 cal/K mol respectively. Likewise we can conclude that the ΔC_p° values for other alkali halides do not vary greatly with the different halide ions, such as Cl^-, Br^-, and I^- ions. On the other hand, the ΔC_p° values for organic solutes with nonpolar groups, such as alkyl alcohol,[25] alkane carboxylic acids,[26] and alkylamines,[26] are all positive, which may be interpreted in terms of the promotion of the water structure around the nonpolar groups in water (hydrophobic hydration).

RNH_3Cl Salts. NH_4Cl is a typical simple salt, the ΔC_p° value being as low as -32 cal/K mol, as may be seen in Table 2. In a previous study of viscosity B coefficients,[14] we proposed that the $-NH_3^+$ ionic part is an electrostrictive structure-breaker. Table 2 indicates the negative ΔC_p° values for $MeNH_3Cl$ and $EtNH_3Cl$. Leduc, Fortier, and Desnoyers[20] showed that the $\bar{C}_p^\circ$—$\bar{C}_p^\circ$(int) values for $MeNH_3Br$ and $EtNH_3Br$ are negative, whether the $\bar{C}_p^\circ$(int) value is taken as a liquid or a solid state. Therefore, it may be concluded that the electrostrictive hydration due to the charge-bearing nitrogen atom may interfere with the interaction of hydrophobic methyl or ethyl groups with water in RNH_3Cl salts. In the cases of $PrNH_3Cl$ and higher homologues, the ΔC_p° values become positive, and they increase with an increase in the chain length. They are classifiable as hydrophobic structure-making solutes. The average increment in the ΔC_p° values per methylene group from $MeNH_3Cl$ to higher homologues is about 16 cal/K mol; this value corresponds approximately to the value in the series of nonelectrolytes such as alcohol.[25]

Previous studies of the viscosity B coefficient[14] and the surface activity[27] seem to indicate that $EtNH_3Cl$ may be classified as a weak hydrophobic structure-making solute. Although it is difficult to draw any definite conclusions, the ambiguity in the behavior of this salt in water is probably attributable to the fact that $EtNH_3Cl$ is a borderline solute.

R_2NH_2Cl Salts. As may be seen in Table 2, the ΔC_p° value for Me_2NH_2Cl is negative, but the value is less negative than that of $MeNH_3Cl$, showing the cooperative hydrophobic effect of the two methyl groups. In the cases of Et_2NH_2Cl, Pr_2NH_2Cl, and Bu_2NH_2Cl, the ΔC_p° values become positive, and they are hydrophobic structure-makers. The increments in the ΔC_p° values per methylene group from Me_2NH_2Cl to Bu_2NH_2Cl are about 15 cal/K mol, suggesting that the two alkyl chains can interact independently with water in R_2NH_2Cl series.

R_3NHCl and R_4NBr Salts. The ΔC_p° values for Me_3NHCl and Me_4NBr are about -11 cal/K mol, only slightly less negative than that of Me_2NH_2Cl. Although the ΔC_p° values for ethyl salts and higher homologues are positive in R_3NHCl and R_4NBr salts, the increments in the ΔC_p° values per methylene group from methyl salt to ethyl salt are 10—12 cal/K mol; the values are smaller than the average value of 16 cal/K mol in a series of straight-chain solutes. These facts suggest that methyl and ethyl groups cannot freely interact with water due to the steric configuration in both series. However, judging from the increments in the ΔC_p° values per methylene group from Et_3NHCl to Pr_3NHCl salts and from Et_4NBr to Bu_4NBr salts, the methylene groups of the C-3 position and the longer parts of the alkyl chains attached to the charge-bearing nitrogen atom are free from the steric effect on the interaction with water in both series.

In conclusion, all the methyl salts of the four types of alkyl-substituted ammonium salts in water are predominantly governed by electrostrictive hydration. $EtNH_3Cl$ is probably a borderline solute. The other salts studied are hydrophobic structure-makers, but the effect of alkyl groups on the hydrophobic hydration is slightly weakenened as a result of the steric configuration in R_3NHCl and R_4NX series.

The Determination of the Activity Coefficients of Pb(II), Cd(II), and Zn(II) Chlorides in *N,N'*-Dimethylformamide by Means of Electromotive-force Measurements of the M(Hg)/MCl_2(DMF)/AgCl; Cells*

Makoto SAITO and Akemi KANAMORI**

Department of Chemistry, College of Liberal Arts, Toyama University, 3190 Gofuku, Toyama 930

(Received January 21, 1975)

Electromotive-forces have been measured for the cells of the M(Hg)/MCl_2(DMF)/AgCl;Ag type at 25.00± 0.01 °C, where M are Pb, Cd, and Zn metals and were M(Hg) are amalgams saturated with these metals. The standard potentials of the corresponding metals relative to the silver-silver chloride have been determined, and the mean activity coefficients and the standard free-energies of formation have been calculated for the solvated salts of $PbCl_2$, $CdCl_2$, and $ZnCl_2$ from the electromotive-foce data. Experimental works were carried out by using an H-shaped Pyrex glass cell which was coated externally with silicon grease to eliminate electrical leakage from the water bath. The electromotive-force measurements were made with a digital voltmeter, the voltage sensitivity and the input impedance of which were 10 μV and 100 megohms respectively. The standard potentials for the cells of the M/MCl_2(DMF)/AgCl;Ag type were 0.327_1 V for $PbCl_2$, 0.576_2 V for $CdCl_2$, and 0.898_6 V for $ZnCl_2$.

In the early measurements of electromotive-force, Ulisch and Spiegel[1] discussed the reproducibilities of silver silver chloride and calomel electrodes in acetonitril as a solvent containing chloride ions. Pavlopoulos and Strehlow[2] measured the standard electrode potentials for various first kind electrodes in formamide. Luksha and Criss[3] determined the standard electromotive-forces for cells of the M(Hg)/MX(NMF)/AgX; Ag type, where M is Li, Na, K, or Cs and where X is either Cl^- or Br^-, and determined the activity coefficients of alkali metal ions in anhydrous *N*-methylformamide (NMF). Marple[4] studied the nonpolarizability of Cd(Hg)/$CdCl_2$ as reference electrode for polarographic studies in anhydrous *N,N'*-dimethylformamide (DMF). Studies of various reversible chloride electrodes which are used in dimethylsulfoxide, DMF, and propylene carbonate were carried out by Synott and Butler.[5] According to their paper, thallium, lead, and cadmium chloride electrodes were all stable in DMF, but the $CdCl_2$ was apparently the most stable in potential. The initial potential, 1.653 V, varied by less than 1 mV over the next 12 hr. In the present study, the electromotive-forces have been measured for cells of the M(Hg)/MCl_2/AgCl; Ag type, where M are Pb, Cd, and Zn metals and where M(Hg) are amalgams saturated with these metals. The standard potentials of the corresponding metals relative to the silver-silver chloride electrode were determined, and the mean activity coefficients and standard free-energies of formation were obtained for the solvated salts of $PbCl_2$, $CdCl_2$, and $ZnCl_2$.

Experimental

Solvent. DMF purified by the method described in a previous paper[6] was used. The specific conductivity of the DMF used was $7.0\sim7.5\times10^{-8}$ ohm^{-1} cm^{-1} at 25 °C. Karl-Fisher titrations indicated the water content in the distilled DMF to be less than 0.03%.

Anhydrous Metal Chlorides. Anhydrous metal chloride was prepared from hydrated metal chloride by treating it with thionyl chloride according to Tyree's method.[7]

Amalgams. Lead, cadmium, and zinc amalgams were prepared by the method of Kolthoff.[8] A quantity of metal was gently heated together with mercury and a small amount of diluted sulfuric acid, and then the amalgam thus prepared was carefully washed with diluted sulfuric acid and stocked under diluted sulfuric acid. The amalgam used as a heterogeneous (saturated) one.

All the other reagents used were of an analytical grade.

Electrodes. The Ag-AgCl electrode was prepared from Pt wire plated with silver by means of the electrolytic method.[9-10] The electrode was made up from 0.50 cm-diameter Pt wire sealed in Pyrex glass. Lengths of wire up to 15 cm were left exposed and spiralled, and then it was plated with silver by means of electrolysis from a mixed solution of silver nitrate and potassium cyanide. Eight electrodes were prepared at a time, and those with a bias potential greater than 0.3 mV were discarded. All the electrodes were stored in double-distilled water before use. The dropping analgam electrode used had a flow rate of 1~ 2 s/drop. No effect of the flow rate on the electromotive force (EMF) of the cells could be observed as had been reported by Walfenden *et al.*[11] and Scatchard and Tefft.[12]

Apparatus. The H-cell was made of Pyrex glass, and the two electrodes inserted into the cell were fixed with a silicon rubber stopper. The cell, coated externally with silicon grease to eliminate an electrical leakage from the water bath, was thermostatted on the water bath at 25.00±0.01 °C.

All the electromotive-force measurements were made with a Kuwano Electric Instruments, model DM-750, digital voltmeter. The voltage sensitivity and the input impedance of this voltmeter were 10 μV and 100 megohms respectively.

Experimental Procedures. About a 0.1 molal metal chloride DMF stock solution was prepared by dissolving a quantity of anhydrous metal chlorides in DMF in an ice bath. The concentration of metal chloride in the stock solution was determined by chelatometric titration[13] with EDTA before the solution was used in each experiment.

The electromotive-foce measurements were carried out in

* Presented at the 22nd Annual Meeting of the Japan Society for Analytical Chemistry, Fukuoka, November 23—26, 1973.

** Present address.: Scientific Investigation Research Laboratory, Toyama Prefectural Police Headquarters, 1-7 Shinsogawa, Toyama 930.

the manner described by Luksha and Criss.[3] Readings were taken approximately every 2 min, for a period of 45 min in general, but in a few cases for as long as 90 min.

Results and Discussion

The electromotive-force of a cell containing 2—1 electrolytes and with its electrodes in their standard states is given by:

$$E = E^\circ - \frac{3RT}{nF} \ln m\gamma_\pm, \quad (1)$$

where the symbols have their usual meanings. The expanded Debye Hückel equation gives the mean activity coefficient for the 2—1 electrolyte as:

$$\log \gamma_\pm = -\delta_\gamma \sqrt{m} + \beta m,$$

where: $$\delta_\gamma = 6.3213 \times 10^6 \frac{\rho_0^{1/2}}{(\varepsilon T)^{3/2}}, \quad (2)$$

β is a constant, m is the molality, and ρ_0 and ε are the density and the dielectric constant of the solvent respectively. For DMF at 25 °C, ε is 36.7 and ρ_0 is 0.944 g/cm^3, giving a value of 0.1148 kg/mol for δ_γ. The substitution of Eq. (2) into Eq. (1) and the rearrangement of the terms give:

$$E + \frac{3RT}{nF} \ln m - \frac{(2.303)3RT\delta_\gamma \sqrt{m}}{nF} = E^\circ - \frac{(2.303)3RT\beta m}{nF}, \quad (3)$$

The substitution of the appropriate constants into Eq. (3) leads to

$$E + 0.0887 \log m - 0.455\sqrt{m} = E^\circ - 0.0887\beta m, \quad (4)$$

The cell employed in this experiment is written as:

$$M(Hg)/MCl_2(DMF)/AgCl;\ Ag. \quad (a)$$

The measured potential of the (a) cell is not the electromotive force represented by E in Eq. (4), but, rather, a potential, E', related to E by:

$$E' = E - E'', \quad (5)$$

where E'' is the potential of a cell of this type:

$$M/MCl_2(soln)/M(Hg). \quad (b)$$

To correct the observed potential to that which one would obtain for a pure metallic electrode, the E'' value must be added to the observed potential. Making this substitution and setting the left-hand side of Eq. (4) equal to E''' gives:

$$E''' = E^\circ - 0.0887\beta m. \quad (6)$$

The resultant potentials then refer to a cell employing a pure metallic electrode and may be written as the (c) cell:

$$M/MCl_2(DMF)/AgCl;\ Ag \quad (c)$$

The relationships between the electromotive-force and the time of measurements at various concentrations are shown in Fig. 1 for the zinc chloride cell. As may be seen from Fig. 1, the potentials reached an equilibrium within 10 min from the begining of the measurements. The data obtained are summarized in Table 1. The first two columns give the molality of the cell solution and the measured potential respectively. The third column gives the potential required to correct the observed potential to that for a pure metallic electrode that is, the potential corresponding to the electromotive-force for cells of the (b) type cell. The values of the potential are listed from the literature.[13,14] The fourth column gives the values of E''' in Eq. (6), and the fifth column gives the potentials for cells of (c) type cell. The E''' values are plotted against the molality and extrapolated to an infinite dilution by the method of least-squares to obtain E°. Some typical results obtained are shown in

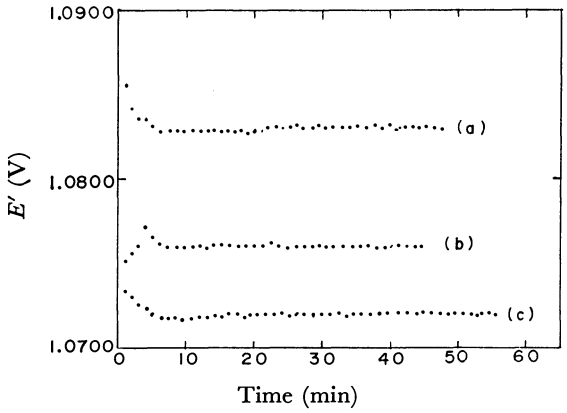

Fig. 1. Stability of electromotive-force for cell of type(a). (a): 0.1117 m $ZnCl_2$, (b): 0.1861 m $ZnCl_2$, (c): 0.2606 m $ZnCl_2$.

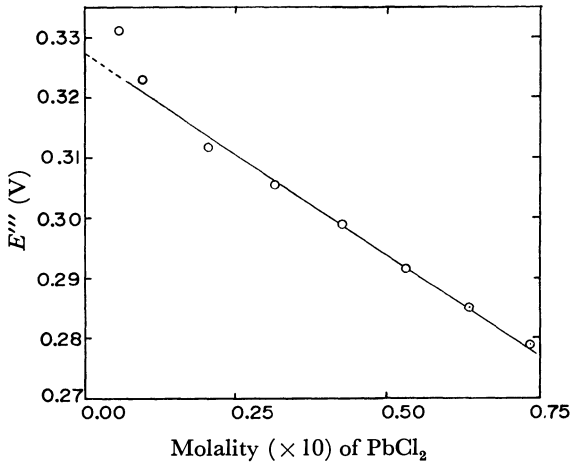

Fig. 2. Relationship between E''' and molality for $PbCl_2$ cell.

Fig. 2. Although the plots in the case of a concentration higher than 0.1 mol of a cell solution are not shown in Fig. 2, the relationship between the electromotive-force and the concentration of metal chloride makes a curve with a gentle slope. It may be considered that the dissociation of metal chloride in DMF becomes difficult in proportion to the increasing concentration of the salt. The standard potentials for the cells of the (c) type as evaluated by the least-squares treatment, are given in

Table 2. Standard potentials for cell of type (C)

Cell	$E°$ (V)
Pb|$PbCl_2$ (DMF)|AgCl; Ag	0.327_1

coefficients for a round concentration of metal chloride in cells of the (c) type listed in Table 3. The plots of the activity coefficients against the concentrations of metal chlorides related to this work are shown in Fig. 3.

Standard Free-energies of the Solvated Electrolytes. The general reaction for the (c) cell is:

$$M(s) + 2AgCl(s) = 2Ag(s) + MCl_2(soln),$$

and the corresponding standard free-energy change for this reaction is:

$$\Delta G° = G°_{f_{MCl_2(soln)}} + 2G°_{f_{Ag(s)}} - G°_{f_{M(s)}} - 2G°_{f_{AgCl(s)}} = -nFE° \qquad (8)$$

where $G°_{f_{MCl_2(soln)}}$ is the standard free-energy of the formation of a solvated MCl_2. The standard free-energy of the formation of a solvated salt, MCl_2, is then given by:

$$G°_{f_{MCl_2(soln)}} = 2G°_{f_{AgCl(s)}} - nFE° \qquad (9)$$

The values for the standard free-energies of formation have also been calculated for the corresponding solvated salts; they are listed in Table 4.

Table 4. Standard free-energies of formation of solvated metal chlorides in DMF

Salt	$-G_f°$ (kcal/mol)	
	DMF	H_2O
$PbCl_2$	67.54	68.51
$CdCl_2$	79.03	81.28
$ZnCl_2$	93.90	97.88

The standard free-energy of the formation for silver chloride was obtained from Lange:[16] $G°_{f_{AgCl(s)}} = -26.22$ kcal/mol. The standard free-energies of the formation of solvated lead, cadmium, and zinc chlorides in aqueous solutions are also listed in Table 4, thus facilitating a comparison of these data. As may be seen from Table 4, the free-energy values in DMF were larger than in the aqueous solution. It may, therefore, be considered that these metal chlorides in DMF have larger solvation energies than in aqueous solutions, for the free-energy of the formation of MCl_2 (s) is always the same in these solvents.

The *cis-trans* Isomerization of 2-Butenes Photosensitized by Adsorbed Acetone

Kiyoshi OTSUKA and Akira MORIKAWA

Department of Chemical Engineering, Tokyo Institute of Technology, Ookayama Meguro-ku, Tokyo 152

(Received January 23, 1975)

The anomalous acceleration of the rate of the *cis-trans* isomerization of 2-butenes is observed in the photosensitization of acetone adsorbed on porous Vycor glass. The anomaly is explained by means of a chain mechanism which is compatible with the triplet-triplet energy transfer mechanism. The chain carrier may be radicals formed by the dissociation of the lowest triplet acetone, resulting from the less efficient quenching of the triplet acetone by butenes at lower butene pressures. The preferential quenching of the acetone by the *cis* isomer to by the *trans* isomer of 2-butenes suggests that the geometrical factor plays a significant role in the reaction in the adsorption phase.

It was shown in a previous report[1] that the photosensitized isomerization of 2-butenes by ketones adsorbed on porous Vycor glass proceeds by means of the mechanism of the triplet-triplet energy transfer from ketones to 2-butenes. At a low pressure of 2-butenes, anomalously high rates of isomerization have been observed when acetone is used as a sensitizer. This anomaly cannot be explained in terms of the reaction scheme proposed previously.[1] We intend to report here the details of the isomerization of 2-butenes photosensitized by the adsorbed acetone on the porous Vycor glass and to suggest a mechanism for interpreting the anomaly mentioned above.

Experimental

The properties and the pretreatment of the porous Vycor glass, and the apparatus and the method used in the photosensitized isomerization, were identical with those described in the previous report.[1] The light from a Toshiba H-400-P medium-pressure mercury lamp was filtered by passing it through 1-cm path of water and a Toshiba UV-29 glass filter (transparent >270 nm), so that the adsorbed acetone was excited to its lowest singlet state. The adsorption of acetone and the sensitized reaction were carried out at room temperature. The amount of acetone remaining in the gas phase was negligibly small during the course of the reaction.

The *cis*-2-butene was a high-purity product of the Phillips Petroleum Co. The *trans*-2-butene and 1-butene were purchased from Takachiho Kagaku Kogyo Co. The butenes were further purified by trap-to-trap distillation in a high-vacuum apparatus. A spectro-pure-grade acetone obtained from Wako Pure Chemical Industries, Ltd., was purified in a similar manner. The nitric oxide was an extra-pure-grade product of the Takachiho Kagaku Kogyo Co. and was used without further purification.

Results and Discussion

The illumination of the porous Vycor glass plate on which acetone has been preadsorbed induces the *cis-trans* isomerization of 2-butenes without any double-bond migration reaction. Using 100% of *cis*-2-butene as the starting material, the initial rates of *trans*-2-butene formation, $R^0_{c\text{-}t}$, were obtained at the various amounts of the adsorbed acetone. Figure 1 shows the relation between $R^0_{c\text{-}t}$ and I, the relative light intensities absorbed by acetone at different coverages (θ=0.13~0.49).

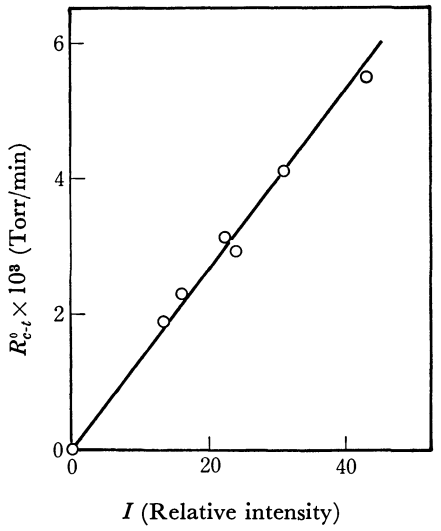

Fig. 1. The relation between $R^0_{c\text{-}t}$ and I.
The initial pressure of *cis*-2-butene, $P^0_{c\text{-}B}$ is 120 Torr.

The proportionality between them guarantees that the *cis-trans* isomerization will be sensitized by adsorbed acetone.

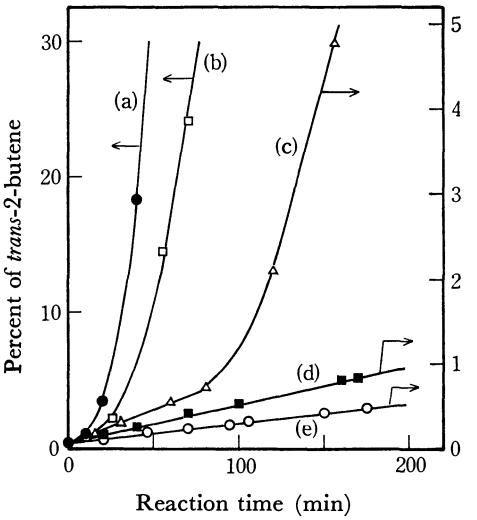

Fig. 2. The time-courses of the photosensitized isomerization at various $P^0_{c\text{-}B}$.
The coverage of the adsorbed acetone, θ_A, is 0.24.
(a); 14 Torr, (b); 18 Torr, (c); 41 Torr, (d); 80 Torr, (e); 125 Torr.

The time-course of the formation of *trans*-2-butene at different initial pressures of *cis*-2-butene are indicated in Fig. 2. At high pressures, *trans*-2-butene is formed at a constant rate, while at pressures less than ~40 Torr the rate of the *trans* isomer formation is accelerated. Although the scattering of the incident light by the porous adsorbent results in an inaccurate estimate of the absolute quantum yield, the roughly calculated values for the *trans*-2-butene formation after the acceleration, for instance, for the curves of (a) or (b) in Fig. 2, exceed 10 at a reaction time longer than 40 min. However, those for the data at high butene pressures never exceed unity.

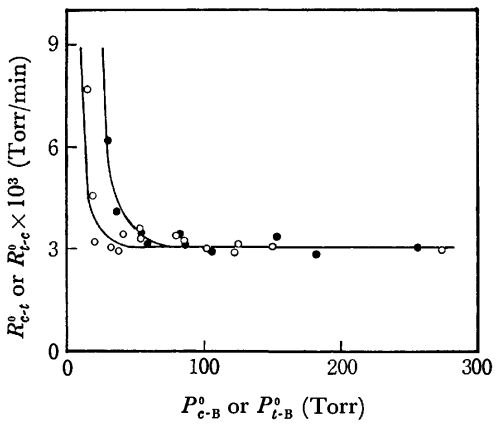

Fig. 3. The effect of butene pressure on the initial rate of the photoisomerization.
$\theta_A=0.24$, —○—; $R^0_{c\text{-}t}$, —●—; $R^0_{t\text{-}c}$.

The pressure effect on $R^0_{c\text{-}t}$ and $R^0_{t\text{-}c}$, the initial rate of *cis*-2-butene formation from 100% *trans*-2-butene, is indicated in Fig. 3. The rates observed at low pressures show a very steep increase with a decrease in the pressure, and $R^0_{t\text{-}c}$ is always greater than $R^0_{c\text{-}t}$, while at high pressures of butenes neither rate depends on the pressure and both give the same value.

The most general mechanism for the photosensitized *cis-trans* isomerization by acetone on the solid surface is given by the following processes:[1]

$$^0A(a) \xrightarrow{h\nu} {}^1A(a) \longrightarrow {}^3A(a) \quad (1)$$

$$^3A(a) \longrightarrow {}^0A(a)\ (+\text{heat or } h\nu) \quad (2)$$

$$^3A(a) + {}^0A(a) \longrightarrow 2{}^0A(a) \quad (3)$$

$$^3A(a) + t\text{-}{}^0B(a) \longrightarrow {}^0A(a) + {}^3B(a) \quad (4)$$

$$^3A(a) + c\text{-}{}^0B(a) \longrightarrow {}^0A(a) + {}^3B(a) \quad (5)$$

$$^3B(a) \longrightarrow \alpha\cdot t\text{-}{}^0B(a) + (1-\alpha)\cdot c\text{-}{}^0B(a) \quad (6)$$

where ^0A and ^3B represent the ground-state acetone and the triplet 2-butene respectively, when the other symbols have their usual meanings,[1] and where the suffix (a) indicates the adsorbed state of the individual species.

Steady-state approximations for $^3A(a)$ and $^3B(a)$ give the following equations:

$$R^0_{t\text{-}c} = (1-\alpha)I_0\phi_{isc}k_4[t\text{-}{}^0B]/(k_2+k_3[{}^0A]+k_4[t\text{-}{}^0B]) \quad (7)$$

$$R^0_{c\text{-}t} = \alpha I_0\phi_{isc}k_5[c\text{-}{}^0B]/(k_2+k_3[{}^0A]+k_5[c\text{-}{}^0B]) \quad (8)$$

Here, the quantum yield of $^3A(a)$ or ϕ_{isc} must be close to unity, as has been verified in the liquid phase.[2] The independence of both rates from the change in the butene pressure at $P^0_{t\text{-}B}>\sim 60$ Torr and $P^0_{c\text{-}B}>\sim 40$ Torr, as is shown in Fig. 3, may reasonably be ascribed to the triplet-energy transfer by means of Eq. (4) or (5) being faster than that by the deactivation (Eqs. (2) and (3)).[1] The proportionality between $R^0_{c\text{-}t}$ and I also suggests that Process (3) is slow compared to Process (5) or (4).

The rapid increase in the rates and the anomalously high quantum yield in the low-pressure range can not be explained only by Processes (1)~(6). The difference between the photostationary state ratio, $([t\text{-}{}^0B]/[c\text{-}{}^0B])_{pss}$, at a high pressure of butene, 2.8~3.0, and that at a low pressure, 2.2~2.4, suggests that the dominant mechanisms for the two pressure ranges are different. The following mechanism conceivably predominates in the low-pressure range:

$$^3A(a) \longrightarrow R\cdot(a) \quad (9)$$

$$R\cdot(a) + c\text{-}{}^0B(a) \longrightarrow R\text{–}B\cdot(a) \quad (10)$$

$$R\cdot(a) + t\text{-}{}^0B(a) \longrightarrow R\text{–}B\cdot(a) \quad (11)$$

$$R\text{–}B\cdot(a) \longrightarrow R\cdot(a) + \beta\cdot t\text{-}{}^0B(a) + (1-\beta)\cdot c\text{-}{}^0B(a) \quad (12)$$

$$R\cdot(a) + R\cdot(a) \longrightarrow P(a) \quad (13)$$

where R· is presumably the methyl or acetyl or a reactive product produced from these radicals; R–B·, a complex between 2-butene and R· in which the π-bond opening of butene may be established, and P, the termination product of R·. The *cis-trans* conversion occurs in Process (12), accompanying a regeneration of the chain carrier, R·. It is conceivable that, at low butene pressures, the formation of the chain carrier, R·, from the triplet acetone (Process (9)) becomes remarkable, since the efficiency of the triplet quenching by butenes (Process (4) or (5)) is low. The assumptions that the chain carrier, R·, and, accordingly, R–B·, accumulate with the time give an explanation for the accelerating rate and the high quantum yield mentioned above. The acceleration appears in the earlier stage of the reaction for lower pressures of butenes because of the fast accumulation of radicals. The abnormally high rates in the low-pressure range (Fig. 3) must be attributed to the difficulty of obtaining the initial rate, excluding the contribution of the chain mechanism, because of a rapid acceleration.

In the course of the reaction at the butene pressure of 86 Torr, the butene in the gas phase was condensed by means of a liquid-nitrogen trap at Point (A) in Fig. 4, followed by a sudden vaporization after 15 min at (B). The very rapid formation of *trans*-2-butene is seen in the first analysis of the butenes after Point (B). Then, the reaction proceeded steadily, with a velocity identical with that observed before the condensation. The rapid formation of *trans*-2-butene in Fig. 4 may also be caused by the accumulation of R· during the condensation of butene in the gas phase. The addition of 0.7 Torr of nitric oxide to 17.3 Torr of *cis*-2-butene prevented the acceleration of the rate, and the *trans*-2-butene production proceeded proportionally with the time under the low conversion, as had been seen at high pressures of butene.[3] This suggests that the R· must be captured by Process (14) resulting in no accumulation of the radicals:

$$R\cdot + NO \longrightarrow RNO \longrightarrow \text{stabilized} \quad (14)$$

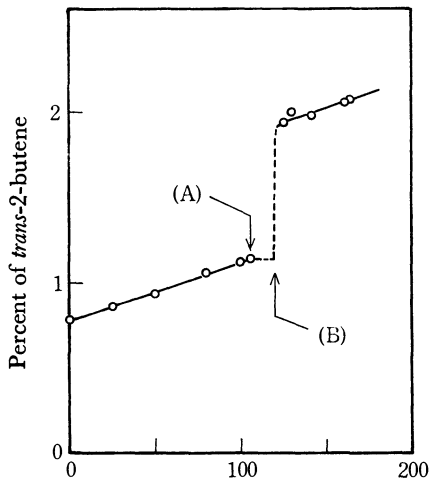

Fig. 4. The effect of condensation of butenes during the photoisomerization.
$P^0_{c\text{-}t}$=86 Torr, θ_A=0.24
At point (A); condensation, (B); vaporization.

At pressures of butene higher than 60 Torr, the ratio of $R^0_{c\text{-}t}$ to $R^0_{t\text{-}c}$ is unity (Fig. 3). Then, the blanching ratio, α, is obtained as 0.5 from Eq. (15):

$$R^0_{c\text{-}t}/R^0_{t\text{-}c} = \alpha/(1-\alpha) = 1.0 \quad (15)$$

k_5/k_4 was estimated to be 2.8~3.0 from Eq. (16):

$$([t\text{-}^0\mathrm{B}]/[c\text{-}^0\mathrm{B}])_{pss} = (k_5/k_4)(\alpha/(1-\alpha)) = 2.8\sim3.0 \quad (16)$$

In the liquid phase, the ratios of the quenching rate constant for the *cis* and *trans* isomers of 2-pentene sensitized by acetone were estimated to be 1.0 and 1.30 by Borkman and Kearns[2b] and Saltiel *et al.*[5] respectively. In contrast to these results, we have concluded that the preferential quenching by the *cis* isomer occurs in the adsorbed layer. This is consistent with the result that the contribution of the chain mechanism is remarkably more pronounced in $R^0_{t\text{-}c}$ than in $R^0_{c\text{-}t}$ under the same pressure (See the low-pressure range in Fig. 3). Although the features of the complex formation in the quenching of acetone by 2-butenes are not clear at present, the difference in the geometrical structures of 2-butene isomers may play an important role in establishing the ease of such complex formation so far as the reaction in the adsorbed layer is concerned.

Uranyl Ion-Sensitized Isomerization of the Stilbenes in Solution

Ryoka MATSUSHIMA,* Tsuneo KISHIMOTO, and Morio SUZUKI

Department of Industrial Chemistry, Faculty of Engineering, Shizuoka University, Hamamatsu 432

(Received March 20, 1975)

By selective excitation of the uranyl ion with light of $\lambda \geqq 365$ nm, a deoxygenated acetone solution containing *cis*- or *trans*-stilbene and the uranyl ion finally reaches a photostationary state, whose isomer ratio, $(t/c)_{pss}$, varies from 1 to 3 depending on the concentrations of the uranyl ion and the stilbenes. A close correlation is found between the features in the sensitized isomerization and the phosphorescence quenching of the sensitizer. Comparison with the results of halogen radical induced isomerization suggests that catalytic isomerization by free radicals is not an important process. A triplet-triplet energy transfer mechanism is proposed, which is supported by the oxygen effect and considerations on the lowest excited state of the uranyl ion, *i.e.*, its long lifetime and triplet energy level higher than that of the stilbenes.

The uranyl ion in solution at room temperature is both phosphorescent and reactive towards many organic compounds.[1,2] This allows a possible elucidation of the reaction mechanism as regards both primary and secondary processes.[3,4] Kemp and his co-workers have studied the excited state and radical intermediates in the photoredox reactions of the uranyl ion with organic compounds by laser flash absorption spectroscopy[5] and ESR detection.[6]

Uranyl ion as a photosensitizer does not seem to have been studied.[2] We reported on the aquation of the hexacyanocobaltate (III) ion[7] and *cis-trans* isomerization of the stilbenes[8] sensitized by the uranyl ion in solution, triplet-triplet energy transfer process being suggested in both cases. In the uranyl ion-sensitized isomerization of the stilbenes an abnormal value of the photostationary state isomer ratio was observed,[8] which suggests some special effects of organic-inorganic interactions in the excited states. The present work was undertaken to investigate the features and the mechanism of the uranyl ion-sensitized *cis-trans* isomerization of the stilbenes in solution.

Experimental

All the reagents and solvents were of guaranteed grade. Acetone solutions of the uranyl ion were dried over anhydrous sodium sulfate, after uranyl nitrate hexahydrate had been dissolved in acetone. Acetone solutions containing stilbene and uranyl ion were put into 7 mdm^3 ampoules and were deoxygenated by bubbling purified nitrogen current followed by sealing. The sealed ampoules were irradiated with light of $\lambda \geqq 365$ nm from a 100 W high-pressure mercury lamp with glass filters, in order to avoid direct excitation of the stilbenes. Temperature was maintained near 10 °C during the course of photolyses. After irradiation acetone was evaporated under reduced pressure at 40 °C, 50 Torr a small amount of alcohol being added in order to eliminate the acetone completely. The residue was shaken with aliquots of chloroform and 0.1 mol·dm^{-3} aqueous perchloric acid. The chloroform layer, which was washed with water followed by drying through anhydrous sodium sulfate, was adequately diluted with ethanol for measurement of the absorbance. The relative concentrations of the stilbenes were calculated from absorbances at 320 nm and a calibration graph.

Photoreaction quantum yields were measured by the optical train system with two cells (each having two plane parallel windows) arranged in series and a monochromatic parallel light beam from a 500 W high-pressure mercury lamp with a suitable arrangement for obtaining a monochromatic and parallel light. Ferric oxalate solution was used as an actinometer.

Quenching constants were obtained from the Stern-Volmer plot for the emission intensity at the 510 nm peak with excitation at 436 nm. Measurements were carried out without deoxygenation since no significant effect of dissolved oxygen was observed. Absorption and emission measurements were carried out with a Hitachi 124-type spectrophotometer and a Hitachi 204-type fluorescence spectrophotometer, respectively.

Results and Discussion

Photostationary States. The changes in the absorption spectra of the stilbenes (in ethanol after elimination of acetone and the uranyl ion from the reaction mixture) due to the uranyl ion-sensitized *cis*→*trans* and *trans*→*cis* isomerizations in deoxygenated acetone solution with $\lambda \geqq 365$ nm are shown in Fig. 1. An isosbestic point appears near 260 nm. After a long period of irradiation both the sensitized *cis*→*trans* and *trans*→*cis* isomerizations give the same isomer ratio (*c*-4, *t*-5).

Under similar conditions, but in the absence of the uranyl ion, no significant (direct) photoisomerization took place. No thermal isomerization was found for the uranyl–stilbene mixture in deoxygenated acetone solution after being left to stand at 40—45 °C in the dark for 5 hr.

Figure 2 shows the change in the *trans*/*cis* mole fraction against the time of irradiation under experimental conditions identical with those in Fig. 1. The existence and constancy of the photostationary state can be confirmed. The isomer ratios at the photostationary state, $(t/c)_{pss}$, obtained in a similar manner to that shown in Fig. 1, for various concentrations of the stilbenes and the uranyl ion, are summarized in Table 1. The concentration dependence of $(t/c)_{pss}$ can be noted. The $(t/c)_{pss}$ values in Table 1 are in the range 1—3, whereas those for the triplet-sensitized isomerization of the stilbenes with organic sensitizers whose triplet energies are 230—250 kJ/mol are in the range 0.31—0.43.[10]

Figure 3 shows the plot of the reciprocal of the quantum yield of the sensitized *cis*→*trans* isomerization, $1/\phi$, *vs.* the reciprocal of the initial concentration of *cis*-stilbene, $1/[cis]$, giving a straight line with an intercept of 16.5 and a slope of 6.5×10^{-3} mol/dm^3. The Stern-Volmer quenching of the uranyl phosphorescence by *cis*

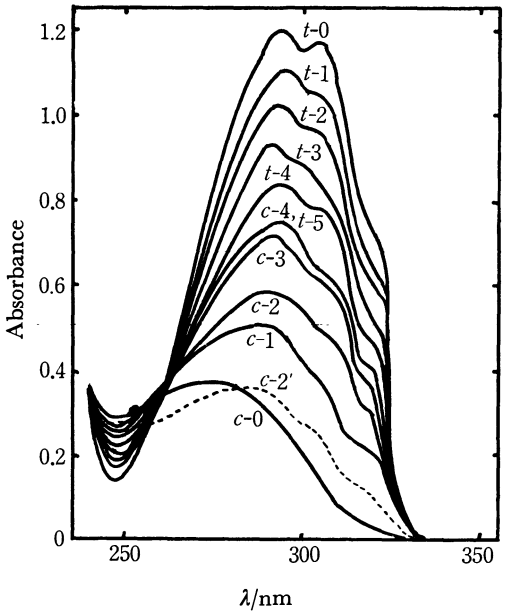

Fig. 1. The changes in the absorption spectra of the stilbenes (in ethanol after elimination of the uranyl ion and acetone from the reaction mixtures) due to the uranyl ion-sensitized *cis*→*trans* and *trans*→*cis* isomerization with light of $\lambda \geq 365$ nm. Both concentrations of the uranyl ion and the stilbenes were 2×10^{-3} mol/dm^3. The irradiation periods for the sensitized *cis*→*trans* isomerization were, *c*–0: 0 min, *c*–1: 30 min, *c*–2: 90 min, *c*–2′: 90 min irradiated without deoxygenation, *c*–3: 120 min, *c*–4: 360 min, and for the sensitized *trans*→*cis* isomerization, *t*–0: 0 min, *t*–1: 30 min, *t*–2: 60 min, *t*–3: 90 min, *t*–4: 180 min, *t*–5: 360 min.

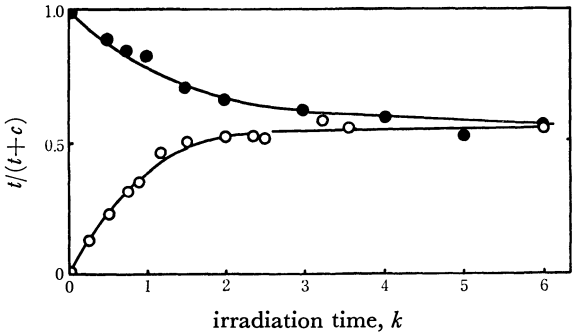

Fig. 2. Photostationary state reached after a long period irradiation of the mixture of the uranyl ion and the stilbenes. Conditions were the same as those shown in Fig. 1.

Table 1. The $(t/c)_{pss}$ values at various concentrations of the uranyl ion (U) and the stilbenes (S)

[S]$\times 10^3$ mol/dm^3	[U]$\times 10^2$ mol/dm^3	$(t/c)_{pss}$
2.0	0.02	0.96
2.0	0.20	1.25
2.0	2.0	1.63
2.0	10	1.77
20	0.20	3

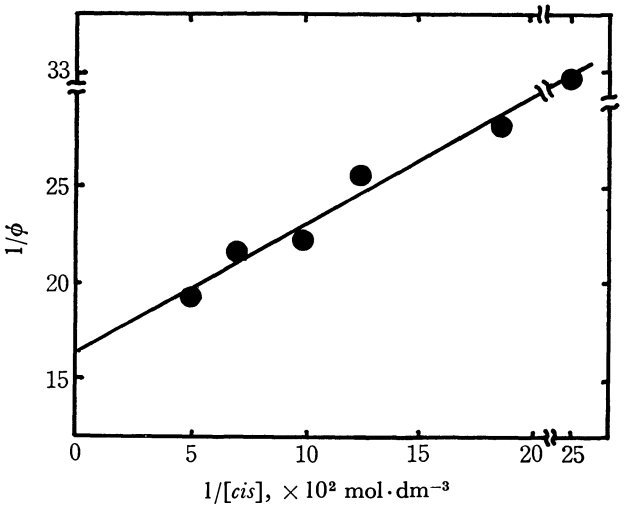

Fig. 3. Plot of $1/\phi$ *vs.* $1/[cis]$. The concentration of the uranyl ion was 2×10^{-3} mol/dm^3.

stilbene was $(4 \pm 2) \times 10^3$ dm^3/mol under similar conditions though no precise value was available because of the weak phosphorescence intensity of a 0.002 mol/dm^3 uranyl ion in acetone as compared to the solvent (impurity) emission. The ratio of the intercept to the slope in Fig. 3, 2.5×10^3 dm^3/mol, is compatible with the quenching constant.

Effects of Dissolved Oxygen. No significant oxygen effect on the phosphorescence intensities of the uranyl ion was observed either in the presence or absence of quenchers (stilbenes).

The lack of oxygen quenching on the phosphorescent emission in solutions has been reported for some rare earth metal ions,[11] which is assumed to be due to the well-shielded inner shells. In contrast, a significant interference effect of the dissolved oxygen was found on the sensitized isomerization, (curve *c*-2′, Fig. 1 irradiated without deoxygenation) as compared to the curve *c*-2. The curve *c*-2′ indicates a decrease in the total concentration of the stilbenes, or oxidation. These effects of oxygen might suggest the intermediacy of either an exciplex or the triplet stilbenes. The latter possibility can be excluded since the lifetime of the stilbene triplet is too short (10^{-8} s) to be effectively intercepted by the dissolved oxygen;[9] the effect of oxygen might reflect the interception of uranyl-stilbene triplet exciplex.

Rate Parameters. Since the uranyl ion is excited to its lowest triplet state[12] (E_T=245 kJ,[3] $\tau_p = 10^{-4} - 10^{-6}$ s[1,5]) whose level is higher than the lowest triplet states of the stilbenes (200 and 230 kJ[10]), triplet energy transfer from the excited uranyl ion to the stilbenes is feasible. Thus the correlation between the features in the phosphorescence quenching and the sensitization processes suggests triplet energy transfer mechanism as the major process for the sensitized isomerization. On the other hand, studies on the quenching of the uranyl phosphorescence by a series of aromatic hydrocarbons indicate that the primary interaction involves the formation of exciplexes between the excited uranyl ion and the aromatic hydrocarbons.[3]

Thus the following scheme can be postulated for the sensitized *cis*→*trans* isomerization, where S, S′, U, ^{3}U*,

and $^3U^*\cdots S$ represent *cis*-and *trans*-stilbenes, the ground state and the excited state uranyl ions, and the exciplex, respectively.

$$U + h\nu \longrightarrow {}^3U^* \xrightarrow{k_p} U + h\nu_p \quad (1)$$

$$^3U^* \xrightarrow{k_d} U \quad (2)$$

$$^3U^* + S \underset{k_b}{\overset{k_q}{\rightleftharpoons}} {}^3U^*\cdots S \xrightarrow{k_t} U + S' \quad (3)$$

$$^3U^*\cdots S \xrightarrow{k_c} U + S \quad (4)$$

Since the reverse dissociation of the exciplex is an endothermic process, the rate constant k_b is assumed to be negligible as compared to k_t and k_c which are assumed to be of rapid exothermic processes. Thus, the steady state assumption for $^3U^*\cdots S$ might lead to

$$\frac{I_p^\circ}{I_p} = 1 + \left(\frac{k_q}{k_p+k_d}\right)[S] \quad (5)$$

$$\frac{1}{\phi} = \frac{k_c+k_t}{k_t}\left(1+\frac{k_p+k_d}{k_q[S]}\right) \quad (6)$$

The plot of $1/\phi$ *vs.* $1/[S]$ should give a straight line, and the ratio of the intercept to the slope should be equal to the Stern-Volmer quenching constant. These requirements are satisfied. From Eq. (6) and the intercept in Fig. 3, the decay ratio k_t/k_c is estimated to be 15.5 which differs a great deal from the corresponding value, 1.6, expected from pure triplet energy transfer processes with sensitizers whose triplet energies are 230—240 kJ.[10]

An alternative mechanism to the triplet energy transfer would include catalytic isomerization of the stilbenes by paramagnetic species or free radical intermediates of the photoredox reaction between the uranyl ion and the solvent molecules, since free rsdicals and certain paramagnetic substances have been found to be very effective catalysts for *cis*→*trans* isomerizations of olefins.[13] Some free radicals have also been detected in the photoreactions of alcohols, aldehydes, ketones, and carboxylic acids, with uranyl ion.[6] If the catalytic process by free radicals or paramagnetic species is the major one for the present reaction, it should lead exclusively to the *trans* isomer which is thermodynamically more stable. It is unlikely that such a catalytic process is the major process in the present photoreaction, since the mole fraction of the *cis* isomer at the photostationary state is 0.45 or more. Partial involvement of such a catalytic process, however, might be possible, which would lead to larger $(t/c)_{pss}$ values than those expected from pure triplet energy transfer processes.

Exclusion of Free Radical Induced Isomerization. In order to test the possible contamination of free radical processes in the uranyl ion-sensitized isomerization of the stilbenes, free radical induced isomerization of the stilbenes has been investigated under comparable conditions. Addition of 0.02 mol/dm^3 *n*-propanol did not alter the $(t/c)_{pss}$ value in the uranyl ion-sinsitized *cis-trans* isomerization of the stilbenes in acetone (uranyl ion 0.02 mol/dm^3, stilbene 0.002 mol/dm^3), indicating that *cis-trans* isomerization by the free radical $R_2\dot{C}OH$[3,6] produced in the photoredox reaction is of no significance. The inefficiency can be ascribed to the very short lifetime of the aliphatic radicals. Table 2 shows that the catalyzed *cis-trans* isomerization of stilbenes by bromine or iodine atom does not occur in acetone, whereas iodine atom-induced isomerization occurrs in hexane to give exclusively the *trans* isomer in accord with thermodynamic considerations. These results suggest no significant contamination of free radical processes in the uranyl ion-sensitized isomerization of the stilbenes in acetone.

TABLE 2. FREE RADICAL INDUCED ISOMERIZATION OF THE STILBENES BY IRRADIATION WITH LIGHT OF $\lambda \geqq 400$ nm.

Solvent	Initial isomer[a]	I_2 10^2 mol/dm^3	Br_2 10^2 mol/dm^3	Irradiation time, hr	$\left(\frac{t}{c+t}\right)_{final}$
n-Hexane	*cis*	2.0		5	1.0
	trans	2.0		4	1.0
Acetone	*cis*	2.0		6	0.0
	cis		2.0	7	0.0
	trans	2.0		10	1.0
	trans		2.0	6	1.0

a) Initial stilbene concentration was 0.02 mol/dm^3 in each run.

Another mechanism in which stilbene cation radical ion intermediate is involved can be considered, since the excited state uranyl ion is a powerful oxidizing agent towards various organic compounds. However the degree of the charge transfer (δ) in the exciplexes of a series of aromatic hydrocarbons with the uranyl ion has been estimated to be small, $\delta \leqq 0.2$, in an acetone–water solution.[3] The small δ value implies that the formation of aromatic radical cation intermediates (which corresponds to complete charge transfer, $\delta = 1$) is unlikely.

The large difference in k_c/k_t and $(t/c)_{pss}$ as compared to those for organic triplet sensitized isomerization might at least partly be related to internal paramagnetic and/or heavy atom effects on the decay ratio k_c/k_t of the uranyl-stilbene exciplex. More probably, the π-electron density of the ethylenic bond in the stilbene moiety (in the uranyl-stilbene exciplex) would decrease due to the electron donation from the stilbene to the uranyl moiety, *i.e.*, $(U^{*\delta-}\cdots S^{\delta+})$, so that the formation of thermodynamically more stable *trans* isomer would be favorable.

The change in $(t/c)_{pss}$ with that in the concentration of of the uranyl ion or the stilbenes may suggest that, in addition to the unimolecular decay of the exciplex ((3) and (4)), bimolecular deactivation of the exciplex by the ground state uranyl ion or the stilbenes with a deactivation ratio k_c'/k_t' different from k_c/k_t for the unimolecular decay process becomes significant. No satisfactory explanation for the concentration dependence of $(t/c)_{pss}$ is available as yet.

The Effect of the Pressure on the Electrical Conductivity of Zinc Sulfate in Water

Yoshihiro TANIGUCHI, Takashi WATANABE, and Keizo SUZUKI

Department of Chemistry, Faculty of Science and Engineering, Ritsumeikan University, Kita-ku, Kyoto 603

(Received March 22, 1975)

The electrical conductivity of $ZnSO_4$ in water was measured at high pressures up to 3000 kg/cm² and at 25 °C. The dissociation constant of the ion pair (K_m) increased with an increase in the pressure. The volume change ($\Delta V°$) accompanying the dissociation was -8.0 ± 0.5 ml/mol at 25 °C. The distance of the closest approach (å) of the ion pair, calculated using the observed K_m value and the theoretical equation of Bjerrum, increased with an increase in the pressure. In view of these $\Delta V°$ and å values, the ion pair of $ZnSO_4$ was assumed to be of the solvent-separated type. It was also concluded that the number of water molecules separating the ions constituting an ion pair increases with an increase in the pressure.

The structure of the ion pairs of metal sulfates in water has been studied from electrochemical and thermodynamical measurements,[1-3] ultrasonic absorption measurements,[4-6] and spectroscopic measurements.[6-8] As a result, it has been found that there exist two types of ion pairs. One is the contact type, and the other is the separated one with one or more solvent molecules between sandwiched. From the heat of dilution data, Larson[3] has concluded that ion pairs of $MgSO_4$, $NiSO_4$, and $ZnSO_4$ are separated by more water molecules than those of $CaSO_4$, $CuSO_4$, and $CdSO_4$. Their tendency to form a contact ion pair is in the same order as their ionic radii, which is in good agreement with the results from IR reported by Larsson[7] and those from the visible absorption spectrum reported by Smithson and Williams.[8]

The information as to the volume change accompanying the dissociation of the ion pair, $\Delta V°$, obtained from dilatometry[9] and the pressure effect on the dissociation constants of ion pairs[10-15] may be a useful indication of whether a particular ion pair is of the "solvent-separated" or "contact" type. It is well known that the volume change accomapanying the dissociation of electrolytes shows a negative sign upon electrostriction, a negative sign caused by the electrostatic interaction between ions and their surrounding solvent molecules.[16] Therefore, the magnitude of the volume decrease accompanying the dissociation of ion pairs may be expected to be smaller for the solvent-separated type, in which the ions are hydrated in the ion-pair state, than for the contact type.

In the present experiment, we attempted to measure the electrical conductivity of $ZnSO_4$ in water up to 3000 kg/cm² at 25 °C and to clarify the structure of the ion pair by considering the $\Delta V°$ value together with the value of the ionic distance of the closest approach of the ion pair at high pressures.

Experimental

Materials. Zinc sulfate of a special grade was used without further purification. The conductivity water was prepared by repeatedly distilling the water from a mixed-bed deionizing column. The specific conductivity of this water was 1.320×10^{-6} mho/cm at 25 °C. The solutions of zinc sulfate were prepared in the approximate concentration range from 5.0×10^{-4} to 1.0×10^{-3} M at 25 °C.

Method. The apparatus and the procedure used to obtain the electrical conductivity under high pressures have been described in detail elsewhere.[17]

Results and Discussion

The measured equivalent conductances (Λ) are listed in Table 1, together with the limiting equivalent conductances ($\Lambda°$), which were determined by the extrapolation of the Kohlrausch plots,[18] Λ *vs.* $\sqrt{c}$, to an infinite dilution. From these data, the dissociation constants of the ion pair were calculated by the method by Hamann, Pearce, and Strauss.[12] The dissociation degree (α) of the ion pair was determined by inserting the experimental conductances (Λ) and the theoretical values (Λ^i), calculated from Eq. (2) and given by Davies, Otter, and Prue,[19] into Eq. (1):

Table 1. Equivalent conductances (Λ) and limiting equivalent conductances ($\Lambda°$) of $ZnSO_4$ at 25 °C and at various pressures.

Pressure kg/cm²	Concentration at 1 atm, equiv./l (10^{-4})					
	$\Lambda°$	Λ				
	0.0	5.0	6.0	7.5	9.0	10.0
1 (atms)	132.8	116.0	114.4	112.1	110.1	108.8
500	135.4	119.8	118.1	116.2	114.2	113.2

$$\alpha = \frac{\Lambda}{\Lambda^i} \tag{1}$$

$$\Lambda^i = \Lambda° - \left[\frac{R\Lambda°}{1+B\text{å}\sqrt{2\alpha c}} + E\right]\frac{2\sqrt{\alpha c}}{1+2B\text{å}\sqrt{\alpha c}} \tag{2}$$

where:

$$R = \frac{32.816\times10^7}{(\varepsilon T)^{3/2}} \tag{3}$$

$$B = \frac{5.029\times10^9}{(\varepsilon T)^{1/2}} \tag{4}$$

$$E = \frac{165.00}{\eta(\varepsilon T)^{1/2}} \tag{5}$$

$$\mathring{a} = \frac{2e^2}{\varepsilon k T} \tag{6}$$

Here, ε and η are the dielectric constant and the viscosity of water respectively, k is the Boltzmann constant, T is the absolute temperature, e is the protonic charge, and c is the molarity. The activity coefficient ($f_\pm$) was predicted by the Debye-Hückel limiting law at the c concentration as follows:

$$-\log f_\pm = \frac{2A\sqrt{\alpha c}}{(1+2B\mathring{a}\sqrt{\alpha c})} \tag{7}$$

where A is $7.2984\times 10^6/(\varepsilon T)^{3/2}$. In applying the above equation to the conditions under a high pressure, the ε values calculated by the Owen-Brinkley equation[20] and the η data observed by Cappi[21] were used.

The dissociation constant (K_m) is given by:

$$K_m = \frac{m\alpha^2 f_\pm^2}{1-\alpha} \tag{8}$$

where m[22] donates the molality of $ZnSO_4$ and where the activity coefficient of ion pairs is assumed to be unity. The K_m values obtained are listed in Table 2. The pres-

ent value at atmospheric pressure, 4.55×10^{-3} equiv./l, may be compared with that of 4.90×10^{-3} equiv./l observed by Owen and Gury[24] and by Patterson and Freitag,[25] that of 4.4×10^{-3} equiv./l observed by Denney and Monk[26] from their electrical conductivity measurements, and that of 4.17×10^{-3} mol/l observed by Nair and Nancollas[1] from the electromotive force. These results, ranging from 4.17×10^{-3} to the 4.90×10^{-3} mol/l presented above, rather deviate from the value of 3.24×10^{-3} mol/l reported by Izatt *et al.*[27] on the basis of their calorimetrical determinations and from that of 5.4×10^{-3} equiv./l reported by Davies[28] on the basis of the electrical conductivity. Table 2 shows that K_m increases with an increase in the pressure. Therefore, the formation of the ion pair is depressed by an increase in the pressure.

The $\Delta V°$ value at 1 atm accompanying the dissociation of the $ZnSO_4$ ion pair was obtained graphically by the following equation:

$$\Delta V° = -RT(\partial \ln K_m/\partial P)_T \tag{9}$$

where R is the gas constant. The obtained $\Delta V°$ value of -8.0 ± 0.5 ml/mol agrees with that of -8.2 ml/mol for $ZnSO_4$[29] and is close to those of -8.5 ml/mol[10] and -7.7 ml/mol[14] for $MgSO_4$ and that of -7.4 ml/mol[11] for $MnSO_4$, but it is larger than that of -10.2 ml/mol[14] for $CaSO_4$. The absolute $\Delta V°$ values of the above divalent metal sulfate ion pairs are much smaller than those of -20.4 ± 0.5 ml/mol[30] and -28.9 ml/mol[31] accompanying the dissociation of H_2O and NH_4OH respectively. The smallness of the absolute values of $\Delta V°$ in comparison with the values for the ionization of weak acid and bases shows that the ions are extensively hydrated in the ion-pair state. The order of the $\Delta V°$ values for divalent metal sulfates is independent of their ionic radii. The tendency to form a solvent-separated ion pair shown by the data of the volume change is not in good agreement with the results obtained from the heat of dilution.[3]

Information about the distance of the closest approach of ion pairs derived from both the observed dissociation constant and the theory of the ion association by Bjerrum will contribute to clarifying the structure of ion pairs. The K_m is related theoretically to $\mathring{a}$ by:

$$K_m = \frac{1000}{4\pi N Q(b)\rho}\left(\frac{\varepsilon k T}{4e^2}\right)^3 \tag{10}$$

where:

$$Q(b) = \int_2^b x^{-4}e^x dx \tag{11}$$

$$b = \frac{4e^2}{\mathring{a}\varepsilon k T} \tag{12}$$

ρ is the density of water at a given temperature and pressure,[23] and the relation between log $Q(b)$ and b obtained by Harned and Owen[32] was used. Table 3 shows the $\mathring{a}$ values obtained at each pressure up to 3000 kg/cm². The value at 1 atm, 4.3 Å is larger than that of 3.47 Å for the interionic distance of the $ZnSO_4$ crystal.[33] Therefore, the solvent-separated type is assumed for the ion pair. This is the same as the conclusion obtained from the volume change.

Table 3. Distance of the closest approach ($\mathring{a}$) of $ZnSO_4$ ion pair at 25 °C under various pressures.

Pressure, kg/cm²	$\mathring{a}$, Å
1 (atm)	4.3
500	4.4
1000	4.5
1500	4.8
2000	5.0
2500	5.3
3000	5.5

The present results, to be found in Table 3, show an increase in the $\mathring{a}$ value with an increase in the pressure; this is in disagreement with the results derived by Nakahara *et al.*,[13] Inada *et al.*,[14] and Ueno *et al.*[15] However, from the study of the pressure effect on the equilibrium of tight ion pairs⇄loose ion pairs for sodium and lithium fluorenyl in tetrahydrofuran, Claesson *et al.*[34] found that the pressure shifted the equilibrium towards the loose ion pairs. The fact that the structure of the solvated ion pairs strongly depends on the dielectric constant of the solvent has been clarified in a nonaqueous system by Griffiths and Symons.[35] They showed

that the tendency to form the solvent-separated ion pair increased with the increase in the dielectric constant of the solvent. The application of pressure causes an increase in the dielectric constant of the solvent. Therefore, the increase in the δ value with an increase in the pressure suggests that the ion pair may be expected to become more hydrated as the pressure increases, in spite of the contraction of the water in the hydration sheath of the ion pair by the compression. This consideration was already predicted about small free ions, *i.e.*, sodium and potassium ions, by Kay and Evans[36] from the point of view of the structural change of bulky water as a result of the pressure effect on the Walden product. On the contrary, Horne[37] has suggested that the pressure breaks up the structure of the hydration of small ions. Nakahara *et al.*,[38] have reported that no pressure effect can be found in the hydration number of potassium chloride up to 5000 kg/cm^2, assuming that the average volume of water molecules in the hydration sheath is equal to that of bulky water under pressure. The conclusions about the structure of the solvated ions derived from the pressure effect on the electrical conductivity have thus been conflicting. In order to solve this problem, information about the density of the water in the hydration sheath under pressure will be necessary, along with that about the structure of the bulky water under pressure.

CNDO/2 Difference Electron Density Contours in Saturated Three-membered Rings

Tetsuzo Ito

The Institute of Physical and Chemical Research, Wako-shi, Saitama 351

(Received April 19, 1975)

Theoretical difference electron density contours in the NCC, CCC, and OCC ring planes of ethyleneimine quinone, *cis*-1,2,3-tricyanocyclopropane and tetracyanoethylene oxide molecules, respectively, were calculated by the CNDO/2 molecular orbital method. They are qualitatively in good agreement with the experimental contours, and have reproduced the most characteristic features of the observed electron distributions in the bent bonds in the three-membered rings. The theoretical difference contours in the three-membered ring planes of aziridine, cyclopropane and oxirane molecules have shown essentially the same bonding electron distributions as the corresponding contours in the more complex molecules mentioned above.

The saturated CCC, NCC, and OCC three-membered rings are typical examples of highly strained structures. Coulson and Moffitt[1] have shown the bent bond nature in cyclopropane by a valence bond treatment of the molecule. Several diffraction studies of electron distributions have also revealed the bent bonds in these three-membered rings: the CCC rings in 2,5-dimethyl-7,7-dicyanonorcaradiene[2] and in *cis*-1,2,3-tricyanocyclopropane,[3] the OCC ring in tetracyanoethylene oxide,[4] and the NCC ring in ethyleneimine quinone.[5]

Although various kinds of molecular orbital calculations have recently been reported on these three-membered ring systems,[6] the results are not given in a form suitable for comparison with diffraction observations. In the present work, therefore, appropriate difference electron density contours were calculated by the semi-empirical CNDO/2 molecular orbital method,[7] and compared with the experimental contours.[3-5]

Theoretical Model

Let us first summarize the definition of the X-ray difference electron density. It is usually defined as:

$$\overline{\Delta\rho}_o(\boldsymbol{r}) = \bar{\rho}_{cryst}(\boldsymbol{r}) - \sum_j^{atoms} \bar{\rho}_j(\boldsymbol{r}), \quad (1)$$

where $\bar{\rho}_{cryst}$ is the observed electron density in the crystal; the second term is the calculated electron density of the "free atoms model", in which the atoms (or the ions) in the unit cell of the crystal are assumed to be free atoms (or free ions) with spherical electron distributions ρ_j, and be placed at the same positions as they occupy in the crystal. The bars on the ρ's indicate the time-average over thermal vibration.

In practice, however, $\overline{\Delta\rho}_o$ is obtained by Fourier summation of the differences between the observed and calculated structure factors, F_o—F_c, over lattice planes:

$$\overline{\Delta\rho}_o(\boldsymbol{r}) = (1/V)\sum_h\sum_k\sum_l [F_o(hkl) - F_c(hkl)] \times \exp[-2\pi i \boldsymbol{S}_{hkl}\cdot\boldsymbol{r}], \quad (2)$$

where V is the unit cell volume of the crystal, and $\boldsymbol{S}_{hkl}$ is the scattering vector of a plane, *hkl*. F_c is the Fourier transform of the second term in Eq. (1); it can be calculated by:

$$F_c(hkl) = \sum_j^{atoms} f_j T_j \exp 2\pi i \boldsymbol{S}_{hkl}\cdot\boldsymbol{r}_j, \quad (3)$$

where f_j is the theoretical free atom scattering factor of the j-th atom in the unit cell, whereas the nuclear position $\boldsymbol{r}_j$ and the thermal vibration factor T_j can be obtained from crystal structure analysis. The X-ray difference density defined by Eqs. (1)—(3) is called the difference Fourier synthesis or the D-synthesis.

A theoretical difference electron density can be defined in analogy with Eq. (1) as follows:

$$\Delta\rho_c(\boldsymbol{r}) = \rho_{mol}(\boldsymbol{r}) - \sum_j^{atoms} \rho_j(\boldsymbol{r}), \quad (4)$$

where ρ_{mol} is the theoretical electron density of a free molecule; the second term represents again the "free atoms model", the summation extending over the atoms which constitute the molecule. The theoretical difference density of Eq. (4) was originally introduced by Roux and coworkers.[8] For a molecule in a closed shell electron configuration, the molecular electron density can be expressed as:

$$\rho_{mol}(\boldsymbol{r}) = 2\sum_i^{occ} \psi_i^2(\boldsymbol{r}), \quad (5)$$

where ψ_i is the i-th molecular orbital, and the summation is taken over the molecular orbitals occupied with pairs of electrons.

In the CNDO/2 approximation,[7] molecular orbitals are obtained as linear combinations, with coefficients $\boldsymbol{C}_o$, of the orthogonalized atomic orbitals of the valence shells. Therefore, deformation of the 1s core electrons by molecule formation is ignored in the present model. Eq. (5) can be evaluated in a straightforward way by transforming the coefficients $\boldsymbol{C}_o$ to the coefficients $\boldsymbol{C}_s$ for the Slater type atomic orbitals by the Löwdin transformation $\boldsymbol{C}_s = \boldsymbol{S}^{-1/2}\ \boldsymbol{C}_o$.[9] The electron density of a spherical free atom, ρ_j in Eq. (4), can be represented by a single valence s atomic orbital $\chi_{s,j}$:

$$\rho_j(\boldsymbol{r}) = N_j \chi_{s,j}^2(\boldsymbol{r}), \quad (6)$$

where N_j is the number of the valence electrons of the j-th neutral free atom; N_j is 1, 4, 5, and 6 for H, C, N, and O atoms, respectively. Eq. (6) is consistent with the CNDO/2 scheme in which the 2s and 2p atomic orbitals of an atom are given the same Slater exponent; in this case, spherically averaged density distribution of a 2p electron is identical with the density distribution of a 2s electron. The theoretical difference density defined by Eqs. (4)—(6) may be called the "molecule—free atoms" density.

It is evident from the definitions that both the experi-

mental and theoretical difference densities represent the deviations of the densities in a crystal or in a molecule from those of the "free atoms model". Although both densities represent approximately the same physical quantity, the following two factors distinguish between the two. (a) The effect of thermal vibration (the thermal smearing of the electron density) is not taken into account in $\Delta\rho_c$, whereas $\overline{\Delta\rho}_o$ is inevitably influenced by thermal vibration. The effect will be examined in future studies. (b) The effect of the crystal field (the intermolecular interaction) is ignored in the calculation of ρ_{mol}. The effect is considered to be generally small compared with that of chemical bonding, but strong interactions such as hydrogen bonding may not be ignored.

Results and Discussion

The theoretical difference electron density contours in the NCC, CCC, and OCC ring planes of ethyleneimine quinone, *cis*-1,2,3-tricyanocyclopropane and tetracyanoethylene oxide molecules, respectively, were calculated by Eqs. (4)—(6), and compared with the experimental contours.[3-5] The molecular geometries found in the crystal[3-5] were used for the CNDO/2 calculations.

Ethyleneimine Quinone. The electron density in ethyleneimine quinone, 2,5-di(1-aziridinyl)-*p*-benzoquinone, $C_6H_2O_2(NC_2H_4)_2$, was studied by X-ray at 110 K.[5] The two aziridinyl groups are equivalent in the crystal because the molecule lies on an inversion center.

The CNDO/2 calculations[7] were performed for the whole molecule with 72 valence electrons. The "molecule–free atoms" map in the NCC ring plane (Fig. 1) may be compared with the X-ray contours (Fig. 2).

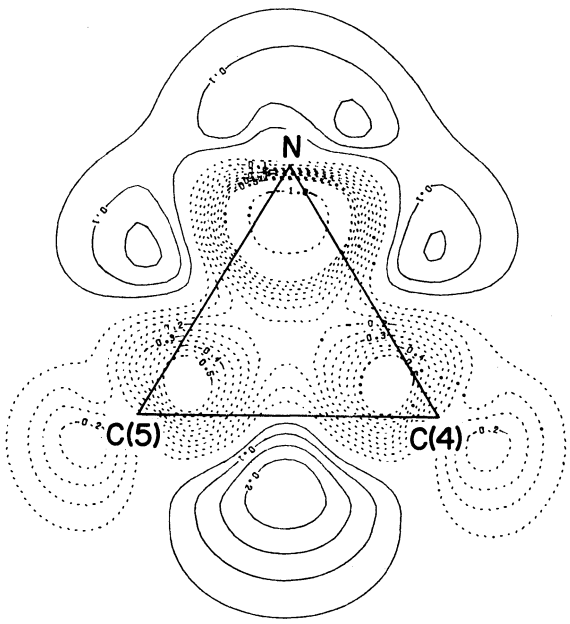

Fig. 1. Theoretical difference electron density contours, the "molecule—free atoms" map, in the NCC ring plane of ethyleneimine quinone.
Negative contours are dotted and zero contours are omitted. The contours are at intervals of 0.05 above −0.5, and 0.5 below −0.5 e.Å^{-3}.

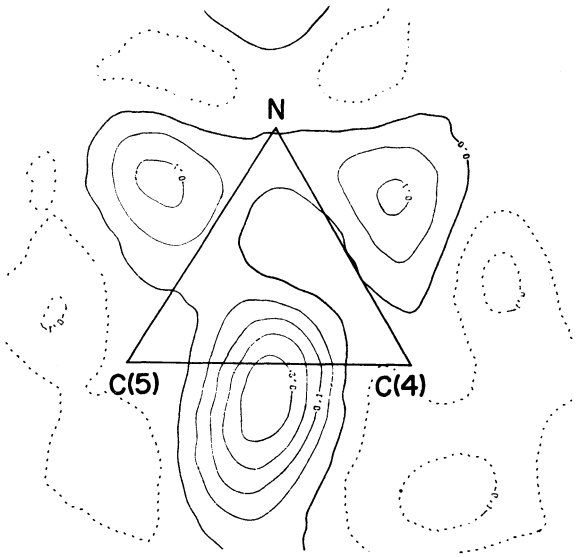

Fig. 2. X-Ray difference Fourier map in the NCC ring plane of ethyleneimine quinone.[5]
Negative contours are dotted. The contours are at intervals of 0.05 e.Å^{-3}.

The two maps are qualitatively in good agreement in the internuclear regions where both the theoretical and experimental densities are less influenced by systematic errors (see below). Both maps clearly illustrate characteristic features of the bent bond; bonding electron peaks of about 0.1 and 0.2 e.Å^{-3} are observed in the N–C and C–C bonds respectively, but displaced outside of the NCC triangle. The broad peak at the back of the nitrogen atom in the theoretical map is a tail-off of the nitrogen lone pair electrons.

The sharp depressions near the nuclear positions in the theoretical map are absent in the X-ray map. The following systematic errors in $\overline{\Delta\rho}_o$ and $\Delta\rho_c$ may account for the discrepancies: (a) The atomic parameters (the nuclear positions $\boldsymbol{r}_j$ and the thermal parameters T_j) determined by the X-ray structure analysis may be systematically in error. In fact, they were so determined as to give the best fit between the observed and calculated structure factors, that is, to minimize $\overline{\Delta\rho}_o$ in Eq. (2). Therefore, any aspherical features of electron distributions around the nuclear positions which could be fitted by the expression Eq. (3) were absorbed into apparent changes of atomic parameters, especially into those of anisotropic thermal parameters. In this respect, determination of the atomic parameters by neutron diffraction is preferable.[10] (b) Thermal vibration which will considerably smear out the sharp depressions is not taken into account in the present theoretical model. (c) The CNDO/2 electron density near the nuclear position may be a poor approximation to the true density.

cis-1,2,3-Tricyanocyclopropane. The electron density in *cis*-1,2,3-tricyanocyclopropane, $(CHCN)_3$, was studied by Hartman and Hirshfeld[3] by X-ray at room temperature. The molecule lies on a three-fold symmetry axis through the center of the ring in the crystal. Bonding electron peaks of 0.05 e.Å^{-3} have been observed in the C–C bonds, 0.32 Å outside of the CCC triangle.[3]

The molecule has 42 valence electrons. The "mole-

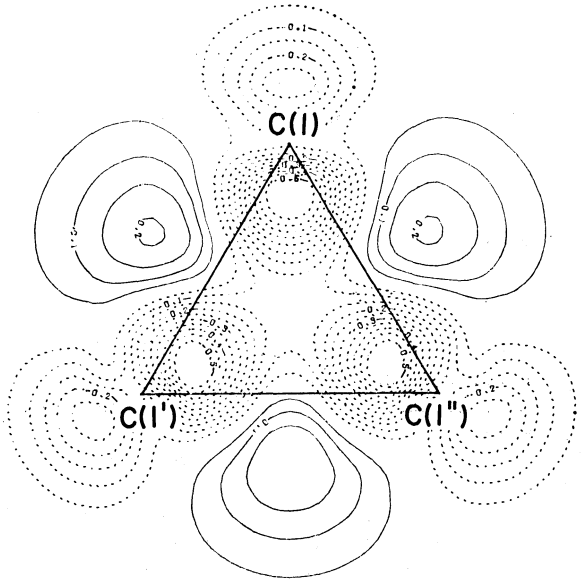

Fig. 3. The "molecule—free atoms" map in the CCC ring plane of *cis*-1,2,3-tricyanocyclopropane. The scale is the same as in Fig. 1.

cule—free atoms" map in the ring plane is shown in Fig. 3. The distribution of the bonding electrons is in qualitative agreement with the X-ray observations.[3] However, the theoretical peak heights of 0.15 e.Å^{-3} are three times higher than the experimental ones.

Tetracyanoethylene Oxide. The electron density in tetracyanoethylene oxide, $OC_2(CN)_4$, was studied by Matthews and Stucky[4] by a combined use of X-ray and neutron diffraction at room temperature. In this case, the electron density of the "free atoms model" in Eqs. (1)—(3) was calculated with the atomic parameters determined by neutron diffraction; a difference electron density map obtained with X-ray F_o and neutron F_c is called an X—N map.[10] The X—N map in the OCC ring plane of the molecule has revealed a bonding peak

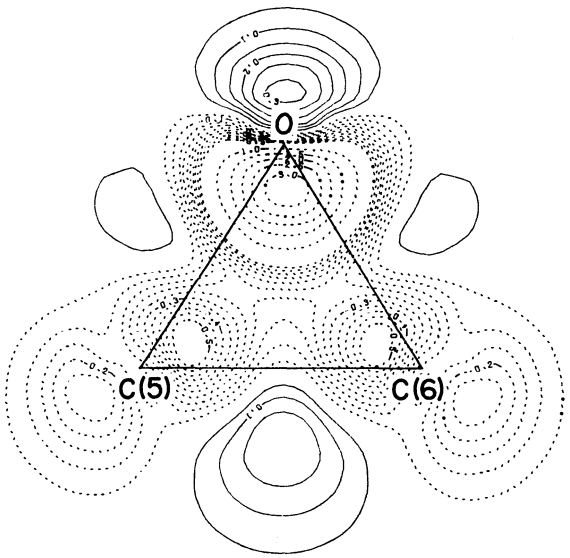

Fig. 4. The "molecule—free atoms" map in the OCC ring plane of tetracyanoethylene oxide. The scale is the same as in Fig. 1.

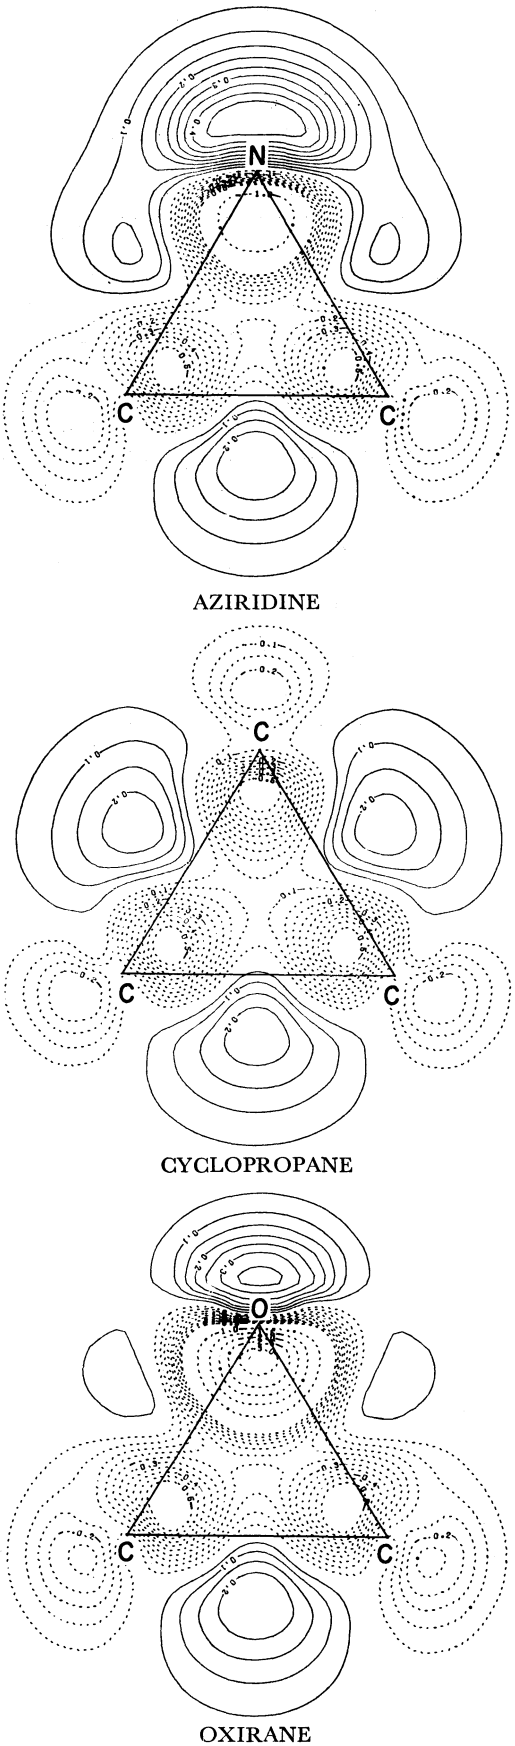

Fig. 5. The "molecule—free atoms" maps in the three-membered ring planes of aziridine, cyclopropane and oxirane. The scale is the same as in Fig. 1.

of 0.45 e.Å^{-3} in the C–C bent bond region, but the bend in the C–O bonds has been obscured by the tail-off of the broad peak of 0.35 e.Å^{-3} at the center of the ring.[4]

The molecule has 50 valence electrons. The "molecule—free atoms" map in the ring plane is shown in Fig. 4. The positive peak in the C–C bent bond is much higher than those in the C–O bonds, qualitatively in agreement with the experimental observations. Quantitatively, however, the theoretical peak heights are about three times lower than the experimental ones. The experimentally observed electron build-up at the center of the ring is not reproduced in the theoretical map.

It should be noted that in this case of tetracyanoethylene oxide, in which the experimental difference density was obtained with the neutron atomic parameters, the sharp depressions near the nuclear positions in the theoretical map are in qualitative agreement with the experimental observations.[4]

Related Molecules. The "molecule—free atoms" maps in the ring planes of aziridine, $NH(CH_2)_2$, cyclopropane, $(CH_2)_3$ and oxirane, $O(CH_2)_2$ molecules were also calculated (Fig. 5). The molecular geometries used were taken from the literature.[11] The electron distributions in the bent bond regions are essentially the same as those obtained for ethyleneimine quinone, *cis*-1,2,3-tricyanocyclopropane and tetracyanoethylene oxide, respectively.

The numerical calculations were performed on the FACOM 230—75 computer of this Institute. The author wishes to thank Dr. Tsunetoshi Kobayashi of the University of Tokyo for his valuable advice in performing the CNDO/2 calculations.

Electron Scavenging by Bromobenzene in the Radiolysis of Heptane, 1-Hexene and Their Mixtures

Masatoshi BABA and Kenji FUEKI

Department of Synthetic Chemistry, Nagoya University, Chikusa-ku, Nagoya 464

(Received April 28, 1975)

A quantitative study has been made of electron scavenging by bromobenzene in the radiolysis of heptane, 1-hexene and their mixtures. Experimental data were analyzed using Schuler's scavenging function. It has been found that the total ion yields are 4—5 G units in these liquids and the value of the reactivity parameter decreases with increasing fraction of 1-hexene. Further analysis of the data was made in terms of the exponential spatial distribution function for the electrons. A discussion is given to physical parameters derived from such analysis.

In recent years considerable efforts have been focussed on reactions of electrons in irradiated liquid hydrocarbons. Chemical and physical methods have both been applied to elucidation of quantitative aspects of electron reactions in liquid hydrocarbons. Most previous studies of electron reactions were concerned with electrons in alkanes.

In the present work we have made a quantitative study of electron scavenging by bromobenzene in the radiolysis of heptane, 1-hexene and their mixtures. We have determined the total ion yields and values of the reactivity parameter from the Schuler plot of experimental data. We have further analyzed the experimental data in terms of the exponential spatial distribution function for the electrons and derived from such analysis some physical parameters that are related to the behavior of electrons in these liquid hydrocarbons. We also include in this paper a comparative study of electron distributions in irradiated cyclohexane and 2,2,4-trimethylpentane.

Experimental

Bromobenzene (Nakarai Kagaku research grade) was distilled and passed through a column of activated alumina. Heptane (Merck spectrograde) was passed through a column of activated silica gel. The purity of heptane was 99.9% and a major impurity was hexane. 1-Hexene (Tokyo Kagaku Seiki standard material, >99% stated purity) was used as received. Impurities in 1-hexene were not identified.

Samples containing the desired amount of bromobenzene were degassed by freeze-pump-thaw cycles and sealed off the vacuum line. The samples were irradiated at 23 °C with ^{60}Co γ-rays for one hour at a dose rate of 3.19×10^{19} eV g^{-1}.hr^{-1}. The dose absorbed in the samples was determined by correction for the appropriate electron density differences. The benzene produced from bromobenzene was measured by a Hitachi K53 gas chromatograph with a flame ionization detector. The column used in the gas chromatograph was 30% hexatriacontane on Celite 545.

Results and Discussion

Yield of Electrons Scavenged by Bromobenzene in Heptane–1-Hexene Solutions. Figure 1 shows plots of the yield of benzene produced *vs.* the concentration of 1-hexene for heptane–1-hexene solutions. In Fig. 1, curves a and b show such plots for the solutions containing 0.238 and 0.0143 M bromobenzene, respectively. It is seen in

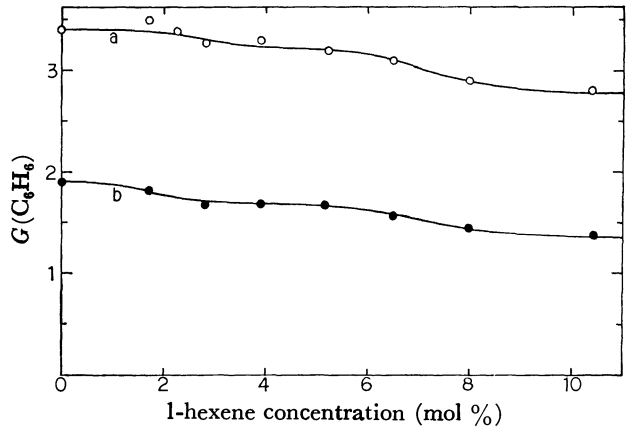

Fig. 1. The yield of benzene *vs.* concentration of 1-hexene in heptane–1-hexene solutions containing (a) 0.238 M and (b) 0.0143 M bromobenzene.

Fig. 1 that the yield of benzene decreases gradually with increasing 1-hexene concentration. It appears that significant decreases in benzene yield are observed around 2 and 7 mol% 1-hexene. The decrease of the benzene yield at 10.5 mol% 1-hexene amounts to 0.6 and 0.5 G units for the solutions containing 0.238 and 0.0143 M bromobenzene, respectively. Further, we have measured the yield of benzene as a function of the bromobenzene concentration for (a) heptane solutions, (b) heptane–1-hexene solutions (5.54 mol% 1-hexene), (c) heptane–1-hexene solutions (10.5 mol% 1-hexene) and (d) 1-hexene solutions. The concentration of bromobenzene was varied from 1.4×10^{-2} to 3.2×10^{-1} M. The data have been treated by assuming the reaction mechanism presented in the previous paper[1] and applying the scavenging function (Eq. (1)) developed by Schuler and his coworkers.[2]

$$\frac{1}{G(C_6H_6)-G_{fi}}=\frac{1}{G_{gi}}+\frac{1}{G_{gi}\alpha^{1/2}S^{1/2}} \qquad (1)$$

where G_{fi} and G_{gi} represent the yields of free and geminate ions, respectively, S is the concentration of bromobenzene, and α is a parameter which represents the reactivity of the electron toward the solute relative to the recombination processes. Figure 2 shows plots of Eq. (1) for four sets of experimental data. These results indicate that the data correspond to the predicted concentration dependence. Since it was difficult to measure the free ion yield by our analytical technique, values of G_{fi} for pure heptane and 1-hexene were taken from Ref.

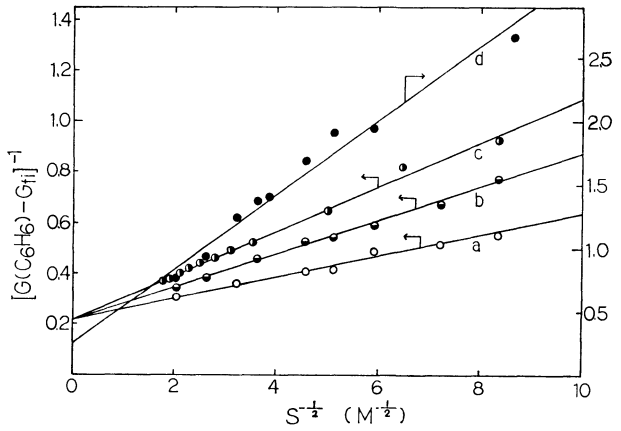

Fig. 2. Plots of $[G(C_6H_6)-G_{fi}]^{-1}$ *vs.* [bromobenzene]$^{-1/2}$ for heptane–1-hexene solutions. a: heptane, b: heptane–5.54 mol% 1-hexene, c: heptane–10.5 mol% 1-hexene, d: 1-hexene.

3, and those for the heptane–1-hexene mixtures were estimated in a manner that will be described later. The geminate ion yield and the total ion yield, G_t, determined from Eq. (1) are given in Table 1 together with the free ion yield used. The values of G_t thus obtained are 4.7—4.8 for pure heptane and heptane–1-hexene mixtures, and 4.0 for pure 1-hexene. The G_t values of 4.7—4.8 are somewhat higher than those obtained for alkanes in the previous work.[1] The G_t value of 4.0 for 1-hexene is based on the data points more scattered than those for the other solvents, and this value of G_t is perhaps a lower limit for the total ion yield in 1-hexene. Values of the reactivity parameter α are also given in Table 1. It is seen in Table 1 that the value of α decreases with increasing fraction of 1-hexene and the α value in 1-hexene is about 1/36 of that in heptane. The significance of this trend in α will be discussed later.

Prior to a further analysis of the present experimental data, we will make a comparative study of spatial distribution functions and scavenging functions for electrons in cyclohexane and 2,2,4-trimethylpentane because such a study should provide a basis for further analyzing our data on the heptane–1-hexene systems.

Table 1. Values of the parameters derived from Schuler's scavenging function

Fraction of 1-hexene (mol %)	G_{fi}	G_{gi}	G_t	α (M^{-1})
0	0.13[a]	4.5_5	4.7	27
5.54	0.12[b]	4.7	4.8	10
10.5	0.12[b]	4.6	4.7	6.3
100	0.062[a]	3.9_5	4.0	0.75

Spatial Distribution and Scavenging Functions for Electrons in Cyclohexane and 2,2,4-Trimethylpentane. Spatial Distributions: First, we attempt to compare the exponential spatial distribution function (Eq. (2))[4] for electrons in cyclohexane and 2,2,4-trimethylpentane with the corresponding spatial distribution function (Eq. (4))[5,6] derived from Schuler's lifetime distribution function[7] by assuming the time-distance relation given by Eq. (3).[8]

$$\left.\begin{aligned}\phi(r) &= 0 && \text{for } r \leq r_0\\ \phi(r) &= (4\pi br^2)^{-1}\exp[(r_0-r)/b] && \text{for } r \geq r_0\end{aligned}\right\} \quad (2)$$

where b is the electron range parameter, r_0 is the reaction radius and r is the ion-electron separation distance.

$$t = r^3/(3Dr_c) \quad (3)$$

Here D is the sum of the diffusion constants of the ion and electron, and r_c is the Onsager distance $r_c=e^2/\varepsilon kT$, where e is the electronic charge, ε is the dielectric constant of a liquid, k is Boltzmann's constant and T is the absolute temperature.

$$\phi_g(r) = \frac{\lambda}{4\pi Dr_c}\left[\left(\frac{3Dr_c}{\pi\lambda r^3}\right)^{1/2} - \exp\left(\frac{\lambda r^3}{3Dr_c}\right)\operatorname{erfc}\left(\frac{\lambda r^3}{3Dr_c}\right)^{1/2}\right] \quad (4)$$

where $\lambda=k/\alpha$ and k is the rate constant for reaction of the electron with a scavenger. Since Eq. (4) is applicable to geminate electrons, it is required for a quantitative comparison between the two distribution functions that the exponential distribution function also be normalized with respect to the geminate electron distribution. Therefore, we have actually used Eq. (5) for comparison instead of Eq. (2).

$$\phi_g(r) = (G_t/G_{gi})[1-\exp(-r_c/r)]\phi(r) \quad (5)$$

The probability of finding the geminate electrons between r and $r+dr$ is given by Eq. (6).

$$\Phi(r)dr = 4\pi r^2\phi_g(r)dr \quad (6)$$

Values of physical parameters used in the calculations are listed in Table 2. Since the diffusion constant of the electron is usually much greater than that of the ion, the diffusion constant D may be approximated by the diffusion constant of the electron, D_e, which is related to the electron mobility μ_e by $D_e=kT\mu_e/e$.

Figures 3 and 4 show the spatial distribution $\Phi(r)$ for the geminate electrons in cyclohexane and 2,2,4-trimethylpentane, respectively. In these figures, curve a represents the exponential distribution function and curve b shows Schuler's distribution function. It is seen in Figs. 3 and 4 that curve a is very close to curve b down to the ion-electron separation distance $r\sim35$ Å for cyclo-

Table 2. Physical parameters used in the calculation of spatial distributions of electrons in cyclohexane and 2,2,4-trimethylpentane

Solvent	r_c (Å)	b (Å)	μ_e ($cm^2\ V^{-1}\ s^{-1}$)	Solute	α (M^{-1})	k ($M^{-1}\ s^{-1}$)
Cyclohexane	279[a]	57.5[b]	0.24[c]	CCl_4	12[e]	2.7×10^{12} [g]
2,2,4-Trimethylpentane	291[a]	96.1[b]	7[d]	C_2H_5Br	5[f]	6.3×10^{12} [c]

hexane and $r\sim60$ Å for 2,2,4-trimethylpentane. Experimentally, quantitative kinetic studies of electron scavenging in liquid hydrocarbons are usually made at solute concentrations less than 0.5 M. It can be shown that most of the electrons scavengeable in scavenging experiments are distant from their parent ions farther than the distances mentioned above.[9] Thus, it is expected that the exponential distribution function would be able to account for experimental results on electron scavenging in liquid hydrocarbons. This also implies that the choice of the reaction radius is practically a trivial problem. It should be stressed that the exponential distribution function has the advantage that the range parameter b can be readily determined from the free ion yield by Eq. (7).

$$\int_0^\infty \phi(r) \exp(-r_c/r) 4\pi r^2 dr = G_{fi}/G_t \tag{7}$$

A calculation is described below on the concentration dependence of electron scavenging in cyclohexane and 2,2,4-trimethylpentane.

Scavenging Functions: It has been shown by Hummel[10] that the recombination probability $P_{q,r}$ of an ion-electron pair separated by r in the presence of scavenger is given by Eq. (8).

$$P_{q,r} = \frac{2\exp(-qr)[1-\exp(-r_c/r)]}{1+\exp(-2qr)+2qr^2r_c^{-1}[1-\exp(-r_c/r)]} \tag{8}$$

where $q=(kS/D)^{1/2}$ and S is the concentration of scavenger. The yield of electrons scavenged, $G(e_{sc}^-)$, in the presence of scavenger is given by Eq. (9).

$$G(e_{sc}^-) = G_t\int_0^\infty \phi(r)(1-P_{q,r})4\pi r^2 dr \tag{9}$$

Empirically, the concentration dependence of the yield of electrons scavenged by a scavenger in liquid hydrocarbons can be well described by Schuler's scavenging function (Eq. (10)).[2]

$$G(e_{sc}^-) = G_{fi} + G_{gi}\{(\alpha S)^{1/2}/[1+(\alpha S)^{1/2}]\} \tag{10}$$

Figures 5 and 6 show the concentration dependence of the yields of electrons scavenged by carbon tetrachloride in cyclohexane and by ethyl bromide in 2,2,4-trimethyl-

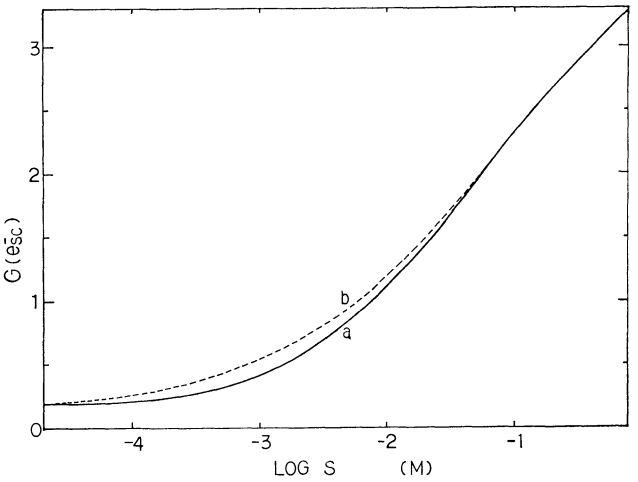

Fig. 5. The calculated concentration dependence of the yield of electrons scavenged by carbon tetrachloride in cyclohexane. a: calculated from Eq. (9) using the exponential distribution function, b: calculated from Schuler's scavenging function (Eq. (10)).

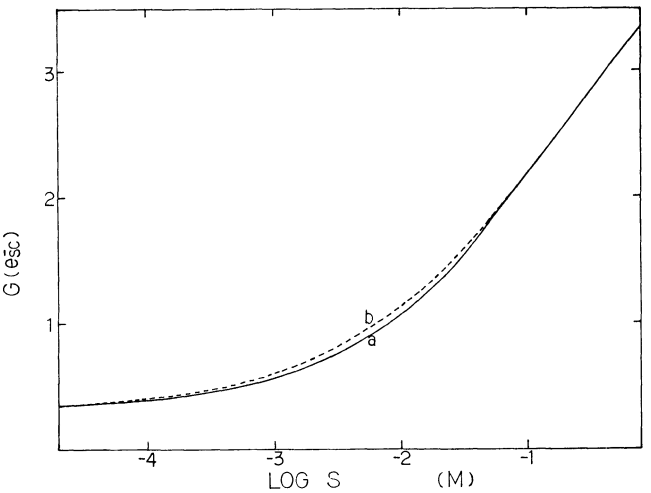

Fig. 6. The calculated concentration dependence of the yield of electrons scavenged by ethyl bromide in 2,2,4-trimethylpentane. a: calculated from Eq. (9) using the exponential distribution function, b: calculated from Schuler's scavenging function (Eq. (10)).

pentane, respectively. In these figures, curve a was calculated from Eq. (9) using the exponential distribution function for $\phi(r)$ and curve b was obtained from Eq. (10). It is seen in Figs. 5 and 6 that the shape of curve a is similar to that of curve b over the entire range of the scavenger concentration studied. Although there is some discrepancy between curves a and b around $S\sim10^{-3}$M for cyclohexane, the experimental data points lie between the two curves in this concentration region.[7] Thus, we have been able to demonstrate that the exponential distribution function can well account for the concentration dependence of electron scavenging in liquid hydrocarbons and that this is due to the fact that the exponential distribution function is similar in its significant portion to Schuler's distribution function.

Analysis of Experimental Data on Electron Scavenging by Bromobenzene in Heptane, 1-Hexene and Their Mixtures. In this section, we will describe the procedure to evaluate physical parameters of the hydrocarbon mixtures, analyze using the exponential distribution function the concentration dependence of the yield of electrons scavenged by bromobenzene in heptane, 1-hexene and their mixtures, and discuss the significance of physical parameters derived from such analysis.

Physical Parameters of Heptane-1-Hexene Mixtures: The electron range b of a mixture is given by Eq. (11).[11]

$$(bd)^{-2} = x_1(b_1d_1)^{-2} + x_2(b_2d_2)^{-2} \qquad (11)$$

Here the density d of the mixture is obtained as $d=x_1d_1+x_2d_2$, where d_1 and d_2 are the densities of the mixture components, and x_1 and x_2 are their mole fractions. The free ion yield in a mixture can be determined from Eq. (7) using b in Eq. (11). The free ion yields thus obtained are given for the heptane–1-hexene mixtures in Table 1. The dielectric constant ε of a mixture can be calculated from the Clausius-Mosotti equation (Eq. (12)).

$$\varepsilon = [1+(8\pi\bar{\alpha}n/3)]/[1-(4\pi\bar{\alpha}n/3)] \qquad (12)$$

Here the isotropic polarizability $\bar{\alpha}$ of the mixture is given by $\bar{\alpha}=x_1\bar{\alpha}_1+x_2\bar{\alpha}_2$, where $\bar{\alpha}_1$ and $\bar{\alpha}_2$ are the isotropic polarizabilities of the mixture components, and the number density n of molecules in the mixture is given by $n^{-1}=x_1n_1^{-1}+x_2n_2^{-1}$.[12]

Comparison between the Calculated and Observed Yields of Electrons Scavenged: Using Eqs. (7), (8), and (9) we have calculated the yields of electrons scavenged by bromobenzene in heptane, 1-hexene and their mixtures. Figure 7 shows the calculated and observed yields of electrons scavenged plotted against the concentration of bromobenzene. It is seen in Fig. 7 that the calculated curves agree well with the experimental data within experimental error. The parameters used in the calculations are b, k, and D. The electron range b was obtained from the free ion yield as already mentioned. The rate constant k for reaction of the electron with a scavenger and the diffusion constant D appear only as the ratio of k/D in Eq. (8). Accordingly, k/D is the only adjustable parameter in the calculations. The curves shown in Fig. 7 were calculated with the properly chosen values of k/D by best fitting them to the experimental data. The values of k/D thus obtained are given in Table 3. Knowing the value of D or the electron mobility, we can get the value of k. Unfortunately, values of D are not known for electrons in our systems, so we are unable to determine values of k. The relative values of k/D are also given in Table 3 as $(k/D)_N/(k/D)_1$, where $(k/D)_1$ stands for heptane. It is seen in Table 3 that the relative value of k/D decreases with increasing fraction of 1-hexene. If the reaction of the electron with bromobenzene in these liquid hydrocarbons is diffusion-controlled, *i.e.*, k is directly proportional to D, the relative value of k/D should be unity for all the hydrocarbons studied. It is not the case for our systems. This result indicates that electron scavenging by bromobenzene in these hydrocarbons is not a diffusion-controlled reaction. For comparison we have also calculated the relative value of k/D using the time-distance relationship derived from the Nernst-Einstein relation. In this approximation, Eq. (13) holds.[13]

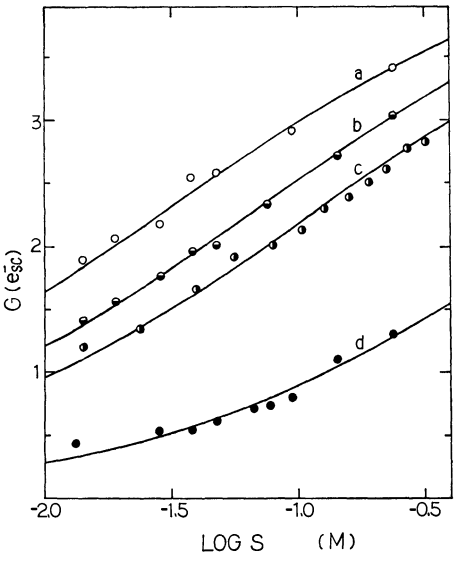

Fig. 7. The calculated and observed yields of electrons scavenged *vs.* concentration of bromobenzene in heptane–1-hexene solutions. a: heptane, b: heptane–5.54 mol% 1-hexene, c: heptane–10.5 mol% 1-hexene, d: 1-hexene. Curves show the calculated yields.

$$k/D = 3\alpha r_c/b^3 \qquad (13)$$

From Eq. (13) we can calculate k/D with known values of α, r_c and b. The relative values of k/D thus obtained are given in the last column of Table 3. It can be seen from Table 3 that these relative values of k/D are in good agreement with those derived from the theoretical scavenging function. Such an agreement implies that the effect of Brownian motion on the behavior of electrons in the Coulomb field is rather small for the electrons scavengeable at the scavenger concentrations studied.

It has recently been shown[14] that the rate constant k for reaction of the electron with a scavenger in different hydrocarbon solvents is, in some cases, proportional to the square root of the electron mobility μ_e in the corresponding solvents. If we assume that this relation between k and μ_e holds for our systems, we can calculate the relative value of μ_e from that of k/D. The relative values of μ_e thus calculated are given in Table 3 as μ_N/μ_1, where μ_1 stands for heptane. It is seen in Table 3 that

Table 3. Some physical parameters derived for electrons in heptane, 1-hexene and their mixtures

Fraction of 1-hexene (mol %)	k/D[a] ($10^{14}M^{-1}$ cm^{-2})	N	$\frac{(k/D)_N}{(k/D)_1}$[a]	μ_N/μ_1[b]	$\frac{(k/D)_N}{(k/D)_1}$[c]
0	2.3	1	1	1	1
5.54	1.1	2	0.47	4.5	0.41
10.5	0.67	3	0.29	12	0.27
100	0.20	4	0.087	130	0.082

a) Determined from the best fit of the calculated scavenging curve to the experimental data. b) Based on the assumption that k is proportional to $\mu_e^{1/2}$. c) Calculated using the Nernst-Einstein relation.

the value of μ_N/μ_1 increases with increasing fraction of 1-hexene, and the electron mobility in 1-hexene is two orders of magnitude greater than that in heptane. If we assume that the electron mobility in heptane is 0.06 $cm^2\ V^{-1}\ s^{-1}$ based on the electron mobility in hexane (0.09,[16] 0.07,[20] 0.08[14] $cm^2\ V^{-1}\ s^{-1}$), we obtain $\mu_e=$ 7.8 $cm^2\ V^{-1}\ s^{-1}$ for electrons in 1-hexene, which is of the same order of magnitude as the electron mobilities in 2-methylpropene (1.44 $cm^2\ V^{-1}\ s^{-1}$),[21] *cis*-2-butene (2.2 $cm^2\ V^{-1}\ s^{-1}$),[21] 2-methyl-2-butene (3.6 $cm^2\ V^{-1}\ s^{-1}$)[20] and 2,3-dimethyl-2-butene (5.8 $cm^2\ V^{-1}\ s^{-1}$).[21] It is possible, however, that the value of μ_e thus derived for electrons in 1-hexene is somewhat overestimated, since the reactivity parameter α is rather sensitive to the experimental data on electron scavenging.

Kinetic Analysis of the Transitory Overshooting of the H^+ Concentration in the Cation-exchange Membrane System

Noriaki TAKEGUCHI, Isamu HORIKOSHI, and Shigeo TANAKA
Faculty of Pharmaceutical Sciences, University of Toyama, Gofuku, Toyama 930
(Received May 6, 1975)

Overshooting with respect to the H^+ concentration was studied quantitatively. Systems of two species of cation and one species of anion were studied for example, the 0.2 M-NaCl (initial, s-side): Collodion-Polystyrene sulfonic acid membrane: 0.02 M-NaCl+0.002 M-HCl (l-side, constant). The volume of the l-side solution was greatly larger than that of the s-side solution. The composition of the former was not altered measurably by the transport of ions across the membrane. Because the cation-exchange membrane used was not highly selective, both cation and anion were permeable. The final composition of the s-side solution became equal to the composition of the l-side solution. In the course of changes toward the final equilibrium, the H^+ or HCl concentration temporarily reached far above the final value. An analytical interpretation with two parameters was given, in which the concentration of the most slowly movable ion in the membrane, Cl^-, was assumed to decrease monotonously. Moreover, the concentration of next slowly movable ion, Na^+, was assumed to change as a result of the force which tends to bring the system toward the imaginary Donnan equilibrium. The Na^+ concentration at the imaginary Donnan equilibrium toward which the s-side solution is approaching at any given instant was obtained as follows. The (H^+ concentration)/(Na^+ concentration) ratio at the equilibrium is the same as the corresponding ratio in the l-side. Moreover, the total concentration of H^+ and Na^+ at the imaginary Donnan equilibrium is equal to the existing Cl^- concentration in the s-side solution.

Teorell[1] investigated the transport of ions against their concentration difference between two solutions across a cation-exchange membrane separating these solutions under the simultaneous influence of a concentration gradient and a potential gradient within the membrane. The ions are transported against their concentration difference between outside solutions, but they move in the direction of their electrochemical potential difference. Woermann[2] reinvestigated the Teorell model quantitatively at a steady state.

Neihof and Sollner[3] and Sollner[4] presented electrochemical models which might have potential biological significance in explaining the abilities of living cells. These abilities are: (1) to accumulate electrolytes in their sap up to concentrations far in excess of the surrounding milieu and (2) to take up different species of the same charge in ratios which are vastly different from the ratio in which these ions are present in the surrounding milieu. The Sollner models are based on the transitory effects called the "overshooting" and "depletion" effects. The transitory effects arise in the course of the spontaneous drift toward the Donnan membrane equilibrium of systems in which two or more species of ions of the same charge, coexisting in one solution, exchange at greatly different rates across a membrane of a high anionic or high cationic selectivity against some other species of ions in the other solution. They assumed the existence of a partial membrane equilibrium in which the permeability of the most slowly movable ion was taken to be negligibly small until the system had attained the maximum drift. From the partial membrane equilibrium, they estimated the maximum drift of the effect. Their experimental values of the maximum drifts from the final equilibria were about 90% of the estimated values. In the Sollner model, the membrane of a high anionic or high cationic selectivity was used. That is, only cationic or anionic species of ions are permeable across the cationic or anionic membrane respectively.

It seemed that it would be interesting to extend the Sollner model to a more general membrane model in which a membrane is not perfectly ionic-selective, that is, in which it is permeable to both cation and anion. This makes it possible to apply the overshooting effect to such leaky (low-electrical-resistance) membranes as gastric mucosa and the collecting tubule in the kidney. In this paper we will report on the overshooting with respect to the H^+ concentration in systems which have two species of cation and one species of anion, using membranes which do not have perfect cationic selectivity.

Another point we wish to report on here is a quantitative analysis of the overshooting effect. As has been described above, Neihof and Sollner[3] estimated only the value of the maximum drift. We will formulate the full-time course of the H^+ overshooting effect, using a kinetic theory together with the imaginary Donnan equilibrium, to which the system tends to approach.

Description of Systems

The isothermal systems studied in this paper are composed of three compartments; one is the membrane phase that separates the other two compartments of ionic solutions. We shall call these two solutions the s-side and the l-side solutions hereafter. We assumed that the changes in the concentrations of the ionic species in the l-side solution were negligibly small during the experiment. This assumption was made possible by taking the volume of the l-side solution as extremely large compared with that of the s-side solution. For the H^+ overshooting effect, the following system was studied. The s-side solution included only NaCl at the initial state (its initial concentration, c_i). The l-side solution included NaCl (c_1) and HCl (c_2), where $c_i > (c_1+c_2)$. In the system, the H^+ concentration is equal to the HCl concentration because the system has only one species of anion, Cl^-. The ionic selectivity of the

cation-exchange membrane used here was not too high, so the anionic species of ion could also permeate slowly across the membrane. The permeation velocity of Cl^- was very slow compared with the fast permeations of the cations, however. When the test-tube-shaped membrane, which has the s-side solution inside, was immersed in the l-side solution, the H^+ concentration in the s-side solution began to increase rapidly as a result of interdiffusions. In due time, the H^+ concentration reached a maximum that far exceeded the final equilibrium value. Next, it gradually decreased. Finally, it settled to the final equilibrium value, *i.e.*, the H^+ concentration in the l-side solution. It should be noted that, if the system did not have the overshooting effect ($c_i < (c_1 + c_2)$), the H^+ concentration reached its final value without exceeding the final equilibrium value.

Materials and Methods

The test-tube-shaped membranes, 8 cm in length and 2 cm in diameter, were made of sulfonated polystyrene and collodion. The polystyrene sulfonic acid was synthesized following the method by Kato, Nakagawa, and Akamatsu;[5] its % of sulfonation was about 75%. Polystyrene sulfonic acids (1.59 g for Membranes 1 and 2 and 2.17 g for Membrane 3) were mixed with 300 ml of a 5% w/w collodion solution. Table 1 summarizes

Table 1. Characteristics and properties for membranes

	Membrane number		
	1	2	3
Membrane thickness (mm)	0.22	0.10	0.024
Water content	0.715	0.359	0.093
θ(M)	-8.3×10^{-3}	-1.07×10^{-2}	-7.14×10^{-2}
Electric resistance (Ω cm^2)	250	240	260
k_1 (min^{-1})	0.043	0.015	0.0028
k_2 (min^{-1})	0.556	0.193	0.0997

the characteristic data of these membranes—that is, the average membrane thickness, the water content of the membrane, the effective charge density of the membrane in the KCl solution, and the electric resistance of the membrane. The water content of the membrane is defined as the net weight of water absorbed in the membrane phase divided by the total weight of the wet membrane. The effective charge density of the membrane, θ(M), was measured following the method described in a paper by Kobatake, Takeguchi, Toyoshima, and Fujita.[6] The electrical resistance of the membrane (Ω cm^2) was measured on a membrane which had been soaked in a 0.1 M-NaCl solution at 30 °C prior to the measurement.

The s-side solution (20 ml) was placed in the test-tube-shaped membrane. A combination electrode (Beckmann, Type 39030, Calif., U.S.A.) was immersed in the s-side solution in order to measure the continuous change in the H^+ concentration. The volume of the l-side solution was about 20 l. Both solutions were stirred by bubbling air, and their temperatures were kept at 35 $\pm$0.1 °C

Results

In Fig. 1, the solid lines show the changes in the H^+ concentration in the s-side solution as a function of the time for Membranes 1, 2, and 3. The initial concentrations of NaCl in the s-side solution were 0.2042 M for Membranes 1 and 3 and 0.1950 M for Membrane 2. Moreover, the l-side solution contained 0.0247 M-NaCl and 0.0022 M-HCl for Membranes 1 and 3 and 0.0220 M-NaCl and 0.0024 M-HCl for Membrane 2.

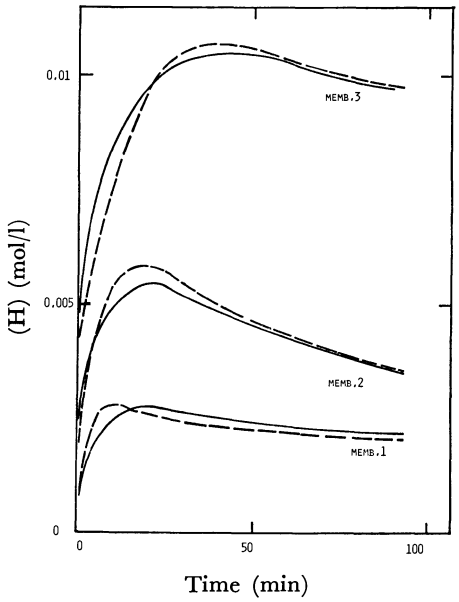

Fig. 1. Time dependencies of the H^+ concentration in the s-side solution. Solid lines show experimental curves for Membranes 1, 2, and 3. Broken lines show calculated curves from Eq. (8) with k_1 and k_2.

The H^+ concentrations of the s-side started from zero and thereafter increased rapidly beyond the final equilibrium values in a few minutes. They went up to the maximum values of 0.0028 M, 0.0054 M, and 0.010 M for Membranes 1, 2, and 3 respectively. Their maximum values were 1.32 times (Membrane 1), 2.25 times (Membrane 2), and 4.37 times (Membrane 3) as large as their final values. After reaching their maximum values, the H^+ concentrations descreased gradually. It took a long time to attain the final equilibrium values (3—24 hr after the start of the experiments).

Discussion

First, we will check the applicability of the concept of the partial membrane equilibrium to our present system. Following the idea by Neihof and Sollner,[3] the maximum values of the H^+ concentration can be calculated on the basis of the partial membrane equilibrium. The maximum values of the H^+ concentration were calculated as 0.0165 M for Membranes 1 and 3 and 0.0192 for Membrane 2. However, the experimental values were about 1/6, 1/4, and 2/3 times as

large as the calculated maximum values for Membranes 1, 2, and 3 respectively. These large discrepancies between the maximum experimental values and the maximum calculated values mean that the permeation of the most slowly movable ion, Cl^-, cannot be neglected even in the initial process. Therefore, we cannot apply the explanation based on the partial membrane equilibrium to a membrane which has a relatively low ionic selectivity, such as the membrane used here.

We shall now propose a kinetic analysis which can formulate the whole time dependence of the transitory effect. The water permeability of the membrane was assumed to be negligibly small. In the system there exist three kinds of ionic species which are movable across the membrane. As for the permeability velocities of these ions through the cation-exchange membrane, the fastest one is H^+, because of its large ionic mobility, the second is Na^+, and the slowest is Cl^-, because of its repulsive interaction with fixed negative membrane charges. Below, the ionic concentration (in M) will be placed within parentheses.

Because its movement in the membrane is the slowest, the transport of Cl^- through the membrane might be rate-determining for this kind of interdiffusion. Hence, its time-dependent change in the concentration is expected to be relatively monotonous in the system. It was assumed that an equation for the first-order reaction could express the decrease in the Cl^- concentration in the s-side solution, (Cl). That is,

$$(Cl) = [(Cl)_i - (Cl)_f] \exp(-k_1 t) + (Cl)_f \quad (1)$$

where $(Cl)_i$ and $(Cl)_f$ are the initial and final concentrations of Cl^- in the s-side solution respectively ($(Cl)_i = c_i$ and $(Cl)_f = (c_1 + c_2)$) and where k_1 is the velocity rate parameter for Cl^-.

The system, in the course of changing toward the final equilibrium, is not in a steady state, but in a transient state. Therefore, we cannot expect the Donnan equilibrium to be materialized during the experiment except at the end. However, there still exists a driving force which tends to bring the system to the imaginary Donnan equilibrium. The imaginary Donnan equilibrium can be calculated as follows. We made two additional assumptions in the calculation of the imaginary Donnan equilibrium. One is that the permeability of Cl^- is negligibly small in this calculation only. The other is that the activity coefficients of all ions in solutions are unity. The ratio of the imaginary concentrations of two permeable ions in the s-side solution, *i.e.*, $(H)_{imaginary}/(Na)_{imaginary}$, should be identical with the ratio of their corresponding concentrations in the l-side solution from the Donnan equilibrium. That is,

$$c_2/c_1 = (H)_{imaginary}/(Na)_{imaginary}. \quad (2)$$

From the electric neutrality condition, the total imaginary cation concentration in the s-side solution may be said to be equal to the existing Cl^- concentration in the s-side solution, *i.e.*:

$$(H)_{imaginary} + (Na)_{imaginary} = (Cl). \quad (3)$$

From Eqs. (2) and (3), we obtain:

$$(Na)_{imaginary} = [c_1/(c_1+c_2)](Cl) \equiv \gamma(Cl) \quad (4)$$

where $\gamma(=c_1/(c_1+c_2))$ is considered to be constant during the experiment.

An important assumption was made regarding the transport of Na^+. The Na^+ concentration in the s-side solution was forced to change by the driving force, which would tend to bring the Na^+ concentration, (Na), toward the calculated Na^+ concentration of the imaginary Donnan equilibrium, (Na)imaginary. This follows:

$$d(Na)/dt = -k_2[(Na) - (Na)_{imaginary}] \quad (5)$$

where k_2 is another velocity rate parameter for Na^+. Here, $k_2 > k_1$ because the permeability of Na^+ is much greater than that of Cl^-. By combining Eqs. (1), (4), and (5) and by integrating, we get:

$$(Na) = [k_2\gamma/(k_2-k_1)][(Cl)_i - (Cl)_f] \exp(-k_1 t) + \gamma(Cl)_f + I_0 \exp(-k_2 t) \quad (6)$$

where I_0 is the integral constant. The I_0 is determined from the initial condition; *i.e.*, at $t=0$, $(Na)=(Cl)=(Cl)_i$. That is,

$$I_0 = (Cl)_i - [k_2\gamma/(k_2-k_1)][(Cl)_i - (Cl)_f] - \gamma(Cl)_f. \quad (7)$$

The H^+ concentration in the s-side solution, (H), is given as follows from the electric neutrality condition:

$$(H) = (Cl) - (Na) = (1-\gamma)(Cl)_f + [1 - k_2\gamma/(k_2-k_1)] \times [(Cl)_i - (Cl)_f][\exp(-k_1 t) - \exp(-k_2 t)] - [(Cl)_f - \gamma(Cl)_f] \exp(-k_2 t). \quad (8)$$

In order to determine the two parameters, k_1 and k_2, from the experiment, we got a limiting equation from Eq. (8). Considering γ as near unity ($c_1 \gg c_2$) and neglecting the term of $\exp(-k_2 t)$ in the third brackets on the right-hand side of Eq. (8) compared with the term of $\exp(-k_1 t)$ in the range of large t values because $k_2 > k_1$, we obtain:

$$\log[(H) - (1-\gamma)(Cl)_f] = -k_1 t/2.303 + \log\{[1 - k_2\gamma/(k_2-k_1)][(Cl)_i - (Cl)_f]\}. \quad (9)$$

In Fig. 2, the left-hand side of Eq. (9) is plotted against t for Membranes 1, 2, and 3. From their gradients and the intercepts of straight broken lines in the range of large t values, k_1 and k_2 were obtained. In Table 1,

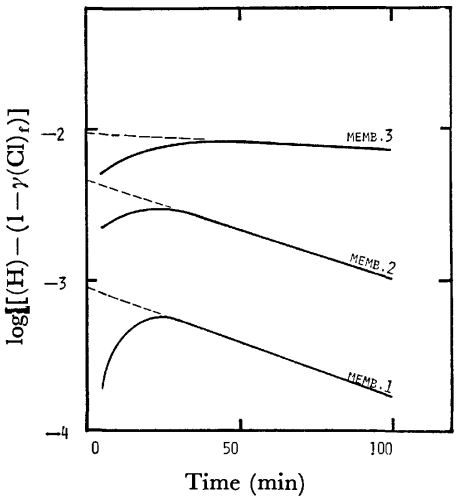

Fig. 2. Plots of $\log[(H)-(1-\gamma)(Cl)_f]$ *vs.* time t.
From gradients and intercepts of straight broken lines, k_1 and k_2 were obtained. Solid lines show experimental data.

k_1 and k_2 are shown along with other membrane characteristics.

The time dependencies of the H^+ concentration for Membranes 1, 2, and 3 calculated from Eq. (8) with k_1 and k_2 in Table 1 are represented in broken lines in Fig. 1. The coincidence between experimental curves and calculated curves was found to be generally good. Although it is felt that the analysis is rather too simple, this good coincidence could mean that the most significant aspects of the phenomena are included in the above analysis. It may be noted that the overshooting effect becomes larger as k_1 and k_2 become smaller and as the effective charge density of the membrane, θ, becomes larger.

A partial derivative of Eq. (8) with time becomes zero at the time when the overshooting effect reaches its maximum. Thus, the time t at the maximum effect, t_{max}, is given as:

$$(k_2-k_1)t_{max} = \ln(k_2/k_1) + \ln I_0 - \ln[1-k_2\gamma/(k_2-k_1)] - \ln[(Cl)_i-(Cl)_f]. \quad (10)$$

The t_{max} values were calculated from Eq. (10) to be 8, 17, and 39 min for Membranes 1, 2, and 3 respectively. The calculated t_{max} values are in good agreement with the experimental values. When $(Cl)_i<(Cl)_f$, Eq. (10) has no solution. In fact, experiments under the condition of constant 1-side composition (0.0247 M-NaCl+0.0022 M-HCl) showed that the overshooting effects were not found at 0.01 M and 0.02 M-NaCl initial concentrations in the s-side solution, although the effects *were* observed at an initial concentration higher than 0.05 M-NaCl in the s-side solution.

Chemical Reaction of Electron Donor-Acceptor System: A New Mechanism for the Tricyanovinylation Reaction of Some Aromatic Amines with Tetracyanoethylene

Takashi NOGAMI, Yoshiki HASEGAWA, Yasuhiko SHIROTA, and Hiroshi MIKAWA

Department of Applied Chemistry, Faculty of Engineering, Osaka University, Yamadakami, Suita, Osaka 565

(Received May 13, 1975)

The tricyanovinylation reactions of several aromatic amines with tetracyanoethylene (TCNE) were investigated kinetically by observing the change of the absorbance of the charge-transfer (CT) band in 1,2-dichloroethane. The pseudo first order rate coefficient of the decay of the CT-complex (k_{obsd}) was found to obey the relation, $k_{obsd}=kKD^n/(1+KD)$ (K: association constant of CT-complex; D: initial concentration of donor molecule), where $n=1$ in *N,N*-diethylaniline (DEA)–TCNE and *N,N*-di-*n*-butylaniline (DBA)–TCNE systems and $n=2$ in *N*-methyl-*N*-ethylaniline (MEA)–TCNE system. Since the currently accepted mechanism for the tricyanovinylation reaction cannot explain the case of $n=1$, we have proposed a new reaction mechanism which can explain all the kinetic data reported hitherto. Two characteristic points are involved in the new mechanism, *i.e.*, one is the unimolecular reaction of the CT-complex or the bimolecular reaction between reactants to form the σ-complex, and the other the decomposition of the σ-complex back to the component molecules. The reactions of MEA, DEA, and DBA with TCNE were discussed based on the new mechanism.

There have been extensive studies on the role of charge-transfer (CT) interaction in chemical reactions.[1] The tricyanovinylation (TCV) reactions of several aromatic amines with tetracyanoethylene (TCNE)[2-11] are the most typical reaction systems involving the formation of CT-complex. The clarification of the TCV reaction mechanism is very important, since it gives us fundamental information as to the role of the CT-complex to the reaction which has been left ambiguously yet.

Z. Rappoport studied systematically the TCV reactions of *N,N*-dimethylaniline (DMA) and *N*-methylaniline (MA) with TCNE for the first time,[2,3] and found that the 1 : 1 CT-complex (DA) formed between reactants gradually disappears to form the intermediate zwitterionic σ-complex (σ) or neutral adduct tetracyanoethane derivative (NA), and thereafter the final tricyanovinyl compound (TCVP) is slowly produced. The reaction scheme proposed by him is shown as Scheme 1. These two steps of reactions could be followed independently by an electronic absorption measurement because of the large difference in the reaction rates. In the first step, the decay of the CT-complex followed the rate equation (I-1),

$$-\frac{d[DA]}{dt}=k_{obsd}[DA]=\frac{kKD^2}{1+KD}[DA] \qquad (I\text{-}1)$$

where [DA], D, K, k_{obsd}, and k denote the CT-complex, initial concentration of a donor molecule (D), association constant of the CT-complex, pseudo first order rate coefficient of the CT-complex and the coefficient for the process between the CT-complex and the σ-complex, respectively. This kinetic equation has to date been understood by the mechanism as described in Scheme 1. Namely, Z. Rappoport has postulated in this mechanism a bimolecular reaction between DA and D, which is considered to be inevitable in order to introduce D^2 term in the numerator of k_{obsd}, and he considered an exchange reaction of a complexed D and a free D in this process. The reactions of D with σ and NA have been considered as the proton abstraction reactions from σ and NA with D.

Scheme 1.

The kinetic studies on the cycloaddition reactions of electron-donating olefins with TCNE[12,13] and on the ionization reaction in *N,N*-diethyl-*p*-toluidine–TCNE system[14] have revealed that the reaction should be interpreted as either a unimolecular transformation of the CT-complex or a bimolecular reaction of D with A. Namely, the bimolecular reaction between CT-complex and D has not been involved in these reaction kinetics. We have had questions for a long time why a bimolecular reaction of CT-complex with free D must be involved only in the TCV reaction, and this question prompted us to study the TCV reactions of higher *N*-alkylanilines, *N*-methyl-*N*-ethylaniline (MEA),

N,N-diethylaniline (DEA) and *N,N*-di-*n*-butylaniline (DBA), with TCNE in order to make clear the role of the CT-complex in the reaction. As the results, unimolecular reaction of the CT-complex or the bimolecular reaction between reactants were observed in DEA–TCNE and DBA–TCNE systems as shown later in this paper, being inconsistent with the currently accepted Rappoport mechanism. Therefore, we wish now to propose another mechanism for TCV reaction which can explain all the kinetic data reported hitherto and is considered to be more reasonable than the currently accepted one.

Experimental

Materials. DMA, DEA, and DBA were purchased from Tokyo Kasei Kogyo Co., Ltd. MEA was synthesized according to the literature.[15] All these amines were refluxed with sodium and thereafter distilled *in vacuo*. Special attention was made in the distillation of DBA to exclude *N*-monobutylaniline contained. The purity of the amines was confirmed by a gas chromatography. TCNE was purified by repeated sublimations. Commercially available 1,2-dichloroethane was shaken with KOH, washed with water, followed by extraction dried with $CaCl_2$ one day, refluxed with CaH_2, and finally distilled.

Measurements. The electronic absorption spectra and kinetic studies were made by a Hitachi 124 spectrophotometer. Thermostated water was circulated around the quartz observation-cell compartment (optical path length is 10 mm), and the donor and acceptor reservoirs. Donor and acceptor solutions were mixed directly in the observation cell. Initial absorption measurements could be made within 15 s after mixing.

Results and Discussion

Spectroscopic Course of the Reaction. The reactions in MEA–TCNE, DEA–TCNE, and DBA–TCNE systems were followed spectroscopically at a room temperature, using 1,2-dichloroethane as a solvent. Figure 1 shows the spectral change in MEA–TCNE system as a typical example. As the decrease of the CT-band at the long wavelength region, two new absorption bands, one locating at 440 nm with the vibrational structure and the other at 530 nm, increase gradually. The former band is assigned as a well-known TCNE anion radical[16] and the latter as tricyanovinylated product, *p*-tricyanovinyl-*N*-methyl-*N*-ethylaniline. The $TCNE^-$ band was observed for about one hour, and disappeared completely after all. The fate of $TCNE^-$ is unknown yet, but one possibility is that $TCNE^-$ is an intermediate for the formation of TCVP. Although we cannot answer to this possibility at present, independent study showed that TCVP is produced mostly through NA as shown below. The mixture of the equimolar ratio of MEA and TCNE showed the absorption band at 288 nm, and this band decreased gradually to produce TCVP. Although we could not isolate the species peaking at 288 nm because of its conversion into TCVP, it is safely assigned as NA in view of its quite similar absorption spectrum to that of the authentic NA in DMA–TCNE system.[5]

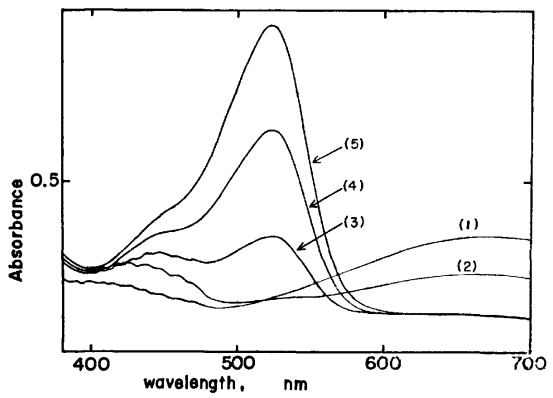

Fig. 1. Spectroscopic course of the reaction in MEA–TCNE system in 1,2-dichloroethane measured at a room temperature. $[MEA]=3.0\times10^{-2}$ M, $[TCNE]=3.0\times10^{-4}$ M. (1) 20 s, (2) 8 min, (3) 45 min, (4) 87 min, (5) 122 min after mixing.

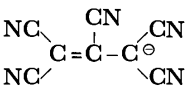
Almost similar spectroscopic change was observed also in DEA–TCNE and DBA–TCNE systems, and TCVP was found to be produced mostly from NA. However, these systems produced also pentacyanopropenide anion (PCP)[17] (λ_{max}=410, 430 nm) as another reaction product. PCP is probably produced by the reaction of $TCNE^-$ with TCNE as evidenced previously.[17]



PCP

Yields of Reaction Products. The yields of TCVP and PCP under the kinetic work condition were estimated by measureing the electronic absorption spectra of the mixtures of the donor and acceptor solutions after keeping them for a few days at room temperature (Table 1). In these cases, the authentic extinction coefficients of PCP[17] and TCVP[18] were used. Each TCVP tends to increase slowly even several days after mixing the donor and acceptor solutions. Therefore, the yields of TCVP become higher than those in Table 1 day by day. This fact is due to the slow reaction rate from NA to TCVP. In other words, these reaction systems produce NA relatively fast, and it converts into TCVP very slowly. Therefore, the decrease in the CT-absorption does not correspond to the increase of TCVP. Furthermore, the correspondence between the decrease of the CT-complex and the increase of NA

Table 1. Yields of TCVP and PCP

	Yield of TCVP (%)	Yield of PCP (%)
$[MEA]=0.4$ M, $[TCNE]=1.0\times10^{-3}$ M	90[a]	—
$[DEA]=0.4$ M, $[TCNE]=1.0\times10^{-3}$ M	24[a]	23[a]
$[DBA]=0.8$ M, $[TCNE]=8.3\times10^{-4}$ M	49[b]	9[b]

a) Measured two days after mixing. b) Measured six days after mixing.

could not be measured because of the overlap of the absorption band of NA with those of the component molecules. No noticeable reaction product other than TCVP and PCP was observed in these systems. Table 1 shows that the formation of TCVP is the main reaction at least in MEA–TCNE and DBA–TCNE systems.

Thermodynamic Parameters of the CT-complex. The association constant of the CT-complex was obtained from the extrapolation of the decay of the CT-complex to zero time to make Benesi-Hildebrand (B-H) plot by the least-squares method. Figures 2, 3, and 4 show the B-H plots of MEA–TCNE, DEA–TCNE, and DBA–TCNE systems, respectively, in 1,2-dichloroethane at several temperatures. Clearly 1:1 CT-complexes are formed in these systems. The Arrhenius plots of the association constants of the CT-complexes (K) in these systems give straight lines to obtain the standard enthalpy ($\Delta H°$) and the entropy ($\Delta S°$) changes. The values of K, $\Delta H°$, and $\Delta S°$ in these systems together with those

in DMA–TCNE systems measured in 1,2-dichloroethane are summarized in Table 2. The value of K at each temperature is used in the analysis of the following decay kinetics of the CT-band.

The Decay Kinetics of the CT-band. The decay of the CT-band was followed at the appropriate band positions (DMA–TCNE, 675 nm; MEA–TCNE, 750 nm; DEA–TCNE, 800 nm; DBA–TCNE, 800 nm) with the donors in large excess over TCNE. Varying the concentration of the donor keeping that of TCNE constant, plots of log I_{CT} (I_{CT}: the absorbance of the CT-complex at the wavelength measured) against time (t) give straight lines at several temperatures in all systems studied as shown for DBA–TCNE system as a typical example in Fig. 5, which shows that the decay rate of the CT-complex is of the first order with respect to the CT-complex. It was also found that the decay rate of the CT-complex is independent of the initial concentration of TCNE. Table 2 shows the values of the pseudo first order rate coefficients of the CT-complex

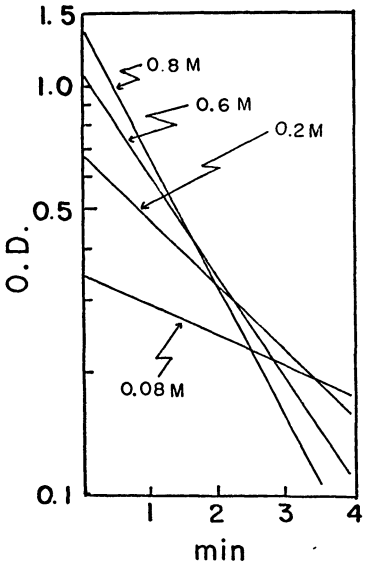

Fig. 5. The decay of the CT-band with time measured at 30 °C. [TCNE]=4.98×10^{-4} M. The concentration of DBA is indicated in the figure.

(k_{obsd}) in these systems, those of $k_{obsd}(1+KD)$ and of $k_{obsd}(1+KD)/D$ at various initial donor concentrations (D). The values of $k_{obsd}(1+KD)/D$ are almost constant irrespective of the initial donor concentrations within the experimental error in DMA–TCNE and MEA–TCNE systems but vary with the change of the donor concentrations in DEA–TCNE and DBA–TCNE systems. Fig. 6 shows the plot of $k_{obsd}(1+KD)/D$ against KD in MEA–TCNE system, and Figs. 7 and 8 those of $k_{obsd}(1+KD)$ against KD in DEA–TCNE and DBA–TCNE systems, these plots being obtained by the least squares method. The former and the latter plots are designated hereafter as "second order plot" and "first order plot," respectively, since $k_{obsd}(1+KD)$ is quadratic with D in the former plot and linear with D in the latter. One can see from Figs. 6, 7, and 8 that MEA–TCNE system gives straight lines in the second order plot and DEA–TCNE and DBA–TCNE systems in the first order plot at several temperatures measured. The kinetic studies on the TCV reactions of DMA–TCNE and *N*-methylaniline (MA)–TCNE systems have shown that the second order plots are linear in these systems,[2,3] and this is also confirmed in the former system in this study. On the other hand, the values of $k_{obsd}(1+KD)$ was found to be proportional to D^3 in the *N*-tricyanovinylation reactions of aniline (A)–TCNE system[10] (such a D^3 dependence is designated as "third order plot"). Therefore, the following results are derived from the kinetic studies on the TCV reactions carried out hitherto.

First order plot (DEA–TCNE,[19] DBA–TCNE[19])

$$k_{obsd}=\frac{kKD}{1+KD}$$

Second order plot (MA–TCNE,[3] DMA–TCNE,[2] MEA–TCNE[19])

$$k_{obsd}=\frac{kKD^2}{1+KD}$$

Third order plot (A–TCNE[10])

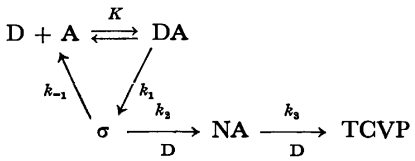
$$k_{obsd} = \frac{kKD^3}{1+KD}$$

The first order plot obtained in this study is the first example for the TCV reaction, although the first order plot is rather general in many reaction systems involving CT-complex such as 2+2 and 4+2 cycloaddition reactions[12,13] and ionization reactions.[14] As stated previously, Z. Rappoport and P. G. Farrell explained the second order plot in the TCV reaction as resulting from the bimolecular exchange reaction between a complexed donor and a free donor, and this assumption has been accepted to be general for the TCV reaction (Scheme 1). By this currently accepted mechanism, however, the first order plots observed in DEA–TCNE and DBA–TCNE systems are difficult to understand. We considered, therefore, that a more general reaction scheme must exist for the TCV reaction, and the decay kinetics of the CT-complex obeys first order plot or second order plot, and sometimes third order plot, by applying the special conditions to the new reaction scheme.

New Mechanism for the TCV Reaction. We wish now to propose another mechanism which can also satisfy all the kinetic data reported hitherto as described in Scheme 2.



Scheme 2.

Two characteristic points are involved in the new mechanism, *i.e.*, (1) unimolecular reaction from CT-complex to zwitterionic σ-complex, and (2) dissociation reaction of zwitterionic σ-complex back to the component molecules. The other reaction steps (the reactions from σ to NA and from NA to TCVP) are the same as the currently accepted mechanism, and the introductions of D in these steps are due to the proton abstraction reactions from σ and NA with basic D molecule (see Scheme 4).

Applying the steady state approximations to the unstable σ-complex,[20] the decay of the CT-complex is derived as follows.

$$\frac{d[DA]}{dt} = k_{obsd}[DA] = \frac{k_1k_2KD^2}{(1+KD)(k_{-1}+k_2D)}[DA] \quad \text{(II-1)}$$

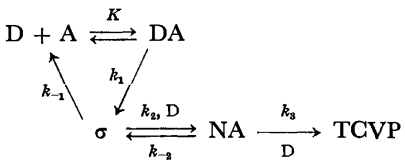
$$\approx \frac{(k_1k_2/k_{-1})KD^2}{1+KD}[DA] \quad (k_{-1} \gg k_2D) \quad \text{(II-2)}$$

$$\approx \frac{k_1KD}{1+KD}[DA] \quad (k_{-1} \ll k_2D) \quad \text{(II-3)}$$

The equation (II-1) reduces to (II-2) to give the second order plot if $k_{-1} \gg k_2D$ holds, and (II-2) is essentially identical with (I-1), *i.e.*, k in (I-1) is reinterpreted in the new mechanism as (k_1k_2/k_{-1}). That is to say, in the currently accepted mechanism the presence of DA+D reaction has been assumed in order to make the D term in the numerator of k_{obsd} quadratic, and in our new mechanism this is effected by introducing a back reaction from the σ-complex to the reactants. On the contrary, if $k_{-1} \ll k_2D$ holds, the equation (II-1) reduces

to (II-3) to give the first order plot. In other words, in our new mechanism if the rate of the decomposition of the σ-complex to the component molecules (k_{-1}) is much faster than that of the conversion of the σ-complex to neutral adduct (k_2D), the second order plot is obtained and if in the reverse case, the first order plot is obtained.

We insist here that the former condition may hold in MA–TCNE and DMA–TCNE systems. Concerning the MEA–TCNE system, we observed the TCV reaction as well as the ionization reaction of the component molecules. The existence of the ionization process in this system is the characteristic point as compared with MA–TCNE and DMA–TCNE systems. The second order plot observed in MEA–TCNE system is considered to result from the fact that the TCV reaction occurs with the former condition ($k_{-1} \gg k_2D$), and that the TCV reaction dominates over the ionization reaction.[21] It cannot be necessarily said, however, that the latter condition ($k_{-1} \ll k_2D$) holds in DEA– and DBA–TCNE systems. The discussions on these two systems are shown later in this paper.



Scheme 3.

The cubic dependence of D in the numerator of k_{obsd} (third order plot) observed in aniline–TCNE system[10] is interpreted in our new mechanism in terms of the reversibility of both processes of the σ-complex and the neutral adduct formations probably due to the instability of the neutral adduct in this system. This is consistent with the fact that the absorption band of neutral adduct could not be detected by an electronic absorption spectra in this system. The reaction scheme for this system is given as Scheme 3. Applying the steady state approximations to the σ-complex and neutral adduct, the following kinetic equations are derived, where k_{-2} denote the reaction rate coefficient from neutral adduct to σ-complex.

$$-\frac{d[DA]}{dt} = k_{obsd}[DA]$$

$$= \frac{k_1k_2k_3KD^3}{(1+KD)(k_{-1}k_2+k_{-1}k_3D+k_2k_3D^2)}[DA] \quad \text{(III-2)}$$

$$\approx \frac{(k_1k_2k_3/k_{-1}k_{-2})KD^3}{1+KD}[DA] \quad \text{(III-2)}$$

$$(k_{-1} \gg k_2D, \text{ and } k_{-2} \gg k_3D)$$

The rate equation (III-1) reduces to (III-2), the third order plot, if $k_{-1} \gg k_2D$ and $k_{-2} \gg k_3D$ hold simultaneously.

Discussions on the New Mechanism. At present, we have no direct evidence for the new mechanism, but we beleive that the new mechanism is more reasonable from the following reasons.

(1) The reaction of a complexed TCNE with a free donor, the currently accepted mechanism, is difficult to understand in such an electrophilic substitution reaction as TCV reaction, because the electron accepting property of the complexed TCNE may be sufficiently weakened. Furthermore, no experimental evidence has been found which shows the existence of the exchange reaction between a complexed donor and a free donor.

(2) The kinetic deuterium isotope effect was found to exist for the decay of the CT-complex between DMA–TCNE and 4-deuterio-*N*,*N*-dimethylaniline–TCNE systems.[7] The currently accepted mechanism cannot explain this result, since hydrogen abstraction reaction is not involved in the reaction of DA with D. On the other hand, the new mechanism can explain the isotope effect in view of the fact that the rate of hydrogen abstraction reaction from σ-complex (k_2) is involved in k_{obsd}, *viz.*,

$$k_{obsd} \approx \frac{(k_1k_2/k_{-1})KD^2}{1+KD}.$$

(3) The kinetic studies for the 2+2 and 4+2 cycloaddition reactions of electron donating olefins with TCNE[12,13] and ionization reaction in *N*,*N*-diethyl-*p*-toluidine–TCNE system[14,21] have revealed that the reaction should be understood as either unimolecular transformation of the CT-complex or bimolecular reaction between a free donor and an acceptor molecules. These results suggest that the unimolecular transformation of the CT-complex is favored over the bimolecular reaction between the CT-complex and a free donor. Thus, the primary process of the chemical reaction involving the formation of the CT-complex is systematically understood by the same mechanism.

(4) The assumption of back process of the zwitterionic σ-complex to the component molecules is reasonable, which has recently been evidenced in the 2+2 cycloaddition reaction of isomeric enol ethers with TCNE.[22]

(5) The new mechanism which involves σ-complex as an unstable intermediate and neutral adduct tetracyanoethane derivative as an accumulating intermediate is in accord with the fact that the latter has actually been isolated,[7,8] while the former cannot be detected even by the spectroscopic technique. The explanation in the literature[7] that the isolable neutral adduct may arise by rapid rearrangement of the σ-complex and may not be on the reaction path of the overall TCV reaction under the kinetic work conditions seems to be unattractive.

Discussions on the TCV Reaction in DEA–TCNE and DBA–TCNE Systems. As stated above, the decay of the CT-complex obeyed the first order plot in DEA–TCNE and DBA–TCNE systems. These results are now discussed based on the new mechanism. The following three cases can be considered as the reason of the first order plots in these systems.

(1) As stated in the description of the new mechanism, these systems are in the condition that the decomposition rate of σ-complex is much slower than the reaction rate from σ-complex to neutral adduct, *i.e.*, $k_{-1} \ll k_2D$. This may be rationalized by the stability of the σ-complexes in these systems because of the increasing donor properties of DEA and DBA as compared

with MA, DMA, and MEA, and the decomposition rate of the σ-complex back to the component molecules may be considerably reduced.

(2) The steric effect of the bulky alkyl groups attached to the amino nitrogens of DEA and DBA hinder the proton abstraction reaction of these amines from the σ-complex, and the conversion of the σ-complex into the neutral adduct is a unimolecular reaction.[23] Thus, in this case k_2D in equation (II-1) must be replaced by k_2 to give

$$k_{obsd} = \frac{(k_1k_2/(k_{-1}+k_2))KD}{1+KD}.$$

(3) The ionization reaction dominates over TCV reaction.[21] Which of these three cases actually holds is now under investigation.

Concerning the ionization reaction, three mechanisms are conceivable, *i.e.*, ionization from (1) component molecules, (2) CT-complex, and (3) σ-complex. In order to know the ionization mechanism, the ESR studies are now under investigation.[14]

Comments. The followings are the additional comments to be noted. (1) We have discussed the mechanism based on the unimolecular transformation of CT-complex to the σ-complex (Scheme 2). However, another mechanism is also possible in which σ-complex is produced from the component free molecules and the CT-complex exists in a side reaction as shown in Scheme 2'. The reaction scheme and rate equation are as follows.

$$D + A \overset{K}{\rightleftharpoons} DA$$

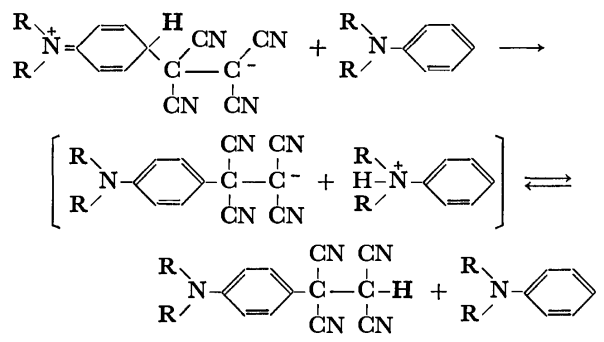
$$\sigma \xrightarrow[D]{k_2} NA \xrightarrow[D]{k_3} TCVP$$

$$-\frac{d[DA]}{dt} = \frac{k_1'k_2D^2}{(1+KD)(k_{-1}+k_2D)}[DA] \qquad (II'-1)$$

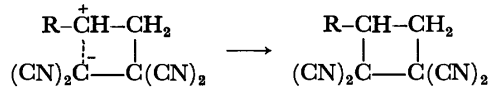
Scheme 2'.

Where, k_1' is the rate coefficient from the component molecules to the σ-complex. The two mechanisms,

TCV reaction



Cycloaddition reaction



Scheme 4.

Schemes 2 and 2', are indistinguishable kinetically. The detailed discussions will be reported in the near future.

(2) It has been reported that the decay of the CT-complex obeys the first order plot in many cycloaddition reactions of electron rich olefins with TCNE.[12,13] The apparent difference in the rate equations for the decay of the CT-complex between the TCV reaction and the cycloaddition reaction is understandable as resulting from the fact that in the TCV reaction one more donor molecule participates in abstracting a proton from the σ-complex in the neutral adduct formation process, while in the cycloaddition reaction such a process is not involved (Scheme 4).[24]

(3) It has been to date insisted that the CT-complex is the essential intermediate in the TCV reaction based on the mechanism of the bimolecular reaction of the complexed donor and a free donor. In the new mechanism, however, the kinetic data alone cannot tell whether or not the CT-complex is the true intermediate in the TCV reaction.[24]

The Application of Molecular-flame-absorption Spectroscopy to the Elucidation of Chemical Interferences in Indium Atomic Absorption Spectrometry

Hiroki HARAGUCHI and Keiichiro FUWA*

Department of Chemistry and Physics, The National Institute for Environmental Studies, Yatabe-machi, Tsukuba-gun, Ibaraki 300-21

**Department of Agricultural Chemistry, Faculty of Agriculture, The University of Tokyo, Yayoi, Bunkyo-ku, Tokyo 113*

(Received May 17, 1975)

The atomic absorption spectrometry of indium was investigated in air-acetylene and nitrous oxide-acetylene flames. The atomic absorptions of indium were significantly interfered by HCl, $HClO_4$, and HBr in both the flames. The chemical interferences can be explained by the formation of diatomic molecules, such as InCl and InBr, the molecular absorption spectra of which were really observed in flames.

The atomic absorption spectrometry of indium has been studied by several workers.[1-4] It has been established by the studies that indium is interfered with by several cations[2] and anions[4] in the air-acetylene flame and even in the nitrous oxide-acetylene flame. Popham and Schrenk reported analytical interferences by HCl, HBr, H_2SO_4, and H_3PO_4 in the concentration range of less than 1M and suggested an interfering mechanism resulting from the formation of diatomic molecules in the flames.[4]

Recently, the molecular absorption spectra of various species in flames have been investigated, and such molecular species as SO_2, PO, InF, InCl, InBr, InO, AlF, AlCl, and AlO have been found.[5-11] Furthermore, it has been shown that these molecular absorption spectra in the flames can be used not only for the determination of non-metallic elements,[5-7] but also for the elucidation of the chemical interferences.[8,9] Hence, in this paper, the chemical interferences due to various hydrogen acids in indium atomic absorption spectrometry have been investigated by means of molecular absorption spectroscopy.

Experimental

Samples. The indium oxide (In_2O_3; 99.9%) was purchased from Mitsuwa Chemical Ind. Co. The acids used were of a guaranteed ragent grade. The sample solutions were prepared by dissolving properly weighed amounts of indium oxide in acidic aqueous solutions.

Instruments. A Hitachi 207 Atomic Absorption Spectrophotometer was used for the measurements of the atomic and molecular absorptions. The hollow cathode-discharge tube of indium was obtained from Hitachi Manufacturing Ltd., and that of the deuterium lamp, from the Hamamatsu TV Co. A Hitachi 207-0100 High-voltage Power Source was used as the power supply for the deuterium lamp.

Procedures. The experimental conditions for the measurements of the atomic and molecular absorptions in the air-acetylene and nitrous oxide-acetylene flames are summarized in Table 1. In the case of the atomic absorption spectrometry, the "sample flow rates," which are referred to the volumes of the sample solutions aspirated into the burner for a minute, are affected to some extent by the viscosities of the solutions and change the atomic absorptions of indium. Therefore, the dependences of the atomic absorptions on the sample-flow rates have been investigated. The results are shown in Fig. 1, where the sample flow rates were changed by using several kinds of capillary tubes with different diameters and lengths. The sample flow rates were measured with a graduated cylinder.

Table 1. Experimental conditions in atomic and molecular absorption spectrometry

I) Atomic absorption	
Analytical lines	303.9 nm, 325.6 nm, 412.5 nm, 451.1 nm
Lamp	hollow cathode lamp of indium
Lamp current	15 mA
Flame height	10—20 mm
Air-acetylene flame;	
air flow rate	13 l/min
acetylene flow rate	3 l/min
Nitrous oxide-acetylene flame[a];	
nitrous oxide flow rate	6 l/min
acetylene flow rate	4 l/min
Spectral band width	0.34 nm
II) Molecular absorption[b]	
Analytical lines	(303.9 nm for In)
	273.0 nm for InO
	267.2 nm for InCl
	284.6 nm for InBr
Lamp	hollow cathode lamp of deuterium
Lamp current	25—35 mA

a) A water-cooled burner for nitrous oxide-acetylene flame was used. b) Other conditions were the same with those in atomic absorption spectrometry.

The molecular flame absorption spectrum shown in Fig. 5 was obtained by measureing the absorbances at wavelengths separated by intervals of 1Å, as has been reported previously,[11] the deutrium lamp was used as a continuous light source. The dependences of the atomic and molecular absorptions of In, InO, and InCl on the HCl concentration, which are shown in Fig. 4, were also measured using the deuterium lamp.

Results and Discussion

The calibration curve for the atomic absorption of indium was linear in the concentration range from 0 to 10 μg/ml when 0.1—1 M HNO_3 aqueous solutions of indium with various concentrations were used as the sample solutions. The sensitivity (1% absorption) for

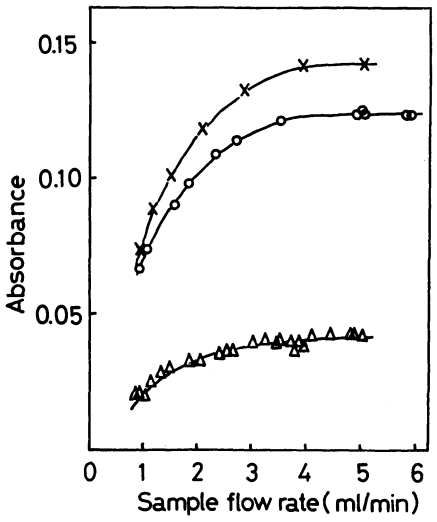

Fig. 1. Sample flow rate *vs.* atomic absorptions of indium at several analytical lines in the air–acetylene flame.
The concentration of indium is 20 μg/ml.

—△—: 412.5 nm, 451.1 nm.

the analytical lines of 303.9, 324.6, 410.5, and 451.1 nm were 0.5, 0.6, 1.7, and 1.7 μg/ml respectively.

Dependences of the Atomic Absorptions on the Sample-flow Rate. The atomic absorptions of indium are much affected by the sample-flow rates. The experimental curves for the relation between the absorbances of atomic indium in the air-acetylene flame and the sample-flow rates are shown in Fig. 1; these curves correspond to the results with respect to some analytical lines. In all the cases, the absorbances of indium significantly decrease when the sample-flow rates become smaller than 3.5 ml/min, while they are almost constant over 3.5 ml/min. Similar results have been obtained by Fuwa *et al.* in flame-emission spectrometry[12] and by Takada and Nakano in atomic absorption spectrometry.[13] In the emission spectrometry, the intensity is very dependent on the sample-flow rate, and the maximum intensity was observed clearly at a definite sample-flow rate.[12] These results have been explained in terms of the cooling effect of the aspirated water on the flame temperature. This is because the population of atoms in the exited states, which determines the sensitivity of emission, depends much on the flame temperature. In atomic absorption spectrometry, on the other hand, the population of atoms in the ground state determines the sensitivity; it dose not depend greatly on the change in the flame temperature.[13] Therefore, the results in Fig. 1 indicate that the changes in the sample-flow rates are not so meaningful in atomic absorption spectrometry as in emission spectrometry.

Interferences of Hydrogen Acids. The dependences of atomic absorptions in the air–acetylene flame on the concentration of hydrogen acids are shown in Fig. 2. When the concentrations of acids become larger, the viscosities of the sample solutions increase and the sample-flow rates decrease significantly, below 3.5 ml/min in some cases. Such effects of acids were particularly remarkable in the cases of H_2SO_4 and $HClO_4$.

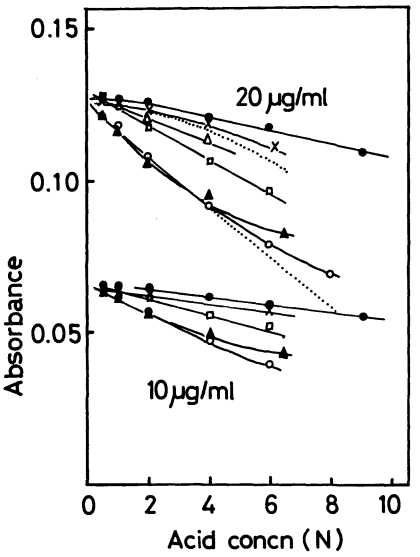

Fig. 2. Chemical interfering effects of hydrogen acids on atomic absorptions of indium at 303.9 nm in the air–acetylene flame.
The concentration of indium is 10 and 20 μg/ml. The dotted lines show the obserbed values in the cases of H_2SO_4 and $HClO_4$, and the continuous lines do the corrected values with respect to the viscosities of the sample solutions in the respective case.
—●—: HNO_3, —×—: H_2SO_4, —△—: HI,
—□—: HBr, —▲—: HCl, —○—: $HClO_4$.

These circumstances are shown in Fig. 2, where the observed values have been corrected using the results shown in Fig. 1. In the cases of other acids, the effects of the viscosities of the solutions were smaller or negligible. From Fig. 3, it can be seen that the stomic absorptions of indium are considerably interfered with by various hydrogen acids as the acid concentrations increase. The interferences become larger in the following order; $HNO_3 < H_2SO_4 < HI < HBr < HClO_4 \cong HCl$. These interferences can not be excluded even in the nitrous oxide–acetylene flame, as is shown in Fig. 3. It should be noted here that indium in $HClO_4$ is interfered with to almost the same extent as that in HCl.

Sastri *et al.* investigated the atomic absorptions of Ti, Zr, Ta, Hf, and so on in cyclopentadiene and acetylacetonate complexes, and suggested that the dissociations of metal complexes into atoms in the flame are controlled by the atoms directly coordinated with the central metal ion in ligands.[15,16] According to their investigation of the distributions of cobalt atoms in the flame, Fujiwara *et al.* also suggested the formation of intermediate molecules between the central metal ion and the coordinating atom in the case of cobalt(III) complexes.[17] Moreover, Popham and Schrenk explained the interferences of hydrogen acids less than 1 M with the atomic absorptions of indium by suggesting the formation in the flame of such intermediate compounds as InO and InCl.[4] Actually, Marks and Welcher observed the flame emissions of such diatomic molecules as AlO and TiO and interpreted the metallic inter-element interferences in aluminum atomic absorption spectrometry as occurring because of the reaction between the diatomic molecules.[18] The studies cited

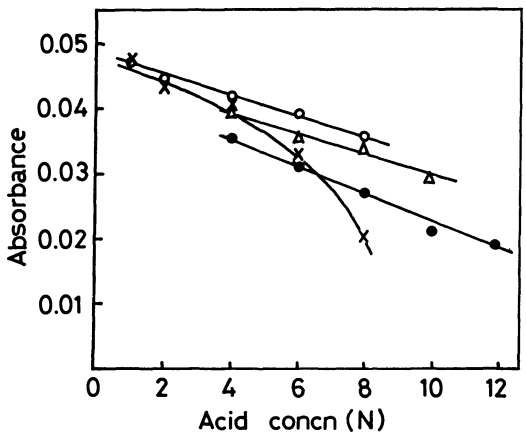

Fig. 3. Chemical interfering effects of hydrogen acids on atomic absorptions of indium at 303.9 nm in the nitrous oxide–acetylene flame.

above suggest the important roles of the intermediate molecules, such as the diatomic molecules, in the chemical-interfering phenomena. With respect to the HCl and HBr solutions of indium, the molecular absorptions of InCl and InBr have been observed in the air–acetylene flame, when the solutions are aspirated into the flame.[8-11]

TABLE 2. DISSOCIATION ENERGIES OF DIATOMIC MOLECULES OF INDIUM[21]

Molecule	Dissociation energy (eV)
InO	3.3 ±0.5
InI	3.35±0.15
InBr	4.0 ±0.15
InCl	4.5 ±0.15
InF	5.35±0.15
InH	2.5[a]

a) Cited from "Flame Spectroscopy" by R. Mavrodineanu and H. Boiteux, John Wiley & Sons, New York (1965).

It has been established by the ^{115}In-NMR study that indium ions in various hydrogen acids exist as such complexes as $In(H_2O)_6^{3+}$ in HNO_3 and $HClO_4$, $In(SO_4)_2^-$ in H_2SO_4, and $In(H_2O)_{6-n}X_n^{3-n}$ in HCl, HBr, and HI, where X is Cl, Br, and I and where n is 0—4.[19,20] If we take into consideration the suggestions with respect to the decompositions of various complexes in the flames, as proposed by Sastri *et al.*[15,16] and Fujiwara *et al.*,[17] it is possible that indium in various acidic solutions produces, in the flame, such diatomic molecules as InO, InS, InCl, InBr, and InI as intermediate compounds. If so, the interferences due to hydrogen acids may have some correlation with the dissociation energies of the suggested diatomic molecules. The dissociation energies of the diatomic molecules are listed in Table 2.[21] The order of magnitudes of the dissociation energies is really consistent with that of the interferences due to hydrogen acids except for the case of $HClO_4$. This may support the idea of the formation of diatomic molecules in the flame. Indium in the $HClO_4$ solution behaves similarly to that in HCl in both the air–acetylene and nitrous oxide–acetylene flames. This may be ascribed to the formation of InCl by a secondary reaction in the flame in the case of $HClO_4$. This interfering mechanism will be elucidated in the next section.

The reason why the interferences of acids cannot be overcome even in the nitrous oxide–acetylene flame may be ascribed to the fact that the dissociation energies of the diatomic molecules shown in Table 2 are large enough so that the diatomic molecules are dissociated into atoms only with difficulty, even in the nitrous oxide–acetylene flame.

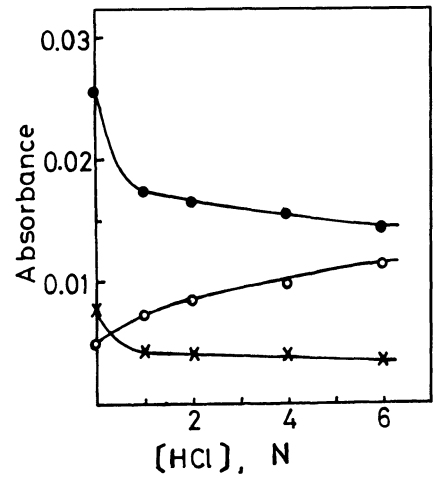

Fig. 4. Concentration of HCl *vs.* atomic and molecular absorptions of indium in the air–acetylene flame.
The concentration of indium is 0.05 M, and a deuterium lamp was used.
—●—: In at 303.9 nm, —×—: InO at 273.0 nm,
—○—: InCl at 267.2 nm.

Interfering Mechanisms. In order to elucidate the interfering mechanisms suggested above, the atomic and molecular absorptions for the indium atoms, InO and InCl, in the air–acetylene flame were measured in terms of the HCl solution of indium, using a deuterium lamp. The results are shown in Fig. 4, where the concentration of indium was 0.05 M and where the analytical lines for In, InO, and InCl were 303.9 nm, 273.0 nm, and 267.2 nm[11] respectively. As the concentration of HCl increase, the absorbances of InCl increase, while those of In and InO decrease. This fact indicates that the interfering effect of HCl is apparently due to the formation of InCl in the flame. The increase of the interference at the high concentrations of HCl may also be affected by that of the complex formation of indium with chlorine in solution.[20] In the case of HBr, result similar to that in Fig. 4 was obtained, and it was ascertained that the formation of InBr is essential to the interfering effect of HBr.

In Fig. 5 the absorption spectrum is shown; it was measured by aspirating the $HClO_4$ solution of indium into the air–acetylene flame. It should be noted here that the broad bands observed in the range from 265 to

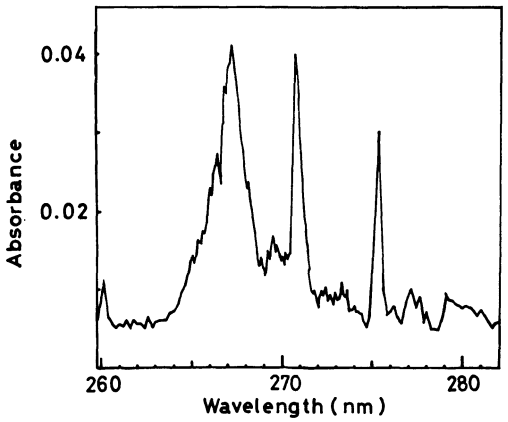

Fig. 5. Absorption spectrum in the airacetylene flame, which are measured with aspirating an 2 N $HClO_4$ solution of 0.05 M indium into the flame.

270 nm correspond to those of InCl.[11] This result indicates that the following reactions for the formation of InCl occur in the flame and that InCl is produced:

$$In(ClO_4)_3 \xrightarrow{\Delta} In^* + 3Cl^{**} + 6O_2$$
$$HClO_4 \xrightarrow{\Delta} Cl^{**} + OH + 3/2O_2$$
$$In^* + Cl^{**} \longrightarrow InCl$$

where Δ indicates a pyrolysis reaction. The formation of InCl in the case of the $HClO_4$ solution of indium explains well the results of atomic absorption spectrometry shown in Figs. 2 and 3.

Construction of a high resolution calorimeter of an adiabatic type for single crystals is described. It uses a bank of thermistors for high resolution measurements in addition to a miniature platinum resistance thermometer. The results of heat-capacity measurements on benzoic acid as a standard material showed the inaccuracy of $\pm 0.1\%$ and the imprecision was confirmed to be less than $\pm 0.05\%$ between 50 and 275 K.

Singularities observed in thermodynamic properties of a substance at the critical point are characterized by the quantities known as the critical exponents. These quantities are of paramount importance in the study of critical phenomena and their determination as well as verification of various relation expected to hold among them are central problems of experimental and theoretical investigations in this field.[1,2] Elucidation of the nature of a phase transition by determining reliable values of the critical exponents requires measurement of the thermodynamic quantities with high resolution both in the independent variable (particularly, the temperature) and in the quantity measured. Although the heat capacity exponents have been evaluated for a number of substances, lack of sufficient resolution in the measurement diminishes their reliability in a large number of cases. Among the notable exception in this respect is the excellent high resolution heat capacity measurement performed by Buckingham, Fairbank and Keller[3] on the λ-transition in liquid ^{4}He. Other critical phase transitions which have been studied include those in magnetic and dielectric substances and binary liquid mixtures.[4-10] As to the dielectric transitions, with which we are concerned mainly, reliable high resolution heat capacity data are deplorably limited in number and in the substance dealt with.

There are two types of calorimeter used for high-resolution measurement which operate on different principles. One is the discontinuous heating method (the DC method) and the other the stationary state method (the AC method).[11] We adopted the DC method, in view of the problem of the present interest. Although the AC method has desirable features that the measurements can be made with smaller amount of the sample and easily operated automatically, it has the demerits: the specimens to be studied are limited to non-volatile substances and the absolute values of the heat capacities are very difficult to determine. On the other hand, the DC method has no restrictions on specimens and yields the absolute value of heat capacities and is able to detect a minute 1-st order component which sometimes accompany the critical point. This last possibility is also important for characterization of the phase transition phenomenon.

This paper describes an adiabatic-type high-resolution calorimeter which works in the temperature range between 12 and 300 K. The accuracy of this apparatus was determined by the measurement of heat capacities of benzoic acid. The results[12] of the high resolution measurement on the single crystal of $SnCl_2 \cdot 2H_2O$ revealed the reliability of this apparatus.

Experimental

Construction of Apparatus. The calorimeter consists of four major parts, *viz.*, the cryostat, the adiabatic-control circuit, the temperature-measuring circuits and the energy supply and its measuring circuit (Fig. 1). A special feature of the apparatus is that it is equipped with two thermometers, a platinum resistance thermometer and a thermistor thermometer. The former provides an accurate temperature scale based on the International Practical Temperature Scale 1968, while the latter enables precise measurement of small temperature increment of the calorimeter. The platinum resistance thermometer is also used for calibrating the thermistor. This feature endows the apparatus with a unique capability of measuring the heat capacity with high accuracy and precision. Details of the calorimeter design and construction are described in the following.

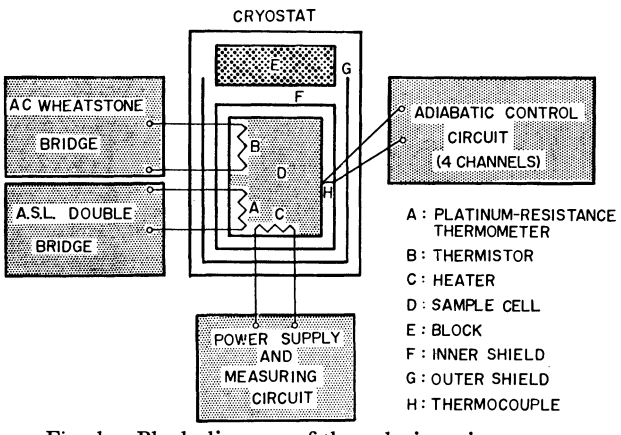

Fig. 1. Block diagram of the calorimetric system.

1) Cryostat. Figure 2 shows a schematic drawing of the cryostat. The calorimeter cell (A), whose detailed construction is given below, is suspended in the inner adiabatic jacket (B) with a 0.5 mm thick nylon cord at the top. Its horizontal position relative to the jacket is adjusted to the center of the jacket with three thinner nylon cords attached at the bottom of the cell. The inner jacket of a thin copper shell of 0.5 mm thickness consists of three parts, *i.e.*, a cylinder, upper cone (these two weighing 114 g) and a bottom cone (22 g). The bottom cone is firmly attached to the cylinder with three pairs of screw. The temperature of the inner

jacket is controlled relative to that of the cell. The outer jacket (C) is also a temperature-regulated copper cylinder (275 g) whose function is to prompt establishment of the adiabatic condition of the cell by keeping a stabilized temperature difference between the inner jacket and itself. The copper block (D) is a temperature-controlled heat reservoir, which helps the inner jacket to work correctly by tempering the thermal agitation coming down through the leads. The block has a large mass for this purpose and a copper bobbin for winding the heater wires. These three temperature-controlled components are suspended in the inner vacuum can (E) from the bottom of the coolant container (F). The latter is surrounded by the outer vacuum can (G) which is normally immersed in an appropriate coolant, usually liquid nitrogen or methanol-dry ice mixture according to the temperature region being studied.

The leads for the thermometers, heaters, and thermocouples are tightly wound around the inner jacket and the block, and then around the sleeve (H) attached to the bottoms of the inner coolant container in turn and finally led out through a Dekhochinsky seal and a glass-hermetic seal. The lead wires to the calorimeter cell are connected with terminals insulated by teflon attached to the inner jacket. The spaces in the inner can and between the inner and the outer can are evacuated independently to *ca.* 0.2 mPa by an oil vacuum pump.

2) Calorimeter Cell. The calorimeter cell for the samples of single crystals is shown schematically in Fig. 3. This is a chromium-plated copper cylinder, about 30 mm in diameter and 60 mm long with the wall 0.3 mm thick.

A dismountable lid on the top end of the cell allowed loading it with a large snugly-fitting single crystal. The vacuum-tight closure was achieved by applying a thin layer of Apiezon N grease between the lapped faces of the flanges of the cylinder and the lid and fixing them tightly together with eight pairs of screw. An indium O-ring with 0.5 mm diameter can also be used. This closure could hold cell at 0.1 mPa. The two types of thermometers are attached to the outside of the cell. One is a miniature platinum-resistance thermometer (Model S 1059, the Minco Products, USA). It is 13 mm long and 3 mm in diameter and has a nominal resistance 100 Ω at 0 °C. It is placed in a closely fitting copper tube soldered on the bottom face of the cell. The other is a bank of five glass-bead thermistors (Shibaura Denshi, model NSB) for the high resolution measurements. The glass beads were wrapped in a small piece of thin copper sheet, and soldered on the side of the cell side by side. Nominal resistance of each of the thermistor is 4 kΩ at 0 °C and 0.13 kΩ at 100 °C. The connection of the five thermistors was changed so as to obtain the resultant resistance of 10—20 kΩ in the temperature interval of interest. This cell had a copper bobbin, 0.2 mm thick and of a slightly smaller diameter than the inner diameter of the cell itself. On this bobbin the calorimeter heater was wound bifilarly and cemented in place with GE adhesive. The heater wire was double silk wrapped constantan (Driver & Harris AWG No. 36) with total resistence of 100 Ω. The primary role of the bobbin is to promote temperature homogeneity in the cell during the heat-on period. Helium gas for improving thermal conduction within the sample space could be admitted before seal-off.

3) Adiabatic Control. The heat-transfers between calorimeter cell and its environment may be caused by three factors, that is, the convective heat leak which was eliminated by maintaining vacuum in the calorimeter system, the radiative heat transfer and the heat transfer by conduction along the leads bundle. As regards the radiative heat transfer it was reduced by gold-plating the inner surface of the radiation jacket and chromium-plating the outer surface of the calorimeter cell to obtain high reflectivity. To minimize the heat transfer by conduction, the leads to the calorimeter cell must be as thin as possible, but it is in conflict with the requirement of high electric conductivity of leads. To minimize heat exchange by the second- and third-mentioned mechanisms, the temperature of the inner jacket, about which leads were wound tightly, must be equalized to that of the

outer surface of the calorimeter cell, and especially to minimize the temperature gradient along both surfaces is required in order to reduce the radiation heat transfer. Temperatures of the bottom cone and other part of the inner jacket are controlled separately. The resistances of the heater wires were adjusted so as to make the power dissipation in the side and cone proportional to their respective mass (cylinder, uppercone 100 Ω and bottom cone 50 Ω). Thermocouples (Chromel P-constantan) were attached at five locations on the inside and outside of the cylinder and at three locations on the bottom cone. The two thermocouples insulated by cellophane adhesive tape were covered with small thin phosphor bronze plates which were attached to the inner bottom cone with two screws. These thermocouples detects temperature difference between the cell and the side and between the cell and the bottom of the adiabatic jacket. During a test run of the apparatus, it was found that the thermal conductivity between the inner and outer jackets was so small that the inner jacket, especially its bottom was liable to over-heat. It was remedied by linking thermally the bottoms of the two jackets with copper wire of appropriate length and diameter. The thermocouples (Chromel P-constantan) sense the temperature differences between the block and the inner jacket and between the outer jacket and the inner jacket, and the currents flow through the heater of the block (200 Ω) and the outer jacket (197 Ω). The temperatures of the block and the outer jacket were usually maintained lower than that of the inner jacket by several kelvin. On-off type of the regulator action, even if it is satisfactory in regard to the stability of the regulation, would caused strong noise in the thermometer circuits to the point of saturating the detectors. This difficulty was overcome by proportional mode of action which regulates the input power to the jacket heater smoothly in proportional to the temperature imbalance. The control system only with the proportional function could not automatically follow the temperature variation of the calorimeter cell at the early stage of and immediately after the heating period. Therefore, the off-set voltages, which were determined at an equilibration and a heating periods respectively, had to be readjusted quickly. To reduce the labor of paying attention to the off-set signal indicators, an integral action was added to the proportional action. In this improved regulator system (Fig. 4) the thermocouple voltage was measured and amplified with DC microvoltmeter (Keithley model 149), the output of which was fed into the proportional-integrating circuit as an error signal, and drove the jacket heater. The heater current was normally less than 50 mA. By using this circuit the temperature difference between the inner jacket and the calorimeter cell was less than 0.5 mK during both equilibration and heating periods.

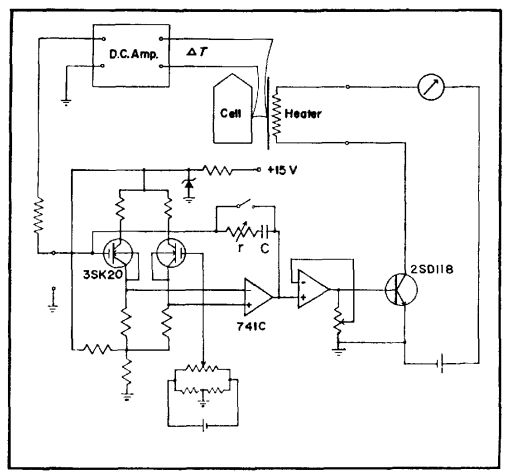

Fig. 4. Electric proportioning-integrating circuit.

4) Measurements of the Temperature. a) Circuit System for the Platinum Resistance Thermometer: The miniature platinum resistance thermometet was used as a temperature sensor which determined the absolute temperature scale. The precision AC double bridge (Automatic System Laboratory Inc. Model H8) with inductively coupled ratio arms was used to measure the thermometer resistance. This bridge has the merit that it requires only one balancing operation, since use of alternating current eleminates the effect of thermal emf's. However, some care had to be paid to the characteristics of the apparatus on using it in low temperature calorimeter, as will be described below. The basic circuit of this bridge is shown in Fig. 5 which, for the sake of clarity, does not contain

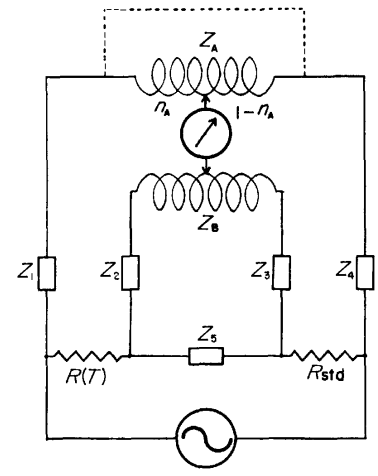

Fig. 5. Basic circuit of the ASL AC double bridge.

any phase balancing component. $R(T)$ is a resistance of the thermometer, R_{std} is a resistance of the standard resistor and Z_1, Z_2, Z_3, Z_4, and Z_5 represent lead impedances. Z_A and Z_B are impedance of the inductive ratio arms which have 4×10^5 Ω at 390 Hz and n_A and n_B the ratios of the arms. The equation of the balance which is that of the Kelvin double bridge is given precisely by

$$R(T) = R_{std}\left[\frac{n_AZ_A+Z_1}{(1-n_A)Z_A+Z_4}+Z_5\frac{(1-n_B)Z_B+Z_3}{Z_B+Z_2+Z_3+Z_5}\times\frac{n_AZ_A+Z_1}{(1-n_A)Z_A+Z_4}-\frac{n_BZ_B+Z_2}{(1-n_B)Z_B+Z_3}\right]. \quad (1)$$

In this bridge $Z_A=Z_B$, $Z_1=Z_2$, $Z_3=Z_4$ and Z_A and Z_B are much larger than Z_1, Z_2, Z_3, Z_4, and Z_5, so if n_A and n_B are not close to unity or zero, this equation is simplified as given below,

$$R(T) = R_{std}\frac{n_A}{1-n_A}\left[1+\frac{Z_1}{n_AZ_A}-\frac{Z_4}{(1-n_A)Z_A}\right]. \quad (2)$$

If ultimately high-precision measurement of the resistance is required, the ratio n_A must lie between 0.2 and 0.8, so the value of the standard resistor has to be varied in accordance with the resistance of the thermometer. For this purpose, three standard resistors (100 Ω, 6.238453 Ω, 0.390430 Ω) were prepared and kept in the box thermostated within ±0.03 K.

Three corrections had to be made in the measurements by using this AC double bridge. The first was correction for eliminating the effects of the impedance of the leads. If Z_1 and Z_4 were much smaller than Z_A, the last two terms in Eq. (2) were neglected, so Eq. (2) becomes to be $R(T)=R_{std}n_A/(1-$
